We observed strong EAG responses to 10% volumetric concentrations of a wide variety of scent compounds emitted by moth-pollinated flowers, including aromatic esters, aldehydes, and alcohols, oxygenated monoterpenoids, a sesquiterpenol, fatty-acid derivatives and assorted aliphatic and aromatic nitrogen-bearing compounds. Similarly, Brantjes (1973) recorded large EAGs using two other hawkmoth species (*Deilephila elpenor* L. and *M. sexta*), in response to 13 individual floral compounds (mostly terpenoids and aromatics) and to floral scent extracts from nine plant species, but his data were not presented quantitatively. Collectively, these results demonstrate that nectar-feeding hawkmoths are capable of detecting a wide range of floral and vegetative volatiles from diverse chemical classes. This broad olfactory vocabulary includes floral compounds (e.g., 2-phenylethanol and phenylacetaldehyde) that typify noctuid moth-pollinated flowers such as *Silene vulgaris* (Caryophyllaceae; Pettersson, 1991; Knudsen and Tollsten, 1993) and *Abelia grandiflora* (Caprifoliaceae; Haynes et al., 1991). Indeed, these and other "noctuid" flowers are often visited by sphingids (Nilsson, 1983; Pettersson, 1991; Wasserthal 1993).

We observed strong EAG responses to eight aliphatic GLV compounds, particularly to C_6 alcohols and C_8 acetates. Many of these compounds also are

potent EAG stimulants for *M. sexta* (Schweitzer et al., 1976; Light unpubl. data) and *Pieris* butterflies (van Loon et al., 1992). However, the GLVs are smaller and more volatile molecules than most of the aromatic and terpenoid test compounds; thus, the number of GLV molecules delivered during a stimulatory puff would be proportionally higher than that of larger, less volatile odorants. Although vegetative/leaf volatiles are clearly important to ovipositional decision-making in female *M. sexta* (Yamamoto et al., 1969; Ramaswamy, 1988), the role of GLVs as potential olfactory stimulants during *Hyles* oviposition bouts has not yet been examined. *H. lineata* is extremely polyphagous throughout its range, utilizing plants from the Nyctaginaceae, Onagraceae, Polygonaceae, Portulacaceae, Rosaceae, Scrophulariacaea, and Vitaceae as ovipositional sites and larval hosts (Wiltshire, 1957; Hodges, 1971; Common, 1990). Host species or genus-specific vegetative volatiles appear to function as important olfactory cues to females of *M. sexta*, which oviposit only on Solanaceae (Tichenor and Seigler, 1980), but host choice by gravid *Hyles* females may depend more on general cues, such as the ubiquitous GLVs and terpenes such as caryophyllene, myrcene, and pinene (Visser et al., 1979; Light et al., 1992a, 1992b, 1993; van Loon et al., 1992).

Functional Group Variation

Significant differences in antennal responsiveness correlated with structural variation in pheromone or plant volatile chemistry have been observed in hawkmoths (Reed et al., 1987), butterflies (van Loon et al., 1992) and other phytophagous insects (see Light et al., 1988, 1992a, 1992b). In our experiments, the importance of specific functional groups in determining EAG response potency depended strongly on the particular carbon skeleton geometry and/or chemical class. For example, oxygenated monoterpenoids elicited significantly higher EAG responses than did monoterpenes (Figures 1A, B, Table 2), the chief difference among them being the presence of a hydroxyl group (e.g., linalool vs. myrcene). Among the aliphatic GLVs, our results document a clear superiority in EAG potency of aliphatic alcohols over aldehydes. However, differences in levels of carbon skeleton saturation and double bond (C=C) geometry were not associated with statistically significant EAG differences.

We detected significant amounts of variation in EAG responses to diverse aromatic esters, aldehydes, and alcohols (Table 3), especially to benzoic acid esters and salicylates (Table 4), yet few specific functional group comparisons resulted in significantly different EAG responses. Benzaldehyde was a more potent antennal stimulant than either of the substituted benzaldehydes, vanillin and veratraldehyde, especially for female moths (Figs. 1A, C), but these differences did not translate into significant within-class variance (ANOVA, Table 4). Similarly, we did not detect significant variance associated with differences

in *para*-position oxidation among such compounds as eugenol, methylisoeugenol, vanillin, and veratraldehyde (ANOVA, Table 4).

Pairs of aromatic compounds that varied in the presence or absence of *ortho*-substituted hydroxyl-groups, such as methyl benzoate vs. methyl salicylate and benzyl benzoate vs. benzyl salicylate did not differ significantly. Methyl anthranylate, methyl salicylate and methyl-2-methoxybenzoate share a common skeleton but substitute amino-, hydroxyl- and methoxyl- groups, respectively, for the *ortho*-position hydrogen of methyl benzoate. However, mean EAG responses to these compounds did not differ significantly from those to methyl benzoate itself. Among salicylates, methyl salicylate elicited significantly higher EAGs than did benzyl salicylate, but this result could be an artifact of benzyl salicylate's higher molecular weight (40% larger) and lower volatility (Appendix 1). From these data, we are unable to infer whether *H. lineata* moths possess separate antennal receptors for chemically similar plant volatiles such as methyl salicylate and methyl anthranylate, which are quite distinct to the human palate (oil of wintergreen and concord grape, respectively), or whether functional group differences bear any physiological or behavioral importance to these insects.

Dose-Response Sensitivities

Foraging hawkmoths undoubtedly encounter a rich and broad spectrum of plant odors while in flight and during floral visitation. The dose-response data suggest that *H. lineata* moths are sensitive to most *C. breweri* floral compounds at a dose of ca. 1 ng on filter paper. This keen receptivity supports the possibility that scent compounds function as long-distance attractants to foraging hawkmoths (Tinbergen, 1958; Bratjes, 1973). Our results mirror those of Van Loon et al. (1992; *Pieris* butterflies) in showing that EAG rank orders may change with different stimulant dosages (e.g., eugenol and methylisoeugenol; Figure 3C, F, Table 6), suggesting that certain plant volatiles may have different behavioral or physiological activities at different concentrations. In the absence of behavioral bioassays or choice experiments, however, it is difficult to determine physiologically relevant odorant concentrations as emitted from a flower. The identification of floral volatiles using dynamic headspace sorption is usually used as a qualitative analytical procedure (Bergström et al., 1980; Bicchi and Joulain, 1990), but at best provides quantitative data only on cumulative floral odor emission per unit fresh weight over time (usually 12–24 hours; Raguso and Pichersky, 1995). These studies provide little if any inference (and usually an overestimation) of the actual concentrations of floral scent compounds encountered by foraging moths in a wind-borne odor plume (Murlis et al., 1992). Subtle changes in scent production or concentration, similar to changes in color, may convey information on nectar reward or physiological condition to a foraging insect (Weiss, 1991; Dobson, 1994). Thus, antennal sensitivity to floral scent

compounds across a range of concentrations might be as important to a moth during a floral visit as it is to a moth flying upwind in search of a flower.

EAGs and the C. breweri-H. lineata Interaction

In our study of the *C. breweri-H. lineata* pollination interaction, we have identified aromatic esters (benzyl acetate and methyl salicylate) and oxygenated monoterpenoids (linalool, linalool oxides) as the principal floral volatiles (>80% of GC-MS peak area; Raguso and Pichersky, 1995) and the most potent antennal chemostimulants. Aromatic esters and oxygenated terpenoids are among the most common scent components identified from hawkmoth-pollinated flowers spanning diverse plant families (Loughrin et al., 1990; Kaiser, 1991, 1993; Knudsen and Tollsten, 1993). Aromatic esters, in particular, are suspected to function as floral attractants of many hawkmoth species (Morgan and Lyon, 1928; Hodges, 1971; Nilsson, 1983), but they are not restricted to the aromas of night-blooming flowers (Knutsen and Tollsten, 1993). The presence of the uncommon N-bearing oxime compounds and oxygenated sesquiterpenes (e.g., farnesol and nerolidol) in many temperate and tropical hawkmoth-pollinated flowers has led many authors to suggest that these compounds function as hawkmoth attractants (Nilsson et al., 1985; Kaiser, 1993; Knudsen and Tollsten, 1993). Our data do not suggest anything unusual about these compounds at the level of antennal detection (see Figures 1B, C).

The EAG is believed to represent the sum of receptor potentials elicited in all sensory neurons by stimuli presented to the antennae (Boeckh et al., 1965; Schweitzer et al., 1976; Mayer et al. 1984). In essence, a discernible EAG response greater than the control stimulation indicates that a moth's antenna is sensitive to that odorant at the trial dosage. However, the behavioral activities of compounds can only be identified through controlled behavioral bioassays conducted in field or laboratory settings (Dodson et al., 1969; Jacobson et al., 1976; Tichenor and Seigler, 1980; Haynes et al., 1991).

CONCLUSIONS

Our EAG studies of *Hyles lineata* olfaction firmly establish that these moths can detect all of the floral scent compounds of *Clarkia breweri* at physiologically relevant concentrations. These results are consistent with the hypothesis that hawkmoths can detect the floral scent of this plant from a distance. In addition, male and female moths demonstrated a broad olfactory vocabulary, showing strong EAG responses to a variety of aromatic, aliphatic, terpenoid and nitrogen-bearing scent compounds found in the floral and vegetative tissues of many plants utilized by hawkmoths as nectar and oviposition resources. Considering

these findings, the behavioral responses of hawkmoths to diverse floral odors are not likely to result from gross differences in antennal receptor physiology, but rather from differences in individual experiences and/or central nervous system organization. The hypothesis that the floral scent of *C. breweri* could function as a long-distance attractant cannot be rejected by these findings, but EAG data are not sufficient to demonstrate behavioral attraction, arrestment, or repulsion, but only the capacity for olfactory detection. Behavioral experiments using live hawkmoths in wind tunnels or flight cages will be required to test this hypothesis.

Acknowledgments—This research was funded by National Science Foundation Grant MCB-9218989 to E. Pichersky, and by a Sigma Xi Grant-in-Aid of Research and fellowships from the California Native Plant Society, the Theodore Roosevelt Fund of the American Museum of Natural History, the Horace Rackham Dissertation Grant, the O. Newcombe Botany Fellowship, and an NIH-Genetics Training Grant at the University of Michigan to R. Raguso. We acknowledge H. Dobson, T. Rizke, B. Roy, L. Teuber, and R. Thorp for valuable discussions and especially thank M. Koch for his translation and discussion of von Knoll's work. We are indebted to C. Conlon, J. DeBenedictus, A. Shapiro and especially M. Sitter and R. Weich for their assistance in acquiring living *Hyles* moths. We thank R. Flath for his chemical expertise and for some of the stimulant compounds used in this study. We benefited from the editorial suggestions of J. Glendinning, B. Moon, M. Martin, and M. Willis and two anonymous reviewers and the statistical advice of G. Fowler, M. Meyer, and C. Welch. We are most grateful to Z. Cardon, C. Ley, M. Whooley, and especially C. and P. Adams and A. and P. Howard for their kind hospitality and assistance during this study.

APPENDIX 1. TEST COMPOUNDS, PURITIES, SOURCES, AND JUSTIFICATION FOR INCLUSION IN STUDY

Compound (Class[1])	Formula	MW	B.P. °C	Purity	Source	Justification[2]
Aromatic Compounds						
benzyl alcohol (1)	C_6H_6O	94	205	92%	Eastman/White	3,4
benzaldehyde (1)	C_7H_6O	106	178	99%	Aldrich	3,4
indole (6)	C_8H_7N	107	254	95%	Eastman	3
phenylacetaldehyde (1)	C_8H_8O	120	194	–	Aldrich	4
2-phenylethanol (1)	$C_8H_{10}O$	122	205	–	Eastman/White	4
(*E*)-cinnamic aldehyde (1)	C_9H_8O	132	248	95%	R. Flath	3,5
methyl benzoate (2)	$C_8H_8O_2$	136	200	98%	Fritzche	3
benzyl acetate (2)	$C_9H_{10}O_2$	150	214	99+%	Aldrich	1,3,4
methyl (2,6) anthranylate	$C_8H_9O_2N$	151	*	–	CPL	5
methyl salicylate (2)	$C_8H_8O_3$	152	224	98%	Aldrich	1,3
vanillin (1)	$C_8H_8O_3$	152	285	99%	Aldrich	1
methyl cinnamate (2)	$C_{10}H_{10}O_2$	162	262	99%	Aldrich	5
eugenol (1)	$C_{10}H_{12}O_2$	164	255	99%	Aldrich	1

[a]Chemical classes assigned as follows:
1 = aromatic alcohols and aldehydes
2 = aromatic esters
3 = fatty-acid derived compounds
4 = monoterpenes
5 = oxygenated terpenoids
6 = N-bearing compounds (aromatic and aliphatic)

APPENDIX 1. Continued

[a] Justification for inclusion in study:
1. present in floral headspace GC-MS analysis of *Clarkia breweri* (Raguso and Pichersky, 1995).
2. "green leaf volatiles", ubiquitous in vegetation.
3. present in many hawmoth-pollinated, night-blooming flowers (Knutsen and Tollsten, 1993).
4. present in many noctuid moth-pollinated flowers (Haynes et al., 1991; Knutsen and Tollsten, 1993).
5. similar to other test compounds but varying in one functional group (see text).

[b] Boiling point data at atmospheric pressure not available in Merck Index, CRC Handbook of Chemistry and Physics, Sigma/Aldrich Handbook of Chemical Safety.

Received September 11, 1995; accepted May 26, 1996

Abstract—Wounding increases the levels and activities of several defense-related proteins in the foliage of the tomato plant, *Lycopersicon esculentum* Mill. Evidence indicates that two of these responses, the systemic increases in polyphenol oxidase and proteinase inhibitors, are regulated by an octadecanoid-based signalling pathway which includes the wound hormone, jasmonic acid. It is not known whether other responses to wounding are also regulated by this same signalling pathway. In this paper, we show that application of jasmonates (jasmonic acid or its volatile derivative, methyl jasmonate) in low concentrations to foliage of young tomato plants induced, in a dose-dependent manner, the same protein responses–polyphenol oxidase, proteinase inhibitors, lipoxygenase, and peroxidase–as does *Helicoverpa zea* Boddie feeding. Application of jasmonic acid to a single leaflet of four-leaf tomato plants induced these four proteins in a spatial pattern nearly identical to that produced by localized feeding of *H. zea*. Exogenous jasmonic acid also decreased suitability of foliage for the beet armyworm, *Spodoptera exigua* Hubner in the laboratory. Based on these results, we conducted an experiment to measure the effects of jasmonic acid spray under field conditions. We provide the first evidence that jasmonic acid spray on field plants induces production of chemical defenses above the levels found in unsprayed controls. Exogenous jasmonic acid sprayed on plants in agricultural plots increased levels of polyphenol oxidase and proteinase inhibitors. Because application of jasmonic acid induces these defensive compounds at low concentrations in a manner similar to natural wounding, it may prove to be a useful tool for stimulating plant resistance to insects in the field.

Key Words—Jasmonic acid, methyl jasmonate, induced phytochemistry, induced resistance, polyphenol oxidase, peroxidase, lipoxygenase, proteinase inhibitors, *Helicoverpa zea*, *Spodoptera exigua*.

INTRODUCTION

In many plants, localized wounding increases allocation to defensive chemistry in wounded tissues as well as in distant, unwounded portions of the plant (Baldwin, 1994). Systemic responses of this sort require a mobile signal(s), generated at the site of wounding, to regulate their expression. Several putative signal molecules have been identified, among them the linolenic acid derivative, jasmonic acid (JA) (Reinbothe et al., 1994). In many plant species, wounding increases endogenous levels of JA, and exogenous JA stimulates the expression of defensive chemistry (Reinbothe et al., 1994). The latter fact suggests that it may be possible to use applications of JA to stimulate induced plant resistance on a large scale in the field without damaging individual plants.

In foliage of the tomato, *Lycopersicon esculentum* Mill, caterpillar feeding initiates an array of defense-related responses which exhibit a characteristic spatial pattern (Stout et al., 1996). The most prominent systemic responses are the increases in the levels and activities of polyphenol oxidase (PPO) and of two proteinase inhibitors (PIs). Local responses include increased activity of the oxidative enzyme lipoxygenase (LOX) in addition to the PPO and PI responses. Peroxidase (POD), another oxidative enzyme, is also induced, but less markedly and consistently, by caterpillar feeding. All of these proteins are thought to decrease the nutritive value of tomato foliage to herbivores, particularly noctuid larvae (Duffey and Felton, 1991). Evidence indicates that the most prominent protein responses–the systemic increases in the levels of PIs and PPO–are coregulated at the transcriptional level by an octadecanoid-based signal transduction pathway which includes JA (Farmer et al., 1992; Constabel et al., 1995). Application of JA or its volatile derivative, jasmionic acid methyl ester (methyl jasmonate, MJ) to tomato foliage causes increased production of PI and PPO mRNA and proteins (Farmer et al., 1992), and wounding increases endogenous JA levels in young tomato plants (Doares et al., 1995). It is unknown, however, whether other chemical responses to caterpillar feeding are controlled by the same signalling pathway as the PPO/PI response, or whether these other responses are controlled by separate signalling pathways. It is also not known whether the increase in plant resistance to subsequent herbivores which occurs as a result of caterpillar feeding and which is presumably causally related to one or more of the chemical changes can be simulated by application of JA.

In this paper, we show that application of jasmonates to tomato foliage induces lipoxygenase and peroxidase activities in addition to proteinase inhibitors and polyphenol oxidase, and show that the spatial pattern of this chemical

induction is nearly identical to the spatial pattern of induction by feeding of the noctuid, *Helicoverpa zea*. We also demonstrate that exogenous JA causes a systemic increase in plant resistance to herbivory which is similar to that caused by *H. zea* feeding. These results prompted us to test the effects of exogenous JA on the defensive chemistry of field-grown tomato plants. We report here that application of JA to tomato plants in large field plots induced both polyphenol oxidase and proteinase inhibitors. Our results show that jasmonic acid may be a useful tool for increasing plant resistance on a large scale in agricultural conditions.

MATERIALS AND METHODS

Laboratory Experiments

Plant Growth. Tomato plants (*Lycopersicon esculentum* CV. "Castlemart") were used at the four-leaf stage in all experiments (23–27 days after planting). Plants were grown in a greenhouse in soil, watered daily, and fertilized weekly with a 15-30-15 P-N-K fertilizer. Greenhouse temperature was regulated at 32°C ± 5°; natural light was not supplemented.

Chemicals. Jasmonic acid methyl ester was purchased from Bedoukian Research, Inc. (Danbury, CT) and, when necessary, converted to jasmonic acid following the method of Farmer et al. (1992). All other chemicals were from Sigma.

Application of Jasmonates to Plants. Plants were treated with MJ by saturating cotton-tipped applicators in an ethanol:MJ (9:1) solution and placing the applicators in a growth chamber without physically contacting the plants to be treated. Control plants were placed in a separate growth chamber. Plants were kept in the growth chambers for 12 hours, after which they were placed in a greenhouse until chemical assays were performed. Both growth chambers were maintained at 25°C and plants were maintained under light during exposure to MJ.

For JA experiments, JA was dissolved in circa 1 ml/gm of acetone, then dispersed in water to the desired concentration. JA was sprayed on plants until run-off using an atomizer; if necessary, surrounding leaflets were shielded with a piece of paper. Control plants were sprayed with water which contained acetone at the same concentration used for the JA treatment.

Effect of Exogenous Jasmonates on Plant Chemistry in the Laboratory. The effects of JA and MJ on the activities of tomato defensive chemistry were evaluated in a series of experiments conducted in the spring of 1995.

Initial experiments were conducted to determine the effect of exposure to MJ on the activities of the putative defenses PPO, POD, LOX, and PIs. Plants

assigned to the MJ treatment were exposed to an MJ-rich atmosphere for 12 hours as outlined above, removed to a greenhouse for an additonal 36 hours, then assayed for protein activities. Leaflets from the third leaf of both control and treated plants were used for protein assays. This experiment was performed twice, with 11 plants/treatment, and the growth chambers used for the two treatments were switched in the two experiments.

Local induction of exogenous JA (i.e., induction in leaves which had had contact with JA) was assessed by spraying the third leaves of four-leaf plants with solutions of JA of several concentrations (0 mM, 0.1 mM, 1 mM, and 10 mM). Leaves were sprayed in a greenhouse and the plants kept in the greenhouse for 48 hours before performing protein assays. Protein activities were assayed only from leaves which had had contact with JA. Leaves from eight plants were sprayed per concentration.

Systemic induction by JA was compared to systemic induction by feeding of larval *H. zea* (corn earworm) in three experiments. For the first two experiments, terminal leaflets of third leaves were sprayed with JA (0.5 mM) or wounded with larval *H. zea* by confining a fourth-instar larva to the leaflet with a clip cage. A third group of plants was sprayed with water containing acetone as a control. For the third experiment, the insect feeding treatment was omitted. Two days after spraying/wounding, leaflets from four positions on the plant were harvested for chemical analyses: the wounded/treated leaflet, a leaflet adjacent to the treated leaflet, a leaflet from the leaf below the treated leaflet, and a leaflet from the leaf above the treated leaflet.

Effect of Induction on Herbivore Performance in the Laboratory. Two short-term (one day) and one longer-term (seven days) feeding assays were used to test the effect of induction by jasmonates on the suitability of foliage for the noctuid *Spodoptera exigua* Hubner. *S. exigua* larvae were obtained as eggs from the USDA (Stoneville, MS) and raised on artificial diet until the late second to early fourth instar, depending on the assay (approximately 6–10 days). To initiate asays, larvae were taken off diet, starved for two to six hours (to allow guts of larvae to void), weighed, and chosen for uniformity of size. Starved larvae were placed with one or two leaflets from either treated or untreated plants on moist filter paper in a petri dish and allowed to feed. To terminate the assay, larvae were removed from leaflets and weighed after starving them for one hour. One short-term experiment utilized leaflets from the third leaves of control or MJ-treated plants; the second short-term experiment used unsprayed leaflets from JA-sprayed or control third leaves. In the third experiment, leaflets were from JA-sprayed or unsprayed third leaves and insects were allowed to feed for seven days. Leaflets were switched every two or three days and leaflets for the JA treatment were taken from plants sprayed two or three days earlier. Relative growth rates were calculated using fresh weights according to the methods of Waldbauer (1968).

Field Experiments

Effect of Exogenous Jasmonic Acid on Plant Chemistry in the Field. A one-quarter acre field of tomato plants (*L. esculentum* CV "Ace") containing sprayed and unsprayed plots was established in May 1995. The field was randomly divided into 2 × 3 m plots; 30 replicates of each treatment. The field was maintained by the Department of Vegetable Crops, University of California, Davis, CA. The tomatoes were planted in ten beds spaced one meter apart and 70 meters long. The beds were pretreated with herbicide, fertilized, manually weeded, and furrow watered weekly for the duration of the experiment. When the seedlings emerged they were thinned so that they were six inches apart and as the plants grew they continued to be thinned so that mature plants were spaced every two feet. Our field was surrounded by tomato fields on two sides, a road and unplanted fields on the others.

The treatment plots were first sprayed with JA on June 1, when the plants were in the five leaf stage, and subsequently on June 13, June 28, and July 25, until the chemical effects of induction were no longer detactable. On June 1, 13, and July 25, JA was sprayed at 0.5 mM, and on June 28 at 0.25 mM. With each application, circa 0.125–0.250 micromoles of JA per plant was applied using a backpack sprayer. Control plants were sprayed with a water/acetone solution as in the laboratory experiments.

Chemical assays were conducted throughout the summer. Assays were conducted two–three days following each spray and at irregular intervals between sprays. In young plants, the third terminal leaflet was collected. In larger plants, old (fourth oldest) and young leaflets were collected. Young leaves were marked with string before fully expanded and used for assays the following week to standardize age. Leaflets were excised from plants using a razor and transported on ice to the laboratory for chemical analysis. Fifteen plants were selected from each treatment and for all assays, plants were assayed only once.

An additional plot of tomatoes was established in September 1995 to determine if young plants were inducible late in the season. Tomato seedlings were grown in the greenhouse for one month and then transplanted outside into a 100 ft long row surrounded by open space. Plants were spaced every 8 inches and each plant was randomly assigned to the spray or no spray treatment. A pre-treatment assay was conducted to ensure that PPO levels were uniform between plants before the treatments were imposed (N = 12 per treatment). PPO was assayed two weeks following spray (N = 15 per treatment).

Chemical Assays

Protein Assays. Enzymes were extracted by homogenizing weighed leaflets in 1.25 ml of ice-cold 0.1 M K Phos buffer containing 7% (w:v) polyvinyl-polypyrrolidine, then adding 0.4 ml to 10% (v:v) Triton X-100 and vortexing

the mixture. The homogenate was centrifuged at 10,000 *g* for ten min and the resulting supernatant used directly for spectrophotometric assays of PPO, POD, and LOX activities. For PPO assays, 20–30 μL of enzyme extract was added to 1 ml of a caffeic acid solution (2.92 mM in pH 8 K Phos buffer) and the increase in OD at 470 nm of the mixture measured. POD activity was also measured as an increase in OD_{470} after addition of 20–30 μL of enzyme extract to 1 ml of a substrate solution consisting of 2.92 mM guaiacol in pH 8 K Phos buffer with H_2O_2 added as a cofactor. The LOX assay measured the appearance of conjugated dienes at 234 nm (Hildebrand and Hymowitz, 1981). The reaction mixture consisted of 15–20 μL of enzyme extract added to 2.9 ml of 0.4 mM linoleic acid dispersed in a 0.1 M K Phos buffer (pH 7) containing Tween-20 (0.1%). Change in absorbance was monitored for at least 5 min. The activities of all three enzymes are expressed as ΔOD/min/gm of fresh leaf tissue.

The PI assay was based on the ability of plant extracts containing proteinase inhibitors to inhibit the digestion of the artificial protease substrate benzoyl tyrosine ethyl ester (BTEE) by commercial proteases. Proteinase inhibitors were extracted from individual leaflets by grinding them in a 50 mM Tris HCl buffer (pH 7.8, 3 ml/gm leaf tissue) containing 7% polyvinylpolypyrrolidine, 1.67 mM phenylthiourea, 0.3 M KCl, and 0.4 mM ascorbic acid. This extract was immediately frozen for later use. For assays, the thawed extract was centrifuged at 13,000 *g* for ten min and the supernatant used as the source of PIs. In a quartz cuvette, 25 μL of the PI extract was added to 25 μL of 0.001 N HCl containing 0.001 mg of chymotrypsin and the mixture allowed to incubate for ten min. After incubation, 2.9 ml of 0.5 mM BTEE was added to the cuvette and the increase in absorbance at 256 nm measured. For every run of samples, a control consisting of chymotrypsin and BTEE without plant extract was also run, and PI activities of samples expressed as % chymotrypsin activity relative to this control. The relationship between % inhibition of chymotrypsin and concentration of proteinase inhibitor is linear for a wide range of proteinase inhibitor concentrations (Stout, unpublished data).

RESULTS

Effects of MJ on Tomato Foliar Chemistry

Short-term exposure to MJ vapors had marked effects on the activities of defense-related proteins in tomato foliage. The effects of MJ on PPO and PI activities were particularly pronounced, with approximately three-fold induction of both protein activities in both trials (Table 1). Exposure to MJ caused a two-fold induction in POD activity in the second trial but not in the first (Table 1). LOX activity was also higher, but not significantly so, in MJ-treated plants than in control plants.

Local Induction by Exogenous JA in the Laboratory

Leaves which had been sprayed with JA did not differ in appearance from unsprayed leaves except at the highest concentration of JA (10 mM), which caused leaf necrosis and was clearly phytotoxic. Contact with JA at the lower concentrations increased the activities of PPO and PIs in a dose-dependent manner, but there was no further increase in the activities of these proteins at the highest concentration (Figure 1). LOX activities also increased with increasing JA concentrations, with a sharp rise at the highest concentration (Figure 1). POD activities, in contrast, were not affected by contact with JA except at the highest concentration (Figure 1).

Systemic Induction by Exogenous JA in the Laboratory

Because the battery of responses induced by jasmonate–PPO, PIs, LOX, and, inconsistently, POD–was the same as that resulting locally from caterpillar feeding (Stout et al., 1996), we next asked whether the pattern of systemic induction resulting from a localized application of JA was the same as the systemic pattern of induction resulting from localized caterpillar feeding. To answer this question, we compared the local and systemic induction caused by spraying 0.5 mM JA on the terminal leaflet of the third leaf with the induction caused by *H. zea* feeding at the same leaflet position. Protein activities were compared in the damaged leaf (enzymes only), in undamaged leaflets from the damaged leaf, in leaflets from a leaf below the damaged leaf, and in leaflets

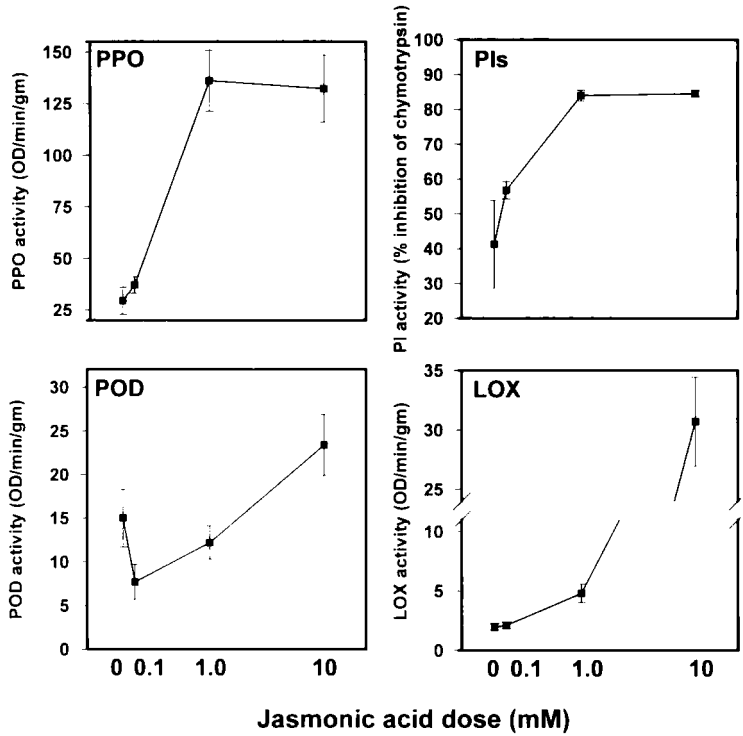

FIG. 1. Effect of several concentrations of jasmonic acid on the activities of the proteins polyphenol oxidase, proteinase inhibitors, lipoxygenase, and peroxidase. Jasmonic acid was suspended in water and applied to leaflets as a spray; each point represents the mean activity from eight sprayed leaflets each from a different plant. Means accompanied by different letters are significantly different ($p < 0.05$; one-way ANOVA followed by a Tukey mean separation).

from a leaf above the damaged leaf. In general, the pattern of responses to JA mirrored the responses to *H. zea* feeding (Table 2). Induction of PPO–in terms of the ratio of PPO activity in control plants to PPO activity in damaged/treated plant–was strongest in the damaged leaf and undamaged leaflets of the damaged leaf (approximately two- to twelve-fold), present but weaker in the leaf below the damaged leaf (1.5- to nine-fold), and weakest or absent in the leaf above the damaged/treated leaf (at most, three-fold). Induction of PIs was more uniformly systemic in both JA-treated and damaged plants. Induction of LOX, in contrast, was confined to the damaged leaflet except in one instance of *H. zea* feeding. POD was induced inconsistently by both JA and caterpillar feeding,

[a] Enzyme activities are expressed as ΔOD/min/gm fresh leaf tissue; PI activities are expressed as %inhibition of chymotrypsin activity relative to a control run with chymotrypsin and BTEE only (see methods).

[b] Four-leaf plants were wounded or treated at the terminal leaflet of the third leaf. Activities were assayed from the damaged/treated leaflet, a leaflet adjacent to the treated leaflet, a leaflet from a leaf below the treated leaflet, and a leaflet from the leaf above the treated leaflet. There was insufficient leaf material available to assay both enzyme and PI activities at the damaged position.

and induction by both treatments was strongest in the damaged leaf. POD induction was weaker than that of PPO, LOX, and PIs.

Effect of Jasmonate Exposure on Plant Resistance

Larvae reared on leaflets from MJ- and JA-treated plants in the laboratory exhibited lower relative growth rates (gm/gm/day) than larvae reared on control leaflets of the same age in all three feeding experiments (Figure 2). The reduction in growth rate on jasmonate-treated plants ranged from 25–80%. This between-treatment difference was seen despite variation in growth rates between experiments, which presumably occurred because of differences in the age of larvae

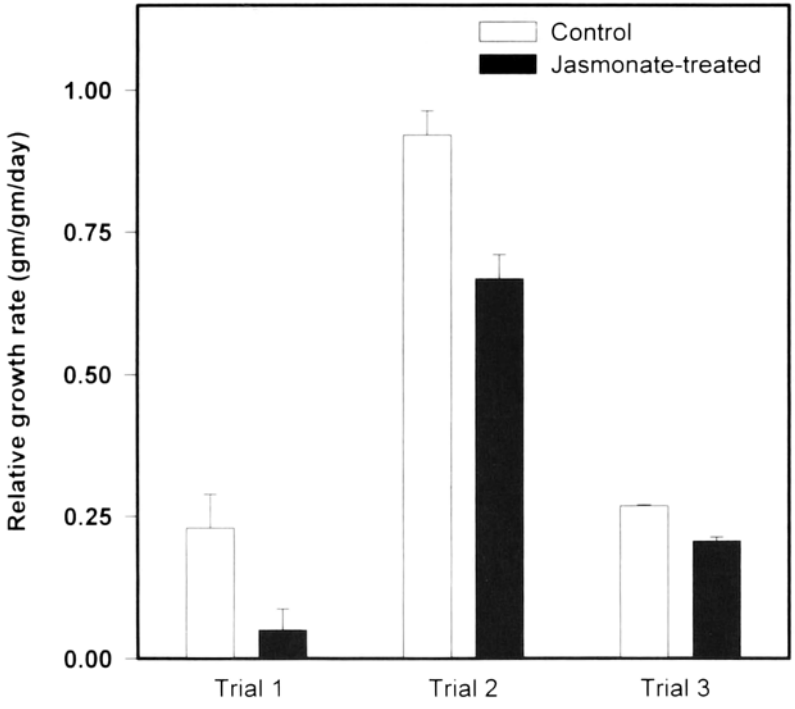

FIG. 2. Relative growth rates ± SE (gm/gm/day) of *Spodoptera exigua* larvae raised on excised control and jasmonate-treated leaflets. In all cases, third leaves of four-leaf plants were used. In the first experiment, plants were treated by exposing them to methyl jasmonate vapors, while spray applications of jasmonic acid were used in the other experiments. The first two assays are short-term (one day) assays; the last experiment lasted seven days. The differences in growth rates between treatments are significant for all three experiments. The number of replicates per treatment ranged from 11 to 16 in each experiment.

used and because of differences in the conditions and methods of the assays. This reduction in relative growth rates of insects on leaflets from sprayed plants was probably due in part to a reduction in consumption rate, which was lower in both of the JA feeding assays (data not shown).

Systemic Induction by Exogenous Jasmonic Acid in the Field

Jasmonic acid spray increased levels of PPO in old and young leaves of young plants (Figure 3A,B). The effect of JA diminished as the plants aged. In early June, differences in PPO activity in sprayed plants were detected in both

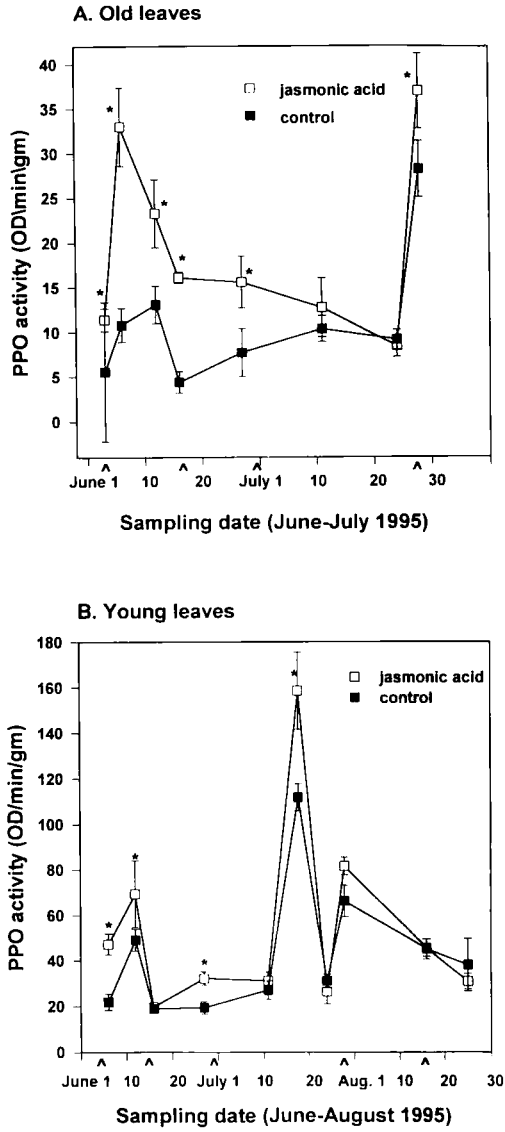

FIG. 3. Polyphenol oxidase levels in old leaves (3A) and young leaves (3B) of field grown plants in summer 1995. Activity in control and jasmonic acid treated plants were compared using a one-way ANOVA on each sample date with 15 replicates of each treatment. Stars indicate significance below the 0.05 level. Arrows along *x*-axis indicate spray dates.

June 3	44.8 ± 4.1	12.6 ± 0.9	40.2	< .001
June 6	56.6 ± 3.2	22.6 ± 6.1	27.5	< .001
June 16	28.9 ± 7.9	19.5 ± 4.2	1.2	0.28

old and young leaves with young leaves containing higher chemical levels than old leaves. PI activities were higher in sprayed plants on the June 3 and 6 sample dates, but not on June 16 (Table 3). After the June 28 spray, PPO activity was increased in old leaves of sprayed plants, but this effect was not significant. After spraying JA on July 25, PPO activity in old leaves was greater on sprayed plants; young leaves exhibited the same trend but the difference was not statistically significant. In August, PPO activity in young leaves of large plants was not increased by respraying.

JA spray on seedlings planted in September induced higher levels of PPO activity than unsprayed controls ($n = 12$ per treatment, jasmonic acid = 44.57 ± 5.89 (mean ± se), control = 22.43 ± 6.34; df = 1, 22; $F = 6.59$; $p = 0.02$) indicating that the loss of chemical induction in the older plants in August was caused by age and not by season. Chemical differences were not found between the treatments in the pretreatment assay (data not shown).

DISCUSSION

Two approaches have been taken to the study of herbivore-induced plant responses. The first is a mechanistic approach which seeks to determine the chemical and physiological changes induced by herbivory. The second is an ecological approach which examines the impact of induced responses on herbivores. For the most part, these two approaches have not been coupled in a single system. This study represents the first in a series of experiments aimed at determining the effects of artificial stimulation of plant defensive chemistry on populations of herbivores in the field. We show here that jasmonic acid, a putative component of the wound-response pathway in plants, is a valuable tool for manipulating levels of plant defensive chemistry in the laboratory and field. The use of jasmonic acid in the tomato system presents an opportunity to link mechanistic and ecological approaches to induced plant responses.

Application of jasmonic acid to greenhouse grown plants simulated insect wounding in several important respects. The array of chemicals induced by exogenous jasmonic acid was the same as that induced by *H. zea* feeding. Moreover, the spatial distribution of chemical changes following localized application of JA was the same as the spatial distribution of changes following localized *H. zea* feeding. We also found that the chemical changes induced by JA were correlated with a decrease in the suitability of JA-treated plants to *S. exigua* larvae, as occurs following *H. zea* feeding. This increase in foliar resistance was a systemic phenomenon: leaflets used in the two JA feeding experiments had had no contact with JA.

Based on these greenhouse results, we conducted experiments to determine whether artificial application of jasmonic acid in the field induced PPO and PIs, the two most prominent inducible chemicals in greenhouse experiments. Workers have speculated that because plants in the field are subject to many stresses, including insect wounding and physical abrasion, plants in the field may always be induced (Karban and Myers, 1989); however, our data suggest that some plant secondary chemicals remain inducible in the field for two months in spite of these stresses. During the early part of the experiment, both PPO and PIs were strongly induced by exogenous JA (Table 3, Figure 3). PPO remained consistently strongly inducible throughout the first month of the experiment and sporadically inducible during the next month (Figure 3). The loss of PI induction on June 16 (Table 3) may have been because the effect of the jasmonic acid spray wore off or because the plants were induced by other factors.

Many workers have proposed the use of induced resistance as a means of arthropod pest control in agriculture (Kogan and Paxton, 1983; Karban and Baldwin, 1997), but our experiments are the first to demonstrate that plant defenses against insects can be artificially stimulated on a large scale. The artificial stimulation of plant resistance to pathogens using exogenous chemical elicitors is an emerging strategy for pathogen management (Reinbothe et al., 1994; Karban and Baldwin, 1977). Several groups studying the salicylic acid pathway have conducted experiments examining the methods to induce resistance against pathogens in the field (Kessman et al., 1994).

Our greenhouse studies also provide some insights into signalling pathways in tomato. Farmer and Ryan (1992) have forwarded a model for the regulation of wound responses in tomato leaves which involves a lipid-based signalling-system. According to this model, wounding or interaction of plasma membrane receptors with systemic signals (e.g., systemin) causes the release of linolenic acid from the plasma membrane into the cytoplasm. The linolenic acid is then converted by a series of enzymatic reactions to jasmonic acid, which stimulates the expression of defense-related genes. This model was originally generated from data on the proteinase inhibitor response to wounding in tomato foliage; more recent data (Constabel et al., 1995) indicates that the systemic increase in

polyphenol oxidase which occurs following wounding in tomato is also regulated at the transcriptional level by the octadecanoid signal transduction pathway. Our data provide additional support for the hypothesis that JA mediates the PPO and PI responses to wounding, as plants which had received localized applications of JA exhibited higher activities of PPO and PIs in a spatial pattern nearly identical to that produced by localized wounding (Table 2).

Furthermore, our data provide some support for the idea that the lipoxygenase response to caterpillar feeding is also mediated by the octadecanoid pathway. Lipoxygenase activities were consistently induced to higher levels by both JA application and caterpillar feeding; for both treatments, the induction of LOX, unlike the induction of PPO and PIs, was not systemic but was confined to the damaged or treated leaflet. Farmer et al. (1992) presented electrophoretic data which indicated that treating young tomato plants with MJ induced only two proteins in addition to proteinase inhibitors: a 63 kD protein and an 87 kD protein. The former protein is almost certainly polyphenol oxidase (Constabel et al., 1995), while the latter is of similar weight to lipoxygenases from tomato (Zamora et al., 1987). LOX is known to respond to JA treatment in soybean (Creelman and Mullet, 1995).

Although POD activities can be induced by both exogenous jasmonate and *H. zea* feeding, the frequent absence of POD induction in the presence of PPO/PI/LOX induction (Table 2) indicates that the POD response to wounding/JA is probably not regulated in a manner analogous to the PPO/PI responses. Support for this hypothesis comes from the electrophoretic data of Farmer et al. (1992), which showed no proteins of a size consistent with sizes previously reported for peroxidases from tomato and other plants (Marangoni et al., 1989; Bronner et al., 1991). The variability in POD induction, coupled with the fact that strong induction of POD in the dose-response experiment was only observed at the highest concentration of JA, suggests that POD induction may be a secondary result of tissue damage, perhaps involving a separate signalling pathway, rather than a defensive (octadecanoid-mediated) response per se.

The experiments presented in this paper show that jasmonic acid spray in the field simulated the chemical changes caused by natural insect wounding in the laboratory. In future experiments, we will test whether chemical induction by jasmonic acid produces induced plant resistance to herbivores in the field as it does in the laboratory. Preliminary field data indicate that the abundance of aphids and flea beetles is reduced and growth rate of *S. exigua* is slowed on sprayed plants suggesting that artificial chemical induction does increase plant resistance (J. Thaler, unpubl. data).

Abstract—Newly emerged males of *Hyphantria cunea* (Drury) (Lepidoptera: Arctiidae), marked with different fluorescent colors, were recaptured by pheromone trapping. Three Uni-traps, baited with (3Z,6Z)9,10-epoxyheneicosadiene, (9Z,12Z,15Z)octadecatrienal, and (3Z,6Z)9,10-epoxyheneicosa-triene in a 1:10:1 ratio, total 6 mg/dispenser, were placed in a line 15 m apart, perpendicular to the dominant wind direction, and checked after 12, 36, and 60 hr. At dusk, releases of 10–25 males were made over distances from 30 to 250 m, during 4 periods over a soybean field (nonhost plant). Recapture rates were high; of a total of 176 males released, 115 were recaptured with 88% of these within 12 hours. Between 40 and 100% of males were recovered over shorter distances (30–150 m), and between 10–24% at longer distances (200 and 250 m). No other species or unmarked males were captured. The trapping period showed little effect on recaptures. The central trap of the three traps had somewhat higher catches, but the slope of the regression of recapture over distance did not differ among traps. There was a significant decline of recapture over distance ($r = -0.56$) for catches of individual traps but a large

scatter. Summed recaptures per distance gave less scatter and had $r = -0.86$, allowing calculation of the maximum sampling range (R_s) after 60 hr as 340 m with a 95% confidence interval of 190–710 m (regression of arcsin $\sqrt{p}$ and $\sqrt{R}$). The area of sampling, found by integrating the probability function of recapture over distance, from the source to maximum R_s was 7 ha. The high recapture rates and the long R_s, compared to those in the literature for other taxa, indicate that pheromone traps are highly efficient sampling devices in this species.

Key Words—Fall web worm moth, *Hyphantria cunea*, Lepidoptera, Arctiidae, pheromone trap, mark-recapture, sampling range.

INTRODUCTION

The range of action of synthetic pheromone traps is one of the most important variables for design of monitoring and mass-trapping schemes (Schlyter, 1992). Traps baited with synthetic sex-pheromone or attractant are today important tools for monitoring of Lepidoptera and other pest insects (Zhang, 1993). Monitoring population dynamics with pheromone traps is usually simpler than other routine measures (Wall, 1989; Wall, 1990; Weslien et al., 1989). However, for any ecological sampling method the area sampled must be defined (Southwood, 1978). The following terms have been used to describe the range of action of an attractant: (1) "active space" (Bossert and Wilson, 1963), (2) "range of sampling" R_S (Wall and Perry, 1987), (3) "range of attraction" R_A (Wall and Perry, 1987), (4) "range of stimulation" (Wall and Perry, 1987), and (5) "effective attraction radius" R_{EA} (Byers et al., 1989). The theoretical "active space" concept is firmly established in the literature, but requires parameters not generally available (Nakamura and Kawasaki, 1977). Wall and Perry (1987) defined the R_S as "the distance from which insects can be shown to reach the source in a given time period," which can be estimated by mark-recapture tests. R_A is "the maximum distance over which insects can be shown to direct their movement to the source" (Wall and Perry, 1987), and requires either direct observations of insects in flight or mark-recapture over short time intervals. The range of stimulation is defined as "the distance over which an attractant source can be shown to elicit a response like wing-fanning" (Wall and Perry, 1987). A simpler concept, the effective attraction radius, R_{EA}, does not take into account any specific behavior of the insect but is defined as the relative trapping power of baited vs. unbaited traps, expressed in terms of the "effective" trap size (radius) of the baited, active trap (Byers et al., 1989). R_{EA} was initially developed for open sticky traps which always give a nonzero catch even on passive traps. In terms of absolute distance (in one dimension) it follows from the definitions that $R_S >$ range of stimulation $\cong$ active space $> R_A > R_{EA}$, at least if the time of study is not very short (Schlyter, 1992).

The fall web worm moth *Hyphantria cunea* (Drury) is one of the most

important pest insects of fruit, nut, and shade trees in China with status as a quarantine pest due to its destructiveness to the host trees. It originated from North America, but was introduced to Eastern Europe and Northeast Asia in this century, and has caused severe damages in its new geographical and host ranges. In China, it has been recorded feeding on over 100 species of deciduous trees (Zhang and Yu, 1985). Only the "black-headed" race has been recognized in Asia (Zhang and Yu, 1985), although two races, a "black-headed" race and a "red-headed" (or "orange") race have been described from North America (Oliver, 1964; Hidaka, 1972). It has two generations per year in China (Zhang and Yu, 1985). A third generation was recorded in 1994, mainly due to extremely high temperatures during the whole summer (Zhang, unpubl.). Male moths engage in "mating flight" in the early morning 0.5–1.0 hr before sunrise in the second generation (Hidaka, 1972; Calcote and Gentry, 1973; Hirooka, 1983; Zhang et al., 1997), but in the early evening in the first generation (Zhang et al., 1997). The identification and synthesis of its sex-pheromone (Hill et al., 1982; Tóth et al., 1989; Mori and Takeuchi, 1989) has permitted various field studies on the biology and applications of pheromone for this moth (Binda et al., 1990; Senda et al., 1993 and references therein; Zhang et al., 1996; Zhang et al., 1997).

For the fall web worm moth Hirooka and Suwanai (1976) predicted with a diffusion equation that the "effective sphere of pheromone" from a virgin female should have a radius of 5–6 m. This was confirmed by Hirooka (1981) by means of direct observation of zigzag flight behavior of males towards virgin females, giving $R_A \cong 6$ m. Recently, Zhang et al. (1996) also reported a crude estimate of R_A as > 4 m by observation of males approaching synthetic pheromone.

In this study, we wanted to find the slope of a linear or linearized function with intercept m and slope b for the dependence of recapture y on distance x:

$$y = m - b \cdot x$$

From the parameters of such a regression the maximum R_S will equal the intercept with the x-axis. For the x-intercept one may calculate a confidence interval but this interval will be asymmetric and requires a nontrivial calculation (Sokol and Rohlf, 1981). As shown by Schlyter (1992), functions of the action of odor sources over distance are often nonlinear, and thus we will get a probability function of recapture, $P(R)$, over distance, R such that

$$P(R) = \text{retransformation function } (m, b)$$

Such a 1D function will then allow calculating a circular sampling area (2D) by integration to give the area, A, with sampling efficiency of unity, as suggested by Turchin and Odendaal (1996):

$$A = 2\pi \int_0^{R_S} R \cdot P(R)\, dR$$

Such an area may then be directly compared to areas of other sampling methods, such as larval web counts, which by definition have a unity sampling efficiency over their whole area.

In this paper, we estimate by mark-recapture the maximum range of sampling (R_S), and the corresponding sampling area for the fall web worm moth using a synthetic phèromone.

MATERIALS AND METHODS

Materials

Tests were carried out at Lizifang, Zhuanghe county, Liaoning province, P.R. China, from 1993-05-25 (first generation 1993) to 1994-07-31 (second generation 1994). A soybean field with an area more than 500 × 1000 m was chosen as the test site. Nonsticky Uni-traps (with DDVP as the poison) were used in the tests (see Zhang et al., 1996). The three Uni-traps were each baited with a synthetic pheromone dispenser, "92A" from Nitto Denko Co. (3Z,6Z)-(9S,10R)-*cix*-9,10-epoxy--3,6,-henicosadiene, (9Z,12Z,15Z)-9,12,15-octadecatrien-1-al, and (3Z,6Z)-(9S,10R)-*cis*-9,10-epoxy-1,3,6-henicosadiene, in a 1 : 10 : 1 ratio, total 6 mg/dispenser, (Zhang et al., 1996) were set up on bamboo poles 1.8–2.0 m high, in a line 15 m apart perpendicular to the prevailing main wind direction. New emergent male moths, usually collected at 6:00–6:30 PM, were marked with different fluorescent colors on the pronotum and released from various distances (30–250 m) downwind of the trap line. Wind speed was measured ≥3 times per night with a simple rotating cup anemometer.

The distance from the release point to the two off-center traps (the hypotenuse) is somewhat longer than the distances (the opposite) to the central trap (Fig. 1A). The distance, 15 m, between central trap and the off-center trap (the adjacent) is small compared to most distances (the opposite ranges 30–250 m). From the laws of sines and tangents it follows that *hypotenuse* = *opposite*/sin(atan(*opposite/adjacent*)) which simplifies to *hypotenuse* = $15\sqrt{1 + opposite^2/15^2}$. Only for opposite = 30 m is the difference >10% (hypotenuse = 33.5 m), but the exact distances have been used in the regression calculations. The difference in the calculation of the R_S using the inexact value is >10% but for the upper (outer) 95% confidence limit of R_S the error was as much as >50%. Statistical analysis was done with SPSS/PC+™ 5.0.1 (SPSS Inc., Noursis 1990). The intercept and 95% C.L. for the regression were obtained both by the regression facility of AXUM® 3.0 (Trimetrix Inc.) accessed via SPSS and by calculation following the procedure in Sokal and Rohlf (1981).

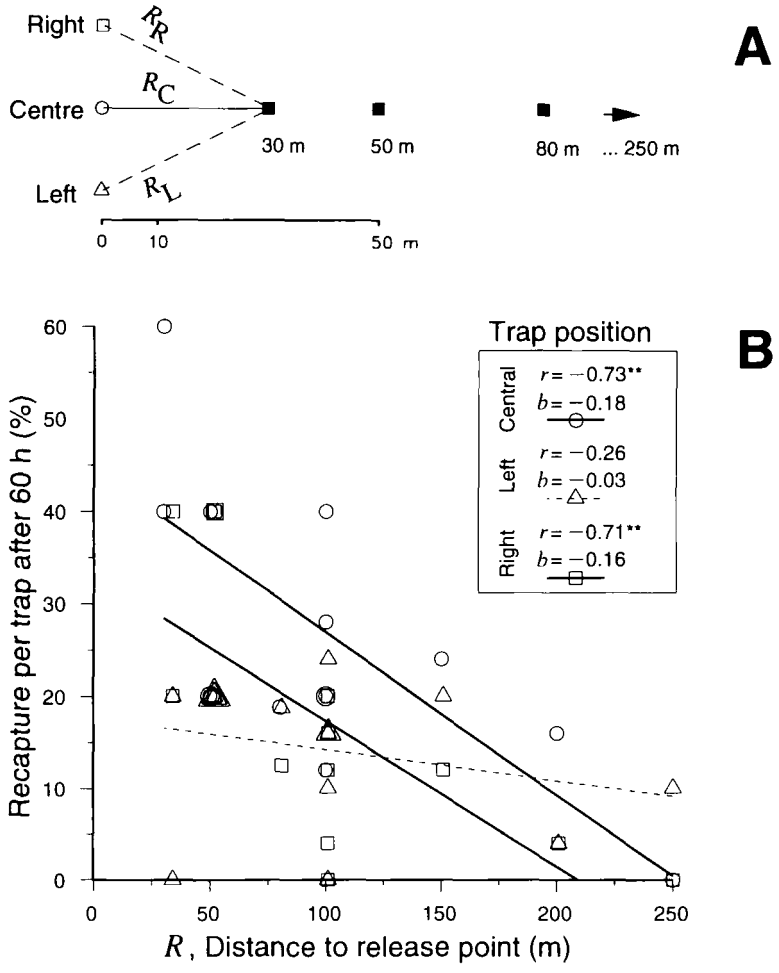

FIG. 1. (A) Experimental layout drawn to scale. (○, △, □) Pheromone traps, (■) Release platforms. R_R, R_C, and R_L) The range from a platform (30 m only drawn) to right, central, and left trap, respectively. The R_R and R_L are $10\% > R_C$ for $R_C = 30$ m. The exact values were used for x-values in regression estimates. (B) Recaptures per trap of *H. cunea* males. For regression lines in correlations: ----) $P > 0.05$ (N.S.), ——) $P < 0.01$ (**). Correlations were made on untransformed data, thus P-value levels are only rough indicators. The central trap position had higher catches than the left trap, while the decline of recapture over distance did not differ (slopes not different, see Table 2). (r) the Pearson correlation coefficient, (b) the slope of the regression line. Each differently sized marker of the same type centered on the same point show one of several overlapping data points. For details on regression parameters, see Table 2.

Methods

For a summary of dates and numbers of males released, see Table 1.

First Generation 1993. At 7:30 PM of May 25, marked males were released from 30 m (10 ♂♂ marked with red color), 50 m (10 ♂♂ marked with blue color), and 100 m (10 ♂♂ with black color) downwind of the trap line. The three Uni-traps were inspected at 7:30 AM on three consecutive days (at 12, 36, and 60 hr after release). The recaptured marked males were removed and counted. The same experiment was repeated once from May 28 to 31, except for marking color (purple, green, and yellow). The wind speed during the possible flight period (i.e., early evening, Zhang et al., 1996) was 1.5–2.5 $m \cdot s^{-1}$.

Second Generation 1993. At 7:30 PM of August 1, 25 ♂♂ marked with black color were released only from 100 m downwind of the trap line, as few newly emerged male moths were available at that time. The traps were checked 12, 36, and 60 hr after release. Wind speed was 0.5–1.0 $m \cdot s^{-1}$ in early morning, when second generation males fly (Zhang et al., 1996).

First Generation 1994. At 7:30 PM of May 17 and 21, 5 and 16 newly emerged ♂♂, marked with black were released from 50 m to 80 m downwind of the trap line, respectively. On May 25, 25 ♂♂ marked with red were also

released from 100 m downwind. Trap monitoring for each distance was carried out at 12, 36, and 60 hr after release. The wind speed during the flight period (early scotophase) ranged 1.5–2.5 $m \cdot s^{-1}$.

Second Generation 1994. At 7:30 PM of July 24, 26, 28, and 31, 25 ♂♂ were marked and released from 100, 150, 200, and 250 m, respectively, downwind of the trap line, using a different color each day. Traps were monitored as above. Wind speed during the possible flight period (early morning in second generation) ranged from 0.4–0.9 $m \cdot s^{-1}$.

RESULTS

Recaptures per Trap and Night

Rate of recapture gives the basis for estimate of the range of action of a pheromone source. Recapture rates were high, in total 115 of 176 (65%) of the males released were captured. Rates were above 50% in 6 of 10 experiments (minimum 10%, maximum 100%) (Table 1). Total recapture rates were 40–100% over distances 30–150 m. Also at 200 and 250 m recaptures were 10–24% (Table 1). More than 90% of captures took place during the night of release for the first generation and in the next early morning for the second generation. For individual traps, recaptures after 12 hr were on average 18.1 ± 14.4% (±standard deviation SD, $N = 42$), while during the second night (36 hr) recapture was lower by a factor of ten at 1.2 ± 2.5%, and another decadic step lower on the third night (60 hr) at 0.10 ± 0.62%. In total, 103 of 115 (89.6%) males were recaptured during the first night (Table 1). No unmarked males of *H. cunea* and no other moth species were captured.

Rates of recapture are expected to vary with season due to uncontrollable factors such as ambient temperature or moth quality. However, in this work recaptures in different generations and years showed little difference (Table 1). In a 2-way ANOVA the result was $P > 0.2$ for both generation and year ($F < 1.8$, $df = 1,38$ for factors; $P = 0.97$, $F = 0.002$, $df = 1$ for the interaction). The central position of the three trap positions had a somewhat higher catch (ANOVA $P = 0.054$, $F = 3.14$, $df = 2,39$). More interestingly, the slopes of the regression lines on untransformed scales for recapture over distance (Figure 1B), did not differ among traps. There was no interaction of trap position × distance (ANOVA on transformed scales: $P > 0.1$, $F = 1.15$, $df = 12$) and the x-axis intercepts overlapped widely (Table 2).

There was a significant overall decline of recapture over distance ($r = -0.56$, $P < 0.01$**, $N = 42$, untransformed linear data), but the large difference between traps, with the central trap catching more (Figure 1B), made a regression based on the raw data points for each trap an imprecise estimate of R_S.

[a] Untransformed data.
[b] $\arcsin\sqrt{p} - \sqrt{Distance}$ regression.
[c] $\arcsin\sqrt{p} - \log(Distance)$ regression.

Recapture per Release Distance

As there was no interaction between trap position and distance, the data could be pooled for distance. When the catches of the three traps were summed to give one data point per release night and distance, a stronger correlation ($r = -0.856$, $P < 0.001$***, $N = 14$, untransformed data) was found between the total recapture proportion after 60 hr and distance, R. An approximately normal distribution of the dependent variable and an equidistantly spaced (uniform) independent variable was obtained by an arcsin $\sqrt{p}$ transformed catch (y) regressed on $\sqrt{R}$ (x) (Figure 2). The transformed data gave a slightly lower r-value (-0.844, $P < 0.001$***, $N = 14$) than untransformed data. As the x-values (R) are fixed and exactly known, the data allow for the use of a standard Model I linear regression (Figure 2). This type of regression is only a probability

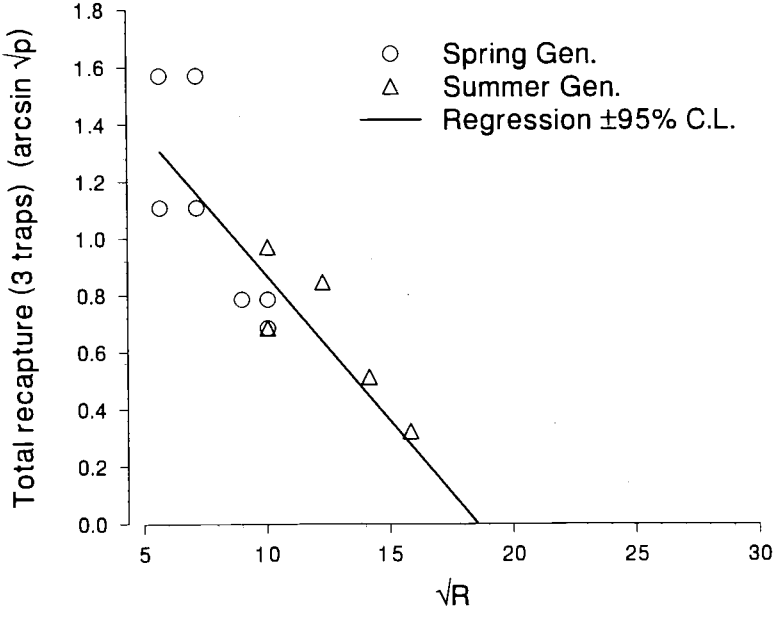

FIG. 2. Recaptures, summed for all 3 traps after 60 hr, of *H. cunea* males released from different distances down-wind a line of the traps. The x-intercept of the catch-distance regression lines corresponds to the maximum sampling range, R_S. Data and the regression line with its 95% confidence limits are displayed on the transformed scales. Regression of transformed y-values (proportion recaptured, in radians; arcsin $\sqrt{p}$) on transformed x-values (release distance, m: $\sqrt{R}$). Equation for regression (with ±SE of parameters): $y = 1.885(\pm 0.187) - 0.102(\pm 0.019)R$, $r^2 = 0.72$, $N = 14$. For more details on regressions parameters, see Table 2.

function (Turchin and Odendaal, 1996) for recapture over distance, but it gives directly the maximum sampling range (1 D), while the area sampled (2 D) requires an integration over the whole circle area to yield the sampling area.

The regression equation (with SE of parameters) for the total catch 60 hr after release was: $y = 1.88(0.19) - 0.102(0.018) \cdot x$, while after the first night at 12 hr it was:

$$y = 1.90\ (0.21) - 0.108(0.021) \cdot x\ (r = -0.83,\ P = 0.0002^{***},\ N = 14).$$

This gives a probability function of recapture, $P(R)$, over distance, R:

$$P(R) = (\sin(1.885 - 0.1016\sqrt{R}))^2$$

after sampling for 60 hr.

The regression allows a prediction of the maximum R_S (equivalent to the intercept with the x-axis) as 344 m with a confidence interval of 190–710 m (Figure 2). Regression of $\arcsin\sqrt{p}$ on $\log(R)$ gave a marginally larger r (-0.859), but gave a wider confidence interval for the intercept with the x-axis (Table 2). The first night of sampling with trap check after 12 hr gave an x-axis intercept close to the value for total catch after 60 hr (Table 2). The proportion of recapture at $y = 0$ (the x-axis intercept) corresponds to the maximum sampling distance (R_S) or the total area affected by the action of the sampling traps.

However, other probabilities of sampling can be estimated. The 0.5 intercept gives a 50% probability of recapture from 120 m (95% C.I.: 40–260 m).

Sampling Area

To get the area, A, where sampling efficiency is unity, we need to integrate the probability of sampling (here estimated as recapture probability, $P(R)$) from the source ($R = 0$) over each annulus of the circle area (dR) to the maximum sampling range (max R_S). The general equation is (modified from Turchin and Odendaal, 1996):

$$A = 2\pi \int_0^{R_S} R \cdot \mathrm{P}(R)\ \mathrm{dR};\ \text{and for our data we have:}$$

$$A = 2\pi \int_0^{\max R_S} R \cdot (\sin(1.885 - 0.1016\sqrt{R}))^2\ \mathrm{dR}$$

which for $R_S = 344$ gives 68,850 m^2 or 6.9 ha. If we would, naively, assume that the sampling efficacy is 100% all the way to the max R_S, the sampling area would be that of a circle with radius = R_S or 37 ha, a considerable overestimate by a factor of 5.4. Alternatively, the 6.9 ha corresponds more realistically to a circle with radius 148 m and sampling efficacy 100%.

DISCUSSION

The reliability of the data gathered here may be regarded as good, both in a biological sense–as recapture rates were consistently high and no difference existed between generations, and statistically–as correlations and regressions were highly significant. The r^2 values for both log and square-root transformed distance were >0.7. The confidence intervals were wide for the intercept with the x-axis (at $y = 0$, giving the maximum R_S), partly caused by the shortage of data points at high R values. This, in turn, depended on the unexpectedly high recaptures found at 100 m ($\geq 40\%$) which prompted investigation of the largest R values only in the latest experiments. Replication at the larger R values was as a result weaker. However, even the lower confidence limit for the maximum R_S is >100 m. As error margins or confidence limits for ranges of action of attractants are rare in the literature, comparisons with precision in earlier studies is hampered and we must still mostly compare estimates of central measures only.

Insects and attractants yield combinations that have widely different ranges of action. Schlyter (1992) said that "In general bark beetles seem to have smaller ranges than moths." However, variation within orders is large. While some Coleoptera such as *Tribolium castaneum* may have a range of attraction of about 2 m (Obeng-Ofori and Coaker, 1990), the curculionid *Cylas formicarius elegantulus*, the sweet potato weevil, has an R_S of at least 280 m (Mason et al., 1990) or as much as 470 m (recalculation by Schlyter, 1992). Even a kairomone response by a predatory beetle, *Teretriosoma nigrescens* Lewis (Histeridae), towards the synthetic pheromone of *Prostephanus truncatus* Horn (Col.: Bostrichidae) has a range of >100 m (Helbig et al., 1992). Some Lepidoptera such as *H. cunea* (this paper), *Cydia nigricana* (Wall and Perry, 1987) and *Chilo suppressalis* (Kondo and Tanaka, 1994), have R_S values >100 m. However, the Oriental peach moth *Carposina niponesis* (Oku et al., 1986) had an indirectly estimated R_S value of only about 20 m, and for the winter moth *Operophthera brumata* L. (Geometridae) Ambrus and Csoka (1992) found flight ranges of marked males to be only about 10 m.

The range of action observed here, longer than earlier reports for moths, could be explained by genetic, physiological, or ecological factors. Populations of an introduced and still spreading species may be selected to have a high frequency of good fliers. A species expanding its range during many generations would also benefit from characteristics that allow mate finding at initially very low population levels, such as high sensitivity of male peripheral and central systems (receptors, sensilla, sensilla frequency, neural pathways, CNS organization) or large amounts of female pheromone (as much as 1 μg/gland content in *H. cunea* reported by Hill et al., 1982). The large antenna of *Hyphantria* and

other arctiids may by themselves give better recaptures as they may act as a larger filter (more sensilla) for airborne molecules than those of the smaller tortricids. *H. cunea* is overall a large moth with good flight capability. Ecological factors, may however, be very important. The open area used, with little obstructions to flight, in combination with nonhost vegetation with no nearby natural pheromone sources will be optimum conditions for finding a source.

Zhang et al. (1997) suggested that "the insect density (web nests of *H. cunea* larvae) in (the coming) generation can also be predicted accurately . . . based on the trap captures" using the same trapping system as used here. For counting of larval webs on trees they used a circular area with radius 30 m. Recaptures at 30 m in our experiments in the open field were between 90 and 100%. The good ecological relation (trap catches–population dynamics) found by Zhang et al. (1997) could thus be anticipated from the behavioral data reported here, with a >90% capturing efficiency of males within the area sampled for larvae.

Our behavioral data might have overestimated R_S (due to the ecological factors discussed above), and the actual proportion caught from within 30 m might have been even higher in an area which had tall vegetation and many sources of natural pheromone (Zhang et al., 1997). Carter et al. (1992) found a poor relationship between male catches and level of defoliation at the leading edge of a gypsy moth *Lymantria dispar* (L.) infestation, which they suggested was due to a too large sampling area of traps compared to that of defoliation observations.

Population density may indirectly influence the range of sampling due to shorter wing lengths in high density populations with larval crowding (Carter et al., 1994). The present study was done in an open field with little physical obstruction of male flight and with no (known) competition with natural female pheromone sources from a resident population, as no unmarked males were found in our traps. Thus, sampling range could be expected to be smaller in a biotope with higher plants or trees and competing attraction sources.

Pheromone traps usually only function to attract the insects down-wind of a trap. Thus, sampling areas calculated by means of the whole circular area, as we simplistically did here, will be larger than the actual area of sampling if the wind direction is stable during the whole period of sampling.

Further studies on the sampling range in *H. cunea* should include tests in other biotopes and varying population levels. In addition replication at longer distances would be prompted by the present results.

The high recapture rates and the long R_S indicate that pheromone traps are highly efficient sampling devices for *H. cunea*. The R_S estimated here will be helpful as a first guide for trap placement in monitoring or mass-trapping schemes.

Acknowledgments—We are grateful to Mr. D. Chu and Mr. Z.-L. Jiang for their assistance in the field and to Dr. Y. Ninomiya and Dr. S. Senda of Nitto Denko Corporation, Osaka, Japan for pheromone dispensers. We thank members of the Pheromone Group in Lund, especially Drs. O. Anderbrant and V. Buda, and Prof. M. R. Paiva (FCT/UNL) for critical comments on earlier versions. The study was made within the project "Exploiting and Application of Pheromones in Main Forest Insects of Northern China" (to Q.-H. Zhang) financed by Ministry of Forestry, P. R. China.

ROLE OF ALLELOPATHY AS A POSSIBLE FACTOR ASSOCIATED WITH THE RISING DOMINANCE OF *Bunias orientalis L.* (BRASSICACEAE) IN SOME NATIVE PLANT ASSEMBLAGES

(Received November 3, 1995; accepted May 16, 1996)

Abstract—Leaf extracts of *Bunias orientalis* were shown to inhibit seed germination of a variety of cultivar plant species and of species cooccurring with *B. orientalis* in the field. Root exudate solutions and leaf litter leachates of *B. orientalis* were tested for their allelopathic activity using seedling growth assays. Additionally, in comparative seedling growth assays soil cores removed from dense *B. orientalis* stands were tested bimonthly for elevated allelopathic effects. The impact of root exudates on seedling growth was generally weak and varied between species. Similar results were obtained for the effect of *B. orientalis* leaf litter leachates on seedlings grown in sand culture relative to the effect of leaf litter leachates of a plant species mixture. When soil as a growth substrate was used, no consistent differences in seedling growth were obtained between the two litter leachate treatments. In the soil core experiment seedlings grown in soil cores collected from a dense *B. orientalis* stand unexpectedly showed better performance than seedlings grown in soil cores collected from a nearby mixed plant stand without *B. orientalis*, at least in early spring and late autumn. Predominating nutrient effects are, therefore, assumed to conceal a potentially increased allelopathic effect of soil beneath dense *B. orientalis* stands. It is concluded that other factors than allelopathy must be investigated to explain the rapid establishment of dense stands of this alien plant species.

Key Words—Allelopathy, *Bunias orientalis*, root exudates, leaf litter leachates, soil cores, growth inhibition.

INTRODUCTION

Recent research has demonstrated allelopathic potential for several aggressive colonizer plant species, many of them being serious weeds (e.g., Weston et al., 1987; Li et al., 1992; Inoue et al., 1992; Yamane et al., 1992a, 1992b; Dolling et al., 1994). However, for some other potent weedy species previously suspected to be allelopathic, no considerable phytotoxic activity could be found, at least in experiments designed to be pertinent to evaluation of natural field conditions (Horsley, 1993; Choesin and Boerner, 1991).

Bunias orientalis L., a perennial Brassicaceae probably native to the southwest of Russia and now naturalized as a weed in most parts of Europe (Tutin et al., 1993) belongs to this group of potent colonizer plants, spreading rapidly in some regions of Central Europe in recent years (Ullmann et al., 1988; Steinlein et al., 1996). Thus, the question arises as to whether the rapid expansion of *B. orientalis* stands is promoted by allelopathic effects.

B. orientalis leaf extracts have been shown to considerably inhibit germination of standard (cultivar) and weedy species in petri dish bioassays. A chemical analysis of these extracts yielded cinnamates and norisoprenoids as possible candidates for this allelopathic effect (Dietz and Winterhalter, 1996). Such bioassays certainly are of value for tests of the allelopathic potential of organisms (Leather and Einhellig, 1986), but often they are not suitable to provide evidence for allelopathic effects in the field (Stowe, 1979; Heisey and Delwiche, 1983; Lawrence et al., 1991). In this respect it is crucial to investigate whether 'natural' pathways of egression of the possible allelochemics (e.g., by root exudation or by leaching of living or decomposing leaves) into the respective growth substrate lead to phytotoxic effective concentrations for receptor plants grown therein. Additionally, investigations of the rhizosphere soil obtained from the field site may be useful for the determination of phytotoxic plant–plant interactions in the field (e.g., see Henn et al., 1988; Li et al., 1992; Horsley, 1993).

The aim of this present study was to determine (i) whether exudates of *B. orientalis* roots impair growth of seedlings in sand culture, (ii) whether leachates from decaying *B. orientalis* leaves show elevated allelopathic effects on seedlings growing in sand or soil as compared to leachates from a plant species mixture and (iii) whether soil collected from dense *B. orientalis* stands inhibits seedling growth relative to soil collected from a nearby plant stand without *B. orientalis* due to possible accumulation of allelochemics, and to determine if there are seasonal variations in the corresponding results.

MATERIALS AND METHODS

Donor and Receptor Plants. For all greenhouse experiments *B. orientalis* donor plants were grown from fruits collected the year before the study at a

location with dense *B. orientalis* stands in the vicinity of Würzburg (Germany). Most of the chosen receptor (indicator) plants are widespread nitrophilic species actually or potentially cooccurring with *B. orientalis*: Seeds of *Lactuca sativa* L. var. Kagraner Sommer/Duna, *Hordeum vulgare* L., *Arctium tomentosum* Mill., *Artemisia vulgaris* L., *Cirsium vulgare* (Savi) Ten, and *Rumex obtusifolius* L. were obtained from Carl Sperling & Co. (Lüneburg, Germany); seeds of *Arrhenatherum elatius* (L.) J. et C. Presl and *Tanacetum vulgare* L. were collected at a nearby field site the year before the study.

Petri Dish Bioassay. In this study we concentrated on perennial receptor species cooccurring with *B. orientalis* in the field. Therefore, at first it was necessary to determine whether they exhibit susceptibility to allelochemics from *B. orientalis* as was previously shown for the cultivar species *L. sativa* and *H. vulgare* and the annual herb *Matricaria inodora* L. (Dietz and Winterhalter, 1996). For that purpose petri dish bioassays were performed to test for germination inhibition for each indicator species. Twenty five seeds each of *T. vulgare*, *C. vulgare*, *A. vulgaris*, and *R. obtusifolius* were sown on filter paper discs within petri dishes (five replica plates each) and were added with 3 ml of *B. orientalis* leaf extract prepared by immersion of leaves in distilled H_2O (20% w/w, 3 d) or distilled H_2O only (control), respectively. Germination percentage was measured after 100 hr in the growth chamber. Additionally, for *R. obtusifolius* showing rapid and complete germination, radicle lengths were measured to the nearest 0.5 mm. *A. tomentosum* and *A. elatius* were excluded from the test due to their prolonged germination behavior. For further details and a discussion of osmotic effects see Dietz and Winterhalter (1996).

Root Exudate Recirculating System. A bioassay of seedling growth inhibition by phytotoxic root exudates was performed following the root exudate recirculating method of Stevens and Tang (1985) in a modified design. Plastic pots of 17.5 cm height, 20 cm diameter (volume 4 l) were used as donor pots and as acceptor pots. Hose unions were fixed centered at the bottom of the pots and connected to plastic tubes with an inner diameter of 1 cm for circulation of nutrient solutions. All tubes were wrapped with aluminium foil to exclude light. Donor and acceptor pots of a recirculating system were set up in a staircase arrangement. Two boards with drilled holes allowing vertical passage of tubes, were used. The board supporting the acceptor pots was lifted 40 cm relative to the board supporting the donor pots, thus enabling nutrient flow from acceptor pots to donor pots by gravity. Nutrient solution flow back to the acceptor pots was managed by means of an electric air pump (flow rate 1.5 liters/hr). The bottoms of the pots were covered with cheesecloth to retain suspended matter from entering the tubes. The cheesecloth was topped with a 5 cm layer of porous clay pebbles (Lecaton, Germany). The rest of the pot volume was filled with coarse grade silica sand (0.7 mm grain size).

To every recirculating system 2.75 l of a modified Hoagland nutrient solution was added once, which was supplemented with ammonia and iron (Smith

et al., 1983). Concentrations of macronutrients were (mmol/l): KNO_3 8.0, $Ca(NO_3)_2$ 3.0, NH_4Cl 5.0, NaH_2PO_4 1.0, $MgSO_4$ 2.0 and Fe-EDTA 0.1. Nutrient levels were monitored using an anion analysator (Biotronik, Germany) and test sets for cations and were maintained by selectively replenishing exhausted salts (mostly phosphate and nitrate). Water loss due to evapotranspiration was determined every day by weighing both pots of each system with a spring-balance (precision $\pm$ 100 g). The lost amount of water was replenished daily. The pH of the nutrient solutions was constant at 6.0 during all experimental runs.

The experiments were performed in a glasshouse with temperature regulation (25°C/10°C daytime maximal temperature/nighttime minimal temperature) and ambient light conditions (but excluding direct sunlight between April and October 1994).

For each indicator species (*L. sativa*, *H. vulgare*, *A. elatius*, and *A. tomentosum*) one experiment was performed using three replicate treatment systems (*B. orientalis* as donor plant, 100% nutrient strength) in parallel with two triplicate control systems (no plants in donor pots, 100% or 60% nutrient strength, respectively). The recirculating systems were randomly assigned to the nine positions on the boards. For the treatment systems vegetative *B. orientalis* plants (mean rosette leaf length of about 25 cm) were removed from the culture pots, the root systems were gently rinsed, and four plants each were then planted into the donor pots. Donor pots of the control systems without *B. orientalis* plants were inoculated with about the same amount of soil which was introduced to the treatment systems adhering to *B. orientalis* roots. For each new experiment the silica sand was completely replaced, the clay pebbles thoroughly washed, and the tubes were either replaced or kept in boiling water for about one hr prior to reuse.

Three days after the start of nutrient circulation a surplus of seeds was sown into each of the receptor pots and covered with a 0.5 cm layer of silica sand. Upon emergence seedlings were thinned to 30 equally sized seedlings/pot. After 12 to 18 days, depending on the receptor species, the seedlings were harvested, shoot and root lengths measured, and dry weights were determined after oven-drying at 70°C for 24 hr. As *L. sativa* seedlings showed high mortality, only proportions of dead, damaged, and vital seedlings, respectively, were determined.

Leaf Litter Leachates. A comparative bioassay of seedling growth inhibition by leaf leachates was performed in the glasshouse (conditions see above) by comparing the effects of *B. orientalis* leaf litter on seedling growth with those of leaf material of a plant species mixture. Six flats (30 × 20 × 5 cm length/width/height) were filled with coarse grained silica sand and another six flats were filled with loamy soil. Leaf material from *B. orientalis* and several cooccurring species was freshly harvested at a location near Würzburg. For both substrates *B. orientalis* leaves (50 g f.w. per flat) were spread on the three flats

each. The remaining six flats were prepared with leaf material (50 g f.w. per flat) from the species mixture: *Artemisia vulgaris* (7.5 g), *Solidago canadensis* L. (11 g), *Heracleum sphondylium* L. (5 g), *Geranium pratense* L. (19 g) and grasses (7.5 g). During the first week the flats were kept wet by spraying them with 0.5 ml/l Wuxal (12 Vol % N, 4 Vol % P, 6 Vol % K) fertilizer solution (flats containing soil) or 1.0 ml/l Wuxal NPK 12-4-6 fertilizer solution (flats containing sand), respectively. Thereupon, all flats were kept moist using tap water. The amount of fluid added was adjusted depending upon evaporation such that the leaves and substrates remained moist all the time to speed up the decomposition process but avoiding leakage through the bottom of the flats. After 12 days the decomposed leaves were moved to the rims of the flats to form a ring. Within this ring a surplus of pregerminated seeds of *A. elatius*, *C. vulgare*, *R. obtusifolius*, and *A. tomentosum* was evenly planted in each flat and slightly covered with the respective substrate. Upon emergence the seedlings were thinned to yield about ten evenly distributed seedlings per species and flat. The seedlings were harvested after a growth period of two weeks, prior to apparent resource competition (mutual overshading). Seedling height, root length, and dry weight (after oven-drying at 70°C) were determined for the flats containing sand. For the flats containing soil, root length was omitted and dry weight was measured for above ground biomass only.

Soil Core Experiment. In order to test for seasonal enrichment of allelochemics in the soil beneath dense *B. orientalis* stands, soil cores (∅ 7 cm, depth 10 cm) were collected at two adjacent sites in the vicinity of Würzburg, one with dense cover (80–90%) of *B. orientalis* and the other with an equally dense mixed plant stand without *B. orientalis* about 20 meters apart (control). The soil type was loamy clay at each site. On March 28, 30 soil cores from each site were collected. The same day, each soil core was transferred into a plastic pot with free water drainage (∅ 8 cm, height 9.5 cm) without mixing up the stratification of the soil. Every pot was planted with four pregerminated seeds of one of the following species: *R. obtusifolius*, *C. vulgare*, *A. tomentosum*, *T. vulgare*, *A. vulgaris*, and *A. elatius*. Five replica pots were used for each species x treatment (site) combination. The seedlings were grown in a growth chamber for four weeks. Light and temperature were regulated as follows: 500 μmol/m^2/sec photon flux density (metal halide lamps); 14 hr light period with 22°C and 10 hr dark period with 10°C. The pots were watered daily with distilled water. Regenerating shoots and seedlings of preexisting species were clipped at soil surface level. The height of the seedlings (*C. vulgare*: rosette diameter) was measured weekly and above ground dry weight (70°C) was determined at harvest. Starting in March, the soil core removal and ensuing seedling growth experiment were repeated every two months until November. The July data set had to be omitted from the analysis due to disproportionate watering of treatment and control pots.

Statistical Analyses. All analyses were run using STATISTICA for Win-

dows (Statsoft, Inc. 1995, Tulsa, OK) with values of $P < 0.05$ accepted as significant.

One factor multivariate analysis of variance (MANOVA) was used to test for overall differences in the root exudate recirculating bioassays employing root length, shoot length, and dry weight of the respective seedlings as dependent variables. If this test was significant, univariate F-tests for each variable were examined to interpret the respective effects. For each variable with significant effect post hoc comparisons (Scheffé-test) were performed to determine the factor levels (*B. orientalis* systems, 100% control systems, 60% control systems) with significant differences.

For the leaf litter leachate experiment MANOVA was used separately for each seedling species. To avoid capitalizing by chance, a Bonferroni-adjusted significance level of $\alpha = 0.0125$ was used (Sokal and Rohlf, 1995). Upon significant results univariate F-tests again were performed for investigation of main effects.

For each experimental run of the soil core experiment, differences between soil core treatments, expressed as above ground dry weight and seedling height at harvest time were tested by using two-way analysis of variance (ANOVA, site x species design). This way the overall site main effect could be tested apart from the species effect. For each significant effect *t*-tests for each seedling species were performed regarding seedling height and dry weight to find out which species contribute to the significant differences between soil cores at the respective seasons. For these tests Bonferroni adjustment was used ($\alpha = 0.0083$).

RESULTS

Petri Dish Bioassay. For all species tested *B. orientalis* leaf extracts showed considerable germination inhibition (Table 1). For *R. obtusifolius* this effect was not obvious from the percentage of germinated seeds but from the greater radicle lengths in the control dishes.

Root Exudate Recirculating System. In general, *B. orientalis* root exudates showed only weak, though significant impact on seedling growth for most of the tested species. For *L. sativa*, the most sensitive species in the test runs, 70% of the seedlings were dead by harvest time and the rest showed leaf necroses in the treatment systems. In the control systems, about 30% of the seedlings remained vital, roughly 30% were damaged and a distinctively lower proportion of seedlings died (45% or 31% in the 100% or 60% control systems, respectively). *H. vulgare* seedlings in the treatment systems showed considerable shorter shoots and roots (by about 20% and 35–40%, respectively) as compared to the controls ($P << 0.001$, Figure 1 A). The comparison between the 60% and 100% nutrient strength controls revealed only minute though significant differences ($P = 0.047$ and 0.019, respectively) due to low variability in this

TABLE 1. INHIBITORY EFFECTS OF *B. orientalis* LEAF EXTRACT ON SEED GERMINATION OF FOUR DIFFERENT INDICATOR SPECIES (PETRI DISH BIOASSAY)

	Germination [%]	
Species	Extract	Control
T. vulgare	0	23
C. vulgare	0	8
A. vulgaris	1	15
R. obtusifolius	91	97
	Mean radicle length [mm]	
Species	Extract	Control

"*p*" = radicle protruding.

species. The dry weight was reduced to a lesser extent ($P < 0.05$, Figure 1 B) for the treatment pots. In this case there was no difference between the controls ($P = 0.473$). For *A. elatius* shoot and root lengths were not significantly different between the treatment and control systems ($P = 0.084$ and 0.563, respectively, Figure 1 C). As compared to the 60% controls, dry weights in the treatment systems as well as the 100% controls were slightly but significantly reduced ($P < 0.001$ and $P = 0.024$, respectively, Figure 1 D). But there was no difference between treatment and 100% controls ($P = 0.325$). Thus, differences in dry weight for *A. elatius* in this case might be attributed mainly to nutrient effects. *A. tomentosum* dry weight was significantly reduced (by about 20%, Figure 1 F) for the treatment systems in comparison to both controls ($P < 0.05$), whereas shoot length showed only marginally significant differences between the treatment and the controls ($P < 0.09$ in both cases). Root lengths were not significantly different ($P = 0.728$).

Leaf Litter Leachates. The overall treatment effect for seedlings grown in flats filled with sand was significant for shoot length and dry weight ($P = 0.033$ and 0.002, respectively), i.e., on average seedling growth was slightly impaired in the *B. orientalis* treated flats as compared to the flats treated with litter of the species mixture (first column in Figure 2). If tested for each species alone, only *A. tomentosum* showed a considerable contribution with marginal Bonferroni-adjusted significance ($P = 0.019$). Here, both shoot lengths and dry weights were reduced by about 25% ($P = 0.002$ and 0.022, respectively). Though not significant if tested separately ($P > 0.2$), the other species further contributed to between-treatment dry weight variance as indicated by the *P*-value (0.002) in the overall test.

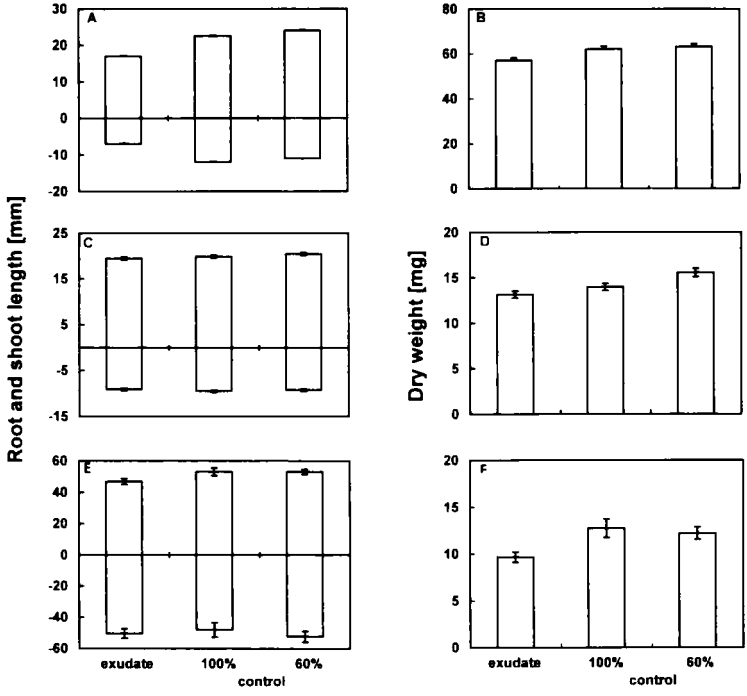

FIG. 1. (A-F) Root and shoot lengths and dry weights of receptor species seedlings grown in *B. orientalis* root exudate solution as compared to the controls. (A, B) *H. vulgare*; (C, D) *A. elatius*; (E, F). *A. tomentosum*. Error bars indicate ± S.E.

No clear growth differences could be obtained from seedlings of *B. orientalis* treated soil flats as compared to soil flats with species mixture leaves (second column in Figure 2). For the soil flats an overall treatment effect was found for dry weight ($P = 0.006$) but not for shoot length ($P = 0.557$). Again, this effect was caused by *A. tomentosum*, which showed a significantly higher dry weight in *B. orientalis* treated flats ($P = 0.003$). All other species neither showed significant differences in dry weight ($P >= 0.05$) nor a consistent trend for this variable for further explanation of between-treatment variance.

Soil Core Experiment. The results of the soil core seedling growth experiment exhibited considerable seasonality. On the whole, seedling growth in soil cores collected in early spring (March) and in late autumn (November) was considerably higher in the samples obtained from the dense *B. orientalis* stand as compared to the non-*B. orientalis* one (Figures 3 and 4). Except for *R. obtusifolius* and *T. vulgare* in the months between, i.e., May and September

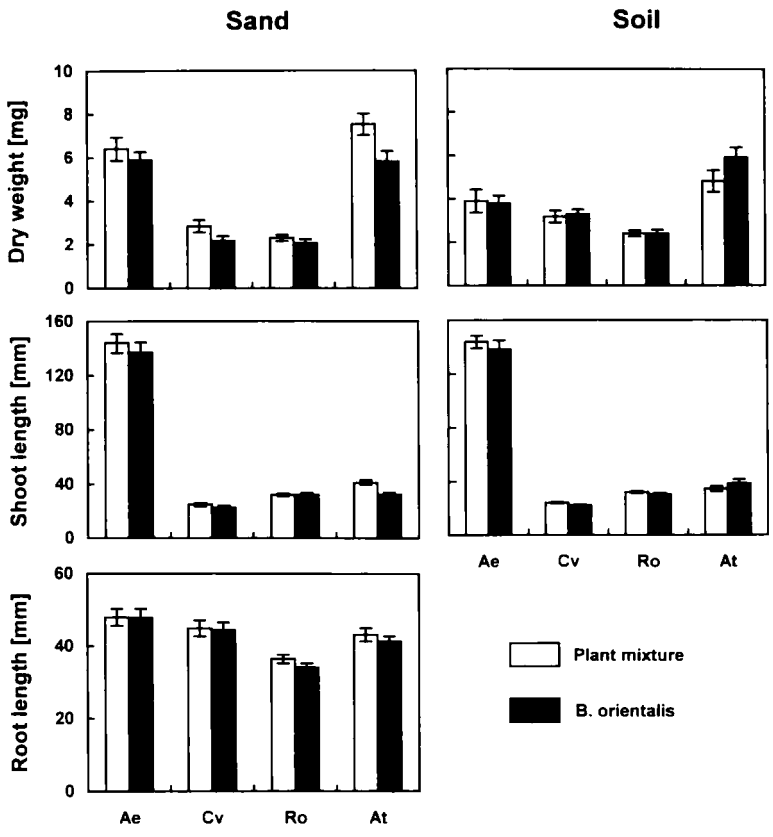

FIG. 2. Results of the leaf leachate experiment. Root lengths, shoot lengths, and dry weights of indicator species seedlings grown in sand culture and soil culture, respectively. Ae = *A. elatius*; Cv = *Cirsium vulgare*; Ro = *R. obtusifolius*; At = *A. tomentosum*. Error bars indicate ± SE.

(July was omitted from the analysis) there were no such prominent growth differences between both treatments (Figure 3).

In March, seedlings showed significantly higher shoot lengths and dry weights in *B. orientalis* soil cores ($P < 0.001$, Figure 3). *C. vulgare* and *A. elatius* differentiated strongly between treatments for both growth parameters ($P < 0.005$). *A. vulgaris* shows marginally significantly better growth in *B. orientalis* soil cores ($P < 0.025$). The other species, except *T. vulgare*, showed no significant differences ($P > 0.08$) though the trend was the same. In May, no significant differences could be observed between the treatments ($P = 0.485$,

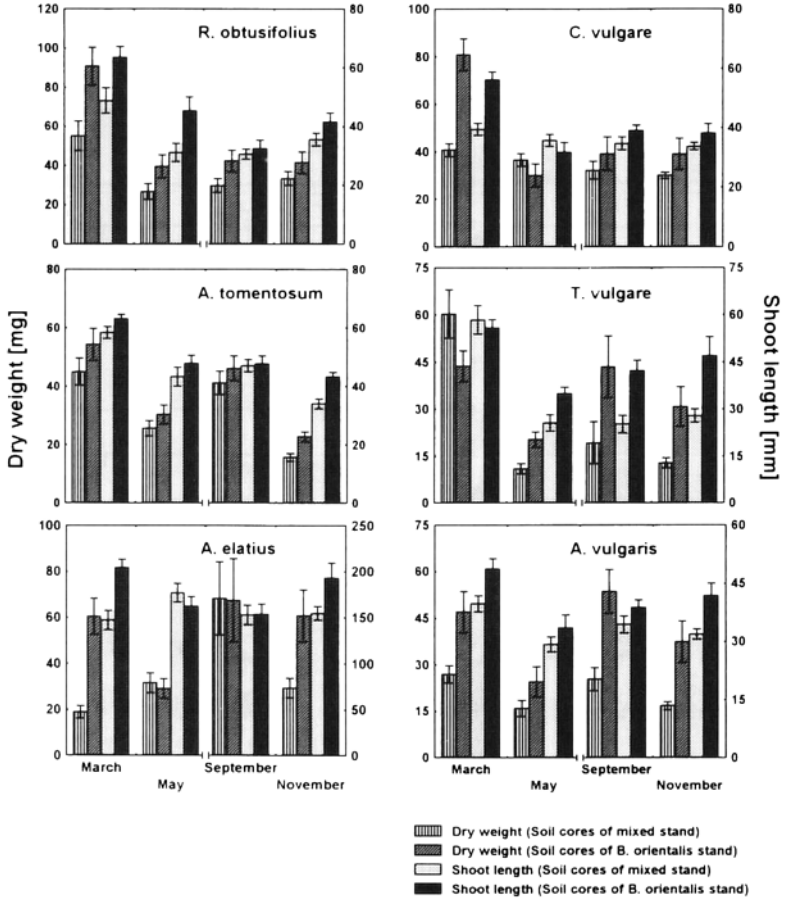

FIG. 3. Results of the soil core experiment. Shoot lengths and dry weights of indicator species seedlings grown in soil cores removed from a dense *B. orientalis* stand or from a mixed stand without *B. orientalis*. Shoot length data are from the measurement at harvest time. Error bars indicate ± SE.

Figure 3). In September, there was again a significant trend for better growth in *B. orientalis* soil cores concerning dry weight ($P = 0.015$) but not for shoot length ($P = 0.068$). No species contributed significantly to this trend when tested separately ($P > 0.03$). In November, performance of seedlings grown in the *B. orientalis* soil samples again were clearly better than in the soil samples from the non-*B. orientalis* stand ($P < 0.001$, Figure 3). This time, *A. tomen-*

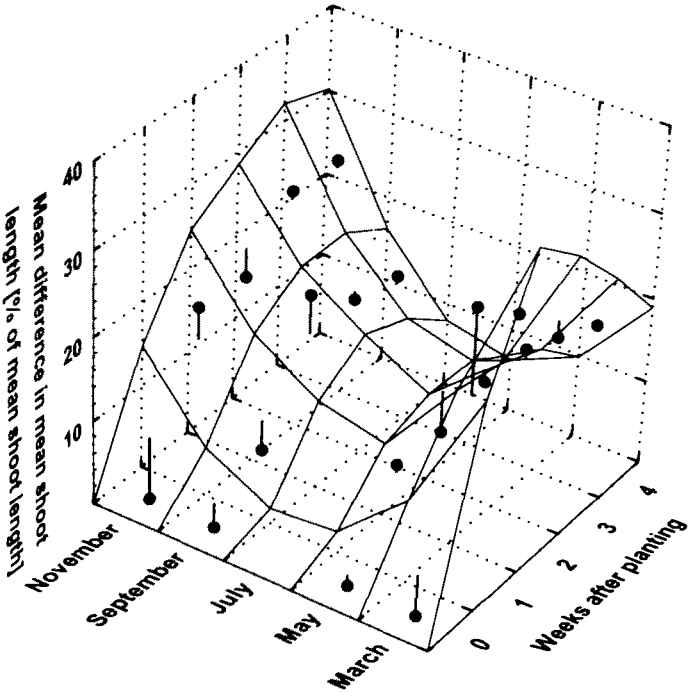

FIG. 4. Time course of differences in shoot lengths between seedlings grown in soil cores removed from a dense *B. orientalis* stand and seedlings grown in soil cores removed from a mixed plant stand. Differences were standardized (% of species mean shoot length) and data were generated by averaging the standardized differences of all six species tested. A spline smoothed surface is fitted to the data points to elucidate the general trend.

tosum and *T. vulgare* contributed most to the observed effect ($P < 0.002$), but also *A. elatius* dry weight ($P = 0.004$) and *A. vulgaris* growth ($P <= 0.01$) were significantly or marginally significantly higher in *B. orientalis* soil cores.

DISCUSSION

Root exudates from *B. orientalis* showed significant inhibitory effects for three out of the four species tested. Pronounced impact could only be observed for shoot and root development of *H. vulgare* and for mortality of *L. sativa*. These species are frequently used as indicator species for bioassays (e.g., Heisey and Delwiche, 1983; Heisey and Delwiche, 1985; Leather and Einhellig, 1986;

Barnes et al., 1986; Li et al., 1992) and therefore, may be predisposed for comparative studies. On the other hand, as cultivated species *L. sativa* and *H. vulgare* might be particularly susceptible to allelochemics compared to other species (see Stevens and Tang, 1985; Yun and Kil, 1992). The two remaining species, *A. tomentosum* and *A. elatius*, which are widespread species naturally cooccurring with *B. orientalis*, showed no or only weak response to root exudates. Of course, the results of our experimental design are limited to evidence of phytotoxic compounds exuded by roots of first-year vegetative plants, but considering the densely packed growth of four of them, in a system with small substrate volume, concentration of exuded allelochemics can be supposed to be higher than in dense *B. orientalis* stands. Moreover, the results of the leaf litter leachate test (see below) suggest that the efficiency of the allelochemics is diminished in (loamy) soil relative to sand substrate. Thus, in the face of our study, a considerable effect of root exudates for allelopathic growth inhibition in the field seems to be very unlikely.

The amount of leaves used for the leaf litter leachate assay (50 g d. w. per 600 cm^2 of substrate area) roughly corresponds to decomposition of 25% of total above ground leaf biomass of dense *B. orientalis* stands (unpublished data). Therefore, considering the shallow substrate layer (thickness 5 cm) of the flats and the prevention of leakage through their bottoms, it is reasonable to assume the concentrations of leached allelochemics in the respective substrates in the flats to be comparable with the conditions at the field site, provided that the decomposition rate of allelochemics *in situ* is sufficently high to prevent marked accumulation (see Rice, 1984).

Decaying leaves of *B. orientalis* weakly reduced seedling growth as compared to decaying leaves of a species mixture when sand was used as a substrate. In the soil design only species-specific growth differences differentiated between the two treatments without a consistent trend. This demonstrates the importance of the chosen substrate for the outcome of experiments aimed at evaluating the effects of allelochemics. On the other hand, a trade-off between beneficial effects of liberated nutrients and inhibitory effects of leached allelochemichs must be taken into account when interpreting the results (Li et al., 1992; Rutherford and Powrie, 1993). Therefore, evidence of the sand design suggests that the proportion of both effects is less favourable in the case of decaying *B. orientalis* leaves. As *B. orientalis* clearly shows no distinctly higher allelopathic effect arising from decomposing leaves compared to other coocurring species, particularly for soil conditions, this egression pathway of allelochemics, too, probably does not contribute to competitive advantage in the field.

The soil core experiment aimed at estimation of accumulation of allelochemics dependent on the season *in situ* yielded the unexpected result that not only no elevated allelopathic potential could be detected for soil from the *B.*

orientalis stand as compared to the non-*B. orientalis* stand during most of the vegetation period, but also soil conditions of the former were considerably improved for seedling growth in early spring and late fall. Obviously, particularly high nutrient input into the upper soil layer by mineralization of the great amount of above ground biomass typical for dense *B. orientalis* stands in autumn and early winter, may be responsible for this effect. Consistently, we observed improved soil conditions, i.e., higher contents of organic matter, in the sampled soil layer. Thus, a possible increase in allelochemics due to massive decomposition of leaf litter from *B. orientalis* seems to be overcompensated by far by remineralization or improvement of the nature of the topmost soil layer, respectively.

An important finding relevant for the initial questioning is that in our experiments considerable species specificity in reaction to the allelochemics or nutrient levels is apparent which was also found in previous research (e.g., Heisey and Delwiche, 1983; Rutherford and Powrie, 1993). Thus, in studies on allelopathy a variety of receptor species should be included to obtain general information about allelopathic effects of species under consideration, unless one is merely interested in effects on a certain target species (as for instance in agricultural research). Consequently, it may be apt to choose species naturally cooccurring with the investigated species in addition to more commonly used indicator species, when one targets at evaluation of the ecological importance of allelopathy *in situ*.

In summary, the results obtained within the scope of our study yielded no evidence for considerable allelopathic effects from *B. orientalis*. This distinctly contrasts the results from the petri dish germination bioassays and once again underscores the incongruity between allelopathic potential, as obtained by bioassays screening plant extracts, and the effectiveness of allelopathy under more natural conditions. Clearly, the conditions for duration, chemical modification, and availability for target plants of allelochemics in (loamy) soil (see Rice, 1984, chapter 14) is distinctly different from pure sand substrate or even more artificial substrates (e.g., hydroponic culture). Even if assumed that there be no distinct nutrient effects in the rhizosphere soil beneath dense *B. orientalis* stands, deposition of allelochemics caused by this species may either be rendered inefficient by the soil chemical reactor and/or may not be distinctly more efficient than deposition of allelochemics of the other cooccurring species.

Thus, and in the face of the at most weakly significant allelopathic effects observed in our study, our data did not support allelopathy as a substantial factor in the competitive ability of *B. orientalis*. We therefore, currently focus on growth patterns (Steinlein et al., 1996) and population dynamical aspects of *B. orientalis* to unravel the key traits underlying the rapid establishment and persistency of its stands.

Acknowledgments—We thank Mrs. E. Hatzung for her skillful technical assistance and for maintenance of the root exudate recirculating systems.

INTERCASTE, INTERCOLONY, AND TEMPORAL VARIATION IN CUTICULAR HYDROCARBONS OF *Coptotermes formosanus* SHIRAKI (ISOPTERA: RHINOTERMITIDAE)

MICHAEL I. HAVERTY,[1,*] J. KENNETH GRACE,[2] LORI J. NELSON,[1] and ROBIN T. YAMAMOTO[2]

(Received November 6, 1995, Accepted May 21, 1996)

Abstract—We characterized the variation in cuticular hydrocarbon mixtures between seven colonies of the Formosan subterranean termite, *Coptotermes formosanus* Shiraki, from the same population. We report differences between castes, between colonies, and within the population over time to assess seasonality. Colonies of *C. formosanus* from Oahu, Hawaii, were sampled for 25 months. Each month, one sample each of 200 workers, 50 soldiers, nymphs, or alates from each colony was subjected to gas chromatography-mass spectrometry (GC-MS) analysis of the cuticular hydrocarbons. We resolved 39 individual peaks and identified 52 individual or isomeric mixtures of hydrocarbons. Only *n*-alkanes and methyl-branched alkanes occur; no olefins were found. Internally branched monomethylalkanes were the most abundant class of hydrocarbons, representing 45% to 50% of the total. 9-;11-;13-Methylheptacosane accounted for over 30% of the total hydrocarbon for all castes. 2-Methyl- and 3-methylalkanes comprise approximately 30% of the total. Internally branched dimethylalkanes constitute 15% to 20% of the total cuticular hydrocarbon. Only one trimethylalkane, 13,15,17-trimethylnonacosane, was found in small amounts. The hydrocarbon mixtures of all four castes were similar. Quantitative differences in hydrocarbon mixtures among the castes were easily displayed using canonical discriminant analysis. Soldiers and workers are significantly different from one another and from nymphs and alates. Nineteen peaks are statistically significant between workers and soldiers. Nymphs and alates were not statistically different. We detected statis-

tically significant quantitative differences between colonies in 18 peaks for workers and 12 peaks for soldiers. Each of the colonies of *C. formosanus* can be separated from the others by the proportions of their hydrocarbon components. We detected statistically significant differences between months of the year for 12 peaks for workers and four peaks for soldiers; two peaks each for workers and soldiers showed distinct, seasonal trends. This seasonal shift in proportions of hydrocarbons correlates with the production of alates.

Key Words—Formosan subterranean termite, *Coptotermes formosanus*, founder event, biogeography, populations, seasonal variation, Isoptera, Rhinotermitidae, cuticular hydrocarbons, Hawaiian insects.

INTRODUCTION

The Formosan subterranean termite, *Coptotermes formosanus* Shiraki, is one of the most economically important subterranean termites species in the world and is a serious threat to wood in structures wherever it occurs (Su and Scheffrahn, 1990). Even though the common name implies that this species is from Formosa (Taiwan), Kistner (1985) considered *C. formosanus* to be indigenous to mainland China on the basis of its associated termitophiles. This species was introduced into Japan prior to 1600 and was first collected in Hawaii in 1907 (Swezey, 1914), although it may have been present as early as 1869 (Tamashiro et al., 1987). Since its introduction into Hawaii, *C. formosanus* has been reported to be established in Guam, Midway Island, Sri Lanka, Taiwan, South Africa, and the mainland United States (Su and Tamashiro, 1987). Morphological examination and characterization of the cuticular hydrocarbons of recent collections of *Coptotermes* from Guam, however, indicate that a species other than *C. formosanus* is present there (Su, 1994; Su and Scheffrahn, 1996; Haverty, unpublished observations). It is possible that two or more species of *Coptotermes* occur on Guam.

Infestations of *C. formosanus* were first noticed in the continental United States about 1965. It is likely, however, that colonies of *C. formosanus* were established soon after the end of World War II. Storage of *C. formosanus*-infested military goods at facilities near port cities of the United States has been implicated as the means of establishment of *C. formosanus* in North America (Beal, 1987). Once *C. formosanus* was firmly settled in locations such as New Orleans, Louisiana; Galveston, Texas; and Charleston, South Carolina, it began to appear in other port cities in the southeastern United States including Baton Rouge, Louisiana, and Hallandale, Florida (La Fage, 1987).

The analysis of cuticular hydrocarbon components of *C. formosanus* indicates that this species is separable from other species of *Coptotermes* characterized thus far on the basis of qualitative differences in cuticular hydrocarbons (Brown et al., 1990, 1994; Haverty et al., 1991, 1992). Quantitative differences

in cuticular hydrocarbons have been used to separate geographic populations of *C. formosanus* (Haverty et al., 1990a). Analysis of the cuticular hydrocarbons of workers from several colonies each from Hallandale, Florida; New Orleans, Louisiana; Lake Charles, Louisiana; and Honolulu, Hawaii suggests that *C. formosanus* was introduced into the United States numerous times (Haverty et al., 1990a). Populations from two geographically proximate locations, New Orleans and Lake Charles, displayed quantitatively different hydrocarbon mixtures, which strongly supports the hypothesis that at least two separate introductions were made into the state of Louisiana (Haverty et al., 1990a; La Fage, 1987). Since 1980, indications of established infestations in inland areas such as Auburn, Alabama; Meridian, Mississippi; Orlando, Florida; Atlanta, Georgia; and La Mesa, California, suggest this species may now be transported in infested wood products or potted plants via domestic commerce (Atkinson et al., 1993; Chambers et al., 1988; La Fage, 1987; Sponsler et al., 1988).

Allozyme electrophoresis has not yet proven to be a useful technique for investigating the distribution of *C. formosanus* populations in the United States. Korman and Pashley (1991) used standard starch gel electrophoresis to examine allozymic differentiation in colonies of *C. formosanus* from four populations (New Orleans, Lake Charles, Hallandale, and Honolulu). Very little variation was found. They found only limited differentiation in allele frequencies between populations, but concluded that mainland populations did not result from a single introduction.

Strong and Grace (1993) surveyed 13 colonies of *C. formosanus* in Hawaii and resolved 29 protein loci using cellulose acetate gel electrophoresis. Eight of these loci proved to be stable, but were found to be monomorphic across all colonies. Subsequently, preliminary results from starch gel electrophoresis confirmed the observation by Korman and Pashley (1991) of a low level of polymorphism at the glucose phosphate isomerase (Gpi) locus (Strong and Grace, 1993). Neither Korman and Pashley (1991) nor Strong and Grace (1993) were able to separate colonies or populations (several colonies from the same area) of *C. formosanus* by analysis of allozymes.

Similar conclusions were reached by Broughton and Grace (1994) when they surveyed mitochondrial DNA restriction sites from 10 colonies of *C. formosanus* from Hawaii. They discovered that there was no variation in mitochondrial DNA in any of the colonies they examined. Their results corroborate the findings of Korman and Pashley (1991) and Strong and Grace (1993) that *C. formosanus* populations in Hawaii, and on the U.S. mainland, have a very low level of genetic polymorphism, and suggest that this species was depauperate of genetic variation in comparison to the approximate 40% polymorphic loci for the Class Insecta as a whole (Nevo 1978). The survey of these geographically distinct colonies of *C. formosanus* on the Hawaiian islands of Oahu and Maui by Strong and Grace (1993) and Broughton and Grace (1994) raise

the possibility that the extremely low level of allozyme and mitochondrial DNA variation among these colonies was indicative of a "founder" event.

While the possibility of a single founder event in Hawaii is intriguing, resolution of this question by genetic techniques has thus far proven difficult. Since quantitative differences in cuticular hydrocarbons have been detected among geographically disparate populations of *C. formosanus* (Haverty et al., 1990a; Su and Haverty, 1991), we proposed to test whether resolution of quantitative differences in cuticular hydrocarbon mixtures of different colonies of *C. formosanus* within the same population or geographic area was possible. We report here the results of a study to characterize the variation of cuticular hydrocarbons of different colonies of *C. formosanus* from the same population (all from the island of Oahu). We report differences between castes, between colonies, and within the population over time to assess seasonality. This examination of the intrinsic variation in cuticular hydrocarbons will serve as the basis for developing optimal sampling regimes for further examination of variation within the species and assessment of potential founder events around the world.

METHODS AND MATERIALS

Collection of Termites. Samples of *C. formosanus* were collected monthly for 25 months (September 1990 through September 1992) from seven colonies from four separate locations on the island of Oahu, Hawaii. Four colonies were on the campus of the University of Hawaii: two adjacent to Gilmore Hall (Upper Gilmore and Lower Gilmore), and one each adjacent to Pope Hall and the former location of the Publication Building. One colony each was located in Kaneohe, on the Waipio Peninsula, and at the Poamoho Experiment Station of the University of Hawaii. The colony at the Poamoho Experiment Station is not a natural colony; it was derived from an incipient colony of unknown laboratory stock and was placed on the site in 1979 by Dr. Minoru Tamashiro [see Strong and Grace (1993) for details]. Samples were collected from each colony using the trapping technique developed by Tamashiro et al. (1973).

Each month termites from each colony were separated from wood, carton, soil, and other debris and one sample each of 200 workers, 50 soldiers, and up to 50 of nymphs or alates were placed in Petri dishes and dried in a desiccator with Drierite®. Termites were dried while alive, until they died, and then for an additional five days. We found that killing termites before drying them in ambient, laboratory air often resulted in decomposition of the termites. Concurrently, each month two voucher samples from each colony consisting of two or three individuals from each caste present were preserved in 80% ethanol; one sample was kept at the University of Hawaii and one kept at the Pacific

Southwest Research Station in Albany, California. About every three to four months, accumulated dried samples were shipped to California for characterization of the cuticular hydrocarbons. Dried samples were held at ambient temperature in Hawaii and California until they were extracted.

Hydrocarbons of C. formosanus. Detailed descriptions of extraction procedures for specific termite species have been previously published elsewhere (Blomquist et al., 1979; Howard et al., 1978, 1982, 1988; Haverty et al., 1988, 1990a,b). In our laboratory in California, dried termite samples were transferred to clean 20-ml vials and immersed in 10 ml of *n*-hexane for ten min. The resulting extract of cuticular lipids was pipetted through four cm of activated Biosil A in a Pasteur pipette minicolumn to isolate the hydrocarbon components. The hydrocarbon extract was then evaporated to dryness under nitrogen and redissolved in 60 μl of hexane.

Gas chromatography-mass spectrometry (GC-MS) analyses of the hydrocarbons were performed on a Hewlett-Packard 5890 gas chromatograph equipped with a capillary column (25 m × 0.2 mm ID, HP-1) and a Hewlett-Packard 5970B Mass Selective Detector. The system was interfaced with HP Chemstation software for data acquisition and analysis. Helium was the carrier gas, column flow was 2 ml/min, and the GC-MS was operated in the split mode with a ratio of 7 : 1. The GC was temperature programmed from 200° to 320°C at 3°C/min with a final isothermal hold of 16 min. Electron impact (EI) mass spectra were obtained at 70 eV, and scanning was done from 55 to 640 mass units every 1.0 second.

Quantification of individual hydrocarbon peaks was done by integrating the total ion chromatogram resulting from summation of mass ion abundances. Because of the large number of peaks representing co-eluting compounds and the necessity of checking these peaks for the presence of all compounds, all samples were analyzed and quantified this way. Past analyses using a flame ionization detector, rather than a mass selective detector, gave poor resolution of later-eluting peaks (see Haverty et al., 1990a) and important information may have been lost regarding high molecular weight hydrocarbons (C37 and higher).

n-Alkanes and methyl-branched alkanes were identified by their mass spectral fragmentation patterns (Blomquist et al., 1987; Nelson et al., 1980; Pomonis et al., 1980) and corroborated by calculating equivalent chain lengths (ECL) (Nelson and Sukkestad, 1970; Jackson and Blomquist, 1976). Mass spectra of dimethylalkanes were interpreted as described in Page et al. (1990b) and Nelson et al. (1980). Mass spectra of a trimethylalkane was interpreted as described by Page et al. (1990a).

In the text and tables, shorthand nomenclature has been used to identify individual hydrocarbons or mixtures of hydrocarbons. For example, heptacosane becomes *n*-C27; 3-methylheptacosane becomes 3-MeC27; 3,15-dimethyl-

heptacosane becomes 3,15-DimeC27, and 13,15,17-trimethylnonacosane becomes 13,15,17-TrimeC29. Hydrocarbons are presented in the table in the order of elution on our GC/MS system.

GC-MS peak areas were expressed as percentages of the total hydrocarbon fraction. The response variable for all statistical tests was the percentage of each individual peak, which may represent two or more co-eluting compounds (see Table 1). Summary statistics (mean and standard deviation of the percent of each peak or hydrocarbon component) were calculated for each caste combining all colonies and collection dates.

Intercaste, Intercolony, and Seasonal Variation in Hydrocarbons. We examined different transformations of the percentages of the hydrocarbons; none provided uniform improvement in skewness or kurtosis. As a result, all statistical treatments of data to assess intercaste, intercolony, and seasonal variation were conducted with actual percentages.

Differences between workers and soldiers were determined by a *t*-test of the percentage of each peak (or hydrocarbon component) with colonies (summed over all 25 collection periods) representing the replicates (i.e., $N = 7$ for each caste). Differences between colonies or months of the year were determined by analysis of variance of the percentage of each peak, separately for workers and soldiers. Statistical differences were tested to maintain an overall $\alpha = 0.05$ for the analysis of each of the 39 hydrocarbon peaks. Thus for each *t*-test or analysis of variance, the significance of the *t* or F statistic was tested at the $\alpha = 0.001$ level ($\alpha = 0.05/39$, where 39 is the number of statistical analyses conducted, one for each of the 39 hydrocarbon peaks).

Differences of hydrocarbon patterns between castes and between colonies were revealed by canonical discriminant analysis to provide two-dimensional displays of the chosen variables. Canonical discriminant analysis is a dimension-reduction technique related to principal component analysis and canonical correlation that derives a linear combination of quantitative variables (in this case, the percentage of hydrocarbon components) that summarizes between-class variation. The procedure that we used computes and tests Mahalanobis distances for pairwise comparisons of the colonies. Statistical analyses were accomplished with the TTEST, ANOVA, and CANDISC procedures of SAS System Release 6.08 (SAS 1990).

RESULTS AND DISCUSSION

Hydrocarbons of C. formosanus. Improvements in chromatographic equipment (replacing a flame ionization detector with a mass selective detector) and extraction technique (drying specimens before extraction with hexane and increasing the sample size to 200 individuals) allowed us to improve earlier

TABLE 1. HYDROCARBON MIXTURES (MEAN AND STANDARD DEVIATION) OF WORKERS, SOLDIERS, NYMPHS, AND ALATES OF *Coptotermes formosanus* FROM SEVEN COLONIES FROM OAHU, HAWAII, COLLECTED OVER 25 CONSECUTIVE MONTHS

[a] Carbon number is the total number of carbons in the parent chain, excluding methyl groups, e.g., 3-MeC25 = 3-methylpentacosane.
[b] An isomeric mixture. These components co-elute in this peak.
[c] Because of incomplete separation of these hydrocarbons both peaks are included as one value.
[d] Sample size = 175 for workers, 172 for soldiers, 42 for nymphs, and 9 for alates.
[e] Means (SD) for workers and soliders followed by "*" are significantly different at the $\alpha = 0.001$ level by t-test. Means followed by "#" represent significant differences among colonies for workers or soldiers, and means followed by "†" represent significant differences among collection months for workers or soldiers at the $\alpha = 0.001$ level by analysis of variance.

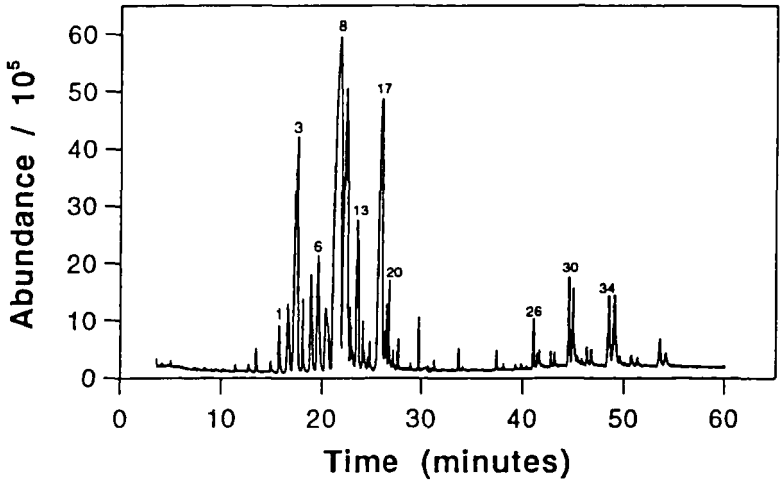

FIG. 1. Total ion chromatogram from 200 workers of *C. formosanus* from Pope Hall, University of Hawaii campus, Honolulu, Hawaii, in May 1992.

characterizations of the cuticular hydrocarbons of *C. formosanus* (Haverty et al., 1990a, 1991, 1992; McDaniel, 1990). We were able to resolve 39 individual peaks and characterize 52 individual or isomeric mixtures of hydrocarbons (Table 1 and Figure 1) from this species. Only *n*-alkanes and methyl-branched alkanes were found. *C. formosanus* does not make any olefins.

Normal alkanes present were *n*-C25, *n*-C26, *n*-C27, *n*-C28, and *n*-C29. Of the *n*-alkanes, *n*-C27 was the most abundant, comprising 2.4 and 5.7% of the total hydrocarbon for workers and soldiers, respectively, and intermediate amounts for nymphs and alates. The other *n*-alkanes generally represented no more than 1.2% each of the total hydrocarbons (Table 1).

Internally branched monomethylalkanes with methyl groups positioned at the nine carbon or greater elute about 0.7 carbon units in front of the *n*-alkane with the same number of total carbons. Their mass spectra have strong *m/z* ions representing cleavage internal to the methyl branch for which the ratio of even to odd is close to one (Blomquist et al., 1987). We identified isomeric mixtures of internally branched monomethylalkanes with parent carbon chains ranging from C25 to C43, except for C31, C32, C34, and C36. Positions of methyl branches ranged from carbon 9 to 18 (Table 1). Methyl branches located on even-numbered carbons were found only when the parent chain of the hydrocarbon had an even number of carbons, while branches on odd-numbered carbons were found to occur on hydrocarbons with either odd or even number of carbons in the parent chain. Internally branched monomethylalkanes were the

most abundant class of hydrocarbons produced by *C. formosanus*, representing roughly 45 to 50% of the total hydrocarbon. One isomeric mixture, 9-;11-;13-MeC27, accounted for over 30% of the total hydrocarbon for all castes surveyed (Table 1 and Figure 1).

2-Methylalkanes have an ECL of approximately 0.4 carbon units less than the corresponding *n*-alkane with the same number of total carbons and give a spectrum with a strong $(M-43)^+$ ion and a weaker $(M-15)^+$ ion. 3-Methylalkanes have an ECL of approximately 0.3 carbon units less than the corresponding *n*-alkane with the same number of total carbons and give a spectrum with a strong $(M-29)^+$ ion and a weaker $(M-57)^+$ ion. 2-Methyl- and 3-methylalkanes were identified for C25 to C29. In many cases the two peaks were not completely resolved on our system. These terminally branched monomethylalkanes comprise approximately 30% of the total hydrocarbons (Table 1 and Figure 1).

Internally branched dimethylalkanes constitute 15 to 20% of the total cuticular hydrocarbon fraction of *C. formosanus* (Table 1). There were two types of internally branched dimethylalkanes, those with either three methylene groups or those with one methylene group separating the methyl branches, representing roughly equal proportions of this class of compounds. Dimethylalkanes, such as 13,17-DimeC37 and 15,19-DimeC37, eluted about 1.4 carbon units before the corresponding *n*-alkane with the same number of total carbons, as did 14,18 and 16,20-dimethylalkanes. 9,13-Dimethylalkanes were present at C27, C28, and C29 and co-eluted with the 2-methylalkane of the same parent chain length.

Dimethylalkanes with one methylene group between methyl branches are not common in insects (Blomquist et al., 1987; Lockey, 1988), however, these compounds are fairly abundant in *C. formosanus* (Table 1). These alkanes have fragmentation patterns similar to other dimethylalkanes, except that an additional strong ion pair represents the daughter fragment formed by cleavage internal to the second methyl branch (Nelson et al., 1980). This ion pair has an even to odd ratio close to one. Another characteristic of this fragmentation is the relatively high intensity of the ion pairs representing the fragment ions formed by cleavage external to the second methyl branch, which have even to odd ratios of less than one (Nelson et al., 1980). The elution times for these compounds are 0.2 to 0.3 carbon units less than those of the other internally branched dimethylalkanes seen in this insect (Haverty et al., 1990a; Pomonis et al., 1980). Dimethylalkanes with one methylene spacing eluted slightly later than the monomethylalkane with the same parent chain length. Usually the two peaks did not fully resolve and thus were integrated as one peak. They occur together at C28, C29, C30, C37, C39, C41, and C43. The exception is the isomeric mixture 13,15-; 15,17-DimeC31, as no monomethyl alkane was identified at C31.

Terminally branched dimethylalkanes with the first branch on the 3-carbon had a strong $M-29^+$ ion and eluted about 1.0 carbon unit in front of the corresponding *n*-alkane with the same number of total carbons. These compounds

were not very abundant (less than 0.5 % of the total hydrocarbons) and occurred only at C27 and C29 (peaks 12 and 21, Table 1 and Figure 2). All were found to have the first methyl branch on the 3 carbon and the second on the 7, 15, or 17 carbon.

Only one trimethylalkane was identified: 13,15,17-TrimeC29. This compound was previously identified by McDaniel (1990). As in his study of *C. formosanus*, 13,15,17-TrimeC29 represented less than one percent of the total hydrocarbon. This is a symmetrical molecule with one methylene group separating each methyl branch, and it is not common in insects (Blomquist et al., 1987; Lockey, 1988). The ion patterns diagnostic for unusual, monomethylene interrupted spacing (1,1) were extrapolated from similar spectra for dimethylalkanes. The spectrum for 13,15,17-TrimeC29 is shown in Figure 2. The ion pair at 210/211 indicates a daughter fragment ion as described in the dimethyl section. The abundant ions at 238/239 and 280/281 represent fragment ions formed by cleavage external to the second and third methyl branches, respectively.

There were a few miscellaneous alkanes present in trace amounts that were inconsistently detected (i.e., 2-MeC24; 3,7-DimeC31) or that were in such small quantities as to be difficult to characterize and/or quantify. These compounds were disregarded for the quantitative purposes of this study.

Comparisons with Earlier Studies of Hydrocarbons of C. formosanus. The cuticular hydrocarbons of *C. formosanus* in the United States were previously characterized concurrently by Haverty et al. (1990a, 1992) and McDaniel (1990). McDaniel (1990) identified numerous mono- and dimethylalkanes, in trace amounts, in *C. formosanus* [see Table 1, McDaniel (1990)] that were not detected by Haverty et al. (1990a). McDaniel (1990) also identified the unique trimethylalkane, 13,15,17-TrimeC29, in trace amounts. In the study reported in this paper, we found and identified most of these compounds as well as numerous other hydrocarbons not seen by McDaniel (1990) or Haverty et al. (1990a, 1992). These include: *n*-C28, *n*-C29, 2-MeC28, 2-MeC29, 3-MeC28, 3-MeC29, 14-;15-MeC30, 14-;15-;16-MeC38, 13-;14-;15-;16-;17-;18-MeC40, 15-;16-;17-MeC42, 3,15-;3,17-DimeC27, 3,15-;3,17-DimeC29, 9,13-DimeC27, 9,13-DimeC28, 9,13-DimeC29, 12,14-;13,15-DimeC28, 13,15-DimeC29, 13,15-DimeC30, 13,15-;15,17-DimeC31, 15,17-DimeC37, 15,17-DimeC39, 15,17-DimeC41, 15,17-DimeC43, 14,18-DimeC38, 14,18-; 16,20-DimeC40, 14,18-DimeC42.

The possible reasons that these hydrocarbons were not detected in previous studies may be that sample sizes were inadequate [Haverty et al. (1990a) used only 50 to 100 workers or soldiers], or that the termites were processed when fresh or frozen rather than dried. Haverty et al. (1996) recently found that the extraction of hydrocarbons is more efficient if the specimens are dry rather than fresh or frozen. In our earliest investigations of hydrocarbons of *C. formosanus* (Haverty et al., 1990a), quantification was done using a flame ionization detec-

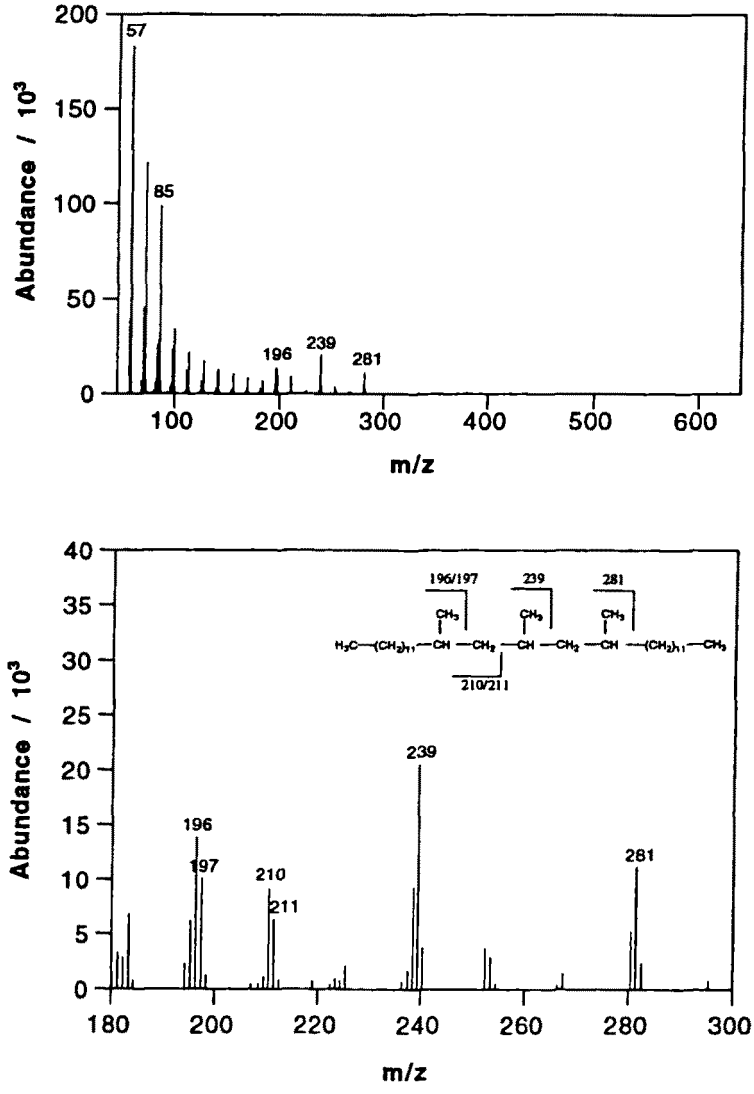

FIG. 2. Mass spectrum of 13,15,17-trimethylnonacosane from 200 workers of *C. formosanus* from Pope Hall, University of Hawaii campus, Honolulu, Hawaii, in September 1992.

tor; many of the smaller peaks, especially those at higher molecular weights (>C31), were not resolved. In addition, samples used for GS-MS analyses by Haverty et al. (1990a) were apparently not of sufficient concentration to detect and identify all of these peaks.

Intercaste Variation in Hydrocarbons. The cuticular hydrocarbon patterns of all four castes examined appear to be qualitatively quite similar. When we examined quantitative differences between workers and soldiers we found 19 of the 39 peaks to be statistically different at the $\alpha = 0.001$ level (Table 1). A few of these differences involve hydrocarbons that rarely were seen in the soldier samples, such as peaks 12, 15, 21, 24, 25, 27, 28, and 29 (Table 1). These hydrocarbons occur in workers in trace to slight amounts ($\leq 0.24\%$); in many worker samples these peaks were not resolved either. We suggest the absence of these peaks in soldier samples might be the result of a smaller sample size, resulting in less absolute hydrocarbon in the sample, i.e., the soldier samples were likely more dilute than those of the workers. Soldier samples included only 50 individuals whereas worker samples included 200 individuals. We did not, however, calculate differences in absolute quantities of hydrocarbons of any caste.

Nymphs and alates were collected on very few occasions compared to workers and soldiers. Because of the sporadic nature of these collections we did not compare them statistically to either workers or soldiers; nymphs and alates occurred seasonally and were not collected equally over the 25 collection periods. Many peaks in nymphs (27–29, 32, and 33) and alates (25–29, 31–33, 36, and 37) were seldom resolved and usually resulted in trace amounts. In some cases (peaks 27–29, 32–33, and 36–37) the hydrocarbons were never detected for alates and only occasionally for nymphs. These peaks that occur in trace amounts or are absent in nymphs and alates occurred in minute amounts ($<0.38\%$) in workers, with the exception of 13,17-; 15,19-DimeC39, which represented an average of 1.03% of the total hydrocarbon in workers. As was the case with soldiers, we attribute the absence of these peaks in nymph and alate samples to a smaller sample size, resulting in less absolute hydrocarbon in the sample. Nymph and alate samples included, at the most, 50 individuals whereas worker samples included 200 individuals.

Our sampling regime for this study was so extensive that the differences in hydrocarbon mixtures among the castes were easily displayed using canonical discriminant analysis (Figure 3). Soldiers and workers are statistically different from one another and from nymphs and alates at the $\alpha = 0.001$ level (Table 2). Nymphs and alates were not significantly different from one another at $\alpha = 0.001$.

Brown et al. (1996) found similar intercaste differences in *Drepanotermes perniger* (Froggatt) in Australia. All castes and stages were qualitatively similar

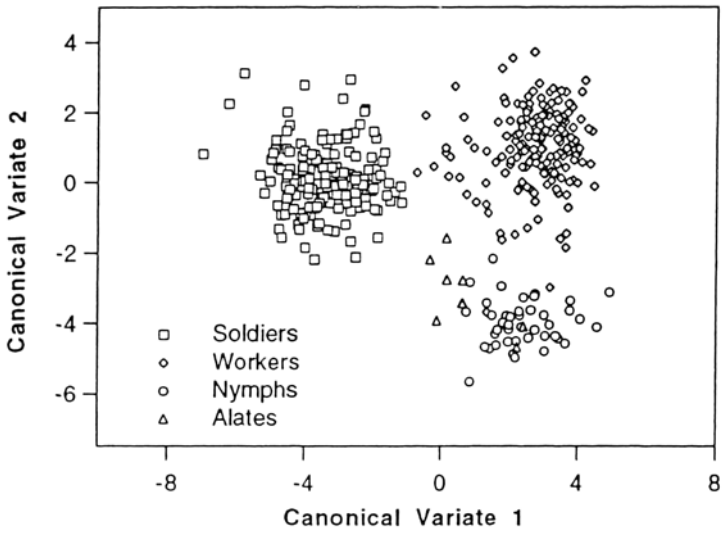

FIG. 3. Plot of four castes of *C. formosanus* from seven colonies from four locations in Oahu, Hawaii, along two axes of canonical discriminant space.

and quantitative differences were judged to be minor. The main differences were in amounts of 3-MeC27, I-MeC27, 3,X-DimeC25, and 3,X-DimeC27. Castes were easily separated by canonical variate analysis; the differences appear to diminish with age of the individuals.

Intercolony Variation in Hydrocarbons. We assessed differences between colonies separately for hydrocarbons of workers and soldiers by analysis of variance for each peak. We detected statistically significant differences (α = 0.001) between colonies in 18 peaks of workers and 12 peaks of soldiers. One of the goals of this research project was to separate or identify colonies on the

Nymph			9.74

[a]Probabilities of Mahalanobis distance test the different between each value and zero. Distances with an '†' are statistically greater than zero at the α = 0.001 level.

basis of their hydrocarbon mixtures. Because there were so many statistically significant differences and they seldom involved the same hydrocarbons, we used all hydrocarbons in canonical discriminant analysis.

We were able to display differences between colonies with plots of hydrocarbon proportions along two axes of canonical discriminant space (Figure 4) and to test the similarity between colonies. Statistical analyses of Mahalanobis distances for all possible comparisons of workers or soldiers from these seven colonies indicate that all distances are statistically different from zero (Table 3). In other words, each of these seven colonies of *C. formosanus* can be separated from all the others on the basis of the concentrations of their cuticular hydrocarbon components.

Brown et al. (1996) used canonical variate analysis to separate geographic localities of *D. perniger*. Intercolony differences (from the same geographic location) were much smaller than geographic differences. As with intercaste differences, the absolute differences between geographic areas were small.

Seasonal Variation in Hydrocarbons. When we examined each of the 39 hydrocarbon values for the 25 collection periods, we obtained 30 statistically significant differences for workers and 24 for soldiers. Such a large number of statistically significant differences may simply be a result of differences between the extreme values (high and low) for the quantities of hydrocarbons over the 25-month period. It is quite possible that so many significant differences resulted from artifacts of technique. These problems with technique could involve slight differences in the way the termites were dried and/or held in our laboratories in Hawaii or California over the 25 months of this study. Also, the chromatographic sensitivity could very well have changed over that period of time. Both of these effects could have been operating concurrently. A more likely explanation is that there was, in fact, a seasonal effect.

To test the hypothesis of a seasonal effect, we combined our samples so that we were evaluating differences between months of the year rather than 25 separate, sequential collection periods. Thus, for each month of the year, we characterized the seven colonies twice, except for September; this month we characterized the seven colonies three times. In this way, we felt that we could determine any seasonal differences, not just chance statistically significant differences among the 25 collection periods, that were repeatable over the 2-year period.

We detected statistically significant differences ($\alpha = 0.001$) between months of the year for 12 hydrocarbon peaks of workers and 4 peaks from soldiers. We then visually examined the monthly trends of each of these statistically significant hydrocarbon peaks to determine whether the differences were due to a seasonal trend or simply due to extreme differences between the months with the most and least amount of the particular hydrocarbon peak. We found that two different hydrocarbon peaks each for workers and soldiers showed distinct

seasonal trends (Figure 5). These trends were also obvious when colonies were examined separately for each of these hydrocarbon peaks. For these particular peaks, the trends were not an artifact of one or two colonies determining the average value for the month nor were they an artifact of technique. The differences were truly seasonal and were repeated from year to year. The statistically significant differences for the other peaks (10 for workers and 2 for soldiers) were due to differences between the extreme values; no seasonal trend was evident.

The biological significance of these trends is not obvious, but the major shifts in proportions for these hydrocarbon peaks correlate with the timing of the production of alates of *C. formosanus* on Oahu. Although alates of *C. formosanus* can be collected throughout the year, the major flights occur in May through July (Bess, 1970). This is almost exactly the same period (April through June) that alates were found in the colonies we sampled.

It seems reasonable to assume that these statistically significant shifts in amounts of hydrocarbon components are associated with the flight of the alates.

