Because the extracts of swabs that contained odor samples were well below the sensitivity of GC-MS, we used human GC-O to detect and semiquantify these odors. The presence and quantity of 15 odors from 20 individual samples were used in principle component analysis. Chromatograms were generated for each sample and indicated the presence and quantity (duration of elution time/peak width) for odors shared among individuals. For example, one female from the Harvard colony and another from the Sterling colony shared seven common odors that differed in quantity (Figure 2). None of the four control swabs indicated a detectable odor when analyzed using GC-O. The first four principle components accounted for 67.9% of the variation and were subsequently used in discriminant function analysis (Table 1). Examination of character loadings for the first four principle components revealed that the first principle component was most heavily loaded with the peak widths of the chemicals eluting at retention times 848 and 1007. The second principle component was most heavily loaded with the chemical at retention time 1187 and most negatively associated with the odor emitted at 1302. Odors detected at 1076 and 1149 both loaded most strongly on the third principle component, and those detected at 772 and 1145 loaded most heavily on the fourth

TABLE 1. PRINCIPAL COMPONENT ANALYSIS OF VOLATILE ODORS IN *E. fuscus*[a]

Component	Eigenvalue	Difference	Proportion	Cumulative variation
Prin 1	3.21536	0.329315	0.214357	0.21436
Prin 2	2.88604	0.643554	0.192403	0.40676
Prin 3	2.24249	0.402898	0.149499	0.55626
Prin 4	1.83959	0.557045	0.122639	0.67890

[a] Measurements of 15 volatile odors from female *Eptesicus fuscus* were collapsed to four principle components. The first four principle components describe 67.9% of the variation and were used in discriminant function analysis.

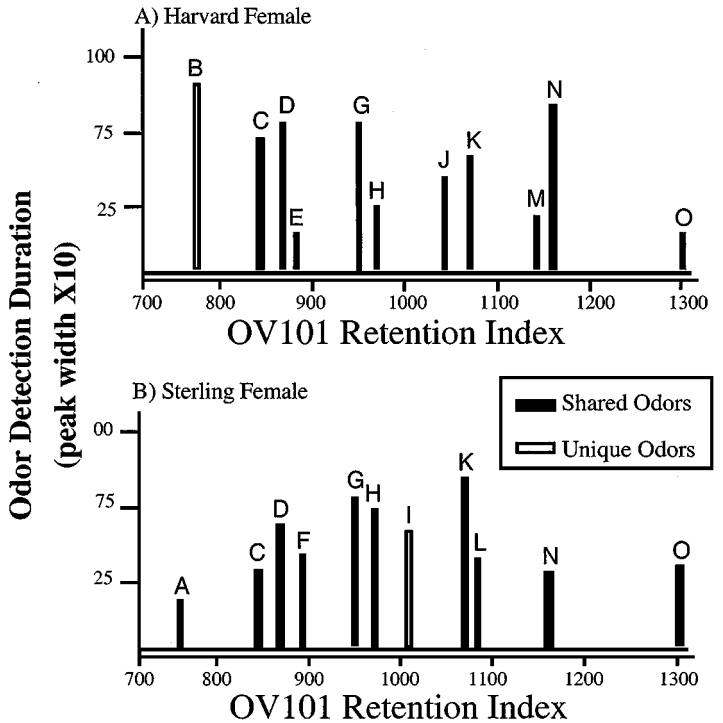

FIG. 2. GC-O chromatograms from two adult female *Eptesicus fuscus* collected from two different maternity colonies in central Massachusetts. These two females shared seven common chemicals (as determined by retention time and descriptions of odors) and quantity (peak width). Letters refer to variables listed in Table 2.

principle component (Table 2). While individuals varied in the relative contribution of each odor component (Figure 2), principle component analysis clearly revealed a separation of odor signature by colony (Figure 3).

Using the first four principle components, discriminant function analysis with cross-validation correctly classified 100% of the bats analyzed from Sherborn ($N = 6$), Harvard ($N = 4$), Milford A ($N = 3$), and Milford B ($N = 3$). For the Sterling colony ($N = 4$), two individuals were incorrectly classified as belonging to the Milford A colony.

From similarities in odor descriptors and OV-101 retention indices, likely chemical matches were found for 14 of the 15 odors used in the colony analysis. A literature search of these compounds shows that many of the chemicals identified as being potential matches were important in other biological systems (Table 3).

TABLE 2. RETENTION TIMES, DESCRIPTORS, AND PCA LOADINGS FOR THE 15 VARIABLES[a]

Variable	Retention time	Descriptor	Component loadings			
			Prin 1	Prin 2	Prin 3	Prin 4
A	772	Fruity	0.2136	−0.2632	0.0982	−0.4592

[a] The 15 variables were used in the principle component analysis of odors detected in female *Eptesicus fuscus*. The variables that load most heavily on the first four principle components are underlined. The first principle component is most heavily loaded for variables C and I; the second principle component for variables L and O; the third for K and N and the fourth for A and M.

DISCUSSION

It has become increasingly evident that olfactory cues are used by bats to identify individual colony members (Schmidt, 1988; Brooke and Decker, 1993), as territorial markers (Höller and Schmidt, 1993; Haffner, 1995; French and Lollar, 1998), and in mother–infant recognition (e.g., Watkins and Shump, 1981; Gustin and McCracken, 1987; Esser and Schmidt, 1989; De Fanis and Jones, 1995a; see Bloss, 1999 for a review). Olfactory cues may also be used by bats to complement auditory cues associated with mother–infant recognition (e.g., Thomson et al., 1985; Balcombe, 1990; Jones et al., 1991; Balcombe and McCracken, 1992; De Fanis and Jones, 1996).

This study provides the first evidence that female big brown bats, recognize the scent from members of their own colony. De Fanis and Jones (1995b) found similar results in the common pipistrelle, *Pipistrellus pipistrellus*. As in the study of De Fanis and Jones (1995b), we were not able to determine whether bats responded to the odor of familiar individuals or whether a group-distinct odor was recognized. Notwithstanding, the similarity among odors produced by members of the same colony of *Eptesicus fuscus* is supported by our chemical analysis. Discriminant function analysis was successful in grouping odor signatures by

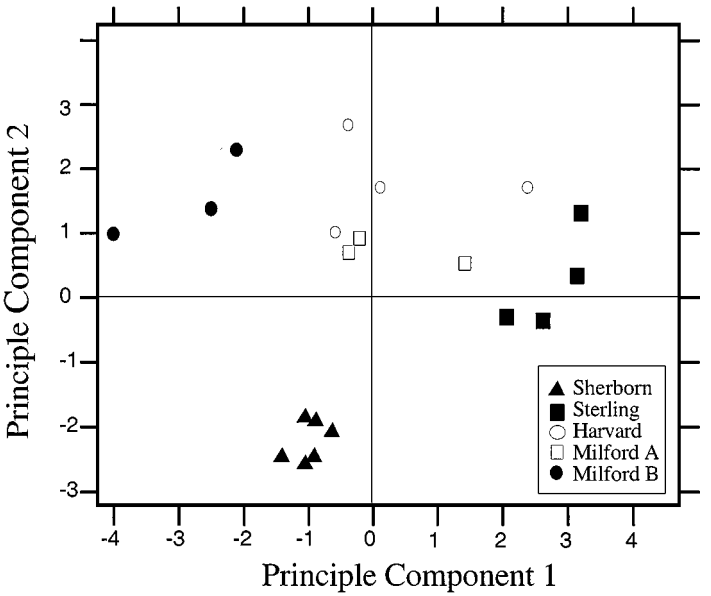

FIG. 3. Principle component analysis of the overall body odor female *Eptesicus fuscus* was used to collapse 15 measured odor variables into four components (see Table 1). This analysis reveals a separation of colonies by the first and second principle components.

the correct colony in a majority of cases, providing evidence for colony-specific odor signatures.

If colony members share similar odor signatures with one another more than they do with conspecifics from other colonies, the logical question becomes what factors produce these similarities? The consistency of odors among colony mates may be due to similarity in microbial cultures, shared food sources, identical roosting substrate, genetic relatedness, or a combination of any or all of the above.

Odors may be derived from several sources. Secretions from specialized glands, urine, or feces or by-products of microbial metabolism may all contribute to the overall odor of an individual. For example, glandular pockets of the fish-eating bat, *Noctilio leporinus*, contain pungent odors (Brooke and Decker, 1993, 1996). When bacteria from these pockets have been cultured, the odors produced were similar to those produced by the bats that were sampled (Studier and Lavoie, 1984). Thus, group-specific odors may reflect unique bacterial cultures shared by grooming or roosting in proximity to members of the same colony (Dapson et al., 1977; Studier and Lavoie, 1984). Members of the genus *Eptesicus* possess well-developed facial and pararhinal glands (Quay, 1970), which may contribute to odor production.

TABLE 3. POSSIBLE CHEMICALS ASSOCIATED WITH ODORS DETECTED FROM GC-O ANALYSIS OF *Eptesicus fuscus*[a]

RI	Possible compound(s)	Biological activity in other systems
772	Methyl-2-methylbutanoate	?
788	Ethyl butanoate	Dung beetle attractant (Burger et al., 1995)
848	2-Methyl-1-butanol	Sap beetle attractant (Nout and Bartelt, 1998; Bartelt and Wicklow, 1999)
870	(*E*)-2-Hexene-1-ol	Green capsid bug attractant (Groot et al., 1999); spined soldier bug attractant (Sant'Ana et al., 1999)
884	Ethyl valerate	?
896	[A]2-Furfurylthiol or [B]2-acetyl-1-pyrroline	[A]Corn volatile (Buttery and Ling, 1998); [B]mousy aroma in wines (Herderich et al., 1995); maize volatile (Bredie et al., 1998)
949	Heptanol	?
960	[A]6-Methyl-5-hepten-2-one or [B]1-octen-3-ol	[A]Volatile involved in attracting aphid-tending ants (Cordova-Yamauchi et al., 1998); ant pheromone (Do Nascimento et al., 1998); aphid parasitoid attractant (Du et al., 1998); aphid spacing chemical (Gonzales et al., 1999); [B]vertebrate volatile attractant to mosquitos (Takken, 1999) and ticks (Osterkamp et al., 1999); green capsid bug attractant (Groot et al., 1999)
1007	Phenylacetaldehyde	Sternal gland secretion in male koalas (Salamon and Davies, 1998); fall armyworm attractant (Meagher and Mitchell, 1998); floral scent attracting Lepidoptera (Omura et al., 1999a,b) and Hymenoptera (Meagher and Mitchell, 1999)
1049	(*E*)-Ocimene	Volatile released by damaged cotton plant (Rose et al., 1998) or broad bean (Du et al., 1998) which attracts herbivore enemies
1076	2-Phenylethanol	Sheep blowfly attractant to host odor (Park and Cork, 1999); pineapple beetle (Zilkowski et al., 1999), house fly (Chapman et al., 1998), twelve-spotted lady beetle and green lacewing attractant (Zhu et al., 1999)
1087	Linalool	Volatile released by damaged plants is an attractant for spined soldier bugs (Sant'Ana et al., 1999); lavender compound used in aromatherapy (Lis-Balchin and Hart, 1999); green capsid bug attractant (Groot et al., 1999); volatile used by Egyptian cotton leaf worm to decriminate between damaged and undamaged plants (Jonsson and Anderson, 1999); moth-pollinated flower volatile attractant to hawkmoths (Raguso et al., 1996; Raguso and Light, 1998)
1145	Benzyl acetate	Moth-pollinated flower volatile attractant to hawkmoths (Raguso et al., 1996; Raguso and Light, 1998)
1149	?	?
1292	*O*-Aminoacetophenone	Component of Japanese weasel anal sac (Acree et al., 1990); mountain beaver (Nolte et al., 1993) and bird repellent (Clark, 1998)

[a] The potential compounds were determined using the descriptors and OV-101 retention times listed on the Flavornet (Acree and Arn, 1997). Many of these chemicals have been shown to be biologically active odorants in other systems. The retention index (RI) refers to the average RI used in this study and corresponds to the retention times listed in Table 2. A question mark denotes that the RI and odor desciptors did not match any listed on the Flavornet or the compound was not found in recent literature.

By a similar mechanism, members of a colony that forage in the same general area may share a similar diet. Diets of different big brown bat colonies are known to differ in insect composition (Whitaker, 1995). The metabolism of related food items, especially by related individuals could produce similar volatile by-products and, thus, affect overall body odor (Schellinck et al., 1997). In our study, two members of the Sterling colony were misclassified into the Milford A colony. These colonies are separated by approximately 45 km. Individuals from the two Milford colonies, separated by only 2 km were not misidentified as belonging to the other Milford maternity roost. This evidence suggests that shared diet may not be an important factor in determining colony odor. However, further investigations using dietary controls are needed to assess this possible source of odor production, since even bats from the same roost may forage in different locations and consume varied diets. In addition, roosting substrate should be evaluated, as individuals in our study may have responded to the familiar odor of their roost in behavioral tests.

Female *Eptesicus fuscus*, especially those from maternity colonies in human-made structures, tend to show high site fidelity during pregnancy and lactation (Brigham and Fenton, 1986). After disturbance, colony members often relocate as a group, indicating that roosting assemblages may function as social groups rather than random aggregations of individuals (Brigham and Fenton, 1986). Since our banding records support female philopatry, inhabitants of these maternity roosts are likely to be genetically related. Colony-specific scents could be the result of genetically related individuals that produce similar odors.

The major histocompatibility complex (MHC) has been shown to affect the odor of an individual (Eggert et al., 1996, 1998). MHC is a highly polymorphic group of genes that controls the immune system's recognition of self and nonself (Eggert et al., 1998; Penn and Potts, 1999). Although the precise mechanism for how MHC loci influence odor production is not entirely clear, based on olfactory cues, some rodents and humans are able to distinguish individuals who vary in this gene complex (Eggert et al., 1998; Penn and Potts, 1998). A similar mechanism might exist in bats if chemosensory recognition of kin occurs among individuals that share similar MHC regions. Further studies are needed to elucidate such a recognition system in bats, and a first step would be to evaluate the degree of genetic relatedness among colony members.

