Howler monkeys are the most widely distributed of platyrrhine (New World) primates, ranging from northern Argentina to southern Mexico, and are the best studied in the wild (Milton, 1980; Neville et al., 1988), although surprisingly little is known of the ecology of Amazonian populations (*Alouatta belzebul* and *Alouatta seniculus*). The data that are available (Julliot and Sabatier, 1993; Queiroz, 1995; Jardim, 1997) indicate that Amazonian howlers may be more frugivorous than those in other biomes, although folivory is seasonally important, as shown here.

The primary function of geophagy is thought to be the provision of mineral supplements, in particular such elements as sodium and calcium (Davies and Baillie, 1988; Hirabuki and Izawa, 1990; Mahaney et al., 1999). Soil may also be an important digestive aid for folivores, through the absorption of toxins, the balancing of gastric acidity (Oates, 1978; Davies and Baillie, 1988; Johns and Duquette, 1991; Aufreiter et al., 2001), and for its clay content (Ketch et al., 2001). Secondary compounds such as tannins, alkaloids, and terpenoids are especially abundant in mature leaves (Feeny, 1992). One alternative interpretation is that ingested soil helps combat endoparasite infestation (Bicca-Marques and Calegaro-Marques, 1994; Knezevich, 1995; Mahaney et al., 1997).

In the present study, data are presented on the occurrence of geophagy in free-ranging *A. belzebul* at a site in eastern Brazilian Amazonia, the first data on this type of behavior in this species. Ingestion of soil appears to be a relatively frequent activity, although it was confined to the second half of the study period, during which the proportion of leaves in the study group's diet practically doubled.

While geophagy is clearly correlated with the occurrence of folivory, it remains unclear whether and to what extent it provided mineral supplements or aided in the digestion of leaves.

METHODS AND MATERIALS

The 33,000-ha Ferreira Penna Scientific Station (*Estação Científica Ferreira Penna*, ECFPn) is located in the northernmost extreme of the Caxiuanã National Forest (1°41′S, 50°29′W), in the Brazilian state of Pará, eastern Amazonia. The research station is covered almost entirely by primary lowland Amazonian *terra firme* forest, bordered by blackwater *igapó* swamps (Almeida et al., 1993). Annual precipitation is between 2000 and 2500 mm, with a marked rainy season between December and May.

The present study focused on a social group of *A. belzebul* (denominated group "L" in Souza, 1999, and Souza et al., 2002) with nine members, one adult male, three adult females, one subadult male, two subadult females, and two infants. The group was monitored and habituated to the presence of human observers between July and October 1997, and the behavior of study group members was monitored systematically from November 1997 to August 1998. For the purposes of the present study, this period was divided into two five-month sessions, referred to here as the "wet season" (November to March) and the "dry season" (April to August).

Quantitative behavioral data were collected in scan samples, following procedures adapted from previous studies of *Alouatta* (Bonvicino, 1989; Mendes, 1989; Queiroz, 1995; Jardim, 1997). Five-minute scans of the study group were conducted at 15-min intervals throughout the diurnal cycle (06:00–19:00 hr) on three to five days each month. During each scan, the activity state of each visible group member was recorded at the moment of sighting. Only records of feeding behavior are considered here. Whenever the subject was observed ingesting an item of food, its characteristics were recorded (e.g., ripe fruit, flush leaf, flower bud), and the source was marked for taxonomic identification (see Souza, 1999; Souza et al., 2002). In addition, behavioral sampling was used for the recording of all observed occurrences of specific behavior categories, including geophagy. On each occasion that a group member was observed ingesting soil during the observation period, the source, location and individual(s) involved were recorded, as was the duration of soil ingestion.

Samples of approximately 1000 g of soil were collected from three of the termitaria exploited by study group members and from the ground in proximity to them and sent directly to the laboratory for drying and analysis. Termites found in three of the nests were collected in 70°C ethanol and deposited at the Zoology Department of the Goeldi Museum for identification.

The mineral content of the soil sample was analyzed using X-ray diffraction (XRD) on a Philips PW1050 diffractometer using a PW3710 control system. The XRD diagrams were obtained under the following equipmental conditions: copper anode, tension of 45 kV, electrical current of 40 mA at an interval of 4 to 60° 2θ. The mineral quantification was carried out through stoichiometric calculations using the chemical data of whole sample material. The chemical composition of the whole sample was defined using atomic absorption spectrometry, calorimetry, and titrimetry. Organic carbon was analyzed by using a modified Walkley-Black method (EMBRAPA, 1979), and determined by titration and trituration.

RESULTS

Overall, study group members fed primarily on leaves (60.54% of feeding records, with identified items), with the remainder of their diet being composed of fruit (35.08%) and flowers (4.38%). The relative contribution of leaves and fruit to the study group's diet changed drastically between the two seasons (Table 1). There was a similar shift in the consumption of leaves of different maturity. In the wet season, a majority (51.3%) of the leaves ingested were mature, whereas in the dry season, their contribution to the consumption of vegetative plant parts fell to only 4.0%.

Ingestion of soil from termitaria by study group members was not observed during wet-season months, but was recorded on eight of the 24 complete observation days carried out between April and August (12 scan records, 14 behavioral records). Observation time—number of scan samples—was only slightly (8.4%) longer during the dry season, so the marked seasonal contrast in the frequency of geophagy cannot be accounted for by differences in sampling effort. Despite the clear seasonal pattern, the temporal distribution of geophagy bouts was highly irregular. The group was observed returning to the same termitarium on some consecutive days, but also apparently ignored termitaria on other days, even when passing through the same tree crowns in which they were located.

TABLE 1. SEASONAL VARIATION IN DIET OF *A. belzebul* STUDY GROUP AT ECFPn

Item	Number of records (% of total)	
	Wet season	Dry season
Fruit	177 (53.5)	71 (18.9)
Leaves	135 (40.8)	293 (77.9)
Flower	19 (5.7)	12 (3.2)
Records (scan samples)	331 (1079)	376 (1170)

Three different termitaria were exploited, all located at heights of over 10 m from the ground. Termites collected from three termitaria belonged to the family Termitidae, although only one sample was identified to species—*Labiotermes labralis*. Geophagy was typically initiated by the alpha male, followed by the females and their young. On most occasions, at least three group members ingested soil from the termitarium sequentially, extracting it with their hands or directly with their mouths. The behavior was invariably brief, and mean bout duration (time between the initiation of geophagy by a group member and the ingestion of the last piece of soil by this or another individual) was 3:44 ± 1:29 min ($N = 11$). Overall, the sum of the evidence, in particular the relatively short duration of bouts, indicates clearly that the ingestion of soil, rather than termites, was the primary objective of the ingestion of material from the termitaria. Fragments of termites were found in only one of the total of 51 fecal samples collected during the study.

Soil from the study area is composed primarily of kaolinite, quartz, anatase, and amorphic iron compounds (Kern and Costa, 1997), and the samples collected here exhibited similar characteristics (Table 2). Soil and termitaria samples at the same sites were also similar in composition, except that the organic content of termitaria was three to four times that of the soil. Samples become generally more similar when mass is balanced by excluding the organic matter, although the iron mineral appears to be enriched. As might be expected, the chemical composition of different samples is also similar (Table 3). There is little doubt, however, that the termitaria were constructed from local soils.

While the main chemical elements are similar in samples from the same site, Na, K, Mg, and Ca are concentrated between two- and eightfold in termitaria (with

one exception—Na at site 2) when compared to local soil (Table 4). It seems likely that this concentration of alkaline and calkaline elements is a by-product of the introduction of organic matter by the termites during nest building. It is difficult to say to what extent the howlers' exploitation of soil from termitaria—rather than the forest floor—might have been motivated by such differences, given their highly arboreal habits (study group members were never observed in the canopy at heights of less than 6 m above the ground).

DISCUSSION

Geophagy appears to be relatively common in howler monkeys compared to other platyrrhines. However, the present study represents the first record of geophagy for *A. belzebul*, despite the fact that the feeding ecology of this species has been studied in detail in both Atlantic Forest (Bonvicino, 1989) and Amazonian (Jardim and Oliveira, 1997) biomes. The latter study was also conducted at the

TABLE 4. RATIO OF ELEMENTS IN TERMITARIA/SOIL

Site	Na	K	Mg	Ca	Mn
1	1.9	2.9	1.7	7.8	1.0
2	1.0	1.9	2.0	4.8	1.3
3	2.4	2.0	2.5	5.8	0.9

ECFPn, although it focused on a different study group (denominated "M" in Souza et al., 2002). The lack of records in both these studies reinforces the correlation with folivory found in the present study, given that the study animals were relatively frugivorous in both cases. Group M was, in fact, monitored during the equivalent of the wet-season period as defined here, during which the proportion of fruit in its diet was even larger than that recorded for group L (Jardim and Oliveira, 1997).

Members of the third group ("A" in Souza et al., 2002) that was monitored at the site during the same period as the present study were observed ingesting soil on three occasions, all during the dry season. It remains unclear, however, whether this relatively small number of records was the result of a real difference in the frequency of geophagy in this group or a consequence of sampling factors, given the irregularity of the behavior, as observed in group L. Certainly, it does not appear to be related to differences in the diet of group A, which was at least as folivorous as group L, especially during the dry season. More recent studies of *A. belzebul* at sites in eastern (A. Pinto, personal communication) and central Amazonia (Souza, personal observation) indicate that geophagy is widespread in Amazonian populations of this species.

Curiously, Izawa (1993) reported that *A. seniculus* apparently avoided termitaria made by the species recorded here, *Labiotermes labralis*, while preferring those made by species of the genus *Constrictotermes*. Exploitation of termitaria of the latter genus was also recorded for *A. seniculus* by Julliot and Sabatier (1993). Izawa (1993) suggested that the howler monkeys' apparent preference may have been related to termite predator avoidance strategies rather than the composition of its termitaria, although ingestion of soil by *A. belzebul* from the termitaria of *L. labralis* in the present study appears to contradict this.

Overall, the occurrence of geophagy during the dry-season months, when the consumption of leaves increased considerably, suggests that the primary function of this behavior may be as a digestive aid, as suggested in studies of other folivorous primates (Oates, 1978; Julliot and Sabatier, 1993; Milton, 1993). Plant chemical defenses are composed of secondary metabolites such as tannins, alkaloids, and terpenoids and are most abundant in immature fruits and mature leaves (Feeny, 1992). These compounds have an unpleasant taste and can be lethal to folivores (Milton, 1993). As observed in other mammals (Klaus et al., 1998), the high clay content and organic matter found in the soil ingested in the present study may help to absorb these compounds. Of course, the mineral content of the ingested soil cannot be ignored (Table 4; Davies and Baillie, 1988; Hirabuki and Izawa, 1990), but in the absence of data on the composition of fruit and leaves consumed during different seasons, it would be premature to conclude that mineral supplementation may have been the primary motivation for the ingestion of soil. Obviously, more detailed information on the chemical composition of the food items exploited by the howler monkeys would permit a more conclusive interpretation of the functional aspects of geophagy in this species.

Acknowledgments—This study was supported by the graduate training council of the Brazilian government (CAPES) and the Brazilian National Research Council (CNPq). We would like to thank the staff of the Ferreira Penna Research Station, in particular, the director, Dr. Pedro Lisboa, Benedito Costa, and Flávio "Pão." Special thanks to Francisco Juvenal L. Frazão for advice on geochemical analyses, Dr. Maria Lúcia Macambira for the identification of termite species, and Ana Lúcia Pina for unpublished data from the study site.

Abstract—*p*-Nonylphenol isomers and other aromatic compounds were found in roots and stalks of the plant *Cichorium endivia* subsp. *divaricatum*. These compounds were characterized by high-resolution capillary GC-MS.

Key Words—*Cichorium*, *p*-nonylphenol isomers, medicinal herb, GC-MS.

INTRODUCTION

Alkylphenol ethoxylates belong to the group of nonionic surfactants (Dodge, 1998) and, in particular, nonylphenol ethoxylates have found use in the chemical manufacturing industry, in cosmetics, and as agrochemicals in different countries (Bennie, 1999). Nonylphenols are found in high concentrations in some sewage sludges that may be spread on agricultural lands (Bennie, 1999). Sewage treatment plants discharge significant amounts of nonylphenol ethoxylate degradation products in their final effluents and digested sludges compared to what enters the plant (Maguire, 1999). Alkylphenols and their ethoxylates also are found in sediments, river estuaries (Björn et al., 1997), and in marine waters of the Israeli Mediterranean coast (Zoller and Hushan, 2000).

Nonionic surfactants are extremely toxic to aquatic organisms and accumulate in macrophytic algae, particularly *Cladophora glomerata* (Ahel et al., 1993), other freshwater organisms (Ahel et al., 1993; Servos, 1999) that can then be eaten by fish, shellfish (Bennie, 1999; Tsuda et al., 2000), and mollusks (Björn et al., 1997). Traces of some nonionic surfactants are also found in different tissues of a wild duck (Ahel et al., 1993). Alkylphenols have been detected in 190 food samples purchased from markets, including fish, meat, and vegetables (Sasaki et al., 1999).

This report describes the composition of *p*-nonylphenols that were identified by gas chromatography–mass spectrometry (GC-MS) from wild species of *Cichorium endivia* subsp. *divaricatum* (Asteraceae).

METHODS AND MATERIALS

Plant Material. Cichorium endivia L. subsp. *divaricatum* (Schousb.) P. D. Sell was collected at Sdot Micha place (November 1999), about 25 km west of Jerusalem. A voucher specimen is kept at the Natural Products Department, School of Pharmacy. The plant was collected and identified by Prof. A. Danin (Institute of Life Science, Hebrew University).

Extraction Procedure. Dried stalks and roots of *C. endivia* subsp. *divaricatum*, were separately homogenized in a high-speed unit, and successively percolated for 2 hr each with pentane, CH_2Cl_2, and 10% NaOH in MeOH at 60°C. The aqueous phase was acidified and volatile compounds were extracted with pentane and CH_2Cl_2. Extracts were combined and the solvent was removed under reduced pressure. The oil sample (100 mg) was dissolved in toluene, and 1% sulfuric acid in methanol was added. The mixture was left overnight in a stoppered tube at 50°C, then, water (10 ml) was added. Volatile compounds were extracted with pentane and then CH_2Cl_2. The solution was filtered and solvent removed under reduced pressure. The oil residue was dissolved in $CH_2Cl_2$and stored at −20°C prior to GC-MS analysis.

GC-MS Analysis. GC-MS was performed with a Hewlett Packard 6890 series II chromatograph linked to a HP 5973 mass detector equipped with an HP automatic injector and a 30-m long, 0.25-mm ID, 0.25-μm film thickness HP-5MS capillary column. The ionization energy (EI) was 70 eV, the carrier gas was He (flow 1.0 ml/min), and the injection block temperature was 250°C. The GC oven temperature was programmed as follows: initial temperature 100°C (2 min) followed by a temperature increase of 15°C/min up to 260°C (10 min) and then 20°C/min to the final temperature of 290°C (10 min). Identification of the compounds was established using the synthetic *p*-nonylphenols (obtained from Sigma-Israel and ChemTech., Ltd, Israel), and also the Wiley 7th Edition Library.

RESULTS AND DISCUSSION

Analysis of the total oil extracts from the stalks of a wild population of *C. endivia* subsp. *divaricatum*, collected in a dry state in November 1999, showed that they contain *p*-nonylphenol isomers and some other aromatic compounds. In order to unequivocally characterize the *p*-nonylphenol isomers and other aromatics in the mixture, it was necessary to achieve a good separation of all isomers of *p*-nonylphenols present in the natural extract. Figure 1B shows the gas chromatogram of the *p*-nonylphenol isomeric mixture and other aromatics. Concentrations of *p*-nonylphenols were found to be 138.6 and 23.4 μg/kg in dried roots and stalks, respectively.

There are several mass spectra of *p*-substituted alkylphenols that can be examined in order to provide insight to unknown *p*-nonylphenol isomers. All *p*-alkylated phenols produce a molecular ion in the EI mode followed by cleavage of the alkyl group. Mass spectra can be grouped into three categories with respect to the α-carbon on the alkyl chain: primary ($-CH_3-$), secondary ($-CHR_1-$), and tertiary ($-CR_1R_2-$). The GC-MS ion chromatogram includes seven separated characterized ions (*m*/*z*): 107, 121, 135, 149, 163, 177, 191, and also the molecular ion 220, which is common for all *p*-nonylphenol isomers (Figure 2). Primary α-carbon *p*-nonylphenols form the base peak fragment ion *m*/*z* 107 via simple benzylic cleavage. The fragment ions of *m*/*z* 107 and 121 are also common to all *p*-nonylphenols (peaks 5–16) (Figure 2). Secondary α-carbon *p*-nonylphenols, with one hydrogen attached to the benzylic carbon, fragment to the α-methyl carbocation *m*/*z* 121. Tertiary α-carbon compounds produce spectra with *m*/*z* 135 as the base peak. The dimethyl carbocation is stable and, therefore, its formation is energetically favorable. The propyl fragment results in a large abundance of *m*/*z* 149 ions. Presence of the base peak of *m*/*z* 163 can be interpreted by loss of a butyl fragment from the β-carbon.

Several papers deal with HPLC (Björn et al., 1997; Tsuda et al., 2000) or GC-MS analysis of *p*-nonylphenol isomers and their ethoxylates (Bhatt et al., 1992; Wheeler et al., 1997; Hao et al., 2000; Nakamura et al., 2000). For identification of all *p*-nonylphenol isomers, we used mass libraries and also the mass spectra of model alkylphenols as reported by Bhatt et al. (1992) and Wheeler et al. (1997).

Occurrence of different alkylphenol types isolated from plants has been reported (Tyman, 1991; Kozubek and Tyman, 1999). Alkenyl phenols with short-chains (C_8 and C_{10}) were isolated from the medicinal plant *Piper gibbilimbum* (Piperaceae; Papua New Guinea) (Orjala et al., 1998). The phenolic lipids with long-chains (C_{11}–C_{15}) were isolated from the liverwort *Schistochila appendiculata* (Asakawa et al., 1987) and identified from the oil of *Anacardium occidentale* (Anacardiaceae) (Tyman, 1991).

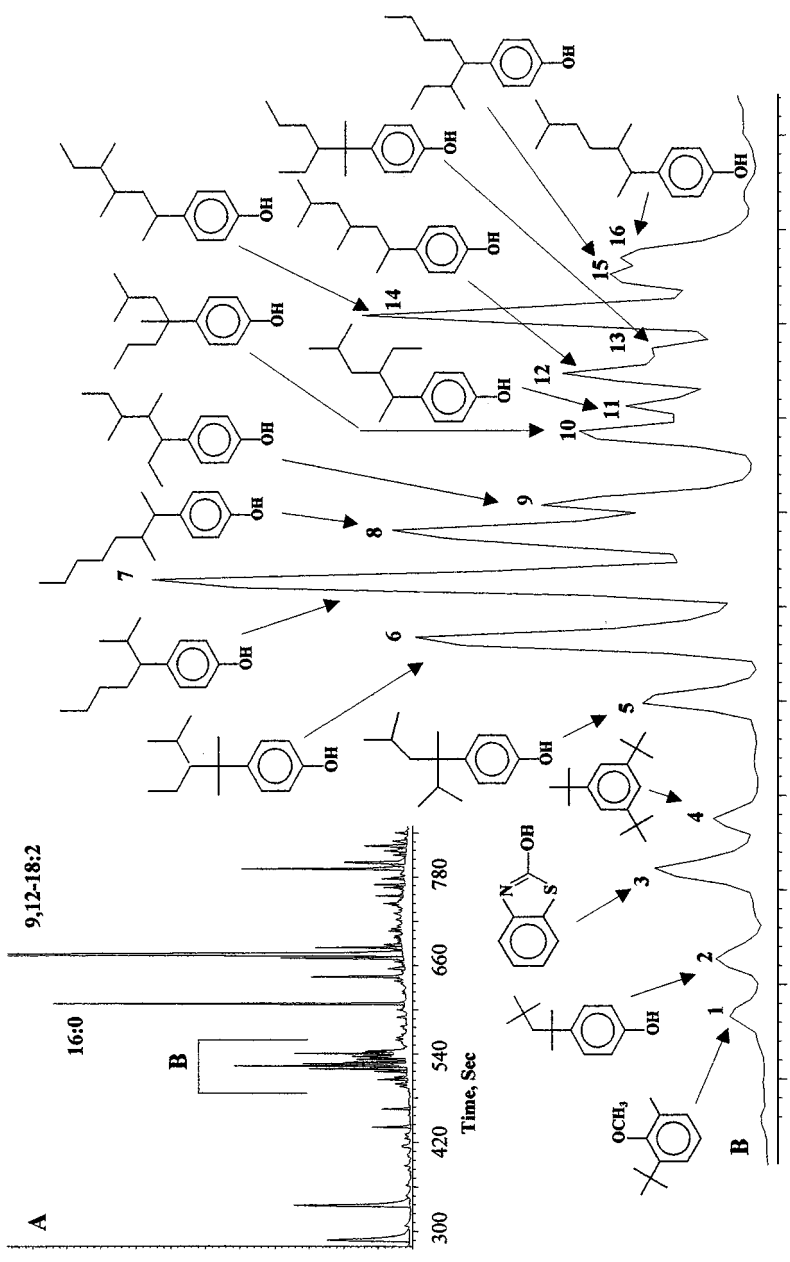

FIG. 1. GC-MS chromatogram of total extract from the stalks of *Cichorium endivia*. (A) Full run 2000 sec. Major components: hexadecanoic acid, methyl ester (16:0, 7%) and octadecadienoic acid, methyl ester (9,12–18:2, 38.5%). FIG. 2. GC-MS selected ion monitoring chromatograms illustrating *p*-nonylphenol isomer coelution. Peaks numbers and structures refer to Figure 1.

The goal of the work described in the present paper was to identify *p*-nonylphenol isomers and other aromatics in the wild medicinal plant *Cichorium endivia* subsp. *divaricatum*. We do not know the origin of nonylphenols in the roots and stalks of this plant; however, it is reasonable to assume that the phenols

can accumulate from groundwater. Checking this hypothesis requires additional studies.

Abstract—The volatile constituents of the supposed defensive secretions of the glandular pouches of the adults of both sexes of the cockroach *Therea petiveriana* have been shown to contain *N*-3-methylbutylacetamide (MBA) and *N*-3-methylbutylpropanamide (MBP), which represented 60% of the volatile fraction. The other 40% included acidic, aromatic, and aldehydic compounds. Behavioral experiments demonstrated that the secretion acts as an alarm pheromone for adults.

Key Words—Dictyoptera, Polyphagidae, *Therea petiveriana*, exocrine glands, pheromones, alarm.

INTRODUCTION

Therea petiveriana (Dictyoptera, Polyphagidae) belongs to a basal family of cockroaches (Grandcolas, 1993, 1997) and was reported from peninsular India (Princis, 1964). It is a fossorial species, inhabiting rubbish heaps around human habitations as well as in humus accumulations in certain isolated pockets of the scrub jungles and semiarid zones of south India. The adults exhibit a strong tendency towards gregarious activities. They are essentially crepuscular, and during nonactive

periods they remain subterranean. Adult males and females are macropterous, but flightless. When disturbed, they raise their wings and evert on either side, on the second and third abdominal segments, a pair of brown pouches (Gerstaecker, 1861; Livingstone and Ramani, 1978; Brossut and Sreng, 1985). These organs, described in various species of Polyphagidae (Grandcolas, 1997), are absent in the nymphal instars. Normally, the pouches are never visible and are withdrawn into the body cavity. The exposed surface of the pouch reveals numerous chitinous pleats of varying heights, which bear whorls of fine setae that are generally enveloped with secretion (Livingstone and Ramani, 1978).

In several families of insects, the functions of medium-sized exocrine glands producing complex mixtures have been well investigated. On the other hand, most of the very large exocrine glands were "so obviously" defensive (Roth and Alsop, 1978) that few investigations have been conducted on their other possible functions. Since the preliminary observations of Livingstone and Ramani (1978) on *T. petiveriana* suggested a defensive or alerting function of the pouch, we undertook a chemical analysis of the pouch glandular secretions. The alarm role of the whole secretion and of its two major identified components were investigated.

METHODS AND MATERIALS

Insects. Colonies of *T. petiveriana*, obtained from the Laboratoire de Primatologie (CNRS UA 373, Station biologique de Paimpont, France), were maintained in glass aquaria (60 × 40 × 20 cm) at 28–30°C, 80% relative humidity, and 12L:12D photoregime. The insects had free access to dry dog food and water-soaked cotton pads. It was difficult to maintain this species under laboratory conditions, and it was impossible to breed large colonies.

Preparation of Extracts. Adults of both sexes (30 to 40 days old) were cooled for a few minutes at −20°C before use. The four glandular pouchs were artificially everted using light pressure on the abdomen with forceps. Then, the glands of one individual were cut using microscissors and pooled in a vial containing 100 μl of distilled methylene chloride (CH_2Cl_2) and 500 ng of 2-phenylethanol as internal standard. The pieces were allowed to soak for 15 min at room temperature. Then the extracts were filtered through glasswool and kept at −20°C until analyzed.

Chemical Analysis. GC analyses of extracts were performed using a Packard 437A chromatograph fitted with a flame-ionization detector. CP Wax 58 CB (30 m × 0.25 mm ID, 0.22-μm film thickness, Chrompack) and CP Sil 5 CB (30 m × 0.25 mm ID, 0.22-μm film thickness, Chrompack) fused silica capillary columns were used for analyses. After concentration of the extract to about 10 μl under gentle nitrogen flow, 2 μl of sample was injected into a split-splitless injection system, operating with a split flow of 25 ml/min and a septum purge of

2 ml/min. The split port was closed during injection and then opened for 30 sec after injection. The column was held isothermally at 40°C for 2 min, then programmed at a rate of 20°C/min for 1 min, 2°C/min to 150°C, and then 10°C/min to 250°C. Hydrogen was used as carrier gas (50 cm/sec velocity at room temperature). The injector and detector temperatures were 250 and 270°C, respectively. Collection of the data was done automatically by PC software (Maestro, Chrompack).

GC-MS was carried out using a Nermag R 10-10 C quadrupole mass spectrometer coupled with a HP 5890 gas chromatograph (Hewlett Packard). The GC conditions were the same as those just described. The column was connected directly to the ion source of the spectrometer through a heated transfer line maintained at 260°C. Electron impact (EI) mass spectra were obtained at 70 eV with a 0.8-sec cycle, the instrument scanning from 25 to 300 amu with a source temperature of 150°C. Chemical ionization (CI) spectra, using ammonia (NH_3) and deuterated ammonia (ND_3) with a source pressure of 0.3 torr, were obtained at 90 eV with a source temperature of 90°C, the instrument scanning from 60 to 300 amu in 0.7 sec.

Compounds were identified by comparing their spectra to those of the libraries of the EPA/NIH (Heller and Milne, 1978), of the NIST/EPA/MSDC (Lias and Stein, 1990), and of the Laboratoire de Recherches sur les Arômes (INRA, Dijon, France). Except for *N*-3-methylbutylpropanamide (MBP) (gift from Dr. R. Henry, INSA, Lyon, France), all other identified chemicals were purchased from Interchim (Montluçon, France). Identification of all the compounds was checked by analyzing the natural products and their synthetic counterparts under the same conditions on CP Sil 5 CB and CP Wax 58 CB columns. Numerous components of the secretion appeared in quantities of <1 ng/insect; consequently, the majority of them were not identified and quantified.

Fourier transform infrared (FTIR) spectra were taken in the gas phase with a Bruker IFS 85 FTIR spectrometer that was coupled, via a Bruker gold-coated light-pipe (20 cm $\times$ 0.8 mm ID) maintained at 220°C, to a Carlo-Erba 5160 gas chromatograph. The GC instrument was equipped with the same column as that already described, an on-column injector, and a flame ionization detector. Helium was used as the carrier gas (35 cm/sec velocity at 220°C), and the oven temperature was programmed from 40 to 220°C at 3°C/min. Nitrogen gas was introduced into the transfer line to reduce peak broadening within the light-pipe, resulting in a total gas flow rate of 5 ml/min. The spectral resolution was 8 cm^{-1}, and the time resolution was reduced from 12 collected interferograms per second to four effective ones by adding three interferograms in real time. A narrow-band (4800–600 cm^{-1}) mercury–cadmium–telluride detector was used.

Chemical ionization and FTIR analyses were used to characterize the two major components of the secretion (peaks 5 and 6). Quantitative analyses were made on five males and four females. The response factor was determined for each of the identified major compounds at 1, 10, 100, and 500 ng. These response factors were used for quantitative analyses.

Behavioral Observations. All the observations were performed in open plastic arenas (12 × 8 × 5 cm) at the same temperature and relative humidity as described above. The behavioral experiments were conducted between the second and the fourth hours of the scotophase using 30- to 40-day-old adults of both sexes.

In order to determine the role of the secretion at close-range on adults of both sexes, we tested the activity of various amounts (1, 10, 100, 500, and 1000 ng) of the major components MBA and MBP and compared their activity to the whole secretion. Because of the lack of insects to be tested, only one dosage of the whole secretion was investigated; this concentration corresponds to the secretion from one adult (1 eq/insect).

A small piece of filter paper (0.2 × 2 cm) was mounted on an iron stem. Preliminary tests confirmed that the device did not elicit any insect behavior. The paper was impregnated with the solution to be tested. After evaporation of the solvent (CH_2Cl_2), the paper was brought within 1 cm of the insect antennae and maintained for a maximun of 1 min. The reaction of the insect was noted and the corresponding latency period before a behavioral response recorded. Each experiment was replicated 10 times on different subjects and the data was compared by using a Mann-Whitney *U* test.

RESULTS

Chemical Identification. A typical GC trace derived from the pleural glandular secretions of adults of both sexes revealed the presence of a mixture of volatile compounds and long-retention-time (>70 min) constituents, with an estimated ratio of 25:75 (Figure 1). No qualitative difference appeared between males and females. The only quantitative differences between the secretions of both sexes were found in peaks 5, 6, and phenol.

Based on their MS spectra, the major long-retention-time compounds were identified as saturated or unsaturated fatty acids (e.g., C_{14}, C_{16}, C_{18}, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$ acids). All these acids are known to be part of the insect fat body. The volatile fraction of the secretion showed the presence of about 40 volatile compounds (molecular weight from 60 to 200). The two major compounds (peaks 5 and 6) represent about 60% of this fraction. The rest of the secretion is a mixture of saturated acids (12%), aromatic (10%), and aldehydic (2%) compounds (Figure 1). Only six of the identified compounds appeared to be present at >1 ng/insect (Table 1).

Compound 5 was unambiguously identified as *N*-3-methylbutylacetamide (MBA), or *N*-isoamylacetamide, by comparison of its mass [electron impact (Figure 2a) and chemical ionization modes], and FTIR spectra (Figure 3a) and retention index with those of an authentic standard. Quantitative analyses revealed that MBA represented about 47% of the volatile fraction of the whole male secretion and about 30% of the volatile female fraction (Table 1).

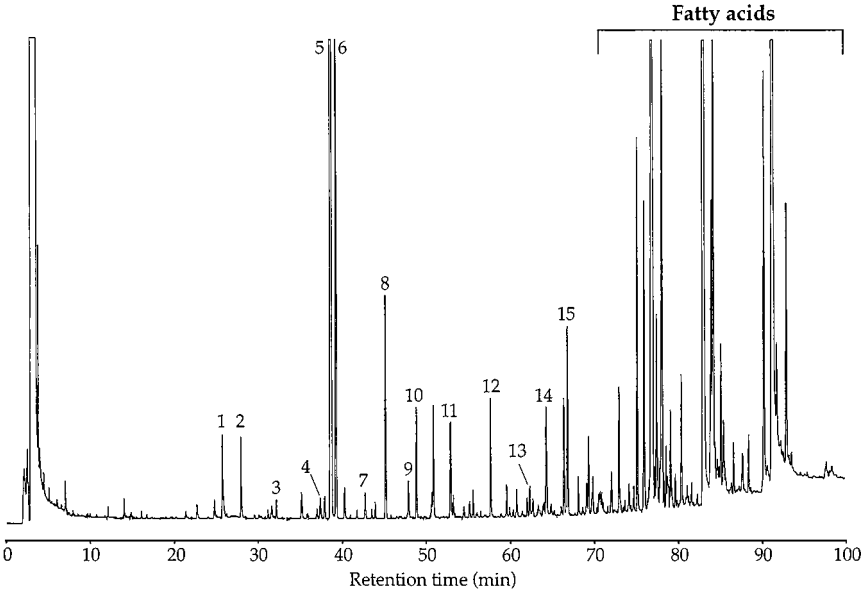

FIG. 1. Typical GC trace and identified compounds of the defensive secretion from male *T. petiveriana*: 1, nonanal; 2, acetic acid; 3, butanoic acid; 4, hexanoic acid; 5, *N*-3-methylbutylacetamide (MBA); 6, *N*-3-methylbutylpropanamide (MBP); 7, heptanoic acid; 8, phenol; 10, *p*-cresol; 11, nonanoic acid; 12, decanoic acid; 13, undecanoic acid; 14, indol; 15, dodecanoic acid.

TABLE 1. RELATIVE PROPORTIONS OF THE MAJOR IDENTIFIED COMPOUNDS OF DEFENSIVE SECRETIONS FROM *T. petiveriana* MALES AND FEMALES[a]

Compound	Proportion (ng, mean ± SEM)		
	Males ($N = 5$)	Females ($N = 4$)	P
Nonanal	2.80 ± 0.75	3.00 ± 0.71	0.695
MBA	244.80 ± 11.16	89.00 ± 10.42	0.014
MBP	13.40 ± 2.42	63.75 ± 7.92	0.014
Phenol	13.00 ± 1.10	16.50 ± 1.12	0.014
p-Cresol	14.16 ± 1.85	17.50 ± 1.66	0.083
Nonanoic Acid	6.00 ± 1.41	6.50 ± 1.12	0.618

[a] MBA, *N*-3-methylbutylacetamide; MBP, *N*-3-methylbutylpropanamide. *P*, Mann-Whitney *U* test.

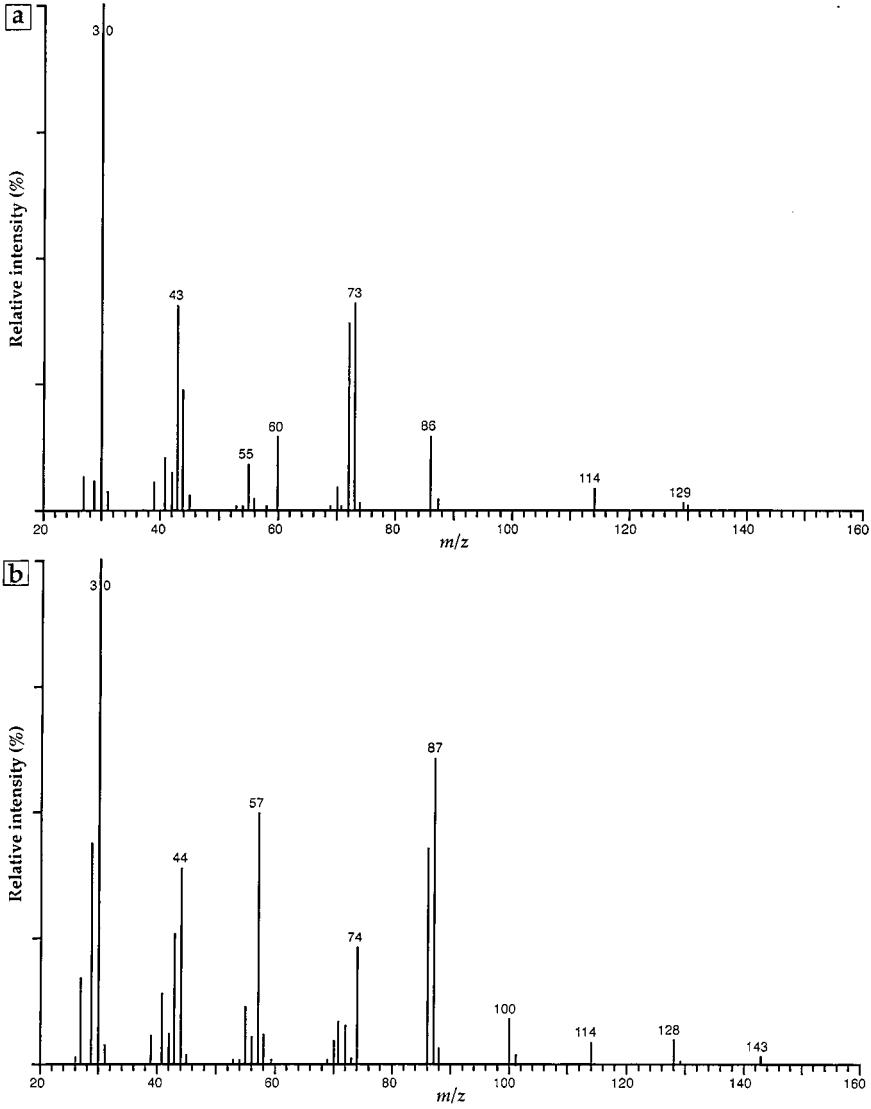

FIG. 2. Electron impact mass spectrum of peaks 5 (a) and 6 (b) identified as *N*-3-methylbutylacetamide (MBA) and *N*-3-methylbutylpropanamide (MBP), respectively.

The mass spectrum of compound 6 showed a parent peak of low intensity at *m/z* 143 (Figure 2b). This mass spectrum was not found in mass spectral data bases. Its molecular weight of 143 was confirmed by the observation of the ions *m/z* 144 $(M+H)^+$ and *m/z* 161 $(M+NH_4)^+$ in the CI (NH_3) mass spectrum. The

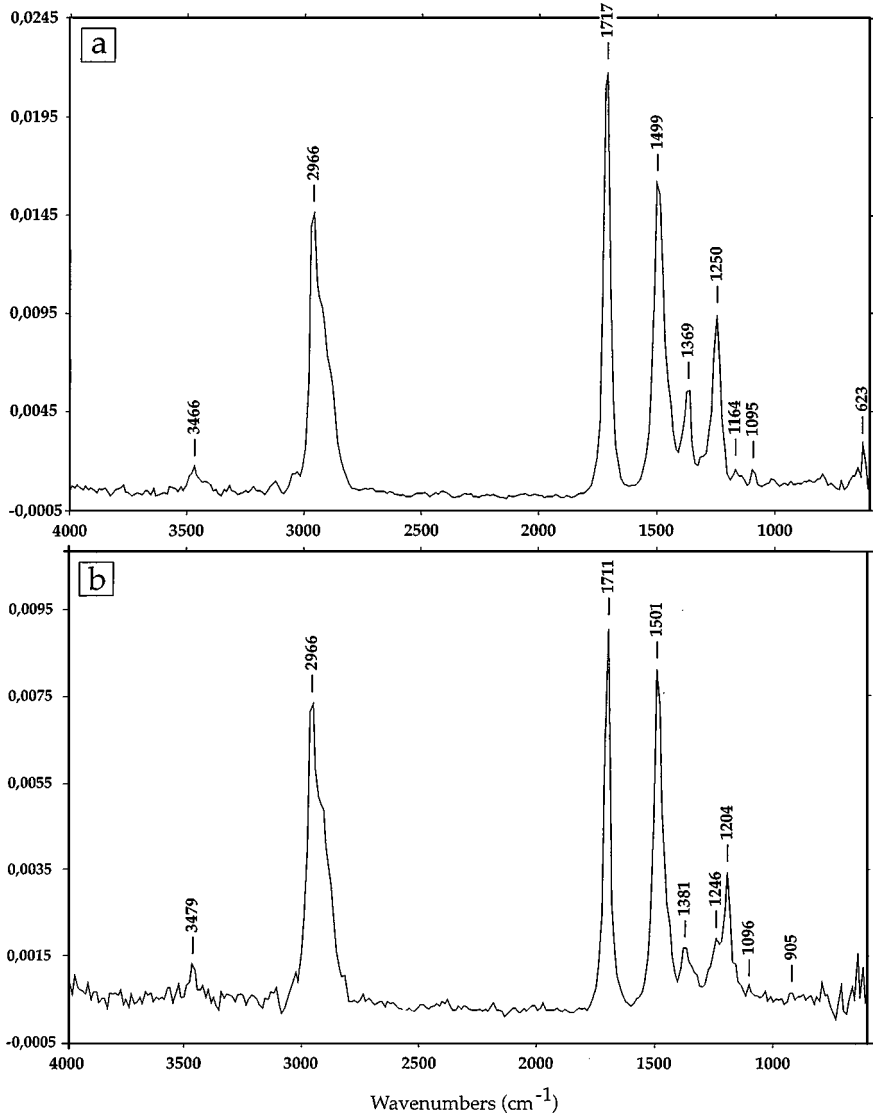

FIG. 3. GC infrared spectrum of peaks 5 (a) and 6 (b) identified as *N*-3-methylbutylacetamide (MBA) and *N*-3-methylbutylpropanamide (MBP), respectively.

exchange of one hydrogen for deuterium has been processed by deuterated ammonia chemical ionization. The CI (ND_3) spectrum showed a shift of the ions from *m*/*z* 144 to *m*/*z* 146 and from *m*/*z* 161 to *m*/*z* 166, corresponding to $(M–H+D_2)^+$ and $(M–H+D+ND_4)^+$, respectively. A similar shift was observed in the CI (ND_3)

TABLE 2. CLOSE-RANGE ACTIVITY OF VARIOUS AMOUNTS OF DEFENSIVE SECRETION COMPONENTS MBA AND MBP ON *T. petiveriana* ADULTS OF BOTH SEXES[a]

	Latency period (sec, mean ± SEM)					
	Males ($N = 10$)			Females ($N = 10$)		
Amount (ng)	MBA	MBP	*P*	MBA	MBP	*P*
10	29.90 ± 8.10	28.70 ± 5.60	0.649	28.20 ± 2.43	22.50 ± 4.52	0.011
100	13.30 ± 4.03	18.20 ± 2.44	0.011	19.60 ± 3.35	13.60 ± 2.73	0.002
500	3.50 ± 1.12	4.40 ± 1.11	0.001	3.60 ± 1.62	3.20 ± 1.66	0.538
1000	2.40 ± 1.43	2.70 ± 1.42	0.006	2.60 ± 1.02	2.70 ± 1.19	0.937

[a] Latency period of insects running away. MBA, *N*-3-methylbutylacetamide; MBP, *N*-3-methylbutylpropanamide. *P*, Mann-Whitney *U* test.

mass spectrum of isoamylacetamide. A comparison of the infrared spectra of MBA and of compound 6 (Figure 3b) supported the idea that these two compounds were analogs. Thus, the presence of the bands at 1711 cm^{-1} ($\nu_{C=O}$), 3479 cm^{-1} (ν_{N-H}) and 1501 cm^{-1} (ν_{N-H}) in the FTIR spectrum revealed an amide function (Nyquist, 1984).

All these observations led us to conclude that compound 6 was *N*-3-methylbutylpropanamide (MBP) or *N*-isoamylpropanamide. Coinjection with the authentic sample confirmed that the synthetic and isolated compounds were identical. In males, MBP represents about 16% of the volatile fraction, whereas its amount is higher in females (30% of the volatile fraction) (Table 1).

Close-Range Activity of Secretion. The biological activities of MBA and MBP showed that these two components were repellent to both sexes (Table 2). Males and females did not respond to 1 ng of the two tested compounds. For highest concentrations, all the individuals ran away from the chemical source in the same way; higher concentrations (10–1000 ng) elicited faster escape responses.

When the equivalent of one male glandular extract was tested, the reaction of both sexes was similar and all the tested individuals ran away from the chemical source immediately (2.10 ± 0.70 sec for males, 2.20 ± 0.75 sec for females). However, when the female glandular extract was presented, the tested females escaped more quickly ($P < 0.001$) than did the males (2.50 ± 0.81 sec for females; 6.40 ± 2.79 sec for males). Additionally, our data showed that females responded in the same way when they were confronted with male or female glandular extracts, whereas males were more repelled by male extracts. ($P < 0.001$)

DISCUSSION

Cockroaches possess a complex abdominal glandular exocrine system (Brossut and Roth, 1977; Brossut and Sreng, 1980). The identified pheromones

play different roles in the courtship and mating sequences (Nishida et al., 1974, 1976; Persoons et al., 1990; Sreng, 1990). Glandular defensive secretions occur in various species (Roth and Alsop, 1978; Brossut, 1983), especially in the Polyzosteriinae, in which ventral intersegmental defensive glands seem to be the rule (Stay, 1957; Chada et al., 1961; Waterhouse and Wallbank, 1967; Brossut and Sreng, 1980). The defensive glands are located on the pleura, abdominal spiracles, or abdominal interstermites or intertergites. Allomones are especially efficient at deterring some nonswarming predators (Eisner et al., 1959).

In many species of cockroaches, habitat selection is different for nymphs and sexually mature adults (Schal et al., 1984). Most nymphs live on the ground, where shelters are abundant, while adults, who are often exposed to many potential predators while searching for mates, need more efficient defenses. Nymphs and adults of the Blattidae species have evolved specific defensive strategies. Nymphs depend on the secretion of deterrent glues produced by abdominal segments (Ichinosé and Zennyoji, 1980; Schal et al., 1982; Abed et al., 1994), while adults spray the secretion of their large defensive sternal glands. The burrowing nymphs of *T. petiveriana* never revealed the presence of glues on nymphs (Farine, personal observations), whereas defensive glands were present in adults.

The diversity of compounds that have been identified as exocrine products in arthropods has emphasized the biosynthetic versatility that these invertebrates possess. The products of exocrine glands almost invariably consist of mixtures of compounds, and the roles of minor constituents in augmenting the value of defensive exudates have been well established.

Our chemical data revealed that, besides the two major identified amides, which represent 60% of the volatile defensive components of *T. petiveriana*, about 25% of the secretion was composed of saturated acids, as well as aromatic and aldehydic chemicals. References to the defensive secretions of Dictyoptera, Hymenoptera, Coleoptera, and Hymenoptera (Tschinkel, 1975; Klinger and Maschwitz, 1977; Staddon, 1979; Blum, 1981; Dettner, 1987; Aldrich, 1988; Morgan and Mandava, 1988) have shown that a number of acidic, aldehydic, and aromatic compounds reported in this study appeared as deterrents for either invertebrate or vertebrate predators (Blum, 1981, and references therein). A blend of many compounds of various chemical families could thus increase the potency of the defensive secretion of *T. petiveriana*, especially against ants, which are known to be common predators of numerous insects.

Simple amides such as MBA have long been identified in California sherry (Webb et al., 1966), tobacco (Demole and Berthet, 1972), and wines (Schneider et al., 1998; Miklosy et al., 2000). In insects, the two identified amides in *T. petiveriana*, MBA and MBP, were first reported in the rectal glandular secretion of males of various species of fruit flies (Metcalf, 1990, and references therein) and from the venom of wasps (Heath and Landolt, 1988; Weston et al., 1997). In the Queensland fruit flies *Dacus tryoni* and *D. neohumeralis*, sexually

excited males emit an oily secretion with a sweet pungent odor, that is distributed by wing fanning; this attracts the specific females over a range of several meters. The source of the secretion is a glandular complex that opens into the rectum (Fletcher, 1969; Schultz and Bousch, 1971). In these two species, the secretion was identified as a mixture of six aliphatic amides in which MBA and MBP appeared as major compounds (Bellas and Fletcher, 1979). In *D. dorsalis*, MBA elicited zig-zag anemotactic flight in mature and virgin females (Kobayashi et al., 1978). In *Vespula squamosa*, *N*-isopentylacetamide, or MBA, was described as a pheromone that elicits alarm and attack behavior (Heath and Landolt, 1988). However, the same component attracts the workers of *V. vulgaris* when used at low concentration, whereas larger amounts were repellent (Weston et al., 1997).

Our behavioral observations showed that the adults of *T. petiveriana* escaped when low and large concentrations of MBA and MBP were used alone. However, when the whole secretion of female was tested at the concentration of one insect equivalent, females escaped more quickly than did the males. This could suggest a higher sensitivity of the females to the alarm pheromone or the existence of a residual female sex pheromone that could interfere with the escape behavior of the males. If so, females would respond fast to the defensive/alarm components in female extracts, whereas males would "hesitate" before escaping because they perceive the sex pheromone. Both sexes respond equally to male extracts because there is no sex pheromone.

As observed in social or gregarious insects, a defensive compound may serve alarm or aggregation functions when components are excreted in greater or lesser quantities (Calam and Youdeowei, 1968; Levinson and Bar Ilan, 1971; Ishiwatari, 1974, 1976; Lockwood and Story, 1985, 1986; Schmuck, 1987; Farine, 1989; Blum, 1996). Thus, a similar function of the secretion in *T. petiveriana* could be hypothesized. Unfortunately, because of the lack of insects to be tested, the activity of the lower concentration of the secretion remains unknown.

(Received December 3, 2001; accepted April 18, 2002)

Abstract—Geranyl butyrate (GB) and (*E*,*E*)-farnesyl butyrate (FB) were identified in the pheromone gland extract of females of the click beetle, *Agriotes brevis* (Candeze) (Coleoptera: Elateridae) as the major sex pheromone components. Polyethylene vial dispensers containing 20–200 mg of a 1:1 mixture caught high numbers of beetles. Captures did not decrease even after 73 days of field exposure of dispensers. At sites where both *Agriotes sputator* L. and *A. brevis* were present, the above baits were selectively catching only *A. brevis*, despite the fact that GB is also the main pheromone component of *A. sputator*, suggesting that FB has a role in reproductive isolation. In the early part of the season, traps into which the insects could both crawl and fly captured more *A. brevis* than designs where the insects could only fly in. Trap design was not

important later in the season. This indicates the need for future development of a trap suitable for use throughout the whole season.

Key Words—Click beetles, *Agriotes brevis*, Coleoptera, Elateridae, *Agriotes sputator*, geranyl butyrate, (*E*,*E*)-farnesyl butyrate, pheromone, identification, field trapping, trap design.

INTRODUCTION

The click beetle *Agriotes brevis* (Candeze) (Coleoptera: Elateridae) is one of the economically most important click beetle pests in Europe. In fact, it can be considered the main pest on maize and other crops in Italy (Rusek, 1972a; Furlan, 1999; Furlan et al., 2000). In the Czech Republic and other European countries, it must also be considered a key species (Rusek, 1972b). According to sightings of adults, the presence of *A. brevis* is widespread in central and southern Europe (Platia, 1994).

The present study was undertaken to identify the chemical composition of the female-produced sex pheromone of *A. brevis*, in order to develop a species-specific pheromone trap for this species. Pheromone traps are used for the detection and monitoring of many insect pests, and in some cases the synthetic pheromone is used for direct control of populations through mating disruption. Pheromone trapping may be an easy, effective, and cheap method to determine precisely the distribution of this species and to implement IPM strategies (Furlan et al., 1997).

METHODS AND MATERIALS

Insects. Adult *A. brevis* specimens were collected from the colonies maintained at the San Donà laboratory according to methods described elsewhere (Furlan, 1998). Rearing in cages and vials started from females or larvae collected in Piemonte (northwestern Italy), Veneto (northeastern Italy), and Lazio (central Italy); the females obtained in overwintering cells were kept isolated in single vials with humid soil and some rye grass leaves until pheromone extraction was performed at the time when the male swarming was observed in the field.

Live insects were taken to the Budapest laboratory. Female sex pheromone gland extracts were prepared as described by Russian authors (Oleschenko et al., 1976; Ivaschenko and Adamenko, 1980), i.e., by carefully piercing the pheromone gland with a fine glass capillary and collecting the liquid inside into the capillary. The liquid samples obtained were dissolved in analytical grade hexane (MercK KGaA, Darmstadt, Germany) to make up stock solutions.

Gas Chromatography. Gas chromatography (GC) was performed on a Hewlett-Packard 5890 gas chromatograph (Hewlett-Packard, Palo Alto, California, USA) equipped with a flame ionization detector, using the following

columns: (1) SP 2340 fused silica (30 m × 0.32 mm ID; 0.20 μm; 1.5-m retention gap at the beginning of the column; Supelco Inc., Bellefonte, Pennsylvania, USA); split–splitless injector; temperature, 210°C; helium was used as the carrier gas at 1.5 ml/min; septum purge 2 ml/min; temperature program: 60°C, 1 min; 10°C/min to 100°C; 5°C/min to 220°C; held at this temperature for 20 min. (2) HP Ultra 1 cross-linked methyl silicone gum phase (25 m × 0.2 mm ID; 0.33 μm; 2.5 m retention gap at beginning of column; Hewlett-Packard); on column injector; carrier gas: helium at 1.5 ml/min; supply flow 30 ml/min; temperature program: 60°C for 1 min; 10°C/min to 100°C; 5°C/min to 220°C; held at this temperature for 40 min.

Coupled Gas Chromatography–Mass Spectroscopy. Coupled gas chromatography–mass spectrometry (GC-MS) was carried out by electron impact at 70 eV using a double focusing VG 70/250 SE mass spectrometer (Vacuum Generators, Manchester, UK) linked to a HP 5890 gas chromatograph. Separations were performed on a fused silica capillary column (50 m × 0.25 mm ID) coated with FFAP as the stationary phase (Macherey and Nagel, Düren, Germany). Helium was used as carrier gas. The column was operated at 60°C for 3 min and programed to 220°C at 3°C/min.

Traps. Bottle traps were funnel traps home-made from 2-liter transparent plastic bottles by cutting the bottle below the neck (ca. 10 cm) and placing the cut part upside down into the remaining bottom of the bottle (Figure 1). The resulting funnel entrance diameter was ca. 8 cm; the funnel hole diameter was ca. 2 cm. A transparent plastic sheet (10 × 10 cm) was placed in a vertical position immediately above the opening of the funnel. The bait dispenser was attached to the vertical plastic sheet so that the attractant-containing part was hanging into the large opening of the funnel.

VARb funnel traps were the plastic CSALOMON VAR funnel traps produced by the Plant Protection Institute, Budapest, Hungary, except that a transparent

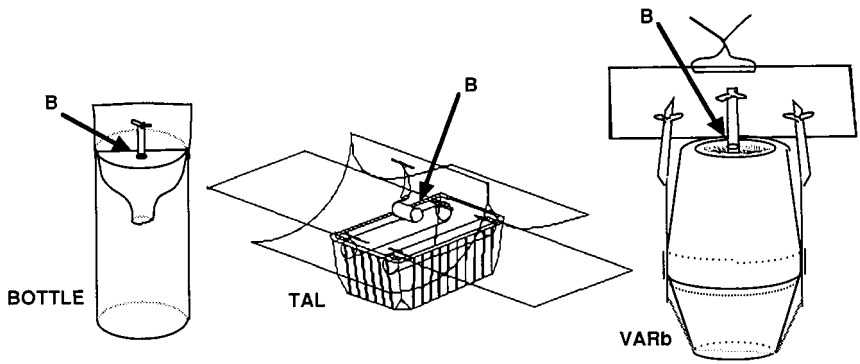

FIG. 1. Schematic diagrams of bottle, TAL, and VARb trap designs. B = position of bait dispenser.

plastic sheet (23 × 10 cm) was placed in a vertical position immediately above the opening of the funnel (Figure 1). A bait dispenser was attached to the vertical plastic sheet so that the attractant-containing part was hanging into the opening of the funnel. The funnel entrance was 13 cm ID, the hole of funnel was 3 cm ID and the height of funnel was 10 cm. Beetles falling down through the funnel were caught in a ca. 1-liter plastic container.

The TAL traps were modified pitfall traps. They consisted of a brick-shaped plastic box, a roof made of a folded plastic sheet into which the hanging bait was fixed and two other sheets on both sides of the plastic box that provided a smooth surface for beetles entering the trap and leading them into the plastic box. At the bottom of the box, a 10- × 16-cm sticky sheet was placed to make escape from the trap harder (Figure 1). The dimensions of the plastic box were: 17 cm long, 11 cm wide, and 6 cm high.

The YATLOR traps were made of plastic at the Italian laboratory and were similar in shape and size to the Estron trap described earlier (Oleschenko et al., 1987; Kudryavtsev et al., 1993).

Insects could get into the TAL and YATLOR traps by both crawling and flying, but could get into the VARb and bottle traps only by flying.

Chemicals. Geranyl butyrate (GB) was purchased from Bedoukian Inc. (Danbury, Connecticut, USA) and was >99% pure by GC. (*E*,*E*)-Farnesyl butyrate (FB) was synthetized. For the synthesis, (*E*,*E*)-farnesol (96%), butyryl chloride (98%), and (4-dimethylamino)pyridine (99%) were obtained from Sigma-Aldrich Kft. (Budapest, Hungary), while other chemicals were purchased from Reanal Finechemical Co. (Budapest, Hungary) and were of highest purity available. Analytical grade pyridine was dried over potassium hydroxide pellets. Column chromatography was carried out with 0.063- to 0.200-mm silica gel (Reanal Finechemical Co.). Proton NMR spectra were recorded on a Bruker WM-300 spectrometer at 300 MHz using tetramethylsilane as reference. For the synthesis of FB, butyryl chloride (9.9 ml, 95 mmol) was added to an ice-cooled solution of (*E*,*E*)-farnesol (15.2 g, 68 mmol), anhydrous pyridine (11 ml, 136 mmol), (4-dimethylamino)pyridine (0.20 g), and benzene (130 ml) while stirring. After stirring the mixture at room temperature overnight, it was diluted with hexane (150 ml) and poured onto ice-cold water (150 ml). The phases were separated and the aqueous layer extracted with hexane (50 ml). The organic layers were combined; washed with 15% HCl solution, water, and saturated $NaHCO_3$ solution; dried over Na_2SO_4; filtered; and concentrated. The crude product was purified by column chromatography using hexane as eluent to give 19.2 g (96%) of the title product as a pale yellow oil.

^{1}H NMR (CDCl3) 0.94 (t, $J = 7.3$ Hz, 3H), 1.59 (bs, 6H), 1.67 (s, 3H), 1.70 (s, 3H), 1.94–2.32 (m, 12H), 4.58 (d, $J = 7.1$ Hz, 2H), 5.08 (m, 2H), 5.34 (t, $J = 7.1$ Hz, 1H).

Bait Dispensers for Traps. Bait dispensers for the tests were prepared by adding the required amounts of synthetics into 0.7 ml polyethylene vials with lid (No. 730, Kartell Co., Italy) in hexane solutions. After having allowed the hexane to evaporate, the lid of the dispensers was closed and the dispensers were wrapped individually in pieces of aluminum foil. All dispensers were stored at -30°C until use.

Field Trapping. Field tests were conducted at several sites in Hungary, Italy, and Bulgaria. Traps were set up in blocks. Each block was comprised of one of each treatment. The distance between traps within a block was 5–10 m. The distance between blocks ranged from 50 to 100 m. Traps were moved one position forward within a block at each occasion when the traps were inspected; at the same time, captured beetles were recorded and removed.

Capture data were transformed to $(x + 0.5)^{1/2}$ and were analyzed by ANOVA. Treatment means were separated by Duncan's New Multiple-Range Test. In case one of the treatments was catching no beetles, the difference of the catch of other treatments from zero catch was analyzed by one-sample t test. All statistical procedures were conducted using the software packages StatView v4.01 and SuperANOVA v1.11 (Abacus Concepts, Inc., Berkeley, California, USA).

Description of Single Field Experiments. Preliminary tests were conducted from May 23 to August 8, 1997, in Eraclea, in the Veneto region of Italy in an alfalfa field by using bottle traps. Traps were inspected weekly over 77 days, providing 33 data points (11 inspections of 3 block replicates).

The ratio of GB and FB was evaluated in the following field tests: March 13–May 13, 1998, in Eraclea, Veneto region, Italy, by using TAL traps in an alfalfa field—traps were inspected every 6–7 days over 61 days, providing 9 data points (9 inspections of 1 block replicate); May 20–June 13, 1998, in Eraclea, Veneto region, Italy, by using bottle traps in a maize field—traps were inspected every 2–3 days over 24 days, providing 24 data points (7 inspections of 3 block replicate); March 28–June 8, 1998, in Debrecen, Hajdú-Bihar County, Hungary, by using VARb traps in an alfalfa field—traps were inspected every 8–9 days over 72 days, providing 32 data points (8 inspections of 4 block replicates); and April 2–May 15, 1998, in Eraclea, Veneto region, Italy, by using YATLOR traps in a sugar beet field—traps were inspected every 3–4 days over 43 days, providing 41 data points (13 inspections of 3 block replicates).

Catches with TAL versus Bottle Traps. Captures by traps baited with a 1:1 mixture of GB and FB (200 mg) were compared in the following experiments: March 30–April 26, 1998, in Eraclea, Veneto region, Italy, in a maize field—traps were inspected every 3–4 days over 27 days, providing 14 data points (7 inspections of 2 block replicates). April 26–July 7, 1999, in Eraclea, Veneto region, Italy, in an alfaalfa field—traps were inspected every 10–12 days over 72 days, providing 18 data points (6 inspections of 3 block replicates).

Other Field Tests. A 1:1 mixture of GB and FB was compared at different doses (20, 60, and 200 mg) from April 2 to May 19, 1999, in Eraclea, Veneto region, Italy, in a sugar beet field with YATLOR traps. Traps were inspected every 4–5 days over 45 days, providing 40 data points (10 inspections of 4 block replicates).

Bait longevity in the field was studied from February 29 to June 18, 2000, with YATLOR traps baited with a 1:1 mixture of GB and FB in a sugar beet field in Eraclea, Veneto region, Italy. Traps with fresh baits were added on April 5 and May 3. Aged baits were coming from traps operated at the same site preceding the test for the respective aging periods. Traps were inspected between April 5 and May 3 every 7–8 days over 28 days, providing 16 data points (4 inspections of 4 block replicates); and between May 3 and June 18 every 10–12 days over 46 days, providing 12 data points (3 inspections of 4 block replicates).

Monitoring at a site with both *A. brevis* and *A. sputator* populations was performed in Sofia, Bulgaria at the Botanic Garden of the Bulgarian Academy of Sciences from April 20 to July 27, 2000. Two TAL traps were used for *A. brevis* and two VARb traps for *A. sputator*. Traps were inspected each week. The *A. brevis* bait contained 30 mg of both GB and FB, while the *A. sputator* bait contained 30 mg of GB.

Seasonal monitoring for *A. brevis* was conducted in Eraclea, Veneto Region, Italy (March 4–June 30, 2000) in a sugar beet field with four YATLOR traps baited with 60 mg of an 1:1 mixture of GB and FB; baits were renewed at monthly intervals.

RESULTS AND DISCUSSION

Gas chromatographic analyses revealed two major peaks in the gland extract of female *A. brevis* in the relative ratios of 1:3, 1:2.8, and 1:2.4 for the northwestern, central, and northeastern populations, respectively (Figure 2). The retention times on both the SP-2340 and the Ultra-1 columns of the earlier eluting peak corresponded to the data of synthetic geranyl butyrate (GB), while the later eluting peak matched the retention times of (*E*,*E*)-farnesyl butyrate (FB). Mass spectra confirmed these assignments. The amount of the major pheromone component was estimated to be 5.5, 7.9, and 5.1 μg/female gland for the northwestern, central, and northeastern populations, respectively.

Apart from the above two compounds, GC-MS analyses revealed the presence of traces of geranyl hexanoate, farnesyl acetate, geranyl pentanoate, and geranyl 3-methylbutyrate in all gland extracts. Traces of β-farnesene could be detected only in extracts from the southwestern and northeastern populations.

Since the results did not show any substantial differences in the composition of the pheromone gland extracts between the three populations, it was decided to

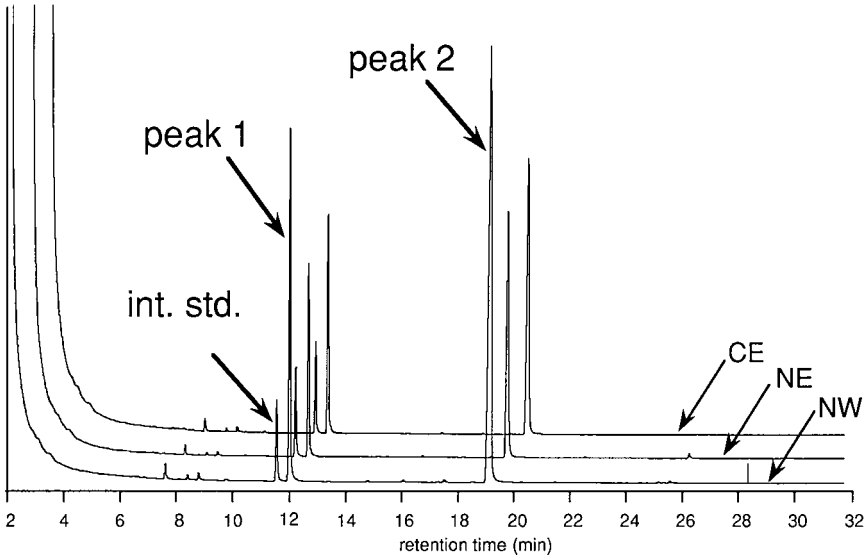

FIG. 2. GC trace of pheromone gland extracts of *A. brevis* populations on a SP-2340 capillary column. Internal standard was dodecyl acetate (50 ng). CE = central; NE = northeastern; NW = northwestern populations. Traces from different extracts are staggered by 0.3 min.

continue with testing the field activity of the two major compounds in the Veneto region of Italy.

In earlier field tests while screening known pheromone components of click beetle species in Italy, low catches of *A. brevis* males were occasionally observed in traps baited with GB (Furlan and Tóth, unpublished data), indicating that this compound might play a role in the pheromonal communication of the species, but was not sufficiently active for practical use.

Preliminary field tests set up in 1997 based on the first results of GC gland extract analyses showed that traps baited with a 1:1 mixture of GB and FB (5 mg each) caught a number of beetles (17.7 ± 7.8, mean $\pm$ SE), while those baited with FB alone (5 mg) caught only 1.5 ± 0.7 males. Traps with GB (10 mg; the dosage catching regularly low numbers in the previous screening tests) alone caught 0.1 ± 0.1 male beetles.

In tests comparing the field activity of the two compounds and their mixtures (Table 1), in Italy the 1:1 and 10:1 mixtures of GB and FB tended to show significantly higher catches of *A. brevis* than the 1:10 blend. With one exception, the single compounds caught the lowest numbers. In the Eraclea test in 1998, the activity of the 10:1 blend did not differ from that of the 1:1 blend and GB or FB alone. When used alone, there was a tendency of GB to attract more, but the

difference was significant only in one case. No other click beetle species were caught in the course of these tests in Italy. It was concluded that a 1:1 ratio of the two compounds is highly attractive towards *A. brevis*, and this mixture was used in the ensuing dosage tests.

To our surprise, in the tests in Hungary, no *A. brevis* were captured with the 1:1 blend. Instead, large numbers of the closely related *A. sputator* were caught in traps baited with only GB (Table 1). Other combinations caught negligible numbers, although catches in traps baited with mixtures containing large amounts of this compound caught slightly better than traps with little or no GB. This compound is the known main pheromone component of *A. sputator* (Kudryavtsev et al., 1993, Siirde et al., 1993; Yatsynin et al., 1986, 1996) and attracted large numbers of this species into traps also in other tests in Hungary (Tóth and Furlan, unpublished data).

The presence of FB in the ratios tested was strongly inhibitory towards *A. sputator*. This suggested a role for this compound in maintaining reproductive isolation between *A. brevis* and *A. sputator* in regions where they cooccur. In a test in 2000 aimed at monitoring the flight pattern of *Agriotes* spp. throughout the spring and summer seasons in Bulgaria, traps baited with the 1:1 blend caught a total of 364 *A. brevis* and no *A. sputator*, while traps baited with GB alone caught 2 *A. brevis* and 52 *A. sputator*, respectively. Although a direct comparison of catch figures is not possible since the two types of baits were set up in different trap designs in this test, this apparent specificity of the respective trap and bait combinations indirectly confirms the hypothesis on the role of FB in reproductive isolation between the two species.

TABLE 2. CATCHES OF *A. brevis* BEETLES IN TRAPS BAITED WITH FRESH OR FIELD-AGED DISPENSERS CONTAINING DIFFERENT DOSES OF 1:1 MIXTURE OF GERANYL BUTYRATE AND (*E*,*E*)-FARNESYL BUTYRATE[a]

Aged in field (days)	Amount in bait (mg)	Beetles caught (*N*, mean ± SE)	
		April 5–May 3	May 3–June 18
0 (fresh)	30	68.75a ± 6.78	11.08a ± 3.04
	60	89.50a ± 11.99	7.92a ± 2.81
31	30	not tested	7.42a ± 2.48
	60	not tested	7.83a ± 2.31

	60	77.19a ± 8.39	not tested
73	30	not tested	9.50a ± 3.27
	60	not tested	8.91a ± 4.30

[a] For significance see Table 1.

In a 1999 test comparing different doses of the 1:1 mixture of GB and FB, traps with 20-mg, 60-mg, and 200-mg doses caught 19.5 ± 2.6, 21.1 ± 2.5, and 23.7 ± 3.8 beetles (mean ± SE), respectively. No significant difference was found between the means (ANOVA, DNMRT, $P = 5\%$). Unbaited traps captured 1.1 ± 0.3 insects, significantly lower than catches with all dosages of the baited traps.

In longevity tests of dispensers, no difference was observed at any of the two dose levels tested between the performance of fresh or aged baits even when aged for >73 days (Table 2).

In conclusion, a 1:1 mixture of GB and FB in 30- to 60-mg amounts in polythene dispensers can be recommended as a bait for *A. brevis* traps for agricultural use. In preliminary tests conducted throughout several months during the spring and summer, the presence of adult insects was shown from the beginning of March to the end of May (Figure 3) with a peak in the second half of April. The bait composition described in the present study clearly shows good perspectives for agricultural usage.

In the course of these studies, several trap designs were used: in some designs insects could get in without flying ("crawl-in" traps), in some others only by flying ("fly-in" traps). In a preliminary direct comparison of crawl-in and fly-in trapping devices, it was found that during the first half of the flight period many more *A. brevis* were captured in the crawl-in traps, while later in the flight the fly-in traps worked equally well (Table 3). This phenomenon might have resulted from the possibility that earlier in the season with cooler temperatures, *A. brevis* adults could not take wing so easily as later with warmer temperatures, although no direct observation of insect behavior was conducted in this study. In any case, more detailed studies, carried out at several sites in the geographical range of the species, are needed to study the influence of trap designs before an *A. brevis* trap

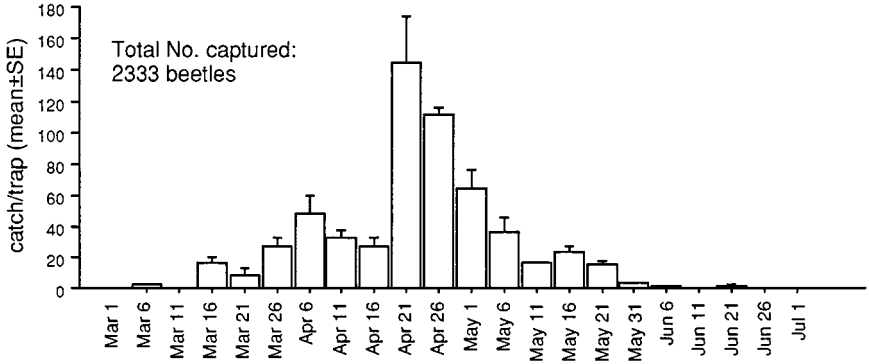

FIG. 3. Seasonal captures of *A. brevis* in traps baited with a 1:1 mixture of geranyl and (*E*,*E*)-farnesyl butyrate in Italy.

for general use can be fully developed. For a sensitive monitoring device, both the bait and the trap design should be optimized for maximal effect in catching the target pest.

Of the two compounds now identified as pheromone components of *A. brevis*, GB has already been described as a pheromone component in several *Agriotes* spp., i.e., *A. gurgistanus* Fald. (Yatsynin et al., 1980, 1996), *A. lineatus* L. (Yatsynin et al., 1991), and *A. ponticus* Step. (Yatsynin and Rubanova, 1990). The presence of this compound has also been shown in pheromone gland extracts (without data on behavioral activity) of *A. medvedevi* Dolin and *A. obscurus* L. (Yatsynin et al., 1996). In *A. sputator*, GB is clearly the main behaviorally active pheromone component (Yatsynin et al., 1986; Kudryavtsev et al., 1993; Siirde et al., 1993), while the behavioral significance of traces of FB found in gland extracts is not clear (Yatsynin et al., 1996). Closely resembling the results of pheromone analysis of *A. brevis* in this study, GB and FB together compose the pheromone of *A. meticulosus* Candeze (Yatsynin et al., 1991, 1996). Both GB and FB were also detected

TABLE 3. CATCHES OF *A. brevis* BEETLES IN TRAPS OF TWO DIFFERENT DESIGNS BAITED WITH 10 mg OF 1:1 MIXTURE OF GERANYL BUTYRATE AND (*E*,*E*)-FARNESYL BUTYRATE[a]

	Beetles caught (N, mean ± SE)

as minor components in gland extracts of *A. proximus* Schwarz and *A. ustulatus* Schaller (Yatsynin et al., 1996), where their behavioral relevance remains to be clarified. The presence of only FB also has been shown in gland extracts of *A. infuscatus* Desbr. (Yastsynin et al., 1996).

Consequently, the pheromone composition of *A. brevis* described in the present study seems to be well integrated into the general scheme of biologically active terpene esters of the genus *Agriotes* (see also Borg-Karlson et al., 1988): The biogenetic principle in the formation of specific pheromone components is based on the combination (esterification) of acyclic isoprenoid alcohols with short chain acids. Disposable variants are provided in the number of isoprene subunits and double-bond configurations at the terpene site (Tolasch and Tóth, unpublished data) and on chain length and methyl branching at the acid moieties.

In conclusion, we demonstrated the usefulness of the mixture of GB and FB formulated in polythene vial dispensers for the development of an *A. brevis* pheromone trap usable in agricultural practice. The issue of the optimal trap design still needs to be addressed, as in the present tests a crawl-in design was better in the early part of the flight period, while both crawl-in and fly-in designs performed well later on. The use of a crawl-in design later in the season has the drawback that occasionally large numbers of predatory beetles (adults and larvae of carabids, silphids, etc.) may also be captured, probably due to the volatiles from carcasses of insects captured earlier in the traps. Efforts for integrating design characteristics to develop an optimal trap design for click beetles are under way.

(Received January 15, 2002; accepted April 14, 2002)

Abstract—Attraction of *Metamasius hemipterus* (Oliver) to gallon and bamboo traps baited with insecticide-treated sugarcane, the male-produced pheromone, 4-methyl-5-nonanol, and 2-methyl-4-heptanol is more efficient if ethyl acetate is added. The optimal traps are ground-level gallon traps baited with insecticide-laced sugarcane, pheromone, and ethyl acetate. Capture rates of ground-level gallon traps are doubled by placing an insecticide-laced pad under the trap, but significantly decreased by placing the trap on a stick above ground. The efficiency of ground-level gallon traps is the same as ground level ramp traps. Mass-trapping *M. hemipterus* in newly planted sugarcane using ground level bamboo traps baited with insecticide-laced sugarcane and pheromone over six months revealed populations were low for the first two months, became maximum at five months, and declined thereafter. Capture rates of traps bordering newly planted and mature sugarcane were not significantly different from capture rates of traps in the interior of the plots. Capture rates of bamboo traps containing only insecticide-laced sugarcane and deployed at 30 traps/ha averaged 6 weevils/trap/week compared with 66 weevils/trap/week for traps additionally containing pheromone lures and deployed at 5 traps/ha. Capture rates for bamboo traps baited with insecticide-laced sugarcane and pheromone and deployed at 10 and 15 traps/ha were 43 and 38 weevils/trap/week, respectively. Total captures were higher in those plots with a higher density of insecticide-laden sugarcane and pheromone baited traps, and the differences were approximately proportional to trap density in the range of 5–15 traps/ha. Capture rates of traps containing insecticide-laced sugarcane and pheromone were always higher than of traps containing only insecticide-laced sugarcane, but in the first two months after planting the differences were much greater than in months 3–6 after planting.

Key Words—4-Methyl-5-nonanol, 2-methyl-4-heptanol, aggregation pheromone *Metamasius hemipterus*, West Indian sugarcane weevil, pheromone trapping, sugarcane.

INTRODUCTION

The West Indian sugarcane weevil, *Metamasius hemipterus sericeus* (Oliver), is a pest of sugarcane, *Saccharum officinarum* L., in regions of Central and South America above 1100 m in which climatic conditions provide cool and humid conditions for weevil reproduction and where crop cultivars may be restricted to varieties that are susceptible to weevil attack (Badilla et al., 1985). Weevils are attracted to the cut ends of sugarcane stalks (billets) laid in the ground during replanting. Females oviposit in and larvae mine the replanting stock, thus destroying nodal tissue and decreasing germination frequency. In some regions, damage to billets can reach as high as 60% and can result in production losses estimated at over 25% (Badilla et al., 1985). Development time from egg to emergent adult is approximately two months (Badilla et al., 1985).

Recommended practice to manage economically damaging populations of this weevil is to place bamboo traps containing insecticide-treated sugarcane in fields at planting for two months. In this work, we initially examined the relative efficiency of different trap designs, trap elevation, and baiting protocols. We also examined the relative efficiency of different mass-trapping protocols by using ground-level bamboo traps baited with insecticide-laced sugarcane or this component as well as male-produced aggregation pheromone (Perez et al., 1997).

METHODS AND MATERIALS

Field Site. Experiments were carried out in the 1200-ha Hacienda Juan Viñas sugarcane plantation in central Costa Rica. This is an elevated wet tropical region. The plantation has sugarcane of all ages, with most plantings bordered by roads. Mass-trapping plots were newly replanted sugarcane surrounded on three sides by 8-months-old sugarcane and on the fourth side by a road bordered by 8-month-old sugarcane. Mass-trapping plots were separated by at least 100 m of 8-month-old sugarcane.

Traps. Bamboo traps consisted of halved 4–5 cm diameter 0.8 m bamboo into which were cut on each side $\sim$0.6-m $\times$ 0.5-cm-wide slits for insect entry. Into these traps were placed four or five pieces of halved sugarcane stalk ($\sim$20 cm) previously immersed in Sevin 80 (3% A.I., 1-naphthyl *N*-methylcarbamate). Pheromone lures were laid in the trap with the sugarcane. Each trap was bound together with two pieces of wire, placed on the ground, and covered with litter from the

field to preserve moisture. Gallon traps were 4-liter yellow plastic containers with 10-cm × 15-cm windows cut in each large side ~5 cm from the bottom to allow insect entry. Ramp traps consisted of two yellow square molded plastic containers 13.5 × 13.5 × 3 cm mounted with open ends toward each other and separated by 5 cm. To the lower container were attached four ramps 12 × 12 cm that inclined between the top of the lower container and the ground. A picture of the trap is in Alpizar et al. (2000). Each trap contained four or five pieces of insecticide-treated halved sugarcane stalk (20 cm). Pheromone and ethyl acetate lures were hung from a wire just under the top of the trap.

Comparison of Gallon and Ramp Traps. Each trap contained five pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI), a pheromone lure, and an ethyl acetate lure. Traps were placed 50 m apart in 6- to 10-week planted sugarcane in Hacienda Juan Viñas, Costa Rica, November 30–December 14, 2001. Insects were counted and removed and traps were rerandomized between the first and second weeks.

Lures. Pheromone lures were commercially available Metalure [4-methyl-5-nonanol–2-methyl-4-heptanol (8:1)] formulated in membrane release devices that released ~3 mg/day. Ethyl acetate was formulated in membrane release devices that released ~100 mg/day (ChemTica Internacional, Apdo. 159-2150, San Jose, Costa Rica). Release rates were determined by weight loss under a daily temperature regime of 28 ± 2°C maximum and 17 ± 2°C minimum.

Statistics. Captures were analyzed for normal distribution and, where necessary, transformed to achieve homoscedasticity. ANOVA (fully factorial routine) was conducted using Systat 5.2.1. Means are always presented untransformed. Means followed by different letters in the figures are significantly different by Bonferonni t test ($P < 0.05$).

RESULTS AND DISCUSSION

A previous elucidation of the aggregation pheromone of *M. hemipterus* identified 4-methyl-5-nonano and 2-methyl-4-heptanol as the two components that yielded the highest biological responses in field trapping (Perez et al., 1997). While the participation of 4-methyl-5-nonanol in the aggregation pheromone of this weevil is undisputed, it was reported that either 2-methyl-4-octanol or 2-methyl-4-heptanol could be used with 4-methyl-5-nonanol to attract *M. hemipterus* in Colombia (Ramirez-Lucas et al., 1996). The present study used a mixture of 4-methyl-5-nonanol and 2-methyl-4-heptanol that has repeatedly been more attractive in Costa Rica than other mixtures of male-produced volatiles. Previous work established that addition of pheromone to insecticide-laced sugarcane-containing traps significantly increases capture rates of *M. hemipterus* (Giblin-Davis et al., 1996; Perez et al., 1997). Although other food additives have been investigated,

none has been found to be a better synergist for the aggregation pheromone than insecticide-laced split sugarcane stalk (Oehlshlager et al., unpublished results; Cerda et al., 1999).

Trap Optimization Experiments. Our initial experiment established that ground level gallon traps and bamboo traps were equally efficient when similarly baited and that insecticide-laced sugarcane in traps remained effective for at least two weeks (experiment 1; Figure 1). In this experiment, we found that captures during the second week were greater than captures during the first week. This is not unexpected since attractiveness of sugarcane to *M. hemipterus* is associated with its fermentation, the rate of which varies under field conditions. We next investigated the effect of addition of ethyl acetate to gallon traps (experiment 2; Figure 2). This experiment confirmed the earlier report that a combination of insecticide-laced sugarcane, pheromone, and ethyl acetate was more attractive than the binary combination of sugarcane and pheromone (Giblin-Davis et al., 1996).

Since it is common practice in sugarcane plantations to use ground-level bamboo traps to capture *M. hemipterus* (Badilla et al., 1985), we conducted a

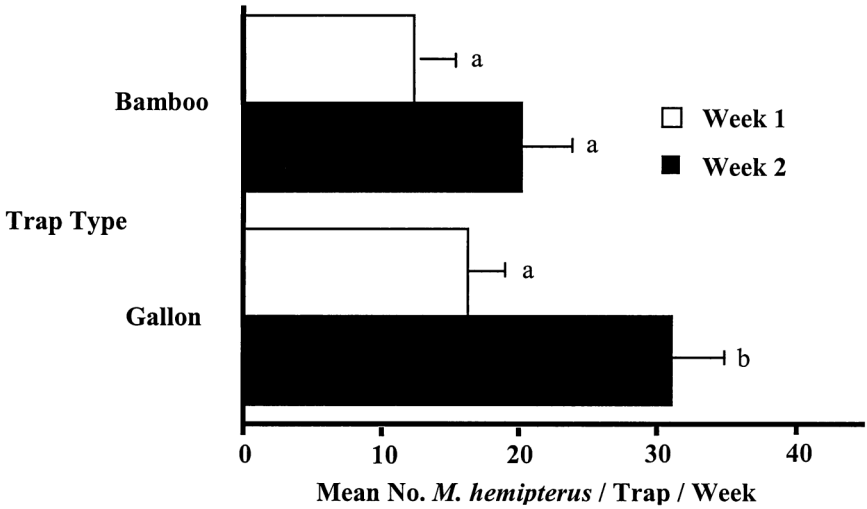

FIG. 1. Effect of trap type on *M. hemipterus* captures. Mean (+SEM) weekly capture of *M. hemipterus* in ground-level gallon and ground-level bamboo traps, each containing a pheromone lure and four pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI). Traps were placed 20 m apart in newly planted sugarcane (within one month of test) in Hacienda Juan Viñas, October 22–November 8, 1996. No significant difference between capture rates of the two trap types was detected in the first week (no statistical analysis presented), but in the second week ANOVA ($N = 9$) of log $(X + 1)$-transformed data gave $F_{1,16} = 4.49$, $P < 0.05$. Bars followed by different letters are statistically significant.

further experiment that determined that the addition of ethyl acetate to bamboo traps containing insecticide-laced sugarcane and pheromone increased capture rates (experiment 3; Figure 3). In experiment 3, we also determined that gallon traps baited with insecticide-laced sugarcane, pheromone, and ethyl acetate were more effective if placed on the ground than if elevated on sticks 0.5 m above the ground (Figure 3). The higher capture rate of ground-level traps is consistent with the preference of *M. hemipterus* for buried sugarcane stalk. The higher efficiency of ground-level traps is at variance with earlier reports in which it was observed that capture rates were higher in traps elevated above ground compared to those on the ground (Giblin-Davis et al., 1996; Cerda et al., 1999). The differences most probably reside in the ease with which *M. hemipterus* can enter the present ground-level traps. The present ground traps were surrounded by crop residue that was pushed along the sides of the gallon traps so that weevils landing on the ground near the trap could easily walk into the open sides of the trap. The higher capture rate of ground-level traps is consistent with our observations that *M. hemipterus* fly to the area of a trap, land, and then walk in. This is similar to

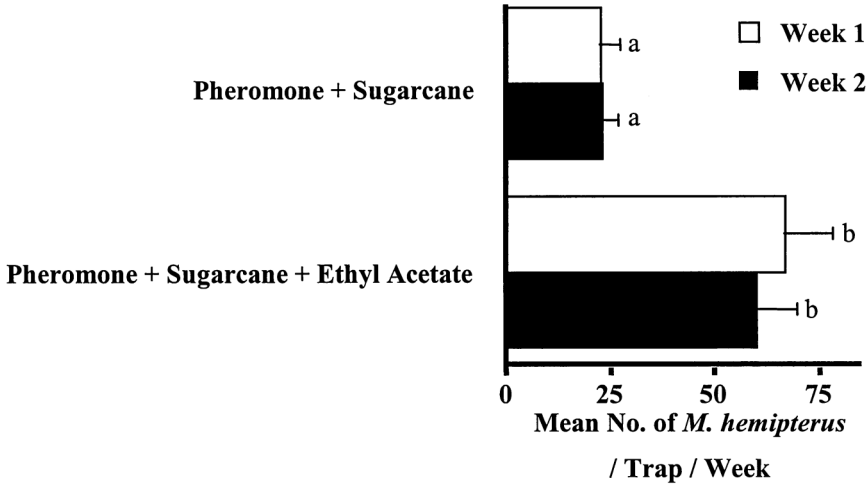

FIG. 2. Effect of semiochemical bait on *M. hemipterus* capture in gallon traps. Mean (+SEM) weekly capture of *M. hemipterus* in gallon traps each containing four pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI). Traps were placed 20 m apart in newly planted sugarcane in Hacienda Juan Viñas, November 8–22, 1996. ANOVA ($N = 10$) of week one captures gave $F_{1,18} = 7.88$, $P < 0.05$, week two $F_{1,18} = 7.15$, $P < 0.05$. Bars followed by different letters are statistically significant.

the behavior of *R. palmarum* that is also more efficiently captured if large landing surfaces are present within easy crawling distance of the traps (Oehlschlager et al., 1993a,b).

The above suggested that a ground-level killing agent might increase the efficiency of the trap. With the goal of intercepting weevils attracted to the area of the trap but not entering, we placed 20- × 20- × 0.5-cm insecticide-soaked sponge pads under gallon traps (experiment 4; Figure 4). Capture rates of ground-level gallon traps baited with insecticide-laced sugarcane, pheromone, and ethyl acetate were similar to equivalently baited gallon traps that were placed on insecticide-laced pads, and the insecticide-laced pads captured similar numbers of *M. hemipterus*. The trap–pad combination captured twice as many insects as the trap without pads. When this experiment was conducted in drier climates, it was found that if the pad is dry it does not retain significant numbers of insects compared to normal traps (D. Alpizar and M. Fallas, unpublished observations). In the present experiment, we used a very high (1.2 ml/day) release rate of ethyl acetate for all traps. It has been determined that capture rates in ground-level gallon traps baited with insecticide-laced sugarcane and pheromone and ethyl acetate steadily increase as the release rate of ethyl acetate is increased from 100 to 1.2 ml/day, the highest release rate studied (McDonald et al., 1996). The most effective trap is the insecticide-laced

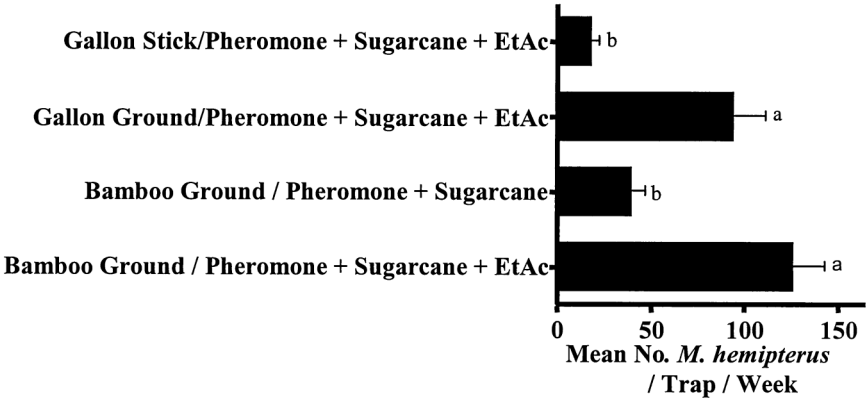

FIG. 3. Effect of trap type, trap elevation, and semiochemical bait on *M. hemipterus* captures. Mean (+SEM) weekly capture of *M. hemipterus* in bamboo or gallon traps in Hacienda Juan Viñas in 3-month-old sugarcane December 15–23, 1996. All traps contained four or five pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI). While all gallon traps additionally contained pheromone and ethyl acetate lures, bamboo traps were additionally baited with pheromone or pheromone and ethyl acetate lures. Additionally, gallon traps were filled to the lower window with Sevin 80 (3% AI) suspension that immersed the sugarcane. Gallon traps on sticks were ~0.5 m above ground level or on the ground. All bamboo traps were on the ground. All traps were ~20 m part between treatments and replicates. ANOVA ($N = 10$) gave $F_{3,32} = 15.38$, $P < 0.05$. Bars followed by different letters are statistically significant.

sugarcane–pheromone–ethyl acetate gallon trap placed on an insecticide-laced pad at ground level.

We have previously examined the relative effectiveness of the ground-level open gallon trap with a ramp trap, a plastic trap that allows weevils to crawl in easily and that is effective in the capture of *Cosmopolites sordidus* (Alpizar et al., 2000). These traps were equally effective when baited with insecticide-laced sugarcane, pheromone, and ethyl acetate. During the two-week trial (experiment 5), the total mean capture of *M. hemipterus*, in gallon traps and ramp traps was forty nine and thirty five, respectively [ANOVA ($N = 20$) $F_{1,18} = 1.82$, NS].

Mass-Trapping Experiments. The usual practice to manage populations of *M. hemipterus* in freshly planted sugarcane is to place 30 insecticide-laced sugarcane-containing bamboo traps/ha at the time of planting and leave them in place for two months. Since the above experiments demonstrated that bamboo traps containing insecticide-laced sugarcane and phermone were more effective, we conducted mass-trapping experiments using bamboo traps baited with both insecticiede-laced sugarcane and pheromone. Although addition of ethyl acetate lures to these traps would have made them even more effective, this component

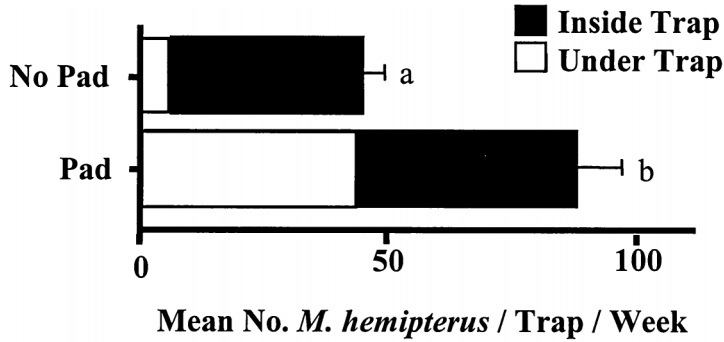

FIG. 4. Effect of the presence of an insecticide-laced pad under semiochemical-baited gallon trap on *M. hemipterus* captures. Mean (+SEM) weekly capture of *M. hemipterus* in gallon traps in Hacienda Juan Viñas sugarcane plantation, January 29–February 2, 1997. All gallon traps contained pheromone and 12 ethyl acetate lures (releasing ~1.2 ml/day of ethyl acetate) as well as four or five pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI). Traps were placed on ground with or without a 20- × 20- × 0.5-cm sponge pad presoaked in Sevin 80 (3% AI). ANOVA ($N = 7$) gave $F_{1,12} = 21.34$, $P < 0.05$. Bars followed by different letters are statistically significant.

was not used in the mass-trapping experiments because the release device available required frequent replacement, and it was not considered acceptable for extended field use. In the mass-trapping experiments, we deployed bamboo traps baited only with insecticide-laced sugarcane at a density of 30 traps/ha and bamboo traps baited with insecticide-laced sugarcane and pheromone at densities of 15, 10, and 5 and traps/ha (experiments 6 and 7, respectively). Each trap density was deployed in three 1-ha plots of newly planted sugarcane for 6 months.

The capture rate of *M. hemipterus* in all mass-trapping plots was low during first two months after planting but increased in months three to five before decreasing in the sixth month (Figure 5).

For two mass-trapping protocols, we examined the capture rates of bamboo traps baited with insecticide-laced sugarcane and pheromone that were located on the perimeter of the trapping plots with those traps that were located on the interior of the trapping plots. In the three 1-ha mass-trapping plots with 30 sugarcane-baited bamboo traps/ha, traps were placed on an approximately 18-m grid, with 16 traps on the perimeter of each plot and 14 traps located in interior positions. In each of the three mass-trapping plots with 15 insecticide-laced sugarcane- and pheromone-baited bamboo traps/ha, traps were placed on an approximately 25-m grid, with 14 traps in each plot on the perimeter and 9 traps located in interior positions. For these two trapping protocols, we found capture rates in perimeter traps to be within 20% of the capture rates of interior traps for each date during the entire six-month trial. That is, there was no evidence for migration of weevils

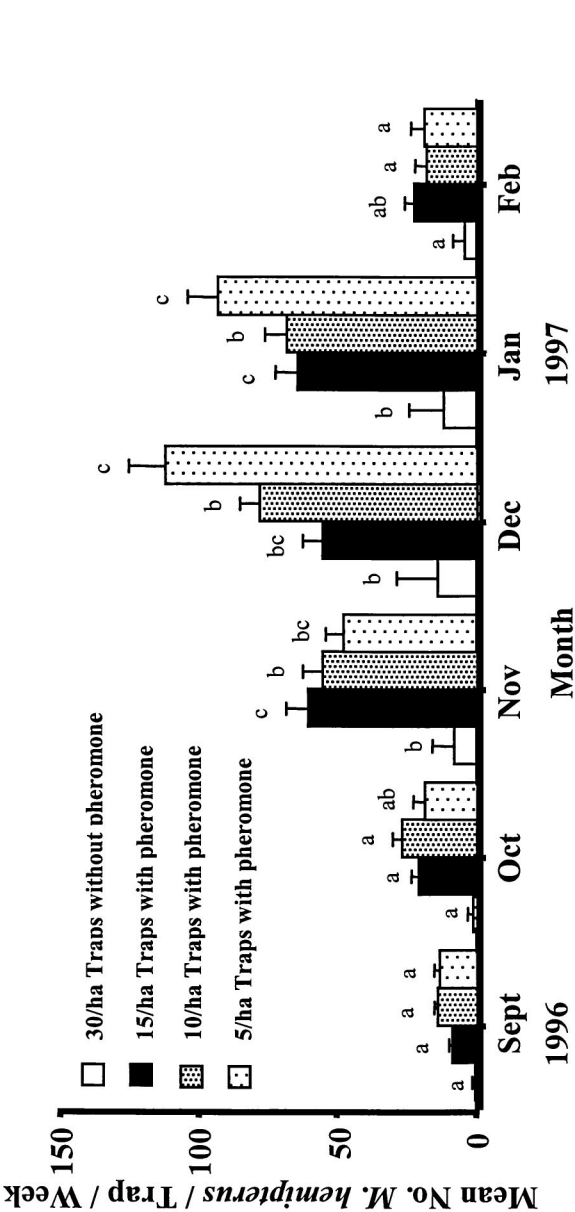

FIG. 5. Effect of trap bait and trap density on *M. hemipterus* captures. Mean (+SEM) weekly capture of *M. hemipterus* in ground level bamboo traps placed in 1-ha plots of newly planted sugarcane in Hacienda Juan Viñas, Costa Rica, September 1996–February 1997. All traps contained five pieces of 20-cm-long halved sugarcane stalk previously immersed in Sevin 80 (3% AI). Traps in plots with 15, 10, or 5 traps/ha additionally contained pheromone lures. Insects were counted and removed weekly, sugarcane was renewed biweekly, and pheromone lures were renewed when liquid was no longer visible in the lure. ANOVA for 30 traps/ha: $F_{5,834} = 24.93$, $P < 0.05$; for 15 traps/ha: $F_{5,414} = 20.64$, $P < 0.05$; for 10 traps/ha: $F_{5,274} = 17.99$, $P < 0.05$; for 5 traps/ha: $F_{5,129} = 30.73$, $P < 0.05$. Captures in plots containing the same trap density were averaged for each month and averages statistically compared month to month for the same trap density. Bars followed by different letters are statistically significant.

to the mass-trapping plots in the early stages of the trapping or for a build up of *M. hemipterus* in the center of the newly replanted mass-trapping plots during the latter part of the trapping. When similar trapping experiments were conducted in mature oil plam with *R. palmarum*, which is a much stronger flier, we found perimeter traps consistently captured two to three times more insects than those in the interior of the trapping area (Oehlschlager et al., 1995).

Bamboo traps baited only with insecticide-laced sugarcane and deployed at 30/ha were the least efficient, capturing an average of only 6 weevils/trap/week, while those baited with sugarcane and pheromone and deployed at 5/ha were the most efficient, capturing an average of 66 weevils/trap/week over the entire six-month trial. Traps baited with sugarcane and pheromone and deployed at 10 traps/ha (43 weevils/trap/week) and 15 traps/ha (38 weevils/trap/week) were of intermediate efficiency.

In the three 1-ha plots receiving 30 insecticide-laced sugarcane-containing bamboo traps (no pheromone lure)/ha, a total of 5217 weevils/ha were captured over the six-month trial. In the three 1-ha plots containing 15 insecticide-laced sugarcane- and pheromone-containing traps/ha, a total of 15,608 weevils/ha were captured during the six-month trial. This is ∼1.3 times more than the 11,636 weevils/ha captured in the plots containing 10 similarly baited traps/ha, and ∼2.3 times more than the 6676 weevils/ha captured in the plot containing only 5 similarly baited traps/ha. It is clear that use of insecticide-laced sugarcane- and pheromone-baited traps offers advantages and that use of as many traps as is economically feasible, at least up to 15/ha, results in removal of proportionally more weevils.

Month-by-month comparison of relative capture rates of bamboo traps baited only with insecticide-laced sugarcane with traps containing insecticide-laced sugarcane and pheromone revealed that in the first two months of the experiment, traps baited with insecticiede-laced sugarcane and pheromone captured ∼17 times as many insects as those with only insecticide-laced sugarcane (Figure 6). The relative efficiency of traps baited with insecticide-laced sugarcane and pheromone dropped to ∼6 times that of traps containing only insecticide-laced sugarcane during months 3–6 of the trials (Figure 6). This significant change is attributed to a difference in the attractiveness of the two components. In the early part of the trial, sugarcane had just been planted, and migrating weevils are expected to be primarily searching for mates and sites for oviposition. Additionally, in the early stages of infestation, there are few pheromone sources in the mass-trapping plots to compete with pheromone emanating from traps. During this period, it is reasonable that traps containing pheromone would be relatively more attractive than those without it. As colonization proceeds, location of unoccupied oviposition sites is likely to be dominant factor, and reliance on pheromone might be expected to decrease. Additionally, in the latter stages of infestation, there are many pheromone sources in the mass-trapping plots to compete with

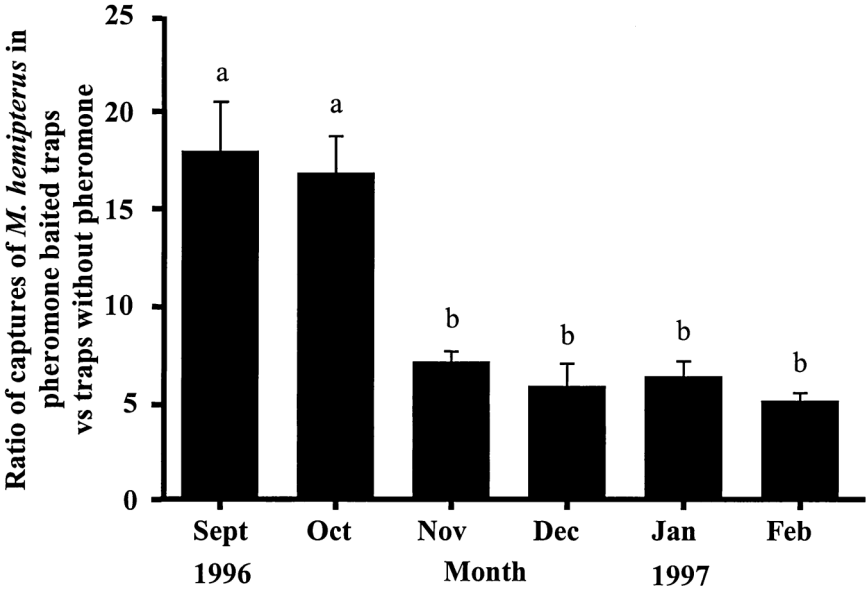

FIG. 6. Ratios of weekly capture of *M. hemipterus* in sugarcane vs. sugarcane and pheromone-baited bamboo traps over time. Ratios of weekly captures of *M. hemipterus* in 30 sugarcane-only bamboo traps containing only insecticide-laced sugarcane to weekly captures in bamboo traps containing insecticide-laced sugarcane and pheromone lures (experimental details as for Figure 5) placed at densities of 15, 10, and 5 traps/ha in newly planted sugarcane at Hacienda Juan Viñas, Costa Rica 1996–1997. ANOVA ($N = 3$) gave $F_{5,12} = 17.52$, $P < 0.05$. Bars followed by different letters are statistically significant.

pheromone emanating from traps. In these circumstances, one would expect differences in attraction between pheromone-containing and pheromone-free traps to decrease.

Acknowledgments—We wish to thank the technical staff at Hacienda Juan Viñas for excellent field assistance.

Abstract—Intermale variation in pheromone signaling has been confirmed and quantified by measurements of pheromone produced by single adult male *Prostephanus truncatus* (Horn) (Coleoptera: Bostrichidae). Males varied in both the amounts of the two components of their aggregation pheromone and the ratio of one component to the other. The mean rates of production of the pheromone components T1 and T2 were 1.9 and 0.5 μg/day, respectively. There were repeatable differences among males in the amounts of T2 produced and the proportion of T1 in the pheromone blend over two weeks. Of the 15 males studied, one released a large burst of pheromone in a short period, while the remainder, if they did release, did so over an extended period. This suggested that there may be two alternative release strategies and the significance of this is discussed.

Key Words—Aggregation pheromone, individual variation, sexual selection, larger grain borer, *Prostephanus truncatus*.

INTRODUCTION

The larger grain borer, *Prostephanus truncatus* (Horn) (Coleoptera: Bostrichidae), is an important pest of farm-stored maize and dried cassava in Africa and Central America (Hodges, 1986; Markham et al., 1991). Once a male has reached a suitable food source, an aggregation pheromone is released consisting of two components, 1-methylethyl (*E*)-2-methyl-2-pentenoate and 1-methylethyl (*E*,*E*)-2,4-dimethyl-2,4-heptadienoate (Cork et al., 1991; Dendy et al., 1991), given the trivial names Trunc-call 1 and Trunc-call 2 (T1 and T2), respectively. Natural and synthetic pheromone are attractive to both females and males in the laboratory

(Boughton and Fadamiro, 1996; Hodges and Dobson, 1998) and field (Leos-Martinez et al., 1995; Scholz et al., 1997; Hodges et al., 1998). Synthetic pheromone is used as a lure in traps to monitor the pest (Richter and Biliwa, 1991; Fandohan et al., 1992; Pike et al., 1992) and also *Teretrius nigrescens* (Lewis) (Coleoptera: Histeridae), a predator of *P. truncatus* (Rees et al., 1990; Boeye et al., 1992).

It has been proposed that male *P. truncatus* produce aggregation pheromone primarily to attract females as potential mates and that other males respond opportunistically by aggregating, representing a fitness cost to the signaler in terms of increased competition for mates and possibly for food (Hodges et al., 1999). This hypothesis is supported by the observations that aggregation pheromone is only produced by males (Cork et al., 1991), males shut down signaling with pheromone after adult females arrive (Smith et al., 1996), and the sex ratio of beetles caught from the field is female-biased (Scholz et al., 1997; Hodges et al., 1998). Both laboratory and field bioassays have shown that *P. truncatus* can distinguish between the pheromone signals of different males and that some males are more attractive than others (Birkinshaw and Smith, 2000). The signals of individual males have never been chemically quantified, however. The temporal stability of signals is also unknown. Birkinshaw (1998) suggested that the relative attractiveness of a range of males was consistent over three days, but after five days, this order had changed (although insects were moved between jars of medium in between time).

In this study, we measured the signals from 3- to 5-day-old adults for 24 days in order to determine the degree of intermale variation in signaling and the stability of intermale differences over time, given fairly constant conditions.

METHODS AND MATERIALS

The beetles used were adults of a Ghanaian strain collected from the field in 1996 and cultured on yellow maize in a CTH room at $27 \pm 1^{\circ}C$, $60 \pm 5\%$ relative humidity on a 12-hr light–dark cycle. Newly emerged virgin adults, 1–2 days old, were removed from pupal cells. Males were selected according to the form of the clypeal tubercles (Shires and McCarthy, 1976) and placed on wheat flour for two days. Just before the start of pheromone collection, each male was placed on a single maize grain since males only produce pheromone in the presence of food (Cork et al., 1991; Smith et al., 1996). To provide the beetles with easy access to the maize, each grain was drilled to give a single, blind-ending tunnel (2 mm diam.).

Pheromone was collected from individual males under the same conditions of temperature and relative humidity. Beetles in maize grains or control grains without beetles were placed singly in glass vessels of 30 cm^3 capacity (Fisher Scientific) through which air was drawn at a rate of l000 cm^3/min by electrical diaphragm pumps (Capex Mk II; Charles Austin). The intake air was purified by passage

through a filter containing activated charcoal (20 × 2 cm, 6–18 mesh), and the output air was passed through filters containing Porapak Q (200 mg, 50–80 mesh; Phase Separations) to collect volatiles emitted. A glass round-bottomed flask (1000 cm^3) was also connected in the system, between the pump and collection filters, to act as a buffer against pressure variations induced by the pump. The air was pumped continuously during the test and the Porapak filters were changed at intervals of one, two, or three days over a period of 24 days (see Figure 1 below). Studies with two Porapak filters connected in series showed that both T1 and T2 were fully retained on the first filter for at least three days. Breakthrough of T1 was apparent after six days, but there was no breakthrough of T2 after 13 days.

Volatiles collected on the Porapak were eluted with dichloromethane (750 μl; Fisher Scientific Distol grade) and octyl acetate (5 μg) added as an internal standard. Samples were assayed by gas chromatography, using a fused silica capillary column (30 m × 0.32 mm ID) coated with CPWax 52CB (Carbowax equivalent; Chrompack), with helium carrier gas and flame ionization detection. The temperature was held at 60°C for 2 min, then programmed at 6°C/min to 230°C. The injector temperature was 200°C, and the detector temperature was 240°C. The sample (2 μl) was injected splitless and not concentrated to avoid loss of pheromone components. Data were captured and processed with EZCHrom V.6 software. Amounts of the two pheromone components were calculated by comparison of peak areas with that of the internal standard and application of the corresponding factors. The latter were derived by calibration of pure synthetic components against the internal standard at the 5-μl level. Peak identity was confirmed at intervals by gas chromatography–mass spectrometry (GC-MS; Finnigan MAT ITD700, Thermoquest) using similar chromatographic conditions. The threshold of minimum detectable quantities of pheromone was determined by visual estimation of the magnitude of the smallest reliably detected peaks.

In the first test, there were nine beetles and one control, and this test was then repeated. The results of the two tests were similar (i.e., did not form two distinct data sets, see Figures 2 and 3 below), and for statistical analysis they were combined, giving a total of 15 observations on male pheromone release, since three sets of data were missing due to mortality and a failure in sexing, and the two controls. The repeatability (r) of male differences in signal characteristics, both the absolute amounts of T1 and T2 and proportion of T1 in the blend, was calculated as r = variance between individuals/(variance between individuals + variance within individuals) (Du et al., 1987). The significance of the temporal stability of differences between the same male signal characteristics, absolute amounts of T1 and T2, and proportion of T1 in the blend were assessed by calculating the correlation coefficient between signals produced on day 7 and those produced by the same males on day 21. These days were chosen as they encompassed a period of steady pheromone output for most males.

RESULTS

During the first three days that the beetles were on maize, the pheromone collected on filters was below reliably quantifiable amounts and was estimated to be at or below 10 ng/beetle/day of either component (Figure 1). From day 5 onwards, detectable amounts of pheromone were released by most beetles (Figures 2 and 3) over extended periods, but in one case there was a very large burst of release. In this case, some 70 μg of T1 and 22 μg of T2 were released over a period of only two days, followed by little or no further production. The total amount released by this beetle during the period of study was greater than any other male (Figure 2 and 3), although similar to the 24-day cumulative values of several other males that released 50–60 μg of T1 and 15–20 μg of T2. No detectable amounts of pheromone were observed in the controls.

On average, almost four times as much T1 was produced as T2 (Table 1). The relative proportions of T1 and T2 were less variable than the absolute amounts of T1 and T2 among males. Furthermore, the differences that did exist in this blend among males were more repeatable than the differences in amounts of T1 or T2 (Table 1; Figure 4).

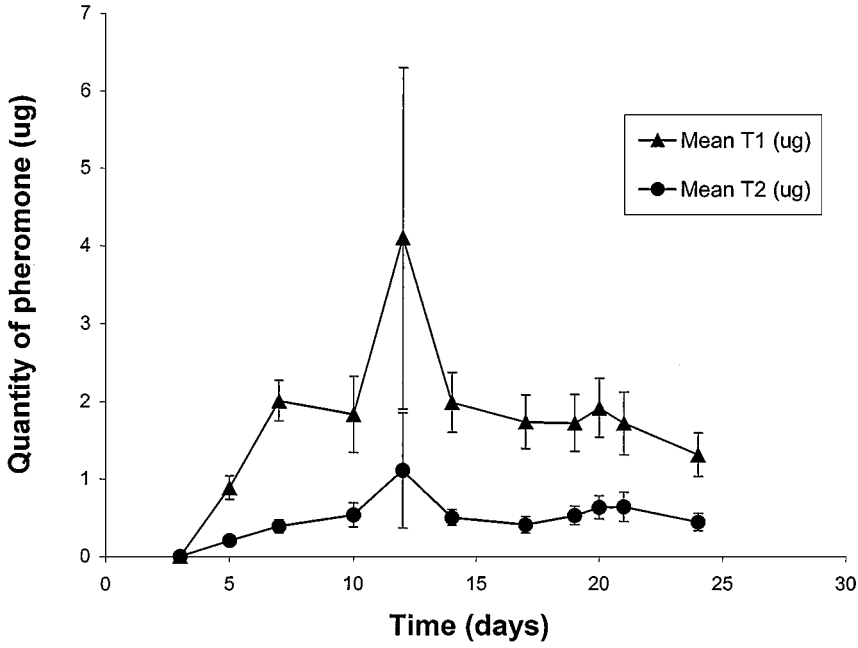

FIG. 1. Mean rate of pheromone output from male *P. truncatus* for pheromone components T1 and T2 (μg/day). Error bars are standard errors of the mean $N = 15$.

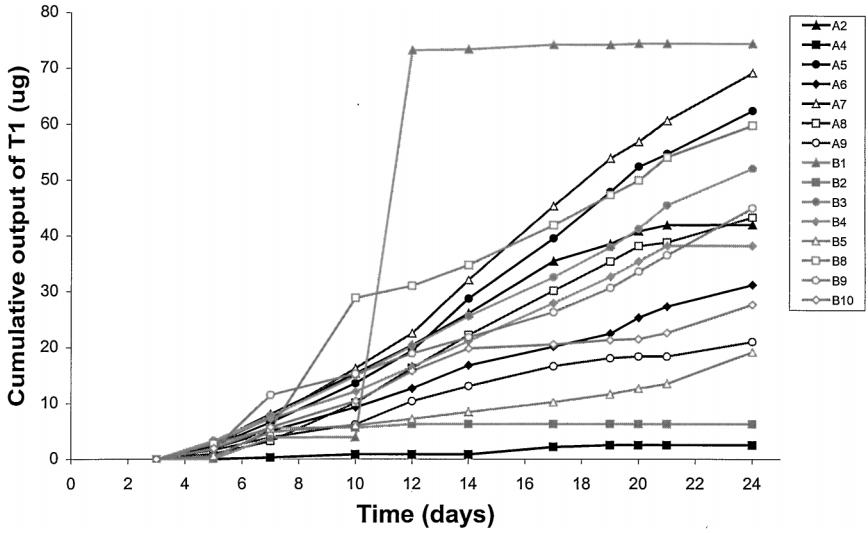

FIG. 2. Cumulative output of pheromone component T1 plotted individually for each male *P. truncatus* (A = first test, B = second test).

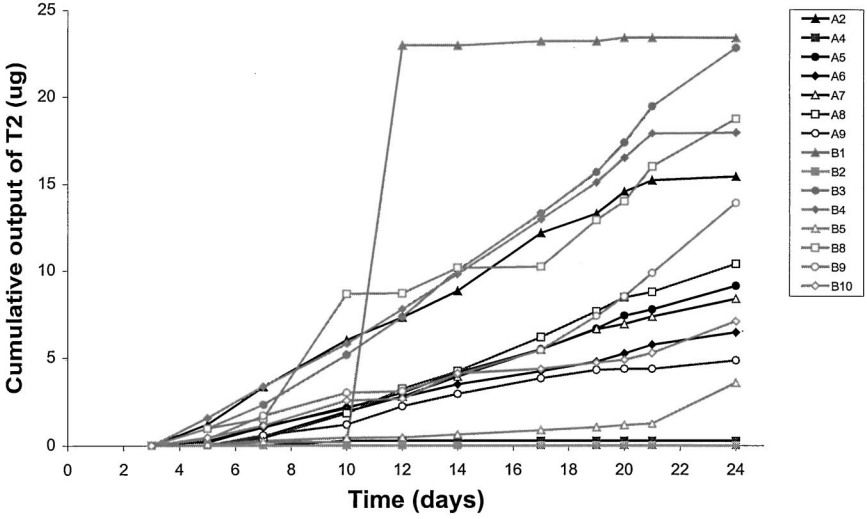

FIG. 3. Cumulative output of pheromone component T2 plotted individually for each male *P. truncatus* (A = first test, B = second test).

TABLE 1. SUMMARY STATISTICS OF QUANTITIES OF PHEROMONE COMPONENTS T1, T2, AND PERCENTAGE OF T1 IN AGGREGATION PHEROMONE BLEND PRODUCED BY INDIVIDUAL MALE *P. truncatus*

	T1	T2	T1[a]
Mean (of each male mean)[b]	1.9 (μg/day)	0.5 (μg/day)	81%
Coef. variation among males[b]	58%	75%	12%
Repeatability among males (r)[c]	0.44	0.49	0.57
Correlation coefficient between day 7 and day 21	0.32 ($N = 15$, NS)	0.57 ($N = 15$, $P < 0.01$)	0.69 ($N = 11$, $P < 0.005$)

[a] Only data where males produced a detectable signal were included.
[b] Using all data from day 5 onwards.
[c] Using data from day 7 to day 21.

No significant correlation ($r = 0.28$, $df = 14$, $P > 0.1$) was found between the rate of total pheromone production and the ratio of the two components among males (Figure 5).

DISCUSSION

During the first three days that male *P. truncatus* were placed on food, rates of pheromone production were below reliably quantifiable amounts in this study

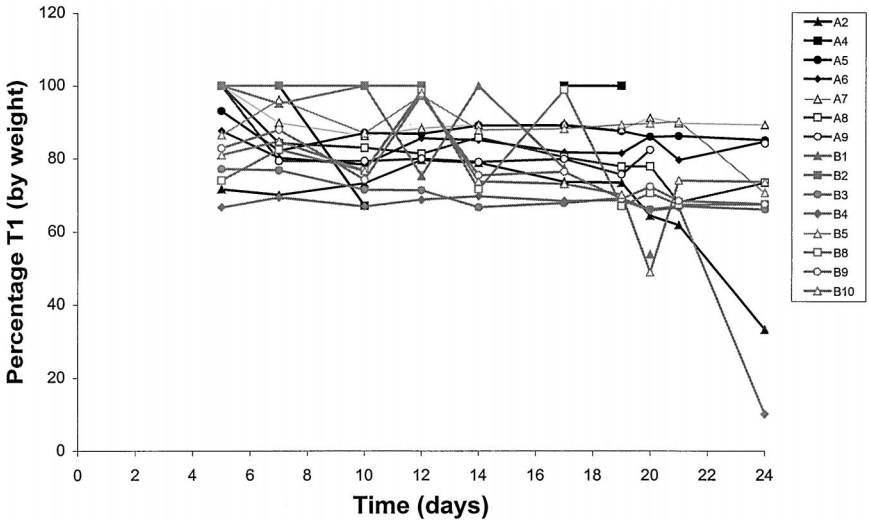

FIG. 4. Percentage of pheromone component T1 in the blend (by weight) plotted individually for each male *P. truncatus* against time.

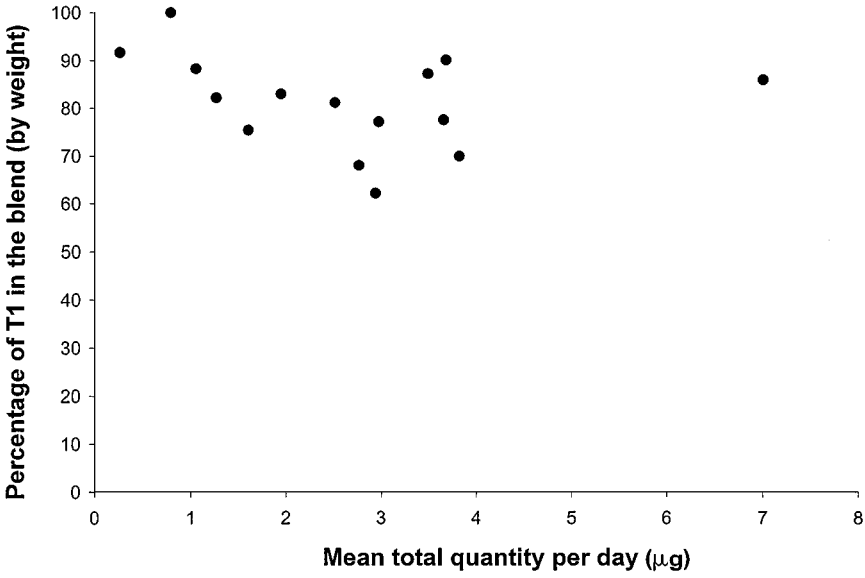

FIG. 5. Mean percentage pheromone component T1 in the blend vs. mean total quantity (T1 + T2) produced per day for each male *P. truncatus* for those days where measurable quantities of pheromone were produced.

($\leq$10 ng/beetle/day). However, bioassay studies have shown that both female and male *P. truncatus* respond to males that have only been present in grain for 24 hr (Hodges and Dobson, 1998); thus, it seems that the beetles respond to quantities of pheromone below our detection limits.

For most beetles, pheromone release extended over the 24 days of the study; however, one male released a single large burst of pheromone in this time. It is possible that this represents an alternative signaling strategy. The average weight of pheromone (T1 + T2) produce by males was 2.4 μg/day, and as the average weight of a beetle is about 3.5 mg (S. Addo, unpublished data), this amounts to 0.06% of body weight. However, in the extreme case, 92 μg was released in a two-day burst. This amounts to a daily rate equivalent to 1.3% of body weight. Little pheromone was produced after the large burst, suggesting that the high energy-costs involved could not be sustained, although this male did not release much more pheromone in two days than several others did in 24 days. If the pheromone burst is indeed an alternative strategy, then presumably the short attraction time is compensated for by the attraction of mates from greater distances. There may be more subtle advantages in avoidance of predation by the histerid beetle *T. nigrescens*, which shows a kairomonal response to *P. truncatus* pheromone (Rees et al., 1990; Boeye et al., 1992). However, this may only be clarified once host location by the predator is better understood.

Intermale variation in aggregation pheromone signaling, as suggested by the behavioral studies of Birkinshaw and Smith (2000), has now been confirmed directly, strengthening their hypothesis that features of the aggregation pheromone signal could be sexually selected. Compared to acoustic or visual signals, direct quantification of individual pheromone outputs are rare (but see Pope et al., 1984; Pavis and Barre, 1993; Miklas et al., 2000; Zhang et al., 2000). Recently, however, the pheromone release from a relative of *P. truncatus*, *Rhyzopertha dominica* (F.) (Coleoptera: Bostrichidae), has been measured (Bashir et al., 2002). The male-produced aggregation pheromone of *R. dominica* also has two components, dominicalure 1 (D1) and dominicalure 2 (D2), and chemical structures are similar to those of T1 and T2 (Williams et al., 1981). Indeed, *P. truncatus* is attracted to traps baited with D1 and D2 (Hodges et al., 1983). Comparing the data sets, *P. truncatus* and *R. dominica* produce pheromone at comparable rates (typically 2–4 μg/day). The percentage of component 1 (D1 or T1) in the blend is lower from *R. dominica* than from *P. truncatus* if the components are compared by weight or in terms of the number of molecules of each. The absolute amounts of T1 and T2 are more variable than those of D1 and D2 reported by Bashir et al. (2002), although their ratios have about the same stability. The more variable values for *P. truncatus* were not attributable simply to the large burst of pheromone release in one of the males. Variation in pheromone outputs among male *R. dominica* has been shown to be connected to differences in the body weight (Bashir et al., 2002). Unfortunately, in the current study, the weight of the male *P. truncatus* was not recorded, although in previous work no link could be demonstrated between the weight of males and the attractiveness of their volatile pheromone signals (Birkinshaw, 1998).

The aggregation pheromone signals of male *R. dominica* are phenotypically plastic and can be altered by placing males on different plant hosts (peanuts compared to maize) and by crowding a male with many females (Bashir, 2000). It is already known that *P. truncatus* males greatly reduce their signal in the presence of females (Smith et al.,1996). The possible influences of plant host type on pheromone release by *P. truncatus* are as yet unknown, although males signaling on cassava were found to be less attractive than those signaling on maize in a walking bioassay (Birkinshaw, 1998).

The next logical step is to link chemical quantification of individual pheromone blends to bioassay data to find out which blends are the most attractive. This was recently attempted in *Rhyzopertha dominica* (Bashir, 2000). However, features of the blends, e.g., the ratio between the components, were not good determinants of responders' choices. However, in the case of *P. truncatus*, there is evidence that the blend is important. Artificial lures holding a total of 2 mg of T1 and T2, at a ratio of 2:1, released a blend that is a closer mimic of the natural pheromone than at a ratio of 1:1. Flight traps loaded with the 2:1 ratio lures captured significantly more beetles (Hodges et al., unpublished data).

Abstract—The first male-produced sex attractant pheromone in the parasitic Hymenoptera has been identified. The elaborate courtship behavior of *Melittobia digitata*, an idiobiont that parasitizes the last larval instar or the pupal stage of solitary bees and wasps, involves a series of coordinated movements of legs, wings, and antennae, initiated after the female is attracted to the blind, flightless male. We identified α- and β-*trans*-bergamotene as the active compounds of the male *M. digitata* sex attractant. Variation in the release of the sex pheromone by males and the pheromone load during aging is also described.

Key Words—Sex recognition, sex pheromone, sesquiterpene, parasitoid, courtship.

INTRODUCTION

Courtship behavior in the parasitic Hymenoptera has been much investigated, focusing especially on the evolution of displays and on reproductive strategies (Matthews, 1975; Assem and Jackmann, 1982; Assem, 1986; Ayasse et al., 2001). In only a few cases have cues eliciting these reproductive behaviors been identified (Quicke, 1997; Kainoh, 1999 for review). Among chalcidoids, courtship typically involves a reciprocal series of movements of the wings, legs, and antennae (Assem and Povel, 1973; Assem and Jackmann, 1982).

Melittobia (Hymenoptera: Eulophidae) is one of these chalcidoids that has been thoroughly investigated (Evans and Matthews, 1976; Assem et al., 1982; Matthews et al., 1985; Gonzalez et al., 1996). All known species are polyphagous, gregarious ectoparasitoids, with a remarkable biology and sexual dimorphism (Dahms, 1984a,b). Females of the second type (short wing morph, SWM) never leave the confines of the host's nest. They will copulate and lay their eggs on the same host on which they developed. These eggs will develop into the type form (long wing morph, LWM or dispersive morph) that typically copulates before dispersing (Dahms, 1984b). Males of *Melittobia* are brown (females are black), blind, flightless, and the antennal scape is markedly differentiated (Dahms, 1984c). *Melittobia* males remain in the host cocoon and wait for the eclosion of their female siblings, with whom they copulate (Dahms, 1984b).

Courtship behavior of *Melittobia* is elaborate, involving a series of alternating movements of different appendages (wing fanning, leg wagging, and antennal rubbing/stroking). After mounting females, males typically fan their wings and wag mid- and/or hind legs while rubbing and clasping the female's antennae with their own antennae (Dahms, 1973; Evans and Matthews, 1976; Assem and Jackmann, 1982; Gonzalez et al., 1996; Guinan et al., 2000).

Unlike the male-oriented response to females as reported for many insects, courtship initiation in *Melittobia* begins with attraction of females to males. Females first contact males, and the response of virgin females to males has been suggested to be due to the presence of a male sex pheromone (Hermann et al., 1974; Gonzalez et al., 1985; Matthews et al., 1985). Interestingly, females also respond to males of different *Melittobia* species in laboratory tests (Matthews et al., 1985), suggesting that even relatively distantly related species might use the same or closely related pheromones.

Although the biosynthesis and endocrine regulation of pheromone production are well studied for some groups of insects, the physiology and chemistry of pheromones in parasitoids have received relatively little attention (Tillman et al., 1999). In the majority of the studies in which a chemical is indicated, the structure(s) is not identified, and in those cases where sex pheromones have been successfully isolated and identified, all have been female-produced (Quicke, 1997; Kainoh, 1999 for review).

Here we report on the identification of a male pheromone of *Melittobia digitata* that attracts females prior to initiation of courtship. We also provide data on the male's pheromone load and rate of release at different ages.

METHODS AND MATERIALS

Insects. Melittobia digitata was reared on blowfly pupae, *Neobellieria bullata* (Diptera, Sarcophagidae) (Carolina Biological Supply), under controlled conditions ($26 \pm 1^{\circ}C$; $60 \pm 10\%$ relative humidity; 14L:10D). Pupae of the host had

the anterior end of the puparium removed with the aid of a surgical blade before they were offered to females of *M. digitata* (one pupa, five females). After development, pupae of the parasitoid were collected and transferred to new vials for eclosion and mating, after which new hosts were offered.

Bioassays. We first tested the response of females of different ages to males. Virgin females from day 1 to 10 after eclosion were released individually into the bottom part of a 5-cm-diam. plastic dish, that was placed upside down on the top of a glass surface. Two circular openings on the lateral side of the dish were plugged with size #1-gelatin capsules (20 mm long $\times$ 6.6 mm diam.) (Electron Microscopy Sciences, Ft. Washington, Pennsylvania, USA). Each gelatin capsule had a small pinhole (1.5 mm diam.) on the end facing the interior of the dish. A single male was placed in one of the gelatin capsules while the other was used as a control. Attractiveness of males to females was measured by counting the number of females entering the male cell after 1 hr of their release. Females were released individually into each arena (25 arenas/age group), and each female was considered as a replicate.

Extraction of Males for Fractionation and Bioassays. Males of *M. digitata* were removed from the rearing containers during the pupal stage and individually transferred to gelatin capsules prior to emergence. After emergence, 0- to 1-day-old males were extracted in ethyl ether (1 μl ether/male) for 1 hr. Samples were collected, transferred to new vials, and stored at -80°C, if not immediately used.

The same testing arena described above was used to test the activity of the male extract, its fractions, and that of synthetic compounds. In these cases, a group of ten 1- to 2-day-old females was released in each plate. The test solution was applied to 3- $\times$ 3-mm squares of Whatman No. 1 filter paper, air dried, and inserted into the gelatin capsule. Ethyl ether was used as control, with 10–22 replicates for each treatment. For the experiments where the extract was tested against different fractions, each square was treated with 2 male equivalents. In experiments where synthetic compounds were compared to the whole male extract, squares were treated with standard volume (given by the area of the peaks in the sample), and the concentration used was later determined by using a known concentration of a synthetic compound as standard (59 ng/square).

Collection of Male Volatiles for Identification. Volatiles released by males of *M. digitata* were collected by using an all-glass collection system with Porapak Q 80/100 (Alltech Associates) as a trapping material. An in-line activated charcoal filter (16 cm $\times$ 4 mm) was used to purify the air before it entered the system. The filter was connected to a male joint by Tygon tubing, and the female joint was connected to the male joint of the collection chamber (100 ml). Both male and female joints (standard ground-glass joint, 14/20) of the collection chamber were plugged with glass wool to prevent insects from leaving this chamber. A second glass tube, containing a microcolumn (collection trap), was connected to

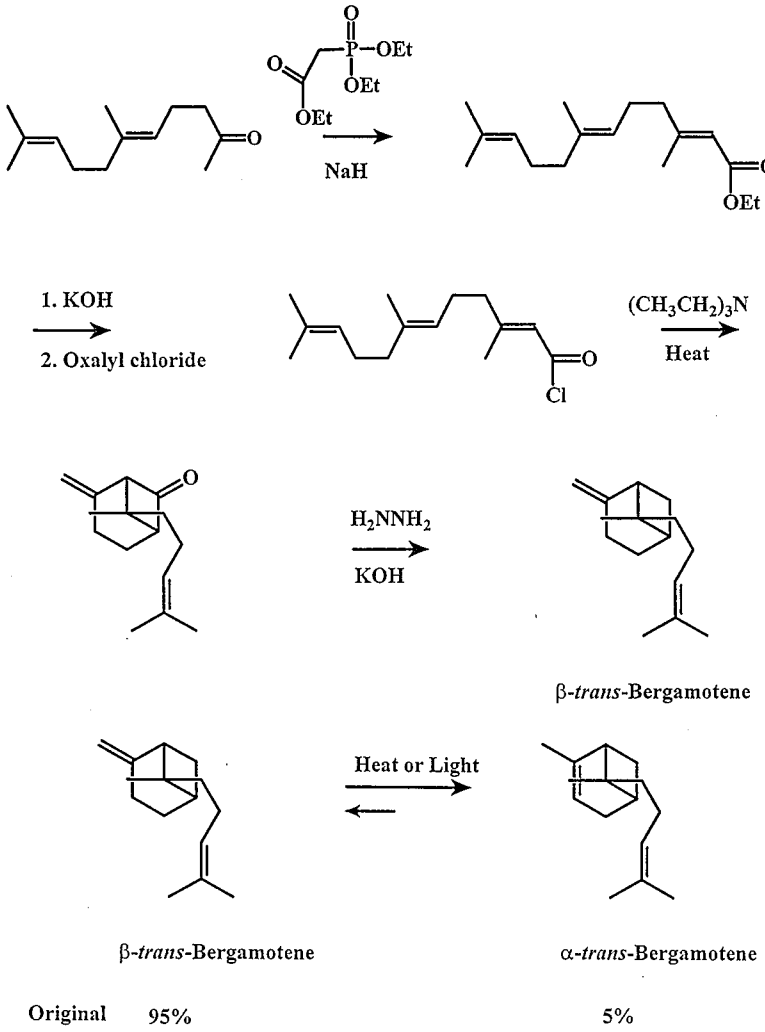
the female joint of the collection chamber. Microcolumns consisted of 6.5-cm-long glass tubes (0.15 mm ID) filled with 12 mg of Porapak Q. Both ends of the tubes were plugged with glass wool, and tubes were rinsed with methylene chloride and ethyl ether before each collection. For each collection, approximately 100 newly emerged males were placed in the collection chamber for 4 days. Air was passed into the system at 20 ml/min. The airflow was measured using a bubble meter, connected to the end of the microcolumn. Columns were washed with 100 μl ethyl ether, and samples were pooled and stored at -80°C before analysis.

GC Analysis and Separation. Samples were concentrated by collecting the desired fractions in an all-glass GC preparative system (Williams and Vinson, 1980) attached to a Varian 3700 GC, equipped with a 3% OV-101 Chrom 750 80–100, 4-m $\times$ 4-mm-ID column (185 to 260°C at 25°C/min). Fractions were collected at specific times after the injection of the sample and were divided as follows: fraction 1, compounds 1–3; fraction 2, compounds 4–8; fraction 3, compounds 9–11 (Figure 2).

Collection for Quantification. Males of known age (1, 2, 4, 6, 8, and 10 days old) were used for quantification of the volatiles released, using a solid-phase microextraction fiber (SPME) (Supelco, Bellefonte, Pennsylvania, USA). Individual variation in the release of the male pheromone of *M. digitata* was measured by isolating single males in a 250-μl glass LV insert (Alltech Associates, Deerfield, Illinois, USA), inside a 2-ml glass vial with Teflon-lined septum screw cap. The SPME was introduced into the insert, and the fiber exposed over 2 hr. After collection, the sample was immediately injected in splitless mode into a HP 6890 GC, equipped with a BP-20 carbowax column (25 m $\times$ 0.25 mm ID) (SGE, Ringwood, Australia) (initial temperature $=$ 50°C for 5 min; to 150°C at 15°C/min; to 185°C at 5°C/min; to 225°C at 20°C/min; 138 KPa He as the carrier gas). Five replications were taken for each age group.

We also assessed the pheromone load and release of groups of five males at different ages, because many single males would not release sufficient volatiles for the detection of both isomers of *t*-bergamotene. Males were placed in 250-μl glass inserts, and the SPME-collected volatiles were analyzed as described before. Three replicates were run for each age group. After collection of the volatiles with SPME, males were extracted in ethyl ether for quantification of the pheromone available at that particular stage (pheromone load). Ten microliters of ether was added to 5 males. After 30 min, the solvent was collected, and the males washed with a second 10 μl of ether. Samples were pooled, and 1 μl was injected into the GC (as above). The amount of α- and β-*trans*-bergamotenes collected with SPME or extracted with ether was calculated by using standards of known concentrations. The values obtained for release (SPME) were compared to those available in tissues of the insect (pheromone load—ether extract), and used to estimate the rate of pheromone release by this species.

GC and GC-MS. Analytical GC was done with Hewlett Packard 5890 or 6890 instruments with column injection and flame ionization detection. Columns used were SGE BP1 and BP20 (25 m × 0.25 mm ID), with helium as carrier gas at 138 KPa. Mass spectroscopy was performed on a Hewlett Packard GC-MS 5989B instrument using a SGE BP1 column (25 m × 0.25 mm ID), temperature programmed at 40°C for 9 min to 280°C at 15°C/min. NMR spectra were acquired on a Bruker ARX-500 instrument by using a 5-mm HCN or 3-mm HBB probe with $CDCl_3$ solvent.



Isolation of α-trans-Bergamotene. *α-trans*-Bergamotene was initially obtained from essential oil of sweet basil, *Ocimum basilicum* (Aura Cacia, Weaverville, California, USA). The essential oil was distilled under vacuum (bp 100–130°C/9 mm Hg) and collected by preparative GC [Varian 3700, with a 3% OV-101 Chrom 750 column (80–100; 4 m × 4 mm ID); 185 to 260°C at 25°C/min].

Synthesis. *α-trans*- and *β-trans*-Bergamotene were prepared by the method of Kulkarni et al. (1987), which consists of reaction of the ylide of triethyl phosphonoacetate with geranyl acetone, followed by saponification, preparation of acid chloride using oxalyl chloride, cyclization by ketene formation with triethylamine in refluxing toluene, and ketone removal using hydrazine with potassium hydroxide (Scheme 1). As was the case for the insect-produced materials, it was found that *α-trans*-bergamotene was produced from the *β-trans*- form on standing (Scheme 1). Synthetic material was purified by the preparative GC described above.

RESULTS AND DISCUSSION

Bioassays. Females of *M. digitata* of different ages were equally attracted to males in our experimental arena (Figure 1), but 10–40% of females did not respond to males. This fact may be explained by the great variability found in the release of pheromone by individual males (see below).

The attractiveness of females to the whole-body extract of males was comparable to that of females that were offered males instead (Figures 1 and 3). We were able to detect 11 different volatiles released by males of *M. digitata* (Figure 2). Two fractions of the male pheromone were as attractive to females as the whole male extract (Figure 3). Purification of active components by preparative GC and analysis by GC-MS and NMR produced a definitive identification of *α-trans*-bergamotene (peak 1) and *β-trans*-bergamotene (peak 4). The spectral properties of synthetic materials were identical to those of the insect-released compounds and to literature values of Snider and Beal (1988) and Kulkarni et al. (1987) for the α and β forms respectively. *α-trans*-Bergamotene MS (m/z, %) = 204 (2.6), 119 (100.0), 93 (92.6), 69 (54.9), 91 (47.3), 107 (45.3), 105 (37.0), 55 (36.3), 79 (33.1), 120 (27.8); ^{1}H NMR (δ) 5.23 (br s, vinyl), 5.19 (br t, vinyl), 1.72, 1.68, 0.85 (CH_3); ^{13}C NMR (δ) 144.5 (s), 131.0 (s), 125.3 (d), 116.5 (d), 45.4 (d), 41.2 (s),

The retention times of synthetic bergamotenes and insect-related compounds were indistinguishable on a BP-1 column (35°C for 1 min, to 155°C at 15°C/min, to 185°C at 5°C/min, to 220°C at 20°C/min): synthetic α-*trans*-bergamotene and insect-related compound 1 (Figure 2) = 8.7 min; synthetic β-*trans*-bergamotene and insect-related compound 4 (Figure 2) = 9.1 min, and in between C_{14} (8.5 min) and C_{15} (9.4 min) standards; and on a BP-20 column (35°C for 1 min, to 155°C

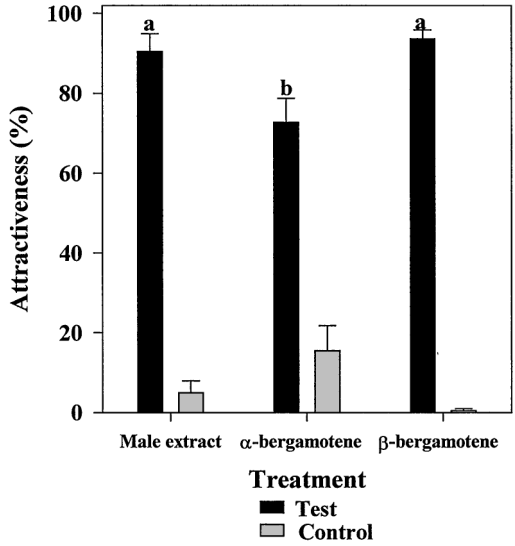

FIG. 4. Response (%) of *M. digitata* females to the synthetic isomers of *trans*-bergamotene identified in the male pheromone blend (Bars followed by the different letters are significantly different by the SNK method, $P < 0.05$; Kruskal-Wallis: $H = 13.67$; $df = 2$; $P = 0.001$, $N = 22$).

at 15°C/min, to 185°C at 5°C/min, to 225°C at 20°C/min): retention time of synthetic α-*trans*-bergamotene and insect-related compound 1 (Figure 2) was 9.2 min, and synthetic β-*trans*-bergamotene and insect-related compound 4 (Fig. 2) had a retention time of 10.13 min, both in between C_{16} (9.17 min) and C_{17} (10–18 min) standards.

Synthetic α-*trans*- and β-*trans*-bergamotene were both attractive to females of *M. digitata*, but α-bergamotene was not as active as the β isomer (Figure 4). Dilution tests of these compounds and the whole extract of males of *M. digitata* showed no difference in the activity between α- and β-bergamotene, but α-bergamotene was always less active than the male extract (Table 1).

Pheromone Release. There is a great variability in the release of pheromone among males of *M. digitata* of the same age, especially at those ages with the highest release rate (Figure 5). Pheromone release was low soon after male emergence (3.9 ng/2 hr), peaking 18.6 ng/2 hr, two days after emergence, and decreasing to only 4.3 ng/2 hr at the end of their life (Figure 5). Release of the male pheromone of *M. digitata* decreases with aging after peaking at the second day after male emergence (Figure 6A) and follows the changes in the pheromone load (Figure 6B). When comparing the amount of pheromone released (Figure 6A) with the amount of pheromone extracted from tissues of the insect (pheromone

TABLE 1. RESPONSE OF VIRGIN FEMALES OF *Melittobia digitata* TO DILUTIONS OF MALE EXTRACT, α-*trans*-BERGAMOTENE AND β-*trans*-BERGAMOTENE (INITIAL CONCENTRATION = 59 NG)

Sample	Female response (%, mean ± SE)[a]			
	5.9 ng	0.59 ng	0.06 ng	Mean
Male extract	79.3 ± 5.6	66.1 ± 8.6	36.9 ± 8.9	60.8 A
α-*trans*-Bergamotene	60.0 ± 9.1	28.5 ± 9.5	10.8 ± 4.0	33.1 B
β-*trans*-Bergamotene	63.8 ± 8.6	54.6 ± 10.2	25.4 ± 7.0	47.9 AB
Mean	67.7 A	49.7 B	24.4 C	

[a]Means in the same column or row followed by the same letters are not statistically different by using Tukey test ($P < 0.05$) (two-way ANOVA: dilution: $F = 21.4$; $df = 2, 116$; $P < 0.001$; Treatment: $F = 8.6$; $df = 2, 116$; $P < 0.001$; Interaction: $F = 0.5$; $df = 4, 116$; $P = 0.706$).

load, Figure 6B), it was also observed that the pheromone is released soon after synthesis as the male ages. *M. digitata* males 1–4 days-old released 14.8–24.4% of their pheromone load in 2 hr, while older males (6–10 days-old) released 91.6–213.0% of the pheromone they had available (Figure 6A,B), which indicates older males release their pheromone as soon as the pheromone is produced. The β isomer is converted to the α isomer on standing, but the α isomer is always present, indicating lack of regio specificity by the sesquiterpene synthase as noted in previous

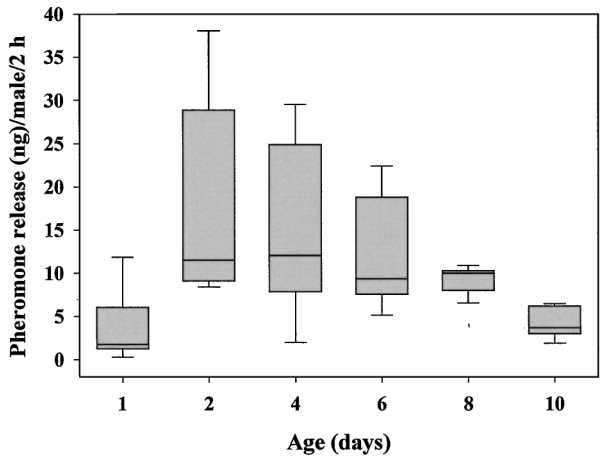

FIG. 5. Pheromone release by *M. digitata* males of different ages. Pheromone is expressed as the sum of α- and β-*trans*-bergamotenes; boxes represent 25th and 75th percentiles, lines within the boxes mark the median, whiskers above and below the boxes indicate the 90th and 10th percentiles.

studies of isolated enzyme (Huang et al., 2000; Benedict et al., 2001). The ratio of α- and β-bergamotene remained constant at approximately 5:95 over the lifespan of these males (data not shown).

Although α- and/or β-*trans*-bergamotenes have been reported from a variety of plants, these chemicals are mostly described as minor components of their sesquiterpene fraction (Minyard et al., 1966; Bestmann et al., 1988; Leitão et al.,

1991; Njoroge et al., 1996; Sanda et al., 1998; Pino et al., 2000). They can be found as major components in a few exceptions, such as in the oil of *Lansium anamay-alanum* (Krishnappa and Dev, 1973). However, α-*trans*-bergamotene is the isomer most commonly reported in essential oils from plants, with the β isomer being more rare (Minyard et al., 1966; Bestmann et al., 1988; Flath et al., 1994a,b; Kite and Leon, 1995; Asekun and Ekundayo, 2000). α-*trans*-Bergamotene was also reported as a component of the volatiles released by corn plants in response to the attack of herbivores, but it did not seem to play any role in the response of the third trophic level (Turlings et al., 1991). This chemical has also been identified as one of the components in Angelica seed oil, which is attractive to males of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedmann) (Diptera: Tephritidae) (Flath et al., 1994a). However, further tests demonstrated that α-*trans*-bergamotene was not attractive to males of this fly (Flath et al., 1994b). Furthermore, α-*trans*-bergamotene has also been described as a minor component among the nine volatiles of the male pheromone of the fruit flies, *Anastrepha suspensa* (Loew) and *A. ludens* Loew (Diptera: Tephritidae) (Rocca et al., 1992), but there is no evidence that this component plays any important role in the attractiveness of females of these flies.

This is the first demonstration that males of *M. digitata* produce and release a pheromone attractive to females and the first to chemically identify male-produced pheromone in the parasitic Hymenoptera. β-*trans*-Bergamotene was identified as the main compound of this pheromone, and the β isomer was as active as the whole male extract (Figure 4). The α isomer is also active but, no synergism was noted (data not shown).

Melittobia spp. develop, emerge, and mate within the cocoon of their host. Therefore, the pheromone is probably effective only over a very short range. Matthews et al. (1985) previously discussed the role of the male pheromone as either an aggregation or a sex pheromone and concluded that it would be a sex pheromone in that it appears to function to aggregate and/or arrest virgin females inside the host's cocoon. Mated females and other males do not respond to the male pheromone.

For *M. digitata*, the male pheromone is undoubtedly important for the initiation of courtship, but it may not lead to sex recognition. Rather, the male sex pheromone seems to be the first signal in a series of cues leading to sex recognition and ultimately copulation in this species. Its lack of specificity was suggested by the fact that females would also respond to males of other *Melittobia* species (Matthews et al., 1985).

We have also observed the courtship behavior of *M. digitata*, *M. femorata*, and *M. australica* by exposing virgin females to interspecific males. Although these females were initially attracted to nonconspecific males, they rejected them at very close distances or soon after antennal contact (unpublished data). Males, on the other hand, attempted to copulate with any female, and they engaged in courtship behavior if they managed to mount them. Females avoided interspecific males by

moving away but, in those cases where females were mounted, they restricted antennal contact by folding their antennae against the head (antennal contact is a characteristic of *Melittobia* courtship) or by actively trying to dislodge the males from their backs (unpublished data). These behaviors suggest that *Melittobia* may use at least one other chemical cue for sex recognition, probably a contact or a short-range pheromone.

We have shown that the release of pheromone by *M. digitata* males and the attractiveness of single females to males were quite variable. These results, combined with the fact that females have been shown to prefer certain males over others and that the preference is often maintained in subsequent tests, contribute to the hypothesis that this pheromone can also be used by females as a basis for mate selection. Birkinshaw and Smith (2000) demonstrated that the aggregation pheromone of *Prostephanus truncatus* (Coleoptera: Bostrichidae) was also used during the process of sexual selection. These authors argued that phenotypic variability in pheromone production could be a possible mechanism enabling females to make choices among possible mates.

The male-produced pheromone could also have a role in the fitness of females. Due to their haplodiploid method of sex determination, Godfray (1994) postulated that females of parasitoid wasps would be less likely to invest energy in the production of a sex pheromone since they have the ability to reproduce without insemination. He argued that natural selection should favor the capability of producing pheromones if the production of both sons and daughters would be advantageous. *Melittobia* females fit this prediction and do not invest in sex pheromones. However, *Melittobia* males do allocate part of their energy to pheromone production. Because males are flightless, mating at locations other than the host cocoon is unlikely. Females that disperse to search for hosts without mating would be at a fitness disadvantage compared to mated females competing for a host since female offspring production would be compromised. Thus, a male pheromone that promotes early insemination might be advantageous for females.

Abstract—*Phaseolus vulgaris* L. cv. 'Pinto' bean is a local lesion host for the plant pathogen Southern bean mosaic virus (SBMV) and its vector is the Mexican bean beetle, *Epilachna varivestis* Mulsant. The objective of this study was to determine if prior feeding by the beetle would affect 'Pinto' bean's resistance to SBMV and determine if ribonuclease (RNase), a major constituent of beetle regurgitant, mediated the plant's response to the virus. 'Pinto' bean plants fed upon by beetles had increased resistance to plant viruses compared to non-wounded or mechanically wounded and buffer-treated plants. Plants that were mechanically wounded and treated with RNase had increased resistance to plant viruses that was equal to plants fed upon by adult beetles. The induction of plant pathogen defenses could be a good adaptation for the plant in the presence of a beetle and pathogen threat. This evidence suggests that RNase activity in the beetle regurgitant could function as an insect-derived elicitor of plant resistance to viruses.

Key Words—Saliva, induced resistance, vector, virus, systemic acquired resistance, elicitor, ribonuclease, RNase, regurgitant.

INTRODUCTION

Only recently have characterized oral secretions from insects been determined to alter plant defenses beyond mere mechanical wounding (Mattiacci et al., 1995; Alborn et al., 2000; Musser et al., 2002). Three characterized components of caterpillar oral secretions have been identified that elicit or alter plant defenses, all of which are found in herbivorous caterpillars. These elicitors of plant defenses include β-glucosidase in *Pieris brassicae*, volicitin in *Spodoptera exigua* (Mattiacci et al., 1995; Alborn et al., 2000), and glucose oxidase (GOX) in *Helicoverpa zea* (Felton and Eichenseer, 1999; Eichenseer et al., 1999; Musser et al., 2002).

Regurgitant from insects can stimulate anti-herbivore defenses, plant growth, and phytopathogen resistance (Felton and Eichenseer, 1999). The elicitors β-glucosidase and volicitin have been determined to stimulate anti-herbivore defenses (Mattiacci et al., 1995; Alborn et al., 2000. However, GOX has been found to play a role in the suppression of induced anti-herbivore defenses for *H. zea* (Musser et al., 2002). Tobacco plants fed upon by caterpillars with the ability to secrete saliva had lower levels of nicotine than those tobacco plants fed upon by caterpillars that could not secrete saliva because of cauterized spinnerets (Musser et al., 2002). Glucose oxidase also appears to be an elicitor of plant pathogen defenses. Treatment of wounded soybean plants with GOX reduced the severity of the bacterial disease, *Pseudomonas syringae* pv. *glycinea*, and induced an increase in the phytoalexin daidzein (a marker of systemic acquired resistance) when compared to wounded plants treated with a buffer (Felton and Eichenseer, 1999).

Until now, there was no published evidence that RNases may function as herbivore salivary elicitors of plant defenses. However, exogenous application of RNase increases the resistance of tobacco plants to fungal infection (Galiana et al., 1997). In addition, RNases appear to be induced locally and systemically in wounded *Arabidopsis* plants independent of jasmonate wound signaling as well as salicylic acid found in plant-pathogen defenses (LeBrasseur et al., 2002). RNase has also been shown to play a role in the transmission of plant viruses by beetles (Gergerich et al., 1986). Regurgitant of the Mexican bean beetle, *Epilachna varivestis* Mulsant, contains high levels of RNase (2600 Kalnitsky units; equivalent in activity to 1 mg/ml) (Gergerich et al., 1986). High levels of RNase activity in Mexican bean beetle regurgitant inhibit transmission of non-beetle vectored plant viruses. When these non-beetle transmittable viruses are applied to the beetle in regurgitant during natural feeding, or when regurgitant or RNase is mixed with the viruses and applied to a mechanically wounded plant, the plants do not become infected. Beetle vectored viruses are able to infect plants despite the presence of RNase in beetle regurgitant (Gergerich et al., 1983, 1986). Southern bean mosaic virus (SBMV) is a virus that is vectored by the Mexican bean beetle, and is capable of being transmitted in the presence of RNase in the inocula used in mechanical wounding (Gergerich et al., 1983, 1986). The objective of this study was

to determine whether the RNase that is present in the regurgitant of the Mexican bean beetle might induce systemic resistance to SBMV.

METHODS AND MATERIALS

Plants and Insects. *Phaseolus vulgaris* L. cv. 'Pinto' seeds were sown in 4-L plastic pots containing Redi Earth Peat-Lite Mix, a potting soil mixture (Scott-Sierra Horticulture Products Company, Marysville, OH). Plants were grown in a greenhouse with a 14-hr photoperiod, using natural light conditions and high pressure sodium lights (1000 W), and day and night temperatures between 33°C and 25°C. Plants were watered daily and fertilized weekly (N:P:K = 15:30:15, American Plant Food Company, Creve Coeur, MO). Mexican bean beetles were reared from eggs obtained from Charles Helms (University of Illinois). The beetle colony was maintained on 'Pinto' bean, a local lesion host for SBMV.

Viruses. SBMV was maintained in 'Black Valentine' bean, a systemic host for this virus. Approximately once every two weeks, virus was transferred by mechanical rub-inoculation to healthy seedlings that had been dusted with carborundum. Purification of SBMV from 'Black Valentine' bean was performed in a manner described by Gergerich et al. (1983).

Beetle Feeding Experiment to Test Plant Susceptibility to Virus Infection. Seedling 'Pinto' bean plants (9 days old) with fully expanded primary leaves were fed upon by a single adult Mexican bean beetle caged on one of the primary leaves for 24 hr. The clip cage composed of two, 4-cm diameter medicine-cups, held together by a hair clip. 'Pinto' bean plants were also mechanically wounded with a 4-cm^2 garlic press on one primary leaf. Half of these mechanically wounded plants were treated with 0.01 M potassium phosphate buffer, pH 7.0; the other half were treated with 1 mg/ml ribonuclease A (RNase A, Qiagen Valencia, CA) diluted in the buffer. Mexican bean beetle regurgitant contains RNase activity and substrate specificity similar to 1 mg/ml of RNase A (Gergerich et al., 1986). The mechanically wounded area was caged with a clip cage. As a control treatment, non-wounded plants had a clip cage attached to one primary leaf. After 24 hr, the cages and beetles were removed and plants were given a 48-hr recovery period. The opposite seedling leaf was then mechanically inoculated with SBMV in the manner described above. The leaf was inoculated with a 10^{-4} dilution of a purified SBMV preparation (22 mg/ml) in 0.01 M potassium buffer, pH 7.0. Five days later, the local lesions on the inoculated leaf were counted. To aid in the consistency of lesion counting between leaves, the lesions were counted in three 1-cm^2 squares directly adjacent to the mid-vein. Each replication consisted of ten random plants for treatment with seven replications. The mean lesion number for the experiment was compared with a Fisher's least significant differences (LSD) test in a one-way ANOVA with JMP.

RESULTS AND DISCUSSION

'Pinto' bean seedlings that were fed upon by the Mexican bean beetle, or mechanically wounded and treated with RNase had significantly fewer local lesions (>20% less) than non-wounded and mechanically-wounded plants without RNase (Fisher's LSD; Figure 1). Non-wounded and mechanically-wounded plants had similar levels of local lesions and were not significantly different from each other; but there was a trend towards more local lesions for the non-wounded bean plants. However, this is not the first example of beetle feeding reducing infection rates in plants. Beetle feeding on *Rumex obtusifolius* has been shown to reduce the rate of infection by fungal pathogens (Hatcher and Paul, 2000).

'Pinto' bean plants are systemically more resistant to SBMV following Mexican bean beetle feeding as indicated by a reduction in local lesions on bean leaves. Upon infection of SBMV or bean pod mottle virus (BPMV), the 'Black Valentine' cultivar may develop whole plant infection, while the 'Pinto' cultivar only forms local lesions. In general, the difference between the pathogen-resistant cultivars and non-resistant cultivars appears to be due to the speed and strength of induction of the systemic acquired resistance pathway (SAR) (Morris et al., 1998). However, additional experiments have demonstrated that beetle feeding increases systemic resistance for BPMV in 'Black Valentine' bean plants (Musser,

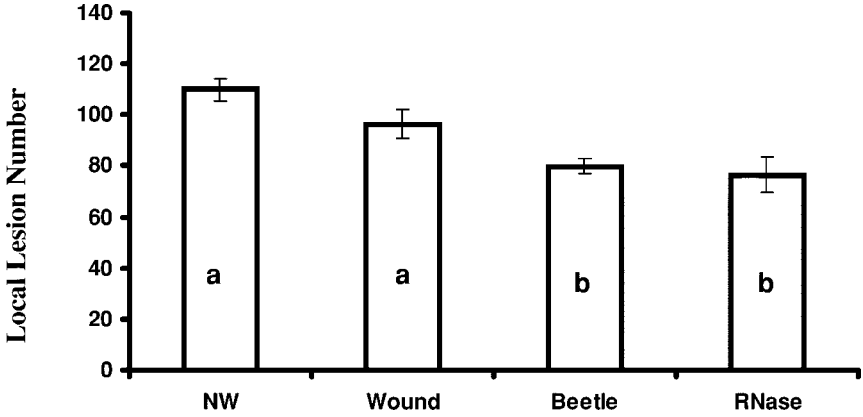

FIG. 1. Reaction of 'Pinto' bean plants to SBMV inoculation after beetle feeding or treatment of mechanical wounds treated with RNase or buffer. Lesion number is the total number of local lesions in three 1-cm^2 squares on the inoculated leaf. Different letters represent statistically significant differences between treatments at $P < 0.05$. Bars indicate mean $\pm$ s.e. Legend: NW = untreated bean plants, Wound = mechanically wounded leaf treated with buffer, Beetle = leaf fed upon by beetle, and RNase = mechanically wounded leaf treated with RNase.

unpublished data). Although the bean plant exhibits systemic resistance to the beetle vectored virus, it does not appear that RNase is linked to SAR formation (LeBrasseur et al., 2002).

Ribonuclease activity is found in the Mexican bean beetle regurgitant at high levels (Gergerich et al., 1983, 1986). 'Pinto' bean leaves that were wounded and treated with RNase had stimulated virus resistance that was active at least three days after wounding. This evidence suggests that RNase activity in the regurgitant of the Mexican bean beetle functions as an elicitor of plant pathogen defenses. For bean plants, insect feeding and RNase could be a reliable predictor of impending pathogen infections. From an evolutionary perspective, this could be considered a good adaptation for the bean plant to increase resistance to virus infection when confronted by an insect and pathogen threat. Interestingly, the RNase present in beetle regurgitant has been shown to inhibit infection of most plant viruses when the viruses are deposited by the beetle in regurgitant during feeding (Gergerich et al., 1983, 1986). Thus, the induction of resistance on a systemic level can be regarded as a second line of defenses against those viruses that are beetle transmissible, i.e., the viruses that are able to infect a plant in spite of the presence of RNase in beetle regurgitant.

Ribonuclease found in the beetle regurgitant appears to have elicitor qualities in plant resistance to viruses. However, it has yet to be determined if RNase activity in the beetle regurgitant effects anti-herbivore defenses of plants, and what function RNase activity in the regurgitant has for the beetle. This study further demonstrates the need to understand the biochemical constituents of insect oral secretions in the elicitation of induced plant defenses.

Acknowledgments—We thank Shaun Steele, Jon Smith, John Goff, Spencer Williams, and the 2000 and 2001 students of the Upward Bound Math and Science Academy for their assistance in performing this research. Partial funding for these experiments was supported by the Arkansas Agricultural Experiment Station.

DO EURASIAN BEAVERS SMEAR THEIR PELAGE WITH CASTOREUM AND ANAL GLAND SECRETION?

FRANK ROSELL*

Faculty of Arts and Sciences, Department of Environmental and Health Studies, Telemark University College, N-3800 Bø in Telemark, Norway

Department of Zoology, Norwegian University of Science and Technology, N-7491 Trondheim, Norway

(Received May 10, 2002; revised June 17, 2002; accepted July 8, 2002)

Abstract—The scent-matching hypothesis postulates that scent marks provide an olfactory link between a resident owner and his territory, and that this enables intruding animals to recognize the chance of escalated conflicts. However, it is unclear if Eurasian beavers (*Castor fiber*) mark their own pelage with castoreum from their castor sacs (i.e., the same material used in territorial marking); and/or if beavers mark their pelage with anal gland secretion (AGS) from the anal glands to waterproof the pelage and to act as a "living-scent mark." Chemical analysis (gas chromatography and mass spectrometry) of hair samples from 22 live-trapped beavers revealed that castoreum compounds were not present in any samples, AGS compounds were found from 3 animals (13.6%) around the cloaca, and the compound squalene was found in all the samples. Beavers may release castoreum directly into the water when it meets an intruder. Thereby, the "scent mark" in the water can provide an olfactory link between a resident owner and his territory. Squalene, in contrast to AGS, may be essential for keeping beaver pelts water-repellant.

Key Words—Beaver, *Castor fiber*, anal gland secretion, castor sacs, castoreum, pelage, GC-MS, hair, squalene, Norway.

INTRODUCTION

The scent-matching hypothesis postulates that scent marks provide an olfactory link between a resident owner and his territory, and that this enables intruding animals to recognize the chance of escalated conflicts. If the smells match, then the animal that the intruder has met must be the territory owner. If the hypothesis were

true, one would expect owners to (1) mark where intruders are most likely to encounter marks; (2) mark themselves with the substances used to mark the territory; (3) make themselves available for scent matching by intruders; and (4) remove or replace marks of others (Gosling, 1982).

All family members of Eurasian beavers (*Castor fiber*), except kits less than five months old, participate in marking the territory at scent mounds close to the water's edge (Wilsson, 1971; Rosell, 2002). Predictions 1, 3, and 4 for the scent-matching hypothesis have all received some support for the Eurasian beaver (Rosell, 2002). However, prediction 2 needs to be further clarified. Castoreum (primarily a mixture of secondary metabolites from urine) i) is the main scent signal used in the defense of beaver territories during winter (Rosell and Sundsdal, 2001). However, the anal gland secretion (AGS) may function to waterproof the pelage. Excision of the anal glands seems to reduce the ability of the pelage to repel water (Walro and Svendsen, 1982). Prohibition of autogrooming in Eurasian beaver produces similar results (Wilsson, 1971). AGS may also act as a chemical messenger in the water territory sensed through close range or contact with the animal (Rosell, 2002).

The aim of this study was to investigate and to search for characteristic chemical compounds from the castor sacs and the anal glands in the beaver pelage in an attempt to clarify if (1) beavers mark themselves with castoreum from their castor sacs i.e., the same material used in territorial marking; and/or if (2) beavers mark themselves with AGS from the anal glands to waterproof the pelage and to act as a "living-scent mark."

METHODS AND MATERIALS

Study Area and Animals. Twenty-two beavers were live-trapped (15 males and 7 females) from 9 different territories during June 2 to August 18, 2000, by using landing nets in the municipalities of Nome and Sauherad in Telemark County, Norway. Beavers were from different age-classes (1−>6 years old), weight varied from 3–24.5 kg, and they were trapped between 2100–0230 hr (see Rosell and Hovde, 2001 for further details about handling, sex, and age determination).

Sample Collection. Hair samples were collected from 3 different places on the beavers: 1) at the back just above the scaly tail, 2) around the cloaca, and 3) on the belly. Samples were collected using clean scissors. I cut off hair onto a sheet and thereafter stored it in a 100 ml glass vial. After each sampling, the scissors were cleaned with alcohol and dried with a propane gas burner.

I collected castor sacs and anal glands from 60 animals shot locally during the normal hunting season from 28 January–6 May 1997–99 and used the castoreum and AGS from these animals as the basis for comparison with possible castoreum and AGS compounds present in the hair samples. See Rosell and Sundsdal (2001)

for a review of types of compounds found in castoreum and AGS. All samples were stored at -20°C until chemically analyzed (for further details see Rosell and Sundsdal, 2001).

Sample Preparation. Hair samples (0.15 g) were extracted overnight in 10 ml toluene. The solutions were filtered in a glass funnel with Schleicher & Schuell 595 paper filter. Thereafter, the hair was squeezed as dry as possible with a glass rod on the filter. The solutions were evaporated to a volume of 0.25 ml in a Heidolph VV 2011 rotary evaporator to concentrate the solution. See Rosell and Sundsdal (2001) for preparation of AGS and castoreum.

Chemical Analysis. One μl of the resulting solution was injected into a Hewlett-Packard 6890 Series II gas chromatograph equipped with a nonpolar HP-5 MS 5% phenyl-methyl-siloxane column (30.0 m $\times$ 0.25 mm ID $\times$ 0.25 μm film thickness) installed in a Hewlett-Packard 5973 Series mass spectrometer detector with a split/splitless inlet used in the splitless mode (for further details see Rosell and Sundsdal, 2001). The main focus of my study was to determine if the beavers had castoreum and/or AGS in their pelage. Therefore, positive identification of the compounds was not attempted, i.e., comparison with a known standard was not done. However, the compound squalene was positively identified (see results/ and discussion). Rosell and Sundsdal (2001) showed that this method worked well to detect compounds from the castoreum and the AGS in scent marks on snow.

RESULTS AND DISCUSSION

I found no compounds from the castor sacs on the pelage, which suggests that beavers do not mark themselves with castoreum. However, it is well known that beavers urinate into the water, i.e., release castoreum (Wilsson, 1971). They also release castoreum when frightened, e.g., when captured and handled (personal observation). Beavers may have adopted an alternative strategy, i.e., they may release castoreum directly into the water when they meet an intruder. Thereby, the "scent mark" in the water can provide an olfactory link between a resident owner and his territory, and this will enable an intruding animal to gauge the chance of escalated conflicts.

Compounds from the anal glands were found in 3 of 22 animals (13.6%) but only around the cloaca area (1 (male, 3 years old), 8 (male, >5 years old) and 19 (female, 4 years old) compounds, respectively). This suggests that beavers do neither mark themselves with AGS to waterproof the pelage, nor act as a "living scent mark." Wilsson (1971) was not able to observe that the beaver systematically touched the opening of the anal glands or the area around these during grooming. For the Eurasian beaver, the AGS is a thick paste of a greyish color in females, and is an oily fluid with a whitish or pale straw color in males. For the North American beaver (*C. canadensis*), the AGS of the two sexes show also a consistent difference

regardless of age: it is brown and viscous in males, but it is whitish or light yellow and runny in females (see Rosell and Sun, 1999). Obviously, the viscous secretion of the Eurasian female and the North American males would make the pelage sticky and would lessen water repellency of the pelage. The differences in viscosity between the sexes make it also unlikely that the anal glands have been developed to waterproof the pelage.

The sebaceous glands in the skin of mammals produce lipid mixtures (sebum) which coat the skin and hair. A relative minor contribution to this lipid film is made by the lipids arising from the keratinized cells of the epidermis (Lindholm et al., 1981). The results from this study showed that the hydrocarbon squalene ($C_{30}H_{50}$) was positively identified in all the hair samples. Squalene is also found in the skin surface lipids of the North American beaver (Lindholm and Downing, 1980). Therefore, when beavers groom, the pelage is cleaned, the hair shaft is aligned, maintaining maximum loft, and the hairs are probably oiled with the aid of squalene, which reduces water permeability. This could explain why prohibition of autogrooming in Eurasian beaver reduced the ability of the pelage to repel water (Wilsson, 1971). In addition to the natural lipid squalene, the density of the underfur (23 000 cm^{-2} on the ventral and 12 000 cm^{-2} on the dorsal surface), the guard hairs, and the surface tension of the water help to prevent water from penetrating to the skin (Novak, 1987). Thus, squalene, in contrast to AGS, may be essential for keeping beaver pelts water-repellant.

Acknowledgments—I thank Bjørnar Hovde for his excellent help in the field, Bjørn Steen for help with the chemical analyses, and Dr. Howard Parker for comments on an earlier draft. The study was supported financially by Telemark University College, Bø, Norway.

Abstract—Broad bean plants (*Vicia faba*) infested by the pea aphid, *Acyrthosiphon pisum*, play a key role in the in-flight orientation of the parasitoid *Aphidius ervi*, by producing host-induced synomones (HIS). These volatiles are herbivore-specific and are systemically released from insect-free parts of an infested plant, suggesting the existence of an elicitor circulating throughout the plant. This study was designed to investigate whether the plant metabolic changes, leading to HIS biosynthesis and emission, can in some way trigger similar responses in neighboring plants through aerial and/or root communication. Uninfested broad bean plants maintained in the same pot together with plants infested by *A. pisum* became more attractive towards *A. ervi* females when tested in a wind-tunnel bioassay. This change was not observed when root contact was prevented among plants that had their aerial parts in close proximity, suggesting that an exudate from the roots of the infested plant may cause the induction of the attractive volatiles in uninfested plants. Broad bean plants grown hydroponically also produce pea aphid induced signals that attract *A. ervi*. When an intact (uninfested) plant was placed in a hydroponic solution previously used to grow a pea aphid-infested plant, it became attractive to parasitoids, while an intact plant placed in a solution previously used to grow an intact plant did not undergo such a change.

These results indicate that plant-to-plant signaling in this tritrophic system may occur at the rhizosphere level and is most likely mediated by a systemically translocated elicitor.

Key Words—Synomones, phytopheromones, wind tunnel, flight behavior, Aphidiinae, Aphididae.

INTRODUCTION

Plants use different ways of defending themselves against herbivorous arthropods. Recruiting natural enemies of herbivores by releasing attractive volatiles appears to be a widespread phenomenon that has been referred to as indirect defense to distinguish it from the direct defense that a plant displays in the form of structures or metabolites reducing or inhibiting herbivore attack (Dicke, 1999). In most cases, the emission of attractive volatiles is triggered by the feeding activity of herbivores. These volatiles are commonly referred to as herbivore-induced synomones (HIS), to stress the mutual benefit gained by both plants and natural enemies (see Vet and Dicke, 1992 for detailed references), although some scientists remain sceptical about the real benefits obtained by the plant (Meijden and Klinkhamer, 2000).

A considerable degree of blend specificity has been convincingly demonstrated in a number of tritrophic systems (for review see Dicke and van Loon, 2000). Furthermore, in many cases, it has been shown that these volatiles are systemically emitted by the plant, and tissue damage at the emission site is not required (Turlings and Tumlinson, 1992; Dicke, 1994; Potting et al., 1995; Röse et al., 1996). The volatile blends emitted in response to herbivore feeding are often different from those induced by mechanical damage (Turlings et al., 1995; Takabayashi and Dicke, 1996). Herbivore oral secretions have been shown to elicit this specific plant reaction when applied to mechanically damaged plant tissues or systemically delivered to the plant (for review see Dicke and van Loon, 2000). The role of these elicitors in activating the signal transduction pathways triggering the biosynthesis of HIS has been partly elucidated and, to date, two herbivore-derived elicitors have been identified from two different caterpillar species (Mattiacci et al., 1995; Alborn et al., 1997; for review see Walling, 2000). However, the elucidation of the ecological role of these substances within complex natural food webs is still in its infancy.

The foraging behavior of the aphid parasitoid *Aphidius ervi* Haliday (Hymenoptera: Braconidae) has been investigated intensively in recent years, elucidating the role of semiochemicals associated with both first and second trophic levels (Guerrieri et al., 1993, 1997, 1999; Du et al., 1996, 1997, 1998; Powell et al., 1998). It has been demonstrated that the plant plays a key role in the in-flight orientation of this parasitoid by emitting HIS (Guerrieri et al., 1993; Du et al.,

1996). Furthermore, these volatiles are herbivore-specific and are produced when a certain threshold of infestation, in terms of number of aphids and hours of feeding activity, has been reached (Du et al., 1996; Guerrieri et al., 1999). Finally, it has also been demonstrated in this system that the synomones are systemically released from insect-free parts of the infested plant, suggesting the existence of an elicitor circulating throughout the plant (Guerrieri et al., 1999).

This study addresses whether the plant metabolic changes leading to HIS biosynthesis and emission can in some way trigger similar responses in neighboring plants through aerial and/or root communication. Plant-to-plant communication remains a difficult issue to deal with (Chamberlain et al., 2001), especially in the context of phytopheromones (Pickett and Poppy, 2001), but tritrophic systems and their complexity may offer interesting experimental opportunities to analyze this intriguing phenomenon from a new perspective.

METHODS AND MATERIALS

Experimental Animals

A. ervi was reared on its natural host *Acyrthosiphon pisum* (Harris) (Homoptera: Aphididae), maintained on potted broad bean plants (*Vicia faba* L., Angiospermae: Leguminosae, cv. Aquadulce). Aphid and parasitoid cultures were kept in separate environmental chambers at $20 \pm 1^{\circ}$C, $65 \pm 5\%$ relative humidity, 18L:6D photoperiod. The parasitoid culture was periodically refreshed by adding adults emerging from field collections of *A. pisum* mummies.

Insect parasitoids used in the bioassays were reared as synchronized cohorts by exposing heavily infested plants for 24 hr to 1-day-old, mated females; after a week the resultant mummies were clipped from the plant and isolated in glass test tubes (60×8 mm) plugged with cotton-wool. Experimental females were mated and fed with a 50% honey solution and used between the first and the second day after emergence. All experiments were conducted between the third and the seventh hr from the onset of the photophase.

Wind Tunnel

Behavioral observations were carried out in a wind tunnel similar to that described by Miller and Roelofs (1978), modified according to Guerrieri et al. (1993). The wind speed, monitored with a hot-wire anemometer (Alnor, model CGA-26), was adjusted to 25 ± 1 cm/sec in all experiments. The exhausted air was vented to outside the wind-tunnel room. The light intensity in the flight chamber was around 3600 lux at the take-off point. A black and white striped pattern was placed beneath the flight chamber floor to aid visual orientation.

Bioassay

All the experiments were carried out at $20 \pm 1^{\circ}$C, $65 \pm 5\%$ relative humidity. Individual parasitoids were used only once and were released from an open-ended glass test tube held on a plastic base so that the take-off point was exactly in the middle of a cross section of the flight chamber. Fifty to 75 parasitoid females were tested for each target by releasing them individually into the odor plume 30 cm downwind from the target. Parasitoids were observed for a maximum time of 10 min, and flight behavior data were recorded and analyzed with the aid of event-recording software (The Observer, Noldus Information Technology, Wageningen, The Netherlands). A flight response was considered as oriented towards the experimental target when the female flew directly upwind and landed on or not further than 5 cm away from the target. Experiments were conducted on several days and targets were presented in a random order each day to reduce the effect of any temporal variability in responsiveness.

Soil-Based Experiments

Experiment I: Rhizosphere-Transfer. Four 7-day-old broad bean plants were potted together in sterile soil in a 15-cm-diam plastic pot and, after 2 days, two of them were infested with several hundred *A. pisum*. Aphids were prevented from moving onto uninfested plants by means of a cylindrical cage placed over infested plants. The cage was made from an overhead transparency sheet (A4 size) with the top and a 15×10-cm lateral window covered with anti-insect net. This allowed the passage of light and the normal circulation of air to prevent the wilting of infested plants. After 5 days, the infested plants were gently removed from the pot and the uninfested plants (referred to as PHC-pot-conditioned, where PHC = plant–host complex) were immediately tested in a no-choice wind-tunnel bioassay. Four uninfested plants were prepared as described above, and two of them were caged but not infested and eventually removed after 5 days while the remaining two acted as a control (referred to as P-pot-conditioned, where P = uninfested plant).

Experiment II: Aerial Transfer. Seven-day-old broad bean plants were potted in pairs in sterile soil. After 2 days, some of them were infested with several hundred *A. pisum* and surrounded by pots containing uninfested plants. Aphids were prevented from moving onto uninfested plants as described in experiment I. The aerial parts of the neighboring treatment plants (infested and uninfested) were separated by the same distance as in experiment I, but their roots were now confined in separate pots. After 5 days, uninfested plants that had been in close aerial contact with infested plants (referred to as PHC-air-conditioned) were tested in a no-choice wind-tunnel bioassay. Uninfested plants grown close to other uninfested plants caged as described above (referred to as P-air-conditioned) acted as controls.

Hydroponic Experiments

Hydroponic Plant Culturing. Broad bean seeds (cultivar Aquadulce) were potted in sterile soil and kept in a glasshouse at 20°C. After 10 days, the seedlings were gently removed from the soil, the cotyledons peeled and the roots rinsed with bidistilled water, carefully brushing away all soil particles. They were then placed in glass beakers containing a hydroponic solution made with Murashige and Skoog basal salt mixture (referred to as MS hereafter) (Sigma, M5524), 2 g/liter, and maintained in an environmental chamber at 20°C. Each beaker, containing two seedlings, was wrapped in aluminum foil to hold the plants in position and to prevent the light from reaching the roots. Every 2 days, the hydroponic solution in each beaker was renewed. These were used as the starting plants for experiments III and IV.

Experiment III: Effects of Hydroponic Culture on Plant Signaling. The hydroponic solution was replaced after 2 days, and some of the plants were infested with several hundred *A. pisum*. After 3 days, uninfested and infested plants were used in a no-choice wind-tunnel bioassay to test their attractiveness to *A. ervi* females.

Experiment IV: Hyrdoponic Transfer of an Elicitor. Infested and uninfested plants were obtained as described for experiment III, but after 3 days, all of them were removed from their beakers and substituted with new uninfested plants. After 24 hr, plants conditioned by hydroponic solution from uninfested or infested plants (referred to as MS-P–conditioned and MS-PHC–conditioned, respectively) were used in a no choice wind-tunnel bioassay.

Statistical Analyses

The number of parasitoids responding to each target in any experiment was compared by a G test for independence with William's correction (Sokal and Rohlf, 1995). The resulting values of G were compared with the critical values of χ^2 (Rohlf and Sokal, 1995).

RESULTS

Experiment I: Rhizosphere Transfer. This experiment was designed to assess whether uninfested plants could be conditioned to produce attractive volatiles when planted together with infested plants in the same pot. Uninfested plants that had been potted together with infested plants (PHC-pot-conditioned) were significantly more attractive than control plants (P-pot-conditioned) ($\chi^2 = 14.48$; $df = 1$; $P < 0.001$ for oriented flights; $\chi^2 = 10.68$; $df = 1$; $P < 0.005$ for landings on the target) (Figure 1). In fact, 88% of tested *A. ervi* females showed oriented flight towards PHC-pot-conditioned plants and 84% landed on the target, compared with 54%, in both cases, against P-pot-conditioned plants.

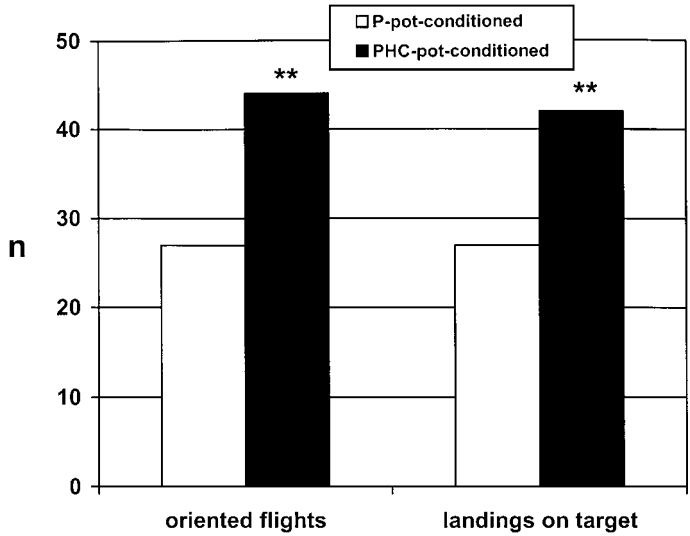

FIG. 1. Flight response of *Aphidius ervi* females towards two uninfested plants that were potted together with either two uninfested (P-pot) or two infested (PHC-pot) plants. In the latter case, aphids were prevented from moving onto uninfested plants by means of cylindrical cages made of anti-insect net. After removing the two uninfested or infested plants, the remaining two, always uninfested, were used as targets in wind-tunnel bioassays. A total of 10 plants (five pairs) and 50 female parasitoids were used for each test on four consecutive days. Significant differences within each behavioral response category are denoted ($^{**}P = 0.001$).

Experiment II: Aerial Transfer. This experiment was designed to assess whether the volatiles produced by infested plants could induce uninfested plants placed nearby, but planted in different pots, to produce volatiles attractive to *A. ervi* females. Uninfested plants placed close to separately potted, infested plants (PHC-air-conditioned) elicited similar flight responses and landings on the target by *A. ervi* females as those recorded for control plants (P-air-conditioned) ($\chi^2 = 0.059$; $df = 1$; $P < 0.9$) (Figure 2).

Experiment III: Effects of Hydroponic Culturing on Plant Signaling. This experiment was designed to assess whether the use of a hydroponic solution as a growing medium would affect the flight behavior of *A. ervi*, in response to volatile plant and host stimuli. There were significant differences between the percentages of oriented flights and landings on the target by *A. ervi* females recorded for MS-P (36%, 32%) and MS-PHC (70%, 56%) ($\chi^2 = 11.68$, $df = 1$; $P < 0.001$ for oriented flights; $\chi^2 = 5.83$; $df = 1$; $P < 0.025$ for landings on the target), consistent with results previously recorded for soil grown plants (Guerrieri et al., 1993). (Figure 3).

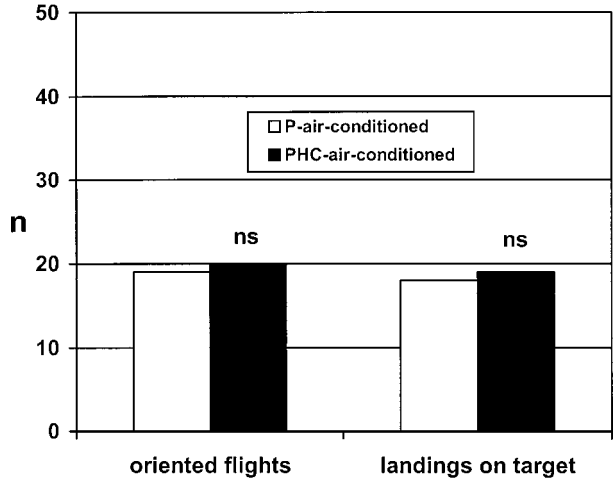

FIG. 2. Flight response of *Aphidius ervi* females towards two uninfested plants potted together and placed in close proximity to either two uninfested (P-air) or two infested (PHC-air) plants. The experimental plan was similar to that described in Figure 1, but root contact was prevented by keeping the plants in different pots, while their aerial parts were maintained at the same distance as in the previous experiment. A total of 10 plants (five pairs) and 50 female parasitoids were used for each test on four consecutive days. There were no significant differences, within each behavioral response category.

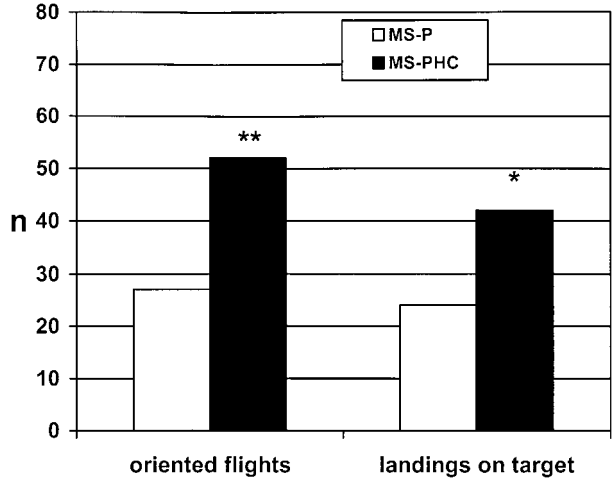

FIG. 3. Flight response of *Aphidius ervi* females towards two uninfested (MS-P) or two infested plants (MS-PHC) grown in hydroponic solution. A total of 10 plants (five pairs) and 75 female parasitoids were used for each test on four consecutive days. Significant differences within each behavioral response category are denoted ($^{*}P = 0.05$; $^{**}P = 0.001$).

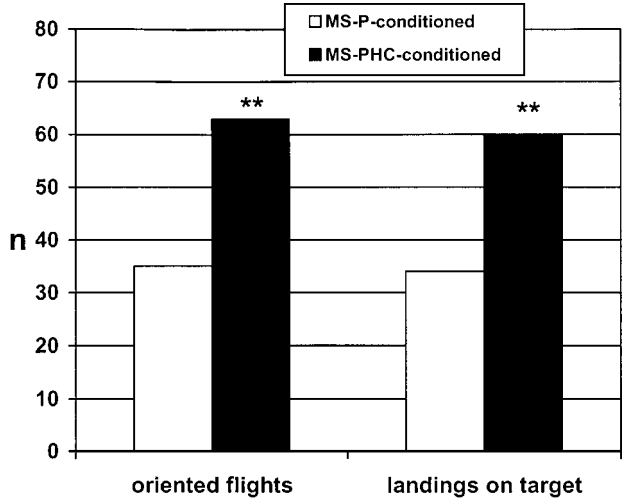

FIG. 4. Flight response of *Aphidius ervi* females towards two uninfested plants conditioned by keeping them for 24 hr in a hydroponic solution previously used to grow either two uninfested (MS-P) or two infested (MS-PHC) plants for three days. A total of 10 plants (five pairs) and 75 female parasitoids were used for each test on four consecutive days. Significant differences within each behavioral response category are denoted ($^{**}P = 0.001$).

Experiment IV: Hydroponic Transfer of an Elicitor. This experiment was designed to assess whether the compounds released by infested plants into the hydroponic solution could induce uninfested plants to emit volatiles attractive to *A. ervi* females. Uninfested plants that had been maintained for 24 hr in a hydroponic solution previously occupied by infested plants (MS-PHC-conditioned) were significantly more attractive than control plants (MS-P-conditioned) to *A. ervi* females (Figure 4). In fact, MS-PHC-conditioned plants elicited more oriented flights (84%) and landings on the target (80%) than MS-P-conditioned plants (46.7% and 45.3%, respectively)($\chi^2 = 19.79$; $df = 1$; $P < 0.001$ for oriented flights; $\chi^2 = 19.60$; $df = 1$; $P < 0.001$ for landings on the target).

DISCUSSION

Previous studies on the flight behavior of *A. ervi* have shown that broad bean plants emit volatiles attractive to this parasitoid as a consequence of infestation by its host *A. pisum* (Guerrieri et al., 1993; Du et al., 1996). Furthermore, these volatiles are released from insect-free parts of infested plants, suggesting either the existence of compounds (elicitors) circulating throughout the plant and regulating

these emissions or, more unlikely, movement of the attractive compounds themselves throughout the plant (Guerrieri et al., 1999).

The present study demonstrates that some compounds responsible for the production of aphid-induced plant volatiles, to which parasitoids are attracted, can be exchanged below ground between adjacent plants via root exudates, in the system *V. faba–A. pisum–A. ervi*. Uninfested plants, placed for some days with their roots and air-space contiguous with those of infested plants, became as attractive to parasitoid females as the infested plants, eliciting significantly more oriented flights and landings on the target compared to control plants. There could be two explanations for this phenomenon. Either an elicitor is released into the rhizosphere or air, which acts like a phytopheromone, causing neighboring plants to produce volatiles that attract parasitoids, or the attractive volatiles are adsorbed onto neighboring plants, which then re-release the volatiles. However, this enhancement of attraction was not evident when the root contact was prevented (experiment II), suggesting that aerial transfer of an elicitor or aerial adsorption of attractive volatiles and their subsequent re-release would not explain this phenomenon. In fact, uninfested plants placed in close proximity to infested plants but in separate pots, elicited similar percentages of oriented flights and landings on the target as control plants, and these values were not different from those recorded for uninfested plants of the same age, which were grown without any kind of conditioning (Guerrieri et al., 1993, 1999). However, an increased attractiveness of plants towards parasitoids can be obtained through aerial conditioning of uninfested plants by using a volatile phytopheromone. For example, intact broad bean plants placed for 24 hr in a glass vessel in the presence of (*Z*)-jasmone, became as attractive to *A. ervi* in wind-tunnel tests as infested plants. This was thought to be due to the increase in the production of (*E*)-β-ocimene, known to attract other parasitoids (Birkett et al., 2000). However, these experiments used synthetic *cis*-jasmone at concentrations higher than that normally released by damaged plants, and, thus, a conclusive demonstration of a phytopheromone still remains elusive for scientists working with plant signalling (Pickett and Poppy, 2001).

The presence of compound(s) exchanged between plants via the rhizosphere was confirmed by experiment IV, in which an infested plant incubated for 24 hr in a hydroponic solution recently vacated by an infested plant became as attractive as the infested plant for *A. ervi* females, in terms of both oriented flights and landings on target, and significantly more attractive than control plants. Control plants placed in hydroponic solution showed poor attractiveness, compared with aphid infested plants, as previously reported for soil-grown plants (Guerrieri et al., 1993; Du et al., 1996).

The combined results of our tests with soil-grown and hydroponic-grown systems show that below-ground communication between adjacent plants can influence above-ground emission of volatiles that regulate tritrophic interactions.

However, a possible role of aerial transfer of a signal or direct adsorption of attractive volatiles cannot be totally ruled out, even though its importance appears to be marginal in our test system.

In another tritrophic system, a detached leaf of lima bean incubated for 3 days with its petiole in the water where a leaf infested with the spider mite *Tetranychus urticae* Koch had been previously placed for 7 days became as attractive as infested leaves to the predatory mite *Phytoseiulus persimilis* (Athias-Henriot), when tested in a Y-tube olfactometer (Dicke et al., 1993). More recently, these results were confirmed by using an elicitor collected from whole lima bean plants that had only one primary leaf infested with spider mites (Dicke and Dijkman, 2001). Furthermore, the leaves coming from an uninfested plant incubated for 3 days in the water where an infested plant had previously been reared for 7 days became, in a Y-tube olfactometer, as attractive to *P. persimilis* as infested leaves and significantly more attractive than control leaves.

Even though Dicke's research differs from that reported in the present paper in terms of the plant material used (detached leaves versus whole plants), the methods used (Y-tube olfactometer versus wind tunnel), and principally in the natural enemy studied (predator versus parasitoid), the results are for the most part highly comparable (Dicke et al., 1993; Guerrieri et al., 1999). However, in the spider mite–predator system, the required time of exposure of the uninfested plant to the elicitor is longer than that evident for the hydroponic experiment in our study, in which an exposure of only 24 hr was sufficient to make a whole uninfested broad bean plant attractive to *A. ervi*. This difference could be a reasonable consequence of the different plant defense pathways that are activated by these phytophagous arthropods, characterized by different feeding habits. Aphids, as well as the few other piercing/sucking insect species studied so far, by producing relatively limited tissue damage, induce defense-signaling pathways (salicylate dependent, jasmonic acid/ethylene dependent) most commonly activated by bacterial, fungal, and viral pathogens (for review see Walling, 2000; Moran and Thompson, 2001). In contrast, spider mites are cell content feeders, causing substantial cellular damage and induce jasmonic acid-dependent wound-response genes, even though salicylate also plays a role in signal transduction (Ozawa et al., 2000; Arimura et al., 2002). However, a shorter time of incubation (12 hr) in a solution containing the regurgitant of a beet armyworm caterpillar *Spodoptera exigua* (Hübner) was sufficient to make a cut stem of a corn seedling attractive to the parasitoids *Cotesia glomerata* (L.) and *Microplitis croceipes* Cresson (Turlings et al., 1993), suggesting that the amount of both leaf damage and elicitor delivered may also play a role.

Even though in our system we have not tested the minimum time of incubation of an uninfested plant, placed in a solution vacated by an infested plant, necessary to make it attractive to female parasitoids, it is reasonable to speculate that this may be related to aphid density and, in turn, to the amount of elicitor(s) released into the medium. Previous research has demonstrated an aphid

density–feeding duration interaction (Powell et al., 1998, Guerrieri et al. 1999) and the use of rhizopshere studies could allow us to determine how much of this interaction can be explained simply by the quantity/quality of an elicitor entering the plant.

The process involved in the exchange of root exudates between plants in the broad bean–*A. pisum*–*A. ervi* system requires further investigation. In particular, it would be interesting to verify for how long the conditioned plant remains attractive; it is already known that an infested plant from which aphids have been removed retains its level of attractiveness to *A. ervi* for 24–48 hr, after which it loses its attractiveness (Du et al. 1997, Guerrieri, unpublished data). It also would be useful to determine if root exudates are herbivore-specific: it has been demonstrated that volatiles released from a broad bean plant infested by the nonhost *Aphis fabae* (Scopoli) were significantly less attractive to *A. ervi* than those from plants infested by the host *A. pisum* (Du et al., 1996; Guerrieri et al., 1999). This could also help in assessing whether the elicitors circulating throughout the plant are intact components of host saliva or are synthesized de novo by the plant in response to host saliva, or if they derive from enzymatic activities present in the aphid watery saliva (Miles, 1999; Walling, 2000). Finally, but equally important, it would be useful to determine if root communication can trigger the activation of plant direct defense pathways against herbivores. However, it will not be easy to unravel the molecular bases of these plant–plant communication mechanisms due to the paucity of information available on root signals implicated in this process.

The results presented in this study may have some interesting ecological implications. Parasitoids are known to use mainly chemical stimuli to locate their victims. In the first steps of host location, as defined by Vinson (1985), the plant can play a key role by producing herbivore-induced volatiles that couple a high reliability (i.e., the presence of the host) to a high detectability (plant volatiles are quantitatively more abundant than host volatiles) (Vet and Dicke, 1992). When uninfested plants are conditioned to emit herbivore-induced synomones by contact with the root exudates of neighboring infested plants, they all lose their individuality and behave in concert. This may serve to enhance the volatile signal that attracts natural enemies of the infesting herbivore, to the benefit of the infested plant. Then, the net result of plant-to-plant conditioning is the creation of a concentrated "focus of attractiveness," that benefits both the plant community and the natural enemy population.

These purely speculative and intriguing scenarios require considerable research to be substantiated. At this stage, it is important to clarify the mechanistic aspects of insect–plant interaction leading to plant signaling, to understand whether these volatiles are part of the complex active mechanisms of plant resistance or are simply by-products that parasitoids successfully exploit. Only by filling this gap in our knowledge, both at physiological and molecular levels, can we provide meaningful insights for developing more realistic ecological theories.

Abstract—When attacked by herbivorous insects, many plants emit volatile compounds that are used as cues by predators and parasitoids foraging for prey or hosts. While such interactions have been demonstrated in several host–plant complexes, in most studies, the herbivores involved are leaf-feeding arthropods. We studied the long-range plant volatiles involved in host location in a system based on a very different interaction since the herbivore is a fly whose larvae feed on the roots of cole plants in the cabbage root fly, *Delia radicum* L. (Diptera: Anthomyiidae). The parasitoid studied is *Trybliographa rapae* Westwood (Hymenoptera: Figitidae), a specialist larval endoparasitoid of *D. radicum*. Using a four-arm olfactometer, the attraction of naive *T. rapae* females toward uninfested and infested turnip plants was investigated. *T. rapae* females were not attracted to volatiles emanating from uninfested plants, whether presented as whole plants, roots, or leaves. In contrast, they were highly attracted to volatiles emitted by roots infested with *D. radicum* larvae, by undamaged parts of infested roots, and by undamaged leaves of infested plants. The production of parasitoid-attracting volatiles appeared to be systemic in this particular tritrophic system. The possible factors triggering this volatile emission were also investigated. Volatiles from leaves of water-stressed plants and artificially damaged plants were not attractive to *T. rapae* females, while volatiles emitted by leaves of artificially damaged plants treated with crushed *D. radicum* larvae were highly attractive. However, *T. rapae* females were not attracted to volatiles emitted by artificially damaged plants treated only with crushed salivary glands from *D. radicum* larvae. These results demonstrate the systemic production of herbivore-induced volatiles in this host-plant complex. Although the emission of parasitoid attracting volatiles is induced by factors present in the herbivorous host, their exact origin remains

INTRODUCTION

When attacked by herbivorous arthropods, at least 23 plant species release volatiles that attract natural enemies of these herbivores (reviewed in Takabayashi and Dicke, 1996; Dicke, 1999b; Sabelis et al., 1999). Herbivore-induced plant volatiles are easily detectable and very reliable cues for foraging natural enemies, since they are produced in large amounts by plants, but only when the plants are under herbivore attack (Dicke, 1999a). Consequently, they are frequently described as the major chemical cues used by foraging parasitoids and predators in long-range host or prey location (Dicke and Sabelis, 1988; Dicke et al., 1990; Turlings et al., 1990; Vinson, 1991; Tumlinson et al., 1992, 1999; Vet and Dicke, 1992; Geervliet et al., 1994; Drukker et al., 1995; van Alphen and Jervis, 1996; Guerrieri et al., 1999; Pickett et al., 1999). In several cases, the attractive volatiles were released not only by the infested parts of plants, but also systemically by uninfested parts of infested plants, which probably further increases the detectability of the signal (Dicke et al., 1990, 1993; Turlings and Tumlinson, 1992; Potting et al., 1995; Röse et al., 1996; Cortesero et al., 1997; Guerrieri et al., 1999). In addition, a few studies have shown that uninfested plants treated with herbivore regurgitant release attractive volatiles, thereby demonstrating that the elicitor of attractive volatile release can originate from herbivores (Turlings et al., 1993; Mattiacci et al., 1994; Alborn et al., 1997). While the release of volatiles attracting parasitoids and predators appears rather widespread in the plant kingdom, in most studies, the herbivores studied to date have been leaf-feeding arthropods (Couty et al., 1999; Dicke, 1999b; Sabelis et al., 1999).

We studied the long-range plant volatiles involved in host location in a system based on a very different interaction, since the herbivore is a fly—the cabbage root fly, *Delia radicum* L. (Diptera: Anthomyiidae)—whose larvae feed on the roots of many cole plants. The parasitoid studied, *Trybliographa rapae* Westwood (Hymenoptera: Figitidae), is a specialist larval parasitoid of a few fly species belonging to the genus *Delia*. In particular, it attacks *D. radicum* L., *D. floralis* Fall., and *D. platura* Meig. (Wishart and Monteith, 1954; Wishart, 1957; Wishart et al., 1957). It is a koinobiont endoparasitoid that can develop on the three developmental stages of *D. radicum* (Jones, 1986; Tamer, 1994). All *T. rapae* hosts feed by digging galleries in the roots of their host plants (Jones, 1986). *T. rapae* females use three types of behaviors to locate host larvae buried in the plant tissues: antennal searching, ovipositor probing, and vibrotaxis (Vet and van Alphen, 1985). If larvae are located beneath the skin of the root, females

probe through the plant tissues with their ovipositor, but if larvae are concealed in the middle of the root, females slip through the galleries to reach them (Jones, 1986).

Little is known about the role of plant volatiles in host habitat location and host location of *T. rapae*. Vet (1985) and Jones (1986) have demonstrated that *T. rapae* females are attracted from a distance by volatiles emanating from *Brassica* roots and can distinguish volatiles from uninfested over infested and/or naturally decaying roots.

Because host larvae are concealed in galleries located inside buried cabbage roots, long-distance host location may be especially difficult in this parasitoid, in particular, no visual signals are available to detect damaged plants at a distance. In such a context, volatile cues may be of special importance, but they may be difficult to detect if released only by the buried root.

In the present work, we determined the attractiveness of different parts of uninfested and infested turnip plants for *T. rapae* females using a four-arm olfactometer. The possible factors triggering the emission of female-attractive volatiles were also investigated.

METHODS AND MATERIALS

Insects

The *D. radicum* culture originated from a colony maintained by the Institut National de la Recherche Agronomique (INRA) in Le Rheu, Brittany, in France.

T. rapae originated from *D. radicum* pupae collected from field Crucifera in Brittany in 1994. The strain has been refreshed yearly. The parasitoid was reared in a climate controlled room ($20 \pm 1^{\circ}$C, $60 \pm 10\%$ relative humidity, 16L:8D), on larvae of *D. radicum* fed on roots of turnip (*Brassica campestris* L.) or swede (*B. napus* L.) according to the rearing technique described in Neveu et al. (1996). After emerging from pupae, 5–10 females were kept with the same number of males in a plastic Petridish (8 cm diam. 2.5 cm high) that contained acacia honey and damp cotton wool. Food and water were regularly replenished.

All experiments were conducted with 3–6-day-old mated females. The females had no previous experience with plant or larval volatiles and had no oviposition experience. At least 1 hr before conducting the olfactometric tests, females were introduced individually in to plastic Petridishes placed in the olfactometer room.

Plants

Turnip plants were obtained from commercial roots (undetermined variety) that weighted approximately 100 g. They were placed in a climate controlled room ($20 \pm 1^{\circ}$C, $60 \pm 10\%$ RH., 16L:8D) where whole plants were grown in

350-ml plastic pots containing damp sand. Plants were watered every 2–3 days and kept for 1–2 weeks until they developed 3–10 new leaves.

Olfactometer Setup

Responses of *T. rapae* females to volatile chemicals emitted by different odor sources were measured in a four-arm olfactometer (Pettersson, 1970; Vet et al., 1983) with some modifications. Reconstituted compressed air (80% nitrogen and 20% oxygen) was circulated through a water bottle before entering the exposure chamber through the four arms. Air left the chamber through a hole in the chamber floor that was covered with a fine mesh to prevent insects from escaping the chamber. The chamber was constructed of Plexiglas. Its internal dimensions were 10 mm in height and 93 mm at its narrowest width across. The top Plexiglas plate had a central hole (12 mm diam.) closed with a plug.

Airflow in each of the four arms was adjusted with a flowmeter (Shorate 150 with glass float, Fisher-Rosemount) to 200 ml/min, thereby creating four distinct fields that were equal in size in the exposure chamber. These fields were visualized with a black background and smoke (chemical reaction of NH_4OH and HCl). The sharpest edges were produced with a flow rate of 200 ml/min through each arm. Therefore, experiments were conducted with an airflow of 200 ml/min. After circulating through the olfactometer, the air was released outside the experimental room.

To deliver the odor to one of the four fields of the olfactometer, the corresponding arm was connected with silicon tubing to a plastic box ($24 \times 18 \times 10$ cm) containing the odor source and tightly closed with adhesive plastic tape. Empty plastic boxes were connected to the control odorless fields (pure air). A circular neon light source underneath the olfactometer provided even illumination of 400 lux in the exposure chamber. The olfactometer setup was placed in a temperature controlled room ($19 \pm 2^{\circ}$C). Preliminary tests with 72 females showed that in pure air, female behavior was similar in the four fields of the olfactometer.

Bioassay Procedure

Individual female parasitoids were introduced through the top hole of the exposure chamber and placed on the fine mesh. Observations started when the female left the center and lasted for 2 min. If the female left the exposure chamber through one of the arms and entered the silicon tubing or the plastic box containing the odor source for more than 10 sec (a period after which females were never observed returning to the exposure chamber in preliminary experiments), the test was terminated and the remaining experimental time was counted as being spent in that field. Every 10–15 observations, the position of the odor field(s) was changed and the exposure chamber was washed with 95% alcohol and an antistatic chemical

(Altunet). Between odor trials, the chamber and the plastic boxes were washed with a neutral detergent (RBS 25) and rinsed with water. We measured the time spent in each field. Parasitoids were discarded if they: needed more than 5 min to leave the center; stayed only in the half of the odor field contiguous to the center; did not move for more than 60 sec; or returned for more 30 sec to the center. Insect paths in the exposure chamber were recorded with a video camera placed on top of the olfactometer.

Odor Sources

Each odor source consisted of one plant (part or whole) per plastic box. Plants were either uninfested or infested. Infested plants were obtained by depositing approximately 100 *D. radicum* eggs, 0–24 hr old with a small paintbrush. They were tested in the olfactometer 5–7 days after the infestation occurred. In all cases, only roots were infested, as *D. radicum* larvae are strictly root feeders.

When leaf volatiles were tested in the olfactometer, a special device was used to isolate the soil, the root, and the plant collar from the leaves over which the air was blown. This device consisted of a plastic cover with a 1-cm-diam. hole in the middle placed on the pot at the time of planting. Each cover was tightly closed with adhesive tape around the pot, and the hole was elongated with a vinyl sleeve (at least 3 cm in height) and Teflon tape, which covered the plant collar.

Response of T. rapae Females toward Uninfested Plants. The following odor sources were tested: uninfested whole plant (WP-UNINF); uninfested root (Rt-UNINF); and leaves from an uninfested plant (Lf-UNINF). In all cases, plants were never exposed to any larval damage.

Response of T. rapae Females toward Infested Plants. The following odor sources were tested:

1. infested root (Rt-INF): The eggs used to infest the root were deposited on the internal face of two halves of a root, placed on damp sand in a glass dish (15 cm diam.).

   For the following 2 odor sources, a root was cut in half. One half was used for UndRt-INF and the other for UndRt-UNINF.
2. Undamaged part of an infested root (UndRt-INF): One half of a root was infested. Just before the olfactometric tests, the damaged part, i.e., the part that contained the larvae, their tunnels, and any damaged tissue, was removed and the remaining part was tested.
3. Undamaged part of an uninfested root (UndRt-UNINF): The other half of the root was laid on damp sand and was left uninfested. Approximately the same part of the root as above was removed.
4. Leaves of an infested plant (Lf-INF): To infest the plant, the eggs were deposited on the top of the root.

Origin of Attractive Volatiles. The following odor sources were tested:

1. Leaves of water stressed plants (Lf-STRESS): Plants were only watered at the time of planting. At the time of the olfactometric tests, leaves were slightly withered.
2. Leaves of artificially damaged plant (Lf-ARTIF): Ten superficial cuts were made with a scalpel (about 1 cm in length, 0.5 cm in depth) at the plant's collar. To mimic feeding behavior of the root-feeder larvae, this treatment was repeated each day for 4 consecutive days. Olfactometric tests were conducted 4–6 hr after the last cuts were performed.
3. Leaves of artificially damaged plants treated with crushed larvae (Lf-ARTIF + CL): Twenty-five 5- to 7-day-old larvae were washed in distilled water, dried on filter paper, and crushed with a glass rod in a drop of water onto a slide. The liquid obtained was applied with a paintbrush on the cuts of an artificially damaged plant obtained as described above. New crushed larvae were applied to fresh artificial damage each day for 4 consecutive days.
4. Leaves of artificially damaged plants treated with larval salivary glands (Lf-ARTIF + SG): Twenty-five 5- to 7-day-old *D. radicum* larvae were dissected and their salivary glands were extracted with precision forceps and placed in a Ringer solution. Each pair of glands was torn apart, crushed with a needle, and then applied with a paintbrush on the cuts of an artificially damaged plant obtained as described above. New glands were applied to fresh artificial damage each day for 4 consecutive days.

Data Analysis

Homogeneity of times spent in fields of the olfactometer was analyzed by using ANOVA. Pairwise comparisons of time spent in each of the four fields were made by using Scheffe tests.

RESULTS

Response of T. rapae Females toward Uninfested Plants. Naive *T. rapae* females were not attracted to volatiles emanating from an uninfested turnip plant. Volatiles from either whole plants (Figure 1A) or leaves (Figure 1C) did not increase the time spent in the odor field compared to pure air ($F = 0.47$, $df = 3$, $P > 0.05$ vs. $F = 2.28$, $df = 3$, $P > 0.05$). Females preferred the pure air fields to the one odorized with an uninfested root, indicating possible avoidance ($F = 7.76$, $df = 3$, $P < 0.001$) (Figure 1B).

Response of T. rapae Females toward Infested Plants. Volatiles emanating from a root infested with *D. radicum* larvae were attractive to females (Figure 2A) ($F = 19.55$, $df = 3$, $P < 0.001$). Females also preferred volatiles from the

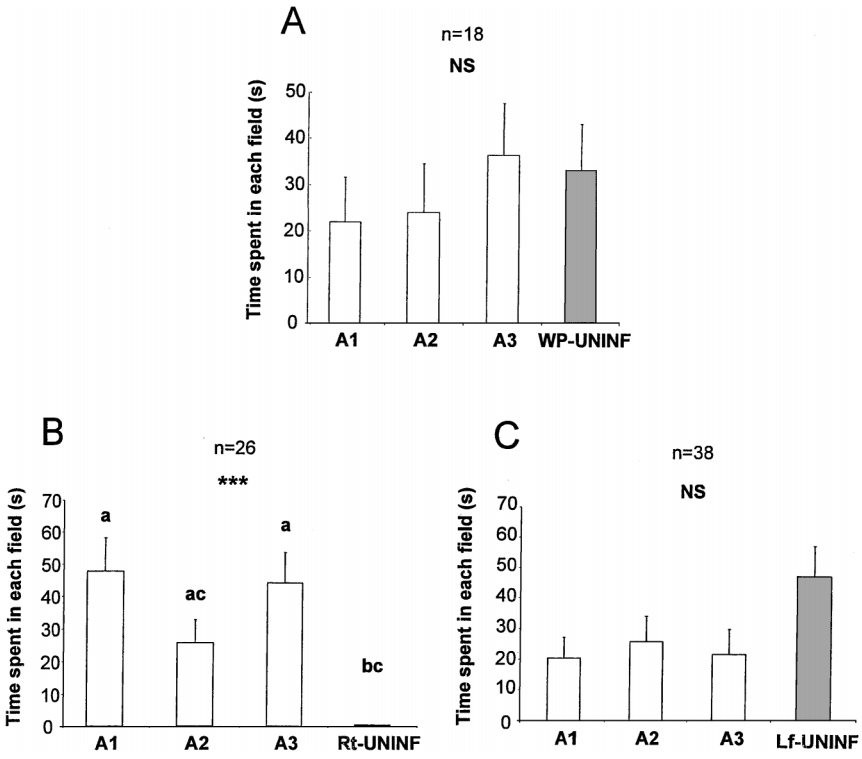

FIG. 1. Mean time spent (±SE) in each field of a four-arm olfactometer by inexperienced *T. rapae* females exposed to voltatiles from uninfested turnips. One field tested the volatiles from (A): a whole turnip (WP-UNINF), (B) a root (Rt-UNINF), or (C) leaves (Lf-UNINF). The other three fields tested pure air (A1, A2, A3). Means with different letters are significantly different (ANOVA followed by Scheffé test). NS: no significant, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

undamaged part of an infested root to volatiles from the undamaged part of an uninfested one (Figure 2B) ($F = 25.26$, $df = 3$, $P < 0.001$). Furthermore, they preferred volatiles from undamaged leaves of root-infested plant to volatiles from undamaged leaves of an uninfested plant (Figure 2C) ($F = 42.19$, $df = 3$, $P < 0.001$).

Origin of Attractive Volatiles. As leaves of root-infested plants were highly attractive, the factors responsible for the emission of attractive volatiles were investigated. Volatiles emanating from leaves of a water-stressed plant were not attractive (Figure 3A) ($F = 0.49$, $df = 3$, $P > 0.05$). Volatiles emanating from leaves of an artificially damaged plant were not attractive either; the females tended to prefer pure air (Figure 3B) ($F = 3.44$, 3 $df = 3$, $P < 0.05$). However, females preferred

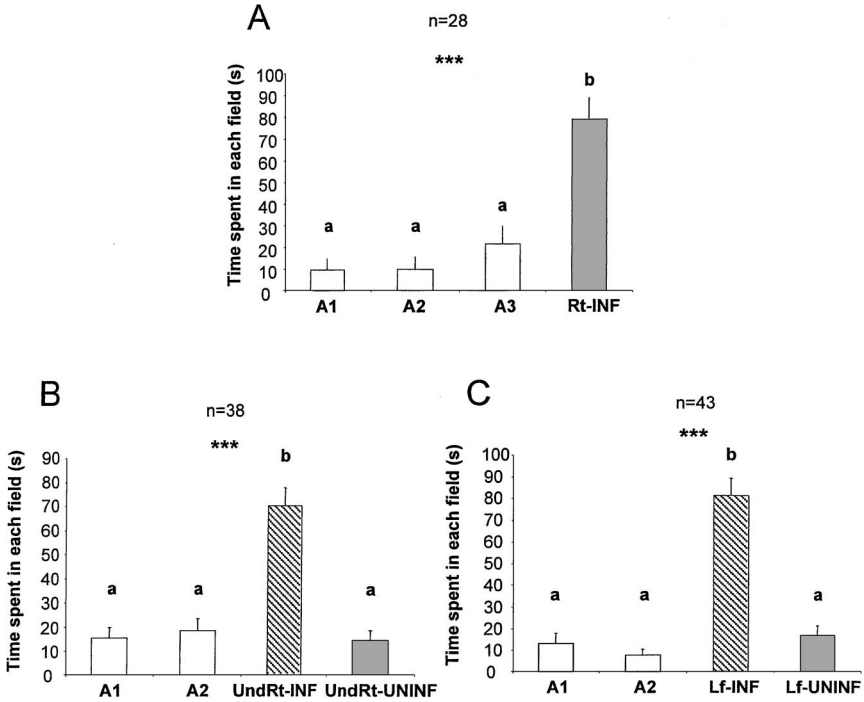

FIG. 2. Mean time spent (±SE) in each field of a four-arm olfactometer by inexperienced *T. rapae* females exposed to volatiles from infested turnips. (A) One field tested the volatiles from an infested root (Rt-INF), and the other three fields tested pure air (A1, A2, A3). (B and C) One field tested the volatiles from either a root (Rt-INF)(B) or leaves (Lf-INF)(C) of an infested turnip, and another field tested the volatiles from either a root (Rt-UNINF)(B) or leaves (Lf-UNINF)(C) of an uninfested turnip, while the other two field tested pure air (A1, A2). Means with different letters are significantly different (ANOVA followed by Scheffé test). NS: no significant, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

volatiles from artificially damaged plants treated with crushed larvae to volatiles from artificially damaged plants only or to pure air ($F = 26.40$, $df = 3$, $P < 0.001$) (Figure 3C). When an artificially damaged plant was treated with larval salivary glands, females were not attracted to volatiles from its leaves, when tested against volatiles from leaves of an artificially damaged plant and pure air (Figure 3D) ($F = 2.73$, $df = 3$, $P > 0.05$).

DISCUSSION

Response to Plant Volatiles. Our study demonstrated that *T. rapae* females are not attracted to volatiles emanating from uninfested turnips whether presented

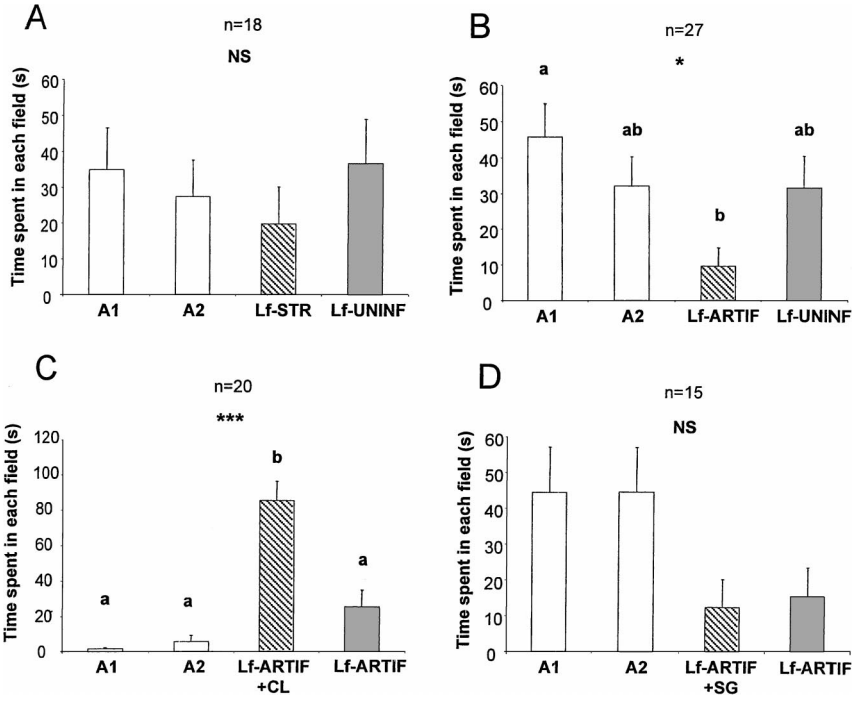

FIG. 3. Mean time spent (±SE) in each field of a four-arm olfactometer by inexperienced *T. rapae* females exposed to leafs odor of uninfested turnips submitted to different treatments. (A and B) One field tested volatiles from either a water-stressed turnip (Lf-STR)(A) or an artificially damaged turnip (Lf-ARTIF) (B), and another field tested volatiles from an uninfested plant (Lf-UNINF), while the other two fields conducted pure air (A1, A2). (C and D) One field tested the volatiles from an artificially damaged turnip treated either with crushed larvae (Lf-ARTIF+CL)(C) or salivory glands (Lf-ARTIF+SG(D), and another field tested the door of artificially damaged turnip (Lf-ARTIF); the other two fields tested pure air (A1, A2). Means with different letters are significantly different (ANOVA followed by Scheffe test). NS: no significant, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

as whole plants, roots, or leaves. This lack of response toward uninfested plants has been observed in other parasitoid species (Turlings et al., 1990; Guerrieri et al., 1993; Potting et al., 1995; Finidori-Logli et al., 1996; Du et al., 1996; Steidle and Schöller, 1997) and may be attributed to the low reliability of this signal to inform the parasitoid of host presence (Vet et al., 1991; Vet and Dicke, 1992).

In contrast, our results demonstrated that volatiles emanating from infested turnip roots were attractive to *T. rapae* females that are able to distinguish uninfested turnip roots from infested turnip roots.

We showed that volatiles emanating from the undamaged part of an infested root were more attractive than volatiles from an uninfested root. This demonstrates that the emission of attractive volatiles is not restricted to the infested part of the root. Moreover, attractive volatiles are emitted not only by the root itself but also by undamaged leaves of a damaged plant. Indeed, *T. rapae* females preferred volatiles from the leaves of an infested turnip to volatiles from uninfested turnip leaves. Therefore, it can be concluded that volatiles attracting *T. rapae* females are emitted systemically by plants infested by *D. radicum* root-feeding larvae. Systemic release of volatiles under herbivore attack has been demonstrated in four other plant species: lima bean (*Phaseolus lunatus*) (Dicke et al., 1990), corn (*Zea mays*) (Turlings and Tumlinson, 1992; Potting et al., 1995), cotton (*Gossypium hirsutum*) (Röse et al., 1996, Cortesero et al., 1997), and broad bean (*Vicia faba*) (Guerrieri et al., 1999). Our study demonstrates for the first time, That most herbivores attacking these plant species feed on aerial parts of plants; the emission of parasitoid-attracting volatiles from leaves of plants receive herbivore attack at the root level. Systemic release of plant volatiles is advantageous for *T. rapae* foraging females because *D. radicum* are concealed in the roots, whereas parasitoids forage for hosts in flight.

Turnips become attractive to *T. rapae* females only after being infested by *D. radicum* larvae. The volatiles involved in this attraction could be isothiocyanates, the volatiles specific to the genus *Brassica*. In this genus, the development of the turnip root fly *D. floralis*, a species close to *D. radicum*, induces chemical modifications in the plants attacked (Birch et al., 1990, 1992; Hopkins et al., 1993, 1995). In particular, larval damage to roots induces a modification in leaf glucosinolate composition: the concentration in aliphatic glucosinolates increases and the concentration in indole-based glucosinolates decreases (Birch et al., 1992). Glucosinolates are nonvolatile precursors of volatile isothiocyanates. Based on these results, it is plausible that *T. rapae* females modify leaf isothiocyanates and that this modification is induced by *Delia* spp. larval attacks on the roots. Additional chemical analysis is necessary to confirm this hypothesis, however.

Origin of Attractive Volatiles. The damage inflicted by *D. radicum* larvae on turnip roots usually generates water stress. This stress could induce the release of volatiles attracting *T. rapae*, as has been shown in lima bean (*Phaseolus lunatus*). Takabayashi et al. (1994) demonstrated that females of the acarian predator *P. persimilis* preferred volatiles emitted by water-stressed plants to those from nonstressed plants. However, in our study, volatiles emanating from leaves of a water-stressed uninfested turnip were not more attractive for *T. rapae* than volatiles from leaves of normally watered uninfested turnips. Therefore, water stress does not appear to induce the release of attractive volatiles.

Another possible factor triggering the emission of volatiles could be mechanical damage caused by *D. radicum* larvae. In many host-plant complexes, volatiles

released by an artificially damaged plant, such as green leaf volatiles, are attractive for parasitoids (Turlings et al., 1990; Whitman and Eller, 1990; McAuslane et al., 1991, Steinberg et al., 1993; Geervliet et al., 1994; Mattiacci et al., 1994; Potting et al., 1999). However, an artificially damaged turnip was not attractive for *T. rapae* females. In most cases, the release of the compounds occurs immediately after the damage and then rapidly decreases (Turlings et al., 1995). In our experiments, the damage was done made each morning for 4 consecutive days, and the olfactometric tests were performed in the afternoon of the fourth day. Consequently, green leaf volatiles were probably released in low amounts during the olfactometric tests.

Finally, the release of volatiles could be due to the contact of plant tissues with one or several compounds originating from *D. radicum* larvae. When an artificially damaged plant was treated with crushed larvae, its leaves very attractive for *T. rapae* females. This result demonstrates that the elicitor of volatiles systemic release originated from the host larvae and that the attractive volatiles emitted are herbivore-induced volatiles.

Herbivore-induced volatiles have been found in other systems involving leaf feeder or leafminer caterpillars (Petitt et al., 1992; Potting et al., 1995; Dutton et al., 2000). In these systems, the elicitor often originated from caterpillar saliva, since parasitoids are attracted by uninfested plants treated with caterpillar regurgitant (Turlings and Tumlinson, 1992; Turlings et al., 1993, Mattiacci et al., 1994; Potting et al., 1995). A few elicitors have been identified (Mattiacci et al., 1995; Alborn et al., 1997; Felton and Eichenseer, 1999). One of them was isolated from the saliva of the beet armyworm *Spodoptera exigua*, and named volicitin [*N*-(17-hydroxylinolenoyl)-L-glutamine] (Alborn et al., 1997). Volicitin is the most active compound of the herbivore saliva and is responsible for the release by maize of volatiles attracting parasitoids of the genus *Cotesia* and *Microplitis croceipes* (Turlings et al., 2000). Recent studies have shown that volicitin and related compounds are present in the saliva of more than 10 different Lepidoptera species (Pohnert et al., 1999; Halitschke et al., 2001; Mori et al., 2001). The second elicitor identified is the enzyme β-glucosidase. This enzyme is present in the regurgitant of *Pieris brassicae* caterpillars and triggers the release of volatiles by Brussels sprouts (Mattiacci et al., 1995). Placed in a solution of this enzyme, a leaf releases volatiles as attractive to *Cotesia glomerata* females as those emitted by an artificially damaged plant treated with caterpillar regurgitant.

Because of the results obtained in these two studies, we hypothesized that the elicitor also would be present in the saliva of *D. radicum*. However, our results showed that attractive volatiles were not released when salivary glands of *D. radicum* larvae were applied to an artificially damaged turnip. In our study, it was not possible to collect oral secretions by squeezing the larvae as was done with *S. exigua* or *P. brassicae* caterpillars (Turlings and Tumlinson, 1992; Mattiacci

et al., 1994). Therefore, we chose to apply dissected crushed salivary glands instead. The digestion of plant tissues is external in dipteran phytophagous larvae (Grassé, 1951), and it is possible that the portion of saliva collected with our method was ineffective or that the amount of saliva was insufficient to induce volatile release.

Another explanation is that the elicitor of volatile release is not present in salivary glands but in another part of the larvae, such as the digestive tract. Indeed, digestive caeca could enclose microorganisms that could induce plant release of attractive volatiles. Effects of microorganisms on volatile compound production has already been demonstrated in several studies (Croft et al., 1993 in Bruin et al., 1995; Doughty et al., 1996). In the *Cruciferae–D. radicum* system, several bacteria are involved in the decay of plant tissues that follows feeding by dipteran larvae (Johnson, 1930; Doane and Chapman, 1964). These bacteria are present in the digestive tract and in adult feces, on eggs and larvae, and inside the puparia of *D. radicum*. They are also present in the digestive tract of the figitid and staphylinid parasitoids of *D. radicum* (Johnson, 1930). The influence of these bacteria on the attraction of *T. rapae* females toward leaves remains to be investigated.

We have shown that infested turnips systemically emit herbivore-induced plant volatiles that attract the parasitoid *T. rapae*. Our next objective is to study the costs and benefits of these volatiles for the plant. As underlined by Turlings and Benrey (1998) and van der Meijden and Klinkhamer (2000), it has long been considered that plants have evolved mechanisms to actively attract natural enemies of their herbivores. If this hypothesis is true, attracting parasitoids should result in increased plant fitness. Until now, only one study has demonstrated increased fitness (seed production) when comparing a plant infested by unparasitized herbivores and one infested by parasitized herbivores (van Loon et al., 2000). However, herbivore-induced plant volatiles can be perceived and used not only by natural enemies of herbivores, but also by all other organisms present in the environment, e.g., herbivores, predators of parasitoids, hyperparasitoids, and neighboring plants, and such organisms could negatively impact plant fitness. For example, it seems that in most systems, many herbivores are attracted rather than repelled by volatiles released by infested plants. Indeed, it has been shown that herbivores can exploit these plant signals to locate their host plants and to get information on the presence of competitors and/or on the defensive state of the plant (Dicke and Vet, 1999; Dicke and van Loon, 2000). Such questions should be addressed in the *T. rapae–Cruciferae–D. radicum* complex to ascertain whether herbivore-induced volatiles are really part of the active defense system of turnip plants.

Acknowledgments—This work was supported by a grant from the Groupement d'Intérêt Scientifique "Lutte Biologique et Intégrée en cultures légumières dans l'Ouest de la France." We thank Dr. L. Kaiser for her advice on olfactometric experiments and M. Rault for maintaining the fly colony.

Abstract—Induction of plant volatiles by leaf-chewing caterpillars is well documented. However, there is much less information about volatile induction by insects with different feeding habits. We studied the induction of plant volatiles by a piercing–sucking insect, the western tarnished plant bug *Lygus hesperus* Knight. Adults of both genders and nymphs of *Lygus* induced the local emission of a blend of volatiles from both cotton and maize. Feeding by *Lygus* also induced the systemic emission of volatiles that was similar but less complex than the blend emitted at the site of feeding. Infestation by mated, mature adult females (>4 days old), but not by nymphs or mature males, caused detectable emission of α-pinene, myrcene, and (*E*)-β-caryophyllene, compounds that are stored in the glands of cotton tissue. This indicated that damage to glands in the petiole and leaf by the female ovipositor, rather than feeding, contributed significantly to the emission of these volatiles. Girdling the plant stem to disrupt phloem transport markedly decreased the movement of ^{14}C-labeled photosynthetic products to the apex of the plant, and this treatment also markedly reduced the amount of systemically induced volatiles caused by *Lygus* feeding. *Lygus* salivary gland extracts were capable of inducing emission of the same volatile blend as measured for plants infested by feeding insects or treated with volicitin, an elicitor isolated from caterpillar regurgitant. The results indicate that

L. hesperus is capable of inducing the emission of plant volatiles and that induction is caused by an elicitor that is contained in the insect salivary gland.

Key Words—*Lygus hesperus*, induction, volatiles, systemic signal transport, salivary glands, volicitin.

INTRODUCTION

Herbivore feeding induces plants to emit a blend of volatiles that in turn attracts natural enemies of the herbivores (e.g., Turlings et al., 1995; Dicke, 1999). These herbivore-induced volatiles are emitted not only at the site of herbivore feeding, but also systemically from undamaged portions of the plant (Turlings and Tumlinson, 1992; Röse et al., 1996). This activation and release of volatile organic compounds (VOC's) is considered fundamental in associations involving plants, phytophagous insects, and their natural enemies and is well documented for interactions between plants and leaf chewing caterpillars (Lepidoptera) (see review by Dicke and Vet, 1999). Such leaf-eating larvae can activate plant defense responses by introducing enzymatic or other chemical signals present in the regurgitant of the caterpillar. At least two elicitors, a β-glucosidase identified from *Pieris brassicae* L. gut regurgitant (Mattiacci et al., 1995) and *N*-(17-hydroxylinolenoyl)-L-glutamine (volicitin) isolated from *Spodoptera exigua* Hübner oral secretions (Alborn et al., 1997), have been shown to induce the emission of plant volatiles. Identification of volicitin and other structurally related compounds from several members of the Lepidoptera (Pohnert et al., 1999; Mori et al., 2001; Halitschke et al., 2001), suggests a common interspecies plant–insect signaling mechanism.

Phloem-feeding insects (Homoptera) also induce plant volatiles that attract natural enemies. Aphid-induced emission of plant volatiles can mediate foraging behavior of aphid parasitoids (e.g., Du et al., 1998; Powell et al., 1998; Guerrieri et al., 1999), but to date there are no reports of the mechanism by which aphids activate plants or trigger systemic VOC emissions.

Lygus spp. are pests with feeding traits shared by chewing and sucking insects. As other members of the Heteroptera, *Lygus* bugs have modified piercing-sucking mouthparts (Miles, 1972). The mandibular stylet that repeatedly penetrates the plant tissue causes mechanical damage (Strong, 1970; Tingey and Pillemer, 1977), while the uptake of liquefied plant components defines it as a sucking insect. This uptake of plant components occurs after constituents from the insect's saliva, including digestive enzymes, are injected into the plant tissue (Cohen, 1998; Agustí and Cohen, 2000).

This study was initiated to examine the induction of VOC emissions in plants by the polyphagous herbivore *Lygus hesperus* Knight (Hemiptera: Miridae). Thus far, most studies of VOC activation by herbivore feeding have focused on chewing lepidopterans even though piercing–sucking hemipterans such as *Lygus* spp. can

do significant agricultural damage by feeding on reproductive structures, leaves, stems, and petioles (Wilson et al., 1984). *Lygus hesperus* is found on over 100 plant species (Scott, 1977) and is an important pest in many crops, including legumes, cereals, fruits, vegetables, and various seeds and grains (Tingey and Pillemer, 1977). Here, we addressed the following specific questions: (1) Does *L. hesperus* feeding induce local and systemic emission of volatiles in plants? (2) Is volatile induction affected by *L. hesperus* developmental stage or gender? (3) If induction is systemic, how is the systemic signal transported within the plant? (4) Can emission of plant volatiles be induced by extracts of *L. hesperus* salivary glands?

METHODS AND MATERIALS

Plants and Insects. Four- to 5-week-old cotton (*Gossypium hirsutum* L. cv. Delta Pineland 5415) plants with 4–6 fully expanded true leaves and 10- to 14-day-old maize (*Zea mays* L. var. LG-11) seedlings were used for the experiments. Both plant species are suitable hosts for *L. hesperus* (Scott, 1977).

Cotton plants were grown in insect-free greenhouses as described in detail by Rodriguez-Saona et al. (2001). Maize plants were grown indoors in 16-cm-diam. pots using Pro-Gro potting soil with 8 g Osmocot 14-14-14 fertilizer (Scotts-Sierra Horticulture, Marysville, Ohio, USA) added to the soil at the time of planting. High-pressure sodium and metal halide lamps provided a light intensity of 700 μmol photons/m^2/sec. Room temperature was maintained at $29 \pm 4^{\circ}$C with $40 \pm 10\%$ relative humidity under a 16-hr photoperiod and an 8-hr dark period.

Adults of the western tarnished plant bug, *L. hesperus*, were collected from alfalfa fields (Maricopa, Arizona) and held in 30- $\times$ 30- $\times$ 30-cm polypropylene cages (Megaview Science Education Services Co., Ltd., Taichung, Taiwan) placed in environmental chambers maintained at $25 \pm 2^{\circ}$C and $65 \pm 10\%$ relative humidity under a 14L:10D photoperiod. *Lygus* nymphs and adults were maintained on a diet that consisted of fresh green beans and carrots, supplemented with pink bollworm eggs (Beards and Leigh, 1960) or on artificial diet (Debolt, 1982). *Spodoptera exigua* larvae were reared on an alfalfa-based diet (Henneberry and Kishaba, 1966) and maintained at $28 \pm 2^{\circ}$C and 50% relative humidity under a 14L:10D photoperiod. Both insect colonies were maintained at the Western Cotton Research Laboratory, Phoenix, Arizona.

Collection and Analysis of Plant Volatiles. For all experiments, volatiles were collected from plants maintained in the greenhouse (cotton) or the plant growth room (maize). Cotton volatiles were collected using a push–pull volatile collection apparatus constructed after Heath and Manukian (1994) [see Rodriguez-Saona et al. (2001), for details]. Charcoal-purified air entered from the top of a glass chamber and passed over a plant at a rate of 5 liters/min. Plant volatiles were collected by pulling 20% of the air inside of the chamber (1 liter/min rate) through

a Super-Q adsorbent (Alltech, Deerfield, Illinois, USA) filter trap. Volatiles from maize seedlings were collected using a 60-cm-high × 14-cm-diam. glass cylinder placed over the aerial portion of plants. Air was passed over the plants at 3 liters/min and was pulled through filter traps at 1 liter/min. The remainder of the air was vented out the bottom of the system through the opening, loosely sealed with cotton, around the stem of the plant.

A system with four independent chambers allowed for simultaneous collection of volatiles from four plants. Cotton volatiles were extracted from the collection filters and analyzed by gas chromatography (GC) as described by Rodriguez-Saona et al. (2001). Volatiles from maize seedlings were extracted from traps with 150 μl methylene chloride. An internal standard (*n*-nonyl acetate 40 ng/μl) in 5 μl of methylene chloride was added. Aliquots 1-μl of the extract were injected onto a capillary GC (Hewlett-Packard 6890) with a 15-m × 0.25-mm-ID fused silica column and a 0.1-μm-thick bonded methylsilicone. Injections were made in a splitless mode for 0.3 min with an injector temperature of 230°C and the detector temperature of 250°C. The column was held at 40°C for 0.5 min, increased 12°C/min to 180°C, and then increased to 40°C/min to 220°C and held for 2 min. Helium was used as a carrier gas at a linear flow velocity of 35 cm/sec. For each sample, volatiles were quantified based on comparison of their peak areas with that of the internal standard. Compounds were identified by GC–mass spectroscopy (GC-MS) as described by Rodriguez-Saona et al. (2001); spectral data were compared with synthetic standards from commercial sources and spectra from the National Institute of Standards and Technology (NIST, 1995) database.

Volatile Emission from Plants Infested with Lygus. Thirty to 40 adult bugs (mixed sexes) were collected from the colony and placed on a plant 18 hr prior to collecting volatiles in order to allow the insects to become conditioned to the new diet. Preliminary observations showed that this insect density was sufficient to cause significant induction of volatile emission and also allowed for continued insect growth and development. Volatile collection was initiated at 10:00 hr. Volatiles from cotton plants were collected continuously for 8 hr, while maize volatiles were collected for 6 hr/day during two consecutive days. Controls were included to test for volatile emission from plants with no insects or from chambers that contained 30–40 adult bugs with a source of water but no plants. In some cases, insects were removed from the plants prior to placing the plants in the collection chambers. Each treatment was replicated at least four times.

To determine the effects of developmental stage and gender on induction of plant volatiles, emitted volatiles were measured after placing nymphs (fourth or fifth instars) or sexually mature adult (>4 days old) females or males of *L. hesperus* on cotton plants. Thirty to 40 individuals from each group were placed on the plants for 18 hr prior to initiating volatile collection at 10:00 hr on the following morning. Samples were collected continuously for 8 hr. Each treatment was replicated at least four times. In addition, the total number of eggs oviposited

on each plant by adult females was recorded. Gender differences in induction of VOC emissions were also tested for maize plants.

Systemic Induction of Volatiles by Lygus Feeding. To determine if feeding by *Lygus* triggers a systemic response in cotton, 30–40 adult *L. hesperus* (mixed sexes) were restricted to two lower leaves of a cotton plant while volatiles were collected from the portion of the plant above the infested leaves. Volatiles were collected as previously described with the difference that only the upper portion (undamaged leaves) of plants was enclosed inside the collection chamber, while the lower two leaves where the insects were feeding remained outside (see Röse et al., 1996, for details). *Lygus* bugs were contained on the lower leaves by using fine-mesh nylon bags sealed at the opening with Velcro. Control plants had two lower leaves enclosed by empty bags. Volatiles were collected for a 32-hr period by collecting for 8 hr/day beginning at 10:00 hr on each of four consecutive days. Treatments were replicated at least four times.

To test if the systemic induction of volatile emissions in cotton is mediated by chemical signals transported via the phloem, phloem transport was disrupted between the site of herbivory and the portion of the plant from which volatiles were collected. The stems of cotton plants were girdled by using a bare constantan wire (approximately 0.7 mm diam.) that was heated electrically with a variable AC voltage controller set at 5% of maximum power (Bruening and Egli, 1999). The wire was wrapped around the stem and heated for 5 sec, removed, then wrapped around the stem in the opposite direction and heated again for 5 sec. This treatment caused a large burned circle around the stem that cut deep into the tissue such that, upon dissection, no living tissue was visible. The girdled plants were secured to stakes and left overnight without further treatment to ensure that xylem transport was not disrupted; if the leaves remained turgid the following day, the plant was used for experimentation. All of the phloem-severed plants used for experiments remained turgid during the following week in which plants were visually inspected.

Thirty to 40 sexually mature adult (mixed sexes) *L. hesperus* or four third-instar *S. exigua* were placed on two leaves below the girdled area or on comparable leaves of nongirdled control plants. Volatiles were collected from insect-free leaves above the girdled site as previously described for systemic induction experiments. Volatile emission was also measured for control plants that were girdled and free from insects. Treatments were replicated at least five times.

To test the effectiveness of the girdling treatment, we measured the translocation of ^{14}C from leaves below the girdle to apical portions of the plant. Photosynthetically fixed carbon is transported predominantly in the phloem tissue (Buchanan et al., 2000). A large leaf located below the stem girdle but not used for insect feeding was labeled with $^{14}CO_2$. A comparable leaf for nongirdled controls was also labeled. An airtight bag was placed over the leaf and tightly secured around the petiole with wire. Five hundred microliters of gaseous $^{14}CO_2$ (0.025 μCi/μl)

liberated from acidified [^{14}C] $NaHCO_3$ was injected into the bag. After 3 days, tissue samples were taken from the labeled leaf, from the apex of the plant (small flower buds and very small leaves <1 cm long), and from small leaves (<8 cm long) from the top of the plant. Tissue samples were also collected from plants that were not labeled with $^{14}CO_2$. Immediately after sampling, a small amount of plant tissue was powdered in liquid N_2 and homogenized in 750 μl of 0.5 M HCl. The entire sample was transferred into scintillation vials, mixed with 5 ml of scintillation cocktail and counted. Treatments were replicated at least five times.

Dissection of Lygus Salivary Glands. Adult *L. hesperus* were caged on maize Pioneer var. 3223, for 2–3 days. Cages were held in an environmental chamber maintained at $27 \pm 1^{\circ}$C and $70 \pm 10\%$ relative humidity under a 14L:10D photoperiod. Prior to dissection, insects were aspirated from cages and held at 4°C for ca. 30 min. *Lygus* were pinned in a paraffin-filled Petri dish and submerged in cold (4°C) phosphate-buffered saline (PBS), pH 7.4. Salivary glands were then removed intact and rinsed in cold distilled water.

During dissection of *Lygus* adults it was noted that female salivary glands appeared to be larger than those of males. To determine differences in size between salivary glands of male and female *L. hesperus*, salivary glands were dissected from living insects as described above. Only one gland was measured from each insect. Glands were submerged in a small drop of PBS and measured to the nearest 0.03 mm using a dissecting scope with ocular micrometer at 45× magnification. Ten measurements were made on each gland: maximum lengths of the primary lobe, accessory lobe, and accessory gland; diameters of the primary lobe and accessory lobe at three equidistant locations along the length of each lobe; and maximum diameter of the accessory gland (see Baptist, 1941).

The volume of each salivary gland was estimated by treating the gland as a cylindrical solid, i.e., volume = (length)π[(diameter)/2]^2. Separate calculations were made for the primary lobe, accessory lobe, and accessory gland. For the primary lobe and accessory lobes, we used the mean of the three diameter measurements. Volume estimates for the primary lobe, accessory lobe, and accessory gland were then summed to give the absolute estimate of volume (cubic millimeters) for each salivary gland.

Induction of Maize Volatiles by Lygus Salivary Gland Extracts. Extracts of *Lygus* salivary glands dissected from living females were used to test for activity in inducing plant volatile emission from maize seedlings. One hundred glands were placed together in a 1-ml cone-bottom glass vial with 10 μl of distilled water and held at –80°C prior to the preparation of extracts. Each 100-gland sample was extracted in 50 μl of distilled water by sonicating the samples for 15 min. After centrifuging for 5 min, the supernatant was transferred to a new vial and used for induction experiments. Ten-day-old maize seedlings were cut at the stem close to the soil and incubated for 12 hr at room temperature in a laboratory with no supplemental light starting at 21:00 hr in 1-ml shell vials containing either 10 μl

of *Lygus* salivary gland extract or 10 μl of 30 μM synthetic volicitin, plus an additional 490 μl of a 50 mM sodium phosphate buffer, pH 8.0. Control plants were incubated in 10 μl of distilled water plus 490 μl of buffer solution. The following morning, seedlings were removed from the vials, the severed ends were wrapped in wet cotton, and the seedlings were placed in 37-cm-long $\times$ 4-cm-diam. closed glass cylinders. Air was passed over the plant at a rate of 600 ml/min and was pulled by vacuum through a filter trap attached at the opposite side of the chamber. Volatiles from 12 seedlings were collected simultaneously in parallel glass chambers in the plant growth room. Volatiles were collected for 6 hr (10:00–16:00 hr) and analyzed as previously described. Each treatment was replicated at least five times.

Voucher Specimens. Voucher specimens of *L. hesperus* are deposited in the USDA-ARS Systematic Entomology Laboratory, Beltsville, Maryland, USA.

Statistical Analysis. Differences among treatments were analyzed by using a completely randomized one-way ANOVA (SigmaStat, San Rafael, California, USA). If significant differences were detected, a pairwise multiple comparison procedure (Tukey test) was conducted. Differences between two treatments were analyzed using two-tailed student *t* tests (SigmaStat). The number of eggs oviposited per cotton plant was regressed versus the amount of constitutive volatiles emitted.

RESULTS

Volatile Emission from Plants Infested with Lygus. Lygus infestation of both cotton and maize induced the emission of several plant VOC's (*t* tests; $P < 0.05$; Figure 1). Infestation of cotton and maize plants increased volatile emissions by 12- and 5-fold, respectively, as compared to insect-free controls. For cotton, the herbivore-induced volatiles included (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, (*E*)-β-farnesene, (*E*,*E*)-α-farnesene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Figure 1). These compounds were induced by infestation with nymphs and adult males and females (data not shown), and many of the compounds were detected even after removing the insects from the plants prior to collecting volatiles (Figure 1). These same inducible volatiles are emitted from cotton plants infested by chewing caterpillars (Paré and Tumlinson, 1997a,b). In addition, cotton plants infested with a mixture of mature males and ovipositing females also emitted large amounts of α-pinene, β-pinene, myrcene, limonene, and (*E*)-β-caryophyllene. These constitutive terpenes are stored in the glands of cotton tissue (Elzen et al., 1985) and are emitted when the glands are mechanically ruptured (Paré and Tumlinson, 1997a,b). There was no detectable emission of the constitutive volatiles from nymph-infested plants (data not shown).

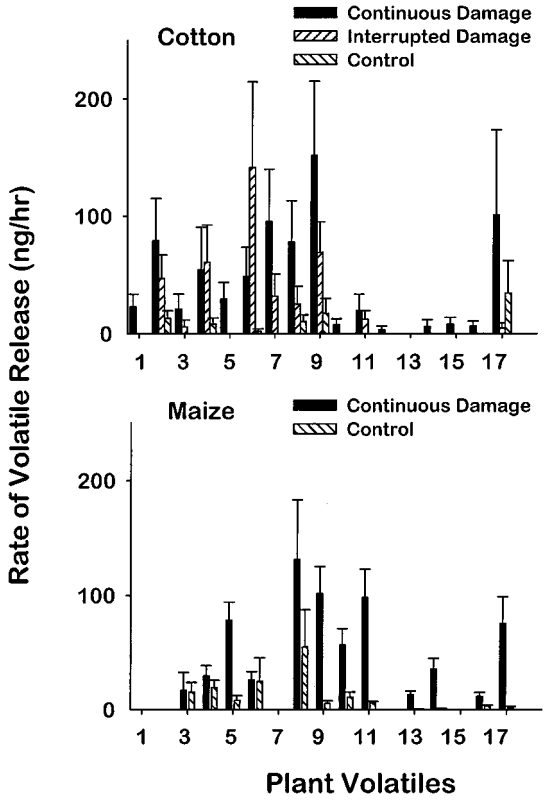

FIG. 1. Volatiles collected from the aerial portions of cotton or maize plants: (1) infested continuously with adult *Lygus hesperus*; (2) from which insects were removed from the plants prior to volatile collection; or (3) maintained free from insects. **1** = (*E*)-2-hexanal; **2** = α-pinene; **3** = β-pinene; **4** = myrcene; **5** = (*Z*)-3-hexenyl acetate; **6** = limonene; **7** = (*E*)-β-ocimene; **8** = linalool; **9** = (*E*)-4,8-dimethyl-1,3,7,-nonatriene; **10** = indole; **11** = (*E*)-β-caryophyllene; **12** = α-humulene; **13** = α-*trans*-bergamotene; **14** = (*E*)-β-farnesene; **15** = (*E*,*E*)-α-farnesene; **16** = nerolidol; **17** = (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Volatiles were collected continuously for 8 hr (cotton) or 6 hr/day over two consecutive days (maize), starting at 10:00 hr. Bars represent the mean + 1 SE; $N \geq 4$. Total cotton volatile emissions (mean $\pm$ 1 SE): continuous damage = 1010.9 ± 399.9; interrupted damage = 397.2 ± 197.6; control = 85.07 ± 40.8. Total maize volatile emissions: continuous damage = 981 ± 190.8; control = 201.4 ± 23.0.

When studied in more detail, emission of constitutive volatiles was significantly higher when mated females were feeding on the plants as compared to males of the same age (data not shown; $t = 2.75$; $df = 12$; $P = 0.017$). Mated females laid an average of 143 ± 16 (mean $\pm$ SE) eggs per plant, and regression analysis

indicated a strong positive relationship between the number of eggs laid and the emission of the constitutive volatiles ($F = 24.9$; $df = 1,5$; $P = 0.004$; $r^2 = 0.83$).

Lygus bugs that were caged in collection chambers in the absence of plants emitted the pheromone (*E*)-2-hexenyl butyrate (data not shown). Aldrich et al. (1988) previously reported that this compound accounts for about 70–80% of the total volatiles emitted from male and female *L. hesperus*. The compound was not detected in the volatile blend emitted by plants after the insects were removed, indicating that plants emitted little or no (*E*)-2-hexenyl butyrate.