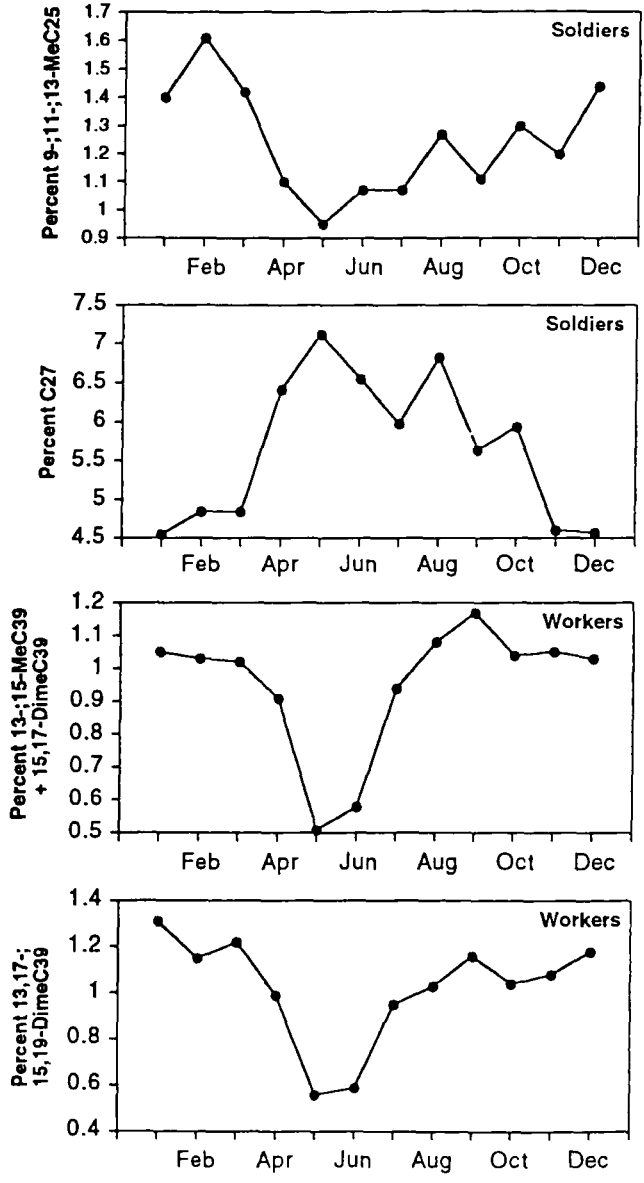

FIG. 5. Seasonal differences in hydrocarbons of *C. formosanus* soldiers (9-; 11-; 13-MeC25 and C27) and workers (13-; 15-MeC39 + 15,17-DimeC39 and 13,17-; 15,19-DimeC39) as a percentage of total hydrocarbons detected.

With the production of imagoes, the mature nymphs have metamorphosed and some individuals in the "worker" category will then differentiate to immature nymphs during this period. This would likely change the composition of the individuals remaining in the "worker" classification. Similarly, as the flight season approaches, termite colonies usually increase their investment in soldiers (Haverty and Howard, 1981; Howard and Haverty, 1981). Thus, a significant proportion of the individuals in the "worker" category are also differentiating to soldiers in April and May. After each flight many soldiers leave the nest to provide protection for the departing alates. Many of these soldiers are sealed out of the nest and lost to the colony (Bess, 1970; Nutting, 1969). The events surrounding the flight of the alates will result in a mix of young and old soldiers which could possess slightly different hydrocarbon mixtures.

Our survey of hydrocarbon mixtures of the same colonies for 25 months does not yet confirm that these colonies were derived from a single introduction to the Hawaiian Islands, or at least introductions of very closely related individuals. Given that *C. vastator* Light is suspected to have been introduced into Hawaii, and apparently was established at one time (Bess, 1970), it is quite possible that *C. formosanus* was introduced (and established) numerous times into Hawaii. The volume of movement of civilian and military materiel from the Far East through the Port of Honolulu and Pearl Harbor could easily have resulted in multiple introductions. However, confirmation of one or more founder events will require a broader sampling of *C. formosanus* populations within Hawaii, and comparison with populations from distant regions, such as Japan, Taiwan, and North America.

From the results reported here, we know that intercolony variation is greater than intracolony variation in cuticular hydrocarbon composition. We also know that we can characterize the colonies by quantifying hydrocarbons from either workers or soldiers; we need not collect data from both castes. Therefore, we propose that subsequent research on the biogeography of *C. formosanus* emphasize sampling hydrocarbons only from workers from as many separate colonies as possible from a given location, similar to the study of *D. perniger* by Brown et al. (1996). To minimize seasonal variation it is advisable to sample all colonies at times other than during the flight season. This latter criterion has the disadvantage of not providing imagoes for voucher specimens, but does provide a greater "window" for collecting.

Acknowledgments—The authors are extremely thankful to J. A. Baldwin for his assistance in comprehending this very large sampling of *C. formosanus* colonies. His help in interpreting the multivariate analyses was the key to this research project. This research was supported, in part, by a cooperative agreement between the University of Hawaii and the Pacific Southwest Research Station. This paper is Journal Series No. 4176 of the Hawaii Institute of Tropical Agriculture and Human Resources.

(Received November 13, 1995; accepted May 16, 1996)

Abstract—Aggregation pheromones of *Drosophila immigrans*, *D. phalerata* and *D. subobscura* were demonstrated by testing attraction of adult flies to hexane extracts of the flies in a windtunnel bioassay. Extracts of adult males of all species attracted conspecific males and females. However, *D. subobscura* flies were attracted only when the extract was applied on food. GC-MS analysis identified (Z)-11-octadecenyl acetate (cVA) in the extracts of adult male *D. immigrans* and *D. phalerata*. Both species were attracted to synthetic cVA. Male and female *D. subobscura* produced 5,9-pentacosadiene, 5-pentacosene, 2-methylhexacosene and 5,9-heptacosadiene, while only male *D. subobscura* produced (Z)-5-tricosene and minor amounts of cVA.

Key Words—Aggregation pheromones, (Z)-11-octadecenyl acetate, (Z)-5-tricosene, 5,9-pentacosadiene, windtunnel, Drosophilidae.

INTRODUCTION

Drosophila flies that breed in ephemeral habitats such as decomposing fruits and mushrooms often have aggregated distributions (Rosewell et al., 1990;

*To whom correspondence should be addressed.

0098-0331/96/1000-1835$09.50/0 © 1996 Plenum Publishing Corporation

Jaenike and James, 1991). Aggregative behavior in *Drosophila* flies is mediated by pheromones that can act in concert with odors of the habitat of the flies and indicate a suitable habitat for mating and oviposition (Bartelt et al., 1986; Schaner et al., 1987). An aggregated distribution may reduce interspecific competition and facilitate coexistence between species (Atkinson and Shorrocks, 1981; Ives, 1988), but should also be important for finding mates. *Drosophila* aggregation pheromones are produced by males and attract flies of both sexes (Bartelt and Jackson, 1984; Bartelt et al., 1985; Jaenike et al., 1992). The pheromones are transferred to females during mating and transferred further to an oviposition site by female flies (Bartelt et al., 1985). It has been suggested that these pheromones have functions in addition to aggregation behaviors, such as preventing matings of newly mated females and interactions between males (Zawistowski and Richmond, 1986).

Aggregation pheromones of *Drosophila* are generally volatile esters, ketones or unsaturated hydrocarbons (Bartelt et al., 1985, 1988; Moats et al., 1987). Several species produce the same compound; for instance, species of the *Drosophila melanogaster* group all have (*Z*)-11-octadecenyl acetate as an aggregation pheromone (Bartelt et al., 1985; Schaner et al., 1987, 1989). Such nonspecific pheromones can cause interspecific aggregates of related flies in a breeding habitat (Jaenike et al., 1992). However, flies also have a range of cuticular hydrocarbons that are assumed to take part in regulating mating behaviors (Scott et al., 1988; Cobb and Jallon, 1990). A mixture of these compounds may give species specificity at close range.

Apart from increasing the risk of intraspecific competition, aggregation pheromones can also affect the risk of parasitization as parasitoid wasps are attracted to the pheromones of adult *Drosophila* flies when searching for their larval hosts (Wiskerke et al., 1993). However, the risk of an individual *Drosophila* larvae to be attacked by a parasitoid should decrease at increasing densities of flies according to the functional response of the parasitoid (Hertlein and Thorarinsson, 1987). Recently a study on parasitoid wasps showed new and unexpected results when both generalist and specialist larval parasitoids of drosophilids were attracted to aggregation pheromones of adults of some host as well as some nonhost species (Hedlund et al., 1996). To interpret the results of the latter study, the aggregation pheromones of the *Drosophila* species involved need to be chemically identified.

From the study of parasitoid-host interactions (Hedlund et al., 1996) we have chosen three species, *Drosophila phalerata* (Meigen) and *Drosophila subobscura* (Collin) with a European distribution and one cosmopolitan species, *Drosophila immigrans* (Sturtevant) (Wheeler, 1981). This study aims at identifying aggregation pheromones of these three species not only to increase the knowledge of communication of *Drosophila* but also that of parasitoid-host interactions.

METHODS AND MATERIALS

Fly Cultures

Drosophila immigrans was reared on a medium of apple, water, agar, sugar and yeast. The culture originated from flies reared out of fruits collected in orchards in The Netherlands.

D. subobscura was reared in the same way as *D. immigrans*. The culture was established from flies reared from sap fluxes of trees originating from The Netherlands.

D. phalerata was reared on decaying *Agaricus hortensis* mushrooms. The culture originated from flies reared out of *Phallus impudicus* mushrooms collected in The Netherlands.

The flies were reared in 250 ml glass vials at 20°C on a 16:8 (L:D) photocycle. Fly pupae were washed out of the vial and transferred to 200 ml glass vials containing a layer of water agar.

Fly Extracts. Flies were separated by sex 0–6 hr after emergence from the pupae and transferred to new glass vials with a layer of water agar and honey on a strip of filter paper. To get sexually immature and mature flies the flies were collected at day one and day seven, respectively, and soaked in hexane (100 flies ml^{-1} hexane) at room temperature. The crude extracts were removed after 24 hr and kept at −20°C until further analysis.

GC-MS Analysis. The crude extracts were analyzed with gas chromatography (GC) and mass spectrometry (MS). Male- and female-derived extracts were compared by capillary gas chromatography (DB-1 column, 15 m length, 1 μm film thickness, 0.25 mm ID; temperature programmed from 50°C to 300°C at 10°C per min, with a final hold of 10 min at 300°C). GC retention indices relative to *n*-alkanes were calculated for sex-specific compounds and other, relatively abundant compounds. The Hewlett Packard 5890 gas chromatograph was equipped with splitless injector, flame ionization detector, and Hewlett Packard 3396A integrator. Electron impact mass spectra were obtained for the detected sex-specific compounds on a Hewlett Packard 5970 Mass Selective Detector with capillary GC inlet. Additional analyses were performed after removal of fatty acids by washing samples with 5% (w:w) Na_2CO_3 solution, since the large broad, fatty acid GC peaks could have obscured minor sex-specific compounds.

Saturated hydrocarbons were identified from mass spectra and GC retention indices. Unsaturated hydrocarbons and esters were identified by mass spectra, GC retentions, and mass spectra of dimethyldisulfide (DMDS) adducts (Carlson et al., 1989). The DMDS derivatives allowed location of double bonds, and double bond configuration was determined by GC retention in comparison with authentic standards. Sex-specific compounds were considered as possible pher-

omone components. When possible, synthetic versions of the sex-specific compounds were evaluated in the bioassay to verify behavioral activity.

Synthetic Compounds. (*Z*)-11-octadecenyl acetate, also called cis-vaccenyl acetate (cVA) was purchased from Sigma (St Louis, USA). The 5-tricosenes were prepared by the method of Sonnet (1974) from pentanal and (octadecyl)triphenylphosphonium bromide, and the *Z* and *E* isomers were separated by $AgNO_3$-HPLC as described by Heath and Sonnet (1980).

Bioassays. All bioassays were done in a cage (width 30 cm, depth 40 cm, height 35 cm) with nylon mesh (0.1 mm) along its long sides. A fan outside the cage generated an air flow of 0.1 m s^{-1} inside the cage. Each cage was stocked with 300 flies 16 hr before the tests. The flies were two to nine days old and of equal sex ratio. They were left with honey and water until the tests started. Fly extracts or synthetic compounds were applied to a filter paper (1 cm × 6 cm strip). The solvent was allowed to evaporate and the filter paper was inserted into a small glass vial (5.5 cm × 1.5 cm diameter). A drop of water was applied on the bottom of the vial. When a food substrate was present in the vial, either a 5 mm layer of an apple-yeast mixture (15:1) (w:w) or pieces of decaying mushrooms (*Agaricus hortensis*) were placed at the bottom of the vial. In each test two vials were placed inside the cage and perpendicularly to the air flow. One vial contained a hexane control and the other an extract or a synthetic compound dissolved in hexane. Tests with *D. phalerata* and *D. subobscura* lasted for 5 min while tests with *D. immigrans* lasted for 10 min. During this period of time the flies were allowed to enter a vial. At the end of the test the vials were capped with a cotton plug. The number and sex of the flies were determined. Subsequent tests separated by 3 to 5 min between the tests were done with the same cage. The cage was stocked with fresh flies each experimental day. All tests were performed at 20°C.

Each treatment (female extract, male extract etc.) was replicated 10 to 20 times and a series of treatments was carried out each experimental day (block design) so that any variation due to daily activities of the flies could be eliminated. A treatment was compared to its control with a Wilcoxon two sample test (Sokal and Rohlf, 1981) and a Kruskal-Wallis (Hollander and Wolfe, 1973) test compared the number of flies in traps of different treatments.

RESULTS

Hexane extracts of mature male and female *D. immigrans* were attractive to both sexes (52% males, 48% females) when responses were compared to a hexane control (Table 1). However, more than twice as many flies responded to male extracts as to female extracts. The GC-MS analysis revealed that extracts of mature males contained small amounts (30 ng/male fly) of (*Z*)-11-hexade-

cenyl acetate and large amounts (750 ng/male) of (Z)-octadecenyl actetate, i.e., cVA (Tables 2, 3). Both sexes also produced 2-methyloctacosane and 2-methyltriacontane. When synthetic cVA was presented in the bioassay, flies were attracted to cVA independent of sex (50% males, 50% females) (Table 1). A combination of cVA and food (apple and yeast) increased the number of flies attracted to cVA by about five times compared to tests based on cVA only. However, the proportions of flies attracted to cVA vs. control were the same in both cases.

Bioassays of hexane extracts of *D. phalerata* showed that flies of both sexes (53% males, 47% females) were attracted to adult male extracts (Table 1). The same compounds were identified in these extracts as in those produced by *D. immigrans*, i.e., (Z)-11-hexadecenyl acetate and cVA (Tables 2, 3). *D. phalerata* flies were also attracted to cVA in the bioassay (Table 1). However, when cVA was tested in combination with decaying mushrooms the response of the flies did not increase. The number of *D. phalerata* flies attracted to extracts of males was about two to three times higher than when cVA was tested alone or in combination with mushroom.

D. subobscura flies of both sexes (52% males, 48% females) were attracted to hexane extracts of male flies, but only when the extracts were applied on

attract flies in the windtunnel bioassay (Table 4). However, as these compounds were not tested in combination with food, further experiments are needed to reveal the attractivity of the compounds together with a food substrate.

DISCUSSION

The aim of this study was to identify the aggregation pheromones of the three *Drosophila* species involved. Both males of *D. immigrans* and males of

2-methyltriacontane	male & female	25

D. phalerata produce (*Z*)-11-octadecenyl acetate (cVA) as a major pheromone component. In both species extracts of male flies as well as synthetic cVA attract male and female flies, and we conclude that cVA is an aggregation pheromone compound. However, male extracts of *D. immigrans* attract twice as many flies as pure cVA, and in the case of *D. phalerata* male extracts attract almost four times as many flies. The pattern of higher attractivity to extracts than to pure cVA has been shown for other cVA-producing species such as *D. melanogaster* (Bartelt et al., 1985), whereas other species, such as *D. simulans*, show no difference in attractivity between fly extracts and synthetic cVA (Schaner et al., 1987). A higher level of attractivity to fly extracts than to pure cVA, or to female extracts as in *D. immigrans*, may indicate that there are other compounds present in the extracts that are active in eliciting aggregative behaviors of the flies. Other compounds may be produced in small amounts by both sexes but have to act in concert with cVA to attract flies. (*Z*)-11-hexadecenyl acetate that was found as a male specific compound of *D. immigrans* and *D. phalerata* is produced in small amounts and may be a possible coattractant. Although further work is needed to test the activity of (*Z*)-hexadecenyl acetate and chemically identify other active compounds, cVA can be regarded as a major aggregation pheromone of *D. immigrans* and *D. phalerata*.

Aggregative behavior of *D. subobscura* was only observed towards male fly extracts in combination with food of the flies. To identify the main aggregation pheromone compound(s) of *D. subobscura* further work is needed with testing attractivity of flies to combinations of identified compounds and food, and fractionation of the extracts. However, the identified hydrocarbons reveal a system quite different from that of *D. immigrans* and *D. phalerata*. Rather it has similarities with the aggregation pheromones of the *D. virilis* subgroup in which a combination of hydrocarbons and male specific compounds elicits aggregative behaviors (Bartelt et al., 1986).

The presence of food odors seems to be necessary for *D. subobscura* to respond to a pheromone whereas it increases the attractivity of cVA for *D. immigrans*. Coattraction of flies to food odors and aggregation pheromones may be a general pattern among many *Drosophila* species. The attractivity of aggregation pheromones such as cVA have been shown to increase in combination with food substrates for several fly species of the *melanogaster* species group (Schaner et al., 1987; 1989). Other types of pheromone compounds, e.g., tiglates of flies of the *virilis* species group, can also be synergistic in combination with food odors (Bartelt et al., 1986).

cVA, the aggregation pheromone of *D. immigrans* and *D. phalerata*, is produced by a number of species within the subgenus *Drosophila* and the subgenus *Sophophora* (Bartelt et al., 1985; Schaner et al., 1987, 1989; Jaenike et al., 1992). The risk of increasing interspecific competition that follows upon the use of the same aggregation pheromone compound may be reduced in nature

by different usage of microhabitats. Of the three species studied here only two produce cVA as the major pheromone compound and of these *D. immigrans* breeds mainly in fermenting fruit (Atkinson and Shorrocks, 1977), whereas *D. phalerata* is a woodland species that breeds in decaying mushrooms (Janssen et al., 1988). The attraction of flies to a combination of food odors and aggregation pheromones, as discussed above, will probably decrease the risk of competition between the species. However, fly species with similar aggregation pheromones and breeding sites have been shown to form interspecific aggregations (Jaenike et al., 1992).

EXPERIMENTS ON BIOASSAY SENSITIVITY IN THE STUDY OF ALLELOPATHY

ESPEN HAUGLAND* and LARS OLAV BRANDSAETER

The Norwegian Crop Research Institute, Plant Protection Center
Department of Herbology, N-1432 Aas, Norway

(Received August 16, 1995; accepted May 16, 1996)

Abstract—The purpose of these experiments was to study the effects of various experimental procedures and conditions on bioassay sensitivity in allelopathic studies. The following factors were considered: bioassay methods, choice of test species, the effect of osmotic potential on germination and growth of the test species, growth in dark or in light and the effect of concentrating the extracts in vacuo. Extracts from rape and rye were used in the studies to act as allelopathic agents. Ryegrass appeared as the most sensitive test species when grown horizontally on quartz sand, while radish was the most sensitive test species when grown on filter paper in transparent boxes at a 45° angle. Root length was the most sensitive growth variable measured. Percent germination appeared a more sensitive measure than the speed of germination index, "S", when germinated seeds were counted after one and two days for radish and ryegrass, respectively. A rise in the osmotic potential affected germination more than root length, and radish appeared more sensitive to a rise in osmotic potential than ryegrass. A confounding of germination and root length inhibition may therefore, give misleading results.

Key Words—Allelopathy, bioassay, evaporator, germination, growth conditions, growth parameters, osmotic potential, radicle elongation, sensitivity, test species.

INTRODUCTION

Bioassays are useful and necessary tools for studying the allelopathic potential of plant or soil extracts and for evaluating the activity of the extracts during purification and identification of allelopathic compounds. Nearly all reports on

allelopathy describe some type of bioassay method used to demonstrate allelopathic activity (Leather and Einhellig, 1986). Generally there are two types of measurements for testing biological activity of allelopathic compounds: the measurements of specific biological activity (e.g., inhibition of photosynthesis) or measurements of some aspects of growth (e.g., germination, root dry weight). Putnam and Duke (1978) and Leather and Einhellig (1986) reviewed various bioassays for the study of allelopathy. The most widely used bioassay to test allelopathic activity in an extract is the technique of seed germination in petri dishes on filter paper, sand, soil or agar. Numerous studies also include plant growth bioassays, but the effect on germination is often not separated from the effect on growth (e.g., Liu and Lovett, 1993; Kato-Noguchi et al., 1994).

Various factors influence the sensitivity of a bioassay. Different test species may have varying sensitivity to specific allelopathic compounds (e.g. Krogmeier and Bremner, 1989) or to aqueous extracts (e.g., White et al., 1989). In some studies the main goal is to rank different species in their sensitivity to the active compounds (e.g., Smith and Martin, 1994), but in other studies it is important to select the most sensitive test species for detecting low limits of the allelopathic compounds. In both types of studies it is important to realize the possibility of an interaction between the test species and the bioassay method. Recording germination is a commonly used measurement, but several investigations have revealed that this is not the most sensitive parameter (Leather and Einhellig, 1986). Root length has often shown to be a more sensitive parameter, but roots are not as easy to measure as germination, and the design of the bioassay method may influence the growth of the roots. Water potential is important in the germination process (Bradbeer, 1988) but will also influence the growth of the seedlings. The osmotic potential will influence the results of the bioassay test, and variation in sensitivity to osmotic potential between test species may occur. Although Anderson and Loucks (1966) demonstrated the importance of solution osmotic potential when testing plant extracts, very few studies on allelopathic effects include osmotic effect (Leather and Einhellig, 1986). Wardle et al. (1992) found that the allelopathic effects could be substantially overestimated when the osmotic effects were not taken into account. Interactions between experimental conditions can also affect the results, as found between osmotic potential and water uptake in light or in dark for lettuce (*Lactuca sativa* L.) (Nabors and Lang, 1971).

Clearly a variety of bioassay methods and experimental factors influence the results of bioassays in the study of allelopathy. The lack of standardized bioassays makes comparisons between different studies very difficult, and even reports originating from the same laboratory differ in the conduct of the assay (Leather and Einhellig, 1986). Therefore, the aim of the present investigation was to study if, and in case to what extent, bioassay method, test species,

osmotic potential, light conditions, and evaporator treatments influence the results and the sensitivity of growth parameters in a bioassay.

METHODS AND MATERIALS

General

Winter-rape (*Brassica napur* L. ssp. *oleifera* DC. cv. "Bambu") and winter-rye (*Secale cereale* L. cv. "Danko") were greenhouse-grown in pots under day/night regime of 16/8 hr (High-pressure sodium lamps/15000 lux) and a temperature of 20°C. Above ground plant tissue from 40 days old plants of rape and rye were collected and cut separately into pieces of 2 to 3 cm length. Half of the plant matter was oven dried at 50°C for 72 hr before extraction. In the dry matter extraction a concentration of 1 g dry matter per 20 ml distilled water was prepared. As the fresh plant material was too voluminous, it was not possible to obtain the same concentration in fresh matter extraction. In this procedure, concentrations of 0.52 g dry matter of rye per 20 ml and 0.68 g dry matter of rape per 20 ml were made. The mixture of plant matter and distilled water was agitated for 5 hr on an orbital shaker at room temperature (24°C). Extracts were filtered through two metal-filters, 0.630 mm and 0.212 mm, before vacuum-filtration through filter paper (Whatman #1). To obtain the same concentration in the fresh matter extracts as in the dry matter extracts (1 g/20 ml on a dry matter basis), the fresh-matter extracts were reduced about 50% in vacuo (40°C), and then diluted to give concentrations of 1 g dry matter/20 ml. The extracts were stored at −20°C until used.

Radish (*Raphanus sativus* L., cv "Cherry Belle orig.") and Italian ryegrass (*Lolium multiforum* Lam. var. *italicum* cv "Mondora") were used as test species in the germination and growth bioassays. A 2 mm radicle length was considered as fulfilled germination. When used in growth assay, the seedlings were pregerminated for 48 hr.

Two types of bioassay methods were used in the experiments. Method 1 included plastic dishes (18 cm in diameter, 4 cm deep) containing 150 g of quartz-sand (mean particle size = 0.28 mm) covered with a glass plate. The quartz sand was moistened with 45 ml extract or distilled water (control). The seeds or seedlings were placed on the surface of the sand. As the accuracy of measurements of radicle elongation in petri dishes is questionable (Leather and Einhellig, 1988), a second bioassay method (Method 2) was developed to obtain easy and fast measurements of root length. For this method transparent square boxes (24 cm long, 11 cm wide and 7 cm high) were used with two layers of filter paper (Munktell 1701, art. no. 261 024) in the bottom of the box. The filter papers were moistened with 30 ml extract or distilled water (control). The

seedlings of the test species were placed on the filter paper along a horizontal line in the upper part of the box with the root pointed downwards. The boxes were arranged at a 45° angle which gave straight roots and root length was easy to measure. The transparent box-system was also used in the germination assay. It was then placed horizontally with two layers of filter paper in the bottom supplied with 20 ml extract or distilled water. All experiments were conducted under the same conditions, in a constantly illuminated (Luma Standard LE 58W Vit-S) growth chamber at 22°C.

Screening Experiment with Test Species and Plant Extracts Using Bioassay Method 1

The experiment was established as a screening experiment with the experimental factors of test species (radish and ryegrass), plant extracts (rape and rye), extracts from fresh or dried material, and two concentrations (1 g/20 ml and 1 g/60 ml). The dry and fresh matter extracts of rape and rye (1 g/20 ml) were diluted to give the concentration 1 g/60 ml. Bioassay Method 1 was used in this experiment. Fifty seeds of Italian ryegrass or radish were placed on the surface of the sand. Germinated seeds were counted after five days for radish and six days for ryegrass. Root length, shoot length, root dry weight, and shoot dry weight were measured on the seeds that germinated. A 2^k factorial design was used with $k = 4$ (Montgomery, 1984).

Experiment with Bioassay Methods and Test Species

This experiment was set up to separate the effects of germination and growth inhibition, to compare the two bioassay methods, and to study the interaction between bioassay methods and test species. The experiment covered the following concentrations: 0 (distilled water), 1 g/120 ml and 1 g/60 ml. Only dry matter extract of rape was used. To study the effect on germination, the extracts (20 ml each) were added to the transparent square boxes with filter paper. One hundred seeds of radish or ryegrass were placed in each box. Germinated seeds were counted and removed daily for five days. Both bioassay methods were used in the study of seedling growth with 20 seedlings of radish or ryegrass in each box/dish. Root length, shoot length, root dry weight, and shoot dry weight were measured after four days for both test species.

Experiment on the Effect of Osmotic Potential on Germination and Growth

The experiment was conducted to evaluate the effects of osmotic potential on germination and growth of radish and ryegrass. Five concentrations of polyethylene glycol 6000 MW (PEG) were evaluated: 0%, 5%, 10%, 15%, and 20% on a weight basis. Effects on germination were evaluated using horizontally

placed boxes and germinated seeds were counted and removed daily for five days. Bioassay Method 2 was used to evaluate the effects on root and shoot growth. Root and shoot length were measured after four days.

Osmotic potentials for dry matter extracts of rape and rye and PEG solutions were determined using a vapor-pressure osmometer. The potentials were the same for the rye and rape extracts and were for the 1/120, 1/60, and 1/20-concentrations 24, 54, and 157 mOsm, respectively. The 5, 10, and 15% PEG-solutions were selected to fit these figures and showed potentials of 17, 65, and 133 mOsm, respectively, while the 20% PEG concentration showed an osmotic potential of 252 mOsm.

Experiment on the Effect of Light on Root Length Inhibition

To study whether light conditions could affect radish root length sensitivity to allelopathic compounds, radish seedlings were grown in light or dark with distilled water or dry matter extract of rape (1 g/120 ml). Dark growth conditions were obtained by covering the transparent boxes with aluminum foil. Root length was measured after four days.

Experiment on the Effect of Evaporator Treatment

This experiment was conducted to evaluate whether an evaporator could have any deviating effect beyond the effect of concentrating the extracts. The evaporation procedure was as follows: the volume of the sample was reduced 50% in vacuo (40°C) followed by diluting the concentrated extracts with distilled water to obtain the starting concentrations of 1 g/120 ml and 1 g/60 ml, respectively. Dry matter extracts of rape and rye were used with radish seedlings as test species in bioassay Method 2. Root length was measured after four days.

Statistical Considerations

Speed of germination index "S" was calculated as described by Bradbeer (1988) and Wardle et al. (1991) as

$$S = \left[\frac{N_1}{1} + \frac{N_2}{2} + \frac{N_3}{3} + \frac{N_4}{4} + \frac{N_5}{5} \right] \times 100$$

Where N_1, N_2, . . . , N_5 are the proportion of seeds that germinated on day 1, 2 . . . 5. Except for percent germination and speed of germination, all variables were transformed to logarithms to homogenize variances and to allow proportional comparisons to be made. To evaluate the sensitivity of test species by using the actual values of root and shoot measurements (and not relative values), the interactions including the test species factor and the concentration factor can be used. When plotting logarithmic transformed values, the lines which can be

drawn for each species between concentrations would be parallel if there is no difference in sensitivity between the test species. If there are differences in sensitivity between test species, these lines would not be parallel, which would be shown by a significant interaction term of test species × concentrations. The advantage of using this technique for testing sensitivity in comparison with relative values (percent of control), is the avoidance of the less statistically appropriate relative values.

The experiments were established as complete factorial designs and analysis of variance was performed. Interactions including up to three factors were used in the statistical models, except for interactions with the replicate effect, which were all included in the error term. Logarithmic transformed values are presented as geometric means. All experiments were repeated three times, each time representing one replicate in the statistical analysis.

RESULTS

Screening Experiment with Test Species and Plant Extracts Using Bioassay Method 1

Radish was the more sensitive test species for all parameters observed (Table 1). Root length was the most sensitive parameter. Percent germination was about as sensitive as the measurements on shoots, but much less sensitive than root length. There were significant differences between effects of extracts from rape and rye on root length, root dry matter, and shoot dry matter, with the extract from rye giving the greatest reduction in growth of the test species. Although the effect was significant, the difference in root length between extracts from rape and rye was only 1 mm. Extract from a dried material was much more effective in reducing plant growth than those made of fresh material. As expected, phytotoxicity was more severe at the higher concentration than the lower one.

Experiment with Bioassay Methods and Test Species

Significant differences in cumulative germination between days, extract concentrations, and test species were recorded (Figure 1). The results for test species are presented in separate figures for convenience. There were greater differences between the concentrations during the first two days than later on, especially with ryegrass as test species. Sensitivity of the germination parameter was highest for radish at day one and at day two for ryegrass. The figures indicate a delay in germination for both species for both extract concentrations, which was also shown significantly by the speed of germination index "S" (Table 2). Radish germinated faster than ryegrass, while ryegrass germination seemed to be less affected by increasing extract concentration.

TABLE 1. MAIN EFFECTS OF TEST SPECIES, TYPE OF EXTRACT, AND CONCENTRATIONS ON GERMINATION, ROOT LENGTH AND DRY MATTER (DM) AND SHOOT LENGTH AND DM. VALUES WITHIN MAIN EFFECTS AND MEASUREMENT ARE CONSIDERED SIGNIFICANTLY DIFFERENT AT THE 5% LEVEL WHEN FOLLOWED BY DIFFERENT LETTERS (PERCENT OF CONTROL IN PARENTHESES)

		Root		Shoot	
	Germination % (% of control)	length mm (%)	DM mg (%)	length mm (%)	DM mg (%)
Test species:					
ryegrass	69a (79)	8a (41)	16a (58)	21a (76)	21a (76)
radish	43b (47)	2b (17)	19a (31)	2b (42)	91b (48)
Extract from:					
rape	57a (64)	5a (32)	19a (49)	7a (62)	49a (65)
rye	55a (62)	4b (26)	15b (42)	6a (56)	39b (59)
Material:					
fresh	74a (83)	14a (49)	37a (72)	14a (90)	83a (93)
dried	38b (43)	1b (10)	7b (17)	3b (29)	22b (32)
Concentration:					
1 g/60 ml	69a (78)	9a (41)	25a (59)	10a (76)	64a (76)
1 g/20 ml	43b (48)	2b (18)	11b (31)	4b (43)	29b (49)

Root and shoot length and shoot DM were more sensitive parameters in bioassay Method 2 than in Method 1 (Table 3). In this experiment, ryegrass was the more sensitive test species, while root length was the most sensitive parameter. The variance analysis showed, however, significant interaction in root length between test species, extract concentration and bioassay method ($P = 0.0001$), indicating that length of radish roots was most sensitive when using bioassay Method 2, while length of ryegrass roots was most sensitive when grown in Method 1.

The Effect of Osmotic Potential on Germination and Growth

The effects of PEG on germination are shown in Figure 2. All main factors and interactions appeared significant in the statistical analysis. Increasing proportion of PEG reduced the germination of ryegrass, and a considerable decrease in germination was recorded when PEG-concentration exceeded 15%. In radish this "threshold value" appeared already above 10% PEG. In the speed of germination index "S" (Table 4), radish had the fastest germination at 0 and 5% PEG, while ryegrass was the faster one at 10% PEG and above. In root length ryegrass was the least sensitive at 5, 10, and 15% PEG, while radish appeared less sensitive to changed osmotic potential than ryegrass at 20% (Table

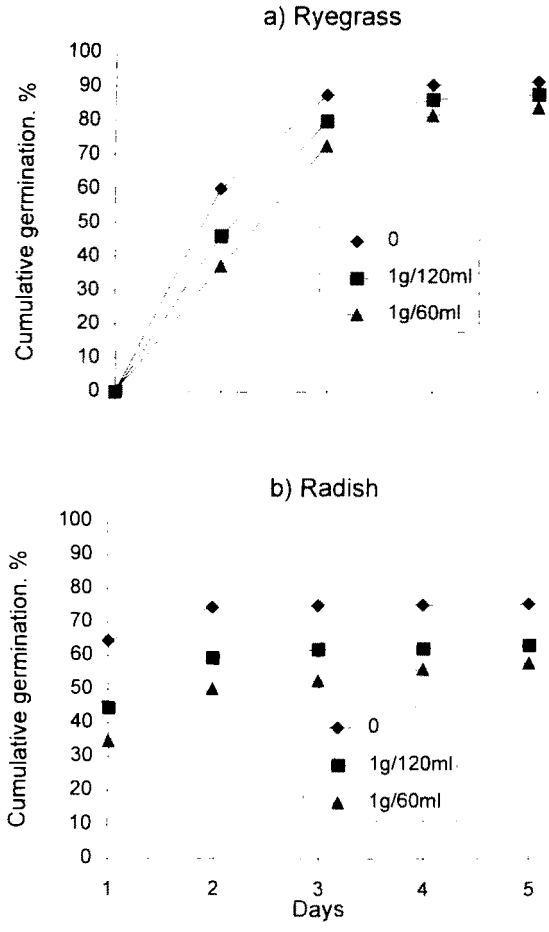

FIG. 1. The interaction between day of recording, plant extract concentration and the test species ryegrass (a) and radish (b) in cumulative germination ($p_{days \times test species \times concentration} = 0.01$).

5). Germination was more affected by increased osmotic potential than root length.

The Effect of Light on Root Length Inhibition

Radish root length was significantly longer when grown in dark than in light ($P = 0.0001$). There was also a significant interaction between the light

[a] $P_{\text{test species} \times \text{concentration}} = 0.0003$

factor and extract concentration ($P = 0.006$), showing that radish root length was a more sensitive parameter when grown in dark than in light.

The Effect of Evaporator Treatment

The phytotoxicity of the extracts was not changed during evaporation. Neither could a significant interaction between the evaporation factor and the extracts be shown.

PEG concentrations are 0% (-◆-) 5% (-■-), 10% (-●-), 15% (-×-) and 20% (-*-) on a weight basis ($p_{\text{days} \times \text{PEG-concentration} \times \text{testspecies}} = 0.0001$).

DISCUSSION

Percent germination has commonly been used to measure the effects of allelopathic compounds. This is a rapid method for a large number of samples. However, Leather and Einhellig (1985) indicated that percent germination may not be the most sensitive parameter. Speed of germination may be a more sensitive indicator of allelopathic effects (Wardle et al., 1991) as allelochemicals may delay germination rather than affect the final germination percentage. In the present investigation percent germination was a more sensitive indicator than

speed of germination, one and two days after initiating the germination bioassay for radish and ryegrass, respectively. In addition to being more sensitive, recording data one or two days after sowing is less time consuming than daily recordings for several days required for computing the speed of germination index. In the present investigation, root length was the most sensitive parameter for detecting growth retarding substances. These results are consistent with previous studies (e.g., Leather and Einhellig, 1986; Wardle et al., 1991; Wardle et al., 1992).

The screening experiment, in which the effect on germination and growth was confounded, indicated that radish was a more sensitive test species than ryegrass. The experiment which included both bioassay methods on the other hand showed that test species sensitivity depends on bioassay method, and rye-

grass was the more sensitive species when bioassay Method 1 was used, while radish was the more sensitive when Method 2 was used. These contradicting results may be explained by the confounding of germination and growth inhibition in the screening experiment. Germination of radish was more affected by the extracts than germination of ryegrass. Also, when evaluating the effects of osmotic potential on germination by using PEG, we found that radish was more sensitive to a rise in osmotic potential than ryegrass. The PEG experiment was conducted in continuous light, and germination of radish can be inhibited by light when exposed to osmotica (Bewley and Black, 1994), while no inhibition occurs when germinated in darkness. This kind of interaction may also have caused the differences in sensitivity between the two test species.

Comparison of PEG-solutions and extracts with similar osmolality, showed that the effect of PEG was much lower than those of the extracts indicating that the activity of the extracts is not an effect of osmotic potential alone. Osmotic potential also affected germination more than root length. This shows, as the contradicting results of the experiments with plant extracts also do, the importance of separating effects on germination from effects on growth.

Radish root length was a more sensitive variable in dark than in light. Other species react to light conditions in other ways. Shilling and Yoshikawa (1987) found that root growth of barnyardgrass (*Echinochloa crus-galli* (L.) PB.) and hemp sesbania (*Sesbania exaltata* (Raf.) Cory) were more sensitive under light conditions, and that all measurements of shoot growth were generally more inhibited in the dark than under light conditions. The species to be used in bioassays should therefore, be considered under which circumstances it is most sensitive.

We have compared two types of bioassays. When the test species were grown in boxes at 45° on filter paper, the root growth was straight and much easier to measure than when grown horizontally on quartz sand. When growing the test species on filter paper, some paper stuck to the root making the root DM measurement inaccurate. A disadvantage of the present bioassays is that they need a rather large amount of substrate/liquid. We used 45 ml in Method 1 and 30 ml in Method 2. This is much more than can be applied when using bioassay as a part of a separation with HPLC, where 1–2 ml is an appropriate amount. On the other hand, relatively large volumes of solutions/extracts can be important in developing a sensitive bioassay. Weidenhamer et al. (1987) reported that the number of seeds relative to the solution volume used in a seed germination bioassay influenced results. They found that the amount of ferulic acid available to each seed influenced germination, rather than the concentration of the chemical in the solution. The present bioassay method on filter paper also gave low standard deviation of the mean, indicated by a statistically significant difference of one to two millimeters.

Many investigators (e.g., Shilling et al., 1985; Kato-Noguchi et al., 1994) used evaporation in vacuo for increasing concentration of the extracts without testing the effect of the evaporator treatment. We did not find any effects of such a treatment on the activity of the extracts in the present investigation. The most important question when using an evaporator is probably whether the boiling points of the active substances are lower or higher than that of the extraction liquid, in our case water. If the boiling points of the active substances are lower than that of the extraction liquid, there is a possibility of losing the active substances in the concentration process. Additionally evaporator treatments may cause changes in chemical structures and phytotoxicity of allelochemicals.

It is important to confirm the results from the laboratory bioassays in field studies as proposed by Fuerst and Putnam (1983). It is in this context an advantage if the bioassay reflects the field conditions as well as possible. Krogmeier and Bremner (1989) tested the effects of phenolic acids on germination and seedling growth on germination paper and in sand. Although the phenolic acids affected germination and growth on germination paper, no such effects were detected in soil. On the other hand, indications of delayed germination was found by Moore et al. (1994) in a study of cover crop mulches. Under certain conditions the number of emerged *Amaranthus retroflexus* L. seedlings was reduced compared with bare soil in early summer, while no differences in total number of seedlings over the entire season were observed. The observed delay in germination under field conditions could additionally be a response of changed physical conditions, e.g., lower soil temperature, as well as a response of allelopathic compounds. Obviously, there are needs for developing field techniques for separating the effects of allelopathy from other factors. Rape and rye were not included in the present investigations to compare phytotoxicity of the species. Although bioassays using water extracts from plants are useful to prove the existence of allelopathic substances in them, these effects often disappear under field conditions (Etherington, 1975) due to adsorption to soil particles, decomposition and leaching (Almeida, 1985). Additionally varying phytotoxicity between species is dependent on environmental factors (Mason-Sedun and Jessop, 1989) and age (Wardle et al., 1993) and these important factors were not included in the present investigations.

In conclusion, bioassay methods, test species, light conditions, and osmotic potential and interactions between these factors clearly influence the sensitivity and the results of the bioassays. Confounding the effects on germination and growth may lead to misinterpretation of the results. It is important to realize that the bioassay performance and its relationship to field conditions are vital for confirming the results of bioassays by field test. Therefore, it may be necessary to optimize the conditions in the bioassay for each case of study.

(Received November 20, 1995; accepted May 19, 1996)

Abstract—We tested the hypothesis that green leaf volatiles act as antiaggregants for the mountain pine beetle (MPB), *Dendroctonus ponderosae* Hopkins. In coupled gas chromatographic-electroantennographic detection (GC-EAD) analysis MPB antennae responded to 30 ng doses of all six-carbon green leaf alcohols tested [1-hexanol, (*E*)-2-hexen-1-ol, (*Z*)-2-hexen-1-ol, (*E*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-ol], but not to the aldehydes, hexanal or (*E*)-2-hexenal, or to alcohol or aldehyde homologues with more or fewer than six carbon atoms. In field trapping experiments a blend of green leaf alcohols [1-hexanol, (*Z*)-2-hexen-1-ol, (*E*)-3-hexen-1-ol and (*Z*)-3-hexen-1-ol] effectively disrupted the response to attractive semiochemicals; a blend of the aldehydes hexanal and (*E*)-2-hexenal was inactive. The two best disruptants, (*E*)-2-hexen-1-ol and (*Z*)-3-hexen-1-ol, reduced catches of both sexes to levels not significantly different from catches in unbaited control traps. They also reduced the attack on trees baited with attractive MBP pheromones to a level not significantly different from that on unbaited control trees. Neither of the clerid predators captured, *Enoclerus sphegeus* (F.) nor *Thanasimus undatulus* (Say), was repelled by green leaf volatiles. Our results suggest that green leaf alcohols are promising disruptants which may be used to supplement the antiaggregation pheromone, verbenone, in protecting single high-value trees as well as carefully selected stands with low-level populations of MPBs.

Key Words—Mountain pine beetle, *Dendroctonus ponderosae*, Coleoptera, Scolytidae, antiaggregant, verbenone, green leaf volatiles, 1-hexanol, (*E*)-2-hexen-1-ol, (*E*)-3-hexen-1-ol, (*Z*)-2-hexen-1-ol, (*Z*)-3-hexen-1-ol.

INTRODUCTION

The mountain pine beetle (MPB), *Dendroctonus ponderosae* Hopkins, is the most destructive insect pest of pines in western North America (Furniss and Carolin, 1977). A number of strategies and tactics have been developed and implemented for integrated MPB management in British Columbia (Borden and Lindgren, 1988; Maclauchlan and Brooks, 1994). However, there is a need for environmentally acceptable tactics, such as the use of antiaggregants, to protect high value commercial timber stands, as well as stands in such areas as campgrounds, parks, and riparian zones (Amman et al., 1989, 1991; Lindgren et al., 1989; Gibson et al., 1991; Shea et al., 1992; Amman, 1994).

Most research with antiaggregants for the MPB has focused on the antiaggregation pheromone verbenone (Lindgren and Borden, 1989, 1993; Amman, 1994; Borden, 1996). Attempts to develop verbenone as a reliable tool for controlling MPBs have utilized either aerially dispersed verbenone-impregnated pellets (Shea et al., 1992), or bubble-cap release devices affixed to trees at 10 m centers throughout a stand (Amman et al., 1989; Lindgren et al., 1989). While both methods are sometimes effective (Amman et al., 1989, 1991; Lindgren et al., 1989; Shea et al., 1992), results have been inconsistent from year to year in lodgepole pine forests (Gibson et al., 1991; Shea et al., 1992), and none of the trials in ponderosa pine forests has yielded significant results (Bentz et al., 1989; Lister et al., 1990; Gibson et al., 1991). Verbenone does appear to have the ability to protect single, high-value trees from attack (Borden and Lindgren, 1988; Shore et al., 1992).

Recent research has supported the hypothesis that combinations of semiochemicals can be much more effective than a single disruptant (Borden, 1996). Although research on combinations of disruptants has focused on semiochemicals produced by con- or heterospecific bark beetles, it may be possible to integrate "resistant" and nonhost kairomones into an antiaggregant blend.

Changes in host suitability could be detected through kairomones such as 4-allylanisole (also known as methyl chavicol or estragole) (Hobson 1995). Stark et al. (1968) reported a 70% drop in 4-allylanisole content in ozone-damaged ponderosa pines which were preferentially attacked by western pine beetles, *Dendroctonus brevicomis* LeConte. 4-Allylanisole has since been found to disrupt the response to attractant-baited traps by six *Dendroctonus* and one *Ips* species (Hayes et al. 1994; Hayes and Strom, 1994; Werner 1995; Hobson 1995).

One particularly ubiquitous group of nonhost chemicals, the green leaf volatiles (GLVs), are also promising candidates for improved disruptant blends. GLVs are six carbon alcohols, aldehydes, and derivative esters commonly found in green plants (Visser et al., 1979; Visser, 1986; Whitman and Eller, 1990). Formed through oxidative degradation of leaf lipids, GLVs are released contin-

ually by leaves (Visser and Avé, 1978). They can function as attractive kairomones (Visser et al., 1979; Guerin et al., 1983; Kamm and Buttery, 1983; Katsoyannos and Guerin, 1984), synergistically enhance attraction to sex pheromones (Dickens et al., 1990), or act as synomones in tritrophic interactions in which natural enemies of herbivores are attracted to GLVs released by herbivore-damaged plants (Turlings et al., 1990, 1993; Whitman and Eller, 1990; Ramachandran and Norris, 1991).

GLVs have also shown disruptive activity. Although a blend of GLVs attracts the Colorado potato beetle, *Leptinotarsa decemlineata* Say, to host plants, none is attractive alone, and even a slight change in the ratio of GLVs can decrease attraction (Visser and Avé, 1978). Two compounds, not in the attractive blend, were also active in electrophysiological tests and disrupted positive anemotaxis to potato odor; (*Z*)-2-hexen-1-ol, present in potato foliage, was a weak disruptant, whereas a compound absent from potato foliage, (*Z*)-3-hexen-1-ol (Visser et al., 1979), was a strong disruptant (Visser and Avé, 1978). Similarly, hexanal and 1-hexanol disrupted the response of three species of bark beetles, the southern pine beetle, *Dendroctonus frontalis* Zimmerman, the eastern fivespined ips, *Ips gradicollis* (Eichhoff), and the small southern pine engraver, *Ips avulsus* (Eichhoff), to traps baited with attractant semiochemicals. (Dickens et al. 1991, 1992, 1993, 1995).

Our objective was to test GLVs as disruptants that could potentially enhance the disruptant activity of verbenone as an operational tool against the MPB.

METHODS AND MATERIALS

Electrophysiological Studies. Eighteen synthetic chemicals, GLVs or their homologues containing more or fewer carbon atoms (Table 1), were analyzed (30 ng each in 1 μl of hexane) by coupled gas chromatographic-electroantennographic detection (GC-EAD) (Arn et al., 1975). MPB-infested lodgepole pine bolts were collected near Princeton, B.C., and placed in cages in the laboratory. Emerged beetles were removed from cages daily and used immediately in GC-EAD analysis. The apparatus employed a Varian 3400 gas chromatograph equipped with a DB-5-coated, fused silica column (30 m $\times$ 0.32 mm I.D.) (J & W Scientific, Folsom CA). The recording electrode was placed into the antennal club of an intact immobilized beetle with a micromanipulator (Type M, Leitz Canada, Willowdale, Ontario), and the indifferent electrode was inserted into the head. Both *exo*- and *endo*-brevicomin (10 ng each in 1 μl of hexane) were used as standard stimuli in all tests. Beetles that did not respond to brevicomin were discarded.

Field Trapping Experiments. Four randomized, complete block trapping experiments were conducted in 1993 and 1994 in stands of lodgepole pine,

[b]Purity as listed by manufacturer.

Pinus contorta var. *latifolia* Engelmann, near Princeton, British Columbia. Locations, dates, and numbers of replicates are given in Figures 1–4. All experiments utilized 12-unit multiple funnel traps (Lindgren, 1983) hung from ropes or poles. Traps were deployed in lines with 25 m between traps and lines. All chemicals, sources, release devices, and release rates are listed in Table 2. The GLVs tested were chosen because they were often referred to in the literature, and were cheap and easy to obtain. Release rates of verbenone were lower than optimal to allow the effects of GLVs to be detected.

Except where otherwise stated, three control treatments were used to assess the effectiveness of candidate disruptants: (1) attractive control, consisting of a three-component MPB lure (Borden et al., 1987a); (2) disruptant control, consisting of a MPB lure plus verbenone; and (3) unbaited trap.

Experiment 1 compared the disruptive effect of hexanal (Dickens et al., 1992) vs. hexanal plus a blend of four other GLVs (released separately) (Table 2). The aim of Experiment 2 and 3 was to discern the most active components of the GLV blend. Experiment 2 compared the disruptive effect of green leaf aldehydes, alcohols, or both, added to MPB lures. Because the green leaf

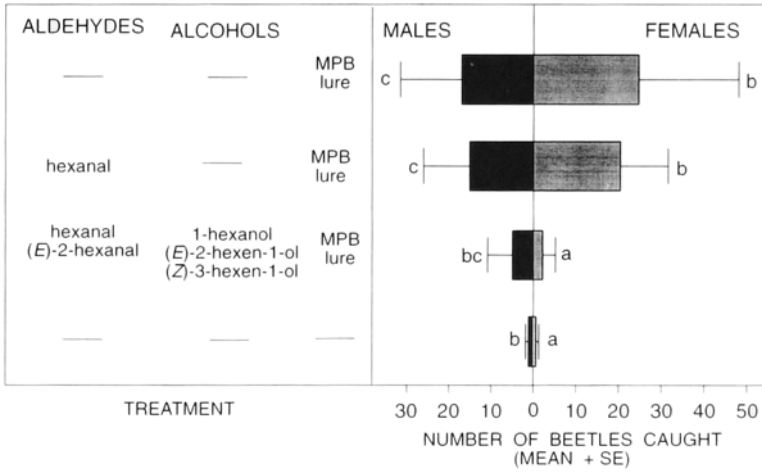

FIG. 1. Response of *Dendroctonus ponderosae* in Experiment 1 to multiple funnel traps baited with MPB lures alone, and in combination with hexanal or hexanal plus four other green leaf volatiles released from separate devices (Table 2). McNulty Ck., near Princeton, B.C., Aug. 22–31, 1993, N = 10. For each sex, bars associated with the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$.

alcohols were the most repellent GLVs in Experiment 2, they were tested individually in Experiment 3; there was no MPB lure control in this experiment. In Experiment 4, the two best individual GLVs from Experiment 3 were tested with or without verbenone, to determine if they could enhance the repellency of verbenone.

Captured MPBs were collected within a week and stored in a freezer until counted and sexed. The numbers of two species of clerid beetles captured were also recorded.

Tree-Baiting Experiment. The two most potent GLVs, (*E*)-2-hexen-1-ol and (*Z*)-3-hexen-1-ol, were tested in Experiment 5 for their ability to deter attack on trees baited with MPB tree-baits (Phero Tech Inc., Delta, B.C.) releasing the attractive pheromones *trans*-verbenol and *exo*-brevicomin. The experiment was set up on July 19, 1995 with randomized complete blocks in Cutting Permit No. 18 (Weyerhaeuser Canada Ltd., Princeton, B.C.) in a mature stand of predominately lodgepole pine attacked at a moderate level by the MPB. Experimental trees were 25 m apart, and included those left as unbaited controls (11 trees), baited with MPB tree-baits (nine trees), or baited with MPB tree baits plus the two GLVs (ten trees) (Table 2). All release devices were stapled ≥ 2 m high on the north face of the tree. Mean diameters ($\pm$SE) at 1.3 m high

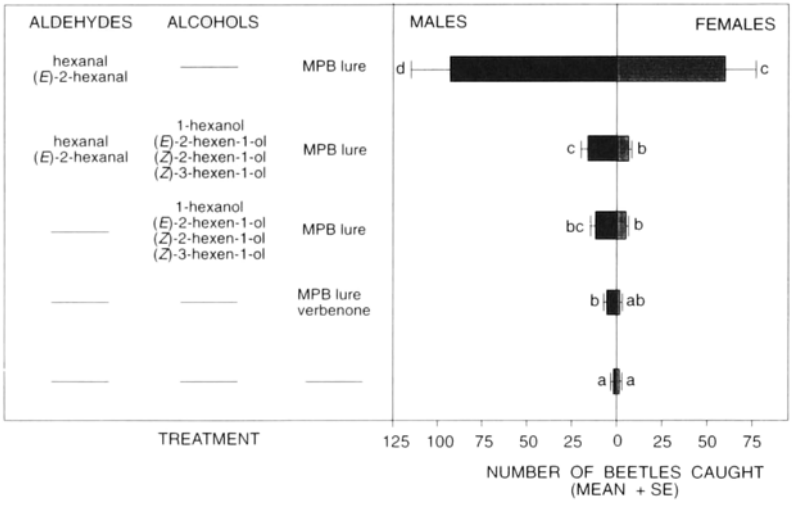

FIG. 2. Response of *Dendroctonus ponderosae* in Experiment 2 to multiple funnel traps baited with MPB lures in combination with green leaf alcohols, aldehydes, or both (Table 2). Willis Ck., near Princeton, B.C., July 11–23, 1994, N = 20. For each sex, bars associated with the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$.

for the trees in the three respective treatments were 25.4 ± 0.8, 25.5 ± 2.1, and 24.9 ± 1.3 cm.

The experiment was assessed on July 25, and August 10, 1995. On both dates the MPB attack density was counted in two 20 × 40 cm panels at eye level on the east and west faces of each experimental tree. At the second assessment all trees ≥ 15 cm in diameter within 5 m of each experimental tree were classed as not attacked, attacked with 1–4 attacks in the two 20 × 40 cm sample areas (< 31.25 attacks per m^2), or mass-attacked with ≥ 5 attacks in the two sample areas (≥ 31.25 attacks per m^2).

Statistical Analysis. In all cases $\alpha = 0.05$. To satisfy criteria for normality and homoscedasticity, trap catch and attack density data were transformed by $\log_{10}(x + 1)$ (Zar, 1984). ANOVA (GLM procedure, SAS Institute Inc., 1985), and the Ryan-Einot-Gabriel-Welsch Multiple Q-test (REGWQ procedure, SAS Institute Inc. 1985; Day and Quinn 1989) were used to determine differences between means in all experiments. Orthogonal contrasts (SAS Institute Inc., 1985) were also used to compare treatment means to the blank trap for low catches of clerid predators in Experiment 2. In Experiment 3, nonparametric Mann-Whitney-Wilcoxon tests (Zar, 1984) were used to test the hypothesis that trap catches to two semiochemical treatments containing green leaf alcohols

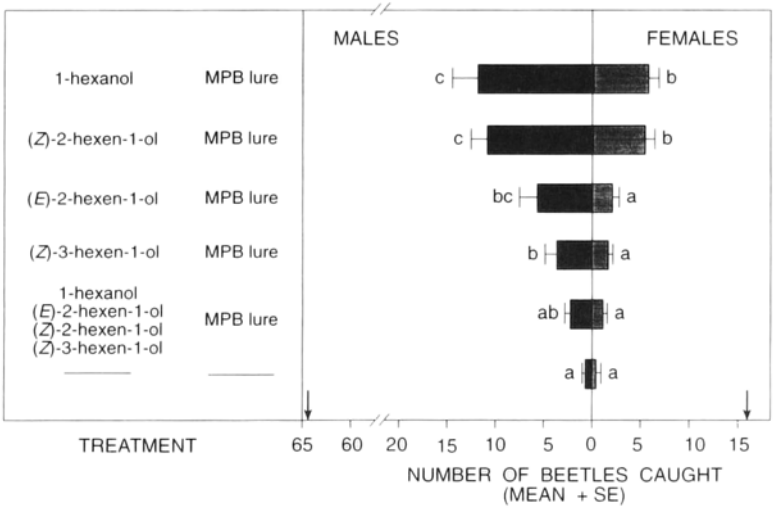

FIG. 3. Response of *Dendroctonus ponderosae* in Experiment 3 to multiple funnel traps baited with MPB lures in various combinations with green leaf alcohols. Willis Ck., near Princeton, B.C., July 23–Aug. 1, 1994, N = 16. Arrows on x-axis indicate mean catches (N = 2) in monitoring traps adjacent to the experiment, serving as a partial attractive control. For each sex, bars associated with the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$.

were significantly lower than catches in two nearby MPB monitoring traps containing attractive lures. The proportions of trees within 5 m of treatment trees in Experiment 5 that were attacked at any density or were mass-attacked were compared by chi-square tests for multiple proportions (Zar, 1984).

RESULTS AND DISCUSSION

Electrophysiological Studies. In GC-EAD analyses MPB antennae responded to all six-carbon alcohols tested, including 1-hexanol, (*E*)-2-hexen-1-ol, (*Z*)-2-hexen-1-ol, (*E*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-ol (Table 1). Responses (0.1–0.3 mV) were reproduced in at least two tests. These six-carbon alcohols were tested in field experiments, except for (*E*)-3-hexen-1-ol which is too expensive to be used operationally. At the 30 ng doses tested, MPB antennae did not respond to any of the six-carbon aldehydes or to homologous alcohols or aldehydes containing more or fewer carbon atoms.

Field Trapping Experiments. Hexanal was an ineffective disruptant when released at 1.2 mg per 24 hr in Experiment 1 (Figure 1). This result differs from

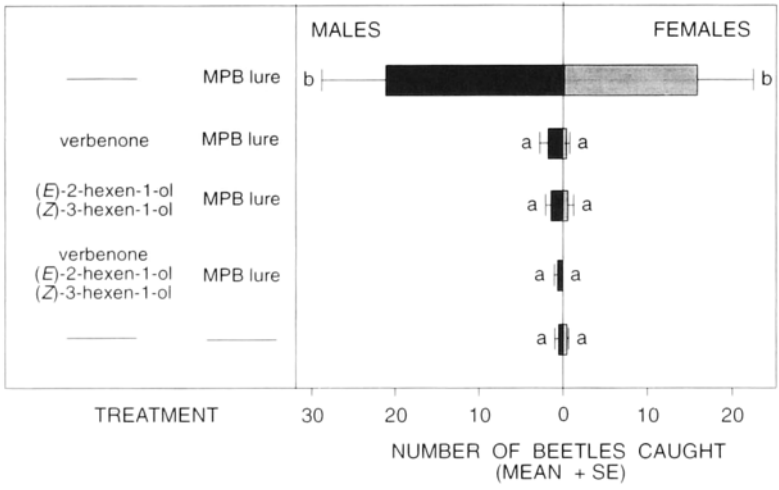

FIG. 4. Response of *Dendroctonus ponderosae* in Experiment 4 to multiple funnel traps baited with MPB lures alone or in combination with two green leaf alcohols, verbenone, or both. Willis Ck., near Princeton, B.C., Aug. 12–16, 1994, N = 10. For each sex, bars associated with the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$.

the finding of Dickens et al. (1992) that hexanal was a more effective disruptant than 1-hexanol for three other species of bark beetles. In other experiments (results not shown) hexanal released at rates up to 7.0 mg per 24 hr also had no significant disruptive effect. The lack of an antennal response to hexanal is in agreement with its behavioral inactivity. The blend of GLVs in Experiment 1, however, strongly reduced catches of both sexes, with catches of females being not significantly different from those in unbaited traps. Experiment 2 demonstrated that a green leaf alcohol blend comprising 1-hexanol, (*Z*)-3-hexen-1-ol, (*E*)-2-hexen-1-ol, and (*Z*)-2-hexen-1-ol (the latter not tested in Experiment 1), was competitive with verbenone as an antiaggregant, whereas the aldehydes, hexanal and (*E*)-2-hexenal were poor disruptants and did not enhance the effect of the alcohols (Figure 2).

(*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol in Experiment 3 were the most potent green leaf alcohol antiaggregant components of the mixture from Experiment 2 (Figure 3). Each of these alcohols alone disrupted the response of both sexes of MPB to the same level as a blend of all four alcohols, and reduced catches of females to levels not significantly different from those in unbaited traps. Although MPB lure controls were not included in Experiment 3, mean catches ($\pm$SE) (N = 2) in nearby monitoring traps baited with MPB lures were 64.0 $\pm$ 13.0 males and 16.5 $\pm$ 2.5 females, respectively (Figure 3, arrows). These

[c] Determined in laboratory at 24°C. All other release rates determined by Phero Tech, Inc. at 22°C.

catches were significantly higher (one-tailed Mann-Whitney-Wilcoxon tests, $P < 0.05$) than those to traps baited with MPB lures plus either 1-hexanol or (*Z*)-2-hexen-1-ol, indicating that these two alcohols also have disruptive properties. A combination of (*Z*)-3-hexen-1-ol and (*E*)-2-hexen-1-ol in Experiment 4 (Figure 4) had the same disruptive power as verbenone, reducing catches of male and female MPBs by 94% and 96%, respectively, compared to the attractive MPB lure control.

The reduction in trap catches caused by GLVs, ranging from 71% in Experiment 1 to 96% in Experiment 4, compares favorably with results of other

investigators, particularly when release rates (Table 2) are considered. When hexanal was released at 0.3 ml per 24 hr from traps also containing attractants, trap catches of *D. frontalis*, *I. grandicollis*, and *I. avulsus* were reduced by 46, 54, and 69%, respectively (calculated from tabular data in Dickens et al. 1992). 4-Allylanisole also caused significant reductions in response by *D. frontalis* (about 25–38%, calculated from Figures 1 & 2 in Hayes et al., 1994), and a 77% reduction in response by *D. ponderosae* (Hayes and Strom, 1994), but the release rates were very high, 160–1237 and 160 mg per 24 hr, respectively. At a similarly high release rate of 0.5 ml per 24 hr, 4-allylanisole caused reductions in response to attractant-baited traps by *D. brevicomis*, *D. ponderosae*, and *Ips pini* (Say) of 60, 71, and 29%, respectively (Hobson, 1995).

Tree-Baiting Experiments. At both assessment dates, the mean attack density by MPBs in trees baited with tree-baits plus GLVs was significantly lower than that on trees baited with MPB baits alone, and no different from that on unbaited control trees (Table 3). By the second assessment, nine of ten trees baited with MPB baits plus GLVs, and seven of 11 unbaited trees were attacked, but only three trees in each category were mass-attacked. In contrast, eight of

TABLE 3. EFFECT ON ATTACK BY *Dendroctonus ponderosae* IN EXPERIMENT 5 CAUSED BY AFFIXING DEVICES RELEASING TWO GLVS, (*e*)-2-HEXEN-1-OL AND (*Z*)-3-HEXEN-1-OL, ON TREES ALSO BAITED WITH MPB TREE-BAITS. CUTTING PERMIT NO. 18, APPROXIMATELY 20 KM SOUTHWEST OF PRINCETON, B.C., SET UP JULY 19, 1995

[a] MPB tree-baits (Phero Tech) contain *trans*-verbenol and *exo*-brevicomin. Release rates of these pheromones and the GLVs are as given in Table 2.

[b] Attack densities for each assessment date followed by the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$. Percents within a column followed by the same letter are not significantly different, chi-square test for multiple proportions, $P < 0.05$.

nine trees treated with MPB baits alone were mass-attacked. The GLV treatment reduced the total proportion of "spillover" attacks on trees surrounding experimental trees to a level intermediate between that for trees baited with MPB baits alone and that for unbaited control trees. It had no effect on the proportions of mass-attacked trees (Table 3). The GLVs were as effective as the antiaggregation pheromone, verbenone, in reducing attack density on trees baited with MPB pheromones, but not as effective in reducing spillover attacks (Borden and Lindgren, 1988).

The antennal responses (Table 1) and behavioral activity induced by green leaf alcohols in field trapping and baited tree experiments (Figures 1–4, Table 3) supports the hypothesis of Dickens et al. (1991, 1992) that GLVs are used by scolytids in host selection. GLVs may direct MPBs away from nonhost trees and may also help them to detect and fly above a deciduous understorey (Safranyik et al., 1992), possibly explaining why MPB tree baits placed on lodgepole pines within a dense understorey of Sitka alder, *Alnus sinuata* (Regel) Rydb., were ineffective at inducing mass-attack (Borden et al., 1986).

Associated Insects. Both *Enoclerus sphegeus* (F.) and *Thanasimus undatulus* (Say), clerid predators of the MPB (Furniss and Carolin, 1977), were captured in large numbers in Experiment 2 (Figure 5). *E. sphegeus* responded

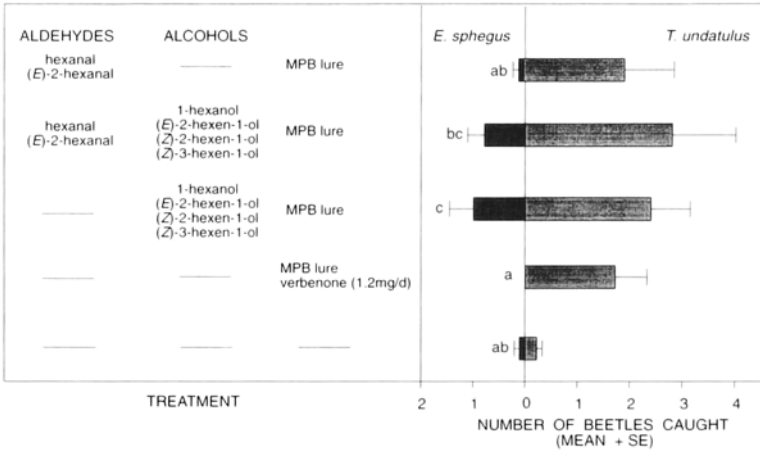

FIG. 5. Response of 20 *Enoclerus sphegeus* and 90 *Thanasimus undatulus* in Experiment 2 (Fig. 2) to multiple funnel traps baited with MPB lures in combination with verbenone, or green leaf alcohols, aldehydes, or both. Bars for *E. sphegeus* associated with the same letter are not significantly different, Ryan-Einot-Gabriel-Welsch Multiple Q-test, $P < 0.05$, $N = 10$. Orthogonal contrasts on *T. undatulus* catches indicated that all semiochemical-baited traps caught significantly more beetles than the unbaited traps ($P = 0.004$).

significantly only to traps baited with MPB lures plus GLV alcohols, whereas all semiochemical-baited traps caught significantly more *T. undatulus* than unbaited traps. Neither *E. sphegeus* nor *T. undatulus* were repelled by GLVs, and *E. sphegeus* may even have been slightly attracted by six-carbon alcohols. Similarly, 4-allylanisole did not reduce the response of *Thanasimus dubius* (F.), or *Temnochila chlorodia* (Mannerhein) to the attractant pheromones of their prey (Hayes et al., 1994 Hayes and Strom, 1994). In contrast, the response by predatory beetles, *Rhizophagus depressus* (F.), to ethanol was disrupted by nonhost volatiles (Schroeder, 1992).

The responses of clerid predators (Figure 5) are consistent with the hypothesis that semiochemicals associated with prey are used as host-finding kairomones by entomophagous insects (Borden 1982). *E. sphegeus* was previously shown to respond to *exo*-brevicomin (Borden et al. 1987b), a pheromone found in numerous species of scolytids. *T. undatulus* responds strongly to frontalin, another common aggregation pheromone in scolytids (Borden 1982).

Practical Implications. Of the candidate antiaggregants tested for the MPB, verbenone and the green leaf alcohols appear to be the most promising. Ipsdienol, the principal aggregation pheromone of the heterospecific competitor, *I. pini*, significantly disrupts response of MPBs to attractive baits (Hunt and Borden 1988; Wilson 1995), but it is expensive and may not be viable operationally except for protection of single, high-value trees. Green leaf alcohols have the advantage of being cheap and easy to obtain, but more work is needed to bring them to an operational level for use against the MPB. A disruptant blend of verbenone with GLVs (Dickens et al. 1993, 1995), and possibly with interspecific synomones, and resistant host or nonhost kairomones, may prove to be a reliable tool for operational protection of trees and stands. Because 4-allylanisole can protect trees from attack by the southern pine beetle (Hayes and Strom, 1995), it could be a component of an operational blend. A disruptant blend could be an even more powerful tool if used with attractants in a "push-pull" tactic (Lindgren and Borden 1993; Borden 1995).

Abstract—Tannins are one of the most broadly distributed types of plant secondary compounds, and have been the focal point for many studies of plant/herbivore interactions. Tannins interact strongly with proteins, so that the fate and effects of ingested tannins are in part dependent on the mode of interaction of the tannin with dietary and endogenous proteins in an herbivore's gut. We investigated the factors affecting the precipitation of proteins by phlorotannins from three species of marine brown algae: *Carpophyllum maschalocarpum*, *Ecklonia radiata*, and *Lobophora variegata*. Phlorotannins were precipitated by proteins in a pH-dependent and concentration-dependent fashion. Precipitation also varied as a function of the presence of reducing agent, the type of phlorotannin or protein used, and the presence of organic solvents such as hydrogen bond inhibitors. Of particular significance was the ability of some phlorotannins to oxidize and form covalent bonds with some proteins. In contrast, under similar experimental conditions three types of terrestrial tannins (procyanidins, profisetinidins, and gallotannins) apparently did not form covalent complexes with proteins. Our results suggest several ways in which the biological activity of phlorotannins may vary as a function of the properties of the gut environment of marine herbivores. Moreover, we identify specific structural characteristics of phlorotannins which affect their tendency to oxidize, and thus, their potential effects on marine herbivores.

INTRODUCTION

Tannins, or polymeric phenolics, are one of the most broadly distributed types of plant secondary metabolites in terrestrial (Harborne, 1991) and marine (Ragan and Glombitza, 1986) plants. Tannins have important effects on both marine and terrestrial herbivores, but there is substantial variation in the biological activities of tannins against different herbivores (Bernays et al., 1989; Steinberg, 1993; Appel, 1993; Boettcher and Targett, 1993). In part this variation is because tannins do not have a single biological activity, but may act as feeding deterrents (Steinberg, 1988; Clausen et al., 1990); digestibility reducing agents (Robbins et al., 1987; Boettcher and Targett, 1993); or toxins (Bernays et al., 1980).

The variation in biological activity of tannins is due in part to variation in tannin structure (Zucker, 1983). For example, terrestrial tannins bind proteins selectively (Hagerman and Butler, 1981), and some mammals utilize that selectivity by secreting salivary tannin-binding proteins which neutralize specific tannins (Hagerman and Robbins, 1993). Even minor structural variation, such as stereoisomerism, affects the activity of some terrestrial proanthocyanidins as feeding deterrents (Clausen et al., 1990). The ability of phlorotannins to inhibit protein assimilation by an herbivorous fish varied with the molecular weight of the tannin (Boettcher and Targett, 1993). Phlorotannins from different species of brown algae also varied in their activity as feeding deterrents for marine herbivores (Steinberg and van Altena, 1992; van Altena and Steinberg, 1992) although the structural elements leading to the variation in activity were not identified.

The variation in the biological activity of tannins can also be attributed to variations in the gut physiology and biochemistry of various herbivores. For example, the ability of tannins to precipitate proteins is dependent on pH, the presence of surfactants, and the concentration of metal ions (Hagerman and Butler, 1978; Martin and Martin, 1984; Tugwell and Branch, 1992). All of these factors affect how tannins affect herbivores, and how herbivores can minimize the detrimental effects of tannins on ecological or evolutionary time scales (Bernays et al., 1989; McArthur et al., 1991).

The ability of tannins to precipitate protein has been examined in many studies. However, with few exceptions (Tugwell and Branch, 1992; Boettcher and Targett, 1993), most of the work on interactions between proteins and tannins has been done using terrestrial tannins (Hagerman, 1992). It may be inappropriate to draw conclusions about marine herbivore/phlorotannin interactions based on knowledge about terrestrial tannins. Phlorotannins (1–4, Figure

1), which are known only from the Phaeophyta (brown algae) (Ragan and Glombitza, 1986), are structurally quite unlike terrestrial tannins (5, 6, Figure 1). Furthermore, the gut morphology, physiology, and biochemistry of marine herbivores are quite unlike those of terrestrial herbivores (Horn, 1989). We have therefore conducted experiments designed to define the parameters that control

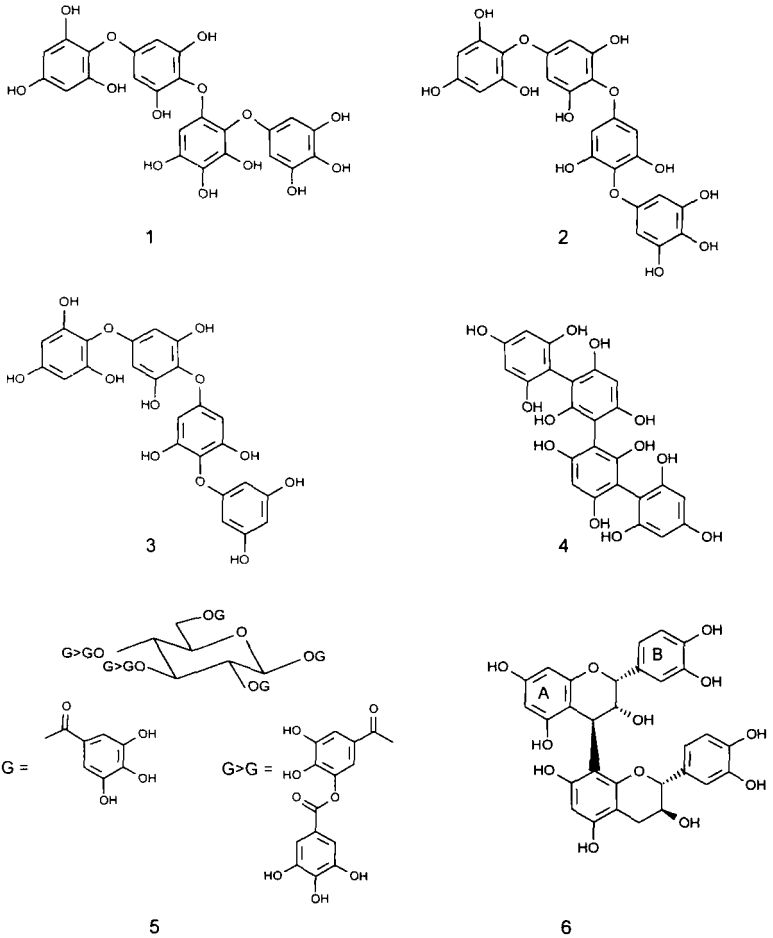

FIG. 1. Structural formulae of various tannins. 1, tetrafuhalol A, is a fuhalol-type phlorotannin; 2, hydroxytetraphlorethol, is a hydroxyphlorethol-type phlorotannin; 3, tetraphlorethol C, is a phlorethol-type phlorotannin; 4, tetrafucol A, is a fucol-type phlorotannin; 5, heptagalloyl glucose, is a gallotannin; 6, epicatechin-4β → 8-catechin (procyanidin B-1), is a procyanidin-type condensed tannin.

precipitation of phlorotannins by proteins. Phlorotannins from three species of brown algae and several proteins were used to evaluate structure-activity relationships. We examined the effects of pH, of hydrogen bonding solvents, and of detergents and hydrophobic solvents on the interaction between phlorotannins and proteins.

In the course of our study, it became clear that oxidation reactions were an important feature of phlorotannin chemistry. It has been postulated that oxidation of tannins may be crucial to their biological activity (Appel, 1993), and it has been demonstrated that tannic acid precipitates protein more effectively in the presence of oxidants (Leatham et al., 1980). However, we believe that our work with phlorotannins is the first clear demonstration of a role for spontaneous oxidation in the formation of tannin-protein complexes. We were unsuccessful in our attempt to demonstrate similar reactions for several representative terrestrial tannins.

METHODS AND MATERIALS

Reagents

Phlorotannins were purified from *Ecklonia radiata* (Order Laminariales) and *Carpophyllum maschalocarpum* (Order Fucales) using methods developed by Ragan and Glombitza (1986) as modified by Steinberg and van Altena (1992). High (>100,000 amu) and moderate (5,000–100,000 amu) molecular weight phlorotannins from *Lobophora variegata* (Order Dictyotales) (Boettcher and Targett, 1993) were provided by Nancy M. Targett (University of Delaware, Lewes, Delaware, 1995). Terrestrial tannins were purified from *Sorghum* grain, from commercial tannic acid or from crude commercial quebracho tannin (Hagerman and Butler, 1980b; Asquith and Butler, 1985; Hagerman and Klucher, 1986). Phlorotannin preparations were comprised of polydisperse tannins with molecular weights ranging from 6,000–100,000 (Van Altena and Steinberg, 1992; Boettcher and Targett, 1993). Condensed tannins from *Sorghum* grain or quebracho did not contain any low molecular weight phenolics (Hagerman and Butler, 1980b). Purified tannic acid is a mixture of polygalloyl esters ranging from pentagalloyl glucose to decagalloyl glucose (Hagerman and Klucher, 1986).

Proteins and 2,4-dimethoxybenzaldehyde (DMBA) were obtained from Sigma Chemical Co., St. Louis, MO. Radiolabeled bovine serum albumin was prepared by reacting $Na^{125}I$ with bovine serum albumin in the presence of Chloramine T (Hagerman and Butler, 1980a). The iodinated protein was dialyzed either against Buffer J or against Buffer J containing 15 mM DTT (dithiothreitol) prior to conducting precipitation assays. Protein compositions, isoelectric points, and molecular weights were obtained from the literature (Sugiyama et al., 1968;

Mahler and Cordes, 1971; Peters, 1975; Malmud and Drysdale, 1978; Paech, 1985).

Phlorotannin solutions (10 μg/μL) were prepared daily in methanol. Proteins were dissolved in 0.11 M sodium chloride and stored at 4°C. Most proteins were prepared as 10 μg/μL solutions, but ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBPC) was prepared as a saturated solution (approximately 2.5 μg/μL) and centrifuged to yield a clear solution.

Acidified acetic acid was prepared by mixing concentrated hydrochloric acid with glacial acetic acid (16 mL concentrated hydrochloric acid per 100 mL solution). Fresh solutions of DMBA (2 g/100 mL glacial acetic acid) were prepared fresh daily; this solution turned purple with age (Stern et al., 1996).

For the standard precipitation reactions at pH 5.0, Buffer J was prepared (0.1 M acetate, 0.43 M sodium chloride, pH 5.0) and stored at 4°C. For pH profiles, 0.1 M sodium phosphate buffers were prepared at various pH values between 2 and 12. A stock 1 M solution of the reducing agent DTT in water was prepared and stored at −20°C. Buffers were brought to a final concentration of 15 mM DTT daily by adding an appropriate amount of the stock solution of DTT.

Phlorotannin-Protein Precipitation Assay

We used the new DMBA assay, described more fully in Stern et al. (1996), to measure phlorotannins after they were precipitated by protein. Buffer (180 μL) was mixed with the phlorotannin solution (10 μL of 10 μg/μL phlorotannin) in conical glass centrifuge tubes (12–15 mL capacity). Protein (20 μL of 10 μg/μL protein) was added and the samples were mixed. The samples were incubated for 30 min at room temperature, and were then centrifuged at 2000 × *g* for 15 min. The supernatants were removed by aspiration and the surfaces of the pellets were gently washed with 100 μL buffer. The samples were centrifuged again for 5 min, and the supernatants removed by aspiration.

In order to quantitate the phlorotannin in the precipitates, it was necessary to redissolve the precipitated complexes. In the initial experiments with protein and phlorotannin, the protein-phlorotannin precipitates were dissolved directly in glacial acetic acid containing DMBA and hydrochloric acid. Although this was successful for preliminary experiments with *Ecklonia* tannin and bovine serum albumin, as we began to extend the work we found that in some cases the protein-phlorotannin precipitate did not completely dissolve in this reagent. We unsuccessfully tested a variety of conditions such as extremes of pH or addition of protein denaturants for dissolving the precipitates. We found that for most proteins the complex could be completely dissolved by vigorous agitation of the precipitate in 10 μL of N,N-dimethylformamide. This procedure was used in all subsequent assays.

Immediately after dissolving the pellets, 1.25 mL of the acidified acetic acid was added to each sample. It was necessary to add the acidified glacial acetic acid reagent immediately after dissolving the precipitate in the dimethylformamide to prevent destruction of the phlorotannin. At timed intervals, 1.25 mL of DMBA reagent was added to each sample; the samples were immediately mixed and placed in a water bath at 30°C. Exactly 60 min later, the absorbance of each sample was determined at 510 nm (Stern et al., 1996).

A small amount of phlorotannin adsorbed to the tubes, resulting in background absorbance. To correct for that background, a sample containing phlorotannin and buffer but no protein was treated like the other samples and its absorbance (typically about 0.06) was subtracted from the absorbance for each sample. The total amount of phlorotannin used in each experiment was determined by reacting 10 μL of the phlorotannin solution, 10 μL N,N-dimethylformamide and 1.25 mL of the acidified acetic acid with 1.25 mL of DMBA reagent for exactly 60 min at 30°C. The amount of phlorotannin precipitated was calculated as a percent of the total amount of phlorotannin.

Precipitation of ^{125}I Bovine Serum Albumin

This assay was used to determine the amount of protein precipitated by the various phlorotannins. In this assay, the amount of radiolabeled protein precipitated is determined by direct radiochemical counting. Since it is not necessary to dissolve the tannin-protein complex to count the radiolabeled protein, this assay was particularly useful for quantitating insoluble covalent complexes obtained with phlorotannins.

Tannins were dissolved in methanol and 100 μL was added to 300 μL of the appropriate buffer containing 50 μg of iodinated protein. The concentration of the tannin in the solution was set so that not all of the protein precipitated. After 15 min the samples were centrifuged, the supernatants were removed and the precipitates were gently washed with 100 μL of the appropriate buffer. The samples were centrifuged again, the supernatants were removed and the precipitates were counted with a gamma counter.

RESULTS

Precipitation of Phlorotannin by Protein

In order to determine how biologically relevant parameters affect the interaction between phlorotannins and protein, it was first necessary to optimize the conditions for precipitation. We evaluated the effects of time, temperature, and reactant concentrations on precipitation of phlorotannins by proteins. Precipitation of *Ecklonia* phlorotannins by protein occurred rapidly (Figure 2a). The

amount of phlorotannins precipitated was similar for incubation times ranging from 15 min to 24 hr, and at temperatures ranging from 4°C to 35°C. Precipitation of *Carpophyllum* phlorotannins increased slowly with time when the reducing agent DTT was present in the incubation mixture (Figure 2b). We routinely incubated phlorotannins and protein for 30 min at room temperature before analyzing the precipitate.

The composition of the phlorotannin-protein precipitate was dependent on both the amount of protein and phlorotannins present. When the protein-to-phlorotannin mass ratio was small ($<2:1$), between 60 and 100% of the phlorotannins were precipitated and all of the protein was precipitated. The efficiency of phlorotannin precipitation depended on the phlorotannins, the protein and the buffer used. If the protein-to-phlorotannin ratio was large ($>5:1$), less than 60% of the phlorotannins were precipitated, and only a fraction of the protein was precipitated. The mass ratio of protein-to-phlorotannin was routinely set at 2:1 to maximize the amount of phlorotannin that was precipitated.

Effects of Reducing Agents

We found that even dimethylformamide did not completely dissolve precipitates formed by *Carpophyllum* phlorotannins and certain proteins especially when the protein-to-phlorotannin ratio was small. Precipitates comprised of *Carpophyllum* phlorotannins and trypsin, chymotrypsin, or cytochrome c were dark-colored and resistant to dissolution. *Ecklonia* phlorotannins and cytochrome c also formed dark-colored precipitates which were difficult to redissolve. The color of these complexes suggested that oxidation reactions were involved, and the resistance to dissolution suggested covalent bonds had formed between the tannin and the protein. We used reducing agents to evaluate the role of oxidation. When the phlorotannins were mixed with any of these proteins in buffer containing high concentrations of reducing agents, such as 50 mM β-mercaptoethanol or 15 mM DTT, the complexes which formed were pale colored and could usually be dissolved in dimethylformamide. This indicated the importance of oxidation in phlorotannin-protein interactions, so we subsequently routinely added 15 mM DTT to the incubation buffer.

The addition of reducing agents also had the benefit of maximizing the color yield obtained in the DMBA assay. For example, when DTT was omitted from the reaction mixtures, less *Carpophyllum* phlorotannins were detected in precipitates formed during long (6–24 hr) incubations with protein than were detected after short (30 min) incubations (Figure 2b). In the presence of reducing agent, the amount of precipitated *Carpophyllum* phlorotannins increased with long incubations. It is likely that during the long incubation without reducing agent the phlorotannins spontaneously oxidized, decreasing their reactivity with DMBA. We minimized oxidative interference with the DMBA assay by incor-

porating the reducing agent DTT in the precipitation step and by maintaining the redissolved samples at low pH, since phenolic oxidation occurs less readily at lower pH values (Ronlan, 1978).

Composition of Phlorotannin-Protein Complexes

For all proteins tested, the amount of either *Carpophyllum* or *Ecklonia* phlorotannins detected in the precipitate was increased by the addition of the reducing agent DTT to the incubation buffer (Figure 3). Further experiments with phlorotannins from *Lobophora* indicated that the magnitude of the effect of DTT was both protein- and phlorotannin-specific. For example, precipitation of high molecular weight *Lobophora* phlorotannins by RuBPC or pepsin was not affected by DTT, but precipitation by bovine serum albumin, lysozyme, or trypsin was DTT-dependent (Figure 3). The amount of low molecular weight *Lobophora* phlorotannins precipitated was not affected by addition of DTT for any protein tested (Figure 3).

We used radiolabeled bovine serum albumin to confirm the effect of reducing agents on phlorotannin precipitation. We determined the amount of protein precipitated by phlorotannins or terrestrial tannins in the presence and absence of reducing agents. The amount of protein precipitated by *Carpophyllum* or by high molecular weight *Lobophora* phlorotannins was increased by addition of DTT to the incubation mixture (Table 1). The reducing agent did not affect the amount of protein precipitated by *Ecklonia* or low molecular weight *Lobophora* phlorotannins, or by the three terrestrial tannins. Not only was precipitation of tannic acid, a terrestrial gallotannin, insensitive to DTT (Table 2), but we found that fairly vigorous conditions were required to oxidize gallotannins. We were able to oxidize gallotannins only at pH values above 8 in the presence of an oxidant (A. E. Hagerman and S. Y. Harper-Avilla unpublished data). In contrast, we have found that some phlorotannins are susceptible to oxidation by air in slightly acidic to neutral solutions.

The activity of the reducing agent was pH-dependent (Figure 4). In general,

FIG. 2. Kinetics of phlorotannin precipitation by bovine serum albumin. Phlorotannin (10 μg) was mixed with protein (20 μg) in pH 5 phosphate buffer. After the indicated incubations, mixtures were centrifuged, and the supernatants aspirated off. The pellets were redissolved in acidified acetic acid and reacted with DMBA in acetic acid at 30°C for exactly 60 min before the absorbance at 510 nm was determined. Each point represents the mean of three determinations and the error bars represent standard deviations. a, Precipitation of *Ecklonia* phlorotannin at 4°C, 27°C, or 35°C. b, Precipitation of *Carpophyllum* phlorotannin at 25°C in the presence or absence of DTT, a reducing agent.

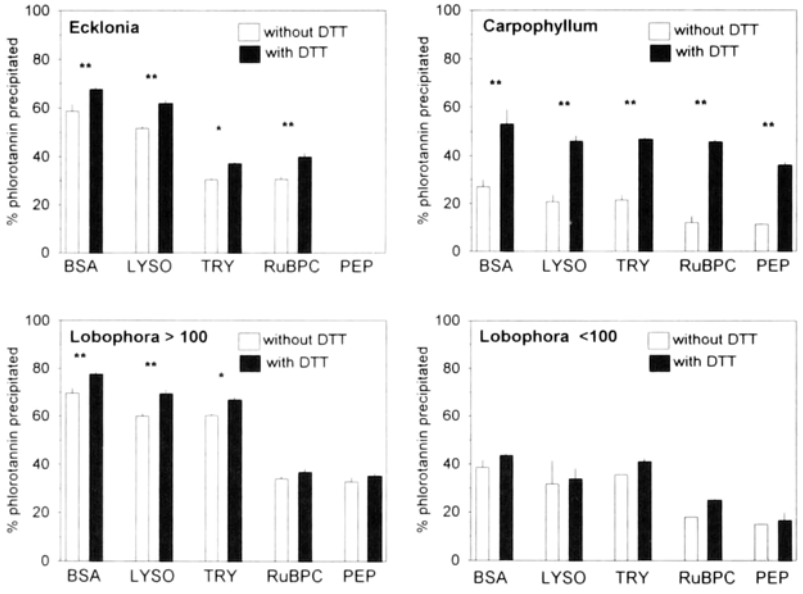

FIG. 3. Precipitation of phlorotannin in the presence and absence of DTT, a reducing agent. The standard DMBA method was used, but DTT was omitted from buffer J for reactions without DTT. Each bar represents the mean of three replicates. Significantly different values (t-test) between treatments with and without DTT are indicated (** for $P < .01$, * for $P < .05$).

addition of DTT had little effect on the composition of protein-phlorotannin complexes formed at low pH. DTT increased the amount of phlorotannin precipitated at slightly acidic, neutral, or basic pH values.

Phlorotannin-Protein Interactions

To evaluate interactions between unoxidized phlorotannins and proteins, we examined the effects of pH and of various solvents on precipitation in the presence of reducing agents. The precipitation of phlorotannins by various proteins is strongly pH-dependent (Figure 4; Figure 5). The shape of the pH profile is largely dictated by the characteristics of the protein. The pH range which favored precipitation was related to the acidity or basicity of the protein. For example, the very acidic protein pepsin (pI = 2.2) was precipitated only in acidic solutions (pH < 6). The slightly acidic proteins bovine serum albumin (pI = 4.9) and RuBPC (pI = 4.9) were precipitated in slightly acidic to neutral

TABLE 1. PRECIPITATION OF RADIOLABELED BOVINE SERUM ALBUMIN BY VARIOUS TANNINS IN THE PRESENCE OR ABSENCE OF DTT. THE AMOUNT OF ^{125}I-BOVINE SERUM ALBUMIN IN THE TANNIN-PROTEIN PRECIPITATE WAS DETERMINED BY GAMMA COUNTING. TO ENSURE THAT CHANGES IN THE AMOUNT OF PROTEIN PRECIPITATED COULD BE DETECTED, THE PROTEIN-TO-TANNIN MASS RATIO WAS SET SO THAT THERE WAS ALWAYS SOME UNPRECIPITATED PROTEIN LEFT IN THE REACTION MIXTURE. THE VALUES ARE MEAN ± SD FOR THREE REPLICATES. SIGNIFICANTLY DIFFERENT VALUES BETWEEN TREATMENTS WITH AND WITHOUT DTT ARE INDICATED (*t*-TEST; ** FOR $P < .01$, * FOR $P < .05$)

solutions (pH 4-6). The basic proteins trypsin (pI = 10.5) and lysozyme (pI = 11.1) were precipitated in slightly acidic to basic solutions (pH 4-10).

The nature of the interaction between phlorotannin and protein was further probed by adding various organic modifiers to the reaction mixture. If tannin-protein precipitates are stabilized by hydrogen bonds between the tannin and the protein, then hydrogen bonding solvents should interfere with precipitation. If hydrophobic forces stabilize the tannin-protein complex, then nonpolar solvents or detergents should interfere with precipitation. We found that several different organic solvents influenced the precipitation of phlorotannins by bovine serum albumin. The magnitude of the effect was dependent on the properties of the solvent and on the phlorotannin (Table 2). In general, the most effective inhibitors of precipitation were dimethylformamide and dioxane. The ability of dimethylformamide to inhibit precipitation of phlorotannin by protein was consistent with its ability to dissolve phlorotannin-protein complexes. Methanol inhibited the precipitation of only a single phlorotannin, from *Ecklonia*, and stimulated precipitation of the high molecular weight phlorotannin from *Lobophora*.

The effects of the organic solvents on precipitation were concentration dependent. For example, 10% dimethylformamide or dioxane had little effect

TABLE 2. PRECIPITATION OF PHLOROTANNINS IN THE PRESENCE OF ORGANIC MODIFIERS. THE INDICATED ORGANIC SOLVENT WAS SUBSTITUTED FOR PART OF THE BUFFER TO ACHIEVE 10% SOLVENT IN THE INCUBATION MIXTURE. on precipitation of high molecular weight *Lobophora* phlorotannin (Table 2). However, if the mixture of phlorotannin and protein contained 20% of either of these solvents, precipitation of high molecular weight *Lobophora* phlorotannin was inhibited 60% (dioxane) or 70% (dimethylformamide).

Adding as little as 1 to 3% of the nonionic detergent Triton X 100 to incubation mixtures containing bovine serum albumin and *Ecklonia* or *Carpophyllum* phlorotannin completely prevented precipitation.

DISCUSSION

The effects of tannins or phlorotannins on herbivores varies significantly in both terrestrial (Bernays et al., 1989) and marine (Steinberg and van Altena, 1992; Steinberg et al., 1995) systems. Some of the basis for this variation is documented for terrestrial herbivores, and includes characteristics of both the herbivores and of the tannins (Martin and Martin, 1984; Bernays et al., 1989; Clausen et al., 1990; Hagerman and Robbins, 1993).

In marine systems, the effects of phlorotannins on herbivores vary as a function of the type of phlorotannin (Steinberg and van Altena, 1992; Boettcher

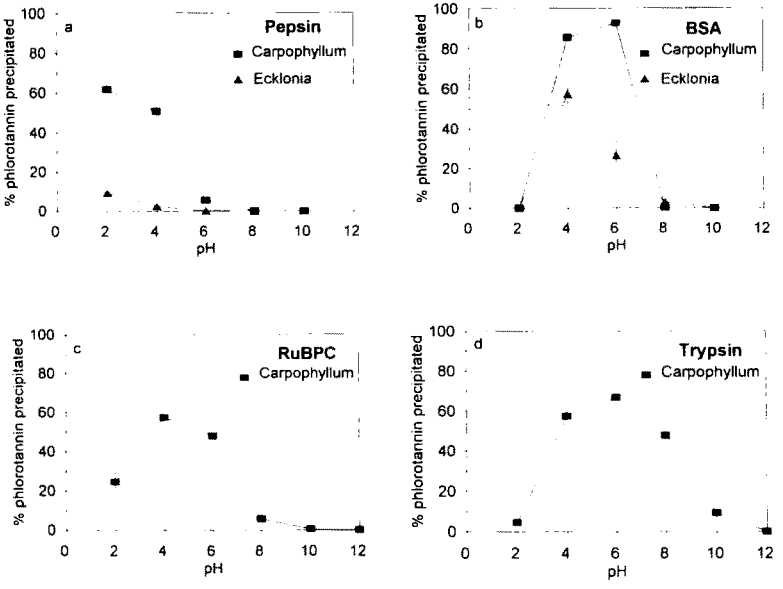

FIG. 5. Precipitation of *Carpophyllum* or *Ecklonia* phlorotannin by proteins as a function of pH. Tannin and protein were incubated in 0.1 M phosphate buffers containing 15 mM DTT. and Targett, 1993), the characteristics of the gut environment (Tugwell and Branch, 1992), the herbivore species (Steinberg and van Altena, 1992) and the geography (Van Alstyne and Paul, 1990; Steinberg and van Altena, 1992; Steinberg et al., 1995). For the most part, the specific mechanisms of action of phlorotannins which underlie this variation are unknown.

Reactions of Oxidized Phlorotannins

Appel (1993) proposed that phenolic oxidation may have significant ecological implication and we have obtained detailed experimental evidence for reactions between oxidized tannins and protein. A mechanism for formation of covalent complexes between protein and oxidized plant phenols was proposed by Pierpoint (1969a), and reactions between oxidized simple phenolics, such as chlorogenic acid, and protein have been demonstrated (Pierpoint, 1969b; Felton et al., 1992). Leatham et al. (1980) demonstrated that tannic acid treated with peroxidase and hydrogen peroxide precipitated more protein than untreated tannic acid. However, evidence accumulated under a wide range of conditions indicates

that in the absence of added oxidants, oxidation is not involved in the reactions between terrestrial tannins and proteins (Haslam, 1989; Hagerman, 1992). In contrast, we have found that the phlorotannins from marine algae spontaneously oxidize and react with protein to form dark colored complexes resistant to dissolution unless a reducing agent is present.

We initially recognized oxidation in the phlorotannin system because of difficulties we encountered when attempting to redissolve some phlorotannin-protein precipitates for analysis. Dark-colored precipitates resistant to solubilization were obtained especially when *Carpophyllum* phlorotannins were incubated with protein in alkaline solution. The precipitates could not be redissolved by hydrogen bond-breaking solvents, such as dimethylformamide or by protein denaturants, such as sodium dodecyl sulfate, leading us to postulate that covalent bonds were stabilizing these complexes. The color of the precipitates was consistent with the orange-brown colors of oxidized phenolics (Pierpoint, 1969a).

We used mild reducing agents to demonstrate the importance of oxidation in phlorotannin-protein interactions. We found that when 15 mM DTT was included in the mixture of phlorotannins and protein, light colored precipitates formed. These precipitates were easily dissolved in dimethylformamide, suggesting that the protein-phlorotannin complex formed under these conditions involved noncovalent interactions. The reducing agents were effective with a variety of proteins and phlorotannins over a broad pH range. We obtained similar results using an alternative reducing agent, β-mercaptoethanol, in place of DTT.

The method of analysis that we employed (Stern et al., 1996) is particularly well suited to detecting insoluble covalent complexes between oxidized tannins and protein. Our method is dependent on resolubilizing the precipitate; irreversible, covalent complexes were readily recognized. Tugwell and Branch (1992) examined phlorotannin-protein interactions but did not report any effects that can be attributed to oxidation. They analyzed the supernatant after removal of the precipitate and thus did not assess solubility or other characteristics of the precipitates. Our study was not designed to examine soluble tannin-protein complexes stabilized by either noncovalent or covalent bonds (Hagerman and Robbins, 1987).

In most of our experiments, more phlorotannins were detected in precipitates formed under reducing conditions than in precipitates formed under oxidizing conditions (Figure 2). This increased precipitation could be an artifact resulting from the higher color yield of DMBA with reduced phlorotannins. An additional source of artifact could be the improved solubility of complexes formed under reducing conditions, since the assay only detects the phlorotannins that can be redissolved after precipitation. To eliminate these possible interferences, we performed precipitation reactions using a radiolabeled protein. Precipitated, labeled protein is determined by direct radiochemical counting so interferences in the assay are eliminated. For *Carpophyllum* phlorotannins and moderate

molecular weight *Lobophora* phlorotannins more protein was precipitated under reducing conditions than under oxidizing conditions (Table 1). This clearly demonstrates that the effects of reducing agents on phlorotannin precipitation are not artifacts of our method of analysis.

Oxidation is more important for interactions of phlorotannins with some proteins and less important for other proteins. The proteins examined differ in many respects, including size, amino acid composition and isoelectric point. The role of oxidation for precipitation of phlorotannins by RuBPC was particularly variable. RuBPC precipitation of *Carpophyllum* phlorotannins was enhanced more by the addition of DTT than was the precipitation of any other protein, but addition of DTT had no effect on precipitation of high molecular weight *Lobophora* phlorotannins by RuBPC. RuBPC is unusually large (560,000 amu) and is a 16-mer comprised of two types of subunits. The other proteins used in these experiments range in size from 14,400 amu (lysozyme) to 65,000 amu (bovine serum albumin) and are all single polypeptide chains. RuBPC contains an unusual number of reduced thiols (96 cysteines per 16-mer of spinach RuBPC), which may make it particularly susceptible to oxidation. Of the other proteins examined, bovine serum albumin contains 17 disulfide bonds (cystines) and one cysteine residue; the other proteins contain three to six cystines and no cysteine.

Tannin Structure and Oxidation Reactions

The tendency of phenolics to oxidize is affected by the nature of substituents and the position of substituents on the phenolic (Ronlan, 1978). The presence of an electron withdrawing group such as a carboxylic acid or an ester makes the phenolic more difficult to oxidize; thus, the redox potential of *para*-hydroxy benzoic acid is higher than the redox potential of phenol (Table 3). Electron donating groups such as alkyl, aryl, ether, or hydroxyl groups make the phenolic easier to oxidize. Among the electron donating groups, alkyl and aryl groups have the smallest effect, ether groups have a larger effect and hydroxyl groups have the largest effect on oxidation potential (compare *ortho*-methyl phenol, *ortho*-methoxyphenol and catechol, Table 3). Substituents *ortho* or *para* to a phenolic group change the redox potential more than *meta* substituents. For example, the redox potentials of catechol and hydroquinone (*ortho* and *para* substituted, respectively) are much lower than the redox potential of phenol while the redox potential of resorcinol (*meta* substituted) is intermediate (Table 3).

We found that the susceptibility of tannins to oxidation can be explained by examining the structural characteristics of the tannins. The susceptibility of some phlorotannins to oxidation is a consequence of extensive substitution by aryl ethers (1, 2, and 3, Figure 1). The ether groups are strong electron donating

TABLE 3. REDOX POTENTIALS OF SIMPLE PHENOLICS

Structure	Substitutent pattern and type	Redox potential (V)
	phenol unsubstituted	0.62[a] 0.63[b]

	catechol *ortho* hydroxyl electron donating	0.18[a]
	*para*-hydroquinone *para* hydroxyl electron donating	0.18[a]
	resorcinol *meta* hydroxyl electron donating	0.39[a]

[a] $E_{p/2}$ vs. standard calomel electrode, pH 7 phosphate (Meites & Zuman 1974)
[b] $E_{1/2}$ vs. standard calomel electrode, pH 5.6 isopropanol/H_2O (Suatoni et al. 1961)

groups, especially when they are positioned *ortho* or *meta* to phenolic groups as in the phlorotannins. Ether substituents facilitate oxidation of the resorcinol-like phenolic subunits of the phlorotannins.

The phlorotannins from *Carpophyllum* were more susceptible to oxidation than any other tannin we examined. Both the amount of protein and the amount of phlorotannins precipitated were enhanced by the addition of reducing agent to the protein-*Carpophyllum* mixtures (Figure 3, Table 1). The mixture of phlorotannins found in *Carpophyllum* includes fuhalols (1, Figure 1) (Ragan and Glombitza, 1986) and hydroxyphlorethols (2, Figure 1) (Glombitza and Li, 1991a). Both of these types of phlorotannin characteristically have *ortho* hydroxy groups on the terminal unit. The addition of the strong electron donating hydroxyl group *ortho* to the other hydroxyl groups on the terminal unit of the *Carpophyllum* phlorotannins enhances sensitivity to oxidation. In contrast, the phlorotannins from *Ecklonia* are less susceptible to oxidation (Figure 2, Table 1); phlorotannins from *Ecklonia* such as phlorethols (3, Figure 1) do not contain any hydroxyl groups in the *ortho* orientation (Ragan and Glombitza, 1986). We found that the phlorotannins from *Lobophora*, like those from *Ecklonia*, have a limited tendency to oxidize, but nothing is known about the structural chemistry of the phlorotannins from *Lobophora*.

These results suggest that structural differences between the phlorotannins may substantially influence the interaction between phlorotannins and proteins. Consequently, the ability of herbivores to counteract the effects of different phlorotannins by controlling the redox potential of the gut will also vary. Based on the limited structural data available, we predict that ether-linked phlorotannins which have *ortho* substituted hydroxyl grops on one or more rings will generally be the most susceptible to oxidation. We predict that phlorotannins which are aryl-aryl linked, such as the fucols (4, Figure 1), will be least susceptible to oxidation, since aryl groups are weaker electron donating groups than aryl ethers. This prediction could be tested by using methods like those developed by Glombitza (e.g., Glombitza and Li, 1991a; Glombitza and Li, 1991b; Li and Glombitza, 1991) to determine the structures of isolated phlorotannins, and then determining the redox potentials of those purified compounds. Our studies were done with mixtures of phlorotannins, making it impossible to specifically evaluate the contribution of each type of phlorotannin to oxidation reactions.

The terrestrial tannins did not appear to oxidize spontaneously (Table 2) despite the catechol-like arrangement of hydroxyl groups common to these tannins (5 and 6, Figure 1). Examination of the other substituents on the terrestrial tannins explains their insensitivity to oxidation. For the gallotannins (5, Figure 1), each of the phenolic rings bears at least one electron withdrawing ester group, diminishing susceptibility to oxidation. The condensed tannins have alkyl substituents on both the phenolic rings (A ring and B ring of 6, Figure 1). Alkyl substituents are poor electron donating groups, and apparently do not enhance

oxidizability of the phenolic rings sufficiently to promote air oxidation of the condensed tannins. It would be useful to directly determine the redox potentials of various phlorotannins and terrestrial tannins in order to better understand their relative susceptibility to oxidation.

Noncovalent Phlorotannin-Protein Interactions

Insight into the types of bonds that stabilize tannin-protein complexes can be obtained by varying the composition of the solution in which tannin-protein complexes are formed. For example, covalent bonds between oxidized phenolics and protein are likely to form at high pH since phenolics are more readily oxidized at high pH (Ronlan, 1978). Our observations on covalent complexes were consistent with that general trend. In the absence of reducing agent, we detected brown complexes resistant to dissolution at pH values above 4 but not at more acidic pH values.

The pH profiles we obtained for precipitation of reduced phlorotannins by proteins are similar to the profiles for precipitation of terrestrial tannins (Hagerman and Butler, 1978; Martin and Martin, 1983; Hagerman and Klucher, 1986) or phlorotannins (Tugwell and Branch, 1992) for the same proteins. Precipitation of proteins generally occurs most readily at pH values near the pI, because ionic repulsion is minimized at that pH (Mahler and Cordes, 1971). The general pattern of precipitation by phlorotannins was consistent with that trend.

High pH should favor either ionic or covalent interaction; at pH values above about 9 phenolic groups are ionized. Reduced phlorotannins were not precipitated by most proteins at high pH values. However, trypsin and lysozyme precipitate some phlorotannin at pH 10 (Figure 3, Figure 4), suggesting either ionic interactions or oxidation of the phlorotannin even in the presence of DTT. Further studies are necessary to distinguish between these two possibilities.

In the presence of the reducing agent, phlorotannin-protein interactions were inhibited by a variety of solvents (Table 2). Inhibition by hydrogen-bonding solvents such as dimethylformamide or acetone provides evidence that hydrogen bonding plays an important role in precipitation. Dimethylformamide is a more effective inhibitor because it is a stronger hydrogen bond acceptor than is acetone.

Hydrophobic forces appear to play a minor role in formation of phlorotannin-protein precipitates. The temperature independence of precipitation (Figure 1) suggests that hydrophobic forces are not important in formation of phlorotannin-protein complexes (Kennedy, 1990). Furthermore, the dependence of precipitation on pH suggests that hydrophobic forces do not stabilize these complexes, since hydrophobic interactions are generally pH-independent. Nonetheless, precipitation is inhibited by some nonpolar solvents such as dioxane, and ethanol inhibited precipitation more effectively than its more polar analogue,

methanol (Table 2). Tugwell and Branch (1992) found that gut surfactants inhibited the interaction between the *Fucus* phlorotannin and RuBPC and we found that the nonionic detergent Triton X 100 inhibited precipitation. The effects of these nonpolar solution modifiers indicates that the interaction between reduced phlorotannins and proteins involves nonpolar interactions as well as strong hydrogen bonds.

CONCLUSIONS

This is the first study to compare the reactions of phlorotannins and terrestrial tannins with proteins. The work demonstrated that oxidized tannins can form covalent complexes with proteins, and confirmed the hypothesis that redox conditions may be an important determinant of the biological activity and fate of tannins (Appel, 1993). Our study suggests that oxidative reactions are common among certain phlorotannins, but that oxidation of terrestrial tannins may be rare. It is logical to conclude that gut redox conditions should be examined in marine herbivores which consume phlorotannin-containing brown algae. For example, the redox potential of the gut might be relatively unimportant for an herbivore which consumes *Ecklonia*, but gut redox potential could be an important determinant of the fate and effects of *Carpophyllum* phlorotannin.

In addition to redox conditions, we found that pH and solution composition influenced phlorotannin-protein interactions. The phlorotannin-protein complexes which formed in a reducing environment were similar to terrestrial tannin-protein complexes that have been characterized earlier. Thus, we believe that in marine herbivores, as in terrestrial herbivores, variation in sensitivity to dietary tannins is due to variation in herbivore gut chemistry such as pH, surfactant concentrations, and presence of tannin-binding proteins (Bernays et al., 1989; McArthur et al., 1991). We have recently confirmed that concentrations of metal ions (sodium, potassium, calcium, and magnesium) significantly influence precipitation of phlorotannins by proteins (Tugwell and Branch, 1992; Mason and Hagerman unpublished data). These results suggest that marine herbivores could control the effects of tannins by controlling salt concentration in the gut. We are currently extending those studies to explore the basis for the metal ion effects.

We have demonstrated that one of the activities of phlorotannins, ability to precipitate proteins, is related to the chemical structures of the tannins. Similar structure-activity relationships have been found for terrestrial tannins. Understanding how structure influences biological activity is an essential component to understanding the effects of phlorotannins on herbivores.

Acknowledgments—Nancy M. Targett (University of Delaware, Lewes, Delaware, 1995) generously provided purified phlorotannins from *Lobophora*. We appreciated the assistance of Matt Riebel and Brice Nelson.

(Received February 5, 1996; accepted May 27, 1996)

Abstract—We examined several of the mechanisms that have been reported to enable polyphagous grasshoppers (Orthoptera: Acrididae) to tolerate ingested hydrolyzable tannins: hydrolysis, adsorption on the peritrophic envelope, and peritrophic envelope impermeability. None of these mechanisms explain the tolerance of *Melanoplus sanguinipes* to ingested tannic acid. In this species, tannin hydrolysis was 12–47% complete, adsorption accounted for less than 1% of the tannic acid contained in the midgut, and the peritrophic envelope was permeated by several gallotannins. The foregut is the main site for the chemical transformation of tannic acid in this species. In *Phoetaliotes nebrascensis*, hydrolysis was more extensive (82% complete), but the peritrophic envelope was readily permeated by two gallotannins. Oxidizing redox conditions were found in the guts of both species, and ingested tannins were oxidized in *M. sanguinipes*. We hypothesize that the tolerance of some polyphagous grasshoppers to ingested hydrolyzable tannins may be the consequence of their ability to tolerate the reactive oxygen species generated by polyphenol oxidation, whereas others may rely on rapid and extensive hydrolysis.

Key Words—Orthoptera, Acrididae, grasshopper, *Melanoplus sanguinipes*, *Phoetaliotes nebrascensis*, peritrophic envelope, peritrophic membrane, hydrolyzable tannin, tannic acid, oxidation, hydrolysis.

INTRODUCTION

Grasshoppers (Orthoptera: Acrididae) vary greatly in their sensitivity to ingested hydrolyzable tannins. Polyphagous species are remarkably tolerant, being able to survive on diets containing 20% tannic acid without inhibition of feeding, reduction in the efficiency of utilization of nutrients, formation of lesions in the midgut epithelium, or any other adverse effect commonly associated with tannin sensitivity (Bernays, 1978; Bernays and Chamberlain, 1980; Bernays et al., 1980). Graminivorous species are less tolerant of tannic acid than polyphagous species. For several graminivorous grasshoppers, tannic acid has been shown to reduce feeding and cause lesions in the midgut, which may prove lethal if the feeding period is sufficiently long (Bernays, 1978; Bernays et al., 1980; Raubenheimer, 1992). Two mechanisms have been proposed to contribute to the tolerance of polyphagous grasshoppers to tannic acid: rapid hydrolysis (Bernays, 1978; Bernays and Chamberlain, 1980) and containment within the peritrophic envelope (Bernays et al., 1980; Bernays and Chamberlain, 1980).

Since the publication of the seminal papers of Bernays and others (Bernays, 1978; Bernays and Chamberlain, 1980; Bernays et al., 1980), there have been a number of advances in our understanding of the effects of tannins on insects and of the permeability properties of the peritrophic envelope, advances suggesting that the explanation proposed for tannin tolerance in generalist grasshoppers is still not complete. For example, our recent studies of tolerance in Lepidoptera (Barbehenn and Martin, 1992, 1994), which demonstrated that the containment of tannic acid within the endoperitrophic space is not sufficient to confer tannin tolerance, requires a re-examination of the putative protective role of the peritrophic envelope in grasshoppers. In addition, the recognition that the agents responsible for the adverse effects of ingested polyphenols are often not the polyphenols themselves, but rather oxidation products, such as quinones, or by-products of oxidation, including reactive oxygen species such as hydrogen peroxide, superoxide anion radicals, and hydroxyl radicals (Appel, 1993; Ahmad, 1995; Cadenas, 1995; Felton, 1995; Summers and Felton, 1994), requires a re-examination of the chemical fate of ingested polyphenols in grasshoppers in order to determine whether or not they are oxidized.

The purpose of the present study is to re-examine the basis for tannin tolerance in polyphagous grasshoppers. We have examined several potential mechanisms in two grasshopper species in the subfamily Melanoplinae, *Melanoplus sanguinipes* and *Phoetaliotes nebrascensis*. *M. sanguinipes* is a highly polyphagous species with a diet varying from 50–78% forbs over its range in the midwestern United States (Gangwere et al., 1976; Joern, 1983). Although *P. nebrascensis* consumes more grasses and fewer forbs than *M. sanguinipes* (Joern, 1983), it has mixed-feeder mandibles (Isely, 1944) indicative of a polyphagous species. *M. sanguinipes* has a high tolerance to ingested tannins (Ber-

nays et al., 1980). We are unaware of any studies to determine the sensitivity of *P. nebrascensis* to ingested tannins. However, tannic acid is not an effective feeding deterrent for either species (Bernays et al., 1980; Mole and Joern, 1994).

In our experiments we used commercial tannic acid from oak galls so that we could compare our results with those of earlier workers. However, since the simple gallotannins comprising tannic acid differ from the more complex gallotannins found in the common host plants of polyphagous grasshoppers, we have also included in our experiments a tannin isolated from fireweed (*Epilobium angustifolium*), oenothein B. This tannin is representative of a widely occurring class of oligomeric hydrolyzable tannins that consist of core carbohydrates linked by oxidatively coupled galloyl groups (Okuda et al., 1993).

In this study, we have conducted experiments that address the following questions: (1) How extensively are hydrolyzable tannins hydrolyzed while passing through the gut? (2) In what region of the gut does most of the hydrolysis occur? (3) Do redox conditions in the gut favor polyphenol oxidation? (4) Are ingested tannins oxidized in the gut? (5) How does the fate of a complex hydrolyzable tannin (fireweed tannin) differ from the fate of the simple gallotannins found in tannic acid? (6) How much tannic acid is adsorbed by the peritrophic envelope? (7) Is the peritrophic envelope permeable to tannic acid?

METHODS AND MATERIALS

Insects and Plants. Eggs of *M. sanguinipes* were obtained from the USDA (Bozeman, MT). A colony was maintained in a screen cage (1 m × 0.5 m × 0.5 m) with a 150-W light bulb placed against the screen to provide a heat gradient (16h L:8h D). Nighttime temperature was ambient (ca. 22°C). Insects were reared from egg-hatch on romaine lettuce (*Lactuca sativa longifolia*) and wheat bran. *P. nebrascensis* were collected as third- and fourth-instar nymphs in western Nebraska. A colony was maintained on rye (*Secale cereale*) seedlings and bran under the same conditions described for *M. sanguinipes*. Adult insects were used for all experiments.

Polyphenols. Tannic acid from *Quercus infectoria* (Fagaceae) galls was purchased from Sigma Chemical Company (St. Louis, MO; lot 64F-0049). Fireweed tannin was extracted from *E. angustifolium* (Onagraceae) leaves (Zhao, 1995). Gallic acid was purchased from Sigma Chemical Co.

Polyphenol Analysis. The gallotannins present in tannic acid were identified by comparing chromatograms (normal- and reverse-phase HPLC) with chromatogams of authentic samples of galloyl glucose esters isolated from tannic acid on a Sephadex LH-20 column (Hagerman et al., 1992). Calibration curves (plotting log retention time as a function of the number of galloyl groups) were constructed using data obtained with authentic standards in either normal- or

reverse-phase HPLC. The regression equations are log retention time = (0.085 × no. galloyl groups) + 0.415 (r^2 = 0.999) for normal-phase, using the linear portion of the curve up to pentagalloyl glucose (Figure 1), and log retention time = 0.160 × no. galloyl groups) + 0.098 (r^2 = 0.998) for reverse-phase, using the linear portion of the curve between tri- and pentagalloyl glucose. Purified fireweed tannin is composed primarily of oenothein B (Okuda et al., 1993), as determined by NMR and mass spectrometry (Zhao, 1995).

Quantitative analyses of polyphenols in sample extracts were conducted with reverse-phase HPLC using a Vydac C-18 column (4.5 mm × 250 mm; 5 μ) and Supelco C-18 guard column (10 μ). The mobile phase was 23% (v/v) acetonitrile in double-distilled water containing 1% acetic acid, unless otherwise noted. The flow rate of the mobile phase was 1.0 ml/min. Sample aliquots (20–30 μl) were injected with a Shimadzu autoinjector. Peaks were detected at 280 nm (Shimadzu UV-visible detector, 0.002 AUFS) and quantified with a Shimadzu C-R4A integrator. In all cases, peak areas were corrected for the presence of interfering substances found in the control samples. Standard curves were calculated for tannic acid, fireweed tannin and gallic acid to convert peak areas to μg polyphenol.

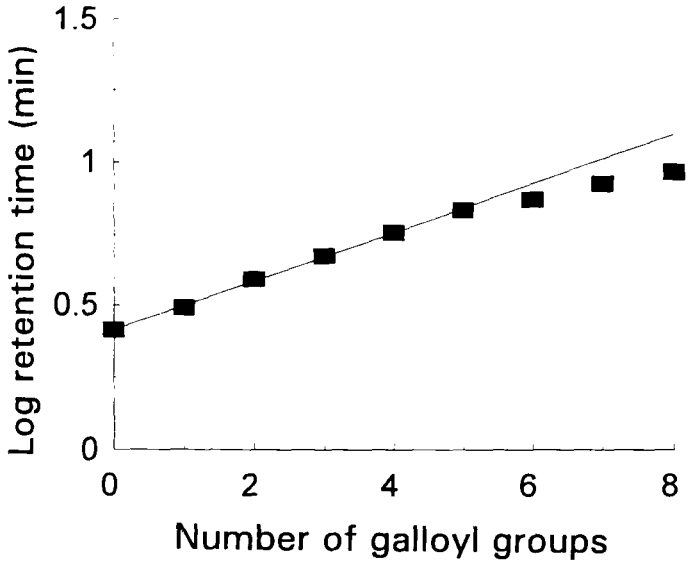

FIG. 1. Normal-phase HPLC calibration curve for gallic acid and galloyl glucose esters. The linear portion of the curve fits the regression equation log retention time = (0.085 × no. galloyl groups) + 0.415 (r^2 = 0.999).

Polyphenol Budgets. Dry-mass polyphenol budgets were determined using insects fed either artificial diet or foliage. Polyphenol-containing artificial diet was prepared by mixing the polyphenol (2.6% DW tannic acid, 2.6% DW fireweed tannin, or 2.2% gallic acid) with the dry ingredients of the Douglas fir tussock moth diet (Bioserve; Frenchtown, NJ), and hydrating as directed by the manufacturer. Polyphenol-coated lettuce (2.5% DW tannic acid or 4.6% DW gallic acid) and rye grass (4.0% DW tannic acid or 4.2% DW gallic acid) were prepared by allowing 15 μl or 13 μl of a 70% acetone solution of the polyphenol to evaporate on 22 mm diameter lettuce discs or 8 cm long rye grass leaves. Control lettuce discs and grass leaves were treated with 15 μl and 13 μl of 70% acetone, respectively.

Insects were placed individually in ventilated 470 ml plastic containers in an incubator (30°C; 16:8 light:dark) and randomly assigned to treated or control food. Initial fresh weights of food offered to each insect, and fresh weights of representative samples of each food, were measured to the nearest 0.1 mg. After feeding for one day they were fed a polyphenol-free chaser diet (foliage for insects previously fed artificial diet, and artificial diet for insects previously fed foliage). Frass was collected once approximately 24 hr after the initiation of feeding on the treated or control diets, and again after chaser diet appeared in the frass. All frass pellets were examined under a dissecting microscope, so that pellets containing egested polyphenols (i.e., pellets containing the treated diet) could be separated from pellets consisting entirely of the chaser diet. To confirm that all egested polyphenols were contained in the frass from the treated food, samples of frass from the chaser diets in three experiments were also analyzed for polyphenols. No tannic acid was found in frass from the chaser diets, but 1–4% of the total gallic acid egested was contained in this frass. Frass samples were stored at −20°C until all samples were collected, and lyophilized. Food samples for determining %DW, and uneaten food remains, were dried at 60°C (2 d). The amount of food consumed (DW) was calculated as the difference between food offered and food remaining.

Polyphenols were quantified in ground lyophilized frass and food samples. Entire samples or 5 mg aliquots were extracted three times in 1.0 ml of 70% acetone containing 0.001 M ascorbic acid at 22°C (±1°C). Extracts were centrifuged (4 min, 13,600 g), and the supernatant solutions were pooled, concentrated under a stream of nitrogen, and lyophilized. Lyophilized extracts were resolubilized in 500 μl of mobile phase (20 or 23% acetonitrile in double-distilled water containing 1% acetic acid), filtered (0.45 μ, Gelman GHP), and analyzed as described above. In most experiments using artificial diet, the gallotannins that eluted in the range of 4–8 min (Figure 2) were quantified. The gallotannins that eluted in the range of 5–13 min (Figure 2) were quantified for budgets using lettuce or rye grass. The water content of each polyphenol used was measured after drying at 60°C and subtracted from the weights of standards

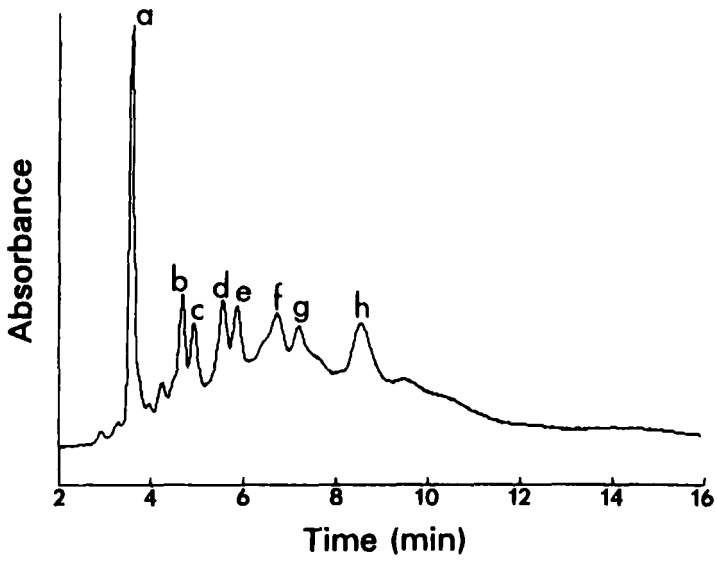

FIG. 2. Tannic acid separated on a Vydac reverse phase (C-18) column using 23% aqueous acetonitrile (with 1% acetic acid) as the mobile phase. Peak a is gallic acid, b and c are isomers of trigalloyl glucose, d and e are isomers of tetragalloyl glucose, f and g are isomers of pentagalloyl glucose, and h is hexagalloyl glucose.

and amounts of polyphenols added to food. Tannic acid is stable in the artificial diet that we used, and can be completely recovered using our extraction and HPLC methods (Barbehenn and Martin, 1992).

Tannin Hydrolysis. The extent of tannin hydrolysis was calculated from measurements of the amounts of gallic acid (GA) ingested and egested by insects used to measure tannin budgets. The extent of hydrolysis of galloyl esters in the ingested tannin was calculated from the expression 100 × (μg GA in frass derived from hydrolysis)/(theoretical μg GA yielded by complete hydrolysis of ingested tannin). The amount of gallic acid in frass derived from hydrolysis was calculated as (μg GA egested) − [(μg free GA ingested) × (% recovery in frass of ingested GA)]. The theoretical amount of gallic acid yielded by complete hydrolysis of ingested tannin was calculated from the expression (μg tannin ingested) × (μg GA produced per μg tannin hydrolyzed) × (% recovery in frass of ingested GA). The weights of gallic acid and tannin ingested were calculated from the expressions (mg food consumed) × (% GA in food) and (mg food consumed) × (% tannin in food), respectively. Tannic acid was found to yield 70% of its weight in gallic acid upon complete hydrolysis (Barbehenn and Martin, 1992). Based upon this determination, we calculated that tannic

acid would yield 69% gallic acid if the free gallic acid was removed from the tannic acid before hydrolysis. We used the calculated yield of 69% gallic acid in this study. Using the structural formula for fireweed tannin (Okuda et al., 1993), it can be calculated that this tannin would yield 22% of its weight in gallic acid upon complete hydrolysis. The percent recovery in frass of ingested gallic acid was found to be 81.5% in artificial diet and 79.8% on lettuce for *M. sanguinipes*, while 100% of ingested gallic acid was recovered in the frass of *P. nebrascensis*.

Changes in Tannic Acid and Gallic Acid Concentrations Along the Gut. *M. sanguinipes* were fed an artificial diet containing 2.6% tannic acid. Insects were dissected, as described above, and samples (2–20 mg fresh weight) of the foregut, anterior midgut, posterior midgut, and hindgut contents were quickly removed and weighed to the nearest 0.01 mg on a Cahn microbalance. Samples were immediately placed in test tubes containing 1.0 ml of 70% acetone containing 0.001 M ascorbic acid, macerated, extracted, and stored covered with parafilm at −20°C (4 d). Extracts were centrifuged, and supernatant solutions were evaporated under a stream of nitrogen and lyophilized. Lyophilized extracts were resolubilized in 500 μl of mobile phase and analyzed using HPLC as described above (30 μl aliquots). Polyphenols that eluted between 4.5–10 min (Figure 2) were quantified in standards and extracts. Concentrations of polyphenols were expressed on a dry weight basis by determining the average percent dry weight (60°C, 2d) of the gut contents in each of the regions of the gut from three insects.

The concentrations of tannic acid and gallic acid that would have been present had there been no assimilation of nutrients from the gut were calculated from the actual concentrations measured: 100 × (μg polyphenol)/[(μg sample) × (1 − assimilation efficiency)]. The assimilation efficiency (55.9% ±4.3 SE) was measured in *M. sanguinipes* using food and other conditions identical to those used in this experiment. The assumption underlying this calculation is that an assimilation efficiency of 55.9% approximates the actual assimilation efficiency throughout the midgut (Dadd, 1970; House, 1974). No correction of the polyphenol concentrations measured in the foregut was necessary since absorption from the foregut is negligible in grasshoppers (Maddrell and Gardiner, 1980).

Gut pH and Redox Conditions. Insects that had fed continuously on their rearing plants were chilled and dissected as described above. Microneedle pH (MI-408P) and silver-silver chloride reference (MI-401) microelectrodes (Microelectrodes, Londonderry, NH) were inserted through pairs of small holes cut in the gut wall. Redox potentials were measured with 0.02 in. platinum redox (MI-800) and silver-silver chloride reference (MI-401) microelectrodes using the same holes immediately following the pH measurements. Measurements in *M. sanguinipes* were made with a Metrohm/Brinkman (model 103)

millivolt and pH meter, and those in *P. nebrascensis* were made with a Corning (model 340) millivolt and pH meter. Observed redox potentials were converted to standard redox potentials (E_h) by adding 200 mV, and pe was calculated as $E_h/59.2$ (Appel and Martin, 1990). Overall redox conditions were summarized by the "redox parameter" (pH + pe), which gives equal weight to proton and electron availability in determining the thermodynamic favorability of oxidation in a complex system (Appel and Martin, 1990).

Polyphenol Oxidation. The amounts of soluble brown pigments in the food and frass of control and polyphenol-fed grasshoppers were measured as an indicator of the oxidation of ingested polyphenols (Barbehenn and Martin, 1994). Aliquots (5 mg) were extracted three times in 1.0 ml of 70% acetone containing 0.001 M ascorbic acid at 22°C (±1°C). Extracts were centrifuged (4 min, 13,600 g). The supernatant solutions were pooled, and the absorbance (420 nm) of each solution was measured with a Zeiss spectrophotometer. The net amount of brown pigment formed per mg frass was calculated by subtracting the amount of brown pigment present per mg in the food. Brown pigment formation in the frass of insects fed food with or without added polyphenols was compared with Mann-Whitney U-tests using SYSTAT (Wilkinson, 1990).

Adsorption of Tannic Acid on the Peritrophic Envelope. Tannic acid adsorption *in vivo* was assayed by feeding *M. sanguinipes* tannic acid-coated lettuce leaf discs (3.3% tannic acid). Leaf discs were coated with 15 μl of a solution of tannic acid (27 mg/ml) in 70% acetone (treatment) or 70% acetone (control). After the acetone had evaporated, two leaf discs were fed to each insect. Freshly treated leaf discs were offered after 12 hr. The insects were kept in ventilated plastic containers in an incubator at 30°C (16 hr L: 8hr D). After approximately 24 hr, chilled (−20°C, 12 min) insects were dissected, and the peritrophic envelope surrounding the food in the midgut and anterior hindgut, but not the caeca, was removed as one piece from the gut. Although the peritrophic envelope present in the caeca was not extracted, the peritrophic envelope in the main region of the midgut includes peritrophic envelope that had previously been in the caeca. The peritrophic envelope was cut longitudinally, separated from the food contents, and rinsed for 15–30 sec in three 100 μl drops of a buffer (pH 7.0) containing 5 mM Tris(hydroxymethyl)aminomethane, 45 mM Tris(hydroxymethyl)aminomethane hydrochloride, 20 mM $CaCl_2$, 3 mM NaCl, 227 mM KCl, 41 mM $MgSO_4$, 6 mM ascorbic acid, and 440 mM fructose. The peritrophic envelope was drained for 10 sec on filter paper and weighed to the nearest 0.01 mg. Polyphenols adsorbed on the peritrophic envelope were extracted twice at 22°C in 500 μl of 70% acetone containing 0.001 M ascorbic acid. Extracts were centrifuged (4 min, 13,600g) and the pooled supernatant solutions were concentrated under a stream of nitrogen after brief storage (12 h, −20°C). Lyophilized extracts were resolubilized in 250 μl of mobile phase, filtered, and 30 μl aliquots were analyzed with HPLC as described above. Fresh

weights and dry weights (60°C, 2 d) of the peritrophic envelope of six control insects were measured to the nearest 0.01 mg in order to express the amount of polyphenols adsorbed on the peritrophic envelope on a dry weight basis. The dry weight/wet weight ratio of the peritrophic envelopes was 0.19 ± 0.09. The gut contents of the dissected insects were also dried and weighed to calculate the maximum amount of tannic acid that was present in the endoperitrophic space.

To confirm that tannic acid was completely removed from the peritrophic envelopes by extraction in 70% acetone, each peritrophic envelope was hydrolyzed in 500 μl of 2 M HCl at 100°C for 20 min. Hydrolysates were neutralized with 500 μl of 2 M NaOH and lyophilized. The lyophilized hydrolysates were resolubilized in mobile phase (300 μl), filtered, and 30 μl aliquots were analyzed with HPLC, as described above. No gallic acid was observed in the chromatograms of the hydrolysates, demonstrating that tannic acid had been completely extracted from the peritrophic envelopes in 70% acetone.

Permeability of the Peritrophic Envelope to Polyphenols. M. sanguinipes that had fed on lettuce were chilled (−20°C, 9 min) and their guts were excised. The foregut and anterior midgut (including the caeca) were removed. The hindgut was ligated with a silk suture (size 6-0). Tannic acid (40 mg) was dissolved in 1.0 ml of 0.1 M phosphate buffer (pH 7.0) containing 0.01 M ascorbic acid, and the solution was purged with nitrogen to prevent oxidation before being introduced into the insect. Using a Hamilton microsyringe (10 μl) held with a micromanipulator, 2.0 μl of phosphate buffer (N = 3) or tannic acid solution (N = 10) was injected through the open (anterior) end of the midgut into the endoperitrophic space. A suture was used to clamp the anterior end of the midgut around the needle of the syringe to prevent leakage of the injected polyphenol solution. The anterior midgut was then ligated, and a small hole (0.9 ± 0.1 mm^2) was cut through the midgut wall to expose the peritrophic envelope. After rinsing the gut preparation for approximately 10 sec in each of three beakers of Tris buffer (described above), each gut preparation was placed in 1.5 ml of Tris buffer in the well of a tissue culture plate and incubated for 1.5-2 hr. Following incubation, the incubating solutions (1.5 ml) were transferred to test tubes, frozen (−20°C) and lyophilized. The contents of the midgut of each insect was extracted twice in 1.0 ml of 70% acetone (containing 0.001 M ascorbic acid) for 30 min at 22°C. Extracts were combined and centrifuged (4 min, 13,600g), and the supernatant solutions were concentrated under a stream of nitrogen. Concentrated extracts were lyophilized and stored at −20°C in a dessicator until they were analyzed with HPLC. Lyophilized samples were resolubilized in 0.5 ml (for incubating solutions) or 1.0 ml (for gut contents) of 20% acetonitrile containing 1% acetic acid, and filtered. Aliquots of samples (30 μl for incubating solutions, 20 μl for gut contents) and standards (25 μl) were analyzed with HPLC as described above. The mobile phase was 20% acetonitrile containing

1% acetic acid for incubating solutions, and 25% acetonitrile containing 1% acetic acid for gut contents.

This experiment was repeated using *P. nebrascensis*, with the following modifications: all insects were fed rye grass seedlings, distilled water (2 μl) was injected into the midguts of four insects (controls), tannic acid was injected into the midguts of six insects, gallic acid (2 μl, 40 mg/ml) was injected into the midguts of four insects, holes cut through the midgut wall averaged 2.2 ± 0.5 mm^2 and the mobile phase was 20% acetonitrile containing 1% acetic acid for all samples and standards.

Damage to the peritrophic envelopes during the dissection process was determined by observing whether a plume of dark gut fluid leaked from the exposed area. Any damage that was not detected during dissection was determined by examining the tannin permeation data for statistical outliers (Wilkinson, 1990). No outliers were observed in the data sets. Data from both experiments are presented as total μg polyphenols permeating the peritrophic envelope, since the amounts of polyphenols permeating the peritrophic envelope were not significantly correlated with either incubation time or hole diameter.

RESULTS

Composition of Tannins. Using either normal- or reverse-phase HPLC, the components of tannic acid elute in order of increasing number of galloyl esters (Figures 1 and 2; Hagerman et al., 1992). The conditions chosen for reverse-phase HPLC did not resolve the components of the tannic acid completely, but allowed for the higher molecular weight components to be measured (e.g., peak h; Figure 2). Isomers of several polygalloyl glucose esters were resolved as split peaks (Figure 2). Tannic acid from *Q. infectoria* (Sigma) contained an average of 10.2% trigalloyl glucose (peaks b and c), 21.1% tetragalloyl glucose (peaks d and e), 24.6% pentagalloyl glucose (peaks f and g), and 20.2% hexagalloyl glucose (peak h). The tannic acid used in this study also contained an average of 4.4% gallic acid (peak a). Mono- and digalloyl glucose and galloyl glucose esters larger than hexagalloyl glucose, which collectively account for the remaining 19.5% of the tannic acid, could not be quantified accurately with reverse-phase HPLC. Fireweed tannin contained oenothein B (>80%), gallic acid (<1%), and some lower molecular weight compounds that were not identified.

Tannin Budgets. Only a small fraction of the tannins ingested by either *M. sanguinipes* (5–25%) or *P. nebrascensis* (22%) could be recovered from their frass (Table 1). The tannins that were recovered from the frass of *P. nebrascensis* consisted primarily of tetragalloyl glucose, whereas low concentrations of several gallotannins were present in the frass of *M. sanguinipes*, but these were poorly resolved using HPLC.

Tannin Hydrolysis. In *M. sanguinipes* 12.1-46.9%, and in *P. nebrascensis* 82.0%, of the galloyl ester groups of the ingested tannins were hydrolyzed (Table 2). In *M. sanguinipes* tannic acid was more extensively hydrolyzed when ingested in an artificial diet than when ingested on lettuce leaves, and tannic acid was more susceptible to hydrolysis than fireweed tannin.

Changes in Tannic Acid and Gallic Acid Concentrations Along the Gut. The tannic acid content of the foregut was substantially less than that of the diet, identifying the foregut as a major site of transformation of tannic acid (Figure 3). In contrast, the gallic acid content of the foregut was 3.6 times higher than in the food, demonstrating that hydrolysis accounts for the loss of some tannic acid in the foregut. However, we calculate that hydrolysis can

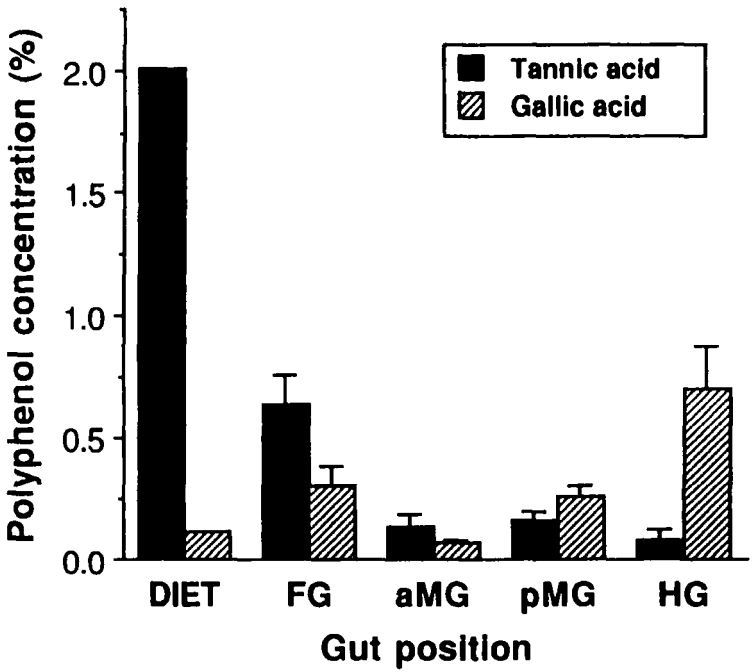

FIG. 3. Change in the percentage (DW) of tannic acid and gallic acid in artificial diet passing through the guts of *Melanoplus sanguinipes*. Gallic acid in the diet is an impurity in tannic acid. The percentage of polyphenols in the absorptive regions of the gut (midgut and hindgut) were transformed to the percentage of polyphenols in an equivalent mass of food, using the expression: (μg polyphenol)/[(μg sample/(1 − 0.559)], where 0.559 is the average approximate digestibility of the food. FG = foregut, aMG = anterior midgut, pMG = posterior midgut, and HG = hindgut.