Group recognition via olfactory or other cues could facilitate the stability of social groups. Familiar individuals are more likely to cooperate and avoid agonistic interactions than those with infrequent contact or that are unrecognized (Lewis, 1995). Roosting groups are important for bats, especially in maternity colonies where stable temperatures are vital for proper development of the young (Kunz and Hood, 2000). The cost of thermoregulation is decreased by clustering behavior (Herreid, 1967; Trune and Slobodchikoff, 1976; Bonaccorso et al., 1992; Lewis, 1995). The recognition of colony mates may also facilitate winter aggregations in hibernacula.

When the possible chemical identities of the 15 odors used in the study were investigated, 11 of the 14 potentially identified compounds were found to be biologically active in other taxa (Table 3). For example, the odor described as musty, with an average retention index of 1007 (Table 2), is probably phenylacetaldehyde with a retention index of 1004 (Acree and Arn, 1997). This compound was identified as a heavily loaded variable in the first principle component (Table 2) and may be important in colony recognition. Phenylacetaldehyde is present in the secretion from the sternal gland of male koalas (Salamon and Davies, 1998). It is also an attractant for many lepidopteran (Omura et al., 1999a,b) and hymenopteran species (Meagher and Mitchell, 1999). The biological importance of an odor among diverse taxa is not surprizing given the homology that exists in the olfactory detection systems of a wide diversity of organisms (Acree and Bloss, 1996).

Most of what is understood about pheromones comes from the study of insects. This group accounts for about 70% of all described species, and many of these are agricultural crop pests (Agosta, 1992). Since considerable research is devoted to understanding insect attractants and repellents, most compounds identified as potential chemicals in big brown bat colony odor also were considered to be important in insect systems (Table 3). In fact, many of the insect families represented in Table 3 have been reported in the diet of *E. fuscus* (Whitaker, 1995; W. R. Hood, unpublished data). As the study of chemical ecology expands, many insect pheromones have been shown to be biologically important in vertebrates (Acree and Bloss, 1996).

Our study does not unequivocally demonstrate that colony members recognize each other using olfactory cues or that group-distinct colony odors are present. However, it does suggest that female big brown bats prefer the odor of a roost-mate to that of a conspecific from another colony. Such a preference may promote colony stability and, thus, have implications for foraging, kin recognition, and mating. Olfactory cues, like the well-studied auditory cues of bats may be important in establishing and maintaining social interactions within a species.

Acknowledgments—We thank T. Kingston, R. Nishida, K. White, and anonymous reviewers for their helpful comments on this manuscript, as well as E. Lavin for his technical support. We also thank the Frechette, Ferguson, Hoffman, and Zahn families who provided access to their barns. This study was funded by a dissertation improvement grant from the National Science Foundation (IBN 9801137), a Theodore Roosevelt grant from the American Museum of Natural History, NSF-REU support (DBI 9605257), and an American fellowship from the AAUW.

(Received April 18, 2001; accepted December 7, 2001)

Abstract—The salticid spider *Cosmophasis bitaeniata* preys on the larvae of the green tree ant *Oecophylla smaragdina*. Gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS) reveal that the cuticle of *C. bitaeniata* mimics the mono- and dimethylalkanes of the cuticle of its prey. Recognition bioassays with extracts of the cuticular hydrocarbons of ants and spiders revealed that foraging major workers did not respond aggressively to the extracts of the spiders or conspecific nestmates, but reacted aggressively to conspecific nonnestmates. Typically, the ants either failed to react (as with control treatments with no extracts) or they reacted nonaggressively as with conspecific nestmates. These data indicate that the qualitative chemical mimicry of ants by C. bitaeniata allows the spiders to avoid detection by major workers of O. smaragdina.

Key Words—Chemical mimicry, cuticular hydrocarbons, nestmate recognition, inter-specific exploitation, predation.

INTRODUCTION

The resident workers of many species of ants attack and kill nonnestmates that try to enter the nest (e.g., Jaisson, 1991). Nevertheless, there are many records of nonnestmates living within the nests of these species (see Hölldobler and Wilson, 1990 for review). Nonnestmates survive inside these nests if they can

prevent the resident ants from attacking them or can defend themselves against ant attack (Eisner et al., 1978). This can be achieved through a combination of morphological and chemical mimicry, defensive chemicals, appeasement secretions, and behavioral strategies (reviews in Kistner, 1979; Dettner and Liepert, 1994; Haynes and Yeargan, 1999; Lenoir et al., 2001).

Cuticular hydrocarbon mimicry is the most commonly recognized mechanism that myrmecophiles and termitophiles use to deceive their social insect hosts (Dettner and Liepert, 1994). Resident workers routinely attack conspecifics and other species whose cuticular hydrocarbons are qualitatively and/or quantitatively different from those of the nest inhabitants (Henderson et al., 1990; Bagneres et al., 1991; Bonavita-Cougourdan et al., 1993, 1997; Habersetzer, 1993; Takahashi and Gassa, 1995; Vauchot et al., 1996). Thus, access to the nest by myrmecophiles and termitophiles requires a degree of mimicry of the cuticular hydrocarbons of the host (e.g., Hölldobler, 1971).

The cuticular hydrocarbon profiles of several ants and termites and their associates have been identified by gas chromatography–mass spectrometry (GC-MS), but these studies did not include recognition bioassays (e.g., Howard et al., 1980, 1990a,b; Vander Meer et al., 1989; Howard, 1992; Howard and Infante, 1996; Bagneres et al., 1996; Völkl et al., 1996; Vauchot et al., 1998; Lenoir et al., 2001). Simply revealing similarities between species in their cuticular hydrocarbons is not sufficient to demonstrate that the cuticular hydrocarbons function as camouflage or that they represent species or colony-specific recognition cues. Cuticular hydrocarbons may be acquired by a myrmecophile simply as a by-product of living in an ant colony and may not communicate any signal to the ant. Thus, recognition bioassays are essential to demonstrate that chemical mimicry or camouflage occurs when the cuticular hydrocarbons of a myrmecophile resemble those of its host. Other studies that have examined morphological and/or behavioral traits involved in the deception of ants by myrmecophiles have generally assumed that chemical mimicry or chemical camouflage is also involved (Garnett et al., 1985; Breed et al., 1992; Völkl and Mackauer, 1993; Feener, 1995; Völkl, 1995; Weissflog et al., 1995).

More recent studies have combined chemical analyses with behavioral bioassays, and they reveal that two different groups of chemical compounds may be used in nestmate recognition. Moritz et al. (1991) show that the death's-head hawk moth, *Acherontia atroposa*, which parasitizes colonies of the honeybee, *Apis mellifera*, chemically camouflages itself in a bouquet of fatty acids that makes the moth chemically "invisible" to the bees. However, it was not determined whether the bees used these fatty acids in nestmate recognition. Liepert and Dettner (1993) demonstrated with recognition bioassays that the aphidiid wasp *Lysiphlebus cardui* uses chemicals located on its cuticular surface to avoid being attacked by the ant *Lasius niger.* This ant guards the aphids that the wasp parasitizes. The chemicals were subsequently identified as methyl-branched alkanes rather than fatty acids

(see Liepert and Dettner, 1996). These studies indicate that nestmate recognition and the deception of social insects is mediated by both methyl-branched alkanes and fatty acids (see also Bonavita-Cougourdan et al., 1987; Franks et al., 1990).

It is generally thought that host cuticular hydrocarbons are acquired by the myrmecophile during contact with the host (Vander Meer et al., 1989; Akino et al., 1996). Most myrmecophiles come into direct physical contact with their host (Vander Meer and Wojcik, 1982; Vander Meer et al., 1989; Franks et al., 1990; Howard et al., 1990a,b), and the host often attacks myrmecophiles before they have acquired the mimetic cuticular hydrocarbons (Franks et al., 1990). These ant-derived hydrocarbons are probably not cuticular but rather originate from the hydrocarbon-rich postpharyngeal glands of the attacking ants (Howard et al., 1990b). The postpharyngeal hydrocarbons are similar to the cuticular hydrocarbons. Indeed, if the contents of the postpharyngeal gland are spread onto the cuticle of an ant, it will be accepted as a nestmate (Soroker et al., 1994; Hefetz et al., 1996).

The importance of chemical cues in the deception of ants by a brood predator that avoids direct contact with its host remains poorly understood (Akino et al., 1999; Elmes et al., 1999). The salticid spider *Cosmophasis bitaeniata* lives within the nests of the ant *Oecophylla smaragdina*, where it preys on the ant larvae but avoids direct contact with the workers (Allan and Elgar, 2001). Workers of *O. smaragdina* construct nests by binding together leaves with silk produced by larvae; a mature colony of *Oecophylla* may contain between 100,000 and 500,000 workers (Hölldobler and Wilson, 1978) that may construct as many as 150 nests across 12 trees (Way, 1954). Major workers of *Oecophylla* aggressively defend their colony from intruders of other species or conspecifics from neighbouring colonies (Hölldobler, 1983; Dejean, 1990; Keegans et al., 1991). Major workers attack most arthropods they encounter and consequently reduce the numbers of insects on the trees they inhabit (Lokkers, 1986, 1990). Individuals of *C. bitaeniata* are able to enter nests of ants apparently undetected. Here, we investigate whether the cuticular chemicals (hydrocarbons or fatty acids) of *C. bitaeniata* mimic those of *O. smaragdina* by using gas chromatography (GC) and gas chromatography–mass spectrometry (GC-MS). Recognition bioassays are conducted to examine whether the relationship between *C. bitaeniata* and *O. smaragdina* is facilitated by chemical mimicry and whether *C. bitaeniata* is able to mimic the nestmate recognition cues of its host.

METHODS AND MATERIALS

Gas Chromatography. The cuticular chemicals of the spider *C. bitaeniata* and the major workers, minor workers, and larvae of *O. smaragdina* were extracted with hexane and then analyzed by using capillary gas chromatography. Individuals of each species and caste were collected from the campus of James Cook University in Townsville, Australia. Immediately after collection, the ants, larvae, and spiders

were immersed in separate vials, each containing 100 μl of HPLC-grade hexane for 10 min, then each vial was agitated for 1 min on a vortex mixer before the specimens were removed. The hexane solution was evaporated under a stream of nitrogen. Immediately prior to analysis, 10 μl of hexane was added to each sample and 1 μl of this solution analyzed by gas chromatography using a Shimadzu 17A gas chromatograph with a 5% phenyl and 95% methyl siloxane stationary phase (S.G.E. BPX5, 25 m $\times$ 0.33 mm ID; 0.5 μm). The temperature program ramped from 60°C to 300°C at 20°C/min. The temperature was held constant for 3 min at 300°C prior to ramping at a rate of 2°/min to 330°C where it was held constant for 10 min. The retention time was 40 min. The injector was operated in splitless mode for 1 min at 350°C. The detector was kept at 375°C.

Gas Chromatography–Mass Spectrometry (GC-MS). Mass spectra were determined on a VG Micromass 70-70F mass spectrometer interfaced directly to a Hewlett-Packard 5792A capillary gas chromatograph and a VG 11-250 data system. The column used was a bonded-phase capillary methylsilicone (Alltech Econocap, SE30; 25 m $\times$ 0.33 mm ID; 0.25 μm). Injections of the hexane solutions were made on-column at 60°C using a Hewlett-Packard 19290A on-column inlet. Electron ionization mass spectra were obtained at an ionization voltage of 70 eV and a source temperature of 200°C. The mass spectra in conjunction with ECL values were used to determine the chemical identity of the individual hydrocarbons.

Behavioral Bioassay. The bioassays examined the response of foraging *O. smaragdina* major workers to discs of filter paper, thereby ensuring that chemical cues only were detected. The cuticular hydrocarbons were extracted from the animals using hexane, and 1-cm discs of filter paper were then submerged in the supernatant. There were four treatments comprising extracts from: (1) 15 nestmate major workers collected from one colony of *O. smaragdina*, (2) 15 nonnestmate major workers collected from another colony of *O. smaragdina*, (3) 15 *C. bitaeniata* collected from the same colony as the nestmate major workers, and (4) control filter papers immersed in hexane alone. There were insufficient numbers of spiders available to examine intercolony variation, and, thus, each ant and spider pair was collected from a different nest, but all of the nests sampled within each treatment were collected from a single colony.

Field-collected ants and spiders were cooled at 4°C for 5 min prior to cuticular hydrocarbon extraction. All 15 animals from each treatment were immersed in 2 ml of hexane for 10 min, followed by 1 min of agitation on a vortex mixer. The animals in each treatment had to be pooled to ensure that the concentration of cuticular hydrocarbons on the individual filter papers would be equal to that of a single worker, since losses can occur with solvent extraction procedures (Brill and Bertsch, 1985). This procedure resulted in one sample for each treatment. The total extractable cuticular hydrocarbon content per animal was estimated by comparing GC response factors for animal extracts with known concentrations

of standard hydrocarbons (SGE standards (up to C_{30}) supplied by Alltech). This analysis indicated that individual ants and spiders possessed a total extractable cuticular hydrocarbon content of ~400 ng/spider and ~750 ng/major worker.

The hexane extract from each treatment was separated through a column of silica gel (Biosil) to remove polar and glandular constituents that may influence the responses of foraging workers. These four samples were then concentrated to 20 μl under a stream of nitrogen. The resulting 20 μl was pipetted in equal 2-μl aliquots onto ten, 1.27-cm-diam. discs of Whatman filter paper. The filter paper discs were left at room temperature for 10 min to ensure that the hexane evaporated. Individual filter papers were placed onto the foraging trails of major workers using forceps. Ground foraging trails were chosen in preference to tree foraging trails to prevent the discs of filter paper falling from trees. The number of foraging major workers of *O. smaragdina* that walked within 1 cm of the disc of filter paper was vocally recorded onto a dictaphone for 3 min. The immediate response of these foraging ants to the disc of filter paper was also recorded.