Feeding by *L. hesperus* on maize seedlings induced the emission of (*Z*)-3-hexenyl acetate, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, α-*trans*-bergamotene, (*E*)-β-farnesene, (*E*)-nerolidol, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Figure 1). Adults of both genders induced similar amounts of the same blend of volatiles from maize plants (data not shown; $t = 0.11$, $P > 0.05$).

Systemic Induction of Cotton Volatiles by Lygus Feeding. The systemic induction of plant volatile emission was evident when comparing insect-free control plants with plants that had *Lygus* adults enclosed on lower leaves that were outside of the VOC collection chamber ($t = 5.13$, $P < 0.05$; Figure 2). Systemically induced compounds included (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, linalool, (*E*)-4,8,dimethyl-1,3,7-nonatriene, (*E*)-β-farnesene, (*E*,*E*)-α-farnesene, and

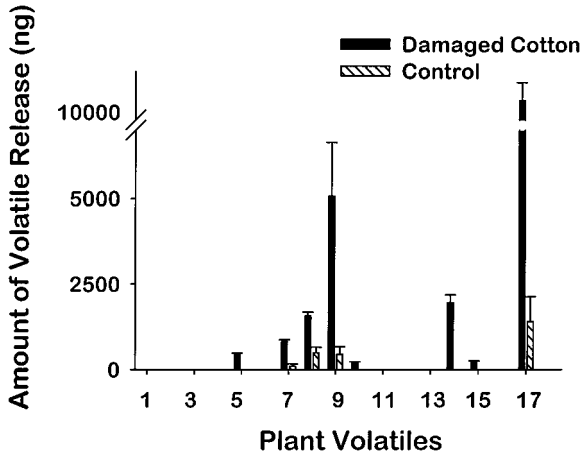

FIG. 2. Systemic induction of volatile emission from cotton plants by *Lygus hesperus* feeding. Volatiles were collected from portions of the plant not infested with insects or from a similar portion of control plants maintained free from insects. Volatile designations are same as described in Figure 1. Cumulative volatiles emitted during the photoperiod of four consecutive days were collected. Bars represent the mean + 1 SE; $N = 4$. Total volatile emissions: damaged cotton = 22536.7 ± 5394.3; control = 2448.1 ± 1159.4.

[d] Data obtained from Figure 2.
[e] Data not determined.

(*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. The same compounds were emitted systemically from cotton plants infested with *S. exigua* (Paré and Tumlinson, 1998; Rodriguez-Saona et al., 2001).

Girdling of cotton stems substantially disrupted phloem transport as observed by the movement of photosynthate in the plant. The transport of photosynthetically fixed $^{14}CO_2$ from a leaf below the girdled region to the apical portions of the plant was reduced by up to 90% compared to the nongirdled control plants (Table 1). This difference was observed for both apical tissue and small leaves near the apex of the plant. The girdling treatment was severe, such that live tissue was not readily detectable and stems had to be tied to stakes to remain upright. However, approximately 75% of the plants treated in this manner maintained turgid leaves above the stem girdle for at least one week, indicating that water could still move through the girdle to the top of the plant.

The systemic induction of volatile emission from cotton plants was markedly reduced for plants that had been heat-girdled around the stem (Table 1). The induced response of girdled plants was reduced by 60–70% compared with VOC emissions from nongirdled plants.

Induction of Maize Volatiles by Lygus *Salivary Gland Extracts*. Female glands were nearly twice the volume of male glands ($t = 3.59$; $P < 0.001$), with the mean volume for female salivary glands averaging 0.35 ± 0.04 mm^3 (mean ± SE, $N = 30$), while male salivary glands averaged 0.18 ± 0.03 mm^3 (mean ± SE, $N = 20$). The larger female glands were used for the bioassays.

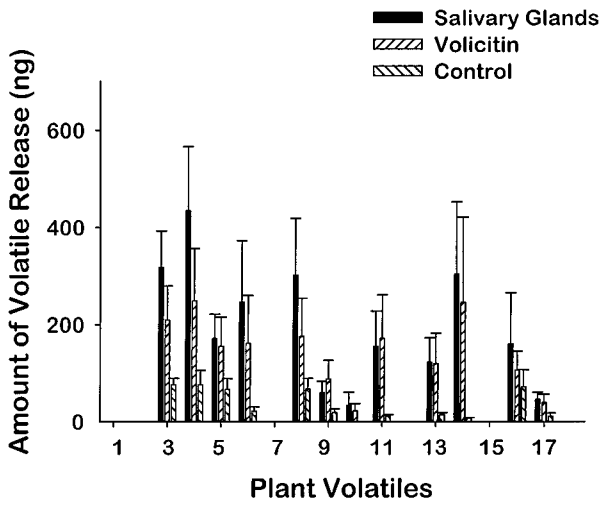

FIG. 3. Volatiles collected from maize seedlings incubated with distilled water (control), the caterpillar elicitor volicitin, or *Lygus hesperus* salivary gland extracts. Volatile designations are the same as described in Figure 1. Volatiles were collected for 6 hr starting at 10:00 hr. Bars represent the mean + 1 SE; $N = 5$. Total volatile emissions: salivary glands = 3124 ± 825.6; volicitin = 1959.9 ± 625; control = 576.8 ± 113.7.

Lygus salivary gland extracts induced the emission of the same blend of volatiles from maize seedlings as observed for live insects (Figures 1 and 3). Additionally, the volatile blend emitted was similar to the blend induced by the caterpillar elicitor volicitin (Figure 3).

DISCUSSION

Lygus hesperus feeding on cotton and maize plants induced the emission of plant volatiles (Figure 1) and, with the exception of the constitutive compounds stored in the cotton tissue glands, a similar induction of volatiles was caused by nymphs, mature males, and ovipositing females. Mature ovipositing females caused the emission of significant amounts of the constitutive volatiles from cotton, and the level of emission was closely associated with the number of eggs laid on a plant. In some cases, oviposition damage has been observed to activate induced responses in plants (Meiners and Hilker, 1997, 2000). Although our experiments could not distinguish whether oviposition alone induced the emission of the nonconstitutive volatiles, it can be concluded that mechanical damage to glands by oviposition contributed significantly to the emission of the constitutive volatiles. Female *L. hesperus* inserted their eggs inside the leaves, petioles,

and stems, causing rupture of glands adjacent to the oviposition site (Rodriguez-Saona, personal observation). Our results indicated that insect feeding per se was the predominant factor leading to the emission of the non-constitutive volatiles from cotton plants.

Lygus feeding induced the emission of a similar blend of volatiles as observed for caterpillars (Loughrin et al., 1995; Paré and Tumlinson, 1997a,b): In their experiments using ^{13}C-labeled CO_2, Paré and Tumlinson (1997a,b) demonstrated that these volatiles were synthesized de novo at the site of feeding. Kessler and Baldwin (2001) also reported a similar blend of volatiles was emitted from field-grown *Nicotiana attenuata* Torr. ex Wats plants infested by caterpillars or the piercing–sucking insect *Dicyphus minimus* (Heteroptera: Miridae). Similar to experiments with caterpillars feeding on plants (Röse et al., 1996; Paré and Tumlinson, 1998), *L. hesperus* feeding systemically induced the emission of a blend of plant volatiles that, with the exception of the constitutive glandular compounds, was qualitatively similar to the blend emitted from leaves that incurred direct feeding activity (Figure 2).

Heat-girdling of cotton stems significantly decreased the emission of systemically induced volatiles (Table 1). However, although not significant statistically, the insect-infested girdled plants consistently emitted greater quantities of volatiles than girdled plants kept free from insects (Table 1). Thus, translocation of the signal, presumably chemical, initiated by *Lygus* was attenuated but not completely blocked by disruption of stem phloem tissue. The girdling treatment also disrupted phloem transport, as indicated by the approximately 10-fold decrease in translocation of photosynthetically fixed $^{14}CO_2$ compared to nongirdled controls. However, as for volatile induction, a small but consistent amount of ^{14}C was detected in the apex of girdled plants. This continued low level of movement of phloem products across the wound site may be due to a transfer of phloem materials to the xylem at the site of girdling, followed by xylem transport to the upper parts of the plant. The fact that the upper leaves maintain their turgor subsequent to stem girdling confirms the flow of water in the xylem tissue. The difference in magnitude of the girdling effect on inhibiting ^{14}C translocation and blocking the systemic emission of volatiles may simply be due to a high potency of the systemic signal in inducing volatile emissions. In the case of systemin, a mobile signal molecule present in tomato, femtomole quantities of this polypeptide are sufficient to activate the systemic induction of proteinase inhibitors (Ryan and Pearce, 1998).

Although the nature of the elicitor has yet to be determined, the fact that *Lygus* salivary gland extracts induced the emission of volatiles from maize seedlings suggests the presence of an elicitor that triggers volatile emissions. Indeed, the blend of volatiles induced by *Lygus* salivary gland extracts was similar to the blend induced by treatment with authentic volicitin, which has been isolated from the oral secretions of caterpillars (Figure 3). Volicitin treatment apparently stimulates the octadecanoid pathway (Alborn et al., 2000), leading to the production of

jasmonic acid, a growth regulator known to stimulate VOC emissions from leaves (see Boland et al., 1998, for review). In fact, the same volatiles induced by *L. hesperus* (Figure 1) and *S. exigua* (Paré and Tumlinson, 1997a,b) in cotton are activated locally and systemically by exogenous treatment of methyl jasmonate, a volatile derivative of jasmonic acid (Rodriguez-Saona et al., 2001). Thus, while definitive determination of the elicitor in *Lygus* salivary glands is lacking, there is the possibility that the mechanism of volatile induction caused by *Lygus* feeding is similar to the response induced by volicitin.

In summary, we have shown that feeding by a phytophagous piercing–sucking insect induces the emission of plant volatile compounds in a manner comparable to the well-documented response observed for caterpillars. Similarities in the volatile blends emitted by both types of herbivores, by *Lygus* salivary gland extracts, and by the caterpillar elicitor volicitin, indicate that *Lygus* feeding activates the same biosynthetic pathway as caterpillars. Volicitin and other related compounds have been isolated from the regurgitate of various caterpillar species (Pohnert et al., 1999; Halischke et al., 2001). However, the amounts of these compounds for each species may vary (Mori et al., 2001), resulting in specificity in the plant's response to damage (De Moraes et al., 1998). Therefore, although caterpillars and piercing–sucking herbivores may share similar elicitor(s) in their salivary glands that induce a common plant-volatile signaling pathway, the plant response may vary with the amounts of elicitor(s) produced by these two different herbivores.

Herbivore-induced plant volatiles serve as important cues in host location by natural enemies (e.g., De Moraes et al., 1998; Kessler and Baldwin, 2001), and several parasitoids and predators attack the nymphs and adults of *Lygus* bugs (Ruberson and Williams, 2000). Whether or not plant volatile emission induced by *L. hesperus* feeding provides a foraging cue to these natural enemies remains to be determined.

Acknowledgments—We thank Donald Brummett for his expertise in cotton plant culture, for developing the stem girdling technique, and for his assistance in the analysis of plant volatiles by gas chromatography. We also thank Dr. Jacquelyn Blackmer, Dr. Glen Jackson, and Linda Lee for providing *L. hesperus* nymphs and adults for our experiments. We are very grateful to Verónica Manrique for her assistance in dissecting *L. hesperus* salivary glands. Synthetic volicitin was generously supplied by Dr. Hans T. Alborn and Dr. James H. Tumlinson (Center for Medical, Agricultural and Veterinary Entomology, USDA, Gainesville, Florida, USA). An early draft of this paper was kindly reviewed by Drs. Glen Jackson, Eric Schmelz, and Heather McAuslane. This work was supported in part by NRI Competitive Grants Program/USDA (award #35320-9378).

Abstract—*Murgantia histrionica*, the harlequin bug, is an aposematic pentatomid that feeds on toxic crucifer plants. By performing predator trials, we found that the bugs are distasteful to several species of bird predators. Given this, we tested the hypothesis that the bugs sequester toxins from the crucifer plants they feed on for use in defense against predation. We used high-pressure liquid chromatography for analyses and tested if *M. histrionica* sequesters toxic chemicals from its crucifer diet. We found that *M. histrionica* sequesters mustard oil glycosides, precursors to zootoxic mephitic nitriles, and that sequestration is characteristic of the plant species fed upon. Glucosinolate titers in *M. histrionica* bodies were 20–30 times higher than in their guts. We found that cabbage-fed *M. histrionica* had higher titers of cabbage glucosinolates than bugs that were fed on a cabbage diet and then switched to a diet of garden nasturtium. This indicates that *M. histrionica* immediately sequesters chemicals from whichever plant it feeds upon. The study shows that *M. histrionica* can sequester glucosinolates from its host plants for use in defense against predation and that the bugs can retain the glucosinolates for an extended period of time.

Key Words—Sequestration, glucosinolate, mustard oil glycoside, Hemiptera, Heteroptera, Pentatomidae, *Murgantia histrionica*, aposematism, Brassicaceae, crucifer.

INTRODUCTION

Insects are known to sequester plant secondary compounds, making them unpalatable to potential predators (Duffey, 1980; Blum, 1981; Bowers, 1990). By 1973, Rothschild listed 43 insect species thought to store host plant chemicals, and since then the number has grown substantially (Duffey, 1980; Bowers, 1990), with new examples added annually (e.g., Bowers and Stamp, 1997; Geuder et al., 1997; Dobler et al., 1998, 2000; Wink et al., 2000; Sime et al., 2000; Müller et al., 2001). However, to our knowledge, only two groups of true bugs (Heteroptera) have been shown via chemical analysis to sequester plant secondary compounds. Some Rhopalidae (*Jadera* and *Leptocoris*) sequester cyanoglucosides from seeds of Sapindaceae (Braekman et al., 1982; Aldrich, 1988), and some Lygaeidae (*Oncopeltus*, *Caenocoris*, *Spilostethus*, and *Lygaeus*) sequester cardenolides from Asclepiadaceae or Apocyanaceae (Von Euw et al., 1971; Duffey and Scudder, 1972; Scudder and Duffey, 1972), while another (*Neacoryphus*) sequesters pyrrolizidine alkaloids from *Senecio* (Asteraceae) (McLain and Shure, 1985).

The paucity of examples of sequestration among the Heteroptera is unexpected considering their abundance and feeding ecology. Indeed, well over 20,000 heteropteran species feed on plants (Schuh and Slater, 1995), and many of these specialize on chemically defended plant taxa (Aldrich, 1988; McGavin, 1993). Sequestration is most often seen in insect herbivores that specialize on toxic plants (Bowers, 1990). Furthermore, true bugs are often conspicuously colored (Schuh and Slater, 1995), a trait regularly associated with chemical defense (Pasteels et al., 1986; Guillford, 1990). Most Heteroptera expel odorous defensive secretions when disturbed, and these defensive secretions may account for the evolution of aposematic coloration in bugs. However, chemically defended insects often possess a two-component allomonal system consisting of an odorous, volatile secretion that startles, alerts, or warns potential predators, backed up by less volatile internal toxins that are often derived from host plants and that sicken predators after ingestion (Brower, 1984; Whitman, 1988). Furthermore, as Aldrich (1988) reported, some Heteroptera possess a bitter or offensive taste independent of any secretion. In other bug species, palatability to predators depends on diet (McLain, 1984). Taken together, this evidence suggests that sequestration of host plant compounds in the Heteroptera is probably more common than currently recognized and that many examples of sequestration await discovery (Aldrich, 1988).

An ideal candidate for sequestration of host plant compounds is the harlequin bug, *Murgantia histrionica* (Hahn) (fam. Pentatomidae). This agricultural pest (Metcalf et al., 1962; McPherson, 1982; McPherson and McPherson, 2000), native to Central America (Walsh, 1866; McPherson, 1982) exhibits many of the characteristics associated with the chemical defense syndrome (Pasteels et al., 1983; Whitman et al., 1985). They are large, diurnal, conspicuously colored with black and orange or red markings, slow moving, resistant to flying, and often

clumped, making them easy to find and capture, yet they have few predators (Ludwig and Kok, 1998). Harlequin bugs specialize on plants in the cabbage family (Brassicaceae), such as cabbage, broccoli, kale, turnip, radish, horseradish, mustard, rape, etc. (McPherson, 1982). Plants in this family often have a hot or sharp taste due to high concentrations of mustard oil glycosides, compounds known for their antifeedant and toxic properties (Louda and Mole, 1991; Zrybko and Rosen, 1997; Aliabadi and Whitman, 2001). Aldrich et al. (1996) recently detected aglycones of mustard oil glucosides in harlequin bugs, suggesting that *M. histrionica* obtained these compounds from its crucifer host plants.

As in virtually all pentatomids, *M. histrionica* possesses metathoracic scent glands (MTGs); however, the glands are much smaller than in most other members of this family (Aldrich et al., 1996), and they expel less secretion upon disturbance. Indeed, we were unable to obtain any liquid from the MTGs of many of the individuals we collected from the field or the laboratory (Whitman, unpublished). The MTG secretion contains primarily (2*E*, 6*E*)-octadienedial, with small amounts of (*E*)-2-octenal and (2*E*, 6*E*)-octadiene-1,8-diol diacetate (Aldrich et al., 1996). In addition, when squeezed, harlequin bugs expel a frothy fluid from the margins of the prothorax containing two odorous alkylmethoxypyrazines (Aldrich et al., 1996), a class of compounds thought to function as warning odors in a large number of chemically defended insects (Guilford et al., 1987; Kaye et al., 1989; Moore et al., 1990; Aldrich et al., 1997). The prothoracic fluid also appears to contain three thiocyanides (*sec*-butyl isothiocyanate, methylthiopropyl nitrile, and methylthiobutyl nitrile) (Aldrich et al., 1996), which are related to glucosinolates commonly found in cabbage (Fenwick et al., 1983). In this paper, we demonstrate that harlequin bugs sequester mustard oil glucosides from their crucifer host plants and that the specific compounds sequestered depend on the plant species fed upon. We also show that some birds reject harlequin bugs as prey.

METHODS AND MATERIALS

Insects. Harlequin bugs, *Murgantia histrionica* (Hahn), were collected from wild mustard plants in Clearlake, California, USA, in 1997 and thereafter cultured at room temperature in the laboratory at Illinois State University on cabbage, mustard, and kale.

Experiment 1—Single-Plant Diets. We established colonies of harlequin bugs on six different plant species: *Sinapis alba* (white mustard), *Crambe abysinnica* (crambe), *Armoracia rusticana* (horseradish), *Brassica oleracea* (cabbage), *Tropaeolum majus* (garden nasturtium), and *Buddleia davidii* (butterfly bush). For the first three, the plants and insects were raised in isolated outdoor plots at the ISU farm. For the remaining three, colonies of bugs were established in the laboratory and fed leaves of store-bought cabbage or garden-grown nasturtium or butterfly bush. Each colony remained on its single plant species diet for 4–9 weeks

(4 weeks on butterfly bush, after initial growth on cabbage), which, for all diets except butterfly bush, was long enough for the bugs to complete a generation. Bugs on butterfly bush lived, but did not grow or reproduce. The first four plant species are Brassicaceae, whereas nasturtium and butterfly bush are Tropaeolaceae and Loganlaceae, respectively. The three plant families are not closely related, but nasturtium contains a mustard oil glucoside, glucotropaeolin, as a major constituent. After 4–9 weeks, bugs from each diet were chemically analyzed for presence of glucosinolates.

Experiment 2—Effects of Host-Plant Transfer. In order to investigate the effects of host-plant transfer on potential sequestration, we analyzed the glucosinolate contents of bugs reared on two diets: cabbage for 6 months and then switched to nasturtium for either 3 or 6 days.

Experiment 3—Glucosinolate Titers in Guts and Bodies. To determine if glucosinolates were present in body tissues other than the gut, we raised harlequin bugs for 6 months on cabbage, then dissected out the digestive system, being careful not to contaminate the insect hemocoel with gut contents. We analyzed 20 guts and 20 degutted bugs for presence of glucosinolates.

Chemical Analysis. We extracted plants by immersing foliage (0.6–0.9 g fresh weight) in 5 ml boiling water for 10 min. Bugs were extracted in batches of 5 (ca. 0.3 g total weight) from each plant by quick freezing before immersion in boiling water for 10 min. We filtered the resulting aqueous extracts, then added these to individual DEAE Sephadex columns for enzymatic desulfation of the glucosinolates, according to the method of Minchinton et al. (1982). High-pressure liquid chromatography (HPLC) of the desulfoglucosinolates was conducted on a Hewlett Packard model 1100 apparatus equipped with a diode array detector. The column was a C-18 Luna 3μ, 150×4.6 mm (Phenomenex, Torrance, California, USA), with a flow rate of 0.75 ml/min. A solvent program of water and acetonitrile was used, with 100% H_2O from 0 to 5 min, a linear increase in acetonitrile to 35% at 35 min, and a linear increase to 100% acetonitrile at 40 min. Injections of 100 μl from 4 ml total sample were used, and the UV absorption of the eluate was monitored at 229 nm.

Frozen bug guts and degutted bodies were extracted in the same way in batches of 5, then analyzed by HPLC; the column was a semipreparative C-18 Luna 5μ, 250×10 mm (Phenomenex), with a flow rate of 1.8 ml/min. The same water/acetonitrile solvent gradient was used as for the analytical column.

We did not attempt quantitative analysis due to a lack of standard compounds; however, we made comparative estimates of quantities present in the bugs based on peak area units as a result of integration of the chromatographic peaks. We tentatively identified individual glucosinolates based on retention times, comparison with extracts of plants of known glucosinolate composition, and UV spectra.

Predator Trials. To determine if harlequin bugs were palatable to bird predators, we trained wild European starlings, *Sturnus vulgaris*, and house sparrows,

Passer domesticus, to come to a ground-level feeder (a 30- × 30-cm board) containing adult, larval, and pupal mealworms (*Tenebrio molitor*), and small pieces of raw pork. After 4 days of training, we began testing the birds by observing their behaviors from a blind, 3 m distant. We used harlequin bugs that had been reared on brown mustard, *Brassica juncea*. All insects in all tests were frozen and then thawed before use, and all tests were conducted on May 30, 1999, a cloudless, humid summer day. Except for trial 4, all trials ended about 4 min after the last control insect was removed from the feeder. Crickets (*Acheta domesticus*) were not offered during the training period, but were offered during the trials. Hence, our experimental design allowed us to test the responses of birds to known palatable prey (mealworms), novel palatable prey (crickets), and novel unpalatable prey (harlequin bugs). Trial 1 took place at 14:02 hr. Two boards were placed 10 cm apart. Board 1 contained 8 adult crickets; board 2 contained 8 adult harlequin bugs. Trial 2 took place at 14:38 hr. A single board was placed out containing 7 adult, 7 larval, and 1 pupal mealworm, 7 pieces of pork, and 7 adult harlequin bugs. Trial 3 took place at 15:20 hr. We placed 14 adult and 13 larval mealworms, 6 pieces of pork, and 19 adult harlequin bugs onto a single board. Trial 4 took place at 15:35 hr. We placed 16 adult harlequin bugs onto a single board; this trial continued for 1 hr. Trial 5 took place at 17:50 hr. We placed 9 adult and 11 larval mealworms, 8 adult crickets, and 12 adult harlequin bugs onto one board.

RESULTS

Chemical Analysis of Single-Plant Diets. Insects from each of the four colonies of harlequin bugs that fed on a single crucifer diet and the bugs that fed on nasturtium showed qualitative differences in glucosinolate content, matching, for the most part, the chemistry of the plant species fed upon (Table 1). Insects fed cabbage contained sinigrin and glucobrassicin (Figure 1), the two most prominent glucosinolates in cabbage. White mustard contained glucosinalbin, which eluted at 15.8 min, and this matched the major peak (at 15.8 min) from extracts of the harlequin bugs fed on this plant (Figure 2). Extracts of crambe plants revealed sinigrin at 13.2 min and additional glucosinolates, probably gluconapin at 13.7 min, progoitrin at 17.7 min, and hydroxyglucobrassicin at 18.3 min. An additional compound at 25.6 min matched the retention time and UV spectrum of gluconasturtiin. The adult harlequin bugs fed on crambe showed three peaks at 13.1, 13.6, and 17.6 min, matching the retention times and UV spectra of sinigrin, gluconapin, and progoitrin (Figure 3). Insects fed horseradish contained sinigrin, which eluted at 13.5 min and an unknown at 28.0 min. Analysis of adult harlequin bugs raised on horseradish indicated the presence of sinigrin at 13.6 min, but not the unidentified peak at 28.0 min (Figure 4). Glucotropaeolin was the major glucosinolate in garden nasturtium (28.5 min), and in bugs fed this noncrucifer, glucotropaeolin eluted at the same time (Figure 5). Butterfly bush contained no glucosinolates,

TABLE 1. COMPOUNDS DETECTED IN SIX DIFFERENT PLANT SPECIES AND IN HARLEQUIN BUGS RAISED ON THEM

Plant species	Compounds detected in	
	Food plant	Harlequin bug
Cabbage (*Brassica oleracea*)	sinigrin (21.5)[a], glucobrassicin (≈31.0)	sinigrin (21.5), glucobrassicin (≈30)
White mustard (*Sinapis alba*)	glucosinalbin (15.8)	glucosinalbin (15.8)
Crambe (*Crambe abyssinica*)	sinigrin (13.2), gluconapin (13.7), progoitrin (17.7), hydroxyglucobrassicin (18.3), gluconasturtiin (25.6)	sinigrin (13.1), gluconapin (13.1), progoitrin (17.5)
Horseradish (*Armoracia rusticana*)	sinigrin (13.5), unknown (28.0)	sinigrin (13.6)
Garden nasturtium (*Tropaeolum majus*)	glucotropaeolin (28.5)	glucotropaeolin (28.5)
Butterfly bush (*Buddleia davidii*)	none detected	sinigrin (21.5)

[a] HPLC Retention time (minutes).

but sinigrin and other glucosinolates were present in the harlequin bugs fed this control for 4 weeks.

Host-Plant Transfer. Adult harlequin bugs fed cabbage for 6 months, then transfered to nasturtium for 3 days or 6 days, contained sinigrin, glucobrassicin,

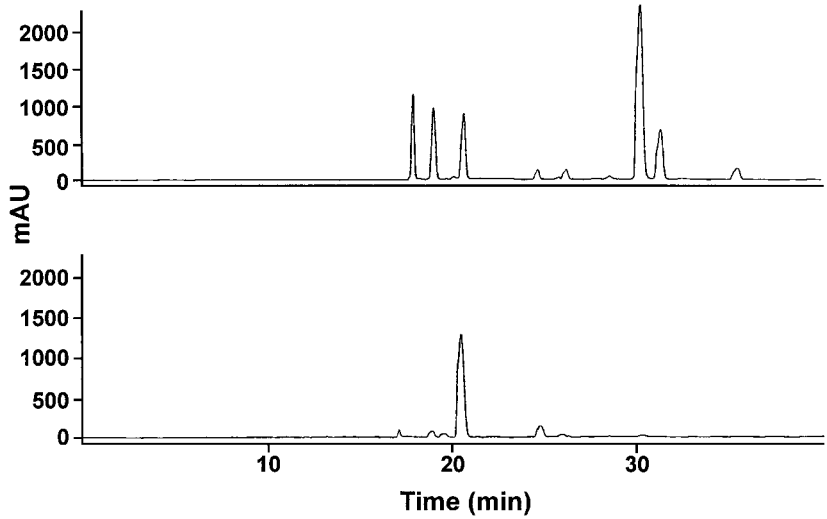

FIG. 1. Harlequin bugs (bottom) fed cabbage (top). Peak at 21.5 min (top) is sinigrin and peak at 31.0 (top) is glucobrassicin.

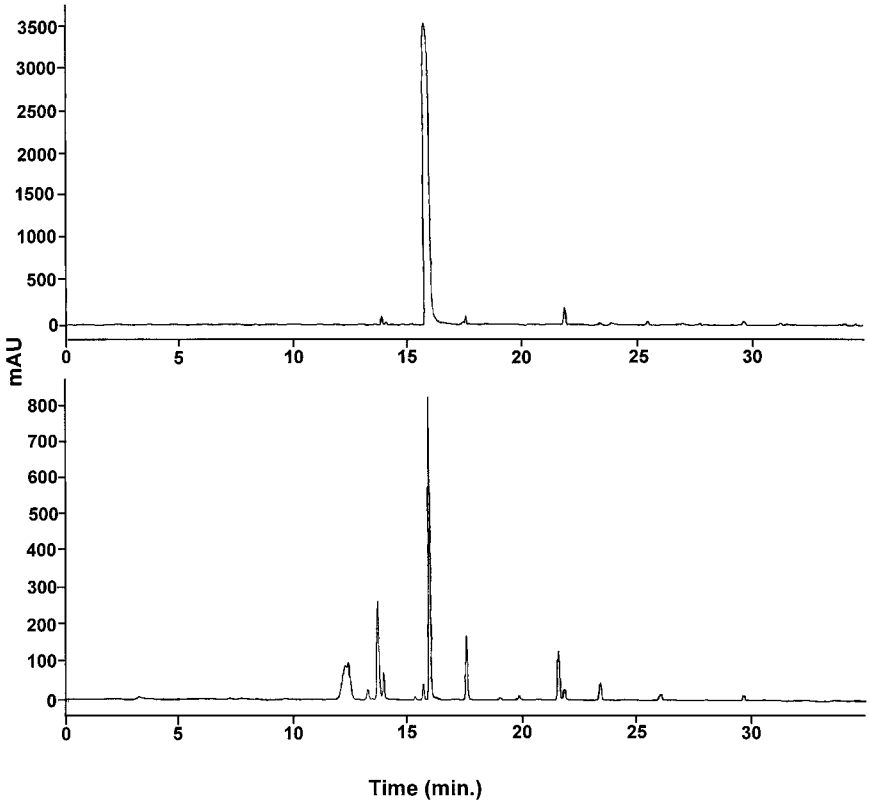

FIG. 2. Harlequin bugs (bottom) fed white mustard (top). Glucosinalbin peak appears at 15.87 min (top).

and glucotropaeolin, suggesting that the bugs had acquired substances from both diets. In animals fed nasturtium for 3 days (Figure 6a), sinigrin was the major peak whereas in animals fed nasturtium for 6 days (Figure 6b), sinigrin was reduced and glucotropaeolin was the major peak.

Glucosinolate Presence in Degutted Bugs. Harlequin bug guts and degutted bodies contained both sinigrin and glucobrassicin, the two major glucosinolates in cabbage, but the bug bodies had higher concentrations of both compounds than the bug guts. In addition, both the guts and bodies contained sinigrin in higher concentrations than glucobrassicin, despite the predominance of glucobrassicin in cabbage (data not shown).

Predator Trials. At least six sparrows and four starlings visited the feeders during the course of the five trials. Normally, two to three birds fed at the feeder at any one time, with six individuals feeding simultaneously on one occasion. In all

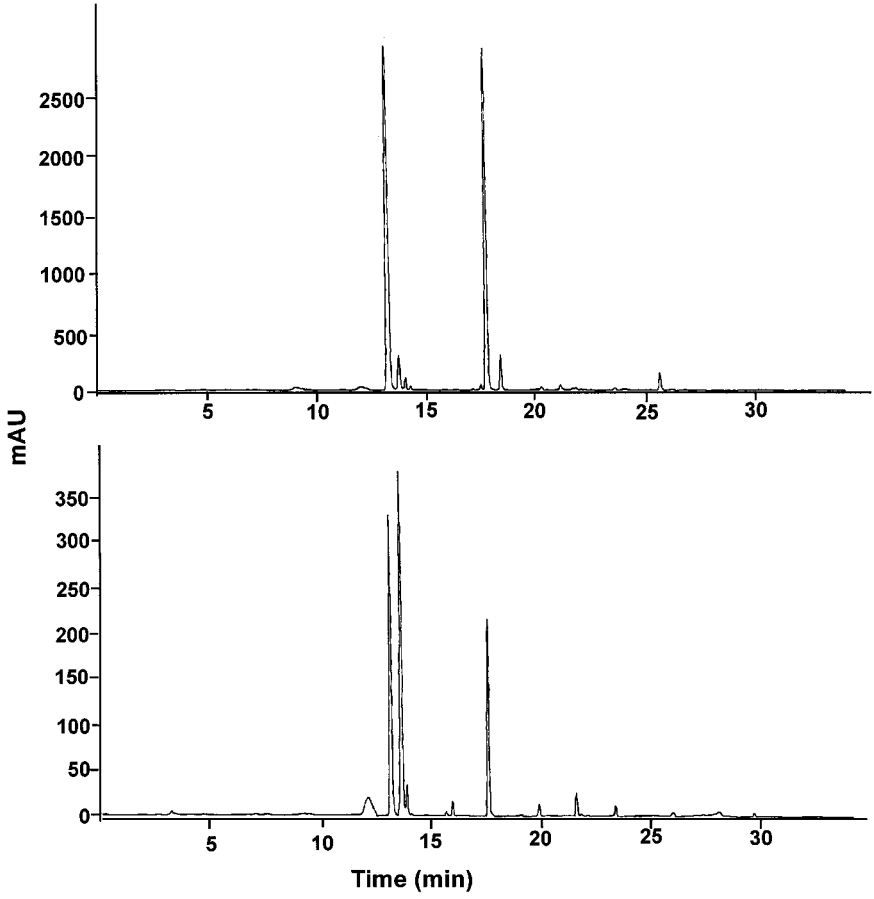

FIG. 3. Harlequin bugs (bottom) fed crambe (top). Sinigrin appears at 13.2, gluconapin at 13.7, progoitrin at 17.7, hydroxyglucobrassicin at 18.3, and gluconasturtiin at 25.6 min (top).

trials, birds arrived at the feeders within 6.5 min of the start of the trial. Individual birds normally remained at the feeder for less than 2 min, during which time they took four to seven prey items, then flew away. In trials 1, 2, 3, and 5, all control food items (crickets, pork, and mealworms) were removed from the feeder by 14, 7, 8, and 20 min, respectively.

During the trials, birds demonstrated a strong preference for crickets, pork, and larval, pupal, and adult mealworms, but rejected nearly all harlequin bugs (Table 2). Over the course of the five trials, the birds removed all 91 control (palatable) food items offered, but only 3 of the 62 harlequin bugs offered. On

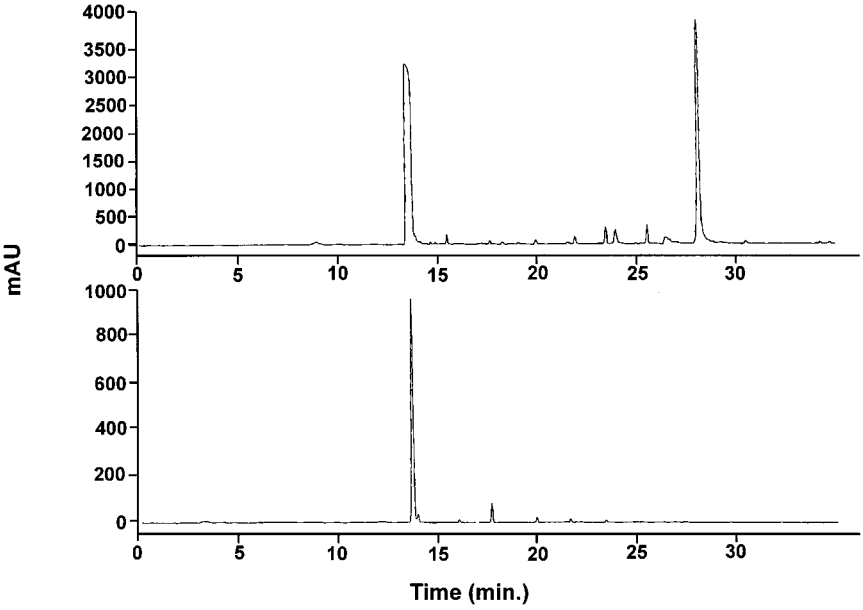

FIG. 4. Harlequin bugs (bottom) fed horseradish (top). The two major peaks for horseradish (sinigrin and unknown, respectively) appear at 13.5 and 28.0 min.

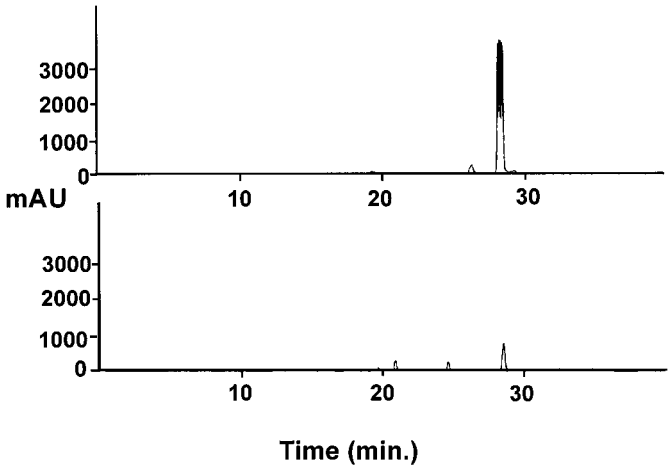

FIG. 5. Harlequin bugs (bottom) fed garden nasturtium (top). The major glucosinolate for this plant is glucotropaeolin (28.5 min).

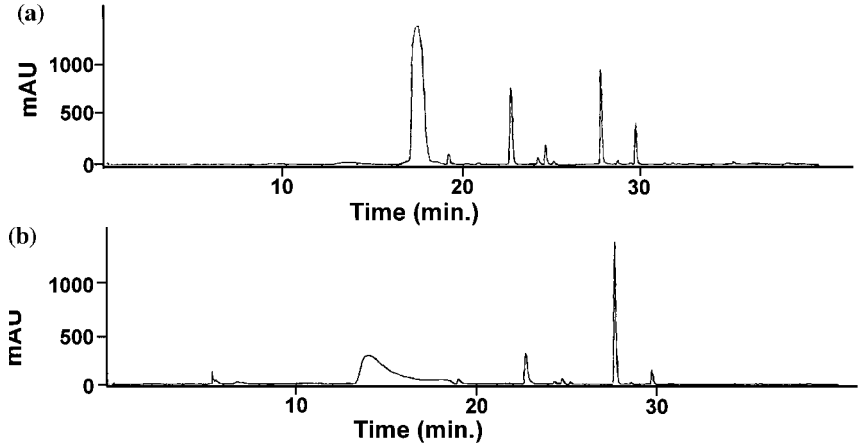

FIG. 6. (a) Harlequin bugs fed cabbage for 6 months, then transferred to garden nasturtium and allowed to feed for 3 days. Sinigrin (17.5 min), glucotropaeolin (27.5 min), and glucobrassicin (29.5 min). (b) Harlequin bugs fed cabbage for 6 months, then transferred to garden nasturtium and allowed to feed for 6 days. Sinigrin (14.0 min), glucotropaeolin (27.5 min), and glucobrassicin (29.5 min).

three occasions, we observed a sparrow pick up, then drop, a harlequin bug. On three other occasions, we found harlequin bugs on the ground away from the feeder, suggesting that they had been flung or knocked away by birds. In trials 1, 2, 3, and 5, many birds returned to the feeder after all control prey items had been taken. These birds moved about the feeder and inspected the remaining harlequin bugs (cocked or lowered their heads), but did not feed on them. When only harlequin bugs were offered (trial 4), starlings inspected the feeder 4 times and sparrows inspected 12 times, during a 1-hr period, but no harlequin bug was attacked.

TABLE 2. PREY REMOVED BY WILD STARLINGS AND HOUSE SPARROWS FROM A FEEDER

	Control items (N)		Harlequin bugs (N)	
Trial	Offered	Removed	Offered	Removed
1	8	8	8	1
2	22	22	7	0
3	33	33	19	1
4	0	0	16	0
5	28	28	12	1
Total prey	91	91	62	3

DISCUSSION

The results suggest that harlequin bugs sequester glucosinolates from crucifer host plants and thereby gain defensive benefits. To our knowledge, this is the second example of sequestration in the large family Pentatomidae, the fourth example of sequestration of plant toxins among the Heteroptera, and the third example of sequestration of crucifer glucosinolates by an insect (Aliabadi and Whitman, 2001; Müller et al., 2001). Larvae of the large white butterfly, *Pieris brassicae*, feed on crucifers and apparently sequester glucosinolates, making the adults the most toxic of all British Pieridae (Alpin et al., 1975). In contrast, *P. brassicae* caterpillars reared on artificial diets are readily consumed by birds, suggesting that they lose their repellent qualities when denied a source of glucosinolate.

The chemical analysis of whole bodies demonstrates that harlequin bugs are capable of acquiring a range of glucosinolates from their diet and that the specific compounds obtained reflect the plant species consumed. Bugs fed cabbage acquire cabbage glucosinolates. Bugs fed crambe contain glucosinolates specific to crambe, and bugs fed garden nasturtium contain the glucosinolate specific to that plant. These substances can be acquired from either plants in the cabbage family or from those in other families (e.g., Tropaeolaceae), if they contain glucosinolates.

The host plant transfer studies show that bugs that fed on garden nasturtium for only 3 days contained appreciable quantities of glucotropaeolin, a glucosinolate specific to this plant. These studies also suggest that the bugs can retain acquired glucosinolates for some time. For example, bugs transferred from cabbage to garden nasturtium, a plant that contains no sinigrin, still possessed a high titer of sinigrin after 6 days of feeding only on nasturtium. Because 6 days is long enough for the bugs to empty their guts of cabbage sap, the presence of sinigrin implies sequestration. Indeed, indirect evidence suggests long-term storage of glucosinolates: the adult bugs fed 4 weeks on butterfly bush, a plant devoid of glucosinolates, still contained small amounts of sinigrin, probably held from the time when they were originally reared on cabbage.

The presence of glucosinolates in whole body extracts of harlequin bugs does not necessarily demonstrate sequestration, because the glucosinolates may have been present only in the gut. True sequestration normally requires that the substance move out of the gut into other body tissues. In the case of cabbage-fed insects, sinigrin was found in both the gut and degutted body, but nondigestive tissues contained much higher concentrations of glucosinolates ($\sim$20–30 $\times$ greater) than guts, indicating that these compounds are concentrated in the body. The fact that sinigrin was not detected in insects fed white mustard or garden nasturtium (Table 1) suggests that the bugs do not synthesize this substance autogenously.

It is not known how the harlequin bug obtains the enzymes necessary to break down glucosinolates. Cruciferous plant tissues contain myrosinase, an enzyme that

degrades glucosinolates into volatile toxins (Fenwick et al., 1983). Therefore, the harlequin bug could sequester myrosinase along with glucosinolates, manufacture the enzyme, or do both.

In our experiments, sparrows and starlings did not consume harlequin bugs. This feeding aversion could have arisen via several mechanisms, including neophobia (Coppinger, 1970; Schlenoff, 1984; Sargent, 1990), dietary conservatism, innate or learned fear of aposematic color patterns (Guilford, 1990), or distasteful external chemicals such as MTG or prothoracic gland secretions (Whitman et al., 1990; Aldrich, et al. 1996). However, it is possible that the birds were deterred, in part, by the presence of plant-derived glucosinolates, because these compounds are known to be distasteful, aversive, or toxic to a wide range of predators, including vertebrates (Aliabadi and Whitman, 2001). Furthermore, insects that contain sequestered glucosinolates are generally shunned by predators. Finally, our observations argue against neophobia, dietary conservatism, or innate fear of warning patterns, because: (1) the birds readily attacked crickets the first time offered (trial 1); and (2) during the feeding trials, we observed birds picking up harlequin bugs in their beaks, and three bugs disappeared, presumably eaten or at least carried away by birds. The birds were not deterred from sampling the bugs; hence rejection was probably based on taste.

Although this is only the fourth known example of sequestration in the true bugs, this phenomenon is probably common, given the large number of warningly colored bugs that feed on chemically defended plants.

Acknowledgments—We thank Susan Webb who supplied us with insects, Brianna Aliabadi and Dr. Steve McElfresh for editing the figures and reviewing the manuscript.

(Received February 4, 2002; accepted May 19, 2002)

Abstract—We investigated the growth-reducing effects of pyrrolizidine alkaloids (PAs) from *Senecio jacobaea* on nine plant-associated fungi (five strains of *Fusarium oxysporum*, two of *F. sambucinum*, and two of *Trichoderma* sp). Fungal growth was monitored on water agar media containing different concentrations of monocrotaline, retrorsine, or a purified extract of PAs from *S. jacobaea*. The growth rate of six strains was inhibited by PAs at the highest test concentration (3.33 mM), with the magnitude of the inhibition (7–35%) being dependent upon the specific fungus-PA interaction. In general, the PA extract caused the largest inhibition. However, the fungi isolated from *S. jacobaea* were positively affected by the PA extract (7–9%). Retrorsine N oxide was as effective as retrorsine in its inhibition of mycelium growth.

Key Words—*Senecio jacobaea*, pyrrolizidine alkaloids, anti fungal activity, retrorsine, N oxide, monocrotaline.

INTRODUCTION

Members of the plant genus *Senecio* produce a wide range of secondary metabolites. The best known are the pyrrolizidine alkaloids (PAs), which are also found in other genera of the Asteraceae such as *Eupatorium*, as well as in the Boraginaceae, Fabaceae, and Orchidaceae (Hartmann, 1999). PAs are ester alkaloids that can be found in as plants tertiary amines and their N oxides. In *Senecio*, PAs are synthesized in the roots as N oxides (Hartmann and Toppel, 1987),

*To whom correspondence should be addressed. E-mail: hol@rulsfb.leidenuniv.nl

0098-0331/02/0900-1763/0 © 2002 Plenum Publishing Corporation

and the corresponding tertiary PAs are regarded as degradation products of N oxides.

In *Senecio* species, 124 different PA structures have been described (Hartmann and Witte, 1995), and in a single species like *Senecio jacobaea* L., up to 14 PAs can be found (Witte et al., 1992). In addition to possessing a large variation of PA structures, *Senecio* species vary greatly in the amount of PAs produced, a trait that has been shown to have a genetic component (Vrieling et al., 1993).

The major function of PAs is assumed to be defense against herbivores. PAs cause severe liver damage in many mammalian species (Mattocks, 1986), sometimes resulting in death (Molyneux et al., 1991). PAs may deter generalist insect herbivores (Van Dam et al., 1995) or have a negative influence on their growth (Vrieling et al., 1991). Specialist herbivores are sometimes attracted by PAs and sequester them for their own defense (Boppré, 1986; Schneider, 1987; Hartmann and Witte, 1995). Adapted insects store plant-derived PAs preferably as N oxides. N oxidation is believed to be a detoxification mechanism (Cheeke, 1994).

The target of PAs in mammals is cytochrome P-450 (Huan et al., 1998). In vitro assays have demonstrated that PAs can interfere with neuroreceptors (Schmeller et al., 1997) and protein synthesis (Wink et al., 1998). Moreover, recombinagenic activity of integerrimine, a PA from *Senecio*, has been detected in somatic cells of *Drosophila melanogaster* (Campesato et al., 1997).

The potential role of insect herbivores has received a great amount of attention in studies attempting to understand the selective forces behind PA diversity. The arms race between plant and attacker is hypothesized to lead to a continuous circle of adaptation by both the attacker and the producer, resulting in the continuous development of new defense compounds produced by plants (Ehrlich and Raven, 1964). However, pathogens such as fungi and bacteria can also be a threat to plant fitness and, therefore, may also influence the selection of defense mechanisms.

Little is known about the potential of PAs to inhibit fungal growth, and has, to date, been reported only for PAs from *Heliotropium* (Jain and Sharma, 1987; Marquina et al., 1989; Reina et al., 1995, 1997). It is unknown to what extent defense against plant pathogenic fungi has attributed to the diversity of PAs in *Senecio*. In this study, a range of plant-associated fungi was tested for their sensitivity to pyrrolizidine alkaloids from *S. jacobaea* and *Crotalaria spp*. Experiments were performed to address the following questions: (1) Do PAs affect fungal growth? (2) Are all PAs equally effective? (3) Do fungi differ in their sensitivity? (4) Are fungi from *S. jacobaea* adapted to PAs from this plant species? (5) Are N oxides equally toxic as bases?

METHODS AND MATERIALS

Experimental Design. The effects of different concentrations of PAs were tested on nine fungal strains in a block design with 10 replicates. In a second

experiment, the effects of retrorsine and retrorsine N oxide were tested on three fungal isolates in a block design with ten replicates.

PAs. Three pure PAs and a mixture of PAs (PA bulk) were used. Monocrotaline (99% pure), retrorsine (99.8% pure), and retrorsine N oxide (>99% pure) were purchased from Sigma-Aldrich (Schnelldorf, Germany). The PA bulk was extracted from leaf material of *S. jacobaea* using a modified version of the method developed by Koekemoer and Warren (1951). Dried milled plant material (1 kg) was soaked in methanol for 24 hr. The filtered methanol solution was evaporated, and the residue was dissolved in sulfuric acid (0.25 M). Chlorophyll and waxes were removed by repeated extraction with petroleum ether and diethylether. The N oxide forms of alkaloids were reduced to tertiary alkaloids by adding zinc dust to the acidic solution. The solution was filtered and brought to pH >10 by adding ammonia. The reduced PAs were extracted by repeated washing with dichloromethane. The composition of the evaporated dichloromethane washing was determined on a GC (HP 6890, 30 m × 0.25 μm, HP-1). The conditions were as follows: injector 250°C, temperature programme 0-22-5-250, split mode 1–30, carrier gas N_2 at 0.9 ml/min, pressure 56 kPa; detector FID. The main PAs (>10% of the total amount of PAs) of the PA bulk were senecionine (12%), seneciphylline (22%), jacobine (24%), and jaconine (24%). The PA content of the extract was 80%, as determined by a color reaction. This was a modification of a method developed by Mattocks (1967), who used monocrotaline (99% pure) as an external standard. To control for the 20% impurity, the crude PA extract was redissolved in dichloromethane and extracted with sulfuric acid. There was residue left in the dichloromethane that did not contain PAs. To check whether the PA bulk extract contained fungal growth-reducing compounds, other than PAs, this residue was included as a treatment, hereafter referred to as the "non-PA fraction." All PAs were dissolved in phosphate-buffered 50% methanol solution (pH 6) before mixing with the fungal growth medium.

TABLE 1. NAMES, ORIGINS AND MAINTENANCE OF FUNGAL SPECIES

Code[a]	Species	Host plant	Origin	Storage

[a] Codes are abbreviations of species names and hostplants. Different numbers refer to different isolates.
[b] PDA = potato dextrose agar.

Fungal Isolates. Nine plant-associated fungal isolates were used (Table 1). Two fungi (taken from the NIOO-CTO collection) originated from unknown host plants. The seven other isolates were collected from dune plants, three from roots of PA producing plants (*S. jacobaea* and *S. vulgaris*), and four from non-PA-producing plants (*Leontodon* sp. *Carex* sp.).

To isolate the fungi, 1-cm pieces of roots were surface sterilized with natriumhypochloride 1% for 10 sec. The root pieces were placed on malt pepton medium, and fungi were isolated from the mycelium that developed on the agar. Isolated fungi were grown on potato dextrose agar. As inoculum for the first experiment, six agar plates were used with 14-day-old cultures of each fungus. For each PA, the inoculum originated from two plates to minimize variation within the treatment. In the second experiment, a subset of three from the nine isolates were used.

Bioassay. Water agar (Oxoid) was sterilized for 20 min at 100 kPa and 120°C and cooled to 50°C, after which the filter-sterilized alkaloid solutions were added. Segmented Petri dishes (Omnilabo, Breda, The Netherlands) were filled with water agar containing either the PA dissolvent only or the dissolvent with 3.33, 0.33, or 0.033 mM alkaloids. These concentrations are within normal plant PA range for *Senecio*. The PAs were tested in separate Petri dishes. For the PA mixture extracted from *S. jacobaea*, a molecular weight of 352 was assumed. This was based on the average molecular weights of senecionine, seneciphylline, jacobine, and jaconine, which were dominantly present in the extract. The 0.033 mM treatment of PA bulk was replaced by the non-PA fraction of the bulk. Fungal plugs (1 cm diam.), taken from the margins of a growing colony, were placed in the central corner of each compartment at the start of the experiment. Petri dishes were stored in darkness at 20°C. Radial growth of the fungal mycelium was measured daily in millimeters. The experiment lasted 30 days, at which time most dishes were completely covered with mycelium. In the monocrotaline treatment, three species did not grow for unknown reasons; no mycelium growth was observed on the PA agar and the control agar. Therefore, data are shown for six fungi instead of nine. In the second experiment, three treatments were present in each Petri dish: retrorsine (3,33 mM), retrorsine N oxide (3,33 mM), and a control with dissolvent.

Statistics. Due to the large variation in fungal growth among dishes, fungal growth rate was chosen as the experimental parameter. Growth rate was estimated as the slope of the linear relation between mycelium radius (mycelium radius >1 mm) and days after inoculation. Comparisons of means of the effects of different PA concentrations were tested with Friedman and Wilcoxon tests for related samples. The growth rate of a treatment was compared to the growth rate of the control in the same Petri dish. For comparisons of the effect of different PAs, mycelium growth rates relative to their controls were compared with Kruskal-Wallis and Mann-Whitney tests for unrelated samples. For all tests SPSS 8.0 was used (SPSS Inc., 1998).

RESULTS

PAs had a variable effect on fungal growth (Figure 1). For several fungus–PA combinations, the growth rate on agar with PA was lower than on the control. In total, six fungi showed reduced growth on agar with PAs. However, not all PAs had the same effect. The magnitude of inhibition depended on the fungus–PA combination. *Trichoderma* sp. was most sensitive, with a relative growth rate of 65% on agar with retrorsine or PA bulk. *F. oxysporum* Sjac was more inhibited by monocrotaline than by the other two PAs.

Mycelium growth was not always negatively influenced by the PA treatments. Five fungi were stimulated at intermediate concentrations of the PA bulk, and two fungi were stimulated even at the highest concentration of PA bulk (Figure 1). Both of these latter isolates were isolated from *S. jacobaea*. The non-PA fraction of the bulk, which replaced the 0.033 mM in the PA bulk, did not show a difference from the control, except for *F. sambucinum* Leo, which was inhibited by this bulk control. However, the inhibition by the 3.33 mM PA bulk was significantly stronger.

Retrorsine N oxide was as effective as retrorsine (Figure 2) in the inhibition of mycelium growth.

DISCUSSION

To our knowledge, this is the first time that PAs from *S. jacobaea* have been shown to inhibit fungal growth. PAs from *Heliotropium* have shown antifungal effects in different assays. Jain and Sharma (1987) demonstrated the inhibition of two fungal species, *Curvularia lunata* and *Fusarium moniliforme* by lasiocarpine N oxide by using an in vitro paper disk diffusion assay. Marquina et al. (1989) also used an agar diffusion method to show growth inhibition of *Aspergillus niger* by lasiocarpine. Reina et al. (1995, 1997) cultured *Fusarium* sp. on potato dextrose agar to which lasiocarpine, 3′-acetyltrachelanthemine, floridinine, or europine were added. *Fusarium moniliforme* was most sensitive to this treatment, with 49% mycelium growth inhibition at a concentration of 1.5 mM 3′-acetyltrachelanthamine. PAs from *Heliotropium* species differ in structure from those of *Senecio*. Retrorsine and monocrotaline are macrocyclic diesters, while the *Heliotropium* alkaloids are open chain diesters.

In most cases, a dose effect is visible, although in a few exceptional cases the lower concentration showed a greater inhibition than observed for the highest concentration, e.g., *F. oxysporum* Svul on monocrotaline. In some cases, the intermediate concentration stimulated fungal growth, whereas the highest concentration was inhibitory, e.g., *F. oxysporum* Care on PA bulk. The concentrations at which most of the inhibitory effects were found (3.33 mM and 0.33 mM) are comparable to PA concentrations found in plant tissue (3–0.3 mM wet weight) under natural

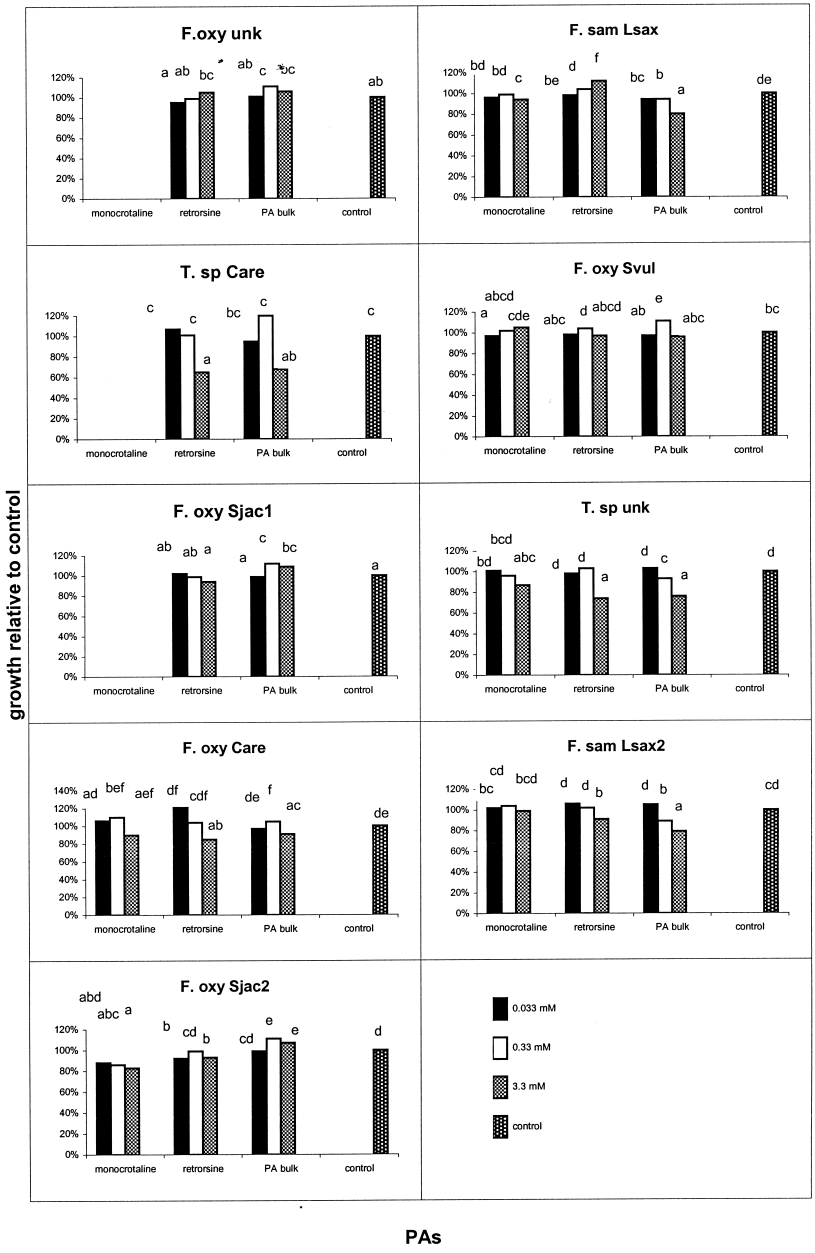

FIG. 1. The growth rate of nine fungi on medium with PAs at three different concentrations compared to the control. Different letters indicate a significant difference ($P < 0.05$, $N = 10$)

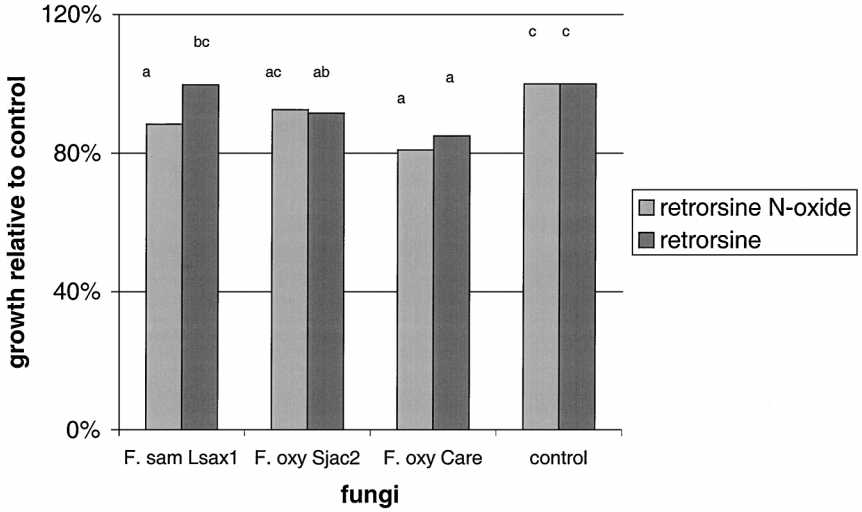

FIG. 2. The growth rate of three fungi on agar with retrorsine and retrorsine N oxide. Different letters indicate a significant difference ($P < 0.05$, $N = 10$)

conditions (Hol, unpublished results). We can only speculate about PA concentrations in the rhizosphere outside the root tissue. Low amounts of PAs have been detected in soil around the roots (E. van der Meijden, personal communication). Hartmann et al. (1989) did not detect PAs in the medium of in vitro cultured *Senecio vulgaris* roots. Similarly, Sander and Hartmann (1989) found no release of PA N oxide in the culture medium. Nevertheless, it is possible that, in soil, sloughing root cells with their PAs form a protective layer.

The tested PAs never totally arrested fungal growth. The growth rate was decreased for some fungi, while others exhibited an initial delay in mycelium growth followed by a normal growth rate. Such growth inhibition or delay may change the competitive abilities of pathogenic and nonpathogenic fungi in vivo, give the plant extra time to raise other defenses, or allow the plant root to escape the fungal attack. With regard to this last possibility, it is interesting to note that a vulnerable root tip can move 4 mm out of reach within 24 hr (Asplund and Curtis, 2001). Due to the artificial nature of our system, this study cannot be interpreted as definite evidence for the protection of plants by PAs. The types of hyphae growing in soil or on fungal growth medium may be very different. Aerial mycelium may be dominant in the Petri dish but not in soil.

pH was a factor in our experiment, but may be less important in plants, which are well buffered. Originally, the experiment was carried out without buffer in the medium. PAs increased the pH of the medium, potentially affecting fungal growth. However, repetition of the experiment, using a buffered system, gave

the same result, indicating that pH could not explain the observed fungal growth effects.

Not all tested compounds showed the same activity. Monocrotaline had a smaller spectrum of activity than retrorsine and the PA bulk. PA bulk was the most active. Growth-reducing effects from compounds other than PAs in *Senecio* spp. have been shown before, such as essential oil of *Senecio graveolens* (Perez et al., 1999), and β-sitosterol from *Senecio lyratus* (Kiprono et al., 2000). As the non-PA fraction of the bulk in general did not show an effect on fungal growth, it seems unlikely that fungal growth reducing compounds other than PAs were present in the extract. Therefore, despite the fact that the extract was not pure, the growth reducing effects are probably attributable to PAs only.

Several explanations are possible for the larger activity of the PA bulk. Combinations of compounds may be more effective than a single compound. We were not able to test for synergistic effects of different PAs in the extract, because not all the alkaloids from the extract were available in pure form. Besides possible synergistic effects, we cannot exclude the possibility that the stronger effect of PA bulk is due to other PAs, like senecionine and jacobine, which may be more active than retrorsine and monocrotaline. Furthermore, it should be pointed out that the PA composition of aboveground plant parts, which we used as the basis for the PA extract, is more diverse than that found in the roots. Tinney et al. (1998) found up to 93% senecionine and its stereoisomer integerrimine in the roots of reproducing *S. vulgaris*. In other plant parts, this varied between 40 and 55%. Therefore, the composition of the PA mixture was probably more diverse than the PA mixture that root-associated fungi in *S. jacobaea* will meet under natural conditions.

Remarkable differences in fungal sensitivity were observed in relation to the host plant. The relative resistance of fungi isolated from *S. jacobaea* and *S. vulgaris* for the PA bulk suggests that adaptation may have taken place. Adaptation to PAs is known for specialized insects, which are able to sequester and use them for their own protection (Boppré, 1986). Adaptation by fungi is also known for other secondary metabolites (Morrissey and Osbourn, 1999), although additional isolates from PA-producing plants will need to be tested in order to determine the generality of fungal adaptation to PAs.

In our experiment, PAs were tested as tertiary alkaloids, while the N oxides are more common in plants. The N oxide is considered to be a nontoxic form, ideal to store in the plant or specialized insect. However, in assays studying the interaction of alkaloids with neuroreceptors and acetylcholine-related enzymes, the N oxide was sometimes more active than the tertiary alkaloid, depending on the receptor tested (Wink et al., 1998). Jain and Sharma (1987) showed that lasiocarpine did not inhibit fungal growth, but its N oxide did. In the present experiment, both the tertiary base and its N oxide were found to be inhibitory, with the N oxide slightly more effective than the tertiary base. As a consequence, the results of this

experiment with PAs in the tertiary form may underestimate the potential effects of PAs in nature.

The present results indicate that PAs may act as defense mechanisms against phytopathogenic fungi. Potential effects on saprophytic fungi, such as the *Trichoderma* sp., and beneficial fungi, such as myccorhiza, are, however, still unknown and require additional study. We still do not know the exact role of PA concentration and diversity in plants under natural conditions with respect to defense against soil borne fungi, and further research is necessary to determine the role of fungi in the evolution of PA diversity.

Acknowledgments—This research was supported by a grant from the Gratama foundation. We thank Ed van der Meijden, Peter Klinkhamer, Klaas Vrieling, Robert Thomson, and George Kowalchuk for critically reading the manuscript, two anonymous refererees and the editor for valuable comments, and Saskia Gerards for identification of the fungal isolates.

Abstract—Extracts of the dorid nudibranch *Asteronotus cespitosus* from two geographically separate regions of Australia and from the Philippines were compared using thin-layer, high-performance liquid and gas chromatography and ^{1}H NMR analysis. Halogenated metabolites were detected in all mollusk specimens. The major component detected in digestive tissue of specimens from the Great Barrier Reef in northeastern Australia was 4,6-dibromo-2-(2′,4′-dibromophenoxy)phenol (**1**), with minor amounts of 3,5-dibromo-2-(3′,5′-dibromo-2′-methoxyphenoxy)phenol (**2**). In a specimen collected from northwestern Australia, only 3,5-dibromo-2-(3′,5′-dibromo-2′-methoxyphenoxy)phenol was found. The specimen from the Philippines contained 2,3,4,5-tetrabromo-6-(2′-bromophenoxy)phenol (**3**) together with a novel chlorinated pyrrolidone (**4**). In addition, the sesquiterpenes dehydroherbadysidolide (**5**) and spirodysin (**6**) were detected in the digestive organs and mantle tissue of the nudibranchs from the Great Barrier Reef and from the Philippines, whereas these chemicals were not found in the specimen from northwestern Australia. All of the chemicals (**1**-**3**,**5**, and **6**) have previously been isolated from the sponge *Dysidea herbacea*, as have chlorinated metabolites related to **4**. This is the first time the characteristic halogenated metabolites that typify *Dysidea herbacea* have been reported from a carnivorous mollusk, which implies a dietary origin as opposed to de novo synthesis.

Key Words—Mollusk, nudibranch, *Asteronotus*, bromophenols, sesquiterpenes, chlorinated peptides, marine chemistry, sponge chemistry, *Dysidea herbacea*, evolution, systematics.

INTRODUCTION

Chemical studies conducted on nudibranchs (Mollusca: Gastropoda: Opisthobranchia) have shown that their secondary metabolites (natural products) can be derived from dietary sources or from de novo biosynthesis (Cimino et al., 1985; Graziani et al., 1996; Gavagnin et al., 2001). In one of the first rigorous comparative studies on mollusk chemistry, the different sponges that had been eaten by the Pacific mollusk *Cadlina luteomarginata* were identified. The relationship between the sponge diet and the terpene metabolites detected in this mollusk was then analyzed (Hellou and Andersen, 1982; Thompson et al., 1982). Faulkner et al. (1990) subsequently reviewed the chemistry of six opisthobranch species, including *C. luteomarginata*, from the Eastern Pacific and concluded that some species show pronounced geographic variation in metabolite composition, probably due to availability of preferred food. In contrast, other species displayed the same chemistry irrespective of geographic location and were, therefore, considered likely to be synthesizing their own metabolites. In those animals that sequester chemicals, certain metabolites that were identified could vary according to geographic location (Faulkner et al., 1990; Fontana et al., 1993), or seasonally (Thompson et al., 1982), and also among animals found in the same locality (Faulkner et al., 1990). Furthermore, nudibranchs store only some of the metabolites obtained from food (Thompson et al., 1982; Cimino and Sodano, 1994; Dumdei et al., 1997a). Kubanek et al. (2000) suggested that certain species of nudibranchs might have the ability either to carry out de novo biosynthesis or to retain defensive chemicals according to habitat–specific factors or need.

To date, de novo synthesis of natural products has been detected in very few (13) species of opisthobranchs and appears to have evolved more than once, as this ability has been identified in taxonomically unrelated groups (Cimino and Ghiselin, 1998, 1999). The sources of natural products found in opisthobranchs include sponges, cnidarians, algae, tunicates, and other opisthobranchs (Avila, 1995). However, the majority of chemicals isolated thus far from nudibranchs originate from sponges upon which they feed (Cimino and Sodano, 1994; Avila, 1995; Cimino et al., 1999).

Previous workers noted that the metabolites from food may be found in the digestive tract or in the mantle tissue (Avila et al., 1990; Fontana et al., 1994, 1999) (Slattery et al., 1998), whereas metabolites synthesized de novo have a tendency to be restricted to mantle tissue or other organs used in defense (Cimino and Ghiselin, 1999; Gavagnin et al., 2001). Some studies have noted the transfer of the substance from the digestive system to organs such as the gills, the mantle dermal formations, and the cerata (Avila et al., 1990; Fontana et al., 1994, 1999; Slattery et al., 1998). It has been suggested that the tissue distribution of certain chemicals may offer evidence of de novo biosynthesis regulation (Kubanek et al., 2000).

The present study reports the possible dietary origins, anatomical distribution, and the geographic variation of the chemical metabolites of the dorid nudibranch *Asteronotus cespitosus* found in the tropical Indo-Pacific Ocean. Neither chemical studies nor reports of food sources have been previously reported in the literature for the genus *Asteronotus*, which has been placed in the family Discodoridiidae Bergh, 1891 (Valdés, in press). We report the isolation of two terpenes [spirodysin (**6**) and dehydroherbadysidolide (**5**)], three bromodiphenyl ethers [2-(2′,4′-dibromophenoxy)-4,6-dibromophenol (**1**), 2-(3′,5′-dibromo-2′-methoxyphenoxy)-3,5-dibromophenol (**2**), and 2,3,4,5-tetrabromo-6-(2′-bromophenoxy) phenol (**3**)], and a new hexachlorinated alkaloid (**4**) closely related to the sponge metabolite dysideapyrrolidone. Possible evolutionary implications of the study results are also presented.

METHODS AND MATERIALS

General Procedures. Analytical thin layer chromatography (TLC) was done using precoated silica gel Merck Kieselgel F_{254} plates with hexane–dichloromethane (1:1) as the eluant. The chromatograms were sprayed with a mixture of vanillin–sulfuric acid or with ethanolic $FeCl_3$ solution.

Gas chromatography–mass spectrometry (GC-MS) analysis was performed on a Hewlett-Packard model 5890A with an MS 5970 spectrometer. The samples were injected at 100°C using an autosampler. Dichloromethane (DCM) was used as a carrier.

High-performance liquid chromatography (HPLC) was performed on a Waters & Associates, Inc., model 501 with a Waters 410 differential detector using a μ-Porasil 300 × 7.8 mm 10 μm column, or on an Agilent 1100 with a 1100 series variable wavelength UV detector using a C-18 250 × 10.0 mm 10 μm column.

One- and two-dimensional nuclear magnetic resonance (NMR) spectra were obtained for sample solutions in $CDCl_3$, at room temperature with a Bruker DRX500 spectrometer (^{1}H, 500 MHz) with a 5-mm TXI-Zgrad probe or with a Bruker DMX750 (^{1}H, 750 MHz) with a 2.5-mm TXI-Zgrad probe.

Collection of Samples. A total of four adult specimens of *Asteronotus cespitosus* (van Hasselt, 1824) (Mollusca: Gastropoda: Opisthobranchia) were collected from three locations. Two specimens were collected from the reef flat at Heron Island, Great Barrier Reef, eastern Australia and were frozen at −70°C. One specimen was collected by SCUBA from near Enderby Island, Dampier Archipelago, northwestern Australia. This specimen was immersed in acetone at 0°C. An additional specimen was collected by SCUBA from the Batangas region in the Philippines, and stored in acetone at 0°C. All specimens were shipped to the University of Queensland, Brisbane, Australia for analysis.

Extraction and Chemical Analysis. One frozen specimen from Heron Island was dissected and the viscera, including the digestive system, was separated from the mantle tissue. The mantle tissue (approximately 30 g) was extracted with DCM–MeOH (1:1) at room temperature for 3 hr; then the solvents were removed to give a brown semisolid. The residues were partitioned in DCM, dried with $MgSO_4$, filtered through a cotton plug, and evaporated under nitrogen to yield 38 mg crude extract. This extract was purified by flash chromatography on silica using a step gradient of hexane–DCM (1:1) to 100% DCM, then 100% MeOH. Fractions containing sesquiterpenes (<1 mg) were further purified by normal-phase HPLC using 5% EtOAc in hexane to give reference samples of dehydroherbadysidolide (**5**) and spirodysin (**6**) for NMR analysis. The isolated weight of each purified terpene was approximately 0.1 mg. The recovery of each terpene could not be quantified precisely because of the volatility of these metabolites. The digestive system of the specimen was extracted separately in DCM–MeOH (1:1) at room temperature to give an olive green residue. The residue was partitioned in DCM, dried with $MgSO_4$, filtered through a cotton plug, and evaporated under nitrogen to yield 49 mg of extract. The semisolid was purified by flash chromatography on silica using a step gradient of hexane–DCM (1:1) to 100% DCM, then through 100% MeOH. Fractions containing bromophenols (1.7 mg) were further purified by normal-phase HPLC with refractive index detection and using 5% EtOAc in hexane to give 1.5 mg of 4,6-dibromo-2-(2′,4′-dibromophenoxy)phenol (**1**).

The second frozen specimen from Heron Island was dissected, and the mantle tissue (approximately 30 g) was extracted using DCM–MeOH (1:1) at room temperature, the solvent was removed to give a brown semisolid. The residue was partitioned with DCM, dried with $MgSO_4$, and the organic solution was filtered through a cotton plug and evaporated under nitrogen. The crude extract weighed 22 mg and was shown to contain dehydroherbadysidolide and spirodysin by NMR, but was not analyzed further. The digestive system of this specimen was also extracted in DCM–MeOH (1:1) at room temperature to yield 161 mg extract. The extract was purified by flash chromatography on silica using a step gradient of hexane–DCM (1:1) to 100% DCM, then through 100% MeOH. Fractions of interest were further purified by normal-phase HPLC using 5% EtOAc in hexane to give 1.7 mg of 4,6-dibromo-2-(2′,4′-dibromophenoxy)phenol (**1**) and 0.13 mg of 3,5-dibromo-2-(3′,5′-dibromo-2′-methoxyphenoxy)phenol (**2**).

For the Philippine specimen, The mantle tissue (approximately 36 g) was extracted using DCM–MeOH (1:1) at room temperature for 3 hr; then the solvents were removed to give a brown semisolid. The residues were partitioned in DCM, dried with $MgSO_4$, filtered through a cotton plug, and evaporated under nitrogen to yield 5 mg crude extract. Digestive tissue (9 g) from the specimen was extracted with DCM. The DCM-soluble portion was dried over $MgSO_4$, filtered, and evaporated under nitrogen to give 5 mg of extract. The crude extract was purified by flash chromatography on silica using a step gradient of 100% hexane, DCM,

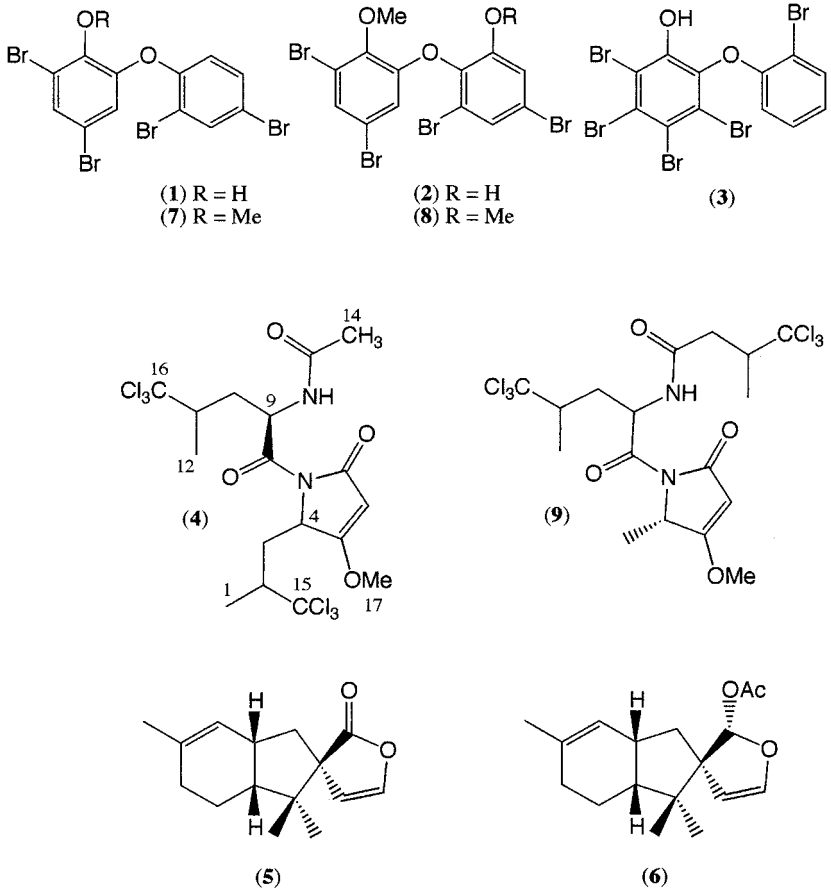

FIG. 1. Compounds found in the tropical Nudibranch *Asteronatus cespitosus*.

ethyl acetate through to 100% MeOH. The bromophenol-containing fractions were further purified by normal-phase HPLC to give <1.0 mg of 2,3,4,5-tetrabromo-6-(2′-bromophenoxy)phenol (**3**), while the chlorinated alkaloid (**4**) was isolated in 0.5 mg yield by reverse phase chromatography using MeOH–H_2O (9:1) with UV detection at 240 nm.

For the Dampier specimen, approximately half (50 ml) the acetone from the specimen collected at the Dampier Archipelago was concentrated and then partitioned with DCM. The DCM-soluble portion was dried over $MgSO_4$, filtered, and evaporated under nitrogen to give 5 mg. The crude extract was purified by flash chromatography on silica using a step gradient of 100% hexane, DCM, ethyl

acetate through to 100% MeOH. The bromophenol-containing fractions were further purified by normal-phase HPLC to give 1.4 mg of 3,5-dibromo-2-(3′,5′-dibromo-2′-methoxyphenoxy)phenol (**2**).

Methylation of Bromophenol Metabolites. Solutions of bromophenols **1** and **2** (each 1 mg) in diethyl ether were treated with diazomethane in diethyl ether at 0°C overnight; then the solvents were removed under a stream of nitrogen to give the methylated products **7** and **8** (0.8 and 0.9 mg, respectively).

Cytotoxicity Assays. Compounds **1**, **2**, **5**, and **6** isolated from *Asteronotus* were tested for cytotoxicity (IC50 correlation) against P388 cells based on luminescence detection of ATP according to standard procedures.

RESULTS

The major polybrominated diphenyl ether 2-(2′,4′-dibromophenoxy)-4,6-dibromophenol (**1**), found exclusively in the digestive tract of *A. cespitosus* collected from Heron Island, was identified by comparison of proton NMR data for the free phenol (Carté and Faulkner, 1981) and its methylated derivative (**7**) (Kuniyoshi et al., 1985; Cameron et al., 2000) with literature data. The digestive tract of both specimens from Heron Island also contained traces of a second bromophenol identified as 3,5-dibromo-2-(3′,5′-dibromo-2′-methoxyphenoxy)phenol (**2**) by comparison of the ^{1}H NMR data for the free phenol and its methylated product (**8**) with literature data (Carté and Faulkner, 1981; Norton et al., 1981). In the first specimen, the ratio of **1** to **2** was >50:1, while in the second it was 15.7:1.

Digestive tissue from a specimen collected in the Philippines contained the known 2,3,4,5-tetrabromo-6-(2′-bromophenoxy)phenol (**3**) (Salva and Faulkner, 1990) together with the novel chlorinated pyrrolidone (**4**). The structure of **4**, $[\alpha]_D + 4.8$ [$c = 0.0004$ g/ml (**4**) in $CHCl_3$)], followed from its molecular formula, determined by HR-ESMS on the (M + H) ion at 528.9796 ([^{35}Cl]$C_{17}H_{23}N_2O_4Cl_6$ requires 528.9789), together with analysis of NMR data. The ^{13}C NMR showed signals for 16 carbons only (Table 1); signals at 93.7, 168.8, and 179.0 ppm, together with a ^{1}H signal at δ 5.10 (s) were attributable to a pyrrolidone ring (Hofheinz and Oberhänsli, 1977; Unson et al., 1993). The NMR also displayed signals for two trichloromethyl groups (^{13}C; 105.3 and 105.2 ppm) and an *N*-acetate (^{1}H δg.00; ^{13}C 23.6 and 169.5 ppm). In the ^{1}H NMR, a signal at δ 2.82 (^{1}H, m, H-11) was coupled to two multiplets at δg.67 and 2.68 (H-10; each ^{1}H), and to a methyl doublet at δ 1.42 (H-12), consistent with a trichloroleucyl residue (Dumdei et al., 1997b). The δ 1.67 and 2.68 signals were further coupled to a multiplet at δ 5.77 (H-9) that was adjacent to an –*N*-H signal at δ 6.30. A second trichloroleucyl moiety could also be identified since a methyl doublet at δ 1.36 (H-1) was coupled to a signal at δ 2.77, which was coupled to multiplets at δ 2.04 and 2.40 and further coupled to a double doublet at δ 4.73 (H-4). There was an

[c]Not detected in ^{13}C NMR spectrum; comparison with data for **9** suggests signal may be obscured by that of C-7 or C-13. No HMBC correlation from H-9 visible.

HMBC correlation between H-6 of the pyrrolidone ring and C-4 at 58.2 ppm. The chemical shifts of the H-10 signals are consistent with *R* stereochemistry at H-9 (Dumdei et al., 1997b; Stapleton et al., 2001); no stereochemistry could confidently be assigned to H-4. All known trichloromethyl metabolites isolated from marine sources have *S* stereochemistry at the trichloromethyl-substituted carbons (Dumdei et al., 1997b). There was an insufficient amount of (**4**) for degradative studies to confirm the proposed absolute stereochemistry.

Mantle tissue from Heron Island and Philippine samples of *A. cespitosus* did not contain these halogenated metabolites. Instead these extracts were found to contain the sesquiterpenes dehydroherbadysidolide (**5**) and spirodysin (**6**), which were identified by comparison of their GC-MS profiles with reference samples and by comparison of their ^{1}H NMR data with the literature (Kazlauskas et al., 1978; Cameron et al., 2000).

The *Asteronotus* specimen collected in northwestern Australia was stored for approximately two months in acetone and was not partitioned into mantle and digestive tissue. The specimen was shown to contain bromophenol (**2**); by

comparison with the Heron Island and Philippine data, we infer that this metabolite may have been localized in digestive tissue. Although the extract from Northwestern Australia did not contain either of terpenes **5** or **6** that were found in the Great Barrier Reef specimens, it did contain traces of other sesquiterpenes by GC-MS; however, the amounts were insufficient for analysis by 500 MHz NMR.

Compounds **1**, **2**, **5**, and **6** isolated from *Asteronotus* were tested for cytotoxicity and showed activity against P388 cells at 0.029, 0.012, 0.03 and 0.008 mg/ml, respectively. Thus, the bromophenols and terpenes showed comparable cytotoxicity, with spirodysin the most potent metabolite.

DISCUSSION

This is the first reported isolation of the two sponge terpenoid compounds, spirodysin and dehydroherbadysidolide, from a marine mollusk. In addition, three polybrominated diphenyl ethers, also found previously in sponges, are reported from a nudibranch. This is the first reported isolation of polybrominated diphenyl ethers from a carnivorous mollusk, although a closely related metabolite was found in the sea hare *Aplysia dactylomela* and in its algal diet (Kuniyoshi et al., 1985). GC-MS analysis and NMR provided the positive identification of these known compounds. A novel chlorinated pyrrolidone, structurally related to metabolites previously isolated from sponges, was also isolated. This is the first example of a marine pyrrolidone metabolite in which the heterocyclic ring may be derived from trichloroleucine and acetate (Harrigan et al., 2000).

Halogenated natural products characterize sponges of the genus *Dysidea*. Brominated diphenyl ethers have been isolated from sponges from the Great Barrier Reef (Cameron et al., 2000) and from Western Australia (Capon et al., 1981). *Dysidea herbacea* from the Great Barrier Reef is known to contain (**1**) as a secondary metabolite (Flowers and Garson, personal communication). The bromophenol (**2**) has been previously isolated from samples of *Dysidea herbacea* from Australia and the Caroline Islands (Norton et al., 1981), while (**3**) has been reported from the Philippines (Salva and Faulkner, 1990) as has dysideapyrrolidone (**9**) a close structural analogue of (**4**) (Unson et al., 1993).

According to Faulkner et al. (1990), geographic variation in the chemistry of a particular species of nudibranch indicates that the metabolites are of dietary origin rather than synthesized de novo. However, we cannot assume that the lack of variation in chemistry automatically indicates de novo synthesis because it could also simply imply that the food species are widespread.

Krug et al. (1995), noting the presence of certain chemicals in the mantle tissue of *Sclerodoris tanya*, suggested that this was an indicator of de novo synthesis if the same chemicals were absent from the digestive organs. In the case of *Asteronotus*, all the specimens examined had different chemistry. Although the

sample size is small, it appears that the chemicals vary geographically. Furthermore, the sesquiterpenes isolated were in both mantle and digestive tissue and so are unlikely to be products of de novo synthesis. Thus, we infer that the chemicals isolated from *Asteronotus* are of dietary origin. Since five out of the six metabolites are known *Dysidea herbacea* compounds, previously isolated from sponges collected in the same geographic locations as our mollusk collections, we hypothesize that *Asteronotus cespitosus* was eating *D. herbacea* or a closely related sponge. In particular, the detection of brominated and chlorinated metabolites, both of which are characteristic of *D. herbacea,* in the Philippine specimen of *Asteronotus* is suggestive of a *D. herbacea* origin, since it is highly unlikely that the nudibranch could have independently evolved two such distinctive biosynthetic capabilities. However, we have never encountered specimens of *Asteronotus* on or eating this sponge and cannot eliminate the possibility that these same chemicals may be contained in other sponge species. It appears possible, however, that *Asteronotus* has similar dietary requirements in all three geographic locations.

The results suggest that the dorid nudibranch *Asteronotus* shares traits with closely related nudibranchs. First, from our data, this species selectively sequesters certain potent chemicals, particularly sesquiterpenoids, that it probably obtains from its food source. The ability to sequester sesquiterpenes has previously been noted for other species of Doridoidea: *Cadlina* and *Tyrinna* (Cimino and Ghiselin, 1999).

Second, in the case of *Asteronotus* as well as with other dorid nudibranchs, we speculate that the animals eliminate chemicals that would be either too potent to incorporate into body tissue or not as effective as defensive chemicals. Faulkner and Ghiselin (1983) first suggested this scenario when discussing the adaptability of organisms in general. They reasoned that food materials would be selectively retained with the most defensively effective compounds accumulated, while less effective ones would be discarded. Alternatively, Pennings et al. (1999) suggested that accumulating dietary derived metabolites in the digestive organs occur to detoxify a diet that is chemically potent.

Polybrominated diphenyl ethers have been shown to be cytotoxic (this study) and active in brine shrimp lethality tests (Handayani et al., 1997). Other studies have shown these compounds to be active against gram-positive bacteria, gram-negative bacteria, and phytopathogenic fungi (Unson et al., 1993; Handayani et al., 1997), to act as enzyme inhibitors (Fu et al., 1995), and to function as potent fish-feeding deterrents (Pennings et al., 1994). Some polychlorinated metabolites show strong antifeedant properties (Unson, 1993).

Sesquiterpenes such as spirodysin are closely related in structure to terrestrial plant-derived insect antifeedants (Schulte et al., 1980). These compounds, isolated from *Dysidea herbacea* and closely related sponges, have been found to have ichthyotoxic or antifeedant properties (Thompson et al., 1982; Unson, 1993; Marin et al., 1998) as well as antifouling properties (Sera et al., 1999).

Considering the data from the present and previous studies, it seems a reasonable hypothesis that the dorid nudibranch *Asteronotus* retains the sesquiterpenes for the antifeedant and/or ichthyotoxic properties. It is possible that the brominated diphenyl ethers are eliminated as too toxic to incorporate (in view of the enzyme inhibitory properties and the results of the cytotoxicity tests performed during this study) rather than being less effective in predator deterrence. If additional live animals become available, analyses of the feces from these nudibranchs would enable us to further test our hypothesis regarding the elimination of diphenyl ethers from the dietary tract.

A third characteristic that may be shared by *Asteronotus* with closely related dorids is the additional defense mechanism of cryptic coloration that may be a consequence of diet-derived pigments. Other dorids such as *Rostanga* acquire their coloration from the sponge on which they feed (Faulkner and Ghiselin, 1983). Some *Asteronotus* have the same brownish yellow color found in some *Dysidea* sponges. It may be that *Asteronotus* developed coloration to resemble its sponge diet or its coral habitat. Although protective coloration is common in marine invertebrates, it is possible that in the case of *Asteronotus*, the camouflage may be a consequence of the sponge diet (Marin et al., 1997). If *Asteronotus* is protected chemically, crypsis may not be required for defense. Camouflage is not an effective defense against predators such as sea stars, nudibranchs, and crustaceans that do not have eyes and are not visual. However, it is possible that *Asteronotus* may be protected both chemically and visually.

Cimino and Ghiselin (1999) note that chemical defense may be the catalyst for the evolution of opisthobranch gastropods. The common ancestor of the nudibranchs is thought to have used terpenoids derived from sponges for chemical defense, and this ability is retained by *Asteronotus* (Cimino and Ghiselin, 1999). Faulkner and Ghiselin (1983) have noted that the distribution of chemicals in a phylogenetic tree will provide useful information when making evolutionary interpretations. Brunckhorst (1993) and Valdés and Gosliner (1999) used chemical metabolites as characters in phylogenetic analyses of dorid nudibranchs.

Comparison of the chemical metabolites found in *Asteronotus* with the most closely related genus, *Halgerda* (Fahey and Gosliner, 2001) will allow for evolutionary hypotheses concerning defense mechanisms. Collection and analysis of additional specimens of *Asteronotus* and other opisthobranchs, along with the sponges upon which they are found feeding can provide opportunities to examine predator–prey coevolution.

Acknowledgments—The authors thank Clay Bryce from the Western Australian Museum for the *Asteronotus* specimen from the Dampier Archipelago. Thanks to John Walker from the University of Sydney for the two *Asteronotus* specimens from Heron Island. Mary Jane Adams collected the *Asteronotus* specimen in the Philippines. Bronwin Stapleton assisted with the technical aspects of the extraction process and performed some of the NMR analyses. Andrew Flowers of the Centre for Phytochemistry, Southern Cross University, kindly conducted the cytotoxicity studies. This research

was partially funded by Woodside Petroleum and the California Academy of Sciences, Research Division who sponsored S.J.F.' fieldwork at the Dampier Archipelago. The National Science Foundation partially funded this research through PEET grant DEB #9978155 (phylogenetic systematics of dorid nudibranchs) to Terrence M. Gosliner. The Australian Federation of University Women funded S.J.F. through a Freda Bage Fellowship. The Australian Research Council provided funds to M.J.G. through grant #A00104788. Specimens were collected under permits organized and/or issued by The Western Australian Museum for the participants at the Woodside Dampier Marine Biological Workshop 2000; by the Great Barrier Reef Marine Park Authority to John Healy, #g98/110 and by the Bureau of Fisheries and Aquatic Resources, Philippines to Terrence Gosliner, #10-2001. The two anonymous reviewers provided very helpful comments, and we appreciate their efforts.

ORIENTATION OF THE FIDDLER CRAB, *Uca cumulanta*: RESPONSES TO CHEMICAL AND VISUAL CUES

ROBERTO CHIUSSI* and HUMBERTO DIAZ

Centro de Ecologia
Instituto Venezolano de Investigaciones Cientificas
Apartado 21827, Caracas 1020A, Venezuela

(Received April 7, 2000; accepted May 12, 2002)

Abstract—Behavioral responses of the fiddler crab *Uca cumulanta* to flat geometric shapes mimicking natural objects were measured in a circular arena by using zonal recovery as a behavioral measurement. Crabs were tested either in presence or absence of odors from two common predator species, the blue crab *Callinectes sapidus*, and the pufferfish *Sphoeroides testudineus*. The study tested the hypothesis that *U. cumulanta* have different behavioral responses to visual cues in the presence of chemical cues associated with predators. Escape direction tests demonstrated that *U. cumulanta* is able to show zonal recovery behavior based upon astronomical references. When tested in water lacking predator odor, crabs failed to exhibit a consistent orientation if a single silhouette target was interposed in the landward direction. However, when animals were tested in different predator odor concentrations, an orientation response was obtained at 10 and 20 g/liter/hr blue crab odor and 10 g/liter/hr pufferfish odor, demonstrating *U. cumulanta* ability to detect the potential presence of its natural predators by this odor. Thus, the hypothesis was supported, and the results suggest that behavioral responses to chemical and visual cues are involved in predator avoidance.

Key Words—Fiddler crabs, *Uca*, chemical cues, vision, behavior.

INTRODUCTION

Orientation is basic to all motile animals living along shorelines (Herrnkind, 1983). Directional movement usually consists of *y*-axis orientation (Ferguson, 1967), in which animals move upshore or downshore along a line perpendicular to the shoreline. Local landmarks, beach slope, waves, and celestial cues can direct these movements. Among decapod crustaceans, *y*-axis orientation is well documented

0098-0331/02/0900-1787/0 © 2002 Plenum Publishing Corporation

for brachyuran crabs (Herrnkind, 1983; Cameron and Forward, 1993), anomuran crabs (Rebach, 1981; Dunham and Schöne, 1984; Watt et al., 1985; Altizer and Forward, 1993), and shrimps (Ugolini et al., 1988; Goddard and Forward, 1989).

Visual cues, such as natural and artificial objects, including two-dimensional shapes, can influence or guide directional orientation in specific situations (Herrnkind, 1983). A shape discrimination capability in decapod crustaceans is strongly suggested by studies of visual orientation in fiddler crabs (Herrnkind, 1972, 1983; Langdon and Herrnkind, 1985), mangrove crabs (Díaz et al., 1995b), and hermit crabs (Orihuela et al., 1992; Díaz et al., 1994, 1995a).

Although visual orientation is well documented in shallow-water decapod crustaceans, there is limited knowledge about integration of information sensed by both visual and olfactory stimulation. The striped leg hermit crab, *Clibanarius vittatus*, increases the chance to encounter an empty gastropod shell by integrating proprioceptive inputs from the host shell, chemical cues, and visual recognition (Hazlett and Herrnkind, 1980; Rittschof, 1980a,b; Hazlett, 1982; Gilchrist, 1984; Rittschof et al., 1990; Orihuela et al., 1992; Díaz et al., 1994, 1995a,b). In another hermit crab, *C. antillensis*, object discrimination is based on visual and chemical information (Chiussi et al., 2001). Chemical and visual cues are also involved in predator avoidance of megalopae of the blue crab *Callinectes sapidus* (Díaz et al., 1999).

The present study examines the orientation of *Uca cumulanta* Crane, 1943 to visual and chemical cues, testing the hypothesis that adult fiddler crabs have different behavioral responses to visual cues in the presence of chemical cues associated with predators. For behavioral measurement, we utilized zonal recovery, a capability, in which, as in many other mobile intertidal animals, *U. cumulanta* is able to maintain or return—in case of previous displacement—to portions of the beach that offer them favorable conditions (Herrnkind, 1983; Pardi and Ercolini, 1986; Chiussi and Diaz, 2001). The fiddler crab *U. cumulanta* occurs only in Venezuela, Curaçao, and Suriname (Carmona-Suarez and Conde, 1996), in the intertidal zone of sheltered banks of muddy shores or sandy mud shores close to mangroves, but not under their shade. Populations are usually concentrated somewhat below mid-tide level (Crane, 1975).

METHODS AND MATERIALS

Adults of *U. cumulanta* (carapace width: 8–12 mm) were collected from the littoral zone of a small sandy shore at the perimeter of a mangrove forest (Mochima National Park, Venezuela, 10°20′N, 64°20′W). The onshore direction (YL) at the collection site was 150°, where 0° corresponds to the magnetic North. Crabs were tested at the site on the same day of collection and then returned to their habitat. They were assayed in a circular Plexiglas arena (22 cm diam.) supported on a metal

platform 1 m high. A 5-cm-high white wall surrounded the arena, with a white translucent diffuser at the bottom. The wall allowed animals to see a considerable portion of the sky, but hid the surrounding landscape from view. The bottom of the arena had a plunger attached, which was used to introduce the crabs into the center of the arena. The silhouette of a tested crab was viewed from underneath through the translucent floor. The arena was filled to a depth of approximately 4 cm with aged filtered seawater (36 ± 1 psu, $26 \pm 1^{\circ}$C). Individuals were released in seawater, because this medium provokes rapid response in fiddler crabs as well as in many other supralittoral and littoral crustaceans (Herrnkind, 1983; Pardi and Ercolini, 1986). To ensure no odors from organic sources were present in the seawater used in experiments other than those released by the experimental crabs, the seawater was filtered through an 800-kDa membrane and aged for one week in the dark.

Fifty individuals were tested in each experimental condition. A test was initiated by introducing a single animal in the center of the arena by means of the plunger. The first point of contact with the arena's wall was recorded as the orientation direction (10° accuracy). Individuals that did not reach the arena's wall within 60 sec were recorded as not responding. After each trial, individuals were placed in a large glass bowl containing aged seawater. If individuals were used in a different test on the same day, at least 30 min elapsed between trials.

Control Tests. This test was designed to verify a crab's ability to assume the onshore direction in a confined environment. Individuals were tested with astronomical cues present (e.g., sun, clear sky) at two different times of day (from 08:00 to 10:00 hr and from 12:00 to 13:00 hr). In order to test possible interpopulational changes in zonal recovery behavior due to geographical change of the habitat, a second group of 50 crabs that originated from a beach with a different YL axis (245°), was also tested.

Visual Cues. A single target attached to the outside of the arena wall served as a visual cue. It was positioned in the onshore direction. Six targets were used. They consisted of flat shapes subtending different visual angles: (1) two black horizontal rectangles (20°, 90°); (2) striped rectangles with parallel black and white bars (20°, 90°); every bar subtended a 2° angle; (3) black ovals positioned vertically and horizontally. The target dimensions were (height width, in centimeters): oval (2.48×0.87), 20° striped and black rectangles (1.90×2.48), and 90° striped and black rectangles (1.90×15.70).

Visual and Chemical Cues. Aged seawater was conditioned with odors released from an individual predator of known weight introduced in a glass container with a known volume of aged seawater and maintained for variable intervals of time to obtain different odor concentrations. For example, a predator weighting 50 g, placed in 20 liters of aged seawater for 1 hr would render an odor concentration of 2.5 g/liter/hr ($50/20 \times 1$ hr), while if the same animal is left for 2 hr,

an odor concentration of 5 g/liter/hr would be obtained. Crabs were tested for orientation to visual cues in aged seawater conditioned by two predators: the blue crab *Callinectes sapidus* Rathbun and the pufferfish (Tetradontidae) *Sphoeroides testudineus* (Linnaeus, 1758).

A preliminary predator odor trial was performed to establish the optimal predator odor concentration, i.e., the odor concentration that evoked a behavioral response to a target. In this case, we tested a horizontal oval as a target with the following odor concentrations: 2.5, 5, 10, 20, and 40 g/liter/hr. The optimal odor concentration, which was 10 g/liter/hr for both predators, was used with the six selected targets.

Laboratory Tests. Laboratory tests were carried out in the absence of astronomical references. Crabs were tested with each one of the targets with and without a chemical stimulation (predator conditioned water). In the laboratory, the illumination was provided by a circular fluorescent lamp (Philips, model TLE 32W/54) delivering an intensity of 56.5 μmol photons m^2 sec at the center of the arena. The circular lamp was positioned around the arena in a way that its outer edge was 2 cm outside the test arena wall.

Statistical Analysis. Circular statistical methods were used to analyze the data distribution (Zar, 1996). The resulting mean angle (a°) and length of the mean vector (r) were calculated for each experimental condition. The mean vector (r) has values from 0.00 to 1.00 and varies inversely with the amount of dispersion in a data set. The Rayleigh test (z) determined whether the distribution was different from uniformity. The V test for the mean angle determined whether the mean angle differed from the expected direction (YL). In the case of the visual cue tests, the expected angle was established a priori in the middle of the target. For an escape response, we predicted the expected orientation would be the opposite direction from the center of the target ($\pm 180^\circ$). The bimodality of some distributions was analyzed by doubling the angles (Zar, 1996). For the figures and tables, if the z statistic for the Rayleigh test indicated the distribution was uniform, then the distribution was designated as not significant (NS). Alternatively, if the z statistic indicated the distribution was nonuniform ($P < 0.05$), then the V test was run, and u indicated the significance level.

RESULTS

Control Tests. In all three cases by varying the relative position of the sun and YL axis, crabs oriented towards their respective onshore directions, regardless of the time of day. These results allowed us to choose 120° as the direction for the target position in all the successive tests.

Visual Cues. In water devoid of chemical cues, crabs showed no preferential response when exposed to each targets (Table 1) except for the 20° black rectangle.

[a] Treatments are: no odor, pufferfish odor (10 g/liter/hr) and blue crab odor (10 g/liter/hr). Expected direction for control tests was assumed as the YL direction (150°). Symbols: *N*, responding sample size; *r*, mean vector length; *a*(°), mean vector angle, *z*, value for the Rayleigh test; sig., significance of the statistical test value (NS, not significant; $^{*}P < 0.001$ for Rayleigh test or $^{**}P < 0.005$ for *V* test); *u*1, value for *V* test calculated assuming as expected direction the center of the target (120°); *u*2, value for *V* test calculated assuming the angle opposite to the target (300°); Az., mean direction of sun azimuth during tests in the field.

In this case, the observed distribution was diametrically bimodal, towards and away from the target.

Visual and Chemical Cues. When crabs were presented with a horizontal black oval silhouette in water conditioned by different concentrations of predator odor, they exhibited an escape response with 10 g/liter/hr pufferfish odor and a diametrically bimodal distribution with 10 and 20 g/liter/hr blue crab odor (Table 2). Crabs showed no preferential response when exposed to the other concentrations of both predator species (Table 2). Therefore, we utilized concentrations of 10 g/liter/hr of both predator species with all other targets.

In the presence of 10 g/liter/hr water conditioned by pufferfish, fiddler crabs showed a significant orientation towards the vertical oval silhouette (Table 1). In contrast, they exhibited an escape response to the 20° black rectangle and the 20° and 90° striped rectangles (Table 1), orienting in the opposite direction (300°). A

[a] Fifty animals were used for each treatment.

diametrically bimodal distribution was observed when the crabs were exposed to the 90° black rectangle (Table 1).

With 10 g/liter/hr blue crab odor, animals showed an escape response away from the 20° black rectangle and the 90° striped rectangle (Table 1). When presented with the 90° black rectangle, the 20° striped rectangle and the vertical oval, the crabs oriented uniformly (Table 1).

Laboratory Tests. When surrounded by the white background with no chemical cue, *U. cumulanta* displayed a uniform distribution (Table 3), which indicated there was no directional bias due to the apparatus or technique. When presented with each one of the six targets, animals always exhibited a uniform distribution (Table 3).

In the presence of 10 g/liter/hr pufferfish odor, crabs showed significant orientation towards the 90° black rectangle (Table 3). In contrast, they exhibited an escape response to the 20° and 90° striped rectangles (Table 3). A uniform distribution was displayed with other targets (Table 3). In water with 10 g/liter/hr blue crab odor, animals showed the same distributional pattern observed in the pufferfish odor tests (Table 3).

DISCUSSION

Different stimuli can be perceived in different manners and intensities; they also can simultaneously affect animals in their natural habitat. Thus, there is a need to integrate stimuli perceived by different sensory systems (sight, smell,

[a] Treatments are: no odor, pufferfish odor (10 g/liter/hr), and blue crab odor (10 g/liter/hr. For symbols see Table 1.

touch, etc.). Integration of stimuli results in more appropriate behavioral responses (Hazlett, 1996, 1997, 1999, 2000). The present study proves that fiddler crabs, *Uca cumulanta*, have the capability to integrate information from both visual and chemical cues. Predator odor evoked an escape response in *Uca cumulanta* when striped targets and some black targets were presented.

As observed in other decapod species (Rebach, 1981) including *Uca* species (Herrnkind, 1983), *U. cumulanta* on its home beach is able to show zonal recovery behavior based upon astronomical references, such as sun and polarized light in the sky (Chiussi and Díaz, 2001). Zonal recovery allows animals living in ecotonal environments to maintain or return to particularly favorable zones or to escape from sources of stress as quickly as possible (Herrnkind, 1983). This behavior was used as a biological measurement for evaluating the capacity of *U. cumulanta* to integrate sensory information. For this, a visual stimulus was presented alone or simultaneously with a chemical cue to test zonal recovery behavior.

When a target was presented in the predicted onshore direction of the crabs home beach (YL) in the presence of the astronomical cues, crabs failed to orient in a consistent direction, except in the presence of a 20° black rectangle (Table 1). In

the latter case, the orientation distribution was found to be symmetrically bimodal. In all other cases, crabs did not display any directional preference (Table 1). In a similar test carried out at the laboratory, without any astronomical cues, crabs also failed to orient in a particular direction (Table 3).

Chemical cues from two common predators, the pufferfish *Sphoeroides testudineus* and the blue crab *Callinectes sapidus*, were used. Since the behavioral response might vary with odor concentration (Forward et al., 1996), crab orientation was observed in tests using a single visual target (horizontal black oval) and varying odor concentrations (see Table 1). As a result, a behavioral response was obtained at blue crab odor concentration of 10 and 20 g/liter/hr and a pufferfish odor concentration of 10 g/liter/hr. The fish odor evoked an avoidance response, while the blue crab odor induced a bimodal response significantly different from a uniform distribution. Thus, the results indicate that *U. cumulanta* is able to detect the presence of its natural predators by their odor. As reported in recent studies (Mckelvey and Forward, 1995; Forward et al., 1996), chemical detection is possible within a range of concentrations, beyond which responses disappear. Using concentrations that evoke a directional orientation (Table 1), fish odor evoked an avoidance response to black oval, 20° black and striped rectangles, and 90° striped rectangle.

In contrast, when a 20° black vertical oval was presented en route to the beach, crabs oriented towards it. This response was interpreted as a refuge-seeking response. When a black rectangle subtending 90° was presented, a significant number of crabs oriented in the onshore direction but avoided the rectangle reaching the arena's wall at both ends of the target (Table 1). It seems that crabs interpret the 90° black rectangle as an obstacle in their route towards their home beach area. The same pattern, as observed in field experiments, was encountered in laboratory trials with pufferfish odor (Table 3).

The results suggest that in the presence of chemical cues *U. cumulanta* can show different responses to different shapes. There are two types of visual identification, one based on the simple dimensional characteristics of figures. In this case, a crab's response is proportional to changes in height, width, or both dimensions of the target. In the other case, identification is by association, in which an animal associates shapes to typical objects in its habitat (Langdon and Herrnkind, 1985). None of the targets presented to *U. cumulanta* resembled any object in the crab's natural surroundings. However, such targets mimic characteristics of particular objects in their habitat. Discrimination by dimensional characteristics is unlikely because *U. cumulanta* respond differently to targets of equal proportion (e.s., 90° black and striped rectangles). Similar responses have been observed for *U. pugilator* (Langdon and Herrnkind, 1985), for juveniles of the mangrove crabs *Aratus pisonii* and *Chlorodiella longimana* (Díaz et al., 1995b), and the hermit crab *Clibanarius vittatus* (Orihuela et al., 1992; Díaz et al., 1994). In these cases, the orientation responses towards the tested figures probably resulted from associating

the target dimensions to habitat elements such as marsh grass leaves for *U. pugilator*, mangrove leaves or props for *A. pisonii*, hollow spaces for *C. longimana*, and shell shapes for *C. vittatus*. In the case of *U. cumulanta*, the orientation away from the striped target might be interpreted as an escape response, with crabs viewing the striped figures as either a fish school or a seagrass meadow from which a predator might attack. Pufferfish and blue crabs inhabit seagrass meadows (Cervigon, 1978; Carmona-Suarez and Conde, 1996), and odors of both evoke escape responses (Tables 1 and 3), which supports the hypothesis that under appropriated chemical stimulation, *U. cumulanta* is able to discriminate shapes according to typical elements from its natural habitat.

(Received November 29, 2001; accepted May 5, 2002)

Abstract—The male-produced sex pheromone of the red-shouldered stink bug, *Thyanta pallidovirens* (Stål) (Hemiptera: Pentatomidae) consists of a blend of methyl (*E*2,*Z*4,*Z*6)-decatrienoate (*E*2,*Z*4,*Z*6–10:COOMe), and the sesquiterpenes (+)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene. In laboratory bioassays, sexually mature males attracted sexually mature females but not males, and females did not attract either sex. Extracts of volatiles collected from sexually mature males contained compounds not present in extracts from females or sexually immature males, and male-produced extract was attractive to females. Biological activity was lost when the extract was fractionated, indicating that the pheromone consisted of at least two components having different chemical properties. Individually, pheromone components were not attractive to females, but *E*2,*Z*4,*Z*6–10:COOMe in combination with at least one of the three male-produced sesquiterpenes was attractive. The presence of more than one sesquiterpene in the blend did not increase attraction, indicating redundancy in the pheromone signal. Male extract was as attractive as a blend reconstructed from synthesized compounds, indicating all biologically active components had been identified. In bioassays conducted at dusk in a 1- × 1- × 1-m screen field cage, females were attracted to synthetic pheromone lures. In field trials, adult female *T. pallidovirens* were attracted to pheromone-baited traps in relatively low numbers. The profile of volatiles released by sexually mature males of a congeneric species, *Thyanta accerra custator* McAtee, was remarkably similar to that of male *T. pallidovirens*, with the exception that

the former species produced (*E*)-2-decenal, a compound that was not found in *T. pallidovirens* extracts.

Key Words—Sex attractant pheromone, Pentatomidae, redundant, methyl (*E*2,*Z*4,*Z*6)-decatrienoate, sesquiterpene, α-curcumene, zingiberene, β-sesquiphellandrene, *Thyanta pallidovirens*, *Thyanta accerra custator*.

INTRODUCTION

True bugs in the family Pentatomidae (Heteroptera), commonly known as stink bugs, are notorious for the copious quantities of pungent defensive chemicals that they produce when disturbed (Aldrich 1988, 1995). The defensive chemicals, which are produced and stored in large metathoracic glands, are composed of blends of short-chain saturated, mono- and diunsaturated esters, aldehydes, and 4-oxo-alkenals, with the blends being qualitatively similar between species (Aldrich 1988, 1995). It is less well known that phytophagous stink bugs also produce sex pheromones from unicellular glands in the abdomen (Pavis and Malosse, 1986; Lucchi 1994). From the examples known (reviewed in McBrien and Millar, 1999), the pheromone is produced by males rather than females, and the components are chemically distinct from the defensive compounds, consisting of terpenoids, methyl esters of multiply conjugated carboxylic acids, and in one recently reported case, a macrolide lactone (Leal et al., 1998). However, the roles of the pheromones, and even the critical components of blends, have not been examined methodically and are not well understood. Studies of the pheromone blends are further complicated by the fact that stink bugs use two distinctly different sensory modalities for intersexual communication, with sex pheromones being used for longer-range orientation, and substrate-borne vibrational signals being used for intersexual communication at shorter ranges (e.g., Ota and Çokl, 1991; Çokl et al. 2001). It has also been suggested that the pheromones may stimulate production of the shorter-range vibrational signals that are used by males to locate females once they are on the same plant or substrate (Miklas et al., 1999).

Stink bugs are polyphagous and cause sporadic to chronic damage in a wide variety of crops, including grains, cotton, vegetables, berries, fruits, and nuts (Schaefer and Panizzi, 2000; McPherson and McPherson, 2000). For the past several decades, bugs often were kept to economically insignificant levels by pesticides applied to control other insects (Turnipseed and Greene, 1996). However, crop damage by stink bugs is increasing as an unintended consequence of recent fundamental changes in crop protection, such as the widespread deployment of genetically modified crop plants that express gene products from *Bacillus thurengiensis* (*B.t.*). Because the *B.t.* proteins expressed by a plant are active against only a limited number of insect families or even genera (some Lepidoptera or Coleoptera, depending on the *B.t.* strain), these plants are not protected from attack by other insects (Wilson et al., 1992; Federici, 1999). For example, the deployment of

transgenic cotton in the southeastern United States, and the subsequent reduction in pesticide applications has been correlated with increased feeding damage by pentatomid and mirid bugs (Turnipseed and Greene, 1996; Greene et al., 1999). An analogous situation has arisen in pome fruits, in which the reduction or elimination of insecticide sprays to control the primary pest (codling moth) in favor of pheromone-based mating disruption has contributed to a massive resurgence of stink bug damage in apple and pear crops (McGhee and Brunner, 1996). In a US Department of Agriculture-sponsored areawide project to control the codling moth with mating disruption, stink bug damage reached levels as high as 50% in some orchards in the Pacific Northwest in 1998 (J. F. Brunner, personal communication). In those crops, problems with stink bugs and other secondary pests may jeoparize the continued implementation of mating disruption of codling moth in the Pacific Northwest, with the threat of massive damage to fruit crops from stink bugs and other secondary pests providing an incentive for growers to resume multiple prophylactic applications of broad-spectrum pesticides.

The red-shouldered stink bug, *Thyanta pallidovirens* (Stal) (Hemiptera: Pentatomidae) is a pest of a variety of crops in western North America, including pistachios, pome fruit, tomatoes, legumes, and cruciferous crops (Rice et al., 1988; Anonymous, 1991; Schotzko and O'Keeffe, 1990). This insect is also a vector of plant pathogens, including *Botryosphaeria dothidea*, a fungal pathogen infecting pistachio (Daane et al., 2000). Because of its agricultural importance, it was chosen as a useful target for studies aimed at developing practical applications for stink bug semiochemistry. Preliminary studies of *T. pallidovirens* mating behaviors had shown that females were attracted to males, consistent with the presence of a male-produced pheromone (Wang and Millar, 1997).

Our goals in the work reported here were twofold. First, we wanted to carry out a methodical, bioassay-driven identification of the sex pheromone of the stink bug *T. pallidovirens*, with the specific aim of determining the roles of individual components in the attractant. Second, we wanted to assess whether stink bug pheromones have potential for use as attractants for sampling stink bug populations, analogous to the attractant baited traps that are used for sampling many other agricultural and quarantine pests.

We report here that sexually mature male *T. pallidovirens* produce a sex attractant pheromone with several unusual features. The pheromone is composed of four compounds, including a thermally unstable, straight-chain ester probably derived from an acetogenin biosynthetic pathway, and three chiral sesquiterpene hydrocarbons. Whereas the ester is an indispensable part of the blend, any one, any two, or all three sesquiterpenes apparently can constitute the rest of the attractant. To our knowledge, this degree of redundance is unprecedented in an insect pheromone blend. Furthermore, the profile of volatiles produced by sexually mature males of a congeneric species, *Thyanta custator accerra*, was examined, and was found to be remarkably similar to that of male *T. pallidovirens*.

METHODS AND MATERIALS

Insects. A laboratory colony of *T. pallidovirens* was started from bugs collected from alfalfa, vetch, or pistachio from sites near Davis, Fresno, and Riverside, California, USA. Field-collected individuals were added to the colony during the summer months each year. Insects were reared in a controlled environment room at 24°C ±1°C, 55 ± 10% relative humidity, with a 16L:8D photoregime provided with Sylvania Octron 32 W fluorescent lights. Insects were fed raw sunflower seeds and peanuts, organically grown green beans, and alfalfa bouquets in water. From December to April, food was supplemented with cuttings of annual weeds [London rocket, *Sisymbrium irio* (Brassicaceae) and shepherd's purse, *Capsella bursa-pastoris* (L.) (Brassicaceae)]. Food was replaced every other day.

The main colony was maintained in a wooden cage (76 × 46 × 46 cm) with filter paper (12.5 cm diam.) provided as an oviposition substrate, and new adults were added every other day. Eggs were collected from 20 breeding pairs kept individually in cylindrical paper cartons (10 × 9 cm) with screen tops; pairs were changed weekly. Eggs were collected every other day and held on filter paper in plastic Petri dishes (10 cm diam. × 2 cm high) until hatch. Newly hatched nymphs were provided with food within 24 hr of eclosion to prevent desiccation. Second-instar nymphs were transferred to larger plastic containers (16 cm diam. × 7 cm high) with two 2-cm-diam. screen-covered holes on the sides for ventilation. Fourth instars were transferred to similar, but larger plastic containers (15 cm diam. × 14.5 cm high), with two screened ventilation holes, with 20 insects per container. To increase the internal surface area and provide insect perches, a folded piece of filter paper (12.5 cm diam.) and a folded piece of 0.25-in. mesh hardware cloth were placed inside each container.

Two days after the final molt, adults for experiments (see below) were separated by sex and held as virgins in screen-topped paper cylinders (12.5 cm diam. × 16.5 cm high). After use in experiments, adults were returned to the breeding colony.

Thyanta custator accerra McAtee were field-collected from mesquite (*Prosopis* spp.) and Russian thistle (*Salsola tragus* L.) from Aricopa and Pima counties, Arizona, USA; from buckwheat *Erigonum fasciculatum* (G. Bentham) and alfalfa in Riverside County, California, and from buckwheat in San Bernadino County, California, from June to September 1998. *T. c. accerra* were reared and handled using the methods described above for *T. pallidovirens*, except food was supplemented with buckwheat.

Preparation of Insect Extracts. Headspace odors were collected from three groups of virgin adult male and female *T. pallidovirens* during August and September 1997. Headspace samples were collected from each sex separately, and the same cohort of bugs was aerated continuously for approximately 2 weeks to follow changes in the profile of compounds produced by bugs as they became sexually

mature and to collect sufficient quantities of insect-produced volatiles for analyses and bioassays. The collection apparatus was set up next to a window in a laboratory with controlled air temperature ($24 \pm 2^{\circ}$C). Natural light was supplemented with two 4-ft Sylvania Octron 32 W fluorescent lights mounted above the aeration chamber to provide a 16L:8D light cycle to prevent bugs going into diapause.

Cohorts of male and female bugs (12–24 bugs of each sex) were placed in horizontal, two-piece cylindrical glass aeration chambers (28 cm $\times$ 8.0 cm ID) with O-ring-sealed middle joints. The chambers were lined with window screen for the bugs to perch on, and three green beans and five sunflower seeds were supplied as food. Bugs were coaxed carefully into the chambers to prevent discharge of defensive secretions. Activated charcoal-filtered, humidified air (1 liter/min) was pulled through the system by vacuum. Insect-produced odors were trapped on a collector made from a glass tube (0.4 cm ID) containing a 1-cm bed of activated charcoal (50–200 mesh, precleaned by thermal desorption at 200°C under N_2; Fisher Scientific, Pittsburgh, Pennsylvania, USA) held in place by glass wool plugs. Collectors were changed every second day, at which time fresh food was also provided. Trapped odors were eluted from the collectors with 3- to 200-μl aliquots of pentane, followed by 3- to 200-μl aliquots of ether. Extracts were stored at -20°C in brown glass vials with Teflon cap liners until used for bioassays or analysis.

To determine the onset of production of male-specific odors as males became sexually mature, aeration of the first cohort began with bugs $<$39 hr old. In subsequent aerations collecting male-produced volatiles for analysis and bioassays, aerations were started with 4- to 6-day-old bugs, close to the time when pheromone production was expected to begin.

To provide materials for bioassay and analysis, a larger cohort of male bugs (77 males) was aerated in similar fashion in a larger chamber (35 cm $\times$ 15 cm ID), with an airflow of 5 liters/min and a larger collector (0.6 cm ID, 1.5-cm bed of activated charcoal).

For *T. c. accerra*, headspace volatiles were collected from seven groups of virgin adult males and three groups of females during August 1998 and from January to June 1999 (mean number of male bugs ($\pm$SEM) per cohort $= 9 \pm 2$, range $=$ 3–17 bugs per cohort; mean number of female bugs per cohort $= 7 \pm 5$, range $=$ 2–16). Aerations in August 1998 were made with field-collected insects, and later aerations used insects taken from the laboratory colony. Methods for collecting volatiles, and the equipment used, were identical to those used with *T. pallidovirens*, with the exception that we began aerations with 4- to 6-day-old bugs. Defensive compounds were not collected from *T. c. accerra*.

Collection of Defensive Compounds. Metathoracic glands (MTG) of five sexually mature virgin adults of both sexes were dissected following the method of Gilby and Waterhouse (1965), and the contents of each gland were analyzed. A drawn-out glass capillary tube was inserted into the MTG of each bug to collect the

fluid contents, the fluid was dissolved in 200 μl pentane, and the pentane solution was analyzed by gas chromatography–mass spectrometry as described below. In addition, groups of virgin adult male and female bugs were aerated separately in a glass aeration chamber for 1 hr as described above, except that the glass chamber was shaken vigorously for 3 min immediately before the aeration began, to induce discharge of defensive compounds.

Fractionation and Analysis of Insect Extracts. A solid-phase extraction cartridge (2.8 ml, containing 500 mg silica gel; Alltech #209250) was conditioned by eluting with 6 ml 25% ether in pentane, followed by 6 ml pentane. An aeration extract from mature male bugs in 2.5 ml pentane was loaded onto the cartridge, which was then eluted sequentially with 3×2 ml pentane, and 3×2 ml ether, collecting each aliquot as a separate fraction. Hydrocarbons eluted in fraction 1 (which included the pentane used to load the sample + the first 2-ml aliquot) and the ester eluted in the first ether fraction.

Extracts and fractions of extracts were analyzed by gas chromatography (GC) using a Hewlett-Packard (Avondale, Pennsylvania, USA) 5890 instrument equipped with a DB-5 (30 m $\times$ 0.25 mm ID, 25 μm film, J&W Scientific, Folsom, California, USA), a DB-17 (30 m $\times$ 0.25 mm ID, 25 μm film), or a DB-WAX (30 m $\times$ 0.32 mm ID, 25 μm film) column. Helium carrier gas was used, with a temperature program of 50°C for 1 min, then 10°C/min to 250°C for all columns. Injector and detector temperatures were 250°C and 275°C, respectively.

To confirm the identification of the thermally unstable $E2,Z4,Z6$–10:COOMe, a combined aeration extract from male bugs was analyzed by high-pressure liquid chromatography (HPLC) using a Hewlett-Packard Series 1050 instrument equipped with an Econosil column (250 $\times$ 4.6 mm, 5 μm silica; Alltech, Deerfield, Illinois, USA), eluted with 0.5% tetrahydrofuran in hexane. The eluent was monitored at 230, 254, and 300 nm with an HP 1040A diode array detector.

Identification of Pheromone Components. The identification of the male-specific ester component has been previously described (Millar, 1997). The sesquiterpene components were tentatively identified by comparison of GC retention time and mass spectral data with literature data (Adams, 1995; Joulian and König, 1998; NBS-NIH mass spectral database). Identifications were confirmed by comparisons with authentic standards.

Determination of Absolute Configurations of Sesquiterpenes. Racemic α-curcumene was resolved to baseline on a Cyclodex B capillary column (30 m $\times$ 0.25 mm ID, J&W Scientific) operated isothermally at 90°C, with 140 kPa helium headpressure. Zingiberene and β-sesquiphellandrene were not resolved on the Cyclodex B column. Consequently, zingiberene and β-sesquiphellandrene were dehydrogenated to α-curcumene (Jackman, 1960) before analysis. Thus, a 100 μl aliquot of the hydrocarbon fraction of the volatiles from males (see above) was concentrated to $\sim$10 μl in a conical vial, 100 μl of a benzene solution of 1,2,3,4-tetrachlorobenzoquinone (20 mg/ml) was added, and the vial was sealed

and heated at 80°C for 1 hr. The resulting mixture was passed through a 1-cm plug of silica gel, eluting with pentane. The filtrate was analyzed on the Cyclodex B column.

Chemicals. *E*2,*Z*4,*Z*6–10:COOMe (chemical purity >97.3%; isomeric purity >98.7%); (Millar, 1997) and (±)-α-curcumene (chemical purity >98.8%); (Hall et al., 1975) were synthesized as previously described. (−)-Zingiberene (chemical purity >98.4%; isomerically pure) was isolated from commercial ginger oil, *Zingiber officinalis* (Spectrum Chem. Co., Gardena, California, USA) as previously described (Millar, 1998). (−)-β-Sesquiphellandrene was isolated from ginger oil as follows. The oil was vacuum distilled to produce a fraction enriched in sesquiterpenes (bp 60–100 at 0.1 mm Hg). Four grams of this fraction were stirred for 48 hr with 4 g maleic anhydride in 20 ml THF to remove zingiberene as the Diels-Alder adduct. The mixture was concentrated, 100 ml hexane was added, and the mixture was stored at −20°C overnight to precipitate excess maleic anhydride. The mixture was then filtered, and the filtrate was purified by flash chromatography (5 × 25 cm column of 230–400 mesh silica gel, activated by heating at 125°C overnight), eluting with hexane (500 ml), and 500 ml each of 0.2, 0.4, 0.4, 1, and 10% CH_2Cl_2 in hexane. After combination of like fractions and Kugelrohr distillation (oven temp ~70–90°C, 0.1 mm Hg), 440 mg of impure (+)-α-curcumene (56% pure; 39% β-bisabolene), 125 mg impure β-bisabolene (77% pure), and 414 mg (−)-β-sesquiphellandrene (89.1% pure) were obtained. NMR spectra of isolated (−)-β-sesquiphellandrene were obtained on a GE QE-300 spectrometer: ^{1}H NMR (300 MHz): δ 6.16 (dd, 1H, J = 9.9, 2.5 Hz), 5.70 (d, 1H, J = 9.7 Hz), 5.12 (m, 1H), 4.75 (br s, 2H), 2.44 (dt, 1H, J = 16.5, 4.6 Hz), 2.3 (m, 1H), 2.23 (m, 1H), 2.0 (m, 2H), 1.74 (m, 1H), 1.70 (s, 3H), 1.62 (s, 3H), 1.57 (m, 1H), 1.4 (m, 2H), 1.22 (m, 1H), 0.86 (d, 3H, J = 8 Hz). ^{13}C NMR (75.48 MHz): δ 15.9, 17.7, 24.4, 25.7, 26.0, 30.4, 34.3, 36.6, 40.5, 109.8, 124.7, 129.5, 131.2, 135.2, 143.8. The carbon and proton spectra were a satisfactory match to literature data (Sy and Brown, 1997).

Y-Tube Bioassays. Two-choice bioassays with a vertical glass Y-tube were carried out with virgin adult males and females (9–12 days old) as previously described (McBrien et al., 2001).

Live Bugs as a Pheromone Source. All four possible combinations of potential pheromone producers (with a green bean) and responders were bioassayed (attraction of females to odors from males on a bean, females to females, males to females, and males to males) versus a control (a green bean in a flask). All insects used as sources of attractant and as responders were sexually mature virgins. Because females were attracted to males, and all other combinations failed to demonstrate attraction, females were used as responders in all further experiments.

Insect Extracts as a Pheromone Source. Ten bug-hour equivalents of crude male extract in pentane (containing approximately 2 μg *E*2,*Z*4,*Z*6–10:COOMe, 4 μg α-curcumene, 4 μg zingiberene, and 0.4 μg β-sesquiphellandrene) were

bioassayed versus a pentane control, with virgin female *T. pallidovirens* responders. Extracts or solvent controls were pipetted onto circular pieces of filter paper (1.5 cm diam.) held in the top of each arm by wire loops inserted inside the top joints of the Y tube.

A portion of the male extract was fractionated into an ether and a pentane fraction (see above); the major component of the ether fraction was *E*2, *Z*4, *Z*6–10:COOMe, and the major components of the pentane fraction were three sesquiterpenes, α-curcumene, zingiberene, and β-sesquiphellandrene. The biological activity of each fraction was tested against a pentane blank, with the amounts of each fraction standardized so that each component was present in the same amounts as in the whole extract.

Synthetic Chemicals as a Pheromone Source. The amounts of each pheromone component (*E*2,*Z*4,*Z*6–10:COOMe, ($\pm$)-α-curcumene, ($-$)-zingiberene, and ($-$)-β-sesquiphellandrene) used in laboratory bioassays were equivalent to the amounts present in attractive male extract (see above), except that the amount of α-curcumene was doubled because the synthetic compound was racemic (2 μg of ester, 8 μg of α-curcumene, 4 μg of zingiberene, and 0.4 μg of β-sesquiphellandrene). The following treatments were tested versus pentane controls: (1) each individual component; (2) ester plus one sesquiterpene, for all possible binary blends; (3) ester plus two sesquiterpenes, all blends; and (4) complete four-component blend. The complete blend was also tested versus each of the two- and three-component blends in parts 2 and 3 above. Finally, the two-component blend of the ester plus ($-$)-β-sesquiphellandrene was assayed versus male extract. The previous bioassays had shown that this blend was as attractive as all other combinations of ester and sesquiterpene, so it was used for testing against the extract. The amounts of each component in the insect extract and the reconstructed blend were equal.

Field Cage Study Using Synthetic Pheromone Components. ($\pm$)-α-Curcumene and *E*2,*Z*4,*Z*6–10:COOMe were synthesized as described above. Zingiberene was isolated from ginger oil, and ($-$)-β-sesquiphellandrene was synthesized as described by Chavan et al. (1997), as an $\sim$1:1 mixture with its C-6 epimer ($>$96.8% of the purified product). Because the synthesized material was a 1:1 mix of epimers, the dose of the synthetic mixture used on lures was doubled.

A 1- $\times$ 1- $\times$ 1-m field cage was set up in the Agricultural Operations experimental fields, University of California, Riverside, following the protocols described by McBrien et al. (2001). Fifteen minutes before the start of each bioassay, two freshly cut bouquets of alfalfa were positioned 0.5 m apart on the cage floor, and a 1-m piece of cotton yarn was strung from the base of each bouquet to a wire loop attached to the roof immediately above each bouquet. At the top of each string, the base of a 4-cm-long stalk of alfalfa was attached to the roof using a wire loop and positioned so that it extended straight down beside the string. Several of the insects walked on the roof of the cage during the trial and could approach the strings from the top instead of the cage floor. The treatment string lure was saturated with 3.5 ml

of pentane containing 0.4 mg of $E2,Z4,Z6$–10:COOMe, 1.6 mg of α-curcumene, 0.8 mg of zingiberene, and 0.16 mg of β-sequiphellandrene, and the control string was soaked with 3.5 ml of pentane alone. The pentane was allowed to evaporate, and the strings were hung from the cage roof, with the position of the treatment and control strings alternated for each replicate.

Thirty minutes before beginning a bioassay, 13–32 virgin female *T. pallidovirens* (mean $\pm$ SD:21 $\pm$ 8.5), were placed in a 25- $\times$ 15- $\times$ 15-cm cardboard box with two green beans. The inside walls of the box were lined with Fluon-coated sticky tape to prevent insects from crawling out of the box, the bottom of the box was lined with plain white paper that could be lifted out (see below), and the top was covered with fine mesh cloth. After 10 min, the beans were removed, and the insects were introduced into the field cage (2–3 min after the strings were positioned), being careful to minimize disturbance of the bugs. The mesh screening was removed from the box and placed just inside the front wall of the field cage so that any insects on the screening would be free to disperse in the cage. The paper liner was lifted out of the bottom of the box and placed inside the front wall beside the screening, equidistant from each bouquet. The bioassay was repeated on six evenings during August 1999, approximately 40 min before sunset. After 40 min, the number of females on each bouquet was counted.

Field Trials. Three field trials were carried out in tomato fields near Davis, California, USA, from July to September 1998 and during September 1999 using commercial stink bug traps (Sierra Ag., Fresno, California, USA) modeled after those described by Aldrich et al. (1991). Traps were placed beside tomato plants so that they were touching the vegetation and insects could crawl into the screen-cone openings. Treatments within a replicate were randomly assigned to each trap, and traps were placed at least 10 m apart. Treatments were replicated three to six times, and once every 7 days, insects in each trap were removed, identified to species and sex, and counted. Baits consisted of 11-mm red rubber septa (Wheaton, Millville, New Jersey, USA) loaded with methylene chloride or hexane solutions of the test compounds and with 0.5% butylated hydroxytoluene (BHT) added as stabilizer.

In an attempt to achieve approximately the same profiles of compounds from a rubber septum bait as were seen in the GC traces of male-produced bug volatiles, the amount of each compound loaded onto a septum for placement in the field was adjusted for differences in volatility. These differences were estimated using the following procedure. Red rubber septa ($N = 3$) were loaded with 2 mg of methyl ($E2,Z4$)-decadienoate (a thermally stable ester with one less double bond than $E2,Z4,Z6$–10:COOMe; Bedoukian Research, Danbury, Connecticut, USA), 5 mg of the sesquiterpene hydrocarbon fraction of ginger oil, and 0.75 mg of BHT in 100 μl of methylene chloride, and left to dry for 3 hr. Septa were then placed in the glass aeration chambers used to collect volatiles from bugs (see above). Air purified by passage through an activated charcoal filter was pulled through the system by vacuum at a flow rate of 1 liter/min. The headspace volatiles were trapped

on a 1-cm bed of activated charcoal held in a glass tube (0.4 cm ID) as described above. The relative amounts of the four compounds in the original solution before loading on septa were compared to the relative amounts emitted by septa over time. Collectors were changed hourly for the first 3 hr, and then once a day for 7 days. Collectors were eluted as described above, and the relative amounts of zingiberene, α-curcumene, β-sesquiphellandrene, and methyl ($E2,Z4$)-decadienoate in extracts were determined by GC analysis, for each collection period. Because the ratio of the four components was fairly constant from 3 days onward, the mean values for days 3–7 were calculated and compared to the original solution. Using β-sesquiphellandrene as the standard, the ratios of ester, α-curcumene, and zingiberene to β-sesquiphellandrene were 1.5, 2.0, and 1.3 times higher in aeration extracts than in the original solution. These correction factors were used when preparing lures for the field.

The first field test (July 22–August 12, 1998) compared the attraction of bugs to traps baited with red rubber septa treated with hexane solutions of $E2,Z4,Z6$–10:COOMe and the sesquiterpene hydrocarbon fraction of ginger oil [see above; 69% (+)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene in a ratio of 0.62:2.29:1, plus 31% other sesquiterpenes] to traps baited with solvent-treated controls. Each lure was loaded with 10 mg ester, 29 mg oil, and 1.67 mg BHT, and treatments were replicated six times.

A second field trial (August 21–September 4, 1998), replicated three times, compared the four-component blend of $E2,Z4,Z6$–10:COOMe + the three sesquiterpenes, binary blends of $E2,Z4,Z6$–10:COOMe and one sesquiterpene, ester alone, and a solvent-treated control. Lures were loaded with 5 mg of $E2,Z4,Z6$–10:COOMe plus appropriate amounts of the sesquiterpenes, using the purified materials used in the laboratory bioassays.

A final field trial (September 1–15, 1999) retested the same treatments (four replicates) as used in the second experiment, with the inclusion of a treatment consisting of the mixture of the three sesquiterpenes alone, with no ester.

Statistical Analysis. Y-tube bioassay data were analyzed using a χ^2 test with one degree of freedom, using the Yates correction factor (Steel et al., 1997). Because different numbers of bugs were used for each replicate in the field-cage studies, the proportion of bugs on each bouquet, as a percentage of the total number of bugs on both bouquets, was calculated for each replicate. After arcsine transformation (Steel et al., 1997), means were compared with a two-sample t test.

Because of the low trap catches in field trials, trap catches for each treatment and sex were pooled for the duration of each experiment. In the first field trial, data were analyzed using a nonparametric two-factor analysis of variance, with treatment and sex as the main factors (Zar, 1984). In all statistical tests, $\alpha = 0.05$.

Trap catches per treatment in trials 2 and 3 were too low for statistical analysis. However, the results are presented because they corroborate the results of the laboratory and field cage bioassays.

RESULTS

In Y-tube bioassays, odors from sexually mature males attracted female bugs [treatment 25, control 5, $\chi^2 = 12.03$, $P < 0.001$), but not males [treatment 13, control 11, $\chi^2 = 0.25$, not significant (NS)], and live females did not attract either sex (female responders: treatment 10, control 10; male responders, treatment 12, control 8, $\chi^2 = 0.017$, NS). Based on these results, further bioassays tested only the attraction of sexually mature females to a pheromone source.

An extract of male-produced volatiles collected on activated charcoal was more attractive to female *T. pallidovirens* than nontreated controls (extract 27, control 3; $\chi^2 = 17.63$, $P < 0.001$). Comparisons of gas chromatograms of aeration extracts from sexually immature and mature males, and sexually mature males and females (Figure 1) determined that sexually mature male *T. pallidovirens* produced at least four compounds that were not present in females or immature males. Furthermore, the initiation of pheromone production in males coincided with the onset of sexual maturity as determined by Wang and Millar (1997).

Fractions of the extract eluted from silica gel with pentane and ether were not attractive (pentane 11, control 13, $\chi^2 = 0.042$, NS; ether 8, control 12, $\chi^2 = 0.45$, NS), suggesting that the attractant was a synergistic blend of at least two

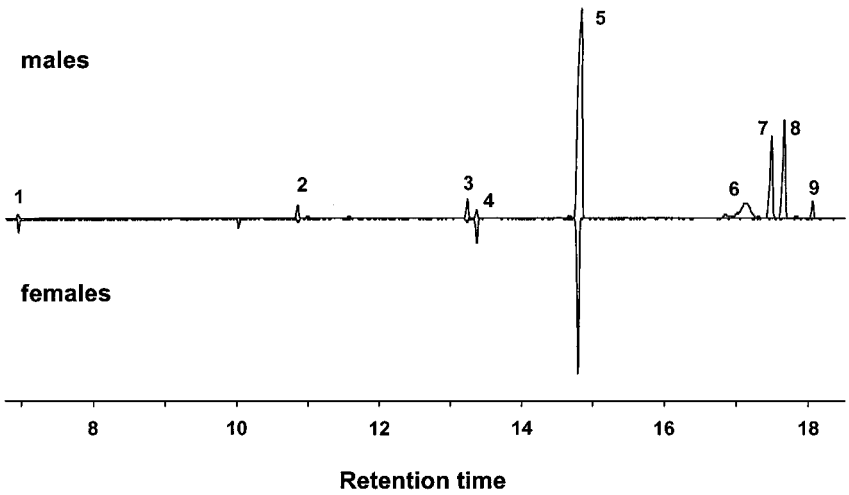

FIG. 1. Gas chromatograms of extracts of volatiles collected from male (top) and female (bottom, inverted) *Thyanta pallidovirens*. 1, (*E*)-2-hexenal; 2, (*E*)-2-octenal; 3, dodecane; 4, (*E*)-2-octenyl acetate; 5, tridecane; 6, distorted peak from thermal decomposition of methyl *E*2,*Z*4,*Z*6-decadienoate; 7, (α)-curcumene; 8, zingiberene; 9, β-sesquiphellandrene. Retention time is in minutes.

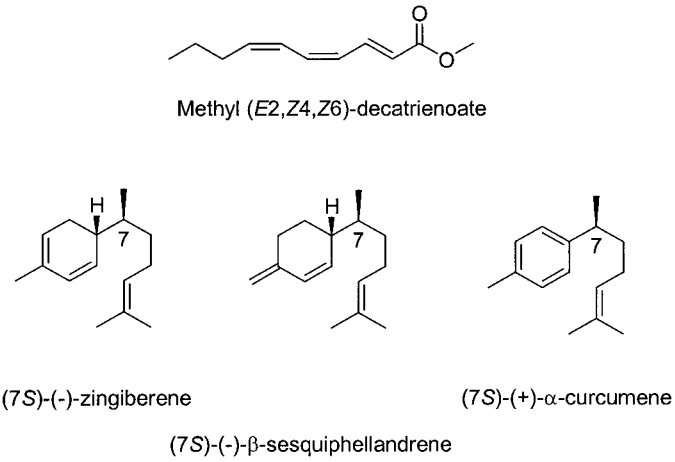

FIG. 2. Structures of male-specific compounds produced by adult *Thyanta pallidovirens*.

components with different polarities. Analysis of the two fractions by GC and GC-MS determined that the ether fraction consisted exclusively of $E2,Z4,Z6$–10:COOMe (Millar, 1997) (Figure 2). The pentane fraction contained three male-specific sesquiterpene hydrocarbons, all with bisabolane skeletons (Figure 2). The first two of these were tentatively identified from their distinctive mass spectra and matches with database spectra (NBS-NIH database) as α-curcumene [m/z (abundance) 202 (34), 119 (100), 132 (86)] and zingiberene [m/z 204 (13), 119 (100), 93 (99)]. The third compound [m/z 204 (15), 161 (31), 133 (26), 120 (23), 93 (53), 92 (33), 91 (47), 77 (42), 69 (100), 55 (33), 41 (99)] was tentatively identified from a combination of literature retention indices and mass spectra (Adams, 1995; Joulain and König, 1998) as β-sesquiphellandrene, an isomer of zingiberene. The identifications were confirmed by matching mass spectra and matching retention times on DB-5, DB-17, and Cyclodex B GC columns (see below) with those of authentic standards. The mean ratio of α-curcumene to zingiberene to β-sesquiphellandrene in extracts from three cohorts of male bugs (bugs per cohort = 16, 77, and 11, respectively) was 9.4:9.8:1.0 (range of values versus β-sesquiphellandrene: for α-curcumene, 13.3–6.5; zingiberene, 10.4–9.2). Because the ester was destroyed during GC analysis, it was not possible to determine the ratio of the ester to the sesquiterpenes accurately by GC.

The absolute configurations of the three sesquiterpenes were determined as follows. First, racemic α-curcumene was resolved to baseline on a Cyclodex B GC column (90°C isothermal, retention times 82.08 and 83.38 min), and the earlier eluting peak was identified as the (7*S*)-(+)-enantiomer (König et al., 1994; Joulain and König, 1998) by injection of an authentic sample isolated from ginger oil.

Although the retention times of the insect-produced zingiberene and β-sesquiphellandrene matched those of standards of (7*S*)-(−)-zingiberene and (7*S*)-(−)-β-sesquiphellandrene isolated from ginger oil (Buckingham, 1994; König et al., 1994), samples of the opposite enantiomers and the racemic forms of these two compounds were not available. Consequently, another method of conclusively proving the absolute configurations was required. Thus, the sesquiterpene fraction from the male volatiles was dehydrogenated with 3,4,5,6-tetrachloro-1,2-benzoquinone (Jackman, 1960), converting the insect-produced zingiberene and β-sesquiphellandrene to α-curcumene. The resulting sample gave a single peak on the Cyclodex B column at the retention time of (7*S*)-(+)-α-curcumene, with no trace of the 7*R* enantiomer, proving that the configuration at the 7 position in the insect-produced α-curcumene, zingiberene, and β-sesquiphellandrene must be *S* for all three compounds.

A number of other compounds were identified in the aeration extracts from both sexes, including (*E*)-2-hexenal, (*E*)-2-octenal, (*E*)-2-octenyl acetate, undecane, dodecane, and tridecane. These compounds, and others, were found in the metathoracic gland contents, and most were also found in aeration extracts from bugs that had been disturbed by vigorous shaking (Table 1). These compounds were tentatively identified by comparison of spectra with those in the NIH-NBS mass spectral database, and identifications were confirmed by comparison of GC

TABLE 1. COMPOUNDS IN METATHORACIC GLANDS OF FIVE MALE AND FIVE FEMALE *Thyanta pallidovirens* RELATIVE TO MOST ABUNDANT COMPOUND, TRIDECANE[a]

	Amount (%, mean ± SE)			
	Metathoracic glands		Shaken bugs	
Compound	Males	Females	Males	Females
(*E*)-2-Hexenal	7.3 ± 2.1	7.5 ± 1.1	3.7	
(*E*)-2-4-Oxo-hexenal	9.3 ± 2.9	7.1 ± 3.5		
(*E*)-2-Hexenyl acetate	1.2 ± 0.6	0.8 ± 0.4		
(*E*)-2-Octenal	13.2 ± 4.2	9.1 ± 2.7	6.3	0.07
(*E*)-2-Octenol	0.04 ± 0.02	0.2 ± 0.1		
Undecane	0.5 ± 0.1	0.4 ± 0.08	0.7	0.05
Dodecane	3.4 ± 0.5	3.7 ± 0.5	3.2	0.3
(*E*)-2-Octenyl acetate	9.6 ± 3.9	10.5 ± 3.8	1.7	0.004
(*E*)-2-Decenal	0.002 ± 0.002	0		
Tridecane	100	100	100	100
Tetradecane	0.0700 ± 0.01	0.06 ± 0.007		
(*E*)-2-Decenyl acetate	0.006 ± 0.006	0.01 ± 0.01		
Pentadecane	0.3 ± 0.04	0.3 ± 0.04		

[a]Also shown are mean percentages of compounds (relative to tridecane) in extracts from bugs disturbed by shaking.

retention times (DB-5 and DB-17 columns) and mass spectra with those of authentic standards. (*E*)-2-4-oxo-hexenal was also present in extracts from both sexes and was tentatively identified by comparison with a reference spectrum from J. R. Aldrich (US Department of Agriculture, Beltsville Maryland, USA). The identification was confirmed with a synthesized standard (Marques et al., 2000). These compounds are well-known stink bug defensive chemicals (Aldrich, 1995).

Having identified the male-specific compounds in the aeration extracts and synthesized or isolated quantities sufficient for testing, laboratory bioassays were continued with *E*2,*Z*4,*Z*6–10:COOMe, (±)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene. None of the synthetic pheromone components alone were attractive when compared to pentane controls, but binary blends of *E*2,*Z*4, *Z*6–10:COOMe with any one of the three sesquiterpenes were significantly more attractive than controls (Table 2), demonstrating that the pheromone blend consists of at least two components. When given a choice between the four-component (4-C) blend of *E*2,*Z*4,*Z*6–10:COOMe plus all three sesquiterpenes and a pentane blank in the Y-tube bioassay, the 4-C blend was more attractive to female *T. pallidovirens*(treatment, 28, control 2 responders; $\chi^2 = 20.83$, $P < 0.001$). However, further bioassays demonstrated that the 4-C blend was no more attractive than any blend of *E*2,*Z*4,*Z*6–10:COOMe with any one or any two of the sesquiterpenes (Table 3). To our knowledge, this degree of redundance is unprecedented in an insect pheromone blend.

In a final Y-tube bioassay, there was no difference in the responses of females to a binary blend of *E*2,*Z*4,*Z*6–10:COOMe plus (−)-β-sesquiphellandrene and an extract of volatiles from males (synthetic blend 14, extract 11 responders; $\chi^2 = 0.16$, $P > 0.05$), indicating that the two-component blend was as attractive as the insect-produced volatiles.

TABLE 2. RESPONSES OF FEMALE *Thyanta pallidovirens* TO INDIVIDUAL PHEROMONE COMPONENTS OR BLENDS OF PHEROMONE COMPONENTS COMPARED TO PENTANE CONTROLS IN Y-TUBE BIOASSAY[a]

Treatment	Number of responders		χ^2
	Treatment	Control	
*E*2,*Z*4,*Z*6–10:COOMe	14	17	0.13 ns
(±)-α-Curcumene	5	15	4.05*
(−)-Zingiberene	8	12	0.45 ns
(−)-β-Sesquiphellandrene	10	10	0.05 ns
*E*2,*Z*4,*Z*6–10:COOMe + (±)-α-curcumene	25	5	12.03***
*E*2,*Z*4,*Z*6–10:COOMe + (−)-zingiberene	24	6	9.63**
*E*2,*Z*4,*Z*6–10:COOMe + (−)-β-sesquiphellandrene	26	4	14.70***

[a] χ^2 values followed by asterisks indicate significant differences between treatments and controls (*$P < 0.05$; **$P < 0.005$; ***$P < 0.001$).

TABLE 3. FEMALE *Thyanta pallidovirens* RESPONDING TO 4-COMPONENT (4-C) BLEND[a] vs. BLENDS OF *E*2,*Z*4,*Z*6–10:COOMe WITH TWO SESQUITERPENES OR ONE SESQUITERPENE IN Y-TUBE BIOASSAY[b]

Treatment	Number of responders		χ^2
	Treatment	4-C blend	
4-C blend–(−)-zingiberene	10	10	0.05
4-C blend–(±)-curcumene	9	11	0.05
4-C blend–(−)-β-sesquiphellandrene	10	10	0.05
*E*2,*Z*4,*Z*6–10:COOMe + (−)-β-sesquiphellandrene	15	11	0.35
*E*2,*Z*4,*Z*6–10:COOMe + (±)-α-curcumene	11	9	0.05
*E*2,*Z*4,*Z*6–10:COOMe + (−)-zingiberene	11	11	0.05

[a] 4-C blend: (*E*2,*Z*4,*Z*6–10:COOMe, (±)-α-Curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene)
[b] No treatment was significantly different from the 4-C blend by χ^2 analysis.

Field Cage Study. The four-component synthetic blend was more attractive to females than a pentane control in field cage trials (treatment, mean ± SE, 77.8 ± 1.9% of responding bugs; control 22.2 ± 1.9%, $t = 6.19$, $df = 10$, $P < 0.001$). During these trials, most of the movement towards the baited alfalfa bouquets occurred within the first 10–15 min after the bugs were introduced into the cage. Any flight occurred immediately after introduction of insects into the cage, but bugs almost never flew directly to the alfalfa bouquets, only to the cage walls or ceiling. Females approached baited alfalfa bouquets almost exclusively by walking or a series of short hops. Once on the alfalfa bouquets, all but three of the bugs remained there for the duration of the trials. Of all the bugs released, an average of 48.4 ± 2.3% had not gone to either bouquet by the end of the trial and were classified as nonresponders. Most of these bugs wandered around the roof or floor of the cage and aggregated around the perimeter of the cage where the roof and walls joined.

Field Trials. Although trap catches were low in all field tests, reconstructed blends of the male-produced compounds were attractive specifically to adult female *T. pallidovirens*. In the first trial, 19 female and 1 male *T. pallidovirens* were caught in traps baited with synthetic pheromone, which was more than the single female *T. pallidovirens* trapped in nonbaited controls (nonparametric two-way ANOVA, $\chi^2_{0.05,1} = 5.46$, $P < 0.025$). A total of 60 *T. pallidovirens* females and 3 males were captured in trials 2 and 3 (Table 4). Bugs were caught only in traps baited with blends of *E*2,*Z*4,*Z*6–10:COOMe with at least one sesquiterpene; no bugs were caught in traps baited with the ester alone, the sesquiterpene blend, or the control, and no nymphs were caught in any trap.

Traps baited with *T. pallidovirens* pheromone components were also species-specific. The only other stink bug species found in traps was *Euschistus conspersus*.

TABLE 4. *Thyanta pallidovirens* FEMALE AND MALE ADULTS CAPTURED IN JUG TRAPS BAITED WITH SYNTHETIC SEX PHEROMONE COMPONENTS OR SOLVENT-TREATED CONTROLS[a]

	Lure composition							
Responder	e,s,c,z	e + s	e + c	e + z	e	s,c,z	Blank	Total
Trial 2:								
Female	6	3	4	17	0	[b]	0	30
Male	0	0	0	1	0	[b]	0	1
Trial 3:								
Female	5	7	6	12	0	0	0	30
Male	0	0	1	1	0	0	0	2

[a] Traps were placed in tomato fields near Davis, California, USA. Trial 2: August 21–September 4, 1998; 3 replicates. Trial 3: September 1–15, 1999; 4 replicates. Lure composition codes: e = ester (*E*2,*Z*4,*Z*6–10:COOMe), s = (−)-β-sesquiphellandrene, c = (±)-α-curcumene, z = (−)-zingiberene.
[b] Trial 2 did not contain this treatment.

During trials 1 and 3, respectively, one *E. conspersus* female, and two *E. conspersus* females and one nymph were caught in traps baited with *T. pallidovirens* pheromones. However, during trials 1 and 2, traps baited with *E. conspersus* pheromone captured 98 and 47 adult *E. conspersus*, respectively, in the same fields during the same period, indicating that *E. conspersus* populations were present and that the few individuals caught in the *T. pallidovirens* traps were probably random captures.

Analysis of Volatiles from Thyanta custator accerra. The profile of volatiles produced by sexually mature male *T. c. accerra* ($\geq$10 days old) was qualitatively and quantitatively very similar to that of male *T. pallidovirens* (Figure 3). The extracts differed only in the presence of (*E*)-2-decenal in the *T. c. accerra* extracts (Figure 3), the structure of which was confirmed by retention time and mass spectral matches with a synthetic standard. *E*2,*Z*4,*Z*6–10:COOMe was found in all aeration extracts from sexually mature males, and HPLC analysis, as described above for *T. pallidovirens* extracts, proved that the insects produced only the *E*2,*Z*4,*Z*6 isomer. The mean proportions of the three sesquiterpenes and (*E*)-2-decenal, with β-sesquiphellandrene arbitrarily set at 1, were α-curcumene, 10.5 ± 0.8; zingiberene, 15.4 ± 1.1; and (*E*)-2-decenal, 3.1 ± 0.6. The absolute configurations of the sesquiterpenes were not determined. The ester, the three sesquiterpenes, and (*E*)-2-decenal were not found in extracts from sexually immature males, sexually immature females, or sexually mature females.

DISCUSSION

Only adult female *T. pallidovirens* were attracted to insect-produced or synthetic pheromone blends, indicating that the male-produced compounds constitute

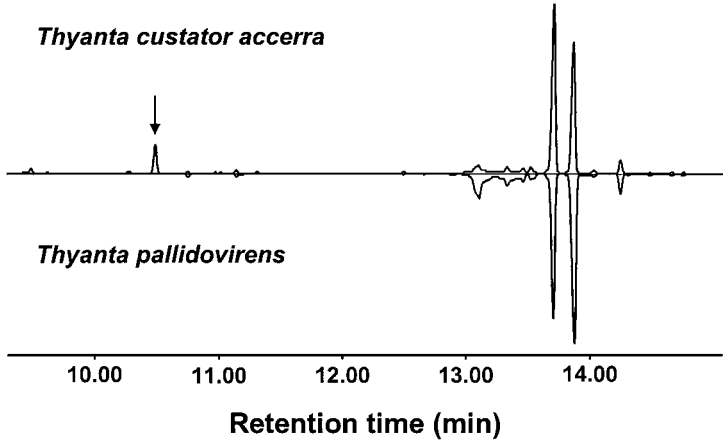

FIG. 3. Gas chromatograms of extracts of volatiles collected from sexually mature male *Thyanta custator accerra* (top trace) and *Thyanta pallidovirens* (bottom trace, inverted). The arrow indicates the presence of (*E*)-2-decenal in the *T. c. accerra* extract. The other peaks are as labeled in Figure 1.

a sex pheromone rather than an aggregation pheromone, as is the case with the stink bug *Acrosternum hilare* (McBrien et al., 2001). In contrast, males of several other phytophagous pentatomids are reported to produce aggregation pheromones that attract both sexes and in some cases nymphs (Harris and Todd, 1980; Aldrich et al., 1991; James et al., 1996; Sugie et al., 1996; Leal et al., 1998). However, it must be pointed out that these apparent aggregations may be the result of stimuli other than the pheromone being tested, such as chemical attractants or arrestants, or vibrational signals produced by bugs already caught in the traps.

There are several possible explanations for the production of attractant pheromones by male rather than female bugs. For example, male *T. pallidovirens* invest heavily in reproduction, with virgin males donating 17% of their body mass to virgin females during mating (Wang and Millar, 1997). There is also evidence of male mate choice in *T. pallidovirens*, with males terminating copulation with small females before sperm was transferred (Wang and Millar, 1997). The important role that males play in attraction, courtship, and assessment of females may contribute to the adaptive significance of the attractant pheromone being produced by males.

Selective pressure from natural enemies may offer an alternative explanation for males being the pheromone-producing sex. Stink bugs suffer heavy predation from specialist predators and parasitoids that eavesdrop on the bugs' semiochemical emissions to locate their prey (Mitchell and Mau, 1971; Aldrich et al., 1989; Aldrich, 1995; Millar et al., 2001). Because female *T. pallidovirens* lay a number of egg masses spaced out over their adult lifetime (Wang and Millar, 1997), their reproductive potential is directly related to their longevity. In contrast, a male bug

mating with a virgin female transfers enough sperm to fertilize 50% of the eggs that she produces during her lifetime (Wang and Millar, 1997). Consequently, the risks of signaling, although still high, may be less for males than females.

Of the four sex-specific compounds produced by *T. pallidovirens* males, *E*2,*Z*4,*Z*6-10:COOMe is a novel natural product. However, the *E*2,*E*4,*Z*6–10:COOMe isomer recently has been identified as a male-produced pheromone component of another pentatomid, the brown-winged green bug, *Plauti stali* Scott (Sugie et al., 1996). Both of these esters also are closely related to *E*2,*Z*4–10:COOMe, a pheromone component of several *Euschistus* spp. (Aldrich et al., 1991). Thus, the unsaturated straight-chain 10-carbon methyl ester is a recurring motif in stink bug semiochemistry.

The three male-produced sesquiterpenes, (+)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene, are relatively common components in essential oils, and in a curious coincidence, the major portion of the sesquiterpene fraction of commercial ginger oil consists of these three compounds, even to the extent of having the same stereochemistry. β-Sesquiphellandrene [possibly the (−) enantiomer], was recently identified as a pheromone component of the pentatomid *Piezodorous hyberni* (Leal et al., 1998), but neither α-curcumene nor zingiberene have been reported previously from heteropteran secretions.

During our studies with *T. pallidovirens*, we had an opportunity to examine the volatiles of a congener, *T. custator accerra*, which is sympatric with *T. pallidovirens* in the southwestern United States. Morphologically, these species are difficult to differentiate (McPherson and McPherson, 2000) but there can be no doubt that they are different species because they have different chromosome numbers (Rider and Chapin, 1992). Although the volatiles produced by both species were remarkably similar, the presence of (*E*)-2-decenal in *T. c. accerra* but not *T. pallidovirens* extracts suggests that this compound may function as a component of a species-specific pheromone signal.

The low numbers of bugs caught in field trials has hampered clarification of many details of the pheromone blend. The low trap catches may reflect an inherently weaker attraction to pheromones than is typically seen with other groups of insects such as Lepidoptera, for several reasons. First, low trap catches have been observed with several phytophagous stink bug species, including *Nezara* spp. (Aldrich et al., 1993), *Euschistus* spp. (Aldrich et al., 1991, 1995; Borges et al., 1998;), *Piezodorus* spp. (Borges et al., 1998), *Biprorulus bibax* (James et al., 1996), and *Acrosternum hilare* (McBrien and Millar, unpublished data). Second, a specialist predator of *T. pallidovirens*, the wasp *Astata occidentalis* Cresson (Hymenoptera: Sphecidae) was attracted to synthetic *T. pallidovirens* pheromone (Millar et al., 2001), indicating that the chemistry of the synthetic pheromone was correct and that the dose tested was within a biologically relevant range. Third, phytophagous stink bugs mate numerous times during their lifetimes of weeks to months, during which they feed continuously. Consequently, there is less

urgency for stink bugs to mate than for ephemeral insects with nonfeeding adult stages, which must find mates quickly before they exhaust their energy reserves and die.

The two-part mate location behavior, mediated by pheromonal and vibrational cues, also may have contributed to low trap captures. Pheromone alone, in the absence of the vibrational signals, may provide little inducement for bugs to orient towards and enter a trap. Consequently, our trap captures may represent only a fraction of the insects attracted to the vicinity of a pheromone-baited trap. Furthermore, *T. pallidovirens* and other phytophagous pentatomids [*A. hilare* (McBrien et al., 2001), and *Chlorochroa* spp. (Ho and Millar, 2001a,b)] responding to pheromone lures showed little inclination to fly. This suggests two possibilities. First, the pheromones may act over relatively short range, because a responder would be unlikely to walk more than a few meters. Second, the pheromone may attract a responder to the general vicinity of a pheromone producer, with subsequent mate location behaviors being mediated by substrate-borne vibrations. Thus, a responding insect using the pheromone to orient to the vicinity of a pheromone producer must be on a substrate rather than flying in order to detect the vibrational signals that mediate the final steps of mate location.

The fact that *T. pallidovirens* are attracted by $E2,Z4,Z6$–10:COOMe and any one of the three sesquiterpenes has practical implications for commercial formulation of lures. Furthermore, bugs were indifferent to the (−)-enantiomer in formulations containing racemic α-curcumene, and to *epi*-sesquiphellandrene in formulations containing synthesized (−)-β-sesquiphellandrene, so that these cheaper stereoisomeric mixtures can be used in lures. Even blends of $E2,Z4,Z6$–10:COOMe with the sesquiterpene fraction of commercial ginger oil, containing approximately 70% of the three bug-produced compounds, were attractive. The fact that these baits, and baits formulated with one to three sesquiterpenes, either pure or as mixtures of stereoisomers, attracted female *T. pallidovirens* illustrates the flexibility in the responses of these insects to a wide palette of pheromone formulations.

In summary, male *T. pallidovirens* produce a sex pheromone consisting of at least two and as many as four components. The pheromone attracted only females in all types of bioassays used, with no indication that males or immatures were attracted. Trap catches were low, and further development of traps and lures will be required to produce an effective system for sampling *T. pallidovirens* populations. Because stink bugs use both pheromonal and vibrational signals for mate location, it may be necessary to incorporate both types of signals into trap designs.

Acknowledgments—We thank the California Pistachio Commission, the Washington State Tree Fruit Research Commission, and the University of California Integrated Pest Management Project for financial support of this work. We also thank David A. Rider, North Dakota State University, for conclusive identifications of insects, and Jay F. Brunner and Christian Krupke for reviewing the manuscript.

EFFECTS OF RELATIVE HUMIDITY, TEMPERATURE, AND POPULATION DENSITY ON PRODUCTION OF CUTICULAR HYDROCARBONS IN HOUSEFLY *Musca domestica* L.

NICO NOORMAN* and CORNELIS J. DEN OTTER

Group Sense Organs and Behaviour

(Received November 2, 2001; accepted May 5, 2002)

Abstract—The production of cuticular hydrocarbons by both males and females of *Musca domestica* L. under very wet conditions (90% relative humidity) compared to the production at 50 and 20% relative humidity is delayed up to at least 3 days after emergence from the pupae. Eight days after emergence, however, males contain the same amounts of hydrocarbons at 90, 50, and 20% relative humidity, whereas females at 90% still possess less of these substances than at 50 and 20%. It is suggested that this is due to the fact that males, being more active than females, need more cuticular hydrocarbons to prevent water loss. No indication is found that relative humidity has a different effect on the production of the sex pheromone, muscalure [(*Z*)-9-tricosene] by females than on the production of the other hydrocarbons. Male and female flies produce more hydrocarbons at 35°C than at 20°C. On females, the relative amounts of nonacosane and methyl- and dimethylnonacosanes are significantly higher at 35°C than at 20°C. Female flies produce some (*Z*)-9-tricosene after eight generations at low population density in contrast to females at high population density, which did not produce muscalure. We suggest that because of the relatively large contribution to the total population, the properties of a small number of females are likely to be expressed sooner in the next generations of small populations than in those of large populations.

Key Words—*Musca domestica*, sex pheromone, muscalure, (*Z*)-9-tricosene, cuticular hydrocarbons, environmental effects.

INTRODUCTION

The cuticular hydrocarbons of insects provide a barrier to water diffusion, thus preventing desiccation of the animals. However, some of these substances may also act as semiochemicals and may play a role in mating behavior. In houseflies, several hydrocarbons on the body surface of females induce sexual behavior in males. (*Z*)-9-Tricosene is considered to be the main component of this sex pheromone (Carlson et al., 1971, 1974; Mansingh et al., 1972; Richter et al., 1976; Uebel et al., 1976; Rogoff et al., 1980; La-France et al., 1989; Adams et al., 1995).

It is known that environmental factors may affect the production of cuticular hydrocarbons (Hadley, 1977, 1978; Toolson et al., 1990; Gibbs et al., 1991). In several species of arthropods, higher temperatures and lower humidities result in a greater proportion of cuticular *n*-alkanes relative to branched alkanes and/or unsaturated hydrocarbons. These differences in hydrocarbon composition account for concomitant differences in cuticular permeability to water (Toolson and Hadley, 1979; Hadley and Schultz, 1987). Gibbs et al. (1995) suggested that production of sex pheromone by *Musca domestica* females might increase cuticular transpiration. Because the pheromone components are unsaturated or methyl-branched, this might lead to higher permeability to water.

In previous studies (Noorman and Den Otter, 2001), we found that (*Z*)-9-tricosene comprised up to 20–30% of the total hydrocarbons on females of a strain that had been cultured for many generations in the laboratory at constant temperature and relative humidity. On wild-type females, however, less than 0.5% of this component was present. It appeared that on females of subsequent generations of laboratory populations, the quantities of both (*Z*)-9-tricosene and tricosane—the production processes of which were shown to be closely linked—increased, whereas the amounts of the other cuticular hydrocarbons remained the same. This led us to assume that although temperature and humidity may affect the production of all cuticular hydrocarbons, temperature and humidity mainly determine the quantities of the nonpheromonal components. (*Z*)-9-Tricosene, however, may be produced primarily as a result of a selection process in high-density populations in isolated environments, as females with higher quantities of this substance on their body are more attractive to males. These females may be the first to mate and oviposit fertile eggs. Their progeny may, therefore, survive in higher numbers in the next generation than those of females producing lower amounts of (*Z*)-9-tricosene. It may be expected that this selection proceeds faster in high-density than in low-density populations.

This paper presents results of studies designed to test these hypotheses. We investigated the effects of relative humidity, temperature, and population density on the production of various hydrocarbons in males and females of *Musca domestica*.

METHODS AND MATERIALS

Insects. Larvae of *Musca domestica* were obtained from a cow-house with pigsty (Pesse strain) and poultry breeding (Van Diermen strain) in the Netherlands. To investigate the effects of relative humidity on cuticular hydrocarbon production, experiments were carried out with Pesse flies cultured in the laboratory for about 40 generations (Pesse-40) at 25°C, 50% relative humidity, and 12L:12D photoregime. Eight-day-old females of this strain contained about 3 μg muscalure/fly.

Immediately after emergence, 10 male and 10 female flies were placed together in a cage ($15 \times 8 \times 5$ cm). Six cages were used, two of which were kept at about 90% relative humidity, two at 50% relative humidity, and two at about 20% relative humidity. In order to obtain 90% relative humidity, the cages were placed on a rack in the rearing room in a Perspex container ($50 \times 50 \times 50$ cm), the bottom of which was covered with a layer of tap water. Ventilation took place through holes in the walls of the container. To achieve 20% relative humidity, the bottom of the container was covered with oven-dried silicagel, which was replaced before it was saturated with water. For 50% relative humidity, the cages were placed in an empty container from which the upper cover was removed. Every day the actual temperature and relative humidity in the cages were recorded. The temperature and relative humidity in the cages were 25.8 ± 0.5°C, and 19.1 ± 1.5%, 47.2 ± 1.4% and 91.8 ± 2.0%, respectively. Hydrocarbon quantities were determined on flies of each of these groups 3 and 8 days after emergence.

To establish the effects of temperature, Pesse flies were used from a strain reared for about 30 generations (Pesse-30) in the laboratory at 25°C, 50% relative humidity, and 12L : 12D photoregime. Eight-day-old females of this strain contained about 1 μg muscalure/fly. Hydrocarbon quantities of 8-day-old flies from two cultures were compared. Immediately after emergence, the flies of these cultures had been placed at 20 and 35°C, respectively, in cages ($30 \times 30 \times 40$ cm) containing about 100 males and females.

The effects of population density on cuticular hydrocarbon composition were studied using Van Diermen flies. Flies originating from the first generation grown in the laboratory were reared for 8 successive generations (F_1–F_8) at 25°C, 50% relative humidity, and 12L : 12D photoregime in cages ($30 \times 30 \times 40$ cm) containing either less than 20 or more than 300 flies. Hydrocarbon quantities on 8-day-old flies of the F_1 and F_8 generations were compared.

All flies were fed a mixture of powdered milk, sugar, and yeast (5:5:1 by weight). Water was present ad libitum in a tube filled with cotton. In the first two series of experiments, flies of only one generation that already produced considerable amounts of muscalure were studied, because we expected an immediate effect on cuticular hydrocarbon production when changing the abiotic factors of

temperature and relative humidity. Since, however, the amount of (*Z*)-9-tricosene production is supposed to be primarily the result of a selection process in isolated high-density populations, we compared, in the third series, flies from two generations, starting with a culture that did not produce detectable amounts of (*Z*)-9-tricosene.

Chemical Analysis. Individual flies were immersed in 0.2 ml hexane and shaken for 1 min, to bring the hexane in full contact with the whole cuticle, after which the fly was kept in this fluid for 1 hr for extraction of the cuticular hydrocarbons. The hydrocarbons were not separated from the nonhydrocarbon compounds because in *Musca domestica* the cuticular wax layer (above C_{20}) consists almost exclusively of hydrocarbons except for some oxygenated compounds (Mpuru et al., 2001).

Gas chromatography was performed on a Hewlett Packard 5890 series II gas chromatograph. Two microliter aliquots of individual extractions were injected into a WCOT fused silica CP-Sil-5 CB column (25 m $\times$ 0.32 mm ID; film thickness, 0.25 μm; Chrompack) with injector at 250°C and FID at 300°C. The flow rate of the helium carrier gas was 26 cm/sec. The split ratio was 56:1. GC oven temperature was programmed from 50 to 300°C at 10°C/min. 2-Nonanone was used as an internal standard. A calibration curve of this chemical in relation to some relevant hydrocarbons was made in order to calculate the proper amounts of the cuticular hydrocarbons. Muscalure and the other hydrocarbons were identified by comparing the retention time with reference runs of alkanes and (*Z*)-9-alkenes or with data from the literature. In an earlier study (Noorman and Den Otter, 2001), hydrocarbons were identified by mass spectrometry, and this indicated that the relevant hydrocarbons can be distinghuised by differences in retention times. Quantities of the hydrocarbons were expressed as percentages of the internal standard or as micrograms.

RESULTS

The total amounts of cuticular hydrocarbons on males and females, 3 and 8 days old, that had been kept at different relative humidities from emergence are presented in Figure 1. The amounts of hydrocarbons on both 3-day-old males and females were higher at 20 and 50% than on those kept at 90% relative humidity. (Mann-Whitney U test, $P < 0.01$). Eight days after emergence, the total hydrocarbon quantities on the flies became higher at all relative humidity levels compared to day 3 (Mann-Whitney U test, $P < 0.01$). In addition, the amounts on 8-day-old males at 90% relative humidity were no longer lower than on those kept at 50 and 20%. This is in contrast to the females of which 8-day-old specimens at 90% relative humidity still contained less hydrocarbons than those kept at the lower relative humidities. (Mann-Whitney U test, $P < 0.05$).

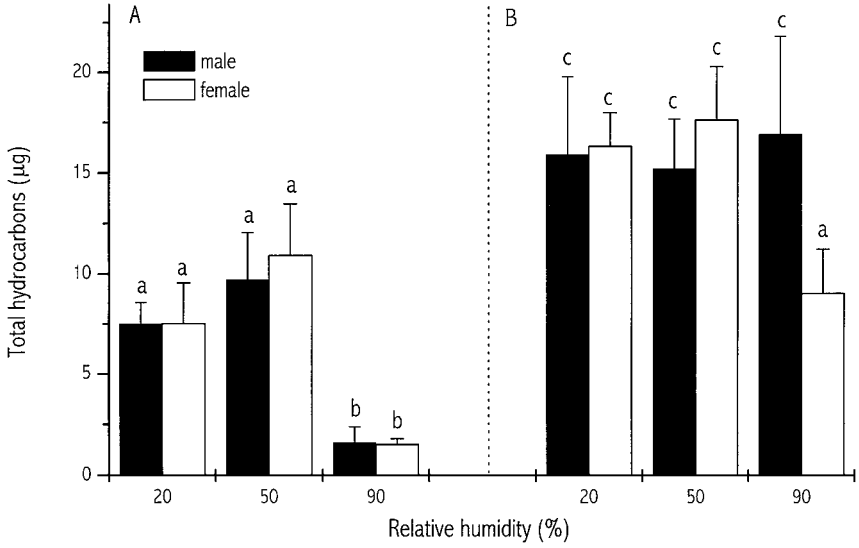

FIG. 1. Amounts of total cuticular hydrocarbons of males ($N = 5$) and females ($N = 10$) of *M. domestica*, 3 (A) and 8 (B) days after emergence, at different relative humidities. Error bars represent standard deviations. Averages labeled with different letters differ significantly.

The amount of the most abundant hydrocarbon compounds present on the cuticle of the flies is about 90% of the total cuticular hydrocarbons (Figure 2). The hydrocarbon profiles of males and females differed considerably; males had relatively high quantities of (*Z*)-9-heptacosene, whereas females had relatively high amounts of (*Z*)-9-tricosene, tricosane, and (Z)-9-heptacosene. On day 8, the amounts of hydrocarbons were higher than on day 3, but the hydrocarbon profiles of the males and females were still about the same. The amounts of (*Z*)-9-tricosene plus tricosane on females are about 15% of the total cuticular hydrocarbon quantity on day 3 after emergence and about 30% of the total on day 8 at each of the three relative humidities.

Striking differences in the total amounts of hydrocarbons on 8-day-old male and female flies were present between flies kept at 20°C and at 35°C (Figure 3). Males at 35°C produced about 80% more hydrocarbons than males kept at 20°C (19.5 and 10.7 μg, respectively); females at 35°C produced about 50% more than females kept at 20°C (21.2 and 13.9 μg, respectively). In male flies, the relative amounts of the various hydrocarbons produced at the two temperatures did not differ significantly, whereas in female flies the relative amounts of nonacosane and of the methyl- and dimethylnonacosanes were higher at 35°C than at 20°C

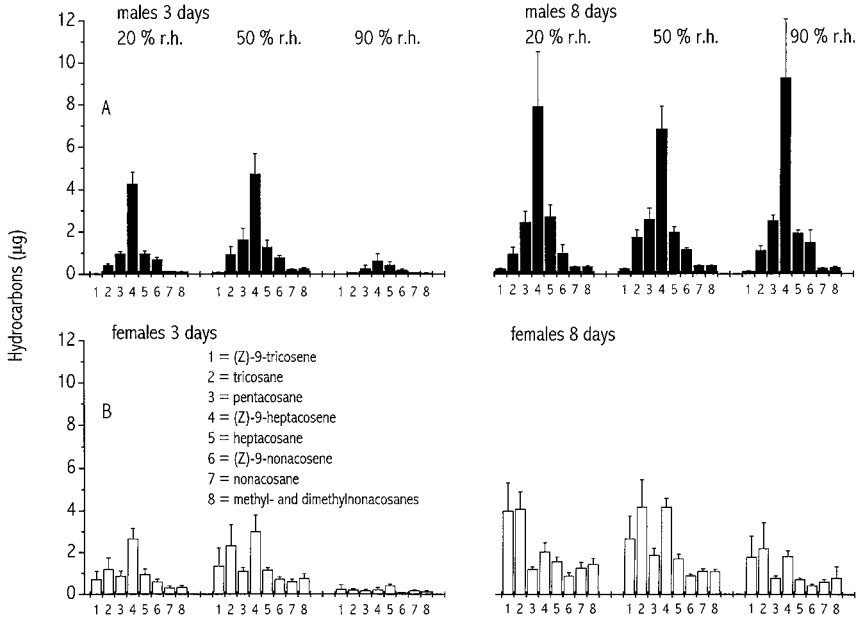

FIG. 2. Amounts of cuticular hydrocarbons on males (A, $N = 5$) and females (B, $N = 10$) of *M. domestica*, 3 and 8 days after emergence, at different relative humidities. Error bars denote standard deviations.

(t test, $P < 0.01$). Although at 20°C females appeared to produce less muscalure than at 35°C (1.0 vs. 1.4 μg), this difference was not significant. The relative amounts of the remaining hydrocarbons of females kept at 20°C and at 35°C did not differ. Hence, the production of muscalure is not different from the production of these hydrocarbons at the two temperatures.

The total amounts of the hydrocarbons on the first generation wild-type Van Diermen males (11.9 μg) and females (16.5 μg) did not differ from those on the eighth generation flies kept at low or high density (males 11.4 and 14.3 μg, females 19.2 and 14.0 μg, respectively, Mann-Whitney U test, $P > 0.05$) (Figure 4). The hydrocarbon profiles of the males were similar to those of the males of the Pesse strains used in the previous experiments (cf. Figures 2A, 3A, and 4A), whereas those of the females differed considerably from the Pesse females (cf. Figures 2B, 3B, and 4B). On 8-day-old Van Diermen females, nonacosane and methyl- and dimethylnonacosanes were the most abundant hydrocarbons. Females of the low-density population contained (*Z*)-9-tricosene, although the amounts were low.

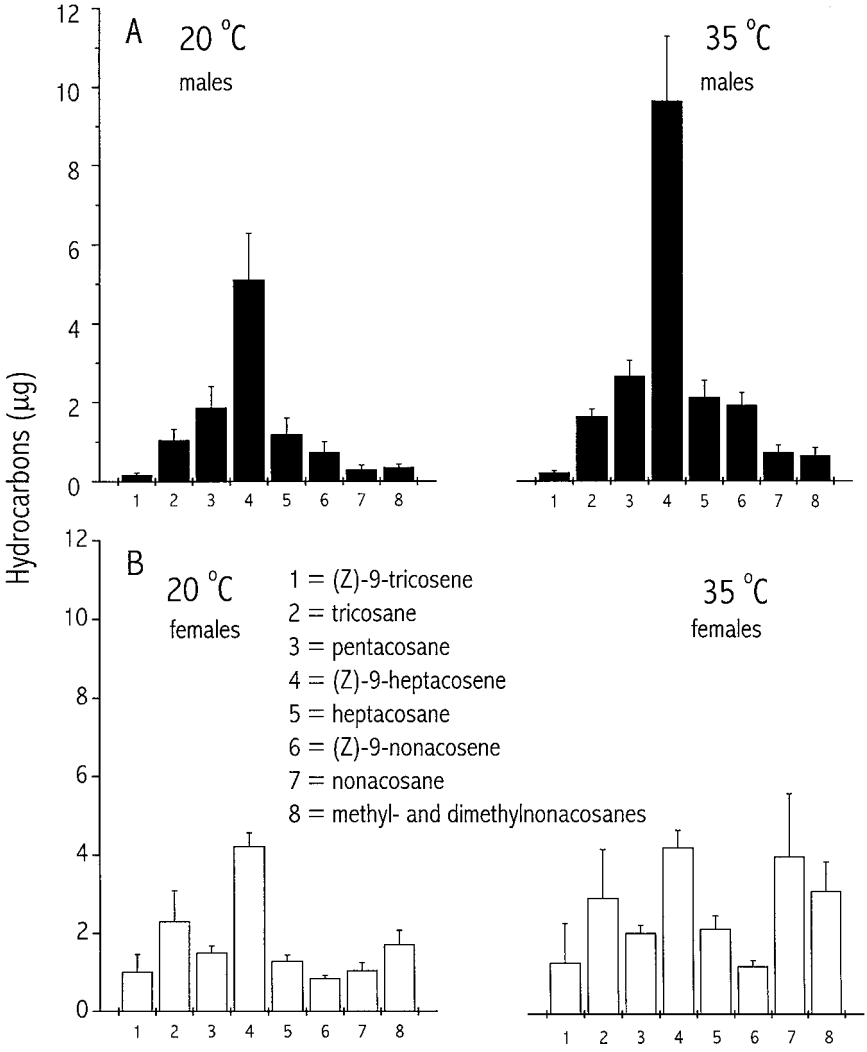

FIG. 3. Amounts of cuticular hydrocarbons on 8-day-old males (A, $N = 5$) and females (B, $N = 10$) of *M. domestica* at 20 and 35°C. Error bars denote standard deviations.

DISCUSSION

Evaporation of water through the cuticle can be expected to be lower at higher relative humidity. Therefore, smaller amounts of cuticular hydrocarbons may be needed to protect the flies from desiccation. Toolson and Hadley (1979)

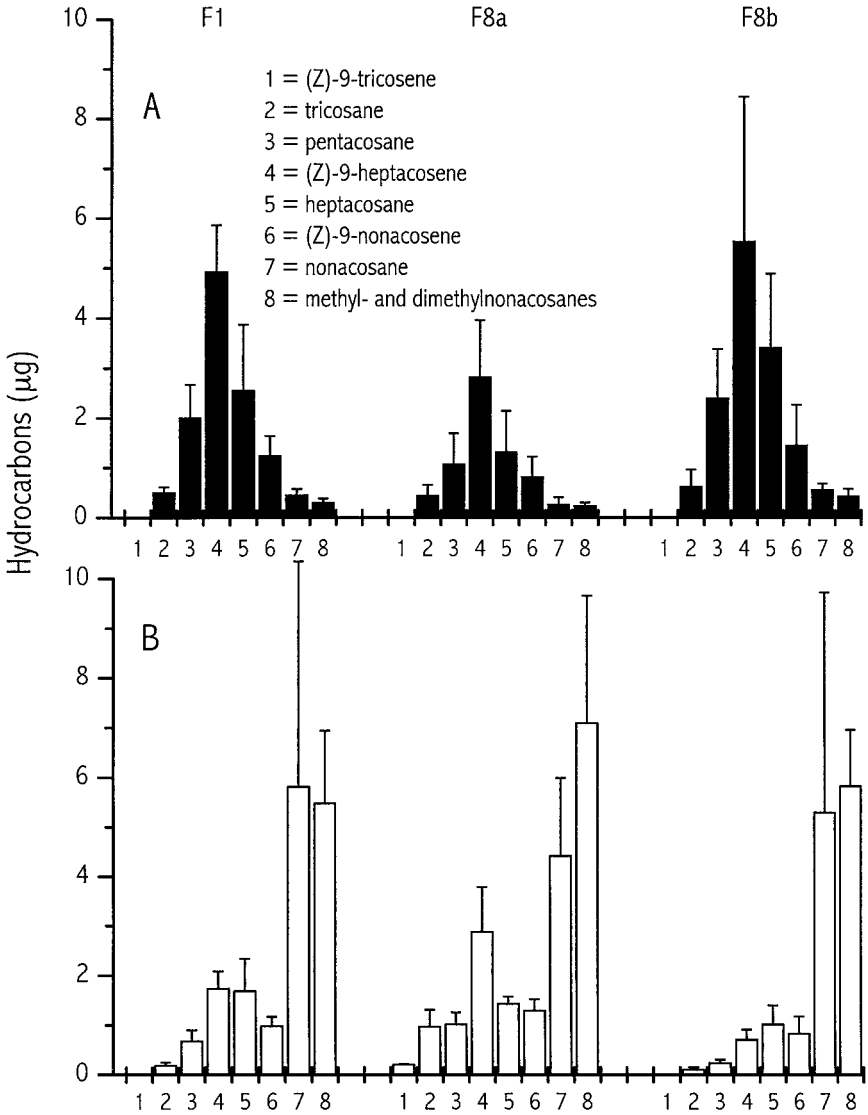

FIG. 4. Amounts of cuticular hydrocarbons on 8-day-old first laboratory generation (F1) males (A) and females (B) of *M. domestica* and on males and females of the same strain kept in culture for eight generations at different population densities (F8a <20 and F8b 300 flies/cage). $N = 10$ for each generation. Error bars indicate standard deviations.

observed marked seasonal changes in the relative abundance of cuticular hydrocarbons of the scorpion *Centruroides sculpturatus*, the percentage of *n*-alkanes in the epicuticular hydrocarbon decreasing considerably in warmer months, whereas the proportion of branched alkanes increased. Hadley and Schultz (1987) showed a correlation between water loss rates and quantities and composition of cuticular hydrocarbons. In the tiger beetle, *Cicindela obsoleta*, a summer-active species that inhabits dry grasslands, the cuticular hydrocarbon fraction only contains saturated hydrocarbons, whereas on the body of *C. oregona*, a spring- and fall-active species that lives along water courses, about 50% of the hydrocarbons are unsaturated. The presence of unsaturated hydrocarbons is thought to increase the permeability of the hydrocarbon layer to water. Indeed, Hadley and Schultz (1987) found a significant negative correlation between water loss rate and the quantity of saturated hydrocarbons.

We found that both males and females of 3 days old flies reared at 90% relative humidity possessed remarkably lower amounts of saturated and unsaturated hydrocarbons than those reared at 20 and 50%. Eight days after emergence, however, males kept at 90% relative humidity contained the same amounts of hydrocarbons as those kept at 20 and 50%, whereas females still had less hydrocarbons on their cuticle. A possible explanation may be that, in general, males are more active than females, mainly due to intensive mating behavior (personal observations). As a consequence, males may need more cuticular hydrocarbons to prevent water loss than less active females. The hydrocarbon profiles of the females cultured at different relative humidities are about the same. This suggests that the production of (*Z*)-9-tricosene, the main component of the female sex pheromone, may not be affected by changes in humidity to the same extent as of the other hydrocarbons.

The melting temperatures of the alkenes, methylalkanes, and alkanes isolated from 4-day-old houseflies are -0.2, 29.9, and 41.5°C, respectively (Gibbs et al., 1995). The melting temperature (midpoint of phase transition) of the mixture of all cuticular hydrocarbons was 36.8°C in females and 39.4°C in males. However, the transition of lipids from the solid to the liquid phase ranges over 10–15°C. The necessity to keep the melting temperature of the cuticular lipid mixture within a certain range can probably affect the amounts in which certain hydrocarbons are produced, depending on different environmental circumstances. We observed that the relative amounts of nonacosane and methylnonacosanes on females were higher at 35°C than at 20°C. This may have led to an increase of the melting temperature of the whole mixture of cuticular hydrocarbons. The hydrocarbon profiles on male flies were, however, the same at the two temperatures. The melting temperature of all cuticular hydrocarbons is higher in males than in females (Gibbs et al., 1995). Probably there is no reason to change the amount and composition of hydrocarbons on males in an environmental temperature range of 20°C to 35°C.

In the low-density population cultures (<20 flies/cage), all females of the eighth generation produced a low amount of muscalure, whereas no muscalure was found on the high-density (>300 flies/cage) females. We were able to compare eight generations, but nevertheless, after this limited number of generations, differences in (*Z*)-9-tricosene production between the two populations could already be observed. We found (*Z*)-9-tricosene on all the females of the low-density population analyzed, and each fly contained about the same amount of this compound. Surprisingly, none of the females of the high-density populations produced detectable amounts of (*Z*)-9-tricosene. Probably, this difference developed by chance. The properties of one or a few females are likely to be expressed in relatively more individuals in the next generations of small (laboratory culture populations) than in large (wild-type) populations. It is shown that selection can sneak in rapidly. This effect should always be a point of attention in laboratory colonies.

The clear difference in the hydrocarbon profiles between 8-day-old females of the Pesse-30 and -40 strains and the Van Diermen strain may be explained by focusing on the main function of cuticular lipids in general, i.e., to provide a barrier to water loss. The insects will need a certain amount of cuticular lipids in order to regulate water balance in an effective way. When (*Z*)-9-tricosene and tricosane in female houseflies are present only in small amounts, this is compensated for by other hydrocarbons (nonacosane and methyl- and dimethylnonacosanes). This assumption seems plausible when considering the total amount of hydrocarbons on females of the Pesse-40 and Van Diermen strains in the experiments carried out at the same temperature and humidity (25°C, 50% relative humidity). Females of both populations produced about the same amount of total hydrocarbons irrespective of the hydrocarbon profiles. In previous studies, Noorman and Den Otter (2001) also found that both first-generation Van Diermen and Pesse females in the laboratory produced low or undetectable amounts of (*Z*)-9-tricosene and relatively high amounts of nonacosane and methyl- and dimethylnonacosanes. Since no significant differences in the hydrocarbon profiles between these first-generation females of the Pesse and Van Diermen strains existed, strain differences do not appear to be responsible for the differences in hydrocarbon profiles.

The overall conclusions of the experiments are that relative humidity and temperature play a prominent role in the production of cuticular hydrocarbons and that the effects on the production of muscalure and the other hydrocarbons are similar. The population-density experiment showed that in a small number of generations selection might give rise to differences in muscalure production among populations. The fact that, in contrast to high-density population females, the low-density population cultures produced some muscalure suggests that population density is not the main factor for inducing muscalure production.

(Received June 15, 1997; accepted May 6, 2002)

Abstract—The presence of an alarm pheromone was demonstrated in the deutonymphal stage of the oribatid mite, *Nothrus palustris* (C. L. Koch). The active principle was identified as 3,7-dimethyl-(*E*)-2,6-octadienal, geranial, and was shown to be active at doses of 10–100 ng. This is the first such pheromone identified in oribatid mites.

Key Words—Alarm pheromone, geranial, oribatid mites, *Nothrus palustris*, opisthonotal gland.

INTRODUCTION

While maintaining a culture of *Nothrus palustris* (C. L. Koch) (Oribatida: Nothridae), which was started from field-collected deutonymphs, the following phenomena were noticed: (1) the species tended to aggregate into a colony when feeding on fallen leaves or filter paper, (2) if one or several mites at the center of the aggregation were crushed with forceps or a needle, aggregating mites around them started to escape, and the aggregation became loose within several minutes. The same escape behavior was reproducible when a small filter paper (3×3 mm)

impregnated with the hexane extracts of nymphal bodies was placed at the center of the aggregation. These finding suggested that deutonymphs of the species possess an alarm pheromone that is discharged as a volatile compound on being crushed, possibly from a pair of opisthonotal glands (Howard et al., 1988), and that the active compound is extractable from nymphal bodies by hexane.

We report here identification of the alarm pheromone of the oribatid mite as 3,7-dimethyl-(*E*)-2,6-octadienal, geranial. The compound seems to be widely distributed among Oribatida (Sakata et al., unpublished data), whereas its geometric isomer 3,7-dimethyl-(*Z*)-2,6-octadienal, neral, is a major compound distributed widely among Astigmata (Kuwahara, 1999).

METHODS AND MATERIALS

Mites. About 200 individuals of *Nothrus palustris* (C.L. Koch) (Oribatida: Nothridae), consisting mainly of deutonymphs together with larvae, protonymphs, and tritonymphs, were collected on August 10, 1996, from litter and soil on the campus of Yokohama National University, Hodogaya-ku, Yokohama, Japan, by Tullgren funnel extraction. The species inhabits forest litter as a decomposer and has been recorded in many parts of the Palaeartic region (e.g., Sellnick and Forsslund, 1955). Nymphs were raised to adults in the laboratory by feeding with forest litter. Adults were used to confirm the species, because it was difficult to identify the species in the nymphal stages. Mites at these stages were white in color and had a fragile appearance, unlike the well sclerotized adults.

Bioassay. Groups of 20 deutonymphs were transferred into containers comprised of open glass tubes (1 cm diam. $\times$ 2 cm high) with a glass plate as the bottom. Glass Petri dishes (9 cm diam.) were inverted and used as plates. The container was set up on a circle (1 cm diam.) drawn underneath the Petri dish. Mites in the container were allowed to settle for (10–20 minutes) to offset handling effects, then the glass tubes were removed with minimal disturbance. At the center of the circle in which mites were left motionless, either a filter paper (3×3 mm) with a candidate compound dissolved in 3 μl of hexane or a freshly crushed mite body was introduced. Numbers of mites remaining within the circle were then counted every minute for 5 min. Filter paper impregnated with hexane (3 μl) alone was used as a control.

Instruments. Gas–liquid chromatography (GC) was carried out on a Hewlett Packard HP-5890 series II Plus equipped with a flame ionization detector. An HP-5 capillary column (0.32 mm diam. $\times$30 m, 0.33 μm film thickness) was used at a temperature program of 60°C to 290°C at 10°C/min, with an initial 2 min hold at 60°C. Samples were analyzed in splitless mode using He at 1.23 ml/min as the carrier gas. The chromatogram was processed with an HP 3396 series II integrator. GC-mass spectrometry (GC-MS) was performed on an Hewlett Packard 5989B

mass spectrometer coupled with an HP-5890 series II Plus gas chromatograph in splitless mode, using the same capillary column and conditions as described above.

Preparation of Hexane Extract. A mite (a deutonymph, protonymph, tritonymph, or an adult) was transferred with a needle into a small conical-bottomed tube (handmade, 8 mm diam. × 30 mm long) and 3 μl of hexane was added. The resulting hexane rinse was collected with a microsyringe at 3 min after introduction of the solvent. Then, all portions of the rinse were subjected to either GC or GC-MS analysis. Similar hexane rinses from a substantial number of mites (not counted) were used for preliminary bioassay and silica gel (Wakogel C-200) column chromatography.

RESULTS AND DISCUSSION

Upon exposure to a piece of filter paper impregnated with the hexane rinse (3 μl) prepared from a deutonymph, tested deutonymphs showed escape behavior from the arena, possibly due to the presence of the alarm pheromone. GC analyses of the mite extract revealed that each hexane rinse from all nymphal stages (protonymph, deutonymph, and tritonymph) indicated the same profile (Figure 1). The extract consisted of at least four components (compound A, t_R 2.82 min; compound B, t_R 6.59 min; compound C, t_R 7.12 min; and compound D, t_R 16.50 min), of which compound C was the major component. Compounds A, B, and D were minor components at nymphal stages. In contrast, the profile from the adult rinse was different from those of nymphs. Compound A was the major component, followed by compound D. Compound C was a trace component together with many unknown peaks (Figure 1). Although reliable GC profiles were not obtained from mites at larval stages, possibly due to their small body size, the same profile as that of nymphs was assumed. This is the first example of an oribatid mite in which the that major components in the extract (possibly the exudates from the oil gland) change through development from nymphal to adult stages.

Compound A (t_R, 2.82 min) showed an M^+ ion peak at m/z 152 (18%) and the base ion peak at m/z 109 (100%) with the following diagnostic ions at m/z 124 (44%), 94 (58%), 79 (77%), 77 (23%), and 43 (60%). This mass spectrum was identical to that of dehydrocineole (Ayorinde et al., 1984), and its t_R was also the same as that of the compound present in the astigmatid mite *Caloglyphus rodriguezi*. Consequently, compound A was identified as dehydrocineole. Among astigmatid mites, the compound is distributed only among species belonging to the genera *Caloglyphus*, *Schwiebea*, and *Rhizoglyphus* (Kuwahara, 1991, 1995, 1999).

Compounds B (t_R 6.59 min) and C (t_R 7.12 min) indicated both identical tRs to those derived from the standard citral, a mixture of 3,7-dimethyl-(*E*)-2,6-octadienal, geranial, and 3,7-dimethyl-(*Z*)-2,6-octadienal, neral. These compounds also showed the same characteristic GC-MS spectra with an M^+ ion each at

m/z 152 (3% and 9%) and the same base ion at m/z 69 (both, 100%) and were identical to those reported previously (Kuwahara et al., 1980). Compounds B and C were, thus, identified as neral and geranial, respectively.

Compound D showed an M^+ ion at m/z 292 (16%) and the base ion at m/z 55 (100%) with the following diagnostic ions at m/z 222 (2%), 208 (4%), 194 (5%), 180 (7%), 166 (10%), 152 (14%), 138 (16%), 124 (26%), 110 (35%), 96 (78%), 82 (80%), 69 (58%), and 41 (60%). Although the mass spectrum and t_R were identical to those obtained from a standard of 6,9-heneicosadiene from the astigmatid mite *Suidasia medanensis* as a minor component (Kuwahara, 1991, 1995, 1999), double bond positions and their geometry remain obscure.

When the hexane rinse was subjected to SiO_2 column chromatography and separated by elution with a sequence of ether–hexane mixtures, the alarm pheromone activity was recovered in the 10% ether/hexane eluate. The active fraction consisted of both compounds B and C, confirmed by GC and GC-MS analyses. The SiO_2 column chromatographic behaviors of these two compounds also coincided with that of citral. The isomeric purity of geranial was calculated as more than 90% among the nymphal extracts (Figure 1).

The alarm pheromone activity demonstrated by a squashed deutonymph coincided with that of the filter paper impregnated with doses of 10–100 ng of geranial (Table 1). The actual quantity of geranial determined by GC analysis was 91.4 ± 20.4 ng (mean $\pm$ SD, $N = 10$) per deutonymph, and this value was consistent with the bioassay results. Although there were no differences in the behavior of mites between exposure to 0.1 ng of synthetic genarial (isomer purity $>95\%$) and the control, escape behavior was observed to synthetic geranial at doses >1 ng. No activity was observed in response to synthetic neral (isomer purity $>95\%$), which was at least 10-fold less active than geranial.

In summary, the alarm pheromone found in deutonymphs of *Nothrus palustris* was identified as geranial. As the compound was also detectable in the extract from mites at all nymphal stages as the major component (Figure 1), its pheromonal

5	10	11	2	0	0	0

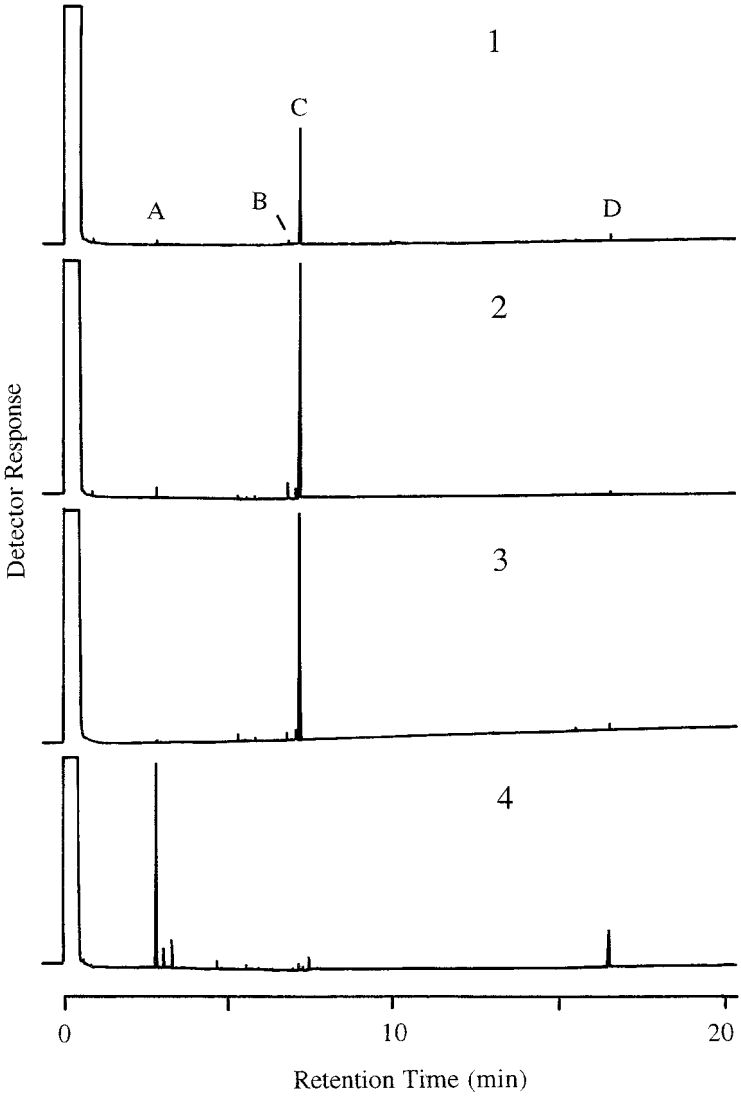

FIG. 1. Typical gas–liquid chromatograms of hexane extract of *Nothrus palustris* on an HP-5 fused silica capillary column at a temperature programmed condition from 60°C to 290°C at 10°C/min. 1: from a protonymph, 2: from a deutonymph, 3: from a tritonymph and 4: from an adult. Peak A: dehydrocineole, peak B: neral, peak C: geranial, and peak D: heneicosadiene.

function was also presumed to be present in mites at all stages. Although adults exhibited the same escape behavior on exposure to geranial at 100 ng, the GC profile was completely different to that of nymphal stages. Geranial was only a trace component in the extract, and dehydrocineole was the major component, followed by 6,9-heneicosadiene as the second largest. It is, therefore, unlikely that geranial functions as the alarm pheromone in adults. The reason for the adult behavior against high doses of geranial has yet to be clarified.

Mites at the nymphal stages were white in color and their epidermis was soft and fragile, similar to those of Astigmata. This might be why the alarm pheromone is required for nymphal stages, i.e, to minimize physical damage caused by natural enemies, similar to the case in Astigmata. On the other hand, adults possess a fully sclerotic brown epidermis that may protect the mites from various ecological pressures and may lessen their dependence on the alarm pheromone.

This is the first report of a semiochemical identified in an oribatid mite, possibly as a component of a pair of oil glands (the opisthonotal glands). The same gland is distributed among four cohorts of Oribatida: Parhyposomata, Mixonomata, Desmonomata, and Brachypylina (Norton, 1994). These glands have been shown to produce monoterpenes (Sakata et al., 1995, Raspotnig et al., 2002) and aromatics (3-ethyl phenol, γ-acaridial, and 1-methyl-2-naphtol) (Sakata and Norton, 2001), together with various hydrocarbons. However, their biological functions have not previously been clarified. Many studies of the ecology and biology of this species as a model of oribatid mites were reviewed by Krivolutsky et al. (1995) and Lebrun (1970), but the occurrence of an alarm pheromone has not been reported previously. The present identification of the alarm pheromone is the first step in the semiochemical study on the oil glands of Oribatida. Many other examples will likely be found in future studies. In the case of astigmatid mites, three kinds of pheromones are known in the total of 52 species examined: the alarm pheromone in 16 species, the aggregation pheromone in 2 species, and the sex pheromone in 5 species (Kuwahara, 1999). This is also the first species in which intrinsic differences were observed in the major component between adult and nymphal stages.

Among the 52 species of astigmatid mites examined to date, neral-rich citral has been shown to be distributed in 28 species, and neral functions as the alarm pheromone in five species. Geranial-rich citral is found in six species [(two species of Histiostomatidae, and in *Dermatophagoides pteronyssinus*, *Chaetodactylus nipponicus*, *Tyrophagus neiswanderi*, and *Schwiebea* sp. (Chiba)], among which geranial functions as the active principle of the alarm pheromone in *Histiostoma laboratorium*. Neral is the major component of citral among Astigmata (Kuwahara, 1999). On the other hand, among Oribatida geranial seemes to be the more dominant component, although current information regarding the neral–geranial ratio in Oribatida is limited (Sakata et al., unpublished data). This is the second example of geranial functioning as the alarm pheromone in two suborders, Astigmata and Oribatida, and the first example of the pheromone present in Oribatida.

Acknowledgments—This study was supported in part by a Grant-in-Aid for Scientific Research From Ministry, of Education, Science and Culture of Japan (No. 08406010, 09556010, 09876091 and 6379). Part of the study was presented at the 10th International Congress of Acarology held in Canberra 1998 (See Shimano et al., 2001)

(Received December 17, 2001; accepted May 20, 2002)

Abstract—Optically pure synthetic enantiomers of (*E*)-conophthorin [(*E*)-7-methyl-1,6-dioxaspiro[4.5]decane], one of the volatiles affecting coniferophagous bark beetles, were tested on antennae of *Ips typographus, I. duplicatus, I. subelongatus, Dendroctonus micans*, and five *Scolytus* spp. by using combined gas chromatography–electroantennographic detection (GC-EAD). EAD dose–responses indicated that all three *Ips* species perceived only the naturally occurring and quantitatively dominant (5*S*,7*S*)-enantiomer, while its antipode, (5*R*,7*R*)-(*E*)-conophthorin was antennally inactive. Response thresholds for the *Ips* species were estimated as between 0.1 ng and 1 ng, or lower. The antennal responses of the *Ips* species caused by 100 ng of the (5*R*,7*R*)-enantiomer might be due to 1% impurity-(the active (5*S*,7*S*)-enantiomer) in the (5*R*,7*R*)-sample. At the 50-ng level, *D. micans* and five angiosperm *Scolytus* species (*S. intracatus, S. mali, S. ratzeburgi, S. rugulosus, and S. scolytus*) responded strongly to the (5*S*,7*S*)-enantiomer, while the (5*R*,7*R*)-enantiomer was antennally inactive. Currently updated knowledge on the natural occurrence, and electrophysiological and behavioral activity of (*E*)-conophthorin is summarized.

Key Words—*Ips typographus, Ips duplicatus, Ips subelongatus, Dendroctonus micans, Scolytus, Hylesinus, Phloeophthorus,* (*E*)-conophthorin, enantiomers, 1-hexanol, nonhost volatiles, antennae, GC-EAD, dose–response.

INTRODUCTION

Recent studies indicated that coniferophagous bark beetles not only recognize the aggregation pheromones of conspecifics as well as host kairomones, but are also able to perceive and avoid nonhost volatiles (NHVs) from angiosperm trees in their natural habitats (Huber, 2001; Zhang, 2001; Zhang and Schlyter, 2002, and in preparation). Among these, (*E*)-conophthorin, (*E*)-7-methyl-1,6-dioxaspiro[4.5]decane, is one of the major NHVs found in the bark of several angiosperm species in Europe [*Betula pendula* Roth., *B. pubescens* Ehrh. (Betulaceae), *Populus tremula* L. (Salicaceae), and *Quercus suber* L. (Fagaceae)], and in North America [*Populus tremuloides* Michx., *P. trichocarpa* Torr & A. Gray, *Acer macrophyllum* Pursh. (Aceraceae), and *Betula papyrifera* Marsh.] (Francke et al., 1995, Byers et al., 1998; Huber, et al., 1999, 2000a,b; Zhang et al., 2000). It elicited antennal responses from >10 species of coniferophagous bark beetle species (Zhang and Schlyter, in preparation) and caused a significant reduction in the response of more than 15 species of conifer-infesting scolytids to attractant-baited traps (Huber, 2001; Zhang, 2001; Zhang and Schlyter, in preparation). Quite recently, the combination of (*E*)-conophthorin with other NHVs and verbenone has shown potential for successful tree protection against mass attacks of *Dendroctonus ponderosae* Hopkins and *Ips typographus* (L.) (Huber and Borden, 2001; Jakuš et al., 2002).

(*E*)-Conophthorin was first identified as a male-specific compound in the ash bark beetle *Leperisinus fraxini* (F.) as well as in workers of the social wasps, *Paravespula vulgaris* (L.), *P. germanica* (F.), and *Dolichovespula saxonica* (F.) (Francke et al., 1978, 1979). It was later found to be a male-produced repellent pheromone of several species of Scolytidae (Coleoptera) (Kohnle et al., 1992; Pierce et al., 1995; Birgersson et al., 1995; Dallara et al., 2000; De Groot and DeBarr, 2000) and an aggregation pheromone component in two twig scolytids, *Pityophthorus* spp. (Dallara et al., 2000). A detailed compilation on the occurrence of spiroacetals in insects has been published recently (Francke and Kitching, 2001). Both the *E*- and *Z*-stereoisomer of conophthorin (Figure 1) were detected in various natural sources (both plants and insects), but the *E*-isomer was dominant in all taxa studied (with the *E*/*Z* ratios ranging from 2:1 to 40:1) (see Table 1 for details). The determination of the enantiomeric composition of (*E*)-conophthorin from natural sources indicated a strongly biased 5*S*,7*S*-configuration, with an *ee* of 30–100%.

The objective of the present investigation was to test whether the antennae of some angiosperm bark beetles (*Scolytus* spp.) and the spruce bark beetles, *Ips typographus* (L.), *I. duplicatus* (Sahlb.), and *Dendroctonus micans* (Kugelann), as well as the Asian larch bark beetle, *Ips subelongatus* Motschulsky [formerly recognized as *I. cembrae* (Heer) in the West; see Stauffer et al. (2001) for species status] would respond to both enantiomers of (*E*)-conophthorin or only detect

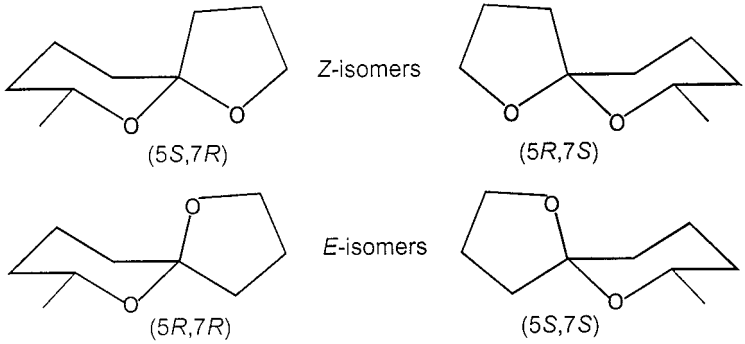

FIG. 1. Stereoisomers of conophthorin.

the major (5*S*,7*S*)-enantiomer. To answer this question, we used a combined gas chromatography–electroantennographic detection (GC-EAD) technique in a dose–response fashion, with optically pure synthetic enantiomers as well as GC-EAD and on-line enantiomeric separation of racemic (*E*)-conophthorin with a chiral stationary phase.

METHODS AND MATERIALS

Insects and Chemicals. Adults of *Ips typographus* and *I. duplicatus* were taken from laboratory cultures (It-114 and Id-05), originally collected from Norway and Inner Mongolia, China, respectively.*I. subelongatus* adults were collected directly from naturally attacked *Larix principis-rupprechtii* Mayr. trees, Inner Mongolia, China.

Dendroctonus micans (Kugelann) were collected from the bark of naturally infested Norway spruce, *Picea abies* Karst. at Clermont-Ferrand, France. Angiosperm bark beetles were obtained from naturally infested logs collected in the vicinity of Hamburg, Germany, which had been brought to the lab: *Hylesinus crenatus* (F.) in common ash, *Fraxinus excelsior* L.; *Phloeophthorus rhododactylus* (Marsh.) in broom, *Sarothamnus scoparius* (L.); *Scolytus intricatus* (Ratzeburg) in oak, *Quercus robur* L.; *S. mali* (Bechstein) in plum, *Prunus domestica* L.; *S. ratzeburgi* Jason in birch, *Betula pendula* Roth; *S. rugulosus* (Ratzeburg) in plum, *Prunus domestica* L.; and *S. scolytus* (F.) in elm, *Ulmus minor* Mill. Analyses for unambiguous identification of (*E*)-conophthorin in beetles was carried out by coupled gas chromatography–mass spectrometry (GC-MS) as described elsewhere (Francke et al., 1996).

Both enantiomers, (5*S*,7*S*)-(*E*)-conophthorin (97%; *ee* = 98%) and (5*R*,7*R*)-(*E*)-conophthorin (91%; *ee* = 98%), were synthesized according to the procedure

described by Jacobson et al. (1982). The stereogenic center at C-7 was introduced through the preparation of optically active 4-pentyne-2-ol (the chiral open chain component in Jacobson's synthesis) from acetylene and optically pure (2*S*)-methyloxirane (Aldrich). Racemic (*E*)-conophthorin (87%) was purchased from Phero-Tech. In addition, 1-hexanol (>98%; Aldrich), one of the active non-host green leaf volatiles (GLVs) in many *Ips* bark beetles (Zhang et al., 1999a,b), was used as an active control.

GC-EAD. GC-EAD analyses with *I. typographus*, *I. duplicatus*, and *I. subelongatus* were carried out in Sweden on antennae (with the severed head) of both sexes by using an HP 6890 gas chromatograph equipped with a 30-m × 0.25-mm × 0.25-μm fused silica column coated with HP-Innowax. A computerized electroantennodetection system (IDAC card and the program EAD ver. 2.3 from Syntech, Hilversum, The Netherlands), as described in detail by Zhang et al. (2000), served for antennal recordings. The tested (*E*)-conophthorin samples were dissolved in hexane at the following doses: 0.1, 1, 10, and 100 ng/μl. For the 1-hexanol active control, only the 100 ng/μl solution was used. For each GC-EAD run, ca. 2 μl of (*E*)-conophthorin solution plus ca. 2 μl of 100 ng/μl 1-hexanol (combined in the same syringe) were injected. Thus, after a 50:50 split in the GC, there should be ca. 100 ng of 1-hexanol and 0.1, 1, 10, and 100 ng of (*E*)-conophthorin (depending on the doses used) passing over the antennal preparations. The EAD responses were normalized to the relative response (%) to the active control.

GC-EAD analyses of *D. micans* and angiosperm bark beetles were carried out in Germany with cut off antennae of both sexes by using an HP 5890 GC with the same Syntech EAD system. Enantiomeric separation of (*E*)-conophthorin was achieved by using a 40-m × 0,25-mm-ID fused silica column coated with heptakis-*O*-(6-TBDMS-2,3-dimethyl)-β-cyclodextrin, operated at 100°C (*D. micans*) or 60°C for 3 min, then programmed to 160°C at a rate of 3°/min (*Scolytus* spp.).

RESULTS

Among angiosperm scolytids, (*E*)-conophthorin has earlier been reported from *Leperisinus fraxini* (Francke et al., 1979; Kohnle et al., 1992) and *Taphrorychus bicolor* (Dallara et al., 2000). We have now identified this spiroacetal in the frass produced by boring beetles of *Scolytus ratzeburgi, Phloeophthorus rhododactylus, and Hylesinus crenatus*. Since we could not find this compound in the respective host material, we suppose it to be beetle-produced.

In our EAD experiments, no antennal responses at the 0.1 ng level (i.e., 2 μl of 0.1 ng/μl solution injected) were found in *I. typographus* to either enantiomer or to the racemate of (*E*)-conophthorin [(±)-tC], while the antennal response to 100 ng of 1-hexanol (active control) was obvious (Figures 2 and 3A). When tested at the 1-ng level, the 5*S*,7*S*-enantiomer elicited significant antennal response to a level similar to that caused by 100 ng of 1-hexanol (Figure 3A), whereas the

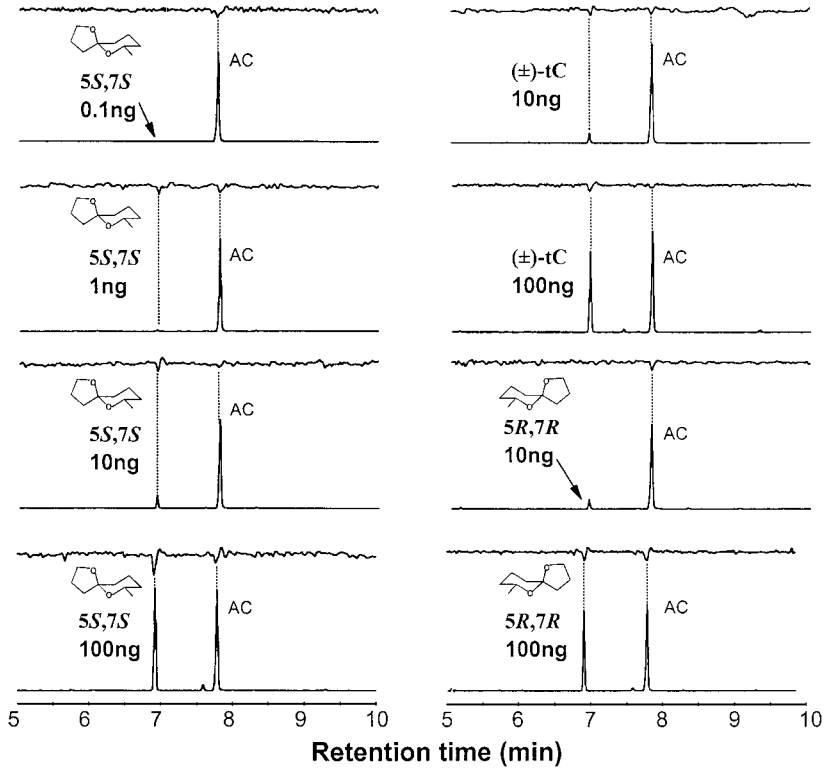

FIG. 2. Representative GC-EAD dose–response recordings on *Ips typographus* antennae to (5*S*,7*S*)-conophthorin, its antipode, and the racemate, (±)-tC. AC: active control, 100 ng of 1-hexanol.

(5*R*,7*R*)-isomer gave no responses. At the 10-ng level, again the racemate and the 5*S*,7*S*-enantiomer elicited strong EAD responses, which were stronger than that of 100 ng of 1-hexanol (Figure 3A), while the (5*R*,7*R*)-enantiomer was still inactive (Figures 2 and 3A). However, when the dosage went up to 100 ng, a clear EAD response to the (5*R*,7*R*)-sample was detected, with its response level similar to 100 ng of 1-hexanol (Figures 2 and 3A). Antennal responses to the (5*S*,7*S*)-enantiomer and the racemate were again much stronger than the active control (Figures 2 and 3A). An almost identical dose–response pattern as in *I. typographus* was found in *Ips duplicatus* (Figure 3B). Responses by *I. subelongatus* were also similar, but its relative responses to the (5*S*,7*S*)-enantiomer at levels of 1 to 100 ng seemed to be lower than those of the two other *Ips* species (Figure 3C). Additional tests on a pine bark beetle, *Orthotomicus erosus* (Woll.) (collected from naturally attacked *Pinus pinaster* Aiton trees, France) indicated that at the 10-ng level, the (5*R*,7*R*)-enantiomer was antennally inactive, while the (5*S*,7*S*)-enantiomer

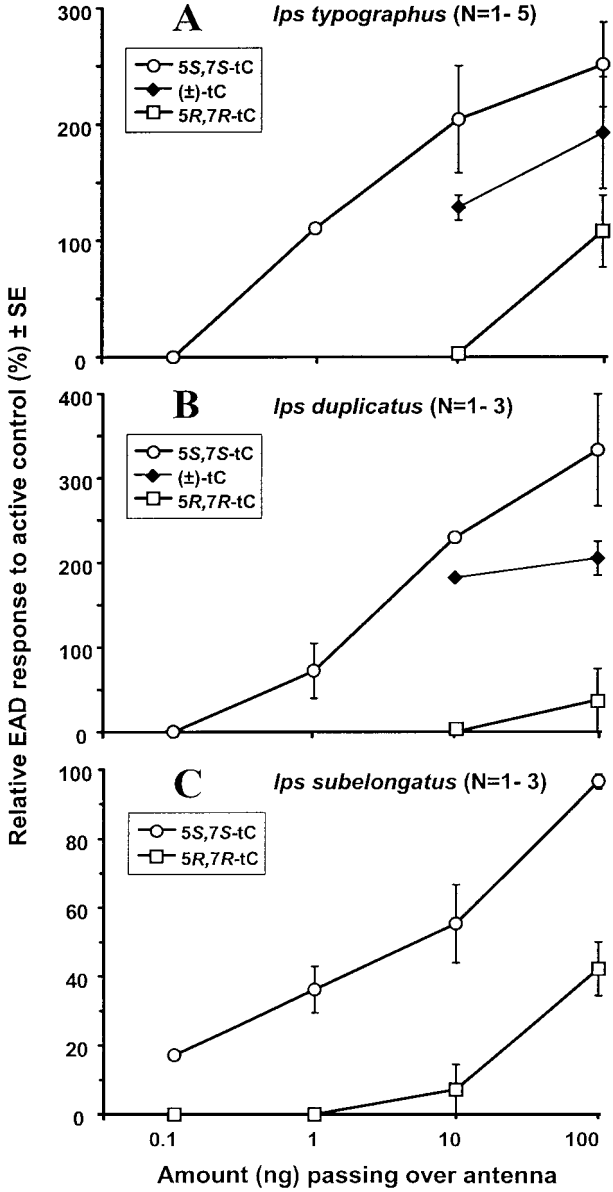

FIG. 3. EAD dose-responses by *Ips typographus* (A), *I. duplicatus* (B), and *I. subelongatus* (C) to different (*E*)-conophthorin enantiomers (5*S*,7*S*; 5*R*,7*R*) and the racemate, (±)-tC. The responses were normalized as the relative response (%) to active control (100 ng of 1-hexanol). For each dosage, and compound, 1–5 antennae were tested. (±)-tC was not tested on *I. subelongatus*.

elicited a strong EAD response similar to that caused by 100 ng of 1-hexanol (data not shown). There were no differences in the response patterns between males and females of these *Ips* species.

Using a similar GC-EAD technique, but equipped with a chiral column (coated with a modified cyclodextrin as the stationary phase), we tested (*E*)-conophthorin on males and females of a coniferophagous scolytid, *Dendroctonus micans*, and several angiosperm *Scolytus* species (*S. intricatus*, *S. mali*, *S. ratzeburgi*, *S. rugulosus*, and *S. scolytus*). Under the above experimental conditions, the enantiomeric separation showed an α value of 1.1 (retention time of the (5*S*,7*S*)-enantiomer divided by that of the (5*R*,7*R*)-enantiomer). While all antennae responded well to (5*S*,7*S*)-conophthorin, no reactions were recorded with its first eluting antipode, up to the 50-ng level (Figure 4A,B). In our investigations, antennae of *Hylesinus crenatus* and *Phloeophthorus rhododactylus* provided no answers [despite the fact that the beetles produce (*E*)-conophthorin], possibly due to experimental difficulties with antennal preparations.

DISCUSSION

Our results on GC-EAD dose–response indicate that only the (5*S*,7*S*)-enantiomer is detected by antennae of the three *Ips* species (probably *O. erosus* as well), with their response thresholds being between 0.1 and 1 ng, or lower, while the (5*R*,7*R*)-enantiomer is antennally inactive. The EAD responses caused by (5*R*,7*R*)-conophthorin at 100 ng (Figures 2 and 3A–C) could be explained by presence of ca. 1% of the (5*S*,7*S*)-enantiomer in the synthetic (5*R*,7*R*)-sample. The trace amount of this impurity (ca. 1 ng) would be sufficient to elicit an antennal response at the level similar to that caused by the active control (Figures 2 and 3). The enantiomeric selectivity of our chiral GC column was efficient enough to show the differential antennal activity of the two enantiomers of (*E*)-conophthorin (Figure 4).

Dose responses of insect antennae to semiochemicals have been widely studied by a stationary EAG technique [i.e., puffing volatiles over the antennal preparation (see Zhang, 2001 and references therein)], due to low costs, high throughput, and simplicity of handling. However, data concerning dosages used in EAG recordings usually represent the amounts of compounds loaded on the filter paper, which provides no information about the actual amounts of the tested compounds released during each puff. Moreover, EAG responses may depend on the experimental set up, and the activities of compounds with different volatilities can not be compared directly. However, using GC-EAD techniques, dosages of compounds with different volatilities can be easily controlled, and the amount of substances passing over the antenna1 preparations can be precisely determined. Furthermore, GC-EAD using a chiral column makes it possible to test the electrophysiological activity and response thresholds of highly pure

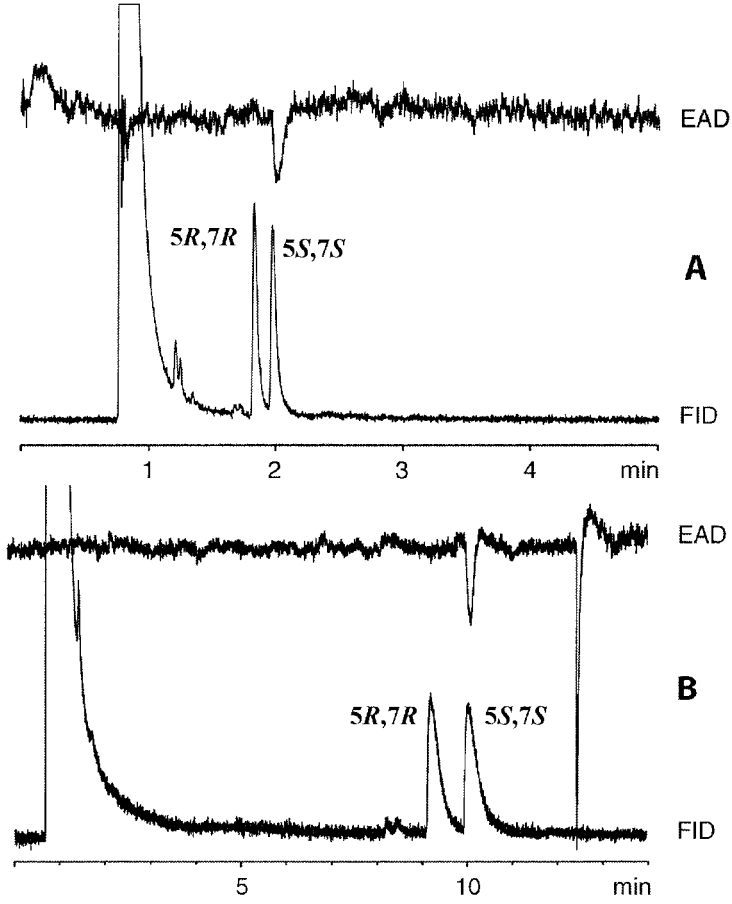

FIG. 4. (A) GC-EAD recording on *Dendroctonus micans* antenna. Response to the enantiomers of (*E*)-conophthorin separated upon chiral gas chromatography (conditions see Methods and Materials). (B) Representative GC-EAD recording on *Scolytus* antennae (here *S. ratzeburgi*). Response to the enantiomers of (*E*)-conophthorin separated upon chiral gas chromatography (conditions see Methods and Materials). Reactions of the other *Scolytus* spp. were similar. The sharp signal at 12.5 min is due to a puff of racemic (*E*)-conophthorin directly into the make-up airstream of the EAD system (not passing the GC system) to check whether the preparation is correctly functioning.

stereoisomers of chiral compounds without using synthetically obtained optically pure enantiomers (which may not always show an ee of 100%), as depicted in Figure 4.

Table 1 summarizes the current updated knowledge on the natural occurrence (production), and physiological as well as behavioral activity of conophthorin,

especially the *E* isomer. This spiroacetal appears to be widespread among several taxa of insects and plants. It may function as a male-produced repellent pheromone, a nonhost antiattractant synomone in bark beetles, and as an aggregation pheromone component in two twig beetle species (Table 1). The biological significance of the antennal reaction of the angiosperm bark beetles to (*E*)-conophthorin is largely unknown. However, in the ash bark beetle, *Leperisinus fraxini*, it acts as an intraspecifically active repellent (Kohnle et al., 1992). In most cases studied, only the naturally occurring and quantitatively dominant (5*S*,7*S*)-enantiomer was physiologically and behaviorally active, and no antagonistic or synergistic effects of the minor (5*R*,7*R*)-enantiomer were detected. The importance of the stereochemistry on the biological activity of chiral semiochemicals has been thoroughly reviewed by Mori (1998).

(*Z*)-Conophthorin also exists in nature (Table 1), but it is significantly less abundant and thermodynamically unstable. Due to lability, handling of pure enantiomers of (*Z*)-conophthorin is still impossible (W. Francke, unpublished results). Therefore, it does not seem to have any practical potential. It should be noted, however, that in many cases the naturally occurring conophthorin shows a lower *E*/*Z* ratio than a synthetic mixture prepared from the open chain ketodiol. A higher amount of the *Z*-isomer means that the original natural signal is thermodynamically unstable and may change the *E*/*Z* proportion with time and environmental conditions. Whether this phenomenon is of any biological significance, i.e., providing additional information for the receiver, e.g., about the age of the signal, awaits further investigation.

Evidence is increasing that (*E*)-conophthorin plays an important role in chemical ecology in general, and in host selection/nonhost avoidance in particular, of conifer bark beetles. It seems to be a good candidate to push conifer bark beetles away from their host trees. The latest investigations in Canada and Europe indicate that combinations of (*E*)-conophthorin with other NHVs and verbenone has shown potential for successful tree protection against mass attacks of *D. ponderosae* and *I. typographus* (Huber and Borden, 2001; Jakuš et al., 2002). Our findings on the enantiospecific antennal response to 5*S*7*S*-conophthorin by scolytid beetles, and the inactivity of its antipode, provide further support of the use of racemic (*E*)-conophthorin in future pest management programs against economically important bark beetles and other pest insects.

Acknowledgments—We thank Dr. A.-K. Borg-Karlson at Organic Chemistry, KTH, Sweden for checking purity; Guo-Fa Chen and Guang-Tian Liu for collecting *I. subelongatus* from China, and Dr. H. Jactel for sending *O. erosus* from France. Docent P. Anderson is recognized for his continued practical and theoretical support during electrophysiological work at Alnarp. Björnstorp estate generously supplied trees for use in beetle cultures. This study was supported by grants from SJFR (No. 23.0521/96; No. 24.0293/98) and an EU-INCO project (TATRY) (IC15-CT98-0151). W. F. wishes to thank the Fonds der chemischen Industrie for financial support.

MODULATION OF EXPLORATORY BEHAVIOR IN FEMALE MICE BY PROTEIN-BORNE MALE URINARY MOLECULES

CARLA MUCIGNAT-CARETTA*

Department of Human Anatomy and Physiology
University of Padova
Via Marzolo 3, 35131 Padova, Italy

(Received September 10, 2001; accepted May 13, 2002)

Abstract—Male pheromones are believed to attract females and repel male mice in open field tests but, when tested in more complex environments, they can attract male mice in usually avoided areas. Females were tested in an apparatus with one dark and one light side, in the absence or presence of male urine or the major urinary proteins (MUPs) bearing the natural ligands. Diestrous females were slower in leaving from the dark area when male urine or MUPs were present in it. Estrogen-primed females showed the opposite behavior, with an increase in the same latency. The light-avoidance behavior of prepubertal females, or females reared without males was not influenced by the presence of male chemosignals. The results show that adult female mice can react to MUP-borne volatiles as to adult male urine and use them as cues of male mice, if they were previously exposed to male cues during infancy. MUP-borne molecules are, thus, the olfactory trace of males in the environment and modulate mice exploratory behavior.

Key Words—Major urinary proteins, pheromones, urine, lipocalins, light-avoidance, mice.

INTRODUCTION

Male mice excrete several molecules in urine that are used as chemical cues to communicate their gender and social and reproductive status (Halpern, 1987). Urine is also used to mark the territory (Reynolds, 1971; Harrington, 1976). It represents a convenient aqueous medium that can be excreted in different amounts and in different situations (Hurst, 1990a,b). Male urine conveys chemical signals that act

* E-mail: carla.mucignat@unipd.it

0098-0331/02/0900-1853/0 © 2002 Plenum Publishing Corporation

on both male and female mice, by modifying their behavior and modulating their hormonal status, with a direct involvement of the neuroendocrine hypothalamus (Keverne, 1983). Tests performed in simple environments showed that adult male urine attracts adult female mice and is submitted to prolonged investigation, while urine from castrated or prepubertal males is less attractive to females (Scott and Pfaff, 1970; Jones and Nowell, 1974). Dominant male urine attracts females the most (Hurst, 1990b; Mossman and Drickamer, 1996). The smell of adult male urine is attractive only to adult female mice, in fact prepubertal females prefer adult female chemosignals. The switch of female preference for adult male odor occurs at puberty (Coppola and O'Connell, 1988; Drickamer, 1989).

Different classes of molecules serve as chemical signals. Most are volatile molecules, but they can also be peptides. Chemical cues convey complex messages, such as those concerning sex and social status, possibly by combining different components. Mouse urine is rich in major urinary proteins (MUPs), which play a role in neuroendocrine modulation (Vandenbergh et al., 1975; Mucignat-Caretta et al., 1995a; Brennan et al., 1999; Marchlewska-Koj et al., 2000). MUP bind and carry small molecules as ligands in the urine, and act as pheromone carriers and reservoirs (Bocskei et al., 1992; Cavaggioni and Mucignat-Caretta, 2000). Some of the ligands are androgen-dependent molecules that act as male cues. The synthetic analogs of 2-*sec*-butylthiazoline and 2,3-dehydro-*exo*-brevicomin, two of the MUP volatile pheromones (Bacchini et al., 1992; Robertson et al., 1993), can concurrently induce aggressive behavior in male mice (Novotny et al., 1985). Moreover, the excretion of these two MUP ligands is androgen-dependent (Schwende et al., 1986), like the production of MUP (Clissold et al., 1984).

MUP-borne molecules have been shown to induce the same behavioral responses as intact male urine. In a simple preference test, they are avoided by adult males and preferred by adult females, while prepubertal mice do not display these preferences (Mucignat-Caretta et al., 1998). MUP-borne molecules can strongly influence male behavior in the presence of a receptive female by turning male sexual activity into aggressive behaviors (Mucignat-Caretta and Caretta, 1999a). These molecules can modify the light-avoidance behavior of male mice (Mucignat-Caretta and Caretta, 1999b), act as male cues, and elicit the same responses as intact male urine. If a mouse has to explore a new environment, which contains a well-illuminated area and a dark one, it shows a consistent behavior by choosing the dark side of the cage. The latencies in moving between the two compartments have been exploited to measure emotional reactivity in mice (Louilot et al., 1989) and have been used here to understand how (and which) pheromonal stimuli can modulate the behavior of mice in a relatively nonuniform environment.

Since responses to social odors are influenced by the hormonal status of the receiver, females in the diestrous phase of the estrous cycle were tested, measuring the escape latencies from one compartment to the other, first in the control condition without chemical stimuli, and then in the presence of male urine or MUPs on either

side of the apparatus. Since adult females modified their light-avoiding behavior in the presence of adult male urine in a different way from that already described for adult males (Mucignat-Caretta and Caretta, 1999b), it was relevant to look for an effect of MUP-borne volatiles that are as active in males as male urine. We tested whether MUPs purified from adult male urine in native conformation (with the ligands bound) modified the behavior of female mice as male urine does. We also tested for a differential response in estrogen-primed receptive female mice. This is an intriguing phenomenon, since it has been reported that adult females usually are attracted by male pheromonal cues in a simple environment, irrespective of the phase of their estrous cycle (Mossman and Drickamer, 1996). We also studied prepubertal females, since the responses to chemosignals are known to vary according to the age of the receiver, the preference of females for male odors becoming patent at puberty (Drickamer, 1989, Mucignat-Caretta et al., 1998). Finally, since the neuroendocrine responsivity to male pheromones is enhanced by previous exposure to male urine during infancy (Mucignat-Caretta et al., 1995b), adult diestrous females that were reared without fathers or any adult male were tested to see if they displayed the same responses to male pheromones as adult diestrous females reared with males.

METHODS AND MATERIALS

Subjects. The experiments were carried out according to Italian law on animal experiments and handling. Swiss mice (*Mus musculus*) were maintained at $23 \pm 1^{\circ}$C, on a 12L:12D photoregime with lights on at 6:00 AM. Mice were weaned at 21 days of age and then lived in groups (maximum six animals) of the same sex and age. Adult animals were tested at around 5 months of age. The estrous phase in adult females was checked by vaginal smears. In experiment 1, eleven females in the diestrous phase were tested in the presence or absence of adult male urine in the test cage. In experiment 2, seven females in the diestrous phase were tested with or without MUPs that were presented also to mice in experiments 3–5. In experiment 3, a group of seven estrogen-primed adult females was tested. All had a vaginal smear typical of estrus, characterized by cornified cells. Estrogen priming consisted of five daily injections of 17β-estradiol in oil (1 mg/kg body weight). Estrogen-primed females were chosen instead of naturally cycling females in order to reduce the variability, because estrus lasts only a few hours, and the hormonal peaks change widely among the early and late phases of estrus. Moreover, estrogen-primed females are a model of receptive females (Clark, 1993) and have already been used to test behavioral modifications induced by urinary chemical cues (Mucignat-Caretta and Caretta, 1999a). In experiment 4, a group of eight prepubertal females, 26 days old, was tested. In experiment 5, six females were tested. They were reared without adult males and had never come into contact

with adult males or their chemosignals. They were in the diestrous phase of their estrous cycle. All females in all experiments were virgins and naive with respect to sexual behavior. They had never come into contact with adult males prior to the test, except for their fathers during the preweaning period (for females tested in experiments 1–4). Male littermates were present in all litters up to weaning. In male mice during the first 21 days of life, there is no production or excretion of MUPs or MUP-associated androgen-dependent substances, as revealed by electrophoresis (unpublished observations) and gas chromatography (Mucignat-Caretta et al., 1995a).

Behavioral Assays. The behavioral test has been described previously (Mucignat-Caretta and Caretta, 1999b) and was based on a procedure sensitive to motivational changes (Crawley and Goodwin, 1980; Louilot et al., 1989; Misslin et al., 1989). The main innovation here consists of the introduction of pheromonal stimuli in to the test cage. The test apparatus consisted of a plastic cage divided into two compartments ($21 \times 27 \times 15$ cm each) by a plastic wall with a 4×3.5-cm opening. One (white) compartment had no cover to allow illumination (2000 lux) and behavioral recordings. The other (black) side was closed. Stimuli were put in five dishes (1.5 cm diam. $\times$ 0.5 cm high), four at the corners and one at the center of each compartment. A plastic mesh cap prevented contact with the chemical stimuli.

One hour before the test, mice were allowed free exploration (9 min) of the test cage in the absence of chemical signals. The test began when the mouse was put into the dark compartment. The first measurement (dark-to-light time, DL1) was the time elapsed from this moment to the complete crossing of the door (all four paws in the light compartment). The mouse was then put briefly in its home cage, to allow cleaning of the test cage if needed, and subsequently released in the light compartment. Thereafter, the time spent in the light compartment up to the complete crossing of the door toward the dark side (light-to-dark time, LD) was measured. The mouse could then return freely to the light compartment: the time spent in the dark compartment up to the crossing of the door to the light compartment was the second dark-to-light time (DL2). The maximum time allowed for each measure was 3 min. The control test was performed without chemical stimuli in the apparatus. The other two conditions consisted of putting a fixed amount (100 μl) of adult male urine or MUP (20 mg/ml solution) in each well, either in the dark (condition: MUPs on dark) or in the light compartment (condition: MUPs on light). The cage was cleaned, and the number of urine spots, possibly related to countermarking, and fecal pellets, related to autonomic activation, was counted after DL1 was recorded at the end of each test (training period; control–no chemical stimuli; stimuli on light compartment; stimuli on dark compartment).

Statistical Analysis. The data on latencies were analyzed separately for each experiment, with a two-way ANOVA, with the factors condition (control, urine, MUPs on light, and urine or MUPs on dark) and Test (DL1, LD, DL2). Post-hoc

Newman-Keuls comparisons were conducted whenever appropriate. The order of administration of trials was counterbalanced for the mice.

Biochemical Procedures. MUPs were purified according to Mucignat-Caretta and Caretta, 1999b. Urine from a pool of 12–20 adult male mice (3–4 month old) was collected overnight and frozen. After thawing, it was used directly or to purify MUPs, and then centrifuged (10,000 g, 30 min). The supernatant was filtered onto paper, then concentrated through an ultrafiltration cell (Amicon YM10, 10,000 Da cutoff) under nitrogen pressure. The eluate was chromatographed through a G-50 (Pharmacia) molecular sieve column (1.5 cm ID, 60 cm long, 4 ml/hr flow), and samples (5 ml each), were collected. Samples containing MUPs were rechromatographed through the G-50 column. The MUP-containing fractions were pooled and reconcentrated as above. The purified stimuli were analyzed by denaturing gel electrophoresis, where a single band of apparent molecular mass around 18–19 kDa could be detected, as well as by gas chromatography, where the typical profile of MUP ligands (Mucignat-Caretta et al., 1995a; Marchlewska-Koj et al., 2000) could be observed.

RESULTS

Mean latencies +SEM for all experiments are shown in Figure 1. Table 1 reports the number of mice urinating and defecating in each period and the respective number of urine drops and fecal pellets in each of the two compartments. Since only a small number of mice showed either of these responses, the data were not further analyzed.

Experiment 1 on diestrous females tested with male urine showed that the factor Test was significant, $F_{2,20} = 44.987$, $P < 0.001$, with LD faster than both DL1 and DL2. DL2 also was different from DL1, a result best explained by the significant interaction Test × Condition, ($F_{4,40} = 6.428$, $P < 0.001$) that showed that for control and urine on light condition, DL1 and DL2 are not different, while for condition urine on dark, DL2 is significantly shorter than DL1.

The ANOVA on data from diestrous females tested with MUPs (experiment 2) revealed that the factor Test reached significance ($F_{2,12} = 21.284$, $P < 0.001$), with LD faster than DL1 and DL2. The interaction Test × Condition also was significant ($F_{4,24} = 3.089$, $P < 0.05$) as in experiment 1; for control and MUPs on light conditions, DL1 and DL2 do not differ, while for condition MUPs on dark, DL2 is shorter than DL1.

The analysis on estrogen-primed females tested with MUPs (experiment 3) showed that the factor Test was significant ($F_{2,12} = 11.008$, $P < 0.01$), with LD faster than the other two latencies. The interaction Test × Condition also was significant ($F_{4,24} = 3.108$, $P < 0.05$). The post-hoc test showed that while for the control and MUPs on light conditions the latencies in the three tests do not differ,

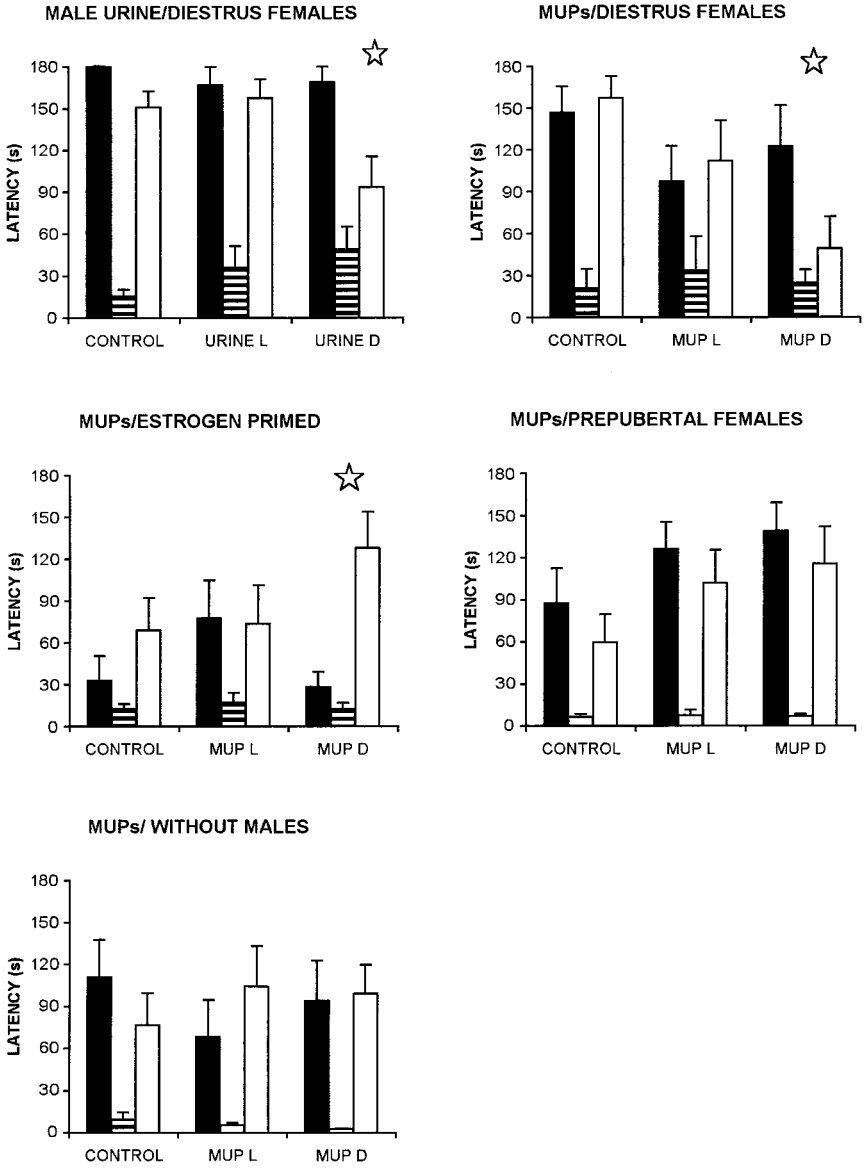

FIG. 1. The effect of male chemical cues on the light-avoidance behavior of different groups of female mice. Filled bars refer to DL1 (the first dark-to-light) latency, shaded bars to LD (light-to-dark) latency, and open bars to DL2 (the second dark-to-light) latency. Means + SEM are shown. The following conditions were tested: control: no chemical stimuli in the environment; urine (or MUP) L: stimuli on the light compartment; urine (or MUP) D: stimuli on the dark compartment. $^{*}P < 0.05$, DL2 different from DL1.

Control	0	0	2	5D
MUP L	0	0	0	0
MUP D	0	0	3	5D

[a] At the end of each test (indicated in the first column) the following data were obtained: the total number of mice that urinated, the number of urine drops counted in each compartment; the number of mice that defecated and the number of fecal pellets in each compartment (D: dark; L: light). In the first column, the following conditions are indicated: training period, control (no chemical stimuli), chemical stimuli (male urine or MUP) on light compartment, stimuli on dark compartment.

for the condition MUPs on dark, DL2 is longer than DL1 and LD. The absolute values of the latencies for the control condition in estrogen-primed females are smaller than in all other groups of mice that have been tested. This can be related to an increased reactivity already described as a consequence of estrogen priming (Rodier, 1971).

The ANOVA on prepubertal females (experiment 4) showed only a significant effect on Test ($F_{2,14} = 28.3750$, $P < 0.001$) with LD shorter than the other latencies (DL1 and DL2). On the other hand, the ANOVA on females reared without adult males (experiment 5) showed that the only significant factor was Test ($F_{2,10} = 14.049$, $P < 0.002$) with LD shorter than DL1 and DL2.

DISCUSSION

Stimuli acting through the olfactory systems modify a variety of physiological and behavioral responses ranging from puberty onset and blocking pregnancy (Keverne, 1983; Tirindelli et al., 1998), to aggressive behavior and urine marking (Maruniak et al., 1986). The present data address the question of the impact of specific fractions of male urine on exploratory behavior in female mice of different ages and hormonal status. The dark–light emergence test is based on the conflict between the need to avoid brightly illuminated areas and the tendency to explore new environments. This conflict results in mice spending more time in the dark chamber (Crawley and Goodwin, 1980; Misslin et al., 1989). The present findings confirm that light avoidance behavior is present in all groups of mice that have been tested and provide some information on how female mice cope with relevant stimuli coming from different sensory modalities. All groups of mice in the control condition display a preference for the dark compartment over the illuminated one; they go faster from the light compartment to the dark one (LD) than the reverse, as expected. When present, an effect is apparent on DL2 latency, when the mouse has to freely return to the light compartment, after having experienced both the dark and the light side. The effect of chemosignals only on DL2 measurements was also apparent in males (Mucignat-Caretta and Caretta, 1999b). This is possibly related to the fact that the mouse has already experienced both sides of the cage, and, thus, can choose its preferred side.