TABLE 1. DRY MASS BUDGETS FOR TANNIC ACID (TA) AND FIREWEED TANNIN (FWT) INGESTED BY *Melanoplus sanguinipes* AND *Phoetaliotes nebrascensis*[a]

Diet (N)	Tannin ingested	Tannin egested	Percent tannin recovered
Melanoplus sanguinipes			
TA in artificial diet[b] (12)	666.3 ± 74.9	153.1 ± 23.6	22.5 ± 2.4
TA in artificial diet[c] (9)	34.4 ± 4.7	7.4 ± 0.7	24.7 ± 3.6
FWT in artificial diet (11)	1402.7 ± 91.2	166.4 ± 21.7	12.3 ± 1.6
TA on lettuce leaves[d] (12)	398.5 ± 25.1	21.6 ± 4.2	5.3 ± 1.0
TA on lettuce leaves[d] (10)	478.9 ± 49.4	22.7 ± 7.4	5.4 ± 1.6
Phoetaliotes nebrascensis			
TA on rye leaves[d] (9)	420.8 ± 8.7	94.3 ± 21.4	22.5 ± 5.2

[a] Data expressed as mean μg/insect ± SE.
[b] TA components eluting between 4–8 min (Figure 2) from a Vydac C-18 column were quantified.
[c] TA ingested was estimated from the weight of frass produced and an average approximate digestibility of 55.9%. TA egested was measured in frass pellets dissected from the hindgut. TA components eluting between 4.5–10 min (Figure 2) from a Vydac C-18 column were quantified.
[d] TA components eluting between 5–13 min (Figure 2) from a Vydac C-18 column were quantified.

TABLE 2. HYDROLYSIS OF TANNIC ACID (TA) AND FIREWEED TANNIN (FWT) DURING PASSAGE THROUGH THE GUTS OF *Melanoplus sanguinipes* AND *Phoetaliotes nebrascensis*[a]

Diet (N)	Total tannin ingested	Net GA egested[b]	Percent galloyl esters hydrolyzed[c]
Melanoplus sanguinipes			
TA in artificial diet (9)	40.1 ± 5.4[d]	8.3 ± 2.0	46.9 ± 12.3
FWT in artificial diet (11)	1402.7 ± 91.2[e]	52.7 ± 5.3	19.7 ± 1.6
TA on lettuce leaves (12)	526.8 ± 33.2[e]	34.6 ± 19.3	12.1 ± 6.6
TA on lettuce leaves (10)	694.3 ± 66.5[e]	32.1 ± 17.8	13.0 ± 7.6
Phoetaliotes nebrascensis			
TA on rye leaves (9)	438.3 ± 8.7[f]	250.3 ± 28.7	82.0 ± 8.2

[a] Data expressed as mean μg/insect ± SE.
[b] Calculated from the expression (μg GA egested) − [(μg GA ingested) × (%recovery of ingested GA)].
[c] Calculated from the expression (net μg GA produced)/[(μg tannin ingested) × (μg GA produced per μg tannin hydrolyzed) × (%recovery of ingested GA)]. TA yields 69% GA and FWT yields 22% GA upon hydrolysis. The percent recovery of GA ingested in artificial diet by *M. sanguinipes* was 81.5, and 79.8 when fed on lettuce. In *P. nebrascensis* all GA was recovered.
[d] TA ingested was calculated from the weight of frass produced and an average approximate digestibility of 55.9%.
[e] Tannin ingested was calculated from the %DW of tannin added to the food and the amount of food consumed.

account for no more than 45% (±7.6 SE) of the tannic acid lost from the diet in the foregut. There was a further drop in the concentration of tannic acid in the anterior midgut, identifying this region as an additional site of transformation of tannic acid. The correct concentration of tannic acid and gallic acid in the anterior midgut depends upon the extent of nutrient assimilation in this region, and may be less if an assimilation efficiency of 55.9%, which we used to correct the food mass, is excessive. By contrast, if no nutrient assimilation had occurred in the anterior midgut, then the percent tannic acid and gallic acid in the anterior midgut would have been 0.88 ± 0.15% and 0.33 ± 0.04%, respectively. The large increase in the concentration of gallic acid in the hindgut was presumably due to the excretion of assimilated gallic acid by the Malpighian tubules.

Gut pH and Redox Conditions. The pH throughout the guts of *M. sanguinipes* and *P. nebrascensis* is mildly acidic to neutral (Table 3). The redox conditions measured throughout the guts of both species are oxidizing (positive Eh, pH + pe > 9) (Table 3).

Polyphenol Oxidation. Polyphenol oxidation generates brown pigments (Hathway and Seakins, 1957; Thomson, 1962; Leatham et al., 1980; Igarashi and Yasui, 1985; Cilliers and Singleton, 1989). There was a significant increase ($P < 0.01$) in the amounts of brown pigments in the frass of insects that consumed tannic acid or fireweed tannin in an artificial diet (Table 4). There was no significant increase in brown pigment formation in *M. sanguinipes* that ingested gallic acid in artificial diet, consistent with the high recovery of ingested gallic acid in the frass (81.6%). Because of the high background absorbance in plant extracts, this method could not be used as an indicator of polyphenol oxidation in insects fed treated foliage.

Adsorption of Tannic Acid on the Peritrophic Envelope. When *M. sanguinipes* was fed tannic acid-coated lettuce, less than 1% of the total tannic acid

present in its midgut was adsorbed on the peritrophic envelope (Table 5). The tannic acid that was adsorbed on the peritrophic envelope of *M. sanguinipes* consisted of roughly equal amounts of tetragalloyl and hexagalloyl glucose.

Permeability of the Peritrophic Envelope to Polyphenols. Several gallotannins were found to permeate the peritrophic envelope of *M. sanguinipes* (Table 6). For example, the peritrophic envelope was permeated by 10.8% of the tetragalloyl glucose present in the tannic acid that was injected into the midgut, or 15.0% of that which was still detectable in the midgut and incubating solution at the end of the incubation period. In *P. nebrascensis*, the peritrophic envelope was permeated by 19.8% of the tetragalloyl glucose that was initially injected into the midgut, or 26.9% of that which was still detectable in the midgut and incubating solution at the end of the incubation period. The peritrophic envelopes of both species were freely permeable to gallic acid (Table 6). When pure gallic acid (80 μg) was introduced into the midgut of *P. nebrascensis*, an average of 28.7 μg (35.9 ± 5.0%) diffused through the peritrophic envelope.

DISCUSSION

Most of the tannin ingested by *M. sanguinipes* (75–95%) and *P. nebrascensis* (78%) is removed during passage through the gut. In *M. sanguinipes*,

[a]Tannic acid was introduced into the midguts of insects by injecting 2 μl of a 4% solution of tannic acid in pH 7 phosphate buffer. Gut preparations were incubated for 1.5–2 hr. Data are presented as mean ± SE.

the primary sites of tannin removal are the foregut and the anterior midgut. We can envision *a priori* three processes that would result in the removal of tannins from an insect's gut: hydrolysis, adsorption on the peritrophic envelope, and oxidation. The first two are potential detoxification mechanisms. By contrast, the third is a process that potentially contributes to tannin toxicity.

In agreement with earlier studies (Bernays, 1978; Bernays and Chamberlain, 1980), we found that gallotannins are hydrolyzed in the guts of polyphagous grasshoppers. The extent of hydrolysis was much less in *M. sanguinipes* than in *P. nebrascensis*, and varied widely depending upon the type of tannin and nature of the diet in which it was ingested. The limited extent of tannin hydrolysis in *M. sanguinipes* argues strongly against the idea that this transformation plays a significant role in the detoxification of tannins in this species. For hydrolysis to result in detoxification, it must be extensive and it must result in the formation of nontoxic products. Partial hydrolysis, in which one gallotannin is converted into another with fewer galloyl groups, will be an effective detoxification mechanism only if the lower molecular weight gallotannin is significantly less toxic than the higher molecular weight analogue. The failure of partial hydrolysis to protect an insect from tannins is illustrated by the tannin-sensitivity of *Locusta migratoria*, a grasshopper in which 43% of the galloyl groups of ingested tannic acid are hydrolyzed (Bernays, 1978). We conclude, therefore, that hydrolysis is not a general mechanism that is sufficient to explain the widespread tolerance among polyphagous grasshoppers of hydrolyzable tannins.

Adsorption on the peritrophic envelope is a second mechanism by which tannins might be removed from the gut milieu, thereby protecting grasshoppers from the potential toxic effects of ingested tannins (Bernays and Chamberlain, 1980). We have not confirmed the earlier report that significant quantities of tannic acid are adsorbed by the peritrophic envelopes of polyphagous grasshoppers. Whereas Bernays and Chamberlain (1980) reported that the peritrophic envelope of *Schistocerca gregaria* adsorbed 100% of its weight in tannic acid *in vivo*, we found that the peritrophic envelope of *M. sanguinipes* adsorbed less than 1% of its weight in tannic acid. The different results obtained in the two studies may reflect the selection of different species or the use of different analytical methods. In the earlier study, adsorbed tannic acid was estimated by measuring the A_{270} of the HCl-hydrolyzate of the peritrophic envelopes of insects fed tannic acid-treated foliage. However, it was not established whether the A_{270} was due to gallic acid or to other compounds solubilized during hydrolysis. The method used in the present study (HPLC) entailed both the identification and quantification of specific gallotannins adsorbed by the peritrophic envelope. Whether the different results are due to our use of different species or different techniques, the conclusion is the same: the removal of tannic acid from the gut lumen by adsorption on the peritrophic envelope is not a general mechanism explaining the widespread tolerance among polyphagous grasshoppers of hydrolyzable tannins.

In further contrast to the earlier report that the peritrophic envelopes of tannin-tolerant grasshoppers are impermeable to tannic acid (Bernays et al., 1980), we have found that some of the gallotannins in tannic acid readily move across the peritrophic envelopes of *M. sanguinipes* and *P. nebrascensis*. In previous studies, the impermeability of the peritrophic envelope to tannins was inferred from the absence of lesions in histological sections (Bernays et al., 1980; Steinly and Berenbaum, 1985). Alternatively, the permeability of the peritrophic envelope to tannins was inferred from the presence of midgut lesions, or from the accumulation of polyphenols in damaged midgut tissues. The validity of this indirect approach is questionable; it is possible that tannins could cross the peritrophic envelope but not damage, or accumulate in, midgut tissues. In this study, we evaluated the permeability of the peritrophic envelope to tannins by direct measurement of the amounts of specific gallotannins that diffused from the endo- to the ectoperitrophic space. From our observation that the peritrophic envelopes of *M. sanguinipes* and *P. nebrascensis* are permeable to some gallotannins, we conclude that the tannin-tolerance of generalist grasshoppers does not result simply from the containment of tannic acid within the endoperitrophic space.

In our studies of *Malacosoma disstria* and *Orgyia leucostigma* (Lepidoptera), we found that tannic acid was oxidized in the midgut of *M. disstria*, a tannin-sensitive species, but not in the midgut of *O. leucostigma*, a tannin-

tolerant species (Barbehenn and Martin, 1992, 1994). These findings lead us to expect that tannin-tolerance in polyphagous grasshoppers would be associated with a lack of oxidation of tannic acid in their guts. However, conditions in the guts of both species favor oxidation. Oxidizing redox conditions have also been found in the guts of *Locusta migratoria* (Bignell, 1984) and *Ageneotettix deorum* (Barbehenn, unpublished data), suggesting that oxidizing conditions are a common feature of the grasshopper gut. Further evidence that tannins are oxidized in the guts of *M. sanguinipes* is provided by the observation of elevated levels of brown pigments in the frass of insects feeding on tannin-containing diets. These measurements cannot be used to calculate the actual amount of polyphenol oxidized, since the relationship between the amount of absorption at 420 nm and the amount of polyphenol oxidized has not been determined. However, if oxidation accounts for the difference between the amount of tannin ingested and the amount that can be recovered from the frass plus the amount determined to have been hydrolyzed, then the percent oxidized was substantial in *M. sanguinipes*: 28% in artificial diet and 83% on foliage. Thus, the ability of some polyphagous grasshoppers to tolerate ingested tannins results from their protection from the consequences of polyphenol oxidation, not from the absence of oxidation.

Antioxidant systems are well known in insects (Ahmad, 1995; Felton, 1995; Felton and Summers, 1995). Gut tissues may be protected from reactive oxygen species by enzymes, such as catalase and glutathione transferase peroxidase, and antioxidants, such as ascorbic acid. The polysaccharides and proteoglycans of the peritrophic envelope may also trap oxygen radicals generated in the midgut lumen (Felton and Summers, 1995). Felton and Summers (1995) showed that oxidative damage to midgut tissues was reduced *in vitro* in proportion to the mass of peritrophic envelope present. Thus, the hypothesis that the peritrophic envelope plays a critical role in protecting polyphagous grasshoppers from tannins remains a viable one, although the role may be to scavenge oxygen radicals, rather than to contain tannins within the endoperitrophic space. This possibility seems especially plausible considering the finding of Bernays and Simpson (1989) that the peritrophic envelopes of tannin-tolerant grasshoppers are thicker, and potentially capable of scavenging more oxygen radicals, than those of tannin-sensitive species.

Finally, we propose that the structural organization of digestion in grasshoppers may contribute to the ability of some species to tolerate ingested tannins. The foregut is not only a region in which a substantial amount of digestion occurs (Robinson, 1964; Price and Robinson, 1966; Evans and Payne, 1964; Droste and Zebe, 1974), but it is also the most active region for the hydrolysis, and probably the oxidation, of ingested tannic acid in *M. sanguinipes*. Grasshopper foreguts contain copious quantities of dark gut fluid ("tobacco juice"). The dark color of this fluid is consistent with the occurrence of polyphenol

oxidation in the foregut. In *M. sanguinipes*, most of the oxidation of tannic acid appears to take place in the foregut, since hydrolysis can account for only 45% of the tannic acid lost before ingested food reaches the anterior midgut. Because the foregut is lined with impermeable cuticle (Maddrell and Gardiner, 1980; Chapman, 1982), polyphenol oxidation in this region would not pose a threat to sensitive gut tissues, as it would in the midgut. Thus, the grasshopper foregut may function as an oxidation-resistant reaction vessel, in which the oxidation of ingested tannins occurs prior to their passage into the more sensitive midgut.

Acknowledgments—We are grateful to Dr. Anthony Joern for supplying us with *P. nebrascensis*, and Dr. Douglas Street for *M. sanguinipes*. We thank Dr. Elizabeth A. Bernays for commenting on the manuscript, and Kuenok Lee and Judith Scofield for providing valuable laboratory assistance. This work was funded by NSF grant no. IBN 9407128 to M.M.M. and R.V.B.

(Received February 28, 1996; accepted May 16, 1996)

Abstract—The Monarch butterfly (*Danaus plexippus*) sequesters cardiac glycosides (CG) for its chemical defense against predators. Larvae and adults of this butterfly are insensitive towards dietary cardiac glycosides, whereas other Lepidoptera are sensitive and intoxicated by ouabain. Ouabain inhibits Na^+,K^+-ATPase by binding to its α-subunit. We have amplified and cloned the DNA-sequence encoding the respective ouabain binding site. Instead of the amino acid asparagine at position 122 in ouabain-sensitive insects, the Monarch has a histidine in the putative ouabain binding site, which consists of 12 amino acids. Starting with the CG-sensitive Na^+,K^+-ATPase gene from *Drosophila*, we converted pos. 122 to a histidine residue as in *Danaus plexippus* by site-directed mutagenesis. Human embryonic kidney cells (HEK) (which are sensitive to ouabain) were transfected with the mutated Na^+,K^+-ATPase gene in a pSVDF-expression vector and showed a transient expression of the mutated *Drosophila* Na^+,K^+-ATPase. When treated with ouabain, the transfected cells tolerated ouabain at a concentration of 50 mM, whereas untransformed controls or controls transfected with the unmutated *Drosophila* gene, showed a substantial mortality. This result implies that the asparagine to histidine exchange contributes to ouabain insensitivity in the Monarch. In two other CG-sequestering insects, e.g., *Danaus gilippus* and *Syntomeida epilais*, the pattern of amino acid substitution differed, indicating that the Monarch has acquired this mutation independently during evolution.

Key Words—*Danaus plexippus*, *Danaus gilippus*, *Syntomeida epilais*, *Syntomis mogadorensis*, cardiac glycosides, Na^+,K^+-ATPase, target site modi-

INTRODUCTION

Cardiac glycosides (CGs) are produced in many unrelated plant families, such as the Scrophulariaceae, Apocynaceae, Asclepiadaceae, Ranunculaceae, Brassicaceae, Liliaceae, Celastraceae, and few others. Even a few animals, such as toads and beetles, can produce their own CGs (Harborne, 1993; Teuscher and Lindequist, 1987).

The molecular target of CGs is the Na^+,K^+-ATPase. CGs inhibit this ion pump and thus destroy the ion gradients that are necessary for many cellular functions, including neuronal activity, secondary active transport systems and muscle contraction. These activities would explain the general toxicity of CGs in animals and their use as arrow poisons in many parts of Africa (Neuwinger, 1994). CGs are widely employed therapeutic agents; in the heart muscle the partial inhibition of Na^+,K^+-ATPase results in higher Na^+ concentration in muscle cells, which in turn activates a Na^+/Ca^{++} channel. Elevated Ca^{++} levels directly influence muscle contraction by activation of the tropomyosin/myosin/actin system.

A number of insects, especially moths and butterflies, sequester the defence compounds of their host plants and use them for their own protection against predators (reviews in Bernays and Chapman, 1994; Brown and Trigo, 1995; Harborne, 1993; Rosenthal and Berenbaum, 1991; 1992; Wink, 1993). The pioneering works of M. Rothschild, T. Reichstein, L. Brower, and coworkers, have established cardiac glycosides (CGs) as one of the best studied groups of secondary metabolites which are widely used as acquired defense compounds in insects (for review see: Brower, 1984; Brown and Trigo, 1995; Harborne, 1993; Rosenthal and Berenbaum, 1991; Rothschild, 1972b; Rothschild et al., 1972; Duffey and Scudder, 1972).

These specialized insects, which are often aposematically colored, are able to take up and store plant-derived CGs. Examples include grasshoppers (e.g., *Poekilocerus*, *Phytmaeteus*; Euw et al, 1967; Harborne, 1993; Rothschild, 1966; Rothschild, 1972b), aphids (e.g., *Aphis nerium*; Malcolm, 1990; Rothschild et al., 1970), lygaeid bugs (e.g., *Oncopeltus*, *Caenocoris*, *Spilostethus*, *Lygaeus*, *Apterola*, *Arocatus*, *Aspilocoryphus*, *Aulacopeltus*, *Graptostethus*, *Haemobaphus*, *Lygaeospilus*, *Melanerythrus*, *Microspilus*, *Horvathiolus*; Euw et al., 1971; Malcolm, 1990; Rothschild, 1972b; Rothschild et al., 1971; Scudder et al., 1986), beetles (*Tetraopes*, *Epicauta*; Rothschild, 1972b). Diptera (*Zenilla*; Rothschild, 1972b) and Lepidoptera (e.g., *Danaus*, *Syntomeida*, *Euchaetias*, *Arctia*, *Empyreuma*; Harborne, 1993; Nickisch-Rosenegk et al., 1990; Roth-

schild, 1972a,b; Rothschild et al., 1973). Insects sequestering CGs are usually protected against predators such as birds (Brower, 1984; Brower and Fink, 1985; Brower and Van Zandt Brower, 1964; Brower et al., 1968, 1975, 1982; Cohen, 1985; Rothschild, 1966; 1972a; Reichstein et al., 1968; Seiber et al., 1980, 1986; Ritland, 1991), although specialists can overcome the defense barrier (Fink and Brower, 1981; Glendinning, 1992).

Among organisms that sequester CGs, the Monarch is probably the best-studied taxon. Larvae of *Danaus plexippus* L. feed on milkweed plants of the genus *Asclepias*. Sequestration and storage of cardiac glycosides by monarchs is a selective process in both quantitative and qualitative terms (Brower et al., 1982; Lynch and Martin, 1987; Martin and Lynch, 1988; Malcolm, 1990; Malcolm and Brower, 1989; Reichstein et al., 1968; Roeske et al., 1976; Seiber et al.; 1980, 1986). Monarchs appear to regulate their overall content of cardiac glycosides in such a way that an appropriate cardenolide capacity necessary for chemical defense is achieved, although a substantial part of the monarch population has a low cardenolide content (Brower et al., 1972; Brower and Mofitt, 1974; Ritland, 1991). Out of the complex pattern of cardenolides that are present in food plants, the butterflies selectively store polar cardenolides but not the more lipophilic apolar glycosides (Brower, 1984; Brower et al., 1988; Groeneveld et al., 1990; Malcolm et al., 1989). Since many CGs are polar compounds, they cannot pass biomembranes by simple diffusion. A carrier-mediated uptake system which could explain the observed selectivity has been proposed for CG uptake in *D. plexippus* (Frick and Wink, 1995) and also in other CG-insects such as *Syntomeida epilais* (Nickisch-Rosenegk et al., 1990), and *Oncopeltus fasciatus* (Detzel and Wink, 1995). Cardiac glycosides are apparently not stored in all tissues of the monarch, but preferentially in the exoskeleton of the butterfly, i.e., the wings, the cuticle and in the fat body (Brower and Glazier, 1975; Brower et al., 1988; Frick and Wink, 1995; Seiber et al., 1986). This peripheral storage seems to provide a chemical defense barrier against non-adapted enemies, but some predators (birds and mice) can learn to avoid the cardenolide-rich tissues (Brower et al., 1988; Fink and Brower, 1981; Glendinning, 1990). For example, feeding experiments in three mouse species (*Peroscomys melanotis*, *P. aztecus*, and *Reithrodontomys sumichrasti*) with intact monarch butterflies of differing CG content showed that CG-rich cuticular material (wings, integuments) was clearly rejected, whereas CG-free butterflies and tissues of low CG content were preferred (Glendinning, 1990). Mice picked up CG-rich butterflies in their mouth, but immediately dropped them. No signs of biting and chewing were observed, but it appeared that they tasted the cuticle.

It was shown experimentally (C. Frick and M. Wink, unpublished), that *D. plexippus* larvae can tolerate CG doses exceeding 1200 mg/kg body weight (which would kill almost any other animal). Therefore, as a prerequisite for CG utilization, *Danaus* must have evolved either insensitivity in its Na^+,K^+-ATPase

and/or detoxification mechanisms (such as storage in the integument). Indeed, its Na^+,K^+-ATPase cannot be inhibited by CGs (Holzinger et al. 1992; Vaughan and Jungreis, 1977). How can we understand the insensitivity of Na^+,K^+-ATPase at the molecular level? The Na^+,K^+-ATPase consists of two subunits, a catalytic and ouabain-binding α-subunit with 1016 amino acids and a β-subunit with 302 amino acids (Lingrel et al., 1990; Shull et al., 1985). The α-subunit shows eight transmembrane domains and the main ouabain binding site is probably positioned in the extracellular loop between the transmembrane domain H1 and H2 (amino acid position 111–122; Figure 1a) (Lingrel et al., 1990). This putative ouabain binding site covers 36 nucleotides. In rats, a ouabain insensitive enzyme has been reported in which the substitution of arginine for glutamine at position 111 and aspartic acid for asparagine at position 122 is responsible for CG insensitivity, as compared to sensitive Na^+, K^+-ATPases from man or sheep (Lingrel et al., 1990). Recently, evidence was also presented that the first transmembrane segment of Na^+,K^+-ATPase confers ouabain resistance to MDCK canine cells (Canessa et al., 1992) and digoxin/digitoxin insensitivity (Askew and Lingrel, 1994).

A few years ago we started to analyze the apparent CG-insensitivity of CG-sequestering insects at the molecular level. Using the sequence information available (Lingrel et al., 1990; Shull et al., 1985), oligonucleotide primers were constructed to amplify the H1–H2-loop of Na^+,K^+-ATPase from sensitive and nonsensitive insects by PCR (Table 1). Nucleotide sequences obtained from the lepidopterans *Danaus plexippus*, *Manduca sexta*, and *Creatonotos transiens* showed a high homology to those of the α-subunits from other organisms, especially to that from *Drosophila* (Tables 1, 2). Introns of different lengths were found between the amino acid positions 109 and 110, just adjacent to the ouabain binding site (Holzinger et al., 1992).

Comparing the nucleotide sequences and the derived amino acid sequences of the ouabain binding site (Table 2), 9 of the 12 amino acids of the insects studied were identical. Whereas, substitutions at positions 115 and 119 are probably not significant, position 122 appears to be critical (Lingrel et al., 1990): A histidine is present in *D. plexippus* (Figure 1b) whereas ouabain-sensitive insects and vertebrates carry an asparagine instead. Since histidine changes the receptor properties to a high degree, we assume that this target site modification in Monarchs may lead to a ouabain insensitive Na^+,K^+-ATPase.

In this communication, we provide direct evidence that the amino acid substitution in the putative ouabain binding site (Holzinger et al., 1992), is indeed a critical mutation contributing to cardiac glycoside insensitivity in the Monarch. In addition, we have analyzed whether other insects which store cardiac glycosides, such as *Danaus gilippus* (Ritland, 1991) or *Syntomeida epilais* (Nickisch-Rosenegk et al., 1990; Rothschild et al., 1973), exhibit a similar adaptation.

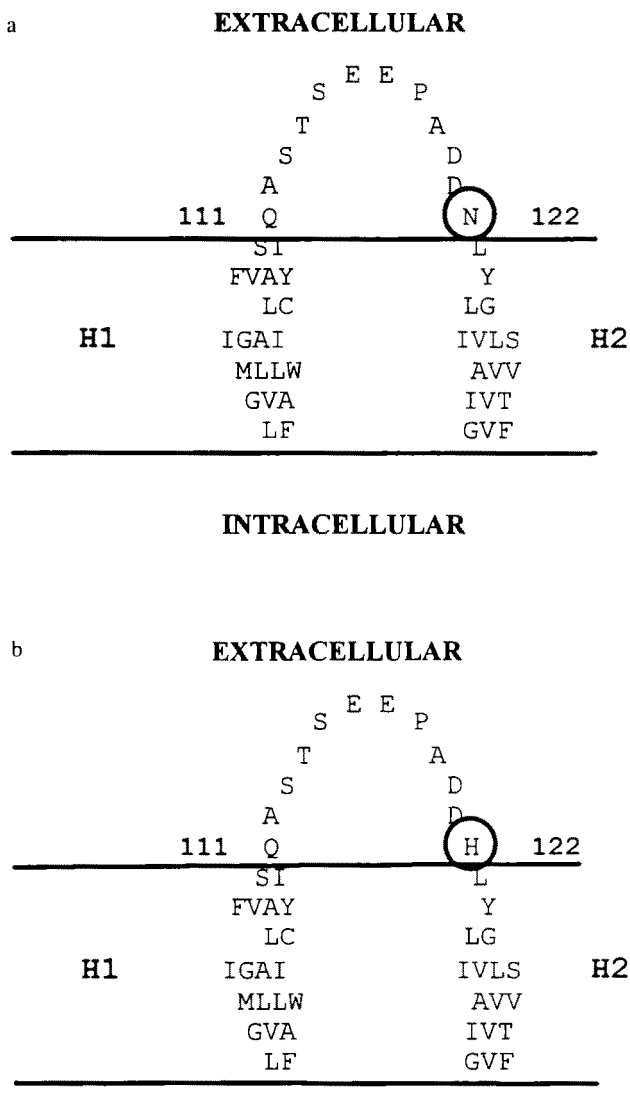

FIG. 1. H1-H2 region of *Drosophila* Na^+,K^+-ATPase α subunit. a. The circled amino acid was target of a point mutation; b. Asparagine was exchanged to histidine (circle) by site-directed mutagenesis, resulting in an extracellular loop similar to that of the Monarch.

MATERIAL AND METHODS

Animals

Eggs of *D. plexippus* came from a laboratory colony kept at the Boyce Thompson Institute for Plant Research at Ithaca (USA). In Germany larvae were reared on *Asclepias syriaca* and a few generations of Monarchs were grown in a greenhouse in the summers of 1991 to 1993. *D. gilippus* were obtained as adults; *S. mogadorensis* was reared on *Taraxacum* and *S. epilais* on *Nerium oleander*. The latter three species were provided by D. Schneider.

Molecular Characterisation of the Putative Ouabain Binding Site

DNA was isolated from adult animals of *D. plexippus*, *D. gilippus*, *Syntomis mogadorensis*, and *Syntomeida epilais* using the CTAB-method (Doyle and Doyle, 1990). About 1.5 μg of DNA was amplified by Taq-polymerase and the oligonucleotide primers A: 5′ CTG TGG ATC(T) GGT(A) GCT(GC) ATT CT 3′ and B: 5′ACC ATG TTC(T) TTG AAC(G) GAT TCC ATG ATC TT 3′. The PCR reaction was carried out in 50 μl reaction volume. This contained 1 μg genomic DNA, one unit of Taq DNA polymerase, 50 mM KCl, 10 mM Tris-HCl (pH 9.0), 1.5 mM $MgCl_2$, 0.01% gelatin (w/v), 0.1% Triton X-100, 50 μM dNTPs, and 10 pmoles of each primer. The solution was overlayed with 50 μl mineral oil. PCR temperature program was 4 min at 94°C, 30 cycles (1 min 95°C, 1 min 55°C, 1 min 72°C), finally, 5 min at 72°C. Non-incorporated nucleotides and primers were digested by phosphatase and exonuclease and PCR products were sequenced using the USB direct sequencing kit (USB, Braunschweig). Autoradiograms were evaluated manually.

Site-Directed Mutagenesis of the Na^+,K^+-ATPase Gene

For the conversion of ouabain binding site of the *Drosophila* gene to the corresponding one of *D. plexippus*, only a single base substitution in the codon encoding amino acid 122 is necessary. For creating this point mutation we used the PCR-based overlap extension strategy (Higuchi et al., 1988). The plasmid pSVDF (Takeyasu et al., 1988) containing the *Drosophila* Na^+,K^+-ATPase α subunit gene (obtained from D. M. Fambrough) was used as PCR template. Plasmid DNA was prepared by column chromatography (Qiagen). Both steps of the PCR reaction were carried out in 50 μl reaction volumes as described above. During the first step, 50 ng template DNA and the following primer pairs were used (modification underlined): Primer C 5′ CTCGCCCTCGCGGATGACGGT 3′ and D 5′ GCCGGCCGACGA-TCATTTGTATCTGGG 3′ in one tube, primer E 5′ GTTTTCCCAGTCAC-GACGTTGTA and F 5′ ACAAATGATCGTCGGCCGGCTCC 3′ in another

tube produced fragments of 156 and 562 bp length. After purification by agarose gel electrophoresis these products were used in equimolar amounts in the second step, by adding ten pmoles of primers C and E, which hybridize to the flanking sequences of the annealed products. The resulting cassette was purified, cut with Kpn I and ligated in pUC21 (Boehringer). Most of the derived clones contained the desired modification without further changes. The modified Kpn I fragment containing the sequence for the ouabain binding site was cut out of pUC21, separated by agarose gel electrophoresis, and ligated into the expression vector pSVDF construct.

Maintenance and Transfection of HEK-Cells

Human embryonic kidney cells (Eaton et al., 1986) were obtained from P. Seeburg (ZMBH, Heidelberg), and maintained in MEM with Earle's Salts (GIBCO), 10% FCS (Flow Laboratories), 1% (200 mM) L-glutamine, (Boehringer) and 1% penicilline-streptomycine (Flow Laboratories). Cells of half-confluent plates (10 cm, Costar) were transfected by using a modified $CaPO_4$ precipitation technique (Chen and Okayama, 1987). Fourty-eight hours after transfection, cells were washed with phosphate-buffered saline and scraped into a denaturing solution and further processed for RNA isolation. Expression of Na^+,K^+-ATPase in HEK cells was compared by dotblot analysis of RNA, following the procedure described by the manufacturer (Pall Biodyne B membrane).

RESULTS AND DISCUSSION

Transfection of HEK Cells with a Mutated Drosophila Na^+,K^+-ATPase Gene

As shown in Table 2, the amino acid sequence of the putative ouabain binding site of the *Drosophila* Na^+,K^+-ATPase is very similar to those of other CG-sensitive organisms. Using a site-directed mutation approach via specific PCR primer we have substituted the asparagine residue in position 122 with a histidine as in *D. plexippus* (Figures 1B and 2). The successful and correct mutation was corroborated by direct sequencing.

The gene was then ligated with the expression vector pSVDF (confirming the correct reading frame by sequence analysis), which is suitable for the transient expression of genes in animal cells (line HEK 293). As can be seen from a Northern hybridization (Figure 3) of RNA extracted from transfected and untransfected cells, which were hybridized with the *Drosophila* Na^+,K^+-ATPase gene, a transient expression of the construct takes place 24–72 hr (with a maximum after 48 hr) after transfection. The transfected cells were left for 24 hr before starting the ouabain experiments.

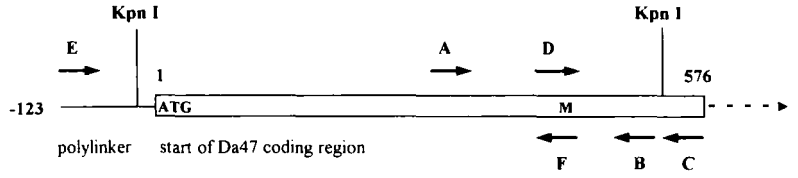

FIG. 2. Location and direction of the primers. The construct encloses a part of the polylinker and the start region (576 bp) of *Drosophila* Na^+,K^+-ATPase of the Da47 clone. Kpn I sites are at position −39 and 544 relative to the start codon. Primers A and B were used to amplify the ouabain binding site; primer pairs C/D and E/F were employed for site directed mutagenesis; the point mutation (M) is located at position 433. To obtain the "mut construct" the mutated fragment is cleaved at the Kpn I sites (size 583 bp) and ligated to the rest of the unmutated *Drosophila* gene which was also cleaved by Kpn I.

Human embryonic kidney cells (HEK cells) are sensitive towards ouabain. When it is added to the growth medium at 50 nM, cells do not grow but die. As can be seen from Figure 4, cell numbers (initial number was set at 100%) decreased by more than 54% 40 hr after adding 50 nM ouabain. However, when HEK cells were transfected with the Mut-construct (expressing the mutated Na^+,K^+-ATPase gene), cells did not die and the cell numbers were 106% 40 hr after ouabain was added (Figure 4). In a parallel experiment, cells were transfected with the unmutated *Drosophila* clone (Da47 cells); whereas cell

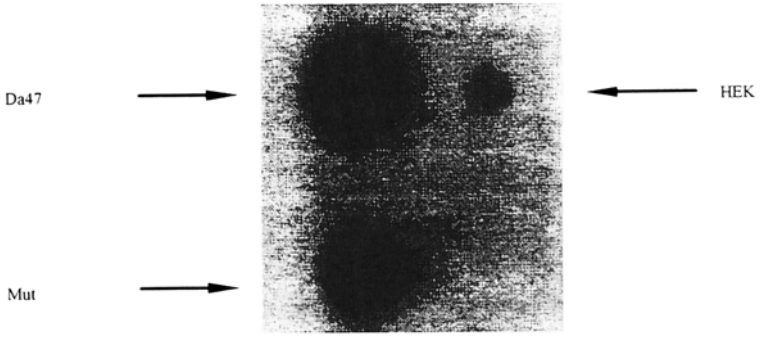

FIG. 3. Dotblot analysis of RNA from transfected and untransfected cells. Total RNA was prepared from HEK cells transfected with pSVDF plasmid DNA containing the wild type (Da47) or modified (Mut) Na^+,K^+-ATPase gene (α cDNA). After spotting 5 μg RNA onto the membrane, the blot was probed with an α subunit-specific PCR product. RNA from untransfected cells (HEK) show the normal expression level of the cell line.

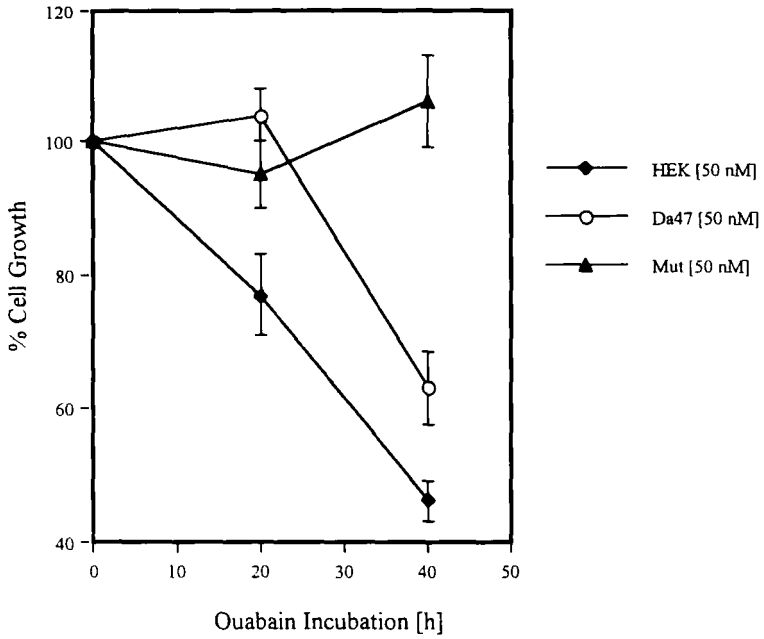

FIG. 4. Effect of ouabain on the growth of HEK cells. HEK cells transfected with pSVDF plasmid DNA containing the wild type (Da47) or modified (Mut) Na^+,K^+-ATPase gene (α cDNA) were grown in the presence of 50 nM ouabain. The cell number was determined at ouabain addition, 20 hr and 40 hr later and compared with untransfected control cells (HEK). Four plates were assayed for each set of experiments. The error bars show standard errors.

numbers were identical after 20 hr as compared to the Mut-clone, cell numbers dropped to ca 63% after 40 hr; a value that significantly differs from the Mut-value after 40 hr (Figure 4). In another set of experiments, ouabain was added at a concentration of 25 nM. Under these conditions cell numbers after 40 hr (initial number was set to 100%) were 262% in Mut-cells, 232% in Da47-cells and 182% in nontransformed HEK cells. These data clearly show that a point mutation at position 122 (substitution of his for asn) is indeed critical for ouabain toxicity, suggesting that this modification mediates cardiac glycosides insensitivity in the Monarch. However, it cannot be ruled out that an additional substitution (Schultheis et al., 1993) might also have occurred which could further amplify the insensitivity. A similar rationale was put forward by other authors who had transfected Hela cells with Na^+,K^+-ATPase genes in which the CG binding site had been modified by single amino acid substitutions (Lingrel et al., 1990; Askew and Lingrel, 1994; Jaisser et al., 1992; Schultheis et al., 1993).

Amino Acid Sequence of the Ouabain Binding Site in Danaus gilippus and Syntomeida epilais

Danaus gilippus and *Syntomeida epilais* are aposematically colored insects that store dietary CGs (Nickisch-Rosenegk et al., 1990; Ritland, 1991; Rothschild et al., 1973), whereas *Syntomis mogadorensis* (a related ctenuchid moth) eliminates CGs with the feces (Wink and Schneider, 1990). Using PCR primers developed to amplify the ouabain binding site of insects (Holzinger et al., 1992), we could obtain single PCR products which were directly sequenced. As can be seen from Table 1, these species also have an intron between positions 109 and 110, just flanking the ouabain binding site as was the case in *Manduca sexta*, *Creatonotos transiens* (Holzinger et al., 1992) and a few other insects (Emery et al., 1995). The derived amino acid sequence of the binding site of *D. gilippus* and of *S. mogadorensis* (Table 2), shows the typical pattern of CG-sensitive insects; i.e., the mutation found in the Monarch at position 122 could not be detected. In *S. epilais*, an amino acid substitution was visible at positions 115 and 119; since these substitutions also occur in sensitive enzymes of humans, sheep and other insects (Table 2) they cannot be responsible for CG-insensitivity. Because *D. gilippus* and *S. epilais* store CGs in the body and should be CG-insensitive, they must have developed a different target site modification.

CONCLUSIONS

Our experiments provide direct evidence that a single amino acid substitution in the ouabain binding site of Na^+,K^+-ATPase can confer resistance to ouabain in the Monarch. Genetically, such a mutation is straight-forward and only involves a point mutation of the corresponding gene. This mutation is an important requisite for CG sequestration and the utilization of CGs as acquired defense compounds; other adaptations apparently involve specific uptake and storage mechanisms.

Since many adaptations seem to be necessary for CG exploitation, it would be plausible to assume that these traits have been selected once during evolution and then maintained during further speciation processes. However, it is surprising that CG formation and sequestration can be found in many genetically unrelated organisms. CG insensitivity in the Monarch and in the other insects obviously depends (according to our molecular data) on different mechanisms; it is thus clearly a convergent trait and not derived through common ancestry. For CG production in genetically unrelated plant families and for CG sequestration in various groups of insects, we recently arrived at the same conclusion (Wink and v. Nickisch-Rosenegk, unpubl. data). CGs strongly interfere with an important molecular target of animals, i.e., the Na^+,K^+-ATPase and is thus a very potent toxin. Utilization of CGs for defence obviously grants a substantial

advantage for organisms, which could explain why CG adaptations became selected several times and independently during evolution.

Acknowledgments—Financial support by the Deutsche Forschunsgemeinschaft (Wi 719/10-1) is gratefully acknowledged. Eggs of *D. plexippus* were kindly supplied by Dr. A. Renwick (Boyce Thompson Institute for Plant Research, Ithaca, NY). Prof. Dr. D. Schneider (MPIV Seewiesen) had provided *D. gilippus*, *S. epilais*, and *S. mogadorensis* for previous experiments. Douglas M. Fambrough (Johns Hopkins University) kindly supplied us with a clone containing the Na^+, K^+-ATPase gene of *Drosophila*). We thank Prof. Dr. U. Seeburg (ZMBH, Univ. Heidelberg) for providing HEK cells and Prof. Dr. W. Huttner (Neurobiology, Univ. Heidelberg) for cell culture facilities.

(Received February 20, 1996; accepted June 10, 1996

Abstract—Ethyl ether, ethanol, and water extracts of meadowfoam (*Limnanthes alba* Hartweg ex. Benth.) seedmeal were prepared and bioassayed against velvetleaf (*Abutilon theophrasti* Medicus) and wheat (*Triticum aestivum* L. "Cardinal"). Both the ethyl ether and ethanol fractions, but not the water extract, inhibited velvetleaf and wheat radicle elongation. Fractionation of the extracts indicated that (3-methoxyphenyl)acetonitrile (3-MPAN) was the active compound from both extracts, comprising >97% of the active ethanol fraction. 3-Methoxybenzyl isothiocyanate, which had been previously shown to be the major breakdown product of glucolimnanthin, the major *L. alba* glucosinolate, was not detected in either extract. Radicle elongation of velvetleaf and wheat were inhibited by 3-MPAN with I_{50} (the concentration required to inhibit growth by 50%) values of approximately 4×10^{-4} M (velvetleaf) and 7×10^{-4} M (wheat).

Key Words—Meadowfoam, *Limnanthes alba*, limnanthaceae, seedmeal, glucosinolate, glucolimnanthin, 3-methoxybenzyl isothiocyanate, (3-methoxyphenyl)acetonitrile, phytotoxicity, soil amendment.

INTRODUCTION

Meadowfoam (*Limnanthes alba* Hartweg ex. Benth.) is a commercial oilseed crop grown in the Willamette Valley of Oregon for its unusual fatty acids which are of value in the manufacture of cosmetics, lubricants, and plastics (Kleiman and Princen, 1991). At the present no uses have been found for the seedmeal remaining after oil extraction, so it has been discarded as waste. As part of an ongoing project examining alternative weed control methods, we are conducting research on the use of extracted meadowfoam seedmeal as a soil amendment/fertilizer. We observed in preliminary field studies that weed populations were reduced in fields to which seedmeal had been applied. Meadowfoam seeds contain the glucosinolate glucolimnanthin (Miller et al., 1964; Bartelt and Mikolajczak, 1989). Glucolimnanthin would not be expected to be extracted with the oil, as it is not soluble in the solvent (hexane) used for oil extraction and therefore, should be retained in the seedmeal. Glucosinolate degradation products include isothiocyanates, nitriles, and thiocyanates (Figure 1), although formation of thiocyanates is rare. Whether isothiocyanates or nitriles are formed depends on several factors, including prior treatment of the plant tissue, pH or type of glucosinolate present (VanEtten and Tookey, 1983). Some of these degradation products, especially certain isothiocyanates, have been shown to be potent biocides (Lewis and Papavizas, 1971; Brown et al., 1991; Gamliel and Stapleton, 1993; Brown and Morra, 1995; Delaquis and Mazza, 1995). Glucolimnanthin from unextracted *Limnanthes alba* seed has been shown to break down to form primarily 3-methoxybenzyl isothiocyanate (3-MBITC), which was highly toxic to several insect larvae (Bartelt and Mikolajczak, 1989). The poten-

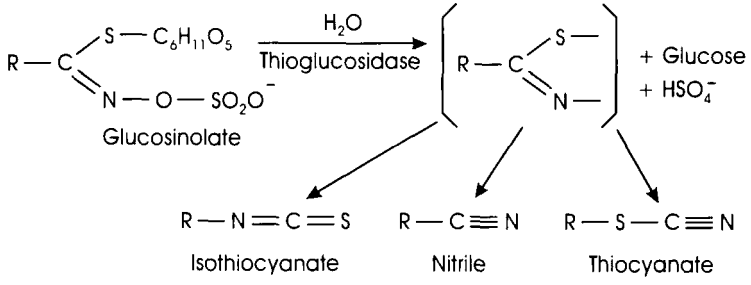

FIG. 1. Pathway and major products of glucosinolate degradation.

tial of using meadowfoam seedmeal as a soil amendment prompted us to determine if the observed reduction in weed populations were due to phytotoxins such as 3-MBITC, and if so, to identify the inhibitory compound(s).

METHODS AND MATERIALS

Gas Chromatography and Spectroscopy. Gas chromatography (GC) was performed using a Hewlett-Packard 5890 Series II gas chromatograph with a Hewlett-Packard HP3396 integrator. Columns used were fused silica DB-1 capillaries (0.25-μm film thickness, 15 m $\times$ 0.25 mm ID, J & W Scientific, Folsom, CA). Mass spectra were produced by introducing samples through a Hewlett-Packard 5890 gas chromatograph connected to a Hewlett-Packard 5971 Mass Selective Detector. ^{1}H and ^{13}C NMR spectra relative to tetramethylsilane were measured in $CDCl_3$ or D_2O at 400 and 100 MHz, respectively, with a Bruker ARX-400 spectrometer.

Extract Preparation. Hexane-extracted meadowfoam seedmeal was obtained from the Oregon Meadowfoam Growers Association, Salem, Oregon. Extracted seedmeal was first ground in a coffee grinder to a fine powder to facilitate extraction. Samples of 100 g were each extracted with 300 ml of ethyl ether, allowed to stand covered for 24 hr and filtered through folded filter paper circles (Whatman 2V). The extraction was repeated twice with additional 300 ml aliquots of ether, each time allowing the seedmeal to remain in the ether for 1 hr. The filtrates were combined and concentrated by rotoevaporation. The seedmeal was air-dried and extracted three times with absolute ethanol (300 ml for each extraction). The resulting extracts were combined and concentrated by rotoevaporation. The remaining seedmeal was extracted three times with distilled water (300 ml), the extracts combined and freeze-dried.

Chromatography of Extracts. The ethyl ether and ethanol extracts were chromatographed on a 4 $\times$ 52 cm column of Sephadex LH-20, using dichloromethane-ethanol, 1 : 1 (v/v) as the eluent. Ten fractions from the ether extract, and seven from the ethanol extract corresponding to colored bands were collected. Fractions found to be active by bioassay (see below) from both extracts were analyzed by GC. Comparison of retention time with a commercially-available standard (Aldrich), and GC-MS and NMR analysis identified the compound as (3-methoxyphenyl)acetonitrile (3-MPAN). Prominent diagnostic mass spectral ions, their relative intensities, and ^{1}H- and ^{13}C-NMR spectra for 3-MPAN are as follows: EI-MS [m/z (%)]: 147 (100), 132 (22), 117 (18), 116 (19), 107 (14), 91 (10), 77 (33). ^{1}H-NMR (400 MHz, $CDCl_3$): 3.81 (s, 3H); 4.67 (s, 2H); 6.87 (m, 3H); 7.29 (t, J = 7.9 Hz, 1H). ^{13}C-NMR (100 MHz, $CDCl_3$): 48.5 (CH_2); 55.24 (CH_3); 112.33 (CH); 113.73 (CH); 118.91 (CH); 129.96 (CH); 132.25 (C); 135.64 (C); 159.95 (C).

Glucosinolate Analysis of Seedmeal. Because unhydrolyzed glucosinolates present in the seedmeal may be further degraded to phytotoxins when in soil, glucosinolate concentrations were determined using a modified aglycone analysis procedure developed by Daxenbichler and VanEtten (1977). One hundred g of seedmeal were blended in a Waring blender with 500 ml of 30% (v/v) aqueous methanol and allowed to stand for 1 hr. The eluate was filtered through folded Whatman 2V filter circles and the marc washed with additional aliquots (~200 ml each) of aqueous methanol. The eluate volume was reduced by rotoevaporation in which all of the methanol was removed. The residue was transferred to a centrifuge tube with water to which 2 ml of a 0.5 M barium acetate/lead acetate solution was added, and the mixture was centrifuged (2500 rpm, 10 min). The supernatant was decanted (the pellet was discarded), freeze-dried, and redissolved in 15 ml of 0.05 M K-phosphate buffer, pH 7.0 to which 25 mg of thioglucosidase (Sigma) was added. Fifteen ml of CH_2Cl_2 containing 1 mg/ml butyl isothiocyanate as an internal standard was added to the buffered solution, and was shaken at 30 C for 2 hr. After shaking the organic layer was separated from the aqueous layer and analyzed by GC.

Analysis of Headspace Volatiles by Solid Phase Microextraction. Residual glucolimnanthin in the seedmeal may be further degraded to volatile phytotoxins such as 3-MPAN or 3-MBITC. Volatiles released from seedmeal that was wet to field capacity and allowed to remain moist and aerated for up to 7 days were examined using a solid phase microextraction (SPME) device (Supelco, Inc., Bellefonte, Pennsylvania). Briefly, SPME consists of a 1-cm fused silica fiber which is coated with a stationary phase, and attached to a stainless steel needle/plunger which is contained in an adjustable holder. The fiber is extended and placed in the headspace above the sample, where organic compounds adsorb to the stationary phase, reaching equilibrium in 2–30 min. After the sample is adsorbed, the fiber is withdrawn into the needle, and rapidly introduced into a gas chromatograph injector, where the adsorbed compounds are thermally desorbed onto the column (Zhang and Pawliszyn, 1993; Boyd-Boland et al., 1994). Headspace volatiles of the seedmeal were obtained by placing 100 g of seedmeal in a 600 ml beaker, and subsequently wetting the seedmeal to field capacity with distilled water. Aluminum foil was placed over the beaker, sealed, and allowed to stand for 15 min. After this time, the SPME device (which had been preconditioned immediately before by placing it into a second GC injection port not connected to the column) containing a 100 μm polydimethylsiloxane phase fiber was inserted through the foil into the headspace above the wet seedmeal, the fiber extended and allowed to adsorb volatiles for 15 min. After sample adsorption, the fiber was withdrawn and immediately injected into the GC by inserting the needle through the injector port septum and extending the fiber inside the injector insert for 0.2 min. Subsequent GC methods were the same as with liquid samples.

Seedling Radicle Elongation Bioassay. Wheat (*Triticum aestivum* L. "Cardinal") and velvetleaf (*Abutilon theophrasti* Medicus; purchased from Valley Seed Service, Fresno, California) seeds were surface disinfected with 0.5% commercial chlorine bleach for 15 min, after which they were rinsed with and then soaked in sterile distilled water for 2 hr. Seeds were wrapped in sterile paper towels saturated with water and incubated overnight in darkness at 25°C. All crude and column extracts were assayed by adding extracts to autoclaved water agar (1.0% w/v) at the rate of 1 mg extract/ml agar, after the agar had cooled to ~40°C. Fifteen ml of the agar-extract mixtures were placed in 9.0 cm plastic petri dishes, and five germinated seedlings were placed on the agar in the petri dishes. The dishes were incubated in darkness at 25°C on 45° slants, then evaluated visually for radicle growth.

Solutions of 3-MPAN, 3-MBITC and glucolimnanthin were assayed as above by adding stock solutions of the compounds in methanol (3-MPAN, 3-MBITC) or water (glucolimnanthin) to cooling water agar (the control contained methanol only). Radicle lengths (6 plates of 4 seedlings each) were measured after 48 h of incubation, and I_{50} values (the amount of each compound required to reduce radicle elongation by 50%) were determined from the intercept of 50% of the control with a best fit line of the data using regression analysis (StatView, Abacus Concepts, Berkeley, CA).

RESULTS AND DISCUSSION

Identification of the Phytotoxin. Both ethyl ether and ethanol extracts visibly inhibited velvetleaf and wheat radicle elongation, while the water extract had no effect. Fractionation of the crude extracts on the Sephadex LH-20 column gave one fraction in each extract that was inhibitory to radicle elongation in bioassays, although the active ether fraction was less inhibitory than the active ethanol fraction when tested at 1 mg extract/ml agar. Comparisons with GC retention times of a commercial standard, GC-MS and ^{1}H-, ^{13}C-NMR spectral data indicated that the inhibitory compound was 3-MPAN. The 3-MPAN peak accounted for ~97.5% of the total peak area of the active ethanol fraction (Figure 2), and greater than 90% of the active fraction from the ether extract. The remaining ~2.5% in the ethanol extract was identified as 3-hydroxy-3-methylbutanenitrile by comparison of sample mass spectra with published mass spectra (Spence and Daxenbichler, 1980). 3-MPAN is a hydrolysis product of glucolimnanthin, the major glucosinolate of *L. alba* and several other *Limnanthes* species (Miller et al., 1964; Bartelt and Mikolajczak, 1989). The 100 g of the seedmeal we tested contained 149 mg of extractable 3-MPAN. Unextracted *L. alba* seed was shown to release primarily (~90%) 3-methoxybenzyl isothiocyanate (3-MBITC) during hydrolysis, with only minor (~10%) amounts

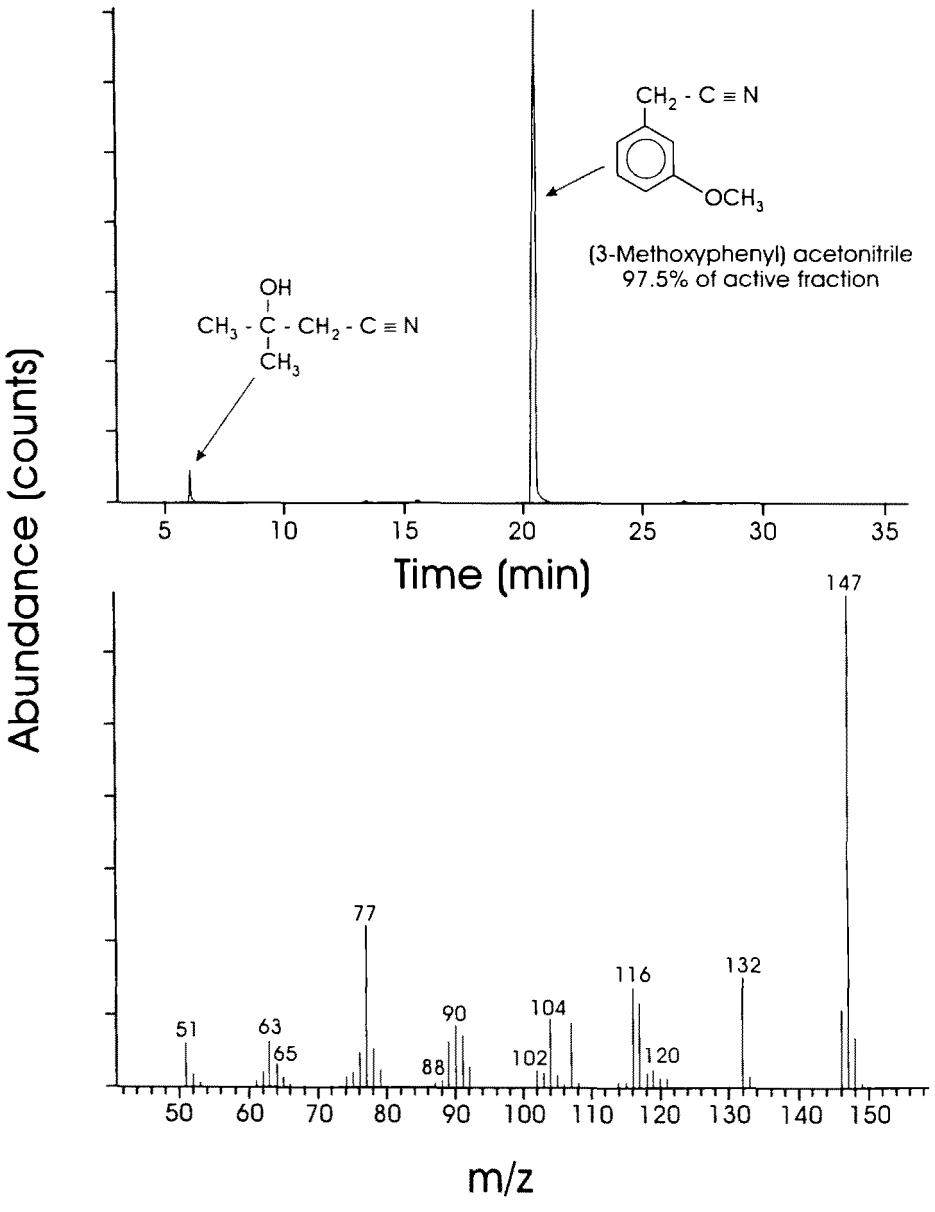

FIG. 2. Gas chromatograph of active ethanol fraction (top) and mass spectrum of 3-MPAN (bottom).

of 3-MPAN (Bartelt and Mikolajczak, 1989). 3-MBITC was not detected in either the ether or ethanol extracts. However, it is known that the hydrolysis products of glucosinolates vary with conditions of hydrolysis or prior treatment of the sample (Cole, 1976; Van Etten and Tookey, 1983), and that nitriles are produced under high temperature autolysis, as meadowfoam seed are heated to 220–230 C prior to oil extraction to inactive native thioglucosidase activity (K. D. Carlson, personal communication).

Glucosinolate Analysis. Reaction of unhydrolyzed glucosinolates in the seedmeal with exogenous thioglucosidase produced a markedly different chemical profile than with solvent extraction (Figure 3). 3-MBITC was the major (74.6%) peak, equal to 49 mg of 3-MBITC per 100 g of seedmeal, while 3-MPAN only accounted for 8.9% of the total peak area, or approximately 6 mg per 100 g of the seedmeal. 3-Hydroxy-3-methylbutanenitrile (1.9% of the total peak area), 5,5-dimethyloxazolidine-2-thione (6.4%) and an unknown (the mass spectra suggests a hydroxy-substituted 3-MPAN; 8.2%) were the other compounds detected.

Analysis of Headspace Volatiles by SPME. Relative concentrations of volatiles collected over headspace gases of wet meadowfoam seedmeal by SPME

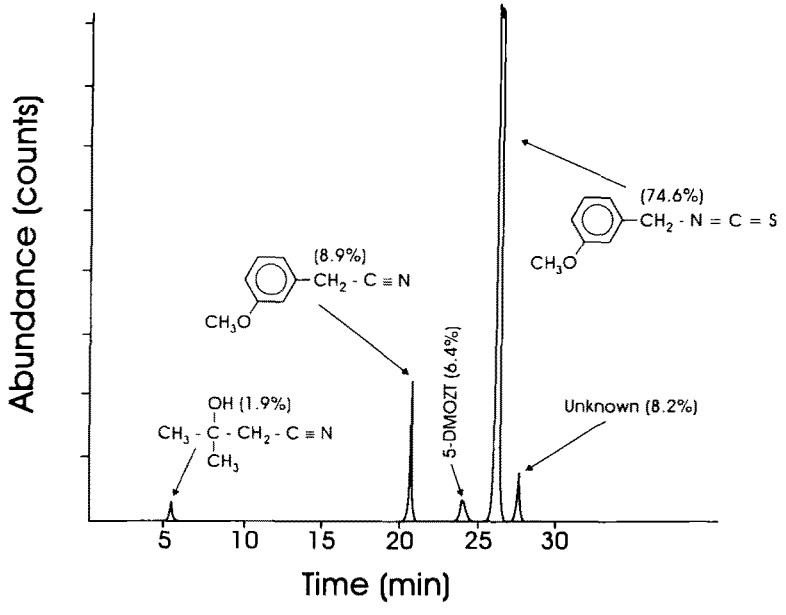

FIG. 3. Gas chromatograph of thioglucosidase-catalyzed degradation products of residual glucosinolates in seedmeal.

TABLE 1. RELATIVE CONCENTRATIONS OF VOLATILE COMPOUNDS COLLECTED BY SPME OVER HEADSPACE GASES OF MOISTENED MEADOWFOAM SEEDMEAL

Time after seedmeal moistened	% of total volatiles collected[a]		
	3-MPAN	Nonanal	3-Methoxy benzaldehyde
Initial	94.3	2.0	0.7
1 day	95.3	1.4	0.7
2 days	94.7	1.7	0.8
4 days	96.1	1.3	0.6
7 days	98.8	0.2	0.1

[a] Values represent the mean of three replicates.

are shown in Table 1. Due to the nature of SPME, quantification of compounds is difficult, so only percentages of total volatile compounds collected are shown. 3-MPAN accounted for over 94% of the total volatile profile in the freshly-moistened seedmeal, with other significant peaks identified by comparison of retention times and mass spectra of standards as nonanal (~2% of the total peak area) and 3-methoxybenzaldehyde (~0.7%). Seedmeal that was kept moist, aerated and allowed to decompose contained more 3-MPAN after seven days than freshly-moistened seedmeal, accounting for over 98% of the volatiles collected. 3-MBITC was not detected at any sampling time, even though the glucosinolate analysis indicated that significant levels of unhydrolyzed glucolimnanthin remained in the seedmeal after hexane extraction. Evidently the extraction procedure altered glucolimnanthin degradation, as Bartelt Mikolajczak (1989) had shown that intact *L. alba* seed produced primarily 3-MBITC, not 3-MPAN.

Toxicities of 3-MPAN, 3-MBITC and Glucolimnanthin. 3-MPAN, 3-MBITC and glucolimnanthin were assayed against velvetleaf and wheat seedlings to determine phytotoxic levels of each compound. The calculated I_{50}'s for 3-MPAN were 4.1×10^{-4} M and 7.4×10^{-4} for wheat and velvetleaf, respectively (Figure 4). 3-MBITC was considerably more phytotoxic, with I_{50}'s of 2.0×10^{-6} M (velvetleaf) and 5.0×10^{-6} M (wheat). 3-MBITC, although not detected in the seedmeal extracts, has been previously identified as an active component of meadowfoam seeds. Bartelt and Mikolajczak (1989) found that 3-MBITC was the primary active compound against European corn borer (*Ostrinia nubialis* Hübner) and fall armyworm (*Spodoptera frugiperda* J. E. Smith) larvae, with 3-MPAN having little or no effect on these insects. Glucolimnanthin was only slightly inhibitory to radicle elongation at the highest concentrations tested (10^{-3} and 10^{-2} M for velvetleaf and 10^{-2} M for wheat). The low toxicity of gluco-

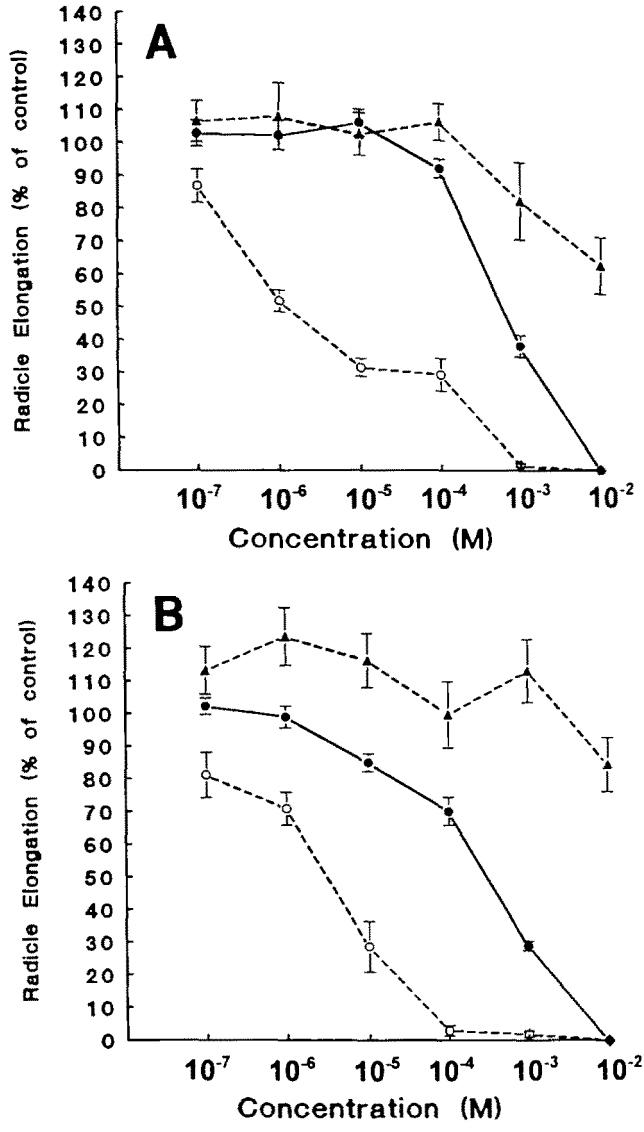

FIG. 4. Inhibition of velvetleaf (A) and wheat (B) radicle elongation by 3-MPAN (—●—), 3-MBITC (--○--), or glucolimnanthin (--△--). Bars represent ±1 SE.

limnanthin is similar to that reported by Brinker and Spencer (1993) for the glucosinolate glucoraphenin (4-methylsulphinyl-3-butenyl glucosinolate). The low phytotoxicity of glucolimnanthin was not surprising, as Bialy et al. (1990) found that glucosinolates were generally much less phytotoxic than their degradation products to wheat germination and growth.

Although our data suggest that 3-MPAN is far less phytotoxic than 3-MBITC, the relatively large amounts we found in the seedmeal help to explain the herbicidal activity we observed in our preliminary field studies. The amount of 3-MBITC produced by enzymatic degradation of the remaining glucolimnanthin represents only about one-third of the 3-MPAN directly extracted from the seedmeal. However, the much higher toxicity of 3-MBITC toward the bioassay species indicates that this compound would likely reach phytotoxic levels if the residual glucolimnanthin was primarily hydrolyzed to 3-MBITC in the soil. Although we were unable to detect any 3-MBITC in volatiles collected from moistened seedmeal, we did not examine seedmeal decomposing in soil. Brown and Morra (1995) found that defatted rapeseed meal with intact, unhydrolyzed glucosinolates severely inhibited lettuce (*Lactuca sativa* L.) seed germination while rapeseed meal in which most of the glucosinolates had been previously hydrolyzed had little or no effect on seed germination. The major volatile (>80%) released initially (0.3–2.3 hr) by moistened rapeseed meal in this study was 3-butenyl isothiocyanate, with the corresponding nitrile (3-butenyl nitrile), comprising approximately 7% of the total. Presumably during the production of the rapeseed meal, sufficiently high temperatures necessary to deactivate native thioglucosidase activity were not reached. Variability in soil type, pH (e.g., acid conditions favor the formation of nitriles) and microbial flora would likely produce different volatile profiles than we found in our study. Indeed, thioglucosidases capable of hydrolyzing glucosinolates to isothiocyanates have been isolated from bacteria and fungi (Fenwick et al., 1983). Perhaps under field conditions residual glucolimnanthin in the seedmeal would be converted to 3-MBITC by microbes, increasing its herbicidal activity. We are currently conducting more extensive field studies to determine the feasibility of using meadowfoam seedmeal as a soil amendment for weed control.

Acknowledgments—We thank The Oregon Meadowfoam Grower's Association for furnishing the seedmeal, Dr. David Weisleder for providing the NMR spectra, and Ms. Carlotta Williams for technical assistance.

BOOK REVIEW

Analyses in Insect Ecology and Management. Larry Pedigo and Michael Zeiss. Iowa State University Press, Ames, Iowa, 1996. Hardback, ISBN 0-8138-2861-9, 168 pp. $64.95.

There is an essential suite of quantitative tools with which any applied entomologist working in pest management should have a working knowledge. This book attempts to provide an overview with working examples of many of these tools. The authors suggest that the book is intended as a primer that can be used in an autotutorial mode by students or professionals or as a laboratory manual for graduate-level courses in insect ecology or pest management. The book is organized into eight short chapters and is accompanied by a diskette of DOS computer programs (ENSTAT) that complement many of the lessons. Each chapter concludes with sample problems to exemplify the topic area covered, a series of questions, and a bibliography of selected papers. An answer key is available free of charge from the publisher. There is no index.

The first chapter is a short introduction to using the statistical portion of ENSTAT along with several small data sets for practicing use of the software. The software can perform simple one and two-way analysis of variance, chi-square analysis and simple linear regression. The program would be useful to undergraduate or beginning graduate students with little experience in statistical analysis. Most professionals and upper level graduate students will find the program's capabilities limited and would be better off learning to use one of the more widely available statistical packages. Data entry is clumsy and the user cannot import existing data files nor export data sets for further analyses.

Chapter 2 provides general coverage of the spatial distribution of insect populations. Some of the more common theoretical distributions such as the Poisson, negative binomial, and binomial distribution are explained and exemplified. Taylor's power law is covered briefly, but other common methods for empirically describing dispersion, for example the patchiness regression based on Lloyd's mean crowding index, are not mentioned. ENSTAT programs are provided to determine goodness of fit of field data to Poisson and negative binomial distributions.

Chapters 3 and 4 address the development of sampling plans. The third chapter covers basic development of sequential sampling plans for pest management application based on Wald's methods. These sequential plans basically allow a given pest population to be classified as either above or below a predetermined threshold level. They are typically quite efficient because few sam-

0098-0331/96/1000-1951$09.50/0 © 1996 Plenum Publishing Corporation

ples are needed to classify low or high population densities. Standard formulae are presented for calculating sequential stop lines based around the binomial, negative binomial, Poisson, and normal distributions. The software includes spreadsheet-based programs for calculating sequential stop lines for all but the normal distribution, and for estimating average sample number and error rates as a function of pest density. The chapter concludes with a reprint of a journal article exemplifying the development of a sequential sampling plan for a soybean pest. The fourth chapter discusses a specialized use of sequential sampling (time-sequential) that attempts to classify whether a pest population is increasing or decreasing over time. Much of the concept and detail of the method is covered in a reprinted article by the first author. Again, ENSTAT contains a module for calculating stop lines.

The degree-day model for predicting temperature-dependent development of insects is the subject of Chapter 5. Coverage here is elementary and the reader may want to consult references in the bibliography and software for greater detail. For example, there is no discussion of the sinewave method or of methods that use both a lower and upper development threshold. The software for calculating and accumulating degree-days contains a few bugs, but does permit the user to specify upper developmental thresholds and provides output using the rectangular, triangular, and sinewave method.

The next two chapters cover the development and analysis of life tables. The text section is brief, with most of the detail provided in reprints of all, or parts of, several classic references by Harcourt, Ives, and Southwood. Good example data sets are provided for the practice construction and analysis of age-specific life tables. The authors also provide a fairly detailed set of step by step instructions for doing k-factor and key-factor analyses, techniques that attempt to identify causative factors in the population dynamics of a species over time and/or multiple sites. The text and bibliography discuss density-dependence, but do not address the continuing controversy over the validity of various techniques for measuring density-dependence. ENSTAT contains a module for life table construction.

The final chapter covers the concept and develompent of economic injury levels (EIL), one of the most fundamental components of modern IPM. The book focuses on the EIL model of Pedigo and provides step by step instructions on how to calculate an EIL for a specific soybean pest. Again, the chapter concludes with a reprint of a journal article. The authors do not discuss other EIL models nor present methods for determining the economic threshold, the actual pest density at which suppressive action should be implemented.

Analyses in Insect Ecology and Management is well written, and printed in fairly large type in single columns making it easy to read. Based on the subject matter covered, the level of detail, and the presentation format, the book would be most useful as a supplemental text for upper undergraduate or lower

level graduate laboratory courses in insect pest management. Cost may be prohibitive, particularly if another book is required for the lecture portion of the course. Professionals wanting a good reference to some quantitative techniques would probably be a bit frustrated by the lack of depth, and those using the book in an autotutorial mode would definitely want to obtain the answer key. I am not a big fan of books that reprint original research articles that could be easily obtained elsewhere, but the approach does provide for self-contained lessons. The ENSTAT software has a few bugs, but is useful in furthering the educational value of the text. Most graduate students and professionals will quickly outgrow the programs.

PHENYLPROPENOID PHENOLICS IN SWEETBAY MAGNOLIA AS CHEMICAL DETERMINANTS OF HOST USE IN SATURNIID SILKMOTHS (*Callosamia*)

(Received December 15, 1995; accepted June 13, 1996)

Abstract—Host plant chemistry can play an important role in determining the evolution of host use patterns in herbivorous insects by influencing host selection, consumption, and assimilation of foliage. We used a comparative approach to test the hypothesis that specialist herbivores of sweetbay magnolia (*Magnolia virginiana*) possess adaptations that allow them to overcome chemical deterrents or toxins that prevent herbivory by unadapted herbivores. The three silkmoth species in the genus *Callosamia* can be collectively regarded as specialists on magnoliaceous hosts; however, only the monophagous *C. securifera* is able to complete development on sweetbay magnolia, its natural host. In laboratory assays with intact foliage, both *C. angulifera* and the polyphagous *C. promethea* fed readily on sweetbay but were unable to survive past the third instar. Two neolignan compounds, magnolol and a biphenyl ether, were found to reduce neonate growth and survival of unadapted herbivore species when painted on acceptable host leaves at concentrations similar to those found in sweetbay foliage. Both compounds significantly reduced neonate growth of *C. angulifera* and *C. promethea* but had no effect on the sweetbay specialist, *C. securifera*, indicating that the latter species possesses the unique ability in the genus to tolerate, metabolize, or otherwise circumvent the phytochemical defenses of this host.

Key Words—Phenolics, sweetbay magnolia, silkmoths, Saturniidae, phenylpropenoids, *Magnolia virginiana*, *Callosamia*, host plant chemistry.

INTRODUCTION

Early in the development of plant–herbivore theory, host plant chemistry was recognized as an important determinant of host use patterns of phytophagous insects on both an ecological and evolutionary scale (Fraenkel, 1959; Ehrlich and Raven, 1964). More recently, enthusiasm for the importance of plant chemistry in the evolution of insect–plant interactions has been tempered by the recognition that natural enemies, pathogens, and other ecological restrictions may exert equally powerful and potentially conflicting, pressures on host use patterns (Lawton and McNeill, 1979; Price et al., 1980; 1986; Scriber and Lederhouse, 1992; Bernays and Graham, 1988). Nonetheless, in many cases where herbivore phylogenies and host use patterns can be reasonably well defined, there is little doubt that host plant characteristics do profoundly influence the evolution and diversification of some phytophagous taxa (Benson et al., 1975; Mitter and Brooks, 1983; Farrell and Mitter, 1990). Plant allelochemicals, in particular, appear to have played a central role in the evolution of host patterns in *Papilio* butterflies (Feeny et al., 1983; Feeny, 1991; Miller, 1987; Scriber, 1988), leaf beetles (Futuyma and McCafferty, 1990), *Euphrydras* checkerspot butterflies (Bowers, 1988), and *Heliconius* butterflies (Spencer, 1988). Thus, the concept of toxic and/or deterrent compounds acting as chemical constraints or barriers to host use remains a prominent feature in discussions of phylogenetic patterns of host use (Miller, 1987; Berenbaum et al., 1986; Feeny, 1991; Nitao et al., 1992; Nitao, 1995; Scriber et al., 1989).

The presence of robust chemical defenses in plants can present substantive evolutionary hurdles for host range expansion or shifts to novel hosts. Such alterations in host use patterns may require behavioral changes, such as those involved in oviposition and feeding, as well as physiological or metabolic changes that allow the herbivore to utilize efficiently the particular nutritional and chemical characteristics of the new host. Thus, specific allelochemicals or nutritional characteristics may act as chemical barriers in both ecological and evolutionary patterns of resource use of herbivores lacking these adaptations (Berenbaum et al. 1986, 1991). Demonstrations of the deterrent or toxic effects of phytochemicals on individual herbivore species reveal little information regarding the potential evolutionary significance of these compounds. However, comparative measures of the effects of plant compounds on closely related herbivores have proven to be valuable for identifying metabolic or detoxicative constraints on host use (Erickson and Feeny, 1974; Blau and Feeny, 1978; Berenbaum, 1978, 1981; Lindroth et al., 1986, 1988; Scriber et al., 1989; Nitao et al. 1992).

The wild silkmoths in the genus *Callosamia* (Saturniidae) represent a good model system for investigating the role of plant chemistry on the evolution of host use patterns. Collectively, this small group of saturniids can be

considered specialists on magnoliaceous hosts, yet the three species in the genus differ dramatically in both breadth of diet and their ability to survive on specific host plants. *C. securifera* is a specialist, feeding exclusively on sweetbay magnolia (*Magnolia virginiana*) in the southeastern United States. In contrast, *C. angulifera* is oligophagous and feeds primarily on tuliptree (*Liriodendron tulipifera*: Magnoliaceae) and occasionally spicebush (*Lindera benzoin*: Lauraceae). The third species, *C. promethea*, is highly polyphagous and feeds on deciduous trees in over five different plant families, including black cherry (Rosaceae), sassafras and spicebush (Lauraceae), tuliptree (Magnoliaceae), ash and lilac (Oleaceae), buttonbush (Rubiaceae), and others (Ferguson, 1972; Peigler, 1976; Stone 1991). Although sweetbay occurs within the geographic distributions of the two *Callosamia* species with broader feeding habits, neither *C. promethea* (with the exception of some populations in Maryland; H. Pavulaan, personal communication) nor *C. angulifera* use it as a host. Laboratory observations of early instar feeding behavior led to the hypothesis that sweetbay foliage is toxic to unadapted herbivores.

This study was undertaken to confirm and characterize the phytochemical basis for the differential performance of the three wild silkmoths on sweetbay magnolia in an effort to understand the evolution and physiological basis of host specialization within the *Callosamia* lineage.

METHODS AND MATERIALS

Larval Performance on Fresh Leaves. The relative suitabilities of tuliptree, sassafras, and sweetbay as hosts for each *Callosamia* species was evaluated in June 1989 using measures of neonate growth rates and survival on intact foliage. Newly eclosed larvae were weighed and reared individually in Petri dishes on detached leaves kept fresh with water-filled plastic vials with rubber caps. The relative growth rate of each larva was calculated as RGR = [ln (final mass) − ln (initial mass)/2 days]. First-instar survival was determined by the number of larvae that successfully completed the molt to the second stadium. Tuliptree and sassafras foliage used in the feeding trial was collected in Ingham County, Michigan; sweetbay foliage was from potted trees (originally obtained from Herren Nursery, Florida Division of Forestry) maintained in a greenhouse at Michigan State University for several years. Insects used in the assays on host foliage were from five wild-collected *C. securifera* females (Highlands County, Florida), one *C. promethea* (Wisconsin) and one *C. angulifera* female (Lebanon County, Pennsylvania). While better representation of populations would have been desirable, additional females were not available. Larvae were distributed evenly across the three hosts (25–30 larvae per host) and reared at 24°C and a 18:6 light-dark photoperiod. Because the *C. promethea* trial was conducted 10

days earlier than the other two species, each species trial was analyzed separately. Significance of differences in growth rates on sassafras, tuliptree, and sweetbay were tested by one-way analysis of variance followed by Tukey's multiple range test.

Extraction and Bioassay of Crude Extracts from M. virginiana *Leaves.* Fresh sweetbay leaves (mixture of young and old) were removed from trees, freeze-dried, and milled. The powdered leaf material (435 g) was sequentially extracted at room temperature with hexane (6 liters), ethyl acetate (6 liters), and methanol (2 liters). Removal of solvent *in vacuo* yielded 36.9 g, 16.9 g, and 54.34 g of residue, respectively.

Because *Callosamia* larvae do not accept artificial diet, extracts were painted on fresh leaves of tulip tree, which is an acceptable host for both *C. promethea* and *C. angulifera*. Extracts were dissolved in an appropriate solvent (hexane or methanol) and applied to the top surface of detached leaves with a syringe. The amount applied to each leaf was adjusted for the fresh weight of that leaf to approximate concentrations in fresh *M. virginiana* leaves (grams of extract per gram of fresh leaf). Control leaves were treated with an equivalent volume of the appropriate solvent. Freshly treated leaves were added after 24 hr or as needed.

Newly eclosed larvae were weighed and allowed to feed individually on treated leaves in plastic cups for 72 hr at 24°C and a 18:6 light–dark photoperiod, after which they were reweighed and 48 hr relative growth rate calculated as described above. A 1-cm layer of moistened plaster of Paris in the bottom of each cup served to maintain mositure and leaf turgor during the experiment. Larvae used in bioassays were obtained from field-collected or first-generation laboratory females (*C. promethea* were from Cass County and Otsego County, Michigan; *C. angulifera* were wild females from Greensville County, Virginia, and Florence County, South Carolina). Due to the difficulty of coordinating egg hatch of female moths to obtain similar-aged neonates, only two families of each species were represented in each assay. Fifteen neonates were used in each treatment. Tukey's HSD multiple comparison test was used to detect differences ($P < 0.05$) in growth rate of each species on the extracts.

Isolation and Bioassay of Individual Compounds from Active Fraction. The hexane fraction (12.78 g) of sweetbay extract was found to be the most active against neonates, so its constituents were further separated using centrifugal partition chromatography (Sanki Engineering, Kyoto) using the lower phase of hexane–acetonitrile–ethyl acetate–water (40:35:25:5) as the mobile phase at a flow rate of 3.2–3.8 ml/min at 900 rpm. Three major compounds were purified by flash column (Sigma silica 230–400 mesh, 60 Å eluted with hexane–ether 4:1) and preparatory thin layer chromatography (silica gel, 2000 μm tapered Uniplate, Analtech, Newark, Delaware, developed twice in hexane–ether 4:1). The final purification yielded three neolignan compounds: 4,4′-diallyl-2,3′-di-

hydroxybiphenyl ether (147.8 mg), 5,5′-diallyl-2,2′-dihydroxybiphenyl (100 mg) and 3,5′-diallyl-2′-hydroxy-4-methoxybiphenyl (207.6 mg). These compounds were identified from NMR, MS, UV, and IR spectra (Nitao et al., 1991). Structures for these compounds are shown in Figure 1 and hereafter they are referred to as the biphenyl ether (**1**), magnolol (**2**), and methoxyhonokiol (**3**), respectively.

The biphenyl ether, magnolol, and methoxyhonokiol were bioassayed at 0.03%, 0.125% and 0.5% (grams of compound per gram fresh tuliptree leaf) against *C. promethea* neonates using the leaf-painting technique described previously. Natural concentrations of these compounds in sweetbay foliage were estimated to be 0.46, 0.31, and 0.64% fresh wt (FW), respectively, from our extraction procedure, but dose–response curves are more informative than single-dose assays of plant secondary metabolites because concentrations of com-

FIG. 1. Structures of *Magnolia virginiana* neolignans active against larvae of unadapted *Callosamia* silkmoth species. **1** = 4,4′-diallyl-2′,3′-dihydroxybiphenyl ether; **2** = magnolol; **3** = 4-methoxyhonokiol.

pounds in plants in the field may vary considerably. Assays were replicated three times using *C. promethea* collected from distantly separated geographic locations (Montgomery County, Maryland; Lebanon County, Pennsylvania; several locations in Wisconsin and Michigan), with 6–10 larvae represented per concentration per assay. Because *C. angulifera* were difficult to obtain, only magnolol was tested against this species. (*C. angulifera* larvae were from wild females collected in Cass County, Michigan; Greensville County, Virginia; and Mississippi). In the *C. angulifera* assays, magnolol was assayed at five doses rather than three (0.1, 0.2, 0.3, 0.4, and 0.5% grams of compound per gram fresh leaf). As an additional check of the leaf-painting technique, the responses of *C. securifera* neonates (several families from Highlands County, Florida) to magnolol and the biphenyl ether were assayed at 0.1, 0.3, and 0.5%. Larval response to host chemicals was measured in terms of 48-hr relative growth rate. Data from the replicate assays were pooled, and a polynomial regression model used to test for linear and quadratic dose-dependent effects.

RESULTS

Larval Performance on Intact Host Plants. Relative growth rate and first-instar survival of both *C. promethea* and *C. angulifera* were considerably reduced on sweetbay compared to the two acceptable hosts (Figure 2A and B), whereas *C. securifera* performed as well on sweetbay as on sassafras and significantly better than on tuliptree. First-instar survival for *C. promethea* and *C. angulifera* was less than 30% on sweetbay but ranged from 90 to 100% on acceptable hosts. *C. securifera* survival was greater than 70% on sweetbay compared to 62% on sassafras and 85% on tuliptree. The patterns of short-term larval growth rates corresponded closely with larval survival, with the exception of *C. securifera*'s response to tuliptree. On this host, growth was significantly lower than on sweetbay and sassafras, although survival remained high. No conspicuous differences in larval feeding rate were observed, suggesting that the reduced growth and survival were not entirely due to strong antifeedant effects.

Separation and Bioassay of Crude Extract. Of the three major fractions, the hexane extract produced the greatest reduction in larval growth rate (one-way ANOVA, *C. promethea*: $F = 7.86$; $df = 1, 3$; $P < 0.001$; *C. angulifera*: $F = 9.79$; $df = 1, 3$; $P < 0.001$). *C. promethea* and *C. angulifera* responded similarly to all three fractions with a significant reduction of growth on leaves treated with the hexane extract compared to controls [Figure 3A: *C. promethea* (mean ± SE) 0.26 ± 0.04 mg/mg/day; *C. angulifera* 0.34 ± 0.03 mg/mg/day]. *C. angulifera* growth on leaves treated with the ethyl acetate fraction was also significantly lower than on control leaves (0.45 ± 0.03 mg/mg/day). Percent survival of both species was also lowest on leaves treated with the hexane

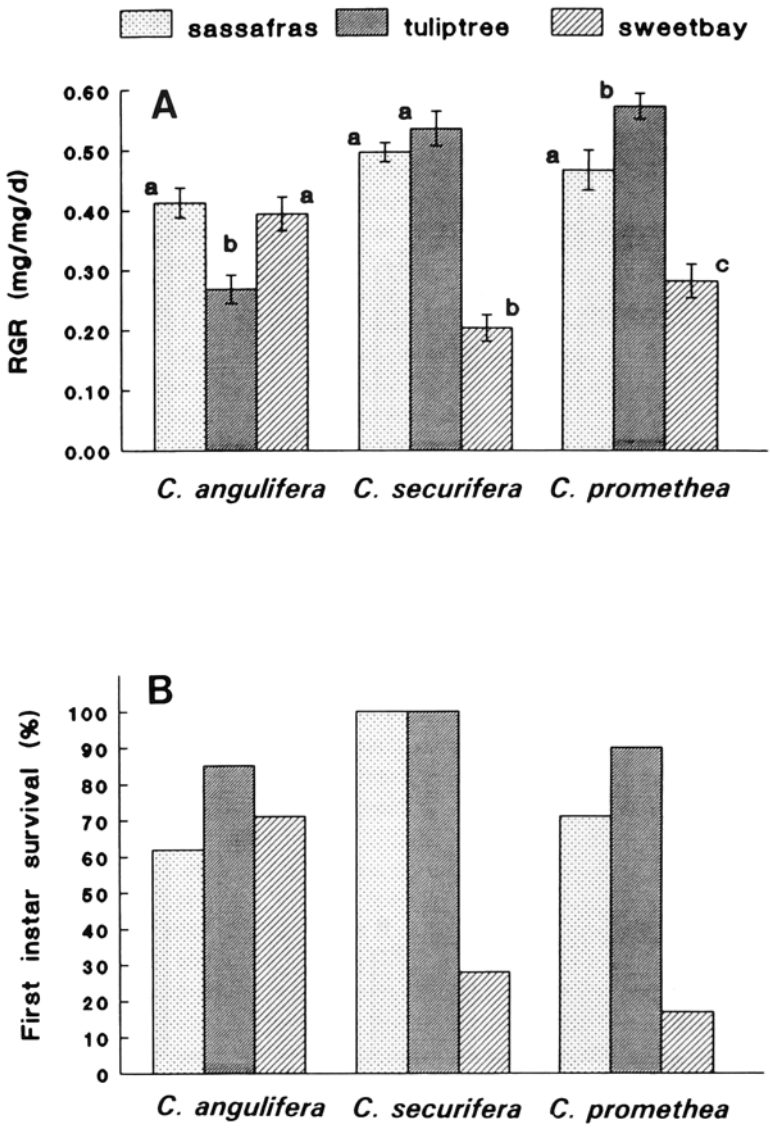

FIG. 2. Relative growth rate and first-instar survival of *C. securifera*, *C. angulifera*, and *C. promethea* on sassafras (*Sassafras albidum*), tuliptree (*Liriodendron tulipifera*), and sweetbay magnolia (*Magnolia virginiana*). Different letters denote significant differences in growth among host plants for each species. $N = 25$–30 larvae.

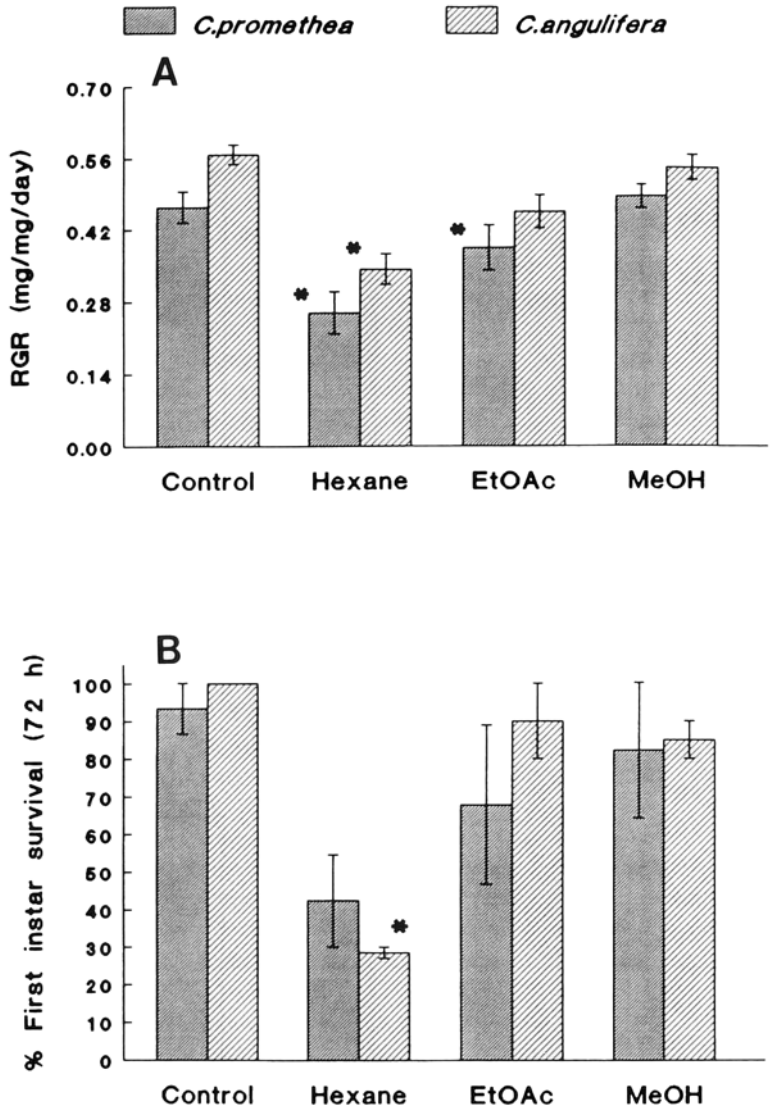

FIG. 3. Relative growth rates and survival of neonate larvae of the two unadapted silkmoth species, *C. promethea* and *C. angulifera*, on tuliptree leaves painted with extracts from *Magnolia virginiana* foliage. Bars represent the means ± SE for 15 larvae from at least two geographically separated populations. Asterisks denote treatments that differ significantly from the control.

fraction [Figure 3B: *C. promethea* (mean ± SE) 42.3 ± 12.3 mg/mg/day; *C. angulifera* 28.5 ± 1.5 mg/mg/day].

Isolation and Bioassay of Individual Compounds from Active Fraction. Magnolol and the biphenyl ether were active against larvae of the unadapted species (Figure 4A and B) at concentrations approximating those found in fresh leaf material (0.31 and 0.46% FW for magnolol and the biphenyl ether, respectively). Relative growth rates of *C. promethea* larvae were significantly decreased by both magnolol (linear response: $F = 14.31$; $df = 1,75$; $P = 0.003$) and the biphenyl ether (linear response: $F = 18.89$; $df = 1,74$; $P = 0.001$). *C. angulifera* neonate growth was also significantly decreased by magnolol (linear response: $F = 18.01$; $df = 1,149$; $P = 0.001$) in a dose-dependent fashion. As expected, *C. securifera* larvae were unaffected by magnolol and the biphenyl ether across all doses. Methoxyhonokiol (Figure 4C) had no significant effect on *C. promethea* performance (linear response: $F = 0.64$; $df = 1,30$; $P = 0.430$).

DISCUSSION

Our results demonstrate that foliar chemistry may have a strong influence on the performance of *Callosamia* species on sweetbay. The poor growth and survival of *C. promethea* and *C. angulifera* on this host could be explained largely by the activity of two neolignan compounds, magnolol and the biphenyl ether, isolated from the foliage. When assayed individually at doses similar to those found in fresh leaf material, each compound reduced larval growth to levels similar to those observed on intact foliage. Potentially, the presence of either or both of these compounds could block host shifts by herbivores that lack specific metabolic mechanisms to cope with them, even within lineages that are adapted to utilize Magnoliaceous hosts, such as *Callosamia*. In this taxon, the use of sweetbay apparently requires specialized metabolic adaptations to allelochemicals other than those that accompany the ability to feed on tuliptree or those associated with a highly polyphagous feeding habit.

Host plant chemistry can affect larval performance through antifeedancy or other behavioral effects, as well as by toxic or antinutritive means (Bernays and Chapman, 1987; Feeny, 1991). Although distinguishing toxicity from antifeedancy in insect bioassays is often problematic, we saw no evidence that the compounds we isolated were acting as strong antifeedants in our assays, as larvae appeared to feed equally on treated and control leaves. This indicates that the painting of the extracts on the leaves was a legitimate technique to use in this instance. Moreover, many lignans have been reported to have biological activity (MacRae and Towers, 1984; Bernard et al. 1989; Faure et al., 1990), and both magnolol and the biphenyl ether are known to possess a broad spectrum

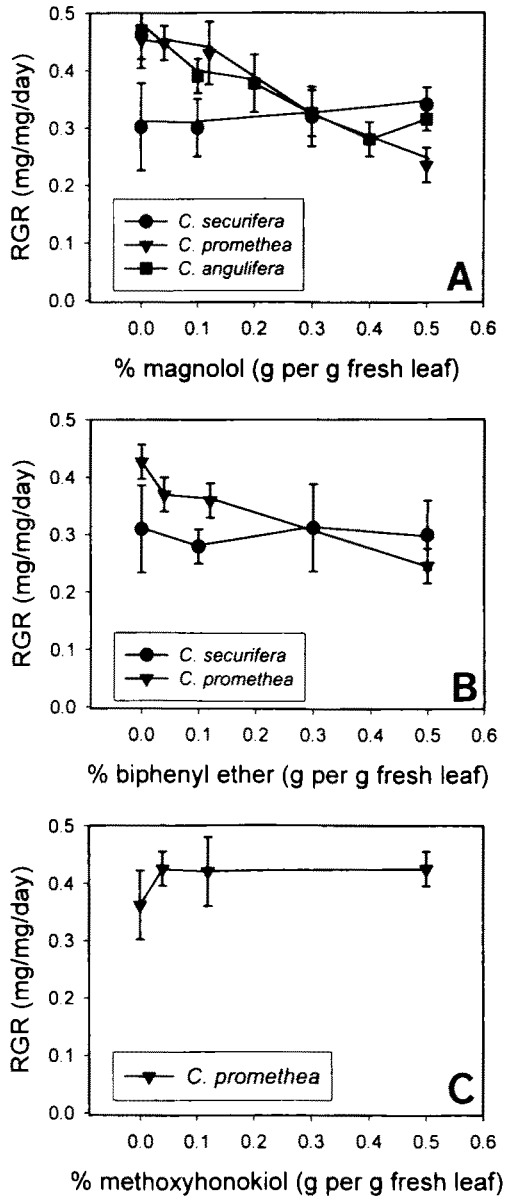

FIG. 4. Concentration-dependent effects of magnolol on the three *Callosamia* species. The relative growth rates of *C. promethea* and *C. angulifera* decreased significantly with increasing magnolol concentrations ($P < 0.003$; $P < 0.001$), whereas *C. securifera* was unaffected. Each value represents the mean ± SE of three replicate assays with 6–10 larvae per replicate.

of antimicrobial and insecticidal activity against other organisms, including other lepidopteran larvae (Clark et al., 1981; Nitao et al., 1991, 1992).

In the course of our laboratory experiments, *C. promethea* populations from many geographic locations (Wisconsin, Michigan, Pennsylvania, Maryland) were assayed, and no evidence of the ability to utilize sweetbay as a host was found, with the exception of a population near Rockville, Maryland, which were utilizing sweetbay in the wild. Bioassays of insects from these populations indicated that they are no less susceptible to the deleterious effects of magnolol and the biphenyl ether than other *C. promethea* populations (0.5% biphenyl ether reduced RGR from 0.41 mg/mg/day on control leaves to 0.19 mg/mg/day; 0.5% magnolol reduced RGR from 0.37 on control leaves to 0.21 mg/mg/day). A more likely explanation is that sweetbay growing in Maryland contains lower concentrations of neolignans than trees in other geographic regions. Spatial, temporal, intra- and interplant variation in foliar chemistry is a common occurrence in natural plant populations, resulting from both genetic and environmental factors. Sweetbay can be found growing in a variety of habitats across its range, exhibiting considerable plasticity in deciduousness, growth habit, and leaf shape. There may be geographic differences in leaf chemistry between the northern and southern populations as well. The negative effects of magnolol and the biphenyl ether in bioassays were linearly concentration dependent; thus it seems reasonable to expect that foliage containing lower concentrations will have less of an impact on larval performance.

It would appear that *C. securifera* possesses unique biochemical and/or physiological traits that afford larvae a greater tolerance of the toxic phytochemistry of its preferred host. However, it is not clear whether these traits are derived characteristics that evolved in association with increased feeding specialization of this species or whether they represent a more primitive character state that has subsequently been lost in other species of *Callosamia*. Attributing evolutionary patterns of host single causal determinants, such as current host chemistry, must be done with the great caution (Barbosa, 1988; Rausher, 1988; Thompson, 1988). Without accurate knowledge of the phylogenetic relationship of the three *Callosamia* taxa, the evolutionary significance of current ecological responses to magnolol and the biphenyl ether is difficult. We have little information about ancestral and derived traits in *Callosamia*, and estimates of genetic distance from allozyme electrophoresis (Johnson et al., 1996) indicate that the three species are essentially equidistant from each other. This is in contrast to our initial assumption that *C. securifera* was more closely related to *C. angulifera*, based on its historical placement as a subspecies of the latter by many taxonomists until the temporal reproductive isolating mechanism was described (Brown, 1972; Ferguson, 1972). Gene flow between the three species is prevented by diurnal separation of mating times: *C. securifera* females call in late morning, *C. promethea* in late afternoon, and *C. angulifera* mate after dark.

Although the physiological mechanisms controlling mating time are unknown, it would not be difficult to imagine that a relatively simple change may have produced more or less simultaneous isolation of the three species. It is conceivable that the inability of unadapated *Callosamia* to survive on sweetbay contributed to selection for mechanisms preventing hybridization between sweetbay feeding populations and those feeding on other hosts.

Compounds other than neolignans may also be involved in the chemical defenses of sweetbay magnolia, as a variety of biologically active compounds, such as phenolics, quaternary alkaloids, and sesquiterpene lactones have been isolated from other *Magnolia* and *Liriodendron* species (Doskotch and Flom, 1972; Rao and Juneau, 1975; Rao and Davis, 1982; El-Feraly and Yee-Ming, 1978; Barbosa et al., 1990). However, the biphenylpropanoids have been implicated as important determinants of the differential host use patterns of another group of Magnoliaceae and Lauraceae specialists, the *troilus* and *glaucus* lineages of the *Papilio* swallowtail butterflies (Nitao et al. 1992; Nitao 1995). The unsuitability of *M. virginiana* to *Papilio palamedes* and *P. troilus* appears to be linked to these neolignans, particularly magnolol, which reduces survival of neonates of both of these species but has no effect on *P. glaucus*, which utilizes the plant as a host in the southern part of its range. Interestingly, *P. troilus* is able to survive on leaves painted with the biphenyl ether, perhaps because similar chemicals in its lauraceous hosts (primarily sassafras and spicebush) endow it with behavioral or physiological preadaptations for biphenyl ether compounds (Nitao et al., 1992). This does not appear to be the case for *C. promethea*, which frequently feeds on the same Lauraceous hosts but clearly does not possess a similar tolerance for biphenyl ether compounds.

A better understanding of the specific biochemical/physiological adaptations of *C. securifera* to magnolol and the biphenyl ether and of the phylogenetic relationship of this species within the genus should improve our ability to evaluate the mechanisms and possible physiological trade-offs involved in the evolution of host plant specialization in the group.

Acknowledgments—This project would not have been possible without the generous support and advice of J. K. Nitao. We also thank M. P. Ayres, J. L. Bossart, D. A. Herms, R. C. Lederhouse, J. Miller, and H. Pavulaan for constructive discussion throughout the project. D. Bantz, D. Biddinger, J. Frey, T. Herig, M. Nielson, H. Pavulaan, R. Peerie, L. Simon, F. Stehr, J. Tuttle, and W. Westrake helped procure the insects needed for bioassays. Financial support was provided by National Science Foundation doctoral dissertation improvement grant BSR 9101121 to K.S.J., Sigma Xi, and the Hutson Research Fund at Michigan State University.

DISRUPTION OF MALE ORIENTAL FRUIT MOTH TO CALLING FEMALES IN A WIND TUNNEL BY DIFFERENT CONCENTRATIONS OF SYNTHETIC PHEROMONE

C. J. SANDERS* and G. S. LUCUIK

(Received August 28, 1995; accepted June 19, 1996

Abstract—Disruption of male Oriental fruit moth orientation to calling females was studied in a wind tunnel by surrounding calling female moths with septa loaded with synthetic pheromone. At the lowest loadings, 0.01 and 0.1 μg, which produced release rates well below those of calling females, some males flew to septa instead of the females. At loadings of 1 and 10 μg, which produced release rates close to those of a calling female, more than half the males flew to septa instead of the females, but there was little evidence of habituation at any of these loadings. At higher loadings, 100 and 1000 μg, upwind flight of males was arrested, and many males remained inactive, indicating habituation. Preexposure of the males for 3 hr to ambient pheromone concentrations in the tunnel had no significant effect on numbers of disrupted males. However, at the 1000-μg loading, most of the males that had been preexposed to the synthetic pheromone remained inactive. This may indicate a higher level of habituation than among males that had not been preexposed, most of which flew, although they subsequently showed flight arrestment. Levels of disruption were similar to those found for the spruce budworm in comparable experiments. In both species, less than 1% of the males were able to locate females when time-averaged concentrations of synthetic pheromone were above 20 ng/m^3. However, levels of inactivity and flight arrestment were higher among male Oriental fruit moths than among male spruce budworms, which may explain why Oriental fruit moths are more susceptible to disruption than are spruce budworms.

Key Words—Oriental fruit moth, sex pheromone, mating disruption, wind-tunnel tests.

INTRODUCTION

Synthetic pheromones are being used for the operational control of several lepidopterous pests (Cardé and Minks, 1995; and review in Ridgway et al., 1990). However, the exact manner by which the synthetic pheromone causes disruption is not known, which limits our ability to refine blends, dosages, application rates, and optimum types of formulation.

Wind tunnels provide a convenient method of examining insect behavior in response to pheromones under controlled conditions. In wind-tunnel experiments Sanders (1982, 1985, 1995, 1996) simulated field disruption of the spruce budworm [*Choristoneura fumiferana* (Clem.)], by surrounding calling female moths with dispensers of synthetic pheromone and then measuring the ability of male moths to locate the females. When the dispensers released synthetic pheromone at, or slightly above, the same rate as a calling female, a significant number of males flew to the synthetic sources instead of the females (false-trail following), but when males were left in the tunnel for a few hours they remained active and eventually located the females. This suggests that false-trail following by itself would not have prevented mating and that some other mechanism, such as habituation, is necessary to prevent males that have followed false trails from eventually locating the females. However, there was no evidence of habituation until release rates of synthetic pheromone from the disruptant dispensers were one or two orders of magnitude greater than release rates of natural pheromone by calling females (Sanders, 1985, 1995, 1996). This created a time-averaged atmospheric concentration of approximately 20 ng/m^3, which suggests that concentrations of synthetic pheromone should be maintained at least this high in the field to ensure effective mating disruption.

Mating disruption trials against the spruce budworm have met with limited success (Sanders and Seabrook, 1982; Seabrook and Kipp, 1986), which makes it difficult to compare wind-tunnel results with field results. Available evidence indicates that mating disruption becomes more effective the closer the synthetic blend is to the natural, female-emitted blend (Minks and Cardé, 1988). In the case of the spruce budworm, it is probable that the identified pheromone, a 95:5 blend of (*E*)-:(*Z*)-11-tetradecenal (Sanders and Weatherston, 1976; Silk et al., 1980), is incomplete (Alford et al., 1983; Sanders, 1984). Therefore, we have turned for comparisons to the Oriental fruit moth, *Cydia molesta* (Busck), a species that has been thoroughly researched, has a well-identified pheromone, and is successfully controlled by mating disruption in many parts of the world (Rothschild and Vickers, 1991). The pheromone was identified by Cardé et al. (1979) as a four component blend: (*Z*)-8-dodecenyl acetate, (*E*)-8-dodecenyl acetate, (*Z*)-8-dodecen-1-ol, and dodecanol. Numerous experiments have shown that a three-component blend, lacking the dodecanol, at the same concentrations as those released by calling virgin moths, elicits the full suite of mating behaviors

and that all three components in the appropriate ratios are necessary for optimum responses (Baker and Cardé, 1979a; Baker et al., 1981; Linn et al., 1986, 1987). Charlton and Cardé (1980) found that septa loaded with 100 μg of the three-component blend outperformed three caged virgin females, and Rothschild (1974, 1975) found that virgin female moths outcompeted both closed polyethylene caps loaded with 100 μg and polyethylene microcapillary tubes loaded with 50 mg of (*Z*)-8-dodecenyl acetate but that contained lower than optimum amounts of the other two components. No direct comparisons have been made between the potency of virgin female Oriental fruit moths and septa loaded with a range of concentrations of the synthetic pheromone. However, Witzgall (1996) has presented evidence from wind-tunnel observations that responses to females differ from responses to the synthetic blend, which suggests that the synthetic blend is not the exact equal of the female-produced pheromone. With this in mind, evaluations of the effectiveness of mating disruption should be carried out with calling female moths, and not just synthetic pheromone sources.

In an effort to further our understanding of why mating disruption has been limited in its success against the spruce budworm and what the mechanisms of disruption are in general among the Lepidoptera, we carried out experiments with the Oriental fruit moth in our wind tunnel. We compare the results with previous work with the spruce budworm (Sanders, 1996), which determined the ability of males to locate caged virgin female moths that were surrounded by dispensers emitting synthetic pheromone.

METHODS AND MATERIALS

Insects. The insects were provided by Dr. R. M. Trimble and staff of the Vineland Research Station of Agriculture and Agri-food Canada, Vineland Station, Ontario, Canada, from laboratory rearing stock established in the early 1970s with insects obtained from the Niagara peninsula (Trimble, personal communication). Larvae were reared on green thinning apples at the Vineland Research Station following the techniques described by Pree (1985). The mature larvae were provided with strips of corrugated cardboard that the larvae enter when ready to pupate. The cardboard strips containing larvae and pupae were then sent in insulated containers to the Sault Ste. Marie laboratory of the Canadian Forest Service. Here the pupae were sexed, and the male and female pupae were placed in separate cages in separate rooms, each maintained at 21°C and 70% relative humidity. Moths were collected daily and placed in 30-cm × 20-cm × 30-cm-high cages to await the experiments. Both male and female moths were kept on 17 L:7 D cycles. For the males scotophase was 20:30–03:30 hr. For the females scotophase was advanced to 15:00–22:00 hr to program them to be actively calling while the experiments were carried out (Baker

and Cardé, 1979b; Lacey and Sanders, 1992). The cages were sprayed with a water mist each day to provide drinking water for the moths.

Chemicals. Rubber septa (A. H. Thomas, Philadelphia, Pennsylvania; catalog No. 1780J07) that had previously been extracted with ethanol by the technique of Steck et al. (1979) were used to dispense the disruptant chemicals. Synthetic Oriental fruit moth pheromone was obtained from Bedoukian Research Inc. (Danbury Connecticut), identified as: "product P900, Bedoukian Oriental fruit moth Technical Pheromone, 93% (*Z*)-8-dodecenyl acetate, 6% (*E*)-8-dodecenyl acetate and 1% (*Z*)-8-dodecenol." A stock solution of 1 mg/ml in cyclohexane was then prepared, and this was serially diluted to provide solutions containing the appropriate quantities of the synthetic pheromone. Aliquots of 100 μl of these solutions were pipetted into the rubber septa to provide the required loadings.

Release rates of the synthetic pheromone from these septa can be calculated using the formulae:

$$R = M * 1/t^{1/2} * \log_n 2$$

and

$$M = M_o e^{(-t * 1/t^{1/2} * \log_n 2)}$$

(Butler and McDonough, 1979) where R is the release rate, M_o is the amount of pheromone loaded into the septa, M is the amount of pheromone remaining in the septa at the start of the observation period, and $t^{1/2}$ is the half-life of the active ingredient, which in the case of *Z*8–12:OAc is 36.8 days (McDonough and Butler, 1983; McDonough et al., 1989). Calculated release rates per septum after five days for septa loaded with 0.01, 0.1, 1, 10, 100, and 1000 μg of *Z*8–12:OAc were 7.1 pg/hr, 71.4 pg/hr, 714 pg/hr, 7.1 ng/hr, 71.4 ng/hr, and 714.0 ng/hr, respectively. These figures are approximately three times higher than emission rates from rubber septa obtained by Baker et al. (1980) by direct measurement of adsorption on glass surfaces.

Wind Tunnel. The wind tunnel used in these experiments has been described previously (Sanders, 1982). It is constructed of plate glass and is 90 cm × 90 cm in cross section and 2 m long. Wind speed was about 50 cm/sec and the light intensity about 35 lux. For these experiments, as with previous experiments on spruce budworm (Sanders, 1996), a sheet of plate glass was mounted horizontally in the tunnel as an artificial floor, separating the tunnel vertically into two equal halves. A wire frame was placed in the top half with 16 locations marked on it for mounting the rubber septa. These were positioned in four rows, A, B, C and D, which were 100, 124, 148, and 172 cm from the downwind end of the tunnel, respectively. Rows A and C had six septa in a 2 × 3 grid, the top three septa were 10 cm from the roof, the bottom 10 cm up from the floor, with two septa on the centerline of the tunnel and the others 12.5 cm in

from the sides. Rows B and D had two septa, each positioned at mid-height of the half tunnel, 30 cm in from opposites sides. Each septum was backed by a square of paper, 2.5 × 2.5 cm, to create a turbulent plume.

Methods. At 11:00 hr on the day of each experiment, rubber septa loaded with the appropriate concentration of the synthetic pheromone were pinned to each of the 16 locations on the wire frame in the upper half of the tunnel. At the same time, two 2-day-old virgin females were placed in small screen cages, 3 cm in diameter and 2.5 cm long, which were positioned on a stand in the upper half of the tunnel within the array of rubber septa, 30 cm from the upwind screen, halfway between the artificial floor and the roof, and 30 cm in from one side of the tunnel. Also at 11:00 hr on the day of each experiment, ca. 30 2-day-old males were placed individually in small screen cages, half of which were placed on a rack in the lower half of the tunnel, the other half on a rack in the upper half of the tunnel. The males in the upper half of the tunnel were placed on the opposite side of the tunnel to the target females. This ensured that they were not exposed to the plume from the target females, although they were continually exposed to synthetic pheromone from the septa.

Starting at 14:00 hr, the cages containing the males were moved one at a time directly downwind of the target females, 30 cm in from the end of the tunnel. The lid was removed from the cage and the following behaviors of each male were recorded and timed: (1) wing-fanning, (2) taking flight, (3) locking on to the female plume and passing a point 50 cm from the downwind end of the tunnel, (4) proceeding upwind past a point 100 cm from the downwind end of the tunnel (row A of the septa), and (5) landing on a septum or the cages housing the female moths. Each male was allowed 1 min to respond, and each assay was terminated if the male landed on an inside surface of the tunnel and remained inactive for >10 sec.

Analyses. Comparisons of numbers of males responding were carried out by the G test for homogeneity (Sokal and Rohlf, 1981). Comparisons among response times were carried out by first transforming the data to logarithms, which normalized the distributions, and then subjecting the transformed data to multivariate analyses, using the Minitab GLM procedure (Minitab Inc., State College, Pennsylvania). Standard deviations were calculated from the untransformed data.

RESULTS

Responses to Single Lures and Females with No Background of Synthetic Pheromone

Maximum levels of response were evoked by septa loaded with 1 or 10 μg of the synthetic pheromone, and these were not significantly different from

TABLE 1. PERCENTAGES OF MALE ORIENTAL FRUIT MOTHS RESPONDING IN WIND TUNNEL TO TWO CAGED, VIRGIN FEMALE MOTHS OR TO SINGLE RUBBER SEPTA LOADED WITH DIFFERENT AMOUNTS OF SYNTHETIC PHEROMONE[a]

response levels to the two caged virgin female moths (Table 1). At lower loadings, 0.01 and 0.1 μg, the number of moths wing-fanning in response to the septa declined significantly. Furthermore, among those males that did wing-fan in response to the two lower loadings, the latency period until the start of wing-fanning was longer than in response to either the caged females or to the higher loadings of synthetic pheromone; there was also a tendency for the males to fly upwind more slowly in the presence of the lower loadings (Table 2). Above the optimum loadings, significantly more males showed arrestment of upwind flight, which resulted in the moths veering off to the inside surfaces of the wind tunnel without reaching the pheromone sources (Table 1). Again there was a tendency for the males to fly more slowly as the loadings of synthetic pheromone increased above the optimum (Table 2).

Responses in the Presence of Backgrounds of Synthetic Pheromone

Wing-Fanning. Most of the males that had been kept in the lower half of the tunnel in pheromone-free air (naive males) wing-fanned immediately when moved to the upper half of the tunnel, downwind of the target females, regardless of the background concentration (Tables 3 and 4, Figure 1). Among the experienced males that had been preexposed to synthetic pheromone in the top half of the tunnel, most responded immediately at the lower concentrations (10 μg and lower), but at the higher concentrations significantly fewer wing-fanned,

and those that did wing-fan took significantly longer to respond (Tables 3 and 4, Figure 1).

Success in Locating Females. The numbers of males able to locate the female moths decreased as the concentration of synthetic pheromone in the septa was increased (Table 3, Figure 1), but the decreases were not significant until loadings were greater than 1 μg/septum (time-averaged atmospheric concentration 20 pg/m^3). At a loading of 1000 μg (time-averaged atmospheric concentration about 20 ng/m^3), virtually no males reached the virgin females (i.e., disruption was complete).

At the lower loadings (10 μg/septum or less) those males that did not locate the females went to septa instead (i.e., false-trail following). However, at the two highest loadings, 100 and 1000 μg/septum, the majority of the disrupted males were either inactive and did not fly, or if they flew they ceased upwind flight and eventually flew to the sides of the tunnel without reaching either septum or females. In this there were significant differences in behavior between the experienced and naive males. The majority of the naive males at both the 100- and 1000-μg loadings took flight but failed to sustain upwind flight. The same pattern occurred among the experienced males with the 100-μg loading, but at the 1000-μg loading the majority of experienced males remained inactive and did not take flight. Among both naive and experienced males the durations of flight before the males alighted on the inner surface of the tunnel were significantly shorter at the 1000-μg loading than at the 100-μg loading.

[a]Half the males were exposed in the wind tunnel to the ambient pheromone conditions for 3 hr before assays (experienced males), the other half (naive males) were kept in pheromone-free air. Numbers in the same column followed by the same letter are not significantly different (G^2 test of homogeneity, $P = 0.05$).

DISCUSSION

In order to compare the results of these experiments on Oriental fruit moths with previous work on spruce budworms (Sanders, 1996), comparable data are required on release rates of the chemicals from the rubber septa. No direct measurements have been made of release rates of spruce budworm pheromone from rubber septa. Therefore, release rates were calculated by the Butler and McDonough (1979) method. Release rates of Z8–12:OAc, the major pheromone component of the Oriental fruit moth, calculated by the Butler and McDonough (1979) method, are approximately three times higher than those obtained by glass-surface adsorption by Baker et al. (1980). Reasons for these differences are not obvious. They may be because of differences in the characteristics of the septa or because the loaded septa used by Baker et al. (1980) were aged for

[a]Males were divided into two groups, one kept for 3 hr in presence of the ambient pheromone (experienced males), the other kept in pheromone-free air until exposure (naive males). Numbers in the same column followed by the same letter are not significantly different (Tukey's procedure, $P = 0.05$).

only 12 or 16 hr. However, for comparative purposes, the calculated release rates by the Butler and McDonough (1979) method will be used here.

When presented with single septa (i.e., a nondisruptive situation) in the wind tunnel, male Oriental fruit moths responded optimally to loadings of 1 or 10 μg, and the responses at these loadings were not significantly different from responses to two virgin female moths. These results conform well to previously published results with single septa. Baker et al. (1981), Baker and Haynes (1989), and Linn et al. (1988) all showed that the optimum loadings of synthetic Oriental fruit moth pheromone containing about 6% of the *E* isomer to be between 3 and 30 μg/septum for upwind flight of the male moths. Release rates from septa loaded with 1 and 30 μg, calculated by the Butler and McDonough (1979) method are between 1 and 20 ng/septum/hr, which spans the release rates of pheromone from calling female Oriental fruit moths (Baker et al., 1980;

Lacey and Sanders, 1992). The fact that the responses at the loadings of 1 or 10 μg were not significantly different from responses to two virgin female moths supports the conclusion that the three-component pheromone blend is very close in composition to the female-released blend.

Flight arrestment to single septa became significant at a loading of 100 μg and complete arrestment occurred at 1000 μg. Baker et al. (1981) and Linn et al. (1988) found significant arrestment at the 30-μg loading, with very high levels of arrestment at 100-μg and 300-μg loadings. These loadings correspond to calculated release rates of 70 ng/septum/hr, which is only three times that of the highest release rates recorded from individual female moths (Lacey and Sanders, 1992), and 700 ng/septum/hr, respectively.

In the case of the spruce budworm, optimal responses occurred with loadings of 1 μg up to 1000 μg/septum (Sanders, 1992). Furthermore, even at the highest loading tested against male spruce budworm, 1000 μg/septum, there was no evidence of flight arrestment (Sanders, 1992). The half-life of a 14-carbon aldehyde in a rubber septum is 43 days (Heath et al., 1986) and for (*Z*)-8-dodecenyl acetate, 36.8 days (McDonough et al., 1989). The release rates will therefore be very similar, which indicates that male spruce budworms can orient upwind in much higher concentrations of pheromone than can male Oriental fruit moths. However, there is evidence that the identified pheromone of the spruce budworm is incomplete (Alford et al., 1983; Sanders, 1984), and whether the same levels of behavior would occur in the presence of a complete pheromone blend remains to be seen.

The three-component synthetic pheromone blend of the Oriental fruit moth evokes the full suite of behavioral responses (Baker and Cardé, 1979a; Baker et al., 1981; Linn et al., 1986, 1987), which suggests that it is close to the natural pheromone. However, as the wind-tunnel observations of Witzgall (1996) have shown, there is the possibility that additional minor components remain unidentified. The ultimate question is whether or not male moths can locate calling females, not just rubber septa. Therefore, in both the previous experiments on the spruce budworm and those described here on the Oriental fruit moth, the ability of male moths to locate virgin female moths was used to assess

FIG. 1. Responses of male Oriental fruit moths in a wind tunnel to two female moths surrounded by rubber septa loaded with synthetic pheromone. The upper graph is of males kept in the upper half of the wind tunnel where they were exposed to the synthetic pheromone continually for 3 hr before being moved downwind of the two caged females (experienced males), the lower graph is of males kept in the lower half of the tunnel in pheromone-free air before being moved to the upper half, downwind of the two caged females (naive males).

disruption. As in the previous work on spruce budworms, effects on male Oriental fruit moths were concentration dependent. At release rates below those of calling female moths (the 0.01 and 0.1 μg loadings), there were no reductions in the numbers of males orienting to the females. At release rates approximating those of the calling females (the 1.0- and 10-μg loadings), males were still able to orient (i.e., there was no evidence of habituation), but as many or more males went to the septa as to the females, which confirms that at these loadings the septa were competitive with the females. When the females were surrounded by septa loaded with 100 or 1000 μg, disruption was almost complete and, as would be expected from the results with the single septa, most males were either completely inactive or their upwind flight was arrested, both of which indicate habituation.

Of particular interest is the fact that disruption measured as the reduction in numbers of male Oriental fruit moths reaching the females was not significantly different between the experienced and naive males for any of the loadings of synthetic pheromone. However, significantly more experienced males remained completely inactive at the higher loadings than did naive males. This indicates that exposure of male Oriental fruit moths to ambient pheromone for a few hours increases the level of habituation as was shown by Figueredo and Baker (1992), and as was also found in similar experiments with the spruce budworm (Sanders, 1996).

Field trials have indicated that the spruce budworm is not as susceptible to mating disruption as the Oriental fruit moth (Sanders, 1979; Sanders and Seabrook, 1982; Vickers, 1990; Rice and Kirsch, 1990; Rothschild and Vickers, 1991). The major difference in the behavior of the two species in these wind-tunnel experiments is the high levels of habituation (inactivation and flight arrestment) among the Oriental fruit moth males in the presence of septa loaded with 100 and 1000 μg compared to the spruce budworm (Figure 2), where at the same loadings few male spruce budworms showed evidence of habituation.

It is now well established that successful upwind orientation by male moths to pheromone sources depends upon fluctuations in pheromone concentration caused by air turbulence (e.g., Baker and Haynes, 1989; Vickers and Baker, 1994; Mafra-Neto and Cardé, 1995). Moreover, pulsing signals are more effective than continuous signals in causing habituation (Bartell and Lawrence, 1976; Kuenen and Baker, 1981). It is also probable that in any operational mating disruption program there will be fluctuations in concentrations of the synthetic pheromone that allow male moths to successfully orient and fly upwind (false-trail following). In recognition of this, turbulence was deliberately created in these wind-tunnel experiments. Unfortunately, the measurement of instantaneous pheromone concentrations in turbulent air is not simple (e.g., Rumbo et al., 1995), and for designing mating disruption programs it is more practical to

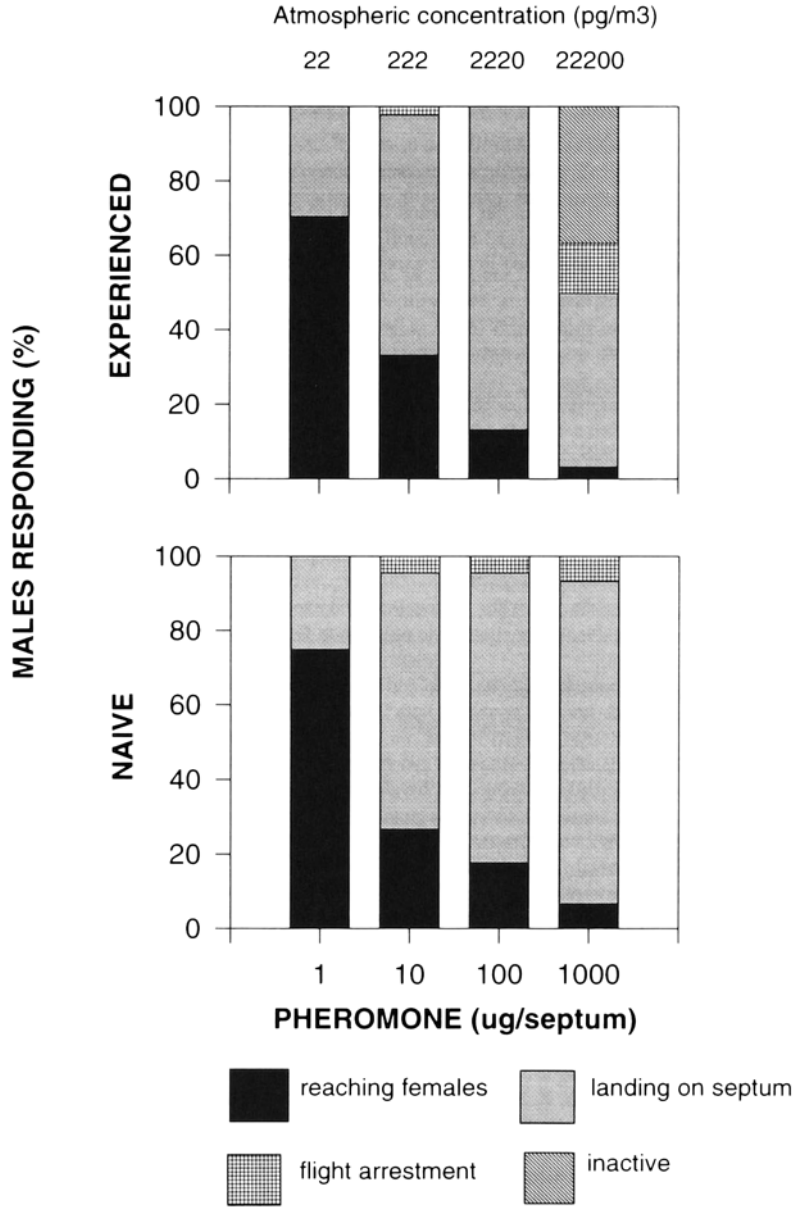

FIG. 2. Responses of male spruce budworm moths in a wind tunnel under the same conditions as those for oriental fruit moth in Figure 1. Modified from Sanders (1996).

define time-averaged concentrations with the assumption that turbulence will create the necessary fluctuating signals. The results with the spruce budworm (Sanders, 1996) and also with the Oriental fruit moth reported here suggest that for effective disruption, time-averaged atmospheric concentrations of synthetic pheromone must exceed 20 ng/m^3.

Acknowledgments—We would like to thank Dr. R. M. Trimble, Agriculture and Agri-food Canada, Vineland Station, Ontario, and his support staff, Patricia Vickers and Cheryl Tyndall, for rearing and supplying the moths used in these experiments and for maintaining a steady supply of such excellent quality insects.

(Received September 1, 1995; accepted June 20, 1996)

Abstract—The presence of deleterious secondary metabolites to western flower thrips (WFT) (*Frankliniella occidentalis* Pergande) in several chrysanthemum (*Dendranthema grandiflora* Tzvelev) cultivars was tested. WFT performance on leaf sap mixed with artificial diet was compared to WFT performance on a control of artificial diet mixed with water. Leaf sap of six of 10 chrysanthemum cultivars tested had a significant negative effect on WFT performance and therefore contained deleterious secondary metabolites. Leaf sap of a resistant and a susceptible chrysanthemum cultivar were fractionated by gel to study the role of secondary metabolites in greater detail. None of the 20 individual fractions obtained had a negative effect on WFT performance, whereas after mixing of these fractions activity was found again. Moreover, WFT performance on the fraction mixture of the resistant cultivar was significantly lower than on the susceptible fraction mixture. The results suggest that WFT resistance in the cultivars studied was caused by several secondary metabolites that had an additional or synergistic negative effect on WFT performance. The role of a deficiency of primary metabolites in WFT resistance of chrysanthemum was also investigated. WFT performance on leaf sap with and without extra primary metabolites (artificial diet) was compared. The variance in WFT performance was significantly smaller when extra primary metabolites were added; WFT performance on leaf sap with and without extra primary metabolites was not correlated. The results suggest that resistance was partly caused by a deficiency of primary metabolites.

Key Words—Chrysanthemum, *Dendranthema grandiflora*, western flower thrips, *Frankliniella occidentalis*, host plant resistance, chemical defense, artificial diet, synergism, primary metabolites, secondary metabolites.

INTRODUCTION

In chrysanthemum (*Dendranthema grandiflora* Tzvelev) 76% of the variation in resistance among cultivars to western flower thrips (WFT) (*Frankliniella occidentalis* Pergande) could be explained by the variation in chemical composition of the leaves (De Jager et al., 1995b). This was concluded from a highly significant positive correlation found between WFT performance on intact leaves and on leaf sap of 10 different chrysanthemum cultivars. The compounds responsible for WFT resistance are unknown.

The majority of the studies that have been reported on the chemical mechanisms of insect resistance are concerned with single compounds or single classes of compounds that deter insect feeding (Berenbaum and Zangerl, 1992; Rosenthal and Berenbaum, 1991; Kennedy and Barbour, 1992). Two major problems are involved with this single compound approach. First, because many different chemical compounds are known to have a deleterious effect on insect performance, it is difficult to select only one particular compound to study the mechanism of insect resistance (Berenbaum and Zangerl, 1992). Second, some studies proved additional or even synergistic effects between different compounds that can easily be overlooked when single compounds are studied (Berenbaum and Neal, 1985; Stadler and Buser, 1984; Hay et al., 1994). We prefer to start with total plant extracts that are fractionated until the chemicals responsible for insect resistance are identified (Lewis and Van Emden, 1986).

Primary metabolites are generally beneficial and may also be involved in insect resistance if they occur in limiting concentrations (Bernays and Chapman, 1994; Slansky, 1992). Therefore, along with secondary metabolites, the role of primary metabolites also should be studied.

In this study, the mechanism of chemical resistance to WFT in chrysanthemum was investigated. First, the role of deleterious secondary metabolites was studied by measuring WFT performance on leaf sap of several chrysanthemum cultivars mixed with artificial diet. In more detailed analyses, leaf sap of a resistant and a susceptible cultivar was fractionated by means of gel filtration and WFT performance on the different fractions was measured. Relative larval growth and survival after three days were used as measures of WFT performance. These parameters had proved to be quick and reliable measures (De Jager et al., 1995b). To study the role of primary metabolites in WFT resistance, performance of WFT larvae on leaf sap with and without extra primary metabolites (artificial diet) was compared.

METHODS AND MATERIALS

Plant and Insect Source. Ten chrysanthemum cultivars covering a large range in resistance were selected for the experiments (De Jager et al., 1995a). The cultivars, referred to as cv. 1, 2, 3, 5, 6, 9, 11, 14, 15, and 31, were coded by the breeding companies Fides Research and Breeding B.V. (De Lier, The Netherlands) and Chrysanthemum Breeder Association N.V. (Ter Aar, The Netherlands).

Commercially produced chrysanthemum cuttings were dipped in Savona (a nonpersistent mixture of natural fatty acids; Koppert, Berkel en Rodenrijs, The Netherlands) to kill pest insects. Next, the cuttings were dipped in Rapid root 1 (rooting powder with 0.1% 3-indolylbutyric acid; Koninklijke Brinkman, Maasland, The Netherlands) to stimulate root growth and planted in small compost blocks of 64 cm^3. Desiccation and burning of the cuttings were prevented by covering the cuttings with plastic and a layer of filter paper. This cover was removed after two weeks. The rooted cuttings were planted in 9-cm-diameter pots with a 3:1 compost-vermiculite mixture. Plants were placed at random in the growth room. From then on, the plants received 75 ml of nutrient solution (15:20:25 NPK; EC = 2 mS/cm) once a week. The plants were watered when necessary to keep the compost humid. The growth room with mercury lamps (27 W/m^2) was programmed for a 16L:8D photoperiod, 20°C, and a relative humidity of 70%. After four weeks, light conditions were changed from long day length to short day length (8L:16D) as is the practice in chrysanthemum breeding to induce flowering.

The laboratory colony of WFT used for the experiments was reared for several months on the flowers of a susceptible cultivar (cv. 8), grown under commercial greenhouse conditions. For verification of the thrips species, a sample of the laboratory colony was regularly sent to G. Vierbergen, a thrips specialist of the Plant Protection Service (Wageningen, The Netherlands). The WFT were reared in a growth room with fluorescent lamps (58 W, white 33, Splendor), a 12L:12D photoperiod, 20°C continuously, and a relative humidity of 65%. For all experiments 0-to 1-day-old larvae were used. To obtain these larvae, fresh flowers were put in the rearing cages six days before the beginning of the experiments. At the beginning of the experiment, the flowers were torn apart and the first instars were collected.

Artificial Diet. A multiorder diet as described by Singh (1983) was modified to prepare a liquid artificial diet on which WFT could feed and grow. We only used the soluble ingredients of the multiorder diet (Table 1) since that would facilitate the ingestion of the food by WFT. The diet was prepared at a concentration two times higher than described by Singh (1983). In tests it was mixed (1:1 v/v) with different extracts, which finally resulted in a concentration

TABLE 1. COMPOSITION OF ARTIFICIAL DIET FOR *F. occidentalis*

Group	Ingredient	Quantity (w/w)
1	Casein	7.0%
	Wesson's salt	2.0%
2[a]	Cholesterol	0.1%
	Linoleic acid	0.5%
3[b]	Vanderzant vitamin mix	4.0%
	Sucrose	6.0%
	Distilled water	80.4%

[a]Ingredients of group 2 were dissolved in 50 ml dichloromethane, mixed with group 1, and then dichloromethane was evaporated.
[b]Ingredients of group 3 were dissolved in H_2O, mixed with groups 1 and 2, and then the pH was adjusted to ca. 6.5 with 4.0 M KOH.

of the added soluble ingredients that was exactly the same as described by Singh (1983). To study the nutritional value of the artificial diet, WFT performance on artificial diet and other chrysanthemum diets was compared.

Secondary Metabolites. Twenty cuttings of each of the 10 selected cultivars were grown in a growth room as described in the first section. After five weeks, all leaves of 10 plants per cultivar were harvested and leaf sap was separated from the largest leaf fragments in a food processor. The leaf sap was stored for several days at −80°C. To test WFT performance on leaf sap with about the same concentration of leaf constituents as in intact leaves, the sap was concentrated twice by freeze-drying prior to mixing it (1 : 1 v/v) with artificial diet.

Leaf Sap Fractionation. One hundred cuttings of chrysanthemum cultivars 2 (resistant) and 15 (susceptible) were grown as described in the first section. After six weeks, the leaves of all plants were harvested and put in a food processor where the leaves were mashed to make leaf sap. Leaf sap could be collected from a cup at the bottom of the processor that was placed under a sieve. The leaf sap was stored for several weeks at −20°C.

Prior to fractionation a dose–response test was performed for both the resistant and the susceptible cultivar. A mixture of artificial diet and leaf sap (1 : 1 v/v), with final concentrations of 0.5, 1, and 2 times the starting concentration of leaf sap, was fed to WFT larvae in the bioassay.

Fractionation of leaf sap was performed by gel filtration. The gel filtration method was chosen because there was no knowledge of the type of chemical compound(s) causing WFT resistance in chrysanthemum. Gel filtration is a fast method to separate chemical compounds and gives a minimum chance of specific binding to the column. Moreover, it was possible to use water as eluent, which is the most common compound of leaves. Sixty grams of Sephadex LH-20 gel

(Pharmacia) was swollen in about 400 ml distilled water for one night at 4°C. The gel was poured in a column with a length of 45 cm and a diameter of 3 cm. The homogeneity and reproducibility of the packed column was confirmed with 15 ml of a solution of blue dextran (4.7 mg/ml) and NaCl (0.5 M). Water was used as eluent.

Leaf sap was centrifuged for 10 min at 18,000*g* at room temperature to remove leaf particles. Leaf sap of cv. 2 and cv. 15 was concentrated 6.9 and 7.9 times, respectively, by freeze-drying. The concentrated sap (8.7 g of cv. 2 and 7.6 g of cv. 15) was placed on top of the gel for fractionation. Water was used as eluent and 30 fractions of about 15 ml each were collected and weighed. The fractionation was performed at 4°C. Absorbance was measured at 280 nm. On the basis of the absorbance it was decided to measure the effect on larval performance of fractions 6–25 of cv. 2 and 6–23 of cv. 15. During fractionation of cv. 2, a precipitate was formed on top of the column. The leaf sap was allowed to enter the column and was eluted with about 60 ml water, after which the precipitate was removed. The effect of all fractions and the precipitate on WFT performance was tested as described in the bioassay section. One milliliter of all fractions was taken for the bioassay. The remains of the fractions were freeze-dried in order to determine the dry weight to fresh weight (DW/FW) ratio. With these ratios the concentration of leaf constituents tested was estimated to be about 0.7 and 0.8 times the concentration in intact leaves of cv. 2 and cv. 15, respectively.

The fractionation by gel filtration was repeated with minor changes. In the second experiment, 5 ml of 13.4 and 13.7 times concentrated leaf sap of cv. 2 and 15, respectively, was placed on top of the column. A precipitate was formed during fractionation of the leaf sap of both cultivars. To test whether any activity was lost during fractionation, a mixture was made with 1 ml of each of fractions 6–25, freeze-dried, and resuspended in 1 ml distilled water. The effect of this mixture of WFT performance was tested in the bioassay. Prior to the bioassay, the fractions were concentrated about twofold to obtain a higher concentration of leaf constituents compared to intact leaves. On the basis of the DW/FW ratio, the test concentrations of leaf sap finally were calculated to be 2.6 and 2.9 times the normal concentrations of leaf sap of cv. 2 and cv. 15, respectively.

Primary Metabolites. Leaf sap from the 10 chrysanthemum cultivars prepared for the secondary metabolite experiment was also used for the experiment on primary metabolites. WFT performance on leaf sap mixed with water or with extra primary metabolites (artificial diet) was tested as described in the bioassay section. By addition of the artificial diet, the concentration of primary metabolites (proteins, amino acids, and sugars) was estimated at about 5 to 8 times higher than in intact chrysanthemum leaves (Soldaat, 1991; Bernays and Chapman, 1994). To get a test concentration of all other leaf constituents that was about the same as in intact leaves, the leaf sap was concentrated twice prior to

mixing it (1 : 1 v/v) with water or artificial diet. The coefficient of variation (V) was calculated for the treatment with and without extra primary metabolites and differences were tested as described by Sokal and Rohlf (1981). In addition, a Pearson correlation coefficient was calculated between both treatments.

Bioassay. Special observation plates of clear plastic were used to study larval performance on different liquid media (De Jager et al., 1995b). A liquid medium was put in the small cups of the bottom plate and covered with maximally stretched parafilm. WFT are able to feed through parafilm (Teulon, 1992; De Jager et al., 1995b). A middle plate with six holes was placed on top of the parafilm to keep the WFT larvae separated. The middle plate was covered by a top plate.

The day before the start of the experiment, the test media were put in the observation plates and stored at 4°C. On the first day of the bioassay 30 first-instar WFT larvae were introduced on each medium in the observation plates. Next, the length of each larva was measured. After two days all surviving larvae were transferred to observation plates with fresh media because in preliminary experiments we found that the quality of the media decreased after two days. The length of surviving larvae was measured again after three days. The relative growth in three days (length on day 3 divided by length on day 0) and the percentage of surviving larvae after three days was calculated for each observation plate. Relative growth and survival per observation plate were multiplied to get a general measure of larval performance (De Jager et al., 1995b). Bioassays were performed under the same conditions as the WFT were reared.