RESULTS

Cuticular Hydrocarbons. The cuticular hydrocarbon profiles of the major and minor workers, larvae of *O. smaragdina* and *C. bitaeniata* are shown in Figure 1. These profiles show little similarity up to a retention time of about 20 min, and since the components represented are present in ants (particularly the workers), they are likely to be derived from gland material. These early components are predominantly shorter chain *n*-alkanes, and such lipids are well known from the Dufour glands. In contrast, 14 peaks with retention times of 20–40 min and ECLs of 2700 to 3755 were routinely present in every chromatogram. The spider *C. bitaeniata* did not contain any species-specific cuticular hydrocarbons, and its components were identical with those numbered peaks of *O. smaragdina*.

The structures of the components represented by these 14 peaks were identified by GC-MS (Table 1) and are all well-known components of insect cuticular hydrocarbons (see Lockey, 1988). Only three hydrocarbon types were present; peak 1 represented the *n*-alkane heptacosane, and the other 13 were all either internally branched monomethylalkanes or internally branched dimethylalkanes with chain lengths from C_{29} to C_{37}. Branching showed the usual pattern of being exclusively on odd-numbered carbon atoms when the chain contained an odd number of carbons, and on both odd and even numbered carbon atoms when the chain length was even. All the dimethylalkanes showed a three methylene unit separation between the two branching positions. In all cases these peaks represented mixtures of isomers. However, for convenience we simply refer to them as single components.

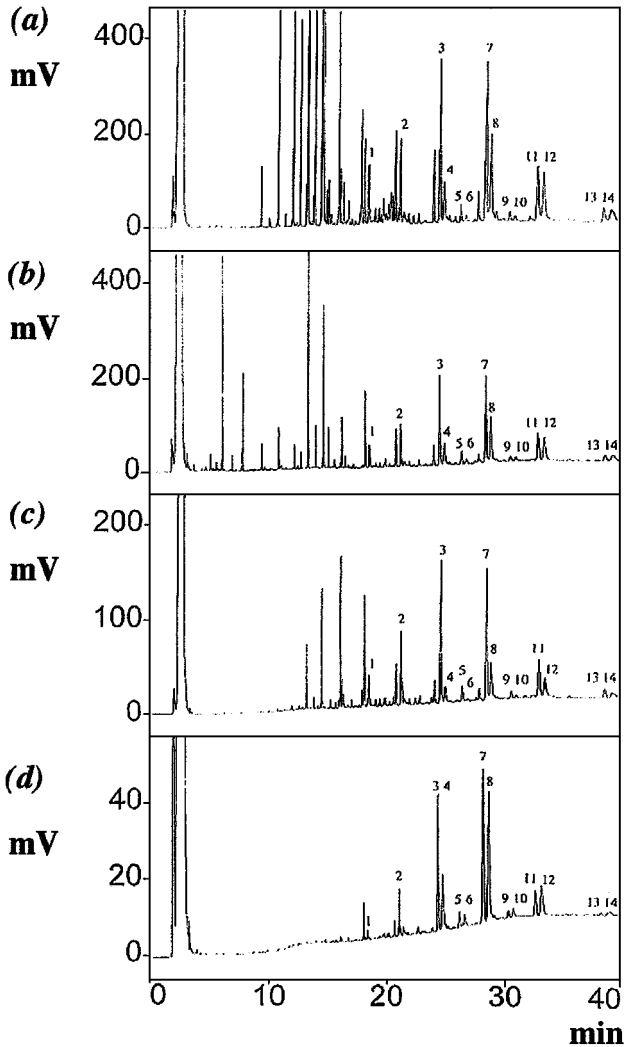

FIG. 1. Gas chromatogram of (a) major workers of *O. smaragdina*, (b) minor workers of *O. smaragdina*, (c) larvae of *O. smaragdina*, and (d) *C. bitaeniata*. Each peak in (d) is marked from 1 to 14, and peaks in common with *C. bitaeniata* are labeled in the other traces.

Behavioral Bioassay. The number of foraging workers of *O. smaragdina* that came within 1 cm of the filter papers was not significantly different among treatments (Table 2). The extracted hydrocarbons on the filter papers would have low vapor pressure, thus producing a small active space and be detected only by

[b] Control discs were immersed in hexane only. *$P < 0.05$; **$P < 0.001$.

contact or at close range (Blum, 1987). We identified four categories of responses of the foraging major workers of *O. smaragdina*. Workers that simply walked within 1 cm of the disc of filter paper but did not stop or otherwise make any obvious response were classified as making no response to the disc. Workers that stopped and touched the disc of filter paper with their antennae but did not open their mandibles made a nonaggressive response. Workers that raised their abdomen, opened their mandibles, and/or bit the disc of filter paper were deemed aggressive, and we scored an aggression index by summing the number of each of these interactions.

The response of workers towards the filter papers depended upon the treatment (Table 2). Control discs and discs with the extracted cuticular chemicals of *C. bitaeniata* were ignored by foraging workers more frequently than discs with nestmate or nonnestmate treatments (Dunnett post-hoc comparison with nestmate treatment: *C. bitaeniata*, $q = 4.2$, $P < 0.001$; control, $q = 4.4$, $P < 0.001$; nonnestmate ant, $q = 0.2$, $P > 0.9$). In contrast, workers exhibited higher frequencies of nonaggressive interactions toward discs with the extracted cuticular chemicals of nestmates and were significantly more aggressive toward discs with the extracted cuticular chemicals of nonnestmates (Dunnett post-hoc comparison between nestmate and nonnestmate treatment: $q = 11.8$, $P < 0.001$).

DISCUSSION

The cuticular hydrocarbons of *C. bitaeniata* closely resemble those of its host ant *O. smaragdina*, and the ants react less aggressively to extracted cuticular hydrocarbons of nestmate workers and spiders than to nonnestmate workers. Further, workers of *O. smaragdina* become more active in the presence of the congenor spiders *C. micans* and *C. micarioides*, which do not associate with these ants, than when in the presence of either their nestmates or *C. bitaeniata* (Allan and Elgar, 2001). Since *C. bitaeniata* preys on the larvae of their host ant (Allan and Elgar, 2001), these data suggest that this myrmecophile spider is an aggressive chemical mimic. This is the first demonstrated example of this kind of mimicry by myrmecophile spiders (see Elgar, 1993; Cushing, 1997; see also Allan et al., 1996).

Fourteen hydrocarbons typically present in the gas chromatogram of *C. bitaeniata* were identified as *n*-alkanes and internally branched methylalkanes and dimethylalkanes. Despite the lack of volatility of hydrocarbons of this type, they are thought to be important in nestmate recognition for social insects (Bonavita-Cougourdan et al., 1987, 1993; Provost et al., 1994). While the 14 cuticular hydrocarbons of the spiders were present on the cuticles of the major and minor workers and the larvae of the host ant *O. smaragdina*, the latter shows some quantitative differences among castes. It is, therefore, possible that the mimicry of these ants by *C. bitaeniata* may be caste specific.

Myrmecophiles may have species-specific cuticular chemicals in addition to their host-resembling chemicals. For example, the lipids on the cuticle of the myrmecophilic cricket *Myrmecophilus* sp. comprise hydrocarbons and wax esters, but only the hydrocarbons decrease when the cricket is isolated from ants, suggesting that while the esters are specific to the cricket, the hydrocarbons may be acquired from the ants (Akino et al., 1996, see also Akino et al., 1999). In contrast, *C. bitaeniata* has no species-specific cuticular chemicals. Why some species that live with social insects possess species-specific cuticular chemicals and others do not (e.g., Vander Meer et al., 1989; Moritz et al., 1991) is not clear. However, there is some suggestion that termitophiles and myrmecophiles that biosynthesize their mimetic chemicals are less likely to have species-specific chemicals (Howard et al., 1990a).

The behavioral bioassay using discs of filter paper indicates that the chemical mimicry reduces the level of aggressive behavior directed towards the myrmecophiles by their host. Foraging major workers attacked the extracted cuticular hydrocarbons of nonnestmates but were not aggressive towards the extracted cuticular chemicals of nestmates, myrmecophiles, or controls. These data are consistent with those from other recognition bioassays that examined whether cuticular hydrocarbons are used by ants to discriminate between conspecific workers (Morel et al.,

1988; Takahashi and Gassa, 1995; Bonavita-Cougourdan et al., 1997; Thomas et al., 1999). However, the hexane extracts of *C. bitaeniata* are not perceived to be chemically identical to those of nestmate or nonnestmate workers. While foraging *O. smaragdina* workers more frequently failed to respond to the control and *C. bitaeniata* treatments than to the cuticular hydrocarbons of conspecifics, nonaggressive interactions were more frequently observed in the spider and nestmate treatments than in the control and nonnestmate treatments.

There are several possible explanations for these patterns. First, the foraging major workers may have responded to the spiders as if they were nonalarmed nestmate workers, but responded to the nestmates and nonnestmate ants as if they were alarmed. This might arise if the ants were able to release alarm pheromone shortly before being immersed in hexane. Second, the cuticular hydrocarbons of spiders may resemble a generalized species odor that does not contain a colony identification cue. Finally, the cuticular hydrocarbons of ants function as colony-recognition cues, although the spiders do not mimic the major worker caste, but rather the larvae or minor caste of *O. smaragdina*.

Resolving these alternatives depends in part on whether cuticular hydrocarbons alone act as colony-specific recognition cues in ants. The hexane extract of *C. bitaeniata* was filtered through silica gel and, thus, only contained cuticular hydrocarbons. Any behavioral response by foraging ants towards filter papers covered in spider extracts can, therefore, be attributed only to these components. However, the lack of response by the workers to these compounds suggests that hydrocarbons alone may not be used to distinguish between nestmates and nonnestmates. A distinction is often drawn between a species odor and a colony odor (e.g., Vander Meer and Wojcik, 1982; Habersetzer, 1993), and fatty acids and esters may be more important in recognition between colonies than cuticular hydrocarbons (Franks et al., 1990; Kaib et al., 1993). If spiders mimic *O. smaragdina* at the species level but not at the colony level, they could disperse to adjacent colonies without eliciting aggression from workers. Thus, the alkanes and internally branched methylalkanes and dimethylalkanes of *C. bitaeniata* may not be a colony-specific cue, but rather a more generalized species identification cue. However, this raises the question of which chemical cues are used by *O. smaragdina* to distinguish between nestmates and nonnestmate conspecifics.

It is possible that the cuticular chemicals of spiders did not elicit the same response from foraging workers as that of nestmates because *C. bitaeniata* does not mimic the major caste of *O. smaragdina.* Several myrmecophiles are chemical mimics of the larvae of their hosts (Hölldobler, 1971; Garnett et al., 1985; Vander Meer et al., 1989; Howard et al., 1990b). If the relative proportions of hydrocarbons differ between different castes within a species (Howard et al., 1982; Bonavita-Cougourdan et al., 1993; Haverty et al., 1996), then *C. bitaeniata* may mimic the relative proportions of the cuticular hydrocarbons of either the minor workers or the larvae of *O. smaragdina*.

Our data raise more general issues about the extraction of cuticular compounds for recognition bioassays involving ants and termites. Typically, these compounds are extracted using hexane or pentane (e.g. Thomas et al., 1999), and, thus, are at risk of being contaminated by glandular compounds. For example, the gas chromatograms of *O. smaragdina* have many compounds that are more volatile than the numbered cuticular compounds, all of which are missing from the chromatogram of *C. bitaeniata*. One procedure is to place the solvent extract through silica gel to remove nonhydrocarbon compounds, but this does not remove volatile hydrocarbons originating from glands (see Bonavita-Courgourdan, 1989; Bagneres et al., 1991). Evaporating the solvent (hexane or pentane) from extracts with nitrogen may eliminate volatile glandular hydrocarbons. However, volatile mandiblular and Dufour gland secretions may play a role in colony odor (Jaffe, 1983; Su and Haverty, 1991; Dani et al., 1996). Although glandular chemicals are generally not considered appropriate as a colony-specific cue due to their volatility (Smith and Breed, 1995), their presence in the separated hexane extract of the workers of *O. smaragdina* may have altered the behavior of the foraging major workers. Thus, recognition bioassays of cuticular hydrocarbons that rely on the extraction of chemicals in organic solvents (e.g., hexane) may be confounded by the presence or absence of noncuticular chemicals that may or may not play a role in colony and/or species recognition.

Acknowledgments—We thank Danielle Clode, Konrad Dettner, and Laurent Keller for their comments and suggestions; Trevor Anderson and Mark Blows for the use of their facilities at James Cook University; Valerie Todd Davies for identifying the spider and the financial support of the Australian Research Council (grant A19331563).

(Received July 2, 2001; accepted December 9, 2001)

Abstract—The enantiomerically pure diastereoisomers (1*R*,4*S*,4a*R*,7*S*,7a*R*)-(**1**) and (1*R*,4*R*,4a*R*,7*S*,7a*R*)-dihydronepetalactol (**2**) were synthesized diastereoselectively from a renewable resource, (4a*S*,7*S*,7a*R*)-nepetalactone (**3**), isolated as the main constituent of the essential oil of the catmint plant *Nepeta cataria*. The stereochemistry of the compounds was determined by NMR spectroscopy and X-ray crystallography, and the compounds were identified, respectively, as neomatatabiol and isoneomatatabiol, natural products from *Actinidia polygama*, for which the lactol stereochemistry was previously incompletely defined. Compound **1** was found to catch significant numbers of three species of lacewing in the field: in Korea, *Chrysopa cognata*, and in the United Kingdom, *Nineta vittata* and most notably *Peyerimhoffina gracilis*. All species caught in significant numbers were found more frequently in traps releasing **1** than **2**, while more *C. cognata*, *C. formosa*, and *C. phyllochroma* were found in traps releasing (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**4**). The catch of *P. gracilis* with **1** is of particular interest as this lacewing has only recently been recorded in the United Kingdom.

Where sexed, the lacewings of all species trapped were found to be male, implying a possible pheromonal role for these or structurally related compounds.

Key Words—*Nepeta cataria*, *Chrysopa cognata*, *Chrysopa formosa*, *Chrysopa phyllochroma*, *Nineta vittata*, *Peyerimhoffina gracilis*, lacewing, pheromone, dihydronepetalactol, neomatatabiol, isoneomatatabiol.