Adult diestrous females in the control condition show a clear preference for the dark compartment, as demonstrated by longer latencies to escape from the dark compartment (DL1 and DL2) compared to the latency to enter in the dark compartment (LD). As expected, no difference can be discerned between the first and the second latency to escape from the dark side (DL1 and DL2). When adult male urine or MUPs are present in the dark compartment, a significant reduction in DL2 time is observed. This behavior suggests that the chemical cues borne by MUPs are a sufficient stimulus for the mouse to behave as in the presence of male urine, and hence to escape from the usually preferred dark side.

Stud males present the opposite tendency: they enter the light side faster when MUPs or male urine are present in it (Mucignat-Caretta and Caretta, 1999b). It is reasonable to speculate that nonreceptive females prefer to avoid an environment in which the presence of males is evident, while male mice tend to explore it, possibly in relation to a countermarking behavior (Hurst, 1990a). On the other hand, receptive females in the same condition (MUPs on dark) show a significant increase of DL2. This result can be described as the preference of estrous females for MUPs-associated chemical cues that attract them. In contrast, despite having already experienced male cues from their fathers, prepubertal females seem not to be influenced in any way by male cues and display light-avoidance behavior irrespective of male cues. These results confirm that the responsivity to male urinary

chemosignals develops at puberty. The data from females reared in the absence of adult males indicates that, as for other pheromonal effects (Mucignat-Caretta et al, 1995b), the behavioral responsivity to male chemosignals is modulated by the experience of stimuli during the early phases of development.

Autonomic activation within each group, measured as the number of mice that defecated, did not seem to vary in the different conditions. Moreover, urination acts were not frequent; only estrogen-primed females urinated more when chemical stimuli were present in the apparatus, and this result, if confirmed by further studies, would support a role for these stimuli as meaningful indicators of sexual identity.

Overall, the results of the present experiments indicate that MUP-borne molecules elicit different responses in groups of females of different age and hormone status. It can be concluded that MUP-borne molecules act as male cues since they are avoided by diestrous females as much as male urine and are attractive to estrous females. This effect of male cues is evident after puberty, as shown in experiment 4, and is influenced by the previous experience of the females (experiment 5).

The present data help to clarify the mechanism of coding the sexual identity of the emitter: in this respect, the volatile molecules bound by MUPs are sufficient to act as male chemosignals, so they are the minimal information that signals the presence of a male mouse. Consistent with this hypothesis, is the combination of environmental conditions and chemical signals that elicits differential responses in the different groups of mice. This behavior can be more differentiated compared to that seen in less complex tests. For example, there is no difference in the behavior observed in estrous and nonestrous females towards urinary stimuli presented in a uniform environment (Mossman and Drickamer, 1996). The present experiments discriminate more subtle differences in behavior: nonestrous females avoiding male cues and receptive females preferring them. This is not surprising, since gonadal steroid hormones modulate the activity in different areas of the brain, including those involved in chemical perception and sexual behavior. Some of the sexually dimorphic nuclei in the brain pertain to the main or the accessory olfactory pathways, like the nuclei of the medial amygdala and medial preoptic hypothalamus (Brennan and Keverne, 1997); they express gonadal steroid receptors, and their activity is modulated by circulating steroid hormones. During the estrous phase both the expression of the neuropeptide cholecystokinin and the electrical activity in these nuclei (Simerly, 1990; Li et al., 1992) are characterized by maximal sensitivity to pheromonal stimuli.

In conclusion, the present data show that urinary chemical cues, and in particular MUPs bearing ligands, modify the light-avoidance behavior of female mice, depending on the age and endocrine status of the receiver. The system composed of MUPs and ligands is, thus, perceived as a complex signal that mediates different pheromonal effects, both endocrine (Mucignat-Caretta et al., 1995) and behavioral.

(Received February 19, 2002; accepted May 21, 2002)

Abstract—GC-MS analysis of the anal sac secretion from the hooded skunk, *Mephitis macroura*, showed the following seven major components comprised 99% of the volatiles in this secretion: (*E*)-2-butene-1-thiol, 3-methyl-1-butanethiol, *S*-(*E*)-2-butenyl thioacetate, *S*-3-methylbutenyl thioacetate, 2-phenylethanethiol, 2-methylquinoline, and 2-quinolinemethanethiol. Minor volatile components identified in this secretion are phenylmethanethiol, *S*-phenylmethyl thioacetate, *S*-2-phenylethyl thioacetate, bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, bis(3-methylbutyl) disulfide, and *S*-2-quinolinemethyl thioacetate. This secretion is similar to that of the striped skunk, *Mephitis mephitis*, differing only in that it contains four compounds not reported from the striped skunk: phenylmethanethiol, *S*-phenylmethyl thioacetate, 2-phenylethanethiol, and *S*-2-phenylethyl thioacetate.

Key Words—Mephitidae, *Mephitis macroura*, hooded skunk, anal sac secretion, (*E*)-2-butene-1-thiol, 3-methyl-1-butanethiol, *S*-(*E*)-2-butenyl thioacetate, *S*-3-methylbutenyl thioacetate, 2-phenylethanethiol, 2-methylquinoline, 2-quin-olinemethanethiol.

INTRODUCTION

The defensive secretions sprayed from the anal sac of skunks are well known for their malodorous nature. The striped skunk has been the subject of many chemical investigations (Swarts, 1862; Löw, 1879; Aldrich, 1896; Aldrich and Jones, 1897; Stevens, 1945; Andersen and Bernstein, 1975; Andersen et al., 1982; Wood, 1990). The volatile components in the spray of two other North American skunks, the spotted skunk (Wood et al., 1991) and the hog-nosed skunk (Wood et al., 1993) have also been identified. In the present study, we report the volatile components of the anal sac from the hooded skunk, *Mephitis macroura*.

METHODS AND MATERIALS

The defensive secretion from a single male hooded skunk from Hidalgo County, New Mexico, USA, was examined. A sample of the secretion was obtained from each anal sac of the anaesthetized animal by inserting a needle into the sac and withdrawing the contents. The secretion was placed in a screw-cap vial, and shipped at ambient temperature to Arcata, California, USA. Within 3 days of collection, a 20-mg portion of this secretion from each gland was placed in 1.5 ml of dichloromethane and analyzed by gas chromatography–mass spectrometry (GC-MS).

The GC-MS analyses were performed on the dichloromethane extracts in a splitless mode (0.5 min), using a Hewlett-Packard GCD Plus fitted with a 30-m $\times$ 0.25-mm cross-linked phenyl methyl silicone capillary column (HP-5MS). The gas chromatograph was programmed so the oven temperature was kept at 40°C for 4 min, then increased to a final temperature of 325°C at a rate of 30°C/min and kept at this temperature for 2 min. Mass spectral fragments below $m/z = 39$ were not recorded. The relative amount of each component was determined as the percent of the total ion current (TIC).

Identification of the components was done by comparison of mass spectra and gas chromatographic retention times to reference compounds. (*E*)-2-Butene-1-thiol, *S*-(*E*)-2-butenyl thioacetate, *S*-3-methylbutenyl thioacetate, 2-quinolinemethanethiol, and *S*-2-quinolinemethyl thioacetate were obtained from striped skunk secretion (Andersen and Bernstein, 1975; Wood, 1990). 3-Methyl-1-butanethiol, 2-phenylmethanethiol, and 2-methylquinoline were purchased from Aldrich Chemical Co. 2-Phenylethanethiol was prepared by the method of Urquhart et al. (1955) from (2-bromoethyl)benzene. *S*-phenylmethyl thioacetate and *S*-2-phenylethyl thioacetate by reacting phenylmethanthiol or 2-phenylethanethiol with acetyl chloride. The mass spectrum of *S*-phenylmethyl thioacetate is (EI-MS): $m/z = 166$ (M^+, 19), 124(9), 123(26), 122(20), 121(5), 92 (8), 91(100), 89(5), 77(9), 64(17), 63(7), 51(9), 50(4), 45(20), and 43(72), and that of *S*-2-phenylethyl thioacetate is (EI-MS): $m/z = 180$ (M^+, 3), 135(3), 105(12), 104(100), 103(3), 92 (5), 91(32),

79(3), 78(5), 77(9), 65(9), 63(3), 51(6), 43(44), and 39(4). Bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, and bis(3-methylbutyl) disulfide were prepared by treatment of the defensive secretion with iodine as described by Wood (1990). Mass spectra have previously been reported for (*E*)-2-butene-1-thiol, 3-methyl-1-butanethiol, *S*-(*E*)-2-butenyl thioacetate, *S*-3-methylbutenyl thioacetate, 2-methylquinoline, 2-quinolinemethanethiol, bis[(*E*)-2-butenyl] disulfide, (*E*)-2-butenyl 3-methylbutyl disulfide, and bis(3-methylbutyl) disulfide by Wood (1990); for 2-phenylethanethiol by Wood et al. (1991); and for phenylmethanethiol in the NIST 1998 computerized mass spectral library.

RESULTS AND DISCUSSION

The GC-MS analyses on two samples of hooded skunk anal sac secretion are reported in Table 1. The variation in composition between the two anal sacs was small and disappeared on rounding to two figures. The analyses showed seven major components at a concentration greater than 1% to make up 99% of the volatiles (Figure 1). These compounds and their retention times (R_t), are (*E*)-2-butene-1-thiol (**1**, $R_t = 3.06$ min), 3-methyl-1-butanethiol (**2**, $R_t = 4.19$ min),

TABLE 1. COMPOSITION OF MAJOR VOLATILE COMPONENTS OF ANAL SAC SECRETION FROM FOUR SPECIES OF NORTH AMERICAN SKUNKS[a]

Compound	Amount (%)			
	Hooded skunk[b]	Striped skunk[c]	Spotted skunk	Hog-nosed skunk
(*E*)-2-Butene-1-thiol	32	38–40	30–36	71
3-Methyl-1-butanethiol	39	18–26	48–66	
S-(*E*)-2-Butenyl thioacetate	16	12–18		17
S-3-Methylbutanyl thioacetate	7	2–3		
Phenylmethanethiol	0.3		0.2–0.8	1
2-Phenylethanethiol	1.4		2–5	
2-Methylquinoline	2.3	4–11	0.3–0.9	2
Bis[(*E*)-2-butenyl] disulfide	trace		trace	3
S-Phenylmethyl thioacetate	trace			
(*E*)-2-Butenyl 3-methylbutyl disulfide	0.5	0.2–1.6	0.2–0.6	
Bis(3-methylbutyl) disulfide	trace		0.1–0.2	
S-2-Phenylethyl thioacetate	0.2			
2-Quinolinemethanethiol	1.3	4–12	0.2–0.3	0.5
S-2-Quinolinemethyl thioacetate	trace	1–4		

[a] In order of increasing retention times. Data from Wood (1990) and Wood et al. (1991, 1993).
[b] Variation of composition for the two anal sacs was small and disappeared on rounding to two figures.
[c] Compounds less than 1% were not identified in this study.

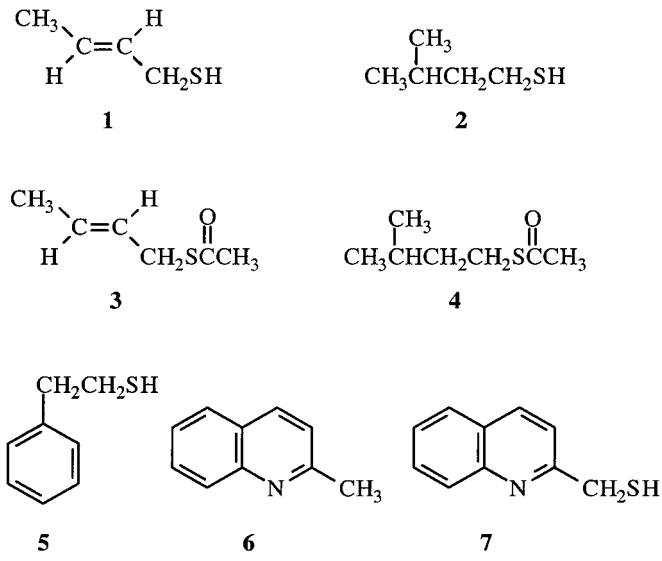

FIG. 1. Major components form *Mephitis macroura* defensive secretion: (*E*)-2-butene-1-thiol (**1**), 3-methyl-1-butanethiol (**2**), *S*-(*E*)-2-butenyl thioacetate (**3**), *S*-3-methylbutenyl thioacetate (**4**), 2-phenylethanethiol (**5**), 2-methylquinoline (**6**), and 2-quinolinemethanethiol (**7**).

S-(*E*)-2-butenyl thioacetate (**3**, $R_t = 6.77$ min), *S*-3-methylbutenyl thioacetate (**4**, $R_t = 7.12$ min), 2-phenylethanethiol (**5**, $R_t = 8.08$ min), 2-methylquinoline (**6**, $R_t = 8.77$ min), and 2-quinolinemethanethiol (**7**, $R_t = 10.24$ min).

Seven minor components were identified from this secretion (Figure 2). These compounds and their retention times (R_t) are phenylmethanethiol (**8**, $R_t =$ 7.49 min), bis[(*E*)-2-butenyl] disulfide (**11**, $R_t = 8.81$ min), *S*-phenylmethyl thioacetate (**9**, $R_t = 8.94$ min), (*E*)-2-butenyl 3-methylbutyl disulfide (**12**, $R_t =$ 9.00 min), bis(3-methylbutyl) disulfide (**13**, $R_t = 9.23$ min), *S*-2-phenylethyl thioacetate (**10**, $R_t = 9.33$ min), and *S*-2-quinolinemethyl thioacetate (**14**, $R_t =$ 11.23 min). This is the first report of *S*-phenylmethyl thioacetate and *S*-2-phenylethyl thioacetate as natural products. All other compounds have previously been identified in skunk spray (Andersen and Bernstein, 1975; Wood, 1990; Wood et al., 1991, 1993).

Table 1 compares the defensive secretion of four skunk species. The defensive spray of the hooded skunk is similar to that of the striped skunk, as reported by Wood (1990). If differs by having four additional compounds that were not reported from the striped skunk. These are phenylmethanethiol, 2-phenylethanethiol, *S*-phenylmethyl thioacetate, and *S*-2-phenylethyl thioacetate. 2-Phenylethanethiol has been reported from spotted skunk defensive secretion (Wood et al., 1991) but

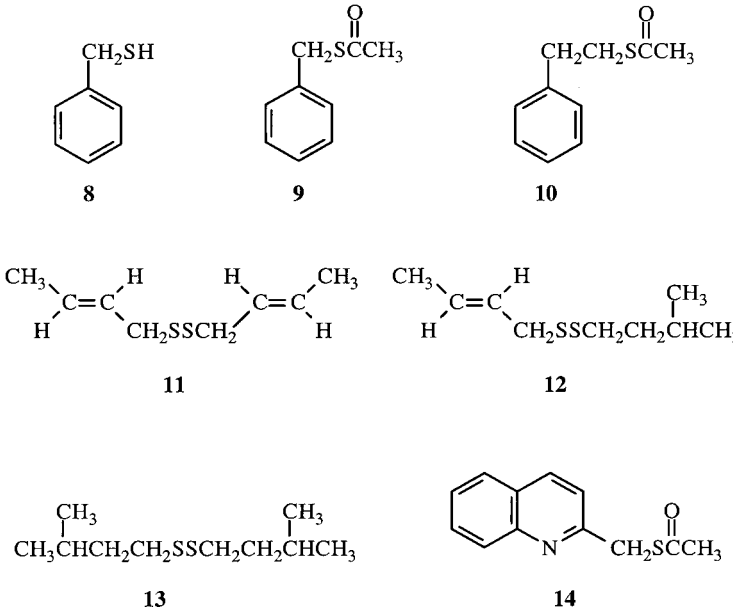

FIG. 2. Minor components identified in *Mephitis macroura* defensive secretion: phenylmethanethiol (**8**), *S*-phenylmethyl thioacetate (**9**), *S*-2-phenylethyl thioacetate (**10**), bis[(*E*)-2-butenyl] disulfide (**11**), (*E*)-2-butenyl 3-methylbutyl disulfide (**12**), bis(3-methylbutyl) disulfide (**13**), and *S*-2-quinolinemethyl thioacetate (**14**).

not from the hog-nosed skunk (Wood et al., 1993). The relative amounts of the two most abundant compounds are also different. In the hooded skunk, 3-methyl-1-butanethiol is the major compound, while (*E*)-2-butene-1-thiol is more abundant in the striped skunk.

The hooded skunk, striped skunk, and the hog-nosed skunk have a thioacetate derivative for each of the free thiols in their secretion. Perhaps the components in these skunks' defensive spray are biosynthesized as the thioacetates and then hydrolyzed to the thiol, as thioacetates are used in many biosynthetic pathways. These thioacetates may make the effects of this secretion longer lasting. The thioacetate derivatives can hydrolyze slowly and continue to release the offensive-smelling thiols over a period of time. Anecdotal reports about pets sprayed by striped skunks, indicate that skunk odor later returns to sprayed animals when their hair is wet.

Several DNA studies have been done on the relatedness of the three skunk genera: striped and hooded skunks (*Mephitis*), spotted skunks (*Spilogale*), and hog-nosed skunks (*Conepatus*). These studies indicate that skunks of the genus *Mephitis* and *Spilogale* may be more closely related to each other than either is to the genus *Conepatus* (Dragoo et al., 1993; Dragoo and Honeycutt, 1997). Variations

in the defensive spray of these three genera were examined to see if they support this relationship (Table 1). Of the major free thiols, *Mephitis* secretion has (*E*)-2-butenethiol, methylbutanethiol, and phenylethanethiol as does *Spilogale*, while *Conepatus* has only (*E*)-2-butenethiol. On this basis, *Mephitis* and *Spilogale* may seem more closely related. However, *Mephitis* and *Conepatus* have thioacetate derivatives of all of the free thiols, types of compounds that are missing from *Spilogale*. On this basis, *Mephitis* and *Conepatus* seem to be more closely related. Thus, examination of presently known secretion components can neither confirm nor refute genetic studies, but if the secretions from other *Conepatus* spp. are different, they could support these studies.

Acknowledgments—We thank Gábor Rácz for bringing the injured skunk to our attention for care. Additionally, we thank Michael J. Richard, DVM, with the Albuquerque Biological Park for his assistance with the anesthesia protocol.

Abstract—During investigations into the control of insect damage to maize crops in subsistence farming in Kenya, which involved intercropping with repellent plants, the fodder legumes silverleaf (*Desmodium uncinatum*) and greenleaf (*D. intortum*) were also found to reduce dramatically the infestation of maize by parasitic witchweeds such as *Striga hermonthica*. This effect was confirmed by further field testing and shown to be significantly greater than that observed with other legumes, e.g., cowpea, as were the concomitant yield increases. The mechanism was investigated, and although soil shading and addition of nitrogen fertilizer showed some benefits against *S. hermonthica* infestation, a putative allelopathic mechanism for *D. uncinatum* was observed. In screenhouse studies, a highly significant reduction in *S. hermonthica* infestation was obtained when an aqueous solution, eluting from pots in which *D. uncinatum* plants were growing, was used to irrigate pots of maize planted in soil seeded with high levels of *S. hermonthica*. Growth of the parasitic weed was almost completely suppressed, whereas extensive infestation occurred with the control eluate. Laboratory investigations into the allelopathic effect of *D. uncinatum*, using samples of water-soluble chemical components exuded from cleaned roots, demonstrated that this

involved a germination stimulant for *S. hermonthica* and also an inhibitor for haustorial development.

Key Words—Allelopathy, maize, *Striga*, *Desmodium*, nitrogen, shading, silverleaf, germination stimulant, suicidal germination.

INTRODUCTION

The witchweeds are parasitic plants that, after germination, attach to the roots and cause considerable interference with normal development of their host plants (Parker and Riches, 1993). Witchweeds threaten the staple food of over 100 million people in Africa (M'boob, 1989; Musselman et al., 1991; Lagoke et al., 1991). Of the 23 species prevalent in Africa, *Striga hermonthica* (Scrophulariaceae) is the most significant, parasitizing a wide range of crops including maize, sorghum, millet, fonio, rice, and sugar cane (Musselman, 1994; Berner et al., 1996). Other witchweed species of importance in Africa are *S. aspera*, *S. asiatica*, and *S. passargei* on cereals, *S. gesnerioides* on cowpea, and *Alectra vogelli* (Scrophulariaceae) on cowpea, groundnut, and soybean. Although *S. aspera* originally parasitised wild grasses, it now has an extended host range that includes maize (Carson, 1989). Seeds can remain viable in the soil for up to 20 years and can be spread by both mechanical and cultural processes. This study focuses on *S. hermonthica*, for which there are currently no viable control methods suitable for the socioeconomic conditions of the most afflicted regions in Africa (Lagoke et al., 1991; Berner et al., 1995).

Control of *S. hermonthica* was observed during the development of a control strategy against stem borers in maize in eastern Africa. The strategy involved creating a push–pull effect using highly attractive trap crops to aggregate oviposition of adult stem borers, for example, *Busseola fusca* (Noctuidae) and *Chilo partellus* (Pyralidae), away from the central maize stand, and intercropping between the maize rows with repellent plants (Khan et al., 2000). The most effective of the repellent intercrops was molasses grass, *Melinis minutiflora*, and this plant additionally caused an increase in parasitization of those stem borers that were not aggregated away from, or directly repelled from, the maize (Khan et al., 1997). However, the legumes silverleaf, *Desmodium uncinatum*, and greenleaf, *D. intortum*, were also investigated as intercrops because of their high value as cattle forage and for their role in fixing atmospheric nitrogen. In trials in the Suba district of Kenya, where *S. hermonthica* is highly prevalent, these legumes were found to give an unexpected and dramatic reduction in infestation by this witchweed.

The objective of the current study was to compare directly the effect of *Desmodium* species with that of other plants reported to reduce colonization by witchweeds (Carson, 1986) and to investigate the mechanism by which control of the parasitic plant is effected. This could be by increasing available nitrogen, by

offering shade, or by an allelopathic effect involving chemicals associated with the roots, all of which are mechanisms known to give some control of these parasitic weeds (Press and Gurney, 2000).

METHODS AND MATERIALS

Seeds. Seeds of the following plants were employed in these studies: silverleaf, *Desmodium uncinatum* (Jacq.) DC. (Fabaceae), greenleaf, *Desmodium intortum* (Mill.) Urb. (Fabaceae), maize, *Zea mays* L. (Poaceae) (var. Hybrid 513), African witchweed, *Striga hermonthica* (Del.) Benth. (Scrophulariaceae), soybean, *Glycine max* (L.) (Fabaceae) (var. EAI 3600), sun hemp, *Crotolaria juncea* L. (Fabaceae), and cowpea, *Vigna unguiculata* (L.) (Fabaceae) (var. ICV 2).

Field Trials. Field trials were conducted at ICIPE's Mbita Point Field Station in the Suba District of Kenya, on the shores of Lake Victoria, where *S. hermonthica* poses a serious constraint to the cultivation of cereals. Field plots with at least 100 *S. hermonthica* seeds/250 g soil were used for all experimental trials.

To evaluate the effects of different legumes on the reduction of witchweed infestation, maize was intercropped in alternate rows with one of five species of legumes: cowpea, soybean, sun hemp, greenleaf, or silverleaf. Maize was planted with a row-to-row distance of 75 cm and a plant-to-plant distance of 25 cm within a row. A control plot of a maize monocrop was also included. The six treatments were randomized and planted in six replications in a 6×6 quasicomplete Latin square design (Baily, 1984; Smart et al., 1994). Each treatment plot was 6 m $\times$ 6 m. The maize used was a witchweed-susceptible, medium maturity commercial variety, Hybrid 513, recommended for mid-altitude regions with moderate rainfall. The trials were planted during the 1998 long rainy season (March to July). Infestation levels were assessed nondestructively by selecting, at random, 63 maize plants in each treatment plot and counting the number of emerged *S. hermonthica* plants present. Crop yields were evaluated by harvesting a 5-m $\times$ 5-m block in the center of each plot, leaving a 1-m unharvested border to avoid edge effects.

To investigate the role of shading, nitrogen, and allelopathy in witchweed suppression by *D. uncinatum*, field trials were established during the long rainy season of 1999 and the short rainy season of 1999–2000. Field plots, 6 m $\times$ 6 m, were arranged in a six-block quasicomplete design (Baily, 1984; Smart et al., 1994). Each treatment appeared next to every other treatment twice in both rows and columns, thus balancing out treatment interactions. The treatments were: (1) maize intercropped with *D. uncinatum* with or without 120 kg nitrogen/ha, (2) a maize monocrop with or without 120 kg nitrogen/ha, and (3) a maize monocrop with artificial ground shading made of maize straw (Hybrid 513) with or without 120 kg nitrogen/ha. The *S. hermonthica* seed level in each plot, before and after each cropping season, was measured at the National Sugar Research Centre, Kenya

Agricultural Research Institute, Kibos, Kenya, using the method described by Eplee and Norris (1990). Nitrogen content in each plot, before and after each cropping season, was measured at the National Agricultural Research Laboratory, Kenya Agricultural Research Institute, Nairobi, Kenya, using the Kjeldahl method (Shugar et al., 1981). During the experiment, light intensity, soil temperature, and humidity were monitored four times in all treatments, when the maize was 30, 60, 90, and 120 days old, and the results were averaged. Emergence and attachment of *S. hermonthica* to maize were measured, and maize plant height and cob yield were recorded.

Pot Culture Experiments. An experiment to investigate the effect of nitrogen availability in soil on witchweed infestation was conducted in a screenhouse by planting maize (Hybrid 513) and *D. uncinatum* together in pots (20 cm diam.) with autoclaved soil to which nitrogen (at the rate of 0, 30, 60, and 120 kg/ha) had been added. The tests were conducted with or without the presence of a nitrogen-fixing bacterium, *Rhizobium* sp., inoculum CB 627 (the taxonomy of this group is ambiguous and has not yet been assigned a species by molecular sequencing). The soil in each pot was infested with approximately 3000 *S. hermonthica* seeds, and emergence of witchweed in each pot and height of maize plants were measured at intervals.

To investigate the possibility of an allelochemical mechanism for *S. hermonthica* suppression, an aqueous solution of chemical components, eluting from 20 cm pots in which *D. uncinatum* plants were growing, was used to irrigate maize planted in soil infested with approximately 3000 *S. hermonthica* seeds/pot. To compare the effect of fixed nitrogen with that of the allelochemicals alone, *D. uncinatum* was planted with or without the nitrogen-fixing bacterium, *Rhizobium* sp. (CB 627). Autoclaved soil was used in all experiments, and no additional nitrogen was applied. The pots containing *D. uncinatum*, which received distilled water at a rate of 1.25 ml/min, were placed on shelves, thus allowing the flow of water by gravity through the pots into the maize pots situated below (Figure 1). Comparisons were made between maize plants irrigated by root eluates from *D. uncinatum* (with or without *Rhizobium* sp.) and those irrigated by water passing through pots containing only autoclaved soil (with or without *Rhizobium* sp.). Emergence and attachment of *S. hermonthica* to maize, and maize plant heights, were monitored in all treatments.

Laboratory Experiments. For surface sterilization and preconditioning of *S. hermonthica*, seeds were soaked in a 1% NaOCl solution (commercial bleach diluted fivefold) for 6–8 min with continuous shaking, rinsed with distilled water five times, and 30–40 seeds transferred to glass fiber disks (1.1 cm diam., GF/A). Each disk was wetted with distilled water (50 μl), and 10 such discs were placed in a plastic Petri dish (9 cm diam.), wrapped with Parafilm to prevent the disks from drying, placed in a polythene bag, and incubated at 25°C for 14 days.

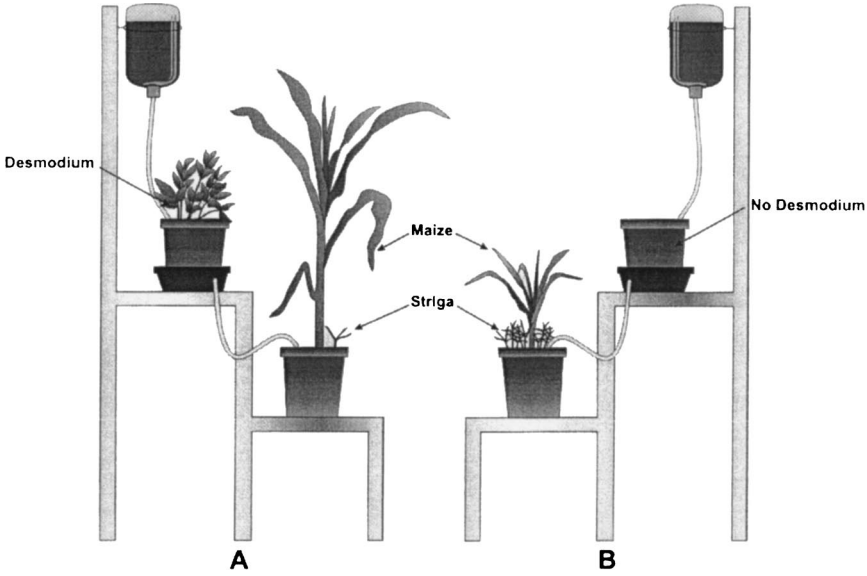

FIG. 1. Diagram of experiment to investigate the allelochemical mechanism of *Desmodium uncinatum* in suppressing *Striga hermonthica* infestation of maize. Comparison was made between maize plants irrigated by root eluates of *D. uncinatum* (A) with those irrigated by water passing through pots containing only autoclaved soil (B).

For the germination assay, glass fiber disks containing preconditioned *S. hermonthica* seeds (30–40/disk) were placed on filter paper (Whatman No. 1) to remove most of the moisture. The disks were returned to the Petri dish, and the test solution (50 μl) was applied to each disk. The Petri dish was wrapped with Parafilm and placed in an incubator at 35°C. Germinated seeds were counted under a dissecting microscope after 24–48 hr.

For the haustorium growth assay, haustorium lengths from the germinated *S. hermonthica* seeds were measured with an ocular meter (calibrated at $\times$20 magnification) mounted on a dissecting microscope 24 hr after the germination assay. The Petri dish containing germinated seeds was then placed in an incubator at 25°C and the haustorium length measured again after a further 24 hr.

For the collection of chemicals exuded from roots, *D. uncinatum* plants were grown in autoclaved soil (3 kg) containing different numbers of *S. hermonthica* seeds (0, 350, 700, and 1400/kg soil) in plastic pots (20 cm diam.) for varying periods (10, 15, 19, 20, 35, 45, 55, 69 days). At the end of each period, the soil was carefully washed off and the *D. uncinatum* plants (eight per treatment) transferred to glass columns (3.5 cm diam.) containing distilled water (20 ml) to collect the chemicals exuded by the cleaned roots. The aqueous exudate was assayed after

24 hr. Maize plants (four per treatment) were similarly grown in soil (3 kg) for two weeks, washed, and transferred to glass columns (3.5 cm diam.). These samples were used as the control.

For both field and pot experiments, differences in means were analyzed using one-way analysis of variance (ANOVA), and means were compared using Tukey's studentized range test (SAS Institute, 1996). Data in Table 3 (below) were analyzed using Student's *t*-test. In all studies, a $P \leq 0.05$ indicated significance.

RESULTS

In the field, intercropping of maize with the fodder legumes *D. uncinatum* and *D. intortum* significantly reduced *S. hermonthica* infestation, when compared to the maize monocrop, and significantly increased maize yields (Table 1). Of the other legumes tested, only cowpea gave a significant reduction in *S. hermonthica* infestation, but significantly less than the *Desmodium* spp. and with no increase in the maize yield.

The nitrogen and shading treatments, and the combined nitrogen and shading treatment, gave some suppression of *S. hermonthica* as compared to the maize monocrop plots (Table 2). However, a significantly greater reduction in *S. hermonthica* infestation was achieved by the *D. uncinatum* intercrop and the combined *D. uncinatum* and nitrogen treatments. As expected, there was a strong correlation between the numbers of witchweed plants per maize plant and the maize plant height and crop yields, and for both seasons, *D. uncinatum* had a greater effect on these than all the other treatments. Although shading had a significant effect on the *S. hermonthica* infestation, particularly in the 1999–2000 short rains, there was no commensurate increase in maize yield. A significant reduction in the numbers of *S. hermonthica* seeds in the soil was recorded in plots where *D. uncinatum* had been intercropped with maize (Table 3), with other treatments showing no change or a significant increase in the seed count. The only treatment showing a consistent

[a]Numbers in a column followed by a different letter are significantly different ($P < 0.5$) by Tukey's studentized range test. Data are means of six replications; each replication is a mean of four observations at different growth stages of maize.

The pot experiment to investigate the effects of nitrogen and *D. uncinatum* on suppression of *S. hermonthica* infestation in maize demonstrated that, in control pots, high levels of nitrogen application reduced and delayed emergence (Table 5). However, the effect of *D. uncinatum*, with or without nitrogen-fixing bacteria, was significantly greater in this regard compared to the nitrogen application alone. At all stages of maize development, the height of maize plants intercropped with *D. uncinatum* was greater than that of control plants with or without nitrogen (Table 6).

The dramatic effect of the aqueous solution of chemicals eluting from pots in which *D. uncinatum* plants were growing (Figure 1) on suppression of *S. hermonthica* infestation, and the concomitant increase in maize plant height, are shown in Figures 2 and 3. The aqueous samples of chemicals exuded by cleaned *D. uncinatum* roots were tested in laboratory experiments to investigate the mode of

action. There was no evidence for the production of a germination inhibitor by *D. uncinatum*, since the root exudate induced germination of *S. hermonthica* as effectively as the maize root exudate (Table 7). Indeed, it would appear that, in the initial stages (days 15–19), the *D. uncinatum* root exudates were more effective in this aspect than the maize root exudate. Furthermore, exudates from roots of *D. uncinatum* grown in soil at increasing densities of *S. hermonthica* infestation did not subsequently inhibit germination of *S. hermonthica* seeds (Table 8). However, when the seeds were exposed to root exudates from *D. uncinatum* and examined

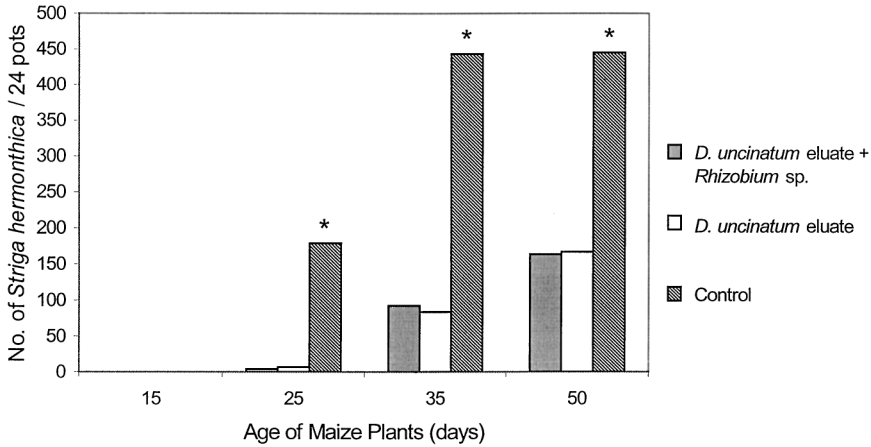

FIG. 2. Effect of *Desmodium uncinatum* root eluate (with and without nitrogen-fixing *Rhizobium* sp. bacteria) on numbers of *Striga hermonthica* parasitizing maize. Within each age group of maize, the treatment marked with an asterisk is significantly different ($P < 0.05$) by Tukey's studentized range test.

TABLE 7. GERMINATION OF *Striga hermonthica* SEEDS TREATED WITH AQUEOUS ROOT EXUDATES FROM *Desmodium uncinatum* OF DIFFERENT AGES

Treatment	Germination (%)				
Age of *D. uncinatum* (days)	15	19	35	55	69
Maize exudate + water (1:1)	21.7 ± 2.7 a	21.7 ± 2.7 a	47.9 ± 2.7 a	44.1 ± 2.6 a	44.1 ± 2.6 a
D. uncinatum exudate	50.5 ± 2.8 b	35.7 ± 3.4 b	50.8 ± 3.2 a	42.8 ± 3.6 a	54.7 ± 2.6 a
Maize exudate + *D. uncinatum* exudate (1:1)	51.7 ± 2.7 b	44.3 ± 3.9 b	50.3 ± 2.6 a	43.6 ± 3.0 a	44.4 ± 4.0 a
Distilled water	0.0 ± 0.0 c	0.0 ± 0.0 c	0.9 ± 0.5 b	0.0 ± 0.0 b	0.0 ± 0.0 b

after 24 and 48 hr, the primary haustoria were significantly shorter relative to those exposed to maize exudates (Table 9). Inhibition of the primary haustoria was observed irrespective of whether the *D. uncinatum* had been grown in *S. hermonthica* infested or clean soil.

DISCUSSION

The initial field trial clearly demonstrated that intercropping with *D. uncinatum* and *D. intortum* produced significant and dramatic reductions in the infestation of maize plants by *S. hermonthica*. The overall yield increases result from a

combination of witchweed and stem borer control, the latter arising from the use of the *D. uncinatum* intercrop to repel gravid stem borers from the maize. However, these data are presented as an indication of the ability of the overall strategy to address both aspects of the maize pest complex, with subsequent studies directed solely at control of *S. hermonthica*. Many claims have been made for the value of intercropping with other plants, for example, *Celosia argentina* L. (Amaranthaceae) and *Dolichos lablab* L. (Fabaceae), in witchweed control, but the effects reported are weak (e.g., Carson, 1986). Indeed, some suggested intercrops such as sweet potato, *Ipomoea batatus* L. (Convolvulaceae) (Oswald et al., 1999), would present considerable competition to the maize itself.

The use of *Desmodium* species to control parasitic witchweeds is showing promise. This has stimulated further investigations into the mode of action, for which a number of possible mechanisms have been considered, i.e., by increasing the available nitrogen in the soil, by offering shade, or through an allelopathic effect caused by chemicals released from *Desmodium* spp. roots. Such mechanisms are known to give some control of witchweeds (Press and Gurney, 2000). In the context of allelopathy for root-derived chemicals, three possible mechanisms were investigated: (1) inhibition of *S. hermonthica* seed germination by an exudate from *D. uncinatum*; (2) production by *D. uncinatum* of a germination inhibitor following attempts by *S. hermonthica* seedlings to attach to the plant; (3) inhibition of growth of the primary and/or upper haustoria.

Although, in the field, the nitrogen and shading treatments and the combination of nitrogen and shading suppressed *S. hermonthica* emergence, maximum suppression was provided by *D. uncinatum* and the combined *D. uncinatum* and nitrogen treatment. There is documented evidence of suppression of witchweed by added nitrogen sources (Mumera and Below, 1993; Press and Gurney, 2000). *D. uncinatum* is capable of fixing 100–180 kg nitrogen/ha under Kenyan conditions, and there is evidence that some of the nitrogen is passed to the companion plant (Muyekho *et al*., unpublished report). It has also been proposed that the suppression of witchweed by a leafy intercrop may be due to shading effects (Parker and Riches, 1993; Press and Gurney, 2000). This may reduce temperature and raise humidity over the emerging witchweed plants, thus reducing transpiration and the supply of nutrition from the host plant. Although, in this study, there were benefits from nitrogen and shading on suppression of *S. hermonthica* and growth of maize in the field, the laboratory pot experiments clearly demonstrated an additional allelopathic effect associated with *D. uncinatum*. The greater effect of *D. uncinatum* compared to physical and nutritional factors indicated an additional activity strongly suggestive of allelopathy, which is also reflected in the depletion of viable *S. hermonthica* seeds in the soil after both cropping seasons.

An allelopathic mechanism was demonstrated by the pot experiments described in Figures 1–3, i.e., water-soluble chemical components associated with *D. uncinatum* roots are responsible for suppression of *S. hermonthica* infestation. The role of chemicals specifically released by cleaned *D. uncinatum* roots was further investigated, but there was no evidence of germination inhibition, which had

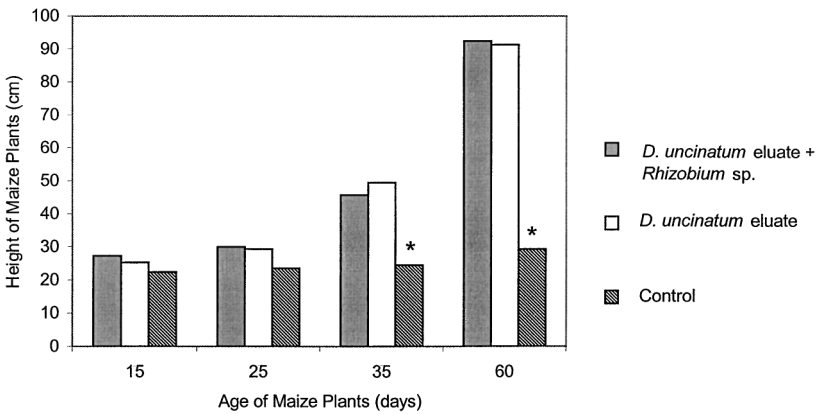

FIG. 3. Effect of *Desmodium uncinatum* root eluate (with and without nitrogen-fixing *Rhizobium* sp. bacteria) on height of maize plants growing in *Striga hermonthica* infested soil. Within each age group of maize, the treatment marked with an asterisk is significantly different ($P < 0.05$) by Tukey's studentized range test.

originally been expected. The first possible mechanism (1, above) is, thus, discounted. Indeed, there is evidence for the production of a potent germination stimulant by root exudates of *D. uncinatum*. The second possibility (2, above) is discounted because of the demonstration that root exudates from *D. uncinatum* growing in soil infested with *S. hermonthica* at increasing densities did not subsequently inhibit germination of *S. hermonthica* seeds. The fact that chemical components of *D. uncinatum* root exudates gave a significant inhibition of haustorial growth after 48 hr demonstrated a mechanism (3, above), in which haustorial development in the parasitic process is implicated.

The discovery of the potential of *Desmodium* spp. in the suppression of *S. hermonthica* infestation has opened the possibility for new practical witchweed control methods commensurate with East African subsistence farming (Khan et al., 2000). The allelopathic effect of chemicals exuded from the roots that interfere with haustorial development, combined with the potent chemical stimulants causing suicidal germination, provide not only direct witchweed control, but also a significant depletion of viable seeds in the soil. Full chemical elucidation of the allelopathic agents is ongoing, but fractionation by HPLC has already demonstrated that the germination stimulants in *D. uncinatum* root exudates can be isolated from the haustorial inhibitors. Certain novel polyphenolic compounds have been tentatively identified from active fractions and await confirmation of activity and structures in synthesis studies.

Research into the factors stimulating germination of flowering parasitic weeds has been under way for a number of years (e.g., Netzly et al., 1988), and work on eliciting suicidal germination is ongoing (e.g., Wigchert et al., 1999). In addition, a great deal is known about the chemistry involved (Sugimoto et al., 1998; Welzel et al., 1999). However, no practical exploitation in weed control has yet ensued. The sophisticated mode of action demonstrated here, comprising both germination stimulation and haustorial inhibition, when fully elucidated, may give exploitable leads that are urgently needed, not only in subsistence agriculture, but also to address future world demands in agricultural production and in developing new approaches for molecular biology in weed control (Gressel, 2000).

Acknowledgments—IACR receives grant-aided support from the Biotechnology and Biological Sciences Research Council of the United Kingdom, which is also providing additional funding under the Biological Interactions in the Root Environment (BIRE) initiative. Field studies in Africa are funded by the Gatsby Charitable Foundation and the Rockefeller Foundation. We thank Dr. G. Odhiambo of Kenya Agricultural Research Institute, Kibos, Kenya, for helping to count *S. hermonthica* seeds in soil. We also thank Mr. M. Kithakoi and Mr. D. Nyagol for technical assistance.

(Received July 29, 2002; accepted August 14, 2002)

Abstract—Hitherto, odorant-binding proteins (OBPs) have been identified from insects belonging to more highly evolved insect orders (Lepidoptera, Coleoptera, Diptera, Hymenoptera, and Hemiptera), whereas only chemosensory proteins have been identified from more primitive species, such as orthopteran and phasmid species. Here, we report for the first time the isolation and cloning of odorant-binding proteins from a primitive termite species, the dampwood termite, *Zootermopsis nevadensis nevadensis* (Isoptera: Termopsidae). A major antennae-specific protein was detected by native PAGE along with four other minor proteins, which were also absent in the extract from control tissues (hindlegs). Multiple cDNA cloning led to the full characterization of the major antennae-specific protein (ZnevOBP1) and to the identification of two other antennae-specific cDNAs, encoding putative odorant-binding proteins (ZnevOBP2 and ZnevOBP3). N-terminal amino acid sequencing of the minor antennal bands and cDNA cloning showed that olfaction in *Z. n. nevadensis* may involve multiple odorant-binding proteins. Database searches suggest that the OBPs from this primitive termite are homologues of the pheromone-binding proteins from scarab beetles and antennal-binding proteins from moths.

Key Words—Odorant-binding protein, chemosensory protein, *Zootermopsis nevadensis nevadensis*, Isoptera, Termopsidae, olfaction, dampwood termite.

INTRODUCTION

Insects perceive the world through small molecules that carry essential information about nestmates, food sources, intruders, and many other environmental cues. These hydrophobic semiochemicals are solubilized by odorant-binding proteins (OBPs) and transported through an aqueous environment (sensillar lymph) to the olfactory receptors, where the signal transduction starts (Kaissling, 2001). OBPs have been identified and/or cloned from various insect orders, such as Lepidoptera, Coleoptera, Diptera, Hymenoptera, and Hemiptera (Vogt et al., 2002). These proteins, subdivided into pheromone-binding proteins (PBPs) and general odorant-binding proteins (GOBPs), all have a hallmark of six conserved cysteine residues forming three disulfide bridges (Leal et al., 1999; Scaloni et al., 1999), which are essential for the rigidity of their three-dimensional structures (Horst et al., 2001; Sandler et al., 2000). A third class of small proteins has been identified in several sensorial organs from a number of insect orders (Lartigue et al., 2002). Although they may function as carrier proteins (Lartigue et al., 2002 and references therein), they have been separated into a group of chemosensory proteins (CSP), characterized by four cysteine residues and with low sequence similarity to OBPs. Interestingly, a thorough search for olfactory proteins in insect orders other than Lepidoptera (Marchese et al., 2000 and references therein) revealed that species from primitive insect orders, such as Orthoptera and Phasmatodea, possess CSPs, but not OBPs. This study was aimed at the identification of olfactory proteins from the primitive Dictyoptera, which includes the orders Mantodea (mantids), Blattodea (cockroaches) and Isoptera (termites). Here, we report the identification and cloning of OBP homologues in the dampwood termite, *Zootermopsis nevadensis nevadensis* HAGEN (Isoptera: Termopsidae).

METHODS AND MATERIALS

Protein Analyses. Termite colonies were collected from ponderosa pine (*Pinus ponderosa* DOUGL. EX LAWS) stumps on the Eldorado National Forest near Placerville, California. Colonies were maintained in culture in 41 plastic containers (Rubbermaid Inc., Wooster, Ohio) for 5–6 months. Workers were anesthetized on ice and their antennae and hindlegs were collected with forceps under a microscope. After homogenizing in 10 mM Tris-HCl, pH 8 with an ice-cold Dounce tissue grinder (Wheaton), homogenates were centrifuged twice at 13,500 $\times$ g for 10 min at 4°C. The supernatants were concentrated by centrifugation under vacuum, analyzed by 15% native polyacrylamide gel electrophoresis (15% PAGE); bands were visualized with Coomassie blue R-250. For N-terminal amino acid microsequencing, proteins were separated by PAGE, transferred to polyvinyl difluoride (PVDF) membranes using electroblotting, identified bands were cut out and analyzed on a Procise Protein Sequencing System (Applied Biosystems).

cDNA Cloning and RT-PCR. Total RNA was extracted by TRIzol (Invitrogen) including 200 ng of glycogen (Invitrogen) from 130 antennae of workers. First strand cDNA was synthesized by using SuperScript II (Invitrogen) as transcriptase and SMART RACE cDNA Amplification Kit (Clontech). Degenerate primer,

5′-GC(A/C/G/T)AA(A/G)GA(A/G)GT(A/C/G/T)GA(C/T)GA(A/G)AA-3′

was designed on the basis of amino acid sequence of N-terminal region (AKEVDEK) of isolated antennae-specific protein. GCGTTTTTTTTTTTTTT (GCGT15) primer was used as a reverse primer. *Taq* DNA Polymerase in Storage Buffer B (Promega) was used as *Taq* polymerase. PCR were performed as follow: 70 cycles of 94°C for 1 min, 40°C for 2 min and 72°C for 3 min. PCR product was ligated into pBluescript SK (+) (Stratagene) and sequenced at an automated DNA sequencing facility (Davis Sequencing). More than 4 independent clones were sequenced to eliminate possible PCR mutations. For 5′-RACE a gene specific primer (Z1-r),

5′-CGATGGCCCTCTTCCACGATCTCTGGCGGT-3′,

was designed, and PCR was carried out as in the instruction manual of SMART RACE cDNA Amplification Kit. For cloning two other cDNAs, we used a N-terminal degenerate primer, GCGT15 primer and 4 gene-specific primers,

5′-CTCAACATGACTGGCAGTTTCCCCGATGAG-3′ (Z2-f),

5′-CCGAACGCCTCCTTCAACTTAGCGGCGACC-3′ (Z2-r),

5′-AATGAAGTGCTCGATCACCGGGACAACAGC-3′ (Z2-r2)

and

5′-GGAAACCCTTGCAGCTTCTCCACCACTGTC-3′ (Z3-r)

and performed PCR-cloning described above. Molecular mass, isoelectric point, BLAST database search, and ClustalW alignment of amino acid sequences were performed by MacVector (Accelrys). Signal peptide was predicted by SignalP V1.1 (http://www.cbs.dtu.dk/services/SignalP/). For RT-PCR, cDNAs were synthesized from total RNA extracted from antennae and legs as described above. The following combinations of gene-specific primers were used to detect the transcript of the cloned odorant-binding proteins:

Z1-f, 5′-GTGTCATGGTCGAACTCATGGCTCTCAACG-3′

and Z1-r (for ZnevOBP1), Z2-f and Z2-r (for ZnevOBP2), and

Z3-f, 5′-ACTTCGGCAGTTTCCCGGATGAGTCCGACC-3′,

and Z3-r (for ZnevOBP3). For detection of actin transcript (control), two degenerate primers were used: Actin-1,

5′;-AA(C/T)TGGGA(C/T)GA(C/T)ATGGA(A/G)AA-3′

and Actin-2,

5′-GCCAT(C/T)TC(C/T)TG(C/T)TC(A/G)AA(A/G)TC-3′.

To amplify OBP cDNAs 25 cycles of a stepwise program (94°C for 5 sec; 55°C for 10 sec; 72°C for 3 min) were carried out. Actin cDNA was amplified by 45 cycles of a stepwise program (94°C for 1 min; 45°C for 2 min; 72°C for 3 min). PCR products were separated by 1% agarose gel.

RESULTS AND DISCUSSION

Our protein-based approach leads us to the identification of olfactory proteins by comparing the profile of proteins isolated from antennae and control tissues. A major antennae-specific protein was identified by native PAGE analyses of proteins from workers of *Z. n. nevadensis* (Fig. 1A).

The putative olfactory protein migrated faster than our reference protein, the pheromone-binding protein from *Bombyx mori*, BmPBP, and showed an N-terminal amino acid sequence (LTGRAFERAKEVDEK-RS; -indicates no signal) with 55% sequence identity (70% similarity) to the previously identified olfactory proteins (Pam6m and Pam6f) from the American cockroach, *Periplaneta americana* (Picimbon and Leal, 1999). In order to obtain further sequence information, the cDNA encoding this protein was cloned. A single-banded cDNA (550 bp) was amplified with a degenerate primer (based on the N-terminal amino acid sequence) and an GCGT15 primer. With this partial sequence available, we designed a gene specific primer, determined the 5′-region, and obtained the full length of cDNA, which encoded a protein with 151 amino acid residues (Fig. 1B). The predicted cleavage site of the signal peptide was in agreement with the N-terminal amino acid sequence of the isolated protein. Calculated molecular mass and the isoelectric point for the mature protein were 14,849 Da and pI 4.84, respectively. BLAST database search indicated considerable sequence similarity with previously identified odorant-binding proteins, with the highest scores (30–33% identity) to odorant-binding proteins from the scarab beetles *Exomala orientalis*, *Anomala osakana*, *Popillia japonica*, *Anomala cuprea*, and *A. octiescostata*, *Phyllopertha diversa*, *Heptophylla picea* and *Holotrichia parallela* (Deyu and Leal, 2002 and references therein). The sequence of a cockroach OBP, *Leucophaea maderae*, in the database (accession number AY116618) showed only 12% identity to ZnevOBP1. In addition to significant sequence similarity, the antennae-specific protein from *Z. n. nevadensis* possesses the hallmark of odorant-binding protein, six cysteine residues (at positions 16, 46, 50, 88, 97, and 106) (Fig. 1B). Hence,

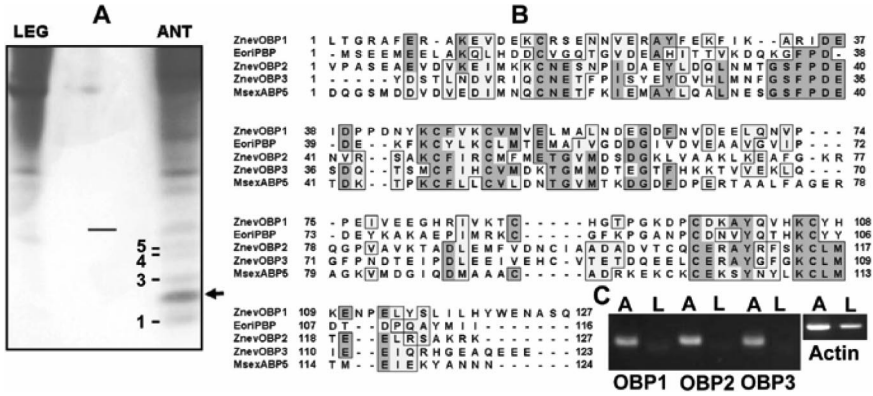

FIG. 1. Gel electrophoresis analysis of proteins extracted from *Z. n. nevadensis*, sequence alignment of deduced amino acids from the cloned OBP cDNAs, and RT-PCR analysis of transcription. (A) Soluble proteins analyzed by a 15% native PAGE and stained with Coomassie blue. LEG, control tissue; 100 midlegs-equivalent. ANT, 400 antennae-equivalent. Arrow indicates the major antennae-specific binding protein. Numbers are given to other minor antennae-specific proteins by their order of mobility. Migration of a reference protein, the pheromone-binding protein from *B. mori* (BmPBP), is denoted by a bar in the empty lane. A band with mobility similar to BmPBP was not antennae-specific. (B) Alignment of ZnevOBP1 with the protein in the database with the highest sequence identity, namely, the pheromone-binding protein from the Oriental beetle, *E. orientalis* (EoriPBP; AB040144). Alignment of ZnevOBP2 and ZnevOBP3 with the best fitting protein, i.e., the antennal-binding protein of *M.* sexta (MsexABP5; AF393498). For clarity, the putative signal peptide and the first 15 amino acid residues of MsexABP5 were omitted. The cDNA sequences for ZnevOBP1, ZnevOBP2, and ZnevOBP3 have been submitted to the GenBank database with accession numbers AY135381, AY135382, and AY135383, respectively. (C) RT-PCR data. cDNA fragments (ca. 100 bp) were amplified with gene-specific primers and antennal template (A), but not with template derived from legs (L). cDNA fragments (450 bp) of actin (control) were amplified using templates from both legs (L) and antennae (A).

we suggest that the isolated protein is an odorant-binding protein and named it ZnevOBP1.

While sequencing multiple clones for ZnevOBP1, we were able to identify two other cDNAs encoding putative odorant-binding proteins, which we named ZnevOBP2 and ZnevOBP3. One cDNA (ZnevOBP2) encoded a protein with 148 amino acid residues. The mature protein (127 amino acid residues) gave a calculated molecular mass and isoelectric point of 14,173 Da and pI 4.95, respectively. Interestingly, as the pheromone-binding protein from *Manduca sexta* (MsexPBP1) (Vogt et al., 2002), this protein has seven cysteine residues (Cys-17, 47, 51, 95, 104, 106, and 115) (Fig. 1B). The other cDNA (ZnevOBP3) encoded a

protein with 143 amino acid residues, the first 20 residue being the putative signal peptide. The calculated molecular mass and isoelectric point for the mature protein were 14,272 Da and pI 4.07, respectively. This protein possesses 6 cysteine residues in a pattern similar to that of ZnevOBP1, i.e., Cys-12, 42, 46, 88, 98, and 107. BLAST search indicated that ZnevOBP2 and ZnevOBP3 shared significant sequence similarity with several insect odorant-binding proteins, the highest scores being the antennal binding protein cloned from *M*. sexta MsexABP5 (AF393498), which showed 41 and 35% identity to ZnevOBP2 and ZnevOBP3, respectively (Fig. 1B).

In order to test whether the cloned cDNAs were related to the minor antennae-specific proteins from *Z. n. nevadensis* (see Fig. 1A), we attempted to determine the N-terminal amino acid sequences of bands 1, 3, 4, and 5. Given the scanty amounts of these proteins in the antennae, the obtained sequences were short, and the readings of the first amino acid residues were not reliable. However, the partial sequences showed that these minor antennae-specific bands are not encoded by the cloned cDNAs. Bands 1 and 3 gave partial sequences Ser-Pro-Leu/Phe-Asp and Gln-Met-Glu-Glu starting from the second and third residues, respectively. On the other hand, bands 4 and 5 gave sequences Val-Lys-Gln and Met-Leu-Asn, starting from the fourth residue. None of these residues is identical to those at the same positions in ZnevOBP2 and ZnevOBP3.

Two lines of evidence suggest that termites have multiple olfactory proteins. First, the minor bands 1, 3, 4, and 5 are specific to the antennae and show mobility similar to most acidic odorant-binding proteins identified to date; they are probably OBPs. Secondly, RT-PCR showed that ZnevOBP2 and ZnevOBP3 are also specific to antennae (Fig. 1C). In conclusion, the evidence from *Z. n. nevadensis* suggests that olfaction in termites (Isoptera) is mediated by multiple odorant-binding proteins.

Acknowledgments—We thank Brooke S. Pannell for collection of antennae for protein extracts. This research was supported by the department, college, and Chancellor's office at the University of California-Davis.

INTRODUCTION—SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

Periodically the journal devotes an entire issue to a particular sub-discipline of chemical ecology. The last such volume was September 2000 [26(9)] when the topic was allelopathy. This current volume developed from a conversation between Mark Hay and John Romeo during the poster session at the International Society of Chemical Ecology annual meeting at Lake Tahoe in July 2001. Mini-reviews were solicited and a call for papers was advertised in the journal. What results here is a series of reviews that cover many important recent developments in the field and a group of papers that illustrate some of the exciting work being done in laboratories worldwide.

The mini-reviews and the direction and likely force of the next wave in aquatic chemical ecology are summarized in the Preface by Mark Hay. The contributed papers (seven selected from several that were submitted) range from studies of pheromones to induction of chemical defenses and to chemically mediated tritrophic interactions. The paper by Ichinose illustrates the importance of coupling biological and chemical studies. His work shows that age and body size of freshwater snails determine their alarm responses to predators, and this is apparently linked to a developmental production of chemicals. The role of bacterial metabolites is nicely shown in the work of Harder et al., who implicate their role in cueing settlement of larval polychaetes. Walenciak et al. demonstrate the potential biotic complexity of aquatic trophic interactions by showing that gut symbionts in aquatic moths are affected by the tannin-containing macrophytes included in their diets. Induced responses in aquatic organisms, as in terrestrial ones, take many forms. While Küpper et al. show that kelps challenged by a pathogen induce increased resistance via production of oligosaccharides, Thorton and Kerr indicate that unusual pseudopterosins (diterpene glycosides) are induced in gorgonian corals by decreasing UV radiation and heavy mollusk, but not fish, predation. Jung et al. show that a major secondary metabolite (the sesquiterpene caulerpenyne in this case) from a green alga found in reef habitats, undergoes metabolic transformation after wounding of the alga. Finally, Ingvarsdóttir et al. have shown that even lowly parasitic sea lice use pheromones to find mates!

A cursory look at the techniques and methods used by these workers shows not only the unique difficulties encountered in working with organisms from aquatic systems, but also how far the discipline's technology has evolved. The range

0098-0331/02/1000-1895/0 © 2002 Plenum Publishing Corporation

includes traditional extraction and spectroscopic identification, freeze shocking and enzyme kinetics (Jung et al.), and PCR and sequence analysis for establishing genetic affinity (Walenciak et al.). The range of compounds encountered is varied even within this small sample of papers and includes most classes of natural products (phenolics, terpenoids, alkanes/alkenes/ketones, oligosaccharides). Only alkaloids are not represented. In many cases, the chemistry is unknown (Ichinose) or known in only a nonspecific general way (Ingvarsdóttir et al., Küpper et al., Walenciak et al.), but in others, the compounds (Thorton and Kerr, Harder et al.), and their metabolism (Jung et al.) are understood in significant detail.

The editors thank all those who contributed to this endeavor with special acknowledgment to the driving force of Mark Hay. We hope the issue will stimulate thinking and work in this exciting area.

PREFACE

THE NEXT WAVE IN AQUATIC CHEMICAL ECOLOGY

MARK E. HAY*

School of Biology
Georgia Institute of Technology
Atlanta, Ga 30332-0230 USA

Aquatic chemical ecology is a recent, but dynamic and rapidly developing, discipline that has become a recognized field only within the last two decades. As an example, a 2001 book on marine chemical ecology (McClintock and Baker, 2001) lists thousands of references with nearly 90% being post-1982 and about 50% being post-1992. Prior to the 1980s, some chemists were exploring marine organisms for novel secondary metabolites and some ecologists were documenting patterns that appeared to be chemically-mediated, but it was uncommon for the chemistry and ecology to be rigorously merged. In the 1980s, marine chemists and ecologists began collaborating to explore types of chemically mediated interactions that had been investigated previously in terrestrial systems (e.g., consumer–prey interactions). These studies benefited greatly from the intellectual infrastructure of terrestrial investigations and models. However, aquatic investigations also provided increased depth to the general fields of chemical ecology, community ecology, and evolution by: (1) testing theories derived for terrestrial systems in evolutionary independent aquatic systems; (2) assessing the ecological function of secondary metabolites under field conditions where investigators did not need to rely on assumptions about the important consumers, primary selective pressures, or relative roles of consumers vs other selective agents; and (3) integrating the specific metabolites and interactions being investigated into a larger community-based framework so the cascading effects of chemically mediated interactions on marine diversity and community organization could be understood. Most initial studies focused on understanding the ecological or evolutionary consequences of prey chemical defenses—an area well represented by terrestrial investigations. This

provided opportunities for a host of marine–terrestrial contrasts that advanced our understanding of chemical ecology in both aquatic and terrestrial systems.

In addition to studies of defense, investigations of chemically mediated foraging, habitat selection, induction of metamorphosis, host–symbiont interactions, and mate tracking and recognition have been conducted in aquatic systems. To be ecologically realistic, these investigations often demand complex integration of behavior, sensory ecology, chemistry, hydrodynamics, and micro- or molecular biology. Achieving such integration is an obvious challenge, but significant advancements are being made, and the field seems poised to merge these disciplines in ways that will provide rigorous mechanistic insights into major processes regulating populations and affecting the structure and function of entire communities.

The mini-reviews presented in this issue attempt to demonstrate both the exceptional opportunities and significant challenges involved in aquatic chemical ecology. In recent years, comprehensive reviews focused on chemical-mediation of biotic interactions in aquatic systems have become a growth industry (e.g., Hay and Fenical, 1988; Davis et al., 1989; Paul, 1992; Pawlik, 1992, 1993; Hay, 1996; Weissburg, 2000; Zimmer and Butman, 2000; McClintock and Baker, 2001). Given these recent summaries, the mini-reviews requested for this issue were targeted at research areas in the early stages of development, but demonstrating great promise. Authors were challenged to be strategic rather than comprehensive in their coverage and to focus more on opportunities, challenges, and needs than on summarizing previous investigations. The mini-reviews, therefore, represent a terse synopsis of dynamic areas within the field, along with a call for focused investigations that will shape the future.

The reviews champion greater focus on: (1) the underlying physiological and molecular basis of metabolite synthesis, turnover, and deployment; (2) chemical mediation of interactions among microbes and between microbes and hosts; (3) understanding how hosts can use chemical signals to regulate microbial behavior (rather than survival via antibiotic activity) as a defense against enemies or to facilitate mutualist microbes; (4) an appreciation of the ontogeny of chemical defense among organisms with complex life-cycles, and the repercussions of this for the evolution of life history and behavioral traits; (5) understanding how the flow environment in which interactions occur may facilitate or hinder consumer foraging and prey escape via affects on transmission and detection of chemical signals; (6) employing a nonreductionist approach that tests for emergent responses to suites of multiple, and sometimes conflicting, chemical cues; and (7) elucidating the cascading effects of secondary metabolites on nontarget organisms and how these effects may impact larger scale patterns such as food-web structure, community composition, rates and pathways of biogeochemical cycles, and the coupling of aquatic with terrestrial systems.

Although the questions and approaches outlined in these mini-reviews are general, they are addressed in systems (e.g., freshwater, the plankton), life stages

(e.g., larvae), or organisms (e.g., marine microbes) where previous investigations have been adequate to demonstrate exciting possibilities, but where much progress is needed and now possible. The authors of these mini-reviews focus on exciting subdisciplines that are just beginning to flourish. It is hoped that the excitement and significant opportunities presented in these reviews will stimulate other investigators to accept the intellectual and methodological challenges noted by these authors and push the field forward to new frontiers.

(Received May 4, 2002; accepted June 6, 2002)

Abstract—We focus this mini-review on how naturally occurring chemical cues mediate ecological interactions, especially interspecific competition and predation in freshwater communities. Although freshwater chemical ecology lags behind terrestrial and marine chemical ecology, we identify recent progress toward: (1) identifying the chemical composition of cues important in food web interactions, e.g., specific glucosinolates, benzyl succinoates, and lignoids as deterrents to herbivory on freshwater macrophytes; (2) employing a nonreductionist approach that tests for emergent responses to suites of multiple chemical cues, e.g., trade-offs in snail refuge-seeking behavior in the presence of chemical cues from both fish and crayfish; (3) investigating how abiotic forces, such as hydrodynamics, impact chemical communication across a broad spatial and temporal scale, e.g., drift responses of mayfly nymphs to whole-stream additions of trout cue; and (4) quantifying the importance of genetic variability, e.g., how chemical cues change selective pressures of local environments. The questions of interest in freshwater chemical ecology cross taxonomic boundaries; traverse broad spatial and temporal scales; demonstrate nonlinear, unpredictable results; and necessitate a multidisciplinary approach for adequate understanding.

Key Words—chemical cue, kairomone, identification, scale, communication, behavior, predator–prey, flow, genetic variability.

INTRODUCTION

Chemical cues are important signals in aquatic environments, where visual and auditory senses are often ineffective. As we illustrate in this review, chemical communication among freshwater species mediates many aspects of both predation and interspecific competition, forces that play key roles in determining community structure and ecosystem function. Recent advances in aquatic chemical ecology are enhancing our understanding of the connections between individual behavior and ecosystem function. We synthesize results at individual, population, and community levels, emphasizing the importance of investigations at multiple spatial and temporal scales.

Because terminology in the field of chemical communication is often ambiguous (Oldham and Boland, 1996), we explain our use of terms. We use the term "chemical cue" as a synonym for "allelochemical," a cue carrying information that mediates interactions between two organisms (*sensu* Dicke and Sabelis, 1988). Consistent with previous authors, we use the terms "kairomone" to indicate communication between different species and "pheromone" to indicate information relayed within a species (Wisenden and Millard, 2001). In addition, we discuss organisms in terms of their role as signalers versus receivers of infochemicals (*sensu* Dicke and Sabelis, 1988). Throughout the review, we address ecological interactions that are mediated by naturally occurring chemicals (not human-made chemicals). We also try to point out where the exact chemical structure of a cue is known versus generalized knowledge about groups of chemical compounds.

Several recent freshwater-oriented reviews overlap or focus on subsets of our topic: chemical communication (Brönmark and Hansson, 2000); alarm signaling (Chivers and Smith, 1998); predator–prey interactions (Kats and Dill, 1998); benthic interactions (Dodson et al., 1994); and planktonic interactions (Larsson and Dodson, 1993; Tollrian and Dodson, 1999). Rather than attempting to be comprehensive, we rely on these reviews, and emphasize selected publications of the past 5–10 years.

We first present patterns of recent publications that reveal what questions, organisms, and habitats have been studied. Second, we discuss specific advances that involve: (1) quantitative isolation and identification of chemical cues; (2) behavioral trade-offs that occur for organisms responding to multiple chemical cues; (3) abiotic influences that span spatial and temporal scales; and (4) characterization of underlying genetic variability of signalers and responders. Finally, we highlight remaining opportunities and challenges for research in this dynamic field.

PATTERNS OF RECENT PUBLICATION

With a literature survey using *Current Contents* and *Biological Abstracts* (Winspirs 4.0) from 1992 to 2001, we quantified the temporal trend of publications

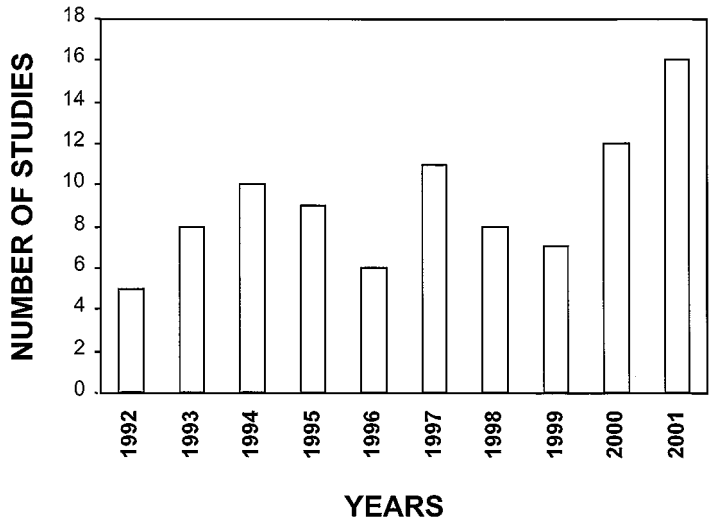

FIG. 1. Number of studies in freshwater chemical ecology from 1992 to 2001 that met our search criteria (in *Biological Abstracts* and *Current Contents*) with keywords: chemical cue, chemical communication, or kairomone.

relating to chemical communication in freshwater habitats. We classified the organisms in these publications as either senders or receivers (Dicke and Sabelis, 1988). Three keyword searches (chemical cue, chemical communication, kairomone) provided limitations for our survey. We limited our search using keywords that we believe freshwater ecologists would most likely use to explore the world of chemical ecology. This delineation limited our search to cues influencing relevant ecological interactions versus identification of nonrelevant or anthropogenic chemicals.

Our restricted search suggests that publications on freshwater chemical ecology are increasing at a slow rate (Figure 1). In addition, striking patterns emerge regarding the types of organisms that act as senders versus receivers of chemical cues (Figure 2). Although our literature search included broad classes of chemical cues, our results suggest that kairomones mediate the majority of species interactions in freshwater systems. Fish and predacious insects act largely as senders, while zooplankton comprise the most studied receivers. Available evidence suggests that some organisms, such as tadpoles, act only as receivers of cues from predators. While other organisms, such as predacious insects, may be both receivers of cues from larger predators as well as senders of their own cues to a lower trophic level, such as zooplankton (especially *Daphnia*).

Our survey confirms Kats and Dill's (1998) assertion that the majority of studies on aquatic chemical communication involve fish–zooplankton interactions. Furthermore, we may only identify some organisms as receivers, when, in

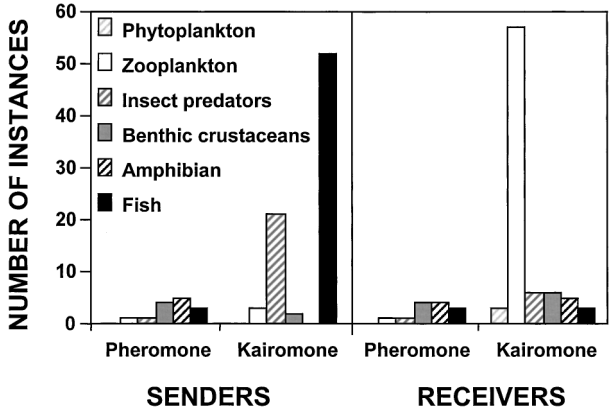

FIG. 2. Number of instances that different taxonomic groups appear as senders or receivers of chemical cues in studies identified from our literature search (1992–2001). Insect predators include both pelagic (Diptera: *Chaoborus*) and benthic (Odonata: *Enallagma*) organisms. Benthic crustaceans include amphipods, isopods, and crayfish. In most instances, fish act as senders and zooplankton serve as receivers.

actuality, those organisms are influencing other inconspicuous organisms in less well-studied interactions. On top of these documented complex patterns, considerable phenotypic plasticity and underlying genetic variability undoubtedly exists in how organisms respond to cues. These complexities indicate that freshwater chemical ecology will develop most quickly with an interdisciplinary approach (Oldham and Boland, 1996).

The patterns illustrated (Figures 1 and 2) represent both standing and flowing freshwater habitats. The duration and orientation of chemical cues may, however, depend partly on the type of freshwater habitat and the organisms present (Figure 3). In lotic systems (i.e., streams), chemical cues from mobile foragers such as trout (McIntosh et al., 1999) or crayfish (Moore and Grills, 1999) may be strongly unidirectional, diluting as they proceed downstream (although see Dahl et al., 1998). In contrast, recycling or renewal of chemical cues by less mobile organisms is more likely in lentic systems (i.e., macrophytes in lakes) (Figure 3). In addition, organisms showing strong site fidelity may also create areas in which cues are recycled. Finally, we might predict chemical cues to be relatively more important in aquatic systems that lack light, such as groundwater or cave environments. However, examples of chemical communication in subsurface organisms are, to our knowledge, nonexistent. We highlight below four promising avenues of recent advances that point the way toward enhanced interdisciplinary research. Future interdisciplinary endeavors will illustrate the importance of chemical ecology in mediating population, community, and ecosystem processes in freshwaters.

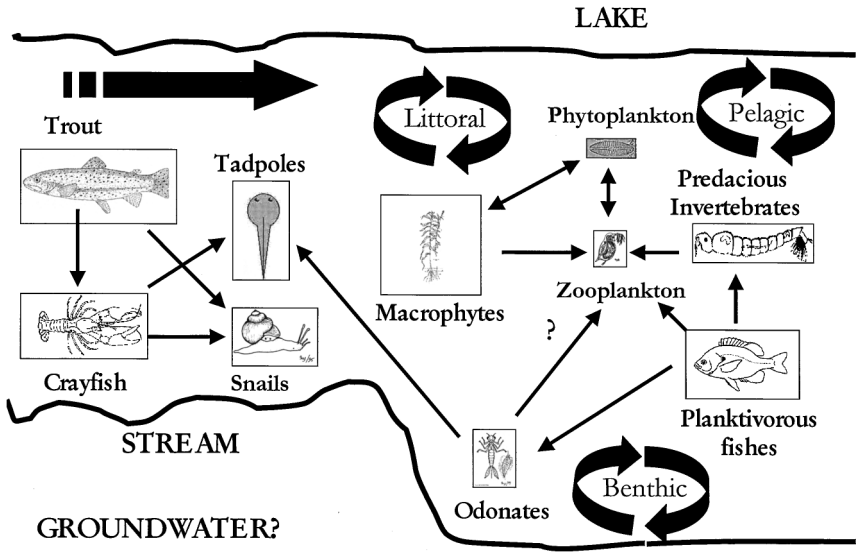

FIG. 3. Schematic of potential interactions mediated by chemical cues in either stream or lake habitats. Large arrows indicate direction of water flow. Curved large arrows suggest that water, and subsequently chemical cues, would circulate or be recycled. Smaller lines with arrows originate with the sender of the chemical cue and point to a potential receiver. Line drawings come mostly from BIODIDAC and a few noncopyrighted images from the Internet. Image of diatom can be found at Bowling Green State University's Algal Images.

RECENT ADVANCES

Quantitative Characterization of Chemical Cues

Probably every ecologist working on chemical ecology would like to know the exact chemical composition of the cue they have documented (Brönmark and Hansson, 2000). Knowledge of chemical structures would advance our insight into the metabolic origins, likely receptors, and the likely persistence and relative importance of different cues (Dodson et al., 1994). However, many ecologists are not trained in biochemistry and do not have the facilities, personnel, or funding necessary to investigate the identity of their chemical cue.

To explore how competition and predation regulate freshwater community structure, ecologists often refer to ecologically relevant chemical cues largely without knowing the chemical structure of the compounds in question. The ecologist places his/her focus on the result of the interaction that takes place when two or more organisms cooccur. A chemist, on the other hand, wants to know what specific chemical environment influenced the result of the interaction. Therefore,

scientists approach the same model system at different scales with different goals. Integrating these approaches, chemical identification with ecological results, is a sizable challenge.

Most compounds that freshwater ecologists suggest act as cues have not been isolated, purified, or structurally identified through complete biochemical assays. Only a few related to freshwater herbivory on macrophytes have been identified or quantified (Newman et al., 1996; Wilson et al., 1999; Kubanek et al., 2001), far fewer than analogous work in terrestrial and marine habitats. Instead, discussion of compounds in freshwater systems is generalized chemically, as groups of compounds (i.e., phenolics) or by chemical properties (lipophilicity, polarity, heat stability, etc . . .). Below we highlight interactions between organisms that show the greatest potential for complete characterization and identification of ecologically relevant chemical cues.

Phytoplankton–Zooplankton Interactions. Hessen and van Donk (1993) showed that the presence of the grazer *Daphnia magna* stimulated formation of large colonies in the green alga *Scenedesmus*. Exposure to *Daphnia*-cued water also increases the proportion of fatty acids that occur in *Scenedesmus* (Lürling et al., 1997), a possible mechanism to maintain buoyancy. These colonies are more difficult for daphnids to graze (Lürling et al., 1997) and, thus, potentially change the magnitude of top-down control of algae in lakes.

Von Elert and Franck (1999) characterized the active infochemical released by *D. magna* as an olefinic (i.e., an alkene with only one carbon–carbon double bond), low-molecular-weight (<500 Da) carboxylic acid. Furthermore, bioassays excluded hydroxyl and amino groups as fractions of the infochemical essential for biological activity (von Elert and Franck, 1999). Concentration of 1 liter of *Daphnia*-cued water using C-18 solid-phase extraction (C-18 SPE), followed by desorption with methanol (10 ml), evaporation, and later resuspension (100 ml methanol), produced similar colony formation as occurred when *Scenedesmus* was exposed to nonfractionated *Daphnia*-cued water (Lürling and von Elert, 2001). Collectively, these studies suggest that the daphnid infochemical responsible for colony formation is moderately lipophilic.

Other studies suggested that urea produced by *Daphnia* also induces colony formation in *Scenedesmus* (Wiltshire and Lampert, 1999). However, urea is a polar molecule without lipophilic portions, thus constituting a substantially different molecule from those tested in other bioassays. Consequently, debate continues as to which molecule, or combination of molecules, acts as an infochemical that induces colony formation in *Scenedesmus*. By separating out urea from a more lipophilic substance using C-18 SPE, Lürling and von Elert (2001) suggest that the colonizing-inducing activity of *Daphnia*-cued water is more lipophilic than urea-related. However, the specific identity of the structure(s) remains unresolved.

Stepping beyond *Daphnia* as the model of aquatic chemical communication, measurable quantities of heptadecene-1 exist within swarms of another

zooplankter, *Polyphemus pediculus* (Wendel and Jüttner, 1997). This volatile organic compound was identified using gas chromatography–mass spectroscopy (GC-MS) and may serve as a pheromone to maintain swarms. Wendel and Jüttner (1997) speculate that swarms may reduce mortality from predation. Heptadecene-1 is available as a pure compound, thereby encouraging further experiments on the ecological role of this chemical cue.

Fish Kairomones and Vertical Migration of Daphnia. Although we know that predators prompt diel vertical migration (DVM) of *Daphnia* and other zooplankters, we know relatively little about the chemical cues responsible for this well-studied phenomenon. Similar to other examples, ecologists can only speculate about the chemical nature of the cue(s), as specific molecules are still unknown. Bioassays suggest that the vertical migration-inducing kairomone in *Daphnia* is a freely dissolved compound of low molecular weight ($<$500 Da), with a lipophilic component, but no carboxyl-, phosphate-, or sulfate groups (von Elert and Loose, 1996). Amplitude of migration is also related to the concentration of this kairomone (von Elert and Pohnert, 2000), illustrating the importance of future tests of natural field concentrations.

Behaviorally or with life history strategies, *Daphnia* often do not distinguish between exposures to different fish species. Ecologists might hypothesize that these generalized responses indicate that kairomones from different species of fish are similar, if not identical (von Elert and Loose, 1996). However, chemists may question whether the active metabolites produced by these different fishes are the same, given that a structure has yet to be determined. This line of thought can only remain speculation until the chemical structures of these cues are actually characterized.

The most recent advancement with the zooplankton–fish system is one in which a hypothesis was rejected by follow-up studies. Boriss et al. (1999) proposed that trimethylamine (TMA) constituted the active component in fish cue, but subsequent investigations showed that daphnids responded only to concentrations of TMA higher than would naturally occur (Pohnert and von Elert, 2000). Furthermore, studies of life history responses of various daphnids to TMA have produced mixed results (Sakwińska, 2000; Lass et al., 2001). Not focusing on any specific compound, Ringelberg and Van Gool (1998) suggested that bacteria produced the kairomone responsible for inducing vertical migration, as antibiotic-treated perch-cued water suppressed migratory responses of *Daphnia*. However, treatment of fish-cued water with antibiotics did not eliminate migration by daphnids. Furthermore, antibiotics would only kill bacteria, not degrade a previously produced compound. Therefore, the origin and identity of the cue(s) responsible for inducing vertical migration remain a mystery.

Defense Compounds of Aquatic Macrophytes. Many freshwater macrophytes, like terrestrial plants and marine macroalgae, harbor chemical defenses (Lodge et al., 1998; Hay and Lodge, unpublished data). Only a few studies actually identify

the composition of deterrent secondary metabolites (Newman et al., 1996, Bolser et al., 1998, Kubanek et al., 2000). Perhaps more common are studies that speculate that unidentified macrophyte phenolics (benzene-ringed compounds with an —OH group), or subclasses of phenolics including tannins (phenolics that can precipitate proteins) or lignans (structural phenolics), are deterrents to herbivores (Lodge, 1991; Cronin, 1998; but see Dorn et al., 2001) and also to epiphytic algae (Gross et al., 1996).

It is important, however, to emphasize that not all phenolics or tannins are deterrent compounds. For example, Bolser et al. (1998) found that the crayfish *Procambarus clarkii* preferred macrophyte species both with high (*Typha angustifolia*) and low (*Ceratophyllum demersum*) phenolic concentrations, thus contradicting the hypothesis that phenolics always act as a deterrents to herbivory. To our knowledge, no study specifically isolates and identifies a freshwater tannin as a deterrent to herbivory. Furthermore, confusion may occur as to what compounds are being tested, depending on laboratory procedures. Colorimetric assays often used to quantify deterrent compounds do not discriminate among classes of molecules and instead capture total phenolics. Therefore, a danger exists in making generalizations about the deterrent properties of large, variable groups of compounds like phenolics.

Instead, the greatest advances in this field come from studies that have actually identified compounds responsible for deterring herbivory. For example, Newman et al. (1996) demonstrated that glucosinolate deterred multiple herbivores from consuming watercress (*Nasturtium officinale*). In addition, habenariol (bis-*p*-hydroxybenzyl-2-isobutylmalate) deters the crayfish *Procambarus clarkii* from feeding on the freshwater orchid *Habenaria repens* (Bolser et al., 1998; Wilson et al., 1999), and numerous lignoids deter this same crayfish from feeding on lizard's tail, *Saurus cernuus* (Kubanek et al., 2001). Besides influencing herbivory, specific plant compounds may affect competition between submerged macrophytes and phytoplankton. For example, *Myriophyllum spicatum* (Eurasian water milfoil) produces a hydrolyzable polyphenol, tellimangradin II, which deters algal growth (Gross et al., 1996). The possibility that allelopathic compounds play important roles in stabilizing alternative states of lake ecosystems—clear water macrophyte-dominated or turbid algal-dominated (Scheffer et al., 1993)—is an important hypothesis awaiting rigorous testing.

Trade-Offs and Multiple Cues

While identification of active compounds has been part of the advances described above, the multiplicity of cues in many freshwater environments requires that nonreductionist approaches be applied. Testing isolated compounds may often be a poor simulation of natural conditions, and, on practical grounds, we are unlikely to identify all the relevant compounds in the foreseeable future. For

example, extensive bioassays and chemical detective work led to the identification of bis-*p*-hydroxybenzyl-2-isobutylmalate (Bolser et al., 1998; Wilson et al., 1999) and several lignan compounds (Kubanek et al., 2000). However, in both cases, other deterrent metabolites in the water-soluble and lipid fractions remain unidentified (Hay, personal communication). Furthermore, the structural complexity of some molecules makes it difficult to identify pertinent structures, and small stereotypic changes in the molecule may enhance or negate the molecule's "activity" as a cue in communication. Therefore, while collaborating with chemists to identify compounds is recommended, progress in understanding the role of chemicals in community and ecosystem processes does not need to wait on complete chemical characterizations.

The influences of multiple chemical cues may not always be additive (Turner et al., 1999), and predictions based on exposure to only one cue at a time may be incorrect (Sih et al., 1998; Hazlett, 1999). Testing whole suites of chemical cues, in combination with single cue tests, may allow the researcher more power in extrapolation (Peckarsky et al., 1997). For example, a natural suite of (unidentified) littoral zone chemicals caused *Daphnia magna* to grow and reproduce more slowly than when grown in spring water (Burks et al., 2000). Laboratory experiments confirmed that daphnids altered their life history traits in response to cues from both macrophytes (waterweed, *Elodea canadensis*) and fish (roach, *Rutilus rutilus*). This result partially explains the paradox between historical studies documenting *Daphnia* avoidance of macrophytes, and recent studies illustrating that macrophytes can provide a refuge for *Daphnia* against predation by fishes (Burks et al., 2001). Without predation risk, daphnids avoid macrophytes because a reproductive cost comes with exposure. This cost may be outweighed by benefits of reduced mortality from fish predation in vegetated habitats.

Behavioral or life history trade-offs may require multiple chemical cues. For example, predator-induced diapause (production of ephippia) in *Daphnia magna* requires cues from both crushed-up conspecifics and kairomones from fish (Slusarcyzk, 1999). Therefore, organisms need to possess the ability to distinguish among multiple chemical cues. Dytiscid beetles (*Acilius sulcatus*) discriminate between chemical cues from hungry and satiated perch (*Perca fluviatilis*) and between perch satiated on fish versus those satiated on dytiscids (Åbjörnsson et al., 1997). Damselflies (*Enallagma sp.*) consistently decreased their movement and foraging in the presence of cues from crushed-up sympatric organisms (pike, *Esox lucius*, fed fathead minnows, *Pimephales promelas*). However, damselflies only responded to cues from biologically unrelated organisms (i.e., mealworms, *Tenebrio molitor*) with previous exposure to an actively foraging predator (Chivers et al., 1996). Even neurologically simple organisms such as flatworms (*Dugesia dorotocephala*) recognize fish odor as an indication of risk based on a single, simultaneous exposure to crushed conspecific and predator cues and do not respond to fish odor without the conspecific cue (Wisenden and Millard, 2001). Thus,

even apparently simple prey exhibit complex, chemically mediated responses to predators.

The presence of multiple predators may also elicit nonlinear, or unpredictable responses. When exposed to chemical cues from crayfish (*Orconectes rusticus*), physellid snails avoided covered habitats in contrast to seeking refuge when exposed to cues from pumpkinseed sunfish (*Lepomis gibbosus*). However, exposure to chemical cues from both predators produced an intermediate response (Turner et al., 1999, 2000), instead of the predicted response to the most dangerous predator. Identifying which cues are dominant controls in species interactions can be a challenging task. Trout cues suppress the impact of stonefly cues in inducing drift by stream-dwelling *Baetis* mayflies (Peckarsky and McIntosh, 1998), and cues from planktivorous fishes override the repellency of macrophytes in *Daphnia* (Lauridsen and Lodge, 1996; Burks et al., 2001).

Bullfrog tadpoles (*Rana catesbeiana*) exhibited nonadditive responses to multiple predators (i.e., dragonfly *Anax junuis* and bluegill *Lepomis macrochirus*), as only small tadpoles decreased their swimming with both predators and significantly more so with dragonflies (Eklöv, 2000). In testing responses of six larval anurans (wood frogs, leopard frogs, American toads, bull frogs, green frogs, and grey treefrogs) to five different predators (mudminnows, dragonfly larvae, newts or salamanders, dytiscid beetles, and belostomatid water bugs), Relyea (2001) found that the six prey species exhibited different responses to the same predator and that each prey species responded differently to the assorted predators. Clearly, the natural environment is full of predators and cues. Studies examining interactions among multiple cue effects will increase our understanding of the role of chemical ecology in structuring natural freshwater communities.

Abiotic Influences That Span Spatial and Temporal Scales

In many cases, the impact of chemical cues depends on the abiotic context, including light, temperature, and hydrodynamics. Chemical cues from light and predators are known to act in concert to prompt vertical migration of *Daphnia* (Brewer et al., 1999). *Chaoborus* only migrated toward light in the presence of chemical cues from fish occurring in combination with a moonlight gradient (O'Bryan and Forrester, 1997). More studies that identify proximate versus ultimate cues will add to our understanding of ecological interactions.

Temperature may also change the costs and benefits of responding to kairomones from predators (although see Sakwińska, 1998). For example, helmet size of *D. ambigua* reared with *Chaoborus* kairomones decreased with decreasing temperatures below 23°C (Hanazato, 1991). Furthermore, mortality of large helmeted daphnids increased at high temperatures (above 28°C). Thus, exposure to predator chemical cues reduced the tolerance of *Daphnia* to high water temperatures that commonly occur during summer.

Hydrodynamically different freshwater environments also influence the duration and properties of chemical cues. In streams, we generally assume that chemical cues originate upstream and influence taxa downstream. However, Dahl et al. (1998) demonstrated that *Gammarus pulex* uses chemical cues from downstream predators (trout) to assess drift behavior. Thus, eddies may play an important role in dispersing cues.

In freshwater systems, the best demonstration of the effect of flow involves crayfish foraging and orientation, analogous to the well-studied effects of flow and chemical cues on blue crabs and lobsters in marine systems (Zimmer and Butman, 2000). Crayfish (*Orconectes rusticus*) located food more quickly in streams with cobble (turbulent flow) versus sand substrate (more laminar flow) (Moore and Grills, 1999). Cobble breaks up the plume and increases dispersion, while laminar flow localizes the cue in parts of the stream not occupied by crayfish. The spatial distribution of complex odor cues (food + predator presence) also significantly impacted crayfish foraging (Tomba et al., 2001) when predator cue occurred in the middle of an artificial stream. Under this scenario, crayfish spent more time using side shelters and less time finding the food source. Thus, orientation to food and predator cues in changing flow regimes may strongly influence community interactions and ecosystem function. Experiments should test responses to chemical cues across a range of natural field conditions, including diverse spatial and temporal scales.

Studies that address larger spatial and temporal scales may discover patterns not apparent or predictable from extrapolation of smaller scales (Peckarsky et al., 1997). For example, McIntosh et al. (1999) pumped "trout-cued" water into a trout stream and monitored drift response of the mayfly, *Baetis bicaudatus.* Minimal drift occurred during the day in streams containg either background trout cues or added cues, but significantly less drift occurred at night in the stream where additional trout cues were added (McIntosh et al., 1999). Thus, mayflies quickly responded to the presence of trout cues. This group also added cued water into fishless streams and found that size at maturity of *Baetis* declined in streams where trout cues occured (Peckarsky et al., 2002). To test how quickly naive prey fishes respond to a predator, Brown et al. (1997) added juvenile pike to a 4-acre pond filled with fathead minnows. Minnows recognized chemical cues from pike after only 2 days, whereas fright responses to a visual cue did not occur for up to 8 days. Potential prey show differential responses to chemical cues, depending on experience. Lake-dwelling *Chaoborus* species (that coexisted with fish) exhibited no preference among ovipositing sites, while pond species showed an ovipositing preference for fish-free water (Berendonk, 1999). These results suggest that ovipositing behavior, influenced by chemical cues from fish, contributes to landscape-level patterns in *Chaoborus* distribution.

Looking for geographic patterns in predator avoidance, Covich et al. (1994) found that two species of physellid snails responded equally to crayfish taken from

their own habitat or from another geographic region. This result suggested that some generality exists in the crayfish kairomone. However, crawl-out responses of six snail species exposed to a single crayfish suggested species-specific responses that depended on microhabitat use (Covich et al., 1994). Thus, more studies investigating the generality of cues are needed to establish a contextual basis for prey response.

In addition to conducting research on large spatial scales, investigating time scales at which responses occur and cues last is also a topic ripe for study. De Meester and Cousyn (1997) suggest that behavioral responses of *Daphnia* to fish kairomones are rapid and reach their maximum after only a few hours. After exposure to chemical cues from fish, daphnids immediately sought refuge in macrophytes and maintained that response for at least 6 hours (Lauridsen and Lodge, 1996). Hazlett (1999) also found the behavioral effect on crayfish of predator odors from snapping turtles lasted only about 2 hours. Life history traits, on the other hand, may take longer to respond to chemical cues depending on genetic differences (see below) and may be enhanced in response to low food concentrations (Weber, 2001). Therefore, when addressing the generality of chemical cues, ecologists must explicitly consider the spatial and temporal scales relevant to the whole suite of chemical cues offered in a particular habitat or set of connected habitats. The relevance of chemical ecology to community and ecosystem ecology will be enhanced by larger and longer studies.

Chemical Communication within a Genetic Context

As the field of chemical ecology advances, studies not only need to identify important morphological and behavioral responses elicited by chemical cues, but also contrast phenotypic plasticity with underlying genetic variability. Increasing numbers of studies use *Daphnia* (which are parthenogenic most of the time) as a model to test the role of phenotypic and genetic variability and the broader evolutionary significance of chemically mediated responses (Lass and Spaak unpublished). Expression of ecologically relevant traits varies both within and between *Daphnia* populations (Stirling and Roff, 2000; for review, see De Meester, 1996a; Lass and Spaak unpublished). The presence of chemical cues from predators changes the selective pressures of local environments. For example, De Meester (1996b) measured the phototactic swimming behavior of ten *Daphnia* clones isolated from three different lakes (fishless, few fish, and numerous fish). Phenotypic plasticity differed among clones, with some altering their behavior more than others in the presence of fish. Furthermore, *Daphnia* clones from habitats with fish responded significantly more strongly to fish kairomones than daphnids from fishless systems (Boersma et al., 1999).

Genetic diversity may depend, in part, on the connectedness of the aquatic system. The self-contained nature of lentic systems may set boundaries for gene

flow and encourage local adaptation (De Meester, 1996a). However, for a lotic system, Storfer and Sih (1998) argue that gene flow between stream salamander populations (*Abystomas barbouri*) swamps local adaptation to chemical cues emanating from permanent streams with fish. Studies that begin to quantify the genetic variation associated with responses to chemical cues will add much insight to a growing field of interest.

OPPORTUNITIES AND CHALLENGES

Our review highlights several areas of freshwater chemical ecology poised for rapid progress. Research that identifies and quantifies chemical cues, such as the multifaceted approach used to characterize the *Daphnia–Scenedesmus* system, serves as a model for the study of inducible defenses (Tollrian and Harvell, 1999; van Donk et al., 1999; Lürling and van Donk, 2000). Recent identification of defensive compounds in freshwater macrophytes show the promise of this area to serve as a new arena in which to test theories of plant–herbivore interactions developed for terrestrial and marine systems. Further advances in freshwater inducible defenses, plant–herbivore interactions, and other areas will require greater collaboration of natural product chemists and ecologists to establish standard bioassays and chemical identification techniques that are practical and ecologically relevant.

Whether chemical cues are identified or not, much can be learned quickly with additional experiments using the natural suites of compounds existing in different habitats within lakes and streams. While cruder chemically, these sorts of experiments lead to rapid identification of larger scale patterns of trade-offs involving multiple cues. Identifying such patterns is essential to a more complete understanding of the organization of freshwater communities and the function of aquatic ecosystems. New studies should explore the importance of chemical communication in light-limited aquatic systems, such as groundwater or within caves. Such studies are relevant ecologically and provide rich material for subsequent chemical characterization.

In order to provide maximum insight into natural interactions, experiments must include realistic mimics of the complex abiotic milieu (flow, temperature, light, etc.) in which chemical cues are perceived by organisms (Moore et al., 2000). Comparisons of lake and stream environments may be especially fruitful. Freshwater environments provide excellent model organisms for the study of phenotypic and genetic responses to chemical cues and chemically mediated trophic interactions. Rapid progress can be made in this area, in a way that emphasizes the importance of chemical ecology to evolutionary ecology.

Overall, freshwater chemical ecology lags behind terrestrial and marine chemical ecology but provides vast immediate opportunities for interdisciplinary work of high relevance to chemistry, ecology, and evolution. Combining ecologists' desire to "assign ecologically relevant biological activity to natural products" with

chemists' desire to "unravel inter-organism communication at the molecular level" (Oldham and Boland, 1996) will lead to rapid progress of broad significance. These "ecologically relevant" interactions involve multiple species, vary within species, and take place within contextual environments dictated by flow, abiotic influences, and scale. Thus, questions in the field should increasingly attract other disciplines, including geneticists, physicists, and hydrologists. We must integrate these multiple perspectives and become "cued" into the diverse disciplinary cues.

Acknowledgments—We thank Jay Frentress for assisting with literature searching and Chris Tolleson for reading a draft of the manuscript. We also thank Mark Hay for a constructive review of this manuscript. R.L.B. thanks participants of the 1998 OIKOS Nordic Ecology Symposium (Chemical Communication in Aquatic Systems) for starting her thinking about these issues. Our projects funded by the American Scandanavian Foundation (to R.L.B.), the Fulbright Foundation (to R.L.B.), Institute for Wetland and Waterfowl Research (to D.M.L. and A. J. Froelich), NOAA (NA46RG0419-2 and 643-1532-04 to D.M.L.) and NSF (DEB 94-08452 and DEB 91-07569 to D.M.L.; and GER 94-5265-001 to R.L.B.) were central to the development of our work in this area.

Abstract—Since chemical ecology emerged as a field of marine science, it has been strongly influenced by studies of chemically mediated interactions in land-based systems. Marine chemical ecologists, like their terrestrial counterparts, initially focused on identifying natural products and evaluating the potential ecological roles of these products as defenses, attractants, or other cues. Now, like our land-based colleagues, we must increase our focus on the physiological and biochemical mechanisms that underlie the chemical interactions, paying particular attention to regulation of biosynthetic pathways, within-plant and between-plant signaling cues, and comparative and functional genomics. Here, we review the current state of knowledge regarding a heterogenous group of macrophyte natural products, the marine tannins and simple phenolics, to illustrate how such information is critical to future attempts to predict their ecological roles.

Key Words—Marine chemical ecology, macrophytes, phenols, tannins, terrestrial – marine comparison.

INTRODUCTION

Plant tannins and related phenolic substances are common in marine ecosystems. They are produced by submerged vascular plants, emergent saltmarsh vegetation,

and mangroves, as well as by brown algae. These reducing substances have primary roles in marine plants, serving as putative osmoregulatory substances in seagrasses and as components of cell walls in both marine vascular plants and brown algae (e.g., Schoenwaelder and Clayton, 1999). Phenolics also possess secondary roles. Many are antimicrobial agents, presumed to protect macrophytes against pathogen attack (Harrison and Chan, 1980; Vergeer and Develi, 1997), and some have also been identified as herbivore deterrents and herbivore digestion reducers, thought to increase macrophyte fitness by reducing herbivore pressure (e.g., Harrison, 1982; Boettcher and Targett, 1993; Pavia and Toth, 2000; but see Targett et al., 1995). Recent evidence also indicates that phenolics may protect macrophytes against harmful ultraviolet radiation (e.g., Pavia et al., 1997).

Traditionally, such discoveries have mirrored similar advances made for phenolic-rich plants on land, in part because marine ecologists have often borrowed biochemical techniques and ecological models of plant defense originating from terrestrial studies. More recently, however, advances in our understanding of phenolic production in marine plants have lagged, primarily because there have been few marine studies aimed at understanding the mechanisms of phenolic synthesis at the physiological, biochemical, and molecular levels. Dramatic variations in the phenolic contents of marine macophytes are commonly observed, but the regulation of phenolic production in marine macrophytes at the pathway or gene level has been largely unexplored. For example, the biosynthetic pathways for production of polyphenols in brown algae are still not known, despite the fact that polyphenols occur in most brown algal orders, can be present at concentrations as high as 25% of an alga's dry mass, and have been suggested to mediate numerous ecological interactions (Ragan and Glombitza, 1986; Targett and Arnold, 1998). Plant signaling molecules have not been well studied in marine macrophytes either, although they are known to be involved in the coordination of phenolic-based responses for terrestrial plants. As a result, we currently know little about the intrinsic and extrinsic factors regulating phenolic metabolism in these organisms. Yet this knowledge is crucial to our further understanding of how marine tannins and related phenolics influence plant–herbivore and plant–pathogen interactions in marine systems. The following review highlights the current state of knowledge regarding marine tannins and related phenolics and seeks to encourage interactions between terrestrial and marine chemical ecologists, especially in attempts to understand phenol production at the pathway and/or gene level.

MARINE VASCULAR PLANTS

Shikimate-Derived Phenolics

Phenolics derived from shikimate have long been associated with antipathogen and antiherbivore defense in land plants (Hammerschmidt and

Smith-Baker, 1999). These substances (and their oxidized products) have demonstrated roles as antimicrobial agents, herbivore deterrents/stimulants, digestion reducers, defense-related signaling molecules, and cell wall strengtheners (see Nicholson and Hammerschmidt, 1992). Concentrations of these shikimic acid and phenylpropenoid pathway products vary dramatically in organisms, and these variations have often been shown to affect the fitness of plants, including agriculturally important species.

The majority of plant phenolics, including simple phenolic acids, condensed and hydrolysable tannins, and lignins, among many others, are products of the shikimic acid (SA) and phenylpropenoid (PP) pathways (e.g., Singh et al., 1991). The SA pathway occurs in bacteria, fungi, and vascular plants and begins with the condensation of the carbohydrate intermediates erythrose-4-phosphate and phosphoenol pyruvate to generate chorismate, from which the aromatic amino acids phenylalanine, tyrosine, or tryptophan are produced (Herrmann, 1995). These amino acids can be allocated in vascular plants for either protein biosynthesis or, alternatively, for the production of polyphenolics via the PP pathway (Jones and Hartley, 1999). The production of phenylpropenoids (e.g., C_6–C_3 compounds) begins with the deamination of aromatic amino acids and results in the formation of cinnamic and *p*-coumaric acids, from which more complex phenolics arise (e.g., Seigler, 1998). As a result, significant fractions of a plant's carbon and nitrogen pools can be tied up in intermediates and end products of the SA/PP pathways.

The regulation of the SA/PP pathways has been well studied in land plants. It has been demonstrated, for example, that activities of the enzyme 3-deoxyarabino-heptulosonate-7-phosphate synthase (DAHPS), which determines the rate at which carbohydrate intermediates enter phenolic metabolism, are induced by wounding and pathogen attack in tomato, potato, parsely, and *Arabidopsis* (e.g., Muday and Herrmann, 1992). Furthermore, isoforms of the enzyme phenylalanine ammonia lyase (PAL), which directs the flow of amino acids away from protein synthesis and towards the PP pathway for the production of hydroxycinnnamic acids, are responsive to extrinsic factors. Not surprisingly, PAL activities have been linked to the production of flavonoids, condensed tannins, and lignins (Liu and McClure, 1995; Lavola et al., 2000). This trade-off between the production of aromatic amino acids and polyphenols is of particular interest to plant ecologists since it forms the foundation of several popular ecological models of plant defense (e.g., Bryant et al., 1983; Jones and Hartley, 1999). Marine vascular plants also produce significant, and varying, amounts of phenolic substances; however, unlike for terrestrial plants, there have been no previous studies of the SA/PP pathway enzymes, their regulation by environmental factors, or their roles in plant defense against pathogens in any marine vascular plant. As the following examples illustrate, our understanding of marine plant–herbivore and plant–pathogen interactions would benefit greatly from molecular and biochemical

studies of the SA/PP pathway, and its regulation by intrinsic and extrinsic factors.

Seagrass Phenolics

Seagrass beds are productive ecosystems that occur along the coasts of most continents (Macia, 2000). Fifty-eight seagrass species have been described. All share a similar basic anatomy: blades emerge from short shoots (i.e., ramets) that, in turn, arise from a continuous rhizome, or underground primary stem (Dawes, 1998). Seagrasses are a rich source of phenolic substances, including phenolic acids, sulfated phenolic acids, and flavones, condensed tannins, and lignins; but not hydrolyzable tannins. In this regard, the phenolic secondary chemistry of seagrasses is similar that of the terrestrial grasses from which they evolved. Despite this, there is currently no information regarding the regulation of the SA/PP pathway in these plants, and only a few attempts have been made to link seagrass secondary chemistry to plant fitness in the face of herbivory and pathogen attack.

Simple phenolic acids are abundant and account for as much as half of the measured phenolics in seagrasses (Vergeer et al., 1995; Vergeer and Develi, 1997). The array of phenolic acids produced by seagrasses is dependent upon the species, population, and tissue examined and may include caffeic acid, protocatechuic acid, *p*-coumaric acid, *p*-hydroxybenzoic acid, ferulic acid, vanillic acid, and gentistic acid, among others (McMillian et al., 1980; Quackenbush et al., 1986; Ravn et al., 1994). Phenolic acid conjugates are also common; for instance, McMillian et al. (1980) found sulfated conjugates in all 43 species they examined. Concentrations of phenolic acids vary dramatically. For example, concentrations of rosmarinic acid and caffeic acid in eelgrass, *Zostera marina*, varied seasonally, ranging from 0.4 to 19.2 mg/g Dry Mass (DM) (Harrison and Durance, 1989; Ravn et al., 1994). Seagrasses also accumulate significant levels of condensed tannins (i.e., proanthocyanins) in leaf and shoot tissues. For example, concentrations of 3–11% DM have been recorded in the leaves of turtlegrass, *Thallasia testudinum*, from the Gulf of Mexico and Caribbean Sea (Arnold and Tanner, data not shown), and recent studies suggest that proanthocyanin levels vary significantly over brief periods of time (Arnold and Tanner, data not shown). Lignin concentrations vary as well, from <1 to 5% DM, but remain somewhat lower than concentrations found in terrestrial grasses (see Dawes, 1998).

Additional evidence for variable phenolic contents in seagrasses is provided by studies using nonspecific measures of 'total' phenolics, i.e., Folin-reactive substances. While the Folin assays do not discriminate among the various classes of plant phenolics, they have revealed additional examples of varying phenolic contents in seagrasses (Harrison and Durance, 1989; Vergeer et al., 1995). Clearly, levels of simple and polymeric phenolics in seagrasses can be both high and highly variable.

The potential ecological roles of the phenolic acids present in seagrasses have not been studied extensively. There is evidence that phenolic acids, which arise early in the SA/PP pathway, have the potential to serve as antimicrobial agents, herbivore deterrents, and osmoregulatory agents (Harrison and Chan, 1980; Harrison, 1982; Ravn et al., 1989; Vergeer and Develi, 1997). The majority of these studies have been laboratory-based investigations, however, and it remains unclear how influential phenolic acids are in determining seagrass fitness in nature. Similarly, there is no evidence indicating that condensed tannins or lignins have roles in seagrasses defense against herbivores or pathogens. Below, we summarize the current state of our knowledge regarding the potential roles of seagrass phenolics in widely studied plant–herbivore and plant–pathogen interactions.

Herbivory. Sea urchins, fishes, green turtles, manatees and dugongs consume seagrass tissues, especially in tropical grassbeds. In addition, seagrasses harbor numerous species of mesograzers, which feed primarily on the epiphytes present on seagrass blades. Yet, overall rates of herbivory in seagrass beds are typically low; for instance, grazers remove 10–50% of seagrass primary production, compared to 60–97% of marine macroalgae production (Hay and Steinberg, 1992; Cebrian et al., 1998; Macia, 2000). A large portion of seagrass biomass is not consumed by herbivores but rather is recycled as detritus, especially in temperate ecosystems (Zieman and Zieman, 1989). However, dramatic examples of grazing have been observed, usually in tropical ecosystems (Valentine and Heck, 1991; Greenway, 1995). For example, urchins, the predominant grazer on tropical species, have been observed to denude seagrass beds in the Caribbean Sea, Gulf of Mexico, Mediterranean Sea, and Gulf of Aqaba, as well as along the coasts of Australia and Japan (see Heck and Valentine, 1995). Seagrasses respond to, and are affected by, grazers. Herbivory can decrease primary production in cases where it results in the loss of photosynthetic tissues (Valentine and Heck, 1991; Cebrian et al., 1996); it may increase production where it removes leaf epiphytes (Thayer et al., 1984); it may, depending upon the resource status of plants, affect the growth rates of leaves and shoots (Cebrian et al., 1998). Plant phenolic metabolism may also be affected. Wound-induced production of condensed tannins and total reactive phenolics has been observed in several populations of turtlegrass, *T. testudinum*, subjected to simulated herbivory (Arnold and Tanner, data not shown). Herbivores, in turn, can also be affected by characteristics of the seagrasses they consume. Valentine and Heck (2001) demonstrated that changing nitrogen contents of seagrass tissues influenced grazing by the urchin *Lytechinus variegatus.* In this study, the herbivores grazing in unfertilized grassbeds compensated for the lower nutritional quality by increasing consumption compared to urchins grazing on N-rich plants from fertilized grassbeds.

The potential for seagrass phenolics to serve as chemical defenses against herbivores, while intriguing, has been rarely considered (but see Harrison, 1982). For example, while it seems reasonable to expect these vascular plants to respond

to herbivores, it remains to be seen if (or how) real herbivory induces altered phenolic contents as artificial wounding does. Future studies examining the response of pathway enzymes and gene expression would be helpful, for while plants often respond at these levels immediately, it typically takes a period of days or weeks before grazer-induced accumulations of phenolics can be detected. Moreover, since the potential for phenolics to serve as defensive agents can be influenced by oxidation (see Appel, 1993), it would be worth examining activities of polyphenol oxidase enzymes or the expression of related genes sequences as well. Finally, given the clonal nature of seagrasses, it is worth exploring the possibility of a systemic response, resulting from the translocation of chemical signals via the vascular system.

Disease Resistance. Evidence also exists to support a role for phenolics in seagrass disease resistance, particularly with regard to the wasting disease that contributes to rapid population declines for certain species. This disease has been implicated in the mass mortalities of eelgrass occurring in North America, Europe, and New Zealand, as well as the continuing decline of turtlegrass in Florida Bay (USA) (Short et al., 1986; Duranko and Kuss, 1994). It causes expanding necrotic lesions on blades and shoots and leads to mortality of a large percentage of affected plants (Muehlstein, 1992; Den Hartog, 1996). Disease outbreaks have long-lasting effects on seagrass populations; for example, many eelgrass populations affected by the disease in the 1930s have not fully recovered, and some were driven to local extinction (see Short et al., 1986; Muehlstein et al., 1988). The pathogenic organism infecting eelgrass is *Labyrinthula zosterae* Porter et Muehlstein, a net-forming protist of the phylum Labyrinthulomycota. A related species is associated with turtlegrass, *T. testudinum* (Duranko and Kuss, 1994; Zieman et al., 1999). *Labrinthula* spp. are nearly ubiquitous in coastal marine ecosystems and only periodically, for unknown reasons, do they become virulent pathogens (Muehlstein, 1992; Vergeer and Den Hartog, 1994). It has been observed, however, that the emergence of the disease is often preceded by declines in plant health linked to a variety of changing environmental conditions, such as decreased light levels, elevated temperatures, and high salinities (as reviewed in Den Hartog, 1996). Disease resistance has also been linked to levels of plant phenolics. Specifically, the phenolic content of eelgrass leaves and shoots has been correlated with resistance to the wasting disease in mesocosm experiments (Buchsbaum et al., 1990), and seagrass phenolics possess growth-inhibiting activity against *Labyrinthula* spp. grown in culture (Vergeer and Develi, 1997). Moreover, these putative phenolic defenses are inducible. Levels of both total reactive phenolics and caffeic acid can be induced by *Labyrinthula* sp. attack (Vergeer et al., 1995).

An understanding of the mechanisms of seagrass–pathogen interactions could be helpful in explaining and/or predicting seagrass die-offs. For example, it is interesting to note that many of the environmental factors linked to wasting disease

outbreaks are known to inhibit the SA/PP pathway in land plants. Decreased light levels and elevated nutrient concentrations, two hallmarks of coastal degradation previously suggested as triggers of wasting disease outbreaks, inhibit enzymes of these pathways in land plants. If seagrass phenolics do have a role in determining disease resistance and if the SA/PP pathway of seagrasses is affected by coastal eutrophication, then this may help to explain the timing of past seagrass die-offs or, potentially, serve as a bioindicator of future events.

Emergent Plants

Phenolic-rich vascular plants also occur in tidal plant communities, including salt marshes and mangrove forests. Salt marshes occur over a wide range of latitudes, from arctic to subtropical habitats and are composed of a variety of emergent species, including grasses, herbs, and shrubs. Mangrove forests are tropical communities, which are dominated by several species of mangals. Both types of communities act to stabilize coastal sediments, contribute to land formation and serve as nursery habitats. Both have suffered from overexploitation.

Salt marsh plants accumulate relatively high levels of phenolic substances that may protect them from herbivores and that leach, as so-called humic substances, into nearby waters (e.g., Filip and Alberts, 1989). Rates of herbivory on salt marsh plants are generally low; however, grazing is not homogeneous. Grazing by phytophagous insects, migratory waterfowl, and marine invertebrates can vary, and there is some evidence that plant phenolics are influential in these interactions (e.g., Buchsbaum et al., 1984). For example, growth of the salt marsh periwinkle, *Littoraria irrorata*, on *Spartina alterniflora*-based diets has been negatively correlated with the phenolic content of the food (Baerlocher and Newell, 1994), and the phenolic content of sawgrass leaves in the Florida everglades has been linked to rates of herbivory and fungal infection. In the latter case, the phosphorus-enriched plants had lower phenolic contents and higher rates of grazing and infection (Richardson et al., 1999). These examples provide support for the view that phenolics influence grazing; however, many other plant characteristics also contribute to the observed patterns of herbivory (e.g., see Pennings et al., 2001). In mangroves, tannin concentrations are reported to range from 8.8 to 40.8% DM, and levels of total reactive phenolics vary from 11.1% to 48.8% DM (Basak et al., 1996, 1998). These levels are high enough that the dried bark of certain mangrove species was used to tan leather (Dawes, 1998). The characteristic blackened prop roots of these plants are the result of phenolic exudates that react with ferric ions from the soil solution (Kimura and Wada, 1989). Variations in tannin contents and total phenolic levels occur. For example, Feller (1996) provided evidence for increased phenolic contents in leaves of phosphorus-enriched mangroves. Other variations in phenolic content have been negatively correlated with plant protein levels in some studies (Basak et al., 1998), but not others (Basak et al.,

1996). Such variations are likely to have ecological significance. Phenolics from mangroves act to modify sediments near prop roots (Kimura and Wada, 1989) and may negatively affect meiofaunal species in mangrove estuaries (Alongi, 1987). In addition, they are predicted to influence rates of decomposition in mangrove forests. For example, a field study aimed at assessing the effect of nutrient enrichment on stands of dwarf red mangrove *(Rhizophora mangle*) indicated that leaf phenolic contents were linked to rates of decomposition in belowground sediments, but not in aboveground leaf litter (see Feller, 1996). Attempts have been made to correlate phenolic contents with herbivory but these have yielded mixed results. In a study of 10 mangrove species in India, herbivore damage was negatively correlated with leaf tannin contents (Kathiresan, 1992). While the leaf-eating mangrove crabs *Sesarma messa* and *S. smithii* from Australia have been observed to prefer tannin-free over tannin-rich leaves (Camilleri, 1989; Steinke et al., 1993), feeding by the congener *Sesarma meinerti* from South Africa is unaffected by leaf tannin levels (Micheli, 1993). The balance of data to date suggests that phenolics act as one of many factors influencing litter decomposition and herbivory.

Like the case illustrated for seagrasses previously, there have been few studies of salt marsh plant phenolic metabolism, especially at the molecular and/or biochemical levels. Future studies of this sort are likely to aid in efforts to: (1) understand how increases in atmospheric CO_2 concentrations are likely to affect the phenolic content of marsh grasses and whether or not these would influence rates of organic matter recycling in wetlands (e.g., Wilson et al., 1986), (2) better predict the outcome of plant–herbivore interactions, including those associated with biocontrol of invasive wetland plants (see Wecker et al., 2000), and (3) evaluate the potential affects of coastal eutrophication on the secondary chemistry of these plant communities.

MARINE NONVASCULAR PLANTS

Acetate-Derived Tannins

Polyacetate-derived phenolics occur in a wide range of terrestrial and aquatic organisms, including algae, bacteria, fungi, lichens, and vascular plants. Many are bioactive and have roles as toxins, antibiotics, immunosuppresants, antitumor agents, and antiparasitic agents. Well-known examples include: aflatoxin, a potent cytotoxin and carcinogen produced by certain fungal species; erythromycin, a commonly prescribed antibiotic from *Streptomyces* sp.; urushiols, skin irratants produced by poison ivy, *Toxicoderndron radicans*; and the polyacetates from the fungus *Ceratocystis ulmi*, which contribute to the symptoms of Dutch elm disease (Seigler, 1998 and references therein). Polyacetates (i.e., polyketides) are

generated via the condensation of acetate and malonate units, in a manner similar to the synthesis of fatty acids (Packter, 1980). The sequential condensation of acetate and malonate units is catalyzed by polyketide synthase (PKS) enzyme complexes. Thousands of polyacetate natural products arise as variations on this basic metabolic theme, and their production is considered to be an example of combinational chemistry (Reynolds, 1998). Interestingly, some phenolics of vascular plants are generated using both PKS enzyme complexes and the aforementioned SA/PP pathway. These arise from the precursors chalcone and 6′-deoxychalcone, SA/PP pathway intermediates that are generated by the enzyme chalcone synthase, a plant-specific polyketide synthase.

Brown Algal Phenolics

In marine systems, the most widely studied polyacetate phenolics are the phlorotannins of marine brown algae. Brown algal phenolics are sequestered in cellular microvesicles called physodes (Ragan and Craigie, 1976) or, alternatively, are incorporated in brown algal cell walls (Schoenwaelder and Clayton, 1999). Phlorotannins are similar to the condensed tannins of vascular plants with regard to their basic chemical properties and observed ecological roles. For instance, reduced phlorotannins bind to metal ions and a variety of macromolecules, including proteins, carbohydrates, and nucleic acids and may function as cell wall components, putative spermatozoid inhibitors, UV sunscreens, antibacterial agents, herbivore deterrents, and digestion inhibitors (for review see Ragan and Glombitza, 1986; Stern et al., 1996; Targett and Arnold, 1998). However, unlike the condensed tannins, phlorotannins are not products of the SA/PP pathway. They are believed to arise from the condensation of acetate and malonate units via a polyketide synthase (PKS) type enzyme complex although, to date, no such complex has been described in brown algae.

Phlorotannin levels vary dramatically. For example, in macrophytes from the temperate and tropical Atlantic, northeastern Pacific, and Antarctic Oceans, concentrations of 5–12% DM are common; however, tropical Indo-Pacific populations possess uniformly low levels (<2% DM) (Ragan and Glombitza, 1986; Steinberg and van Altena, 1992; Targett et al., 1992, 1995). Regional variations also occur and have been linked to macrophyte age, algal size, irradiance levels, nutrient availability, herbivore densities, and season (Ragan and Glombitza, 1986; Van Alstyne et al. 2001). Such variation is one reason why algal phlorotannins have been so often used in tests of plant defense theory in marine systems: the degree to which phlorotannin levels vary in nature is similar to that observed for tannins in vascular plants. Tests of these ecological theories using phlorotanin-rich algae as model systems have been numerous, examining macrophytes in both the field and in culture. However, the majority of studies have been correlative and,

to date, no ecological theory or model has emerged as an acceptable predictor of algal phlorotannin levels (see Cronin, 2001). At a larger scale, the absence of phlorotannin-rich algae in the tropical Indo-Pacific has not been explained. Recently, both the effectiveness of phlorotannins as herbivore deterrents and their classification as secondary metabolites have been questioned.

We suggest that these and other debates regarding the roles of brown algal phlorotannins would benefit from evaluations of brown algal physiology. For instance, some of the difficulties in testing the assumptions and predictions of these ecological theories are due, in part, to the lack of pathway- and gene-level information regarding phlorotannin production, as the following examples illustrate.

Carbon–Nutrient Balance Hypothesis (CNBH). This hypothesis originated from studies of woody plants in boreal forests and proposes that plant phenolic contents may vary with regard to resource availabilities (see Bryant et al., 1983). According to the CNBH, such links arise because carbon-based defenses (e.g., polyphenolics and terpenoids) accumulate when amino acid biosynthesis is restricted by nitrogen limitation. Such a response is hypothesized to improve plant fitness since carbon-based defenses would then accumulate under conditions when nitrogen-rich tissues would be most difficult to replace (Bryant et al., 1983). Tests of this model have examined carbon-based defenses from a wide range of terrestrial plant species as well as plant cell cultures (Kubek and Shuler, 1980) and marine macrophytes (Buchsbaum et al., 1990). The CNBH has been commonly used in attempts to account for variations in brown algal phlorotannin contents, with varying success (see Pavia and Brock, 2000 and references therein; Cronin, 2001).

In recent years, the CNBH theory has become increasingly criticized (see Hamilton et al., 2002). While some carbon-based compounds (e.g., phenolics) are often observed to vary as predicted by the CNBH, many other compound types (e.g., terpenoids) do not seem to follow CNBH prediction (Cronin, 2001). Differences among various classes of carbon-based defenses may be the result of differential regulation of the associated biosynthetic pathways or differences in product turnover rates and, therefore, costs (Cronin, 2001). Terrestrial chemical ecologists have also grown increasingly frustrated by the lack of a mechanistic basis for the CNBH, which does not indicate exactly how its predicted trade-offs may be generated in plant cells. As a result, other, more mechanistic models have been proposed in an attempt to link variations in plant phenolic contents with environmental stressers via specific metabolic mechanisms. For example, the protein competition model of Jones and Hartley (1999) shares many of the predictions also made by the CNBH but bases these predictions on a clear understanding of the SA/PP pathway, particularly the role of PAL in generating trade-offs between the production of aromatic amino acids and hydroxycinnamic acids. Its firm foundation in plant metabolism makes its specific assumptions more testable than those of the CNBH.

In retrospect, it is interesting to consider the use of the CNBH in past studies of brown algal phlorotannins, especially since recent observations suggest that this model should *not* apply to these compounds. For example, the CNBH is presumed to be effective in predicting variations of immobile defenses, i.e., those with low rates of turnover; however, recent evidence suggests phlorotannin turnover rates, like some vascular plant tannins, are relatively high (Arnold and Targett, 2000). Furthermore, the model is not expected to accurately predict variations for compounds that, like phlorotannins, possess multiple secondary roles and/or a combination of both secondary and primary roles (Arnold and Targett, 2002). In addition, there is no known metabolic mechanism in phlorotannin biosynthesis that would result in a trade-off between phlorotannin production and protein synthesis, like that resulting from the deamination of amino acids in the SA/PP pathway of vascular plants. This leads to the intriguing question of why intraspecific variations in phlorotannin levels are sometimes consistent with the predictions of the CNBH.

Induction. In some brown algae, accumulations of phlorotannins can be induced by herbivore grazing and simulated herbivory (Van Alstyne, 1988, 1989; Hammerstrom et al., 1998; Toth and Pavia, 2000), as well as by the presence of waterborne cues from grazing herbivores (Toth and Pavia, 2000) and the presence of airborne methyl jasmonate (Arnold et al., 2001). The response has been suggested to increase plant fitness, and there is indirect evidence supporting this stance. For instance, grazing by littorine snails is discouraged by the development of this induced response in the intertidal algal, *Fucus distichus* (= *F. gardneri*) (Van Alstyne, 1990). In addition to site-specific accumulations of polyphenols, plant-wide responses to grazing have been observed. In *Fucus* sp., for example, elevated polyphenol levels may propagate to undamaged fronds of the same plant, and grazing can result in the initiation of adventious branching as well (Van Alstyne, 1988, 1990). However, the ways in which these macrophytes perceive damage and coordinate a defensive response remain a mystery. Ironically, the presence of the phlorotannins themselves have impeded efforts to characterize enzymes and/or genes associated with this induced response, as they typically interfere with nucleic acid extractions. Nevertheless, recent studies of induced responses are beginning to reveal some intriguing clues. For example, oligoguluronates have been demonstrated to activate an oxidative burst in kelps (Collen and Davison, 1999; Küpper et al., 2001), and polyphenol induction can be activated by herbivore-specific cues (Pavia and Toth, 2000) and the presence of airborne methyl jasmonate (Arnold et al., 2001). Salicylic acid, a phenolic compound involved in the systemic responses of vascular plants, has been identified in brown algae (Legaz et al., 1985), but its roles in algal defense, if any, have not been examined. Certainly, when compared to what is known regarding signal transduction and pathway regulation in land plants, it is clear that our understanding of induced phenolic metabolism in brown algae is in its infancy.

SUMMARY

As these case studies illustrate, although marine tannins and related phenolic substances are common in marine macrophytes, we know very little about the physiological mechanisms controlling (poly)phenol metabolism in these organisms. As a result, marine macrophytes are generally treated as black (or green or brown) boxes. A better understanding of the biosynthetic pathways and key regulatory steps leading to phenol production in marine macrophytes would help us to predict variations in phenolic concentration in response to specific biotic and abiotic factors, understand local and systemic responses to herbivores, generate hypotheses regarding the evolution of defense strategies in marine macrophytes, and rigorously test ecological theories in marine ecosystems.

Acknowledgments—Discussions with Chris Tanner and Anne Boettcher and the comments of an anonymous reviewer improved the manuscript. NSF grants EEP 0114458 and OCE 0117313 to T.M.A. and OCE 9618112 to N.M.T. were critical to the development of the ideas presented.

(Received May 21, 2002; accepted June 5, 2002)

Abstract—Colonization of surfaces in marine benthic environments is often one of the most significant moments in the life history of benthic organisms, representing, for example, a change from a planktonic to a benthic existence, a shift from a mobile to a sessile life form, or the initiation of pathogenesis. Many of the surfaces that are colonized are, in fact, other marine organisms, and in a general sense there is widespread evidence that specific chemical cues derived from marine organisms affect colonization by both marine prokaryotes and eukaryotes. However, detailed information for any one system on the nature of such cues, their distribution in situ, and their effects on the demography of colonizers is rare. Here, we selectively review the literature on chemical cues for colonization in the sea, focussing on contrasts between positive (inducers) and negative (inhibitors, deterrents) cues and on prokaryote/eukaryote interactions. We also consider whether generalized life history or natural history characteristics of colonizers (i.e., the mobility of a propagule, the extent to which a species is a habitat generalist or specialist, etc.) affect their response to chemical cues, and we touch briefly on some recent highlights relevant to the critical interplay between hydrodynamics and chemistry. A number of important methodological concerns are now being addressed through the introduction of field assays and analyses for chemical cues, and through molecular techniques for the characterization of

microbial biofilms. These developments are encouraging, as is the increasingly multidisciplinary and cross-taxonomic approach to research in this area.

Key Words—fouling; larval inducers biofilms; infection; chemical signalling.

INTRODUCTION

Most marine benthic organisms spend some portion of their existence—hours to many months, depending on the taxa—in the water column as larvae, spores, or other planktonic forms. The transition from a planktonic to a benthic existence is a fundamental change in the life history of benthic organisms and, by definition, requires colonization of a surface. These surfaces may be living (other marine organisms) or inanimate (primary substrata), although given the ubiquitous presence of microbial biofilms in marine systems (Wieczorek and Todd, 1998; Holmström and Kjelleberg, 2000), truly "inanimate" surfaces are probably rare.

As with other interactions among marine organisms, colonization of surfaces in the sea can be chemically mediated, with naturally produced metabolites acting as both positive and negative cues. Although we know that such cues can range from general properties of water chemistry such as salinity (Welch and Forward, 2001) to specific organic metabolites (Tsukamoto et al., 1999), the exact nature of the cues, their distribution in the habitat, and their importance for the demography of the interacting organisms is poorly known for all but a few systems. This contrasts with chemically mediated marine consumer–prey interactions, where a number of metabolites have been characterized, quantified, and shown to have strong effects on the behavior, demography, or community properties of consumers or their prey (see reviews in McClintock and Baker, 2001).

There are a number of recent reviews on chemical cues for colonization that together provide a comprehensive background for the subject (Fusetani, 1997; Slattery, 1997; Wieczorek and Todd, 1998; Fingerman et al., 1999; Holmström and Kjelleberg, 2000; Zimmer and Butman, 2000; Hadfield and Paul, 2001; Rittschof, 2001; Steinberg et al., 2001). Even a condensed overview of the topic as a whole is not practical here and, thus, we focus on a few general issues in the field that we believe are topical and important, while emphasizing the diversity of interactions that fall within the topic. Our focus will be on organisms as producers of naturally occurring cues as well as responders, in keeping with this volume's theme of interactions among organisms. Finally, we use the term "colonization" here in a broad sense, recognizing that the term can encompass a variety of different processes.

INDUCERS VERSUS INHIBITORS

Chemical cues can either enhance (inducers) or inhibit (inhibitors, "natural antifoulants") colonization. Most inducers of colonization appear to be primary metabolites such as sugars and/or carbohydrates or amino acids, peptides, and/or

proteins. They are also often water soluble or, if larger insoluble macromolecules, have water-soluble components that also function as cues. For example, small naturally occurring peptides induce settlement or metamorphosis of larvae of abalone (Morse, 1992; Roberts, 2001), oysters (Zimmer-Faust and Tamburri, 1994), sand dollars (Burke, 1984), nudibranchs (Lambert et al., 1997), and jellyfish (Fleck et al., 1999). Larger insoluble proteins induce settlement of barnacles (Clare and Matsumura, 2000). Carbohydrates induce settlement of corals (Morse and Morse, 1991, 1996), sea slugs (Krug and Manzi, 1999), and sea urchins (*Holopneustes purpurascens*) (Williamson et al., 2000), although an additional algal derived cue also induces metamorphosis of *H. purpurascens* (R. Swanson et al., unpublished). Partially characterized inducers of invertebrate settlement from bacterial biofilms are also frequently carbohydrates (Kirchman et al., 1982; Szewzyk et al., 1991). For both carbohydrates and proteins, the extent to which the active component of the cue is insoluble and surface bound versus released and water soluble is not always clear, and both may be present for inducers of corals (Morse and Morse, 1991), abalone (Morse, 1992), and barnacles (Clare and Matsumura, 2000). Glycoglycerolipids, compounds of mixed carbohydrate–fatty acid biosynthesis, from the green alga *Ulvella lens* induce settlement and metamorphosis of sea urchins (Takahashi et al., 2002). Fatty acids alone may also act as naturally occurring inducers of larval settlement, although the best known example of fatty acid inducers, for the tube worm *Phragmatopoma lapidosa californica* (Pawlik and Faulkner, 1986; Pawlik, 1990), has been challenged (Jensen and Morse, 1990; Jensen et al., 1990). One of the few fully characterized inducers, lumichrome from the ascidian *Halocynthia roretzi*, is a derivative of riboflavin (Tsukamoto et al., 1999).

A few inducers do not fit this general pattern of primary metabolites. The nonpolar secondary metabolite haliclonacyclamine from the sponge *Haliclona* sp. 628 induces settlement, but not metamorphosis, of the ascidian *Herdmania curvata* (Green et al., 2002) and, thus, is an example of a metabolite that acts on only one of the cascade of processes involved in colonization. A more general exception may be the nonpolar bacterial signal molecules acylated homoserine lactones (AHLs), the inducers in regulatory pathways, which control a wide range of colonization-relevant phenotypes in gram-negative bacteria (reviewed by Dunny and Winans, 1999; Whitehead et al., 2001; see below).

In contrast to inducers, deterrents appear to be primarily nonpolar secondary metabolites (Steinberg et al., 2001). Better known examples include halogenated furanones from the red alga *Delisea pulchra* (de Nys et al., 1995; Dworjanyn et al., 1999; Dworjanyn, 2001), terpenoids from the brown alga *Dictyota menstrualis* (Schmitt et al., 1995), and a variety of metabolites from sponges (Walker et al., 1985; Kubanek et al., 2002; Faimali et al., 2002). A much wider array of nonpolar metabolites from marine eukaryotes, when extracted from whole organisms, also deter colonization (Clare, 1996; Rittschof, 2001), but it is mostly unclear whether these compounds are active at surfaces in situ (de Nys and Steinberg, 1999).

Several explanations have been proposed for the differences in the nature of inducers versus deterrents (Rittschof, 1990; Steinberg et al., 2001). First, selection pressures acting on deterrents are different. Selection for deterrents should act most strongly on the producing organism, which needs to deter a broad suite of typically generalist (Wahl and Mark, 1999) colonizers that will usually have alternative sites for settlement. Selection for inducers should act primarily on the receiving organism to maximize its ability to detect and respond to cues, regardless of whether those cues are passively or actively produced.

Second, deterrents need act only at the surface of the producer, which is facilitated by metabolites that associate with the organic surfaces of producing organisms and have low solubility in seawater. In contrast, the inducers should be detectable from as far away as possible, which will be facilitated by water-soluble metabolites that often "leak" from the producing organism. This may explain why large insoluble inducers derived from, for example, cell walls often appear to have associated water soluble cues, which are either separate metabolites or dissociable components of the larger molecule (Morse and Morse, 1991; Krug and Manzi, 1999; Clare and Matsumura, 2000).

Third, given the potential for rapid dilution of cues once in the water column, inducers should be present in as high a concentration as possible. Individual non-polar secondary metabolites are typically produced at $<1\%$ of the dry weight of an organism, and as surface components they may be present at much lower levels (Dworjanyn et al., 1999). Primary metabolites—particularly carbohydrates—in marine organisms can be present at much higher concentrations.

Finally, organisms should be preadapted to use primary metabolites as inducers. Many marine organisms can absorb nutrients—simple sugars, amino acids—directly from the environment, and can respond to concentration gradients of these nutrients *via* chemotaxis (Amsler and Iken, 2001). In such instances, the nutrients (primary metabolites) function directly as signals. Nutrients in aquatic systems often accumulate at surfaces and, thus, provide a strong cue for the presence of surfaces even when no longer directly utilized as food. Many organisms also use primary metabolites—particularly peptides and amino acids or their derivatives—as components of internal signal transduction systems (Rittschof, 1990; Slattery, 1997). Thus, the receptor machinery for responding to similar but externally derived signals is already available to many taxa.

Methodological Issues: Characterization, Localization, and Quantification of Cues

The actual indentity of cues for colonization, whether they are present at or near a surface, and, if so, at what concentrations is known for remarkably few metabolites, and the issues for deterrents versus inducers again appear different in this respect. Because many inducers are small water-soluble molecules present against a background of similar molecules or complex macromolecules that may

be components of cellular skeletons, they have proven hard to characterize (Krug and Manzi, 1999; Clare and Matsumura, 2000; Hadfield and Paul, 2001). There are few source-specific, ecologically relevant inducers of colonization for which chemical structures are known. Examples include lumichrome from the ascidian *Halocynthia roretzi* (Tsukamoto et al., 1999), the floridoside–isethionic complex from red algae (Williamson et al., 2000), haliclonacyclamine from the ascidian *Herdmania curvata* (Green et al., 2002), glycoglycerolipids from the green alga *Ulvella lens* (Takahashi et al., 2002), and bacterial acylated homoserine lactones (Dunny and Winans, 1999).

In contrast, because most known deterrents are small nonpolar metabolites, they are amenable to the standard techniques of natural products chemistry. For deterrents, the primary issue has been whether the metabolites are present at or near the surface of the organism at biologically effective concentrations (Clare, 1996; de Nys and Steinberg, 1999). Examples of deterrents that have been localized and quantified at or near the surface are relatively few and mostly exist for seaweeds or sponges. Furanones from the red alga *Delisea pulchra* are encapsulated in vesicles in gland cells that are present at the surface (Dworjanyn et al., 1999) and release the compounds to the surface at concentrations what deter common epibiota (de Nys et al., 1995, 1998; Maximilien et al., 1998). Terpenoids in natural concentrations of surface extracts from the brown seaweed *Dictyota menstrualis* deter settlement of the bryozoan *Bugula neretina* (Schmitt et al., 1995). In contrast, other algal metabolites either do not appear to be present on the surface (de Nys et al., 1998) or if released at the surface are not present at sufficiently high concentrations (Jennings and Steinberg, 1997). Information on the localization of sponge secondary metabolites is rapidly increasing (e.g., Salomon et al., 2001; Faimali et al., 2002, Kubanek et al., 2002), and some of these metabolites are present at the (often morphologically complex) surface of sponges. Quantification of sponge deterrents is still relatively rare (Kubanek et al., 2002), but includes some of the earliest work on this topic (Walker et al., 1985). For bacterial biofilms, concentrations of inducers have been shown to vary dramatically on very small scales. Charlton et al. (2000) found that concentrations of acylated homoserine lactones (AHLs) in biofilms in flow cells were 3–4 orders of magnitude higher than in the bulk fluid millimeters above the biofilm. A variety of both high-tech [flow cytometry, immunolabeling, epiflourescence, and confocal laser microscopy, (XPS)] and low tech (surface swabbing and extraction, analysis of water samples collected at specified distances from a source) are now available for investigating and quantifying chemical cues at surfaces.

PROKARYOTE–EUKARYOTE INTERACTIONS

Marine prokaryotes: (1) communicate among themselves during the establishment of surface communities (such as in the formation of microbial biofilms), (2)

as colonists respond to eukaryotic chemical cues, and (3) are, in return, important as producers of cues for the settlement of eukaryote propagules.

Research on chemical communication among bacteria as a modulater of colonization of surfaces is a growth industry, but only recently is it intersecting with analogous studies for marine eukaryotes. Much of this work focuses on bacterial cell–cell signaling (reviewed by Dunny and Winans, 1999; Whitehead et al., 2001; Winans and Bassler, 2002), also known as quorum sensing because of its importance in high-density bacterial populations. The two most widely known examples of bacterial signaling are the acylated homoserine lactone (AHL) and autoinducer 2 (AI-2) systems. The details of the two systems differ (as do aspects of each system among different bacteria), but each is based on small signaling molecules (AHLs or the recently identified AI-2 signal, respectively) that diffuse between and into bacterial cells. These signals dock into a receptor protein, initiating a series of cellular and molecular events leading to the rapid up-regulation of bacterial phenotypes often used for surface colonization or association with eukaryote hosts. These phenotypes include biofilm formation (Davies et al., 1998; Lynch et al., 2002), bacterial surface motility (Eberl et al., 1999), production of extracellular products that allow for colonization or attack of hosts (Kievit and Iglewski, 2000), and host-microbe symbioses (Rodelas et al., 1999; Visick and Ruby, 1999).

Although the marine squid–luminescent bacteria symbiosis is one of the model systems for AHL regulation (Visick and Ruby, 1999), the more general role of microbial signaling systems for marine surface dwelling bacteria is not yet well understood. However, it is likely that it will be generally important for bacterial colonization of marine surfaces. Such signaling systems are widespread in bacteria in general (Dunny and Winans, 1999; Winans and Bassler, 2002), including marine species, and the signals are present in situ in both natural aquatic (McLean et al., 1997) and marine (M. Taylor et al., unpublished) biofilms. Both marine (Kjelleberg and Steinberg, 2002) and terrestrial (Bauer and Robinson, 2002) eukaryotes have evolved metabolites that specifically interfere with these signaling systems and thereby inhibit colonization by bacteria. More generally, the potential for chemical communication among marine bacteria at surfaces appears high (Burgess et al., 1999).

Most research on the response of prokaryote colonists to eukaryote hosts has focused on deterrents, and there are numerous studies on the inhibition of microorganisms by extracts or metabolites from marine eukaryotes done in a biomedical or other applied contexts (e.g., Hornsey and Hilde, 1974; Hellio et al., 2001). More recently, deterrence of bacterial colonization has been put in a more ecological context (e.g., Wahl et al., 1994; Maximilien et al., 1998; Kubanek et al., 2002). Interestingly, a number of these later studies highlight specific effects against bacterial colonization per se, rather than generalized bacteriostatic or growth effects. For example, Wahl et al. (1994) demonstrated that metabolites from ascidians

specifically inhibited attachment of bacteria. Halogenated furanones from the red alga *Delisea pulchra* also inhibit specific colonization phenotypes of marine bacteria (Maximilien et al., 1998) at natural concentrations with little or no effects on growth or survival of the bacteria. The likely mechanism for this effect is the inhibition of bacterial signal based regulatory systems by furanones. We (Manefield et al., 1999, 2002; Rasmussen et al., 2000; McDougald et al., 2001) and others (Ren et al., 2001) have shown that furanones specifically interfere with both the AHL and AI-2 systems, resulting in inhibition of phenotypes such as surface motility, exoenzyme production, and biofilm formation and/or stability.

Chemical cues from eukaryotes may also significantly affect the community composition of surface-associated bacterial assemblages. Several chemically rich tropical marine algae have an unusually high proportion of gram-positive bacteria on their surfaces (Jensen and Fenical, 1995), relative to the predominance of gram-negative bacteria in seawater (e.g., Mullins et al., 1995; Cottrell and Kirchman, 2000). Similarly, both culturing studies and pattern analysis of PCR-products via denaturing gradient gel electrophoresis (DGGE) has revealed a high proportion of gram-positive bacteria, particularly high G-C gram-positive strains, on the surface of those portions of *Delisea pulchra* that are richest in furanones (Holmström et al., unpublished). Although key field experiments that directly test the role of eukaryote metabolites on community composition of surface associated bacteria have not yet been done, these and other (Holmström et al., 1996; Burgess et al., 1999; Friederich et al., 2001) studies of the bacterial flora of eukaryotic hosts suggest that such communities differ significantly from those in the surrounding seawater.

A somewhat different, but potentially widespread, mechanism for the inhibition of microbial colonization and infection of marine eukaryotes is the so-called oxidative burst, described for several species of seaweeds (Weinberger and Friedlander, 2000a,b; Bouarab et al., 2001; Kupper et al., 2001). Analogous to the oxidative burst in terrestrial plants, the response is induced by oligosaccharides generated by the degradation (such as through bacterial metabolism) of host cell wall constituents or by bacterial peptides (Weinberger and Friedlander, 2000b). The oligosaccharides induce the production of hydrogen peroxide by the host at concentrations sufficient to kill marine bacteria in laboratory studies. Several seaweeds respond similarly to endophytic algal parasites (Bouarab et al., 2001).

As well as responding to eukaryotic signals, marine prokaryotes—particularly when within microbial biofilms—have a strong influence on the colonization of surfaces by higher organisms (reviewed by Wieczorek and Todd, 1998; Holmström and Kjelleberg, 2000), both in laboratory assays and in the field (Keough and Raimondi, 1995). Most evidence for the effects of biofilms on settlement is for larvae of marine invertebrates (Wieczorek and Todd, 1998), and some larvae (i.e., the tubeworm *Hydroides elegans*) require a biofilm for settlement (reviewed in Hadfield and Paul, 2001). Colonization by at least some macroalgae is also influenced by biofilms (Joint et al., 2000).

Biofilms can enhance or deter settlement of eukaryotic propagules**.** However, the chemical cues from biofilms that are responsible for modulating settlement have mostly not been characterized, or quantified in situ. Inducers of settlement from bacteria investigated to date appear to be polysaccharides or to have polysaccharide components (Kirchman et al., 1982; Szewzyk et al., 1991). Deterrents are diverse. Bacterial ubiquinone inhibits settlement of barnacles (Kon-ya et al., 1994). *Pseudoalteromonas tunicata* produces several distinct metabolites, ranging from a small water-soluble metabolite to a large protein, which individually inhibits bacteria, fungi, algal spores, or invertebrate larvae (reviewed by Holmström and Kjelleberg, 1999). The inhibitory properties of *P. tunicata* are particularly interesting in that its distribution at several sites in both Denmark and near Sydney, Australia, appears restricted to hosts such as *Ulva lactuca* and *Ciona intestinalis*, which lack known endogenous deterrents. [This conclusion of host specificity is based on DGGE and quantitative real-time PCR analysis of bacteria on these and other common potential hosts (Skovhus, unpublished)]. Thus, bacteria such as *P. tunicata* may provide a mechanism for chemical deterrence of colonization for hosts that lack their own defenses (Armstrong et al., 2001; Kjelleberg and Steinberg, 2002).

This later suggestion highlights the potential for cues from living surfaces to emanate from a host or from the associated biofilm (and specific bacteria within the biofilm, e.g., Unabia and Hadfield, 1999). Inducers of settlement from coralline red algae are an excellent example of this issue. Cues associated with coralline algae induce settlement of a range of marine invertebrates, including abalone, seastars, and corals (reviewed by Hadfield and Paul, 2001). In all three of these examples, there is evidence for at least some species that the relevant cues derive from biofilms rather than from the host (Johnson and Sutton, 1994; Roberts, 2001; Negri et al., 2001). Cues acting synergistically between biofilms and hosts may also be a common phenomenon, as Negri et al., (2001) showed for bacterial inducers of settlement of coral larvae, which are effective only in the presence of calcareous substrata. Other difficulties arise because the bacteria that are the putative source of the cues may be unculturable. Finally, although we have argued that bacterial biofilms on the surface of eukaryotes can affect settlement of eukaryote propagules, it is illuminating to consider the biomass of bacteria on a surface and its implications for the amount of cue that can be produced. Typical reported densities from SEM counts (10^6–10^7 cells/cm^2) (Wahl, 1995; Maximilien et al., 1998) of average sized marine bacteria ($1 \times 1 \times 2$ μm) on the surface of marine eukaryotes represent approximately 2–20 μg of biomass per cm^2 of surface (wet weight; assumes 1 $\mu g = 1 \mu m^3$) for all strains combined. At these densities, a typical cue that is active in the low micromolar range would need to represent a significant fraction of the metabolic output of the bacteria to be effective in situ, particularly if exuded.

Methodological Issues: Marine Chemical Ecology and Molecular Microbiology

Understanding the role of microbial biofilms in chemical ecology would be substantially enhanced if we knew what bacteria were out there and in what numbers. It is encouraging that molecular-based tools for community analysis of prokaryotes are developing rapidly (reviewed by Dahllöf, 2002) and are beginning to be applied to assemblages on marine surfaces. The distribution of different bacterial groups can be analyzed directly (microscopically) using fluorescent in situ hybridization (FISH). FISH is limited in a practical sense by the number and taxonomic level of available oligonucleotide probes and by the suitability of different target genes and, thus, is most suitable for targeting specific bacterial species or groups. Other methods for community-wide analyses use extracted DNA directly for slot-blot hybridization or for DNA microarrays in which template genes are probed with DNA or PCR products from the environmental sample. Several other techniques based on pattern analysis of PCR products separated on gels allow for rapid comparisons between different samples or communities. Common examples include denaturing or temperature gradient gel electrophoresis (DGGE and TGGE, respectively). Comparisons of the banding patterns between samples and reference strains in DGGE, or sequencing of individual bands followed by comparisons with sequence libraries, then allow for identification of species. Finally, although in its infancy, detection of bacterial function genes in situ (Dahllöf, 2002), such as those responsible for the production of cues, may ultimately provide an alternative to chemical methods for detecting cues in situ.

EPIPHYTES, PARASITES, SPECIALISTS, GENERALISTS, AND SESSILE VERSUS MOBILE COLONISTS

The consequences of variation in the life history of plants or herbivores have played a fundamental role in the development of theory on plant–herbivore interactions (reviewed by Cronin, 2001). In contrast, the effects of variation in life history or general natural history parameters on chemical mediation of surface-based interactions are largely unexplored. Life history properties of epibiota vary enormously, from bacteria with generation times of hours to invertebrate larvae, which can spend months in the plankton. Mobility of propagules and benthic forms varies from active swimmers to immobility. These differences should in principle provide a rich source of general hypotheses regarding the relative importance of chemical cues for different colonizers. For example, the degree of stringency by which a propagule responds to a cue should reflect both a) the length of time in which it can remain competent and delay settlement and b) the extent to which it or the resulting juvenile can depart the initial site of settlement following a mistake. Thus, we might expect relatively short-lived, nonmotile spores of sessile red algae to be both more

resistant to deterrents and to rely less on specific chemical inducers of settlement than relatively long lived, motile invertebrate larvae (or motile algal propagules). In the only direct test of such ideas, Krug and Zimmer (2000) found no differences in the response of planktotrophic versus lecithotrophic larvae of the slug *Alderia modesta* to carbohydrate cues from its golden green algal host *Vaucheria longicaulis.*

We can also ask whether colonizers that respond strongly to chemical cues are primarily habitat specialists or generalists. Wahl and Mark (1999) have argued that most epibiota are generalists, and many common species or genera of epibiotic algae (e.g., *Enteromorpha, Polysiphonia, Ectocarpus*) or invertebrates (*Hydroides, Bugula*) have wide geographical distributions and occur across a range of habitats or host species. Such organisms might be expected to respond less stringently to specific inducers of colonization than taxa that have a narrow host or habitat range. Some of the strongest responses to inducers are for organisms that are either relatively narrow in their habitat use (Krug and Manzi, 1999; Williamson et al., 2000) or that settle/metamorphose primarily in response to cues associated with conspecifics (Zimmer-Faust and Tamburri, 1994; Tsukamoto et al., 1999).

Several authors have speculated on the role of biofilms in the context of specialized versus generalized cues for colonization. Johnson et al. (1997) suggested that colonization of marine invertebrates was broadly mediated by biofilms, with habitat generalists responding to many components of biofilms in the habitat, and more specialized organisms responding to specific bacterial strains within biofilms. Steinberg et al. (2001) argued that habitat generalists should respond to components of biofilms that are broadly distributed across habitats or hosts, with specialists responding to cues associated with specific hosts or conspecifics. These suggestions raise a number of questions, including: (1) What is the composition of biofilms on different hosts or in different habitats, e.g., is there sufficient variation in biofilm composition across hosts or habitats to provide specialist cues? (2) Are specific strains of bacteria present in sufficient biomass to present a detectable, localized cue for specialist colonizers? Again, the emerging tools of molecular analysis of microbial communities should help answer these questions.

Finally, parasites often represent the most specialized organisms in many systems, yet the chemical ecology of marine host–parasite interactions is largely unexplored. Compounds that deter fungal endophytes or pathogens have been identified (Gil-Turnes et al., 1989; Jensen et al., 1998), but any understanding of how parasites find and infect hosts is largely restricted to a few studies of algal endophytes and their carbohydrate signals. Endophytic algae distinguish between agarophytes (nonhosts) and carrageenophyte hosts (Sanchez et al., 1996) and between different life history stages of host species based on the presence of specific oligosaccharides derived from host plant cell wall (reviewed by Bouarab et al., 2001). Carbohydrates (sulfated galactans) are also the signal for host infection by the fungal parasite *Pythium porphyrae* on its host *Porphyra yezoensis* (Uppalapati

and Fujita, 2000). In this later example, a broad range of red algae induces attachment and encystment of *P. porphyrae*, but a host specific cue is needed to induce the final stage of infection (appressorium formation).

CHEMISTRY, HYDRODYNAMICS, AND DEMOGRAPHY

A major issue for any consideration of chemical cues for colonization is the ability of organisms to detect and respond to relevant cues in the complex hydrodynamic environment found in marine benthic habitats. This topic has been a focus of the field (particularly for invertebrate larvae) for many years (Butman, 1987; Zimmer and Butman, 2000) and is reviewed separately in this volume (Weissburg). However, several relatively recent advances are worth noting. Importantly, cues are now being deployed in the field (e.g., in natural flow regimes) including inducers (Raimondi and Morse, 2000; Browne and Zimmer, 2001) and inhibitors (Henrikson and Pawlik, 1995; Christie et al., 1998; Maximilien et al., 1998; Kubanek et al., 2002). Although various methodological issues remain (e.g., what is the concentration and presentation of cues in artificial matrices relative to the natural source?), these studies have often demonstrated strong effects for chemical cues. The study of Raimondi and Morse (2000) is particularly notable, as they included the cue for coral settlement in a multifactorial field experiment in which the importance of the cue relative to other factors was assessed.

Many propagules of marine organisms are also turning out to be much better swimmers than originally thought, implying that their capacity to respond actively to chemical cues is also much greater than initially believed. Larvae of many fish species are capable of both high speeds and sustained swimming effort (Leis and Carson-Ewart, 1997; Fisher and Bellwood, 2002), and some marine bacteria can swim at hundreds of body lengths per second and take advantage of channels and other microstructures in water as a way of enhancing their chemotactic responses (Blackburn et al., 1998). Other aspects of propagule behavior—such as the extent to which a response to a cue relies on a concentration gradient versus a concentration threshold—can also significantly affect the ability of a propagule to respond to a chemical cue in situ. Ultimately, from an ecological perspective, the goal is to understand how the distribution of a chemical cue in situ affects the demography of the target organism(s) (Raimondi and Morse, 2000; Williamson et al., 2000). The developing focus on in situ analyses and deployment of cues, propagule behavior, and colonization should enhance our understanding of the chemical ecology of colonization in the same way that it has furthered other branches of marine ecology.

CONCLUSIONS

There are good reasons to be positive about the future of research on chemical mediation of colonization in the sea, as the past five years or so have seen a

number of significant advances. These include the first characterizations of many inducers of invertebrate settlement, an explosion in research on bacterial chemical ecology (signaling) and biofilm biology, the first detailed quantifications of surface deterrents, field experiments using purified cues, advances in molecular techniques with considerable utility for the field, and, related to this the increasing interface between molecular mechanisms and ecological consequences (Kjelleberg and Steinberg, 2002; Green et al., 2002). Encouragingly, a more diverse view of the topic appears to be emerging, incorporating novel developments in host–parasite or prokaryote–eukaryote interactions as well as research into longer standing areas such as induction of invertebrate larval settlement.

Acknowledgments—Our research on chemical mediation of surface colonization has been supported by Australian Research Council Large Grants to P.D.S., S.K., and R.d.N., an ARC Research Fellowship to R.d.N., and the Centre for Marine Biofouling and Bio-Innovation. We thank J. Partridge and O. Ison for their help in preparing the manuscript.

MINI REVIEW

ECOLOGICAL CONSEQUENCES OF CHEMICALLY MEDIATED PREY PERCEPTION

(Received June 14, 2002; accepted June 18, 2002)

Abstract—To locate food, mobile consumers in aquatic habitats perceive and move towards sources of attractive chemicals. There has been much progress in understanding how consumers use chemicals to identify and locate prey despite the elusive identity of odor signals and the complex effects of turbulence on chemical dispersion. This review highlights how integrative studies on behavior, fluid physics, and chemical isolation can be fundamental in elucidating mechanisms that regulate species composition and distribution. We suggest three areas where further research may yield important ecological insights. First, although basic aspects of stimulatory molecules are known, our understanding of how consumers identify prey from a distance remains poor, and the lack of studies examining the influence of distance perception on food preference may result in inaccurate estimation of foraging behavior in the field. Second, the ability of many animals to find prey is greatest in unidirectional, low turbulence flow environments, although recent evidence indicates a trade-off in movement speed versus tracking ability in turbulent conditions. This suggests that predator foraging mode may affect competitive interactions among consumers, and that turbulence provides a hydrodynamic refuge in space or time, leading to particular associations between predator success, prey distributions, and flow. Third, studies have been biased towards examining predator tracking. Current data suggest a variety of mechanisms prey may use to disguise their presence and avoid predation; these mechanisms also may produce associations between prey

distributions and flow environments. These examples of how chemical attraction may mediate interactions between consumers and their resources suggest that the ecology of chemically mediated prey perception may be as fundamental to the organization of aquatic communities as the ecology of chemical deterrence.

Key Words—Chemical attraction, chemosensation, community structure, flow, foraging, odor plumes, olfaction, orientation, predator-prey, turbulence.

INTRODUCTION

Over the last 15 years, investigating how natural metabolites mediate biotic interactions has provided valuable insight into the forces shaping the structure of marine communities. Chemical ecology is a vibrant field that helps explain why prey are rare, how animals should allocate energy in their defense, and the role of generalist versus specialist predators in regulating community structure (Hay, 1996). These issues have been studied largely through a focus on chemical defense, and studies of how chemical deterrents affect biotic interactions have become the type of investigation most closely identified with the field of chemical ecology in general. However, just as some chemicals deter consumers, others allow consumers to identify and locate prey from a distance. Although not as fully developed as the study of deterrents, the study of chemical attractants may be of equal importance in determining how biotic interactions affect populations and communities and is an area poised for exciting new developments.

Chemically mediated prey search and identification has been examined in a number of different organisms and in systems ranging from abyssal depths to shallow subtidal and intertidal communities. These studies have emphasized tracking behavior, the properties of sensory systems necessary for odor-guided navigation, or the characterization of attractant compounds. Only rarely have workers investigated the ecological implications of long-distance perception and location of prey in natural communities or realistic laboratory settings. We believe this reflects technical challenges in establishing basic features of chemically mediated attraction, rather than lack of appreciation for, or disinterest in, consequent ecological implications.

The molecular nature of chemical stimuli and the distribution of signals in nature determine how consumers are able to discern and locate prey. Thus, acquiring a basic understanding of the identity of attractant molecules and the physics of odor dispersal is necessary to evaluate the ecological implications of distance perception, but is technically challenging. First, consumers are more likely to use mixtures, perhaps of common compounds, rather than single cues to identify prey. In some cases, the difference between a highly attractive versus a less enticing mixture is simply the ratio of its components, rather than the presence or absence of a distinctive moiety (e.g., Carr and Derby, 1986a,b; Steullet and Derby, 1997).

Identifying attractant stimuli, therefore, is likely to be more difficult than determining the nature of a unique predator deterrent. Second, unlike most deterrent compounds, attractant compounds that mediate distance perception are released into the water. Consequently, extraction and identification of attractants must begin with aqueous solutions derived from intact prey and may be hindered by the considerable dilution of the stimulus. Third, because attractants are transported to animals by flow, it is also necessary to determine the properties of chemical signals in turbulent fluids. However, progress in understanding both the chemical nature of attractant compounds and the role of physical processes in structuring odor signals is now sufficient so that examining ecological implications of chemically mediated predation is feasible.

The purpose of this review is to summarize the progress in understanding chemically mediated prey search and to highlight the potential ecological implications of chemically mediated foraging for community organization. The current state of knowledge enables us only to hint at how prey identification and localization by waterborne cues may affect ecological patterns and processes. Yet, even these brief glimpses may help broaden the field of chemical ecology and move the study of chemical attractance beyond behavioral analysis and characterization of stimulus properties to an understanding of effects on population regulation and community structure. Given the availability of recent reviews on chemical plumes in relation to flow, navigational and guidance strategies, and the chemical nature of attractant compounds (Carr, 1988; Carr et al., 1996; Vickers, 2000; Weissburg, 2000; Zimmer-Faust and Butman, 2000), we focus this review more narrowly and address important issues that are still unsettled or ones where greater understanding may provide insights into basic ecological processes.

THE NATURE OF CHEMICAL ATTRACTRANTS

Despite decades of investigation, the identity of waterborne attractants is still unclear, even for well characterized systems. This surprising fact has two main explanations. First, as noted above, chemical characterization of complex mixtures is technically challenging. Second, the goal of many early studies was to examine physiological properties of the chemosensory system of aquatic animals (e.g., Pearson and Olla, 1977; Carr, 1978; Carr and Derby, 1986a,b) that were poorly known at that time. Consequently, initial bioassays of attractant molecules tended to employ easily identifiable, common, and widely available constituents of animal (or occasionally plant) tissue such as amino acids, nucleotides, and simple sugars or organic acids. Although these chemicals are present in flesh, it is not always clear that they are released in sufficient quantities to mediate distance perception (see below), and they may primarily elicit feeding as opposed to orientation.

There is broad agreement that amino acids and other small molecules are highly stimulatory. Mixtures of 6–25 amino acids, sometimes with quaternary

ammonium compounds, nucleotides, and simple organic acids, have been extensively employed and usually are more effective than any single component (Carr, 1978, 1988; Zimmer-Faust and Case, 1982b; Carr and Derby, 1986a,b; Zimmer-Faust, 1989; Carr et al., 1996), although individual nucleotides can be highly attractive (Zimmer-Faust, 1993). For instance, Carr (1978) used a mixture of betaine and 18 amino acids to assay responses of the shrimp *Palaemonetes pugio*. Still, there is considerable debate regarding the significance of current observations for identfying attractant compounds. Although low-molecular-weight metabolites are clearly important feeding cues, the hypothesized primacy of these substances for orientation has not received a rigorous and comprehensive evaluation (Zimmer-Faust, 1989; Zimmer-Faust and Butman, 2000). Zimmer-Faust (1989) summarizes caveats and provides suggestions on ways to assay attractant compounds that are appropriate for examining distance perception.

Ecologically relevant experiments must present consumers with a flux of attractant molecules similar to that emanating from natural prey. Unrealistically intense chemical cues can stimulate chemosensors that normally mediate near-source search or feeding rather than distance search, because neurons in various appendages may be sensitive to the same suite of compounds but differ in their sensitivity to these chemicals (Caprio et al., 1993; Voigt and Atema, 1992; Weissburg and Derby, 1995). Consumers responding to abnormally elevated signals may not be displaying true distance tracking but, instead, behaviors that occur close to the source or reflexive motions involved in feeding and ingestion. Extracts of ground prey flesh almost certainly result in more intense signals and different mixtures of stimuli than consumers normally experience. Even prey soaks or body washes may produce unnatural stimulus intensities, particularly if prepared using multiple prey soaked in relatively small volumes for long time periods. Few studies have measured flux rates of potential attractant compounds released by living or dead prey as a way to scale flux rates of stimuli in experiments. Limited observations suggest considerable variance in the release of amino acids or ammonia waste products among different prey and differences in the quantity and identity of compounds released by injured, freshly dead, and live prey (Zimmer et al., 1999; Finelli et al., 2000). Mixtures of the 18 most abundant amino acids from bivalve or crustacean flesh released at natural flux rates attracted mud snails (*Ilyanassa obsoleta*) at rates to similar those of fresh carrion, but blue crabs remained disinterested in amino acid plumes mimicking the composition and flux from freshly injured clams (Zimmer et al., 1999; Finelli et al., 2000). Since flux rates in the two experiments differed substantially, the results do not necessarily indicate that crustaceans will not track amino acid plumes, only that injured bivalves do not release these metabolites in sufficient quantities. The concentration of amino acids released by live bivalve prey is less than that found in ambient seawater and below the limit of detection by HPLC, suggesting that amino acids are unlikely to attract consumers to bivalves under natural conditions (Zimmer et al., 1999). The

propensity of marine animals to absorb and not release amino acids (Wright and Manahan, 1989; Manahan, 1990) further suggests they may be generally inappropriate cues. Peptides mediate the predatory response of oyster drills at nanomolar levels (Rittschof, 1990), although the release rates from prey have not been determined. Lobsters appear to be attracted not to amino acids, but to unidentified high molecular weight compound(s) (Zimmer-Faust and Case, 1982a).

The search for a single compound, or even a class of compounds, that stimulates tracking in a particular species may be quixotic, particularly if composition and concentration is as variable across prey species as suggested by current studies (e.g., Zimmer et al., 1999; Finelli et al., 2000). Animals can detect a large number of compounds, and the combinatorial scheme used to identify chemical blends permits the recognition of a variety of mixtures (Derby and Atema, 1988; Sorensen and Caprio, 1997). Given this diversity in production and recognition, why should we expect animals to utilize only a limited range of potential information? It may be that certain compounds make poor signal molecules because they are naturally present at high concentrations with little correlation to prey availability or are not persistent over spatial or temporal scales that would facilitate tracking. A continued focus on identifying metabolites that serve as attractants under natural conditions and the environmental context in which they occur (e.g., flow, turbulence) will be necessary to resolve these issues. Future studies also are necessary to diversify the types of animals for which attractants have been successfully identified. Current data are overwhelmingly derived from predators or scavengers of carrion, with crustaceans being particularly well represented. Few studies have examined the orientation of herbivores to plant extracts or plant-conditioned water (but see Mann et al., 1984; Klinger and Lawrence, 1985; Rahman et al., 2000)

MECHANISMS OF ANIMAL NAVIGATION

Navigation to distant chemical sources often has been investigated in flumes using aqueous extracts of animal tissues (Moore and Atema, 1991; Moore and Grills, 1999) or occasionally, live prey (Weissburg and Zimmer-Faust, 1993, 1994). Perhaps the most important discovery from this work has been that odor signals available to large aquatic animals are affected significantly by turbulence (Zimmer-Faust et al., 1988; Moore and Atema, 1991; Weissburg and Zimmer-Faust, 1993). The resulting signal is complex, unpredictable, and highly variable in space and time (Figure 1), which constrains the strategies animals use to find distant chemical sources. Understanding how interactions between the signal source and environment affect the resultant plume characteristics, and how animals devise effective navigational strategies, can help establish the natural conditions where olfactory-mediated predation will be important.

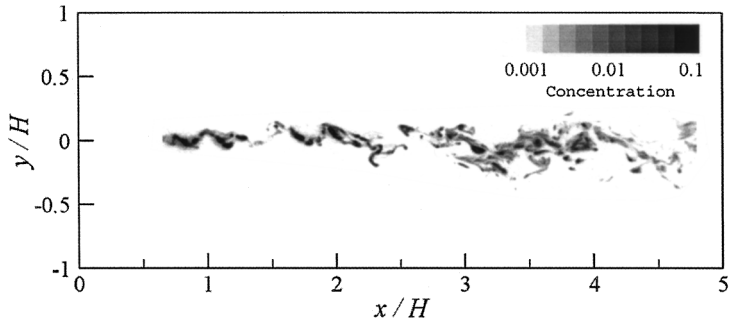

FIG. 1. Chemical concentration field of a turbulent odor plume generated in a laboratory flume. Image shows the chemical concentration field in a chemical plume measured by laser-induced fluorescence. The intensity of light emitted by a dye tracer is captured by a camera and converted to concentration, which is expressed as a proportion of the source concentration (inset). The *y* axis is the cross-stream distance and the *x* axis is the along-stream distance, each expressed relative to the water height, *H* (20 cm). Dye was released from a 3-mm-diam. nozzle located 2.5 cm above the bottom into a flow of 5 cm/sec. Flow is from left to right. Data and further details of this method may be found in Webster et al., (2002).

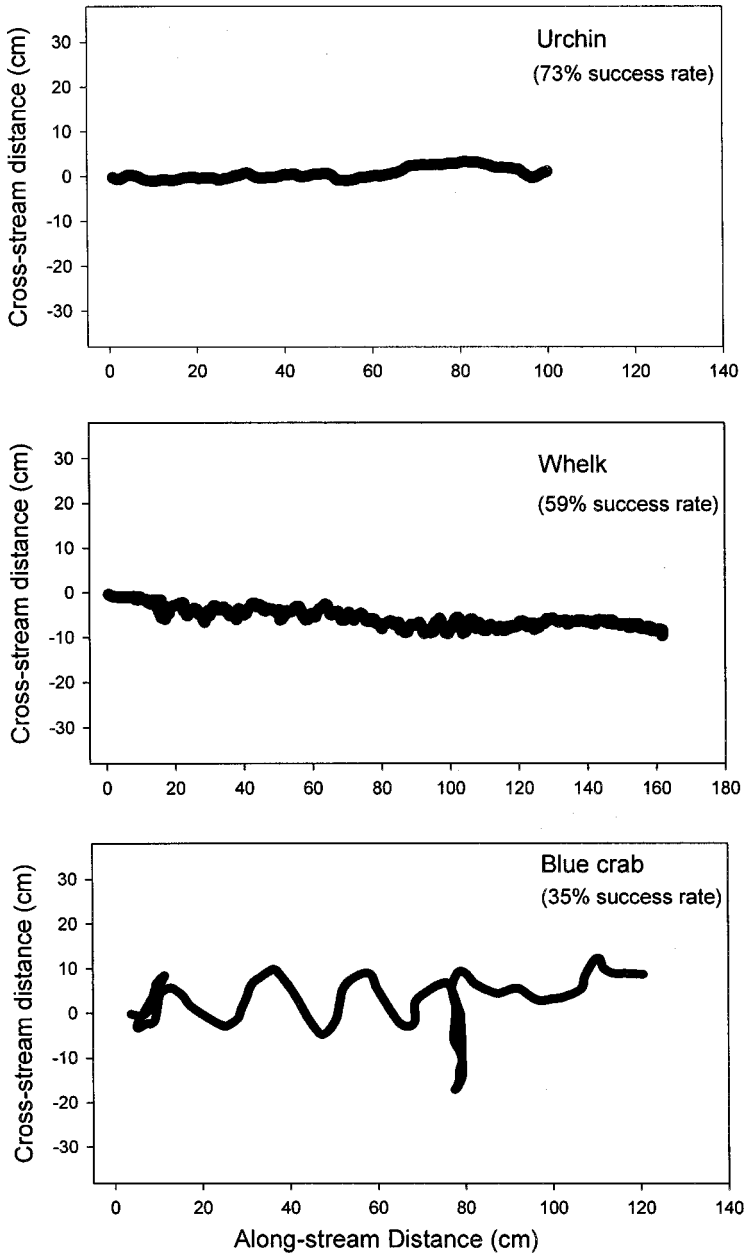
Crustaceans, fishes, gastropods, and echinoderms all orient to waterborne plumes of stimuli derived from animal flesh (Hamner and Hamner, 1977; Moore and Atema , 1991; Lapointe and Sainte-Marie, 1992; Weissburg and Zimmer-Faust, 1993; Montgomery et al., 1999; Weissburg, 2000). Herbivorous organisms, such as some Echinoidea, are thought to be opportunistic diners that find food through fortuitous random encounters, but this may reflect a lack of realistic tests. Several urchin species move towards palatable seaweeds (Mann et al., 1984; Tertsching, 1989) or selectively to seaweeds that differ in their value as food versus sheltering sites (Hay et al., 1986).

The most useful studies for understanding guidance mechanisms are those that take place in natural environments or in carefully controlled, hydrodynamically appropriate settings generated in flumes. Static tanks or Y mazes cannot accurately reproduce the fluid environment experienced by aquatic foragers and are of limited utility. Flumes have been popular due to the difficulty of visualizing animal behavior and monitoring flow in the field, but such facilities are constrained in the scales of turbulence they can generate. Consequently, we have a poor understanding of how large-scale flow features affect consumer foraging in nature. Limited observations suggest that some animals have difficulty following odor plumes with substantial cross-stream movements produced by large-scale turbulence (Lapointe and Sainte-Marie, 1992).

Crustaceans have been extensively studied in quantified or controlled flow conditions (Moore and Atema, 1991, Moore et al., 2000; Weissburg and

Zimmer-Faust, 1993, 1994; Finelli et al., 2000; Weissburg et al., 2002). Blue crabs, and probably most crustaceans, cannot sample long enough at a given location to estimate local average concentrations reliably due to their relatively rapid movement combined with high variability of turbulent chemical plumes (Webster and Weissburg, 2001; Weissburg et al., 2002). In fact, the difficulty of obtaining accurate mean estimates of many odor signal properties indicates they convey little information when sampled temporally, suggesting that using local averages to gauge upstream progress is unlikely to be successful (Webster and Weissburg, 2001; Weissburg et al., 2002). Blue crabs appear to utilize a combination of odor-triggered response to flow (rheotaxis) combined with spatial sensing of concentration fields (Zimmer-Faust et al., 1995; Webster and Weissburg, 2001; Weissburg et al., 2002). Together these two mechanisms allow animals to move generally upstream towards the source while maintaining contact with the odor plume. Odor-triggered rheotaxis appears common for many animals that search for prey in aquatic habitats (Weissburg, 2000).

Riverine or strongly tidal flows present relatively simple fluid environments where animals may rely commonly on rheotaxis because water movements are nominally unidirectional. Not only is flow information available to help guide navigation, but advection causes a net transport of odor, potentially resulting in a long-distance signal. In these simple flows, animals may follow plumes to baited traps located tens of meters away (Lapointe and Sainte-Marie, 1992; Skajaa et al., 1998), suggesting these regions may be unusually permissive of distant source localization, particularly if current velocities are slow and turbulence minimal (see below). However, animals in wave-driven oscillatory flows (Mead and Koehl, 2000), or in areas where bottom topography may produce complex currents (e.g., reefs) also are proficient foragers. A priori, we expect that the effective tracking distances in these habits will be reduced as compared to behavior in unidirectional flows, due both to the difference in physical transport and the absence of a reliable flow cue. Oscillatory flows limit the net movement of odor, whereas complex flows may create a more difficult signal to track because of both large-scale meander and the negative impact of small-scale turbulence (see below).



Animals inhabiting more complex flow environments may reduce their reliance on rheotaxis. Lobsters are thought to use predominantly chemical information during tracking, although firm tests are lacking and conclusions have been based on indirect evidence from studies in limited flow conditions or from behavior of animals with experimentally induced sensory deficits (Reeder and Ache, 1980; Devine and Atema, 1982; Moore and Atema, 1991). These observations provide evidence regarding the importance of chemical information but cannot exclude a rheotactic component. More direct tests are rare, but would include probing for upstream locomotion in response to brief chemical pulses or water velocities below which navigation is impaired (Weissburg and Zimmer-Faust, 1993; Mafra-Neto

and Cardé, 1994, 1998; Finelli et al., 2000), or examining whether animals follow flow streamlines. Flow provides potentially valuable information that could greatly greatly enhance the efficiency of navigation, making it important to establish the conditions under which animals employ rheotaxis.

Animals may commonly use accessory cues such as flow or gravity to supplement information from chemical signals. An odor source that generates substantial turbulence in its wake or releases odor in the form of a vertical jet creates a plume that is initially elevated above the substrate and attaches to the bottom downstream of the source. Thus, consumers of substrate-bound food may interpret a sudden loss of signal to mean that they are close to the source. Foragers sometimes use the substrate as an accessory cue (thigmotaxis) and concentrate search efforts on the bottom following signal loss. Even capable swimmers may fail to find sources above the bottom when employing this strategy (Tamburri and Barry, 1999). Similarly, some pelagic animals tend to follow odors downward once they have detected a chemical signal (Hamner and Hamner, 1977), which might limit their ability to track mobile prey as opposed to passively sinking objects.

Turbulence disrupts odor plumes, renders individual filaments less detectable, and increases larger scale plume meander (Murlis, 1986; Moore et al., 1994; Weissburg et al., 2002). As expected, blue crabs show diminished search success and efficiency when challenged with more turbulent flows (Weissburg and Zimmer-Faust, 1993). Crayfish rarely seem inconvenienced by these conditions, and in fact, may search more effectively in moderate turbulence (Moore and Grills, 1999). The sensory basis for these behavioral differences in response to elevated turbulence remains unknown. For some animals, detrimental effects of turbulence may be a function of the relationship between animal sensory capabilities and length and time scales of odor features (Weissburg, 2000). Animals that move quickly through a plume perceive odor on a very coarse scale and have little choice but to respond to intense, instantaneous plume features. Sluggish predators may have the opportunity to sample more finely in time or space, resulting in an ability to estimate the local plume concentration that would be less affected by increased turbulence. Indeed, initial studies with whelks and echinoderms suggest that they maintain largely similar performance as turbulence is increased and have little apparent difficulty tracking odor in conditions where blue crabs are inefficient (Figure 2). In addition, blue crab search success is significantly lower at flow speeds

FIG. 2. Comparison of prey tracking in various aquatic animals. The figure shows typical paths of urchins (*Lytechinus variegatus*), whelks (*Busycon canaliculatum*), and blue crabs (*Callinectes sapidus*) tracking odor plumes in a laboratory flume. The odor source consisted of metabolites released from freshly dead, intact bivalves. All other conditions are the same as described in Figure 1. Shear velocity is approximately 3.1 mm/sec. Search success is given in parentheses.

Urchin
(73% success rate)
Whelk
(59% success rate)
Blue crab
(35% success rate)
Cross-stream distance (cm)
Along-stream Distance (cm)

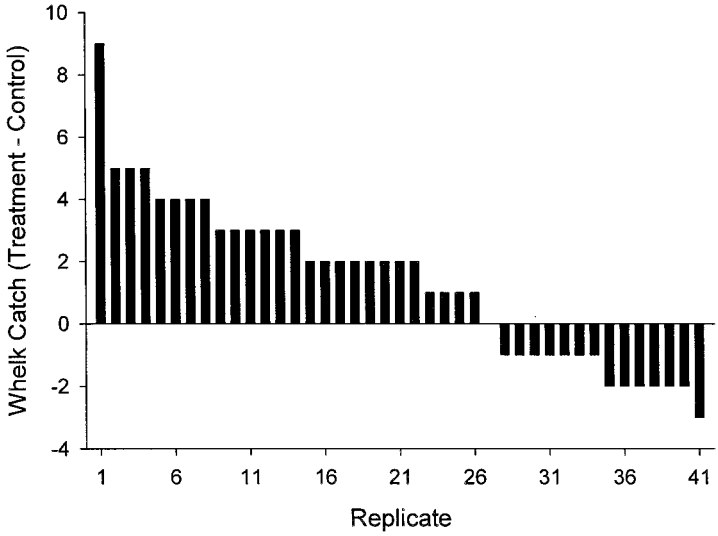


FIG. 3. Response of whelks to elevated turbulence in the field. Data show the difference between the numbers of whelks caught in traps modified to increase turbulence versus unmodified (control) traps. Traps generating increased turbulence caught an average of 1.4 more whelks than control traps and a pair-wise t-test indicates a significant effect of trap type on whelk catch ($t = 3.34$, $P < 0.001$, $N = 41$).

of 5 cm/sec than 1 cm/sec (Weissburg and Zimmer-Faust, 1996), whereas neither whelks (M. Ferner and M. Weissburg, unpublished data) nor urchins (D. Pisut and M. Weissburg, unpublished data) show decreased success across these speeds. In an initial study (M. Ferner and M. Weissburg, unpublished data), whelks were more attracted to baited traps that were modified to enhance turbulence when pairs of modified and unmodified traps were placed in similar flow environments (i.e., on opposite stream banks; Figure 3).

ECOLOGICAL IMPLICATIONS

Many aquatic organisms that hunt via olfaction can exert large effects on prey species, and sometimes, entire communities. Digging predators such as crustaceans or gastropods often control bivalve abundance (Virnstein, 1977; Micheli, 1997; Nakaoka, 2000), and their predatory activities cause local disturbances resulting in the death or emigration of non-target organisms (Pennings and Bertness, 2001). Such disruptions create considerable environmental heterogeneity that may be at least partially responsible for community patchiness. Urchins may aggregate in response to food, and dense urchin assemblages can denude large tracts of

vegetation (e.g., Estes et al., 1998; Rose et al., 1999). Given the current knowledge of chemically mediated foraging, it is opportune, perhaps essential, that we take steps to examine the ecological consequences of this process. Below we highlight a few avenues that may be particularly well suited in this regard.

Prey: Cueless or Clueless?

Until now, we have been fascinated by predator behavior, while prey have been relegated to the role of convenient stimulus sources. This short-sightedness may be understandable, but ignores the fact that predators evoke responses even from prey species often considered as having limited behavioral flexibility. As examples, when gastropods sense foraging crabs, they increase shell thickness and decrease foraging (Trussel, 1996). Mussels respond to consumers by thickening shells, increasing byssal attachment strength, and forming denser aggregations (Cote and Jelnikar, 1999; Leonard et al., 1999). Although prey cannot necessarily eliminate the expulsion of metabolites used as signals by predators, they may reduce the apparency of these emissions to make tracking more difficult for predators.

Given that some predators best track prey in conditions of smooth flow, regions of intense turbulence may represent a hydrodynamic refuge (Weissburg and Zimmer-Faust, 1993). This refuge may be spatial, resulting in the dispersal of prey into habitats with turbulent flow. It also may be temporal if prey actively liberate chemical cues during periods of high flow to render their signal undetectable. Some animals cannot feed unless they also expel waste plumes (e.g., bivalves). Prey attempting to hide their chemical signature consequently may suffer reduced growth as a nonlethal effect of minimizing their apparency to consumers. In fact, bivalves grow more slowly in the presence of predators, even when shielded from direct interactions (Nakaoka, 2000), suggesting alteration in the duration, and perhaps distribution, of feeding times.

Prey may have other means of disguising their presence beyond altering the timing of chemical release. Given the tendency of animals to search the ground for odor sources, animals may make themselves more difficult to locate if they expel plumes with sufficient vertical momentum so that chemical cues are transported far downstream before reattaching to the substrate. This strategy would be particularly effective when animals are in slow flows, since under these conditions the jet will travel farther from the substrate before its vertical momentum is lost (Moore et al., 1994). Animals that can capitalize on the ability to produce vertical jets may enjoy an advantage in slower flows relative to other potential prey.

Appropriate interindividual spacing also may reduce the risk of detection. Close neighbors may produce signals that interact (Monismith et al., 1990), increasing the cross-stream span of the plume as well as the flux of potential stimulants. Predators, therefore, may be more easily alerted to the presence of prey and find the signal easier to track than when they encounter plumes from a single individual.

Larger interindividual spacing may be particularly beneficial for prey that have a minimal impact on the surrounding flow (e.g., burrowing bivalves). Animals whose bodies generate substantial flow disturbances might actually benefit from aggregating more closely to enhance turbulence. If prey generate sufficient turbulence, their plume may disperse so quickly that it becomes difficult to detect even when prey density is high. These interactions may have implications for patterns of demography across regions of different odor-tracking permissiveness that have yet to be tested.

Significantly, prey often may use waterborne odors from predators to modify their behavior in response to immediate threats (Kats and Dill, 1998; Trussel, 1996). Habitats favorable for odor tracking may, therefore, increase both the ability to forage and to detect predators. Many animals, such as echinoderms, gastropods, or small crustaceans, are simultaneously both predators and prey. The ultimate consequences of enhanced odor detection are not predictable a priori but present a number of intriguing possibilities. For instance, foragers with more acute sensing of potential predators may be favored even in habitats where they may be more vulnerable to detection, whereas those less able to perceive predator odors may be restricted to more hydrodynamically marginal environments.

Competition and the Race for Food

The mounting evidence that olfactory foragers may differ in their skill at tracking signals in turbulent conditions suggests that individual predator species may be tuned for efficient foraging in given environments and that turbulence is a relevant dimension of the environment affecting the distribution and abundance of potential competitors. Even in the absence of strong competition, animals may gravitate towards conditions where they experience the greatest foraging success, suggesting that habitat choice, and consequently, the intensity of predation by particular species, may be affected by turbulence levels.

The partitioning of olfactory environments along a turbulence intensity axis may be particularly important for slow versus rapidly moving consumers, as these represent the end points of a spectrum of potential navigational strategies. In areas of low turbulence, a rapidly moving forager has the advantage, since plume conditions allow an animal responding to momentary bursts of intense odor to locate the source with speed and precision. A consumer employing this strategy reaches its goal before an animal using a time-consuming strategy dependent on local averaging. In more turbulent flows, the race for food is not necessarily to the swift, since local averaging may be the only effective tracking strategy where odor fields are dilute and bursts of high concentration are rare. As a result of the suitability of different navigational strategies across flow regimes, slow-moving time-averagers may be proficient at predation or scavenging in turbulent habitats, whereas more rapid crablike strategies should predominate where turbulence is

low. This hypothesis has yet to be examined. Since turbulence is affected by factors acting on regional (e.g., tidal amplitude) or local (e.g., bottom topography) scales (Wright, 1989; Mann and Lazier, 1991), the interaction between hydrodynamic environments and sensory strategies may produce differences in patterns of predation both between and within systems.

Predators that use different signal structures to locate prey would be expected not only to have distinct habitat preferences and predatory efficiencies even in similar environments, but perhaps preferences for different prey characteristics. By example, slow-moving consumers capable of computing local concentration can integrate in time to estimate flux, which for a given current speed is proportional to the product of metabolite concentration and release rate. Temporal integration is not necessary for rapidly moving animals that use perception of intense odor bursts to navigate. Flux is essentially meaningless for these consumers; instantaneous estimates of burst concentration provide the information used to find prey. Interestingly, crabs and whelks vary in size selectivity for their bivalve victims, with whelks tending to consume larger prey (Nakaoka, 2000). A number of potential explanations exist, but one possibility is that crabs and whelks do not use the same signal properties to guide navigation and, therefore, respond differently to prey of different sizes. Assuming larger prey have higher release rates, as opposed to releasing more concentrated stimuli, flux will increase, whereas properties of individual odor bursts may change little, if at all. Larger bivalve prey might, therefore, present a more attractive signal for whelks than smaller prey, which would be consistent with gastropods such as *Ilyanassa* that demonstrate increased aggregation to odor sources with greater fluxes (Zimmer et al., 1999). Crabs simply may be unable to discern prey size from a distance, and upon contact reject larger items in favor of smaller bivalves, which they can open more easily (Arnold, 1984). Alternatively, crabs may use some unknown odor or hydrodynamic feature, such as excurrent jet size or velocity, to select smaller prey. Chemically mediated strategies capable of producing differences in predation might serve to define, at least partially, functional guilds. Mobile aquatic predators often have been assigned to guilds based on foraging mode [e.g., burrowing, digging, subsurface (Woodin, 1983) or stomach contents (Hines et al., 1990)]. These criteria may not be completely diagnostic when predators utilize different plume features in order to find their prey. Patterns of community regulation may be contingent on the degree to which its members are functionally redundant (members of the same guild; Strong, 1992), making accurate guild delineation necessary to thoroughly understand community dynamics.

Patterns of Preference

Many consumers in aquatic systems eat a variety of living prey (e.g., Hines et al., 1990), and some also may derive considerable nutrition from scavenging

(Britton and Morton, 1994). Factors that mediate patterns of prey choice have not been explored, particularly in realistic field settings. In the field, diet will be determined by the ability to detect an item from a distance, and once the prey has been contacted, by its palatability, degree of chemical or morphological defense, and nutritive value. In contrast, many feeding assays are conducted in small arenas where distance detection is minimized, so that postdiscovery factors are the primary arbiter of feeding decisions. This may confound accurate identification of consumer preference and result in unrealistic estimates of consumer impact on particular diet items. Nutritious, tasty, but undetectable food may be less prevalent in consumer diets than suggested by assays failing to account for distance perception.

Diet preferences also might be contingent on whether predators use differences in the quality (composition) of the odor signal or merely the quantity of stimulatory molecules, to identify and track their prey. The difference between these two scenarios is significant, since dining choices mediated by odorant composition reflect specialization on particular prey items, and specialists may exert different effects in communities than generalists. Understanding the basis of diet preferences, therefore, may help illuminate the role of given predators in aquatic communities. There is abundant evidence that aquatic predators posses the capability to identify chemical mixtures characteristic of particular food items and discriminate among them (Carr and Derby, 1986; Derby and Atema, 1988; Wight et al., 1990; Sorensen and Caprio, 1997). As noted above, it is unclear whether these stimulus mixtures are relevant to the task of source localization, as opposed to ingestion behavior. Chemical composition of amino acid solutions derived from injured prey has no significant impact on attractiveness of the snail *Ilyanassa* when presented at equal flux rates (Zimmer et al., 1999). One possibility is that scavengers use general and ubiquitous cues such as amino acids or nucleotides, whereas animals seeking live prey use more specific molecules. This supposition is consistent with the little evidence available regarding attractant compounds for scavengers and predators. Although *llyanassa* is primarily a deposit feeder, it must scavenge carrion for survival and reproduction (Curtis and Hurd, 1985). Juveniles of the predatory snail *Urosalpinx* feed exclusively on balanoid barnacles, which they find using a specific peptide cue (Rittschof, 1990).

CONCLUSIONS

The chemical ecology of deterrent compounds has provided insight into species interactions by successfully blending techniques from analytical chemistry, behavior, and ecology. The study of attractant compounds is poised to make important contributions, but in order to do so, must adopt a similar interdisciplinary perspective. The basic tools of chemical analysis, fluid dynamics, and behavior are now sufficiently advanced and, in some cases, have been combined in novel ways to examine odor tracking. The continuation of these efforts, particularly realistic

field experiments and in situ manipulations of chemical and fluid environments, has the potential to address many intriguing issues. With increased attention and effort, the ecology of attraction may become as important to understanding marine communities as the study of chemical deterrence.

Acknowledgments—We thank Mark Hay, Julia Kubanek, Jeannette Yen, and David Fields for thoughtful comments on earlier drafts; Don Webster for supplying the plume images for Figure 1; and the students in the IGERT program for providing a spirited and energetic environment.

(Received June 6, 2002; accepted June 18, 2002)

Abstract—Because marine animals and plants are continuously exposed to a large diversity of potentially harmful microorganisms, it seems reasonable to hypothesize that potential hosts might produce bioactive compounds to deter microbial attack. However, little is known about how host metabolites may defend against harmful microbes or facilitate the growth or colonization of helpful symbionts. While there is a large body of literature describing the antimicrobial activities of marine secondary metabolites, we are only now beginning to understand how these compounds function in an ecological context. For example, there is mounting evidence that nontoxic concentrations of secondary metabolites can have significant effects on microbial behavior, suggesting that certain host–microbe interactions are chemically mediated. Herein, we discuss the importance of employing ecologically relevant assays to elucidate microbiological effects and the need to develop a better understanding of host–microbe associations within an ecologically realistic context. Continued research in this field along with improved techniques will certainly provide further insight into how microbes have influenced the evolution of secondary metabolite production in marine organisms.

Key Words—Antimicrobial defense, secondary metabolites, microbial attachment, microbial challenges, microbial interactions, microbial swarming.

INTRODUCTION

The interdisciplinary field of chemical ecology involves investigations to understand the ecological function and evolutionary significance of secondary metabolite production by animals, plants, and microbes. In general, secondary metabolites are thought to enhance the fitness of the producing species, a concept supported by many studies that have documented their roles in mediating intra- and interspecific interactions (recently reviewed by Rosenthal and Berenbaum, 1992; Harborne, 2001). In the ocean, predator–prey interactions, spatial competition, and larval settlement cues have been the central focus of marine chemical ecology (e.g., Hay and Fenical, 1988; Paul, 1992; Pawlik, 1992; Hay, 1996; McClintock and Baker, 2001). Studies in this field have led to a solid understanding of how secondary metabolites from marine animals and plants affect other species and support the now well-accepted theory that secondary metabolites provide important defensive functions against consumers and competitors. Despite this progress, the effects of secondary metabolites on potentially harmful marine microorganisms remain largely unknown. This is somewhat surprising, considering that marine pathogens can have devastating effects on entire populations (Litter and Litter, 1995; Correa and Sanchez, 1996; Smith et al., 1996; Martin et al., 2002), suggesting that marine microorganisms exert significant selective pressures on marine animals and plants. Investigating the microbiological effects of secondary metabolites in an ecological context is extremely important if we are to develop a clear understanding of the extent to which microorganisms have influenced the evolution of secondary metabolites.

There is a strong ecological rationale for the maintenance of antimicrobial chemical defenses by marine invertebrates and plants. Seawater, unlike air, typically contains 10^7 viruses, 10^6 bacteria, 10^3 fungi, and 10^3 microalgae/ml (Reinheimer, 1992), all of which include members that have been identified as causative agents in a variety of marine infectious diseases (Andrews, 1976, 1979; Sparks, 1985a,b; Correa, 1997). Given that marine invertebrates and plants lack cell-based immune responses and are continuously exposed to a broad array of potentially deleterious microorganisms, it is reasonable to hypothesize that the production of bioactive secondary metabolites could act as a fundamental mechanism of antimicrobial defense. While secondary metabolites have previously been suggested to function as defenses against marine pathogens (Paul, 1992; Hay, 1996), methods to address this hypothesis are only now being developed and, as a result, we are now getting our first glimpse of their potential roles in mediating interactions between the producing organisms and microbial enemies.

Further rationale for investigating the role of secondary metabolites in mediating microbial interactions comes from the well-documented observations that marine plants and animal are host to a variety of often specific microorganisms (Sieburth, 1975, 1979). Contrary to inanimate surfaces, which are colonized in a

rapid and predictable manner by a diverse assemblage of marine microbes (ZoBell and Allen, 1935; Wahl, 1989), biotic surfaces frequently harbor species-specific microbial communities (Baker and Orr, 1986; Wardell et al., 1983; Wahl, 1995) that can be highly variable and distinct from those found in the surrounding environment. While little is known about the potential role of secondary metabolites in the regulation of these associations, an understanding of the types of microbial behaviors that may be chemically mediated, such as chemotaxis, adhesion, swarming, and biofilm formation (recently reviewed by Lawrence et al., 1995; Fletcher, 1996; Steinberg et al., 2001; Amsler and Iken, 2001), can provide a framework within which to investigate the ecological relevance of molecules that mediate microbial physiology and behavior.

The purpose of this paper is to explore to what extent secondary metabolites from marine organisms influence the behavior of potentially pathogenic, or otherwise harmful, marine microorganisms. Herein, we provide a brief review of how crude marine extracts and purified secondary metabolites produce ecologically relevant effects on marine microbes. Although several assays have been developed to investigate the effects of secondary metabolites on the behavior of harmful microbes (reviewed by Jenkins et al., 1998), the difficulty of developing bioassays that are relevant to natural systems has clearly been a major limitation to the development of this field. Despite these challenges, there now exists a small but compelling body of literature that provides strong evidence for the role of secondary metabolites in antimicrobial chemical defense.

CHEMICAL INTERACTIONS BETWEEN MARINE ORGANISMS AND ASSOCIATED MICROBES

The significant interest in the pharmacological potential of marine natural products has resulted in a wealth of literature describing antimicrobial activities of marine secondary metabolites against biomedically important microorganisms (Rinehart et al., 1981; Reicheldt and Borowitzka, 1984; Carté, 1996). In addition, studies investigating the ecological role of antibiotics have reported antimicrobial effects of secondary metabolites against marine bacteria (Azumi et al., 1990; Kim, 1994; Koh, 1997; Newbold et al., 1999). While these studies provide evidence that marine secondary metabolites can have antimicrobial properties, the ecological significance of these activities is uncertain. In fact, several studies have noted a lack of correlation between antibiotic activity and epibacterial abundance (Bakus et al., 1985; Davis et al., 1989; Wahl et al., 1994) suggesting that either antibacterials are not involved in the regulation of surface-associated bacteria or that traditional antibacterial bioassays may not be adequate predictors of the ecological functions of secondary metabolites.

The detection of antimicrobial activity measures the direct inhibition of microbial growth, which is only one potential mechanism by which epibacterial

abundance and pathogenicity can be controlled. Aside from toxicity or growth inhibition, marine secondary metabolites may also influence microbial surface colonization by inducing a negative chemotactic response (Chet et al., 1975; Chet and Mitchell, 1976; Amsler and Iken, 2001) or by affecting various stages of the attachment and colonization process (Steinberg et al., 2001; Kjelleberg and Steinberg, 2002). Assays that measure the effects of extracts or purified secondary metabolites on microbial behavior (reviewed by Jenkins et al., 1998), such as chemotaxis, adhesion, and surface swarming, have the potential to demonstrate the extent to which microbial surface colonization is chemically mediated. Based on available data, behavioral assays seem inherently more predictive of ecological function than assays that simply measure toxicity. Although only a handful of studies have employed behavioral assays to investigate the ecological roles of secondary metabolites, these have been used effectively to relate the activity of organic extracts and isolated compounds from marine invertebrates (Wahl et al., 1994; Slattery et al., 1995; Bryan et al. 1996) and plants (Jensen et al., 1998; Maximilien et al., 1998) to epibacterial abundances on the producing organisms. In the following, a brief review of these studies is provided in an effort to explore the extent to which secondary metabolites from marine organisms mediate interactions with cooccurring and potentially deleterious microbes.

Animal–Microbe Interactions

Wahl et al. (1994) were among the first to provide evidence that marine organisms chemically mediate bacterial surface colonization. In their study, epibacterial abundances on two cooccurring ascidians, *Polyclinum planum* and *Cystodytes lobatus*, were investigated. Scanning electron micrographs revealed that the surface of *P. planum* was heavily colonized by diatoms and a variety of bacteria, while that of *C. lobatus* was virtually free of associated microorganisms. The numbers of culturable bacteria from both ascidian species corroborated the SEM results and led the authors to explore the hypothesis that epibacterial abundances were chemically controlled in these two temperate ascidian species.

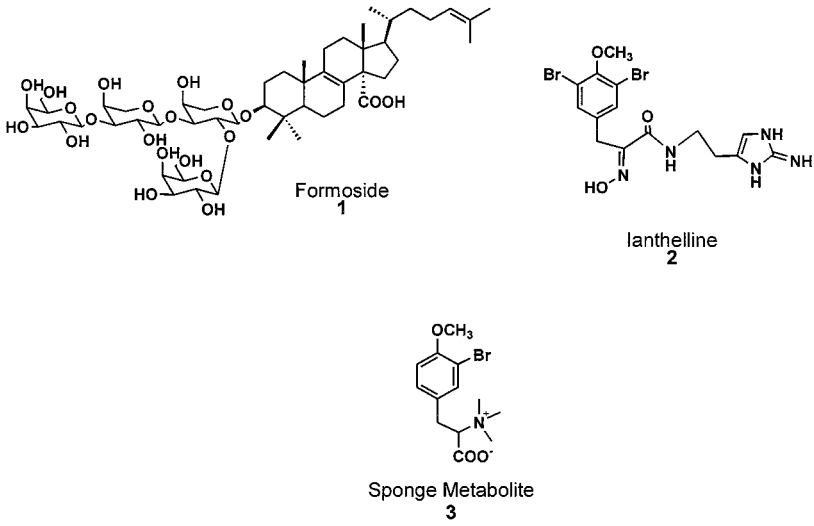
To test this hypothesis, Wahl et al. (1994) investigated the effects of ascidian extracts on microbial attachment and growth. The ability of bacteria to attach to a surface was tested using a bioassay in which bacteria isolated from both ascidians were allowed to settle onto agar surfaces containing extract-treated and control areas. The effects of ascidian extracts on bacterial settlement were determined by comparing the numbers of cells attaching to extract treated and control surfaces. In addition, the extracts were tested for antibacterial activity using standard disk diffusion assays (Acar, 1980) against 36 bacterial strains isolated from the surfaces of both ascidians. While extracts from both ascidian species exhibited variable and generally low levels of antimicrobial activity, the extracts of the sparsely colonized

C. lobatus, tested at concentrations below those estimated to occur in the tissues of this species, were found to significantly inhibit bacterial attachment relative to controls. In contrast, the numbers of bacteria settling on agar surfaces containing extracts of the heavily colonized *P. planum* were significantly greater than those settling on controls. These results provided good evidence that the settlement of surface-associated microorganisms was chemically controlled in both ascidian species. Interestingly, settlement activities of ascidian extracts correlated well with epibacterial abundance, while antimicrobial activities did not, providing some of the first experimental evidence that antimicrobial chemical defenses may function by mechanisms other than toxicity.

Slattery et al. (1995) used a similar assay to investigate the effects of extracts from three Antarctic soft corals (*Alcyonium paessleri*, *Clavularia frankliniana*, and *Gersemia antarctica*) on the settlement and growth of cooccurring bacteria. While extracts of all three soft corals exhibited minimal antimicrobial activity, chloroform extracts from *Alcyonium paessleri* and *Gersemia antarctica*, as well as methanol extracts from *Gersemia antarctica*, significantly inhibited bacterial attachment in a modified slide assay (Little et al., 1986; Wahl et al., 1994). This provided further evidence that extracts tested at nontoxic concentrations can have significant effects on bacterial behavior, leading the authors to conclude that both *A. paessleri* and *G. antarctica* rely on secondary metabolites to inhibit bacterial attachment to their surfaces (Slattery et al., 1995).

Ecologically relevant effects on cooccurring marine bacteria have also been demonstrated with echinoderm body wall extracts. While potent antimicrobial activities have been reported for crude extracts and specific compounds (saponins) isolated from echinoderm species (Rinehart et al., 1981; Bryan et al., 1994), Bryan et al. (1996) were the first to investigate the effects of echinoderm extracts on bacterial settlement. Using a spectrophotometric 96-well microtiter plate assay, modified from Shea and Williamson (1990), Bryan et al. (1996) assessed the effects of echinoderm body wall extracts on the attachment of the marine bacteria *Deleya marina* and *Alteromonas luteo-violacea*. Testing extracts at natural tissue concentrations, the authors demonstrated that the extracts of three echinoderm species significantly inhibited bacterial attachment, while the extracts of eight species significantly enhanced attachment. Interestingly, the extract of one of the three species that inhibited attachment (*Goniaster tesselatus*) was shown in a previous study (Bryan et al., 1994) not to be toxic to microbes.

Additional evidence that secondary metabolites from marine animals may be involved in antimicrobial chemical defense comes from a study of Caribbean sponges. A survey conducted by Newbold et al. (1999) revealed that crude organic sponge extracts have a wide range of antimicrobial activities against ecologically relevant marine bacteria. To further investigate the chemical basis of these activities, Kubanek et al. (2002) used a settlement assay modified from that of Jensen et al. (1998) to guide the isolation of the active constituents in the extracts.



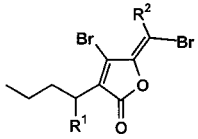


FIG. 1. Animal-derived secondary metabolites with potent behavioral effects on cooccurring marine bacteria.

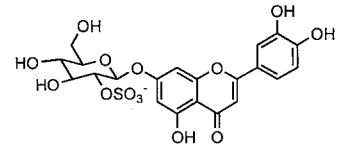
Using the marine bacterium *Vibrio harveyi* as a guide, Kubanek et al. (2002) demonstrated that formoside (**1**, Figure 1), isolated from the sponge *Erylus formosus*, significantly inhibited bacterial attachment at nearly two orders of magnitude below natural tissue level concentrations. Using the same assay, Kelly et al. (unpublished.) demonstrated that ianthellin (**2**, Figure 1), isolated from the sponge *Ailochroia crassa*, and the bromotyrosine derivative **3** (Figure 1), produced significant inhibitory effects on bacterial attachment and swarming, respectively. Thus, it was possible to assign the activities associated with crude extracts to individual secondary metabolites and to demonstrate that these compounds had significant effects on bacterial behavior at whole tissue concentrations. However, it is important to note that whole-tissue concentrations might not necessarily be the same as surface concentrations, which cooccurring microbes are more likely to experience in nature. With the exception of Kubanek et al. (2002), none of the previously discussed studies determined surface concentrations of extracts tested. Conducting settlement assays with surface concentrations rather than whole tissue concentrations could provide valuable information to interpret results in a more ecologically relevant way.



Plant–Microbe Interactions

Although few marine plants have been investigated for their ability to mediate microbial interactions through the production of secondary metabolites, the

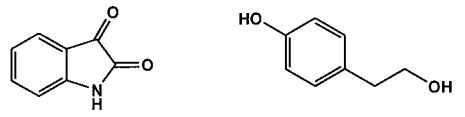
results obtained to date have been intriguing. The most in depth studies have been performed on the red alga, *Delisea pulchra*, which is known to produce a series of structurally related halogenated furanones (**4**, Figure 2) (Kazlauskas et al., 1977; de Nys et al., 1993). Scanning electron micrographs of the alga revealed that epibacterial abundances near the holdfast were significantly higher than those found on the apical tips (Steinberg et al., 1997), where the highest concentrations of halogenated furanones were detected (de Nys et al., 1996). These observations led Maximilien et al. (1998) to explore the hypothesis that halogenated furanones are involved in mediating bacterial colonization on the surface of *D. pulchra*.

To test this hypothesis, Maximilien et al. (1998) measured epibacterial abundances and distributions on *D. pulchra* as well as on three cooccurring algal species and tested the effects of crude extracts and halogenated furanones in a series of microbial behavioral assays. To ensure that the bacteria used in these assays were exposed to ecologically relevant furanone concentrations, Maximilien et al. (1998) conducted their assays within a range of concentrations found to occur on the surface of *D. pulchra* (de Nys et al., 1998). Naturally occurring surface concentrations were determined by dipping the plant into nonpolar solvents for 40 secs, a period determined not to damage surface cells (de Nys et al., 1998). Overall, Maximilien et al. (1998) determined that crude extracts of tissues from *D. pulchra* had no significant inhibitory effect on the growth of 144 ecologically relevant bacterial strains isolated from the surface of *D. pulchra* and the surrounding environment. Since toxicity did not provide an adequate explanation for the low numbers of bacteria observed on the surface of *D. pulchra* relative to other cooccurring algae, Maximilien et al. (1998) proceeded to test the effects of crude extracts and purified furanones on the ability of bacteria to swim, attach, grow, and swarm, four important characteristics associated with surface colonization. These experiments included some of the first field experiments addressing the microbiological effects of marine secondary metabolites and represent an important step towards testing extracts and purified compounds against an ecologically relevant, natural assemblage of microorganisms.

Initial field studies revealed that crude extracts and furanones **4b** and **4c** (Figure 2) strongly inhibited the ability of bacteria to attach to a surface (Maximilien et al., 1998). These results led to further studies aimed at determining whether host versus nonhost strains of bacteria differed in their ability to swim, attach, grow, and swarm in the presence of these compounds. To perform these experiments, three bacterial strains isolated from the surface of *D. pulchra* and three isolated from the surfaces of nearby rocks were selected. Although the effects on the four behavioral characteristics varied among isolates, a trend in the results indicated that attachment was inhibited in nonhost bacteria while growth and swarming were inhibited in host bacteria (Maximilien et al., 1998). These results may explain why nonhost strains were not found on the alga's surface and why host strains had limited surface distributions. It is interesting to note that secondary metabolites may control the density of surface associated microbes, allowing growth of a limited number of epibiotic microbes rather than maintaining an axenic surface. This strategy might represent one mechanism by which the host minimizes the risk of counter adaptation, which would be likely to occur if secondary metabolites would be toxic to associated microbes.



Other evidence that plant secondary metabolites affect cooccurring microorganisms comes from the study of a group of protist decomposers known as thraustochytrids. These fungilike microorganisms occur widely in coastal marine environments (Moss, 1986; Raghukumar et al., 1992) and are known to be important decomposers of plant material (Miller and Jones, 1983; Bremer, 1995). It has long been suspected that phenolic compounds produced by marine plants function as a chemical defense (Sieburth and Conover, 1965; Sieburth, 1968) by inhibiting decomposers such as thraustochytrids from attacking live plant material. However, there has been little chemical evidence implicating specific compounds in this process. Working with extracts of the the seagrass *Thalassia testudinum*, Jensen et al. (1998) isolated and described a sulfated flavonoid (**5**, Figure 2) with potent physiological and behavioral effects on the co-occurring thraustochytrid, *Schizochytrium aggregatum*. Initial experiments revealed that significantly fewer thraustochytrids were associated with healthy living tissue of *T. testudinum* than with tissue that had been sterilized and placed back into the field for 48 hr. Using *S. aggregatum* as a guide, the possibility of a chemical basis for this observation was investigated and led to the isolation and characterization of the water soluble flavonoid luteolin 7-*O*-β -D-glucopyranosyl-2″-sulfate (**5**, Figure 2). This compound inhibited the growth of *S. aggregatum* with an IC_{50} of 270 μg/ml, a concentration about 15 times lower than the average values in seagrass tissues. This compound was also found to significantly inhibit the attachment of *S. aggregatum* in an assay modified from Wahl et al. (1994), supporting the author's contention that it may function as a defense against marine decomposers (Jensen et al., 1998). Although sulfated flavone glycosides had been previously isolated from terrestrial plants, they are most prevalent in halophytes and their production was believed to represent a

physiological adaptation to the marine environment (Harborne, 1977). This study provided the first evidence that a specific compound belonging to this class of secondary metabolites may function in antimicrobial chemical defense.

Current work in our laboratory has also indicated that other marine algae produce secondary metabolites that inhibit the development of known marine pathogens and potentially deleterious microorganisms. Recently, J. Kubanek et al. (personal communication) found that extracts of the tropical brown alga *Lobophora variegata* inhibited the growth of four of six potentially pathogenic microbes. One of these strains, *Dendryphiella salina*, an ascomycete known for its role in the decomposition of algal tissue, was chosen for the bioassay-guided chemical fractionation of the *L. variegata* crude extract. These assays were performed in microtiter plates and the extracts, fractions, or pure compounds were incorporated into agar substrates at whole tissue concentrations and tested for their effects in fungal growth. This assay led to the isolation of a molecule that possesses extremely potent antifungal activities not only against *D. salina* but also against the known algal pathogens *Lindra thalassia* and *Lulworthia fucicola.* In a separate study, M. Puglisi et al. (personal communication) investigated the effects of extracts of the green alga, *Penicillus captiatus*, on the ubiquitous marine pathogen *L. thalassiae*. Using a similar microtiter plate assay, two unusual secondary metabolites were isolated (not yet fully identified) with potent antifungal activity. These studies clearly demonstrate that marine plants produce secondary metabolites that, when tested at whole tissue concentrations, have significant effects on marine plant pathogens and saprophytes.

Microbe–Microbe Interactions

In an interesting twist to the concept of antimicrobial chemical defense, there is evidence that symbiotic microbes can chemically defend a host against microbial infection. This phenomenon was demonstrated in a series of experiments probing the observed resistance of crustacean eggs toward a fungal pathogen (Gil-Turnes et al., 1989; Gil-Turnes and Fenical, 1992). Crustacean egg masses are primarily composed of proteins and polysaccharides (Hunt, 1966; Flower et al., 1969), making them excellent substrates to support microbial growth. Scanning electron micrographs of the surfaces of eggs from the estuarine shrimp *Palaemon macrodactylus* revealed that they were colonized by a monoculture of a bacterium that was subsequently identified as an *Alteromonas* sp. (Gil-Turnes et al., 1989). When the bacteria were removed by treatment with penicillin, the egg mass became extremely susceptible to infection by the oomycete *Lagenidium callinectes*, a common crustacean pathogen (Armstrong et al., 1976; Fisher et al., 1978). Colonization by *L. callinectes* caused death of embryos within hours. Reintroduction of the cultured bacterial symbiont to the penicillin-treated eggs restored resistance against *L. callinectes*, providing strong evidence that the epibiotic bacteria provide

a chemical defense for the host. Chemical investigation of the cultured bacterium led to the isolation and description of 2,3-indolenedione (isatin) (**6**, Figure 3), which was found to be a potent inhibitor of *L. callinectes* growth (Gil-Turnes et al., 1989). A similar study revealed that the egg masses of the American lobster, *Homarus americanus*, were colonized by a gram-negative bacterium that produced the antifungal metabolite 4-hydroxyphenethyl alcohol (tyrosol) (**7**, Figure 3) in pure culture (Gil-Turnes and Fenical, 1992). The production of antimicrobial chemical defenses by symbiotic microorganisms represents an added level of complexity to the mechanisms by which marine plants and animals avoid the deleterious effects of microbial pathogens.

SUMMARY

It is becoming increasingly clear that marine secondary metabolites can have significant ecological effects on potentially deleterious microorganisms. The effects on bacteria and fungi documented to date, which range from antibiotic activities to specific effects on microbial behavior, suggest that in some marine animals and plants, secondary metabolites function as an antimicrobial chemical defense. These defenses may be straightforward, e.g., the direct inhibition of a pathogen via the production of an antibiotic (Jensen et al., 1998), or they may be more subtle, e.g., the induction of a negative chemotactic response or the interference with a chemically mediated signaling pathway required for bacterial surface colonization (Givskov et al., 1996; Kjelleberg et al., 1997). What has become evident from this work is that when careful studies are performed using ecologically relevant microorganisms and realistic estimations of secondary metabolite concentrations, the complex effects of these adaptive metabolites can be deciphered.

Although the evidence that marine invertebrates and plants maintain antimicrobial chemical defenses is growing, a number of obstacles must be overcome before a complete understanding of the ecological importance of these microbiological effects can be obtained. Among the most pressing issues is the estimation of the concentrations of secondary metabolites experienced by microorganisms in

nature. Testing extracts and purified compounds at natural or whole-tissue concentrations is a logical starting point and has proven effective in studies of predator deterrence; however, these methods may not translate to the microbial level. Methods to estimate surface concentrations, such as that developed by de Nys et al. (1998), represent important innovations in this regard; however, this task becomes more challenging in the case of spatially complex organisms like sponges, and they do not account for compounds that are released directly into the surrounding seawater. Equally important is choosing the appropriate microorganisms against which to test the hypothesis of chemical defense. Test microorganism selection remains a significant challenge, considering how little is known about which microorganisms are potentially deleterious. A logical place to start is with known pathogens or cooccurring microorganisms that possess the capacity to colonize a surface. It is also critical that assay results, such as antibacterial activities, are correlated with microbiological observations, such as bacterial abundance, and that field assays be developed so secondary metabolites displaying activities in the laboratory can be tested against natural assemblages of microorganisms. Although progress is being made in all of these areas, it is clear that continued advances in this field will require methodological innovations as well as a better understanding of the nature of microbial interactions with marine invertebrates and plants.

Another important conclusion that can be drawn from the studies performed to date is that assays that measure toxicity alone are inadequate predictors of antimicrobial chemical defenses. There is mounting evidence that secondary metabolites can have significant effects on microorganisms at nontoxic concentrations (Wahl et al., 1994; Slattery et al., 1995; Bryan, 1996; Jensen et al., 1998; Maximilien et al., 1998), and for this reason, assays that measure behavioral responses such as chemotaxis and the ability to swim, attach, and swarm, are proving to be more informative in assessing the spectrum of possible ecological effects than assays that simply measure toxicity. Results from behavioral assays have also made it possible to demonstrate that secondary metabolites can attract microorganisms (Wahl et al., 1994; Bryan, 1996) and, thus, these metabolites may help ensure colonization by preferred epibionts. Studies addressing the roles of secondary metabolites as chemical attractants will help elucidate the potential roles of secondary metabolites in maintaining favorable microbial associations and symbioses.

While it is clear that marine invertebrate and plant secondary metabolites can have significant effects on microorganisms, the effect of pathogenic and saprophytic microbes on the host are not well understood. Secondary metabolites that affect microbial processes such as swimming, attachment, growth, and swarming, have been implicated as having defensive functions for the producing organism. However, by definition, a defensive function implies that in the absence of the chemical defense, the producing organism would sustain harm from the microbe. Thus, a clear understanding of the microorganisms in the ocean, and their associations with plants and animals is of fundamental importance to any conclusions

drawn from experiments investigating the microbiological functions of secondary metabolites.

The compelling conclusion that plants and animals appear to maintain antimicrobial chemical defenses leads to subsequent questions about the degree to which diverse selective pressures, such as predation and microbial infection, have influenced the evolution of secondary metabolite biosynthesis. It remains unclear if different compounds function in different defensive roles or if individual compounds have multiple ecological functions. If the latter is correct, then the evolution of antimicrobial chemical defenses in response to microbial challenge may be constrained due to other ecological pressures (Schmidt et al., 1995) thereby compromising the host's ability to respond to microbial attack. This may explain the occurrence of microbial epidemics such as infections by *Aspergillus sydowii* in Caribbean gorgonians (Smith et al., 1996) and by bacteria in coralline algae (Litter and Litter, 1995). Since the roles of plant and invertebrate metabolites in deterring macroscopic predators are relatively well known, it will be important to take these results into consideration when assessing the evolutionary significance of antimicrobial chemical defenses.

Overall, there is a growing body of evidence supporting the hypothesis that marine plants and animals maintain antimicrobial chemical defenses. With methodological improvements and a better understanding of host-microbe interactions, it should be possible to provide further insight into the adaptive strategies against microbial pathogens and establish the extent to which secondary metabolites regulate microbial interactions.

Acknowledgments—We are grateful for the continued financial support of the National Science Foundation, Chemistry Division (Currently Grant CHE-0111270 to William Fenical), and their long-term interest in marine chemical ecology. In addition, we appreciate research opportunities in the field provided by funding to J. R. Pawlik and thank the captain and crew of the *R/V Seward Johnson.*

MINI REVIEW

CHEMICAL DEFENSE OF EARLY LIFE STAGES OF BENTHIC MARINE INVERTEBRATES

NIELS LINDQUIST*

Marine Sciences Program

Institute of Marine Sciences
Morehead City, North Carolina 28557, USA

(Received May 22, 2002; accepted June 5, 2002)

Abstract—Accurate knowledge of factors affecting the survival of early life stages of marine invertebrates is critically important for understanding their population dynamics and the evolution of their diverse reproductive and life-history characteristics. Chemical defense is an important determinant of survival for adult stages of many sessile benthic invertebrates, yet relatively little consideration has been given to chemical defenses at the early life stages. This review examines the taxonomic breadth of early life-stage chemical defense in relation to various life-history and reproductive characteristics, as well as possible constraints on the expression of chemical defense at certain life stages. Data on the localization of defensive secondary metabolites in larvae and the fitness-related consequences of consuming even a small amount of toxic secondary metabolites underpin proposals regarding the potential for Müllerian and Batesian mimicry to occur among marine larvae. The involvement of microbial symbionts in the chemical defense of early life stages illustrates its complexity for some species. As our knowledge of chemical defenses in early life stages grows, we will be able to more rigorously examine connections among phylogeny, chemical defenses, and the evolution of reproductive and life-history characteristics among marine invertebrates.

Key Words—Chemical defense, juveniles, larvae, life-history evolution, marine invertebrates, mimicry, predation, reproductive characteristics, symbiosis, taxonomic constraints.

INTRODUCTION

The risk of early life stage mortality is a critical component of models and debates concerning the evolution of the different reproductive and life-history characteristics exhibited by marine invertebrates (e.g., Vance, 1973; McEdward, 1997). In these discussions, predation often is assumed to be a major source of mortality for early life stages. The purpose of this review is to bring forward ideas and hypotheses regarding the role of chemical defenses against predation in the ecology of early life stages (i.e., eggs to juveniles) of marine invertebrates and the potential involvement of secondary metabolites in the evolution of marine invertebrate life histories and reproductive characteristics.

Many marine organisms from low to high latitudes and in both benthic and pelagic habitats are effectively defended from diverse types of predators by noxious secondary metabolites (see reviews by Paul, 1992; Pawlik, 1993; Hay, 1996; McClintock and Baker, 2001). Defensive chemistry is particularly common among soft-bodied sessile invertebrates such as sponges, octocorals, and ascidians that can dominate some subtidal habitats where rates of herbivory and predation are especially intense (e.g., coral reefs). Given the demonstrated importance of chemical defenses for the survival of adult marine organisms and for multiple life stages of terrestrial plants (Janzen, 1971; Swihart and Bryant, 2001), it seems reasonable that they may also be important throughout the ontogeny of marine species. Chemical defense of marine larvae is becoming increasingly well documented, and because McClintock et al. (2001) recently reviewed this topic, only a brief synopsis of the primary literature on larval chemical defense is presented. Instead, I place the chemical defenses of early life stages (egg, embryos, larvae, and juveniles) in a larger evolutionary framework and ask how these defenses may affect the evolution of, for example, egg and larval size, brooding versus broadcast spawning, timing of spawning, and dispersal potential. Additionally, some less obvious, yet potentially important, ecological and evolutionary implications for the chemical defense of early life stages are discussed.

OVERVIEW OF EARLY LIFE-STAGE CHEMICAL DEFENSE

Direct examination of defensive secondary metabolites in eggs and larvae has been conducted for saponins in sea stars (Howden et al., 1975), didemnin cyclic peptides and tambjamine alkaloids in tunicates (Lindquist and Fenical, 1991; Lindquist et al., 1992), terpenes in soft corals and gorgonians (Coll et al., 1995; Harvell et al., 1996; Slattery et al., 1999), and halogenated phenols and alkanes in polychaetes (Cowart et al., 2000) (Figure 1). Additional studies on the palatability of early life stages or their extracts illustrate the breadth, and potentially limits, of chemical defenses among taxonomically diverse marine invertebrates. Eggs,

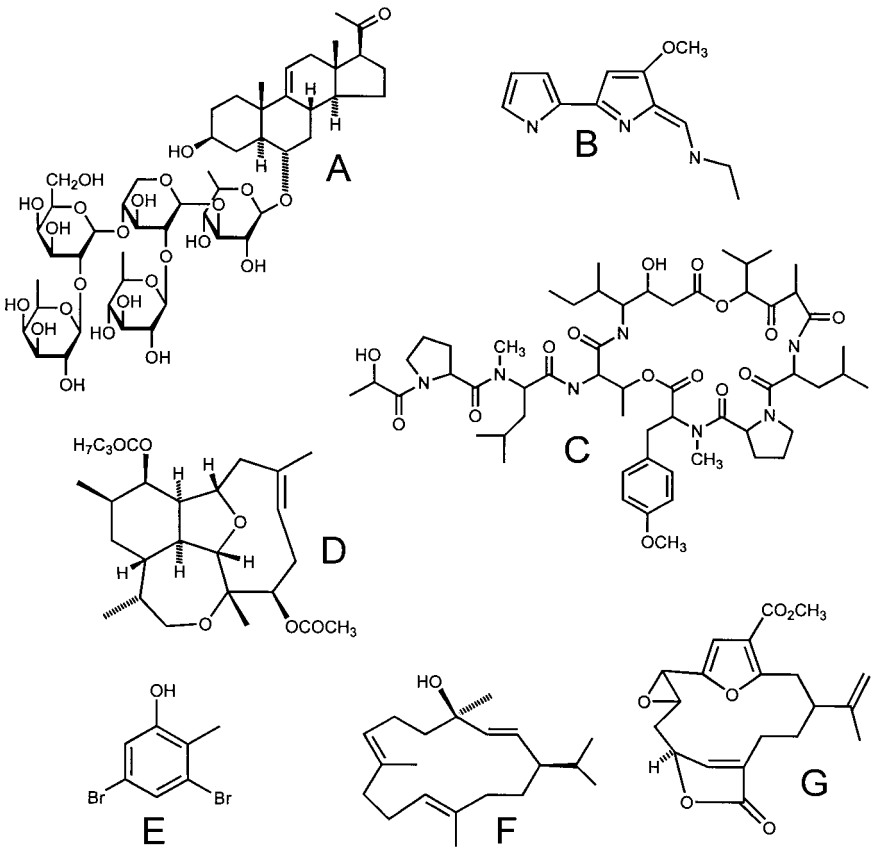

FIG. 1. Representative structures of secondary metabolites isolated from eggs, embryos, and larvae of marine invertebrates: (A) saponin, *Acanthaster planci*; (B) tambjamine E, *Sigillina signifera*; (C) didemnin B, *Tridemnin solidum*; (D) asbestinin, *Briareum asbestinum*; (E) bromophenol, *Capitella* sp; (F) (−)-*epi*-thunbergol, *Lobophytum crassum*; (G) pukalide, *Sinularia polydactyla.*

embryos, and larvae most commonly reported to be distasteful and to have deterrent extracts are from sessile invertebrates like sponges (Lindquist, 1996; Lindquist and Hay, 1996; Uriz et al., 1996; McClintock and Baker, 1997), brooding gorgonians and soft corals (Harvell et al., 1996; Lindquist and Hay, 1996; Kelman et al., 1998), hydroids (Lindquist and Hay, 1996), bryozoans (Lindquist and Hay, 1996; Lopanik et al., unpublished), and colonial tunicates (Young and Bingham, 1987, Lindquist et al., 1992). The few mobile taxa with species reported to have unpalatable eggs and larvae include sea stars and holothurian (sea cucumbers) (Lucas et al., 1979; Cowden et al., 1984; McClintock and Vernon, 1990; McClintock and

Baker, 1997; Iyengar and Harvell, 2001) and shell-less gastrods (Pawlik, 1993), but also a crustacean (Luckenbach and Orth, 1990) and a polychaete (Martin et al., 2000). In contrast to the above findings, Bullard et al. (1999) using taxonomically diverse field-captured larvae found no evidence of chemical defense among crustaceans, gastropods, and polychaetes—three very specious taxa that dominate the meroplankton (see also Cowden et al., 1984). Bullard et al. (1999) did find some suggestion of chemical defenses among the few sponge, cnidarian, nemertean (a "worm" unrelated to polychaetes), and sea star larvae caught.

TAXONOMIC CONSTRAINTS AND EVOLUTIONARY IMPLICATIONS

Orians and Janzen (1974) asked, "Why are embryos so tasty?", after pointing out that birds, reptiles, amphibians, and fishes all lose large proportions of their eggs and larvae to predators and that the evolution of distasteful eggs and larvae should be favored. They hypothesized that eggs and larvae generally lack chemical defenses due to: (1) autotoxicity, especially for actively growing tissues, (2) energetic constraints, and (3) trade-offs between deterrence and potential developmental rates of the young. Given the increasing number of marine species now known to have chemically defended eggs and larvae (McClintock et al., 2001), the lack of distasteful eggs and larvae noted by Orians and Janzen (1974) is likely due to the rarity of chemical defenses among vertebrates in general. Taxonomic constraints on the production of chemical defenses may exist among marine invertebrates as well.

The most chemically rich invertebrate taxa in the oceans are generally sessile, soft bodied, and clonal. Their soft tissues and inability to move away from predators make them highly vulnerable, but the noxious and toxic chemicals they possess enhance their persistence in hostile habitats where predation is intense. Clonal growth likely facilitates the evolution of chemical defenses because distasteful individuals can survive bouts of partial predation, while promoting learned aversion by co-occurring predators. In contrast, solitary organisms are less likely to recover from a significant loss of tissue. This also is true of marine larvae, even those of clonal invertebrates, because they are small solitary organisms.

Marine invertebrates have diverse reproductive and larval traits that offer differing degrees of protection against potential predators (Young and Chia, 1987; Morgan, 1995). The timing of spawning, either seasonal or daily, can help early life stages avoid some types of predators. The small size of many larvae, as well as being nearly transparent or cryptically colored, helps them avoid detection by visually foraging predators. Smaller larval size typically correlates with higher adult fecundity, but smaller larvae must usually feed (= planktotrophy) and grow in the plankton for weeks to months before reaching a size that is competent to settle. This may lead to extensive dispersal on currents and an increased risk of never

encountering suitable adult habitat. Some larvae are highly mobile and can often escape when attacked. Others produce an array of potential morphological barriers, such as spines and setae. Morphological defenses may deter some predators (Morgan, 1995), while other consumers easily circumvent morphological barriers (Cowden et al., 1984; Bullard et al., 1999). If larval development is partially or entirely benthic, developing embryos and larvae are usually dispersed within gelatinous egg masses or enclosed in tough protective capsules. Many of the above traits co-occur among larvae of taxa that are not known to be chemically defended and may be their best bets for reducing larval losses to predators.

In contrast to certain morphological traits, chemical defenses can be broadly effective against diverse types of predators (Paul, 1992; McClintock and Baker, 2001), and some simultaneously diminish competition, fouling, disease, or stress from UV radiation (e.g., Schmitt et al., 1995; Stachowicz and Lindquist, 1997). While palatable larvae appear to be selected to avoid exposure to, or detection by, predators (e.g., by being small, translucent, released at night, and dispersing away from the benthos), chemically defended larvae are commonly conspicuous, day active, and remain near the benthos during their short swimming stage. Because many chemically defended larvae are unharmed following attacks by fish and benthic particle feeders (Young and Bingham, 1987; Lindquist, 1996; Lindquist and Hay, 1996), the seascape "seen" by chemically defended larvae may be one largely devoid of successful predators, whereas predators abound in the same habitat as "seen" by a poorly defended larva. The high survival of distasteful larvae following attack and rejection by predators also indicates that the evolution of chemical defenses could occur at the level of an individual larva—evoking group or kin selection to explain the evolution of larval chemical defenses is not necessary. Jackson (1986) pointed out that philopatry (i.e., settling near one's parents) appears common among clonal benthic invertebrates and can result in dense, genetically closed populations (Grosberg and Quinn, 1986); thus, kin selection could further facilitate the evolution of chemical defenses in early life stages and adults.

If the "problem" of predation has largely been solved by the production of chemical defenses, then the larval stage should be free to evolve traits that reduce losses due to other sources of mortality, even at subsequent life stages. As newly settled juveniles, the survival of benthic invertebrates is enhanced by increased size (e.g., Jackson, 1985). Because large larvae typically produce large juveniles, selection could strongly favor increased larval size, if larger size is not constrained by opposing disadvantages. Selection for larger size may occur with chemically defended larvae because the corresponding increase in apparency to visual predators should not increase a larva's risk of mortality and may actually enhance predator recognition and learned avoidance of distasteful larvae. Because distasteful larvae are at less risk from visual predators, they can also be released during daylight hours when they can use strong photic cues to detect protected settlement sites (dark

cracks or crevices) where early juvenile stages will experience less stress from high UV or indiscriminate scraping by large fishes and invertebrates (Young and Chia, 1984; Lasker et al., 1998; Maldonado and Uriz, 1998). Consistent with the above hypotheses, chemically defended larvae are commonly large and released during daylight hours (Lindquist et al., 1992, 1997; Lindquist and Hay, 1996), whereas predators generally constrain palatable larvae from exhibiting such traits.

Rigorous examination of the roles chemistry plays in the life-history evolution of marine invertebrates is both helped and hampered by various constraints. The lack of diverse secondary metabolism among some taxa allows for broad comparisons at the level of phyla, but confounding factors are numerous. For example, sponges are the most primitive metazoans and have only a rudimentary differentiation of their cells and tissues (Ruppert and Barnes, 1994). Thus, sponges probably could not evolve a highly differentiated larva with elaborate feeding capabilities. Despite this drawback, comparing the chemical and life-history characteristics of sponges with colonial tunicates, which are primitive chordates, is enlightening. Tunicates have great cellular diversity and tissue differentiation and are certainly capable of having evolved a feeding larval stage [see hypotheses regarding the origins of the pelagic tunicates called larvaceans (Ruppert and Barnes, 1994)]. Yet ecologically, sponges and colonial tunicates are equals in many respects. Both groups are sessile, benthic filter feeders known to possess a diverse array of biologically active secondary metabolites (Faulkner, 2002, and previous reviews cited therein). Many species in both taxa brood large, aposematically colored larvae that are spawned during daylight hours and that are chemically defended against predators (Young and Bingham, 1987; Lindquist et al., 1992; Lindquist and Hay, 1996). Thus, it seems plausible to hypothesize that their ability to produce bioactive compounds at various life stages has played a role in the convergence of their life histories. Opportunities to investigate within-phyla or within-class relationships between chemistry and life histories could also focus on the Echinodermata and Ascidiacea, respectively, both of which exhibit reproductive diversity among chemically rich and chemically depauperate sub-taxa.

CHANGES IN CHEMICAL DEFENSES AMONG LIFE STAGES

Identifying changes in defensive chemistry among different life stages of marine invertebrates may provide clues about chemically mediated interactions important to the survival of large adults on exposed benthic substrates, small larvae in planktonic environments, and small juvenile stages that typically inhabit physical or biological refuges from large mobile predators. Will one compound adequately defend against different suites of predators in vastly different habitats, or has selection tailored the chemistry at each life stage to act against those predators most capable of inflicting mortality at each life stage?

The first comparison of secondary metabolites between adult and larval stages was for the crown-of-thorns sea star (Howden et al., 1975). In both eggs and adults, they found similar levels of the same saponins; a pioneering study subsequently demonstrated that these saponins deterred feeding by planktivorous reef fishes (Lucas et al., 1979). Later investigations found the same class of secondary chemistry among the different life stages of colonial tunicates (Lindquist et al., 1992), gorgonians (Harvell et al., 1996), soft corals (Slattery et al., 1999), and polychaetes (Cowart et al., 2000), although concentrations of individual metabolites can vary widely among different life stages. Secondary metabolites found in all life stages are possibly broadly effective at deterring diverse guilds of predators, but this hypothesis has not been tested.

In contrast, some marine invertebrates show a distinct lack of chemistry in one or more life stages, a situation potentially useful for testing the hypotheses that these metabolites: (1) only deter predators most likely to prey on the chemically rich life stage, (2) have costs that outweigh the benefits at some life stages, and (3) are possibly unrelated to defense against consumers. Coll et al. (1995) provide examples of egg-specific terpenes in broadcast-spawning soft corals that seem unrelated to predator deterrence (but see Slattery et al., 1999). These terpenes do, however, attract sperm, thereby increasing fertilization rates. Harvell et al. (1996) reported fluctuations in levels of asbestinin diterpenes among life stages of the surface-brooding gorgonian *Briareum asbestinum*, with dips in their concentrations occurring at the embryo–larval and larval–juvenile developmental transitions. They suggest that these dips conform to the hypothesis of Orians and Janzen (1974) by reducing chemical levels when tissues are metabolically very active. While virtually nothing is know about the origins of defensive chemistry in early life stages, the fluctuations measured by Harvell and coworkers in *B. asbestinum* suggest active diterpene synthesis at all life stages.

Early post-settlement stages of many sessile marine invertebrates are morphologically vulnerable to predation (Gosselin and Qian, 1997; Hunt and Scheibling, 1997), yet the cost of a chemical defense may outweigh the benefits for newly settled juveniles. High rates of growth should be of overwhelming importance for the early post-settlement stages because the probability of individual mortality decreases with increasing size (Jackson, 1985). If this hypothesis is generally true, and assuming a trade-off exists between growth and defense, will the production of a chemical defense found in the adult and their reproductive products (i.e., eggs, embryos and larvae) always shut down during the early juvenile stages to increase rate of growth? If so, at what age or size does production of the chemical defense re-emerge? Growth at the expense of defense should not be favored, if predation on undefended juveniles is intense, and rapid growth does not provide a sufficient escape from predators. Selective settlement into cryptic habitats (cracks and crevices), which is common for larvae of many sessile benthic invertebrates, exposes newly settled juveniles to small predatory mesofauna, such as polychaetes,

gastropods, and crustaceans, that can be abundant within refuges (up to $\sim 58,000$ individuals/m^2 on coral reefs) (Klumpp et al., 1988). Thus, do predatory mesofauna within refuges represent a significant source of early post-settlement mortality that can be intense enough to select for defense over growth?

Osman and Whitlatch (1995) provide examples of the dramatic impact mesoconsumers can have on populations of early-stage juveniles. They found that small gastropods could eliminate new recruits of two species of colonial ascidians, whereas juveniles of a third, morphologically similar ascidian were largely unpalatable, suggesting a chemical defense. For the two species with palatable juveniles, their susceptibility to predation by snails dramatically decreased 2 weeks after settlement. In addition to possibly attaining a refuge in size, the reduction in predation could be due to an upswing in the production of chemical defenses by the 2-week-old juveniles. Unfortunately, simultaneous assessments of growth rates and the palatability of juvenile extracts have not been reported for these three ascidians.

Uriz et al. (1996) report palatability data for adults, larvae, and juveniles of two Mediterranean sponges that suggest chemical defenses operate to defend both species from predation, but not at all life stages. Their use of different predators in assays with adult versus larval and juvenile stages precludes a direct comparisons among all three life stages. However, among their larvae, 1-week-old juveniles, and 2-week-old juveniles, all larval and juveniles stages of *Dysidea avara* were rejected by a co-occurring fish, whereas only the 2-week-old juveniles of *Crambe crambe* were rejected. These results suggest that there may be considerable variation in palatability among larval and early juvenile stages.

LOCALIZATION OF CHEMISTRY

Two important questions regarding potential ecological roles for bioactive secondary metabolites in larvae, as well as the other life stages, are, "Where is the chemistry localized?" and "Can it be mobilized?". Compounds that are internalized and immobile are unlikely to function in larval defense as the cue that predators detect and respond to in rejecting a larva. This hypothesis flows from observations that the surface of distasteful larvae attacked and rejected by fish are not disrupted and that most attacked and rejected larvae survive, settle, and successfully metamorphose (Young and Bingham, 1987; Lindquist and Hay, 1996). Lindquist and Hay (1995) demonstrated that some predators do not detect and respond to the presence of physiologically harmful secondary metabolites but (1) if capable of learned aversion, quickly generalize on the "flavor" of the food and use cues other than the toxic metabolites to reject the prey, or (2) if incapable of learned aversion, suffer chronic depressions in fitness that could select for individuals among predator species that recognize and reject small toxic prey as food. These results

indicate that harmful secondary metabolites sequestered within larvae could play a role in defense but one which would require some larval mortality before predators learn or evolve to recognize and avoid chemically harmful early life stages.

To date, few studies provide any data on the localization of ecologically important metabolites in early life stages of marine invertebrates. Lindquist and Fenical (1991) suggested that the yellow-colored tambjamine alkaloids that defend larvae and adults of the tropical tunicate *Atapozoa* sp. (= *Sigillina signifera*) from predatory fishes are localized in the animal's highly colored granular amebocyte blood cells. These blood cells circulate throughout the larvae, and many occur near the larval surface. It is not known whether these compounds are exuded by either the larvae or the adults. Although it is not readily apparent how compound localization will be routinely determined for the small and difficult-to-work-with early life stages, innovative methodologies that address this issue will significantly advance our understanding of larval and juvenile chemical ecology.

MIMICRY

For invertebrate species that typically co-occur, have overlapping reproductive seasons, and produce chemically defended larvae (e.g., sponges on coral reefs), selection could favor the evolution of Müllerian mimicry complexes in which unpalatable larvae of different species converge on a similar aposematic color pattern. Although Dunlap and Pawlik (1996) found no correlation between the color of adult sponges and their palatability, aposematic coloration seems to be a common characteristic of many distasteful larvae (Young and Bingham, 1987; Harvell et al., 1996; Lindquist and Hay, 1996), even coming from adults lacking bright coloration (N. Lindquist, personal observation). Tests to document Müllerian mimicry complexes among chemically defended larvae have not been conducted.

The existence of Batesian color mimics of unpalatable, aposematically colored larvae also lacks empirical support. Presently, no larvae are reported to be both palatable to fishes and brightly colored. However, Young and Bingham (1987) demonstrated that learning among visually orienting predators could select for Batesian color mimics. They found that fish reject palatable tunicate larvae dyed to match the bright orange color of unpalatable larvae from the tunicate *Ecteinascidia turbinata* after previously sampling and rejecting *E. turbinata* larvae.

A novel Batesian mimicry system suggested by current data, but which is highly speculative, is that predators reject larvae of some species, not because the larvae possess noxious or toxic metabolites, but simply because they "taste" like a chemically defended larva. Although this hypothesis sounds paradoxical, it is based on observations of distasteful larvae surviving attacks unscathed, which strongly suggest that fish and other predators taste or smell surface-associated chemicals that cause them to reject a larva as prey. Thus, if toxic larval chemistry on the

surface can not be detected (Lindquist and Hay, 1995) or is internalized, larvae of a few chemically defended species potentially could reduce predation rates on non-chemically defended species simply if, on the surface, the chemically benign larvae mimic the flavor or odor of unpalatable larvae. This taste-based mimicry could act independently of visual cues, implying that even nonvisual predators, such as benthic particle feeders, might evolve to reject chemically benign larvae. Empirical studies with birds (e.g., Roper and Marples, 1997) and mammals (e.g., Provenza et al., 2000) and modeling studies (Augner and Bernays, 1998) indicate that flavors and odors can act as cues for toxic foods, and, thus, support mimicry systems.

DEFENSE BY SYMBIOSIS

A provocative hypothesis, originating primarily among marine natural products chemists (e.g., Kobayashi and Ishibashi, 1993; Faulkner et al., 1999), is that microbial associates are the true source of biologically active compounds isolated from some species of chemically rich invertebrates, primarily among sponges, bryozoans, and colonial tunicates. Many of these invertebrates harbor microbial symbionts and possess secondary metabolites with structural similarities to known microbial metabolites, yet few studies have convincingly demonstrated symbiont production of these metabolites. Two of these studies (Gil-Turnes et al., 1989; Gil-Turnes and Fenical, 1992), however, showed that externally brooded embryos of some crustaceans harbor surface-associated bacteria shown to produce secondary metabolites that inhibit infection by pathogenic microorganisms. Because crustaceans are not generally known to possess bioactive secondary metabolites, these studies illustrate the power of bacterial symbionts in protecting early life stages against pathogens, which is potentially a common phenomenon among many invertebrate taxa (see also Benkendorff et al., 2000).

More recently, Lindquist and coworkers (unpublished data) have found another example of a symbiont contributing to host defense, including its early life stages. These are unusual symbioses on Indo-Pacific coral reefs between conspicuous isopods and epibiotic microbial communities dominated by cyanobacteria, which give the isopods a bright red color and produce a chemical defense repulsive to fishes. For isopods, juveniles emerge directly from female brood pouches; because the mother hosts defensive microorganisms, ample opportunity exists for direct transmission of these ectosymbionts between isopods generations. In the field, even the smallest juveniles are covered by cyanobacteria. Among captive isopods, newly emerged juveniles, which hatch "naked," quickly become covered by the protective symbionts, suggesting that they behaviorally acquire them from their mother or neighboring isopods.

A most intriguing example of the involvement of a symbiont in the chemical protection of early life stages against predation is that of the bryozoan *Bugula*

neritina. Lopanik et al. (unpublished data) demonstrated that bryostatins protect larvae of *B. neritina* against predation by fish. Adults and larvae of this bryozoan host a unique bacterial symbiont, Candidatus *Endobugula sertula*, which is the putative source of the pharmacologically potent bryostatin macrolides (Davidson et al., 2001). Because the larvae carry only a small number of *E. sertula* cells (~3000 per larva) (Haygood et al., 1999), those carried by the larvae are not likely the source of the larval bryostatins. A much higher abundance of the symbiont occurs in the bryozoan's funicular cords, which transport nutrition between zooids and to the developing embryos, and in the ovicells where the larvae develop (Haygood, personal communication). Thus, a more plausible hypothesis for the origin of the larval bryostatins is that *E. sertula* in the funicular cords and the ovicells produce bryostatins that are transported by an unknown mechanism to the developing larvae.

SUMMARY

Given that bioactive natural products can deter feeding by diverse types of predators, the potential for these chemicals to diminish predation on early life stages seems great and, therefore, of major importance for understanding the evolution of life histories and reproductive characteristics of marine invertebrates. Life-history models incorporating parameters based on our developing understanding of early life-stage mortality, morphology, and behavior for individual species and their relationships to deterrent chemistry will yield more accurate hypotheses and predictions for investigating the population dynamics of many benthic marine invertebrates. For species with low larval mortality, population bottlenecks must occur at other life stages, most likely among populations of newly established juveniles, which, according to the hypothesis of Orians and Janzen (1974), may be constrained in their ability to elaborate a chemical defense.

While life-history models examine potential fitness advantages for incremental changes in various egg or larval characteristics (McEdward, 1997), chemical defenses have perhaps their primary impact on whether or not a larva can survive exposure to the intense predation common in many benthic habitats. For larvae of most species that can not produce a chemical defense, an exposed existence is unlikely in benthic habitats. Secondarily, if predation is not an issue for species with chemically defended larvae, then their larvae may be free to evolve characteristics, such as a short swimming duration and large size that minimize larval and juvenile mortality, respectively, by limiting dispersal away from suitable habitat and yielding larger juveniles immediately after settlement and metamorphosis.

As our knowledge of chemical defenses in early life stages of marine invertebrates grows, we will be able to examine connections among phylogeny, ecology, chemical defenses, and reproductive characteristics more rigorously. The results

of these analyses should provide a reasonable ability to confidently examine more general and far-reaching hypotheses about the roles of secondary metabolites in larval and juvenile ecology and for life-history evolution of marine invertebrates.

Acknowledgments—I thank the Journal *of Chemical Ecology* for the invitation to write this review. Much of the author's work presented in this review has been funded by the National Undersea Research Center at the University of North Carolina at Wilmington under NOAA grant numbers NA88AA-D-UR004 and NA36RU0060 and by NSF grants OCE 89-15304 (N.L.), OCE 89-11872 (M. Hay), CHE 90-08621 (W. Fenical), OCE 92-02847 (M. Hay), and OCE 00-02723 (N.L.).

MINI REVIEW

COMMUNITY AND ECOSYSTEM LEVEL CONSEQUENCES OF CHEMICAL CUES IN THE PLANKTON

MARK E. HAY[1,*] and JULIA KUBANEK[1,2]

(Received April 1, 2002; accepted June 4, 2002)

Abstract—Aquatic organisms produce compounds that deter consumers, alter prey behavior, suppress or kill target and nontarget species, and dramatically affect food-web structure, community composition, and the rates and pathways of biogeochemical cycles. Toxins from marine and freshwater phytoplankton create health hazards for both aquatic and terrestrial species and can significantly affect human activities and the economic vitality of local communities. A reasonable case can be made that phytoplankton metabolites such as dimethyl sulfide (DMS) link interaction webs that span hundreds to thousands of kilometers and connect production from oceanic phytoplankton to desert cacti and coyotes via zooplankton, fishes, and sea birds. The possible role of DMS in global heat budgets expands this effect even further. The ecosystem-wide and potentially global consequences of aquatic chemical cues is an underappreciated topic that warrants additional attention.

Key Words—Aquatic chemical ecology, biotoxin, complex interactions, DMS, harmful algal bloom, phytoplankton, zooplankton.

INTRODUCTION

Chemical signals produced by aquatic organisms play important roles as deterrents of consumers, pathogens, and competitors and as cues used for foraging, reproduction, and assessing danger from a variety of natural enemies. Such direct

effects are becoming well documented in a variety of aquatic systems (Hay, 1996; Tollrian and Harvell, 1999; McClintock and Baker, 2001). In this review, we emphasize that these same chemical cues commonly have indirect and cascading effects on the ecology and evolution of entire communities and ecosystems. These larger-scale spatial and temporal effects are less well studied and understood. As such, they offer considerable intellectual challenges to, and opportunities for, enhancing our appreciation for how chemical cues produce cascading impacts on species, communities, and ecosystems beyond the initial group of directly interacting organisms. Given our charge to focus on novel and less well-known topics for this mini-review, we chose to emphasize chemical cues among planktonic organisms. Direct effects of chemical cues in these systems is poorly known relative to those documented in benthic systems (Hay, 1996; McClintock and Baker, 2001). Additionally, studies of chemically mediated planktonic interactions have rarely progressed to the point of unambiguously identifying the metabolites responsible. However, it is clear that chemically mediated interactions are omnipresent among the plankton and that chemical cues commonly produce cascading effects far beyond the initial participants. We discuss examples of this below.