In order to compare bioassays that were performed in different weeks, a control medium of artificial diet and distilled water was included in each bioassay and WFT performance was calculated relative to the control. Differences between the media in larval performance was tested by ANOVA followed by Duncan's multiple-range test. To test whether WFT performance was significantly lower on the fraction mixture of the resistant cultivar (cv. 2) than on the susceptible cultivar (cv. 15), an unpaired, one-tailed Student's t-test was used (Macintosh program: Statview 512+).

RESULTS

Artificial Diet. WFT performance on artificial diet and on several chrysanthemum diets was compared. Larval performance on artificial diet was higher than on chrysanthemum leaves and leaf sap (Table 2). However, WFT performed even better on chrysanthemum petals with or without pollen (Table 2). We expect that these differences in WFT performance were mostly related to the diets because all experiments were performed with the same laboratory colony of WFT under completely similar conditions (De Jager and Butôt, 1993; De Jager et al., 1995b).

TABLE 2. RELATIVE LARVAL GROWTH × SURVIVAL OF *Frankliniella occidentalis* AFTER THREE DAYS ON DIFFERENT CHRYSANTHEMUM DIETS AND ARTIFICIAL DIET

Diet	Relative growth × survival[c]	Source
Intact leaves[a]	1.11 ± 0.07 b	De Jager et al. (1995b)
Leafsap[a]	0.77 ± 0.15 a	De Jager et al. (1995b)
Petals[a]	1.60 ± 0.04 c	De Jager and Butôt (1993)
Petals + pollen[a]	1.81 ± 0.04 c	De Jager and Butôt (1993)
Artificial diet[b]	1.26 ± 0.04 b	Present paper

[a] Mean of four different cultivars (cv. 1, cv. 2, cv. 5, and cv. 6).
[b] Mean of the experiments presented in this paper.
[c] Means indicated with the same letter are not significantly different (ANOVA: $F = 23.44$, $P < 0.0001$).

Secondary Metabolites. WFT performance on leaf sap mixed with artificial diet differed significantly between cultivars and the control ($F = 2.18$, $P = 0.038$) (Figure 1). Compared to the control of artificial diet and water, the mixtures of diet and leaf sap of five resistant chrysanthemum cultivars (2, 3, 5, 9, and 11) and one moderately resistant cultivar (31) had a significant negative effect on larval performance. No effect on larval performance was found when artificial diet was mixed with the leaf sap of two highly susceptible cultivars (6 and 15) and two other moderately resistant cultivars (1 and 14).

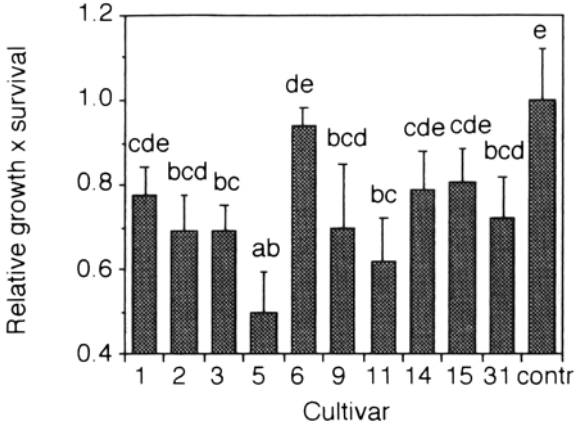

FIG. 1. Relative growth × survival (±SE) of *F. occidentalis* larvae after three days on leaf sap or water (control) mixed with artificial diet. Larval performance on 10 different chrysanthemum cultivars was compared. Means indicated with the same letter are not significantly different.

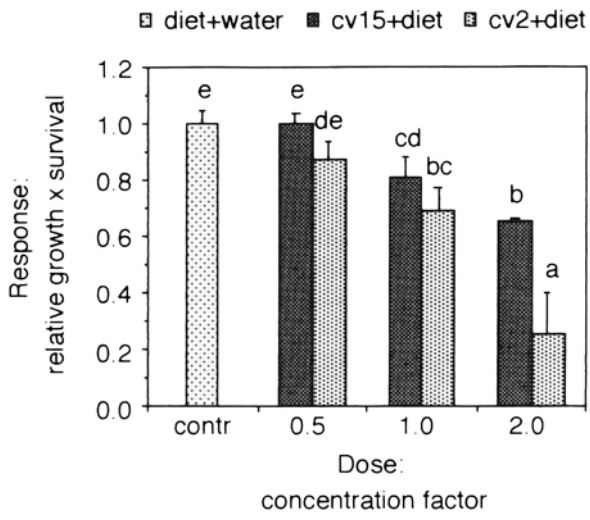

FIG. 2. Dose–response of *F. occidentalis* larvae on different dilutions of leaf sap mixed with artificial diet (1 : 1 v/v). The leaf sap of a resistant (cv. 2) and a susceptible (cv. 15) chrysanthemum cultivar was used.

Leaf Sap Fractionation. The results of the dose–response test of both the resistant and the susceptible cultivars are plotted in Figure 2. Significant differences in WFT performance were found among the different doses of leaf sap ($F = 12.4$, $P = 0.001$). Larval performance on the susceptible and the resistant cultivar only differed significantly when leaf constituents were concentrated twice compared to an intact leaf.

From the absorption patterns, it can be seen that the fractionation, both of the resistant and the susceptible cultivars, was reproducible (Figure 3). Relative larval growth × survial did not differ significantly among the individual leaf sap fractions after the first fractionation (cv. 2, $F = 1.13$, $P = 0.34$; cv. 15, $F = 0.97$, $P = 0.50$) (Figure 4). After the second fractionation, none of the individual fractions had an effect on WFT performance, although leaf constituents were tested in about a threefold higher concentration compared to the first fractionation (cv. 2, $F = 1.14$, $P = 0.33$; cv. 15, $F = 0.63$, $P = 0.88$) (Figure 4). The mixtures of fractions, however, had a significant negative effect on larval performance compared to the control (cv. 2, $F = 11.91$, $P = 0.001$; cv. 15, $F = 5.54$, $P = 0.001$). Larval performance was significantly lower on the mixture of the resistant cultivar than on the mixture of the susceptible cultivar ($t = 1.90$, $P = 0.047$).

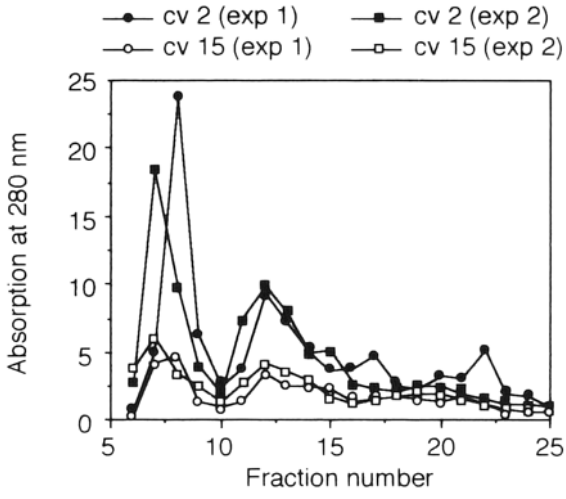

FIG. 3. Elution diagram obtained when leaf sap of a resistant (cv. 2) and a susceptible (cv. 15) chrysanthemum cultivar were fractionated. The leaf sap of both cultivars was fractionated twice (experiments 1 and 2).

Primary Metabolites. Relative growth × survival of WFT larvae differed significantly among cultivars between the treatments with and without extra primary metabolites [$F = 2.1$, $P = 0.039$ (cultivar); $F = 196.3$, $P = 0.001$ (treatment); $F = 1.1$, $P = 0.41$ (interaction)]. Addition of extra primary metabolites to chrysanthemum leaf sap had a positive effect on WFT perfor-

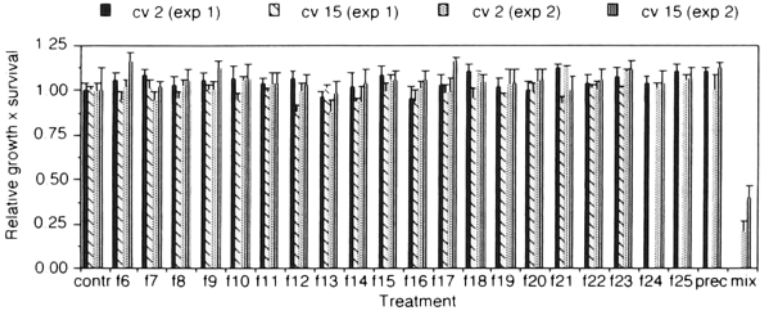

FIG. 4. Relative growth × survival (±SE) of *F. occidentalis* larvae measured on different chrysanthemum leaf sap fractions (f6–f25), a mixture of all fractions (mix), the precipitate (prec), and the control (contr). All these substrates were mixed with artificial diet. Leaf sap of a resistant (cv. 2) and a susceptible cultivar (cv. 15) were used.

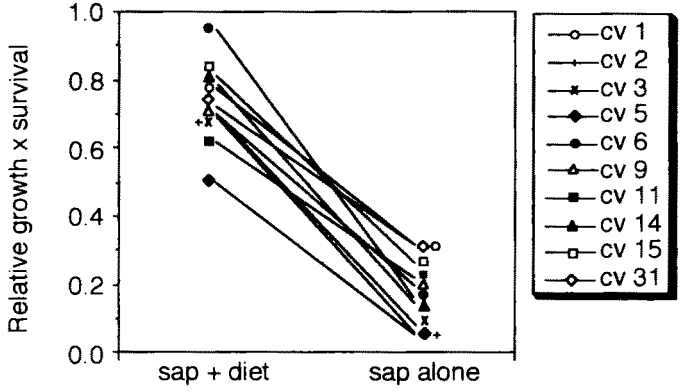

FIG. 5. Interaction between chrysanthemum cultivar and treatment (with or without primary metabolites) for relative growth × survival of *F. occidentalis* larvae.

mance. The variation in larval performance among cultivars was significantly lower ($F_s = 15.0$, $P < 0.05$) on leaf sap with extra primary metabolites ($V = 0.16$) than on leaf sap without extra primary metabolites ($V = 0.55$). The extent of the positive effect of primary metabolite addition depended on the cultivar (Figure 5). This resulted in a Pearson correlation coefficient between larval performance on both treatments that was not significant ($R = 0.16$, $P = 0.66$) (Figure 6).

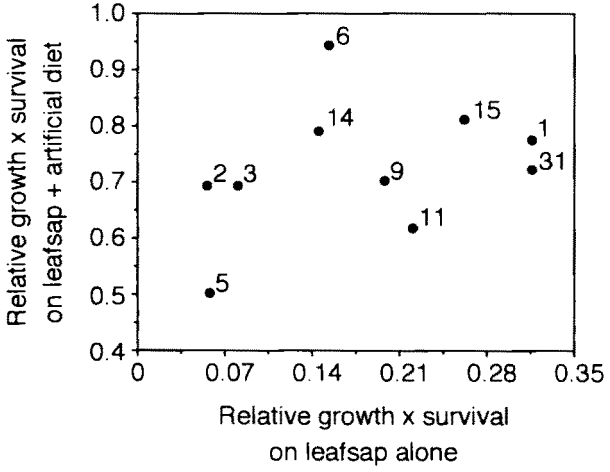

FIG. 6. Relation between WFT performance on leaf sap with and without extra primary metabolites (artificial diet). Leaf sap of 10 different chrysanthemum cultivars was used.

DISCUSSION

Leaf sap of six of 10 chrysanthemum cultivars had a significant negative effect on larval performance compared to the control. With exception of cv. 31, which is moderately resistant, intact plants of these cultivars are very resistant to WFT (De Jager et al., 1995b). Because the leaf sap was mixed with artificial diet, the negative effect could not be due to a deficiency of primary metabolites. Therefore, we concluded that deleterious compounds were present in these cultivars. For reasons of clarity, in this paper the term "secondary metabolites" is used to indicate these compounds.

None of the individual leaf sap fractions of both the resistant and the susceptible cultivars showed a negative effect on larval performance, whereas the fraction mixtures did. Moreover, larval performance on the mixture of the resistant cultivars was significantly lower than on the mixture of the susceptible cultivars. Again these effects could not be due to a deficiency of primary metabolites. Therefore, we concluded that different deleterious secondary metabolites were working additionally or synergistically in both the resistant and susceptible cultivars. The resistant cultivars appears to have more deleterious secondary metabolites than the susceptible cultivars.

The variation in resistance among cultivars was strongly reduced when extra primary metabolites in the form of an artificial diet were added. This suggests that differences between cultivars in WFT resistance were partly caused by a deficiency of primary metabolites. This agrees with the results of other studies [in rice to *Stenchaetothrips biformis* Bagnall (Thayumanavan et al., 1990); in cucumber, tomato, pepper, and lettuce to *F. occidentalis* (Mollema and Cole, 1995)]. Larval performance on leaf sap with and without extra primary metabolites was not significantly correlated. This suggests that the cultivars did not lack the same amount of primary metabolites because, if that had been the case, a positive correlation would have been found. This also suggests that the absence of primary metabolites was not related to the presence of deleterious secondary metabolites. This means that a cultivar that lacked primary metabolites independently did or did not contain deleterious secondary metabolites.

The artificial diet had a good nutritional value compared to chrysanthemum leaves and leaf sap, although feeding on petals with and without pollen resulted in a much better relative growth × survival (Table 2). The artificial diet proved to be very useful for measuring the activity of different chrysanthemum extracts to WFT larvae. The cultivars we used to perform the dose–response test differed strongly in resistance as intact plants (De Jager et al., 1995a). However, when leaf sap of both cultivars was mixed with artificial diet, significant differences in WFT performance were found only when leaf constituents at higher concentrations than in intact leaves were offered to the WFT. The activity of different chrysanthemum extracts mixed with artificial diet could best be measured in

about a twofold concentrated form compared to intact leaves. It must be kept in mind, however, that plant chemicals can have a different effect on insects when their test concentration is very different from the concentration in the plant (Lewis and Van Emden, 1986; Bernays and Chapman, 1994).

WFT resistance in chrysanthemum appears to be of a complex nature. The presence of different deleterious secondary metabolites and the absence of beneficial primary metabolites seemed to be involved. This agrees with observations that in chrysanthemum different genetic markers each explained only a low percentage of the variation in WFT resistance in a segregating F_1 family (F. Wolff, personal communication).

(Received December 15, 1995; accepted June 20, 1996)

Abstract—Four compounds have been identified as sex pheromone constituents of the scarab beetle *Anomala albopilosa albopilosa*, namely (*R*, *Z*)-5-(−)-(oct-1-enyl)oxacyclopentan-2-one (buibuilactone), 2-(*E*)-nonenol, 2-(*E*)-nonenal, and methyl benzoate (in the ratio 10:3:3:1). The diel rhythm of pheromone release in *A. a. albopilosa* showed a peak at the beginning of the scotophase, which is also a peak of mating activity. On the other hand, the similar species *A. cuprea* utilizes a two-constituent sex pheromone, having a common major component, but the pheromone is released both during scoto- and photophase. Temporal difference in mating activity and pheromone release along with chemical diversity seem to form the basis for maintaining species specificity in pheromonal communication between *A. a. albopilosa* and *A. cuprea*.

Key Words—Coleoptera, Scarabaeidae, GC-EAD, methyl benzoate, 2-(*E*)-nonenal, 2-(*E*)-nonenol, (*R*, *Z*)-5-(−)-(oct-1-enyl)oxacyclopentan-2-one.

INTRODUCTION

Despite the fact that some scarab beetles (Coleoptera: Scarabaeidae) in the subfamily Rutelinae utilize closely related or even the same sex pheromone compounds, temporal and/or geographical isolation plays an important role in isolating the sexual communication channel among these species. *Anomala cuprea* and *A. albopilosa sakishimana*, for example, use a mixture of two lactone compounds, buibuilactone and japonilure, but cross-attraction does not take place because the two species are geographically isolated. The former occurs on the mainland of the Japanese archipelago whereas the latter is restricted to Miyako Island in the south of Japan (Leal et al., 1994b). On the other hand, *A. octiescostata*, also occurring on the mainland, utilizes the same blend of lactones as *A. cuprea*, but they are seasonally isolated. The flight season of *A. octiescostata* is in early spring whereas that of *A. cuprea* occurs in summer (Leal et al., 1994a).

This scenario prompted us to investigate the pheromonal communication of *A. albopilosa albopilosa* Hope ("aodogane" in Japanese), a similar species that shares the same habitat and a common flight season with *A. cuprea*.

METHODS AND MATERIALS

Insects. Beetles were first collected in light traps inside Chiba Prefectural Agricultural Experiment Station. In order to start a laboratory colony, eggs laid by the field-captured females were collected daily and transferred to wet sand in ice cream cups, which were kept at 25°C. After hatching, grubs were transferred individually to ice cream cups filled with moist (or damp) leaf mold. Adults were fed on an artificial diet for wild silk moth (Nihon Chlorella Co.) at 25°C, 70% relative humidity, and 16L:8D photoperiod.

Collection of Insect Volatiles. Airborne volatiles of *A. a. albopilosa* adults, supplied only with syrup on pieces of cotton (or grape leaves), were collected on an all-glass aeration apparatus. This consisted of a 1-liter reaction flask and a two-necked flaskhead. A glass collector (1 cm ID) was packed to a depth of 1.5 cm with Super Q (Alltech, Deerfield, Illinois), which was held in place with glass wool. The collector was attached to the flaskhead with a ground glass reduction joint. The incoming air passed through similar glasss tubes packed with activated charcoal (1.2 cm ID, 30 cm) and Tenax TA (Alltech) (1 × 1 cm) and was bubbled into distilled water before entering the collection system. The reaction flask was placed inside an incubator maintained at 25°C and a 16L:8D photoperiod. The trapped materials were extracted with hexane, and the solutions were concentrated to 0.1 beetle-equivalents. In order to investigate the diel rhythm of sex pheromone release in *A. a. albopilosa*, aeration was carried out for 24 hr, with exchange of the trap columns every 2 hr.

Isolation of Pheromone. Volatiles collected from the headspace of virgin female beetles were subjected to flash column chromatography, on silica gel (Wako C-200) by successive elution with hexane–ether mixtures in the following order: 100:0, 95:5, 90:10, 80:20, 50:50, 0:100.

Indoor Bioassay. The attractancy of the synthetic sex pheromone blend was tested in a flight tunnel (4 × 1.5 m) operated at an airflow of 40 cm/sec, 0.9 lx, 78% relative humidity, and 26°C. Five experiments were conducted during the first 2 hr of the scotophase utilizing only males ($N = 5$) that were restless (the so-called "active males") at the time of the bioassays. Pieces (2 × 2 cm) of filter paper containing the synthetic blend or solvent only (control) were set in the upwind end of the tunnel at a height of 75 cm and 2.6 m away from the release point for the beetles. Males were placed individually inside the arena at a height of ca. 75 cm in a wire mesh platform and their behavior was observed for 20 min. After each assay, the test males were removed and clean air was passed through the wind tunnel at high speed for 10 min.

Analytical Procedures. Gas chromatography (GC) was carried out on a Hewlett-Packard 5890 II Plus instrument equipped with a split/splitless injector, electronic pressure control, a flame-ionization detector, and an HP 3365 Series II Chemstation. High-resolution GC analyses were performed with polar and nonpolar capillary columns: HP-Innowax and HP-5MS (30 m × 0.25 mm × 0.25 μm; Hewlett-Packard), respectively. These columns were operated at the following conditions: (1) 50°C for 1 min, increased to 180°C at a rate of 4°C/min, held at this temperature for 1 min, increased to 230°C at a rate of 10°C/min, and finally held at this temperature for 10 min; (2) 50°C for 1 min, increased to 120°C at a rate of 5°C/min, held at this temperature for 1 min, increased to 250°C at a rate of 10°C/min, and finally held at this temperature for 10 min; and (3) 70°C for 1 min, increased to 230°C at a rate of 10°C/min, and held at this temperature for 20 min. Chiral resolution was achieved on a γ-cyclodextrin-based capillary column, Chiraldex GTA (20 m × 0.25 mm × 0.25 μm; Astec, Whippany, New Jersey) operated at 150°C and 2.5 kg/cm^2 (flow rate 119 cm/sec; linear velocity 9.42 ml/min). Gas chromatography–mass spectrometry (GC-MS) was carried out either with an HP 5890 II Plus gas chromatograph linked to a mass selective detector MSD 5972 (Hewlett-Packard) or on a Hewlett-Packard gas chromatograph electron-ionization detector GCD Series. Chromatographic resolution was achieved on HP-5MS and HP-Innowax columns operated under the same conditions for GC.

RESULTS AND DISCUSSION

Analysis of airborne volatiles from male and female beetles fed only on syrup showed the occurrence of four female-specific compounds (Figure 1). The same chemical differences were observed when the beetles were fed on grape

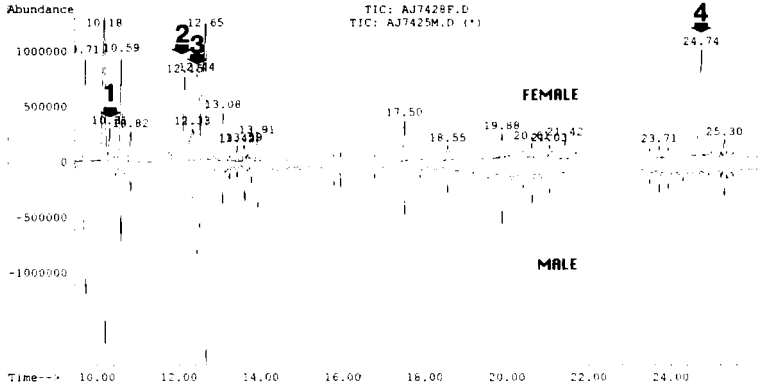

FIG. 1. Reconstructed total ion monitor chromatograms obtained from airborne volatiles of *A. a. albopilosa* virgin females (top) and unmated males (bottom).

leaves during the aeration, but the profiles were highly contaminated with compounds from the foodstuff. Utilizing a male antenna as the sensing element, GC-EAD showed that these four peaks were also EAD-active.

2,4-Hexadienoic acid, found in the extracts from both males and females, gave a distorted (leading edge) peak that interfered with detection of peaks 2 and 3 (Figure 1). This problem was overcome by collecting the airborne volatiles from females in a shorter time span (2 hr) during the time the insects were restless inside the aeration apparatus (first 2 hr after the lights went off). This gave a very clean GC-MS profile that corroborated the occurrence of only four female-specific compounds (Figure 2). Comparison of the retention times of the peaks in the male and female GC profiles may be misleading. Peak 3, for example, co-eluted with epoxilinalool (pyranoid type linalool oxide), which is produced by both male and female beetles (Figure 1). Mass spectral analyses along with the short time collection of volatiles overcame this problem and showed that in fact peak **3** is a female-specific compound.

Based on mass spectrometric data (Figure 3) and retention times on polar and nonpolar columns, the four female-specific compounds were identified as (**1**) methyl benzoate, (**2**) 2-(*E*)-nonenal, (**3**) 2-(*E*)-nonenol and (**4**) 5-(oct-1-enyl)oxacyclopentan-2-one [(*R*-buibuilactone]. We have identified the pheromone glands of scarab beetles in the subfamily Rutelinae, and the four constituents of the sex pheromone system for *A. a. albopilosa* were obtained also by direct extraction of these sex pheromone glands (Tada and Leal, unpublished data).

Two of these compounds have been previously identified as sex pheromone constituents of other scarab species. 2-(*E*)-Nonenol is a sex pheromone of *A.*

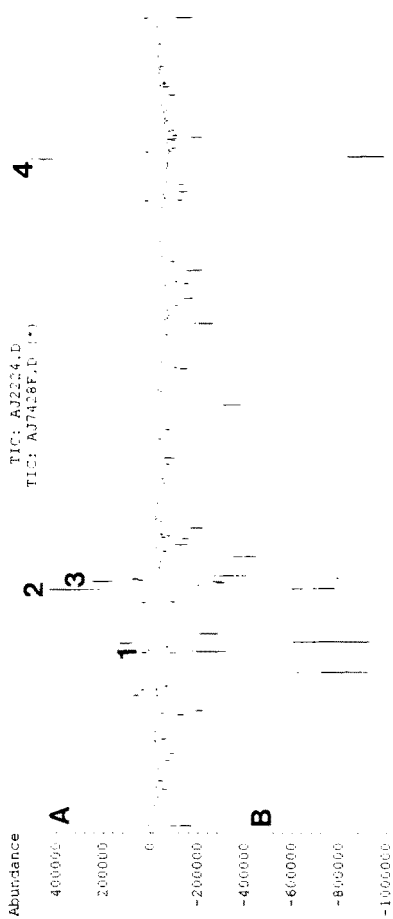

FIG. 2. Reconstructed total ion monitor profiles of the extracts of *A. a. albopilosa* virgin females collected only during hours 2 and 4 at the beginning of the scotophase (A) and for 24 hr (B).

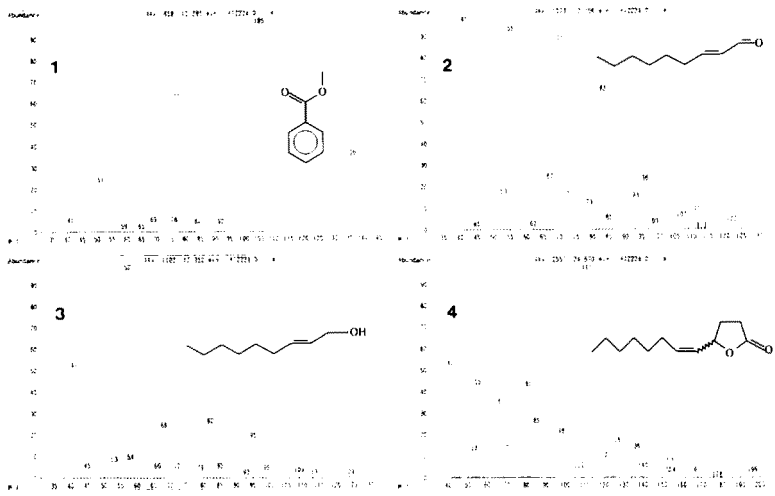

FIG. 3. Mass spectra of the four female-specific compounds identified as the sex pheromone constituents of *A. a. albopilosa*.

schonfeldti (Leal et al., 1992) and a minor constituent of the sex pheromone system of *A. daimiana* (Leal et al., 1993a). Buibuilactone, on the other hand, has been identified as a major constituent of the sex pheromone system of *A. cuprea* (Leal, 1991), *A. octiescostata* (Leal et al., 1994a), and *A. albopilosa sakishimana* (Leal et al., 1994b) as well as a minor component for *A. daimiana* (Leal et al., 1993a). In all these pheromonal systems, the natural buibuilactone had the *R* configuration. Chiral analysis of the natural product isolated by flash chromatography showed that buibuilactone from *A. a. albopilosa* also had the same stereochemistry (Figure 4). The double-bond configuration was assigned by comparison of retention times of the natural product with those of synthetic (*R*, *Z*)- and (*R*, *E*)-buibuilactone. On the basis of all data, peak 4 was fully identified as (*R*, *Z*)-5-(−)-(oct-1-enyl)oxacyclopentan-2-one.

The sex pheromone system of *A. a. albopilosa* is, thus, a multicomponent system. Typically, the ratio of the four constituents was 10:3:3:1 for (*R*)-buibuilactone, 2-(*E*)-nonenal, 2-(*E*)-nonenol, and methyl benzoate. The sex pheromones of rutelines are likely fatty acid derivatives (Leal, 1996), but methyl benzoate is an exception.

The behavioral response of males to a synthetic blend of the sex pheromone was observed in a flight tunnel (Table 1). Males transferred to the platform inside the flight tunnel exhibited a sequence of behavior in response to the synthetic sample. They extended their antennae with open lamellae, oriented

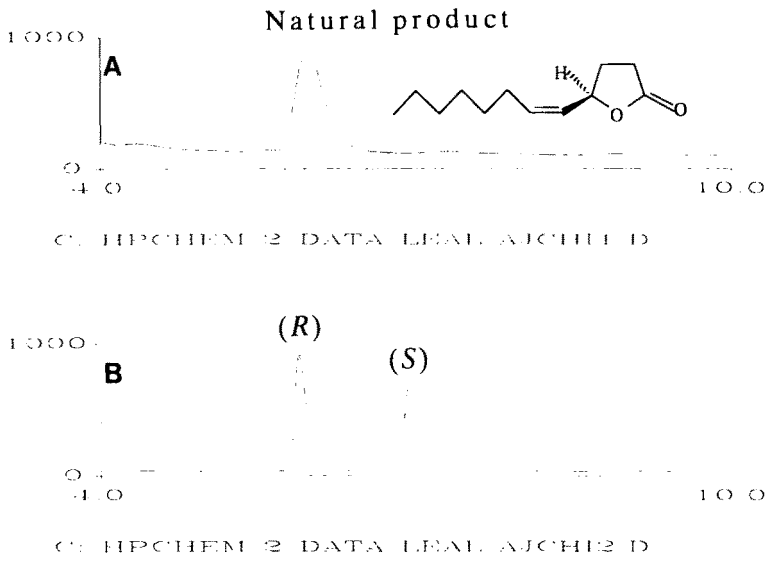

FIG. 4. Enantiomeric resolution of buibuilactone on a chiral column, Chiraldex GTA. (A) Natural product (splitless injection); (B) racemic mixture (split injection). The broader peak of the natural lactone than that of the synthetic counterpart is due to the effect of a higher solvent volume loaded on the column with the diluted natural sample.

with upwind flight, and landed on the pheromone source. After landing on the pheromone-impregnated filter paper, males searched the source with their heads very close to the source while performing abdominal movements typical of precopulatory behavior (attempting to copulate with the pheromone source). Some of the males that left the pheromone source (including those that fell down

	Control	Pheromone[a]
Took flight	20	100
Touched source	0	96
Left source and returned	0	64
Searched on source and/or tried to copulate	0	60

[a](*R*)-buibuilactone + 2-(*E*)-nonenol + 2-(*E*)-nonenal + methyl benzoate (10:3:3:1, 1 μg = 2 FE).

during searching on the source) returned to the filter paper and started searching behavior again.

It took 3–10 min for males to reach the pheromone source after they were placed inside the arena. After locking onto the plume and proceeding in upwind flight, males were somehow attracted to the light, especially those that had left the source and were in a second flight towards the source.

Behavioral responses in a wind tunnel could not be quantified with the Japanese beetle (M. G. Klein, personal communication) and some other scarab species (Leal, unpublished data), but it has been successfully measured with other scarab species (Domek et al., 1990; Leal, 1991; Leal et al., 1992, 1993a, 1994a; Zhang et al., 1994). Nevertheless, in the present case, it has been very difficult to quantify differences in male responses to different ratios of pheromone blends not only in a wind tunnel, but also in field tests (Leal et al., 1994a). Development of more accurate bioassay(s) is needed to determine the optimum ratio of the four constituents of *A. a. albopilosa* sex pheromone system.

Although the differences in the pheromone chemistry of *A. cuprea* and *A. a. albopilosa* may play an important role in providing these two similar species with species-specific chemical signals, temporal isolation also seems to play an important role in providing isolated sexual communication channels for these two species. Female *A. cuprea* release sex pheromone both in scoto- and photophase in nearly equal amounts (Leal et al., 1993b), whereas *A. a. albopilosa* has a diel rhythm of pheromone release with a peak in the 2 hr at the beginning of the scotophase (Figure 5), although small amounts of the pheromone were also detected during the photophase. The peak of pheromone release coincided with the time females were restless (active) inside the aeration apparatus and were copulating in the rearing room. The pattern of pheromone release for the other three compounds was similar, but only the titer of the major constituent was measured.

Species specificity of the communication channel in some species is attained by temporal differences in mating activity. Flight and mating of the southern masked chafer, *Cyclocephala lurida*, begins at dusk and terminates about 2 hr later, while the peak activity of the northern masked chafer, *C. borealis*, occurs between midnight and 4 AM. Females of the two species produce a sex pheromone that is attractive to males of either species (Potter, 1980). GC-EAD experiments (unpublished data, in collaboration with Prof. Jerrold Meinwald) showed that *C. borealis* male antennae responded also to the sex pheromone released by *C. lurida* and provided further evidence that the two sympatric species share at least one sex pheromone component (Leal, unpublished data). The rhythm of pheromone release suggested that mating activity in *A. a. albopilosa* reaches a peak at the beginning of the scotophase, whereas *A. cuprea* seems to have a broader mating activity.

In conclusion, populations of *A. cuprea* and *A. a. albopilosa* utilize dif-

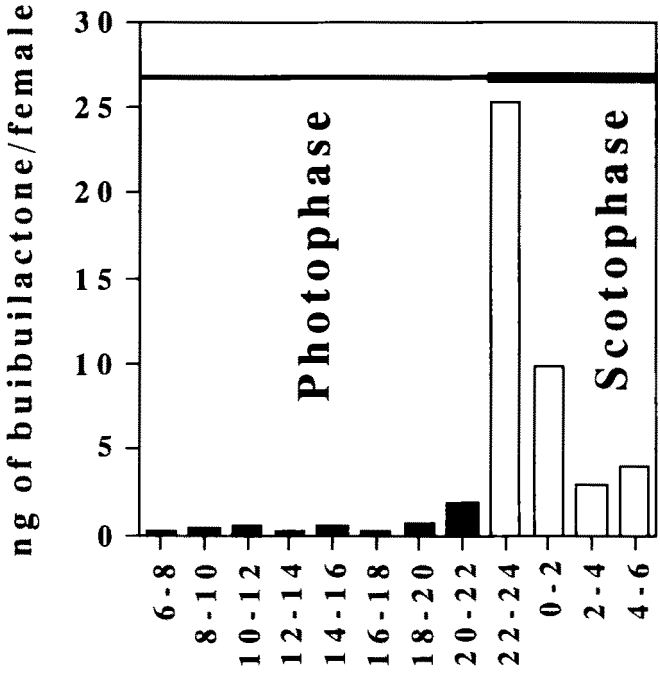

FIG. 5. Diel rhythm of *A. a. albopilosa* activity as demonstrated by the release of the major sex pheromone constituent. The profile of the other three constituents of the sex pheromone system showed a similar pattern.

ferent sex pheromone systems, with the latter having a more complex four-constituent blend. The two species have only one common constituent. This chemical diversity, along with the temporal difference in mating activity, seems to form the basis for maintaining species specificity in pheromonal communication between *A. a. albopilosa* and *A. cuprea*.

FOOD DEPRIVATION AFFECTS PREFERENCE OF SHEEP FOR FOODS VARYING IN NUTRIENTS AND A TOXIN

JIAN WANG and FREDERICK D. PROVENZA*

Department of Rangeland Resources
Utah State University
Logan, Utah 84322-5230

(Received January 2, 1996; accepted June 21, 1996)

Abstract—We investigated how food deprivation affected preference of lambs for foods that varied in concentrations of nutrients and a toxin. Thirty lambs (10 lambs/treatment) were fed different amounts of alfalfa pellets (high in protein, marginal in energy for growth) as a basal ration (20, 40, or 60 g/kg body weight). Every morning, prior to ingesting the basal ration of alfalfa pellets, each lamb was offerend three foods for 15 min. The foods contained different amounts of energy and a toxin, depending on the addition of barley (energy) and LiCl (toxin) to alfalfa. The proportions of barley and LiCl changed every five days during the 25-day study. The results showed: (1) all lambs preferred food that was high > intermediate > low in energy (barley) in the absence of LiCl, but all lambs decreased consumption of foods high in energy as LiCl concentrations increased; (2) the greater the level of food deprivation, the lower the consumption of foods containing LiCl, even if the foods provided high levels of energy; (3) lambs moderately food deprived or fed ad libitum ingested more LiCl than lambs that were highly deprived; and (4) lambs quickly (15 min/day) regulated intake of foods in response to changes in barley and LiCl concentrations. Thus, our results suggest that the interaction between nutritional status and toxicosis plays an important role in food preference of lambs. Our findings also suggest that toxic plants may kill herbivores that lack nutritious alternative foods not only because the animals are forced to be less discriminating, but also because they are more susceptible to toxins.

INTRODUCTION

Herbivores face challenges in attempting to forage because plant chemistry changes constantly as a result of changes in the environment (McKey, 1979; Gershenzon, 1984; Harborne, 1991; Bryant et al., 1992). For instance, changes in weather (e.g., frost, cloudy weather) can alter levels of toxins and cause normally innocuous forages to become toxic (Everist, 1981). Water stress and nitrogen fertilization also increase concentrations of toxic compounds (e.g., cyanogenic glycosides, alkaloids, phenolics, terpenes) in some plant species (Gershenzon, 1984). Conversely, many plant species that grow in fertile soils and in shade contain lower levels of feeding-deterrent metabolites and higher levels of nutrients than plants that grow on infertile soils and in sunshine (Bryant et al., 1983). Thus, herbivores must select diets from foods whose toxin and nutrient concentrations fluctuate constantly.

In addition to changes in plant chemistry, an animal's nutritional needs also change throughout its lifetime in response to changes in its physiological condition, and from meal to meal depending on the nutrient content of the foods it ingests. Macronutrients (i.e., energy and protein) play a primary role in nutrition and food preference. For instance, lambs strongly prefer food high in readily fermentable energy, and they acquire strong preferences even for poorly nutritious foods like straw when straw is eaten during intraruminal infusions of energy (Villalba and Provenza, 1996). Nonetheless, their food preferences depend on what they just ate. For instance, lambs fed a basal ration high in energy (grain) subsequently prefer food lower in energy and higher in protein (alfalfa); those fed a ration high in protein (alfalfa) subsequently prefer food high in energy (grain) (Wang and Provenza, 1996). Their preferences also depend on how long it has been since they ate. When lambs are food deprived overnight, they prefer foods high in energy (barley), regardless of whether or not their basal ration is high in energy or protein (Wang and Provenza, 1996). Nonetheless, lamb's preference for barley over alfalfa decreases immediately (1 hr) after eating a meal of barley, and the more barley eaten, the greater the decrease in preference (Phy and Provenza, 1996). Thus, preference for food high in energy or protein depends on whether or not a lamb just ate a meal high in energy or protein.

Most studies treat nutrient needs and toxin avoidance as separate processes, but the interaction between these factors may play an important role in food preference. Animals may select toxic foods high in nutrients, or they may reject nutritious foods containing toxins, depending on their nutritional status. Herbivores often eat nutritious foods that contain toxins, and their intake is limited by their ability to detoxify or tolerate the toxin, which may be related to their nutritional state (Freeland and Janzen, 1974; Lindroth, 1988; McArthur et al., 1991; Smith, 1992; Foley et al., 1995; Illius and Jessop, 1995). Lambs regulate nutrient (Wang and Provenza, 1996) and toxin (Wang and Provenza, unpub-

lished data) intake based on their physiological condition, but little is known about how nutritional status interacts with toxicosis to affect food selection. Our objective was to assess the effects of different levels of food deprivation on the preferences of lambs for foods containing different amounts of energy and a toxin. Our primary interest was to learn if lambs fed alfalfa (which is high in protein but marginal in energy for growth) would ingest food high in energy, even if the food contained a toxin.

METHODS AND MATERIALS

The experiment was conducted during June of 1994 at the Green Canyon Ecology Center near Utah State University in Logan, Utah. Lambs (average body weight of 28 kg) were crosses of Columbia, Rambouillet, Suffolk, Targhee, and Finnish Landrace breeds. At 3 months of age, 30 lambs were moved to adjacent individual pens (1.3 m × 2.7 m in size), where they had access to water and mineral blocks ad libitum throughout the experiment.

Determining Ad Libitum Intake. For two weeks prior to the trials, all lambs were fed alfalfa pellets ad libitum and the daily intake (24 hr) of pellets by each lamb was measured. Lambs ate an average of 1700 g of alfalfa pellets daily [about 60 g/kg body weight (BW)/day].

Levels of Food Deprivation. We varied level of food deprivation by offering lambs (10 lambs/treatment) different amounts of alfalfa pellets (1) 20 g/kg BW/day (one third of ad libitum intake); (2) 40 g/kg BW/day (two thirds of ad libitum intake); or (3) 60 g/kg BW/day (ad libitum intake). Treatment 1 (20 g/kg BW/day) provided enough energy to meet lambs' requirements for maintenance, but not for growth (NRC, 1985). These three levels of deprivation were maintained throughout the 25-day trial.

Trials. Ten days after imposing the food-deprivation treatments, lambs were offered 400 g each of three foods. Barley and LiCl were added to alfalfa to create foods: (1) high, (2) intermediate, and (3) low in energy and a toxin, respectively (Tables 1 and 2). Barley and alfalfa were ground and mixed uniformly. The proportions of barley and LiCl in foods 1 and 2 changed every five days during the 25-day trial. All three foods always contained the same total concentrations of NaCl plus LiCl (NaCl tastes similar to LiCl) (Hill and Mistretta, 1990).

Lambs were offered the three foods from 08:00 to 08:15 hr daily. Intake of each food was measured immediately after each preference test. The amount of alfalfa pellets provided to each lamb for the remainder of the day was adjusted on the basis of energy intake of the test foods to maintain the level of food deprivation constant within treatments. The test foods were provided in three

TABLE 1. FOODS OFFERED TO LAMBS DURING 25-DAY EXPERIMENT

Days	Foods offered (15 min/day)
1–5	1. 50% alfalfa + 50% barley
	2. 75% alfalfa + 25% barley
	3. 100% alfalfa
6–10	1. 50% alfalfa + 50% barley + 2% LiCl
	2. 75% alfalfa + 25% barley + 1% LiCl + 1% NaCl
	3. 100% alfalfa + 2% NaCl
11–15	1. 25% alfalfa + 75% barley + 2% LiCl
	2. 50% alfalfa + 50% barley + 1% LiCl + 1% NaCl
	3. 100% alfalfa + 2% NaCl
16–20	1. 25% alfalfa + 75% barley + 3% LiCl
	2. 50% alfalfa + 50% barley + 1.5% LiCl + 1.5% NaCl
	3. 100% alfalfa + 3% NaCl
21–25	1. 25% alfalfa + 75% barley
	2. 50% alfalfa + 50% barley
	3. 100% alfalfa

adjacent food boxes attached to the wire panels that comprised each pen. We changed the positions of the three foods daily.

Statistical Analyses. The analysis of variance was a factorial with repeated-measures (Hicks, 1993). There were three treatments (20, 40, or 60 g/kg BW/day of alfalfa pellets) and three foods (high, intermediate, and low in energy and a toxin). Animals (10/treatment) nested within treatments was the error term used to test for differences among treatments. Animals/treatments × food was the error term used to test for differences in foods and to test the food × treatment interaction. Day (five days of tests within each period) was the repeated

TABLE 2. DIGESTIBLE ENERGY (DE) AND DIGESTIBLE PROTEIN (DP) CONCENTRATIONS OF FOODS USED IN EXPERIMENT[a]

Foods	DE (Mcal/kg)	DP (%)
100% alfalfa	2.3	10.9
75% alfalfa + 25% barley	2.5	10.6
50% alfalfa + 50% barley	2.8	10.4
25% alfalfa + 75% barley	3.1	10.1

[a]Calculated values for DE and DP are based on the following values obtained from Nutrient Requirements of Sheep (NRC, 1985): alfalfa 2.27 Mcal/kg DE, 10.9% DP; barley 3.35 Mcal/kg DE, 9.8% DP.

measure in the analyses. We separated the 25-day trial into five periods of five days each, based on the different foods offered, and analyzed each period separately using the SAS statistical program (Cody and Smith, 1991; Hatcher and Stepanski, 1994).

RESULTS

The largest fluctuations in intake of the three foods occurred in lambs receiving only 20 g/kg BW/day (Figure 1). In the absence of LiCl (days 1–5), preference was food 1 (high barley) > food 2 (medium barley) > food 3 (alfalfa) ($P < 0.001$). When LiCl was added to foods 1 and 2 (days 6–15) and then increased (days 16–20), preference changed to food 3 > 2 > 1 ($P < 0.01$ food × day interaction). When LiCl was removed from foods 1 and 2 (days 21–25), lambs' preference reverted to 1 > 2 > 3 ($P > 0.05$), and intake of foods 1 and 2 exceeded that on days 1–5, when barley content was less.

The response of lambs moderately food-deprived (40 g/kg BW/day) was intermediate to that of lambs fed 20 or 60 g/kg BW/day (Figure 2). In the absence of LiCl in the foods (days 1–5), food preference was food 1 (high

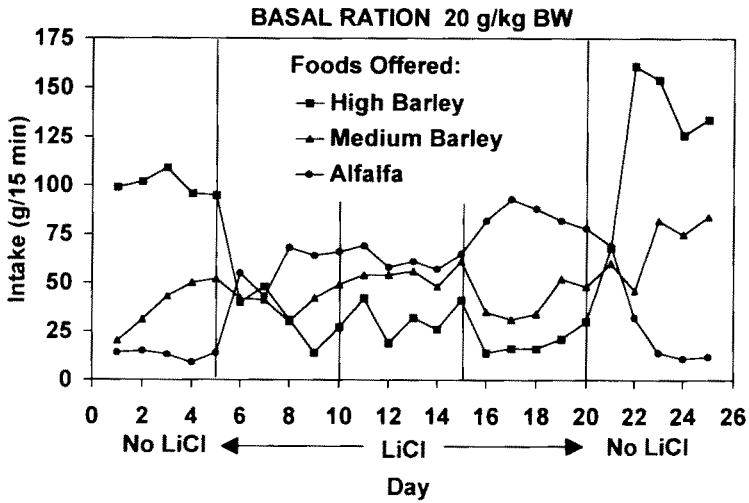

FIG. 1. Intake of three foods by lambs offered 20 g/kg BW/day of alfalfa pellets as a basal ration. Vertical lines represent changes in nutrient and toxin content of the three foods (see Table 1 for details). Standard errors were calculated for each feeding period: days 1–5 SEM = 6; days 6–10 SEM = 7; days 11–15 SEM = 8; days 16–20 SEM = 5; days 21–25 SEM = 10.

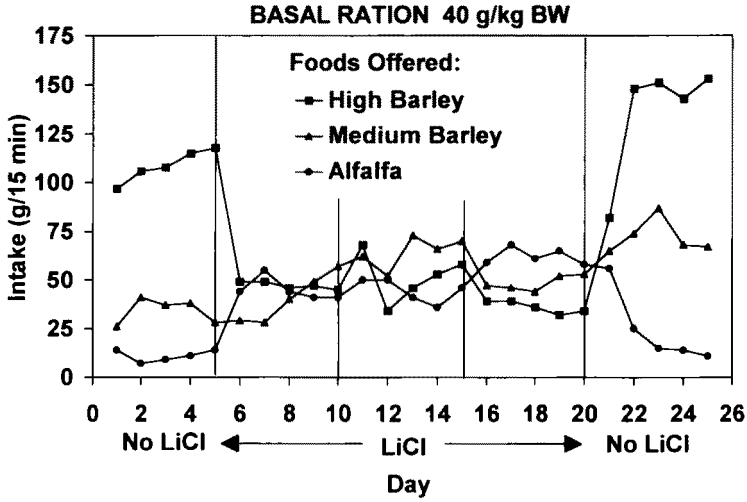

FIG. 2. Intake of three foods by lambs offered 40 g/kg BW/day of alfalfa pellets as a basal ration. Vertical lines represent changes in nutrient and toxin content of the three foods (see Table 1 for details). Standard errors were calculated for each feeding period: days 1–5 SEM = 6; days 6–10 SEM = 7; days 11–15 SEM = 8; days 16–20 SEM = 5; days 21–25 SEM = 10.

barley) > food 2 (medium barley) > food 3 (alfalfa) ($P < 0.01$). When LiCl was added to foods 1 and 2 (days 6–10), intake of food 1 decreased and intake of food 3 increased ($P < 0.01$ food by day interaction), and there was no difference in intake of the three foods ($P > 0.05$). Increasing barley concentrations (days 11–15) resulted in food preferences of 2 > 1 > 3 ($P > 0.01$ food by day interaction). A further increase in LiCl (days 16–20) resulted in a food preference of 3 > 2 > 1 ($P < 0.05$). Upon removal of LiCl (days 21–25), food preferences reverted to 1 > 2 > 3 ($P < 0.01$), and intake of foods 1 and 2 exceeded that on days 1–5, when barley constant was less.

Lambs with ad libitum access to alfalfa (60 g/kg BW/day) changed intake of the three foods when barley and LiCl concentrations changed (Figure 3). When foods contained no LiCl (days 1–5), food preferences were food 1 (high barley) > food 2 (medium barley) > food 3 (alfalfa) ($P < 0.01$). When LiCl was added to foods 1 and 2 (days 6–10), intake of food 1 decreased, intake of food 3 increased, and intake of food 2 remained the same ($P < 0.05$ food × day interaction). During days 11–15 when LiCl levels remained the same but barley concentrations increased in foods 1 and 2, intake of foods 2 and 3 increased, and intake of food 1 remained the same ($P < 0.01$ food × day interaction). Nevertheless, food preferences were still 1 > 2 > 3 (days 6–15,

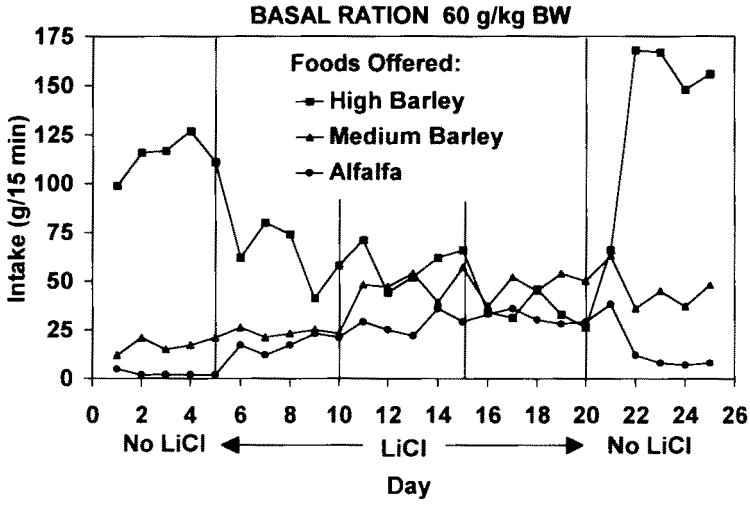

FIG. 3. Intake of three foods by lambs offered 60 g/kg BW/day of alfalfa pellets as a basal ration. Vertical lines represent changes in nutritent and toxin content of the three foods (see Table 1 for details). Standard errors were calculated for each feeding period: days 1-5 SEM = 6; days 6-10 SEM = 7; days 11-15 SEM = 8; days 16-20 SEM = 5; days 21-25 SEM = 10.

$P < 0.05$). When LiCl increased further in foods 1 and 2 (days 16-20), consumption of food 2 exceeded that of foods 1 and 3 ($P < 0.05$). When LiCl was removed from foods 1 and 2 (days 21-25), lambs' preference reverted to food 1 > 2 > 3, and intake of foods 1 and 2 exceeded that on days 1-5, when barley content was less.

Thus, food selection by lambs experiencing different levels of food deprivation can be summarized as follows. Intake of food 1 (high barley) did not differ among treatments when none of the foods contained LiCl (days 1-5, 21-25), but all lambs decreased intake when LiCl was added (days 6-20). However, consumption of food 1 was inversely related to level of food deprivation ($P < 0.05$). Lambs fed ad libitum ate less food 2 (medium barley) than lambs that were highly or moderately food deprived during days 1-10 and 21-25 ($P < 0.05$). All lambs ate more food 3 (alfalfa) during days 6-20 when LiCl was added to foods 1 and 2 ($P < 0.05$); consumption was most deprived > moderately deprived > not deprived ($P < 0.05$).

Lambs in the three treatments differed in their intake of LiCl when LiCl was added to foods 1 and 2 during days 6-20 ($P < 0.05$). Lambs highly deprived of food consumed less LiCl (40 mg/kg BW, SEM = 0.78) than lambs that were moderately deprived (57 mg/kg BW, SEM = 0.79) or fed ad libitum

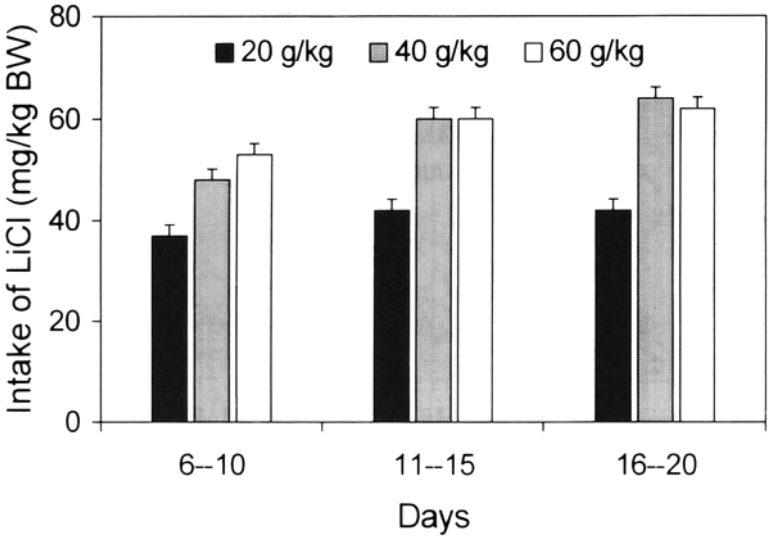

FIG. 4. Intake (SEM = 2.2) of LiCl by lambs offered 20, 40, or 60 g/kg BW of alfalfa as a basal ration during days 6–20 of the experiment.

(58 mg/kg BW, SEM = 0.77). Moreover, increasing barley levels enhanced intake of LiCl by lambs offered 40 or 60 g/kg BW/day of alfalfa. As barley concentrations were increased to 75% in food 1 and 50% in food 2 (from days 6–10 to days 11–15), the intake of LiCl increased from 48 to 60 mg/kg BW ($P < 0.05$) for lambs moderately deprived and from 53 to 60 mg/kg BW ($P < 0.05$) for lambs fed ad libitum (Figure 4). Lambs most food deprived increased intake of LiCl from 37 to 42 mg/kg BW, but the difference was not significant ($P > 0.05$). When the level of barley remained the same, but the level of LiCl increased in foods 1 and 2 (days 16–20), none of the lambs increased intake of LiCl (Figure 4).

DISCUSSION

Lambs quickly (15 min/day) regulated intake of foods in response to changes in the concentrations of energy (barley) and a toxin (LiCl). In the absence of LiCl, all lambs strongly preferred food high > intermediate > low in barley, and the higher the barley content of the food, the greater the preference (i.e., compare days 1–5 with days 20–25 for all treatments). The response to barley was expected because the lambs' basal ration of alfalfa was high in protein but marginal in energy for growth (Wang and Provenza, 1996). Nevertheless, despite

the strong preference for food high in energy, all lambs decreased consumption of foods high in energy as LiCl concentrations increased, and the greater the level of food deprivation, the lower the consumption of foods containing LiCl. Lambs most food deprived ingested lower levels of LiCl (40 mg/kg BW/day) than lambs that were moderately deprived (57 mg/kg BW/day) or fed ad libitum (58 mg/kg BW/day), in spite of the high concentration of barley (energy) in these foods. Thus, the interaction beween nutrient status and toxin avoidance apparently played an important role in food preference.

The adverse effects of food deprivation were evidently aggravated by the ingestion of LiCl because LiCl causes hypoglycemia [e.g., in rats and cattle (Johnson et al., 1980)]. This could explain why lambs fed only 20 g/kg BW of alfalfa pellets showed less preference for food containing LiCl, and it would also explain why increasing the barley content of the food (i.e., from days 6–10 to days 11–15) caused lambs fed 40 or 60 g/kg BW to increase their intake of LiCl. Inadequate nutrition can also decrease substrate needed by animals for detoxification processes (McArthur et al., 1991), and the maximum absorbed allelochemical dose may depend on the supply of cosubstrate for conjugation (Foley et al., 1995; Illius and Jessop, 1995). For instance, a reduction in the sulfur-containing amino acids methionine and cysteine can reduce serum inorganic sulfate in rats and reduce acetaminophen conjugation with sulfate (Glazenberg et al., 1983). Fasting increases acetaminophen toxicity in rats, as glucuronidation and sulfate formation are reduced (Price et al., 1987).

Managers often attempt to reduce livestock losses by preventing food-deprived animals from grazing areas that contain poisonous plants, based on the assumption that food-deprived animals are more likely to consume toxic doses of poisonous plants (Krueger and Sharp, 1978; Stoddart et al., 1975; Dwyer, 1978; Ralphs and Sharp, 1987; James et al., 1992). It is also possible that food-deprived animals are more susceptible to the effects of toxins (Foley et al., 1995; Illius and Jossop, 1995). Thus, a level of toxin that may be safe for satiated animals may not be safe for animals that are food deprived.

Many believe food-deprived animals select foods less discriminately and are more likely to overingest poisonous plants. Our results suggest this is not likely to occur if other foods are present, even in limited amounts. Food-deprived lambs strongly preferred foods high in energy (barley), but they avoided foods high in barley when they contained LiCl. Cattle also ingest less tall larkspur, a serious poisonous plant on mountain rangelands in the western United States, with decreasing levels of rumen fill (Pfister et al., 1988).

Several theories seek to explain how herbivores track changes in nutrients and toxins in variable environments (Provenza and Balph, 1990). Some postulate that animals associate food flavor (odor and taste) with postingestive feedback (Garcia, 1989; Provenza et al., 1992; Provenza, 1995, 1996), which enables animals to experience the consequences of food ingestion, thereby determining

preferences for flavors. On this basis, lambs may have identified changes in the flavor intensity of barley, alfalfa, and LiCl, which they associated with positive and aversive postingestive effects from nutrients and a toxin. Flavor-feedback relationships thus may enable animals to recognize changes in nutrients and toxins, thereby allowing them to adjust intake accordingly.

Acknowledgments—We are grateful to T. Phy, C. Scott, and B. Burritt for assistance with the experiments. We thank C. Cheney, L. Coppock, J. Pfister, and M. Ralphs for reviewing the manuscript. This research was supported by grants from the Cooperative State Research Service and the Utah Agriculture Experiment Station. (Received February 12, 1996; accepted June 21, 1996)

Abstract—We studied seasonal and between-tree variation in the composition and content of total and individual low-molecular-weight phenolics (LMWP) in leaves of mountain birch trees (*Betula pubescens* ssp. *tortuosa*). The major phenolic compounds were chlorogenic acid, quercetin-3-*O*-β-D-glucuronopyranoside, myricetin-3-*O*-(5-acetyl)-L-rhamnopyranoside, and 1-*O*-galloyl-β-D-(2-*O*-acetyl)-glucopyranose. The content of total phenolics, as well as the sum of individual LMWP, varied only slightly among trees while variation in contents of individual LMWP was large. Concentrations of almost all phenolics decreased during the growing season but pairwise correlations between individual phenolics remained similar over the whole season indicating tree-specific LMWP profiles over the season. Among flavonoids, the between-tree component of variation was 2.6 times as large as the seasonal component, while for variation of nonflavonoids the between-tree component was larger than the seasonal one. To explain the significant correlations within both flavonoid and nonflavonoid compounds, we discuss the biogenesis of LMWP in birch leaves, as well as their ecological role.

Key Words—*Betula pubescens* ssp. *tortuosa*; birch; phenolics, flavonoid glycosides; among-tree variation; seasonal variation.

INTRODUCTION

The value of host plant tissue for herbivores is a function of its biochemical composition and physiological state of the plant. General theories of plant defenses share the basic assumption that secondary compounds are responsible for plant resistance, including induced defenses, and that these, rather than nutritive factors, represent the critical chemical factors explaining variance in herbivore performance (but see, e.g., Haukioja et al., 1991; Berenbaum, 1995). Plant phenolics are known for their negative effects on insects and they have played an important role in theories of plant–herbivore interactions (Feeny, 1976; Rhoades and Cates, 1976; Coley et al., 1985), and they are the defensive compounds generally measured from plant tissue.

However, in addition to their possible defensive role against herbivores, phenolics in plants have a suite of other possible functions, including antidesiccation, UV protection, growth regulation, etc. (Kuiters, 1989; Li et al., 1993; Lois, 1994; Northup et al., 1995). Furthermore, they seem to accumulate in slowly growing plants and plant tissues. The original idea of all phenolics having a basically similar and nonspecific effect on herbivores via protein precipitation (Feeny, 1976; Schultz, 1989) is far too simple. Different phenolics can vary in their biological activity, and in the mechanism of action on herbivores. Some phenolics may have a direct toxic effect on herbivores or require oxidation for realization of their ecological activity (Felton et al., 1989; Appel, 1993).

Total phenolics in birch leaves, and in many other plants, correlate negatively with insect performance (Haukioja et al., 1985). Furthermore, it is known that total phenolics may experience strong seasonal patterns, but what happens among individual phenolics is not well understood. We have recently identified 33 low-molecular-weight phenolics (LMWP) in the leaves of white (*Betula pubescens*) and silver (*B. pendula*) birches (Ossipov et al., 1995, 1996) by preparative HPLC and determined their structures on the basis of chromatographic (analytical HPLC), chemical (hydrolysis), and spectroscopic (UV, MS, ^{1}H NMR and ^{13}C NMR) techniques. In this paper we examine the composition and content of low-molecular-weight phenolics in leaves of individual mountain birch trees over a season to find out how well total phenolic deteminations describe seasonal and between-tree variation in the contents of individual low-molecular-weight phenolics of the leaves of mountain birch.

METHODS AND MATERIALS

Plant Material. The experimental mountain birches [*Betula pubescens* Ehrh ssp. *tortuosa* (Lebed.) Nyman] were mature, wild trees growing near the Kevo

Subarctic Research Station (69°45'N, 27°01'E) in northern Finland. The study area lies at about 150 m above sea level and is covered with almost pure mountain birch forest. We sampled foliage of the same 20 birch trees that were originally randomly chosen from a homogeneous forest plot and marked individually by Hanhimäki et al. (1996).

Short shoot leaves from individual trees were sampled on July 1 and 20, and August 24, 1994, always between 9 and 10 AM. Leaves even at the earliest sampling date were almost full grown. Sampling dates were designed to coincide with the peak feeding of the two most important insect herbivores of the mountain birch, the autumnal moth, *Epirrita autumnata* (early July) and the sawfly, *Dineura virididorsata* (August), as well as to include an intermediate date when many mid-season sawflies consume foliage (Hanhimäki et al., 1995). Since the short shoot leaves of the mountain birch burst simultaneously in spring, all the leaves within a tree were of the same age on a given sampling date and matured similarly between the sampling dates. Excised leaves were placed in plastic vials and returned to the laboratory on ice. For determination of phenolic compounds, the birch leaves were vacuum dried and stored in plastic vials at −20°C.

Extraction of Phenolics. The dried leaves (0.5 g) were ground for 2 min with Ultra-turrax T 25 in 25 ml of 70% aqueous acetone. The homogenate was centrifugated at 2500*g* for 10 min and the pellet was reextracted with 25 ml of 70% aqueous acetone for 60 min under continuous stirring. After centrifugation the combined extracts were evaporated to dryness under low pressure at 40°C. The residue was dissolved in 10 ml of water and centrifuged. Then the solution was filled to 25 ml of water and stored in a freezer (−20°C). Extraction efficiency of phenolic compounds was confirmed by reextracting the pellet three times with 25 ml of 70% aqueous acetone and checking these solutions by HPLC.

Total Content of Phenolics. A modification of the Folin-Ciocalteau method (Torres et al., 1987) was used for measurement of total content of phenolic compounds. A 0.1-ml extract was delivered to a 15-ml tube and mixed with 5.9 ml water. One milliliter of this diluted extract was mixed with 1.0 ml 1 N Folin reagent (Folin-Ciocalteau's phenol reagent, Fluka, BioChemica, Buchs, Switzerland) in the centrifuge tube (10 ml volume) and the mixture was allowed to stand for 2–5 min. Then 2 ml of 20% Na_2CO_3 was added. After a 10-min incubation at room temperature, the mixture was centrifuged at 1500*g* for 8 min and the absorbance was measured at 730 nm on a Perkin-Elmer Spectrophotometer 550. Three replicates of each sample were analyzed. The standard curve was prepared with known concentrations of gallic acid.

Quantification of LMWP. Before the HPLC analysis of phenolics, the extract was filtered through Millex-HV_{13} 0.45-μm filter (Millipore, Bedford, Massachusetts). The HPLC system consisted of Merck-Hitachi Pump L-6200 A,

Merck-Hitachi L-4250 UV-VIS Detector (Hitachi, Tokyo, Japan), Perkin-Elmer LC-235 Diode Array Detector (Shimadzu, Kyoto, Japan), and Shimadzu C-R6A Chromatopac Integrator (Shimadzu, Kyoto, Japan). The sample was injected on Spherisorb ODS-2 column (250 × 4.6 mm ID, 5 μm; Phase Sep. Ltd.) and the flow rate was 1.0 ml/min. Detection was performed at 280 nm, 0–40 min; 360 nm, 40–60 min; and 280 nm, 60–110 min. Two solvents were used; solvent A was 5% formic acid and solvent B was acetonitrile. The gradient was as follows: 0–5 min, 100% A (Isocratic); 5–60 min, 0–30% B in A (linear gradient); 60–70 min, 30–60% B in A (linear gradient); 70–80 min, 60% B in A (Isocratic). Quantitative determinations were carried out by the external standard method using gallic, *p*-coumaric, and chlorogenic acids, quercetin, myricetin, and kaempferol as standards, assuming a similar molecular extinction coefficient for aglycones and glycosides (Winter and Herrmann, 1986).

The relative standard error in the quantitation of LMWP, ranging from 2.2% to 11.2% (small peaks) based on HPLC analysis of five leaf samples of the same tree, provides an estimation of the error involved.

Statistical Analysis. The distributions of a few phenolic compounds deviated from the normal. The homogeneity of variances was tested with Cochran's test; for a few phenolic compounds, the variances differed significantly. There were, however, no deviations from normality or homoscedasticity with these compounds. Significance of variations in the content of phenolic compounds were tested by a two-way ANOVA. The correlations between individual phenolic compounds during the growing season were tested with Pearson's correlation analysis (Proc Corr, SAS Institute, Cary, North Carolina).

RESULTS

Identification. Up to 30 individual low-molecular-weight phenolic compounds in the leaves of the mountain birch were detected by HPLC (Figure 1). Composition of LMWP in the leaves of mountain birch were closely consistent with our earlier analyses of white and silver birch leaf chemistry (Ossipov et al., 1995, 1996). The identified phenolics included both flavonoid (peaks 4, 5, 11, 13, 20–36) and nonflavonoid (peaks 1, 2, 6, 8, 9, 12, 14, 18, 19) compounds.

We detected 21 flavonoids and identified 11 of them on the basis of UV spectroscopy data as flavanols (peaks 4, 5, 13, 20–22, 25), quercetin glycosides (30, 32), or kaempferol glycosides (35, 36). The identified flavonoid compounds were the glycosides of *m*yricetin, M-3-*O*-β-D-glucuronopyranoside (23), M-3-*O*-β-D-galactopyranoside (24), and M-3-*O*-L-(acetyl)-rhamnopyranoside (26); glycosides of quercetin, Q-3-*O*-β-D-glucuronopyranoside (27), Q-3-*O*-β-D-galactopyranoside (28), Q-3-*O*-α-L-arabinofuranoside (29), Q-3-*O*-α-L-(4″-*O*-ace-

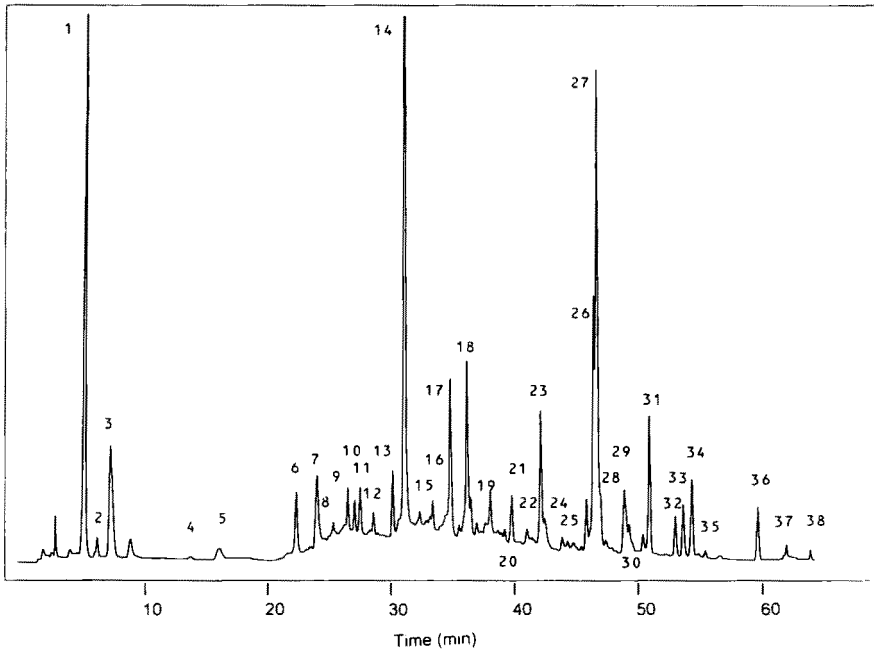

FIG. 1. Typical trace of HPLC analysis of soluble low-molecular-weight phenolics (1–40) in the leaves of mountain birch trees. Spherisorb ODS-2 column (250 × 4.6 mm ID, 5 μm) at a flow rate of 1.0 ml/min with gradient of acetonitrile in 5% aqueous formic acid; detection wavelength at 280 nm. Peak 1, 1-*O*-galloyl-β-D-(2-acetyl)-glucopyranose; 2, gallic acid; 4 and 5, flavanois; 6, neochlorogenic acid; 8, *cis*-5-*p*-coumaroylquinic acid; 9, *trans*-5-*p*-coumaroylquinic acid; 11, (+)-catechin; 12, 1-(4″-hydroxyphenyl)-3′-oxopropyl-β-D-glucopyranose; 13, flavanol; 14, chlorogenic acid; 18, *trans*-3-*p*-coumaroylquinic acid; 19, *cis*-3-*p*-coumaroylquinic acid; 20–22, flavanols; 23, myricetin-3-*O*-β-D-glucuronopyranoside; 24, myricetin-3-*O*-β-D-galactopyranoside; 25, flavanol; 26, myricetin-3-*O*-α-L-(acetyl)-rhamnopyranoside; 27, quercetin-3-*O*-β-D-glucuronopyranoside; 28, quercetin-3-*O*-β-D-galactopyranoside; 29, quercetin-3-*O*-α-L-arabinofuranoside; 30, quercetin glycoside; 31, kaempferol-3-*O*-β-D-glucopyranoside; 32, quercetin glycoside; 33, kaempferol-3-*O*-α-L-rhamnopyranoside; 34, quercetin-3-*O*-α-L-(4″-*O*-acetyl)-rhamnopyranoside; 35 and 36, kaempferol glycosides. Peaks 3, 7, 10, 15, 16, 17, 37, and 38 were not identified.

tyl)-rhamnopyranoside (34); and glycosides of kaempferol, K-3-*O*-β-D-glucopyranoside (31) and K-3-*O*-α-L-rhamnopyranoside (33). Compound 11 was identified as the flavanol, (+)-catechin.

The identified nonflavonoid compounds were gallic acid (peak 2) and its derivative, 1-*O*-galloyl-β-D-(2-*O*-acetyl)-glucopyranose (1); derivatives of caf-

feic acid, neochlorogenic acid (6, *trans*-5-p-caffeoylquinic acid) and chlorogenic acid (14, *trans*-3-caffeoylquinic acid); and derivatives of *p*-coumaric acid, *cis*-5-p-coumaroylquinic (8), *trans*-5-*p*-coumaroylquinic (9), *trans*-3-*p*-coumaroylquinic (18), and *cis*-3-*p*-coumaroylquinic (19) acids. Peak 12 was identified as 1-(4″-hydroxyphenyl)-3′-oxopropyl-β-D-glucopyranose.

Seasonal Variation. The mean total phenolics content in the leaves of mountain birch in early, mid-, and late summer was 103, 93, and 89 mg/g of dry wt, respectively; the average decline from early July to late August was 14%.

The mean content of the main individual low-molecular-weight phenolics and total content of phenolics in the leaves of the 20 trees used in our study are shown in Table 1. For quantitative calculations, the main 18 phenolic compounds were considered; the remaining 12 compounds (peaks 4, 5, 8, 9, 11–13, 20–22, 25, 35, 37 and 38) were disregarded due to lower levels of accumulation and poor separability of the respective peaks. Most phenolic parameters showed significant differences among sampling dates (Table 2).

The mean total LMWP content of foliage in early, mid-, and late summer was approximately 48, 41, and 38 mg/g of dry wt, respectively. The average decline was 21%, i.e., steeper than in the case of total phenolics. The average seasonal decline of nonflavonoid compounds ranged from 52% (6) to 70% (19), except for peak 14, the average content of which increased 12% in July, followed by a 15% drop in late August. The content of individual flavonoid compounds declined at the same time from 7% (28) to 37% (23). The amount of most phenolic compounds declined evenly during the three sampling dates, but compound 1 declined rapidly in July, over 80% of total decrease. The average content of flavonoid compounds 26, 28, and 30, however, increased over 10% in late summer compared to mid-summer.

Between-Tree Variation. Differences in the composition of LMWP between the 20 trees were small, and most compounds could be detected from each tree. However, compounds 32, 34, and 36 were found in less than one third of the trees, and compounds 1, 2, 6, and 30 occurred in small or trace amounts in some of the trees.

The quantitative variation in phenolic compounds was large throughout the growing season (Table 1). Between-tree variation was significant at $P < 0.001$ in all phenolics through the growing season, except for gallic acid (peak 2). In early summer the coefficients of between-tree variation (CV) of nonflavonoid compounds ranged from 42% (19) to 93% (6), and of flavonoid compounds from 36% (27) to 264% (36), being less than 70% for two thirds of the compounds. The tendency was similar throughout the growing season. Still, the coefficient of between-tree variation of total content of LMWP (the sum of individual compounds) and total phenolics varied during the season only between 23 and 27% and 14 and 17%, respectively.

TABLE 1. CONTENT OF LOW-MOLECULAR-WEIGHT PHENOLICS AND TOTAL PHENOLICS IN LEAVES OF 20 MOUNTAIN BIRCH TREES ON THE THREE SAMPLING DATES (EARLY, MID, AND LATE SEASON)[a]

[a] Refers to peak numbers in Figure 1.
[b] *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$.

The content of the major individual LMWP of mountain birch, chlorogenic acid (peak 14), varied among trees between 4.6 and 31.1 mg/g of dry wt (CV = 60%) in early summer. At the same time the content of other main nonflavonoid compounds (1, 6, 18, and 19) ranged from 0.1 to 1.5 mg/g of dry wt, except compound 1, which varied from 0.1 to 12.0 mg/g of dry wt (CV = 85%).

The main flavonoid compounds of mountain birch are quercetin-3-*O*-β-D-glucuronopyranoside (peak 27), myricetin-3-*O*-(5′-ac.)-L-rhamnopyranoside (26) and myricetin-3-*O*-β-D-glucuronopyranoside (23), the contents of which varied in early summer between 3.9 and 16.5 (CV = 36%), 1.2 and 10.5 (CV = 53%), and 0.8 and 6.2 (CV = 48%) mg/g of dry wt, respectively. The main kaempferol glycoside of mountain birch is compound 31, K-3-*O*-β-D-glucopy-

ranoside, whose amounts varied between 0.8 and 4.1 mg/g of dry wt (CV = 49%).

Intraspecific Relationships of LMWP. Intraspecific relationships of phenolic compounds are shown in Tables 3 and 4 (not all the correlations are shown). Tree-specific correlations between most individual phenolic compounds remained similar over the whole season.

The amounts of nonflavonoid compounds (peaks 14, 18, and 19) correlated positively ($P < 0.01$) over the growing season, except for compound 19 in late summer samples. These compounds also correlated positively with total LMWP content, e.g., correlation coefficients of compound 14 with total content of LMWP varied between 0.87 and 0.95 ($P < 0.001$) over the whole season. The amounts of gallic acid (2) and the acetylated form of β-glucogallin (1) correlated positively ($P < 0.001$) in early and mid-summer samples.

The main flavonoid compound, quercetin-3-*O*-β-D-glucuronopyranoside (27) correlated positively, but weakly, with quercetin-glycosides (28 and 29), and negatively with compounds 30 and 34 (Table 4). Between quercetin gly-

[a] Refers to peak numbers in Figure 1.
[b] $*P < 0.05$; $**P < 0.01$; $***P < 0.001$.

cosides (32 and 34) and kaempferol glycoside (36) the correlations were strongly positive ($P < 0.01$), as between kaempferol glycosides (31 and 33), and myricetin glycosides (23 and 24) ($P < 0.01$) (Table 4). Myricetin-3-*O*-β-D-galactopyranoside (24) and quercetin-3-*O*-β-D-galactopyranoside (28) correlated also positively through the growing season.

DISCUSSION

Understanding the importance of correlations between the concentrations of individual LMWP presumes understanding the biogenesis of these compounds. Figure 2 shows a simplified scheme of biosynthesis of the phenolics in woody plants that may be extended to birch.

The original substance for the synthesis of phenolic compounds in plants is phenylalanine, one of the end products of the shikimate pathway. Only gallic and protocatechuic acids are formed from an intermediate compound of the shikimate pathway—from dehydroshikimic acid (Gross, 1992). The positive correlation between the contents of gallic acid (2) and the acetylated form of β-glucogallin (1) in birch leaves is due to the presence of biosynthetic connections between these phenolics: gallic acid is a precursor of acetylglucogallin. Moreover, the low concentration of gallic acid indicates that its formation is a limiting step on the pathway of acetylglucogallin synthesis.

The biosynthesis of chlorogenic acid is possible in higher plants via *p*-coumaroyl or caffeoyl derivatives. Both routes are realized in different plants (Zenk, 1979). However, the positive correlation between the contents of chlorogenic (14) and *cis*- and *trans*-3-*p*-coumaroylquinic acids (18, 19) supports our assumption that in the birch leaves the biosynthetic pathway involves reactions of *p*-coumaroyl-CoA esterification by quinic acid and hydroxylation of 3-*p*-coumaroylquinic acid to chlorogenic acid (Figure 2).

Unlike in many other woody plants, in which the concentration of quinic acid may reach 10–12% of dry weight (Ossipov and Shein, 1990), birch leaves did not accumulate quinic acid, apparently due to its active transformation to 3-*p*-coumaroylquinic acids and especially to chlorogenic acid, the concentration of the latter being as high as 4% of dry weight in some trees. In addition, the high correlation coefficient between *trans*- and *cis*-3-*p*-coumaroylquinic acids (0.92–0.94, $P < 0.001$) supports our assumption that the formation of the *cis* form in the birch leaves is an enzymatic process that occurs under intercellular control (Ossipov et al., 1996).

There are four main groups of flavonoids in the birch leaves: the kaempferol, quercetin, and myricetin glycosides and the flavanols. Flavonoids of these groups correlated with each other differently. Correlations between glycosides within the same group and between glycosides of different groups varied from

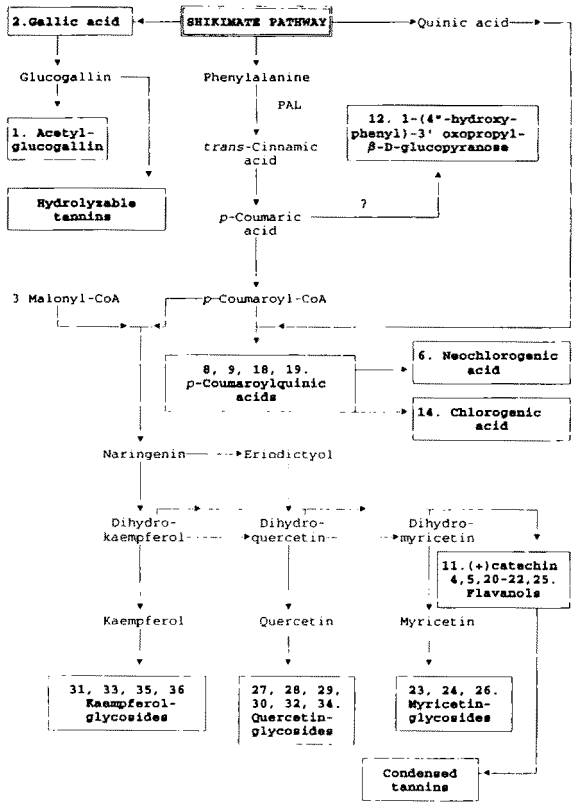

FIG. 2. Biogenesis of birch phenolics.

positive and negative (Table 4). However, the pathway of flavonoid synthesis involves a number of intermediates. Moreover, some of the flavonoids are not the end products of metabolism. In birch leaves they can be used in the biosynthesis of polymeric compounds.

Seasonal Variation. Total phenolic content has been shown to increase through the growing season in foliage of many perennial plant species (Feeny, 1970; Dement and Mooney, 1974; Lawton, 1976; Cooper-Driver et al., 1977), but no strong seasonal trends have been found in others (Macauley and Fox, 1980, Schultz et al., 1982, Baldwin et al., 1987).

In the mountain birch, the contents of both total phenolics and individual LMWP declined towards the end of growing season. The seasonal decrease in the phenolic contents may result from three main causes: (1) decreasing rate of their biosynthesis, (2) conversion into insoluble cell wall bound components,

and (3) active transformation into oligo- and polymeric compounds, for example, tannins or lignins. Moreover, this may be partly due to a dilution effect because of an increasing relative content of cell-wall components in the leaf; cellulose, hemicellulose, pectin, and lignin.

In our case, since we sampled even-aged short shoot leaves only, aging of leaves was important for the decrease of phenolics. Basically similar or variable seasonal trends have been shown with phenolic glycosides in the leaves of *Populus* (Thieme, 1971, Lindroth et al., 1987), and of *Salix* (Thieme, 1965, 1971, Julkunen-Tiitto, 1989).

Between-Tree Variation. Earlier, Haukioja et al. (1985) showed that the coefficient of variation in total phenolics among mountain birch trees ranged from 12 to 24%, which corresponds well to the results of the present study. Similarly, coefficients of variation of different phenolic compounds among trees in our study were about the same as those found by Suomela et al. (1995). Similar results were obtained with phenolic variation in the bark of winter-dormant seedlings of *Betula pendula* of several origins (Tahvanainen et al., 1991), and in leaves of several *Artemisia* species (Wilt et al., 1992).

When comparing between- and within-tree variation of LMWP for randomly sampled same-aged mountain birch trees, Suomela et al., (1995) showed that trees accounted, in general, for most of the total variance in different foliage phenolics. In 24 of the 27 components, trees accounted for over 75% (in most cases over 90%) of the total variance.

Our results contrast with flavonoid variation in *Chondrapetalum*. Harborne et al. (1985) found that while different collections of *C. microcarpum* had identical flavonol glycoside patterns and the same percentage of total flavonoids, the relative amounts of all the compounds (simple glycosides of myricetin, laricitrin, and syringenin) differed. In mountain birch, amounts of total LMWP and total phenolics differed among trees only slightly compared to variation in individual phenolic compounds.

Seasonal Versus Between-Tree Variation. Our results of seasonal and between-tree variations in mountain birch foliage through the growing season are consistent with the variability in *Artemisia* species (Wilt et al., 1992; Wilt and Miller, 1992). In mountain birch, the relative importance of seasonal and between-tree variations changed with different phenolics. The coefficients of seasonal and between-tree variations of total phenolics and of total LMWP were at a similar level through the growing season, but differences in individual LMWP were much larger. There was a clear difference between flavonoid and nonflavonoid compounds. The average coefficient of between-tree variation for flavonoids (except 32, 34, and 36) was 57%, whereas the average coefficient of seasonal variation was 22%; i.e., between-tree variation for flavonoid compounds was on average 2.6 times as large as temporal changes through the growing season. For nonflavonoid compounds the average coefficient of between-

tree variation varied between 65 and 72%, whereas the average coefficient of seasonal variation was 59%; i.e., between-tree variation for nonflavonoid compounds was less than half of the within-season variation.

Ecological Implications. The contents of total phenolics and of total LMWP decreased in the course of the season. Concentrations obviously had been even higher at the beginning of the summer, before our first sampling event, as indicated by high phenolic values in small, expanding leaves (unpublished). This contrasts with the common belief that foliage phenolics increase with season. The observation behind this opinion dates to Feeny (1970), who found that the content of condensed tannins in oak leaves increased from spring to autumn, and this observation provided a plausible explanation for the prevalence of spring feeding by insects. The mechanism by which these compounds distributed insect feeding was assumed to be binding of leaf proteins into indigestible complexes. At that time, tannins and phenolic compounds in general were assumed to be quantitative defenses, and nonspecific in action. However, with tannins and precursors of tannins, plants synthesize and accumulate in cells a great variety of LMWP: hydroxybenzoic and hydroxycinnamic acids, acetophenones, flavonoids, stilbenes, and lignans. The defensive functions of these compounds are not clear yet.

Although total phenolics in mountain birch foliage correlate negatively with performance of the most important insect herbivore of birch, the autumnal moth (Haukioja et al., 1985; Suomela et al., 1995), the main phenolic compound, chlorogenic acid, was not significant (Suomela et al., 1995). The biological relevance of this observation is unclear since the true role of chlorogenic acid and some other phenolic compounds may be expressed only after they have been oxidized by polyphenoloxidases or peroxidases (Appel, 1993) to quinones (Duffey et al., 1986). These highly reactive molecules undergo nucleophilic attack by the amino and sulfhydryl side chains of proteins, forming irreversible, covalent bonds (Hurrel et al., 1982; Pierpoint, 1983). The interaction of quinones with other components of cells (carbohydrates, free amino acids, and lipids) also is possible (Takechi and Tanaka, 1987; Felton et al., 1989).

A lack of the content of pooled phenolics on herbivores is further indicated by the fact that growth rates of larvae of a number of herbivorous species on mountain birch decreased strongly within the season (Hanhimäki et al., 1995). As both total phenolics and individual LMWP decreased within the season, the detrimental effects of phenolics cannot explain the reduced growth rate. As such, this is not surprising since the insensitivity of many herbivores to plant phenolics is well known (Bernays, 1981; Martin and Martin, 1982). They may not reduce digestibility (Martin et al., 1987), and the inhibition of protein digestibility may depend on the substrate (Duffey et al., 1986; Felton et al., 1989).

A potential source of confusion for the role of foliage phenolics for insects is that in many cases only soluble phenolics have been analyzed. At the present

time, however, it is well known that a number part of phenolic compounds (proanthocyanidins, some flavonoid glycosides, ferulic acid) are bound, apparently indissolubly, to plant tissue (Shen et al., 1986; Stafford, 1988; Strack et al., 1989). It has been suggested that these insoluble forms of plant polyphenols are bound by covalent linkages to polysaccharides or other structures in the developing cellular matrix. Attention has been drawn to the possible analogies with the structure of lignin and the process of lignification in forming xylem cells (Bate-Smith, 1954; Bate-Smith and Lerner, 1954; Shen et al., 1986; Haslam, 1988).

The mechanism of action of birch foliage phenolics on insects many depend on the specific chemical structure of the phenolics. Moreover, our results show that at different stages in birch leaf development, different groups of phenolic compounds may play a major role. A possible explanation for the decrease in the content of soluble phenolic compounds during the process of leaf maturation (see Table 1) may be transformation of soluble forms of phenolics to insoluble ones, for example, into the cell-wall bound compounds. Hence, the accumulation of phenolics in the cell wall of birch leaves and the increase of leaf toughness might be important causative factors in the decreasing suitability of birch leaves to some herbivores towards the end of growing season. Testing of this idea will require analysis of individual compounds and not of pooled contents of phenolics only.

(Received September 5, 1995; accepted June 24, 1996)

Abstract—Larvae of the ascidian *Clavelina moluccensis* do not settle in the field on the sponge *Crella incrustans* and are deterred from settling by crude chemical extracts of the sponge. Progressive refinement of extracts, guided by bioassays, led to the identification of *lyso*-platelet-activating factor (*lyso*-PAF) from the sponge. *lyso*-PAF is inhibitory in assays using ascidian, bryozoan, barnacle, and algal settlement and mussel byssal attachment. Its role in the field has not yet been demonstrated.

Key Words—*lyso*-Platelet-activating factor, *Crella incrustans*, *Clavelina moluccensis*, antifouling, fouling, marine settlement, marine chemical ecology, *Bugula*, *Xenostrobus*, *Balanus*, *Ulva*, mussel, sponge, ascidian.

INTRODUCTION

This paper originated from a research program on the ecology of coexisting, sessile, filter-feeding marine invertebrates on hard substrata (e.g., Butler, 1991; Butler and Chesson, 1990). The ecology of such organisms is characterized by intense competition at least for space, if not also for access to the water column with its suspended food (Buss, 1979a). These invertebrates also need defense against fouling by other organisms, predation by relatively large organisms, and

*To whom correspondence should be addressed.

infection by microorganisms. Our particular concern here is their capacity to resist macrofouling-settlement on them by other marine invertebrates.

Defenses may lie in structure (e.g., spines, skeletal inclusions) and in flexibility of growth form (Buss, 1979b; Buss and Jackson, 1981; Dyrynda, 1986; Jackson, 1977a,b), but it is clear that many have chemical defenses. These can protect them against settlement by larvae or overgrowth by adults of other species and, indeed, can enable them to gain further space for themselves or their progeny (Coll, 1992; Bakus et al., 1986, 1990; Davies et al., 1989; Dyrynda, 1986; Pawlik, 1992b; Richmond and Seed, 1991; Wahl, 1989; Holmström and Kjelleberg, 1994).

These defenses are of interest in themselves and for understanding the ecology of sessile assemblages. It is also reasonable to look among these organisms for potential natural antifouling agents that can be used to replace the effective but environmentally dangerous treatments based upon the heavy metals tin and copper (Claisse and Alzieu, 1993; Evans and Clarkson, 1993).

The mechanism of marine fouling on hard substrata involves an extremely complex interaction—not simply an obligate, linear succession—among (1) the adsorption of inert organic and inorganic molecules onto an underwater surface, (2) the development of a microbial film (microfouling), (3) the adsorption of inert particulate matter, and (4) the settlement and development of algal spores and invertebrate larvae (macrofouling) (Clare et al., 1992). There is little information about how these factors interact in the processes of organisms attaching to one another and hence little understanding of the various mechanisms by which they might resist it.

A first step is simple documentation of lack of fouling of certain sessile organisms (Davis et al., 1991; Dyrynda, 1986; Wahl and LaFargue, 1990; Walls et al., 1993); a second is the isolation and characterization of compounds that might be responsible for this activity. Further questions depend on the interest of the investigators. It may be asked whether a given molecule functions in the living organism in the way found with assays of pure compound. It is also important to know where the compound is located in the organism, how it is produced, and how its presence evolved (e.g., Coll, 1992; Maida et al., 1995; Schmitt et al., 1995; Walls et al., 1995). If the focus is on the discovery of new antifouling technology, then much of the foregoing may be of little interest and investigation may proceed directly to incorporation into coatings and testing in application (Price et al., 1992).

Davis et al. (1991) found that larvae of the ascidian, *Clavelina* (*Podoclavella*) *moluccensis* (Sluiter) (Clavelinidae: Aplousobranchia), strongly avoided settling on the sponge, *Crella incrustans* (Carter 1885) (Demospongiae: Poecilosclerida: Crellidae), among others. Indeed, *C. incrustans* in the field has almost no other macroorganisms growing on its surface. They also reported that crude chemical extracts of *C. incrustans* deterred larval settlement. This paper

shows that one pure compound isolated from *C. incrustans* has antifouling activity.

METHODS AND MATERIALS

Collection of Sponges

SCUBA divers collected sponge samples by hand from the pilings of the pier at Edithburgh, South Australia, at approximately 4–5 m depth. They were immediately stored at 0°C for transport and then kept frozen at −20°C until required. Since the isolation of compound **1** was bioassay driven and continued over an extended period of time, fresh collections of sponge were made prior to each bioassay period to guard against loss of activity by decomposition of the active components during storage. Sponges are notoriously difficult to identify underwater and therefore a voucher specimen of each sponge colony was lodged with the Queensland Museum (Brisbane, Australia). Its identity was confirmed as *Crella incrustans* (Carter, 1885) by Dr. John Hooper of the museum. Additional vouchers were lodged in the South Australian Museum, Adelaide, Australia.

Bioassays

The approach used was progressive refinement of sponge extracts, directed by bioassays, toward the isolation of single compounds. The chemical purification procedure began by partitioning crude acetone extract between ether and water, then between 1-butanol and water. The ether soluble compounds were then partitioned between hexanes and 20% aqueous methanol. The four extracts thus obtained were bioassayed, and the most active fraction was selected for the next step. The initial bioassays used the same species of colonial ascidian, *Clavelina moluccensis*, as that used by Davis et al. (1991), who made field observations on the deterrence of settlement of ascidian larvae by sponges and sponge extracts. Then, seeking wider evidence of activity, avoidance of species-specific artifacts, greater speed, sensitivity, and reduced costs, we moved to laboratory assays using bryozoan larvae, mussels, barnacle larvae and algal gametes.

Bioassay with Larvae of Clavelina moluccensis. Assays, conducted beneath the Edithburgh jetty, the site of collection of the sponge, were structured as follows. Extracts were dissolved in a solvent and painted onto one half of a 45-mm-diameter filter paper; the other side was painted with the solvent alone to act as control. Each filter paper was placed in the lid of a 70-ml screw-top polystyrene container, filled with seawater, taken underwater, and a single larva, caught in a syringe, was "injected" into each container. Thus, each larva provided a single, independent, binary choice between extract and control, which

occupied equal areas of paper symmetrically placed in the container. The containers were left underwater (cap and filter paper uppermost) for several hours to allow the larvae to settle, after which each container was scored as to whether settlement had occurred on the extract or control half of the filter paper. Other results were also observed, such as settlement on the walls of the plastic container or still swimming, but these were irrelevant for the purposes of statistical analysis. The null hypothesis for the assay was that if the extract had no influence, then, of those larvae that settled on the paper, half should be expected to settle on each side. The G test (log-likelihood ratio test) was used to test the fit to a 1:1 ratio and, where relevant, to test for differences between trials and between different extracts.

The test samples were applied to the Whatman No. 1 or Whatman No. 111 filter paper in the following manner. Filter papers were folded in half and the test material, generally dissolved either in diethyl ether or a 1:1 mixture of diethyl ether and methanol, was applied as a 0.1-ml aliquot over one half of the filter paper, taking care not to encroach onto the other half. The test sample half of the filter paper was distinguished by placing a small graphite pencil dot near the edge. Once the filter paper had dried, the same solvent (0.1 ml) used for the sample was applied to the other half of the filter paper to act as the control. In the case of compound **1** and related samples it was necessary to add chloroform to properly solubilize the sample. A typical solvent mixture was 11:10:7 methanol–chloroform–diethyl ether.

Bioassay with Larvae of Bugula neritina. The bryozoan *Bugula neritina* (Linnaeus) broods its developing larvae, and they are ready to settle shortly after release. Colonies of *B. neritina* collected from pontoons in a yacht basin at Outer Harbour, Port Adelaide, were kept in laboratory aquaria at 18°C in the dark for two to three days before being transferred to plastic food containers and exposed to bright light to induce larval release. Larvae were collected individually with a syringe and transferred with approximately 5 ml seawater to experimental trays.

The basic design was as for the *Clavelina* assay, a binary choice by a single larva in each container, leading to the same statistical test. The experimental containers were white square, high-impact polystyrene weigh trays, 34 mm interior length. A pencil line was drawn to divide the bottom into halves; one side was painted with extract and labeled E with pencil, the other painted with solvent. Generally several treatments (different extracts or different concentrations of the same extract) were run simultaneously. A control (solvent–solvent) comparison was included with each run. The control was painted with solvent on both sides, with one side being labeled C. This should conform to the 1:1 null hypothesis and should also give a high survival and settlement rate; if it did not, we would suspect that some other factor, e.g., condition of larvae or

seawater, was influencing results. Thirty or more trays were set up for each treatment. The solvent used was 3 : 1 ether–methanol.

Trays were positioned randomly to obviate possible effects of position on the bench. They were left for 4–14 hr, and larvae were scored as settled, not settled, or dead on either extract or solvent side. As with the *Clavelina* assay, the major statistical test was of the null hypothesis that of those larvae that did settle in choice trays, equal numbers would settle on the control and extract sides. A second G test compared the proportion dead in trays containing the extract (choice trays) with that in solvent–solvent controls. If significantly more were dead in choice trays, the extract was scored as "toxic."

Bioassay with Xenostrobus pulex. This method is modified after that used by Ina et al. (1989). Black mussels, *Xenostrobus pulex* (Lamarck), preferably about 1 cm in length, were collected from the breakwater at Gulf Point Marina, North Haven, South Australia. A small rubber stopper was fixed with Superglue to either the right or left valve of the shell, approximately 1 mm from the umbo on the ventral side, 30 on the right and 30 on the left valve per treatment. Four cards were set up (pasteboard, 7 × 13 cm) for each treatment. Ruled pencil lines divided the card into thirds parallel to the long axis. Extract was dissolved at known concentration into a known quantity (0.5 ml for four cards) of solvent (1 : 1 ether–methanol), which was painted evenly onto the central third of the card and on the two outer strips. On control cards solvent was applied to the whole card. Fifteen mussels were attached to each card by gluing their rubber stoppers on with Superglue. They were positioned along the pencil lines, eight on one side, seven the other, in an alternating pattern—umbos left–right–left, etc., to minimize the chance of a spurious result caused by any gradients in the room or by the asymmetry of mussels (Figure 1). Each mussel was positioned with its byssal gape above the pencil line; it could attach its byssal threads on either side of the line, and the null hypothesis was that if the extract had no influence, then 50% of them would be expected to attach towards the center of the card and 50% towards the outer side. Mussels would normally attach a number of byssal threads, some of which may be either side of the line, and each mussel was given a single score, viz., the side on which the greater number of threads was attached. Each card was placed in a separate food container, covered with seawater, left overnight at 18°C, then removed and scored. Results for the four cards of each treatment were tested for homogeneity and pooled if appropriate.

Bioassays Using Cyprid Settlement of Balanus amphitrite amphitrite *and Gamete Settlement and Germling Development of* Ulva lactuca. Both bioassays were performed by Dr. R. De Nys (School of Biological Sciences, University of New South Wales, Australia). The assay with cyprids of *Balanus amphitrite amphitrite* Darwin 1854 employed the method of Rittschof et al. (1992) as used

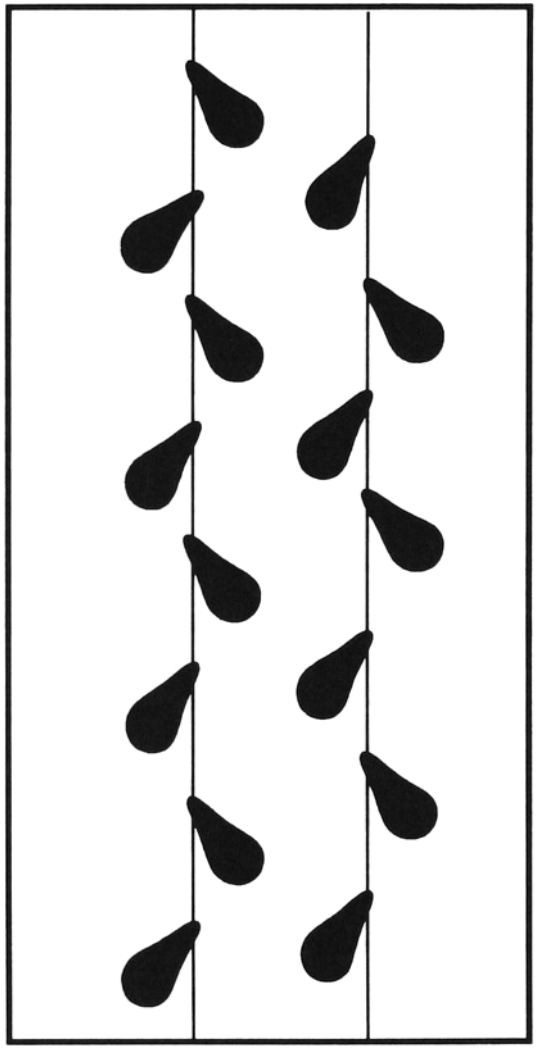

FIG. 1. Layout of mussels, *Xenostrobus pulex*, mounted on small rubber blocks above test card. Extract solution is painted between the lines, solvent control outside them.

by De Nys et al. (1995). Compound **1** was dissolved in ethanol (99.7% +) at concentrations ranging from 500 μg/ml to 50 ng/ml. A 1-ml aliquot of test solution was added to a polystyrene Petri dish (surface area 20 cm^2), resulting in a concentration range of 25 $\mu g/cm^2$ to 2.5 ng/cm^2. Control dishes were prepared, to which 1 ml of ethanol or no ethanol was added. Dishes were dried on a shaker prior to addition of 5 ml of sterile filtered (0.22 μm) seawater. Settlement assays were conducted by adding 45–65 cyprids to each dish. Each concentration of compound **1** was tested in triplicate. Test dishes were kept at 28°C in a 15L:9D cycle for 24 hr. After 24 hr, the test was terminated by addition of three drops of formaldehyde and nonsettled larvae filtered from the dish. Settled and nonsettled cyprids were counted.

Compound **1** was tested in a similar manner in the gamete bioassay with *Ulva lactuca* Linnaeus, in amounts ranging from 25 μg to 25 ng/cm^2 using the method from Fletcher (1989) modified by De Nys et al. (1995).

General Chemical Data

Infrared (IR) spectra were obtained on a Bio-Rad 3200 FT spectrophotometer. One dimensional ^1H, broad band decoupled ^{13}C, and DEPT NMR spectra were measured on either a Bruker ACP 300 MHz or AM 500 MHz spectrometers. Chemical shifts were assigned by comparison with shift of the carbon or residual proton in chloroform-d_1 (δ 77.0 and 7.24, respectively). Matrix-assisted laser-desorption ionization (MALDI) mass spectra were obtained with a Finnigan MAT Lasermat spectrometer in a 2,5-dihydroxybenzoic acid matrix.

All solvents were either HPLC grade or were redistilled from glass. Sephdadex LH-20 (Pharmacia) was used in partition and gel permeation chromatography with chloroform, hexanes, ethanol (10:10:1) and methanol, respectively, as the eluants. LiChroprep RP-18, 40–63 μm (Merck) reverse-phase silica gel was used for flash chromatography (Blunt et al., 1987). Normal-phase silica gel separations (Speedy column; Coll and Bowden, 1986), Merck Silica-gel H, and Chromatotron (Harrison Research; cornstarch incorporated with Merck Silica-gel 60 PF) were also attempted. Reverse-phase HPLC was carried out using a Waters isocratic system with a variable wavelength UV detector and an Exsil 100/10 ODS, 25 × 1.0-cm, semipreparative column (Activon). The course of separations was monitored by TLC (Merck, silica gel, 0.25-mm layer) using phosphomolybdic acid/ceric sulfate or Dragendorff's reagent for visualization.

Isolation of Compound 1

Typically, the frozen sponge (350 g, dry extracted weight) was chopped into 2-cm cubes and macerated in a Waring blendor with acetone, filtered through

diatomaceous earth, and then resuspended in fresh acetone. This procedure was repeated four times. Acetone was removed from the combined filtrate by rotary evaporation leaving an aqueous residue. The aqueous residue (500 ml) was extracted with 1-butanol (4 × 200 ml), dried under vacuum, and further partitioned between hexanes (400 ml) and 20% aqueous methanol (400 ml). The methanol layer was dried under vacuum to give 8.7 g sponge extract.

Purification and Identification of Compound 1

Crude extract (2.4 g) was partitioned on a Sephadex LH-20 column and the first fraction (0.72 g) was resubmitted to the column to give a fraction greatly enriched in compound **1** [R_f 0.2, 1-butanol, acetic acid, water (3 : 1 : 1); 0.28 g]). Final purification was achieved by reverse-phase flash chromatography (0.5% acetic acid in methanol) followed by reverse-phase HPLC (0.5% acetic acid in methanol). Fractions containing compound **1** were combined, and the solvent removed by rotatory evaporation to give 0.08 g of a white amorphous solid: mp 160°C (wide, decmpd); $[\alpha]_D$ − 3.5 (c = 0.63, $CH_3OH/CHCl_3$ 1 : 1); IR ($CHCl_3$ cast) 3200 (OH), 2915, 2859 (C–H), 1240, 1050, 960, 830, 750 cm^{-1}; ^1H NMR (500.1 MHz, $CDCl_3/CD_3OD$) δ 4.20 (bs, 2 H, $W_{1/2}$ 16 Hz), 3.90 (bt, 1 H, J = 10 Hz), 3.84 (m, 1 H), 3.77 (m, 1 H), 3.57 (bs, 2 H, $W_{1/2}$ 13 Hz), 3.36 (m, 6 H), 3.18 (s, 9 H), 1.47 (pentet, 2 H, J = 6.7 Hz), 1.18 (bs, 26 H), 0.80 (t, 3 H, J = 6.7 Hz); ^{13}C NMR (75.5 MHz, $CDCl_3/CD_3OD$) δ 71.1 (s, CH_2), 70.0 (s, CH_2), 69.1 (d, CH, J = 7.3 Hz), 66.8 (d, CH_2, J = 5.0 Hz), 65.7 (bs, CH_2), 58.4 (bs, CH_2), 53.2 (bs, CH_3), 31.2 (s, CH_2), 29.0 (s, CH_2), 28.7 (s, CH_2), 25.4 (s, CH_2), 22.0 (s, CH_2), 13.1 (s, CH_3); MS (MALDI) m/z 482, Calc for $C_{24}H_{53}O_6PN$ (M + H): mol wt, 482.

RESULTS

Davis et al. (1991) had shown that crude extracts of *Crella incrustans* could deter the settlement of the larval ascidian *Clavelina moluccensis*. The major difficulty in isolating the active component in the crude material was the fact that the test organism was only available for a maximum of four weeks each year. Below we give a description of the isolation and identification of the settlement deterrent as it progressed over a number of years. The initial strategy, developed to make the most efficient use of each bioassay period, relied on testing fractions of the crude extract obtained by means of a variety of chromatographic methods just before the bioassay period with the hope of correlating the active fractions and being able to focus more quickly on the active component. As was discovered, this strategy had the added advantage of side-stepping problems of loss of activity due to the nature of a particular chromatographic procedure.

November 9–13, 1991

Crude acetone extract of sponge was partitioned between water and diethyl ether and then 1-butanol. The 1-butanol fraction was split in two, one half being submitted to gel permeation chromatography (giving fractions 3-161A–E) and the other chromatographed on silica-gel by Speedy column (giving fractions 3-161F–J). The diethyl ether portion was evaporated under vacuum and further partitioned between hexanes and 20% aqueous methanol. A portion of the methanol fraction was then partitioned on a Sephadex column to give seven fractions (3-159D–J).

Fractions 3-159F–I, 3-161A–C, and G, H, and J were tested against *C. moluccensis* larvae. Results for each fraction are given in Table 1, which includes results from some runs on the same extracts used as checks later in the season (November 22–27, below). The data for different runs on the same extract were not heterogeneous and have been pooled here.

Clearly, sample sizes achieved for some tests were small, the power of the tests is correspondingly low, and some nonsignificant results mean little, but 3-159G and H were significantly repellent and 3-161H significantly attractive (we use these terms to mean no more than the fact that more larvae settled away from or on the extract, respectively, without implying anything about the mechanism).

These results showed that: (1) the active component was not efficiently extracted into diethyl ether from the original acetone extract, (2) silica-gel chro-

TABLE 1. NOVEMBER 1991 *C. moluccencis* FIELD ASSAY RESULTS[a]

matography resulted in the loss of the active component, and (3) the active component was present in the middle fractions after partition chromatography and appeared to be in the early fractions after gel permeation chromatography.

November 22–27, 1991

The aqueous acetone extract from a new collection of *C. incrustans* was exhaustively extracted with diethyl ether, dried under vacuum, and partitioned between hexanes and 20% aqueous methanol. The methanol fraction was partitioned on Sephadex to give six fractions (3-185C–H), and the middle four (3-185D–G) were separated into nine fractions each (3-193, 3-187, 3-189, and 3-191A–I, respectively) by gel permeation chromatography.

Bioassays commenced with the larger mass fractions, which showed clearly defined spots by TLC. Initially a qualitative settling deterrent response was sought, and it was not until the fifth day of testing that a positive result was observed among early fractions from the gel permeation column (3-187A, 3-191A). On the sixth day, further testing of these fractions showed that the deterrent response was statistically significant. Activity appeared also to be present in 3-193A and 3-189B, although not statistically significantly; it was not possible to run further tests on these fractions. Bioassay data are summarized in Table 2, in which runs on a given extract have been pooled if not significantly heterogeneous. Again, some sample sizes are small and results should be treated cautiously, especially for those marked as having a low sample size, where cell expectations are three or less.

The ^{1}H and ^{13}C NMR of the chromatographically similar repellent fractions indicated that they consisted almost entirely of a single organic compound bearing glycerol and phosphocholine subunits reminiscent of a choline phospholipid. Visualization of TLCs of these fractions with Dragendorff's reagent confirmed the presence of a compound with a nitrogenous functional group.

These results clearly suggested the targeting of a particular compound in the sponge extract that could be detected by NMR, but partition chromatography appeared not to be an efficient means of purifying it.

November 4–8, 1993

An aqueous acetone extract from a new collection of *C. incrustans* was extracted with 1-butanol, dried under vacuum, and partitioned between hexanes and 20% aqueous methanol. The methanol fraction was submitted to two passes over gel permeation chromatography, and the fraction containing the bulk of the Dragendorff-positive component was separated by reverse-phase flash chromatography into seven fractions (4-127A–G). Fraction 4-127E was purified by reverse-phase HPLC to a single compound (4-129E) whose NMR spectra were essentially identical to those obtained for the previously active fractions. Frac-

tions 4-127B, C, and D, and the compound 4-129E were tested for settling deterrence against the larvae of *C. moluccenis*.

Several concentrations of 4-129E were compared in an attempt to determine an appropriate concentration for assays that would deviate significantly from a 1 : 1 ratio. Five concentrations were used (see Table 3) and the set of trials run over three days. The pooled data are given in Table 3. For 4-129E, the proportions settling on control versus extract papers were significantly heterogeneous between concentrations at the 5% level. Overall, the data deviated significantly at the 0.1% level from a 1 : 1 ratio: the fraction was clearly repellent. Although only the three highest concentrations were significant, the two lowest showed a trend in the same direction.

Mussel and Bryozoan Bioassays

A sample of *C. incrustans* collected from Edithburgh in February 1992 was extracted with acetone and the resulting extract partitioned between hexanes, 20% aqueous methanol, 1-butanol, and water. The mussel assay was applied to all four fractions, with no significant effect detected. The hexanes and 1-butanol fractions were tested with *Bugula* at 130 ng/cm^2, both giving significant repellent effects. The effect of *lyso*-PAF should be seen in the 1-butanol and perhaps methanol fractions but definitely not in the hexanes fraction; the activity towards *Bugula* in those fractions must be due to some other compound(s).

From the November 13, 1991, collection of *C. incrustans* (which yielded the fractions 3-187, 3-189, 3-191, 3-193 used in the second series of field bioassays on *Clavelina*), pooled fractions 3-193B, 3-189B, and 3-191A were refractionated by a reverse-phase Sep-Pak Classic Cartridge C18 (Waters), methanol–water step gradient, to yield fractions 3-257A–D. Fractions 3-257A–C were tested against *Bugula*, and fractions C and D were pooled and further separated using a reverse-phase Sep-Pak, methanol–water step gradient, to yield six fractions, 3-259A–F, which were also tested against *Bugula*. The results revealed the following: Fraction 3-257A was toxic, 3-257B had no significant effect, 3-257C was toxic, 3-259A was repellent, 3-259B–E were all toxic, and 3-259F was repellent.

Clearly, there was something in these fractions that was strongly deterrent or toxic to *Bugula*. The activity detected with the *Clavelina* assay in the field was presumably present in these fractions and may have been responsible for the result; if so, it seems that *Bugula* is very sensitive to it. In retrospect, it would appear that a major proportion of this material was compound **1**, and these observations are consistent with our results on the pure compound.

Compound **1** (fraction 4-141B) was tested in the mussel and bryozoan assays, and a sample given to Dr. R. De Nys for the cyprid and *Ulva* assays. Results are summarized in Table 4.

In the mussel assay, only the highest concentration tested gave significant inhibition of byssal attachment. The bryozoan assay was not used at that concentration because the next two in the series were significantly toxic to the larvae; at 2.2 $\mu g/cm^2$ all larvae died, cf. 3% in control dishes; at 1.1 $\mu g/cm^2$, >50% died (cf. 15% in controls); at 546 ng/cm^2 and 273 ng/cm^2, death rates were not significantly different from controls but there was significant (5% level) avoidance of settlement on the extract. (At 546 ng/cm^2, however, there was significant heterogeneity between the three trials, one of them not showing deterrence). Below 273 ng/cm^2 neither toxic nor repellent effects were detected. In the *B. amphitrite* cyprid assay, compound **1** was inhibitory only at the highest concentration tested; at a surface concentration of 25 $\mu g/cm^2$, 23% of cyprids settled ($N = 3$, SE 3.35, each individual test involved ≥ 43 cyprids) compared

to ca. 50% settlement in all other concentrations and ethanol and seawater controls, e.g., ethanol controls 47% ($N = 3$, SE 2.15). In the *Ulva* assay, there was zero settlement at 25 $\mu g/cm^2$, whereas at all lower concentrations, settlement was the same as controls, ca. 25 germlings/cm^2.

Identification of Compound 1

The most prominent signal in the ^{13}C NMR spectrum appeared at δ 29.0, which is typical of methylene groups in a long aliphatic chain. Signals at δ 13.1 (CH_3), 22.0 (CH_2), and 31.2 (CH_2) correspond to a methyl terminus at one end of the chain. The lack of a carbonyl signal in either the IR or ^{13}C NMR spectrum suggested that the chain was linked to the remainder of the molecule through an ether group rather than an ester. The carbons α, β, and γ to the ether linkage were detected at δ 70, 28.7, and 25.4, respectively. The remainder of the signals in the ^{13}C NMR spectrum are all grouped between δ 72 and 53, typical of carbons attached to heteroatoms. A notable feature of these signals was that almost all were either broadened or appeared as doublets, suggesting coupling to an atom like phosphorus. The ^1H spectrum, besides showing features consistent with a long aliphatic chain, had a 9H signal at δ 3.18, which suggested the presence of a trimethyl ammonium group in the structure and possibly a choline-based terminus. This is supported by the broad signal at δ 53.2 (CH_3), and further signals at δ 58.4 (CH_2) and 65.7 (CH_2) in the ^{13}C spectrum for the ethyl linkage between the two heteroatoms of choline. A third terminus was identified as an alcohol group from the IR spectrum (3200 cm^{-1}). On the basis of this analysis, it was suggested that the compound was a glycerophosphocholine with an unusual ether-linked aliphatic chain at one of the remaining alcoholic positions of glycerol, while the third remained unattached. Comparison of our NMR data with that of *lyso*-platelet activating factor (compound **1**) (Convert et al., 1984) showed that they were identical in all respects (Figure 2).

Two points remained to be determined about the structure, viz., the length of the alkyl chain and whether compound **1** was optically active. Since no sp^2 proton signals appeared in the ^1H spectrum, the alkyl chain length and the presence of homologs could be readily determined by low-resolution MALDI

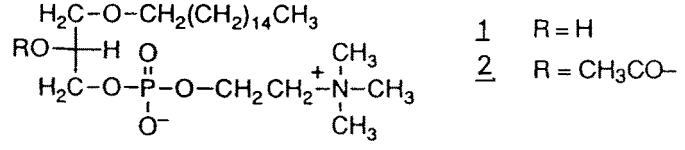

FIG. 2. Structure of compound **1**, *lyso*-PAF, and compound **2**, PAF.

mass spectrometry. In the event, only one significant peak was detected at *m/z* 482, $[M+H]^+$, which corresponds to a chain length of 16 carbons. The $[\alpha]_D$ value of $-3.5°$ indicated that compound **1** was not racemic and had the *R* or Sn configuration (Fusetani et al., 1986). Thus compound **1** was identified as 1-hexyldecyl-sn-glycerol-3-phosphorylcholine (*lyso*-PAF).

DISCUSSION

Sponges have been one of the groups of sessile invertebrates most actively studied by marine natural products chemists since, in an extremely competitive environment, they often appear to be undefended by any physical processes (Bakus et al., 1986; Davis et al., 1989) and they offer relatively large amounts of lipophilic material for investigation. Large numbers of compounds with novel structures and diverse biological activity have been found in sponges (Minale et al., 1976; Faulkner, 1994). Despite this level of activity, however, the role of these compounds in their environment has rarely been investigated. This is not surprising given the complexity of the task of testing hypotheses about ecologically significant chemical interactions in the marine environment.

Paul (1992) has noted three criteria that need to be addressed for the ecological significance of an antifouling compound to be established. They are: (1) Is the compound available to the potential fouling organism at sufficient concentrations to act as a deterrent? (2) Is the fouling species one that may potentially foul the organism in nature? (3) Does the compound deter fouling under natural conditions?

Jensen et al. (1990) have, in a different but relevant context, suggested two further criteria: (4) Is the compound isolated a true metabolite of the organism (or its symbionts) and not artificially derived during collection or extraction from an associated but otherwise inactive substrate? (5) Can a normally nondeterrent surface be made deterrent by application of the compound?

If antifouling activity is demonstrated in the field, we might go further and ask more detail about its origin—whether it is produced by the organism itself or by symbionts, and in either case by what biochemical pathway and with what evolutionary origin. These are interesting but not ecological questions; there is a temptation to move in their direction because they may be more tractable than the ecological questions, but the above ecological criteria must be met before these other questions have meaning.

In our procedure of identification of *lyso*-PAF as a fouling deterrent of the larvae of *C. moluccensis* we have largely satisfied four of the five criteria. *C. incrustans* and *C. moluccensis* share a common environment, and it has been shown that the surface of *C. incrustans* is significantly avoided by the larval ascidian (Davis et al., 1991). The bioassays were of necessity conducted under

natural conditions to the extent that wild larvae were used as the test organisms and with regard to seawater constitution and temperature. The test used in the bioassay was a test of the difference between surfaces (viz., filter paper) coated and not coated with the compound. *C. incrustans*, when collected, was noticeably free of epibionts and readily torn off from above its substratum (a timber piling), thus giving confidence that the source of *lyso*-PAF is the sponge itself. The reproducibility of the extraction of the antifouling component in the sponge and the inherent stability of *lyso*-PAF points to it being a true metabolite of *C. incrustans* (or of closely associated commensals). Paul's (1992) first question concerning the available concentration of *lyso*-PAF encountered by the settling *C. moluccensis* larvae remains to be answered; we cannot say whether it is present at the surface of the undisturbed sponge and hence able to influence a larva on approach or contact. Nevertheless, we have clearly shown it is active as an antifouling agent and therefore it was interesting to ascertain its activity against a variety of fouling organisms. Besides the original *C. moluccensis* larvae, *lyso*-PAF was tested for settlement deterrence in four other assays. Some of these have been used in other laboratories and, as a result, it is possible to compare the activity of *lyso*-PAF with that of other compounds known to have antifouling properties.

In the *Balanus amphitrite* cyprid assay, 25 $\mu g/cm^2$ of *lyso*-PAF yielded significant inhibition (23% settlement vs. 47% in ethanol controls); compare the *Delisea pulchra* extract, 0% settlement at 2.5 $\mu g/cm^2$ (De Nys, personal communication) and the near zero value for bacterium D2 films $\leq$48 hr old (Holmström et al., 1992). Kon-ya et al. (1994) and Keifer et al. (1986) report relevant results for 2,5,6-tribromo-1-methylgramine (TBG) and renillafoulins, but it is difficult to compare these concentrations in solution with our concentrations per unit area.

In the *Bugula neritina* larval assay, *lyso*-PAF was toxic above 1.1 $\mu g/cm^2$ and gave significant settlement inhibition above 273 ng/cm^2, whereas renillafoulins did not deter larvae of *B. neritina* (Davis et al., 1989; Pawlik, 1992b). When *lyso*-PAF was tested in the assay using gametes of *Ulva lactuca*, there was zero settlement at 25 $\mu g/cm^2$ but no inhibition at lower concentrations; compare the *Delisea pulchra* extract, which yielded zero settlement at 25 ng/cm^2 (De Nys, personal communication).

Byssal thread attachment by *Xenostrobus pulex* was significantly inhibited at 4.37 $\mu g/cm^2$. In a similar assay using *Mytilus edulis*, 80 $\mu g/cm^2$ $CuSO_4$ was the concentration required for maximal repellant activity in a five-step scoring system starting at zero activity (Ina et al., 1989), while the comparable value for crude MeOH extracts from *Undaria pinnatifida* and *Costaria costata* was 4 mg/cm^2, and for purified glycerolipids from them, on the order of 1 $\mu mol/cm^2$ (Katsuoka et al., 1990). Clearly, the results are mixed, and it is difficult to

compare the activity of *lyso*-PAF with that of other fouling deterrents, but the assays all indicate a deterrent effect.

In testing compound **1** itself (Table 4), the bryozoan assay was much more sensitive than the mussel, cyprid, and *Ulva* assays. The mussel assay detected repellent activity only at 4.4 $\mu g/cm^2$, while the bryozoan assay showed toxicity down to 1.1 $\mu g/cm^2$ and repellence down to 273 ng/cm^2. The cyprid and *Ulva* assays showed repellence at 25 $\mu g/cm^2$. The *Clavelina* assay detected repellence at and above 3.8 $\mu g/cm^2$. This difference in sensitivity of the assays appears to be general. Apart from *Crella incrustans*, in our program, so far 17 species (14 sponges, 3 ascidians) have been tested using various extraction procedures, and the *Bugula* assay has detected repellent activity in more fractions than *Xenostrobus*. Most of the active fractions have been polar lipophilic compounds (soluble in "wet" ether) with molecular weights between approximately 600 and 1500 amu as estimated from their behavior in gel permeation chromatography (i.e., Sephadex LH-20 with methanol or methanol–chloroform). *B. neritina* responded to at least one fraction from every species tested. Despite their cosmopolitan distribution, *B. neritina* larvae seem to be deterred from settling by a wide variety of marine organism extracts; for this reason we consider them of limited value in antifouling assays.

Compound **1**, *lyso*-PAF, besides being present in a variety of mammals including humans, has been found in a hydroid (Fusetani et al., 1986), a starfish (Iorizzi et al., 1991), and an earthworm (Noda et al., 1992). The identification of *lyso*-PAF as a settling deterrent raises several questions. How does its chemical structure relate to its deterrent activity, how does it compare with the structures of other putative settling deterrents, and does the vast amount of knowledge available about its action in mammalian systems suggest any insight into its action as a settling deterrent of marine invertebrates?

We shall not detail the relevant arguments and literature here, but outline the possibilities briefly. Antifouling activity has been attributed to certain nitrogen heterocycles (Targett et al., 1983; Kon-ya et al., 1994; Walls et al., 1995), and this activity may be due to a cationic group that may interfere with ion transport mechanisms; *lyso*-PAF bears such a cationic center due to a quaternary ammonium group. Another group of deterrent compounds can be said to have a broadly detergent-like structure, with a polar head group and a nonpolar tail (e.g., Mizobuchi et al., 1993), and we note that *lyso*-PAF has the overall structure of a detergent, with the trimethyl ammonium as the polar headgroup and a long aliphatic ether as the hydrophobic tail. It has been shown to be cytolytic and membrane perturbing (Weltzien, 1979). This possibility may be testable, because *lyso*-PAF is optically active. A significant reduction of deterrent activity of the unnatural *S* enantiomer compared to the *R* enantiomer would imply the existence of a specific receptor site on the *C. moluccensis* larva, rather

than some general detergent-like activity. We have recently initiated a structure–function study that seeks to determine the importance of the aliphatic chain length, the presence of the chiral center, and the ammonium group to the antifouling activity of *lyso*-PAF.

Almost nothing is known about the biochemistry of settling deterrence in marine invertebrates, but there are some remarkable similarities in the biochemistries of settlement induction and of PAF (Morse, 1990; Pawlik, 1988, 1990, 1992a,b), and one might pursue these on the assumption that the deterrence and induction of settlement are linked biochemical pathways. The most interesting similarities are in the roles of inorganic cations and of arachidonic acid as they relate to signal transduction mechanisms.

This paper concentrates on antifouling activity, which was the genesis of the work, but of course sessile invertebrates such as *C. incrustans* are exposed to other risks (predation, infection), and there are many mechanisms that may function to defend the organisms from these risks. Further, any of these mechanisms may have more than one function (Paul, 1992; Schmitt et al., 1995). We make no attempt here to examine other possible functions or to postulate evolutionary or immediate biochemical origins. These are important topics for further work.

Acknowledgments—The authors wish to thank Mark Duncan for assistance with the mass spectroscopy. We are grateful to Ian Magraith, Wendy Jones, Andrew Melville, Colin Simpson, Jonathon Stevenson, Joanna Strzelecki, Craig Styan, and Rosemary Swart for technical assistance with sponge collection and the bioassays. The work was supported by a grant from the Australian Research Council. Field work was based at the Coobowie Marine Research Station, University of Adelaide.

(Received January 17, 1996; accepted June 24, 1996)

Abstract—The sexual behavior of the ectoparasitoid *Diglyphus isaea* is described. Recognition of the female by the male occurs at close range. Males initiate courtship behavior in the presence of a living female regardless of age, as well as in the presence of a female killed by freezing. Courtship behavior is not observed in the presence of a dead female washed with organic solvents but could be elicited using a lure covered with a female organic extract. These findings demonstrate that each sex develops a specific chemical signature that can be dissolved in hexane and transferred to a lure. Analysis of organic extracts by gas chromatography revealed chemical dimorphism between the two sexes. Gas chromatography coupled with mass spectrometry showed that the main components in females were esters of medium-chain fatty acids and long-chain 11-alcohols. There were few hydrocarbons. Female esters, which were present in only small proportions in males, were recovered in the nonhydrocarbon fraction obtained after fractionation of the total extract on a silica-filled microcolumn as a mixture containing 11-heneicosyl, 11-docosyl, 11-tricosyl, 11-tetracosyl, and 11-pentacosyl octanoate, and 11-docosyl, 11-tricosyl, 11-tetracosyl, and 11-pentacosyl decanoate. These results demonstrate that there is a specific gender-related chemical signature.

Key Words—Hymenoptera, Eulophidae, *Diglyphus isaea*, courtship behavior, contact pheromones.

INTRODUCTION

The entomophagous hymenopteran *Diglyphus isaea* Walker is a larval ectoparasitoid that attacks numerous leafminer species including *Liriomyza trifolii* Burgess. The mating behavior of *Diglyphus* has not been previously studied, but we suspected that, as in many insects, pheromones allow sex recognition and possibly induce the courtship dance.

An obvious prerequisite for mating is the male and female encounter. Several factors complicate encounters in *Diglyphus*. First, unlike other parasitoid Hymenoptera, e.g., *Trichograma* (Suzuki and Hiehatri, 1985), in which encounters are promoted by infestation of the same host, *Diglyphus* is a nongregarious parasitoid and the likelihood that a male and female should emerge in the same place is low. Second, protandrism is well documented in parasitoid Hymenoptera (Suzuki and Hiehatri, 1985). Third, male *Diglyphus* develop more quickly (Minkenberg, 1989; Cheah, 1987) and thus emerge before females.

Our preliminary studies ruled out emission of volatile pheromones by either sex and showed that sex encounters take place on leaves parasitized by leafminer larvae to which both sexes are attracted by plant volatiles (Finidori-Logli, 1994; Finidori-Logli et al., 1996). This finding accounted for how the two sexes came together in the same place and time, but did not explain of how male and female *Diglyphus isaea* recognize one another on the same leaf.

In the present study, ethological tests using the chemical lure method (Howard et al., 1982; Bonavita-Cougourdan et al., 1987; Bagnères et al., 1991) were performed to assess the role played by chemical signals in the strategy used by males and females to recognize one another for mating. Contact sex pheromones have been documented in several invertebrate groups, e.g., Diptera (Uebel et al., 1977; Carlson et al., 1978; Huyton et al., 1980; Antony and Jallon, 1982), Orthoptera (Warthen et al., 1981), and spiders (Hegdekar and Dondale, 1969).

METHODS AND MATERIALS

Insects. Diglyphus used in these experiments were reared according to the "alternate open-field and caged ovipositing" method (Lyon, 1976) at a permanent rearing facility set up by the INRA in Antibes, France.

Ethological Testing. Experiments consisted of comparing the attractive effects of a living female and five different lures on males. The first lure was a female killed by freezing. The second lure was a female killed by freezing and

washed twice for 10 min in hexane. After the second washing, gas chromatography (GC) was performed on an extract to ensure that no more chemical signals were present on the cuticule. The third lure was a female killed by freezing, washed in hexane, and then covered with the whole extract obtained as described below. The fourth lure was a female killed by freezing, washed in hexane, and then covered with the apolar fraction of the whole extract. The fifth lure was a female killed by freezing, washed in hexane, and then covered with the polar fraction of the whole extract.

Males were tested individually in the presence of one female, or one of the five lures. All tests were carried out on the bottom of a Petri dish (6 cm diameter) covered with damp filter paper. Each test was replicated 20 times. The following five responses characteristic of courtship behavior were quantified: lateral trembling (I), mounting the female (II), palpating with antennae (III), genital contact (IV), and copulation (V). Statistical comparison of the male responses in the different test series was done using the Mann-Whitney test in a Statgraphics software (version 3.0).

Chemical Analysis. Extracts used to prepare lures for ethological tests were obtained from 200 females in 400 μl of hexane. These extracts were applied either whole or separately as apolar and polar fractions. Separation was performed on a microcolumn constructed by packing a capillary tube (8 cm length, 0.5 cm diameter) with Chromagel silica (particle size: 40–60 μm, 230–400 meshs) that was rinsed and dried in a drying chamber. The apolar fraction was obtained by elution with hexane. The polar fraction was obtained by elution with a mixture of hexane and diethylether (95:5).

For GC analysis, 20 extracts of each sex were obtained by immersion in hexane and concentrated under nitrogen. Females and males were killed by freezing and weighed. Female extracts were obtained from 20 individuals and male extracts from 40 individuals. GC was performed on a Delsi-Nermag system DN 200 equipped with a flame-ionization detector (FID), a split/splitless injector (splitss 15 sec), and a Chrompack CPSil5 CB apolar capillary column (25 m $\times$ 0.25 mm $\times$ 0.25 μm). The carrier gas was helium at 1 bar. Temperature was programmed from 70°C to 150°C at 30°C/min, and then from 150°C to 320°C at 5°C/min. Compounds were quantified using an *n*-alkane not present in the natural extract as internal standard. For females, 50 μl of a solution containing 400 ng of heneicosane (n-C_{21}) was added to the total extract. For males the same amount of nonacosane (n-C_{19}) was added. Equivalent chain length (ECL) (Miwa, 1963) was calculated for each compound using a mixture of internal standards from the n-C_{18} to the n-C_{40}, coinjected with the total extract.

Results were collected on an Enica 21 integrator. Quantifications were performed using a Lotus 1.2.3 spreadsheet (version 3.1) after correction of peak surfaces by applying the coefficient of Bagnères et al. (1991), to take into

account the sensitivity of the FID. Each product was quantified as a percentage (relative proportion), quantity per insect, and quantity per milligram of insect body weight.

For identification of female and male extracts, analyses were performed by electron impact (at 70 eV) followed by examination under positive chemical ionization ($CI^+/CH_4{}^+$, 150 eV) on a Hewlett-Packard HP 5890 Series II chromatography system coupled to a quadrupole MS Engine Hewlett-Packard 5989A mass spectrometer. The coupled system was controlled by a Chemsystem HPUX management system running Unix software. Carrier gas pressure (helium) was 2 bars with a source temperature of 240°C, a quadrupole temperature of 100°C, and an interface of 300°C. Masses were scanned from 45 (95 in CI^+) to 600 *m/z* at a mean rate of one scan per second. The chromatography system was equipped with an HP5 apolar capillary column (30 m × 0.25 mm × 0.25 μm). In addition, a GC-MS system VG 70/250 SE connected to an HP 5890 gas chromatograph, was used at 70 eV under the conditions described earlier (Schmitt et al., 1991).

Identification of Behaviorally Active Compounds. Identification of the natural aphrodisiac compounds was achieved by comparison with the following synthetic compounds, not commercially available.

Esters of Secondary Alcohols. Synthesis of reference compounds followed standard procedures (Weygand and Hilgetag, 1970). The 11-alkanols were prepared from undecanal (Merck) and appropriate Grignard reagents obtained from alkylbromides (Merck) in diethylether. Esterification was performed by reaction of the alcohol and corresponding acylhalogenide in pyridine.

Derivatization Reaction. Reduction of naturally occurring esters was carried out as follows: the polar fraction obtained from 400 females was brought to a volume of 100 μl. To this solution, 20 mg of lithium alumina hydride (carefully prewashed with pentane) was added. After 30 min a few drops of water were added and the organic layer was separated. After flash chromatography on Florisil (hexane–diethylether 95:5) and concentration, the sample was submitted to GC-MS (VG instrument) analysis without further purification.

RESULTS

Description of Courtship Behavior. After introduction into the Petri dish, males and females first explore the new surroundings. This exploratory phase is characterized by walking and leaping on the bottom, walls, and cover of the dish. The antennae are in constant movement. In all tests males recognized females only at close range (a few millimeters). Regardless of the age of the female, the male initiated the following courtship dance. First the male stops near the female and begins lateral oscillations with its wings extended towards

the female (20 of 20 tests). Next the male mounts on the back of the female and begins palpating her with his antennae. A receptive female allows this palpation while an unreceptive one flees. The male usually gives up after two unsuccessful attempts. If consent is obtained, the genitals are brought into contact as palpation with the antennae continues, and finally copulation with insemination occurs. There is no identifiable postcopulation behavior.

Courtship behavior using females killed by freezing was initiated in 19 of 20 tests (Table 1, Figure 1). Palpation with the antennae occurred in only 10/20 tests, genital contact in only 7/20, and copulation in only 2/20 (i.e., 10% success rate). Failure to complete courtship dance, especially in the last three responses, was probably due to the immobility of the female, which may cause the male to lose interest. Thus, while chemical signals are certainly involved in triggering courtship, these observations suggest that additional signals are necessary for completion of courtship.

Courtship behavior was not observed in any of the 20 tests carried out using a female that had been washed in hexane (Table 1, Figure 1). This finding confirms the aforesaid hypothesis that recognition of the female by the male

TABLE 1. MALE BEHAVIOR IN PRESENCE OF LIVING FEMALE (L), DEAD FEMALE (D), FEMALE WASHED WITH HEXANE (W), OR LURE COVERED WITH TOTAL EXTRACT (W+T), POLAR EXTRACT (W+P) OR APOLAR EXTRACT (W+A)[a]

Females or lures	Male behavior				
	I	II	III	IV	V
L	20	19	17	17	15
D	19	14	10	7	2
W	0	0	0	0	0
W + T	20	14	11	3	3
W + P	20	18	13	10	8
W + A	8	6	2	1	0

[a]The behavioral items observed were (I) lateral trembling, (II) mounting on the female, (III) palpating with the antenna, (IV) genital contact, and (V) copulation. Male responses were compared using the Mann-Whitney test, $*P < 0.05$, $**P < 0.01$, $***P < 0.001$.

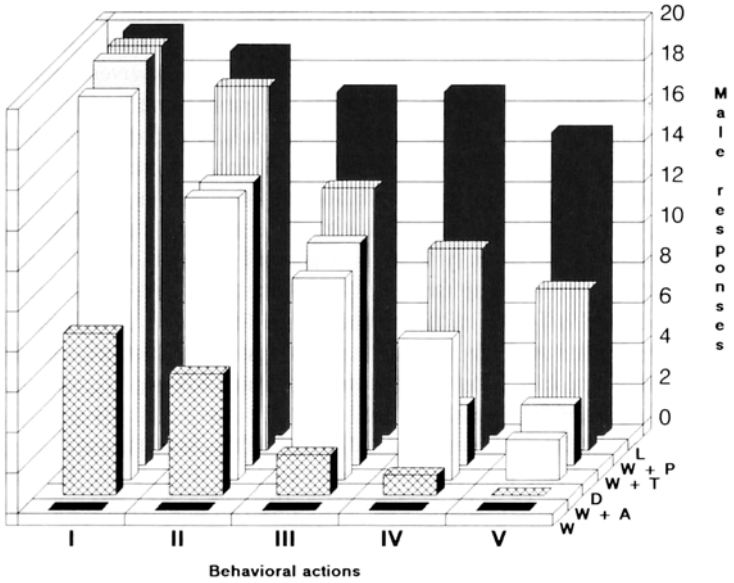

FIG. 1. Results of lure tests. The x axis indicates five items of courtship behavior: (I) lateral trembling, (II) mounting, (III) palpating with the antenna, (IV) genital contact, (V) copulation. The y axis indicates the number of positive male responses, N (number of males) = 20. The z axis indicates the test situation: W, male in the presence of a female washed with hexane (i.e., lure); W + A, male in the presence of a lure covered with apolar extract; D, male in the presence of a dead female; W + T, male in the presence of a lure covered with total extract, W + P, male in the presence of a lure covered with polar extract, L, male in the presence of a living female.

depends on cuticular chemical signals. A few preliminary bioassays were performed using washed lures covered with male extracts. No male response was ever observed, thus demonstrating that the aphrodisiac signal came exclusively from the female.

Courtship behavior resumed when a lure covered with 2 μl of the total hexane extract (i.e., the equivalent of one female) was used. Lateral oscillations were observed in 20 of 20 tests and mounting in 14 of 20 (Table 1, Figure 1). This finding supports the assumption that the chemical signal is located on the cuticle.

Lures prepared using the apolar phase did not restore courtship behavior in males. Lateral oscillations were observed in only 8 of 20 tests and copulation was never observed (Table 1, Figure 1).

In contrast, lures prepared with the polar phase restored courtship behavior in males. The first four responses of the courtship dance were observed in all 20 tests. Copulation was observed in 8 of 20 tests. This demonstrates that the polar fraction carries the most active principle for recognition of a sex partner.

Chemical Analysis. GC-MS analyses revealed qualitative and quantitative gender-related differences (sexual dimorphism) in the cuticular composition of *Diglyphus isaea* (Figure 2). Analysis of total extracts from males and females showed that most prominent products were apolar or moderately polar molecules, with long chains with 16–33 carbon atoms. These are classic findings for cuticular lipid extracts (Lockey, 1988; de Renobales et al., 1991). These substances can be divided into two groups, i.e., hydrocarbons and esters. Compounds identified in the cuticle of *D. isaea* (males and females), and corresponding amounts quantified in the stable part of the extract (from n-C_{23}) are listed in Table 2. Eleven common acids, methyl esters, or ethyl esters with C_{16} and C_{18} were detected only sporadically and are not included in the table.