INTRODUCTION

The cyclopentanoids (4a*S*,7*S*,7a*R*)-nepetalactone (**3**) and (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**4**) (Figure 1) comprise the sex pheromones of a number of pest aphids (Aphididae), either as single compounds or as species-specific blends (Dawson et al., 1987, 1989). Aphid species including *Myzus persicae*, *Aphis fabae*, *Acyrthosiphon pisum*, *Sitobion fragariae*, *Tuberocephalus momonis*, and *Rhopalosiphum padi* have been trapped in the field using synthetic samples of these pheromone components (Dawson et al., 1990; Hardie et al., 1997; Boo et al., 2000). In addition, predatory species of lacewing such as *Chrysopa cognata* (Chrysopidae) are caught in traps releasing the same compounds, leading to the suggestion that, just as many aphid species use similar sex pheromones, lacewing predators may be using these compounds as kairomones in locating prey (Boo et al., 1998). Earlier literature reports revealed that the lacewing *Chrysopa septempunctata* was attracted to the vine *Actinidia polygama* (Actinidiaceae), a plant that generates two dihydronepetalactols previously named neomatatabiol and isoneomatatabiol (Hyeon et al., 1968), structurally related to **3** and **4**. The present work aimed to synthesize neomatatabiol and isoneomatatabiol and to determine unambiguously their stereochemistry. Studies were then undertaken to compare the potency of the aphid sex pheromone components **3** and **4** with the dihydronepetalactols related stereochemically to **3**, and to correlate lacewing catches in the field with the lactol stereochemistry not reported previously.

FIG. 1. Structures of aphid sex pheromone components (4a*S*,7*S*,7a*R*)-nepetalactone (**3**) and (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**4**).

METHODS AND MATERIALS

Experimental Chemistry

NMR spectra were obtained using the Bruker 500 Avance NMR spectrometer. GC-MS analysis employed the VG-Autospec (Fisons Instruments) with a siloxane column (50 m × 0.32 mm ID; 0.52 μm) operated from 30°C to 250°C at 5°C/min; EI at 70 EV, 250°C. GC analysis was on an HP-5 siloxane column (30 m × 0.32 mm ID; 0.25 μm) operated from 40°C to 150°C at 5°C/min and from 150°C to 250°C at 10°C/min. Compounds eluted at 16.42 (**2**), 16.93 (**1**), 31.08 (**11**), and 31.44 min (**10**).

(*1*R,*4*S,*4a*R,*7*S,*7a*R)*-Dihydronepetalactol (**1**).* The essential oil from *N. cataria* (10.0 g, 60.2 mmol) was dissolved in ethanol (250 ml) under a hydrogen balloon with 10% palladium on charcoal (600 mg) as a catalyst. The mixture was stirred overnight, filtered, and the solvent removed *in vacuo*. A portion of the crude product (2.0 g, 11.9 mmol) was dissolved in dry THF (30 ml) at –78°C under nitrogen. DIBAL (13.1 ml, 1 M in hexanes) was added slowly and the mixture warmed to room temperature over 1 hr. The reaction was quenched without acidification, extracted with diethyl ether, and the combined organic extracts were dried ($MgSO_4$), filtered, and concentrated *in vacuo*. Purification by flash column chromatography (30% diethyl ether in petroleum ether) and recombination of the purest fractions gave **1** as a clear colorless oil (1.02 g, 50%). $[\alpha]_D^{20} - 1.1^\circ$ ($c = 9.0$, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 4.41 (1H, d, $J = 9.1$ Hz, H-1), 3.66 (1H, dd, $J = 5.2$, 11.8 Hz, *pro-R* H-3), 3.28 (1H, t, $J = 11.8$ Hz, *pro-S* H-3), 3.02 (1H, br s, OH), 2.25 (1H, m, H-4a), 2.14 (1H, m, H-4), 2.06 (1H, m, H-7), 1.98 (1H, m, *pro-R* H-6), 1.59 (1H, m, *pro-R* H-5), 1.46 (1H, m, H-7a), 1.44 (1H, m, *pro-S* H-5), 1.17 (1H, m, *pro-S* H-6), 1.00 (3H, d, $J = 6.9$ Hz, 7-CH_3), 0.80 (3H, d, $J = 7.1$ Hz, 4-CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) δ 97.1 (C1), 67.3 (C3), 53.2 (C7a), 41.7 (C4a), 34.5 (C7), 32.3 (C6), 30.1 (C4), 23.9 (C5), 22.4 (7Me), 14.7 (4Me); $m/z = 170$ (0.16%, M^+), 81 (100%), 67 (96), 41 (77), 137 (65), 39 (58), 95 (55), 109 (50), 79 (44), 152 (42, M^+-18), 82 (40), 27 (39), 110 (37), 107 (36), 55 (36), 53 (34), 43 (26), 77 (26), 29 (25).

*(1*R,*4*R,*4a*R,*7*S,*7a*R)*-Dihydronepetalactol (**2**).* The essential oil from *Nepeta cataria* (10.0 g, 60.2 mmol) was dissolved in methanol (100 ml) at 0°C. A solution of sodium borohydride (2.51 g, 66.2 mmol) in ice cold methanol (100 ml) was added to the mixture by cannula, and the reaction mixture was stirred until complete. The pH was adjusted to 7 after the addition of water (250 ml), and the mixture was extracted with diethyl ether. The combined organic extracts were washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. A portion of the crude mixture (3.0 g, 17.9 mmol) was dissolved in ethanol (75 ml) under a balloon of hydrogen with 10% palladium on charcoal (200 mg) as a catalyst. The mixture was stirred overnight, filtered, and the solvent evaporated to yield a colorless oil containing

a 91:9 mixture of diastereoisomers (2.91 g, 96%). Purification of 2.91 g of the mixture by flash column chromatography (30% ether in petroleum ether) and recombination of the purest fractions gave **2** as a colorless oil (1.85 g, 64%). $[\alpha]_D^{20} + 9.4^\circ$ ($c = 6.2$, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.12 (1H, br s, H-1), 4.17 (1H, br s, OH), 3.60 (1H, t, $J = 11.0$ Hz, *pro-R* H-3), 3.42 (1H, dd, $J = 4.7$, 11.3 Hz, *pro-S* H-3), 2.00 (1H, m, H-7), 1.92 (1H, m, *pro-R* H-6), 1.88 (1H, m, H-4a), 1.68 (1H, m, *pro-R* H-5), 1.52 (1H, m, *pro-S* H-5), 1.46 (1H, m, H-4), 1.44 (1H, m, H-7a), 1.19 (1H, m, *pro-S* H-6), 1.01 (3H, d, $J = 6.3$ Hz, 7-CH_3), 0.79 (3H, d, $J = 6.6$ Hz, 4-CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) δ 92.8 (C1), 64.1 (C3), 51.1 (C7a), 41.5 (C4a), 33.6 (C7), 31.5 (C6), 30.9 (C4), 27.9 (C5), 20.0 (7Me), 15.5 (4Me); $m/z = 170$ (0.4%, M^+), 67 (100%), 81 (91), 137 (78), 41 (76), 95 (62), 39 (55), 109 (45), 152 (42, M^+-18), 79 (42), 27 (37), 110 (34), 53 (33), 55 (33), 82 (32), 107 (31), 77 (26).

*(1*R*,4*S*,4a*R*,7*S*,7a*R*)-Dihydronepetalactol Dimer (**10**).* Isomer **1** (420 mg, 2.47 mmol) was dissolved in diethyl ether (15 ml) and 6 N HCl (9 drops) and stirred overnight. The solvent was removed by rotary evaporation, and the residue was purified by flash column chromatography (10% diethyl ether in petroleum ether) to yield **10** as a clear colorless oil (300 mg, 75%). $[\alpha]_D^{20} - 25.5^\circ$ ($c = 10.2$, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 4.51 (1H, d, $J = 7.4$ Hz, H-1), 3.65 (1H, dd, $J = 4.9$, 11.3 Hz, *pro-R* H-3), 3.27 (1H, t, $J = 11.3$ Hz, *pro-S* H-3), 2.25 (1H, m, H-4a), 2.22 (1H, m, H-4), 1.96 (1H, m, H-7), 1.94 (1H, m, *pro-R* H-6), 1.57 (2H, m, *pro-R* H-5, H-7a), 1.43 (1H, m, *pro-S* H-5), 1.12 (1H, m, *pro-S* H-6), 0.99 (3H, d, $J = 6.6$ Hz, 7-CH_3), 0.80 (3H, d, $J = 6.6$ Hz, 4-CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) δ 98.1 (C1), 66.9 (C3), 50.6 (C7a), 40.9 (C4a), 35.0 (C7), 32.9 (C6), 29.6 (C4), 24.3 (C5), 21.8 (7Me), 14.8 (4Me); $m/z = 322$ (0.012%, M^+), 81 (100%), 67 (83), 137 (80), 41 (76), 95 (71), 109 (58), 39 (55), 152 (51), 70 (49), 153 (47), 107 (47), 110 (46), 27 (39), 55 (37), 53 (36), 93 (31), 77 (28), 43 (27).

*(1*R*,4*S*,4a*R*,7*S*,7a*R*)-Dihydronepetalactol Dimer (**11**).* Isomer **2** (2.41 g, 14.2 mmol) was dissolved in a mixture of diethyl ether (100 ml) and 6 N HCl (4 ml) and stirred overnight. The solvent was removed by rotary evaporation and the crude residue purified by flash column chromatography (10% diethyl ether in petroleum ether) to yield **11** as a white solid (1.76 g, 77%). Mp 110–113°C; $[\alpha]_D^{20} - 39.1^\circ$ ($c = 5.8$, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.02 (1H, br s, H-1), 3.36 (1H, dd, $J = 4.9$, 11.0 Hz, *pro-S* H-3), 3.29 (1H, t, $J = 11.0$ Hz, *pro-R* H-3), 2.01 (1H, m, H-7), 1.92 (1H, m, *pro-R* H-6), 1.79 (1H, m, H-4a), 1.68 (1H, m, *pro-R* H-5), 1.50 (1H, m, *pro-S* H-5), 1.44 (1H, m, H-4), 1.37 (1H, m, H-7a), 1.15 (1H, m, *pro-S* H-6), 1.00 (3H, d, $J = 6.4$ Hz, 7-CH_3), 0.75 (3H, d, $J = 6.4$ Hz, 4-CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) δ 92.7 (C1), 64.4 (C3), 50.8 (C7a), 41.8 (C4a), 33.6 (C7), 31.6 (C6), 31.1 (C4), 27.9 (C5), 19.9 (7Me), 15.4 (4Me); $m/z = 322$ (0.001%, M^+), 67 (100%), 137 (97), 81 (96), 41 (77), 95 (73), 153

(59), 39 (59), 109 (51), 152 (50), 79 (49), 110 (43), 107 (39), 27 (37), 53 (35), 55 (34), 77 (29), 93 (28), 91 (26).

X-Ray Crystallography

Crystals of **11** suitable for single crystal X-ray structure determination were grown by recrystallization from hexane. A single crystal of **11** was mounted on a glass fiber using high-vacuum grease. X-ray measurements were made with a Bruker SMART CCD area-detector diffractometer with Mo-K_α radiation ($\lambda =$ 0.71073 Å); structure solution SHELXTL program system version 5.1, 1998.

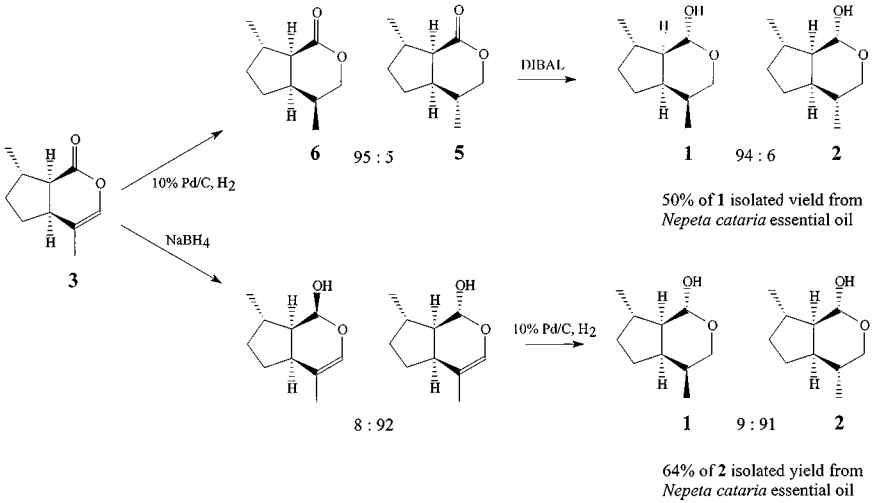
*Crystal Data for **11**.* $C_{20}H_{34}O_3$; $M = 322.47$, orthorhombic, space group *P2(1)2(1)2(1)*, $a = 8.7397(13)$ Å, $b = 9.4463(14)$ Å, $c = 22.898(3)$ Å, $U =$ 1890.4(5) Å^3, $Z = 4$, $D_c = 1.133$ Mg/m^3, μ(Mo-K_α) 0.074 mm^{-1}, $F(000) =$ 712, $T = 173(2)$ K, 3336 independent reflections with $2\theta < 50^\circ$. Refinement of 212 parameters converged at final $R_1 = 0.0434$, $wR_2 = 0.0806$.

Field Trapping in Korea

Field trapping experiments were carried out at the Suwon Agricultural Campus of Seoul National University and in the campus arboretum during July and August 2000. Wing trap dispensers (IMP Technology Inc.) and rubber septa (Sigma) were used. The traps were mounted 1.5 m above the ground and 2 m apart. The traps were checked and rotated 90° at 06:00 hr every morning. Analysis of trap catches was carried by using the GLIM statistics program (Crawley, 1993). The analysis was carried out declaring Poisson errors, with the catch for each replicate treated as independent.