PHYTOPLANKTON TOXINS IN LAKES

Given the smaller size and contained nature of lakes and ponds relative to oceans, ecosystem level effects of chemically mediated interactions could be most apparent in these systems. Indeed, there are numerous cases in which toxins produced by pelagic freshwater cyanobacteria have been shown, or suspected, to produce strong effects on both aquatic organisms and nearby terrestrial species, including humans. Cyanobacterial poisoning of animals has been reported since the 1800s. Kills have included fishes, birds, dogs, livestock, and 50 renal dialysis patients in Brazil (Jochimsen et al., 1998; Chorus, 2001). In many cases, liver-targeting cyanobacterial microcystins are believed to have caused mortality. Microcystins are contained within cyanobacteria cells and are not commonly released into the water. However, cell lysis releases microcystins, and these can persist in freshwater systems for several weeks because their cyclic structure and unusual amino acid composition renders them resistant to degradation by many common bacterial proteases. Thus, animals can be affected via consumption of cells or via water-borne exposure to these released toxins. However, despite the copious literature on microcystins and closely related compounds, numerous other assays and chemical investigations suggest that cyanobacteria produce many as yet unidentified peptides, depsipeptides, lactones, alkaloids, and other metabolites with broad-reaching effects, some of which may be responsible for the ecological consequences attributed to microcystins (Chorus, 2001).

Humans who have ingested water exposed to cyanobacterial blooms have experienced abdominal pain, nausea, vomiting, diarrhea, headache, fever, muscular

pain, sore throat, dry cough, blistering of the mouth, atypical pneumonia, and elevated liver enzymes (Chorus, 2001). Illnesses in Europe, Australia, and the United States have been tracked to toxic cyanobacteria, but the role of the particular compounds causing these symptoms has not been clearly demonstrated. Given these symptoms, humans alter their behavior once cyanobacterial blooms are detected. This includes prohibition of human uses [drinking, swimming, water-contact activities—especially for those with compromised livers (e.g., alcoholics, those infected with hepatitis B)] and treatment of drinking water by filtration, chlorination, sieving, floculation with chemicals, adjustment of pH, and ozonation.

Numerous investigations have also demonstrated the effects of cyanobacterial metabolites on aquatic organisms. Survival, growth, and time of hatching were modestly affected when fish embryos were exposed to ecologically realistic concentrations of dissolved microcystins; older fish exposed to microcystins exhibited altered levels of mobility and feeding and shifted activity between day- and nighttime patterns (Chorus, 2001). Given the dramatic trophic cascades that fish feeding produces in lakes (Carpenter et al., 1985), these altered behaviors may affect ecological patterns and processes throughout the entire body of water.

Some zooplankters (e.g., copepods) are discriminating feeders that select among phytoplankton particles based on characteristics including taste (Porter, 1977). In contrast, other zooplankters (e.g., *Daphnia*) feed more indiscriminately and do not appear to select based on flavor or other chemical signals (DeMott, 1986; DeMott et al., 1991). Because they are more willing to feed on the foods that are offered, these indiscriminate feeders offer unusual opportunities for assessing the consequences of consuming toxic prey. Lampert (1982) surveyed how the presence of the toxin-producing cyanobacterium *Microcystis aeruginosa* affected 13 species of cladocerans and demonstrated that the smaller species were less affected than the larger ones. He speculated that this differential tolerance could drive seasonal shifts in species composition within the zooplankton community. Differential effects of the toxic cyanobacteria *Anabaena affinis* on cladocerans and rotifers can also reverse competitive outcomes among zooplankters and may change the species composition and size structure of zooplankton communities (Gilbert, 1990; Kirk and Gilbert, 1992). An overview of recent investigations (Christoffersen, 1996) suggests that cyanobacteria: (1) affect both phytoplankton and aquatic macrophytes via allelopathic compounds, (2) disrupt linkages between phytoplankton production and zooplankton growth, and (3) shift rates and pathways of energy flow, nutrient cycling, and degradation from pelagic to benthic zones. Thus, phytoplankton metabolites appear to produce cascades throughout the food web, affecting not only community structure and species composition, but also fundamental pathways and rates of biogeochemical cycles.

As might be expected from the strong effects noted above, cyanobacteria that produce toxic compounds can exert strong selection on herbivores, altering their genotypes over relatively short periods of time. As an example, Hairston et al.

(2001) hatched eggs of *Daphnia galeata* that had been deposited in stratified lake sediments over a span of 35 years; the prevalence of planktonic cyanobacteria had increased substantially during this 35-year period. *Daphnia* representing genotypes from three distinct deposition times were fed either a palatable alga, or a mix of the palatable alga plus the toxic cyanobacterium *Microcystis aeruginosa*. Effects of the cyanobacterium on the performance of each genotype demonstrated that *Daphnia*'s ability to tolerate the cyanobacteria had increased within little more than a decade.

Phytoplankton may also respond to, or be chemically manipulated by, other phytoplankton. Keating (1977) monitored bloom sequence in a lake over a three-year period, then tested the effects of cell-free filtrates of dominant cyanobacteria on other phytoplankters that either preceded or followed the cyanobacterial bloom. Filtrates suppressed predecessors in five of eight trials (no effect in the other three) while enhancing successors in six of nine trials (no effect in the other three). This suggests that allelopathic agents may affect the sequence of blooms in lakes, but the involvement of particular compounds has not been demonstrated.

PHYTOPLANKTON TOXINS AND EFFECTS IN THE SEA

Phytoplankton dominate primary production in the world's oceans and are found in almost all marine habitats. Approximately 7% of phytoplankton species are known to form large-scale blooms, dramatically impacting marine communities. Of these, about one third have been documented to produce noxious compounds that kill marine organisms or that are subject to trophic transfer and bioconcentration in animals (Smayda, 1997). The tendency of phytoplankton to form blooms, coupled with their ability to be moved over hundreds of kilometers and to produce potent toxins, can result in massive wildlife kills and shutdowns of coastal tourism and fisheries, dramatically impacting local economies and the health and function of coastal ecosystems. The increased frequency and wider geographic distribution of toxic algal blooms (Anderson, 1989) have become major environmental and health concerns around the world (NRC, 1999). Many phytoplankton toxins are passed to higher trophic levels, eventually reaching fishes, marine mammals, and human consumers (Shumway, 1990). Animal kills worldwide have been attributed to phytoplankton compounds with diverse molecular structures including polycyclic polyketides, macrolides, isoprenoids, and amino acid-derived compounds produced by dinoflagellates, diatoms, and other microalgal taxa (Figure 1). Much remains to be learned about how blooms initiate, why populations of phytoplankton expand so rapidly, how they are affected by interactions with other organisms, and why blooms stop. The crucial ecological question of why many microalgal species produce potent neurotoxins remains unanswered, although these compounds clearly have dramatic consequences

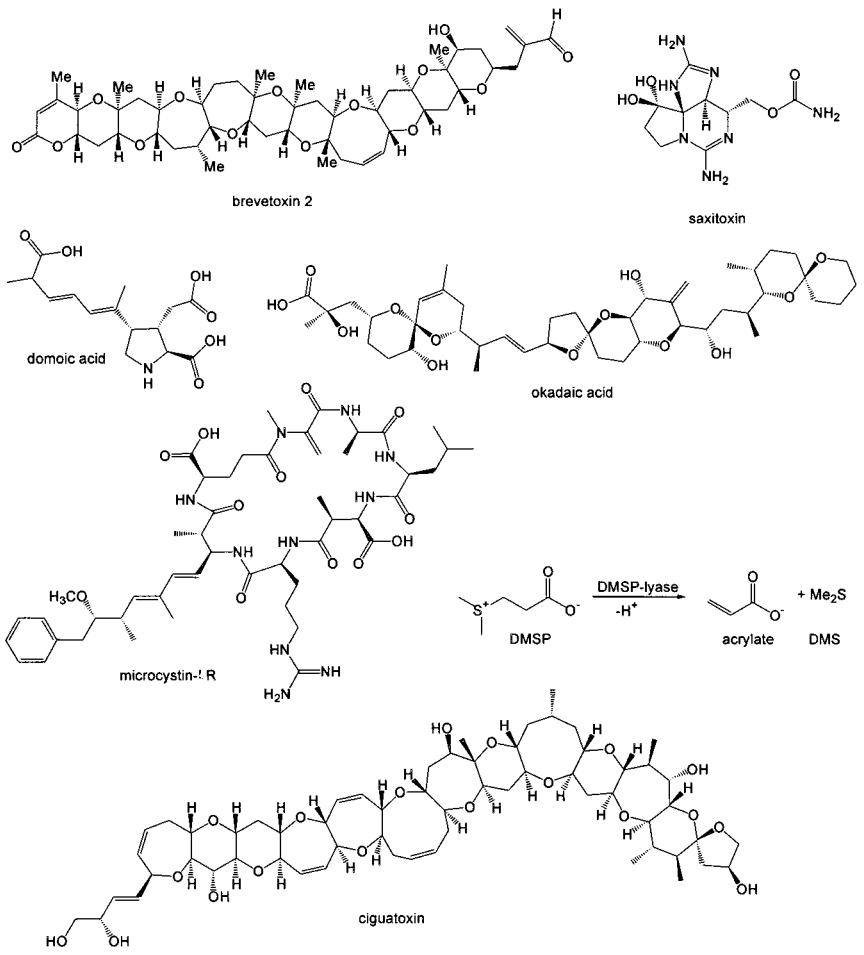

FIG. 1. Microalgal metabolites that affect food-web structure, community composition, human health and economy, and/or the rates and pathways of biogeochemical cycles.

on populations of many marine species, on community structure, and often on ecosystem function.

Microalgal blooms that involve transfer of algal metabolites to fish or filter-feeding shellfish, that cause animal mortality, and/or that reduce coastal water quality are referred to as harmful algal blooms (HABs) because of their negative economic and human health consequences. In the United States, conservative estimates of direct and indirect costs due to HABs averaged $49 million per year for the period 1987–1992, including public health, commercial fishery,

recreation/tourism, and monitoring/management costs [reported in year 2000 US dollars (Anderson et al., 2000)]. Ciguatera poisoning, the most prevalent human illness caused by ingestion of HAB toxins, sickens 50,000 people in tropical countries each year, and the reported numbers are believed to represent only 20–40% of the actual cases (NRC, 1999). Ciguatera toxins such as ciguatoxins, maitotoxin, and gambieric acids are produced by benthic dinoflagellates such as *Gambierdiscus toxicus* that grow epiphytically on seaweeds and on coral rubble. The toxins are bioconcentrated through the food web as herbivorous fishes and invertebrates feed on seaweeds and small turf communities harboring the dinoflagellates. Toxins consumed by the herbivores are then transferred, via predation, to larger fishes such as moray eels and barracuda. During the process of bioconcentration, the parent metabolites may be altered to become more toxic, generating greater risk for humans consuming top carnivores from reefs (Yasumoto and Murata, 1993). Many species of tropical fishes accumulate these toxins without showing signs of physiological stress; however, when these fish are consumed by humans, ciguatera toxins activate voltage-gated sodium channels, causing gastrointestinal and respiratory distress, followed by neurological problems, bone and joint pain, and chronic fatigue that can last for months or years. Because the distribution of ciguateric dinoflagellates is geographically patchy but generally persists over time, fishermen and local residents often know which reefs harbor contaminated fishes.

There has been a strong association between large-scale animal kills and blooms of several pelagic microalgal species, such as *Karenia brevis* (ex *Gymnodinium breve*), which produces brevetoxins. Immunohistochemical and pathological data have supported the role of brevetoxins in the death of animals such as manatees (Bossart et al., 1998), and strong circumstantial evidence points to brevetoxins as the cause of death for dolphins, pelicans, and various fishes and invertebrates during several blooms over the last century (Gunter et al., 1948; Steidinger et al., 1973).

Toxins produced by HABs can fundamentally affect entire marine ecosystems, can impact locations hundreds or thousands of kilometers from where blooms initially form, and can even affect human activities and terrestrial ecosystems. As an example, in 1987–1988, satellite images showed a bloom of *Karenia brevis* initiating along the Gulf coast of southern Florida, being transported northward by the Gulf Stream, and being delivered to inshore North Carolina by a loop current from the Gulf Stream. *K. brevis* had never before been seen so far north of the tropics. This unanticipated bloom had a variety of deleterious effects including: (1) massive scallop mortality in coastal North Carolina, (2) closure of shellfish harvesting, (3) respiratory distress in humans and pets along coastal beaches with 48 documented cases of human illness attributed to brevetoxicosis, and (4) reduced coastal tourism and recreation by humans; costs to coastal communities were estimated at $24 million due to loss of the shellfish harvest alone (Tester and Fowler, 1990).

The effects of HABs on coastal resources and on charismatic megafauna such as whales, dolphins, and manatees are relatively well documented compared to their potential effects on less obvious systems such as detrital food webs and soft-sediment communities (e.g., Gunter et al., 1948; Kvitek, 1993; Bossart et al., 1998). When toxic blooms senesce, do their natural products affect detrital pathways or biogeochemical cycles and rates of processing? The direct effects of compounds are unknown, but faunal changes do occur in soft-bottom communities beneath toxic algal blooms. When Olsgard (1993) monitored soft-bottom communities at depths of 69–184 m and described changes in fauna over a five-year period that contained a bloom of the toxic flagellate *Chrysochromulina polylepis*, he found a bloom-associated depression in numbers of both species and individuals; this effect persisted for nearly two years following the bloom. Although such contrasts confound the effects of phytoplankton toxins with the potential effects of increased detrital biomass and decreased light/oxygen, they suggest the potential for substantial chemically mediated effects on detritivore communities.

Diatoms belonging to the genus *Pseudonitzschia* also have cascading effects on coastal food webs. On both the east and west coasts of North America, these diatoms have been shown to produce domoic acid, a neuroexcitatory amino acid that enters the food web through shellfish such as mussels (Bates et al., 1989) and filter-feeding fishes such as anchovies (Scholin et al., 2000). Humans, sea lions, cormorants, and other consumers of toxic fish or shellfish have all been killed by domoic acid poisoning in episodes that have only been documented in the last 15 years. Domoic acid kills mice at concentrations similar to those found in contaminated seafoods, and the toxin was isolated from the body fluids of animals that died after consuming these foods, providing strong support for toxin-induced mortality (Bates et al., 1989; Scholin et al., 2000).

When neurotoxic dinoflagellates such as *Alexandrium* spp. bloom in coastal waters, they are consumed by filter-feeding animals such as butter clams. These clams are relatively unaffected by consuming the toxins because their neurons are insensitive to saxitoxin and other closely related sodium channel-blocking toxins produced by *Alexandrium* spp. (Kvitek, 1993). Saxitoxins are concentrated in clam siphons where small fish can detect them during "siphon-nipping" predatory behavior, leading the fish to avoid toxic clams. Siphon-nipping behavior by fishes may have selected for the sequestration of toxins in these more exposed regions of the clams. When clam toxicity levels are high, sea gulls and sea otters reduce their overall feeding on clams and reject clam siphons. Thus, the microalgal toxins are transferred from primary producers to clams, where they act as a chemical defense against the next trophic level, deterring both aquatic (otters and fishes) and terrestrial (birds) vertebrate predators. Because otters avoid toxic shellfish and suffer physiological distress if they mistakenly feed on them, the dinoflagellate blooms that occur primarily in protected bays may historically have restricted otters from these bloom areas and limited the feeding activities of these keystone

species to outer coasts where clams have lower concentrations of dinoflagellate-derived toxins (Kvitek, 1993). Because otter feeding has dramatic cascading effects on nearshore ecosystems, turning unproductive urchin barrens into productive and species-rich kelp forests (Estes and Duggins, 1995), restriction of otters due to microalgal toxins has the potential to fundamentally alter the distribution, abundance, and function of entire coastal ecosystems (Duggins et al., 1989, Kvitek, 1993). Consequently, these phytoplankton metabolites have cascading effects on community structure and on temporal and spatial ecosystem dynamics involving seaweeds, invertebrates, fishes, and keystone predators such as otters.

Additionally, recent work by Bricelj et al. (2000) has shown that some bivalves show differential susceptibility to the accumulation of dinoflagellate toxins and to their negative physiological effects. In experiments in which softshell clams (*Mya arenaria*) from two populations were exposed to toxic *Alexandrium tamarensis*, clams from the population with no previous history of exposure to *Alexandrium* showed higher mortality, lower respiration, impaired burrowing capacity, reduced food clearance rates, and a 10-fold lower toxin accumulation, relative to clams from a historically exposed location. Failure of clams to burrow could have negative consequences for toxin-susceptible individuals, because exposed bivalves are more vulnerable to predatory birds and crustaceans. Thus, exposure to occasional blooms of toxic *Alexandrium* may lead to increases in the number of toxin-resistant individuals in a population, due to differences in fitness between resistant and susceptible bivalves. Ongoing changes in the frequency and geographic distribution of toxic microalgae may result in further selection for tolerance of toxins among filter-feeding organisms whose populations show variance in their degree of resistance to toxins. This could produce a gradual increase in the levels of toxins contained in bivalves that humans harvest. The mechanism(s) by which some bivalves minimize the effects of phytoplankton toxins are as yet unknown, although the possibility of resistance-conferring mutations in mollusk sodium channels is the subject of current investigation (V. M. Bricelj, personal communication).

Although phytoplankton metabolites can enter food webs via shellfish and filter-feeding fishes, phytoplankton face the greatest threat of herbivory from grazing zooplankton including ciliates, copepods, rotifers, tintinnids, and invertebrate larvae (Turner and Tester, 1997). The greatest opportunity for chemically mediated interactions may therefore occur between phytoplankton and zooplankton. Nevertheless, toxicity of phytoplankton compounds has generally been determined against vertebrates rather than zooplankton, with effects on zooplankton being uncertain. Zooplankters sometimes prefer, or perform better on, nontoxic versus toxic species or clones (e.g., Huntley et al., 1986; Teegarden, 1999). However, correlations such as these can be confounded by other microalgal characteristics, including differences in morphology, nutritional value, and chemicals other than known neurotoxins. Purified phytoplankton compounds added to seawater containing copepods have occasionally been found to negatively affect zooplanktonic grazers (e.g.,

Miralto et al., 1999), although it is unlikely that this method adequately represents the consumption of compounds as part of a natural diet. Rigorously documenting how zooplankters are affected following consumption of particular compounds may demand further technological developments. Despite uncertainty regarding the effect of phytoplankton metabolites on zooplankton behavior and physiology, a handful of studies have shown that some zooplankton (e.g., copepods) do accumulate phytoplankton metabolites such as brevetoxins (Tester et al., 2000). Thus, zooplankton provide another route whereby phytoplankton toxins can enter the food web and reach higher consumers such as fishes, whales, and humans. If zooplankters avoid feeding on phytoplankters due to their production of specific compounds or selectively graze on nontoxic phytoplankton (favoring the proliferation of toxic phytoplankton), then phytoplankton compounds may play a crucial role in the initiation and persistence of large-scale harmful algal blooms.

Additionally, toxic microalgae may proliferate due to the allelopathic effects of their excreted metabolites on competing microalgae. For example, in cross-culturing experiments, medium preconditioned by the benthic dinoflagellate *Prorocentrum lima* reduced growth of diatoms (Windust et al., 1996) and other epiphytic dinoflagellates (Sugg and VanDolah, 1999). Windust et al. (1996, 1997) reported that okadaic acid, a product of *P. lima* that inhibits protein phosphatases, depressed diatom growth, and they proposed that less toxic sulfated and diol esters are rapidly biotransformed to okadaic acid upon release from *P. lima* cells and/or upon contact with competing cells. *P. lima* was found to be considerably less sensitive to okadaic acid than were other microalgae. In contrast, Sugg and VanDolah (1999) showed that although protein phosphatase activity of competing dinoflagellates was inhibited by *P. lima* exudates and by pure okadaic acid, reduced growth of competitors was associated with a nonokadaic acid fraction.

PREY RESPONSES TO CHEMICAL CUES FROM CONSUMERS

Many marine and freshwater zooplankton undergo diel vertical migration (DVM), usually living at darker depths during the day and feeding in surface waters at night when their visually foraging predators are less active. This behavior is cued by chemical detection of zooplankton predators (De Meester et al., 1999). DVM apparently lessens zooplankton susceptibility to consumers, but the (as yet unknown) compounds mediating this behavior also affect biogeochemical processes systemwide. As an example, in marine systems, about 15–50% of all metazoan zooplankton biomass above 500 m moves to near the surface at night and migrates to depths of 300–600 m during the day (Longhurst and Harrison, 1988). Given the permanent density discontinuity at 40–200 m in tropical and subtropical oceans, this migration can transport carbon and nutrients below the pycnocline, mediate the alkalinity of surface waters, and influence CO_2 uptake at the surface. As zooplankters migrate from the photic zone to below the pycnocline, assimilated

carbon and nutrients move with them. Some of this stays in the deeper waters due to respiration, excretion, and predation by deep-water consumers. It is estimated that the flux of respired carbon due to DVM equals 13–58% of computed particulate sinking flux across the pycnocline and adds 5–20% to current estimates of global sinking flux of organic carbon across the pycnocline (Longhurst et al., 1990).

Available nitrogen often limits production in the photic zone, and DVM further lowers available nitrogen. Crude calculations indicate that exudation of nitrogen from zooplankton performing DVM may move 21% of the total nitrogen pool below the photic zone (Longhurst and Harrison, 1988). Thus, when zooplankton detect chemical evidence of nearby consumers and initiate diel vertical migrations, their behavior moves significant quantities of both carbon and nitrogen from the photic zone to below the pycnocline, affecting both biogeochemical fluxes and the structure of marine food webs. Given the smaller and more contained nature of lakes versus oceans, these chemically cued processes might produce even stronger effects in stratified freshwater systems. However, because lakes are more prone to climatic disturbance, the stratification of nutrients could be "reset" more frequently.

Just as zooplankton chemically sense their consumers and undertake DVM, some phytoplankton chemically sense zooplankton grazers and respond in adaptive ways. Solitary cells of phytoplankton such as *Scenedesmus acutus* often form colonies that are more resistant to grazing if they are exposed to water conditioned by feeding *Daphnia* (Van Donk et al., 1999). Rather than inducing increased resistance, dinoflagellates use chemical indicators of zooplankton presence to determine when to excyst and emerge from the sediment "seed bank" into the water column. When Hansson (1996) incubated sediment cores in containers with no zooplankton, zooplankton in a cage so that they could not access the emerging phytoplankton, or dead zooplankton (presenting the chemical signals from *Daphnia*, but not their feeding action), a sixfold greater emergence was found in the absence of zooplankton than in either other treatment. In field assays, both *Peridinium wisconsinense* and *P. pusillum* emerged in greater numbers from sediments in lakes with small zooplankon populations than ones with larger populations. Additionally, like zooplankton, some species of mobile phytoplankton also undergo diel vertical migration, often moving to deep waters when their consumers move to shallow waters (Jones, 1993). Thus, (as yet unknown) chemical cues from zooplankters appear to be perceived by microalgae, producing effects on seasonality, succession, and composition of phytoplankton communities (Rengefors et al., 1998).

CHEMICALLY CUED CASCADES OVER THOUSANDS OF KILOMETERS?

Microalgal metabolites that function as defenses against ciliate or zooplankton consumers have the potential to create cascades of interactions that span

hundreds or thousands of kilometers and involve species and interactions that are far removed from the initial participants. One of the most interesting examples of this is the cascading effect that phytoplankton-generated dimethylsulfide (DMS) and acrylate appear to have on ciliates, zooplankton, fishes, sea birds and, potentially, desert plants, desert animals, and global weather patterns.

Many grazers selectively avoid, or less heavily utilize, phytoplankton strains that have high potential to cleave dimethylsulfoniopropionate (DMSP) enzymatically to DMS and acrylate when ingested by grazers (Figure 1) (see review by Wolfe, 2000). This potential appears to be regulated more by levels of the enzyme DMSP lyase than by levels of DMSP. The biochemical nature of the variance in DMSP lyase is not known, but consumers like ciliates and dinoflagellates avoid strains with high ability to create DMS and acrylate from DMSP, relative to strains with lesser ability to do this. DMS should rapidly diffuse from consumers, potentially providing a cue for other organisms. Acrylate sterilizes consumer guts and cascades through food chains from common phytoplankton such as *Phaeocystis*, to dominant zooplankton like euphausids, and finally to higher level consumers such as penguins, with antimicrobial effects in the guts of both the primary and secondary consumers (Sieburth, 1960).

In areas of high productivity, significant quantities of DMS are released into surface waters, held in benthic pore waters beneath areas of high productivity, and released into the atmosphere (Andreae, 1985). There are numerous examples of atmospheric DMS being elevated three- to sixfold over background levels near productive areas such as polar frontal zones. Thus, DMS is often associated with areas of high productivity, areas where planktivores are feeding, areas of increased krill density, and areas where fishing success by birds is likely to be greater.

There is mounting evidence that certain species of sea birds with strong olfactory capabilities use DMS as a foraging cue and that the use of an area by these birds sets up a cascade of increased use by other birds that do not have olfactory systems that are as highly developed. Nevitt (2000) provides a convincing overview of this topic. Certain tube-nosed seabirds (procellariiformes) have among the largest olfactory bulbs of any birds and forage over hundreds and even thousands of kilometers of featureless ocean searching for patchily distributed foods such as krill, squid, and fish. Field tests have shown that these birds are attracted to fishy odors (cod liver oil, tuna oil, fish homogenate) and that a specific subset of the smaller and more cryptic species that have especially strong olfactory capabilities are attracted to DMS dispersed in either water or air (Nevitt et al., 1995). For many organisms that migrate over long distances and use odors as cues, the notion of homing to odors produced hundreds or thousands of kilometers away seems unlikely due to turbulence disrupting odor plume gradients and due to dilution dropping signals below detection limits. Nevitt notes that DMS signals from damaged phytoplankton can persist for hours to days and suggests that birds use DMS associated with upwelling areas, seamounts, or other productivity

discontinuities, as olfactory guideposts to aid navigation to general fishing areas. Once in productive areas, they may use more localized searching strategies.

A second strategy for these birds is to fly directly from the colony to feeding grounds that are hundreds or thousands of kilometers away. To do this, procellariiformes may rely on spatial memory, experience, olfactory guideposts, or other navigational cues associated with persistent olfactory signals along bathymetric features. Numerous species of albatross and the white-chinned petrels seem to use this strategy, flying directly to distant feeding grounds without foraging along the way. These feeding grounds are not constant, but can fluctuate in space and time; therefore, birds may start area-restricted foraging only after changes in olfactory cues indicate a productive fishing area (Nevitt, 2000).

On research cruises where DMS and bird densities were recorded, blue petrels and prions were significantly associated with areas where DMS levels were highest (Nevitt, 2000). DMS is a predictor of krill grazing, and petrel and prion diets are composed predominantly of crustaceans, including krill, amphipods, and copepods. Surveys of areas with high, medium, and low DMS levels indicated that prions were the primary users of high DMS level sites. At medium- and low-concentration sites, prions were present, but there were also approximately 15 additional species of birds. This pattern suggests that high DMS sites may be new patches that erode over time. It seems possible that prions use superior olfaction to find sites first and specialize on these until competing birds, or predatory birds, become common. Later-arriving species seem to be less sensitive to DMS signals and may visually cue on foraging prions to find more productive sites. This is consistent with findings that smaller, more cryptic species such as prions and storm-petrels respond strongly to DMS-scented slicks or aerosols, whereas larger, more visible species do not (Nevitt et al., 1995). This process may link local production of phytoplankton chemical cues to abundant zooplankton and fishes, and then to birds and terrestrial systems that are hundreds of kilometers distant. As seabirds move marine biomass and nutrients to nesting sites on distant terrestrial habitats, they are providing nutrient and energy subsidies to these terrestrial systems. Such marine inputs can fundamentally alter resource-starved terrestrial systems by producing demonstrable, and often dramatic, increases in the growth rates or densities of organisms as diverse as desert cacti, coyotes, beetles, and spiders (Polis and Hurd, 1996; Rose and Polis, 1998; Sanchez-Pinero and Polis, 2000). The DMS affecting this transfer of energy and nutrients can even be argued to produce broader-scale effects, in that atmospheric oxidation products of DMS are important in the formation of aerosols in the lower atmosphere, affecting cloud formation, altering the earth's albedo, and impacting global heat balance (Charlson et al., 1987).

The cross-ecosystem effects of aquatic chemical cues that we describe here should not be unique to the plankton. Such interactions probably occur in numerous systems, but are simply underinvestigated. Leaves falling from trees into

forest streams are one of the primary energy sources for these streams, but little is known about how specific metabolites contained in these terrestrial leaves affect aquatic systems in terms of rates of degradation, use by shredding insects, or stream food webs and biogeochemical cycles in general. Similarly, when large masses of chemically defended seaweeds are torn from tropical reefs and deposited on deep sand or mud plains, do the metabolites in these tissues affect microbial processes, biogeochemical cycles, or the species normally using these sedimentary environments? Chemical signals directed at target organisms in one community may commonly affect nontarget species in other systems—this possibility seems worthy of further attention by experimentalists.

Acknowledgments—Our research on phytoplankton chemical ecology is supported by NSF grant OPP 0083381 (M.E.H.) and OCE-0134843 (J.K.). Henrik Pavia, Gunilla Toth, Joseph Montoya, John Parker, Deron Burkepile, Alan Wilson, and John Romeo provided comments that improved the manuscript.

(Received April 19, 2002; accepted June 16, 2002)

Abstract—A hypothesis that size selection of prey by predators elicits size-specific responses from prey was examined. Freshwater snails, *Pomacea canaliculata*, ages 1, 3, 7, 15, 30, or 60 days, were given an extract of 3-day-old snails, and 3-day-old snails were given extracts of snails of the other ages or eggs. Snails 15 days or younger crawled out of the water in response to the 3-day-old snail extract, but older ones did not. The 3-day-old snails responded to the extracts of snails of all examined ages, but not to the extract of eggs. Snails of four size classes, 3-days-old, small (shell lengths 8–12 mm), medium (13–20 mm), and large (>28 mm) were given extracts of snails of each of these four classes. The 3-day-old snails crawled out of the water in response to the extract of 3-day-old snails, but showed a lower or no response to other extracts. Larger snails buried themselves in the soil in response to the extract of snails of similar sizes. These responses are discussed in the context of the evolution of the snail's avoidance behavior in response to the size-dependent prey choice by the predator.

Key Words—Alarm response, apple snail, crawling, ontogenetic differentiation, *Pomacea canaliculata*, predator-prey relationship, self-burying.

INTRODUCTION

Prey use chemical cues to detect predators (Dodson et al., 1994; Chivers and Smith, 1998; Kats and Dill, 1998; Zimmer and Butman, 2000). Some anurans also use mechanical stimuli (Warkentin, 1995; Chivers et al., 2001). Peptides, disaccharides,

* E-mail: ichis@affrc.go.jp

0098-0331/02/1000-2017/0 © 2002 Plenum Publishing Corporation

and ammonium ions have been identified as cues (Rittschof, 1990; Kats and Dill, 1998; Zimmer et al., 1999; Rahman et al., 2000). These cues are effective only at low concentrations (Petterson et al., 2000; Von Elert and Pohnert, 2000). Selection pressure by predators causes prey to change their life history strategy (Skelly and Werner, 1990; Buskirk, 2000; Lardner, 2000). Prey can respond to predators in several ways (Boersma et al., 1998), although local populations may have fewer responses than the species (Laurila, 2000; Von Elert and Pohnert, 2000). The prey's response depends on how the predator attacks.

The presence of predators such as crayfish and fish causes freshwater snails to seek habitats where predator pressure is weaker (Turner et al., 1999, 2000; Lewis, 2001). Snails can escape predators by crawling out of the water (Alexander and Covich, 1991a,b; Covich et al., 1994; Lewis, 2001) or by self-burying in the soil (Snyder and Snyder, 1971). Crawling out of the water avoids small predators, such as dragonfly larvae, small fish, or crayfish (Rowe, 1987; Slootweg, 1987; Cook, 1989), but exposes snails to bigger predators, such as birds (Beissinger, 1983; Donnay and Beissinger, 1993). Therefore, snails that are subject to predation by bigger predators need to respond differently. Hence, snails may have evolved size-dependent avoidance behavior (Covich et al., 1994; Dodson et al., 1994).

Growth- or size-dependent avoidance behaviors by snails have rarely been reported (e.g., Watt and Young, 1992; Mondor et al., 2000). Snyder and Snyder (1971) reported that *Pomacea paludosa* adults bury themselves to avoid predators. Halwart (1994) noticed that small *P. canaliculata* snails crawled above the water surface in an aquarium when they were maintained with common carp, an effective predator. Thus, snails may change their avoidance behavior as they grow. This hypothesis was tested by using *P. canaliculata* (Lamarck) (Gastropoda: Ampullariidae) of various ages and sizes, and the difference in avoidance behaviors is discussed in relation to the behavior of predators.

METHODS AND MATERIALS

Effects of Aging on Juvenile Snails. Six egg masses of *P. canaliculata* were collected in September to October 1999 in Saga, southern Japan. Each egg mass was kept individually in a Petri dish (90 $\times$ 20 mm) in the laboratory at 24 $\pm$ 1°C under a lighting regime of 16 hr light–8 hr dark (16L:8D). More than 1000 hatchlings emerged from each egg mass on 13 October. The snails from each egg mass were cultured in an aquarium (225 $\times$ 160 $\times$ 210 mm) in 2 liters of water. The water was changed every day, and then the snails were fed a spoonful of ground artificial bait for carp (Nippon Pet Food Co. Ltd., Tokyo, Japan). Dead hatchlings were removed when the water was changed. At 1, 3, 7, 15, 30, and 60 days after hatching, 60 snails were taken randomly from each aquarium. These snails are referred to as

age-varied snails hereafter. Also on each of these days, 360 3-day-old snails of an additional egg mass were used. These 3-day-old snails are referred to as age-fixed snails hereafter.

On each experiment day, 10 age-varied snails from each egg mass were transferred to each of six test tubes with 50 ml deionized water. Similarly, 10 of the age-fixed group were placed in each of 36 test tubes. Thus, 72 test tubes (36 for the age-varied group and 36 for the age-fixed ones) were prepared on each experiment day. The test tubes were kept in the laboratory at $24 \pm 1^{\circ}$C. One hour after transfer, 3–10 more age-varied and -fixed snails were taken from each aquarium and air-dried for 20 min. The weight of these snails, pooled by each egg mass, was measured to the nearest 0.001 mg. Snails from the aquarium were macerated in 0.001 M EDTA in a volume 1000 times their weight in a Petri dish. The supernatant is referred to as the extract. The maceration mimicked chewing of the snails by predators. Immediately after the extracts were prepared, the number of snails above the water surface (a_1) in each test tube was counted, and 0.5 ml of extract was gently dropped onto the water surface. All test tubes of the age-varied snails (receiver) received the extract of the age-fixed snails (sender), and each of the six tubes of the age-fixed snails received the extract of one of the age-varied snails. Thus, both receiver and sender were replicated six times for each egg mass on each experiment day. Application of 0.5 ml of EDTA alone evoked no significant response by snails. At 1 hr after the extract was added, the number of hatchlings above the water surface (a_2) was counted. The response (Rp) in each test tube was evaluated as:

$$Rp = (a_2 - a_1)/(10 - a_1). \quad (1)$$

Because only crawling out of the water was tested in this experiment, Rp was defined as 0 when $a_2 \leq a_1$ in a given test tube. Because a_1 was always ≤ 10, Rp was always 0. After the observation, the snails in each test tube were air-dried in the laboratory for 20 min and weighed to the nearest 0.01 mg. Means of arcsine-transformed Rp were compared by a two-way ANOVA for egg mass (random factor) and snail age (fixed factor).

Multiple-regression analyses of the hatchlings' response against mean weight of receiver or sender and age were performed. It was assumed that the hatchling's response to the extracts would be reduced as both the receivers and senders grew and their mean weight increased.

Response of 3-Day-Old Snails to Egg and Adult Snails. In a second experiment, 360 3-day-old snails of one egg mass from Saga were prepared as in the first experiment. Newly laid egg masses (30×10 mm) and adult females and males also were collected on this day from a canal in Kumamoto-ken, southern Japan. The experiment was performed in April to June 2000. As in the first experiment, 36 test tubes were prepared, and, 1.5 hr later, six tubes were each given 0.5 ml of either 0.001 M EDTA or extracts of 3-day-old snails, egg mass, adult females,

or males, or nothing. One hour later, the snail response was evaluated as before. The experiment was performed seven times. Mean responses were compared by a two-way ANOVA among the egg masses as a random factor and among the extracts as a fixed factor.

Comparison of Responses between Juvenile and Fully Grown Snails. In a third experiment, egg masses and snails of various sizes were collected from August to September 2000 in rice fields in Kumamoto-ken. The egg masses were placed in Petri dishes (90 × 20 mm) and kept in an incubator at 24 ± 1°C and 16L:8D. Snails of four size classes were used: 3-day-old snails, small snails (shell lengths 8–12 mm), medium (15–20 mm), and large (28 mm). Up to 100 snails of each class were placed in an aquarium (190 × 125 × 120 mm), that was submerged in a deeper aquarium (4 × 2 × 0.5 m) with 30 cm soil on the base, above which water was kept 10 cm deep. Females and males of the large class were put in different aquaria of the same size. Seven days before assumed hatching of the collected egg masses, 12 snails of each size class were taken from the snail stock and separately put in an aquarium (225 × 160 × 210 mm) with 2 liters of water. Snails hatched from egg masses were maintained as in the previous experiment. The experiment was replicated 18 times.

On the morning of the third day after hatching, 10 aquaria (225 × 160 × 210 mm) with 2 cm of soil and 2 liters of water were prepared. About 2 hr later, three 3-day-old snails and one snail of each size class were placed in each aquarium. One and a half hours later, 20 more 3-day-old snails and one to two snails of each of small to large classes were taken from the stock and air-dried for half an hour. The snails were weighed, and extracts of each class were prepared as before. The numbers of snails on the soil or wall in the water, on the wall above the water, buried in the soil, and floating beneath the water surface were counted. Then, 20 ml of 0.001 M EDTA or extract was given to each aquarium. Pairs of aquaria received the same extract, and the results of each pair were pooled. Snail behaviors were observed at 0.25, 0.5, 1, 2, 12, and 24 hr after addition of the extracts. Crawling above the water, floating beneath the water surface, and burial in soil were considered avoidance behavior. Resting on the soil or walls or closing the operculum were considered nonresponding behaviors. The avoidance response to a given extract at a given time was evaluated as:

$$Rp = (b_2 - b_1)/(c - b_1), \tag{2}$$

where b_1 and b_2 are the numbers of snails showing avoidance behavior before the extract was applied and at a given time, respectively, and c is the total number of snails in the paired aquaria, i.e., 6 for the 3-day-old snails, 2 for the small, medium, female and male snails, and 4 for large snail (female + male). The means of *Rp* in each snail class were compared among extracts by one-way ANOVA.

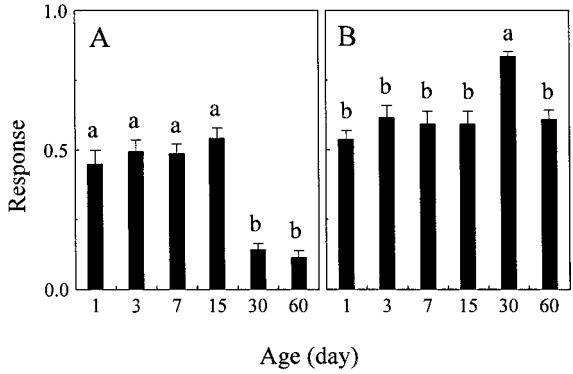

FIG. 1. Responses of 1-to 60-day-old snails to extract of 3-day-old snails (A) and those of 3-day-old snails to extracts of 1-to 60-day-old snails (B). Columns and bars denote the mean and 1 SE, respectively. Letters above the bar in each panel indicate significant difference at $P < 0.05$ by a Tukey's test.

RESULTS

Effects of Aging on Responses of Juvenile Snails. The age-varied snails reduced their responses to the extract of 3-day-old snails after the snails reached 30 days old (Figure 1A). The responses were different among egg masses ($F_{5,25} = 9.201$, $P < 0.001$) and among ages ($F_{5,25} = 23.150$, $P < 0.001$), but the interaction of these factors was not significant ($F_{25,180} = 1.547$, $P = 0.055$). A Tukey's test revealed differences at $P < 0.05$ in responses between 1–15 days and after 15 days, but the response was not different either within 1 to 15 days or 30 and 60 days.

Responses of the age-fixed snails were less varied (Figure 1B). The response was different among ages ($F_{5,25} = 12.512$, $P < 0.001$), but not among egg masses ($F_{5,25} = 2.211$, $P = 0.085$), and the interaction of these factors was significant ($F_{25,180} = 1.901$, $P = 0.009$). A Tukey's test revealed a difference at $P < 0.05$ between the response to the extract of the 30-day-old snail and the responses of the extracts of snails of the other ages, among which differences were not detected.

Multiple-regression equations for the response of the age-varied snails to 3-day-old snail extract and that of the age-fixed snails to extracts of age-varied snails were, respectively,

$$Rp = -0.0085a + 0.0014w + 0.5099, \quad r^2 = 0.250 \tag{3}$$

$$Rp = 0.0014a + 0.0001w + 0.6002, \quad r^2 = 0.015 \tag{4}$$

Where *Rp* is the response, *a* is the snail age on the experiment day, and *w* is the snail weight. The coefficient of age in equation 3 was significant ($F_{1,213} = 12.072$, $P < 0.001$), but that of weight was not ($F_{1,213} = 0.284$, $P = 0.595$). The coefficient of either variable in equation 4 was not significant ($F_{1,213} = 0.631$, $P = 0.428$ in age or $F_{1,213} = 0.000$, $P = 0.984$ in weight). The results indicate that age had a negative influence on snail response, but weight had none. Thus, snails crawled above the water until 15 days old in response to extract of the same-aged snails, and 3-day-old snails responded to the extract of any snails aged up to 60 days.

Responses of 3-Day-Old Snails to Egg and Adult Snails. The 3-day-old snails responded much less to the extracts of eggs, females, and males than to the extract of 3-day-old snails (Figure 2). The response was different among the extracts ($F_{5,30} = 29.809$, $P < 0.001$), but not among egg masses ($F_{5,30} = 1.305$, $P = 0.286$), and the interaction was significant ($F_{30,216} = 4.364$, $P < 0.001$). A Tukey's test revealed differences in response at $P < 0.05$ between the extracts of the 3-day-old snails and the others. Since responses to EDTA and the egg did not differ from each other, eggs did not cause a response.

Size-Dependent Response. Alarm responses of snails of all classes were highest at 0.5–1 hr (Figure 3). The response was different between extracts in all snail classes: $F_{4,624} = 55.308$, $P < 0.001$ in the 3-day-old snail; $F_{4,624} = 8.370$, $P < 0.001$ in the small snail; and $F_{4,624} = 14.685$, $P < 0.001$ in the medium snail. Responses were not different between large female and male snails ($0.046 \pm$

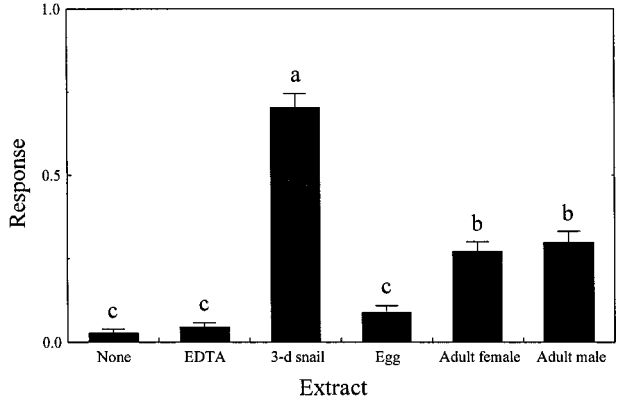

FIG. 2. Reponses of 3-day-old snails to 0.001 M EDTA and extracts of eggs, 3-day-old snails, adult females, and adult males. The response of the snails in the test tube without any extract is represented by "None." Columns and bars denote the mean and 1 SE, respectively. Letters above the bars indicate significant difference at $P < 0.05$ by a Tukey's test.

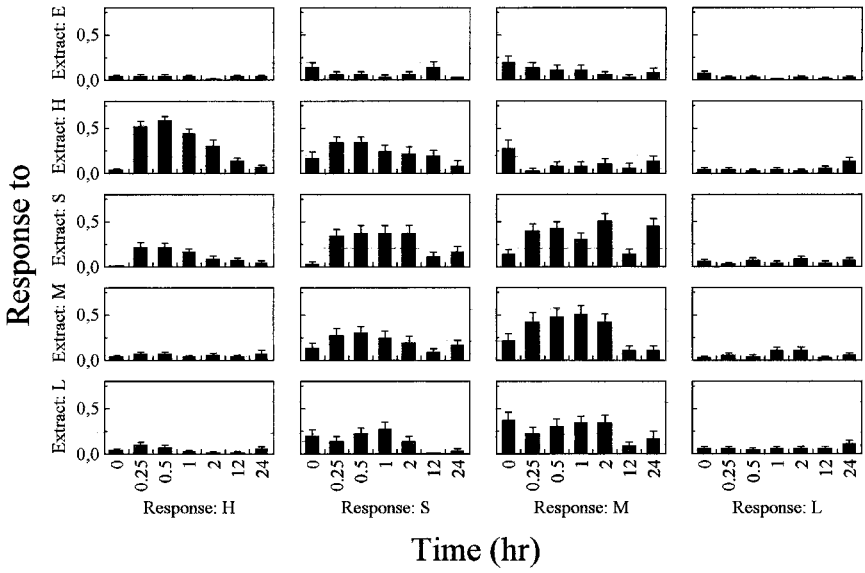

FIG. 3. Responses of 3-day-old (H), snail (S), medium (M) and large snails (L) to 0.001 M EDTA (E) and extracts of these snails. Bars correspond to observations made at 0.25, 0.5, 1, 2, 12, and 24 hr, and represent mean response ± 1 SE.

0.006 SE in female and 0.044 ± 0.006 SE in male; $F_{1,1077} = 0.108$, $P = 0.743$). Responses in each class snail were not different between the extracts of females and males ($F_{1,646} = 0.000$, $P = 0.998$), although the medium-sized snails responded more than the other snails did (Figure 4). Hence, the female and male large snails were pooled as the large class.

Since most responses occurred within 1 hr, snail responses within 1 hr were evaluated again by equation 2. Most 3-day-old snails crawled above the water in response to the extract of the same class and responded less or little to the other extracts (Table 1). On the other hand, most small and medium-sized snails buried themselves in soil in response to extract of the same or adjacent size classes. However, the large snails responded less to all extracts than the other snails did. The mean *Rp* shown by each class to the extract of the same class was different among classes (ANOVA, $F_{3,68} = 7.804$, $P < 0.001$). A Tukey's test showed a difference at $P < 0.05$ between the large class and the others, but the responses were not different among 3-day-old, small, and medium classes. Hence, small to medium snails contain cues stimulating alarm responses in other snails of their sizes, but large snails contain little or no cues to stimulate snails of any size.

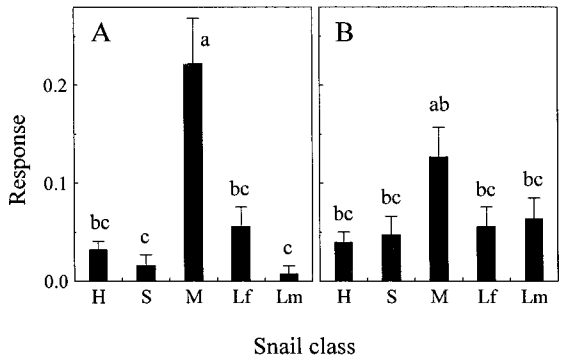

FIG. 4. Responses of 3-day-old (H), small (S), medium (M), large female (Lf) and large male (Lm) snails to extracts of large female (A) and large male (B) snails. Bars denote mean response ±1 SE with letters indicating significant difference at $P < 0.05$ by a Tukey's test.

TABLE 1. RESPONSE OF SNAILS OF EACH SIZE CLASS TO 0.001 M EDTA OR EXTRACT OF SNAILS OF EACH SIZE CLASS

Responding snails	Extract	Response (mean ± SD)			
		Crawling	Floating	Burying	Total
3-day-old	EDTA	0.00 ± 0.00	0.06 ± 0.08	0.02 ± 0.08	0.07 ± 0.12c
	3-day-old	0.61 ± 0.19	0.06 ± 0.12	0.00 ± 0.00	0.68 ± 0.12a

[a] Significant difference at $P < 0.05$ by a Tukey's test in the total response in each size class is represented by lowercase letters.

DISCUSSION

Alarm responses of age-varied snails to the extract of 3-day-old snails were age-dependent. Snails responded until 15 days old, but responses of older snails were much reduced. On the other hand, 3-day-old snails responded similarly to extracts of any snail between ages 1–60 days (Figure 1). Since shell lengths reach about 10 mm within one month after hatching (Estebenet and Cazaniga, 1992), the small snail in Table 1 corresponds to such age. Hence, snails change their alarm response from crawling above the water to self-burying at some age between 15 and 30 days. Furthermore, the alarm response can be elicited by an even more diluted extract than the extract used in the present study (Snyder and Snyder, 1971). Thus, the change in the alarm responses with the snail's growth can be explained by the predator–prey relationship, not by the way of making the extracts.

Since predators attack prey of sizes that are easy to handle (Cook, 1989), they adopt different attacking behavior in accord with prey sizes or select prey of limited sizes (Rowe, 1987; Alexander and Covich, 1991a). The predator's choice of prey size encourages prey to ignore attacks on different sizes, because of the cost of response (Slootweg, 1987; Rowe, 1987; Cook, 1989; Alexander and Covich, 1991b; Dodson et al., 1994; Chivers and Smith, 1998; Lewis, 2001). If different sized prey are attacked by different predators showing different behaviors, the prey will respond only when they perceive cues from the victims of similar sizes, and their responses may be size-dependent. If the hypothesis is true for *P. canaliculata*, predators should use different strategies to catch snails of different sizes.

Pomacea snails, which live in shallower places in rivers in Latin America (De Castellanos and Fernández, 1976), are preyed upon by aquatic insects and fingerlings when the snails are small, and by turtles, alligators, birds, and mammals when they are larger (Murphy, 1955; Vaz-Ferreira et al., 1965; Snyder and Snyder, 1971; Guimarães, 1981; Beltzer, 1985; Donnay and Beissinger, 1993; García, 1996; Santos et al., 1996; Stevens et al., 1999). Kai et al. (2001) report that carp of about 20 cm body length can eat snails with shells <10 mm. Although the carp is not native to Latin America, the results of Kai et al. suggest that fish of such a size preyed upon snails of these sizes there. Larger fish that can eat larger snails may not be able to approach the shore, but larger snails should be subject to predation by birds and mammals. In this situation, crawling above the water is safe for juvenile snails with shells <10 mm, and self-burial is efficient for larger snails.

Prey respond to signals from predators and victims (e.g., Crowl and Covich, 1990; Ball and Baker, 1996; Nyström and Åbjörnsson, 2000; Pettersson et al., 2000; Chivers et al., 2001; Chivers and Mirza, 2001; Laurila, 2001). If *P. canaliculata* snails respond to substances from the conspecifics, my results (Figures 1 and 2; Table 1) indicate that snails 1–15 days old contain substances that cause juvenile snails to respond, but older snails and eggs do not. This suggests that the substances

are produced when the snail body is formed and disappear at some age from 15 to 30 days. After the substances disappear, other cues that induce self-burying are produced in the snail. These new substances also disappear when the snails have shell lengths of about 30 mm. Thus, the snail's response to these substances changes with growth. In other words, the change in the snail's response to predators must be linked with the production of alarm substances in the body.

Acknowledgments—This study was undertaken as a part of the research project on the control of the apple snail by the Ministry of Agriculture, Forestry, and Fisheries of Japan. I thank Dr. Wada for his suggestions on the study and Mr. Yoshida for help with the experiments.

Abstract—The bacterial component of marine biofilms plays an important role in the induction of larval settlement in the polychaete *Hydroides elegans*. In this study, we provide experimental evidence that bacterial metabolites comprise the chemical signal for larval settlement. Bacteria were isolated from biofilms, purified and cultured according to standard procedures. Bacterial metabolites were isolated from spent culture broth by chloroform extraction as well as by closed-loop stripping and adsorption of volatile components on surface-modified silica gel. A pronounced biological activity was exclusively observed when concentrated metabolites were adsorbed on activated charcoal. Larvae did not respond to waterborne metabolites when prevented from contacting the bacterial film surface. These results indicate that an association of the chemical signal with a sorbent-like substratum may be an essential cofactor for the expression of biological activity. The functional role of bacterial exopolymers as an adsorptive matrix for larval settlement signals is discussed.

Key Words—*Hydroides elegans*, larval settlement, biofilm, chemical signal, bacteria, exopolymers.

INTRODUCTION

The life cycle of many sessile marine invertebrates includes a larval stage. A critical phase during the larval lifespan occurs when dispersed larvae gain the ability to attach and subsequently metamorphose into sedentary juveniles called settlement (Crisp, 1974; Scheltema, 1974; Chia, 1978). Larval settlement is a nonrandom process, i.e., surface exploration and the final choice of an attachment site are guided by specific signals associated with a marine substratum (Pawlik, 1992; Rodriguez et al., 1993).

The bioorganic film on marine surfaces is a major source of larval settlement signals (Brancato and Woollacott, 1982; Hadfield et al., 1994; Wieczorek and Todd, 1998; Maki, 1999). Biofilms are complex agglomerates of microorganisms (bacteria, diatoms, protozoa, and fungi) enclosed in a matrix of extracellular polymers (Costerton et al., 1995; Rittschof, 1997). The temporal and spatial variability of environmental factors such as tidal height, flow regime, and nutrient availability is distinctly reflected in the species richness and evenness of bacterial populations in marine biofilms (Strathmann and Branscomb, 1979; Strathmann et al., 1981; Wieczorek et al., 1995; Olivier et al., 2000). Due to their responsiveness to changes in environmental conditions, bacteria are important informative signposts for surface-exploring larvae. A broad range of marine invertebrate larvae are able to distinguish between bacterial communities of different composition, physiological condition, and growth phase, indicating a subtle and finely tuned larval response to bacteria-derived information about the substratum (Bonar et al., 1986; Le Tourneux and Bourget, 1988; Pearce and Scheibling, 1991; Keough and Raimondi, 1996).

The induction of larval settlement by bacteria is reportedly due to both waterborne metabolites (Cameron and Hinegardner, 1974; Fitt et al., 1990; Rodriguez and Epifanio, 2000) and cell surface-associated signals (Kirchman et al., 1982; Maki and Mitchell, 1985; Maki et al., 1990; Szewzyk et al., 1991). Only a few classes of bacteria-derived settlement signals have been recognized, such as lipids (Leitz and Wagner, 1993; Schmahl, 1985), oligopeptides (Neumann, 1979), glycoconjugates (Kirchmann et al., 1982; Szewzyk et al., 1991), and DOPA-mimetics (Weiner et al., 1989). However, no larval settlement signal of bacterial origin has been purified or elucidated so far. The underlying mechanism of the induction of larval settlement by marine bacteria is largely unknown.

In this study, we extended our previous investigations on the induction of larval settlement in the polychaete *Hydroides elegans* (Haswell) by marine bacteria. The assessment of individual bacterial isolates revealed an equiproportional ratio of highly inductive to moderately inductive to noninductive bacterial species (Lau and Qian, 1997; Unabia and Hadfield, 1999; Lau et al., 2002). Larval settlement was exclusively invoked by viable cells of inductive bacteria (Lau and Qian, 2001). To investigate the role of bacterial metabolites as presumptive chemical signals

for larval settlement in *H. elegans*, we intended a comprehensive bioassay-guided isolation and gas-chromatographic analysis of bacterial metabolites. This investigation included the metabolites of four bacteria: *Roseobacter* sp., *Rhodovulum* sp., *Micrococcus* sp., and *Vibrio* sp. The former two are inductive; the latter two are noninductive for larval settlement in *H. elegans* and served as control strains.

METHODS AND MATERIALS

Larval Culture Procedures. Colonies of *Hydroides elegans* were obtained from submerged rafts at a fish farm in Clear Water Bay, Hong Kong. The tubes of sexually mature individuals were cracked to release gametes. After fertilization, gametes were transferred into aerated 2-liter beakers containing 0.22-μm-filtered seawater (FSW) and algal food medium (*Isochrysis galbana*, Tahitian strain, 10^5 cells/ml). The larval culture was incubated at 24°C under a 15:9 hr (light:dark) photocycle. After 4 days, larvae were transferred into new FSW and food medium. When the morphology indicated competence (Wisely, 1958) after day 5 or 6, the larvae were sieved out and immediately used in bioassays.

Bacterial Cultures. Stock cultures of bacteria (*Roseobacter* sp., *Rhodovulum* sp., *Micrococcus* sp., and *Vibrio* sp.) were obtained from the Marine Bacteria Culture Collection at the Hong Kong University of Science and Technology (strain designations UST950701-009, UST950701-012, UST950701-006, and UST950701-007, respectively). Aliquots (2 ml) of stocks were individually inoculated into 300 ml of sterile culture broth [0.5 % (w/v) peptone, 0.3 % (w/v) yeast extract] prepared with charcoal-filtered artificial seawater (ASW). These cultures were incubated at 30°C and grown for 48 hr to stationary phase in order to enrich the broth with bacterial metabolites.

Liquid–Liquid Extraction of Bacterial Metabolites. Spent culture broth was separated from bacterial cells by centrifugation and sterile filtration (0.22 μm). Bacterial metabolites were isolated from broth by liquid–liquid extraction (LLE) in disposable hydromatrix-filled cartridges (Chem-Elut, 5 ml; Varian Inc). Cartridges were loaded with 5 ml of broth and extracted with 5 ml of chloroform (analytical grade). Extracts were concentrated to 1 ml under *vacuo* and stored at −80°C until analysis. Autoclaved culture broth and ASW were treated accordingly and served as controls. Extractions were repeated twice with samples from different batches of bacterial cultures.

Isolation of Volatile Bacterial Metabolites. Volatile bacterial metabolites were isolated by closed-loop stripping (CLS) according to Grob and Zürcher (1976). We modified the CLS apparatus to serve as a microbial bioreactor (Figure 1). For this purpose, a 2-liter vessel (Normag) was filled with 1.5 liters of culture broth, autoclaved, and subsequently inoculated with bacteria. The closed loop was formed by connecting the vessel with a 0.22-μm membrane-filter (Microfiltration Systems) and two cartridges of preconditioned, surface-modified silica gel (C_8 and

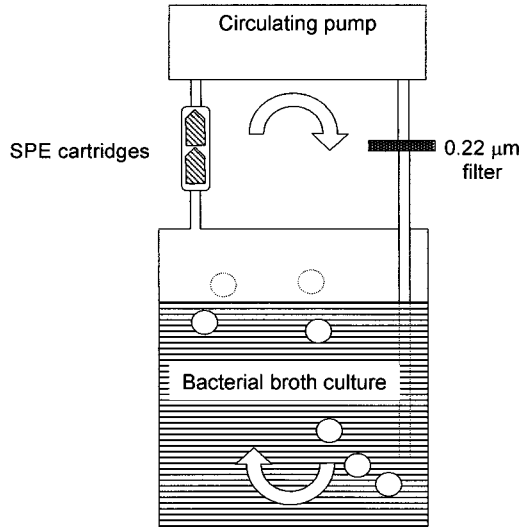

FIG. 1. Schematic diagram of the closed-loop stripping apparatus. The bacterial culture broth was continuously purged by a circulating air stream. Volatile metabolites were adsorbed on pre-conditioned, surface-modified silica gel (C_8 and CN).

CN; 50 mg, Bond-Elut, Varian Inc.). The utilization of solid-phase extraction cartridges for CLS has been reported previously (Priesnitz, 2000). The headspace volume of approximately 500 ml was continuously circulated (ca. 30 ml/min) through the system by a magnetically clutched micropump (Metal Bellows Corp.). Besides sweeping volatile metabolites out of the aqueous phase onto the sorbents, this principle served to aerate the bacterial culture, keep the sorbents moist, and sterilize the circulating airstream. The bacterial culture was grown in the vessel at 25°C for 48 hr while volatile metabolites were stripped and trapped. Subsequently, the cartridges were eluted with 50 μl of acetone (analytical grade). Controls were prepared by stripping culture broth without bacteria. The isolation procedures were repeated twice with samples from different bacterial cultures. After CLS, aliquots of cultures were grown on marine agar to check for potential contamination by other bacteria.

In addition to CLS, a purge-and-trap system (Tekmar) was used to isolate volatile metabolites from stationary phase cultures. This procedure served as a qualitative control to evaluate the efficiency of the preparative CLS methodology. A small volume (50 ml) of spent culture broth was purged with helium for 15 min, while volatile components were trapped on a Carbowax cartridge (Tekmar: ALS 2016; LSC 2000). Adsorbed compounds were subsequently concentrated in a liquid-nitrogen-operated cryofocusing module after heating the Carbowax cartridge to 150°C. Autoclaved culture broth and ASW were analyzed accordingly

and served as controls. The isolation procedures were repeated twice with samples from different batches of cultures.

Analytical Procedures. All samples were analyzed by coupled gas chromatography–mass spectrometry (GC-MS). Samples were separated by GC (Hewlett-Packard 5890 Series II) on a fused silica capillary column (DB5; 30 m; 0.25 mm ID). The temperature program was as follows: 5 min isotherm at 40°C, 40–150°C at 10°C/min, and 2 min isotherm at 150°C. Samples were injected on-column (1 μl) or, in the case of purge-and-trap, by heating the cryo-focusing module to 200°C. Samples were detected by MS (HP 5972) at 70 eV. The ion source temperature was 162°C; the scanning range was m/e 40–300.

Larval Bioassays with Bacterial Films. Bacteria at stationary growth phase were harvested from broth cultures, washed by centrifugation (3000*g*), and resuspended in sterile FSW at 10^8 cells/ml. Aliquots (5 ml) were transferred into polystyrene Petri dishes (Falcon, #1006) and incubated for 3 hr for the attachment of bacteria on the dish surface. Subsequently, the dishes were dip-rinsed (10 times) and filled with sterile FSW and 20 larvae. This experimental setup is referred to as the "single-dish assay." A double-compartment test vessel was used to concurrently test the effect of attached bacteria and their waterborne metabolites on larval settlement (double-dish assay). The compartment, one of which was covered with a bacterial film, were separated by a nonpenetrable mesh for larvae (90 μm). The vessel received 40 larvae (20 per compartment) and was mounted on an orbital shaker (50 rpm) to facilitate the diffusion of waterborne bacterial metabolites during the bioassay.

Larval Bioassays with Isolated Bacterial Metabolites. Aliquots (50 μl) of bacterial metabolites in the chloroform and acetone extracts were adsorbed onto charcoal wafers (self-made from carbonized wood) and glass slides (Corning). The charcoal wafers ($5 \times 5 \times 1$ mm) were activated by heat (200°C, 2 hr), and glass slides were acid-rinsed prior to utilization. Control substrata were prepared with pure organic solvents. Pretreated substrata were fixed on the bottom of the wells of a multiwell tissue culture plate (Falcon, #3043) with double-sided adhesive tape. Individual wells were filled with 2 ml of FSW and 20 competent larvae.

Assessment of Biological Activity. In all bioassays, larval behavior was continuously monitored throughout the first 30 min and subsequently recorded after 1, 2, 4, and 24 hr. Each sample (five replicates) was investigated along with controls of unfilmed Petri dishes or solvent-treated charcoal and glass substrata. The settlement stage of the larvae was determined according to morphological descriptions in Carpizo-Ituarte and Hadfield (1998). Experiments were repeated twice with different batches.

Statistical Analysis. All bioassays were performed with five replicates. The percentages of larval settlement in individual experimental treatments were arcsine-transformed. In order to improve the transformation, a value of $1/(4x)$ (x representing the number of larvae per test vessel) was assigned to replicates with no

larval settlement (Zar, 1996). Since settlement data did not meet the normality assumption (Shapiro-Wilk's W test), they were analyzed nonparametrically. This was achieved by transformation of values to ranks followed by one-way ANOVA and Tukey's multiple comparison (Conover and Iman, 1981). Pairwise comparisons were performed with Student's *t* test. The data presented in the figures are not transformed. Results were considered reproducible when individual statistical evaluations of experimental repetitions produced the same statistical outcome.

RESULTS

Larval Response to Bacterial Films. In the single-dish assay, larvae immediately displayed a distinctive settlement response upon encountering films of *Roseobacter* sp. and *Rhodovulum* sp., i.e., they established surface contact and began to crawl over the film surface. Within 5 min, larvae firmly attached and began to secrete the primary mucous tube. During the next 4 hr, attached larvae developed branchial lobes, which subsequently developed into radioles. After 5 hr, juvenile worms secreted a calcareous tube. No statistical difference was observed between the larval response to films of *Roseobacter* sp. and *Rhodovulum* sp. ($p = 0.668$; 24 hr). In contrast, the percentage of responding larvae was lower in treatments with bacterial films of *Micrococcus* sp. and *Vibrio* sp. ($p < 0.001$; 24 hr) (Figure 2A). In the double-dish assay, the larval response to films of *Roseobacter* sp. and *Rhodovulum* sp. was analogous to the single-dish assay above, whereas no response was observed in the respective unfilmed compartment of the test vessel (Table 1). The bacterial film density in these assays was in the range of 10^5 to 10^6 cells/mm^2.

Larval Response to Bacterial Metabolites. The chloroform extracts induced significant levels of larval settlement when adsorbed to charcoal. Settlement occurred exclusively on the surface of the charcoal wafer, but not on the test vessel. No statistical difference in larval settlement was observed among the four metabolite-containing samples ($p > 0.153$, Tukey's test; 24 hr; Figure 2B). No settlement was observed in the negative controls (i.e., charcoal pretreated with pure

chloroform, and chloroform extracts of sterile ASW and culture broth) ($p < 0.04$, 24 hr; Figure 2B, Table 2). With the exception of *Rhodovulum* sp. ($p = 0.093$, *t* test; 24 hr; Figure 3), the percentage of settlement on glass was lower than on charcoal ($p < 0.016$, 24 hr; Figure 3). The volatile metabolite samples originating from the CLS procedure did not induce larval settlement (Table 2).

Analytical Results. The analysis of major constituents in the metabolite samples originating from the different isolation procedures and bacterial strains is summarized in Table 2. The major composition differed with respect to the isolation

Note: ^{CN} refers to compounds retained on the silica-bonded nitrile phase (CN). If not indicated otherwise, compounds were retained on octyl phase (C_8).

[a] The biological activity (BA) is denoted by the symbols (+) and (−). The composition of bacterial metabolites from closed-loop stripping and purge-and-trap is given for each bacterial strain. The composition of the liquid–liquid extracted metabolites of the four strains is summarized in the last column.

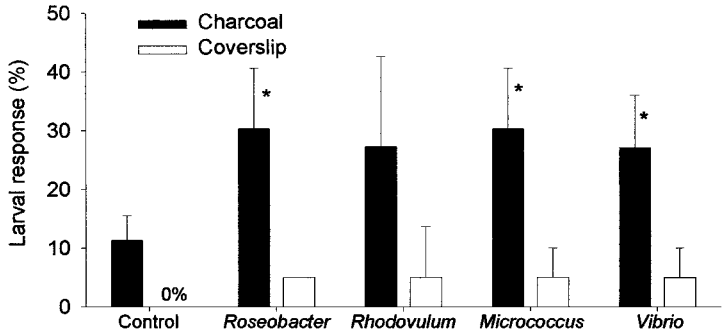

FIG. 3. Larval settlement in response to charcoal- and glass-adsorbed chloroform extracts of bacterial metabolites. Data are mean percentages (±1 SD; 5 replicates) of larval settlement after 12 h. * Statistically significant difference (Student's t test, $\alpha = 0.05$).

procedure but was relatively homogenous among the four different bacterial strains. The metabolites from CLS consisted mainly of alkanes, alkenes, and alkylated hydroxyketones, while dimethylated oligosulfides comprised the major compound class in the purge-and-trap isolation. The composition of the chloroform extracts was more complex compared to that from CLS but comprised the same classes of compounds. The gas chromatograms of the chloroform extracts revealed a similar peak pattern among the four bacterial strains (Figure 4). The broad assignment of compound classes is summarized for the retention windows of 3–11, 11–13, and 13–17 min (Table 2).

DISCUSSION

The aim of this study was to isolate bacterial metabolites and investigate their presumptive role as chemical signals for larval settlement in *Hydroides elegans*. Bacterial suspension cultures were used as sources for bacterial metabolites. This approach was advantageous over the production of metabolite-enriched seawater from bacterial films in order to yield bacterial metabolites in a preparative scale. The bacteria chosen belong to different phylogenetic branches, including gram-positive (*Micrococcus* sp.), *α-Proteobacteria* (*Roseobacter* sp. and *Rhodovulum* sp.), and *γ-Proteobacteria* (*Vibrio* sp.).

A broad isolation strategy for bacterial metabolites, encompassing liquid–liquid extraction and closed-loop stripping, was chosen for the enrichment of the putative chemical signals for larval settlement. A general description of the CLS technique and detailed reports of successful isolations of volatile pheromones from seawater samples can be found in Zeeck et al. (1991), Gassmann et al. (1995), and Bartels-Hardege et al. (1996). The two isolation procedures resulted in chloroform

extracts containing mainly lipophilic metabolites and acetone extracts containing volatile metabolites in a wide range of polarities. In order to remove the organic solvents, the samples were adsorbed on activated charcoal and glass substrata, which served as vehicles for bacterial metabolites in larval bioassays.

The larval response to the charcoal-adsorbed chloroform extracts was the same as that to the inductive films of *Roseobacter* sp. and *Rhodovulum* sp., both in terms of the magnitude of the larval response (Figure 2A) and the rate of morphogenesis (see Carpizo-Ituarte and Hadfield, 1998, for morphogenetic details). Since the controls did not elicit any larval response in the bioassay, the observed biological activity was likely due to extracted bacterial metabolites rather than culture broth components. This result shows for the first time that a fraction of waterborne bacterial metabolites served as a chemical signal for the induction of larval settlement in *H. elegans*. It further indicates that larval settlement is not due to a synergistic effect of dissolved and surface-bound signals. This possibility has been raised previously by Unabia and Hadfield (1999) and Lau and Qian (2001), and has been confirmed in the oyster *Crassostrea gigas* (Bonar et al., 1986; Fitt et al., 1990).

In contrast to the pronounced biological activity of the charcoal-adsorbed chloroform extracts, no larval response resulted from air-dried extracts on glass slides. The latter is likely due to the absence of biologically active components on the glass slide, suggesting that the association of the chemical signal with a suitable substratum is an essential cofactor for the induction of larval settlement by bacterial metabolites. A similar concept was supported by the outcome of the concurrent investigation of bacterial cells and waterborne metabolites in the double-dish assay (Table 1). Here, the bacterial metabolites originated exclusively from the compartment bearing the bacterial film. However, no concentration gradient of waterborne bacterial products was supposed to be present in the agitated vessel, as indicated by the rapid and homogenous diffusion of a dye in a control vessel (data not shown). Since larval settlement was exclusively observed in the filmed compartment, the presence of the bacterial film was thought to be essential for the inductive effect of bacterial metabolites. The combined observations of induction of larval settlement by waterborne bacterial metabolites and the exclusive occurrence of larval settlement in the filmed compartment of the test vessel indicated that an association of waterborne metabolites with the bacterial film surface was prerequisite for the inductive effect.

We hypothesize that the association of bacterial metabolites with the film surface is facilitated by high binding affinities of exopolymers surrounding

←

FIG. 4. Gas chromatograms of chloroform extracts of bacterial metabolites of *Roseobacter* sp., *Vibrio* sp., *Rhodovulum* sp., and *Micrococcus* sp. GC conditions (Hewlett-Packard 5890 Series II): 30 m fused silica capillary column (DB-5), 0.25 mm ID; temperature program: 40°C for 5 min, 40–150°C at 10°C/min, 150°C for 2 min.

the bacterial cells. Exopolymers are surface-active molecules comprised of heteropolysaccharides, proteins, and glycoproteins. They can be regarded not only as an adsorptive "sponge," but also as a diffusion barrier for metabolites (Decho, 1990). We have previously demonstrated that exopolymers themselves do not evoke a settlement response in *H. elegans* larvae (Lau et al., unpublished). However, the results of the current study indicate exopolymers are essential as mediators of larval settlement or as vehicles for chemical signals. Owing to their distinctive binding properties (Rees, 1976), exopolymers may retain bacterial metabolites on the cell surface and, thus, render the induction of larval settlement. This hypothesis is in accord with a similar suggestion on the role of bacterial exopolymers in mediating larval settlement in oysters (Decho and Zimmer-Faust, 1996).

Thus far, our data demonstrated that the four bacterial strains produced a chemical signal for larval settlement in suspension culture. However, this effect was not paralleled by the induction activity of these strains' monospecific films. In contrast to *Roseobacter* sp. and *Rhodovulum* sp., the monospecific films of *Micrococcus* sp. and *Vibrio* sp. did not evoke larval settlement (Figure 2A). What was the reason for this discrepancy? Provided that exopolymers mediate larval settlement by binding inductive bacterial metabolites to the cell surface, the lack of a settlement response on the films of *Micrococcus* sp. and *Vibrio* sp. may be related to the properties of exopolymers in these bacteria. It is well known that the quantity and quality of exopolymers may vary drastically among strains or even within the same strain under different conditions (Sutherland, 1985; Decho, 1990). Moreover, bacteria lacking exopolymers are common (Cowen, 1992). Thus, the effect of a monospecific bacterial film on larval settlement may likely be affected by the possession, quantity, and quality of exopolymers. However, a correlation of the bacterial strains activity on larval settlement with the properties of their exopolymers is currently not possible since the relative amounts of exopolymers of the four strains under investigation, as well as their composition, are unknown. An alternative explanation for the discrepancy may be that *Micrococcus* sp. and *Vibrio* sp. produce lower quantities of inductive metabolites *Roseobacter* sp. and *Rhodovulum* sp. Provided this case, biological activity was detected only after enriching the metabolites by the isolation procedures employed in this study.

The chromatographic and spectroscopic analysis of isolated metabolites revealed a similar composition among the four bacteria (Figure 4, Table 2). The bulk of components in the chloroform extracts (LLE) was dominated by compounds of low to medium polarity, such as alkylated alkanes, alkenes, and alkylated hydroxyketones in the volatility range bracketed by *n*-heptane and *n*-eicosan. The composition of the more volatile fraction of bacterial metabolites enriched by the CLS technique differed more distinctly among the individual bacterial strains, but the major compound classes were the same as in the chloroform extracts. However, these samples did not evoke a larval response in the bioassay. The purge-and-trap analysis specifically pointed to high concentrations of dimethylated oligosulfides

in the volatile fraction of bacterial metabolites. These compounds are well known as bacterial degradation products of organic sulfur compounds (McCarty et al., 1993). Since the sulfides were absent in the samples obtained by LLE, they may not contribute to the induction activity.

We are currently developing a liquid-chromatographic protocol for a preparative bioassay-guided isolation and purification of the biologically active chloroform extracts. The similarity in composition of the four extracts under investigation may allow the separation procedure to be standardized.

Acknowledgments—The authors thank A. Brakenhoff, I. Roehl, and F. Priesnitz for technical support during work carried out at the University of Oldenburg, Germany. We express our gratitude to the Safety and Environmental Protection Laboratory at HKUST, namely, Ms. W. P. Leung for her assistance in operating the purge-and-trap unit. This study was partially supported by a joint research scheme between the DAAD, Germany and the RGC, Hong Kong (G_HK006/00) and RGC grants CAG01/02_SC01, HKUST6133/99M, HKUST6100/02M to P. Y. Qian.

Abstract—The submerged living larvae of *Acentria ephemerella* were fed in the laboratory with either *M. spicatum* or *Potamogeton perfoliatus*, two of their host plants. Larvae exhibited a reduced growth when fed *M. spicatum*, a freshwater angiosperm that contains high concentrations of tannins, secondary metabolites known for their herbivore-deterrent and antimicrobial properties. In this study, we investigated the influence of food-derived tannins on gut microbiota. Bacterial densities in the guts did not differ between the food regimes, ranging from 2.8 to 13.3 $\times$ 10^6 cells per gut. Gut bacteria were characterized with cultivation techniques and subsequent identification of the strains by molecular methods. We isolated 17 bacterial strains belonging to all subdivisions, i.e., we identified α-, β-, and γ-proteobacteria, *Cytophyaga/Flavobacteria* (CF) and several Gram-positive bacteria. All except one Gram-positive strain were found in the guts of larvae fed with *P. perfoliatus*. Gram-positive bacteria and bacteria of the CF cluster were more sensitive to polyphenol-containing extracts of *M. spicatum* in an agar diffusion assay than strains of the α- or γ-proteobacteria subdivision. Our results suggest an influence of food-derived tannins on gut microbiota in *A. ephemerella*.

Key Words—Aquatic angiosperm, gut symbionts, hydrolyzable tannin, polyphenol, freshwater macrophytes.

INTRODUCTION

Tannins (polyphenols) are secondary metabolites known for their ability to bind and precipitate proteins or enzymes (Spencer et al., 1988). However, some herbivores are well adapted to tannin-containing plants (Manuwoto and Scriber, 1986; Barbehenn and Martin, 1992). Despite numerous investigations, the precise mechanisms of tannin–herbivore interactions are still unknown.

An important function of tannins in plants is to provide protection against a wide range of potential phytopathogenic microorganisms (Field and Lettinga, 1992). Tannins possess diverse antimicrobial activities (Scalbert, 1991); thus, tannins could also be influencing gut microbiota of herbivores. Consequently, Schultz et al. (1992) hypothesized "that any negative impacts of plant polyphenols on insects or vertebrates may be no more than a fortuitous side effect of plant interactions with microbes."

Larvae of the aquatic moth *Acentria ephemerella* (Lepidoptera: Pyralidae) feed on both tannin-containing and tannin-free freshwater macrophytes, causing substantial damage (Gross et al., 2001, 2002). *Acentria* grows significantly more slowly when fed *Myriophyllum spicatum* than when fed tannin-free pondweeds (Choi et al., 2002). *M. spicatum* contains approximately 10% tannins based on dry weight (Gross et al., 1996).

The impact of food-derived tannins on gut microbiota of lepidopteran larvae has been investigated only in the economically important species *Lymantria dispar* and its pathogen *Bacillus thuringiensis* (Appel and Schultz, 1994). The present study was conducted to characterize naturally occurring gut bacteria of the freshwater moth *Acentria ephemerella.* We compared the gut microbiota of larvae fed tannin-free *P. perfoliatus* and larvae fed tannin-containing *M. spicatum* to each other and to those epiphytic bacteria found on the respective host plants. Finally, we investigated the susceptibility of gut microbiota to extracts from both macrophytes and pure phenolic compounds.

METHODS AND MATERIALS

Sampling. M. spicatum and *Potamogeton perfoliatus*, both food plants of *Acentria* larvae (Gross et al., 2002), were sampled either by snorkeling or by SCUBA diving in Untersee, a shallow part of Lake Constance, Germany, in August 2001. Samples were stored in coolers and transferred to a 4°C cooling chamber at the institute. The fresh plant material was divided into three groups the next day. Apical shoot sections (upper 2–5 cm of shoots) and green leaves from the upper 25 cm were separated from the first group of plants. These were ground with a mortar and pestle in liquid nitrogen and freeze-dried separately for further

extraction. Individual leaves were picked for harvesting epiphytic bacteria from the second group. Leaves were chosen randomly from the upper 25 cm; no apical shoot sections were taken. Larvae were picked from the remaining plant material and kept in 1.5-liter glass jars in lake water. Larvae were only collected from *P. perfoliatus* since no larvae were present on *M. spicatum* at the sampling date. Larvae were divided into two groups and, for two days, fed constantly with apical shoot sections of either *M. spicatum* or *P. perfoliatus*.

Harvesting Bacteria. To isolate epiphytic bacteria, about 10 mg fresh weight (FW) of leaf material was suspended in 1 ml sterile sodium tetrapyrophosphate (PPi) solution (0.1 M) in an Eppendorf vial (1.5 ml). PPi had been shown to facilitate a good recovery of attached bacteria in arthropod guts (Cazemier et al., 1997). Preliminary experiments revealed PPi also as an appropriate detergent for harvesting epiphytic bacteria, since it did not show any influence on growth of isolated bacteria. The leaves were sonicated in an ultrasonic bath for 30 sec, shaken for 15 min at 1100 rpm in an Eppendorf thermomixer, and then sonicated for another 30 sec. One aliquot of this bacterial suspension was taken for direct counts of bacteria; the remaining suspension was used for cultivation.

In order to retrieve gut bacteria, larvae were first sterilized with 70% ethanol to avoid contamination with microorganisms attached to their surface. Larvae were dissected under a stereomicroscope; the complete intestinal tract was removed and separated into fore-, mid-, and hindgut. Each gut segment was separately immersed in 250 μl sterile PPi, squeezed with a sterile preparation needle, and treated by sonication as described above to yield gut bacterial suspensions.

Bacterial Counts. One hundred microliters of bacterial suspensions, either from leaves or *Acentria* guts, were fixed with 100 μl formaldehyde (10%, v/v) and diluted with water to a final volume of 1 ml. We used only ultrapure and sterilized water for microbiological and biochemical analysis. Staining was performed with 100 μl of 4′,6-diamidino-2-phenylindole (DAPI; 10 μg/ml in 1% formaldehyde, v/v), and the mixture was incubated for 30 min in the dark. The stained bacteria were filtered on 0.2 μm black Nucleopore filters and counted under a Nikon epifluorescence microscope (Labophot 2). Of each microscopic preparation, 10 microscopic fields (0.08 $\times$ 0.08 mm) were counted.

The surface area of the freshwater macrophytes used was calculated from the dry weight of the plant samples according to Sher-Kaul et al. (1995). Bacterial densities in the gut of *Acentria* were quantified per gut segment (fore-, mid-, or hindgut) and per volume of gut fluid. For the latter we had to make some approximations. Although we used third to fourth instar larvae (for size classes see Gross et al., 2001, 2002), they were still too small to determine their gut volumes accurately. Consequently, we measured the head capsule widths to determine larval size. For an estimate of the gut volume, we assumed that the length of the larvae was correlated with the head capsule width and converted the latter to length

sizes (100 μm head capsule width set equivalent to 1.6 mm length). We further estimated a mean gut diameter of 1 mm and calculated gut volumes using these measures.

Isolation of Bacteria. Bacterial suspension in appropriate dilutions was spread on modified CPS agar (Collins and Willoughby, 1962) containing 0.5 g tryptone (Oxoid), 0.5 g peptone (Difco), 0.5 g soluble starch (Merck), 1 ml glycerol, 0.2 g K_2HPO_4, and 0.05 g $MgSO_4$. The plates were incubated aerobically for 3 days at 24°C. This method yielded distinct colonies. Representative colonies were selected on the basis of morphological criteria, such as colony size, pigmentation or surface structure, and recultured. Several isolates were obtained from guts and leaves, some from different sources looked similar. Therefore, all isolates were compared by means of denaturing gradient gel-electrophoresis (DGGE) for further characterization.

PCR and DGGE. Bacterial DNA of cultured cells was isolated in water at 100°C for 15 min. After centrifugation for 5 min at 13,600 g, 1 μl of supernatant containing bacterial DNA was taken as template for PCR. Small subunit rRNA genes were amplified by PCR using the primers 5′-GC-clamp-CCTACGGGAGGC AGCAG-3′ (forward) and 5′-CCGTCAATTCMTTTGAGTTT-3′ (reverse) (Muyzer et al., 1998). PCR was performed in 50-μl assays with a GENIUS thermocycler (Techne, Cambridge, UK). One unit of Taq DNA polymerase (Eppendorf Master Taq) was used. PCR conditions were an initial denaturation step of 3 min at 94°C, followed by a touchdown protocol of 20 cycles in which the DNA was denatured for 1 min at 94°C, annealed for 1 min starting at 65°C, and decreased 0.5°C/cycle to 55°C and extended for 2 min at 72°C. This was followed by nine cycles in which the annealing temperature was 55°C. PCR products were examined using agarose gel electrophoresis and ethidium bromide staining.

DGGE of PCR products was performed by the method described by Muyzer et al. (1996) with the use of a DCode System (Bio-Rad Laboratories). Products were analyzed on a 6% (w/v) polyacrylamide gel with a linear gradient from 20 to 60% denaturant [100% denaturant contained 7 M urea and 40% (v/v) formamide]. Electrophoresis was performed for 16 hr at 95 V and a temperature of 60°C. After electrophoresis, gels were stained for 15 min with SYBR Gold (0.1 μl/ml; Molecular Probes), rinsed in water, and photographed on a UV transilluminator with a black and white Polaroid camera. Isolates with different banding patterns were taken as different bacterial species.

Sequencing. To further characterize isolates, DNA obtained as described above was taken as a template for another PCR. The annealing temperature started at 60°C; thus, the touchdown protocol consisted of only 10 cycles followed by 19 cycles in which the annealing temperature was 55°C. No GC clamp was added in this step. The PCR product was purified with a GFX PCR DNA and gel band purification kit (Amersham Pharmacia Biotech) following the instruction manuals

of the manufacturer. Sequencing reactions were performed at GATC Biotech AG (Konstanz, Germany). The resulting sequences were analyzed with the online database BLAST (http://www.ncbi.nlm.nih.gov/BLAST/).

Extraction of Plant Material. Freeze dried plant powder was extracted with 70% aqueous acetone (v/v; 10 ml/pg DW) for 2 hr at 15°C. Suspensions were continuously stirred in an Eppendorf thermomixer (interval mode, 1 min at 1100 rpm, 1 min pause). After centrifugation (10 min, 13,600*g*, 4°C), the supernatant was stored at 4°C, and the pellet was resuspended in acetone and extracted as above. Supernatants were combined and dried in a vacuum evaporator. The residue was redissolved in 50% methanol to a final concentration of 100 μg (DW)/ml.

Bacterial Assays. Bacterial assays were performed to analyze the inhibitory effects of crude plant extracts. We used CPS agar, adjusted with NaOH to pH 8.4 before autoclaving. Crude plant extracts were applied in 5-μl aliquots to agar plates and allowed to dry. Stepwise application of droplets yielded final extract concentrations equivalent to 0.5, 1, and 2 mg of extracted plant material. Controls used 20 μl of 50% methanol. Each extract and each concentration was tested in duplicate. As indicator organisms, isolated bacterial strains from agar plates were suspended in water and their optical density (OD_{600}) was adjusted to 0.1. These suspensions were diluted 1:50 with water in order to get distinct colonies on the plates. Then 0.1 ml of these suspensions was spread on the agar plates and incubated at 24°C for 48 hr. The presence of inhibition zones was recorded and their diameters measured. Bacterial assays were performed with upper leaf extracts from *M. spicatum* and *P. perfoliatus*. We also performed one series with extracts of apical shoot sections of *M. spicatum*, and one series with upper leaves of *M. spicatum*, both using CPS agar with a pH of 7.0 and small Petri dishes (32 mm diam.). In this case, only the highest extract concentration equivalent to 2 mg DW of plant material was used.

A third experiment was performed to verify that polyphenolic compounds in *M. spicatum* were responsible for antimicrobial effects in crude extracts. We first treated extract with polyvinyl polypyrrolidone (PVPP) to remove phenolic compounds. Secondly, we compared the inhibitory strength of extract with pure phenolic compounds applied in equivalent concentrations. PVPP-treatment of the crude extract to remove phenolic compounds was performed as described recently (Gross et al., 1996). The content of phenolic compounds was measured with the Folin-Ciocalteau assay and expressed as tannic acid equivalents; the concentration of tellimagrandin II was quantified by HPLC (Gross et al., 1996). Extract used in experiment III contained 160 μg tannic acid equi valents and 27 μg tellimagrandin II per milligram of plant dry weight. Accordingly, we used 27 and 160 μg of (+)-catechin, gallic acid, and tannic acid (Sigma Aldrich) in the assays. Purified tellimagrandin II was available in only a limited amount, and we used 10 μg per assay. All tests were performed in triplicate.

RESULTS

Bacterial Counts. Bacteria in the gut of *Acentria* may, at least in part, be derived from epiphytic bacteria of their host plants. Therefore, we measured bacterial density on both *M. spicatum* and *P. perfoliatus*. The former had $1.43 \pm 0.83 \times 10^6$ cells/cm^2 and the latter $2.51 \pm 0.89 \times 10^6$ cells/cm^2 surface area ($N = 5$ each; mean $\pm$ SD; Student's t test; $t = 2.17$, $P = 0.055$; Table 1).

Instar stages of *Acentria* larvae can be derived from the size of their head capsule (Gross et al., 2002). Head capsule width ranged from 462 to 897 μm (641 ± 212 μm, $N = 5$) in *P. perfoliatus* and from 550 to 1482 μm (871 ± 337 μm, $N = 6$) in *M. spicatum* fed larvae. Table 1 summarizes densities of bacteria in the fore-, mid-, and hindgut of larvae fed with *P. perfoliatus* or *M. spicatum*. Bacterial counts varied from 0.39 to 10.01×10^6 ($1.9 \pm 1.8 \times 10^6$) cells per gut segment. There was no significant difference between cell numbers in the different gut segments nor was there a difference between cell numbers in larvae raised on different food sources. Bacterial densities did not correlate with head capsule width.

Characterization of Bacterial Isolates. We selected bacterial strains from agar plates based on colony size, morphology, and color. Dominant morphotypes of epiphytic bacteria from both plants were selected for further characterization. This yielded 17 strains. Furthermore, 29 isolates were obtained from guts of larvae fed with *M. spicatum* and 18 from those fed with *P. perfoliatus*. Of the 64 isolates selected based on morphological differences, only 17 were genetically different according to DGGE. These strains were further characterized by sequence analyses (Table 2).

Small subunit rRNA gene sequences of these 17 isolates were compared with the online database BLAST. Sequence similarities ranged between 97 and 100%.

TABLE 1. BACTERIAL COUNTS IN *Acentria* GUTS AND ON MACROPHYTE LEAVES

Treatment	Bacterial counts ($\times 10^6$)[a]	N
Acentria fed with *P. perfoliatus*		
Foregut	1.8 ± 1.2	5
Midgut	2.1 ± 0.9	5
Hindgut	1.3 ± 1.4	4
Acentria fed with *M. spicatum*		
Foregut	3.6 ± 3.5	6
Midgut	1.1 ± 0.8	6
Hindgut	1.7 ± 1.0	6
P. perfoliatus leaves	2.5 ± 0.9	6
M. spicatum leaves	1.4 ± 0.8	6

[a] Values are the mean $\pm$ SD. Counts for gut segments are cells/segment; for leaves, cells/cm^2 leaf area.

[e] Apical shoot sections.

Ten strains showed 100% identity with known bacteria. The four isolates with only 97% homology probably represent previously unknown bacteria. Members of α-, β-, or γ-proteobacteria, the CF cluster (*Cytophaga/Flavobacteria*), and Gram-positive bacteria were identified.

Sequence analyses revealed that only three bacterial strains dominated the cultivable fraction of epiphytic bacterial population. Two of them belonged to the CF cluster. One showed the closest relation to an as yet uncultivated epilithic bacterium, and the other to *Chryseobacterium defluvium*. Both cases exhibited only 97% conformity with described species. The third strain showed 100% similarity with the common freshwater bacterium *Aeromonas veronii*. All three epiphytic strains were also detected in guts of *Acentria*. One of them and two other proteobacteria were found in *Acentria* guts of both treatments (Table 2). A surprisingly high proportion of Gram-positive strains were found in larvae fed with *P. perfoliatus* (5 of 11) compared with larvae fed with *M. spicatum* (1 of 9).

Bacterial Assays. The antimicrobial activity of plant extracts was measured with a modified agar disc diffusion assay. None of the bacterial isolates was inhibited by extracts of *P. perfoliatus*, even when applied in the highest concentration equivalent to 2 mg plant biomass (DW) extracted. Tannin-containing extracts of *M. spicatum* inhibited most strains, even at the lowest concentration used (Table 2). The size of the inhibition zone increased with higher extract concentrations used. Extracts made with apical shoot sections of *M. spicatum* caused larger inhibition zones than those made with upper leaves using the same concentration. HPLC analysis showed that in our extracts apical shoot sections contained 30% more tellimagrandin II based on dry weight compared to upper leaf extracts. Tellimagrandin II is the major hydrolyzable tannin in *M. spicatum* (Gross et al., 1996). The inhibition of bacterial isolates also differed with the pH of the agar plates used and the *M. spicatum* parts extracted. Using extract equivalent to 2 mg plant dry weight, we observed smaller inhibition zones of bacteria on neutral agar plates (pH 7.0) compared to alkaline conditions (pH 8.4) with 9 of 11 strains.

The susceptibility of bacterial isolates towards *M. spicatum* extract varied on alkaline media. Isolates belonging to the α- or γ-proteobacteria exhibited only a weak inhibition. Two of the α-proteobacteria were not inhibited with the lowest extract concentration. One strain, *Enterobacter* sp. (γ-proteobacteria) was not affected at all. Another member of this subgroup, *Aeromonas* sp., was only slightly inhibited with the highest concentration used. Two other γ-proteobacteria (*Acinetobacter* and *Pseudomonas*) exhibited inhibition zones almost as large as those observed for Gram-positive bacteria. The inhibition zone of Gram-positives at the lowest concentration ranged from 10 to 20 mm. Inhibition of the only β-proteobacterium isolated was comparable to that of Gram-positive bacteria. Isolates belonging to the CF cluster exhibited the highest susceptibility towards *M. spicatum* extract.

TABLE 3. INHIBITION[a] OF SELECTED BACTERIAL STRAINS BY *M. spicatum* EXTRACTS AND PHENOLIC COMPOUNDS

	Comamonas	*Pseudomonas*	*Chryseobacterium*
M. spicatum extract (1 mg)	17 ± 0	23 ± 1	23 ± 2
PVPP treated (1 mg)	0	0	14 ± 1
Tannic acid			
160 μg	20 ± 1	22 ± 0	30 ± 1
27 μg	13 ± 2	14 ± 1	19 ± 2
Gallic acid			
160 μg	>40.0	>40.0	>40.0
27 μg	13 ± 0	26 ± 1	23 ± 1
(+)-Catechin (160 μg)	0	0	0
Tellimagrandin II (10 μg)	4 ± 0	9 ± 2	11 ± 0

[a] Mean $\pm$ SD (mm).

The susceptibility of three selected strains were tested with *M. spicatum* extract, extract treated with PVPP, and pure phenolic compounds on alkaline media (Table 3). PVPP treatment caused a disappearance of inhibition in two of three strains and greatly reduced the inhibition in the CF strain. Gallic and tannic acid as well as tellimagrandin II inhibited all selected strains, whereas catechin was inactive. This indicates a high susceptibility of bacterial isolates towards tannins in *M. spicatum.*

DISCUSSION

Our study investigated the allelochemical interactions between freshwater macrophytes, the herbivorous aquatic moth *Acentria ephemerella* and their gut symbionts. We fed larvae of *Acentria* with a tannin-free (*Potamogeton perfoliatus*) or a tannin-rich (*Myriophyllum spicatum*) macrophyte. Tannins are well-known herbivore deterrents (Bernays, 1981), but they also have antimicrobial effects (Scalbert, 1991; Field and Lettinga, 1992). Our hypothesis is that food-derived tannins influence the naturally occurring gut microbiota of lepidopteran larvae, which may lead to an altered performance of the larvae. Larvae exhibited reduced growth when fed with *M. spicatum* (Choi et al., 2002). Results of this study show that gut bacteria of *Acentria* are affected by secondary metabolites of the freshwater macrophytes on which larvae were feeding.

We found evidence for the presence of gut symbionts in larvae of *Acentria*. Direct DAPI counts of bacteria revealed densities of $2.8–13.3 \times 10^6$ cells/gut. Converting this to gut volume (see Methods and Materials section), we determined bacterial densities of $0.3–2.2 \times 10^6$ cells/μl. For other arthropods, $0.07–190 \times 10^6$ cells/μl gut fluid have been reported (Cazemier et al., 1997). To our knowledge,

our study is the first to present quantitative data on bacterial densities in guts of Lepidoptera.

Bacterial numbers did not vary between fore-, mid-, or hindgut, and no correlation between the bacterial counts and the size of the larvae was found. So far, it has not been possible to evaluate which factors influence the density of gut bacteria in Lepidoptera, since so little is known in this field. The large variability observed in bacterial densities of different gut segments or larvae may have several explanations. First, bacterial densities in Lepidoptera may naturally show large fluctuations. A few days before metamorphosis, lysozyme is secreted in the midgut in some Lepidoptera larvae (Russell and Dunn, 1991), which would account for lower densities at that time. Second, the rearing procedure can influence bacterial densities. We observed higher densities of bacteria in larvae kept for a prolonged time in the laboratory compared to larvae taken fresh from the field (data not shown). This indicates that laboratory conditions can alter densities of gut bacteria.

We assume that the gut microbiota in *Acentria* is mainly derived from inoculates through the respective food plants. The bacterial densities on the two plants used in our study differed only marginally (Table 1). We did not observe any difference between the mean abundance of bacteria in larvae fed with *P. perfoliatus* or *M. spicatum*. At least two possibilities could account for this: either, tannins from *M. spicatum* may not affect gut bacteria or, the gut bacterial community may have been shifted to more tannin-tolerant strains.

To investigate the inhibitory effect of plant extracts on *Acentria* gut bacteria, we isolated several strains from larvae on different food treatments and performed agar diffusion assays. Sequence analysis revealed only a little overlap in the bacterial isolates from larvae fed with either *P. perfoliatus* or *M. spicatum* (Table 2). None of the strains were inhibited by extracts of leaves from *P. perfoliatus*, even when high concentrations were used. In contrast, extracts of upper leaves from *M. spicatum* inhibited the growth of all but one strain (Table 2).

The antimicrobial effect of *M. spicatum* extracts is, for the most part, due to polyphenols, as was shown by the PVPP assay and comparison with pure phenolic compounds. At present, we cannot fully exclude that some nonphenolic compounds have additional effects, since one strain (*Chryseobacterium* sp.) still exhibited an inhibition after PVPP treatment of the extract.

These experiments were performed using CPS agar with alkaline conditions (pH 8.4 before autoclaving) to mimic Lepidoptera midgut conditions (Appel and Martin, 1990; Clark, 1999). Alkaline conditions promote the autoxidation of tannins and phenolic compounds of lower molecular weight (Appel, 1993). This enhances their toxicity towards microorganisms (Field and Lettinga, 1992). Accordingly, the inhibition zones were always smaller with all but two strains tested when using neutral CPS agar (pH 7.0, Table 2). The inhibition zones in the assay increased when the same amount of extract from apical shoot sections of

M. spicatum were used. Apical shoot sections contain much higher concentrations of polyphenols, among them tellimagrandin II, as was shown with our extracts and in previous studies (Gross, 2000). This indicates a dose-dependent growth inhibition of bacteria by milfoil polyphenols.

We observed considerable differences in the susceptibility of the strains towards these extracts. In our study, both α- and γ-proteobacteria displayed the weakest inhibition of all isolates. The two strains belonging to the CF cluster (*Cytophaga/Flavobacteria*) exhibited the largest inhibition. We found these strains in high densities on the plants, indicating that they are transient, and that the larvae obtained them with their food. To our knowledge, inhibition of flavobacteria by tannins has not been investigated before.

The high susceptibility of Gram-positive bacteria towards polyphenols is in accordance with previous findings (Henis et al., 1964; Puupponen-Pimia et al., 2001). Gram-negative bacteria are thought to be better protected against tannins because of the structure of their outer membrane (Field and Lettinga, 1992). Gram-positive bacteria with a high GC content were found exclusively in guts from larvae fed with *P. perfoliatus*. We assume that the absence of Gram-positive bacteria with high GC content in guts of larvae fed with *M. spicatum* may be a result of the higher sensitivity towards polyphenols in this freshwater macrophyte.

Our results provide the first evidence for the allelochemical effect of *M. spicatum* tannins on gut symbionts in *Acentria*. Due to the small proportion of culturable bacteria, culture studies like ours do not provide sufficient information to observe bacterial community shifts. Consequently, culture-independent studies are needed to verify these findings for the whole bacterial community.

Abstract—Forty-five species of brown algae (Phaeophyceae) were surveyed for their capacity to respond by an oxidative burst to challenges with alginate oligosaccharides. Intertidal frondose brown algae (Fucales) constitutively released high quantities of peroxide. The capacity to recognize oligoguluronates and to react with an oxidative burst was confined to alginate-rich taxa with complex thallus morphology, epitomized by the sporophytes of Laminariales. When kelp sporophytes were impaired in their capacity to perform an oxidative burst by the NAD(P)H oxidase inhibitor diphenylene iodonium, they were readily degraded by their bacterial epiflora. Thus, in these algae, the oxidative response is an essential element of natural resistance. We also report on the establishment of a well-defined experimental system for investigations on kelp immunity, with *Laminaria digitata* as the host and its phaeophycean endophyte, *Laminariocolax tomentosoides*, as the pathogen. We found that an alginate-triggered oxidative burst significantly induces resistance in *Laminaria digitata* against infection. From these findings we infer that oligoalginate signals are important cues in the interaction between laminarialean kelps and potential pathogens.

Key Words—Marine algae, kelps, *Laminaria*, *Laminariocolax*, *Macrocystis*, oligoalginates, oxidative burst, natural resistance, induced resistance.

INTRODUCTION

In marine macroalgae, competition and predation have been thought of as the major factors determining the structure of natural populations and communities (e.g., Lubchenco and Gaines, 1981; Carpenter, 1990; Norton et al., 1990). Interactions with pathogens were considered too rare to have any significant impact on seaweed populations. Therefore, the importance of defense reactions against pathogens for understanding the functioning of marine ecosystems has been somewhat overlooked, and deciphering host-pathogen interactions in algae is still in its pioneering phase (Correa, 1997; Potin et al., 1999).

Only a few marine pathosystems have been studied in some detail. These are mainly in the Rhodophyta. Weinberger et al. (1999) described an oxidative burst triggered by oligoagars in *Gracilaria conferta*, showing that accumulation of hydrogen peroxide induces the elimination of agar-degrading epiphytic bacteria from the thallus surface (Weinberger and Friedlander, 2000). Bouarab et al. (1999) demonstrated the role of carrageenan sulfation patterns in regulating the virulence of *Acrochaete operculata*, a pathogen of *Chondrus crispus*. *C. crispus* gametophytes reacted with a significant release of hydrogen peroxide in their culture medium when challenged by *A. operculata* cell-free extracts.

With respect to brown algae, we showed recently that oligomeric degradation products of alginate, the main matricial cell wall polysaccharide in this lineage, elicit an oxidative burst in the sporophytes of the kelp *Laminaria digitata* and trigger a cascade of signaling events (Küpper et al., 2001). Alginate is a linear polysaccharide made of homopolymeric blocks of β-1,4-D-mannuronic acid (oligomannuronates) or α-1,4-L-guluronic acid (oligoguluronates), and blocks with mixtures of both monomers (Haug et al., 1974). At micromolar concentrations or less, the homo-oligomeric fragments composed of guluronate residues elicited a transient, yet strong oxidative response, whereas polymannuronate blocks were inactive in *L. digitata* (Küpper et al., 2001).

Laminariales (kelps) are colonized by various morphologically distinguishable bacteria (Pellegrini and Pellegrini, 1982; Corre et al., 1989), including alginate-degrading strains such as *Pseudomonas alginovora* (Boyen et al., 1990a). In Japanese mariculture systems of *Laminaria japonica*, the alginolytic bacterium *Pseudoalteromonas elyakovii* was identified as the causative agent of the wounded-spot disease (Sawabe et al., 2000). In natural populations, kelp sporophytes are also frequently infested by phaeophycean endophytes, resulting in disease symptoms such as warts, crippled thalli, and twisted stipes and blades (Apt, 1988; Kawai and Tokuyama, 1995; Peters and Schaffelke, 1996; Peters and Ellertsdóttir, 1996; Ellertsdóttir and Peters, 1997; Burkhardt and Peters, 1998). Field observations (A. F. Peters, unpublished) suggest that mortality of such endophyte-infested adults is increased, mainly because stipes of infected individuals cannot resist the increased drag. In mature sporophytes, the presence of endophytes inhibits

sorus formation (Peters and Schaffelke, 1996; Lüning et al., 2000). Altogether, pathogenic microorganisms are likely to be an important parameter in the fitness of these brown algae.

Based on the biochemistry of host-pathogen interactions in terrestrial plants and on the above-mentioned observations in the Rhodophyta, one might expect that recognition of alginate oligosaccharides followed by an oxidative response is a key point in the defense strategies of brown algae against microbial epiphytes or pathogens. However, it is not known whether brown macroalgae other than the morphologically relatively complex and perennial *Laminaria digitata* also recognize this elicitor. Hence, we have surveyed a number of brown algal groups, including species and life-history stages with a simple morphology, for their ability to sense the presence of oligoguluronate fragments, as shown by the release of reactive oxygen species (ROS) into their surrounding medium. The potential role of the oxidative burst in the natural resistance of kelps was then further investigated by loss-of-function experiments, using an irreversible inhibitor of the mammalian oxidative burst-generating NAD(P)H oxidase, diphenylene iodonium. Finally, we report on controlled inoculations using a convenient host-pathogen system to assess the biochemical basis of immunity in brown algae, using sporophytes of *Macrocystis pyrifera* and *L. digitata* and their natural endophytic pathogens of the genus *Laminariocolax*.

METHODS AND MATERIALS

Algal and Microbial Materials. We used field specimens of various brown algal species collected from the seashore near Roscoff (Brittany, France) and Kiel (Baltic Sea, Germany). Additional species were grown as unialgal laboratory cultures originating from various localities (Table 1). Axenic sporophytes of *Macrocystis pyrifera* were obtained from a pair of axenic gametophytes from Chile (Magellan Strait). The brown algal endophytes, *Laminariocolax tomentosoides* (Farlow) Kylin (LtoH) and *L. macrocystis* (Peters) Peters (Lmac LM2) have been described previously (Burkhardt and Peters, 1998; Peters, 1991). Algae were grown in Provasoli ES medium (Starr and Zeikus, 1987) prepared with natural seawater. Cultures, illuminated with daylight-type fluorescent lamps at an irradiance of 9 μmol photons/m^2/sec for 10 hr/day, were maintained at 10 $\pm$ 1°C in 10-ml Petri dishes and transferred to fresh medium at 1- or 2-week intervals.

The oomycete *Eurychasma dicksonii* (Wright) Magnus was available in a unialgal culture in its host *Pylaiella littoralis* (L.) Kjellm., as described previously (Müller et al., 1999). The epiphytic bacterium *Pseudomonas alginovora*, strain XO 17 isolated from *Laminaria digitata* (Corre et al., 1989) was grown in ZoBell medium (ZoBell and Upham, 1944) as previously described (Boyen et al., 1990a).

Measurements of Hydrogen Peroxide Levels. Experiments were carried out in a 12°C temperature-controlled room, except for warm-water species (*Dictyota*

[a] Basal hydrogen peroxide release was determined by following the concentration in dishes of control plants over 3 hr, while permanent concentrations refer to measurements in the culture vessels in which the algae had been kept for at least one week. In some cases, culture medium from a stock culture collection was examined, in which algal samples were untouched for a minimum of one year in 4 ml of culture medium. Where appropriate, significance of results was verified by a *t* test. The relative strength of the oxidative burst after oligoguluronate addition is indicated by: ++, peak H_2O_2 at least 10 times the basal release, $P < 0.01$; +, peak H_2O_2 at least 5 times the basal release ($P < 0.01$, +/−, $0.01 < P < 0.05$), and −, none of the previous logic conditions fulfilled, no significant response. In cases where no oxidative response to alginate oligosaccharides was observed for all the tested species for a given genus, at least one species was also elicited with valinomycin, which had been shown to activate the burst-producing machinery downstream of GG recognition (Küpper et al., 2001). Abbreviations: gam = gametophytes, sp = sporophytes.

[b] Origin of plant material/culture collections: (1) Akira F. Peters, Kiel; (2) Dieter G. Müller, Konstanz; (3) IM = Ingo Maier, Konstanz.

phlyctaenodes, Zosterocarpus oedogoniae), which were tested at 20°C. Hydrogen peroxide concentrations were measured using the luminol chemiluminescence method with a Lumat LB 9507 luminometer as described by Küpper et al. (2001). Both the total amounts of hydrogen peroxide in the medium around plants and the kinetics of H_2O_2 release by brown algal cultures (50–500 mg blotted fresh weight in 10 ml of 0.22-μm-filtered seawater) either in the presence or in the absence of oligoguluronates (150 μg/ml) were monitored, in triplicate, consisting of sampling seawater from three dishes containing the same ratio of biomass/volume of medium. Negative results with oligoguluronates were validated by treatment with the K^+ ionophore valinomycin (5 μM). This potassium carrier had previously been shown to activate the burst-producing machinery downstream of GG recognition (Küpper et al., 2001). Aliquots of 400 μl (out of 10-ml samples) were taken per measurement. All assays were evaluated using two-tailed, paired sample *t* tests.

Cell-free extracts of *Laminariocolax tomentosoides* were prepared as follows. Unialgal cultures were blotted dry on filter paper, weighed, frozen in liquid nitrogen, and ground in an Eppendorf tube with a micropestle and Fontainebleau sand. To a fresh weight of ca. 20 mg algae, 300 μl of extraction buffer (50 mM Tris HCl, 50 mM NaCl, 10 mM $MgCl_2$, 1 mM PMSF; all from Sigma) were added. The samples were vortexed for 1 min, incubated for 5 min (4°C), and centrifuged for 5 min at 10,000*g*. The supernatant was recovered and stored at −20°C until use. Fifty μl of this extract was added to the *L. digitata* sporophytes either 1 hr prior to, or simultaneously with, the addition of alginate oligosaccharides. A similar procedure was used to prepare cell-free extracts from *Pylaiella littoralis* infected or not by *Eurychasma dicksonii.*

Challenge with Epiphytic Bacteria and Endophytes. The involvement of the oxidative burst in the natural resistance of kelps to their natural epiflora was assessed as follows. Axenic sporophytes of *Macrocystis pyrifera*, 2–5 mm in thallus length and in groups of five individuals, were incubated for 10 min in the presence of the NAD(P)H oxidase inhibitor diphenylene iodonium (1, 2.5, 5, and 10 μM from a 1 mM stock solution in DMSO; from Sigma), and thereafter transferred to fresh medium. Some plants were elicited with oligoguluronates at 150 μg/ml for 1 hr before the DPI treatment. The thalli were then inoculated with *Pseudomonas alginovora* (4.5×10^8 colony forming units per 3.1 ml well), and inspected daily for the occurrence of lesions. Alternatively, the natural bacterial epiflora of *M. pyrifera* was reestablished by adding a droplet of culture medium containing *Macrocystis*-associated bacteria from Chile. For comparison, unialgal sporophytes of *L. digitata* (i.e., cultures containing the natural bacterial epiflora from the start) were also subjected to the same DPI treatment.

To address the potential role of oligoalginate signals in the induced resistance of kelps, *L. digitata* sporophytes 2–20 mm in thallus length were elicited with oligoguluronates (GG) (150 μg/ml) for 1 hr. The GG was added to three replicates of groups of five plantlets. After GG treatment, the thalli were transferred to 50 ml

fresh culture medium. The GG treatment was repeated at daily intervals for 14 days, each day to a new set of 15 thalli. Then, all *L. digitata* sporophytes were inoculated with *L. tomentosoides* zoospores, as follows. A culture of sporulating filamentous endophytes in a volume of 500 μl was added to each dish of *Laminaria*. Controls consisted of eight replicates of algae untreated prior to endophyte inoculation and of six replicates of GG-treated sporophytes, which were not inoculated with the pathogen. After coculture for 3 days, the *Laminaria* sporophytes were transferred to fresh medium, which was renewed weekly, and they were examined at 3-day intervals until 3 weeks after the inoculation.

The intensity of disease symptoms and the state of the plants was judged by an unbiased, independent observer, according to the following relative scale: 0, no symptoms of pathogen infection nor unusual necroses; 1, infections and/or necroses only very marginal; 2, few infections or necroses: overall plants in good shape; 3, strong infections or necroses in at least one plant, but other plants of the same batch in good shape; 4, strong infections and necroses in several plants; 5, strong infections, at least one plant dead; and 6, massive infections, all plants dead.

The scores of the replicates of days 1–3, 4–6, 7–9, 10–14 before inoculation of endophytes were grouped and statistically analyzed using a one-way ANOVA with days before addition of endophytes as factor. Multiple mean comparisons were made with the Tukey-Kramer test. After the experiments, all plants were fixed and mounted on paper. They were deposited in the herbarium of the Marine Station, Roscoff.

RESULTS

Oxidative Response in Brown Algae to Treatment with Oligoguluronates. The 45 species belonging to 11 orders of brown algae were monitored for levels of hydrogen peroxide in their surrounding medium, in the absence or presence of alginate oligosaccharides (Table 1). In members of the order Laminariales, steady-state peroxide concentrations in the oligoalginate-free culture dishes were usually below 1 μM for the gametophytes, and below 500 nM for the sporophytes. In *L. digitata* and *L. ochroleuca* sporophytes, the H_2O_2 concentrations were typically in the range of 200 nM. Only in the culture of female *Chorda filum* gametophytes were higher concentrations measured (Table 1).

When challenged with oligoguluronates, culture-raised, young sporophytes of *Chorda filum*, sporophytes of all the *Laminaria* species tested, as well as those of *Macrocystis pyrifera*, *Lessonia nigrescens*, and *Saccorhiza polyschides* reacted with a rapid, strong oxidative burst. *Macrocystis pyrifera* sporophytes (Figure 1A) displayed a maximum of H_2O_2 release 10 times higher than the basal emission ($P \leq 0.01$). Rates of H_2O_2 accumulation were typically as high as 0.3–0.5 μmol/g fresh weight (FW) for centimeter-long parenchymatic thalli within 15 min of the addition of alginate oligosaccharides (due to the higher surface–volume ratio,

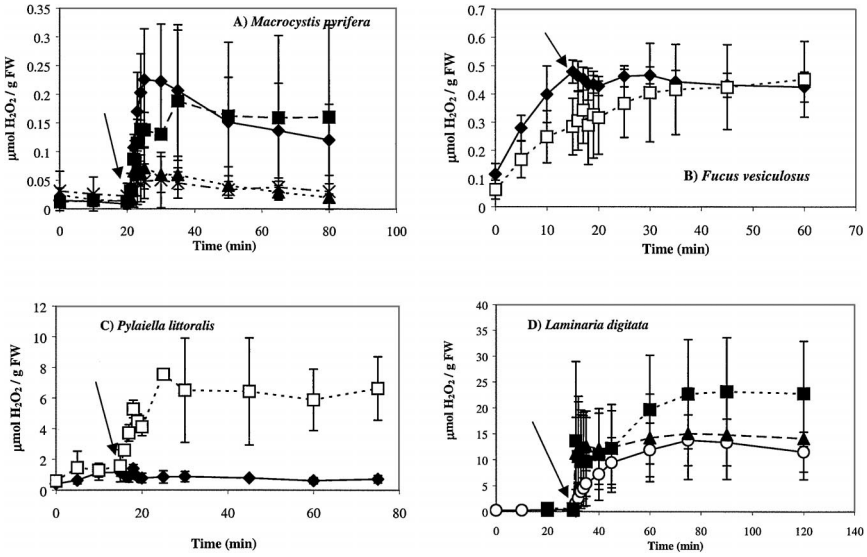

FIG. 1. Hydrogen peroxide concentrations in the culture medium of various brown algae, in the presence or absence of alginate oligosaccharides (GG blocks, 150 μg/ml). Addition of elicitors is marked by an arrow. (A) *Macrocystis pyrifera* sporophytes (Laminariales): GG only, diamonds; 1 μM DPI, squares; 2.5 μM DPI, triangles; 5 μM DPI, asterisks. Note that DPI suppressed the GG-triggered oxidative burst. (B) *Fucus vesiculosus* (Fucales): control, diamonds; GG, squares. (C) *Pylaiella littoralis* (Ectocarpales), control, diamonds; GG, squares. (D) *Laminaria digitata* (Laminariales), challenged with 150 μg/ml GG (circles), cell-free extracts from healthy *Pylaiella littoralis* (triangles) or from *Pylaiella littoralis* infected with *Eurychasma dicksonii* (squares). Error bars indicate standard deviation of the average concentration of H_2O_2 measured in three replicates.

this value could be up to an order of magnitude higher for smaller thalli). In the case of *L. digitata*, *L. ochroleuca*, and *L. pallida*, accumulation of H_2O_2 was very transient, with complete scavenging accomplished around 30 min after the addition of the elicitor. Large (i.e., several meters long) field-collected sporophytes of *L. hyperborea*, *L. ochroleuca*, and *Saccorhiza polyschides* exhibited high constitutive rates of peroxide release and were less or not at all responsive to the elicitor. The minimum size for *Laminaria digitata*, *Lessonia nigrescens*, and *Macrocystis pyrifera* sporophytes to respond with an oxidative burst following incubation with alginate oligosaccharides was 1 mm. Smaller, embryonic sporophytes did not react. With the exception of *L. ochroleuca*, gametophyte cultures of Laminariales did not exhibit an oxidative response following incubation with alginate oligosaccharides.

Outside the Laminariales, the macroscopic thalli of only a few species were found to react by an oxidative burst upon challenge with alginate oligosaccharides.

In the Fucales, all of the species tested constitutively released considerable amounts of hydrogen peroxide. Only *B. bifurcata*, which displayed a maximum of H_2O_2 release more than 5 times higher than the basal emission ($P \leq 0.01$), *P. canaliculata*, *S. muticum* ($0.01 < P \leq 0.05$) and, in few cases, *Fucus vesiculosus* exhibited an enhanced peroxide emission upon addition of oligoguluronates (Table 1, Figure 1B). Among the Desmarestiales, only *Desmarestia dudresnayi* reacted strongly to incubation with the elicitor, while *D. aculeata* and *D. ligulata* showed much weaker oxidative responses (Table 1).

Among the Ectocarpales with erect filamentous thalli, *Pylaiella littoralis* was unique in performing a relatively strong and rapid oxidative burst after the addition of oligoguluronates (Figure 1C); and displayed a peak of H_2O_2 release 5 times higher than the basal emission ($P \leq 0.01$). *Eurychasma*-infected cultures of *P. littoralis* maintained steady-state peroxide levels one order of magnitude higher than healthy cultures. Virus infection in *Pylaiella* coincided with a weaker response to elicitor treatment. The filamentous stages of *Elachista stellaris* and *Spermatochnus paradoxus* displayed weak rates of peroxide release, although *S. paradoxus* maintained fairly high peroxide levels in long-term cultures. They also exhibited a rapid, but comparatively weak, reactivity upon elicitor addition. No other species of Ectocarpales tested showed a burst, with no difference due to the presence or absence of virus infections. After challenging with oligoalginate elicitors, no oxidative response was observed in microthalli of the Scytothamnales, Sporochnales, and Syringodermatales, in exact filamentous thalli of the Tilopteridales and Cutleriales, or in the two filamentous species *Microzonia velutina* and *Zosterocarpus oedogoniae* (Table 1).

Inhibition of Oxidative Burst Abolishes Natural Resistance of Kelp Sporophytes towards Epiphytic Bacteria. To further investigate the potential role of the oxidative response in the control of microorganisms by brown algae, sporophytes of Laminariales were subjected to loss-of-function experiments as follows. The capacity to perform an oxidative burst was suppressed with an NAD(P)H oxidase inhibitor, diphenylene iodonium (DPI), and thalli were then challenged by epiphytic bacteria. As shown in previous experiments with *L. digitata* (Küpper et al., 2001) and in Figure 1A for *M. pyrifera*, DPI completely suppressed the oligoalginate-induced oxidative reaction in kelp sporophytes.

In a first series of experiments (Table 2), axenic sporophytes of *M. pyrifera* were inoculated with the epiphytic alginolytic bacterium, *Pseudomonas alginovora*. Controls with bacteria-free *M. pyrifera* sporophytes confirmed that the treatment with DPI up to concentrations as high as 10 μM had no direct toxic effect on the plants. In the absence of DPI and upon cocultivation with the bacterium, *M. pyrifera* sporophytes also survived for several weeks, without any signs of disease. In contrast, the DPI-treated axenic sporophytes were rapidly attacked by the bacterium, resulting in decoloration within 3–5 days and, finally, complete disintegration at ca. 10 days after the addition of DPI and inoculation (Table 2).

TABLE 2. EFFECT OF NAD(P)H INHIBITOR DIPHENYLENE IODONIUM (DPI) ON INTERACTION BETWEEN *Macrocystis pyrifera* AND EPIPHYTIC BACTERIUM *Pseudomonas alginovora* STRAIN XO 17[a]

Treatment	Bacterial challenge	*N*	Observations
Axenic, untreated control	−	5	normal pigmentation
	+	5	normal pigmentation
DPI, 10 min 1 μM	−	5	plants normal, few apically bleached
	+	5	plants seriously damaged, except a few stipes and meristems completely bleached
2.5 μM	−	5	normal pigmentation and growth
	+	5	plants entirely bleached except a few stipes and meristems
5 μM	−	5	some plants are bleached (except stipes), one half in normal condition
	+	5	all plants bleached except stipes, some are less damaged than those exposed to 10 μM DPI + bacteria
10 μM	−	5	plants in good shape, normal pigmentation
	+	5	strongly bleached, incl. stipes

[a] The observations recorded here are representative for 7 replicated experiments with similar results. The + and − signs refer to the presence or absence of inoculum, respectively. *N*: number of plants tested for a given condition.

Similar experiments were performed with nonaxenic cultures of young sporophytes of *L. digitata*. Even after moderate DPI treatments (5 μM for 1 hr), *L. digitata* plantlets were rapidly (within 3 days) attacked by their natural bacterial epiflora, displaying symptoms similar to the decaying of axenic, DPI-treated *Macrocystis* plantlets artificially inoculated with *Pseudomonas alginovora*. Similar results were also observed when *M. pyrifera* sporophytes were reinoculated with their natural bacterial epiflora (data not shown).

Development of Model Pathosystem for Assessment of Induced Resistance in Kelp Sporophytes. In an attempt to identify a suitable pathogen for artificial infection experiments, kelp sporophytes were challenged with the oomycete *Eurychasma dicksonii*, which had been shown to infect members of many orders of brown algae, including both gametophytes and embryonic sporophytes of *L. digitata* (Müller et al., 1999). However, no artificial infection could be established with *E. dicksonii* in *L. digitata* sporophytes with a size greater than 1 mm. In contrast, two brown algal endophytes of the genus *Laminariocolax* (Ectocarpales), *L. tomentosoides* and *L. macrocystis*, did produce infections in a reliable and reproducible manner. When *L. digitata* or *M. pyrifera* plantlets, 2–20 mm in size, were inoculated with sporulating *Laminariocolax* filaments, the pathogens grew both endo- and epiphytically (Figure 2A,B). *Laminariocolax* caused serious growth perturba-

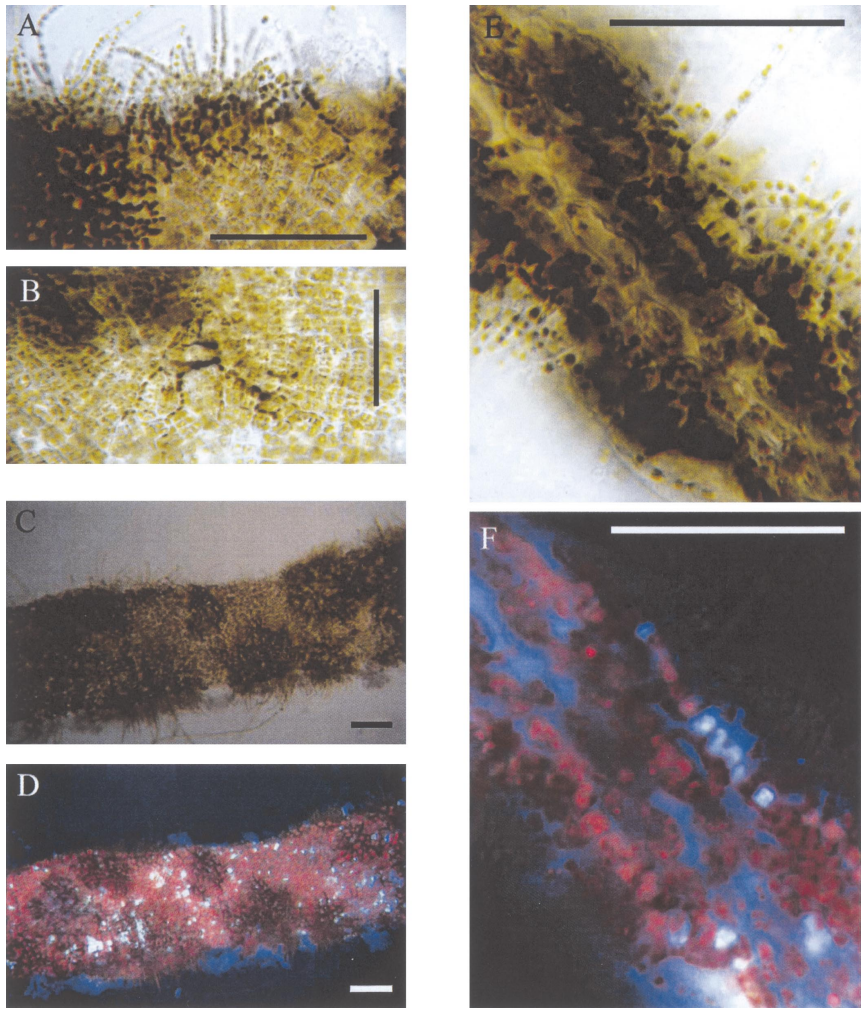

FIG. 2. Infection of *Laminaria digitata* by the endophyte *Laminariocolax tomentosoides* (all scale bars correspond to 100 μm). Superficial views of *Laminariocolax*-infected *L. digitata* plants showing that the pathogen lives both epiphytically (A) and endophytically, as filaments in the intercellular spaces (A, B). (C) On heavily infected plantlets, dense tufts of *Laminariocolax* are visible. (D) Under UV excitation massive necroses are visible as regions with bright blue autofluorescence. (E, F) Section of a strongly infected *L. digitata* plantlet, densely covered with *Laminariocolax* filaments. Penetration of *Laminariocolax* filaments is often accompanied by accumulation of bright blue autofluorescent compounds in the surrounding cortical host cells. *Laminariocolax* filaments in the medulla of this *Laminaria* plant are visible by their darker red plastid fluorescence compared to the brighter red fluorescence of *Laminaria*.

tions of host thalli, finally overgrowing its hosts, with dense tufts of *Laminariocolax* on the heavily infected plantlets (Figure 2C), accompanied by massive necroses (Figure 2D), and frequently resulting in thallus death. Under UV-light observation, the penetration or protrusion zones of infecting *Laminariocolax* filaments (Figure 2E) showed an accumulation of bright-blue autofluorescent compounds (Figure 2F). The first symptoms, consisting of local necroses, were visible within 10 days of inoculation, but the extent of infection was best assessed at one month after inoculation.

Laminariocolax tomentosoides and *L. macrocystis* were found to be cross-infective and attacked both *M. pyrifera* and *L. digitata*. Cell-free extracts of neither brown algal endophyte induced accumulation of H_2O_2 in *L. digitata* sporophyte cultures instead, addition of the cell-free extracts 60 min prior to elicitation with 150 μg/ml oligoguluronates considerably inhibited the oxidative burst (Figure 3A). Cell-free extracts of *Laminariocolax* indeed exhibited a high peroxide-scavenging capacity. Typically, 100 μl extract per 10 ml of seawater degraded 10 μM hydrogen peroxide to over 95% within less than 5 hr, 50% within the first 15 min. However, reactivity of *Laminaria* sporophytes was reestablished after transfer to fresh medium lacking endophyte extract (Figure 3B). In contrast, cell-free-extracts from the nonpathogenic ectocarpoid *Pylaiella littoralis* triggered an oxidative burst response in *L. digitata*, while extracts of *Pylaiella littoralis* were twice as active when the alga was infected by the oomycete *Eurychasma dicksonii* (Figure 1D).

Alginate Oligosaccharides Induce Resistance in Laminaria digitata against *Laminariocolax tomentosoides*. The potential role of the oxidative burst in protecting *Laminaria* sporophytes from infections by brown algal endophytes was next addressed, by treating *L. digitata* plantlets with alginate oligosaccharides at a concentration of 150 μg/ml, followed by challenge with *L. tomentosoides*. Nonelicited sporophytes inoculated with the endophyte displayed the symptoms described above (Figure 2 and 4A–D), i.e., dense infestation by endo- and epiphytic *Laminariocolax* filaments and conspicuous necrotic lesions. In contrast, young sporophytes that had been incubated for 2 hr in the presence of oligoguluronates, allowed to grow for 8 days in normal seawater medium, and then challenged by *L. tomentosoides* sporulating filaments were remarkably well protected against infection. Very few if any epi- or endophytic filaments were visible and even fewer necroses occurred (Figure 4E–H). Remarkably, while untreated plants showed a strong, localized accumulation of blue autofluorescent compounds in the cortical cells around penetrating *Laminariocolax* filaments (Figure 4D), the oligoguluronate-treated plants exhibited a less intense, but ubiquitous cortical accumulation of blue-autofluorescent compounds (Figure 4H).

Using a relative scale to score the extent of infection and various time intervals between elicitation of *Laminaria digitata* thalli with alginate oligosaccharides and inoculation by *Laminariocolax tomentosoides*, we next investigated the time required for the induction of resistance and its duration.

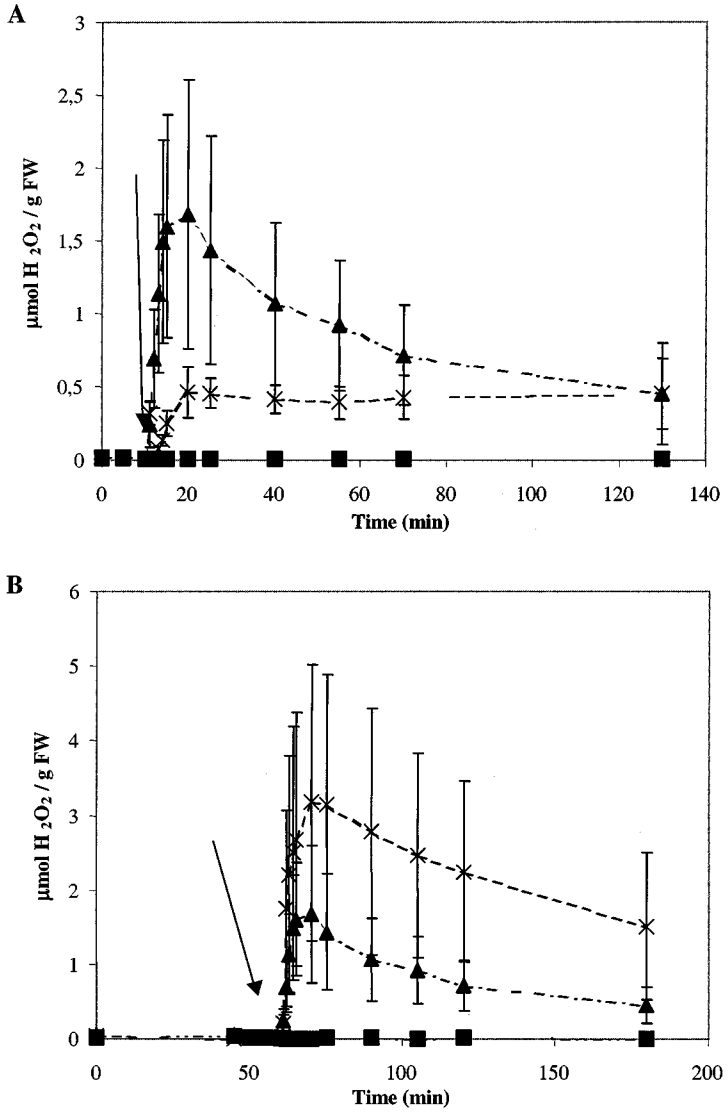

FIG. 3. *Laminariocolax tomentosoides* cell-free extracts scavenge the reactive oxygen species generated by the oxidative burst in *Laminaria digitata* (addition of 150 μg/ml GG is marked by an arrow). (A) *Laminariocolax* extracts added 1 min after GG elicitation, asterisks; control, squares; GG only, triangles. (B) Cell-free extracts were added for 45 min, medium was changed completely, and the elicitors were added 15 min later. In contrast to the above, the treated plants (asterisks) were unhindered in their oxidative burst response. Error bars indicate standard deviation of the average concentration of H_2O_2 measured in 3 replicates.

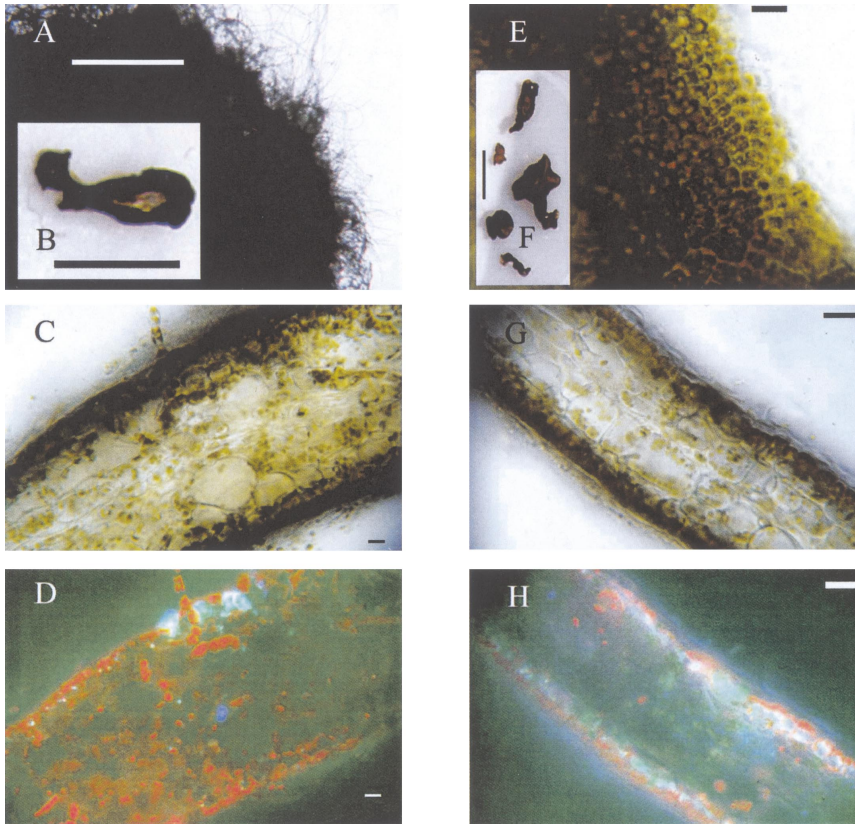

FIG. 4. Oligoguluronates induce resistance to *L. tomentosoides* in *L. digitata*. In controls (A–D), plantlets are completely overgrown (A, B), and frequently penetrated by (C, D) *Laminariocolax* filaments. As shown also in Figure 2, penetrating filaments are often surrounded by bright blue autofluorescent compounds (D). *Laminaria digitata* plantlets were elicited with alginate oligosaccharides for 2 hr with 150 μg/mlGG, grown for 9 days in PES medium, then inoculated with *Laminariocolax tomentosoides* (E–H). Hardly any epi- or endophytic *Laminariocolax* filaments were visible, and the cortex of GG-treated plants often showed accumulation of autofluorescent compounds, although this was less intense and much more widespread and diffuse than in untreated plants. Photographs were taken 34 days after inoculation with the pathogen. Scale bars: A, 1 mm; B, F: 1 cm; C, D, E, G, H: 10 μm.

There was a statistically significant difference in the intensity of symptoms between plantlets subjected to the different treatments (ANOVA, $F = 9.254$, $P = 0.0001$). Treatments with oligoguluronates more than 7 days before endophyte inoculation were significantly less infected than controls untreated before

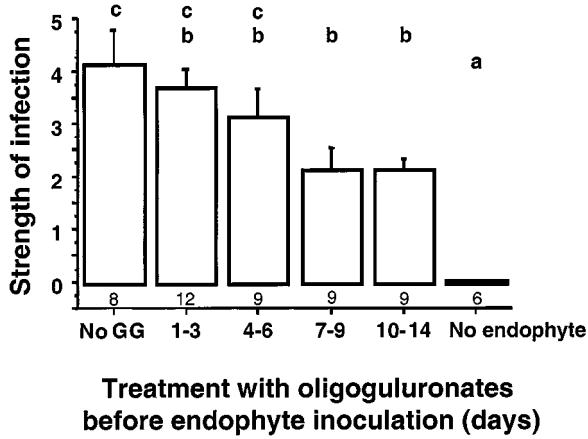

FIG. 5. Strength of the infection of *Laminaria digitata* by the endophyte *Laminariocolax tomentosoides* after treatment with oligoguluronates at various intervals before pathogen inoculation. At 3 weeks after inoculation, relative intensity of symptoms, from 0 (complete resistance) to 6 (highest strength of infection, see Methods and Materials section), was determined by an independent observer. Error bars indicate variability of strength of infection, expressed as the standard deviation of the marks attributed to a given series of plants. Analysis was by one-way ANOVA (see Methods and Materials). Letters above the bars denote significant groupings based on Tukey-Kramer multiple-comparison tests ($P < 0.05$). N below the bars indicates number of replicates.

challenge with the pathogen (Figure 5). Interestingly, the reduction of the strength of infection was progressive and the treatments with oligoguluronates less than 7 days before inoculation showed weaker resistance. Although the treatment with oligoguluronates did not prevent the occurrence of some minor symptoms, it reduced their intensity and conferred a protection that persisted for >7 days.

DISCUSSION

In any host–pathogen interaction, recognition of the occurrence of an attack is the first line of defense. This may involve recognition of the attacker, through either the perception of exogenous signals (defined as exogenous elicitors of defense responses), or of degradation products from the host itself (endogenous elicitors), or both. Therefore, in Laminariales, the oxidative response to the perception of alginate oligosaccharides is probably related to the sensing of damage by microorganisms of the alginate-rich cell wall matrix of kelps. Among the natural bacterial epiflora of Laminariales, many strains have been

reported to harbor alginate-degrading enzymes. These include nonpathogenic bacteria, such as the one used in this study, *Pseudomonas alginovora* (Boyen et al., 1990a), and pathogenic strains, such as the agent of the spot-wounded disease in *L. japonica*, *Pseudomonas elyakovii* (Sawabe et al., 2000). No alginolytic activities have so far been reported in brown algal endophytes. However, scanning electron microscopy investigations of the early stages of the development of *Laminariocolax* and *Laminarionema* zoospores suggest that their mode of penetration may involve the enzymatic degradation of host surfaces rather than a mechanical disruption (Heesch and Peters, 1999). Finally, alginases have been detected in marine fungi (Wainwright and Sherbrock-Cox, 1981) as well as in a variety of kelp grazers, including mollusks and echinoderms (see Boyen et al., 1990b). On the other hand, oligoguluronate signaling may also be related to the need for recognizing challenge by alginate-containing brown algal endophytes and epiphytes.

Elicitor recognition, at the surface or in the cytosol of host plant cells (Ebel and Mithöfer, 1998), is followed within minutes by a so-called oxidative burst, which consists of the accumulation of ROS, such as superoxide ions, hydrogen peroxide, or hydroxyl radicals, via the activation of plasma membrane-associated NAD(P)H oxidases or apoplastic peroxidases. Several, convergent lines of evidence emerging from this study show that accumulation of ROS is an essential component of the defense system of kelp sporophytes against potentially harmful microorganisms. In loss-of-function experiments, in which the capacity of performing an oxidative burst was suppressed by the NAD(P)H oxidase inhibitor diphenylene iodonium, axenic sporophytes of *Macrocystis pyrifera* became very susceptible to the alginate-degrading, yet naturally nonpathogenic bacterium, *Pseudomonas alginovora*. Similarly, control of the bacterial epiflora by nonaxenic sporophytes of *Laminaria digitata* was shown to depend on a DPI-sensitive mechanism, because this kelp species is similarly capable of triggering an oxidative response following recognition of alginate oligosaccharides (Küpper et al., 2001). It follows that, in Laminariales, the capacity of releasing activated oxygen species appears as a central, causal element for keeping the bacterial epiflora at a tolerable level. This conclusion is consistent with previous findings showing that apoplastic peroxide concentrations, such as those occurring during an oxidative burst, can inhibit the growth of kelp-associated bacteria (Küpper et al., 2001). It suggests that activated oxygen species may have a direct role in controlling the growth of potentially pathogenic microorganisms. Such a biochemical basis for the interaction between kelps and alginolytic bacteria is reminiscent of the ecological relationship between red algal agarophytes and their agar-degrading epiphytic bacteria, which also depends on the capacity of the host to perform an oxidative response following recognition of agar oligosaccharides (Weinberger and Friedlander, 2000; Weinberger et al., 2001).

Reciprocally, in gain-of-function experiments by incubation with alginate oligosaccharides, elicited *L. digitata* sporophytes became resistant to infection by

their natural endophytic pathogen *Laminariocolax tomentosoides*. A 1-hr incubation in the presence of alginate oligosaccharides is known to induce a strong emission of H_2O_2 in *L. digitata* (Küpper et al., 2001), further indicating that the oligoguluronate-induced oxidative burst also plays a central role in the induction of resistance to the endophyte. This observation in kelp sporophytes is in agreement with the report that the oxidative burst in *Chondrus crispus* is a key element in establishing resistance to its green algal pathogenic endophyte *Acrochaete operculata* (Bouarab et al., 1999) and also with studies indicating a major role of H_2O_2 in the induction of systemic acquired resistance in higher plants (Alvarez et al., 1998; Van Camp et al., 1998).

Other observations in this study indirectly support the above conclusions. In natural populations, the sporophytes of Laminariales can show a nearly 100% prevalence of pathogenic endophytes, with severe disease symptoms such as warts, crippled thalli, and twisted stipes (Ellertsdóttir and Peters, 1997). We show here (Figure 3) that, unlike extracts of the closely related ectocarpoid, *Pylaiella littoralis*, *Laminariocolax* cell-free extracts not only are not recognized by *L. digitata* sporophytes, but also are capable of quenching the alginate-induced oxidative response. This finding suggests that the infective success of these endophytic pathogens may be due to their capability to avoid recognition or even to suppress the defenses of the host. In contrast to *Laminariocolax*, *Eurychasma dicksonii* is fended off by the sporophytes of Laminariales, whereas it is a natural pathogen to a large variety of brown algal groups (Küpper and Müller, 1999; Müller et al., 1999). As suggested in Figure 1D, this oomycete may produce compounds that are specifically recognized by *L. digitata*. Remarkably, also, the virulence of this pathogen correlates well with the inability of its brown algal hosts to perform an oxidative burst. In particular, the threshold size (ca. 1 mm) above which infection by *Eurychasma* was no longer observed in *L. digitata* sporophytes is coincident with the threshold size for the acquisition of the capacity to respond with an oxidative burst to elicitation with alginate oligosaccharides.

However, we show here that protection of *L. digitata* against *L. tomentosoides* was not significantly established until at least 7 days after host elicitation with oligoguluronates and that it persisted for one more week. These observations suggest that secondary, long-term defense mechanisms are induced downstream of the oxidative burst, a build-up of immunity that probably requires the progressive up-regulation of biosynthetic enzymes as well as ultrastructural changes. Thus we postulate that the establishment of resistance involves the synthesis of chemical defenses, which are either toxic to *Laminariocolax* zoospores and/or result in the host cell wall strengthening, providing a barrier against penetration by the pathogen.

Chemical defenses of marine brown algae include secondary metabolites such as terpenoids and polyphenols (Hay and Fenical, 1988, 1992; Steinberg, 1992; Hay and Steinberg, 1992; Cronin and Hay, 1996; Hay, 1996; Targett and Arnold, 1998; Pavia and Toth, 2000), as well as fatty acid-derived compounds such

as C_{11} hydrocarbons (Hay et al., 1998; Schnitzler et al., 1998). Interestingly, accumulation of UV autofluorescent material was observed in the *L. digitata* plantlets elicited with alginate oligosaccharides as well as at the penetration sites of *Laminariocolax* filaments, and we hypothesize that these UV fluorescent compounds correspond to aromatic secondary metabolites such as phlorotannins. It was demonstrated that these defense metabolites are inducible by grazers in brown algae (Pavia and Toth, 2000) and that this can increase resistance to further grazing (Toth and Pavia, 2000). There is still some debate, however, as to the nature of the signals that induce the up-regulation of phlorotannins. In Laminariales, mechanical wounding induces rapid accumulation of these compounds (Hammerstrom et al., 1998). In contrast, in the fucalean *Ascophyllum nodosum*, mechanical wounding did not properly mimic the action of the grazer *Littorina obtusata* regarding the build-up of phlorotannin defenses (Pavia and Toth, 2000). In light of our results, we propose that, besides mechanical wounding, signaling through alginate oligosaccharides may be a cue for the recognition of grazing by marine molluscs.

Among the 11 brown algal orders under investigation here, high levels of constitutive release of hydrogen peroxide were observed in species that feature filamentous erect thalli or microthalli. Such a behavior may constitute a nonenzymatic mechanism for the detoxification of activated oxygen species generated from photosynthesis or respiration (Collén and Davison, 1999). The alginate-induced oxidative response was found in one member of the Ectocarpales (*Pylaiella littoralis*), and in the sporophytes of all of the Desmarestiales and Laminariales tested. Whereas most fucoids and filamentous species, including the gametophytes of Laminariales, were insensitive to challenges with oligoguluronates (at least in terms of the oxidative response.

Based on recent phylogenies of brown algae (Draisma et al., 2001; Rousseau et al., 2001), no clear evolutionary pattern can be drawn from the distribution of the alginate-induced oxidative response in this survey. However, it was found in one member of the Ectocarpales, in the Desmarestiales, and in the Laminariales, i.e., clades that have evolved the most recently. With the exception of *P. littoralis*, the capacity to perform an alginate-induced oxidative burst may also be thought of as a developmentally regulated characteristic of the alginate-rich members of brown algae with complex, foliose, or frondose macrothalli, such as the sporophytes of Laminariales. Compared to the sporophytes, kelp gametophytes are very susceptible to infection by *Eurychasma dicksonii* (Müller et al., 1999) and the protist parasite *Maullinia ectocarpii* (Plasmodiophorales, Maier et al., 2000). The usually short life span and simple morphology of gametophytes may have necessitated a constitutive rather than an inducible defense system. It can not be ruled out, however, that the macrothallic brown algae that do not respond to a challenge with oligoguluronates by a burst of H_2O_2 are probably endowed with other, inducible defense mechanisms or that they possess other responses to oligoalginate challenge. In this respect, the fucoid *Ascophyllum nodosum*, which was

not responsive to oligoalginates (Table 1), was nevertheless recently shown to be capable of expressing inducible defenses against herbivores (Pavia and Toth, 2000).

In conclusion, the capacity to recognize alginate oligosaccharides as defense signals is limited to a few members of brown algae. From a bioenergetic viewpoint, elicitor recognition followed by a massive, yet transient, release of hydrogen peroxide appears as a rather economic (in terms of redox equivalents required for the reduction of oxygen) and finely tuned form of defense signaling. In addition, our study shows that recognition of alginate oligosaccharides and the related oxidative response are involved with natural and induced immunity of kelps against epiphytic bacteria and endophytes. In any case, these elicitors can now be used to explore the biochemical basis of kelp immunity, including identification of the chemical nature of the inducible defenses. In particular, the *Laminaria digitata–Laminariocolax tomentosoides* host–pathogen system employed in this study provides an experimental model to further investigate the regulation mechanisms and the biological activity of phlorotannins in kelps.

Acknowledgments—We would like to thank Ingo Maier (University of Konstanz) for providing laboratory cultures of various algal species (Table 1). Claire Gachon (Ecole Normale Supérieure, Paris) and Doris Bliestle (Photographic laboratory, University of Konstanz) contributed to microscopy and photography of infected plants, respectively. F.C.K. was supported by fellowships from Studienstiftung des Deutschen Volkes (Bonn) and the European Commission (Program MAST-III).

(Received August 28, 2001; accepted April 4, 2002)

Abstract—A number of biological and physical stimuli have been evaluated as inducers of pseudopterosin biosynthesis in the sea whip *Pseudopterogorgia elisabethae.* Data indicate that the production of pseudopterosins can be significantly increased in response to high levels of predation by the mollusk *Cyphoma gibbosum* and in response to decreased levels of UV/visible radiation. High levels of feeding by *Chaetodon capistratus* and an artificial wounding of the sea whip did not result in increased pseudopterosin levels.

Key Words—*Pseudopterogorgia elisabethae*, induction, terpene, marine, biosynthesis, pseudopterosin, predation.

INTRODUCTION

The pseudopterosins represent a class of diterpene glycosides produced by the octocoral, *Pseudopterogorgia elisabethae*. As with many natural products, diverse congeners of the pseudopterosins exist and vary with geographic location. Pseudopterosins A–D were isolated from the nonpolar fraction of the extract from *P. elisabethae* collected from Sweetings Cay, Bahamas (Look et al., 1986). Pseudopterosins E and F are major components of *P. elisabethae* from Bermuda, while pseudopterosins G–J are minor components from the same organism. Pseudopterosins K and L have been found in *P. elisabethae* from samples collected at Great Abaco Island in the Bahamas (Roussis et al., 1990). Little is known about the ecological role of the pseudopterosins although, Fenical (personal communication) has demonstrated that these natural products act as fish feeding deterrents.

The pseudopterosins are antiinflammatory and analgesic agents with potencies superior to that of existing drugs such as indomethacin in mouse ear models (Look et al., 1986). These compounds appear to act by a novel mechanism of action; they are not active against PLA_2, cyclooxygenase, and cytokine release, or as regulators of adhesion molecules. Evidence suggests the pseudopterosins block eicosanoiod release rather than biosynthesis in murine macrophages (Mayer et al., 1998). Purified pseudopterosins are also used commercially in a cosmetic product, which has generated additional interest in these natural products (Rouhi, 1995).

Factors that control the production and modify the concentration of the pseudopterosins in *P. elisabethae* are unknown. In the course of our studies with this gorgonian (Coleman et al., 1999; Coleman and Kerr, 2000), we have observed that the concentration of the pseudopterosins varies among different geographic locations and also among individuals within one reef area. It is not known whether these differences are due to genetic or environmental factors. There is a limited amount of literature regarding the inducibility of terpenes of terrestrial origin; however, much of the data indicates that many of these natural products are inducible. Various groups have demonstrated the inducibility of paclitaxel and other taxoids with methyl jasmonate in cell cultures of *Taxus canadensis*, *T. cuspidate*, and *T. baccata* (Ketchum et al., 1999a,b; Laskaris et al., 1999). In one study (Laskaris et al., 1999), geranylgeranyl diphosphate synthase activity was rapidly induced in response to the addition of methyl jasmonate to *T. baccata* cell suspension cultures. In the grand fir, *Abies grandis*, biosynthesis of monoterpenes, sesquiterpenes, and diterpenes was shown to be inducible by stem wounding at the level of gene activation; an increase in enzyme activity of the respective terpene synthases was also observed (Bohlmann and Croteau, 1999). Herbivore-induced terpene biosynthesis has been demonstrated in maize (Degenhardt and Gershenzon, 2000). Specifically, upon herbivore attack, maize emits a mixture of volatile compounds including an unusual acyclic C_{11} homoterpene.

The goal of the study described herein is to identify factors that modify the concentration of pseudopterosins in the host gorgonian. Developing an understanding of the ecological role of the pseudopterosins, and specifically identifying induction stimuli, may provide valuable information for a controlled production of these compounds.

METHODS AND MATERIALS

Fieldwork was performed at the east end of Grand Bahama Island, at a depth of 12 m. A area 20×30 m^2 that had a dense gorgonian fauna was selected for the study. *P*. elisabethae is difficult to identify according to morphological characteristics; thus, following a tentative visual identification, each gorgonian was sampled and assayed for the presence of the characteristic pseudopterosins by TLC analysis. Clippings of ca. 10–15 cm of each *P. elisabethae* were removed prior to and

following each treatment in order to quantify changes in pseudopterosin content. Individual gorgonians with at least two branches were selected so that separate, intact branches could be removed for both analyses.

Biological Stimuli. To determine the effects of grazing on the inducibility of pseudopterosins, known predators were confined to an area with one *P. elisabethae* as the only food source. Twenty four-eyed butterfly fish, *Chaetodon capistratus*, were collected from the same site as that used for the induction experiment. Strong mesh-type nylon rope nets with 5-mm openings were used to contain two fish around each of 10 *P. elisabethae.* Another 10 nets acted as a control, containing only the gorgonian and no fish. Floats were placed on the top of the nets to keep them afloat, while the base of the nets encircled the substratum of the gorgonian and were secured with plastic ties. In addition, there were two metal rings, with a rigid 50-cm-diam., which did not allow the nets to touch the branches of the colonies.

Another 20 of the tagged gorgonians were used for the flamingo tongue snail experiment. Thirty flamingo tongue snails, *Cyphoma gibbosum*, were collected and a 2-mm hole was drilled into their shell using a dental diamond burr. In this process, we were careful not to harm the snail's mantle. (This procedure was performed with a group of *C. gibbosum* prior to our induction study to confirm that this would not be harmful to the snails.) Three snails per gorgonian were threaded and tied to the main axis of 10 *P. elisabethae* to create an abnormally high level of feeding on the corals. The snails were placed on the main axial tissue of the gorgonian. Every day, observations were made to ensure the snails were still attached and feeding on the corals. Three fishing lines were tied to each of the other 10 *P. elisabethae* for the control group. Both experiments were left in place for a total of five days, and clippings were removed for post treatment analysis.

Physical Stimuli. To determine the effects of physical stimuli on the inducibility of pseudopterosins, 20 *P. elisabethae* were tagged and divided into two groups—treatment and control. The 10 treatment gorgonians were artificially wounded by slashing with dive knives on all major branches over their entire surface twice a day for 5 days. The 10 control organisms were subject to identical conditions but were not slashed with knives. Prior to treatment, a 10-cm clipping was removed from all gorgonians. At the conclusion of the experiment period, a posttreatment sample similar to the pretreatment sample was removed.

Visible and Ultraviolet light. To determine the effect of visible and UV light on the inducibility of pseudopterosins, 10 *P. elisabethae* were subjected to reduced radiation by shading with acrylic sheets. Frames were constructed using PVC pipes with a 2.4-cm diam. Each frame measured 1×1 m, and acrylic sheets were attached to one side of each frame by plastic ties. Five of the gorgonians had acrylic sheets suspended above them that blocked UV radiation. The other frames blocked visible and UV radiation from reaching the other five. Since the PVC frames are neutrally buoyant, four polypropylene ropes were attached to the corners of the

frames, and the other end of the ropes were tied to four concrete blocks. This allowed the frames to be suspended 5–10 cm above the organisms. Pretreatment and posttreatment clippings were removed from each of 10 gorgonians.

Chemical Analysis. Pseudopterosins were extracted and purified from the experimental clippings according to the following protocol. Each organism was cut into 1-cm pieces and lyophilized for a period of 48 hr. Each sample was extracted three times for 24 hr with 40 ml methanol–methylene chloride (1:1) and concentrated to dryness. The crude extract was partitioned between MeOH–H_2O (9:1) and hexanes, and the resulting MeOH–H_2O layer subsequently extracted with CH_2Cl_2. The latter fraction, containing the pseudopterosins, was evaporated to dryness. The weight of the crude pseudopterosin fraction was obtained, and sufficient ethyl acetate was added to each sample to provide uniform concentrations. The individual pseudopterosin extracts were then further purified by normal phase HPLC using a gradient of hexanes–ethyl acetate (60:40) to ethyl acetate over 25 min. A calibration curve was generated by the use of HPLC utilizing pseudopterosin standards so that the concentrations of the pseudopterosins in our test samples could be quantified.

Pseudopterosin C (Ps C) concentrations were reported as a measure of the overall pseudopterosin content. Ps C is the predominant component of this mixture (ca. 75%) and, thus, is indicative of the overall changes occurring. While not reported in detail, the other pseudopterosins exhibited similar changes in concentration to that reported for Ps C.

Statistical Analysis. The response was taken as the difference between the pseudopterosin content of the pretreatment and posttreatment clippings from each organism. For the fish, snail, and artificial wounding experiments, an analysis of variance was performed using one-way ANOVA to determine if any change in the pseudopterosin content was significant. Results of the UV/visible blocking experiments were analyzed by paired comparison *t* tests. The null hypothesis states that there will be no significant difference in the pseudopterosin content between the control and treatment groups.

RESULTS

Certain fish and mollusks have been observed to prey upon *P. elisabethae*. Lasker (1985) reported that the four-eyed butterfly fish, *Chaetodon capistratus*, feeds on the polyps of *Pseudopterogorgia* spp. The flamingo-tongue snail, *Cyphoma gibbosum*, is a gorgonian specialist and has been observed feeding mainly on the axial tissues of gorgonians including *P. elisabethae* (personal observation; Steudler et al., 1977; Vrolijk and Targett, 1992). These predators were, therefore, selected as potential inducers of pseudopterosin biosynthesis.

In the attempted induction by *C. capistratus*, in which a pair was enclosed with a *P. elisabethae* by a net, intense feeding by the fish on the gorgonian was

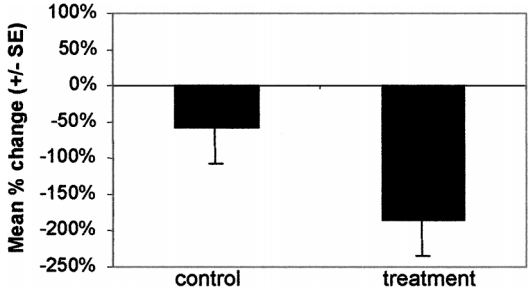

FIG. 1. Effect of elevated *C. capistratus* feeding on pseudopterosin C content. Bars indicate mean $\pm$ SE, $N = 10$.

observed daily. Analysis of the pseudopterosin content of the pre- and posttreatment clippings of the 10 *P. elisabethae* used in this experiment and the 10 control populations indicated that the pseudopterosin content did not significantly change over the treatment period (Figure 1). The one-way ANOVA analysis afforded a P value of 0.558 ($\alpha = 0.05$). The decrease in the pseudopterosins observed in both the control and treatment groups may be a result of decreased health of the corals during this experiment but is not fully understood at this time.

The experiment designed to provide abnormally high levels of feeding by the mollusk *C. gibbosum* resulted in greatly elevated pseudopterosin concentrations (Figure 2). The snails were observed on a daily basis to be feeding on the gorgonian tissue yet this resulted in only a modest amount of damage (Figure 2). ANOVA gave a P-value of 0.002 ($\alpha = 0.05$), indicating the inducibility of pseudopterosin biosynthesis by predation of *C. gibbosum*.

As discussed above, stem wounding has been demonstrated to lead to an induction in terpene biosynthesis in terrestrial systems. It is evident from Figure 3 that the artificial wounding of the gorgonian tissue resulted in only a minimal

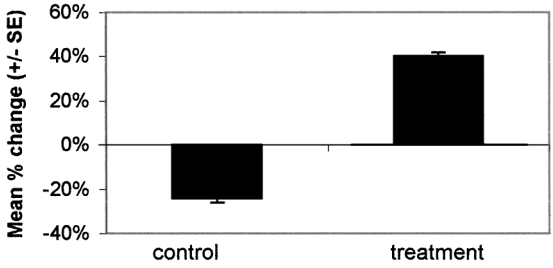

FIG. 2. Effect of *C. gibbosum* feeding on pseudopterosin C content. Bars indicate mean $\pm$ SE, $N = 10$.

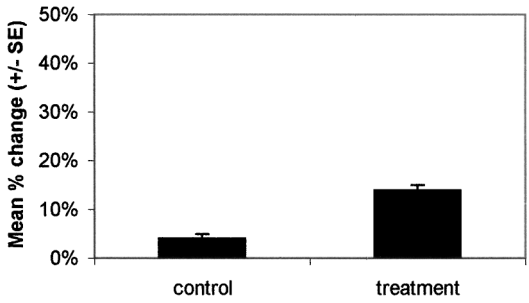

FIG. 3. Effect of rasping of *P. elisabethae* on pseudopterosin C content. Bars indicate mean $\pm$ SE, $N = 10$.

apparent increase in pseudopterosin content. In fact, when the data were subjected to ANOVA, the difference was shown to be not significant.

The effect of decreased visible and UV radiation on pseudopterosin biosynthesis was examined by installing frames with acrylic sheets 5–10 cm above specimens of *P. elisabethae*. The acrylic sheets blocked either UVB or both UVB and visible light from the gorgonians. We were aware that this design allowed some indirect light to reach the corals. The goal of our experiment was not to rigorously exclude all UV or UV/visible light, but only to decrease the amount of radiation significantly. Pre- and posttreatment clippings were removed, and the pseudopterosin content was determined. An analysis of the 10 organisms that were subjected to reduced UV and UV/visible radiation was performed by paired comparison *t* tests. The difference in concentrations of pseudopterosin between the pre- and posttreatment clippings was calculated and the average difference was compared to the null model of zero change. The blocking of UV radiation and both visible and UV radiation increased the pseudopterosin content by approximately 100% in the treatment groups with P values of 0.04 and 0.07, respectively ($\alpha = 0.05$). This is significant, and the null hypothesis was rejected (Figure 4). Interestingly, these results are contrary to those reported by Kinzie (1993) with reef building corals.

DISCUSSION

The overall goal of these experiments was to identify factors responsible for the induction of pseudopterosins in the gorgonian *P. elisabethae.* Our data indicate that the biosynthesis of these natural products can be significantly increased in response to high levels of predation by the mollusk *C. gibbosum* and in response to decreased levels of UV/visible radiation. The induction in response to predation by the mollusk is somewhat comparable to insect-induced terpene biosynthesis in vascular plants. The blocking of UV/visible radiation increased the pseudopterosin

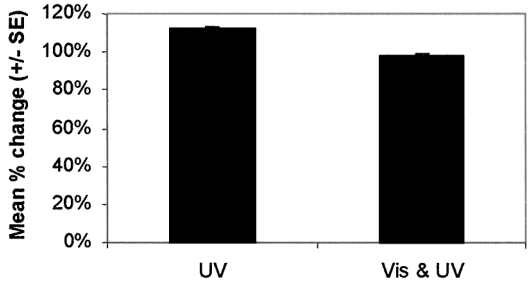

FIG. 4. Effect of blocking UVB and UVB/visible radiation on pseudopterosin C content. Bars indicate mean ± SE, $N = 5$.

content by approximately 100% in the treatment groups. This is intriguing, as the ecological significance is not immediately clear. It seems to suggest the involvement, either directly or indirectly, of a photosynthetic organism in pseudopterosin biosynthesis. Zooxanthellae are well known to be associated with gorgonians and may be involved in this biosynthetic pathway.

To our knowledge, the data with *C. gibbosum* and UV/visible radiation represent the first demonstration of induction of pseudopterosin biosynthesis. The lack of a significant induction in pseudopterosin biosynthesis in response to fish feeding and artificial wounding experiments does not necessarily imply that these stimuli are not inducers (or a mimic of an inducer). Rather, it is conceivable that our experimental protocol did not permit the detection of pseudopterosin induction. Experiments to explore the induction of pseudopterosin biosynthesis more fully are underway.

Acknowledgments—We thank Florida Sea Grant for financial support (grant. R/LR-MB-8) and the Florida Institute of Oceanography for providing ship time aboard the *R/V Bellows*. We would also like to acknowledge N. Lindquist (UNC) for assistance with some of the field experiments.

(Received January 4, 2002; accepted June 12, 2002)

Abstract—The invasive green alga, *Caulerpa taxifolia*, that has spread rapidly after its introduction into the Mediterranean and the North American Pacific, reacts to wounding by transforming its major metabolite caulerpenyne (**1**). This wound-activated reaction involves the transformation of the bis-enol acetate moiety of **1**, releasing reactive 1,4-dialdehydes. The ability to perform this transformation is found also in both the noninvasive Mediterranean *C. prolifera* and the invasive *C. racemosa*. Trapping experiments, as well as transformation of the model substrate geranyl acetate, suggest that all three investigated *Caulerpa* spp. rely on esterases that act upon wounding of the algae by subsequently removing the three acetate residues of caulerpenyne. The resulting reactive 1,4-dialdehyde oxytoxin 2 (**9**) can be identified by liquid chromatography–mass spectrometry and is unstable in the wounded tissue. Caulerpenyne transformation occurs rapidly, and severe tissue damage caused degradation of more than 50% of the stored caulerpenyne within 1 min in all three algae. Prevention of the enzymatic reaction before extraction, by shock freezing the tissue with liquid nitrogen, was used for the determination of the caulerpenyne content in intact algae. It gives about twofold higher values compared to an established methanol extraction protocol. The speed and mechanism of the wound-activated transformation, as well as the caulerpenyne content in intact tissue of invasive and noninvasive *Caulerpa* spp., are comparable. Thus, this enzymatic transformation, despite

being fast and efficient, is likely not the key for the success of the investigated invasive species.

Key Words—Activated defense, green algae, *Caulerpa*, caulerpenyne, chemical defense, invasive algae, Mediterranean, terpenes, quantification, esterase, 1,4-dialdehydes.

INTRODUCTION

Members of the order Caulerpales are some of the most abundant and widely distributed algae throughout the tropical oceans. This group of siphonous green algae is among the best investigated, both biologically and chemically (Paul and Fenical, 1987; Meyer and Paul, 1992). Growing in reef habitats with intense grazing, these algae have developed efficient chemical defenses that are mainly based on terpenoids. The accidental introduction of *Caulerpa taxifolia* (Vahl) C. Agardh into the Mediterranean in 1984 (Meinesz and Hesse, 1991) and its success in conquering the new habitat (Belsher and Meinesz, 1995; Delgado et al., 1995; Ceccherelli and Cinelli, 1997; Meinesz et al., 2001) has only recently put the focus back on these seaweeds. In addition to its light and temperature tolerance (Garcia et al., 1996; Komatsu et al., 1997) and fast growth (Komatsu et al., 1994; Meinesz et al., 1995), its chemical defense also has facilitated the invasion (Guerriero et al., 1992, 1993; Bellan-Santini et al., 1996).

Recent monitoring revealed that *C. taxifolia* is not the only invasive *Caulerpa* species spreading in the Mediterranean. One introduced variety of *C. racemosa*, *C. racemosa* var. *occidentalis* (J. Agardh) Borgesen, with high temperature tolerance, was identified and has been spreading continuously since the early 1990s (Verlaque et al., 2000). Besides those introduced and invasive species, there exist the indigeneous noninvasive *C. prolifera* (Forsskal) Lamouroux that has been proven to be useful in comparison studies for investigations of the factors determining the invasive potential (Sant et al., 1996).

The role of the sesquiterpene caulerpenyne (**1**) (Figure 1), initially isolated from Mediterranean *C. prolifera* (Amico et al., 1978), in the chemical defense of species of *Caulerpa* has been investigated in numerous studies. Caulerpenyne acts as a feeding deterrent to tropical sea urchins (McConnell et al., 1982) and has been related to the poor food quality that *C. taxifolia* has for Mediterranean sea urchins (Boudouresque et al., 1996). It inhibits the growth of microorganisms, interferes with the development of fertilized sea urchin eggs, and is toxic to larvae and adults of potential herbivores (Paul and Fenical, 1986; Pesando et al., 1996; Lemée et al., 1997; Ricci et al., 1999). On the other hand, studies with herbivorous tropical fishes have shown that caulerpenyne does not defend the plants against these macroherbivores (for an overview see Meyer and Paul, 1992). Several studies have focused also on the caulerpenyne content in various *Caulerpa* species (e.g. Paul and Fenical, 1986; Meyer and Paul, 1992; Gavagnin et al., 1994; Amade and

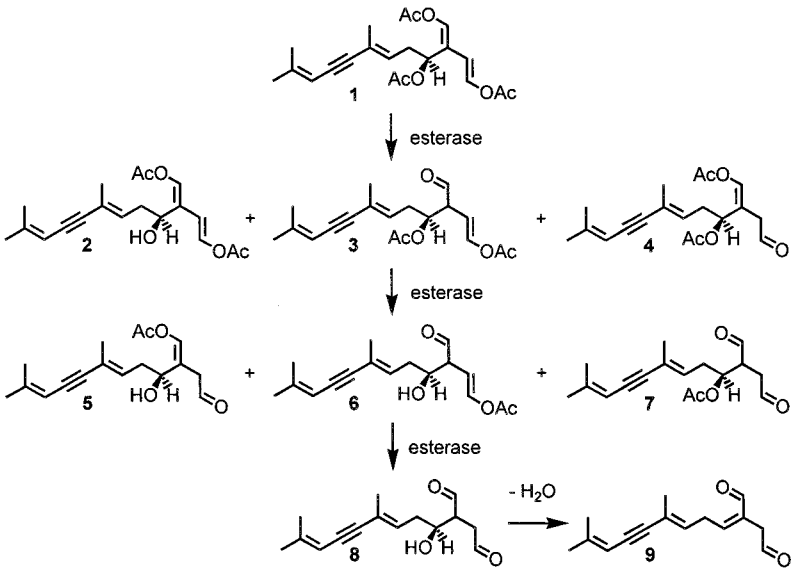

FIG. 1. Stepwise deacetylation of caulerpenyne **1** by esterases from *C. taxifolia*. (**9** = oxytoxin 2; **4** = oxytoxin 1).

Lemée, 1998). Throughout this order, caulerpenyne was found to be the major or one of the major secondary metabolites, the overall content varied depending on species, location, and season. The aquarium derived strain of *C. taxifolia* (Jousson et al., 1998, 2000; Wiedenmann et al., 2001), spreading in the Mediterranean, can contain up to 1.9% of the algal dry weight (DW) of caulerpenyne, but this value depends on season and depth (Amade and Lemée, 1998). In contrast, Pacific *C. racemosa* species collected in Guam contained only 0.2–0.5% DW (Meyer and Paul, 1992). Not only does the caulerpenyne content vary among different species but also within different parts—fronds and stolons—of one individual alga (Meyer and Paul, 1992).

While these investigations have mainly focused on caulerpenyne, recent evidence suggests that the presence of caulerpenyne-derived sesquiterpenes in wounded algal tissue also have to be taken into account. We found that upon mechanical wounding of *C. taxifolia*, caulerpenyne is rapidly transformed into reactive aldehydes (Jung and Pohnert, 2001). This reaction is comparable to the wound-activated conversion of the diterpene halimedatetraacetate into the potent feeding deterrent halimedatrial in algae of the related genus Halimeda (Paul and Van Alstyne, 1992). The identified products from *C. taxifolia* and the use of model substrates suggest an enzymatic transformation as shown in Figure 1 (Jung and Pohnert, 2001).

The resulting aldehydes **4** and **9** from *C. taxifolia* are of the oxytoxin family and have been previously found in defensive secretions and parapods of specialized mollusks feeding on *C. prolifera* (Gavagnin et al., 1994). Under attack, these mollusks secrete a toxic mucus or, if molested further, detach their tail or parapods to distract the enemy and escape. The mucus and the parapods contain the aldehydes **4** and **9** as well as caulerpenyne and are capable of deterring various predators (Cimino et al., 1990; Thibaut et al., 2001). Although directly involved in the defense of slugs against predatory fishes (Gavagnin et al., 1994), the role of these metabolites in a wound-activated algal defense has yet to be evaluated.

Facing the spread of *C. taxifolia* in the Mediterranean, the question arose as to whether the wound-activated transformation of caulerpenyne acting immediately after tissue damage is an important key to success for this species alone or whether this mechanism is universally found among Caulerpales. The major aim of this work was to address this question by performing a comparative study of the production of reactive aldehydes by different *Caulerpa* spp. upon wounding.

Since significant amounts of caulerpenyne are transformed within seconds after wounding (Jung and Pohnert, 2001), a new quantification protocol had to be developed that avoids this reaction during the extraction process. This was achieved by shock freezing the algae with liquid nitrogen prior to extraction, thus suppressing enzyme activity during the work-up. One focus of the present work, therefore, was to provide means to determine and compare the caulerpenyne content in intact tissue of different *Caulerpa* species. We chose three *Caulerpa* species of the Mediterranean: the introduced and invasive aquarium-derived strains *C. taxifolia* and *C. racemosa* and the noninvasive Mediterranean *C. prolifera*. Comparing invasive and noninvasive species from the same habitat will help establish the role of wound-activated caulerpenyne transformation to reactive aldehydes as a potential defensive strategy.

METHODS AND MATERIALS

General. MS-grade solvents were purchased from Riedel de Haen (Seelze, Germany). HPLC-APCI-MS (atmospheric pressure chemical ionization): A Hewlett-Packard HP1100 was equipped with a Macherey-Nagel normal phase Nucleosil 50–7 column (250 $\times$ 4 mm) for LC separation; a Finnigan LCQ with APCI interface was used for detection. High-resolution gas chromatography–mass spectrometry GC-HR-MS was performed on a Micromass MasSpec double-focusing magnetic sector mass spectrometer (geometry EBE) connected to a Hewlett Packard HP6890 II gas chromatograph, equipped with a DB-5 (J&W Scientific) capillary column (30 m $\times$ 0.25 mm, 0.25 μm).

Algal Collection and Cultivation. Samples of 1 kg of the three studied species were collected in the south of France during mid- to late summer when the three species exhibit their maximum growth and biomass. Since it is not possible to

collect the three species from one sampling site, care was taken to select all species from calm water. *C. taxifolia* was collected at Villefranche-sur-Mer (France) in July 2000, at a depth of 5 m. *C. prolifera* was collected at Cap d'Antibes (France) in October 2001, at 1 m, and *C. racemosa* was obtained from Villefranche-sur-Mer also in October 2001 at a depth of 15 m. All algae were transferred to aerated aquaria with 10–30 liters of artificial seawater (Instant Ocean, Aquarium Systems, Mentor, Ohio, USA) for preequilibration before extraction. The aquaria were illuminated with a 14L:10D photoregime and kept at $24 \pm 2^{\circ}$C. Half the water was exchanged monthly. Only intact individuals with a weight of 1–3 g that did not show any sign of mechanical damage or bleaching were randomly selected for extraction.

Extraction and Quantification of Caulerpenyne. For the determination of the caulerpenyne content in intact tissue, enzymatic degradation was prevented by freezing 3 g of the algae (fronds and stolons) with excess liquid nitrogen. The cold material was ground to a powder and treated with 3 ml ethyl acetate containing 1 mg/ml 4-methoxyacetophenone (Amade and Lemée, 1998) as an internal standard. During warm-up to 0°C, grinding was continued and the cold mixture was centrifuged 5 min at 15,000*g* for phase separation. The organic phase (20 μl) was used directly for quantification with normal-phase (NP)-HPLC-MS [diode array detector (DAD), detection wavelength 252 nm]. HPLC gradient was: hexane–ethyl acetate; 1 ml/min: 0%, 12 min 25%, 18 min 35%, 18 min 0%, 25 min 0% ethyl acetate. Reextraction of the algal residues with 2×3 ml of ethyl acetate showed an extraction efficacy of $>95\%$ caulerpenyne in the first step. For comparison, other extraction methods were tested on the frozen algal powder. One method used 3 ml of methanol containing 1 mg/ml 4-methoxyacetophenone instead of ethyl acetate as solvent. 20 μl of the alcoholic solution were analyzed directly with NP-HPLC-MS. Repeated extractions ($3\times$) showed poor and unreliable extraction efficacy for the first extraction step (78–91%). The other method tested the extraction protocol of Bligh and Dyer (1959) using a ternary mixture of water, chloroform, and methanol as solvent. To 3 g ground algal material obtained after freezing with liquid nitrogen, 1.25 ml chloroform and 2.5 ml methanol containing 3 mg 4-methoxyacetophenone were added and shaken for 2 min. For phase separation, 1.25 ml water and 1.25 ml chloroform were added. After centrifugation, 20 μl of the organic phase were applied to NP-HPLC-MS. While the extraction efficacy was around 95%, the caulerpenyne purification was complicated by elevated amounts of extracted lipids.

Purity of the caulerpenyne signal was monitored by using DAD and MS detection (APCI). For quantification, a linear calibration curve obtained with purified (column chromatography with SiO_2 and Florisil) caulerpenyne was used. The response was linear from 0.1 to 10 μg caulerpenyne ($P < 0.001$, $R = 0.99$, $N = 3$).

Transformation Experiments. For measurements at $t = 0$, the algal material was shock-frozen with liquid nitrogen before extraction as described above. Injury

was simulated by manually grinding 2–3 g of the algae for 30 sec to homogeneity. The homogenate was shock-frozen after defined intervals to prevent further enzymatic degradation and was then extracted with ethyl acetate (1 ml/g algal fresh weight) containing the internal standard. LC quantification was performed as described above. For the relative quantification of oxytoxin 2 (**9**), the APCI MS ion at $m/z = 231$ (Jung and Pohnert, 2001) was monitored and compared to the same ion of caulerpenyne. The identity of oxytoxin 2 (**9**) in the fresh extracts of wounded algae was verified by GC-HR-MS: 230.1305; calculated: 230.1307 [$C_{15}H_{18}O_2$]; EI-MS (70eV; m/z (%): 230(100), 215(42), 201(15), 187(59), 159(45), 143(15), 131(17), 115(14).

Derivatization of Crude Algal Extracts. Trapping experiments using 4 g algal material and 1 ml of a saturated ethanolic 2,4-dinitrophenylhydrazine (DNPH) solution were performed as described previously (Jung and Pohnert, 2001).

Enzymatic Transformation of Model Substrates. 5 g of the algae were carefully ground with 20 mg of geranyl acetate in 5 ml seawater. After defined time spans, 500 μl samples were taken and extracted with 100 μl dichlormethane. GC-MS was used for the identification and quantification of geraniol and geranyl acetate, respectively.

RESULTS

Caulerpenyne Content in Intact Algae. We compared the caulerpenyne content in the three *Caulerpa* species selected. These were frozen with liquid nitrogen before extraction to prevent enzymatic caulerpenyne degradation (Figure 2). While *C. taxifolia* and *C. prolifera* contain almost the same amount of caulerpenyne,

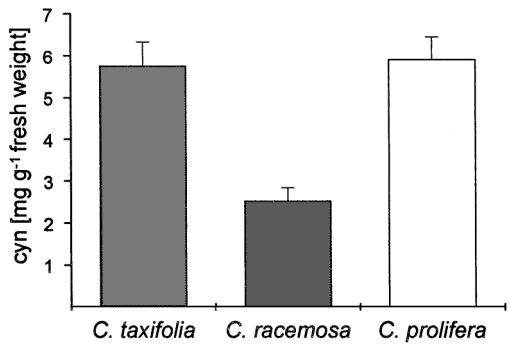

FIG. 2. Mean values ($\pm$ SE; $N = 3$) of caulerpenyne (cyn) per gram of algal fresh weight in intact tissue of three different *Caulerpa* spp.; intact algal material was shock-frozen, ground, and extracted with 1 ml/g alga ethyl acetate containing 1 mg/ml 4-methoxyacetophenone as internal standard.

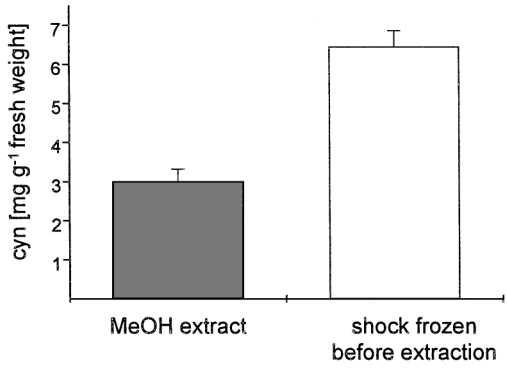

FIG. 3. Determination of caulerpenyne (cyn) content in *C. taxifolia* grown in one aquarium following two different extraction protocols. An established method (Amade and Lemée, 1998) that involves overlaying of the algae with methanol and freezing the set-up overnight is compared with the protocol introduced here. Extracting algae that have been shock-frozen prior to grinding with ethyl acetate increases the determined amount twofold. Mean values ($\pm$ SE; $N = 10$) of caulerpenyne are given per gram of algal fresh weight.

6 mg/g of algal fresh weight, the caulerpenyne content in *C. racemosa* was only half this value.

Caulerpenyne from *C. taxifolia* was quantified with two different extraction methods using algae that were equilibrated in one aquarium for 10 months (Figure 3). Following the protocol of Amade and Lemée (1998) involving the transfer of rinsed algae into methanol (10 ml methanol per gram wet alga), which was then frozen overnight, an overall content of 3 ± 0.31 mg caulerpenyne per gram algal fresh weight was determined. Freezing the algae with liquid nitrogen prior to grinding and extraction with ethyl acetate led to an overall content of 6.44 ± 0.41 mg caulerpenyne per gram algal fresh weight, which was twice the amount found with the former method. Comparable amounts of caulerpenyne were also found after extraction of the shock-frozen algae with a solvent mixture according to Bligh and Dyer (1959). In contrast, extraction of the frozen material with methanol led to an underestimation of caulerpenyne in the intact tissue.

Caulerpenyne Transformation by Wounded Algae. Wounding was simulated by manually grinding the algae to homogeneity, and the reaction was stopped by shock-freezing the wounded tissue with liquid nitrogen after certain intervals before extraction. The wound-activated caulerpenyne degradation in the three *Caulerpa* species was compared (Figure 4). In all three species, the caulerpenyne content was significantly reduced within 1 min after wounding. Differences occurred in the initial caulerpenyne content and the speed of degradation in the first minutes. A reduction to 50% of the amount of caulerpenyne after 1 min was found in

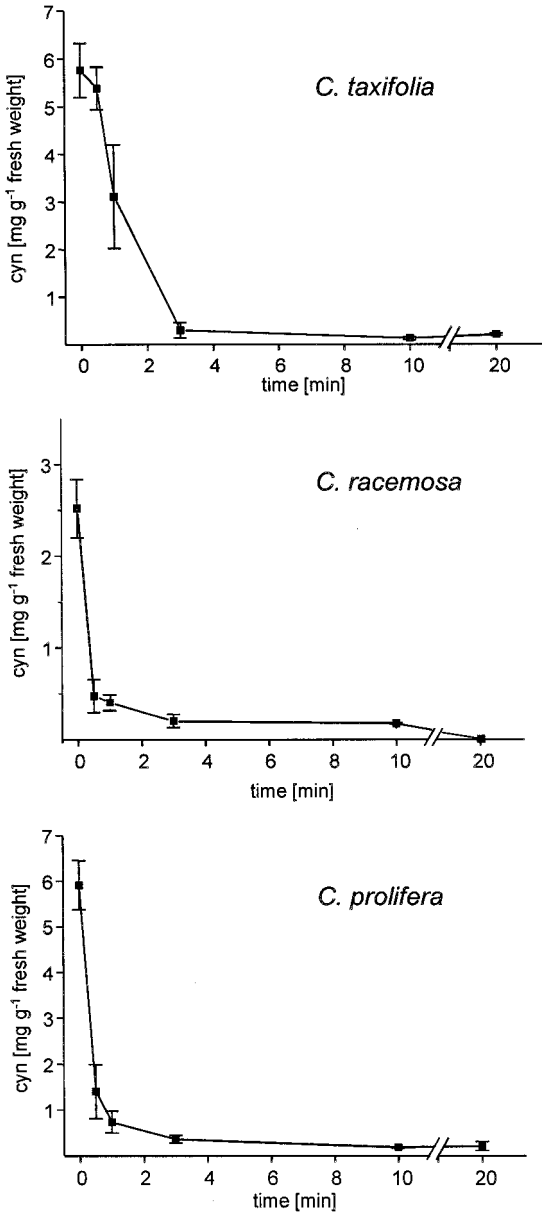

FIG. 4. Wound-activated caulerpenyne (cyn) degradation in three different *Caulerpa* spp.; the dots indicate mean values (± SE; $N = 3$) of caulerpenyne content per gram of algal fresh weight in wounded algae shock-frozen after defined intervals and extracted with ethyl acetate.

C. taxifolia. Although the initial caulerpenyne content found in intact *C. racemosa* (Figure 4) is only half of that in intact *C. taxifolia*, the ratio of caulerpenyne being transformed within the first minute after wounding is comparable. In *C. prolifera*, the most pronounced wound-activated transformation was observed. One minute after wounding, the caulerpenyne content in *C. prolifera* was reduced to 11% of the initial value. A problem that arose during these experiments concerned the polymerization of wounded algal material. In coenocytic green algae, the formation of a wound plug, which prevents loss of protoplasm after wounding, is essential to the survival of these plants (Dreher et al., 1982). This polymer formation occurs after disruption of the cell wall, so that 20 min after wounding further extraction of caulerpenyne and caulerpenyne derived products was hindered.

The ratio of the end product (oxytoxin 2) to the starting product (caulerpenyne) determined in HPLC-MS measurements exhibits a dynamic course. In the first 3 min, the relative amount of oxytoxin 2 (**9**) increases, but after 3 min, when caulerpenyne degradation slows, a decrease of this compound is detectable. It is likely that the reactive 1,4-dialdehyde oxytoxin 2 (**9**) undergoes further reaction with, for example, nucleophiles from the wounded algal tissue. The identity of oxytoxin 2 (**9**) was verified directly after shock-freezing and extracting wounded algal tissue of *C. prolifera* by HR-MS.

Trapping of Reactive Aldehydes. The detection and identification of aldehydes resulting from the wound-activated transformation of caulerpenyne was difficult because of their reactivity and instability. While the amount of oxytoxin 2 (**9**) as the end product shows a transient character, the detection of the intermediates **2–8** is only possible after trapping, followed by concentration. If 2,4-dinitrophenylhydrazine (DNPH) is used as a trapping reagent, the labile intermediate aldehydes react with the reagent to form stable hydrazones that can be concentrated and be submitted to HPLC-UV and HPLC-MS analysis (Jung and Pohnert, 2001). Trapping experiments with DNPH on wounded *C. prolifera* resulted in the detection of a complex series of closely related hydrazones, bearing one or two derivatized aldehydic groups. Their characteristic fragmentation patterns, molecular ions, chromatographic behavior as well as the comparison with hydrazones derived from wounded *C. taxifolia*, were in agreement with derivatives of **3–8** and **9** after elimination of water (Jung and Pohnert, 2001). The stepwise cleavage of acetyl residues and the rapid activation after disruption of cell compartmentation suggests the involvement of an enzymatic mechanism.

Esterase Activity in Wounded Algae. The action of an enzymatic esterase mechanism was verified by using model substrates. The sesquiterpene farnesyl acetate and, to challenge substrate specificity, the monoterpene geranyl acetate were applied to wounded algal tissue. Indeed, esterases transformed these acetates into their corresponding alcohols. GC-MS analysis allowed monitoring of the formation of the deacetylated alcohols farnesol and geraniol. This mechanism, previously shown to be active in *C. taxifolia* (Jung and Pohnert, 2001), is also found

in *C. prolifera* and *C. racemosa* after wounding. Amounts of up to 4 mg acetate per gram algal fresh weight were transformed into the corresponding alcohols within 1 hr by all three *Caulerpa* spp. Again, as with the wound-activated transformation of caulerpenyne itself, *C. prolifera* proved to be the most efficient alga in the transformation of the model substrate.

DISCUSSION

We recently reported that the invasive alga *C. taxifolia* transforms its major secondary metabolite, the sesquiterpene caulerpenyne, into highly reactive aldehydes (Jung and Pohnert, 2001). The current study was undertaken to determine if this wound-activated cleavage of acetyl moieties from caulerpenyne (Figure 1) is restricted to the invasive *C. taxifolia*, or if it is a more general feature of invasive and noninvasive *Caulerpa* spp. As shown with trapping experiments and the kinetic analysis (Figure 4), all three species investigated react to wounding with rapid transformation of caulerpenyne into a mixture of reactive and partly unstable aldehydes.

The rapid spread of *C. taxifolia* since its introduction into the Mediterranean (Meinesz et al., 2001), as well as after its first detection in California (Kaiser, 2000), has been attributed to factors such as fast growth and high temperature and substrate tolerance, as well as to an efficient chemical defense (Bellan-Santini et al., 1996). The results presented here show that the caulerpenyne content is comparable in the invasive *C. taxifolia* and the noninvasive *C. prolifera*, but is lower in the invasive *C. racemosa* (Figure 2). The caulerpenyne content of this variety of the latter species was investigated for the first time. The values given here have to be interpreted carefully, since earlier studies (Amade and Lemée, 1998) indicated that the caulerpenyne content in *C. taxifolia* can vary depending on season and depth. A variation in caulerpenyne content was also found in different plant parts (Amade and Lemée, 1998; Meyer and Paul, 1992). For comparison, in this study we collected all algae from calm water and extracted whole plants after preequilibration in aquaria. A careful season-dependent reinvestigation of different *Caulerpa* spp. in selected locations using the new quantification method introduced here will be required for a detailed survey.

The results, however suggest that the difference in the overall caulerpenyne content in intact tissue is not substantially higher in invasive species. The ability to transform this metabolite, after tissue disruption, into reactive aldehydes occurs in the invasive *C. taxifolia* as well as in the noninvasive Mediterranean *C. prolifera*. This noninvasive species transforms caulerpenyne even faster than *C. taxifolia* (Figure 4). In addition, LC-MS characterization and trapping experiments of the transformation products show a similar product spectrum in both algae. *C. racemosa* also exhibits activated transformation of caulerpenyne but contains

a lower overall content of this metabolite compared to either of the investigated species (Figure 2). All these results suggest that the ability of an enzymatic caulerpenyne transformation to reactive aldehydes is not the major factor determining the invasive potential of Caulerpales.

Wound-activated transformation of caulerpenyne consists of the subsequent cleavage of the three acetyl groups present in the molecule. Previous findings using geranyl and farnesyl acetate as model substrates indicate that after wounding, esterases from *C. taxifolia* can cleave these groups with remarkable efficacy (Jung and Pohnert, 2001). While transformation of the model substrates leads to geraniol and farnesol, respectively, the bis-enol acetate moiety of caulerpenyne is cleaved into enols that immediately tautomerize to their corresponding aldehydes. Trapping experiments with DNPH, as well as the LC-MS investigations performed in this study, show that in both *C. taxifolia* and *C. prolifera*, intermediates towards **9** (Figure 1) are detectable. Thus, in both algae, and most likely also in *C. racemosa* that degrades caulerpenyne with similar kinetics, a stepwise transformation of caulerpenyne is observed. The similarity of transformation mechanisms is further supported by the fact that all three algae accept geranyl acetate as a substrate. The kinetic experiments (Figure 4) are in accordance with the observation that the transformation of geranyl acetate is more efficient in *C. prolifera* compared to the other investigated species. Our experiments show that the end product, after cleavage of all three acetyl functions and elimination of water, oxytoxin 2 (**9**) does not accumulate in the wounded algal tissue. Oxytoxin 2 (**9**) can be detected by LC–MS and GC-MS when freshly wounded algae are extracted, and its relative amount compared to caulerpenyne in the algal tissue reaches a maximum 2–3 min after wounding. If not continuously produced, the amount decreases rapidly, presumably by adduct formation and copolymerization. The inherent instability of oxytoxin 2 (**9**) is the likely reason that this molecule was not detected in the numerous previous studies on the secondary metabolites of *Caulerpa* spp. In contrast, the more stable intermediate oxytoxin 1 (**4**) was reported in a detailed analysis of minor metabolites from *C. taxifolia* (Guerriero et al., 1992). Remarkably, the aldehydes oxytoxin 1 (**4**) and oxytoxin 2 (**9**) have been detected previously in the secretion and mucus of sacoglossan herbivores that live in close association with *C. prolifera* (Cimino et al., 1990; Gavagnin et al., 1994). Despite the instability of oxytoxin 2 (**9**), which could not be purified by chromatography, these mollusks are able to accumulate the deacetylated aldehydes in their tissue (Cimino et al., 1990). Whether the mollusks rely on esterases from *Caulerpa* spp. for the transformation of caulerpenyne or utilize their own enzymes will need to be explored.

In algae of the family Caulerpaceae and Udoteaceae, terpenoid metabolites with bis-enol acetate structures are widespread, and several aldehydic analogs that can formally arise from the transformation of these acetylated precursors have been detected (Paul and Fenical, 1987). The first observed example of an activated chemical defense in the marine environment was reported from *Halimeda*

spp. (Udoteaceae), which transforms the bis-enol acetate halimedatetraacetate, presumably via deacetylation, to the more active halimedatrial (Paul and Van Alstyne, 1992). In this case, the unique structure of the postulated intermediate 1, 4-dialdehyde allows an intramolecular enzyme-assisted cyclization to the more stable halimedatrial (Paul and Van Alstyne, 1992). In the light of these studies and our results, a more detailed investigation of the biotransformation of the bis-enol acetates by these green algae is required for a full understanding of wound-activated transformation of their secondary metabolites.

Indirect evidence for the wider distribution of a wound-activated transformation of secondary metabolites was recently given by Cetrulo and Hay (2000), who submitted the extracts of 40 seaweeds to a TLC comparison of the metabolic profile before and after wounding. In both tested *Caulerpa* species (*C. mexicana* and *C. prolifera*), they observed the degradation of a not-further-characterized metabolite 30 sec after wounding. Nevertheless, they did not find any activated chemical defense in experiments where extracts of the wounded algal tissue were coated onto a palatable seagrass. In the light of our findings, these bioassays might not encompass a wound-activated defense due to the instability of the caulerpenyne-derived aldehydes that could degrade during the food impregnation or the assay period. In a comprehensive study of the chemical defense of tropical Caulerpales, Paul and Fenical (1986) tested a multitude of bis-enol acetates and corresponding aldehydes from algal extracts. They observed that, in general, compounds possessing one or more aldehyde functional groups tend to have higher biological activities in antimicrobial-, fish feeding-, sea urchin egg cleavage assays and toxicity tests on larval and adult stages of potential herbivores. These results indicate that it is likely for caulerpenyne deacetylation products shown in Figure 1 to exhibit increased effects against herbivores and pathogens compared to caulerpenyne. Due to the observed instability of the aldehydes, a careful experimental protocol for bioassays will be required, as some of the standard methods that involve incorporation of extracts or secondary metabolites in an artificial diet are not sufficient.

These bioassays, as well as the activity assays of caulerpenyne itself, have to take into account that the total caulerpenyne content in previous studies may have been significantly underestimated. Since transformation of more than 50% of the initial caulerpenyne content was observed in all species investigated within only 1 min after tissue disruption (Figure 4), even in standard solvent extraction procedures caulerpenyne transformation cannot be excluded. Our improved method involves shock-freezing of the intact algal tissue with liquid nitrogen before extraction. Ethyl acetate extracts more than 95% of the caulerpenyne from the frozen algal powder in one step with high reproducibility and allows fast and direct GC and LC analysis not only of caulerpenyne but also of its transformation products. Thus, this solvent proved superior compared to methanol or the solvent mixture of Bligh and Dyer (1959), where poor extraction success was observed and the work-up procedure did not allow the detection of labile caulerpenyne derived

aldehydes. Using the liquid nitrogen ethyl acetate procedure, an underestimation of caulerpenyne in the intact algae due to enzymatic transformations is prevented, and compared to a standard methanolic extraction procedure (Amade and Lemée, 1998), we recovered about twice as much caulerpenyne from *C. taxifolia* (Figure 3).

In summary, we provide the basis for a detailed reexamination of the defensive chemistry of *Caulerpa* species that has to take into account the dynamic effects observed after wounding of the tissue, resulting in reactive transformation products of caulerpenyne.

Acknowledgments—We thank Prof. Dr. W. Boland for support during the preparation of this work. We also thank Dr. Andy Jarvis, Ryan Lauchli, and Dieter Spiteller for helpful comments. Janine Rattke is acknowledged for HR-MS measurements. The Deutsche Forschungs-gemeinschaft is acknowledged for financial support.

(Received February 1, 2002; accepted May 31, 2002)

Abstract—The role of olfaction and diffusible pheromones in mate location behavior of sea lice, *Lepeophtheirus salmonis*, was assessed with Y-tube behavioral bioassays. The pheromone "emitting" animals were located in a chamber in one arm of a Y-tube arena, with artificial seawater flowing through both arms. Adult male sea lice displayed both activation and directional responses to seawater conditioned with preadult II virgin females, but were only activated by mated adult female conditioned water. Further, when males were given the choice of preadult II virgin females or mated adult females, a significant number of males chose the arm with the preadult II virgin females. Adult males showed activation responses when presented with water conditioned with adult males but were not attracted to them. When presented with adult males, preadult II virgin females showed only directional responses, but not activation responses. Preadult II virgin female conditioned water was extracted using solid-phase extraction (SPE) protocols pioneered for semiochemical isolation. Adult male sea lice showed significant directional responses to the preadult II virgin female SPE extract. Distillation under vacuum was performed on the extract to give a distillate comprising components with a molecular weight range and physical properties comparable to those of compounds utilized as volatile semiochemicals by terrestrial organisms and a residue comprising components with higher molecular weight range comparable to those utilized as involatile semiochemicals. Adult males were found to be both significantly activated and attracted to

the distillate, but not to the residue. This research provides evidence that small, lipophilic organic molecules are used by sea lice as sex pheromone signals to locate a member of the opposite sex.

Key Words—Copepoda, sea lice, salmon, behavior, mate location, mate recognition, chemoreception, chemical ecology, semiochemicals, chemotaxis.

INTRODUCTION

Sea lice, *Lepeophtheirus salmonis*, (Copepoda: Caligidae) are ectoparasites on wild and farmed salmonids, with Atlantic salmon (*Salmo salar* L.) as their main host. Sea lice have a huge financial impact on the salmon farming industry due to the damage they inflict. The industry is largely dependent on the use of veterinary medicines for their control. Environmental concerns and the development of resistance both highlight the need for alternative approaches to sea louse control and for the development of integrated pest management strategies. The use of semiochemicals is one such approach being explored.

After the identification of the first moth sex pheromone, it was suggested that synthetic pheromones could act as efficient communication disruptants and would have high potential as components of integrated pest management (Wright, 1965; Howse et al., 1996; Pickett et al., 1997). Mating communication has been characterized in many insects, and semiochemicals have been used successfully in pest control, in particular the sex pheromones of Lepidoptera and aggregation pheromones of Coleoptera (Howse et al., 1996; Pickett et al., 1997). In aquaculture, studies of sea louse chemical ecology, particularly pheromones and other semiochemicals that influence louse behavior, could provide alternative pest control methods to the use of veterinary medicines.

In contrast to other reproductive features, little is known on the role of chemical cues in mating in copepods, although their significance has been recognized for more than 30 years. Existing evidence suggests that chemical communication in the Copepoda is as complex as described for terrestrial insects. Chemical cues often mediate courtship and mating in aquatic organisms (Katona, 1973; Miller, 1989; Zimmer-Faust, 1991; Ritchie et al., 1996; Doall et al., 1998; Frey et al., 1998; Hull et al., 1998; Kelly et al., 1998; Strickler, 1998; Tsuda and Miller, 1998; Weissburg et al., 1998; Yen et al., 1998), and generally females produce pheromones that attract males and affect their behavior. However, no molecules have been characterized that definitely function as sex pheromones in aquatic organisms. Furthermore, the transmission and reception signals used are not known in any aquatic animal (Snell and Nacionales, 1990; Snell and Morris, 1993).

Semiochemicals form important alternatives to pesticide control by luring, trapping, and disrupting the behavior of insects (Vale et al., 1988; Howse et al., 1996). Kairomones and allomones, i.e., host odor cues or host-masking chemicals,

attract/repel different species respectively, and sex/aggregation pheromones attract the same species (Brown et al., 1970; Law and Regnier, 1971; Blum, 1996). In both marine and terrestrial systems, nonvolatile, hydrophilic semiochemicals detected by contact or gustatory neurophysiological mechanisms are involved in recognition of mates, hosts, or other food sources, and the expectation might be that these would account for the majority of marine interactions. However, processes involving low-molecular-weight lipophilic semiochemicals also exist in marine as well as in terrestrial systems, and in some cases can predominate (Pohnert and Boland, 1997; Ingvarsdóttir et al., 2002). Such compounds possess sufficient solubility for transport in an aqueous medium, which is analogous to transport by means of volatility in air for the terrestrial systems.

The objective of this study was to investigate the role of semiochemicals in sea louse mate recognition and to test the hypothesis that small, lipophilic organic molecules are involved, with physical properties similar to those mediating host location by sea lice (Ingvarsdóttir et al., 2002) and in the chemical ecology of terrestrial organisms. Such pheromones would have potential in integrated sea louse management strategies, for example, in the development of effective traps for sea louse monitoring and control. This would reduce the input of veterinary medicines in aquaculture and provide control programs with intrinsically low environmental impact.

METHODS AND MATERIALS

Sea Lice. Late developmental stages of sea lice (*Lepeophtheirus salmonis*), i.e., adult males (AM), adult females (AF), and preadult II virgin females (PF), were collected from salmon farms on the west coast of Scotland. The lice were kept in fresh seawater from the collection site, on ice, during transport to the University of Aberdeen aquarium. The lice were maintained separately as males and females in the absence of hosts in 25-liter tanks at Aberdeen University at 12°C in artificial aerated seawater of 32‰ salinity and were used from 12 hr to 7 days after collection. Lice normally were observed to show less activity and higher mortality rates after more than 7 days off fish, and healthy batches did not show significant changes in behavioral bioassays within the 7 days after collection (Ingvarsdóttir unpublished).

Y-Tube Assays. A Y-tube arena was situated on top of a light box, and a camera mounted above the arena and linked to a VCR traced the behavior of the lice in the arena. The movements of the lice were recorded on videotape. Y-tube bioassays allowed the sea lice to exhibit a preference for different stimuli compared with seawater controls and also allowed measurement of their activation responses to different stimuli (Ingvarsdóttir et al., 2002). The glass Y tubes had a 16-mm-diam. bore. The arms were 14 cm and the main leg 15.5 cm long (Figure 1). Water flowed through each arm from a reservoir at 30 ml/min. Inlets and outlets of the Y tube

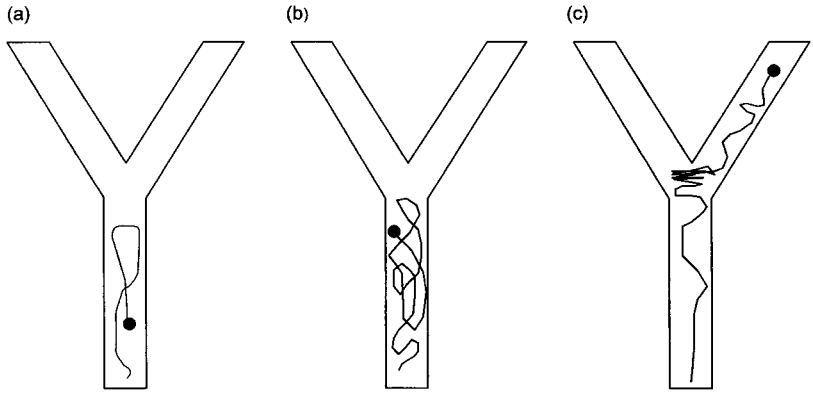

FIG. 1. Diagrammatic representations of Y-tube arena and typical louse activity patterns taken from videotape for activation and taxis behavior of adult male sea lice. Activation was recorded as (a) low activity with distance moved less than twice the length of the base of the Y-tube and (b,c) high activity categories, with distance moved more than twice the length of the base of the Y-tube or choice of arm made. Taxis was recorded as the number of lice entering the odor arm vs the number of lice entering the control arm (redrawn from Ingvarsdóttir et al., 2002).

were made of glass pipets fixed into plastic tops. The tops fitted over the openings on the arms and leg to make watertight seals. There was a clear demarcation of the flow down each arm, and a mixing of the water from each arm in the main leg of the apparatus was demonstrated with food dyes. In double control runs, artificial seawater was introduced into both arms of the Y tube.

The Y-tube experiments were set up in two different ways. Either six individuals of a specific sex and developmental stage (PF, AF, or AM) were placed in a chamber in one arm of the Y-tube and an empty chamber placed in the other arm, with seawater flowing through the chambers in both arms, or previously collected louse-conditioned water (see below) was introduced into one arm while seawater alone was introduced into the other arm prior to introduction of a sea louse. The arm containing the stimulus source was changed regularly, with washing in between, to ensure that there was no positional bias. The chamber restraining the animals to one arm of the Y tube was made up of two pieces of 1-cm Perspex tube inserted into the top of the arm with 200-μm nylon mesh dividing the first chamber from the arm, and another piece of 200-μm mesh between the tubes to keep the animals within the chamber, ensuring water flow over the animals. A single sea louse was introduced into the base of the main leg of the Y tube and allowed 10 mins to respond, typically by moving up the main leg and into one of the arms. Using the Y-tube assay, both overall activity and directional responses were measured in adult male sea lice and preadult II virgin females. Sea louse activation was defined by the degree of movement within the Y tube. Behavior was divided

into two categories, low (Figure 1a) and high (Figure 1b,c) activity (Ingvarsdóttir et al., 2002). Frequencies of intermediate categories between Figure 1a and 1b were low but were defined as less (low) or more (high) than twice the length of the leg of the Y tube. Movement into either arm, regardless of stimulus, was included in the high activity level (Figure 1c). For overall activity levels, the numbers of individuals in low and high activity categories in the presence of different stimuli were compared to those observed with seawater alone. Directional responses (taxis) were measured by the movement of the louse up the main leg and into one of the arms. The number of individuals choosing the stimulus arm instead of the control arm within the 10 min test period were compared with those of seawater controls in both arms. Statistical differences were assessed by χ^2 analysis.

Sea Louse Conditioned Water. Seawater conditioned with preadult II virgin female (PF), adult mated female (AF), and adult male (AM) was prepared by placing six individuals of a specific developmental stage and sex into chambers (as described above) at the top of both arms of a Y tube. Seawater from a reservoir flowed through the chambers at 30 ml/min and was collected in a glass beaker from the outlet of the Y tube. Seawater running through empty chambers divided by mesh was used as a control. Extracts reconstituted for behavioral bioassays were made up to the original concentration with artificial seawater.

Solid-Phase Extraction and Vacuum Distillation. A portable closed solid-phase extraction (SPE) system was used for extracting potential semiochemicals from PF conditioned water (5.17 liters). Artificial seawater (5.0 l) was used as control. The SPE columns [International Sorbent Technology (IST) Limited, Hengoed, Glamorgan, UK] consisted of 6-ml glass cartridges containing layered phases [C_2 (500 mg) over ENV+ (200 mg)]. The extractions were performed using a VacMaster-10 SPE manifold (IST). The SPE cartridges were conditioned prior to extraction with 2 ml HPLC grade methanol, followed by displacement with distilled water (2 ml). Following completion of extraction, interference analytes remaining on the cartridges were removed with distilled water (2 ml). The contents of the cartridges were then extracted with distilled ethanol (2 ml). SPE extracts were separated into two fractions by distillation under vacuum (0.04 torr) for 24 hr at 25°C as described previously (Pickett and Griffiths, 1980). The vacuum distillate comprised components with a molecular weight range comparable to those utilized as volatile semiochemicals by terrestrial organisms, while the residue arising from the vacuum distillation comprised components with insufficient or no volatility. For bioassays, the fractions were redissolved in ethanol and made up to the original extraction volume by adding artificial seawater.

RESULTS

Activation Responses of Sea Lice to Mating Stimuli in Y-Tube Experiments. The activation responses of adult male (AM) and preadult II virgin female (PF)

TABLE 1. ACTIVATION RESPONSE OF SEA LICE TO MATING STIMULI IN Y-TUBE ARENA

Test animal[a]	Odor source	Activity		*N*	*P*
		Low[b] (%)	High[c] (%)		
AM	Seawater control	60.2	39.8	83	
AM	PF conditioned water	25.5	74.5	47	<0.001
AM	PF SPE extract	39.4	60.6	33	<0.05
AM	PF SPE extract: vacuum distillate	29.4	70.6	17	<0.05
AM	PF SPE extract: distillation residue	65.0	35.0	20	NS
AM	AF	40.0	60.0	45	<0.05
AM	PF and AF (in separate arms)	13.3	86.7	30	<0.001
AM	AM	41.7	58.3	48	<0.05
PF	Seawater control	63.3	36.7	30	
PF	AM	58.3	41.7	36	NS

[b] Defined as category a in Figure 1.
[c] Defined as categories b and c in Figure 1.

sea lice in the Y-tube bioassay to stimuli derived from the same or different sexes and developmental stages are shown in Table 1. Sixty percent of the AM and PF showed low activity when clean artificial seawater was presented in both arms of the Y tube. In the presence of PF conditioned water, a highly significant increase in adult male activity was observed ($P < 0.001$). Similar results were obtained for PF SPE extract of the conditioned water ($P < 0.05$), and when fractions of the PF extract prepared by vacuum distillation were tested, a significant increase in activity was found only with the vacuum distillate, i.e., the low-molecular-weight fraction ($P < 0.05$). The AM showed increased activity in response to both adult mated females (AF) ($P < 0.05$), and the combined stimulus of AF and PF ($P < 0.001$) presented in separate arms of the Y tube. Further, AM were found to demonstrate a significant activation response in the presence of other males ($P < 0.05$). However, there was no increase in activity, in comparison to seawater controls, for PF to AM.

Directional Responses (Upstream Positive Rheotaxis) of Sea Lice to Mating Stimuli in Y-Tube Experiments. In seawater controls, sea lice showed no particular preference for either arm (Figures 2 and 3). Attraction of AM to PF was clearly demonstrated in the Y-tube experiments (Figure 2). The PF, PF SPE extract, and the PF vacuum distillate of the SPE extract increased the number of AM lice moving to the stimuli, compared to the control arm ($P < 0.001$, <0.05 and <0.05, respectively) (Figure 2). No attraction of AM to the residue arising from the vacuum distillation of the PF SPE extract was observed (Figure 2). Very few males responded directionally to the vacuum distillation residue of the PF extract, and it was not possible to perform χ^2 analysis on the results due to the low numbers. The AM were activated by both AF and AM but did not show significant directional

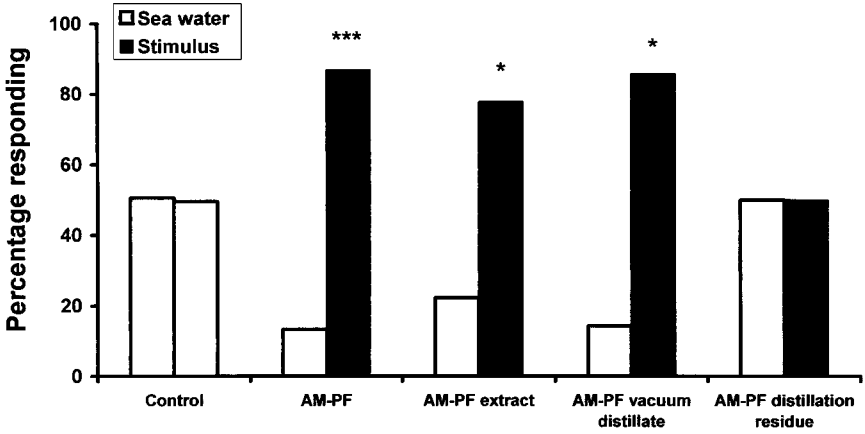

FIG. 2. Taxis response of adult male (AM) sea lice to preadult II virgin female (PF) -derived stimuli in a Y-tube arena. Seawater control, $N = 93$; PF conditioned water, $N = 68$; PF extract, $N = 18$; PF vacuum distillate, $N = 14$; PF distillation residue, $N = 4$; $^{*}P < 0.05$; $^{***}P < 0.001$ (χ^2 analysis). χ^2 analysis was not performed on the results for the PF distillation residue, as numbers were low due to very low activation to the stimulus (see Table 1).

responses to either of these (Table 1, Figure 3). In a competitive assay, in which males were presented with PF or AF in separate arms of the Y tube, there was a significant response to PF ($P < 0.05$) (Figure 3). Although the PF did not show an overall significant increase in activity in response to AM (Table 1), there was an attraction to the males with all 11 of the PF that showed "high activity" levels choosing the treatment arm ($P < 0.01$) (Figure 3).

DISCUSSION

Chemical communication is important in the mating process of many copepods. It is believed that contact chemoreception aids the males of copepods and harpacticoids in distinguishing female developmental stage (Ritchie et al., 1996; Hull et al., 1998; Kelly et al., 1998). Sea lice, *L. salmonis*, use chemoreception to detect a potential host (Devine et al., 2000; Ingvarsdóttir et al., 2002). In this study, they have been shown to be capable of detecting potential mates by the same means. From these findings, it can be concluded that adult *L. salmonis* use both distant and close-range chemical cues to locate a mate. Experimental work on the mate-finding behavior in the Copepoda has mainly concentrated on 3D tracking of individuals (adult males and unmated females) and observations on mate guarding (Katona, 1973; Griffiths and Frost, 1976; Lonsdale et al., 1988, 1998; Maier, 1995; Anstensrud, 1992; Strickler. 1998; Tsuda and Miller, 1998; Doall et al., 1998; Frey

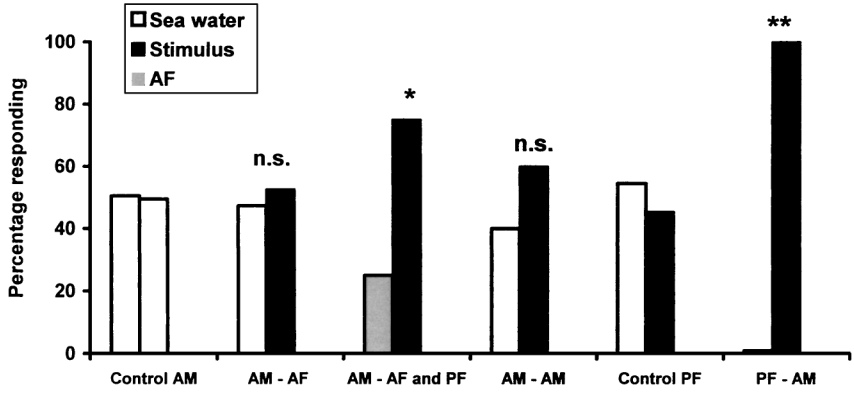

FIG. 3. Taxis response of adult male sea lice (AM) to adult mated females (AF), AF in one arm and preadult II females (PF) in the other, AM, and responses of PF to AM. et al., 1998; Hull et al., 1998; Kelly et al., 1998; Lonsdale et al., 1998; Weissburg et al., 1998). In this study, activation of individuals and directional responses of sea lice to other individuals were recorded. Upstream positive rheotaxis of adult male lice to preadult II virgin females was established. Several different species of Copepoda have been found to follow host- and mate-related semiochemical trails, and species-specific mate recognition systems have been found for several species (Blades and Youngbluth, 1980; Frey et al., 1998; Lonsdale et al., 1998; Devine et al., 2000; Ingvarsdóttir et al., 2002 and unpublished). To further support the trail following of the different species of Copepoda, Yen et al. (1998) showed that the low Reynolds number regime of zooplankton conserves distinct species-specific cues affecting their behavior, and where viscosity limits forces to the molecular scale, trails of diffusible odor persist. Further, Dusenbery and Snell (1995) suggested that efficient use of diffusible pheromones was related to the size of the organism and showed that copepods are above the minimum size for diffusible pheromones that markedly improve mate location probabilities.

The presence of females alters male behavior of the harpacticoid *Tigriopus japonicus* (Kelly et al., 1998). The adult males showed a preference only for conspecific virgin females as partners. This supports the findings of Hull (1997), Ritchie et al. (1996) and Hull et al. (1998) on mate guarding in *L. salmonis*. In our study, male sea lice were activated by the presence of different developmental stages, preadult II virgin females, adult mated females, and other males. However, males of *L. salmonis* could distinguish between adult mated female stimuli and preadult II virgin female stimuli, with over 75% of the males choosing the virgin females. The males were also directionally attracted to preadult II virgin female

SPE extract and the vacuum distillate of the extract but not to adult mated females or to adult males. The vacuum distillate comprised components with a molecular weight range comparable to those of compounds utilized as volatile semiochemicals by terrestrial organisms, while the residue arising from the vacuum distillation comprised components with little or no volatility. Attraction of the males to only the vacuum distillate supports our initial hypothesis that sea lice would use low-molecular-weight diffusible pheromones for mate location and is also in agreement with other postulations on the molecular size of the components of copepod sex pheromones (Lonsdale et al., 1998). Production of a diffusible pheromone by virgin females may cease immediately upon mating (Lonsdale et al., 1998; Kelly et al., 1998), which also is in agreement with our study, as males were not directionally attracted to adult mated females. It is, therefore, not contact pheromones that attract the males initially, but long distance chemical cues that initiate their search for virgin females.

Adult male lice were activated by odors from other adult males and adult mated females but did not show upstream rheotaxis behavior to these chemical cues. A proportion of the preadult II virgin females showed such behavior to adult males, but there was no obvious activation response from the females as a whole. The significance of these findings is not yet understood as they are too preliminary to draw any conclusions. However, it should not be ruled out that other pheromonal components signaling the presence of conspecifics or potential mates may also be present in *L. salmonis*.

In order to incorporate these findings into integrated pest management strategies, it is important to gather further information on the precise chemical composition of the diffusible virgin female-produced pheromones and to test individual compounds to determine the most attractive elements within the preadult II virgin female extract. This would clarify the role of the chemical cues involved in mate location in *L. salmonis.* Such work is currently being carried out.

Acknowledgments—The project was supported by a NERC Link Aquaculture grant (SAL 11) with the Scottish Salmon Growers Association and the Shetland Salmon Farmers Association (now SQS), in collaboration with Marine-Harvest McConnell and Landcatch UK. We thank Chris Brodie of Loch Duart Ltd, Jim Treasurer and Richard Hopewell of Marine-Harvest McConnell, Ian McIntire of Lighthouse of Scotland, Eric Twelves of Salar, Paul Ratter of Hydro Seafood, Robert Lochart of Aquascott Seafarms Ltd, and Hunter Inkster affiliation for facilitating the collection of sea lice. The input of Dr. A. W. Pike, University of Aberdeen, Dr. J. Reader, University of Nottingham and Dr. O. Jones, AgriSense BCS Ltd, is gratefully acknowledged. IACR receives grant-aided support from the Biotechnology and Biological Sciences Research Council (BBSRC) of the United Kingdom.

OBITUARY

JEFFREY B. HARBORNE (1928–2002)

Jeffrey Harborne, who died July 21, 2002, was irrevocably linked to phytochemistry. He was associated with the journal *Phytochemistry* for 32 years, serving both as executive editor, and as editor-in-chief from 1986-1999. He was founder of the journal *Phytochemical Analysis*, and series editor of *Methods in Plant Biochemistry*. His influence on the field of chemical ecology is both seminal and enormous. Many readers of this journal may have first encountered his work in his book *Introduction to Ecological Biochemistry*, now in its 4th edition, and used worldwide as a text to introduce students to chemical ecology and as a reference by scientists working in natural products chemistry and ecology alike. This book probably has done more to foster interest in chemical ecology than any other single publication in the field. It has been the inspiration for countless studies in our field. He was a pioneer and a giant.

Educated at Wycliffe College and the University of Bristol, he developed a life-long interest in flavonoids. He later pursued research on plant pigments at UCLA where he worked with T. Geissman. For many years he was a biochemist at the John Innes Institute, Hertford, UK during which time, with Tony Swain,

0098-0331/02/1100-2119/0 © 2002 Plenum Publishing Corporation

he was instrumental in the establishment of what later became the Phytochemical Society of Europe. He formed a long-term collaboration with Vernon Heywood, and since 1968 he was at the Botany Department at the University of Reading. He authored over 270 research papers and reviews, and was author, editor, or co-editor of 40 books (including *Phytochemical Methods*, *Plant Chemosystematics* with B.L. Turner, *A Dictionary of Plant Toxins*, and 5 others on flavonoids. He was a frequent contributor to this Journal.

Professor Harborne's many honors included being the recipient of: the Silver Medal for life time achievement of the International Society of Chemical Ecology, the first Silver Medal from the Phytochemical Society of Europe, the Gold Medal in Botany from the Linnean Society of London, the first joint award of the Phytochemical Societies of Europe and America honoring lifelong contributions, the Pergamon Phytochemistry Prize for plant biochemistry, and election to Fellowship of the Royal Society. He was an invited speaker at countless international symposia, and he spent time as a visiting professor in Brazil, Texas, California, and Illinois.

Whether or not you were privileged to know Jeffrey Harborne, you are nevertheless indebted to him. His admirers and many friends among the readers of the Journal and the membership of the ISCE will certainly be recalling some personal anecdote that is a bittersweet reminder of what we will miss. His passing touches us, not only because of our wonder at his myriad scientific accomplishments, but also because he was an exceptional man. He was gentle and generous and had a humble and self-effacing nature that is rare. He was also a devoted Anglican who worked for many years as warden of Christ Church in Reading.

We dedicate this issue to his memory.

Arabidopsis ECOTYPE VARIABILITY IN CAMALEXIN PRODUCTION AND REACTION TO INFECTION BY *Alternaria brassicicola*

I. A. KAGAN* and R. HAMMERSCHMIDT

Department of Plant Pathology
Michigan State University
East Lansing, Michigan 48824-1312, USA

(Received August 28, 2001; accepted June 12, 2002)

Abstract—Camalexin production was compared in 24 ecotypes of *Arabidopsis thaliana*. Detached *Arabidopsis* leaves were inoculated with *Cochliobolus carbonum*, an incompatible pathogen of *Arabidopsis*, to test the ability of each ecotype to produce camalexin. Whole plants were inoculated with *Alternaria brassicicola*, a crucifer pathogen, to determine if there was a correlation between the ability of an ecotype to produce camalexin and its resistance to *A. brassicicola*. All ecotypes were capable of producing camalexin, but the amounts produced relative to the Columbia ecotype (used as a standard) varied within and among ecotypes, and among experiments. Different degrees of resistance to *A. brassicicola* were observed among ecotypes, both macroscopically and microscopically. Extraction of *A. brassicicola*-inoculated leaves revealed that only four ecotypes (two resistant and two susceptible) produced easily detectable amounts of camalexin in response to this pathogen. TLC plate bioassays suggested that *A. brassicicola* was relatively insensitive to camalexin, thus casting some doubt on the importance of this compound in defense. These studies suggest that the role of camalexin in disease resistance varies among different *Arabidopsis* populations in nature, and they provide some clues to other possible determinants of resistance to *A. brassicicola*.

Key Words—*Arabidopsis thaliana*, ecotypes, *Cochliobolus carbonum*, *Alternaria brassicicola*, camalexin, disease resistance, microscopy, thin-layer chromatography, bioassays.

INTRODUCTION

Phytoalexins are low-molecular-weight antimicrobial compounds that accumulate in plants after infection by microorganisms (Paxton, 1981). Since the postulation of their existence by Müller and Börger in 1940, and the first isolation of a phytoalexin in 1960 (reviewed in Deverall, 1982), over 350 phytoalexins have been found in about 30 different plant families (Kuć, 1995; Hammerschmidt, 1999).

Phytoalexins within a plant family are often in the same chemical class (Hammerschmidt, 1999). Those of the family Brassicaceae (Cruciferae), for example, consist of an indole ring with a sulfur-containing moiety (Pedras et al., 1997). The cruciferous weed *Arabidopsis thaliana* produces camalexin (Figure 1) as its principal phytoalexin (Tsuji et al., 1992). This is also the principal phytoalexin of the crucifers *Camelina sativa* (Browne et al., 1991), *Arabis lyrata* (Zook et al., 1998), and *Capsella bursa-pastoris* (Jimenez et al., 1997). As with other phytoalexins, the antimicrobial nature (Browne et al., 1991; Ayer et al., 1992; Tsuji et al., 1992; Conn et al., 1994; Rogers et al., 1996; Pedras and Khan, 1997; Pedras et al., 1998) and *de novo* synthesis of camalexin upon infection (Tsuji et al., 1992; Glazebrook and Ausubel, 1994; Callaway et al., 1996; Zhao and Last, 1996; Jimenez et al., 1997; Mhiri et al., 1997; Zook et al., 1998; Sigareva and Earle, 1999; Thomma et al., 2001) suggest that it may play a role in disease resistance.

The initial approach to determine the role of camalexin in defense against pathogens was to isolate camalexin-deficient mutants and compare their disease phenotypes to that of the wild-type. Five such phytoalexin-deficient *(pad)* mutants of *Arabidopsis*, each representing a mutation in a different gene, have been isolated from ethyl methane sulfonate (EMS) -mutagenized seed of the Columbia-0 and Columbia-glabrous ecotypes (Glazebrook and Ausubel, 1994; Glazebrook et al., 1997).

To date, none of the *PAD* genes is known to be specific to camalexin biosynthesis, although *PAD3* is a strong candidate (Zhou et al., 1999). The *PAD4* gene, which has been isolated (Jirage et al., 1999), is a regulatory gene that stimulates salicylic acid (SA) production in response to certain pathogens (Glazebrook et al., 1997; Zhou et al., 1998). SA, in some, but not all cases (Nawrath and Métraux, 1999), potentiates camalexin production (Zhao and Last, 1996; Zhou et al., 1998).

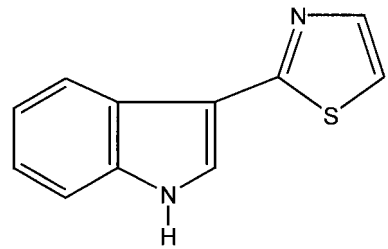

FIG. 1. Camalexin, 3-(2-thiazolyl)indole.

Since SA is required for many defense responses (Vernooij et al., 1994), the disease phenotype of *pad4* could reflect the absence of those other responses and not the absence of camalexin. Because EMS can cause mutations in many different genes (see Robbelen, 1966; Koornneef and van Loenen Martinet, 1983; for examples), some of the other *pad* mutants could also be affected in genes not directly related to camalexin biosynthesis.

As an alternative approach to determining the contribution of camalexin to disease resistance, we examined natural variation in *Arabidopsis* populations. Many ecotypes of *A. thaliana* are available, and although similar enough to be considered one species, they differ genetically in some respects because of selection pressures imposed by the different environments of origin. These differences can include variation in resistance to certain pathogens. For example, different ecotypes of *Arabidopsis* differed in their ability to resist infection by the slime mold *Plasmodiophora brassicae* (Fuchs and Sacristan, 1996), cauliflower mosaic virus (Leisner and Howell, 1992; Callaway et al., 1996), turnip crinkle virus (Dempsey, 1996; Dempsey et al., 1997), the bacterium *Xanthomonas campestris* pv. *campestris* (Tsuji et al., 1991), and the oomycetes *Albugo candida* (Holub et al., 1995) and *Peronospora parasitica* (Mauch-Mani et al., 1993). In those cases, resistance was due to the presence of one or more resistance (R) genes. The types of R genes varied among ecotypes, which may have been a reflection of the disease pressure on the location where each ecotype was collected.

Plant species in different environments also differ in the types of compounds that they produce. For example, the same pine species, in different locations, will qualitatively and quantitatively produce different piperidine alkaloids (Gerson and Kelsey, 1998). Plant species within a genus may also vary in one type of secondary metabolite. Some oat species produce avenacins, which are saponins that provide resistance to the wheat pathogen *Gaeumannomyces graminis* var. *tritici*. Other oat species are avenacin-deficient and are susceptible to that pathogen (Osbourn et al., 1994). Such location- and species-dependent variability in secondary metabolite production may reflect differences in selection pressures of the habitats from which the species originated.

Similarly, the absence of camalexin production in some *Arabidopsis* ecotypes may reflect differences in selection pressures of their original habitats. Since camalexin is not effective against all pathogens (Rogers et al., 1996; Pedras et al., 1997), it is reasonable to think that genes for camalexin production would be lost in habitats where it was useless. However, as genes for production of precursors might remain if any conferred a selective advantage in a habitat, a survey of ecotypes could yield clues about the biosynthesis as well as the physiological role of camalexin.

In this study, we looked for variation in camalexin production among *Arabidopsis* ecotypes and for possible correlations with differences in response to a crucifer pathogen. Twenty-four ecotypes of *A. thaliana* were screened for the ability to produce camalexin when inoculated with the fungus *Cochliobolus carbonum*,

a maize pathogen that induces high concentrations of camalexin in the Columbia ecotype of *Arabidopsis* (Glazebrook et al., 1997; Zook and Hammerschmidt, 1997). At the same time, symptoms that developed after inoculation with the fungus *Alternaria brassicicola*, a common crucifer pathogen (Ellis, 1968), were evaluated. Correlations were sought between resistance to *A. brassicicola* and the ability to produce camalexin.

METHODS AND MATERIALS

Reagents and Chemicals. Camalexin was prepared from a mixture of *Arabidopsis* extracts and from two chemical syntheses. Both syntheses followed the method of Ayer et al. (1992), except that in one case, tetrahydrofuran was used as a solvent instead of benzene. The pooled camalexin was purified by preparative TLC (Whatman plates, 1000 μm thickness) and recrystallized from hexanes–acetone (4:1, v/v) to give a final yield of 20 mg. The purity and concentration of a sample were checked by HPLC by using the method of Glazebrook et al. (1997). Part of the purified camalexin was redissolved in methanol to give a 0.5 mg/ml solution, which was stored at -20°C. Indole-3-carboxaldehyde was purchased from Sigma or Aldrich Chemical Companies and used without further purification (Sigma) or after recrystallization from 95% ethanol (Aldrich). Indole-3-carboxylic acid was obtained from Aldrich. Solvents used for HPLC were of HPLC grade, as was the methanol used for TLC. All other chemicals were of reagent grade or better.

Plant Material and Plant Growth Conditions. The following *Arabidopsis* ecotypes were purchased from Lehle Seed Company (Round Rock,Texas, USA): Aua/Rhön, Bensheim, C24, Cape Verde, Columbia-0, Columbia-glabrous, Dijon G, Estland, Greenville, Kendalville, Landsberg erecta, Mühlen, Niederzenz, Nossen, RLD, RLD1, S96, Turk Lake, and Wassilewskija. Ecotypes Ksk-1, Kas-1, Wei-1, and WA-1 were provided by S. Somerville (Carnegie Institute, Washington, DC, USA). Ecotype Anna was provided by J. Conner (Kellogg Biological Station, Michigan State University, Hickory Corners, Michigan, USA). Seeds were stored over desiccant at room temperature or at 4°C.

Plants were grown in clay pots of 10 or 14.5 cm diameter. Soil (Baccto High Porosity Professional Planting Mix) was wetted with Peters Professional Fertilizer (2.49 g/liter) and covered with a 1- to 2-mm layer of fine vermiculite. Three days after germination, seedlings were fertilized with about 20 ml of fertilizer. Fertilization was repeated once a week, with the amount increasing to about 150 ml/pot by the third week. Plants were grown at 21°C on a 16 hr light regime.

Fungal Cultures and Inoculations. Cochliobolus carbonum (ATCC 90305) and *Alternaria brassicicola* (Trail and Koller, 1993) were grown on V-8 agar according to Tuite (1969, recipe 248) with the following modifications: 160 ml V-8 juice, 1 g calcium carbonate, and 14 g agar were used. Seven- to 14-day-old cultures, grown at room temperature on a 24-hr light regime, were used. For inoculations with *C. carbonum*, excised leaves were inoculated on the abaxial side with

0.1 ml of a spore suspension (2.0×10^5 spores/ml), and incubated in Petri dishes lined with moistened filter paper. *A. brassicicola* spores (2.0×10^5 spores/ml in water + 0.05 % Tween-20) were sprayed onto intact plants with an atomizer. To maintain a humid environment conducive to fungal infection, plants were covered for 24 hr with moist plastic bags, which were then slit to allow gradual equilibration (about 36 hr) with the outside environment. Symptoms were first recorded about 60 hr after inoculation, when bags usually were removed. Symptoms were then recorded daily for 3–7 more days.

Cytological Analysis of A. brassicicola Infection. Leaves of one susceptible and two resistant ecotypes, and of one ecotype with an intermediate degree of resistance, were excised 19, 48, and 72 hr after inoculation. Leaves were placed in glass Petri dishes lined with 2 layers of Whatman No. 1 or No. 4 filter paper saturated with ethanol–acetic acid 3:1 (v/v), which removed pigments and fixed the tissue (Zeyen et al., 1995). Additional solution was pipetted over leaves once or twice a day to keep them from drying. After a few days, ethanol alone was added to the leaves. Prior to microscopy, leaves were rinsed 3–5 times with deionized water (changed every 3–12 hr over 1–2 d), mounted in glycerol on microscope slides, and stored at 4°C. Light micrographs were taken with a Leica microscope at 400× magnification, using Nomarski differential interference contrast (DIC) optics.

Extraction of Camalexin from Inoculated Leaves. For each sample of leaves inoculated with *C. carbonum*, inoculum droplets from 10 leaves (total volume of 1 ml) were collected 24 hr after inoculation, and after dilution with one-half volume of water, the leaf diffusates were extracted 3 times with an equal volume of ethyl acetate. Although camalexin is frequently extracted by boiling leaves and droplets together in 80% methanol (Glazebrook et al., 1997), the droplet extraction method was used because it allowed more rapid sample preparation. Since at the inoculum concentration used, the majority of camalexin is in the leaf diffusates (Kagan and Hammerschmidt, 2001), the camalexin in droplets was considered an accurate representation of the amount in the entire leaf. The pooled organic phases were evaporated to dryness under reduced pressure at 40°C, redissolved in 1 ml methanol, transferred to glass tubes, evaporated under a stream of nitrogen at 40–60°C, and stored at 4°C or −20°C.

To examine camalexin production in response to *A. brassicicola*, plants were sprayed with a spore suspension containing 2×10^5 spores/ml. At 48 hr after inoculation (a time when camalexin concentrations were usually high in *C. carbonum*-inoculated plants), 0.1–0.7 g of leaves (6–15 leaves per replicate in one experiment, and 50–75 leaves per replicate in another) were excised for extraction. The leaves were weighed and boiled in 80% methanol (15 ml/0.1 g tissue) for 20 min. Samples were stored at 4°C for 24–60 hr and then concentrated under reduced pressure at 40–45°C to remove the majority of the methanol. The concentrated extract was diluted with one-half volume of water and then extracted 3 times with an equal volume of chloroform. The pooled chloroform fractions were dried over anhydrous sodium sulfate and then evaporated and stored as described for the leaf diffusate extracts.

Thin-Layer Chromatography (TLC) of Extracts. Droplet extracts were redissolved in 35 μl of ethyl acetate, and the entire sample was loaded (in 5-μl aliquots) onto washed and activated silica gel G TLC plates [20 $\times$ 20 cm, silica thickness: 200 μm on plastic-backed plates (Selecto Scientific), and 250 μm on glass-backed plates (Analtech)]. Leaf extracts were dissolved in 35–60 μl of methanol, depending on the starting amount of leaf tissue. Standards of camalexin (5 μg), as well as the putative precursors indole-3-carboxaldehyde and indole-3-carboxylic acid (usually 1.25–5 μg, and 2.5–5 μg, respectively) were also loaded. Plates were developed once in chloroform and then twice in chloroform–methanol 19:1 (v/v).

The TLC plates were photographed with Kodak slide film (100 ASA) under long-wave or short-wave ultraviolet light, with an Olympus OM-1 camera. A Kodak Wratten filter for blue light covered the camera lens. Photographing plates required a 1- to 1.5-min exposure under long-wave UV, and a 2.5-min exposure under short-wave UV light.

Bioassays for Evaluation of Camalexin Production in Response to C. carbonum and A. brassicicola. To provide a visual record of camalexin production among the different ecotypes, as well as of other antimicrobial compounds, TLC plates were sprayed with a suspension of *Cladosporium cucumerinum* spores (usually 3–3.5 $\times$ 10^6 spores/ml) in half-strength potato-dextrose broth (per liter: 100 g potatoes, 5 g dextrose) and incubated in a humid chamber for 3 d. Fungal hyphae and spores are produced everywhere on the plates except in areas containing antifungal compounds. TLC plates containing extracts of *A. brassicicola*-inoculated leaves were sprayed with *A. brassicicola* (5×10^5 to 1×10^6 spores/ml). Cultures used for bioassays were 7–11 days old.

Quantification of Camalexin. Camalexin was quantified from the bioassayed plates by assuming a directly proportional relationship between the radius of a zone of inhibition (ZOI) and the logarithm of the mass of compound present (Lazarovits et al., 1982). The ZOIs at the R_f of camalexin were traced onto paper and scanned with a Hewlett-Packard ScanJet 4c scanner (resolution of 150 dots per inch in the horizontal and vertical directions). The area in pixels was determined with the Jandel Sigma-Scan program. These numbers were converted into square centimeters based on the number of pixels in standards of known size. The radius (r) of the zone of inhibition was calculated from the formula $A = \pi r^2$, and the mass of camalexin was determined from a standard curve (Figure 2) of inhibitory zone radius versus $\log_{10}$ of mass.

RESULTS

Phenotypic Characterization of Responses to Alternaria brassicicola. The traits used to indicate disease resistance varied between ecotypes and experiments. An ecotype could appear susceptible because of extreme chlorosis on one occasion

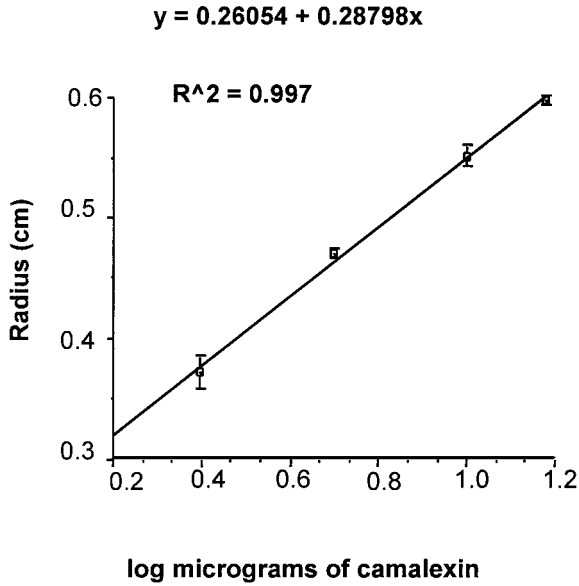

FIG. 2. Relationship between $\log_{10}$ of micrograms of camalexin and radius of zone of inhibition on TLC plates bioassayed with *Cladosporium cucumerinum*. Mean radii were determined from zones of inhibition on two separate TLC plates, onto which known amounts of camalexin were loaded.

and because many large lesions formed on another occasion. Consequently, the ecotypes in Table 1 were grouped by degree of resistance (high, intermediate, or low), and not by a range of disease scores. Phenotypic traits seen consistently in an ecotype were noted.

In general, symptoms of *A. brassicicola* infection consisted of circular brown or gray lesions (1–20 per leaf), 0.5–1.5 mm in diameter. The larger lesions were sometimes irregularly shaped and possibly consisted of several smaller lesions that had coalesced. Chlorosis, although sometimes induced by mock inoculation, was associated primarily with infection. Three general types of chlorosis were observed: (1) yellowing of the entire lesion-containing area with no clear point of origin, (2) yellowing that radiated outward from the leaf midrib to cover the lesion-containing area, or (3) a yellow halo around the lesion. The latter is fairly typical of *A. brassicicola* infection (Ellis, 1968; Conn et al., 1988).

On some plants, infected leaves wilted and became necrotic 3-7 days post-inoculation (dpi). Even on plants with no apparent symptoms of infection, it was common to find at least one of the oldest leaves dead 3–5 dpi. Older leaves seemed more susceptible than younger leaves to *A. brassicicola*.

TABLE 1. ECOTYPES STUDIED FOR CAMALEXIN PRODUCTION AND *A. brassicicola* RESISTANCE: NAME AND/OR ABBREVIATION, ORIGIN, AND DISEASE PHENOTYPE

Ecotype name	Origin	Degree of resistance[a] and distinctive phenotypic traits, if any
Anna	USA	High resistance, symptoms very rare
Bensheim (Be)	Germany	High
Greenville (Gre)	USA	High
Kendalville	USA	High
Ksk-1	Keswick, England	High
Muehlen (Mh)	Poland	High
Nossen	Germany	High
RLD	Rschew, Russia	High; leaves sometimes developed lesions but seldom became chlorotic
S96	Koorneef Group, Netherlands	High
Turk Lake	USA	High; symptoms rare
Aua/Rhön (Aa)	Germany	Intermediate resistance
Cape Verde (Cvi)	Cape Verde Islands	Intermediate; large lesions and profuse chlorosis
Columbia-0 (Col-0; no genetic markers)	USA	Intermediate; variable symptoms (<5% to 15% diseased leaves)
Estland (Est)	Estland, former USSR	Intermediate
Landsberg erecta (La-er)	Germany	Intermediate
Niederzenz (Nie)	Germany	Intermediate to low; lesions usually small (<0.5–1 mm diam.) and numerous (5–10 per diseased leaf)
RLD-1	Rschew, Russia	Intermediate to high; large necrotic zones following lesion development
WA-1	Warsaw, Poland	Intermediate; large circular lesions
Wassilewskija (Ws)	Russia	Intermediate
Wei-1	Weiningern, Switzerland	Intermediate to low; round lesions about 1.5 mm diam.
C24 (glabrous strain used in transformation)	Collected by B. Damm	Low resistance; large lesions, usually at margins
Columbia-glabrous (Col-gl; glabrous leaves used as a genetic marker)	USA	Low; large lesions at margins and rapid development of wilting and necrosis
Dijon G (Di-G)	Dijon, France	Low
Kas-1	Kashmir Province, India	Low

[a] High resistance: lesions on fewer than 10% of leaves; little chlorosis. Intermediate resistance: lesions and necrotic/chlorotic areas on 10–40% of leaves. Low resistance: large lesions and profuse chlorosis; symptoms affecting 50-100% of leaves by end of observation period.

Highly resistant plants had lesions on fewer than 10% of the leaves, and infected leaves were seldom chlorotic. Dead rosette leaves were sometimes the only indications of pathogen infection. Plants with intermediate resistance had lesions and necrotic/chlorotic areas that could be quite large, but on only 10–40% of the leaves. This category included plants with gradually increasing numbers of diseased leaves during the observation period. Plants with low resistance had large lesions on many leaves, frequently accompanied by profuse chlorosis, at the start of the observation period. Up to 50–100% of the leaves were infected by the end. Necrosis, wilting, and death in the most susceptible plants were observed by 3–4 dpi.

The degree of resistance or susceptibility in each ecotype depended partly on light regime and inoculum concentration. When plants were grown under less light, some of the normally resistant ecotypes, such as Bensheim, had severe disease symptoms. At a high inoculum concentration (3.5×10^5 spores/ml), almost all of the ecotypes tested (Mühlen, RLD1, RLD, Columbia-0, Greenville, Kendalville, Estland, S96, Aua/Rhön, Nossen, and Anna) with the exception of Anna, appeared susceptible. At a lower inoculum concentration (1.0×10^5 spores/ml), all plants tested (Anna, Columbia-0, Columbia-glabrous, Cape Verde, C24, Ksk-1, Landsberg erecta, Niederzenz, Wei-1, Wa-1, Wassilewskija, and Kas-1) appeared resistant except for Niederzenz, Wei-1, and Wassilewskija.

Symptoms could vary considerably between experiments. For example, although Dijon G consistently had lesions and chlorotic leaves, it sometimes had large lesions within chlorotic areas or had many small necrotic lesions less than 0.5 mm in diameter.

Cytological Analysis of Infection in Resistant and Susceptible Ecotypes. No striking differences were seen in numbers of conidia per square centimeter on the surfaces of susceptible and resistant ecotypes, although some clusters of conidia created localized differences. For example, although the micrographs in Figures 3 and 4 show about 6 conidia on the surface of Turk Lake, and 3 conidia on the highly susceptible Kas-1 and highly resistant RLD, the average numbers of conidia per leaf were similar. Therefore, resistance to *A. brassicicola* was not due to discrepancies in the amount of viable inoculum. More differences were noticed in hyphal development and tissue response. On the resistant Turk Lake (Figure 4A), conidia formed unusually short germ tubes, and penetration events were rare. On the resistant RLD (Figure 4B), germ tubes were about as long as on the susceptible Kas-1 (Figure 3). However, fewer lesions and less browning were seen in RLD than in Kas-1 cells. Micrographs of RLD leaves viewed under UV light (not shown) revealed a fluorescent orange material permeating the tissue, suggesting the presence of phenolic compounds.

Camalexin Production in Response to C. carbonum. Because compatible pathogens sometimes do not elicit phytoalexin production (Zhao and Last, 1996),

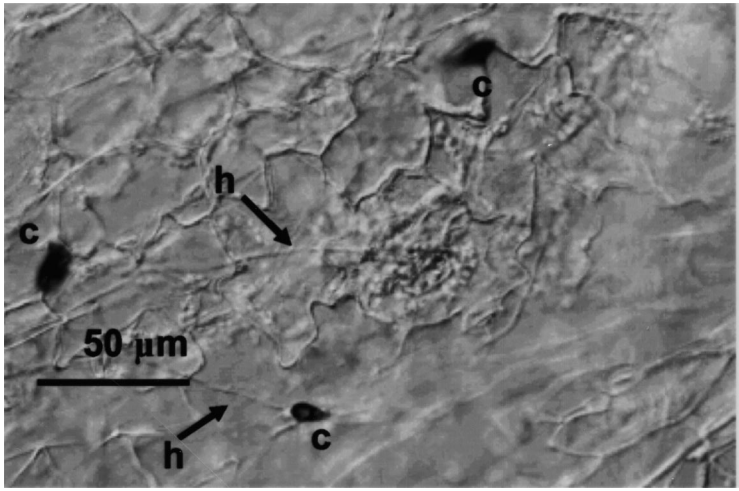

FIG. 3. Light micrographs (400× magnification, Nomarski optics) of ecotype Kas-1 (low degree of resistance) 48 hr after inoculation. One of the 3 conidia (c) has germinated, forming a long hypha (h) extending into a cell.

an incompatible pathogen was needed as a neutral inducer. *C. carbonum* is an incompatible pathogen of the Columbia ecotype and known to elicit large quantities of camalexin (Glazebrook et al., 1997). Quantifying camalexin from the areas of ZOI's on bioassayed TLC plates, although less accurate than the HPLC method used previously (Kagan and Hammerschmidt, 2001), provided a quick visual assessment of ecotype variability in production of camalexin and of other antimicrobial compounds.

As seen in Figure 5, other antimicrobial compounds were detected. However, because they were not seen consistently in different experiments, they were not analyzed further. The putative precursor indole-3-carboxylic acid (approximate $R_f = 0.2$–0.3) was detected under short-wave UV light in most extracts. Whether it was present as a precursor or metabolite was not determined. It was not antimicrobial (Figure 5); nor was the indole-3-carboxaldehyde (Figure 5), another putative precursor that was not detected in the extracts [possibly because indole-3-carboxaldehyde concentrations tend to reach a maximum about 6 hr postinoculation and then decrease (Kagan and Hammerschmidt, data not shown)].