In extracts obtained from males (mean weight $\cong$ 0.04 mg), the main components were hydrocarbons, (more than 80% of the cuticular mixture, see Table 2). These hydrocarbons are all saturated and can be classified into two categories: n-alkanes, which account for 16% of the cuticular extract (0.7 μg/mg

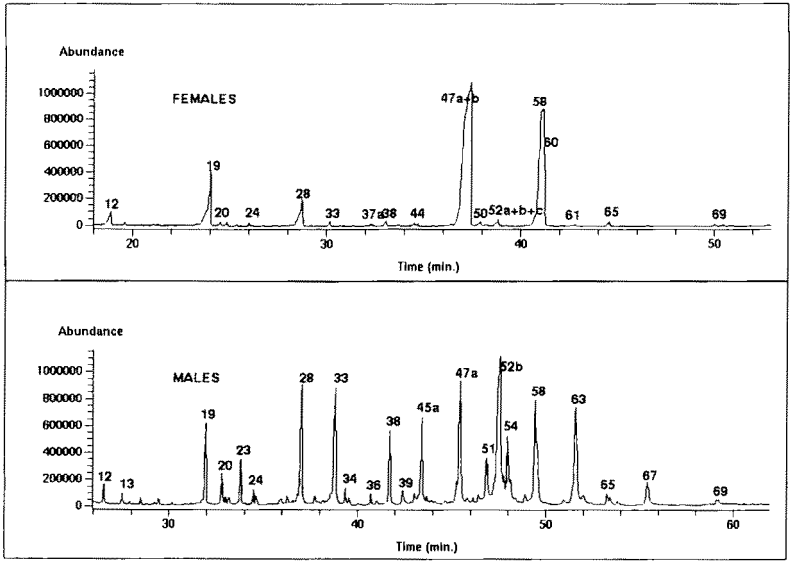

FIG. 2. Total ion chromatograms (TIC) of female (top) and male (bottom) *Diglyphus isaea*. For peak numbers see Table 2.

"Compounds expressed as percentages and quantities in nanograms per milligram of insect weight, with standard deviation (SD) in parenthesis.

of insect weight), and branched alkanes with one or more methyl groups. Male *Diglyphus* contain 19% monomethylalkanes (0.8 μg/mg of insect weight), 46% dimethylalkanes (1.9 μg/mg of insect weight), and 4% trimethylalkanes (0.2 ng/mg insect weight).

Extracts obtained from females (mean weight ≅ 0.1 mg) contained the same hydrocarbons as males but in different proportions (Table 2). Hydrocarbons accounted for only 29% of the cuticular mixture. The largest group was *n*-alkanes, which accounted for half of the hydrocarbons (16%, or 0.7 μg/mg of insect weight). In males the largest group of hydrocarbons was dimethylalkanes.

The most pronounced difference between males and females involved nonhydrocarbon compounds, which accounted for the remaining 70% of the cuticular extract in females, (2.9 μg/mg of insect weight) versus 14% in males (0.8 ng/mg of insect weight). Peak 47a, one of the three major nonhydrocarbon compounds (>5% of the total mixture) accounts for 31% (about 1.3 μg/mg of insect weight) of the female cuticular mixture, peaks 58–60 account for 32%, and peak 64 for 5%.

GC-MS analysis of the nonhydrocarbon fraction obtained from females revealed a series of bis-homologous compounds whose mass spectral data did not fit with the classic fragmentation scheme for *n*-esters of Attygalle et al. (1987). The EI spectrum of the first major compound (peak 47a) showed the highest visible fragment at *m/z* 322 ($C_{23}H_{46}$ upon high resolution mass spectrometry) and a particularly intense signal at *m/z* 127 ($C_8H_{15}O$). While the alkene fragment was regarded as a result of a MacLafferty rearrangement, the oxygen-containing fragment together with a doublet of low intensity at *m/z* 144/145 pointed to octanoic acid as a partial structure (Tengö et al., 1985). With chemical ionization, the fragmental ion was strong, whereas the molecular ion 465, which corresponds to $(M-1)^+$, was weak. These findings are consistent with an ester with 31 carbon atoms: 23 at the alcohol side and 8 at the acid side. Comparison of the spectra of the natural compounds and synthetic compounds with a straight-chain primary alcohol showed no concurrence (the molecular ion was present and very clear in EI). According to an earlier work (Tengö et al. 1991), the target compounds did not represent classic wax-type esters. As a result, we identified esters of octanoic and decanoic acids, with secondary alcohols that have a pronounced acyl/protonated-acid signal, especially when the alkoxy moiety is close to the middle of the chain (Blomquist et al., 1972; Tengö et al., 1985), with a chain length from 21 to 25 carbons atoms. Nine esters were identified in females as compared to only six (with two in trace amounts) in males. The three absent esters in males were the two with 24 carbon atoms (peaks 52c and 61), and peak 52a (a docosyl decanoate) (see Table 2).

Reduction of the crude nonhydrocarbon fraction with lithium alumina hydride yielded 1-octanol and 1-decanol (as determined by their spectra using

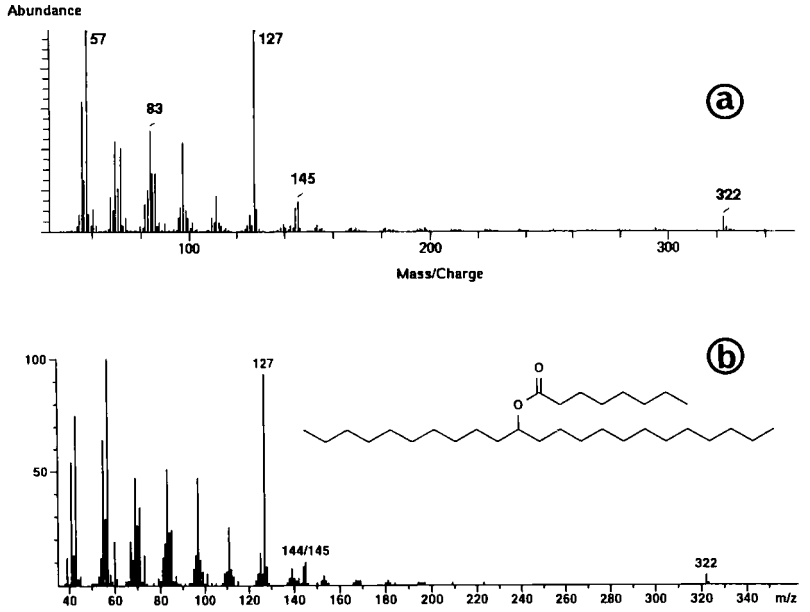

FIG. 3. Mass spectrum of the natural 11-tricosyl octanoate (a) and its synthetic compound (b).

authentic reference samples) and 11-tricosanol along with small amounts of 11-heneicosanol and 11-pentacosanol. 11-Docosanol and 11-tetracosanol were not observed, probably because these products accounted for less than 1% of the mixture. A synthetic sample of 11-tricosyl octanoate produced the same mass spectrum as the natural product, coeluted upon gas chromatography (Figure 3), and yielded the same key fragments as those reported by Blomquist et al. (1972) and Warthen and Uebel (1980). The same was true for the other 11-alkanol esters. Attempts to determine the absolute configurations of the esters failed, due to the great similarity of the alkyl chains side of the functional group. Further ethological tests with pure synthetic enantiomers are needed to establish the absolute configuration of the natural pheromones.

DISCUSSION

This study demonstrates that in *Diglyphus isaea* recognition of a female by a male occurs at close range, i.e., within a few millimeters. Recognition appears to be based mainly on chemical signals, and the role of visual signals was negligible in our experimental conditions. The fact that the male no longer

detects a female washed with hexane proves that the signal triggering male courtship behavior is on the female cuticle. This is further confirmed by the fact that the compounds involved can be extracted and transferred to a lure. Based on observations of male behavior, we speculate that contact pheromones are involved.

Our results in *Diglyphus isaea* indicate that the principal compounds inducing male courtship behavior are contained in the nonhydrocarbon fraction of the female cuticular extract. With regard to nonhydrocarbon compounds, the cuticular lipid composition is more varied quantitatively and qualitatively in females than in males. These substances appear on images upon emergence and do not change during adulthood. In a previous study (Finidori-Logli, 1994), we did not observe these oxygenated products in *Diglyphus* nymphs. This finding contrasts with results in *Melanoplus differentialis*, in which ester levels are high in last-instar nymphs but low in adult females (Warthen and Uebel. 1980). Lockey (1985) noted the presence of oxygenated compounds in 19 species of different genera. In this regard, it has been observed that the quantity of oxygenated compounds in the cuticle varies according to developmental stage in some species (Danehower and Bordner, 1984; Backer et al., 1979).

Since the method used to collect the insects did not rule out contact between the two sexes before collection, the possibility that the nonhydrocarbon products observed on the cuticle of males were acquired by contact with females cannot be ruled out. The chemical dimorphism that we observed between male and female, due essentially to long-chain esters, has been observed previously by other groups (Warthen and Uebel, 1980; Warthen et al., 1981). The latter authors were the first to suggest that sex recognition was based on differences in the cuticular mixture of long-chain esters and hydrocarbons.

In insects the cuticle is coated by lipids, the largest group being hydrocarbons (Lockey, 1988, de Renobales et al., 1991). In addition to the well-known protective role of lipids especially against desiccation (Hadley, 1981), there is now growing evidence that they also provide chemical behavioral signals (Howard, 1993). A few studies are available concerning cuticular hydrocarbons of parasitic Hymenoptera (Takashashi et al., 1990; Howard, 1992; Howard and Liang, 1993; Bagnères et al., 1996). In *Diglyphus isaea*, the hydrocarbon composition of the cuticle is sex specific. The male cuticle is extremely rich in branched alkanes, while the female cuticle is composed almost exclusively of *n*-alkanes and 3-methylalkanes.

Contact sex pheromones whose biosynthetic pathways are now better understood (Schal et al., 1994), especially regarding those of cuticular origin, seem to be under hormonal control (Wicker and Jallon, 1995a,b). In *Drosophila*, a portion of antennal lobe and mushroom bodies are involved in olfactory processing and may function in the recognition of contact sex pheromone and in control of sex-specific behavior (Ferveur et al., 1995).

The quantity of oxygenated derivatives of hydrocarbons on the cuticle is low (Lockey, 1988). The most common nonhydrocarbon products are primary fatty acids, alcohols, esters of these acids, ketones, and aldehydes. On the insect cuticle, secondary alcohols, esters of secondary alcohols, hydroxylated acids, diols, steroids, and terpenes are less frequent, but long-chain wax-type esters are not so uncommon (Blomquist and Jackson, 1979; Jackson, 1981; Buckner, 1993). Blomquist and Jackson (1973) found that in *Melanophus sanguinipes* *n*-alkanes were hydroxylated to secondary alcohols, and their esterification took place on the surface layer. Esters are typical constituents of exocrine secretions of many Hymenoptera, especially bees, and are frequently found on the surface layer (Francke, 1986; Francke et al., 1984). Long-chain esters (e.g., *n*-octadecyl hexadecenoate) have been described in mixtures with hydrocarbons in the Dufour gland of parasitic bees (Sick et al., 1994). This is the first report of secondary wax esters with 11-alcohols and short-chain acids. To the best of our knowledge, these alkyl-alkanoate compounds have only been described in species of *Melanoplus* (Buckner, 1993) and, unlike *Diglyphus*, were made up of acids with longer chains (between 10 and 20 carbons).

Our experience also indicates that tactile feedback plays a role early in courtship. While the chemical composition of the cuticle allows the male to recognize the female, it is by movements, especially of the antenna, that he is able to determine if the female is receptive. This mode of female recognition, obtaining consent after contact, has also been described in braconids (Matthews, 1974), and in particular in *Ascogaster reticulatus* (Kainoh, 1986), but never in Eulophidae.

While our findings help to explain how sex partners recognize each other at close range, the question of long-range recognition remains open. Several factors suggest that long-range recognition is necessary. Males emerge before the females and usually do not stay on the leaves from which they emerge. Females begin searching for a host within the first hour after emergence. Leaving long-distance recognition to chance would not only be a waste of time but also jeopardize procreation. Thus, there must be factors that promote encounters and ensure reproduction in parasitoids.

One possibility is that encounters result from intense searching at the side of the prey, i.e., at the plant area. We have not studied this hypothesis, but a very interesting finding reported from in-cage studies (Finidori-Logli, 1994) suggests a possible answer. Finidori-Logli et al. (1996) reported that a male that demonstrates no interest in an isolated female at long range was attracted to the same female when she was placed on a bean plant leaf. This attraction was even stronger if the leaf had been mined. This suggests that the male uses odoriferous signals from the plant to locate the area where he has the best chance of finding a female. Thus, encounters between the sexes in *Diglyphus isaea* could depend on a close-range signal involving cuticular contact pheromones,

as demonstrated in the present study, and on a long-range perception of volatile compounds from the host plant.

(Received October 30, 1995; accepted July 2, 1996)

Abstract—Using data from the arboreal nesting *Nasutitermes acajutlae* (Holmgren), we propose standard collection and extraction methodology for characterization of cuticular hydrocarbons of termites under field conditions in the tropics. Specifically, we evaluated: (1) the effect of the duration and the number of extractions; (2) the effect of drying termites before extraction; (3) the effect of sample size; (4) the effect of solvents (ethanol versus hexane) on cuticular hydrocarbon profiles. Olefins comprise ca. 70% of the cuticular hydrocarbons of *N. acajutlae*. Hydrocarbons consist of two distinct groups: early-eluting components, primarily *n*-alkanes and methyl-branched alkanes, and late-eluting compounds, which consist almost exclusively of unsaturated components with one to six double bonds. Soldiers have more early-eluting compounds than workers or alates. Nests from the same island had qualitatively similar, but quantitatively dissimilar hydrocarbon mixtures. Brief extractions of 300 live workers in 10 ml of hexane for only 20 sec produced a hydrocarbon mixture equivalent to a 10-min extraction. Long-term extraction of 300 workers in hexane for two years resulted in different mixtures of hydrocarbons. Drying workers tended to enhance extraction of the less abundant unsaturated compounds such as $C_{41:4}$ and $C_{41:5}$. A single extraction of a

minimum of 100 workers (live or dried), with hexane for 20 sec to 10 min is best; these extraction regimes resulted in mixtures of hydrocarbons that are quantitatively very similar. For quantitative comparisons, extracts from dried samples should not be compared to those from live samples. Storage in ethanol caused numerous unidentified, nonhydrocarbon compounds to be extracted either from the cuticle or from internal tissues.

Key Words—*Nasutitermes acajutlae*, chemotaxonomy, Isoptera, Termitidae, tropical termites, gas chromatography, cuticular hydrocarbons, olefins, mass spectrometry.

INTRODUCTION

Termites play an essential role in the ecological dynamics of many tropical ecosystems, recycling nutrients and aerating soils in forests, mangrove swamps, and grasslands. Some species of termites are also economically important as structural pests in urban, as well as rural, areas of the tropics. The termite fauna of tropical regions is known to be diverse, but species diagnosis remains equivocal in many groups. Cuticular hydrocarbons are useful for discriminating termite species in tropical (Haverty et al., 1990b, 1991a, 1992, 1997; Howard et al., 1988) and temperate (Haverty et al., 1988, 1991a; Howard et al., 1978, 1982a,b; Thorne and Haverty 1989; Thorne et al., 1993) regions. Species sorting and diagnosis based on such chemical separation may then be used to facilitate discovery of morphological criteria for discriminating species (Haverty et al., 1988; Thorne and Haverty, 1989) and delimiting geographic distributions (Thorne et al., 1993).

Comparative research for characterizing cuticular hydrocarbons for taxonomic or ecological studies will necessitate uniform protocols among investigators. Field circumstances must also be considered. In the tropics, termites are usually collected far from laboratory facilities. Hydrocarbon extractions must therefore be delayed until well after the insects have been collected. Standard preservation techniques, such as freezing, are usually impractical. Keeping subcolonies, groups, or samples of a specific size alive and healthy for more than a few hours is very difficult. Hot sun and predacious ants usually render field samples unusable, and live cultures are prone to problems with humidity, food stress, and pathogenic fungi. Collection of specimens directly into 70% or 85% ethanol may partially extract hydrocarbons or include some debris and potential contaminants. Long-term retention of specimens in ethanol or in a solvent such as hexane for extended periods, although potentially quite convenient, may also extract internal hydrocarbons and confound the characterization of cuticular hydrocarbons.

We have collected termites from the islands in the Caribbean and have also received specimens collected by colleagues, for characterization of cuticular

hydrocarbons. The method of collection has varied among these efforts. To interpret these data we must know if different collection/extraction regimes are equivalent or comparable. We also want to recommend the most appropriate technique for a given taxon to collaborating scientists.

In the earliest studies of termites that introduced the concept of species specificity of cuticular hydrocarbons, it was not specified how the insects were handled before extraction (Howard et al., 1978, 1982a). In later studies of chemical mimicry by termitophilous staphylinids, Howard et al. (1980, 1982b) separated the termitophiles from the termites and froze the beetles at −20°C before extraction. Haverty et al. (1988) froze *Zootermopsis* spp. individuals, then subsequently thawed them to room temperature before extraction. The termites were brought from the field to the laboratory alive (Haverty et al., 1988). However, after extracting a few live termites, one of us (L.J.N.) noticed that the termites convulsed and emptied their gut contents into the hexane during the process. Freezing the insects, followed by extraction of the specimens at ambient temperature, prevented this possible source of contamination.

Subsequent studies of cuticular hydrocarbons of termites have used live termites extracted in the field or in the laboratory [Howard et al., 1988 (for *Nasutitermes*); Haverty et al., 1990b (for *Nasutitermes*), 1991a, unpublished (for *Reticulitermes*)], or termites dried in the field and later extracted in the laboratory [Haverty et al., 1990a, 1996b (for *Coptotermes*), 1991a, 1992 (for *Reticulitermes* and *Coptotermes*)]. Our preliminary results comparing extraction of live versus dried *Nasutitermes acajutlae* (Holmgren) indicated that the resulting hydrocarbon mixtures were not equivalent.

Many of our colleagues find it difficult to dry termites while collecting termites in the tropics because of logistical problems. Ovens, heating lamps, and electricity are not always available. Since drying is often impractical, many researchers prefer to collect termites directly into alcohol or hexane. Collectors also do not want to divert their efforts away from maximizing the number of samples they can collect while in the field. The usual field technique is to place termites directly into 80% or 100% ethanol for later transmittal to the museum or laboratory. Detailed comparisons of cuticular hydrocarbon patterns derived from extractions of live or dried termites or termites stored for extended periods in ethanol or hexane are thus warranted and are one focus of this study.

Another factor affecting the assessment of the cuticular hydrocarbon pattern is the number of insects that are extracted or quantity of hydrocarbon extracted. In some studies a variable number of individuals (and mixture of castes) was included. Haverty et al. (1991a) used from 15 to 200 *Reticulitermes* spp. workers per sample in their preliminary study of this genus. In most of our studies an exact number of termites was extracted: individual *Zootermopsis* spp. pseudergates, nymphs, soldiers, or alates (Haverty et al., 1988); 100 *Coptotermes formosanus* Shiraki workers or soldiers (Havery et al., 1990a); 200 *C. formo-*

sanus workers or 50 soldiers (Haverty et al, 1996b); and 100 *Nasutitermes costalis* (Holmgren) or *N. ephratae* (Holmgren) large workers (Haverty et al., 1990b).

Extraction of too few individuals can result in a diluted extract and require a deviation from a standard technique. Characterization of hydrocarbons from dilute extracts would likely underestimate or not detect the less abundant compounds and overestimate the abundant compounds. We know of no published studies to determine the minimum number of individuals necessary to characterize the cuticular hydrocarbons of any termite taxon.

One of the primary reasons we began studies of extraction methodology was to remedy a problem encountered during studies of the cuticular hydrocarbons of *N. corniger* (Motchulsky), *N. ephratae*, and *N. costalis* (Haverty et al., 1990b; Howard et al., 1988). Haverty et al. (1990b) experienced difficulty obtaining a sufficiently large hydrocarbon sample by extracting 100 large workers of *N. costalis* or *N. ephratae* in the field in Trinidad. The samples taken during that study were barely sufficient to allow quantification of the hydrocarbon mixtures. Thus, we designed a first set of experiments in 1989 to better understand the difficulties experienced with the characterization of cuticular hydrocarbons from *N. costalis* and *N. ephratae*.

Given that any taxonomic or ecological study entails processing a large number of samples, it is essential to keep the method of analysis as consistent as possible. We have developed chromatographic conditions and mass spectral acquisition parameters that give optimal results for the vast majority of insect samples. We therefore focused our efforts on comparing various collection and extraction regimes using our standard analytical technique.

In the present study, we attempted to define a standard methodology for collecting and extracting termites under field conditions. Our field work was based at our research site on Guana Island, British Virgin Islands (BVI) (Thorne et al., 1994; Haverty et al., 1997). This island has a diverse termite fauna consisting of nine species in three families. The most conspicuous, and apparently abundant, species is the arboreal nesting *N. acajutlae* (Thorne et al., 1994; Scheffrahn et al., 1994). This species, as well as a closely related species, *N. nigriceps* (Holmgren), is numerically and ecologically conspicuous on many of the Caribbean islands (Thorne et al., 1994). A better understanding of the appropriate procedure(s) for sampling and extracting cuticular hydrocarbons of *N. acajutlae* is important to our understanding of the taxonomy, ecology, and biogeography of this and other *Nasutitermes* species. The methodology described here is optimal for sampling and extracting cuticular hydrocarbons for this species and should be applicable to most termites in the tropics. Very small termites, such as *Parvitermes* spp., will likely require larger samples, whereas the larger termites, such as *Neotermes* spp. and *Incisitermes* spp., will require fewer individuals.

For taxonomic studies we consider cuticular hydrocarbons useful primarily for separating species within a genus; obvious and consistent morphological characters usually suffice to separate taxa at higher levels (Haverty et al., 1991b). Hydrocarbons beneficial for taxonomic studies should be abundant, not minor components (at least 1.0%, but preferably 5.0% of the total hydrocarbon component). However, if a hydrocarbon is consistently detected, even in quantities below 1.0%, we would consider it a useful taxonomic character. Useful hydrocarbons should also be unique or present in only a few of the species, or conversely, they should be common in most of the species yet completely absent, rare, or of insignificant quantities in one or a few species. Furthermore, they should have a unique elution time so that they do not coelute with another hydrocarbon in the same species, nor should they elute at a time similar to that of a different hydrocarbon in a different species (Haverty et al., 1991b). From a set of hydrocarbons with these characteristics, dichotomous keys can be constructed. For ecological or biogeographic studies of the same species, examinations of the quantitative differences of the hydrocarbon mixture would be of paramount importance.

In this paper we report the results of studies conducted in 1989 and 1993 to compare and improve our sampling and extraction techniques for the characterization of cuticular hydrocarbons of tropical termites. In 1989 we examined influences of the number and duration of extractions. In 1993 we tried to design studies that would ultimately provide us with an optimal field method for characterizing both the composition and relative abundance of the cuticular hydrocarbons of *N. acajutlae*. We compare methodologies and suggest standard and alternative, acceptable methodologies for both chemotaxonomic and ecological studies of this termite. Specifically, we evaluate: (1) the effect of the duration and the number of extractions; (2) the effect of drying termite specimens before extraction; (3) the effect of sample size; and (4) the effect of solvents (ethanol versus hexane) on the reproducibility of cuticular hydrocarbon profiles.

METHODS AND MATERIALS

Collecting and Sorting Termites. We collected workers and soldiers of *N. acajutlae* during two separate trips (1989 and 1993) to Guana Island, BVI. During each trip different collection techniques were used. In 1989 two nests were sampled near White Sands Beach. Portions of nest material containing workers and soldiers were returned to the laboratory. Nest material was placed in pans and folded cardboard index cards were placed on top of this material. Workers and soldiers climbed onto the cards and then were tapped off into trays, where they were sorted, counted, and prepared for hydrocarbon analyses as described below.

In 1993 we selected 13 colonies from the same area, and we used a modification of a technique demonstrated to us by Dr. Jan Krecek. This is the best technique for collecting large numbers of workers and soliders with the least effect on nest structure. A tangential slice, 2–3 cm deep and 15–20 cm in diameter, was removed from the more fragile exterior portion of a nest and discarded. Over this breach we placed one or two 20-cm × 20-cm squares of moist corrugated cardboard. If we were able to cut the slice from the top of a nest, the corrugated cardboard squares were secured against the surface of the nest with a stone. If the slice was taken from the side of the nest (often we could not reach the top of a nest) the corrugated cardboard squares were secured to the nest with 7.5 cm, galvanized, finishing nails.

As soon as the slice of nest was removed and the corrugated cardboard squares put in place, soldiers swarmed out of the breach and covered the squares; workers immediately retreated into the nest. In less than 60 sec the squares were removed and a collection of nearly pure soldiers was tapped into a collection pan. To readily obtain a nearly pure sample of hundreds to thousands of soldiers, this process can be repeated several times. We then visually scanned all individuals in the collection pan and removed the few workers in the sample.

Workers were collected by leaving the moist squares of corrugated cardboard on the nest for up to 60 min. Once the alarm reaction of the soldiers began to dissipate, workers ventured to the underside of the squares and began to repair the breach. When the cardboard was gently removed, a dense sample of workers adhered to its surface. In contrast to the technique for collecting soldiers, the squares of corrugated cardboard containing the workers (and relatively few soldiers) were placed in a collection pan and returned to the field laboratory for sorting, counting, and preparation of workers for hydrocarbon analyses as described below.

Preparation of Termites for Extraction. Because soldiers squirt glue over the containers and themselves, they were difficult to count individually. For the purposes of cuticular hydrocarbon analyses, we measured ca. 5–8 ml of soldiers (about 500 individuals) in 20-ml scintillation vials (Wheaton scintillation vials, foil-lined caps) for extraction or drying. Workers were separated and individually counted into 20-ml scintillation vials for extraction or drying of the appropriate number of individuals. Alates were occasionally present; when collected, they were individually counted into vials and handled in exactly the same way as the workers.

Additional termites from each of the sampled colonies (with soldiers and alates, when available, as diagnostic castes) were placed in 80% ethanol (from Quantum Chemical Corp., 200-proof punctilious dehydrated alcohol) to serve as voucher specimens. These voucher specimens are kept at the Pacific Southwest Research Station, Albany, California, and the Department of Entomology, University of Maryland, College Park, Maryland.

Standard Extraction Process. Cuticular lipids were extracted by immersing termites in *n*-hexane (EM Science OmniSolv, suitable for HPLC, GC, and residue analysis). Our usual procedure has been a 10-min extraction of 100 termites in 10 ml of *n*-hexane. In this study, we used this procedure as the standard to evaluate the various extraction regimes described in the following sections. The lipid extracts resulting from each of the various methods were pipetted through 4 cm of activated BioSil-A (silica gel, BioRad Laboratories, 100–200 mesh) in Pasteur pipet minicolumns (5 mm ID) in order to isolate the hydrocarbon components. The resulting hydrocarbon extracts were evaporated to dryness under nitrogen and redissolved in 60 μl of *n*-hexane for gas chromatography–mass spectrometry (GC-MS) analyses.

Duration and Number of Extractions. In 1989 we evaluated the following extraction regimes using *N. acajutlae* from Guana Island, BVI, to determine whether we could improve upon extracting 100 live workers in 10 ml of *n*-hexane for 10 minutes:

A. Extract 300 workers in 10 ml *n*-hexane for 10 min (standard technique with an increased sample size).

B. Extract 300 workers three times in 10 ml of *n*-hexane for 10 min, keeping each extract separate to determine if the standard technique left significant quantities of hydrocarbon on the sample.

C. Extract 300 workers in 10 ml of *n*-hexane for 20 sec followed by a 10-min extraction in 10 ml of *n*-hexane, keeping each extract separate to determine whether a brief extraction would produce a mixture of hydrocarbons comparable to the standard, A, extraction.

D. Extract 300 workers in 10 ml of *n*-hexane for 20 sec followed by extracting for 24 hr in 10 ml *n*-hexane, keeping each extract separate (same as extraction B with an extended second extraction) to determine whether an extended extraction would remove additional hydrocarbons from the cuticle or from other tissues.

E. Extract 300 workers in 10 ml of *n*-hexane for 24 hr to allow for a less stringent extraction schedule.

F. Long-term extraction of 300 workers in 10 ml of *n*-hexane for two years to allow field collection with subsequent laboratory storage for an extended period.

Effect of Drying. In 1993 six samples of 100 *N. acajutlae* workers from each of 13 nests were allocated to evaluate the effect of drying termites prior to extraction. The cuticular hydrocarbon profiles of the dried termites were compared to those generated from an extraction of live termites. Live termites were extracted at the Guana Island, BVI, field laboratory by placing each of three samples from each colony directly into separate 20-ml scintillation vials and extracting these samples in 10 ml of *n*-hexane for 10 min (standard procedure A). The hexane from each of 39 vials was then decanted into separate 20-ml

scintillation vials and subsequently returned to our laboratory in California for purification and analysis of cuticular hydrocarbons.

The other three samples of *N. acajutlae* workers from each of 13 colonies were dried by placing 20-ml scintillation vials, each containing 100 individuals, in a wire box over a single 75-W, reflecting, incandescent light. The amount of time required to completely dry termites varied slightly as a function of the position of the vials over the bulb. The position of the vials over the bulb was changed in an attempt to make the drying time similar for each sample. Once termites were completely dried, we attempted to keep them dry by tightly sealing the vials. The vials were returned to our laboratory in California for extraction, purification, and analysis of cuticular hydrocarbons. Until they were extracted, dried samples were kept in a freezer at −20°C in California to prevent possible fungal growth.

Effects of Sample Size. In 1993, samples of 25, 50, 100, or 200 *N. acajutlae* workers from five different colonies were extracted either live or dried as described above. Each combination (sample size × live versus dried × colony) was replicated three times.

Effects of Solvent. In 1993, for each of five colonies, three replicates of 200 workers were placed in 20 ml of 100% ethanol and left in the solvent for 60 days. The ethanol extract was decanted and evaporated to dryness under nitrogen. The extract was then redissolved in 10 ml of hexane and processed by the standard procedure. After the ethanol was drained from the termites, the insects were dried and extracted with hexane following the standard procedure.

Characterization of Cuticular Hydrocarbons. Each sample was analyzed by GC-MS in order that the presence of all compounds could be verified by mass spectral data. These data allowed us to obtain information about coeluting compounds in particular. GC-MS analyses were performed on a Hewlett-Packard (HP) 5890 gas chromatograph equipped with a HP 5970B Mass Selective Detector interfaced with HP Chemstation software. The GC-MS was equipped with an HP-1, fused silica capillary column (25 m × 0.2 mm ID) and operated in split mode (with a split ratio of 8:1). A 3-μl aliquot was injected into the GC-MS. Each mixture was analyzed using a temperature program from 200°C to 320°C at 3°C/min with a final hold of 16 min. Electron impact (EI) mass spectra were obtained at 70 eV. *n*-Alkanes were identified by their mass spectra. Mass spectra of methylalkanes were interpreted as described by Blomquist et al. (1987) to identify methyl branch locations. Alkenes were identified by their retention times relative to *n*-alkanes and/or mass spectra; the latter only for olefins with 35 or more carbons. A typical alkene mass spectrum shows a molecular ion and a series of fragments at 14-mass unit intervals (e.g., 69, 83, 97), similar to those displayed by *n*-alkanes, less 2 mass units. Interpretation of the mass spectra of dienes and polyunsaturated hydrocarbons was extrapolated from this pattern, i.e., for each double bond, the molecular ion is decreased by 2 mass units.

In the text and tables, we use shorthand nomenclature to identify individual hydrocarbons or mixtures of hydrocarbons. This shorthand uses a descriptor for the location of methyl groups (X-Me), the total number of carbons (subscript XX) in the hydrocarbon component excluding the methyl branch(es), and the number of double bonds following a colon (subscript Y). Thus, pentacosane becomes *n*-C_{25}; 11-methylpentacosane becomes 11-MeC_{25}; and pentacosene becomes $C_{25:1}$. Hydrocarbons are presented in the tables in the order of elution on our GC-MS system.

Integration of the total ion chromatogram was performed by the data analysis software (HP59974J Rev. 3.1.2) in the HP Chemstation. GC-MS peak areas were converted to percentages of the total hydrocarbon fraction. These percentages for each hydrocarbon peak were the response variables used to make statistical comparisons among preparation and extraction techniques.

Statistical Analyses. The effect of drying termites before extraction was assessed by a series of *t* tests of the differences between the mean percentage of a given hydrocarbon (three samples from each colony were averaged, which resulted in 13 replicates, one for each colony) from the two conditions (Steel and Torrie, 1960). The significance of the calculated *t* value was tested at $\alpha = 0.00227$ [0.05/22, the number of consistently abundant (0.3% or greater of the total) hydrocarbon peaks for workers]. Our null hypothesis was that the 10-min extraction of 100 dried termites was not significantly different from the standard 10-min extraction of 100 live termites.

The effect of group size was tested with an analysis of variance for each hydrocarbon (Steel and Torrie, 1960). Each treatment combination (sample size × colony) was replicated three times. The four sample sizes were compared separately for termites extracted live or dried. Our null hypothesis was that all sample sizes provide extracts with the same percentages of each hydrocarbon. The significance of the *F* statistic was also tested with $\alpha = 0.00227$. Significant differences among mean percentages for each hydrocarbon were determined by Tukey's honestly significant difference (HSD) procedure. We were looking for the smallest sample size that results in a hydrocarbon profile equivalent in percentage of hydrocarbons to that of the next greatest sample size. A sample size was considered inadequate if it yielded a hydrocarbon mixture that had significantly different percentages from that of the next larger sample size.

RESULTS AND DISCUSSION

Cuticular Hydrocarbons of N. acajutlae

We identified 33 hydrocarbons from workers, 45 from soldiers, and 43 from alates of *N. acajutlae*; a total of 60 different hydrocarbons or isomeric mixtures in this species (Table 1; Figure 1). The hydrocarbons found in all three

[a] Three subsamples of 100 workers from each of 13 colonies. Four subsamples of ca. 4 ml of soldiers from each of 13 colonies. Two subsamples of 25–31 alates from four colonies.

[b] This shorthand (X-MeC_{XX} and $C_{XX:Y}$) uses descriptors for the location of the methyl group (X-Me), the total number of carbons (XX), excluding the methyl branch(es), and the number of double bonds (Y). Locations of double bonds are undetermined.

[c] An isomeric mixture. These monomethylalkanes coelute.

[d] This monomethylalkane and the olefin coelute.

[e] These hydrocarbons were not detected in samples from Guana Island, but were found in samples from Tortola, BVI. $C_{29:1}$ was found in trace amounts in soldiers only; $C_{45:5}$ was found in all three castes, but in amounts averaging $< 1.0\%$.

[f] These two isomers occasionally did not resolve in alates. Therefore, the areas for the two isomers were summed for alates only.

[g] These two isomers occasionally did not resolve. Therefore, the areas for the two isomers were summed.

[h] $C_{43:6}$ was identified only in alates. There were two isomers of $C_{45:1}$ that occasionally did not resolve. Therefore, the areas for the two isomers were summed.

castes segregate into two distinct groups. The early-eluting components are primarily *n*-alkanes, methyl-branched alkanes, and a few normal alkenes. The late-eluting compounds consist almost exclusively of unsaturated hydrocarbons with chain lengths of 37–45 carbons and one to six double bonds and a few monomethyl alkanes in trace amounts (especially in alates). Soldiers have considerably greater proportions of the early-eluting compounds (23–29 carbons) than do workers or alates (Table 1; Figure 1). Whereas workers and alates have at least 88% of the cuticular hydrocarbons with 31 or more carbons, soldiers have only about 69% of these late-eluting compounds. The predominant class

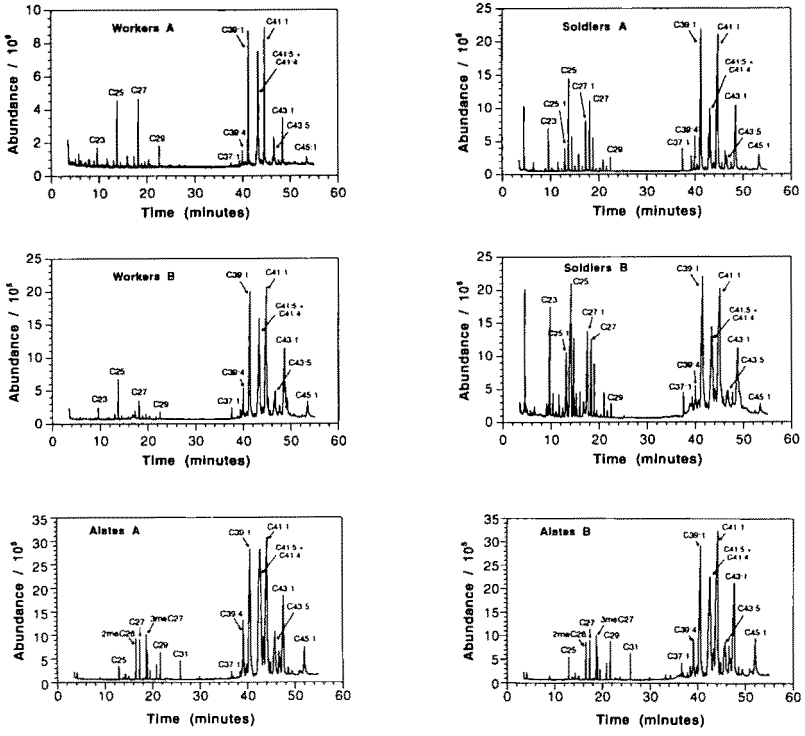

FIG. 1. Total ion chromatograms of the cuticular hydrocarbons of workers, soldiers, and alates of *Nasutitermes acajutlae* (Holmgren) from two colonies (A and B) from Guana Island, BVI. The cuticular hydrocarbon extracts were derived from dried samples of 100 workers, ca. 8 ml of soldiers, and 25 alates collected in October 1993.

of hydrocarbons in all three castes is the olefin fraction (Table 1). No dimethyl- or trimethylakanes were found in workers or soldiers.

n-Alkanes. Normal alkanes ranged from *n*-C_{23} to *n*-C_{33}; *n*-C_{25} and *n*-C_{27} were usually the most abundant. The *n*-alkanes were least abundant in alates, moderately abundant in workers, and most abundant in soldiers (Tables 1; Figure 1).

Internally Branched Monomethylalkanes. This class of hydrocarbon was nearly always encountered, in trivial amounts in workers and in significant amounts in soldiers (5.2% of the total hydrocarbon), and accounted for only 1.4% of the total hydrocarbon in alates. For soldiers most of this class of hydrocarbon eluted early, while those found in alates were in the late-eluting fraction (Table 1).

Terminally Branched Monomethylalkanes. The 2- and 3-methylalkanes occurred in trivial amounts in workers and soldiers. Alates usually had a significant component of 2-methylalkanes. These hydrocarbons were always found in the early-eluting constituents (Table 1; Figure 1).

Dimethyl- and Trimethylalkanes. Only one dimethylalkane was identified: 5,17-dimeC_{25}. It was found only in trivial amounts in alates (Table 1).

Olefins. The unsaturated component is the paramount class of hydrocarbons in the cuticular lipids of *N. acajutlae*. Olefins comprise over 90% of the total hydrocarbons in workers and alates. Because soldiers contain a larger proportion of early-eluting *n*-alkanes, the olefin component amounts to an average of 75.6% of the total hydrocarbons in this caste. For all castes, $C_{39:1}$, $C_{41:5}$, $C_{41:4}$, $C_{41:1}$, and $C_{43:1}$ combined account for >70% of the total olefin fraction (Table 1).

We are confident in our identification of the late-eluting monounsaturated alkenes. The spectra of $C_{39:1}$ and $C_{41:1}$ display the parent ion (546 and 574, respectively) as well as the characteristic fragmentation pattern with the predominant peaks of fragments (83 and 97) being 2 mass units less than would be expected from *n*-alkanes and exceeding fragment 67 in abundance (Figure 2). The polyunsaturated components, for example, $C_{41:4}$ and $C_{41:5}$, are identified by the presence of parent ions (568 and 566, respectively) which are 8 and 10 mass units less than the normal alkane with the same number of carbons (Figure 3).

Polyunsaturated alkenes have not been commonly reported from the cuticular hydrocarbons of termites. However, Moore (1969) was the first to describe the cuticular lipids from a termite, *Nasutitermes exitiosis* (Hill), from Australia. He found a complex mixture of unsaturated components with the predominant component identified as a quadrupally unsaturated, unbranched hydrocarbon, $C_{39:4}$. Similarly, we have identified high-molecular-weight dienes, trienes, and tetraenes from the cuticular lipids of *Cryptotermes brevis* (Walker), *Procryptotermes corniceps* (Snyder), *Incisitermes* spp., *Parvitermes wolcotti* (Snyder), and *N. acajutlae*, as well as other species of *Nasutitermes* from the Caribbean Basin (Haverty et al., 1992, 1997).

Effect of Duration and Number of Extractions

Early in our research on the chemotaxonomy of termites we extracted live or recently frozen individuals. The standard 10-min extraction of 300 live workers of *N. acajutlae* (Figure 4A) allowed us to resolve and characterize most of the components identified for this species (Tables 1 and 2). Additional components were identified by drying termites first (see Table 1 and *Effects of Drying* below). We also discovered that different nests of this species from the same island produced qualitatively similar (not identical), but quantitatively dissimilar, hydrocarbon mixtures (Figure 1; and unpublished observations). Further-

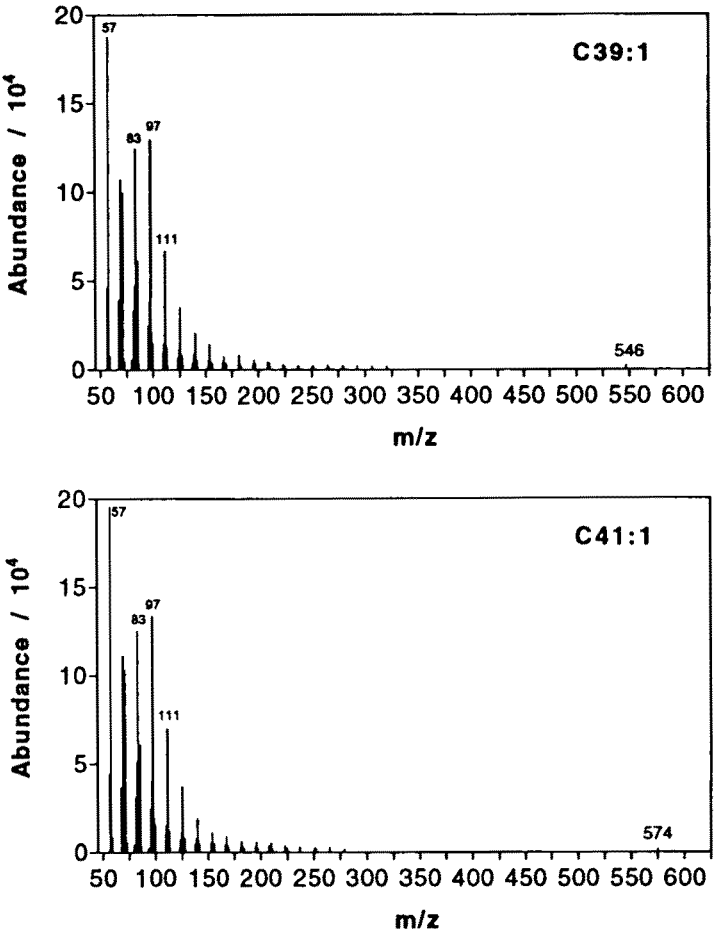

Fig. 2. Mass spectra of nonatriacontene ($C_{39:1}$) and hentetracontene ($C_{41:1}$) from cuticular hydrocarbons from workers of *Nasutitermes acajutlae* from Guana Island, BVI.

more, these colony-specific hydrocarbon analyses are repeatable; when a second group of 300 live workers was extracted using the standard procedure, the hydrocarbon mixtures from each colony were qualitatively identical and quantitatively quite similar (Figure 4A and B1; Table 2). A second 10-min extraction of the same 300 workers resulted in a hydrocarbon mixture that was quite similar to the mixture from the first extraction (Figure 4B2), although the ion abundances of the peaks were about half those in the first extract. A third, 10-min extraction resulted in an extract that did not resemble those from either of the

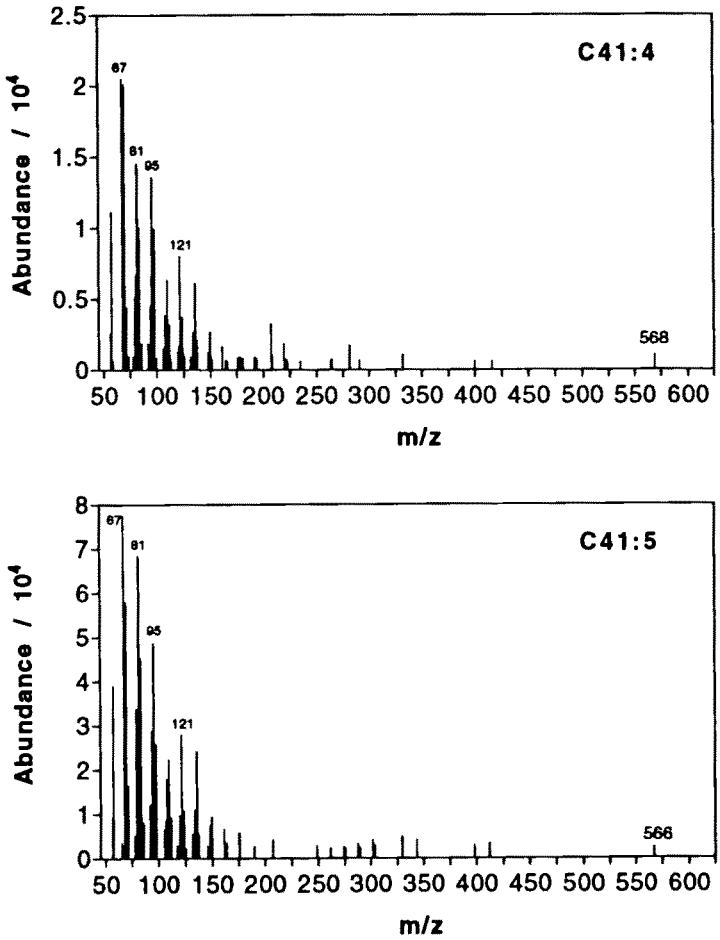

FIG. 3. Mass spectra of hentetracontatetraene ($C_{41:4}$) and hentetracontapentaene ($C_{41:5}$) from cuticular hydrocarbons from workers of *Nasutitermes acajutlae* from Guana Island, BVI.

first two extractions; only the predominant peaks (C_{25}, C_{27}, $C_{39:1}$, and $C_{41:1}$) were detected (Table 2; Figure 4B3).

An extraction of 300 live workers in 10 ml of hexane for only 20 sec appeared to be equivalent to a 10-min extraction (Table 2; Figure 4A, C1, and D1). Furthermore, the 20-sec extraction was repeatable. A subsequent 10-min extraction of the same workers produced a hydrocarbon mixture similar to that of a 20-sec extraction, although the ion abundances of the peaks were about

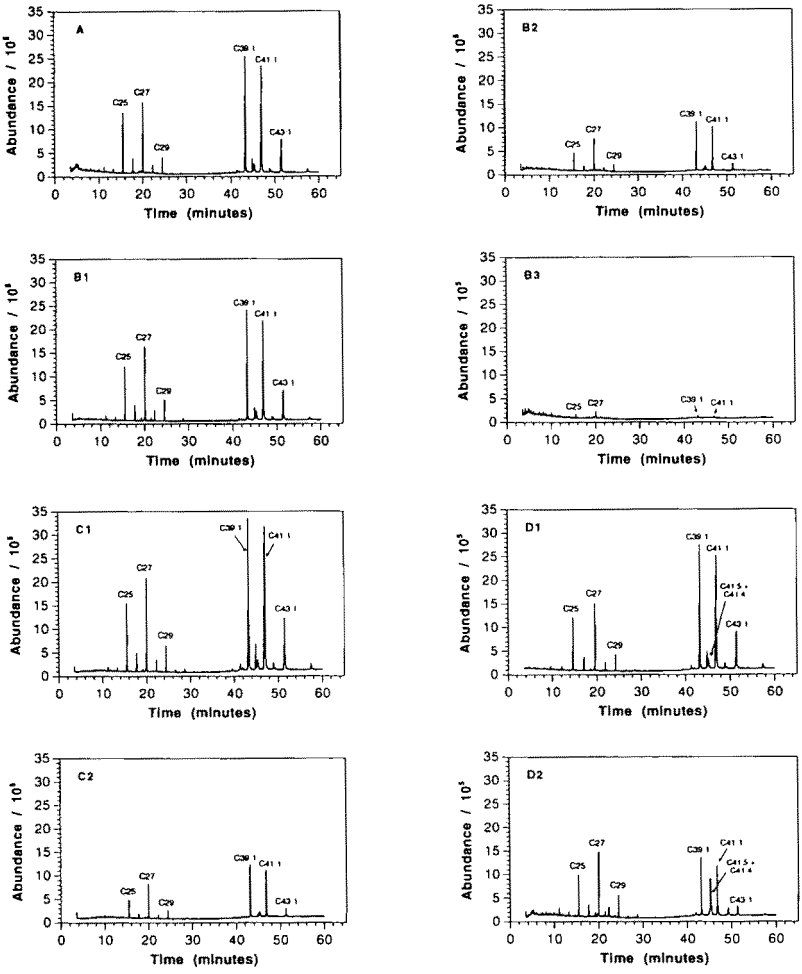

FIG. 4. Chromatograms of cuticular hydrocarbons extracted from 300 live workers from one nest of *Nasutitermes acajutlae* from Guana Island, BVI. A = extraction with 10 ml hexane for 10 min (standard); B1 = first extraction with 10 ml hexane for 10 min (equivanent to the standard); B2 = second extraction of the same termites as B1 with 10 ml hexane for 10 min; B3 = third extraction of the same termites as B1 and B2 with 10 ml hexane for 10 min; C1 = first extraction with 10 ml hexane for 20 sec; C2 = second extraction of the same termites as C1 with 10 ml hexane for 10 min; D1 = first extraction with 10 ml hexane for 20 sec (equivanent to C1); D2 = second extraction of the same termites as D1 with 10 ml hexane for 24 hr; E = extraction with 10 ml hexane for 24 hr; F = extraction with 10 ml hexane for two years. Samples A–F were each derived from independent groups of 300 workers.

[a] Extraction regimes A–F are outlined in the Methods and Materials and in the legend of Figure 4. Extraction procedure F was not included because of numerous unique, unknown, undetermined, or different peaks.

[b] This shorthand (X-MeC_{XX} and $C_{XX\ Y}$) uses descriptors for the location of the methyl group (X-Me), the total number of carbons (XX), excluding the methyl branch(es), and the number of double bonds (Y). Locations of double bonds are undetermined.

half those in the first extract (Table 2; Figure 4C1 and C2). Extraction of 300 workers for 24 hr after a 20-sec extraction resulted in an extract that was different from the standard extraction (10 ml for 10 min) or the 20-sec extraction. Proportional relationships changed dramatically: C_{25} and C_{27} were much more prominent as were $C_{41:4}$ and $C_{41:5}$, in extracts from the second extraction (Table 2; Figure 4A, D1, and D2).

Extraction of 300 workers for 24 hr resulted in a mixture of hydrocarbons that appeared similar to the standard 10-min extraction or to a 20-sec extraction (Table 2; Figure 4A, C1, D1, and E). Holding a sample of 300 workers in hexane for a period of two years provided a radically different mixture of hydrocarbons than the standard 10-min extraction (Figure 4F). Many hydrocarbons that we rarely see in *N. acajutlae* workers (such as C_{22}, $C_{23:1}$, $C_{24:1}$, two isomers of $C_{25:1}$, $C_{26:1}$, 11- and 13-MeC_{25}, $C_{27:2}$, 2-MeC_{26}, $C_{29:2}$, 5-MeC_{29}, $C_{31:1}$, and $C_{43:2}$) were present in quantities exceeding trace ($\bar{X} < 0.3\%$) amounts. One isomer of $C_{25:1}$ was identified in extractions of workers of *N. acajutlae* in 1993. However, the additional isomer (same mass spectrum with a different retention time) was not seen in the 1993 extractions. Furthermore, some compounds (C_{25}, C_{27}, $C_{41:5}$, and $C_{41:4}$) were present in much greater proportions. As a result of these qualitative and quantitative differences, we feel that a characteristic mixture of cuticular hydrocarbons can be obtained with extractions lasting from 20 sec to 24 hr. We do not consider the hydrocarbon mixtures from two-year extractions to be comparable to the standard 10-min extraction.

Effect of Drying

Mixtures of cuticular hydrocarbons extracted from live or dried workers were quantitatively different from one another. Of the 32 hydrocarbon peaks, the percentages of 20 of them were significantly different (Table 3). The most striking differences were exhibited in the late-eluting alkenes (Table 3; Figure 5). Drying the workers before extraction resulted in highly significant differences in the relative amounts of $C_{41:4}$ and $C_{41:5}$. Related to the apparent increased efficiency of the extraction of these compounds was the apparent decrease in the relative amounts of the most abundant compounds, $C_{39:1}$, $C_{41:1}$, and $C_{43:1}$.

In general, drying workers prior to extraction tended to enhance extraction of the less abundant unsaturated compounds. Extraction of 100 dried workers did not result in equivalent mixtures of hydrocarbons when compared to extraction of 100 live workers; these extraction regimes are not comparable for taxonomic or ecological purposes. Using either one of these extraction regimes exclusively would suffice for characterization of cuticular hydrocarbons for ecological studies, because the primary consideration would be for comparing the relative or absolute quantities of hydrocarbons. However, for taxonomic studies, the goal is to identify hydrocarbons that are consistently present even in quan-

[b] Three subsamples of 100 workers from 13 colonies were either placed in a scintillation vial alive, then extracted for 10 min with 10 ml of hexane or placed in a vial, dried over an incandescent light, then extracted for 10 min with 10 ml of hexane.

[c] The critical t for $\alpha = 0.00227$ with 12 df is 3.859 for each comparison for each hydrocarbon. If $|t| > t_c$ then the difference is significant.

tities as low as 0.3% of the total hydrocarbon. Drying termites prior to the extraction greatly increases the chance of consistently detecting hydrocarbons of low abundance, especially the olefin fraction; therefore we feel dried samples should be used for taxonomy.

There is the possibility that these differences are due to the extraction of hydrocarbons from internal tissues. By definition, these hydrocarbons are not

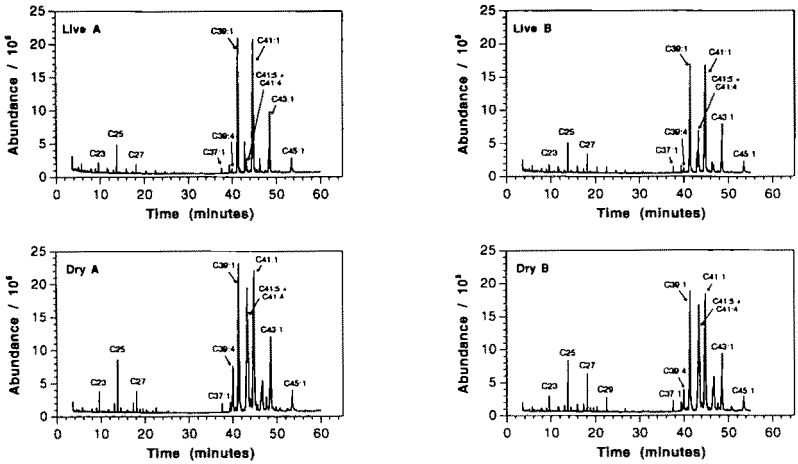

FIG. 5. Chromatograms of cuticular hydrocarbons extracted from 100 workers from two nests (A and B) of *Nasutitermes acajutlae* from Guana Island, BVI. Workers were extracted with 10 ml of hexane for 10 min either alive or after drying.

cuticular lipids, although the components may be the same (de Renobales et al., 1991). Dried termites are more fragile and often lose legs, antennae, or even heads during shipment, and also, the cuticle can become cracked. These conditions could allow the hexane to penetrate and extract lipids from the inner layers of cuticle and internal tissues. It is conceivable that some of the hydrocarbons extracted from our dried samples are not surface hydrocarbons, but those deposited on the external surface of the cuticle of the next instar (Howard et al., 1995). We found no evidence that any abundant hydrocarbons were unique to dried samples. However, the minor components $C_{41:2}$ and $C_{43:2}$ may have been unique to dried samples ($\bar{X} < 0.1\%$ in live samples; $\bar{X} > 0.8\%$ in dried samples for each component).

After examining hundreds of samples of termites extracted alive or after drying, it appears to us that the chromatograms from dried individuals are sharper and have a flatter baseline than those from live, field-extracted individuals. Three possible reasons are: (1) live termites void gut contents when placed in hexane and thus introduce contaminants, (2) live insects have a higher water content in the cuticle and less hydrocarbon is extracted because hexane is hydrophobic, or (3) hexane extracts in vials solubilize contaminants from the vial lids during transit from the field to the laboratory. The vials used were lined with foil, not Teflon. When we stored clean hexane in vials that were upside down, the resulting chromatogram had an uneven baseline similar to that resulting from extraction of live termites; however, no hydrocarbon peaks were seen. Further study of this phenomenon is warranted.

Effects of Sample Size

Statistically significant differences ($\alpha = 0.00227$) in the percentage of hydrocarbon components among sample sizes were found for 16 hydrocarbon peaks from workers extracted alive (Table 4). The most abundant components, $C_{39:1}$ and $C_{41:1}$, were not significantly different among sample sizes. Samples of 25 or 50 workers were found to be significantly different in only three cases: C_{26}, C_{28}, and C_{29}. Samples of 25 workers yielded extracts with hydrocarbon proportions significantly different from samples of 100 workers in 13 cases and from samples of 200 workers in 16 cases (Table 4). Samples of 50 workers yielded extracts with hydrocarbon proportions significantly different from sam-

Means are from three samples from each of five separate nests ($N = 15$). Means for a given hydrocarbon followed by the same letter are not significantly different at the $\alpha = 0.00227$ level.

This shorthand (X-MeC_{XX} and $C_{XX:Y}$) uses descriptors for the location of the methyl group (X-Me), the total number of carbons (XX), excluding the methyl branch(es), and the number of double bonds (Y). Locations of double bonds are undetermined.

ples of 100 workers in seven cases and from samples of 200 workers in 11 cases. Samples of 100 and 200 workers yielded extracts with hydrocarbon proportions significantly different in only two cases. If workers were extracted while alive, it appears that the cuticular hydrocarbon mixtures change the least in samples of 100 or more.

Statistically significant differences ($\alpha = 0.00227$) in the percentage of hydrocarbon components among sample sizes were found for 13 hydrocarbon peaks when workers were extracted after drying (Table 5). Contrary to the results from live workers, the most abundant hydrocarbons $C_{39:1}$ and $C_{41:1}$, did display statistically significant differences among sample sizes. Samples of 25 workers yielded no statistically significant differences from samples of 50 workers for any hydrocarbons. Samples of 25 workers yielded extracts with hydrocarbon proportions significantly different from samples of 100 in 12 cases and from 200 workers in only five cases. Samples of 50 workers yielded extracts with hydrocarbon proportions significantly different from samples of 100 or 200 workers in only one case each (Table 5). Samples of 100 and 200 workers were not found to be significantly different for any of the 22 hydrocarbons analyzed. Similar to the result of extracting live workers, extracting workers after drying changed the least in sample sizes of 100 or more; however, extracts of samples of 50 workers were significantly different only for $C_{39:2}$, which had a relative abundance of 0.0% in samples of 25 or 50 workers and ca. 0.7% in samples of 100 or 200 workers.

The less abundant or trace compounds from extractions of the standard group size (100) are either missing or infrequently recorded (resulting in a lower mean value) in samples of 25 or 50 workers (Tables 4 and 5; Figures 6 and 7). The most abundant compounds, such as $C_{39:1}$ and $C_{41:1}$, have a lower mean value in samples of 100 or 200 workers than in groups of 25 workers (Tables 4 and 5; Figures 6 and 7). This undoubtedly results from the greater contribution of the minor compounds to the total hydrocarbon mixtures in the larger sample sizes; many of these trace compounds are not recorded in the samples of 25 or 50 workers, and they do not add to the total hydrocarbons (Figures 6 and 7). Most of the less abundant components fall below the line of equality (dashed line).

Thus, for workers of *N. acajutlae*, 100 appears to be the optimum sample size for adequately characterizing the cuticular hydrocarbons for quantitative comparisons using our operating parameters, regardless of whether the workers are extracted while alive or after drying. If the goal is to characterize all hydrocarbon components, even though they might be present in trivial amounts, then a larger sample (200–300 workers) should be taken, the extracts should be concentrated beyond our standard 60 μl, or the split ratio of the gas chromatograph should be altered. Collecting fewer insects in the field would save time and add to the convenience of field workers, but altering the chromatographic

TABLE 5. RELATIVE ABUNDANCE (MEAN PERCENT AND STANDARD DEVIATION) OF CUTICULAR HYDROCARBONS FROM FOUR SAMPLE SIZES OF WORKERS FROM FIVE NESTS OF *Nasutitermes acajutlae* (HOLMGREN) FROM GUANA ISLAND, BVI, EXTRACTED AFTER DRYING[a]

Means are from three subsamples from each of five separate nests ($N = 15$). Means for a given hydrocarbon followed by the same letter are not significantly different at the $\alpha = 0.00227$ level.

This shorthand (X-MeC_{XX} and $C_{XX\ Y}$) uses descriptors for the location of the methyl group (X-Me), the total number of carbons (XX), excluding the methyl branch(es), and the number of double bonds (Y). Locations of double bonds are undetermined.

The *F* statistic has a $P < 0.00227$, yet the Tukey's procedure did not separate any of the means for this hydrocarbon.

parameters would increase the complexity and repeatability of laboratory operations. If a sample of 100 workers is not attainable, then concentration of the extract or altering the split ratio must be done or the sample will not be usable.

It is likely that our earlier problem with quantifying hydrocarbons from *N. costalis* and *N. ephratae* (Haverty et al., 1990b) resulted from two confounding problems. First, the workers were extracted live, in the field, which resulted in a less efficient extraction of the hydrocarbons, especially the less abundant components. Second, while 100 workers were used in the extractions, due to the

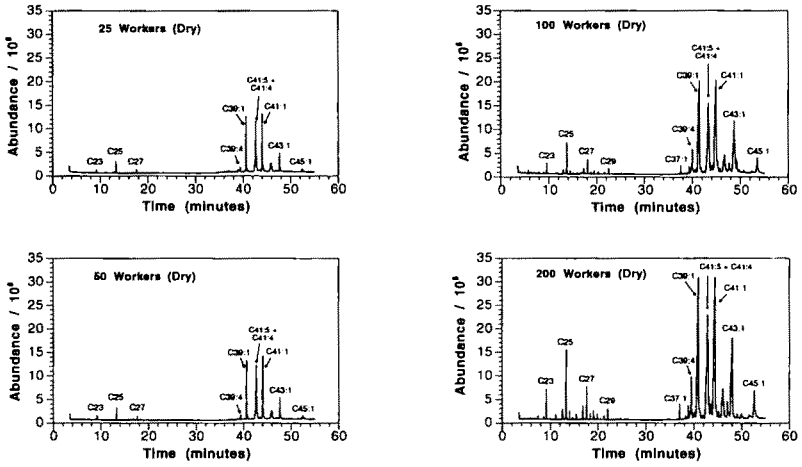

FIG. 6. Chromatograms of cuticular hydrocarbons extracted with 10 ml hexane for 10 min from four sample sizes (25, 50, 100, and 200) of dried workers from one colony of *Nasutitermes acajutlae* from Guana Island, BVI.

size of *N. ephratae*, these collections could very well have been below an acceptable size. Large workers of *N. ephratae*, (dry weight = 0.6 mg) are considerably smaller than large workers of *N. acajutlae* (dry weight = 1.3 mg) (Thorne, 1985); 100 large workers of the former species may not have had sufficient surface lipids to provide an adequate chromatogram.

Effects of Solvent

For field entomologists working in the tropics it would be convenient if storage of termites in 100% ethanol (EtOH) allowed for equivalent extraction of hydrocarbons. Preliminary observations of S. J. Seybold and L. J. Nelson (personal communication) indicated that EtOH will extract cuticular hydrocarbons of adult *Ips pini* (Say) (Coleoptera: Scolytidae). Furthermore, the longer beetles were in EtOH, the greater the extraction efficiency. Their work showed: (1) that the EtOH-extracted insects can be further extracted with hexane, (2) that the EtOH extract can be dried and the lipids redissolved in hexane, and (3) that the hexane solutions of the EtOH extract and the EtOH-extracted-insect extract can be recombined to provide a reconstituted extract for characterization. They have not shown whether the resulting hydrocarbon mixture is comparable to an extract gathered by a standard 10-min extraction with hexane of live or dead insects.

Unfortunately, the resulting extracts for both workers and soldiers of *N.*

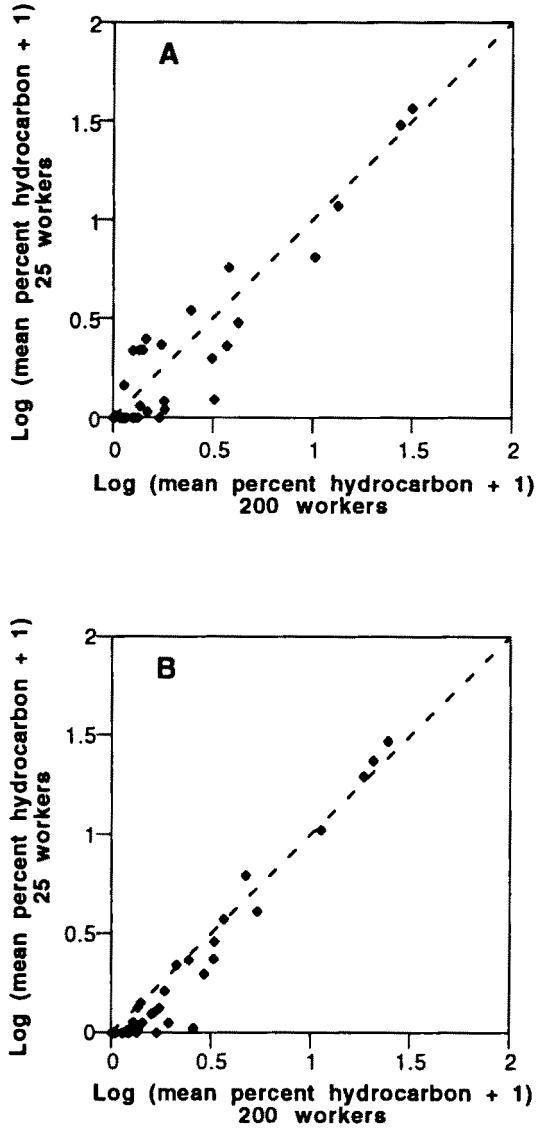

FIG. 7. Log (mean percent + 1) of 34 cuticular hydrocarbon components for groups of 25 and 200 workers extracted either alive (A) or after drying (B). Note: transformation was not done for statistical purposes, but to spread out the points for the less abundant components.

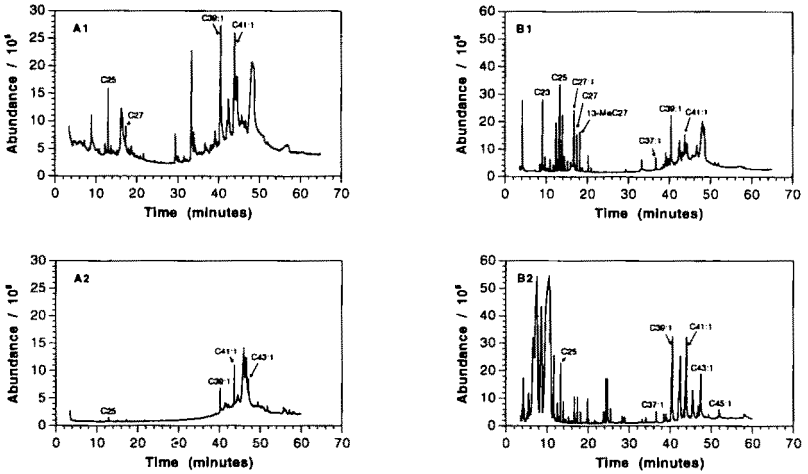

FIG. 8. Chromatograms of cuticular hydrocarbons (and other compounds) from 200 workers (A) or 200 soldiers (B) collected into 100% ethanol. For each caste the first chromatogram (A1 or B1) represents the pattern of compounds that were extracted by the ethanol. The second chromatogram for each caste (A2 or B2) represents the pattern of compounds extracted from the termites after they were stored in ethanol for 60 days, subsequently dried, then extracted with 10 ml of hexane for 10 min.

acajutlae stored in ethanol were not comparable to those where the standard technique was utilized. Storage in ethanol caused numerous, hexane-soluble, unidentified, nonhydrocarbon compounds to be extracted or these nonhydrocarbon peaks were in the ethanol as denaturing components (Figure 8). These compounds were not removed after evaporating the ethanol under nitrogen, redissolving in hexane, and pipetting through activated BioSil-A. Furthermore, enormous amounts of nitrogen and time were required to dry the ethanol samples. As a result of these problems, we did not characterize all 15 samples, because we presumed such a course would only waste resources and could affect our GC-MS. Therefore, unless a different cleanup procedure is developed, storage in ethanol is unacceptable for characterizing the hydrocarbons from *Nasutitermes*.

CONCLUSIONS

Different colonies of *N. acajutlae* produce qualitatively similar, but quantitatively dissimilar hydrocarbon mixtures. These colony-specific profiles appear to be reproducible; multiple extracts from separate samples of each colony are qualitatively identical and quantitatively quite similar. Only one extraction of a

sample of workers is necessary. A very brief extraction (in 10 ml of hexane for only 20 sec) of live workers produces a mixture of hydrocarbons equivalent to a 10-min or a 24-hr extraction. Holding a sample of workers (or soldiers) in hexane for a period of two years results in a radically different extract than the standard 10-min extraction and is not recommended.

Drying workers of *N. acajutlae* before extraction results in highly significant increases in the relative amounts of $C_{41:4}$ and $C_{41:5}$ and an apparent decrease in the relative amounts of the most abundant compounds, $C_{39:1}$, $C_{41:1}$, and $C_{43:1}$. In general, drying workers prior to extraction tends to enhance extraction of the less abundant unsaturated compounds and does not result in equivalent mixtures of hydrocarbons when compared to extraction of live workers. Extracting a minimum of 100 workers (live or dried) with hexane for 20 sec to 10 min seems to be the best method for characterizing cuticular hydrocarbons of *N. acajutlae*. For smaller species, samples of at least 200 would probably guarantee a satisfactory chromatogram.

For quantitative comparisons, the extraction technique should ideally be the same for all samples, i.e., hydrocarbon mixtures extracted from dried samples should not be compared to those extracted from live samples. Extraction of either live or dried termites would suffice for characterization of cuticular hydrocarbons for ecological studies but may not be comparable for taxonomic purposes. For quality of chromatograms and for several logistical reasons, we obtained the best results by drying at least 100 termites and then extracting them by the standard technique (10 min in 10 ml hexane) in the laboratory. Extraction of live termites in the field requires twice the number of vials and transportation of flammable liquids. Even with the potential logistical difficulties involved with drying termites in the tropics, we recommend this as the optimal technique to use.

Acknowledgments—We thank James A. Baldwin for his patient assistance in the statistical analysis of our hydrocarbon data. Gary Blomquist, Coby Schal, and James Lazell constructively reviewed an earlier version of this manuscript. We wish especially to thank the staff of the Guana Island Club and James Lazell for facilitating our studies of the termites of the Caribbean. This work was supported, in part, by National Science Foundation grant DEB-8607407 to B.L.T., a grant to the authors by The Conservation Agency through grants from the Falconwood Foundation, and by a cooperative agreement between the Pacific Southwest Research Station and the University of Maryland.

(Received October 31, 1995; accepted July 2, 1996)

Abstract—The conidial germination of *Colletotrichum fragariae* in water was dependent on population, size germination was inhibited at higher concentrations of conidia in water. The inhibition was considered to be caused by some germination-inhibiting substances exuded from conidia, since the germination did occur after washing the conidia repeatedly. The germination-inhibiting substances were searched for in the acetone extract of potato–sucrose–agar (PSA) cultures of the fungus and five active compounds were isolated. Their structures were characterized spectroscopically. HPLC analysis indicated that one of the isolated compounds among these was exuded not only from mycelia but also from the conidia in water under crowded conditions. We suggest that these compounds control the conidial germination of the fungi.

Key Words—Self-inhibitor, conidia, germination, anthracnose, TLC plate bioassay, *Colletotrichum fragariae*, *Colletotrichum gloeosporioides*, *Glomerella fusarioides*.

INTRODUCTION

Spore germination is inhibited under crowded conditions in a number of fungi over a wide range of taxonomic groups. This phenomenon is considered to be due to fungal metabolite(s) called self-inhibitors that are secreted from the spores (Allen, 1976). These may delay germination until the conditions become more advantageous for fungal growth by spore dissemination (Gottleib, 1973; Allen, 1976; Lax et al., 1985).

The genus *Colletotrichum* or *Glomerella* (anthracnose fungus) is among diverse genera that have been studied with respect to self-inhibition. The existence of a self-inhibitor in this genus was first predicted by Lingappa and Lingappa (1965), who detected several substances with germination-inhibiting activity in extracts of the conidia and mycelia of *Glomerella cingulata* (the perfect stage of *Colletotrichum gloeosporioides*), but failed to isolate and identify them (Lingappa and Lingappa, 1966, 1967, 1969; Lingappa et al., 1973). Lax et al. (1985) successfully isolated the self-inhibitor from *C. gloeosporioides* f. sp. *jussiaea* and identified it as gloeosporone (Meyer et al., 1983), although the proposed structure was revised by later chemical studies (Meyer et al., 1987). Tsurushima et al. (1995) also examined self-inhibitors of this fungus. Although they could not detect a gloeosporone, they did detect three active compounds in the conidial suspension as well as in the culture extract. These compounds inhibited conidial germination and were identified as (*E*)- and (*Z*)-3-ethylidene-1,3-dihydroindol-2-one and (2*R*)-(3-indolyl) propionic acid, respectively. In *C. graminicola*, Leite and Nicholson (1992, 1993) found that the self-inhibitory activity was attributed to the presence of mycosporine–alanine and volatile metabolites.

In this paper, we report that the germination of *C. fragariae* is dependent on the population and is controlled by self-inhibitors.

METHODS AND MATERIALS

Fungi and Culture Conditions

Isolates of *Colletotrichum fragariae* Brooks, *C. gloeosporioides* f. sp. *jussiaea* Peens., *C. gloeosporioides* f. sp. *aeschynomene* Penz., *C. gloeosporioides* (isolate no. 7696), and *C. graminicola* Wilson were provided by Dr. G. Templeton, University of Arkansas. *C. lindemuthianum* Briosi et Cavara IFO 5260, *Glomerella cingulata* Spaulding et Schrenk IFO 7498, *G. furctigena* Saccardo IFO 5951, *G. gossypii* Edgerton IFO 6181, and *G. fusarioides* Edgerton IFO 8831 were obtained from the Institute of Fermentation, Osaka. An isolate of *C. lagenarium* Ellis et Halsted was provided by Dr. T. Tani of Kagawa University. Each strain was cultured and maintained at 26°C in the dark in potato–sucrose–

agar (PSA) medium composed of potato (200 g), sucrose (20 g), agar (30 g) and water (1 liter).

Conidia for the bioassay and for the analysis of inhibitor were harvested by gently brushing 7-day-old PSA plate cultures after adding about 6 ml distilled water. This was filtered through three layers of gauze, and centrifuged at 2350 *g* for 10 min. The conidial pellet was washed twice by resuspension and centrifuged in distilled water before use.

Self-Inhibition Studies

Density Effects. To investigate the effect of densities on germination, conidial suspensions (50 μl) at concentrations of 10^3–10^7/ml were placed in hole slide glass plates, and incubated at 26°C for 20 hr in a moist chamber. The rate of germination was determined microscopically. Three hundred conidia from random fields were counted per plate.

Exudate Effects. The effect of conidia exudates on germination was also examined. The hole slide glass plates were inoculated with 50 μl of a suspension containing 2×10^6 conidia/ml. The water in the suspension was replaced hourly by elimination with filter paper, and the conidia were resuspended with 50 μl of sterile deionized water. A suspension without water replacement was incubated as a control. The conidia were incubated and counted as before.

Purified Inhibitors. Fresh conidia of *C. fragariae* were inoculated in an aqueous solution of a known concentration of a test sample on hole slide glass plates, and the density was adjusted to 10^5 conidia/ml. An aqueous solution containing 0.5% methanol served as control. Inoculated plates were incubated at 26°C for 20 hr under moist conditions, and the percentage of germinated conidia was determined microscopically.

Isolation of Germination Self-Inhibitory Compounds

Germination-inhibitory compounds were isolated from the PSA cultures of *C. fragariae* as shown in Figure 1. Two-week-old cultures were extracted with acetone, and the extract was concentrated under reduced pressure to obtain the residue. This residue was then extracted with ethyl acetate and dried. The dried extract was loaded on a silica gel column, and the column was eluted with a *n*-hexane–ethyl acetate–methanol gradient.

During these separation procedures, the germination-inhibitory compounds were monitored by TLC plate bioassay using *C. lagenarium* as the test fungus (Ueno et al., 1991; Tsurushima et al., 1995). Samples were applied to silica gel TLC plates, and the developed plates were sprayed with PSA medium containing the conidia of *C. lagenarium* for incubation at 26°C in a moist chamber. Inhibitory compounds were recognized as colorless spots in the black-colored

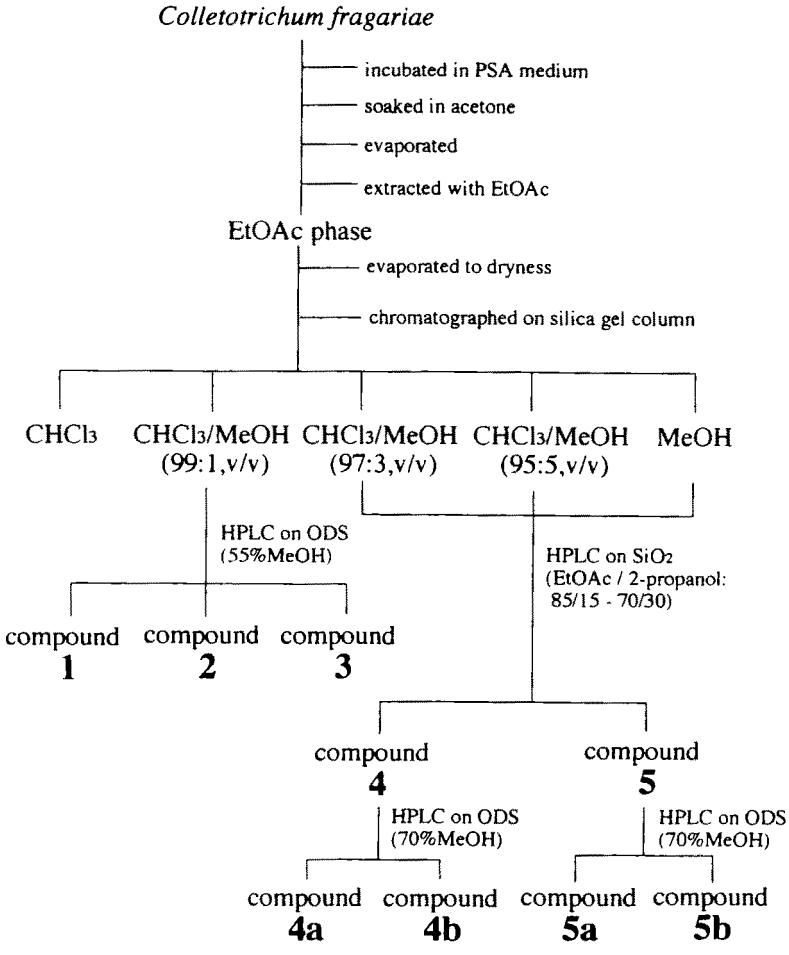

FIG. 1. Isolation of self-inhibitors from culture of *Colletotrichum fragariae*.

background as the fungus grew. A solvent system of benzene–EtOAc–MeOH (50:50:1, v/v) was used for TLC.

Active compounds detected in the $CHCl_3$–MeOH (99:1) fraction were purified by reverse-phase HPLC to give compounds **1–3** (Figure 4). The isolated compounds were identified by spectroscopic analyses. The physicochemical data were as follows:

(*E*)-3-ethylidene-1,3-dihydroindol-2-one (**1**): MS (EI 70eV) *m/z* (%);

159.0643(M^+, 100%, $C_{10}H_9N_1O_1$), 144(52%), 130(42%), 103(5%). ^{1}H NMR (400 MHz, $CDCl_3$) δ; 2.29(3H, d), 6.91(1H, d), 7.03(1H, t), 7.12(1H, q), 7.21(1H, t), 7.57(1H, d), 8.70(1H, s). IR(KBr); 1715 cm^{-1}($\nu_{C=O}$). [α] 0 ($CHCl_3$).

(*Z*)-3-ethylidene-1,3-dihydroindol-2-one (**2**): MS (EI 70eV) *m/z* (%); 159(M^+, 100%), 144(63%), 130(53%), 103(7%). ^{1}H NMR(400 MHz, $CDCl_3$) δ; 2.46(3H, d), 6.83(1H, d), 6.97(1H, q), 6.99(1H, t), 7.18(1H, t), 7.37(1H, d), 7.95(1H, s). IR(KBr); 1712 cm^{-1} ($\nu_{C=O}$). [α] 0 ($CHCl_3$).

(2*R*)-(3-indolyl) propionic acid (**3**): MS (EI 70eV) *m/z* (%): 190 ($[M+H]^+$, 32%), 189(M^+, 23%), 175(3%), 144(100%), 117(9%), 115(9%). ^{1}H NMR (400 MHz, CD_3OD) δ; 1.57(3H, d), 3.97(1H, q), 7.00(1H, d), 7.08(1H, t), 7.15(1H, s), 7.33(1H, d), 7.66(1H, d). [α] -60 (CH_3OH).

Active compounds in the $CHCl_3$–MeOH (97:3 and 95:5) and 100% MeOH fractions were purified by preparative HPLC (UV 254 nm, Cosmosil 10SL 20 × 250 mm column, *n*-hexane–2-propanol gradient of 85:15, 0–22 min; 70:30, 22–50 min, 5 ml/min) to give compounds **4** and **5**.

Analyses of Isolated Inhibitors. The presence of isolated inhibitors in a *C. fragariae* conidia suspension or in another anthracnose fungal culture was analyzed by HPLC. Conidia of *C. fragariae* were suspended in 20 ml of water, with the density being adjusted to 10^7 conidia/ml, and incubated in a capped test tube for 16 hr in a rotary shaker. The suspension was then centrifuged at 2350*g* for 10 min. The supernatant was extracted twice with an equal volume of ethyl acetate. A 2-week-old fungal culture on PSA medium was extracted with acetone. The acetone extract was evaporated under reduced pressure, and the aqueous fraction remaining was then extracted with ethyl acetate. These ethyl acetate extracts were concentrated and subjected to the HPLC analysis on a Cosmosil 5C18AR column and eluted with a mobile phase of 70% MeOH in water. The compounds were identified on the basis of the retention-time on HPLC. The identity was also confirmed by LC-MS measured with a Hitachi M-1000 spectrometer operated in positive ion mode.

RESULTS

Effect of Conidial Concentration on Germination

The germination of conidia of *C. fragariae* was inversely dependent on the conidial concentration (Figure 2). The rate of germination at 10^4 conidia/ml exceeded 80%, whereas the density at 10^7 conidia/ml was less than 10%. Inhibition of the germination at high conidial concentration was reduced by washing the conidia to remove the exudates (Figure 3).

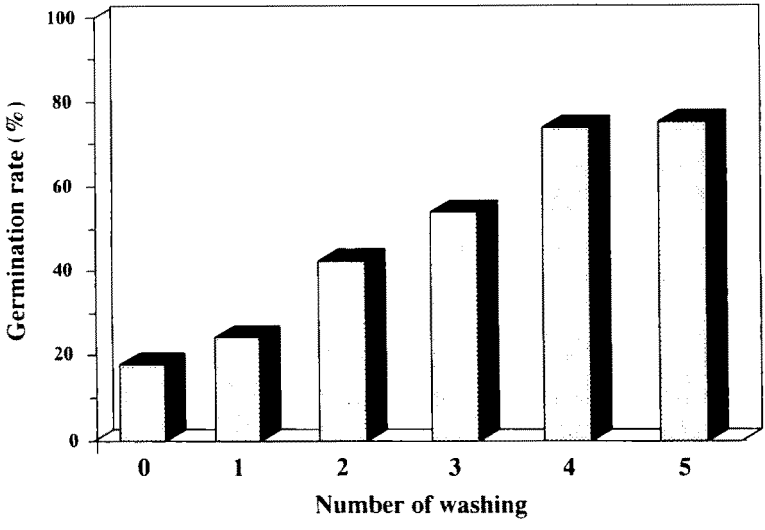

FIG. 3. The effect of washing on conidial germination.

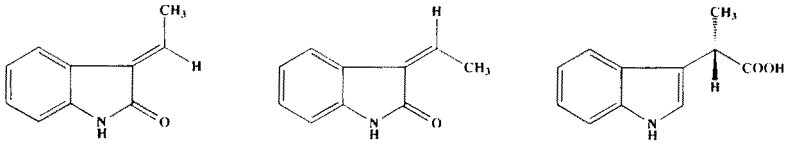

Compound **1** Compound **2** Compound **3**

FIG. 4. Structures of the self-inhibitors from culture of *Colletotrichum fragariae*.

Isolation of Self-Inhibitors from C. fragariae

Germination-inhibitory compounds were searched for in the acetone extract of *C. fragariae* cultured on PSA plates, and active compounds **1–5** were isolated.

Compounds **1–3** were identified as (*E*)- and (*Z*)-3-ethylidene-1,3-dihydroindol-2-one and (2*R*)-(3-indolyl) propionic acid, respectively, on the basis of their physicochemical data (Figure 4). These have also been described as self-inhibitors CG-SI 1, 2, and 3, respectively, from *C. gloeosporioides* (Tsurushima et al., 1995).

Although active compounds **4** and **5** purified by preparative HPLC following silica gel column chromatography gave single spots on TLC in three solvent systems, compound **4** consisted of the compounds **4a** and **4b**, and compound **5**, consisted of **5a**, **5b** according to reverse-phase HPLC (Figure 5). These four compounds gave the essentially same LC-mass spectra with $M+H^+$ ions at *m/z* 387, suggesting that they were isomers.

Analysis of Isolated Inhibitors in Conidia Suspension Solutions

In order to examine whether the isolated germination-inhibitory compounds are actually secreted from conidia, the ethyl acetate extracts of a conidia suspension of *C. fragariae* were analyzed by HPLC and LC-MS. Four compounds detected on the chromatogram (Figure 6) were identical with **1**, **2**, **4a**, and **4b** in terms of chromatographic behavior and MS. Additionally, two unknown compounds were detected on HPLC (peaks c and d in Figure 6), the molecular weights of which were estimated to be the same (386) as those of **4a**, **4b**, **5a**, and **5b** according to LC-MS analyses.

Germination-Inhibitory Activity of Isolated Compounds

Compounds **1–5** inhibited the conidial germination of *C. fragariae* with ED_{50} values of 3, 5, 25, 20, and 15 μg/ml, respectively.

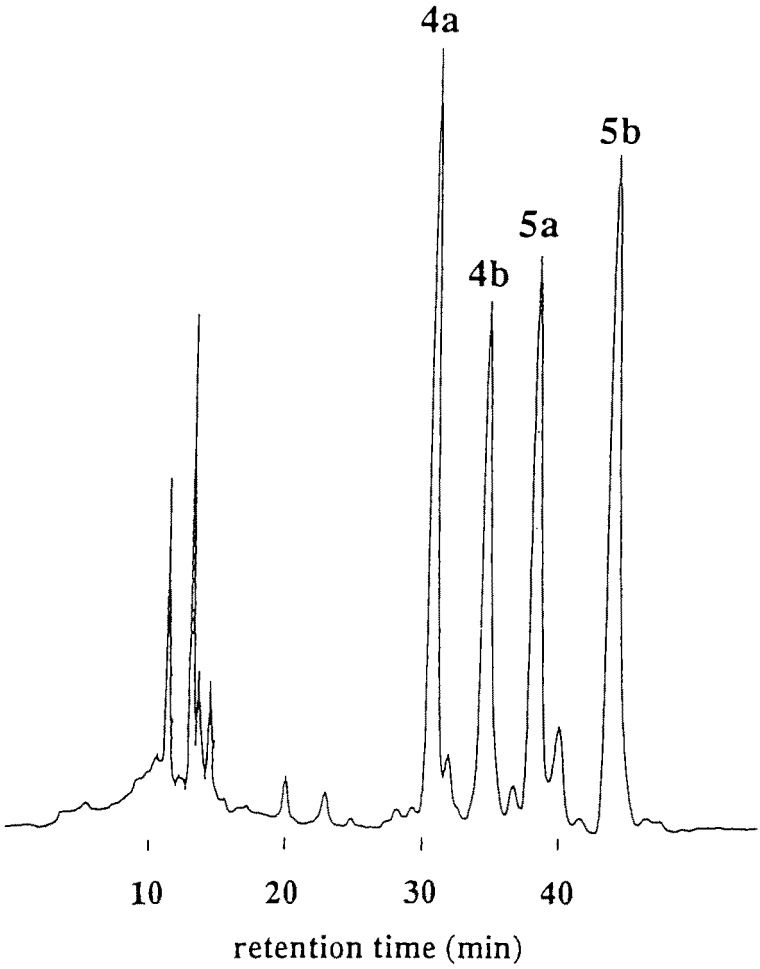

FIG. 5. HPLC chromatogram of self-inhibitor compounds **4** and **5**, from culture of *Colletotrichum fragariae*. Analytical conditions: column—Cosmosil 5C18AR 10 × 250 mm; mobile phase—70% MeOH; flow rate—2 ml/min; detection—UV absorption at 254 nm.

Distribution of Compounds 4 and 5 in Various Species of Anthracnose Fungi

The distribution of new compounds **4** and **5** was surveyed in various species of the genera *Colletotrichum* and *Glomerella* by HPLC and LC-MS. As shown in Table 1, compounds **4** and **5** were present only in a single species, *Glomeralla fusarioides*, in addition to *C. fragariae*.

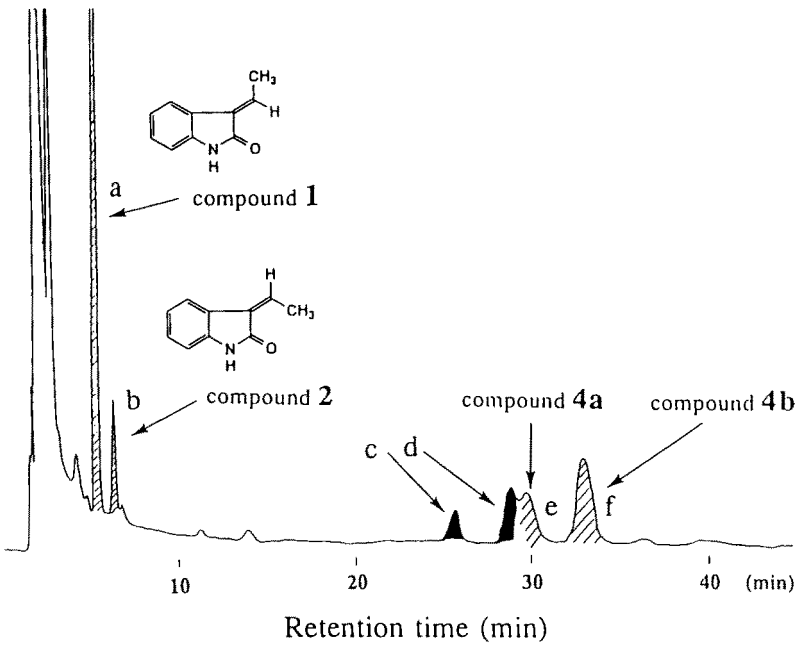

FIG. 6. Detection of self-inhibitors in a suspension of *Colletotrichum fragariae* conidia. Analytical conditions: column—YMC ODS A-302 4.6 × 150 mm; mobile phase—55% MeOH; flow rate—1 ml/min; detection—UV absorption at 254 nm.

DISCUSSION

This is the first paper to describe self-germination inhibition in *C. fragariae* and to demonstrate that conidial germination is inhibited in water at high spore density. A similar phenomenon previously has been observed in other anthracnose fungi, and the germination inhibition was putatively attributed to a "self-inhibitor" that is exuded from the conidia into the germinating fluid (Richardson and Thorn, 1962; Lingappa and Lingappa, 1965, 1966, 1967, 1969; Lingappa et al., 1973). This study has shown that such an endogenous self-inhibitor(s) from conidia is also present in *C. fragariae* and is possibly involved in the observed population-dependent germination inhibition, as the inhibition was diminished by washing the conidia repeatedly.

We searched for the germination-inhibitory compounds by directly extracting the whole culture of *C. fragariae* with organic solvents, and after chromatographic separation of the extract, we isolated active compounds **1**–**5**. Compounds **1**–**3** are indole derivatives, which are identical with the self-inhibitors from *C. gloeosporioides* (Tsurushima et al. 1995). Although the presence of

[a] +: detected, −: not detected.

these compounds in the culture of *C. fragariae* was predicted in a previous study on the basis of HPLC analysis (Tsurushima et al, 1995), this study has confirmed it by spectroscopic analysis of the isolated compounds. Compounds **4** and **5** could not be fully characterized in this study, but the available data suggested that they are novel, at least as self-inhibitors. Reverse-phase HPLC analyses indicated that both of them consisted of pairs of isomers, the properties of which are discussed in more detail below.

Compounds **1**, **2**, **4a**, and **4b** were also detected in the conidial suspension of *C. fragariae*. This result indicates that these compounds are not artifacts arising from solvent extraction of the culture, as contended by Allen (1976), but are genuine factors that are exuded from conidia and play important roles in the regulation of germination. Although compounds **3** and **5** were not detected in the conidial suspension examined in this study, they appeared to be unstable and may have possibly undergone decomposition during the analytical procedures if their amount was small. In this context, **3** was observed to change into **1** and **2** with exposure to light. Moreover, unknown compounds in the conidial suspension (corresponding to peaks a and d in Figure 6) have the same molecular weight as **5a** and **5b**, suggesting that they could have been produced by isomerization of **5a** and **5b**. Because the self-inhibitory activities of these unknown compounds were not determined here, their roles and significance remain unclear.

The inhibitory activities of **1** and **2** were about five times more potent than those of **4** or **5**. These findings, as well as the apparent abundance of **1** and **2** in the conidial suspension as shown in Figure 6, suggest that these compounds contribute mainly to the germination self-inhibition, although the compounds may act synergistically.

The germination inhibitory activities of **1** and **2** have been extensively examined by Tsurushima et al. (1995), who found that **1** and **2** were inhibitory only against the species that produced them, *i.e.*, *C. gloeosporioides* f. sp. *jussiaea* and *C. fragariae*, among 16 species of anthracnose fungi. In this study, the distributions of **4** and **5** were similarly surveyed among anthracnose fungi. We detected them only in *G. fusarioides* and *C. fragariae*. The species-specificity of the inhibitory activities of **4** and **5** is currently under investigation.

Compounds **4** and **5** were so unstable that structural studies were frequently hampered by decomposition during the isolation procedures. These compounds consisted of pairs of isomers according to HPLC analyses. Among these isomers, the relatively stable **4b** could be isolated by rapid and careful manipulation and preparative HPLC. Structural studies by IR, UV, MS, and NMR will be reported in detail elsewhere.

Acknowledgments—We express our sincere gratitude to Prof. George Templeton, University of Arkansas, and the Fermentation Institute, Osaka, for providing strains of *Colletotrichum* and

Glomerella species. We wish to thank Dr. Keiji Hashimoto, Kyoto Pharmaceutical University, for LC-MS measurements. This work was financially supported by the Mitsubishi Foundation.

(Received November 1, 1995; accepted July 2, 1996)

Abstract—The influence of mustelid (weasel) anal-gland compounds (semiochemicals) and a plant antifeedant (pinosylvin) on snowshoe hare (*Lepus americanus*) and meadow vole (*Microtus pennsylvanicus*) feeding damage was investigated. This study has shown conclusively that when applied to spring-planted lodgepole pine seedlings, pinosylvin is effective in significantly reducing feeding damage. Seedlings treated with pinosylvin suffered damage levels of 2.3% and 21.2% compared to the controls with damage levels of 24.5% and 41.0%. Weasel scent was found to reduce damage levels, but the reduction was not statistically significant in all blocks.

Key Words—Synthetic weasel odor, semiochemical, plant antifeedants, pinosylvin, vole, snowshoe hare, biological control, *Microtus pennsylvanicus*, *Lepus americanus*.

INTRODUCTION

Both snowshoe hares (*Lepus americanus*) and meadow voles (*Microtus pennsylvanicus*) are widely distributed across much of boreal North America. Both the hare and vole are known to undergo cyclic fluctuations in abundance, the snowshoe hare having an 8- to 11-year cycle (Keith and Windberg, 1978; Keith et al., 1984; Krebs et al., 1986) and the meadow vole having a 3- to 5-year

*To whom correspondence should be addressed.

cycle (Krebs et al., 1969). During the years of peak hare or vole numbers, feeding damage to conifer plantations by either or both species can be a serious problem (Radvanyi, 1987; Bergeron and Tardiff, 1988; Sullivan and Sullivan, 1983; Sullivan et al., 1988a, 1992).

Both snowshoe hares and meadow voles damage conifer seedlings by clipping the terminal and lateral shoot or feeding upon the cambium of the stem. In all cases the damage inflicted by these herbivores can have serious and devastating consequences for the conifer plantation. In the past, toxicants have been used, unsucessfully, in an attempt to control these pest species. More recently the development of synthetic plant antifeedant compounds and predator odors has provided a more successful alternative for dealing with hare and vole feeding damage.

Pinosylvin. Under natural conditions browsing by snowshoe hares on a variety of boreal plant species results in the production of adventitious shoots that are unpalatable to snowshoe hares (Bryant and Kuropat, 1980). The likely reason for this avoidance of the adventitious shoots is the production of significantly higher concentrations of terpene and phenolic resins in the adventitious shoots than is found in the mature growth forms of the same species (Bryant, 1981).

Pinosylvin, a naturally occurring plant phytoalexin, has been found to be produced in high concentrations by the adventitious shoots of Alaskan green alder (*Alnus crispa*). Laboratory bioassays have determined that this compound deters snowshoe hare feeding and probably explains the avoidance of the juvenile shoots in the field (Bryant et al., 1983; Clausen et al., 1986).

Sullivan et al. (1992) provided both pen and field trials demonstrating that pinosylvin significantly reduced snowshoe hare feeding on lodgepole pine seedlings. This biological control method takes advantage of the herbivores' recognition of an unpalatable substance.

Semiochemicals. Certain predator odors originating from feces, urine, or scent (anal) gland secretions elicit an innate fear response when detected by prey species (Gorman, 1984; Kavaliers, 1988; Jedrzejewski and Jedrzejewska, 1990). This response can result in increased vigilance, less feeding, reduced reproduction, or avoidance of the area (Stoddart, 1976, 1980; Ylönen, 1989, Jedrzejewski and Jedrzejewska, 1990). To date, natural and synthetic predator odors have produced significant avoidance responses in several pest species and reduced damage to forest and agricultural crops (Sullivan and Crump, 1984; Sullivan et al., 1985, 1988b, 1990).

There is also evidence that chemical information exchange occurs within predator species through the secretion of certain compounds. Synthetic anal-gland secretions of the ferret (*Mustela furo*) and urine of the red fox (*Vulpes vulpes*) act as signaling pheromones that attract conspecifics (Whitten et al., 1980; Clapperton et al., 1988, 1989). Zimmerling and Sullivan (1994) presented

evidence that a synthetic mustelid anal-gland compound attracted weasels to treated sites.

The attraction of weasels to a site should increase predation on the prey species, thereby reducing numbers and reinforcing the innate fear response. Thus use of predator odors in combination with plant phytoalexins results in biological control that takes advantage of both the innate fear response of the prey animals and the attraction of predators.

This paper reports on the comparative effectiveness of pinosylvin and synthetic weasel odor in deterring feeding damage by snowshoe hares and meadow voles on lodgepole pine seedlings.

METHODS AND MATERIALS

Study Area. This study was undertaken in the fall of 1994 in Tree Farm License #1 of Skeena Cellulose Inc. near the city of Terrace, British Columbia, Canada. The areas chosen were suffering high levels of feeding damage as voles were in the peak of their population cycle and hare numbers were rising. Two blocks served as replicates to determine the effectiveness of weasel scent and pinosylvin at deterring feeding damage on spring-planted lodgepole pine plug stock. The blocks were 556100 (block A), a 10-ha trial area in an 88-ha cutblock, planted with lodgepole pine in the spring of 1994, and 312900E (block B), a 6.7-ha trial area in a 24-ha cutblock, planted with lodgepole pine in the spring of 1994.

Field Procedures. Within each study site, three 1- to 2-ha sections were marked. Within one of these sections, 200 randomly chosen seedlings were fitted with weasel scent release devices attached to the terminal or upper lateral with a pipe cleaner. The formulation of mustelid semiochemicals was produced by Phero Tech Inc. Delta, British Columbia, Canada. The compounds were encapsulated in 6-cm × 0.4-cm composite polymeric cylinders. These devices consist of a 0.5-mm-thick sheath and a core plastisol formulated with 10 mg active ingredient. This type of device was determined to yield the best controlled release of the odor (Sullivan et al., 1990). The active ingredient was a 1:1 mixture of 2-propylthietane and 3-propyl-1,2-dithiolane after Crump (1978, 1980, 1982).

A second section had 200 randomly chosen seedlings fitted with a plant antifeedant device containing pinosylvin attached to the terminal or upper lateral with a thin wire. The formulation of pinosylvin was produced by Phero Tech Inc. Delta, British Columbia, Canada. Pinosylvin (3,5-dihydroxy stilbene) was encapsulated in a 3.4-cm × 0.3-cm monolithic release device. These devices consist of a sheath and a core plastisol formulated with 32 mg active ingredient. The third section had 200 randomly chosen control seedlings.

Each treated and control seedling was identified in the fall by a blue-painted stake. In April 1995, all treated and control seedlings were revisited and the presence of feeding damage by snowshoe hares or voles was recorded. Damage was recorded as clipped terminal, clipped lateral, both terminal and lateral clipped, or stem gnawed.

RESULTS

Figure 1 gives a comparison of feeding damage within blocks A and B. In both blocks, pinosylvin treated seedlings had significantly lower levels of feeding damage as compared to the control (χ^2, $P < 0.05$). The pinosylvin-treated areas suffered 2.3% damage in block A, and 21.2% in block B, compared to the control areas, which had damage levels of 24.5% and 41.0% in blocks A and B, respectively. In block A, damage to seedlings receiving weasel scent (10.1%) was also significantly different from damage in the control area (χ^2, $P < 0.05$); however, in block B, damage in weasel-scent-treated areas (31.5%) was not significantly different from unprotected seedlings in the control area (χ^2, $P > 0.05$).

In block A, rates of damage were not significantly different between the weasel-scent-treated area (10.1%) and the pinosylvin-treated area (2.3%) (χ^2,

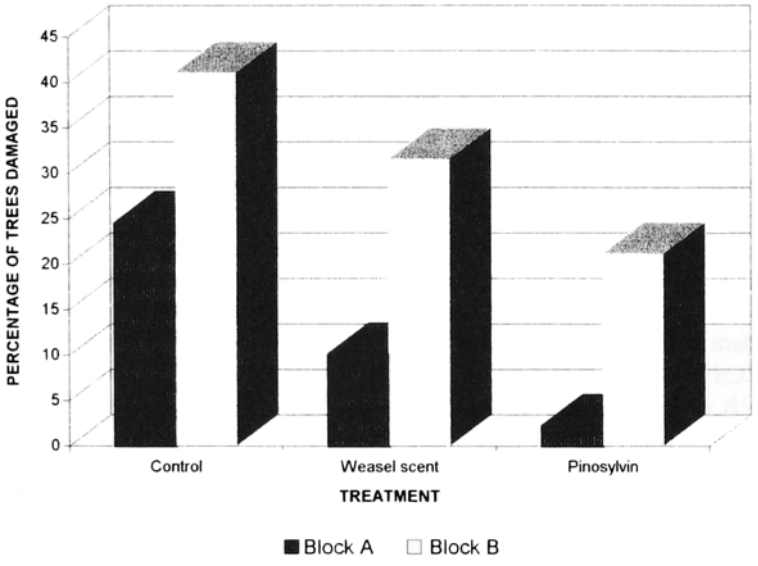

FIG. 1. Feeding damage in blocks A and B.

$P > 0.05$). In block B, the amount of damage in the weasel-scent-treated area (31.5%) was significantly different (χ^2, $P < 0.05$) from damage in the pinosylvin-treated area (21.2%).

Figures 2 and 3 give a breakdown of the type of damage inflicted. In both blocks, the majority of damage in all sections was a clipped terminal. In block A, 90% of the damage in the control and weasel-scent-treated areas consisted of clipped terminals, and in the pinosylvin-treated area 100% of the damage was clipped terminals. In block B, clipped terminals made up 56% of the damage in the control area, 62% in the pinosylvin-treated area, and 83% in the weasel-scent-treated area. Damage suffered in block B also included a percentage of stems gnawed in each section, which was not seen in block A.

DISCUSSION

This replicated trial has provided statistical evidence that pinosylvin is effective in reducing overwinter feeding damage by meadow voles and snowshoe hares, at least when applied to spring-planted, plug stock, pine seedlings. The results for the weasel scent were less convincing. Although weasel scent produced a significant reduction in damage in block A, in block B the reduction was not statistically different from the control.

The large difference in the amounts of damage in each section when compared between blocks indicates that site-specific factors may play a role in the effectiveness of the deterrents. We postulate that the weasel scent works by causing voles and hares to reduce their feeding in the area due to fear of possible predation; however, if there is a shortage of alternative foods, the voles and hares may risk predation rather than starve. We also believe that pinosylvin works best when voles have an alternative source of nutrition, and, as a result, will avoid the seedlings that smell as though they have a high concentration of antifeedant. If, however, an alternative food is in short supply, voles and hares have very little choice, and, as a result,will feed upon the seedlings. The results of this study indicate that voles and hares may be more likely to risk predation than feed on seedlings with high concentrations of antifeedant.

CONCLUSIONS

During periods of high hare or vole numbers and expeted damage to seedlings, pinosylvin, and, to a lesser extent, weasel semiochemicals, may be a useful method of biological plantation protection. Our results suggest that pinosylvin was highly successful in reducing herbivore feeding damage in the spring-planted sites, and weasel scent, although less effective, was also able to reduce

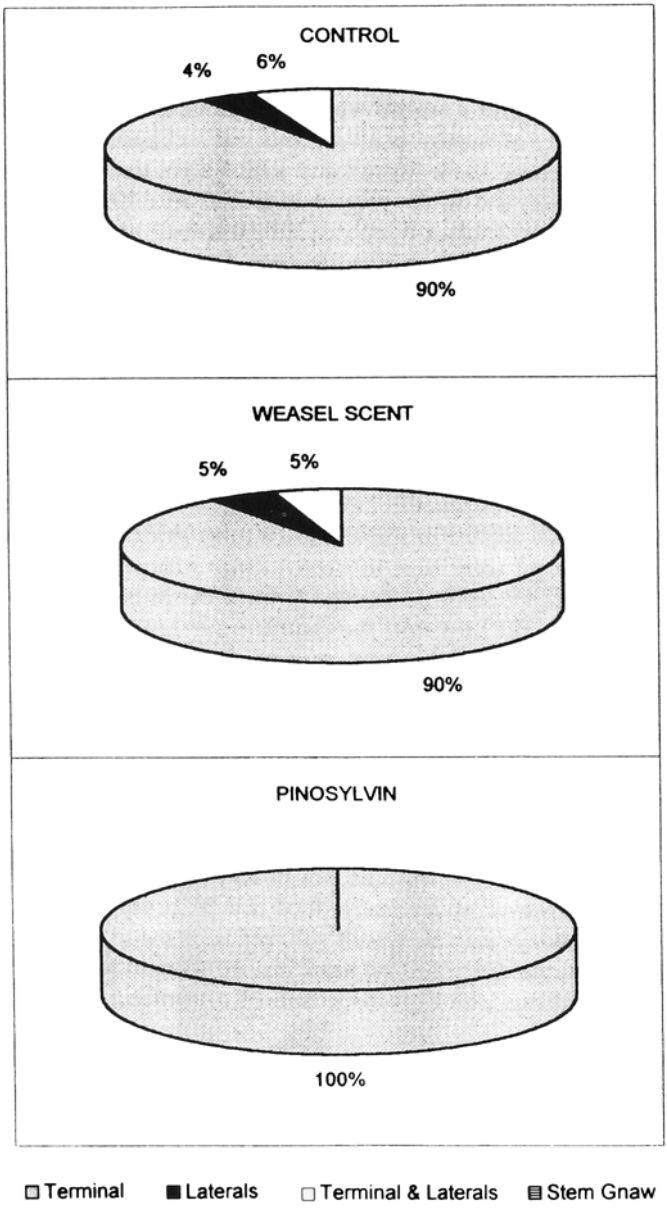

FIG 2. Type of damage in block A.

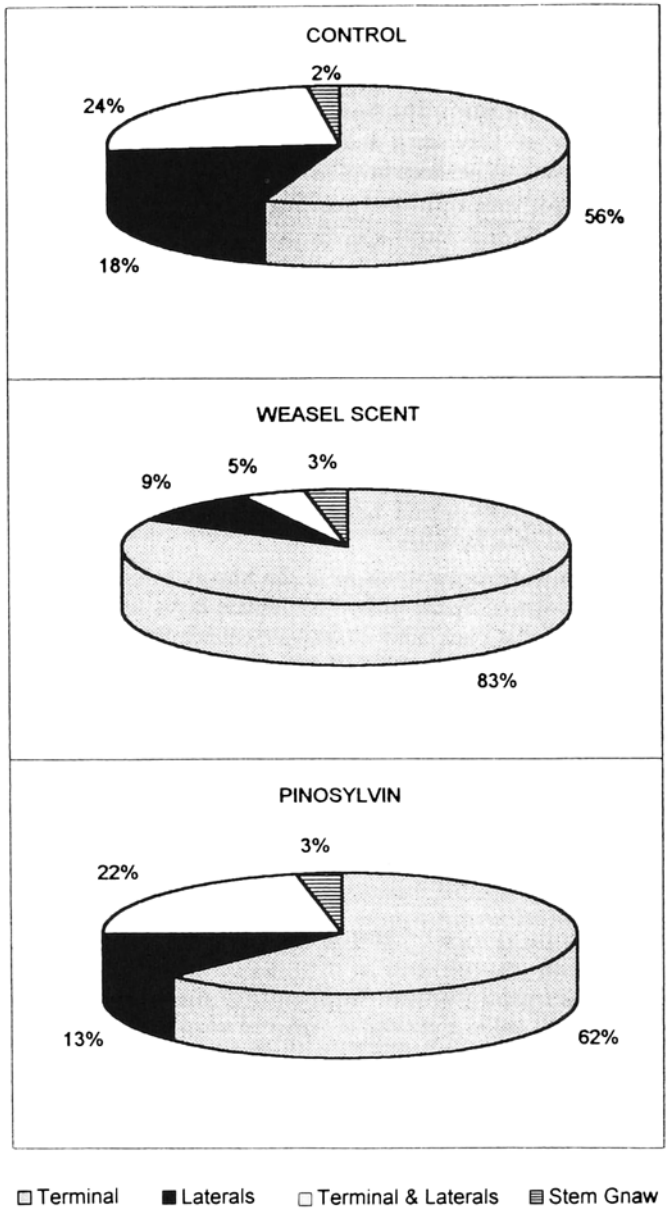

FIG. 3. Type of damage in block B.

feeding damage. These results enhance the desire to use nontoxic methods to control target species and the damage they cause.

Both pinosylvin and synthetic weasel odors have a number of benefits that other deterrents do not have. The first, and in some locations most important, is that the devices are very small and, as a result, have a low visual impact. Secondly, there is no maintenance involved. If attached correctly (devices should be hung on an upper lateral), treated seedlings would not have to be dealt with again. Thirdly, the devices target specific pest species and are not a danger to other wildlife.

The possibility that these herbivores are more likely to risk predation and eat a palatable food source, rather than feed on a source that has a high concentration of antifeedant, raises a number of questions about the role nutrients within the seedlings play in the occurrence of overwinter herbivore feeding damage. If the nutrients responsible for the increased palatability could be identified, then changes in nursery growing regimes might effectively reduce herbivore feeding damage. Pen feeding trials using voles and seedlings grown under different nutrient regimes would be extremely useful in determining which nutrients are keyed onto by voles.

The results also raise questions as to the importance of plant antifeedants in driving the population cycles of both snowshoe hares and meadow voles. It is well documented that plant antifeedants can change significantly after severe browsing (Bryant, 1981; Bryant and Kuropat, 1980; Bryant et al., 1983). Our results indicate that high concentrations of antifeedant may be capable of causing shifts in the feeding behavior of voles and hares to areas of higher predation risk.

TEMPORAL CLUMPING OF BARK BEETLE ARRIVAL AT PHEROMONE TRAPS: MODELING ANEMOTAXIS IN CHAOTIC PLUMES

JOHN A. BYERS

Department of Plant Protection, Chemical Ecology
Swedish University of Agricultural Sciences
S-230 53 Alnarp, Sweden

(Received February 28, 1996; accepted July 2, 1996)

Abstract—The sequence of arrival of the bark beetles *Ips typographus* and *Pityogenes chalcographus* (Coleoptera: Scolytidae) at traps baited with their synthetic pheromones was monitored with a portable fraction collector. Histograms of the natural arrival patterns of both species were nonrandom and clumped at shorter time scales (1-, 2-, 4-, 5-, or 6-min cells) but appeared random at larger time scales (10, 20 or 30 min). Monte Carlo generation of similar histograms showed them to be random at all of these time scales. A stochastic computer model could graphically simulate insect orientation to odor sources based on present theories of odor-modulated anemotaxis and casting. Although this model was used throughout, since it assumes only that insects cast perpendicular to the current wind direction, a second model could slightly improve orientation success. However, the second model requires that the insect remember its ground path (upwind) prior to losing the plume (after an abrupt wind direction change). The effects of casting and flight parameters on orientation success and randomness of arrival sequence within various plumes were determined by simulation. Similarly, the effects of random walks in plume direction, plume width, and wind speed were explored. The results showed that dynamic random variations in plume direction and especially wind speed could cause an otherwise random arrival sequence (e.g., under constant wind) to become clumped and nonrandom. Therefore, the clumped arrival patterns of bark beetles and other insects, including *Spodoptera litura*, at pheromone sources could result from random-walk fluctuations in wind speed and wind direction.

Key Words—Orientation, attraction, odor-modulated anemotaxis, pheromone plumes, casting, simulation models, Coleoptera, Scolytidae, Lepidoptera, Anemotaxis.

INTRODUCTION

In 1984, spruce bark beetles, *Ips typographus* (Coleoptera: Scolytidae), were collected by a fraction collector as they arrived at a trap baited with synthetic pheromone (Byers and Löfqvist, 1989). It appeared that the arrival of these beetles at the trap occurred in groups and not uniformly random during an hour with relatively constant temperature. I questioned this, however, because Ripley (1981) stated that a random pattern, such as a "Poisson forest" or the stars in the sky, appears to a casual observer as a nonrandom pattern of groups (e.g., the mythological constellations). On the other hand, it is reasonable to suppose that nonrandom patterns of arrival could result from difficulties of insects to orient in pheromone plumes under certain meteorological conditions. Thus, the first objective here was to determine whether individuals of two species of bark beetle arrive at pheromone-baited traps in a nonrandom, clumped sequence.

The optomotor anemotaxis mechanism for orientating to phermone sources proposed for insects, especially moths (Kennedy, 1939, 1983; David et al., 1982; Baker and Haynes, 1987; Baker, 1989), probably also functions in bark beetles (Choudhury and Kennedy, 1980). In this theory, an insect attempts to fly directly upwind when in contact with a packet of pheromone-laden air of the plume, but casts (flying back and forth perpendicular to the wind) when contact is lost. In contrast to walking insects, insects that are flying probably cannot use mechanoreceptors to sense the wind direction. However, flying insects can perceive wind direction by observing the ground below: in head-on wind, the ground moves directly underneath during flight. If the visual ground field moves from right to left somewhat, for example, then wind is coming from the left. The insect thus turns to the left to minimize the transverse ground shift and keep the ground moving directly underneath in order to head upwind toward the pheromone source. However, it is not known if all insect species use the same orientation mechanisms when flying within or on the edge of a pheromone plume.

The seminal paper of David et al. (1982) advanced our thinking about how flying insects reach a pheromone source in the field. Their theory, called "odor-modulated anemotaxis," asserts that optomotor anemotaxis and casting are sufficient to cause orientation to the odor source. They showed that wind direction may change rapidly causing a "snaking" of the plume, much as one might spray water from a hose. This occurs because the volume of air passing the odor source continues in a straight line downwind—and thus any insects encountering this volume will experience a wind direction flow that is directly opposite the direction to the source. They maintain that all the insect has to do is fly upwind, using optomotor anemotaxis when detecting pheromone, and cast when not detecting pheromone in the expectation of reentering the plume.

Central to our understanding of orientation is the structure of the pheromone

plume—in which our knowledge also has gone through an evolution. Plumes were visualized earlier as time-averaged Gaussian plumes extending up to several kilometers (Bossert and Wilson, 1963). Other Gaussian plume models have been proposed (Fares et al., 1980), but these and others did not reliably predict when gypsy moth wing-fanning would occur in relation to the mean wind direction (Elkinton et al., 1984). Since then the idea of a filamentous and snaking plume has become the paradigm (Murlis and Jones, 1981; David et al., 1982; Elkinton and Cardé, 1984). The idea of the "active zone" (Bossert and Wilson, 1963) or "active space" (Nakamura and Kawasaki, 1977, 1984; Baker and Roelofs, 1981) is also central to our concept of a plume. Within the active space, the concentration of pheromone molecules is sufficient to elicit a behavioral response in an insect, and this is the area that we spatially visualize as the plume.

My second objective was to make a computer model to simulate the odor-modulated anemotaxis and casting mechanisms associated with a plume in order to understand better how flying insects find a pheromone source. Using Monte Carlo randomization methods, several plume- and insect-related parameters were simulated over wide ranges (overlapping most natural conditions) to help understand their individual effects on insect attraction to pheromone. The third objective was to discover whether certain meterological parameters that varied at random in the simulation model could frequently produce nonrandom, clumped arrival patterns similar to those observed in nature.

METHODS AND MATERIALS

Successive Catches of Bark Beetles Attracted to Pheromone Components. A portable fraction collector similar to that used earlier (Byers, 1983), but with a crystal-controlled timer (Byers, unpublished), was used to sequentially collect flying bark beetles in 1- or 2-min periods during their attraction to pheromone baits. *Ips typographus* were collected this way during one to several hours in a Norway spruce forest clear-cut located in Grib Skov, 30 km northwest of Copenhagen, Denmark (May 29 and June 5, 1984), as they oriented to drain-pipe traps (with funnel) releasing 2-methyl-3-buten-2-ol (50 mg/day) and (1*S*, 4*S*, 5*S*)-*cis*-verbenol (1 mg/day) (Bakke et al., 1977, 1983; Byers et al., 1988). The fraction collector with only a 30-cm-diameter funnel was used to simultaneously collect *I. typographus* and *Pityogenes chalcographus* attracted by pheromone components of both species in another Norway spruce forest clear-cut in Grib Skov (June 16–17, 1987). *P. chalcographus* was attracted by baits releasing chalcogran (46:54 *E*:*Z*, 98% pure from W. Francke, University of Hamburg, Germany) released at 1 mg/day and methyl (*E*, *Z*)-2, 4-decadienoate (99.5% pure, Cyanamid Agrar) at 0.1 mg/day (Francke et al., 1977; Byers et al., 1988,

1990). During collections, the pipe trap + funnel or funnel was strongly tapped every 10–30 sec to ensure that all beetles were immediately collected after landing. Sex and numbers of beetles collected in the periods were determined in the laboratory.

Simulation of Insect Movement during Orientation and Casting in Pheromone Plumes under Windy Conditions. The simulation model (Figure 1) requires 30 input parameters (in units of meters, seconds, degrees, or as indicated). Twenty of these parameters can be varied systematically over a number of simulations. The parameters and their usual values, unless varied during simulation, were: (1) number of simulations per step variable, 8 or 16; (2) number of insects, 50; (3) *x*-axis, 216; (4) *y*-axis, 162; (5) plume length, 100; (6) flight speed in plume, 2; (7) cast proportion, 0.5; (8) number of castings, 2; (9) checks per cast, 20; (10) flight speed outside plume, 2; (11) trap radius, 0.25; (12) minimum wind speed, 0 or 1; (13) maximum wind speed, 1 or 2.5; (14) minimum wind speed enabling anemotaxis, 0.2; (15) maximum wind speed changes/min, 0, 1, 10 or 30; (16) maximum wind speed change per change, 0 or 0.5; (17) angle of maximum turn in plume, 20; (18) angle of maximum turn outside plume, 20; (19) probability of orienting during move when in plume, 1: (20) maximum plume angle, 90 or 160; (21) minimum plume angle, 20 or 90; (22) maximum plume angle changes/min, 0 or 10; (23) maximum plume angle change per change, 0 or 5; (24) maximum plume width angle, 10; (25) minimum plume width angle, 10; (26) maximum plume width angle changes/min, 0 or 5; (27) maximum plume width angle change per change, 0 or 5; (28) number moves per time period, 300; (29) total time periods, 12; and (30) random seed number, varied.

The complexity of the model can be reduced by choosing parameters that are realistic, such as *x* and *y*-axes, plume length, insect number per area, flight speeds, and turning angles (usually ≤ 20 degrees). Variations in other parameters often have little effect or may be optimized, such as cast proportion, number of casts, and number of checks per cast. Many parameters can be ignored by making them equal zero. Other effects can be held constant by setting two parameters equal, for example, minimum and maximum wind speeds both set to 1 m/sec.

The general algorithms for simulation of insect movement and catch by traps have been described in Byers (1991, 1993). A plume in the models is defined geometrically as a pie slice of a circle with width equal to the arc in degrees and length equal to the radius (Sabelis and Schippers, 1984). Insects not in contact with the plume take steps in a forward direction with possible random deviations up to an angle of maximum turn (either right or left at random). Moves are based on either of two speeds (or distances covered in 1 sec) when either inside or outside the plume. However, insects can have less ground speed when casting or when countered by the wind. The ground path

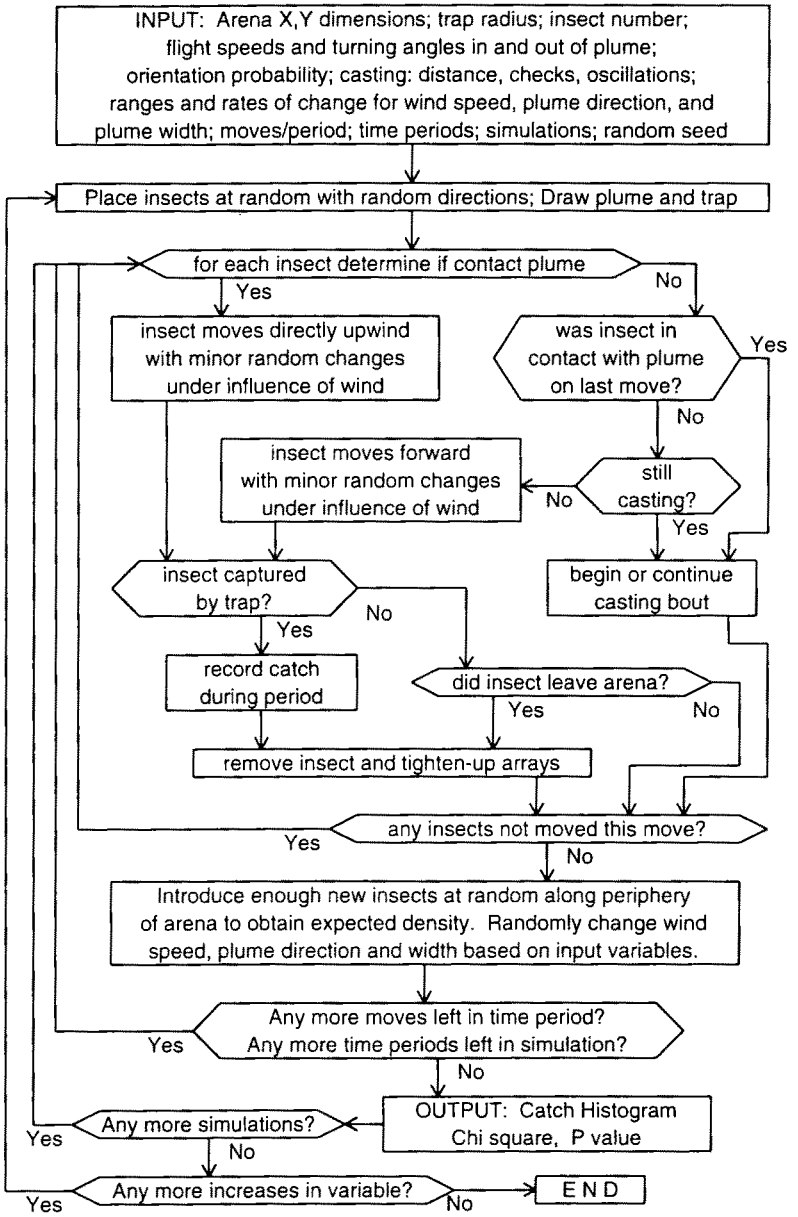

FIG. 1. Flow diagram of graphical computer model for orientation of insects toward pheromone-baited traps while flying in changing wind and plume structure.

of an insect is determined by first calculating the insect vector using polar coordinates of insect flight speed and former direction (or upwind direction if in the plume) plus the random angle of turn, and then adding the wind vector, based on the polar coordinates of wind direction and speed. Insects that land in or cross the trap during a move are caught (Byers, 1991) and recorded for the time period. During a move, any insects that are caught or leave the arena are removed (Figure 1). After all insects have moved a step, the number of insects remaining outside the plume that are not casting is counted. If this number is less than the expected number based on the initial density (minus the plume area), then enough insects are added at the arena's periphery (in proportion to the dimensions) to attain the desired density (Figure 1). This ensures that a relatively constant density of insects surrounds the plume under any conditions.

Modeled insects cast after they step out of a plume, through a plume, or when the plume moves away between insect moves (Figure 1). The algorithm for determining whether an insect is within the plume is based on whether the insect's angle to the source is within the plume angles and that the insect is closer to the source than the plume length. Near the source as the plume narrows, it is possible for insects to "step over the plume," so a second algorithm is used to determine if the insect's move segment intersects either plume segment (Byers, 1992). When an insect either steps over the plume or leaves the plume, it does not begin casting until the next move, whereupon it turns perpendicular to the wind direction by turning either right or left at random.

The distance of a cast, defined as the maximum length of a perpendicular excursion, can be specified as any proportion P of the distance covered in 1 sec while in the plume (flight speed within the plume). The insect takes one move to travel the cast distance and one move to return to the starting point. The insect checks to see whether it is in the plume at several points spaced equidistantly along the cast path. The number of checks can be varied but was usually held constant at 20 in the simulations here. If the insect encounters the plume while casting at any of the check points, it stops at this position and on the next move begins to fly upwind again (Figure 1).

Assuming the plume is not found during a cast and return, the casting oscillation continues until the insect takes a cast in the direction opposite the initial one (a third move) and then returns to the start on the fourth move. More than one casting oscillation can be specified during a bout of casting (in the simulations the default was two oscillations). After casting is completed without success, the insect wanders away to possibly blunder into the plume nearby. This casting algorithm causes insects to orient reliably to the pheromone source except when the plume is very narrow (a few degrees) or very wide. The maximum width of the plume (in degrees) that should allow reliable plume following is calculated from the equation:

$$2\left\{\frac{\pi}{2} - \arcsin\left[\frac{A \sin\left(\frac{\pi}{2} - \alpha\right)}{\sqrt{A^2 + B^2 - 2AB\cos\left(\frac{\pi}{2} - \alpha\right)}}\right]\right\}\frac{180}{\pi} \quad (1)$$

with $A = S - [W/\cos(\alpha)]$ and $B = P\,S - W\tan(\alpha)$ where S is the flight speed (meters per second) within the plume, W is the wind speed (meters per second), P is the cast proportion (≤ 1), and α is the angle of maximum turn within the plume (in radians). The largest α possible for casting to function reliably is limited by the cast proportion according to:

$$\alpha_{max} < \arcsin(P)\frac{180}{\pi} \quad \text{where} \quad \arcsin(P) = ATN\left(\frac{P}{\sqrt{1 - P^2}}\right) \quad (2)$$

The α used in simulations should be less than α_{max} since this angle assumes the most narrow plume possible. The *arcsin* transformation (equation 2), uses the *ATN* (arctan) function of BASIC and should also be used with equation 1.

To understand the effects of certain parameters on catch in simulations, several combinations of parameters were held constant while the magnitude of one parameter was increased stepwise, with 8 or 16 replicates per step and each replicate having 12 time periods consisting of 5 min (300 moves). Attempts were made to simulate the frequency distributions of natural catches by allowing several meteorological parameters to vary at random during simulations. These were wind speed, plume direction angle (wind direction), and plume width. All three variables have two components that can also be varied at random, namely, probable number of changes per minute and maximum random change at each change. The probable number of specified changes, e.g., 10 changes in wind speed per minute, is determined at each move (equal to 1 sec) by whether the random number generated by computer (an eight-digit number < 1) is less than 10/60.

The arrival patterns of bark beetles were analyzed for randomness over different time periods by making histograms of the catches using various cell widths (1–30 min). These histograms were compared to average expected catches based on the total catch divided by the number of histogram cells using chi-square analysis. To check the method, histograms of the same number of cells and total catch were generated by Monte Carlo methods and compared similarly. The catches in the computer simulations were also grouped in 5-min periods and analyzed by chi-square, whereupon exact P values were calculated and averaged for graphical and statistical analyses. Points with bars in the figures

represent upper and lower SEM from 8 to 16 simulation runs (however, some graphs have no bars to reduce complexity). Curves were fitted to the data with the following priority of methods: linear and nonlinear regression, combinations of these, equation fitting by eye, moving average, and connection of points.

RESULTS

Successive Catches of Bark Beetles Attracted to Pheromone Components. A total of 108 (27.8% males) *I. typographus* were collected in 2-min periods over 3.5 hr beginning at 14:30 hr, on May 29, 1984. The pattern of arrival, as shown in a histogram of 5-min periods (Figure 2) summarizing the actual counts (dots), was significantly different from an expected distribution based on a uniform random arrival ($P = 0.028$, chi-square). A Monte Carlo-generated histogram of the same total count shown for comparison was not different, as expected from a uniform random arrival ($P = 0.664$) nor was an average of 10 such distributions (Figure 2). When the natural data and the randomly generated patterns were subdivided into cells of different durations (1–30 min) and ana-

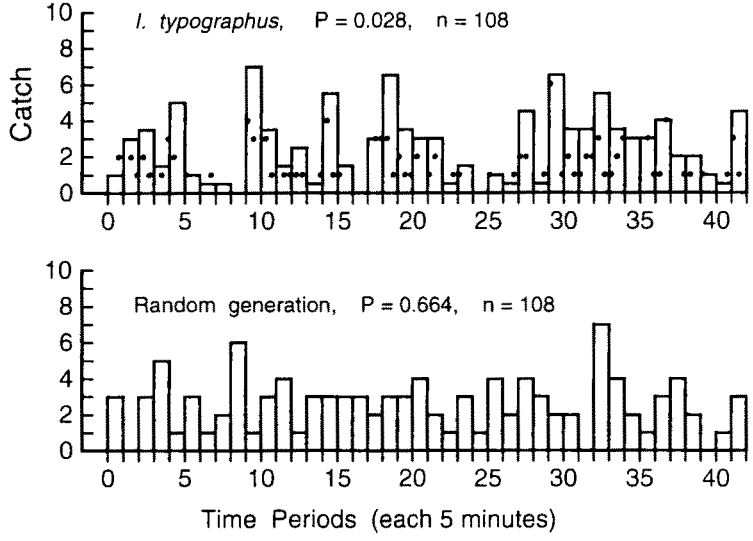

FIG. 2. Top: histogram of *Ips typographus* arrival at pheromone-baited traps (5-min periods over 3.5 hr beginning 14:30 on May 29, 1984; actual 2-min catches represented by dots). Bottom: histogram of Monte Carlo-generated random distributions of the same number of periods and total catch (108). Average P value for 10 generated distributions was 0.56 ± 0.28 (±95% CL).

lyzed by chi-square, only the natural data were significantly nonrandom at 2-, 4-, and 5-min periods, while larger lumpings of the data in cells of 10 or more minutes indicated a relatively constant catch during the whole period (Table 1). On June 5, 1984, 62 (16.1% males) *I. typographus* were caught over an hour period (Table 1) and histograms of cells of 2–6 min also were significantly different from random while larger groupings were not (Table 1).

Over a 40-min period of 2-min collections, 226 (40.7% males) *P. chalcographus* were caught, and the histogram pattern (Figure 3) was significantly different from an expected distribution of random arrival ($P < 0.001$). Similar Monte Carlo-generated distributions, however, were not different from random as analyzed by chi-square (Figure 3). In two other 40-min periods of 1-min collections, 93 (44.1% males) and 81 (39.5%) *P. chalcographus* were caught, and the histograms were significantly different from expected random arrivals at several different lumpings of the data from 1 to 10 min (Table 1). As expected, similar chi-square analyses of Monte Carlo-generated histograms rarely ($\leq 5\%$ cases) were found to be different from random.

The temperature during the 40-min collection periods varied less than 2° and was generally optimal for flight (21–25°C). Winds, measured occasionally with a fan anemometer, varied between 0.8 and 2.3 m/sec (average for 20 sec). Wind direction was observed with a wind vane to change direction up to 60° within a second or two while generally prevailing in one direction (although direction reversals were observed). It appeared that most beetles arrived during lulls in the wind.

Simulation of Insect Movement during Orientation and Casting in Pheromone Plumes under Windy Conditions. The computer model shows on screen whether the parameters specified allow simulated insect orientation toward a pheromone source. When the model was tested under constant conditions (parameters as in Figure 4), the effect of enlarging the width of the plume from 0 to 9° caused a cumulative exponential increase in catch (Figure 4). Thereafter, an increase in plume width up to about 40° caused a linear increase in catch. In theory, the catch should be linearly proportional to the perimeter length of the plume, i.e., a 90° plume will catch twice as many as a 45° plume of the same radius since the arcs are proportional to the plume angles. However, as seen from equation 1, a plume width of more than 39.53° does not allow reliable casting with the parameters specified in Figure 4, and thus the catch declined exponentially ($Y = ae^{-bX}$) above this angular width (Figure 4). The arrival patterns in the simulations at all plume widths had average P values well above significant levels, indicating that arrival was random as should be expected (Figure 4).

Several parameters involving orientation such as checks per cast, casting oscillations, angle of maximum turn within the plume, and probability of orientation at each step were investigated for their affects on arrival at traps. During

a cast an insect must sample the air for pheromone; this can be done only once at the outermost extent of a cast, or many times (equally spaced) along the path of a cast. The orientation success or catch increased with checks per cast approximately in an exponentially hyperbolic relationship [$Y = ae^{(b/X)}$] while having no apparent affect on the randomness of arrival (Figure 5A). This relationship was apparent even with 0.5° plume widths, 0.025 m trap radius, and finer 0.1-sec insect moves. An increase in the number of casting oscillations had no affect on orientation when plume direction remained constant. When the plume was allowed to shift direction at random (10 times per minute), the orientation success became poorer as the random swing became larger (maximum 1, 5, or 10°). However, orientation success increased as the number of casting oscillations increased, the more so the larger the random swing (Figure 5B). No effects on the randomness of arrival were found due to the number of casting oscillations.

An increase in the angle of maximum turn from 0 to 27.8° has little affect on orientation success (Figure 5C), and this is expected based on equation 1 for a 10° wide plume. A plume width above 30° does not allow reliable orientation as seen from equation 2. Across the spectrum of possible insect turn angles,

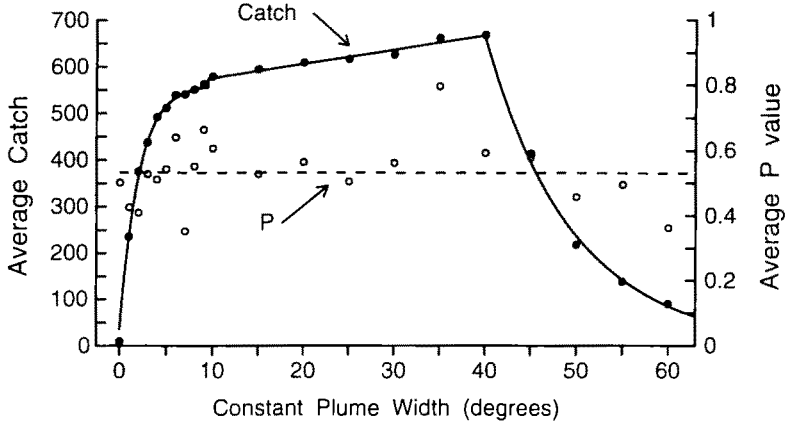

FIG. 4. Effect of plume width angle on the average catch and the average *P* value (chi-square analysis of arrival histogram) over an hour of simulated time. Simulations were performed 16 times at each plume width under the following conditions: 216 × 162-m arena; 100-m plume length; 50 insects; 2 m/sec flight speed both inside and outside plume; 0.25 m trap radius; 1 m/sec constant wind; 20° angle of maximum turn both inside and outside plume; probability of 1 to orient at each step within the plume; 0.5 casting proportion of flight speed within plume; 20 checks per cast; 2 casting oscillations; 90° constant plume direction; plume width angle was varied; constant plume width during a simulation; 300 moves/time period (5 min); and 12 time periods (total 1 hr) per simulation.

FIG. 5. (A) Effect of number of casting checks per cast on the average catch and the average *P* value (chi-square analysis of arrival histogram) over an hour of simulated time. Simulations were performed eight times at each value under the model parameters in Figure 4, except as indicated, and plume width angle was held constant at 5°. (B) Effect of number of casting oscillations on the average catch and the average *P* value (chi-square analysis of arrival histogram) over an hour of simulated time when the plume direction was allowed to vary in direction at 10 directional changes per minute (at random) at a maximum change of 0, 1, 5 or 10° at random. Simulations were performed eight times at each value under the model parameters in Figure 4, except as indicated, and plume direction could range from 20 to 160° while plume width was constant at 10°. there was little effect on patterns of arrival since all average P values indicated no differences from random (Figure 5C). The probability of orientation at each step was usually held constant at 1; however, lower probabilities increase the stochasticity and look more realistic on screen. Although no figure is shown, the average catch (Y) increased form 0 to 600 in relation to the square of the probability of orientation at each step ($0 \leq P_0 \leq 1$) according to $Y = 9.36 + 563.4P_0^2 (r^2 = 1$, parameters as in Figure 4). Again, average P values indicated random arrivals at all orientation probabilities.