Field Trapping in the United Kingdom

Lacewings were caught in clear water traps made of 14-cm-diam. × 2-cm-deep Petri dishes filled with a 1% clear odorless detergent solution. The traps were placed 2 m apart on 1.1-m-high poles. The volatiles were located in the center of the Petri dish above the detergent level, in dispensers made of amber glass vials [Chromacol 08-CPV(A)] with 1-mm holes drilled in the plastic lids. The vials were suspended below plastic shields to prevent rain entering and affecting release rates. Vials contained either the test compound (10 mg) in diethyl ether (50 μl) or ether alone. Traps were located at four woodland edge sites at Silwood Park, Ascot, Berkshire, with 16 traps at each site. In each trial, there were two traps for each treatment at each site. Traps were distributed so that identical treatments did not occur in adjoining traps. During the trial, which was run between May and August 2000, traps were rotated every four to five days. Traps were visited every two to three days, when all trapped lacewings were removed, identified, and

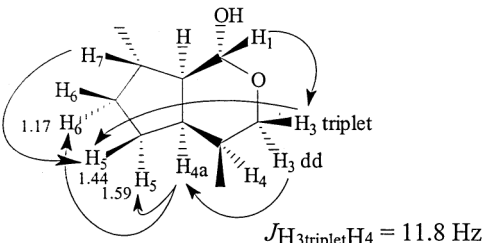


counted, and the solution in the traps was replaced. Analysis of water trap catches was carried with the GLIM statistics program (Crawley, 1993), with the trap totals for each treatment from each site being averaged, and each site treated as a block. The analysis was carried out declaring Poisson errors, with each site treated as an independent replicate.

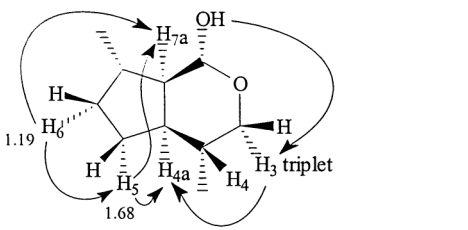
Electrophysiology

Live adult male *Peyerimhoffina gracilis* were collected at Silwood Park, from traps made from clear plastic drinking bottles, during February and March 2001. Electroantennograms (EAGs) were obtained from excised antennae ($N = 7$), using Ag–AgCl glass electrodes filled with a saline solution. The signals generated by the antenna were passed through a high impedance amplifier (Syntech UN-06, Hilversum, The Netherlands), and data storage and processing were carried out with a PC-based interface and customised software package (Syntech). The system for stimulus delivery employed a filter paper strip in a disposable Pasteur pipet cartridge. Samples of test solutions (1 mg/ml in hexane, 10 μl applied) were applied to filter paper strips, and the solvent was allowed to evaporate for 30 sec before the paper strip was placed in the cartridge. A 2-sec stimulus (1 liter/min) was delivered into a purified airstream flowing continuously over the preparation. Results were expressed as a percentage of the response to a standard application of (*E*)-2-hexenal at the same concentration, and analysed for significant differences by Student's *t* test.

RESULTS AND DISCUSSION



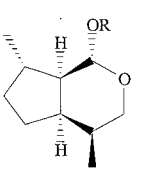
Synthesis and Structure Elucidation. (4a*S*,7*S*,7a*R*)-Nepetalactone **(3)** is found in the essential oil of many species of the *Nepeta* genus (Regnier et al., 1967; Eisenbraun et al., 1980; De Pascual Teresa et al., 1987) but, for high yield and purity, is obtained from *N. cataria* commercially by our collaborators (Botanix Limited) at approximately 90% of **3**. The essential oil was used here without further purification for the synthetic work. Compounds **1** and **2** were synthesized diastereoselectively from **3**, either by hydrogenation followed by lactone reduction in the case of **1**, or by lactone reduction followed by hydrogenation for **2**. Reduction of **3** with 10% palladium on carbon gave a 95:5 ratio of two products by GC, determined to be dihydronepetalactones by GC-MS (Scheme 1). The major component did not have the same spectroscopic properties as that reported for (4*R*,4a*R*,7*S*,7a*R*)-dihydronepetalactone (**5**) (De Pascual Teresa et al., 1987), but full characterization and stereochemical assignment by NMR spectroscopy was consistent with (4*S*,4a*R*,7*S*,7a*R*)-dihydronepetalactone **6**, formed by reduction from the less sterically hindered face. Interestingly, this is the opposite face selectivity to that reported when palladium on strontium carbonate is used as a



SCHEME 1. Divergent diastereoselective synthesis of **1** and **2** from (4a*S*,7*S*,7*R*)-nepetalactone (**3**).

hydrogenation catalyst (Regnier et al., 1967). In our hands, however, reduction with 2% $Pd/SrCO_3$ gave a different result from Regnier et al. (1967) and yielded the same major isomer **6** in a **6:5** ratio of 96:4 by GC. The crude mixture obtained from reduction with 10% palladium on carbon was then further reduced with DIBAL, and the crude product was analyzed by GC to reveal a 94:6 ratio of isomers **1:2**. By altering the order of chemical transformation, it was possible to synthesize **2** diastereoselectively. Borohydride reduction of the essential oil gave diastereomeric nepetalactols in the ratio 92:8, the stereochemistry of which was previously elucidated by X-ray crystallography of a derivative (Dawson et al., 1989). Hydrogenation of this crude mixture then gave a quantitative 91:9 mixture of **2:1** by GC. The diastereoselectivity of hydrogenation of nepetalactone can be explained on steric grounds, but, after borohydride reduction, the face selectivity of hydrogenation is reversed with comparable selectivity. This phenomenon has been observed previously when hydrogenation of *O*-ethoxyethyl protected (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**4**) was reported to occur with the same facial selectivity (Kigawa et al., 1992).

The relative stereochemistry of compounds **1** and **2** was determined by 1D gradient NOE spectroscopy (GOESY) (Figure 2) (Stonehouse et al., 1994). In the case of isomer **1**, the H-1 proton gives a NOE to the triplet at H-3 that, in turn, shows a NOE with a proton at H-5. Due to the known *cis* ring junction of **3**, this is only possible if H-1, H-3 (triplet), and the H-5 proton are all on the same upper face. The other H-3 proton, a doublet of doublets, shows a NOE to proton H-4a that is



1

2

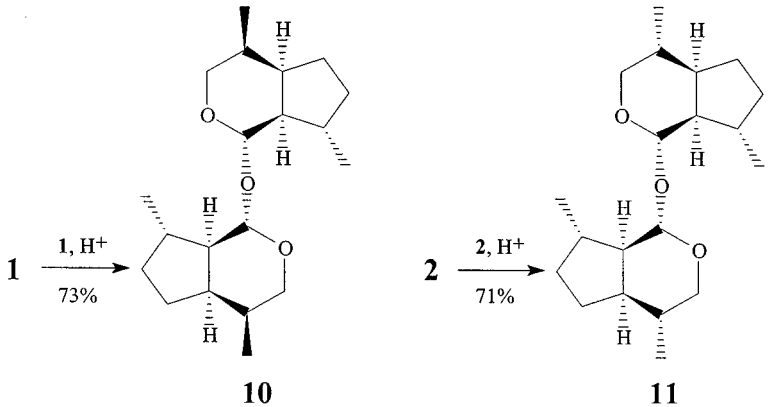


FIG. 2. Assignment of the stereochemistry of (1*R*,4*S*,4a*R*,7*S*,7a*R*)-dihydronepetalactol (**1**) and (1*R*,4*R*,4a*R*,7*S*,7a*R*)-dihydronepetalactol (**2**), showing the structurally revealing GOESY results.

known to be on the back face, verifying the structure. The methyl stereochemistry at C-4 is inferred by the large *trans* diaxial coupling constant of 11.8 Hz between the H-3 triplet and H-4. H-4a also shows a NOE to H-6 (1.17 ppm) and H-5 (1.59 ppm) and finally, a NOE from H-7 to H-5 (1.44 ppm) completes the assignment of the C-5 and C-6 protons. Several derivatives were made of **1** in an attempt to produce crystals for X-ray crystallography (Figure 3). None of compounds **7**–**9** was suitable for X-ray diffraction, but all showed the same NOEs between protons H-1, H-3 (triplet), and H-5, suggesting the same stereochemistry as presented in Figure 3. To ensure that the basic conditions used in generating **7**–**9** (treatment

7 : R = 3',5'-dinitrobenzoyl
8 : R = *p*-bromobenzoyl
9 : R = 3',5'-dinitrobenzyl

FIG. 3. Derivatives of **1** synthesized, which all revealed the same stereochemistry by GOESY spectroscopy.

SCHEME 2. Acid catalyzed dimerization of **1** and **2**.

of **1** with *n*-BuLi in anhydrous solvent followed by the acyl or alkyl chloride) was not epimerizing the lactol center, **7** was saponified in basic conditions and **1** reisolated with no lactol isomerization. An attempt to epimerize the lactol center of **1** using acid conditions was also made but instead of epimerization, **10** was isolated in good yield (Scheme 2). Infrared analysis of compound **10** showed it did not contain a hydroxyl group, and with one set of NMR peaks, it was characterized as a symmetric dimer. A very weak parent ion at *m/z* 322 was detected by electron impact mass spectroscopy. The ion at *m/z* 153 could be rationalized by loss of the $C_{10}H_{17}O_2$ group and the ion at *m/z* 152 by loss of dihydronepetalactol, analogous to loss of water from the monomeric compounds **1** and **2**. Again, NOE studies revealed the same relative stereochemistry as **1**, demonstrating the 1*R* stereochemistry to be the thermodynamically stable configuration as the reaction mechanism must involve equilibrium of **1** with an oxonium ion.

Despite purified **2** giving a single peak by three different GC columns (HP-1, HP-5, and β-cyclodextrin), its NMR spectrum in $CDCl_3$ showed it to be a mixture of two isomers, in a ratio of 90:10. GOESY studies on the major isomer **2** (Figure 2) revealed NOEs between the lactol OH and the H-3 triplet, which, in turn, gave a NOE to H-4a. As the ring junction stereochemistry is known, H-4a, H-3 (triplet), and the lactol OH must all be on the same back face. The stereochemistry at C-4 was assigned using the *trans* diaxial coupling of 11.0 Hz between H-3 (triplet) and H-4. Full assignment of the C-5 and C-6 protons was completed as the H-6 proton at 1.19 ppm shows a NOE to H-7a and the H-5 proton at 1.68 ppm, which in turn also relaxes H-4a and H-7a. GOESY studies on the minor isomer of the $CDCl_3$ solution of **2** revealed a NOE between H-1 and the H-3 triplet, demonstrating it to be the C-1 epimer. The treatment of **2** with acid generated a crystalline dimer, **11**. Mass spectrometry data for **11** were similar to those for **10**

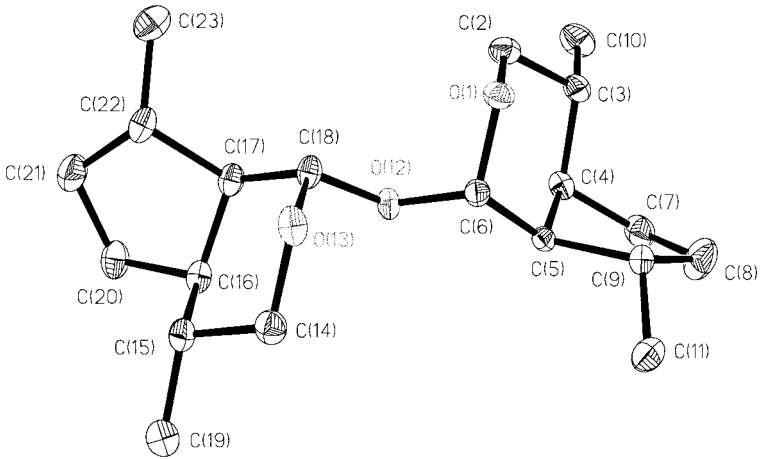

FIG. 4. Ortep diagram of **11**. Ellipsoids are drawn at the 30% probability level.

and crystals were obtained, suitable for X-ray crystallographic study (Scheme 2). The X-ray crystallographic results revealed the relative stereochemistry of **2** and based on the known chiral centers, stereochemistry at C-4 was verified as 4*R* and the thermodynamically stable lactol as 1*R* (Figure 4). By comparing the NMR data and synthetic methodology with the paper of Hyeon et al. (1968), structure **1**, (1*R*,4*S*,4a*R*,7*S*,7a*R*)-dihydronepetalactol, can be termed neomatatabiol and structure **2**, (1*R*,4*R*,4a*R*,7*S*,7a*R*)-dihydronepetalactol, can be termed isoneomatatabiol.

Field Results and Electrophysiology. Field trapping experiments in Suwon, Korea, and at Ascot, United Kingdom, caught several species showing varying preferences for the compounds described above. The initial study in Korea was performed between July 17 and 22, 2000. The traps releasing compound **1** caught significantly more *Chrysopa cognata* than did those releasing **2**. However, compound **4** was more effective than either, and also caught smaller but significant numbers of *Chrysopa formosa* and *Chrysopa phyllochroma* (Table 1). This study

control	0d	0a

[a] All lacewings captured were male. Values are means. Means within a column followed by a different letter are significantly different at $P < 0.05$.

did not differentiate between male and female insects. The next study, which ran from August 2 to 6, 2000, caught fewer insects but they were all found to be male (Table 2). Although the catch means of *C. phyllochroma* (Table 1) and of *C. formosa* and *C. phyllochroma* (Table 2) for the different treatments did not differ significantly, analyses of variance showed the response to **4** to be significant at $P < 0.01$. The third trial studied the response of *C. cognata* to increasing release rates of **1** and **2** (Table 3).

In the United Kingdom, compounds **1** and **2** were initially tested for lacewing attraction in the field from May to July 2000 (Table 4). In this study, 11 specimens of *Nineta vittata* and 19 of *P. gracilis* were trapped, all of which were male. Further trials were performed during July and August 2000 (Table 5), with the addition of traps containing both **1** and **2** at equal concentrations and both at the same concentration as compounds in the other traps. Results showed compound **1** was

highly effective at trapping lacewings compared to the other compounds tested and that isomer **2** did not influence the response to **1**. Of the 198 specimens of *P. gracilis* trapped in this study, only one was female.