Camalexin production in the different ecotypes (Table 2) was measured relative to Columbia-0 because the latter was used as a wild-type plant in earlier studies (Glazebrook et al., 1997; Kagan et al., 1997). Because the purpose of these experiments was to compare camalexin production among inoculated ecotypes, water-inoculated controls were not included. The variability in the amounts of camalexin found in each ecotype indicated that camalexin was not constitutively

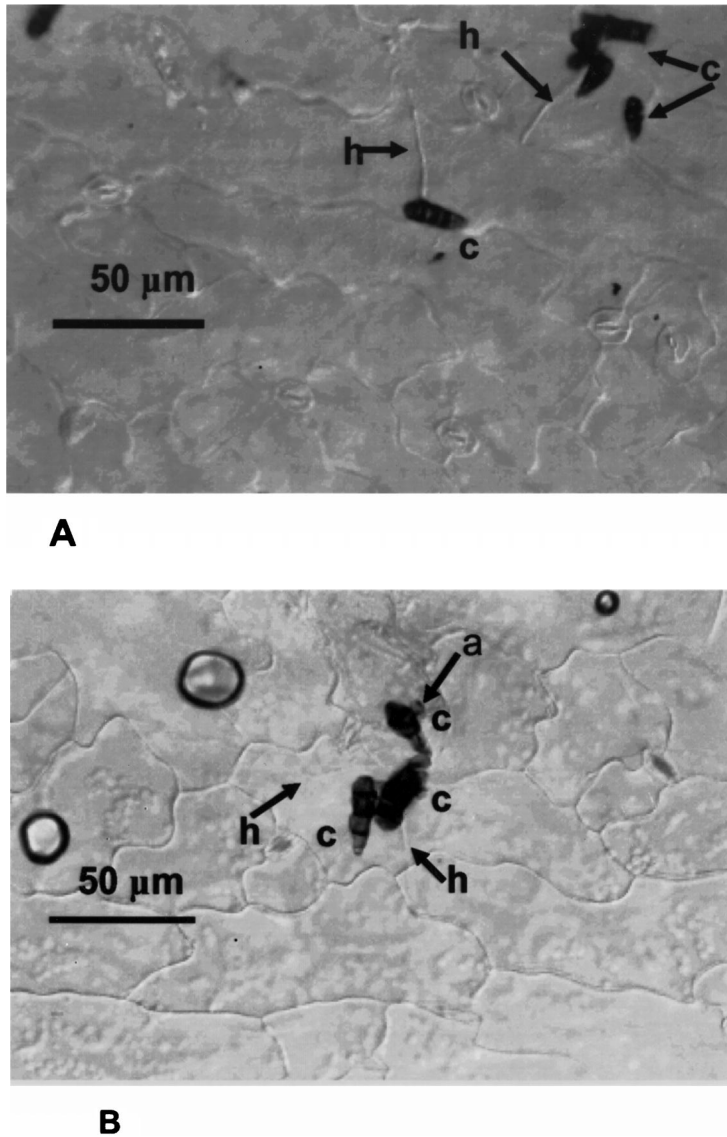

FIG. 4. Light micrographs (400× magnification, Nomarski optics) of ecotypes Turk Lake and RLD (high degree of resistance). (A) Turk Lake, 72 hr after inoculation. Note the short hyphae (h) extending from the conidia (c). (B) RLD, 72 hr after inoculation. The conidium near the top of the figure has formed an appressorium (a) to penetrate the cell directly beneath it. The infected cell appears collapsed. Hyphae are indicated by arrows. Black circles are air bubbles.

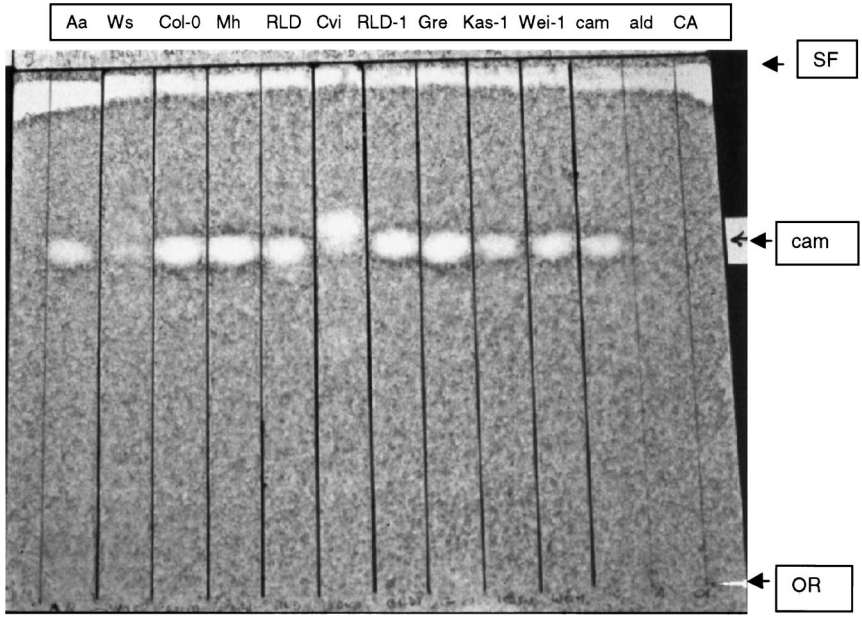

FIG. 5. TLC plate bioassay revealing camalexin accumulation in some *Arabidopsis* ecotypes in response to *Cochliobolus carbonum* (neutral inducer). The plate was sprayed with *Cladosporium cucumerinum* spores and incubated in a humid chamber for 3 d. Ecotypes: Aua/Rhön (Aa), Wassilewskija (Ws), Columbia-0 (Col-0), Mühlen (Mh), RLD, Cape Verde (Cvi), RLD-1, Greenville (Gre), Kas-1, Wei-1. Standards of camalexin (cam), indole-3-carboxaldehyde (ald), and indole-3-carboxylic acid (CA) were also loaded. The location of the camalexin band is shown by the arrow on the right, as are the origin (OR) and solvent front (SF).

produced in any. Eight ecotypes besides Col-0 produced undetectable amounts of camalexin in at least one replicate (Table 2). All ecotypes produced camalexin in at least one experiment (Table 2). However, apart from Dijon G and Wassilewskija, which consistently produced low amounts relative to Col-0 (Table 2, Figure 5), no trends in camalexin production were observed. Some ecotypes were analyzed in 4–5 experiments because they were grown in additional plantings done to obtain data on the poor germinators (Turk Lake, WA-1, and Ksk-1). The extra replicates of ecotypes such as Bensheim, Mühlen, RLD, and RLD-1 confirmed that camalexin production could vary in absolute amounts and in comparison to Col-0. Mühlen, for example, produced 0.73–10 μg in 5 replicates, and the amounts ranged from two-thirds to three times the amount produced by Col-0 in those experiments. Variation in camalexin production relative to Col-0 was due partly to variation in camalexin production in Col-0 itself, which did not always produce detectable amounts

TABLE 2. CAMALEXIN PRODUCTION IN RESPONSE TO *Cochliobolus carbonum*

Ecotype	Range of camalexin produced (μg) per 10 leaves in N replicates[a]	Camalexin concentration, as % of amount produced by Col-0[b]
Anna	0.66–7.2 ($N = 6$)	82–340 ($N = 3$)[c]
Aua/Rhön	0.85–4.2 ($N = 3$)	29–48 ($N = 2$)
Bensheim	0–4.6 ($N = 4$)	380–420 ($N = 2$)
C-24	1.4–3.2 ($N = 4$)	32–210 ($N = 3$)
Cape Verde	0.79–12.5 ($N = 4$)	9.0–230 ($N = 3$)
Columbia-0	0–8.7 ($N = 10$)	not applicable
Columbia-glabrous	0–2.7 ($N = 5$)	12–150 ($N = 4$)
Dijon G	0–1.5 ($N = 5$)	Not determined[d]
Estland	0–2.1 ($N = 4$)	69–120 ($N = 3$)
Greenville	0–8.8 ($N = 4$)	100–200 ($N = 3$)
Kas-1	3.4–5.3 ($N = 3$)	61–310 ($N = 2$)
Kendalville	2.0–3.1 ($N = 3$)	23–35 ($N = 2$)
Ksk-1	1.9–7.1 ($N = 4$)	210–400 ($N = 3$)
Landsberg erecta	1.8–3.3 ($N = 4$)	21–38 ($N = 2$)
Mühlen	0.73–10 ($N = 5$)	67–290
Niederzenz	1.8–4.5 ($N = 4$)	34–120 ($N = 3$)
Nossen	0.40–1.8 ($N = 4$)	18–110 ($N = 3$)
RLD	0–6.6 ($N = 6$)	75–190 ($N = 3$)
RLD-1	2.0–9.0 ($N = 5$)	100–510 ($N = 3$)
S96	2.1–5.6 ($N = 4$)	37–200 ($N = 3$)
Turk Lake	0–6.8 ($N = 4$)	99–130 ($N = 3$)
WA-1	0–2.8 ($N = 3$)	32–140 ($N = 2$)
Wassilewskija	0–1.9 ($N = 2$)	0–22
Wei-1	0.84–5.3 ($N = 4$)	32–190

[a] Leaves were inoculated with *C. carbonum,* and diffusates were extracted after 24 hr. Camalexin on TLC plates was quantified by measuring the area of the zone of inhibition (20I) after bioassay with *Cladosporium cucumerinum*. Mean areas were calculated from 3 scans of a traced ZOI (see Methods and Materials). Replicates were from at least 2 independent experiments. Zeroes indicate an absence of camalexin, or of a measurable ZOI.

[b] Camalexin measured relative to that in the Col-0 ecotype extracted and bioassayed on the same dates.

[c] N values are given in column 3 when different from those in column 2 (occurs if the camalexin relative to Col-0 could not be calculated due to a lack of detectable camalexin in the ecotype or in Col-0).

[d] Quantifiable camalexin was from experiments yielding undetectable amounts in Col-0.

(Table 2). Few correlations were seen between camalexin production in response to a neutral inducer and resistance to *A. brassicicola*. Although the highly susceptible Dijon G was one of the lowest producers, the susceptible ecotypes Kas-1 and C24 produced intermediate amounts of camalexin that were up to 310 % of the amounts produced in Col-0 (Table 2). Furthermore, the highly resistant Nossen produced relatively low amounts of camalexin in absolute (0.4–1.8 μg) and relative terms (18–110 % of Col-0).

Camalexin Production in Response to A. brassicicola. In one experiment, small amounts of camalexin were present in 10 ecotypes (Kas-1, WA-1, Turk Lake, Dijon G, Niederzenz, Anna, RLD, RLD-1, Wassilewskija, Col-0), but in only one of the two replicates. The camalexin band was slightly brighter in Kas-1 and RLD than in the other ecotypes. No zones of inhibition were formed in TLC plate bioassays. When the experiment was repeated with the same ecotypes, minus the Wassilewskija ecotype, and with an approximately fivefold increase in leaf mass, only Kas-1, Anna, and RLD produced enough camalexin to detect under UV light. After bioassay with *A. brassicicola* spores, faint ZOI's at the R_f of camalexin were detectable in extracts from the resistant ecotypes RLD and Anna (which contained two other faint ZOI's, indicating the presence of additional antimicrobial compounds), and from the susceptible ecotypes Kas-1 and Dijon G. The faint ZOI's at the R_f of camalexin may indicate insensitivity of *A. brassicicola* to camalexin, since the ZOI formed by the standard was fainter than on a *C. cucumerinum*-sprayed plate assayed on the same day (not shown).

DISCUSSION

To better understand the role of camalexin in disease resistance, we compared camalexin production in 24 *Arabidopsis* ecotypes and looked for correlations with resistance to *Alternaria brassicicola*, a fungal pathogen of crucifers. Ecotype resistance was classified as high, intermediate, or low (Table 1). These categories encompassed a range of symptoms, which frequently varied within ecotypes from one experiment to the next. This variation in symptoms, within and among ecotypes, suggests that resistance of *Arabidopsis* to *A. brassicicola* may involve multiple defense genes, as found in studies of *Arabidopsis* resistance to *Peronospora parasitica* (Mauch-Mani et al., 1993).

All ecotypes could produce camalexin in response to the incompatible fungal maize pathogen *Cochliobolus carbonum* (Table 2), demonstrating that susceptibility to *A. brassicicola* was not due to an inability to produce camalexin. However, with the exception of the low-producing Dijon G and Wassilewskija, no ecotypes produced consistently high or low amounts of camalexin. The amounts produced in response to this neutral inducer did not, in general, seem correlated with resistance to the crucifer pathogen.

Following *A. brassicicola* inoculation, the only ecotypes producing enough camalexin to inhibit *A. brassicicola* in bioassays were the highly susceptible Kas-1 and highly resistant RLD, and (in one experiment) the highly susceptible Dijon G and highly resistant Anna as well. These results suggest that among the ecotypes tested, camalexin may not be a key factor in resistance to *A. brassicicola*.

Recently, Thomma et al. (1999) demonstrated a role for camalexin in resistance to *A. brassicicola*, based on work with the *pad3* mutant of *Arabidopsis*, which

produces no camalexin in response to this pathogen or to others previously tested (Glazebrook and Ausubel, 1994; Glazebrook et al., 1997). This mutant was more susceptible to *A. brassicicola* than either *pad1* or the wild-type Col-0 ecotype, both of which produced significant amounts of camalexin following *A. brassicicola* inoculation (Thomma et al., 1999). We found that Col-0 produced faintly detectable camalexin in one replicate of one experiment and that the amounts produced did not inhibit *A. brassicicola* in a bioassay. Our results for camalexin production cannot be compared directly to those of Thomma et al., due to differences in bioassay and quantification methods. However, the fact that in two experiments camalexin was detected in both the highly resistant RLD and highly susceptible Kas-1 suggests that for some ecotypes of *Arabidopsis*, factors other than camalexin may be more important in determining resistance to *A. brassicicola*. Other studies of cruciferous phytoalexins have also demonstrated that correlations between phytoalexin production and disease resistance break down when a large number of accessions are examined (Rouxel et al., 1991).

The argument against a primary role for camalexin in resistance to *A. brassicicola* is supported by the relative insensitivity of *A. brassicicola* to camalexin. Faint zones of inhibition in our TLC plate bioassays, suggesting that camalexin poorly inhibited *A. brassicicola* growth, are corroborated by the findings of Thomma et al. (1999) that *A. brassicicola* was completely inhibited by 500 μg/ml camalexin. Although more sensitive to camalexin than *Botrytis cinerea*, which was not inhibited by that concentration, *A. brassicicola* required 5 times more camalexin for complete inhibition than did *Neurospora crassa* (Thomma et al., 1999). Since minimum inhibitory concentrations (MIC's) of camalexin for other pathogens are about 50 μg/ml for *Rhizoctonia solani* (Pedras and Khan, 1997) and 80 μg/ml for *Alternaria brassicae* (Jimenez et al., 1997), it appears that *A. brassicicola* is less sensitive to camalexin than some other tested plant pathogens.

The qualitative results of the infection studies with *A. brassicicola*, along with the results of the bioassays from *C. carbonum*-inoculated plants, lay a foundation for further, more quantitative studies to determine other factors that may be involved in resistance to *A. brassicicola* and the relative role of camalexin among those factors. Camalexin may be required for disease resistance in some ecotypes but not others. Contributing factors to resistance may differ among ecotypes, since cytological analysis of infection revealed different resistance responses. The relatively long hyphae on RLD leaves (Figure 4B) suggested that resistance was due to the synthesis of inducible compounds, such as camalexin, in response to cell penetration. In contrast, the short hyphae on Turk Lake leaves (Figure 4A) suggested inhibition of fungal growth at or near the leaf surface, perhaps due to the presence of preformed antimicrobial compounds. Since ecotype Anna, after inoculation with *A. brassicicola*, contained two faint antimicrobial zones besides camalexin in bioassays, it seems possible that other ecotypes could also contain compounds inhibitory to *A. brassicicola*. For example, the orange fluorescent

material observed by fluorescence microscopy in RLD (see Results) suggested the presence of phenolics, often associated with defense responses and possibly too polar to be separated in the TLC solvent used in this study. As no protein extractions were done, the correlation of resistance with defensins (Penninckx et al., 1996; Thomma et al., 1998, 1999) in the various ecotypes is uncertain. Future work should involve concerted analysis of camalexin, phenolics, and defensins to help determine the relative role of each in disease resistance.

Another possible resistance-determining factor is the response to fungal toxins that may be produced during infection (Knogge, 1996). *A. brassicicola* produces a host-specific toxin that may be an important determinant of pathogenicity (Cooke et al., 1997; Otani et al., 1998). A study of 21 members of the family Brassicaceae demonstrated that following application of toxin-containing spore germination fluids (inoculum droplets filtered to remove spores), the severity of necrosis on leaves was correlated with host susceptibility to *A. brassicicola* (Cooke et al., 1997). More recently, the cause of the necrosis was determined to be a host-specific toxin, named AB-toxin (Otani et al., 1998). The variations observed in ecotype resistance to *A. brassicicola* could reflect the presence or absence of genes for AB-toxin detoxification. Further work should include analysis of AB-toxin concentrations in spore inoculum droplets and a search for correlations between *A. brassicicola* resistance and AB-toxin metabolism.

Future work should also involve studies with other pathogens, as camalexin may have a greater role in ecotype resistance to pathogens sensitive to this compound. It would be interesting to find the compatible and incompatible pathogens that are native to the habitats of the various ecotypes and to look for correlations between resistance, susceptibility, and pathogen sensitivity to camalexin.

This study revealed some factors to consider when comparing camalexin production and pathogen resistance among a wide range of ecotypes. As previously mentioned, other compounds besides camalexin may contribute to resistance, and sensitivity to the pathogen or to its toxin(s) may affect the outcome as well. In addition, thorough kinetic studies need to be done before drawing conclusions about whether an ecotype accumulates high or low amounts of camalexin or other compounds. Earlier studies with Col-0 revealed that plants may accumulate camalexin more slowly on some occasions than on others, thus appearing to be camalexin-deficient if examined at only one time point (Kagan and Hammerschmidt, 2001). In this study, camalexin accumulation in response to *C. carbonum* varied within and among ecotypes. By following that accumulation over several days, HPLC quantification may, in the future, establish clearer differences in production by different ecotypes.

Other factors have the potential to bias the evaluation of resistance to a pathogen. The variations in symptoms observed among experiments, besides suggesting the presence of multiple defense genes, demonstrated the need to consider the model of the disease triangle (Agrios, 1997) when evaluating disease

resistance. Even if a plant has the capacity to resist infection, disease may develop if the environmental conditions are right and the pathogen is sufficiently aggressive. In the case of the ecotypes studied here, differences in light regime or inoculum concentration led to aberrant disease phenotypes. Plants grown under reduced light, and hence somewhat stunted, were generally more susceptible to *A. brassicicola* than plants grown under a normal light regime, and this greater susceptibility may have been due to the fact that the stunted plants, lacking sufficient reserves for normal metabolism, also lacked reserves for defense.

Thus far, the role of camalexin in disease resistance has been evaluated by studying the correlation between camalexin production and disease resistance in a small number of wild-type ecotypes or in the phytoalexin-deficient (*pad*) mutants generated by EMS mutagenesis of the Col-0 or Col-gl ecotypes. Such studies, if expanded to wild-type representatives of a larger number of ecotypes, and in relation to a larger number of pathogens, should provide a more comprehensive picture of the role of camalexin in disease resistance. However, it will be important to base conclusions on a large number of experiments in order to have the most accurate picture of the range of symptom variation, to recognize that inoculum concentrations or simple environmental factors may affect results, and to look for other factors contributing to disease resistance in order to have the best possible evaluation of the relative importance of camalexin.

Acknowledgments—The authors thank W. Reusch and J. Kagan for use of their facilities for camalexin synthesis, J. Conner for providing seed from the Anna ecotype, and S. Somerville for providing Ksk-1, Kas-1, Wei-1, and WA-1 seeds. Also to be thanked are K. Stepnitz and P. Yang-Cashman for helpful advice on photographing TLC plates; the Michigan State University Instructional Media Center for high-quality processing of slides; J. Stein for help with quantifying camalexin on TLC bioassay plates; and T. Murrell, B. Schuster, and K. Roth for technical and moral support. This research was supported in part by the Michigan Agricultural Experiment Station.

(Received February 19, 2002; accepted July 3, 2002)

Abstract—A central component in understanding plant–enemy interactions is to determine whether plant enemies, such as herbivores and pathogens, mediate the evolution of plant secondary metabolites. Using 26 populations of a broadly distributed plant species, sagebrush (*Artemisia tridentata*), we examined whether sagebrush populations in habitats with a greater prevalence of fungi contained antifungal secondary metabolites on leaf surfaces that were more active and diverse than sagebrush populations in habitats less favorable to fungi. Because moisture and temperature play a key role in the epidemiology of most plant–pathogen interactions, we also examined the relationship between the antifungal activity of secondary metabolites and the climate of a site. We evaluated the antifungal activity of sagebrush secondary metabolites against two fungi, a wild *Penicillium* sp. and a laboratory yeast, *Saccharomyces cerevisiae*, using a filter-paper disk assay and bioautography. Comparing the 26 sagebrush populations, we found that fungal abundance was a good predictor of both the activity ($r^2 = 0.36$ for *Saccharomyces*, $r^2 = 0.37$ for *Penicillium*) and number ($r^2 = 0.34$ for *Saccharomyces*) of antifungal secondary metabolites. This suggests that selection imposed by fungal pathogens has led to more effective antifungal secondary metabolites. We found that the antifungal activity of sagebrush secondary metabolites was negatively related to average vapor pressure deficit of the habitat ($r^2 = 0.60$ for *Saccharomyces*, $r^2 = 0.61$ for *Penicillium*). Differences in antifungal activity among populations were not due to the amount of secondary metabolites, but rather to qualitative differences in the composition of antifungal compounds. Although all populations in habitats

with high fungal prevalence had secondary metabolites with high antifungal activity, different suites of compounds were responsible for this activity, suggesting independent outcomes of selection on plants by fungal pathogens. The location of antifungal secondary metabolites on the leaf surface is consistent with their putative defense role, and we found no evidence supporting other functions, such as protection from ultraviolet light or oxidation. That the antifungal activity of sagebrush secondary metabolites was similar for two different fungi provides support for broad antifungal defenses. The incidence and severity of fungal disease in the field (caused by *Puccinia tanaceti*) were similar in moist and dry habitats, possibly reflecting an equilibrium between plant defense and fungal attack, as sites with greater fungal abundance compensated with more effective secondary metabolites. The geographic correlation between fungal abundance and antifungal secondary metabolites of sagebrush, coupled with our other data showing heritable variation in these metabolites, suggests that pathogenic fungi have selected for antifungal secondary metabolites in sagebrush.

Key Words—*Artemisia tridentata,* selective pressures, plant-pathogen interactions, plant defenses, trichomes, sesquiterpene lactones, *Puccinia tanaceti.*

INTRODUCTION

The idea that herbivores and pathogens shape the chemical defenses of their hosts is central to the field of plant–enemy interactions (Ehrlich and Raven, 1964; Edwards, 1992; Rosenthal and Berenbaum, 1992; Rausher, 1992). Yet surprisingly, there is limited evidence that plant enemies exert enough selective pressure on plants to drive the evolution of novel secondary metabolites (Futuyma, 1983; Jermy, 1984; Marquis, 1992; Berenbaum, 1995). In order to demonstrate natural selection in the wild, Endler (1986) argued that it is necessary to show (1) the existence of heritable variation in the trait, and (2) that variation in the trait explains variation in fitness. Furthermore, although it is difficult to identify conclusively the selective agent without manipulative experiments, strong indirect evidence can be obtained by showing that geographic variation in a putative selective agent is correlated with a parallel variation in the defensive trait.

Studies examining the relationship between herbivores and intraspecific variation in plant secondary metabolites have provided evidence for at least some of Endler's criteria. For example, Berenbaum and colleagues have shown that resistance by wild parsnip to the parsnip webworm is chemically based and genetically controlled, although they did not look to see if variation in webworm selective pressure led to different patterns of defense investment (Berenbaum et al., 1986). Mauricio and Rausher (1997) demonstrated that removal of herbivores was followed by a decrease in the amount of glucosinolates and trichome density in subsequent generations of naturalized *Arabidopsis thaliana*. However, for long-lived organisms, it is often not feasible to experimentally manipulate selective

agents or monitor populations for enough generations to demonstrate changes in the frequency of traits. Thus, some studies have used natural variation in the abundance of herbivores within a plant population and then looked for associated patterns of plant defense. Dolinger et al. (1973) demonstrated that populations of *Lupinus* sp. occurring where their specialist herbivore was abundant produced a greater amount and number of alkaloids than populations occurring in areas where the herbivore was rare. Similarly, studies on monoterpenoids in *Satureja douglasii* (Labiatae) and cyanogenic glycosides in *Trifolium repens* and *Lotus corniculatus* (Fabaceae) illustrate that susceptible plant chemotypes occur in sites having fewer herbivores (Jones, 1972, 1988; Rice et al., 1978; Dirzo and Harper, 1982; others in Table 5.1 of Endler, 1986).

Evolution of plant defenses against pathogens is best understood in the case of gene-for-gene interactions (Clay and Kover, 1996; Simms, 1996). These are mediated primarily by plant signaling pathways that recognize the pathogen and induce programmed cell death, an oxidative burst and phytoalexin production (Hammerschmidt, 1999). The majority of fungal pathogens contact leaves as spores or mycelial fragments and infect a leaf by penetrating the leaf epidermis or by entering a stoma (Edwards, 1992). Consequently, the environment at the plant surface plays an important role in fungal adhesion and development (Tucker and Talbot, 2001). For these reasons, plant surface secondary metabolites may mediate plant–pathogen interactions by protecting the leaf from fungal penetration. Nevertheless, the interactions between constitutive metabolites located on the plant surface and pathogens are little studied (Blakeman and Atkinson, 1981; Anderson, 1982; Atkinson and Blakeman, 1982; Hargreaves et al., 1982; Elleman and Entwistle, 1985; Van Etten et al., 1994; Osbourn, 1999; Hakulinen et al., 1999; Sicker et al., 2000).

In this study, we examined the relationship between fungi and antifungal secondary metabolites that are primarily located in glandular trichomes on the leaf surface of sagebrush, *Artemisia tridentata* (Asteraceae). Sagebrush is a long-lived shrub distributed throughout the Western United States (Ferguson, 1964) and is attacked by a number of pathogenic fungi (Farr et al., 1989). The secondary metabolites of sagebrush have been extensively documented (Shafizadeh and Melnikoff, 1970; Kelsey et al., 1973,1982; Bhadane et al., 1975; Brown et al., 1975), although their role in defense against fungal pathogens has not been examined. Sagebrush produces several classes of secondary metabolites, such as coumarins, flavonoids, monoterpenes, and sesquiterpene lactones, that are primarily sequestered in glandular trichomes on the leaf surface (Kelsey and Shafizadeh, 1980; Slone and Kelsey, 1985). The glandular trichomes have cuticular sacs that cover 21–35% of the leaf surface (Kelsey and Shafizadeh, 1980). The secondary metabolites in the glandular trichomes are likely released onto the leaf surface as the cuticular sac matures. In *Artemisia annua*, a cuticular sac forms from secretory cells, accumulates metabolites, and at maturity the sacs rupture discharging their contents to the leaf surface

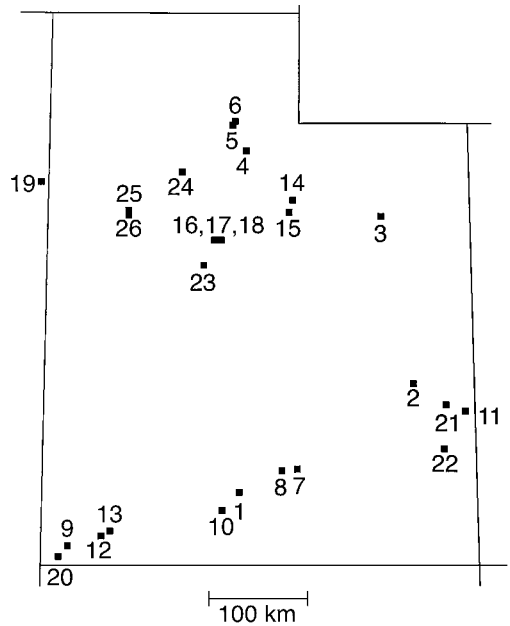

FIG. 1. Geographic locations of the sagebrush populations in and near Utah. Aspect and altitude distinguish sagebrush populations in close proximity.

(Duke and Paul, 1993; Werker, 2000). Sesquiterpene lactones, a major constituent in the glandular trichomes of sagebrush, have been shown to differ among populations (Shafizadeh et al., 1971; Kelsey et al., 1975), but within a given individual, there is no qualitative variation with respect to ontogeny or season (Kelsey, 1974).

Because geographic correlations between a trait and a selective agent are indicative of natural selection, an analysis of geographic variation in host–pathogen interactions is a valuable first step in understanding adaptation (Endler, 1986; Burdon and Thrall, 1999; Lively, 1999; Gomulkiewicz et al., 2000). To test whether selection by fungal pathogens has led to interpopulational differences in the leaf-surface secondary metabolites of sagebrush, we chose 26 populations occurring in diverse habitats and climates in the Intermountain West (Figure 1). Our previous work showed that secondary metabolites of sagebrush had a genetic basis and differed in both number and identity among populations (Talley, 2001). To estimate the potential selective pressure imposed by pathogenic fungi, we measured the fungal abundance and richness within each sagebrush habitat as well as climate conditions likely responsible for fungal prevalence (Talley et al., 2002). We found that fungal abundance and richness varied among populations and were negatively

correlated with vapor pressure deficit (VPD, a measure of the desiccating capacity of the air), temperature, and the average number of consecutive days with maximum diurnal relative humidity $<50\%$, and positively correlated with daily maximum relative humidity (Table 1).

If natural selection has played a role in the evolution of sagebrush antifungal secondary metabolites, among-population variation in these defenses should correspond to the likelihood of attack by fungi. Here, we ask if sagebrush populations in habitats favorable to fungi have a greater activity and a greater number of antifungal secondary metabolites than sagebrush populations in drier habitats. We also examine the possibility that these metabolites might have alternative functions. Finally, we test the prediction that the extent of fungal disease found in the field is a function of both the abundance of fungal pathogens in the sagebrush habitat and the level of antifungal defenses in the sagebrush population. These data, along with our evidence for heritable variation in sagebrush antifungal metabolites (Talley, 2001), will provide a test of the hypothesis that pathogens are important in shaping plant defensive chemistry.

METHODS AND MATERIALS

Study Sites. Twenty-six sites were chosen within the Intermountain West (Figure 1; Appendix A). These included a range of community types: arid grasslands with cacti and yucca; semiarid shrub-steppes with juniper, pinyon pine, and shrubs; moderately arid scrublands with scrub oak; riparian communities with cottonwoods; and subalpine communities with tall forbs, aspen, and spruce.

For 19 of the sites, we recorded the average relative humidity and temperature every 30 min for a complete growing season (mid-March 1999 to mid-October 1999), by using NOMAD dataloggers protected in a weather-proof casing (OM-NOMAD-RH-32; Omega Engineering, Inc; Stamford, Connecticut, USA).

The coolest site (average temperature of 5.6°C for the growing season) had an average VPD of 0.56 kPa. The hottest site (21.8°C) had an average VPD of 2.53 kPa. The average diurnal maximum in relative humidity ranged from 40% to 97% among sagebrush habitats. Higher elevations were generally moister and cooler than lower elevations.

Quantifying Fungal Prevalence. We used the prevalence of fungi in a habitat as an index of the potential selective pressures by fungal pathogens. To quantify prevalence, we measured the abundance and richness of fungi sampled from air and leaf surfaces of nonsagebrush vegetation at each site. We also sampled fungi from the surface of sagebrush leaves to provide another measure of fungal prevalence.

During September of 1998, we measured the fungal abundance and richness on the leaves of sagebrush at 21 of the study sites. Using sterilized scissors,

[a] Values are coefficients of determination (r^2) with the sign of the slope in parentheses. The relationship of fungal abundance and richness with climate parameters is from Talley et al. (2002). Climate parameters are averages for the growing season (March to October, 1999). "*Sacchar.*" = *Saccharomyces.*

we collected 1 cm^2 of leaf material from each of seven haphazardly chosen plants and placed them in a sterile vial (i.e., the seven samples were combined). Leaf samples were stored at 4°C for 1–7 days before culturing. The relationship of diversity and abundance of culturable fungi with storage time was not determined. To remove fungi from leaf surfaces, we soaked and vortexed leaf samples for 15 sec in 7 ml of a sterile aqueous solution containing a 0.5% sodium chloride, 2.0% casein, and 4.0% sucrose. We spread 250 μl of the inoculated solution onto media in Petri dishes (10 cm diam.). We used three types of media all containing 2% granulated agar (Difco, Detroit, Michigan, USA): (1) potato sucrose agar [similar to potato dextrose agar except sucrose is used instead of dextrose (Dhingra and Sinclair, 1995)], (2) casein agar (for 1 L, 5 g casein, 0.5 g NaCl, and 20 g sucrose), and (3) sagebrush-leaf agar. To prepare the sagebrush-leaf agar, we removed surface secondary metabolites on 80 g of fresh sagebrush leaves by washing them in 400 ml of chloroform for 3 min and washing again in 200 ml of chloroform for 1 min. The leaf-surface secondary metabolites were not included in the medium, because they may contain antifungal properties. Leaves were placed under a hood for 1 d in order to remove chloroform and then dried at 70°C to constant weight (1–2 ds). We homogenized dried leaves in 900 ml of water and filtered the leaf extract (Whatman No. 1). We combined 500 ml of leaf extract, 250 ml of H_2O, and 250 ml of Czapek's minerals [(Dhingra and Sinclair, 1995) (1 l of Czapek's aqueous solution contained 2 g $NaNO_3$, 1 g KH_2PO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.5 g KCl, 0.01 g $FeSO_4$, and 1 ml of an aqueous solution of 1% $ZnSO_4$ and 0.5% $CuSO_4$)]. All three media contained ampicillin (60 μg/ml) to eliminate contamination by bacteria. For each site, there were two plates each of potato sucrose agar, casein agar, and sagebrush-leaf agar, giving six plates total per site. We incubated the inoculated plates at ambient temperature (approximately 22°C) for 4 d and examined them. We found little change in the number of colonies after 4 days.

Under a dissecting microscope (10–50 X), we classified colonies into morphotypes based upon colony morphology (effuse, raised, domed or umbonate), color, transparency, and shape (irregular, crenated, or rhiziod). The number of morphotypes was determined for each plate separately, a total of six values per site. We scored fungal abundance as the total number of colonies per plate. We scored fungal species richness as the total number of morphotypes per plate. We did not attempt to identify species or to compare morphotypes among plates. There was no significant effect of the culture medium on abundance or richness measures (Kruskal-Wallis $\chi^2 = 0.60$; $P = 0.74$ and $\chi^2 = 3.50$; $P = 0.17$, respectively), so the fungal abundance and richness at each site was calculated as the mean of the six plates. Fungal abundance and richness on the leaf surfaces of the most common species associated with sagebrush were estimated using similar techniques. We also collected airborne fungi by vertically swiping agar plates 10 times in the air. Results from the air and the nonsagebrush vegetation were combined

and referred to as the fungal abundance and richness of the habitat (Talley et al., 2002).

Extraction of Leaf-Surface Secondary Metabolites. From mid-June to early August of 1998, we collected two replicate samples of leaves from each sagebrush population. For each sample, we pooled approximately 20 g of leaves from each of 20 individuals for each population (a total of 400 g of leaves per population). Individuals were pooled because we found little difference in secondary metabolite composition within populations (Talley, 2001), and we were primarily interested in differences among populations.

One extract was prepared from each 400-g sample (i.e., two extracts per sagebrush population). Sagebrush secondary metabolites were extracted by gently washing intact, fresh leaves for 3 min with 10 ml of chloroform per 2 g of leaves (Kelsey, 1982). We rinsed the leaves again for 10 sec with 5 ml of chloroform per 2 g of leaves. Because the leaves and leaf cuticle were intact and the extraction rapid, we believe the extracts were primarily composed of leaf-surface metabolites. The crude extract was filtered through glass wool to remove residual leaf hairs. Chloroform in the crude extract was removed under vacuum, and the leaf-surface extract was stored at -70°C. Extracted leaves were placed under a hood for 1 d to remove chloroform and dried to constant weight at 70°C (1–2 days). We determined the investment in secondary metabolites gravimetrically as the weight of extract divided by the sum of the dry weight of leaves and extract. Investment is reported as a percent. The amount of extract per leaf-surface area was obtained by extracting leaf disks of 33 mm^2, the same size as the paper disks in the antifungal disk assay (see below). Based on several populations, the average amount of secondary metabolites on 33 mm^2 of sagebrush leaves was approximately 800 μg, and we used this weight in the bioassays. Crude extracts were redissolved in chloroform at a concentration of 200 $\mu g/\mu l$. For all assays, we used 4 μl of the 200 $\mu g/\mu l$ crude extract solution to provide 800 μg/replicate.

Fungal Test Organisms for Bioassays. The relative antifungal activity of the crude extracts from sagebrush populations was determined in growth inhibition bioassays with two nonpathogenic species of fungi. We used a laboratory yeast, *Saccharomyces cerevisiae* [JSY 999 containing three auxotrophic markers, *ura* 3-5, *his* 3Δ200, *leu* 2Δ (Hermann et al., 1997)]. We also used a *Penicillium* sp. that appeared to be the most common fungus at our study sites. In addition, a fungal survey of a salt playa in Utah listed *Penicillium* as the second most common fungus (Weber et al., 2000). Neither *Penicillium* nor *Saccharomyces* are expected to be adapted to sagebrush defenses, so they can be considered as generalized test organisms that might be sensitive to the antifungal metabolites of sagebrush. *Puccinia tanaceti* (the black rust fungus) is the most common obligate pathogen of sagebrush, but was not used as a test organism because attempts by us and others to culture it *in vitro* have never been successful.

We grew *Saccharomyces* overnight (to saturation) in YPD nutrient broth (Difco) at 30°C. To prepare test plates, we inoculated 1 L of YPD nutrient agar (Difco) cooled to 56°C with 4 ml of liquid culture. We grew *Penicillium* on YPD agar in 25 cm^2 sterile NUNC bioassay dishes (Nalge Nunc International, Naperville, Illinois, USA) for 4–5 days. Spores were suspended in a nutrient broth (Homans and Fuchs, 1970) and sprayed directly onto surface of YPD agar. YPD agar contained ampicillin (60 μg/ml) to eliminate contamination by bacteria.

Antifungal Activity of Sagebrush Secondary Metabolites. Antifungal activity of the leaf-surface extract from each sagebrush population was measured as the inhibition of fungal growth around paper disks treated with sagebrush secondary metabolites. We sterilized paper disks (Whatman No. 1, 6.5 mm diam. or 33 mm^2). For both *Saccharomyces* and *Penicillium* assays, we infused three replicate disks with 4 μl of crude extract for each of the two extracts from every sagebrush population, giving six measures per sagebrush population per assay. The chloroform was evaporated in a laminar flow hood leaving 800 μg of leaf-surface extract per disk. The negative control was solvent-treated filter paper (4 μl of chloroform). For the *Saccharomyces* assay, we poured 100 ml of inoculated agar over test disks that had been aseptically glued with sterilized 2% agar to the bottom of 25 cm^2 sterile NUNC bioassay dishes (Nalge Nunc International). For the *Penicillium* assay, the infused disks were placed on the top of the inoculated agar. Plates were incubated at 30°C for 2 days. Using calipers, we measured the annulus around the disk that lacked fungal growth (the zone of inhibition). We noted the strength of inhibition visually by the clarity of the zone of inhibition. Clear zones were given a score of 1.0, zones that had little growth were scored 0.5, and zones with a lot of growth were scored 0.25. Antifungal activity per weight of secondary metabolites (800 μg) was calculated by multiplying the width of the zone by the strength of the inhibition. Because sagebrush populations varied in the amount of secondary metabolites per dry weight of the leaf, we calculated a second parameter, the total antifungal activity (activity per gram of leaf), by taking the product of antifungal activity per weight of secondary metabolites (activity per 800 μg of secondary metabolites) and secondary metabolite investment (grams of metabolites per grams of leaf).

Bioautography and Detection of Antifungal Secondary Metabolites. We used bioautography to determine which of the secondary metabolites in a crude extract were antifungal. In bioautography, compounds are separated by thin-layer (TL) chromatography, and TL chromatograms are overlaid with medium inoculated with a test organism. Areas lacking fungal growth can then be matched to particular areas on the TL chromatograms. In this study, we used two test organisms, *Saccharomyces* and *Penicillium*. Using three replicates of each of the two leaf extracts per sagebrush populations (i.e., six measures per population), we separated secondary metabolites in 800 μg of crude extract by TL chromatography (20 $\times$ by 20-cm aluminum-backed silica gel plates 60 $WF_{254}S$; EM Science, Gibbstown,

New Jersey, USA). We used a solvent system of chloroform–petroleum ether–ethyl acetate 2:2:1 v/v to separate the leaf-surface secondary metabolites (Kelsey et al., 1976). The residual solvent on the TL chromatograph was allowed to evaporate in a biohazard laminar flow hood. The total number of spots was measured as those that were visible under ultraviolet radiation (UV-B, 254 nm and UV-A, 365 nm) and were revealed by sulfuric acid. The 254-nm radiation detected metabolites that absorb at 254 nm and the 365-nm radiation detected metabolites that absorb at 365 nm and that also fluoresce efficiently. To obtain the position of the antifungal secondary metabolites, we placed TL chromatograms in sterile NUNC bioassay dishes. For *Saccharomyces* bioautography, we overlaid TL chromatograms with 40 ml of inoculated YPD nutrient agar. For *Penicillium* bioautography, we sprayed a suspension of spores in a nutrient broth onto the TL chromatogram (Homans and Fuchs, 1970). All media contained ampicillin (60 μg/ml) to eliminate contamination by bacteria. Bioautographs were incubated at 30°C for 2 days. The areas lacking fungal growth (*Saccharomyces*) or spore germination (*Penicillium)* corresponded to secondary metabolites that were antifungal. To record the activity, we overlaid bioautographs with transparencies, traced the areas that lacked fungal growth, and measured the position of the antifungal spots relative to the origin (R_f).

To determine the number of antifungal spots for each population, we considered a spot as present (value = 1) if it occurred in any of the replicates or absent if it occurred in none (value = 0). To compare the number of antifungal spots to the number of visible secondary metabolites, we recorded all spots on the TL chromatograms when viewed under UV and when developed with concentrated sulfuric acid followed by heating for 2 min. The number and position of secondary metabolites were recorded with color photocopies and digital photographs. Our estimates of the number of antifungal secondary metabolites may be conservative, because TLC separates secondary metabolites by polarity, and several antifungal secondary metabolites can comigrate forming a single antifungal spot. Furthermore, secondary metabolites that degrade after extraction and those that work synergistically may not be detectable.

Alternative Functions for Antifungal Secondary Metabolites. We examined whether the antifungal secondary metabolite spots on the bioautograph have alternative functions such as protection from ultraviolet light or oxidation. To determine whether spots on the bioautograph also absorb UV radiation, we visually compared the location of spots absorbing at 254 nm and fluorescing at 365 nm with the location of the antifungal spots.

We determined whether the antifungal spots on the bioautograph could also function as antioxidants. To determine which spots on the bioautograph were antioxidant, we sprayed TL chromatograms with an oxidant solution of 9.0 mg β-carotene (all reagents from Sigma, St. Louis, Missouri, USA) in 30 ml of chloroform, 60 ml of ethanol, and two drops of linoleic acid (Pratt and Miller, 1984). There were three experiments per extract and two extracts per population for a total of six

measures per sagebrush population. We used 200 μg of DL-α-tocopherol acetate and 200 μg of ascorbic acid as positive controls. Plates were placed under an UV-B radiation emitting light and observed for bleaching. Spots on the TL chromatogram that remained orange corresponded to antioxidant secondary metabolites. The positions of the antioxidant secondary metabolites were sketched on the plates with a pencil. Plates were examined every 30 min for 3 hr, and we scored the antioxidant strength of the compounds based upon the length of the time that spots remained orange. In particular, we scored the antioxidant strength of the regions of the TL chromatograph that also showed antifungal activity in the bioautographs with the two fungi.

Soil Analyses. We measured soil properties that might influence plant vitality. To control for variation in soil nutrients due to seasonal fluctuations, we collected soil from 22 sites within a month during the spring of 1999. We discarded the top 5 cm of soil and collected 2–3 kg of soil up to a depth of 20 cm. We dried soil samples for 48 hr or until constant weight at 105°C. We determined the percent silt and clay with a hydrometer. We determined soil pH using 15 g of ground soil in 30 ml of distilled water. To determine percent organic carbon and nitrogen of soil by mass spectroscopy, we first removed the inorganic carbon by bringing soil samples to a pH between 4 and 5 with 5N HCl. Soil samples were then flash combusted on an elemental analyzer (Carlo Erba, Milan, Italy) coupled to an isotope ratio mass spectrometer (Finnigan MAT, Bremen, Germany) operated in continuous flow mode.

Fungal Disease. The most common disease-causing organism on sagebrush in our study was *Puccinia tanaceti*, an obligate pathogen of sagebrush. All spore stages of *P. tanaceti* are reported to occur on one host (Welch and Nelson, 1995), and we are unaware of reports of alternative hosts for *P. tanaceti* on species that cooccur with sagebrush. *P. tanaceti* produces characteristic pustules from sporulation of the black telial sori on the leaf surfaces (Welch and Nelson, 1995). Identification of *P. tanaceti* on leaf specimens was confirmed by D. L. Nelson (personal communication). During October 1999, we scored 25 individuals in each sagebrush population for *P. tanaceti* disease. The fall is the best time of year to score sagebrush plants visually for the presence of *P. tanaceti* disease because that is when the telial sori are present on the persistent leaves (Welch and Nelson, 1995). We chose plants in a population by generating random numbers that corresponded to the distance a plant was along a transect through the population. Disease is commonly reported in two ways: incidence, which is the proportion of individuals in a population that are diseased, and severity, which is the degree to which the individuals in a population are diseased. Because sagebrush has small leaves and diseased leaves generally have multiple pustules, we measured the severity of the disease by examining the entire plant and estimating the percent of diseased leaves on a plant as 0, 5%, 10%, 15%, 20%, 25%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, 95%, or 100%.

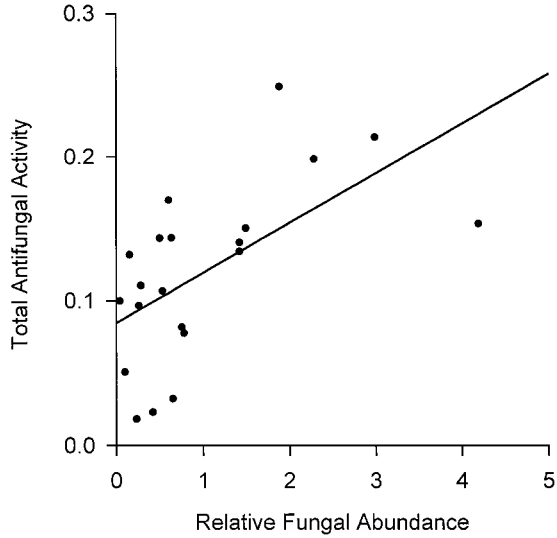

FIG. 2. Total antifungal activity of sagebrush secondary metabolites against *Saccharomyces* as a function of the fungal abundance in the habitat ($r^2 = 0.36$, $P < 0.004$; antifungal activity $= 0.08 + 0.03 \times$ fungal abundance). The units for total antifungal activity are millimeters times grams of secondary metabolites divided by the leaf dry weight where millimeters refer to the width of the zone of inhibition.

Statistical Analyses. We performed univariate and multivariate statistical analyses in SYSTAT, Version 7 (Wilkerson, 1988) and JMP (SAS Institute Inc., Cary, North Carolina, USA). For differences among populations and moisture categories, we applied Kruskal-Wallis nonparametric analysis. Using simple linear regression, we analyzed antifungal activity or the number of antifungal secondary metabolites as a function of fungal abundance and richness and climate parameters.

RESULTS

Relationship of Antifungal Activity with Fungal Prevalence in Habitat and with Climate. We found greater total antifungal activity of sagebrush leaf-surface secondary metabolites in habitats with greater fungal abundance (Table 1; Figure 2; Appendices A and B). Fungal abundance explained 36% and 37% of the variance in antifungal activity in the *Saccharomyces* and *Penicillium* bioassays, respectively. Fungal abundance in the habitat was also positively related to the antifungal activity per weight of metabolites, explaining 29% of the variance in the *Saccharomyces* bioassays and 30% in the *Penicillium* bioassays (Table 1). Even though *Saccharomyces* (Hemiascomycetes) and *Penicillium* (Euascomycetes) are not closely

related fungi, the total activity of secondary metabolites against *Saccharomyces* and *Penicillium* were highly correlated ($r = 0.995$, $P < 0.001$), suggesting broad-spectrum, antifungal activities.

The climate variables that were most highly correlated with the fungal abundance and richness of the habitat (Talley et al., 2002) also were good predictors of total antifungal activity of sagebrush secondary metabolites (Figure 3; Table 1). The climate variable that explained the most variance in total antifungal activity among sagebrush populations was the average VPD, a measure of the desiccating capacity of the air (for example, for total antifungal activity against *Saccharomyces*, $r^2 = 0.60$, $P < 0.001$; Figure 3a; Table 1). A climate variable expressing the duration of unfavorable conditions to fungi, the average number of consecutive days with maximum diurnal relative humidity <50%, was the best predictor of fungal abundance and richness in the habitat (Table 1) (Talley et al., 2002). This climate measure also was negatively related to the total antifungal activity of the sagebrush secondary metabolites against *Saccharomyces* (Figure 3b) and *Penicillium* (Table 1). Similar relationships were found for climate variables and antifungal activity per weight of metabolites (Table 1).

Composition and Number of Antifungal Secondary Metabolites. The bioautograph was divided into six regions, and each region was scored for antifungal secondary metabolites (see Appendix C). Because the regions were broadly defined, the "same" spot from different populations may contain different secondary metabolites that have similar polarities. The number of antifungal secondary metabolites ranged from 0 to 6 among sagebrush populations, and most populations had a unique combination of active spots (Appendix C). Spot 1 was the most common antifungal spot on the *Penicillium* bioautographs, found in 21 of 26 sagebrush populations, but was present in only 3 of 23 sagebrush populations in the *Saccharomyces* bioautographs. Spot 5 was the most common in the *Saccharomyces* bioautographs, found in 12 of 23 sagebrush populations, but also occurred in the *Penicillium* bioautographs (14 of the 26 populations). It is unlikely that among-population variation was due to individual variation within a population. In a related study, we found that most secondary metabolites characteristic of each population were shared by most or all of the individuals within that population (Talley, 2001). Plasticity in response to environmental variation was not investigated. We also found that fungal abundance in the habitat was positively related to the number of antifungal spots in the *Saccharomyces* bioautography ($r^2 = 0.34$, $P < 0.01$; Figure 4), but not the *Penicillium* bioautography ($r^2 = 0.12$, $P = 0.10$).

We found no relationship between the number of antifungal spots and the total number of detectable spots, indicating that increased activity and diversity of antifungal secondary metabolites was not a simple reflection of an increase in the total diversity of secondary metabolites ($r = 0.20$, $P = 0.55$ for *Penicillium*; $r = 0.24$, $P = 0.25$ for *Saccharomyces*). The number of antifungal spots on the bioautographs was highly correlated with the antifungal activity per mass of

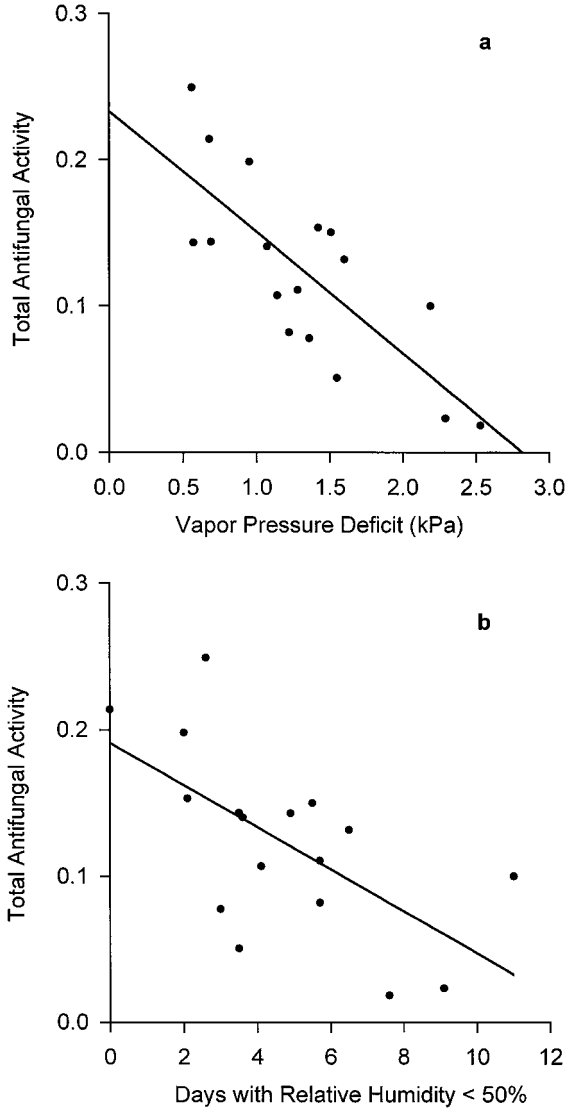

FIG. 3. (**a**) Total antifungal activity of sagebrush secondary metabolites against *Saccharomyces* as a function of the average VPD of the sagebrush habitats ($r^2 = 0.60$, $P < 0.001$; antifungal activity $= 0.23 - 0.08 \times$ the average VPD). (**b**) Total antifungal activity of sagebrush secondary metabolites against *Saccharomyces* as a function of the average number of consecutive days with maximum diurnal relative humidity less than 50% (arh50) ($r^2 = 0.40$, $P < 0.006$; antifungal activity $= 0.19 - 0.01 \times$ arh50). The units for total antifungal activity are millimeters times grams of secondary metabolites divided by the leaf dry weight where millimeters refer to the width of the zone of inhibition.

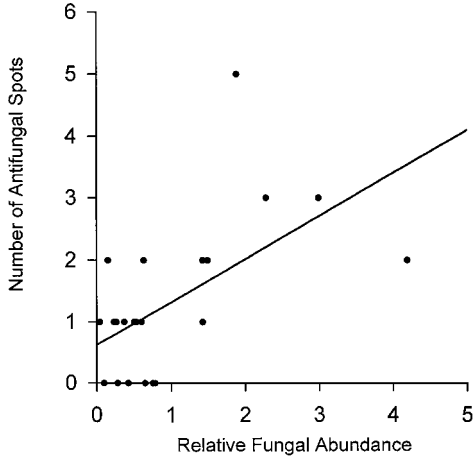

FIG. 4. The number of antifungal spots from *Saccharomyces* bioautography as a function of the fungal abundance in the habitat ($r^2 = 0.34$, $P < 0.005$; number of antifungal spots $= 0.62 + 0.69 \times$ fungal abundance).

metabolites for both *Saccharomyces* and *Penicillium* ($r = 0.85$, $P < 0.001$ and $r = 0.68$, $P < 0.001$, respectively), indicating that the number of antifungal metabolites also contributes to antifungal activity.

Investment in Leaf-Surface Secondary Metabolites. Investment in leaf-surface secondary metabolites averaged 17% (± 2%) of total leaf dry weight, ranging from 12% to 22% across sagebrush populations (Appendix A). We found no relationship between investment in secondary metabolites and fungal abundance in the habitat ($r = 0.17$, $P = 0.41$). The investment in secondary metabolites was not related to climate parameters such as VPD ($r = 0.32$, $P = 0.19$) nor the average number of consecutive days with maximum diurnal relative humidity <50% ($r = 0.33$, $P = 0.18$). We also found no relationship between investment in secondary metabolites and the number of detectable compounds ($r = 0.01$, $P = 0.97$), the antifungal activity per weight of metabolites in the *Saccharomyces* assay ($r = 0.39$, $P = 0.08$), or the number of antifungal compounds in the *Saccharomyces* bioautography ($r = 0.04$, $P = 0.82$). Thus, there was no relationship between the investment in secondary metabolites and either the activity or the diversity of secondary metabolites. The significant positive relationship between total antifungal activity and fungal abundance was, therefore, not due to greater investments in secondary metabolites, but due to greater activity per gram of metabolite.

Alternative Functions for Antifungal Secondary Metabolites. We found no correlation between the number of antifungal spots on the bioautograph and the number of spots absorbing UV light at 254 nm and 365 nm, the number of antioxidant spots, or the strength of the antioxidant spots on the TL chromatograms

of sagebrush secondary metabolites (either for *Saccharomyces* or *Penicillium*, Appendix C). Furthermore, we found no significant relationships between the number of UV absorbing and antioxidant spots or the strength of the antioxidant spots with investment in secondary metabolites, climate variables, geographic location, or fungal abundance and richness.

Relative Fungal Abundance and Richness on Sagebrush Vegetation. The fungal abundance in the habitat was positively correlated with fungal abundance on sagebrush leaves ($r = 0.47$, $P < 0.03$), and the fungal richness in the habitat was positively correlated with the fungal richness on sagebrush leaves ($r = 0.58$, $P < 0.005$). Fungal abundance and richness on the sagebrush leaves were positively correlated ($r = 0.62$, $P < 0.003$).

For *Saccharomyces*, fungal abundance on sagebrush leaves was positively correlated with both the antifungal activity per weight of metabolites and the number of antifungal secondary metabolites ($r = 0.50$, $P < 0.03$; $r = 0.54$, $P < 0.02$, respectively). For *Penicillium*, fungal abundance on sagebrush leaves was positively correlated with the antifungal activity per weight of metabolites ($r = 0.50$, $P < 0.04$), but not the number of antifungal secondary metabolites ($r = 0.17$, $P = 0.44$). There was no relationship between fungal abundance on sagebrush leaves and the total antifungal activity for *Saccharomyces* and *Penicillium*. Fungal abundance in the habitat, assayed as airborne fungi and from leaves of nonsagebrush species, generally had stronger relationships with antifungal activity and climate parameters than did fungal abundance on sagebrush leaves. The leaf-surface antifungal secondary metabolites of sagebrush may eliminate many fungi. Hence, fungal abundance in the habitat may better measure fungal abundance than fungal abundance on sagebrush leaves.

Relationship of Antifungal Activity and Metabolites with Soil Characteristics. We found positive relationships between soil organic carbon and nitrogen and antifungal activity per weight of metabolites in the *Saccharomyces* assay ($r = 0.68$, $P < 0.001$; $r = 0.75$, $P < 0.001$, respectively) and in the *Penicillium* assay ($r = 0.67$, $P < 0.001$; $r = 0.74$, $P < 0.001$, respectively). We also found positive relationships between soil organic carbon and nitrogen and the number of antifungal metabolites in the *Saccharomyces* ($r = 0.65$, $P < 0.001$; $r = 0.69$, $P < 0.001$, respectively) and the *Penicillium* ($r = 0.45$, $P < 0.05$; $r = 0.57$, $P < 0.01$, respectively) bioautographies. Antifungal activity and metabolites did not correlate with soil pH, sand, silt, or clay.

Fungal Disease on Sagebrush. We examined rust disease caused by the obligate fungal pathogen, *Puccinia tanaceti* DC, (Appendix A) as a function of fungal abundance in the habitat, climate variables, and antifungal activity of sagebrush secondary metabolites. Fungal abundance in the habitat positively correlated with variation in rust incidence ($r = 0.42$, $P < 0.03$) and severity ($r = 0.40$, $P < 0.05$) among sagebrush populations even though *P. tanaceti* was not cultured by our fungal census methods. We found no correlation of rust on sagebrush either

with climate or with antifungal activity against *Saccharomyces* or *Penicillium* when variables were considered singly. However, using multiple regression, total antifungal activity combined with the fungal abundance in the habitat explained a significant portion of the variance among populations ($P < 0.05$) for rust incidence ($r^2 = 0.25$ for *Penicillium*, $r^2 = 0.25$ for *Saccharomyces*) and severity ($r^2 = 0.30$ for *Penicillium*, $r^2 = 0.30$ for *Saccharomyces*), suggesting that disease depends on both plant defenses and fungal prevalence.

Comparisons among Habitat Types. To compare potential selection gradients and sagebrush responses among habitats, we divided sagebrush populations into classes of low and high available moisture (based on the VPD of the sagebrush habitat, Figure 5). Sites with high available moisture had a greater fungal abundance in the habitat than sagebrush habitats with low available moisture

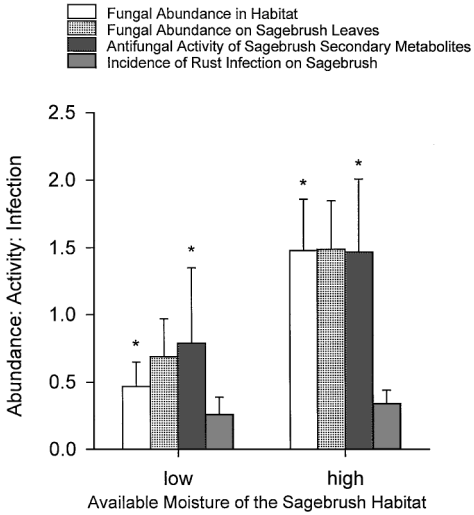

FIG. 5. Fungal abundance in the habitat, fungal abundance on sagebrush leaves, total antifungal activity of sagebrush secondary metabolites against *Saccharomyces*, and incidence of *P. tanaceti* diseases on sagebrush in habitats with high or low moisture availability. Sagebrush populations were divided into low and high available moisture groups based on the VPD of the sagebrush habitat (low moisture = 2.53 to 1.51 kPa, $N = 8$ sites; high moisture = 1.42 to 0.56 kPa, $N = 11$ sites). Fungal abundance is a normalized measure of the number of fungal colonies per plate from both air and vegetation sampling (Talley, 2001). The units for total antifungal activity are mm x g secondary metabolites divided by the leaf dry weight where mm refers to the width of the zone of inhibition. The values for total antifungal activity were multiplied by 10 to make them visible on the figure. Incidence is the proportion of infected individuals within a population. *Statistically significant ($P < 0.05$) differences between sagebrush habitats with high and low available moisture.

(Kruskal-Wallis, $\chi^2 = 5.73$, $P = 0.02$). We found a nonsignificant trend for the fungal abundance and richness on sagebrush leaves ($\chi^2 = 1.71$, $P = 0.19$; $\chi^2 = 0.12$, $P = 0.72$, respectively). Sagebrush populations with high available moisture had greater total antifungal activity of secondary metabolites against *Saccharomyces* ($\chi^2 = 4.04$, $P = 0.04$) and *Penicillium* ($\chi^2 = 4.04$, $P = 0.04$) than sagebrush habitats with low available moisture. We found no difference between low and high moisture classes in the incidence ($\chi^2 = 1.12$, $P = 0.29$) or severity ($\chi^2 = 1.03$, $P = 0.31$) of rust disease caused by *P. tanaceti*.

DISCUSSION

Sagebrush populations are broadly distributed among a range of habitats and climates and may, therefore, have adapted to the local abiotic and biotic selective pressures. Although summer drought is considered to be the most important stress in the region dominated by sagebrush, we propose that pathogens also may be important selective agents. Fungi are mainly limited by moisture and temperature (Cooke and Whipps, 1993; Harrison et al., 1994; Jones, 1998) and are more abundant and speciose in sage habitats with high relative humidity and moderate temperatures than in drier, hotter habitats (Talley et al., 2002). Our data suggest that sagebrush populations that occur in a broad range of habitats experience different levels of selection by fungi, and correspondingly produce different profiles of antifungal secondary metabolites. Furthermore, the primary location of those compounds on the leaf surface is consistent with their role as a defense mechanism against fungi.

Sagebrush makes a substantial investment in leaf-surface metabolites, averaging 17% of dry weight [similar results were found by Kelsey et al. (1983)]. We found that the total antifungal activity of leaf-surface secondary metabolites was positively related to fungal prevalence in the habitat and climate variables favorable to fungi (Table 1, Figure 2). However, the investment in all leaf-surface secondary metabolites (grams of metabolites per grams dry weight of the leaf) was not correlated with fungal prevalence in the habitat or climate. Nor was the investment in all secondary metabolites correlated with either the antifungal activity per weight of metabolites or with the number of antifungal secondary metabolites. These results suggest that most leaf-surface secondary metabolites have little or no antifungal activity. Hence, investment in all secondary metabolites *per se* is not a good measure of sagebrush defense against fungi.

Instead, differences in total antifungal activity among sagebrush populations were due to differences in the toxicity of metabolites to fungi and in secondary metabolite composition. Sagebrush populations in mesic habitats with climates favorable to fungi had greater activity per grams of metabolite and a greater number of antifungal spots as compared to sagebrush populations in habitats with climates

unfavorable to fungi (Table 1). The fact that these results were obtained in assays with fungi from two families of ascomycetes suggests that sagebrush secondary metabolites may function as a defense against a variety of fungi.

Our data are consistent with the hypothesis that plant enemies select for both elevated levels of defense as well as a greater diversity of defensive secondary metabolites. More antifungal secondary metabolites may evolve in plants of high-risk habitats in order to balance the asymmetries in plant–pathogen interactions. In other words, the large effective population sizes and short generation times of pathogens could lead to rapid changes in the species composition of the pathogen community and in gene frequencies within a population of pathogens (May and Anderson, 1990). Under such conditions, multiple antifungal secondary metabolites may provide more effective defense against fungal pathogens. Elucidation of the structure of sagebrush antifungal secondary metabolites may also provide a test of the hypothesis that more active compounds are more biosynthetically derived (Berenbaum, 1978).

Soil nitrogen and organic carbon (but not soil pH or texture) are positively correlated with antifungal activity and metabolites. Although environmental interactions may affect the production of secondary metabolites, we found that sagebrush grown from seeds in a greenhouse retained the secondary metabolite composition and antifungal characteristics of their parent populations (Talley, 2001). Hence, correlation of the soil with antifungal compounds may not be indicative of plant environmental responses, and the differences in antifungal secondary metabolites among sagebrush populations probably have a genetic basis.

Our evidence for a genetic basis of antifungal secondary metabolites as well as for a correlation between antifungal activity and fungal prevalence in the habitat suggests that variation in leaf-surface metabolites may be a consequence of differential selection by fungal pathogens. However, with correlative studies it is difficult to eliminate the possibility that a third factor, which covaries with fungal abundance, may be the real selective agent. For example, antifungal secondary metabolites may have alternative functions, such as UV or oxidation protection, reflection of light, and defense against other sagebrush enemies. Although it is impossible to rule out all alternative functions, we evaluated several of the most likely abiotic functions. One would expect that the UV-B absorbing and antioxidant potential of secondary metabolites would correlate with UV flux as influenced by elevation and latitude. However, we found no such relationship of UV absorbing potential and antioxidant potential with climate or any geographic parameters. There was also no relationship of the number of UV absorbing spots and antioxidant spots with either antifungal activity, the number of secondary metabolites, or fungal abundance and richness in the habitat. Trichomes (and their contents) may function by reflecting light, but this would predict more trichomes in arid habitats (Ehleringer and Mooney, 1978). Instead, we found no evidence for an effect of climate on the investment in leaf-surface secondary metabolites. Thus, we

found no evidence that the antifungal secondary metabolites are serving alternative functions against abiotic stress that would create confounding selection gradients among our study sites.

Our results also suggest that herbivores are probably not important selective agents driving the geographic variation we found in the antifungal secondarymetabolites of sagebrush. If herbivores were important, one might predict a general response for most of the secondary metabolites, but in our study, only the small subset of metabolites (six out of 44) that were antifungal showed a correlation with fungal abundance. The specificity of this response suggests that fungi, rather than other selective agents, are probably the main selective agent influencing the distribution of bioactive secondary metabolites in sagebrush.

Another requirement for demonstrating natural selection is to show that differences in antifungal secondary metabolites lead to differences in plant fitness. As a partial test, we examined the incidence of rust disease caused by the most obvious pathogen on sagebrush, *Puccinia tanaceti*. *P. tanaceti* is an obligate pathogen on sagebrush and can cause a 10-fold reduction in seed production (Welch and Nelson, 1995). Given the potential negative impact on fitness, sagebrush should be selected to have defenses against *P. tanaceti.* We found that rust incidence and severity were not correlated with climate variables and were similar among populations from dry and moist habitats (Figure 5). We suggest that this arises because rust disease is a function of both the favorability of the habitat for fungi and of the defense afforded by leaf-surface secondary metabolites. For example, in hot, dry habitats, sagebrush invests little in antifungal defenses, but harsh abiotic conditions reduce fungal abundance, leading to reduced rust incidence and severity. In contrast, in moist, cool habitats, where there is high fungal abundance and high investment in secondary metabolites by sagebrush, plant defense metabolites have reduced rust incidence and severity. Thus, rust incidence may result from a balance between the prevalence of *P. tanaceti* in the environment and the effectiveness of antifungal defenses in the host plants. Censusing *P. tanaceti* over multiple years, combined with common garden experiments, would provide a test of this hypothesis. We cannot definitively affirm that disease incidence in our study populations is independent of other plant defenses (i.e., leaf toughness, trichome density) because we did not assess variation in the plant defenses.

An alternative interpretation of our results is that rust incidence and severity do not vary geographically because (1) *P. tanaceti* is not sensitive to the same antifungal secondary metabolites as *Saccharomyces* and *Penicillium*, or (2) fungal prevalence does not reflect *P. tanaceti* abundance. Because it was not possible to culture *P. tanaceti* from spores, we could not conduct bioassays to measure toxicity of metabolites against *P. tanaceti.* However, two pieces of evidence suggest that the distribution of *P. tanaceti* across habitats mirrors our measure of fungal prevalence. First, rust was positively correlated with fungal abundance ($r = 0.42$, $P < 0.03$),

suggesting that *P. tanaceti* abundance may vary with environmental conditions in a manner parallel to the other fungi in our study. Second, other *Puccinia* species have moisture and temperature optima that are similar to most mesophils and are consistent with preferences for moist sites (Burrage, 1970; de Vallavielle-Pope, 1995; Hau and de Vallavielle-Pope, 1998; Geagea et al., 1999). Thus, it seems likely that *P. tanaceti* is more prevalent in moist sites but that rust incidence is kept low by effective antifungal metabolites.

The qualitative and quantitative differences in secondary metabolites among sagebrush populations suggest not only that selective pressures by fungal pathogens differ among populations, but also that plant responses to selection represent independent solutions. If all populations in sites with high fungal prevalence had similar secondary metabolites, one might conclude that effective defenses had arisen once and were maintained as the well-defended genotypes spread into similar habitats. This result may be the case for two high-altitude populations of sagebrush that are separated by less than 13 km, Racetrack and Strawberry. Both have highly active extracts with antifungal spots that are similar in number and intensity (Appendix C). However, our data suggest that, although populations from fungal-rich habitats are all well defended, many have arrived at unique solutions, presumably by independent evolutionary trajectories. For example, three of the populations with the most highly antifungal extracts (Emigration, La Sal, and Racetrack) differed in the number of antifungal secondary metabolites, and even shared spots varied in strength (Appendix C). Similarly, when comparing three adjacent populations that differ in altitude but are less than 6 km apart (Tintic High, Tintic Low, and Tintic Wash), the number and activity of secondary metabolites also differed, following trends predicted by fungal abundance (Appendix C). Thus, related populations that appear to differ in potential selective pressures imposed by fungi and in their defensive secondary metabolites likely have independently derived different suites of antifungal defenses.

In summary, much remains to be learned about the evolutionary paradigm of how secondary metabolite defenses arise and are maintained in plants. Consequently, the evolution of plant secondary metabolites due to selection by herbivores and pathogens currently is an area of great interest (Marquis and Alexander, 1992). Nevertheless, the role of pathogens in driving the evolution of secondary metabolites is little understood. To our knowledge, we report the first intraspecific evidence relating the activity and number of antifungal secondary metabolites to fungal prevalence among a large number of natural plant populations. Despite complications in showing that a particular secondary metabolite evolved in response to a particular plant enemy, the relationship between estimated attack levels by plant enemies and the level and diversity of antifungal secondary metabolites provides strong correlative evidence that fungal pathogens have selected for plant chemical defense.

APPENDIX A. LOCATION, FUNGAL PREVALENCE OF HABITAT, RUST, AND INVESTMENT IN SAGEBRUSH SECONDARY METABOLITES[a]

Site No.	Site Name	Elevation (m)	Latitude	Longitude	Fungal abundance in habitat	Rust incidence	Rust severity	Secondary metabolite investment (% dry weight)

[a] "nd": no data. The R_f values indicate the range within which the spots occur. Based on the clarity and inhibition of the spot, we scored the strength of the spot 1.00 for strong, 0.25 for weak and 0.025 for very weak. The antifungal value for a specific spot from a population was calculated by averaging the values among all six replicates. The highest antifungal value that a spot could attain was 1.0, which meant that the spot was strong among all six replicates.

Acknowledgments—We thank Drs. Greg Gilbert, Donald Feener, Denise Dearing, Jon Seger, John Lokvam, Durant McArthur, Leila Shultz, Alma Winward, and Dale Clayton for advice. We are grateful to Dr. Steve Krueger for mapping field sites and to Jonathan Monsor, Mary Moffitt, and Charles Talley for help in the field. Additional thanks to undergraduates Evan Christensen, Derek Hewitt, Angela Hancock, Mara Haslam, and Sandar Lazar for laboratory work. This study was supported by NIH (5 T32 GM07464, Training Program in Genetics, the University of Utah), NSF (DEB 9420031), the Gold Scholarship (Department of Biology, University of Utah), and The Undergraduate Bioscience Research Program (Department of Biology, University of Utah).

(Received February 8, 2002; accepted June 14, 2002)

Abstract—A study was undertaken to assess the effect of parthenin—a sesquiterpene lactone from *Parthenium hysterophorus*—on the germination, growth, and some associated physiological changes in *Ageratum conyzoides*. The study reveals that germination and growth of *A. conyzoides* was severely reduced by parthenin in the concentration range of 50, 100, and 200 μM, while at 400 μM a complete inhibition of germination was observed. The radicle length of *A. conyzoides* was reduced more than the plumule length. Further, the content of the photosynthetic pigment chlorophyll was appreciably reduced in the leaves of test plants spray treated with parthenin at 200 μM concentration. However, this inhibitory effect declined with the passage of time and at 10 days after treatment only a 25% reduction in chlorophyll content was observed compared to 76% on the first day after spray. Likewise, the cellular respiration measured through 2,3,5-triphenyl tetrazolium chloride was found to be less in the treated leaves, and the inhibitory response also declined with time. The content of proteins and carbohydrates decreased with the passage of time after parthenin treatment. The specific activities of the enzymes protease and α- and β-amylase were also adversely affected in the parthenin treated leaves. In the case of protease, the activity decreased with passage of time while those of the amylases increased. Thus, we conclude that parthenin affects the germination and growth of *A. conyzoides* by altering the contents of some macromolecules

and the specific activities of some enzymes. Such observations may be helpful in further exploring parthenin's mode of action.

Key Words—Parthenin, allelochemical, growth, chlorophyll content, enzyme activities, protein content, carbohydrate content.

INTRODUCTION

Plants produce many compounds that play a useful function in their interaction with the environment (Paiva, 2000). These compounds often make plants more successful in terms of competition and reproductive vigor. They are also often responsible for imparting allelopathic activity to plants, including microbes (Rice, 1984). One of the applied aspects of allelopathy is to use allelochemicals as natural herbicides for weed management. Although natural product allelochemicals have been commercially utilized as insecticides, fungicides, and bactericides, their role as natural herbicides has been neglected. One significant aspect of their use as herbicides is that they are relatively environmentally safe and possess novel target sites different from those of traditional herbicides and can, thus, be useful in controlling weeds, particularly those resistant to herbicides (Devine et al., 1993; Dayan et al., 1999b; Duke et al., 2000; Macias et al., 2001).

Sesquiterpene lactones constitute a large group of compounds exhibiting diverse biological activity (Rodriguez et al., 1976; Picman, 1986; Fischer et al., 1989; Macias et al., 1996). These are active even at low concentrations and exhibit specific structure–activity relationships (Beekman et al., 1997; Macias et al., 1999, 2001). Among several biologically active compounds, the phytotoxic potential of sesquiterpene lactones is widely known (Dalvi et al., 1971; Del Amo and Anaya, 1978; Saxena et al., 1991; Macias et al., 1993, 1996, 1998; Dayan et al., 1999a; Galindo et al., 1999). Parthenin, a sesquiterpene lactone and major constituent of tropical weed *Parthenium hysterophorus*, is a known inhibitor of growth (Kanchan and Jayachandra, 1980; Saxena et al., 1991; Kohli et al., 1993; Batish et al., 1997). It is present in the aerial parts of the weed and is known to have a number of properties, such as allerginicity, allelopathic potential, autotoxicity, and toxicity to livestock (Kohli and Rani, 1994). In addition, recently, its pesticidal potential has been explored in terms of ovicidal, antifeedant, herbicidal, and nematicidal activity (Datta and Saxena, 2001). However, little has been done to explore its herbicidal potential except for a toxicity study in aquatic weeds (Pandey, 1996) and one in terrestrial weeds (Batish et al., 1997). For a compound to be an ideal herbicide, it should inhibit seed germination of target species completely with little or no effect on nontarget plants such as crops. Species specificity, thus, is an important aspect of natural herbicides. Parthenin exhibited this property in experiments with *Triticum aestivum* (wheat) and *Ageratum conyzoides* (bill goat weed) where it inhibited germination of *A. conyzoides* but not wheat (Batish et al., 1997).

However, there are no further reports on the phytotoxicity of parthenin towards *A. conyzoides*—a weed commonly associated with wheat in hilly tracts of north India. The present study was conducted to determine the effect of parthenin on the germination and seedling growth of *A. conyzoides* and on related physiological and biochemical characteristics such as chlorophyll content, respiratory activity, water content, soluble protein and carbohydrate concentrations, and protease, α-amylase, and β-amylase enzyme activities.

METHODS AND MATERIALS

Extraction of Parthenin. Parthenin was extracted from the shade-dried powdered leaves of *Parthenium hysterophorus* L. (collected from locally growing wild stands) following the method of Saxena et al. (1991). Parthenin, crystallized as fine colorless needles, was characterized with IR, PMR, and MS (Saxena et al., 1991). Its melting point was 165°C and purity was >98%. For growth experiments, a stock solution of 400 μM parthenin was prepared by dissolving the requisite amount in 2 ml absolute alcohol and then bringing the final volume to 1 l with distilled water. The stock solution was diluted to get solutions of 200, 100, and 50 μM concentrations. The concentration of alcohol in the final solution was 0.2%. The same amount of alcohol added to distilled water served as control.

Growth Experiments. Healthy seeds of *Ageratum conyzoides* L. (bill goat weed; family Asteraceae) were collected from the locally growing wild stands. The effect of different concentrations of parthenin was studied on the germination and early growth of *A. conyzoides* in a laboratory bioassay. Fifty seeds were placed for imbibition in different concentrations of parthenin solutions or distilled water containing 0.2% alcohol (a control) and allowed to imbibe for 18 hr. Imbibed seeds were placed equidistantly on Whatman No. 1 filter paper moistened with 7 ml of respective treatment solution in a 15-cm-diam. Petri dish. For each treatment, five replicates were maintained. All Petri dishes were placed in a seed germinator maintained at 23 ± 2°C, 75 ± 2% relative humidity, 16L:8D photoperiod, and 270 μW/cm^2 energy. After 7 d, the number of seeds germinated, radicle and plumule lengths of the germinated seeds, and their dry weights were measured. The entire experiment was repeated twice. Based on the growth experiment, a parthenin concentration of 200 μM was selected for further studies.

Treatment of Plants. Plants of *A. conyzoides* were raised from locally collected seeds in 10-cm-diam. pots in a growth chamber at 25 ± 2°C temperature, 75 ± 2% relative humidity, 16L:8D photoperiod, and photon flux density of approximately 150 μmol photons/m^2/sec. For this experiment, 1200 g of garden soil (soil–sand, 3:1, w/w) were placed in each pot, and five seeds of *A. conyzoides* were

sown. A week after emergence, these were thinned to two plants per pot. When the plants were 4 wk old, they were sprayed with 200 μM solution of parthenin (or distilled water with 0.2% alcohol as control) so that each plant received 10 ml of treatment solution. The treatment was given for three consecutive days, and for each treatment there were 10 replicates. On the day after the last treatment (hereafter referred to as the first day), the leaves were plucked and used to estimate chlorophyll content, respiratory activity, water-soluble protein and carbohydrate content, and enzyme activities. Similarly, the leaves were again plucked from the treated plants on days 5 and 10 for the estimations.

Chlorophyll Content. Chlorophyll from 30 mg of parthenin-treated or control-treated leaves was extracted in 4 ml of dimethyl sulfoxide (DMSO) as per the method of Hiscox and Israelstam (1979). It was quantified spectrophotometrically using the equation of Arnon (1949) and expressed on dry weight basis as suggested by Daizy and Kohli (1991).

Cellular Respiration. Respiratory activity was determined indirectly using 2,3,5-triphenyl tetrazolium chloride following the method of Steponkus and Lanphear (1967) in which the red formazan formed traps the oxygen released through the respiratory chain, thus allowing the indirect measurement of respiration. It was calculated using the following formula and expressed with respect to control.

$$\%\ \text{Respiratory activity} = \frac{\text{Absorbance of parthenin treated samples at 530 nm}}{\text{Absorbance of control samples at 530 nm}} \times 100$$

Determination of Water-Soluble Proteins and Carbohydrates. For estimating water-soluble proteins and carbohydrates, parthenin treated leaf tissue was crushed in acetone and petroleum ether to remove water, phenol, and lipids. The dried powder was used for the estimation of protein and carbohydrate content. Protein content was determined as per Lowry et al. (1951). The carbohydrate content was estimated using anthrone reagent as per Loewus (1952).

Assay of Enzyme Activities. For preparing crude enzyme extracts, parthenin-treated or control leaf tissue was homogenized in a prechilled mortar and pestle using a small amount of acid-washed sand (pH 7) and 5 ml of 0.1 M phosphate buffer (pH 7). Homogenates were centrifuged at 8000 g, 17,000 g, and 27,000 g for 7, 11, and 5 min, respectively, at a rotor temperature of 4°C in an IEC ultracentrifuge. The supernatant fraction was assayed for enzyme activity. Specific activity of protease was assayed using casein (1% in 0.1 M phosphate buffer, pH 6.0) as a substrate as per Basha and Beevers (1975). Specific activity of α-amylase was assayed as per Muentz (1977) using starch as a substrate solution. The activity of β-amylase was measured following the method of Bernfeld (1951) modified by Dure (1960).

Statistical Analysis. Percent changes in germination, radicle and plumule length, chlorophyll content, cellular respiration, protein and carbohydrate content, and enzyme activities were analyzed using a two-sample t test at α levels of 0.05 and 0.01.

RESULTS AND DISCUSSION

Within the 50–200 μM range of parthenin treatment concentrations, the germination of *A. conyzoides* was significantly reduced. At 400 μM concentration, it was completely inhibited (Table 1). Not only the germination, but also the further growth of the seedlings in terms of radicle and plumule length and seedling dry weight was significantly reduced, particularly at the parthenin concentrations of 100 and 200 μM. A relatively greater effect was observed on the radicle than plumule. At the 200 μM concentration of parthenin, radicle growth of *A. conyzoides* was reduced by nearly 88%. The pattern of growth inhibition was of a dose–response type, i.e., inhibition increased with increasing concentrations. Although the reasons for inhibition/reduction of growth of *A. conyzoides* could not be determined from the present study, recent studies have revealed that allelochemicals such as quassinoids, artemisinin, and volatile cineoles inhibit mitosis and, thus, growth of plants (Dayan et al., 1999a,c; Romagni et al., 2000). Parthenin may cause inhibition of *A. conyzoides* in a similar manner.

Spray treatment with 200 μM parthenin solution on *A. conyzoides* plants grown in pots, showed the chlorophyll content to be significantly reduced on days 1, 5, and 10 after the treatment (Table 2). The chlorophyll content was $<70\%$ of the control on days 1 and 5. However, by day 10 chlorophyll content showed only a 25% reduction relative to the control (Table 2). The reduction in chlorophyll has a direct bearing on photosynthesis. In fact, many allelochemicals are known to reduce chlorophyll content in target species (Einhellig and Rasmussen, 1979; Daizy and Kohli, 1991; Baziramakenga et al., 1994; Dayan et al., 1999a; Romagni et al.,

2000; Singh et al., 2002), but it is unknown whether loss of chlorophyll results from the inhibition of chlorophyll biosynthetic pathway or its degradation. Respiration in the parthenin-treated plants was also reduced (Table 2), with the reduction greatest on the first day (47%), and diminishing with time (22% on day 10) (Table 2). Such an inhibitory effect of parthenin on the respiration of germinating mung bean has also been reported by Kohli et al. (1993). The effect of parthenin on respiration may affect cell metabolism, leading to impaired growth of target species. However, nothing is known about the mechanism of action. Picman (1986) pointed out that parthenin, like other sesquiterpenes, may bind to sulfhydryl bonds of amino acids and proteins and cause irreversible alkylation of key enzymes, thereby impairing general metabolism and causing growth inhibition. In order to establish such a mechanism, we studied the amount of total protein content and its hydrolyzing enzyme protease in the parthenin-treated plants. Furthermore, because parthenin affected the respiration in the target plants and because carbohydrates act as major substrates for this process, we also estimated the amount of carbohydrates and the specific activity of their hydrolyzing enzymes—amylases. Such types of biochemical estimations provide clues regarding the mode and mechanism of action (Dayan et al., 2000).

Treatment with parthenin adversely affected the amounts of some macromolecules, such as water-soluble proteins and carbohydrates, and the specific activities of the enzymes, *viz.*, protease and α- and β-amylase. The protein content decreased in the parthenin-treated plants on the first day, and with the passage of time the decrease was even more pronounced i.e., it was nearly 80% on the fifth and tenth days after the parthenin treatment compared to about 40% on the first day (Table 3). The trend of changes in the carbohydrate content was also similar to that observed for the proteins (Table 3). The specific activity of protease—protein hydrolyzing enzyme—was also reduced in the parthenin treated *A. conyzoides* plants. This indicates an overall affect on protein metabolism. However, unlike protease,

the specific activity of carbohydrate hydrolyzing enzymes—α- and β-amylase—increased with parthenin treatment compared to respective controls (Table 4).

It is clear that parthenin exerts an overall inhibitory effect on the growth and physiology of *A. conyzoides*. The adverse effect on protein and carbohydrate metabolism, as indicated by significant alterations in their amounts, does not explain anything regarding parthenin's mode of action; however, the results serve as indicators for further studies on the mode of action. Pandey (1996) reported that parthenin causes several physiological changes in the water hyacinth, such as damage to cellular membranes, loss of dehydrogenase activity in the roots, and loss of chlorophyll in the leaves, resulting in growth inhibition. Earlier, Pandey et al. (1993) pointed out that inhibitors of *P. hysterophorus* may be acting through their effects on various macromolecules. The present study supports this. Another sesquiterpene lactone, dehydrozaluzanin-C, present in many composites, is phytotoxic to several plant species and causes rapid and pronounced cellular leakage, resulting in secondary effects, such as loss of membrane integrity and affecting amino acid biosynthetic pathways (Galindo et al., 1999; Macias et al., 2000).

Under natural conditions, parthenin released from different parts of the weed may accumulate in toxic concentrations in the soil environment, thereby affecting the population dynamics of associated vegetation and bringing about shifts in weed flora. Additionally, parthenin may also affect other ecological interactions such as antimicrobial, antifungal, and nematicidal activities, thereby providing defense against a number of organisms (Kohli and Rani, 1994).

Parthenin possesses an α-methylene-γ-lactone and an α,β-unsubstituted cyclopentenone ring, around a seven-membered ring, which makes it chemically reactive towards a wide variety of biological nucleophiles. The presence of the unsubstituted ring provides potential for chemical modification. Several derivatives of parthenin have already been prepared, and many of these exhibit greater activity than parthenin itself (Saxena et al., 1991; Datta and Saxena, 2001). Vaughan and

Spencer (1993) indicated that important characteristics for any natural compound chosen to be tested for herbicidal activity are the presence of reactive sites in the structures for chemical alterations and species specificity. Parthenin has potential sites for attachment of other functional groups and has demonstrated species specificity, affecting germination of *Ageratum conyzoides* with little or no effect on wheat (Batish et al., 1997). Thus, it could be an ideal molecule for development as a natural herbicide. Preliminary comparisons with known herbicides suggest that its phytotoxic activity is comparable to 2,4-D (data not shown). The dissipation of the parthenin from the environment in about 30 days (Pandey, 1996) may be of ecological significance in its use as a novel agrochemical compared to synthetic herbicides.

Acknowledgments—Daizy R. Batish and R. K. Kohli are thankful to University Grants Commission (UGC), New Delhi, India, for providing support in the form of a major research project to carry out this work.

(Received January 15, 2002; accepted July 4, 2002)

Abstract—The parasitic mite *Varroa destructor* Anderson and Trueman, the most serious threat to apiculture in many countries of the world, reproduces inside honeybee brood cells. Previous research, using artificial cells for rearing the mite on an *Apis mellifera* larva, indicated that semiochemicals affecting the reproduction of *Varroa destructor* are released into such cells. In order to isolate these semiochemicals, infested artificial cells were extracted with hexane and the extract fractionated twice. Several unsaturated hydrocarbons were identified in the active fraction; some of them were released in higher amounts in case of infestation and were, therefore, bioassayed for their effect on the mite's reproduction. Of five alkenes tested under laboratory conditions, (*Z*)-8-heptadecene, caused a 30% reduction in the mean number of offspring of mites reared in cells treated with this compound.

Key Words—Alkenes, *Apis mellifera*, honeybee, hydrocarbons, reproduction, semiochemical, *Varroa destructor*, (*Z*)-8-heptadecene.

INTRODUCTION

The mite *Varroa destructor* Anderson and Trueman (Mesostigmata Varroidae), which was recently discriminated from *V. jacobsoni* Oudemans (Anderson and Trueman, 2000), is the major pest of the western honeybee (*Apis mellifera*). Unless effective treatments are carried out, bee colonies are destroyed by the mite (Sammataro et al., 2000). Effective control of the parasite has become more difficult since the appearance and spread of mite populations that are resistant to

widely used acaricides (Milani, 1999). The need for alternative control methods suggested research on the honeybee–varroa relationship to find out what enables some bee strains to tolerate the mite (Rosenkranz, 1999). Reduced reproduction of the mite is regarded as the most important factor of tolerance (Fries et al., 1994).

Varroa reproduces on immature stages of the honeybee inside sealed brood cells. In multiple infested cells, a density-dependent reduction of varroa reproduction was observed under both natural (Piletskaya, 1982; Moosbeckhofer et al., 1988; Fuchs and Langenbach, 1989; Martin, 1995) and laboratory conditions (Nazzi and Milani, 1996). Laboratory studies using gelatin cells for rearing the mite on its natural host showed that inhibition of reproduction is caused by substances that are released into infested cells and can be extracted with suitable solvents (Nazzi and Milani, 1996). The aim of this research was to identify such factors.

METHODS AND MATERIALS

Biological Material. Bee larvae and *V. destructor* mites used in all the experiments were taken from *A. mellifera* colonies maintained in Udine (northeastern Italy). The mites and bee larvae were obtained from brood cells capped 0–15 hours before (0–15 pc), according to Chiesa et al. (1989).

Bioassay. A solution of the stimulus to be tested in 10 μl of hexane was applied to the interior of 6.5 mm ID gelatin cells (Capsugel, Coni-Snap, size 1), then one varroa mite and a *0–15 PC* bee larva were inserted into each cell. Gelatin cells treated with 10 μl of hexane were prepared as above and used as a control. Cells were mantained at $34.5 \pm 0.5^{\circ}$C, 75% relative humidity in an incubator for the duration of the experiment. After 10 d, the cells were opened and inspected under a dissecting microscope; the presence and the number of offspring per mite in each cell was noted. Only cells with a normal bee pupa were considered.

Extraction of Inhibiting Factors. Infested cells, in which a bee larva infested with a mite had developed, were obtained according to Nazzi and Milani (1996); only cells with a normal bee pupa and a varroa mite that had reproduced were used. At the end of the rearing cycle, the bee pupae, the varroa mites, and their offspring were removed, and the cells were filled with 380 μl of hexane. After 15 min, the solvent from all extracted cells was transferred into a vial and stored at -20°C.

Fractionation of the Active Extract. The extract of a convenient number of infested cells (normally 30–100 cells) was concentrated under nitrogen and fractionated on a column obtained by packing a Pasteur pipet with 300 mg of silica gel (200–400 mesh, 60Å). The column was eluted with 3 ml of hexane (F1), 10% ether–hexane (F2), and ether (F3). The fractions were then concentrated under nitrogen to 1 cell equivalent (1 CE) per 10 μl of hexane and bioassayed. The experiment was replicated 4 times; about 65 cells per group gave useful information that was used for the statistical analysis.

Saturated and unsaturated hydrocarbons contained in the apolar fraction resulting from the first fractionation (F1) were separated using a column packed with 300 mg of 10% silver nitrate on silica gel (200–400 mesh, 60Å). The column was eluted with 3 ml of hexane (F1A) and ether (F1B). The ether fraction was reduced under nitrogen and passed through a silica column that was eluted with hexane to remove silver ions. The fractions were then concentrated under nitrogen to 1 CE/10 μl hexane and bioassayed. The experiment was replicated 6 times; about 85 cells per group gave useful results that were used for the statistical analysis.

Chemical Identification. Ten infested cells and ten uninfested cells were extracted with hexane, the extracts were pooled and analyzed with a Varian 3400 gas chromatograph coupled to a Varian Saturn 2000 mass spectrometer. The column (30 m $\times$ 0.25 mm ID, CP-SIL 8) was maintained at 40°C for 1 min, then programmed at 10°C/min to 320°C. The carrier gas was helium. The comparison of the percentage composition of the two extracts is based on three replicates of the analysis.

Alkenes released in infested and uninfested cells were also studied by means of solid phase microextraction (SPME). Infested and uninfested gelatin cells were prepared as described above and held in an incubator at 34.5 ± 0.5°C and 75% relative humidity. After 24 hr, five cells of each type were sealed in an air-tight vial, then a SPME fiber (100 μm polydimethylsiloxane) was exposed to the volatiles emitted in the vial for 1 hr and analyzed. Chromatographic conditions were as above, except that the column upper temperature was 250°C.

The compounds in the extracts were identified by comparison of the spectra and the retention times with those of authentic standards that had been either purchased or synthesized. The double-bond position of unsaturated hydrocarbons detected in crude extracts was assessed by derivatization with dimethyl disulfide (Carlson et al., 1989). To determine the stereochemistry of alkenes, 8 CE of the extract were co-chromatographed with authentic standards on silver nitrate impregnated TLC plates. The sections of the plate corresponding to the *Z* and *E* alkenes were extracted with ether and analyzed by GC-MS.

(*Z*)-9-Heneicosene (9C21:1) and (*Z*)-9-tricosene (9C23:1) were purchased from Sigma-Aldrich. (*Z*)-6-Pentadecene (6C15:1), (*Z*)-6-heptadecene (6C17:1), (*Z*)-7-heptadecene (7C17:1), (*Z*)-8-heptadecene (8C17:1), (*Z*)-9-nonadecene (9C19:1), which were identified in the active extract but were not commercially available, were synthesized by partial hydrogenation of the corresponding alkyne using Lindlar's catalyst. Alkynes were obtained by alkylation of a convenient terminal alkyne with 1-bromoalkanes of suitable chain length (Sonnet, 1984).

Bioassay of Compounds Identified in Active Fraction. The alkenes 6C15:1, 8C17:1, 9C19:1, 9C21:1 and 9C23:1 were bioassayed at a concentration of 100 ng/cell. The experiment was replicated 4 times. The number of cells used in each case is given in Table 4. Mortality of mites in cells treated with each compound was compared to that in control cells.

Effect of Double-Bond Position on Biological Activity of Heptadecene. This was assessed by comparing the activity of three different isomers of heptadecene [(*Z*)-6-heptadecene, (*Z*)-7-heptadecene, and (*Z*)-8-heptadecene] on the reproduction of varroa mites reared in cells treated with those compounds. The concentration of chemicals was 100 ng/cell. The experiment was replicated 3 times; about 50 cells per group gave useful information that was used for the statistical analysis.

Statistical Analysis of Data. The offspring per varroa in treated and control cells were compared by means of a two-sample randomization test (Manly, 1997); the randomization distribution was resampled 10^6 times with a computer program written for this purpose. The varroa mortality inside treated cells was compared to that in control cells by means of the *G* test (Sokal and Rohlf, 1995).

RESULTS

Fractionation of the Active Extract. The reproduction of the mites reared in cells treated with the apolar fraction (F1) containing the hydrocarbons was significantly lower than that observed in cells treated with the solvent alone. The medium polarity fraction (F2) showed some activity as well (Table 1), but, due to the poor efficiency of the column used here, this was most likely due to hydrocarbons that had not yet been eluted from the column rather than to other compounds of higher polarity as confirmed by GC analysis of the fraction. Several odd chain length alkanes, alkenes, and branched alkanes were identified in the apolar fraction (F1). Only fraction F1B from the second fractionation, which contained the alkenes, reduced the reproduction of the mites reared in treated cells (Table 2).

Chemical Identification. The monoenes listed in Table 3 were identified in the active fraction; the double bond was located nine carbon atoms from the end of

the chain for most alkenes. Although the presence of small quantities of *E* isomers of the alkenes found in the extracts can not be ruled out, the configuration of the unsaturated hydrocarbons was *Z* in accordance with previous studies on cuticular hydrocarbons of the honeybee (Blomquist et al., 1980).

The amount of alkenes containing 17–25 carbon atoms was higher in the active extract of infested cells than in the inactive extract of uninfested cells (Figure 1). The absolute quantity of alkenes per cell ranged from nanograms, in the case of shorter alkenes, to hundreds of nanograms in the case of longer ones.

SPME analyses showed that higher quantities of heptadecene and pentadecene are emitted in infested cells. On the other hand, traces of alkadienes were also found

TABLE 3. MONOENES IDENTIFIED IN EXTRACT OF INFESTED CELLS[a]

Compound name	Formula	Abundance (%)*	Principal isomers	Other isomers
Pentadecene	$C_{15}H_{30}$	traces	?	
Heptadecene	$C_{17}H_{34}$	0.15	8	
Nonadecene	$C_{19}H_{38}$	7	9	7
Heneicosene	$C_{21}H_{42}$	1	9	7, 8, 10

in the active fraction, but, due to their scarcity, no further studies were possible on these compounds.

Bioassay of Compounds Identified in Active Fraction. Treatment of cells with (*Z*)-8-heptadecene significantly reduced the offspring per female mite, while no significant differences from the control were found for cells treated with (*Z*)-7-pentadecene, (*Z*)-9-nonadecene, (*Z*)-9-heneicosene, and (*Z*)-9-tricosene (Table 4). No significant effect on mite mortality was caused by (*Z*)-8-heptadecene (mite mortality in control cells: 9%, mite mortality in treated cells: 10%; $P > 0.8$).

Effect of Double-Bond Position on Biological Activity of Heptadecene. (*Z*)-8-Heptadecene was active in inhibiting the reproduction of the varroa mite at the concentration tested, while the other two isomers tested did not cause any significant decrease in reproduction (Table 5).

DISCUSSION

The cuticular hydrocarbons of the honeybee and the varroa mite have been studied by several researchers (Blomquist et al., 1980; Francis et al., 1985; Carlson et al., 1989; Nation et al., 1992; Rickli et al., 1994). More recently Salvy et al. (2001) studied the hydrocarbon profile of infested and uninfested bee larvae, pupae, and emerging bees. However, the presence of unsaturated hydrocarbons shorter than 21 carbon atoms has not been reported so far. By extracting artificial rearing cells, we identified three additional alkenes: pentadecene, (*Z*)-8-heptadecene, and (*Z*)-9-nonadecene. (*Z*)-8-Heptadecene, which is released in higher quantities in case of infestation, caused a significant reduction in the reproduction of the mite without causing increased mortality; this rules out a toxic effect of the compound at the concentration tested.

The analysis of cuticular hydrocarbons of uninfested bee larvae and the varroa mite revealed the presence of traces of heptadecene in both cases. An effective technique for rearing *V. destructor* on an artificial diet has not yet been developed. Thus, it is not possible to ascertain directly whether heptadecene found in infested cells is produced by the bee larva following parasitization or by the varroa mite itself.

Mechanical damage produced by the mite feeding on its host can be simulated by piercing the cuticle of the bee larva with a fine pin; in this way, one can induce stress in the larva somewhat similar to that induced by the mite but without the mite being present. By rearing the mite on its host in artificial cells that had

been previously used for rearing a bee larva injured in such a way, we observed a reduction in the reproduction of the parasite in comparison to that observed in cells that had been previously occupied by healthy larvae (offspring per mite in cells that contained a wounded larva in the previous rearing cycle: 1.33, offspring per mite in cells that contained a healthy larva in the previous rearing cycle: 2.35; $P = 0.06$). This suggests that compounds affecting mite reproduction could be produced by a bee larva under stress regardless of the presence of the mite. Actually, evidence that environmental stress can alter the hydrocarbon composition of the insect cuticle has already been reported (Howard et al., 1995 and citations therein). Therefore, it is likely that (*Z*)-8-heptadecene represents an allomone released by the host under stress that affects the reproduction of its parasite.

(*Z*)-8-Heptadecene has already been described as a semiochemical for the mite *Acarus immobilis* (Sato et al., 1993) and was recovered among the volatiles produced by *Dermatophagoides pteronyssus* (Kuwahara et al., 1990). However, to our knowledge, no effect of this compound on the reproduction of any mite or tick has been noted so far. An unidentified fecundity-reducing semiochemical was reported for *Argas arboreus*, but it appeared to be a pheromone produced under crowded conditions by the tick itself (Khalil, 1984).

Although no data exist yet on the correlation between infestation level and heptadecene production by the larvae, the effect of heptadecene on varroa reproduction is similar to that observed in multiple infested artificial cells (Nazzi and Milani, 1996). The identification of this inhibitor of reproduction in *V. destructor* could help elucidate the mechanism of the density-dependent reduction in mite reproduction observed in multiple infested cells.

The identified semiochemicals could be exploited for the control of the parasite. Due to the high number of generations per year in *V. destructor*, even a small reduction in the reproductive rate could have a significant impact on the development of infestation. Identification of such a chemical could make it possible to better understand the factors conferring tolerance to the varroa mite in some bee strains.

Acknowledgments—We wish to thank R. Bortolomeazzi for assistance with GC-MS analysis, D. A. Carlson for suggestions on hydrocarbon separation, M. D'Agaro for technical collaboration in the management of the experimental apiary, M. C. Luszniak for useful advice on alkene synthesis, and Capsugel for providing the gelatin capsules used in the bioassays.

(Received January 7, 2002; accepted June 25, 2002)

Abstract—Sixth instars of the parsnip webworm, *Depressaria pastinacella*, orient by olfaction to bud, male flowers, and female flowers of their primary host plant, *Pastinaca sativa*. Because octyl acetate and octyl butyrate are characteristic of tissues consumed by the sixth instar, we investigated the influence of these esters on webworm feeding behavior and chemo-orientation. Although octyl acetate and octyl butyrate are feeding deterrents, and octyl butyrate is an olfactory repellent, octyl acetate serves as an olfactory attractant. In olfactometers, webworms do not show a preference when given a choice between octyl acetate and host plant tissues. These findings suggest that octyl acetate is a sufficient cue for olfactory orientation. Such behavior may explain differences in the relative abundance of these esters observed among populations of wild parsnip under differential selection pressure from these insects.

Key Words—Olfaction, gustation, attractant, deterrent, volatiles, *Depressaria pastinacella*, *Pastinaca sativa*, Lepidoptera.

INTRODUCTION

The process of host plant location and evaluation is particularly important to insects that consume specific tissues in a narrow range of host species. The parsnip webworm, *Depressaria pastinacella* (Lepidoptera: Elachistidae), is an introduced oligophagous moth effectively restricted throughout much of its range in eastern North America to its introduced host plant wild parsnip, *Pastinaca sativa* (Berenbaum et al., 1986). Later instars feed exclusively upon the buds, flowers, and immature fruits of wild parsnip. Suitable tissues situated within an umbel are

enclosed by silk; the resulting web contains most of the food required by the larvae, which feed within the web until prepupal wandering commences.

Despite an apparently sedentary larval lifestyle, webworm larvae must be able to locate spatially and temporally ephemeral host tissue. Finding the appropriate site for web construction on a host plant is the task of the larva and not the female moth, in that oviposition occurs in spring several weeks before the appearance of reproductive tissues (Gorder and Mertens, 1984). As a result, a female moth cannot directly assess the suitability of the reproductive tissue that her larvae will eventually consume. Eggs are laid on the underside of leaves, and neonate larvae move individually to axillary meristem tissue (Berenbaum and Zangerl, 1992). Even an established web site may not guarantee an adequate food source. Later instars may become physically displaced from or abandon a web site. Individuals may be ousted by conspecifics seeking to usurp an energetically valuable web site (Green et al., 1998). On occasion, later instars may exhaust the food supply within the confines of the web and be forced to locate new plant material. Later instars show both host-searching behavior and mobility between plants (Berenbaum and Zangerl, 1992). The ability to choose a new site may be important for a webworm, because sites vary in their nutritional suitability (Berenbaum et al., 1984, 1989). The ability to obtain information about host tissue location and condition may therefore, be useful to the caterpillar.

As potential volatile cues, wild parsnip contains a variety of essential oil components, including terpenoids, aliphatic fatty acid derivatives, and phenylpropanoids (Berenbaum and Neal, 1985; Zangerl et al., 1997). Of these, the aliphatic esters octyl acetate and octyl butyrate could provide webworms with highly specific information about host plant tissues. Appreciable biosynthesis of octyl acetate and octyl butyrate is taxonomically restricted to a few genera of apiaceous plants (Bicchi et al., 1990), two of which, *Pastinaca* and *Heracleum*, are the principal host plants of the parsnip webworm (Berenbaum and Zangerl, 1991). In these plants, these two esters are the only essential oil components found exclusively within tissues consumed by the webworm; whereas other essential oil components are distributed throughout the plant, octyl acetate and octyl butyrate are produced only in the reproductive tissues (Zangerl et al., 1997).

Given the site-specificity of octyl acetate and octyl butyrate production, we investigated whether these esters serve as kairomones for sixth instars at concentrations found in the plant. As reliable indicators of suitable host tissue, i.e., reproductive structures, these esters could potentially serve as attractants. Conversely, they may be avoided by webworms due to their co-occurrence and correlation with toxic, but nonvolatile, furanocoumarins in the vittae (oil glands) (Carroll et al., 2000). We conducted a series of studies to determine the behavioral effects of these compounds on webworm larvae. Because gustatory responses can be highly specific with regard to compound and concentration, we tested each compound separately. If webworms do show separate olfactory or gustatory responses to

different esters and behave accordingly, production of esters in parsnip plants, which is genetically variable, could be subject to differential selection pressure from these insects (Berenbaum et al., 1986).

METHODS AND MATERIALS

Insects and Plants. The parsnip webworms used in feeding preference and olfactory tests were collected from two different populations in order to obtain a continuous supply of larvae of an appropriate developmental stage. The parsnip webworms used in the feeding preference tests were collected as fourth and fifth instars on wild parsnip growing in the University of Illinois Phillips Tract, located 6 km northeast of the UIUC campus (Champaign County, Illinois, USA). The parsnip webworms used in the olfactory tests were collected as fourth and fifth instars on wild parsnip growing along Wisconsin State Rd. 60, located 1.2 km east of Lodi (Columbia County, Wisconsin, USA). Although phenologically displaced, these two sites are similar. Both old-field sites included several thousand wild parsnip plants that experienced high levels of herbivory by the parsnip webworm. The larvae were transferred to a semidefined artificial diet (Nitao and Berenbaum, 1988) and raised at approximately 18°C under a 16L:8D photoperiod produced by Phillips 40W Cool White fluorescent bulbs. Parsnip plants used in the olfactory tests were collected from Phillips Tract and transferred in pots to a greenhouse.

Feeding Preferences. Sixth instar feeding preferences for different compounds at a range of concentrations were tested under similar protocols, save for diet treatment and the length of observation period. Octyl acetate and octyl butyrate were obtained from ICN Pharmaceuticals (New York, New York, USA); in an analysis of each ester by GC (Hewlett-Packard 5890), no additional compound peaks were detected. In the first experiment, sixth instars were given a pairwise choice between two diet portions consisting of either (1) a diet supplemented with octyl acetate (0.16%), (2) a diet supplemented with octyl butyrate (0.43%), or (3) an unsupplemented control diet. In the second experiment, the pairwise choice was between two diet portions consisting of either (1) a diet supplemented with average concentrations of octyl acetate (0.16%) and octyl butyrate (0.43%), (2) a diet supplemented with low concentrations of octyl acetate (0.016%) and octyl butyrate (0.043%), or (3) an unsupplemented control diet. These diet concentrations represent the range of phenotypic variation present in wild parsnip fruit (Carroll et al., 2000). For all tests, two diet cubes weighing approximately 1.5 g each were placed on opposite sides of a 12-cm glass Petri dish arena. One recently molted sixth instar was introduced into each Petri dish and allowed to feed *ad libitum*. Because webworms enclose their food with silk and remain to feed, we used caterpillar location as an indicator of feeding preference. The location with respect to the two cubes was scored at 12, 24, and 48 hr in the first experiment and at 1, 2, 6, 12, and 48 hr in the second experiment. If a caterpillar was not on a diet cube, the preference was scored as neutral. The preference ratios obtained at each

observation time were compared by a paired sign test. Neutral preferences were not included in the analysis.

Olfactory Preferences. In the olfactory bioassays, octyl acetate and octyl butyrate were introduced to larvae in a manner consistent with the damaging of tissues, i.e., as a single release of esters in a large volume. Olfactory choice tests were performed by using an enclosed Y-tube apparatus. A vertical larval holding chamber was formed by firmly securing a Pyrex glass Y tube against a 3-cc plastic Luer-Lock syringe. An artificial climbing surface, consisting of a 2-mm-wide strip of Whatman No. 1 filter paper configured into a Y shape, was placed inside the chamber to give the larva ample traction. The terminal end of each Y-tube arm was fitted with a 1-ml disposable Pipetman tip with the apical end distally oriented. The narrow diameter of the apical tip allowed for the attachment of polyethylene tubing carrying volatiles from a remote source.

Purified chemicals and whole plant tissues in bud, male flower, female flower, and half-filled fruit stages were evaluated as olfactory sources. We did not attempt to use the actual amount of esters present in a single fruit because of the difficulty of handling such small volumes and because larvae do not encounter single fruits in isolation; instead, we used 1000 times the amount found in a single parsnip fruit (Carroll et al., 2000). The esters were absorbed into a 3.0-cm-diam. disk of Whatman No. 1 filter paper. To obtain fresh plant material, one umbel (approximately 1.5–2.0 g) in an appropriate developmental stage was cut from a plant immediately before use and placed in water to reduce dehydration. Each source was placed into a 500-ml Erlenmeyer flask. Airflow from the source to the chamber was contained within a completely enclosed system connected by polyethylene tubing 1/4 inch i.d. Air filtered through activated carbon passed over the volatile source and was then shunted to an arm of the Y tube. Negative airflow was maintained through the system by the attachment of the syringe to a model 500× Shop-Vac (Shop Vac Corporation, Williamsport, Pennsylvania, USA). Airflow was adjusted to 0.3 m/sec in the larval chamber with the use of a rheostat. Five chambers were run in parallel, all sharing common volatile sources and negative airflow through the use of adjustable gang valves.

In the bioassay, a sixth instar was introduced into the syringe of the chamber with forceps and allowed to move about freely. A preference was scored when the larva touched the pipet tip within an arm. Pilot studies demonstrated that larvae required an average of 10 min to reach the end of an arm after introduction, so larvae were given 20 min to move within the chamber. The preference was scored as neutral if the larva failed to touch either pipet tip within 20 min. Twenty replicates were performed for each pairwise test. Both the glassware and plastic syringes were rinsed between trials twice with acetone, then rinsed twice with Alconox and water, and dried for at least 1 hr in a 60°C oven to remove any remaining volatiles. The preference ratios obtained between each pair of sources were compared by a paired sign test. Neutral preferences were not included in the analysis.

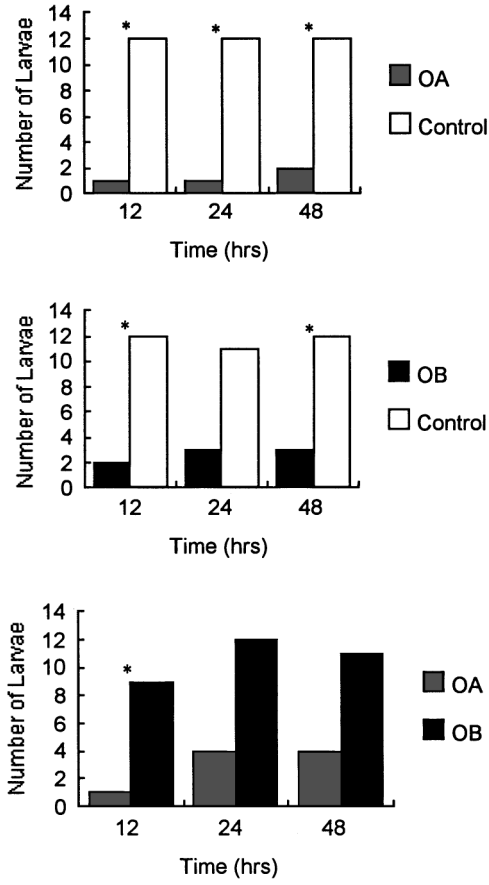

FIG. 1. Feeding preferences of sixth instar *Depressaria pastinacella* toward diets containing either octyl acetate (0.16% OA), octyl butyrate (0.43% OB), or an unsupplemented control diet.

RESULTS

Feeding Preferences. When given a choice, parsnip webworms preferentially fed on octyl ester-free diets rather than on diets containing average levels of either ester (Figure 1). Webworms preferred the control diet over a diet containing octyl acetate during all three observation times (range 12:1 to 12:2; $P < 0.05$, paired sign test). Webworms also preferred the control diet over diets containing octyl butyrate at 12 and 48 hr (range 12:2 to 12:3; $P < 0.05$, paired sign test). In choice

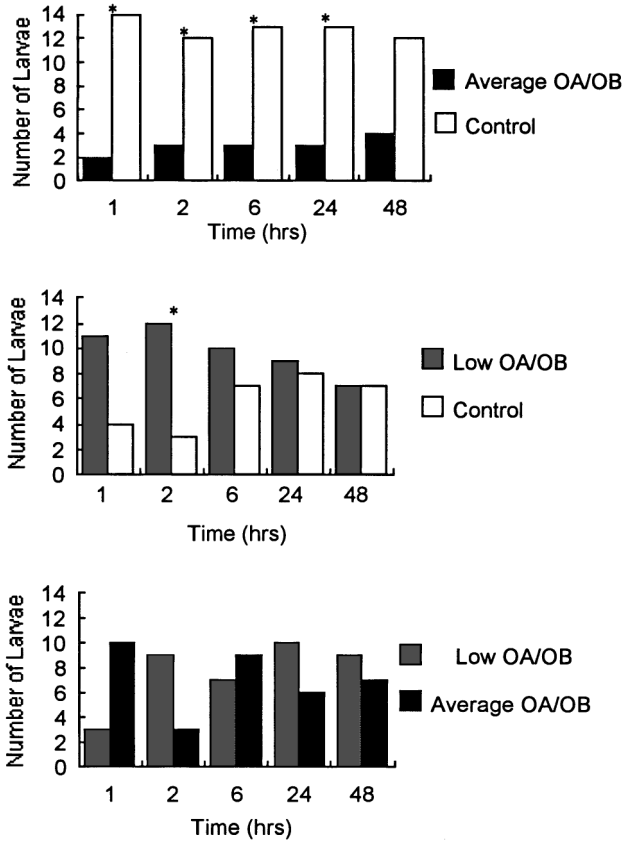

FIG. 2. Feeding preferences of sixth instar *Depressaria pastinacella* toward diets containing different amounts of octyl acetate (OA) and octyl butyrate (OB) (average OA/OB = 0.16% OA and 0.43% OB; low OA/OB = 0.016% OA and 0.043% OB).

tests between the esters, diet containing octyl butyrate was preferred over diet containing octyl acetate at 12 hr (9:1, $P < 0.05$, paired sign test). The same trend was evident at the other observation times, but the differences were not significant, likely because of the sample size used here.

Webworms were also given a choice between diets containing different levels of both octyl esters (Figure 2). The caterpillars preferred the unsupplemented diet over diet containing average levels of the esters at all observation times during the first 24 hr ($P < 0.05$, paired sign test). In contrast, webworms did not consistently prefer unsupplemented diets over diets containing low levels of the esters. The low

Comparison	Ratio	P^b
OA vs. control	20:0	<0.001
OB vs. control	1:18	<0.001
OA/OB vs. control	1:19	<0.001
OA vs. OB	20:0	<0.001
OA vs. OA/OB	13:7	0.263
OB vs. OA/OB	4:16	0.012

[a] OA = octyl acetate; OB = octyl butyrate; OA/OB = octyl acetate and octyl butyrate.
[b] Ratio departure from random distribution by a paired sign test (neutral preferences excluded).

ester diet was preferred over the unsupplemented diet only at the 2-hr observation time. Webworms did not distinguish between diets containing average and low levels of octyl acetate and octyl butyrate ($P > 0.05$; paired sign test).

Olfactory Preferences. In the first set of olfactory tests, each octyl ester was compared with a blank control and then with the other ester (Table 1). The webworms preferred octyl acetate over the control but preferred the control over octyl butyrate ($P < 0.001$, paired sign test). When presented with a combination of octyl acetate and butyrate, larval chose the esters over the control ($P < 0.001$; paired sign test). In pairwise comparisons of compounds, octyl acetate was preferred over octyl butyrate ($P < 0.001$; paired sign test). Webworms preferred the ester combination over octyl butyrate ($P = 0.012$) but failed to show a preference between the ester combination and octyl acetate ($P > 0.05$; paired sign test).

In the second set of olfactory tests, parsnip reproductive tissues in different stages of development were evaluated for their olfactory attractiveness (Table 2). In comparisons of plant tissue against a blank control, webworms preferred buds, male flowers, or female flowers over the control ($P < 0.001$; paired sign test). In contrast, webworms preferred the control over half-filled fruits ($P < 0.001$; paired sign test). Each plant tissue was also compared with the other plant tissues. Webworms preferred buds over half-filled fruits ($P < 0.001$; paired sign test). In all other pairwise comparisons, the webworms showed no preference for one tissue over another ($P > 0.05$; paired sign test).

In the final olfactory tests, the four different plant tissues were compared individually against octyl acetate, octyl butyrate, or a combination of both esters. In all pairwise comparisons, no preference was observed between the tissues and the plant compounds ($P > 0.05$; paired-sign test; data not shown).

DISCUSSION

With respect to gustation, sixth instars clearly preferred to consume ester-free diets rather than diets augmented with average levels of octyl acetate or octyl butyrate, although they will consume ester-supplemented diets in the absence of alternative food sources. These octyl esters, therefore, may serve as feeding deterrents to sixth instars at the average concentration found in mature fruits. However, the deterrence value of the octyl esters is lost when the dietary concentrations are reduced to one tenth the average concentration in fruits. The threshold for feeding deterrence is within the phenotypic range of fruit contents observed in a wild population (Carroll et al., 2000). Therefore, the fruits of some parsnip plants may lack the ester content required for deterrence and may sustain greater damage. The octyl ester content of other parsnip reproductive tissues attacked by the webworm varies around the threshold value. The average octyl acetate and octyl butyrate content of axillary meristem tissue and buds lies well below the threshold, but both the male and female flowers can have ester contents above the levels required for the observed deterrence (Zangerl et al., 1997). Differences in octyl butyrate content between tissues may also explain sixth instar preferences for parthenocarpic fruits over filled fruits, despite the fact that the former are less nutritious and result in lower growth rates. The preferred parthenocarpic fruits, among other differences, have significantly lower amounts of octyl butyrate than the filled fruits, which may account for the preferences observed (Cianfrogna et al., 2002). Thus, dietary octyl acetate and octyl butyrate may not fully deter webworm herbivory but may influence the selection of host plant tissues when different types are available.

Sixth instar responses toward the esters differ with respect to olfaction alone. Octyl acetate is an olfactory attractant, whereas octyl butyrate is an olfactory repellent. Because the two compounds co-occur in essential oils, the preference of webworms toward a combination of both esters was tested. When both compounds are present, the attractiveness of octyl acetate overrides the repellency of octyl butyrate. This apparent loss of repellency may occur in part because the response to octyl butyrate is concentration-dependent. In a preliminary experiment, we tested the response of webworm larvae to two different amounts of the esters using a similar olfactory apparatus. We used 1000 times the average content of a single fruit as the low amount and 10,000 times the average as a high amount for each ester. Octyl acetate was an attractant at both concentrations, but octyl butyrate was consistently deterrent only at the high amount.

The excess volumes used here may simulate the high effective aerial concentrations encountered at close range at established feeding sites where many hundreds of flowers or fruits may be present (the terminal umbel, generally the most heavily infested by webworms, may contain 1000 or more fruits) (Berenbaum et al., 1986). Release of these esters from undamaged tissues is greatly minimized by the localization of the esters within the vittae. Feeding by webworm larve disrupts the vittae and spreads the essential oil components, thereby greatly enhancing the volatilization of oil components. Behavioral responses to such a release of esters could be biologically relevant in that octyl acetate and octyl butyrate may provide valuable cues to webworms about feeding damage on host plants. The loss of these esters from damaged tissues could provide an orientation cue to displaced or foraging webworms about the suitability of host tissues, because the effective aerial concentration of esters around damaged tissues decreases over time as these compounds escape into the air.

Sixth instars show an olfactory preference for plant tissues, except for half-filled fruits, over a blank control. The bias against half-filled fruits may be due to their eventual development into and resemblance to mature fruits, reproductive tissues that are not regularly consumed by sixth instars. In our field plots, half-filled fruits develop into unpalatable mature fruits within a period of three–seven days. An early sixth instar that selected and webbed together an umbel containing half-filled fruits may therefore not have enough suitable tissue to complete its development. In addition, webworms may not readily distinguish between half-filled and mature fruits, due to similarities in their contents of volatile octyl esters, terpenes, and phenylpropanoids. The volatile profile of half-filled fruits resembles that of mature fruits more so than that of the buds and flowers of earlier developmental stages (Zangerl et al., 1997). The observed preference for buds over half-filled fruits may be due to the marked contrast in the volatile profiles of these tissues, the earliest and latest stages attacked by webworms.

The similarity in response of sixth instars to individual compounds in the presence of whole plant tissues suggests that the parsnip webworm does not require

a complex mixture of volatiles to orient successfully to suitable host plant tissue. This response pattern shows that host-specific volatile compounds alone are sufficient cues for larval orientation to host plant tissues in a laboratory environment, even in the absence of widely distributed compounds such as green leaf volatiles that are used for olfactory orientation by some other insects (Visser, 1986). The distinctive olfactory responses of webworms to octyl acetate and octyl butyrate suggest a specific olfaction mechanism, because the two compounds differ by only two carbons in the ester moiety. Such a distinction could be achieved either through the use of two different olfactory receptors or differential cross-patterning; however, the loss of octyl butyrate repellency in the presence of octyl acetate or plant volatiles shows that interference occurs in the response to both volatiles.

The olfactory preferences demonstrated here suggest that parsnip webworms could exert selective pressures for increasing octyl butyrate and decreasing octyl acetate in tissues; in at least one population, octyl acetate variation is heritable (Carroll et al., 2000). Substantial variation in octyl ester content has been reported for some wild parsnip populations. In Stahl and Kubeczka's (1979) survey of wild parsnip in Europe, two chemotypes showed a complete loss of octyl acetate production accompanied by a concomitant rise in octyl butyrate production. Both parsnip plants and webworms are native to Europe and have had a long evolutionary association there. In contrast, records of the interaction between these two species in the United States date back less than 150 years (Riley, 1888). If European webworms show chemosensory preferences similar to those of the American populations described here, the acetate-deficient chemotypes in Europe may be less attractive (less apparent *sensu* Feeny, 1976) to one of their primary herbivores, as a result of selective pressure exerted by this insect (Berenbaum et al., 1986).

(Received May 14, 2001; accepted June 13, 2002)

Abstract—Olfactometer bioassays and electrophysiological studies showed that the lacewing, *Chrysopa sinica*, the aphid parasitoid, *Aphidius* sp., and the coccinellid, *Coccinella septempunctata*, all responded to volatiles from tea aphids, *Toxoptera aurantii*, to hexane or ether rinses of tea aphid cuticles, and to synomones released by aphid-damaged tea shoots, as well as to the tea shoot–aphid complex. Each natural enemy spent more time searching on a filter paper treated with tea aphid honeydew than on a blank control filter paper. The interaction between synomones from aphid-damaged shoots and kairomones from tea aphids enhanced the responses to the plant–host complex. There was a significant, logistic dose–response relationship between the number of natural enemies responding and the odor stimulus concentration. Volatile components from the plant–host complex, obtained by air entrainment, were identified by their mass spectra and retention times and confirmed by comparison with standard samples. These were (*Z*)-3-hexen-1-ol, benzaldehyde, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, ocimene, linalool, geraniol, indole, and (*E*)-2-hexenoic acid. The main components in a hexane rinse from tea aphid cuticle were benzaldehyde, undecane, 2,5-hexanedione, 2,5-dihydrothiophene, linalool, 4-methyl-octane, and eicosane, whereas the main components from an ether rinse were (*E*)-2-hexenoic acid, heptadecane, pentadecane, eicosane, tetratetracontane, and nonadecane. Benzaldehyde elicited the strongest responses from natural enemies in the olfactometer and the largest electroantennogram (EAG) responses. While the amount of odor was small, *Coccinella septempunctata* was slightly more sensitive than *Chrysopa sinica* and *Aphidius* sp. An increase in doses of benzaldehyde, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate caused the EAG responses of each natural enemy to decrease. When the doses of (*Z*)-3-hexen-1-ol, linalool, and geranoil

0098-0331/02/1100-2203/0 © 2002 Plenum Publishing Corporation

increased, EAGs of *Chrysopa sinica* and *Aphidius* sp. increased, but EAGs of *Coccinella septempunctata* decreased. When the dose of indole increased, EAGs of *Coccinella septempunctata* decreased, but those of *Aphidius* sp. increased. This study demonstrates that tea shoot–aphid complexes emit volatile synomones, while the odors from tea aphids, aphid cuticle extracts, and tea aphid honeydew contain kairomones, to which the natural enemies show a logistic dose–response.

Key Words—*Toxoptera aurantii*, *Chrysopa sinica*, *Aphidius* sp., *Coccinella septempunctata*, tea shoot, kairomones, synomones, honeydew, cuticle rinse, behavioral responses, electrophysiology.

INTRODUCTION

Tea is a major crop in China and the high grade teas are processed using the young shoots of the plant. However, the tea aphid, *Toxoptera aurantii* (Boyer) (Homoptera: Aphididae), occurs throughout the Chinese tea region and causes direct feeding damage to tea shoots. In addition, the excreted honeydew on the leaves may be colonized by mildew, which reduces photosynthesis. In Chinese tea gardens, generally, the young tea shoots sprout four or five times a year and are always colonized by populations of tea aphid (Han, 2002). Pesticides are usually not applied to suppress this pest, to avoid residues in the commercial tea, especially in Chinese spring tea. Therefore, the pest can seriously reduce tea output and lower tea quality. The pest also damages tea plants in Japan, India, and Kenya (Das and Kakoty, 1992; Sudoi et al., 1996; Sudoi and Rotich, 1997). In China, larvae and adults of the ladybeetle, *Coccinella septempunctata* L. (Coleoptera: Coccinellidae), are voracious predators of tea aphids; in the laboratory an adult can consume 100–120 aphids per day. The population of *C. septempunctata* closely follows the population of the tea aphid, especially from late April to June and from August to October. Larvae and adults of the lacewing,*Chrysopa sinica* Tjeder (Neuroptera: Chrysopidae), are also important predators of tea aphids. The lacewings largely occur in May and from September to October, and an adult can consume 70–90 tea aphids per day under laboratory conditions. The aphid parasite, *Aphidius* sp. (Hymenoptera: Braconidae: Aphidiinae), also attacks both nymphal and adult aphids. The average percentage of parasitism is around 10% in May–June and about 15% in September–October. The pattern of parasitization sometimes appears to be highly aggregated, with parasitism on groups of adjacent tea branches reaching over 90% (Han, 2002).

Several studies have demonstrated that specific blends of odors produced by herbivore-injured plants as well as those released by the pests themselves are often attractive to certain insect predators and parasitoids (Vet and Dicke, 1992; Dicke, 1994). If the semiochemicals were isolated, identified, and synthesized, we could use them to mediate natural enemies controlling tea aphids. Some attempts have been made to use synomones and kairomones in the manipulation of natural

enemies to suppress pests (Bakthavatsalam and Singh, 1996). However, little is known about the chemical communications among insects in tea gardens, and our understanding of the communication mechanisms between pests and predatory insects is poor (Royer and Boivin, 1999). There are limited reports on chemical communication between pest species and their natural enemies. This study examines the origin and the activity of tea aphid-kairomones and synomones from aphid-damaged tea shoots and their use by various natural enemies, and identifies the active components in these infochemicals.

METHODS AND MATERIALS

Preparation and Analysis of Odors

Volatiles from Tea Shoot–Aphid Complexes. Each of the tea shoot–tea aphid complexes was about 7 cm long with one bud and three leaves, weighing appropriately 0.7 g; it supported about 80–150 tea aphids. Two hundred grams of tea shoot–aphid complexes were placed in a 20 l glass vessel with an inlet and an outlet that was modified according to Turlings et al. (1998). The complexes were replaced at 12-hr intervals. Dried and purified air was guided through the inlet at 250–300 ml/min for 48 hr. A Tenax TA column with 150 mg absorbent (Supelco Co.) activated at 275°C for 4 hr with a nitrogen stream was attached to the outlet. A pump was joined to the column and drew at a flow of 250–300 ml/min for 48 hr. Volatiles were desorbed by eluting the tenax traps with 1 ml freshly distilled hexane. Then 20 μl of a 10^{-4} g/ml decanoic acid ethyl ester were added as an internal standard. The resulting extract was concentrated to about 20 μl under a stream of nitrogen, 2 μl of which were immediately injected into a GC-MS. The gas chromatograph was an HP-5890A model, fitted with a PEG-20M quartz capillary column (30 m, 0.2 mm ID), and the mass spectrometer was the HP-5972 MSD model. The GC oven was maintained at 50°C for 5 min and then programmed to increase at 2°C/min to 250°C. Identifications were confirmed by retention time and peak enhancement on co-injection with authentic commercial samples.

A second 1-ml eluting solution of the volatiles from the same weight of tea shoot-aphid complex, collected by air entrainment, was prepared for behavioral bioassays.

Hexane and Ether Rinses of Tea Aphid Cuticle. About 5000 tea aphids of mixed ages were extracted with 5 ml distilled hexane for 60 sec at room temperature as described by Liepert and Dettner (1996). Ten microliters of a 10^{-4} g/ml decanoic acid ethyl ester were added as the internal standard, then the hexane rinse was concentrated to 100 μl under a gentle stream of nitrogen. Substances were tentatively identified by GC-MS as described above. An ether rinse of the same number of tea aphids was also prepared and analyzed.

A further 1-ml hexane rinse and 1-ml ether rinse of the same number of tea aphids were prepared for behavior bioassays, respectively.

Y-Tube Test for Behavioral Responses of Three Species of Natural Enemies to Various Sources of Infochemicals

Insects and Y-Tube Olfactometer Test Procedure. Tea aphids, *Toxoptera aurantii*, and their natural enemies were all collected from tea gardens. *Chrysopa sinica* and *Coccinella septempunctata* were reared on tea aphids in 500-ml glass containers and were starved for 24 hr before use in behavior tests. The parasitoid, *Aphidius* sp., was reared on colonies of tea aphids. In preparation for the tests, female parasitoids that had emerged from mummies isolated in glass vials were mated within 24 hr of emergence and were not allowed to lay eggs or to have any experience with host-related odors. They were also starved for 24 hr before being used in behavior tests. Each individual natural enemy was tested only once in the bioassays.

The Y-tube olfactometer was modified from that described by Du et al. (1996). The base and arms of the olfactometer were each 10 cm long and the angle between the two arms was 120°. The internal diameter was 1 cm, and each arm was connected to either a glass jar containing an odor source or an empty control jar. An electric pump connected to the base of the Y-tube drew air through a flowmeter, an activated charcoal filter, and a molecular sieve before entering the Y-tube so that it was purified of any contaminating odors. The airflow through each of the arms was maintained at 100 ml/min. A smoke test showed that the air of the odor arm did not mix with that of the control arm at the Y junction. Twenty individuals of each natural enemy were tested, one at a time, against each odor source. Each individual was presented with a choice between the test odor and a blank control. The olfactometer arm chosen by the insect after a 5-min period was recorded. After every 10 individuals tested, the Y-tube was cleaned inside and out with pure ethanol, and the treatment arms were reversed to avoid position effects. A χ^2 test was used to determine significant differences between numbers of natural enemies choosing different odor treatments.

Dose Responses. In each test, the control was clean air. The following odor sources were tested, each at eight or nine different concentrations. Each tea shoot used was approximately 7 cm long and had one bud and three leaves. Aphid-damaged shoots were tested immediately after being collected from the tea garden. The regression relationships between the number of natural enemies responding to an odor source (Y) and the concentration of the odor source (X) were calculated using the statistical software package DPS (Tang and Feng, 2000).

The tea shoot-aphid complexes tested included four aphid-damaged shoots with 200 aphids, 10 shoots with 400 aphids, 15 shoots with 600 aphids, 20 shoots with 800 aphids, 30 shoots with 1200 aphids, 50 shoots with 2000 aphids,

70 shoots with 2800 aphids, and 90 shoots with 3600 aphids. The aphid-damaged tea shoots tested included 5, 10, 20, 40, 60, 80, 100, and 120 shoots from which all aphids had been removed. The tea aphids tested included 200, 250, 500, 1000, 1500, 2000, 2500, 3000, and 3500 complexes of adults and nymphs.

Choice Tests. The following combinations of odor sources were presented in olfactometer choice tests to determine which odor was more attractive: (1) 20 aphid-damaged tea shoots with about 1000 aphids vs. 20 undamaged tea shoots, (2) 20 aphid-damaged tea shoots from which the aphids had been removed vs. 20 undamaged tea shoots, (3) 20 aphid-damaged tea shoots with about 1000 aphids vs. 20 aphid-damaged tea shoots from which the aphids had been removed, (4) hexane rinse of aphid cuticle vs. hexane, (5) ether rinse of aphid cuticle vs. ether, (6) the main components identified from volatile extracts of tea shoot-aphid complexes vs. hexane control: (*Z*)-3-hexen-1-ol, benzaldehyde, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, ocimene, linalool, geraniol, indole, and (*E*)-2-hexenoic acid were, respectively, diluted in hexane and used as odor sources at a concentration of 10^{-4} g/ml. In each case, 1 ml of the odor solution was poured into a 2-ml ampoule, which was then placed, unsealed, in the odor source jar. At the same time, 1 ml hexane was poured into an open ampoule and placed in the control jar.

Searching Responses of Natural Enemies to Aphid Honeydew. A Petri dish was used to collect the honeydew secreted by 8000 tea aphids for 24 hr. Five milliliters of a 50% ethanol solution was poured into the dish and stirred for 10 min. The resulting solution was then concentrated to 2 ml. A 12-cm-diam. filter paper was placed into a clean Petri dish, and 100 μl or 200 μl of concentrated honeydew solution were pipetted onto the center of the paper. This was equivalent to the amounts excreted by 400 or 800 aphids over 24 hr, respectively. After the ethanol had evaporated, a natural enemy was introduced in the center of the paper. The time that *C. sinica* and *Aphidius* sp. spent from touching the center to flying off and the time that *C. septempunctata* spent from touching the center to climbing the edge of the dish were recorded. Fifteen individuals of each species were tested. The bioassays were conducted between 09:00 and 14:00 hr at 21–24°C, 75–83% relative humidity and 3200–3600 lux. The tea plant variety was Longjing 43.

Electrophysiology. Electroantennogram (EAG) recordings from each species of natural enemy were made using Ag–AgCl glass electrodes filled with Ringer's solution. The antenna was excised and penetrated with the reference electrode. The tip of the antenna was cut and placed inside the recording electrode. Odor presentation was similar to that in previous studies (Visser, 1979; Park et al., 2000; Han et al. 2001). Twenty microliters of standard solutions of each test compound were applied to filter paper strips (5 × 60 mm), and solvent was allowed to evaporate for 30 sec before the paper strip was inserted into the glass Pasteur pipet (15 cm long). The tip of the pipet was inserted about 3 mm into a small hole in the wall of a steel tube (15 mm diam. × 15 cm long) directed over the antennal

preparation. An air stimulus controller (model CS-05b, Syntech) was used for air and odor delivery with a constant flow (120 ml/min) of charcoal-filtered and humidified air passed over the antenna through the open end of the steel tube positioned 15 mm from the antenna. During odor stimulation, 20 ml/min of air were applied through the pipet into the main airflow for 0.5 sec. Intervals of at least 2 min were maintained between stimulations, which were delivered in ascending order of concentration. Compounds were tested against 15 individual antennae. The signals were passed through an amplifier (Syntech CS-05), displayed on an oscilloscope and stored in a computer using Syntech Software.

The odor sources were: (1) air entrainment extracts of tea shoot–aphid complexes (TSAC), air entrainment extracts of undamaged tea shoots (UTS), hexane rinse, and ether rinse; (2) benzaldehyde, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexen-1-ol, linalool, geranoil, and indole diluted in hexane at concentrations of 10^{-2}, 10^{-4}, and 10^{-6} g/ml; and (3) filter paper that contained honeydew from 800 tea aphids excreted for 24 hr (the filter paper was cut into strips 60 mm long $\times$ 5 mm wide to fit in the odor delivery glass Pasteur pipet).

RESULTS

Chemical Composition of Several Volatile Infochemicals. Nine components were confirmed in the volatile extract entrained from tea shoot–aphid complexes. (*Z*)-3-Hexen-1-ol, geraniol, (*E*)-2-hexenal, and benzaldehyde were present in the greatest quantities (Table 1). The hexane and ether rinses of aphid cuticle contained many hydrocarbons among their main components. Benzaldehyde was a major component in the hexane rinse (Table 2).

TABLE 1. VOLATILE COMPOSITION OF TEA SHOOT–APHID COMPLEXES AND RELATIVE AMOUNTS

Component	Amount[a]
(*Z*)-3-hexen-1-ol	8.80×10^{-6}
geraniol	5.40×10^{-6}
(*E*)-2-hexenal	4.20×10^{-6}
benzaldehyde	3.30×10^{-6}
ocimene	2.24×10^{-6}
Decanoic acid, ethyl ester (internal standard)	2.00×10^{-6}
linalool	1.20×10^{-6}
(*Z*)-3-hexenyl acetate,	0.24×10^{-6}
(*E*)-2-hexenoic acid	0.20×10^{-6}
indole	0.04×10^{-6}

[a] Units: g/20 μl concentrated resulting extract.

TABLE 2. MAIN COMPONENTS OF HEXANE AND ETHER RINSES OF APHID CUTICLE AND THEIR RELATIVE AMOUNTS[a]

Component	Hexane rinse	Ether rinse
2,5-Hexanedione	1.63×10^{-5}	
Benzaldehyde	6.90×10^{-6}	
linalool	6.50×10^{-6}	
2,5-Dihydro-thiophene	5.00×10^{-6}	
Eicosane	3.50×10^{-6}	2.41×10^{-5}
Undecane	2.95×10^{-6}	
Decanoic acid, ethyl ester (internal standard)	1.00×10^{-6}	1.00×10^{-6}
4-Methyl-octane	0.35×10^{-6}	
2-Hexenoic acid		4.80×10^{-5}
Heptadecane		3.50×10^{-5}
Pentadecane		4.00×10^{-6}
Tetratetracontane		2.90×10^{-6}
Nonadecane		0.50×10^{-6}

[a] Units: g/100 μl concentrated rinse.

Dose Responses of Natural Enemies to Tea Shoot–Aphid Complexes. All three natural enemies responded to tea shoot–aphid complexes in the Y-tube olfactometer, and the number responding and the speed of their response increased as the amount of the odor source increased (Table 3). In the case of *C. sinica*, the difference between the number of natural enemies choosing odor and the number choosing control became statistically significant when the odor source was 50 aphid-damaged shoots with 2000 tea aphids ($P < 0.05$). The level of significance increased when the odor source was at least 70 aphid-damaged shoots

TABLE 3. NUMBER OF NATURAL ENEMIES CHOOSING TEA SHOOT–APHID COMPLEXES OR BLANK CONTROL IN A Y-TUBE OLFACTOMETER[a]

Number of aphids/100	(X_1)	2	4	6	8	12	20	28	36
Number of aphid-damaged shoots	(X_2)	4	10	15	20	30	50	70	90
Number of natural enemies choosing odor (Y) or control									
Chrysopa sinica	Odor (Y)	10	11	12	13	13	15*	17**	19**
	Control	10	9	8	7	7	5	3	1
Aphidius sp.	Odor (Y)	10	10	11	11	12	13	15*	17**
	Control	10	10	9	9	8	7	5	3
Coccinella septempunctata	Odor (Y)	10	12	13	14	15*	17**	18**	19**
	Control	10	8	7	6	5	3	2	1

[a] Notes: χ^2 test is used to determine the difference between number of natural enemies choosing odor and number of choosing control. * and ** indicate significances statistical at $P < 0.05$ and $P < 0.01$, respectively.

with 2800 aphids ($P < 0.01$). There was a highly significant linear regression relationship between the number of natural enemies choosing odor (Y) and the number of aphids/100 (X_1) as well as the number of aphid-damaged shoots (X_2). The relationship can be represented as $Y = 10.4618 - 2.0938\,X_1 + 0.9314\,X_2$ ($R^2 = 0.9899$; $P < 0.001$).

For *Aphidius* sp., the difference between the number of natural enemies choosing odor and the number choosing control became statistically significant only when the odor source was 70 aphid-damaged shoots with 2800 aphids ($P < 0.05$). Again, there was also a highly significant linear regression relationship ($Y = 9.3855 + 0.7186\,X_1 - 0.2057X_2$; $R^2 = 0.9881$; $P < 0.001$).

For *C. septempunctata*, the difference between the number of natural enemies choosing odor and the number of choosing control became statistically significant when the odor source was 30 aphid-damaged shoots with 1200 aphids ($P < 0.05$), and there was a highly significant linear regression relationship ($Y = 11.9787 - 5.7940X_1 + 2.4023X_2$; $R^2 = 0.9693$; $P < 0.001$).

The number of both aphids and aphid-damaged shoots closely corelates with the number of natural enemies locating odor. Therefore, the volatiles emitted from both aphids and aphid-damaged shoots can simultaneously seduce natural enemies. However, the absolute values of coefficients of X_1 and X_2 regarding *C. septempunctata* equation are the largest, which means that both odors attract *C. septempunctata* a little more strongly than the other natural enemies. In fact, when the amount of the odor source is small, *C. septempunctata* is slightly more responsive than *C. sinica* and *Aphidius* sp. (Table 3).

Dose Responses of Natural Enemies to Aphid-Damaged Tea Shoots. Aphid-damaged tea shoots were also attractive to the three natural enemy species (Table 4). For *C. sinica*, the difference between the number natural enemies choosing odor and the number choosing control became statistically significant when the odor source was 60 aphid-damaged shoots ($P < 0.05$). The significance level increased when the odor source was at least 80 aphid-damaged shoots

TABLE 4. NUMBERS OF THREE SPECIES OF NATURAL ENEMIES CHOOSING APHID-DAMAGED TEA SHOOTS OR BLANK CONTROL IN A Y-TUBE OLFACTOMETER[a]

Number of aphid-damaged shoots	(X)	5	10	20	40	60	80	100	120
Number of natural enemies choosing odor (Y) or control									
Chrysopa sinica	Odor (Y)	10	10	12	13	15*	17**	18**	18**
	Control	10	10	8	7	5	3	2	2
Aphidius sp.	Odor (Y)	10	10	12	13	14	15*	16*	18**
	Control	10	10	8	7	6	5	4	2
Coccinella septempunctata	Odor (Y)	10	11	14	16*	16*	17**	18**	18**
	Control	10	9	6	4	4	3	2	2

[a] *and **indicate significance levels of $P < 0.05$ and $P < 0.01$, respectively.

($P < 0.01$). There was a significant logistic regression relationship between the number of natural enemy responding (Y) and the number of aphid-damaged shoots (X), which can be represented as $Y = 19.8737/(1 + e^{0.132-0.022X})$ ($R^2 = -0.9851$; $P < 0.001$). For *Aphidius* sp., the difference became statistically significant when the odor source was 80 aphid-damaged shoots ($P < 0.05$), and there was also a significant logistic regression relationship, $Y = 23.5911/(1 + e^{0.326-0.0117X})$ ($R^2 = -0.9722$; $P < 0.001$). For *C. septempunctata*, the difference became statistically significant when the odor source was 40 aphid-damaged shoots ($P < 0.05$), and again there was a significant logistic regression relationship, $Y = 17.5500/(1 + e^{-0.0287-0.0561X})$ ($R^2 = -0.9678$; $P < 0.0001$).

Logistic responses exist widely in living processes. The responses of natural enemies to odors agree with the model. Similarly, while the amount of the odor source is small, *C. septempunctata* is slightly more responsive than the other two species of natural enemies (Table 3).

Dose Responses of Natural Enemies to Tea Aphids. Tea aphids themselves also send out odors incurring natural enemies (Table 5). In the case of *C. sinica*, the difference between the number of natural enemies choosing odor and the number of choosing control became statistically significant when the odor source was 2000 aphids ($P < 0.05$). The significant logistic regression relationship between the number of natural enemies responding (Y) and the number of aphids/100 (X) could be represented as $Y = 25.6567/(1 + e^{0.5217-0.0405X})$ ($R^2 = -0.9923$; $P < 0.001$). For *Aphidius* sp., the difference became statistically significant when the number of aphids was 2500 ($P < 0.05$), and there was a significant logistic regression relationship that could be represented as $Y = 21.5912/(1 + e^{0.2006-0.0413X})$ ($R^2 = -0.9975$; $P < 0.001$). For *C. septempunctata*, the difference became statistically significant when the number of aphids was 2000 ($P < 0.05$). The significant logistic regression relationship could be represented as $Y = 23.2074/(1 + e^{0.1779-0.0457X})$ ($R^2 = -0.9079$; $P < 0.01$).

TABLE 5. NUMBER OF THREE SPECIES OF NATURAL ENEMIES CHOOSING APHIDS OR BLANK CONTROL IN A Y-TUBE OLFACTOMETER

Number of tea aphids/100	(X)	2	5	10	15	20	25	30

	Control	10	7	6	6	5	3	2

[a] * and ** indicate significance levels of $P < 0.05$ and $P < 0.01$, respectively.

Selectivity of Natural Enemies to Different Odor Sources in Choice Tests. The volatiles from both tea shoot–aphid complexes and aphid-damaged tea shoots were much more attractive to natural enemies than the volatiles from undamaged tea shoots. Furthermore, the volatiles from tea shoot–aphid complexes were slightly more attractive than the volatiles from aphid-damaged shoots, possibly because the interaction between aphids and aphid-damaged shoots strengthens the attraction (Table 6). Hexane and ether rinses of tea aphid cuticles showed some attractive effect on natural enemies. The hexane rinse was slightly more attractive than the ether rinse.

Of nine components identified from the volatile extracts entrained from tea shoot–aphid complexes, statistically significant responses of the natural enemies were recorded only to benzaldehyde and (*E*)-2-hexenal ($P < 0.05$). The responses to benzaldehyde were slightly stronger than those to (*E*)-2-hexenal.

Attraction of Aphid Honeydew to Natural Enemies. All three natural enemy species spent significantly longer searching on filter papers with honeydew than on blank control filter papers ($P < 0.01$) (Table 7). On the honeydew-treated filter paper, the lacewing and the coccinellid actively searched with much turning and reduced walking speeds. They still moved their antennae from side to side and shook their labial palps constantly. The parasitoid exhibited arrestment, antennal examination, and ovipositor probing. Therefore, the honeydew intensively entices natural enemies and appears to provide an important contact semiochemical cue for natural enemies to search tea aphids.

Electrophysiology. EAG responses of three species of natural enemies elicited by air entrainment volatile extracts from tea shoot–aphid complexes were significantly greater than those elicited by extracts from undamaged shoots. Hexane and ether rinses of aphid cuticles also elicited strong EAG responses. EAG responses of *C. septempunctata* and *C. sinica* to these infochemicals were much larger than those of *Aphidius* sp. (Figure 1). In particular, honeydew vividly elicited EAG responses from *C. septempunctata*, which suggests honeydew contains semiochemicals.

Of seven main components in the volatile extracts of tea shoot–aphid complexes, benzaldehyde elicited the biggest EAG responses, followed by (*E*)-2-hexenal and (*Z*)-3-hexenyl acetate. EAG responses of the three species of natural enemies decreased when the dose of the three components increased. When the dose of linalool, geraniol, and (*Z*)-3-hexen-1-ol increased, EAGs of *C. sinica* and *Aphidius* sp. increased, but EAGs of *C. septempunctata* gradually decreased. When the dose of indole increased, EAG responses of *C. septempunctata* decreased, but those of *Aphidius* sp. increased (Figure 2). EAG responses of the predatory or parastic natural enemies to infochemicals appear to change as the concentrations of infochemicals increase or decrease. The numerical values of EAG of one natural enemy differ from those of another. EAGs of *C. septempunctata* are the greatest, and those of *Aphidius* sp. are the smallest.

TABLE 6. DIFFERENCE IN NUMBER FOR NATURAL ENEMIES CHOOSING DIFFERENT ODOR SOURCES IN CHOICE TESTS IN Y-TUBE OLFACTOMETERS[a]

	Odor			Odor			Odor			Odor			Odor		
Natural enemy	TSAC	UTS	Difference	ADS	UTS	Difference	TSAC	ADS	Difference	HR	H	Difference	ER	E	Difference
C. sinica	16	4	*	15	5	*	12	8	NS	12	8	NS	11	9	NS
Aphidius sp.	16	4	*	15	5	*	12	8	NS	12	8	NS	11	9	NS
C. septempunctata	16	4	*	16	4	*	12	8	NS	12	8	NS	11	9	NS

[a] Notes: TSAC: tea shoot-aphid complexes; UTS: undamaged tea shoots; ADS: aphid-damaged shoots; HR: hexane rinse; H: hexane; ER: ether rinse; E: ether; NS: No significant. χ^2 test is used to determine the difference between the number for natural enemies choosing one odor and the number for natural enemies choosing another odor resource in choice tests. * indicates statistical significance of $P < 0.05$.

TABLE 7. DIFFERENCE BETWEEN SEARCHING TIMES (SECONDS) OF NATURAL ENEMIES ON HONEYDEW-TREATED AND ON BLANK CONTROL FILTER PAPERS[a]

	Control	100 μl	200 μl	Difference
Chrysopa sinica	2.1 ± 0.9	10.7 ± 3.4	25.4 ± 12.2	$F = 38.6 > F_{0.01}(2, 42)$
Aphidius sp.	27.0 ± 13.1	117.0 ± 60.9	200.1 ± 72.5	$F = 28.2 > F_{0.01}(2, 42)$
Coccinella septempunctata	8.6 ± 3.6	47.1 ± 15.9	71.9 ± 24.8	$F = 52.1 > F_{0.01}(2, 42)$

[a] Values are mean $\pm$ SE; $F_{0.01}(2, 42) = 5.15$; 15 replicates.

DISCUSSION

Herbivore-induced plant odors play a major role in the foraging behavior of predatory and parasitic insects. Turlings et al. (1998) reported that the aphid, *Rhopalosiphum maidis*, induced no measurable emissions of volatiles when feeding on maize plants and suggested that the *R. maidis*–maize interaction is different from some other known interactions between plants and aphids. Some of the behavioral studies conducted on aphid parasitoids have indicated that induced plant volatiles are involved (Guerrieri et al., 1993; Reed et al., 1995; Du et al., 1996, 1998; Powell et al., 1998). Even uninfested parts of aphid-infested plants have been shown to be attractive to parasitoids (Micha and Wyss, 1995). The seven-spotted ladybird, *Coccinella septempunctata* L. (Coleoptera, Coccinellidae), responded positively to volatiles from aphid, *Rhopalosiphum padi* (L.), from infested plants, *Hordeum vulgare*, and from previously aphid-infested plants, but not to volatiles

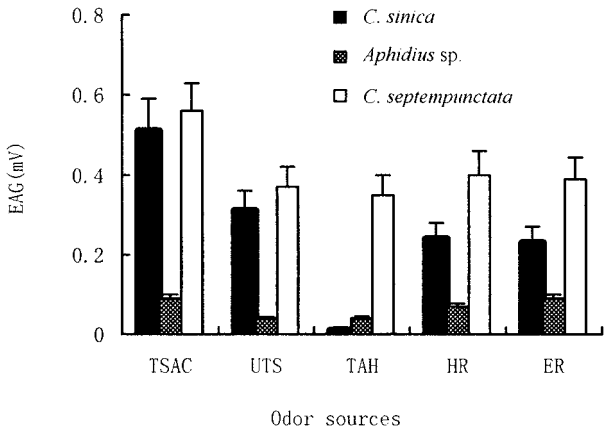

FIG. 1. Electroantennogram responses of three species of natural enemies to the following infochemicals: TSAC: air entrainment volatile extracts from tea shoot-aphid complexes; UTS: air entrainment volatile extracts from undamaged tea shoots; TAH: tea aphid honeydew; HR: hexane rinse of tea aphid cuticles; ER: ether rinse of tea aphid cuticles.

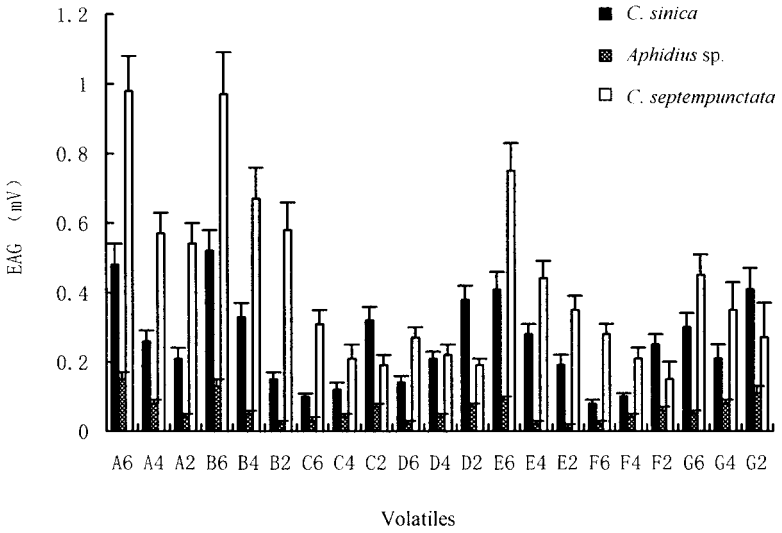

FIG. 2. EAG responses of three species of natural enemies to seven main components in the volatiles entrained from tea shoot–aphid complexes. A6, A4, and A2 stand for 10^{-6}, 10^{-4}, and 10^{-2}g/ml benzaldehyde, respectively. B6, B4, and B2 for 10^{-6}, 10^{-4}, and 10^{-2} g/ml (*E*)-2-hexenal, respectively. C6, C4, and C2 for 10^{-6}, 10^{-4}, and 10^{-2} g/ml linalool, respectively. D6, D4, and D2 for 10^{-6}, 10^{-4}, and 10^{-2} g/ml (*Z*)-3-hexen-1-ol, respectively. E6, E4, and E2 for 10^{-6}, 10^{-4}, and 10^{-2} g/ml (*Z*)-3-hexenyl acetate, respectively. F6, F4, and F2 for 10^{-6}, 10^{-4}, and 10^{-2} g/ml geraniol, respectively. G6, G4, and G2 for 10^{-6}, $10^{-4}$and 10^{-2} g/ml indole, respectively.

from uninfested plants in olfactometer bioassays (Ninkovic et al., 2001). In the present work, we demonstrated that interactions between tea aphids and tea shoots produce volatiles that are attractive to predatory and parasitic natural enemies. The volatiles released by tea shoot-aphid complexes, and the volatiles released by aphid-damaged tea shoots act as long-range cues, while the odors of tea aphids themselves act as short-range cues. The interaction between the kairomones from tea aphids and the synomones from aphid-damaged shoots reinforced the attractive effect of tea shoot–aphid complexes on natural enemies, and allowed them, to some extent, to overcome the "reliability–detectability problem" faced by foraging carnivores (Vet et al., 1991; Vet and Dicke, 1992).

In recent years, aspects of chemical communication via surface lipids and hydrocarbons have been increasingly investigated. Cuticular hydrocarbons play a role as recognition cues in *Apis mellifera carnica* Pollm, allowing recognition of nestmates and conveying information about age, caste, and sex (Fröhlich et al., 2000). The Aphidiine wasp *Lysiphlebus cardui* (Marshall) is the dominant parasitoid of the ant-attended aphid, *Aphis fabae cirsiiacanthoidis* Schrank (Afc), and is

successful because the composition of the cuticular hydrocarbons of the wasp is very similar to that of the ant *Lasius niger* L., allowing *L. cardui* to forage in the aphid colonies without being attacked (Liepert et al., 1996). The hydrocarbons act as chemical mimics. Bakthavatsalam et al. (1999) reported that a hexane wash of the body of *Opisina arenosella* Walker (Lepidoptera: Noctuidae), a major pest of coconut in coastal Karnataka in India, elicited positive responses from its parasitoids, *Goniozus nephantidis* (Muesebeck), *Brachymeria nephantidis* Gahan, and *Elasmus nephantidis* Rohwer in a Y-tube olfactometer. The hexane wash of the larvae of *O. arenosella* had 20 different alkanes, including the five alkanes identified from cuticle rinses of tea aphids, i.e., undecane, eicosane, heptadecane, nonadecane, and pentadecane. The tea aphid cuticle contains many hydrocarbons. Cuticle rinses from tea aphids act as short-range cues or contact semiochemicals for the three natural enemies tested. The hexane rinse of tea aphid cuticle appeared to be slightly more attractive than the ether rinse, and one of the reasons may be that it contained benzaldehyde.

The western flower thrips, *Frankliniella occidentalis* (Pergande), responded to benzaldehyde at a 10% concentration in Y-tube olfactometer bioassays (Koschier et al., 2000). In the field, traps with benzaldehyde were also attractive to western flower thrips (Teulon et al., 1993). Guo et al. (1998) reported that benzaldehyde exists in tea leaves in the form of cyanogenic glycosides, i.e., prunasin, which can be hydrolyzed into benzaldehyde, hydrocyanic acid, and glucose by β-d-glucosidase. The large amounts of benzaldehyde detected in the volatiles entrained from the tea shoot–aphid complexes possibly resulted from enzymes present in the saliva of the aphids, because the oral cavity of many aphids is known to contain β-d-glucosidase (Madhusudhan et al., 1994). Cyanogenic compounds are widely distributed in the plant kingdom (Seigler, 1981) and in several arthropods (Duffey, 1981) and other insects (Davis and Nahrstedt, 1985). These are usually stabilized by glycosylation giving rise to the cyanogenic glycosides or (rarely) by esterification of the hydroxyl function, resulting in the cyanolipids. If a plant or animal tissue is injured, the glycosides are hydrolyzed by glycosidases, and the resulting cyanogenic compounds decompose under the influence of pH or nitrilase activity to a carbonyl component and HCN (Hösei, 1981). This carbonyl component is an aldehyde or ketone, e.g., benzaldehyde in the case of prunasin. The aldehyde often possesses cytotoxic activity, and cyanogenic compounds act as protection agents for plants (Nahrstedt, 1985). Benzaldehyde is the most common benzenoid (Knudsen et al., 1993) and is a minor aromatic component of tea plants. It occurs in tea leaves in trace amounts at levels of about 7.4 mg/kg. However, in the present study, benzaldehyde was detected in higher amounts in the volatiles entrained from aphid-damaged shoots infested with tea aphids. Furthermore, it elicited both strong behavioral responses and electrophysiological responses. We consider it to be an important, aphid-induced component of the volatiles released from tea shoots that influences natural enemy foraging behavior.

The honeydew excreted by the cereal aphid, *Sitobion avenae* (F.), acts as a contact kairomone for the coccinellid *C. septempunctata* (Carter and Dixon, 1984). Honeydew of the rose-grain aphid *Metopolophium dirhodum* (Walker) and of the pea aphid *Acyrthosiphon pisum* (Harris) stimulated the syrphid *Episyrphus balteatus* (Deg.) to lay eggs (Budenberg and Powell, 1992). The wasp *Diaeretiella rapae* (M'Intosh) used honeydew produced by its host, the cabbage aphid *Brevicoryne brassica* (Linnaeus), as a kairomone (Shaltiel and Ayal, 1998). The parasitoid *Aphidius nigripes* Ashmead spent more time searching on potato previously infested with potato aphids, *Macrosiphum euphorbiae* (Thomas) than on fresh plants, while water extracts of the aphid honeydew applied to the surface of foliage or to filter paper disks increased searching time (Bouchard and Cloutier, 1984). Wasps also frequently turned, protracted their abdomen, and tapped the paper with their antennae. Li et al. (1993) identified 12 amino acids and six sugars in honeydew of the citrus white fly, *Aleurocanthus spiniferus* (Quaintance). These constituted an "artificial honeydew," which was sprayed on tea plants in a tea garden, resulting in an increase of 10–20% in parasitism of *A. spiniferus* by *Amithus longiconis* Föster. Seven saccharides and 13 amino acids were identified from the honeydew of tea aphids (Han and Chen, 2000). In the present study, the honeydew had weak volatility and was a searching stimulant to three species of beneficial insects. We also consider that the honeydew acts as an important contact kairomone. EAG responses of *C. septempunctata* to honeydew were stronger than those of *C. sinica* and *Aphidius* sp. This may be because the coccinellids usually crawl up and down on tea plants searching for tea aphids and easily contact honeydew, so they are sensitive to it as a foraging cue.

The present work showed that each natural enemy has its reaction threshold to a semiochemical cue, defined in time and space. When the dose of the odor source increased, the level of response to semiochemicals ascended on a Logistic curve. However, there are differences in electrophysiology and behavioral responses between *C. sinica*, *C. septempunctata*, and *Aphidius* sp. to the same infochemicals. When the dose of the odor source is small, *C. septempunctata* is the most sensitive. When the dose reaches a certain level, all three natural enemies respond equally, for which the mechanism used to receive infochemicals may be responsible.

(Received December 20, 2001; accepted June 6, 2002)

Abstract—*Diachasmimorpha juglandis* is a specialist parasitoid attacking fly larvae in the genus *Rhagoletis* that feed exclusively on walnut fruit husks. In a free-foraging assay comparing response to uninfested, infested, and mechanically damaged fruits, we first determined that *D. juglandis* use host feeding damage on the fruit as a cue for host presence. In another free-foraging assay that used artificial walnut models and wind tunnel experiments, *D. juglandis* distinguished infested from uninfested fruits by using either olfactory or visual cues separately. However, the response rate of wasps in the wind tunnel was raised considerably when visual cues were also available. We analyzed the volatile compounds emitted by cohorts of uninfested, mechanically damaged, and infested fruits 1, 3, 5, 8, and 10 days after oviposition by flies into the infested fruits. Total volatile emissions did not differ significantly among treatments, but quantitative changes in volatiles distinguished infested fruits from uninfested and damaged fruits. The fact that parasitoids did not distinguish between

INTRODUCTION

Insect natural enemies are known to increase their host-searching efficiency by using, as indirect cues, odors associated with the plants on which their hosts feed (Read et al., 1970; Price et al., 1980; Whitman and Eller, 1990; Vet et al., 1995). Parasitoids are often attracted to damaged plants, with the highest response to damage created specifically by a feeding herbivore (Eller et al., 1988; Turlings et al., 1990, 1991a; McAuslane et al., 1991). Unlike simple mechanical damage, herbivore damage to foliage can result in systemic release by a plant of specific volatile compounds. (Turlings et al., 1991b; Turlings and Tumlinson, 1992; Dicke et al., 1993; Röse et al., 1996).

Wasps are known to use visual as well as odor cues to locate leaf-feeding hosts (e.g., Sugimoto et al., 1988; McAuslane et al., 1991; Drost and Cardé, 1992; Wäckers, 1994; Wäckers and Lewis, 1994); however, the use of odor has been emphasized in these systems. In systems in which the host is an internally feeding frugivore, studies examining the roles of both odor and visual cues on parasitoid foraging have focused on how the presence of odor mediates response to visual stimuli in parasitoids (Leyva et al., 1991; Messing and Jang, 1992; Messing et al., 1996; Jang et al., 2000). We are interested in specifically what visual and olfactory cues allow parasitoids to distinguish infested from uninfested fruits.

We examine here the foraging behavior of the opiine braconid parasitoid *Diachasmimorpha juglandis*, which attacks fly larvae in the genus *Rhagoletis* that feed inside the husks surrounding walnut fruits. Walnut fruits are yellowish green when ripe. Flies oviposit clutches of 10–20 eggs in fruits when fruits are on the tree and ripe (i.e., soft enough for a fly to insert her ovipositor) (Papaj, 1994). After a fly has oviposited, the fruit begins to appear more yellow. Eggs hatch in ca. 3 days. The natural rotting process of a fruit is accelerated as larvae feed and develop within, and dark brown patches appear over areas in which larvae have consumed the inner husk material (Henneman and Papaj, 1999). *Diachasmimorpha juglandis* relies on indirect cues for locating infested fruits, because the larvae feed internally. In Arizona, nearly all walnut fruits eventually become infested, but early in the season there are both infested and uninfested fruits available.

Diachasmimorpha juglandis females land preferentially on infested walnuts compared to ripe, uninfested walnuts (Henneman, 1996). Here we used behavioral assays and walnut fruit volatile analysis to test the presence of feeding damage as

a cue used by *D. juglandis* for host presence and to evaluate separately the use of olfactory and visual cues by wasps foraging for hosts inside fruits.

METHODS AND MATERIALS

Wasps were collected in the summer of 1994 as larvae within their fly larvae hosts. Infested walnuts were collected from several sites in southeastern Arizona, USA, including Wet Canyon in the Pinaleño Mountains (Graham County), Garden Canyon in the Huachuca Mountains (Ft. Huachuca, Cochise County), the Catalina Mountains (Tucson, Pima County), and Patagonia Square (Patagonia, Santa Cruz County). After host larvae exited the walnuts and pupated in the sand provided, puparia containing both host pupae and wasp larvae were stored at 5–10°C in the dark until the following summer. About 6 wk after warming pupae at ca. 30°C, adult *D. juglandis* emerged. After emergence, male and female *D. juglandis* adults were caged together to allow mating and were maintained with water and sugar at ca. 30°C for at least 5 d to allow egg development in females (Buckingham, 1975). Five- to 14-d-old females were used in all experiments.

Greenhouse Cage Assay—Real Fruits. The purpose of this assay was to determine whether foraging wasps use fruit damage as a cue for hosts. At least 1 d before the experiment began, female wasps were individually marked with 1–2 dots of liquid tempera paint (ProArt) on the thorax. The evening before testing, marked females were placed inside the greenhouse to allow acclimatization to greenhouse conditions.

Most free-foraging fruit choice assays were conducted in a 3-m-diam. × 3-m tall cylindrical field cage inside the greenhouse, which contained three potted walnut trees, each 2–3 m in height. Data were taken between 10:00 and 16:00 hr on various test days from July to November 1995. There were 1 or 2 test periods of 1–3 hr each on a given day. Temperature during tests ranged from 25° to 35°C, and relative humidity ranged from 30% to 60%. Additional data were collected in August 1995 in a field cage enclosing a branch of a walnut tree at the Southwestern Research Station of the American Museum of Natural History, Portal, Arizona, using wasps collected from the field as adults.

Ten to 30 female wasps were released into the cage on a given test day. At most, 7 of these alighted on at least one walnut fruit. Separate groups of wasps were tested in three experiments which paired three different fruit types: host-infested (= infested), uninfested but mechanically damaged (= damaged), and uninfested and undamaged (= uninfested). Mechanically damaged fruits were manually bruised over roughly 20% of the surface of the fruit, using moderately applied thumb pressure, at least 1 hr before an experiment. Within a few minutes after bruising, the skin of the fruit acquired a brown color that closely resembled feeding damage by *Rhagoletis* larvae and similarly got darker over time. This is

a reproducible technique, similar to leaf damage techniques employed by other workers (Turlings et al., 1990; Turlings and Tumlinson, 1992). Fruits were placed 1–2 m high in the cage and at least 0.5 m apart.

In the first experiment, wasps were presented with 4 infested and 4 damaged fruits. In the second, wasps were presented with 4 damaged fruits and 4 uninfested fruits. In the third, they were presented with 4 infested and 4 uninfested fruits. All fruits used at one time were collected from a single tree, and 3–6 sets of fruits from different trees were used in each experiment. Each set of fruits was used over 2–3 d, when damage covered 20–50% of the surface of the infested fruits, after which all fruits were discarded. The position of each fruit was randomized before every test period. Landings made on each fruit were recorded for all wasps by speaking into a hand-held tape recorder.

Greenhouse Cage Assay—Artificial Models. To assess the role of visual cues apart from odor cues in the landing behavior of wasps, an assay similar to that described above was conducted, except that artificial walnut fruit models (rather than real fruits) were presented to wasps in the greenhouse cage. Use of models allowed us to manipulate visual cues while keeping odor constant. Data were collected under, conditions similar to those of the previous assay, from July to November 1995. A model consisted of a painted plastic sphere, 38 mm diam. (Euromatic County, Leominster, Massachusetts, USA), with ten 3-mm holes punched in it, with an infested fruit inside as an odor source. To make walnut models that matched the color patterns of walnuts that wasps would encounter in the field, we used paint (Behr Premium Plus exterior acrylic latex flat) that was computer color-matched to a ripe fruit (green models) (Henneman and Papaj, 1999). We also painted models to represent fruits that had been damaged by feeding fly larvae, using similarly computer-matched yellow paint (Weatherfighter exterior acrylic latex flat), and brown paint (ProArt Liquid Tempera) (yellow/brown models) (Henneman and Papaj, 1999). Three green models and 3 yellow/brown models (all containing real, infested fruits) were made available to wasps in the cage. All wasps in this experiment had been exposed previously to infested fruits, which had been found to increase their landing response in the greenhouse (M. L. Henneman, unpublished data). Wasps were individually marked and released, and, as in the previous experiment, landings and time spent on each model were recorded for each individual.

Comparisons for all free-foraging behavioral assays were made using a randomization test for matched pairs, which is more powerful than conventional nonparametric methods (Edgington, 1980; Daniel, 1990). The matched pairs consisted of the number of landings by one wasp on one type of fruit or model versus the other type. The probability that each matched pair is random is calculated by comparing each actual pair to a distribution of 20,000 random pairs drawn from the actual data. Comparisons were run using SAS (SAS Institute, 1990).

Wind-Tunnel Assays. We tested the response of wasps to fruits both with and without visible damage. The wind tunnel measured 60 × 60 cm in cross section, and 180 cm in length. Airflow was 20 cm/sec, obtained by placing the downwind end of the tunnel in a fume hood. Illumination was provided by two 150-W incandescent floodlights, with white paper covering the roof of the tunnel in order to diffuse the incoming light. A patterned cloth was placed on the floor to provide an optomotor reference to flying wasps.

We tested wasps 11–25 d old that had emerged in the laboratory and had been exposed to infested walnuts for 2 hr 4–5 d previous to the test. A wasp was released from a small test tube on a platform at the same height at which a single row of walnut fruits was suspended, 20 cm from the floor of the tunnel. If the wasp flew to the side or ceiling of the wind tunnel, she was recaptured and released 1 or 2 more times. A choice was counted when the wasp landed on one of the fruits. Each wasp was tested once.

Three wind tunnel assays were conducted (Table 1). The first was similar to the free-foraging experiment using real fruit. Wasps were presented with an uninfested fruit, an infested fruit into which flies had oviposited 5 d previously (thus, fly larvae were present), and a damaged fruit from each of two walnut trees, for a total of 6 fruits. Damage was visible on the infested and damaged fruits. Positions of the fruit types were randomized every 7 landings by wasps.

The second assay was identical to the first except that the infested fruits had been oviposited into 1 d before, so that they contained fly eggs but no larvae, and lacked visible damage.

In the third assay, infested and uninfested fruits only were presented to wasps, also from two different trees. Fly oviposition in infested fruits occurred 3–4 d previously, and these contained larvae and some slight damage that was oriented upwind, and, thus, invisible to wasps.

TABLE 1. SUMMARY OF WIND-TUNNEL EXPERIMENTS[a]

Experiment	Walnut types (No. of choices) **U**	**I**	**D**	Days since fly ovip. in **I**	Damage visible?	Wasps tested (N)	Response rate (%)	χ^2 Test and P
1	1	9	9	5	yes	45	42.2	$\chi^2 = 6.737$; $P = 0.034$
2	0	0	0	1	no	22	0	
3	0	5		3–4	no	46	10.9	Binomial, $P = 0.03125$

[a] **U** = uninfested, **I** = infested, **D** = mechanically damaged. Two trees were represented in each treatment. **D** walnuts were damaged when physical damage appeared on **I**, at about 5 d after fly oviposition.

Walnut Fruit Volatile Analysis

Volatile Collections. Walnut scent was collected using dynamic headspace sorption (Raguso and Pellmyr, 1998). For each of the undamaged, damaged, and infested odor collections, 4 fruits were excised from 3 individual trees and enclosed in polyacetate oven bags (Reynolds, Inc.) cinched at 300-ml volumes with plastic ties. A electrical diaphragm vacuum pump (Manostat, Inc.) was used to pull scent-enriched air through glass cartridges packed with 30 mg of Tenax GC adsorbent (mesh size 20/35), at a flow rate of 250 ml air/min. Incoming air was drawn through glass cartridges packed with 50 mg of activated charcoal. Scent collections began at 10:00 AM and continued for 5 hr within a dimly lit laboratory, and blank collections were performed in parallel for each collection day in order to control for ambient contaminants. Headspace collections were repeated 5 times for the same fruits over a time course of 10 d so that we could follow time-related changes in the composition of volatile emissions. As damaged areas spread on infested fruits over time, we added mechanical damage to the damaged fruits. After collections, we weighed all walnuts and found no significant differences in fruit mass among the treatment groups (Kruskal-Wallis, $P > 0.3$ day 1–8, $P > 0.08$ day 10). Between collections, fruits were stored at 30°C within individual jars that contained wet sand to provide high humidity.

Sample Preparation and GC-MS Analysis. Trapped volatiles were eluted from adsorbent cartridges using 1 ml of HPLC grade hexane. Each sample was stored in 4-ml borosilicate glass vials with Teflon-lined caps at −20°C until analysis. Samples were concentrated to 75 μl using a flow of gaseous N_2, after which an internal standard of 3.5 ng toluene dissolved in 5 μl hexane was added to each sample to control for unequal concentration volumes (Raguso and Pellmyr, 1998) before injection. Volatile samples were analyzed using a Shimadzu GC-17A gas chromatogram (GC), combined with a Shimadzu QP5000 mass spectrometer (MS) as a detector. The MS was set at 1 scan/sec, scanning masses from 30 to 300 Da, with an EI detector voltage of 1.7–1.95 kV. MS parameters were adjusted daily correcting for baseline drift. Aliquots of 1 μl were injected into the GC (split-splitless injector, splitless mode, temp. 250°C), where component peaks were separated on a polar GC column (EC-Wax = Carbowax, 30 m length, 0.25 mm ID, 0.25 μm film thickness; Alltech, Inc.). Carrier gas was He with a flow rate of 1 ml/min and a split ratio of 1:2. After injection, the column temperature was held at 60°C for 3 min, increased at 10°C/min until 260°C, then held for 7 min. Samples were reinjected on a nonpolar GC column (EC-5; 30 m long × 0.32 mm ID, 1 μm film thickness) (see Levin et al., 2001 for temperature program) for independent evidence supporting compound identification.

Analysis of Chromatogram Data. Chromatogram peaks were tentatively identified through the use of online NIST and Wiley mass spectral libraries (over 120,000 spectra) and then by comparing their spectra and retention times on each

column with those of known standards. Volatiles also detected in ambient controls were subtracted from walnut chromatograms (see Pellmyr et al., 1987). The operational limit of detection using this protocol for total ion chromatogram MS mode is 14 pg of toluene.

Peak areas were integrated using Shimadzu QP5000 Class 5K software and quantitated via comparison with the internal standard. In order to determine whether gross differences in odor emission accompanied different treatments, we calculated total nanograms of scent per gram of fruit per hour, using the internal standard and fresh masses of the walnuts. We then performed repeated measures ANCOVA, using DAY as within-subject variable and TREATMENT as between-subject variable, with individual TREE as a covariate.

Volatile profiles were also compared across trees and treatments using principal component analysis of peak area data (Sokal and Rohlf, 1995). Principal component axes are calculated through hyperellipsoids formed by the correlation of all peak areas in multidimensional space. The first principal component axis (PC1) accounts for the greatest amount of variation in the data, and subsequent axes account for successively smaller amounts of variation. Peaks chosen for comparison were those that were resolved enough for their areas to be accurately calculated, and, through comparisons with other studies, were potentially relevant to herbivore-induced plant signaling and parasitoid host location (Paré and Tumlinson, 1997) (Appendix A). To examine changes in the profiles over time, the analysis was conducted on differences in peak areas between the first collection and each of four subsequent collections.

RESULTS

Greenhouse Cage Assay—Real Fruit. Wasps did not distinguish infested from damaged (mechanically damaged, uninfested) fruits in their landing behavior (Figure 1: Fisher's randomization test for matched pairs, $N = 15$, $P > 0.52$). In the second test, wasps landed more often on damaged walnuts than they did on uninfested (undamaged) walnuts (Figure 1: $N = 15$, $P < 0.01$). Wasps in the third test landed more often on infested walnuts than they did on uninfested walnuts (Figure 1: $N = 15$, $P < 0.021$).

Greenhouse Cage Assay—Artificial Models. Wasps did not land significantly more often on damaged models than on models resembling uninfested fruits (Fisher's randomization test for matched pairs, $N = 17$, $P < 0.09$). However, they approached models closely without landing at times, and if these approaches are added to the analysis, the effect of visual models is significant ($N = 17$, $P < 0.045$). Glas and Vet (1983) found a similar effect with the response of *Diachasmimorpha alloeum* to artificial fruit models, and suggested that, while visual models may be sufficient to attract *D. alloeum*, other cues may help them decide whether or not to land on a fruit.

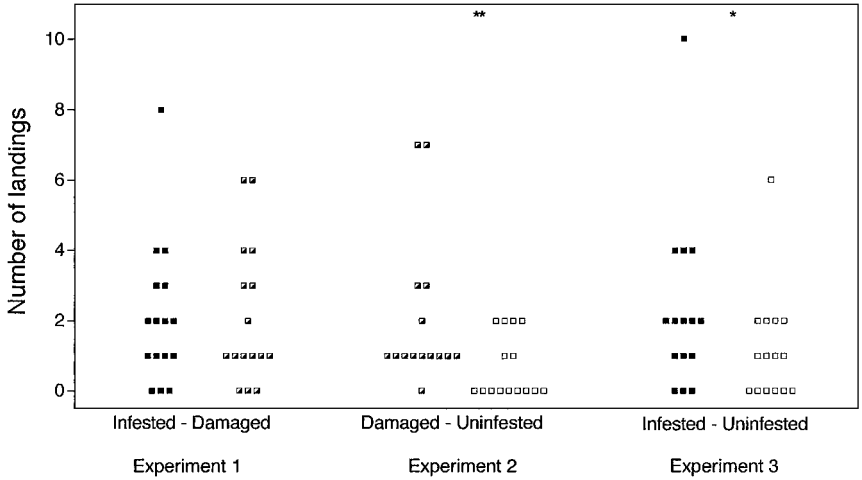

FIG. 1. Summary of all landings made by wasps in all three experiments in the free-foraging greenhouse assay using real uninfested, infested, and damaged fruits. Each square represents the total number of landings by a single wasp on one fruit type. In each experiment, there are totals for both types of fruit for each wasp. Open squares represent uninfested fruits, half-filled squares represent damaged fruits, and filled squares represent infested fruits. $^{*}P < 0.02$, $^{**}P < 0.01$ (Fisher's randomization test for matched pairs; see text).

Wind-Tunnel Assays. Forty-five wasps were released in the first experiment. The results were consistent with those of the free foraging assay (Table 1): more wasps landed on infested and damaged fruits than on uninfested fruits ($\chi^2 = 6.737$, $N = 19$, $df = 2$, $P = 0.034$). Of 22 wasps released in the second assay, in which eggs but no larvae were present in infested fruits, none landed on any fruits (Table 1). Finally, 46 wasps were released in the third experiment, of which all 5 that made a choice landed on infested fruits (Table 1: binomial test, $P < 0.001$).

Volatile Collections

Odor Emission. Overall changes in total volatile emission did not differ dramatically among infested, damaged, and uninfested control walnuts (Table 2), except for an unusual depression of volatile emission among all first-day manually damaged walnuts (Figure 2). Instead, odor differences associated with treatment were subtle and time-dependent (see below). The only significant differences in total odor emission found were among days, which is largely due to odor emission decreasing over time in all treatments (Figure 2), and DAY $\times$ TREE interaction, probably due to genetic variation among individual study trees (Table 2).

TABLE 2. REPEATED-MEASURES ANCOVA ON TOTAL ODOR EMISSION OVER 10-DAY PERIOD

Factor	*SS*	*df*	*MS*	*F*	*P*
Within subjects					
DAY	0.0169	4	0.0042	7.771	0.001
DAY × TREE	0.0099	4	0.0025	4.558	0.009
DAY × TREATMENT	0.0079	8	0.0010	1.820	0.132
Error	0.0109	20	0.0005		
Between subjects					
TREE	0.00005	1	0.00005	0.036	0.858
TREATMENT	0.0011	2	0.0006	0.423	0.676
Error	0.0066	5	0.0013		

Compound Identifications. All compounds identified in the walnut volatile analyses are listed in Appendix A. Volatile chemistry was overwhelmingly isoprenoid; 38 of the 81 compounds were monoterpene-related, while an additional 34 were sesquiterpene hydrocarbons or alcohols. Most remaining compounds were aliphatic alcohols, ketones, or acetates, some of which are lipoxygenase-derived and associated with general plant wounding (Paré and Tumlinson, 1997, 1999).

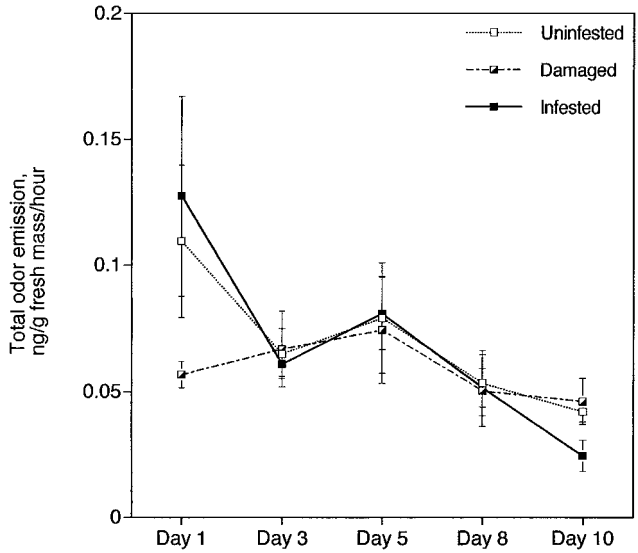

FIG. 2. Plot of total volatile emission for all treatments over the course of the study. Error bars represent standard error.

TABLE 3. RETENTION TIMES AND IDENTITIES OF COMPOUNDS USED IN PRINCIPAL COMPONENTS ANALYSIS[a]

Peak	Compound	Retention time, EC-wax (min)
2	**β-pinene**	4.00
3	**sabinene**	4.28
4	**myrcene**	5.16
5	**α-terpinene**	5.46
6	**2-methyl pentyl ketone**	5.54
7	**limonene**	5.82
8	**β-phellandrene**	6.00
9	**(Z)-β-ocimene**	6.50
10	γ-terpinene	6.69
11	**(E)-β-ocimene**	6.83
12	***p*-cymene**	7.15
13	**α-terpinolene**	7.35
14	(*E*)-**4,8-dimethyl-1,3,7-nonatriene**	7.75
15	3-methyl pentanol	8.02
17	**(Z)-3-hexen-1- ol**	8.91
20	6-hepten-2,4-diol	9.64
21	5-hydroxy-4-octanone	9.74
26	**α-copaene**	10.55
36	**β-caryophyllene**	11.98
37	**β-farnesene isomer**	12.74
45	**α-humulene**	12.88
74	**caryophyllene oxide**	16.39

[a] Identities of bold-faced compounds were confirmed from standard retention times.

Four compounds were found only in infested walnuts, in trace amounts: (*Z*)-3-hexen-1-ol and the putatively identified 3-methyl pentanol, 6-hepten-2,4-diol, and 5-hydroxy-4-octanone. Other compounds [isomers of bergamotene and hexenyl butyrate, indole, (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, methyl salicylate] characteristic of herbivore-induced emissions in cotton, maize, soy, and tobacco (Turlings and Tumlinson, 1992; Dicke, 1994; Röse et al., 1996; McAuslane and Alborn, 1998; Halitschke et al., 2000) were not detected in any walnut samples. Aromadendrene was absent from tree 1, α-guaiene was absent from tree 2, and four other compounds [terpinene-4-ol, β-farnesene isomer 1, (*Z*)- and (*E*)-nerolidol] were absent from tree 3. γ-Gurjunene was absent from both trees 1 and 2. Identifications of the peaks chosen for comparative multivariate analysis of fruit types are presented in Table 3.

Profile Analysis. There were no consistent qualitative differences among uninfested, damaged, and infested fruits at any point in the time series, but there was

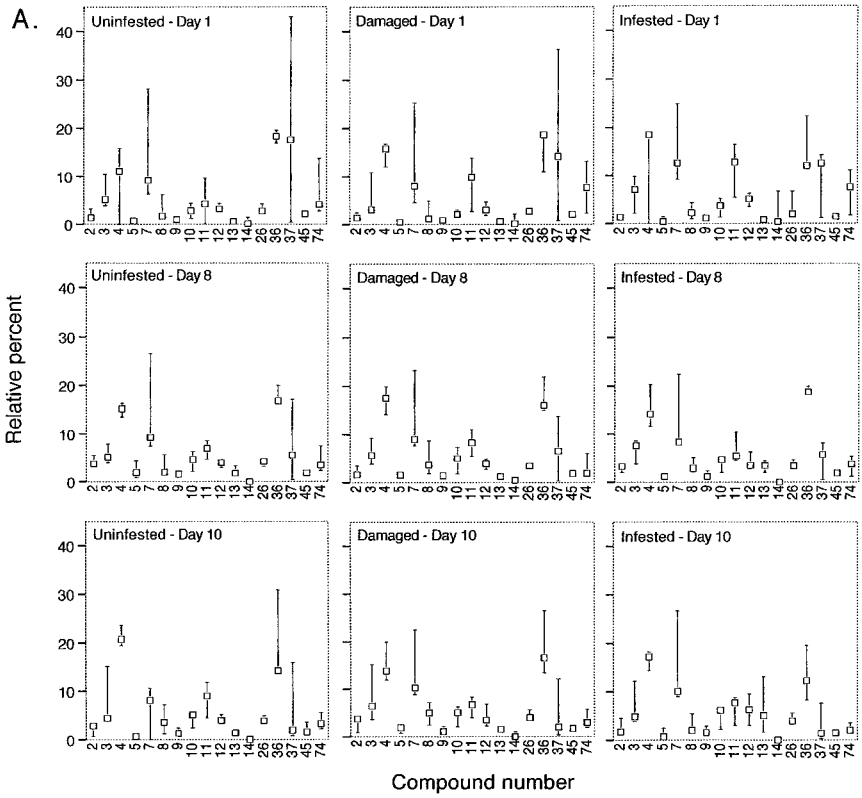

FIG. 3A. Relative peak areas for volatile collections from uninfested, damaged and infested fruits, from all three trees. Plots within A and B are all at the same scale, and show changes in relative peak areas from day 1 to day 8, to day 10. Labels on the *x* axis correspond to compounds listed in Table 2. Each square, low bar and high bar represents a peak area for one tree, divided by the total area of all the peaks in that trace for that tree, $\times 100$. Terpenoids are represented by hollow squares in A; aliphatic ketones and alcohols, compounds 6, 15, 17, 20, and 21, are represented by filled squares in B.

a quantitative effect of an increase in the amounts of aliphatic alcohols and ketones relative to terpenoids in infested fruits in later stages of infestation (Figure 3B). The first volatile collections (when only eggs were present in the infested walnuts) were similar across treatments, but by day 8 clear quantitative differences emerged among the treatments. Infested walnut fruits emitted greater amounts of aliphatic compounds relative to terpenoids than did damaged fruits, whose emissions were greater than uninfested fruits.

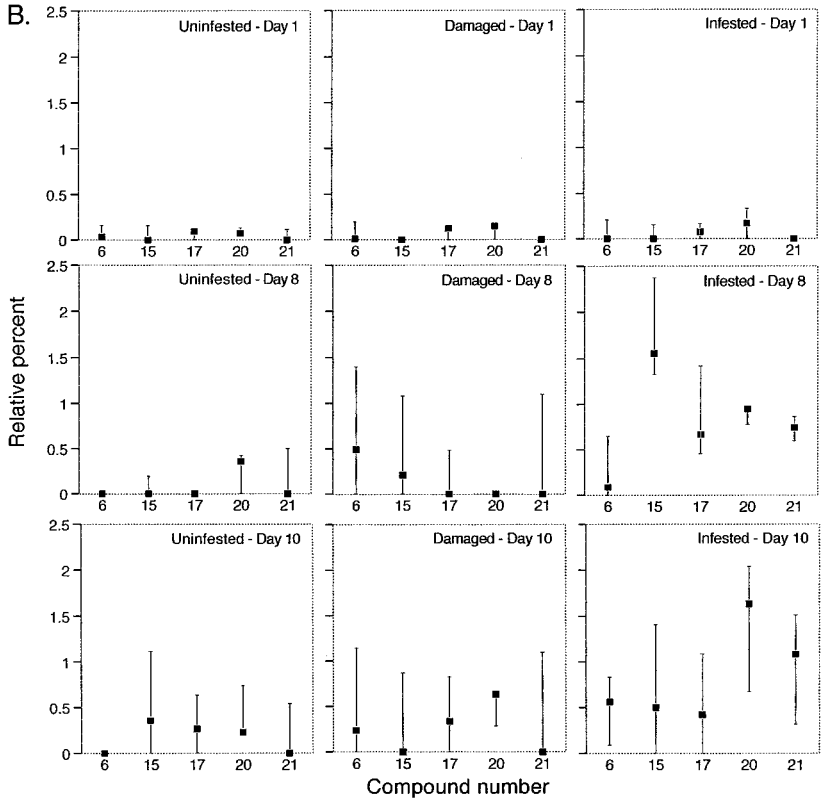

FIG. 3B. Continued.

These differences are quantified in Figure 4A, which plots principal component 1 (PC1) and principal component 2 (PC2) (accounting for 68% and 19% of the variation in the data, respectively) for each TREATMENT × TREE over time. Each symbol on the graph represents a decay profile, or change in the profile compared to day 1. Symbols that are closer together on the graph have similar decay profiles. Decay profiles of all uninfested and damaged fruits, clustered together, were similar throughout the experiment, especially along the PC2 axis. In contrast, the decay profile for the infested fruits from tree 1 on day 3 (when fly eggs had begun to hatch) differed from the others along PC2. On day 5, the decay profiles of all infested fruits were different from the main group, and on day 8, which corresponded to 80% visible damage on infested fruits, these differences were especially pronounced. By day 10, when the infested fruits had turned completely black with feeding damage, two of the infested-fruit treatments had

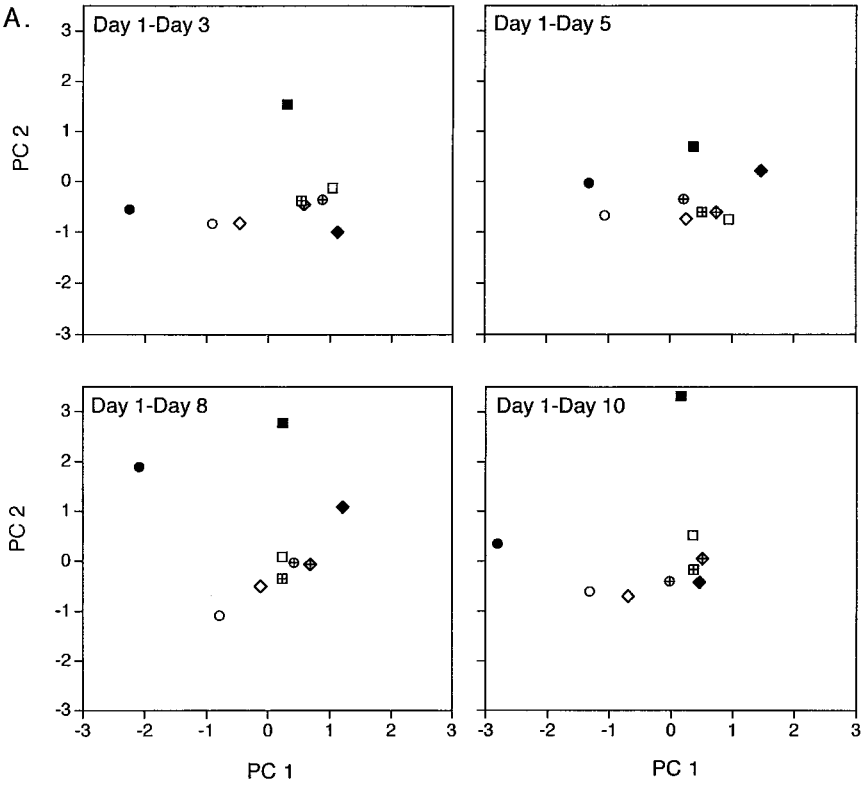

FIG. 4A. Plots of the first two principal components generated by the analysis. The four plots track the changes in volatile compounds over time, with the first collections subtracted from each subsequent collection (days 3, 5, 8, and 10). PC1 accounts for 68% of the variation in the data, and PC2 accounts for 19% of the variation. Symbols of the same shape represent fruits from the same tree: tree 1 = square, tree 2 = circle, tree 3 = diamond. Open symbols represent uninfested fruits, hatched symbols represent damaged fruits, and filled symbols represent infested fruits. (B) Vector correlation plot of peak loadings, showing PC1 (x axis) plotted against PC2 (y axis) (both ranging from -1 to 1) for each compound, with vectors originating from (0,0). Numbers on the vectors correspond to peak numbers listed in Table 3 and Appendix A and vector correlation values are given in Appendix A. Longer vectors point to compounds which influence more the location of the points in A. Solid vectors point to terpenoids, most of which influence mainly PC1; dashed vectors point to aliphatic ketones and alcohols, which influence mainly PC2.

decay profiles along PC2 similar to the main group of uninfested and damaged fruits.

The effects of aliphatic ketones and alcohols are suggested by a vector correlation plot (Figure 4B). For example, differences in profiles between infested fruits

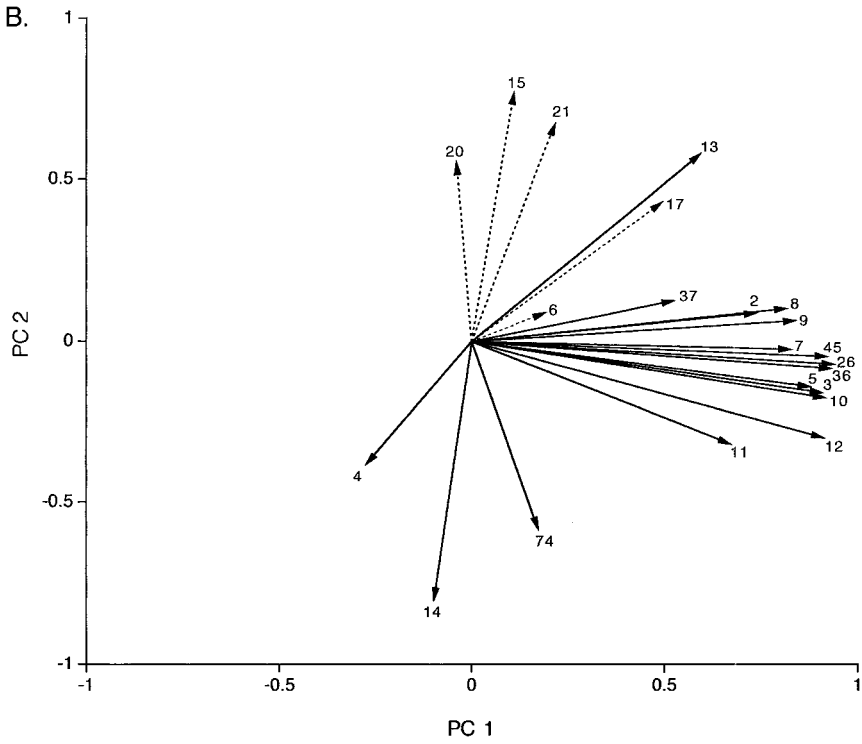

FIG. 4B. Continued.

and the other treatments in Figure 4A can be attributed to the effects of compounds strongly positive for PC2 in Figure 4B—tentatively identified as 3-methyl pentanol (compound 15), (*Z*)-3-hexen-1-ol (17), 6-hepten-2,4-diol (20), and 5-hydroxy-4-octanone (21). In contrast, differences among terpenoids—particularly limonene (7), copaene (26), caryophyllene (36), and humulene (45)—primarily account for the separation of individual trees in Figure 4A along PC1, even though some of these compounds are typically associated with constitutive plant responses to mechanical wounding (Paré and Tumlinson, 1997).

Contrary to previous results that showed the induction of β-farnesene (compound 37, Figure 3A) from living leaves infested by herbivores (Röse et al., 1996), we found no increase in this compound due to infestation. Also contrary to expectations, the emission rate of homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene, a universal herbivore-induced volatile signal in foliage, decreased relative to that of the aliphatic ketones and alcohols (compound 14, Figure 4B). A similar pattern was observed for caryophyllene oxide (compound 74, Figure 4B),

and myrcene (compound 4, Figure 4B). Finally, compounds such as β-pinene (compound 2), caryophyllene (compound 36), and humulene (compound 45), did not show damage-specific increases when compared with undamaged walnuts (Figure 3A).

DISCUSSION

Diachasmimorpha juglandis females distinguish host-infested from uninfested walnut fruits before alighting (Henneman, 1996, 1998). The results of the greenhouse free-foraging assays indicate that wasps use the presence of damage on a fruit as a cue for the presence of hosts because they did not distinguish in their landing choices between infested and mechanically damaged walnut fruits but did prefer damaged to uninfested fruits. Their failure to distinguish between infested and mechanically damaged fruits is intriguing. A large body of previous research indicates that many species of parasitic wasps prefer odors from plants damaged by hosts to qualitatively distinct odors emitted by mechanically damaged plants (e.g., Turlings et al., 1990, 1991a; Whitman and Nordlund, 1994); however, there are some other known exceptions, including a congener of *D. juglandis* that also attacks tephritids in fruits. *D. longicaudata* is not attracted to uninfested peaches but was found to be attracted equally to peaches infested with Caribbean fruit fly larvae and uninfested, but rotting, peaches (Greany et al., 1977). A similar response was found in *Campoletis sonorensis*, an ichneumonid that attacks noctuid moth larvae on many species of plants (McAuslane et al., 1991). A lack of discrimination between mechanical damage and insect-specific damage might be expected whenever plant damage is reliably caused by a host (Vet et al., 1991; Vet and Dicke, 1992). This is almost certainly the case for *D. juglandis*, a specialist on walnut flies, which are the dominant insect frugivores on walnuts. It is probably the case for *D. longicaudata*, which in Hawaii attacks several tephritids in several species of fruit (Leyva et al., 1991). *C. sonorensis* is an extreme generalist, attacking at least 27 species of noctuids (McAuslane et al., 1991), implying that several types of damage would be caused by an acceptable host.

Diachasmimorpha juglandis is apparently sensitive to olfactory differences between uninfested and infested fruits in the early stages of infestation; wasps distinguished fruits in the wind tunnel only 3–4 d after oviposition by flies, when eggs are just beginning to hatch, and odor profiles in infested fruits are just beginning to diverge from those of uninfested fruits (Figure 4A). This suggests that subtle olfactory cues alone are sufficient to attract foraging wasps. In addition, the artificial-model assay indicated that wasps can also use visual cues alone to distinguish between infested and uninfested fruits. The combination of all wind-tunnel results strongly suggests that visual damage is important for attracting wasps, in spite of

the presence of odor: the response rate in the wind tunnel increased more than fourfold when visual cues were available (Table 1).

Parasitoids are well known to use plant odors to locate their hosts (e.g., McAuslane et al., 1991; Kester and Barbosa, 1992; Poolman Simons et al., 1992; Vet and Dicke, 1992; Turlings et al., 1993b). The use of vision is less well known. In a field cage/sticky-trap assay, *D. longicaudata* used color to make landing decisions only in the absence of odor (Messing and Jang, 1992). However, Wäckers (1994) found that olfactory and visual cues had additive effects on the ability of the braconid *Microplitis croceipes* to find leaf-feeding host larvae (*Helicoverpa* spp.). Using both types of cues together, wasps have more complete information and are more successful in finding infested fruits (Drost and Cardé, 1992; Wäckers and Lewis, 1994). Messing and Jang (1992) found that *D. longicaudata* females are able to use odor to orient to fruits over several meters under field conditions. However, they were choosing among different species of fruits rather than infestation levels of the same species. In the canopy of a walnut tree interspersed with infested and uninfested walnuts, visual cues may be more helpful than odors to parasitoids orienting to specific fruits from distances of $\geq$1 m. After they approach a fruit, *D. juglandis* characteristically hover close to the fruit surface for up to 1 sec before they either alight or back away and fly off in another direction. At this stage, wasps may be assessing volatiles in order to decide whether to land (Glas and Vet, 1983). Visual cues have also been found to attract *D. longicaudata* in a wind tunnel (Jang et al., 2000).

Walnut volatiles were collected in order to describe differences among profiles of uninfested, artificially damaged, and infested fruits over time. Overall odor emissions were similar for all treatments. Although total volatile emissions were lower in damaged walnuts than in undamaged or infested walnuts on day 1, independent of tree, damaged fruits were in the same physical state as uninfested fruits at this time, so this difference is not biologically significant. The interaction of DAY $\times$ TREE (Table 2) indicates that trees changed in their total odor output differently over time. There were some qualitative chemical differences among trees; a few terpenoid compounds did not occur in all three trees (Appendix A). Furthermore, quantitative amounts of compounds present in all trees ranged widely (Figure 3). These trees were located at the same field site but differed in other consistent ways, such as timing of fruit development. Genetic differences may account for ecological as well as chemical variation. Because of these differences, replication was a useful, and necessary, approach to the identification of biologically significant differences among treatments. Our data also show some interesting variation in odors based on walnut phenological stage and infestation status. Volatile profiles in numerous fruits, including citrus and soursop (*Annona muricata*), change over time as they become ripe (Kekelidze et al., 1989; Iwaoka et al., 1993) and in apples as they become infested with codling moth larvae (Hern and Dorn, 2001).

Many of the compounds identified from the walnut volatile samples are common mono- and sesquiterpenes. Myrcene, limonene, copaene, and caryophyllene

are present in such taxonomically distinct plants as pine (Barnola et al., 1994) and cotton (Loughrin et al., 1994). Although foliage volatiles are most often studied, limonene, caryophyllene, and other terpenes also occur in citrus fruits (Kekelidze et al., 1989), linalool occurs in apricot fruits (Chassagne and Crouzet, 1995), and α-copaene has been found in tomato (Buttery and Ling, 1993). Mango contains α-pinene, α-terpinolene, *p*-cymene, and limonene, the latter two of which are attractive to the medfly (Hernandez-Sanchez et al., 2001). In addition to attractants to both herbivores (Pivnick et al., 1994) and their natural enemies (Turlings et al., 1993a; Dicke, 1994), terpenes are known to act as feeding repellents (Zhang and States, 1991; Barnola et al., 1994) and, in the context of induced wound responses, as oviposition deterrents (Kessler and Baldwin, 2001). Our data suggest that volatile terpenes are attractive to *D. juglandis*.

These previous studies and the present one suggest that novel compounds are not induced in fruit as they can be in leaf material (e.g., Turlings et al., 1990; Dicke and Van Loon, 2000). Larval infestation of walnut fruits appears simply to accelerate the rotting process, rather than induce novel volatile odors as found in other systems. The most obvious change over time in infested fruits was the increase in production of ketones, which began to occur in uninfested and damaged fruits in the latter stages of the experiment. Figure 3B shows that in uninfested and damaged treatments, compounds 6, 15, 17, 20, and 21 increased very slightly, but they increased more quickly in infested fruits. The one slight difference between uninfested and damaged walnuts was in compound 6, 2-methyl pentyl ketone, which appeared after physical and herbivore damage, but not in uninfested, undamaged fruits.

According to the analysis, the production of aliphatic alcohols and ketones was at least partly responsible for the separation of the infested fruits from the other treatments by day 8 (Figures 4A and B). The largest consistent separation in change between infested fruits and the other treatments occurred at day 8. By day 10, most infested walnuts were completely black and relatively odorless (Figure 2). Interestingly, when walnut fruits are black, they are less attractive to parasitoids (Henneman, 1998). Overall, we conclude that the profiles of mechanically damaged walnuts changed at a rate more similar to those of uninfested walnuts than to those of infested walnuts. This, combined with wind-tunnel results, suggests that wasps provided with visual information were ignoring olfactory information.

In summary, this study indicates that *D. juglandis* females foraging for hosts choose walnuts based on the presence of damage rather than the presence of host larvae *per se*. This lack of distinction makes sense in a system in which damage is nearly always caused by a host. Most wasps distinguished infested walnuts from uninfested walnuts using only olfactory information and distinguished simulated-damaged plastic walnut models from simulated-uninfested models using only visual information, suggesting that wasps can use either type of cue in isolation if necessary. The volatile profiles together with the greenhouse

behavioral assay using real walnut fruits suggest that at a distance, wasps tend to ignore odor and rely on visual cues, perhaps because in nature, odor plumes are indistinct and difficult for a wasp to follow until it is close to the fruit.

APPENDIX. VOLATILE COMPOUNDS IDENTIFIED FROM WALNUT HEADSPACE VIA GC-MS[a]

Compound	Retention time (min)		Relative abundance (%) (calculated on day 1), mean ± SE ($N = 9$)	PCA vector correlations	
	EC-wax	EC-5		PC1	PC2

[a] Identities of compounds in bold type were confirmed from standard retention times.
[b] Present only after day 2 in infested treatment.
[c] Absent from Tree 2.
[d] Absent from Tree 3.
[e] Absent from Tree 1.
[f] Present only in Tree 3.

Acknowledgments—The authors gratefully acknowledge greenhouse staff at the University of Arizona Agricultural Experimentation Station; D. Byrne and E. Draeger, who provided greenhouse space and facilities; as well as D. R. Papaj, who provid wasp and laboratory facilities. The Southwestern Research Station of the American Museum of Natural History also provided research space and facilities. M. Willis and F. Wäckers assisted with wind-tunnel design, and R. Robichaux provided laboratory space for the wind tunnel. We thank J. G. Hildebrand for GC-MS access, and D. M. Light for gifts of odor compound standards. The senior author was supported by funding from the Research Training Grant for the Analysis of Biological Diversification, and the Graduate College at the University of Arizona. R.A.R. was supported by an NIH postdoctoral fellowship through the Center for Insect Science, University of Arizona. The manuscript was improved by the comments from two anonymous reviewers.

(Received February 4, 2002; accepted July 5, 2002)

Abstract—Larvae of *Acentria ephemerella* live fully submerged, feeding on submersed aquatic angiosperms such as pondweeds (*Potamogeton* spp.) and *Myriophyllum spicatum.* Only the latter contains high concentrations of hydrolyzable tannins known to interfere with the growth of insect herbivores. We tested whether larvae grow faster on *Potamogeton perfoliatus* or *M. spicatum* and whether this is due to polyphenols in their food source. Larvae originating from the same egg clutch grew faster and larger on *P. perfoliatus* than on *M. spicatum*. The same growth response was observed with larvae that spent winter diapause on either *P. perfoliatus* or *M. spicatum*. These larvae were fed either with their host plant or the other macrophyte. No prior feeding effect was found, but growth of larvae reared on *M. spicatum* was less than when grown on *P. perfoliatus*. Larvae from another egg-clutch reared on *M. spicatum,* either from lake or cultivated in aquaria, exhibited reduced growth on the lake plants. *P. perfoliatus* contained less than 1% and *M. spicatum* (aquarium or field material) between 5 and 9% phenolic compounds. No differences in nitrogen content of leaves were found, but apical shoot sections of *M. spicatum* exhibited a significantly higher nitrogen content than *P. perfoliatus*. Our results indicate that hydrolyzable tannins are responsible for the reduced growth of *Acentria* when fed with *M. spicatum*.

Key Words—Chemical defense, gallotannin, ellagitannin, aquatic angiosperm, freshwater macrophytes, *Myriophyllum*, pyralid moth.

INTRODUCTION

Herbivory on freshwater aquatic angiosperms can be as intense as on terrestrial vegetation (Cyr and Pace, 1993). Biomass loss of macrophytes (Lodge et al.,

1998) and even changes in macrophyte community composition due to herbivory by both vertebrate (van Donk, 1998) and invertebrate (Johnson et al., 1998; Gross et al., 2001) herbivores have been reported. In the last decade, many studies have shown that chemical defenses of freshwater macrophytes are important, occurring as frequent as in marine or terrestrial macrophytes (Newman et al., 1996; Bolser et al., 1998; Wilson et al., 1999; Kubanek et al., 2000).

Phenolic compounds and especially tannins (polyphenols) are widely recognized as effective herbivore deterrents in terrestrial (Feeny, 1970; Hagermann and Butler, 1991) and marine systems (Steinberg and van Altena, 1992) but not in freshwater plants. Submerged aquatic angiosperms generally contain lower concentrations of phenolic compounds compared to emergent or floating leaved macrophytes (Gross, 1999; Smolders et al., 2000). One exception is *Myriophyllum spicatum* L. (Haloragaceae), which contains high concentrations of phenolics (Smolders et al., 2000), especially gallo- and ellagitannins (Gross et al., 1996; Gross, 1999). Hydrolyzable tannins are the dominant type of phenolics present in *M. spicatum* and other Haloragaceae (Saito et al., 1989; Gross et al., 1996; Nakai et al., 2000). Tellimagrandin II (1,2,3-tri-*O*-galloyl-6 (*S*)-hexahydroxydiphenoyl-ß-D-glucose), the major polyphenol present in *M. spicatum*, has strong algicidal and cyanobactericidal properties (Gross et al., 1996). Its concentration is highest in apical shoot sections where it reaches 1–5% of dry weight and accounts for up to 15% of all hydrolyzable tannins present in milfoil (Gross, 2000; Gross, unpublished results). In addition, condensed proanthocyanidins have been isolated from *M. brasiliense* and *M. spicatum* (Saito et al., 1989; Nakai et al., 2000).

Acentria ephemerella SCHIFFERMÜLLER & DENIS (Lepidoptera; named *Acentria* in the following) are important herbivores on *M. spicatum* (Johnson et al., 1998, Gross et al., 2001). Larvae of this aquatic pyralid moth feed exclusively on aquatic angiosperm tissue and avoid filamentous epiphytic algae (Johnson et al., 1998; Gross et al., 2001). *Acentria* feed on a variety of submerged macrophytes, especially pondweeds (*Potamogeton* spp.), *Ceratophyllum demersum* and *Elodea canadensis*, but avoid others, e.g., *Chara* spp. and *E. nuttallii* (Johnson et al., 1998; Gross and Johnson, unpublished results). Feeding on *M. spicatum* occurs predominantly on the apical shoot sections (Gross et al., 2001, 2002) despite the fact that the highest concentrations of hydrolyzable tannins are present in these plant parts (Gross, 2000). *Acentria* can fully develop on all above-mentioned host plants, but differences exist in the proportion of individuals reaching adulthood (Gross et al., 2001).

Phenolic compounds, especially polyphenols (hydrolyzable and condensed tannins), are well known to interfere with growth and development of many insect herbivores (Feeny, 1976; Hagerman and Butler, 1991). Reduced growth in insects has two major drawbacks. First, a smaller size of female pupae generally results in a lower number of eggs laid by the adult female and a decline in their overall fitness (Haukioja and Neuvonen, 1985; Kaitaniemi et al., 1998; Osier et al.,

2000; Tikkanen et al., 2000). Second, prolonged larval development can result in a higher predation mortality (Feeny, 1976; Benrey and Denno, 1997). However, plant polyphenols may also benefit insect herbivores. Higher tannin content in food plants of *Lymantria dispar* decreased the effectiveness of the bacterial pathogen *Bacillus thuringiensis* (Appel and Schultz, 1994).

We asked whether the polyphenol-rich milfoil would cause changes in growth of larvae similar to that observed in terrestrial lepidopteran larvae. The objectives of our study were to test whether the growth of *Acentria* larvae: (1) is influenced by polyphenol-containing freshwater angiosperms, (2) depends on the amount of polyphenols present in *M. spicatum*, and (3) is determined by prior feeding experiences.

METHODS AND MATERIALS

Plant Samples. Samples of various submerged macrophytes (Table 1) were collected in lakes of the Finger Lakes area of New York, USA, or in northern and southern Germany. The screening for phenolic content in different macrophytes used whole upper shoots (25-cm long). When comparing *P. perfoliatus* and *M. spicatum* from Lake Constance, we dissected the upper 25-cm shoot sections into apical shoot sections, leaves, and stems. Plants were shock-frozen in liquid nitrogen, lyophilized, and stored in the dark at room temperature for further analysis.

Analysis of Plant Chemistry. All analyses were performed with ultrapure water and with analytical-grade (p.a.) or HPLC-grade solvents. Plant material was extracted with 50% aqueous acetone (v/v, 10 mg/ml solvent) over 2 hr and stirred constantly. Solids were centrifuged and the supernatant used for the analysis of the total phenolic content. Phenolic content was measured as described previously (Gross et al., 1996). Extracts were used in concentrations yielding absorbances (A_{750nm}) between 0.1 and 0.5 AU. Calibration curves with tannic acid (Sigma T8406) were used to calculate total phenolic content as tannic acid equivalents (TAE). The PVPP (polyvinylpolypyrrolidone, Sigma P6755) assay was performed to distinguish phenolic compounds from other redox active compounds of non-phenolic origin (Loomis and Battaile, 1966; Gross et al., 1996).

The carbon and nitrogen content of plant samples was measured with an Elementar Analysator NCS 2500 (CE Instruments/Thermoquest) using atropine sulfate as a standard (58.8% C, 4.0% N, C:N molar ratio 17:1). The protein content of leaves was determined by multiplication of the percent nitrogen content by 6.25 (Feeny, 1970). Soluble protein content was not determined because both Lowry and Bradford assays are sensitive to soluble phenolic compounds, and do not provide an exact measurement of protein content in plants with high concentrations of phenolic compounds (Gross, unpublished results).

Growth Assays. We performed three different growth assays using either newly hatched larvae of *Acentria ephemerella* (experiments I and II) from egg

clutches found in summer 1999, or diapausing larvae of *Acentria* (experiment III) found in late September 2000 on senescent shoots of *M. spicatum* and *P. perfoliatus.* All larvae originated from Lower Lake Constance. Macrophytes used in the experiments were either collected weekly in the lake or cultured prior to the experiments for at least three months in aquaria under constant conditions ($18^{\circ}C \pm 1^{\circ}C$, 16L:8D photoperiod, 60 μmol PAR/m^2/sec). Head capsule width of larvae was measured with digital imaging at a mean precision of 1.5%.

Experiment I. To test whether polyphenol-rich *M. spicatum* affects the growth of *Acentria* larvae, we used two different treatments. Either newly hatched larvae were fed lake- or aquarium grown *M. spicatum* or *P. perfoliatus*. A clutch of 340 eggs found on *P. perfoliatus* in Lower Lake Constance on July 12, 1999, was used. Larvae that hatched during July 20–23 were randomly distributed to 12-well microtiter plates (50 larvae per treatment, maintained individually), and the remaining larvae were distributed equally to 100-ml glass jars with the respective food. Water and food were renewed twice a week. The head capsule width of the larvae was measured at intervals of 6 to 12 d. Until day 41, larvae that died were replaced with larvae of equal size from jars fed with the same host plant. The experiment ended at day 89.

Experiment II. In this experiment, we compared whether *Acentria* larvae differ in growth on *M. spicatum* derived from the lake or from aquaria. In Lower Lake Constance, on August 6, 1999, a second egg clutch was found on *P. perfoliatus.* The 370 eggs that hatched between August 10 and 13 were divided into two groups according to the procedure described in experiment I. The experiment ended on day 72 (October 21, 1999) because *M. spicatum* became senescent at this time.

Experiment III. This assay was designed to investigate whether previous food experience would influence the outcome of the growth assays with polyphenol-rich and polyphenol-free freshwater macrophytes. *Acentria* hibernates in the larval stage and bores holes for shelter in lower stem sections of tall growing macrophytes, such as *P. perfoliatus* or *M. spicatum* (Gross et al., 2002). Larvae were collected on September 27, 2000, in Lower Lake Constance, near the island of Reichenau, and stored at $4^{\circ}C$. In March 2001, working on ice, larvae were removed from the stems of macrophytes and freed from their hibernicula. They were placed individually in 30-mm-diam Petri dishes and fed with leaves of the macrophytes used in the different treatments submerged in 5 ml of tap water. Larvae that originated from *M. spicatum* were then fed with either *M. spicatum* or *P. perfoliatus* (MSMS or MSPF treatment). Larvae that came from *P. perfoliatus* plants were fed with either one of the two macrophytes (PFMS and PFPF treatment). In each treatment, 24 larvae were used. Larvae were reared for 53 d, and head capsule width was measured at the start of the experiment and then every 6–10 d.

Statistical Analysis. Data were analysed using the Student *t* test, one- or two-way ANOVA, and Tukey HSD *post-hoc* tests (Statistica 99 edition or SigmaStat, version 2.03).

RESULTS

Plant Chemistry. The phenolic content of aquatic angiosperms belonging to several families varied from < 1% to 15%, measured as tannic acid equivalents (TAE) and based on dry mass dm, (Table 1). Several host plants of *Acentria ephemerella*, such as *Ceratophyllum demersum, Elodea canadensis* and *Potamogeton perfoliatus*, had < 1% TAE in their tissue. All members of the Haloragaceae (*Myriophyllum* spp., *Proserpinaca* sp.) contained > 6.5% dm phenolic compounds, approximately one order of magnitude higher than all other species investigated.

We tested the nutritional quality of the plants used in the growth experiments during late summer 1999. A comparison of leaves from the upper 25-cm shoot sections of *P. perfoliatus* and *M. spicatum*, sampled during late summer of 1998 and 1999, demonstrated that in both years the latter had a significantly higher phenolic content than *P. perfoliatus* (Table 2, 9% vs. 1% TAE in both years, $P < 0.006$). More than 95% of all tannic acid equivalents in *M. spicatum* were phenolic compounds and precipitated with PVPP. Approximately 50% of the tannic acid equivalents in *P. perfoliatus* were of nonphenolic origin. *M. spicatum* plants kept for several months in aquaria exhibited a lower leaf phenolic content than those taken directly from the field (aquarium: $5.5 \pm 0.4\%$ TAE, mean $\pm$ 2 SEM, $N = 9$; lake, samples taken in summers 1998–2000 at peak biomass of

TABLE 1. COMPARISON OF TOTAL PHENOLIC CONTENT OF VARIOUS SUBMERGED MACROPHYTES[a]

Aquatic angiosperms	Tannic acid equivalents (mg/g dm)		Different locations
	Mean $\pm$ 1 SD	Range	
Haloragaceae			
Myriophyllum alterniflorum	79.8 ± 11.0	67.6–88.9	3
M. heterophyllum	66.7 ± 6.6	62.4–74.3	3
M. spicatum	83.2 ± 8.8	68.7–101.7	15
M. verticillatum	67.5	65.4–69.6	2
Proserpinaca palustris	148.6	148.6	1

Ceratophyllum demersum	8.3 ± 1.8	6.5–10.1	3
Elodea canadensis	6.0 ± 1.3	4.9–7.0	3
Najas flexilis	3.6	3.6	1
Potamogeton perfoliatus	9.4 ± 4.5	4.5–12.1	3
Ranunculus trichophyllus	18.9 ± 1.7	16.7–21.0	3

[a] Only data from plants taken during maximum plant biomass at different sites/in different lakes were taken into account. Upper 25 cm of shoot sections were taken for the analysis. Data are presented as tannic acid equivalents based on plant dry mass. Data represent means, 1 SD, and range of samples taken in late summer from different locations.

TABLE 2. COMPARISON OF TOTAL PHENOLIC CONTENT OF SUBMERGED MACROPHYTES USED AS HOST PLANTS IN OUR GROWTH EXPERIMENTS[a]

	Tannic acid equivalents (mg/g dm)			
	M. spicatum	*P. perfoliatus*	*t*	*P*
1998	88.0 ± 16.0	11.6 ± 7.8	8.5	0.001
1999	94.6 ± 30.0	12.1 ± 7.7	5.3	0.006

[a] Only leaves from the upper 25 cm of shoot sections were taken for the analysis. *M. spicatum* and *P. perfoliatus* were collected in Lake Constance during the maximum growing period (July–September) of 1998 and 1999 ($N = 3$ each; mean ± 2 SEM).

M. spicatum: 9.0 ± 1.0% TAE, $N = 9$, Student's t test, $t = 6.0$, $P < 0.001$). Whereas the phenolic content of aquarium plants stayed more or less the same, we observed a steady decline in field milfoil from 12% at the beginning of August to 7% at the end of September and < 5% TAE at the end of October 1999 (linear regression, TAE = 333.5 − 0.99 × (time); $R = -0.97$; $P < 0.001$). When comparing the phenolic content of *M. spicatum* samples taken in late September to late October 1998–2000 with those of aquarium plants, no difference was found (*M. spicatum* fall 5.8 ± 1.3% TAE, $N = 6$; aquarium samples as above, $t = 0.5$, $P = 0.7$).

Nitrogen content is commonly used as a proxy for protein content and thus nutritional quality of host plants for herbivores. Leaves of *P. perfoliatus* and both field- or aquarium grown *M. spicatum* had a nitrogen content of 3.6–3.8% dm, and were not significantly different (Table 3; one-way ANOVA, $P = 0.8$). The apical shoot sections of *P. perfoliatus* exhibited a significantly lower nitrogen content (3.3%) than those of either aquarium or field *M. spicatum* (4.8–5.4%; Table 3; one-way ANOVA, $P < 0.001$). Using the conversion factor of 6.25 (Feeny, 1970), to estimate the content of soluble protein, we calculated a content of 22–24% in

TABLE 3. NITROGEN CONTENT (% OF DM) OF MACROPHYTES USED IN GROWTH EXPERIMENTS WITH *Acentria* LARVAE[a]

	Nitrogen					
	M. spicatum		*P. perfoliatus*			
	Field	Aquarium	Field	*MS*	*F*	*P*

Apical shoots	4.8 ± 0.4 a	5.4 ± 0.5 a	3.3 ± 0.3 b	8.6	20.1	<0.001

[a] Data represent means ± 2 SEM of 6 to 12 independent samples. Results of one-way ANOVAs for each plant part are presented. Different letters indicate treatments that vary significantly at $\alpha = 0.05$.

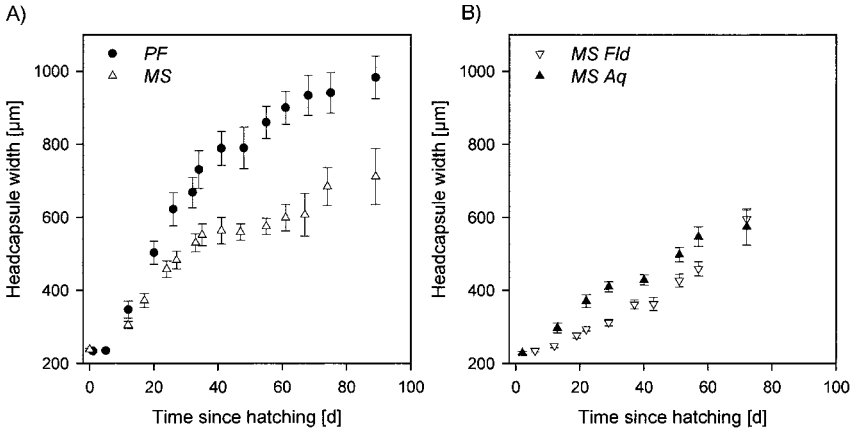

FIG. 1. Newly hatched *Acentria* larvae reared on different freshwater macrophytes. Growth was measured as headcapsule width. A) Experiment I: *Acentria* reared on *Potamogeton perfoliatus (PF)* and *Myriophyllum spicatum (MS)*. B) Experiment II: *Acentria* reared on fresh *M. spicatum* harvested weekly from the lake *(MS Fld)* or cultured in aquaria *(MS Aq)*. $N = 50$ each per treatment in both experiments, $N = 14$–15 per treatment at the end of the experiments. Data represent means $\pm$ 2 SEM.

leaves of *P. perfoliatus* and *M. spicatum*. The carbon content of all plants ranged between 35 and 42% dm and the C:N molar ratio varied from 8:1 to 14:1.

Growth Experiments. In experiment I, larvae developed differently on *P. perfoliatus* and *M. spicatum* (Fig. 1A). Larvae did not differ in size at the beginning of the experiment (*M. spicatum* head capsule widths $= 238 \pm 2\mu$m; *P. perfoliatus* $= 234 \pm 2\mu$m, mean $\pm$ 2 SEM, $N = 50$ each, $P = 1.0$). The average head capsule width of larvae reared on *P. perfoliatus* was larger than when fed with *M. spicatum* (Figure 1A). The two-way ANOVA showed a significant treatment effect ($F_{1,554} = 225.5$, $P < 0.001$), a significant time effect ($F_{7,554} = 180.2$, $P < 0.001$), and the interaction of treatment and time was also highly significant ($F_{7,554} = 9.6$, $P < 0.001$). From the third week until the end of the experiment, larvae were larger on *P. perfoliatus* than on *M. spicatum* ($P < 0.05$). The largest larvae on *P. perfoliatus* reached a head capsule width of 1190 μm; the average size being $983 \pm 58\mu$m ($N = 14$). Some larvae fed with *M. spicatum* also reached a head capsule width of more than 900 μm, but not until the end of the experiment; others stayed well below 600 μm, resulting in the lower mean size ($712 \pm 76\mu$m, $N = 15$). In both treatments, larval size reached a plateau after 40 days, indicating the end of growth.

Experiment II was performed with another egg clutch found on *P. perfoliatus*. This was divided into two treatment groups; one group was fed fresh *M. spicatum* collected weekly in the field, and one was fed *M. spicatum* from aquaria. During most of the experiment, larvae fed with aquarium plants grew better than those

reared on field *M. spicatum* (Figure 1B). Again, in the two-way ANOVA we observed a significant treatment ($F_{1,242} = 199.8$, $P < 0.001$), a significant time ($F_{4,241} = 51.0$, $P < 0.001$), and a significant interaction effect ($F_{4,241} = 5.0$, $P < 0.001$). *Post-hoc* tests revealed significant differences at days 13 to 57 ($P < 0.005$), but not at the end of the experiment (day 72, $P = 0.98$). At this time (end of October) we had to stop the experiment, because milfoil started to decay in the lake. During September and October 1999, field milfoil no longer had a higher phenolic content compared to plants from the aquaria (field 5.8%, aquarium 5.5% TAE, $t = 0.5$, $P = 0.7$).

In experiment III, we investigated whether previous feeding experience would influence the growth of *Acentria* on polyphenol-rich or polyphenol-free macrophytes. This experiment was conducted with larvae that had started winter diapause in either *P. perfoliatus* or *M. spicatum*, and we assumed that these were the plants the larvae fed on previously. Larvae dissected from *P. perfoliatus* or *M. spicatum* stems did not differ in size (mean head capsule width all larvae 556 $\pm$ 16 μm; mean $\pm$ 2 SEM; range 400–707 μm). Larvae then developed differently depending on the macrophyte being offered for food. The two-way ANOVA showed a significant treatment effect ($F_{3,362} = 18.8$, $P < 0.001$), a significant time effect ($F_{4,362} = 293.1$, $P < 0.001$) and a significant time $\times$ treatment interaction effect ($F_{12,362} = 6.9$, $P < 0.001$). Starting with day 15, larvae fed with *P. perfoliatus* (treatments PFPF and MSPF) were significantly larger than those shifted from *P. perfoliatus* to *M. spicatum* (PFMS) ($P = 0.015$). At the end of the experiment, larvae were either large (PFPF/MSPF), or small (PFMS/MSMS) with mean head capsule widths of 1014/989 or 891/834 μm, respectively (Figure 2). *Post-hoc* tests revealed that these treatments differed significantly at day 40 ($P < 0.02$) and day 53 ($P < 0.005$).

DISCUSSION

Our study shows that the performance of a true aquatic shredder–herbivore, *Acentria ephemerella*, is correlated with the presence and amount of phenolic compounds in their host plants. In our screening, all members of the Haloragaceae contained high concentrations of phenolic compounds, approximately one order of magnitude higher than other macrophytes investigated. Smolders et al. (2000) also found that *M. spicatum* had a high phenolic content, reporting a mean concentration in leaves of 8.4%. Phenolic compounds in this species are predominantly gallo- and ellagitannins (Gross et al., 1996). In contrast, according to our assays, *P. perfoliatus* always contained less than 1% phenolic compounds. In another study, *P. perfoliatus* contained less than 2% phenolic compounds (Smolders et al., 2000), and no tannins were found in this species (McClure, 1970).

The mean nitrogen content of 3.6–3.8% dm in leaves of the freshwater macrophytes used in our experiments fits well within the range found in other studies

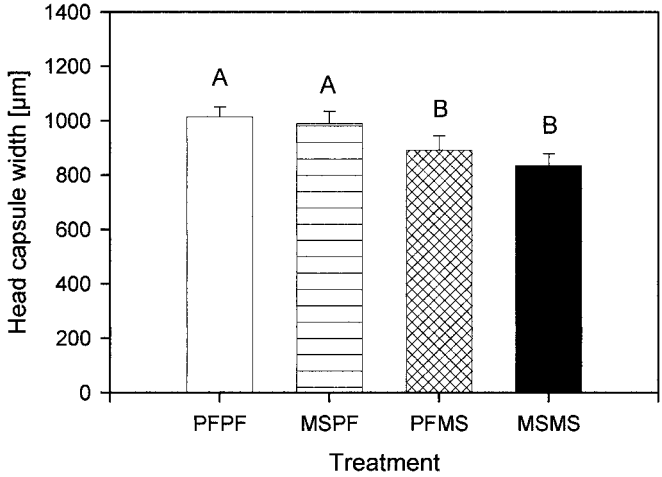

FIG. 2. Experiment III: final head capsule width of *Acentria* larvae that had a winter diapause in their life cycle in shoot sections of either *Potamogeton perfoliatus (PF)* or *Myriophyllum spicatum (MS)*. Larvae were fed in a reciprocal design with either the macrophyte they originated from or the other macrophyte (PFPF, PFMS; MSPF, MSMS). Data represent means $\pm$ 2 SEM of their size at day 53. Different letters indicate treatments that vary significantly at $\alpha = 0.05$.

(Nichols and Keeney, 1976; Spencer and Ksander, 1999). Nitrogen content was the same in all host plants, and was apparently not limiting the growth of *Acentria*. Therefore, the decreased size of *Acentria* in our experiments seems to be a result of the high concentration of polyphenols in *M. spicatum*. Two different experimental designs demonstrated that *Acentria* grew faster on *P. perfoliatus* than on *M. spicatum*. In experiments I and II, larvae differed significantly in size 3 wk after hatching, depending on the source of food offered. In these experiments, larvae originated from the same egg clutch. In experiment III, we used diapausing larvae retrieved from either milfoil or *P. perfoliatus*, suggesting they had used the respective plant for feeding prior to hibernation. Based on our laboratory findings, one would expect field larvae to be smaller on milfoil than on *P. perfoliatus* in fall. However, diapausing larvae from both macrophytes did not differ in size. This can be explained by examining the differences in life-cycle between the plants. Larvae first colonize *P. perfoliatus* in spring, and later move to *M. spicatum* at the end of summer (Gross et al., 2002). This is probably related to the earlier emergence of *P. perfoliatus* and later senescence of *M. spicatum* in Lake Constance. Thus, larvae on milfoil have a longer time for development and may reach the same size for hibernation as those already diapausing in lower stems of *P. perfoliatus* (Gross et al., 2002). Our results in experiment III indicate that larvae stay longer

at different instar stages with *M. spicatum*, thus reaching a similar size later than larvae fed with *P. perfoliatus*.

Apparently, not only the presence but also the amount of polyphenols present in *M. spicatum* determine the final size of *Acentria* larvae. *M. spicatum* from the field or from aquaria exhibited no difference in their nitrogen content. However, field plants contained, on average, twice as much polyphenols as aquarium plants. In the fall at the end of experiment II, this difference disappeared. At that time, larvae in both treatments were the same size. Unfortunately, we could not extend the experiment due to the senescence of *M. spicatum* in the lake. The final proof that polyphenols, especially hydrolyzable tannins, are solely responsible for the reduced growth of *Acentria* can only be obtained with a defined artificial diet to which selected polyphenols are added in various concentrations. Unfortunately, *Acentria* can not be reared on artifical diets. We have tested several commonly used lepidopteran diets (wheat germ-, pinto bean-based diets) or alginate- and agar-based diets used in marine studies. Larvae did not accept any of these and did not survive (Gross, unpublished results).

Feeding preferences of the semi-aquatic moth *Munroessa gyralis* (Pyralidae), were not related to phenolic compounds, protein concentration or the leaf toughness of macrophytes (Dorn et al., 2001). Field observations and laboratory tests show that *Acentria* larvae prefer the apical meristems of *M. spicatum* compared to lower shoot sections (Gross et al., 2001). Apical meristems contain significantly higher concentrations of polyphenols and tellimagrandin II than lower shoots (Gross, 2000). Despite the reduced growth observed in these experiments, larvae can fully metamorphose on *M. spicatum* (Johnson et al., 1998, 2000; Gross et al., 2001, 2002), and are frequently found associated with this macrophyte (Painter and McCabe, 1988; Newman and Maher, 1995; Johnson et al., 2000). Larvae may benefit from feeding at apical tissue of milfoil because of the higher nutrient content and a better protection from visually oriented predators (Gross et al., 2002). Additionally, the antimicrobial activity of polyphenols (Walenciak et al., 2002) may protect *Acentria* from bacterial and fungal pathogens and thus compensate for reduced growth. Whether milfoil polyphenols affect the overall fitness of *Acentria* remains to be elucidated.

In this study, we have shown that *Acentria* exhibits a reduced growth on the polyphenol containing *M. spicatum* compared to *P. perfoliatus.* This may ultimately lead to a lower female fecundity, as observed in many other lepidopteran studies (Haukioja and Neuvonen, 1985; Kaitaniemi et al., 1998; Tikkanen et al., 2000). The antinutritional effects of dietary tannins result most often in a depressed growth rate and feed utilization efficiency (Hagerman and Butler, 1991). Apparently, gut symbiontic microorganisms are also involved in the allelochemical interaction of polyphenols and herbivores (Walenciak et al., 2002). Nonetheless, the exact mechanism of tannin interference with digestion in Lepidoptera is still unknown.

CHEMICAL MEDIATION OF EGG CAPSULE DEPOSITION BY MUD SNAILS

DAN RITTSCHOF,* PRASAD SAWARDECKER, and CAROLINE PETRY

Duke University Marine Laboratory Beaufort, North Carolina 28516, USA

(Received December 26, 2001; accepted June 30, 2002)

Abstract—Mud snails (*Ilyanassa obsoleta* = *Nassarius obsoletus* = *Nassa* obsoleta) deposit eggs in protective capsules on hard substrata in soft bottom environments. We studied sites of egg capsule deposition and snail movement responses to odors to determine if chemoreception plays a role in deposition site selection. From results of field surveys, laboratory experiments, and field experiments, we conclude that mud snails use chemoreception for capsule deposition. Attractive odors originate from mud snail and whelk egg capsules and from living bivalves. Evidence for attractive odors from conspecifics is equivocal. Capsules are deposited on living odor sources and nearby hard substrates. We hypothesize that deposition of capsules on living substrates increases the likelihood that embryos will survive by decreasing the chance of smothering of embryos by sediments.

Key Words—Reproduction, reproductive ecology, behavior, gastropods, egg capsule deposition, mud snail.

INTRODUCTION

Among aquatic gastropods, chemical cues, signals, and pheromones play roles in feeding (Carr, 1967a,b), prey detection, (Carriker, 1955; Rittschof et al., 1983), predator avoidance (Gore, 1966; Snyder, 1967; Atema and Burd, 1975; Duval et al., 1994; Rahman et al., 2000) alarm responses (Snyder, 1967; Atema and Burd, 1975; Duval et al., 1994; Rahman et al., 2000), species recognition (Gore, 1966; Atema and Stenzler, 1977; Stenzler and Atema, 1977; Bretz and Dimock, 1983; Hadfield and Pennington, 1990), predators (Dix and Hamilton, 1993; Duval et al., 1994; Rahman et al., 2000), and reproduction (cf: Painter, 1992; Painter et al., 1999). With respect to aggregation, breeding, and egg deposition, chemically mediated behavior of sea hares is a well-studied marine example.

Sea hares, opistobranch gastropods, are relatively short lived simultaneous hermaphrodites that lay egg strings and mate in large aggregations during an extended reproductive season (Kupfermann and Carew, 1974; Audesirk, 1979; Susswein, et al., 1983, 1984). Temperature is a synchronizing cue (Smith and Carefoot, 1967, Audesirk, 1977). Egg string deposition occurs in specific habitats (Audesirk, 1979). Pheromones from egg-laying individuals and egg strings attract and stimulate other individuals to deposit eggs and to mate. Sperm are transferred in an immature state (Thompson and Bebbington, 1969), and mating does not cause ovulation (Blankenship et al., 1983). Egg laying hormone (ELH) initiates egg-laying and coordinates associated behaviors (Painter, 1992). A bout of egg laying releases pheromones that attract others and initiate mating (Painter, 1992). Attractive pheromones from the egg strings and egg-laying individuals maintain aggregations (Jahan-Parwar, 1976; Audesirk, 1979). At least one pheromone associated with egg strings may be a peptide from the ELH gene family.

The focus of our study is egg capsule deposition by mud snails (*Ilyanassa obsoleta* = *Nassarius obsoletus* = *Nassa obsoleta*). Mud snails are abundant intertidal prosobranch gastropods that occur in spectacular aggregations (Jenner, 1957) on soft bottom sediments on the Atlantic seaboard from Cape Cod to Florida. Mud snail responses to chemicals include scavenging (Dimon, 1905; Curtis, 1985), feeding (Carr, 1967a,b), trail following (Crisp, 1969; Trott and Dimock, 1978; Bretz and Dimock, 1983), alarm (Atema and Burd, 1975), imposex i.e., females with male secondary characters, (Smith, 1971, 1980; Oberdoerster et al., 1998), and alarm to predator odors (Rahman et al., 2000).

Mud snails breed on an incoming tide (Dimon, 1905). On the North Carolina, (USA) coast, breeding occurs in the fall and again in the spring during egg capsule deposition, February to May (Sastry, 1971). Egg capsule deposition is dependent upon water temperature (Scheltema, 1967). By the end of the spawning season, most surfaces where snails are breeding are coated with a continuous fuzzy layer of egg capsules (Jenner, 1957; Sastry, 1971). Our goals in this study were to demonstrate that snail aggregation and egg capsule deposition are chemically mediated and to elucidate sources of chemicals.

METHODS AND MATERIALS

Field Study Site. Field sites were the Carrot Island embayment, a 300-m × 600-m sand and mud flat in the Rachel Carson Estuarine Research Reserve (centered at 34°42.625 N, 76°40.230 W) and NOAA Beach, a 100-m × 40-m mud flat on the eastern side of Piver's Island (centered at 34°43.097 N, 76°40.267 W), in Beaufort, NC, USA. The Carrot Island Embayment was used as a field observation site. NOAA beach was the site of field experiments.

Egg Capsule Deposition. Based upon preliminary observations in 1991, we conducted four field censuses in 1992. We visited each census site only once and conducted each census in the 2 hr around the time of low tide. We first determined the frequency of capsule deposition on the first 120 shell substrates encountered while walking in mud snail areas. In a separate census, we determined the frequency of egg capsule deposition on the first 100 living and dead oysters encountered. In a third and fourth census, we determined the frequency of egg capsule deposition on the first 100 dead oyster valves encountered that were within 30 cm of a living oyster, and the first 100 dead oyster valves that were >30 cm from the nearest living oyster.

Sex, Seminal Receptacle Condition, and Parasitism in Snail Microhabitats. In 1991, we observed that mud snails occurred in tight (touching) aggregations on muddy substrates and around oysters. Snails on sand substrates were rarely touching. In 1992, we collected a total of 99 snails from 5 aggregations on mud, 99 snails from 5 aggregations around oysters, and 90 individuals from sandy areas. Snails were removed from their shells and their sex determined by the color of the gonad. Male gonads are bright orange and female gonads are cream colored (Sastry, 1971; Smith, 1980). Imposex rates in this area are 0–5% (Oberdoerster et al., 1998). We determined whether each female had a full (white) or empty (not white) seminal receptacle, and we determined if snails were parasitized. The gonad and digestive gland were broken open and examined with a dissecting microscope for the presence of life history stages of trematode parasites (Curtis, 1987).

Finally, we looked for pairs of snails in all three microhabitats. Pairs were picked up and pulled apart. If a penis was observed, the pair was counted as copulating, and each was placed in an individual container and returned to the lab for determination of sex, seminal receptacle condition, and parasites.

Collection of Materials. Living and dead oysters, *Crassostrea virginica*, and mussels, *Guekensia* (= *Modiolus) demissa* and *I. obsoleta*, were collected on the east side of Piver's Island and in the Rachael Carson Estuarine Research Reserve. The old valves were collected from shell piles and were intact, not fouled, and had been bleached by the sun. Egg capsules of *Busycoon carica* were collected from the Carrot Island embayment in late November of the previous fall after the opercula had opened and juvenile whelks had crawled out. The whelk egg capsules used in experiments were empty, visibly clean, and intact save the loss of the capsule operculum. Capsules were stored dry at 20–25°C until use. Mud snail egg capsules used in field experiment 2 were intact and contained living embryos in a variety of stages of development.

Assays of Snail Responses to Odors. Ring assays (Duval et al., 1994; Rahman et al., 2000) tested snail responses to odors. A 1-cm-wide $\times$ 4-cm-diam. ring of odor solution was made in a dry finger bowl using a cotton swab. A snail was placed in the center of the ring and its response upon contact was recorded. Snails either moved through the ring without hesitation (no response), turned and followed

(follow), or stopped and turned around (alarm). Thirty snails were tested with each odor solution. Frequencies of responses of following and not following were compared by Z statistic (Walpole, 1974). On each day of testing, 300–400 snails were collected at low tide from near egg capsule deposition areas on NOAA beach and stored damp in a plastic shoebox with lid.

Odors were prepared by soaking approximately equal masses of living substrates in aged filtered seawater (Rittschof et al., 1983). Aged seawater was ambient sea water that had first been filtered to remove particles >1 μm and aged for a week with aeration at room temperature and then passed through a septic 100-kDa filter and aged for at least a month in the dark before use (Rittschof et al., 1984). Living odor sources were a 7.5-cm-high oyster and mussel and 20 living mud snails. Dead odor sources were a dead oyster and mussel valve. Each source was soaked in 1 l of aged, 100-kDa filtered seawater for 1 hr. Test odors were used within 1 hr of generation.

Field Experiments. The area for the two field experiments was NOAA Beach, an east facing sand flat with a population of mud snails. A rectangular test area 8×18 m was established. The length of the rectangle was parallel to the shore. The area was raked to remove all hard substrates. A 50-point grid was established with numbered surveyor flags positioned at the center of 2 square meter areas. The first experiment began in February 2000 before any egg capsule deposition was observed. Forty of the positions were occupied by 10 replicates each of 7.5-cm-high (umbo to valve edge) living oysters and living mussels. The 7.5 cm-high-old dead oyster and dead mussel valves were assigned to points on the grid by using a random numbers table. Substrates were attached to a 7.5×12.5-cm piece of plastic screen with a cable tie. Mud snails were moved so that there were none within 30 cm of each flag, and each screen was fixed in place with the flag. Screens and cable ties were fixed at the final 10 points. The experiment was inspected at low tide until there was clear evidence of egg capsule deposition on several substrates. At that point (approximately 3 weeks), all substrates were collected and egg capsules counted.

The second field experiment, similar in design to the first, was initiated a week after the first was terminated. The apparatus controls were replaced with busycon egg capsules, comparable in surface area to an oyster valve. There were eight replicates of five substrates (living oysters and mussels, shells of oysters and mussels, and whelk egg capsules). The other 10 positions were used for a qualitative assessment of the impact of mud snail egg capsules on capsule deposition. Approximately 100 mud snail capsules deposited during the first experiment screening were affixed on two replicates of each of the five substrates. Capsules were covered with fiberglass window screening to discriminate added capsules from newly deposited capsules.

Experiment 2 was initiated by moving all mud snails within 30 cm of each flag, and then each screen with each treatment was fixed in place with the flag

for that grid point. Experiment 2 was conducted for 6 d. Every day at low tide, an observer counted every mud snail within 30 cm of each flag that marked the substrates without added mud snail egg capsules. After day 6, substrates were collected, and the numbers of capsules on each substrate counted.

RESULTS

Egg Capsule Deposition. Egg capsule deposition was determined for the first 120 shell substrates encountered in mud snail areas (Table 1). The three most common shell substrates, jackknife clams, *Tagelelus* (*pelebius* and *divisus*), oysters, *C. virginica*, and hard clams, *M. mercenaria*, accounted for over 95% of the total substrates and 100% of egg capsule deposition. Egg capsule deposition was disproportionately frequent on oysters, and uncommon on jackknife clams (Null hypothesis (1) capsule deposition was proportional to the frequency of shells $G = 335$, $P < 0.001$, 2 df). Oyster shells, 20% of the total shells, accounted for over 80% of capsule deposition sites. Deposition on jackknife clams was 24-fold lower than the relative abundance of shells.