The rate of catch decreased exponentially (best fit was a Taylor exponential: $Y = e^{a-\sqrt{X}}$) with an increase in the maximum random change in plume direction random walk, when the direction was changed at either 1, 10, or 30 times per minute at random (Figure 6). The catch rate also decreased similarly with an increase in the rate of changes in plume direction (at a maximum random change of 2° per change, figure not shown). Surprisingly, random changes in plume direction (10/min or more) produced a random arrival of insects at the trap over time, except when only a few changes per minute occurred (e.g., 1/min, Figure 6).

The rate of catch declined as a Taylor exponential ($Y = e^{a+b\sqrt{X}}$) with an increase in plume width changes per minute (each change a maximum of 2° at random) when the plume width could vary between 10 and 20° or 10 and 60° (Figure 7). The arrival of insects was different from random when plume widths could vary between 10 and 60° and the number of width changes were greater than about 10/min, but no effects were observed when plume width was restricted in a more realistic range between 10 and 20° (Figure 7).

In preliminary models, attempts to maintain a constant number of insects in the arena were done by replacing any that left the arena or were caught. However, under wind speeds approaching the flight speed, insects accumulated in the plume as they moved slowly toward the source, thus depleting the density surrounding the plume. Since there were less insects available to contact the plume, catch rate decreased with time. In reality, in an ocean of constant insect density, the same density surrounding the plume should persist at any wind speed. Thus, the model was modified so that any insects that either entered the plume (or were casting), left the arena, or were caught were replaced on the arena's perimeter to obtain the specified density. In this case, at higher wind speeds, insects move more slowly toward the source, but the accumulation of insects within the plume perfectly compensates so the rate of catch remains constant, until just below the flight speed when orientation is impossible. The wind speed W at which the average insect within the plume cannot move upwind is determined by the following equation:

$$W = \int_0^{\alpha} S \cos(\beta) \approx \sum S \cos(\beta) \quad \text{and} \quad \beta = 0, 0.0001, \cdots, \alpha \qquad (3)$$

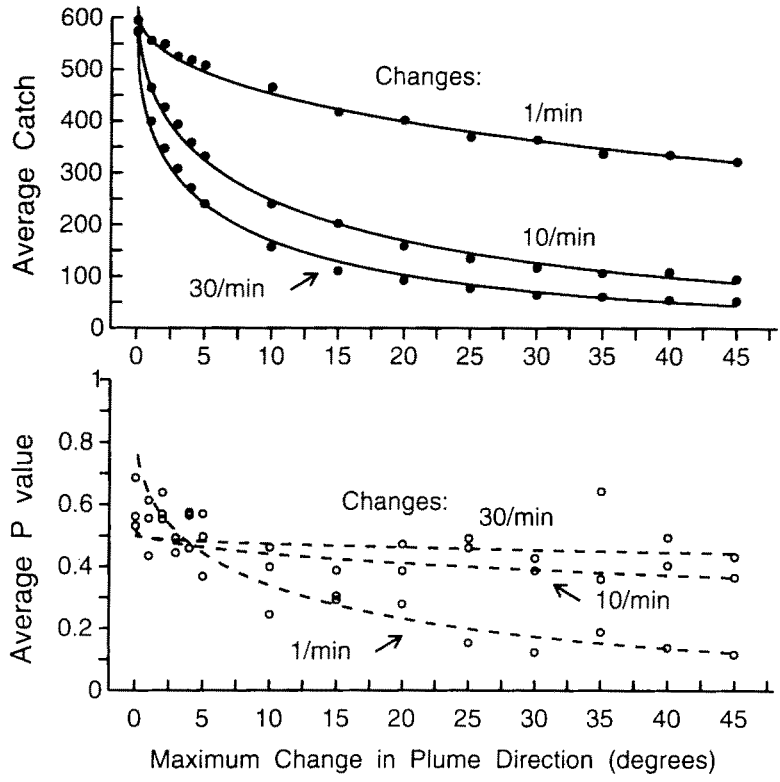

FIG. 6. Effect of maximum change in a random walk in plume direction (1, 10, and 30 changes per minute at random) on the average catch (top graph) and the average P value (bottom graph) (chi-square analysis of arrival histogram) over an hour of simulated time. Simulations were performed 16 times at each value under the model parameters in Figure 4, except as indicated, and plume direction could range from 20 to 160° while plume width was constant at 10°.

where S is the speed within the plume (e.g., 2m/sec) and α is the maximum angle of turn (e.g., 20° in radians).

Variable winds (random walks) over a range of 0 to 2.5 m/sec had little or no effect on rate of catch but did cause the pattern of arrival to become nonrandom or clumped. The arrival pattern swiftly became nonrandom with small increases from 0 to 0.2 m/sec in the maximum wind speed change (at random) occurring approximately 30 times per minute (at random) but then gradually became less clumped and more random with further increases above 0.5 m/sec in maximum changes (Figure 8). The minimum wind speed that

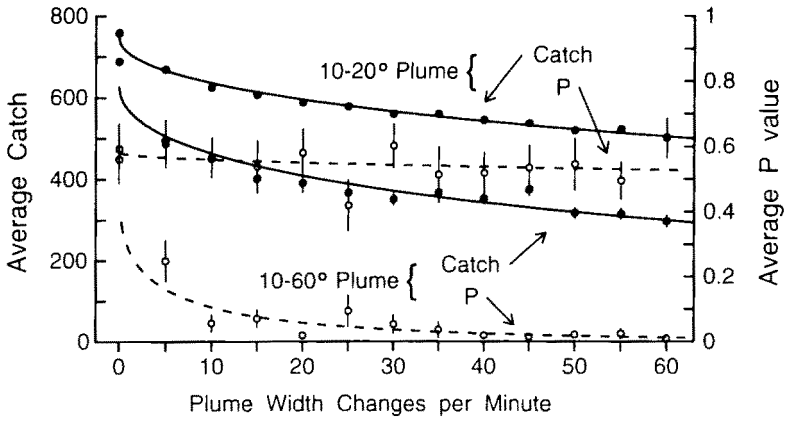

FIG. 7. Effect of number of plume width changes per minute (taken at random) in a random walk at a maximum of 2° per change (at random) on the average catch and the average P value (chi-square analysis of arrival histogram) over an hour of simulated time. Two simulation series were done, one in which the plume width could vary from 10 to 20° and the other with an allowed range from 10 to 60°. Simulations were performed 16 times at each value under the model parameters in Figure 4, except as indicated, and the angle of maximum turn, normally 20°, was reduced to 10° to allow reliable casting on wide plumes.

enabled anemotaxis was set at 0.2 m/sec, assuming upwind orientation is not possible without some air movement (Nakamura and Kawasaki, 1984). Below this wind speed insects in contact with pheromone odor continued to move forward with random deviations like those outside the plume.

Wind speed fluctuations that occurred about 30 times per minute at changes of up to 0.5 m/sec caused the pattern of arrival (Figure 9) to be nonrandom ($P < 0.002$). It appears that catch rate is higher during a lull period following a time with higher winds (Figure 9), although the 5-min rates depend on a complex interaction between wind speed, time, and direction of the speed change.

DISCUSSION

The models here may help us to define, organize, and understand orientation concepts as well as communicate and test that understanding in order to make predictions and comparisons (Worner, 1991). The model has fewer conceptual problems when wind direction, speed, and plume dimensions are held constant at reasonable levels. Objections arise when plume width or direction vary. For example, modeled plumes change direction along their entire length while wind

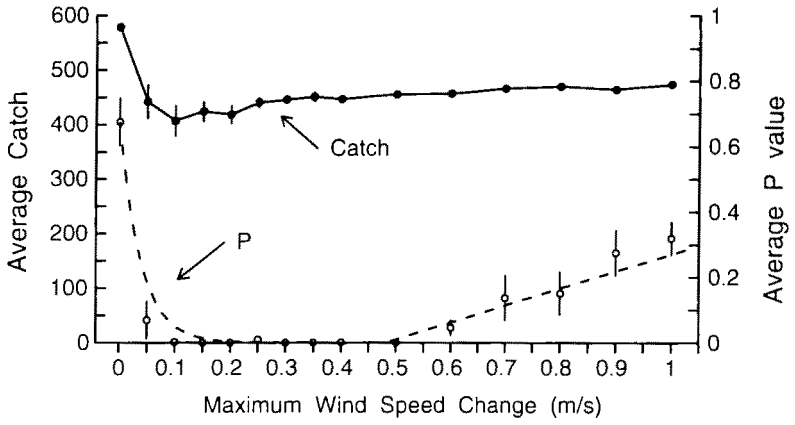

FIG. 8. Effect of maximum change at random in a random walk in wind speed (about 30 changes per minute at random) on the average catch and the average P value (chi-square analysis of arrival histogram) over an hour of simulated time. Simulations were performed 16 times at each value under the model parameters in Figure 4, except as indicated, and wind speed could range from 0 to 2.5 m/sec while plume width was constant at 10°.

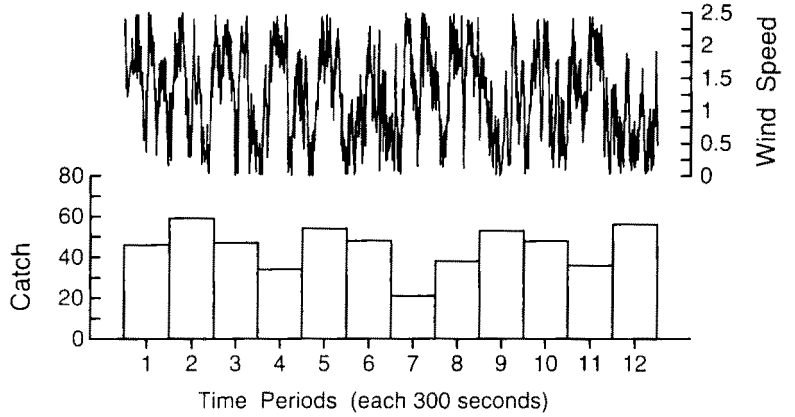

FIG. 9. Top: Wind speed fluctuations during an hour of simulated time in which wind speed could change on average 30 times per minute at a maximum change of 0.5 m/sec at random within a random-walk range between 0 and 2.5 m/sec. The simulation was performed under the model parameters in Figure 8. Bottom: The corresponding histogram of simulated catch, the arrival sequence was significantly different from an expected frequency by chi-square analysis, $P < .002$.

speed and direction changes affect all areas of the arena simultaneously. More realistic snaking plumes are the subject of future models. However, the rate of successful orientations within a snaking plume and the swinging plume here may not be significantly different since an insect would experience odor puffs of the same periodicity and dimension in both models. Granted, only the snaking plume would allow realistic coordinated movements among insects in the arena, but this seems unimportant to arrival rates.

The model density of 50 beetles in a 216 × 162-m arena was 16% of the natural flight density in one spruce clear-cut in Denmark (Byers et al., 1989), but of course natural densities must vary greatly. In any case, the relationships and randomness of arrival patterns found here do not depend on insect density. The trap radius of 0.25 m used in the model is larger than most tree trunks, but probably smaller than the visual attraction radius of many bark beetles to trees under colonization (Tilden et al., 1983; Lindgren et al., 1983). Again, this is not important to the general relationships and temporal arrival patterns, but only in regard to the absolute catches.

In all simulation series, a period of time to reach equilibrium conditions was allowed before beginning to collect arrival data. Further, in a simulation series each simulation served as the equilibrium period for the next simulation, i.e., all subsequent simulations used the same insects and plume dimensions that existed at the end of the preceding simulation (Figure 1). Attaining equilibrium was especially important at wind speeds approaching the flight speed, where many insects, sometimes thousands, could accumulate within the plume.

An increase in the magnitude of plume direction change occurring relatively often (10–30/min) did not have a significant affect on the randomness of arrival (Figure 6), even though the catch decreased with an increase in the magnitude of directional changes. Many changes in plume direction per minute, each of small magnitude, seems realistic, compared to larger directional changes, since the entire plume jumps in the model. Conceptually, a large shift in wind direction might be acceptable if it occurred rarely, since in this case the plume position is usually stationary. In this case, when the plume took major swings in direction only once per minute on average at random, there were more simulations where arrival was not random, increasingly so with larger directional swings (Figure 6). In nature, changes in wind direction might further affect the arrival patterns since the plume could sweep over brood trees or hibernation sites periodically.

Observations of male *Grapholita molesta* moths flying to a pheromone source in the field under shifting winds convinced Von Keyserlingk (1984) that males losing the plume allowed themselves to drift or be pushed over to the plume's new position by the wind. Baker and Haynes (1987) did not find evidence to support this phenomenon; instead, upon leaving a plume, males seemed to "take up an angle approximately 90° across the windline even as the windline

was in the process of shifting." In the simulations here, insects that lost the plume after a wind shift begin casting across the windline, and if unsuccessful in finding the plume, they took their first step forward against the new wind direction (model 1, Figure 10). In a second model (model 2, Figure 10), insects reached the odor source more often in variable winds because, upon losing the plume, they moved forward initially against the previous wind direction (they would have to remember their immediate ground path).

The reason model 2 insects are more successful in reentering the plume is they have a vector (previous wind direction before wind shift) that adds to the new plume/wind direction vector causing the insects generally to veer toward the new plume position. Whether plume direction changes rapidly enough in nature to afford an adaptive benefit to model 2 insects remains an open question (Figure 10). Which of these two models insects use should be investigated. Namely, do the initial paths taken after casting progress in the former wind direction before wind shifting, or in the new wind direction?

Changes in plume width can be likened to turbulence. Only when the plume was allowed to broaden or narrow over an unrealistically large range (10–60°) could changes in width affect the randomness of arrival (Figure 7). This non-

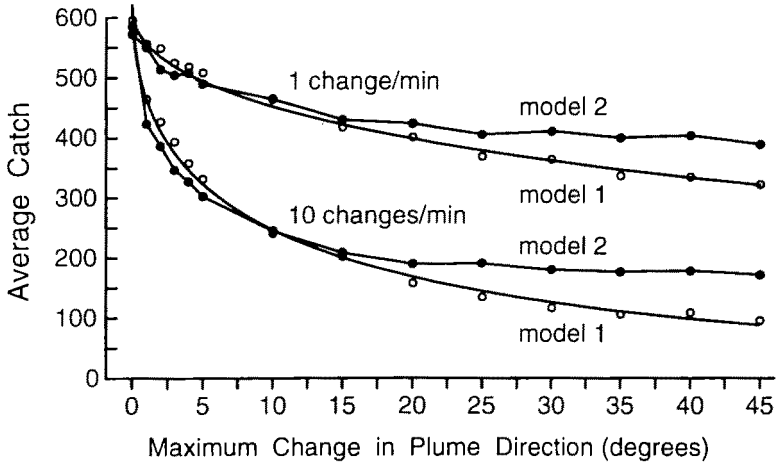

FIG. 10. Effect of maximum change at random in a random walk in plume direction (at 1 or 10 changes per minute at random) on the average catch over an hour of simulated time for model 1 and model 2 insects. Model 1 insects (those used in most simulations) moved forward in the current wind direction after losing the plume during a wind shift. Model 2 insects moved forward in the former wind direction after losing the plume during a wind shift (thus they must remember their previous ground path before casting). Simulations otherwise as in Figure 6.

random effect was probably due to histograms composed of fewer catches with a narrow plume during one period of time compared to larger catches with a wide plume at another time in the simulation (see Figure 4). At a smaller range of 10–20°, no effect of plume width changes could be found on arrival pattern, indicating that at even more narrow and probably more realistic ranges there also would be no affects on randomness.

Random walks in wind speed dramatically modified the arrival pattern to become clumped and nonrandom (Figures 8 and 9). The effects of wind speed fluctuations were most evident when the wind could vary above and below the flight speed. A wind speed of 0.2 m/sec was used as the minimum speed necessary for anemotaxis and corresponds to the finding of Nakamura and Kawasaki (1984) that the moth *Spodoptera litura* oriented poorly at low wind speeds. However, removal of this parameter from the model had little affect on the randomness of arrival.

Compared to moths, relatively less is known about bark beetle flight orientation to pheromone. In the confines of a wind tunnel, bark beetles fly erratically, which has discouraged more detailed studies (Choudhury and Kennedy, 1980; Salom and McLean, 1991a). In the field, bark beetles generally are recaptured downwind in the absence of attractive odors (Salom and McLean, 1991b), but this can be the result of either a directed flight downwind or a random drift with wind (Helland et al., 1984; as in the models here). Salom and McLean (1991b) found *Trypodendron lineatum* flew across wind to opposite sides of a clear-cut valley, although more were caught downwind. Bark beetles are believed to fly upwind to attractive odor sources based on direct observation and on catches of traps correlated with wind direction (references in Byers 1988; Salom and McLean, 1991b). Byers (1988) mounted wind vanes on traps to prove that western pine beetles, *Dendroctonus brevicomis*, fly upwind to pheromone.

Bark beetles can accumulate within a plume at higher wind speeds and appear to fly in groups as in the model. On May 19, 1984, in Denmark in a clear-cut about 1 km from the study site, I observed *Ips typographus* taking off from a brood log pile. Most flew downwind (one beetle at about 3.3 m/sec over 50 m as I ran down a road parallel to its flight path) while fewer beetles flew across the wind. Nearby, I noticed several tens of *Ips typographus* at the same time as they flew slowly upwind to a large fallen Norway spruce undergoing colonization. The beetles were orienting upwind presumably within a pheromone/host odor plume from at least as far as 50 m from the tree. The beetles were tossed horizontally across the wind line, or possibly were casting, as they slowly progressed upwind at a ground speed of at most 0.5 m/sec (compared to my slow walking) and often were blown downwind during gusts. The wind was unidirectional but variable in speed from about 1 to 4 m/sec (fan anemometer at 1.5 m for 20–30 sec). Most individuals were flying at 2–4 m height

(practically all <6 m) while 15–30 m from the tree, but generally lower (1–3 m) when approaching within 10 m of the tree.

Many moths have a zigzagging flight during anemotaxis (Kennedy, 1983; Baker and Haynes, 1987), while model insects flew directly upwind with random deviations. The programmed counterturning flight could be included for more realism but should not greatly affect the relationships since the mean direction of a zigzag is still directly upwind with random deviations. In spite of the simplifications of the model, simulated insects could reliably reach the odor source using only a combination of odor-modulated anemotaxis and casting. Improvements to the model with regard to plume dimensions, orientation and flight movement parameters, and wind effects probably will not alter the basic conclusion that fluctuations in wind speed and direction modify an otherwise random arrival pattern to one that is clumped and nonrandom. Most reports on arrival of insects to traps can not be analyzed for random arrival patterns as done here since the sampling periods were of hours or days (e.g., Byers and Löfqvist, 1989). However, Nakamura and Kawasaki (1984) report the mean wind velocity (every 5 min) with 1-m sampling periods of arrival of *S. litura* to pheromone traps over 2 hr, but they did not speculate about randomness of the arrivals. A chi-square analysis of the *S. litura* data (their Figure 1) shows that this moth exhibited a clumped arrival pattern (23 *df*, $P = 0.03$).

The simulation model is available from the author as a compiled program for IBM-compatible personal computers with VGA monitor (please send a formatted disk). The software also can be downloaded from the Internet (http://alyssum.stud.slu.se:8001/~johnb/software.html).

Acknowledgments—Funding for the project was obtained from the Swedish Agricultural and Forest Research Council (SJFR). I appreciate the helpful discussions and comments of my colleagues here in Alnarp and Lund concerning the model, especially the interest and encouragement of Jörgen Jönsson.

(Received October 23, 1995; accepted July 3, 1996)

Abstract—Analyses of the enantiomeric composition of ipsdienol produced by individual male pine engravers, *Ips pini* (Say), from six populations in British Columbia, support the hypothesis that New York and Idaho races of this species hybridize in southeastern British Columbia. Production profiles, expressed as frequency distributions of (+):(−) ipsdienol ratios [= ratio of (*S*)-(+)-ipsdienol to (*R*)-(−)-ipsdienol], were bimodal for four western British Columbia populations. The (+):(−) ratios ranged from 63:37 to 71:29, consistent with those previously found for the New York race. The profile for a southeastern population from Radium, British Columbia, was intermediate between those for the four western British Columbia populations and that from one population in Kimberley, British Columbia, just south of Radium. Males in the Kimberley population produce predominantly (*R*)-(−)-ipsdienol, typical of California and Idaho males. Response profiles of different individuals of *I. pini*, determined by captures of beetles in multiple-funnel traps baited with ipsdienol of 11 different (+):(−) ratios, were not consistent with production profiles. Populations in Williams Lake and Princeton, in western British Columbia, and Radium, in southeastern British Columbia, had response profiles with maximal attraction to ipsdienol over a broad range of (+):(−) ratios, falling off as enantiomeric purity was approached at either end of the

spectrum. This type of response profile is consistent with that for the New York race, which has been shown to respond optimally to (+):(−) ratios ranging from 40:60 to 70:30. The response profile of the Kimberley population gradually declined from maximal attraction to ipsdienol with a (+):(−) ratio of 2:98 to the lowest response at a (+):(−) ratio of 98:2. The attraction of *I. pini* to chemical stimuli in California is interrupted by ipsdienol with a (+):(−) ratio >5:95, a pheromone of a host competitor, the California five-spined ips, *Ips paraconfusus* Lanier. We hypothesize that the Idaho race, which does not compete with *I. paraconfusus* due to geographical separation, is characterized by a Kimberley-type enantiomeric response profile, intermediate between those of the New York and California races.

Key Words—Ipsdienol, *Ips pini*, Scolytidae, aggregation pheromone, enantiomer, geographic variation, intrapopulation variation, speciation, competitive exclusion.

INTRODUCTION

The principal male-produced aggregation pheromone of the pine engraver, *Ips pini* (Say)(Coleoptera: Scolytidae), is ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol), a monoterpene alcohol with one asymmetric carbon center and two enantiomeric configurations (Seybold, 1993). Pioneering research on volatile extracts trapped from populations of *I. pini* disclosed that males from California (Stewart, 1975; Birch et al., 1980) and Idaho (Plummer et al., 1976) produce only (*R*)-(−)-ipsdienol, while males from New York produce a 65:35 blend of (*S*)-(+) and (*R*)-(−) enantiomers (Lanier et al., 1980).

Recently, pheromone production profiles were determined for populations of *I. pini* based on the enantiomeric ratios of ipsdienol produced by individual beetles (Slessor et al., 1985; Miller et al., 1989). Males in populations from Hat Creek, California, and Kimberley in southeastern British Columbia produce primarily (*R*)-(−)-ipsdienol, with mean (+):(−) ratios [= ratio of (*S*)-(+)-ipsdienol to (*R*)-(−)-ipsdienol] of 9:91 and 11:89, respectively. In each population, however, there are a few beetles that produce primarily the (+) enantiomer. Beetles from Newcomb, New York, are characterized by a bimodal frequency distribution, with respect to enantiomeric composition, with a mean (+):(−) ratio of 57:43. A population from Princeton in southwestern British Columbia is characterized by a similar, but slightly broader, bimodal enantiomeric production profile, with a mean (+):(−) ratio of 66:34.

Seybold et al. (1995a) determined enantiomeric compositions of ipsdienol in volatiles captured from logs infested by males from 35 populations of *I. pini*, representing the North American range of the species. These included one population from southwestern British Columbia and a second population from southeastern British Columbia, very close to the locations used by Miller et al. (1989), and several populations from Washington, Idaho, and Montana. Seybold et al.

(1995a) hypothesized that there are two, possibly three, geographically separate pheromone variants or races of *I. pini*. Males in the "California" race, with a range extending from Washington to Arizona and New Mexico, produce ipsdienol with (+):(−) ratios of 6:94 to 2:98. The eastern "New York" race is characterized by (+):(−) ratios of 68:32 to 44:56. This race ranges from southern Appalachia, north along the Atlantic coast, through the US Lake states, and across the boreal forest of Canada, extending south in British Columbia to the US border. The third "Idaho" race is located in southeastern British Columbia, Idaho, and Montana (and possibly further east, west, and south); its males produce ipsdienol with (+):(−) ratios ranging from 9:91 to 5:95. Seybold et al. (1995a) speculated that the Idaho race may represent a zone of hybridization between the New York and California races.

Responses to ipsdienol-baited traps by *I. pini* in California and New York appear to correspond to the enantiomeric composition of ipsdienol produced by the respective races. In California, *I. pini* are attracted by (*R*)-(−)-ipsdienol. The attraction is significantly interrupted by as little as 5% of the antipode (Birch et al., 1980; Seybold, 1992). In New York, the (+):(−) ratio of ipsdienol eliciting maximal attraction of *I. pini* ranges from 70:30 to 40:60, inclusively (Lanier et al., 1980; Teale and Lanier, 1991; Teale et al., 1994). The enantiospecific response to (*R*)-(−)-ipsdienol in California may be driven by natural selection arising from competition with the California fivespined ips, *Ips paraconfusus* Lanier. Both species breed in *Pinus ponderosae* Laws. and *P. jeffreyi* Grev. & Balf. (Wood, 1982). The reproductive success of individuals of both species is reduced when they infest the same host material (Birch, 1978; Light et al., 1983). Male *I. paraconfusus* produce predominately (*S*)-(+)-ipsdienol as one component of their aggregation pheromone blend (Seybold, 1992; Seybold et al., 1995b). Attraction of *I. paraconfusus* to its pheromone is interrupted by the (−) enantiomer, to which *I. pini* is attracted (Light and Birch, 1977; Birch et al., 1980; Seybold, 1992).

We report the results of experiments in which four additional populations in southern British Columbia were characterized by their ipsdienol enantiomeric production profiles. We also tested different individuals from two of these new populations, as well as those from Princeton and Kimberley, British Columbia, for their field response to ipsdienol with enantiomeric (+):(−) ratios ranging from 2:98 to 98:2. Populations of *I. pini* have been tested previously in California and New York for their responses to ipsdienol over a broad range of enantiomeric ratios (Seybold, 1992; Teale et al., 1994).

METHODS AND MATERIALS

Production Profiles. Bolts of lodgepole pine, *Pinus contorta* var. *latifolia* Engelm., infested with live broods of *I. pini*, were collected from Osprey Lake,

Pemberton, and Williams Lake, British Columbia, in 1986, and Radium, British Columbia, in 1987. Bolts were placed in rearing cages and beetles were collected after they emerged as mature adults. Using the gelatin-pill-capsule technique (Borden, 1967), adult males from each of the four populations were restrained on uninfested bolts of lodgepole pine collected near Princeton, British Columbia. They were allowed to bore into the bark and feed for 24–48 hr. Abdomens from individual males were removed and each was crushed in 150 μl of pentane containing racemic 3-octanol (4.1 ng/μl) as an internal standard. Extracts were analyzed by splitless, capillary gas chromatography using a Hewlett-Packard (HP) 5890 and a fused silica column (J&W Scientific, Folsom, California; 30 m × 0.25 mm ID, 0.25 μm DB-1), before and after derivatization to acetyl lactate diastereomers (Slessor et al., 1985). Only extracts containing > 10 ng of ipsdienol were derivatized. Retention times of ipsdienol and its two derivatives were determined with racemic ipsdienol obtained from Borregaard Fine Chemicals, A.S. (Sarpsborg, Norway), and enantiomeric assignments were made according to Slessor et al. (1985). The identities and integrities of ipsdienol acetyl lactate diastereomers were verified by mass spectrometry using splitless, capillary gas chromatography (HP 5985B).

Response Profiles. For experiment 1, racemic ipsdienol (chemical purity >95%) was obtained from Borregaard Fine Chemicals, A.S. Two enantiomeric mixtures of ipsdienol [(+):(−) ratios of 98:2 and 2:98, respectively] were obtained from E. K. Czyzewska (Department of Chemistry, Simon Fraser University, Burnaby, British Columbia). For experiments 2–4, three enantiomeric mixtures [(+):(−) ratios of 98:2, 50:50, and 2:98, respectively] (chemical purities, 93, 98, and 83%, respectively) were obtained from Phero Tech Inc. (Delta, British Columbia).

In experiment 1, each lure consisted of 10 Microcap disposable pipettes (2 μl) (Drummond Scientific Co., Broomall, Pennsylvania), each sealed at one end and filled with ipsdienol, and placed in a polyethylene, microcentrifuge tube (1.8 ml) (Evergreen Scientific, Los Angeles, California). The release of ipsdienol with different enantiomeric ratios was achieved by adjusting the relative proportion of tubes filled with the different mixtures. The release rate of ipsdienol from each lure was approximately 0.1 mg/day at 24°C (determined by weight loss).

In experiments 2–4, each lure consisted of a 10-cm-length of C-flex tubing (ID = 1.6 mm; OD = 2.4 mm) (Concept Inc., Clearwater Florida), filled with an ethanol solution of ipsdienol (80 mg/ml). Solutions were prepared for each of 11 different enantiomeric ratios of ipsdienol. The release rate of ipsdienol from each lure was approximately 0.6 mg/day at 24°C (determined by collection of volatiles on Porapak-Q).

In all experiments, replicates of 12 eight-unit, multiple-funnel traps (Lindgren, 1983) (Phero Tech Inc.) were set in grids of 3 × 4 in stands of lodgepole

pine. Replicate grids were placed at least 100 m apart, and traps were spaced 10–15 m apart within each replicate. Each trap was baited, and suspended such that the top of each trap was approximately 1.3–1.5 m above ground level. No trap was within 2 m of any tree.

Experiments 1–4 determined the effect of the enantiomeric composition of ipsdienol on the attraction of *I. pini* near Princeton, Williams Lake, Radium, and Kimberley, British Columbia, respectively. Ten replicates were set for experiments 1–3 during the period of May 22–June 9, 1986; July 5–September 6, 1987; and July 7–September 9, 1987, respectively. Eight replicates were set for experiment 4 during the period of July 13–September 6, 1989. The 12 treatments consisted of 11 different enantiomeric ratios of ipsdienol and a control, randomly assigned within each replicate. In experiment 1, the control traps did not have any lures while in experiments 2–4, the control traps were baited with C-flex tubing containing ethanol alone. All lures were replaced, and treatments rerandomized within each replicate, at intervals of 3 to 4 weeks. Trap catches were pooled at the conclusion of each experiment.

Statistical Analyses. Data were analyzed using the SAS statistical package ver. 5.0 (SAS Institute Inc., Cary, North Carolina). Quantities of ipsdienol from individual abdominal extracts from males were transformed by $\ln(Y + 1)$ and subjected to one-way analysis of variance (ANOVA). Scheffé's multiple comparison test was performed when $P < 0.05$. For each population, coefficients of variation (CV) were determined for quantity and enantiomeric composition of ipsdienol, normalized by $\ln(Y + 1)$ and $\arcsin \sqrt{Y}$, respectively (Schlyter and Birgersson, 1989). Distributions of the enantiomeric compositions of ipsdienol, including data sets for populations from Princeton and Kimberley, British Columbia (Miller et al., 1989), were compared by χ^2 tests.

Trap catch data, transformed by $\ln(Y + 1)$ to remove heteroscedasticity, were analyzed by three-way ANOVA using location, treatment, replicate nested within location, and the interaction between location and treatment as model factors. For each location, data were analyzed by two-way ANOVA using replicate and treatment as model factors, first with all treatments and then with only the ipsdienol treatments. Eleven and 10 orthogonal contrasts were conducted for the first and second ANOVA's for each location, respectively, comparing the control against each ipsdienol treatment separately in the first case and comparing the response to racemic ipsdienol against each of the remaining ipsdienol treatments separately in the second.

Sex-ratio data [transformed by $\arcsin(Y)$], for catches ≥ 10, were subjected to full-factorial two-way ANOVA. For each location, untransformed sex-ratio data (not means), for catches ≥ 10, were regressed against the enantiomeric composition of ipsdienol, using treatment as the only factor in a general linear model. Tests of homogeneity of slopes were performed by analysis of covariance (ANCOVA) using location, and the interaction between location and the co-

variate, enantiomeric composition of ipsdienol as model factors. One contrast was performed, comparing the slope for the population in Kimberley against the slope for the remaining populations. For each location, we determined the Pearson correlation coefficient between mean proportional responses to each of 11 enantiomeric ratios of ipsdienol and the associated mean proportion of males in populations producing the same enantiomeric ratio (±5%) as determined above.

RESULTS

Production Profiles. Male *I. pini* from the Pemberton population produced the lowest amounts of ipsdienol per male compared to those from the other three populations (Table 1). Pemberton males were the least vigorous of all populations with respect to rates of boring and feeding. Beetles from Radium were reared from logs with the thickest phloem, probably influencing their vigor and hence the high level of ipsdienol production (Table 1). The quantity of ipsdienol produced by individual males varied markedly within each population (Figure 1), with coefficients of variation ranging from 66.0 to 167.3% (Table 1). As found by Miller et al. (1989) in other populations of *I. pini*, most males contained low quantities of ipsdienol and relatively few contained large amounts.

Pronounced bimodal frequency distributions of the enantiomeric compositions of ipsdienol, previously found for populations from Princeton, British Columbia, and Newcomb, New York (Miller et al., 1989), were found in three additional British Columbia populations (Pemberton, Williams Lake, and Osprey Lake) (Figure 2). Males from all three of these populations produced more (*S*)-(+)-ipsdienol than (*R*)-(−)-ipsdienol with mean (+):(−) ratios ranging from 63:37 to 71:29 (Table 1). There were no significant differences among the distributions of enantiomeric compositions of ipsdienol from the four westernmost British Columbia populations (Pemberton, Princeton, Osprey Lake, and Williams Lake) (χ^2 test, $df = 27$, $P = 0.194$) (Figure 2). The distributions for these populations were significantly different from that for the population from Kimberley (χ^2 test, all $df = 9$, all $P < 0.001$). In contrast, males from Radium produced almost equal amounts of both enantiomers (Table 1). The enantiomeric production profile for these males was significantly different from the profiles for males from the Kimberley population (χ^2 test, $df = 9$, $P < 0.001$) and the four western British Columbia populations (χ^2 test, all $df = 9$, all $P < 0.001$) (Figure 2).

Response Profiles. Ips pini showed considerable variation in attraction to ipsdienol-baited multiple-funnel traps as a consequence of enantiomeric composition (Table 2). In all populations, significantly fewer beetles were caught in traps baited with an ipsdienol (+):(−) ratio of 98:2 than in traps baited with racemic ipsdienol (Figure 3). Significantly fewer beetles were caught in all traps

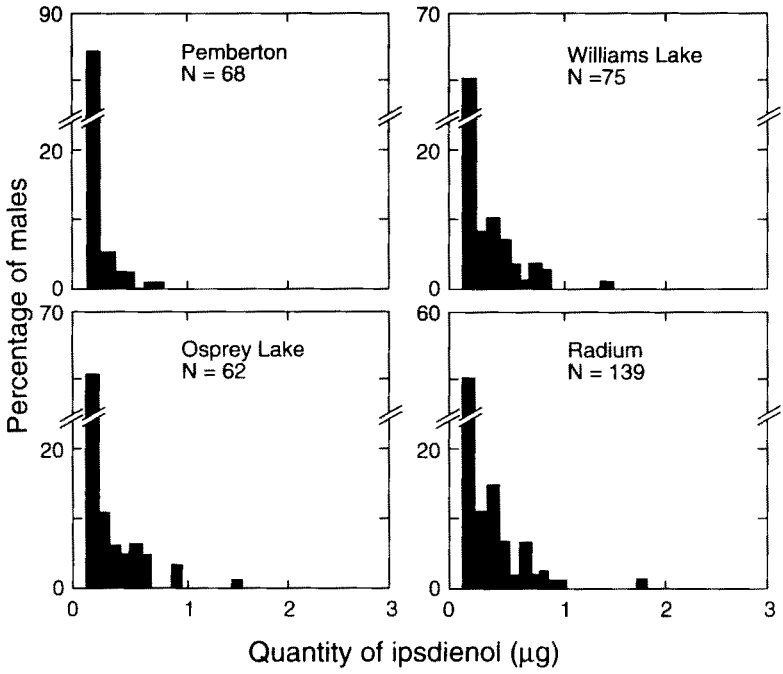

FIG. 1. Frequency distributions of the quantities of ipsdienol produced by individual male *Ips pini* from four populations in British Columbia.

baited with a (+):(−) ratio of 2:98 than in traps baited with racemic ipsdienol in Williams Lake, Radium, and Princeton. Except for one contrast, significantly more beetles were caught in traps baited with ipsdienol than in control traps (orthogonal contrasts, ANOVA, all $P < 0.029$). The exception was in Kimberley, where there was a weakly significant increase of catches in traps baited with a (+):(−) ipsdienol ratio of 98:2 relative to those in traps baited with ethanol alone (orthogonal contrast, ANOVA, $P = 0.079$.

The enantiospecific response profiles varied significantly between locations ($P < 0.001$; Table 2). The most obvious differences were related to the attraction of *I. pini* to (+):(−) ipsdienol ratios of 2:98 and 10:90. For both ratios, catches were low in Williams Lake and Princeton but high in Kimberley (Figure 3). In Radium, catches to traps baited with (+):(−) ratio of 10:90 were high but low to those baited with a (+):(−) ratio of 2:98.

The sex ratio of captured *I. pini* varied among locations and enantiomeric treatments (Table 2). As in California (Seybold, 1992), the proportion of males caught in ipsdienol-baited traps increased as the proportion of (*S*)-(+)-ipsdienol

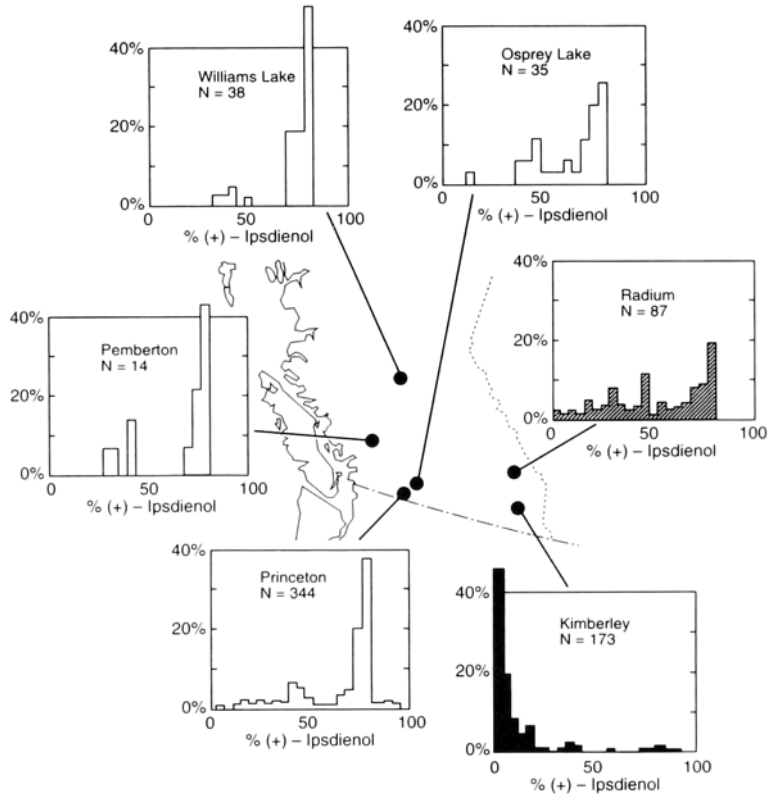

FIG. 2. Frequency distributions of the enantiomeric compositions of ipsdienol produced by individual male *Ips pini* from six populations in British Columbia. Data for Princeton and Kimberley are reproduced from Miller et al. (1989). Histograms with different shading patterns are significantly different (see text).

increased (Figure 4). The slope of the regression line for the Kimberley population was significantly different from that of the other three populations (orthogonal contrast, ANCOVA, $P = 0.003$). Accordingly, the effect of the interaction between location and enantiomeric composition of ipsdienol was not significant when the Kimberley population was omitted from the analysis. When Kimberley was included, the effect was significant ($P = 0.021$; Table 2).

The association between enantiospecific production and response profiles differed between locations. In Radium and Princeton the correlations between mean (+):(−) ipsdienol ratios produced by males within the population and the respective enantiospecific response profile were significantly different from zero

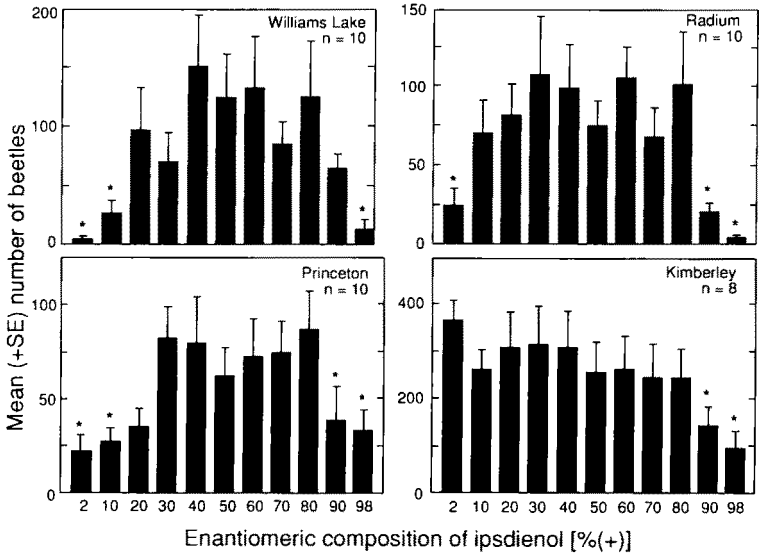

FIG. 3. Effect of the enantiomeric composition of ipsdienol on the capture of *Ips pini* in multiple-funnel traps at four locations in British Columbia. Asterisks indicate significant difference in trap catches relative to those in traps baited with racemic ipsdienol, orthogonal contrasts, $P < 0.08$.

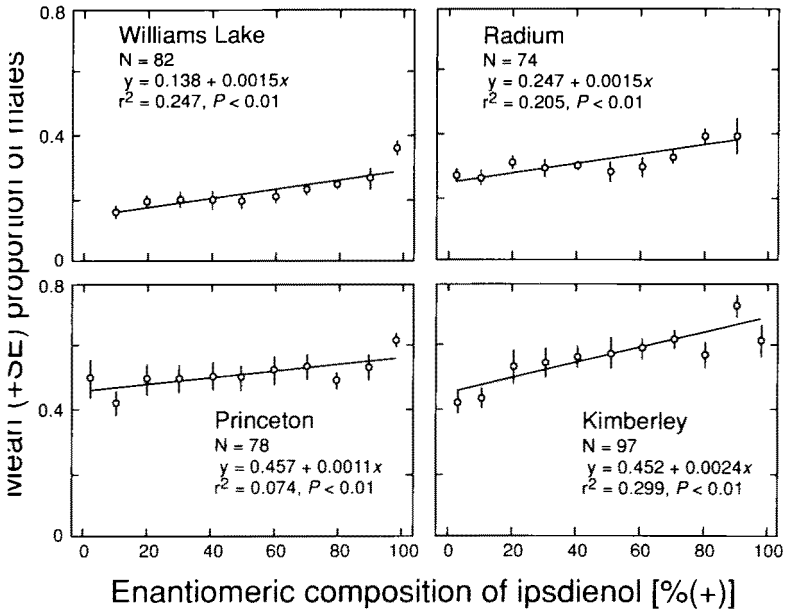

FIG. 4. Effect of the enantiomeric composition of ipsdienol on the sex ratio of *Ips pini* captured in multiple-funnel traps at four locations in British Columbia. Slope of the regression line for Kimberley is significantly different from those for the other three populations (see text).

(Table 3). The correlation was only weakly significant for the population from Kimberley and not significant for Williams Lake. In no case did the variation in one variable explain more than 50% of the variation in the other variable (all $r^2 < 0.475$).

DISCUSSION

The similarity of enantiospecific ipsdienol production profiles for males from the four western-most British Columbia populations examined (Figure 2) to that previously examined from Newcomb, New York (Miller et al., 1989) supports the hypothesis that the New York race ranges across the boreal forest in Canada and extends southward into British Columbia (Seybold et al., 1995a). The similarity of response profiles for populations from Williams Lake and Princeton to that for a population from Syracuse, New York (Teale et al., 1994) further supports this hypothesis, although the distribution was narrower for the

TABLE 3. CORRELATIONS BETWEEN ENANTIOSPECIFIC IPSDIENOL PRODUCTION PROFILES FOR MALE *Ips sini* (SAY) AND ENANTIOSPECIFIC RESPONSE PROFILES OF MALE AND FEMALE *I. pini* IN 4 LOCALITIES IN BRITISH COLUMBIA

Locality	Pearson correlation coefficient (r)	P
Williams Lake	0.356	0.283
Kimberley	0.538	0.088
Princeton	0.624	0.040
Radium	0.689	0.019

Syracuse population. The dissimilarity of the response profile for the Kimberley population to those for the other three British Columbia populations (Figure 2) is consistent with dissimilarities in production profiles previously reported between Kimberley and Princeton populations (Miller et al., 1989). The Kimberley population has previously been identified as part of the Idaho race (Seybold et al., 1995a). In our study, this is the only British Columbia population in which *I. pini* showed a considerable attraction to ipsdienol with a (+):(−) ratio of 2:98 (Figure 2), a preferred ratio for the California race (Birch et al., 1980; Seybold, 1992).

The population from Radium showed characteristics suggesting a combination of traits of the New York race and the Idaho or California races. The enantiospecific production profile was broad (Figure 1), with the highest coefficient of variation (Table 1). The Radium profile lacked both bimodality, common to the New York race, and a sharp peak at a (+):(−) ratio of 2:98, common to the Idaho and California races (Miller et al., 1989; Seybold et al., 1995a). The response profile for the Radium population was also broader than for populations from Williams Lake and Princeton (Figure 3), showing an attraction to a (+):(−) ratio of 10:90. However, beetles in the Radium population were not highly attracted to a (+):(−) ratio of 2:98, as was evident in the Kimberley population. These data suggest that the Radium population lies within an intergradation zone of the New York race and the Idaho or California races.

Our results demonstrated significant variation in the attraction of *I. pini* to ipsdienol for all four populations in British Columbia (Figure 3). In no case did we find evidence of a narrow range of enantiospecific responses to ipsdienol as shown by *I. pini* in California (Birch et al., 1980; Seybold, 1992). The intrapopulational variation in attraction of *I. pini*, with respect to variation in enantiomeric composition of ipsdienol, should reflect the relative benefits gained by the responding individuals. The broad range of equal levels of attraction in all British Columbia populations examined (Figure 3) should, therefore, reflect

similar fitnesses in the responding individuals. However, initial preferences shown by individuals may not be associated with subsequent preferences by the same individuals. Cardé et al. (1976) showed that initial preferences by individual Oriental fruit moths, *Grapholita molesta* (Busk), were not associated with their subsequent preferences, yet the response profiles for the population were the same on both occasions. Such probability functions may be determined, in part, by age and vigor, as well as by genetics. The benefits may accrue from the average of repeated choices among individuals rather than specific choices.

The enantiospecific responses with respect to sex ratio (Figure 4) should reflect differential benefits to males and females. In Kimberley, females showed the strongest preference for ipsdienol when proportions of the (+) enantiomer were lowest. This trend is consistent with the production of predominantly (*R*)-(−)-ipsdienol by males (Figure 2) and the declining profile of total response in the population as the proportion of (*S*)-(+)-ipsdienol increased in the bait stimulus (Figure 3). However, it is not clear why this trend, *albeit* at a lower intensity, should be evident in the other three populations. It is possible that it is a residual sex-linked trait from other selection pressures or, possibly, a trait that cannot vary in a nonlinear fashion due to genetic constraints.

Our results show that the population profile for the response of bark beetles to a pheromone signal may not be predicted necessarily by the population profile for the production of the signal. The broad response profiles for beetles in Kimberley and Williams Lake differed from their narrow production profiles (Figures 2 and 3). The correlations between production and response were not strongly significant in either location (Table 3). In Princeton and Radium, only 39% and 47% of the variation in response was explained by the variation in production (Table 3).

We can only speculate on the composition underlying the response profiles. Populations may consist of generalists with the population response profile equating to the probability profile for response by an individual beetle. Alternatively, populations may have structure through a diverse collection of individuals, each with a narrow response range. Our correlations of population profiles are not necessarily indicative of genetic correlations within individuals.

Our results suggest that pheromone-mediated behavioral separation may not be necessarily a premating isolation mechanism leading to speciation. Two distinct strains of the European corn borer, *Ostrinia nubilalis* (Hübner), occur in Europe and North America, differing in the relative use of (*E*)- and (*Z*)-11-tetradecenyl acetates as pheromones (Kochansky et al., 1975; Klun and Cooperators, 1975; Anglade et al., 1984; Barbattini et al., 1985; Peña et al., 1988; Löfstedt, 1990). The two strains hybridize readily where they are sympatric (Roelofs et al., 1985; Cardé, 1986; Klun and Huettel, 1988). In a similar fashion, *I. pini* in the population from Kimberley showed a lack of enantio-

specificity to ipsdienol even though males in the population were very enantiospecific in the production of ipsdienol. The population from Radium provides evidence of hybridization between two, possibly three, races of *I. pini*, presumbly due to plasticity in behavioral responses.

A complete understanding of the use of pheromones by *I. pini* should also consider the effect of a second pheromone, lanierone (Teale et al., 1991). Attraction of males and females to ipsdienol is synergized by lanierone in New York, Wisconsin, Montana, and British Columbia, yet is unaffected in California (Seybold et al., 1992; Miller et al., 1996).

Abstract—Nestmate recognition was studied in the polydomous ant *Cataglyphis iberica* (Formicinae) in the laboratory. The study examined six colonies collected from two different populations 600 km apart in the Iberian peninsula (Barcelona and Murcia). Introduction of an alien worker into an allocolonial arena always ended in death to the intruder, demonstrating that in this species societies are extremely closed. Dyadic encounters composed of individuals from different colonies in a neutral arena confirmed the existence of high aggression between allocolonial individuals. We also investigated variability in the composition of the major cuticular hydrocarbons between the colonies used in the behaviorial tests. There were marked quantitative differences between the profiles of ants from the two populations, suggesting that the populations are completely segregated. Cuticular profiles within a population tended to be more similar, but were nevertheless colony specific. The degree of colony closure in *C. iberica* seemed to be independent

of geographic distance since aggression between the colonies was always at its maximum, irrespective of their population origin.

Key Words—Ants, Formicinae, polydomy, nestmate recognition, aggression, cuticular hydrocarbons, colony closure, *Cataglyphis iberica*.

INTRODUCTION

Social organization in ants is based on, among other things, colony closure that preserves its social integrity and prevents intrusion by individuals alien to the society. This necessitates a capacity to recognize and discriminate between familiar and unfamiliar individuals. Such discrimination generally induces aggression towards the unfamiliar intruder. As early as 1904, Fielde (1904) hypothesized a chemical role in recognition. Howse (1975) suggested that this discrimination ability was based essentially on a chemical signature that each member of the colony carries on its cuticle, a hypothesis that was subsequently confirmed by experimental work (reviewed by Howard, 1993; Lorenzi et al., 1996). Experiments in which alien cuticular extracts applied to workers elicited aggression towards them by their nestmates lent credence to the role of cuticular lipids in colony recognition (Bonavita-Cougourdan et al., 1987; Nowbahari et al., 1990; Henderson et al., 1990). Nestmate recognition cues can be determined genetically (Vander Meer et al., 1985; Ross et al., 1987; Provost, 1991), but may also include environmental substances that blend into the colony odor (Jutsum et al., 1979; Obin, 1986; Obin and Vander Meer, 1988). Congruency was found between the hydrocarbon composition of postpharyngeal gland contents and those of the cuticular washes (Bagnères and Morgan, 1991; Do Nascimento et al., 1993). Recent studies pointed to the role of the postpharyngeal gland in storing and mixing the recognition chemicals and reapplying them on the cuticle, creating a unified colony odor (Soroker et al., 1994, 1995).

Earlier studies with *Cataglyphis cursor* have shown a correlation between intercolonial aggression and the geographic distance between colonies (Nowbahari and Lenoir, 1984; Nowbahari et al., 1990). In this species, whose colonies multiply by fission, allocolonial workers that originate from neighboring nests are readily accepted, whereas workers originating from distant colonies are always rejected.

Cataglyphis iberica is a monogynous and polydomous species that is limited to the Iberian peninsula (Tinaut and Plaza, 1989; Cerdá and Retana, 1992). Each colony is composed of several satellite nests, between which there is an exchange of individuals through adult transport. Its biology is typical of the majority of species in this genus: it is a diurnal scavenger ant species that is active during the hottest period of the day (Cerdá, 1988; Cerdá and Retana, 1988).

In this study, we tested colonial closure in *C. iberica* and compared intercolonial aggression in relation to divergence in their cuticular hydrocarbon profiles and the geographic distances separating the colonies.

METHODS AND MATERIALS

Origin and Rearing of Colonies. This study was conducted with six colonies collected from two different populations in Spain, about 600 km apart. Three colonies were collected near Barcelona (population B): colony B1, collected from Bellaterra, was comprised of three satellite nests containing a total of 1650 workers. Colonies B2 and B3 were both collected from Sant Cugat (3 km away from Bellaterra), each of which was comprised of two satellite nests containing a total of 1918 and 975 workers, respectively. Three additional colonies were collected in the province of Murcia (population M). Colony M1 was from La Paloma (near Murcia) and included two satellite nests with a total of 1260 workers. Colonies M2 and M3 were collected from Cabo de Gata (about 200 km South from La Paloma) each composed of a single nest containing 450 and 325 workers, respectively.

In the laboratory, the colonies were reared in plastic boxes (11.5 × 8.0 × 2.5 cm) in which the interior relative humidity was maintained at 50%. Each satellite nest occupied one box, but all satellites belonging to the same colony were connected by plastic tubes to a common foraging arena (35 × 35 cm). As the species is very thermophilic (Cerdá and Retana, 1988), the arena was heated to 25 ± 2°C by a lamp to allow adequate temperatures for foraging activity. Food (meal worms, cricket larvae, honey-apple mixture) was provided three times a week and water *ad libitum*. The nests were maintained at 10:14 D:L photoperiod.

Introduction of Workers into an Allocolonial Arena. For each test one worker was introduced into an allocolonial foraging arena that was lined with filter paper. Tests were performed with at least a 1-hr break between replicates, and the filter paper was changed for each replicate. The behavioral interactions with the resident ants were observed while measuring two time variables: the latency before the first attack (first attack time), and the time it took to kill the introduced worker (death time). The number of resident workers that were present in the arena was monitored at the beginning of each test. All tests were conducted between 10:00 and 16:00 hr during the daily activity period of the ants when foragers were present in the arena. Each test lasted until the introduced worker was killed. The tests conducted included all possible combination of the six colonies: B × B (43 tests), M × M (52 tests), and B × M (22 tests).

Dyadic Encounters. Tests of internidal aggression consisted of encounters between two alien ants in a neutral arena made up of a circular plastic box (8

cm in diameter) coated on the inner walls with Fluon. Before each test the arena was thoroughly cleaned with alcohol. Each encounter lasted for 10 min and involved individuals originating from different colonies that were either taken from the same population (type I encounters, six combinations) or taken from different populations (type II encounters, nine combinations) (see Table I below). Initially, five replicates were performed for each combination, which involved different individuals in order to avoid familiarization or cross-contamination by cuticular lipids. The behavior of only one of the contestants (alternatively selected) was recorded in each test, and aggression was calculated as relative frequencies of aggressive acts out of the total interactions observed during the encounter. The following behaviors were considered as aggression: opening of the mandibles, biting, or flexing the gaster. On the other hand, mutual investigation and submissive posture were considered to be neutral or amicable acts. In a few of the tests (~ 12%) there were neither contacts nor interactions between the ants, and the ants displayed mutual avoidance. Such indifference is also often observed in the field. These cases were excluded from further calculations to avoid an artificial lowering of the magnitude of aggression and therefore bias the statistics.

Chemical Analysis. For the chemical analyses, postpharyngeal glands of 30 ants from each population were dissected under distilled water and immediately immersed in 100 μl of pentane for extraction. The pooled samples were analyzed by coupled gas chromatography–mass spectrometry (Finnigan quadrupole or Fisons MD800 quadrupole) in the EI and CI (using methane as reagent gas) modes. The samples were run on an HP-5 fused silica capillary column that was heated from 150°C to 250°C at a rate of 5°C/min, or alternatively on a DB-5 fused silica capillary column that was temperature programmed from 120°C to 300°C at 3°C/min with an initial hold of 3 min. The various hydrocarbons were identified by their fragmentation patterns as compared to published spectra (Nowbahari et al., 1990; Bagnères et al., 1991).

The contents of the postpharyngeal and cuticular washes were compared by gas chromatography using the elution pattern and including reference compounds.

To compare cuticular hydrocarbon profiles between colonies used in the behavioral studies, cuticular washes from individuals were analyzed by gas chromatography. Six individuals were taken at random from each of the colonies and individually analyzed: each ant was washed for 10 min in 1 ml of acetone. The solution was then dried by nitrogen and the residue was redissolved in 30 μl acetone, of which 2 μl were injected into a gas chromatograph (Delsi 300) equipped with a capillary column (Chrompak CPSIL 5 WCOT 25 m × 0.22 mm in diameter), temperature programmed from 100°C to 280°C at a rate of 3°C/min). Peak integration was accomplished with an ENICA 21 integrator.

Calculations and Statistical Methods. All calculations and comparisons

were made by using the mean ± SE. The α value for all the statistical tests used (discriminant analysis, Fisher's PLSD, χ^2, Mann-Whitney, and Pearson's) was less than 5%. The comparison of cuticular profiles of individuals from the studied colonies was performed by a discriminant analysis (Statistica for Windows) based on the compounds with a relative intensity above 1% in at least one of the samples (a total of 33 compounds).

RESULTS

Aggression Towards Ants Introduced into Allocolonial Arena. All ants introduced into an allocolonial arena were eliminated without a single case of adoption. The resident ants in the arena were very aggressive towards the alien intruders and engaged in mortal attack as soon as the intruder ant was detected in the arena. The average latency to the first attack was 19.1 ± 3.3 sec, and the average time that elapsed until the alien ant was killed was 17.0 ± 2.3 min. Significant relationships were found between the two variables (the first attack time and the death time) and the number of foragers present in the arena (Pearson's $r = 0.25$, $P = 0.007$ in both cases), but the low r^2 (=0.06) value indicated that the level of aggressive response was only weakly dependent on the number of resident foragers in the arena.

In addition, the geographic distance between the colonies did not influence the latency of the first attack (Pearson's $r = 0.11$, NS), but geographic distance was weakly but significantly correlated with death time ($r = 0.37$, $P < 0.001$). The greater the geographic distance between the tested colonies, the quicker the alien ants were eliminated.

Aggression during Dyadic Encounters. In eight of the 75 dyadic encounters conducted there were no interactions between ants. These ants neither moved nor was there was any contact between them. These encounters were therefore excluded from further calculations in order to avoid any artificial reduction in the mean aggressive response. In the 67 encounters taken for analysis, workers of *C. iberica* always engaged in aggressive interactions after a short antennal contact, and rarely manifested neutral or amicable behavior. This is reflected in the high value of the frequency of aggressive acts calculated for all the encounters (0.70 ± 0.03).

The frequency of aggressive acts was rather homogeneous between the various combinations, ranging from 0.48 for the encounters involving ants from colonies B3 and M1 to 0.87 for the encounters between ants from colonies B2 and B3. When tests are grouped as type I encounters (workers originating from different colonies from the same population) and type II encounters (workers originating from colonies from different populations), no differences were found between the mean values of aggressive frequencies for each type of dyadic encounter (Table 1, U Mann-Whitney test, $P > 0.1$).

TABLE 1. AGGRESSIVE FREQUENCIES (MEAN ± SE) FOR TYPE I AND II ENCOUNTERS[a]

Dyadic tests	Aggression frequency
Type I tests	
B1-B2(5)	0.69 ± 0.11
B1-B3(5)	0.63 ± 0.14
B2-B3(5)	0.87 ± 0.08
B-B(15)	0.73 ± 0.07[a]
M1-M2(4)	0.71 ± 0.12
M1-M3(3)	0.54 ± 0.12
M2-M3(5)	0.72 ± 0.14
M-M(12)	0.67 ± 0.07[a]
Type II tests	
B1-M1(5)	0.58 ± 0.17
B1-M2(5)	0.73 ± 0.08
B1-M3(4)	0.85 ± 0.10
B2-M1(5)	0.73 ± 0.08
B2-M2(5)	0.70 ± 0.12
B2-M3(4)	0.86 ± 0.07
B3-M1(4)	0.48 ± 0.15
B3-M2(4)	0.76 ± 0.09
B3-M3(4)	0.65 ± 0.08
B-M(40)	0.70 ± 0.04[a]

[a] No differences were found between intrapopulation mean values (Fisher's PLSD, $P > 0.1$).

We further tested whether the levels of intercolonial aggression within a population differed from that between populations. The frequency of aggressive acts in the tests within a population (0.73 ± 0.07 and 0.67 ± 0.07 for populations B and M, respectively) was as high as the frequencies in the tests between populations (0.70 ± 0.04) (Table 1, Fisher's PLSD, $P > 0.10$).

An examination of the workers after an hour of a dyadic encounter showed that despite the high aggression between the ants, the dyadic interactions rarely ended in death (18 deaths of 134 tested workers) or injury (24 injured of 134) to one or both ants. The number of injured and killed workers was not different between type I and type II encounters ($\chi^2 = 0.064$, $P = 0.8$).

Chemical Analysis. The postpharyngeal gland exudates of ants from the two populations contained almost exclusively saturated hydrocarbons, including *n*-alkanes and mono- and dimethyl alkanes ranging from C_{12} to C_{34}. There was an additional series of monomethyl and dimethyl *n*-alkanes of higher molecular weight, but the intensities of the peaks did not allow proper identification (Table 2). The hydrocarbon profiles from ants belonging to populations B and M were qualitatively similar but differed quantitatively. The dominant compounds in the

[a]Compounds with a relative amount that was less than 1% were marked as traces (t). The identity of compounds followed by a question mark is uncertain. The mean values (±SD, $N = 9$) given in the table are calculated from the cuticular hydrocarbon profiles of individuals used in the discriminant analysis.
[b]m = methyl; dm = dimethyl.

ants from both populations were nonacosane and a series of monomethyl and dimethyl nonacosanes. Ants from the Murcia population were distinguishable from those from the Barcelona population by having a larger proportion of heptacosane and octacosane compounds, notably C_{27} and its 13-, 11-, and 3-methyl branched derivatives, 12-methyl C_{28} and a mixture of 11- + 13- + 15-methyl C_{28}. These were present only in traces in individuals from population B. Finally, Barcelona ants were distinguishable by having a larger proportion of hydrocarbons with heavier molecular weight corresponding to hentriacontane, a series of monomethyl and dimethyl hentriacontane, and dimethyl dotriacontane.

Cuticular hydrocarbon profiles of the 36 ants from the six colonies were analyzed by discriminant analysis (Figure 1). A plot of the first and the second variables shows that individuals belonging to the same population clustered together forming two clearly separated groups. These two groups were separated mostly by the first discriminant variable. Within each population, individual grouping according to colony origin is apparent, and colonies were well separated by the second discriminant variable. The compounds that had an important weight in the analysis were heptacosane and a mixture of its 11-, 13-methyl-branched derivatives and 12-methyl C_{28}. It is worth noting that colony M1, which clustered distantly from M2 and M3 based on the hydrocarbon profile,

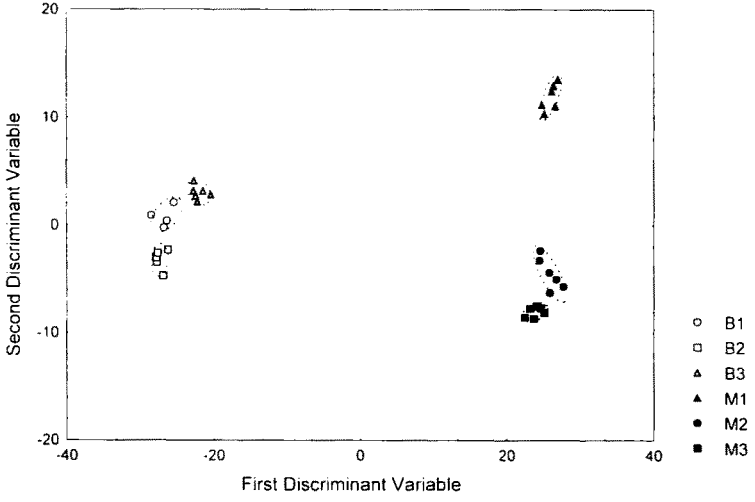

FIG. 1. A plot of the first two principal variables in the discriminant analysis of cuticular hydrocarbons of the six colonies of *Cataglyphis iberica*. Each colony group is surrounded by the confidence ellipse ($P < 0.05$).

was also geographically separated by 200 km from these two colonies (which were collected from the same locality).

We also conducted a discriminant analysis within each population on the basis of the same peaks. The results confirmed those shown in Figure 1. For the 18 ants analyzed on the basis of their cuticular profile within each population, individuals clearly clustered together according to their colony origin. Within population B, the compounds that had an important discriminant impact were a mixture of 15-, 13-, 11-, and 5-methyl C_{29} and 5,9-dimethyl C_{29}; while for population M, the discriminant compounds were 3-methyl C_{27}, 4-methyl C_{28} and 7-methyl C_{29}. This indicates that profile disparities between populations (B–M) and within populations (B–B or M–M) are not due to the same compounds.

DISCUSSION

Polydomous ant species are generally polygynous, with a low nestmate recognition system that seems to be the consequence of the low intracolonial relatedness (Hölldobler and Wilson, 1977; Breed and Bennett, 1987; Bourke and Franks, 1995). This low nestmate recognition system was observed, for example, in *Linepithema humile* (*Iridomyrmex humilis*) (Markin, 1968; Benois, 1973; Keller and Passera, 1989), *Amblyopone pallipes* (Traniello, 1982), and *Myrmica incompleta* (Lenoir et al., 1989). In *C. iberica*, societies are polydomous, but with a single queen per colony. Our results show that these colonies are very closed towards alien conspecifics. Because the colonies are monogynous, we suggest that this intolerance may be due to a high intracolonial genetic relatedness. However, monogyny is not systematically associated with a high colonial closure. In *C. cursor*, which is monogynous but monodomous (Cagniant, 1976), very little aggressive behavior is observed when the individuals come from the same site (Nowbahari and Lenoir, 1984). This low level of aggressive behavior can be explained by its mode of colony foundation, which is achieved through fission, resulting in high genetic relatedness between proximate colonies (Lenoir et al., 1988). The high level of colonial closure in *C. iberica* might have originated from the mode of colony foundation. Some field observations suggest that in this species there is an independent mode of colony foundation (X. Cerdá, unpublished data), which, contrary to fission, results in genetic and geographic proximity being opposed. Thus, even neighboring colonies of *C. iberica* may be genetically dissimilar.

The comparative analysis of cuticular washes revealed quantitative differences in hydrocarbons between the tested colonies. Colonies from the same population (B or M), although distinct from each other, had more similar patterns than between populations. This suggests that nests from Barcelona and Murcia

comprise disparate populations. There is also an indication that the disparity between nests within a population may increase with geographic distance. This was evident from the higher distance in the discriminant analysis (based on the hydrocarbon profile) of one nest from Murcia that was located 200 km away from the others. Moreover, there is no geographical barrier between Barcelona and Murcia, and cuticular profiles of ants collected between the two populations show a quantitative gradual divergence of profiles (Dahbi, unpublished data).

We may link the disparities in cuticular hydrocarbons with aggression exhibited by these ants towards alien ants. We base our assumption on the "Gestalt" model. The individuals that were used in recognition tests are nestmates of those analyzed through chromatography, and we assume the presence of a common colonial odor for workers of the same colony (Soroker et al., 1994). The fact that aggression between colonies was at a maximum irrespective of the degree of similarity in hydrocarbons profile suggests that even the small differences exhibited between the colonies of the Barcelona population are above the recognition threshold and suffice to elicit a full response. This hypothesis, however, has to be tested by using pure hydrocarbons at various quantitative combinations.

Acknowledgments—We thank Andrea Dejean for the first English translation and Nomi Paz for final proof reading. This work was supported by a grant from MEC/MRT (FR91) to Xim Cerdá, and by two French-Spanish cooperation projects (Picasso, Acciones Integradas HF93-133B and HF94-345B).

(Received November 6, 1995; accepted July 9, 1996)

Abstract—The response of *T. lineatum* to ethanol and α-pinene, when used with the pheromone lineatin, was tested for two trap types. Funnel traps, which are passive barrier traps, caught significantly more beetles than drainpipe traps, which require an active response by the beetle to enter the trap. However, the response of *T. lineatum* to the semiochemical treatments did not significantly differ for the two trap types. Treatments that included α-pinene with the pheromone, either with or without ethanol, caught significantly more *T. lineatin* than those with the pheromone alone. When ethanol and or α-pinene were added to the pheromone significantly more female beetles were trapped than with pheromone alone. Male–female ratios were significantly lower for both types of traps when ethanol was included in the bait than for lineatin alone or with α-pinene. A higher percentage of male beetles entered the drainpipe traps than was captured with funnel traps.

INTRODUCTION

The ambrosia beetle *Trypodendron lineatum* (Oliv.) (Coleoptera: Scolytidae) is one of the most significant pests causing damage to commercial wood products

in the northern hemisphere (McLean, 1985). Although considerable effort has been expended investigating the roles of ethanol and α-pinene as primary attractants (Birch, 1978) and as synergists to the response of *T. lineatum* to its pheromone, lineatin (MacConnell et al., 1977), contrary experimental results continue to confuse the issue, particularly in North America. Understanding the role of ethanol and α-pinene in the chemical ecology of *T. lineatum* is important because commercial mass-trapping programs using semiochemical baits are becoming a common component of ambrosia beetle management programs in the wood products industry.

Moeck (1970, 1971) identified ethanol as a primary attractant for *T. lineatum* in laboratory and field tests but found α-pinene to be repellent in laboratory tests. Bauer and Vité (1975) found both ethanol and α-pinene to be mildly attractive to *T. lineatum* when tested in the field separately, but noted a 10-fold synergistic response when the two chemicals were combined. The individual and synergistic responses to these two chemicals in both western Canada and West Germany were confirmed by Nijholt and Schönherr (1976) and in Sweden by Schroeder and Lindelöw (1989).

There is general agreement that (+)-lineatin is the pheromone of *T. lineatum* in both North America and Europe and that the (−)-enantiomer is inactive, because of similar responses to the (+)-enantiomer and the racemic mixture (Borden et al., 1980; Payne et al., 1983).

In continental Europe, the addition of ethanol and α-pinene to both barrier and tree trunk-simulating (drainpipe) traps baited with lineatin has resulted in increased catches of *T. lineatum* over traps baited with lineatin alone (Vité and Bakke, 1979; Klimetzek et al., 1980; Bakke, 1983; Paiva and Kiesel, 1985). From Canada and England, however, conflicting results were reported. Borden et al. (1982) found in Canada that *T. lineatum* catches in both sticky wire mesh traps and drainpipe traps baited with lineatin were not increased by the addition of α-pinene and decreased with the addition of ethanol. In England, Borden et al. (1982) found that lineatin plus ethanol outperformed the other combinations in fin barrier traps and that the addition of α-pinene inhibited response to lineatin in these traps. In drainpipe traps, lineatin, with either or both α-pinene and ethanol, caught more beetles than lineatin alone, but the increased response to the ternary mixture over lineatin alone was primarily attributed to the effects of ethanol. Drainpipe traps baited with lineatin alone caught fewer females and no more males than those baited only with ethanol and α-pinene in England (Borden et al., 1982).

Further work in Canada by Shore and McLean (1983), using drainpipe traps, indicated a significantly greater catch of *T. lineatum* when both ethanol and α-pinene were added to lineatin than when the pheromone was used alone. Salom and McLean (1988), however, found no significant differences between *T. lineatum* catches with lineatin alone or with any combination of ethanol or

α-pinene in field tests with funnel (barrier type) traps in Canada. They also found no increase in response when ethanol was added to lineatin in funnel traps tested in a wind tunnel. When drainpipe traps were used in a tunnel, however, they found that ethanol stimulated females to enter the traps (Salom and McLean, 1990).

Two possible hypotheses for the disparity in experimental results in these European and North American experiments have been put forward: (1) The beetles are responding differently to the baits due to the different types of traps used in the studies. The glass barrier, fin, funnel, and sticky traps are passive types, i.e., beetles simply hit the side of the trap and drop in or stick to it. Drainpipe traps, however, require an active response by the beetle to crawl into one of the many small entrance holes in order to be trapped. It has been hypothesized that lineatin is sufficient to attract beetles to barrier traps but the addition of the host semiochemicals ethanol and α-pinene is required to induce beetles into the holes of the drainpipe trap (Vité and Bakke, 1979; Salom and McLean, 1990). (2) The beetles' response to ethanol and α-pinene can vary significantly as a result of the release rate of the two semiochemicals. A reduced response to traps baited with α-pinene has been noted in a number of studies (Moeck, 1970; Borden et al., 1982; Bakke, 1983). Bakke (1983) found that release rates of approximately 30 mg/day of α-pinene significantly increased the response of *T. lineatum* to its pheromone, whereas release rates of approximately 100 mg/day reduced catches. He suggested that a high release rate of α-pinene in the English experiments (Borden et al., 1982) might account for the poor response to this semiochemical. Likewise, Salom and McLean (1990) suggested that a high release rate of ethanol (1 g/day) used by Borden et al. (1982) in North America may have produced the repellent effect of this semiochemical in drainpipe traps in their experiment as opposed to the positive results they found using 150 mg/day. Moeck (1970) noted in bioassays that ethanol at high release rates was at first attractive to the beetles, but with continued exposure they became anosmic, probably due to anesthetization of their olfactory sensilla.

In this experiment we tested the hypothesis that the primary attractants ethanol and α-pinene play a more important role in attracting ambrosia beetles into active-type drainpipe traps than into passive-type funnel traps when the semiochemicals are released at comparable rates from the two trap types at rates that are considered to be in the optimal range for commercial trapping purposes (Phero Tech Inc., Delta, British Columbia, Canada).

METHODS AND MATERIALS

A replicated experiment was established at a dryland log sorting area near Duncan, British Columbia. Each of the two replicates consisted of four Lindgren

multiple-funnel traps (Phero Tech Inc.) (Lindgren, 1983) and four Scandinavian drainpipe traps (Borregaard A.S., Sarpsborg, Norway, 1980 model) with the four traps in each trap type baited with one of four semiochemical lure combinations: (1) lineatin, (2) lineatin plus ethanol, (3) lineatin plus α-pinene, and (4) lineatin plus ethanol plus α-pinene.

Lineatin was dispensed from two Hercon laminated dispensers, each releasing at 100 μg/24 hr. (All release rates determined by Phero Tech Inc.) Ethanol was released from a 2.5 × 44-cm PVC pouch at 140 mg/24 hr. The experiment was set up and analyzed in an 8 × 8 Latin square design with time and trap position as the rows and columns (Perry et al., 1980; Shore and McLean, 1983). Traps were placed in the field on April 19, 1989, and beetles were collected on April 28, May 4, May 10, May 15, May 25, June 2, June 12, and June 26. After each beetle collection, the eight traps in each replicate were rearranged until all eight treatment and position combinations had been tested. *T. lineatum* were separated from other insects caught in the traps and counted and sexed in the laboratory. The numbers of beetles caught were transformed to $\log_{10}(x + 1)$, and the percentage of male beetles was transformed to arcsin $\sqrt{x}$ to correct for heteroscedasticity in the data sets before being analyzed by analysis of variance. The analysis was conducted separately for male, female, and total numbers of beetles. Student-Newman-Keul's test was used to test for differences among means. All treatment effects and differences among means were tested at $P \leq 0.05$.

RESULTS

The analysis of variance for the number of female, male, and total beetles captured showed significant effects for replicate (square), semiochemical bait, trap type, trap position, and time (Table 1). There were no significant semiochemical bait × trap type interactions, which indicated that the bait effects were the same for both trap types (Table 1). Traps baited with α-pinene plus lineatin or α-pinene plus ethanol plus lineatin caught significantly more beetles than those baited with lineatin alone. Traps baited with ethanol plus lineatin were intermediate in total beetle response (Table 2). For female *T. lineatum*, treatments containing the pheromone plus ethanol and/or α-pinene captured significantly more beetles than traps baited with lineatin alone. Male beetles responded to the pheromone plus α-pinene or the pheromone plus α-pinene plus ethanol in significantly greater numbers than to the pheromone alone. The addition of ethanol alone to lineatin resulted in a slightly higher, but not statistically significant, response by male *T. lineatum* with the drainpipe trap. (Table 2).

The analysis of variance for the percentage of total beetles captured that were male showed significant effects for semiochemical bait ($F = 9.7$, $dp = 3$,

91; $P < 0.001$), trap type ($F = 40.6$, $df = 1, 91$; $P < 0.0001$) and time ($F = 3.3$, $df = 1, 91$; $P < 0.001$). There was no significant bait by trap type interaction ($F = 1.0$, $df = 3, 91$; $P > 0.40$), which indicated that the sexes responded to the different semiochemical baits similarly for both trap types. The addition of ethanol to traps baited with lineatin alone, or lineatin plus α-pinene, resulted in a significant decrease in the percentage of total beetles captured that were male (Table 2).

The total number of beetles, both males and females, captured in the Lindgren funnel traps was significantly greater than the number caught in the drainpipe traps (Table 2). A higher percentage of male beetles was captured in the drainpipe traps than in the funnel traps (Table 3).

DISCUSSION

The finding that funnel traps caught more *T. lineatum* than drainpipe traps in North America confirms previous reports by Lindgren et al. (1983) and McLean et al. (1987). These workers were unable to show statistically significant differences for both sexes, however. Our results show statistically significant differences for both sexes separately as well as for the total catch. The higher percentage of males captured in drainpipe than in barrier traps has been previously reported from Europe (Klimetzek et al., 1980). This result can probably be explained because the female is the first-attacking sex and the male is conditioned to enter the galleries initiated by the females.

The hypothesis that *T. lineatum* response to ethanol and α-pinene when combined with lineatin was related to active or passive trap type was rejected. Beetles responded in a similar manner to the bait combinations in both trap types. The results also confirm the finding of Shore and McLean (1983) that

drainpipe traps baited with the tertiary combination caught more beetles than those baited with lineatin alone. This finding is now extended to funnel traps in North America, which is in disagreement with results reported by Salom and McLean (1988).

The addition of ethanol resulted in a higher percentage of female beetles responding. This has been reported by others (Borden et al., 1982; Bakke, 1983) and probably reflects the chemical ecology of the insect. The female is the pioneer sex in *T. lineatum* and responds to logs in which fermentation has started (Graham, 1968). Thus host odors may be more important to the female and the pheromone more important to the male (Salom and McLean, 1990). In our experiment, however, ethanol increased female response but α-pinene did not. α-Pinene was the more important of the two kairomones in increasing total *T. lineatum* response, but this increase was more in the number of males than females. As *T. lineatum* brood studies have shown a sex ratio of 1 : 1 (Shore et al., 1987), none of the bait and trap combinations attracts sufficient females to maximize mass-trapping efficiency.

In Europe, ethanol and α-pinene have consistently attracted *T. lineatum* either on their own or synergistically with each other and/or the pheromone lineatin in both passive and active trap types (Bauer and Vité, 1975; Nijholt and Schönherr, 1976; Vité and Bakke, 1979; Klimetzek et al., 1980, 1986; Borden et al., 1982; Bakke, 1983; Paiva and Kiesel, 1985; Ramisch and Bombosch, 1986; Schroeder, 1988; Kvamme, 1986; Schroeder and Lindelöw, 1989).

In North America, however, there have been a number of conflicting experimental results involving *T. lineatum* response to ethanol and α-pinene. There are several possible explanations for the differences in experimental results within North America and between North America and Europe. Some of these have been tested and rejected. For example, there is no evidence to suggest different responses to enantiomers of α-pinene or lineatin by North American and European *T. lineatum* (Payne et al., 1983; King et al., 1983; Andryszak et al., 1987). The results reported here suggest that *T. lineatum* responds similarly to semiochemicals whether they are in active or passive trap types, although the sex ratios responding to the two trap types are somewhat different. In North America, experimental design and release rates are two possible factors that may have contributed to conflicting results.

Borden et al. (1982) used a randomized block design and Shore and McLean (1983), Salom and McLean (1988), and the experiment reported here used a Latin square design with time and trap position as the rows and columns. This latter experimental design has the advantage of separating treatment effects from the variation attributed to differences in trap location and time in the analysis of variance, thus making the test more sensitive to treatment differences (Perry et al., 1980). This does not provide an explanation, however, for the difference in results between the findings of Salom and McLean (1988), in which the

addition of ethanol and α-pinene did not enhance trap catches of *T. lineatum*, and the experimental results reported here.

The release rates of lineatin, ethanol, and α-pinene have differed in the North American experiments. Borden et al. (1982) used 1 g/day of ethanol in some experiments, which is considerably higher than the release rates used in other experiments and may explain the repellent response of *T. lineatum* to this bait in those experiments. In other experiments, however, they tested ethanol and α-pinene at lower rates that were later found to be within the optimal range (Bakke, 1983; Lindgren et al., 1983; Klimetzek et al., 1986), and although there was a trend to higher catches with the lower rates, there was still no improvement over the pheromone alone. Further work on optimizing release rates is needed. In Europe, a variety of release rates, experimental designs, and trap types have been used, and the response of *T. lineatum* to ethanol and α-pinene has appeared to be much more consistent.

In Europe, interspecific competition by *T. lineatum* with the hardwood-inhabiting species *T. domesticum* (L.) and *T. signatum* (F.) may have led to stronger host kairomone responses than in North America. *T. lineatum* commonly attacks hardwood species in North America (Wood, 1982; Lindgren, 1986), whereas in Europe this is considered rare (Å. Lindelöw,[2] Forest entomologist, Department of Entomology, Swedish University of Agricultural Sciences, Uppsala, Sweden, personal communication). All three species respond to and produce (+)-lineatin (Klimetzek et al., 1981; Schurig et al., 1982), so there likely is a need for additional compounds to maintain reproductive isolation. Tømmerås (1989) showed that *T. lineatum* has receptors sensitive to volatiles from the nonhost birch. Birch is a host of *T. domesticum*, which was found to be inhibited by α-pinene (Nijholt and Schönherr, 1976).

Our study does not explain discrepancies among North American findings on the role of host kairomones as synergists to lineatin for *T. lineatum*, but it supports the use of host volatiles in commercial trapping programs. It appears that host kairomones are not as important to North American *T. lineatum* as to their European conspecifics. Nevertheless, under certain circumstances, host volatiles play a significant role in the chemical ecology of this species in North America.

ROLE OF PREY ODOR IN FOOD RECOGNITION BY ROCK CRABS, *Cancer irroratus* SAY

STEVE REBACH

Department of Natural Sciences
University of Maryland Eastern Shore
Princess Anne, Maryland 21853

(Received November 13, 1995; accepted July 9, 1996)

Abstract—Rock crabs, *Cancer irroratus*, respond to food odors in low concentration as measured by changes in antennular flicking rate. The responses of rock crabs to prey odor were tested in the presence and absence of visual cues to determine the role of chemical cues in prey recognition. Crabs were attracted to the source of mussel odor introduced into one arm of a Y maze. Natural and artificial prey shells and resin boxes were presented to crabs with and without the presence of mussel extract. The crabs were able to see, handle, and manipulate these objects. Crabs opened and consumed contents that emitted chemosensory cues and ignored identical objects that did not. Rock crabs were attracted to food odors and are capable of utilizing chemical cues to detect, locate, and identify food items.

Key Words—Crustacea, crabs, marine animals, chemoreception, odor, vision, foraging, feeding, *Cancer irroratus*.

INTRODUCTION

Efficient foraging requires that animals expend minimum amounts of energy searching for, handling, or subduing prey and investigating or attempting to feed upon nonfood objects. An efficient or optimally foraging crab should be able to detect cues from distant prey, follow these cues to their source, and then be able to differentiate edible shelled prey from empty shells and other inedible environmental objects such as small stones. Attempting to open extraneous environmental objects increases the possibility of claw damage, which would impair future foraging (Juanes and Hartwick, 1990).

In the mid-Atlantic region, rock crabs, *Cancer irroratus*, migrate annually from depths of up to 700 m to shallower inshore areas (depths of 1–20 m) in

0894-9859/96/1200-2197/$09.50/0 © 1996 Plenum Publishing Corporation

October–November and remain until March–April (Shotton, 1973; Haefner and van Engel, 1975). While in deeper offshore waters, or in turbid, shallow waters, there is insufficient light for food detection by visual mechanisms. Because rock crabs are crepuscular and nocturnal foragers (Rebach, 1985, 1987), vision may not be very useful even in clear, shallow environments.

Crustacea utilize chemoreception in both the finding of food and the initiation of feeding. They detect food by distance chemoreception using their antennules and by contact chemoreception using chemosensory hairs on antennules, carapace, mouthparts and legs (Rittschoff, 1992). Chemical cues released from prey (body odors) provide appropriate stimuli for investigative and attractive phases of feeding, while prey extracts provide natural stimuli for studying ingestive phases of feeding (Zimmer-Faust, 1993). Recent reviews of chemoreception and feeding behavior in crustaceans can be found in Ache (1982, 1988), Carr and Derby (1986), Derby and Atema (1988), and Laverack (1988). Rittschoff (1992) reviews how social, environmental, and physiological contexts determine the result of chemosensory input in the daily life of crabs.

Vision is commonly used in aggressive displays by *Callinectes sapidus* (Jachowski, 1974) and *Carcinus* (Lee and Seed, 1992), and in mating by *Callinectes* (Jachowski, 1974; Milliken and Williams, 1984) and *Cardiosoma* (Ameyaw-Akumfi, 1987). In the hermit crab, *Clibanarius vittatus*, chemical cues from gastropod flesh initiate visually directed shell-seeking behavior in crabs with poorly fitting shells. *Clibanarius* is capable of visually discriminating shapes related to the potential habitability of gastropod shells (Diaz et al., 1994). Langdon and Herrnkind (1985) have demonstrated that the fiddler crab, *Uca pugilator*, is also capable of shape discrimination. Generally, *Callinectes* is a visually oriented species, found in shallow waters where light penetration is good. From underwater, they are capable of capturing the marsh periwinkle, *Littorina*, when the snail is out of water on *Spartina* stems (Hamilton, 1976).

My current research attempts to determine the relative roles of visual and chemosensory modalities in: (1) prey detection, (2) prey location, and (3) prey identification and to consider decision rules used by foragers in responding to food attractants.

METHODS AND MATERIALS

Subjects and Maintenance Conditions. Male rock crabs, *Cancer irroratus*, in intermolt stage and with intact claws, were used for all experiments. Each animal was used only once. Crabs were maintained in 30‰ artificial seawater (Dayno Manufacturing, Inc.) at ambient seasonal temperatures and fed Crustacean Ration (Rebach, 1981) daily, and ribbed mussels (*Geukensia demissa*) once per week. Test crabs were starved for 24 hr to standardize hunger levels prior to testing.

Attraction to Odors. A Y maze 91.4 cm long constructed of 1.2 cm thick Plexiglas was used. Water entered through 6-mm-diameter ports 2 cm from the bottom of the tank, and exited from a 12-mm-diameter opening 12.5 cm from the bottom. A Masterflex dual-head peristaltic pump delivered water at 330 ml/min (165 ml/side) (Figure 1). In control tests, crabs indicated no side preference. Dye studies showed that little mixing occurred at the base of the Y within the 10-min testing time.

Unfiltered seawater entered through one port, and seawater that had passed over three 4.0-cm, freshly cracked ribbed mussels entered through the other. The maze arm dispensing the seawater exposed to mussels was varied randomly. The test tank was drained, washed, and dried between each test.

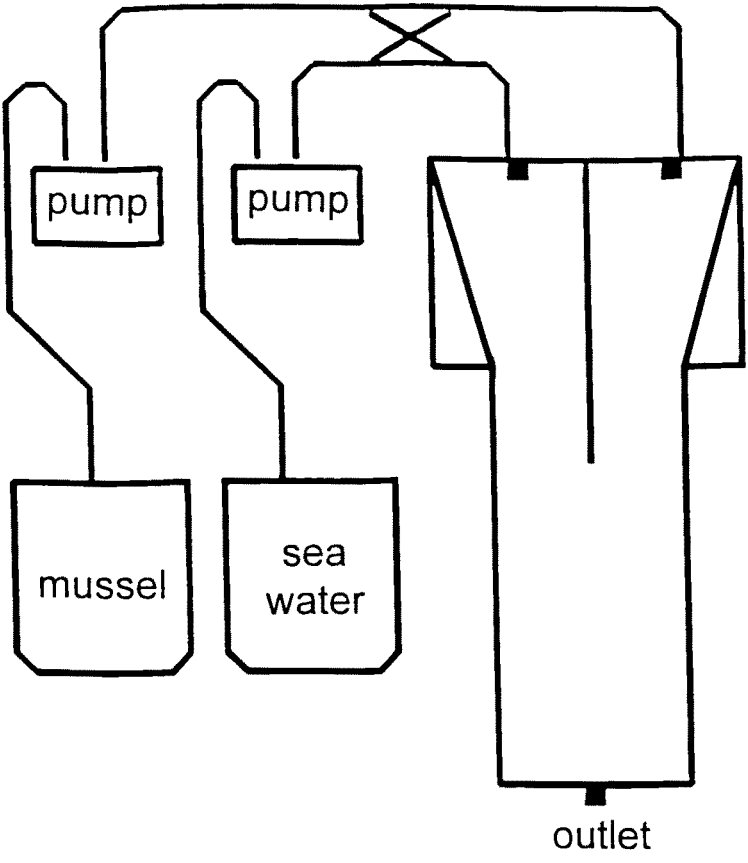

FIG. 1. Setup of Y maze and water delivery system. Samples could be delivered to either arm of the Y maze.

A crab was placed at the base of the Y maze under a weighted, perforated plastic cup (15 cm diameter, 7 cm high) for 10 min before the experiment began. The cup remained in place for 1 min after water flow commenced, then was lifted gently with a remotely operated string.

A video camera, with a wide-angle lens, was positioned above the tank and connected to a monitor and video recorder several feet away. Each crab was observed for 10 min through the monitor, and position and elapsed time were recorded on a schematic diagram of the tank whenever a position change occurred. Choice of a side was determined when a crab spent more than 75% (>7.5 min) in one arm of the chamber beyond the divider. A videorecording of the behavior was made for later reviewing, if necessary.

Food Recognition. Testing was conducted in a 38-liter glass aquarium (50.8 × 25.4 cm), filled $\frac{1}{2}$ full (15 cm) with seawater (30‰) at 12°C. The aquarium had a clear Plexiglas divider, which could be inserted or removed, 13.5 cm from one end.

Crabs were presented with a choice between an odorless prey item (a clean, empty, 4.5-cm-long mussel, boiled for 10 min, and valves reglued) and an item that released prey odor (a sponge soaked in *Geukensia* extract and placed in a small, 3.3 × 3.3 × 1.5 cm opaque, resin box). The opaque box was molded of ProCast 10 (Rudolf Bros. & Co., 960 Walnut St., P.O. Box 175, Canal Winchester, Ohio 43117), a bone white urethane casting resin. Mussel extract was prepared by macerating a freshly caught mussel immediately before the test. From crab eye-level, the mussel and the box offered equal presentation areas. The box had five 3-mm holes drilled in the lid, and contained a sponge soaked in mussel extract. The box and sponge weighed 6.5 g, which approximates the weight of a 4.5-cm mussel.

Experimental crabs were starved and acclimated to the testing tank, with divider in place, for 24 hr before testing. Ten minutes before the experiment began, a box with mussel-extract-soaked sponge and a clean mussel shell were placed at opposite sides of the tank behind the divider. The divider was then raised and the crab's response was monitored. Again, the crab was observed through a video monitor, which offered a dorsal view, and through the side of the tank. When the crab picked up an object and crushed or broke it open, it was considered to have made a choice. If the crab failed to make a choice after 1 hr, the experiment was terminated.

Crabs were subsequently given the choice between boxes with chemical cues (sponge) and empty mussel shells with chemical cues (sponge) to determine if, when odor was held constant, crabs would prefer objects that had the appearance of prey.

Because it is possible that the boiled, dried, mussel shells still provided chemical information from shell proteins, faux mussel shells were cast from the same resin used to make the boxes. Real mussel shells were tested against resin

mussel shells, without using odor-impregnated sponges. Odor was held constant, being absent in both choices. Prior to using the resin shells, several crabs were offered live mussels and faux mussels containing sponges and mussel extract. Each type was consumed in equal amounts. All test series were scheduled to be conducted until 15 individuals had made a choice. Preferences were determined by using a two-tailed binomial test (Siegel and Castellan, 1988).

RESULTS

Control tests ($N = 13$) with the Y Maze indicated that a side preference did not exist. However, when given the choice between seawater that had passed over mussels and control seawater of the same salinity, 10 crabs entered the arm of the maze that dispensed seawater + mussel odor and two entered the seawater arm ($P = 0.038$, $N = 12$). Crabs were frequently observed attempting to climb onto the water dispenser disbursing prey odor and exhibited increased activity upon reaching the test water input port.

When presented with the choice of a box containing a sponge and mussel extract, and dried, empty mussel shells, 12 crabs chose the box, three chose the mussel shell, and three others made no choice (Figure 2A, $P = 0.036$, $N = 15$). A choice was scored when a crab either opened the box or opened the mussel. Most of the crabs crushed the box to get to the mussel-soaked sponge but several were capable of using their chelae to open the box. Although boxes and shells were weighted to approximate the natural weights of mussels of that size class, sponge cubes were less dense than seawater and often floated to the surface of the test tank. At least half the crabs grasped the sponge with their chelae and proceeded to rip it into small pieces, many of which were consumed. The three animals that made no choice remained motionless in the tank. In every case in which a crab handled prey, it made a choice. Crabs not making choices were not considered in the data analysis.

Crabs given a choice between boxes and mussel shells, each containing sponges soaked in mussel extract, and each releasing chemical cues, chose randomly. Seven crabs chose the box with sponge, and eight animals chose the mussel shell with sponge (Figure 2B, $P = 1.0$, $N = 15$). One animal made no choice during the testing period.

For the choice tests between real and faux mussel shells (both without chemical cues), I was unable to test enough crabs to achieve the designated cutoff of 15 animals making a decision before the season ended and crabs became unavailable. Seven crabs chose the real mussel, three chose the faux mussel shell, and 25 made no choice (Figure 2C, $P = 0.344$, $N = 10$). After 25 animals failed to make a choice, this series of tests was abandoned. This large a percentage of animals not making a choice was not observed in any previous

series. The number of crabs making choices when prey odor was present was compared to the number making choices when odor was not present by the Fisher's exact test (Sokal and Rohlf, 1981) and differed significantly ($P < 0.0001$). I then introduced cracked, but unopened, live mussels to crabs that were inactive during the 1-hr test period. These crabs initiated activity, picked up the cracked mussels, opened, and consumed them.

DISCUSSION

Previous work has indicated that rock crabs detect the presence of mussel extract at concentrations as low as 10^{-10} g/liter, measured by increases in antennal flicking rate at increasing concentrations of extract. Concentrations greater than 10^{-7} g/liter induced feeding behavior (Rebach et al., 1990), indicating the ability of crabs to detect and differentiate odors of varying strength from a distance. Increased concentrations of food odors may reflect increased concentrations or value of foods and influence aspects of foraging behavior (Zimmer-Faust, 1989). Chemical cues are important attractants and may be correlated with probable yield and vulnerability of prey. Using models, Kaiser et al. (1993) found that the more concentrated the odor, the greater the preference, the greater the number eaten, and the more time spent handling the model.

The Y maze experiments indicate that rock crabs orient toward and are attracted to prey odor. Prey body odors are ecologically relevant stimuli in assaying exploratory search behavior by foragers (Zimmer-Faust, 1989).

Although crabs may use chemical cues to detect and approach prey, they must still determine which environmental objects are edible and which are not upon arriving at the source of the odor. By choosing boxes and shells containing sponges soaked in mussel extract with equal frequency, crabs apparently did not utilize visual cues in the short-range prey discrimination tests. If visual cues were used in conjunction with odor, mussel shells would have been chosen disproportionately. When mussel extract was not present in mussel shells, crabs chose boxes that released food odors over mussel shells that did not. *Carcinus* has been observed to bite off pieces of plaster models containing mussel homogenate and persisted longer with scented than with odorless models (Kaiser et al., 1993). Prey extracts provide the most natural stimuli for assaying the ingestive phase of feeding, since substances released by the extract are likely to be similar to those escaping as predators consume prey (Zimmer-Faust, 1989). These compounds influence feeding behavior differently in different species. ATP is commonly present in prey tissue extract and rapidly degrades to AMP, which acts as a repellent in the spiny lobster, *Panulirus interruptus* (Zimmer-Faust, 1993), and as a feeding behavior stimulant in *Palaemonetes pugio*, an opportunistic scavenger (Carr and Derby, 1986). *Cancer irroratus* is a predator

and a scavenger (Bigford, 1979), whose diet typically includes hard-bodied prey such as crustaceans, bivalves and gastropods (Hudon and Lamarche, 1989; Stehlik, 1993), and should be attracted by the release of tissue extracts (Rittschoff and Sutherland, 1986).

Tests with empty shells may not be proper controls since mussel shells contain proteins, such as conchiolin, secreted by the mantle (Wilbur and Saleuddin, 1983), and chemical cues might be available even in shells that had been scraped and oven dried. Shells cast of resin allowed removal of all naturally occurring proteins from the test situation. The crabs seldom chose between real shells and faux shells without implanted odors. They often failed to move and appeared unwilling to handle and open environmental objects without appropriate chemical cues to stimulate feeding behavior. The comparison of crabs making choices to those not choosing indicated that, in these experiments, the presence of odor was necessary for making a choice and that visual cues were not sufficient to stimulate investigation of prey. Visual cues did not promote or stimulate feeding activity. The lack of movement was apparently not a matter of lack of hunger because crabs exhibited normal feeding responses when cracked mussels were presented. It appears that the lack of choice was prompted by the lack of chemical cues.

Rock crabs can detect the presence of mussel extract in very low concentrations. The Y maze tests indicate that they are attracted to the source of this odor without the presence of any visual information. When presented with choices in which some objects emitted prey odor, crabs chose these objects whether they were shells of real prey, artificial shells resembling actual prey, or boxes that resemble prey neither in color, shape, nor texture. Likewise, real and artificial objects that did not emit chemosensory information were generally ignored. In fact, crabs often stood on empty mussel shells to facilitate reaching resin boxes. Stehlik (1993), however, found objects of human origin such as fibers, hairs, wood, plastic beads, and plastic sponges in the guts of *C. irroratus* and *C. borealis*. Patches of prey often contain inedible items such as stones and empty shells, and foragers will encounter prey and debris simultaneously and might be fooled by pervasive odors. While feeding, the material being consumed is usually beneath them, making it rather difficult to employ visual cues. Handling times decrease as learning occurs, and crabs can probably learn to avoid inedible objects from experience (Kaiser et al., 1993). When given the choice between real and artificial "covers" for odor sources, choices were made, but no preference was exhibited. When given the same choice without an odor source, no choices were made.

This study indicates that foraging rock crabs make several decisions based on questions such as: (1) is food present? (2) where is it? (3) should it be approached? and (4) is it edible? It appears that chemical cues are necessary

and sufficient for the detection, location, and identification of food items by rock crabs and that visual cues are ignored.

It is interesting to note that in other work in our laboratory, crabs chose larger prey over smaller prey when neither had any associated chemical cues. Visual cues may be utilized to distinguish prey from other environmental objects in the immediate vicinity of the prey, although the foreign objects found in crab guts by Stehlik (1993) might argue otherwise.

Vision may play a role in initiating an appropriate response to a physiological input since social and environmental contexts can influence the responses to chemosensory input. Vision may be used for discrimination when similar odors are produced by living, or recently deceased, predators. The odor of dead conspecifics and living competitors or predators may indicate danger and influence behavior. Responses to odors can also be influenced by molt stage, reproductive stage, and hunger level (Zimmer-Faust, 1989).

My experiments were unable to elucidate the role of visual cues in prey selection. Rock crabs appear to be essentially nonvisual predators. Chemical information directs these crabs to their prey and may provide information about prey quality or quantity. Prey quality may be evaluated by tactile or contact chemoreception, resulting in predatory efficiency by reducing energy expenditure on unprofitable prey items (Kaiser et al., 1993). The data indicate that rock crabs are sensitive to and attracted by food odors and locate, recognize, and identify prey by chemosensory, rather than visual, mechanisms. This may be an adaptation to nocturnal activity, the murkiness of the inshore water, and the lack of light penetration in their offshore habitat.

Acknowledgments—I would like to thank Melanie Wilber for assistance in the preparation of this manuscript, Dr. M. P. Scott and Mr. J. Block for critically reading the manuscript, and Dr. D. P. French for assistance in making the models and for helpful advice. This research was partially supported by NSF grant RII-8704054. STRUCTURES AND ALLELOPATHIC EFFECTS OF *Nuphar* ALKALOIDS: NUPHAROLUTINE AND 6,6′-DIHYDROXYTHIOBINUPHARIDINE

STELLA D. ELAKOVICH* and JIE YANG

Department of Chemistry and Biochemistry
University of Southern Mississippi
Hattiesburg, Mississippi 39406-5043

(Received March 14, 1996; accepted July 9, 1996)

Abstract—Two of the major *Nuphar* alkaloids, nupharolutine and 6,6′-dihydroxythiobinupharidine, were isolated from the aquatic perennial herb *Nuphar lutea* (L.) Sibth. & Sm., yellow water lily. In a lettuce seedling bioassay of the two pure compounds, the former was inactive and the latter was highly inhibitory of radicle elongation at concentrations greater than 2 ppm. Structures and stereochemistry of the two compounds were confirmed by DEPT, ^{1}H-^{1}H COSY, ^{1}H-^{13}C COSY, and ^{1}H-^{1}H NOESY experiments.

Key Words—Allelopathy, aquatic plant, bioassay, *Nuphar lutea*, alkaloids, NMR, nupharolutine, 6,6′-dihydroxythiobinupharidine, Nymphaeaceae.

INTRODUCTION

Earlier work in our laboratory surveyed for potential allelopathic activity some 25 aquatic and wetland plants native to the southeastern United States (Elakovich and Wooten, 1989, 1991; Wooten and Elakovich, 1991). An aqueous extract of the aquatic perennial herb *Nuphar lutea* (L.) Sibth. & Sm., family Nymphaeceae, yellow water lily, exhibited the highest allelopathic potential according to lettuce seedling and *Lemna minor* growth bioassays (Elakovich and Wooten, 1991). An extract of yellow water lily was almost 10 times as inhibitory as the second most active aqueous plant extract, that of *Nymphaea odorata* Ait. *Nuphar lutea* is comprised of nine often poorly differentiated subspecies occurring in rivers, estuaries, bayous, sloughs, marshes, swamps, ditches, lakes, and

*To whom correspondence should be addressed.

ponds of North America and Europe. Where ranges of subspecies overlap, many specimens are intermediate between the overlapping subspecies (Godfrey and Wooten, 1981). Populations of *N. lutea* are often so dense that the water surface is not visible; such populations apparently exclude other hydrophyte growth.

Previous work established that both the leaf and the root and rhizome aqueous extracts of *Nuphar lutea* inhibited *Lemna minor* frond growth and lettuce seedling radicle elongation (Elakovich and Wooten, 1991). Extracts were prepared by blending equal weights of fresh plant material and deionized water and filtering. Inhibition by these *N. lutea* aqueous extracts was found at concentrations of 2.5 parts per thousand (ppt) or greater.

Nuphar lutea produces alkaloids having a regular sesquiterpenic skeleton incorporated into 3-furyl-substituted piperidines or quinolizidines as well as C_{30} alkaloids that contain a sulfur atom along with two 3-furyl substituents (Wrobel and Ruszkowsha, 1979; LaLonde and Wong, 1977; Iwanow et al., 1986). Cullen et al. (1973) examined the antifungal activity of the rhizomes whose medicinal utility had been reported 20 years earlier (Tatarov, 1945). There are no reports on the allelopathic potential of *Nuphar* alkaloids.

Continued discovery of agrochemically active compounds from natural sources supports the notion that new herbicides, insecticides, and antimicrobials may be developed from templates discovered among natural products (Cardellina, 1988). McClure (1970) reiterated the postulation that "Aquatic angiosperms are considered to be descendants of terrestrial plants which have reverted to the aquatic habits of their remote ancestors." He suggested that the initial change from an aquatic to an emergent habitat appears to involve a shift from an essentially anaerobic to an aerobic type of metabolism and would surely be expected to influence the qualitative and quantitative production of secondary constituents. Thus, because aquatic plants occupy different ecological niches than terrestrial plants, they may also produce allelochemicals with different target/nontarget toxicity profiles than terrestrial plants. Some of these biologically active natural products may be developed into commercial herbicides that may be more environmentally acceptable than are present herbicides (Duke, 1986). Data on the plant-growth-inhibitory activity of some 100 species of aquatic and wetland plants have been reported (Elakovich and Wooten, 1995), but there are only a handful of reports on the structure of specific bioactive compounds from these plants.

This paper describes the isolation and full NMR characterization of two of the known alkaloids from *N. lutea* and an examination of the allelopathic potential of these compounds as measured by lettuce seedling bioassay.

METHODS AND MATERIALS

General Experimental Procedures. NMR solution spectra were obtained on a Bruker AC-300 spectrometer using standard pulse sequences and Bruker

software for 2D experiments. IR spectra were obtained in CH_2Cl_2 solution on a Mattson Polaris spectrometer. MS (electron impact) were obtained on a Hewlett Packard 5985 GC/MS system. TLC was performed on 20 cm × 0.25 mm commercial plates with UV detection.

Plant Material. Nuphar lutea sb. *macrophyllum* whole plants were collected from a quiescent pond in Tylertown, Mississippi, during October and November 1991. Plants were washed free of debris, drained of excess water, and divided into two portions: (1) leaves, including blades and petioles; and (2) rhizomes and roots. Plants were dried in a plant dryer, ground to a coarse powder, and stored at room temperature. A voucher specimen was deposited in the University of Southern Mississippi Herbarium, Department of Biological Sciences.

Extraction and Isolation. Two batches of powdered roots and rhizomes of *N. lutea*, 1.7 and 3.0 kg, were extracted according to a method modified from that of Cullen et al. (1973) to yield 17.7 and 26 g of crude alkaloid mixture, respectively. A 5-g portion of the alkaloid mixture was chromatographed over activity III alumina and eluted with hexane (200 ml); hexane-CH_2Cl_2 mixtures as follows: 99:1 (260 ml), 95:5 (525 ml), 90:10 (450 ml), 8:2 (130 ml), 1:1 (470 ml), 1:3 (300 ml); CH_2Cl_2 (1000 ml); and CH_2Cl_2–MeOH 99:1 (200 ml). The CH_2Cl_2–MeOH fraction was rechromatographed over activity II alumina and eluted with CH_2Cl_2 (1000 ml) and CH_2Cl_2–0.4% MeOH (400 ml). The CH_2Cl_2–MeOH fraction was rechromatographed over activity III alumina and eluted with hexane (400 ml), hexane–ether 95:5 (200 ml) and 85:15 (200 ml), and ether (200 ml). The fraction from 85:15 hexane–ether was rechromatographed over activity III alumina and eluted with hexane–ether 95:5 (200 ml) and 90:10 (200 ml). The fraction from 90:10 hexane–ether yielded 28 mg of nupharolutine.

A 15-g portion of the crude alkaloid mixture was chromatographed over activity III alumina and eluted with 1000-ml portions of hexane–triethylamine, 99:1, fractions 1–4; hexane-CH_2Cl_2–triethylamine, 94:5:1, fractions 5–9; 64:35:1, fractions 10–14; 39:60:1, fractions 15–19; 9:90:1, fractions 20–24; CH_2Cl_2–triethylamine, 99:1, fractions 25–29; and CH_2Cl_2–MeOH–triethylamine, 98:1:1, fractions 30–34. Fraction 22 was extracted twice with 100-ml portions of 5% NaOH. The remaining organic phase was concentrated to yield 180 mg of colorless crystals of 6,6′-dihydroxythiobinupharidine.

NMR assignments were made based on DEPT, ^1H–^1H COSY, and ^1H–^{13}C COSY experiments. Stereochemical assignments for nupharolutine were aided by ^1H–^1H NOESY experiments. DEPT spectra allow the identification of carbon signals as methyl groups, methylene groups, methine groups, or quaternary carbons. ^1H–^{13}C COSY spectra allow the correlation of the individual carbon signals with the proton signals of the hydrogen attached to those carbons; ^1H–^1H COSY spectra allow the correlation of hydrogen signals with the other hydrogen signals to which they are coupled. NOESY spectra show signal

enhancement for groups that are close, and thus aid in stereochemical assignments.

Nupharolutine. Mp 102.5–103.5°C. MS *m/e* (% relative intensity) 249 (M^+, 40), 234 (5), 220 (10), 206 (10), 178 (30), 164 (10), 148 (12), 136 (50), 114 (80), 107 (30), 94 (100), 81 (35), 70 (28), 55 (40). These data are consistent with published values (LaLonde et al., 1972; Wrobel et al., 1972a). NMR assignments are given in the Results section.

6,6'-Dihydroxythiobinupharidine. Mp 136.0–139.0°C. MS *m/e* (% relative intensity) 508 (4), 446 (21), 371 (2.4), 337 (2.4), 309 (5.7), 282 (3.3), 268 (3.3), 248 (5.2), 230 (100), 216 (14.2), 188 (3.3), 176 (6.1), 160 (3.8), 148 (5.7), 132 (5.7), 107 (17.0), 94 (86), 81 (25.5). These data are consistent with published values (LaLonde et al., 1970). NMR assignments are given in the Results section.

Bioassays. Lettuce seedling growth bioassays of the crude alkaloid mixture, the two isolated alkaloids, of the known plant growth inhibitor *dl*-2-aminoadipic acid, and of the ethanol solvent were carried out according to previously published procedures (Elakovich and Wooten, 1991) using *Lactuca sativa* Black Seeded Simpson. For the assay of *dl*-2-aminoadipic acid, 10 pregerminated seeds per test plate were used; all other assays used 15 pregerminated seeds per plate. Ethanol added for sample solubilization did not exceed 0.1% of the total 15 ml test volume. Seedlings were allowed to grow at room temperature in the dark for 60–72 hr before either hypocotyls, radicles, or both were measured to the nearest 0.1 cm. Assay results were subjected to analyses of variance and Duncan's multiple-range test.

RESULTS AND DISCUSSION

Nupharolutine, $C_{15}H_{23}NO_2$ **(1),** was isolated from *N. lutea* as glasslike crystals. The ^{13}C NMR and DEPT spectra indicate that the alkaloid has 15 carbons with six methine (δ 143, 140, 110, 69, 60, and 37) five methylene (δ 65, 40, 36, 34, and 29), two methyl (δ 26 and 19), and two quarternary (δ 130 and 68) carbons. The MS indicates a parent ion peak at *m/e* 249 corresponding to $C_{15}H_{23}NO_2$ *Nuphar* alkaloids. The IR contains bands characteristic of hydroxyl absorption (3591 cm^{-1}), the *trans*-quinolizidine ring system (2952 cm^{-1}) (Bohlmann, 1958), and furyl bands (1501–875 cm^{-1}). The ^1H–^1H COSY spin correlations demonstrate that the product could be either nupharolutine **(1)** (Figure 1), or its epimer, 7-epinupharolutine. The IR spectrum of 7-epinupharolutine contains a concentration-independent intramolecular hydrogen-bonding absorption at 3520 cm^{-1}, while **1** displays a hydrogen-bonding absorption at 3520–3300 cm^{-1}, which disappears completely at low concentrations, whereas the band of the epimer persists (LaLonde et al., 1972). The IR spectrum of a dilute (CH_2Cl_2) sample of our product contains no hydrogen-bonding bands, and the

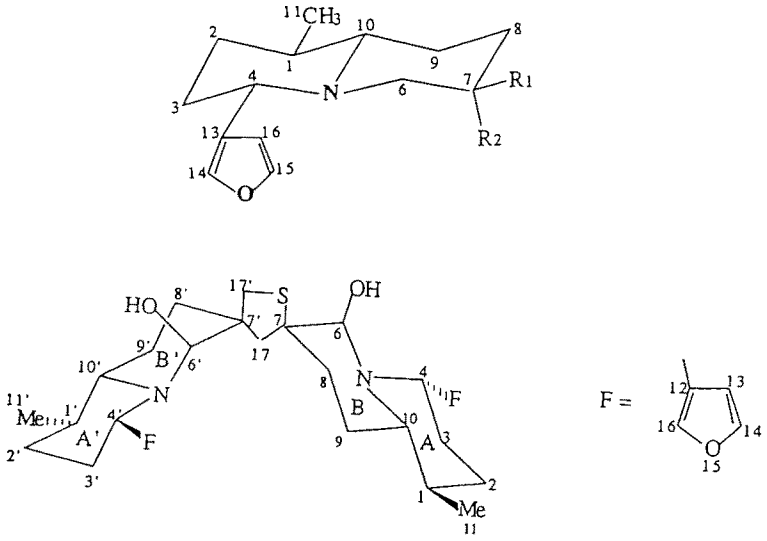

FIG. 1. The structures of nupharolutine (top) and 6,6′-dihydroxythiobinupharidine (bottom). In nupharolutine (top) R_1 = OH and R_2 = CH_3 (C-12); when R_1 = CH_3 (C-12) and R_2 = OH, the compound is 7-epinupharolutine (not isolated or assayed).

MS is consistent with published data for nupharolutine (LaLonde et al., 1972; Wrobel et al., 1972a).

The furyl group chemical shifts are assigned as δ130 (C-13), δ143 (C-14), δ140 (C-15), δ110 (C-16), and δ7.5 (H-14), δ7.4 (H-15), and δ6.4 (H-16) from the ^{1}H–^{1}H and the ^{1}H–^{13}C COSY spectra. The doublet for methyl protons at δ0.9 correlates with the methyl carbon at δ19 (CH_3-11); the methyl carbon at δ26 correlates with the protons at δ1.2 (CH_3-12). Tracing the spin system through the ^{1}H–^{1}H and ^{1}H–^{13}C COSY spectra reveals the proton assignments δ1.4 (H-1), δ1.95 (H-2), δ1.65 (H-3, H-8 and H-10), δ3.0 (H-4), δ1.15 (H-9), and the correlated carbon assignments δ29 (C-2), δ40 (C-3), δ60 (C-4), δ36 (C-8), δ34 (C-9), δ69 (C-10). The remaining three carbons are assigned δ26 (C-12), δ65 (C-6), and δ68 (C-7) from DEPT spectra. The C-6 geminal protons are assigned δ2.70 (H_{eq}-6) and δ1.65 (H_{ax}-6); their COSY cross peak is prominent. The hydroxyl proton occurs at δ3.40.

Stereochemical studies of this compound were focused on C-1, C-4, C-7, C-10, and the nitrogen atom. The strong IR bands at 2952 cm^{-1} support the *trans*-quinolizidine system that defines the stereochemistry of C-10 and the nitrogen atom (Bohlmann, 1958), and its large size requires that the furyl group be equatorial (LaLonde and Wong, 1977). The presence of an H-10 H-11 NOESY cross peak and the absence of CH_3-11-furyl cross peaks demonstrated that the

CH_3-11 methyl group is equatorial. The NOESY cross peak of the C-7 methyl and the furyl H-16 proton suggests that the methyl is axial and confirms that the furyl group is equatorial. Thus, we conclude that compound **1** is nupharolutine.

6,6′-Dihydroxythiobinupharidine, $C_{30}H_{42}N_2O_4S$ **(2)** (Figure 1), was isolated as glasslike crystals. The IR spectrum resembles that of **1.** The ^{13}C NMR and DEPT spectra support a C_{30} alkaloid structure with 2 methyl (δ19.1, 19.2), 10 methylene (δ44.2, 39.6, 35.0, 34.8, 33.4, 33.3, 32.0, 30.3, 29.1, 28.5), 14 methine (δ143.3, 142.9, 140.0, 139.5, 109.5, 109.5, 84.2, 83.3, 58.5, 57.5, 54.6, 54.3, 37.2, 37.1), and 4 quaternary (δ127.9, 127.8, 63.0, 53.3) carbons. The appearances of both the ^1H and ^{13}C spectra resemble those of C_{15} alkaloids; most peaks appear as doublets, which suggests that this C_{30} alkaloid is a dimer with two C_{15} structural units. The ^1H–^1H COSY spectrum is consistent with the stereoisomeric compounds **(2),** known in the older literature as 6,6′-dihydroxythionuphlutine-A (Cullen et al., 1973) and thionupharodioline, and their sulfoxides. The intense ion peak at *m/e* 230 is a characteristic fragment for most *Nuphar* alkaloids; it indicates the dehydroxyl fragment of the C_{15} unit. Other fragmentations include *m/e* 216 (230 − CH_2), 262 (230 + S), and 248 (216 + S). The corresponding ions containing sulfoxide at *m/e* 278 (230 + SO) and 264 (216 + SO) are not present, indicating the isolated product is not a sulfoxide (Wrobel et al., 1972b). The two methyl carbons at δ19.1 and 19.2 (C-11 and C-11′) are assigned from the DEPT spectrum. Their chemical shifts are about 5.7 ppm downfield from that of axial methyls and thus give a clear indication of the equatorial disposition of these methyls (LaLonde and Wong, 1975). The attached protons at δ0.91 (H-11 and H-11′) are assigned from the ^1H–^{13}C COSY spectrum. Tracing the spin systems starting from the methyl protons on the ^1H–^1H COSY spectrum, the proton assignments are found to be: δ1.35 (H-1, H-1′), 1.10–1.35 (H-2, H-2′), 1.6 (H-3, H-3′), 3.6–3.7 (H-4, H-4′), 1.65 (H-8, H-8′), 1.88 (H-9, H-9′), and 2.3 (H-10, H-10′). The attached carbons are revealed from the ^1H–^{13}C COSY spectrum as: δ37.1 and 37.2 (C-1, C-1′), 32.0 and 30.3 (C-2, C-2′), 33.3 and 33.4 (C-3, C-3′), 54.3 and 54.6 (C-4, C-4′), 34.8 and 35.0 (C-8, C-8′), 28.5 and 29.1 (C-9, C-9′), and 57.5 and 58.5 (C-10, C-10′). The two hydroxyl protons were assigned to δ2.00 and 2.40 by the absence of their ^1H–^{13}C correlations in the COSY spectrum. The ^1H–^1H COSY spectrum showed the cross peaks of the hydroxyl protons and the adjacent H-6 and H-6′ protons at δ3.98 and 4.23. The corresponding carbons are δ83.3 (C-6′) and 84.2 (C-6) (Cybulski and Wrobel, 1989). Comparison of the chemical shifts of the two protons with known axial–equatorial data (Wrobel, 1977) suggests they are equatorial and the hydroxyl groups are axial. This is supported by the IR bands characteristic of the *trans*-quinolizidine ring system. The isolated compound thus cannot be thionupharodioline, which possesses equatorial hydroxyl groups on both C-6 and C-6′ and does not possess the characteristic *trans*-quinolizidine ring system bands in its IR (Cybulski and Wrobel, 1989).

The two methylene groups, thiomethylene (CH_2-17′ at δ2.20 and 2.70) and isolated methylene (CH_2-17 at δ1.80 and 1.91) are present in the ^1H–^1H COSY spectrum as isolated spin systems with geminal proton cross peaks. The corresponding carbons are assigned with C-17 at δ44.2 and C-17′ at δ39.6.

The thiolane stereochemistry with respect to the attachment of the AB and A′B′ quinolizidine ring systems has been discussed by Lalonde and Wong, whose studies were based on the structure of thiobinupharidine, thionuphlutine, and neothiobinupharidine, alkaloids having quinolizidine ring attachments at CH_2-17 of ax-ax, ax-eq, and eq-eq, respectively (LaLonde and Wong, 1977; LaLonde et al., 1974). The C-17 resonance is related to the number of axial and equatorial attachments in which the thiomethylene group is involved. The chemical shift of C-17 is gradually shifted downfield in these compounds: δ45.3, 50.6, and 54.5 ppm, respectively. With a C-17 resonance of δ44.2, our compound belongs to the thiobinupharidine stereochemical family of thiaspirane *Nuphar* alkaloids, and it is 6,6′-dihydroxythiobinupharidine **(2).**

In order to compare the activity of a known allelopathic compound in our

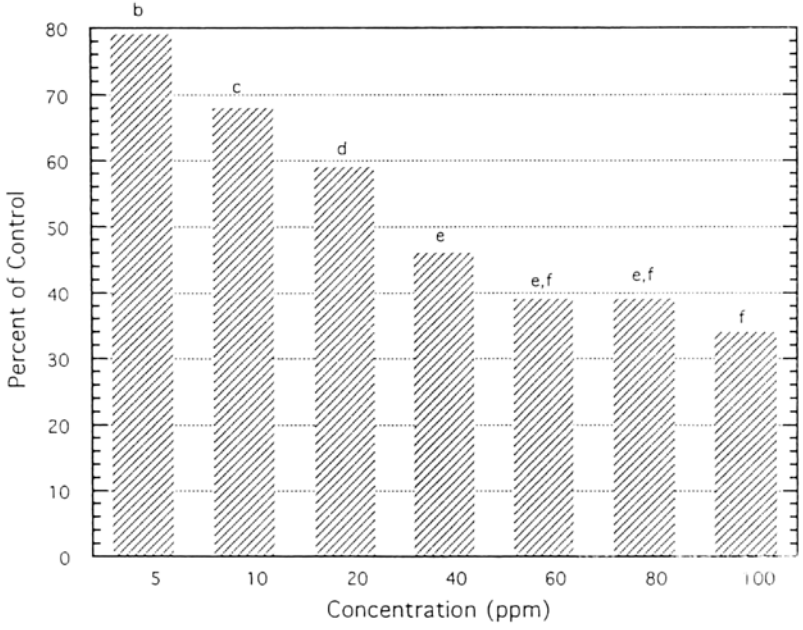

FIG. 2. Bioassay of the known allelopathic compound *dl*-2-aminoadipic acid against lettuce seedling total length (hypocotyls plus radicles). Bars with the same letter are not significantly different according to the Duncan multiple range test at $P \leq 0.05$; the control was different from all treatments.

assay system, we used commercially available *dl*-2-aminoadipic acid in our lettuce seedling bioassay at concentrations of 5–100 ppm. It exhibited progressive inhibitory effects on lettuce seedling whole-plant growth over this concentration range (Figure 2). Growth was reduced to 34% of the control value at a concentration of 100 ppm of compound.

The mixture of *N. lutea* alkaloids strongly inhibited both lettuce seedling radicles and hypocotyls; the inhibitory effect was more than 10 times that of *dl*-2-aminoadipic acid (Figure 3). Radicles appeared to be more sensitive to the alkaloid mixture than hypocotyls. At a concentration of only 6.0 ppm, the growth for radicles was 39% of the control, while for hypocotyls it was 63% of the control. At very low concentrations, 0.15–0.60 ppm, both hypocotyl and radical growth stimulation was observed, but the stimulation did not meet tests of statistical significance. Growth stimulation at low concentrations has been reported for other allelochemicals (Rice, 1984).

Nupharolutine **(1)**, solubilized in water by the addition of ethanol, showed no growth inhibitory effects toward either lettuce radicles or hypocotyls greater

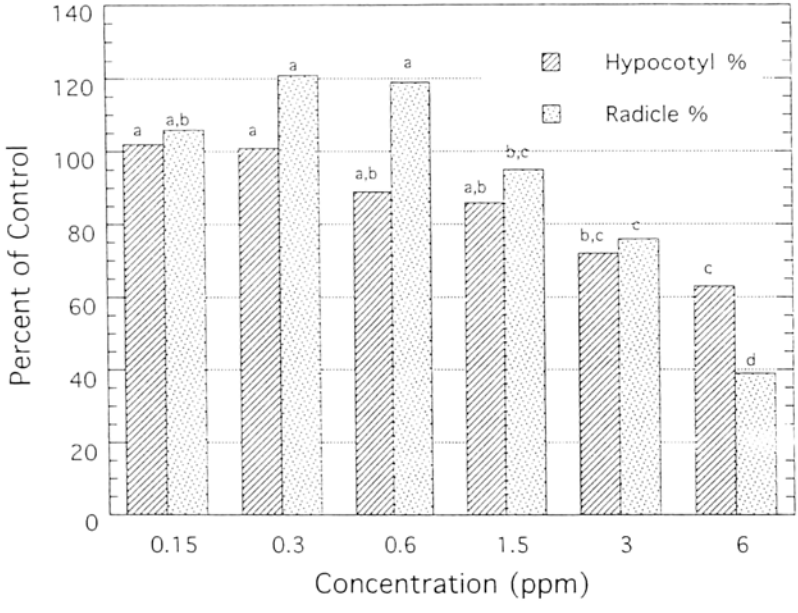

FIG. 3. Bioassay of the crude alkaloid mixture from *N. lutea* against lettuce hypocotyls and radicles. Bars with the same letter (within each assay) are not significantly different according to the Duncan multiple range test at $P \leq 0.05$. The control in the hypocotyl and radicle assays was only different from the crude alkaloid mixture at 3 and 6 ppm.

than those of the ethanol solvent over the range of 1–60 ppm. Nupharolutine is biologically inactive in this testing system. While one might predict that the more important allelopathic compounds from aquatic plants are water-soluble compounds, Fischer and Quijano (1985) described a mechanism by which water-insoluble plant compounds may act as allelochemicals and be transported via micelle formation with long-chain fatty acids.

In contrast to nupharolutine, 6,6′-dihydroxythiobinupharidine **(2)** was twice as inhibitory toward lettuce seedling growth as the crude alkaloid mixture (Figure 4). Radicle growth was reduced to 32, 27, and 17% of the control at concentrations of 1.5, 3.0, and 6.0 ppm, respectively, in one assay. A replicate assay showed no statistically significant inhibition at 1.5 ppm, but growth was reduced to 39% and 34% of the control at 3.0 and 6.0 ppm, respectively. It appears that the concentration 1.5 ppm is near the pivotal concentration between strong inhibition and no inhibition for 6,6′-dihydroxythiobinupharidine **(2).** One assay showed a significant 29% radicle growth stimulation at 0.6 ppm.

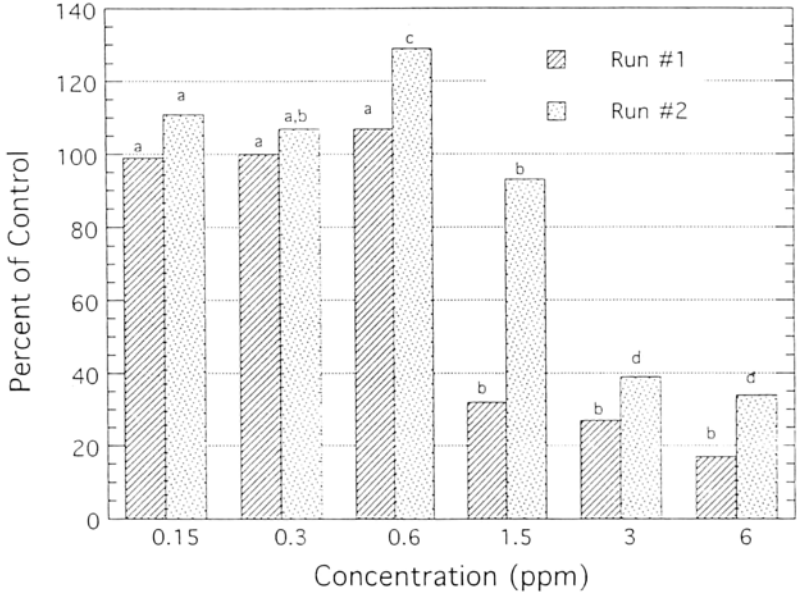

FIG. 4. The bioassay of 6,6′-dihydroxythiobinupharidine with a lettuce radicle assay. Results of replicate runs are shown. Bars with the same letter (within each run) are not significantly different according to the Duncan multiple range test at $P \leq 0.05$. The control in the lettuce radicle assay was different from the inhibitory effect of 6,6′-dihydroxythiobinupharidine at ≥ 3 ppm. At 0.6 ppm the alkaloid was significantly stimulatory in run 2.

Acknowledgments—We are grateful to Dr. Jean W. Wooten for identifying the plant material, locating a population for collection, and for aid in collection. We thank Mr. Dale Suchy for aid in plant collection and processing, and Mr. Brad Taylor for aid in statistical analysis of assay data.

(Received December 29, 1995; accepted July 15, 1996)

Abstract—Resorcinol (1,3-dihydroxybenzene) was identified as one of the major constituents of the exudate of *Nuphar lutea* seedlings, which were raised from seeds and cultivated under axenic conditions. The compound is released from the plants in considerable amounts (up to 15 nmol/seedling/day). Highest rates of resorcinol exudation were measured when the seedlings were incubated under physiological conditions (macronutrient and light supply) that resembled those of natural stands of the plant. An inverse correlation exists between nitrate and/or light supply and resorcinol production. Because of its generally toxic properties, resorcinol is suggested to play a role as an allelochemical in interactions between macrophytes and other organisms of the aquatic ecosystem. A first approach of resorcinol application to zooplankton and phytoplankton organisms resulted in deleterious effects against a *Daphnia* species. Two Cryptophyceae species reduced resorcinol concentration to zero, showing a concomitant increase of the size of starch granule enclosures. Cyanophyceae and Chlorophyceae seemed not to be affected.

Key Words—Exudation, *Nuphar lutea*, Nymphaeaceae, yellow water lily, macrophytes, phytoplankton, zooplankton, phenols, resorcinol, allelochemicals, nitrate, light.

INTRODUCTION

Allelopathy has been suggested to participate in the formation, maintenance, distribution, and succession of terrestrial plant populations (Willis, 1994; Put-

*To whom correspondence should be addressed.

0098-0331/96/1200-2221$09.50/0 © 1996 Plenum Publishing Corporation

nam and Tang, 1986; Rice, 1984; Grodzinsky, 1982). This phenomenon implies the exudation of phytotoxins and/or pretoxins from distinct plant organs (Fischer et al., 1994) and may be considered as a defensive strategy of plants against competitors (Harborne, 1988). For aquatic plants, such mechanisms have often been postulated (Gopal and Goel, 1993; Szczepanska, 1987; Wium-Andersen, 1987; Ostrofsky and Zettler, 1986). Several workers have reported poorly defined compounds, e.g., "complex polyphenolic substances," as exudation products of marine macrophytes (Ragan and Jensen, 1979; Moebus and Johnson, 1974; Hellebust, 1974). Likewise, compounds exuded from several freshwater macrophytes could only roughly be classified as "high" (>1000 Da) or "low" (<1000 Da) molecular weight compounds (Sondergaard, 1981). A recent study, however, proved the existence of a structurally defined polyphenol, eugeniin (1,2,3-tri-*O*-galloyl-4,6-(*S*)-hexahydroxydiphenoyl-β-D-glucose) in extracts and exudates of *Myriophyllum spicatum*, Haloragidaceae (Gross et al., 1996). In bioassays, eugeniin showed particular algicidal properties and was a potent inhibitor of algal exoenzymes, such as alkaline phosphatases (Wetzel, 1993). Among other freshwater macrophytes, *Nuphar lutea* was suspected to possess high allelopathic potential (Elakowich and Wooten, 1991). Because of good germination rates and ready availability of seedlings, this plant seemed to be ideal for laboratory experiments. Moreover, *Nuphar lutea* seedlings were recently shown to exude unknown phenolic compounds in amounts between 0.2 and 1.3 μg phenol/hr g dry weight (Sütfeld, 1993). Here we describe the structural analysis of one of the major constituents of the exudation products and its rate of exudation. A first approach was undertaken to examine the deleterious or beneficial effect of the isolate on some freshwater plankton organisms.

METHODS AND MATERIALS

Cultivation of Seedlings. Seeds of *Nuphar lutea* were harvested from natural stands and vernalized and sterilized as previously described (Sütfeld, 1993). The seeds germinated readily at 20°C. Standard incubation assays consisted of 200 seedlings (up to 16 weeks old) in 800 ml of nutrient solution. A sterile inorganic cultivation medium (Sütfeld, 1993) was modified to contain (mg/liter): Ca^{2+}: 35.0; Fe^{3+}: 0.05; K^+: 0.46; Mg^{2+}: 3.5; Na^+: 46.0; NH_4^+: 0.08; Cl^-: 61.0; HCO_3^-: 122.0; NO_3^-: 0.66; PO_4^{3-}: 0.05; SO_4^{2-}: 14.0, and a mixture of trace elements (Z8) as recommended by NIVA (1986). For special incubation assays, NO_3^- was increased to 93.0 mg/liter; in this case Na^+ was replaced by K^+ (up to 79.0 mg/liter). Cultivation and standard incubation was performed at 20°C and 20 μmol PAR/m^2/sec. Some cultures were germinated and raised in absolute darkness, whereas after germination, other cultures were grown at light intensities up to 900 μmol PAR/m^2/sec. For the latter series, temperature-stabilized

cultivation boxes, equipped with electronic energy-saving light bulbs (Dulux EL, Osram, Germany) were used.

Separation of Exudation Product. The same HPLC equipment as described Sütfeld, (1993) was used with the following alterations: Columns were 4 × 250-mm Spherisorb ODS2, 5 μm (Phase Separations Inc., Norwalk, Connecticut) or LiChrosorb RP18, 5 μm (Merck, Darmstadt, Germany), each equipped with a 4 × 30-mm precolumn (LiChrosorb RP8, 10 μm). Separations were run with H_2O as mobile phase at a flow rate that kept the pressure between 14 and 18 mPa. Aqueous samples from incubation assays were directly applied to HPLC (injection volume 1 ml, using the concentration effect of the ODS2 column); injections of ethanolic samples from compound enrichment were not allowed to exceed 60 μl to keep mobile phase constant (Sütfeld, 1989), and detection of eluted compounds occurred at 281 and 300 nm. After identification of the exudation product, resorcinol (Merck) was used for calibration. Quantitation was performed by peak integration of arbitrary units (AU_{281}). Detector response was linear in the range of 0.1–50.0 nmol/ml; resorcinol content (c) was calculated by $c = 1.79 \times AU_{281}$ (nmol/ml) ($r^2 = 0.996$, $N = 5$). The precision of peak area measurements with repeated injections of the same sample was ±0.8%; statistical analysis was performed using a Statistix version 4.0 package.

Enrichment of Exudation Product. Incubation assays were started by thoroughly rinsing the seedlings with fresh nutrient solution. The formation of the exudation product was monitored by HPLC. At an appropriate time, the nutrient solution was removed and subjected to liquid–liquid extraction: From a given total volume, 250-ml batches each were successively extracted into 300 ml of ethyl acetate (HPLC quality; Merck). The organic phase was then evaporated and the residue was dissolved in ethanol until a clear solution was obtained. Portions of 60 μl were used for HPLC; fractions containing the exudation product were collected. The combined fractions were extracted with ethyl acetate, and the organic phase was evaporated to dryness.

Structural Analysis of Exudation Product. UV spectral data were obtained during peak elution on HPLC by diode-array spectroscopy. TLC was performed on silica gel thin layer plates (Merck) with or without fluorescent indicator. For cochromatography on HPLC and TLC, catechol (1,2-dihydroxybenzene), resorcinol (1,3-dihydroxybenzene), pyrogallol (1,2,3-trihydroxybenzene), and guaiacol (1-hydroxy-2-methoxybenzene) served as reference compounds. TLC (R_f on silica gel, $CHCl_3$–HAc 2:1, water-saturated): pyrogallol 0.44; catechol 0.75; resorcinol 0.61; guaiacol 0.98; exudation product 0.61. All spots were fluorescent blue under UV_{254} and turned pale brownish 2 hr after drying in daylight. HPLC (R_t, λ_{max}): pyrogallol 5.56, 284; catechol 11.27, 284; resorcinol 12.07, 282; exudation product 12.07, 282. Guaiacol ($\lambda_{max} = 281$) did not elute under the given conditions.

^1H and ^{13}C NMR spectra were recorded on a Varian-Gemini 200 instrument

at 199.95 MHz and 50.29 MHz, respectively, in MeOH-d_4 with TMS as internal standard. Chemical shifts are given in δ (ppm). An electron impact (EI) -MS spectrum was obtained with a Finnigan MAT 312 instrument (80 eV). The GC system was a Satochrom GC; cross-linked methylsilicon capillary column (DB-1, J & W scientific) 30 m × 0.32 mm, film thickness 0.25 μm; 150°C–280°C, 3°/min, then isothermally; N_2 34 cm/sec, split 1:20, injection volume 0.6 μl, injector 250°C, FID 290°C. Resorcinol was derivatized to its TMS ether using BSTFA and TMCS. EI-MS *m/z* (rel. int. %): 110 (100), 82 (80), 81 (46), 53 (60). ^{1}H NMR: δ 6.23–6.28 (H-2, H-4, H-5, m, 3 H), 6.94 (H-5, t, 1H). ^{13}C NMR: δ 103.3 (C-2), 107.7 (C-4/C-6). 130.8 (C-5), 159.6 (C-1/C-3).

Estimates of Dry Weight and NO_3^-. Dry weight of seedlings was estimated as previously described (Sütfeld, 1993); for NO_3^- estimation the Spectroquant assay (Merck) was applied, using KNO_3 solution for calibration.

Resorcinol Application Experiments. These were performed on zooplankton and phytoplankton species that were routinely subcultured in the institute. Resorcinol (Merck) was added to a *Daphnia magna* culture (about 100 individuals/500 ml) and to several algae cutlures (about 10^5 individuals/ml) in a final concentration of 25 nmol/ml. During incubation, the resorcinol content was estimated by quantitative HPLC; the fitness of algae cultures was observed by light microscopy. Untreated cultures served as control.

RESULTS

EI-MS and NMR Data. The ^{1}H NMR spectrum of the exudation product in MeOH-d_4 exhibiting a triplet at δ 6.94 and three overlapping aromatic signals at δ 6.23–6.28 and a molecular weight of 110 (EI-MS) suggested resorcinol (1,3-dihydroxybenzene). The ^{13}C NMR spectrum was consistent with the proposed structure. All spectral data, TLC, HPLC, and a GLC of the isolate were in full agreement with authentic material.