Previous work (Hyeon et al., 1968) reported the compounds now defined as **1** and **2** to be attractants of adult male *C. septempunctata* and male *Chrysopa japonica*. We have demonstrated that the field response of adult male *P. gracilis* and *N. vittata* can be attributed to the 1*R*,4*S* stereochemistry of **1**. The preference of adult male *C. cognata* is for 1*R*,4*S* over 1*R*,4*R*, but the overall preference of *C. cognata*, *C. formosa*, and *C. phyllochroma* is for compound **4**.

Results of EAG analysis using male *P. gracilis* collected from the same trapping area showed compounds **1** and **2**, and the two aphid sex pheromone components, (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**4**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**3**), to have significant activity (difference from control, $P < 0.001$), the first eliciting a significantly higher response than the latter three ($P < 0.05$) (Table 6). The results demonstrate that the antennae of *P. gracilis* show a strong response to all the compounds tested in the traps, but the largest EAG response to **1** correlates with the finding that this compound is the most active in the field.

The trapping of large numbers of *P. gracilis* was of interest for several reasons. This species was not known to be native to the U.K. and recent surveys at Silwood Park did not reveal its presence (Hollier and Belshaw, 1992, 1993; see Donato et al., 2001). In addition, during the period of trapping, no specimens of *P. gracilis* were caught in malaise traps or a suction trap present in the same area. Only in the traps releasing cyclopentanoids were large numbers caught. This species is believed to be relatively sedentary (Duelli, 1984) and to have a particular preference for conifer trees, which were not present in the immediate vicinity of the field sites at Silwood Park. Each of the four sites used in this trial was at least 20 m from a tree of a species known to support *P. gracilis* and three sites were approximately 100 m away. This suggests that either the species is more mobile and less constrained by habitat than is currently thought or that these compounds are effective over a considerable distance.

The presence of lacewings in traps releasing aphid sex pheromones and closely related cyclopentanoids may suggest a kairomonal role for these compounds in prey location, as has previously been proposed (Boo et al., 1998). Lacewings are polyphagous and feed on a number of insect species, including aphids. The fact that many aphid species use the same sex pheromone components would allow their use as indicators of aphid prey. Lacewing larvae are insectivorous predators but only a minority of species is predatory as adults; the majority feed on honeydew, nectar, and pollen. Of the species recorded in this study, adults of the genera *Nineta* and *Chrysopa* are insectivorous; *Peyerimhoffina* adults are not. The compounds tested here, therefore, elicit a response from both predatory and nonpredatory species, so it is unlikely that food location by adults is the cause of the observed activity.

It is possible that lacewings are sensitive to these compounds as an aid to the location of suitable oviposition sites. However, aphids only produce their sex

pheromones during the autumn, as part of the sexual stage in the life cycle that culminates in the production of overwintering eggs. In the United Kingdom, lacewings usually overwinter as pupae. Of the British species reported here, *N. vittata* is typically recorded as an adult from May to August (Plant, 1994), and so would not normally be exposed to the aphid sex pheromones. Although *P. gracilis* is present as an adult in the autumn, studies suggest that its oviposition is stimulated by increasing day length (Grimal, 1988). Therefore, it might be expected to utilize prey-produced kairomonal cues to locate suitable oviposition sites during the spring, rather than during the autumn months. If these compounds were functioning as prey-location kairomones, it would be expected that the numbers trapped would either show little sex bias or would be biased towards females looking to oviposit near a food source, as is the case with *Praon* parasitoids of aphids (Hardie et al., 1991). However, only male insects were detected in these trials, suggesting that these compounds, or analogous structures, may play a pheromonal role in intraspecies sexual communication and that their similarity to aphid sex pheromones may be simply incidental.

The possible role played by pheromones in intraspecific communication within the Chrysopidae, and the Neuroptera as a whole, is poorly understood. The only compound identified to date as a lacewing secretion is (*Z*)-4-tridecene, which has recently been identified from *Chrysoperla carnea* and appears to have defensive functions (Zhu et al., 2000). Although close-range communication in the Chrysopidae involves species-specific substrate-borne songs (Henry, 1979), it is thought that sex pheromones are involved in the initial mate location process (Walker et al., 1994). However, no sex pheromones or glandular sources for pheromones have been found. In the related Myrmeleontidae, some pheromones with a role in sexual communication are known, but these species exhibit a lek mating system and the pheromones eliciting a behavioral response are male-produced. Instead of functioning as sex pheromones, they appear to act as aggregation pheromones, with females responding to groups of males rather than to individuals (Yasseri et al., 1998). Although members of the Chrysopidae appear to be solitary and do not lek, a possible role for these compounds as aggregation pheromones cannot be discounted. In the Myrmeleontidae, different species utilize different blends of related compounds, providing species-specific signals (Baeckstrom et al., 1989; Bergstrom et al., 1992). From the results obtained here, in particular the differences in response shown to the compounds by the different *Chrysopa* species, it would seem possible that a similar pattern might be found in chrysopid lacewings. The demonstration that *P. gracilis* antennae respond strongly to all the cyclopentanoids tested, and the behavioral response of males of some species to more than one cyclopentanoid structure, is consistent with the possibility that these, or similar structures, may be natural pheromones.

The reasons for the appearance of *P. gracilis* in the United Kingdom may be speculated as being due to accidental release, its presence previously being

overlooked, wind-borne arrival, or range expansion as a consequence of global warming (Donato et al., 2001). The identification of cyclopentanoid monoterpenes as semiochemicals for a number of lacewings will facilitate monitoring the changing status of the new species and may allow manipulation of natural populations of these beneficial insects in integrated pest control strategies. Further research into the ecological and possibly pheromonal roles of these and related compounds is ongoing.

Supplementary Data—The CIF file for the crystal structure has been deposited at the Cambridge Crystallographic Centre, 12 Union Road, Cambridge CB2 1EZ, UK (www.ccdc.cam.ac.uk) from which it is available on request. The deposition number is CCDC 165880.

ANNOUNCEMENT

19TH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY AUGUST 3–8, 2002, HAMBURG

The 19th annual ISCE meeting will be held at the Department of Chemistry, University of Hamburg, Germany. The conference will begin on the evening of August 3, 2002 (Saturday) and end on the evening of August 7 (Wednesday). The meetings will be hosted by Wittko Francke.

There will be four symposia covering aspects of chemical ecology in symbiosis, molecular biology, insect-plant relationship, and pheromone chemistry.

Both oral and poster presentations are invited from participants. Contributed papers fitting to the symposia are particularly welcome.

Participants are encouraged to arrive on Saturday, August 3, and attend the Social Lecture given by Prof. Dr. Jerrold Meinwald followed by a mixer that evening. The concluding banquet will be held Wednesday evening, August 7.

Further Information may be obtained on the meetings web site http://isce2002.chemie.uni-hamburg.de

IDENTIFICATION AND CLONING OF A FEMALE ANTENNA-SPECIFIC ODORANT-BINDING PROTEIN IN THE MOSQUITO *Culex quinquefasciatus*

YUKO ISHIDA,[1] ANTHONY J. CORNEL,[2] and WALTER S. LEAL[1,*]

[1]*Honorary Maeda-Duffey Laboratory*

[2]*Mosquito Control Research Laboratory, Department of Entomology, University of California Davis, Davis, CA 95616*

(Received January 16, 2002; accepted February 5, 2002)

Abstract—We have identified and cloned a cDNA encoding the first odorant-binding protein isolated from mosquitoes. The protein isolated from female antennae of *Culex quinquefasciatus* (CquiOBP) was not detected in legs (control tissue) or in antennal extracts from males, and showed mobility in native polyacrylamide gels similar to that of the pheromone-binding protein from *Bombyx mori.* The open reading frame of the cloned cDNA encoded a hydrophobic signal peptide (24 residues) and an acid mature protein (pI 5.5) of 125 amino acid residues (calculated molecular mass 14,504 Da). The transcript was detected by RT-PCR with antennal, but not with leg tissues. CquiOPB shared the highest amino acid identity with a product deduced from *Drosophila melanogaster* PBPRP-3 cDNA (58.6%), OBPs from scarab beetles (35%), and moths (28%). In addition, CquiOBP showed the hallmark of insect odorant-binding proteins, the six Cys residues.

Key Words—Odorant-binding protein, mosquito, *Culex quinquefasciatus*, Diptera, Culicidae.

INTRODUCTION

Female mosquitoes perceive the environment through semiochemicals, which they utilize for essential tasks, such as location of hosts (Davis and Bowen, 1994) and oviposition sites (Laurence and Pickett, 1982). To guide the mosquito behavior, these molecules must reach the olfactory receptors located in the dendrites, which are surrounded by a sensillar lymph. The transport of the hydrophobic semiochemicals through this aqueous environment is assisted by proteins, odorant-biding

* To whom correspondence should be addressed. E-mail: wsleal@ucdavis.edu

0098-0331/02/0400-0867/0 © 2002 Plenum Publishing Corporation

proteins (OBPs), which solubilize the ligands, ferry them to their receptors, and protect the molecules from inactivation before their messages are delivered. Research has been conducted to gain a better understanding of the molecular basis of semiochemical perception in the cosmotropical nuisance mosquito *Culex quinquefasciatus* Say (Diptera: Culicidae). *Cx. quinquefasciatus* is a vector of bancroftian filariasis caused by the nematode *Wuchereria bancrofti*, a debilitating helminthic disease that afflicts 119 million people world-wide (Michael et al., 1996). Here, we report the first isolation, identification, and cDNA cloning of a dipteran OBP.

METHODS AND MATERIALS

Protein Extracts and Analytical Procedures. Three to five-day old adult mosquitoes were anesthetized on ice. Females were inseminated, but deprived of a blood meal. Antennae and control tissues (midlegs with tarsi removed) were dissected and homogenized in ice-cold glass homogenizers with 10 mM Tris-HCl, pH 8. Homogenized samples were centrifuged twice at 12,000 rpm for 10 min at 4°C. After concentration, the supernatants were analyzed by native polyacrylamide gel electrophoresis (15% PAGE) and stained with Coomassie blue R-250. For sequencing, proteins were electroblotted onto polyvinyl difluoride membranes, bands were cut, and N-terminal sequences were obtained on a Procise Protein Sequencing System (Applied Biosystems).

cDNA Cloning and RT-PCR. mRNA samples were prepared from 1,000 antennae and 200 midlegs of female *Cx. quinquefasciatus* using TRIzol (Invitrogen) and PolyATract mRNA Isolation Systems (Promega). cDNAs were synthesized by SMART RACE cDNA Amplification Kit (Clontech). *TAKARA LA Taq* (TAKARA) was used as Taq polymerase. To clone CquiOBP cDNA, we used the following primers: the degenerate primer 5′-GA(C/T)GC(A/C/G/T)GA(A/G)TA(C/T)-CC(A/C/G/T)CC(A/C/G/T)CC(A/C/G/T)GA-3′ was designed on the basis of N-terminal amino acid sequence of the isolated protein, GCGTTTTTTTTTTTTTT (3′-RACE), a UPM primer from the SMART RACE cDNA Amplification Kit and a gene-specific primer (GSP1; 5′-RACE), 5′-CCCCCTCCGGATACAGGCAACG-TTTTCCCA-3′, and GSP-2 (RT-PCR), 5′-CGAGGCCATCATTGAGTTCAGC-GACGGCAA-3′. Polymerase chain reactions (PCR) were carried out according to instruction manual of the SMART RACE cDNA Amplification Kit. PCR products were ligated into pBluescript SK(+) (Stratagene) and sequenced. Homology analyses were carried out using FASTA (http://www.ddbj.nig.ac.jp/). Alignment of amino acid sequences was drawn by MacVector (Oxford Scientific).

RESULTS AND DISCUSSION

Native polyacrylamide gel electrophoresis analysis of protein extracts from antennae and legs of *Cx. quinquesfasciatus* showed the occurrence of an

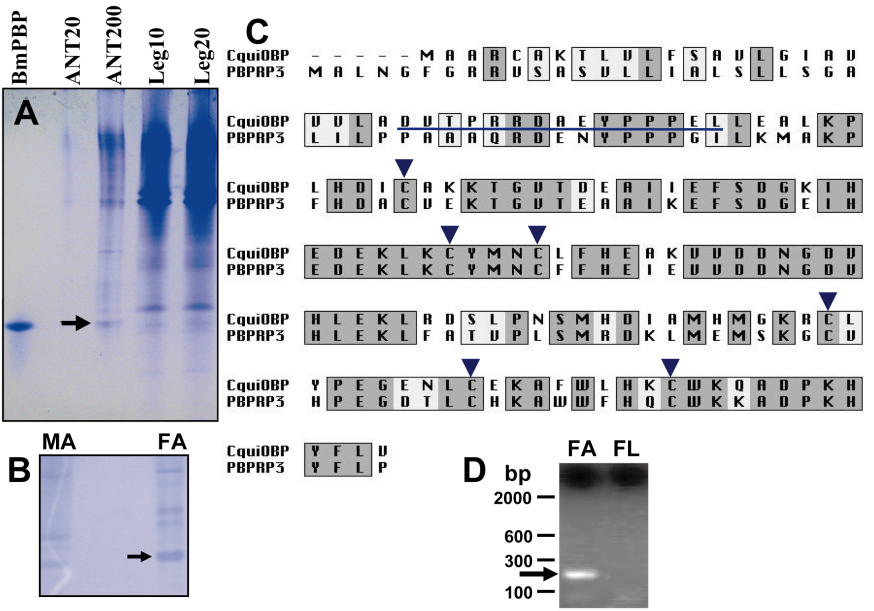

FIG. 1. Gel electrophoresis analysis and cDNA cloning data of the female- and antenna-specific protein from *Cx. quinquefasciatus.* A) Soluble proteins separated on a 15% native PAGE, stained with Coomassie blue. BmPBP, recombinant protein from the silkworm moth *B. mori* as a reference; ANT20 and ANT 200, extracts from 20 and 200 female antennae; Leg 10 and Leg20, extracts from 10 and 20 midlegs as control tissues. The second lane of the gel was left empty to avoid possible contamination from the recombinant protein. B) Comparison of protein profiles from male (MA) and female antennae (FA; 600 antennae of each sex), highlighting a female-specific protein (arrow). C) Sequence alignment of *Cx. quinquefasciatus* odorant-binding protein (CquiOBP) and a product deduced from *D. melanogaster* PBPRP-3 cDNA, which encodes a protein with the highest amino acid similarity in the database. The N-terminal sequence of the mature protein, obtained by Edman degradation, is underlined. Arrowheads show the six Cys residues, a hallmark of insect OBPs. The cDNA sequence has been submitted to the GenBank data base with accession number AF468212. D) cDNA fragment (arrow) amplified with gene-specific primers by using female antenna (FA) cDNA. Under the same conditions, PCR with female leg (FL) cDNA gave only primer dimers (bottom of the gel).

antenna-specific band (Figure 1A), which had a mobility similar to the pheromone-binding protein previously identified from the silkworm moth, *Bombyx mori* (BmPBP). Comparison of extracts from mosquito male and female antennae demonstrated that the antenna-specific protein was also specific to females (Figure 1B). We then transferred the protein from native gels to polyvinyl difluoride membranes to obtain its N-terminal amino acid sequence by Edman degradation.