In the second census, we walked until we encountered 100 live and 100 dead oysters, noting whether or not they were sites of egg deposition. Twenty-six of the dead oysters and 83 of the living oysters were sites of deposition. Snails deposited capsules more frequently on live oysters than on dead oysters (H_o deposition on live = deposition on dead, $G = 141$, $P < 0.001$; 1 df).

In the final two censuses, January 31 and February 4, we walked areas occupied by snails and scored capsule deposition on dead oysters within 30 cm of living oysters and on dead oysters more than 30 cm from the nearest living oyster. In the first, 96 of 100 dead oysters within 30 cm of living oysters were sites of deposition. In contrast, 73 of 97 dead oysters that were more

TABLE 2. SEX, INSEMINATION STATUS, AND PARASITISM OF MUD SNAILS[a]

	Males	Females		Totals
		Full SR	Empty SR	
On mud	4	32	63	99
Parasitized	0	1	28	29
Near oysters	63	36	0	99
Parasitized	0	0	0	0
Singles	9	44	37	90
Parasitized	0	6	13	19
Total	76	112	100	298
Parasitized	0	7	41	48

[a] Numbers of males, females with and without full seminal receptacles, and parasitized animals from aggregations (on mud, and near oysters) and sandy areas. SR = seminal receptacle.

than 30 cm away were sites of deposition. (H_o Deposition <30 cm = Deposition >30 cm, $G = 52$, $P < 0.001$, 1 df). In the second census, deposition was on 68 of 100 shells with capsules 30 cm, and 51 of $100 > 30$ cm away (H_o deposition <30 cm = deposition > 30 cm, $G = 12.4$, $P < 0.001$, 1 df). In total, 164 of 200 dead oysters <30 cm from living oysters and 124 of 197 dead oysters >30 cm from living oysters were sites of egg deposition. Dead oyster shells within 30 cm of living oysters were more likely to be sites of egg capsule deposition than dead shells further than 30 cm from living oysters.

Sex, Seminal Receptacle Condition, and Parasitism in Snail Microhabitats. We collected snails from three microhabitats. We determined sex ratios, whether females had full or empty seminal receptacles, and the percentages of parasitized snails (Table 2). Snail aggregations on mud were 21:1 female to male. Approximately one third of the females had full seminal receptacles, and 45% were parasitized, including one snail with a full seminal receptacle. In contrast, aggregations ratios around oysters were approximately 1:2 females to males. All females had full seminal receptacles, and there were no parasitized snails. The single snails on sand were at a ratio of 9:1 females to males. A little over half (54%) of these females had full seminal receptacles. Of the 26 single animals that were parasitized, 6 had full seminal receptacles. In the total sample, none of 76 males, 7 of 112 females with full seminal receptacles, and 41 of 100 females without full seminal receptacles were parasitized. Contingency analysis showed large differences between the sex distributions and seminal receptacle conditions between distributions. ($G = 170.7$, $P < 0.001$, 4 df). The composition of snails around oysters was different from the composition of snails on mud and sand. More parasitized snails were found in mud aggregations than among single animals on sand (29/64 vs. 19/81; $G = 7.5$, $P < 0.01$, 1 df). Copulating snails were found only in the

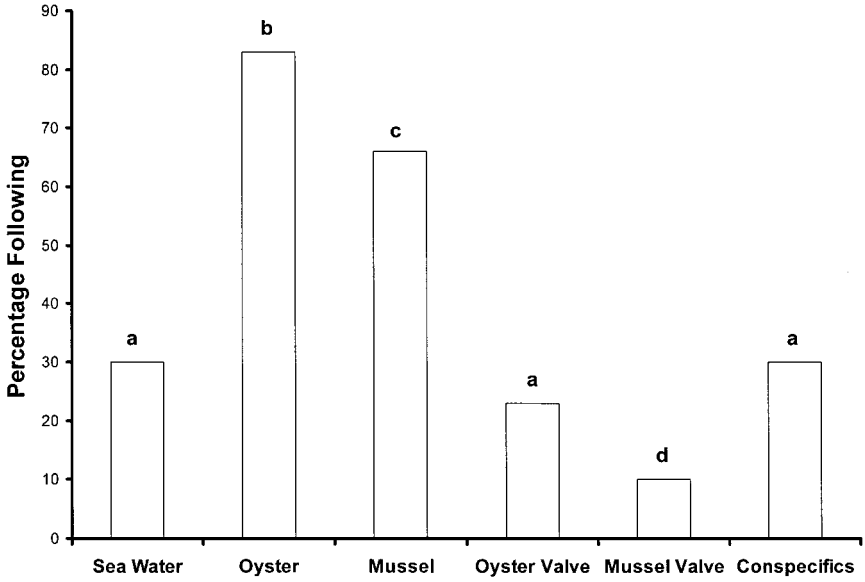

FIG. 1. Following responses of mud snails to odor water. Letters above the bars indicate similar frequencies ($P > 0.05$ same letter) and different frequencies ($P \leq 0.05$ different letters) as determined by proportions tests.

aggregations around oysters. The 12 pairs of snails were each comprised of a male and a female, and none was parasitized.

Snail Responses to Odors. Sea water incubated with living oysters, living mussels, living mud snails, and old oyster and mussel valves and plain seawater were tested for responses in ring assays (Figure 1). Three test conditions (1) seawater; (2) snail odor; and (3) oyster valve odor, resulted in the similar following responses: (9/30, 9/30, and 7/30, respectively (all Z statistics were less than 0.86; all $P > 0.1$). Dramatic increases in following responses occurred in tests with living oyster odor (25/30 for oyster odor vs. 9/30 for seawater, $Z > 10$, $P < 0.001$) and living mussel odor (20/30 for mussel odor vs. 9/30 for sea water $Z > 10$, $P < 0.01$). Mussel valve odor caused a decrease in following (3/30 for mussel valve odor vs. 9/30 for sea water, $Z = 2.6$, $P < 0.01$).

Field Experiments. In field experiment 1, the array tested contained 10 replicates each of a screen control, living oysters and mussels old oyster, and old mussel valves. There were clear differences in egg capsule deposition in the average number of capsules per substrate (Figure 2). Many more capsules were deposited on living oysters (1000s for each substrate) than were deposited on living mussels (10s per each substrate). A few capsules were deposited on several old oyster valves.

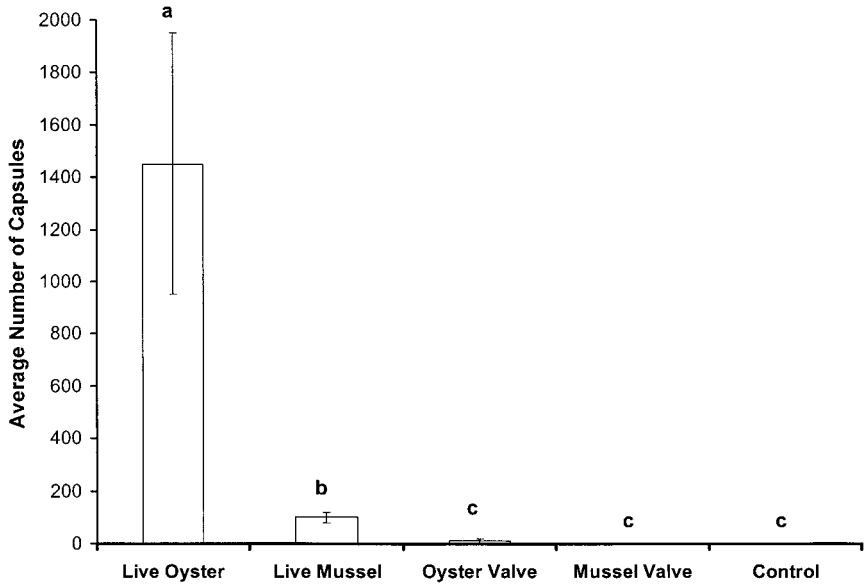

FIG. 2. Egg capsule deposition in field experiment 1. Letters above bars indicate similar ($P > 0.05$ same letter) and different ($P \leq 0.05$ different letter) as determined by ANOVA.

Deposition on oyster valves was not different statistically from mussel valves or screen controls.

In experiment 2, we counted the number of snails within 30 cm of the test substrates at low tide each day. By day 1, snail aggregations within 30 cm of whelk egg capsules, live oysters, and live mussels were developing, and they increased in number daily from an average level of 5–8 on day 1 to as many as 23 on day 6 (Figure 3). Numbers of snails around dead shells remained constant and low, averaging 2 on day 1 and less than 2 on day 6. Whelk egg capsules were most attractive, followed next by live oysters and live mussels.

Egg capsule deposition was related to aggregations. Deposition was dramatically higher on whelk egg capsules than on the other test substrates (Figure 4). Deposition of capsules on living oysters, living mussels, and on dead valves was in a proportion to similar that of experiment 1. No eggs were deposited on dead oyster or mussel valves.

The two test surfaces of each type with attached mud snail egg capsules were assessed for qualitative effects on subsequent mud snail capsule deposition (Figure 4). Mud snails deposited additional egg capsules on all substrates with attached mud snail egg capsules. Capsule deposition was at least 1.5-fold higher on all test substrates with addition of mud snail egg capsules.

DISCUSSION

Field observations indicate that mud snails deposit egg capsules on the exposed valves of living bivalves. Aggregations of snails were found on mud and around living oysters. Snails were individually distributed on sandy substrates. Breeding, parasite-free snails were found in aggregations around oysters. Aggregations around oysters were 2:1 male to female snails and were a site of breeding activity. Breeding activity was not observed in mud aggregations that were 20:1 female–male snails, and about 30% of the females were parasitized. Snails from sandy substrates were similar to aggregations on mud with respect to sex composition, breeding, and parasitism. In laboratory assays, snails followed the odors of living bivalves. From 23 to 30% of the snails followed rings of sea-water, mud snail, and old oyster valve odors. Only 10% of snails followed the odor of an old mussel valve. In field experiments, mud snails were attracted to and deposited egg capsules on living bivalves, on substrates in the immediate vicinity of living oysters, and on or adjacent to mud snail and whelk egg capsules. Aggregations of snails were in response to living bivalves, mud snail egg capsules, and whelk egg capsules. We conclude that both aggregation and egg capsule deposition are chemically mediated, that both sexes are attracted, and that parasitized snails, which are

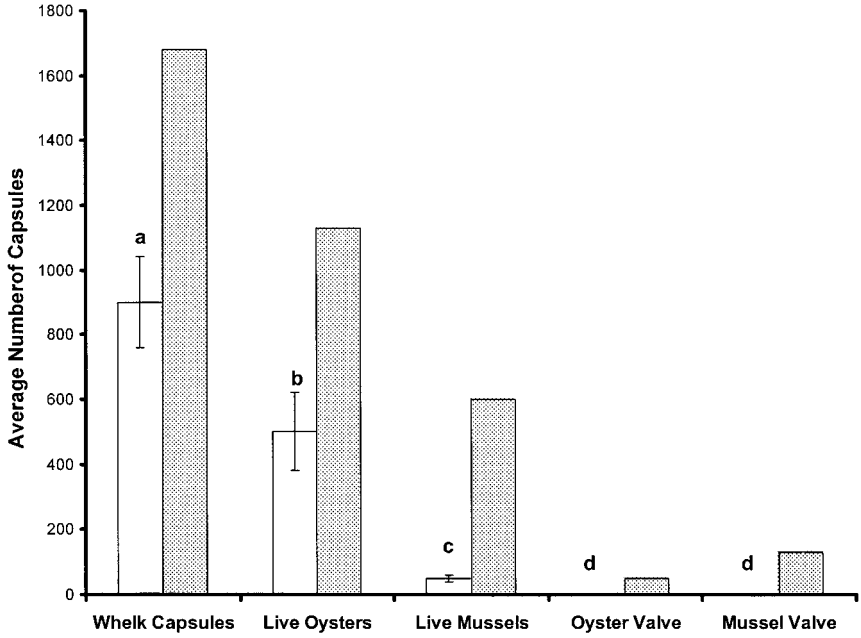

FIG. 4. Average egg capsule deposition observed in field experiment 2. Open bars are substrates ±SEM. Stippled bars are substrates with mud snail egg capsules added. Only means are presented for stippled bars because there were only two replicates of each treatment. Letters above bars indicate similar ($P > 0.05$ same letter) and different ($P \leq 0.05$ different letter) as determined by ANOVA.

functionally castrated, are unlikely to respond to these cues. The results of our studies have many similarities to observations of spawning and mating by sea hares.

Perhaps the most striking similarity between sea hare and mud snail reproduction is the coordinated stimulation of aggregation, deposition, and breeding by chemicals from eggs. In both instances, the result is large aggregations of snails, some of which are depositing eggs and others that are copulating. In both cases, the cues originate from both conspecific and heterospecific egg deposits. Cues from mud snail egg capsules might be related to egg laying hormone (ELH), as it is for sea hare egg strings (Painter et al., 1991; Painter 1992). However, if this is the case, then it is likely that the protein relative of ELH might actually be an integral part of the proteinaceous capsules housing the eggs and embryos of conspecifics and heterospecifics. This conclusion is based upon the observation that empty heterospecific capsules devoid of their embryos and nutritive contents are attractive.

For sea hares (Kupferman and Carew, 1974; Audersik, 1979; Susswein et al., 1983, 1984; Achituv and Susswein, 1985) and for mud snails, aggregations occur in

specific microhabitats. Strings and capsules are deposited in locations that ensure embryos will not be buried or washed prematurely from soft-bottomed environments. However, sea hare spawning aggregations are in sea grass, while mud snail aggregations are around oysters. This suggests that the environmental chemical cues that initiate the aggregations are different.

One option for the organization of mud snail aggregations around living bivalves is the bivalves, which are also reproductive at this time, are secreting ELH or molecules with similar activity that attract snails. Oysters and hard clams have fall and spring spawning intervals that are controlled by temperature. Thus, these animals could be attractive because they are releasing ELH-like molecules. However, if ELH-like molecules are involved, one would expect that egg-laying snails should also be producing attractive odors, as observed for sea hares (rev. Painter 1992; Painter et al., 1998,1999). In the assays conducted in 2000, we did not observe that mud snails were attractive. However, as we did not determine the sex or reproductive condition of the odor-producing or test snails, we will revisit this issue during the 2002 egg capsule deposition season. Alternatively, mud snails could be responding to odors released by bivalves that are attractive to predatory snails such as oyster drills. These odors are produced by both immature and adult bivalves (Carriker, 1955; Rittschof and Gruber, 1988; Rittschof, 1993).

Although we are convinced that egg capsule deposition by mud snails is chemically mediated, we have generated questions about the system that require more study. These questions include: revisiting the issues of aggregation and parasitism in males, studying the attractiveness of reproductive snails, determining whether not immature bivalves are attractive to mud snails, and studying the nature of responses by snails to odors in laboratory assays.

Acknowledgments—Mel Carriker and Larry Curtis stimulated this work through their enthusiasm for mollusks, biology, and life. A host of students from Duke and other institutions shared field and laboratory experiences. The work was funded in part by the Duke University Marine Laboratory. Several anonymous reviewers and the editor contributed to the quality and form of the final manuscript.

Abstract—Prey species show diverse antipredator responses to chemical cues signaling predation threat. Among terrestrial vertebrates, the red-backed salamander, *Plethodon cinereus,* is an important species in the study of these chemical defenses. During the day and early evening, this species avoids rinses from garter snakes, *Thamnophis sirtalis*, independent of snake diet, but late at night, avoids only those rinses from garter snakes that have recently eaten *P. cinereus*. We tested whether the selective, late-night response requires the ingestion or injury of salamanders. In three experiments, we tested *P. cinereus* for their responses to separate or combined rinses from salamanders (undisturbed, distressed, and injured *P. cinereus*) and snakes (unfed, earthworm fed, and salamander-fed *T. sirtalis*). When paired against a water control, only rinses from salamander-fed snakes were avoided. When salamander treatments (undisturbed or distressed) were combined with the snake treatments (unfed or earthworm-fed) and tested against a water control, the combinations elicited avoidance. When selected treatments were paired against the standard rinse from salamander-fed snakes, only the combined rinses from salamanders and snakes nullified the avoidance response to the standard rinse. These data reveal a prey defense mechanism involving chemical elements from both the predator and prey that does not require injury or ingestion of the prey in the formation of the cue.

Key Words—Chemical cues, predation, scent, composition, alarm, synergism, defense, diet, salamander, *Thamnophis sirtalis*, *Plethodon cinereus*.

INTRODUCTION

Essentially all animals face predation threat at some point in their lives (Lima, 1998). Many of these species can significantly reduce predation risk by responding to chemosensory cues from predators or prey, with the cues varying from simple nitrogenous wastes to more specialized, damage-release chemicals stored in prey tissues (reviewed by Weldon, 1990; Kats and Dill, 1998). In some cases, combined chemical information from both the predator and prey appear to evoke a selective response in the prey species, suggesting either a complex chemical cue or multiple cues evoking a similar response. For example, prey individuals may vary their response depending on whether conspecifics occur in the predator's diet, or they may avoid both predator cues and damage-release cues (Chivers and Smith, 1998; Madison et al., 1999a,b; Murray and Jenkins, 1999; Grostal and Dicke, 2000; Chivers and Mirza, 2001). Chemosensory responses can also be context dependent, e.g., the responses vary at different times in the diel cycle (e.g., Madison et al., 1999b), with the size of the predator relative to that of the prey (Puttlitz et al., 1999), with refuge proximity (Sih and Kats, 1991), or seasonally between breeding and nonbreeding periods (Rohr et al., 2002). Despite the large number of species known to respond to chemical traces associated with predation, and despite the well-documented instances of damage-release cues particularly in aquatic species (reviewed by Chivers and Smith, 1998; Chivers and Mirza, 2001), surprisingly little is known about cue components and complexity, especially in terrestrial vertebrates (Kats and Dill, 1998).

The antipredator responses of plethodontid salamanders, especially *Plethodon* sp., have received considerable attention recently (e.g., Cupp, 1994; Lutterschmidt et al., 1994; Chivers et al., 1997; Madison 1999a,b; Murray and Jenkins, 1999; Graves and Quinn, 2000; Hucko and Cupp, 2001; Maerz et al., 2001; Sullivan et al., 2002), and this group offers a good opportunity for elucidating the source and complexity of the chemical cues signaling predation threat among terrestrial vertebrates. Their activity at night when higher relative humidity favors chemoreception (Madison, 1977), their elaborate chemosensory receptors and accessory structures (Madison, 1977), their behavioral sensitivity to a wide range of chemicals related to food, predation, social interactions, and interspecific recognition (Jaeger, 1986; Chivers et al., 1997), their diel shift from a chemically mediated daytime and early evening antipredator response to a late-night response (Madison et al., 1999b), their compromised foraging at night in the presence of predator chemical cues (Maerz et al., 2001), their avoidance of predator chemical cues in both laboratory and field studies (Sullivan et al., 2002); and their relative abundance and accessibility in many woodland habitats (Burton and Likens, 1975), collectively make them suitable for comprehensive studies of chemosensory defenses.

In the context of predation, the genus *Plethodon* appears to respond to four types of chemical cues that are often combined or confused in experimental studies:

(1) cues exclusively from predators (Madison et al., 1999a,b; McDarby et al., 1999; Murray and Jenkins, 1999), (2) "alarm" signals from wounded conspecifics and/or heterospecifics (Chivers et al., 1997; Hucko and Cupp, 2001), (3) "distress" chemicals from stressed, but not injured, conspecifics (Graves and Quinn, 2000; Mathis and Lancaster, 1998), and (4) cues from predators that have recently fed on conspecific prey (Madison et al., 1999a,b; Murray and Jenkins, 1999; Maerz et al., 2001; Sullivan et al., 2002). Cues in the fourth or "diet-specific" category are of interest because of the chemical involvement of organisms belonging to different taxa. These cues are also potentially problematic because they can easily be confused with alarm, distress, or other possible "labeling" substances transferred from prey to the predator that involve a chemical produced from just one source, in this case the prey.

In an effort to clarify the nature of the cue in the diet-specific category, single-source cues, such as alarm substances, must be shown not to be present or sufficient by themselves to elicit the response thought to result from complex, cross-taxon cues. If multi-species involvement in chemical cue production is demonstrated, we theorize three ways that true cross-taxon cues with both predator and prey involvement could be produced. The first requires the gastrointestinal digestion or alteration of a prey substance into a new product that is gradually secreted or excreted from the predator, eliciting avoidance when the chemical is encountered in the environment. A second possibility is that external integumentary or other bodily secretions from both the predator and prey chemically react during an encounter, forming a warning product that is rubbed off along the predator's path. The third possibility is a compositional, nonreactive chemical mixture of chemical products from both prey and predator, where the products only elicit avoidance when they occur together in the same chemical trace.

One of the first steps in distinguishing among the "diet-specific," cross-taxon pathways of cue production is to determine whether the ingestion of prey by the predator is required to generate the chemical cue that elicits a response among conspecific prey, i.e., is diet-specific antipredator behavior really "diet" specific? We approached this problem by collecting rinses from garter snakes and red-backed salamanders and then testing whether salamanders would avoid these rinses only when they were combined. We speculated that late at night when only rinse from salamander-fed snakes is avoided, *P. cinereus* would avoid a rinse of unfed or earthworm-fed snakes combined with undisturbed or noninjured salamanders, but would not avoid the snake or salamander rinses tested separately.

METHODS AND MATERIALS

A total of 416 adult salamanders [*P. cinereus*; snout/vent length (SVL) $>$ 40 mm] and 8 adult garter snakes (*T. sirtalis*; SVL $>$ 36 cm) were collected from

the Binghamton University Nature Preserve (Broome Country, New York, USA). Salamanders and snakes were housed in separate rooms at 15°C (salamanders) and 25°C (snakes) on a natural photoperiod (15L:9D). Salamanders were housed individually in 15-cm diam Petri dishes lined with moistened paper towels. Each salamander was tested once within 10 d of capture and then released at the capture site. Snakes were housed individually in 38-l glass aquaria, provided with a heating block, given crumpled paper towels for cover, and maintained on a diet of *P. cinereus* or earthworms (*Lumbricus* sp.) before and during the experiment. They were released following the experiments.

Salamanders were subjected to distilled water rinses of different snake and salamander treatments or to distilled water only, in two-choice, substrate tests. The methods for preparing treatments and testing salamander avoidance are similar to those of Madison et al. (1999b), with the modifications described below.

Experiment I. Trials with Distressed Salamanders and Earthworm-Fed Snakes. Four treatment rinses were prepared: salamander-fed snake, earthworm-fed snake, distressed salamander, and a combination of the latter two. The salamander-fed snake treatment is a standard treatment used in all our experiments to provide a measure of whether recently captured salamanders are behaving similarly to previously tested salamanders. The rinses from the earthworm-fed snake and the distressed salamander were tested singly and then together against distilled water to determine whether the combination rinse, but not the independent rinses, would elicit avoidance.

The salamander-fed snake rinse consisted of a 200-ml rinse of an adult garter snakes (snake 1) that had been maintained on a diet of 4 *P. cinereus*/w for 2 w prior to sample collection, with 4 of these salamanders (2 male, 2 female) being fed to the source snake just prior to sample collection. Although individual snakes may differ at least in some of their chemical secretions (Oldak, 1976), previous research has shown that the response of individual *P. cinereus* to snake chemical cues does not noticeably vary with the snake used to collect the test rinses (Madison et al., 1999b). In addition, rinses from 18 *T. sirtalis* that have been fed *P. cinereus* over the past 7 yr have never failed to elicit avoidance in *P. cinereus* (Madison, Sullivan, Maerz, McDarby, personal observation). Collection of the snake rinses entailed transferring the snakes to individual 4-l beakers, covering them with 8 layers of cheesecloth secured by rubber bands, placing a heating pad (26°C) under half the beaker base, waiting 72 hr, carefully removing the snake, and then collecting a 200-ml distilled water rinse of all smears, secretions, and excretions deposited in the beaker.

The earthworm-fed snake treatment rinse was identical to the above, except that earthworms equivalent in mass to the salamanders were fed to an adult garter snake (snake 2). The distressed salamander treatment rinse consisted of a 200-ml sample of distilled water in which 4 adult *P. cinereus* (2 male, 2 female) had been held by blunt forceps and agitated for 2 min each until defensive

secretions were released from their tails and body (but where no wounding had occurred).

We filtered all rinses through a 0.45-μm filter to remove solid materials, and divided the filtrate into four 50-ml aliquots. The fourth treatment (combination treatment) was prepared by combining 50-ml aliquots of the earthworm-fed snake and the distressed salamander rinses. The resulting combination rinse, therefore, had half the concentration of each of the two separate components. All four treatments were rapidly frozen in liquid nitrogen, stored in a freezer, and thawed at room temperature just prior to use. Sullivan et al. (2002) showed that salamanders still avoid salamander-fed snake rinse that has been frozen using this method.

For testing (Madison et al., 1999a,b; Sullivan et al. 2002), we placed two filter paper semicircles with a 3-mm gap between them into 15-cm Petri dishes, inoculated the semicircles with 1.5 ml of treatment rinse or distilled water, and randomly placed these test dishes (position and orientation) in an 8×7 pattern on the floor of the test room. A total of 168 salamanders were tested once beginning just after midnight over three consecutive nights. On each night, 14 replicate dishes were prepared for each treatment comparison, giving 14 replicates for each of the four comparisons per night. Thus, 56 salamander dishes were distributed at random and tested in a 8×7 pattern each night. Salamanders were moved to the test room 1 hr prior to the experiments, which began between 24:00 and 01:00 hr. We transferred each salamander under dim red light from the home dish to the test dish with a cotton swab, and placed a 15-mm collar of brown paper around the covered dish to isolate each salamander visually during the transfer process. After all salamanders were distributed ($\sim$10 min), the lights were turned off and the trial was recorded with an infrared, 0-lux, video camera (Sony TRV66) suspended 3 m above the dishes. We scored which semicircle the salamander occupied at 3-min intervals for 1 hr beginning a time 0, which gave 21 positions per salamander. A score of 10 or less for a treatment was recorded as avoidance. Where salamanders straddled the 3-mm gap, two criteria were used to judge side position. If the salamander was moving, the side into which the salamander was moving was scored. If the salamander was not moving, the side occupied by more than half the body, measured from the midpoint of the trunk, was scored. All scoring was performed by an observer blind to treatment type and right/left side in the test dishes. We used a chi-square goodness-of-fit test to determine whether salamander responses to treatments departed significantly from random expectation (Siegel and Castellan, 1988).

Experiment II. Trials with Distressed Salamanders and Unfed Snakes. In the previous experiment, it is possible that any avoidance elicited by the combined rinse of earthworm-fed snake and distressed salamander might have nothing to do with an interaction of snake and salamander chemicals, and instead be a response to an interaction between chemicals from earthworms and salamanders. Experiment II repeats experiment Experiment I, except rinses from unfed snakes replace those

from earthworm-fed snakes, and two snakes are used for each snake rinse. If only the standard and combined rinses elicit avoidance, the results would more clearly indicate that neither ingestion nor injury of the salamander is required to elicit avoidance, and that chemicals from both noninjured salamanders and snakes are required.

Seven treatments were prepared and tested. Treatments A and B consisted of a 200-ml rinse from two different adult garter snakes (snakes 3 and 4) that had not been fed for 3 wk prior to sample collection, a period sufficient to negate a diet effect (Madison et al., 1999b). The use of different snake sources for treatments A and B, and two snake sources for other treatments mentioned below, was an effort to provide an additional test of possible snake source effects, as referred to in experiment 1. Treatment C consisted of rinse from distressed *P. cinereus*, collected in the same manner as in experiment I. Treatments D and E consisted of salamander-fed snake rinse from two different adult garter snakes (snakes 5 and 6) that had been treated identically to the comparable treatment in experiment 1. Treatments F and G were combination treatments made up of equal portions of treatments A and C and of B and C, respectively. The combined treatments were prepared as in experiment 1.

Testing was performed as previously stated. A total of 168 salamanders were tested once just after midnight over three consecutive days. On each night, 7 replicate dishes were prepared for each treatment, except for treatment C (distressed salamander), which was represented by 14 replicated dishes (giving 14 replicates for each of the four main treatments per night). Thus, 56 salamander dishes were distributed at random and tested each night, as in experiment 1.

We used a χ^2 goodness-of-fit test to determine whether salamander responses to treatments departed significantly from random expectation, and then a 2×2 χ^2 contingency test to look for differences between snake sources and between treatments (Siegel and Castellan, 1988). Interactions between *T. sirtalis* and *P. cinereus* can only be inferred using chi-square tests, and since this experiment with unfed snakes was the clearest demonstration of salamander and snake component effects, we used binomial regression with a log–log canonical link in Statistica's (Statsoft, Inc., 1998 version 5.5A) Generalized Linear model (GLZM) to quantitatively test for the predicted snake by salamander interaction. We chose to test for significance of this interaction using the Wald statistic, rather than likelihood ratios, due to its ease and efficiency of computation (Dobson, 1990).

Experiment III. Selected Individual and Combination Treatments Tested Against Rinses from Salamander-Fed Snakes. The previous experiments left unresolved several questions: (1) whether always giving salamanders a choice of moving to nonsoiled substrates would affect their response to treatment substrates, (2) whether salamanders would discriminate between the substrates of two snakes on different diets, and (3) whether the distressed salamanders may have elicited a subtle but nonsignificant avoidance effect that would still act as a prey label in

the combined tests. In a single attempt to address these questions, we paired our standard salamander-fed snake rinse against four treatment rinses: earthworm-fed snake, injured salamander, earthworm-fed snake + undisturbed salamander, and earthworm-fed snake + injured salamander.

Treatment rinses were collected as before, except that two new treatments were prepared: undisturbed salamander and injured salamander. Undisturbed-salamander rinse was collected by housing two salamanders (one male and one female) in separate Petri dishes on moistened filter paper for the 72 hr during which time snake chemical cues were accumulating for the snake rinses. After 72 hr, the filter paper was removed from both Petri dishes and placed in 200 ml of distilled water. The injured salamander rinse was collected using the two undisturbed salamanders above in a two-step procedure. First, they each were immersed in the same 200 ml of distilled water during which they were physically disturbed, identical to the collection of distressed salamander rinse previously described. Second, they were removed, decapitated, and homogenized in the same 200 ml of distilled water with the distress substances. Both rinses were passed through glass wool before use in preparing the test dishes. All tests were performed beginning at midnight immediately after treatment preparation, and all observations were performed and analyzed as in previous studies (Madison, 1999a,b). We used a chi-square goodness-of-fit test to determine whether salamander responses to the different treatments departed significantly from random expectation (Siegel and Castellan, 1988).

RESULTS

The first experiment showed that *P. cinereus* did not avoid rinses from earthworm-fed snake or the distressed salamander when these were tested separately against distilled water in late-night trials. However, salamanders significantly avoided the standard salamander-fed snake rinse ($\chi^2 = 13.71$, $df = 1$, $P < 0.001$). The combined rinse of earthworm-fed snake and distressed salamander was also avoided ($\chi^2 = 7.71$, $df = 1$, $P = 0.005$), despite the concentrations of the components in the combined rinse being half those in the separate rinses (Table 1).

In the second experiment, we first looked for differences in response to the two unfed snakes when tested alone (treatments A and B) or in combination with salamander rinse (treatments F and G). No difference occurred between treatments A and B ($\chi^2 = 0.86$, $df = 1$, $P = 0.35$; Table 2) or between F and G ($\chi^2 = 0.12$, $df = 1$, $P = 0.73$). In addition, no difference in response was given to the two snakes that were fed salamanders (treatments D and E; $\chi^2 = 0.00$, $df = 1$, $P = 1.00$). Thus, the results for each snake source within each treatment were combined for further analyses.

TABLE 1. NUMBER OF SALAMANDERS PREFERRING SUBSTRATES WITH DISTILLED WATER VS. SUBSTRATES WITH DISTILLED WATER RINSES[a]

Trial type	Salamanders preferring (N): Treatment	Water	$\chi^2 b$	P
Ts_{Pc} vs. water	9	33	13.71	<0.001
Ts_W vs. water	17	25	1.52	0.217
Pc_D vs. water	20	22	0.10	0.758
$Ts_W + Pc_D$ vs. water	12	30	7.71	0.005

[a] Rinses were of *T. sirtalis*-fed *P. cinereus* (Ts_{Pc}), *T. sirtalis*-fed earthworms (Ts_W), distressed *P. cinereus* (Pc_D), or Ts_W and Pc_D Rinses Combined ($Ts_W + Pc_D$)
[b] $df = 1$.

The unfed snake treatments (A + B) elicited no avoidance behavior in salamanders during the late-night trials ($\chi^2 = 0.00$, $df = 1$, $P = 1.00$; Table 2), nor did the distressed salamander rinse ($\chi^2 = 0.38$, $df = 1$, $P > 0.50$). However, the salamander-fed snake treatments (D + E) elicited significant avoidance ($\chi^2 = 16.10$, $P < 0.001$), as did the combination treatments (F + G; $\chi^2 = 9.52$, $df = 1$, $P < 0.01$). These results corroborate the results for those treatments that were equivalent in experiment 1 and suggest that natural body secretions or excretions from undisturbed salamanders are sufficient to elicit avoidance when combined with rinses from recently foraging (on earthworms) or nonforaging snakes.

TABLE 2. NUMBER OF SALAMANDERS PREFERRING SUBSTRATES WITH DISTILLED WATER VS. SUBSTRATES WITH DISTILLED WATER RINSES[a]

Trial type	Treatment	Salamanders preferring (N): Treatment	Water	χ^2	P
Ts vs. water	(A) Ts_1	12	9		
	(B) Ts_2	9	12		
		21	**21**	0.00	1.00
Pc_D vs. water	(C) Pc_D	**19**	**23**	0.38	>0.50
Ts_{Pc}vs. water	(D) Ts_{3Pc}	4	17		
	(E) Ts_{4Pc}	4	17		
		8	**34**	16.10	<0.001
Ts + Pc_D vs. water	(F) $Ts_1 + Pc_D$	6	15		
	(G) $Ts_2 + Pc_D$	5	16		
		11	**31**	9.52	<0.01

[a] Rinses were of unfed *T. sirtalis* (Ts), distressed *P. cinereus* (Pc_D), *T. sirtalis*-fed *P. cinereus* (Ts_{Pc}), or Ts and Pc_D combined (Ts + Pc_D). Numbers following Ts refer to the different snakes used. Chi-square results are given for within-trial comparisons ($df = 1$ for each comparison); no differences occurred between snakes within trial types.

Comparing the results of the four main treatments, there was no difference between unfed snake and distressed salamander treatments (χ^2 2 × 2 contingency test, $\chi^2 = 0.19$, $df = 1$, $P = 0.66$), but there was a difference between rinses from unfed snakes vs. salamander-fed snakes ($\chi^2 = 8.90$, $df = 1$, $P = 0.003$) and between unfed snakes vs. the combination of unfed snakes and distressed salamanders ($\chi^2 = 5.10$, $df = 1$, $P = 0.03$). There was a significant difference between distressed salamanders and the salamander-fed snake standard ($\chi^2 = 6.60$, $df = 1$, $P = 0.01$), but a marginally insignificant difference between distressed salamanders and the combined unfed snake + distressed salamander treatment ($\chi^2 = 3.30$, $df = 1$, $P = 0.068$). Finally, there was no difference between the standard rinse and the combined unfed snake + distressed salamander ($\chi^2 = 0.61$, $df = 1$, $P = 0.43$).

Since there was no independent avoidance of unfed snake rinse or distressed salamander rinse, but a significant avoidance of these treatments combined, a snake × salamander interaction was suggested. We combined the data for the standard rinse and the combination rinse of distressed salamander + unfed snake because both contained chemicals from stressed salamander and snake, and then we compared these against the independent results for snakes (treatments A and B) and distressed salamanders (treatment C). An unfed snake × distressed salamander interaction was confirmed using binomial regression ($\text{Wald}_{1,206} = 5.42$, $P = 0.02$).

Finally, in experiment 3, the results of the dual treatment tests gave results consistent with previous predictions and findings for individual treatment tests against a distilled water control. Rinses from standard salamander-fed snake treatments were avoided relative to earthworm-fed snake ($\chi^2 = 5.00$, $df = 1$, $P = 0.03$) and to injured (homogenized) salamander treatments ($\chi^2 = 7.20$, $df = 1$, $P < 0.01$), indicating that neither earthworm-fed snake rinses nor injured salamander rinses were as aversive as the standard rinse (Table 3). The lack of a difference between the combined samples and the standard salamander-fed snake rinse suggests that *P. cinereus* finds these treatments equally undesirable.

DISCUSSION

The results corroborate previous findings that rinses from *P. cinereus*-fed *T. sirtalis* consistently elicit avoidance in laboratory trials when compared to water controls (e.g., Madison et al. 1999a,b; Maerz et al., 2001; Sullivan et al., 2002), regardless of different source snakes being used, and that earthworm-fed snake rinse and unfed snake rinse fail to elicit avoidance in late-night tests when salamander-fed snake rinse continues to elicit avoidance (Madison et al., 1999a,b). The results also show that, under the conditions in our study, rinse from distressed *P. cinereus* repeatedly fails to elicit avoidance. When the combined rinses from distressed

TABLE 3. NUMBER OF SALAMANDERS PREFERRING SUBSTRATES WITH DISTILLED WATER RINSES OF *T.sirtalis*-FED *P.cinereus* (Ts_{Pc}) VS. DISTILLED WATER RINSES OF *T. sirtalis*-FED EARTHWORMS (Ts_W), HOMOGENIZED *P.cinereus* (Pc_H), Ts_W COMBINED WITH UNDISTURBED *P. cinereus* (Pc) (Ts_W + Pc), AND Ts_W COMBINED WITH Pc_H ($Ts_W + Pc_H$).

Trial type	Salamanders preferring (*N*): Treatment	Ts_{Pc}	Ties	χ^{2a}	*P*
Ts_W vs. Ts_{Pc}	15	5	0	5.00	0.03
Pc_H vs. Ts_{Pc}	16	4	0	7.20	<0.01

$Ts_W + Pc_H$ vs. Ts_{Pc}	7	13	0	1.80	0.18

[a] $df = 1$.

P. cinereus and unfed or earthworm-fed *T. sirtalis* elicited avoidance late at night, two things became clear. First, the cue eliciting avoidance behavior must require chemical involvement of both the predator and the prey. Second, neither ingestion by the predator nor distress or alarm substances from disturbed or injured prey is necessary to elicit late-night avoidance in *P. cinereus*.

There are two possible explanations for the above findings: (1) substances from the snake and salamander remained active in the separate rinses and chemically reacted to produce a novel "warning" substance when the rinses were combined, or (2) chemicals from snakes and salamanders only evoke a response when they occur as a mixture in the same scent trace, and in this case, the cue would be compositional rather than being a novel chemical product. It is difficult to determine which of these two hypotheses is more likely. In support of both is that during snake attack, *P. cinereus* usually deposits milky tail secretions directly to the snake's head, and that after ingestion or prey escape, the film remains and the snake goes through head rubbing on the substrate for a few minutes. This behavior has also been reported for *T. sirtalis* in response to the adhesive mucus of earthworms (Cunningham and Burghardt, 1999). Not only is there potential mixing of substances from salamander and snake, but the subsequent effort by the snake to free its integument (eyes, scales) of the gluey matrix would facilitate the deposit of substances in this matrix on the nearby landscape.

The above scenario for a novel chemical cue or a composite cue used by *P. cinereus* late at night does not preclude the concurrent existence of multiple chemical mechanisms involved in antipredator behavior in this species. In fact, the avoidance of any *T. sirtalis* trace during the day or early evening, but only of *P. cinereus*-fed *T. sirtalis* rinses late at night, indicates two mechanisms with temporal dependence (Madison et al., 1999a,b). In addition, other data show a third mechanism in *P. cinereus*: the late-night avoidance of damage-release "alarm" substances (Sullivan, Madison and Rohr, unpublished reults). Damage-release

cues, by themselves, are probably not responsible for the avoidance of the standard salamander-fed snake rinses late at night, since in the present study these alarm cues failed to cancel the effect of the standard rinses in eliciting avoidance. Thus, the new chemical mechanism, which does not require tissue injury, could be the basis for the avoidance of both the combination rinses and the standard rinse from salamander-fed snakes. Whatever the ultimate explanation is, at least four different chemical mechanisms are used by *P. cinereus* in the context of predator avoidance, with the fourth or "dietary" mechanism requiring chemicals from both the predator and prey and being either a compositional mixture or a novel cue formed by a non-ingestive chemical reaction between superficial rinse products from both predator and prey.

Our study is the first demonstration of antipredator behavior being released by a cue where substances from both the predator and prey are required to elicit a response. How common such complex, "cross-taxon" cues may be in nature is unknown, but our findings strongly suggest that future studies should not restrict the search for chemical cues that elicit antipredator behavior to substances released from just the prey or predator.

(Received March 29, 2002; accepted July 5, 2002)

Abstract—Our objectives were to identify and field test the sex pheromone of female Douglas-fir cone gall midge, *Contarinia oregonensis* (Diptera: Cecidomyiidae). Coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of pheromone extract revealed a single compound (**A**) that elicited responses from male antennae. Hydrogenation of pheromone extract, followed by renewed GC-EAD analysis, revealed a new EAD-active compound with chromatographic characteristics identical to those of tridecan-2-yl acetate on five fused silica columns (DB-5, DB-210, DB-23, SP-1000, and Cyclodex-B). Syntheses, chromatography, and retention index calculations of all possible tridecen-2-yl acetates suggested that the candidate pheromone **A** was a tridecadien-2-yl acetate with nonconjugated double bonds. Synthetic candidate pheromone component (*Z,Z*)-4,7-tridecadien-2-yl acetate (*Z*4*Z*7) cochromatographed with **A** on all analytical columns and elicited comparable antennal activity. In GC-EAD analyses that separated the enantiomers (*Z,Z*)-4,7-tridecadien-(*S*)-2-yl acetate (2*S*-*Z*4*Z*7) and (*Z,Z*)-4,7-tridecadien-(*R*)-2-yl acetate (2*R*-*Z*4*Z*7) with baseline resolution, only 2*S*-*Z*4*Z*7 as a component in a racemic standard or in pheromone extract elicited antennal responses. In Douglas-fir seed orchards, sticky traps baited with 2*S*-*Z*4*Z*7 captured

male *C. oregonensis*, whereas 2*R*-*Z*4*Z*7 was behaviorally benign. Comparable catches of males in traps baited with racemic *Z*4*Z*7 (50 μg) or virgin female *C. oregonensis* suggested that synthetic pheromone baits could be developed for monitoring *C. oregonensis* populations in commercial Douglas-fir seed orchards.

Key Words—Douglas-fir cone gall midge, *Contarinia oregonensis*, Cecidomyiidae, sex pheromone, enantiomers, (*Z*,*Z*)-4,7-tridecadien-(*S*)-2-yl acetate, (*Z*,*Z*)-4,7-tridecadien-(*R*)-2-yl acetate.

INTRODUCTION

The life history of the Douglas-fir cone gall midge, *Contarinia oregonensis* Foote (Diptera: Cecidomyiidae) is closely associated with the phenology of its host plant Douglas-fir, *Pseudotsuga menziesii*. In early spring as conelets open for pollination, female *C. oregonensis* eclose from their pupae in the duff, mate, and seek open conelets for oviposition. Females place their eggs singly or in clusters near the base of cone scales by extending their flexible ovipositor. Neonate larvae tunnel into cone scales and induce formation of, and develop within, galls near ovules. In the fall, larvae leave mature cones and overwinter in the duff as prepupae or pupae (Hedlin, 1961).

In natural forests, *C. oregonensis* is one of many insects that feed and develop on seeds. However, in coastal seed orchards of British Columbia, in Canada and Washington and Oregon, in the United States, *C. oregonensis* has become the single most important insect pest of Douglas-fir seeds. Larvae-caused gall formation results in seed fusion to the scale, preventing seed extraction at harvest or destruction of seeds at high populations. Severe infestations destroy the entire seed crop (Hedlin, 1961, 1974; Ruth, 1980).

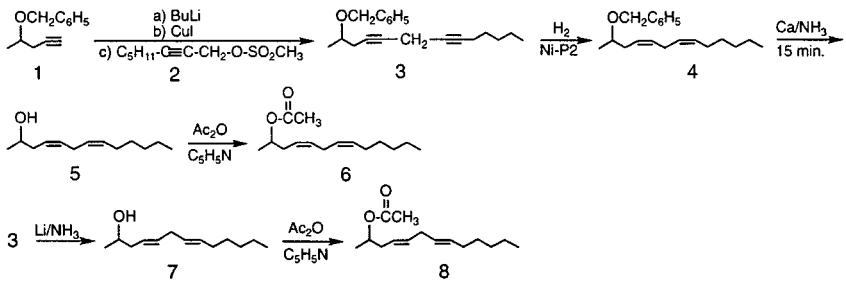
C. oregonensis is the only coastal Douglas-fir seed orchard pest in British Columbia monitored annually. Monitoring entails tedious and time-consuming counts of egg-infested scales in samples of conelets. When a threshold number of infested scales per conelet is reached, insecticidal control of *C. oregonensis* is implemented.

Miller and Borden (1981, 1984) presented evidence for a sex attractant pheromone produced by female *C. oregonensis.* Traps baited with synthetic *C. oregonensis* pheromone would allow investigation of relationships between captures of male *C. oregonensis* and numbers of both egg-infested scales at pollination and galled scales at harvest. If reliable correlations could be established, decisions about *C. oregonensis* control could be based solely on captures of males in pheromone-baited traps. Monitoring of *C. oregonensis* would become simple and effective.

We report identification and field testing of the pheromone.

METHODS AND MATERIALS

Experimental Insects. In late August and early September 1995–1996, mature, dry Douglas-fir cones infested with larvae of *C. oregonensis* were collected into loosely woven burlap sacks. These sacks were then partially submerged in water-filled pails for 2–3 days to induce the mature larvae to leave the cones. After removing the sacks from the pails, the larvae that had exited the cones and sacks and accumulated in the bottom of pails (apparently unaffected by their temporary submergence) were obtained by pouring the water through a No. 30 standard sieve (600 μm). Sieve-restrained larvae were then transferred to 500-ml glass jars half filled with clean, damp sand and closed with fine mesh screening. To break larval developmental diapause, jars were placed in environmental chambers (18°C; 70% relative humidity.) with temperature lowered by 2°C every 5 d to 4°C. After 3.5 months of cold exposure (4°C), jars were subjected to a temperature increase from 4 to 18°C in increments of 2°C every 5 d. Emergent adults were collected several times a day and kept individually in Petri dishes. Ovipositors (with pheromone glands) of calling females and abdominal tips of males were removed and separately extracted in hexane for 5–50 min.



Laboratory Analyses of Pheromone Extract and General Instrumentation. Aliquots of 5–10 female and male equivalents (FE, ME) of abdominal tip extract were analyzed by gas chromatography (GC) and coupled gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975), employing an Hewlett-Packard (HP) 5890 gas chromatograph fitted with a fused silica column (30 m $\times$ 0.25 or 0.32 mm ID) coated with DB-210, DB-5, DB-23, Cyclodex-B (J&W Scientific, Folsom, California, USA) or SP-1000 (Supelco, Bellefonte, Pennsylvania, USA). For GC-EAD recordings, a severed insect head (with both antennae intact) was placed into the opening of a glass capillary electrode (1.0 $\times$ 0.58 $\times$ 100 mm) (A-M Systems, Inc., Carlsborg, Washington, USA) filled with saline solution (Staddon and Everton, 1980). One antenna with its tip removed by spring microscissors (Fine Science Tools Inc., North Vancouver, British Columbia, Canada) was placed into the recording capillary electrode. Coupled GC-mass spectrometric (MS) analyses of pheromone extract (300 FE) and of synthetic standards employed a Varian II Ion Trap GC-MS fitted with the above-referenced DB-5 column.

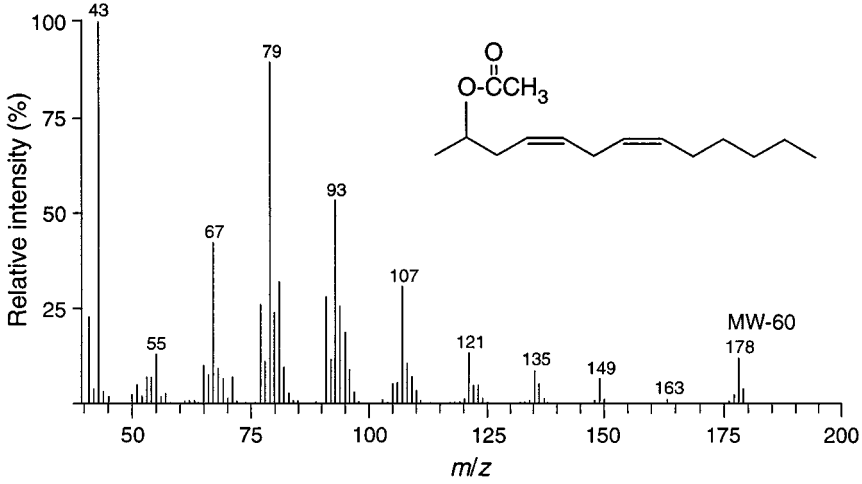
High-performance liquid chromatography (HPLC) employed a Waters LC 626 high-performance liquid chromatograph equipped with a Waters 486 variable wavelength UV visible detector set to 210 nm, HP Chemstation software (Rev.A.07.01), and a normal phase Nova-Pak silica column (60Å, 4 μm; 3.9 $\times$ 150 mm) with 1 ml/min of hexane–ether (97:3) flow. Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on a

Bruker AMX-400 spectrometer at 400.13 MHz for ^{1}H NMR spectra. ^{1}H chemical shifts are reported as parts per million (ppm; δ) relative to TMS. Elemental analyses were performed using a Carlo Erba model 1106 elemental analyzer. Chemicals obtained from commercial sources were used without further purification unless otherwise indicated. All moisture- and air-sensitive reactions were conducted under argon. Column chromatography refers to flash chromatography, using silica gel 60 (230–400 mesh, E. Merck, Darmstadt) (Still et al., 1978).

Syntheses

*(Z,Z)-4,7-Tridecadien-2-ol (**5**) (Scheme 1).* To a THF solution of the benzyl ether of 4-pentyn-2-ol (**1**) (4.35 g, 25 mmol), 11 ml of 2.5 M butyllithium in hexane (10% excess) was added at -70°C. The mixture was stirred under argon and then warmed to -25°C before addition of CuI (475 mg, 0.1 equiv.). After stirring for 1 hr at -25°C, a THF solution of freshly prepared 2-octyn-1-yl methanesulfonate (**2**) (30 mmol) (from 2-octyn-1-ol, methanesulfonyl chloride, triethylamine, 0°C) was added dropwise. The reaction mixture was allowed to warm to room temperature, quenched with aq. conc. NH_4Cl, and after 2 hr of stirring was extracted with hexane–ether (1:1). The desired benzyl ether of 4,7-tridecadiyn-2-ol (**3**) (40% yield) was purified (85% based on GC) by flash chromatography and reduced to the benzyl ether of (*Z*,*Z*)-4,7-tridecadien-2-ol (**4**) by catalytic hydrogenation with P-2 Ni in ethanol. Flash chromatography on $AgNO_3$-impregnated (20%) SiO_2, with a gradient of hexane–ether (99:1 to 95:5) eluent afforded (*Z*,*Z*)-diene (**4**) (76% yield, 94 % pure). Removal of the benzyl group of **4** by exposure to excess calcium (15 equiv.) in liq. ammonia (Hwu et al., 1986) for 15 min at -70°C yielded (*Z*,*Z*)-4,7-tridecadien-2-ol (**5**) (71%) and corresponding monoenes (7%), as determined by GC-MS. Therefore, **5** was repurified by flash chromatography as above to give 1.05 g (5.40 mmol) of pure **5**. Anal. calcd. for $C_{13}H_{24}O$: C 79.13; H 12.22. Found: C 79.53; H 12.32. ^{1}H NMR: $CDCl_3$, δ = 5.31-5.61 (4H, m), 3.88

SCHEME 1. Synthesis of (*Z*,*Z*)- and (*E*,*E*)-4,7-tridecadien-2-yl acetates.



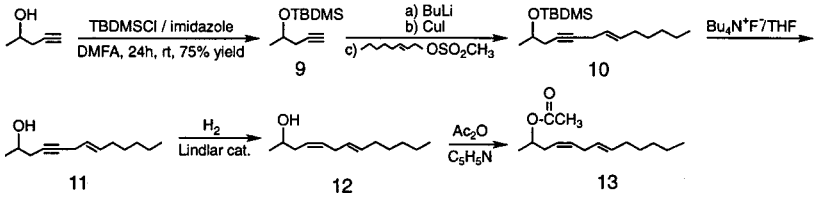


FIG. 1. Mass spectrum of synthetic (*Z*,*Z*)-4,7-tridecadien-2-yl acetate. Varian Saturn II Ion Trap GC-MS.

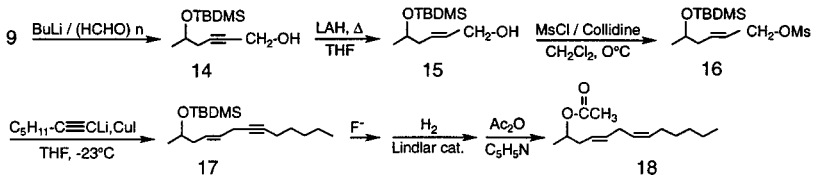
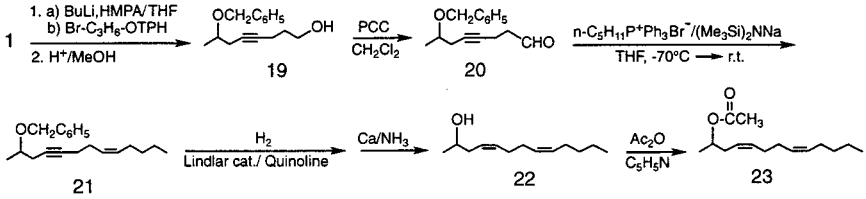
(1H, sextet), 2.85 (2H, t), 2.28 (2H, m), 2.08 (2H, m), 1.34 (6H, m), 1.25 (3H, d), 0.92 (3H, t).

*(Z,Z)-4,7-Tridecadien-2-yl Acetate (**6**) (Scheme 1).* Overnight reaction of **5** with acetic anhydride in pyridine afforded acetate **6** (1.20 g, 5.0 mmol) in 93% yield (20% overall yield based on **1**). Anal. calcd. for $C_{15}H_{26}O_2$: C 75.58; H 11.00. Found: C 75.80; H 10.98. ^{1}H NMR: $CDCl_3$, $\delta = 5.28$–5.54 (4H, m.), 4.92 (1H, sextet), 2.78 (2H, t), 2.31 (2H, m), 2.04 (2H, m), 2.01 (3H, s), 1.27 (6H, m), 1.22 (3H, d), 0.88 (3H, t); mass spectrum as in Figure 1.

*(E,E)-4,7-Tridecadien-2-yl Acetate (**8**) (Scheme 1).* Overnight reaction of **3** (1.13 g, 4.00 mmol) with lithium (20-fold excess) in refluxing liq. ammonia produced as the major product geometrically pure (*E*,*E*)-4,7-tridecadien-2-ol (**7**) (60% yield). It was purified by flash chromatography (see above) and acetylated as above to give (*E*,*E*)-4,7-tridecadien-2-yl acetate (**8**) (0.520 g, 2.18 mmol).



*(Z,E)-4,7-Tridecadien-2-yl Acetate (**13**) (Scheme 2).* 2-*tert*-Butyl-dimethylsilyloxy-3-pentyne (**9**) (5.14 g, 15.6 mmol) was coupled via cuprate with freshly prepared (*E*)-2-octen-1-yl methanesulfonate (15.2 mmol) (from 2-octen-1-ol, methanesulfonyl chloride, collidine at 0°C, 50% yield) in THF. The resulting crude *tert*-butyldimethylsilyl ether of (*E*)-7-tridecen-4-yn-2-ol (**10**) was de-protected with Bu_4NF in THF affording alcohol **11** (80% pure), which was hydrogenated with Lindlar catalyst in hexanes to (*Z*,*E*)-4,7-tridecadien-2-ol (**12**, 1.46 g, 7.43 mmol). Acetylation of purified **12** produced geometrically pure (*Z*,*E*)-4,7-tridecadien-2-yl acetate (**13**, 1.44 g, 6.04 mmol) in 39% overall yield.

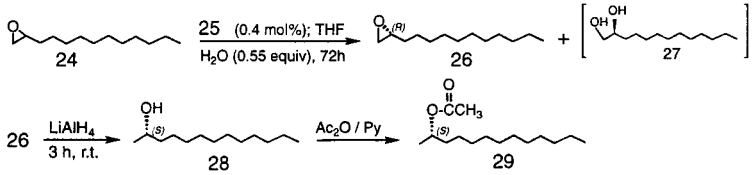


SCHEME 2. Synthesis of (*Z*,*E*)-4,7-tridecadien-2-yl acetate.

*(E,Z)-4,7-Tridecadien-2-yl Acetate (**18**) (Scheme 3).* Compound **9** in THF (5.70 g, 28.8 mmol) (Scheme 1) was extended by one carbon (BuLi at −70°C, then paraformaldehyde, warm to room temperature, and stirring for 24 hr) to the mono-protected diol **14** (95% yield). Reduction of **14** (3.1 g, 13.6 mmol) with lithium aluminum hydride (LAH, 7 molar excess) in refluxing THF produced allylic alcohol **15** (1.90 g, 8.26 mmol) in 60% yield. Metylation of **15** with methanesulfonyl chloride in dichloromethane (0°C) in the presence of 2,4,6-collidine gave 5-(*tert*-butyldimethylsilyloxy)-2-hexenyl methanesulfonate (**16**). Up to 50% formation of the unwanted allylic chloride side product occurred. Reaction of sulfonate **16** with heptynyllithium in the presence of CuI (0.1 equiv.) gave the *tert*-butyldimethylsilyl ether of (*E*)-4-tridecen-7-yn-2-ol (**17**). Removal of the protective group from **17**, hydrogenation, and acetylation (as described for **10** in Scheme 2) afforded after purification (*E*,*Z*)-4,7-tridecadien-2-yl acetate (**18**, 0.18 g, 7.56 mmol) in 9% yield based on **15**.

*(Z,Z)-4,8-Tridecadien-2-ol (**23**) (Scheme 4).* Benzyl ether **1** (4.35 g, 25 mmol) was coupled at −70°C via the lithium salt with 1-*O*-tetrahydropyranyl-3-bromopropanol (1.3 equiv.) [−70°C to room temperature, 24 hr, THF–HMPA (1:1)]. Subsequent removal of the THP group in methanol in the presence of trifluoroacetic acid afforded 7-benzyloxy-4-octyn-1-ol (**19**) (1.32 g, 5.71 mmol). Oxidation of alcohol **19** with PCC in dichloromethane at room temperature, and immediate coupling of the crude aldehyde **20** with *n*-pentylidene triphenylphosphorane in THF yielded the benzyl ether of (*Z*)-8-tridecen-4-yn-2-ol (**21**). Compound **21** partially purified by flash chromatograhy was hydrogenated (4 hr) with Lindlar catalyst in hexanes in the presence of quinoline, and the resulting diene-ether was

SCHEME 3. Synthesis of (*E*,*Z*)-4,7-tridecadien-2-yl acetate.



SCHEME 4. Synthesis of (*Z*,*Z*)-4,8-tridecadien-2-yl acetate.

treated with 10 equivalents of calcium in liq. ammonia for 45 min. Usual work-up and purification of the diunsaturated alcohol **22**, followed by overnight acetylation with acetic anhydride in pyridine, yielded (*Z*,*Z*)-4,8-tridecadien-2-yl acetate (**23**, 0.265 g, 1.10 mmol) in 4.5% yield based on **1**.

*(S)- and (R)-2-Tridecanyl Acetate (**29, 34**) (Scheme 5).* Hydrolytic kinetic resolution of racemic 1,2-epoxytridecane (**24**) (1.75 g, 8.80 mmol) with 25 mg of (*R*,*R*)-(−)-salen complex of Co(II) [Jacobsen's catalyst; (*R*,*R*)-(−)-N,N′-bis (3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexanediaminocobalt(II)] (**25**) (Sigma-Aldrich, Oakville, Ontario, Canada) and 90 μl of water (Tokunaga et al., 1997; Schaus et al., 1998; Gries et al., 2000) yielded after 3 d at room temperature (*R*)-1,2-epoxytridecane (**26**) (0.88 g, 4.44 mmol) which was separated from (*S*)-1,2-tridecanediol (**27**) by flash chromatography (hexanes–ether, 10:1). Ring opening of **26** with LAH in ether afforded (*S*)-2-tridecanol (**28**) (0.84 g, 4.24 mmol). Acetylation of **28** gave (*S*)-2-tridecanyl acetate (**29**) (Kamezawa et al., 1994, Sharma et al., 1996) in 47% overall yield and with an enantiomeric excess (ee) of 91.9%, as determined by GC analysis on a Cyclodex-B column. Corresponding hydrokinetic resolution of **24** with the (*S*,*S*)-(+)-salen complex of Co(II), and corresponding follow-up reactions (see above) afforded (*S*)-1,2-epoxytridecane, (*R*)-2-tridecanol, and finally (*R*)-2-tridecanyl acetate (47% overall yield, 91.3% ee).

2-Tridecenyl acetates with *E* and *Z* unsaturation at C-3 to C-12 were synthesized by oxidation (PCC in dichloromethane) of the dodecenols (available in our laboratory from previous studies) and by immediate reaction of the crude aldehydes

SCHEME 5. Synthesis of (*S*)-2-tridecanyl acetate.

with methylmagnesium bromide in ether followed by acetylation (Ac_2O/Py) of the resulting 2-tridecenols.

Absolute Configuration of Pheromone. The absolute configuration of the pheromone was determined in five steps: (1) acetyl lactate derivatization (Slessor et al., 1985) of racemic (*Z*,*Z*)-4,7-tridecadien-2-ol (**5** in Scheme 1); (2) separation of diasteromeric derivatives by HPLC (conditions described above); (3) removal of the acetyl lactate functionality and acetylation of the resulting enantiospecific alcohols; (4) GC-EAD analyses (Figure 3 below) and field testing (Figure 4 below) of (*Z*,*Z*)-4,7-tridecadien-(*S*)-2-yl acetate (2*S*-*Z*4*Z*7) and (*Z*,*Z*)-4,7-tridecadien-(*R*)-2-yl acetate (2*R*-*Z*4*Z*7); and (5) comparison of retention times (Cyclodex-B column) of the saturated equivalents of 2*S*-*Z*4*Z*7 [(*S*)-2-tridecanyl acetate] and 2*R*-*Z*4*Z*7 [(*R*)-2-tridecanyl acetate] with those of enantioselectively synthesized (*S*)- and (*R*)-2-tridecanyl acetate (Scheme 5).

Field Experiments. Field experiments were conducted in Nootka, Mount Newton, and Saanich Douglas-fir seed orchards, and the Douglas-fir seed orchard at the Saanichton Forestry Centre, all near Saanichton, Vancouver Island, British Columbia. Trees were 11–25 years old with spacings within and between rows ranging from 3.8×6.1 m to 4×10 m. At 15–20-m intervals, self-made sticky 2-l milk carton traps (Gray et al., 1984) were suspended from trees 1.5 m above ground in complete randomized blocks. Traps were baited with a gray sleeve stopper (The West Company, Lionville, Pennsylvania, USA) impregnated with test chemicals in HPLC-grade hexane. All test chemicals were >93% chemically and geometrically pure. Enantiomeric excess of 2*S*-*Z*4*Z*7 and 2*R*-*Z*4*Z*7 was 95.5% and 97.8%, respectively, based on GC analyses on a Cyclodex-B column.

Experiment 1 tested candidate pheromone *Z*4*Z*7 at doses of 1, 10, 100, and 1,000 μg. Experiments 2 and 3 tested *S* and *R* enantiomers of *Z*4*Z*7 singly and in combination at doses of 10 and 2 μg, respectively. Experiment 4 tested attractiveness of racemic *Z*4*Z*7 at 50 μg versus that of caged female *C. oregonensis*.

Despite transformation, trap catch data were not normally distributed and were, thus, analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Bonferroni (Dunn) t test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS AND DISCUSSION

Pheromone Analyses. Comparison of GC traces of abdominal tip extracts of male and female *C. oregonensis* failed to disclose sex-specific volatiles. Coupled GC-EAD analyses of female pheromone extract revealed a single EAD-active compound (**A** in Figure 2) that occurred below detection threshold of the flame ionization detector of the GC. Retention indices (RI) (Van den Dool and Kratz, 1963) of **A** (DB-5: 1605; DB-210: 1872; DB-23: 1932; SP-1000: 1927;

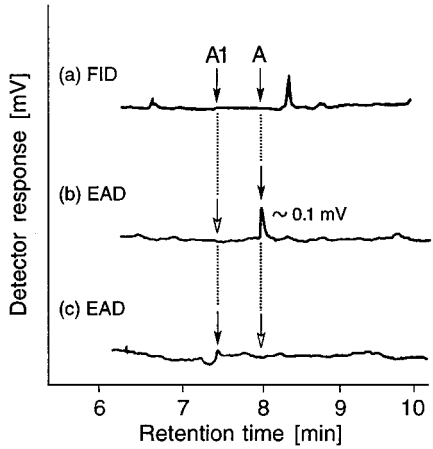


FIG. 2. Representative GC-EAD recording (8 replicates) of pheromone gland extract of female *C. oregonensis*; (**a**) flame ionization detector (FID) chromatograph of 10 female equivalents (10 FE) of pheromone gland extract; (**b, c**) corresponding recording of electroantennographic detector (EAD: male *C. oregonensis* antenna) responses to 10 FE of (**b**) untreated and (**c**) hydrogenated pheromone extract. Chromatography: Hewlett Packard 5890A gas chromatograph; splitless injection; injector temperature: 220°C; detector temperature: 250°C; DB-23 column; temperature program: 100°C (1 min) 10°C per min to 200°C. A = (*Z*,*Z*)-4,7-tridecadien-2-yl acetate; A1 = tridecan-2-yl acetate.

Cyclodex B: 1690), and RI intercolumn differentials, suggested that it had an ester (acetate) functionality. GC-EAD analysis of hydrogenated pheromone extract revealed a new EAD-active compound (**A1** in Figure 2), suggesting that hydrogenation of **A** had resulted in a saturated volatile (**A1**) with different chromatographic characteristics [RIs: 1631 (DB-5); 1890 (DB-210); 1879 (DB-23); and 1870 (SP-1000)]. Compound **A1** was determined to be 2-tridecanyl acetate [an aggregation pheromone component of *Drosophila mulleri* and *D. busckii* (Kamezawa et al. 1994)], which cochromatographed with **A1** on all above-referenced columns and had comparable EAD activity as **A1**. Similar chromatographic characteristics of **A** and **A1** suggested that the former was a tridecen-2-yl acetate. However, syntheses and chromatography of all possible tridecen-2-yl acetates determined that neither co-chromatographed with **A**, nor elicited antennal responses indicative of a potential double bond position.

Hypothesizing then that **A** was a nonconjugated tridecadien-2-yl acetate, candidate tridecadien-2-yl acetates were approximated (Gries et al., 1993) by (1) determining retention index differentials between tridecan-2-yl acetate and each of the tridecen-2-yl acetates (Table 1), and (2) adding these differentials to, or subtracting them from, the respective tridecen-2-yl acetate. For example, the RI 1604

[a] dbp = double bond position.

of (*E*,*E*)-4,8-tridecadien-2-yl acetate on DB-5 was predicted by subtracting the RI differential between tridecan-2-yl acetate and (*E*)-8-tridecen-2-yl acetate (=12; Table 1) from the RI of (*E*)-4-tridecen-2-yl acetate (1616 − 12 = 1604). Taking the data for all five columns into account, (*Z*,*Z*)-4,8-tridecadien-2-yl acetate (*Z*4*Z*8) was predicted to be the most probable diene acetate to match chromatographic characteristics of **A**. However, synthetic *Z*4*Z*8 (Scheme 4) had RIs 1-3 RI units different from those of the target **A** on all five columns.

Strong EAD activity of *Z*4*Z*8 suggested that its molecular structure was similar to that of the candidate pheromone **A**. An allylic double bond in C-3, instead of C-4, would have greatly decreased the RI of the molecule (RG + GG, unpublished data) and was discounted. Hypothesizing then that the geometry and position of the double bond in C-8 was incorrect, (*Z*,*Z*)-4,7-tridecadien-2-yl acetate (*Z*4*Z*7) was synthesized (Scheme 1) as an alternative structure for the candidate pheromone. This compound, but none of its three isomers (*ZE*, *EZ*, *EE*) (Schemes 1–3), cochromatographed with **A** on all columns, and elicited comparable antennal responses.

In GC-EAD analyses that separated the enantiomers of *Z*4*Z*7 with baseline resolution (Figure 3, a), antennal responses were obtained only to the early

eluting enantiomer in a racemic standard (Figure 3, b) or in pheromone extract (Figure 3, c). This enantiomer was determined to have the *S* configuration, because its hydrogenated equivalent had a retention time on Cyclodex-B that was identical with that of enantiospecifically synthesized (*S*)-2-tridecanyl acetate (**29**) (Scheme 5). (*R*)-2-Tridecanyl acetate, in contrast, eluted 0.35 min later. Lack of response to later eluting 2*R*-*Z*4*Z*7 could not be attributed to a refractory period of the antenna, because two sequential injections (at 0.5 min intervals) of isothermally chromatographed 2*S*-*Z*4*Z*7 elicited two very similar antennal responses (Figure 3, d). When 2*S*- and 2*R*-*Z*4*Z*7 were analyzed individually, only the *S* enantiomer was EAD-active, supporting contention that female *C. oregonensis* produce 2*S*-*Z*4*Z*7 for pheromonal attraction of mates.

Field Experiments. In experiment 1, a lure dose of 100 μg of racemic Z4Z7 was more effective than lower or higher lure doses in attracting male *C. oregonensis* (Figure 4, experiment 1), indicating that proper lure loadings are critical for optimal attractiveness. Captures of male *C. oregonensis* in traps baited with 2*S*-*Z*4*Z*7 (Figure 4, experiments 2 and 3) were consistent with EAD-activity only of the *S* enantiomer (Figure 3, b). The few males captured in traps baited with 2*R*-*Z*4*Z*7 (Figure 4, experiment 2) were probably attracted to trace amounts of the *S* enantiomer in the bait. The antipode 2*R*-*Z*4*Z*7 is not part of the *C. oregonensis* pheromone because it elicited neither EAD-activity (Figure 3, b) nor behavioral activity when tested alone at a low dose (Figure 4, experiment 3) or in combination with pheromonal 2*S*-Z4Z7 (Figure 4, experiments 2 and 3). Similar numbers of males captured in traps baited with synthetic *Z*4*Z*7 (50 μg) or virgin female *C. oregonensis* (Figure 4, experiment 4) indicate competitive attractiveness of natural and synthetic pheromone.

Pheromones in Cecidomyiids and Practical Implications. Evidence for female-produced sex pheromones has been reported for 10 cecidomyiids (reviewed by Harris and Foster, 1999) but only four pheromones have been identified. In pioneering studies, (*E*)-10-tridecen-(*S*)-2-yl acetate was determined to be a sex pheromone component of the Hessian fly, *Mayetiola destructor* (Foster et al., 1991; Harris and Foster, 1991; Millar et al., 1991). Attractiveness of this compound to male *M. destructor* in wind-tunnel but not field experiments suggested that female *M. destructor* deploy additional pheromone components that have not yet been identified (Harris and Foster, 1999). Meticulous work by Hillbur et al. (1999, 2000, 2001) deciphered the three-component pheromone of the pea midge, *Contarinia pisi*. Synthetic (2*S*,11*S*)-diacetoxytridecane, (2*S*,12*S*)-diacetoxytridecane, and 2-acetoxytridecane at a blend ratio as found in pheromone gland extracts attracted male *C. pisi* in both wind-tunnel and field experiments. Concurrent work by Gries et al. (2000) revealed the pheromone of the orange wheat blossom midge, *Sitodiplosis mosellana*, to be (2*S*,7*S*)-nonanediyl dibutyrate, which attracted male *S. mosellana* in field experiments in Saskatchewan. While *SR*, *RS*,

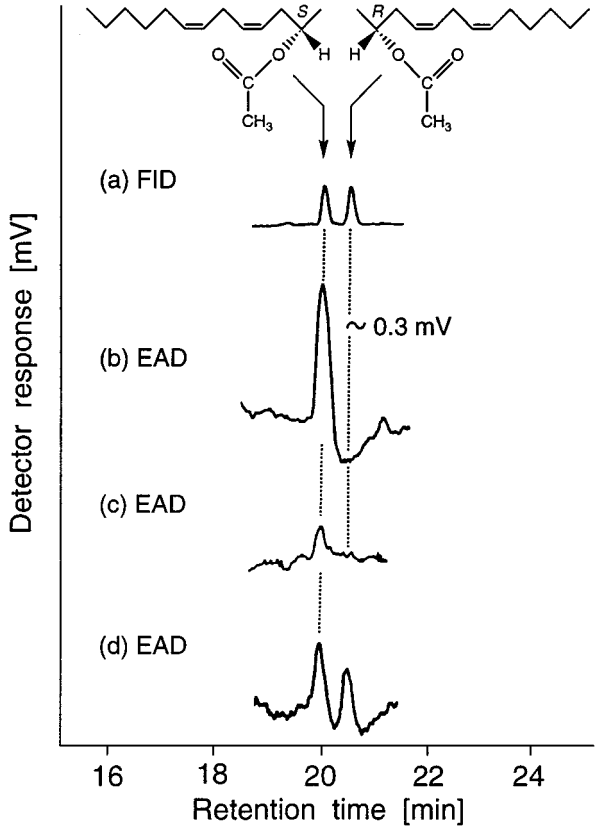

FIG. 3. Representative GC-EAD recording (5 replicates) of synthetic standards and pheromone gland extract of female *C. oregonensis*; (**a**) flame ionization detector (FID) chromatogram of synthetic (*Z*,*Z*)-4,7-tridecadien-2-yl acetate (*Z*4*Z*7) with baseline resolution of the enantiomers (*Z*,*Z*)-4,7-tridecadien-(*S*)-2-yl acetate (2*S*-*Z*4*Z*7; left) and (*Z*,*Z*)-4,7-tridecadien-(*R*)-2-yl acetate (2*R*-*Z*4*Z*7; right); (**b–d**) corresponding recordings of electroantennographic detector (EAD: male *C. oregonensis* antenna) responses to (**b**) synthetic *Z*4*Z*7, (**c**) 10 female equivalents of pheromone gland extract and (**d**) two sequential injections of 2*S*-*Z*4*Z*7. Note: first and second injection of 2*S*-*Z*4*Z*7 were separated by 0.5 min., equivalent to the 0.5 min separation of 2*S*-*Z*4*Z*7 and 2*R*-*Z*4*Z*7 in the racemic standard (**a**); lack of response to later eluting 2*R*-*Z*4*Z*7 (**b**) could not be attributed to a refractory period of the antenna, because two sequential injections (at 0.5-min intervals) of isothermally chromatographed 2*S*-*Z*4*Z*7 elicited two very similar antennal responses (**d**). Chromatography: Hewlett-Packard 5890A gas chromatograph equipped with a chiral Cyclodex-B column; temperature program: 150°C isothermal; split injection of 25 ng per compound with 0.5 ng reaching the EAD detector.

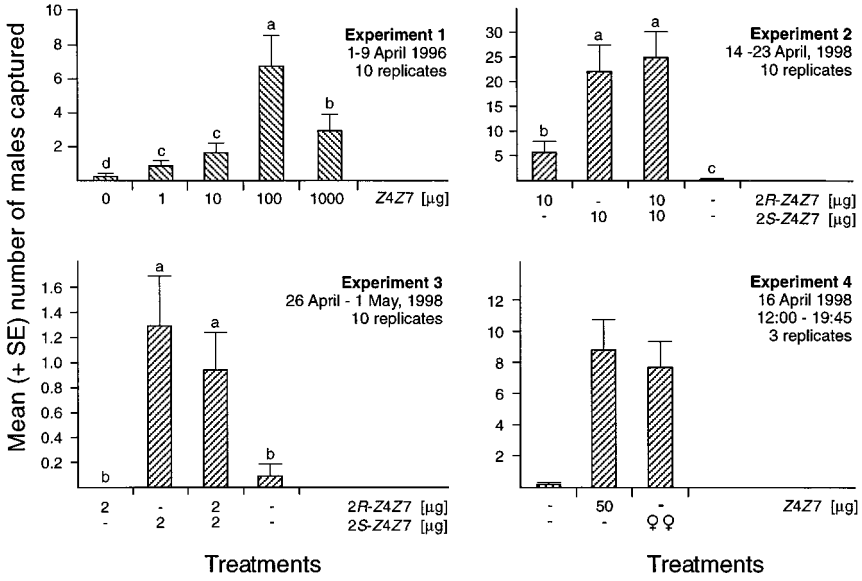

FIG. 4. Mean (+SE) number of male *C. oregonensis* captured during experimental periods in sticky Delta milk carton traps baited with various doses of racemic (*Z*,*Z*)-4,7-tridecadien-2-yl acetate (*Z*4*Z*7) (experiment 1), (*Z*,*Z*)-4,7-tridecadien-(*S*)-2-yl acetate (2*S*-*Z*4*Z*7), and (*Z*,*Z*)-4,7-tridecadien-(*R*)-2-yl acetate (2*R*-*Z*4*Z*7) singly and in combination (experiments 2, 3), or baited with racemic *Z*4*Z*7 or caged virgin female *C. oregonensis* (experiment 4). Douglas-fir seed orchards near Saanichton, Vancouver Island, British Columbia. Bars in each experiment with different letter superscripts are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means [Bonferroni (Dunn) *t* test, $P < 0.05$] (SAS/STAT, 1988).

and *RR* stereoisomers of the pheromone had no adverse effects on attraction of male *S. mosellana*, attraction of male *C. pisi* to the synthetic *C. pisi* pheromone blend (see above) was strongly inhibited by the presence (20%) of the 2*S*,11*R*- and 2*R*,11*S*-stereoisomers of diacetoxytridecane (Hillbur et al., 2001). Male *C. oregonensis*, in contrast, did not perceive the antipode of pheromonal 2*S*-*Z*4*Z*7 (Figure 3, b) and were not inhibited by it (Figure 4, experiments 2 and 3).

The identification of the *C. oregonensis* pheromone should lead to improved monitoring of *C. oregonensis* populations and management decisions in commercial seed orchards. In both 2000 and 2001, numbers of male *C. oregonensis* captured in pheromone-baited traps in seed orchards in Washington and Oregon were correlated with numbers of both egg-infested scales in conelets and damaged seed in cones (Morewood et al., 2002). Trap captures of male *C. oregonensis* are, thus, predictive of seed damage at harvest, and should help orchard managers decide whether insecticidal control of *C. oregonensis* populations is warranted.

Acknowledgments—We thank Dan Rudolph, Carolyn Lohr, Cathy Cook, and Tim Crowder for access to research sites; Dave Holden for technical assistance; Jocelyn Millar for provision of synthetic (*E*)-10-tridecen-2-yl acetate; Bob Birtch for graphical art work; Harold Pierce; Jr., for reviewing the manuscript; and two anonymous reviewers for constructive comments. The research was supported, in part, by grants from the Natural Sciences and Engineering Research Council of Canada and the Operational Tree Improvement Program of Forest Renewal British Columbia.

Abstract—Aliphatic secondary alcohols are components of several aggregation pheromones of important beetle and weevil pests. Some of these pheromones are used frequently for the monitoring and mass trapping of the relevant insects. We encountered severe difficulties in direct GC quantitative analysis of these compounds. Therefore, we developed a simple GC analysis of secondary alcohols converting them to trifluoroacetyl derivatives and using secondary alcohol acetates as internal standards. This method was applied for the quantitative analysis of several secondary alcohols, including the aggregation pheromone components of the almond bark beetle and the red palm weevil. The release rate of the latter pheromone from commercial lures was also determined.

Key Words—Aggregation pheromones, secondary alcohols, trifluoroacetyl derivatives, GC analysis.

INTRODUCTION

Several aliphatic secondary alcohols are common components of aggregation pheromones of weevils and beetles (Bartelt, 1999; Schlyter and Birgersson, 1999). The use of pheromone lures in pest management requires a quantitative determination of the content in order to measure the release rate of the pheromone and the longevity of the lures. Capillary GC analysis, with an internal standard, is the best

method for quantitation. However, peaks of secondary alcohols have a tendency to broaden and tail on different capillary columns, which makes their direct analysis difficult and inaccurate. The problem is particularly severe when analyses are performed repeatedly on the same column.

In this paper, we present a simple GC method of quantitation of secondary alcohols using their trifluoroacetyl derivatives and appropriate acetates as internal standards. The effect of the mode of injection on the analysis has also been studied. The following alcohols were analyzed: 4-methyl-5-nonanol, 4-methyl-3-heptanol, 4-methyl-3-hexanol, and 2-octanol. These alcohols (except 2-octanol) are pheromone components of two agricultural pest insects, the red palm weevil (*Rhynchophorus ferrugineus*) (Perez et al., 1996) and the almond bark beetle (*Scolytus amygdali*) (Ben-Yehuda et al., 2000), respectively.

METHODS AND MATERIALS

Chemicals. Mixtures of syn/anti 4-methyl-3-hexanol and 4-methyl-5-nonanol were prepared by Grignard reaction (Scheme 1) from 2-bromobutane and propionaldehyde and from 2-bromopentane and valeraldehyde, respectively, using magnesium turnings in THF (dried over Na + benzophenone). Distillation was carried out under reduced pressure (142°C/760 mmHg and 87°C/12 mmHg, respectively) to obtain the pure alcohols (97–100% by GC). The acetate derivatives were prepared from the corresponding alcohols and acetic anhydride in pyridine and purified by chromatography on SiO_2, using hexane and 1% ether as eluent. All other chemicals, including syn/anti (60:40) 4-methyl-3-heptanol, were purchased from Aldrich.

SCHEME 1.

Gas Chromatography. Analyses were performed on an HP6890 gas chromatograph equipped with an HP5 column (30 m × 0.25 mm ID; 0.25 μm), flame

ionization detector, and a split/splitless injector. Helium was used as the carrier gas with a flow rate of 1.5 ml/min. The analysis was performed in the split mode with a ratio of 10:1. The column was kept at 50°C for 3 min and then programmed at a rate of 20°C/min to 100°C for the analysis of 4-methyl-3-hexanol, 4-methyl-3-heptanol, and 2-octanol and kept at 60°C for 2 min, and then programmed at a rate of 20°C/min to 130°C for the analysis of 4-methyl-5-nonanol. The injector and detector were maintained at 220°C.

Procedure of Analyses. Solutions of 4-methyl-5-nonanol, 4-methyl-3-heptanol, 4-methyl-3-hexanol, and 2-octanol were prepared in hexane at a concentration of 1 mg/ml ($= 1\ \mu g/\mu l$). Representative aliquots of each solution (1, 5, 10, 50, 75, 100, 150, and 200 μl) were placed in a 4-ml vial containing 1 ml of hexane. Then, an appropriate amount of trifluoroacetic anhydride (50–100 μl) was added, and the vial was shaken thoroughly. The reaction mixture was shaken occasionally for 1 hr at room temperature and then cooled in an ice-bath. The derivatization was terminated by addition of 1 ml of 5% NH_4OH (aq) and 100 μl of a hexane solution containing 100 μg of the appropriate acetate derivative (stock solution of 1 mg/ml). Fifty micrograms of the acetates' internal standard was used for the small amounts of analyzed alcohols (1–10 μg). The mixture was shaken thoroughly, and the organic phase was separated with a pipet. Aliquots of approximately 2 μl of the organic phase were injected (three replicates) into the gas chromatograph. A representative analysis of 100 μg of 4-methyl-5-nonanol with 50, 75, and 100 μg of the corresponding acetate as internal standard was injected several times and gave the same results.

Application of the Method with Red Palm Weevil Pheromone Lures. Pheromone lures of the red palm weevil were purchased from ChemTica (Costa Rica). They contained 750 ± 5 mg pheromone of which 90% is 4-methyl-5-nonanol and 10% is 4-methyl-5-nonanone enclosed in a plastic bag with a membrane (Hallett et al., 1999). The lures were placed in weevil bucket traps in a date plantation in the Eden ranch, Jordan Valley. The traps also contained a mixture of plant material (molasses sugar and dates) in water and a bottle of ethyl acetate. Every 10 d, three lures were removed from the orchard and kept at 4°C until analyzed. The plastic bag containing the pheromone was cut into pieces and immersed in 20 ml of dichloromethane (CH_2Cl_2) to extract the pheromone. The samples were kept in an ultrasound bath for 30 min and left overnight at 4°C. The plastic material was not affected by the solvent. For GC analysis, samples were diluted by a factor of 100. Then, an aliquot of 100 μl was further diluted with 1 ml hexane and 50 μl of the appropriate acetate standard were added.

RESULTS AND DISCUSSION

It is well known that quantitative GC analysis of secondary alcohols is difficult and inaccurate due to peak broadening and tailing (Krupcik et al., 1975).

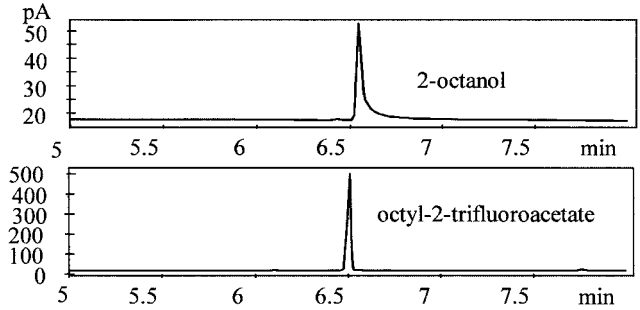

FIG. 1. GC profiles of 2-octanol versus octyl-2-trifluoroacetate. HP5 column was kept at 50°C for 3 min and then programmed at a rate of 20°/min to 100°C. Split ratio 10:1.

Despite the availability of improved capillary GC columns today, secondary alcohols display erratic behavior, particularly with aging columns. The columns are too expensive to be replaced after a short usage. Periodical weighing has been recommended as an alternative method in order to determine release rates of such pheromones from lures (Vickers et al., 1998; A.C. Oehschlager, personal communication). However, loss of weight is not specific to the loss of the pheromone alone. In addition, it gives erratic results due to absorption of dust and moisture. GC–FID analysis, with an appropriate internal standard, is the most accurate method, provided that peaks are sharp and the analysis is consistent.

During our work on mass trapping of the red palm weevil and the almond bark beetle with pheromone lures, we were in need of a reliable quantitative analysis of their respective main pheromone components, 4-methyl-5-nonanol and 4-methyl-3-heptanol. Direct GC analysis of the alcohol gave inaccurate results and, therefore, we looked for an alternative route and decided to use a derivatization method. We chose trifluoroacetylation because this derivatization of alcohols is easy to perform. It is quantitative and the formed trifluoroacetates can be readily analyzed by capillary GC-FID (Krupcik et al., 1994). Peaks are symmetrical and sharp (Figure 1). Therefore, sensitivity is higher as compared with the parent alcohols. The method has been employed for the analysis of alcohols and sugars (Krupcik et al., 1994; Hisatomi et al., 2000). However, as far as we know, trifluoroacetylation has not been used for quantitative analysis of secondary alcohols by GC. The FID response of the acetates and the trifluoroacetates is practically identical (GC-FID factor >0.98), and the latter always elute before their corresponding acetates (Representative example is in Scheme 2 and Figure 2).

4-methyl-3-heptyltrifluoroacetate (Analyte)

4-methyl-3-heptylacetate (Internal standard)

SCHEME 2.

The method was tested with various amounts of 4-methyl-3-hexanol, 4-methyl-3-heptanol, 2-octanol, and 4-methyl-5-nonanol in the range of 1–200 μg. Representative results of 4-methyl-3-heptanol and 4-methyl-5-nonanol, presented in Figures 3 and 4, indicate an excellent correlation (>99%) between the amount of secondary alcohol inserted and detected by the GC method. The use of the acetate of the same alcohol as the internal standard is not essential. For example, 4-methyl-3-hexanol and 2-octanol were analyzed with 4-methyl-3-heptylacetate as the internal standard, and the results were accurate. For better peak shape and resolution, we recommend performing the GC analysis in the split mode and programing the oven temperature so that both the analyte and the standard will be analyzed isothermally. The trifluoroacetylation reaction is quantitative, and no

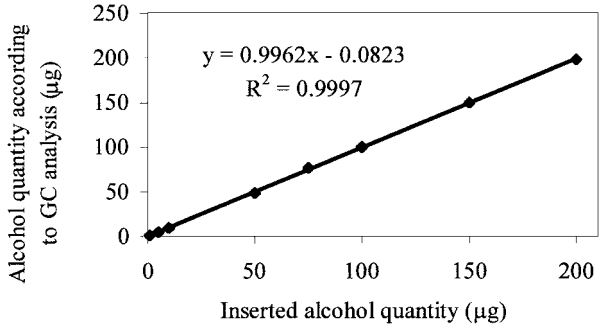

FIG. 3. GC quantitative analysis of 4-methyl-3-heptanol. Each point is the average of three anlyses.

residual alcohol was detected by GC in all cases. The use of varying amounts of alcohols or internal standard does not introduce any significant error, as shown by the excellent reproducibility.

The red palm weevil, *Rhynchophorus ferrugineus* (RPW), is a serious pest of dates. The major component of its aggregation pheromone is (*S*,*S*)-4-methyl-5-nonanol (Perez et al., 1996). Commercial lures, containing racemic syn/anti 4-methyl-5-nonanol, are being used in the Far and Middle East for mass trapping (Hallett et al., 1999; Vidyasagar et al., 2000). The determination of the release rate of the pheromone is essential in order to evaluate the longevity of the lures. Direct analysis of 4-methyl-5-nonanol produced erratic results. We applied our method

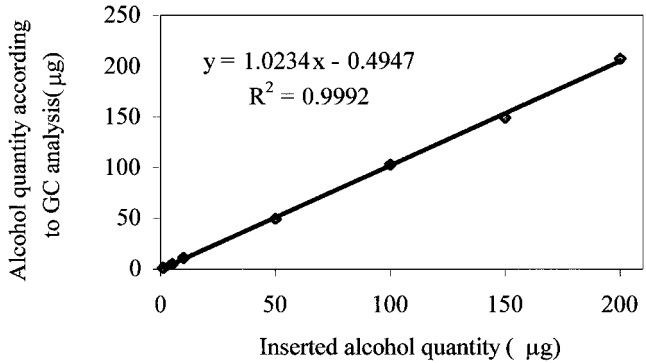

FIG. 4. GC quantitative analysis of 4-methyl-5-nonanol. Each point is the average of three anlyses.

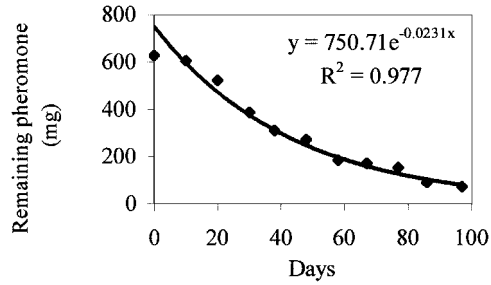

FIG. 5. Release rate of 4-methyl-5-nonanol from the ChemTica lures under field conditions.

and obtained consistent results. The behavior of the lure for the whole period can be represented by an exponential curve (Figure 5). However, the release rate of about 8 mg/day is linear for 58 days, and then the release rate decreases to 3–4 mg/day for another 40 days (Figures 5 and 6). This behavior corresponds with the manufacturer's specifications (release rate of 3–10 mg/day) and the temperature dependence of the release rate. The average temperatures in the plantation for the first period (0–58 d) of the field test was 23.5–36.6°C, and of the second one (58–98 d) was 17–29.8°C.

In conclusion, the quantitation of secondary alcohol aggregation pheromones is of practical importance and is not merely an analytical exercise. Several beetle and weevil pheromones containing such components are being used for mass trapping in Integrated Post Management programs. The method presented in this study will facilitate the evaluation of such lures and will enable the determination of their longevity and release rate profiles.

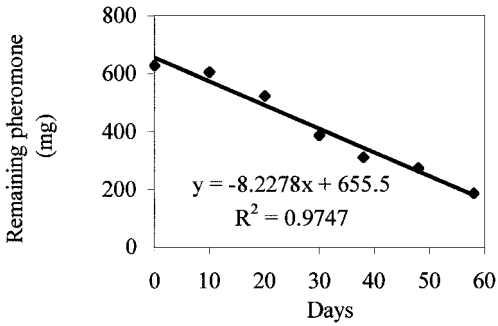

FIG. 6. Release rate of 4-methyl-5-nonanol from the ChemTica lures for the first period of 58 d of the field test.

(Received January 7, 2002, accepted July 9, 2002)

Abstract—Entomophagous insects are often repelled by the secondary compounds of the plants eaten by their prey. These compounds, therefore, take on a defensive role for the phytophagous species that sequester them. Given that numerous entomophagous species are capable of learning, the effects on the foraging behavior of a repeated experience were investigated in the predatory ant *Myrmica rubra*. The sulfur amino acids methyl-cysteine sulfoxide (MCSO) and propyl-cysteine sulfoxide (PCSO) produced by *Allium* plants were identified in caterpillars of the leek moth *Acrolepiopsis assectella*. Three behavioral studies were carried out, with or without prior familiarization with caterpillars reared either on leek or on an artificial diet containing no *Allium* compounds. In choice tests with the two types of caterpillars, unfamiliarized ants displayed a preference for caterpillars reared on the artificial diet, but this preference disappeared or was reversed in both young and old ants after familiarization.

Key Words—Foraging experience, predation, ants, leek moth, prey selection, learning, *Allium*, sulfur compounds, habituation.

INTRODUCTION

Plant secondary compounds found in varying quantities in prey often lead to rejection by generalist predators. The secondary compounds, thus, have a protective role for specialist phytophagous insects (Bernays, 1989; Bernays and Cornelius, 1989; Dyer, 1995). Among the factors that can modulate this defense phenomenon are the secondary compound concentration in the plant (Bjorkman and Larsson,

* To whom correspondence should be addressed. E-mail: thibout@univ-tours.fr

0098-0331/02/1100-2307/0 © 2002 Plenum Publishing Corporation

1991; Hare and Eisner, 1993), the morphology of the prey (Dyer, 1995) and its defensive behavior (Bernays and Cornelius, 1989; Bjorkman and Larsson, 1991), the abundance of predators and their ability to locate the prey (Camara, 1997), or experience and learning.

The involvement of experience acquired by the predator during foraging, and observed in the bug *Podisus maculiventris* (Traugott and Stamp, 1996), has frequently been studied in ants (Dejean, 1988; Dejean et al., 1990; Fourcassié and Traniello, 1993; Hare and Eisner, 1993; Schumann and Buschinger, 1994; Dyer and Bowers, 1996). Similarly, learning seems to play a role in the predatory behavior of ants that are offered caterpillars of the leek moth, *Acrolepiopsis assectella* (Lepidoptera: Yponomeutoidea), a specialist phytophagous species of *Allium* plants (Nowbahari and Thibout, 1992). Caterpillars of the leek moth feed on the leek, *Allium porrum*, a plant that produces nonprotein sulfur amino acids, S-alk(en)yl-cysteine sulfoxides (Boscher et al., 1995) that are precursors of sulfur volatiles (Férary et al., 1998). These caterpillars are attacked markedly less often by *Formica selysi* and *Formica fusca* than those fed on an artificial diet with either little or none of these compounds (Nowbahari and Thibout, 1992).

This work addresses the following questions: Do leek moth caterpillars sequester sulfur compounds? Is it possible to generalize the dietary preference to other ant species? Can the consumption of novel or repellent prey occur as a result of familiarization during the life cycle of the predator?

METHODS AND MATERIALS

The Phytophagous Insect. The caterpillars came from two rearings. The first was carried out on the host plant, the leek (CL: caterpillars on leek), under the following conditions: 16L:8D, synchronous temperature 25°C:18°C, and 70% ± 10% relative humidity. This strain was renewed each year by caterpillars collected in leek fields around Tours, France. The second rearing was maintained for several years in the laboratory on an artificial diet containing 10% of freeze-dried leek leaf powder (Arnault, 1979), on 12L:12D, constant temperature 25°C and 70% ± 10% relative humidity. Eggs were taken from this rearing, and neonatal caterpillars were reared on an artificial diet containing neither leek powder nor leek in order to obtain caterpillars that had had no contact with leek compounds (CD: caterpillars on diet). The CL and CD used at the fifth instar, after sexual differentiation, were killed by freezing at −18°C in order to avoid escape and defensive behavior, before being introduced into the experimental device.

The Predator. The red ant *Myrmica rubra* (Hymenoptera: Formicidae), which has the ability to learn (Le Roux et al., 1997), is common in the Touraine region of France and is an omnivorous polygynous species that builds colonies of several thousand workers (Elmes and Keller, 1993). It lives in open environments such

as prairies, gardens, and fairly damp wastelands and can be a predator of the leek moth. Every year, colonies were taken from the Loire riverbanks near Montlouis at the beginning of September. They were split into several groups (15–30 workers) and maintained at 12L:12D and 24°C. Each group was isolated in a nest consisting of a 15-cm-long × 1.5-cm-diam glass tube in a sleeve of black paper with a water holder at one end. The other end of the nest opened into a hunting area formed by a 5-cm-high × 8-cm-diam. cylindrical box. Twice a week, the ants received half a larva of *Tenebrio molitor* and a drop of honey in the hunting area. During the experiments, *T. molitor* and honey were replaced by two leek moth caterpillars 2 cm away from the junction between the tube and the collecting area, and 1 cm apart.

Analysis of Sulfur Amino Acid Content of Caterpillars. The two major sulfur amino acids produced by *A. porrum* are methyl-cysteine sulfoxide (MCSO) and propyl-cysteine sulfoxide (PCSO) (Freeman and Whenham, 1975). PCSO has been shown to be a repellent for formicines (Nowbahari and Thibout, 1992). The amounts of these compounds were measured in the preimaginal stages of the leek moth. Two CD taken from the diet, 2 CL taken from the leek, 2 CL starved for 5 hr, 2 chrysalids from CL, 40 exuviae from CL, and finally a 10-mg piece of green leek leaf (weight of a caterpillar is approx. 10 mg, of a chrysalis approx. 7 mg, and of an exuvia approx. 0.05 mg) were crushed in methanol. They were centrifuged for 30 min at −4°C at 6000 rpm, and the supernatant was retained. The residue obtained after evaporation of the methanol was diluted in trichloracetic acid at 6% in order to precipitate the proteins and to eliminate them by centrifugation. Amino acids were determined using derivatization coupled with reverse-phase HPLC. The Waters Pico-Tag method (Bidlingmeyer et al., 1984) used phenylisothiocyanate as a derivatization reagent (Auger et al., 1993). The HPLC system used was a Waters chromatograph consisting of a two-pump delivery system and a UV detector with a wavelength fixed at 254 nm. The column was a Waters Novapack C18 (3.9 × 300 mm). The solvent system consisted of two Waters eluents. The addition of controlled quantities of alkyl-cysteine sulfoxides synthesized in the laboratory (Auger and Thibout, 1981) allowed a quantitative study to be carried out by comparing retention time and peak areas. These operations were repeated at least 4 times (Table 1).

Experiments. All experiments were carried out under choice conditions in the ant-rearing room. An experiment began when 1 CL and 1 CD, or 2 CL, were simultaneously placed in the hunting area. A full choice test comprised five consecutive presentations of two caterpillars at 2-d intervals (D1, D3, D5, D7, and D9). Twenty-four hours after introduction, the number of caterpillars of each category taken into the nest was recorded, and their state of consumption was noted as follows: not consumed, partially consumed, or totally consumed.

Preliminary Behavioral Experiment. The ability to distinguish easily between males and females (visible testicles in the male caterpillar) was used as

TABLE 1. CONCENTRATIONS OF SULFUR AMINO ACIDS OF DIVERSE LEEK MOTH INSTARS FROM TWO REARINGS[a]

Instar	*N*	MCSO	PCSO
CD	4	0	0
CL	6	0.9 (0.3–2.7)	3.7 (0.7–5.6)
CL St.	5	t	2.1 (0.8–6.8)
NL	8	0.1 (0–1)	0.9 (0–2.0)
EL	5	7.2 (0-35.8)	62.9 (10.3–137.5)
LL	4	1.5 (0-5.9)	39.1 (13.3–70.7)

[a] Leek leaves are used as control. Values are mean (range). CD: fifth instar caterpillars reared on diet without leek; CL: fifth instar caterpillars reared on leek; CL St.: CL starved for five hour; NL: nymphs (chrysalid) from leek rearing; EL: exuviae from leek rearing; LL: Leek leaves; t: traces; *N*: number of repetitions.

a method of avoiding confusion between CL and CD, i.e., by alternately placing the CL of one sex with the CD of the other sex. In addition, the right–left placing of the caterpillars was also alternated in order to eliminate a potential effect of environmental dissymmetry. Ten groups of 30 workers were tested with some CL in order to check that *M. rubra* behaved in the same way towards males and females.

Behavior of Ants. A first experiment allowed 10 groups of 30 workers that had never been placed previously with leek moth caterpillars (unfamiliarized) to choose between CL and CD. Moreover, ten groups of 15 young workers were fed for 30 days on 2 CL every 2 d (young familiarized). A choice test was then carried out between CL and CD. Subsequent to the behavioral modifications observed after familiarization in young workers, a comparable experiment was done using old workers collected during the previous year and kept in the laboratory for 6 months. Thirty days before the choice test, the 10 groups of 20 old workers (old familiarized) were fed every 2 d with 2 CL in the same way as the young workers. The number of caterpillars taken back to the nest and their state of consumption were noted. The data were compared using a χ^2 contingency test.

RESULTS

Amount of Sulfur Amino Acids in Caterpillars. The sulfur amino acids MCSO and PCSO synthesized by the leek were not detected in the CD (Table 1). The two compounds were generally found in the preimaginal stages of CL. The CL only just taken from the leek were richer in sulfur amino acids than those starved for several hours. The chrysalids arising from rearing on leek were low in sulfur amino acids, whereas the corresponding exuviae were rich. The concentrations of sulfur amino acids measured in the leek moth do not reflect exactly the concentrations

in the hostplant (Table 1). MCSO and PCSO were found in lower quantities in the phytophagous insect than in the green leek leaves, with the exception of the exuviae.

Preliminary Behavioral Experiment. The preliminary experiment concerning choice between male and female caterpillars by unfamiliarized workers showed no significant difference between the two sexes. The numbers of males and females consumed in 24 hr were not statistically different (28% vs. 26% not consumed, 22% vs. 34% partially consumed, and 50% vs. 40% totally consumed; $\chi^2 = 2.229$, $P = 0.32$). It was, thus, possible to use sexual dimorphism as a marker of the origin of *A. assectella* caterpillars.

Behavior of Workers. When the unfamiliarized ants had the choice between a CL and a CD, the number of CD totally or partially consumed was greater than that of the CL (Table 2). After early dietary familiarization with CL, the young (1-month-old) workers showed no preference for either caterpillar category (Table 2). However, in 6- to 8-month-old workers, dietary familiarization with CL led to a tendency to prefer the CL (Table 2).

DISCUSSION

The concentrations of MCSO and PCSO in the caterpillars of the leek moth were generally lower than in the plant and showed a high variability, as indicated by the minimal and maximal values. This variability could come from the hostplant itself, as, the *Allium* genus displays large variations in the concentrations of these compounds, depending on the season, the variety, the organ, or the amount of sulfur in the soil, (Lancaster et al., 1984). While the concentration of these amino acids in the phytophagous insect depends on the plant, it is not an exact reflection of this. The caterpillar contains more PCSO than MCSO, although both are particularly abundant in the cuticle since the exuviae are rich in them, whereas the chrysalids contain little. This agrees with the results obtained in

certain Lepidoptera specialized on plants producing alkaloids in which the cuticle contains the majority of the alkaloids present in the caterpillars (Montllor et al., 1991). Moreover, a high quantity of the sulfur compounds found in the caterpillar must come via the digestive tract. The reduction in these compounds in starved caterpillars in comparison to those that have fed, probably comes from the presence of leek particles in the digestive tract. The accumulation of sulfur amino acids in the caterpillars of the leek moth makes plausible the previous hypothesis on the role of alkyl-cysteine sulfoxides of *Allium* in the protection of *A. assectella* against *Formica* ants (Nowbahari and Thibout, 1992). This role is confirmed in our choice tests, as the unfamiliarized *M. rubra* workers preferred the CD that had never been in contact with the leek.

After repeated encounters with the CL avoided prey, *M. rubra* workers chose their prey differently from unfamiliarized workers. They equally attacked the two categories of caterpillar and, in the case of the old workers, preferred the previously avoided caterpillars to those with which they had been familiarized, i.e., the CL. This adaptation phenomenon is not limited to any particularly sensitive period in young adults, as it is also found in old workers. Moreover it cannot be an imprinting process as has been observed several times in ants (Jaisson, 1975, 1980; Beckers et al., 1994; Schumann and Buschinger, 1994). It is more of a habituation process, which gradually leads to the disappearance and possibly to the inversion of the initial response of the unfamiliarized workers.

Based on the results obtained here, it would be interesting to study the behavior of the ants when they came into contact with the cuticle or the gut of the caterpillars that are rich in sulfur compounds.

Acknowledgments—The authors thank, in particular, J.M. Amé and N. Mandon, and also M. Bodin, S. Lepiffe, S. Lhuilier, M. Martaresche, and L. Servain for their help during the experiments. They are also grateful to Pr. A. Lenoir for comments on the manuscript and to Dr. A. Hefetz for English revision.

TASTE THRESHOLDS AND SUPRATHRESHOLD RESPONSES TO TANNIN-RICH PLANT EXTRACTS AND QUININE IN A PRIMATE SPECIES (*Microcebus murinus*)

(Received March 7, 2002; accepted June 14, 2002)

Abstract—Theories of plant chemical defenses discriminate between quantitative digestibility reducers (e.g., tannins) and qualitative toxins (e.g., alkaloids). Since the differential effect on taste of these compounds is poorly known, we recorded ingestive responses of a primate species, *Microcebus murinus*, to four tannin-rich plant extracts and to quinine, by using the behavioral method of the "two-bottle test." The efficiency of tannic extracts at precipitating protein was measured with the blue BSA method. Inhibition taste thresholds for tannins added to a moderately sweet solution varied between 0.25 and 2 g/l. The threshold for quinine hydrochloride was 0.32 g/l. The profiles of the response/concentration curves established for these astringent and bitter substances were similar, with maximal inhibition of consumption occurring for near-threshold concentrations. The large amounts of quinine required to deter this small-bodied species from feeding were unexpected, given its unspecialized frugivorous/insectivorous diet. We propose that the taste responses of *Microcebus* to tannins have been shaped in relation to the widespread occurrence of efficient polyphenols in food plants, while low responsiveness to quinine reflects a low risk of ingesting toxic alkaloids when feeding on ripe fruits and insects.

Key Words—Tannins, alkaloids, primate, taste, feeding deterrent, diet flexibility.

INTRODUCTION

Plant defense theories hold that plants evolved allelochemicals to protect themselves against consumers (Fraenkel, 1959), with different compounds adapted to different types of herbivores (Feeny, 1976) or were determined by endogenous

factors and nutrient availability (Coley et al., 1985). Although comparative studies in the field of chemical ecology suggest that primate species vary in their tolerance of tannins (e.g., Ganzhorn, 1988; Barton et al., 1993; Wrangham et al., 1998), the efficiency of polyphenols as deterrent substances to primates, remains debated (e.g., Maisels et al., 1994).

There are currently few experimental studies that have assessed whether tannins are rejected, tolerated, or even preferred by primates. To date, tannic acid, a hydrolyzable tannin, has been used as the prototypical stimulus of the astringent taste quality in electrophysiological and behavioral experiments. This polyphenol has a depressing effect on food intake of primates (Simmen, 1994; Simmen et al., 1999b; Iaconelli and Simmen, 1999; Laska, 2000). In contrast, reponses to bitter substances have been determined in many species, and reflect a wide distribution of sensitivities toward these distasteful compounds (for a reviews, see Glaser, 1986; Simmen and Hladik, 1998). Referring to the theories of plant chemical protection, one may wonder whether tannins, which are considered quantitative chemical defenses given their dose-dependent inhibitory activity on protein digestibility, and alkaloids, which are efficient at low concentration, elicit different tastes and are perceived at distinct gustatory thresholds.

The very existence of a taste quality elicited by tannins has been, and still is, disputed by many authors who consider the tactile dimension as the main sensory effect, namely the sensation of dryness in the mouth involving the precipitation of salivary proteins and stimulation of the mechanoreceptors of the tongue (McManus et al., 1981). However, the recording of pulses of the chorda tympani (one peripheral taste nerve), with a very short latency, in response to various tannins—while no responses could be observed in the lingual nerve—strongly suggested that the perception of these substances is multimodal and includes a taste component (Schiffman et al., 1992). In primates, the recording of chorda tympani whole nerve responses (*Microcebus murinus*) and of single fiber responses (*Callithrix jachus*) confirmed neuronal gustatory activity in the presence of tannic acid and indicated that the taste fibers responding preferentially to quinine and other substances tasting bitter to human were also those that responded best to the tannic substances (Hellekant et al., 1993b; Danilova et al., 1998).

In this study, we tested whether the taste threshold and suprathreshold responses obtained previously with tannic acid in a frugivorous/insectivorous species, the lesser mouse lemur *Microcebus murinus* (Simmen et al., 1999b), could be similar in other hydrolyzable tannins and condensed tannins, and, more generally, whether or not ingestive responses differed between polyphenols and alkaloids. The behavioral method of the "two-bottle test" was used, as it proved to yield thresholds comparable to those determined from electrophysiological recordings of the activity of the chorda tympani of *Microcebus murinus* (Simmen and Hladik, 1988; Hellekant et al., 1993a). Bearing in mind the likely interaction between tactile and taste sensations when recording ingestive responses to tannic solutions, we

use the term "astringent taste" as a descriptor of the global oral perception elicited by tannins.

METHODS AND MATERIALS

Rearing Conditions. Behavioral and physiological activities of *Microcebus murinus* are synchronized by daylength variations. In captivity, the breeding season occurs during the phase of long daylength (>12 hr), during which animals are very active, whereas complete gonadal regression, fattening, reduced behavioral activities, and lethargic state occur during the phase of short daylength (<12 hr). To ensure highly synchronized changes in biological activities among individuals over a complete cycle (Perret and Schilling, 1987), animals are routinely exposed to an artificial light cycle consisting of a 3-month period of short days (10L:14D) and a 5-month period of long days (14L:10D).

Experiments started 4 wk following the change between short daylength and long daylength, and they extended over the phase of long daylength. Subjects were sexually mature *Microcebus murinus* males, housed in separate cages (160 cm long × 75 cm wide × 250 cm high) and maintained under constant temperature (25°C) and relative humidity (55%). To reduce the time of isolation of individuals and to avoid impeding the breeding program necessary to the turnover of this primate colony, two distinct test groups were used in experiments. One group consisted of 14 animals tested with tannins, and another group included 9 animals tested with quinine.

Test Procedure and Statistical Analysis. The two-bottle test was used to determine the taste thresholds and suprathreshold responses to four tannin-rich plant extracts and one alkaloid in successive series of tests. The test procedure, derived from that of Glaser (1986), has been described in Simmen et al. (1999b) and is as follows: animals were provided with two feeding bottles, one containing 100 mM fructose solution, and the other containing the same sugar solution mixed with the deterrent substance. The concentration of the deterrent substance was varied at random in each test. Solutions were left at the beginning of the night phase, and the amounts of liquid consumed were recorded 1 hr later. The position of the bottles was determined at random to avoid side-preference effects. Tests were performed before animals were fed their daily meal of fruit, insects, cereal, milk, and fresh water. Before starting experiments with tannins and quinine, animals were provided simultaneously with tap water and a sugar solution at 100, 200, or 300 mM. Habituation to the two-bottle test was considered achieved when a marked preference for the sweet solution was recorded over four successive trials.

The threshold was defined as the lowest concentration of tannin or alkaloid for which the mean difference of consumption between the mixture and the pure fructose solution was significant ($P < 0.05$ with a paired-sample t test). Fructose was used rather than tap water because the volumes of water ingested by an

animal weighing less than 100 g are not reliable measures during short tests. The concentration of the fructose solution at 100 mM was chosen according to the response–concentration curve previously determined for this species: this concentration corresponds to twice the threshold for this sugar and exerts a slight attraction to animals (Simmen et al., 1999b).

The mean percentages of inhibition of the consumption of the mixtures were calculated and plotted against suprathreshold concentrations of tannins and quinine. According to previous investigations of the ingestive responses of *Microcebus* (and another mammal species) to tannic acid mixed with fructose (Simmen et al., 1999b; Iaconelli and Simmen, 1999), the use of a curvilinear regression model (Monod's model) proved to fit the patterns of inhibition with good consistency. Hyperbolic profiles were also obtained in the present study, and we applied this model to compare parameters of rejection among tannins and quinine. The theoretical equation is $y = (ax)/(b + x)$, in which a is the height of the asymptote tending toward 100% inhibition, and b is the concentration corresponding to $a/2$. The use of this model requires a translation of the data along the x-axis to comply with the condition $y = 0$ when $x = 0$. Indeed, the lack of inhibition ($y = 0$) is invariably observed for non-null concentrations. The highest concentration for which there is no inhibitory effect (that is, just below the statistical threshold) was subtracted from each concentration, and negative values were excluded before running the STATITCF program.

Compounds Tested. The fructose concentration at 100 mM (Sigma) in the binary solution and in the alternative feeding bottle (both 10 ml) yielded a caloric value of 0.675 kcal.

The substances tested were quinine hydrochloride (Prolabo) and tannin-rich extracts (powders) from oak bark, chestnut bark, and gallnut (Oenofrance). Together with these hydrolyzable tannins, crude quebracho tannin (provided by A. E. Hagerman) was also tested as a representative of condensed tannins. Different ranges of concentrations were used according to the compound tested: between 0.5 and 10 g/l for oak tannin, gallnut tannin, and quebracho tannin, between 0.05 and 10 g/l for chestnut tannin, and between 0.04 and 1.59 g/l (or 0.1 and 4 mM) for quinine hydrochloride.

Purified tannins other than tannic acid are not commercially available. The tannin powders tested clearly elicit an astringent taste and are used by food companies as taste exhausters for human foods and beverages. In our samples, the degree of purity was 75% in oak tannin, 81% in chestnut and quebracho tannins, and 96% in gallnut tannin. Since a rigorous analysis of taste perception of tannins must await further standardization of purification methods, we performed the blue BSA (bovine serum albumin) method of Asquith and Butler (1985) to compare the efficiency of extracts at precipitating protein. Solutions of 0.5 and 0.25 mg/ml of powders dissolved in diluted methanol served as substrates for precipitating 4 mg of BSA (Sigma; ref. A6003).

TABLE 1. MONOD'S PARAMETERS DESCRIBING INHIBITION OF CONSUMPTION OF MIXTURES AS A FUNCTION OF INCREASING CONCENTRATIONS OF DETERRENT SUBSTANCES

Mixture including	x' (g/l)	a (%)	95% confidence limits of a	b (g/l)	95% confidence limits of b	r^2
Chestnut tannin	0.125	82.3	[75–90]	0.18	[0.13–0.24]	0.99
Gallnut tannin	1.0	88.9	[71–100]	1.22	[0.91–1.53]	0.99
Oak tannin	1.0	82.5	[77–87]	1.22	[0.96–1.39]	0.99
Quebracho tannin	1.5	78.8	[71–86]	1.58	[1.43–1.73]	0.99
Quinine hydrochloride	0.278	81.7	[70–100]	0.279	[0.266–0.302]	0.99

[a] x': observed highest concentration for which no inhibition is observed; a: maximal inhibition; b: concentration of the deterrent substance corresponding to $a/2$, adjusted to x' (see Methods and Materials).

RESULTS

Tannins and quinine were clearly aversive to lesser mouse lemurs. As shown in Figure 1, the inhibition threshold was 0.25 g/l for chestnut tannin ($t = 3.99$, $N = 14$, $P < 0.001$), 1.5 g/l for gallnut tannin ($t = 3.72$, $N = 14$, $P < 0.001$), and 2 g/l for oak tannin and quebracho tannin (respectively, $t = 3.09$, $N = 14$, $P < 0.001$, and $t = 3.99$, $N = 14$, $P < 0.001$). The taste threshold for quinine hydrochloride was 0.32 g/l (or 0.80 mM; $t = 3.97$, $N = 9$, $P < 0.05$). The relative efficiencies of tannin extracts at precipitating bovine serum albumin were as follows: chestnut (1.82 mg/mg, on average, of BSA precipitated) > gallnut (1.52 mg/mg) > quebracho # oak (1.20 and 1.27 mg/mg). The thresholds for tannins tended to correlate negatively with protein precipitation efficiency, i.e., the stronger the precipitation properties, the lower the threshold (i. e. the higher the sensitivity; $r^2 = 0.946$; $P < 0.03$; $N = 4$).

The profiles of suprathreshold responses to increasing concentrations of quinine and tannins are expressed in Figure 2. The various compounds elicited similar profiles of inhibition of the ingestion of mixtures. The parameters of Monod's equation describing these profiles are summarized in Table 1. The correlation coefficients of the nonlinear regressions were high ($P < 0.01$), validating the use of an hyperbolic model. Maximal inhibition (a) was about 80% in all compounds—total inhibition is never observed because the choice procedure requires that animals lick both solutions. The concentration b, corresponding to $a/2$, varied between compounds and mirrored differences between thresholds, the lowest being for chestnut tannin and quinine hydrochloride.

The inhibition potency of the substances can be assessed by examining, in each case, to what extent b deviates from the threshold (relative index of tolerance). By definition, threshold concentrations determined statistically lay on a difference of consumption that, in our case, exceeded 50% (i.e., above $a/2$). Accordingly,

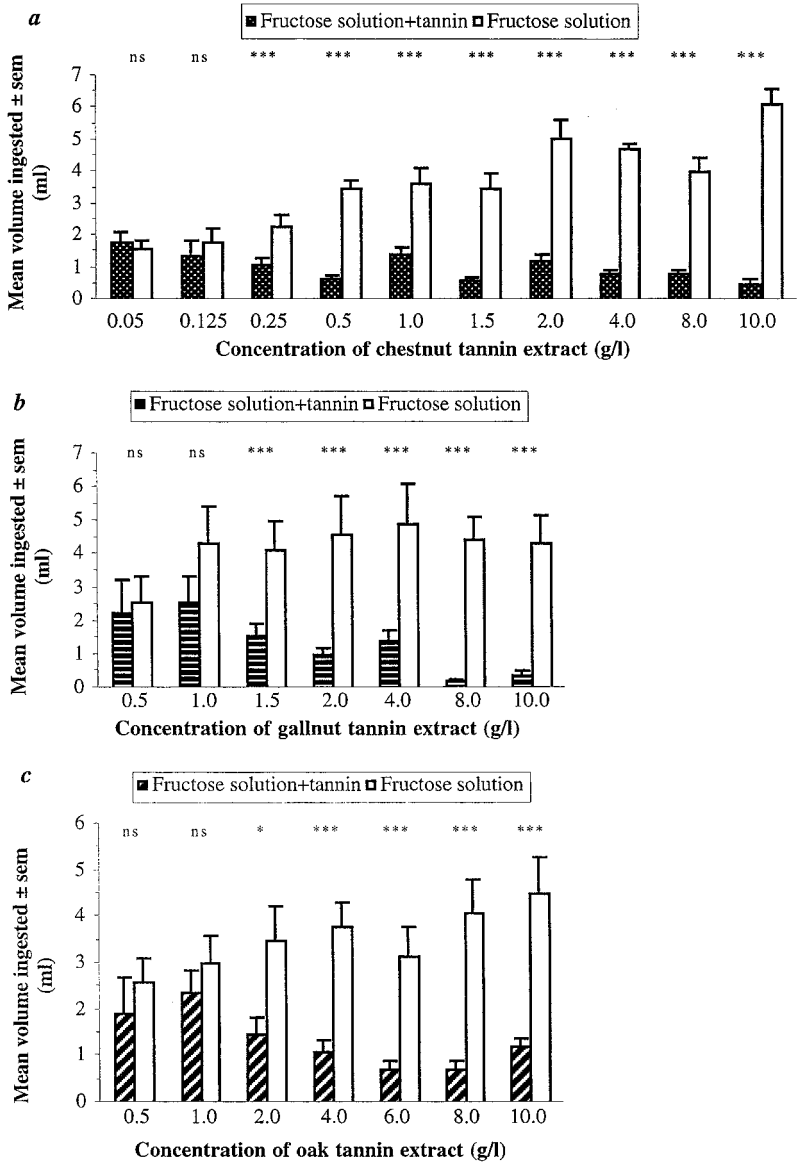

FIG. 1. Taste thresholds for tannin extracts and quinine. *a*: chestnut tannin, *b*: gallnut tannin, *c*: oak tannin, *d*: quebracho tannin, *e*: quinine hydrochloride. The threshold is defined as the lowest tannin or quinine concentration mixed with a fructose solution (100 mM) for which the mean difference of consumption between the mixture and the pure fructose solution is significant ($P < 0.05$ or lower in a paired-sample t test). The number of individuals tested at each concentration is 14 with tannins and 9 with quinine. ns: not significant, $^{*}P < 0.05$, $^{***}P < 0.001$.

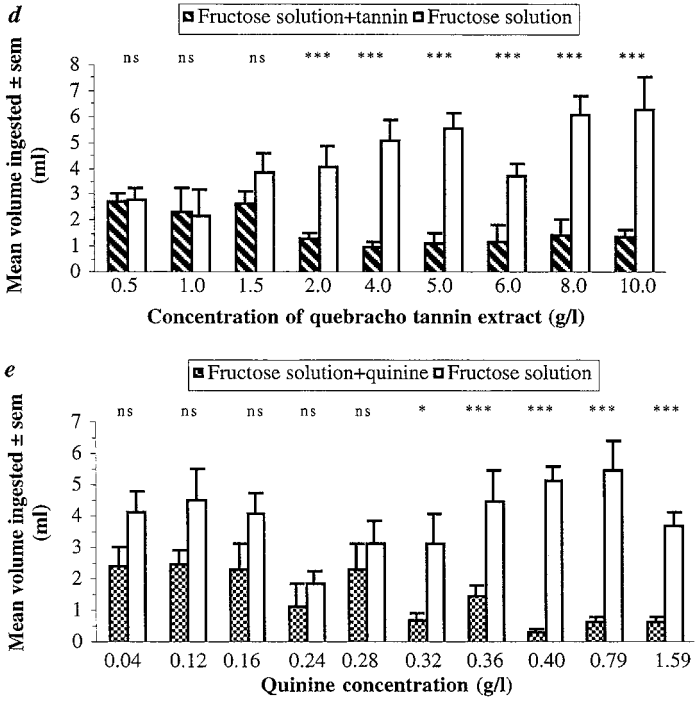

FIG. 1. Continued.

the ratio b/x', where x' is the concentration immediately below the statistical threshold, was calculated instead. This index was close to 1 for every compound tested (1.22:1 for oak and gallnut tannin; 0.18:0.125 for chestnut tannin; 1.58:1.5 for quebracho tannin; 0.279:0.278 for quinine hydrochloride), reflecting a strong rejection of the mixtures for near-threshold concentrations.

DISCUSSION

In a previous experiment on *Microcebus murinus*, we showed that the taste threshold for tannic acid mixed with sugar during the phase of long daylength (0.56 g/L) was close to the "electrophysiological" threshold (0.36 g/L) determined from responses of the chorda tympani proper nerve to pure solutions of tannic acid (Hellekant et al., 1993b; Iaconelli and Simmen, 1999). One may expect that threshold values presented here for other astringent substances (between 0.25 and 2 g/L) and determined during the phase of long daylength, probably closely reflect the minimal peripheral taste sensitivity toward these compounds.

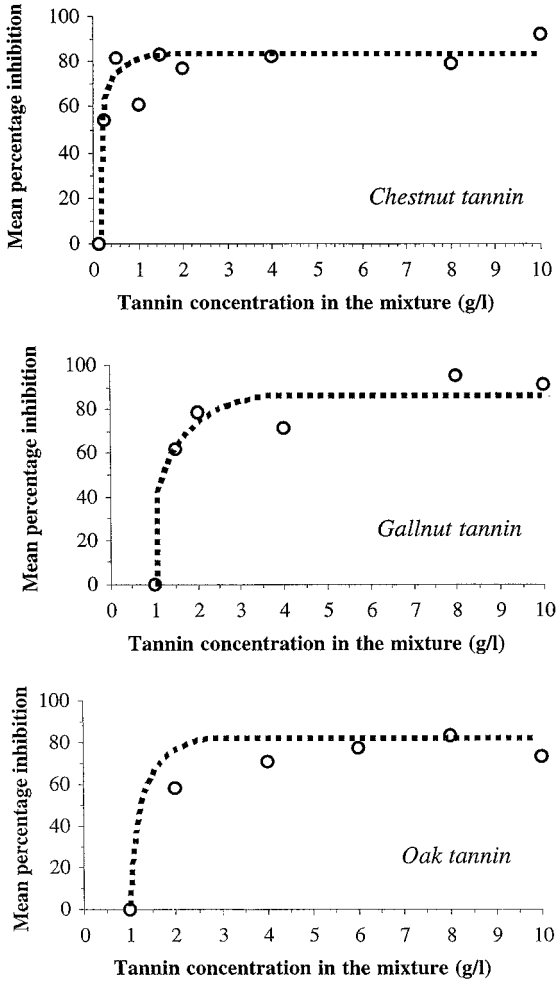

FIG. 2. Profiles of inhibition of the consumption of mixtures as a function of tannin and quinine concentration. Observed inhibition values are figured while curves are derived from parameters of Monod's model expressed in Table 1. As an example, no inhibition is observed for gallnut concentrations $\leq$1g/l, and the equation is $Y = a \cdot (X - 1)/(b - 1) + (X - 1)$, with $a = 88.9$ and $b = 1.22$. The resulting profile is an adjusted plot of calculated Y values against untransformed concentration values.

In other nonhuman primate species tested ($N = 6$) with a methodology identical to that used in this study (mixtures including a near-threshold sugar concentration), thresholds for tannic acid varied between 0.17 and 0.85 g/l (Simmen, 1994; Laska, 2000), with the exception of gorillas (6.8 g/l; (Remis and Kerr, 2002). In

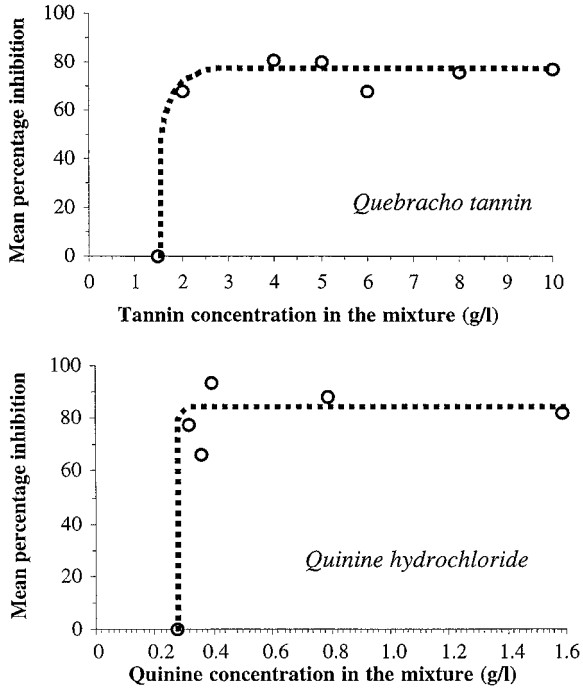

FIG. 2. Continued.

humans, recognition thresholds for tannic acid and oak tannin (from the same batch as the one we used) dissolved in tap water were found to be 0.34 g/l and 0.44 g/l, respectively (Iaconelli, 2000; Hladik et al., 2002). The clustering of thresholds for tannic acid found in most species tested to date contrasts sharply with the sensitivity to the bitter-tasting quinine. Using the two-bottle test, Glaser (1986) reported a threshold for quinine hydrochloride in aqueous solution at 0.32 g/l in *Microcebus*, a result that is strikingly equivalent to ours. This value is one of the highest found among primates, whose thresholds vary by a factor of 1–1000 (Simmen and Hladik, 1998). In addition, the profile of suprathreshold responses to quinine does not differ from those obtained with tannins, and approximately similar amounts of quinine and chestnut tannin (or tannic acid; see Iaconelli and Simmen, 1999) are required to fully deter *Microcebus* from drinking solutions.

Theories of chemical defenses (e.g., Feeny, 1976) separate, among allelochemicals, those whose deterrent effect is dose-dependent, such as polyphenols, from those that are biologically active at low concentration, such as alkaloids. Data obtained in *Microcebus* appear puzzling in this regard. Could it mean that Malagasy forests are poor in plants containing alkaloids, thus exerting little

selective pressure on the discrimination of bitter substances? Potent alkaloids have been extracted from Malagasy plants, and screening tests show that environments inhabited by *Microcebus murinus* and congeneric species include significant proportions of plants containing alkaloids in leaves (Ganzhorn, 1988; Simmen et al., 1999a). While these phytochemical studies indicate that the risk of ingesting poisonous substances is real for leaf-eating animals, *Microcebus murinus* may not be exposed to similar chemical constraints. This species includes predominantly ripe fruit pulps, nectars, gums, and invertebrates in its diet (Martin, 1972; Hladik et al., 1980). The lack of noxious substances in ripe fruits is predicted by theories of mutualism between plants and their dispersers (e.g., Herrera, 1985), and one may hypothesize that a limited risk of encountering harmful substances may stem indirectly from the primary attraction exerted by food items eliciting a sensory reward (including sweet and fatty fruits; Atsalis, 1999). It is significant that the congeneric species *M. rufus*, inhabiting the eastern rain forest of Madagascar, eat fruits lacking alkaloids and containing weak concentrations of condensed tannins (Ganzhorn, 1988). A high threshold can nevertheless contribute to the avoidance of potentially noxious substances. For instance, seeds are known to contain the highest concentrations of alkaloids among plant tissues (McKey, 1974), and inadvertant ingestion of smooth toxic seeds together with pulp is potentially deleterious (Simmen and Sabatier, 1996).

Polyphenols, unlike alkaloids, are widespread substances occurring in unripe fruits, barks, and gums among other plant organs (Swain, 1979). One may expect lesser mouse lemurs to cope more frequently with these allelochemicals than with alkaloids when monitoring fruit ripeness or when collecting gums oozing from tree barks. In this respect, the inhibition thresholds of *Microcebus* for tannins probably correspond to an efficient detection of these chemical defenses.

One aspect that must be mentioned is that the differences we found among taste thresholds for the four tannin extracts correlated negatively with differences in the efficiency of tannins at precipitating protein. This relationship, however, is not confirmed by data on tannic acid, for which a high sensitivity (Iaconelli and Simmen, 1999) corresponds to a weaker precipitation ability (1.04 mg of BSA under experimental conditions described for tannin extracts). It may be that, in the wild, digestibility-reducing effects of tannins are commonly predictable from the intensities of the astringent taste perceived, a relationship that would have been encoded in the gustatory system (see the gustofacial reflex triggered by quinine in primates) (Steiner and Glaser, 1984). In this case, some less toxic tannins eliciting a strong taste would also be rejected.

Despite the steepness of the responses to near-threshold tannin concentrations, *Microcebus murinus* is, to some extent, able to tolerate tannins according to the alimentary context. For instance, tannin–sugar mixtures that are rejected when given the choice between mixtures and a pure sugar solution, may be prefered within a range of above-threshold tannin concentrations (up to at least four fold

the threshold value) if water is presented simultaneously (Simmen et al., 1999b). Sensory tolerance may account for some observations of *Microcebus* feeding on tannin-rich fruits in Madagascar (Atsalis, 1999).

Our experiments provide some basis to assess the limits of diet flexibility. Considering the different profile of suprathreshold responses to tannic mixtures obtained in one other frugivorous–insectivorous mammal species (Simmen et al., 1999b), tolerance of distasteful compounds needs to be investigated in primate species showing distinct dietary trends.

Acknowledgments—We are grateful to Martine Perret (CNRS/UMR 8571) and her collaborators for permission to carry out the taste tests on the *Microcebus* colony in their laboratory at Brunoy. We would like to thank Ann Hagerman who supplied quebracho tannin and gave us useful advice and comprehensive methods to perform protein precipitation tests. We are also grateful to André Marez (IUT, University of Paris XII, Créteil) for his collaboration during the biochemical analyses and to Ethan Pride who improved the text.

(Received April 1, 2002; accepted July 1, 2002)

Abstract—Tall larkspur (*Delphinium barbeyi*) is the principal mountain larkspur responsible for the majority of cattle deaths on mountain rangelands in western Colorado and central and southern Utah in the United States. Ten plants in each of two tall larkspur populations in the mountains near Ferron and Salina, Utah, were marked, and single stalks were harvested periodically through the growing season for 4 yr. Toxic alkaloid concentration [alkaloids containing the *N*-(methylsuccimimido)-anthranilik ester group] was determined by Fourier transform infrared (FTIR) spectroscopy. Individual larkspur plants varied in alkaloid concentrations, especially in early growth (14–38 mg/g). As the concentration declined over the growing season, variation among plants also declined. There were yearly differences in alkaloid concentration among individual plants ($P < 0.01$) and populations ($P < 0.001$), even after accounting for differences in phenological growth between years. Variables such as precipitation, temperature, days since snow melt, growing degree days (sum of mean temperature each day from snow melt), and plant height and weight were all considered in a Mallows Cp multiple regression selection procedure to predict alkaloid concentration. The mixed model procedure in SAS adjusted the regression equation for locations and years. Growing degree days was the best single predictor of alkaloid levels: $ln\ y = (3.581 - 0.00423\ \mathrm{GDD})$, $R^2 = 0.85$. Internal validation of this equation within individual years and locations from which the equation was developed, produced correlations between observed versus predicted values

ranging from $r = 0.73$ to 0.93. External validations on nine other larkspur populations produced correlations ranging from $r = 0.76$ to 0.99. This predictive equation can provide a tool for ranchers and land managers to make management decisions of when to graze cattle in larkspur areas.

Key Words—Tall larkspur, *Delphinium barbeyi*, *N*-(methylsuccinimido)-anthranilic ester, methyllycaconitine, poisonous plant, cattle.

INTRODUCTION

Tall larkspur (*Delphinium barbeyi*) is the principal mountain larkspur responsible for the majority of cattle deaths in western Colorado and central and southern Utah in the United States. Cattle deaths average 2–5% on mountain rangelands, but may exceed 15% in areas where larkspurs are abundant (Pfister et al., 1999). Larkspur plants contain many norditerpenoid alkaloids. Alkaloids containing the *N*-(methylsuccinimido)–anthranilic ester group (MSAL) are most toxic, with methyllycaconitine (MLA) being the most prominent toxic alkaloid (Manners et al., 1995). MLA is a potent neuromuscular blocker, causing paralysis and rapid death from respiratory failure (Dobelis et al., 1999).

Concentrations of alkaloids decline in a concave curvilinear manner as the plants mature through the phenological growth stages over the growing season (Pfister et al., 1994; Ralphs et al., 1997). Concentrations vary year to year (Pfister et al., 1994; Ralphs et al., 1997). It is not known if this results from differences in alkaloid production or simply from differences in phenological growth stages when plants were harvested. Alkaloid levels also differ greatly among plants (Manners and Pfister, 1996).

The first objective of this study was to quantify the variation in toxic alkaloid concentration among individual plants, over the growing season, and among years, then to describe the variation in populations over years and between sites. The second objective was to evaluate various plant and environmental factors that influence growth and determine their ability to predict alkaloid concentration in tall larkspur.

METHODS AND MATERIALS

Tall larkspur plants were sampled at two locations in the mountains of central Utah. The Ferron Reservoir site was 46 km west of Ferron, Utah, at an elevation of 3150 m in the subalpine zone. The second site, Mt. Terrell, was 40 km east of Salina, Utah, at 3230 m, in the ecotone of the aspen and subalpine zone.

Ten uniform tall larkspur plants (30–40 stalks/plant) were randomly selected at each site in 1997 and marked with an orange tent stake with an aluminum number attached. One randomly selected stalk was harvested from each plant on

a weekly basis, beginning shortly after emergence in late June, until senescence in September. Stalks were taken from the same plants at various times during the growing seasons over a 4-yr period. The height and weight of each stalk was measured when harvested, then placed in an airtight plastic bag and immediately frozen with dry ice. Samples were freeze dried, weighed to obtain a dry weight, and ground through a Wiley mill with a 1-mm screen. Alkaloids were extracted, and the concentration of toxic (MSAL) and total alkaloids was measured by Fourier transform infrared (FTIR) spectroscopy (Gardner et al., 1997) This paper deals only with the toxic MSAL fraction.

It was important to determine when larkspur growth began each year in order to compare phenological plant development between years. However, access to these sites early in the season was prevented by snow drifts. Weather recording sites (SNOTEL, automated weather recording sites operated by the Natural Resource Conservation Service) were located 3 km from the Ferron site and 7 km from the Salina site. The pillow data parameter measured weight of the snow pack as an estimate of water content. When this parameter went to 0 in the spring, it signaled the snow pack was gone. Larkspur growth begins immediately after snow melt (Cronin, 1971). The distance of the SNOTEL sites to the research plots precludes precise estimates of the beginning of growth, but it is the best estimate available and a consistent parameter over years. Time of snow melt and subsequent beginning of growth ranged from 5 May to 21 June, across locations and years of the study. Therefore, time was normalized by expressing time as days since snow melt. Daily temperature and precipitation data were also taken from the weather stations.

Variation. To quantify the difference in alkaloid concentration among plants, population summary statistics were calculated (mean, standard error, coefficient of variation, maximum and minimum value, and range of toxic alkaloid concentration) and are presented in Table 1 for 10 plants collected at the same stage of growth each year (flower stage). In addition, toxic alkaloid concentrations of individual plants were graphed to illustrate the range of variation over the 1997 growing season for the two locations (Figure 1).

A single plant was selected from each location to express the variation within the same plant between years. A mixed model analysis of variance using first-order autocorrelation covariate structure (SAS, 2001) was used to compare years. The MSAL values were transformed to the natural log (*ln*), and regressions were calculated by including days since snow melt as a covariate in the model and asking for its solution. Differences in these regressions between years were determined by linear contrasts. The raw data were graphed to illustrate differences in these selected plants between years (Figure 2).

The difference in alkaloid concentrations of tall larkspur populations between locations and years was evaluated in a mixed model analysis of variance similar to that described above. The MSAL data were log transformed, and linear regressions were calculated and compared between sites and among years using

linear contrasts. These log regressions were graphed to illustrate differences in populations over years (Figure 3).

Prediction. The following plant parameters and weather data were considered in multiple regression predictive equations. Plant height was measured when the plants were harvested. Stalks were freeze dried, and dry weight was obtained before extraction of alkaloids. Temperature, precipitation, and time of snow melt were taken from SNOTEL sites. Time was normalized over the 4 yr by expressing it as days from snow melt. Temperatures were converted to heat units or thermal time (measured in growing degree-days since snow melt, GDD). GDD have been used to describe and predict various phenological events in plants (reviewed by McMaster and Wilhelm, 1997) and are calculated as:

$$\text{GDD} = (T_{\max} - T_{min})/2 - \text{base}$$

where $T_{\max}$ and T_{min} are maximum and minimum daily temperatures. Base 4.4/25°C (40/70°F) was selected to represent growing conditions for cool-season species (Ashcroft et al., 1992).

Several statistical methods were used to develop predictive equations. Mallows Cp multiple regression model selection procedure was used to select the variables for the predictive equation (SAS, 2001) using the raw data. This procedure selects for the smallest total squared error and equations with the highest R^2 were selected.

Since alkaloid concentration declined in an exponential curvilinear fashion, the natural log transformation was made of toxic MSAL alkaloid concentrations, and linear regressions were calculated for each parameter. The classification and regression tree (CART) program was used on the log transformed data to define the changes in alkaloid concentration. Finally, the mixed procedure in SAS (SAS, 2001) was used on the log-transformed data to adjust the linear regression equation for the location and year factors in the collection scheme.

Two validations were run on the predictive equations. An internal validation was run on the same data set from which the equation was derived for the two locations each year. Correlations between the observed and predicted values were used to determine the precision of the equations. The accuracy of the equations was evaluated by calculating the mean variance $[\sum (\text{observed - predicted})^2]/n$. The lowest mean variance was most accurate.

An external validation was run on nine other larkspur populations. One population at each of the Ferron and Salina locations was in phenological growth stage similar to the population from which the equations were developed in 2000. The other population at each location in 2000 began growth earlier or later than the equation population (due to when the snow melted). These two data sets were used to determine the effect of different growth rates by using the same recorded environmental variables. Five other data sets from previous grazing studies were

available in which we had the concentration of the toxic alkaloid MLA to compare to predicted values. Correlations between observed and predicted values, and mean variances were used to measure goodness of fit.

RESULTS

Variation among Plants. The toxic alkaloid concentration in tall larkspur plants harvested at the same phenological growth stage (flower stage of growth) at two locations over 4 yr varied from 1.64 to 9.40 mg/g (Table 1). The range of alkaloid concentration was almost as great as the mean. The coefficient of variation (CV, % variation about the mean) of plants in our study harvested at the flower stage of growth each year ranged from 21% to 28% at Ferron and from 26% to 36% at Salina (Table 1). Manners and Pfister (1996) reported the CV of 100 tall larkspur plants sampled in the early flower stage at Manti, Utah (near our Ferron site) and Yampa, Colorado ranged from 40 to 45%.

The relative ranking of alkaloid concentration in individual plants in 1997 was similar over the growing season (Figure 1). Variation among plants containing the highest and lowest amounts of alkaloid was greatest in the early growth (Ferron: 34.4 vs. 17.3 mg/g; Salina: 38.4 vs. 14.6 mg/g, respectively). By about 50 days after snow melt, variation among plants had diminished (Figure 1). Plants also

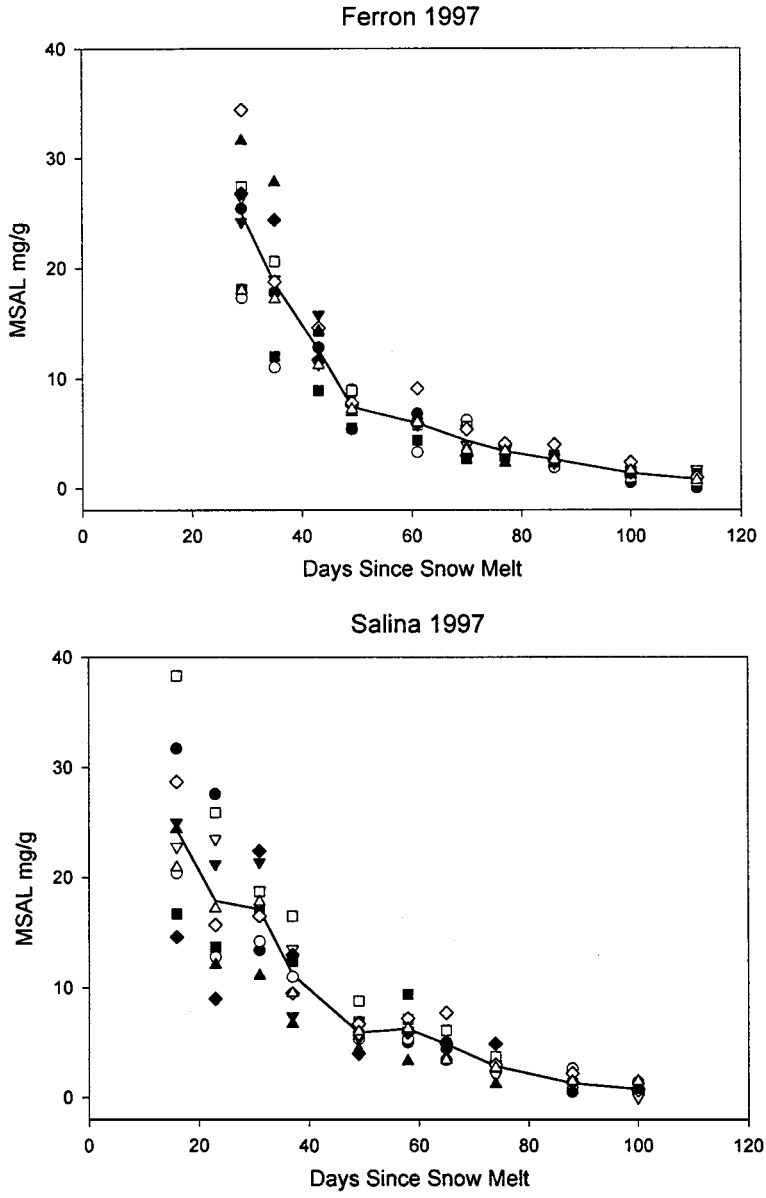

FIG. 1. Range in toxic MSAL alkaloid concentration in 1997 over the growing season at Ferron and Salina. Individual plants are denoted by different symbols ($N < 10$).

maintained their relative ranking in alkaloid concentration over years (data not shown). They varied slightly in numerical ranking, but generally those highest in toxic alkaloids had high levels all 4 yr.

Variation within the Same Plant over Years. Toxic Alkaloid concentration within the same plant varied over years. One plant from each location was selected to illustrate the variation (Figure 2). At Ferron, alkaloid levels of plant 198 differed in 1999 and 2000 ($P = 0.01$). At Salina, alkaloid concentration of plant 367 in 1997 differed from that in 1998 and 1999 ($P = 0.002$). Alkaloid levels at the beginning of the season in 1998 at both locations were somewhat of an anomaly. Levels were low during the first two collections, compared to 1997. June of 1998 was very cold and wet (mean temperature was 4°C lower than 1997 and 5°C lower than the 10-yr average, Ralphs et al., 2000). We speculate that alkaloid synthesis was suppressed during early growth in 1998. Collections in 1999 and 2000 began later in the season and do not reflect the high levels of early growth.

Population Variation between Locations and Years. Overall, there was a difference in alkaloid concentration between locations. Concentration over years and seasons was higher at Salina (8.0 mg/g) than at Ferron (6.9 mg/g) ($P < 0.001$, data not shown). There was also a difference in alkaloid concentration between years ($P < 0.001$). At Ferron, the concentration in 1999 was lower, and the slope of the log regression was less than in the other years (Figure 3). At Salina, concentrations were lower throughout the season in 1998 and 1999 than in the other 2 yr. This suggests that after adjusting for differences in phenology and time for growth, alkaloid concentrations differed in larkspur populations between locations and years.

Predictive Equations. The best single-factor equations selected by the Mallows Cp selection procedure to predict alkaloid concentration were plant height ($R^2 = 0.63$), days since snow melt ($R^2 = 0.68$), and growing degree days since snow melt ($R^2 = 0.72$). The best two-factor equation included growing degree days and plant height ($R^2 = 0.73$). The equations are listed in Table 2.

TABLE 2. PREDICTIVE REGRESSION EQUATIONS

Parameters	Equation	R^2
Raw data		
Plant height	$\hat{y}^a = 23.585 - 0.31\ \text{ht} + 0.00112\ \text{ht}^2$	0.63
Days since snow melt	$\hat{y} = 26.42 - 0.4626\ \text{day} + 0.0021\ \text{day}^2$	0.68
Growing degree days	$\hat{y} = 26.05 - 0.06\ \text{GDD} + 0.0000369\ \text{GDD}^2$	0.72
Height × growing degree day	$\hat{y} = 23.64 - 0.19\ \text{ht} + .000828\ \text{ht}^2 - 0.01568\ \text{GDD}$	0.73
Log transformed data		
Days since snow melt	$ln\ \hat{y} = 3.855 - .03732\ \text{day}$	0.79

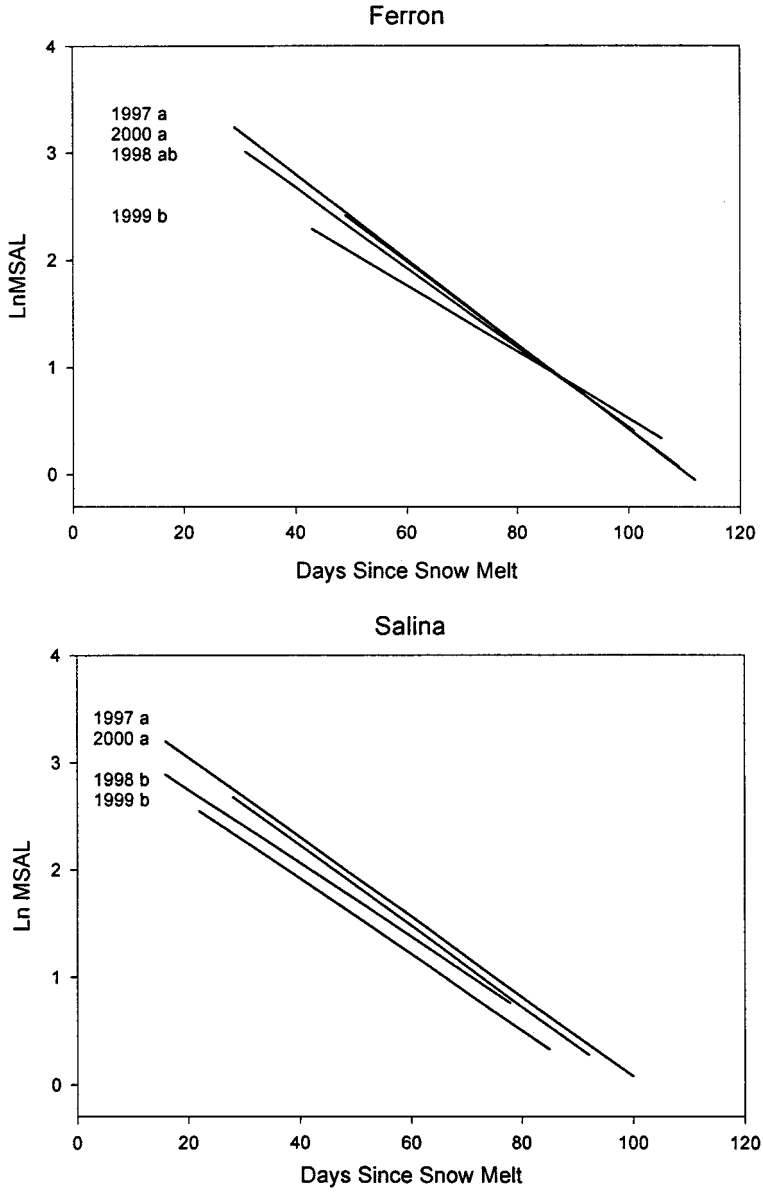

FIG. 3. Population difference between years, expressed as the natural log transformation of toxic MSAL alkaloid concentration for Ferron and Salina. Different letters following the year indicate significant difference ($P < 0.05$).

Growing degree days since snow melt (GDD) was the best single predictor in all of the other procedures. The CART analysis using GDD produced a 7-node tree with an R^2 of 0.84. The mixed procedure in SAS using GDD on log transformed data produced a regression equation with an estimated $R^2 = 0.85$ (Table 2). This was selected as the best and simplest prediction equation based on the highest R^2 value.

The predicted data generated by GDD in the SAS mixed procedure were back-transformed to the natural scale and compared with the observed data in the internal validation (Figure 4) and external validation data sets (Figure 5). Correlations between the observed and predicted values provided a measures of the precision of all the equations (Table 3), and the mean variances provide a measure of the accuracy of the equations (Table 4) and are presented for both the internal and external validation sets.

DISCUSSION

Growing degree days have been used extensively in agronomy and weed science to describe and predict phenological events (see McMaster and Wilhelm, 1977 for review). GDD were used to predict the time of flowering in low larkspur (*D. nelsonii*), and the number of flowers and seed production (Inouye and McGuire, 1991). Growing time (as expressed in Julian days since 1 January) was used to describe toxic alkaloid concentrations in the tall larkspur in Canada (*D. brownii)* in its vegetative stage (Majak et al., 2000):

$$ln\text{MLA} = 6.10059 - 0.031\text{Jday},\ R^2 = 0.79$$

The predictions of toxic alkaloid concentrations, using GDD since snow melt in the log-transformed SAS mixed equation in our study, were fairly close to the observed levels in most of the internal and external validation data sets. One anomaly occurred in the internal validation set in 1998 at both Ferron and Salina (Figure 4). Mean June temperatures were 5°C lower than average and may have suppressed metabolism during the first 3 wk of growth when alkaloids are synthesized (Ralphs et al., 2000).

Another anomaly occurred in the 2000 external validation set. The younger population at Ferron started growth later than the population near the weather station; thus, it was in an earlier phenological growth stage, and the observed toxic alkaloid levels should have been higher than the predicted levels (Figure 5). The older population at Salina was at a lower elevation and began growth earlier, thus, plants were more mature. Alkaloid concentrations were lower than predicted, as would be expected.

The predicted values of MLA in the older data sets at Manti in 1988, 1989, and 1991 were close to the observed values. The predicted value of MLA in the

Comparison of the observed values in previous years with the predicted values from the equation. Horizontal lines denote moderate and low toxic level thresholds.

1992 Manti and Salina data sets deviated from the observed. The correlations were close (Table 3), but the variances were an order of magnitude greater than in other years (Table 4). In this case, the predicted values appear to be invalid. These older studies measured only MLA, which is the major toxic alkaloid. The newer

chemical assays measure the entire MSAL toxic fraction, which may include low amounts of other alkaloids having similar toxicity.

Pfister et al. (1997) defined thresholds of toxicity in tall larkspur. Alkaloid concentrations <3 mg/g were considered low to nontoxic. Concentrations of 3–6 mg/g were considered moderately toxic and could cause poisoning if a cow consumed tall larkspur for 20–35% of her daily diet. Below the moderately toxic threshold, the SAS mixed model equation that used GDD predicted toxic alkaloid concentration accurately.

Online weather data is available from SNOTEL, or can be readily obtained from the states' NRCS water forecasting offices. By observing when snow melted from specific larkspur populations or using the snow melt data from SNOTEL and the maximum and minimum temperature, toxic alkaloid concentration can be estimated at any point in time. Conversely, the alkaloid concentration will drop below the moderately toxic threshold level (6 mg/g) when GDD since snow melt reach 422 (90% confidence interval 385–509), and the low toxicity threshold (3 mg/g) will be reached at GDD 586 (90% confidence interval 546–671).

[a] Variance Calculated as the Mean Difference of the Observed-Predicted Value. Lowest Variance (bold type) Indicates Best Fit. GDD: growing degree days since snow melt.

These generally correspond to the late flower and early pod stages of growth, respectively.

In Summary, individual larkspur plants varied in alkaloid concentrations, especially in early growth. In 1997 when plants were sampled shortly after they emerged from the snow (5–12 cm tall), alkaloid levels varied by over 100% (from 14 to 38 mg/g). Alkaloid levels declined in a curvilinear manner over the growing season. The high concentrations of alkaloids at the beginning of growth were diluted in the increasing plant biomass through the short growing season. As the alkaloid concentration declined over the season, variation among plants also declined. After accounting for differences in phenology and time for growth, both individual plants and populations varied among years. The predictive equation based on growing degree days from snow melt can accurately predict alkaloid levels through the critical regions as toxicity declines from moderate to low toxic thresholds. This predictive equation can provide a tool for ranchers and land managers to make management decisions of when it is safe to graze cattle in larkspur areas.

Abstract—*Artemisia tridentata* ssp. *tridentata* is the dominant and defining shrub in the Great Basin Desert, with well-documented allelopathic tendencies that have generally been ascribed to its most abundantly released secondary metabolites. However, as a minor component, sagebrush releases a highly biologically active substance, methyl jasmonate (MeJA), which is known to function as both a germination inhibitor and promoter in laboratory studies. *Nicotiana attenuata* is a tobacco species native to the Great Basin Desert and grows in newly burned juniper–sagebrush habitats for 2–3 yr following a fire. With a combination of field and laboratory studies, we examined the role of MeJA release from sagebrush by both air and water transport in inhibiting *N. attenuata* seed germination. We demonstrated that sagebrush interacts allelopathically with the seed bank of *N. attenuata* through its release of MeJA. In the field, seeds buried 0–40 cm from sagebrush plants for 4 months in net bags had significantly reduced germination compared to seeds buried similarly but protected in plastic bags. Moreover, germination on soils collected from underneath sagebrush plants was reduced by 60% compared to seeds placed on soils collected between sagebrush plants or outside of the sagebrush population. Exposure to *A. tridentata* seeds and seedlings did not affect *N. attenuata* germination, suggesting that

established sagebrush plants only influence the tobacco's seed bank. In the laboratory, exposure of seeds to sagebrush emissions resulted in germination delays of up to 6 d. Exposure to volatile and aqueous MeJA also inhibited germination of *N. attenuata* seeds at quantities that are released naturally by sagebrush: 3.5 μg/hr and 1.12 μg/seed cup (56 ng/seed), respectively. *A. tridentata* seeds were significantly more resistant to MeJA, being inhibited at 336 μg MeJA (16.8 μg/seed), 300 times greater than the level of aqueous MeJA required to inhibit *N. attenuata* seeds. MeJA inhibited *N. attenuata* germination regardless of the seed's dormancy state and the specific epimer (*trans*- or *cis*-) of MeJA. Germination on sagebrush chaff that had been heated to reduce MeJA content was negatively correlated with the amount of MeJA remaining in the chaff. Germination of a nondormant, conspecific tobacco, *N. trigonophylla*, which grows in the same area but is not associated with fire, is less sensitive than *N. attenuata* to the extracts of sagebrush litter, but similarly sensitive to MeJA. Additionally, four of five other tobacco species that are not known to be associated with sagebrush are less sensitive to MeJA, suggesting an evolved sensitivity to MeJA. To determine the proportion of germination inhibition of a sagebrush extract that could be attributed to MeJA, we serially diluted sagebrush extracts with water and restored the quantity of MeJA of the original extract by adding appropriate quantities of synthetic MeJA; 16–60% of the inhibitory activity of the original extract could be attributed to the MeJA. We conclude that MeJA release from sagebrush plays an allelopathic role for *N. attenuata* seed banks, but other unidentified compounds are also involved.

Key Words—*Artemisia tridentata* ssp. *tridentata*, *Nicotiana attenuata*, *Nicotiana trigonophylla*, allelopathy, methyl jasmonate, germination, seed dormancy.

INTRODUCTION

Allelopathy is defined as a direct or indirect interaction, whereby chemicals released by one organism influence the physiological processes of another neighboring organism (Molisch, 1937; Rice, 1984), and is one of the most controversial of ecological interactions (Harper, 1977; Williamson, 1990). Much of the controversy involves the requirements for proof of an allelopathic interaction and the difficulty of disentangling allelopathy from other ecological relationships, such as resource-based competition (Harper, 1977; Williamson, 1990; Inderjit and del Moral, 1997; Watkinson, 1998). Allelopathy and resource competition are likely to interact in complicated ways, as determined by the complicated effects of variable resource supply on secondary metabolite production and release (Rice, 1984; Bryant et al., 1983; Inderjit and del Moral, 1997). Hence, allelopathic interactions, however minor in themselves, may have large effects by changing the outcome of resource-based competition (Reigosa et al., 1999). Moreover, patterns of plant distribution in nature that have been ascribed to allelopathic interactions, could, after closer scrutiny, be attributed to other ecological interactions. For example, the bare zones around chaparral shrubs, initially thought to result from allelopathic interactions (Muller, 1965), could also be explained by the removal of seeds by

rodents (Bartholomew, 1970). These complications make field-based demonstrations of allelopathy particularly onerous.

Skepticism about the importance of allelopathic interactions in nature has focused attention on the methods employed to demonstrate them (Harper, 1977) and consequently, studies of allelopathy tend to be held to a more rigorous standard of proof than other plant–plant interactions (Harper, 1977; Williamson, 1990). A credible allelopathic interaction must first involve ecologically relevant species that interact in nature. Results from studies that use "standardized" bioassay species, such as lettuce or radish, are difficult to generalize to co-occurring species in natural populations (Inderjit, 1996). The fundamental bioassay technique in allelopathic research of using whole-plant extracts, foliar washings, and decomposing litter was questioned, as these treatments inhibited germination or growth even when derived from plants not suspected of allelopathy, and hence suggested antagonistic relationships between species that could not be associated with patterns found in nature (Stowe, 1979). Second, the chemical(s) that mediates the interaction must be identified and the amounts released into the environment quantified and simulated experimentally (Williamson, 1990). Most studies focus on the most abundant chemicals, which may or may not be the most active chemical players. For conclusive proof of allelopathy, laboratory bioassays must demonstrate that the allelopathic effects can be attributed to the quantities of chemicals released under natural circumstances (Newman, 1978; Putnam and Tang, 1986; Inderjit, 1996). Finally, if population-level consequences of allelopathic interactions are of interest, interactions should be studied during the life history stages that are likely to have the largest demographic effects, and this consideration has focused research efforts on the sensitivity of seeds or seedlings. Allelopathic interactions that affect seed germination of a species either through inhibition or toxicity can occur both during seed-to-seed or plant-to-seed interactions. Seed-to-seed allelopathy, where one seed influences the germination of a co-occurring species (Gressel and Holm, 1964; Wardle et al., 1991; Van Staden and Grobbelaar, 1995; Laterra and Bazzalo, 1999), and plant-to-seed allelopathy, where an established plant influences the underlying seed bank, could alter the plant community structure prior to any resource competition. Complete inhibition is not essential for ecological significane, as delaying or slowing growth can also significantly hinder the competitive abilities of the affected plant and have large fitness effects.

Sagebrush is widely recognized as a species with allelopathic tendencies. Over 250 species of sagebrush (*Artemisia L.*) are distributed throughout the world (Güvenalp et al., 1998), and several studies have reported allelopathic activity in the genus *Artemisia* (Robertson, 1947; Reid, 1964; Friedman et al., 1977; Hoffman and Hazlett, 1977; Kelsey et al., 1978), identifying (possible) germination and growth inhibitors such as artemisinin (Duke et al., 1987, 1988; Chen and Leather, 1990; DiTomaso and Duke, 1991) and several monoterpenes (Weaver and Klarich, 1976). Among the volatiles credited with the inhibitory effects are the major constituents

in sagebrush emissions: camphor and the cineole epimers. Seed germination of a weedy monocot, *Echinochloa crusgalli*, and dicot, *Cassia obtusifolia*, was inhibited by 1,8-cineole, while root growth of *Cucumis sativa* (Muller, 1966) and shoot growth of *E. crusgalli* (Romagni et al., 2000) were reduced by applications of camphor and 1,4-cineole, respectively.

Artemisia tridentata (*Nutt.*) is one of the most widespread and economically important shrubs in North America (Freeman et al., 1991) and the dominant shrub over much of the semiarid western North America, occurring over a wide range of habitat types (Shultz, 1986). For purposes of optimizing grazing potential in western rangelands, there is considerable interest in understanding the interactions between sagebrush, a shrub with low forage value, and grasses and other species with greater forage value (Robertson, 1947). Muller (1966) suggested that in the Great Basin Desert, *A. tridentata* uses allelopathy to dominate in relationships with other species. *Nicotiana attenuata* Torr. ex Wats. (Solanaceae) is a wild tobacco plant also native to the Great Basin Desert (Wells, 1959) and is found in juniper–sagebrush habitats for 2–3 yr immediately following fires. Dormant seeds of *N. attenuata* germinate in response to a combustion product of cellulose (Baldwin et al., 1994) and the removal of nontoxic negative component(s) that suppress germination and are found in the litter of the dominant species that comprise the mature plant communities, including *A. tridentata* ssp. *tridentata* (Preston and Baldwin, 1999). While the specific chemical components that function as the positive germination signals have yet to be identified, the two component control over germination allows this species to time its germination with the postfire environment and locate its germination niche (Preston and Baldwin, 1999).

Since *N. attenuata* plants respond to MeJA, it is also possible that *N. attenuata* seeds may also be sensitive to this biologically active substance and provide a mechanism for sagebrush to interact with the seed bank underneath its foliage. Germination of cocklebur (*Xanthium pennsylvanicum* Wallr.) (Nojavan-Asghari and Ishizawa, 1998), lettuce (Yamane et al., 1981), sunflower (Corbineau et al., 1988, 1989), amaranth (Kepczynski et al., 1999), rapeseed and flax (Wilen et al., 1991) seeds are inhibited by MeJA application. However, all but cocklebur required concentrations $>100\mu$M, levels that may be physiologically irrelevant (Sembdner and Parthier, 1993). Applications of JA and MeJA appear to inhibit the germination of nondormant seeds (e.g., *Quercus robur*;) (Finch-Savage et al., 1996) and stimulate the germination of dormant seeds (e.g., *Acer tataricum*;) (Berestetzky et al., 1991; Daletskaya and Sembner, 1989; Creelman and Mullet, 1997). However, it is not clear if MeJA acts on the dormancy state or if this is a species-specific response. Methyl jasmonate has not been considered in previous allelopathic studies involving *A. tridentata*, probably because it is a minor component within the complex aroma of sagebrush (Preston et al., 2001). It is unlikely that MeJA is the sole chemical responsible for germination inhibition of *N. attenuata* by all later successional species of its habitat (Preston and Baldwin, 1999) since it is not found

in the inhibitory water extracts produced from juniper (*Juniperus osteosperma*) litter, another dominant later successional species (B. Krock, *unpublished data*). However, water extracts produced from sagebrush litter are significantly better at inhibiting *N. attenuata* germination as compared to other species' extracts (Preston and Baldwin, 1999). These results may be explained by MeJA acting in concert with the negative germination signal.

In the laboratory, *N. attenuata* plants delayed in germination have reduced competitive abilities and produce significantly fewer seeds (van Dam and Baldwin, 2001). Small delays in the laboratory bioassays can translate to significant delays in the field (Preston and Baldwin, 1999), causing *N. attenuata* to miss its germination window in the spring. Using field-based experiments, we first determined if tobacco seeds are affected by exposure to natural populations of sagebrush or soil collected near sagebrush. In the laboratory and under more controlled growth room conditions, we examined seed–seed and seed–seedling interactions between these species. Using a range of MeJA concentrations, we determined the sensitivities of *N. attenuata* and *A. tridentata* seeds. To gain a selective advantage from producing allelotoxins, a species must inhibit its potential competitors more than it inhibits itself (Williamson, 1990) and, therefore, we predict that *A. tridentata* will be less sensitive to MeJA. Because different genotypes of *N. attenuata* can vary in dormancy (dormant seeds germinate only after smoke exposure, while nondormant seeds germinate in response to water or nutrients), we examined if MeJA interacts with the seeds' dormancy state. Volatile transport is one pathway for MeJA to reach the seed bank, and we examined if volatile emissions from potted sagebrush plants and volatile MeJA-releasing devices affect the germination of *N. attenuata* seeds exposed for different lengths of time. To determine the proportion of germination inhibition that can be specifically attributed to MeJA, we manipulated the MeJA content of sagebrush chaff by heating, and serially diluting aqueous extracts of sagebrush litter and restoring the original concentrations of MeJA. Finally, we determined the generality of sagebrush's allelopathic effects by exposing seeds of a congeneric species of tobacco that co-occurs in the same habitat as *N. attenuata* and *A. tridentata*, namely *N. trigonophylla*. We exposed the two *Nicotiana* species that are sympatric with sagebrush, as well as five other allopatric *Nicotiana* species to water extracts of sagebrush litter and aqueous dilutions of MeJA.

METHODS AND MATERIALS

Species Description. *Artemisia tridentata* (Nutt.) is generally considered to be composed of four subspecies, *A. t.* ssp. *tridentata*, *A. t.* ssp. *vaseyana* (Rydb.) Beetle, *A. t.* ssp. *spiciformis* (Osterhout) Goodrich and McArthur, and *A. t.* ssp. *wyomingensis* Beetle and Young (Freeman et al., 1991). In this study, we focused on the subspecies *tridentata* and will herein refer to it as *A. tridentata* or sagebrush.

Sagebrush seeds for use in germination bioassays were manually separated from bulk chaff, defined here as a mixture of seeds, flower material, etc., from the floral meristem of the sagebrush plant (obtained from Goble Seed Co., P.O. Box 203, Gunnison, Utah, USA; lot ARTRVA-97). To obtain plants, chaff was sown onto potting soil and watered. The resulting seedlings were transferred to pots containing a 1:1 mixture of potting soil and sand that was supplemented with Osmocote 14:14:14 beads (Scotts Deutschland, Nordhorn, Germany) and micronutrients (Micromax, Scotts Deutschland). Plants were grown in a large growth room with a 16L:8D photoperiod and 27°C day–25°C night temperature cycle, 65% relative humidity with 1000–1500 μM m^2/sec PAR at plant growing level and watered with demineralized water when necessary.

Seeds of *N. attenuata* can be either nondormant [germinating in 9 d in response to water or nutrient (KNO_3) treatments] or dormant (germinating in 9 d in response to smoke treatments). Nondormant genotypes were originally obtained from natural populations in Utah, and the dormant genotypes originated from a population in Arizona. Seeds used were from these genotypes after propagation in the glass house.

Nicotiana trigonophylla is found in desert habitats of southern California and northern Mexico (Goodspeed, 1954) and occurs sporadically in washes in Utah and Arizona, but rarely in close proximity to *A. tridentata* (C.A. Preston and I.T. Baldwin, personal observation). It is not associated with the postfire environment (Wells, 1959) and is nondormant, germinating in response to applications of water or nutrients. Seeds originated from a single plant collection in 1990 in southwestern Utah (SUCS; T41S R17W section 34) and were combined with seeds collected from plants propagated in the glass house after one generation of selfing.

Nicotiana repanda Wildenow ex Lehmann occurs in northeastern Mexico and southern Texas, USA (Goodspeed, 1954). *N. benthamiana* is found in northern Australia's Great Sandy Desert and *N. sylvestris* Spegazzini et Comes occurs exclusively in northwestern Argentina (Goodspeed, 1954). *N. repanda*, *N. benthamiana*, and *N. sylvestris* seeds were originally obtained from the Oxford Tobacco Research Station (P.O. Box 1555, Oxford, North Carolina) and propagated for at least one generation of selfing in the glass house. *N. tabacum*, whose original distribution is obscured by human cultivation, is thought to have originated in northwestern Argentina (Goodspeed, 1954). *N. tabacum* L. cv. Xanthi-nc seeds carrying the N gene were obtained from Dr. Alexander J. Enyedi (Western Michigan University, Kalamazoo, Michigan, USA). *N. glauca* originated in Argentina but has spread widely to temperate regions around the world (Goodspeed, 1954), and seeds used were from a bulk collection of a wild population located near Riverside, California, USA.

Quantification of MeJA in Headspace. Emissions of MeJA were quantified by using methods previously described in Karban et al. (2000), with slight modifications. Briefly, to determine MeJA emissions from potted sagebrush plants, the

whole plant (young) or branches (mature) were enclosed in 1-l plastic containers, and traps were inserted into a hole in the side. To determine MeJA content of treated chaff, 400 mg of each chaff treatment was placed into individual 350-ml glass trapping containers with lids. An air inlet were positioned at the bottom of the chaff by inserting a tube leading from the lid to the bottom of the container. The trap was placed above the chaff through a second hole in the lid. The glass trapping containers containing samples were then placed into a 50°C water bath, and volatiles were collected. Using a diaphragm vacuum pump (model MOA P125 JH, Gast, Benton Harbor, Michigan, USA) pulling air from the headspace at 450 ml/min, volatiles were collected for 3–4 hr from the sagebrush plants and for 6 hr from the chaff treatments. Prior to trapping, 350 ng of triple ^{13}C-labeled MeJA (MW = 227) were added as an internal standard. Volatiles adsorbed on traps were eluted with 4 ml of dichloromethane (CH_2Cl_2) and gently concentrated to 100 μl before GC-MS analysis as described in Karban et al. (2000).

To quantify MeJA in water extracts of sagebrush litter, 10 ml of the aqueous solution were extracted twice with 10 ml CH_2Cl_2. Prior to extraction, 700 ng of $3\times^{13}$C-labeled MeJA were added as an internal standard to each replicate. The solvent was allowed to evaporate gently and the samples were reconstituted in 100 μl CH_2Cl_2 and transferred to a 150-μl glass insert and analyzed by GC-MS.

The *trans–cis* epimeric ratio in commercially available solutions of MeJA (MeJA 92:8 from Aldrich, Gillingham, Dorset, UK; MeJA 80:20 "extra epi" from Bedoukian Research, Danbury, Connecticut) was determined by GC-MS analysis.

Germination Bioassays. The germination inhibition activity of sagebrush, collected soils, sagebrush water extracts, and MeJA dilutions was determined using a previously described seed germination bioassay (Baldwin and Morse, 1994; Baldwin et al., 1994; Preston and Baldwin, 1999). Depending on the experiment, three replicate bioassays were performed in containers, each containing 10–20 *N. attenuata* seeds from nondormant or dormant genotypes. For *A. tridentata*, three or four replicate bioassay containers, each containing between 5-30 seeds were used. Seeds were placed on a thin layer (approximately 3 g) of sterile sand (Merck, Darmstadt, Germany). To determine maximum germination, each experiment also included three or four replicate water-control bioassays or nutrient-control bioassays, in which seeds were treated only with distilled water or 1 mM KNO_3, respectively. Seed cups were placed in a growth chamber (Snijders Scientific, Tilburg, Holland; model S 1084) with a 16L:8D photoperiod and 32°C day–27°C night temperature cycle. Seeds were examined after 72 hr and monitored daily for 9–43 d, depending on the experiment, for radicle emergence. To determine seed viability, 250 μl of 1 mM gibberellic acid$_3$ (GA_3; Duchefa, Haarlem, Netherlands) was applied on the final monitoring day to evaluate treatment effects (day varied with the experiment). Previous trials with *N. attenuata* seeds determined that all viable seeds germinate in response to this GA_3 treatment within 4 d (T. Krügel and C.A. Preston, unpublished data).

Burial of Seed Bags Adjacent to Sagebrush and Seed Germination on Soils Collected Near Sagebrush. In the Great Basin Desert of SW Utah, between-plant distances measured at two *N. attenuata* populations located in recently burned areas bordered by sagebrush populations showed that tobacco was not found closer than 50 cm to an unburned sagebrush (C.A. Preston, unpublished data). Since plants of *N. attenuata* rarely grow near sagebrush plants in the field, this may suggest that components released by sagebrush are inhibiting germination of tobacco seeds from the underlying seed bank. To determine if exposure to sagebrush affected germination of *N. attenuata* seeds residing in the underlying seed bank, we buried bags of seeds different distances from natural sagebrush plants for 4 months. Seed bags, each containing 80–100 nondormant *N. attenuata* seeds, were prepared using plastic "no-see-um" netting (Tent City, Buffalo, New York, USA). The seed bags were buried on February 29, 2000, at a single sagebrush population (Pahcoon site, T41S R18W section 10 in Utah). Twelve sagebrush plants located along the edge of the population were selected, all of approximately the same size and healthy appearance. At each plant, two seed bags, one sealed in a small plastic bag, were buried at four locations along a linear transect leading out of the sagebrush population and into an open area. Seed bags were buried near to the base of the sagebrush, at the edge of the sagebrush canopy, 20 cm from the canopy, and 40 cm from the canopy (locations 1, 2, 3, and 4, respectively; Figure 1, left inset). On June 27, 2000, the seed bags were recovered and brought back to the lab in individual small plastic bags (with the plastic and net bag from each burial site kept together) containing a small amount of the soil from their respective burial sites. A germination bioassay was performed as described above with three replicates of 20 *N. attenuata* seeds from each bag at each site.

To determine if components released by sagebrush could accumulate in the soil surrounding the sagebrush plant in sufficient quantities to affect germination of exposed *N. attenuata* seeds, even when the sagebrush plant was no longer present, we collected soil from different proximities to a population of sagebrush. The underlying A_1 soil horizon was collected at a single *A. tridentata* population (Pahcoon site, T41S R18W section 10) in Utah from directly underneath sagebrush plants (10 replicates), between sagebrush plants (10 replicates) and 10 m outside of the sagebrush population (5 replicates). Soils were brought back to the laboratory, and the general bioassay procedure was followed, except that 1.5 cm^3 of soil was used instead of the sand. Twenty nondormant *N. attenuata* seeds were placed directly on top of the soil, and the soil was saturated with 1 mM KNO_3 to eliminate the possibility that germination responses resulted from nutrient differences between the soil collections. Germination was monitored for 8 d.

Germination of N. attenuata Seeds Exposed to A. tridentath Seeds or Seedlings. To determine if sagebrush seeds or seedlings could influence germination of *N. attenuata* seeds occupying the same seed bank, we combined 10 nondormant *N. attenuata* seeds with 5–30 *A. tridentata* seeds or 5–30 *A. tridentata* 2-to 3-d-old

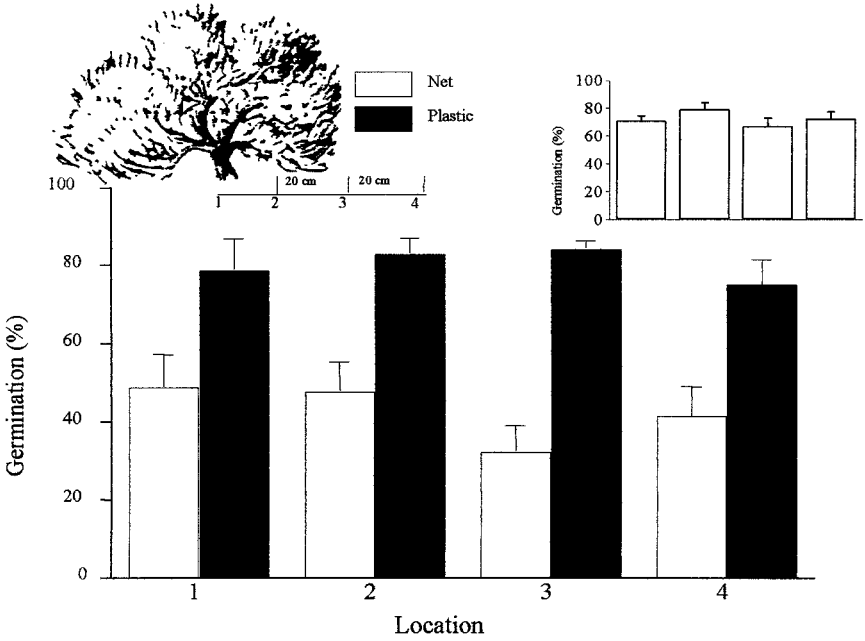

FIG. 1. Mean (+ 1 SEM) seed germination percentages at day 9 and day 16 (inset) of *Nicotiana attenuata* seeds enclosed in bags made of netting (and hence exposed to soil constituents; clear bar) or bags made of netting placed into plastic bags (and hence protected; black bar) and buried for 4 months at different distances from *Artemisia tridentata* ssp. *tridentata* plants in SW Utah. Two seed bags, one exposed and one protected, were buried at four locations in a linear transect from sagebrush plants: (1) directly adjacent to sagebrush trunk; (2) at the edge of the sagebrush canopy; and (3) 20 cm; and (4) 40 cm from the edge of the sagebrush canopy. This burial scheme was repeated using 12 sagebrush plants located along the edges of a single population and the linear transects led into an open area to avoid interference from other sagebrush plants.

seedlings in the seed germination bioassay container. Germination of *N. attenuata* seeds was monitored for 9 d.

Effects of Two Naturally Occurring MeJA Epimers on N. attenuata and A. tridentata Germination. The *cis* epimer of MeJA is thought to be the more biologically active epimer (Beale and Ward, 1998) and the one that may be the airborne signal eliciting herbivore resistance in *N. attenuata* plants growing adjacent to damaged sagebrush in nature (Karban et al., 2000; Preston et al., 2001). To test the sensitivity of *N. attenuata* and *A. tridentata* seeds to the two epimers, we applied a range of quantities of the two epimers and monitored germination. Dilutions of MeJA were made by weighing 2.24 g of MeJA [*trans (trans–cis* ratio, 92:8), Aldrich, Gillingham, Dorset, UK; *cis* (*trans–cis* ratio, 80:20), "extra-epi" MeJA,

Bedoukian Research, Danbury, Connecticut] and adding 10 ml of 1 mM KNO_3 to produce a 1 M MeJA solution. The solution was sonicated and serial dilutions were made by adding 1 ml of the MeJA solution to 9 ml of 1 mM KNO_3. This was repeated to produce solutions in the range of 10^{-2}–10^{-8} M MeJA in 1 mM KNO_3 (see *X* axis of Figure 3 below for amounts of the compounds added to each seed cup). Since preliminary experiments suggested that *A. tridentata* seeds were less sensitive to MeJA application (e.g., more MeJA was required to inhibit germination), MeJA solutions were applied in the range of 10^{-2}–10^{-6} M. Moreover, germination of *A. tridentata* seeds was more variable; hence, four replicate seed cup bioassays were used. In summary, the experiment contained 170 seed cup bioassays in total: 87 *N. attenuata* bioassays with 20 seeds each (2 epimers MeJA $\times$ 7 incremental M solutions $\times$ 2 volumes $\times$ 3 replicates + 3 nutrient-controls) and 83 *A. tridentata* bioassays with 20 seeds each (2 epimers MeJA $\times$ 5 incremental M solutions $\times$ 2 volumes $\times$ 4 replicates + 3 nutrient-controls). The seeds were treated with 0.5 ml of the MeJA solutions and additionally received 1 ml of 1 mM KNO_3 to equalize nutrient levels among all seed cups.

Effect of MeJA on Dormant and Nondormant N. attenuata Seeds. Evidence from several plant species suggests that the effects of MeJA depend on the dormancy state of the seeds. Dormant seeds are stimulated while nondormant seeds tend to be inhibited (Creelman and Mullet, 1997). To determine if this pattern applies to *N. attenuata* seeds, we used two different genotypes, one dormant and one nondormant. Aqueous solutions of MeJA were made in a range of 10^{-3}–10^{-6} M (see previous section). The dormant seeds were treated either with the MeJA dilutions or exposed for 1 hr to a 1:300 dilution of liquid smoke [smoke: water (v/v); House of Herbs, Passaic, New Jersey, USA], that was then removed prior to application of the MeJA treatments. MeJA may stimulate dormant seeds to germinate in the absence of the smoke-derived germination signal, or germination may be affected when seeds have received the signal for germination (and hence ending their dormancy), either by increasing or decreasing the rate of germination.

To determine background and maximum germination, dormant seeds were treated with nutrients or the smoke solution followed by nutrients, respectively. Nondormant seeds were treated only with the MeJA dilutions, and controls were treated with nutrients to determine the maximum germination response. The experiment included 81 seed cup bioassays, with 54 replicate seed cup bioassays containing dormant seeds (2 treatments x 4 incremental M solutions $\times$ 2 volumes $\times$ 3 replicates + 3 nutrient-controls + 3 smoke-controls) and 27 replicate seed cup bioassays with nondormant seeds (1 treatment $\times$ 4 incremental M solutions $\times$ 2 volumes $\times$ 3 replicates + 3 nutrient-controls).

Effect on N. attenuata Germination of Exposure to MeJA and Sagebrush Volatiles. To determine if volatiles released by sagebrush and volatile MeJA could inhibit germination of *N. attenuata* seeds, we placed seed cups downwind of either potted sagebrush plants or MeJA-releasing devices. Twenty-four seed cups (12

with and 12 without lids) each containing 20 nondormant *N. attenuata* seeds on a thin layer of sand were placed into transparent plastic 18.5-l growth chambers (Rubbermaid; Wooster, Ohio) and covered with a piece of UV transparent Plexiglas (UV-T). Airflow was controlled with a fan (7 cm diam.) attached to the outside of each chamber, which pulled air through five small holes drilled on the opposite side of the growth chamber. Fan speed was regulated by a rheostat and used to circulate air through the growth chamber, with the seed cup bioassays located downwind of two potted, young sagebrush plants or a MeJA-releasing device, either releasing MeJA at a low (3.5 μg/hr or high (5 μg/hr) rate. For these devices, we used crimped-top 1.5-ml glass vials with Teflon inner linings containing 0.5 ml MeJA. Changes in the mass of the devices were used to determine MeJA emission rates. Similarly, 24 seed cup bioassays each containing 20 *N. attenuata* seeds on a thin layer of sand, 12 with and 12 without lids, were placed into a large growth chamber with 20 individually potted, mature sagebrush plants. Seed cups were distributed underneath the sagebrush plants. Six seed cups (3 with and 3 without lids) were haphazardly selected and removed 7, 14, 21, or 28 d after being enclosed into the small or large growth chambers. After removal, the seed cups were given sufficient amounts of 1 mM KNO_3 to saturate the sand and placed into a germination chamber. Germination was monitored for 9 d. Emission of MeJA by the sagebrush plants was quantified by volatile trapping of similar sagebrush plants (same age and size).

Germination of N. attenuata on Chaff: Manipulating MeJA Content by Heating. Significant amounts of MeJA were found in the chaff collected from *A. tridentata* plants in natural populations. Using aqueous extraction of three 1-g samples, the chaff was determined to contain approximately 2.57 $\pm$ 0.05 μg MeJA/g. The content of MeJA in the chaff was experimentally manipulated by heating it in an oven for 3 hr at 100°C or for 1 or 3 hr at 150°C to volatilize the MeJA. The amount of MeJA remaining in each chaff treatment was determined by trapping MeJA from the headspace of each sample (see the *X* axis of Figure 6 for rates of MeJA release). A layer of baked or unbaked chaff (approximately 0.1 g) was placed in a seed cup underneath a thin layer of sand, on top of which 10 nondormant or 10 dormant *N. attenuata* seeds were placed, with three replicate seed cup bioassays for each treatment. The dormant *N. attenuata* genotype was used to determine if heating produced substances similar to those found in smoke, which stimulate germination of *N. attenuata*. Two milliliters of 1 mM KNO_3 were added to each seed cup to saturate the chaff and sand layers. Germinated *N. attenuata* seeds were counted after 72 hr and then periodically until day 43. At the end of this period, seeds from each replicate within each treatment that had not yet germinated were removed, washed in distilled water, and transferred to a single seed cup containing only sand. Each seed cup received 1 ml of 1 mM KNO_3 and 500 μl of 1 mM GA_3 to determine the viability of the remaining seeds.

Effects of Water Extracts of Sagebrush Litter and MeJA on a Co-Occurring Congeneric Tobacco. In a previous study investigating positive and negative germination signals for *N. attenuata*, germination of *N. trigonophylla*, on a congeneric species of tobacco that co-occurs in similar habitats as *N. attenuata*, was not inhibited by water extracts produced from juniper litter while *N. attenuata* germination was completely inhibited (Preston and Baldwin, 1999). To determine if water extracts of sagebrush litter and MeJA affected germination of *N. trigonophylla* seeds, we treated seeds with aqueous dilutions of MeJA and extracts of sagebrush litter. For comparison, the treatments were also applied to nondormant *N. attenuata* seeds. Three seed cups for each species were treated with only 1 mM KNO_3 or distilled water as a control. The same sagebrush water extracts and dilutions were used as in the *N. attenuata* MeJA addition experiment, and three cups were treated with only distilled water, as controls.

Can Addition of MeJA to Diluted, Inactive Sagebrush Water Extract Restore Germination Inhibition? Given that sagebrush water extracts are chemically complex, containing many substances that might affect seed germination in addition to MeJA, it is important to determine the proportion of the germination inhibition that can be attributed to MeJA. We determined the MeJA concentration in a water extract of sagebrush litter known to completely inhibit germination of *N. attenuata* seeds, serially diluted this extract until it was no longer inhibitory, and added the appropriate amounts of MeJA to the diluted extracts to restore the amount of MeJA that was present in the original extract (Figure 7C inset). To prepare the extract, we collected the litter-containing A_0 horizon from underneath sagebrush plants at a single population (Apex Mine site, T43S R18W section 36) in Utah and stored it at -20°C until extracted. Seventy-five grams of litter was placed in a 2-l glass Erlenmeyer flask with 1.5 l of distilled water and stirred overnight at room temperature. The aqueous phase was transferred to 50-ml centrifuge tubes and centrifuged in an Avanti J-25 centrifuge (Beckman, Palo Alto, California, USA) at 12,000 rpm for 15 min at 10°C, and the supernatant was used immediately for MeJA quantification and in seed germination bioassays. The sagebrush litter water extract was applied undiluted or diluted with distilled water to produce a final dilution series of (sagebrush litter water extract–water, v/v): 1:0, 1:1, 1:4, 1:9, 1:14, 1:19, 1:24. As a control, three seed cup bioassays were treated only with water (see 0:1 on the *X* axis of Figure 7A,C). The concentration of MeJA was determined by extracting three replicates of 10 ml of undiluted sagebrush litter water extract. Within the samples, there was 195.97 $\pm$ 23.65 ng MeJA/ml. For this germination assay, we calculated the additions of MeJA based on 200 ng/ml. A dilution of MeJA was made by weighing 1.0 mg of MeJA into 10 ml CH_2Cl_2 and distributed to 20-ml glass scintillation vials as required for each dilution. The solvent was allowed to evaporate, and an appropriate amount of sagebrush litter water extract was added. The vials were sonicated to distribute the MeJA and shaken vigorously prior to application to the seeds.

Does MeJA Inhibit Germination of Other Tobacco Species That Do Not Co-Occur with Sagebrush? Given that both *N. attenuata* and *N. trigonophylla* are sensitive to MeJA, we examined if the sensitivity of MeJA is due to the specific habitat in which they co-occur, namely containing sagebrush, or if it is a more general species-specific response. Dilutions of MeJA were made as described in a previous section.

Effects of the Two Naturally Occurring MeJA Epimers on N. attenuata and A. tridentata. Germination were examined, with the exception that distilled water was used instead of 1 mM KNO_3. Serial dilutions were made to produce final aqueous solutions in the range of 10^{-1}–10^{-10} M MeJA. Controls were treated with water only to determine the maximum germination response within each species. All treatments were applied as 1-ml aliquots per seed cup. *Nicotiana* species had three replicate seed cup bioassays for each treatment, and *Artemisia* had five replicate seed cup bioassays for each treatment due to its more variable response. In summary, the experiment included 286 seed cup bioassays, with 231 seed cup bioassays containing *Nicotiana* species [7 species $\times$ 11 incremental M solutions (including water-control) $\times$ 3 replicates] and 55 seed cup bioassays containing *A. tridentata* [1 species $\times$ 11 incremental M solutions (including water-control) $\times$ 5 replicates].

Statistical Analyses. The percentage of all seeds germinating in each bioassay container at each observation was arcsine-transformed to meet the assumptions of normality for the statistical tests. Repeated-measures ANOVAs on the transformed percentages were used to analyze main effects. One-way ANOVAs were used to evaluate differences on the treatments on individual days. Fisher's PLSD *post hoc* tests were performed on data from the final day of the experiments (prior to GA_3 addition) to compare individual treatments. Analyses were performed with the STATVIEW 5.0 statistical package (Abacus Concepts, Berkeley, California).

RESULTS

Burial of Seed Bags and Seed Germination in Soils Collected Near Sagebrush. Seeds in seed bags exposed to soil had delayed germination compared to seeds in seed bags that were in protective plastic bags (Figure 1). However, there were no significant differences in germination rate or final germination percentages among the different locations for seeds in either the unprotected (net; repeated measures ANOVA $F_{18,240} = 0.972$, $P = 0.49$; ANOVA on day 9, $F_{3,40} = 0.864$, $P = 0.47$) or protected bags (plastic; repeated measures ANOVA $F_{18,240} = 1.090$, $P = 0.36$; ANOVA on day 9, $F_{3,40} = 1.574$, $P = 0.21$). Enclosure in plastic bags clearly reduced or eliminated exposure to sagebrush allelochemicals, but alternative explanations for the germination delay should be considered. Plastic bags may have altered the seeds' microenvironment, such as temperature, humidity, and

exposure to soil microbes, and these alterations may account for the germination delay.

To standardize microclimate exposure, we examined the germination of naive seeds on soils collected at different locations in relation to sagebrush. Seeds on soil collected from underneath sagebrush showed less germination than seeds placed on soil collected from between sagebrush plants or outside of the sagebrush population (Figure 2; one-way ANOVA $F_{2,22} = 13.541$, $P = 0.001$). *Post-hoc* analysis revealed that soil collections from between and outside were different from under ($P's < 0.001$) but not different from each other ($P = 0.99$). We conclude that germination of *N. attenuata* seeds can be affected by unknown factors that may be present in the soil from the sagebrush.

Germination of N. attenuata Seeds Exposed to A. tridentata Seeds or Seedlings. The final germination percentages of *N. attenuata* seeds exposed to different numbers of *A. tridentata* seeds or seedlings were not significantly different (one-way ANOVAs: $F_{5,24} = 1.879$, $P = 0.14$ and $F_{3,11} = 2.466$, $P = 0.12$, respectively). Likewise, repeated measures ANOVAs found no differences among the rates of germination (seeds: $F_{30,144} < 0.1$, $P < 0.001$; seedlings: $F_{18,66} = 1.525$, $P = 0.11$). We conclude that neither seed–seed competition nor seed–seedling allelochemically mediated interactions are likely to be important determinants of *N. attenuata*'s seed bank dynamics.

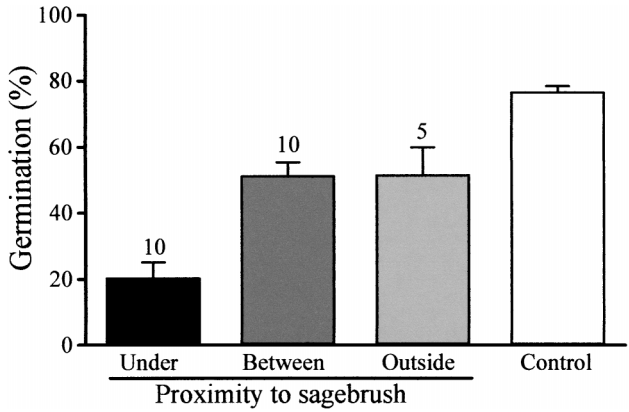

FIG. 2. Mean (+ 1 SEM) seed germination percentages at day 8 for seeds placed on 2 cm^3 of the A_1 soil layer (without litter) from directly under sagebrush plants (black bar), between sagebrush plants (dark gray bar), and approximately 10 m from the sagebrush stand (light gray bar). Seeds germinating on sand served as a control (clear bar). Values above the bars indicate the number of soil collections tested for each site; three replicate seed germination bioassays were used for each soil collection.

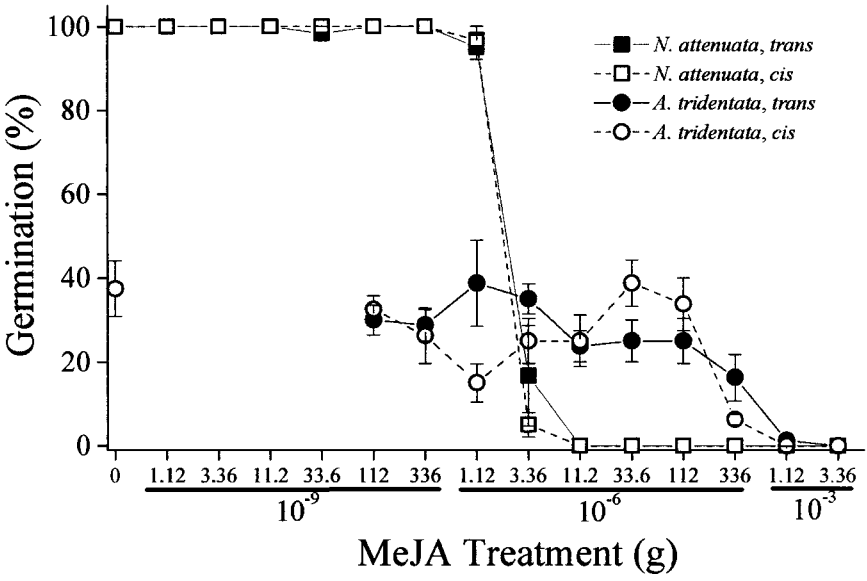

FIG. 3. Mean (±1 SEM) percentage germination response at day 8 for *N. attenuata* (squares) and *A. tridentata* (circles) seeds exposed to increasing quantities of trans- (solid symbols) and *cis*-MeJA (white symbols). The x-axis indicates amount of MeJA (1.12 ng to 3.36 mg/seed cup) applied to the 20 seeds in each bioassay. For each treatment, three replicate bioassays were used for *N. attenuata* seeds and four for *A. tridentata* seeds.

Effects of MeJA Epimers on N. attenuata and A. tridentata Germination. There was no difference between either species in response to *trans*- and *cis*-MeJA (Figure 3; *N. attenuata*: $F_{1,82} = 1.341 \times 10^{-6}$, $P = 0.99$; *A. tridentata*: $F_{1,78} = 0.385$, $P = 0.54$), and the replicates within the *trans* and *cis* treatments were combined for each MeJA amount to increase statistical power for our subsequent analyses. Compared to nutrient-controls, germination was significantly ($P < 0.001$) inhibited in *A. tridentata* when 20 seeds in a seed cup were exposed to 336 μg MeJA (16.8 μg/seed) but in *N. attenuata*, 1.12 μg MeJA was inhibitory for 20 seeds in a seed cup (0.056 μg/seed; $P = 0.016$). The greater tolerance of *A. tridentata* is consistent with predictions for the allelopathic use of a germination inhibitor: the releaser must be less sensitive to the allelochemical than the receiver.

Effect of MeJA on Dormant and Nondormant N. attenuata Seeds. MeJA inhibited the germination of both dormant and nondormant seeds of *N. attenuata*, but dormant seeds were more sensitive than nondormant seeds (Figure 4). Dormant seeds when treated with either water or smoke germinated significantly less when exposed to a range of MeJA quantities (one-way ANOVAs: $F_{8,18} = 2.569$, $P = 0.046$ and $F_{8,18} = 39.107$, $P < 0.001$, respectively). Dormant and nondormant

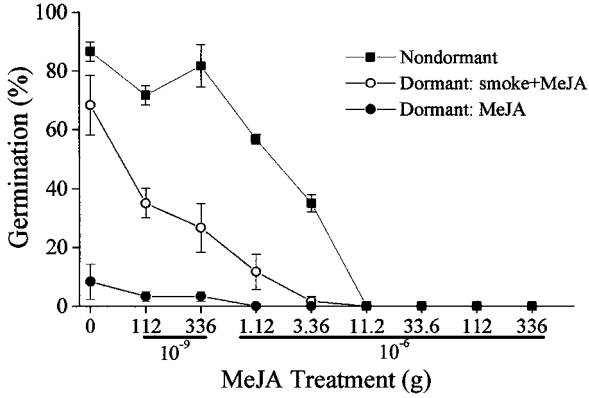

FIG. 4. Mean (±1 SEM) percentage germination response on day 8 for nondormant (squares) and dormant (circles) genotypes of *N. attenuata* seeds to a range of MeJA quantities. Dormant genotypes require exposure to a component of smoke before they initiate germination. Dormant seeds were treated with MeJA either with (open) smoke factors or without (solid) to determine if MeJA might function as a stimulant for the dormant genotypes. Each treatment consisted of three replicate bioassays of 20 seeds each.

N. attenuata seeds had different sensitivities to MeJA (two-way ANOVA $F_{7,32} = 12.705$, $P < 0.001$). *Post-hoc* analyses revealed that the germination of dormant seeds pretreated with smoke was inhibited ($P = 0.004$) below that of smoke-controls when seed cups were exposed to 112 ng MeJA (5.6 ng/seed). However, nondormant seeds revealed a more variable response with significant inhibition at 112 ng ($P = 0.005$) but not at 336 ng ($P = 0.37$) per seed cup (5.6 and 16.8 ng/seed, respectively) and inhibition again at all higher exposures ($P \leq 0.032$). Germination of nondormant seeds in a previous experiment (Figure 4) was inhibited with 3.36 μg MeJA per seed cup (168 ng/seed). Although we cannot directly compare the inhibition amounts between the experiments, it is interesting to note that each of these tested seeds were from different collection sites in Utah. This suggests that the variation between dormant and nondormant lines may be due to differences among genotypes rather than differences in their dormancy state. We conclude that the germination of *N. attenuata* seeds is inhibited by the presence of MeJA, regardless of their state of dormancy.

Effect on Seed Germination of Exposure to Sagebrush and MeJA Volatiles. The environments in this experiment were not replicated and, therefore, we could not compare germination responses between the different environments, but only within an environment (uncovered versus covered). Exposure to MeJA and sagebrush volatiles delayed germination (Figure 5, delays in germination determined by one-way ANOVAs performed on each day to compare transformed germination percentages between covered and uncovered seed cups harvested simultaneously,

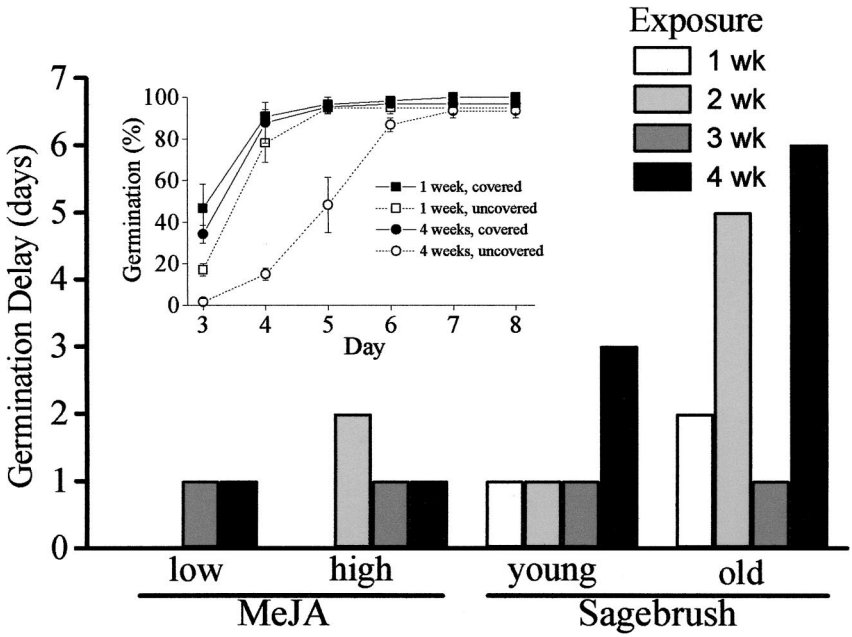

FIG. 5. Magnitude of statistically significant delays in germination of seeds that were exposed for different lengths of time to volatile MeJA or airborne volatiles released from mature or young sagebrush plants. Uncovered seed cups containing 20 *N. attenuata* seeds on dry sand were placed into small growth chambers with either MeJA-releasing devices emitting MeJA at a low (3.5 μg/hr) or high (5.0 μg/hr) rates, two small sagebrush plants (young) or nothing (control). In a large growth chamber, similar seed cups, with or without covers, were haphazardly placed underneath mature sagebrush plants (old). For seed cups with equivalent exposure periods, significant delays from controls were determined with one-way ANOVAs on germination rates on days 3–8. Three replicate germination bioassay containers from each treatment and under each age of sagebrush were removed at weekly intervals. Inset depicts the mean ($\pm$1 SEM) percentage germination response for the seed cups with (solid) or without (open) covers exposed to the volatile emissions of the mature sagebrush plants for 1 wk (squares) or 4 wk (circles) to illustrate how the germination delays were determined.

$Ps < 0.05$). Under our experimental conditions in the laboratory, young sagebrush plants released 8 ng/g/hr plant. Each sagebrush plant in the small growth chamber had an approximate foliage mass of 200 g, indicating that combined MeJA levels from both plants were approximately 3.2 μg/hr. MeJA was released from the releasing devices at low and high rates (3.5 and 5 μg/hr, respectively). The mature sagebrush in the large growth chamber released approximately 2 ng/g/hr. Each

mature sagebrush plant had an approximate foliage mass of 400 g, indicating the total MeJA emission from all mature plants in the large growth chamber was approximately 16 μg/hr. Both volatile MeJA and emissions from sagebrush delayed germination similarly, and the delays appeared to correlate positively with the quantities of MeJA being released. Germination delays were longer in seeds sharing growth chamber space with the mature sagebrush or the high MeJA-releasing device than for seeds sharing growth chamber space with the young sagebrush plants or the low MeJA-releasing device.

Germination of N. attenuata on Chaff; Manipulating MeJA Content by Heating. Heating the chaff to 150°C did not stimulate germination by producing the positive cue; germination of dormant seeds was inhibited by exposure to the heated chaff compared to smoke-treated controls (data not shown; one-way ANOVA $F_{5,12} = 16.731$, $P < 0.001$). *Post-hoc* comparisons revealed that germination of seeds exposed to each chaff treatment was less than in the smoke-controls (Ps < 0.001) and not significantly different than in nutrient-controls (Ps ≤ 0.07). The germination rates in the unheated and the 100°C treatments) were not significantly different from each other ($P = 0.24$) but were less than that of the 150°C treatments ($P < 0.001$). At 150°C, the germination in the 1- and 3-hr heating intervals were not different ($P > 0.39$). The germination response correlated negatively with the quantity of MeJA volatilized from the heat-treated chaff. The amount of MeJA trapped from the headspace represents the amount of MeJA present in the chaff samples (i.e., the lower amounts of MeJA trapped indicate lower quantities of MeJA present in the chaff). Hence, the lower the MeJA emission, the lower the content of MeJA in the chaff, the greater the germination response. After removing the seeds from their respective chaff environments, a high percentage of germination was achieved in each treatment (Figure 6 inset), demonstrating that germination was inhibited by chaff exposure but it was not toxic to the seeds.

Effects of Water Extracts of Sagebrush Litter and MeJA on a Co-Occurring Congeneric Tobacco. Seeds of *N. trigonophylla* responded differently to water extracts of sagebrush litter than did *N. attenuata* seeds (Figure 7A; two-way ANOVA $F_{7,32} = 11.559$, $P < 0.001$). A repeated measures ANOVA revealed that *N. trigonophylla*'s germination rate differed among the dilutions ($F_{35,80} = 4.606$, $P < 0.001$). Seeds treated with the undiluted sagebrush litter water extract germinated slower than all other dilutions (Ps ≤ 0.019), except for the 1:1 dilution ($P = 0.058$), which additionally germinated slower than the 1:14 dilution ($P = 0.041$). *Post-hoc* analyses on final germination percentages on day 8 revealed that *N. trigonophylla* seeds were not inhibited by any dilution of water extract of sagebrush litter (Ps ≤ 0.074) when compared to the water-controls. However, seeds treated with a dilution of 1:14 (sagebrush extract: water, v/v) germinated more than those in the water-control ($P = 0.045$). In contrast, *N. attenuata* seeds were inhibited at all dilutions (Ps ≤ 0.003).

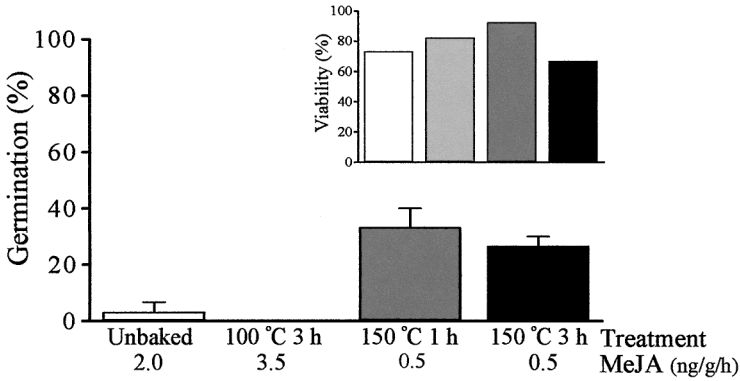

FIG. 6. Mean (+ 1 SEM) germination on day 43 for *N. attenuata* seeds exposed to sagebrush litter or sagebrush litter that had been heated at 100°C for 3 hr (light gray bar), 150°C for 1 hr (dark gray bar), or 150°C for 3 hr (black bar). Each treatment had three replicate bioassay containers, each with 20 seeds. The amount of MeJA released from litter after heating (reflecting the amount of MeJA remaining in the chaff) is shown below the x axis. The inset depicts the viability of all seeds removed from the three replicates of each treatment, determined after seeds were rinsed with water and treated with gibberellic acid (GA_3).

Similarly, *N. trigonophylla* and *N. attenuata* seeds showed different sensitivities to MeJA treatment (Figure 7B; two-way ANOVA on day 8, $F_{8,36} = 9.914$, $P < 0.001$). *Post-hoc* comparisons revealed that the germination of both species was inhibited by the application of 1.12 μg MeJA per seed cup (56 ng/seed) as compared to nutrient-controls (*N. trigonophylla* $P < 0.001$, *N. attenuata* $P = 0.037$). To compare each species for each MeJA treatment, we standardized the germination numbers for day 8 by making them relative to the control by subtracting the germination percentages for each replicate in each treatment from the average germination in their respective nutrient controls and dividing by their respective nutrient-control average. *Post-hoc* analyses revealed that *N. trigonophylla* was more inhibited than *N. attenuata* when seeds were treated with 1.12 (56 ng/seed) and 3.36 μg MeJA (168 ng/seed; Ps ≤ 0.048).

We conclude that germination of nondormant seeds from the co-occurring tobacco, *N. trigonophylla*, can be delayed by water extracts of sagebrush litter but not inhibited. This is in contrast to *N. attenuata*, whose germination can be completely inhibited by the same treatments. While in this experiment it appears that *N. trigonophylla* is more sensitive to MeJA than *N. attenuata*, we can only conclude that both species are sensitive. The variation in the germination response of *N. attenuata* seeds exposed to dilutions of MeJA, possibly due to genotypic variation, makes this experiment insufficient to demonstrate fine-grained differential sensitivities between the two congeneric tobaccos.

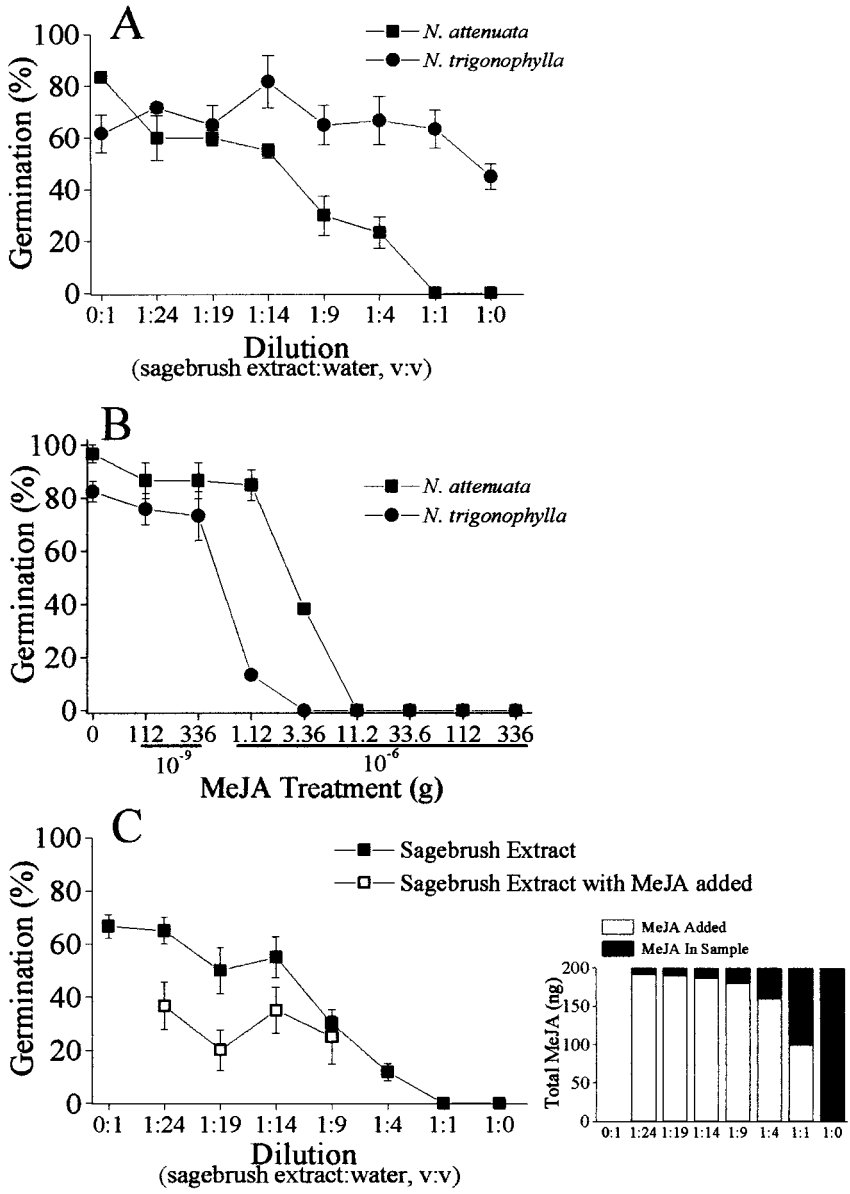

FIG. 7. Mean (±1 SEM) percentage germination response on day 8 for *N. attenuata* (squares) and its nondormant conspecific, *N. trigonophylla* (circles) to (A) dilutions of the water extract produced from intact sagebrush litter, (B) dilutions of MeJA, and (C) dilutions of water extract produced from intact sagebrush litter alone (solid symbols) or

Can Addition of MeJA to Diluted, Inactive Sagebrush Water Extract Restore Germination Inhibition? By diluting the sagebrush extract, we can decrease the inhibition of *N. attenuata* seeds. To determine if MeJA is an active allelopathic agent within the extract, we supplemented the dilutions with quantities of MeJA such that all dilutions had the same quantity of MeJA (200 ng/ml; Figure 7C inset). Water extract produced from sagebrush litter inhibited germination of *N. attenuata* seeds in all dilutions tested as compared to water-controls (Figure 7C, Ps < 0.001). This was also true of water extracts of sagebrush litter with additions of MeJA (Figure 7C, Ps < 0.001). A two-way ANOVA revealed differences between the sagebrush extract alone and sagebrush extracts with the addition of MeJA ($F_{1,16} = 13.621$, $P = 0.002$). However, the undiluted sagebrush extract inhibited germination more effectively than dilutions receiving additional MeJA to restore levels found in the undiluted sagebrush extract (one-way ANOVA $F_{4,10} = 7.730$, $P = 0.004$). Additionally, the 200 ng MeJA/ml (10 ng/seed) contained within the undiluted sagebrush extract is within the range of the quantity of MeJA that begins to affect germination of *N. attenuata* seeds treated with aqueous solutions of MeJA (Figure 5). Comparing the amount of inhibition resulting from the MeJA additions for each sagebrush extract dilution, we determined that 16.67–60% of the inhibitory activity of the original extract could be attributed to the MeJA. We conclude that although MeJA could account for a portion of the inhibitory activity of the extract, it is not the sole inhibitory component, and it likely acts in concert with other allelochemicals.

Does MeJA Inhibit Germination of Other Tobacco Species That Do Not Co-Occur with Sagebrush? Comparing seed germination responses on day 9 within each species, seeds of all tobacco species responded differently to the MeJA treatments (one-way ANOVAs $F_{10,22}$s ≤ 679.39, Ps < 0.001) as did the seeds of *A. tridentata* ($F_{10,44} = 10.95$, $P < 0.001$). *Post-hoc* analysis revealed differences in the amount of MeJA necessary to inhibit germination of each species below that of the water-controls. In this bioassay, *N. trigonophylla* was the most sensitive, with germination inhibited when 0.224 μg MeJA/seed cup (11.2 ng/seed) was applied. Both *N. attenuata* and *N. benthamiana* were inhibited by 22.4 μg MeJA/seed cup (1.12 μg/seed). *N. sylvestris* and *N. glauca* as well as *A. tridentata*

←

supplemented with sufficient quantities of MeJA to restore the MeJA content to levels found in the undiluted extract (open symbols). GC-MS quantification of MeJA contents in three replicate samples from the sagebrush litter water extract revealed that the extract contained 195.97 $\pm$ 23.65 ng/ml. The inset depicts the amount of MeJA added (open bar) to each dilution of the diluted sagebrush water extracts to supplement the MeJA in the sample (black bar), restoring the total MeJA content to 200 ng/ml. Each treatment had three replicate bioassays of 20 seeds.

seeds were inhibited by 224 μg MeJA/seed cup (11.2 μg/seed). *N. repanda* and *N. tabacum* were the least sensitive species, with germination inhibition at 2240 μg MeJA/seed cup (112 μg/seed). Although the quantity of MeJA required to inhibit germination of *N. attenuata* seeds was greater than in previous experiments, it is less than the amount required to inhibit *A. tridentata* germination. Tobacco species that do not co-occur with sagebrush are less sensitive to MeJA, with four of five nonassociated *Nicotiana* species requiring more MeJA to inhibit germination.

DISCUSSION

If an allelopathic interaction is to occur between plant A (sender) and plant B (receiver): (1) plant A must produce an active substance; (2) the substance must leave plant A; and (3) the substance must reach plant B in a concentration sufficient to influence its growth (Newman, 1978). Without question, MeJA is a highly active compound. Sagebrush produces MeJA in prodigious quantities (Farmer and Ryan, 1990; Karban et al., 2000; Hildebrand et al., 2000; Preston et al., 2001) and releases it into its surrounding environment by both volatile and aqueous transport (Karban et al., 2000; Preston et al., 2001). Here, we demonstrate that MeJA is present in sufficient quantities to affect the seed bank of *N. attenuata*.

If MeJA is an active component released by sagebrush that inhibits *N. attenuata* germination, it must enter the environment in amounts that would be active even after environmental dilution. Sagebrush releases MeJA by both volatilization and leaching. The volatile release of MeJA by undamaged sagebrush in the field is approximately 10–20 ng/g/hr (Karban et al., 2000). An average sagebrush plant may have a leaf mass of approximately 1 kg, suggesting that MeJA is released from a single plant at 10–20 μg/hr. Run-off collected by spraying sagebrush with water has approximately 2 ng MeJA/ml (Preston et al., 2001), and water extracts of sagebrush litter contained approximately 200 ng MeJA/ml. Moreover, we estimated the amount of MeJA that accumulates in the A_1 soil layer by approximating the MeJA content of the soil (1:1, potting soil–sand) collected from sagebrush plants growing in the growth chamber. To determine the recovery rate of MeJA, soil not exposed to sagebrush plants was treated with a known amount of MeJA. Samples were placed in volatile trapping containers and positioned in a water bath at 50°C. The MeJA volatilized from the soils was trapped as described in Methods and Materials (see *Volatile Exposure to MeJA and Sagebrush Affecting Germination of* N. attenuata). The average recovery rate from the soil with the known quantity of MeJA was determined to be approximately $8.46 \pm 1.50\%$. Using this recovery rate and assuming a linear relationship, we estimated the MeJA content in soils to be 11 and 14 ng/g under young and mature sagebrush plants, respectively. Germination of *N. attenuata* was significantly inhibited by 1.12 μg MeJA/seed cup (56 ng/seed; Figure 3). When considering the multiple routes of

transport, it is reasonable that MeJA is present in sufficient quantities to influence the seed bank of *N. attenuata*.

One of the principal criticisms of research on allelopathy is the frequent lack of correlation between laboratory bioassays and field studies or observations (Wardle et al., 1996). In the field, germination of *N. attenuata* is inhibited by an unidentified component located under and around sagebrush (Figure 1), with lower germination on soils collected from directly underneath sagebrush than on soils collected from between sagebrush plants and outside of the sagebrush population (Figure 2). This interaction seems to be controlled by adult sagebrush, as *A. tridentata* seeds and seedlings did not affect the germination response of *N. attentuata* seeds when sharing the small environment of a seed cup. This inhibition of germination can be simulated by exposure to volatile emissions of sagebrush and MeJA (Figure 5) and applications of water extracts of sagebrush litter and aqueous solutions of MeJA (Figure 7 and Figures 3 and 4, respectively). By manipulating MeJA levels in natural sagebrush products [chaff (Figure 6), water extracts (Figure 7)], we found a strong negative correlation between *N. attenuata*'s germination and the amounts of MeJA present. However, there is a discrepancy between the MeJA amounts that inhibited germination in the aqueous-and sagebrush water extract-based bioassays. The 200 ng MeJA/ml that was contained in the MeJA-supplemented sagebrush extract dilutions was 11.2 times less than the amount of MeJA that inhibited germination in aqueous dilutions. This may be explained either by the lipophilic components in the sagebrush litter water extract helping to disperse the otherwise insoluble MeJA and increasing its delivery to the seeds or possibly by a synergism occuring between the MeJA and the negative germination signal. In contrast to *N. attenuata*, seeds of *A. tridentata* are significantly less sensitive to applications of MeJA, requiring 300 times the amount of MeJA to inhibit germination. This is consistent with a fundamental prediction about the release of allelochemicals. If a plant is to release an active compound as a general and effective toxin into its surrounding environment, it must become desensitized to the compound itself. Moreover, four of five other *Nicotiana* species that are not known to occur with sagebrush required either the same or more MeJA than sagebrush to inhibit germination. This suggests that *N. attenuata* and *N. trigonophylla* may have evolved sensitivity to their MeJA-releasing neighbor, preventing them from germinating in disadvantageous competitive situations, and the idea further supports that MeJA is an active allelopathic compound in this habitat. Therefore, our bioassays in the laboratory reflect our results from the field. Moreover, we identified the active chemical component.

The final step in demonstrating an allelopathic interaction and the active chemical component responsible for mediating the interaction is the application of the proposed chemical under natural conditions, following the criteria set-up by Koch's postulates (Harper, 1977). While Koch's postulates, proposed for studying disease, are difficult to apply to allelopathic research due to fundamental

differences between how disease spreads in a body (by replication and one-to-one correspondence for microbe and disease) and the activity of allelopathic compounds in the environment [no replication and, instead, degradation as well as possible syngerisms between different components that do not produce one-to-one relationships between chemicals and allelopathic response (Williamson, 1990)], they provide a framework within which to test proposed allelopathic substances. The ultimate test will likely come through genetic manipulation of the plants with proposed allelopathic tendencies to eliminate the release of the putative active components, placing them back into the natural environment and observing the effects. In such an experiment, all other variables, such as resource competition, shading, releases of other chemicals, etc., remain unchanged while the putative toxin is absent. In the absence of a sagebrush plant that does not emit MeJA, our combinations of field and laboratory experiments, nontheless, provide strong evidence that MeJA mediates interactions between sagebrush and seeds of *N. attenuata*.

This example of allelopathy should not necessarily be considered a negative interaction between these species. Inhibition of *N. attenuata* germination likely benefits both the sagebrush plant (by reducing competition) and the *N. attenuata* seed bank (by preserving the seed bank of a poor competitor until competition levels are reduced, most likely by fire). Eavesdropping on chemical signals in its surrounding environment appears to be crucial for *N. attenuata* to locate its postfire niche (Preston and Baldwin, 1999). It may be common that species specializing in this niche are sensitive to the release of substances by later successional species. Annuals also showed reduced density numbers near *Encelia farinosa* (Compositae), including *Emmenanthe penduliflora* (Went, 1949; Friedman, 1987), another annual that germinates in response to component(s) in smoke (Keeley et al., 1985; Keeley and Pizzorno, 1986). However, since MeJA is such a biologically active substance for a large number of plants, it should be considered further in other studies on plant–plant interactions in *Artemisia*-dominated landscapes.

Acknowledgments—We thank Brigham Young University for use of their field station (Lytle Preserve), H. and D. Madrigal for their support during our field experiments, H. Thomas for helping to count seeds and sew the seed bags, Drs. G. Laue and B. Krock for graciously sharing their analytical expertise in the laboratory, E. Claussen for helping with the figures, and S. Lorenz for comments on the manuscript.

(Received August 12, 2002; accepted August 27, 2002)

Abstract—Twenty-nine *Anopheles gambiae* candidate Odorant Binding Proteins (OBPs) were characterized for similarity to OBPs of *Drosophila melanogaster* and other insects. Twenty-five of these sequences were identified by BLAST searching the *A. gambiae* genome database. Several *A. gambiae* sequences were significantly similar to the *D. melanogaster* OBPs OS-E/OS-F, LUSH and PBPRP2/PBPRP5. Exon boundary comparisons suggests that two *A. gambiae* genes are orthologues of OS-E and OS-F, justifying the names *Agam*OS-E (EAA01090, AF437886) and *Agam*OS-F (EAA14641, AF437884). If these are orthologues, then the gene duplication establishing the OS-E and OS-F lineages predated the divergence of mosquitoes and flies. The identification of orthologous OBPs and other chemosensory genes between *D. melanogaster* and *A. gambiae* should accelerate the transfer of physiological and behavioral information between these two species.

Key Words—Odorant Binding Protein, OBP, evolution, odor detection, pheromone detection, chemosensory proteins, *Anopheles gambiae*, mosquito, olfaction.

INTRODUCTION

Odorant Binding Proteins (OBPs) are small water-soluble proteins thought to transport odors to receptor proteins in olfactory neuron membranes (Vogt et al., 1999). OBPs comprise a multigene family; thirteen have been identified in *Manduca sexta* through direct sequencing, and 38 in *Drosophila melanogaster* through direct sequencing and genome analysis (Robertson et al., 1999; Galindo and Smith, 2001;

* To whom correspondence should be addressed. E-mail: VOGT@BIOL.SC.EDU

0098-0331/02/1100-2371/0 © 2002 Plenum Publishing Corporation

Graham and Davies, 2002; Vogt et al., 2002). OBPs are differentially expressed among olfactory sensilla, contributing to the unique phenotypes and odor sensitivities of these sensilla (de Bruyne et al., 2001; Shanbhag et al., 2001). In this study, OBP genes of *D. melanogaster* and other insect species were used to identify OBPs from the *A. gambiae* genome, and the likely *A. gambiae* orthologues of the *D. melanogaster* OBPs OS-E and OS-F (also known as PBPRP3) are identified.

METHODS

Amino acid sequences of previously reported OBPs were used in a BLAST-P search of the *A. gambiae* genome through the NCBI web site (8/2002). This database identifies hypothetical gene coding regions and the corresponding amino acid sequences. Sequences with an E-value of 0.05 or lower were accepted. Sequences were aligned using ClustalX, and a neighbor joining tree was constructed using MEGA2. No effort was made to modify sequences, although previously reported versions of these sequences were used if available. Exon boundaries were determined by translating the genomic sequences into multiple reading frames to identify the amino acid sequences bounding exon/intron transitions.

RESULTS AND DISCUSSION

Table 1 lists 29 candidate OBP genes from *A. gambiae.* Twenty-five unique genes were identified through BLAST search analysis of the *A. gambiae* genome and are listed with the protein accession number (EAA#) and the corresponding gene scaffold (AAA#). Four pairs of identified sequences were considered to represent the same genes; small variations in nucleic acid and amino acid sequences and very low variation in third base positions of codons suggested that differences between members of each pair was either due to allelic variation or sequencing error. Six of the 25 sequences were previously reported from direct sequence analysis (Biessmann et al., 2002). Three additional sequences were also previously reported as *A. gambiae* OBP. The *Agam*D7 gene, encoding a salivery protein, was also identified as a candidate OBP homologue.

Figure 1A shows a sequence similarity tree assembled from an alignment of the 29 candidate *A. gambiae* OBP sequences, 38 *D. melanogaster* OBP sequencs (Galindo and Smith, 2001; Graham and Davies, 2002; Vogt et al., 2002) and OBP related sequences from diverse other species. The long-branch lengths in this tree indicate the considerable sequence divergence between most of these sequences. Most sequences are in branches specific to a given insect group, though several similarity groups do include multiple insect groups. Three similarity groups include both A. gambiae and D. melanogaster sequences: OS-E/OS-F, LUSH, and PBPRP2/PBPRP5. The OS-E/OS-F group includes 1 sequence from Culex

quinquefasciatus (Ishida et al., 2002) and 4 sequences from A. gambiae; this similarity group was further characterized.

OS-E and OS-F are the most similar of the *D. melanogaster* OBPs (Vogt et al., 2002). The OS-E/OS-F genes are adjacent within a 5000 nucleotide region of chromosome 3, have conserved exon/intron boundaries, and are co-expressed in a subset of olfactory sensilla in the adult antenna, and are, thus, assumed to be co-derived from a gene duplication event (Hekmat-Scafe et al., 2000; Vogt et al., 2002).

Figure 1B represents an amino acid alignment of the 7 proteins of the OS-E/OS-F group. All 7 proteins contain 6 cysteins that co-align. Exon boundaries were determined for each sequence (the *Cluex* gene was not available). *Dmel*OS-E and *Dmel*OS-F have two conserved exon boundaries at positions 79 and 104. *Dmel*OS-F has an additional short exon at the extreme C-terminal end (position 194) encoding 5 amino acids (HYFLP), which align with a similar sequence in *Dmel*OS-E (HYFLV). *Agam*(EAA01090) also contains exon boundaries at alignment positions 79 and 104 as well as the C-terminal sequence HYFIP, but lacks a C-terminal exon. *Agam*(EAAl4641) has an exon boundary at alignment position 104 and a C-terminal exon at position 194 with tbe sequence HYFLV, but lacks the position 79 boundary. *Agam*(EAAl4656) and *Agam*(EAAl4622) have only single exons. The genes of *Agam*(EAAl4656), *Agam*(EAAl4622), and *Agam*(EAAl4641) reside in a cluster; *Agam*(EAA14656) and *Agam*(EAAl4622) are separated from

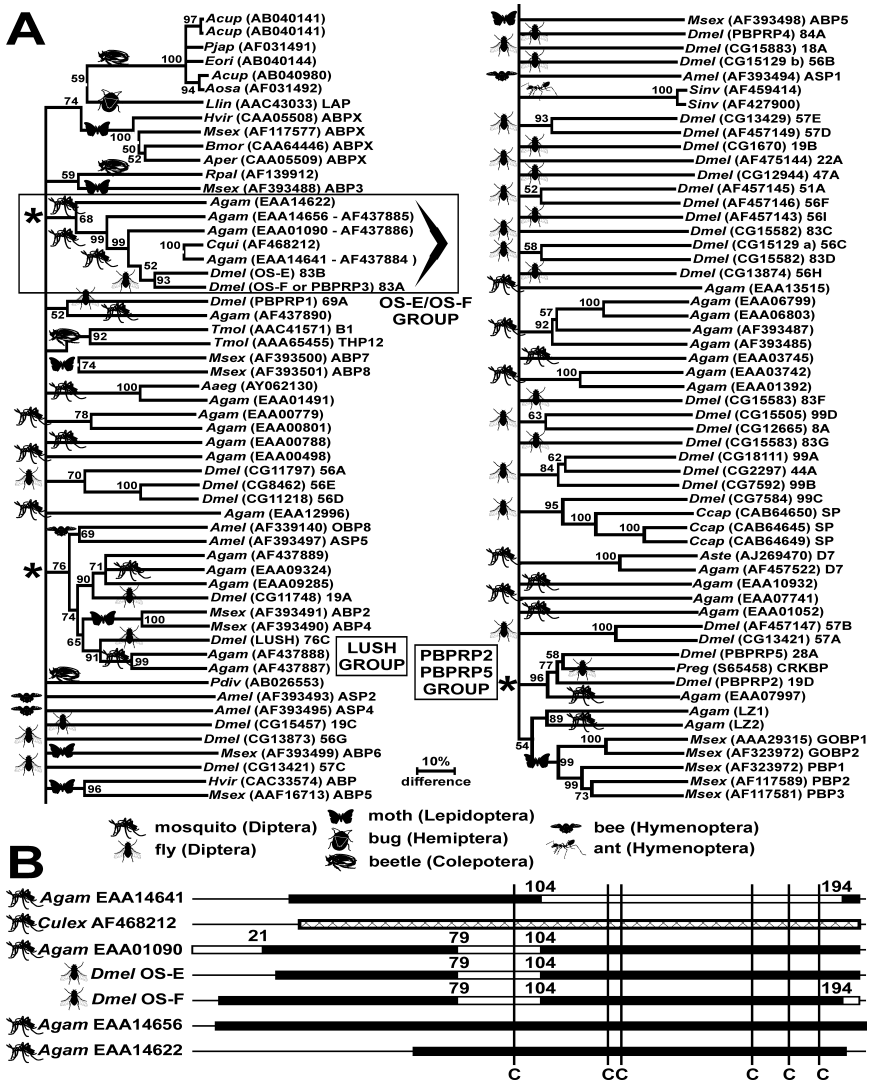

FIG. 1. A. A neighbor joining tree is shown; branches are collapsed to 50% bootstrap support based on 1000 replicates. The single tree was separated in two for ease of viewing. *Agam*LZ1 and *Agam*LZ2 are unpublished from Larry Zwiebel. B. A graphical representation of an amino acid alignment of proteins belonging to OS-E/OS-F similarity group (1A). The overall lengths represented include alignment gaps; the numbers refer to the amino acid position at the C-terminal side of a domain in the aligned sequence. Exon domains are indicated by alternating white-filled and black-filled; vertical lines indicate positions of conserved cysteins (C).

each other by about 3,000 base pairs (bp) and from *Agam*(EAAl4641) by about 200,000 bp. *Agam*(EAA01090) is separated from this cluster by about 40 million bp.

The conservation of exon boundaries suggests the evolutionary history of these genes. The intron-containing *Agam*(EAAl4641) and *Agam*(EAA01090) are presumably derived from a gene duplication based on sequence similarity and conservation of exon boundaries; the two genes presumably later became separated by a translocation event. The gene cluster of *Agam*(EAAl4641), *Agam*(EAAl4656), and *Agam*(EAAl4622) likely derived through gene duplications, since tbe probability of related genes becoming located near each other by translocation is small given tbe overall size of the genome. If this cluster did derive through gene duplication, then *Agam*(EAAl4641) is the likely founder since its relation to *Dmel*OS-E and *Dmel*OS-F suggests an ancestry that predates the divergence of flies and mosquitoes. It is not obvious how *Agam*(EAAl4641) could have produced an intron free copy that then duplicated to *Agam*(EAAl4656) and *Agam*(EAAl4622); perhaps the *Agam*(EAAl4641) transcript was captured by a retrovirus and reinserted into the genome with some homologous recombinatorial bias. This gene cluster is absent in *D. melanogaster* (Vogt et al., 2002) and, thus, may have arisen independently in mosquitos.

Agam(EAA01090) and *Agam*(EAAl4641) are probable orthologues of *Dmel*OS-E and *Dmel*OS-F. Hekmat-Scafe et al. (2000) characterized these genes from multiple *Drosophila* species and suggested OS-E/OS-F diverged early in the evolutionary history of flies. *Agam*(EAA01090) contains both the 79 and 104 exon boundaries, but lacks the 194 boundary that characterizes *Dmel*OS-F. *Agam*(EAAl4641) contains the position 194 exon boundary of *Dmel*OS-F but lacks the position 79 boundary characteristic of both *Dmel*OS-E and *Dmel*OS-F. Assuming that loss of an existing intron is more probable than the random gain of an intron at a specific position, then the presence of the position 194 boundary suggests that *Agam*(EAA01090) and *Dmel*OS-E are orthologues, and *Agam*(EAA01090) might be named *Agam*OS-E. Similarly, *Agam*(EAAl4641) and *Dmel*OS-F are apparent orthologues, but *Agam*(EAAl4641) has independently lost one of its introns (position 79); *Agam*(EAAl4641) might be named *Agam*OS-F. The duplication that established these two gene lineages apparently occurred before the divergence of mosquitoes and flies.

Not all members of the OBP gene family are involved in olfaction (Vogt et al., 2002), and no dipteran OBPs including OS-E and OS-F have actually been shown to bind odor molecules. However, the demonstrated expression of OS-E and OS-F in olfactory sensilla of *Drosophila* (Hekmat-Scafe et al., 1997) and the structural similarities of these two proteins to OBPs that have been shown to bind odors supports their role in odor detection. The conservation of these genes between mosquito and fly suggests OS-E and OS-F have a singularly important function in both species groups.

(Received January 28, 2002; accepted August 9, 2002)

Abstract—We studied the interaction between plants (horsenettle; *Solanum carolinense*) and herbivorous insects (flea beetles; *Epitrix* spp., and tobacco hornworm; *Manduca sexta*) by focusing on three questions: (1) Does variation in nitrogen availability affect leaf chemistry as predicted by the carbon-nutrient balance (CNB) hypothesis? (2) Does variation in plant treatment and leaf chemistry affect insect feeding? (3) Is there an interaction between the insect herbivores that is mediated by variation in leaf chemistry? For three successive years (1998–2001), we grew a set of clones of 10 maternal plants under two nitrogen treatments and two water treatments. For each plant in the summer of 2000, we assayed herbivory by hornworms in both indoor (detached leaf) and outdoor (attached leaf) assays, as well as ambient flea beetle damage. Estimates of leaf material consumed were made via analysis of digitized leaf images. We also assayed leaves for total protein, phenolic, and glycoalkaloid content, and for trypsin inhibitor, polyphenol oxidase, and peroxidase activity. Despite strong effects of nitrogen treatment on growth and reproduction, only total protein responded as predicted by CNB. Leaf phenolic levels were increased by nitrogen treatment, polyphenol oxidase activity was decreased, and other leaf parameters were unaffected. Neither hornworm nor flea beetle herbivory could be related to plant treatment or genotype or to variation in any of the six leaf chemical parameters. A negative relationship between flea beetle and hornworm herbivory was found, but was not apparently mediated by any of the measured leaf chemicals. Because leaf resistance was maintained in low nitrogen plants at the apparent

expense of growth and reproduction, our results support the concept of a fitness cost of defense, as predicted by the optimal defense hypothesis.

Key Words—Carbon–nutrient balance, cost of defense, *Epitrix*, induced defense, insect herbivory, *Manduca sexta*, nitrogen supplementation, optimal defense, plant secondary metabolites, *Solanum carolinense*.

INTRODUCTION

It is well known that plants can physiologically respond to environmental factors (Tuomi et al., 1984; Waterman and Mole, 1989; Baldwin, 1994) and that these changes can affect the actions of organisms with which they interact (Stamp, 1992; Baldwin 1999). For instance, if the secondary metabolite content of the foliage changes in response to some environmental factor, rates of foliar herbivory may also change (Karban and Baldwin, 1997). In this paper, we address two interrelated issues that concern changes in foliar chemistry over time: (1) plant responses to variation in available nutrients, and (2) chemical responses induced by herbivory. The first issue has attracted much attention in recent years, and several hypotheses have been constructed to explain patterns of defense production under different nutrient regimes. In the carbon–nutrient balance (CNB) hypothesis (Bryant et al., 1983), plants should allocate relatively more carbon resources to nitrogen-containing secondary metabolites when the plant has an abundance of nitrogen at its disposal (Muzika, 1993; Gebauer et al., 1998; Mutikainen et al., 2000). Conversely, the CNB hypothesis predicts decreases in strictly carbon-based compounds under conditions of increased nitrogen availability. Other major hypotheses concerning plant response to environmental variation include the growth–differentiation balance (GDB) (Hermes and Mattson, 1992), resource availability (RA) hypothesis (Coley et al., 1985; Bryant et al., 1985), and optimal defense (OD) hypothesis (Rhoades, 1979). Both the CNB and GDB hypotheses may be considered "supply-side" hypotheses, in that they assume that the supply of substrates is the primary controlling factor influencing quantitative variation in secondary metabolites. Conversely, the RA and OD hypotheses may be considered adaptive, "demand-side" hypotheses, which assume that demands placed upon tissues (e.g., for defense) and the selective value of that tissue to the plant are the primary factors influencing quantitative variation in secondary metabolites. While criticism of the CNB hypothesis has been on the rise in recent years (e.g., Gershenzon, 1994; Hamilton et al., 2001), its predictions remain a common framework around which studies of the influence of resource variation upon secondary metabolite variation are built.

The second major issue (induced defenses) has also attracted much attention in recent years. Levels of plant secondary metabolites and defense proteins can change in response to leaf damage (e.g., from insect feeding), and such changes can affect

subsequent feeding by herbivores or plant resistance to microbes and other parasites (e.g., Haukioja, 1991; Baldwin, 1994; Karban and Baldwin, 1997). Under certain circumstances, such effects may result in negative interactions among different herbivore species. This may be particularly true when feeding by one type of herbivore follows feeding by another. Some studies (e.g., Baldwin et al., 1993; Stout et al., 1998; Bolter et al., 1998; Cipollini and Bergelson, 2001) have shown that variation in nutrient availability can affect the induction of chemical responses in plants. However, the extent to which such chemical responses have consequent effects upon herbivory has been little explored (cf., Hartley and Jones, 1997). This area is a critical link between hypotheses concerning plant responses to nutrient variation and those concerning induced responses to herbivory.

We addressed these issues via a study of the interactions between two specialist insect species, *Epitrix* spp. (flea beetles) and *Manduca sexta* (hornworm), and the perennial plant *Solanum carolinense* L. (horsenettle). The plants used in this study were included in an on-going study examining the effect of added nitrogen on plant growth, reproduction, and fruit chemistry for three growing seasons (from the spring of 1998 through the summer of 2000; see details in Methods and Materials). Nitrogen addition approximately doubled plant size in all three years (M. Cipollini et al., unpublished data), which demonstrated the consistent and strong growth response to nutrient variation that must be obtained when addressing the CNB hypotheses. In all three years, variation in plant size produced (by allometric effects) increased fruit number, suggesting strong direct effects of nutrient variation on individual plant fitness. Despite large effects on growth and reproduction, levels of leaf trypsin inhibitor activity (TI), total glycoalkaloid (TGA), total protein, and total phenolics in 1999 were influenced by N addition in ways inconsistent with CNB hypothesis (M. Cipollini et al., unpublished data). In particular, leaf TI and TGA (nitrogen-containing metabolites) levels were unaffected, and total phenolics (carbon-based metabolites) were increased in response to nitrogen addition. Furthermore, none of the leaf chemical variables were found to relate to ambient leaf damage by flea beetles. These results were considered tentative because several potentially important parameters were not measured [e.g., leaf peroxidase (POD) and leaf polyphenol oxidase (PPO)]. Additionally, our simple method of measuring flea beetle damage (counting holes on leaves) may have been inaccurate.

As a follow-up to these earlier results, we initiated a study in the summer of 2000 using the same plants and general study design, but focusing more explicitly on the effects of plant treatment on leaf chemistry and herbivory. Our goal was to assess leaf chemistry more fully and to assess insect damage more accurately via image analysis of photographed leaves. Additionally, we sought to quantify hornworm feeding and growth rate through the use of both indoor and outdoor feeding trials, with the goal of determining if these parameters were influenced either by leaf chemistry and/or by ambient levels of flea beetle damage.

We focused on the following specific questions in our 2000 study: (1) Does plant treatment affect leaf chemistry in a manner consistent with the predictions of CNB theory? (2) Regardless of the effect of plant treatment, does variation in leaf chemistry affect feeding by the two herbivores? (3) Is there evidence of an interaction between flea beetle and hornworm herbivory that may be mediated by induced changes in leaf chemistry?

Based upon CNB theory, we predicted that nitrogen treatment should elevate levels of nitrogen-containing metabolites (total protein, TI, PPO, POD, and TGA) and decrease levels of strictly carbon-based metabolites (phenolics). Because we observed large effects of nitrogen treatment on plant size and reproduction, we expected to see large effects on leaf chemistry and that these changes should affect herbivory. Total protein was expected to positively influence herbivory, whereas the other leaf chemical parameters were expected to reduce herbivory; thus, no *a priori* prediction was made concerning the net effect of the any chemical changes. Based on our observations of changes in leaf morphology following flea beetle attack (e.g., browning and apparent lignification around feeding holes), we expected changes induced by flea beetles to affect subsequent feeding by hornworms. Thus, based upon induced defense theory, we expected answers to our second and third questions to be affirmative. Finally, we asked the more general question of whether variation in nutrient availability might affect any induced responses (thus linking our first question to the second two).

METHODS AND MATERIALS

Experimental Planting Design. In the fall and winter of 1997–1998, 12 clones from each of 10 different maternal plants (Table 1) were propagated from root

[a] Collections of root-stock from a single plant were made at sites no closer than several km apart.

cuttings under greenhouse conditions. Plants were collected from throughout the natural range of *S. carolinense*, from sites separated by several miles to hundreds of miles, with the idea of maximizing potential genetic variation among the clones. Nevertheless, clones derived from near one another might be expected to be more genetically similar, and, thus, might show similar responses. In early April 1998, each clone was transplanted into a 12-liter pot filled with a sandy loam–clay soil mixture made to mimic a typical southeastern US soil. The 120 clones were arranged in a fully randomized array with pots 1 m apart, surrounded by a 2.5-m-high wire mesh fence designed to deter mammalian herbivores but to allow access by pollinators and other insects. Three plants from each clone were subjected to the following manipulations: (a) control (C): to minimize drought stress, watered only if any of the plants in the entire array appeared wilted (when this was done, all 120 plants were watered); (b) water addition (W): watered to complete soil saturation three additional times per week; (c) nitrogen addition (N): 10 g dry ammonium nitrate fertilizer added to the pot four times during each year (mid-April, -May, -June, and -July); and (d) water and nitrogen (N + W): addition of both water and nitrogen. Pots were randomly rearranged on an annual basis, and treatments were continued on the same set of plants until the fall of 2000.

Outdoor Hornworm Feeding Trials and Flea Beetle Damage Assessment. To quantify levels of herbivory by hornworms, we purchased a lab strain from Carolina Biological Supply. A total of about 500 larvae were raised from eggs within individual glass vials on a generic meal provided with the eggs. Incubation of larvae was at 28°C, 14 hr light/10 hr dark, and 50–70% relative humidity. Starting June 20, 2000, terminal branches from each of the 120 plants were selected and photographed in color with a digital camera (Nikon Coolpix 950; 300 dpi) by placing the leaves between a gridded background (to allow subsequent size scaling of images) and a clear Plexiglas plate. The branch was then placed in a 600-ml plastic foam cup along with a single third- to fifth-instar larvae at about 17:00 hr. Lids were fitted tightly to prevent escape of the larvae. Each larva was allowed to feed overnight (15–17 hr). After the feeding trial had ended, the branch was photographed again, larvae were weighed, and the digital photographs were downloaded onto a computer as color jpeg images. This process was completed for all plants over the course of five days. Immediately following each trial, 15 leaves were randomly collected from each plant, freeze-dried, and ground to pass a #40 mesh screen. Another five leaves were randomly collected for use in assessing flea beetle damage. Each of these five leaves was photographed against a backlit screen using the digital camera. These images were downloaded onto a computer as color jpeg images.

Quantification of Growth and Reproductive Variables. Plants were allowed to continue to grow, set fruit, and senesce naturally in the fall. At the end of the fruit-ripening season (late November), all ripe fruits were collected, counted, and

weighed, and all above-ground stem mass was collected, dried to constant mass, and weighed.