Influence of Nitrate on Resorcinol Exudation. Under standard incubation conditions (0.66 mg NO_3^-/liter), resorcinol was, over the time range of observations, continuously being exuded from a batch of 200 seedlings with a linear production rate of approx. 3 μmol/day, resulting in a resorcinol concentration of 20 ± 1 nmol/ml within seven days. Increasing the NO_3^- content of the medium >5.0 mg/liter led to a reduced production rate. Figure 1 shows the kinetics after transferring the seedlings into nutrient solutions containing either 23 or 93 mg NO_3^-/liter. This lowered the resorcinol production rate to approx. 2 or 1 μmol/day, respectively. Under these conditions, the seedlings consumed NO_3^- at an average rate of 5 mg/day. When seedlings were preincubated for some days in medium of high (93 mg NO_3^-/liter) nitrate content, the resorcinol production dropped to zero. When these cultures were transferred into medium

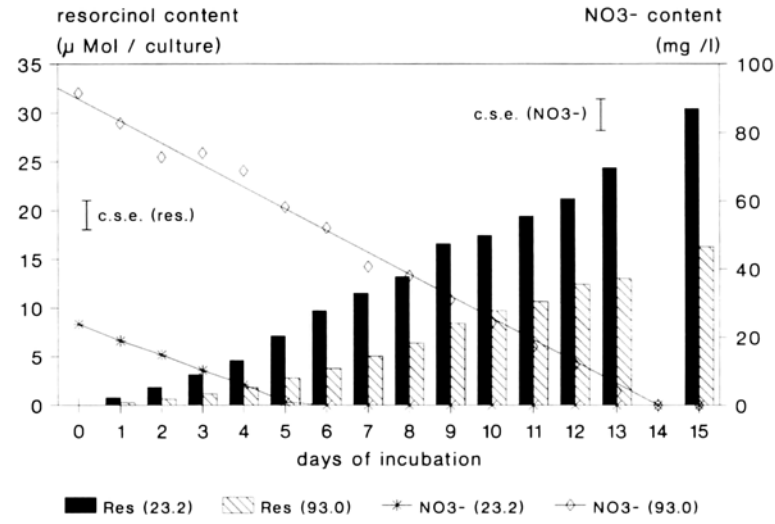

FIG. 1. Resorcinol and NO_3^- contents of nutrient solutions of *Nuphar* seedlings (preincubation in 0.66 mg/ml NO_3^- containing solution) after transfer into solutions containing 23.2 or 93.0 mg NO_3^-/liters. C.s.e., mean values ± common SE. There were five replicates per incubation series.

of lower NO_3^- content (69.9–0 mg/liter, Figure 2), resorcinol production started again, but at a remarkably reduced rate (up to 0.5 μmol/day). Under these conditions, the NO_3^- consumption was likewise reduced, averaging 0.125 mg/day.

Influence of Light on Resorcinol Exudation. When cultivated in the dark and with low (0.66 mg/liter) NO_3^- supply, seedlings of the same age produced amounts of resorcinol that were comparable to those incubated under standard conditions (20 μmol PAR/m^2 sec, Table 1). After increasing the NO_3^- concentration to 46 mg/liter, resorcinol exudation of the "dark" cultures decreased, as was observed for illuminated cultures. Under high light (900 μmol PAR/m^2 sec), resorcinol production stopped, independent of the NO_3^- supply. In contrast to resorcinol production, the amount of other compounds released [so-called "highly polar (HP) fraction"; Sütfeld, 1993] was obviously positively correlated to light supply. Under strong illumination, release of these highly polar compounds was dramatically enhanced, independent of the NO_3^- supply.

Effect of Resorcinol on Some Plankton Organisms. As shown in Table 2, resorcinol (25 nmol/ml) caused death of a *Daphnia magna* culture within five days. During this time, about 7% of the resorcinol added disappeared from the nutrient solution. No morphological effects or disappearance of resorcinol were

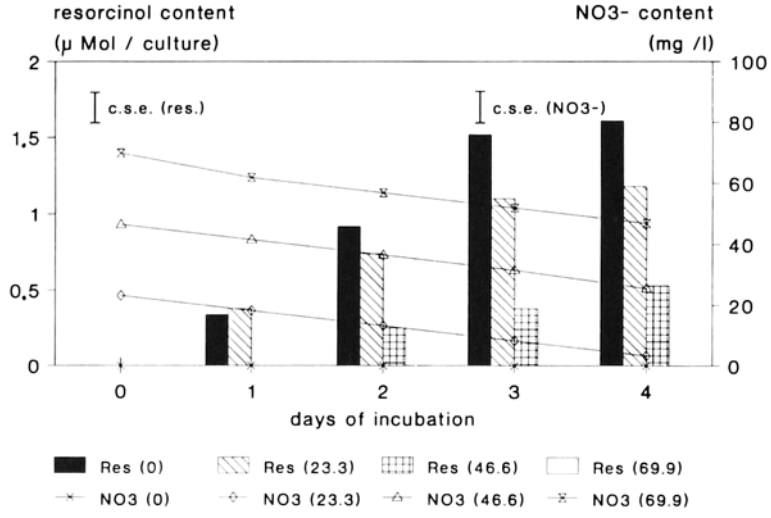

FIG. 2. Resorcinol and NO_3^- contents of nutrient solutions of *Nuphar* seedlings (preincubation in 93.0 mg/ml NO_3^- containing solution) after transfer into solutions containing 0, 23.2, 46.6, or 93.0 mg NO_3^-/liter. There were five replicates.

TABLE 1. INFLUENCE OF LIGHT AND NO_3 ON PRODUCTION OF RESORCINOL AND UNIDENTIFIED PRODUCTS (HPF)

NO_3 (mg/ml)	PAR (μmol/m^2/sec)	HPF (AU)[a]	Resorcinol produced (μmol/culture day)
0.66	20	2.38	1.04[b]
0.66	0	1.50	0.81[c]
46.0	0	3.43	0.12[c]
23.2	20	5.32	0.35
46.0	20	3.39	0
0.66	900	11.57	0
46.0	900	10.91	0

[a] HPF: highly polar fraction, R_t < 4 min; AU: arbitrary units from peak integration on HPLC.
[b] Standard incubation.
[c] Seedlings germinated and raised in absolute darkness.

TABLE 2. EFFECT OF RESORCINOL (25 nmol/ml) ON SOME PLANKTON ORGANISMS

Organism	Length of incubation (days)	Resorcinol uptaken/degraded (%)	Visible effect
Daphnia magna	5	7	death of all organisms
Chlamydomonas sp.	7	0	no effect
Scenedesmus acutus	7	0	no effect
Anabaena sp.	7	0	no effect
Cryptomonas sp.	5	100	s.g.[a]
Rhodomonas sp.	6	100	s.g.[a]

[a] Starch granules increasing in size.

observed on *Chlamydomonas*, *Scenedesmus*, or *Anabaena* cultures within seven days. When administered to *Cryptomonas* or *Rhodomonas* cultures, resorcinol disappeared completely from the nutrient solution within five or six days. During that time, a conspicuous increase in size of white compartments within the cells, supposedly starch granules, was observed.

DISCUSSION

This is, to our knowledge, the first report on the release of nonderivatized resorcinol from a higher plant and the first evidence for exudation of a structurally defined phenol from an undisturbed aquatic macrophyte. It is not known at present whether resorcinol is produced and stored unbound or whether it is liberated from a precursor, e.g., a glycoside.

1,3-Dihydroxy derivatives of benzene and more complex aromatic ring systems (resorcinylic compounds) are widespread products of plant and microbial metabolism (Harborne and Simmonds, 1964; Chapman and Ribbons, 1976). Hegnauer (1990) mentioned the occurrence of resorcinol in the heartwood of *Artocarpus* and *Morus* (Moraceae) species. Alkylated resorcinylic compounds have been reported for tissues of several *Ononis* (Leguminosae) species (Barrero et al., 1994 and references therein) and for the peel or flesh of mango fruits (Droby et al., 1987 and references therein). In the latter case, the accumulation of resorcinol derivatives is considered as a defensive response of the plants against bacterial infection. Release of 5-(12-heptadecenyl)-resorcinol in root exudates of *Oryza* plants was recently demonstrated by Bouillant et al. (1994).

We tried to adapt the physiological conditions for cultivation of *Nuphar* seedlings in the laboratory to those of the natural environment. The results of preliminary experiments showed that vernalization was necessary for germination and that germination could be induced by increasing temperature, in agreement with the findings of Smits et al. (1990) for various Nymphaeaceae. This suggests that germination of *Nuphar* seeds in natural stands takes place when the water temperature exceeds 15°C in the spring. Data for photoactive radiation, obtained from the Schöhsee lake (source of *Nuphar* used here), showed that the PAR under natural *Nuphar* stands, when measured at reasonable depths (1–2 m) on the lake bottom, averages between 5 and 20 μmol/m^2/sec (Ho, 1979; Rai, personal communication, 1995). During this season, the NO_3^- supply of the Schöhsee ranges below 5 mg/liter. This suggests that *Nuphar* seedlings, if rooted in appropriate natural places, should exude resorcinol in a manner similar to laboratory cultures.

Initially, the correlation of low light and/or low NO_3^- supply with high resorcinol production seems to be paradoxical. However, poor environmental conditions may enhance the defensive response of the plants and *vice versa*. These observations are in good agreement with those from studies of terrestrial plants that grow in arid, nutrient-limited regions. Several observations made under arid conditions suggest that nutrient limitation intensifies the allelopathic action of exuded toxins or pretoxins (Williamson et al., 1992; Fischer et al., 1994).

Resorcinol has antiseptic and membrane-affecting properties (The Merck Index, 1983), and its exudation may provide environmental benefits for *Nuphar* seedlings. In contrast to terrestrial locations, allelochemicals exuded from macrophytes into the aquatic environment may be diluted and transported more efficiently to microbes, plants, and animals of their surroundings.

A variety of microorganisms have the enzymatic equipment, i.e., catechol-1,2-oxygenase (Neujahr and Varga, 1970; Shailubhai et al., 1982; Paller et al., 1995) or catechol-2,3-oxygenase (Kachhi and Modi, 1976), to oxidize orthodihydroxybenzene derivatives such as catechol. The quinonoid intermediates produced can undergo a subsequent enzymatic ring cleavage that leads to harmless products. In addition, ortho-substituted benzene derivatives undergo spontaneous oxidation under the influence of UV light in the natural environment (Appel, 1993). However, this does not seem to occur with metadihydroxybenzenes such as resorcinol; biochemical degradation of this compound appears to be limited to a small number of microbial specialists only. Yeasts are able to metabolize resorcinol by anaerobic fermentation (Tschech and Schink, 1985), whereas other fungi degrade resorcinol by enzymatic hydroxylation. In the latter case, pyrogallol (1,2,3-trihydroxybenzene) or hydroxyquinol (1,2,4-benzenetriol) is formed as an intermediate, followed by ring cleavage (Groseclose and Ribbons, 1981; Shailubhai et al., 1983). Organisms that lack 1,3-dihydroxy-

benzene hydroxylases may accumulate resorcinol in the tissues, which may, therefore, quickly reach toxic levels.

The detection of resorcinol as an exudation product of *N. lutea* gives reason to study its ecological significance in freshwater systems. The results shown in Table 2 originated from a preliminary study in which resorcinol was applied to a zooplankton organism (*Daphnia magna*) and to several phytoplankton organisms (*Chlamydomonas, Scenedesmus, Anabaena, Cryptomonas*, and *Rhodomonas*) in a similar concentrations as produced by *Nuphar* seedlings in the previous experiments. The specificity found was surprising: A toxic effect against *Daphnia* was observed, but no effect was observed on the Chlorophyceae or the Cyanophyceae species. Cryptophyceae reduced resorcinol concentration to zero, showing a concomitant increase in the size of their starch granules. This suggests that they might have the enzymatic equipment to metabolize it. These first results suggest that resorcinol acts as an allelochemical in an aquatic medium and may be specifically directed against or beneficially used by other organisms. Investigations on these questions are in progress.

It might be argued that small amounts of an allelochemical exuded into a natural lake waterbody would have little effect on other organisms because of high dilution. Recent observations with terrestrial plants, however, suggest that a "constant flux of allelochemicals. . . , if continually taken up by target species . . . may have significant deleterious effects" (Weidenhamer et al., 1994). This is especially true for the aquatic situation.

Acknowledgments—The help of Dr. D. Bergenthal (Münster, Germany) for recording the NMR spectra, and Dr. H. Luftmann (Münster) for the EI-MS spectrum is gratefully acknowledged. Thanks are due to Mrs. U. Liefländer-Wulf (Münster) for running the GC and Prof. D. S. Seigler (Urbana, Illinois) for linguistic advice.

(Received February 15, 1996; accepted July 15, 1996)

Abstract—Female cowpea weevils, *Callosobruchus maculatus*, produce a sex pheromone that elicits orientation and sexual behavior in males. Bioassay-directed isolation of the sex pheromone was conducted and compounds in the active fraction were identified and synthesized. Volatiles were collected from individual virgin females by adsorption on filter paper discs and hexane extraction. A bioassay was used in which the locomotory response of single males in glass vials was recorded upon exposure to treatments or controls. Crude extracts were subjected to silica gel column chromatography with solvents of increasing polarity; all activity eluted with methanol. Activity in the highly polar methanol fraction suggested a carboxylic acid or a compound with multiple polar functionality. Acid-base partitioning of the crude extract isolated all activity in the acid fraction, confirming that the pheromone was a carboxylic acid. The acid fraction was further fractionated by preparative GC with a Carbowax column. The most active GC fraction contained the following five 8-carbon acids identified by GC-MS and comparison with synthetic can-

didates: 3-methyleneheptanoic acid, (*Z*)-3-methyl-3-heptenoic acid, (*E*)-3-methyl-3-heptenoic acid, (*Z*)-3-methyl-2-heptenoic acid, and (*E*)-3-methyl-2-heptenoic acid. Each of the synthetic acids was active individually for males, and combinations of two or more of the acid pheromones had an additive effect. Upwind flight responses to natural and synthetic pheromones were observed in a flight tunnel. (*Z*)-3-Methyl-2-heptenoic acid was previously identified as the sex pheromone for the related *C. analis*, but this and the other four acid pheromones from *C. maculatus* were inactive for male *C. analis*. There was no cross-attraction between *C. maculatus* and *C. analis* in reciprocal studies using extracted volatiles from females of both species. GC-MS analysis of *C. analis* female volatiles failed to detect any of the *C. maculatus* compounds but did find an unidentified C-8 acid with a GC retention time different from any of the *C. maculatus* pheromones.

Key Words—Carboxylic acids, Leguminosae, pulses, stored products, seed weevils, *Callosobruchus maculatus*, Coleoptera, cowpea weevil.

INTRODUCTION

The cowpea weevil, *Callosobruchus maculatus* (F.), is a serious cosmopolitan pest of stored dried pulses (seeds of Leguminosae). *C. maculatus* larvae feed inside dried seeds, and adults can disperse and infest pulses both in storage and in the field prior to harvest. Among major stored-product pests, *C. maculatus* remains one of the few for which a sex pheromone has not been identified for use in pest-management programs (Burkholder and Ma, 1985; Phillips, 1996). Evidence for the presence of a sex pheromone in *C. maculatus* was reported by Rup and Sharma (1978), and Qi and Burkholder (1982) documented the biology associated with female calling and sex pheromone production. The objective of the current study was to isolate and identify the sex pheromone or pheromones from female cowpea weevils. In the course of these studies, we also examined the sex pheromone of the closely related *C. analis* by performing cross-attraction experiments with collected volatiles and with synthetic pheromones.

METHODS AND MATERIALS

Insects and Collection of Volatiles. C. maculatus were maintained in laboratory cultures that originated from a commercial infestation in Madison, Wisconsin. *C. analis* were procured from a laboratory culture maintained at the USDA ARS Stored-Product Insects Research and Development Laboratory in Savannah, Georgia. Both species were reared on garbonzo beans, *Cicer arietinum* L., at 12% moisture content, 27 ± 2°C, 60 ± 5% relative humidity, with a 16 L:8 D photoperiod using methods of Qi and Burkholder (1982). Newly emerged unmated adults were separated by sex and maintained under the above

environmental conditions. Males were held singly for bioassay in capped 1.5-dr glass vials with 11.0-mm filter paper discs on the floor for footing.

Preliminary studies of air entrainment of volatiles from groups of female *C. maculatus* using adsorbents such as Porapak and Tenax (e.g., Byrne et al., 1975) resulted in extracts with relatively low pheromonal activity. Volatiles were thus collected from individual females by adsorption on 11.0-mm-diam. filter paper discs (Schleicher and Schuell, Keene, New Hampshire). Single newly emerged female beetles were placed with a host seed in corked shell vials that had a single filter paper disc on the floor and a second disk suspended 15 mm above the floor. The suspended disc was impaled on a stainless steel pin that was driven through the middle of the cork stopper of each vial. Up to 100 single-female vial preparations were set up daily and maintained for seven days under the above environmental conditions, after which the filter paper discs were removed and pooled in approximately 100 ml of HPLC-grade *n*-hexane for extraction over a minimum of 24 hr. Extracts were accumulated and stockpiled for several weeks at −20°C until processed. The quantity of pheromone in extracts was expressed as female-day equivalents (FDEs), which represents the amount of pheromone produced by a single female in one day. Thus a hexane extract of volatiles collected from 100 females over a seven-day period would contain 700 FDEs. Total extracts of 5000–30,000 FDEs were used in most isolation procedures. Prior to bioassay or purification extracts were filtered through silanized glass wool, the filter paper discs were given an additional rinsing with another 100 ml of *n*-hexane, and their volumes were reduced under a gentle stream of N_2 to a concentration of about 1.0 FDE/μl. Volatiles from female *C. analis* were collected in the same way as those from *C. maculatus*.

Bioassays. Male beetles of both species that were 3 to 8 days old were used in a simple no-choice vial bioassay (Qi and Burkholder, 1982) to detect pheromone activity during isolation and identification. The vial bioassay involved scoring the locomotory response of a single male in a 1.5-dr glass vial that was exposed to a stimulus on a suspended filter paper disc for 60 sec. Test stimuli were applied to 11.0-mm-diam. filter paper discs in 1.0 μl of hexane, or 1.0 μl of hexane only was applied as a control; 30 sec were allowed for evaporation of solvent before the discs were introduced to test vials. A test disc was attached to the end of a 11-mm-diam. aluminum rod with double-faced tape, and the rod was lowered into the male-containing vial to a point at which the disc was 1 cm above the floor of the vial. Up to four separate vial assays were conducted simultaneously so that responses to various test material and controls could be compared. Males were scored as either not responding or as demonstrating one of three levels of positive response; thus one of four response categories could be assigned. A category 1 response was scored when a male became active within 1 sec of stimulus introduction, ran on the floor of the vial, jumped or flew up to the disc, and typically remained on the disc for the 60-sec duration

of the test, during which copulation behavior was sometimes displayed. A category 2 response was when locomotion and searching occurred during the first 1–5 sec following stimulus introduction. The lowest level of positive response, category 3, was assigned when males began walking and actively searching around the bottom of the vial within 6–60 sec after introduction of the stimulus. A nonresponding male, category 4, typically remained quiescent on the bottom of the vial for the duration of the assay, however, antennal movement was noted because such materials would sometimes prove active at higher concentrations. Each experimental stimulus was assayed against 10–20 different males. Statistical analysis was not done during isolation of the pheromone, as responses were clearly all negative or all positive in one category. When comparing bioassay results of different materials that elicited positive responses, we employed Fisher's exact test (SAS, 1989) to discern differences in response.

Flight responses of 3- to 7-day-old unmated *C. maculatus* males to natural and synthetic pheromones were studied in a wind tunnel composed of 6-mm Plexiglas, very similar to one used by Bartelt et al. (1990), that was 127 cm long × 62 cm high × 61 cm deep. Flight assays were conducted between 09:30 and 14:00 hr under fluorescent lighting in a room maintained at 28°C and 50% relative humidity. Room air was drawn through the tunnel at 8.0 cm/sec, entrained to a laminar flow at the upwind end by passage through a 20-mesh stainless steel screen, and exhausted out of the room. Groups of five male beetles were assayed at a time by releasing them at the downwind end of the tunnel from a 6-cm-diam. Petri dish suspended 26 cm above the floor of the tunnel. Volatiles to be tested were presented on 11-mm-diam. filter paper discs that were impaled on a pin and suspended 26 cm above the tunnel floor at the upwind end. A 28-cm paper circle directly below the odor source on the floor of the tunnel served as a proximity target area for flying insects. Individual flight assays were conducted for 10 min, during which insects were scored for taking flight from the release point, approaching the target within 14 cm (at or past the proximity target), and contacting the source of attractant. We ran a control assay with hexane between each assay with synthetic or natural pheromones.

Instrumentation. Analytical capillary GC was performed on a Hewlett Packard 5890 gas chromatograph equipped with a splitless injector, fused silica column, and a flame ionization detector (FID). Initial column head pressure was 21 psi (1.45 kg/cm^2). Capillary GC analyses were carried out on one of two DB-1 columns (methyl silicone, 0.25-μm film thickness, bonded phase, narrow bore fused silica column, J & W Scientific); for the 30-m × 0.25-mm column, the temperature program was 60°C (1 min), 5°C/min, 210°C (30 min), and for the 50-m × 0.25 mm column, the temperature program was 45°C (1 min), 4°C/min, 200°C (30 min). Both capillary and makeup gases for capillary GC work were nitrogen.

Semipreparative scale column GC fractionation was performed on a Varian 2700 Aerograph instrument. Initial fractionation was done with a 5% OV-101

(Applied Science) on Chromosorb WAW-DMCS 100–120 mesh, 3-m × 7.5-mm-OD glass column. Isolation was ultimately carried out on a 4% Carbowax 20 M (Supelco) on chromosorb G (HP 80–100 mesh, Supelco), 6-m × 6-mm-OD glass column. Both carrier and makeup gases were nitrogen. All GC fractions were collected in glass capillary tubes (3 mm × 30 cm) using a Brownlee-Silverstein thermal gradient collector (Brownlee and Silverstein, 1968).

Mass spectra were obtained with a Finnigan 4500 automated gas chromatography/EI-CI mass spectrometer system (GC-MS). All spectra were obtained at 70 eV. NMR spectra were obtained using a Bruker AMX-300 instrument. All spectra were run in $CDCl_3$; chemical shifts are given in parts per million relative to tetramethylsilane.

Isolation and Analysis. Crude extracts of female *C. maculatus* were concentrated by fractional distillation through a Vigreaux column (17.5 in.). The concentrated extracts were chromatographed on a 150 × 7-mm-OD silica gel column (200–400 mesh, 60 Å) initially using a solvent system of 100% hexane, a mixture of 75% hexane and 25% ethyl acetate, 100% ethyl acetate, and lastly 100% methanol. The second solvent system we employed began with a 1:1 mixture of ethyl acetate and hexane, with subsequent fractions containing 5%, 10%, 20%, 40%, 80% methanol, with the last solvent being 100% methanol. Ten 1-ml fractions were collected from each solvent elution, concentrated under nitrogen, and submitted for bioassay. Results (below) suggested the pheromone was highly polar, possibly composed of alcohols or acids.

To pursue the possibility of an acid pheromone, we subjected a crude female volatiles extract to acid–base partitioning (Figure 1). The concentrated extract was treated with saturated sodium bicarbonate to yield fraction 1 and an aqueous phase. The aqueous solution was extracted with methylene chloride to

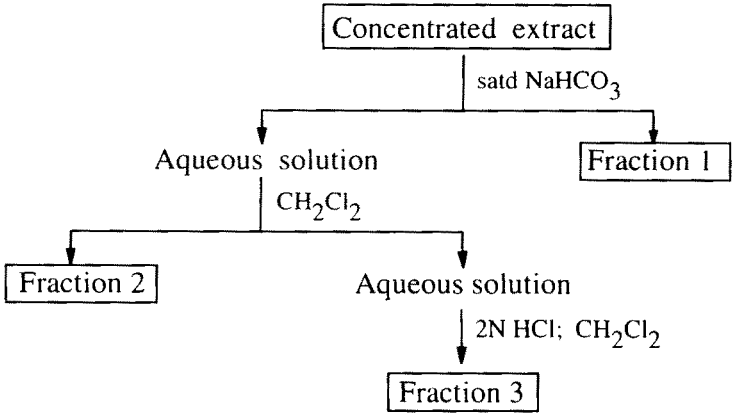

FIG. 1. Acid–base partitioning of crude volatiles extract from female *C. maculatus*.

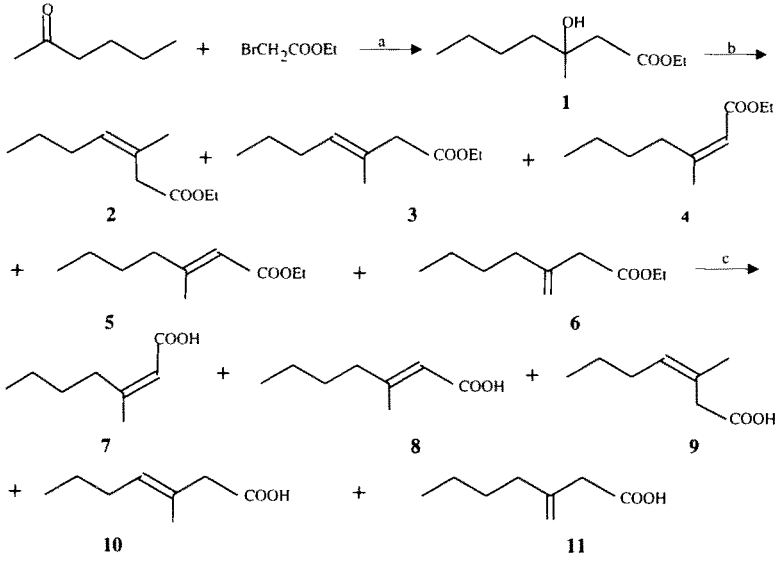
remove polar, nonacid compounds, giving fraction 2. The remaining aqueous phase was acidified with dilute hydrochloric acid and extracted with methylene chloride to yield fraction 3. All fractions were retained for bioassay.

We used a semipreparative-scale, packed column GC fractionation on Carbowax 20 M to isolate the activity from the acidic fraction 3. The temperature program was 45°C (1 min), rising at 4°C/min to 200°C (30 min). Seven subfractions were taken at 10-min intervals and were tested in our bioassay. Because the total amount of material in the active fraction was too small for NMR experiments, no further isolation work was done.

GC-MS analysis of the active Carbowax 20 M fraction revealed a series of methyl-branched heptenoic acids. Because (*Z*)-3-methyl-2-heptenoic acid was reported as a sex pheromone of a related bruchid pest, *C. analis* (Cork et al., 1991), we undertook the synthesis of the α,β-unsaturated and the β,γ-unsaturated 3-methylheptanoic acids.

Syntheses. Two routes were employed to synthesize the branched heptenoic acids. One route was based on the Reformatsky reaction (Hauser and Breslow, 1955). Ethyl 3-hydroxy-3-methylheptanoate was made in high yield from 2-hexanone by way of the Reformatsky reaction with ethyl bromoacetate (Figure 2). Dehydration was carried out nonselectively, and the mixture of α,β- and



a. Zinc turnings, Benzene, reflux; b. $SOCl_2$, pyridine, 110 °C; c. KOH - EtOH, 70 °C.

β,γ-unsaturated esters was separated into individual esters by semipreparative packed column GC fractionation. Finally, the esters were saponified to give the unsaturated acids.

Ethyl 3-Hydroxy-3-methylheptanoate ***(1).*** Zinc turnings (4.6 g, 70 gatm) were added to a solution of 2-hexanone in dry benzene (30 ml). One tenth of a solution of ethyl bromoacetate (12.5 g, 75 mmol) in dry benzene (30 ml) was added to the above mixture. The mixture was warmed until the reaction started, and the remainder of the bromoester was added slowly. After addition, the reaction mixture was refluxed for 3 hr. The reaction was quenched with ammonium hydroxide. The organic layer was washed with brine and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was distilled (62–64°C, 0.4 mm Hg) to yield 11.2 g (84% of a colorless liquid) of compound **1.** ^{1}H NMR (300 MHz): δ (ppm) 0.87 (t, 3 H, CH_3), 1.19 (s, 3 H, CH_3), 1.24 (t, 3 H, CH_3), 1.26–1.60 (m, 6 H, 3 CH_2), 2.36–2.49 (Dd, 2 H, CH_2COO), 3.41 (Bs, 1 H, OH), 4.10–4.17 (q, 2 H, OCH_2). ^{13}C NMR (75.5 Mhz): δ (ppm) 13.9, 14.1, 23.1, 26.1, 26.6, 41.8, 44.9, 60.4, 70.9, 172.9.

Unsaturated Esters ***(2–6).*** Freshly distilled thionyl chloride (2.24 g, 18 mmol) was added dropwise to a solution of compound **1** (2.82 g, 15 mmol) in pyridine with cooling by an ice bath. After the addition was complete, the reaction mixture was heated to 110°C for 1 hr. The mixture was diluted with ether, washed with dilute hydrochloric acid, and the organic phase was dried over anhydrous sodium sulfate. After removal of the solvent, the dark residue was decolorized by elution through a short silica gel column (270 mm × 21 mm OD) with 15% ethyl acetate in hexane. After removal of the solvent, the residue was distilled (85–95°C, 2 mm Hg) to yield 1.38 g (54%) of mixed unsaturated esters **(2–6).** The mixture was subjected to semipreparative-scale packed column GC fractionation to separate pure individual esters. The temperature program was 80°C (10 min), 4°C/min, 230°C (30 min). The NMR data for the unsaturated esters are given below.

The configuration of compounds **4** and **5** were determined from the chemical shifts of methyl groups attached to the carbon–carbon double bond (Silverstein et al., 1991). The chemical shift of the methyl group of compound **4** was at δ ppm 1.86, which corresponded to the *Z* configuration, while that of compound **5** was at δ ppm 2.13, which corresponded to the *E* configuration. The configurations of compounds **2** and **3** were assigned by comparison of their ^{1}H NMR spectra with literature spectra of related 3-unsaturated acids (Cork et al., 1991) and esters (Camps et al., 1987).

Ethyl (3Z)-3-Methyl-3-heptenoate ***(2).*** ^{1}H NMR (300 MHz): δ (ppm) 0.89 (t 3 H, CH_3), 1.18–1.44 (m 5 H, CH_2, CH_3), 1.78 (q, 3 H, $=CCH_3$), 1.94–2.04 (Dq, 2 H, $CH_2C=$), 3.03 (s, 2 H, $=CCH_2COO$), 4.08–4.17 (q, 2H, $COOCH_2$), 5.34 (Dt, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.7, 14.1, 22.7, 23.8, 30.2, 37.6, 60.4, 128.0, 129.0, 171.5.

Ethyl (3E)-3-Methyl-3-heptenoate **(3).** ^{1}H NMR (300 MHz): δ (ppm) 0.89 (t, 3 H, CH_3), 1.18–1.44 (m, 5 H, CH_2, CH_3), 1.68 (s, 3 H, $=CCH_3$), 1.96–2.05 (q, 2 H, $CH_2C=$), 2.97 (s, 2 H, $=CCH_2COO$), 4.13 (q, 2 H, $COOCH_2$), 5.28 (Dt, 1 H, =CH).

Ethyl (2Z)-3-Methyl-2-heptenoate ***(4).*** ^{1}H NMR (300 MHz): δ (ppm) 0.91 (t, 3H, CH_3), 1.23–1.50 (m, 7 H, 2 CH_2, CH_3), 1.86 (q, 3 H, $=CCH_3$), 2.61 (t, 2H, $CH_2C=$), 4.08–4.17 (q, 2 H, $COOCH_2$), 5.63 (m, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.9, 14.3, 22.8, 25.1, 30.3, 33.1, 59.3, 116.1, 160.5, 166.3.

Ethyl (2E)-3-Methyl-2-heptenoate ***(5).*** ^{1}H NMR (300 MHz): δ (ppm) 0.89 (t, 3 H, CH_3), 1.22–1.49 (m, 7H, 2 CH_2, CH_3), 2.11 (t, 2 H, $=CCH_2$), 2.13 (s, 3 H, $=CCH_3$), 4.07–4.16 (q, 2 H, $COOCH_2$), 5.63 (t, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.7, 14.2, 18.6, 22.2, 29.5, 40.6, 59.3, 115.5, 160.0, 166.8.

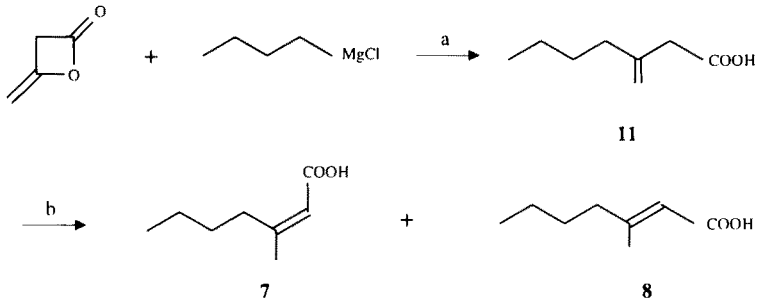
Ethyl 3-Methyleneheptanoate ***(6).*** ^{1}H NMR (300 MHz): δ (ppm) 0.90 (t, 3 H, CH_3), 1.21 (t, 3 H, CH_3) 1.25–1.49 (m, 4 H, 2 CH_2), 2.11 (t, 2 H, $=CCH_2$), 3.03 (s, 2 H, $=CCH_2COO$), 4.14 (q, 2 H, $COOCH_2$), 4.90 (Dd, 2 H, $=CH_2$).

Unsaturated Acids ***(7–11).*** Potassium hydroxide (0.98 g) was dissolved in water (2.1 ml) and diluted with EtOH (6 ml). Each isolated ester (**2–6,** the amount of each ranged from 5 to 100 mg) was dissolved in 1 ml of the KOH solution. The reaction mixture was kept at 70°C for 4 hr. After removal of the ethanol by a nitrogen stream, water was added to the residue and the mixture was extracted with ether. The remaining aqueous solution was acidified with 3 N HCl and extracted with methylene chloride. The extracts were washed with brine and dried over anhydrous sodium sulfate. After removing the solvent, acids **9** and **10** were isolated in a highly pure state. NMR data are given below.

(3Z)-3-Methyl-3-heptenoic Acid ***(9).*** ^{1}H NMR (300 MHz): δ (ppm) 0.89 (t, 3 H, CH_3), 1.24–1.44 (m, 2 H CH_2), 1.81 (q, 3 H, $=CCH_3$), 1.99 (Dq, 2 H, $=CCH_2$), 3.08 (s, 2 H, $=CCH_2COO$), 4.94 (m, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.7, 15.2, 22.7, 30.3, 37.1, 127.4, 129.7, 177.1.

(3E)-3-Methyl-3-heptenoic Acid ***(10).*** ^{1}H NMR (300 MHz): δ (ppm) 0.90 (t, 3 H, CH_3), 1.20–1.45 (m, 2 H, CH_2), 1.71 (d, 3 H, $=CCH_3$), 2.02 (q, 2 H, $=CCH_2$), 3.02 (s, 2 H, $=CCH_2COO$), 5.29 (s, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.7, 16.2, 22.6, 30.1, 44.7, 127.7, 130.1, 178.0.

All five acids showed strong biological activity, but compound **11** could not be isolated in high purity because the amount available from the above procedure was very limited. Furthermore, acids **7** and **8** were slightly contaminated. In order to obtain pure acid **11,** another synthetic route was employed (Figure 3) based on the addition of a Grignard reagent to diketene in the presence of cobalt (Fujisawa et al., 1982). The resulting 3-methyleneheptanoic acid was obtained free of the other isomers. This compound could be cleanly rearranged



a. CoI_2, ether, -78 °C, 5 hr.; b. TsCl-pyridine, 30 °C, 1.5 hr..

FIG. 3. Scheme 2 for synthesis of *C. maculatus* pheromones.

to a mixture of 2*Z* and 2*E* heptenoic acids (ratio 1:2) by treatment with toluenesulfonyl chloride (TsCl) in pyridine. The mixture was separated to give pure compounds **7** and **8** by semipreparative packed column GC fractionation as described above.

3-Methyleneheptanoic Acid ***(11)***. Diketene (8.07 g, 96 mmol) was added to a solution of cobalt iodide (3.40 g, 10.9 mmol) in ether (216 ml) at −78°C under a nitrogen atmosphere. *n*-Butylmagnesium chloride (2.0 M in ether, 60 ml) was slowly added dropwise and stirring was continued at −78°C for 5 hr. The reaction was quenched with 6 N HCl, and the aqueous phase was extracted with ether. The extracts were washed with brine and dried over anhydrous sodium sulfate. Distillation (141–146°C, 33 mm Hg) gave 5.2 g (38%) of compound **11** as a colorless liquid. ^{1}H NMR (300 MHz): δ (ppm) 0.93 (t, 3 H, CH_3), 1.29–1.47 (m, 4 H, 2 CH_2), 2.13 (t, 2 H, $=CCH_2$), 3.08 (s, 2 H, $=CCH_2COO$), 4.93 (s, 1 H, =CH), 4.96 (d, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.9, 22.3, 29.6, 35.6, 41.6, 114.0, 142.0, 178.0.

(2Z)-3-Methyl-2-heptenoic Acid ***(7)***. TsCl (2.86 g, 15 mM) was dissolved in 50 ml of pyridine, and the solution was cooled to 0°C. Compound **11** (1.50 g, 0.5 mM) was added to the above solution. After the addition, the reaction mixture was warmed to 30°C and stirred for 1.5 hr. The reaction was quenched with water (50 ml) and stirred for 0.5 hr. The mixture was poured into cold HCl (6 N, 50 ml) and extracted with ether. The ethereal solution was treated with 10% NaOH. The alkaline solution was acidified with 6 N HCl and extracted with ether. The extracts were washed with brine and dried over anhydrous sodium sulfate. After the solvent was removed, the unsaturated acids **7** and **8** were isolated by packed column GC fractionation. The NMR data for compound **7** were: ^{1}H NMR (300 MHz): δ (ppm) 0.92 (t, 3 H, CH_3), 1.18–1.51 (m, 4 H,

2 CH_2), 1.92 (s, 3 H, $=CCH_3$), 2.14 (t, 2 H, $=CCH_2$), 5.69 (s, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.9, 22.8, 25.4, 30.3, 115.0, 164.0, 170.1.

(2E)-3-Methyl-2-heptenoic Acid (8). ^1H NMR (300 MHz): δ (ppm) 0.92 (t, 3 H, CH_3), 1.18–1.51 (m, 4 H, 2 CH_2), 2.12 (t, 2 H, $=CCH_2$), 2.16 (s, 3 H, $=CCH_3$), 5.70 (s, 1 H, =CH). ^{13}C NMR (75.5 MHz): δ (ppm) 13.9, 22.3, 29.5, 40.9, 114.8, 163.7, 169.0.

RESULTS

Hexane extracts of filter paper-adsorbed volatiles from female *C. maculatus* were consistently very active when tested against conspecific males in single vial bioassays. Typically, greater than 90% of males responded positively to 1 FDE of extract within 5 sec of exposure (response categories 1 and 2). When a dilution series of a particular extract of female *C. maculatus* volatiles was bioassayed against males, the concentration that elicited 50% positive response within the 1-min assay (response categories 1, 2 or 3) was 0.0275 FDE. Male responses diminished to levels similar to that elicited by solvent controls (12% in response category 3, 88% with no response) at female volatile concentrations less than 0.00172 FDE.

Initial fractionation of *C. maculatus* volatiles by semipreparative GC using OV-101 revealed activity in two broad areas of retention corresponding to compounds of C_8 and larger. Combination of these two GC fractions yielded activity equivalent to that elicited by either of the fractions presented singly. When each of the two active fractions was further subfractionated on OV-101, each subfraction was attractive to *C. maculatus* males. The similar levels of activity in numerous contiguous GC fractions suggested tailing or peak broadening of at least one compound, or the presence of a series of structurally similar compounds, all with pheromone activity. Analytical capillary GC and GC-MS of the most active subfractions from OV-101 were inconclusive and did not contain adequate amounts of material for analysis.

Polar gradient silica gel chromatography of *C. maculatus* female volatiles failed to isolate any substantial activity in fractions with hexane, a 4:1 mixture of hexane + ethyl acetate, and pure ethyl acetate (Table 1). Concentration of fractions 17, 18, and 19 to 1/10th their initial volumes revealed activity in the 25–50% response levels, suggesting some limited activity in these polar fractions. Recombination of the original 20 silica gel fractions lacked activity, which indicated that the majority of the pheromone must have remained on the column. Final elution of the column with methanol yielded a fraction that elicited 100% response of male *C. maculatus* within 5 sec in the single vial bioassay (Table 1, fraction 21). A second silica gel chromatography experiment that used increasing concentrations of methanol in a 1:1 mixture of hexane and ethyl

[a] Numbered fractions are sequential collections from a silica gel column; 10-20 males were bioassayed against each fraction.
[b] Categories 1-3 are positive responses and category 4 is no response; see text for details.

acetate found all pheromone activity in the 80% and 100% methanol fractions. Isolation of activity predominantly in the methanol fractions suggested the pheromone was a carboxylic acid. Acid-base partitioning of concentrated whole extract confirmed that the pheromone was a carboxylic acid. Pheromone activity was found only in the reacidified organic acid fraction (fraction 3, Figure 1), and no activity was detected in the deacidified organic fraction (fraction 2) or in the nonacid aqueous phase (fraction 1). Acid-base partitioning of larger hexane extracts of *C. maculatus* female volatiles was thus performed prior to isolation and identification of the pheromone.

The acid fraction of a 32,000-FDE extract of *C. maculatus* female volatiles was subfractionated on GC using Carbowax 20 M, and the last three subfractions of seven were biologically active in single-vial bioassays. Subfraction 6, which had the strongest activity in the bioassay, was analyzed by both EI and CI GC-MS. This analysis revealed five compounds that had suggested structures of methyl-branched heptenoic acids based on fragmentation and tentative matches from the GC-MS spectral library. Because of our GC-MS data and the earlier report of a methylheptenoic acid pheromone in a related species (Cork et al., 1991), we pursued the syntheses of methyl heptenoic acids (above). Comparisons of spectra and GC retention times of synthesized saturated and monounsaturated methyl heptanoic acids with those of the five compounds isolated in subfraction 6 confirmed the identification of the following acids: (3*Z*)-3-methyl-3-heptenoic acid **(9)**, (3*E*)-3-methyl-3-heptenoic acid **(10)**, 3-methyleneheptanoic acid **(11)**, (2*Z*)-3-methyl-2-heptenoic acid **(7)**, and (2*E*)-3-methyl-2-heptenoic acid **(8)**.

Both single-vial and wind-tunnel bioassays showed that all five of the identified acids were active for male *C. maculatus*. In single-vial assays each of the five compounds elicited 75% or greater responses within 5 sec (response categories 1 and 2) when tested at the 100 ng level, and 60% or greater (except for the 2 *Z* acid) when tested at the 10 ng level (Table 2). Comparison of activities among the five acids and a five-way combination found that the 3*Z* and 3*E* compounds elicited the highest responses, and these were similar to the response elicited by the combination. In wind-tunnel bioassays with natural extracts containing female pheromone, all male *C. maculatus* initiated upwind flight, 60–85% of these flew to within the 14-cm radius surrounding the source, and 40–50% contacted the source of pheromone (Figure 4). When 200 ng of each of the five synthetic acids were bioassayed, all compounds elicited upwind flight, but beetles approached and contacted the source only in response to the methylene, 3*Z* and 3*E* acids, and to the five-acid combination.

[a] A minimum of 12 males were bioassayed for each treatment and control.
[b] Categories 1–3 are positive responses and category 4 is no response; see text for details.
[c] Distribution of categorical responses to treatments within a group followed by different letters are significantly different ($P < 0.05$; 4-way Fisher's exact test, to determine the probability that a greater deviation between two data sets exists, was performed on all pairwise combinations).

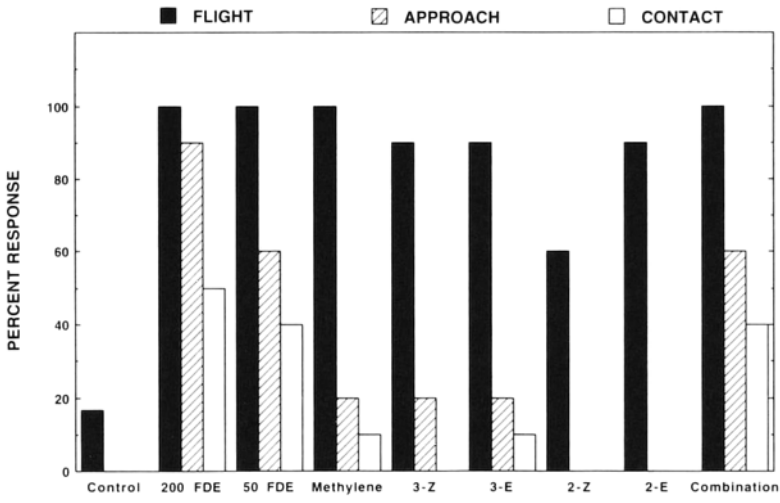

FIG. 4. Responses of male *C. maculatus* in a wind tunnel to natural and synthetic pheromone of females. Histogram bars represent the percentage of males taking flight from the release point (solid), approaching the odor source within a 14-cm radius (hatched), and those making contact with the odor source (open). Treatments were extracts of female volatiles (at 200 and 50 FDE), 200 ng of each of the five synthetic acids discussed in the text, and 200 ng of a combination of the five acids (40 ng each); control was a solvent blank.

Behavioral and chemical studies with *C. maculatus* and *C. analis* proved that the two species were not cross-attractive and that none of the five acids produced by female *C. maculatus* served as a sex pheromone for *C. analis*. In single-vial bioassays males of each species responded best to volatiles collected from conspecific females, and in most cases did not respond to volatiles from the other species (Table 3). Responses of *C. analis* males to the five synthetic *C. maculatus* acids in single vial bioassays did not differ from responses to solvent controls, except for the 2Z acid in one experiment (Table 4). Acid–base partitioning (Figure 1) of an extract of *C. analis* female volatiles confirmed via bioassay that the pheromone for this species was composed of one or more carboxylic acids. GC-MS analysis of the concentrated acid fraction from *C. analis* females, using both full-scan and single-ion monitoring modes, failed to detect any of the five acids identified from *C. maculatus* females. However, a single compound with retention time earlier than the five *C. maculatus* acids was detected, and it had a mass spectrum suggestive of a methylheptenoic acid. Identification of this compound was not pursued in the current project.

DISCUSSION

This study clearly shows that the five identified carboxylic acids are produced by female *C. maculatus* and that they elicit long-range orientation by males. The five acids apparently elicit behavioral responses in an additive manner, since a combination of the five was similar in activity to equivalent amounts of the individual compounds. Vial and wind-tunnel bioassays with synthetic compounds suggest that the 3*Z* and 3*E* acids have greater biological activity than the other acids, but further work is needed. Because these compounds elicit flight response by male *C. maculatus*, we are confident that they could serve as lures for traps to monitor populations of *C. maculatus* in pest management programs.

The sex pheromone of *C. maculatus* is one of only a few sex pheromone systems that have been described for bruchid beetles. Horler (1970) identified an ester from males of *Acanthoscelides obtectus*, but the biological evidence for this specific material serving as a pheromone is limited (e.g., Halstead, 1973). Although Cork et al. (1991) identified compound **7**, (2*Z*)-3-methyl-2-heptenoic

acid, as a single pheromone produced by female *C. analis*, our results do not support their conclusion. Either compound **7** occurs in female *C. analis* at levels below our detection limits, or the pheromone of *C. analis* is composed of one or more acids structurally similar to **7**. Tanaka et al. (1981) reported a female-produced pheromone for *C. chinensis* L. that is composed of a series of hydrocarbons and a dicarboxylic acid; none of the individual compounds were active alone, and activity was demonstrated only when the dicarboxylic acid was presented with the hydrocarbon mix. The pheromone system we report here for *C. maculatus* is based on acids, and does not require synergism by hydrocarbons. The *C. chinensis* work described both short-range attraction and copulation behavior elicited by the sex pheromone (Tanaka et al. 1981; Yamamoto 1990). Although we commonly observed copulation behavior in male *C. maculatus* exposed to natural or synthetic pheromone in vial bioassays, the flight responses

we observed in the wind tunnel indicate these acid pheromones operate as long-range sex attractants.

Acknowledgments—We greatly appreciate the efforts of Olga Andreeva and Kate Lieber in rearing insects and collecting volatiles. The culture of *C. analis* was kindly provided by David Weaver and R. Terry Arbogast of the former USDA ARS Stored Product Insects Research and Development Laboratory in Savannah, Georgia. Statistical analyses were aided by the generous advice of Peter Crump and Erik Nordheim of the University of Wisconsin-Madison. Dr. Aijun Zhang was instrumental in some of the first isolation procedures. We also thank Mr. David Kiemle for GC-MS and NMR studies. This research was supported through base funding of USDA ARS and through a specific cooperative agreement with the Research Foundation of the State University of New York.

(Received February 20, 1996; accepted July 16, 1996)

Abstract—The pheromone system of the eastern tent caterpillar, *M. americanum*, has been identified as a mixture of (*E,Z*)-5,7-dodecadienal and the corresponding alcohol. Field data on the attractiveness of the aldehyde alone were not consistent, but mixtures of aldehyde and alcohol in varying proportions were attractive to males. Addition of small amounts of *E,Z* acetate to *E,Z* aldehyde had no effect on male response, but larger amounts reduced trap catch. Traps baited with *Z,E*, *E,E*, or *Z,Z* aldehydes were not more attractive than blank traps. Pherocon 1C traps fortified with extra adhesive and baited with lures consisting of 500 μg (*E,Z*)-5,7-dodecadienal with either 250 or 100 μg of the corresponding alcohol trapped as many as 100 males/trap/night with means of 15–20. Lures prepared from purified (94% *E,Z*) aldehyde and alcohol were more attractive than those prepared from unpurified (58% *E,Z*) materials.

Key Words—Attractant, reproductive isolation, field trapping, (*E,Z*)-5,7-dodecadienal, (*E,Z*)-5,7-dodecadien-1-ol, eastern tent caterpillar, *Malacosoma americanum*, sex pheromone.

INTRODUCTION

Tent caterpillars of the genus *Malacosoma* are widely distributed over the northern hemisphere and are particularly common in temperate North America (Stehr and Cook, 1968; Fitzgerald, 1995). The forest tent caterpillar (*Malacosoma disstria* Hübner) is the most important economically, being the major deciduous forest defoliator in parts of Canada (Myers, 1993). Its pheromone was identified as a mixture of (*Z*,*E*)-5,7-dodecadienal (*Z*5,*E*7-12 : Ald) and the corresponding alcohol *Z*5,*E*7-12 : OH (Chisholm *et al.*, 1980). Field trapping confirmed these compounds as being attractive to *M. disstria* males in the field, and subsequent studies from the same group (Chisholm *et al.*, 1982) alluded to the fact that these two compounds plus (*Z*)-7-dodecenal were more attractive than virgin females, but details have not been published. The use of *Z*,*E* aldehyde for communication disruption was successful in the field (Palaniswamy *et al.*, 1983) as was use of the *Z*,*E* or *Z*,*Z* diene aldehydes, the *Z*7 monoene aldehyde, or a crude Wittig reaction product isomer mixture of 5,7-dodecadienals (Chisholm *et al.*, 1982). The pheromone of the western tent caterpillar (*M. californicum* Packard) was reported to contain *E*5,*Z*7-12 : Ald as "a component" on the basis of electroantennogram studies, field trapping, and gas chromatography–mass spectrometry (Underhill *et al.*, 1980). Early reports on the Palearctic species *M. neustrium* L. suggested the presence of *Z*5-12 : OH in the pheromone (Melikyan *et al.*, 1980). Subsequent studies did not confirm these components, but instead showed the presence of *Z*5,*E*7-12 : Ald, *E*5,*Z*7-12 : Ald, *Z*5,*E*7-12 : OH, *E*5,*Z*7-12 : OH, *Z*5,*E*7-12 : OAc, and *E*5,*Z*7-12 : OAc in ratio of 0.3 : 1.6 : 0.1 : 1.0 : 0.8 : 0.6 (Konyukhov and Kovalev, 1988). The *EZ* aldehyde or a 3 : 1 mixture of the *EZ* aldehyde and *EZ* alcohol was most attractive in the field.

The eastern tent caterpillar, *M. americanum* (F.), is a widespread inhabitant of eastern North America, usually attacking wild cherry but occasionally a pest on apples, crabapples, or various cultivated *Prunus* spp. We investigated the pheromone of this species for purposes of developing a lure for monitoring and investigating the characteristics of the reproductive barrier between the sympatric *M. americanum* and *M. disstria*. Although a preliminary report on this pheromone has been made (Hill and Roelofs, 1980), we continued our investigations to improve the lures for use in the field.

METHODS AND MATERIALS

Insects. Late instars were collected from black cherry (*Prunus serotina* L.) in the vicinity of Geneva, NY, and reared to pupation in the laboratory on host foliage in growth chambers at 20°C with a photoperiod of 16L : 8D. Females

in Maryland were also collected as late instars from *P. serotina* around Beltsville, MD, and reared to pupation on host foliage in a greenhouse under ambient conditions.

The last two abdominal segments (female tips) were removed from adult female moths during their first scotophase and extracted with Skellysolve B. Airborne collections of female effluvia were carried out as described by Hill *et al.* (1979). Laboratory compressed air was purified by passage through a precolumn of Porapak Q (1.8 × 6 cm), humidified by passage over distilled water, drawn through a glass vessel containing the female moths, and through a Porapak Q collection column (1.8 × 13 cm). Air flow of 1–2 liters/min was maintained by a model 3 Dyna pump. A second outlet from the humidifier served to release excess air. Redistilled methylene chloride was used to elute collected materials from the Porapak.

Gas Chromatography. Gas chromatography (GC) was carried out on a Packard model 7400 instrument. Glass tubing columns (2 m × 4 mm) were packed with 3% OV-1 or OV-101 on 100–120 mesh Gas-Chrom Q or 3% CHDMS (Hi-Eff 8BP, cyclohexanedimethanol succinate) on 100–120 Gas-Chrom Q. Nitrogen was used as carrier gas, and the instrument was equipped with a flame ionization detector. Materials were collected as 1-min fractions in 30-cm glass capillary tubes by connecting the capillary to the outlet of the column with a short piece of Teflon capillary tubing and placing a piece of Dry Ice on top of the capillary.

EAG Tests. Electroantennogram (EAG) studies were carried out by our standard methods as described in the review by Roelofs (1984). Briefly, male antennae were removed, placed in sticky wax in a dish containing insect saline, and connected between chloridized silver electrodes. Test materials, either standards or natural materials collected from the GC, were introduced by puffing 1 ml of air through a disposable pipet containing a standard on a small piece of filter paper, or a capillary tube containing material from the GC, into an airstream passing over the antenna.The electrical response, after amplification, was displayed on a storage oscilloscope. For natural materials, antennal response was plotted versus retention time, and standards were plotted as response versus double-bond position and configuration.

Synthetic Pheromones. Chemicals used in the field studies in Geneva, NY, were obtained from Zoecon Corporation (Palo Alto, CA) (alcohols) or were prepared from the Zoecon alcohols with pyridinium chlorochromate (aldehydes) (Corey and Suggs, 1975) or acetyl chloride–pyridine (acetates). In 1988, *EZ* alcohol was obtained from Darwin Reed (National Research Council, Saskatoon, Saskatchewan, Canada). For the later Maryland studies, *EZ* alcohol was prepared by the method of Chisholm *et al.* (1981), converted to the acetate, and purified by high-pressure liquid chromatography (HPLC) on a silver nitrate–silica gel column (20% $AgNO_3$ on 10 μm Spherisorb, 2 columns in series, 10

mm × 25 cm, toluene eluent at 6 ml min). The crude material in 1994 had a composition of 58% *E,Z*, 38% *E,E*, and 4% *E,E*, and its purity was upgraded by HPLC to 94% *E,Z*, and 6% *E,E*. The material used in 1991 and 1992 was similarly purified to 95% *E,Z* from a separate but similar batch of crude material. After saponification of the purified acetate with KOH–methanol, the alcohol was used directly or oxidized to the aldehyde with CrO_3–pyridine–methylene chloride (Ratcliffe and Rodehorst, 1970).

Evaluation of Lures and Insect Traps. Lures for all traps in both the New York and Maryland studies were prepared by adding the pheromone components in hexane or methylene chloride to rubber serum stoppers (A. H. Thomas #1780 J07). GC examination of ethanol extracts from the stoppers showed no contamination with 1,2-dianilinoethane (*cf.* Steck *et al.*, 1979).

Experiments in New York in 1980 were carried out near Geneva and Ithaca. Trapping was done with Pherocon 1C traps in fields near hedgerows containing *P. serotina*. Traps were set out in a randomized complete block design, with a minimum of 10 m between treatments, and were sampled and rerandomized as indicated in the tables.

For the studies in Maryland, traps were placed along roadsides and in suburban yards near infested *P. serotina* trees in the Beltsville and Laurel areas. Treatments within a replicate were placed at least 10 m apart and replicates were separated by a distance of from several hundred meters to 10 km. Males were counted daily and each trap was then moved (rotated) to the next position in the row. Since some of the replicates were set out along heavily traveled roadsides, this trap rotation was considered more expeditious than rerandomization. Treatments were set out only in years of high populations, as indicated by defoliation of wild cherry trees and numbers of wandering stage larvae. Exact population levels were not determined, but should be comparable for the years presented.

In Maryland (1988 and 1989), both Pherocon 1C traps and water pan traps were used. The water pan traps (Figure 1) consisted of a removable trapping assembly and a retainer. The retainer was a 30-cm-diameter disposable aluminum pie plate nailed to the top of a wooden stake approximately 1 m tall. These were placed *ca.* 10 m apart along suburban roads or in yards. The removable assembly consisted of two facing pie plates, separated by a wooden dowel of sufficient length (*ca.* 12.5 cm) to give a separation at the edges of *ca.* 7.5 cm. This assembly was fastened inside the plate on the stake with spring clamps and contained a 1- to 2-cm layer of soapy water. The lure was held on a wire supported by the upper plate and approximately over the center of the lower plate. The soapy water was replaced as necessary.

For tests in Maryland in 1991, water pans were used to assess longevity of lures. Four replicates of a single treatment were set out for each of three consecutive trials. Traps were checked daily. Lures contained, in addition to

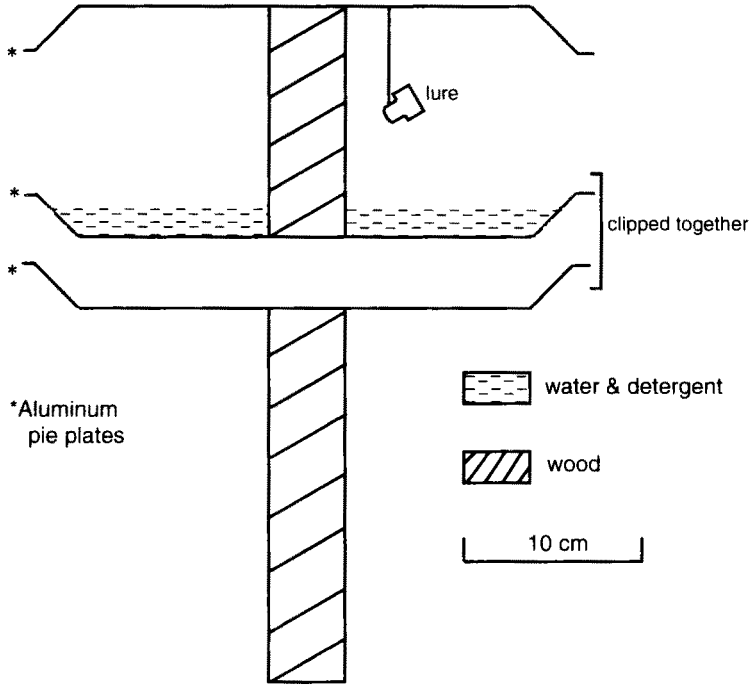

FIG. 1. Cross-sectional diagram of water pan trap. For further details, see text.

pheromone components, BHT and 2-hydroxy-4-methoxybenzophenone as antioxidant and photostabilizer, respectively (Ideses and Shani, 1988).

Field tests in Maryland in 1992 and 1994 were carried out with Pherocon 1C traps. The lures also contained antioxidant and photostabilizer as above.

Data from all tests were transformed $\sqrt{(X + 0.5)}$ and subjected to ANOVA. Data from 1980 tests in New York were analyzed using the Waller and Duncan BSD test under Minitab release 80.1 (Pennsylvania State University). Maryland data were analyzed within the SAS General Linear Models Procedure (SAS Institute, Raleigh, NC) with means separated by Duncan's multiple range test. Data for 1992 and 1994 were also analyzed with the Bonferroni *t*-test with equivalent results.

RESULTS AND DISCUSSION

Gas Chromatography and Electroantennogram Data. The crude extract from 30 female tips was injected onto a nonpolar OV-101 column at 150°C and

the effluent fractions collected as described above. EAG examination of these GC fractions showed activity at 4–5 and 6–7 min (2.0 mV and 1.4 mV, respectively, 1.0 mV at 5–6 min, all others were 0.8 mV or below). Similar analysis of collected airborne-material from 30 females showed activity at 4–5 min (4.8 mV) and 6–7 min (3.7 mV, all others 2.6 mV or below, average of three determinations on the same sample). Retention times of standards were 10:OH (2.5 min), 11:OH (3.9 min), 12:OH (6.0 min), 14:OH (15.3 min), 10:OAc (4.5 min), 11:OAc (7 min), and 12:OAc (11.05 min). The 4- to 5-min extract fraction from OV-101, injected onto a Hi-Eff column at 150°C, gave activity at 6–7 min (3.6 mV), 7–8 min (1.4 mV), and 8–9 min (2.6 mV, background 0.4–0.6 mV), as did the collected fraction from the airborne collection (2.0 mV, 7- to 8- and 8- to 9-min fractions at background of 0.4 mV). The crude extract fraction collected from OV-101 at 6–7 min, reinjected similarly onto the Hi-Eff column, gave activity at 14–16 min (1.4 mV); the airborne collection fraction reinjected gave activity at the same time (3.6 mV, 12–14 min at 1.8 mV, all other fractions at or below 1.4 mV). Hi-Eff retention times of standards were 11:OH (4.85 min), 12:OH (7.85 min), 14:OH (18.3 min), 11:OAc (4.6 min), 12:OAc (7.0 min), and 14:OAc (17.0 min). From these data and our earlier results (Hill and Roelofs, 1980), the pheromone seemed to consist of a mixture of a diunsaturated 12-carbon alcohol and aldehyde.

EAG Standards. Of a standard series of 12- and 14-carbon alcohols and acetates puffed across the male antenna, the greatest activity was elicited by the Z5 followed by the Z7 alcohol. This suggested, by analogy with similar cases (*e.g.*, Roelofs *et al.*, 1971; Kochansky *et al.*, 1975), that the pheromone was a 5,7-diunsaturated system comprising a mixture of alcohol and aldehyde. Diunsaturated standards (gifts of Warren Steck and Mel Chisholm, National Research Council, Saskatoon, Saskatchewan, and Robert Carney, Zoecon Corp., Palo Alto, California) showed the greatest activity from the *E*5,*Z*7-12:Ald among the aldehydes, and from *E*5,*Z*7-12:OH among the alcohols at a level of 100 ng on filter paper. Repeated runs at 100 ng and runs at a level of 10 ng gave similar results. Acetates were essentially inactive.

Evaluation of Lures. In the initial test in New York, the *EZ* aldehyde at a 1-mg level with 0.1 or 1 mg of *EZ* alcohol or 3 mg aldehyde alone were equally active (Table 1), but the aldehyde alone at 1 mg was less active than was the 1 mg + 1 mg treatment. Addition of 0.1 mg of *EZ* acetate to 1 mg of the aldehyde did not significantly reduce the number of males, but reduction occurred with an addition of 1 mg of acetate. Treatments containing other isomers were indistinguishable from blank traps. The second test covered the *EZ* aldehyde and mixtures with the alcohol at higher loadings. The aldehyde by itself at a 2-mg level was no more attractive than the blank trap, but the addition of *EZ* alcohol at levels of 0.2, 2, or 6 mg increased activity significantly.

[a] Three replicates, nine rerandomizations.
[b] Mean number of males trapped per treatment. Means followed by the same letter are not significantly different at $P = 0.05$ by the Waller and Duncan BSD test.
[c] Five replicates, six rerandomizations.
[d] Total males caught per treatment over the course of the test. Totals followed by the same letter are not significantly different at $P = 0.05$ by the Waller and Duncan BSD test.

The first field tests in Maryland used various designs in an attempt to optimize trap catch. Males of *M. americanum* are densely covered with hairlike scales, thus sticky traps frequently show only the scales left after a male escapes. In 1988, sticky traps were used in the initial series and low doses of the aldehyde and alcohol were compared with live females. Only two replicates were used because of the scarcity of females, which had to be replaced daily. Six males were caught by two traps with mixtures of aldehyde + alcohol (1 μg each) over seven days, 18 males were caught at the 10-μg level, and two females per trap caught 16. The second 1988 test compared water pan traps to sticky traps. Aldehyde and alcohol (100 μg each) in Pherocon 1C traps caught 16 males over 28 trap nights, while the same lure with water pan traps caught 24. The alcohol alone caught 3, and 1 mg of the alcohol + 600 μg of the aldehyde caught 28.

This represents an average of at most 1 male/trap/night (maximum catch was five males in a trap overnight). In neither of these studies were catches high enough for the differences to be significant.

The studies in Maryland in 1991 were intended to examine longevity of lures, but due to a pheromone shortage, tests were run only on a very small scale. Mixtures of aldehyde and alcohol (100 μg each, plus BHT and photostabilizer, four replicates) caught totals of 1, 6, 4, 0, and 0 males on successive nights. The lures were replaced with others at a level of 500 μg each with the same stabilizers, and caught 9, 4, 6, 0, 4, 0, and 0 males on successive nights. New 500-μg lures were put out and caught 3, 1, 3, 1, 0, and 0 males. Since these were not out at the same time, they cannot be directly compared, but it is apparent that even with the stabilizers, the lures' attractiveness decreased after a few days. This is hardly surprising, given the well-known susceptibility of multiply-unsaturated compounds to oxidation and isomerization.

For the first test of 1992 (Table 2), the aldehyde + alcohol (500 + 50 μg) treatment was more attractive than the mixture of the same components at 500 + 500 μg. At a level of 50 + 500 μg, attractancy of the mixture was no different from that of a blank trap. The second 1992 test involved closer ratios, but the differences between treatments in this test were not statistically significant.

In 1994, observations made over the previous years were used to design what we hoped would be a greatly improved test. Since Pherocon 1C traps were

TABLE 3. EASTERN TENT CATERPILLAR FIELD TRAPPING RESULTS, BELTSVILLE AND LAUREL, MARYLAND (JUNE 8–JUNE 16, 1994)[a]

Treatment	Males/trap/night[b]
EZ Ald + *EZ* OH (500 μg + 100 μg) (94% *EZ*)	19.09 a
EZ Ald + *EZ* OH (500 μg + 250 μg) (94% *EZ*)	16.41 a
EZ Ald + *EZ* OH (500 μg + 250 μg) (58% *EZ*)	8.59 b
Blank trap	0.0 c

[a] Four treatments, six replicates; sampled, rotated, and lures replaced daily. Traps had extra adhesive applied.

[b] Means followed by the same letter are not significantly different by Duncan's multiple range test or by the Bonferroni *t* test at $P = 0.05$. Total catches per treatment over the course of the test were 1118, 885, 464, and 0, respectively.

not sticky enough for this species, several millimeters of extra Tack Trap (Animal Repellents, Inc., Griffin, Georgia) were added to the trap bottoms. Lures were replaced daily and antioxidant and photostabilizer were added to help overcome the apparent rapid loss of activity. Trap bottoms were replaced as soon as they approached capacity. Greatly improved catches were finally obtained (Table 3). Mixtures of *EZ* aldehyde and alcohol (500 μg + 250 μg or 500 μg + 100 μg, respectively, were equally attractive) prepared from purified components were more attractive than the mixture (500 μg + 250 μg) prepared from the crude alcohol.

CONCLUSION

The best scheme found for trapping *M. americanum* was use of *E*5,*Z*7–12:Ald + *E*5,*Z*7–12:OH (purified on a $AgNO_3$ column) with a level of aldehyde at 0.5–1 mg and the level of alcohol lower by a factor of 2–5. Lures should be replaced daily in sticky traps with extra adhesive. The combination of these techniques enabled mean catches of 15–20 males/trap/day. Although mixtures of pheromone components synthesized from unchromatographed *EZ* acetate were attractive, they were less so than when the purified materials were used.

Since *M. disstria* uses the *ZE* isomer of the aldehyde and alcohol components, and *M. americanum* uses the *EZ isomer*, this provides a mechanism for reproductive isolation, in addition to the differences reported for the time of flight (Sample, 1992). The western tent caterpillar *M. californicum* uses the same major component as *M. americanum*, but since the two species are only marginally sympatric [distribution maps in Stehr and Cook (1968) and Myers (1993)], this should present only a limited problem, even assuming that all the

M. californicum subspecies use the same pheromone. The mechanism of isolation for these two species has apparently not been investigated, however.

Acknowledgments—We thank Warren Steck, Mel Chisholm, Darwin Reed (National Research Council, Saskatoon, Saskatchewan), and Robert Carney (Zoecon Corp., Palo Alto, California) for gifts of various 5,7-12:OH isomers. We also thank Jerome A. Klun for carrying out the purifications of *E*5,*Z*7-12:OAc and Rose Haldemann, Kenneth Wilzer, and Ernest Imle for the use of their property for field studies.

(Received December 4, 1995; accepted July 20, 1996)

Abstract—(6*Z*-9*S*, 10*R*)-Epoxy-octadecene (*SR*-**1**) and (3*Z*, 6*Z*-9*S*, 10*R*)-epoxy-octadecadiene (*SR*-**2**) are sex pheromone components of the mulberry looper (MBL), *Hemerophila atrilineata* Butler. Compounds extracted from female MBL pheromone glands were identified by coupled gas chromatographic–electroantennographic detection (GC-EAD) and GC–mass spectrometry. In field experiments in China, *SR*-**2**, *RS*-**2**, or both combined were hardly attractive, but *SR*-**2** in combination with *SR*-**1** attracted significant numbers of MBL males. Synergistic behavioral activity of *SR*-**1** plus *SR*-**2**, but not of corresponding antipode mixtures, indicates enantiospecificity of MBL pheromone communication. Because blends of racemic and enantiospecific (*SR*) **1** plus **2** were similarly attractive, racemic **1** plus **2** may have potential for mass trapping or confusion of MBL males in commercial mulberry plantations.

Key Words—(6*Z*-9*S*,10*R*)-epoxy-octadecene, (6*Z*-9*R*,10*S*)-epoxy-octadecene, (3*Z*,6*Z*-9*S*,10*R*)-epoxy-octadecadiene, (3*Z*,6*Z*-9*R*,10*S*)-epoxy-octadecadiene, chirality, synergism, mulberry looper, Geometridae.

INTRODUCTION

The mulberry looper (MBL), *Hemerophila atrilineata* Butler (Lepidoptera: Geometridae), is a widespread pest in plantations of mulberry trees, *Morus alba* (L.), throughout the provinces of Jiang Su, Zhe Jiang, Si Chuan, Guang Dong, and Liao Ning in China. Mulberry constitutes the food source for silkworm larvae, *Bombyx mori* L. (Lepidoptera: Bombycidae), raised for production of valuable silk. Sympatric MBL larvae of the spring generation eat buds of mulberry and subsequent generations defoliate trees. Reducing or destroying the food source for *B. mori*, MBL directly interferes with silk production, causing revenue losses to the silk industry. Because insecticides for MBL control would also affect highly sensitive silkworms, methods for MBL management are limited in number and scope. Use of the MBL-specific sex pheromone for mass trapping MBL males offered a potential control tactic. We report the identification of two sex pheromone components of MBL.

METHODS AND MATERIALS

Laboratory Analysis. MBL pupae were field collected in the Su Zhou area of the Jiang Su province and were sent to Simon Fraser University. Pupae were kept in filter paper-lined Petri dishes at a 14L : 10D photoperiod. Emergent moths were separated to avoid mating. One hour into the scotophase, pheromone glands of 1- to 2-day-old virgin females were removed and extracted in hexane for 5 min. Aliquots of one female equivalent of gland extract were subjected to gas chromatographic analysis (Hewlett Packard 5890A) with both flame ionization and electroantennographic detection (GC-EAD) (Arn et al., 1975; Struble and Arn, 1994) on two fused silica column (30 m × 0.25 or 0.32 mm ID) coated with DB-210 or DB-23 (J & W Scientific, Folsom, California). Coupled GC–mass spectrometric (MS) analyses of volatiles in gland extracts were carried out employing a Hewlett Packard 5985B fitted with the DB-210 column referred to above.

Synthetic chemicals, including (6*Z*-9*S*,10*R*)-epoxy-octadecene (*SR*-**1**), (6*Z*-9*R*,10*S*)-epoxy-octadecene (*RS*-**1**), (3*Z*,6*Z*-9*S*,10*R*)-epoxy-octadecadiene (*SR*-**2**) and (3*Z*,6*Z*-9*R*,10*S*)-epoxy-octadecadiene (*RS*-**2**), were synthesized as described by Miller et al. (1987, 1990) and were generously provided by the National Research Council, Saskatoon,Saskatchewan, Canada. Chemicals were >97% chemically pure and had enantiomeric excess (ee) of about 69%.

Field Experiments. Field experiments at Wujiang, China, were set up in randomized, complete blocks with traps and blocks at 30 to 40-m intervals. Traps consisted of an open, soapy water-filled bowl (25 cm diam.), with the pheromone lure suspended by wire in the trap center 2 cm above the water surface. Traps were hung from trees 1 m above the ground and baited with rubber septa (Sigma Chemical Co., St. Louis, Missouri) impregnated with Candidate pheromone components in HPLC-grade hexane. The first experiment (1993) tested *RS*-**2** (100 μg) and *SR*-**2** (100 μg) singly and in binary combination with *RS*-**1** (10 μg) or *SR*-**1** (10 μg). The second experiment (1994) tested *SR*-**2** (50 μg) and *RS*-**2** (50 μg) singly and in combination. Experiment 3 (1994) tested *SR*-**2** (50 μg) singly and in combination with either *SR*-**1** (5 μg), *RS*-**1** (5 μg), or both. Experiment 4 (1995) tested *SR*-**2** (50 μg) plus *SR*-**1** (5 μg) alone or in combination with either *RS*-**2** (50 μg), *RS*-**1** (5 μg), or both.

Statistical Analysis. Data were subjected to nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Student-Newman-Keuls test) (Zar, 1984; SAS/STAT User's Guide, 1988, release 6.03 edition, SAS Institute, Cary, North Carolina 27513).

RESULTS

GC-EAD analyses of female MBL pheromone gland extract revealed six compounds consistently eliciting antennal responses (Figure 1). GC-MS and retention index calculations of the major EAD-active compound (**2** in Figure 1) on several columns indicated a C_{18} diunsaturated epoxide. Subjecting 50 pg of standards of racemic 3, 4-, 6,7-, and 9,10-epoxy-dienes (C_{16}–C_{21}) to GC-EAD analyses revealed that 9,10-epoxy-dienes elicited the strongest antennal responses (Figure 2). (3*Z*, 6*Z*-*cis*-9,10)-Epoxy-octadecadiene had retention, mass spectrometric, and EAD characteristics highly comparable with female MBL-produced **2**. Because 3,4- and 6,7-epoxy-dienes had little EAD activity (Figure 2), and monoene epoxides elute just before diene epoxides on a DB-210 column, EAD-active compound **1** (Figure 1) was hypothesized to be (3*Z*- or 6*Z*-*cis*-9,10)-epoxy-octadecene. In GC-EAD analyses of 6,7- and 9,10-epoxy-monoenes (C_{17}–C_{20}), (6*Z*-*cis*-9,10)-epoxy-octadecene gave the strongest antennal response (Figure 3) and cochromatographed with female-produced **1** on DB-210 and DB-23 columns. Compounds **3**, **4** and **5**, **6** (Figure 1) had retention indices indicative of lower (**3**, **4**) and higher (**5**, **6**) homologs of **1** and **2**, but quantities in gland extracts did not suffice to confirm these structural assignments in spectrometric analyses.

In the first field experiment, *SR*-**2** in binary combination with *SR*-**1** was most attractive to MBL males (Figure 4), whereas mixtures of their antipodes were significantly less attractive. Singly *SR*-**2** or *RS*-**2** were as ineffective as

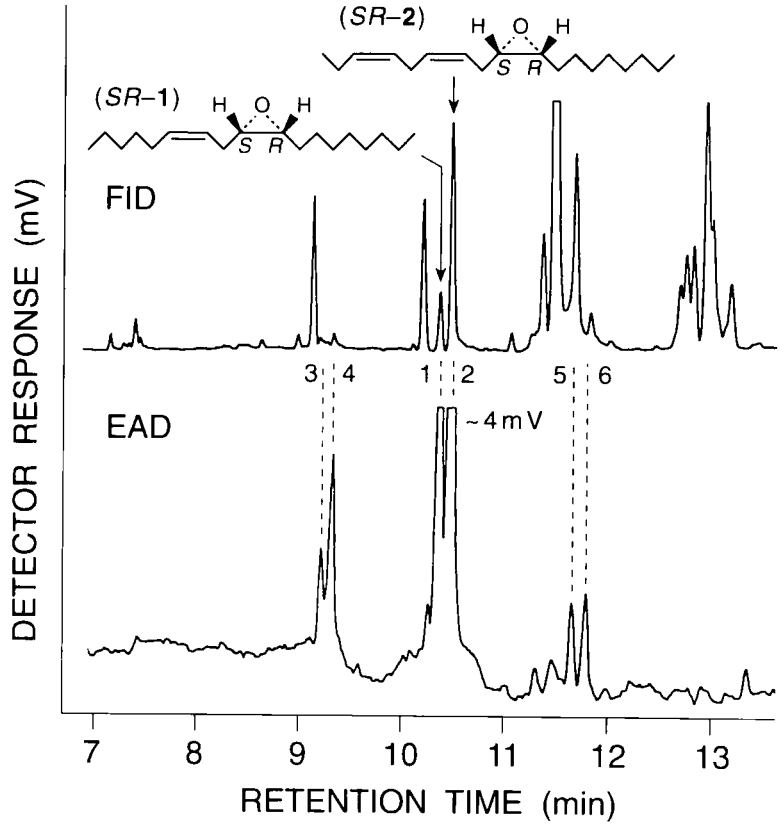

FIG. 1. Flame ionization detector (FID) and electroantennographic detector (EAD: male *H. atrilineata* antenna) responses to one female equivalent of female *H. atrilineata* pheromone gland extract. (6*Z*-9*S*,10*R*)-Epoxy-octadecene (*SR*-**1**) and (3*Z*,6*Z*-9*S*,10*R*)-epoxy-octadecadiene (*SR*-**2**) invariably elicited the strongest antennal responses. Chromatography: splitless injection; injector and FID detector temperature: 240°C; DB-210 column; temperature program: 100°C(1 min), 15°C/min to 180°C, 2°C/min to 220° C.

unbaited traps (experiment 1, Figure 4), and in combination (experiment 2) they failed to attract MBL males. *SR*-**2** was again unattractive in experiment 3, but in combination with either *SR*-**1**, *RS*-**1**, or both attracted a total of 10,6, and 12 MBL males, respectively. *SR*-**2** plus *SR*-**1** alone or in binary and ternary combination with *RS*-**2** and *RS*-**1** (experiment 4) were similarly effective, attracting a total of three to eight MBL males per treatment.

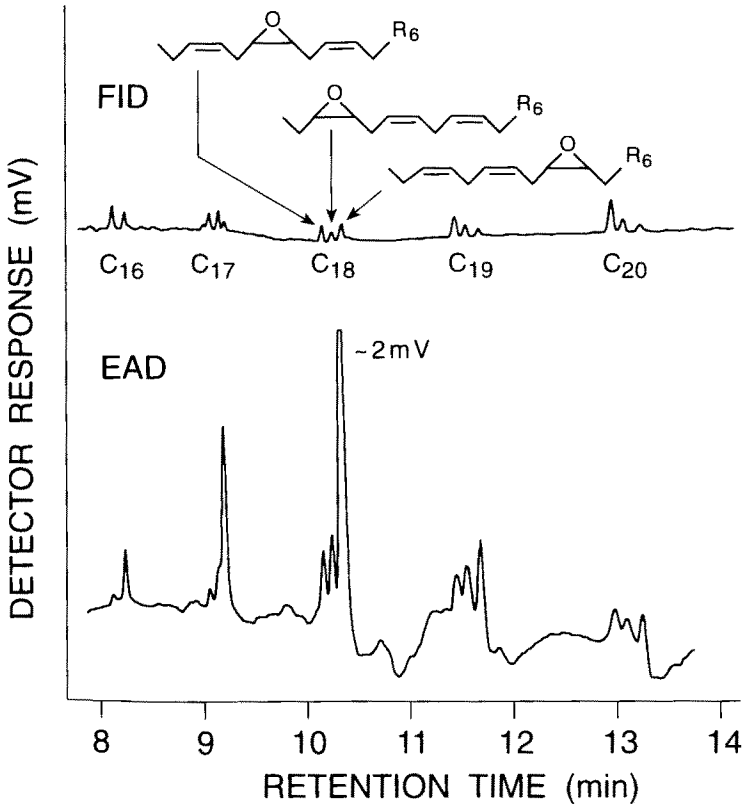

FIG. 2. Flame ionization detector (FID) and electroantennographic detector (EAD: male *H. atrilineata* antenna) responses to 50-pg standards of C_{16}–C_{20} epoxy-dienes. Chromatography as in Figure 1.

DISCUSSION

Evidence that (*Z*6-9*S*,10*R*)-epoxy-octadecene (*SR*-**1**) and (*Z*3,*Z*6-9*S*,10*R*)-epoxy-octadecadiene (*SR*-**2**) are sex pheromone components in female MBL include: (1) female MBL-produced and synthetic *SR*-**2** gave identical mass spectra, cochromatographed on several GC-columns, and elicited comparable antennal responses; (2) antennal responses to synthetic *SR*-**1** and female-produced **1** [second strongest EAD-active compound in pheromone extract (Figure 1)] had identical retention times on DB-23 and DB-210 columns; (3) synthetic *SR*-**1** and

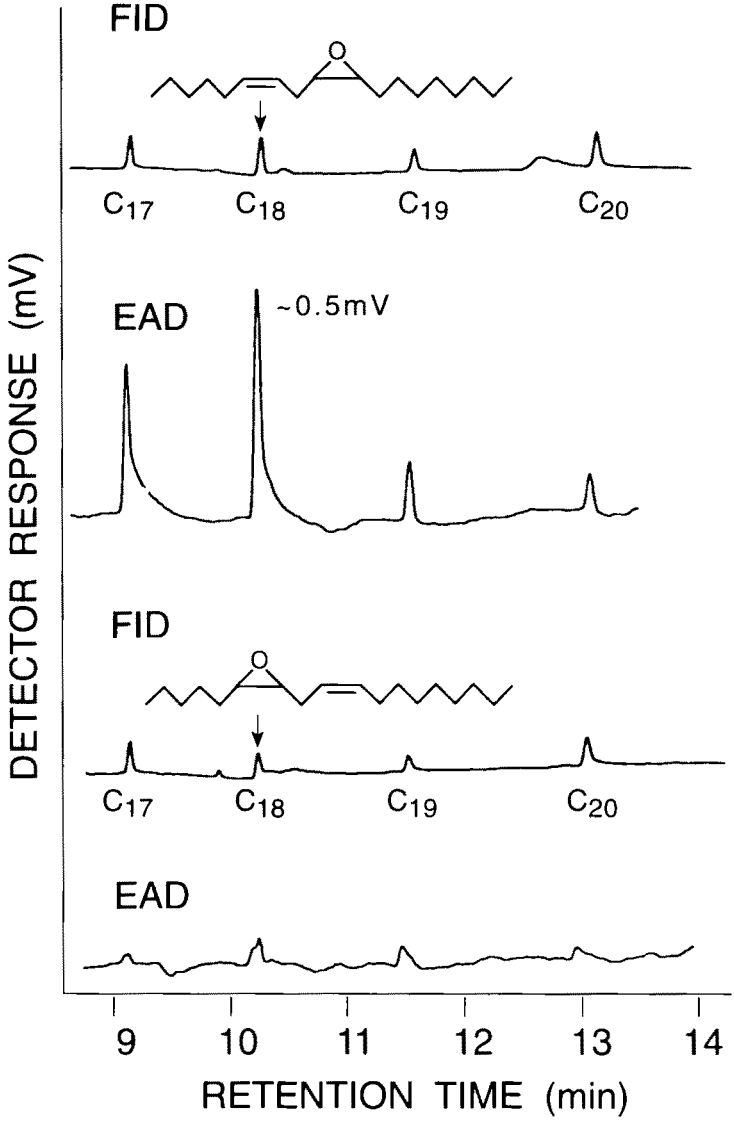

FIG. 3. Flame ionization detector (FID) and electroantennographic detector (EAD: male *H. atrilineata* antenna) responses to 50-pg standards of C_{17}–C_{20} monoene-epoxides. Chromatography as in Figure 1.

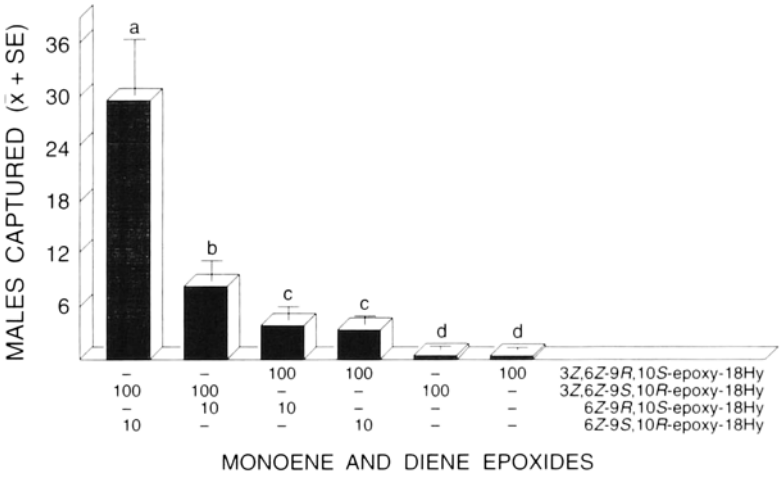

FIG. 4. Captures of *H. atrilineata* males in traps baited with (3*Z*,6*Z*-9*S*,10*R*)-epoxy-octadecadiene (100 μg) [3*Z*,6*Z*,-9*S*,10*R*-epoxy-18Hy (*SR*-**2**)], (3*Z*,6*Z*,-9*R*,10*S*)-epoxy-octadecadiene (100 μg) [3*Z*,6*Z*,-9*R*,10*S*-epoxy-18Hy (*RS*-**2**)], or either one of these epoxides in binary combination with (6*Z*-9*R*,10*S*)-epoxy-octadecene (10 μg) [6*Z*-9*R*,10*S*-epoxy-18Hy (*RS*,**1**)] or with (6*Z*-9*S*,10*R*-epoxy-octadecene (10 μg) [6*Z*-9*S*,10*R*-epoxy-18H6 (*SR*-**1**)] at the campus of Biotechnology College, Su Zhou University, China; June 9–12, 1993; eight replicates. Bats with the same superscript are not significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Student-Newman-Keuls test), $P < 0.05$.

SR-**2** rather than their antipodes elicited strong antennal responses; and (4) *SR*-**1** plus *SR*-**2** were highly attractive in field experiments (Figure 4).

Lack of attraction of MBL males to *SR*-**2** alone but strong attraction to *SR*-**2** plus *SR*-**1** indicates that pheromonal attraction in MBL resides with the presence of (at least) two pheromone components. EAD-active compunds **3**, **4** and **5**, **6** (Figure 1) are likely lower and higher homologs of **1** and **2**, but ultra low MBL population densities in 1994–1995, seriously affecting experiments 2-4, did not allow exploration of their potential behavioral activity. Attractiveness of *SR*-**1** plus *SR*-**2**, but not of corresponding antipode mixtures, indicates enantiospecificity of pheromone communication in MBL. Because blends of *SR*-**1** plus *SR*-**2** or their racemates were similarly attractive (experiment 4), antipodes of MBL pheromone components are either behaviorally benign or not perceived by MBL males.

Enantioselective pheromone production by female MBL has not yet been demonstrated unequivocally, but the technology required for such analyses has recently been developed. Employing specific gas chromatographic conditions

and a tailor-made GC column (König et al., 1992; Pietruszkae et al., 1992), Szöcs et al. (1993) succeeded in separating optical isomers of (3*Z*,9*Z*-*cis*-6,7)-epoxy-nonadecadiene, an epoxy-diene with an even longer chain length than MBL pheromone components.

Epoxides *SR*-**1** and *SR*-**2** are essential for attraction of MBL males and have not previously been reported as sex pheromone components in the Lepidoptera. Multiple phermone component blends in other geometrid moths comprise optical isomers of epoxy-dienes (Millar et al., 1990), epoxy-dienes plus triene hydrocarbons (Millar et al., 1987; Tóth et al., 1992), triene plus diene hydrocarbons (Millar et al., 1990), mono- and dimethyl hydrocarbons (Gries et al., 1991, 1993, 1994), and optical isomers of dimethylated hydrocarbons (King et al., 1995).

Similar attractiveness of enantiomerically enriched *SR*-**1** plus *SR*-**2** and racemic **1** plus **2** (experiment 4) suggests that antipodes of pheromone components do not interfere with the attraction of MBL males. Should racemic **1** plus **2** be as attractive as virgin MBL females, this mixture should be evaluated for mass trapping MBL males or for their disorientation in pheromone-based mating disruption.

(Received February 27, 1996; accepted July 20, 1996)

Abstract—Hexanal, octanal, nonanal, decanal, hexanoic acid, octanoic acid, nonanoic acid, and decanoic acid were identified in the volatile emissions from fifth instars of *Schistocerca gregaria* by coupled gas chromatography-electroantennography (GC-EAD) detection and coupled GC-mass spectrometry (MS). In laboratory assays, synthetic blends of the eight compounds, with acids and aldehydes tested separately, evoked strong aggregation responses from fifth instars, similar to responses evoked by a crude volatile extract of the nymphs. A nymphal fecal volatile phenolic blend of guaiacol and phenol, which we have previously shown to evoke an aggregative response from different stages of the insect, significantly synergized the activity of the blend of eight compounds, suggesting mutually augmentative roles for nymphal and fecal volatiles in evoking aggregation. These results indicate that the aggregation behavior of gregarious second to fifth instars is modulated by three sets of pheromonal compounds: aldehydes and acids emitted by the nymphs themselves and phenols associated with their feces.

Key Words—*Schistocerca gregaria*, locusts, aggregation pheromone, hexanal, octanal, nonanal, decanal, hexanoic acid, octanoic acid, nonanoic acid, decanoic acid, guaiacol, phenol.

INTRODUCTION

Aggregation behavior in the gregarious desert locust *Schistocerca gregaria* is mediated by a complex pheromone system released in the volatile emissions of

*To whom correspondence should be addressed.

the different locust stages, sexes, and their feces (Obeng-Ofori et al. 1993, 1994a,b). The adults aggregate in response to a blend containing phenylacetonitrile, benzaldehyde, guaiacol, and phenol associated with older males (Torto et al., 1994). In the absence of older males, young adults aggregate in response to guaiacol and phenol present in their fecal volatiles and those of nymphal stages with which they associate during fledging (Obeng-Ofori et al., 1994b). In the second, third, fourth, and fifth instars we demonstrated that these nymphal stages respond to one another's volatiles and that no sexual differentiation occurs in the production of pheromone (Obeng-Ofori et al., 1993, 1994a).

We have expanded on these earlier findings by investigating the nymphal-produced pheromone system of *S. gregaria*. We chose as our experimental insects the fifth instars, and herein present the isolation, identification, and behavioral activity of its aggregation pheromone.

METHODS AND MATERIALS

Volatile Collection. Fifty fifth-instar nymphs (three to five days after molt) of mixed sexes were obtained from the ICIPE insectary (Torto et al., 1994), placed in a 5-liter three-necked, round-bottomed flask, and aerated (Obeng-Ofori et al., 1993). A charcoal-filtered airstream (106 ml/min) was drawn over the locusts by a vacuum pump (Cole-Parmer air-cadet) for 15 hr in a room maintained at 30 $\pm$ 2°C. Volatiles were collected on charcoal (120 mg) traps in Pyrex glass tubes (Torto et al., 1994) immersed in an ice bucket. The volatiles were eluted from the charcoal traps with HPLC-grade dichloromethane (5 ml, Aldrich Ltd.), dried over anhydrous Na_2SO_4, and stored in the freezer at -15°C until used.

Analyses of Volatiles. Volatiles were concentrated under a stream of nitrogen at 0°C to 100 μl. Eight microliters were analyzed by gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975) using conditions previously described on a Hewlett-Packard (HP) 5890 Series II gas chromatograph equipped with a FID detector and a Syntech EAD system (Torto et al., 1994). The GC oven was fitted with a HP capillary column (Carbowax 20 M, 50 m $\times$ 0.2 mm ID $\times$ 0.2 μm) and temperature programmed as follows: 60°C (10 min), 5°C/min to 180°C, held for 5 min, and raised at 10°C/min to 220°C. FID and EAD signals were monitored synchronously using a program on a GC/EAD interface card (Syntech) installed in a PC (Harvard Professional Computer, American Megatrends Inc.). The signals were recorded at a fixed speed of 9.2 cm/min and stored as pages of 128 sec (2 min 8 sec) duration. One complete run using the GC-EAD conditions previously described (Torto et al., 1994) generates 25 pages. In addition, the FID signal was plotted on a HP 3396 Series II integrator at 0.5 cm/min. GC-MS analyses were carried out on a VG Masslab 12-250 mass spectrometer (EI, 70 eV) coupled to a HP 5790 gas chromatograph.

Behavioral Assays. A modification of the olfactometer bioassay described previously (Obeng-Ofori et al., 1993) was used to examine aggregation responses by fifth instars and older adults to natural and synthetic pheromones. The bioassay arena was fitted with three pieces of removable wire mesh, one split into two halves, with each half fitted at the bottom of the chamber on the perforated aluminum metal plate, and another fitted in the middle of the chamber while the other piece of wire mesh covered the top (Figure 1). Ten filter paper discs (each 16 mm diameter) were distributed on each of the pieces of wire mesh

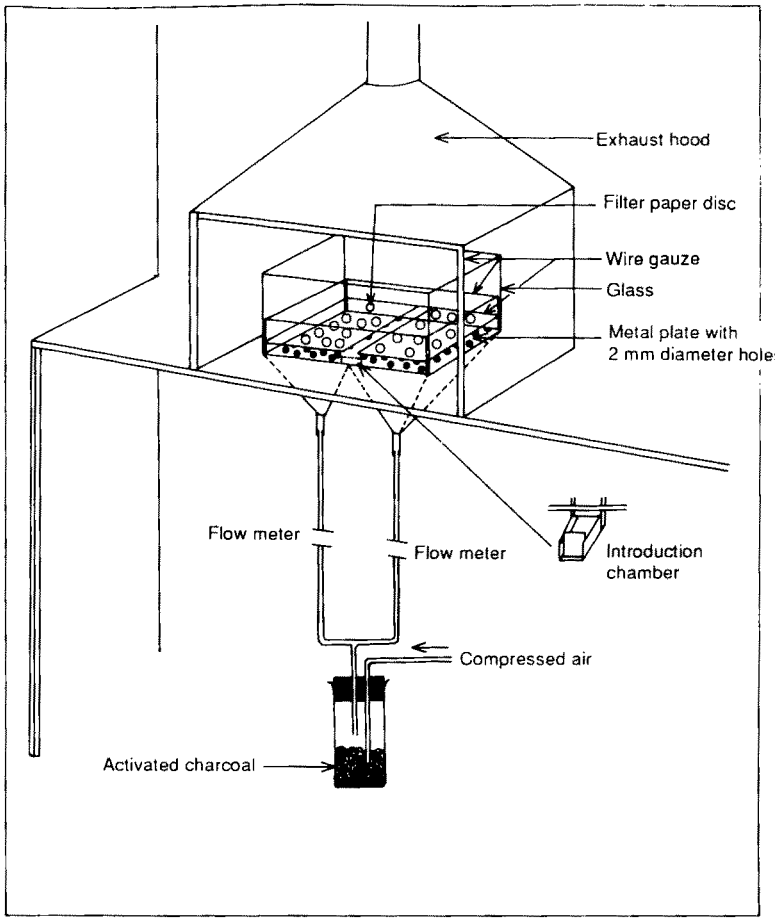

FIG. 1. Diagram of modified single-chamber choice olfactometer bioassay and layout of experimental arena.

placed at the bottom of the chamber. Pheromone extracts in paraffin oil were applied to one set of discs and the control (paraffin oil) on the other set. This modification was necessary to facilitate easy flow of test substances, which are of low volatility, into the airstream of the bioassay arena. Charcoal-filtered air, split into two flow-metered streams, was directly passed into the square pyramidal aluminum funnel attached to the base of the chamber. To avoid accumulation and mixing of the eluate in the assay chamber, the effluent from the olfactometer was extracted into a hood by a fan through a duct.

Bioassays provided a choice of an odor-free control air column and an air column treated with: (1) a volatile collection of fifth instars (crude extract) corresponding to 300, 150, 75, and 37.5 locust hours (LH) (1 LH = volatiles emitted by one locust for 1 hr) (Torto et al., 1994); (2) a 4:9:20:20:14:50:100:16 blend of synthetic hexanal, octanal, nonanal, decanal, hexanoic acid, octanoic acid, nonanoic acid, and decanoic acid (the ratio represents the relative composition of a volatile collection from a single sample of a population of fifth instars at the four doses described in (1); (3) a blend of the aldehydes in relative concentrations present in (2); (4) a blend of the acids also in relative concentrations present in (2); (5) the individual aldehydes as in (3); (6) the individual acids as in (4); (7) preparation as in (2) containing 5 ng each of guaiacol and phenol (nymphal fecal volatile components) (Obeng-Ofori, et al., 1994b); and (8) a blend containing 5 ng each of guaiacol and phenol. Control and treated sides were systematically switched throughout the study to minimize bias.

Sets of five locusts of mixed sexes were bioassayed and were released on the wire mesh which fitted in the middle part of the chamber, and after 10 min the number of insects in each section of the bioassay arena was counted. Uncommitted insects found in the middle part of the arena were treated as nonresponders. All tests were replicated 10 times, and locusts were used only once and discarded. The aggregation index was calculated as $100(T - C)/N$ where T is the number of locusts found in the treated compartment, C is the number of locusts in the control compartment, and N is the total number of locusts tested. If this calculation resulted in a negative number, the aggregation index was assumed to be zero. Aggregation responses were transformed into arcsine and submitted to analysis of variance to compare the effects of natural and synthetic pheromone on fifth-instar aggregation. Mean aggregation responses were compared using the LSD test ($\alpha = 0.05$).

RESULTS

Analyses of Volatiles. EAG-active peaks **1–8** in the crude nymphal volatile extract were identified as hexanal, octanal, nonanal, decanal, hexanoic acid,

octanoic acid, nonanoic acid, and decanoic acid, respectively, by GC-MS (Figure 2). Combined GC-EAD recordings using authentic samples of these compounds on Carbowax and methyl silicone columns confirmed the retention times and EAG activities observed with the natural volatile extract.

Six components with weak activity were identified after analyses of volatile collections from a large number of nymphs (240) as undecanal, dodecanal, pentanoic acid, heptanoic acid, undecanoic acid, and dodecanoic acid. Heptanal,

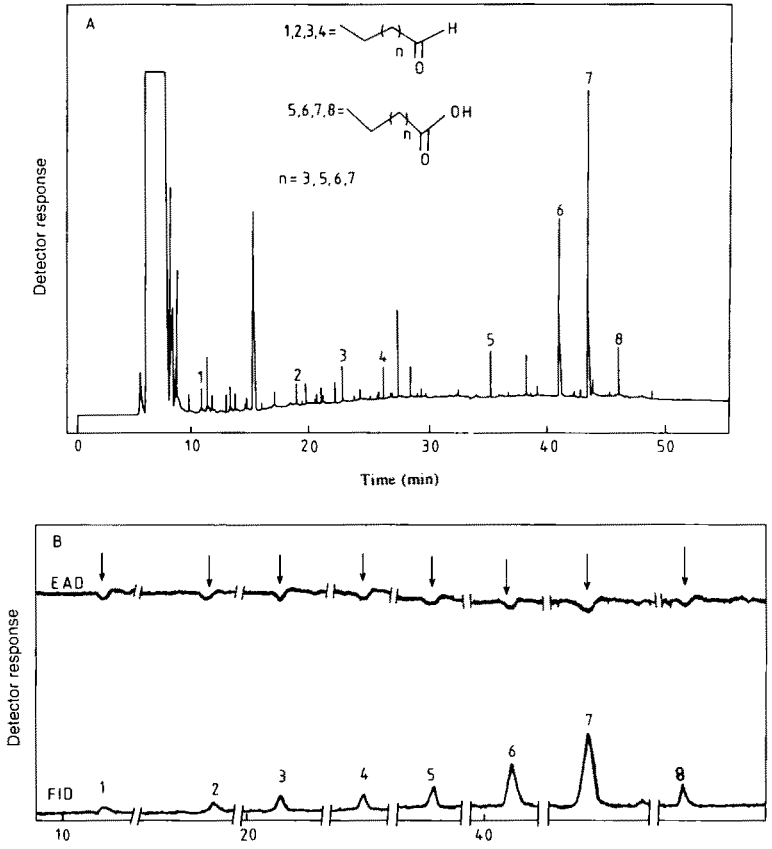

FIG. 2. (A) Gas chromatogram of volatiles collected from fifth-instar nymphs of *S. gregaria* injected onto a 50-m Carbowax 20 M capillary column, and (B) representative reconstructed computer GC-EAD recordings of female *S. gregaria* antennae, responding to compounds **1–8** in the crude nymphal volatile extract.

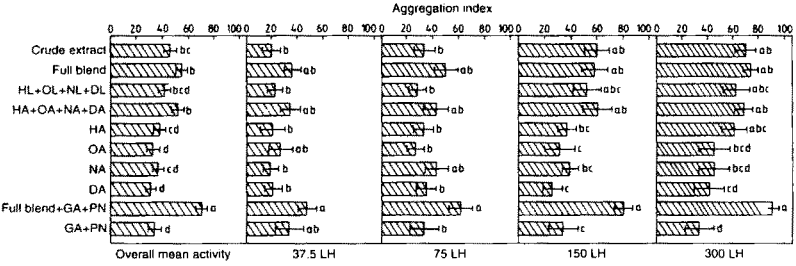

FIG. 3. Dose-response relationships for EAG-active components from fifth-instar volatiles at natural relative concentrations causing aggregation of the nymphs. Means at a particular dose followed by the same letter are not significantly different ($P < 0.05$) by LSD test (percentage transformed to arcsine before analysis). HL = hexanal, OL = octanal, NL = nonanal, DL = decanal, HA = hexanoic acid, OA = octanoic acid, NA = nonanoic acid, DA = decanoic acid, GA = guaiacol, PN = phenol. Full blend = HL + OL + NL + DL + HA + OA + NA + DA.

anisole, benzaldehyde, acetophenone, veratrole, guaiacol, and phenol were also detected in trace amounts.

Behavioral Assays. Responses by fifth instars to the pheromone treatments were dose-dependent (Table 1 Figure 3). Each of the blends consisting of the four acids and four aldehydes evoked strong aggregation responses from nymphs at all doses, similar to the crude extract and the full synthetic blend of the eight compounds. None of the individual aldehydes showed significant activity, but individual acids were moderately active. Addition of guaiacol and phenol to the full blend significantly enhanced aggregation responses in nymphs, particularly at lower doses compared to the crude extract. Overall, the synthetic blend of the 10 compounds evoked significantly stronger aggregation responses from nymphs than the crude extract or the different synthetic blends.

DISCUSSION

Our previous studies focused on the characterization of the aggregation pheromone system of adult gregarious desert locusts (Torto et al., 1994, Obeng-Ofori et al., 1994b). In the present study the volatiles produced by fifth-instars were examined. Eight electrophysiologically active compounds were identified consisting of hexanal, octanal, nonanal, decanal, hexanoic acid, octanoic acid, nonanoic acid, and decanoic acid. Fifth instars responded strongly to the full synthetic blend of the eight compounds, but the blend evoked no significant aggregation response from older adults Table 1, confirming our previous results

that demonstrated stage differentiation in the pheromone systems of gregarious *S. gregaria* (Obeng-Ofori et al., 1993). Individual aldehydes showed no significant activity. Earlier, we had shown that fifth instars aggregated in response to their fecal volatile components guaiacol and phenol (Obeng-Ofori et al., 1994b). Although only trace amounts of these phenols are present in volatile collections of the nymphs themselves, gregarious nymphs are likely to encounter relatively larger concentrations from their fecal droppings (Obeng-Ofori et al., 1994b). Addition of guaiacol and phenol to the full blend significantly enhanced aggregation responses in fifth instars. Thus, the aggregation behavior of nymphal desert locusts appears to be modulated by three sets of pheromonal compounds: short-chain aldehydes and acids produced by gregarious nymphs and guaiacol and phenol associated with their fecal volatiles, which act synergistically. Whether these compounds contribute to different behavioral elements that may be involved in the overall aggregation or have different primary roles in the process remains to be elucidated. The present bioassay was designed to measure gross aggregative effects of candidate materials, and a more detailed study involving the effects of different pheromonal components and blends on different elements of aggregation needs to be undertaken.

Some of the aldehydes and acids detected in the volatiles of the nymphs have been reported as plant constituents (Visser, 1986). The nymphs may synthesize the compounds *de novo* or obtain them from plants. Significantly, solitary nymphs reared on the same food as their gregarious counterparts emit trace amounts of these compounds, but they are not always detectable in their volatile emissions. Several different arthropods produce similar aldehydes and acids in their pheromone glands or volatile emissions, e.g., nonanal, produced in the male pheromone gland of *Galleria mellonella* (L.) (Romel et al., 1992); nonanoic acid, an aggregation–attachment pheromone of *Amblyomma variegatum* (Pavis and Barre, 1993); hexanal, a component in the pheromonal emissions of calling male Mediterranean fruit flies (Flath et al., 1993); and with its carboxylic acid derivative, hexanoic acid, as components of the alarm pheromone system of the leaf-footed bug *Leptoglossus zonatus* (Leal et al., 1994).

In summary, whereas the aggregation behavior of adult gregarious desert locusts is mediated by aromatic derivatives (Torto et al., 1994), aggregation of the second to fifth instars is mediated by straight-chain aliphatic aldehydes and acids that are synergized by fecal phenols. We are currently investigating the semiochemicals associated with aggregation of first-instar gregarious nymphs, which produce no significant amounts of the volatile aggregative signal components identified in gregarious fifth instars.

Acknowledgments—We thank Mr. D. Munyinyi for statistical help and Mr. J. Ongudha for the continuous supply of insects for the study. This work was supported by funds from a consortium of donors coordinated by IFAD through the Consultative Group on Locust Research (CGLR) (IFAD, UNDP, SAREC, and AFESD).

Abstract—Green ash is one of the few tree species rejected as food by larvae of the generalist gypsy moth, *Lymantria dispar* L. (Lepidoptera: Lymantriidae). Such rejection is based especially on chemicals present in green ash foliage. The gypsy moth larval feeding-inhibitory activity is contained in the ethyl acetate extractables of green ash foliage. Three representative column-chromatographed fractions of the extractables contained antifeedant activity. Individual fractions showed weaker antifeedant activity compared to the total ethyl acetate extractables. Acid hydrolysis of the extractables destroyed antifeedant activity and yielded feeding stimulant activity at higher concentrations. The aqueous extractables were not feeding-inhibitory. Compounds in the green ash extractables were separated by TLC, HPLC, CC, and GC.

Key Words—Gypsy moth, green ash, feeding inhibition, *Lymantria dispar*, Lepidoptera, Lymantriidae, *Fraxinus pennsylvanica*, Oleacae.

INTRODUCTION

Herbivores are frequently exposed naturally to a wide variety of dissimilar plants. Such a situation makes nonhost rejection and host-plant selection major herbi-

vore decisions. The unsuitability of nonhosts as food for herbivores is ultimately determined by overall plant defensive strategy, which may involve anatomical, morphological, and/or chemical parameters (Norris and Kogan, 1980). A comprehensive strategy better enables the successful survivor plant species to direct its defenses at the entirety of environmental stresses, whether biological, physical, and/or chemical, and not just at some specific stress, e.g., an herbivorous insect or microbial pathogen (Norris, 1988). Although a nonhost plant decision by most insects is affected by the plant's overall defensive capabilities, repellent and/or deterrent chemicals may play a major role. Feeding-deterrent compounds contribute significantly to the inability of herbivorous insects to use certain plants as hosts (Fraenkel, 1959; Jermy, 1966; Gilbert et al., 1967; Whittaker and Feeny, 1971; Norris, 1990, 1994; Burden and Norris, 1992) and may especially influence the feeding behavior of polyphagous insects (Meisner and Skatulla, 1975; El-Naggar et al., 1980; Doskotch et al., 1980; El-Naggar and Doskotch, 1980; Schultz and Baldwin, 1982; Miller and Feeny, 1983; Barbosa and Krischik, 1987; Bowers and Puttick, 1988, 1989). The polyphagous gypsy moth, *Lymantria dispar* L. (Lepidoptera: Lymantriidae), rejects foliage of the green ash tree, *Fraxinus pennsylvanica* Marsh (family Oleaceae), as a host (Mosher, 1915; Mauffette and Lechowicz, 1983; Odell et al., 1985; Lechowicz and Mauffette, 1986). Chemicals in green ash play a major role in this nonhost rejection.

The present paper is a contribution to a larger effort to define the continuum of chemical defenses in green ash against environmental stresses, which makes this tree a nonhost to the gypsy moth. Our earlier paper (Markovic et al., 1996) addressed locomotory responses of gypsy moth larvae to volatile chemicals emanating from green ash foliage. The present effort addresses the effects of ash-foliage chemistry on larval feeding.

METHODS AND MATERIALS

Insects

Gypsy moth egg masses were obtained from the Otis Air Force Base rearing facility in Massachusetts. If egg masses were not used immediately upon arrival, they were stored at +10°C in darkness. In preparation for hatch, egg masses were surface sterilized for 5 min in 0.1% sodium hypochlorite solution. After sterlization, egg masses were rinsed for 10 min with distilled water and dried.

Rearing was conducted on a wheat germ artificial diet in incubators at 25 ± 1°C with a 15 L:9 D photoperiod. Sterilized individual egg masses were placed aseptically into individual plastic dishes (4 × 15.5 cm) along with a piece of diet (10 × 1.0 × 1.5 cm). Sterile technique was employed throughout the study.

Plants

Leaves for the studies were collected on the University of Wisconsin campus from five green ash (*Fraxinus pennsylvanica* Marsh) trees that had not been recently exposed to aerial and/or other kinds of pesticide application.

Moisture Determination

The fresh weight of *F. pennsylvanica* leaves was determined immediately after sampling. Leaves were put into preweighed weighing bottles, dried for 24 hr at 110°C, cooled in a desiccator, and reweighed in the resealed bottle. Dry weight of the leaves was determined, and the percent of moisture per leaf calculated.

Chemical Analyses

Extraction Procedure. Green ash leaves (100 g) were randomly taken from each tree, placed immediately into a screw-cap glass jar containing 800 ml of 80% methanol (MeOH), and stored in darkness at −20°C until chemical analysis. All individual leaflets were removed from each compound ash leaf per jar, and the resultant denuded leaf petioles were cut into 0.5-cm-long sections. The petiole sections and individual leaflets per jar were combined in 800 ml of 80% MeOH for storage. For processing of samples, we added 100 ml of 100% MeOH and homogenized for 15 min at 50% maximum speed in an Omni-mixer (Ivan Sorvall, Inc., Norwalk, Connecticut). The resultant homogenate was filtered twice through Whatman No. 1 paper under vacuum. The filtrate was reduced to about 15 ml by rotoevaporation at 42 ± 2°C under vacuum. The concentrated MeOH extractables resulting from homogenization of 100 g (fresh weight) of leaves were partitioned in a separatory funnel (3 × 1000 ml of ethyl acetate). Ethyl acetate (EtOAc) fractions were rotoevaporated to dryness and redissolved in an excess of EtOAc (Markovic et al., 1993). Each sample was then placed in a preweighed screw-cap vial, dried under a stream of nitrogen, and weighed. Samples in screw-capped vials were wrapped in aluminum foil and stored at −20°C in darkness.

The remaining aqueous extractables after EtOAc partitioning of MeOH extractables were transferred into a preweighed screw-cap vial, lyophilized for 36–48 hr and the dry weight was determined. Vials with dry aqueous extractables were also stored at −20°C in darkness for later use.

Acid Hydrolysis of Green Ash Extractables. Acid hydrolysis to cleave glycosidic bonds (i.e., to separate algycones from sugars in glycosides) was performed on a 50-mg subsample of the dried EtOAc extractables from 100 g of leaves. This subsample was hydrolyzed 1.5 hr in 60 ml of 2 M hydrochloric acid in a water bath at 98 ± 2°C (Harborne, 1984). The resultant hydrolyzed

subsample was cooled, filtered through Whatman No. 2 paper, and then extracted with 35 ml of chloroform ($CHCl_3$) under vacuum. Extracting hydrolyzed material in ethyl ether (EtO) instead of $CHCl_3$ resolved fewer peaks when applied on the TLC plate. Finally, $CHCl_3$ extractables of each subsample were dried under a nitrogen stream, and their dry weights were determined.

Acid hydrolysis of aqueous extractables was performed in the same way as with EtOAc extractables except that hydrolyzed material was redissolved in EtO.

Fractionation of Green Ash EtOAc Extractables. Activated silica gel (50- to 200-μm particle size) was poured in a slurry of $CHCl_3$–MeOH (9:1) into two glass columns (16-ml and 400-ml volume). Prior to application of the plant material, each column was rinsed with six 25-ml portions of $CHCl_3$–MeOH (9:1). With the 16-ml column, 300 mg EtOAc extractables were applied and six 25-ml fractions were collected in $CHCl_3$–MeOH (9:1) (LaLonde et al., 1976). Fractions 5 and 6 were combined (6.9 mg of dried material) as fraction A, and used for bioassay. We applied 4 g of EtOAc extractables to the 400-ml column and eluted fractions using the following sequential solvent regime: 550, 100, 300, 250, and 250 ml of $CHCl_3$–MeOH (9:1); 150 ml of $CHCl_3$–MeOH (1:1); 200 and 300 ml of $CHCl_3$–MeOH (1:9); and next one 300- and five 200-ml quantities of $CHCl_3$–MeOH (9:1). The last two 200-ml fractions were combined (4.1 mg of dried material) as fraction B and used for bioassay. The preceding elution sequence on the 400-ml column was followed by four 200-ml fractions of 60% aqueous MeOH. The last of the four 200-ml fractions (3.7 mg of dried material) (fraction C) was bioassayed. Eluted fractions were filtered through Whatman No. 2 paper and dried by rotoevaporation or under a stream of nitrogen. Each fraction was then redissolved in an excess of 100% MeOH, passed through a Gelman Nylaflo 0.20-μm filter, and the dry weight determined for bioassay. The chemical profile of each fraction was monitored by HPLC and GC.

Thin-Layer Chromatographic (TLC) Analyses. Each 20 μl of a 10 mg/ml (w/v) sample was vortexed for 6 sec before being spotted with a glass capillary tube on a silica gel TLC plate (20 × 20 cm, 250 μm thick, 5- to 17-μm particle size, and a 254-nm fluorescent indicator) (Sigma Chemicals, St Louis, Missouri). Plates were then developed in a solvent mixture of chloroform–acetone–acetic acid (90:10:1) in a closed glass tank saturated with solvent vapors. The solvent was run up 65% of the plate height, and the plate was allowed to air dry at room temperature. Resolved bands were first detected under 254-nm UV light (Mineral Light Lamp, UVSL-25, Ultra Violet Products, San Gabriel, California). Resolved and dried TLC plates were next examined for resolved compounds with at TLC scanner under UV light (TLC SCAN II, CAMAG Scientific Inc., Wilmington, North Carolina 28405) combined with a CATS3 computing-integrator software program.

High-Performance Liquid Chromatographic (HPLC) Analyses. A 2.5- to 5.0-mg aliquot of each sample was dissolved in 1-ml HPLC-grade MeOH (Aldrich Chemical Company), vortexed for 1 min, and then passed through a Gelman Nylaflo 0.20-μm filter. Just before the injection into the HPLC, each sample was vortexed for 1 min, and a 20-μl volume injected into a Beckman Ultrasphere ODS 5-μ column (4.6 mm $\times$ 25 cm). The eluting solvent consisted of 2% acetic acid–acetonitrile (90% : 10%) for 5 min, a linear gradient to 100% acetonitrile in 25 min, and then back to the starting ratio in 3 min. There were three replicate injections per sample. The HPLC system was controlled by an Altex 422 programming microprocessor and two Altex 100A pumps. The UV detector (Kratos) was set at 254-nm absorbance. Data were integrated and peak areas recorded through a Spectra Physics 4400 computing integrator.

Capillary Gas Chromatography (GC) Analyses. The EtOAc extractables from green ash leaves, and individual fractions therefrom, were analyzed by gas chromatography using a Shimadzu GC-14A GC with a DB-17 capillary column (0.25 mm $\times$ 30 m, 0.25-μm film thickness, J&W Scientific, Folsom, California 95630) and a flame ionization detector (FID), or with a DB-1 capillary column (0.25 mm $\times$ 30 m, 0.25-μm film thickness; J & W) mated via a heated transfer line to a Finnigan MAT ITD 800 series mass spectrometer. The GC was programmed from 40°C for 1 min to 220°C, at 5°C/min. The injector temperature was 220°C and the detector, 265°C. Aliquots of 1–2 μl of the extracted sample were injected in the splitless mode. Retention time, area, and ratio of each resolved peak area to the total resolved peak area were calculated and recorded by a Shimadzu C-R3A Chromatopac computing integrator.

Feeding Bioassays

General Considerations. For feeding bioassays neonates were placed on artificial diet, and the larvae were reared until they reached the third instar. Third instars, 24- to 36 hr old, were removed from other larvae of a given egg mass and placed in groups of 20, with the result that each individual was from a different egg mass. They were then placed in a plastic dish (4.5 $\times$ 11.5 cm) containing a diet cube. Experimental larvae were uniformly starved by removing the cube of diet 4.5–5 hr prior to the initiation of the experiment. Transferring larvae from artificial diet to fresh leaf discs does not significantly disrupt their feeding (Hajek, 1989). An experiment was terminated when at least 50% of the area of a leaf disc in an arena was removed, or when 28 hr had elapsed.

Preference Between Red Oak and Green Ash Foliage. The nonhost/host status of *F. pennsylvanica* foliage regarding *L. dispar* was determined using a preference test. Twenty-four- to 36-hr-old third instars were used in feeding bioassays. Unless otherwise specified, 15 replicates per treatment were used with two larvae from a given egg mass constituting a replicate. Larvae were

provided with green ash and/or red oak leaf discs cut with a No. 8 (1.5-cm-diam) cork borer. The feeding arena consisted of a plastic Petri dish (1.3 × 9 cm) with a 2- to 3-mm-thick layer of paraffin on the bottom of the dish. One 9-cm-diam. No. 1 filter paper was attached to the inside surface of the lid of each arena and another on the paraffin bottom. The top paper was moistened as necessary to maintain the turgidity of the leaf discs. Two 1.2-cm-long insect pins secured each leaf disc to the paper-covered paraffin bottom of the arena.

For the two-choice assay, insects were offered a comparable leaf disc from green ash (treatment) versus red oak (control). Each leaf disc was placed about 1.5 cm from the edge of the arena, leaving about 1.5 cm centrally between the two discs in the arena setup. Two larvae were introduced centrally into the feeding arena.

In the no-choice assay, a single larva was offered either a green ash or a red oak leaf disk. An adjacent treatment- or control-containing arena was considered as the other member in this paired, but no-choice, assay.

Dose–Response Test with Nonhydrolyzed Extractables from Green Ash Foliage. A dose–response study determined the biologically active concentration range for the EtOAc extractables from green ash foliage. The following concentrations were employed: 0.025, 0.05, 0.10, 0.25, 0.5, 1.0, 2.0, 3.0, 5.0, 7.5, 10.0, 15.0 mg/ml (w/v) in 100% MeOH. Two oak (host) leaf discs were presented per assay. Forty microliters of an appropriate concentration of green ash extractables were presented as the treatment on the upper surface on one of the two leaf discs. An equal amount of 100% MeOH was presented as the solvent control on the upper surface of the other leaf disc. Each extractables-containing vial was vortexed 1 min before a sample was removed and applied on a leaf disc. Two third instars were placed centrally between the treated and control discs to initiate the assay.

A second dose–response study determined the presence or absence of biologically active components in the residual aqueous extractables from green ash foliage, and the range of active concentrations, if activity was detected. The following concentrations were employed: 0.1, 0.5, 2.0, 5.0 and 10.0 mg/ml (w/v) in 80% MeOH. The feeding bioassays comparing the activity of aqueous extractables versus the 80% MeOH control were conducted as described for the dose–response tests with EtOAc extractables.

Dose–Response Test with Hydrolyzed Extractables. The following concentrations were employed for the feeding bioassay: 0.10, 0.5, 2.0, 5.0, and 10.0 mg/ml (w/v) in 100% $CHCl_3$. The feeding bioassays comparing the activity of hydrolyzed versus nonhydrolyzed fractions were conducted as described for the dose–response tests with EtOAc extractables.

Only one concentration (i.e., 10 mg/ml) of aqueous extractables was bioassayed in 10 replicates as described for the dose–response test with EtOAc extractables. Forty microliters of hydrolyzed aqueous extractables redissolved

in EtO was presented as treatment, whereas, the control consisted of an equal amount of EtO.

Dose–Response Test with Fractionated EtOAc Extractables. The EtOAc extractables of green ash foliage were fractionated to determine those affecting larval feeding. Fraction A was assayed in 10 replicates of four concentrations (i.e., 0.025, 0.1, 1, and 5 mg/ml); fraction B was assayed in 10 replicates of one concentration (i.e., 3 mg/ml), due to an insufficient amount of material available; and fraction C was assayed in 15 replicates of five concentrations (i.e., 0.05, 0.1, 0.25, 1, and 3 mg/ml). The assay was the same as described for the dose–response test with EtOAc extractables. Forty microliters of either fraction was redissolved in MeOH and presented as treatment, whereas the control consisted of an equal amount of MeOH.

Quantification of Feeding Assays. The remaining portion of uneaten leaf disc was mounted between two glass microscope slides and scanned into a computer file. The computer system consisted of a Macintosh image scanner (Apple Computer, Inc., Cupertino, California), a Macintosh II computer, and a Apple Scan Ofoto image-scanning software program. Images were analyzed for remaining disc area (i.e., expressed in pixels) using the high-resolution extraction and reduction program, Collage (Image Dynamics, Madison, Wisconsin) and a Macintosh II computer (Burden and Norris, 1992).

Statistical Analyses. The remaining area of each of the two leaf discs from each feeding assay was compared using the paired t test. The remaining area of the control disc was subtracted from the remaining area of the treatment disc. A significant difference between treatment and control was determined by the $P < 0.05$ error limit. A stepwise regression was conducted with the dose–response data where the concentration, egg mass, and tree selected represented the independent variables; and the difference (the remaining area of the treatment disc − the remaining area of the control disc) represented the dependent variable. Such a method revealed concentration as the only significant ($P < 0.05$) independent variable; hence, the remaining variables were disregarded. Polynomial regression was plotted using the area-difference versus the log-transformed concentration data.

RESULTS

Chemical Analyses

Composition of Fresh Green Ash Leaves. Fresh foliage contained 2.56% EtOAc extractables, 4.93% aqueous extractables, 22.80% insoluble (80% MeOH) residue, and 69.41% water.

Acid Hydrolysis of Green Ash Extractables. TLC scanning resolved more

peaks in the acid-hydrolyzed than in the nonhydrolyzed EtOAc extractables (Figure 1). This procedure apparently yielded more entities by cleaving bonds within more complex compounds and thus releasing the increased number of simpler molecules. The breakage of glycosides into their constituent aglycones and sugars is one likely source of the increased constituents in the hydrolyzed fraction.

Fractionation of Green Ash EtOAc Extractables. Three fractions (i.e., A, B, and C) (Figure 2) jointly contained most of the peaks present in the total

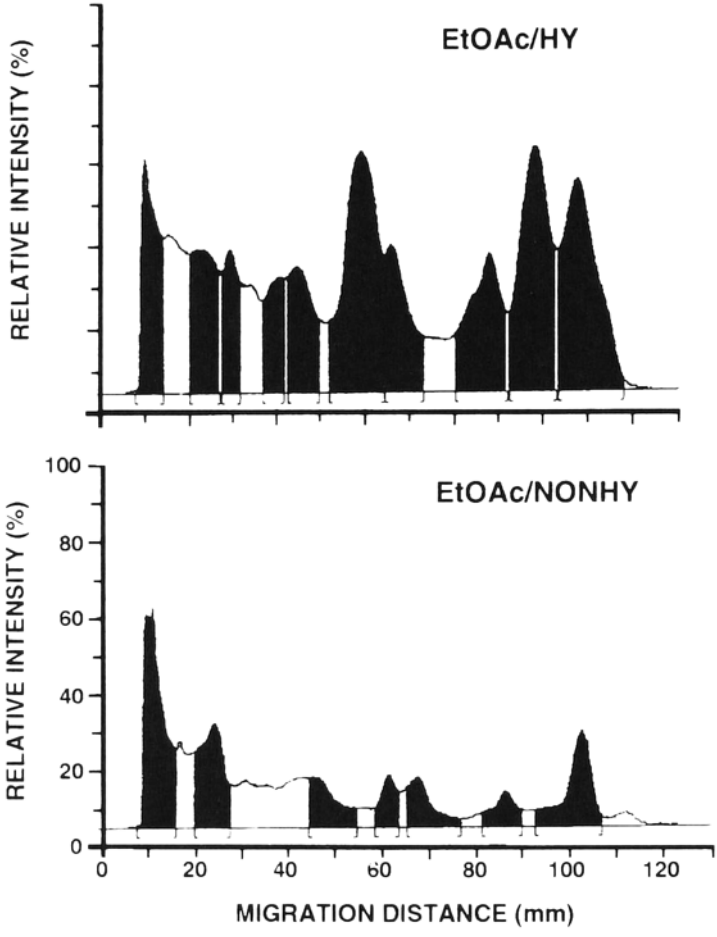

FIG. 1. HPTLC chromatograms of 10 mg/ml of hydrolyzed (EtOAc/HY) and nonhydrolyzed (EtOAc/NONHY) EtOAc extractables of green ash leaves.

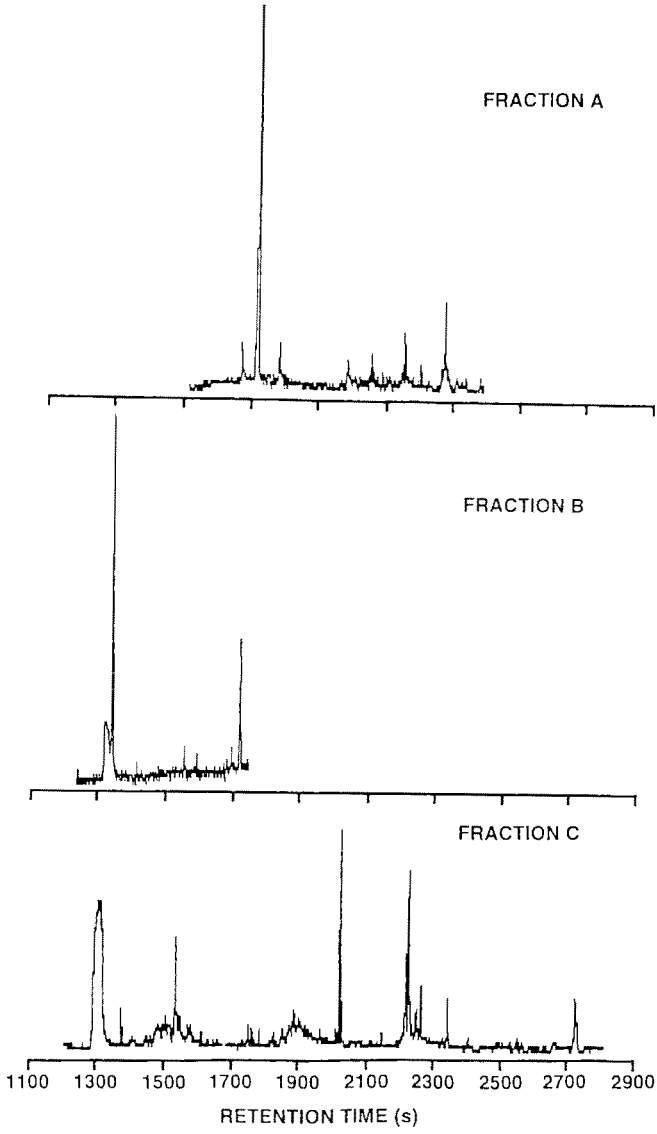

FIG. 2. GC chromatograms of three representative column-chromatographic fractions of the nonhydrolyzed EtOAc extractables. Fraction A eluted in $CHCl_3$–MeOH (9:1) on the 16 ml column; fraction B eluted in $CHCl_3$–MeOH (9:1) on the 400-ml column; and fraction C eluted in 60% aqueous MeOH on the 400-ml column.

EtOAc extractables, but each contained peaks distinct from those in the other fractions.

Feeding Bioassays

Preference Test. When both red oak and green ash leaf discs were presented to larvae in a choice assay, they showed a significant preference for red oak ($P < 0.001$). When red oak and green ash were presented in a no-choice, paired assay, larvae consumed oak significantly more ($P < 0.001$) than ash. Overall, larvae removed less than 2% of the green ash leaf disk area as compared to 52 and 53% of the red oak discs in choice and no-choice assays, respectively.

Dose-Response Test with Nonhydrolyzed EtOAc Extractables. Application of nonhydrolyzed green ash EtOAc extractables caused a significant reduction in larval feeding on the treatment (i.e., red oak leaf disc plus 40 μl of the nonhydrolyzed EtOAc extractables) as compared to the control (i.e., red oak leaf disc plus 40 μl of 100% MeOH) (Figures 3 and 4). The level of antifeedant activity depended on the dosage, e.g., dosages of 2–15 mg/ml caused a significant feeding preference for the control versus treatment at $P < 0.001$. Significantly reduced feeding was observed at 1 mg/ml ($P = 0.002$), 0.5 mg/ml ($P = 0.0043$), 0.25 mg/ml ($P = 0.011$), and 0.1 mg/ml ($P = 0.016$). Tests with

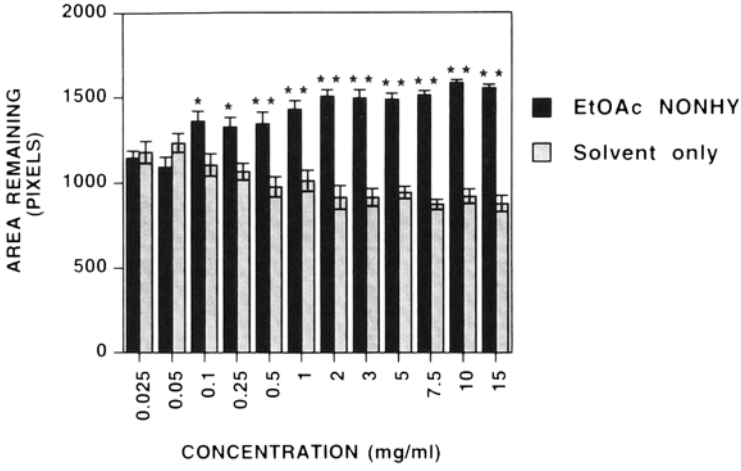

FIG. 3. Dose-response test with 12 different concentrations of nonhydrolyzed EtOAc extractables. Treatment (EtOAc NONHY) bars topped by two asterisks are significantly different from the control (solvent only) by the paired t test at $P < 0.01$; whereas those topped by one asterisk are significantly different at $P < 0.02$.

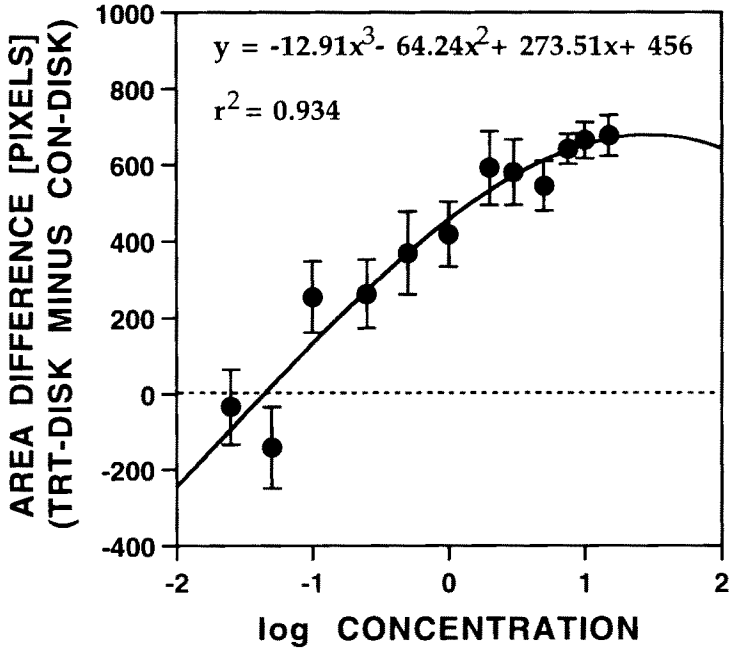

FIG. 4. Polynomial regression of the remaining disc-area difference (trt-disc minus con-disc) in pixels against the log-transformed concentrations. The higher six concentrations are not significantly different from each other (one-way ANOVA).

0.05 and 0.025 mg/ml caused insignificant effects. The six higher concentrations did not significantly differ in their antifeeding activity (one-way ANOVA).

Dose–Response Test with Nonhydrolyzed Aqueous Extractables. None of the five dosages (i.e., 0.1, 0.5, 2, 5, and 10 mg/ml) of nonhydrolyzed aqueous extractables from green ash foliage was significantly inhibitory to larval feeding (Figure 5).

Dose–Response Test with Hydrolyzed EtOAc Extractables. Acid hydrolysis of the otherwise very active EtOAc extractables destroyed antifeedant activity (Figure 6). In addition, such a procedure rendered the two highest dosages (i.e., 5 and 10 mg/ml) significantly more stimulatory to larval feeding ($P = 0.001$ and $P = 0.01$, respectively) as compared to the $CHCl_3$ control. The remaining dosages at 0.1, 0.5 and 2 mg/ml had insignificant effects.

Dose–Response Test with Hydrolyzed Aqueous Extractables. At 10 mg/ml concentration, the hydrolyzed aqueous extractables did not show significant anti-

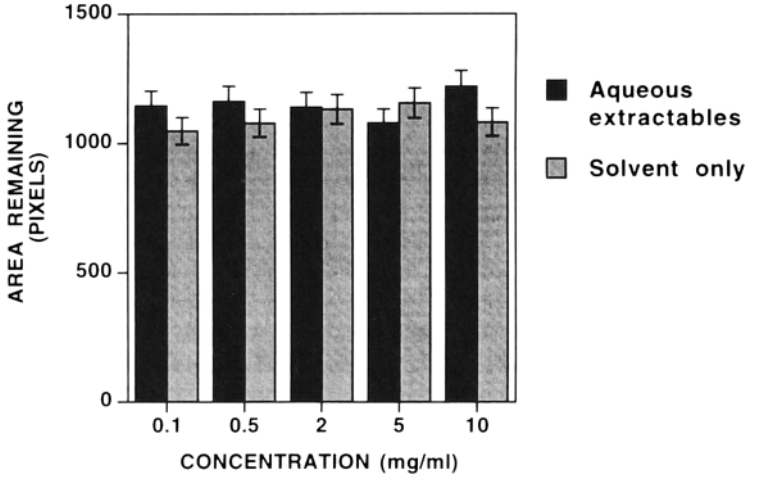

FIG. 5. Dose–response test with five different concentrations of the nonhydrolyzed aqueous extractables.

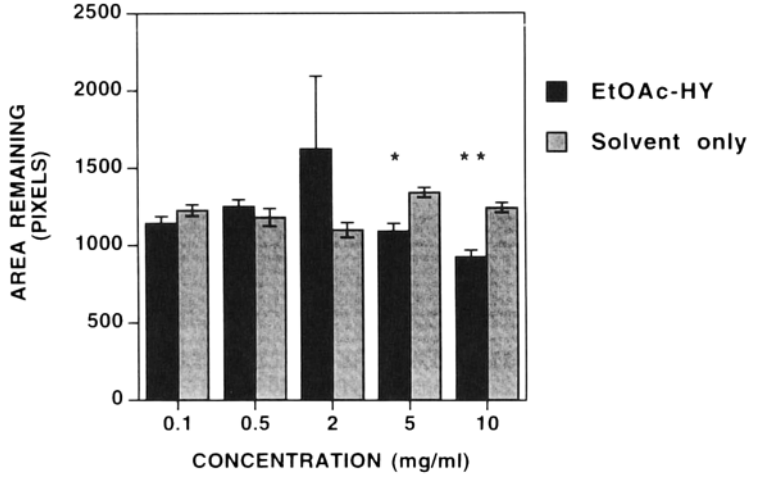

FIG. 6. Dose–response test with five different concentrations of hydrolyzed EtOAc extractables. Treatment (EtOAc-HY) bars topped by two asterisks are significantly different from the control (solvent only) by paired t test at $P < 0.001$, whereas those topped by one asterisk are significantly different at $P < 0.01$. (see text for the exact P values).

feedant activity. Doskotch et al. (1981) suggested that water-soluble compounds usually are less likely to have feeding deterrent activity.

Effects of Fractionation of Nonhydrolyzed EtOAc Extractables on Larval Feeding. Of the four assayed dosages of fraction A (Figures 2 and 7), the highest dosage at 5 mg/ml caused significant ($P = 0.0037$) feeding reduction for the treated versus untreated (control) disc. The remaining concentrations of 0.025, 0.1, and 1 mg/ml did not cause significant antifeedant activity. Fraction B caused a significant ($P = 0.001$) feeding inhibition at 3 mg/ml (Figures 2 and 7). Fraction C (Figures 2 and 7) caused an antifeedant response at 3 mg/ml ($P = 0.01$), but not at 0.05, 0.1, 0.25, and 1 mg/ml.

DISCUSSION

Insects frequently reject plants as hosts due to repellents, deterrents, and/or feeding inhibitors (Jermy, 1966; Gilbert et al., 1967; Norris, 1986, 1994). Gypsy moth larvae reject green ash as a host due to chemicals in green ash foliage. Green ash chemicals deterrent and/or inhibitory to larval feeding are contained primarily in the EtOAc extractables. These extractables caused significant reduction in larval feeding at concentrations as low as 0.1 mg/ml. Increasing the concentration above 2 mg/ml, however, did not cause significantly greater feeding reduction. The chemosensory receptors of the larvae may become saturated at relatively low levels of the EtOAc extractables.

Three representative, GS-verified, column-chromatographic fractions of EtOAc extractables contained antifeedants. Each fraction alone showed weaker antifeedant activity compared to the total EtOAc extractables. Fractionation of extractables from the tulip-tree leaves (Doskotch et al., 1981) and catalpa leaves (El-Naggar and Doskotch, 1980) similarly reduced their deterrency to gypsy moth larvae. More than one component is obviously responsible for the observed feeding-inhibitory activity of EtOAc extractables from green ash foliage. Berenbaum (1985) suggested that plant selection favors a multicomponent chemical defense, which may be directed at multiple target sites. Multicomponent activity frequently encompasses additive elements, in which the combined antifeedant activity of the components is greater than that of any individual component, and/or synergistic elements so that the combined activity is greater than the summed activity of individual components. Some synergistic chemicals (e.g., methylendioxyphenyls) may lack feeding-inhibitory activity but may suppress major detoxifying enzymes (e.g., cytochrome P-450); in this way they can significantly augment the feeding-inhibitory activity of other secondary metabolites (Berenbaum, 1985). Others (e.g., caffeine) have both feeding-inhibitory (or toxic) effects and synergize the biological activity of additional components (Nathanson, 1984). Consequently, the observed greater antifeedant activity in the EtOAc mixture, as compared to a fraction thereof, seems reasonable.