The sequence (DVTPRRDAEYPPPEL) was proline-rich and showed significant amino acid identity to putative odorant binding proteins from *D. melanogaster* (Pikielny et al., 1994). The same protein was not detected in legs.

Our initial approach to clone the cDNA encoding the isolated female and antenna-specific protein was based on a degenerate primer designed according to the N-terminal amino acid sequence and an oligo (dT) to anneal to the poly(A) tail. The initial product amplified by PCR (3′-RACE) was used to prepare a gene-specific primer (GSP-1) so as to obtain the full length cDNA by 5′-RACE. The cloned cDNA consisted of 708 bp, with an open reading frame (ORF) of 450 bp, a 3′-noncoding region characterized by an AATAAA signal located 15 bases upstream of a poly(A) sequence. This cDNA encodes a peptide consisting of 149 amino acids, with the first 24 residues forming the signal peptide. The signal peptide was predicted by using von Heijne's criteria for eukaryotic signal peptides, confirmed by the data for the N-terminal sequence of the mature protein, and showed the expected hydrophobic region in a Kyte-Doolitle profile.

The mature protein encoded by this cDNA consisted of 125 amino acid residues (Figure 1C), with a calculated molecular mass of 14,504 Da, and pI of 5.5. The sequence showed the hallmark of odorant-binding proteins, six Cys residues at positions 26, 53, 57, 95, 104, and 113. In addition, prediction of the secondary structure by the Chou-Fasman method indicated that the protein is helical-rich (60.8%), which is another feature of insect odorant-binding proteins.

The tissue-specificity of the female protein was further investigated by RT-PCR by using two gene-specific primers to give a 199 bp fragment of the ORF. The expected cDNA fragment was amplified with female antenna, but not with leg template (Figure 1D). Because the protein is tissue-specific and shows remarkable similarity to previously identified odorant-binding proteins from insects, we suggest that this female-specific protein from *Cx. quinquefasciatus* is an odorant-binding protein (CquiOBP).

A database search using FASTA indicated that CquiOPB shared significant sequence similarity with putative odorant-binding proteins from *D. melanogaster*, whose native proteins have not been isolated to date. One of these gene products named PBPRP-3 (pheromone-binding protein-related protein) (Pikielny et al., 1994) showed the highest score (58.6% identity) (Figure 1C). The next highest scores were from OBPs from scarab beetles (34–35% identity) (Wojtasek et al., 1999; Peng and Leal, 2001; Deyu and Leal, 2002), whereas lepidopteran OBPs (Vogt et al., 1999) showed lower amino acid identities (<29%).

Various mosquito behaviors are mediated by volatile semiochemicals. It is also known that the semiochemical-detecting machinery is involved in the perception of the synthetic repellent DEET (Leal and Uchida, 1998; Costantini et al., 2001). Therefore, odorant-binding proteins may be invaluable tools for the screening of mosquito attractants and repellents. Given that only compounds that bind to OBPs are transported to the olfactory receptors, a throughput binding assay with

recombinant OBPs would allow the screening of a large number of compounds of potential application in mosquito trapping or repellents.

Acknowledgments—This research was supported by a Specific Cooperative Agreement (No. 58-1275-1-042) with the USDA-ARS Chemicals Affecting Insect Behavior Laboratory, the University of California Systemwide Mosquito Research Fund, and through direct financial support from the department, college, and Chancellor's office at UCD. We thank Drs. Jeffrey R. Aldrich and Jerry Klun (USDA-ARS-Chemical Affecting Insect Behavior Laboratory) for their support for this project and their critique of an earlier draft version of the manuscript.

Abstract—Environmental response genes are defined as those encoding proteins involved in interactions external to the organism, including interactions among organisms and between the organism and its abiotic environment. The general characteristics of environmental response genes include high diversity, proliferation by duplication events, rapid rates of evolution, and tissue- or temporal-specific expression. Thus, environmental response genes include those that encode proteins involved in the manufacture, binding, transport, and breakdown of semiochemicals. Postgenomic elucidation of the function of such genes requires an understanding of the chemical ecology of the organism and, in particular, of the "small molecules" that act as selective agents either by promoting survival or causing selective mortality. In this overview, the significance of several groups of environmental response genes is examined in the context of chemical ecology. Cytochrome P-450 monooxygenases provide a case in point; these enzymes are involved in the biosynthesis of furanocoumarins (furocoumarins), toxic allelochemicals, in plants, as well as in their detoxification by lepidopterans. Biochemical innovations in insects and plants have historically been broadly defined in a coevolutionary context. Considerable insight can be gained by defining with greater precision components of those broad traits that contribute to diversification. Molecular approaches now allow chemical ecologists to characterize specifically those biochemical innovations postulated to lead to adaptation and diversification in plant/insect interactions.

Key Words—Allelochemical, cytochrome P-450, environmental response gene, *Helicoverpa*, olfactory receptor, *Papilio*, substrate recognition site, xenobiotic response element, furanocoumarin, furocoumarin.

INTRODUCTION

The millenium bug, or Y2K bug, is the computer glitch that was a function of the fact that, in the 1950s, IBM engineers, to save memory, used only a two-digit year field; the two-digit field was anticipated to wreak havoc after December 31, 1999 (Anonymous, 2000). Such havoc conspicuously failed to materialize. Thus, an insect perhaps more worthy of the designation Y2K bug is *Drosophila melanogaster*, the vinegar or pomace fly. In March 2000, sequencing of the entire genome of *D. melanogaster* was completed and published, marking the first complete arthropod genome to be sequenced (Adams et al., 2000). This accomplishment may herald a new era within the field of chemical ecology. Since its inception, practitioners of the science of chemical ecology have been concerned mostly with small molecules. Admittedly, some reach impressive size; a case in point may be the extremely large-ring monocyclic polyazamacrolides produced in the defensive secretions of some coccinellid pupae. Ring sizes in some of these remarkable macrocycles can range from 24 to over 150 members (Schroeder et al., 2000), but substances with the cognomen "macromolecules" are only recently subjects for study by chemical ecologists. Protein serving as olfactory receptors and enzymes involved in allelochemical biosynthesis now routinely merit study, but even bigger molecules loom on the horizon.

In the postgenome era, DNA should be an increasing focus of attention even for those with an affection for small, tractable molecules. One reason is that DNA itself is a target site for many toxic natural products. The universal occurrence of DNA makes it a likely evolutionary target for broad-spectrum defense compounds, and the evolution of DNA must reflect in part interspecific interactions among organisms. B-DNA possesses quite a number of nucleophilic reactive sites that interact with natural products (Yang and Wang, 1999). Furanocoumarins (furocoumarins), e.g., benz-2-pyrone compounds produced by a handful of angiosperm plants primarily in the Apiaceae and Rutaceae, covalently bind to thymine and cross-link strands. Ecteinascidin from the marine tunicate *Ecteinascidia turbinata* binds covalently to guanine N-2; the fungal metabolite aflatoxin B1 attacks N-7 guanine. Duacarmycin, a *Streptomyces* product, and bleomycin/pepleomycin, from *Streptomyces verticillus*, induce DNA backbone cleavage. Daunorubicin, initially isolated from *Streptomyces caeruleorubidus*, and doxorubicin, produced by *Streptomyces peucetius*, are anthracycline drugs that can intercalate (as can triostin A and echinomycin, naturally occurring bisintercalator quinoxaline antibiotics from *Streptomyces echinatus* and related species); distamycin A, from *Streptomyces distallicus*, binds in the narrow minor groove associated with AT sequences in B-DNA, and actinomycin D from *Streptomyces* spp. binds to DNA duplexes and interferes with transcription.

Perhaps a more important reason for chemical ecologists to incorporate DNA into their studies is that one of the principal goals of postgenomic biology is to

ascertain gene function, and the function of many genes can be comprehended only within the context of chemical ecology, in particular, the function of those genes that can be considered "environmental response genes." Environmental response genes can be defined as those encoding proteins involved in interactions external to the organism, including interactions among organisms and between the organism and its abiotic environment. General characteristics of environmental response genes, particularly those involved in mediating interactions among organisms and thus allowing for reciprocal evolutionary responses, include (1) very high diversity, (2) proliferation by duplication events, (3) rapid rates of evolution, (4) occurrence in gene clusters, and (5) tissue- or temporal-specific expression. All of these characteristics are consistent with responses to evolutionary pressure emanating from a highly changeable external environment.

Among environmental response genes, then, are those encoding proteins involved in the manufacture, binding, transport, and breakdown of semiochemicals, the principal medium of communication for many species between the organism and its environment. Examples of environmental response genes are numerous. Chemical signals are characterized by producers and recipients, and each has its own set of genes (Table 1). These genes may have genome-level effects that are very different from, for example, the so-called "housekeeping genes." By the same token, the term in common use to contrast with housekeeping genes, i.e., "luxury genes" (e.g., Vinogradov, 1997), sells short the ecological and evolutionary contributions of genes allowing organisms to cope with environmental stress. The lack of correlation between genome size and number of genes (e.g., *Caenorhabditis elegans* at 97 Mb and 19,000 genes and *Drosophila melanogaster* with 180 Mb and 13,000 genes; http://www.ornl.gov/hgmis/faq/compgen.html) has led to the suggestion that evolution proceeds principally by altering patterns of gene expression, rather than by increasing the protein inventory. Environmental response genes may be an exception to the trend; new functions may be acquired by proliferation of new proteins, not just by changes in regulation and expression. Parallel evolution in both gene function and expression pattern may be the key to diversification in environmental response genes. In this overview, the significance of

TABLE 1. SEMIOCHEMICALS AND ASSOCIATED ENVIRONMENTAL RESPONSE GENES

Semiochemical	Producer	Receiver
Pheromone	Biosynthetic genes	Pheromone-binding protein genes
		Odorant receptor genes
		Pheromone-degrading enzymes
Allomone	Biosynthetic genes	Detoxification genes
	Transport protein genes	Transport protein genes
Kairomones	Biosynthetic genes	Odorant receptor genes
		Taste receptor genes

several groups of environmental response genes is examined in the context of chemical ecology.

The "chemical senses" by which organisms perceive information about their environments encompass olfaction, or perception of chemical stimuli in gaseous phase, and gustation (and other forms of contact chemoreception), perception of chemical stimuli as solutes in liquid media. Irrespective of organism, chemical signaling (not only externally but also internally) shares several features. Most, if not all, chemical signaling systems include a receptor that reacts with a signal molecule; many also involve a signal transducer and amplifier. Perireceptor phenomena associated with movement of signal molecules (binding, transport, and degradation) also share many conserved features across a wide range of taxa. Many of the same classes of molecules serve these functions across a variety of taxa.

GENES INVOLVED IN BINDING AND TRANSPORT OF SEMIOCHEMICALS

Taste Receptors. Molecular characterization of taste receptors has eluded investigators for a long time; molecular techniques provided a new and ultimately successful approach to this goal. Clyne et al. (2000) searched the *Drosophila melanogaster* genome to find a large family of putative odorant receptors, which they call the gustatory receptor family; the search algorithm identified proteins with characteristic structural properties (with sequence length around 380 amino acids, and regions encoding seven predicted transmembrane domains, suggestive of G-protein coupled receptors). At the time the study was done, 60% of the genome yielded 75 proteins in the family. Amino acid identity ranges from 34% to less than 10%, indicating tremendous sequence divergence. These gustatory receptors tend to be found in clusters; two large clusters contain four genes, whereas several other clusters contain two or three genes. Tissue specificity is high as well, in that 18 of the 19 characterized are expressed only in the labellum, the gustatory organ. Moreover, gene expression could not be detected in the labellum of a mutant, *pox neuro*, which lacks taste neurons.

Subsequent completion of the genome sequence of *D. melanogaster* unveiled many other members of this group of candidate taste receptors to bring the total to at least 57 genes (http://sdb.bio.purdue.edu/fly/aignfam/odorcpt3.htm). Clyne et al. (2000) concluded that "The large size of this protein family likely reflects the diversity of compounds that flies can detect." Alternatively, expression of individual genes is often restricted to subsets of gustatory neurons in developmentally different sense organs (Scott et al., 2001; Dunipace et al., 2001; Robertson, 2001). Given that so little is known of the chemical ecology of *D. melanogaster* in nature, identifying which compounds were likely selective agents in the evolution of this protein family will be a challenge.