Image Conversion and Filtering. All images were filtered using the "threshold" function of Graphic Workshop for Windows (Alchemy Mindworks, Inc., 1997) to produce monochrome bitmaps. Threshold values (80–130) were used to ensure that leaf material converted to black, while missing leaf material converted to white. Bitmap files were size-standardized and cleaned up using Microsoft Paint for Windows (Microsoft, Inc., 1991–1998).

Image Analysis of Hornworm Feeding. Using the "histogram" function of the Image J program (National Institute of Health, 2000), the number of black pixels (corresponding to leaf area) was determined for each image and for an image of a black square of known area (49 cm^2). Pixel counts were converted to leaf wet mass based upon mass per unit area determinations on two leaves from each plant. We calculated total consumption from estimates of leaf mass at the beginning and end of each feeding trial, and then divided total consumption by larval final mass to calculate relative consumption rate (RCR).

Image Analysis of Flea Beetle Feeding. Using the "histogram" function of the Image J program, we quantified the number of black (leaf material) and white (missing leaf material) pixels for each leaf image. We divided the number of white pixels by the total pixel count to estimate flea beetle damage as proportion of leaf area consumed. Nearly all leaf damage could be ascribed to flea beetles, based upon the uniformly small round holes typically produced by flea beetle species (Mauricio, 1998), and the observation that few other types of herbivorous insects attacked leaves of our study plants.

Indoor Hornworm Feeding Trials. At the same time as outdoor hornworm trials were taking place, we confined individual preweighed second to fourth instars with individual preweighed detached leaves in Petri dishes for 18-hr feeding trials. Petri dishes were maintained under conditions identical to those used for rearing the larvae. For each of four successive trials, we used a single leaf from each of the 120 plants. For each trial, we also placed 20 randomly-selected leaves individually in Petri dishes without larvae for the same period of time, to allow for calculation of expected mass change due to water loss alone. At the end of each trial, we reweighed all leaves and larvae. To determine mass consumed per trial, we estimated the mass of each leaf in absence of herbivory using regression equations based upon isolated leaves (R^2 ranging from 0.952 to 0.989). Actual leaf mass was subtracted from the estimated leaf mass to calculate mass consumed per trial. Leaf mass consumed was divided by the initial larval mass to calculate relative consumption rate (RCR). Mass gained within each trial was divided by the initial larval mass to calculate relative growth rate (RGR) of the larvae. Leaf mass consumption was summed across trials as a means of estimating total consumption, and total mass gain and total relative growth across all four trials was determined using initial and final larval masses.

Leaf Chemical Variables

Leaf Peroxidase (POD). Peroxidase is an enzyme that catalyzes the polymerization of phenolic alcohol monomers into lignin. In addition to its role in lignin formation, POD has roles in the formation of phenoxy and oxygen radicals and in the regulation of auxin levels (Campa, 1991). Because POD contains nitrogen, we predicted that increased nitrogen availability would result in increased POD levels. Mechanical damage, insect wounding, pathogen attack, and addition of wound signaling hormones like salicylic acid and jasmonic acid have been shown to increase POD activity, and increased POD activity has been associated with increased resistance to herbivores (Thaler et al., 1996; Cipollini and Redman, 1999). To assay POD activity, soluble proteins were extracted from freeze-dried and ground leaf samples by incubating 10 mg of sample in 1.5 ml 0.05 M sodium phosphate buffer (pH 6.8) containing 7% PVPP, 1.67 mM phenylthiourea, 0.3 M KCl, and 0.4 mM ascorbic acid. POD activity in soluble protein extracts was determined by following the oxidation of guaiacol in the presence of hydrogen peroxide at 470 nm, as in Cipollini (1998), in an assay adapted for a microplate reader. POD activity was expressed as a change in absorbance at 470 nm per minute per milligram extract protein. Soluble protein content was determined in leaf extracts using the Bradford assay (Bradford, 1976), wth Bio-Rad protein dye reagent and bovine serum albumin as a standard.

Leaf Trypsin Inhibitors (TI). Trypsin inhibitors are antinutritive proteins that competitively inhibit digestive serine proteases of animals and other organisms (Koiwa et al., 1997). As with POD, these proteins were predicted to increase in response to increased nitrogen availability. Trypsin inhibitors have been shown to be inducible in several plant species, and to be affected by nutrient availability (Stout et al., 1998; Cipollini and Bergleson, 2000, 2001). However, flea beetles, like all coleopterans, rely on cysteine proteases for digestion of leaf proteins rather than serine proteases, so it is unlikely that flea beetles would be affected by constitutive or induced variation in TI. However, flea beetle damage may induce increases in TI, to which hornworms should be sensitive. The TI content was determined by examining the radial diffusion of soluble protein extracts through a trypsin-containing agar as in Cipollini and Bergelson (2000). TI content of extracts was expressed as micrograms of TI per milligram extract protein.

Leaf Polyphenol Oxidase (PPO). Polyphenol oxidases are enzymes that catalyze the oxidation of phenolic compounds. Such oxidation can result in quinone formation, polymerization, and other changes that can greatly affect the biological activity of phenolics present in plant tissues (Appel, 1993). As with POD and TI, PPO levels were predicted to increase in response to increased nitrogen availability. It has been demonstrated that PPOs are inducible and associated with increased insect resistance in tomato (Thaler et al., 1996; Cipollini and Redman, 1999). We

assayed leaf protein extracts for PPO activity by following the oxidation of caffeic acid to its colored quinone complex (Thaler et al., 1996) in an assay adapted for a microplate reader. PPO activity was expressed as a change in absorbance at 470 nm per minute per milligram extract protein.

Leaf Total Protein (PROT). As for individual enzymes, total protein was expected to increase in response to increased nitrogen availability; however, no specific prediction was made concerning the effect of leaf damage on total protein content as all manner of responses have been reported in the literature (Baldwin, 1994). Numerous studies have shown that insect feeding may be affected by elevated protein and that the relative growth rates of insects may be enhanced (e.g., Hare, 1987). We analyzed freeze-dried leaf samples for total dietary protein using the Bradford (1976) assay as modified for plant material by Jones et al. (1989), using ribulose 1,5-biphosphate (the most prevalent protein in plant leaves) as an external standard.

Leaf Total Phenolics (PHEN). Phenolics, a group of miscellaneous aromatic compounds ultimately derived from cinnamic acid, may negatively influence feeding and relative growth rates of herbivorous insects through a variety of mechanisms. Many individual compounds and "total phenolics" have been shown to be inducible (Baldwin, 1994; Dixon and Paiva, 1995), and the CNB hypothesis suggests that, since they are carbon-based secondary metabolites, phenolics will decrease in response to increased nitrogen availability (Baldwin, 1994). We analyzed freeze-dried leaf samples for total phenolics using the Coomassie brilliant blue technique (Budini et al., 1980) with the modifications of Graham (1992) and using chlorogenic acid (the most prevalent phenolic in horsenettle leaves) as an external standard.

Leaf Total Glycoalkaloids (TGA). Glycoalkaloids are nitrogen-containing steroidal bases, active against a variety of organisms ranging from birds and mammals to insects and fungi (Hare, 1983; Tingey, 1984; van Gelder, 1990; Cipollini and Levey, 1997a,b). Because glycoalkaloids contain nitrogen, we expected that leaf TGA should be elevated in leaves of nitrogen treated plants, although reports have suggested otherwise for this group of compounds (Nowacki et al., 1976; Hoffland et al., 1999). They have been shown to be inducible in a variety of studies, particularly those focusing on damage to potato tubers (e.g., van Gelder, 1990). We analyzed freeze-dried leaf samples for TGA with the method of Birner (1969) with modifications of van Gelder (1984) with solasodine (the sole N-containing steroidal base in horsenettle leaves) as an external standard.

Statistical Analyses

Outdoor Hornworm Trials (ANOVA/ANCOVA). The dependent variable RCR was analyzed using factorial analysis of variance (independent variables: treatment

and maternal plant), with and without leaf chemical variables as covariates. The incorporation of leaf chemical variables as covariates in this and subsequent analyses was designed to determine the degree to which differences among treatments and/or maternal plants were associated with variation in leaf chemistry.

Indoor Hornworm Trials (ANOVA/ANCOVA). The dependent variables RCR and RGR were analyzed using factorial repeated-measures analysis of variance (independent variables: treatment, maternal plant, trial), with and without leaf chemical variables as covariates. The dependent variables total consumption and total RGR were analyzed using factorial analysis of variance (independent variables: treatment and maternal plant), with and without leaf chemical variables as covariates.

Flea Beetle Damage. We analyzed the dependent variable proportion of leaf removed by flea beetles using factorial analysis of variance (independent variables: treatment and maternal plant), with and without leaf chemical variables as covariates.

Leaf Chemistry as a Function of Plant Treatment (MANOVA/ANOVA). Following transformation as necessary, the leaf chemical variables were included as dependent variables in a factorial multiple analysis of variance (MANOVA: independent variables: treatment and maternal plant). Because the MANOVA was significant, we analyzed each of the dependent variables separately using univariate factorial analysis of variance (ANOVA). These analyses were intended to determine which, if any, of the dependent variables were affected by our treatment conditions.

Correlations between Leaf Chemistry and Insect Feeding. We calculated Pearson correlations among all leaf chemical variables and insect feeding variables. The intent of these analyses was to determine if any of the variation in feeding or performance by the insects was associated with differences in leaf chemistry, regardless of effects of treatment and maternal plant. We adjusted P values for experiment-wise error rates using Bonferroni correction (Simple Interactive Statistical Analysis, 2001).

Effects on Fitness. Using total fruit wet mass as the dependent variable, we used ANCOVA to determine the effects of treatment, and maternal plant on plant fitness, with leaf chemical variables and flea beetle damage as covariates. Individual fruit mass correlated strongly with seed number in a sub-sample of our fruits ($N = 100$; $R = 0.84$; $P < 0.001$). This analysis was designed to determine relative contributions to each of the factors to our estimate of plant fitness.

RESULTS

Leaf Chemistry as a Function of Plant Treatment. Plants under high nitrogen treatments (N, N + W) showed increases in total proteins and phenolics and

a decrease in PPO (Table 2A). Our MANOVA analysis concerning the overall effects of plant treatment and maternal plant on leaf chemisty showed a strong overall effect of plant treatment on leaf chemistry, but no effect of maternal plant (Table 2B). These results could be attributed to significant increases in total protein and total phenolics and to a decrease in PPO in response to nitrogen addition, as supported by our MANCOVA results (Table 2C). While the increase in total protein in response to nitrogen treatment is in support of the CNB hypothesis, the positive effect of nitrogen addition on total phenolics, the lack of an effect on POD, TI, and TGA, and the negative effect on PPO were all in contrast to CNB-based predictions.

Outdoor Hornworm Trials. Based upon our estimate of relative consumption rate (RCR), hornworm feeding in outdoor trials was unrelated to plant treatment and did not vary significantly among maternal plants (clones) (Table 3A). Furthermore, none of the measured leaf chemical variables contributed significantly to the explanation of hornworm feeding, based upon our ANCOVA results (Table 3B).

Indoor Hornworm Trials. As for outdoor hornworm trials, larval total RCR was unaffected by plant treatment and maternal plant (Table 4A). In these trials, however, total phenolics showed a significant effect ($P < 0.05$) upon total RCR when incorporated into the ANCOVA analysis (Table 4B). Results for repeated-measures ANOVA mirrored the across-trial result in showing no effect of plant treatment or maternal plant on within-trial RCR (Table 4C), but a significant effect of total phenolics on RCR (Table 4D). Finally, repeated-measures results for within-trial RGR showed no effect of plant treatment or maternal plant (Table 4E), and no effect of any leaf chemical variable (Table 4F).

Flea Beetle Damage. Our assessment of flea beetle damage with respect to plant treatment, maternal plant, and leaf chemistry showed results generally similar to those found for hornworms (e.g., no effect of plant treatment or maternal plant on leaf damage; Table 5A), and no relationship with any of the leaf chemical variables (Table 5B). In the ANCOVA analysis (Table 5B), leaf POD showed a marginally significant relationship with leaf damage ($P = 0.055$), which may reflect a slight lignification response (or a response by the beetles to lignification).

Correlations between Leaf Chemistry and Insect Feeding. The only correlation that was significant was the negative correlation (Figure 1; $R = -0.276$) between flea beetle damage and feeding by hornworm larvae in outdoor trials (Table 6). In other words, none of the leaf chemical variables were found to relate to any of the insect feeding or growth variables when considered across all treatments and maternal plants. Nevertheless, a negative interaction between feeding by flea beetles and subsequent feeding by hornworms was supported.

Effects on Fitness. Our estimate of short-term plant fitness (total fruit mass) was strongly affected by both plant treatment and maternal plant (Table 7A,B). The effect of plant treatment was associated with a nearly doubling of total fruit mass in nitrogen treated plants, with little or no effect due to water treatment (Table 7C). Upon incorporation of the leaf chemical variables and our estimate of flea beetle damage into the ANCOVA, only leaf PPO was found to relate significantly ($P < 0.05$) to total fruit mass (Table 7D), the effect being slightly positive based upon plots of residuals (not shown). Based upon the lack of significant correlations (results not shown), none of the leaf chemical parameters was associated with variation in plant growth and reproductive parameters. The clones did not differ in above-ground dry mass, but they did differ in total fruit number, average fruit mass, and total fruit mass (Table 7B). Thus, while clones differed in some aspects of growth and reproduction, virtually none of this variation could be associated with the leaf chemical and herbivory parameters measured in this study. Clones derived from distant sources (e.g., N2O, SERC, SEN) performed as well or better than clones derived locally (e.g., TIFT, AUG; Table 7B).

DISCUSSION

This study was designed to address questions related to the effect of plant nutrient variation on both leaf chemical allocation and effects of induced defenses.

Clear support for the CNB hypothesis is lacking in our results. Despite strong effects of supplemental nitrogen on plant size and reproduction, only leaf protein increased in nitrogen-treated plants as predicted by CNB. Leaf total phenolics increased in nitrogen-treated plants, while most other nitrogen-based metabolites were unaffected (POD, TI, TGA) or decreased (PPO). Herbivory was also

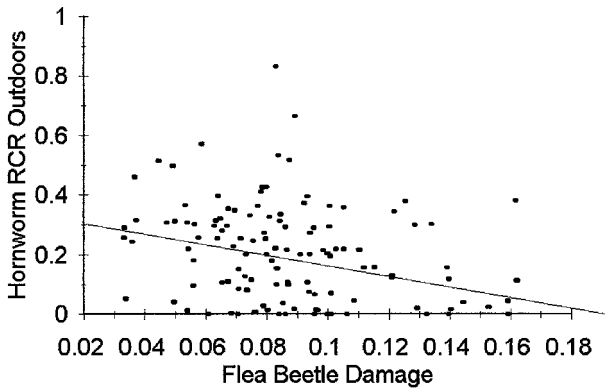

FIG. 1. The relationship between flea beetle damage (proportion of leaf area removed) and tobacco hornworm relative consumption rate (RCR; g dry leaf mass g wet larval mass) in outdoor feeding trials. The fitted line represents the least-squares linear regression of RCR on flea beetle damage.

[a] Data are correlation coefficients, followed by significance level (P values). Asterisks indicate significant effects ($P \leq 0.05$) following adjustment for multiple correlations using Bonferroni adjustment (alpha level was lowered to 0.002 for each test to bring the table-wide alpha level to 0.05.). For definitions of independent variables, see Table 2. Outdoor hornworm RCR = g · dry leaf mass g · wet larval mass^{-1}; Indoor total hornworm RCR = g · wet leaf mass g · wet larval mass^{-1}; Indoor total hornworm RGR = g · wet leaf mass g · wet larval mass^{-1}; Flea beetle damage = proportion of leaf area removed.

unaffected by plant treatment. This mixed bag of results is not entirely surprising, because some studies have shown full support of CNB (e.g., Bryant et al., 1993; Cipollini et al., 1993; Gebauer et al., 1998; Hoffland et al., 2000), numerous others mixed support (e.g., Reichardt et al., 1991; Lavola and Julkunen-Tiitto, 1994; Ruohomaki et al., 1996; Kinney et al., 1997; Keinanen et al., 1999; Mutikainen et al., 2000), and still others no support at all (e.g., Baldwin et al., 1993; Iason and Hester, 1993; Feller, 1995; Kainulainen, 1996). These inconsistent results have left some ecologists wondering if the hypothesis has any intrinsic value in terms of establishing a predictive framework (e.g., Hamilton et al., 2001). Still others have criticized "general defense theories" as a whole (e.g., Stamp, 1992; Haukioja et al., 1994; Langenheim, 1994), in that most studies require specific knowledge of the study system and much *post-hoc* qualification when interpreting results.

One hypothesis with potential for placing such diverse studies in a general framework is the OD hypothesis (Rhoades, 1979; Berryman 1988). Although some of its assumptions are hard to quantify (e.g., the fitness value of a plant part,

TABLE 7. ANOVA AND ANCOVA RESULTS FOR EFFECTS OF PLANT TREATMENT AND MATERNAL PLANT ON GROWTH AND REPRODUCTIVE VARIABLES

[a] ABDMASS = aboveground dry mass (g), FRUITS = total fruit number per plant, AVFTMASS = average wet mass per fruit, FTMASS = total wet fruit mass per plant (g). Identical letters following data indicate values not differing significantly based upon one-way ANOVA.

the fitness value of allocation to secondary metabolites, the "costs" of secondary metabolites) and constraints exist that make predictions complex (Berenbaum and Zangerl, 1988; Linhart, 1991), it is a hypothesis grounded firmly in evolutionary theory. In general, this hypothesis states that plants should allocate resources to secondary metabolites in ways that maximize fitness—the exact ways will depend upon the biology, history, and ecology of the system being studied. With reference to our study, it is possible that nitrogen supplementation increased dietary protein content in leaves, as leaf and whole plant growth was promoted. Increased dietary protein content may have increased the need for antiherbivore defense (due to potentially increased risk of herbivory in protein rich leaves; e.g., Hare, 1987). As a result, phenolic production may have been increased via the up-regulation of enzymes such as POD (as we observed) or phenylalanine ammonia lyase (PAL), which may be a key regulatory factor affecting quantitative variation in total phenolics (Bate et al., 1994; Howles et al., 1996; Jones and Hartley, 1999). The net result would be little difference in levels of insect herbivory in N-treated and control leaves; this is what we found. In a similar vein, our results support the concept of a trade-off between growth/fitness and defense production. Untreated plants were half as large and produced half as many fruits as nitrogen-treated plants, yet produced similar levels of defense compounds and had similar levels of herbivory. It is possible that the maintenance of antiherbivore defense in untreated plants came at the expense of growth and fitness.

Based upon CNB hypothesis, we predicted that glycoalkaloids would increase in response to nitrogen supplementation and that insect feeding would decrease as a result; neither effect was observed. While nonadapted insects seem to be susceptible to glycoalkaloids (e.g., Hare, 1983, 1987; Fragoyiannis et al., 1998), leaf glycoalkaloids are apparently not commonly associated with resistance to specialized insects such as hornworms and flea beetles (Flanders et al., 1992) or to specialized leaf pathogens (Hoffland et al., 1999). In fact, TGA levels in *S. carolinense* leaves are relatively low compared with many other *Solanum* species (Cipollini et al., 2001), possibly suggesting a diminished defensive role for leaf glycoalkaloids in this plant species. While allocation of glycoalkaloids to roots was not measured in this study, it is known that levels of TGA are much higher in roots than in leaves (R. Walls, M. Cipollini, H. Appel, J. Schultz, unpublished data), where a functional role may be important. The lack of an effect of TI on hornworms may have a similar explanation; insect responses to TI may depend upon the degree of specialization of the insect on the host (Broadway, 1995). This pattern seems to be common in studies that have focused on specialized herbivores. This may be because the host and herbivore share a long evolutionary history with resultant "molecular modeling" (sensu Wink, 1998, 1999) of defense and resistance traits, or it may be due to physiological, ecological, or environmental constraints on genetically based chemical responses to herbivory—the "syntheses, synergisms, and sundry other sins" of Berenbaum and Zangerl (1988). In the latter

case, negative effects on specialized herbivores may be seen in some circumstances and not others.

With respect to our second and third questions, which relate to induced defenses, we hypothesized that flea beetles might induce plant defenses and, thus, negatively impact hornworm feeding. Based upon our results, we can only say that a negative relationship was supported, but the source of this negative relationship remains to be identified. In our field experiment, the level of flea beetle damage was not experimentally controlled; rather, flea beetles were allowed to consume plants prior to our observations of leaf chemistry and hornworm feeding. We assumed that leaf chemistry might have changed between the time flea beetles attacked and the time leaves were analyzed; thus, all measured chemical variables should be considered potentially induced in this study. Acknowledging this, patterns of flea beetle feeding might have partly reflected differences in leaf chemistry prior to feeding, and subsequent induction may have produced a saturated response in the plants (because overall flea beetle damage was high). In any case, this is a problem common to field studies that attempt to establish correlations among variables, and at the very least the study addresses these effects within a realistic ecological context. Hence, we can only speculate about the source of the negative interaction between flea beetle damage and hornworm feeding. One possibility is that other leaf chemical or physical defenses (e.g., toughness, thorniness) or signals (e.g., volatiles) might have been induced in plants heavily infested with flea beetles. A second possibility is that the flea beetle damage to leaves may have simply made it physically more difficult for hornworms to efficiently process damaged leaf material, thus slowing consumption rates. Pieces of unconsumed leaf material were commonly encountered in the bottom of cups away from where the larvae stayed and fed (attached to the main branch). This negative relationship was present, but not significant, for the indoor hornworm trials. We surmise that conditions produced in the (less natural) indoor trials may have obscured the relationship identified in the field.

The lack of variation among plant clones was surprising, given the wide area from which they were originally derived. Parameters that showed significant variation among the clones were total fruit number, average fruit mass, and total fruit mass. Based upon total fruit mass (which we considered an estimate of short-term fitness), the two clones that showed highest fitness in 2000 were derived from maternal plants in Maryland (SERC, N2O), thus discounting the idea that adaptation to local (Georgia) conditions might be responsible for variation in plant performance. The effect of maternal clone was not involved in any significant interaction in any of the analyses, indicating that the clones generally responded similarly to treatments and/or herbivory, regardless of genetic background.

In conclusion, the results of this study provide insight into the effects of nitrogen supplementation and induction by herbivores on leaf secondary metabolites and herbivory in this species, but they provide little support for the CNB hypothesis.

Because plants seemed to maintain levels of resistance under low nitrogen conditions at the expense of growth and reproduction, our results show support for some aspects of the OD hypothesis. Future studies focusing on this study system might concentrate on identifying more precisely which secondary metabolites are responsible for the general responses we observed, which genes/enzymes are responsible for these responses, and specifically how these changes influence the common "generalist" herbivores of this plant species. We concur with others in suggesting that framing future studies in terms of the OD hypothesis might be a more productive and insightful approach, in comparison with continued focus on the CNB hypothesis. Our results further suggest that herbivory by one organism can influence herbivory by another via induced responses; however, the mechanism responsible for this effect remains to be discovered for our study system.

(Received May 4, 2002; accepted August 19, 2002)

Abstract—Levels of soluble protein and carbohydrate (raffinose, sucrose, glucose, and fructose) in leaves from a selection of plant species were measured to determine if a relationship existed between these nutrients and infestation by *Frankliniella occidentalis* and *Heliothrips haemorrhoidalis*. Most species of host plant examined contained a higher proportion of protein than carbohydrates, and overall, leaves from species of plants that supported populations of thrips had greater levels of protein than leaves from nonhost species. New leaves and flowers that supported *F. occidentalis* contained high levels of carbohydrate and protein. The quantity of protein in leaves at the top of the tree, *Peumus boldus*, was greater than in leaves from lower levels, and the amount of feeding damage accrued by *H. haemorrhoidalis* was greater on the upper foliage than lower foliage. Oviposition by *H. haemorrhoidalis* was positively correlated to levels of protein in host plants but not to levels of carbohydrates. Overall, levels of soluble protein in plants influenced their susceptibility to thrips more than levels of carbohydrates.

Key Words—Carbohydrate, protein, sucrose, fructose, glucose, raffinose, *Frankliniella occidentalis*, *Heliothrips haemorrhoidalis*, host plant, nutrition, oviposition, feeding damage.

INTRODUCTION

In the last decade, thrips have become of increasing importance as pests, especially in protected crops and in large glasshouses containing botanical collections.

Although researchers have started to gather data about the factors that influence the host selection behavior of thrips, we do not understand fully the impact of primary and secondary metabolites in the host selection of invasive, polyphagous species such as *Frankliniella occidentalis* (Pergande) and *Heliothrips haemorrhoidalis* (Bouché). The ratio of protein to carbohydrate in plants has been reported to affect the performance of species of herbivorous insect (Schoonhoven et al., 1998a). Increased protein quantity is associated with enhanced herbivore survival, growth, and fecundity (McNeill and Southwood, 1978; Mattson 1980; Ohgushi, 1992; Slansky, 1993), although the quality of plant proteins may affect the levels of insect performance (Karowe and Martin, 1989). Research has shown that most herbivorous insects use carbohydrates as feeding stimulants (Bernays and Simpson, 1982; Blaney and Simmonds, 1988) and as important nutrients needed to synthesize body tissue and serve as energy sources (Schoonhoven et al., 1998b). Sugars have also been shown to promote oviposition in some species (Derridji et al., 1996).

Scott Brown (2002) showed that species of plants selected by thrips from among the botanical collection held in the Temperate House, Royal Botanic Gardens, Kew (RBG, Kew), varied in their suitability to support populations of *H. haemorrhoidalis* and *F. occidentalis*. The performance criteria examined included longevity, feeding and oviposition levels, growth, and development of thrips on individual leaves of these plant species. In this study, we test the hypothesis that protein levels in plants will influence the suitability of plants as hosts for thrips more than levels of carbohydrates. We also investigate whether the quantity of carbohydrates and proteins present in foliage influences the oviposition performance of *H. haemorrhoidalis*. In addition, the distribution of soluble proteins and carbohydrates in the foliage of a tall tree, *Peumus boldus* Molina (Monimiaceae), was examined to determine if the location of *H. haemorrhoidalis* on the tree related to the nutritional levels in the leaves.

METHODS AND MATERIALS

Carbohydrate Analysis

In the majority of species of plants, the proportion of soluble carbohydrate consists mainly of sucrose, glucose, and fructose with minor quantities of other compounds such as aminosugars, sugar alcohols, phosphates, and uronic acids (Gonzalez et al., 1989). Four sugars were selected for quantification, representing three sugar categories: oligosaccharides (raffinose), disaccharides (sucrose), and monosaccharides (glucose and fructose). Analysis of sugars in leaf extracts was performed directly using high-pressure liquid chromatography (HPLC).

Preparation of Extracts. Extracts were made up using 50 mg of air dried leaf material from species of plants growing in the Temperate House, RBG, Kew, UK (Scott Brown et al., 1999) (Table 1). Finely ground plant material was placed in

[a] Leaf samples are listed in order of decreasing total carbohydrate values, per species associated with host status.
[b] Leaf (age) or flower, number of replicates protein/carbohydrate.
[c] Host status, Hh = *H. haemorroidalis*, Fo = *F. occidentalis*, N-H = non-host.
[d] Percentage soluble protein calculated from amount of protein in leaves mg/g.
[e] Total carbohydrate = sum total amount of raffinose, sucrose, glucose, fructose.
[f] Protein:Carbohydrate ratio (% of total C + P), where A = higher protein content than carbohydrate ($P < 0.05$), B = similar quantities of protein and carbohydrate, C = higher carbohydrate than protein ($P < 0.05$), D = no statistical comparison available (carbohydrate, $n = 1$).
[g] Asterisk Indicates significantly higher levels of sugars in new or mature leaves of plants of the same species (MW, $P < 0.05$).

a 10-ml glass vial with 4 ml of 80% ethanol and sealed with a screw lid. Vials were placed in a blood-tube mixer (Stuart Scientific) and left rotating at the vertical setting for 16 hr at 4°C. The lid of each vial was released before the vial was placed in a water bath (90°C) for 10 min. Extracts were removed from the water bath and spun in a centrifuge (13,000 rpm for 10 min). The supernatant was removed from each vial with a Pasteur pipete and collected in 5-ml vials and reduced under a nitrogen air stream. The concentrated extract was frozen and freeze-dried. Extracts were taken up in 500 μ1 double-distilled H_2O and mixed thoroughly. Each extract was transferred to an Eppendorf tube and centrifuged (13,000 rpm for 10 min), before being injecting into the HPLC system.

Quantitative Measurement of Primary Sugars Using HPLC. The quantification of sucrose, fructose, glucose, and raffinose in leaf extracts was undertaken using a Waters HPLC system. The mobile phase was a dilute buffer of sodium sulfate (0.01 M) with a flow rate of 0.6 ml/min. Each sample was injected into a 20-μl loop and passed initially through a guard column (Phenomenex) before entering a sodium based carbohydrate column (Phenomenex) maintained at a temperature of 65°C. The separated sugars were detected using a Waters R-400 differential refractometer and recorded by a Waters 745B integrator. A known range of sugar standards, 0.1–10 mg/ml (BDH, Poole, UK) was used to construct a standard reference curve.

Protein Analysis

The most valuable proteins in plants, in terms of nutrition, tend to be the soluble enzymes that are easy for insects to extract and digest (Bernays and Chapman, 1994). This study considered the quantification of soluble protein present in leaf samples of the selected plant species as a measure of nutritional value as hosts of thrips. The bicinchoninic acid protein assay (BCA) (Pierce Chemical, 1996) was used to quantify the amount of soluble protein content of leaf samples in a method described by Smith et al. (1985).

Preparation of Extracts. Leaves were collected from plant specimens located within the Temperate House, RBG, Kew (Table 2) and air dried. Ground leaf material (10 mg) was placed into an Eppendorf tube with 1.5 ml of Tris HCl buffer (pH 8) and mixed with a vortex mixer. The Eppendorf tube was placed in a rotator overnight at 4°C. After centrifuging the Eppendorf tube (13,000 rpm) for 10 min, the supernatant was decanted into a clean tube through Whatman No. 1 filter paper (42.5 mm diam.) (Whatman). Compounds present in leaf extracts, which may interfere with the absorbency readings at 562 nm (Brown et al., 1989), were removed using acetone. Proteins in these samples were precipitated by adding 200 μl of acetone (−20°C) to 50 μl of extract in an Eppendorf tube (1.5 ml), which was thoroughly mixed and then stored at −20°C for 30 min. The extract–acetone solution was removed from the freezer and centrifuged at 13,000 rpm for 10 min. The

TABLE 2. DISTRIBUTION OF *H. haemorrhoidalis* FEEDING IN RELATION TO PROTEIN AND CARBOHYDRATE LEVELS IN FOLIAGE OF TREE SPECIES, *Peumus boldus*

[a] Leaves collected from branches at three height locations (top, middle and lower branches) of *Peumus boldus*.
[b] a = significantly higher levels in top crown than lower crown, b = significantly higher levels in middle crown than lower crown, c = significantly higher levels in top crown than middle crown (Mann-Whitney U test).
[c] Protein–carbohydrate ratio (% of total C + P).
[d] Feeding damage was examined on three different sampling dates; 1 = 10/01/96, 2 = 12/02/96, 3 = 11/03/96, $N = 20$ at each crown level.

acetone could then be poured off, and the protein pellet retained in the Eppendorf tube. A further 200 μl of acetone (-20°C) was added and well mixed with the pellet, and the process was repeated to ensure a clean protein sample. The protein pellet was taken up in 50 μl of double distilled water and mixed thoroughly using a vortex mixer before 1 ml of the bicinchoninic acid reagent solution was added (Smith et al., 1985). All tubes were incubated at 37°C for 30 min. The Eppendorf tubes were removed and cooled to room temperature for 15 min. Absorbency of each extract was then read at 562 nm against the reference sample.

Preparation of BSA Standards. Standards were prepared by diluting the 2.0 mg/ml bovine serum albumin (BSA) stock standard obtained from Pierce Chemical Company with Tris HCl buffer (pH8) (2000, 1500, 1000, 750, 500, 250, 125, and 25 μg/ml), and a standard curve constructed.

Relationship between Thrips Distribution and Protein and Carbohydrate Content of Foliage in a Tall Tree Species. A total of 60 leaves was collected from a Chilean tree, *Peumus boldus*, at three different height locations, top (5 m), middle (3 m), and lower (1 m). The area of feeding damage caused by thrips feeding was measured using a quantimet 520 image analysis system (Cambridge Instruments Ltd.), which, when coupled to a macroviewer, was used to detect the light patches on the leaf surfaces. Leaf collections were repeated on two further occasions for comparison. A further 20 leaves were taken at these crown levels and analyzed for levels of protein and carbohydrate as describe above.

Levels of Oviposition on Several Species of Plants Host to H. haemorrhoidalis. Leaves were excised from selected host plants, and the petiole was placed into a 10-cm glass vial containing distilled water. Vials containing single leaves were corked with cotton wool plugs and placed into Perspex boxes (22 cm long $\times$ 8 cm high $\times$ 12 cm deep, Stewart Plastics) that contained filter paper dampened with distilled water to minimize leaf desiccation.

Pseudopupal (pupae) stages of *H. haemorrhoidalis* were collected from the Australian tree fern, *Cyathea australis* Sm. (Cyantheaceae), situated in the Princess of Wales Conservatory, RBG, Kew. Five pupae were placed on individual leaves of the plant species to be examined, and the box was sealed with a lid and Parafilm® (American National Can™, USA). The box was stored at 27°C, 16L:8D for 3 days. After 3 days, eclosed adults were removed and placed onto fresh leaves of the same species and stored under the same conditions. Leaves were exchanged for fresh material at 7-day intervals for the duration of the time the adult thrips survived. The removed leaves were examined under the microscope in order to measure oviposition. Five to eight replicas for each host species examined were set up.

Analysis of Data

Data were analyzed using Kruskal-Wallis (KW) one-way analysis by ranks and the Mann-Whitney U test (MW), using two-tailed probability (Fowler et al., 1999).

RESULTS

Carbohydrate Levels. The quantity of each of the four carbohydrates varied among the species of plant examined (raffinose KW, $P < 0.01$; sucrose KW, $P < 0.001$; glucose KW, $P < 0.001$; fructose KW, $P < 0.001$; Table 1). Within some species, the levels of carbohydrates varied between young and mature leaves. For example, within *D. acutangula* and *C. alba*, the amounts of carbohydrates were greater in new leaves than mature leaves. In contrast, *S. nepaulensis* and *C. capensis* contained higher levels of carbohydrates in mature leaves relative to new leaves. In *C. capensis*, this was due to greater levels of sucrose, whereas in *S. nepaulensis* the levels of both sucrose and glucose were greater in the mature leaves.

Overall, higher concentrations of sugars were present in the leaves of hosts of *H. haemorrhoidalis* compared with hosts of *F. occidentalis* (KW, $P < 0.05$; Table 1). Host plants of *H. haemorrhoidalis* contained sucrose in greater abundance than glucose (MW, $P < 0.05$), fructose (MW, $P < 0.001$) or raffinose (MW, $P < 0.001$). Leaves of host plants of *F. occidentalis* were also found to contain more sucrose than any of the other three sugars quantified (MW, $P < 0.001$, in each case). The greatest level of carbohydrate was recorded in the young leaves of *D. acutangula* (MW, $P < 0.05$, in all cases): A host plant of both *F. occidentalis* and *H. haemorrhoidalis*. Flowers of *C. capensis*, a host of *F. occidentalis*, contained higher levels of carbohydrates than the leaves (MW, $P < 0.05$).

Protein Levels. The quantity of soluble protein in the foliage of the seventeen plant species varied among species (KW, $P < 0.001$; Table 1). Usually young flush leaves contained higher levels of protein than mature leaves from the same species (KW, $P < 0.05$), although mature leaves of *G. radlkoferi*, a host of *H. haemorrhoidalis*, contained higher levels of protein than occurred in the new leaves (MW, $P < 0.05$). Protein levels in hosts of *H. haemorrhoidalis* and *F. occidentalis* were similar (MW, $P > 0.05$) and, overall, were at higher levels than occurred in the non-hosts (KW, $P < 0.05$). However, the nonhost species *S. harveyanus* and *P. praemorsa* contained as much protein as *D. acutangula*, a host to both species of thrips (MW, $P > 0.05$, in both cases).

Ratio of Protein to Carbohydrate. The ratio of protein to carbohydrate in the foliage of the plants examined showed that most species (88%) contained a higher proportion of protein than carbohydrate (Table 1). The actual amounts of protein and carbohydrate were often greater in host plants than non-host plants.

Relationship between Thrips Distribution and Protein and Carbohydrate Content of Foliage in a Tall Tree Species. Feeding damage caused by *H. haemorrhoidalis* on the foliage of *P. boldus* varied among the three height levels, with the greatest levels of damage evident towards the top of the tree (Table 2). The proportion of protein in leaves was greater at the top of the tree than the bottom. Leaves of *P. boldus* collected from the upper crown contained higher levels

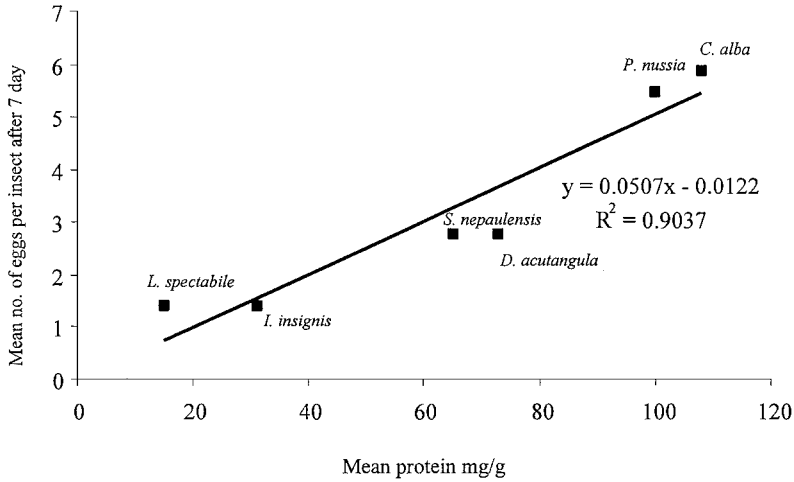

FIG. 1. Oviposition Levels of *H. haemorrhoidalis* in Relation to Soluble protein content in the leaves of six hosts plants.

of sucrose than the lower crown, with both sucrose and glucose being in greater concentrations in the middle crown compared with the lower crown.

Levels of Oviposition on Several Species of Plants Host to H. haemorrhoidalis. The amount of protein in the leaves of hosts of *H. haemorrhoidalis* correlated positively with the number of eggs laid by *H. haemorrhoidalis* ($r^2 = 0.9$; Figure 1). In contrast, oviposition was not correlated to the amount of carbohydrate in the leaves ($r^2 = 0.05$).

DISCUSSION

This investigation has shown that the ratio of soluble protein to carbohydrate (as represented by the four sugars, sucrose, glucose, fructose, and raffinose) in the foliage of 17 species of plants that support thrips varied from 93:7 (*Alsinidendron trinerve* a host for *F. occidentalis*) to 41:49 (*D. acutangula* a host to both *H. haemorrhoidalis* and *F. occidentalis*). The majority of host species contained a higher ratio of protein than carbohydrate, and generally the amounts of protein were greater in host species than nonhosts. These findings, along with the fact that the egg-laying behavior of *H. haemorrhoidalis* was positively correlated to protein content but not to carbohydrate content, support the hypothesis that protein influences the suitability of plants as hosts for thrips more than levels of carbohydrates.

Bernays and Chapman (1994) collated previous research on protein levels in plants and showed that protein and amino acid levels can range from 1% to 40% of the dry weight of foliage. Woody species in the Ericaceae and Myrtaceae contained

low levels of protein, whereas the greatest levels were recorded in herbaceous legumes. In our study, some of the greatest levels of soluble protein were recorded in the large shrubs and trees, such as *Greyia radlkoferi*, *Saurauia nepaulensis* and *Erica canaliculata*, all of which supported large infestations of *H. haemorrhoidalis* (Scott Brown, 2002).

Within a plant, levels of protein and carbohydrate vary and could influence the preferred feeding sites of the thrips. *F. occidentalis* feeds mainly on leaf buds, new leaves, and flowers (Trichilo and Leigh, 1988; Ullman et al., 1992) that usually contain higher levels of protein than the mature leaves (Bernays and Chapman, 1994). Our data show a trend for young leaves to have greater levels of protein than mature leaves, although on the two plants infested with both *F. occidentalis* and *H. haemorrhoidalis*, the levels of protein were higher in the new leaves. This would suggest that protein influences the host selection behavior of *F. occidentalis* more than *H. haemorrhoidalis*. The leaves of the tree *P. boldus* contained a high sugar content and only moderate levels of protein, yet this species suffered extensive damage due to thrips feeding in the Temperate House (Scott Brown, 2002).

Although rates of survival, reproduction, and development of herbivorous insects are linked to nitrogen levels in plants (Strong et al., 1984), sugars are important and stimulate feeding in some thrips (Boyce and Persing, 1939; Morse, 1995; Parella, 1995). However, it is unclear from our results what role carbohydrates play in host selection behavior of thrips. Levels of carbohydrate in plants did not correlate with the oviposition behavior of *H. haemorrhoidalis*. However, within the tall tree *P. boldus*, distribution of thrips at the top and middle of the tree was associated with high levels of carbohydrates, although protein levels were also higher in leaves from the top and middle of the tree. Therefore, is not clear whether the thrips are responding to the proportion of protein, carbohydrate, or both. Further research on a wider range of hosts as well as on diets that contain defined ratios of protein and carbohydrates are required to quantify the role soluble protein plays in the selection behavior and establishment of populations of *F. occidentalis* and *H. haemorrhoidalis*.

Low levels of primary metabolites or increased levels of secondary metabolites, such as alkaloids and tannins, are both factors that can affect plant selection as a food source for insects (Schoonhoven et al., 1998a). To date there is little information in the literature about the types of secondary compounds that could modulate the host selection behavior of thrips. Preliminary experiments using leaf-discs of species that had similar levels of protein and carbohydrates varied in their ability to support thrips (Scott Brown, 2002). This suggests that secondary metabolites in the leaves play a role in plant–thrips interactions. Identification of secondary metabolites in leaves of plant species that are unable to support thrips, such as *Sclerochiton harveyanus*, may provide a valuable lead for compounds that are active against *H. haemorrhoidalis* and *F. occidentalis*, and this will be the focus of further investigations.

Acknowledgments—We thank Jenny Greenwood and Sue Mitchell at the University of Reading, for technical support and helpful suggestions about protein analysis. We are also grateful to the Fleming Trust, UK, for the financial support that made this study possible.

Abstract—A previous study showed that Sitka black-tailed deer (*Odocoileus hemionus sitkensis*) consumption was negatively correlated with monoterpene content in western redcedar (*Thuja plicata*). To test whether these monoterpenes were deterrent to Sitka black-tailed deer, we performed feeding choice experiments with four hydrocarbon (sabinene, myrcene, α-pinene, and $d + l$-limonene) and one oxygenated (α,β-thujone) monoterpene solution at their highest natural concentration in western redcedar foliage. To test whether deer response was species specific, we ran similar experiments on European roe deer (*Capreolus capreolus*) and rusa deer (*Cervus timorensis russa*). In all experiments, monoterpenes were repellent. Solutions with α,β-thujone, the major monoterpene in redcedar leaves, were the most repellent of the solutions tested. We then analyzed how black-tailed and roe deer responded to (1) an increase in concentration of the monoterpenes with the weakest repellent effects (hydrocarbon monoterpenes) and (2) a decrease in concentration of the monoterpene with strongest effect (α,β-thujone). Repellency tended to increase with concentration for hydrocarbon monoterpenes, but remained strong for α,β-thujone. As wild deer regularly feed on plants containing monoterpenes, this raises the question as to how the animals deal with these molecules.

Key Words—Monoterpenes, deer, cervids, feeding choice, herbivory.

INTRODUCTION

Monoterpenes, 10-carbon compounds biosynthesized from two isoprene (2-methyl-1,3-butadiene) units, are widely found as secondary metabolites in plants and are produced by nearly all conifers (Banthorpe and Charlwood, 1980; Bohlmann and Croteau, 1999; Trapp and Croteau, 2001). Numerous studies have shown that higher monoterpene concentrations in plants correlate with lower consumption by ungulate herbivores and, therefore, likely play an important role in the plant–herbivore interaction (Connolly et al., 1980; Personius et al., 1987; Duncan et al., 1994; Riddle et al., 1996; Estell et al., 1998a; Vourc'h et al., 2001). However, other studies have failed to find this correlation (Welch et al., 1983; Behan and Welch, 1985). To prove that monoterpenes are the cause of the deterrence of a plant, one needs to test their effects experimentally. We know of only three studies that have done so, using ungulate herbivore food-choice assays. The first, by Elliot and Loudon (1987), tested the effect of monoterpene odors on captive red deer calves (*Cervus elaphus*). The other two, by Estell et al. (1998b, 2000), tested the effect of monoterpenes on domestic sheep. These studies found that some monoterpenes are indeed deterrent for these particular species. Nevertheless, the possibility exists that different ungulate species vary in response to different feeding deterrents (Oh et al., 1967; Zahorik and Houpt, 1991). Furthermore, exposure to certain compounds can trigger learning processes (Provenza, 1996; Spalinger et al., 1997; Tixier et al., 1998) or adaptations of the rumen flora (Oh et al., 1967) with the consequence that the reaction of the animal will depend on whether it had already encountered a compound in its diet or not.

Vourc'h et al. (2001, 2002) have shown that Sitka black-tailed deer (*Odocoileus hemionus sitkensis*) prefer western redcedar (*Thuja plicata* Dann ex D. Don) leaves that have low monoterpene concentrations. Based on this, the purpose of this study was to test directly the deterrent effect of western redcedar monoterpenes on Sitka black-tailed deer, independently of the plant material the compounds are found in. To explore whether our results applied to other conifer foraging deer species, we ran a second set of experiments with European roe deer (*Capreolus capreolus*), a temperate deer species with similar body size to Sitka black-tailed deer. Finally, we tested the effect of these compounds on a tropical deer species with little dependence on conifers as a food source, the rusa deer (*Cervus timorensis russa*).

METHODS AND MATERIALS

Monoterpenes. Two oxygenated monoterpene isomers (α,β-thujone) and four hydrocarbon monoterpenes (sabinene, myrcene, α-pinene and $d + l$-limonene) have been identified by Vourc'h et al. (2001) in western redcedar leaves and were tested in feeding choice experiments. Monoterpenes were obtained from

Aldrich Chemical (Milwaukee, Wisconsin, USA) except for sabinene, which was obtained from R. C. Treatt (Bury St. Edmunds, Suffolk, England). For α,β-thujone, sabinene, and myrcene, only solutions of technical-grade purity could be obtained. The thujone solution was extracted from western redcedar leaf and contained 65% α,β-thujone (67% β-thujone and 33% α-thujone at equilibrium), 15% fenchone, 10% bornyl acetate, 3% camphor, and a mixture of other minor terpenes. The sabinene solution contained 70% sabinene, 20% β-pinene, 4% α-pinene (tested as pure solution in our experiment), and a mixture of other minor terpenes. The myrcene solution contained 75% myrcene and other minor terpenes. Although these impurities may introduce some noise in the analysis of the effect of the main compounds, they all consist of compounds that occur commonly in most terpene-producing plants and are, for the most part, characterized by low biological activity (T. P. Clausen, personal communication).

We first tested these solutions on Sitka black-tailed deer, roe deer, and rusa deer (with a simplified protocol), with the concentration corresponding, for each monoterpene, to the mean concentration found in young western redceder foliage (Vourc'h et al., 2002). Trees of this age have the highest natural monoterpene concentration observed in western redcedars (Vourc'h et al., 2001, 2002). We defined this concentration as *in vivo* redcedar concentration.

Second, to analyze the effect on monoterpene identity, we tested these solutions at different concentrations, with Sitka black-tailed deer and roe deer. On the basis of the experiment with monoterpenes at *in vivo* redcedar concentration on Sitka black-tailed deer, we separated the solutions into two groups: (1) strongly repellent, meaning deer ate food containing monoterpenes in less than 50% of the trials, and (2) weakly repellent, meaning food containing monoterpenes was eaten in more than 50% of the trials. We then tested whether the strongly repellent solutions retained activity at lower concentrations, defining lower concentration as the minimum concentration of each monoterpene found in young western redcedar foliage (Vourc'h et al., 2002). We tested the second group of solutions at higher concentrations, defining it as the concentration of the most concentrated monoterpene in redcedar foliage, i.e., α,β-thujone. We refer to these two levels as "manipulated concentrations" throughout the remainder of the paper.

The amount of monoterpene solution (MonoSol) to be used in the experiments was calculated by taking into account the concentration that we wanted to achieve (MonoConc), the purity of the manufactured monoterpene solution (MonoPurity), the density of the compound (MonoDensity), and the dry weight of the food substrate (SubstrateDW):

$$\text{MonoSol (ml)} = \frac{\dfrac{\text{MonoConc (mg/g)}}{1000} \times \text{SubstrateDW (g)}}{\text{MonoDensity (g/ml)} \times \dfrac{\text{MonoPurity (\%)}}{100}}$$

This amount was put into 5 ml solvent (85% ethanol and 15% methanol) per 100 g of fresh substrate to form the monoterpene solution. The control solution was made of 5 ml solvent per 100 g of fresh substrate.

Black-Tailed Deer on Haida Gwaii. Feeding choice experiments with Sitka black-tailed deer involved wild deer living on Haida Gwaii (Queen Charlotte Islands, British Columbia, Canada), where western redcedar is a preferred food for that species (Pojar et al., 1980; Coates et al., 1985). To our knowledge, this is the first study testing the effect of secondary metabolites on wild ungulates. Sitka black-tailed deer were introduced from the nearby mainland to Haida Gwaii near the beginning of the 20th century (Carl and Guiguet, 1972). At that time, there was no other large herbivores on the archipelago (Cowan, 1989). Five male and four female free ranging black-tailed deer of Haida Gwaii were used at three different sites: one "natural site" (Vertical Point), and two logging camps (Beattie Anchorage and Eden Lake). One female and two males were 1–2 years old; the others were mature adults. At Vertical Point, deer got used to human presence within a few days. In logging camps, deer were already used to being close to humans.

Black-tailed deer were habituated to eating apples with the solvent for a few days before proceeding to the experiments. For each trial, we prepared two bowls with 100 g of fresh cut apples each. One bowl was sprayed with a monoterpene solution and one with the control solution. We then presented the pair of bowls to one individual deer and let it eat until it moved away. Because we did not stop the trial until the deer moved away, the deer could eat off either bowl. We weighed the amount of food left in each bowl to calculate the amount of food eaten. No weight changes in the food substrate occurred because of the short duration of each trial (3–30 min). Our protocol was to run three to five trials per deer per monoterpene solution at a given concentration. The order of monoterpenes was randomized per deer for a given concentration, starting with the *in vivo* redcedar concentration. No more than three trials per deer and per day were run. The experiment lasted three weeks.

Roe Deer in France. We ran experiments with roe deer raised in captivity at the Centre d'Etudes Biologiques de Chizé (France). Roe deer eat a wide range of plant species from all major taxonomic groups including fungi, ferns, shrubs, deciduous trees, and conifers (Duncan et al., 1998). During the experiment, roe deer had access to a small forest patch with understory and a grassy area. They also had *ad libitum* access to pellets (Caprilat: 18% protein, 3% fat, 8.7% cellulose, 7.2% ash) and water.

The captive roe deer were very sensitive to human presence and could not be kept in individual pens. Therefore, we could not work with individual deer and had to run the experiments in four pens with three to five deer in each (pen 1: three females; pen 2: four females and one male; pen 3: two females and one male; and pen 4: two females and one male). Pens ranged from a 450 m^2 to 1500 m^2 pasture and 2000 m^2 forest. For a given trial in a pen, we presented as many pairs of

monoterpene and control bowls as there were deer in the pen. Each monoterpene bowl contained 100 g of apples with the same monoterpene solution and the control bowl contained 100 g of apples with solvent similar to the experiments with Sitka black-tailed deer (discussed above). We recorded the number of deer that took part in each trial as well as the number of pairs of bowls that were used. After a 2-hr trial, the total amount of control or monoterpene apples remaining in the bowls was weighed for each pen. Because the apple masses could change during the 2 hr that the trials lasted, we put a bowl with 100 g of apples outside each pen and weighed the bowl again at the end of each experiment. The amount of apple consumed was then calculated using the equation:

$$[(H_i \times O_f / O_i) - H_f]$$

where H_i and H_f were the initial and final masses of apples exposed to herbivory, and O_i and O_f the initial and final masses of apples outside the pens (Cronin and Hay, 1996). Our protocol was to run three to five trials per monoterpene solution per pen per concentration at a rate of two trials per day (one in the morning and one in the evening) in each pen. We randomized the order of monoterpene that were tested for a given pen, starting with the *in vivo* redcedar concentration. This experiment took place over a period of two months.

Rusa Deer in New Caledonia. Rusa deer were introduced to New Caledonia from the Indonesian island of Java in the 1870s (Chardonnet, 1988). Before the colonization of the island by Europeans in 1845, there were no large herbivores (Gargominy et al., 1996). Four domesticated rusa deer (a subadult male and a 1- or 2-year-old female, a 2- or 3-year-old stag, and a hind with her young) were available for experiments at the research Station of Port-Laguerre. Before the trials, the deer were raised in paddocks with cultivated grass (*Brachiaria mutica*, *Brachiaria decubems*, and *Pennisetum prurpureum*) and trees (*Calliandra calothrysus* and *Leucaena leucocephala*). During the trials, a similar diet was cut and provided daily to the animals in their cages, where they had *ad libitum* access to water.

For each trial, we presented a pair of monoterpene and control bowls to individual deer as in the experiments with Sitka black-tailed deer. The food substrate was altered to 20 g of fresh bread in each bowl. We tested monoterpenes at *in vivo* concentrations. Assays with myrcene had to be canceled because the quality of the chemical sample deteriorated. Three trials were run per day per deer using the same monoterpene solution. The order of the monoterpenes tested was randomized per deer. The experiment lasted three weeks.

Statistical Analyses. Data for each deer species were analyzed separately. For black-tailed and rusa deer, the statistic unit was a one-deer trial with a single monoterpene at a given concentration. For roe deer, the unit was a one-pen trial with one monoterpene at a given concentration. First, we calculated the frequency of zero values per monoterpene solution at each concentration, i.e., the frequency

of control or monoterpene bowls not being eaten. Then, for each trial, we calculated a log ratio of the proportion of food eaten for each option according to the method described in Elston et al. (1996):

$$\text{Log}\frac{\left(\frac{\text{g of treated food eaten}}{\text{g of treated food presented}}\right)}{\left(\frac{\text{g of control food eaten}}{\text{g of control food presented}}\right)} = \text{Log}\frac{(\text{g of treated food eaten})}{(\text{g of treated food eaten})}$$

For each trial, the sum of the proportions for each option must be 1, i.e., the data are compositional. Therefore, the log ratio transformation was the most appropriate, as it led to analyses in which the unit-sum constraint was automatically satisfied (Elston et al., 1996). If the proportion of food eaten for each option was equal, the log ratio was zero; if deer ate more control food, the log ratio was negative. To deal with the problem of 0 values, i.e., when either the control or treated food was not eaten, we replaced all the 0 values by 0.1 (Elston et al., 1996). To check the robustness of the replacement, we conducted the same analyses with values of 0.5, 1, and 2 instead of zeros, 0.5 g and 1 g being the smallest amount of bread and apple eaten, respectively. The results were consistent.

For black-tailed and roe deer, we tested the effect of concentration and monoterpene identity (= solution effect) by mixed analysis of variance of the log ratios data using the procedure MIXED in SAS (1999). The factors of interest (i.e., solution, concentration, and solution $\times$ concentration) were declared as fixed effects, whereas additional variables assumed to impact the variability of the data were declared as random effects: for black-tailed deer, deer identity and its interaction with fixed effects, as well as the rank of trial nested in deer, for roe deer, pen number and its interaction with the fixed effects, as well as the rank of trial nested in pen, the number of deer taking part in the trial in each pen, and the number of pairs of bowls from which the food was eaten at each trial. The same procedure was used for rusa deer except that the concentration effect in the mixed analysis of variance was not considered. Therefore, the fixed effect was the solution effect, and random effects were deer identity and its interactions with the solution effect, as well as the rank of the trial nested in deer. The variances of the random effects parameters became the covariance parameters. The selected structure was fitted to the data using the method of restricted maximum likelihood (REML). A likelihood-based scheme was used to infer type III F statistics to test the significance of the fixed effects (SAS, 1999). Mean differences were tested by Lsmeans (SAS, 1999). Lsmeans were also used to test whether the log ratios for each monoterpene at each concentration were significantly negative, i.e., whether the monoterpenes had a repellent effect.

RESULTS

All three species of deer smelled the food before tasting it.

Black-Tailed Deer in Haida Gwaii. In all but two of the 10 treatments, each deer was tested at least three time (Table 1). Deer tried the apples in bowls with α,β-thujone at *in vivo* redcedar concentration in only 17% of the trials. For the other monoterpenes, deer tested the bowls with monoterpene solutions in more than 50% of the trials and ate apples in 98% of the control bowls (Figure 1). The only three instances in which deer did not touch control bowls occurred in trials with α-pinene at *in vivo* redcedar concentration (i.e., in 10% of trials for this solution). The percentage of apples actually consumed in bowls with α,β-thujone was less than 2%. It varied between 40 and 70% for the other monoterpenes, whereas the percentage of apples consumed in control bowls was over 80% on average (Figure 2). Figure 3 shows a representative example of a trial for thujone. Because deer ate apples from bowls with α,β-thujone in less than 50% of the trials, α,β-thujone was tested at a diluted manipulated concentration. The other four monoterpenes solutions (sabinene, myrcene, α-pinene, and $d + l$-limonene) were all tasted by deer in more than 50% of the trials. We tested them at one elevated manipulated concentration.

TABLE 1. EFFECTS OF MONOTERPENE SOLUTIONS[a]

	Proportion of pens									
	Thujone		Sabinene		Myrcene		α-Pinene		$d + l$-Limonene	
	In vivo	Manip.	In vivo	Manip.	In vivo	Manip.	In vivo	Manip.	In vivo	Manip.
Sitka black-tailed deer [deer (N) with 3–5 trials/total deer (N) tested]	7/9 a[b]	9/9	9/9	5/9 b	9/9	9/9	9/9	9/9	9/9	9/9
Roe deer [pens (N) with 3–5 trials/total pens (N) tested]	4/5 c	2/2	4/5 c	2/2	5/5	2/2	4/5 c	2/2	5/5	2/2
Rusa deer [deer (N) with 3–5 trials/total deer (N) tested]	4/4	4/4	4/4	4/4	4/4	4/4	4/4	4/4	4/4	4/4

[a] The number of trials was at least 3 and at most 5 in each test. Concentrations of compounds were at *in vivo* levels and at manipulated higher (thujone) or diluted (other compounds) levels.
[b] a, 2 deer with 1 trial only; b, 4 deer with 1 trial only; c, 1 pen with 2 trials only.

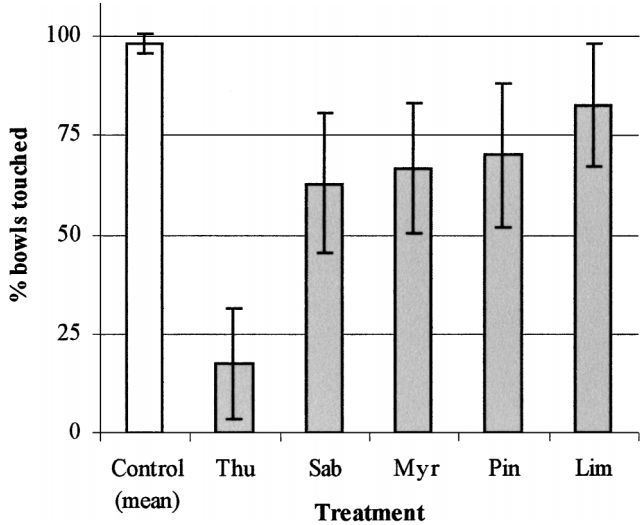

FIG. 1. Percent of bowls with apples that were touched by Sitka black-tailed deer for trials with monoterpene solutions at *in vivo* redcedar concentration or with a control solution. The percentage of control bowls touched is an average over all trials. Vertical bars are 5% confidence intervals bars. Thu = α,β-thujone, Sab = sabinene, Myr = mycrene, Pin = α-pinene, and Lim = $d + l$-limonene.

Deer tasted the content of bowls with the α,β-thujone solution at diluted concentration in 28% of the trials and consumed 12% of the apples. They tasted the content of bowls with elevated concentration of the other monoterpenes in 54–68% of trials, consuming 25% (pinene) to 35% (sabinene) of the apples (Figure 4). Deer tasted the apples in all control bowls, consuming 80–97% of the apples.

For each solution and at both concentrations, the repellent effect was significant, i.e., the mean of the log ratio was significantly smaller than zero ($P < 0.05$ for all cases). Mixed analysis of variance showed an effect of solution ($F_{4,32} = 10.07$, $P < 0.001$), concentration ($F_{1,8} = 11.43$, $P = 0.009$), and the solution $\times$ concentration interaction ($F_{4,32} = 2.99$, $P = 0.033$). The solution effect was significant at *in vivo* redcedar concentration ($F_{4,32} = 9.72$, $P < 0.001$), and at manipulated concentrations ($F_{4,32} = 3.62$, $P = 0.015$). α,β-Thujone solutions were more repellent than the other solutions at both concentrations ($P < 0.05$) (Figures 2 and 4). The repellent effect was greater at the manipulated concentration than at the *in vivo* redcedar concentration for α-pinene and for $d + l$-limonene ($P < 0.05$), but not for the other compounds.

Roe Deer in France. A total of 10 of 14 roe deer took part in the trials: all three deer in pen 1, three of five deer in pen 2, and two of three in pens 3 and 4. Deer in pens 3 and 4 were shy and only took part in the first set of experiments

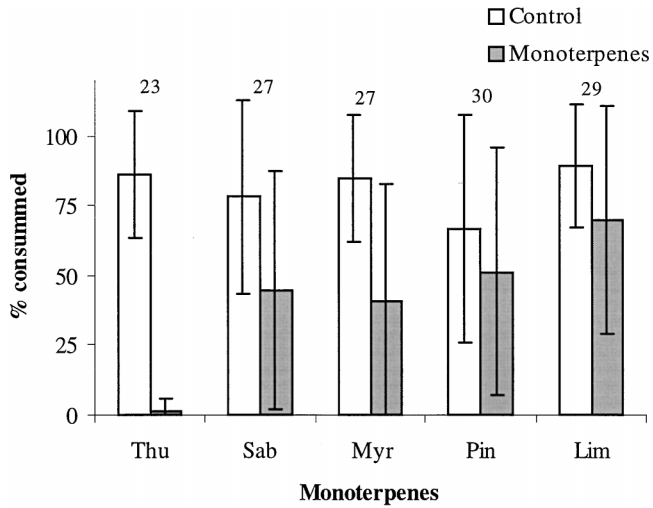

FIG. 2. Average percent of apples consumed by Sitka black-tailed deer in trials with different monoterpene solutions at *in vivo* redcedar concentration or with a control solution. Number of trials per deer varied from 3 to 5 (with some exceptions, see Table 1). Numbers above bars are number of trials. Vertical bars are standard deviations, abbreviations as in Figure 1. All differences in consumption between control and monoterpene bowls are significant ($P < 0.05$).

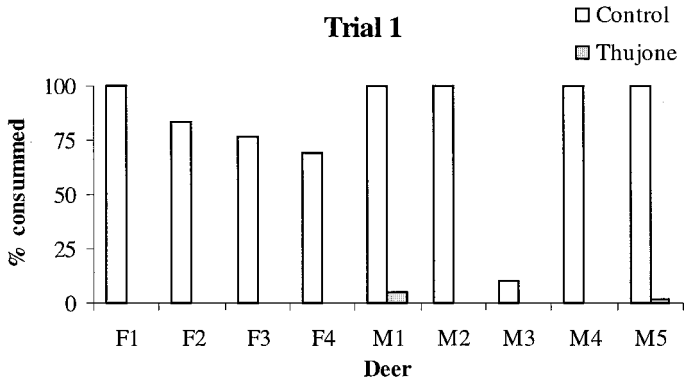

FIG. 3. Representative example of effect of α,β-thujone on Sitka black-tailed-deer consumption. Thujone = bowl of apple with α,β-thujone solution at *in vivo* redcedar concentration. Control = bowl of apple with control solution. F1 to F4 = females 1–4, M1–M5 = males 1–5.

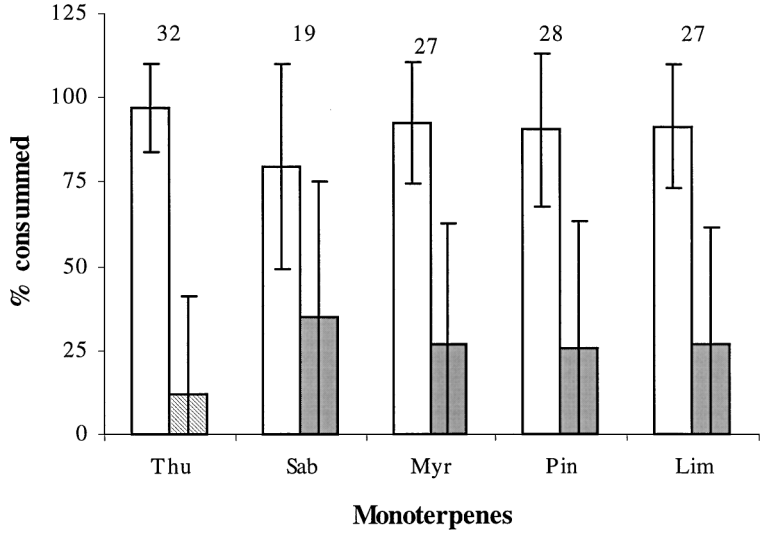

FIG. 4. Average percent of apples consumed by Sitka black-tailed deer in trials with different monoterpene solutions at manipulated concentrations. Hatched bars = monoterpene tested at lower than *in vivo* concentration; shaded bars = monoterpenes tested at higher than *in vivo* concenterations; open bars = control solutions. Vertical bars are standard deviations. Numbers above bars are number of trials. Abbreviations as in Figure 1. All differences in consumption between control and monoterpene bowls are significant ($P < 0.05$).

(*in vivo* concentrations). Except for three cases, at least three trials were run for each of the pens tested (Table 1).

Deer ate apples from the control bowl in each trial except once for the α-pinene, myrcene, and $d + l$-limonene trials at *in vivo* redcedar concentration. At *in vivo* concentrations, food with α,β-thujone was tested in 40% of the trials, that with sabinene in 94%, myrcene in 88%, α-pinene in 62%, and $d + l$-limonene in 65%. Deer tested 62% of bowls with α,β-thujone at diluted manipulated concentration. At elevated manipulated concentration, deer tested 63% of the bowls with sabinene, myrcene, and α-pinene, and 75% of the bowls with $d + l$-limonene. In the trials at *in vivo* concentrations, deer ate less than 2% of the apples with α,β-thujone solution, ate between 19 and 27% of the apples with the other monoterpene solutions, and about 50% of the apples in the control bowls (Figure 5a). In the trials at manipulated concentrations, deer ate about 13% of the apples in the bowls with α,β-thujone at diluted concentration and 9–20% of the apples in trials with the other monoterpenes at elevated concentrations (Figure 5b). In these experiments, deer ate 68–82% of the apples in the control bowls. Figure 6 shows, as an example, the results of the trials for sabinene.

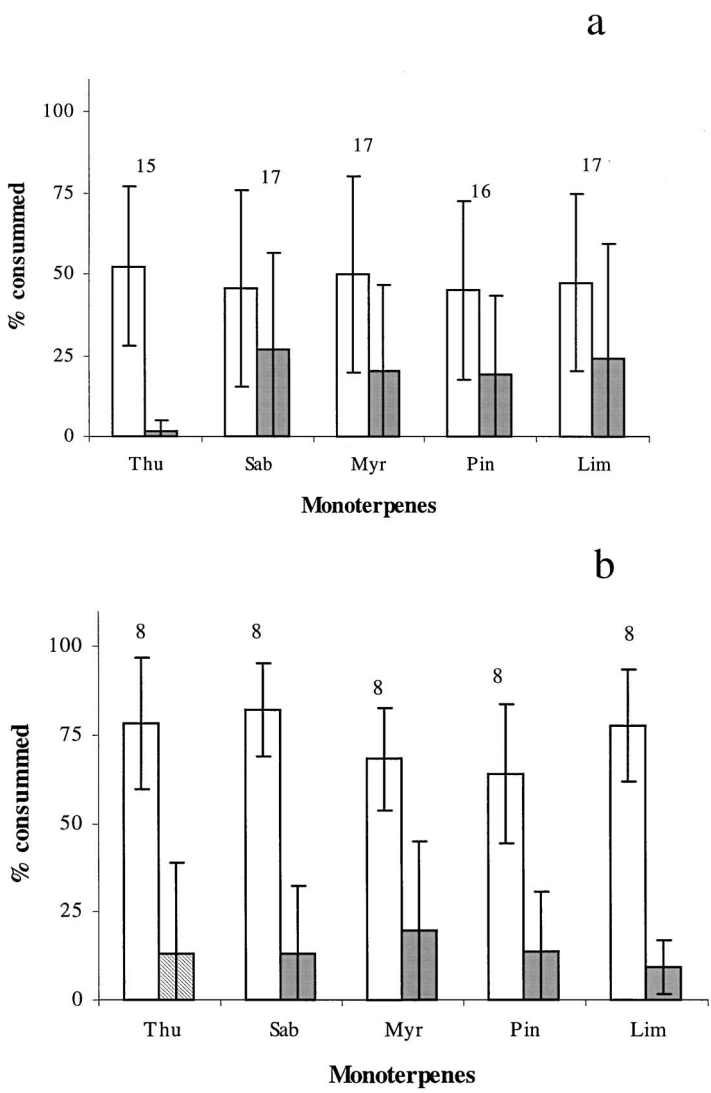

FIG. 5. Average percent of apples consumed by roe deer in trials with different monoterpene solutions at *in vivo* redcedar concentrations (a) and at manipulated concentrations (b). Vertical bars are standard deviations. Numbers above bars are number of trials pooled for all pens. (a) Shaded bares = monoterpene solutions, open bars = control solutions. (b) Hatched = monoterpenes tested at lower than *in vivo* concentration; shaded = monoterpenes tested at higher than *in vivo* concentration; open bars = control solutions. Abbreviations as in Figure 1. All differences in consumption between control and monoterpene bowls are significant ($P < 0.05$), except for sabinene at *in vivo* concentration.

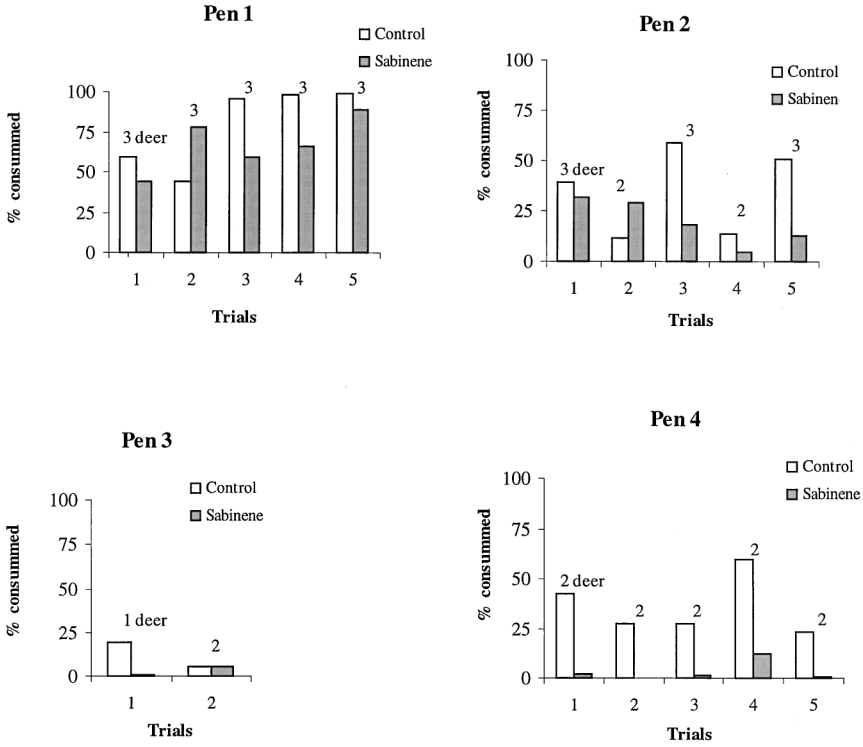

FIG. 6. Example of weak response to sabinene by roe deer from different pens. Deer had access to bowls with apples plus a control solution (control) or with apples plus a sabinene solution at *in vivo* redcedar concentration (sabinene). Numbers above bars are number of deer taking part in the trial in each pen.

The mixed analysis of variance showed no significant effect of the interaction term solution × concentration; therefore, we tested the single effects without the interaction. The solution effect was not significant ($F_{4,8} = 1.84$, $P = 0.207$), nor was the concentration effect ($F_{1,1} = 1.99$, $P = 0.393$). Even though α,β-thujone tended to be more repellent than other solutions at *in vivo* redcedar concentration (Figure 5), the solution effect was not significant either at *in vivo* ($F_{4,12} = 2.25$, $P = 0.124$) or at manipulated concentrations ($F_{4,4} = 0.05$, $P = 0.993$).

For each monoterpene at each concentration, the repellent effect was significant ($P < 0.05$ for all cases), except for sabinene at *in vivo* redcedar concentration ($P = 0.746$).

Rusa Deer in New Caledonia. Three trials were run per monoterpene solution and per deer. Of the bowls with α,β-thujone, sabinene, $d + l$-limonene, and α-pinene, 12%, 74%, 75%, and 100%, respectively, were touched. Note that myrcene

was not tested. All control bowls were touched, and over 95% of their bread was eaten. The percentage of bread eaten in bowls with the α,β-thujone solution at *in vivo* concentration was 2% and was 47%, 88%, and 57%, respectively, for sabinene, α-pinene, and $d + l$-limonene.

The mixed analysis of variance showed a significant effect of solution ($F_{3,9} = 15.05$, $P < 0.001$) at *in vivo* redcedar concentration, the only concentration used. The repellent effect was significant for α,β-thujone, sabinene, and $d + l$-limonene ($P < 0.010$ in each case), but not for α-pinene ($P = 0.315$).

DISCUSSION

Monoterpenes Are Repellent to Deer. The results of this study show that monoterpenes are feeding deterrents to deer. These results confirm the correlation observed between monoterpene content and western redcedar foliage choice by Sitka black-tailed deer (Vourc'h et al., 2001, 2002). The deterrent effect was strongest for the thujone solution, oxygenated monoterpene isomers, extracted from western redcedar leaves. This contrasted with the lower effect of the rest of the monoterpenes tested, which were all hydrocarbon monoterpenes. There was no difference between the repellent effect of these hydrocarbon monoterpenes. A stronger repellency of oxygenated monoterpenes has been suggested by Oh et al. (1967) and Schwartz et al. (1980) but has not always been confirmed (Estell et al., 2000). Diluting the concentration of α,β-thujone did not decrease its repellency. Increasing the concentration of hydrocarbon monoterpenes did increase their repellency for Sitka black-tailed deer. The same trend was observed for roe deer, but was not significant (deer from two of four pens did not take part in the trials on manipulated concentrations, reducing the power of the statistical tests).

Variation among Deer. Despite differences in the experimental protocols, we observed a remarkable homogeneity in the response pattern across species, suggesting a broad effect of monoterpenes on deer food choice. The experiments also revealed some variation in the response of the three deer species studied. At *in vivo* redcedar concentrations, sabinene and α-pinene were not repellent to roe and rusa deer, respectively, but were to Sitka black-tailed deer. A repellent effect of α-pinene on sheep was also observed by Estell et al. (1998b) and on red deer by Elliott and Loudon (1987) at concentrations similar to those in our study. At a lower concentration, however, Estell et al. (2000) did not find a deterrent effect of sabinene on sheep. Finally, Sitka black-tailed deer, which include western redceder in their regular diet, responded more strongly to α,β-thujone than roe deer, which are usually not exposed to redcedar.

Signal Effect and Consequences. Our observations of deer first smelling their food before eating or avoiding it are consistent with the findings of Elliott and London (1987) that indicate it is the odor of monoterpenes that deter red deer. However, for a plant defense to be effective, a signal has to be associated with the

negative consequences of eating the plant (Lawler et al., 1999). Indeed, if there is no physiological consequence associated with a signal, deer will ultimately learn that the food is palatable (Tixier et al., 1998; Villalba and Provenza, 2000). The nature of these negative postingestive effects of monoterpenes is still under investigation. Studies on small mammals (Millet et al., 1981; Hiroi et al., 1995; Höld et al., 2000) have suggested that it could be neurotoxicity. *In vitro* experiments by Nagy et al. (1964), Oh et al. (1967, 1968), and Schwartz et al. (1980) suggested that monoterpenes could inhibit rumen microbial fermentation, but studies based on rumen inocula (Welch and Pederson, 1981; Cluff et al., 1982) suggest that monoterpenes in the rumen might not reach concentrations high enough to affect rumen microorganisms. Further work is needed to fully understand the effect of monoterpenes on cervid digestion.

Monoterpene Effects on Foraging in the Wild. The influence of monoterpenes on deer foraging in the wild is another area where additional work is needed. Indeed, the strong repellent effect of monoterpenes we observed seems to be at odds with the regular consumption (and even the preference) of western redcedar by Sitka black-tailed deer (Pojar et al., 1980; Coates et al., 1985) and with the habit of roe deer to forage on various monoterpene-containing conifers (Duncan et al., 1998). This discrepancy could result from deer in the wild not being able to access more palatable food or from monoterpenes in conifer leaves being less detectable than monoterpenes sprayed on food substrate. It also suggests that deer can deal with monoterpenes once they are ingested, either through detoxification and/or by regulating their toxin intake according to food flavor, toxin, nutrient, and dietary experience (Provenza, 1995, 1996).

For tropical rusa deer, the context is different, as they live on New Caledonia where conifers are present, but whose contribution to deer diet is unknown. Rusa deer may encounter a much more extensive assortment of plants and could have developed a rumen flora and feeding behavior adapted to a more varied array of plant secondary metabolites including monoterpenes (Oh et al., 1967).

Acknowledgments—This research was done as part of a long-term project by the Research Group on Introduced Species (RGIS, rgis@qcislands.net). Funding was provided by the South Moresby Forest Replacement Account (SMFRA), by Forest Renewal British Columbia (FRBC, award PA97335-BRE) and by joint funding from Centre National de la Recherche Scientifique and Ministry of Foreign Affairs of France (PICS 489). FRBC is a partnership of forest companies, workers, environmental groups, First Nations, communities, and government of British Columbia. Funding assistance by FRBC does not imply endorsement of any statements or information contained herein. We thank the British Columbia Ministry of Forests (Queen Charlotte District), the Laskeek Bay Conservation Society, Olympic Forest products, Husby Forest Products, and Western Forest Products for providing logistic support, and R. C. Treatt for providing some Sabinene samples. Funds for the experiments in New Caledonia were provided by CIRAD, IAC, and the French Ministère de I'Aménagement du Territoire et de 1'Environnement (ECOFOR 2000.08). Special thanks to T. Clausen, P. Duncan, D. Forsyth, and N. Guillon, G. Martin, B. Rowsell, M. Salzl, and G. Wiggins, as well as to the people in the Beattie Anchorage and Eden Lake logging camps for their help and insights.

(Received December 10, 2001; accepted July 22, 2002)

Abstract—Iridoid glycosides are a group of terpenoid secondary plant compounds known to deter generalist insect herbivores. In ribwort plantain (*Plantago lanceolata*), the iridoid glycosides aucubin and catalpol can be induced following damage by insect herbivores. In this study, we investigated whether the same compounds can be induced following infection by the fungal pathogen *Diaporthe adunca*, the causal agent of a stalk disease in *P. lanceolata*. Significant induction of aucubin and catalpol was observed in two of the three plant genotypes used in this study following inoculation with the pathogen. In one of the genotypes, induction occurred within 6 hr after inoculation, and no decay was observed within 8 days. The highest level of induction was observed in reproductive tissues (spikes and stalks) where infection took place. In these tissues, iridoid glycoside levels in infected plants were, on average, 97% and 37% higher than the constitutive levels in the corresponding control plants, respectively. Significant induction was also observed in leaves (24%) and roots (17%). In addition to significant genotypic variation in the level of induction, we found genetic variation for the tissue-specific pattern of induction, further broadening the scope for evolutionary fine-tuning of induced responses. Recent studies have revealed a negative association between iridoid glycoside levels in *P. lanceolata* genotypes and the amount of growth and reproduction of *D. adunca* that these genotypes support. However, for the three genotypes used in the present study, differences in resistance were not related to their constitutive or induced levels of iridoid glycosides, suggesting that additional resistance mechanisms are important in this host-pathogen system. We conclude that iridoid glycosides in *P. lanceolata* can be induced both by arthropods and pathogenic micro-organisms. Pathogen

infection could, therefore, potentially enhance resistance to generalist insect herbivores in this species.

Key Words—Constitutive chemical defense, induced chemical defense, *Diaporthe adunca*, genetic variation, *Plantago lanceolata*, plant–pathogen interactions, plant–herbivore interactions.

INTRODUCTION

The role of secondary plant compounds in defense against pathogens has been studied intensively during the past decades (e.g., Bailey and Mansfield, 1982; Harborne, 1993; Hammerschmidt and Kuc, 1995). A wide variety of secondary metabolites appears to be involved in pathogen resistance. Whereas some of these compounds are produced constitutively, many others are only produced in response to pathogen infection, either by hydrolysis or oxidation of preexisting nontoxic substrates, or *de novo* by gene derepression or activation of enzyme systems, as in the case of phytoalexins (Harborne, 1993). An aspect of secondary plant metabolites that has recently attracted attention is their specificity, both with respect to the types of organisms that can induce them and with respect to the types of organisms that they can affect (e.g., Krischik et al., 1991; Barbosa, 1991; Harborne, 1993; Hammerschmidt and Schultz, 1996; Karban and Baldwin, 1997; Paul et al., 1999; Felton and Korth, 2000; Stout and Bostock, 2000). For instance, phytoalexins are generally considered to be specifically active against pathogenic microorganisms, but they often appear to affect the performance of insect herbivores as well. In fact, several groups of secondary plant compounds have been shown to play a role in defense against both insect herbivores and pathogens (for reviews see, e.g., Krischick et al., 1991; Harborne, 1993; Hatcher, 1995; Hammerschmidt and Schultz, 1996), which has raised the question of whether secondary metabolites could serve a "generalized defense function" (Krischik et al., 1991). Groups that can function both as antiherbivory and antimicrobial compounds include isoflavonoids in legumes (Kogan and Fischer, 1991), inducible terpenes and phenolics in conifers (Klepzig et al., 1996), and many alkaloids (Hartmann, 1991) such as nicotin in tobacco (Krischick, 1991), glycoalkaloids in potato and tomato (Sinden et al., 1973, 1978; Roddick, 1974), and quinolizidine alkaloids in lupins (Wink, 1984). Many of these compounds can be induced by either or both types of biotic agents, and could, thus, mediate induced cross-resistance between pathogens and insect herbivores (Hammerschmidt and Schultz, 1996).

An interesting group of molecules in this respect are the iridoid glycosides. Iridoid glycosides are a group of monoterpene derivates found in a large number of plant families (Jensen, 1991) that are produced via the isoprenoid biosynthetic pathway (McGarvey and Croteau, 1995). Their biological effects on insect herbivores are well documented. They generally deter feeding by generalist insect

herbivores but can be used as feeding or oviposition stimulants by some specialists (Bowers, 1991). For instance, the iridoid glycosides aucubin and catalpol that occur in ribwort plantain (*Plantago lanceolata*) reduce the growth of the generalist herbivore *Lymantria dispar*, but they enhance growth of the specialist *Junonia coenia* (Bowers and Puttick, 1988) that uses these compounds as feeding and oviposition stimulants (Pereyra and Bowers, 1988; Bowers and Puttick, 1989; Klockars et al., 1993) and sequesters them for its own defense against predators (e.g., Dyer and Bowers, 1996; Bowers and Stamp, 1997; Camara, 1997). Biological effects of iridoid glycosides on bacterial and fungal microorganisms have also been documented. *In vitro* studies have shown antimicrobial activity of the aglycon form of aucubin and catalpol (the products of enzymatic conversion by β-glucosidase enzymes) (Rombouts and Links, 1956; Ishiguro et al., 1982; Van der Sluis et al., 1983; Davini et al., 1986; Stermitz, 1988). In accordance with these studies, we have recently shown *in vitro* inhibiting effects of the aglycon form of aucubin and catalpol on the growth of *Diaporthe adunca*, a specialist phytopathogenic fungus of *P. lanceolata* (Marak et al., 2002). In addition, our studies suggest *in vivo* antimicrobial effects of these compounds; growth and reproduction of *D. adunca* were significantly reduced on *P. lanceolata* plants artificially selected for high constitutive levels of iridoid glycosides compared to plants selected for low levels of these compounds, the latter group having on average approximately fourfold lower leaf levels of aucubin and catalpol (Marak et al., 2000). Insect herbivores can induce aucubin and catalpol in *P. lanceolata* (Bowers and Stamp, 1993; Darrow and Bowers, 1999; but see Jarzomski et al., 2000), but whether infection by pathogenic fungi can also result in their induction, and hence in a potential increase in resistance to generalist insect herbivores, is as yet unknown.

In this paper, we investigate whether aucubin and catalpol, the main iridoid glycosides that occur in *P. lanceolata*, can be induced following infection with the specialist fungus *D. adunca*. In addition, we investigate the phenological pattern of induction, whether induction is local or systemic, whether it is tissue-specific, and whether the level of induction differs among plant genotypes within a population. Genetic variation for the level of induction of chemical defense has been documented for several natural plant–herbivore systems, but evidence from natural plant–pathogen systems is scarce (Agrawal, 2000). Such variation is a prerequisite for any evolutionary response to selection for increased or decreased inducibility of defense to occur. The scope for evolutionary fine-tuning of induced responses to biotic challenge would even be broader if, in addition, there is genetic variation for the tissue-specific pattern of induction (Karban and Baldwin, 1997). We address four questions: (1) Is there genetic and tissue-specific variation in the constitutive level of the iridoid glycosides aucubin and catalpol among plant genotypes? (2) Is there local and/or systemic induction of iridoid glycosides following fungal infection? (3) Does the level of induction of aucubin and catalpol differ among plant

genotypes? (4) Does the level of induction differ among plant tissues and are such allocation patterns genotype-specific?

METHODS AND MATERIALS

Host Plant. Ribwort plantain (*Plantago lanceolata* L.) is a perennial plant species with a worldwide distribution and a large ecological amplitude (Sagar and Harper, 1964). The species is typically found in roadsides, hayfields, and dry grassland (Haeck, 1992). The plant forms a rosette that can survive during the winter. Flowers are produced in spikes on elongated stalks.

Iridoid glycosides in P. lanceolata. P. lanceolata contains, among others, the two iridoid glycosides aucubin and catalpol (Duff et al., 1965). Aucubin is the biosynthetic precursor of catalpol (Damtoft et al., 1983). In natural populations, iridoid glycoside levels in *P. lanceolata* range from undetectable to ca. 9% of its dry weight (Bowers, 1991). Variation in constitutive iridoid glycoside content in *P. lanceolata* is partially genetically determined (Bowers et al., 1992; Bowers and Stamp, 1992, 1993; Adler et al., 1995). In addition, iridoid glycoside levels in *P. lanceolata* are strongly affected by environment and ontogeny. Average levels vary among habitats and populations (Darrow and Bowers, 1997) and are generally higher in plants grown under high light and low nutrient or water conditions (Fajer et al., 1992; Darrow and Bowers, 1999). Levels generally decrease with plant and leaf age, and change during the growing season (Bowers et al., 1992; Bowers and Stamp, 1992, 1993; Stamp and Bowers, 1994; Adler et al., 1995; Darrow and Bowers, 1997, 1999). Biological effects and induction of iridoid glycosides in *P. lanceolata* have been summarized in the introduction.

Pathogen. The stalk pathogen *Diaporthe adunca* (Rob.) Niessel is an ascomycetous phytopathogenic fungus. It is specialized on *P. lanceolata* and a few other species within the same plant genus (De Nooij and Van der Aa, 1987), and reduces seed production of the plant. In spring, mature asexual spores, derived from asexual fruiting bodies (pycnidia) on overwintered scapes that were infected during the previous season, infect new spikes mainly through rain splashes (Linders et al., 1996). The fungus usually attacks the host stalks (just below the spikes) and grows down the stalks, transforming the green stalks into a black, stromatic tissue with asexual fruiting bodies (pycnidia) that start to sporulate under wet conditions, producing asexual spores (conidiospores). During rain events, new healthy spikes get infected by the asexual spores from these pycnidia through horizontal splash dispersal. Infected stalks show a characteristic downward curvature and suffer reduced seed set because transport of water and nutrient to these stalks is blocked. When the fungus reaches the rosette, the rosette will blacken, and the host will eventually die. The sexual stage of the fungus is heterothallic (Linders, 1996). Perithecia (ascomata) are formed within diseased stalk tissues.

After asexual reproduction from detached, overwintered scapes in spring, perithecia develop from the same diseased stalks (from June until September), producing sexual spores (ascospores).

Cloning of Host Plants. Three plant genotypes of *P. lanceolata* were collected from a roadside population at Papendal (52°00′ N, 5°49′ E), The Netherlands. We refer to these plant genotypes as P1, P2, and P3. Each genotype was cloned into ca. 150 individual rosettes by using a root cutting method (Van der Toorn et al., 1984). The mother plants were grown in pots with a perforated bottom, and these pots were placed on top of other pots filled with compost soil. After 20 weeks, the mother plant was removed and root cuttings established in the lower pots were allowed to grow and form new rosettes for a few weeks.

Preparation of Spore Suspension. Pathogen isolates originated from a nearby roadside population of *P. lanceolata* at Wolfheze (52°00′ N, 5°48′ E), The Netherlands, in 1990. Isolates were stored in the form of experimentally infected stalks at −20°C. A single isolate (016-9002), shown to be highly virulent on a large number of plant genotypes from a number of host populations (E. G. A. Linders, unpublished data), was used for inoculation. To obtain a spore suspension for inoculation, diseased stalks (2-cm pieces) were put on potato dextrose agar (PDA) medium at 22°C. After 4 days, small disks of fungal mycelium were transferred to oatmeal agar Petri dishes containing sterilized healthy plant stalks. The fungus was grown under UV light at 22°C for 3 weeks to induce spore production. A spore suspension of asexual spores containing 10^6 conidia/ml was prepared in sterile water.

Inoculations for Testing the Level of Induction of Iridoid Glycosides. Sixty rosettes per genotype were selected and transplanted in plastic pots ($9 \times 9 \times 10$ cm) with compost–sand (4:1) soil. Pots were completely randomized and plants were grown in the greenhouse under 16 hr light at 22°C/18°C day/night. After the start of male flowering, two spikes of 30 plants per genotype were inoculated by placing 20 μl of spore suspension at the base of the spike. The inoculated spikes were kept wet for two days by covering them with moist plastic bags. Moist plastic bags also covered the spikes of the control plants (30 plants per genotype) for two days. Five replicates of both inoculated and control plants were destructively harvested 6 times after inoculation (6, 12, and 24 hr, 2, 4, and 8 days). The latent period of the fungus is usually in the order of 1–3 weeks. In accordance, no disease symptoms were observed within the duration of the experiment. Each plant was divided into root, leaf, stalk, and spike tissue. The plant material was dried in a freeze drier and ground to fine powder in a mortar.

Inoculations for Testing the Susceptibility of Host Genotypes. In a second experiment, the three genotypes were tested for resistance to *D. adunca*. Twenty-three rosettes per genotype were selected and transplanted in plastic pots ($11 \times 11 \times 12$ cm) with compost–sand (4:1) soil. Pots were randomized and plants were grown in the greenhouse under 16 hr light at 22°C/18°C day/night. After the

start of male flowering, two spikes per plants per genotype were inoculated by placing 20 μl of spore suspension at the base of the spike. The inoculated spikes were kept wet for 2 days by covering them with moist plastic bags. Starting 1 week after inoculation, lesion size (length of blackened area) of each stalk was measured weekly during 4 weeks. To determine the density of the pycnidia that were produced on the diseased stalks, the degree of blackness was scored as: 0 = no pycnidia, 1 = <50% black, 2 = >50% black, and 3 = all pycnidia fused. To assess effects of fungal infection on seed set of the three plant genotypes, spike length and the number of seeds per spike was determined both for noninoculated and for inoculated spikes of five plants per genotype.

Chemical Analyses. Iridoid glycoside content in the plant tissues was analyzed with a gas chromatograph (Gardner and Stermitz, 1988). From each plant, 25 mg of ground material from roots and leaves, 15 mg of stalks, and 10 mg of spikes were extracted in 10 ml MeOH (95%) overnight. Crude extracts were filtered (Whatman No. 4) and the filtrate was evaporated to dryness. The dry residue was dissolved in 2 ml of distilled H_2O and washed three times with 1 ml of diethyl ether. After adding 1 ml of phenyl-β-D-glucose (0.5 mg/ml) as an internal standard, the aqueous layer was evaporated to dryness and the residue was dissolved in 1 ml of MeOH. A 0.10-ml aliquot was removed and placed into a small glass tube and evaporated to dryness. A silylation reagent (Tri-Sil Z, Pierce Chemical Company) was added (0.10 ml), and the closed tube was heated at 70–80°C for 15 min. After the solution was cooled, 1 μl was injected into a gas chromatograph (HRGC Mega 2, FISONS Instruments, Roadano, Italy). The GC was equipped with a split/splitless injector, a WCCT Fused Silica capillary column (Chrompack), and an FID detector. The injector was used in the split mode with a split ratio of 30:1 and a temperature of 275°C. Carrier gas was high-grade helium (99.996%) with a column heated pressure of 12 psi and a linear velocity of 30 cm/sec (1.44 ml/min). The detector temperature was 325°C, with a hydrogen flow of 38 ml/min, air flow of 200 ml/min, and helium flow of 40 ml/min. Samples were run under the following program: initial column temperature 200°C for 1 min, which was then raised to 260°C at a rate of 20°/min and held for 8 min. Peaknet Software Release 3.1 (DX-LAN module, Dionex Corporation, Sunnyvale, California, USA) was used for peak integration and data collection. Retention time (RT) was 7.28 min and 8.29 min for aucubin and catalpol, respectively.

Data Analysis. Effects of plant genotype, tissue, harvest time, and treatment (control vs inoculation) on iridoid glycoside content were tested by a repeated-measurements ANOVA (SAS 6.12, Procedure GLM, SAS Institute, Cary, North Carolina, USA). All factors were specified as fixed effects. The experimental units in this study were pots with individual plants. Measurements of iridoid glycoside levels of the four different tissues on each individual plant can, therefore, not be considered as truly independent. To account for the resulting covariance structure, tissue was treated as a repeated effect. Hence, tissue and all interactions

with tissue were analyzed as within-subject effects. All other effects were treated as between-subject effects. We will refer to the sum of aucubin and catalpol as "total iridoids." Separate analyses were performed for aucubin, catalpol, total iridoids, and the ratio of catalpol to the total iridoids. To improve normality, all chemical data were ln-transformed prior to analysis. To facilitate a discussion of effects of tissue, genotype, and time on the constitutive levels of iridoid glycosides, a second set of analyses was carried out using data of control plants only.

Calculations of fungal growth rate (millimeters per day) on the diseased stalks were based on quadratic regressions of the length of the black, stromatic part of stalks on time. Latent period (t_0) was estimated as the intercept with the x-axis. Average growth rate of the fungus was calculated over the first 21 days after the start of the first symptoms (t_0), the maximum period covered by all plants. For each time interval, the blackness of the infected stalk tissue (pycnidia-density class) produced during that interval was scored, and a mean value weighed by the length of the stromatic part at the corresponding time interval was calculated for each stalk. Analyses of variance were carried out to test differences in fungal growth rate, latent period (ln-transformed), and blackness among the three plant genotypes (Procedure GLM, SAS Institute) followed by *a posteriori* (SNK) contrasts. Chi-square tests were used to test differences in percentage of successful infections among plant genotypes.

RESULTS

Constitutive Levels of Iridoid Glycosides. The constitutive level of iridoid glycosides differed significantly among plant genotypes and plant tissues (Table 1), but not among harvests (Table 1, Figure 1). Reproductive tissues (stalks and spikes) had significantly higher levels of iridoid glycosides than vegetative tissues (leaves and roots), and within reproductive tissues, spikes had higher iridoid glycoside levels than stalks (Table 1, orthogonal contrasts for tissue; Table 2, data for control plants). The ratio of catalpol to the total iridoid glycosides showed a similar pattern, its average value decreasing from 0.68 in spikes to 0.33 in vegetative tissues (Table 2, data for control plants). There was a significant plant genotype × tissue interaction (Table 1), indicating that the magnitude of differences in constitutive levels of iridoid glycosides among plant genotypes depended on plant tissue. Notably, genotype P1 had significantly higher constitutive levels of iridoid glycosides in reproductive tissues, but not in leaves compared to the genotypes P2 and P3 (Figure 2, control plants). Genotypes also showed significant, tissue-specific, differences in the ratio of catalpol to the total iridoid glycosides (Table 1). Genotype P2 on average had a lower catalpol-to-total iridoid ratio than the other two genotypes (Figure 3, control plants).

[a] Tissue is treated as within-subjects factor (repeated measures analysis) and orthogonal contrasts for this factor are given: (1) reproductive (stalk + spike) vs. vegetative (leaf + root) tissue; (2) stalk vs. spike tissue; (3) leaf vs. root tissue. $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$.

Induction of Iridoid Glycosides as a Response to Fungal Infection. Overall, the levels of aucubin and catalpol significantly increased as a response to fungal infection (Table 3, Figures 1 and 2). The earliest observed induction (in the spikes of genotype P2, Figure 1) occurred within 6 hr after inoculation, and the average level of induction of iridoid glycosides was not significantly altered during the first week after inoculation (Table 3, no treatment × harvest interaction). The level of induction was slightly lower for catalpol than for aucubin (Table 2). Although this resulted in a significant reduction in the ratio of catalpol to the total level of iridoid glycosides (Table 3), the overall magnitude of the decrease in this ratio was rather small (Table 2, Figure 3). There were large differences in the level of induction among plant tissues (Table 3, interaction between treatment and plant tissue). The average level of induction was higher in spikes, where infection took place, and stalks (on average 97% and 37% higher than controls, respectively), than in leaves and roots (on average 24 and 17% higher than controls, Table 2). Within reproductive tissues, the level of induction was higher in spikes than in stalks (Table 3, orthogonal contrasts for the interaction between tissue and treatment). The level of induction also varied among genotypes in a tissue-specific way (Table 3). Genotype P1, which contained the highest constitutive levels of iridoid glycosides in reproductive tissues, did not show significant induction in any of the tissues

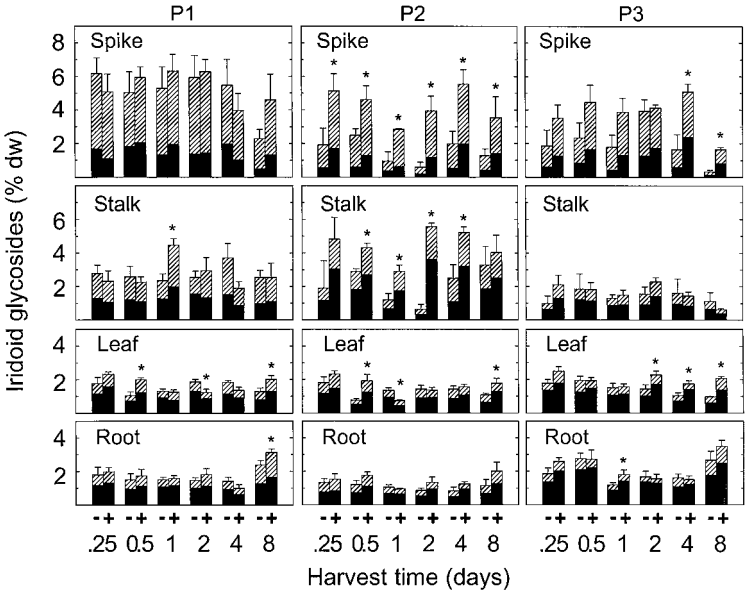

FIG. 1. Time course of the concentrations (% of tissue dry weight) of aucubin (black) and catalpol (shaded) in control (−) and inoculated (+) plants of *P. lanceolata*, between 6 hr and 8 days after inoculation. Data are for three plant genotypes, P1, P2, and P3, and four tissue types. Standard errors refer to the total iridoid glycoside (aucubin + catalpol) content. Asterisks refer to significant differences between iridoid glycoside levels in inoculated plants and their corresponding controls ($P < 0.05$).

(Figure 2). By contrast, genotypes P2 and P3, which showed low constitutive levels in reproductive tissues, showed significant induction in spikes and various other tissues (Figure 2).

Resistance to the Fungus D. adunca. The three genotypes P1, P2, and P3 differed significantly in their resistance to the pathogen isolate used in this study (Table 4). Genotype P3 had the lowest percentage of infection. Plants of this genotype that did become infected supported only limited growth and reproduction of the fungus compared to the other two genotypes. This was caused by a significantly (>1 week) longer latent period of the fungus on this genotype, as well as by a significantly lower density of asexual fruiting bodies of the fungus on infected parts of the stalks. As a result, P3 was the only genotype that was able to maintain seed production after inoculation (Table 4). Genotypes P1 and P2 were completely susceptible to the fungal isolate, and the only difference between these two genotypes was the higher density of fungal fruiting bodies produced on stalks of genotype P1. No differences in growth rate of the fungus were observed among the three plant genotypes. There was no indication that higher levels of resistance among

[a] Values within rows (across tissues) that do not share a common letter are significantly different from each other (SNK multiple comparison of means, $P < 0.05$). The level of induction (%) is expressed as [100 × (inoculated − control)/control], and the significance of induction is indicated by asterisks (one-way ANOVA of control vs. inoculated; NS is not significant, $^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$).

the three genotypes were associated with higher constitutive or induced levels of iridoid glycosides in their reproductive tissues (Figure 2). Both the constitutive level and the total level of iridoid glycosides following infection were actually lower in the resistant genotype P3 than in the susceptible genotype P1, despite the higher level of induction in the spikes of the former genotype. Constitutive levels of iridoid glycosides were equally low in the resistant genotype P3 and the susceptible genotype P2, whereas inducible levels in the stalk were higher in the latter genotype.

DISCUSSION

Induction of Iridoid Glycosides: A Generalized Response to Various Biotic Agents. Induction of secondary plant compounds as a result of fungal, bacterial, or viral infection and the role of these compounds in resistance have been shown in a large number of plant species (e.g., Harborne, 1993; Hammerschmidt and Kuc, 1995). Overall, infection of *P. lanceolata* by the common fungal stalk pathogen

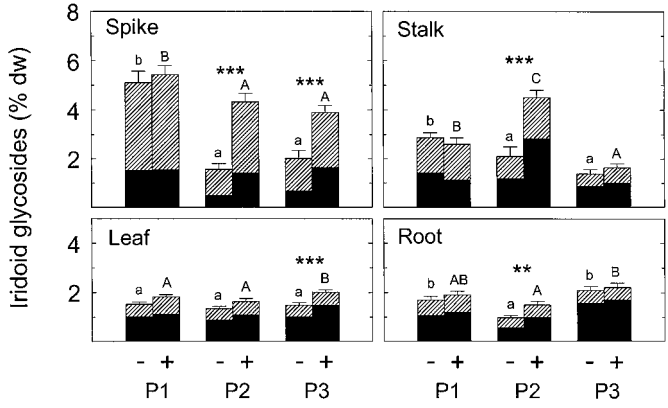

FIG. 2. Concentrations (% of tissue dry weight) of aucubin (black) and catalpol (shaded) in control (−) and inoculated (+) plants of three *P. lanceolata* genotypes, P1, P2, and P3, and four tissue types, averaged over six harvests ($N = 30$). Standard errors refer to the total levels of iridoid glycosides (aucubin + catalpol). Within each graph, total iridoid glycoside levels of genotypes that do not share a common small letter are significantly different from each other within the control treatment (SNK multiple comparison of means, $P < 0.05$). Likewise, capital letters refer to genotype differences within the inoculation treatment. Asterisks refer to significance of differences between inoculated and corresponding control plants, $^{**}P < 0.01$; $^{***}P < 0.001$.

D. adunca resulted in a significant, systemic increase in the levels of aucubin and catalpol in all above-ground plant tissues. The earliest observed induction was rapid, within 6 hr, and no decay of the response was observed within 8 days. To our knowledge, this is the first report of induction of these compounds by a pathogenic microorganism. The group of biotic agents that can induce iridoid glycosides in *P. lanceolata* is, therefore, not restricted to insect herbivores (Darrow and Bowers, 1999), but includes such disparate groups as arthropods and fungal pathogens. There is much recent interest in the degree of specificity of induced responses to arthropods and pathogens. Plants appear to possess a greater ability to distinguish between different types of biotic challenges (i.e., arthropods and pathogens) and to produce different sets of chemicals or gene products in response to each type of challenge than previously acknowledged ("specificity of response," Stout and Bostock, 2000). A growing number of studies present evidence that at least some of the many changes in the level or activity of chemical compounds, enzymes, and defense-related proteins that occur after challenge by phytophages are specific to the type of inducer. Nonetheless, concurrent changes in other compounds may be independent of the type of inducer, i.e., represent a common response to arthropod and pathogen challenge. In *P. lanceolata*, induction of iridoid glycosides appears to be part of such a common response. Growth chamber studies by Darrow and

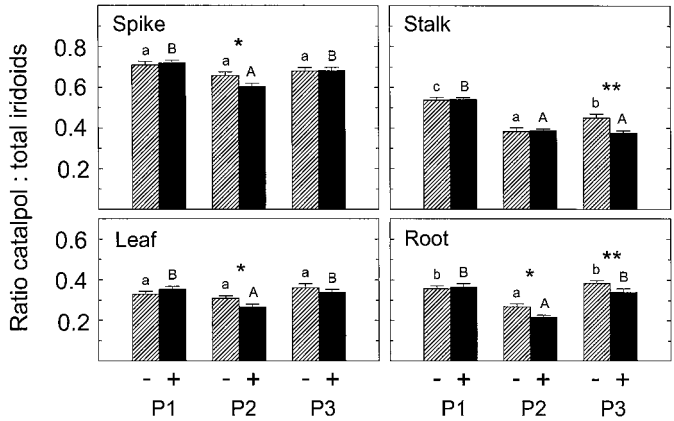

FIG. 3. Ratio of catalpol to the total level of iridoid glycosides (aucubin + catalpol) in control (−, hatched bars) and inoculated (+, black bars) plants of three *P. lanceolata* genotypes, P1, P2, and P3, and four tissue types, averaged over six harvests ($N = 30$). Within each graph, genotypes that do not share a common small letter are significantly different from each other within the control treatment (SNK multiple comparison of means, $P < 0.05$). Likewise, capital letters refer to genotype differences within the inoculation treatment. Asterisks refer to significance of differences between inoculated and corresponding control plants, $^{*}P < 0.05$; $^{**}P < 0.01$. Bars represent 1 SE.

Bowers (1999) have shown that leaf herbivory by caterpillars of the specialist insect herbivore *Junonia coenia* causes a significant increase in the levels of aucubin and catalpol in *P. lanceolata*, although experimental field studies using the same specialist herbivore have yielded more variable results. Levels of catalpol were found to increase (Bowers and Stamp, 1993), decrease (Jarzomski et al., 2000) or be unaffected (Stamp and Bowers, 1996, 2000) by exposure to *J. coenia*, whereas levels of aucubin were not affected in any of these studies. As discussed by Stamp and Bowers (1996, 2000), the inability to detect induction of iridoid glycosides by herbivory in experimental field studies may simply reflect the fact that prevailing biotic or abiotic field conditions such as summer drought can result in an induced status of both plants that are assigned to a herbivory treatment and "control" plants, hence the potential for a further increase in the level of iridoid glycosides by herbivory may be limited under such conditions. In addition to induction by insect herbivores and the fungal pathogen, studies by Gange and West (1994) suggest that increases in the level of iridoid glycosides may also result from infection by arbuscular mycorrhizae, although this should probably be viewed as an incidental consequence of an altered C/N ratio rather than as an active defense response (cf. Karban and Baldwin, 1997). Gange and West observed that treatment of *P. lanceolata* with the fungicide iprodione resulted in reduced levels of mycorrhizal

infection and, counterintuitively, in a reduced C/N ratio. The lower C/N ratio was associated with reduced levels of the carbon-based secondary metabolites aucubin and catalpol and increased feeding by leaf-chewing insects. Although these results are open to alternative interpretations, they illustrate the possibility that infection by below-ground organisms can result in a systemic increase in the levels of iridoid glycosides in above-ground plant tissues. Induction of iridoid glycosides, thus, seems to be a generalized response to challenge by different biotic agents.

In the present study, we were unable to show that higher constitutive and/or induced levels of iridoid glycosides were associated with enhanced resistance to the fungal pathogen *D. adunca*. This is at variance with recent results from a more extensive set of inoculations of 70 full-sib families that had been artificially selected for high and low constitutive levels of iridoid glycosides (Marak, 2000), showing that growth and reproduction of this fungus are reduced on plants selected for high

TABLE 4. NUMBER OF SEEDS PER MILLIMETER OF SPIKE (± 1 SE) PRODUCED BY THREE *P. lanceolata* GENOTYPES, P1, P2, AND P3, AFTER INOCULATION WITH *D. adunca* (INOC.) AND ON UNINOCULATED CONTROLS (CONTR.)[a]

	P1		P2		P3	
Plant genotype	*N*	Mean (s.e.)	*N*	Mean (s.e.)	*N*	Mean (s.e.)
Seeds (*N*) mm (contr.)	5	1.69 (0.18) a	5	2.27 (0.17) b	5	2.51 (0.18) b

[a] The percentage of inoculated plants that became infected, and back-transformed mean values of latent period, growth rate, and an index for the density of asexual fruiting bodies (pycnidia) of the fungus on infected plants are indicated as well. *N*: sample size. Means within a row that do not share a common letter are significantly from each other ($P < 0.05$).

constitutive levels of iridoid glycosides compared to plants selected for low levels of iridoid glycosides. Such an association was predicted on the basis of the *in vitro* antimicrobial activity of the aglycones of aucubin and catalpol (Rombouts and Links, 1956; Ishiguro et al., 1982; Van der Sluis et al., 1983; Davini et al., 1986; Stermitz, 1988, Marak et al., 2002), assuming that the pathogen indeed encounters the iridoid glycosides in their hydrolyzed, aglycone, form. Due to the inherent difficulty of quantitatively detecting these instable iridoid aglycones (Davini et al. 1986; Stermitz, 1988), it is still an open question whether the latter actually occurs and whether, in our experiment, pathogen infection indeed resulted in increased levels of the iridoid aglycones that are required for antimicrobial activity and hence for induced resistance. The fact that, in contrast to the study by Marak (2000), no association between iridoid glycoside levels and resistance was observed in the present study suggests that other factors are involved in resistance as well and that a larger sample of genotypes than the three used in the present study is required to detect such associations. The detection of the negative association between iridoid glycoside levels and resistance in the larger set of genotypes implies that induction can potentially result in increased resistance to the fungus, provided that resistance is still a monotonically increasing function of iridoid glycoside level at high concentrations of these compounds and that the fungus encounters the iridoids at least partly as their aglycones. However, such benefits have yet to be shown. Preliminary studies by C. Jansen (NIOO, Heteren) indicate that when the first flowering stalk on a plant is inoculated, fungal growth on the succeeding stalk, inoculated 1 week later, is slower (21.4 ± 5.7 cm in 5 weeks) than on the first stalk (28.7 ± 5.8 cm; pairwise t test, $t[30] = 6.4$, $P < 0.001$). However, this appears to be an ontogenetic effect rather than an effect of induced resistance, since fungal

growth rates on succeeding stalks of control plants, on which the first stalk was not inoculated, were similarly low (19.9 ± 5.0 cm) as growth rates on the succeeding stalks of plants where the first stalk was inoculated ($t[24] = 1.0$, $P = 0.31$).

Given the broad inducibility of aucubin and catalpol and their potential effects on both arthropods and microorganisms, there is also a potential for reciprocally induced cross-resistance between fungal pathogens and generalist insect herbivores through altered levels of iridoid glycosides in *P. lanceolata*. As discussed by Krischick (1991), there are several implications of such inducible "generalized" defense compounds. First, attack by one type of phytophage could partly determine the suite of phytophages that can subsequently colonize the host and hence indirectly affect the population dynamics of these organisms, as well as local community structure. Second, the resulting plant-mediated interactions between phytophages may affect the type of coevolutionary relationships between plants and phytophages. Since successful attack by one type of phytophage affects the resistance of the host plant to an ensuing, unrelated phytophage, plants susceptible to the first phytophage will have a higher probability of being induced and show increased resistance to the succeeding phytophage. The outcome of selection on resistance to these phytophages is, therefore, no longer independent of each other and hence neither of the phytophages is likely to develop a pairwise coevolutionary relationship with its host but, instead, coevolution is likely to be diffuse (Hougen-Eitzman and Rausher, 1994).

Genotype- and Tissue-Specific Induction of Iridoid Glycosides. Induced defense can only evolve by natural selection if there is phenotypic variation in the level of induction that affects plant fitness and if at least part of that variation has a genetic basis. Heritable variation for the level of induction has previously been reported for 14 natural plant–herbivore and one natural plant–pathogen system (Agrawal, 2000), indicating that, in general, there is potential for a response to selection on levels of induced defense. We found highly significant genotypic differences in the level of induction of iridoid glycosides following challenge of *P. lanceolata* with the pathogenic fungus *D. adunca*. This is in accordance with earlier studies reporting genotypic variation in induction levels in this species following challenge by herbivores (Bowers and Stamp, 1993). The two genotypes with relatively low levels of iridioid glycosides in their spikes both showed induction in this tissue type, whereas the genotype with the highest constitutive level of iridoid glycosides in its spikes showed no induction at all. However, obviously, the sample size of three genotypes is insufficient to address the question of whether there is a general pattern indicating a genetically based trade-off between constitutive and induced defense, as postulated in some evolutionary models of plant defense (Karban and Baldwin, 1997). Our study further shows that in addition to genotypic variation in the average levels of induction, there is also heritable variation for the tissue-specific allocation pattern of induction of iridoid glycosides, as evidenced by the interactions between tissue, genotype, and induction treatment.

This offers scope for further evolutionary fine-tuning of induced responses at the level of specific plant tissues in this system. For instance, there could be an evolutionary response to selection favoring high levels of induction in vegetative parts as opposed to reproductive parts or *vice versa*.

In agreement with a previous study in *P. lanceolata* (Darrow and Bowers, 1999), we found that constitutive levels of iridoid glycosides were higher in reproductive tissues than in vegetative plant parts. Since we lack knowledge of the incidence of attack of different plant tissues in the field and the fitness loss incurred by damage of different tissue types, it is difficult to judge whether this allocation pattern should be interpreted as adaptive or not (Rhoades, 1979; Zangerl and Berenbaum, 1990). Interestingly, the average levels of induction of aucubin and catalpol following challenge by the stalk pathogen *D. adunca* showed a tissue-specific pattern that was similar to the pattern observed for constitutively produced iridoid glycosides: both the absolute and the relative increase in the levels of these compounds in challenged plants was higher in reproductive tissues than in vegetative plant parts. Induction by the stalk pathogen strengthened the existing allocation pattern of constitutively produced iridoid glycosides present in uninduced plants. The similarity of these patterns may reflect a common principle, such as tissue-specific production, decay, or translocation of iridoid glycosides. Alternatively, the observed high level of induction in reproductive organs may be due to factors that are completely unrelated to those governing high constitutive levels of iridoid glycosides in these tissues. Inoculations took place in the spikes, and the level of induction often shows a diminishing response away from the site of attack (Tuomi et al., 1988), which would result in the observed decrease in average induction levels from spikes to stalks, leaves, and roots. The latter explanation is supported by the fact that there is no indication of higher levels of induction in reproductive tissues if herbivory is mainly concentrated in leaves (Darrow and Bowers, 1999). Plants of *P. lanceolata* that were grown at low levels of fertilizer and that were subjected to a 3-day period of herbivory by the specialist leaf chewing insect *J. coenia*, showed ca. 65% induction in the leaves, the site of attack, and ca. 55% in stalks and roots, 4 weeks after termination of the herbivory treatment. One day after herbivory, none of the induction levels were yet significant, the average levels of induction being 25% in leaves, 15% in stalks, and none in the roots (Darrow and Bowers, 1999). The high levels of induction in reproductive tissues observed in the present study may thus reflect the location of attack rather than a general allocation pattern of induction levels.

In general, reproductive plant parts appear to be less inducible than vegetative tissues (Baldwin and Karb, 1995). Karban and Baldwin (1997) speculated that the paucity of studies reporting induction of defense chemicals in reproductive tissues might be due not only to the much larger number of studies that have focused on induction in leaves compared to reproductive parts, but also to the fact that high constitutive levels of defense chemicals might be a more effective way to protect

such valuable tissues that are difficult to replace, than the time-lagged mechanism of induction. An inducible system of defenses for these tissues would provide little additional benefit to plants with constitutively defended reproductive parts. Indeed, in wild parsnip (*Pastinaca sativa),* a monocarpic species in which loss of flowering parts incurs a direct fitness cost (Nitao and Zangerl, 1987) and reproductive parts are the most heavily damaged tissues in the field, fruits show the highest constitutive levels of furanocoumarins but the lowest levels of induction of these defense chemicals (Zangerl and Berenbaum, 1990; Zangerl and Rutledge, 1996). By contrast, our study indicates that constitutively defended reproductive tissues do not necessarily show low levels of induction. We speculate that in *P. lanceolata*, by virtue of the numerous flowering stalks that are produced sequentially during the season, time-lagged systemic induction in reproductive tissues might still protect a significant part of the annual reproductive output of the plant, provided that there is a monotonic increase in the contribution of iridoid glycoside levels to resistance beyond the constitutive levels present in these tissues.

In conclusion, *P. lanceolata* shows heritable variation for the levels of induction of iridoid glycosides, as well as for the within-plant distribution pattern of induction levels following pathogen attack. Since iridoid glycosides can not only deter arthropods and microorganisms, but also be systemically induced by these organisms, they can potentially mediate pathogen-induced resistance to herbivores and *vice versa*. Studies are underway to test whether such effects can actually be observed, or whether they are mitigated by effects of other induced changes in the plant that are bound to occur in response to attack (Paul et al., 1999).

Acknowledgments—We thank Sonja C. Honders for help with inoculations and chemical analyses and two anonymous reviewers for their constructive comments on the manuscript. H.B.M. was supported by a grant from the Egyptian government.

(Received December 17, 2001; accepted July 19, 2002)

Abstract—Fungal infection of Chinese cabbage leaves by *Alternaria brassicae* has earlier been shown to have detrimental effects on larval development of the chrysomelid beetle *Phaedon cochleariae*. Furthermore, adults of this leaf beetle avoid fungus-infected Chinese cabbage leaves for oviposition and feeding. However, herbivory had no impact on fungal growth. In this study, we investigated physiological responses of the host plant to herbivore attack and fungal infection in order to elucidate the mechanisms of the described ecological interactions between the fungus and the herbivore. Changes in primary factors (water, C/N ratio, protein, sucrose) and defense-related plant compounds (glucosinolates, anthocyanins, peroxidase) were measured. Herbivory and fungal infection reduced the sucrose concentration of leaves and increased amounts of indole glucosinolates as well as total anthocyanins. In addition, water content was slightly lower in insect-damaged but not in infected leaves. Higher levels of peroxidase activity resulted exclusively from fungal infection. The C/N ratio and total protein content remained unaffected by either treatment. The implications of the induced plant changes on the herbivore are discussed.

Key Words—Tripartite interactions, phytopathogenic fungus infection, herbivory, induced resistance, cross-effects, nutrients, glucosinolates, anthocyanins, peroxidase, Chinese cabbage, *Phaedon cochleariae*, *Alternaria brassicae*.

INTRODUCTION

Plants have to cope with a multitude of attackers such as pathogenic fungi and herbivores. Damage to plant tissue caused by these antagonists may have a profound impact on host physiology (Hatcher and Ayres, 1997). The alterations of the plant's physiology may be the direct result of fungal growth (involving, e.g., the release of phytotoxins and phytohormones by the parasite) or of wounding by the herbivore. Very often, however, pathogens and herbivores also evoke a variety of active plant responses, including the induction of defensive secondary compounds and shifts in primary metabolism, so-called "civilian responses," which may enable the plant to fend off or to tolerate attackers (Baldwin and Preston, 1999; Hammerschmidt, 1999). Certain plant responses may be induced specifically by either pathogens or herbivores, while other responses lack specificity with regard to the inducing agent. Likewise, the effects of plant responses on the challenge organisms also can be specific (Karban and Kuc, 1999; Stout and Bostock, 1999). However, little is known about the integration of plant reactions to multiple enemies in spite of a wealth of studies concerning inducible responses to either pathogens or herbivorous arthropods (Paul et al., 2000). In the field, herbivorous insects and plant pathogenic fungi frequently co-occur on the same host plant. Therefore, fungi and herbivores may interact indirectly, with the interaction mediated by the induced physiological changes of the host plant. The relationship between the antagonists may be beneficial or detrimental to one or both sides (Hatcher, 1995).

The ecological effects of such tripartite interactions have previously been studied in a system including the crop plant *Brassica rapa* ssp. *pekinensis* (Chinese cabbage), the leaf beetle *Phaedon cochleariae*, and the necrotrophic fungus *Alternaria brassicae* (Rostás and Hilker, 2002a,b). Fungal growth was not affected by feeding damage caused by larvae of *P. cochleariae*, but larval performance was impaired when larvae were fed with parts of Chinese cabbage leaves without symptoms of fungus infection. Larvae feeding on infected Chinese cabbage leaves suffered reduced growth rates. Furthermore, the adults were shown to respond to fungal disease of their host plant. Female beetles avoided diseased leaves for feeding and oviposition.

The present study investigated several traits of plant primary and secondary metabolism of herbivore-damaged and fungus-infected leaves of Chinese cabbage that might be relevant for these observed ecological effects of fungus-infected leaves on larval development and adult behavior in *P. cochleariae.* Only few studies have focused on a direct comparison of responses caused by both pathogens and herbivores on the same host plant (e.g., Stout et al., 1999).

In particular, we assessed: leaf water content, C/N ratio, total proteins, sucrose concentration, concentrations of individual glucosinolates, total anthocyanin concentrations, and peroxidase activity in herbivore-damaged and fungus-infected Chinese cabbage leaves.

Among the various factors that can change the suitability of a host plant for insect consumers is the water content of leaves (Slansky and Scriber, 1985). Pathogenic fungi often enhance the dry matter-to-water ratio of the infected plant by an increase of fungal tissue, by inducing plant cell wall enforcements, or by destroying the leaf epidermis (Duniway and Durban, 1971; Hatcher, 1995; Götz, 1996).

The carbon-to-nitrogen (C/N) ratio is a general indicator of food quality as it may inform about the availability of nutritionally valuable nitrogen in relation to indigestible structural carbohydrates. Growth efficiency of many insect species is correlated with plant nitrogen content (Schoonhoven et al., 1998). A high C/N ratio can, therefore, be detrimental to herbivores (Clancy, 1992). Shifts in carbon and nitrogen concentrations may be caused by the whole spectrum of primary and secondary plant responses following fungal infection and herbivory. These changes may be due to increased photosynthesis, reallocation of storage compounds, the synthesis of proteins or nitrogen-containing allelochemicals, as well as many other responses of the plant (Ayres, 1992; Baldwin and Preston, 1999).

Additionally, we analyzed total protein content as the most important nutrient for herbivorous insects. The concentration of sucrose in herbivore-damaged and fungus-infected leaves was also measured, because sucrose is known as a phagostimulant for several leaf beetles and other insects (Dadd, 1985; Matsuda, 1988). In addition to sucrose, glucosinolates may stimulate feeding in crucifer specialists like the leaf beetle *P. cochleariae* (Nielsen, 1978; Wallsgrove et al., 1999; Fahey et al., 2001). However, the stimulatory effect of glucosinolates may be dose-dependent: specialists have been shown to feed less on individuals of *Brassica rapa* that contained higher glucosinolate levels than on plants of the same population with low glucosinolate concentrations (Siemens and Mitchell Olds, 1996). Glucosinolates are known to be inducible by plant pathogenic fungi and herbivorous insects (Ludwig-Müller et al., 1997; Hopkins et al., 1998). They may also be induced in Chinese cabbage by treating the plants with salicylic acid or jasmonic acid — two compounds that are often involved as wound signals in the defense against pathogens and herbivores, respectively (Ludwig-Müller et al., 1997).

Anthocyanins belong to the large group of flavonoids and are ubiquitous in petals, stems, and leaves of angiosperms. Primarily they are known as the compounds that give flowers their red or blue color or protect the plant against ultraviolet radiation (Harborne and Williams, 2000). However, cyanidin-3-β-glucoside (chrysanthemin) has also been reported as a major factor of resistance in cotton towards *Heliothis virescens* (Hedin et al., 1983). The defensive role of proanthocyanidins (precursors of anthocyanins) against herbivores has been established (Harborne and Williams, 1995).

Finally, we measured the activity of soluble leaf peroxidases (POX). These are widespread plant enzymes that use hydrogen peroxide to oxidize phenolics and other substrates. They are considered to contribute to plant defense against herbivores and fungi in several ways: products from phenolic oxidation may be

cytotoxic, bind to dietary proteins, and inactivate fungal proteins. Additionally, they can contribute to cell wall reinforcement that results in greater leaf toughness (Dowd and Lagrimini, 1997). Increased activity of peroxidases may be induced by herbivore damage and by pathogenic infection. However, the biological functions of peroxidases *in planta* have been difficult to verify and are not yet resolved (Constabel, 1999; Østergaard et al., 2000).

In this study, the above-mentioned physiological parameters are compared between fungus-infected and healthy plants, as well as between herbivore-damaged and unattacked plants. Differences are discussed with respect to the described ecological effects of the tripartite interactions among Chinese cabbage, the fungus *A. brassicae*, and the leaf beetle *P. cochleariae.*

METHODS AND MATERIALS

General. Chinese cabbage plants (*Brassica rapa* L. ssp. *pekinensis* cv. Kantonner) were grown from seed (obtained from Saatzucht Quedlinburg GmbH) in 7- × 8- × 7-cm plastic pots in a greenhouse at ca. 20°C. Standard potting soil (Einheitserde Typ P, Kausek GmbH and Co. KG, Mittenwalde, Germany) was used and one additional dose of fertilizer was applied three weeks after germination. Light from 400-W sodium vapor lamps supplemented natural daylight, providing an illumination of >10,000 lx for 16 hr a day. Plants were assigned to herbivore or fungus treatment when the fifth (first leaf = oldest leaf) had reached maximum size (4–5 weeks). Only the fifth leaf was used for analyses.

Strain BBA 64878 of *Alternaria brassicae* (Berk.) Sacc., the causal organism of blackspot disease, was obtained from the Biologische Bundesanstalt (Berlin-Dahlem, Germany). The fungus was cultured on potato–dextrose agar (PDA) at 20°C without induction of sporulation. Cultures used for inoculation were 5 days old.

A laboratory colony of *Phaedon cochleariae* (F.) was maintained in a climate chamber at 20°C, 70% relative humidity, and a photocycle of 18L:6D. Larvae and adults were fed on Chinese cabbage leaves.

Herbivore Treatment and Fungal Inoculation of Plants. Experimental plants were selected for equal size and arranged in a completely randomized design. A clip cage (21 mm diam., 18 mm high) containing five second-instar beetle larvae was attached to the fifth leaf of an experimental plant. Larvae were allowed to feed for 72 hr in total, removing about 9% of the leaf area. After periods of 24 and 48 hr, the clip cage with the larvae was shifted to an undamaged part of the leaf. Following this treatment, the leaf was excised and used for analyses (see below). Control plants received identical treatment with an empty clip cage.

For the inoculation of Chinese cabbage with the fungus *A. brassicae*, a method described by Gröntoft and O'Connor (1990) was adopted. The fifth leaves of Chinese cabbage plants were inoculated with small mycelium-containing agar

disks (5 mm diam.) punched out from behind the growth front of Petri dish cultures using a cork borer. Two disks were laid with their mycelium-containing side onto the adaxial surface of a leaf half. Upon each disk, and underneath it on the abaxial side of the leaf, a piece of firm foam material ($10 \times 10 \times 7$ mm) was placed. An insect needle (No. 00) was pierced through inoculum, leaf, and foam material, fixing the "sandwich" construction. Control plants were treated equally, but agar disks contained no mycelium. Following inoculation, treated plants and controls were placed under a tent made of thin transparent plastic foil in a completely randomized design for 5 days. The tent ensured an atmosphere of 100% relative humidity, thus enhancing fungal growth. Harvested leaves were cut along their midveins, and the leaf halves bearing no symptoms of fungal infection were used for chemical analyses.

Chemical Analyses. The fifth leaves of herbivore-damaged and fungus-infected plants and their corresponding controls were detached and immediately submerged in liquid nitrogen. Samples were then stored at -70°C until needed. Freeze-dried leaf tissue powder was used in all analyses except for measurements of water content and POX activity. For further preparation, samples were lyophilized for 3 days and ground in a planetary micromill. All spectrophotometric analyses were carried out using an UV–visible spectrophotometer (Ultrospec, 2000, Pharmacia Biotech, Freiburg, Germany). Samples from five plants were assessed in triplicate if not otherwise stated.

Analyses of Primary Compounds. The water content of herbivore-damaged and pathogen-infected leaves was determined from the fifth leaves of 20 plants from each treatment group. Leaves were excised, and the succulent petioles and midveins were removed. The remaining laminas were weighed and then left to dry at 80°C for 2 days. Dried leaves were weighed again and percentage water content was calculated.

Total carbon and nitrogen content was analyzed using a CHN analyzer (Leco CHN-932, Typ 600-800-532). Two milligrams of tissue powder were weighed into 50-mg tin capsules. Carbon and nitrogen concentrations were determined in duplicate.

Total protein content was determined after Bradford (1976) and Jones et al. (1989). Thirty milligrams of lyophilized tissue powder was added to 2 ml 0.1 N NaOH. The suspension was agitated on a vortex mixer for 3 sec, left to extract for 30 min, agitated again for 3 sec, and then centrifuged for 5 min at 12,000g. The supernatant was decanted and vortex mixed for 3 sec. Aliquots of 100 μl of the supernatant or 100 μl of 0.1 N NaOH (blank) were each mixed with 1 ml Bradford dye reagent to which 3 mg/ml soluble polyvinylpyrrolidone (PVP; MW: 40,000) had been added. The absorbance of the leaf extract was read at 595 nm against the dye reagent/NaOH blank. Bovine serum albumin was used as a standard.

Sucrose concentrations of treated and control Chinese cabbage leaves were determined enzymatically. A commercial test kit was used (Boehringer Mannheim

GmbH, Biochemica, Mannheim, Germany; no. 716 260). Thirty milligrams of lyophilized tissue powder were extracted for 1 hr in 2 ml aq. bidest. The homogenate was then centrifuged for 15 min at 12,000*g*, and the supernatant was transferred into 1.5-ml vials. Enzymatic hydrolysis of sucrose was done according to the test kit manual except that only a quarter of the suggested quantities of all buffers and enzyme suspensions was used. Extinction was read at 340 nm.

Analysis of Secondary Compounds. Glucosinolates were extracted and measured as described by Kiddle et al. (2001). Essentially, samples (3×40 mg for each sample) of tissue powder were extracted with 70% v/v MeOH. The extract was bound to preactivated Sephadex A-25, and the glucosinolates were desulfated with purified *Helix* sulfatase for at least 16 hr. The desulfoglucosinolates were eluted with water and stored at -20°C until analyzed by reverse-phase HPLC (Kiddle et al., 2001). Sinigrin was used as the internal standard.

Concentrations of total anthocyanins were analyzed colorimetrically (Manicelli et al., 1984). Tissue powder (3×10 mg for each sample) was vortex mixed with 1 ml of 1% v/v HCl in 100% MeOH in a screw-top microtube. Samples were centrifuged at 4°C for 10 min at 17,000*g*. The supernatant was then carefully removed and absorbance of anthocyanins was measured at 530 nm. A second reading at 657 nm assessed contaminating chlorophylls that absorb in the 530 nm region. Anthocyanin specific absorption unit was $AU = A_{530} - A_{657}$.

To assay peroxidase (POX) activity, 1 g of fresh foliage was homogenized in 2 ml of 50 mM ice-cold sodium phosphate buffer (pH 7.0, containing 0.5 mM EDTA, 5 mM sodium-metabisulfite, and 40 ml/liter protease inhibitor cocktail, Sigma, Deisenhofen, Germany; P 2714). Acid-washed sand (100–200 mg/g tissue) in the mortar improved homogenization. The homogenate was added to 1.25% w/v polyvinylpolypyrrolidone (PVPP) and 1.25% w/v amberlite XAD-4 in a beaker (25 ml) and left on ice for 5 min. The homogenate was then filtered through a muslin cloth into a prechilled centrifuge tube and centrifuged at 4°C for 20 min at 14,000*g*. The supernatant was removed and immediately used as the enzyme source. A 50-μl aliquot of foliar homogenate was assayed with 1 ml of 10 mM 2,2′-azinobis(3-ethylbenzthiazolinesulfonic acid) (ABTS) and 10 mM H_2O_2 (30% v/v) in 50 mM NaH_2PO_4 (pH 6.0). POX activity was estimated at 414 nm and 25°C.

Statistics. Student's *t* tests were used to analyze differences between herbivore-damaged or fungus-infected leaves and their corresponding controls. Due to differing growth conditions (see above) statistical testing was not performed between herbivore-damaged and fungus-infected leaves.

RESULTS

Analyses of Primary Compounds (Table 1). Water content of Chinese cabbage leaves significantly decreased after 3 days of herbivory by second instars

TABLE 1. PRIMARY COMPOUNDS MEASURED IN HERBIVORE-DAMAGED AND FUNGUS INFECTED CHINESE CABBAGE LEAVES AND THEIR RESPECTIVE CONTROLS[a]

	Treatment			
	Herbivory	Control	Fungus	Control
Water content [%]	89.8 (1.59)***	91.4 (0.68)	91.6 (0.81)	91.7 (0.63)
C/N	6.6 (0.54)	7.8 (1.29)	6.1 (0.82)	6.0 (0.24)
Total protein (mg/g foliar dry weight)	61 (4.0)	59 (2.3)	57 (6.7)	57 (7.7)
Sucrose (g/100 g foliar dry weight)	1.5 (0.34)*	2.2 (0.61)	1.2 (0.52)*	2.2 (0.92)

[a] Herbivory = leaves damaged for 72 hr by second instars of *Phaedon cochleariae*. Fungus = leaves 5 days after infection with *Alternaria brassicae*. $N = 5$ (water content: $N = 20$). Values are means (standard deviations). Asterisks denote significant differences (*** $P < 0.001$, * $P < 0.05$; Student's t test for independent samples).

of *P. cochleariae*. However, the reduction did not exceed 2%. In contrast, leaves infected by *A. brassicae* did not differ ($P = 0.847$) in their mean water content from healthy control leaves. The C/N ratio did not significantly differ in leaves receiving either herbivore ($P = 0.096$) or fungus ($P = 0.835$) treatment when compared with their respective controls. Total protein content of Chinese cabbage leaves did not significantly change as a consequence of herbivore or fungal activity (herbivore: $P = 0.376$; fungus: $P = 0.773$). Herbivory and plant pathogenic infection reduced sucrose content as indicated by a 31% loss of foliar sucrose in the case of herbivore-damaged leaves and a 47% decrease in the pathogen-infected leaves (herbivore: $P = 0.018$; fungus: $P = 0.035$).

Analyses of Secondary Compounds. Production of glucosinolates was induced in herbivore-damaged and in fungus-infected leaves (Figure 1). Chinese cabbage leaves on which larvae of *P. cochleariae* had fed showed a 2.6-fold increase in total glucosinolate content compared with untreated control leaves ($P < 0.001$). Glucosinolate content of leaves infected with the fungus *A. brassicae* was 5.9 times higher than healthy tissue ($P < 0.001$). This effect was entirely due to an increase in the concentrations of indole glucosinolates (Figure 1). Glucobrassicin (indol-3-ylmethyl glucosinolate) was 12.3 times higher in herbivore-damaged leaves, while the increase in fungus-infected leaves was 11.6-fold (herbivore: $P = 0.004$; fungus: $P = 0.008$). An accumulation of 4-MeO-glucobrassicin (4-methoxy indol-3-ylmethyl glucosinolate) was observed in leaves treated with the fungus (3.5-fold, $P \leq 0.001$). In herbivore-damaged leaves, a slight increase of about 10% was measured; however, this was not significantly different from the control ($P = 0.693$). Elevated concentrations of neoglucobrassicin (1-methoxy indol-3-yl-methyl glucosinolate) were found in both treatment groups (herbivore: 2.2-fold, $P = 0.027$; fungus: 5.9-fold, $P = 0.002$). Aliphatic glucosinolates were measured only in trace amounts, and these were not affected by either treatment. Concentrations of aromatic glucosinolates were below detectability.

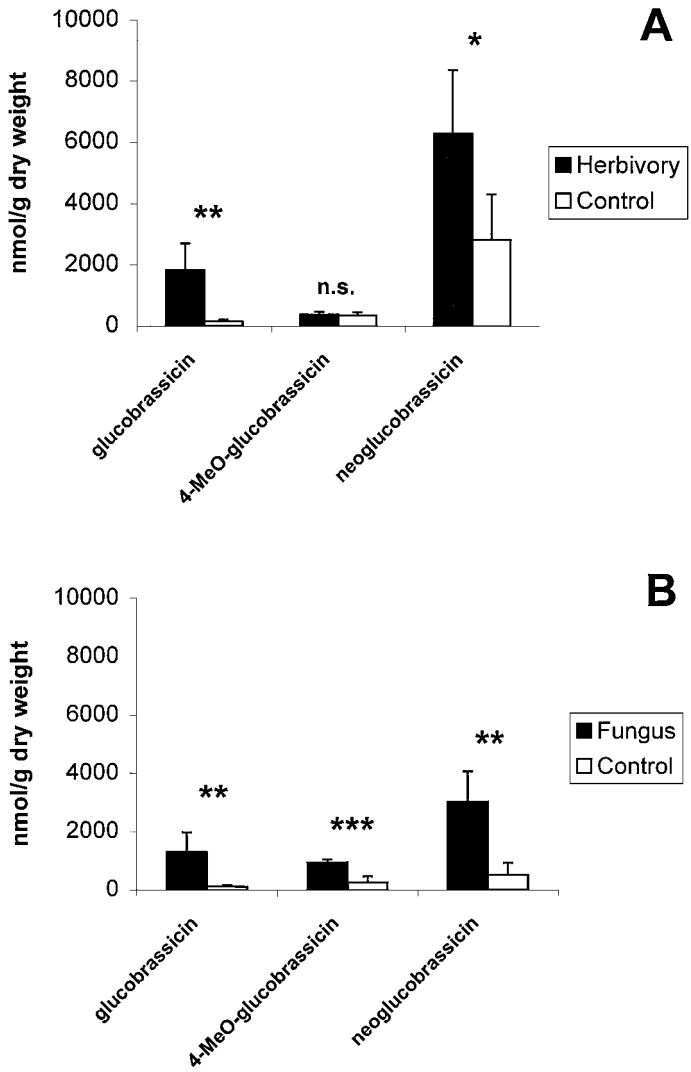

FIG. 1. Concentrations of indole glucosinolates in herbivore-damaged (A) and fungus infected (B) Chinese cabbage leaves. Herbivory = leaves damaged for 72 hr by second instars of *Phaedon cochleariae*. Fungus = leaves 5 days after infection with *Alternaria brassicae*. $N = 5$. Values are means and standard deviations (bars). Asterisks denote significant differences ($^{***}P < 0.001$, $^{**}P < 0.01$, $^{*}P < 0.05$, n.s. = not significant; Student's t-test for independent samples).

TABLE 2. SECONDARY COMPOUNDS MEASURED IN HERBIVORE-DAMAGED AND FUNGUS INFECTED CHINESE CABBAGE LEAVES AND THEIR RESPECTIVE CONTROLS[a]

	Treatment			
	Herbivory	Control	Fungus	Control
Rel. anthocyanin conc. (AU $\times 10^3$)	271 (31.4)***	36 (6.1)	173 (35.3)***	34 (4.9)
POX ($dA_{414} \times 10^2$/min/g foliage)	326 (106.6)	356 (106.2)	1482 (418.0)***	544 (148.5)

[a] Herbivory = leaves damaged for 72 hr by second instars of *Phaedon cochleariae*. Fungus = leaves 5 days after infection with *Alternaria brassicae*. $N = 5$. Values are means (standard deviations). Asterisks denote significant differences (*** $P < 0.001$; Student's t test for independent samples).

Total anthocyanin content was 7.5 times higher in leaves affected by herbivory when compared with undamaged controls ($P < 0.001$). An increase in the anthocyanin concentration by a factor of 5.1 was observed in fungus-infected leaves ($P < 0.001$) (Table 2).

Activity of POX assayed with ABTS as the hydrogen donor differed in herbivore and fungus treated plants (Table 2). Previous feeding by the herbivore did not result in increased POX activity ($P = 0.767$) in Chinese cabbage leaves. However, POX activity was enhanced in leaves infected by the fungus compared to the control treatment (2.7-fold, $P < 0.001$).

DISCUSSION

In this study, we showed that herbivory and fungal infection to some extent induced similar but also differential responses in leaves of Chinese cabbage.

The water content of leaves on which larvae of *P. cochleariae* had fed for 3 days was significantly reduced. It seems obvious that wounding of leaf tissue leads to an increased loss of water. However, this reduction (−1.6%) might be negligible for the beetle larvae, as the total water content of healthy Chinese cabbage leaves was high (>90%, Table 1). Consequently, no signs of wilting were observed. Fungus-infected leaves, on the other hand, did not differ in their water content from healthy leaves. This is consistent with studies that measured the leaf water content of fungus-infected plants in conjunction with herbivore consumption (Kingsley et al., 1983; Hatcher et al., 1994, 1995).

No shifts in the C/N ratio of Chinese cabbage leaves were observed following herbivory or fungal infection. The carbon and nitrogen contents were comparable to those obtained from analyses of commercially grown Chinese cabbage plants (Müller, 1999). Likewise, neither treatment altered the total protein content in the leaves. In contrast, sucrose concentrations were lower in both wounded and infected leaves. It is conceivable that in the case of herbivore-damaged leaves the decrease in sucrose concentration might be a genuine plant response. Exporting

sucrose may be a mechanism for reallocation of valuable nutrients to other unaffected plant parts for compensatory growth. This has been hypothesized for the observed reduction in the concentrations of total free sugars in herbivore-damaged oak leaves (Valentine et al., 1983). The lower sucrose content of the uninfected half of a fungus-infected leaf is most likely due to an altered sink-source relationship caused by the pathogen. Köhle (1989) showed that radiolabeled [^{14}C] sucrose accumulated only in those halves of oilseed rape (*Brassica napus*) leaves that were infected with *Alternaria brassicicola.* Changes in leaf nutrients caused by the activity of herbivores and fungi may vary greatly depending on several factors such as the timing and intensity of feeding damage or infection and the system that has been studied (Hatcher, 1995; Karban and Baldwin, 1997). An increase in carbohydrates other than sucrose, in wounded and infected leaves, may have contributed to the stable C/N ratio after pathogen or herbivore attack.

Following herbivory and fungal infection, a distinct rise in the concentrations of the indole-glucosinolates glucobrassicin, 4-MeO-glucobrassicin, and neoglucobrassicin was observed. Constitutive levels of glucosinolates were higher in control plants of the "herbivore" treatment group than in the "fungus" treatment group. This was probably due to different treatment conditions. Plants inoculated with *A. brassicae* were kept in a tent with higher humidity and higher temperatures. However, a more pronounced induction of glucosinolates was observed in the infected plants. Differing responses were found with regards to 4-MeO-glucosinolate: this compound was induced in leaves infected with the fungus, but not in plants damaged by herbivory. Koritsas et al. (1991) demonstrated similar effects in the stem tissue of *B. napus* cv. Ariana that had been damaged by the chrysomelid beetle *Psylliodes chrysocephala.* Aerial infestation stimulated the production of glucobrassicin (6-fold), 4-MeO-glucobrassicin (2-fold), and neoglucobrassicin (23-fold), while levels of aliphatic and aromatic glucosinolates remained too low to be detected. Accumulation of glucosinolates was also observed in leaves of *B. napus* (cv. Cobra, cv. Bienvenue) following *A. brassicae*-infection (Doughty et al., 1991). The increase was mainly the result of higher levels of indole and aromatic glucosinolates, while concentrations of aliphatic glucosinolates were variable.

Chinese cabbage leaves responded to feeding damage and fungal infection, respectively, by raising the levels of total anthocyanins. Accumulation of anthocyanins is induced by a range of stimuli including UV light, low temperature, phytohormones, and pathogens (Lo and Nicholson, 1998). Interestingly, six-carbon (C_6) volatiles and methyl jasmonate, which are released by insect-damaged plant tissues, have also been demonstrated to induce the production of anthocyanins (Franceschi and Grimes, 1991; Bates and Rothstein, 1998). These volatiles play a role in the plant's defense response against herbivores and may activate the expression of phenylpropanoid-related genes and the production of proteinase inhibitors (Karban and Baldwin, 1997; Bates and Rothstein, 1998).

A significant increase in the activity of POX in the uninfected half of *A. brassicae*-infected leaves was observed. This contrasted with results obtained from Chinese cabbage leaves damaged by *P. cochleariae*, where no significant difference between treated and control leaves was apparent. In one of the few studies investigating the specificity of host plant responses to herbivores and pathogens, the same pattern was evident (Stout et al., 1999). Tomato plants inoculated with the pathogenic fungus *Phytophthora infestans* had increased POX activities. Wounding by *Helicoverpa zea*, on the other hand, showed no such effects. However, the induction of POX by insect feeding is not uncommon and has been demonstrated in tomato by other insects and also in cotton (Bi et al., 1997; Stout et al., 1998). Enhanced POX activity due to infection by *A. brassicae* or *A. brassicicola* was measured in *B. juncea*, with higher activities found in susceptible cultivars (Gupta et al., 1990).

Considering the observed phytochemical responses, what can be inferred from our results that might explain the adverse effects of plant pathogenic fungus infection on the larval performance of *P. cochleariae*? First, there were no changes in the nutrient status of leaves except for a decrease in sucrose concentration as a result of fungal infection. Second, fungal infection invoked higher levels of indole glucosinolates, anthocyanins, and POX activity. When interpreting these data, it is important to be aware that the larval performance of *P. cochleariae* is not affected when larvae consume leaves that were previously fed upon by conspecific larvae (Rostás and Hilker, 2002a). Consequently, one might suggest that all plant responses equally induced by the beetle and the fungus may be excluded as factors responsible for reduced host plant quality, i.e., changes of the concentrations of sucrose, anthocyanins, glucobrassicin, and neoglucobrassicin (Figure 2). In this study, the compounds exclusively induced by *A. brassicae* are 4-MeO-glucobrassicin and POX. However, it seems unlikely that 4-MeO-glucobrassicin can be considered as a resistance factor, since *P. cochleariae* is a crucifer specialist and, therefore, is expected to be able to detoxify glucosinolates (Louda and Mole, 1991). Enhanced POX activity, on the other hand, is more likely to have contributed to an increased resistance of fungus-infected leaves against the herbivore. In cotton, POX, among other oxidative components, was discussed as a contributing factor in resistance against herbivores (Bi et al., 1997). Likewise, overexpression of POX in transgenic tobacco leaves conferred resistance against *Helicoverpa zea* (Dowd and Lagrimini, 1997).

Which of the measured physiological factors could have affected the behavioral response of adult *P. cochleariae* towards fungus-infected Chinese cabbage leaves and may be relevant for the deterrent effect of diseased leaves? When trying to answer this question, it must be considered that adult *P. cochleariae* are not only deterred by fungus-infected leaves, but also by leaves that have been damaged by conspecific larvae (Rostás and Hilker, 2002b). This implies that although there is some overlap of the plant responses to herbivory and fungal infection (Figure 2),

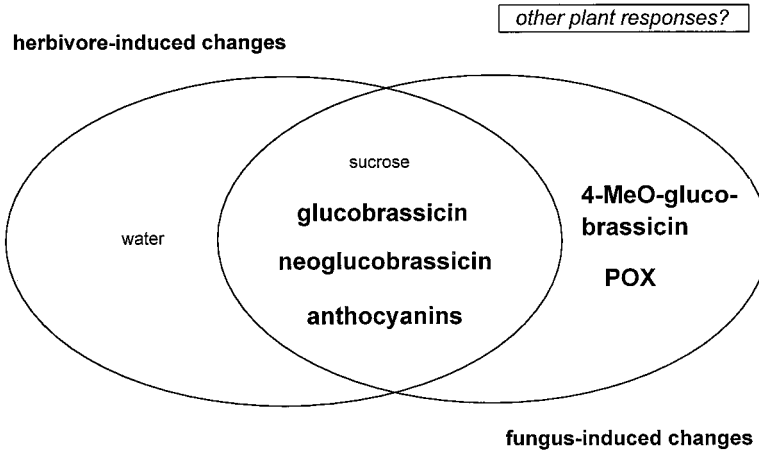

FIG. 2. Overlapping and differential responses of Chinese cabbage leaves due to feeding damage caused by *Phaedon cochleariae* and fungal infection with *Alternaria brassicae*. Compounds written in large bold or small (non-bold) letters showed significant increases or decreases, respectively, in their concentrations due to herbivory or fungal infection compared with corresponding controls.

none of the observed physiological changes can be excluded as putative resistance factors. Two different resistance mechanisms, perhaps with a certain degree of overlap, may have elicited the same reaction in the beetles when confronted with fungus-infected or herbivore-damaged leaves.

Even though the potential role of POX as a factor reducing host plant suitability to *P. cochleariae* is advocated here (see above), it is important to emphasize that plant defenses against herbivores and pathogens are complex phenomena. Certainly, an array of yet unmeasured factors, e.g., fungal toxins, proteinase inhibitors, or phytoalexins, may have also contributed to the resistance effects of the fungus-infected Chinese cabbage plants on the leaf beetle (Bains and Tewari, 1987; Lim et al., 1996; Baur et al., 1998). Future research involving feeding experiments with isolated inducible phytochemicals or transgenic plants will have to elucidate further the underlying mechanisms of plant-mediated cross-effects between *A. brassicae* and *P. cochleariae*.

Acknowledgments—We thank Dr. M. Forstreuter (Technische Universität Berlin) for help with the C/N analyses. We also thank R. Jonas for rearing the leaf beetles. Financial support was provided from the Senate of Berlin (NaFöG grant program) and the FAZIT Foundation (Frankfurt/M.).

Abstract—The brown tree snake (*Boiga irregularis*) is an exotic pest species on Pacific islands, most notably on Guam where it has caused considerable ecological and economic damage. On Guam, the snake commonly associates with people and can be found near or in human habitations. Bites are common, approximately 1 of 1200 emergency room visits to Guam hospitals were reported to be the result of *B. irregularis* bites; 80% of these victims were attacked while sleeping. Most of the attacks occurred on fingers and hands and the attacks appeared to be predatory, rather than defensive, in nature. In order to characterize the mechanism releasing this unusual behavior, we measured the predatory response of *B. irregularis* to chemical stimuli from humans and controls using a lab population that originated from Guam and a wild population from the species' native range in Queensland, Australia. To quantify behavior we measured the proportion of snakes displaying predatory behavior to each of the stimuli, the latency to attack, and the number of tongue-flicks displayed. We quantified predatory behavior using the tongue-flick attack score for repeated measures [TFAS(R)], a common method for quantifying predatory behavior in squamate reptiles. Captive brown tree snakes responded to human skin stimuli with feeding behavior, including predatory attacks, at the same frequency as they did to prey stimuli derived from mice, while never responding to controls with such behavior. Captive snakes also responded to human skin stimuli and prey stimuli with significantly higher TFAS(R) scores than to controls, although there were no differences between the human and mouse stimuli. Wild-caught animals in Australia also responded with predatory attacks to human skin stimuli, while not showing predatory behavior to a blank control and with higher TFAS(R) scores to human skin stimuli than to the control. As *B. irregularis* is a generalized predator that relies heavily on chemical signals to recognize prey,

we hypothesize that the snakes recognize compounds on human skin that may be shared with other prey.

Key Words—Brown tree snake, *Boiga irregularis*, invasive pest species, predatory behavior, feeding stimulus.

INTRODUCTION

The brown tree snake (*Boiga irregularis*) has caused significant ecological and economic damage on the Pacific island of Guam where it was accidentally introduced during or shortly after World War II (Rodda et al., 1992, 1997). The snake flourished on the island, reaching estimated densities of up to 100 snakes per hectare (Rodda et al., 1992). Pest damage includes power outages caused by snakes climbing onto power lines and short-circuiting the system while searching for prey that result in revenue and equipment losses (Fritts et al., 1987).

A generalist predator, brown tree snakes have caused the extinction or extirpation of 9 of 12 native forest birds from the island of Guam, three of which were endemic (Savidge, 1987). In addition, the snakes have negatively affected domestic animals and pets, rodents, lizards, and the endangered Marianas fruit bat, *Pteropus mariannas* (Wiles, 1987; Savidge, 1988; Greene, 1989; Fritts and McCoid, 1991; Rodda and Fritts, 1992). They feed on carrion in the field (R. T. Mason, personal observation; Shivik and Clark, 1997) and also attempt to ingest their own bodies, cage walls, and items in their cage if prey odors or blood are present (M. J. Greene, personal observation). Incidences of cannibalism have been reported on Guam (Engeman et al., 1996). Noteworthy is the fact that they have been reported to attack and kill animals much larger than they can swallow, such as chickens, newborn pigs, and puppies (Fritts, 1988; Fritts et al., 1994).

The brown tree snake associates with humans, and bites are common; approximately 1 of 1200 visits to Guam hospital emergency rooms were reported to be for brown tree snake bites (Fritts, 1988; Fritts and McCoid, 1999). Eighty percent of bite victims surveyed after being treated at medical facilities were bitten while sleeping (Fritts et al., 1994). Of these victims, 52% were younger than 5 years of age, all of whom were bitten while sleeping (Fritts et al., 1994). Fifty-three percent of the victims 5 years of age and older were bitten while sleeping (Fritts et al., 1994).

Fifty percent of all victims attacked while sleeping were bitten on the fingers and hands while the remaining victims were bitten on the arms, legs, neck, back, and face (Fritts et al., 1994). The bite patterns suggest that the snakes were attempting to ingest the fingers and hands of these victims in the same manner they would a prey item (Fritts et al., 1990). Several cases have been reported where parents have found brown tree snakes chewing on the limbs of their children while coiled around the necks and bodies of the children (Fritts et al., 1990; Fritts and McCoid, 1999).

The brown tree snake is a rear-fanged colubrid containing venom of low toxicity to humans (Weinstein et al., 1991; Vest et al., 1991). The venom is delivered through grooved rear fangs when the snake is making deliberate chewing motions on the body of a prey item (Kardong and Lavin-Murcio, 1993). Envenomation is difficult during defensive strikes because the snakes normally respond to provocation with lunging strikes and quick bites (Johnson, 1975). Defensive strikes are quick and involve the front of the jaw, while predatory bites require slower, more deliberate use of the rear fangs in the posterior of the buccal cavity. Envenomation has been reported when snakes attacked sleeping humans (Fritts et al., 1990, 1994).

No deaths have resulted from brown tree snake bites, although many symptoms requiring medical attention have been reported (Fritts et al., 1990, 1994). The most common were discoloration, swelling, and blebs at the bite location. In addition, high pulse, respiratory arrest, lethargy, and droopy eyelids have been described in several cases (Fritts et al., 1990, 1994). It is rare for snakes to attack humans in a predatory manner; aside from a few large constrictors, kraits (*Bungaris* spp) are the only other snakes reported to attack humans in such a way (Minton and Minton, 1980; Fritts et al., 1990).

Initial observations made with captive brown tree snakes in our laboratory showed that they were attracted to objects touched by human hands. In many instances, tongue-flicking behavior displayed to the human odors on these objects was similar to that displayed when feeding on dead prey items, including short, directed tongue-flicks to the objects. Tongue-flicking in snakes serves to transfer chemicals from the environment to the snake's vomeronasal organ, which detects primarily nonvolatile chemical cues (Halpern, 1992). The experiments presented here were designed to measure the feeding response of *B. irregularis* to human skin chemical stimuli and controls by using a bioassay that is sensitive to, and accounts for, both tongue-flicking behavior and predatory behavior.

METHODS AND MATERIALS

Laboratory Snake Bioassay. Ten adult brown tree snakes (3 females and 7 males) were randomly selected from our captive colony for use. The snakes were originally collected on Guam and housed in our laboratory colony for over 6 years before the experiment (Greene et al., 1997). They were fed a diet of thawed frozen mice and chicks every 2–3 weeks, but were not fed 2 weeks prior to the experiment. Ambient room temperature was 23–30°C (mean: 25°C), and relative humidity was 75–80% in the snake room, simulating conditions on Guam. Lighting (14L:10D) was provided by overhead fluorescent lights and by natural sunlight entering the room through windows.

Four treatments were tested in the experiment: (1) a blank control (untreated cotton swab), (2) a general lipid control (a mixture of 100 m vegetable oil in 5 ml hexane), (3) a mouse treatment (positive control), and (4) a human skin treatment.

The mouse treatment was produced by rubbing a swab on the fur and skin of a thawed house mouse (*Mus musculus*) 10 times. The human skin treatment was created by rubbing a single cotton swab on the skin of the arms of four adult humans (2 females and 2 males) five times each. All swabs were used immediately after preparation. The general lipid control was produced by applying 0.5 ml of the dilute lipid to a swab and allowing the solvent to evaporate.

Experiments were conducted during scotophase when the snakes were normally active following methods patterned after earlier studies by Burghardt (1970, 1975; Burghardt et al., 1988). Snakes were tested in their home cages by placing treated or control cotton swabs in the cage approximately 2-cm from the snake's snout. Treatments were presented in a randomized sequential order in a single session with 15 min between tests. The order of snakes tested was random. In all trials, snakes tongue-flicked the swabs within 2 min, making it unnecessary to stimulate a response by lightly touching the swab to the snouts. Trials in which the snake displayed defensive behaviors to the presence of the swab, such as defensive striking or head-hiding (Johnson, 1975), were suspended and redone during a subsequent session.

Trials began when the focal snake tongue-flicked the swab for the first time. Subsequently, the number of tongue-flicks that made direct contact with the swab was counted for 180 sec or until the snake attempted to ingest the cotton swab (in preliminary observations, the latency to attack dead mice ranged from 7 to 288 sec). The feeding behaviors measured were: (1) close-contact tongue-flicking and (2) attacks. We have only observed close-contact tongue-flicking by *B. irregularis* during feeding events on dead prey items, never during predation on live prey or during defensive attacks (M. J. Greene, unpublished data). The behavior consists of short, directed tongue-flicks at the dead prey item with the snout positioned a few millimeters away in which only the bifurcated tips of the tongue protrude from the mouth.

The tongue-flick attack score for repeated measures [TFAS(R)] was used to quantify the predatory response to the swabs (Cooper and Burghardt, 1990). TFAS(R) is a composite measure (combining tongue-flick frequency and latency to attack data) that weighs trials in which snakes attack the stimulus more heavily than trials in which no attacks occur. $\text{TFAS(R)} = \text{TF} + (\text{TL} - \text{latency})$, where TF is the maximum number of tongue-flicks directed at the swabs for any treatment by the focal snake, TL is the trial length in seconds, and latency is the time in seconds to attack the swab from the start of the trial. Higher scores indicate a greater predatory response (Cooper and Burghardt, 1990).

Wild-Caught Snake Bioassay. This experiment was conducted using brown tree snakes collected from their native range in Queensland, Australia. Immediately after capture, snakes were brought back to a laboratory at the University of Queensland where they were housed and tested. Snakes were housed in captivity for less than 7 days, and all interactions with humans were minimized before

testing. Eight snakes (3 males and 5 females) were tested in their home cages using the same protocol as the laboratory study except that only the human odor and blank control treatments were tested (the mouse and general lipid controls were not conducted with the wild snakes because neither were available in the field at the time of the study). Snakes were tested by using a switchback method; on the first night, snakes were randomly chosen to receive either the control or human odor treatment while receiving the other treatment on the second night.

RESULTS

Laboratory Snake Bioassay. The snakes displayed predatory behaviors more often to the mouse and human skin stimuli swabs than to the control swabs (Cochran's Q test: $Q = 26.2$; $df = 3$; $P < 0.001$; Figure 1A). They responded with predatory behavior in 8 of 10 trials (6 attacks) to human skin stimuli and in 10 of 10 trials (6 attacks) to mouse odor, while never displaying predatory behaviors to either control. TFAS(R) scores were higher for the mouse and human treatments than for the controls (Friedman ANOVA: $Fr = 13.6$; $df = 3$; $P < 0.004$; Figure 2A); however, the response to the human stimulus did not differ from the response to the mouse stimulus ($Fr = 0.001$; $df = 1$; $P < 0.999$). There were no sex differences in TFAS(R) scores for any of the stimuli (Mann-Whitney U test: $P > 0.05$ for all comparisons).

Wild-Caught Snake Bioassay. The results were consistent with laboratory data; the snakes responded to the human skin swabs with predatory behavior in 6 of 7 trials (4 attacks) while never displaying predatory behavior to the control ($Q = 6.00$; $df = 1$; $P < 0.014$; Figure 1B). The snakes had a higher TFAS(R) to human skin stimuli than to the control ($Fr = 7.00$; $df = 1$; $P < 0.008$; Figure 2B). There were no sex differences in TFAS(R) scores for any of the stimuli (Mann-Whitney U test: $P > 0.05$ for all comparisons).

DISCUSSION

Captive brown tree snakes collected on Guam and wild-caught snakes from their native habitat in Australia responded to human skin stimuli with predatory behavior. Specifically, close-contact tongue-flicking and deliberate predatory attacks were displayed to both the human- and mouse-treated swabs (a positive control), while never to the negative controls. These data confirm earlier observations in our laboratory of brown tree snakes investigating items touched by human skin, and they may provide a mechanism to explain why the snakes attack sleeping humans on Guam.

We propose that foraging brown tree snakes accidentally make contact with sleeping humans when searching for natural prey in and around homes on Guam. By tongue-flicking the skin of sleeping humans, the snakes may detect

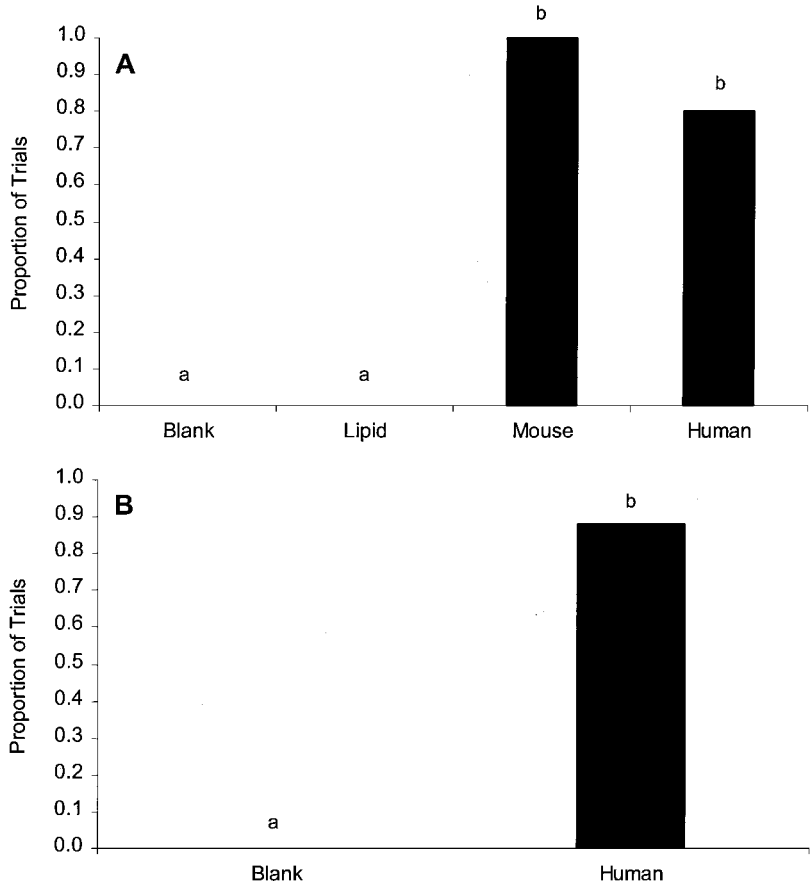

FIG. 1. The proportion of trials in which snakes displayed predatory behavior (close contact tongue-flicks or attacks) to the stimuli for (A) captive snakes originally caught on Guam and for (B) wild-caught snakes from Queensland, Australia. Letters indicate statistical significance between experimental treatments.

semiochemicals that release stereotypical feeding behavior even though the snakes could not ingest the person being attacked. It is unclear if snakes would be attracted to homes specifically because of the presence of human odor, or if the snakes may make accidental contact with humans while searching for prey. This is not the first study to document a predatory response to human stimuli; Chiszar et al. (1993) demonstrated that brown tree snakes show a strong predatory response to human postpartum and menstrual blood.

It appears that the compounds that release feeding behavior from human skin and mice are relatively nonvolatile in nature (for example, the experimental

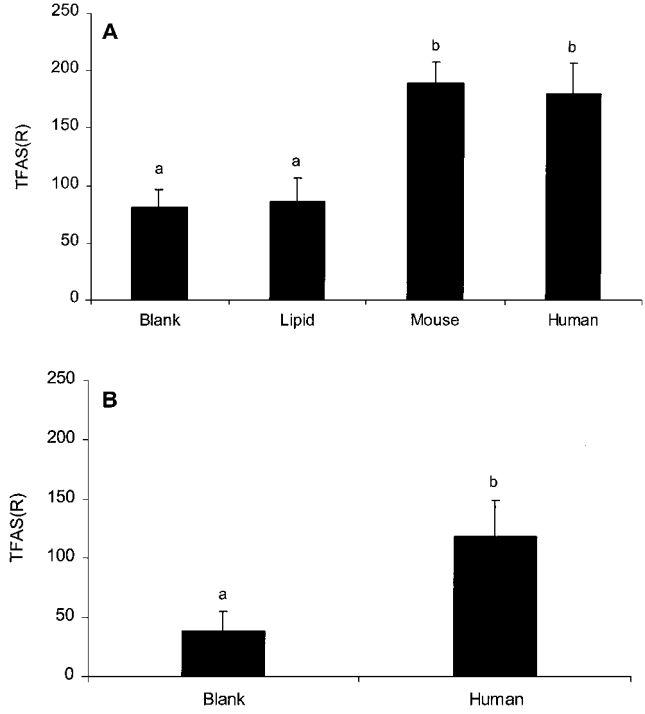

FIG. 2. Tongue-flick attack scores [TFAS(R)] displayed by focal snakes for (A) captive snakes and for (B) wild-caught snakes. Higher TFAS(R) indicate a greater predatory response. Letters indicate statistical significance.

treatments elicited feeding behavior from the snakes several weeks after being stored in a refrigerator). Mammalian skin is covered in a thin film of lipids, composed mainly of sebaceous lipids. Sebaceous glands, associated primarily with hair follicles, secrete a mixture of lipids called sebum onto the skin surface and hair of mammals, while other skin lipids are derived from epidermal cells (Strauss et al., 1991). We hypothesize that this lipid film is a source for the semiochemicals that release feeding behavior in the brown tree snake (Strauss et al., 1991). Human skin lipids are composed of triglycerides (57%), wax esters (26%), squalene (12%), sterol esters (3%), and free sterols (2%) (Greene et al., 1970; Strauss et al., 1991). In mice, the lipid layer is composed mainly of wax diesters (65%), free sterols (13%), sterol esters (10%), and free fatty alcohols (6%) (Wilkinson and Karasek, 1966; Strauss et al., 1991).

The overlap in lipid compounds (or in other types of compounds) between mice and humans might provide an explanation as to why brown tree snakes attempt to prey upon humans. The brown tree snake is known to feed on a diversity of

vertebrate prey, including many species of mammals. We hypothesize that brown tree snakes recognize mammalian prey versus prey of other vertebrate taxa by detecting some skin component common to many mammalian species. Future experiments will examine this in depth; chemical studies will be conducted to determine the chemical structures of compounds that elicit predatory behavior. It would be useful to determine if brown tree snakes respond to specific compounds, or to a broad array of compounds that might be common to their vertebrate prey.

TRANSPORT OF PHENOLIC COMPOUNDS FROM LEAF SURFACE OF CREOSOTEBUSH AND TARBUSH TO SOIL SURFACE BY PRECIPITATION[1]

P. W. HYDER, E. L. FREDRICKSON,* R. E. ESTELL, and M. E. LUCERO

USDA/ARS, Jornada Experimental Range
Las Cruces, New Mexico 88003, USA

(Received December 3, 2001; accepted July 14, 2002)

Abstract—During the last 100 years, many desert grasslands have been replaced by shrublands. One possible mechanism by which shrubs outcompete grasses is through the release of compounds that interfere with neighboring plants. Our objective was to examine the movement of secondary compounds from the leaf surface of creosotebush and tarbush to surrounding soil surfaces via precipitation. Units consisting of a funnel and bottle were used to collect stemflow, throughfall, and interspace precipitation samples from 20 creosotebush (two morphotypes) and 10 tarbush plants during three summer rainfall events in 1998. Precipitation samples were analyzed for total phenolics (both species) and nordihydroguaiaretic acid (creosotebush only). Phenolics were detected in throughfall and stemflow of both species with stemflow containing greater concentrations than throughfall (0.088 and 0.086 mg/ml for stemflow and 0.022 and 0.014 mg/ml for throughfall in creosotebush morphotypes U and V, respectively; 0.044 and 0.006 mg/ml for tarbush stemflow and throughfall, respectively). Nordihydroguaiaretic acid was not found in any precipitation collections. The results show that phenolic compounds produced by creosotebush and tarbush can be transported to the soil surface by precipitation, but whether concentrations are ecologically significant is uncertain. Nordihydroguaiaretic acid was not present in the runoff from creosotebush.

Key Words—*Flourensia cernua*, *Larrea tridentata*, nordihydroguaiaretic acid, total phenolics.

INTRODUCTION

Replacement of arid grasslands by shrubs in the southwestern United States has been ongoing since the late 1800s (Buffington and Herbel, 1965; Archer, 1994). Two shrubs that have increased during this transition are creosotebush [*Larrea tridentata* (Sess. & Moc. ex DC.) Cov.] and tarbush (*Flourensia cernua* DC.). Both of these species have extensive root systems (depths of 5 m or more, radial spreads of 1.5–5 m, and surface roots within 10 cm of the soil surface) allowing efficient harvest of water and nutrients compared to grasses associated with these species whose roots rarely exceed 1.5 m in depth (Gibbens and Lenz, 2001). These two species are also well defended against herbivory. The resin on the leaf surface of creosotebush ranges from approximately 8 to 26% of the dry matter, depending on leaf age (Mabry et al., 1977; Rhoades, 1977). The phenolic fraction typically constitutes 80–90% of the resin (Mabry et al., 1977), and this fraction contains mainly phenolic aglycones, with nordihydroguaiaretic acid (NDGA) being the predominant component (Rhoades, 1977). Approximately 5–10% of the dry weight of creosotebush is NDGA (Mabry et al., 1977). Total phenolics in creosotebush ranged from 9.9% of organic matter in leaves collected between July and October (Holechek et al., 1990) to 3.6% in leaves collected in late fall (Hyder et al., 2002). Tarbush also has a resinous leaf surface (8–12% of dry matter) (Estell et al., 1994), with total phenolics ranging from 6.5 to 8.1% for leaves collected in four growth stages over a 3-year period (Estell et al., 1996).

Shmida and Whittaker (1981) concluded that allelopathic effects did not appear to exist for creosotebush based on spatial associations between herbaceous species and creosotebush. Knipe and Herbel (1966) demonstrated that an aqueous extract of creosotebush inhibited germination of black grama [*Bouteloua eriopoda* (Torr.) Torr.] seeds, but did not affect either bush muhly (*Muhlenbergia porteri* Scribn.) or creosotebush seeds. Bush muhly normally grows in close association with creosotebush, occasionally even to the detriment of the creosotebush (Welsh and Beck, 1976). Cox et al. (1983) observed greater leaf lengths and shoot production on grasses grown in soil collected from under creosotebush than in grasses grown in soil from interspaces. Elakovich and Stevens (1985) showed that NDGA inhibited root and hypocotyl growth in eight plant species. We are not aware of any studies regarding the allelopathic potential of compounds from tarbush. However, many phenolic compounds (individually or in mixtures) have been shown to exhibit allelopathic activity toward a number of plant species based on a variety of criteria (Einhellig, 1987; Li et al., 1993; Inderjit, 1996).

de Soyza et al. (1997) described two growth forms of Chihuahuan Desert creosotebush: hemispherical and inverted cone morphotypes (referred to as U and V morphotypes, respectively). These authors suggested the inverted cone shape, which is found among young plants and those in water-limited environments, enhances deep soil water storage through root channeling, while the hemispherical

shape, which is found in established older plants and plants in environments where water stress is less important, enhances soil nutrient development.

Our objectives were to determine if phenolic compounds from creosotebush and tarbush leaves can be transported to the soil surface via precipitation and if concentrations of secondary compounds in runoff differ between creosotebush morphotypes.

METHODS AND MATERIALS

The study site was in the northern Chihuahuan Desert on the USDA/Agricultural Research Service/Jornada Experimental Range approximately 16 km north of Las Cruces, New Mexico, USA. The site consists of an area of sandy loam soil on a 2° east-facing slope. Depth to the first calcic layer is approximately 0.9 m. Gravel and sand at this site were derived from andesites, monzonites, and rhyolites eroded from the nearby Doña Ana Mountains. Elevation at the site is 1322 m. Long-term (1915–1999) mean annual and growing season (July, August, and September) precipitation for the area is 246 and 133 mm, respectively. Long-term mean monthly temperatures for the coldest (January) and warmest (July) months are 6° and 26°C, respectively. Creosotebush is the dominant shrub on this site, with tarbush, mesquite (*Prosopis glandulosa* Torrey), yucca (*Yucca elata* Engelm.), and Mormon tea (*Ephedra trifurca* Torrey) present as minor components. Grass species include burrograss (*Scleropogon brevifolius* Phil.), fluffgrass (*Dasyochloa pulchella* (Kunth) Steudel), black grama, and bush muhly.

During June 1998, 20 creosotebush [10 of each morphotype, as described by de Soyza et al. (1997)] and 10 tarbush were randomly selected by using a point-quarter method. Each plant was equipped with three precipitation collection devices by using methods described by Martinez-Meza and Whitford (1996). One container collected water intercepted by the shrub canopy and channeled down the stems (stemflow). Stems used for collecting stemflow were selected with a leaf cluster unobstructed from above by other branches. The stem collection unit consisted of a polyethylene funnel (11 cm upper diameter with an area of approximately 95 cm^2) glued to the base of a branch with silicone glue. A hole was cut in the funnel and placed such that the funnel completely surrounded the branch. A Nalgene tube attached to the funnel was inserted into a 500-ml Nalgene collection container through a hole drilled in the lid to minimize evaporation and contamination. The tube fit through the hole loosely to allow pressure equalization as the container filled. A second unit collected water passing through the canopy without stem channeling (throughfall), and a third unit (control) collected rain that had not physically encountered a plant (interspaces). Throughfall and interspace collectors consisted of 500-ml collection containers with funnels inserted directly into the container lids. A throughfall collection unit was placed beneath the canopy of each

plant midway between the base and outer edge of the plant, and an interspace unit for each plant was placed an equal distance between it and the nearest neighboring plant. The collection containers were buried half way in the soil to provide stability and minimize exposure to light. Precipitation events occurred on July 22, 25, and 26, 1998, and samples were collected within 30 min of the end of each event. Occasionally, collection units were destroyed by animals or wind, resulting in fewer than 30 samples for a given runoff source/plant species (or morphotype) combination.

Precipitation samples were analyzed for total phenolics and NDGA. Samples were filtered through 0.2-μm PTFE syringe filters (Millex-FG, Millipore Corp., Bedford, Massachusetts, USA). A Waters 2690 separations module coupled to a Waters 486 UV detector (283 nm) equipped with a Symmetry C-18 column (2.1 $\times$ 50 mm, 3.5-μm particle diameter; Waters Corp., Millford, Massachusetts, USA) was used to analyze filtrate for NDGA (100-μl injection size, 65% water–35% HPLC grade acetonitrile mobile phase, flow rate of 0.3 ml/min). Concentrations were quantified with an external standard curve, and either a blank or an NDGA (minimum 90% purity, Sigma Chemical Co., St. Louis, Missouri, USA) standard (ranging from 1 to 100 ng) was injected after every 10 samples to verify calibration. Total phenolics concentration was analyzed using AOAC (1990) procedures (Folin-Denis method, tannic acid as standard). Samples (2-ml aliquots) were analyzed in duplicate on a Milton Roy Spectronic 401 spectrophotometer (760 nm). Statistical analyses were performed using SigmaStat® for Windows, version 2.03 (SPSS, 1997). Statistical procedures used were Kruskal-Wallis one-way ANOVA on ranks with Dunn's method to test all pairwise multiple comparisons.

RESULTS

Total phenolics were detected in both stemflow and throughfall (Figure 1), with greater concentrations in stemflow than throughfall for both creosotebush morphotypes and tarbush ($P < 0.001$). Total phenolic concentrations were higher in stemflow of creosotebush than tarbush, with no difference between the two morphotypes (Kruskal-Wallis one-way ANOVA on ranks, $Q = 0.175$, $P > 0.05$). Mean Stemflow concentrations were (mean $\pm$ SD) 0.088 ± 0.044 ($N = 26$) and 0.086 ± 0.033 ($N = 29$) mg/ml for the U and V morphotypes, respectively. Total phenolic concentrations in throughfall differed between creosotebush morphotypes (Kruskal-Wallis one way ANOVA on ranks, $Q = 1.088$, $P < 0.05$). Throughfall concentrations were (mean $\pm$ SD) 0.022 ± 0.016 ($N = 26$) and 0.014 ± 0.017 ($N = 26$) mg/ml for the U and V morphotypes, respectively. Tarbush exhibited a similar pattern (Figure 1) of greater total phenolics in stemflow than throughfall. Mean concentrations were 0.044 ± 0.022 ($N = 20$) and 0.006 ± 0.009 ($N = 23$) mg/ml for stemflow and throughfall, respectively. Nordihydroguaiaretic acid was not detected in the creosotebush runoff samples, and does not occur in tarbush.

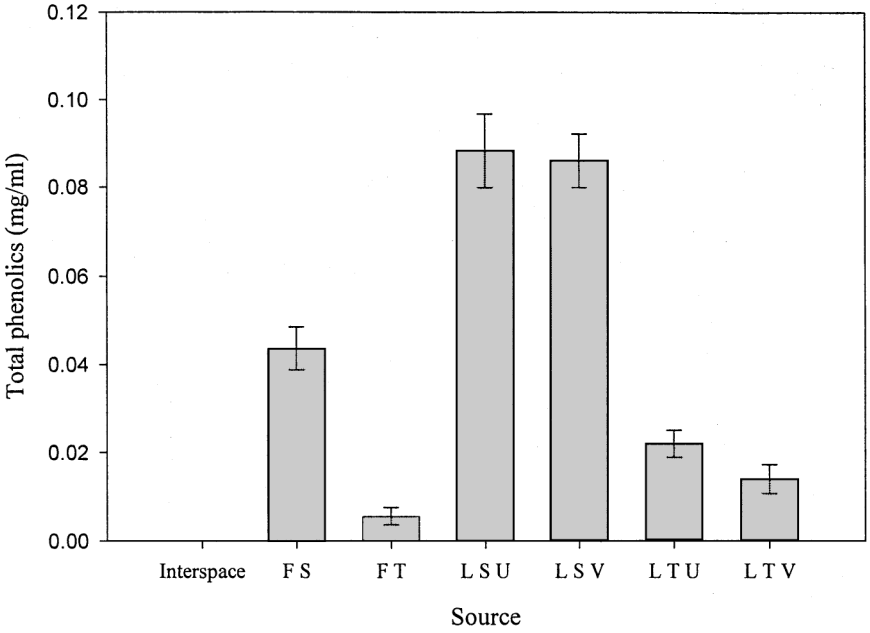

FIG. 1. Total phenolic concentrations (± SEM) in runoff from stemflow (S), throughfall (T), and interspace (I) of tarbush (F) and inverted cone (V) and hemispherical (U) morphotypes of creosotebush (L) during 1998, $N = 5$, 20, 23, 26, 29, and 26, respectively.

DISCUSSION

Creosotebush and tarbush produce phytochemicals with the potential to impact their immediate environment. Phenolic compounds were present in runoff from plant surfaces of both plants, and total phenolic concentrations varied for plant species and source of runoff. Concentration of total phenolics in runoff was greater for creosotebush than tarbush for both sources (approximately two fold for stemflow and three- to four fold for throughfall). Stemflow concentrations were approximately four- to five fold greater than throughfall for both creosotebush morphotypes and nearly an order of magnitude greater than throughfall for tarbush. Concentration of total phenolics in stemflow did not vary between creosotebush morphotypes, but did vary for throughfall (nearly two fold more in U- than V-shaped creosotebush). The hemispherical shape may provide more leaf surface area for precipitation to encounter compared to the inverted cone shape.

Nordihydroguaiaretic acid was not detected in precipitation samples. Potential allelopathic effects of creosotebush are often ascribed to this compound (Knipe and Herbel, 1966; Elakovich and Stevens, 1985). If so, NDGA must reach the soil by

some other presently unidentified route (e.g., leaf litter, root exudates), assuming our results are typical of creosotebush over its geographical and phenological range. Conversely, other phenolic compounds may be responsible for the effects observed in some research, given the wealth of data linking phenolics to allelopathy (Einhellig, 1987; Li et al., 1993; Inderjit, 1996). Lack of movement of NDGA may be due to its hydrophobic nature; this compound is only slightly soluble in water (Botkin and Duisberg, 1949). In prior tests of the effect of creosotebush extracts on seeds of various species, the extracts were obtained by soaking leaves and other tissues in water or Hoagland's solution for extended periods (Dalton, 1962; Knipe and Herbel, 1966; Barbour, 1967). Aqueous extracts (24 hr) of creosotebush contained as much as 150 mg/ml of NDGA (E. L. Fredrickson, unpublished data). Thus, extracts containing high concentrations of NDGA may not be biologically relevant, given the lack of NDGA in runoff observed in this study.

Nevertheless, some phenolic compounds reach the soil surface during precipitation events. Whether they are delivered in quantities sufficient to impact the surrounding environment is unknown. Concentrations of individual phenolics as low as 0.01 mM (Li et al., 1993) and 0.05 mM (Gallet, 1994) have been reported to exhibit allelopathic effects. Total phenolics concentration in our runoff samples would be approximately 0.2–0.4 mM (assuming a mean MW of 200), but this estimate represents a mixture of compounds.

Factors such as intensity, frequency, and duration of rainfall, plant phenology, etc., could affect the amount of secondary compounds delivered to the soil, their distribution (both depth and distance from source), and potential impact on surroundings. For example, Tromble (1988) demonstrated that for creosotebush and tarbush, precipitation events less than 3.6 and 3.0 mm, respectively, would be captured by the canopy and evaporate. Biotic factors may also affect concentrations and persistence of phenolics in the soil. Blum (1998) demonstrated that phenolic acids can have extremely transient lifetimes in soil due to microbial utilization, although Friedman (1987) noted desert ecosystems have properties (low rates of leaching and periodically reduced soil microfauna activity) that may favor persistence of allelopathic compounds.

In conclusion, movement of phenolic compounds from creosotebush and tarbush leaves to the soil surface occurs during precipitation events. Stemflow and throughfall samples from both species contained phenolics, with greatest concentrations in stemflow samples. However, NDGA was not found in any precipitation samples. Actual concentrations of phenolics in soil beneath creosotebush and tarbush are unknown and should be addressed in future work.

(Received January 28, 2002; accepted July 25, 2002)

Abstract—Three commonly employed methods for lignin determination, i.e., the thioglycolic acid (TGA), the acetylbromide (AB), and the acid detergent fiber (ADF) method, were compared using leaves and xylem tissue from five species (*Nicotiana tabacum, Populus* x *canescens, Fagus sylvatica. Quercus robur*, and *Picea abies*). In each case, cell walls were isolated before lignin determination. Each of the three methods estimated a different lignin concentration in a given tissue, except for spruce wood. The "lignin" concentration determined with the AB method was strongly dependent on whether or not the cell walls were subjected to alkaline hydrolysis to remove covalently bound aromatic nonligneous components before lignin determination. Lignin concentrations determined in hydrolyzed cell walls of different tissues and species by the AB method showed a good correlation with those obtained by the TGA method and, thus, were convertible. In contrast, gravimetrically estimated ADF lignins did not or only moderately correlate with lignins measured with methods based on the UV absorbance of the solubilized lignin degradation products. Leaves of a given species generally contained higher ADF-lignin concentrations than the corresponding stem tissue. Both ADF and TGA lignin data of beech were used to calibrate near-infrared reflectance spectra (NIRS) for lignin prediction. Both NIRS calibration procedures gave good statistical fits with correlation coefficients close to 1, indicating that TGA and ADF lignin concentrations of beech can be estimated by NIRS with high accuracy. However, the two calibrations were based

on different empirical terms, showing that TGA and ADF lignins did not share the same physical basis for calibration. C/N analysis revealed the presence of 3.1 and 1.4% nitrogen in ADF lignins of beech leaves and wood, respectively. The major fraction of this nitrogen was recovered in amino acids, which corresponded to 14% and 3% protein in ADF lignins of leaves and wood, respectively. These results show that ADF lignins contain significant concentrations of lignin-bound proteins, which renders this method unsuitable to determine genuine lignin.

Key Words—Acetyl bromide, acid detergent fiber lignin, amino acid, lignoprotein, near infra red reflectance spectroscopy, thioglycolic acid method.

INTRODUCTION

The quantitative determination of lignin is important in ecophysiological research. Lignin is an aromatic heteropolymer predominantly composed of coniferyl alcohol monomers in gymnosperms and of coniferyl and sinapyl alcohol in angiosperms and contains additional *p*-coumaryl alcohol units in grasses (Lewis and Yamamoto, 1990). The subunits are connected by ether (C—O—C) and C—C bonds. Ether linkages dominate, in particular β—O—4 bonds (>50% of the linkages in soft- and hardwoods) (Sjöström, 1993). The quantification of lignin is difficult not only because of its varying monomeric composition but also because lignins are covalently linked with cell wall carbohydrates, proteins, phenolics, or other compounds. These compounds may interfere with determination of lignins leading to over- or underestimation (Monties, 1989).

For determination of lignins, two different principles have commonly been employed: (1) gravimetric methods, which rely on the isolation of lignin or residual cell wall material [e.g., Klason lignin, acid detergent fiber lignin (ADF) (van Soest, 1963; Allen, 1989)] and (2) spectrophotometric methods, which are based on the decomposition of lignins into soluble degradation products and the determination of their absorbance in the UV [e.g., acetyl bromide method (AB), thioglycolic acid method (TGA) (Morrison, 1972; Bruce and West, 1989)]. Both strategies are time-consuming because they require lengthy wet-chemical sample preparation. For routine analysis of large sample numbers high through-put methods are needed. In this respect the use of near-infrared reflectance spectroscopy (NIRS), which takes advantage of the reflectance of chemical bonds in the near infrared, is promising. Near-infrared radiation is absorbed by various chemical linkages such as C—H, O—H, N—H, C=O, C—C, etc., and results in bending, stretching, and twisting of these bonds, leading to characteristic reflectance patterns. NIRS can be applied to milled dry samples without further sample preparation and can be used to determine a range of major chemical components (Foley et al., 1998). NIRS has obtained a certified status to measure moisture, crude protein, and acid detergent fiber content in

forages (AOAC, 1990). It has also been adopted to determine lignin contents, for example, in wood pulp (Easty et al., 1990) and in leaves or leaf litter (Wessman et al., 1988; McLellan et al., 1991; Joffre et al., 1992; Gillon et al., 1993; Bolster et al., 1996).

Cross-comparisons of different methods for lignin determinations are sparse. To date, NIRS methods for lignin determination have been calibrated with Klason or ADF lignins but not with spectroscopic methods exploiting the UV absorbance of soluble lignin degradation products. The goal of the present study was a systematic comparison of three commonly used methods for lignin determination across different species and the application of a gravimetric and spectroscopic method for the calibration of NIRS for lignin determination in different tissues of beech. Because of large differences found between gravimetric and spectroscopic methods, ADF lignins were subjected to C/N and amino acid analysis. The present paper reports for the first time the composition and concentrations of amino acids bound to beech leaf and wood lignins.

METHODS AND MATERIALS

Plant Materials. Stem wood and leaves of field-grown trees (*Picea abies, Fagus sylvatica, Quercus robus trees)* and leaves and debarked stems of greenhouse-grown young plants of *Fagus sylvatica*, *Populus* x *canescens* (hybrid of *P. tremula* x *alba*, clonal material) and of *Nicotiana tabacum* (9-week-old plants) were used for calibration studies. Stem wood from mature 110-year-old dominant beech trees was collected 1.3 m above ground immediately after felling at the field site at Solling (45 m above sea level). Leaves and wood for amino acid analysis in ADF lignins (see below) was collected from about 15-year-old beech trees at the end of August close to the institute (Fuchslöcher). The materials were cut into small pieces, dried at 60 or 70°C (tobacco at 40°C), and were ground to a fine powder (<0.08 mm) in a ball mill (Mikrodismembrator U, Braun, Melsungen, Germany).

Isolation of Structural Biomass for Lignin Analysis. Dry ground plant powder (200 mg) was suspended in 20 ml of washing buffer (100 mM K_2HPO_4/KH_2PO_4, pH 7.8, 0.5% Triton X-100), slowly stirred for 30 min at room temperature, and centrifuged (20 min, 5500g, swing rotor). The pellet was resuspended in washing buffer and washed as above. Subsequently, the pellet was washed 4 times (30 min) in 100% MeOH. The resulting pellet consisted mainly of cell walls, i.e., structural biomass (SBM). The SBM pellet was dried (12 hr at 80°C), weighed, and used for lignin analysis by the thioglycolate method (Bruce and West, 1989).

Alternatively, 400 mg of dry plant powder were suspended in 10 ml of 80% MeOH, stirred for 1 hr at room temperature, and centrifuged at 5500g (20 min). The

pellet was subjected to the following washing steps: 1× (1 M NaCl, 0.5% Triton X-100), 2 × distilled water, 2 × 100% MeOH, and 2 × 100% acetone (30 min each). The resulting AB pellet was used for lignin analysis by the acetylbromide method (Morrison, 1972). The relative weight of the AB pellet (grams of structural biomass per gram of initial dry weight) was slightly lower ($\approx -5\%$) than the weight of TGA pellets. To get rid of esterified phenolics, which interfere with lignin determination by the acetylbromide method, the AB pellet was subjected to alkaline hydrolysis under N_2 (2 M NaOH for 1 hr). The hydrolyzed pellet was washed twice with distilled water and dried at 80°C overnight. The dry pellet was weighed.

Lignin Analyses

TGA Method. Aliquots of 1–2 mg of SBM pellet (3 replicates per individual sample) were weighed into Eppendorf tubes and mixed with 1.5 ml of 2 N HCl and 0.3 ml thiogylcolic acid (adapted after Bruce and West, 1989). Samples were incubated at 95°C for 4 hr and repeatedly mixed. Samples were rapidly cooled on ice and centrifuged for 10 min at 15,000*g* (desk top centrifuge). The supernatant was discarded. Pellets were washed 3-times with distilled water (1 ml). Thereafter, pellets were incubated with 1 ml of 0.5 N NaOH for 18 hr on a shaker at room temperature. The suspension was centrifuged for 10 min at 15,000*g*. The supernatant was carefully transferred into a 2-ml Eppendorf tube. The pellet was resuspended in 0.5 ml 0.5 N NaOH, vigorously mixed, and centrifuged. The resulting supernatant was combined with the first alkaline supernatant and mixed with 0.3 ml conc. HCl. Samples were incubated for 4 hr at 4°C to precipitate the lignothioglycolate derivates. The samples were centrifuged, the supernatant discarded, and the pellet solubilized in 1 ml of 0.5 N NaOH. Absorbance of the resulting solution was measured at 280 nm. Calibration curves were generated by subjecting increasing amounts of 0.5–2.5 mg of commercial lignin (alkaline spruce lignin, Aldrich) to the same procedure. The extinction coefficient of alkaline spruce lignin was $\dot{\varepsilon} = 8.70$ l/g × cm. For comparison, the ADF lignin from beech yielded an extinction coefficient $\dot{\varepsilon} =$ 7.17 l/g × cm.

AB Method. Lignin was determined by the acetylbromide method adapted from Morrison (1972). For this purpose, aliquots of about 2.5 mg of hydrolyzed AB pellet (3 replicates) were mixed with 250 μl of 25% acetylbromide (v/v in glacial acetic acid) and incubated for 30 min at 70°C. Samples were rapidly cooled on ice, mixed with 250 μl of 2 N NaOH, and centrifuged for 5 min at 15,000*g*. An aliquot of the supernatant (250 μl) was mixed with 5 μl of 15 N NH_4OH and 2495 μl of glacial acetic acid. The absorbance of the solution was determined at 280 nm. Calibration curves were generated by subjecting increasing amounts of 0.5–2.5 mg of commercial lignin (alkaline spruce lignin, Aldrich) to

the same procedure. The extinction coefficient of alkaline spruce lignin was $\dot{\varepsilon} = 8.4\ \mathrm{l/g} \times \mathrm{cm}$.

ADF Method. For the gravimetric method of lignin determination (after Van Soest, 1963; Rowland and Roberts, 1994) 1 g of milled dry plant material was weighed (W1) into a 250-ml Erlenmeyer flask and boiled for 1 hr in 100 ml cetyltrimethyl ammonium bromide solution (1 g cetyltrimethyl ammonium bromide in 100 ml of 0.5 M H_2SO_4) under continuous stirring. A drop of octan-2-ol was added as an antifoam agent. The solution was filtered over an ignited and preweighed sinter (Robu-Glas, No. 2, 16–40 μm, Jena) and washed 3-times with 50 ml of hot distilled water. The filtrate was washed with acetone until further decoloration was not observed. The filtrate was dried for 2 hr at 105°C. About 10 ml of cool 72% H_2SO_4 (15°C) was added to the cooled sinter and mixed with the filtrate. Draining acid was refilled keeping the mixture for 3 hr in 72% H_2SO_4. Thereafter, the acid was filtered off under vacuum, and the residue was washed with hot distilled water until it was acid-free. The sinter was dried at 105°C for 2 hr, cooled, and weighed (W2). The sinter was ignited at 500°C for 2 hr, cooled, and weighed to determine ash content of the residue (W3). Lignin (%) was calculated as $(\mathrm{W2} - \mathrm{W3}) \times 100/\mathrm{W1}$.

For the determination of leaf lignins, it was necessary to add a filter aid (Celite 545, Baker, Deventer, The Netherlands).

NIRS Method. Ground, dry plant powder was scanned with monochromatic light at 2-nm intervals in a near-infrared reflectance spectrometer (NIRS system 6500, Foss, Hamburg, Germany) in the range of 400–2500 nm in two replicates per sample. All reflectance values are relative to a ceramic standard. Software used for data collection and data analysis was WINISI-II-Software systems (Foss). Each reflectance spectrum (R) consisted of 1050 data points and was automatically converted to apparent absorbance $[\mathrm{A} = \log(1/R)]$ prior to storing the spectral values. The inset in Figure 1 shows a typical sample spectrum. To minimize scattering and to accentuate fine-scale spectral features, the spectra were math transformed to the second derivative (Figure 1). Calibrations were developed for ADF lignins and TGA lignins using the built-in software package (WINISI-II-Software systems, Foss). The calibration equations were calculated using the modified partial least square regression method (MPLS) (as described by Bolster et al., 1996; Gillon et al., 1999). This calibration type selects wavelengths over the whole spectrum strictly on the basis of statistical correlation (principle component analysis) and is not based on preselected wavelengths. To avoid overfitting, cross-validation was used to obtain the optimal number of terms in the calibration. For this purpose, 5/6 of the samples were used to develop the model and 1/6 for the prediction. This was repeated 6 times and all the residuals of the 6 predictions were pooled to provide a standard error of cross-validation (SECV) of independent samples. The final model was then calculated to obtain the standard error of calibration

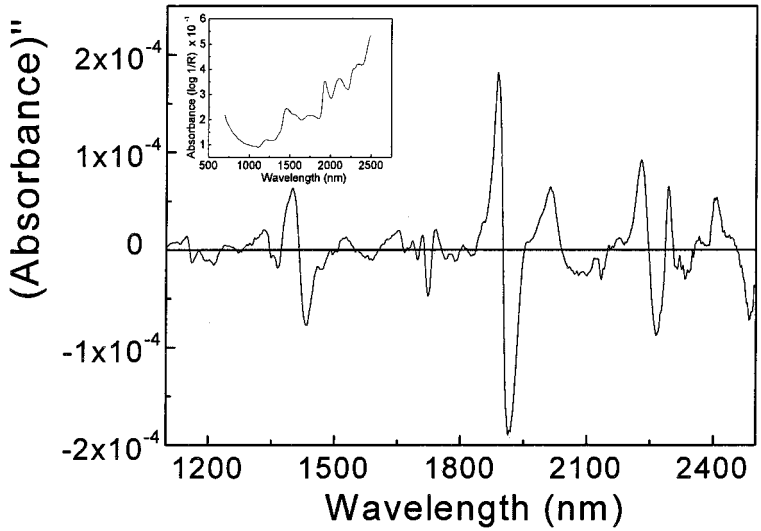

FIG. 1. Near-infrared reflectance spectrum of beech stem wood after log $1/R$ transformation and math treatment (2nd derivative). The original spectrum is shown in the inset. The spectrum is the mean of four samples measured at 2-nm gap width.

(SEC). For each calibration, different mathematical algorithms of the wavelength scans were compared. The math treatment, that gave the lowest SECV was selected. It has been reported that the whole-spectrum calibration mode provides the best fit to the data, but usually the calculated correlation coefficients of individual wavelengths can not be explained in a meaningful way (Bolster et al., 1996). Individual wavelengths that affected calibration were obtained by factor loading. For ADF and TGA lignin calibrations, 6 and 8 factors, respectively, have been obtained representing the wavelengths and biophysical properties indicated in Table 1.

Amino Acid Analysis. For the analysis of amino acids, 30 mg of ADF lignins were incubated in 0.5 ml of 5 N HCl for 24 hr at 105°C. After centrifugation (10 min, desktop centrifuge), the acidic extract was diluted (1:1000), and 40 μl of the dilution were evaporated, subsequently dabsylated, and analyzed by HPLC as described previously (Chang et al., 1992). Instead of dry wood or leaves, ADF lignins were also isolated from fresh plant materials in a washing buffer also containing soluble 2% polyvinylpyrolidine (PVP K-30).

Statistical Analysis. Where appropriate, the data were analyzed by linear regression. The analytical error of individual samples was generally below 5%. Data in the tables and figures indicate means of individual plants ($N = 5$ to 10, $\pm$SD).

[a] The wavelengths were grouped at a step width of 16 nm because the math treatment was based on an interval of 8. The right column of the table indicates the corresponding chemical structures. OT = overtone, CB = carbon bond.

RESULTS AND DISCUSSION

Comparison of Lignin Concentrations Determined by Different Methods and across Different Species. To find out the suitability of different methods for lignin comparisons across species and for different plant tissues, leaves and xylem tissue of four woody and one herbaceous species (*Picea abies*, *Quercus robur*, *Fagus sylvatica*, *Populus* × *canescens*, and *Nicotiana tabacum*, respectively) were analyzed. Three different protocols were used: the TGA method, the AB method before and after alkaline hydrolysis, and the ADF method. Both the AB and TGA methods rely on the solubilization of lignin, in one case due to acetylation, in the other case because of formation of thiolignogylcolic acids. The absorbance of the resulting aromatic compounds was determined in the UV and calibrated with alkaline spruce lignin to determine lignin concentrations. The ADF method is a gravimetric method. The rationale is to remove hemicelluloses and proteins by washing plant materials in acid containing detergents (Rowland and Roberts, 1994). Subsequent treatment with 72% H_2SO_4 results in degradation of cellulose, yielding a residual fraction thought to be mainly composed of lignins. The weight of this fraction corrected for ash contents was taken as "ADF lignin."

The TGA method generally gave lower lignin concentrations in the tissues than the other methods tested (Figure 2). Such differences between different methods for lignin determination have also been reported by others. For example, Pillonel et al. (1991) determined about 7-fold lower lignin concentrations in maize leaves with the TGA method than with the Klason method, which is similar to the ADF method. Surprisingly, we found that leaves contained higher "ADF lignin" contents than stem wood, with the exception of spruce wood (Figures 2A,B). Variable differences were found between the ADF and the TGA methods, e.g., in tobacco leaves 100% ADF lignin corresponded to only 9% TGA lignin, whereas spruce wood gave relatively consistent results (Figure 2). The lignin concentration of dry stem spruce wood accounted for 25% and 27% using the TGA and ADF methods, respectively, and, thus, were in the range of previously reported data [28.2% by Fengel and Wegener (1989) 27.4% by Sjöström (1993)]. The AB method yielded a slightly lower lignin concentration of 21%.

The "lignin" concentrations determined by the AB method were dependent on whether the samples had been subjected to alkaline hydrolysis or not (Figure 2). Alkaline hydrolysis releases phenolics that are covalently bound to lignins (Strack et al., 1989). Since these compounds also have a strong absorption in the UV, they will erroneously be determined as lignins if not removed prior to the acetylbromide treatment. However, alkaline hydrolysis may also result in a small nonspecific loss of lignins (Akin et al., 1995). Except for spruce wood, all other species and tissues analyzed contained significant amounts of aromatic components, which were soluble by alkaline hydrolysis (Figures 2A,B). Leaves generally contained

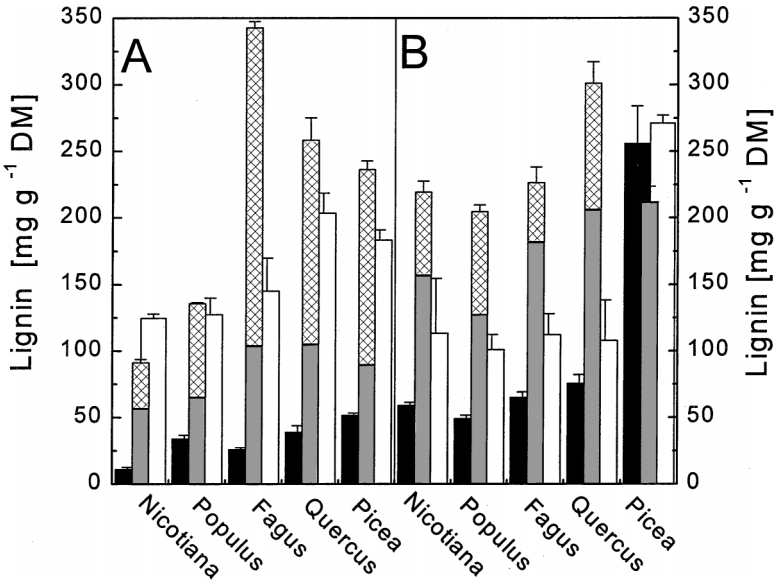

FIG. 2. Lignin concentrations in leaves (A) and stem wood (B) of different plant species. Lignin was determined with the TGA method (black bars), with the AB method before (hatched bars + gray bar) and after alkaline hydrolysis (gray bars), and as ADF lignin (white bars). Bars indicate means of 6 replicates ± SD. DM = dry mass.

higher concentrations of these components than wood (Figures 2A,B). This fraction was particularly high in beech leaves.

To determine whether the methods for lignin determination were convertible, regression analyses were performed. A significant correlation was found between the TGA and the AB methods (Figure 3A, $R = 0.888$, $P < 0.001$), although the absolute lignin concentrations determined by the two methods differed by a factor of 2.58. No correlation was found, however, between lignin determined by the TGA and the AB methods before alkaline hydrolysis ($R = 0.432$, $P = 0.245$, not shown). Furthermore no significant correlation was found for lignin concentrations obtained with the TGA and ADF methods in different species (Figure 3B, $R = -0.274$, $P = 0.474$). However, a moderate correlation existed between TGA and ADF lignins, if different tissues of one species, i.e., beech, were analyzed (Figure 3B, $R = 0.690$, $P = 0.001$).

The results indicate that both UV methods can be used for comparisons of relative lignin concentrations across different species and tissues. However, to obtain convertible estimates for lignin by the two UV methods, it is neccessary to remove cell wall-bound aromatic components by alkaline hydrolysis before the solubilization of lignin by acetyl bromide. Such a step is not necessary for the

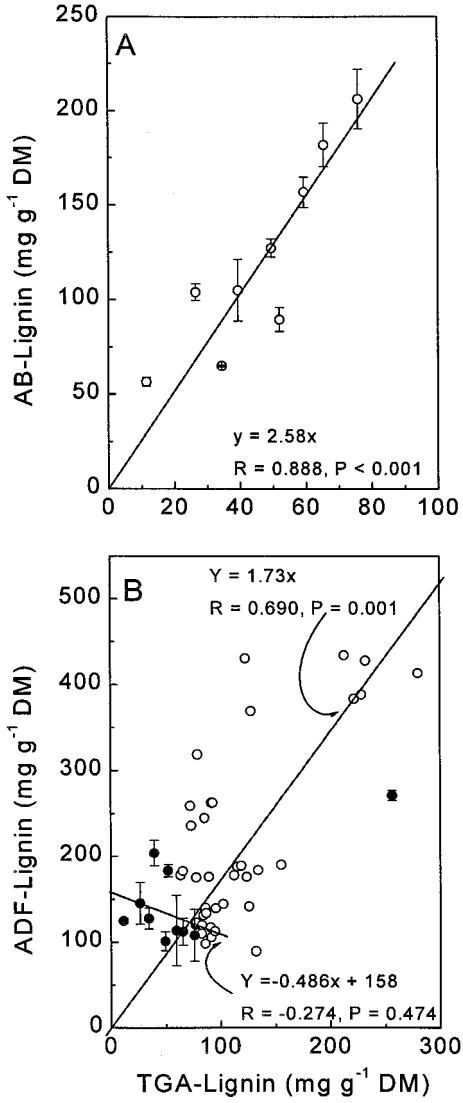

FIG. 3. Correlation analysis between TGA and AB lignin across species (A) and between TGA and ADF lignins (B) across species (full circles) and for different beech tissues (open circles). DM = dry mass.

determination of lignins with the TGA method because thioglycolic acid attacks specifically ether bonds in lignin, which link the monomers at the propanoid unit. The thioglycolic adduct is subsequently separated from other soluble components before measuring its absorbance in the UV. Thus, the TGA method mainly titrates β—O—4-bonds, and, therefore, is specific for lignins. The formation of thiolignoglycolate derivatives is considered a criterion for "genuine" lignin (Freudenberg, 1968). However, because of this specificity for certain properties of lignins, this method is also likely to underestimate the overall lignin concentration. In contrast to the TGA method, the AB method is likely to overestimate the lignin concentration slightly because incubation of cell walls with acetylbromide may lead to some oxidative degradation of structural polysaccharides, especially of xylans, resulting in increased absorbance at 280 nm, the wavelength used to determine lignin (Hatfield et al., 1999). However, it should be pointed out that we used short incubation times with acetyl bromide (30 min), which according to Hatfield et al. (1999) did not yet yield significant unspecific absorbance.

An important result was that the UV methods for lignin determination were not convertible with the gravimetric ADF method for comparisons across species. ADF lignins have been defined operationally as that organic material that can not be digested by 72% sulfuric acid.

Calibration of NIRS for Determination of Beech Lignin. In the literature, ADF lignins, which are prepared in a similar manner as Klason lignins (Rowland and Roberts, 1999), have been employed successfully to develop algorithms for lignin calibration curves by NIRS despite the undefined chemical nature of these "lignins" (e.g., McLellan et al., 1991; Gillon et al., 1993; Bolster et al., 1996). In the present study, we used ADF and TGA lignin data for calibration of NIRS. To avoid problems potentially arising from differences between species, ADF and TGA-lignin concentrations were determined in different tissues of one species, i.e., in leaves, stem wood, and coarse and fine roots of beech (cf. Figure 3B). A typical example of a NIR spectrum is shown in Figure 1 (inset). Based on such spectra, calibrations were developed based on both TGA and ADF lignin determinations (Figure 4). The correlation coefficients of the resulting relationship between measured and predicted values, especially the one determined on TGA-based calibrations, were high (Table 2). Expressed on a percentage basis, the SECV—a measure for the accuracy of the method—was about 1.4 for both calibration procedures (Table 2) and, thus, about 2 times lower than the SECV reported by Joffree et al. (1992). However, in preceding studies, lignins from different plant sources or from leaf litter in different stages of decay have been used (McLellan et al., 1991; Gillon et al., 1993; Bolster et al., 1996). Under these conditions, changes in the matrix structures, which may affect reflectance patterns, can not be excluded and might have caused a slightly higher scattering of the data than in the present study. NIR spectroscopy of lignin has also been successfully applied in pulp analysis (Wallbäcks et al., 1991).

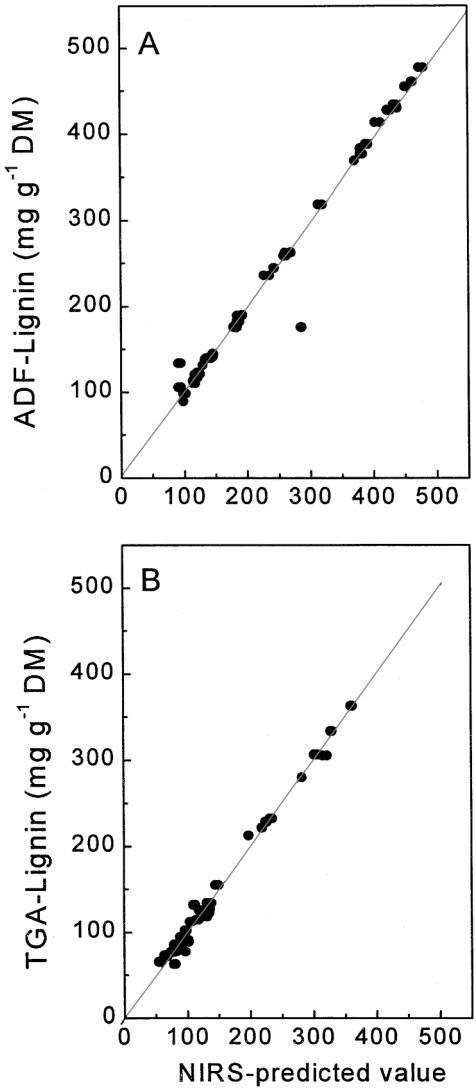

FIG. 4. Relationship between NIRS predicted lignin concentrations and ADF lignin (A) and TGA lignin (B) from different beech tissues. DM = dry mass.

The calibration curves produced here were used to predict native lignin concentrations in stem wood of mature beech trees. Employing the ADF calibration, we obtained a mean lignin concentration of 24.9% (Table 2), which is almost identical with figures published for beech wood previously [22.8% and 24.4%

TABLE 2. PREDICTION STATISTICS OF LIGNIN DETERMINED BY TGA AND ADF METHODS, DETERMINED OVER WHOLE SPECTRAL RANGE (400–2500 nm) AND DETERMINATION OF LIGNINS IN STEM WOOD OF MATURE BEECH TREES WITH NIRS[a]

Lignin	*N*	Mean	Range	SD	SEC	R^2	SECV	MT	Predicted lignin (mg/g)
TGA	92	130.3	63.4–363.1	78.3	8.06	0.989	13.8	2,4,4	87.2 ± 11.5 (n = 12)
ADF	92	231.8	89.6–477.7	119.2	7.56	0.996	13.3	2,4,4	249.6 ± 20.2 (n = 12)

[a] MT = mathematical transformation of spectral data: the first number is the order of the derivative function, the second the segment length of the data points over which the derivative was taken, and the third is the segment length over which the data were smoothed. SEC = standard error of calibration, SECV standard error of cross-calibration.

by Fengel and Wegener (1989) 24.8% by Sjöström (1993)]. Employing the TGA calibration, lignin concentrations of less than 10% were predicted for beech stem wood (Table 2). These values appear low as compared with ADF lignins. In a subset of the stem wood samples, ADF and TGA lignins were determined for validation. The deviation between NIRS-predicted values for ADF lignins and ADF-measured values was 1.3%, and that for NIRS-predicted and measured TGA values 2.7%.

These results clearly show that NIRS calibration curves based on different tissues (leaves, wood, fine and coarse roots) can predict lignin values for beech with high accuracy. However, the absolute lignin concentrations obtained in this way depend on the method chosen for calibration. Both methods employed here show differences in the NIRS calibration, which can not simply be explained by different scaling factors between the two methods because of differences in (1) the range of the apparent lignin concentrations determined by two methods (6.3–36.9% for the TGA, 8.9–47.7% for the ADF method, Table 2) and (2) the distribution of the data over the calibration curve (relatively homogenous distribution of ADF-data, relative clumping of TGA-data). Since the measurements were performed on the same set of samples, it is clear that ADF and TGA lignins must have a different chemical basis. This can also be inferred from results of principle component analysis, because the factors, which have been developed for NIR calibration only on statistical principles and not by *a priori* selection of wavelengths typical for lignin, revealed that different ranges of wavelengths contributed to ADF and TGA lignins, respectively (Table 1). In addition to some overlap, e.g., of wavelengths where aromatic compounds reflect (1428–1444 nm, and 1668–1678 nm), the calibration of ADF lignins was also affected by wavelengths, where amines or amino acids reflect (2036–2055 nm, 2244 nm) and that of TGA lignin by reflection of $\cdot NC{=}CH$ (2140 nm).

Presence of Ligno Proteins in ADF-Lignins. Recently, it has been reported that gravimetrically prepared lignins, e.g., by the Klason or the ADF method, containe nitrogen (Rowland and Roberts, 1999, Dyckmans et al., 2002). To find out

the chemical nature of this nitrogen and to assess the contribution of this fraction to the mass of ADF lignins, C/N and amino acid analyses were performed with beech leaf and wood preparations (Table 3). The following fractions were distinguished: whole-tissue dry matter, ADF lignins, nonligneous cell walls (= SBM ADF lignins), and soluble matter (= whole-tissue dry matter—SBM) (Table 3). The interesting result was that the relative carbon concentration of the different fractions showed only little fluctuation, whereas nitrogen was relatively enriched in ADF lignins compared to nonligneous cell walls or soluble components (Table 3). ADF lignins of leaves contained 11% of the foliar carbon and 17% of the foliar nitrogen, and those of wood contained 11% of the carbon and 41% of the nitrogen. Overall, our data show that about 40% of the leaf nitrogen and 90% of the wood nitrogen were bound to the cell wall fraction. Within this fraction nitrogen was relatively enriched in lignins as indicated by low C/N ratios of ADF lignins as compared with the C/N ratios of other fractions (Table 3). Since the above figures were obtained with preparations of fresh plant materials after extraction of soluble compounds with detergents in the presence of phenol scavengers, unspecific covalent binding of soluble proteins to lignins during extraction is unlikely. If dry plant material is used to isolate SBM and ADF lignins, the concentration of bound nitrogen is about 35% higher (data not shown).

Since cell wall carbohydrates may bind various functional groups forming, e.g., glucosamines, the nature and potential contribution of nitrogen to the mass of ADF lignins is not clear *a priori*. To find out whether the observed nitrogen was proteinaceous, ADF lignins were digested for amino acid analysis. We found

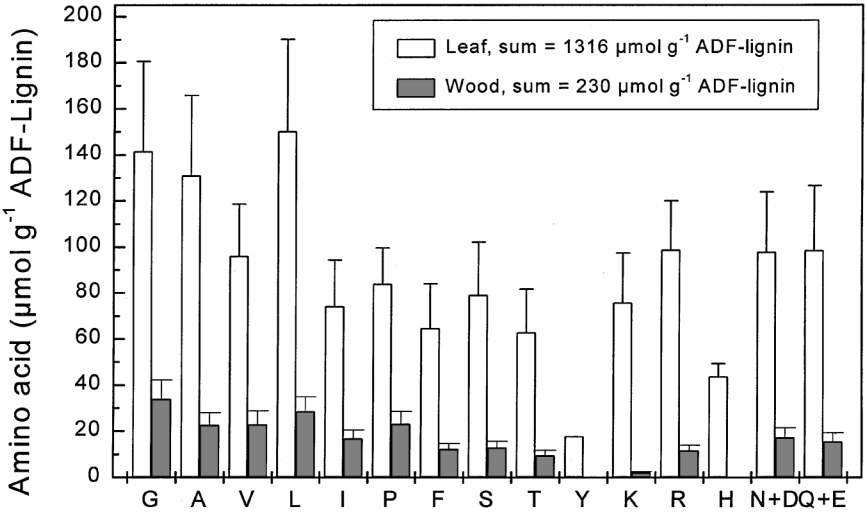

FIG. 5. Amino acids in ADF lignins from wood and leaves of beech (*Fagus sylvatica*) ($N = 5, \pm$SD). The amino acids were indicated with their biochemical one-letter-code: G = glycine, A = alanine, V = valine, L = leucine, I = isoleucine, P = proline, F = phenylalanine, S = serine, T = threonine, Y = tyrosine, K = lysine, R = arginine, H = histidine, N + D = asparagine + aspartate, Q + E = glutamine + glutamate.

that leaf lignins contained approximately a 5.7-fold higher concentration of amino acids than wood lignins (Figure 5). The amino acids covered the known spectrum of proteinaceous amino acids. Sulfur-containing amino acids (methionine, cysteine) can not be detected, and glutamate and glutamine (Q + E), as well as aspartate and asparagine (N + D), can not be separated by this method. Tryptophan, which occurs only at a low frequency in proteins (1.1%), was not found and may have been below the detection limit.

The amino acid spectra of wood and leaf ADF lignins were compared to find out whether the amino acid composition of putative proteins bound to wood-lignins was similar to that of lignoproteins from leaves. For this purpose, the relative frequency of each individual compound was calculated. The relative frequency of amino acids in leaf ADF lignins was plotted against those of wood ADF lignins. Amino acids occurring with the same abundance in both lignins are expected to appear on a curve with a slope of 1 (Figure. 6). Figure 6 shows that some nonpolar amino acids [proline (P), valine (V), and glycine (G)] were relatively enriched in proteins bound to wood lignins, whereas some polar amino acids, characterized by elevated nitrogen content [arginine (R), lysine (K), and histidine (H)] were more abundant in proteins bound to leaf-lignins than in those from wood. Furthermore, tyrosine (Y), an aromatic amino acid with a hydroxyl group, was also

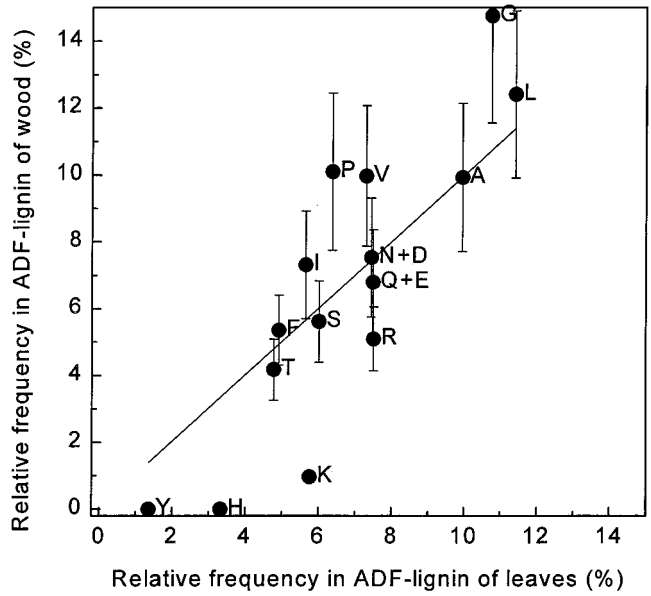

FIG. 6. Relative frequency of amino acids from ADF lignins of wood in relation to the relative frequency of amino acids from ADF lignins of leaves from beech (*Fagus sylvativa*). For wood and leaves, 230 μmol and 1316 μmol amino acid/g ADF lignin, respectively, were set as 100% (data from Figure 4) and used to express the relative frequency of each individual compound. Letters in the figure refer to amino acids using their one-letter-code as in Figure 5.

more abundant in ligno proteins from leaves than in those from wood. The nature and function of these lignoproteins needs to addressed in further studies.

The sum of the amino acids extracted from leaf ADF lignins corresponded to 75% and those from wood ADF lignins to 26% of the total nitrogen found in these fractions. On a mass basis, the amino acids corresponded to 141 mg protein/g ADF lignin in leaves and to 23 mg protein/g ADF lignin in wood. If all nitrogen found in ADF lignins were due to protein, the above figure would increase to 188 mg protein in ADF lignins from leaves, i.e., almost 20% by mass, and to 88 mg protein in ADF lignins from wood, i.e., about 9% by mass.

In summary the comparison of two spectroscopic methods (AB and TGA methods) showed that the amount of lignin determined by its absorbance in the UV may vary significantly depending on the calibration standard and on the pretreatment of the sample. Although the AB method is easy to use and reliable, as pointed out the Rodrigues et al. (1999), one has to be aware that even washed cell walls still contain bound aromatic compounds, which interfere with the lignin determination in a species- and tissue-dependent manner. The TGA method generally

yielded lower lignin concentrations than other methods but was convertible with the AB method and did not require hydrolysis of cell walls before lignin analysis. Both methods can be applied to small samples.

The gravimetric ADF method for lignin determination gave the highest lignin concentrations. However, ADF lignins contained considerable concentrations of bound protein, even though washed cell walls had been used for the preparation. The contribution of proteins to ADF lignins was estimated to be in the range of 2–9% in wood and 14–18% in leaves of beech. These results indicate that the ADF-lignin method will overestimate lignins to different degrees in leaves and wood and, thus, is not suitable to compare concentrations of "genuine" lignin in different tissues. Both ADF and TGA lignins were suitable for calibration of NIRS and predicted the "lignin," i.e., the chemical proper used for calibration, with high accuracy. However, in the case of ADF lignins, the predicted fraction should not be termed lignin but instead, lignoprotein.

It is known that cell walls contain structural protein and, thus, must contain nitrogen (Carpita and Gibeaut, 1993). Furthermore, it has been reported that proteins involved in the synthesis of lignins also become covalently bound during this process (Ros Barcelo, 1997). Still, the fractions of cell wall or lignin-bound nitrogen have not been quantified before. The present study shows for the first time that lignoproteins constitute a significant fraction of nitrogen relative to whole-tissue nitrogen. Despite the apparent abundance of lignoproteins nothing is known about their physiological functions and ecological implications. It is tempting to speculate that this fraction acts as a slow-release fertilizer in forest ecosystems. It will be interesting to study the turnover rate of lignoproteins and their significance in C and N cycles.

Acknowledgments—We are grateful to D. Goldmann and R. Schulz for expert technical assistance and thank Dr. B. Ludwig for helpful comment on the use of NIRS. We owe particular thanks to Dr. F. Krüger and U. Eisenwiener (Institute of Forest Zoology, University Göttingen) for their generous help with their amino acid analysis. Financial support by the DFG is gratefully acknowledged.

(Received November 1, 2001; accepted August 8, 2002)

Abstract—Bruchins are 3-hydroxypropanoate esters of long-chain α,ω-diols from pea weevils and cowpea weevils that have been shown to initiate callus formation on pea pods at extremely low application rates. Synthetic analogs have been prepared and examined to evaluate structural requirements for inducing this unusual neoplastic response. Chain length (optimum length C_{22}–C_{24}) is important, whereas unsaturation within the chain is relatively unimportant. Difunctionality is required for maximum activity, but the α,ω-diols themselves are inactive. Most critical is the ester portion(s) of the molecules; 3-hydroxypropanoate esters are far more active than any analogs examined.

Key Words—Bruchins, mitogens, Bruchidae, 3-hydroxypropanoates.

INTRODUCTION

We recently reported (Doss et al., 2000) the isolation and identification of four compounds, which we have named bruchins, from two species of Bruchidae [pea weevils (*Bruchus pisorum* L.) and cowpea weevils (*Callosobruchus maculatus* F.)] that stimulate rapid proliferation of undifferentiated cells when applied to pea

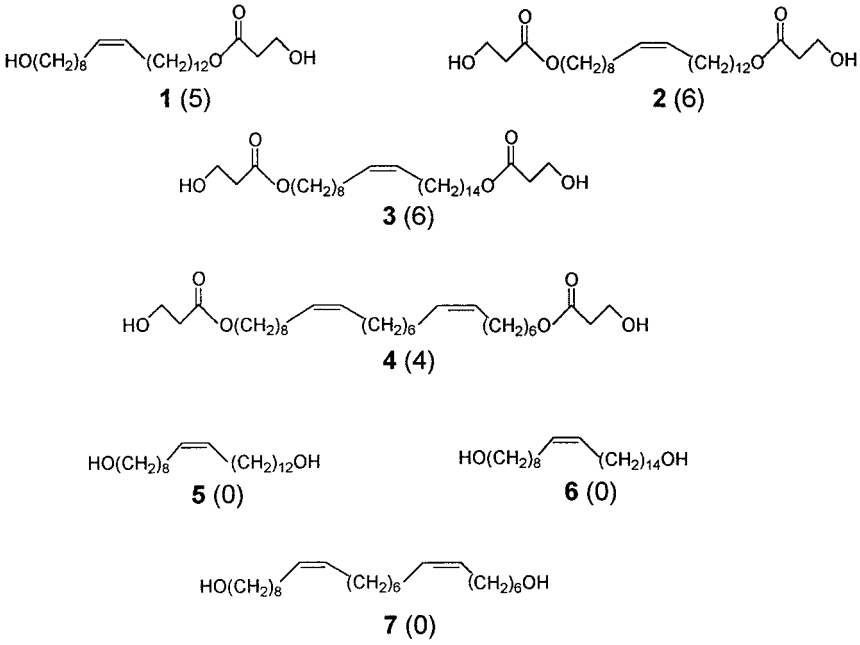

FIG. 1. Naturally occurring bruchins and corresponding α,ω-diols (relative activity in parentheses; see table).

pods (Doss et al., 1995). The work culminating in isolation and identification of these previously unreported compounds was initiated in response to reports that oviposition by pea weevils on pods of pea plants possessing the *neoplastic pod* (*Np*) gene resulted in the formation of neoplastic tissue (callus) beneath the eggs. (Berdnikov et al., 1992). Callus formation, in turn, inhibits larval entry into the pod (Berdnikov et al., 1992; Doss et al., 2000). These neoplasm-inducing compounds, which are mono- and bis-(3-hydroxypropanoate) esters of C_{22} and C_{24} α,ω-diols (**1**–**4**, Figure 1), are unprecedented as plant growth regulators, or for that matter, as natural products, and their remarkable activity (measurable callus formation can result following applications of as little as 0.5 pg of a bruchin) stimulated our interest in what structural features of these compounds contribute to, or are necessary for, this unusual biological activity.

We have described (Oliver et al., 2000) syntheses of the natural bruchins **1**–**4**, and reported that although the mono- and diesters **1** and **2** seemed comparably active in promoting cell division, the corresponding diols **5**–**7** themselves did not stimulate neoplasm formation, indicating that at least one 3-hydroxypropanoate moiety was involved in the growth-triggering response. We describe here a more detailed investigation into the structural requirements for bruchin activity that includes

evaluation of several features of the diol backbone (chain length and rigidity, unsaturation, geometry, structural modification), mono- versus difunctionalization, as well as examination of the effects of a variety of structural modifications in the acid portions of the molecules.

METHODS AND MATERIALS

Because of the large number of compounds discussed in this paper, we are omitting experimental details. Some generalizations concerning experimental procedures and strategies are outlined in the Results and Discussion section and in a previous publication (Oliver et al., 2000), and more specific details on syntheses and/or properties of specific compounds can be obtained from the corresponding author's website: www://barc.usda.gov/psi/caib/oliver.html

Bioassays were conducted using pods from an *Np/Np* pea line that had been selected from an F_4 heterozygote that was itself derived from a cross between C997-332 (*Np/Np*) and I_3 (*np/np*) (Doss et al., 1995). Plants were grown in a greenhouse with a minimum temperature of 16°C, and a maximum temperature of 21°C. Supplementary lighting was provided by high-pressure sodium lamps that were on from 06:00 until 22:00 hr, and a bank of eight fluorescent tubes (Sylvania F96T12/CW/SS) that were run continuously. Under these conditions, the development of spontaneously formed callus was kept to a minimum (Snoad and Matthews, 1969).

For bioassay, pods were removed from the plants at the late flat pod stage (Meicenheimer and Muehlbauer, 1982) and divided into halves by carefully splitting along the suture. The half pods, with immature seeds removed, were placed, with the outer surface up, upon moist filter paper in Petri dishes. Test solutions were applied as 1 μl drops in 50% (v/v) ethanol–water. Test compounds were applied at six levels: 1, 10, 100, 1,000, 10,000, and 100,000 fmol. Each compound was applied at each level to six separate pods using a random design. After test solutions on the pod were allowed to dry, the Petri dishes were covered and placed into a growth chamber (23°C, continuous fluorescent light, 30–40 $\mu E/m^2/sec$). Calli formed in response to application of test solutions were removed and weighed after one week.

RESULTS AND DISCUSSION

Synthesis. Analogs were synthesized by relatively straightforward procedures. The diol backbones of bruchin analogs were, in most cases, constructed by alkylation of appropriately substituted alkynes (see also Oliver et al., 2000), although other procedures included oxidative dimerization of ω-hydroxy-1-alkynes [Glaser coupling (Zweifel and Polston, 1970)] followed by hydrogenation. The diol portion of the symmetrical monoolefinic analog **10h** (Figure 2) was conveniently

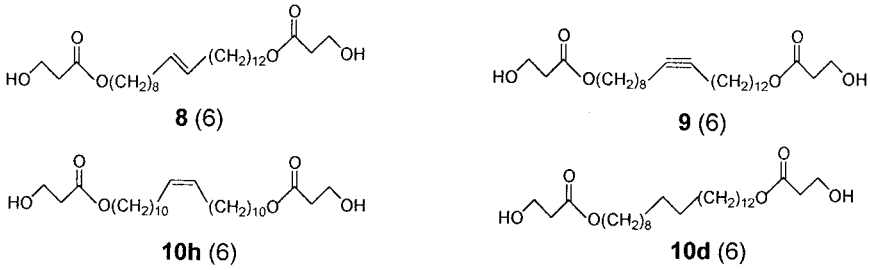

FIG. 2. Geometry, nature, and location of unsaturation (relative activity in parenthesis; see table).

prepared by oxidative dimerization of (11-hydroxyundecyl)triphenylphosphonium ylid (Poulain et al., 1996). The discovery that chain unsaturation was not a requirement for activity facilitated the evaluation of additional structural changes because synthetic procedures did not have to accommodate the unsaturation. Probably the most convenient and economical procedure for construction of 3-hydroxypropanoate esters consists of esterification of an alcohol or diol with 3-(benzyloxy)propanoyl chloride followed by catalytic hydrogenolysis (Oliver et al., 2000), a route not applicable in cases where unsaturation has to be maintained. That general route was used for the majority of the entries in Figures 3 and 4. For the comparison of mono versus diesters of α,ω-diols (Figure 3), it was often practical to react a given diol with slightly more than one equivalent of (3-(benzyloxy)propanoyl) chloride, then separate mono- and diesters by flash chromatography (mobility on silica gel decreased in the order diol > mono-(3-hydroxypropanoate) > bis-(3-hydroxypropanoate). In cases where catalytic hydrogenation was impractical (i.e., where chain unsaturation needed to be maintained), alcohols were esterified with 3-[(*t*-butyldiphenylsilyl)oxy]propanoyl

FIG. 4. Chain length, monoesters of monoalcohols (relative activity in parenthesis; see table).

chloride, then the protecting group was removed with tetrabutylammonium fluoride (Oliver et al., 2000)). The *E* geometric isomer **8** was prepared by inverting the olefin geometry (Sonnet and Oliver, 1976) of the bis-(*t*-butyldiphenylsilyl) ether of **2** followed by deprotection. Diesters depicted in Figure 4 were made by standard techniques, using acid chlorides with protected functional groups in several cases, but simple Fisher esterifications in others. Analogs containing central aromatic rings (**13a–d**, Figure 5) were initiated by double Wittig condensations on phthalaldehydes or *p*, *p*′-biphenyldicarboxaldehyde followed by hydrogenation. The acrylate oxide **14f** was prepared from bisacrylate **14e** by bromoformylation followed by formate hydrolysis and base treatment (Ueno et al., 1974). For esters containing chiral centers, we normally chose racemic precursors to avoid stereochemical bias in the preliminary survey; an exception was **14d** where availability of L-serine was a deciding factor.

Dose–Response to Bruchin Application. Because the response of a pea pod to bruchin application is highly localized (Doss et al., 1995, 2000), and because only a limited amount of callus can form over a given area of the pod, it is possible to saturate the response rather easily. Accordingly, above a certain threshold, there may be little if any measurable effect of increased levels of application. For example, with naturally occurring compound **4**, activity was first observed with the 100 femtomole treatment, and there was no clear-cut effect of higher doses. Because of this, comparison of the relative activity of the various compounds was best made

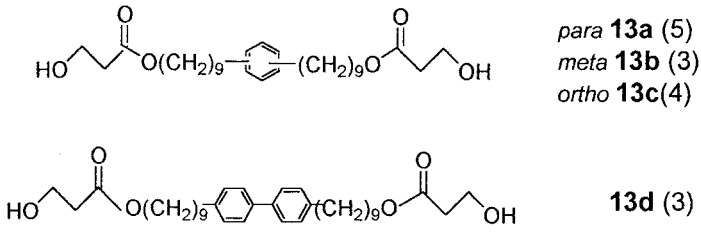

FIG. 5. Diesters of elaborated diols (relative activity in parentheses; see table).

by comparing the minimum active dose, which was taken to be the minimum dose with which half of the six treated pods developed measurable amounts of callus.

Table 1 reports mean weights (milligrams) of calli formed in response to application of test compounds. The column labeled "Score" provides a simple measure of the activity of the compounds where a score of 6 denotes a minimum active dose of 10^0 fmol; a score of 5, a minimum active dose of 10^1, etc. Hence, a score of zero indicates a compound that was inactive at all levels. The latter measure was useful for evaluating relative activities of the compounds.

Structural Parameters and Mitogenic Activity: Chain Unsaturation. All bruchins thus far identified from natural sources (**1**–**4**, Figure 1) contain a (*Z*)-9 double bond. Comparison of synthetic C_{22} analogs **8, 9, 10d,** and **10h** to natural product **2** (Figure 2) revealed that inversion [(*E*)-9-isomer **8**], dehydrogenation [9-alkyne **9**], relocation [(*Z*)-11 isomer **10h**] and removal altogether (saturated analog **10d**) of the double bond resulted in no measurable differences in activity, indicating that neither the presence nor location of unsaturation is particularly important. Moreover, the somewhat lesser activity of doubly unsaturated **4** indicates that increased unsaturation can be deleterious. We suspect that the (*Z*)-9 double bonds of **1**–**4** reflect lipid-based biosyntheses, although the issue has not been addressed experimentally.

Chain Length. After determining the apparent unimportance of unsaturation in the central chain, we synthesized a series of saturated bis- and mono-(3-hydroxypropanoates) with chain lengths ranging from 10 to 30 carbons (**10a**–**10g**, **11d–11h**, Figure 3). The most active compounds are mono- and bis-(3-hydroxypropanoates) of C_{18}–C_{24} α,ω-diols, e.g., **10c**–**10e**; these are the same chain lengths as the naturally occurring bruchins. Activity decreased markedly as chain length increased, and by C_{30} (**10g**) disappeared. It also decreased as the chain was shortened, although not quite as rapidly; barely detectable callus formation was observed at the highest applications of the C_{12} and C_{10} diesters (**10b** and **10a**, respectively.

Mono- versus Bis-(3-hydroxypropanoate) Esters of α,ω-Diols (*Figure 3*). Although Table 1 suggests monoester **1** to be slightly less active than corresponding diester **2**, the same comparison between several pairs of mono- and diesters of other diols, saturated and unsaturated, e.g., **11d–11h** versus **10d–10h** (Figure 3), indicated little or no difference in activity between the counterparts. In other words, removal of one 3-hydroxypropanoate from, for example, **2**, has little effect on activity, whereas removal of both eliminates it altogether. Thus two terminal OHs are decidedly advantageous, but only one 3-hydroxypropanoate ester is required.

3-Hydroxypropanoate Esters of Monoalcohols (Figure 4). Neoplasm formation was also observed following application of 3-hydroxypropanoates of long-chain primary alcohols (i.e., monoalcohols) **12b, 12c**–**12f** (Figure 4). However, the activities of the monoesters of monoalcohols were of a significantly lower level than those of mono esters of α,ω-diols of comparable chain length. Among

[a] Callus formed (mg) in response to treatment of pea pods with synthetic compounds applied at six levels. Values are means ± standard errors for six blocks (pods).
[b] Score from 0–6, with 6 = most active, 0 = inactive (see text).
[c] Synthetic versions of natural bruchins isolated from pea weevil and cowpea weevil.

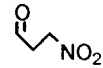
3-hydroxypropanoate esters of monoalcohols, the C_{22} analog **12d** was again the most active, and again activity decreased with increasing chain length until it had disappeared by C_{30} (**12g**). As had been the case with the difunctional counterparts, shortening the chain also led to decreased activity, although measurable activity was maintained through at least C_{10} (**12b**). The methyl ester of 3-hydroxypropanoic acid, (**12a**) was inactive, as was 3-hydroxypropanoic acid itself (**18**). To reiterate: although difunctionality is not an absolute necessity for activity, a terminal OH, even if not part of a (3-hydroxypropanoate) ester, decidedly contributes to optimum activity.

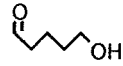
Bulkier and More Rigid Diol Backbones (Figure 5). In view of the apparently less stringent structural requirements for the central chain than for the acids constituting the ester termini, we synthesized some more elaborate analogs wherein aromatic rings were built into the centers of the molecules (**13a–d)**. One purpose was to address the reason for the importance of α, ω-difunctionality—how are two OHs at opposite ends of these long molecules involved in the same process? Having established that a chain length of about 22 carbons was optimum for activity, we tried to approximate that total length in some more rigid analogs. Models suggested that in contrast to the relatively flexible bruchins **1–4**, etc., the termini in analogs **13d** would be able to approach each other only with difficulty. Measurable activity was found for all of **13a–d**, with **13a** being the most active. Although the results do demonstrate the rather wide latitude of 3-hydroxypropanoate esters that can accommodate activity, the results may not contribute greatly to the question of flexibility and difunctionality, inasmuch as the activity of **13d** was no higher than that of some of the monofunctional 3-hydroxypropanoates, e.g., **12d** or **12e**.

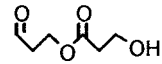
The Acid Portion. A number of diesters of the saturated docosane-1,22-diol were synthesized and tested (Figure 6). In contrast to the diol chain, where within acceptable chain lengths some latitude exists for structural embellishment, it quickly became apparent that strict requirements are imposed on the ester termini. Some of the analogous esters could be considered as possible precursors or metabolites of 3-hydroxypropanoates, but few stimulated measurable cell division in the pea pod assay. Removal of the OH (propanoate ester **14a**), moving it one carbon in either direction (lactate **14b** or 4-hydroxybutanoate **14i**), or adding an additional heteroatom (serine or dihydroxypropanoate esters **14c** or **14d**) all greatly reduced or virtually eliminated activity. The corresponding diacrylate **14e** (a formal dehydration product) and its epoxide **14f** were equally inactive. Bis-(2,3-dihydroxypropanoate) ester **14c** exhibited marginal activity at the highest level of application, the elaborated ester **14j** (itself a 3-hydroxypropanoate) was modestly active, and 3-methoxypropanoate **14k** and the 3-hydroxybutanoate **14h** stimulated significant cell division in the pea pod assay. All of these were considerably less active than **10d**.

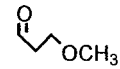
Hydrolysis Products (Figure 7). As mentioned, at least one 3-hydroxypropanoate is necessary for activity. Expected hydrolysis products [the α,ω-diols such as

Acyl-O(CH_2)$_{22}$O-Acyl









No	Acyl	No	Acyl
10d (6)		**14f** (0)	
14a (0)		**14g** (0)	
14b (0)		**14h** (3)	
14c (1)		**14i** (0)	
14d (0)		**14j** (4)	
14e (0)		**14k** (2)	

FIG. 6. Diesters of docosan-1,22-diol (relative activity in parentheses; see table).

5–7 (Figure 1) or **15–17**, (Figure 7)] were inactive. Similarly, 3-hydroxypropanoic acid itself (**18**) elicited no response in the pea pod assay. We have considered the possibility that intramolecular transesterification of a 3-hydroxypropanoate could generate propiolactone **19**, a known mutagen, but have failed in several attempts to trap **19** during hydrolysis of 3-hydroxypropanoate esters. Further, **19** stimulated no response in the pea pod assay.

In summary, we found that a long-chain (preferably about C_{22}, preferably difunctional) alcohol esterified with at least one 3-hydroxypropanoate moiety is essential for mitogenic activity. Moderate changes can be incorporated into the aliphatic portion of the molecules while retaining significant activity, whereas

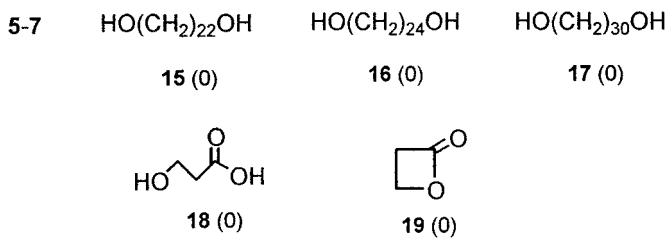


FIG. 7. Possible hydrolysis products (relative activity in parentheses; see table).

little alteration in the ester portion can be tolerated. The actual mechanism of mitogenic action remains under investigation. Transesterification involving 3-hydroxypropanoic acid remains a possibility, but logical hydrolysis products such as the α,ω-diols, 3-hydroxypropanoic acid, or propiolactone fail to promote cell division. Acyl transfer to an unknown cell component is certainly another possibility.

This study grew out of the unusual phenomenon of an insect-derived chemical stimulating neoplastic growth on pea pods (Berdnikov et al., 1992; Doss et al., 1995, 2000). Although callus formation in response to weevil oviposition appears to provide a measure of defense to the pea against entry of a pea weevil larva into the pea pod (Doss et al., 2000), the role or purpose of the bruchins in the insects remains unknown. While this manuscript was in preparation, we learned that Bartelt, Cossé, and coworkers (Bartelt, et al., 2002; Cossé et al., 2002) have identified acetates of unsaturated diols **5** and **6** as cuticular lipids of female wheat sawflies (*Cephus cinctus*) and have shown that these compounds serve as pheromone precursors via oxidative scission of the long chain. To the best of our knowledge, pheromone(s) have not been reported for *B. pisorum*, whereas pheromone components of *C. maculatus* have been reported to be several methyl-branched C_8-carboxylic acids (Phillips et al., 1996). The branched acids bear no obvious structural relationship to **1**–**4**, so at this time we have no reason to invoke a related function for these compounds.

Acknowledgments—We thank Dr. Dorothy Tabi, Mr. Vic Levi, and Mr. Anthony Weatherwax for chemical assistance, and Ms. SreyReath Kuy for help with the pea pod bioassays and data analysis. Mention of a proprietary product or company does not imply endorsement by the US Department of Agriculture.

(Received May 14, 2001; accepted August 3, 2002)

Abstract—The sex pheromone of the American population of *Lyonetia prunifoliella* (Lepidoptera: Lyonetiidae) was reported to be composed of three components, 10,14-dimethyloctadec-1-ene (10me14me-1-ene-18Hy), 5,9-dimethyloctadecane (5me9me-18Hy), and 5,9-dimethylheptadecane (5me9me-17Hy). Studies with a Korean population showed that the 10*S*,14*S* isomer of the major compound was the major electrophysiologically by active stereoisomer. The 5*S*,9*S* isomers of the minar constituents also elicited electrophysiological responses. In field trappings, among the three components, the racemic mixture of 10me14me-1-ene-18Hy attracted *L. prunifoliella* males strongly, and the binary or tertiary combinations with racemic mixtures of the other two components did not increase trap catches. Among the four stereoisomers of 10me14me-1-ene-18Hy, only the 10*S*,14*S* isomer attracted *L. prunifoliella* males, as suggested by the EAG test, and attraction to the other three isomers was not observed. All stereoisomers of each minor component, as well as their racemic components, did not seem to have any additional effect on male attraction in Korea.

Key Words—Sex pheromone, *Lyonetia prunifoliella*, EAG, field trapping, 10,14-dimethyloctadec-1-ene, 5,9-dimethyloctadecane, 5,9-dimethylheptadecane.

INTRODUCTION

Lyonetia prunifoliella (Hübner) [formerly *L. speculella* (Schmitt et al., 1996)] (Lepidoptera: Lyonetiidea) is a small leafminer that damages apple leaves and

* To whom correspondence should be addressed. E-mail: ksboo@plaza.snu.ac.kr

0098-0331/02/1200-2515/0 © 2002 Plenum Publishing Corporation

exists widely in Asia, America, and Europe. Females insert eggs singly into the lower surface of new leaves. Larvae form serpentine mines in the upper half of the leaves (Brown, 1989). Specifically, this moth damages new young trees and is increasing in apple orchards in Korea.

The sex pheromone of *L. prunifoliella* was identified for the North American population as composed of three components: the major one being 10,14-dimethyloctadec-1-ene (10me14me-1-ene-18Hy), and the two minor ones, 5,9-dimethyloctadecane (5me9me-18Hy) and 5,9-dimethylheptadecane (5me9me-17Hy) (Gries et al., 1997). Each of the three components has two chiral centers, so there are four stereoisomers for each chemical.

In Lyonetiidae, cases using specific stereoisomers as a sex pheromone have been reported (Sato et al., 1986; Tóth et al., 1989), but the pheromone chirality has not yet been investigated in *L. prunifoliella*, in part because of difficulty in synthesis and analysis. We synthesized all stereoisomers for the three components of the pheromone system in two different ways. Their activities were tested by EAG measurements and field trapping experiments for two years in Korea.