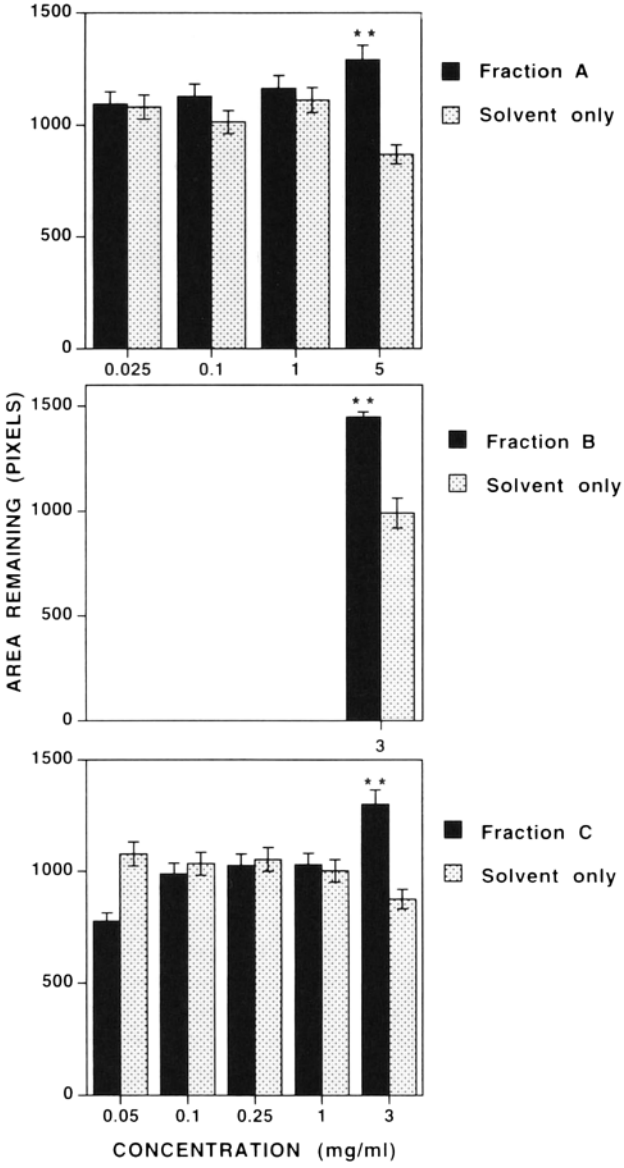

FIG. 7. Dose-response test with fractions A, B, and C of nonhydrolyzed EtOAc extractables separated by column chromatography. Treatment (fraction A, B, or C) bars topped by two asterisks are significantly differnt from the control (solvent only) by the paired t test at $P < 0.01$ (see text for the exact P values). Fraction B was assayed at only one concentration due to insufficient amount of material available.

Acid hydrolysis of EtOAc extractables destroyed antifeedant activity and yielded feeding stimulants. A reasonable explanation might be that hydrolysis broke major antifeedant components, including some glycosides and other complex molecules, into simpler chemicals. In the absence of the previously existing deterrents, existing and/or released compounds such as sugars, phenolics, and/or short-chained fatty acids may act as feeding stimulants. Structural identification of chemicals in the active EtOAc extractables from green ash foliage, their relative proportions, and the feeding-inhibitory activity of such individual components should be carried out.

Acknowledgments—We gratefully acknowledge Mr. Joel K. Phillips, USDA ARS, Stored-Product Insects Research Unit, University of Wisconsin-Madison for GS analyses. We also thank Dr. Robert Bremel, Department of Animal Sciences, University of Wisconsin-Madison for the use and training on the Collage system. This research was supported by the College of Agricultural and Life Sciences, University of Wisconsin, Madison, and in part by funds from U.S. Hatch Project No. 3419.

Abstract—Attraction of both sexes of *Ips plastographus maritimus* Lanier to bark-phloem-xylem discs of Monterey pine, *Pinus radiata* D. Don, was demonstrated in the laboratory. Increasing concentrations of male and female volatiles trapped separately and released in a one-to-one ratio decreased attraction for both sexes combined. Attraction of both sexes to volatiles derived from males and females tunneling together in a one-to-one ratio increased with increasing concentration of extract. Attraction of males and females to male-infested discs and to trapped male volatiles increased with increasing dose of males or male extract. Attraction of males and females to female-infested discs and to trapped female volatiles was also demonstrated. The presence of females in male galleries reduced the attractiveness of infested disks to both sexes combined. Increasing numbers of females, tunneling separately from males in the same disc, reduced attraction of males, but not females. When a constant attractive dose of male volatiles was released with increasing doses of female volatiles, there was no difference in response of

either sex when female volatiles were present compared with the response to male volatiles alone. When a constant attractive dose of male volatiles was released with increasing concentrations of volatiles derived from males and females tunneling together in a one-to-one ratio, attraction of *I. p. maritimus* decreased. Response of females was frequently higher than that of males to the same attractant source. Hence, both sexes produce an attractant, and both sexes tunneling together in the same gallery reduce attraction of males and females to an attractive dose of male attractant.

Key Words—*Ips plastographus maritimus*, Coleoptera, Scolytidae, bark beetle, *Pinus radiata*, host volatiles, aggregation pheromone, sex-specific response, attraction, interruption

INTRODUCTION

Most bark beetles (Coleoptera: Scolytidae) colonizing host trees produce pheromones that attract conspecifics of both sexes, resulting in mass attack of the host (Wood, 1982; Borden, 1985; Raffa et al., 1993). There are exceptions to this pattern of attack; for example, *Dendroctonus micans* Kug. adults are not known to produce aggregation pheromones, and do not mass attack trees (Grégoire, 1988). *Tomicus piniperda* (L.) adults also are not known to produce aggregation pheromones, but they mass attack trees (Byers et al., 1985). *Ips* spp. males initiate galleries on the host by tunneling through the bark and feeding in fresh phloem (Anderson, 1948). In all species studied, males produce a pheromone that elicits the resultant aggregation (Wood, 1982; Borden, 1985; Seybold, 1992; Raffa et al., 1993). In nature, male *Ips* spp. initiate galleries on a new host and are generally joined by one to six females (Bright and Stark, 1973). A mass attack by bark beetles concentrates the same species on host material suitable for feeding and reproduction and is dependent on pheromone production by the sex that initiates attacks on the host (Wood, 1962, 1982; Wood and Vité, 1961). For example, the aggregation pheromone released by male *Ips paraconfusus* Lanier was identified as a mixture of the three monoterpene alcohols, ipsenol, ipsdienol, and *cis*-verbenol (Wood et al., 1966; Silverstein et al., 1966), none of which elicited a response when delivered individually (Wood et al., 1967, 1968). These studies demonstrated a multicomponent attractant pheromone and synergistic effects among pheromone components (Silverstein, 1977). These pheromone components were identified using an olfactometer to assay the upwind walking behavior of *I. paraconfusus* (Wood and Bushing, 1963). More recently this upwind response was shown to be stimulated both by the presence of multiple pheromone components (chemotaxis) and by the airstream (anemotaxis) (Akers, 1989; Akers and Wood, 1989; Akers et al., 1993).

There are 27 species of *Ips* recognized in North America (S. L. Wood, 1982; Lanier et al., 1991), yet only a few species have been subjects of studies

of chemosensory behavior. *Ips plastographus* has been described based on two subspecies of geographic origin: coastal (*maritimus* Lanier) and subalpine [*plastographus* (LeConte)] (S. L. Wood, 1982; Lanier, 1970). Lanier (1970) demonstrated reduced fertility of backcross and F_2 generations between the coastal and subalpine populations, indicating a genetic difference in the populations. Both subspecies of *I. plastographus* have yielded 89–95% (+)-ipsdienol from a mixture of volatiles trapped from male-infested logs (Seybold, 1992). The attractiveness of this compound to either subspecies has not been demonstrated. However, Lanier and Wood (1975) demonstrated a strong response of female *I. p. maritimus* to male-produced frass in the laboratory. Females of three species of *Ips* from other subgeneric groups were not attracted to this frass. A pheromone response of *I. p. plastographus* males and females to male-infested logs of *Pinus ponderosa* Laws. was indicated in limited field trials (Lanier, 1970). *Ips plastographus maritimus* frequently colonizes *Pinus radiata* D. Don (Monterey pine), *P. muricata* D. Don (bishop pine), and *P. contorta* var. *contorta* Dougl. (shore pine) (Bright and Stark, 1973; S. L. Wood, 1982). *Ips plastographus plastographus* typically infests *P. contorta* var. *murrayana* Grev. and Balf. (Sierra lodgepole pine), and *P. contorta* var. *latifolia* Engelm. (Rocky Mountain lodgepole pine) (S. L. Wood, 1982).

The upwind walking response of *I. p. maritimus* to various sources of volatiles was measured in an open arena olfactometer. Volatiles originated either directly from uninfested host tissue or host tissue infested with male or female or both sexes of *I. p. maritimus* or from volatiles trapped from air passing over uninfested or infested host tissue. *I. p. maritimus* was the subject of this study because it is a potential vector of *Fusarium subglutinans* f. sp. *pini* (Storer and Dallara, 1992), the causal agent of pitch canker disease of pines. The objectives were to: (1) determine if males and females produce an attractive aggregation pheromone, and (2) determine if females produce an interruptive aggregation pheromone.

METHODS AND MATERIALS

Collection of Beetles and Host Material

Branch and stem sections of recently fallen *P. radiata* that had been colonized by *I. p. maritimus* were collected in 1994 and 1995 from Santa Cruz and San Mateo Counties in California, and placed in rearing cages (Browne, 1972). Following emergence, males and females were separated by the presence of the *pars stridens*, a stidulatory structure on the vertex of the female's head (Lanier and Cameron, 1969), and stored at 4–5°C in Petri dishes containing moist filter paper. Uninfested *P. radiata* logs for production of volatiles and for

disc assays were collected in 1994 and 1995 from Santa Cruz and Contra Costa Counties, California.

Preparation of Behavioral Stimuli

Uninfested and Infested Host Discs. Bark-phloem-xylem discs (hereafter termed discs) were prepared by cutting a fresh *P. radiata* log through the bark and phloem and into the xylem with a 5-cm cylindrical hole cutter. Discs were excised with a wood chisel and placed in clean Petri dishes. Discs were prepared either immediately before beetles were introduced or were prepared and refrigerated not more than 24 hr before beetles were introduced. Males or females were introduced into the discs in holes drilled 3 mm in diameter and 5 mm into the disk. Each drilled hole extended through the bark and phloem and onto the surface of the xylem of the disc. Beetles were confined under wire mesh that was secured on the bark surface by staples or under a gelatin capsule secured by a No. 2 insect pin. Beetles were allowed to feed in discs for approximately 24 hr before the discs were assayed.

Six disc treatments were prepared in which only one sex of *I. p. maritimus* was used. These treatments were: 0 insects; 3 or 6 males; and 3, 6, or 9 females. In addition, five disc treatments were prepared using both sexes in different sex ratios. In these cases male galleries were initiated in the discs 24 hr before introduction of females. Females were either added to male galleries or added to their own galleries in freshly drilled holes adjacent to male galleries. If females were to be added to male galleries, males were secured in their galleries by a pinned gelatin capsule, and females were added after removing the capsule. If females were introduced in different galleries from the males, fresh holes were drilled for females immediately before their introduction. In both instances the females were secured in the discs with fine wire mesh. Of the five disc treatments prepared with both sexes present, all contained six male beetles. No females were added to one disc; females were added to the male galleries in two discs in ratios of one female per male and two females per male; and females were introduced into separate galleries in two discs in ratios of one female per male and two females per male.

Chemical Extracts of Volatiles Trapped from Uninfested and Infested Host Tissue. Pinus radiata logs, approximately 30 cm in length, and with a phloem thickness of at least 2 mm, were artificially infested with male and/or female beetles. This phloem provided enough feeding material for the duration of the volatile collection period. Three logs were prepared for each of four treatments. The treatments included: 0 insects; a total of 140 males (distributed over three logs); a total of 180 females (distributed over three logs); and a total of 168 males and 168 females (distributed over three logs). Logs with either males or females tunneling alone were prepared 24 hr prior to volatile collection. Logs

containing male and female beetles tunneling together were prepared by introducing the females 24 hr after the males and commencing with volatile collection 24 hr after the introduction of the females, i.e., 48 hr after introduction of the males.

To trap host- and insect-produced volatiles, beetle-colonized logs were placed into 19-liter glass carboys for approximately 168 hr. Air was drawn through activated charcoal into these chambers and passed through Porapak Q (50–80 mesh, Supelco Inc., Bellefonte, Pennsylvania) to trap compounds volatilizing from the insect-colonized and uncolonized host tissue (Seybold, 1992). The Porapak was extracted with 350 ml of pentane, and the extract was concentrated by rotary evaporation to produce a 10-ml stock solution of crude extract. The stock solution was stored at −35°C.

Behavioral Assay

An open arena olfactometer (Figure 1) was used to assay the attraction of walking *I. p. maritimus* to various olfactory stimuli. The experimental method

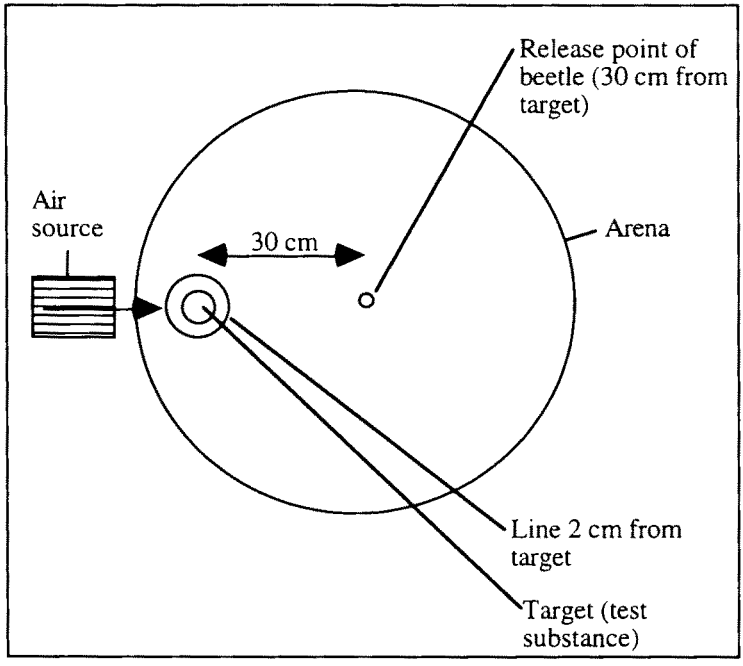

FIG. 1. Olfactometer with arena, air source and direction, target, and release point indicated.

used was adapted from Wood and Bushing (1963) as modified by Seybold (1992). Airflow into the arena at 0.76 ± 0.2 m/sec from a fan was maintained with a rheostat. A receptacle just downwind in the airstream was designated as the target and contained an infested or uninfested disk of *P. radiata* or a chemical extract. The olfactometer chamber was prepared before each assay by cleaning the arena with 70% ethanol and covering the arena with disposable newsprint sheets. The ethanol was evaporated from the arena under maximum air speed for a minimum of 20 min before the arena was covered with newsprint. The disposable sheets allowed the test beetles to maintain a secure footing and reduced the possibility of cross-contamination between treatments. A circular pencil mark was drawn on the paper 2 cm immediately preceding the target. Individual beetles were placed facing the target, 30 cm downwind of the target. A beetle passing the 2-cm mark within a 2-min time limit was considered to have responded to the test substance in the target and was scored as a positive response. Whenever possible, 30 individual males and females were exposed to a treatment, except where the supply of beetles was limited. All beetles were examined prior to the assay to ensure that they were alive, with intact legs and antennae.

Stock solutions of extracts were designated as having a concentration of 10^0, and dilutions were prepared from the extracts to produce concentrations of 10^{-1} to 10^{-6}. The diluted extracts were stored long-term at 4°C. During the assays the diluted extracts were placed on Dry Ice to reduce evaporation. To assay each beetle against a dilution of trapped volatiles, extracts were loaded into 5-μl micropipets (Drummond Scientific Co., Broomall, Pennsylvania). The micropipet was mounted on a foil-covered holder and placed under the airstream in the olfactometer. Newly loaded micropipets were used for each beetle.

Increasing concentrations of male, female, and male and female extracts were tested to determine their attractiveness to individual male and female *I. p. maritimus*. To simulate males and females tunneling separately in a ratio of one to one, extracts from each sex were released at simultaneously increasing concentrations. To investigate possible interruptive effects, a known attractive dose of male extract (10^{-2}) was released with either increasing doses of female extract or increasing doses of extracts from males and females tunneling together.

Statistical Analyses

Hierarchical log-linear analyses (Zar, 1984) were conducted to determine the relationship among three variables: response, dose, and sex. Response was determined from the number of beetles reaching the target within the 2-min time limit. Dose was the number of beetles in the host disc or the concentration of the extract of volatiles. Sex was the gender of the responding beetle. Analyses were carried out using SPSS Release 6.0 (SPSS Inc., Chicago, Illinois, 1993), which produces a best-fit final model for each data set.

Where the two-way interaction between dose and response was significant, sexes were grouped for orthogonal pairwise comparisons between doses by calculating the G statistic for each comparison (Sokal and Rohlf, 1981). If the two-way interaction between sex and response was significant, doses were grouped for the purpose of reporting the response by each sex. If the final model included a three-way interaction, pairwise comparisons were computed by sex for response versus dose. Comparisons were made between the highest and lowest doses. In each case, the comparisons were designed to contrast response to higher doses with response to lower doses.

For the data from the volatiles derived from beetle-infested logs, Spearman rank correlations were calculated to compare the ranking of the dose and the ranking of the response. This was done to determine whether the rank of the dose correlated significantly with the rank of the response. The significance of the R_s values calculated were assessed using tables of R_s with a low N (Siegel, 1956). If the correlation coefficients were significant, pairwise comparisons were not calculated. When the factor of dose was a component of the best-fit model, orthogonal pairwise comparisons were carried out as described previously.

RESULTS

Uninfested and Infested Host Discs

Experiment 1: The attraction of male and female *I. p. maritimus* was significantly greater when a host disc was present, than when it was not (dose * response, $P < 0.0001$) (Table 1, A). Of those beetles exposed to uninfested host discs, 40.8% approached the target, while 25.0% of the beetles approached the target when the host was not present. Overall, females were more likely to approach the target than males (38.0% vs. 28.2%) (sex * response, $P = 0.024$).

Experiment 2: The attraction of male and female *I. p. maritimus* to host discs infested with males was dependent on the number of males tunneling in the host (dose * response, $P < 0.001$) and increased with increasing numbers of males in the host (Table 1, B). Response by both sexes combined was greater when the host disc contained three or six males than when the host disc contained no beetles (66.7% vs. 30.0%, $G = 21.83$, 1 df, $P < 0.01$). More beetles were attracted to host discs containing six males than host discs containing three males (78.3% vs. 55.0%, $G = 7.36$, 1 df, $P < 0.05$). Response did not depend on the sex of the responding beetle (Table 1, B).

Experiment 3: Male and female *I. p. maritimus* were attracted to host discs containing females (dose * response, $P = 0.003$) (Table 1, B). Attraction of both sexes combined was greater when the host disc contained three, six, or nine female beetles than when the host disc contained no beetles (55.0% vs.

		Sex * response	Female	0.83	0.57	0.50	
5	Different	Dose * sex * response	Male	0.58	0.63	0.13	
			Female	0.83	0.60	0.80	

[a] Paired comparisons based on the outcome of the log-linear analyses are reported in the text. N = 30 except; b, N = 100; c, N = 120; d, N = 130.

30.0%, $G = 11.42$, 1 *df*, $P < 0.01$). There was no significant difference in attraction between host discs containing three, six, or nine females. Response did not depend on the sex of the responding beetle (Table 1, B).

Experiment 4: When exposed to host discs that contained one or two females tunneling in male galleries, the combined response of males and females decreased compared with the response to discs that contained just males (47.5% vs. 70.0%, $G = 8.29$, 1 *df*, $P < 0.01$) (dose * response, $P < 0.004$). There was no significant difference in attraction when beetles were exposed to either one or two females in a male gallery. Overall response of females was higher than males (63.3% vs. 46.7%) (sex * response, $P = 0.024$) (Table 1, C).

Experiment 5: When the number of females tunneling separately from males increased from one to two, male response decreased significantly while female

response did not (Table 1, C). Response was dependent on both dose and sex (dose * sex * response, $P < 0.001$). Male response was lower when two females were tunneling side by side with one male than when one female was tunneling side by side with a male (13.3% vs. 63.3%, $G = 16.45$, 1 *df*, $P < 0.01$); female response remained unaffected.

Chemical Extracts of Volatiles Trapped from Uninfested and Infested Host Tissue

Experiment 6: The response of male and female beetles to the stock solution and to the 100× dilution of the crude extract of volatiles from uninfested logs of *P. radiata* did not significantly differ from the response to pentane (43.3%, 48.3%, and 41.7% response, respectively; Table 2). None of the interactions involving these host volatiles were significant.

Experiment 7: The response of male and female *I. p. maritimus* to extracts from *P. radiata* logs infested with males increased as the dose of volatiles increased (Table 2). Response was dependent on dose (dose * response, $P < 0.001$), and the ranking of response was positively correlated with the ranking of the dose ($R_S = 1.00$, $N = 6$, $P < 0.01$). Overall, female attraction was greater than male attraction (48.9% vs. 37.2%; sex * response, $P = 0.025$).

Experiment 8: The response of male and female *I. p. maritimus* to extracts from *P. radiata* logs infested with females was dependent on the dose of the volatiles (Table 2) (dose * response, $P < 0.001$). Although the ranks of dose and response did not correlate, orthogonal comparisons indicated that the greatest attraction occurred before the highest dose. Overall response of both sexes combined was higher to extracts from female beetles tunneling in the host than to pentane alone (47.1% vs. 25.0%, $G = 9.69$, 1 *df*, $P < 0.05$). Attraction to the two highest doses of female extract tested (10^{-2}, 10^{0}) was lower than to the two lowest doses (10^{-4}, 10^{-3}) (35.8% vs. 62.5%, $G = 14.52$, 1 *df*, $P < 0.01$). There was no significant difference in attraction between the two lowest doses of extract. The highest dose (10^{0}) was less attractive than the next highest dose (10^{-2}) (15.0% vs. 56.7%, $G = 24.43$, 1 *df*, $P < 0.01$). Overall, females were more likely than males to respond to any dose of female extract (48.1% vs. 36.1%; sex * response, $P = 0.045$).

Experiment 9: Male and female *I. p. maritimus* were attracted to extracts from logs in which males and females tunneled in a one-to-one ratio in the same gallery, and attraction increased with increasing dose (Table 2). Response was dependent on dose (dose * response, $P < 0.001$), and there was a positive correlation between the ranks of dose and response ($R_S = 1.00$, $N = 5$, $P < 0.05$). Response did not depend on the sex of the responding beetle.

Experiment 10: Response of males and females to male-derived extracts and female-derived extracts released simultaneously in a one-to-one ratio gen-

TABLE 2. PROPORTIONS OF MALE AND FEMALE *Ips plastographus maritimus* ATTRACTED TO INDIVIDUAL EXTRACTS OF VOLATILES FROM *Pinus radiata* LOGS CONTAINING MALE OR FEMALE BEETLES OR FROM LOGS CONTAINING BOTH MALE AND FEMALE BEETLES IN THE SAME GALLERY[a]

Exp.	Sex of beetles in log from which extract was prepared	Interactions from log-linear model ($P < 0.05$)	Sex of responding beetle	Concentration of extract						
				0 (pentane)	10^{-6}	10^{-4}	10^{-3}	10^{-2}	10^{-1}	10^{0}
6	No beetles	None	Male	0.40				0.53		0.40
			Female	0.43				0.43		0.47
7	Male	Dose * response	Male	0.27		0.23	0.23	0.53	0.43	0.53
		Sex * response	Female	0.23		0.33	0.50	0.43	0.73	0.70
8	Female	Dose * response	Male	0.27		0.46b	0.60c	0.43		0.17
		Sex * response	Female	0.23		0.70	0.80c	0.70		0.13
9	Male & Female	Dose * response	Male	0.17	0.23	0.47		0.53		0.80
			Female	0.20	0.20	0.20		0.57		0.57

[a]Paired comparisons based on the outcome of the log-linear analyses are reported in the text. $N = 30$ except: b, $N = 28$; c, $N = 15$.

erally decreased with increasing concentration of the extracts (Table 3). Response was dependent on dose (dose * response, $P < 0.001$). There was no significant correlation between the ranks of dose and response. Attraction was higher to all combinations of beetle-derived extracts than to pentane alone (60.1% vs. 33.3%, $G = 14.37$, 1 *df*, $P < 0.01$). The three lowest doses were more attractive than the two highest doses of volatiles (65.7% vs. 52.1%, $G = 5.37$, 1 *df*, $P < 0.05$), and the highest of the three lower concentrations (10^{-2}) was less attractive than the other two lowest concentrations (10^{-4}, 10^{-3}) (53.3% vs. 72.3%, $G = 6.05$, 1 *df*, $P < 0.05$). There were no differences in response between the two highest or the two lowest concentrations. Response did not depend on the sex of the responding beetle (Table 3).

Experiment 11: When a fixed attractive dose of male volatiles was released with increasing doses of female volatiles, response was dependent on the dose of female volatiles (dose * response, $P = 0.025$) (Table 3). There was no significant correlation between the ranks of dose and response. There was no difference in the combined response to treatments in which female volatiles were present, compared to the male volatiles alone, but attraction was lower at the lowest dose of female volatiles (10^{-4}) than at the next highest dose (10^{-3}) (55.0% vs. 78.3%, $G = 7.36$, 1 *df*, $P < 0.05$). No other doses were significantly different. Regardless of dose, females were more likely to reach the target than males (75.0% vs. 59.4%; sex * response, $P = 0.002$).

Experiment 12: When a fixed attractive dose of male volatiles was released with increasing concentrations of volatiles derived from males and females tunneling together in a one-to-one ratio, attraction of *I. p. maritimus* decreased (Table 3). Response was dependent on dose (dose * response, $P = 0.037$), and the ranks of response and dose were negatively correlated ($R_s = -0.90$, $N = 5$, $P < 0.05$). The overall level of attraction of females was higher than for males (64.7% vs. 50.0%; sex * response, $P = 0.012$).

DISCUSSION

Tunneling male *I. p. maritimus* elicited attraction in the laboratory (experiment 2). This result supports an earlier study where *I. p. maritimus* females were strongly attracted to male frass or ethanol extracts of frass (Lanier and Wood, 1975). The presence of a male aggregation pheromone in *I. p. maritimus* is supported by earlier investigations of several *Ips* spp. (Wood et al., 1966; Lanier, 1970; Lanier and Wood, 1975; Birch et al., 1980; Wood, 1982; Borden, 1985; Raffa et al., 1993). In addition, a dose–response relationship for extracts from male-infested logs was demonstrated for *I. p. maritimus* (experiment 7).

This study suggests that female *I. p. maritimus* also produce an attractant pheromone (experiments 3 and 5), but at higher concentrations female volatiles appear to decrease in attractiveness (experiment 8). This decrease in attraction

[a] Paired comparisons based on the outcome of the log-linear analyses are reported in the text. $N = 30$ except: b, $N = 25$; c, $N = 27$; d, $N = 23$; e, $N = 22$; f, $N = 16$.

[b] In experiments 11 and 12, a fixed attractive dose of male extract (10^{-2}) is always present.

suggests that at high levels, pheromone components produced by females may prevent overexploitation of the host. *Ips latidens* (LeConte) females also produce a pheromone (Seybold, 1992), but laboratory studies indicate that it is not an attractant at any dose. Female *I. latidens* pheromone reduces the response to the male-produced attractant (Seybold, 1992). This does not appear to be the case with female *I. p. maritimus* (experiment 11). In nature, *Ips* spp. females generally tunnel only when the male is present inside the common gallery system. This joining of males and females may influence the production of pheromone compounds in both sexes. An attractant pheromone produced by an *Ips* spp. female has not been previously reported, but attractant pheromone components are produced by both sexes in several species of *Dendroctonus* (Wood, 1982).

When male and female *I. p. maritimus* were introduced into separate galleries, only male response was interrupted (experiment 5). In nature, these volatiles would be produced only after joining has occurred. An exception to this behavior occurs in *I. p. plastographus*, in which males and females have been observed in separate galleries in Sierra lodgepole pine. This rare observation has been attributed to the overwintering behavior of this species (Johnson, 1954; Lanier, 1967). *Ips plastographus maritimus* male galleries containing one or two females were less attractive to both males and females than discs containing only tunneling males (experiment 4). Attraction was also reduced when increasing doses of extracts from males and females tunneling together were released with an attractive doses of male extract (experiment 12). The release of simultaneously increasing doses of male extract and female extract caused a reduced response at the highest concentration (experiment 10). However, in the presence of an attractive concentration of male extract, increasing concentrations of female-produced extract did not cause a decreased response for males or females (experiment 11) as was observed for males when males and females were tunneling side by side in host discs (experiment 5). Further work is required to determine why the female extract did not reduce the male response. Varying the dose of both male and female attractant to produce an entire response surface (e.g., Akers and Wood, 1989; Akers et al., 1993) may reveal interruptive activity as observed with males and females tunneling side by side (experiment 5). Chemical identification studies are needed to determine whether or not the male interruptant(s) produced by males and females tunneling side by side or together are the same. Clearly, joining is required for female interruption (c.f. experiments 4 and 5).

Responses of males and females to extracts of volatiles produced by males and females tunneling together (in a one-to-one ratio) increased with increasing concentration of extracts (experiment 9). These attractants also function as interruptants when released with an attractive dose of male extract (experiment 12).

Further studies are needed to determine attractant/interruptant activity of volatiles produced by one-to-two and one-to-three (male to female) sex ratios.

In *I. p. maritimus*, mating is not required to produce interruption (experiments 5 and 10). Borden (1967) showed that attraction of *I. paraconfusus* females to excised guts and frass in the laboratory decreased as the number of females joining males increased. However, his experiments did not establish whether mating was necessary to produce this effect after joining occurred. Byers (1981) showed that logs infested with male and female *I. paraconfusus* in a ratio of 1:3 reduced attraction of males, but not females, to male-infested logs in the field. These results support, in part, our experiment 12, in which an extract of volatiles produced by males and females tunneling together elicited a decreased response by males to an attractive dose of male-produced volatiles.

Stridulation by females (Barr, 1969) may stimulate male-produced, interruptive volatiles, as has been shown for *Dendroctonus pseudotsugae* Hopkins (Rudinsky, 1969). Males of *D. brevicomis* LeConte also produce attractive (frontalin) and interruptive (verbenone) compounds that regulate the response of the attacking population to a female-produced attractant (*exo*-brevicomin) (Byers et al., 1984). In *Dendroctonus* spp., females initiate galleries on the host, and only one male joins the female gallery. Reduced attraction after the males join the female, as shown for *D. ponderosae* Hopkins (Edson, 1978), may prevent overexploitation of the host, therefore increasing the probability of brood survival.

Female *I. p. maritimus* response to all pheromone sources was greater than male response. *Tomicus piniperda* (Byers, 1989), *I. pini* (Birch et al., 1980), *I. paraconfusus* (Wood, 1962; Borden, 1967; Seybold, 1992), *I. confusus* LeConte (Birch et al., 1977), and *I. latidens* (Wood et al., 1967, Seybold, 1992), have also shown this sex-specific response in the laboratory. Polygamous joining increases the chances for male reproductive success. The lowered attraction of males to male galleries and to male galleries joined by females increases the chances for colonization to occur on nearby uninfested areas on the same tree and on nearby trees, and thus prevents overutilization of host material.

This study demonstrates that *I. p. maritimus* produces male and female aggregation pheromone components and that the presence of one or two females in the male gallery decreases attraction of both sexes combined. Identification of the male and female attractant pheromone components would provide a useful technique for trapping *I. p. maritimus* in order to determine the phoresy (capacity of insects to carry fungus) of *Fusarium subglutinans* f. sp. *pini* (causal agent of pitch canker disease), a pathogen first discovered in California in 1986 (McCain et al., 1987). This bark beetle is known to carry this pathogen (Storer and Dallara, 1992), but, unlike *I. paraconfusus* and *I. mexicanus* (Hopkins) (Fox et al., 1991), its importance as a vector of the fungus is unknown. Identification of the female- and male-produced interruptants of male and female attraction to

male-produced pheromones may also provide a useful technique for preventing attacks by *I. p. maritimus* and perhaps other *Ips* spp.

Although *I. p. maritimus* were attracted to cut discs of *P. radiata* (experiment 1), they were not attracted to either of two doses of volatiles trapped from uninfested logs of *P. radiata* (experiment 6). The lack of attraction of the extract may have occurred because the doses of host volatiles used for assay were too concentrated or the compounds in the discs that elicited attraction may not have been trapped from the logs by Porapak Q. In some scolytids attraction to the host is a subtle effect, requiring extensive sampling (Moeck et al., 1981). *Ips latidens* and *Hylastes gracilis* LeConte have been shown to respond in the field to host volatiles from lodgepole pine in British Columbia (Miller et al., 1986; Miller and Borden, 1990). *Ips grandicollis* (Eichh.) responds to physiologically weakened *Pinus taeda* L. (Werner, 1971, 1972). Laboratory studies by Gast et al. (1993) suggested a host response by *I. pini*, although a response to air alone was not presented to control for the low response (9.8–13.9%) to host odors. The attraction of *I. p. maritimus* to *P. radiata* increases the likelihood that beetles will find a suitable host soon after dispersal. Less exposure time to environmental hazards will increase the likelihood of survival and reproduction (Wood, 1982).

Further work is needed to verify host response by *I. p. maritimus*. Although there was a significant attraction to host discs, the response to trapped volatiles was not demonstrated. Additional work is needed to determine if the response of *I. p. maritimus* to host volatiles can be interrupted. Such a tactic would prevent production of aggregation pheromones and thereby may be more effective in preventing host colonization than interrupting pheromone production during host colonization.

Acknowledgments—The authors are grateful to John Hudson of Coastways Ranch, and the Califronia Department of Parks and Recreation for permitting the removal of bark-beetle-infested material, to Tony Trieu and Jae Chung for assistance with laboratory work, and to Rodney G. Myatt and Ronald E. Stecker for their support of this work. Funding for this work was provided by Regional Research Project W-187, and Cooperative Research Agreement PSW-92-0014CA between D.L.W and the USDA Forest Service Pacific Southwest Research Station Chemical Ecology of Forest Insects Project.

Townsville, QLD, Australia

(Received February 16, 1996; accepted July 22, 1996)

Abstract—The responses of Australian hermit crabs to two types of shell-related odor cues were compared. Introduction of gastropod snail odor elicited an increase in grasping of shells in all four species tested (*Clibanarius infraspinatus*, *C. taeniatus*, *C. virescens*, and *Diogenes avarus*). However, the magnitude of response in the case of *C. virescens* was significantly lower than the responses of individuals of the other species. Individuals of *C. infraspinatus* responded to introduction of conspecific hemolymph with an increase in both locomotion and the frequency of grasping of shells. *C. infraspinatus* also responded to the hemolymph of the other three species, and there were no differences in the magnitude of the responses depending upon the source of the hemolymph. When individuals of *C. infraspinatus* were exposed to snail odor and conspecific hemolymph at the same time, the responses were indistinguishable from those shown to hemolymph alone.

Key Words—Hermit crabs, odors, snail odor, hemolymph, *Clibanarius* spp., *Diogenes avarus*, gastropods, crustaceans.

INTRODUCTION

The variety of ways that hermit crabs find and obtain appropriate gastropod shells for occupation is impressive. The use of chemical cues to locate potential shells for occupation has been particularly well studied in recent years (Hazlett and Herrnkind, 1980; Kratt and Rittschof, 1991; Rittschof, 1980a,b; Rittschof et al., 1990). Two main categories of shell-related cues have been investigated:

0098-0331/96/1200-2317$09.50/0 © 1996 Plenum Publishing Corporation

cues emanating from the degradation of snail flesh and cues associated with conspecific hemolymph. The latter would be released in the environment in the event of the death or injury of another hermit crab, which may indicate to hermit crabs that a shell is available for occupation. Injury-related cues work both intraspecifically to stimulate the investigation of the shells of other hermit crabs and to a lesser extent across species (Rittschof et al., 1992). Odor cues from damaged conspecifics are effective for both aquatic and terrestrial species (Small and Thacker, 1994; Thacker, 1994).

Cues from the degradation of snail flesh stimulate both an increase in locomotory behavior and an increase in the frequency of grasping of other shells by hermit crabs (Hazlett, 1979; McLean, 1974; Rittschof et al., 1992). At least in *Clibanarius vittatus*, the grasps are very brief unless the shell grasped is the same species as that indicated by the odor and is unoccupied (Hazlett and Rittschof, 1996). The response to conspecific hemolymph is also an increase in locomotion and frequency of grasping behavior, but with this cue the grasps tend to be longer in duration and more readily involve full investigation of a shell even if occupied (Hazlett, 1996a). Responses to both cues tend to be stronger when crabs occupy shells that are either too small or too large (Katz and Rittschof, 1993; Rittschof et al., 1992).

The vast majority of the reports on responses to these types of chemical cues have been on species common in the intertidal areas along the east coast of the United States, especially *Clibanarius vittatus*, as well as *Pagurus pollicaris* and *Pagurus longicarpus* (McLean, 1974; Rittschof, 1980a,b). While the responsiveness of these species to cues is well established, it is of interest to compare the types of responses shown by those species to that of other species of hermit crabs to examine the generality of this category of shell-acquiring behavioral responses and to look for differences in responses among species and to relate them to either phylogeny or ecological differences. In addition, the responses of individuals of one species of hermit crab to the hemolymph from a series of sympatric Australian species were studied to look at the question of what factors limit the degree of cross-species reactivity. Finally, the responses of individuals of *Clibanarius infraspinatus* were recorded when two inputs were presented simultaneously and compared to those recorded when single inputs were presented to examine the nature of stimulus integration.

METHODS AND MATERIALS

Observations were made in the laboratory at James Cook University, Townsville, Queensland, Australia, during February and March 1995. The behavior of crabs was recorded before and after exposure to potential chemical cues from either snails, hermit crabs, or both. The crabs used were all intertidal

species in the Family Diogenidae, and all were collected at Rowes Bay, Townsville, Queensland, and transported to the laboratory. Crabs of a particular species were held in aquaria prior to being placed in round plastic dishes for observations of behavior patterns.

The species tested with snail odor (see below) were *Clibanarius infraspinatus*, *Clibanarius taeniatus*, *Clibanarius virescens*, and *Diogenes avarus*. *C. virescens* is found in rocky intertidal areas, while the other three species are from sandy, mudflat areas that are often divided into narrow pools at low tide (Haig and Ball, 1988). In addition to tests with snail odors, responses of individuals of *Clibanarius infraspinatus* were recorded following addition of conspecific hemolymph, hemolymph from other species of hermit crabs, and a combination of conspecific hemolymph and snail odor.

In all tests, sets of four crabs at a time were placed in an observation dish (21 cm in diameter) filled to a depth of 2.5 cm with seawater and the bottom covered with about 1 cm of clean sand. These opaque dishes were rinsed in running seawater between each trial. Imaginary lines across the dish connecting marks on the sides of the dishes divided the bottom surface into four quarters. After a 1-min acclimation period, I recorded the number of lines crossed by the four crabs during a 3-min observation period and the number of times any crab grasped the shell of another crab with its walking legs. The grasps were categorized as long (lasting more than 1 sec) or brief (lasting about 1 sec) because work with another species of hermit crab indicated that different length grasps were executed depending upon the type of stimulus detected.

Each set of four crabs was tested first with a control solution of seawater added to the observation dish, and then test solution(s) were added and records of locomotion and grasping were made for 3 min. For each test and control solution, between 16 and 20 replicate sets of four crabs were utilized for each species.

Snail odor was prepared by the freeze–thaw technique of Rittschof (1980b), utilizing 10 g of snails in 200 ml of seawater. The snail flesh in seawater was frozen overnight and allowed to thaw to room temperature for use on a day of testing. The supernatent, which will be referred to as snail odor, was drawn off as needed for tests. While this solution contained a variety of gastropod products, Kratt and Rittschof (1991) have demonstrated that the shell-related responses to such a solution are the same as the responses to solutions generated by the action of digestive enzymes from snail predators acting on snail muscle. The snails used were a mixture of *Thais leuteostoma* and *Morula marginalba*. These are common intertidal gastropods in Rowes Bay, and the shells are occupied by some individuals of all the species tested. In all snail odor tests, 1 ml of the test solution was introduced into the observation dish.

Hermit crab odor solutions were prepared by crushing 3.2 g of the appropriate species of hermit crab and mixing the flesh with 50 ml of seawater.

Rittschof et al. (1992) demonstrated that the shell-related behavior patterns shown by hermit crabs exposed to damaged conspecific individuals were in response to peptides in conspecific hemolymph. Therefore, although the preparations used in this study contained a variety of hermit crab chemicals, the preparations will be referred to as hemolymph. Because the hermit crab species differ in size, the number of individuals used to make up the solutions varied: one individual of *C. infraspinatus*, two of *C. taeniatus*, six of *C. virescens*, and 18 of *D. avarus*. One milliliter of the test solution was introduced into the observation dish for each test.

The responses of individuals of *C. infraspinatus* to the introduction of the conspecific hemolymph solution in their field-collected shells was very weak compared to the responses shown by individuals of other species tested (*C. vittatus*) (Hazlett, 1996a; Rittschof et al., 1992). Therefore, to increase the shell-related motivation of crabs, the shell apertures of 30 individuals were clipped back with a pair of pliers to make the shells smaller than desired by those size crabs (Katz and Rittschof, 1993). These crabs with clipped shells were tested with conspecific hemolymph, and these same individuals were utilized in tests with all remaining hermit crab preparations. In addition, these crabs were tested with a combination of snail odor and conspecific hemolymph introduced simultaneously.

Initially to look for an effect of the introduction of potential chemical cues, the behavioral scores during the control period (seawater introduction) and test period were compared by paired t tests. In order to compare the magnitude of the response of the various species, the difference between scores on locomotion and grasping during the control and test period was calculated for each replicate, and these scores were compared across species by ANOVA. In some cases, individual contrasts (Wilkinson, 1988) were used to determine which treatments or species were different from one another.

RESULTS

Individuals of all four of the species tested with snail odors responded to introduction of the snail solution, but there were differences among the species. *Diogenes avarus* showed an increase in locomotion ($t = 3.2$, $df = 19$; $P = 0.005$), but none of the other species showed a change in the rate of locomotion, although there was a trend toward increased locomotion for *C. virescens* ($t = 2.06$, $df = 15$; $P = 0.057$) (Figure 1). All four species showed a significant increase in the number of brief grasps and in the number of long grasps executed following the introduction of the snail odor (Figure 1). However, there were differences between the species in the frequency of this grasping response to snail odor introduction (Figure 2). When the differences between test and control

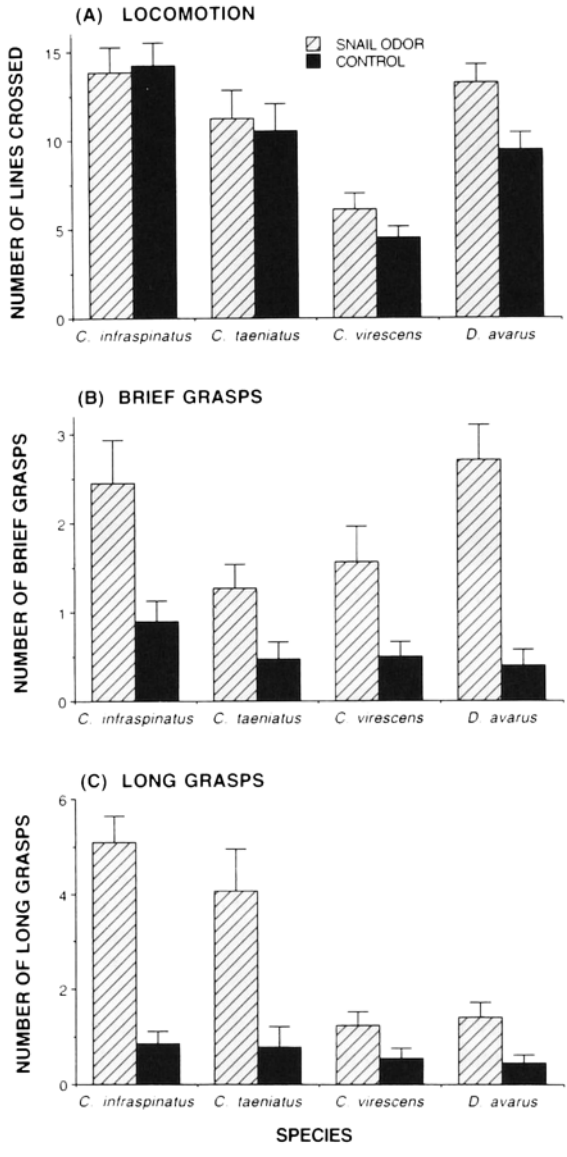

FIG. 1. Scores for behavioral parameters (means + standard errors) during introduction of seawater control (black bars) and snail odor (crosshatched bars) for four species of Australian hermit crabs.

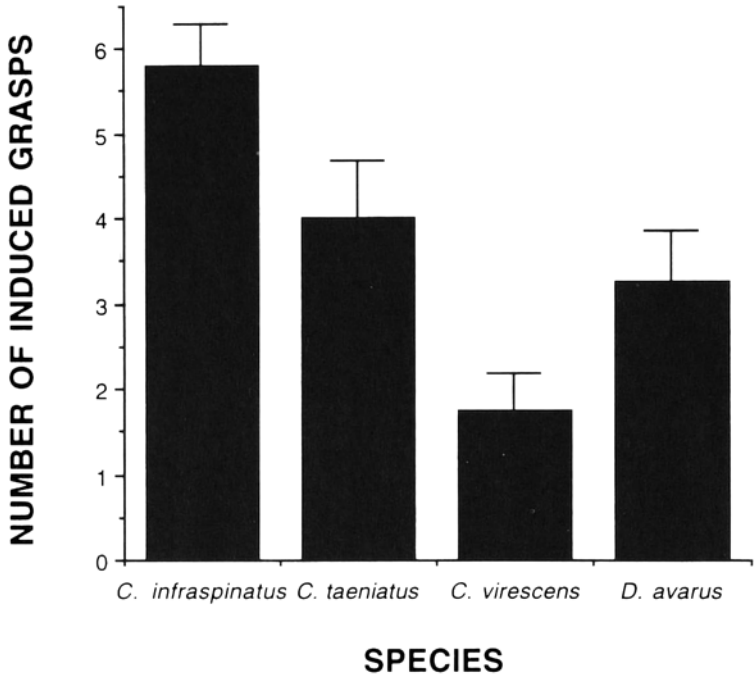

FIG. 2. Difference (mean + standard error) between number of grasps by individuals of four species of hermit crabs during control water and snail odor introductions.

periods for brief grasps and long grasps were summed for each replicate and the species compared, there were significant differences (ANOVA $F = 20.3$, $dp = 4, 78$; $P < 0.001$). This difference apparently is a result of the weaker response (although statistically significant) of individuals of *C. virescens* to snail odor (individual comparisons of *C. taeniatus* vs. *C. virescens* yielded $F = 29.6$, $dp = 1, 78$; $P < 0.001$; *C. virescens* vs. *D. avarus*, $F = 5.23$, $dp = 1, 78$; $P = 0.023$).

There were very weak responses of the individuals of *C. infraspinatus* to conspecific hemolymph when in their field-collected shells. None of the behavioral parameters showed a significant difference between test and control periods (t test values associated with $P > 0.05$). Following the clipping of the shell apertures, these crabs did show a strong response to conspecific hemolymph with regards to increases in locomotion ($t = 5.89$, $df = 14$; $P < 0.001$) and in both types of grasping behavior (brief grasps, $t = 2.43$, $df = 14$; $P = 0.029$; long grasps, $t = 3.23$, $df = 14$; $P = 0.006$) (Figure 3). The responses of individuals of *C. infraspinatus* to test solutions prepared from the other species

[a]Test solutions were made using the hemolymph from different species of sympatric hermit crabs.

of hermit crabs were also significantly different between test and control periods for every species (Table 1) for at least the rate of locomotion and the number of long grasps [which are the more typical responses shown to hemolymph (Hazlett, 1996a)]. There were no differences among the species as sources of input for individuals of *C. infraspinatus* (Figure 4). Testing the magnitude of the difference between test and control periods, there were no species effects on the magnitude of increase in locomotion (ANOVA $F = 2.20$, $df = 6, 92$; $P = 0.098$), frequency of brief grasps ($F = 1.62$, $df = 6, 92$; $P = 0.195$), or frequency of long grasps ($F = 1.19$, $df = 6, 92$; $P = 0.323$). All of the diogenid species tested elicited responses of similar magnitude, although individual comparisons indicated that the scores for locomotion were significantly different between hemolymph from *C. infraspinatus* and *D. avarus* ($F = 5.93$, $df = 1, 92$; $P = 0.018$).

When individuals of *C. infraspinatus* were stimulated with both snail odor and conspecific hemolymph at the same time, they showed responses characteristic of hemolymph alone (Figure 5). A comparison of the three conditions (snail alone, hemolymph alone, combination) yielded a very significant difference among treatments for change in locomotion ($F = 6.23$, $df = 1, 43$; $P = 0.004$) and change in the frequency of long grasps ($F = 5.94$, $df = 1, 43$; $P = 0.005$). There was no effect on brief grasps ($F = 1.26$, $df = 1, 43$; $P = 0.294$). Individual comparisons showed that for locomotion and long grasps there were significant differences between hemolymph and snail and between the combination stimulus and snail odor (all $P < 0.01$), but no difference between the combination and hemolymph ($P > 0.60$). Both of the odors stimulated grasping and increases in locomotion when presented alone but they did not at all sum together in their effects when presented at the same time.

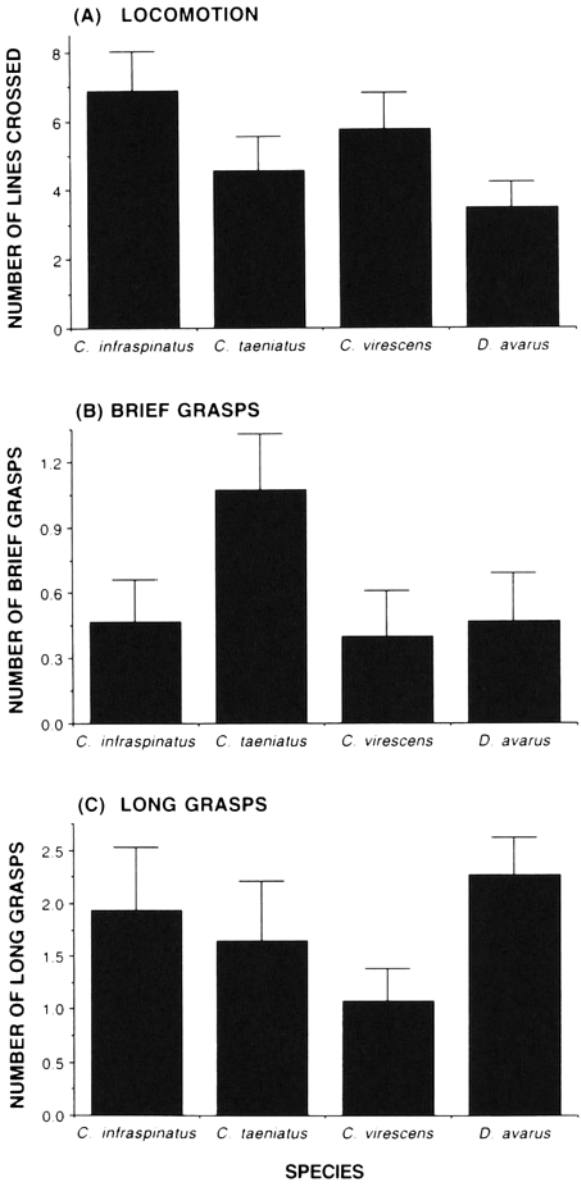

FIG. 4. Difference (mean + standard error) in behavioral scores for individuals of *C. infraspinatus* between control water introductions and introduction of the hemolymph of four species of hermit crabs.

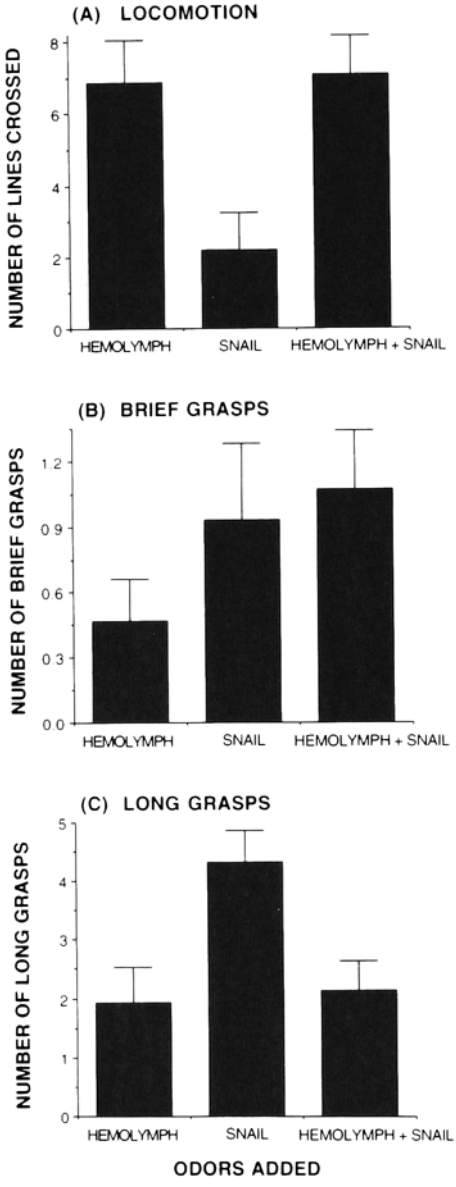

FIG. 5. Difference (mean + standard error) in behavioral scores for individuals of *C. infraspinatus* during control water and test odor introductions.

DISCUSSION

The use by hermit crabs of chemical cues that increase their chances of finding an empty gastropod shell is clearly widespread. In addition to species found along the southeastern coast of the United States, all four of the species tested in Australia showed strong responses to odors from degraded snail flesh. Given the importance of the shell resource to hermit crabs (Hazlett, 1981), the use of an accurate indicator of empty shells is understandable.

While all four Indo-Pacific species showed a significant response to snail odor, the variation in the strength of the response is quite interesting. The lack of an increase in locomotion after detecting snail odor shown by several of the species is puzzling since an increase in locomotion is one of the responses reported for other species (Hazlett, 1996a). The large increase in the number of long grasps induced by snail odor in *C. infraspinatus* and *C. taeniatus*, compared to the more modest (but significant) increase shown by individuals of *C. virescens* and *D. avarus*, is somewhat surprising, because this pattern is different than the responses of *C. vittatus* studied in North Carolina (Hazlett, 1996a), which physically most closely resembles *C. infraspinatus* and *C. taeniatus*. The pattern of a more marked increase in brief grasps shown by *D. avarus* and *C. virescens* is similar to that shown by *C. vittatus*. However, this may reflect something as simple as the generally slower movement of *C. infraspinatus* and *C. taeniatus* as compared to the other species.

The total number of grasps induced by detection of snail odor was significantly weaker for one species (*C. virescens*). This is the only species commonly found in a different habitat, the rocky intertidal zone, compared to the other species tested. *Clibanarius infraspinatus*, *C. taeniatus*, and *Diogenes avarus* (this study), as well as *C. vittatus*, *Pagurus longicrapus*, and *P. pollicaris* (McClean, 1974; Rittschof, 1980a), all inhabit sloping sandy beaches or mudflat areas. These areas would seem to have greater opportunities for orientation to sources of chemical cues due to the more predictable patterns of water movement at low tide as compared to the rocky intertidal zone. Preliminary field observations on *Calcinus tibicen* in the Caribbean and *Calcinus elegans* in Hawaii (both from rocky intertidal areas) also indicated a low level of responsiveness to snail odor (Hazlett, unpublished observations) compared to the species from sandy beaches. An alternative that cannot be ruled out with the data available is that crabs in rocky intertidal areas are in better-fitting shells and thus are less responsive to shell-related odor cues.

The responses of individuals of *Clibanarius infraspinatus* to preparations containing conspecific hemolymph adds to the list of hermit crabs that show a shell-related response to this type of chemical cue. Hermit crabs in poorly fitting shells respond to conspecific hemolymph by grasping nearby gastropod shells (Rittschof et al., 1992) and investigating them, i.e., executing grasps that are

long in duration (Hazlett, 1996a). In this study, the surprising result is the similarity of responses by individuals of *C. infraspinatus* to solutions containing hemolymph from other species. Even though one of the species lives in a different habitat (*C. virescens*) and one is in a distantly related diogenid genus (*Diogenes avarus*), the overall response level to the different solutions was very similar. This is in contrast to the results reported by Rittschof et al. (1992), in which *C. vittatus* did not respond at all to hemolymph from two *Pagurus* species that live in the same area and the responses of the *Pagurus* species were much weaker to hemolymph from other than conspecifics. It is possible this results from greater phylogenetic differences in the case of diogenid and pagurid species since they are in different families. Some have suggested that these two families represent separate evolutions of the hermit crab life-style (McDonald et al., 1957), although McLaughlin (1983) has argued for monophyly. This possible explanation can also apply to the results of Thacker (1994) on terrestrial species where *Coenobita compressus* (Family Coenobitidae) responded just as strongly to conspecific hemolymph odors and odors from the hemolymph of the congeneric species *Coenobita clypeatus*, but the land hermit crabs did not respond to the hemolymph of the aquatic diogenid species he tested. Since hermit crabs are rarely specialists on any particular shell type (Hazlett, 1981), it seems reasonable that any injured hermit crab is a potential source of an empty shell for almost any other hermit crab, irrespective of the species of crab.

The response of individuals of *C. infraspinatus* to the combination of hemolymph odor and snail odor are very similar to the responses shown by individuals of *C. vittatus* when presented with a combination of inputs (Hazlett, 1996a; Rittschof and Hazlett, unpublished data). In both species, hemolymph-related responses seemed to overrule any snail-induced responses. While shell-seeking responses to detection of conspecific (or other hermit crab) hemolymph are shown only by crabs in poorly fitting shells (Rittschof et al., 1992), those crabs appear to be more strongly influenced by that cue than by the more specific cue resulting from degradation of snail flesh. While it is possible that in both studies reporting this result, the concentration of the hemolymph cue was stronger than the concentration of the snail cue, there is an alternative explanation. The hemolymph cue, while indicating some degree of danger, is a more general signal of shell availability since the potentially empty shell can be any species of shell in the area, while the snail flesh cue provides information on the potential availability of a single species of shell. While detection of one cue frequently inhibits the responses associated with another cue, the hierarchy of influence is usually one of predator cues overruling resource-related cues (Hazlett, 1996a,b; Mitchell and Hazlett, 1996). In this study, the inhibition is by the more reliable of the resource-related cues.

Acknowledgments—I wish to thank the staff at James Cook University for their assistance in making this study possible, Patsy McLaughlin for confirmation of species identification, and Catherine Bach and Dan Rittschof for their comments on the manuscript.

(Received December 27, 1994; accepted July 23, 1996)

Abstract—The principal behaviorally active volatile component (ca. 90%+) of the sex pheromone glands of *Lutzomyia longipalpis* from Jacobina, Brazil, has been isolated and characterized as a novel homosesquiterpene with the structure 3-methyl-α-himachalene ($C_{16}H_{26}$). A minor component (ca. 10%) of the gland extract has also been identified as the sesquiterpene α-himachalene ($C_{15}H_{24}$). This work confirms that there are at least 3 members of the *L. longipalpis* species complex.

Key Words—Sex pheromone, tergal gland, *Lutzomyia longipalpis*, 3-methyl-α-himachalene, homosesquiterpene, mass spectrometry, high-performance liquid chromatography, nuclear magnetic resonance.

INTRODUCTION

The sandfly, *Lutzomyia longipalpis* (Lutz & Neiva) (Diptera: Psychodidae) is the vector of the protozoan parasite *Leishmania chagasi* (Cunha & Chagas) (Kinetoplastida: Trypanosomatidae), the causative agent of visceral leishmaniasis in the New World. Male *L. longipalpis* release a sex pheromone from glands that can be seen as pale patches on the third or third and fourth tergites of the abdomen (Lane et al., 1985). The pheromone can attract females (Ward

et al., 1989; Hamilton et al., 1994) from distances of up to 60 cm to filter paper discs that have been impregnated with extracts prepared from whole pheromone glands (Morton and Ward, 1989).

The sex pheromone gland of *L. longipalpis* from Jacobina in northeastern Brazil contains several detectable compounds. However, only the principal volatile component of the gland extract (90%+) is responsible for the attraction of females. In bioassays performed with isolated gland components, the second most abundant compound (ca. 10%) and other trace compounds did not influence the activity of the sex pheromone (Hamilton et al., 1994). Further evidence that only the major component of the gland extract was pheromonally active was provided by Dougherty et al., (1995), who showed that only one type of olfactory cell in the ascoid sensillum on the female antenna was stimulated by the sex pheromone gland extract.

L. longipalpis is a species complex. Gas chromatography–mass spectrometry analysis by Lane et al., (1985) and Phillips et al., (1986) identified two populations based on unidentified components produced by the pheromone glands. One population produced compounds with a molecular weight of 218 and the other a molecular weight of 272. These molecular weights and the fragmentation patterns suggested that the components were homosesquiterpene ($C_{16}H_{26}$) and diterpene ($C_{20}H_{32}$) hydrocarbons. Hamilton and Ward (1991) suggested that there could be up to six different populations of *L. longipalpis* and that the homosesquiterpene-producing populations could be further subdivided on the basis of the type of homosesquiterpene they produced. Recently, a new homosesquiterpene has been found in a population of *L. longipalpis* from Costa Rica (Hamilton et al., 1996b) and a diterpene has been found in *L. pessoai*, a related species (Hamilton and Ward, 1994).

The sex pheromone of *L. longipalpis* from Lapinha in southern Brazil has recently been characterized as a novel homosesquiterpene, with the structure proposed as 9-methylgermacrene-B (Hamilton et al., 1996a). The objective of this current work was to characterize the homosesquiterpene pheromone of the Jacobina population of *L. longipalpis*.

METHODS AND MATERIALS

Insects. L. longipalpis were maintained in colony as described previously by Hamilton et al., (1994) at a temperature of 26°C, 98% relative humidity, and a 12 L:12 D photoperiod. The colony was established from adults collected in Jacobina, Bahia State, Brazil (40°31'W 11°11'S). Extracts for analysis were prepared either from dissected glands or by extracting large numbers of whole male flies in hexane (Hamilton et al., 1994, 1996a). Extracts prepared from whole sandflies were filtered through glass wool to remove solid debris prior to

further analysis and preparative HPLC. All extracts were reduced under N_2 to produce an extract with a final concentration of one male equivalent (ME) per microliter.

Column Chromatography. Column chromatography was performed on a silica gel micro column prepared by placing BioSil-A (20–44 μm) (BioRad, Hemel Hempstead, Hertfordshire, UK) silica gel (0.25 g) in a Pasteur pipet. The column was precleaned by eluting sequentially with hexane (10 ml) (pesticide grade, BDH, Poole, Dorset, UK) followed by diethyl ether (10 ml) (chromatography grade, BDH). The hydrocarbon fraction was eluted by hexane (3 column volumes).

Gas Chromatography. GC analysis was carried out using a J&W DB-1 capillary column (Alltech, Carnforth, Lancashire, UK) (30 m × 0.32 mm ID, 0.25-μm phase thickness) in a Shimadzu model 15-A gas-chromatograph (FID 310°C) (Shimadzu Corp. Kyoto, Japan) linked to a Shimadzu CR-5A data-pac integrator. Injection of extract was via a Grob split/splitless injector in the splitless mode (0.6 min sampling time) at 180°C. Carrier gas was helium at 1 ml/min. The GC was temperature programmed with an initial 2 min at 45°C, then a rise of 10°C/min to 250°C followed by a rise of 15°C/min to a final isothermal period at 310°C (4 min). The detector (flame ionization) temperature was set at 310°C.

High-Pressure Liquid Chromatography (HPLC). Analysis was carried out on two Waters Resolve C18 analytical columns (3.9 × 300 mm) in series with a Resolve C18 precolumn, heated to 30°C in a Waters HPLC; 600E multisolvent pump and gradient controller, U6K injector, and 991 photodiode array detector (Waters, Watford, UK). The mobile phase was acetonitrile–isopropanol (70:30) at 1 ml/min, sparged with helium at 25 ml/min prior to and during analysis. Standards used for calibration and monitoring of separations were (−)-β-caryophyllene and caryophyllene oxide (Aldrich, Gillingham, UK) (1 μg/μl, 10 μl injection). Fractions for further GC, GC-MS, and NMR analysis were collected manually in 10-ml acid-cleaned beakers as they eluted from the HPLC detector. The nonpolar fraction of the gland extract was recovered from the relatively polar mobile phase by a liquid–liquid separation.

Gas Chromatography–Mass Spectrometry (GC-MS). Coupled gas chromatography–mass spectrometry was performed on a Hewlett-Packard 5880A GC with an HP-1 capillary column, 50 m × 0.32 mm ID, 0.25-μm film thickness, directly coupled to a VG 70-250 MS, electron impact (EI), 70 eV, 250°C. Sample was introduced via a cold on-column technique. The GC was temperature programmed with an initial 5 min at 30°C, then a rise of 5°C/min to a final isothermal period at 250°C.

Additional analysis was carried out on a Hewlett Packard 5890 II+ gas chromatograph with an HP-5MS capillary column, 30 m × 0.25 mm ID, 0.25-μm film thickness, directly coupled to a Hewlett Packard 5972A benchtop mass

spectrometer, EI, 70 eV, 165°C. Samples were introduced via a split/splitless injector (splitless mode, sampling time 0.7 min, 180°C). The GC was temperature programmed with an initial 2 min at 50°C, with an increase of 10°C/min to a final isothermal period at 250°C (10 min).

GC-MS studies were performed on crude extracts from dissected glands, hexane fractions from the BioSil-A column, and on reduction and epoxidation products.

Hydrogenation of Sex Pheromone. Ten male equivalents of *L. longipalpis* extract (10 μl) were placed in a small micro reaction vessel prepared from a Pasteur pipet. Palladium black (20 μg) (Aldrich Chem. Co.) catalytic reducing agent was added and the mixture was shaken. Hydrogen was blown over the solution for 2 min. The micro vial was inverted, trapping hydrogen in the bulb of the vial, and then placed (inverted) in a 25-ml inverted screw-top glass tube that was filled with hydrogen, sealed, and kept at room temperature for 2 hr prior to analysis.

Epoxidation. Dimethyldioxirane (DMD) reagent was prepared as described by Adam et al. (1987). *L. longipalpis* extract (100 μl = 100 ME) was eluted from a Florisil (350 mg) pipet column in hexane (2 ml). Volume was reduced under N_2 to 100 μl and placed in a 1-ml vial and reagent (40 μl) added. The reaction was allowed to proceed for 24 hr before analysis by GC and GC-MS.

Standards. α-Himachalene was obtained from the nonpolar fraction of the Himalayan deodar (*Cedrus deodara*, Loud.) (Krishna Rao et al., 1952). A series of *n*-alkane standards, C_{12}–C_{21} (Sigma Chem. Co., Poole, UK) were analyzed by GC to provide comparative retention time data.

NMR. HPLC collected material was prepared for NMR by partitioning the HPLC eluent in double-distilled H_2O and distilled ether. The organic phase was reduced under N_2 and gradually exchanged with deuterochloroform ($CDCl_3$).

NMR spectra were recorded in $CDCl_3$ solution using tetramethylsilane as the interal standard (δ = 0.0). Proton NMR spectra (^{1}H NMR) were recorded at 400 MHz on a Jeol JNM-GX400 with Fourier transform facility. The ^{13}C NMR spectra were similarly recorded at 100 MHz.

RESULTS

GC, HPLC, and Silica Gel Column. Analysis of crude extract by GC gave a small, sharp peak at 9.90 min (11%) (compound a) and a large, sharp peak at 10.47 min (89%) (compound b) (the sex pheromone, Hamilton *et al.*, 1994). A number of other compounds were present in trace amounts between 8.8 min and 12.07 min. The hexane eluant of the silica gel column gave both compounds, a and b, on GC. HPLC of the crude *L. longipalpis* extract gave a small peak at 10.62 min (10.6%) (compound c, λ_{max} 202.8 nm) followed by one large

peak at 10.92 min (89.3%) (compound d, λ_{max} 204.2 nm). These HPLC peaks were resolved on the baseline, and when collected, back extracted, and analyzed by GC, were found to be equivalent to GC compounds a and b, respectively.

Gas Chromatography–Mass Spectrometry (GC-MS). The mass spectrum of compound b (R_t = 38.05 min) is given in Figure 1. The mass spectrum of compound a (R_t = 36.73 min) was found to be *m/z* 204 (M^+, 35), 93(100), 94(81), 41(78), 119(72), 79(64), 69(59), 105(57), 90(49), 121(44), 161(42), 189(42), 55(42), 131(40), 147(18), 175(6).

Upon injection of the reduction products of the whole extract, two main isomer peaks were found with similar spectra: R_t = 38.22 min, *m/z* 222 (M^+, 6), 55(100), 70(96), 41(83), 97(62), 81(54), 123(53), 109(21), 151(17), 137(10), 207(9), and R_t = 38.90 min, *m/z* 222 (M^+, 6), 100(55), 69(85), 41(81), 81(60), 97(60), 123(58), 109(22), 151(16), 137(12), 207(8).

Analysis of the epoxidation products of the whole extract gave two principal isomeric products: R_t = 15.63 min, *m/z* 250 (M^+, 10), 73(100), 60(89), 43(82), 129(34), 185(22), 83(20), 109(16), 97(15), 228(12); and R_t = 16.75 min, *m/z* 250(M^+, 18), 43(100), 100(80), 55(68), 178(40), 69(33), 81(23), 109(23), 135(23).

NMR. Proton ^1H and 2D ^1H–^1H NMR experiments were done on isolated sex pheromone, compound b. Full ^1H NMR assignments were not possible in the 1.1- to 2.1-ppm region due to the complexity of the spectrum and some impurities, but clear signals were obtained at 0.97(s), 1.01(s), 1.02 (d, J = 7), 2.30(m), 2.81(m), 4.77(s), 4.82(s), 5.52(m). For ^1H–^1H NMR, strong corre-

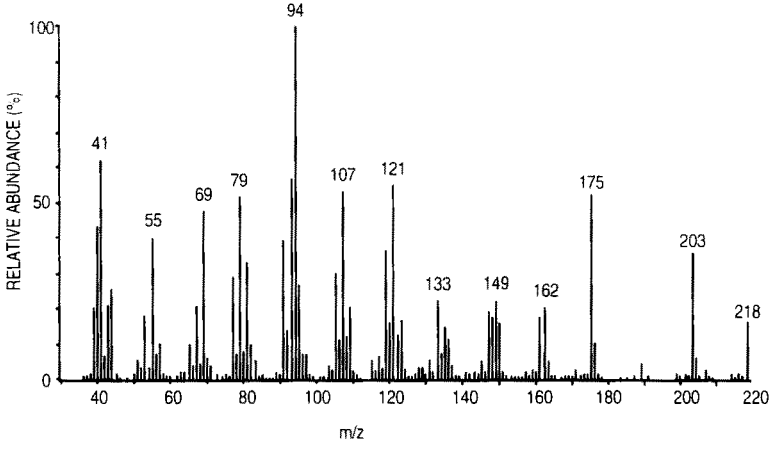

FIG. 1. Mass spectrum of homohimachalene from *Lutzomyia longipalpis* from the Jacobina region of Brazil. (Compound b)

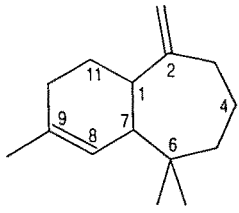
lations were observed between shifts at: 5.52–1.65, 2.81–2.10, and 2.30–1.02 ppm. Full NMR assignment of the α-himachalene standard was achieved using 2D NMR experiments (^{1}H-^{1}H and ^{13}C-^{1}H correlations (Figure 2). The strong ^{1}H-^{1}H correlations are shown in Figure 2B with arrows.

DISCUSSION

HPLC analysis and elution from a Florisil column by hexane suggested hydrocarbon structures for a and b. The mass spectra suggested a molecular weight of 204 amu for compound a and 218 amu for compound b. Reduction and epoxidation of b gave products with molecular weights higher by 4 amu (222, m^+) and 32 amu (250, M^+), respectively, establishing the presence of two double bonds. UV λ_{max} data for c (= a) and d (= b) indicated that these double bonds were not conjugated.

GC-MS analysis of the components a and b of the pheromone glands of *L. longipalpis* from Jacobina suggested a sesquiterpene as the minor component and a homosesquiterpene as the later-eluting major component. The sesquiterpene (a) had a spectrum closely similar to that published for α-himachalene (NIST, 1990). α-Himachalene from the essential oil of Atlas cedarwood, authenticated by MS and NMR spectroscopy, gave peak enhancement on GC with the *L. longipalpis*-derived product. This confirmed the minor component (compound a) as α-himachalene (structure I). Although this did not confirm the absolute



I

stereochemistry, the *cis* configuration is assumed for compound a because of identity with authentic α-himachalene for which the *cis* configuration has been proven (Tabacchi et al., 1974).

The proposed homosesquiterpene (compound b) had a mass spectrum similar to that expected for an α-himachalene but an extra methyl group was indicated. There were also strong similarities between the proton NMR spectra of α-himachalene and the sex pheromone compound b. The *gem*-dimethyl groups gave absorbances at 0.97(s) and 1.00(s) for α-himachalene compared with 0.97(s) and 1.01(s) for compound b. The protons on the bridgehead C-1 in α-him-

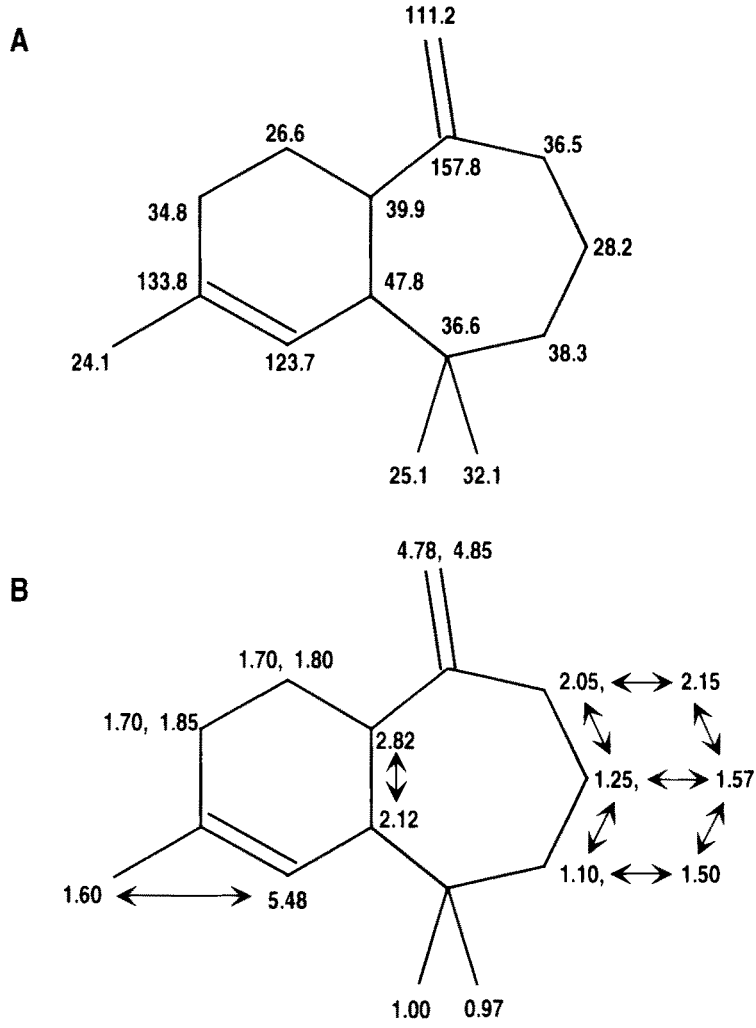


FIG. 2. NMR assignments for α-himachalene compound a: (A) ^{13}C assignments, (B) ^{1}H assignments (strong ^{1}H–^{1}H correlations are shown with arrows). ^{1}H–^{13}C correlations are consistent with these assignments.

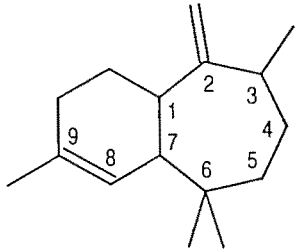
achalene gave an absorbance at 2.82 compared with 2.81 ppm in compound b. The exomethylene at C-2 in α-himachalene gave absorbancies at 4.78 and 4.85 compared with 4.77 and 4.82 ppm in compound b. The C-8 olefin in α-himachalene gave an absorbance at 5.48 compared with 5.52 ppm in compound b.

As with α-himachalene, compound b showed strong correlations between the methyl on C-9 (1.65) to olefinic proton on C-8 (5.52), and also between the bridgehead protons on C-1 and C-7 (2.81 and 2.10). These spectral details strongly support the α-himachalene type structure for the pheromone.

The pheromone has an additional methyl group at 1.02 ppm as a doublet with the 7-Hz coupling to a proton at 2.30 ppm. The abolition of strong ^1H-^1H correlations in the pheromone for the protons on carbons 3, 4, and 5 (Figure 2B) suggests positioning of the methyl in this part of the cycloheptane ring. From biosynthetic considerations, C-3 is the favored position (Hamilton et al.,1996a) i.e., the homohimachalene equivalent to the 9-methylgermacrene proposed as comprising the sex phermone of another member of the *L. longipalpis* species complex from Lapinha (Minas Gerais State, Brazil).

Thus, the proposed structure for the sex pheromone is 3-methyl-α-himachalene, systematically named 2-methylene-3,6,6,9-tetramethylbicyclo-[5,4,0]undec-8-ene (structure II).



II

The two isomeric GC peaks for the reduced and the epoxidized products presumably arose from the diastereoisomers generated by the asymmetry at C-2 and C-9 in these products. The change in the base peak from *m/z* 93 to 94 caused by the additional methyl group (although *m/z* 94 and 93 remain abundant) is not yet explained, but a rearrangement of the *exo*-double bond in the MS source could in turn allow generation of a monocyclic C_7H_{10} radical ion (*m/z* 94). Synthesis of the candidate compound with structure II is now in progress to confirm this assignment and to establish the absolute stereochemistry of the molecule at C-1, C-3, and C-7. Comparison with authentic α-himachalene suggests that the C-1 and C-7 positions of compound b (structure II) have the *cis* configuration. Insufficient compound b was available for further structural confirmation by more sophisticated NMR experiments.

Sex pheromones are responsible for mate discrimination (Roelofs and Comeau, 1969) and as such can function in species isolation. Characterization of sex pheromones can be a valuable aid in the differentiation and classification of species where no morphological differences are discernible (Roelofs and Cardé, 1974; Dugdale, 1990; Löfstedt et al., 1994). Within the *L. longipalpis*

species complex, sex pheromones are indicative of the reproductively isolated groups of sandflies first described by Ward et al. (1983, 1988) and, along with other prezygotic mating barriers such as interpulse sound frequencies produced by wing beats (Ward et al., 1988) and postzygotic barriers described by Lanzaro et al. (1993), maintain species isolation in sympatric populations. This work has shown that in the *L. longipalpis* species complex there are at least two populations (taxa) producing different homosesquiterpene sex pheromones.

The 9-methylgermacrene-B structure previously proposed for the sex pheromone of *L. longipalpis* from Lapinha (Hamilton et al., 1996b) and 3-methyl-α-himachalene could be derived from a common precursor such as 8-methylfarnesylpyrophosphate, although the alternative methyl migration or methylation cannot be ruled out. The biosynthetic relationship of these compounds with the diterpene produced by some members of the species complex is unclear. Recent work has shown that in the Sobral region of Brazil some members of the complex product diterpene exclusively, whereas other members of the complex produce predominantly 9-methylgermacrene-B with small amounts of diterpene (Hamilton and Ward, unpublished observations). There is the possibility that the homosesquiterpenes arise through modification of a common diterpene precursor (by, for example, oxidative loss of four carbons) analogous to biosynthesis of the homoterpenes (Boland and Gäbler, 1989; Donath and Boland, 1994). Nonetheless the homosesquiterpene structures currently proposed indicate a structure for a diterpene precursor unexpected from normal isoprenoid biosynthesis.

Acknowledgments—This work was carried out with the financial support of the Wellcome Trust, London. IACR-Rothamsted receives grant-aided support from the Biotechnology and Biology Sciences Research Council of the United Kingdom. Our grateful thanks are due to Mr. S. Chantler (Quest International) for the generous gift of Atlas cedarwood oil.

Abstract—Ovipositing black swallowtail butterflies, *Papilio polyxenes*, make their final host-selection decisions on the basis of compounds present on the leaf surface. Little information is available, however, on the chemistry of leaf surfaces. The purpose of this study was to develop a technique to extract and quantify the concentrations of compounds from the leaf surfaces of *Daucus carota*, one of the main host species for *P. polyxenes*, with particular reference to compounds already identified as contact oviposition stimulants, namely *trans*-chlorogenic acid (CA) and luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucopyranoside (L7MG), as well as its degradation product luteolin-7-glucoside (L7G). Plant surfaces were extracted by dipping leaves sequentially in pairs of solvents: (1) $CHCl_3$–MeOH, (2) near-boiling H_2O, (3) $CHCl_3$–near-boiling H_2O, and (4) CH_2Cl_2–CH_2Cl_2. The resulting extracts were fractionated and analyzed using high-performance liquid chromatography. The leaf-surface concentrations of each compound were calculated using regressions relating leaf surface area to leaf weight that were obtained from measurements of field-collected carrot plants. All four methods removed the three compounds from carrot leaf surfaces, but the solvent systems differed in effectiveness. The chloroform–near-boiling water solvent system performed better than the other solvent combinations, but not significantly so. This system also extracted the highest number of polar, UV-absorbing compounds. Methylene chloride was significantly less efficient than the other methods. An additional test confirmed

that the chloroform–near-boiling water method removed compounds from the surface alone and probably not from the apoplast or symplast. Surface concentrations of CA (up to 600 ng/cm^2 leaf surface) were substantially greater than those of the two flavonoid compounds. No clear seasonal trend in concentrations was evident from the limited number of sampling dates.

Key Words—*Papilio polyxenes*, Papilionidae, *Daucus carota*, Apiaceae, oviposition, leaf surface, contact chemoreception, HPLC, flavonoid glycosides, chlorogenic acid.

INTRODUCTION

The initial host plants of the larval offspring of the black swallowtail butterfly, *Papilio polyxenes*, are chosen by the egg-laying female adult (Blau, 1981; Feeny et al., 1983, 1985). A gravid female locates a potential host plant on the basis of olfactory and visual cues, which may lead the female to land on the plant (Feeny et al., 1989). Once on a leaf, the female chooses whether or not to oviposit after sensing chemical cues on the leaf. Upon landing, the female drums her foretarsi on the leaf surface, bringing contact chemoreceptors located on the ventral surface of the foretarsi into contact with chemical stimuli present on the leaf surface (Feeny et al., 1983; Roessingh et al., 1991). Based on the stimuli perceived through this drumming behavior, the *P. polyxenes* female may curl her abdomen and oviposit. As in several other groups of phytophagous insects (Städler, 1986; Traynier and Hines, 1987; Linley, 1989), contact chemoreception during oviposition by butterflies appears to be limited to the leaf surface itself; no studies have yet revealed any penetration of the leaf cuticle due to drumming behavior (e.g., Städler, 1986; Bart and Williams, 1993; but see Boppré, 1978, 1983 for exception in Danaidae).

Larvae of *P. polyxenes* feed almost exclusively on plants of the family Apiaceae (Tietz, 1972). In New York, the main host plant of *P. polyxenes* is the umbellifer *Daucus carota* (Feeny et al., 1985). Commonly known as wild carrot or Queen Anne's lace, this plant is a winter annual found throughout the northeastern and northcentral United States where it has a patchy distribution and occurs in secondary successional areas (Peterson and Simon, 1986). From ethanolic extracts of carrot foliage, Feeny et al. (1988) identified two major contact stimulants for *P. polyxenes*: *trans*-chlorogenic acid (CA) and luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucopyranoside (L7MG), a flavonoid malonate. Roessingh et al. (1991) confirmed the stimulatory characteristics of these compounds and identified some of the chemoreceptors in *P. polyxenes* that respond to these stimuli. Feeny et al. (1988) discovered that the flavonoid malonate was an unstable compound that degraded under natural conditions when the malonic acid group dissociated from the flavonoid. Luteolin-7-glucoside (L7G), the fla-

vonoid hydrolysis product, was also recovered from ethanolic extracts of carrot foliage. It was not an oviposition stimulant for *P. polyxenes*, and preliminary evidence suggested it may be an oviposition deterrent. Additional stimulant compounds, as yet unidentified, were present in the carrot fractions containing bases and polar neutrals (sugars and inositols) (P. Feeny et al., unpublished data).

Past work on the identification of the oviposition stimulants for *P. polyxenes* from *D. carota* has been based on whole-leaf extracts. Since stimulant isolation and chemical characterization require large quantities of plant material, whole-leaf extracts are necessary in order to obtain sufficient amounts of the compounds of interest. It has been assumed, but never proved, that the stimulant compounds are present on the leaf surface (Feeny et al., 1983).

Although Richmond and Martin (1959) reported the extraction of phenolic compounds from apple leaves by 10-sec dips in diethyl ether, they noted some leaching of compounds from the leaf interior, and it remains unclear how much material originated from the leaf surface. There has been much subsequent discussion as to the likelihood that flavonoid glycosides and other polar compounds can occur within the nonpolar waxy matrix of the leaf surface (Harborne, 1973; Hunt and Baker, 1980; Wagner, 1982; Robinson, 1991). Recent studies, reviewed below, have demonstrated clearly that several classes of polar compounds are indeed present on leaf surfaces, although the mechanisms of transport and storage remain unclear.

Oviposition stimulants for insects have typically been extracted from leaf surfaces by dipping leaves for several seconds in various solvents. The suitability of different solvents for particular extractions depends critically on the polarity of the stimulant compounds. Most chemical explorations of the leaf surface have used methylene chloride to extract the surface compounds (Städler and Buser, 1984; Proksch et al., 1985, 1986; Bohm and Constant, 1990; Bohm and Chan, 1992; Bohm, 1993; Reid and Bohm, 1993). This organic solvent of medium polarity has been used with success to extract sesquiterpenoids and other relatively nonpolar compounds (Städler and Roessingh, 1991), but it may have been insufficient to remove polar compounds present in the epicuticular waxes or the cuticle proper. Cold water was used to extract more polar compounds such as fructose and other water-soluble carbohydrates from leaf surfaces of *Zea mays* (Derridj et al., 1987; Fiala et al., 1990). Neither cold water nor methanol alone were effective in extracting stimulants for *Delia radicum* or *Pieris rapae*; however, extraction of glucosinolates and other stimulants for these insects required either hot water or methanol preceded by a chloroform or methylene chloride dip (Städler and Roessingh, 1991; Renwick, et al., 1992; van Loon et al., 1992; Baur et al., 1996). Hot water was also used by Zobel and Brown (1988) to extract furanocoumarins from the leaves of *Ruta graveolens*. Städler and Roes-

singh (1991) concluded that stimulants must generally be embedded quite deeply in the waxy leaf cuticle so that they can be extracted only when the waxy layer is dissolved (chloroform/methylene chloride) or melted (hot water).

In early work on oviposition stimulants for *P. polyxenes*, Feeny et al. (1983) found that stimulant activity could not be extracted from the surfaces of carrot leaves by individual organic solvents or by cold water. In fact, the leaves retained their stimulant activity even after immersion in 2 N HCl for 30 min at 40°C; only as temperatures were increased above 60°C, presumably causing softening and disruption of the waves, did the leaves lose their ability to stimulate oviposition. Since the major stimulants, CA and L7MG, are both easily hydrolyzed by dilute HCl, this was evidence that these polar stimulants are indeed embedded in the surface wax, as concluded by Städler and Roessingh (1991).

The purpose of this study was threefold: (1) to confirm the presence of contact oviposition stimulants for *P. polyxenes* on the leaf surfaces of *D. carota*, (2) to develop the most efficient extraction technique for the removal of these stimulants from the surface of *D. carota* leaves, and (3) to quantify the concentrations of these chemicals on the leaf surface.

METHODS AND MATERIALS

Surface Area Regressions. Foliage of carrot, *Daucus carota*, was taken fresh from the field in the vicinity of Ithaca, New York, in spring 1990 and transported to the laboratory on ice. Additional carrot foliage was taken from greenhouse cultures at Cornell University. All petioles were cut just below the point of attachment of the first leaflets, and the fresh weight and length of each leaf was recorded. All parts of each leaf were then mounted on paper sprayed with Scotch brand Spray Mount Artist's Adhesive (3M). This paper was covered with clear plastic and photocopied to make a permanent record of leaf surface area before wilting began.

The photocopied images of leaves were scanned using an Apple flatbed scanner. On all photocopied sheets, a 0.5-square-inch standard was included for calibration. The pixels of the scanned images were then counted using a pixel-counting program provided by M. Lapidus. The calculated surface area of each leaf was doubled to account for both the upper and lower leaf surfaces. Least-squares regressions were calculated for leaf surface area versus leaf weight and for leaf surface area versus leaf length.

Plant Material for Surface Extracts. Four collections of *D. carota* foliage were taken fresh from the field in the vicinity of Ithaca, New York, from June 1994 to October 1994. The cut petioles of individual leaves were placed in Aquapiks (Cleveland Plant and Flower Co., Wholesale Florists, Binghamton,

New York 13905) and transported to the laboratory on ice. The leaves within a single collection were assigned randomly to four treatment groups. Within each treatment group the fresh weight of the leaves, including petioles, was obtained prior to surface extraction. Each treatment group contained between 10.0 and 13.0 g of leaves. After surface extraction, the petioles were cut from the leaves below the point of attachment of the first leaflets and weighed separately. The petiolar weight was subtracted from the total leaf weight to obtain the laminar weight.

Solvent Extraction Systems. Four solvent systems (treatments) were used to extract chemicals from the surfaces of carrot leaves. For system 1 ($CHCl_3$–MeOH), a freshly cut leaf in this treatment group was dipped in 200 ml of $CHCl_3$ for 10 sec and held above the solvent to drip for 10 sec. The leaf was then dipped in 200 ml MeOH for 7 sec and allowed to drip for 10 sec. All leaves in the group were dipped individually in the same aliquot of solvent. For system 2 (near-boiling H_2O), leaves were dipped individually in 300–350 ml of near-boiling H_2O (HPLC grade, temperature at least 94°C) for 2 sec and were allowed to drip for 10 sec. For system 3 ($CHCl_3$–near-boiling H_2O), each leaf was first dipped for 10 sec in 200 ml of $CHCl_3$ and allowed to drip for 10 sec. The leaf was then dipped for 1 sec in 300 ml of near-boiling H_2O and allowed to drip for 10 sec. For system 4 (CH_2Cl_2–CH_2Cl_2), leaves were dipped individually in 300 ml of CH_2Cl_2 for 30 sec and allowed to drip for 10 sec. This was repeated in a second volume of CH_2Cl_2. Since the CH_2Cl_2 evaporated rapidly, solvent volume was kept constant throughout the extraction by addition of more solvent. All solvent fractions were stored in the freezer until preparation for HPLC analysis.

Solvent Timing Study. Two collections of *D. carota* foliage were taken fresh from the field in the vicinity of Ithaca, New York, in July 1995. The cut petioles of individual leaves were placed in Aquapiks and transported to the laboratory on ice. The leaves from both collections were combined and assigned randomly to six treatment groups. Within each treatment group the fresh weight of the leaves, including petioles, was obtained prior to surface extraction. After surface extraction, the petioles were cut from the leaves below the point of attachment of the first leaflets and weighed separately. The petiolar weight was subtracted from the total leaf weight to obtain the laminar weight. The leaves from each treatment were extracted with solvent system 3 ($CHCl_3$–near-boiling H_2O). In these extractions, the dipping time in $CHCl_3$ was kept constant at 10 sec, but each treatment group received successively longer dipping times in the near-boiling H_2O (with times of 1, 2, 3, 4, 5, and 7 sec, respectively). All solvent fractions were stored in the freezer until preparation for HPLC analysis.

Preparation of Surface Extracts for HPLC Analysis. The organic fractions were concentrated in vacuo at 40°C to a volume of 20–40 ml and then extracted three times with equal volumes of H_2O (HPLC grade). The resulting aqueous

layer was kept, and the original organic layer discarded. The aqueous surface washes were concentrated in vacuo at 40°C to a volume of 20–40 ml and then extracted three times with equal volumes of $CHCl_3$. The original aqueous layer was kept, and the $CHCl_3$ wash discarded. In a solvent system containing both an organic and aqueous wash, the final aqueous layers after extraction for both washes were combined. All final extracts were concentrated in vacuo at 40°C to a final volume of 1 ml.

HPLC Methodology. Analyses of surface extracts were carried out on a Waters multisolvent delivery system (M6000 pump, U6K injector) and monitored between 200 and 600 nm (Waters 991 photodiode array (PDA) detector). The analytical reverse-phase C-18 column (Phenomenex IB-sil, 4.6 × 250 mm, 5 μm with 4.6 × 30 mm C-18 guard column) was eluted at a flow rate of 1.0 ml/min using a stepped gradient (Table 1). Calibration and quantification of the PDA data were done by analysis of eight standard solutions containing CA, L7G, and L7MG (500, 250, 150, 60, 30, 15, 7.5, and 4.875 μg of each compound per ml, respectively, giving from 5000 to 48.750 ng of each compound per injection). Calculation of calibration curves and quantification of the known compounds in the surface extracts was performed by Millennium 2010 Chromatography Manager software (Millipore, Inc.).

Sources of Standard Compounds. CA was purchased from Sigma. L7G was purchased from Indofine Chemical Company. The L7MG standard was purified from fresh *D. carota* foliage using a modification of the procedure described by Feeny et al. (1988). Foliage of carrot was taken fresh from the field in the vicinity of Ithaca, New York, in May 1994. The cut petioles of individual leaves were placed in Aquapiks and were transported to the laboratory in coolers containing ice packs. Leaves, 40 g fresh weight at a time, were

immediately blended in boiling 95% EtOH for 5–10 min and the extract filtered. After removal of the EtOH by evapoaration in vacuo at 40°C, the resulting aqueous suspension was centrifuged and then extracted sequentially (each three times) with equal volumes of hexane, diethyl ether (Et_2O), $CHCl_3$, and ethyl-acetate (EtOAc). The post-EtOAc aqueous fraction was concentrated in vacuo at 40°C and adjusted with H_2O to a concentration of 20 gle/ml (1 gle = amount of material extracted from 1 g fresh weight of carrot leaves).

Preparative fractionation of the post-EtOAc aqueous fraction was carried out on an open column (4.1 cm ID) packed with 100.0 g C-18 prep LC packing (Bakerbond, 40-μm particle size). Five milliliters (100 gle) of the post-EtOAc aqueous fraction was applied to the column and eluted successively with 1000 ml 1% acetic acid (HOAc) in H_2O, 1000 ml 20% MeOH in 1% aq. HOAc, 1200 ml 40% MeOH in 1% aq. HOAc, and 500 ml pure MeOH. The brown band that was eluted from the column at the beginning of the pure MeOH fraction was concentrated in vacuo at 40°C and was further fractionated on a second open column (1.9 cm ID × 25.0 cm) packed with C-18 prep LC packing. The column was successively eluted with 275 ml 30% MeOH in 1% aq. HOAc (fraction 1), 460 ml 20% MeOH in 1% aq. HOAc (fraction 2), 230 ml 40% MeOH in 1% aq. HOAc (fraction 3), and 100 ml pure MeOH. The L7MG was collected by repeated HPLC of fraction 3 on a semi-prep C-18 column (Phenomenex IB-sil, 10 × 250 mm, 5 μm). Its identity was confirmed by matching its retention time and UV spectra with the time and spectra of previously isolated luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucoside (Feeny et al., 1988).

Data Analysis. Statistical comparisons between the regression lines of the surface area correlations for field and greenhouse leaves were carried out using the *F* test for difference between two regression coefficients (Sokal and Rohlf, 1981). Statistical comparisons among the four solvent methods were carried out using the Quade test (Conover, 1980).

RESULTS

Leaf Surface Areas. Although surface area varied linearly with both leaf length and leaf weight, weight was a better predictor of surface area, explaining 98% of the surface area variation in field carrot leaves (Figure 1) and 97% of the variation in greenhouse leaves (Figure 2). The variation of surface area with leaf weight differed significantly between field carrot leaves and greenhouse carrot leaves, as greenhouse leaves had more surface area per gram of leaf ($P < 0.001$, *F* test). The variation of surface area with leaf length also differed significantly between the two groups ($P < 0.01$, *F* test).

Solvent System Comparison. CA, L7G, and L7MG were present in surface extracts obtained using each solvent system, but the systems differed in their

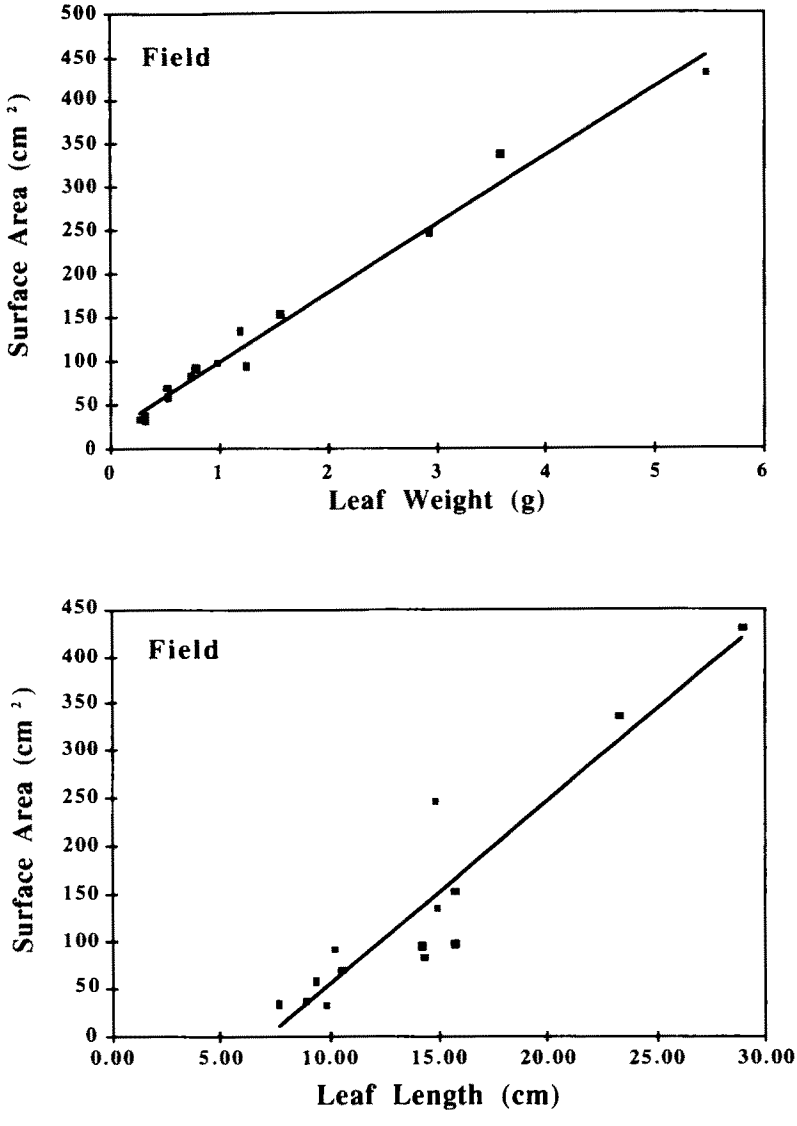

FIG. 1. Relationship of leaf surface area to leaf weight and leaf length, respectively, of field-collected *Daucus carota*. For leaf weight: $y = 78.731\ x + 18.615$ ($r^2 = 0.9827$). For leaf length: $y = 19.231\ x - 139.92$ ($r^2 = 0.8803$).

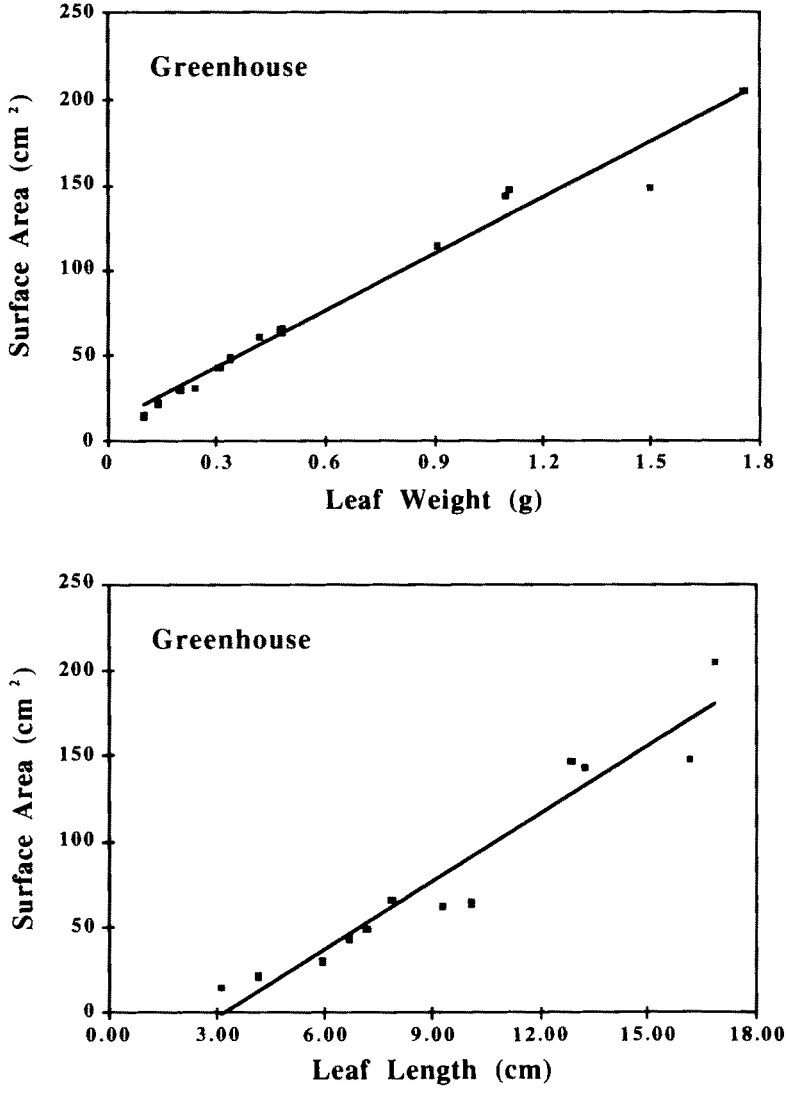

FIG. 2. The relationship of leaf surface area to leaf weight and leaf length, respectively, of greenhouse-grown *Daucus carota*. For leaf weight: $y = 109.37\ x + 9.7964$ ($r^2 = 0.9725$). For leaf length: $y = 13.192\ x - 42.924$ ($r^2 = 0.9263$).

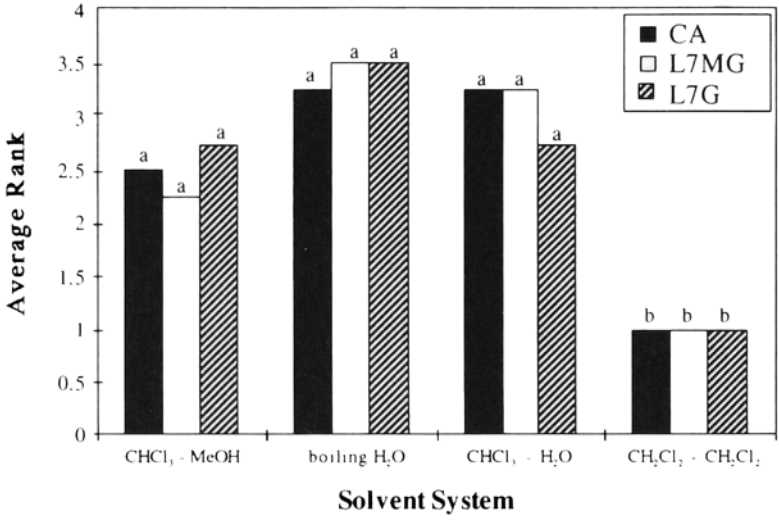

FIG. 3. Comparison of the efficiency of four solvent systems for extracting chlorogenic acid (CA), luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucoside (L7MG), and luteolin-7-β-D-glucoside (L7G) from leaf surfaces of *Daucus carota*. Efficiency was based on the amounts of a compound detected in surface extracts obtained by each solvent system. The method that removed the highest quantity of a compound received a rank of 4; the method that removed the lowest quantity received a rank of 1. The score given is the average of four replicate samples. Bars with different letters are statistically different ($P < 0.05$, Quade test).

efficiency of extraction (Figure 3). System 4 (CH_2Cl_2–CH_2Cl_2) was significantly less efficient in extracting the polar compounds from the leaf surfaces ($\alpha < 0.05$, Quade test). In fact, no detectable amounts of L7G were found in one of the four methylene chloride samples, and L7MG was not detectable in three of the four methylene chloride samples. System 2 (near-boiling H_2O) and system 3 ($CHCl_3$–near-boiling H_2O) tended to extract higher quantities of the polar compounds from the carrot leaf surfaces than did system 1 ($CHCl_3$–MeOH). The superiority of the aqueous methods was not significant statistically, however, probably due to the low number of replicates in the study.

The four solvent systems also varied in the overall number of polar, UV-absorbing compounds extracted from the carrot leaf surfaces and revealed in HPLC traces. System 3 ($CHCl_3$–near-boiling H_2O) extracted 34 compounds on average from the leaf surfaces. Near-boiling water (system 2) removed 32 compounds on average, and the chloroform–methanol system (system 1) extracted

26 compounds. The methylene chloride solvent system (system 4) extracted an average of only 15 compounds from carrot leaf surfaces.

Compound Quantification. CA was present at much higher concentrations, ranging from 19.2 to 596.2 ng/cm^2, in the $CHCl_3$–near-boiling H_2O surface extracts than were the flavonoid glycosides (Figure 4). This same pattern was also found in the surface extracts in the other three solvent systems. L7G and L7MG were present in extracts at much lower concentrations, ranging from 0.8 to 26.8 ng/cm^2 and 0.9 to 8.2 ng/cm^2, respectively (Figure 4).

There was also seasonal variation in the concentrations of the compounds on the leaf surface (Figure 4). Leaves from the fall rosette foliage had lower concentrations of CA on their surfaces than did the foliage of adult leaves (those from the July and August collections). Although there were also seasonal differences in the concentrations of the flavonoid compounds, no apparent trend was evident from the limited number of sampling dates.

Solvent Timing Study. In the chloroform–near-boiling water solvent system, the amount of time the leaves were dipped in the water affected the amounts of compounds extracted from the leaves (Figure 5), with the quantity extracted from leaves increasing sharply when dipped in water for more than 2 sec.

DISCUSSION

There is debate in the literature as to the possibility of flavonoid glycosides being located on the leaf surface. Harborne (1973) and Wagner (1982) present evidence to show that flavonoid glycosides are confined almost entirely to plant cell vacuoles. However, Hunt and Baker (1980) found naringenin-7-glucoside in the cuticle of tomato fruits and concluded that "flavonoid glycosides occur extensively in the outer epidermis of leaves and fruits but their precise location within this layer has not been clearly established" (p. 1418). Recent studies comparing leaf surface and interior flavonoid composition found flavonoid glycosides in the leaf interior, and only the less polar flavonoid aglycones on the leaf surface (Proksch et al., 1985, 1986; Bohm and Constant, 1990; Bohm and Chan, 1992; Bohm, 1993; Reid and Bohm, 1993). Robinson (1991) described the consensus of research in this area when he stated, "it has been suggested as a general rule that the [flavonoid] glycosides are found within cells" (p. 192).

Although the nonpolar cuticle provides a barrier between the plant leaf interior and the leaf surface, movement of polar compounds through the cuticle has been shown in several plant species. Tukey (1970) documents the diversity of chemicals found in plant leachates, including sugars, sugar alcohols, organic acids, and phenolics. The pesticide literature provides many examples of polar components of applied pesticides moving from the leaf surface into the leaf

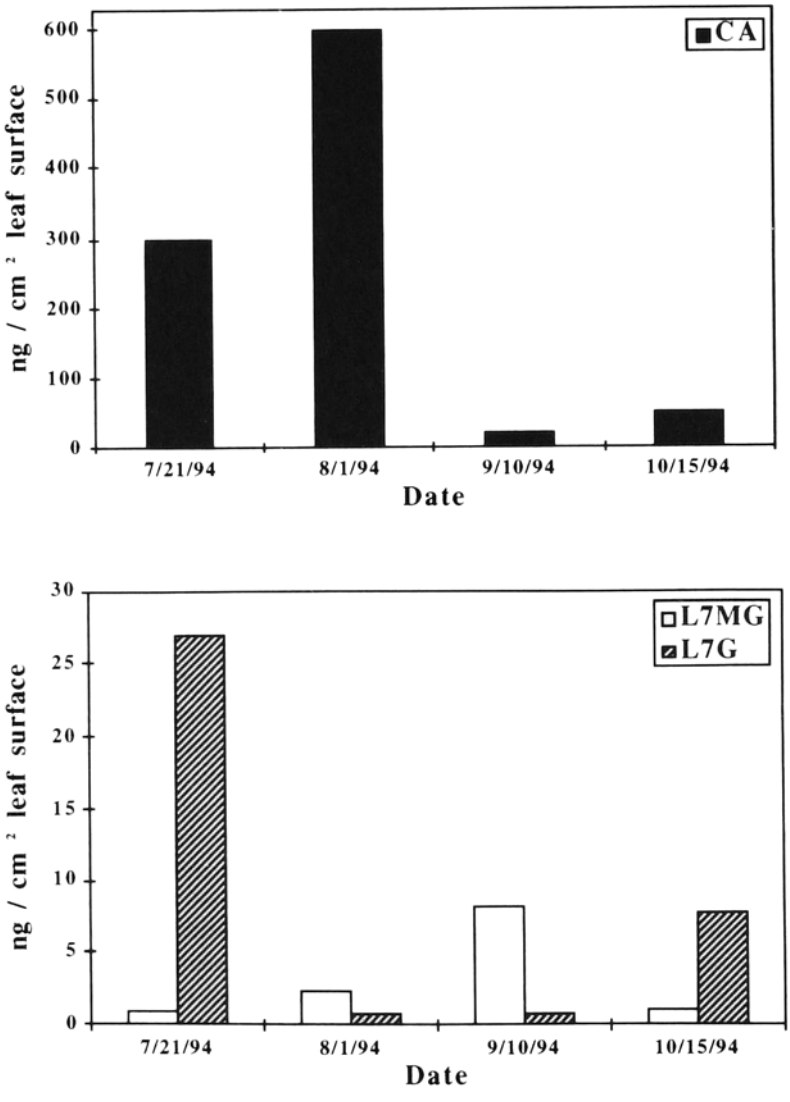

FIG. 4. Quantities of chlorogenic acid (CA), luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucoside (L7MG), and luteolin-7-β-D-glucoside (L7G) removed from leaf surfaces of *Daucus carota* using the chloroform–near-boiling water method.

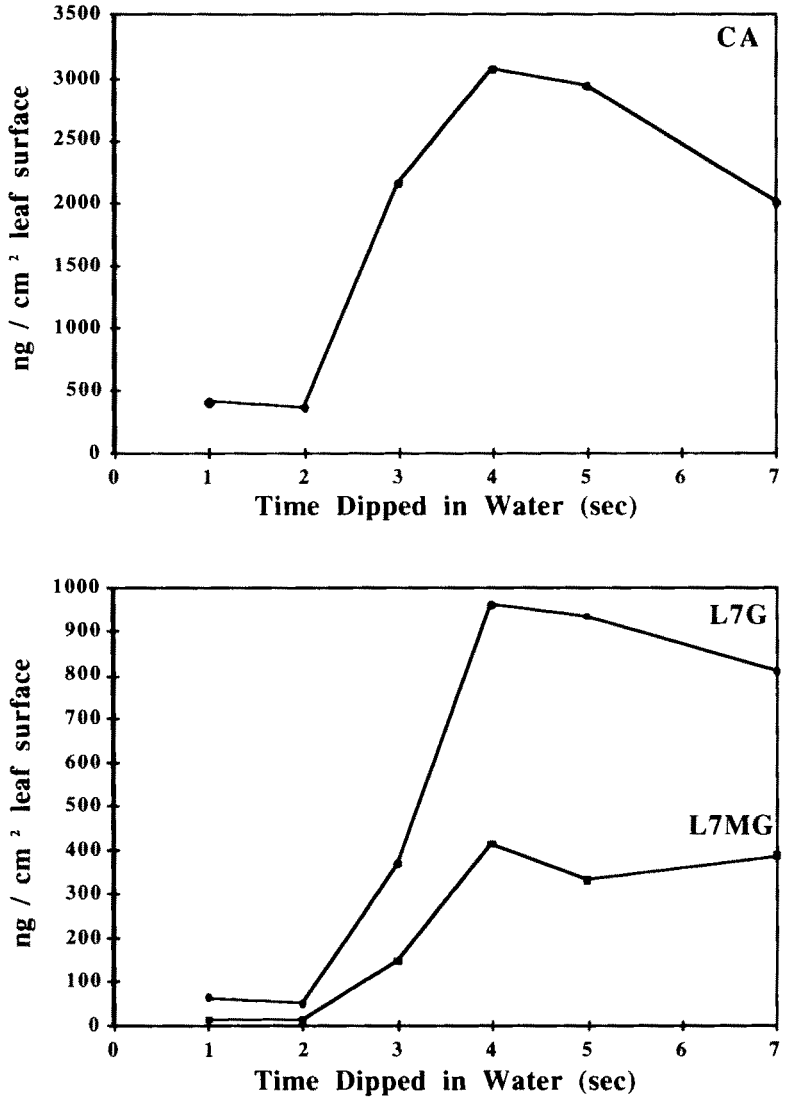

FIG. 5. Quantities of chlorogenic acid (CA), luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucoside (L7MG), and luteolin-7-β-D-glucoside (L7G) removed from *Daucus carota* leaf surfaces using chloroform and near-boiling water, with successively longer dipping times in water.

interior (see Merrall, 1981; Price, 1982 for references). Merrall (1981) hypothesized that an aqueous or polar pathway existed to explain the facile uptake of hydrophilic and ionic materials that were incompatible with lipids. Price (1982) also reviewed literature support for possible hydrophilic pathways extending from the aqueous apoplast to the cuticle surface but concluded that the evidence in favor of such a theory was rather indirect. More recent work has documented the presence of cuticular pores and transcuticular canals in 63 taxa among 32 families (Miller, 1985, 1986). Derridj et al. (1996) described the kinetics of soluble carbohydrate movement from leaf tissues through the cuticle to the leaf surface. From these studies it can be concluded that the cuticle is not a complete barrier to polar compounds, although the actual mechanism for the passage of polar compounds through the cuticle is unknown.

This current work confirms the presence of the flavonoid glycosides luteolin-7-β-D-glucoside and luteolin-7-*O*-(6″-*O*-malonyl)-β-D-glucoside in leaf surface extracts of *Daucus carota*. The solvent timing study with the chloroform–near-boiling water solvent combination suggests that brief extractions in the water (1–2 sec) remove compounds from the surface alone and not from the apoplast or symplast. It is reasonable to believe that these extracts reflect the presence of the compounds on the leaf surface itself.

Many of the past studies conducted on leaf surfaces used methylene chloride as the solvent for surface extraction (Proksch et al., 1985, 1986; Bohm and Constant, 1990; Bohm and Chan, 1992; Bohm, 1993; Reid and Bohm, 1993). Since methylene chloride significantly underperforms as an extraction solvent in comparison to more polar solvents, and often fails to extract the flavonoid glycosides to any detectable extent, it does not appear to be a suitable solvent for extracting polar compounds from the leaf surface of wild carrot.

Since extraction methods can vary greatly in the amounts of compounds extracted from the leaf surface, it is important to find the method best suited for the compounds of interest to the investigator (see also Städler and Roessingh, 1991; van Loon and van Meer, 1991; Renwick et al., 1992). For extracting the leaf surfaces of *D. carota*, a solvent combination of chloroform and near-boiling water performs somewhat better than other solvents and solvent combinations tested for extraction of polar compounds. It is also a versatile solvent combination that can extract nonpolar compounds in addition to polar compounds. With brief dipping times in water, the method appears to remove compounds from the leaf surface without sampling from the leaf interior to any appreciable extent.

Since swallowtail butterflies make their final oviposition decisions based on leaf surface chemistry, it is important to study chemical stimulants present on the leaf surface itself. Little is yet known concerning the relationship between chemical profiles of leaf surfaces, as perceived by egg-laying females, and the

chemical content of leaf interiors, which are consumed by the feeding larvae. The work described here provides a possible avenue for investigating such relationships.

DETERMINATION OF FEEDING PREFERENCE OF FORMOSAN SUBTERRANEAN TERMITE (*Coptotermes formosanus* Shiraki) FOR SOME AMINO ACID ADDITIVES

JIAN CHEN and GREGG HENDERSON*

Department of Entomology
Louisiana Agricultural Experiment Station
Louisiana State University Agricultural Center
Baton Rouge, Louisiana 70803

(Received June 21, 1995; accepted August 14, 1996)

Abstract—A choice feeding test using 21 amino acids was conducted to determine the feeding preference of Formosan subterranean termite, *Coptotermes formosanus* Shiraki, in the laboratory. Significantly more filter paper treated with D-aspartic acid or L-glutamic acid was consumed by Formosan subterranean termites than was control filter paper treated with water. In two-choice feeding tests, termites consumed significantly more filter paper treated with D-aspartic acid or L-aspartic acid than paper treated with water. Adding L-proline, L-lysine, or L-isoleucine to filter paper significantly increased consumption compared with control filter paper in no-choice tests. The use of amino acid additives in termite baits is briefly discussed.

Key Words—Formosan subterranean termite, *Coptotermes formosanus*, feeding test, amino acids, aspartic acid, proline, glutamic acid.

INTRODUCTION

The Formosan subterranean termite, *Coptotermes formosanus* Shiraki, is a cosmopolitan pest that attacks both living trees and structural wood (Bess, 1970; Lai et al., 1983). Chemical and physical barriers, wood preservatives, termiticides, and nest excavations are commonly used to control Formosan subterranean termites (Spink, 1967; Su et al., 1991b; Tamashiro et al., 1991; Li et al., 1994). Baiting as a means of controlling subterranean termites was initiated in

1967 (Esenther and Gray, 1968). Over the years, materials used in the bait matrix have included wood blocks (French and Robinson, 1981), toilet paper rolls (Haverty et al., 1975), corrugated cardboard (La Fage et al., 1983), and cork (French et al., 1986). Since the initiation of termite bait research, considerable time and effort have been spent to find slow-acting and nonrepellent or less repellent bait toxicants (Jones, 1984; Haverty et al., 1989; Su et al., 1991a; Su, 1994), preferred cellulose sources and attractive additives in the bait matrix (Esenther and Beal, 1979), and ways to exploit termite foraging behavior in the bait design (Su, 1994). The aim of all these efforts is to induce termites to preferentially feed on the toxic bait. Thus, the chemistry of the matrix is one of the most important factors in determining bait success.

Generally, termite foods are high in cellulose but low in nitrogen (Brooks, 1963). Because nitrogen is usually limited in naturally occurring termite food (Cowling and Merrill, 1966), nitrogen additives may increase food acceptance and consumption. Hungate (1941) observed that a nitrogen source added to wood with a low nitrogen content increased wood consumption by *Zootermopsis*, *Kalotermes*, and *Reticulitermes* spp. Nitrogen additives also increased the fecundity of mated pairs of *Zootermopsis nevadensis* (Hagen) (Shellman-Reeve, 1990). On a diet of a cellulose (toilet paper) and nitrogen, food consumption by the desert termite, *Gnathamitermes tubiformans* (Buckley), increased as dietary amino acid nitrogen levels increased (Spears and Ueckart, 1976). Mishra (1992) reported that *Neotermes bosei* Snyder (Kalotermitidae) was attracted to proline, aspartic acid, and methionine. Yaga (1972) noted that Formosan subterranean termites consumed filter paper treated with amino acids but failed to include data in his report.

Our goal was to investigate the effect of amino acids on food (filter paper) consumption by Formosan subterranean termites using multiple-choice and no-choice feeding tests. These tests could lead to cheap and effective additives for termite bait enhancement. Feeding preference of termites on D-aspartic acid and L-aspartic acid was also assessed in two-choice feeding tests by using termites from different colonies to determine whether feeding preference remained consistent for termites from different colonies.

METHODS AND MATERIALS

Termites were collected from colonies infesting houses and trees in New Orleans, Lake Charles, and Ascension Parish, Louisiana. Collected termites were kept at room temperature (23–28°C) in plastic containers (20 cm diam., 20 cm height) with sand (No. 4 blasting sand) and moistened corrugated cardboard.

Multiple-Choice Feeding Test. The test apparatus is illustrated in Figure 1.

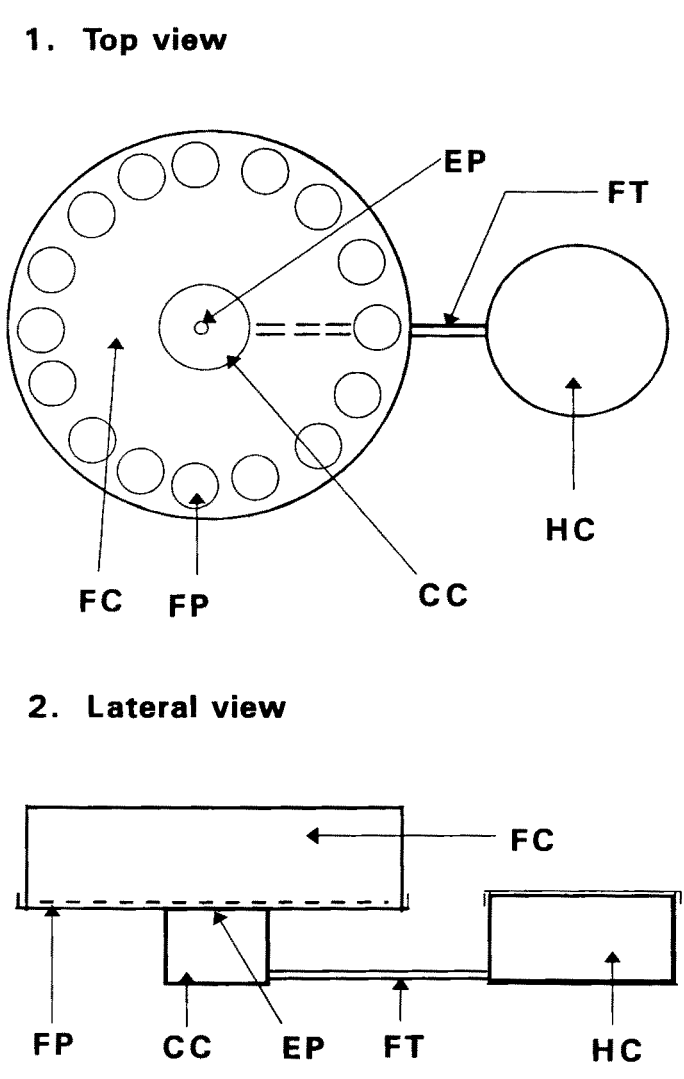

FIG. 1. Choice feeding test apparatus. CC: connecting container, EP: exit path, FC: feeding chamber, FP: filter paper circle, FT: foraging tube, HC: home container.

All termites used in this test came from one colony collected from a home in New Orleans, Louisiana. One hundred fifty workers and 15 soldiers were introduced into a home container (8.41 cm diam., 3.33 cm height, Tristate Plastics, Inc., Dixon, Kentucky) containing 200 g of No. 4 blasting sand that served as

a moisture reservoir. The home container was connected by a foraging tube (0.5 cm inner diam., 13 cm long, Tygon tube) to a connecting container (5.08 cm diam., 3.65 cm height, Tristate Plastics, Inc.) that was filled with moistened sand. A 3-mm-diam. hole (exit path) in the center of the connecting container lid allowed termites to pass upward into a feeding chamber (18.09 cm diam., 7.62 cm depth, Tristate Plastics, Inc.) where the termites had access to food choices consisting of 22 filter paper circles (1.5 cm diam., grade 1, Whatman) fixed to the bottom of the feeding chamber with minute pins. The distance from the exit path to the center of each filter paper circle was 8 cm. After termites were introduced into the home container, the exit path was covered with a piece of Tygon tubing, which prevented the termites from entering the feeding chamber. When termites had tunneled through the home container and connecting container and appeared in the exit path of each apparatus, the tube covering the exit path was removed, so that the feeding tests in all containers ($N = 10$) began simultaneously. Each apparatus was completely buried in moistened vermiculite within a plastic box (31.12 cm long, 22.86 cm wide, and 10.48 cm height, Tristate Plastics, Inc.) to maintain high humidity, decrease outside vibration, and block light.

Amino acids tested were glycine, L-methionine, L-leucine, L-isoleucine, L-cysteine, *trans*-4-hydroxyl-L-proline, *cis*-4-hydroxyl-L-proline, L-lysine, L-proline, L-histidine, L-tryptophan, L-alanine, L-phenylalanine, L-asparagine, L-arginine, L-threonine, L-serine, D-aspartic acid, L-glutamic acid, L-glutamine, and L-valine (purity 99+% by TLC, Sigma Chemical Company, St. Louis, Missouri). Amino acids were dissolved in distilled, deionized water (distilled water supplied through laboratory taps was then deionized using a Barnstead NANOpore Ultrapure Water System) to provide 0.01 M solutions. Solutions that were 0.01 M in strength were selected for testing based on the results of Allsopp's (1992) work on the phagostimulant effect of amino acids on subterranean larvae of *Antitrogus parvulus* and *Lepidiota negatoria* (Coleoptera: Scarabaeidae). Twenty microliters for each amino acid solution were applied to a filter paper circle with a micropipet after it was dried at 80°C for 24 hr, cooled in a desiccator for 5 hr, and weighed. Amino acid solutions and control applications of distilled, deionized water were randomly assigned to a filter paper circle in each feeding chamber ($N = 10$). After five days of termite foraging, filter paper circles were removed. The sand on the filter paper circles, if any, was removed by using a fine forceps. The filter paper circles were dried at 80°C for 24 hr, cooled in a desiccator for 5 hr, and weighed. A completely randomized block design was used with 10 blocks (containers) and 21 amino acids as treatments, and one distilled, deionized water as the control. The response variable was the food consumption (micrograms per termite per day). The 10 replications were conducted simultaneously. The data were analyzed by ANOVA (SAS Institute, 1988), and Tukey's mean comparison was used to compare the dif-

ference in food consumption between the amino acid treatments and control filter paper circles.

Two-Choice Feeding Test. D-Aspartic acid and L-aspartic acid were tested in an experimental apparatus similar to that used in the multiple-choice feeding test, except that the feeding chamber was smaller (8.41 cm diam., 3.33 cm height) and only two food choices were presented to the foraging termites. One filter paper circle was treated with 20 μl of 0.01 M D-aspartic acid or 0.01 M L-aspartic acid (purity 99+% by TLC, Sigma Chemical Company). The other filter paper circle was treated with 20 μl of distilled, deionized water. The four termite colonies tested with D-aspartic acid were collected from four different trees: maple (*Acer* sp.), green ash (*Fraxinus* sp.), elm (*Ulmus* sp.) in New Orleans, Louisiana, and bald cypress [*Taxodium distichum* (L.) Rich.] in Lake Charles, Louisiana. Tests with colonies from maple and green ash were replicated six times, and tests with colonies from elm and bald cypress were replicated 10 times. For L-aspartic acid tests, two termite colonies were collected from houses in Ascension Parish and New Orleans, Louisiana. Tests for both colonies were replicated 10 times. The experimental procedure was the same as that of the multiple-choice feeding test except that the feeding duration was reduced to 48 hr, and 50 worker termites and five soldier termites were used. Because there were only two food choices in the feeding chamber, a paired-sample *t*-test was used to compare the mean consumption of D-aspartic-acid-treated filter paper circles or L-aspartic-acid-treated filter paper circles with filter paper circles treated with distilled, deionized water separately for each colony.

No-Choice Feeding Test. Termites used in this experiment were collected from an infested building in Lake Charles, Louisiana. One hundred worker termites and 10 soldiers were placed in each of 48 plastic Petri dishes (8.41 cm diam., 3.33 cm height, Tristate Plastics, Inc.). Dishes received filter papers (Whatman No. 2, 1.30 $\pm$ 0.007 g dry weight) that were moistened with 2 ml of a 0.01 M amino acid solution of one of 15 amino acids, or distilled, deionized water alone. The experiment was replicated three times (16 treatments $\times$ 3 replications = 48 dishes). Amino acids tested included glycine, L-isoleucine, L-methionine, L-leucine, L-cysteine, *trans*-4-hydroxyl-L-proline, L-lysine, L-proline, L-histidine, L-alanine, L-phenylalanine, L-threonine, L-serine, L-asparagine, and D-aspartic acid (purity 99+% by TLC, Sigma Chemical Company). Termites were held at 27–28°C for 10 days and then filter papers were removed, dried at 80°C for 24 hr, cooled in a desiccator for 5 hr, and weighed. A completely randomized design with three replicates was used with 15 amino acids as treatments and one distilled, deionized water as the control. The response variable was the food consumption (micrograms per termite per day). The data were analyzed by one-way ANOVA. Tukey's mean comparison test was used to compare food consumption among the treated and control filter paper circles.

RESULTS

Multiple-Choice Feeding Test. Mean food consumption (Figure 2) was significantly different between amino acid treatments and control ($F = 2.29$, $df = 21, 189$; $P = 0.002$) but there were no significant differences between the 10 replicates for each treatment ($F = 0.92$, $df = 9, 189$; $P = 0.506$). Of the 21 amino acids tested, only D-aspartic acid or L-glutamic acid significantly increased consumption compared with distilled, deionized water controls ($P < 0.01$, Figure 2). There was no significant difference in food consumption between filter paper circles treated with D-aspartic acid and those treated with L-glutamic acid ($P > 0.05$).

Two-Choice Feeding Test. Termites from each of the four colonies preferentially fed on the filter paper circles treated with D-aspartic acid over filter paper circles treated with distilled, deionized water (Table 1). Termites from each of the other two colonies preferentially fed on the filter paper circles treated with L-aspartic acid over filter paper circles treated with distilled, deionized water (Table 2).

No-Choice Feeding Test. Mean filter paper consumption in the no-choice test was significantly different between amino acid treatments and control ($F =$

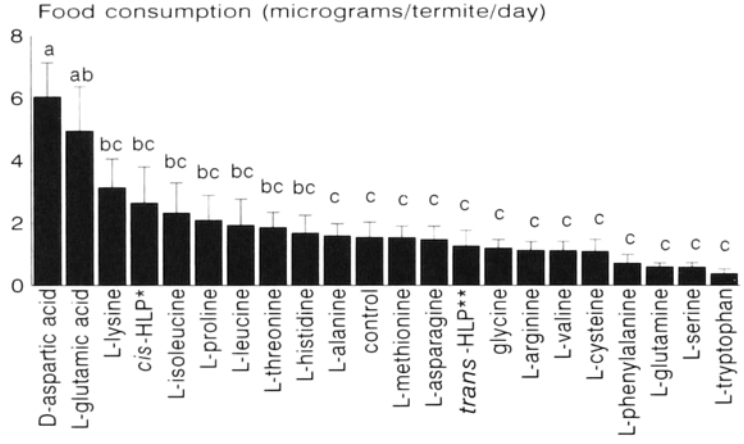

FIG. 2. Mean consumption (+SE) of filter paper circle treated with one of 21 amino acids or distilled, deionized water (control) by Formosan subterranean termites under a multiple-choice bioassay. L-Aspartic acid was not included in this bioassay. Means with the same letter are not significantly different ($P > 0.05$) using Tukey's mean separation. **cis*-HLP: *cis*-4-hydroxyl-L-proline. ***trans*-HLP: *trans*-4-hydroxyl-L-proline.

TABLE 1. FEEDING PREFERENCE BETWEEN FILTER PAPER CIRCLES TREATED WITH D-ASPARTIC ACID (TREATMENT) AND TREATED WITH DISTILLED, DEIONIZED WATER (CONTROL) (MEAN FOOD CONSUMPTION ± SE) BY FORMOSAN SUBTERRANEAN TERMITES COLLECTED FROM LAKE CHARLES AND NEW ORLEANS, LOUISIANA (TEST DURATION: 48 HOURS)

Colony[a]	Loss in dry mass (mg)			Paired-sample *t*-test *P* value
	Treatment	Control	Difference	
1	3.76 ± 0.22	3.13 ± 0.19	+0.63	<0.05
2	3.94 ± 0.40	2.12 ± 0.32	+1.82	<0.01
3	3.32 ± 0.50	1.30 ± 0.18	+2.02	<0.01
4	1.97 ± 0.16	0.70 ± 0.16	+1.27	<0.01

[a]Colony 1 was collected from bald cypress tree in Lake Charles, Louisiana, colonies 2, 3, and 4 were collected from elm, green ash, and maple trees respectively, in New Orleans, Louisiana.

7.35, $df = 15, 32$; $P < 0.01$) (Figure 3). Consumption of filter paper treated with glycine, L-methionine, L-leucine, L-cysteine, *trans*-4-hydroxyl-L-proline, L-histidine, L-alanine, L-phenylalanine, L-threonine, L-serine, L-asparagine, or D-aspartic acid was not significantly different from consumption of filter paper circles treated with distilled, deionized water (Figure 3). Only consumption of filter papers treated with L-proline, L-isoleucine, or L-lysine was significantly greater than consumption of control filter papers ($P < 0.001$ for L-proline, $P = 0.036$ for L-lysine, $P = 0.001$ for L-isoleucine).

TABLE 2. FEEDING PREFERENCE BETWEEN FILTER PAPER CIRCLES TREATED WITH L-ASPARTIC ACID (TREATMENT) AND TREATED WITH DISTILLED, DEIONIZED WATER (CONTROL) (MEAN FOOD CONSUMPTION ± SE) BY FORMOSAN SUBTERRANEAN TERMITES COLLECTED FROM ASCENSION PARISH AND NEW ORLEANS, LOUISIANA (TEST DURATION: 48 HOURS)

Colony[a]	Loss in dry mass (mg)			Paired-sample *t*-test *P* value
	Treatment	Control	Difference	
1	2.51 ± 0.56	0.46 ± 0.32	+2.05	<0.05
2	3.26 ± 0.82	0.55 ± 0.38	+2.71	<0.05

[a]Colony 1 was collected from a house in Ascension Parish, Louisiana, colony 2 was collected from a house in New Orleans, Louisiana.

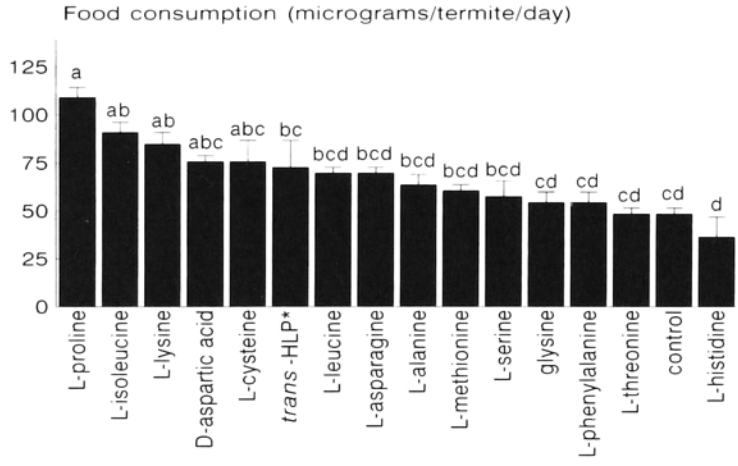

FIG. 3. Mean consumption (+SE) of filter paper circle treated with one of 15 amino acids or distilled, deionized water (control) by Formosan subterranean termites given no choice. L-Aspartic acid was not included in this array. Means with the same letter are not significantly different ($P > 0.05$) using Tukey's mean separation. **trans*-HLP: *trans*-4-hydroxyl-L-proline.

DISCUSSION

Nitrogen is essential in fulfilling life functions of many animals including Formosan subterranean termites. Although there is evidence of nitrogen fixation in termites (Potrikus and Breznak, 1977), whether nitrogen fixation can meet all of the termite's nitrogen requirements remains unanswered. Results of our study indicated that Formosan subterranean termites preferred filter paper containing certain amino acids. This suggests that Formosan subterranean termites may feed preferentially on food sources high in nitrogen and, thus, take a proactive role in providing the colony with needed nitrogen.

Unexpectedly, our experiments also suggest that aspartic acid and glutamic acid may play an important role in the feeding preference of Formosan subterranean termites for sugarcane, which they seriously damage in some areas of south China (Dai and Luo, 1980). Aspartic acid, glutamic acid, and alanine are three of the most common free amino acids in sugarcane raw juice, and aspartic acid and glutamic acid are the most common amino acids in proteins of the cane juice (Irvine, 1985). Sugarcane bagasse (residue of milling or diffusing cane) is used as an additive material to increase the attractiveness of Formosan subterranean termite baits in China (Zhao, 1981). About half (by weight) of the freshly squeezed bagasse is fiber and the remaining weight is residual juice (Chen, 1985).

In nature, D-amino acids are found only in small peptides of bacterial cell walls and in some peptide antibiotics. Although intestinal protozoans and bacteria aid in food digestion by termites, the question of whether termites can utilize D-amino acids as nitrogen sources can be answered only by further experiments. A preliminary study indicates that extended feeding (>30 days) on D-aspartic-acid-treated cardboard is toxic to Formosan subterranean termites (Henderson, unpublished data).

There were differences between the results of our no-choice and choice tests. Inconsistencies between results of choice and no-choice feeding tests have been reported previously (Meehan and Wilde, 1989). Consumption data from no-choice tests must be interpreted carefully since less nutritious food sources sometimes result in increased feeding in order to compensate for the lower nutritional value of a food, as found in tests with lepidopteran larvae fed differing amounts of nitrogen (Slansky and Feeny, 1977; Scriber, 1979). Likewise, data resulting from choice experiments in the laboratory may not always be most likely to represent actual field results (Meehan and Wilde, 1989). We feel that our research indicates that the simple addition of specific amino acids to a termite bait may increase consumption and improve bait efficacy, but this must be tested in the field.

Acknowledgments—We are grateful to Drs. J. D. Barbour, J. B. Graves, D. P. Prowell, L. D. Foil, D. J. Boethel, and J. R. Fuxa for a review of this paper.