METHODS AND MATERIALS

Insects. Pupae of *L. prunifoliella* were collected in apple orchards in Gunwi, in the southern part of Korea, sexed, and kept at 22–25° and 60–70% relative humidity, under 16L:8D photoperiod. Adults were placed in Petri dishes containing moist filter paper coated with sugar. Females and males were kept separate to prevent mating.

Chemicals. The synthetic sex pheromone components were 10,14-dimethyloctadec-1-ene (10me14me-1-ene-18Hy), 5,9-dimethyloctadecane (5me 9me-18Hy), and 5,9-dimethylheptadecane (5me9me-17Hy). Their racemic mixtures were synthesized by G. Gries, as reported previously by Francke et al. (1988), Riba et al. (1990), and Gries et al. (1997). All the pure stereoisomers of the three chemicals were synthesized as reported by Tamagawa et al. (1999). The second set of the pure stereoisomer samples was synthesized according to Nakamura and Mori (2000).

Antennal Preparations for EAG Tests. For electroantennogram recordings, 3- to 7-day-old adult moths were momentarily anaesthetized with carbon dioxide. Their antennae, with both ends cut off, were mounted between the reference silver electrode and the recording silver electrode with electrode gel (Parker Laboratories Inc.).

EAG Tests. A charcoal-filtered airstream was blown continuously over the antennae via a stainless steel tube during every EAG test. Test compounds were dissolved in hexane, applied onto the filter paper and placed in a Pasteur pipet after evaporation of the solvent. A filter paper had 25–50 ng of each

component. The Pasteur pipet connected to the stimulus air controller (model CS-05) (Syntech, the Netherlands) was used for stimulation. Signals were amplified with a (UN-06) amplifier (Syntech), and displayed on the computer with interface. EAG tests were carried out with three or four insects for each isomer or racemic mixture. EAG response to chemicals was compared with that of the hexane (control).

Field Experiments. Field trappings were carried out in apple orchards in Gunwi, Korea, for two years, in 1999 and 2000. Rubber septum (IPM Technology Inc.), as a pheromone dispenser, was impregnated with a racemic mixture, a pure optical isomer of pheromone components, or their binary or tertiary mixtures in HPLC-grade hexane. The trap was baited with a rubber septum containing the chemicals. Butylated hydroxytoluene as an antioxidant was added to the lure in an amount equal to that of the pheromone components. Wing traps (IPM Technology Inc.) were hung on trees 1.5 or 2 m apart from each other. Traps were set up randomly irrespective of replicates ($N = 3$–5). Pheromone components were tested for their male attractivity in single, binary, or tertiary combinations with the racemic mixtures, or with pure stereoisomers for the three components of 10me14me-1-ene-18Hy, 5me9me-18Hy, and 5me9me-17Hy, which were referred to as compounds A, B, and C, respectively.

Statistical Analysis. Data from the EAG tests and field experiments were statistically analyzed by analysis of variance (ANOVA) with the SAS program (SAS Institute Inc., Cary, North Carolina, USA, 1996). If treatment means were significantly different at the 5% level or lower, they were compared by the least significance difference (LSD) test.

RESULTS

Electroantennograms. Among the four stereoisomers of the major component (10me14me-1-ene-18Hy), only the 10*S*,14*S* isomer elicited a strong electrophysiological response from the *L. prunifoliella* male antennae (Figure 1a). Other stereoisomers (10*S*,14*R*, 10*R*,14*R*, 10*R*,14*S*) were EAG-inactive. In the case of the two minor components (5me9me-18Hy and 5me9me-17Hy), the 5*S*,9*S* isomers also elicited an electrophysiologically strong response (Figures 1b,c), with the other stereoisomers (5*S*,9*R*, 5*R*,9*R*, 5*R*,9*S*) being EAG-inactive.

In binary combination tests, the EAG response to the 10*S*,14*S* isomer of 10me14me-1-18Hy did not seem to be affected by addition of other stereoisomers (10*S*,14*R*, 10*R*,14*R*, 10*R*,14*S*) (Figure 2a). Again, the EAG response of the *L. prunifoliella* male antennae to binary mixtures of the 10*S*,14*S* isomer of the major component with the 5*S*,9*S* isomer of each minor component was no different from the response to the single 10*S*,14*S* isomer of the major component (Figure 2b). Females did not respond to any stereosiomers or racemic forms of the three pheromone components in the EAG test.

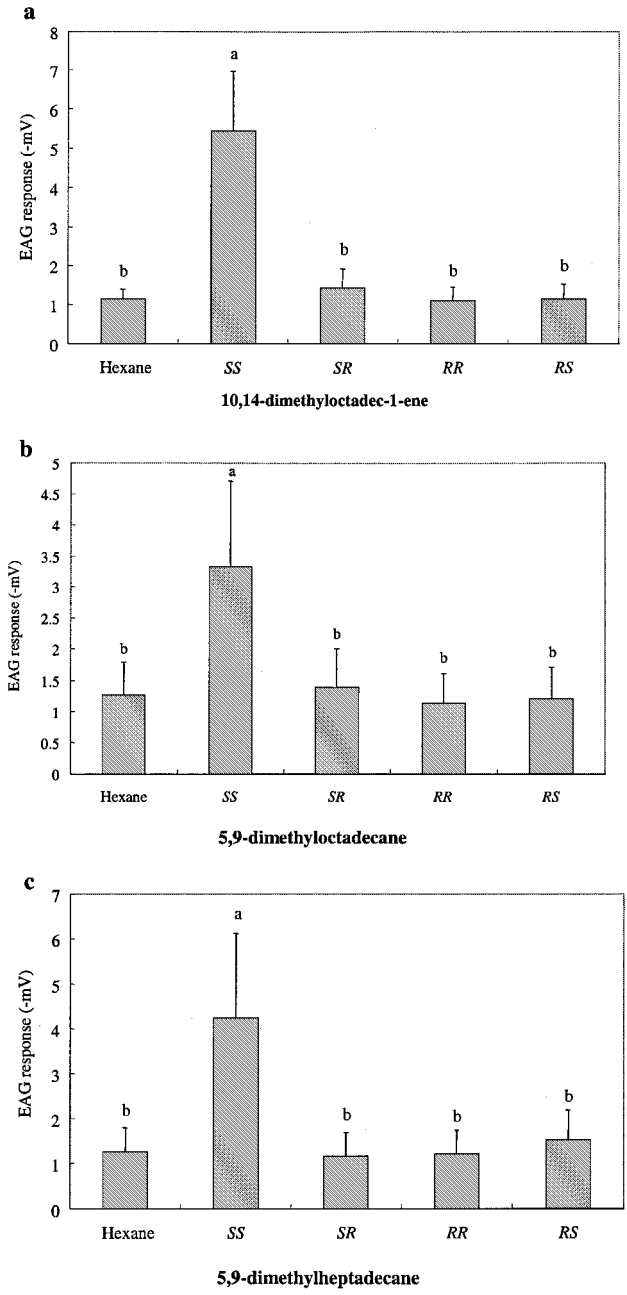

FIG. 1. The EAG response of *L. prunifoliella* male (virgin) antennae to four different stereoisomers of 10,14-dimethyloctadec-1-ene (a), 5,9-dimethyloctadecane (b), and 5,9-dimethylheptadecane (c) (50 ng each) ($N = 4$). Error bar indicates standard error.

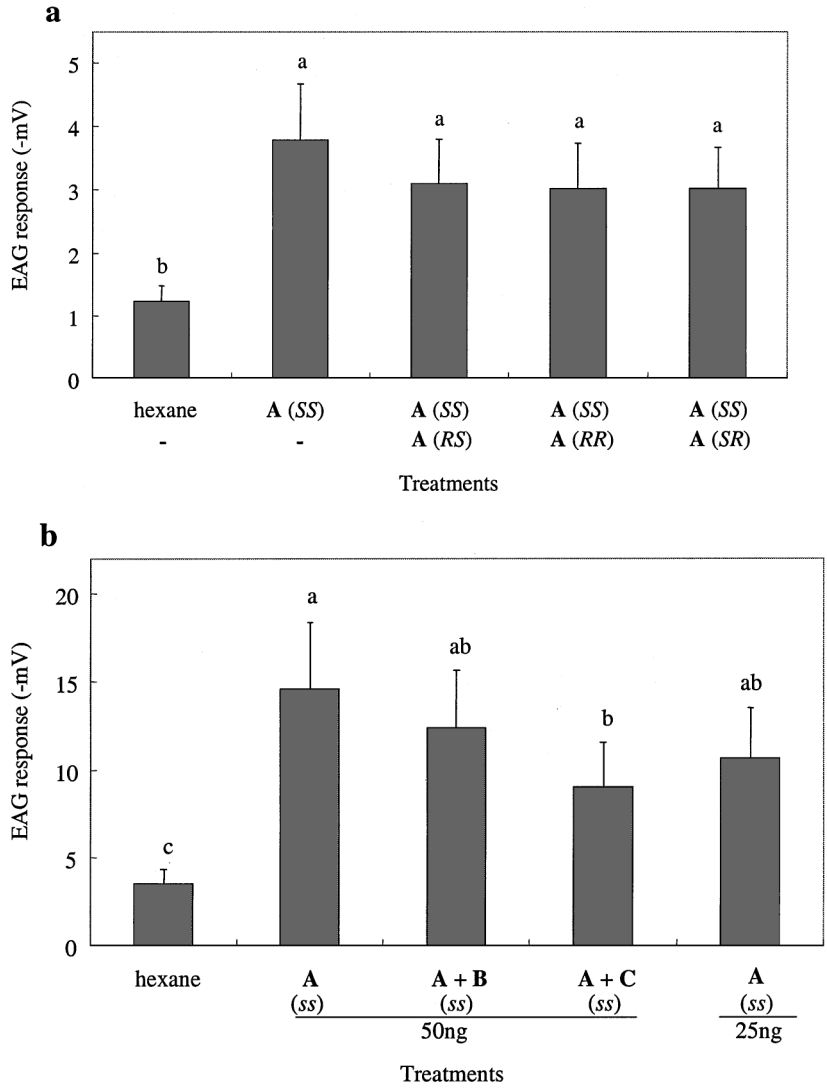

FIG. 2. The EAG response of *L. prunifoliella* male (virgin) antennae to binary mixtures of the 10*S*,14*S* isomer [A (*SS*)] of 10,14-dimethyloctadec-1-ene (A) with its other isomers [A (*RS*), A (*RR*), A (*SR*)] (50 ng each) (a), and to a single 10*S*,14*S* isomer [A (*SS*)] or its binary mixtures with each *SS* isomer of the other two minor components (b). (A: 10,14-dimethyloctadec-1-ene, B: 5,9-dimethyloctadecane, and C: 5,9-dimethylheptadecane) ($N = 4$). Error bar indicates standard error.

Field Experiments. By itself, the racemic form of the major component, 10me14me-1-ene-18Hy, attracted many *L. prunifoliella* males in the field (Figure 3a,b). Traps baited with its binary or tertiary combinations with 5me9me-18Hy and/or 5me9me-17Hy did not capture more males than those baited with the major component alone. A single treatment or a binary mixture of the racemic form of the two other minor components, 5me9me-18Hy and 5me9me-17Hy, did not attract *L. prunifoliella* males at all (Figure 3b).

Among the four stereoisomers of 10me14me-1-ene-18Hy, only the 10*S*,14*S* isomer attracted male *L. prunifoliella* (Figure 4). Catches in traps baited with 10*S*,14*R*, 10*R*,14*R*, or 10*R*,14*S* were not observed. In addition the 10*S*,14*S* isomer of 10me14me-1-ene-18Hy attracted many more *L. prunifoliella* males than an equal amount of its racemic mixture (Figure 4).

In tests with tertiary combinations of the 10*S*,14*S* isomer of 10me14me-1-ene-18Hy with eight stereoisomers and racemic forms of the two other minor components, only the 5*S*,9*S* isomer of 5me9me-18Hy slightly increased the number of males caught (Figures 5a,b).

DISCUSSION

This study demonstrates through EAG tests and field trapping experiments that among the three components reported to be sex pheromones for the North American population (Gries et al., 1997) of *L. prunifoliella*, the major component 10me14me-1-ene-18Hy alone is essential in attracting *L. prunifoliella* males in Korea. Among the four stereoisomers of the major component, the 10*S*,14*S* isomer alone showed activity in attracting *L. prunifoliella* males in the field, and no electrophysiological or field attractiveness of other stereoisomers was observed. This result is similar to that of *Leucoptera scitella* (Tóth et al., 1989) and *Lambdina fiscellaria* (Li et al., 1993), which have only one stereoisomer as the active pheromone component. In other species, more than one stereoisomer often affects attraction. For example, for *L. clerkella* using 14-methyl-1-octadecene as pheromone, the *S* isomer is the major component of the sex pheromone, and the addition of the *R* isomer to the *S* isomer had a synergistic effect (Sato et al., 1986). *Nepytia freemani* uses (3*S*,13*R*)-3,13-dimethylheptadecane as the major pheromone component, and the addition of any other isomer to the active *SR* isomer also increased attractiveness of the single 10*S*,13*R* isomer (King et al., 1995).

In the Korean population of *L. prunifoliella*, GC-EAD analysis confirmed that 10me14me-1-ene-18Hy was the major component (unpublished data), but the other two components could not be identified. In field tests, components attracting male moths in the Korean population seemed to be different from those in the American population. For the American population, *L. prunifoliella* males were attracted best to the tertiary mixture of the three components,

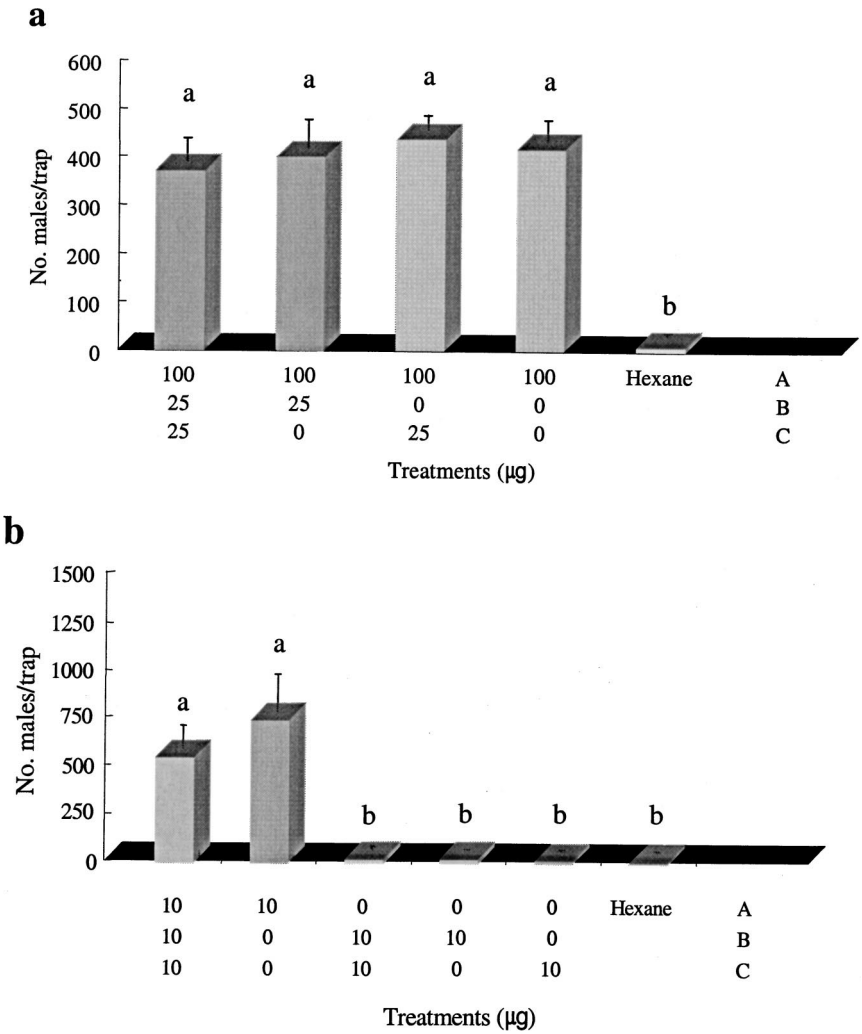

FIG. 3. The mean number of *L. prunifoliella* males caught in traps baited with a racemic mixture of 10,14-dimethyloctadec-1-ene (A), or its binary or tertiary mixture with the racemic form of the other two minor components in Gunwi (June 21–August 2, 1999) (a), and single or various mixtures of the racemic form of the three components in Gunwi (August 18–September 7, 1999) (b). (A: 10,14-dimethyloctadec-1-ene, B: 5,9-dimethyloctadecane, C: 5,9-dimethylheptadecane) ($N = 5$). Error bar indicates standard error.

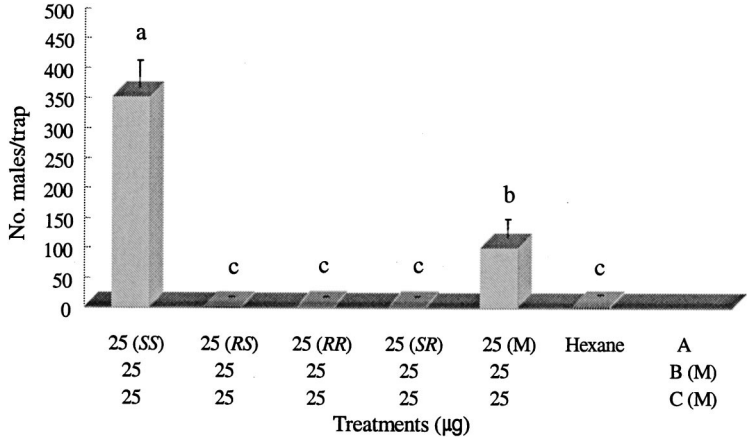

FIG. 4. The mean number of *L. prunifoliella* males caught in traps baited with tertiary mixtures of each stereoisomer or the racemic form (M) of 10,14-dimethyloctadec-1-ene (A) with the racemic form of the other two minor components 5,9-dimethyloctadecane (B) and 5,9-dimethylheptadecane (C), in Gunwi (June 2–21, 1999). ($N = 5$). Error bar indicates standard error.

10me14me-1-ene-18Hy, 5me9me-18Hy, and 5me9me-17Hy (Gries et al., 1997). Binary mixtures were also better than the major component alone. In contrast, in Korea, the major component, 10me14me-1-ene-18Hy, as a single component attracted *L. prunifoliella* males (Figures 3a,b). Binary or tertiary combinations with the other two components did not increase captures, even though *L. prunifoliella* males could electrophysiologically sense each *SS* isomer of the two minor components. Trap catches were slightly enhanced with the 5S,9S isomer of 5me9me-18Hy in tertiary combination with the other two components (Figure 5a). Racemic minor components did not affect attraction in any combination with the 10me14me-1-ene-18Hy (Figures 3a,b). The two minor components, especially the 5*S*,9*S* isomers, may have some other effect on mating, because the male moth could sense them. More research is needed to determine their function.

The reason for the difference between the American and Korean populations is not clear yet. One possibility is a difference among the leafminer species, perhaps at a subspecies level. The leafminer in Japan was reported to be *L. prunifoliella malinella* (Matsumura) (Yamada et al., 1970; Sekita and Yamada, 1979), different from those in America. Because Korea is close to Japan, the leafminer in Korea may be the same as that in Japan. However, the Korean leafminer has not yet been examined at the subspecies level. Such geographic variations in sex pheromone composition exist with many other insects and also with moths in Korea (Sugie et al., 1991; Cork et al., 1992). As an example, the optimum ratio for attracting

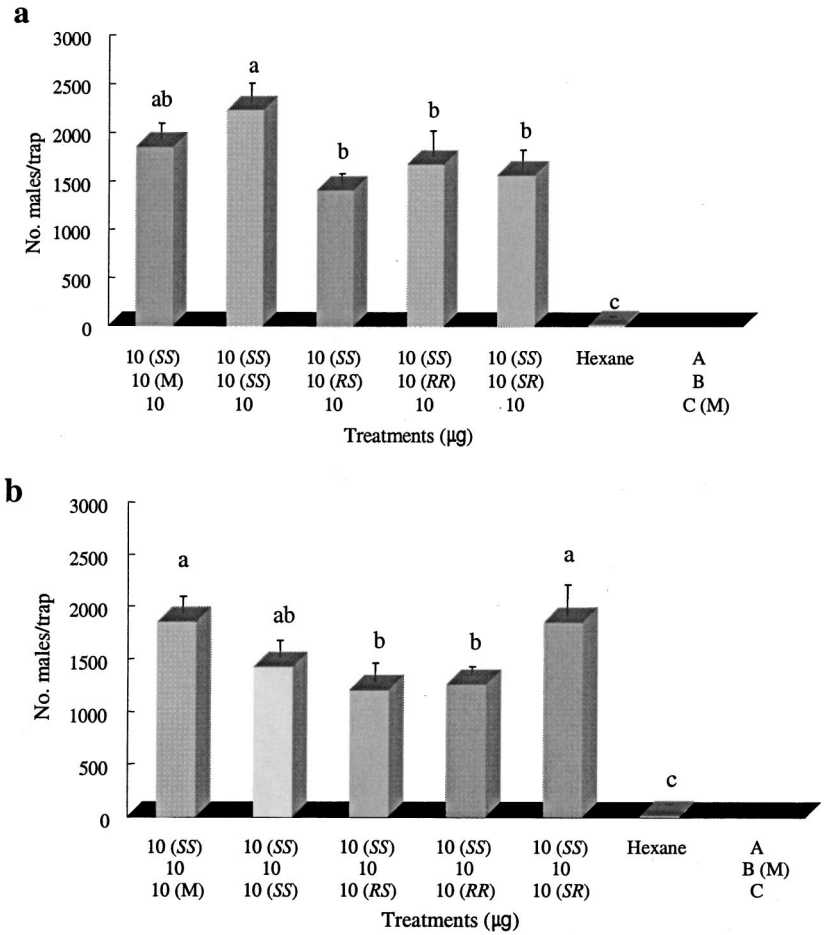

FIG. 5. The mean number of *L. prunifoliella* males caught in traps baited with tertiary mixtures of the 10*S*, 14*S* isomer of 10,14-dimethyloctadec-1-ene [A(*SS*)] with pure isomers or the racemic form of 5,9-dimethyloctadecane (B) and the racemic form of 5,9-dimethylheptadecane (C) (a), and with the racemic form of 5,9-dimethyloctadecane (B) and pure isomers or the racemic form of 5,9-dimethylheptadecane (C) (b) in Gunwi (August 18–September 7, 1999). ($N = 5$). Error bar indicates standard error.

Phyllonorycter ringoniella males in Korea [4:6 ratio of (*Z*)-10-tetradecenyl acetate and (*E*,*Z*)-4,10-tetradecadienyl acetate] was different from those reported in Japan (10:3) or China (7:3 to 6:4) (Boo, 1998). This trend of different pheromone compositions was more apparent among insect species with low mobility, at least in Korean cases (unpublished data).

Because the leafminer population is currently increasing in Korea, monitoring it in apple orchards is becoming important for its management. Since the two minor components, 5me9me-18Hy and 5me9me-17Hy, have no practical effect on field attraction of *L. prunifoliella* males, the major component, 10me14me-1-ene-18Hy, could be used by itself to monitor them in Korea. Moreover, the attractivity of the racemic mixture of the major component is sufficient when compared with that of two virgin females in the field (unpublished data). It would be more reasonable to use the racemic mixture because the synthesis of the pure isomer of 10*S*,14*S*-10me14me-1-ene-18Hy will be more expensive and time-consuming, and because other stereoisomers (10*S*,14*R*, 10*R*,14*R*, 10*R*,14*S*) in combination with the 10*S*,14*S* isomer do not have any negative or positive effect on male trapping.

Acknowledgments—This work was partly supported by the Brain Korea21 Project and a Korean Agricultural R & D Promotion Center project. We thank Prof. G. Gries of Simon Fraser University, Canada, for the generous gift of racemic mixtures of three pheromone components, and two anonymous reviewers for their valuable suggestions and comments in improving the original manuscript.

(Received January 15, 2002; accepted August 7, 2002)

Abstract—Using gas chromatography with flame ionization detection (FID) and electroantennographic detection (EAD) in parallel, butanoic acid, skatole, and (*E*)-2,6-dimethyl-6-octen-2-ol were identified as constituents of the abdominal sex-attracting secretion of the male dung beetle, *Kheper subaeneus*, which reproducibly elicited EAD responses in male and female antennae. This is the first report of the occurrence of (*E*)-2,6-dimethyl-6-octen-2-ol as a natural product, for which the name (*E*)-subaeneol is proposed. In some experiments, a few other constituents of the secretion also gave reproducible responses in specific male and female antennae but did not elicit responses when the analyses were repeated with other antennae. The major volatile constituent of the secretion, identified as (*S*)-(+)-2,6-dimethyl-5-heptenoic acid, is one of these EAD-active compounds. Both this compound and (*E*)-2,6-dimethyl-6-octen-2-ol were synthesized from authentic starting materials for comparison with the natural products.

Key Words—Scarabaeinae, *Kheper subaeneus*, dung beetle, sex attractant, insect semiochemicals, electroantennography, terpenes, semiochemical synthesis.

INTRODUCTION

Male ball-rolling dung beetles of the genus *Kheper* produce a white, flocculant proteinaceous carrier material containing minute amounts of complex mixtures of volatile organic compounds acting as sex attractants for females. The secretion is extruded from several hundred tiny openings in a depression on either side of the

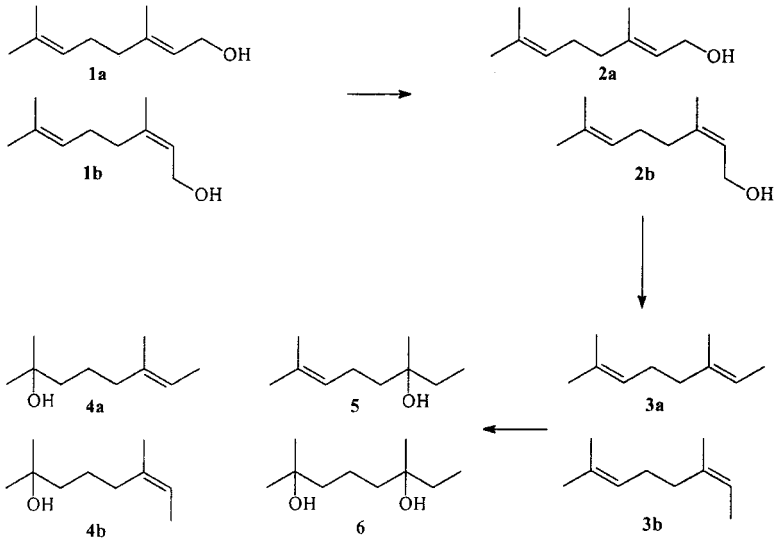
first abdominal sternite. It is then broken up into fine particles and released into the air by brushes on the tibia of the male. The ecological importance of dung beetles in general and biological aspects of the production and function of the abdominal sex attractant secreted by male *Kheper* dung beetles has been discussed in previous communications on this subject (Burger et al., 1983, 1990, 1995; Burger and Petersen, 1991, 2002). Hexadecanoic acid, 2,6-dimethyl-5-heptenoic acid, (*E*)-nerolidol, and skatole, were previously identified as the major volatile organic constituents of the abdominal secretion of *K. lamarcki.* (Burger et al., 1983). The abdominal secretion of *K. nigroaeneus* contains the EAD-active constituents (*R*)-3-methylheptanoic acid and skatole. A third EAD-active constituent of this secretion was not identified, as it is present in such a low concentration that it could barely be detected by gas chromatography (GC) using flame ionization detection (FID) (Burger and Petersen, 2002). A third *Kheper* species, *K. subaeneus*, occurs in parts of the Hluhluwe Game Reserve, about 50 km from the Mkuzi Game Reserve (both in South Africa) where *K. nigroaeneus* and *K. lamarcki* are found. In this communication, we report the identification of the EAD-active constituents of the abdominal sex-attracting secretion of male *K. subaeneus.*

METHODS AND MATERIALS

Collection of Material. We initially attempted to catch *K. subaeneus* dung beetles in pitfall traps baited with rhinoceros or horse dung in Hluhluwe Game Reserve, a method that was used effectively to catch *K. nigroaeneus* in Mkuzi Game Reserve. Probably due to the availability of large quantities of rhinoceros dung in the parts of the game reserve where these beetles are found, this method proved ineffective in catching *K. subaeneus* in Hluhluwe. *K. subaeneus* were, therefore, collected annually during the first week of November from 1988 to 1995 from rhinoceros dung middens along dirt roads near the main entrance gate of Hluhluwe Game Reserve. The dung beetles were transported to Stellenbosch, South Africa, and were kept in greenhouses. The secretion was collected as described in the previous paper in this series on semiochemicals of the Scarabaeinae (Burger and Petersen, 2002).



Analytical Methods. Gas chromatographic determinations were carried out with a Carlo Erba 4160 gas chromatograph with parallel flame ionization and electroantennographic detection (FID/EAD). The instrument was equipped with a 40-m $\times$ 0.3-mm glass capillary column coated with OV-1701-OH at a film thickness of 0.375 μm. Helium was used as carrier gas at a linear velocity of 28.5 cm/sec at 40°C, and a temperature program of 2°C/min from 40°C to 250°C (hold) was employed. Chiral gas chromatographic analyses were done on a glass column (25 m $\times$ 0.3 mm) coated with 10% heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV-1701-OH at a film thickness of 0.25 μm, using H_2 as carrier gas at a linear velocity of 50 cm/sec. The column was programmed at 2°C/min from 40°C to

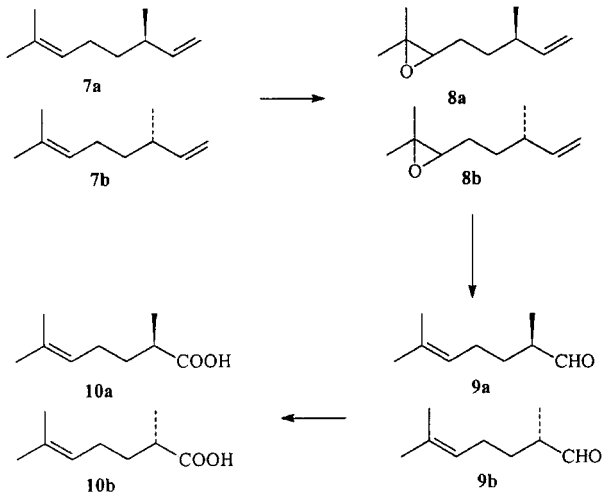
190°C (hold). The instrumentation for GC analysis of dung beetle secretions with FID and EAD recording in parallel using dung beetle antennae as sensing elements has been described by Burger and Petersen (1991). In short, an antenna was inserted lengthwise into the air duct, as this arrangement produced a less noisy baseline than positioning the antenna sideways in the airstream, a position in which the club of the antenna is subjected to the effect of the turbulent mixing of the effluent and ambient air. The antenna was protected against heat radiation from the gas chromatograph by a heat shield cooled with water at 18°C. Electrical responses in the antenna were recorded via Ag–AgCl electrodes placed in pipets filled with saline solution containing NaCl (7.5 g/liter), $CaCl_2$ (0.21 g/liter), KCl (0.35 g/liter), and $NaHCO_3$ (0.2 g/liter), as well as polyvinylpyrrolidone K90 (Fluka, 49 g/liter) to increase its viscosity (Van der Pers, 1980). Antennal responses were amplified with a Murphy Developments AMS-025 amplifier and were recorded on an Omniscribe recorder. Over a period of about 5 years, EAD/FID analyses were done with at least 80 male and as many female insects. Only one antenna of each dung beetle was used so that the beetle could still be used for the collection of secretion.

Mass spectra were recorded on a Carlo Erba QMD 1000 quadrupole mass spectrometer using the column and gas chromatographic conditions specified above. ^{1}H and ^{13}C NMR spectra of synthetic compounds and intermediates were recorded at 299.905 and 75.42 MHz, respectively, at 25°C on a Varian VXR 300 NMR spectrometer.

Reference Compounds. Commercially available reference compounds and starting compounds for the synthesis of other reference compounds were purchased from Merck (Darmstadt, Germany), Fluka (Buchs, Switzerland), or Sigma-Aldrich (Cape Town, South Africa).

(*E*)-2,6-Dimethyl-6-octen-2-ol (**4a**) was prepared from geraniol (3,7-dimethyl-2,6-octadien-1-ol) (**1a**) according to Scheme 1. Tetrachloromethane (69.3 g; 450 mmol) was added during 90 min to a stirred and chilled (0°C) solution of geraniol (**1a**) (61.6 g; 400 mmol) and triphenylphosphine (115.3 g; 440 mmol) in dry acetonitrile (350 ml). The temperature of the reaction mixture was allowed to rise gradually to 22°C at which temperature it was stirred for a further 19 hr. Pentane (300 ml) was added to the reaction mixture, which was stirred at room temperature for 15 min and left overnight at −15°C to allow precipitation of triphenylphosphine oxide. The precipitate was removed by filtration of the cold suspension. Pentane and acetonitrile were removed on a rotary evaporator, the remaining material diluted with pentane, the solution cooled to −15°C, and the precipitate filtered off. This procedure was repeated until no further triphenylphosphine oxide precipitated. Removal of the solvent and repeated fractionation gave a colorless oil (27.4 g; 39.7%), bp 106–107°C/22 mm Hg, containing (*E*)-8-chloro-2,6-dimethyl-2,6-octadiene (**2a**) in 97.6% purity (GC-MS). MS: m/z (%) = 159(0.3), 157(1), 136(10), 129(4), 121(9), 105(5), 93(57), 91(26), 79(25), 77(23), 69(100), 68(23), 67(23), 53(14), 41(53), 39(30). ^{13}C NMR ($CDCl_3$): $\delta = 41.17$ (t, C-1);

SCHEME 1.



120.31 (d, C-2); 142.78 (s, C-3); 39.47 (t, C-4); 26.25 (t, C-5); 123.61 (d, C-6); 131.99 (s, C-7); 25.68 (q, C-8); 16.12 (q, CH_3C-3); 17.71 (q, CH_3C-7).

(*E*)-8-Chloro-2,6-dimethyl-2,6-octadiene (**2a**) (27.4 g; 159 mmol) was slowly added to a stirred solution of lithium aluminum hydride in tetrahydrofuran (THF) (380 ml; 0.02 g/ml; 200 mmol). The reaction mixture was refluxed for 4 hr, allowed to cool to room temperature, and diluted with pentane (150 ml). The precipitated inorganic material was filtered off. Conventional work-up procedures and distillation of the product gave a colorless oil (16.9 g; 77.2%); bp 77°C/ 40 mm Hg, containing 98.0% (GC-MS) of (*E*)-2,6-dimethyl-2,6-octadiene (**3a**); MS: m/z (%) = 138(3), 123(15), 109(1), 107(2), 95(38), 81(3), 79(3), 77(2), 69(100), 67(11), 55(5), 53(7), 41(53), 39(8). ^{13}C NMR ($CDCl_3$): δ = 26.38 (q, C-1); 131.98 (s, C-2); 125.11 (d, C-3); 27.45 (t, C-4); 40.42 (t, C-5); 136.49 (s, C-6); 118.93 (d, C-7); 14.02 (q, C-8); 18.34 (q, CH_3C-2); 16.34 (q, CH_3C-6).

Solid mercury(II) acetate (3.2 g; 10 mmol) was added in one batch to a stirred solution of the diene (**3a**) (1.38 g; 10 mmol) in THF (40 ml) and water (10 ml) at 22°C to produce a yellow reaction mixture (Brown et al., 1972). The reaction mixture became colorless after 6 min, and it was stirred for a further 2 hr. A solution of sodium hydroxide (1.2 g NaOH in 10 ml H_2O) was added in one batch to the reaction mixture, followed immediately by the rapid addition of a solution of sodium borohydride and sodium hydroxide (0.19 g $NaBH_4$ and 1.2 g NaOH in 10 ml H_2O). The temperature of the reaction mixture rose to 38°C, and mercury started to precipitate. The reaction mixture was stirred for 30 min,

after which the supernatant solution was decanted from the mercury and saturated with K_2CO_3, resulting in the separation of the THF layer containing the organic material from the saturated K_2CO_3 solution. Careful concentration of the THF phase on a rotary evaporator gave a mixture of the organic products (1.41 g) containing the starting material (**3a**), an unidentified product that could possibly be a cyclic ether formed from the starting material (Brown et al., 1972), the two terpenols (**4a**) and (**5**), and 2,6-dimethylocta-2,6-diol (**6**) in a ratio of 24:33:29:3:11. This procedure was repeated several times and the products (10.4 g) combined for column chromatographic fractionation on silica gel (450 g, Merck 60, 230–400 mesh). Elution with 10% ether in hexane gave a fraction (1.16 g) containing the desired terpenol (**4a**) and the terpenol (**5**) in a ratio of 97:3 (GC-MS). This fraction was subjected to bulb-to-bulb distillation (135°C/25 mm Hg) for spectrometric characterization. The major constituent was 2,6-dimethyl-6-octen-2-ol (**4a**); m/z (%) = (138)7, 123(20), 109(3), 95(6), 83(19), 82(100), 69(23), 67(80), 59(57), 55(23), 43(30), 41(3). ^{13}C NMR ($CDCl_3$): $\delta = 29.87$ (q, C-1); 71.67 (s, C-2); 44.17 (t, C-3); 23.31 (t, C-4); 40.67 (t, C-5); 136.31 (s, C-6); 119.15 (d, C-7); 13.95 (q, C-8); 29.87 (q, CH_3C-2); 16.14 (q, CH_3C-6). The minor constituent was 3,7-dimethyl-6-octen-3-ol (**5**); m/z (%) = 156(2), 141(17), 138(9), 127(8), 123(40), 113(13), 109(18), 95(13), 85(19), 81(18), 71(100), 69(25), 67(23), 58(19), 55(30), 53(12), 43(68), 41(45), 39(20).

(*R*)-(−)-2,6-Dimethyl-5-heptenoic acid (**10a**), was prepared from (*R*)-(−)-3,7-dimethyl-1,6-octadiene [(−)-β-citronellene] (**7a**) according to Scheme 2. A solution of 3-chloroperbenzoic acid (containing 6% 3-chlorobenzoic acid) (8.23 g;

SCHEME 2.

44.85 mmol) in chloroform (100 ml) was added over 1.25 hr to (*R*)-(−)-3,7-dimethyl-1,6-octadiene (**7a**) in chloroform (40 ml) at such a rate that the temperature of the reaction mixture did not exceed −10°C. The progress of the partial epoxidation of the β-citronellene was monitored by GC analysis and was completed after stirring the reaction mixture an additional 2 hr at −10°C. The 3-chlorobenzoic acid was filtered off, and the temperature of the filtrate allowed to rise to room temperature. The filtrate was washed with NaOH solution (0.45 M, 40 ml), Na_2CO_3 solution (5%), saturated brine and dried. Removal of the solvent under reduced pressure gave a colorless oil (6.87 g; 99.3%) containing 95.9% (GC-MS) of (R)-(−)-6,7-epoxy-3,7-dimethyl-1-octene (**8a**). MS: m/z (%) = 139(4), 125(2), 121(3), 111(6), 95(14), 85(13), 82(16), 81(100), 79(18), 71(30), 69(39), 68(50), 67(60), 59(64), 55(53), 54(40), 53(20), 43(44), 41(64), 39(37).

Ozone was passed through a solution of the epoxide (**8a**) (6.22 g, 40.32 mmol) in dry dichloromethane (350 ml) at −70°C until, after about 35 min, the reaction mixture developed a light purple color. The excess of ozone and oxygen was removed as quickly as possible by passing nitrogen through the reaction mixture for 40 min. This solution was carefully concentrated to 40 ml, cooled to 0°C, and added to a cold suspension of zinc (15.0 g; 229.4 mmol) in acetic acid (39 ml) containing sodium acetate (3.41 g; 41.52 mmol) and sodium iodide (10.72 g; 68.64 mmol) (Knöll and Tamm, 1975). The bulk of the dichloromethane was removed under reduced pressure, and the resulting solution was stirred for 2 hr at room temperature. The zinc was filtered off, and the solution of the reaction products in acetic acid was extracted repeatedly with dichloromethane. The combined extracts were washed with saturated brine and water, dried, and the solvent removed to yield a liquid product (5.52 g; 97.7%) containing 71.5% (GC-MS) of the target product, (*R*)-(−)-2,6-dimethyl-5-heptenal (**9a**). MS: m/z (%) = 140(3), 107(2), 97(1), 93(1), 91(2), 83(12), 82(100), 81(7), 70(5), 69(24), 67(46), 57(5), 56(16), 55(21), 53(10), 43(8), 42(7), 41(51), 39(16).

(*R*)-(−)-2,6-Dimethyl-5-heptenal (**9a**) was oxidized to the corresponding acid with chromic acid. Chromic acid solution (24 ml, containing 4.79 g of CrO_3 in 3 M H_2SO_4) was slowly added to a stirred solution of (*R*)-(−)-2,6-dimethyl-5-heptenal (**9a**) (3.85 g; 27.46 mmol) in acetone (40 ml). The color of the reaction mixture changed from orange to a dirty green, and a precipitate of inorganic salts was formed. The acetone solution of the organic products was decanted from the inorganic material, the acetone evaporated under reduced pressure, and the residual material dissolved in dichloromethane. The inorganic precipitate was dissolved in water (100 ml) and repeatedly extracted with dichloromethane. All of the dichloromethane extracts were combined and extracted with NaOH solution (3 M; 30 ml). This basic solution was extracted five times with dichloromethane to remove all of the unsaponified material, after which it was acidified with dilute sulfuric acid (3 M; 5.5 ml) and the organic acid extracted with dichloromethane. Conventional work-up methods and distillation

gave the target compound, (*R*)-(−)-2,6-dimethyl-5-heptenoic acid (**10a**) (2.07 g) in a yield of 48.3%, bp 112–114/5 mm Hg, $[\alpha]_D^{25} = -18.27^\circ$(neat), 95.7% ee (GC). MS: m/z (%) = 156(9), 138(13), 110(4), 95(7), 83(88), 82(49), 74(58), 69(46), 67(38), 55(48), 53(12), 41(100), 39(30). ^{13}C NMR ($CDCl_3$): δ = 183.04 (s, C-1); 38.84 (d, C-2); 33.56 (t, C-3); 25.62 (t, C-4); 123.48 (d, C-5); 132.42 (s, C-6); 25.68 (q, C-7); 16.86 (q, CH_3C-2); 17.65 (q, CH_3C-6).

(*S*)-(+)-2,6-Dimethyl-5-heptenoic acid (**10b**) was prepared from (+)-β-citronellene (**7b**) according to Scheme 2 and the procedures described for its *R* enantiomer. (*S*)-(+)-6,7-Epoxy-3,7-dimethyl-1-octene (**8b**) was obtained as a colorless oil (6.73 g; 97.3%) in a purity of 96.8% and converted to (*S*)-(+)-2,6-dimethyl-5-heptenal (**9b**), which was used without purification for the preparation of (*S*)-(+)-2,6-dimethyl-5-heptenoic acid (**10b**) (2.12 g; 48.1%). bp 117–118/5 mm Hg; $[\alpha]_D^{25} = +24.6^\circ$(neat), 96.3% ee (GC). MS: m/z (%) = 156(10), 138(14), 110(4), 95(7), 83(97), 82(52), 74(65), 69(48), 67(43), 55(50), 53(11), 41(100), 39(28). ^{13}C NMR ($CDCl_3$): δ = 183.02 (s, C-1); 38.82 (d, C-2); 33.55 (t, C-3); 25.61 (t, C-4); 123.45 (d, C-5); 132.44 (s, C-6); 25.68 (q, C-7); 16.86 (q, CH_3C-2); 17.65 (q, CH_3C-6).

RESULTS AND DISCUSSION

In their natural habitat, male *K. subaeneus* can often be observed exhibiting the typical secretion-producing behavior, which can be summarized as follows. Oriented with the head upwind and the front two pairs of legs on the dung surface, the male raises his hind legs and lowers his head into the dung. The legs are retracted simultaneously inwards towards the sides of the body and are then simultaneously extended. This movement results in the tibial brushes brushing the controlled-release proteinaceous material (Burger et al., 1990), extruded from the abdomen as fine fibers and containing the sex attractant, against the rows of curved abdominal bristles. This causes puffs of attractant to rise into the air from both sides of the insect. After a short time of approximately 20–30 sec, the retraction and extension of the hind legs are repeated. This procedure is kept up until a female arrives or the male is disturbed by other insects in or on the dung (Burger et al., 1983). Although their population density was rather low in Hluhluwe Game Reserve during the late 1980s, five or more males were often found calling on one large rhinoceros dung midden. In contrast, calling behavior has not been observed with the same frequency in *K. lamarcki* in Mkuzi Game Reserve. In captivity, however, this situation was reversed, and the secretion of male *K. subaeneus* was collected only in small quantities on only a few occasions. A total of only a few milligrams were collected over a period of 5 years from about 700 males. A gas chromatogram of the volatile organic fraction of the abdominal secretion of *K. subaeneus* is shown in Figure 1. The general appearance of this gas chromatogram is similar to that of

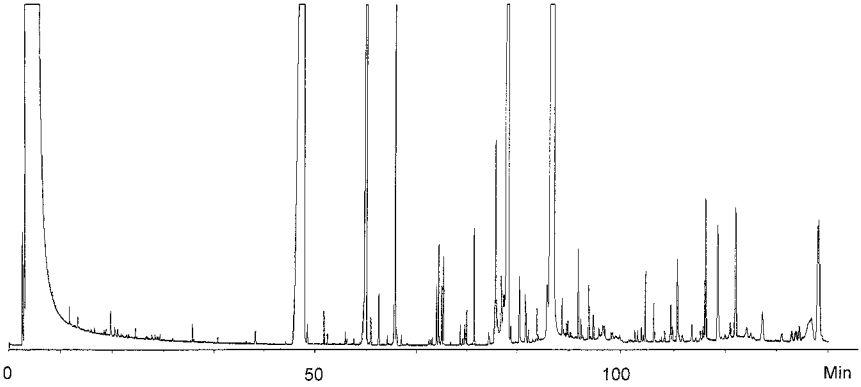


FIG. 1. Total ion chromatogram (GC-MS) of an extract of the male abdominal secretion of the dung beetle *Kheper subaeneus*. Gas chromatographic conditions are given in the text.

K. nigraeneus (Burger and Petersen, 2002) in that both secretions contain mostly heavy constituents. However, only a relatively small percentage of the compounds present are common to both secretions.

A typical GC analysis with FID and EAD recording in parallel using a female antenna as sensing element is shown in Figure 2. The constituent eluting at a retention time of 4.98 min was identified as butanoic acid (*n*-butyric acid) from its mass spectrum and coelution with the synthetic compound. Although the EAD response is weak, it was present in all EAD chromatograms. The constituent eluting at 28.27 min was identified as 3-methylindole (skatole) and is also present in the abdominal secretions of *K. lamarcki* (Burger et al., 1983) and *K. nigroaeneus* (Burger and Petersen, 2002). Although barely detectable by FID, the constituent eluting at 17.75 min gave a strong and reproducible EAD response. This constituent elutes with a shorter retention time than the EAD-active constituent that remained unidentified in the male abdominal secretion of *Kheper nigroaeneus* (Burger and Petersen, 2002). Male antennae produced similar EAD/FID analyses.

After the gas chromatographic analyses had been completed, only about ten times the quantity used for the analysis shown in Figure 2 was available for further analytical work. All of this material, collected during the previous five summer seasons, was used in a final attempt at obtaining some mass spectral information on the structure of the constituent eluting at 17.75 min. Using a very high electron multiplier setting, the mass spectrum shown in Figure 3 was obtained. The spectrum contains several ions typically found in the spectra of the monoterpenes. This and the presence of compounds with terpenoid character in the abdominal secretions of other *Kheper* species prompted us to compare the retention time and mass spectrum of the unknown compound with those of selected model terpenoid compounds. It became clear that the unknown compound was not a cyclic

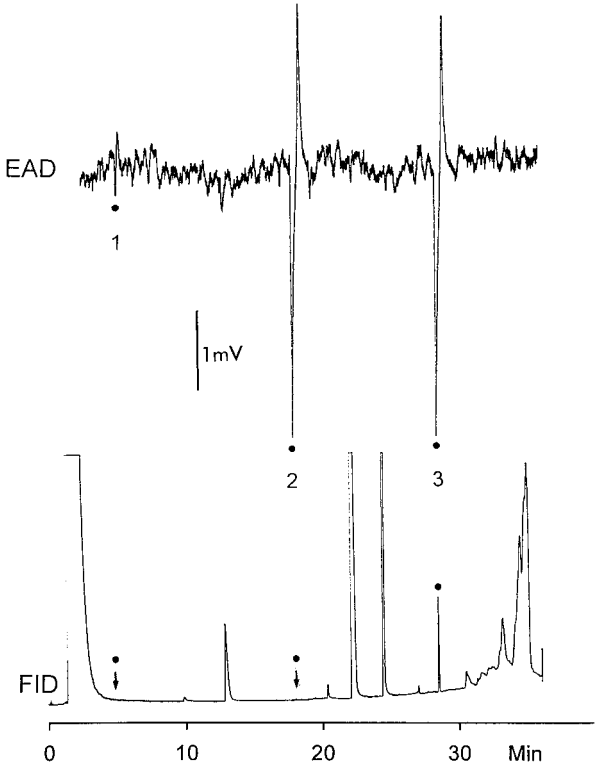

FIG. 2. First part of a gas chromatographic analysis of an extract of the male abdominal secretion of *Kheper subaeneus* with EAD and FID recording in parallel using a female antenna as sensing element. Chart speed was 0.5 cm/min. Gas chromatographic conditions are given in the text. The poor separation of later eluting peaks is due to overloading of the column. Assignment of EAD-active constituents: 1 = butanoic acid; 2 = (*E*)-2,6-dimethyl-6-octen-2-ol; 3 = skatole.

or acyclic monoterpene or a primary monoterpene alcohol and that it could probably be a tertiary monoterpene alcohol, albeit not one of the tertiary terpenoid alcohols that we had available for comparison. Partial hydroxylation of (*E*)- and (*Z*)-3,7-dimethyl-1,6-octadiene with mercury(II) acetate gave a mixture of alcohols containing, among others, 2,6-dimethyl-7-octen-2-ol, which had a retention time similar to that of the EAD-active constituent of the secretion but a slightly different mass spectrum. It was, therefore, concluded that the unknown constituent could possibly be a similar tertiary alcohol but with its double bond in a different position. Conversion of a mixture of geraniol (**1a**) and nerol (**1b**) [(*E*)- and (*Z*)-3,7-dimethyl-2,6-octadien-1-ol, respectively], via the corresponding chlorides (**2a**)

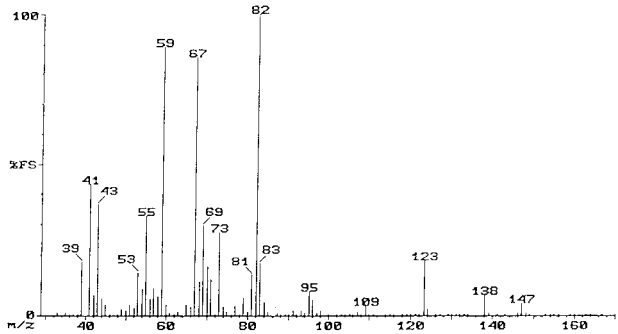

FIG. 3. Mass spectrum of the EAD-active constituent [(*E*)-2,6-dimethyl-6-octen-2-ol] of the male abdominal secretion of *Kheper subaeneus* eluting at 17.75 min in the gas chromatogram shown in Figure 2.

and (**2b**), to (*E*)- and (*Z*)-2,6-dimethyl-2,6-octadiene, (**3a**) and (**3b**), respectively (Scheme 1), and subjecting this mixture to partial hydroxylation, gave a mixture containing the two unchanged terpenes (**3a** and **3b**), the two terpenols (**4a** and **4b**), the terpenol (**5**), and the terpenediol (**6**). One of the terpenols was EAD-active and had the retention time and mass spectrum of the unknown compound. From the relative retention times of the three terpenols, it was concluded that the EAD-active one could possibly be (*E*)-2,6-dimethyl-6-octen-2-ol (**4a**).

The configuration of the double bond in the EAD-active compound was confirmed by repeating the synthesis with geraniol according to Scheme 1. Geraniol [(*E*)-3,7-dimethyl-2,6-dien-1-ol] (**1a**) was, thus, converted to (*E*)-8-chloro-2,6-dimethyl-2,6-octadiene (**2a**). Reduction of this chloride with lithium aluminum hydride gave the diene (**3a**). Partial hydroxylation of the diene (**3a**) by mercuration-demercuration according to Brown and Geoghegan, (1967) i.e., by the addition of the diene to a quantity of mercury(II) acetate equivalent to the hydroxylation of one of the double bonds, gave a mixture of the unchanged diene (**2a**), the target compound, (*E*)-2,6-dimethyl-6-octen-2-ol (**4a**)**,** 3,7-dimethyl-6-octen-3-ol (**5**), and 2,6-dimethyloctane-2,6-diol (**6**) in which the diols **4a** and **5** were present in an approximate ratio of 1:1. Although the two trisubstituted double bonds in the diene **3a** are so similar that totally regioselective hydroxylation was not expected to be feasible, reverse addition, i.e., addition of the mercury(II) acetate to the diene according to Brown et al. (1972), gave the terpenols **4a** and **5** in a ratio of 91:9. A fraction containing the desired terpenol, **4a**, and the terpenol **5** in a ratio of 97:3 was isolated from the crude product by column chromatography. As far as could be ascertained, (*E*)-2,6-dimethyl-6-octen-2-ol (**4a**) is a new natural product for which the name (*E*)-subaeneol is proposed.

In addition to butanoic acid, (*E*)-2,6-dimethyl-6-octen-2-ol, and skatole, which reproducibly elicited EAD responses in male and female antennae of *K.*

subaeneus, some other constituents of the abdominal secretion in a few instances also gave EAD responses. Because of the nonreproducibility of the EAD results, the minor EAD-active constituents of the secretion could not be identified. However, the major volatile constituent of the secretion, eluting at 47.2 and 22.1 min in the gas chromatograms shown in Figures 1 and 2, respectively, also gave an EAD response in about 5–10% of the analyses. This compound was identified as the chiral 2,6-dimethyl-5-heptenoic acid, which had previously been identified in *K. lamarcki* (Burger et al., 1983). (*R*)-(−)-2,6-Dimethyl-5-heptenoic acid (**9a**) was synthesized from commercially available (*R*)-(−)-3,7-dimethyl-1,6-octadiene [(−)-β-citronelene] (**7a**) by epoxidation of the trisubstituted double bond to give the unsaturated epoxide (**8a**), ozonolysis of the double bond in this compound, and simultaneous deprotection of the double bond (Knöll and Tamm, 1975) giving the unsaturated aldehyde (**9a**) and oxidation of the aldehyde to (*R*)-(−)-2,6-dimethyl-5-heptenoic acid (**10a**) according to Scheme 2.

Racemic 2,6-dimethyl-5-heptenoic acid could be resolved by gas chromatography on a capillary column coated with heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin/OV-1701. It was found that the synthetic acid (**10a**) and the natural compound did not coelute from this chiral column. Therefore, the natural compound had to be (*S*)-2,6-dimethyl-5-heptenoic acid (**10b**). This enantiomer, which coeluted with the natural compound was synthesized from (*S*)-(+)-3,7-dimethyl-1,6-octadiene [(+)-β-citronellene] (**7b**) according to a sequence of steps similar to those used for the synthesis of the *R* enantiomer (**10a**), as shown in Scheme 2.

Although the mass spectrum of the synthetic acid is identical to that of the natural compound and it coeluted with the natural compound from the chiral GC column, it did not elicit EAD responses in a large number of male and female antennae that were used in EAD/FID measurements. This is not unexpected in view of the observation that the natural compound also did not reproducibly elicit EAD responses. From the research done with dung beetles over many years, it is clear that semiochemical communication in dung beetles is extraordinarily complex, and as far as the inconsistency of antennal responses in EAD analyses with the antennae of this and other *Kheper* species is concerned, there are various factors that could be taken into consideration. It is, for example, possible that there could be some natural variation in the population in terms of antennal responses. Because the research had to be done with captured insects, it was not possible to determine the age, physiological state, etc of the insects that were used in these experiments, factors that could have influenced the EAD results. The possibility that the response of an antenna to the volatile constituents of the secretion could depend on the concentration of the components flowing over the antenna was investigated, but this does not seem to explain the inconsistent results obtained with (*S*)-2,6-dimethyl-5-heptenoic acid (**10b**) and some of the other minor constituents of the secretion. Another factor that has to be considered is that the best EAD results are mostly obtained when an EAD-active compound is eluted as a sharp peak

from the GC column. Better results are often obtained when higher programming rates are used. Many of the volatile constituents of the secretion are carboxylic acids or other polar compounds that elute as more or less pretailing peaks from apolar columns. If an EAD active constituent is eluted as a pretailing peak, it is possible that the receptors on the antenna become saturated at a level below the detection threshold of the system. In the present investigation, a capillary column coated with OV-1701-OH was used because it is known that underivatized fatty acids are eluted with better peak shapes from this phase than from other apolar and even moderately polar stationary phases. A detailed investigation of the effect of the choice of stationary phase and programming rate on EAD/FID analyses with dung beetle antennae have, however, not yet been undertaken. Using a modulating device, which delivers the effluent of the column as sharp pulses into the humidified airstream of the EAD setup, could possibly solve the problem of pretailing peaks in EAD analyses.

Unfortunately, as in the research on *K. nigroaeneus* (Burger and Petersen, 2002), field tests with synthetic materials have so far not produced positive results. The problems associated with field tests of the synthetic attractant constituents of *Kheper* dung beetles were discussed in a previous communication (Burger and Petersen, 2002).

The results obtained in interspecific EAD analyses revealed that considerable interspecific semiochemical communication could take place between dung beetles in the same area. This aspect will be dealt with in a forthcoming communication.

Acknowledgments—Support of this work by the University of Stellenbosch and the Foundation for Research Development, Pretoria, is gratefully acknowledged. The authors are indebted to the Natal Parks, Game, and Fish Preservation Board for permission to study dung beetles in Mkuzi Game Reserve.

(Received November 1, 2001; accepted August 19, 2002)

Abstract—Extracts of Dufour's gland of the ponerine ant, *Gnamptogenys striatula*, were analyzed by using the combination of gas chromatography and mass spectrometry. Series of esters of the new homoterpenoids (2*E*,6)-3,4,7-trimethyl-2,6-octadiene-1-ol (4-methylgeraniol) and (2*E*,6)-3,4,7-trimethyl-2,6-nonadiene-1-ol (bishomogeraniol) with unbranched medium-chain fatty acids were identified. Transformation of the chiral natural products into 1,4-di(trifluoroacetoxy)-3-methylpentane and comparison of its gas chromatographic retention time on a modified cyclodextrin phase with that of synthetic optically active reference samples proved the stereogenic center to keep (*S*)-configuration. (2*E*,4*S*,6)-3,4,7-Trimethyl-2,6-octadien-1-yl decanoate and the corresponding dodecanoate are the main volatiles in the extracts.

Key Words—*Gnamptogenys*, Dufour's gland, homoterpene, 4-methylgeraniol, terpenoid esters.

INTRODUCTION

Hymenoptera use various glands to produce chemical signals involved in intraspecific and interspecific systems of communication. In ants, Dufour's gland

* To whom correspondence should be addressed. E-mail: francke@chemie.uni-hamburg.de

0098-0331/02/1200-2541/0 © 2002 Plenum Publishing Corporation

plays a complex role, and, depending on the genus and species, its secretion may contain a plethora of components. The chemical structures of the compounds may be highly diverse, ranging from straight-chain acetogenines and classical isoprenoides to methylated terpenes (Francke and Schulz, 1999).

Among the ponerine ants investigated so far, *Ectatomma ruidum* (Bestmann et al., 1995), *Gnamptogenys menadensis* (Gobin et al., 1998) as well as *G. striatula* (Blatrix et al., 2002) employ Dufour's gland secretion for trail marking. In this paper, we describe the structure elucidation of a few homoterpene esters as volatile components in Dufour's gland of *G. striatula*, representing a new class of natural products.

METHODS AND MATERIALS

Analyses. Pentane extracts of Dufour's glands of *G. striatula* were prepared as described by Blatrix et al. (2002). Analyses were carried out by coupled gas chromatography mass spectroscopy (GC-MS). A Hewlett-Packard gas chromatograph 5890 (Palo Alto, California, USA) was linked to a double-focusing sector-field mass spectrometer VG 70/250 SE (Vacuum Generators, Manchester, UK) operated at 70 eV. Alternatively, a quadrupole instrument (MD 800/GC 8060, Fisons, Ismaning, Germany) was employed. Using helium as carrier gas, separations were achieved with a 60 m $\times$ 0.25-mm-ID, 0.25-μm film DB5-MS fused silica column (J & W Scientific, Folsom, California, USA) under the following conditions: 2 min 50°C, then programmed to 280°C at a rate of 5°C/min. In addition, a 50-m $\times$ 0.25-mm-ID, 0.27-μm film FFAP fused silica column was operated under the following conditions: 3 min 50°C, then programmed to 220°C at a rate of 3°C/min. NMR spectra were recorded with a Bruker AMX 400 (Karlsruhe, Germany); chemical shifts (δ) are given in parts per million relative to tetramethyl silane; coupling constants J are given in Hertz.

The separation of stereoisomers of 1,4-di(trifluoroacetoxy)-3-methylpentane was carried out by using a 25-m $\times$ 0.25-mm-ID fused silica capillary coated with 6-methyl-2,3-dipentyl-γ-cyclodextrin operated at 55°C; hydrogen served as carrier gas.

Syntheses. Fine chemicals and solvents were purchased from Aldrich or Merck and were of highest purity available. Purifications of synthetic products were carried out by column chromatography on silica gel (Merck 60–240 mesh) using mixtures of hexane and ethyl acetate.

Preparation of racemic (2*E*,6)-3,4,7-trimethyl-2,6-octadiene-1-ol (4-methylgeraniol) and (2*E*,6)-3,4,7-trimethyl-2,6-nonadiene-1-ol (bishomogeraniol) followed the procedure of Ohnuma et al. (1989) (Figure 1). Starting from

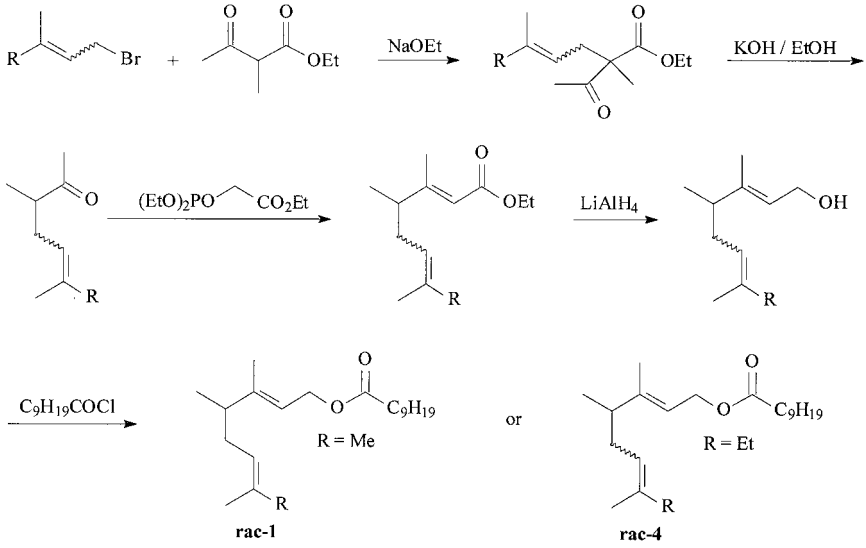

FIG. 1. Synthesis of homoterpene esters.

1-bromo-3-methyl-2-butene, the scope of the synthesis, work-up, and NMR data of 4-methylgeraniol were essentially the same as described in the literature . Similarly, our synthesis of racemic bishomogeraniol started with the reaction of 1-bromo-3-methyl-2-pentene with ethyl 2-methylacetoacetate. Terpenoid alcohols were esterified with fatty acid chlorides by standard procedures.

Spectroscopic data of (2*E*,6)-3,4,7-trimethyl-2,6-octadien-1-yl decanoate (4-methylgeranyl decanoate) (1) are as follows:

MS (70 eV): m/z [%] = 322 (0.04), 253 (4), 156 (8), 155 (75), 150 (15), 135 (18), 121 (7), 108 (9), 107 (39), 106 (6), 99 (18), 95 (27), 94 (15), 93 (6), 91 (5), 85 (22), 83 (9), 82 (49), 81 (30), 79 (11), 71 (33), 70 (6), 69 (93), 67 (50), 57 (41), 55 (37), 53 (16), 43 (62), 42 (12), 41 (100).

^{1}*H NMR (400 MHz, CDCl*$_3$*)*: δ [ppm] = 0.88 (t, 3H, J = 7.12 Hz, 10-H), 0.99 (d, 3H, J = 6.61 Hz, CH_3 linked to 4′-C), 1.21–1.34 (m, 12H, 4-H to 9-H), 1.55–1.69 (m, 11H, 3-H/8′-H/CH_3 linked to 3′-C), 1.98 (dd, 2H, J = 7.12 Hz, 5′-H), 2.08–2.16 (m, 1H, 4′-H), 2.29 (t, 3H, J = 7.12 Hz, 2-H), 4.59 (d, 2H, J = 7.12 Hz, 1′-H), 5.04 (t, 1H, J = 6.61 Hz, 6′-H), 5.33 (t, 1H, 2′-H).

^{13}*C NMR (101 MHz, CDCl*$_3$*)*: δ [ppm] = 13.62/14.11/17.85/18.82/25.77 (q, 10-C/8′-C/CH_3 linked to 3′-C/CH_3 linked to 4′-C), 22.67/24.37/25.05/29.17/29.27/29.43/31.88 (t, 3-C to 9-C), 33.49 (t, 5′-C), 34.44 (t, 2-C), 42.88 (d, 4′-C), 61.21 (1′-C), 117.72 (d, 2′-C), 122.92 (d, 6′-C), 132.09 (s, 7′-C), 146.12 (s, 3′-C), 173.94 (s, 1-C).

Spectroscopic data of (2*E*,6)-3,4,7-trimethyl-2,6-nonadien-1-yl decanoate (bishomogeranyl decanoate) (4) are as follows:

MS (70 eV): m/z [%] = 336 (0.02), 253 (4), 164 (12), 156 (8), 155 (71), 149 (10), 135 (19), 108 (9), 107 (28), 106 (5), 99 (11), 95 (22), 94 (12), 85 (20), 83 (62), 82 (79), 81 (25), 79 (12), 71 (35), 69 (14), 68 (5), 67 (64), 57 (24), 56 (7), 55 (100), 53 (11), 43 (26), 41 (39).

^{1}*H NMR (400 MHz, CDCl$_3$)*: δ [ppm] = 0.88 (t, 3H, J = 7.12 Hz, 10-H), 0.96 (t, 3H, J = 7.63 Hz, 9′-H), 0.99 (d, 3H, J = 6.61, CH_3 linked to 4′-C), 1.20–1.35 (m, 12H, 4-H bis 9-H), 1.55–1.68 (m, 8H, 3-H/CH_3 linked to 7′-C/CH_3 an 3′-C), 1.99 (q, 2H, 8′-H), 2.05 (dd, 2H, J = 6.61 Hz, 5′-H), 2.08–2.18 (m, 1H, 4′ H), 2.30 (t, 2H, J = 7.63 Hz, 2-H), 4.59 (d, 2H, J = 7.12 Hz, 1′-H), 5.04 (t, 1H, J = 7.63 Hz, 6′-H), 5.33 (t, 1 H, J = 6.61 Hz, 2′-H).

^{13}*C NMR (101 MHz, CDCl$_3$)*: δ [ppm] = 12.89/13.60 (q, CH_3 linked to 3′-C/CH_3 linked to 7′-C), 14.10 (q, 10-C), 18.80/18.86 (q, 9′-C/CH_3 linked to 4′-C), 22.68/24.84/25.05/29.17/29.27/29.44/31.88 (t, 3-C to 9-C), 32.46/33.28 (t, 5′-C/8′-C), 34.44 (t, 2-H), 42.93 (d, 4′-C), 61.20 (t, 1′-C), 117.72 (d, 2′-C), 121.40 (d, 6′-C), 133.62 (s, 7′-C), 146.99 (s, 3′-C), 173.54 (s, 1-C).

*Synthesis of 1,4-Di(Trifluoroacetoxy)-3-Methylpentane (**8**) (Figure 2A).* To a −78°C cold solution of 0.50 g (5.00 mmol) 3-methyltetrahydrofuran-2-one (**5**) in 8 ml hexane was added 6.5 mmol of diisobutylaluminum hydride (6.5 ml of a 1 M solution in heptane). The solution was slowly warmed to room temperature and added to 50 ml of a saturated aqueous solution of ammonium chloride. After stirring for 40 min, 20 ml of diethylether were added, and the organic layer was separated. The aqueous solution was extracted 3 times with diethylether, and the organic layers were combined, washed with brine, dried over anhydrous magnesium sulfate, and concentrated *in vacuo* to yield the lactol **6**. This was immediately converted to the diol **7:**. To a −78°C cold solution of 300 mg (2.88 mmol) crude **6** in 4 ml dry tetrahydrofuran was added 5 mmol methyl lithium (5 ml of a 1 M solution in hexane). After warming to room temperature, the solution was poured on ice/diethylether. After separation of the organic layer, the aqueous phase was extracted 8 times with portions of 20 ml of dichloromethane. The combined organic layers were washed with brine, dried over magnesium sulfate, and concentrated *in vacuo*. The crude 3-methyl-1,4-pentanediol (**7**) was purified through column chromatography. Trifluoroacetylation (Blau, 1993) of **7** yielded a mixture of all stereoisomers of 1,4-di(trifluoroacetoxy)-3-methylpentane (**8**).

^{1}*H NMR (400 MHz, C$_6$D$_6$)*: δ [ppm] = 0.49 (d, 3H, J = 6.87 Hz, CH_3 linked to 3-C), 0.98–1.03 (m, 3H, 1-H), 1.07–1.13 (m, 1H, 3-H), 1.59–1.65 (m, 2H, 4-H), 3.58–3.69 (m, 2H, 2-H), 3.79–4.00 (m, 2H, 5-H).

^{13}*C NMR (101 MHz, C$_6$D$_6$)*: δ [ppm] = 14.43/14.60 (q, CH_3 linked to 3-C), 25.11/26.96 (q, 1-C), 29.48/30.26 (t, 4-C), 40.68 (d, 3-C), 66.62 (d, 2-C), 67.55 (t, 5-C). (Trifluoracetylgroups not visible)

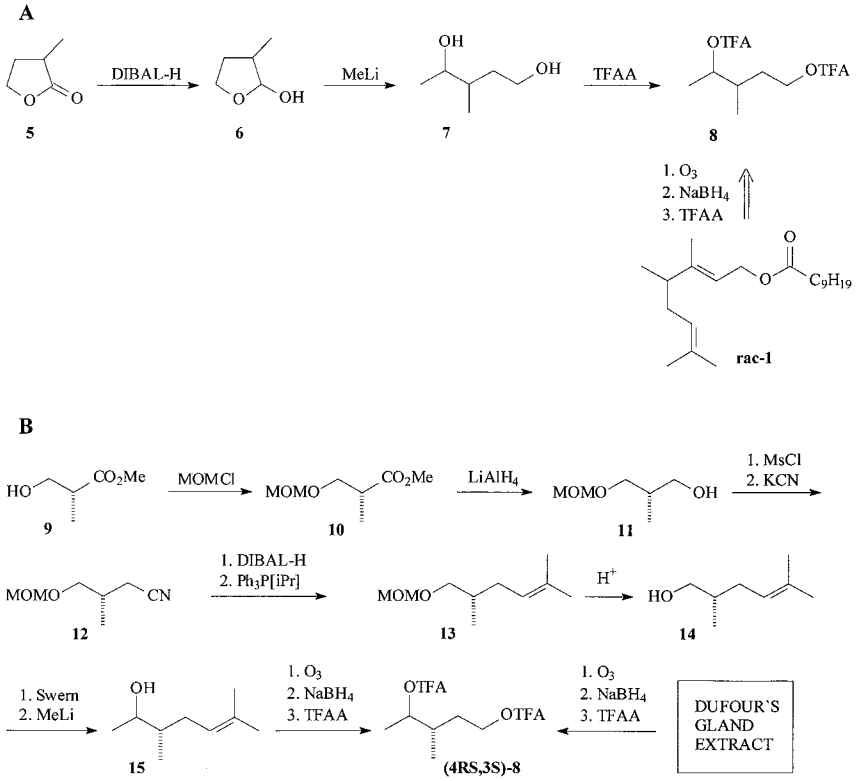

FIG. 2. (A) Synthesis of racemic 1,4-di(trifluoroacetoxy)-3-methylpentane and degradation of synthetic 4-methylgeranyl decanoate; (B) synthesis of (3*S*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane and degradation of naturally occuring homoterpene esters.

MS: 268 (1), 228 (1), 210 (1), 181 (2), 169 (7), 142 (4), 141 (42), 113 (17), 99 (6), 97 (11), 84 (3), 83 (36), 82 (15), 70 (2), 69 (100), 67 (19), 56 (15), 55 (89), 53 (11), 47 (21), 45 (3), 43 (3), 41 (30), 39 (14).

*Synthesis of (3*S,*4*RS*)-1,4-Di(Trifluoroacetoxy)-3-Metehylpentane (3*S,*4*RS*)-**8** (Figure 2B). Methyl (*R*)-3-methoxymethoxy-2-methylpropanoate (**10**).* To an ice cold solution of 10.0 g (84.7 mmol) commercially available methyl (*R*)-3-hydroxy-2-methylpropanoate (**9**) and 21.8 g (169 mmol) diisopropyl amine in 50 ml dry dichloromethane, 10.2 g (127 mmol) chloromethylmethylether was added dropwise. After stirring for 4 hr at room temperature, the mixture was poured on ice. The organic layer was separated, and the aqueous layer was extracted 3 times with diethylether. The combined organic solutions were washed with a saturated aqueous solution of ammonium chloride and brine and dried over magnesium sulfate. After concentration *in vacuo*, column chromatography yielded 12.8 g (79 mmol, 93%)

of methyl (*R*)-3-methoxymethoxy-2-methylpropanoate (**10**) as a light yellow oil $[\alpha]_D = -12.5$ ($c = 2.31$ in $CDCl_3$)

^{1}*H NMR (400 MHz; CDCl$_3$)*: (δ [ppm]; *J* (Hz): 4.62 (2H, m, H-1), 3.36 (3H, s, MeO), 3.50–3.44 (1H, m, H-4), 3.39–3.34 (1H, m, H-4′b), 2.55 (1H, dd, H-2á), 2.22 (1H, dd, H-2′b), 2.31–2.24 (1H, m H-3′), 1.02 (3H, d, Me-3). $J_{2a,2b} = 5.3$, $J_{2a,3} = 15.3$, $J_{2b,3} = 7.6$, $J_{Me-2} = 6.6$.

^{13}*C NMR (101 MHz, CDCl$_3$, DEPT)*: δ [ppm]: 178.6 (C-1), 96.5 (C-1′), 72.0 (−), 55.2 (+), 38.3 (+), 30.6 (−), 16.9 (+).

MS: 162 (2), 147 (14), 131 (8), 103 (21), 69 (100), 45 (26).

*(S)-3-Methoxymethoxy-2-Methylpropanol (**11**).* To a −5°C cold suspension of 3.42 g (90 mmol) lithium aluminum hydride in 120 ml dry diethylether was added a solution of 12.6 g (78 mmol) of **10** in 20 ml dry diethylether. After stirring at room temperature over night, 50 ml diethylether were added. To the vigorously stirred mixture were added 14 ml of a 2 M aqueous solution of sodium hydroxide. After stirring for 1 hr, the precipitate was filtered off, and the residue was washed with diethylether. The combined organic layers were dried over magnesium sulfate, and the solvent was removed *in vacuo*. The obtained crude (*S*)-3-methoxymethoxy-2-methylpropanol (**11**), $[\alpha]_D = -5.68$ ($c = 2.50$ in CH_2Cl_2), was used for the next step without further purification.

^{1}*H NMR (400 MHz; CDCl$_3$)*: δ [ppm]; *J* (Hz): 3.64–3.58 (2 H, m, H-1), 3.52–3.45 (2H, m, H-3), 3.34 (3H, s, MeO), 3.63 (2H, s, OCH_2O), 2.08-1.98 (1H, m, H-2), 0.92 (3H, d, Me-2). $J_{2,Me} = 7.1$.

^{13}*C NMR (101 MHz, CDCl$_3$, DEPT)*: δ [ppm]: 96.6 (−), 72.1 (−), 67.1 (−), 55.3 (+), 35.6 (+), 13.5 (+).

*(S)-4-Methoxymethoxy-3-Methylbutyronitrile **12**.* Crude **11** obtained in the previous step (8.9g = 66 mmol) was taken up with a solution of 11.1 g (110 mmol) of triethylamine in 130 ml dichloromethane. After cooling to −10°C, 10.67 g (93.6 mmol) of mesylchloride were added. After stirring for 30 min, the solution was poured on ice. The organic layer was separated, and the aqueous layer was extracted 3 times with portions of 40 ml diethylether. The combined organic layers were washed with brine and dried over magnesium sulfate. Removal of the solvent *in vacuo* yielded (*S*)-1-mesyloxy-3-methoxymethoxy-2-methylpropane, which was immediately used for the next step: The mesylate, obtained in the previous step, was dissolved in 180 ml dry dimethylsulfoxide, and 7.61 g (117 mmol) potassium cyanide were added. The solution was stirred over night at 40°C and subsequently poured on ice. The aqueous mixture was saturated with sodium chloride and extracted 6 times with portions of 50 ml diethylether. The combined organic solutions were washed with brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the product was purified by column chromatography yielding 8.69 g (60.8 mmol = 75 % starting from **10**) of pure (*S*)-4-methoxymethoxy-3-methylbutyronitrile, **12** $[\alpha]_D = -1.06$ ($c = 2.84$ in $CHCl_3$).

^{1}H NMR (400 MHz; $CDCl_3$): δ [ppm]; J(Hz): 4.62 (2H, s, H-1), 3.53 (1H, dd, H-3a′), 3.48 (1H, dd, H-3′b), 3.37 (1H, s, MeO), 2.50 (1H, dd, H-1a′), 2.39 (1H, dd, H-1b′), 2.22–2.11 (1H, m, H-2′), 1.10 (1H, d, Me-2).

^{13}C NMR (101 MHz, $CDCl_3$, DEPT): δ [ppm]: quarternary C not observed, 96.6 (−), 70.6(−), 55.4(+), 31.1(+), 21.4 (−), 16.3(+).

MS: 142 (4; M^+-1), 113 (8), 82 (18), 55 (22), 45 (100).

*(S)-1-Methoxymethoxy-2,5-Dimethylhex-4-ene (**13**).* To a −78°C cold solution of 8.65 g (60.5 mmol) of the nitrile **12** in 70 ml hexane 67 mmol of diisobutylaluminum hydride (67 ml of a 1 molar solution in heptane) was added dropwise. During a period of 3 hr the mixture was slowly warmed to −20°C. Subsequently, the mixture was warmed to 0°C and poured on to a mixture of 50 ml hexane and 80 ml of a saturated aqueous solution of ammonium chloride and vigorously stirred for 1 hr. The layers were separated, and the aqueous layer was extracted 4 times with portions of 50 ml diethylether. The combined organic layers were washed with brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the residue was filtered over silica to yield 8.33 g (49.0 mmol = 81%) of the target aldehyde, (*S*)-4-methoxymethoxy-3-methylbutanal, which was immediately used in the next step: To a −30°C cold suspension of 25.9 g (60 mmol) isopropyl triphenylphosphonium iodide (purchased from Lancaster) in dry tetrahydrofuran was added 60 mmol *n*-butyl lithium (37.5 ml of a 1.6 M solution in hexane). The red solution was stirred for 20 min and cooled to −50°C. Subsequently, a solution of 7.5 g (50 mmol) of (*S*)-4-methoxymethoxy-3-methylbutanal in 20 ml tetrahydrofuran was added. The mixture was warmed to room temperature and added to an ice cold, vigorously stirred mixture of 80 ml water and 80 ml hexane. The layers were separated, and the aqueous phase was extracted 4 times with portions of 30 ml hexane. The combined organic solutions were washed with brine and dried over magnesium sulfate. The crude product was purified through column chromatography yielding 6.71 g (39 mmol = 78%) of (*S*)-1-methoxymethoxy-2,5-dimethylhex-4-ene, **13**, as a light yellow oil, $[\alpha]_D^{25} = +2{,}71$ ($c = 0.4425$ in hexane).

^{1}H NMR (400 MHz; $CDCl_3$): δ [ppm]; J(Hz): 5.16–5.10 (1H, m, H-4′), 4.62 (2H, s, H-1), 3.39 (1H, dd, H-1′a), 3.36 (3H, s, MeO), 3.30 (1H, dd, H-1′b), 2.08 (1H, m, H-3′a), 1.87 (1H, m, H-3′b), 1.70 (3H-, s, Me-5), 1.60 (3H, s, Me′-5′), 0.93 (3H, d, Me-2′). $J_{1'a,1'b} = 9.2$, $J_{1'a,2'} = 6.1$, $J_{1'b,2'} = 6.6$, (3H, d, Me-2).

^{13}C NMR (101 MHz, $CDCl_3$, DEPT): δ (ppm): 132.5 (q), 122.5 (C-4′), 96.6 (C-1), 72.9 (C-1′), 55.1 (MeO), 34.3 (+), 32.0 (−), 25.8 (+), 17.8 (+), 16.9 (+).

*(S)-2,5-Dimethylhex-4-en-1-ol (**14**).* To a stirred solution of 3,0 g (17,4 mmol) of **13** in 30 ml methanol were added 5 drops of concentrated hydrochloric acid at room temperature. After 5 hr the mixture was cooled to 0°C and neutralized by slowly adding solid sodium hydrogen carbonate. After removal of ca. 70% of the solvent *in vacuo*, 40 ml water and 40 ml diethylether were added. The layers were separated, and the organic layer was extracted 5 times with portions of 40 ml diethylether. The combined organic layers were washed with brine and dried over

magnesium sulfate. The crude product was purified by column chromatography yielding 2.00 g (15.7 mmol = 90.0%) of (*S*)-2,5-dimethylhex-4-en-1-ol, **14**, as a colorless oil $[\alpha]_D^{25} = -0.562$ ($c = 1.38$ $CHCl_3$).

^{1}*H NMR (400 MHz; CDCl$_3$)*: δ [ppm]; J(Hz): 3.52 (1H, dd, H-1a), 3.44 (1H, dd, H-1b), 2.11–2.04 (1H, m, H-3a), 1.92–1.84 (1H, m, H-3b), 1.73–1.66 (1H, m, H-2), 1.71 (3H, s, Me-5), 1.62 (3H, s, Me-5), 0.92 (3H, d, Me-2). $J_{1,1} = 10.7$, $J_{1,2} = 6.1$, $J_{2,\mathrm{Me}} = 6.6$.

^{13}*C NMR (101 MHz, CDCl$_3$, DEPT)*: δ [ppm]: 132.8 (q), 122.6 (C-4), 68.2 (C-1), 31.9 (−), 36.5 (+), 25.8 (+), 17.8 (+), 16.6 (+).

(2 RS*,3*S*)-3,6-Dimethylhept-5-en-2-ol (**15**).* A solution of 3.6 g (46.5 mmol) dimethylsulfoxide in 10 ml dry dichloromethane was added dropwise to a −70°C cold, vigorously stirred solution of 2.92 g (23.0 mmol) oxalylchloride in 80 ml dry dichloromethane. After stirring the solution for 20 min, a solution of 1.95 g (15.3 mmol) of the alcohol **14** in 5 ml dichloromethane was added. After stirring for another hour at −70°C, 14.8 g (91.8 mmol) triethylamine were added. During the following hour, the mixture was allowed to warm to 0°C and subsequently poured on 150 ml ice water. After separation of the layers, the aqueous layer was extracted 3 times with portions of 50 ml diethylether. The combined organic solutions were washed with diluted hydrochloric acid, a saturated solution of aqueous hydrogencarbonate, and brine. The solution of the obtained (*S*)-2,5-dimethylhex-4-enal was dried over magnesium sulfate, carefully concentrated *in vacuo*, and immediately used for the next step.

^{1}*H NMR (400 MHz; CDCl$_3$)*: δ [ppm]; J(Hz): 9.65 (1H, d, H-1), 5.12–5.07 (1H, m, H-4), 2.44–2.32 (2H, m, H-3), 2.18–2.07 (1H, m, H-2), 1.70 (3H, s, Me-5), 1.62 (3H, s, Me-5′), 1.08 (3H, d, Me-2). $J_{1,2} = 1.5$, $J_{2,\mathrm{Me}} = 6.6$.

^{13}*C NMR (101 MHz, CDCl$_3$, DEPT)*: δ [ppm]: 205.3 (C-1), 134.1 (C-5), 120.6 (C-4), 46.8 (+), 29.1 (C-3), 17.9 (+), 15.3 (+), 13.1 (+).

To a −78°C cold solution of 80 mg (635 μmol) of freshly prepared (*S*)-2,5-dimethylhex-4-enal in 2 ml dry tetrahydrofuran, was added 1.5 mmol methyllithium (1.5 ml of a 1 M solution in hexane). The solution was warmed to room temperature and poured on a mixture of 20 ml ice water and 20 ml diethylether. After separation of the layers, the aqueous layer was extracted 3 times with portions of 20 ml of diethylether. The combined organic solutions were washed with brine, dried over magnesium sulfate, and concentrated. The crude product was purified by column chromatography to yield 60 mg (415 μ mol = 64%) of the diastereomers (2*RS*,3*S*)-3,6-dimethylhept-5-en-2-ol, (**15)**.

^{1}*H NMR (400 MHz; CDCl$_3$)*: δ [ppm]; J(Hz): 5.15 (m, 1H, H-5), 3.72 (m, 0.6H, H-2), 3.65 (m, 0.4H, H-2), 2.12 (m, 1H, H-4), 1.88 (m, 1H, H-4), 1.71 (s, 3H, Me-6), 1.61 (s, 3H, C-7), 1.55 (m, 1H, H-3), 1.17 (d, 0.6x3H, Me-1), 1.15 (d, 0.4 × 3H, Me-1), 0.89 (d, 0.6 × 3H, Me-3), 0.88 (d, 0.4 × 3H, Me-3).

^{13}*C NMR (101 MHz, CDCl$_3$):* δ [ppm]: mixture of diastereomers, all visible signals are listed: 132.6 (C6), 123.1 (C5), 71.8 (C2), 71.0 (C2), 41.0 (C3), 40.4

(C3), 31.5 (C4), 25.9 (C-Me-6), 20.4 (C1), 19.8 (C1), 17.8 (C7), 15.1 (Me-3), 14.0 (Me-3).

Following the transformation of **9** into **15**, the same sequence was started from methyl (*S*)-3-hydroxy-2-methylpropanoate to produce the complementary pair of diastereomers, (3*R*,4*RS*)-3,6-dimethylhept-5-en-2-ol, showing the same spectroscopic data as **15**.

*Transformation of Unsaturated Precursors into 1,4-Di(Trifluoroacetoxy)-3-Methylpentane, **8**.* A solution of ca. 0.5 mg of the diastereomers (2*RS*,3*S*)-3,6-dimethylhept-5-ene-2-ol, **15**, in 2 ml dichloromethane was transferred to a 5 ml septum-capped vial equipped with an inlet capillary and an outlet. The vial was cooled to -78°C, and a gentle stream of ozone was passed through the solution until it turned blue. Subsequently, pure oxygen was passed through for 10 min, and 10 mg of solid sodium borohydride was added. The suspension was stirred for 2 hr and filtered over cotton. To the clear solution were added 15 mg of trifluoroacetic acid anhydride at 0°C. This mixture was carefully concentrated to dryness, and the residue was dissolved in 50 μl of dichloromethane. This sample was directly analyzed by GC-MS. The transformation of (2*RS*,3*S*)-3,6-dimethylhept-5-ene-2-ol, **15**, into (3*S*,2*RS*)-1,4-ditrifluoroacetoxy)-3-methylpentane, (3*S*,2*RS*)-**8**, proved to be quantitative. The same transformation procedure was carried out with concentrated pentane extracts of Dufour's glands of *G. striatula*.

RESULTS AND DISCUSSION

The gas chromatogram of a pentane extract of Dufour's gland of *G. striatula* showed two major components (Blatrix, et al., 2002). The mass spectrum of the main component **1** revealed a molecular ion at $M^+ = 322$ (Figure 3). The base peak of the spectrum at $m/z = 155$ ($C_{10}H_{19}O$ upon HR-MS) and two very small signals at $m/z = 172$ and $m/z = 173$ (acid and protonated acid) as well as the presence of $m/z = 60$ revealed **1** to be an ester of decanoic acid (Francke et al., 2000). An abundant signal at $m/z = 150$ ($C_{11}H_{18}$ upon HR-MS) representing the alkene fragment corresponding to the alcohol component, suggested the alcohol to be an undecadienol ($m/z = 168$ corresponding to the molecular weight of the alcohol present) with a primary hydroxyl function (Tengö et al., 1985; Francke et al., 2000). Signals at $m/z = 253$ ($M^+ - 69$) and $m/z = 69$ indicated a dimethylallyl substructure, typical for open chain terpenes like geraniol. Considerations on the incorporation of homomevalonate during the biosynthesis of the target terpenoid (Francke and Schulz, 1999) suggested the additional carbon to generate a 3,4,7-trimethyl-2,6-octadiene-1-yl moiety or its 3-ethyl-7-methyl-2,6-octadiene-1-yl isomer.

The mass spectra of **2**, the second major component among the Dufour's gland volatiles and that of a minor compound, **3**, showed molecular ions at $M^+ = 350$

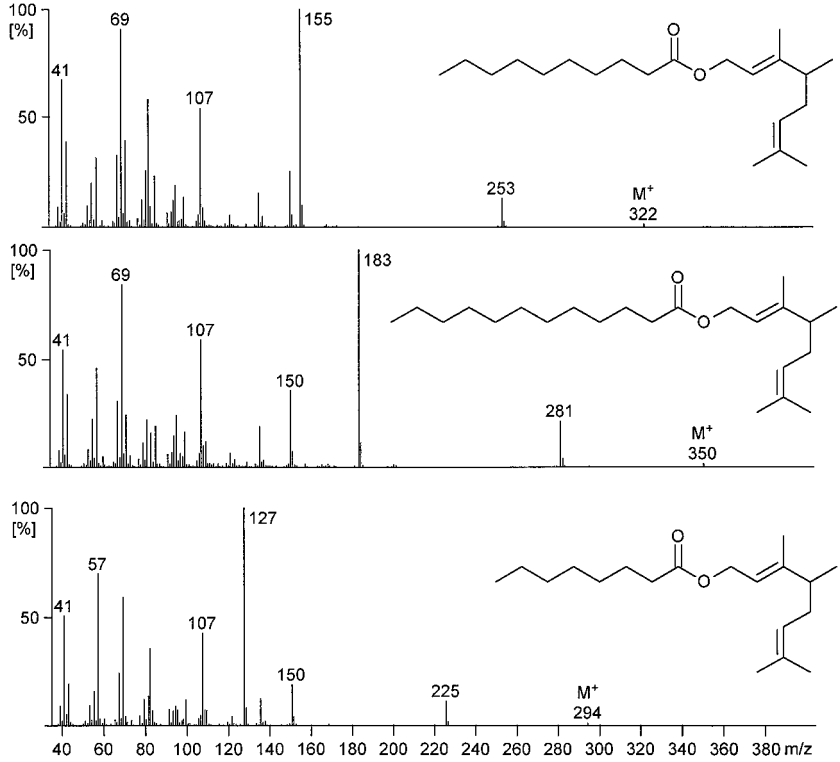

FIG. 3. 70-eV mass spectra of the main volatiles **1–3** in the pentane extract of Dufour's gland of *G. striatula*.

and $M = 294$ as well as base peaks at $m/z = 183$ and $m/z = 127$, respectively, and a similar fragmentation pattern in the lower mass region (Figure 3). This suggested the compounds to be the dodecanoate and the octanoate of the same alcohol component as in ester **1**. Small amounts of esters of this alcohol and other carboxylic acids, e.g., the hexanoate, heptanoate, nonanoate, undecanoate, and tridecanoate were also found (see Blatrix et al., 2002).

Microozonolysis of the natural extract followed by reduction and trifluoroacetylation of the degradation product furnished a compound that perfectly matched the gas chromatographic properties and the mass spectrum of synthetic 1,4-di(trifluoroacetoxy)-3-methylpentane (Figure 2B). This finding revealed the target alcohol to be the homoterpene 3,4,7-trimethyl-2,6-octadiene-1-ol (4-methylgeraniol) and, thus, the natural volatiles to be carboxylic acid esters thereof.

The mass spectrum of another minor constituent of the extract, compound **4**, is shown in Figure 4. The compound eluted later than the major decanoate **1** but

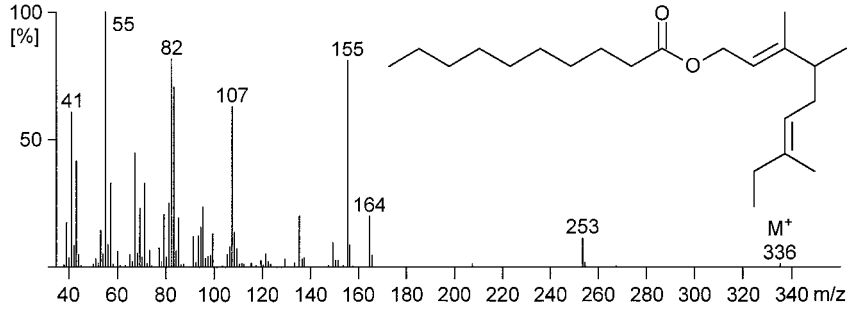

FIG. 4. 70-eV Mass spectrum of compound **4** in the pentane extract of Dufour's gland of *G. striatula.*

also showed a base peak at $m/z = 155$, again suggesting a decanoic acid ester. However, compared to 4-methylgeraniol in **1**, the alcohol component contained an additional carbon atom as indicated by the corresponding alkene fragment at $m/z = 164$ (see Figure 4). Since the spectrum showed only a small signal at $m/z = 69$ but abundant fragments at $m/z = 253$ ($M^+ - 83$) and $m/z = 83$, the additional carbon was clearly attached to the tail of the 4-methylgeraniol. Thus, the alcohol was the bishomogeraniol, 3,4,7-trimethyl-2,6-nonadiene-1-ol. Apart from its decanoate **4**, several other esters of this alcohol were detected (see Blatrix et al., 2002).

Unambiguous proof for the postulated structures was obtained through the synthesis of both (2*E*,6)-3,4,7-trimethyl-2,6-octadiene-1-ol and (2*E*,6)-3,4,7-trimethyl-2,6-nonadiene-1-ol and esterification with the appropriate carboxylic acids (Figure 1). The syntheses of both terpenoid alcohols and their esters were straightforward following a known procedure (Ohnuma et al., 1989). Since that of bishomogeraniol started with an *E*/*Z*-mixture of 1-bromo-3-methyl-2-pentene, a mixture of the 2*E*,6*Z* and 2*E*,6*E* alcohols was obtained. Unambiguous structure assignments of the stereoisomers by NMR-spectroscopy was based on NOE experiments using the methylene groups C-5 and C-8, as well as the methyl group at C-7 of (2*E*,6)-3,4,7-trimethyl-(2,6)-nonadiene-1-ol. The relative proportion of the 2*E*,6*Z* and the 2*E*,6*E* esters synthesized as the final products was 1:1.6. Mass spectra and gas chromatographic retention times of all synthetic esters completely matched those of corresponding natural products.

Since both terpenoids show a stereogenic center, the absolute configuration of the natural products remained to be determined. As mentioned earlier, ozonization of the extract, reductive work-up, and trifluoroacetylation yielded 1,4-di(trifluoroacetoxy)-3-methylpentane. A synthetic mixture containing all four stereoisomers was perfectly separated upon GC using a modified cyclodextrin as the stationary phase (Figure 5, trace a).

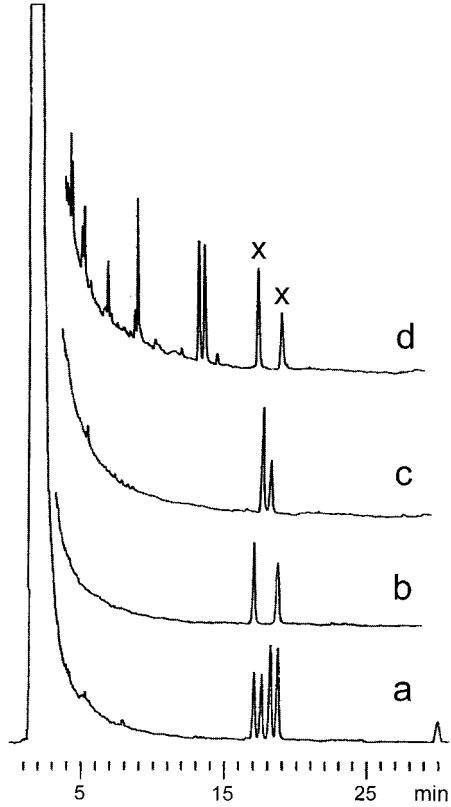

FIG. 5. Gas chromatographic separation of the four stereoisomers of 1,4-di (trifluoroacetoxy)-3-methylpentane (trace a), (3*S*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane (trace b)[1] (3*R*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane (trace c), and the 1,4-di(trifluoroacetoxy)-3-methylpentane (trace d) obtained after ozonization/derivatization of Dufour's gland extract. For conditions see text.

Upon ozonization/derivatization, the two series of esters of 4-methylgeraniol and bishomogeraniol furnish the same product, 1,4-di(trifluoroacetoxy)-3-methylpentane, **8**. During this procedure, an enantiomerically pure homoterpene yielded one pair of diastereomers since the second stereogenic center at C-4 of the derivative is introduced through the degradation process. Indeed, after derivatization, the natural extract produced only two peaks on the chiral stationary phase at the relevant retention time (Figure 5, trace d marked with $\times$s) proving the natural products to be enantiomerically pure. Consequently, samples of **8** with a defined configuration at the methyl branching were needed for the assignment of the absolute configuration of 1,4-di(trifluoroacetoxy)-3-methyl pentane derived from the

natural product through comparison of gas chromatographic retention times with authentic reference compounds.

Our synthesis of these substances started from commercially available methyl (*S*)-3-hydroxy-2-methylpropanoate **9** (Figure 2B), which was protected at the hydroxy group to furnish the ester **10**. This was reduced to **11** and converted to (*S*)-4-methoxymethoxy-3-methylbutyronitrile, **12**, through a conventional sequence. Reduction of the nitrile to the corresponding aldehyde with diisobutylaluminium hydride and Wittig reaction with isopropyl triphenylphosphonium iodide yielded (*S*)-1-methoxymethoxy-3,6-dimethylhex-4-ene, **13**. Deprotection, Swern oxidation of the resulting primary alcohol, and reaction with methyl lithium provided a mixture of diastereomers, (2*RS*,3*S*)-3,6-dimethylhept-5-ene-2-ol, **15**.

This product, which we also used in the synthesis of homoterpenes (Lehmann and Francke, unpublished), was submitted to the previously described ozonization/derivatization. Upon gas chromatography on the cyclodextrin column, the obtained (3*S*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane produced two peaks, which matched two of the four peaks obtained with the mixture of all four stereoisomers, generated from racemic 4-methylgeraniol. Correspondingly, the remaining two peaks of the mixture of stereoisomers matched the retention times of (3*R*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane (Figure 5, trace b and c) derived from (3*R*,2*RS*)-3,6-dimethylhept-5-ene-2-ol.

As seen in Figure 5, trace d, ozonization/derivatization of crude Dufour's gland extract yielded two peaks that coincided with those produced by (3*R*,4*RS*)-1,4-di(trifluoroacetoxy)-3-methylpentane (Figure 5, trace c). The 3*R*,4*RS*-stereoisomers (Figure 5, trace c) could not be observed (detection limit 1–2%). This proves that at least all esters of 4-methylgeraniol and of bishomogeraniol present in amounts of $>1\%$ of the Dufour's gland volatiles show (4*S*)-configuration.

Esters of monoterpene alcohols with straight chain fatty acids like geranyl octanoate have been identified as volatiles of several bee species (Bergström and Tengö, 1974), and they also occur in other organisms. However, esters of C_{11} or C_{12} homoterpenes represent a new class of natural products. The biosyntheses of the two new alcohols may involve the incorporation of one or two homomevalonate units, respectively (Figure 6) (Francke and Schulz, 1999). This is supported by the fact that (*S*)-4-methylgeraniol has been enzymatically prepared through the action of a farnesyl pyrophosphate synthetsase on a mixture of 3-methyl-2-butene-1-yl diphospate and (*E*)-3-methyl-3-pentene-1-yl diphosphate (Koyama et al., 1980). The new terpenoid alcohols show the same vicinal dimethyl branching as faranal (3*S*,4*R*,6*E*,10*Z*)-3,4,7,11-tetramethyl-6-10-tridecadienal, the trail pheromone of the pharaoh's ant, *Monomorium pharaonis* (Kobayashi et al., 1980). The same branching pattern is also present in (3*E*,6*E*,10*Z*)-3,4,7,11-tetramethyl-1,3,6,10-tridecatetraene, one of the trail pheromone components of the fire ant, *Solenopsis invicta* (Alvarez et al., 1987). Homofarnesenes and bishomofarnesenes have

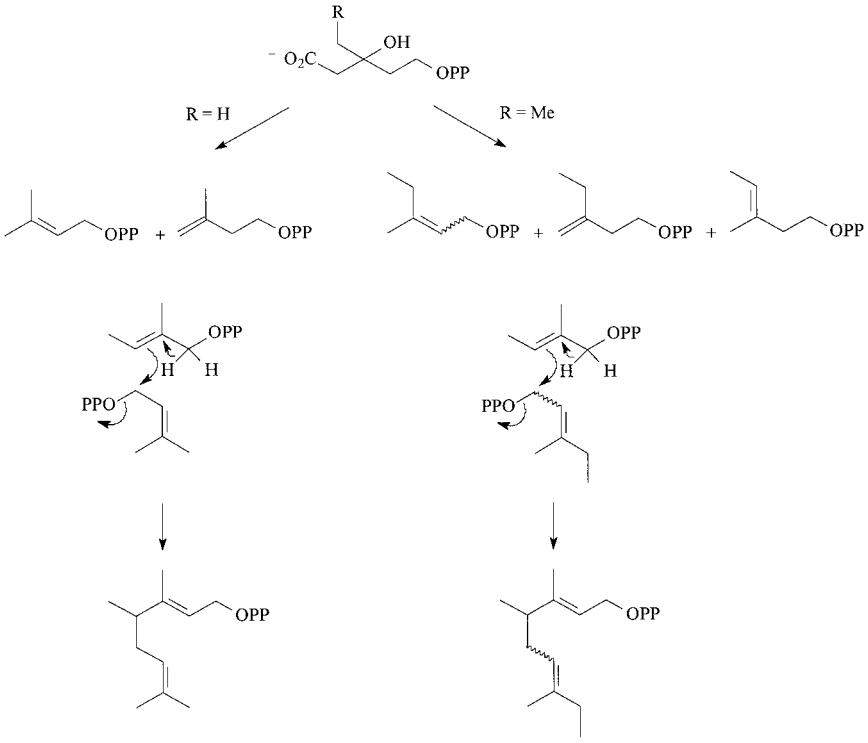

FIG. 6. Possible biosynthesis of 4-methylgeraniol and bishomogeraniol.

been repeatedly reported as constituents of Dufour's gland secretions of *Myrmica* ants (Morgan et al., 1979; Cammaerts et al., 1981; Attygalle and Morgan 1982; Attygalle et al., 1983). However, the structures of these compounds show ethyl branching instead of geminal dimethyl branching, which points to a slightly different biosynthesis from homomevalonate. Interestingly, methyl (4*S*,10*R*,11*S*,2*E*, 6*E*)-10,11-epoxy-7-ethyl-3,4,11-trimethyl-2,6-tridecadienoate [(+)-4-methyl juvenile hormone I], possibly formed from three homomevalonate units, shows a vicinal dimethyl substructure as well as internal ethyl branching.

Elucidation of the biological significance of the main terpenoid esters identified in Dufour's gland of *G. striatula* is described in the following paper (Blatrix et al., 2002).

(Received November 1, 2001; accepted August 19, 2002)

Abstract—Dufour's gland is the origin of the trail pheromone of *Gnamptogenys striatula*. Chemical analysis of the glandular extracts revealed a series of new natural products, especially esters of (2*E*)-3,4,7-trimethyl-2,6-octadien-1-ol (4-methylgeraniol), and (2*E*)-3,4,7-trimethyl-2,6-nonadien-1-ol (a bishomogeraniol isomer) with medium-chain fatty acids. Bioassays with synthetic racemates of the esters revealed that the 4-methylgeranyl esters are highly active as trail pheromones, while the bishomogeranyl esters are either marginally active or not active at all. Assays with the individual 4-methylgeranyl esters showed each of them to be inferior to the glandular secretion in eliciting trail following. However, the mixture of racemic 4-methylgeranyl octanoate and the corresponding decanoate and dodecanoate, the main Dufour's volatile constituents, is as active as the natural secretion at similar concentration. We conclude that the trail pheromone constitutes a mixture of at least the 4-methylgeranyl esters identified in the gland. Since *G. striatula* generally preys on small arthropods rather than monopolizing large resources, we assume that trails are rarely used during foraging, but more often during nest migration. Production of new societies in this species is generally performed by budding, a period of considerable predation risk. Utilizing trails for efficient displacement in this context is, therefore, highly

adaptive. This behavioral repertoire may also provide the ants with additional means of food resource exploitation.

Key Words—*Gnamptogenys*, Dufour's gland, trail pheromones, 4-methylgeranyl esters.

INTRODUCTION

Mass recruitment of conspecifics to a food source constitutes a complex process that starts by alert behavior performed by scout ants, inducing the surrounding ants to exit the nest. Subsequently, these ants generally follow the chemical trail previously laid by the scout ant during its return from the food source. The information encoded in trail pheromones often constitutes several signals, such as excitatory (recruitment) cues that induce the ants to leave the nest as well as follow the trail, orientation cues that direct the ants to the food source, and often synergistic compounds that enhance recruitment. Ants use a variety of glands encompassing a plethora of compounds to mark their trails. Therefore, it is hard to predict which gland is used in a given species (Hölldobler and Wilson, 1990).

The trail pheromones of only a few ponerine ants have been disclosed. Most species utilize the poison gland exudate to mark the trail and often the pygidial gland for recruiting and inducing potential foragers to exit the nest. For example, in *Pachycondyla (Megaponera) foetens*, actinidine from the pygidial gland stimulates the ants to forage, while *N*,*N*-dimethyl uracil from the poison gland releases trail-following behavior (Janssen et al., 1995). Ponerine poison gland products can also be made up by propanoate units or originate from a mixed acetate–propanoate biosynthesis (Francke and Schulz, 1999). For example, *Leptogenys diminuta* uses (3*R*, 4*S*)-4-methyl-3-heptanol as a single trail pheromone component (Attygalle et al., 1988), whereas *L. peuqueti* uses a complex mixture of acetates and alcohols (Janssen et al., 1997). *Ectatomma ruidum* and *Gnamptogenys menadensis* are unusual among the ponerine ants investigated to date in employing Dufour's gland secretion for trail marking. All-*trans* geranylgeranyl acetate, the major component in the secretion of *E. ruidum*, is the most active, accompanied by the less active corresponding alcohol geranylgeraniol (Bestmann et al., 1995). Dufour's gland secretion of *G. menadensis* is typified by a mixture of straight-chain hydrocarbons and terpenes, with heptadecane and bishomo-β-farnesene as major components, respectively. Whether or not all of the glandular components or specific compounds comprise the active trail pheromone was not determined (Gobin et al., 1998).

The ponerine ant *Gnamptogenys striatula* belongs to the tribe Ectatommini and exhibits a derived social structure, similar to that of some "higher" ants (Blatrix, 2000). Colonies can contain up to 1200 workers, a large number for a ponerine, and 60 queens, about 60% of which are functional, resulting in one of the highest degrees of polygyny in ants (Blatrix and Jaisson, 2001). Most *Gnamptogenys*

species feed on small arthropods, and *G. striatula* is known to be a generalist predator (Lattke, 1995). Sweet liquids weakly attract workers, and predation on large arthropods (i.e., requiring several workers for transportation) has been observed only occasionally in the field (Blatrix, personal observation).

In this study, we investigated the glandular origin and chemical nature of the trail pheromone in *G. striatula*.

METHODS AND MATERIAL

Ants. Colonies of *G. striatula* were collected near Itabuna (Bahia, Brazil) and reared in the laboratory in artificial nests made of plaster of Paris. Extracts of various body parts were obtained by cutting frozen ants and crushing the appropriate body parts in pentane filled vials. Glandular extracts were obtained by dissecting frozen ants in distilled water under a stereomicroscope and placing the appropriate gland in pentane (0.1 body part or gland equivalents per microliter).

Chemical Analyses. For chemical analyses, pentane extracts were concentrated and analyzed by coupled gas chromatography mass spectrometry: A Hewlett-Packard gas chromatograph 5890 (Palo Alto, California, USA) was linked to a mass spectrometer VG 70/250 SE (Vacuum Generators, Manchester, UK) (Klimetzek et al., 1989). With helium as the carrier gas, separations were achieved with a 60-m $\times$ 0.25-mm-ID, 0.25-μm film DB5-MS fused silica column (J & W Scientific, Folsom, California, USA) under the following conditions: 2 min at 50°C, then programmed to 280°C at a rate of 5°C/min.

Quantification of Dufour's gland content was done by gas chromatography using pools of 10 glands extracted in pentane containing 100 ng of octadecane as an internal standard. The samples were run on a Hewlett-Packard gas chromatograph equipped with a DB-1 capillary column, temperature programmed from 110°C (1 min hold) to 300°C at 10°C/min. The total amount of glandular content was calculated by peak integration as compared to the internal standard.

Synthetic reference samples of racemic (2*E*,6)-3,4,7-trimethyl-2,6-octadien-1-ol (4-methylgeraniol) and (2*E*,6)-3,4,7-trimethyl-2,6-nonadien-1-ol, as well as corresponding fatty acid esters, were prepared according to known methods (Ohnuma et al., 1989; Schulz et al., 2002)

Bioassays. Artificial trails were made with 20 μl of the test solution applied on one arm of an ellipse (20 cm long) drawn on a sheet of paper (0.1 part or gland/μl). The other arm was applied with the control solution. A short trail before and after each ellipse was made with abdominal extracts (0.1 abdomen equivalents/cm; trail length 5 cm) because preliminary studies revealed that extracts of this body part induced the best trail-following behavior. Trails were applied 10 min before each test to allow the solvent and alarm eliciting substances to evaporate (unpublished data). For some tests, a circular area was marked (2.5 cm diam.) at the bifurcation point to assess the number of ants that congregated at that point before selecting

between the arms of the ellipse (decision circle). Adult dead *Drosophila* were provided at the end of the trail, but to prevent trail overmarking by returning ants, all the ants that held a prey between the mandibles were immediately aspirated. For each test, two successive ellipses were drawn creating two bifurcation points. Assignment of the arms (test or control) in each ellipse was at random.

Before each test, all foraging ants were confined within the nest and the nest entrance blocked until the beginning of the test. Trail following was measured by recording the number of ants on each arm of the ellipse and in the "decision circle" ("hesitating ants") every 15 sec during a 10-min test. The cumulative number (mean $\pm$ SD) of ants in each of the ellipse arms and the mean proportion of hesitating ants (= number of hesitating ants/total number of recorded ants during the test) in the decision circle served for scoring trail-following activity. The numbers of ants on each arm were compared with a Wilcoxon matched-pairs test.

RESULTS

In the preliminary tests, the ability of different body parts (head, alitrunk, and abdomen) to elicit trail following was tested against a pentane control. Since in all cases the ants preferred and followed the body part extracts over pentane, we modified the assay and tested the various body parts against each other (Table 1, tests 1 and 2). Abdominal extracts were more active than those from alitrunk or

TABLE 1. TRAIL-FOLLOWING RESPONSE OF WORKERS TO BODY PARTS OR GLANDULAR EXTRACTS[a]

Test	Extract	Cumulative number of ants on trail (mean $\pm$ SD)	*N*	*P*
1	Abdomen	22 ± 8	12	<0.01
	Alitrunk	7 ± 3		
2	Abdomen	45 ± 24	12	<0.01
	Head	13 ± 12		
3	Alitrunk	31 ± 18	12	<0.01
	Dufour's gland	62 ± 18		
4	Alitrunk	41 ± 19	12	NS
	Poison gland	33 ± 20		
5	Alitrunk	49 ± 24	12	<0.01
	Pygidial gland	13 ± 10		
6	Abdomen	58 ± 20	10	NS
	Dufour's gland	49 ± 15		
7	Poison + Dufour's glands	75 ± 23	12	<0.01
	Rest of the abdomen	46 ± 11		
8	Poison + Dufour's glands	48 ± 19	12	NS
	Dufour's gland	55 ± 23		

[a] The mean numbers of ants on each arm of the ellipse were compared by a Wilcoxon matched pairs test (N = number of tests performed).

heads. In the next set of tests, the activity of various abdominal glandular secretions was compared to the alitrunk extract. Only Dufour's gland was more active than the alitrunk, but the glandular secretion was still less active than the whole abdominal extracts (Table 1, tests 3–6). To assess whether more than one gland is involved in trail signaling, combined extracts of poison and Dufour's glands were compared to the rest of the abdomen. The combined glandular extract was more active than the whole abdominal extract. However, when the combined Dufour's–poison glands extract was tested against Dufour's gland extract alone, there was no preference between the two alternative trails (Table 1, tests 7 and 8). Thus, Dufour's gland secretion accounts for all the trail pheromone activity, and there is no synergism with the content of the poison gland.

Quantification of Dufour's gland secretion, based on pools of 10 glands, revealed an average of 173.1 ± 70 ng volatile constituents per gland. Chemical analysis of the glandular content by combined gas chromatography/mass spectrometry (GC-MS) showed the presence of a multicomponent mixture, dominated by esters of (2*E*,6)-3,4,7-trimethyl-2,6-octadien-1-ol (4-methylgeraniol) (Schulz et al., 2002). This homologous series of esters ranged from traces of the hexanoate to tridecanoate (including one decenoate and two dodecenoates), with the octanoate, the decanoate, and the dodecanoate esters as the major components (Figure 1, Table 2). A second series, comprising minute amounts of the octanoate,

the decanoate, and the dodecanoate of (2*E*,6)-3,4,7-trimethyl-2,6-nonadien-1-ol was also identified. Careful GC-MS analyses using synthetic reference samples proved the esters of the 2*E*,6*E* alcohol to be accompanied by even smaller amounts of the earlier eluting 2*E*,6*Z* stereoisomers. In addition, small amounts of geranyl decanoate and geranyl dodecanoate, octanoate, and decanoate esters of unknown terpenoid alcohols, unidentified terpenoids, and two straight chain aldehydes, octadecenal and eicosenal were identified in the secretion.

Synthetic racemates of the three major 4-methylgeranyl esters and two of the bishomogeranyl esters (Schulz et al., 2002; marked with an asterisk in Table 2) were bioassayed as described above. A mixture of the five esters at a concentration of 200 μg/ml each (total of 1 μg/cm trail) was more active than pentane (blank), and

induced trail following by the foragers. Moreover, there were no differences in trail following between the synthetic mixture and extracts of Dufour's gland (Table 3, tests 1 and 2). In order to determine the active threshold of the mixture, serial dilutions (1/100, 1/250, 1/500, 1/1000) of the original mixture were tested against pentane. At 1/250 dilution (4ng/cm trail), the synthetic mixture still induced trail-following behavior, but the number of ants that followed the trail was considerably reduced. On the other hand, a great proportion of the ants (0.78) congregated inside the circle drawn at the bifurcation point. Both parameters indicated that this dilution was nearly at the threshold concentration for response (Table 3). At lower concentrations, the ants were not able to detect the synthetic trail mixture. The number of ants in the test arm was small and not different from the control arm, and the proportion of hesitating ants increased considerably (1/500: 0.97, 1/1000: 0.94).

Tests with individual synthetic esters revealed that the 4-methylgeranyl esters were all active, with large numbers of ants following the synthetic trail and almost none the pentane applied arm (Table 4, tests 1–3). Of the bishomogeranyl esters, the decanoate was totally inactive (Table 4, test 4), whereas the dodecanoate ester was significantly more active than pentane (Table 4, test 5). However, in the latter case, the cumulative number of ants on the trail was low. There were no differences in the proportion of hesitating ants when tested with either of the bishomogeranyl esters, and in both cases the number was considerably higher when compared to any of the 4-methylgeranyl esters.

To verify that only the 4-methylgeranyl esters are active, two alternative trails, one containing 4-methylgeranyl decanoate and the second bishomogeranyl

TABLE 4. TRAIL-FOLLOWING RESPONSE OF ANTS TO PENTANE SOLUTIONS OF PURE RACEMATES OF SYNTHETIC ESTERS AND TO PENTANE EXTRACTS OF DUFOUR'S GLAND[a]

Test	Test solution	Proportion of hesitating ants[b]	Cumulative number of ants on trail (mean ± SD)	N	P

[b] For definition, see materials and methods.

decanoate, were offered to the ants. The ants followed the trail of 4-methylgeranyl decanoate without hesitation (Table 4, test 6). Further tests aimed at assessing whether the single synthetic compounds found to be most active (products 5, 11, and 19 in Table 2) are as active as the glandular secretion. Dufour's gland was superior to any of the three 4-methylgeranyl esters tested (Table 4, tests 7–9), but the mixture of all three products at a concentration of 10 ng/cm trail was as active as Dufour's gland secretion (Table 4, test 10).

DISCUSSION

Ponerine ants are known to use visual cues and tandem running as orienting systems, while species using trail pheromone are far less common. Trail strategy in ponerine ants seems to occur in three contexts: foraging on immobile and large quantities of resources, species with army-ant-like behavior, and colony migration.

In the case of foraging, species specialized on termite predation or nectar exploitation show well-defined trail-following behavior (Longhurst et al., 1979; Maschwitz and Schonegge, 1983; Hölldobler, 1984; Breed and Bennett, 1985). *Leptogenys diminuta* displays army ant habits and uses trails to conduct raids (Attygalle et al., 1988; Maschwitz et al., 1989), while other *Leptogenys* species use trails during colony migration. There are not enough field studies of *G. striatula*, to determine unequivocally when trails are mostly used. Although in our bioassay we tested trail following in a foraging context, this does not necessarily indicate that the ants use it in that context in the field. It is possible that ants reacted to the signal in a context-independent manner. On the other hand, since these ants are generalist predators of arthropods (Lattke, 1995) and rarely monopolize immobile and large quantities of resources or exhibit any army-ant-like behavior (Blatrix personal observation), we hypothesized that their use of trail pheromones in a foraging context should be rare. We believe that trail deposition in this species is largely linked to frequent nest moving, as was also suggested for *G. menadensis* (Gobin et al., 1998). Colonies are known to perform budding and frequent migrations (Giraud et al., 2000), which seem to be important traits of the life history of this species. Moreover, budding is probably the only way for colonies to multiply. Movement of the colony during budding or migration is risky because of predation, and it is expected to be efficient. We, therefore, hypothesize that orientation by a trail pheromone, rather than tandem running, has evolved in this species in relation to its particular life history.

Our findings demonstrate that Dufour's gland is the origin of the trail pheromone in *G. striatula*. This gland was also shown to be the source of trails deposited by *G. menadensis* and *E. ruidum* (Bestmann et al., 1995; Gobin et al., 1998), all of which belong to the tribe Ectatommini. Other species belonging to the subfamily Ponerinae, on the other hand, use poison and pygidial gland secretion for trail communication. This may indicate a phylogenetic trend in glandular usage, although the number of species studied so far is too limited for generalization. None of the other abdominal glands showed comparable activity. We also could not detect any synergism in trail following between the Dufour's and poison glands.

Chemical analysis of the glandular secretion revealed it to be dominated by series of esters of medium-chain fatty acids with either 4-methylgeraniol or bishomogeraniol. Despite being a rather complex mixture, three esters of 4-methylgeraniol, i.e., the octanoate, the decanoate, and the dodecanoate, comprised about 85% of the total secretion. The chemistry of Dufour's gland in *G. menadensis* differs from that of *G. striatula*, emphasizing the disparate chemical evolution of pheromones that took place in ants. While that of *G. menadensis* is equally rich in linear hydrocarbons and terpenes (Gobin et al., 1998), that of *G. striatula* is almost exclusively composed of terpenoid esters. The chemical disparity between the two *Gnamptogenys* species is not entirely surprising because, although they belong to a single genus, they are not phylogenetically closely related. Furthermore,

G. striatula is a South American species, whereas *G. menadensis* originates in Southeast Asia. Nonetheless, there seems to be consistency in the fact that Dufour's gland constituents represent acetogenines and/or mevalogenines, since the compounds of *G. striatula* represent an interesting combination of these two structural principles.

To ascertain the biological activity of the new natural products identified in Dufour's gland of *G. striatula* and further investigate the possible involvement of particular compounds, synthetic racemates of the three major 4-methylgeranyl and two of the bishomogeranyl esters were tested for trail pheromone activity. There was a clear difference in the activity of the two types of compounds. While the 4-methylgeranyl esters were highly active, bishomogeranyl decanoate was devoid of activity, and bishomogeranyl dodecanoate was only marginally active. It is worth noting that the bishomogeranyl esters were only minor or trace constituents in the secretion and perhaps can be regarded as by-product of the biosynthesis of the 4-methylgeranyl esters or as components of fine tuning in interspecific discrimination. The additional methyl group in bishomogeranyl esters lowered and even abolished trail pheromone activity, underlining the specificity of ant reactions to the active compounds.

From the results obtained with single compounds, it became evident that the pheromone represents a multicomponent mixture. While all of the single active substances were inferior to Dufour's gland secretion, the mixture, even at a lower concentration than the natural Dufour's gland constituents, was as active as the glandular exudates. Since the racemic mixture proved to be active while the natural compounds are represented by almost pure 4*S* enantiomers (Schulz et al., 2002), there are strong indications that, in contrast to many other chiral pheromones, the nonnatural antipode is either biologically inactive or that the configuration at the stereogenic center plays a minor role in trail pheromone activity. Similar phenomena are also known from other chiral semiochemicals and have been carefully reviewed (Mori, 1998). It is still unclear whether the different components delineate different information, or whether those facilitate trail specificity. More studies with closely related species from the same geographic region, as well as studies on the foraging and budding behaviors of *G. striatula* in the field are needed to clarify this point.

Abstract—Cuticular hydrocarbons were extracted from workers of 63 different nests of five species of *Tetramorium* ants (Hymenoptera: Formicidae) from Austria, Hungary, and Spain. The GC-MS data were classified (data mining) by self-organizing maps (SOM). SOM neurons derived from primary neuron separation were subjected to hierarchical SOM (HSOM) and were grouped to neuron areas on the basis of vicinity in the hexagonal output grid. While primary neuron separation and HSOM resulted in classifications on a level more sensitive than species differences, neuron areas resulted in chemical phenotypes apparently of the order of species. These chemical phenotypes have implications for systematics: while the chemical phenotypes for *T. ferox* and *T. moravicum* correspond to morphological determination, in *T. caespitum* and *T. impurum* a total of six chemical phenotypes is found. Three hypotheses are discussed to explain this disparity between morphological and chemical classifications, including in particular the possibility of hybridization and the existence of cryptic species. Overall, the GC-MS profiles classified by SOM prove to be a practical alternative to morphological determination (*T. ferox*, *T. moravicum*) and indicate the need to revisit systematics (*T. caespitum*, *T. impurum*).

Key Words—Self-organizing maps (SOM), *Tetramorium* ants, Formicidae, cuticular hydrocarbons, chemical signature, gas chromatography-mass spectrometry, data mining, systematics, hybridization, cryptic species.

INTRODUCTION

Many aspects of ant behavior such as conspecific and allospecific recognition (e.g., Errard and Vienne, 1994) and chemical mimicry (e.g., D'Ettorre and Errard, 1998) rely on a chemical signature in which hydrocarbons play a major role (Nelson and Blomquist, 1995). In central Europe, five species of *Tetramorium* ants are known: *T. caespitum*, *T. impurum*, *T. rhenanum*, *T. moravicum*, and *T. ferox* (Seifert, 1996). They belong to the *caespitum* group, which was not included in the fundamental worldwide revision of the genus (Bolton, 1980). Since then, the morphology (e.g., Schulz, 1996), genetics (e.g., Baur et al., 1996), and pheromones (e.g., Morgan and Ollett, 1987) of the central European *Tetramorium* species have been repeatedly investigated in systematic context. Nevertheless, the systematic position of these ants remains unclear (Seifert, 1996). Investigations on cuticular hydrocarbons of the central European species have not yet been undertaken. Morphological determination of the known species of this region is difficult and in some cases not unequivocal (e.g., Schlick-Steiner and Steiner, 1999).

Cuticular hydrocarbon profiles are species-specific (e.g., Bagnères and Morgan, 1991) and are, at least partially, due to genetic inheritance (Bonavita-Cougourdan and Clément, 1994, Dahbi et al., 1998). Furthermore, although our knowledge of the various roles played by hydrocarbons has increased steadily (Blomquist et al., 1998), GC-MS data of cuticular hydrocarbons have only rarely been used for systematic purposes in ants (Nowbahari et al., 1990), unlike in termites (e.g., Haverty et al., 1988) and bark beetles (e.g., Page et al., 1997).

So far, studies comparing different cuticular hydrocarbon patterns in social insects have used descriptive linear mathematical techniques (e.g., Haverty et al., 1990, Bonavita-Cougourdan and Clément, 1994) with the exception of Bagnères et al. (1998), who applied multilayer perceptron, i.e., a supervised artificial neural network, for caste separation within termite populations by using different selections of cuticular hydrocarbons as input.

Self-organizing maps (SOM) were introduced in 1981 (Kohonen, 2001) and represent a neural network algorithm based on unsupervised training (Kohonen, 2001). They have an immense advantage over supervised algorithms such as multilayer perceptron since the final target values of any vectors need not be known. Up to now SOM have been successfully used in numerous applications, including image analysis and exploratory data analysis. Therefore, they have become an important tool in data mining, in knowledge discovery in databases (KDD), and especially in assessing classifications.

In this work, we applied SOM based on a hexagonal output grid of 8×6 neurons for comparison and classification of components intensity profiles of GC-MS data of cuticular hydrocarbons from samples of four central European *Tetramorium* ant species. This investigation is part of a multidimensional approach to systematics and determination of the central European species of *Tetramorium*.

METHODS AND MATERIALS

Animals. Workers from a total of 63 colonies of *T. caespitum* ($N = 32$), *T. impurum* ($N = 13$), *T. moravicum* ($N = 13$) and *T. ferox* ($N = 4$) were collected in eastern Austria and Hungary (Table 1) between June and October 2000. One colony of *T. semilaeve* (Sant Cugat, Spain) was added as an outgroup. Ants were collected with an aspirator made of Teflon and glass components, which was frequently cleaned with *n*-heptane p.A., and then transferred to clean glass vials with Teflon-coated caps. After anesthesia by cooling to -21°C, the ants were stored at this temperature until further processing.

Morphological Determination. Nest series were morphologically determined according to the key in Seifert (1996).

Extraction of Cuticular Hydrocarbons. Ants were warmed to room temperature. Five workers from each colony that were ensured not to be callow workers [which have slightly different hydrocarbon profiles (Dahbi et al., 1998)], were extracted in 80 μl of *n*-heptane for 10 min, in order to obtain extracts robust to little variation of extraction time (Vander Meer et al., 1989). While in similar studies pentane (e.g., Nowbahari et al., 1990) or hexane (e.g., Vander Meer and Lofgren, 1985) were used, heptane combines the advantage of a higher boiling point and better quality of GC-MS data. In order to test reproducibility, we additionally extracted four single workers from at least one colony of each species.

GC-MS Analysis. Extracts were analyzed by coupled gas chromatography–mass spectrometry (GC-MS) on a Hewlett-Packard 5973 mass selective detector coupled with a HP 6890 GC-system. MS-spectra were recorded in EI mode at 70 eV, within a mass range of 40–500 mass units and a scan cycle time of 0.7 sec. A detector temperature of 250°C and an injector temperature of 300°C were chosen as GC conditions. A Carbowax column (25 m, 0.25 mm) was used. Temperature was programmed from 100°C to 150°C at 30°C/min and from 150°C to 300°C at 5°C/min. The carrier gas was helium (1 bar). A 1-μl sample was injected in splitless mode.

Profiling of GC-MS Data. For profiling (repeated comparison) of chromatograms, some suitably defined standard format as vector entities is necessary. At the onset, we used components intensity profiles of 71 and 41 selected components, respectively, i.e., a vector of dimensionality of 71 and 41, respectively. The GC-MS profile of a single sample with 71 components was used as primary or master GC after corresponding synchronization (using relative intensity normalization and a combination of "offset" and "stretch") with secondary GC (and in turn with all remaining samples) to detect these 71 peaks in secondary GC (and in turn in all remaining samples) and to determine their peak heights. MS data are not necessary for the generation of the resulting components profiles, but the mass spectra in the GC-MS data provide additional proof that the corresponding peaks are really derived from the same compound.

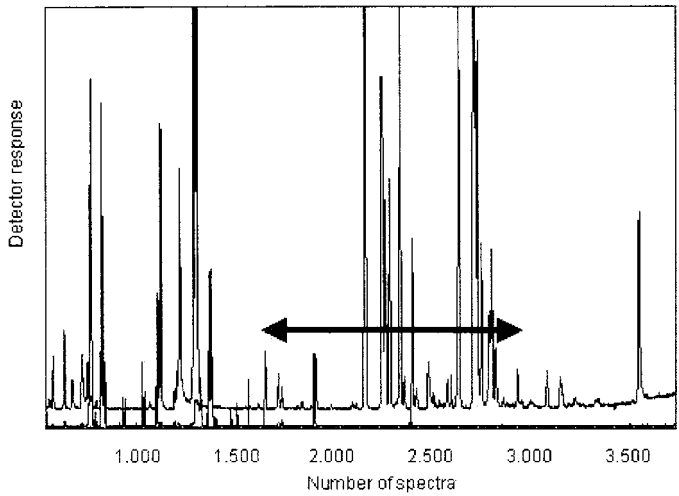

FIG. 1. The 41 hydrocarbon intensity peaks (peaks 26–66, range indicated by arrow) are selected for the final analysis by PCA and SOM; SID (single ion detection) for a fatty acid ethylester (below).

Selection of Hydrocarbons by PCA. To ensure that only hydrocarbons were selected in the data analysis, PCA was performed on mass spectra contributing to a given sample (relative proportions of all compounds $>0.2\%$ of TIC), sorting out fatty acids and all other compounds. Only the remaining 41 hydrocarbon intensity peaks (peaks 26–66 $=$ 41; Figure 1) were used for analysis. While the signature that is detected by nestmates and foreign individuals is an entire mixture of substances on the cuticular surface, our selection of a narrow band represents a compromise to optimally correlate the characteristics of the analytical interpretation with the morphological determination.

Self-Organizing Maps (SOM). SOM visualization was based on a hexagonal output grid of 8×6 neurons. Neurons of the first round (primary neuron separation), which contained at least three samples, were subjected to another round (hierarchical SOM, HSOM) of separation, resulting in subneuronal classification. Hexagonal output grid and u-Matrix were used for visualizing similarities between neurons and subneurons, respectively. According to these, neuron areas were formed for grouping of data on a higher scale.

RESULTS

Classification of GC-MS Data by PCA and SOM. PCA was not able to separate the samples when all components intensity peaks were included in data analysis. SOM led to a grouping of 26 neurons (Table 1). After selection of hydrocarbons

[a] Based on all 71 and on the selected 41 components intensity peaks; morphological determination, geographic origin, month of collection and number of extracted workers.

(reduction of components intensity peaks from 71 to 41) as described above, PCA was still not able to sort the data. SOM resulted in a total of 21 neurons (Table 1, Figure 2) visualized in a hexagonal output grid (Figure 3). HSOM (performed on the 12 primary neurons containing at least three samples) resulted in a total of 39 subneurons (2–5 subneurons per neuron, Table 1).

Correlations between Morphological Determination and GC-MS Profiles. As distance between neurons in the hexagonal output grid (Figure 3) reflects similarity of GC-MS data, neighboring neurons are grouped to neuron areas. Neurons containing only measurements of single workers are not taken into consideration. We define nine neuron areas (Figure 4): four areas, one for each of *T. semilaeve*, *T. moravicum*, *T. ferox*, and *T. caespitum*, and five neuron areas containing *T. caespitum* together with *T. impurum*.

Table 1 lists the neuronal classification of a total of 84 GC-MS profiles (60 profiles of five pooled workers, 24 profiles of single workers), the corresponding morphological determinations, and the sample sites. The four pooled samples of *T. ferox* are classified as belonging to neuron 19, those of *T. moravicum* (13 samples) to neuron 43. Furthermore, *T. semilaeve* from Spain, used as outgroup, was distinct (neuron 1) from the ingroup taxa. In contrast, samples morphologically determined as *T. impurum* are mixed together with some samples of *T. caespitum* in five neurons (neuron 5, 16, 21, 30, 46). The rest of the *T. caespitum* samples are classified into eight separate neurons (neuron 3, 29, 31, 41, 42, 44, 45, 47). Primary neuron separation partially seems to differentiate on a level that is more sensitive than the species level.

The subneuronal classification results in a high number of subneurons per species. The numbers of undivided entities (subneurons plus neurons contain-

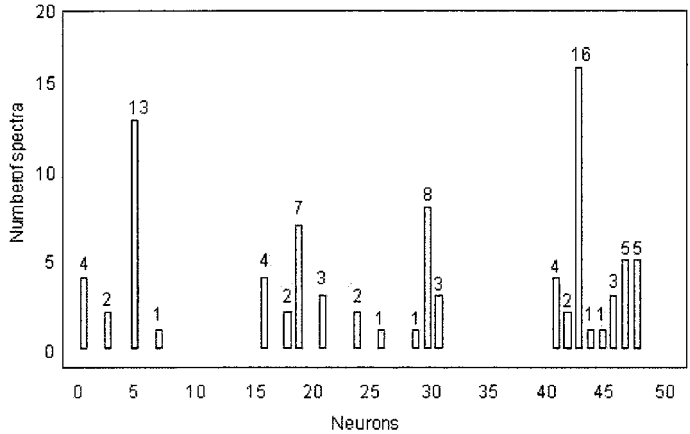

FIG. 2. Results of SOM based on 41 components intensity peaks of the 84 samples, visualized as number of samples per neuron.

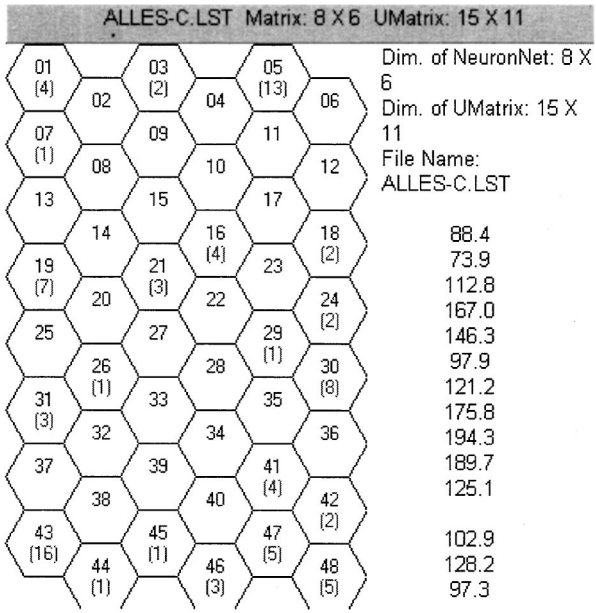

FIG. 3. Results of SOM based on 41 components intensity peaks of the 84 samples, visualized as hexagonal output grid. Numbers in hexagons: neuron number (above), number of samples per neuron (below).

ing less than three profiles, profiles of singular workers excluded) are 29 for *T. caespitum* (32 nests), 8 for *T. impurum* (12 nests), 9 for *T. moravicum* (13 nests), and 3 for *T. ferox* (4 nests), and the total number of undivided entities is 49, as Table 1 reveals. Nevertheless there still is one subneuron containing a profile of each *T. caespitum* and *T. impurum*. Overall HSOM seems to differentiate at a level much more sensitive than between species.

Correlations between Geographic Origin and GC-MS Profiles. There is no correlation between sampling sites and neuronal classification of the GC-MS hydrocarbon profiles. Instead, a case-by-case comparison of two conspecific nests (*T. caespitum*) from sampling sites about 80 km apart shows similar profiles (Figure 5) that are classified as neuron 3, which represents a separate neuron area. SOM analysis of the data set results in similar conclusions (Table 1): Different nests of *T. moravicum* (of which systematic status and morphological determination have never been questioned) from the same sampling site belong to different subneurons (TM20, TM21), while nests of *T. moravicum* from two sampling sites, 22 km apart, belong to the same subneuron (TM21, TM23).

Correlation between Date of Collection and GC-MS Profiles. According to the SOM analysis (Table 1), there is no evident correlation between the neuronal

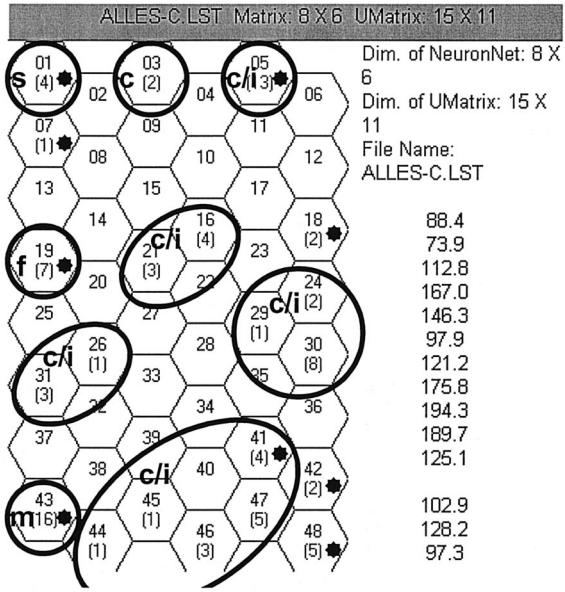

FIG. 4. Nine neuron areas are defined, based on the location of the neurons in the hexagonal output grid. Neurons containing exclusively single workers are not taken into consideration. (Numbers in hexagons: neuron number above, number of samples per neuron below, neurons containing samples of single workers marked with asterisks, c = *T. caespitum*, c/i. = *T. caespitum* and *impurum*, f = *T. ferox*, m = *T. moravicum*, s = *T. semilaeve*).

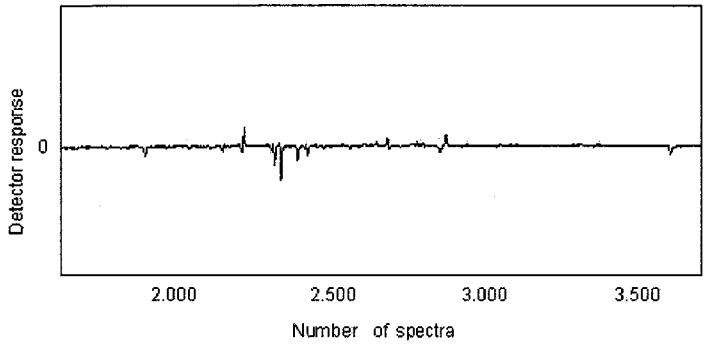

FIG. 5. Resulting residual intensities after subtraction of the two GC-MS components intensity profiles of TM47 and TM59.

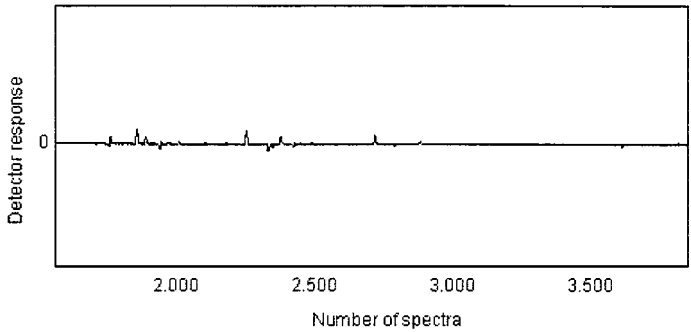

FIG. 6. Resulting residual intensities after subtraction of the two GC-MS components intensity profiles of TM42b and TM42c.

classification of the GC-MS hydrocarbon profiles and the date of collection. Different nests of *T. caespitum* sampled in the same location and on the same date (July 2) belong to different subneurons (TM40, TM41), while nests of *T. caespitum* collected in July and September belong to the same subneuron (TM41, TM47).

DISCUSSION

Reproducibility. For all species, four individual workers from the same nest were separately tested for the reproducibility of GC-MS measurements and similarity of profiles. The profiles of two *T. impurum* workers from the same nest are similar. After subtraction of one profile from the other, only weak residual intensities remain (Figure 6). However, this is not true in all cases: one of four single measurements of *T. ferox* and *T. moravicum* was classified as belonging to a different neuron. This result is surprising since the similarity of profiles of individual workers from the same nest has been proven repeatedly (e.g., Nowbahari et al., 1990). It is known that quantitative intracolonial variations may be due to different categories of workers (Bonavita-Cougourdan and Clément, 1994) and may be influenced by endoparasites (Trabalon et al., 2000). Yet, these factors cannot explain all the variation in our data set, as in some cases the variation exceeds the level of interspecific variation. One explanation for this may be related to the technical problem of measuring the level of chemicals in single workers due to a low intensity of component peaks. Measurements of single individuals are technically possible, but since they are accompanied by a reduced reliability, further consideration will be restricted to the pooled measurements of five workers only.

Comparison of PCA and SOM for Classification of Hydrocarbon Patterns. The results obtained by PCA and SOM reveal the greater ability of SOM to separate the data. PCA uses a simple projection of data points on a plane defined mostly

by the first and second eigenvectors, whereas SOM uses so-called weight vectors that are placed within and near the data vectors after the training epochs. The nearby locations in the input space correspond to the neighboring neurons. These weight vectors define centers of so-called Voronoi regions (Kohonen, 2001). The data within these are assigned to the particular weight vector and visualized by the particular net neuron; thus, the number of weight vectors equals the number of neurons. In the final state, the weight vectors are laid down like a flexible net over the hypersurface built by the data vectors. Thus, SOM reveals much more information about the structure of the data than PCA. In contrast, PCA is always totally reproducible, whereas visualization of SOM results is dependent in part on: (1) the structure of the SOM used, (2) the order of data input (because it is practically impossible to choose totally isotropic means of visualization and, therefore, the position of the neurons in the chosen means of visualization is slightly distorted), and (3) the number of training epochs.

Correlations between Geographic Origin and GC-MS Profiles. Dahbi et al. (1996) found marked quantitative differences between separate populations (600 km apart) of the ant *Cataglyphis iberica*. No population genetic data concerning the central European species of *Tetramorium* are available to decide whether the investigated nests of eastern Austria and Hungary belong to separate populations. Nonetheless, the distance between the sample sites of eastern Austria (maximum distances of 105 km) and the lack of geographic separation suggest that they belong to the same population. Whether the more distant nests of *T. caespitum* from Hungary (180 km to the next *T. caespitum* sample site in Austria) belong to a separate population cannot be decided on the basis of our data set. Since the differences of GC-MS data are of the same order of magnitude as those between the Austrian nests of *T. caespitum*, we think the differences found are not due to geographic variation but to other reasons. We conclude that all samples of each of the four species sampled in central Europe belong to a continuous population.

Correlation between Time of Collection and GC-MS Profiles. Quantitative variations between samples of one nest over a period of several months have been reported (Vander Meer et al., 1989; Nielsen et al., 1999). These investigations were designed to detect potential season specificity of hydrocarbon patterns in one species and, thus, it was important to collect samples at one particular date (Nielsen et al., 1999). We chose to collect samples over a five-month period to take into account possible seasonal variations and to detect differences among the *Tetramorium* nest profiles that may be due to phylogenetic distance. Because of this sampling strategy, significant differences in the hydrocarbon profiles should be more robust and stable to seasonal variations.

Chemical Phenotypes and Implications for Systematics. The GC-MS profiles of the samples in the nine neuron areas, which we defined (Figure 4), are distinct enough to be considered as chemical phenotypes. The morphologically determined *T. moravicum*, *T. ferox*, and *T. semilaeve* coincide with distinct chemical

phenotypes. However, this is not the case for *T. caespitum* and *T. impurum*, where six distinct chemical phenotypes occur that are characterized by quantitative and qualitative differences. So far, only quantitative variations among conspecific workers of different colonies are known (Morel et al., 1988, Yamaoka, 1990, Bonavita-Cougourdan and Clément, 1994, Nielsen et al., 1999). Our results contradict Billen et al. (1986), who found that contents of Dufour glands of workers of *T. caespitum* and *T. impurum* from England, Belgium, and France are similar, but species-specific. Our results support the findings of Schlick-Steiner and Steiner (1999), where morphological determination of nest series of *T. caespitum* and *T. impurum* from Vienna was not unequivocally possible in all cases. Although only two ant species are concerned, the SOM analysis reports the occurrence of six chemical phenotypes. Biological explanations for this are discussed in the following three hypotheses.

1. The theory of a species-specific cuticular hydrocarbon profile could not be demonstrated for these species. This hypothesis is unlikely and does not hold true for the central European species *T. moravicum* and *T. ferox*, which partially occur syntopically with *T. caespitum* and *T. impurum*. In fact, it would contradict all published ethological and sociobiological findings in this field (see references in the introduction).

2. A natural hybridization of *T. caespitum* and *T. impurum* occurs. This phenomenon has been shown to exist in ants by chemical, genetic, and morphological means [e.g., *Solenopsis invicta* and *S. richteri* (Vander Meer and Lofgren, 1985; Diffie et al., 1988; Ross et al., 1987), *Leptothorax nigriceps* and *L. unifasciatus*, (Seifert, 1984)]. In the case of *S. invicta* and *S. richteri*, it was more evident from the GC-MS data of the cuticular hydrocarbons, since a clear intermediate chemical phenotype existed that combined components of both species. However, this does not necessarily occur with hybrids, especially when the hybrids are fertile in two or more generations, as discovered by Buschinger (2001) when back-crossing occurs and when the chemical signature is expressed in a dominant–recessive mode. If this hypothesis is true, *T. caespitum* and *T. impurum* would remain as valid systematic entities. It can be expected that morphological characters for the determination of hybrids will be found, as they are known for hybrids of other ant species [e.g., *Formica rufa* x *polyctena* (Seifert, 1996)].

3. One or more cryptic species exists. Morphological analyses of central European ants have repeatedly split up frequently occurring species into one or more species [*Lasius niger* and *L. platythorax* (Seifert, 1991); *Lasius alienus*, *L. paralienus*, and *L. psammophilus* (Seifert, 1992)]. In addition, the application of methods from other disciplines further facilitates our knowledge of systematics at this high level [Haverty et al. (1988) for termites, Pinto et al. (1997) for Trichogrammatidae, Nowbahari et al. (1990) for the ant *Cataglyphis cursor*]. If this hypothesis is true, it would entail many changes in systematics and determination.

Hence, while recognizing the need for other analyses, especially on morphology and genetics, to evaluate these hypotheses and, in general, to elucidate the condition of *Tetramorium* spp. in central Europe, the results of the presented SOM classification will be used as a basis on which to map further results. The rather intuitive approach of SOM (cf., Kohonen, 2001) facilitates positing hypotheses, which by further approaches can be verified, modified, or completely falsified. In a similar way, classification by SOM can be readily applied to other chemical, ecological, and systematic studies of social insects, in particular where prior work on clearly identifiable groupings is absent. Furthermore it could be tested in neighboring fields such as population genetics.

Acknowledgments—This work is part of an interdisciplinary project of the University of Agricultural Sciences, Vienna. We are grateful to Xavier Espadaler (Universitat Autonoma, Barcelona) for obtaining live specimens of *T. semilaeve*, to Robert Wagner (University of Vienna) for GC-MS measurements, and to Bernhard Seifert (Museum of Natural History, Görlitz), Alfred Buschinger (Technical University, Darmstadt), and Erhard Christian (University of Agricultural Sciences, Vienna) for valuable discussions, as well as to John Plant (University of Vienna) for linguistic revision.

(Received July 19, 2001; accepted August 6, 2002)

Abstract—The red imported fire ant *Solenopsis invicta* Buren, has evolved sophisticated chemical communication systems that regulate the activities of the colony. Among these are recruitment pheromones that effectively attract and stimulate workers to follow a trail to food or alternative nesting sites. Alarm pheromones alert, activate, and attract workers to intruders or other disturbances. The attraction and accumulation of fire ant workers in electrical equipment may be explained by their release of pheromones that draw additional worker ants into the electrical contacts. We used chemical analysis and behavioral bioassays to investigate if semiochemicals were released by electrically shocked fire ants. Workers were subjected to a 120 V, alternating-current power source. In all cases, electrically stimulated workers released venom alkaloids as revealed by gas chromatography. We also demonstrated the release of alarm pheromones and recruitment pheromones that elicited attraction and orientation. Arrestant behavior was observed with the workers not electrically stimulated but near those that were, indicating release of unkown behavior-modifying substances from the electrically stimulated ants. It appears that fire ants respond to electrical stimulus by generally releasing exocrine gland products. The behaviors associated with these products support the hypothesis that the accumulation of fire ants in electrical equipment is the result of a foraging worker finding and closing electrical contacts, then releasing exocrine gland products that attract other workers to the site, who in turn are electrically stimulated.

Key Words—Semiochemicals, pheromones, alarm, attraction, electric field, fire ant, behavior, recruitment.

INTRODUCTION

The red imported fire ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae), occurs in densities at least five times greater in the southern and southeastern United States than in its native South American habitat (Porter and Savignano, 1990; Porter et al., 1992). This large biomass of aggressive fire ants dominates the ecological community (Porter and Savignano, 1990) and interferes with human activities (Lofgren, 1986). One unusual effect on human activities is fire ant damage to electrical equipment, in which large numbers of ants invade outdoor electrical apparatuses, create short-circuits, foul conductive materials, and jam internal mechanisms (Eagleson, 1940; Vinson and MacKay, 1990), all of which can lead to destruction of circuitry.

Alternating-current frequencies, heat, ozone, magnetic fields, and wire insulation have no effect on ants (MacKay et al., 1989). Fire ants were initially reported to be attracted to electrical fields along with several other ant species (MacKay et al., 1992a,b). However, Slowik et al. (1996) reported that fire ants are not attracted to electrical fields, but instead probably release chemicals that excite and attract other ants to the release site after ants contact bare, bridgeable conductive surfaces, such as exposed wires or contact points.

Electrical stimulation of worker ants causes incapacitation, death, and aggression towards sister workers (Slowik et al., 1996). In addition, both voluntary (not induced by electrical stimulation) and involuntary (displayed by electrically stimulated ants) "gaster-flagging" was observed (Obin and Vander Meer, 1985; Slowik et al., 1996). Gaster flagging signals the release of defensive venom alkaloids (Obin and Vander Meer, 1985). Therefore, the release of semiochemicals by electrically shocked worker ants in the vicinity of infested circuitry may cause destructive aggregations of fire ants in electrical equipment (Slowik et al., 1996).

Pheromonal chemical cues are the most important form of communication among ants (Vander Meer and Alonso, 1998), and several pheromone systems of *S. invicta* have been investigated. For example, an alarm/excitant pheromone is involved in mating flight activity (Obin and Vander Meer, 1994; Alonso and Vander Meer, 1997). A recruitment pheromone is produced by the Dufour's gland and is released via the sting apparatus (Wilson, 1959). This complex recruitment pheromone system has several concentration- and context-related functions. Pheromones attract workers (Vander Meer et al., 1988), modulate their general responsiveness [i.e., orientation induction (Vander Meer et al., 1990)], and orient workers along a pheromone trail to food (Vander Meer et al., 1981). Fire ant venom is primarily composed of piperidine alkaloids, readily analyzed and well characterized (MacConnell et al., 1971; Leclercq et al., 1994). Venom functions in defense against intruders, in procurement of prey, and as an antimicrobial agent to maintain hygienic conditions within a colony (Obin and Vander Meer, 1985).

Venoms of other social hymenopterans such as bees, wasps, and hornets can be experimentally collected by electrical stimulation (O'Connor et al., 1963). In the field, honeybees (*Apis mellifera* L.) housed near extra-high-voltage power lines are induced to sting and release venom when electrified by as little as 900 nA of current after alighting on wet hive entrances (Bindokas et al., 1988). Fire ants, like honeybees, may also release venom and perhaps other semiochemicals when electrically shocked. These released chemicals might contribute to the observation that large masses of fire ants are often found in electrical circuitry, causing the equipment to malfunction (Vinson and MacKay, 1990). We report here the results of experiments that investigate, through behavior-specific bioassays and chemical analyses, what pheromones or semiochemicals are released by electrically stimulated fire ants.

METHODS AND MATERIALS

Source of Monogyne Solenopsis invicta Colonies. Queenright monogyne *S. invicta* colonies were obtained by rearing colonies from newly mated queens or by excavation of field nests. Monogyne colonies from the field were characterized by low mound density, well-developed large nests, polymorphic characteristics of colony workers (Greenberg et al., 1985), no more than one queen found, and a high level of intraspecific aggression (Morel et al., 1990). Excavated field colonies were brought to the laboratory only if the colony queen was found, and then the colony workers and brood were isolated by a standard float-out procedure (Banks et al., 1981). All colonies isolated after excavation were placed in plastic rearing trays (52 × 39 × 7.5 cm). Inside walls of trays were painted with Fluon (Dupont, Wilmington, Delaware, USA) to keep ants from escaping. Each colony was provided with Petri dish nest cells (14 cm diam. × 2.5 cm deep) with a Castone substrate (Dentsply Co., York, Pennsylvania, USA) and cotton-stoppered water tubes (Obin, 1986). Colonies were reared on crickets and 10% sugar water absorbed in wads of tissue. Rearing temperatures were maintained between 21 and 28°C, and the light–dark cycle was variable.

Preparation of Electrical Wire. A standard receptacle plug was attached to one end of common electrical cord (ca. 2 m). At the other end of the cord, ca. 2 cm of insulation was removed. Separately, insulation was stripped from 18-gauge wire, except for 5 mm on one end. The 18-gauge wire was soldered to the available end of the common electrical wire. Heat-shrink Teflon tubing was placed over each of soldered connections and wrapped with electrical tape. A piece of heat-shrink Teflon tubing was also placed over the wire ends that still had a small amount of insulation remaining. This functioned to hold the wires ca. 1 mm apart. The bare wires (5 cm long) were bent appropriately to better contact the floor and side of the test vial (20-ml scintillation vials), taking care to keep them 1 mm apart and

not touching each other. Wires were energized by plugging the electrical cord plug into an adjustable power supply containing a 1-A fuse that was connected to a standard 120 V, alternating-current power source.

General Experimental Procedure. Test worker ants (ca. 50) were randomly selected from laboratory-maintained monogyne *S. invicta* colonies (see above) and placed into 20-ml scintillation vials that had their inside lip painted with Fluon to help keep the ants inside the vial. The vial was clamped to a ring stand for stability. The wire was plugged into the adjustable power supply and gently inserted into the vial of ants. Ants were allowed to settle down without electrical stimulation for at least 15 min. The power was turned on and adjusted to 110 V. Ants walking across both bare wires would complete the electrical circuit and become electrically stimulated. After 2 min, the power was turned off and the ants were removed from the wire and vial with feather forceps. The bent end of the wire was placed on the lip of a clean and labeled 20-ml scintillation vial. Hexane (Burdick and Jackson, Muskegon, Michigan, USA; GC^2 grade) was added to the top of the bare wire one drop at a time with a disposable Pasteur pipet and allowed to run down the length of the wire to the bend where it dropped into the vial. This was repeated several times to ensure that all potential compounds released by the ants were removed from the wire. The hexane wire rinse was transferred to an autosampler vial for analysis by GC or for bioassay. The vial in which the worker ants were electrically stimulated was also carefully rinsed with hexane and subjected to chemical analysis or bioassay. If headspace samples (air in the vial) were needed, the vial in which the ants were electrically stimulated was immediately capped after the ants were removed. The procedure for the alarm bioassay is described in detail below.

Analysis of Venom Alkaloids and Cuticular Hydrocarbons. Immediately after an electrical stimulation treatment or control was complete and the worker ants were removed, 10 μl of a 100 ng/μl hexane solution of *n*-tetracosane were added to the test vial as an internal standard. Similarly, prior to rinsing the treatment or control electrical wire with hexane, 10 μl of a 100 ng/μl hexane solution of *n*-tetracosane were added to the collection vial as an internal standard. After addition of the internal standard, the treatment or control samples were treated as described above. Prior to GC analysis, all samples were brought to a volume of 100 μl and transferred to 300-μl autosample inserts.

Gas chromatography (GC) was carried out with a Varian 3700 (Varian, Palo Alto, California, USA) gas chromatograph equipped with a flame ionization detector and a split/splitless injector operated splitless for 0.33 min after which the splitter was turned on (90:1 ratio). Injector and detector temperatures were 300°C. Samples were injected into the system using an autosampler (Leap Technologies, Chapel Hill, North Carolina, USA). Analyses were performed on a DB-1 fused silica column (0.32 mm ID $\times$ 30 m; 0.25-μm film thickness; J & W Scientific, Folsom, California, USA). The oven was programmed from 150 to 285°C at 10°C/min with a 2-min hold. Data were analyzed with Turbochrome Workstation

Version 6.1.0.1 (Perkin Elmer, Norwalk, Connecticut, USA). Peak assignments for the venom alkaloids and cuticular hydrocarbons were based on the GC analysis of authentic *S. invicta* alkaloids and hydrocarbons obtained by overnight soaking of *S. invicta* workers in hexane (see Vander Meer et al., 1985; Ross et al., 1987).

Preparation of Poison and Dufour's Gland Extracts. The poison gland and the Dufour's gland are attached to the sting apparatus. The poison gland produces the piperidine alkaloids that are used by workers in defense and prey procurement. The Dufour's gland is located at the base of the sting and its products exit to the outside via the sting. The Dufour's gland is the source of the fire ant recruitment pheromone. The worker sting apparatus was removed in water with the aid of a dissecting microscope (Leica MZ-8, Heerbrugg, Switzerland) by placing and holding the ant in the water ventral side up. With another pair of forceps, the sting apparatus was removed by grabbing the last segment of the abdomen and pulling it out along with the sting apparatus. Once removed, the fat bodies were taken away, exposing the two glands. At this point, either gland could be obtained by pinching it off where it attaches to the sting apparatus. Excess water was removed by touching the gland carefully to a piece of tissue. The gland was transferred to a probe, then into a vial containing hexane where it was macerated. The volume of hexane was adjusted to give the required concentration in terms of gland equivalents.

Alarm Bioassay. Worker groups were taken from each of 15 mature monogyne *S. invicta* colonies maintained in the laboratory. Approximately 100 workers and a small amount of brood from each colony were placed in small plastic tray ($7 \times 22 \times 5$ cm), whose inner sides were painted with Fluon to prevent escape. The bottom of one half of the tray was covered with a thin layer of moist Castone. Red cellophane was placed over the Castone end of the tray to induce the workers to settle down with their brood. After the ants settled down (at least 30 min), the red cellophane was carefully removed. Tests were carried out only on subcolonies that were calm.

The bioassay required an observer and an assistant. The assistant prepared test samples for the observer so that the observer did not know the sample identity. Test samples consisted of 3 ml of air or headspace (vapor above a sample contained in a vial) drawn into a syringe (5 ml, plastic, Henke-Sass Wolf Co., Tuttlingen, Germany). The assistant randomly assigned each sample to a worker group, so that all worker groups were tested with each of the test samples and controls. The observer positioned the syringe 1–2 cm directly above a selected quiescent worker group, then 1 ml of vapor was slowly released over the workers. Prior to the actual test, the observer determined the blank air release rate that did not initiate a reaction from the worker ants. Reactions were rated on a scale of 1–4 (1 = no reaction, 2 = no more than raised heads and/or antennation of the air, 3 = one worker reacted with rapid movement, and 4 = several workers exhibiting an excited reaction). All tests were conducted with a room temperature of 28°C and standard overhead fluorescent lighting.

Air from an empty vial was tested as a negative control, and 10–25 workers (shaken) were used as a positive control. Shaking disturbed the workers and induced them to release alarm pheromone. Only those series of tests in which appropriate reactions to the negative and positive controls were obtained were used for analysis. Each replicate from a treatment was assayed at least five times, as were the negative and positive controls. We found that greater consistency was obtained for the positive control if there was a vial of workers for each replicate. The following treatment samples were evaluated: Electrically stimulated ants (stimulation time 120 sec); electrically stimulated ants (20 sec); shaken ants (with vial lid off for 120 sec); shaken ants (vial lid off $<$10 sec); and poison sac contents (1 gland equivalent/10 μl hexane absorbed onto a filter paper strip, solvent allowed to evaporate and placed in the bottom of a bioassay vial, headspace taken immediately).

The McNemar test for significance of changes (Sokal and Rohlf, 1981) was used for analysis of the alarm reaction bioassay data. For this analysis, scores of 1–2 were considered no reaction, and 3–4 were counted as alarm. The number of worker groups that displayed an alarm reaction to the test sample but not to the negative control was compared to the number of worker groups that reacted to the negative control but not to the test sample.

Orientation Bioassay. The orientation bioassay presumably measures the ability of workers to detect and follow a chemical trail. The procedure was a modification of that described by Barlin et al. (1976) and Jouvnenaz et al. (1978). Queenright, monogyne colonies were used in the bioassay. The orientation bioassay apparatus consisted of a ramp leading to a test platform (7.5 $\times$ 10 cm), which was connected by a tongue depressor to a similar size platform on which were food items, e.g., crickets or a cotton ball saturated with honey–water (1:1). The legs of the two platforms were painted with Fluon, which forced the ants to move up the ramp and across the test platform to the food platform. A piece of plain paper (7.5 $\times$ 10 cm) was placed on the test platform. The above-described apparatus was set up on a colony tray floor, and worker ants were given time to develop a natural trail to the food platform. Test pieces of paper were prepared by lightly marking in pencil two arcs on opposite sides of the paper from the center of one end to the center of the other end. Test solutions (10 μl) were streaked evenly along one of the arcs, and the appropriate solvent control streaked along the other arc. The test paper was air-dried for about 20 sec, then the natural trail paper on the test platform was replaced with the test paper. If, within 3 min, one ant followed the treatment arc from start to finish, the test was considered positive. A negative test was characterized by confusion at the two trail ends. Samples evaluated were the wire rinse (A) and the vial rinse (B) from electrically stimulated workers in the vial, the wire rinse (C) and vial rinse (D) from nonelectrically stimulated workers in a vial, and (E) the hexane vial rinse of worker ants in a vial without the wire. There were five replicate samples for each of the treatments. All samples

from electrically stimulated ants were adjusted to 250 μl total volume of hexane prior to use. Samples that did not give a positive orientation bioassay were concentrated to 50 μl volume and retested in the bioassay. If the samples did not show activity at this concentration, they were assumed to not have measurable activity.

The Dufour's Gland Equivalents Released by Electrically Stimulated Ants. Samples that showed positive orientation bioassay activity were systematically diluted with hexane until the samples were inactive. Dufour's gland extracts were prepared at a starting concentration of 1 Dufour's gland equivalent (DE) per 10 μl. Serial (1:2) dilutions were made with hexane, and orientation bioassays conducted until the extract was inactive. This was repeated three times. The Dufour's gland equivalent deposited by electrically stimulated ants on the wire and in the vial was determined by comparing the last active concentration of Dufour's gland extracts with the last active dilution of the wire and vial samples from electrically stimulated ants. Knowing the starting volume and the dilution regime allowed the estimation of Dufour's gland equivalents in the wire and vial samples.

Olfactometer Bioassay. A Y-tube olfactometer was used to determine if attractant compounds were released by electrically stimulated worker ants. The bioassay apparatus was similar to that described by Vander Meer et al. (1988). The positive standard was 0.3 queen equivalents of dissected and extracted queen poison sacs (poison sacs from 10 polygyne queens in 300 μl of hexane), the source of the queen attractant pheromone. A null hypothesis of equal numbers of ants in each arm was tested with chi-square analysis. Samples collected from electrically stimulated worker ants were evaluated in the olfactometer bioassay only if a positive response was obtained in the orientation bioassay, since workers are 200–300 times more sensitive to recruitment pheromone in the orientation bioassay than in the olfactometer bioassay (Vander Meer, 1986).

RESULTS

The Ant Response. Worker ants calmly walked on the vial surfaces prior to energizing the bare copper wires that were in the test vials. On energizing the system, worker ants bridging the two wires responded by gaster flagging, curling their gaster toward the wire in a stinging movement, and rapid, random movement in the vial. Other workers that were not initially electrically stimulated, reacted with alarm behaviors, including gaster flagging, and moved excitedly toward the wires, where if they made contact with both wires, they too were induced to exhibit the defensive behaviors described above. Interestingly, before the end of the bioassay (2 min), worker ants not on the wire aggregated quietly away from the wire ends. This was in sharp contrast to their rapid movement at the beginning of the test. Approximately 15–25 workers were electrically stimulated during the 2-min course of the experiment (mean $\pm$ SE: 22.8 $\pm$ 1.26 workers, $N = 8$). Some

of these workers did not survive the treatment. The observed reaction of the ants to electrical stimulation suggested that we could expect to find venom alkaloids and evidence for the release of alarm pheromones.

Venom Alkaloids and Cuticular Hydrocarbons. Both classes of compound can be readily analyzed by GC in a single chromatogram (Ross et al., 1987). All expected piperidine alkaloid components (six) characteristic of *S. invicta* were found. The quantitative results for the venom alkaloids are shown in Figure 1. The total amount of venom alkaloid from the wire rinse of electrically stimulated ants was greater than the treatment vial rinse (mean ± SE: 3.33 ± 0.56 μg vs. 0.23 ± 0.04 μg; $N = 5$ and 4, respectively; unpaired t test, $df = 7$; $t = 4.905$, $P = 0.002$) and by inference any of the controls (see Figure 1). This is a direct reflection of the observed worker defensive behaviors induced by electrical stimulation. The wire was the main target of the ants, but gaster flagging and venom-throwing may have also distributed venom onto the inner walls of the vial. In addition, some worker ants not on the wire may have been stimulated to release venom into the vial. The amount of venom found in the treatment vials also was greater than any of the control samples (treatment vial rinse vs. control wire rinse: mean ± SE: 0.23 ± 0.04 μg vs. 0.06 ± 0.01 μg; unpaired t test, $df = 7$, $t = 5.939$, $P = 0.002$). The amount of alkaloid found on the control wire and in the control vial were not

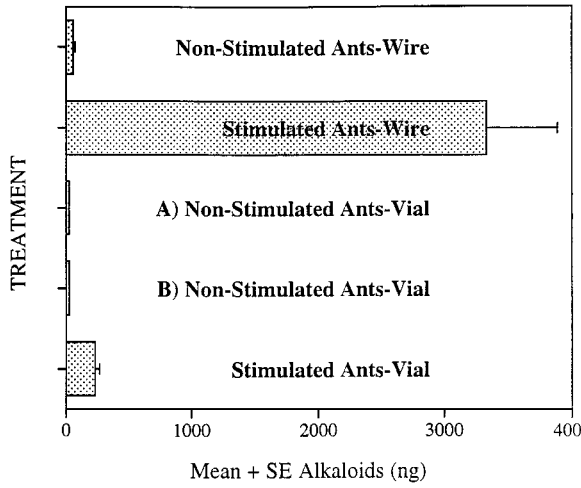

FIG. 1. Results are shown for the quantitative analysis of *S. invicta* venom alkaloids found on the wire or the vial for the control and treatment samples indicated. (A) "Non-stimulated ants-Vial" is the vial rinse that matches the "Non-Stimulated Ants-Wire" sample. This control had the wire inserted as in the electrically stimulated samples but the wire was not energized. (B) "Non-stimulated Ants-Vial" was a control that had worker ants, but did not have the wire inserted. $N = 5$.

different (unpaired t test, $df = 7$, $t = 2.127$, $P = 0.066$). Perhaps the disturbance of putting the wires into the vials with ants induced some of the workers to attack and release some venom on the wire. The mean amounts of venom in control vials were the same regardless of whether the wires were inserted or not (mean $\pm$ SE: 0.03 ± 0.01 μg vs. 0.03 ± 0.01 μg, respectively).

The principal source of cuticular hydrocarbons are from the cuticle of the insect; however, in most ants, including the fire ant, a cephalic lumen, called the postpharyngeal gland, is a copious source of the same hydrocarbon components that are found on the cuticle (Soroker et al., 1994). In our electrical stimulation experiments, the hydrocarbons could be passively transferred from worker cuticle to the wire and/or vial or they could be regurgitated from the postpharyngeal gland through the pharynx and mouth to the wire or vial substrate. Treatment and control vials did not differ in the total amount of cuticular hydrocarbons deposited in the vial during the 15-min acclimation time and the 2-min treatment time (mean $\pm$ SE: 77.0 ± 18.3 ng vs. 78.5 ± 10.4 ng; unpaired t test, $df = 7$, $t = -1.451$, $P = 0.944$).

Alarm Bioassay. Figure 2 shows the results of initial bioassays aimed at determining if electrically stimulated ants released alarm pheromone. Headspace

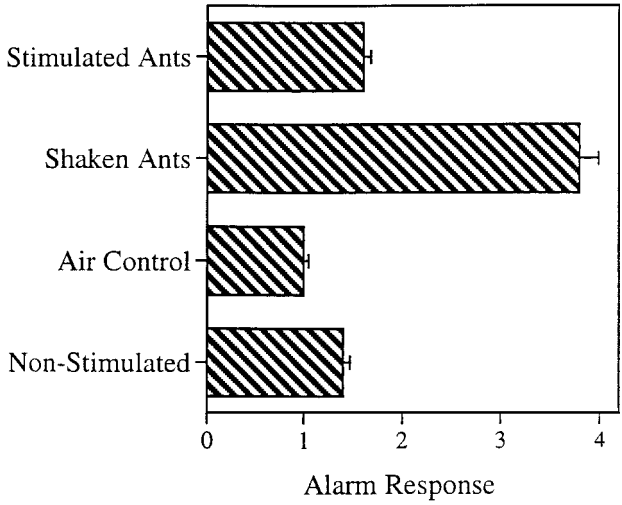

FIG. 2. Alarm bioassay results for headspace from vials in which worker fire ants were electrically stimulated and three controls. Shaken ants represents a positive control. Non-stimulated worker samples are a negative control, and laboratory air is another negative control. The results show that under standard experimental conditions the headspace above electrically stimulated ants does not elicit an alarm response in the alarm bioassay. Results are shown as the mean and SE of 10 replicates.

samples from electrically stimulated ants did not elicit a significantly different alarm reaction from workers than the nonelectrically stimulated controls (McNemar test: $G = 1.04$, $P > 0.05$; $N = 25$), but was different from the shaken ant positive control (McNemar test: $G = 18.5$, $P < 0.001$; $N = 25$). These results did not correspond to expectations based on behavioral observations.

Figure 3 shows the results of shaking worker ants in the vial (positive control) and then not sampling the opened vial for 2 min, the normal duration of the electrical stimulation. Allowing the volatiles generated from the shaken ants to dissipate for 2 min gave a result different from the positive control of shaken ants with the headspace sample taken immediately (McNemar test: $G = 13.86$, $P < 0.001$; $N = 10$). The results for shaken ant samples allowed to stand for 2 min was no different from the unshaken ant negative control (McNemar test: $G = 0$; $P > 0.05$; $N = 10$). Based on this result, we modified our electrical stimulation time to 20 sec, immediately after which the wire was removed and headspace samples were withdrawn for evaluation in the alarm bioassay. The results are shown in Figure 4. The electrically stimulated (20 sec) headspace samples elicited greater alarm response than the appropriate nonstimulated control (McNemar test: $G = 13.86$, $P < 0.001$; $N = 10$; mean $\pm$ SE: 3.9 ± 0.10 vs. 1.4 ± 0.16, respectively). However, there were no differences between the headspace samples of electrically

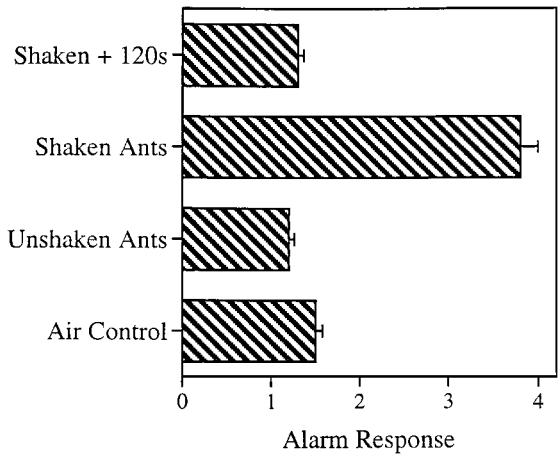

FIG. 3. Alarm bioassay results for headspace from vials in which worker fire ants were shaken to release alarm pheromone. For shaken ants (positive control) the headspace sample was taken immediately after shaking. Samples represented by shaken + 120 sec were shaken as above but the vial was left open for 120 sec prior to taking the headspace sample. Unshaken worker samples were a negative control as was laboratory air. The results show that while shaken ants release alarm pheromone, the pheromone components are highly volatile and evaporate by 120 sec after shaking. Results are shown as the mean and SE of 10 replicates.

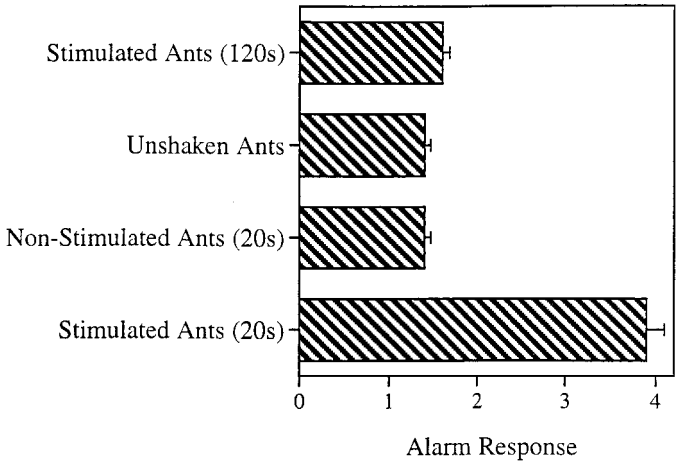

FIG. 4. Alarm bioassay results for headspace from vials in which worker fire ants were electrically stimulated for 120 sec and 20 sec. Unshaken ants was a negative control. Non-stimulated ants (20 sec) was another control where the nonenergized wire was inserted into the vial with worker ants and the headspace sample was taken after 20 sec. The results demonstrate that the alarm pheromone is released early during the electrical stimulation and evaporates out of the vial by the end of the standard 120-sec electrical stimulation time period. Results are shown as the mean and SE of 10 replicates.

stimulated workers and the headspace from the positive control, shaken workers (McNemar test: $G = 1.39$, $P > 0.05$; $N = 10$).

To test whether or not the venom alkaloids were responsible for the observed alarm activity, we applied one poison gland equivalent to a piece of filter paper, allowed the hexane to evaporate, and placed the paper into a typical bioassay vial (20 ml). The vial was capped and the headspace associated with that vial was tested for alarm activity. There was no difference between the air control and the headspace from above the poison sac samples (McNemar test: $G = 1.39$, $P > 0.05$; $N = 10$). Thus, we demonstrated that the contents of the poison sac (primarily venom alkaloids) were not responsible for the alarm response.

Orientation Bioassay. The orientation bioassay results are shown in Figure 5. All hexane rinse samples (wire and vial, $N = 5$) from electrically stimulated ants gave positive orientation bioassay results. The assay provides a "yes" or "no" answer to orientation activity. We calculated the DE by comparing electrically stimulated ant sample (wire and vial hexane rinses) bioassay results with results from Dufour's gland extracts at known volume and DEs. Both electrically stimulated ant samples and the Dufour's gland samples were systematically diluted until orientation activity was lost. The mean last positive bioassay for the Dufour's gland samples was 0.0015 DE (SE $= \pm 0.0005$). This corresponds to ca. 0.9 pg/cm

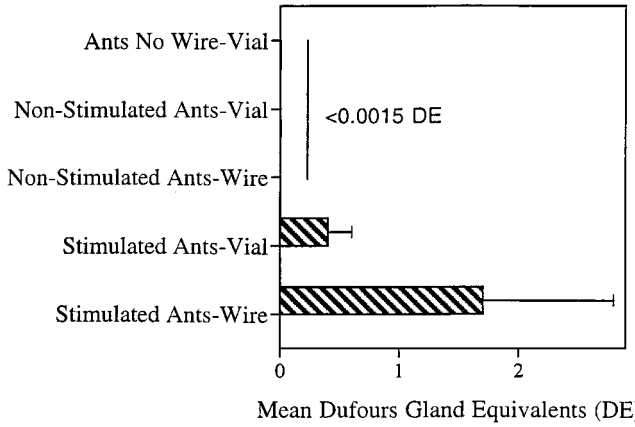

FIG. 5. Results from a recruitment orientation bioassay. Serial dilutions of treatment samples were carried out until the samples no longer gave positive results in the orientation bioassay. These results were compared with serial dilutions of Dufour's gland extracts (the source of the pheromone) containing known Dufour's gland equivalents (DE). The number of DE could then be calculated for each of the treatment samples. Only electrically stimulated workers released detectable quantities of the orientation pheromone. All other samples had to have <0.0015 DE—the lowest detectable amount. Results are shown as the mean and SE of 5 replicates.

of (*Z*,*E*)-α-farnesene, the recruitment orientation pheromone (Vander Meer et al., 1981). Knowing the starting volume of the electrically stimulated ant samples and monitoring their systematic dilution (or initial concentration) to the last positive orientation bioassay response, we related this to the results with the Dufour's gland extracts and calculated the DE of each sample (Figure 5). The initial bioassay of the controls (vial and wire rinses from samples that had ants, wire inserted, but not electrically stimulated) were negative even after fivefold concentration; therefore, they had to contain <0.0015 DE (Figure 5). Similar results were obtained with vial samples that had ants but no wire inserted (Figure 5). Like the venom alkaloids, more Dufour's gland products were deposited on the wire than on in the vial, although there was no significant difference between the two sets of samples (wire, 1.7 ± 1.1 DE vial, 0.4 ± 0.2 DE; $df = 8$, $t = 1.094$, $P = 0.359$; $N = 5$).

Olfactometer Bioassay. Each wire hexane rinse ($N = 5$) was tested in the olfactometer bioassay three times. Chi-squared analysis of the two-choice olfactometer showed that each of the wire hexane rinse replicates was attractive to worker fire ants (for each of the five replicates, $df = 1$, $\chi^2 > 3.85$, $P < 0.05$; null hypothesis of equal response to treatment and control). The mean percent of the ants responding to the treatment side of the olfactometer was 67.5 (SE = 1.5, $N = 5$). In contrast, there was not enough recruitment pheromone deposited by

electrically stimulated ants in the vial to release a response in the olfactometer bioassay ($df = 1$, $\chi^2 < 3.85$, $P > 0.05$). The mean percent of ants responding to the treatment side of the olfactometer was 56.7 (SE = 1.1, $N = 5$). The response of worker ants to the queen poison sac extract positive control was $75.5 \pm 2.6\%$ ($N = 5$, 0.33 queen equivalents/10μl hexane).

DISCUSSION

Fire ants use a wide array of semiochemicals for defense and intraspecific communication (Vander Meer and Alonso, 1998). Our results demonstrate that electrically shocked fire ants indiscriminately release exocrine gland products. Venom alkaloids from the poison sac and recruitment pheromone from the Dufour's gland were released through the sting apparatus. Alarm pheromone was released, presumably, from mandibular glands (Alonso and Vander Meer, 1997). Although not considered an exocrine gland, postpharyngeal gland contents can be regurgitated through the mouth during trophallaxis (Soroker et al., 1994). Hydrocarbons are the major class of compound found in the postpharyngeal gland, and these compounds are easily analyzed by GC (Lok et al., 1975; Vander Meer et al, 1985). Chemical analysis for hydrocarbons specific to *S. invicta* (Ross et al., 1987) from electrically stimulated fire ant workers failed to show release of postpharyngeal gland products. Release of exocrine gland products from other glandular sources, e.g., maxillary and labial glands, or the hindgut are probable, but not detectable due to our lack of knowledge regarding the behaviors and chemistry associated with these potential semiochemical sources. Interestingly, by the end of the electrical stimulation period, workers that had not been directly affected by the electrical current were inactively aggregated away from the electrified wire. This behavior may have been released by an unknown pheromone or was the result of exposure to high concentrations of known semiochemicals, e.g., venom alkaloids.

Our previous investigations into the behaviors associated with fire ant mating flights (Obin and Vander Meer, 1994; Alonso and Vander Meer, 1997) showed that the alate excitant pheromone used to initiate mating flights was produced by the mandibular glands. The products were further shown to be extremely short-lived and were released in small quantities and/or were of high volatility. Similarly, an alarm pheromone response was released from the crushed heads of workers (Wilson, 1962) and was reproducible in our laboratory (R.K.V.M., unpublished data). Our work here supports the ephemeral nature of the fire ant alarm pheromone, which, to be effective, must quickly dissipate when the threat is no longer detected (see alarm pheromone review in Vander Meer and Alonso, 1998).

Release of recruitment and alarm pheromones by an electrically stimulated worker has direct implications toward the accumulation of fire ants in electrical equipment. The estimated number of worker Dufour's gland equivalents released

by electrically stimulated fire ant workers was almost 1000 times the amount needed for significant worker attraction in the olfactometer (Vander Meer, 1986; Vander Meer et al., 1988) described here. In addition, one of the behaviors associated with alarm pheromones is attraction toward the worker releasing the alarm pheromone (Vander Meer and Alonso, 1998). Taken together, it is reasonable to assume that other fire ant workers in the vicinity of the semiochemical-releasing worker would be drawn toward the live contacts.

There are many species of ants that maintain large populations (see Hölldobler and Wilson, 1990), but none rival the high population densities of *S. invicta* in the United States. After its accidental importation into the United States in the 1930s (Lofgren, 1986), the population densities of the ant are about five times greater than found in their native South America (Porter et al., 1992), and in the United States can be as high as 100–120 mature monogyne colonies per hectare. Each colony maintains up to 250,000 workers or 30 million ants per hectare (3000 worker ants/m^2). Even if one assumes that only 5–10% of the workers are foraging, there are still 150–300 workers/m^2. Thus, it is likely that a foraging worker accidentally bridges live contacts in electrical equipment, releasing pheromones that attract nearby workers to the live contacts. These workers, in turn, release exocrine gland products, which increase pheromone concentration and the probability of attracting additional workers to the live contacts. We believe that the high population densities and the "weedy" nature (Tschinkel, 1987) of *S. invicta* is why this ant presents such a significant problem relative to electrical equipment.

Earlier work investigated the effect of electrical fields on *S. invicta* and several other ant genera (MacKay et al., 1992a,b). The authors concluded that workers from all species tested ($N = 10$) were attracted to electrical fields and that the number of ants accumulated at the electrical contacts increased with increasing voltage (directly related to electrical field strength). Our results for the fire ant present a pheromone-based alternative to their potential attraction to electric fields. All ant species are social and have evolved pheromone systems that help to maintain the health and social structure of the colony (see Vander Meer and Alonso, 1998; Hölldobler and Wilson, 1990). Therefore, there is a high probability that other ant species will also release exocrine gland products in response to electrical stimulation, which would then explain their apparent attraction to electrical fields (MacKay et al., 1992b). The differences in our conclusions may be based in semantics, since MacKay et al. (1992a) state in their discussion that while the ants accumulated at the electrically activated disks, "visual observations did not suggest the ants oriented to the powered disks." Orientation of the workers toward the powered disks would constitute "attraction," not simply that there were a number of ants at the disk after 10 min (see Vander Meer and Morel, 1988; Vander Meer and Alonso, 1998). Thus, our results support the report by Slowik et al. (1996) that electrically stimulated fire ants are not attracted to electrical fields, but may release pheromones that result in aggregations of ants at the site of electrical stimulation.

(Received January 23, 2002; accepted August 5, 2002)

Abstract—The small millipede *Niponia nodulosa* (Polydesmida: Cryptodesmidae) emits an earthy smell when disturbed. This smell was obtained from hexane extracts from both sexes at the sixth and seventh instars and adult stages, and was found by GC/MS analyses to be composed of two compounds, 1-octen-3-ol as the major component and geosmin as the minor component. This is the first report of these compounds in secreted substances from millipedes. As they showed little repellent activity against foraging ants in bioassays, their biological function as defensive allomones was not clearly elucidated. However, both compounds provoked negative chemotaxis of conspecific millipedes in a Y-tube olfactometer, especially 1-octen-3-ol, which was active at a dose equivalent to the content of a single millipede. Such biological activity suggests that this compound is involved in intraspecific communication in this millipede and may play a role as an alarm pheromone.

Key Words—Polydesmid millipede, *Niponia nodulosa*, secretion substances, 1-octen-3-ol, geosmin, Y-tube olfactometer, repellency, alarm pheromone.

INTRODUCTION

When disturbed, most millipedes discharge defensive secretions from body-segment glands. These secretions have been studied in a wide variety of millipedes

[3]Present address: Division of Environmental Sciences, Faculty of Integrated Arts and Sciences, Hiroshima University, Higashi-Hiroshima 739-8521, Japan.

and show order specificity in the distribution of major components such as hydrogen cyanide, phenols, 1,4-benzoquinones, and alkaloids (Eisner et al., 1978). For example, the order Polydesmida includes millipedes that produce hydrogen cyanide, benzaldehyde (Blum and Woodring, 1962), and mandelonitrile, regarded as the precursor of these substances (Mori et al., 1995; Noguchi et al., 1997b; Ômura et al., 2002). In addition, particular polydesmid species also emit phenol derivatives (Blum et al., 1973; Duffey et al., 1977; Mori et al., 1994; Noguchi et al., 1997a). The orders Spirobolida and Spirostreptida emit secretions containing mainly 1,4-benzoquinone derivatives (Monro et al., 1962), whereas secretions from the orders Glomerida and Polyzoniida contain characteristic alkaloids (Meinwald et al., 1966; Smolanoff et al., 1975; Wood et al., 2000). These substances are adhesive, irritating, or toxic and contribute to chemical defense against various predators (Eisner and Meinwald, 1966; Pasteels et al., 1983). However, their biological functions, except as chemical defense systems, have not been examined in detail.

Niponia nodulosa Verhoeff (Polydesmida: Cryptodesmidae, *makuragi yasude* in Japanese) is distributed in Japan (Honshu, Kyushu, and Okinawa islands) and Formosa and shows gregarious inhabitation among fallen leaves in deciduous broad-leaved forests (Shinohara and Tanabe, 1999). When disturbed, this species emits an earthy smell, which is different from that of other polydesmid secretions previously described. The present study was conducted to clarify the chemical composition of the millipede secretion and to examine the potential bioactivities of the secretion substances.

METHODS AND MATERIALS

Millipedes. N. nodulosa at nymphal (sixth and seventh instar) and adult stages were collected from litter around fallen timber of deciduous broad-leaved trees in the botanical gardens of Kyoto University of July to September 2000. Collected millipedes were reared in the laboratory for at least 10 days by feeding litter at 25°C under a 16L:8D photoperiod in plastic Petri dishes (9 cm OD $\times$ 2 cm height). Petri dishes were kept humid by spraying with water every other day.

Extraction of Millipedes. Millipedes were sexed, their body length and weight measured with minimal disturbance, and then separately soaked in hexane (150 or 200 μl for adults, and 50 μl for nymphs) for 3 min. These extracts with the characteristic earthy odor were collected by decantation and subjected to chemical analyses.

Chemical Analyses. Crude extracts were analyzed by gas chromatography (GC) and by mass spectrometry coupled with gas chromatography (GC-MS). GC analyses were carried out on a Hewlett Packard HP6850A instrument equipped with a flame ionization detector, using an HP-5 fused-silica capillary column (0.25 mm ID $\times$ 30 m, 0.25-μm film thickness). Oven temperature was programmed from 60°C to 290°C at 10°C/min with an initial 2 min hold at 60°C. Samples were

injected in splitless mode at 240°C using He as the carrier gas. Chromatograms were processed using an HP3395 integrator. GC-MS analyses were performed at 70 eV using an HP5989B mass spectrometer coupled with an HP5890 series II plus GC in splitless mode, using the same capillary column and the same analytical conditions as described above. Identification of components was based on comparison of GC retention data and mass spectra with those of authentic samples. Each component was quantified using *n*-hexadecane as the internal standard.

Ants Bioassay. To assess the effect of the millipede secretion, identified components were subjected to a repellent bioassay using ants, *Pristomyrmex pungens* Mayr (Hymenoptera: Formicidae). A block of granulated sugar (average size: 3.2 × 2.7 × 1.3 mm) was glued on a cover glass (18 × 18 mm, 0.15-mm thickness) and baited with the authentic chemical dissolved in dichloromethane. After evaporation of the solvent by air-drying, treated bait was exposed to wild foraging ants in a greenhouse at 27°C between 14:00 and 16:00 hr. Numbers of ants foraging on the treated bait and those avoiding the bait were counted for 15 min. The repellent activity at a given dose was expressed as a percentage between numbers of foraging and of avoiding ants. Tests at each dose were replicated three times using different baits. Treatment with the solvent alone had no repellent effect on ants.

Bioassay of Conspecific Millipedes. To evaluate the intraspecific biological function of the millipede secretion, chemotaxis was examined with seventh instar nymphs and adults using a transparent Y-tube olfactometer (Figure 1; a 40-mm

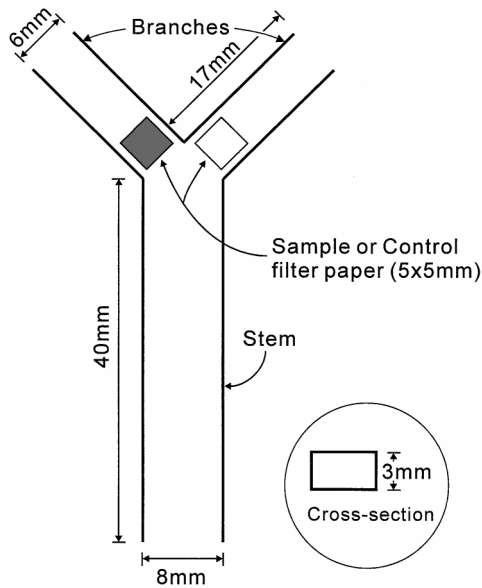

FIG. 1. Schematic drawing of the Y-tube olfactometer used for millipede bioassay.

stem 8 mm wide and 3 mm in height cross section, and two 17-mm branches 6 mm wide and 3 mm in height cross section). Bioassays were conducted in the laboratory at 25°C under illumination with an 18-W fluorescent light. Small pieces of filter paper (5 × 5 mm) were treated with either authentic chemicals dissolved in dichloromethane (sample) or with the dichloromethane alone (control). After removal of the solvent by evaporation at room temperature, one sample and one control were randomly placed into each branch of the olfactometer. To imitate the soil environment, the atmosphere in the olfactometer was kept without airflow. Millipedes were individually introduced into the olfactometer from the stem and were observed to advance. Although most millipedes advanced toward either the sample or control branch, several stopped a short distance from the junction and backed to the entrance of stem. In cases where both branches contained the control, no backward locomotion was observed. Therefore, it was reasonable to assume that the response was caused by the odor of the test compound. Each millipede was tested five times using different filter papers treated with the same dose of compound, and the frequencies of locomotion toward the sample or control or backward locomotion were recorded. The olfactometer was cleaned with ethanol and air-dried between replicates. The responsiveness of each millipede was quantified based on the two criteria: percentage of backward locomotion in five trials, and repellency index defined by the following equation,

$$\text{Repellency index} = \frac{(F_c - F_s)}{(F_c + F_s)}$$

where F_c is the frequency of locomotion toward the control, and F_s denotes the frequency of locomotion toward the sample. An index of 1 represents no choice to sample, while that of -1 represents no choice to control. Test chemicals at respective doses were examined using seven individuals of each sex at the same stage.

Test Chemicals. Authentic chemicals were purchased from commercial sources (Tokyo Chemical Industry and Wako Pure Chemical Industry). Their purities were assessed by GC and found to be above 97%.

RESULTS

Chemical Composition of Millipede Secretion. The millipede extract had two peaks (**A** and **B**); a major peak **A** at t_R 5.33 min and a minor peak **B** at t_R 12.13 min on GC analyses (Figure 2). The major component had a base ion at m/z (relative intensity, %) 57 (100) and the following diagnostic ions at m/z (%) 99 (6), 85 (11), 72 (19), and 43 (19), although no apparent M^+ ion was observed. The minor component gave an M^+ ion peak at m/z (·) (%) 182 (8), base ion at m/z (%) 112 (100), and the diagnostic ions at m/z (%) 149 (14), 125 (16), 97 (12), 83 (9),

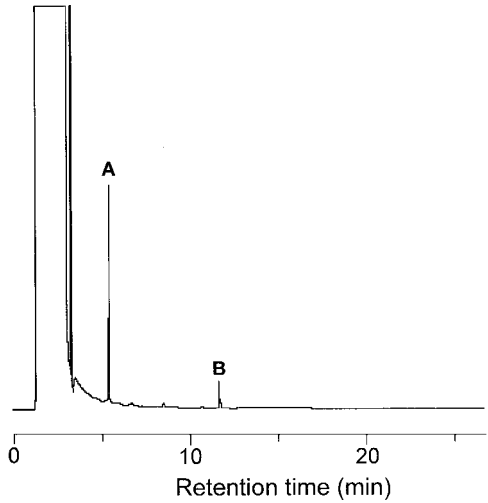

FIG. 2. A typical gas chromatogram of the hexane extract of an adult millipede, *Niponia nodulosa*. See text for the analytical conditions. Peak A, 1-octen-3-ol; peak B, geosmin. The large peak at t_R 3.2 min was noise.

67 (8), 55 (13), and 41 (9). By comparison with authentic samples, **A** and **B** were identified as 1-octen-3-ol and geosmin, respectively.

The amounts of secretory components varied with the developmental stage of millipedes (Table 1). 1-Octen-3-ol was present in approximately equal amounts in the two nymphal stages, while the average amount in adults was three fold

TABLE 1. CHEMICAL COMPOSITIONS OF HEXANE EXTRACTS FROM THREE STAGES OF *Niponia nodulosa*

Stage and sex	Body length (mm ± SD)	Body weight (mg ± SD)	Amount per millipede (ng ± SD)[a]	
			1-Octen-3-ol	Geosmin
6th instar nymph				
Male	7.8 ± 0.9	8.4 ± 2.1	127.5 ± 30.4 (1.52)[b]	7.6 ± 4.6
Female	8.4 ± 0.5	9.4 ± 0.9	120.2 ± 33.7 (1.28)	7.7 ± 4.4
7th instar nymph				
Male	11.9 ± 0.3	23.5 ± 1.6	125.7 ± 26.3 (0.53)	19.5 ± 8.6
Female	12.5 ± 0.5	26.5 ± 1.7	137.1 ± 65.1 (0.52)	16.5 ± 9.7
Adult				
Male	17.4 ± 0.8	54.4 ± 8.4	450.1 ± 179.4 (0.83)	38.7 ± 21.1
Female	17.6 ± 0.4	62.2 ± 3.3	481.0 ± 126.8 (0.77)	19.0 ± 10.4

[a] $N = 6$.
[b] Amount of 1-octen-3-ol as a percentage of body weight.

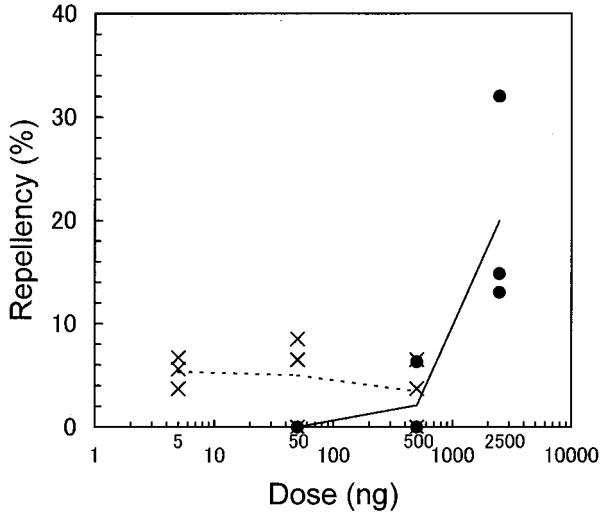

FIG. 3. The repellent effects of 1-octen-3-ol (•) and geosmin (×) on wild ants, *P. pungens*, evaluated using blocks of granulated sugar. The solid line denotes the dose–response curve for 1-octen-3-ol, while the broken line represents that for geosmin.

greater than in nymphs. This component comprised 0.5–1.5% of the body weight and reached the highest percentage by weight in sixth instar nymphs. In contrast, geosmin was detected in trace amounts and tended to increase with developmental stage. No significant differences were observed between the sexes in amount of either component at the same developmental stage (*t* test).

Repellency to Ants. Neither 1-octen-3-ol nor geosmin was repellent to ants (Figure 3). Upon exposure to the potential bait, most ants were observed to forage immediately, indicating that it had little contact repellency. In addition, remote repellent activity was vague at a short distance from the bait. 1-Octen-3-ol was slightly active (19.9%) at a dose of 2500 ng, which is approximately five fold higher than the average adult content. Geosmin was inactive within the dose range of 5–500 ng.

Repellency to Conspecific Millipedes. 1-Octen-3-ol stimulated negative chemotaxis of *N. nodulosa* at a dose equivalent to the average secretory content in millipedes (Figure 4). Although the frequency of backward locomotion was variable, this compound was slightly effective at a dose of 100 ng (14.3% on average). The average repellency index was moderate (20.2) at a dose of 100 ng and was elevated to 64.6 at a dose of 2500 ng, where this millipede preferred the odorless control to the test sample ($P < 0.05$, Wilcoxon's signed-ranks test). These results suggest that 1-octen-3-ol is repellent to consepecific millipedes. No significant differences were observed among the sexes (Mann-Whitney *U* test).

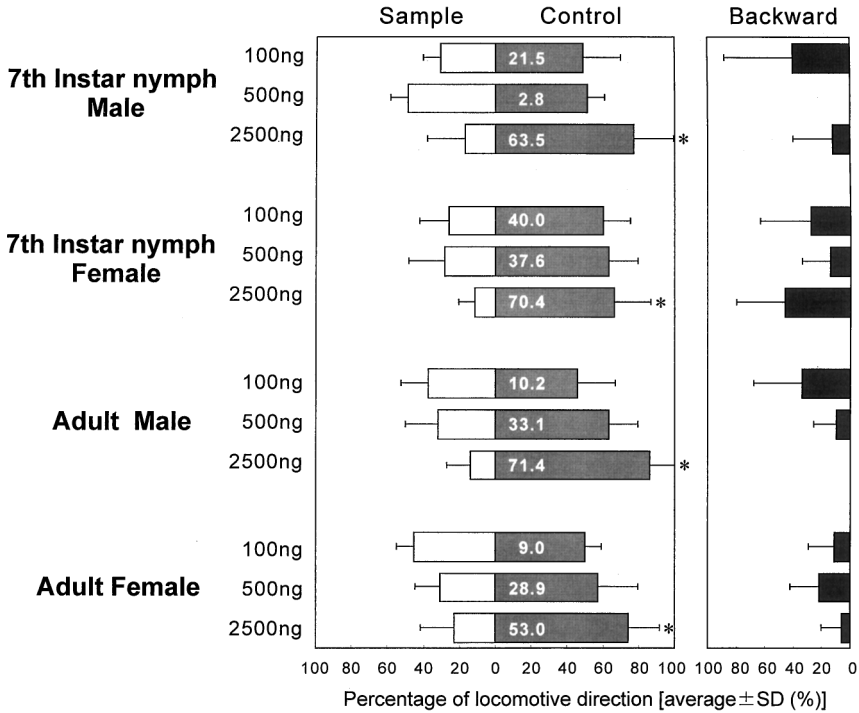

FIG. 4. Effects of 1-octen-3-ol on the chemotaxis of *N. nodulosa* in bioassays using a Y-tube olfactometer. White, gray, and black columns indicate the percentages of millipede locomotion toward sample, control, and backward locomotion, respectively. White figures on the gray columns represent repellency indexes (see text) at the respective dose of sample. Significant differences between samples and control are indicated by asterisks ($^*P < 0.05$ by Wilcoxon's signed-ranks test).

Geosmin induced backward locomotion (31.5%) and a high repellency index (84.0) at a dose of 250 ng (Figure 5: $P < 0.05$, Wilcoxon's signed-ranks test). Although the high dosage showed negative chemotaxis for *N. nodulosa*, this compound was inactive at lower doses (10 and 50 ng), equivalent to the contents of a single millipede. No significant differences were observed among the sexes (Mann-Whitney *U* test).

DISCUSSION

The secretion from *N. nodulosa* was composed of two compounds, 1-octen-3-ol as the major component and geosmin as the minor component. Neither compound has been previously reported from millipede secretions. The amount of

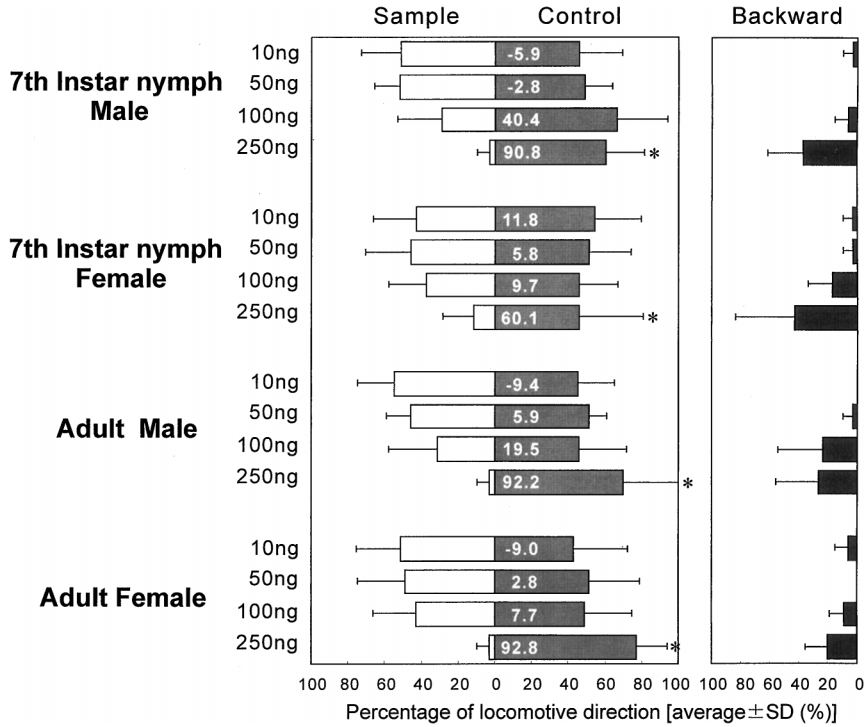

FIG. 5. Effects of geosmin on the chemotaxis of *N. nodulosa* in bioassays using a Y-tube olfactometer. White, gray, and black columns indicate the percentages of millipede locomotion toward sample, control, and backward locomotion, respectively. White figures on the gray columns represent repellency indexes (see text) at the respective dose of sample. Significant differences between samples and control are indicated by asterisks ($^*P < 0.05$ by Wilcoxon's signed-ranks test).

1-octen-3-ol was in the range of 0.5–1.5% of body weight, which is considerably greater than those of the major components (range of 0.1–0.2%) in other Japanese polydesmids (Mori et al., 1994, 1995; Noguchi et al., 1997a,b; Kuwahara et al., 2002; Ômura et al., 2002). This was deemed to be characteristic of *N. nodulosa*.

1-Octen-3-ol was first identified in the odor of Japanese matsutake mushroom (Murahashi, 1936, 1938) and has been well documented as a major volatile substance in various mushrooms (Pyysalo, 1976; Rapior et al., 1996a,b, 1997; Beltran-Garcia et al., 1997). In mushrooms, 1-octen-3-ol is biosynthesized by the enzymatic cleavage of linoleic acid (Wurzenberger and Werner, 1982; Assaf et al., 1995). Geosmin is an earthy-smelling substance and has been isolated from actinomycetes (Gerber and Lechevalier, 1965), cyanobacteria (Medsker et al., 1968), and mushrooms (Breheret et al., 1999). Bentley and Meganathan (1981) reported

that geosmin in streptomycetes is biosynthesized via the isoprenoid pathway. Both substances are regarded as microbial volatile organic compounds (MVOCs) (Jelen and Wasowicz, 1998; Fischer et al., 1999). Therefore, we speculated that these substances in *N. nodulosa* were sequestered from fungi or biosynthesized from litter in the diet. In our preliminary analyses, however, neither compound was detected from litter in the millipede habitat. To determine the origins of these substances in millipedes, further detailed investigations are required.

Most polydesmid millipedes possess chemical defense systems and secrete hydrogen cyanide and benzaldehyde as common defense substances (Towers et al., 1972; Duffey et al., 1974, 1977; Duffey and Towers, 1978). However, particular species such as *Euryurus australis* (Duffey et al., 1974) and *Eucondylodesmus elegans* (Kuwahara et al., 2002) utilize other secretory substances for chemical defense. The observation that *N. nodulosa* has different secretory components from other species indicates a diversity of defensive systems in polydesmid millipedes.

To assess the effects of defensive substances, bioassays are generally conducted using ants (e.g., Smolanoff et al., 1975; Kuwahara et al., 2002). In the present study, the secretory substances of *N. nodulosa* exerted little repellency against foraging wild ants. Although the ants tested are not a natural predator for *N. nodulosa*, it is possible that this millipede secretion is inactive toward ants. In contrast, the two secreted substances stimulated negative chemotaxis in conspecific millipedes; in particular, 1-octen-3-ol was active at a dose equivalent to the content of a single adult. On the basis of these results, we speculate on two possible roles for the millipede secretion.

The first is as a defensive allomone. Recently, 1-octen-3-ol was reported to act as a slug antifeedant (Wood et al., 2001) and as a sensory irritant for mice (Korpi et al., 1999). Moreover, MVOCs such as 1-octen-3-ol and geosmin are indicators of food spoilage (Jelen and Wasowicz, 1998; Fischer, 1999; Schnürer et al., 1999). Upon exposure to these volatile substances, predators may recognize potential health hazards and avoid the source. Therefore, it is likely that the secretory substances in *N. nodulosa* repel other potential predators (e.g., carbides, earwigs, and spiders), although little information is available regarding natural predators of this species. As Beltran-Garcia et al. (1997) reported that 1-octen-3-ol in mushroom shows antifungal activities similar to several secretory substances of polydesmid millipedes (Roncadori et al., 1985), this substance in *N. nodulosa* may serve a role in chemical defense against harmful microbes.

The other potential role is as a chemical messenger mediating intraspecific communication (pheromone). Some social or gregarious insects have evolved the capacity to use their defensive allomones as alarm pheromones (Pasteels et al., 1983). The species of millipede examined in the present study is gregarious in nature, and colonies consist of a mixture of all developmental stages in summer. We postulate one possible role of the secretory substance is as an alarm pheromone based on the following four observations: (1) the active compound originates from

the species; (2) the avoidance behavior of the millipede is reproducible upon exposure to the compound; (3) the activity is seen on exposure within the content range of a single individual; and (4) the compound is emitted in response to disturbance. However, the present repellent effect was weaker than those reported previously for alarm pheromones in other arthropods. This might have been because the conditions in our bioassay differed from those in nature, or it may suggest another potential role, e.g., as an epideictic pheromone in a gregarious population.

Millipede secretions have attracted a great deal of attention due to their interspecific roles as defensive allomones. Although intraspecific effects were suggested by the characteristics of millipedes such as soil microhabitat, gregarious population, and migration behavior known as outbreak, there have been few studies of such potential effects. The present study indicates the potential for such effects in *N. nodulosa*, and further investigation should be conducted to elucidate the ecological function of the allomones produced by this species.

(Received February 12, 2001; accepted July 15, 2002)

Abstract—The volatile components of the chin gland secretion of the wild European rabbit, *Oryctolagus cuniculus* (L.), were investigated with the use of gas chromatography. Studies of the chemical nature of this secretion by previous workers demonstrated that it was important in the maintenance of social structure in this species. This study identified 34 different volatile components that consist primarily of aromatic and aliphatic hydrocarbons. Especially common are a series of alkyl-substituted benzene derivatives that provide most of the compound diversity in the secretion. Samples of chin gland secretion collected from animals at three different geographical locations, separated by more than 100 km, showed significant differences in composition. This work suggests that variation among populations needs to be considered when undertaking semiochemical research. Alternate nonparametric methods are also used for the analysis of chromatographic data.

Key Words—Rabbit, *Oryctolagus cuniculus*, social structure, glandular secretion, gas chromatography, mass spectrometry, behavior, chemolfactory communication multidimensional scaling, variation.

INTRODUCTION

The chemical constituents of mammal scent gland secretions have been studied in a wide variety of species. Although there are large differences among the suite of compounds occuring in various species, there is also some commonality. Many of

the components are aromatic, or even terpenic (Brownlee et al., 1969; Thiessen et al., 1974; Raymer et al., 1986; Novotny et al., 1990; Salamon, 1994; Perrin et al., 1996). The most common pattern is a mixture of aromatic and aliphatic compounds of varying chain length. The functional groups that appear to be most important are the oxygenated ones, especially the carboxylic acids, aldehydes, and ketones.

Almost all semiochemical studies have concentrated on samples collected from a species at only one location and at one time of the year and have interpreted the analysis of such collections as the defining semiochemical signal of the species. There are few studies of terrestrial species that consider animals from multiple sites. When such an analysis has been performed (e.g., Cantoni et al., 1996), the study has been of only one sex. However, there is no reason to assume that there are no changes in the secretions produced by animals from different places.

The primary method used to determine the chemical components of mammalian scent gland secretions is gas chromatography–mass spectrometry (GC-MS). In samples that contain a large number of compounds, it is often not merely the presence or absence of a few compounds that is important, but also the relative amounts of each component. The common method of visual comparison between chromatograms becomes impossible with this type of data set.

The majority of studies that use a statistical method for comparing chromatograms use principal components analysis (PCA) (e.g., Dudzinski, 1974; Dudzinski et al., 1975; Mykytowycz and Hesterman, 1975; Kryger, 1981; Smith et al., 1985; Belcher et al., 1986; Natynczuk and MacDonald, 1994; Salamon and Davies, 1998; Stewart et al., 1999; Lawson et al., 2000). In this type of analysis, the data array is thought of as defining the positions of samples in relation to axes that represent the full set of peaks in the chromatogram, one axis for each peak. Typically, there are many peaks, so the samples are points in a high-dimensional space. In PCA, the axes are moved to include the maximum amount of variation and variables in the minimum number of new axes. There are two major problems in the use of PCA. The first assumes that the data are normally distributed and secondly that the distances between points may become distorted when projected (Clarke and Warwick, 1994a).

Chromatographic data bear some similarity to ecological data in that both typically can be dominated by zero entries. As well, the nonzero counts show large variation and highly right-skewed distributions (Clarke and Warwick, 1994a). Informal display methods, such as clustering or multidimensional scaling (MDS) ordination, may be more valid statistical approaches, as they do not assume normal distributions. MDS works on a sample dissimilarity matrix, not on the original data array. Fewer assumptions are made about the nature and quality of the data when using MDS than with any other ordination method. Thus, MDS can provide a more realistic picture of the data. The main advantage of MDS is its greater ability to represent more complex relations accurately in low-dimensional space (Clarke and Warwick, 1994a).

To determine whether clumps of individuals are significantly different from each other, an analysis of similarity (ANOSIM) may be used. The ANOSIM tests are a range of Mantel-type permutation of randomization procedures, making no distributional assumptions. These tests depend only upon rank similarities, and thus, are, able to deal with this type of data. A SIMPER analysis can also be used to determine which peaks are most important in contributing to any differences among sites and also in determining how similar individuals are within each site. A coefficient of dispersion, calculated for these data, is a measure of dispersion based on the difference in average distance among replicate samples for a group in an MDS configuration.

The European rabbit [*Oryctolagus cuniculus* (L.)] is a species that previously has been studied semiochemically. The social structure of the rabbit is maintained in the field by the use of scent marks; including glandular secretions (Mykytowycz, 1966a–c, 1968; Hayes et al., 2002; fecal mounds (Mykytowycz and Gambale, 1969), and urine (Bell, 1981). The secretion of the submandibular cutaneous (chin) gland has been correlated especially with the maintenance of social structure. The chin glands of dominant male rabbits have a higher secretory activity than those of other individuals within the social group (Mykytowycz and Dudzinski, 1966), and these animals also show more scent-marking behavior than do other rabbits (Mykytowycz, 1968; Verberne and Blom, 1981; González-Mariscal et al., 1993). At least one of the components of the chin gland secretion is found only in the secretion from dominant males and not in that from subordinate individuals (Hayes et al., 2001). This suite of ecological and social behavior of the rabbit makes it an appropriate species to use for semiochemical analysis.

Goodrich (1983) examined the headspace volatiles of the rabbit chin secretion and found them to be mainly of an aromatic structure (including some aldehydes, ketones, and phenyl compounds), with only a few aliphatic compounds (aldehydes, ketones, and *n*-butanoic acid). Also present in the secretion are less volatile components, such as fatty acids and proteins (Goodrich and Mykytowycz, 1972).

In the present study, a comparison, using MDS and ANOSIM, was made among samples collected at three different, geographically well-separated sites to ascertain whether there was variation in the secretion throughout the range of the rabbit in Australia.

METHODS AND MATERIALS

Samples were collected from animals living at three different locations throughout east central New South Wales: Hope Farm, Cattai National Park (150°52′E, 33°33′S) located on the east bank of the Hawkesbury River in the west of Sydney (Hope Farm samples) ($N = 43$), Oaky Creek (142°22′E, 33°25′S), a NSW Agriculture study site between Bathurst and Orange in the central tablelands of New South Wales (Bathurst samples) ($N = 18$), and field enclosures of the Commonwealth

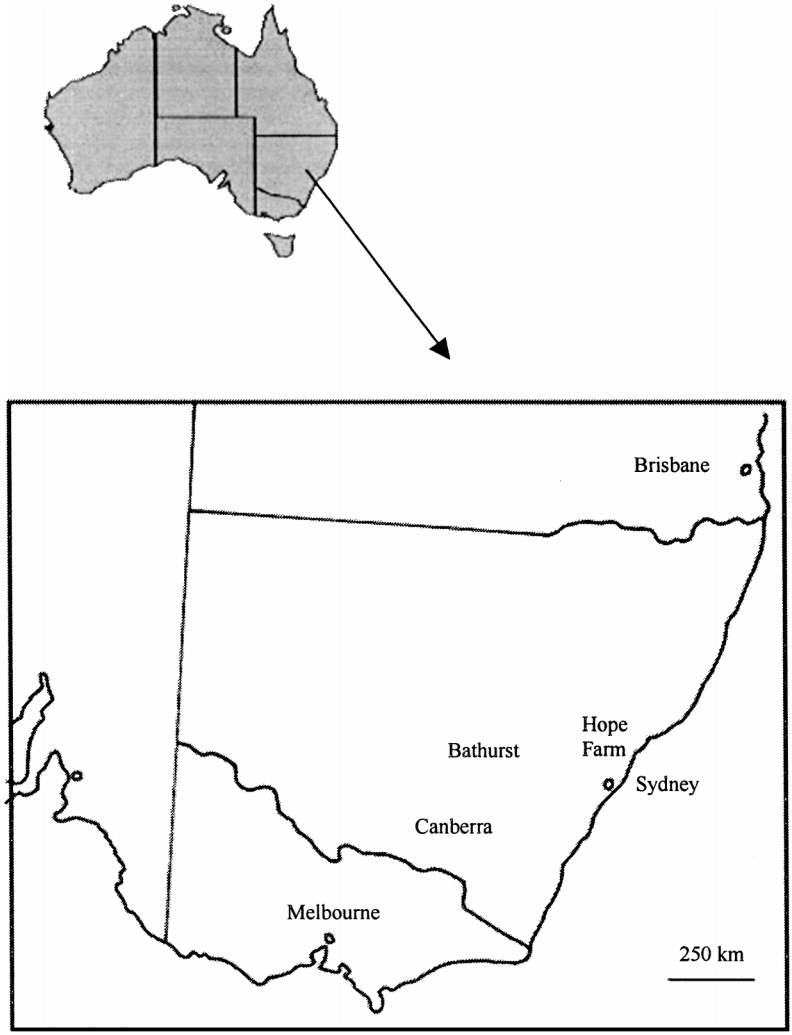

FIG. 1. A map of the southeastern portion of mainland Australia showing the location of the three sites used for sample collection of swabs of rabbit chin gland secretion.

Scientific and Industrial Research Organisation (CSIRO), Division of Wildlife and Ecology at Gungahlin (149°8′E, 35°15′S) near Canberra (Canberra samples) ($N = 22$) (Figure 1).

Wire box traps were placed near entrances to warrens that were in active use. Chin gland secretions were collected from the animals live-trapped in the field. To

collect the secretion, an area of approximately 2 cm^2 of fur was clipped from the chin area of the rabbit with scissors. A cotton bud, previously baked at 140°C for at least 4 hr to remove volatile contaminants, was swabbed over the clipped region 20 times. The swab was placed into a headspace vial (10 ml), and the vial was closed with an airtight Teflon-faced rubber seal for analysis by dynamic headspace gas chromatography. All samples were stored in the dark in a freezer at −20°C until analyzed. Duplicate swabs were taken.

The vial was heated to 30°C in a heating block. Laboratory air (3.2 liter) was pumped through a charcoal trap, then over the sample at a flow rate of 13 ml/min. After passing over the sample, the air flowed through gas chromatography injection port liners packed with the adsorbent agent Tenax TA (35/60 mesh; (90 ± 2 μg). At the end of the collection time (246 min), the liner was placed in the injector port of a GC (HP5890 Series II). The Tenax was thermally desorbed with a programmable temperature vaporizer (PTV) (Activon).

Analysis was conducted with a Hewlett Packard 5890 Series II gas chromatograph (GC) equipped with a flame ionization detector and fitted with a silica capillary column (SGE, model BP-1, 25 m long, 0.22 mm ID and 0.1-μm film thickness). Data were acquired under the following GC conditions—inlet temperature: 200°C, carrier gas: nitrogen at 23 cm/sec, split ratio: 1:20, detector temperature: 260°C, temperature program: initial temperature 45°C, initial time 5 min, rate 8°C/min, final temperature 250°C, final time 5 min. The temperature program for the PTV was—initial temperature: 40°C, ramp rate: 16°C/sec, final temperature: 200°C.

The identities of peaks in the chromatogram were determined by use of another HP5890 GC coupled to a mass spectrometer (HP 5971A, Hewlett Packard) (GC-MS) with an attached PTV. Data were acquired under the following GC conditions—inlet temperature: 260°C, carrier gas: helium at 1.1 ml/min, split ratio 1:2, detector temperature 260°C, temperature program: initial temperature 40°C, initial time 5 min, rate 8°C/min, final temperature 250°C. The MS was held at 190°C in the ion source using an ionization energy of 70 eV and a scan rate of 0.9 scans/sec. The PTV program was—initial temperature: 35°C, ramp rate: 12°C/sec, final temperature 220°C. Peak identities were assigned by comparison with the Wiley mass spectral library. Confirmation of the identity of several compounds was obtained with authentic samples (Sigma) using the same sampling method and comparison of retention times (see Table 1 below).

An external standard hydrocarbon mixture (C_8–C_{18}) was injected into the GC and analyzed under the same conditions to enable calculation of Kovats indices.

Sample blanks were run twice every week to ensure that volatiles recorded were from the secretion and not due to the sampling procedure. The blanks consisted of an unused cotton bud analyzed by the same procedure as for the samples. The number of peaks in blank and sample swabs was compared by analysis of variance (GMAV5, 1997).

Each integrated peak in the chromatogram was assigned an arbitrary number. The numbering system was kept consistent between sample runs, so that a peak of a given number in a chromatogram corresponded to the same peak in other chromatograms. The Wiley spectral library and a Kovats analysis were used to assign identities to the numbered peaks.

The presence of peaks in the chromatogram and their relative areas were examined statistically by a nonparametric method [multidimensional scaling (MDS)] to ascertain if any differences could be detected among animals from different locations. MDS uses a similarity matrix of the data and produces a graphical representation. Each point in the MDS represents an individual rabbit, and points that are close together (clumped) correspond to individuals with similar peak composition (presence and abundance) (Clarke and Warwick, 1994b).

To determine whether clusters of individual rabbits were significantly different from each other, an analysis of similarity (ANOSIM) was used. A SIMPER analysis was used to determine which peaks were most important in contributing to any differences among sites and also how similar individuals within each site were. A coefficient of dispersion was also calculated for these data. Software used for the multivariate analysis was Primer 5 for Windows (V 5.2.4, 2001).

RESULTS

There were significantly fewer peaks detected in the chromatograms from blank swabs (1.09 ± 0.25) than in swabs from rabbits (17.4 ± 1.59) (ANOVA, $F = 206.46$, $P < 0.001$).

Compounds detected in the swabs of the chin region of the European rabbit are listed (Table 1). Ethylbenzene, phenol, benzaldehyde, acetophenone, and 4-methylphenol (*p*-cresol) have been previously identified in rabbit chin gland secretion (Goodrich, 1983). The proportion of samples containing peaks from the three sites and the average relative percentage area of the peak are also given.

The MDS analysis shows a grouping of individual samples from each site that creates three different groups (ANOSIM: Global $R = 0.724$, $P = 0.001$). The Canberra population shows a tight clump with a low dispersion coefficient (0.345) and an average similarity within the group of 80% (SIMPER). This location has a signal that is different from the other locations (ANOSIM: $R = 0.684$ and $R = 0.975$ for Bathurst and Hope Farm, respectively, $P = 0.001$).

Both Bathurst and Hope Farm have similar levels of dispersion that are greater than that for Canberra (1.301 and 1.17, respectively), with an average similarity within the group of 47 and 52%, respectively (SIMPER). Even with this greater dispersion and some overlapping of individuals, these locations are still different from each other (ANOSIM: $R = 0.491$, $P = 0.001$) (Figure 2). The Bathurst samples sorted into two groups, but this separation is not due to either age or sex.

TABLE 1. LIST OF COMPOUNDS FROM RABBIT CHIN GLAND SECRETION[a]

Peak	Kovats index	Identification	I.D. method	% of animals with peak				Average relative % area of peak		
				Bathurst	Canberra	Hope Farm	Total	Bathurst	Canberra	Hope Farm

[a] The experimentally derived values of the Kovats Index are given, as is the identification method (mass spectrum, retention time or both). The percentage of rabbits from each site [Bathurst ($N = 18$), Canberra ($N = 22$) and Hope farm ($N = 43$)] in which the peak occurs and the average relative percentage area of the peak in each sample is also shown. ? = tentative identification of the compound.

[b] Most important compounds in distinguishing between samples from each of the sites (SIMPER).

[c] Confirmed by authentic samples.

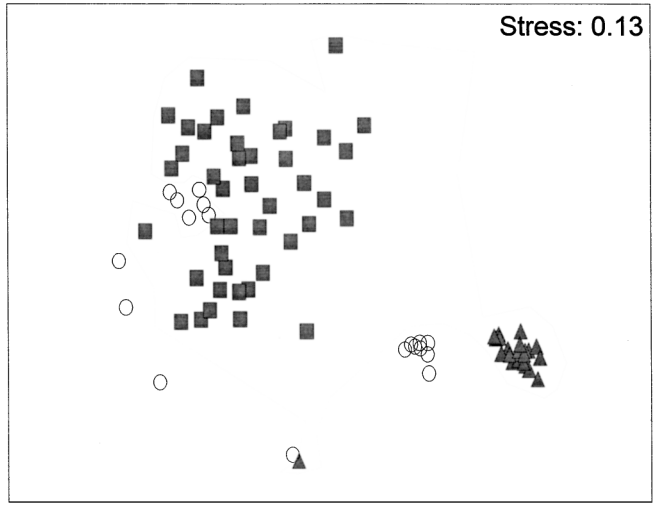

FIG. 2. Multidimensional scaling (MDS) ordination based on a Bray-Curtis similarity matrix of the three sites Bathurst (○), Canberra (▲), and Hope Farm (■) rabbits.

The majority of the differences among groups were in the relative intensities of the peaks. However, there were two incidences of an exclusive compound. Peak 59 (tentatively identified as 2-methylisopropylphenol) was found only in the swabs of rabbits from the Canberra site and was present in all animals. However, it is not important in the separation of Canberra animals from samples at the other sites. Peak 44 (unidentified) was found in 72% of individulas at Hope Farm and not in those at the other two sites. It distinguished the Bathurst and Hope Farm sites (Table 1). There are two other peaks that are specific to only one site; however, both of these were found in only one animal and are unlikely to be biologically relevant.

DISCUSSION

MDS analysis indicated that animals may be grouped according to site on the basis of compounds present in the headspace above their chin gland secretions. These differences are predominantly due to changes in the relative proportion of the peaks rather than to changes in the compounds present.

Some of the identified compounds were detected in the swabs from virtually every rabbit examined (e.g., ethylbenzene). Others were detected only in swabs from one individual of the 83 examined (e.g., peaks 54 and 49). Those compounds that were detected in the secretion of only one or two individuals are less

likely to be an important part of the semiochemical message than those that occur regularly.

There were four compounds found only in samples at one site, and one of these (peak 44) was important in distinguishing among sites. It is not clear, however, what significance they may have to the rabbits.

The between-suite variation is also within the compounds that are most commonly found in chin gland secretions, such as ethylbenzene and xylene, both of which occure in all animals swabbed, rather than in the more rare components. These differences are not due to secondary plant compounds, and, thus, do not seem to be related to diet differences. They are rather likely due to some more fundamental difference among rabbits from different places.

While the Bathurst and Canberra populations derive from the same release of rabbits 100 generations ago, the Hope Farm rabbits are at least partly derived from a different genetic stock from Europe (Stodart and Parer, 1988; Phillips et al., 2002). The differences observed among secretions found at different sites may by due to genetic differences among populations. Genetic studies using allozymes, mitochondrial DNA, and microsatellites show that there can be large differences in allele frequencies among locations separated by only a few kilometers (Richardson, 1981; Zenger, 1996; Vachot, unpublished results). Parallel changes in the genes underlying the metabolic pathways leading to the compounds secreted could form the basis of the observed changes in concentrations. The production of distinctive compounds at Canberra and Hope Farm is worthy of further study. The animals from Canberra, although kept in outdoor enclosures, have a limited ability to interbreed. The low variation in these samples may be due to a loss of heterozygosity due to higher levels of inbreeding.

An MDS analysis may allow a more thorough examination of chromatographic data than does the more commonly used PCA. PCA has little flexibility in defining dissimilarity. Ordination is essentially a technique for converting dissimilarities of chemical composition among samples into Euclidean distances between these samples in a 2- or higher dimensional plot. PCA defines dissimilarity as the Euclidean distance between two samples in the full *n*-dimensional space; however, this is a poor way to define sample dissimilarity. Having defined dissimilarity as distance in the *n*-dimensional space, PCA converts these distances by projection onto the 2- or 3-dimensional-ordination plane. This may distort some distances. Two samples that are relatively far apart on the axis representing the third principal component can end up being coincident when projected (perhaps from "opposite sides") onto the plane formed from the first two principal components (Clarke and Warwick, 1994a).

As well as obtaining a more accurate knowledge of the entire suite of compounds associated with a particular species, by using several different study sites a researcher is able to get some idea of what compounds are important. Those compounds that are conserved across different locations are more likely to from part

of a species-wide message than are those that are specific to one locality. Isolation of individuals by distance can be used to ascertain the important components of a semiochemical message.

Many of the previous semiochemical studies on mammals have been conducted on small sample sizes of organisms (<20) that have been collected from only one location (Müller-Schwarze, 1972; Black-Cleworth and Verberne, 1975; Yarger et al., 1977; Raymer et al., 1986; Apps et al., 1988; Schultze et al., 1988; Jemiolo et al., 1991; Richardson, 1991; Price and Feistner, 1994; Brown et al., 1996; Eggert et al., 1996; Rasmussen et al., 1996; Salamon and Davies, 1988). This study identified differences in the semiochemical secretion of the chin gland among rabbits from different sampling sites. Variation among animals occurs, and in order to define the semiochemicals, produced by a species it is important to examine a large number of individuals at more than one time of year and from more than one place.

Acknowledgments—The authors thank C. Herlihy and K. Stephenson (UWS) for technical and field assistance and W. Eickhoff (ATTORI) for assistance in the MS analysis. This research was carried out under UWS ACEC Permit No. ARP97-2 (part of ARP92-13). The authors thank the NSW National Parks and Wildlife Service, NSW Agriculture, and CSIRO for permission to conduct this research on their field sites. Financial support was provided by the Co-operative Research Centre for Biological Control of Vertebrate Pest Populations.

CHEMICAL POLYMORPHISM OF THE CUTICULAR LIPIDS OF THE CABBAGE WHITE *Pieris rapae*

(Received September 3, 2002; revised October 9, 2002; accepted October 10, 2002)

Abstract—The epicuticular composition of different body parts of the Cabbage White, *Pieris rapae* L., was investigated using GC and GC/MS. The major group of components, hydrocarbons, occurs in two distinct classes, which show different distributions on the cuticle of the insects. Unbranched shorter chain compounds (C_{21} to C_{31}, linear group) dominate on body, head and wings, while longer chain, polymethyl-branched compounds (C_{35} to C_{39}, branched group) are predominantly found on the antennae. Several other components like 1,3-pentacosadiene and oxygenated aliphatic compounds occur in minor amounts on the cuticle. The reason for this polymorphism is discussed.

Key Words—*Pieris rapae*, alkanes, alkenes, alkadienes, alcohols, alkanediols, cuticle, cuticular lipids, tetrahydrofurans.

INTRODUCTION

The epicuticular lipids of insects have been extensively studied by modern gas chromatographic and mass spectrometric methods, the predominant class of compounds being alkanes. Numerous reviews have been published dealing with the composition of the insect cuticle and its function as a barrier between the body and the environment or as a carrier of information (e.g., Nelson and Blomquist, 1995). Nevertheless, comparative analyses among different body parts have rarely been performed (see references cited in Howard, 1993; Buckner et al., 1994; Young et al., 2000), and antennal lipids have been neglected. During our studies on the mating system of Pierid butterflies, we found striking differences in the composition of the surface lipids of the Cabbage White, *Pieris rapae*, among different body regions.

METHODS AND MATERIALS

About 20 freshly eclosed butterflies of *P. rapae* L. (Lepidoptera: Pieridae) were killed by freezing, sexed, and dissected into wings, body (thorax, abdomen, and legs), head, and antennae. Extracts of the different body parts were obtained by a short rinse with pentane (Merck, Suprasolv). Care was taken to avoid contamination of the sample with hemolymph by not allowing contact of solvent and cut surfaces. The different extracts were subjected to GC and GC-MS analyses as previously described (Shulz, 2001). SPME analyses were performed by rubbing a 100 μm PDMS fiber, conditioned at 250°C, on all the respective body parts. This procedure was repeated twenty times to obtain enough material for analyses. All individual analyses were repeated three to five times. Derivatization with dimethyldisulfide (DMDS) was performed according to Francis and Veland (1981).

RESULTS AND DISCUSSION

The analyses revealed that hydrocarbons are the major class of lipids present on the epicuticle in all samples. They were characterized by well established methods based on the interpretation of mass spectra and gas chromatographic retention indices (Carlson et al., 1998; Schulz, 2001). Two different alkane groups could be distinguished: Straight chain alkanes ranging in chain length from C_{21} to C_{31} (linear group) and di-, tri-, and tetramethyl branched alkanes with longer chain length (C_{35} to C_{39}, branched group). In the first group, small amounts of methyl branched alkanes and also straight chain 1-alkenes co-occurred. The double bond of the alkenes is predominately located at C-1, which was proven by DMDS derivatization {e.g., characteristic ions for 1-heneicosene $m/z = 327$ (100, M-61) and 61 (21)}. This position is rarely found in insect lipids (Howard, 1993; Nelson and Blomquist, 1995). The two alkane groups showed clear differences in their abundance among different body parts. The linear group predominates on the body and the head, while it is markedly reduced on the antennae where the branched group predominates. This latter group is found in smaller amounts on the other body parts as well. On the wings, a modified linear group predominates, which is reduced in the amount of the shorter chain members (Figure 1). The two sexes did not differ in the distribution of hydrocarbons over the respective body parts, as proved by separate analyses. SPME analyses revealed that the identified compounds are present on the surface of the outer cuticle.

Unique compounds are (*E*)- and (*Z*)-1,3-pentacosadiene, not previously reported from insects, which are most abundant on the head and not accompanied by any homologs, as found with the other hydrocarbons. Several long chain oxygenated compounds like C_{29} 2,5-dialkyltetrahydrofurans (present only on the

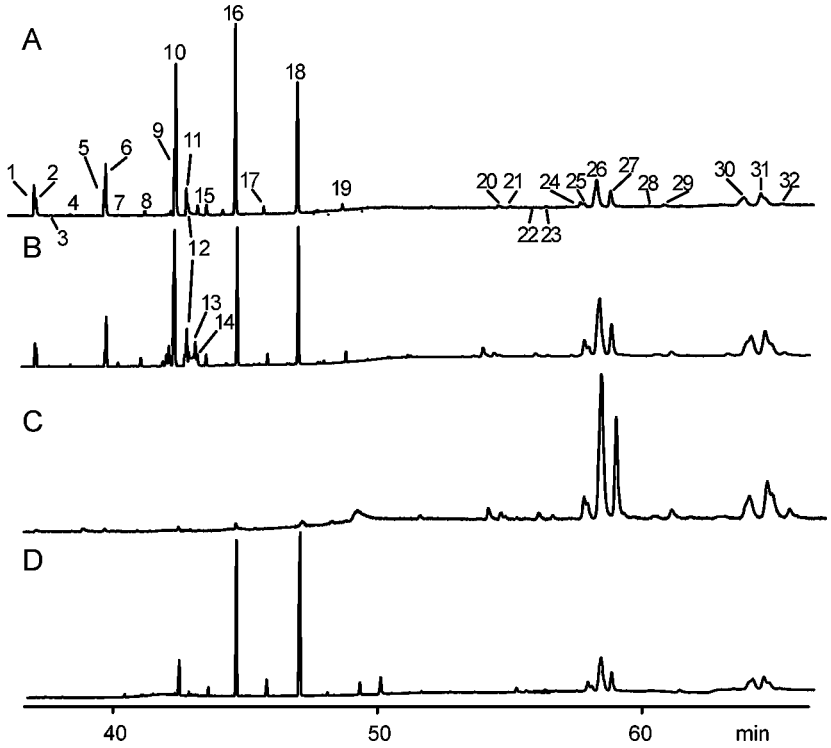

FIG. 1. Gas chromatograms of solvent extracts of cuticular lipids of *P. rapae*. A: body; B: head; C: antennae; D: wing. Numbers refer to Table 1.

antennae), alkyl methyl ethers, secondary alcohols, and corresponding 1,2-, 1,3-, and 1,4-diols, like 6,9-nonacosanediol, were also identified. They often occur in enhanced proportions on the antennae or the head.

While qualitative differences in the composition of different body parts have been observed occasionally in insects, no such large differences as found in the present study have been reported. There might be several reasons for the observed chemical polymorphism. The water permeability of the epicuticle of insects seems to depend on the melting point of the lipids (Gibbs, 2002). Because methyl branchings have a much stronger influence on the melting temperature of hydrocarbons than chain length (Gibbs, 2002)., it can be safely assumed that the branched group of hydrocarbons has a lower melting point than the linear group. This might result in higher water loss, higher fluidity, and, most importantly, also higher diffusion rates of dissolved molecules. The first event in the olfactory process is adsorption or solution of a signal molecule on the antennal cuticle. The molecule then has to travel by diffusion to pores in the sensillum surface, where it is caught by a

binding protein (Kanaujia and Kaissling, 1985; Kaissling, 2001). This diffusion is certainly faster in materials with higher fluidity, a probable reason for the enhanced proportion of multi-branched hydrocarbons on the antennae. A fast transport of signal molecules on the antennal surface has been shown by Kanaujia and Kaissling (1985). Furthermore, the different patterns and singular components of the cuticular lipids may be used in chemical communication (Nelson and Blomquist, 1995), especially at close range and in the contact phase of courtship and mating behavior. This might be one reason for the presence of unique compounds on certain body surface areas. Most likely a distribution of lipids as in *P. rapae* may also be found in many other insects.

Book Review

Insect Physiology and Biochemistry. By J. L. Nation. CRC Press, Boca Raton, Florida. $109.95. 485 pp. ISBN 0-8493-1181-0

Dramatic discoveries in molecular biology, recombinant genetic manipulation of plants and animals, and genomics, all promising remarkable advances in crop sciences, public health, and medicine, fill the daily news. Few among the public are aware of or credit many of these advances to knowledge derived from fundamental studies of insect physiology and biochemistry and especially of the genome of the fruit fly *Drosophila melanogaster*.

Studies of the form and function of insects have enjoyed a long history, yet only in the last century have investigations of the biology of insects so vastly enriched science and, by association, human welfare. The short lives of insects and their high reproductive potential permit rapid life cycle investigations that are difficult with "higher" longer lived animals. Since all eucaryotic organisms share common developmental and biochemical pathways regulated by genes, biologists, especially physiologists, evolutionary biologists, geneticists, biochemists, and molecular biologists, concentrate their investigations on insect models. Early physiology textbooks related form and function, with scant inclusion of insect biochemistry beyond obvious elements that could be borrowed from studies of human biochemistry. With time, increasing biochemical investigation targeted directly to insects, along with exploration of the genome of the fruit fly, birthed the modern disciplines of genetics and molecular biology. Equally, the information from insect science and its impact on plant and animal protection from insect pests and disease vectors, as well as the toxicological concerns emerging from worldwide pesticide usage, has sparked increased demand for appropriate courses throughout academia.

Basic formal coursework in insect physiology, once relegated nearly exclusively to students in academic departments of entomology, parasitology, vector biology, and toxicology, now command an important presence in the curriculum of nearly all-aspiring biological scientists irrespective of their interest in the fundamental or applied sciences. Advances in plant pest and disease vector control taken together with contributions of insect science to studies of biochemistry, chemical ecology, evolution, genetics, and molecular biology are commanding reasons for

0098-0331/02/1200-2633/0 © 2002 Plenum Publishing Corporation

instruction focussed on the physiology and biochemistry of the Class Insecta that composes the principal animal biota of earthlife.

Textbooks serve principally to introduce students to the basics of a discipline and awareness of the expanding literature of the subject. The recently published textbook *Insect Physiology and Biochemistry* by Professor James L. Nation of the University of Florida accommodates very well the need for a contemporary introduction to the subject. Composed of fifteen chapters, the text is arranged conventionally, beginning with Embryogenesis and ending with Reproduction and an appendix that positions the Class Insecta among related taxa to familiarize the invertebrate challenged student with the status of these dominant planetary lifeforms. All chapters combine contemporary research data with excellent illustrations and recent references. Early insect physiology texts often rigorously referenced the works of pioneering contributors; some with credits even to Aristotle. Fortunately, this current work disdains such practice, favoring for the most part recent studies and interpretations. Nation has clearly set the goal of demonstrating the basic aspects of insect physiology and biochemistry to undergraduate students largely free of the complexities required by more advanced students. This is achieved in a remarkably readable and well-illustrated volume.

The first chapter Embryogenesis relates the development of primordial cells and their differentiation into tissues, then segmentation and organogenesis and their regulation by known gene groups. Elements of biochemistry enter the text with the chapters on Digestion and Nutrition and continue throughout most of the following chapters with expansion in the chapter on Intermediary Metabolism. It is noteworthy that the chemistry is introduced in close support of physiological functions. Thus, elements of chemistry highlight the function rather than dramatize the author's personal store of detailed biochemical minutiae. Would that this practice was more generally adhered to in introductory texts. The following chapters i.e., Neuroanatomy, Neurophysiology, Muscles etc. focus on the specific form and function of each organ system and are clearly presented and illustrated.

Given my personal research interests I turned directly to the chapter on Hormones and Development to obtain some flavor of the organization, clarity, and content of a chapter I felt most competent to criticize. This chapter is organized around the anatomy of the endocrine organs and details their regulation of metamorphosis and reproduction. It provides a broad overview of insect endocrines, eschewing extraneous detail and resisting review of the comparative aspects of invertebrate/vertebrate endocrinology.

The penultimate chapter on Pheromones precedes the final chapter on Reproduction and is usefully positioned to highlight the participation of chemical communication among insects for co-location of the sexes for reproduction (i.e., sex pheromones). This fascinating chapter (my favorite) clearly sets forth the various modes of chemical communication among insects, and classifies them according to the behaviors elicited (i.e., which benefits). The treatment of receptors, binding

proteins, signal transduction, biosynthesis, and pheromone blends, however brief, is quite comprehensive for an introductory treatment. Some investigational methods including electrophysiological tools and plume theory are also described. Certainly the detailed chemistry of hundreds of pheromones is known, but Nation wisely imparts details of but a few model structures. The biological relationships chosen to illustrate the elements of insect chemical communication are broad, topical, comprehensive, and composed to introduce students to this dynamic research area. I was astonished at the author's restraint being aware of his own studies and enthusiasm for the subject. Although he mentions the use of pheromones in plant and public health protection, I would have liked to see this expanded a bit for the students anticipating applied careers.

Nation has a splendid feel for his subject and his direct and lucid presentations clearly derive from his classroom lecturing experience. He concisely essays the quanta of knowledge to address the introductory needs of students, yet provides the references appropriate to lead the serious student well beyond. This is particularly true in the chapter on Nutrition, which seemed especially comprehensive. Reviewers are supposed to find and detail things they do not like about the books they judge, but I am unable to find areas of neglect or errors of fact. On the first read I would have expected an expansion on the pheromone chapter to include the author's special insights on *Tephridid* flies or a broader treatment of the burgeoning literature on the pheromones of social insects. Yet, if I stand in the author's shoes for a moment I can see that expansions on such large specialties easily become a black hole in an introductory text. The most critical comment I can make is to wish for some mention of how the study of the insect physiology and biochemistry has benefited humanity i.e., development of environmentally safe methods of plant and public health protection and advances in genetics and medicine.

Insect Physiology and Biochemistry provides an excellent introduction of the subjects to the undergraduate for whom it was written and will serve as a primer for the non-specialist eager to employ insects as their research models. The text is clear, well arranged and a pleasure to read. It presents the broad concepts and focuses on contemporary references rather than exhaustive inclusion of the contributions of the pioneering investigators of insect sciences so well documented in previous texts and monographs. In all, this textbook is an impressive work, emblematic of Nation's ability to present clearly the salient highlights of insect physiology and biochemistry. Its wide adoption as a teaching text is assured.

ANNOUNCEMENT

FONDATION JEAN-MARIE DELWART AWARD 2003 IN ANIMAL AND HUMAN ETHOLOGY CHEMICAL COMMUNICATION

The Jean-Marie Delwart Foundation will award in 2003 a Prize for an original work or series of works, individual or collective in the field of *Chemical Communication*, dealing with the specific action of certain substances on the organisms (Invertebrates, Vertebrates including Man, Plant/Animal relations, etc.) in relation with the corresponding behavioral patterns.

The Prize, in the amount of $10.000, will be attributed to works written or translated in French or in English, which should be sent by April 15th 2003 to the following address:

Fondation Jean-Marie Delwart
Attn: Raphaëlle Holender
U.C.L. Bâtiment Pythagore
4, Place des Sciences (Bte 4)
B-1348 Louvain-la-Neuve
Belgique
E-mail: fondation.j.m.delwart@skynet.be

The applications can be submitted either by the candidates themselves or by recognized specialists in the field considered or again by academic institutions (Academies, Universities, Faculties, Departments, Centres of Research, etc.). In all cases, the applications will be accompanied by a letter of presentation, a detailed curriculum vitae and a complete list of publications (in quadruplicate). The candidates are requested to send copies of the works they consider most linked with their application (reprints and/or books).

The Jury is composed of members of the scientific committee of the Jean-Marie Delwart Foundation and of members of the Académie Royale des Sciences de Belgique.

The Prize will be awarded in December 2003 at the occasion of the Public Session of the Académie Royale des Sciences de Belgique.

KEYWORD INDEX TO VOLUME 28

Acacia, 921
Acacia sedillense, 617
Acetate esters, 807
Acetyl bromide, 2483
Acetyloxynonanal, 9-, 407
Acid detergent fiber lignin, 2483
Acrididae, 1065, 1329
Activated defense, 2091
Adoxophyes privatana, 1473
Aedes aegypti, 983, 1497
Ageratum conyzoides, 1173
Aggregation pheromone, 407, 479, 523, 1527, 1654, 1665, 2299
Agriotes brevis, 1641
Agrites sputator, 1641
Agrobacterium, 333
Alarm, 1629, 2271, 2585
Alarm cue, 555, 1007
Alarm pheromone, 433, 1831, 2601
Alarm response, 2017
Alarm substance, 433
Alcohols, 601, 807
Aldehyde, 385, 601, 807
Alder leaf litter, 983
Alkaloids, 939, 1511, 2315
Alkane, 385
Alkene, 385, 2181
Allelochemical, 873, 2169
Allelochemical stress, 617
Allelopathy, 229, 617, 1173, 1871, 2343
Allium, 2307
Allomonal barrier, 969
Allomone, 1565
Alouatta belzebul, 1613
Alternaria brassicae, 2449
Alternaria brassicicola, 2121
Amanita, 333
Amazonia, 1613
American crocodile, 769
Amino acid, 2483
Amino-3-Cyclopropylbutanoic acid, 2-, 333
Amino-5-chloro-4-pentenoic acid, 2-, 333
Ammonia, 1549
Amphibians, 1007
Anal gland secretion, 1287, 1697
Anal sac secretion, 1865
Anastrepha ludens, 1549
Anisole, 515
Anisopteromalus calandrae, 1209
Anobiidae, 741
Anomala osakana, 1075
Anopheles gambiae, 2371
Antennae, 1839
Anthocyanins, 2449
Antialgal activity, 1091
Antifeedants, 117
Antifungal activity, 1763
Antimicrobial activity, 317