Olfactory Receptors. Like gustatory receptors, olfactory receptors, characterized by multiple transmembrane domains, are extremely diverse within most genomes characterized to date. In the genome of the free-living nematode *Caenorhabditis elegans*, Robertson (1998) examined genes in the serpentine *str* (seven transmembrane receptor) family encoding seven-transmembrane G-protein coupled receptors related to ODR-10 diacetyl chemoreceptors (with a known function in detecting environmental chemicals) and identified 197 members of this group. The family shares a close relationship with another family of serpentine receptors, *srd* (serpentine receptor class D), with approximately 55 genes. In a subsequent study, Robertson (2000) discovered another family of candidate serpentine chemoreceptors: the *srh* (serpentine receptor class H) family, which contains 214 genes and 90 pseudogenes. As much as 6% of the genome may encode over 500 chemoreceptors, constituting up to 4% of *C. elegans* proteins, an indication of the importance of chemical senses to this soil-dwelling organism. Phylogenetic analyses suggest frequent gene duplication events, e.g., as many as 85 duplication events in family *srh* can be inferred to have occurred since *C. briggsae* and *C. elegans* differentiated. *C. elegans* is by no means unique in its reliance upon functional chemoreceptor genes; in mammals, olfactory receptors may number in excess of 1000, representing 1% of the gene complement.

Pheromone-Binding Proteins. Odorant-binding proteins in a wide range of organisms serve to transport generally hydrophobic environmental odorants to internal (olfactory) receptors. This is known to be a large family in *D. melanogaster*; Rubin et al. (2000) list 14 members of the family, and subsequent investigation has brought the number up to 39 (H. Robertson, personal communication). Among the odorant-binding proteins of insects are pheromone-binding proteins (PBP); these are involved in the protection and transport of pheromones from the external environment to internal receptors, and, like other members of the family, these proteins act generally as lipophilic ligand-transporting agents. In insects, they have been characterized in extracellular fluids bathing receptor cells in antennal hemolymph. Willett (2000) has conducted a study of pheromone-binding proteins within the genus *Choristoneura* in order to ascertain the forces driving diversification and differentiation in this group of proteins. *Choristoneura* is a genus of leaf-rolling caterpillars of economic importance, and a considerable amount of effort has been invested in characterizing the pheromones they produce. The putative ancestral pheromone is an acetate; the pheromone occurs as an alcohol in *C. parallela* and as an aldehyde in *C. fumiferana*. Willett (2000) was interested in finding evidence of selective impact on PBPs in association with changes in pheromone composition, specifically changes in the ratio of nonsynonymous to synonymous substitutions indicative of diversifying selection. Evidence of changes in PBPs corresponding to changes in pheromone composition was found in the case of *C. fumiferana*, with its novel aldehyde pheromone. However, other pheromone changes (e.g., chain

lengthening in *C. muriana* and a shift to an alcohol in *C. parallela*) are not reflected in changes in PBP.

BIOSYNTHETIC AND DETOXIFICATIVE PROTEINS

Over a quarter century of studies in chemical ecology have made clear the importance of semiochemical biosynthesis and detoxification to organisms across a wide range of taxa. Perhaps the best known group of environmental response genes are the cytochrome P-450s. Cytochrome P-450 monooxygenases (P-450s) comprise a large superfamily of heme-thiolate proteins that metabolize a wide range of both endogenous and exogenous hydrophobic compounds by incorporating oxygen into a functionalized product. This generalized reaction, converting lipophilic substrates into hydrophilic products, means that these enzymes display great versatility; reactions catalyzed by P-450s include such oxidative transformations as monooxygenations, NO-synthase type oxidations, dehydrogenations, and peroxidase-type oxidations and nonoxidative reactions such as dehydrase activity, nitric acid reductase activity, and isomerization (Mansuy, 1998). Thus, these enzymes participate in a tremendous variety of transformations, including both biosynthetic and detoxification reactions.

A standardized nomenclature based on levels of amino acid sequence identity is in use for this huge superfamily (Gonzalez and Gelboin, 1989). Sequences sharing over 40% identity are placed in a family (designated by a number); those sharing over 55% identity are placed in a separate subfamily (designated by a letter), and those sharing over 97% identity are recognized as allelic variants at a locus (designated by a number).

The number of P-450s represented in a genome varies with the organism. They make up one of the largest superfamilies in plants; the recent genome sequencing of *Arabidopsis thaliana* revealed over 280 P-450 genes (Paquette et al., 2000). In *Drosophila melanogaster*, 90 P-450s have been characterized, of which only seven are thought to be pseudogenes (Tijet et al., 2001a), and in *C. elegans* there are at least 60 P-450 genes (Gotoh, 1998). Gonzalez and Nebert (1990) suggested that P-450s began to diversify over 400 million years ago, concomitant with the colonization of terrestrial habitats by plants and herbivorous animals. The rapid diversification may have been a consequence of reciprocal selection pressures whereby plants biosynthetically evolve novel defense compounds, and insects (and other herbivores) overcame the erstwhile toxins with novel detoxification pathways. Multiple gene duplication events allowed P-450s to acquire new functions in the presence of new environmental stress factors while retaining ancestral metabolic capabilities. Thus, P-450s may well be the consummate environmental response genes, evolving and diversifying to a certain extent in the context of both interspecific and intraspecific interactions.

However, protein diversification is only one of several possible evolutionary mechanisms. P-450 expression is regulated in response to a wide range of factors, including developmental stage and exposure to both endogenous and exogenous substances (Tables 2 and 3). The majority of studies have focused on synthetic xenobiotics as inducers, whose efficacy was initially determined in studies of human P-450 (e.g., phenobarbital); their ecological significance is often difficult to interpret. The relative contributions of P-450 diversification and regulation of expression to the evolution of plant/animal interactions are unknown and will likely remain unknown until ecologically relevant inducers can be identified.

Despite the enormous significance of ecological interaction in understanding P-450s, the ecological function and evolutionary history of most P-450s have yet to be determined. The vast majority of studies of P-450s involve humans, particularly in the context of understanding drug metabolism and carcinogenesis (in that P-450s can act as activators of procarcinogens as well as detoxification enzymes) (e.g., Guengerich, 1998). Although there is no question that such work is of great importance to human health, it does not provide a great deal of insight into the evolutionary processes that led to P-450 diversification; humans are uniquely effective at circumventing the action of natural selection and adapting the environment to themselves rather than adapting themselves to the environment (Berenbaum, 1999). In organisms other than vertebrates, the emphasis in P-450 studies is generally on human-produced xenobiotics as substrates. Until recently, in plants, efforts in characterizing function have focused on elucidating the role of P-450s in herbicide tolerance (Werck-Reichart et al., 2000); similarly, most work with insect P-450s has been in the context of characterizing genes associated with resistance to synthetic organic insecticides (Scott, 1999).

The environmental context of P-450 evolution is perhaps best characterized in plants. Many P-450s have been characterized at the enzyme level and are known to participate in the biosynthesis of allelochemicals (Table 4, Fig. 1). As autotrophs, plants (with rare exceptions) are reliant upon biosynthesis, rather than sequestration, for the acquisition of secondary compounds. Moreover, as sedentary organisms that form the base of most food webs, they are subject to intense selection pressure from herbivores and have few options other than chemical or morphological defense for reducing the impact of herbivores (Berenbaum, 1995a). Thus, the allelochemical inventory of plants is staggering; over 40,000 compounds have been characterized. P-450-mediated transformations may well be involved in the biosynthesis of the majority of these compounds. Genome sequencing of plants with known secondary chemistry will facilitate elucidation of the function of many P-450 genes, as has already proved to be the case in *A. thaliana*; great strides have been made, e.g., in characterizing the genes governing glucosinolate biosynthesis (Table 4). Moreover, as in animals, P-450s play an important role in xenobiotic detoxification in plants; herbicides and other environmental toxins are metabolized by an array of P-450s (Table 4).

CYP6D1	*Musca domestica*	benzo[*a*]pyrene, methoxyresorufin, deltamethrin, cypermethrin, chlorpyrifos	Scott (1999)

The *C. elegans* genome has revealed more than 60 P-450 genes (Gotoh, 1998), with gene structures "strikingly divergent within each group." The majority may deal with xenobiotic substrates—all of the P-450s characterized show relationships to mammalian CYP2, CYP3, and CYP4 subfamilies, which are involved in xenobiotic metabolism. Because the chemical ecology of *C. elegans* in nature is not particularly well characterized, elucidating the specific catalytic properties of these P450s will be challenging.

Drosophila genome sequencing has yielded 90 P-450s (Tijet et al., 2001a) (http://ag.arizona.edu/p450/insectlist.html), the function of the vast majority of which is unknown. Although much attention has been focused on P-450 participation in detoxification of such xenobiotics as insecticides, the majority of P-450s in *Drosophila melanogaster* may be involved in allowing this relatively generalized consumer of microbes and microbial fermentation products to deal with the wide range of microbial products, rather than plant allelochemicals, encountered. Furthermore, Danielson et al. (1998) have documented P-450 involvement in detoxification of cactus alkaloids in cactophilic *Drosophila* species; CYP families 4, 6, and 27 may be involved, as suggested by induction in the presence of potential cactus-derived substrates (Table 2).

Other degradative functions of P-450s may involve endogenous substrates involved in intraspecific communication; in a small expressed sequence tag project with *Manduca sexta*, Robertson et al. (1999) reported the presence of three P-450s that are candidate odorant degrading enzymes. P-450s are also involved in the biosynthesis of other intraspecific chemical signals such as pheromones and cuticular hydrocarbons, and such hormones as ecdysone and juvenile hormone (Feyereisen, 1999). Thus, given the multitude of functions of P-450s in insects,

TABLE 4. PLANT P-450S WITH KNOWN FUNCTIONS[a]

CYP number	Function	Reference
CYP51	obtusifoliol 14 *a*-demethylase

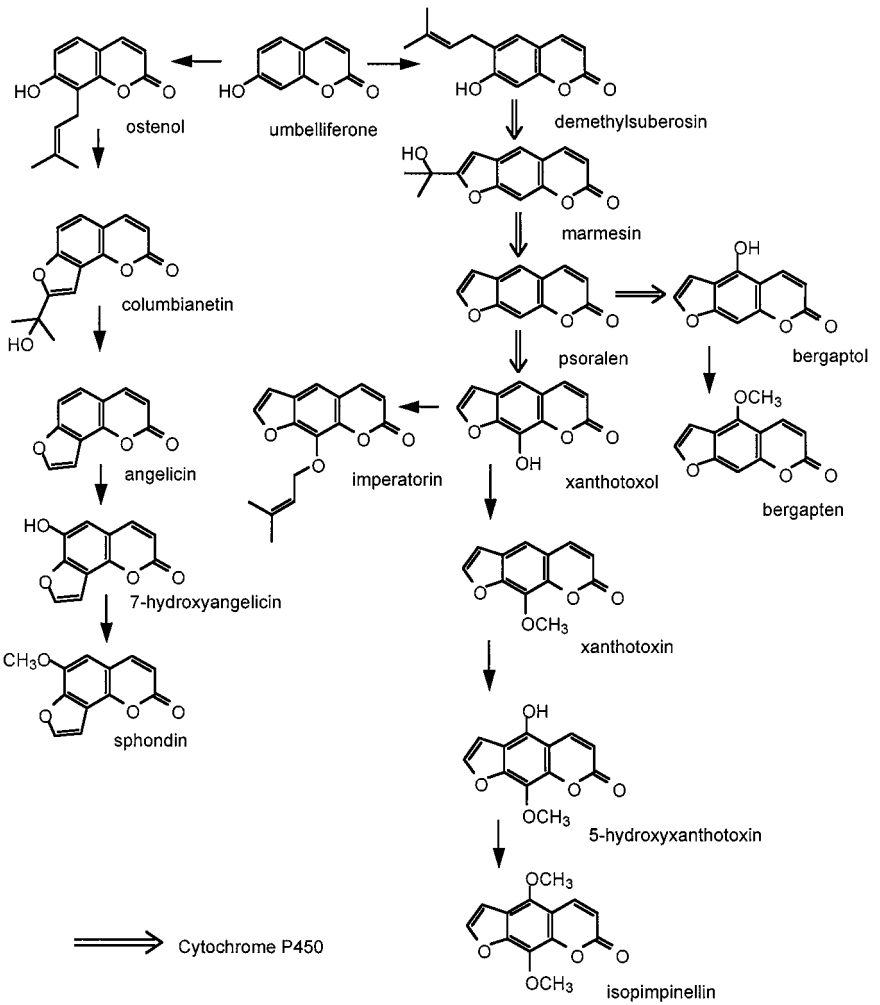

FIG. 1. Biosynthetic pathway leading to furanocoumarin production. Hollow arrows indicate steps known or suspected to be catalyzed by cytochrome P-450s. Angular furanocoumarin synthesis on left of figure, linear furanocoumarin synthesis on right of figure.

their diversity in at least the single insect genome characterized is not altogether surprising.

Like other environmental response genes, P-450s appear to arise and diversify via gene duplication and acquisition of new functions. Some are involved in metabolism of endogenous substrates, such as hormones, but extreme diversification appears to be a hallmark of the xenobiotic-metabolizing P-450s. To understand

the evolutionary diversification of P-450s, it is, therefore, important to identify the environmental chemicals (natural as well as synthetic) that act as selective agents promoting change.

P-450s in Plant/Insect Interactions—Furanocoumarins as Exemplars. The coevolutionary interactions between flowering plants and herbivorous insects (collectively constituting over half of all terrestrial species) are thought to have generated much of the terrestrial diversity on the planet. Ehrlich and Raven (1964) suggested that the evolution of biochemical novelty leads to speciation in angiosperms and that subsequent biochemical innovations in detoxification lead to speciation in herbivores associated with those plants: "If recombination or mutation appeared in a population of insects that enabled individuals to feed on some previously protected plant group, selection could carry that line into a new adaptive zone. Here it would be free to diversify." Generally, biochemical innovations in insects and plants have been broadly defined, e.g., the ability to feed on a particular plant, in the case of an insect, or the ability to biosynthesize a particular toxin, in the case of a plant. Rarely have specific adaptive traits been identified biochemically or genetically. Considerable insight can be gained by defining with greater precision components of those broad traits that contribute to diversification. Molecular approaches now allow chemical ecologists to characterize those biochemical innovations that are postulated to lead to adaptation and diversification in plant/insect interactions. A case in point involves plants that contain furanocoumarins and the insects that eat them; for both insects and plants, P-450s are essential mediators of the interaction.

Furanocoumarins owe their toxicity to their ability to bind covalently to DNAs and proteins in the presence of ultraviolet light; moreover, in the presence of molecular oxygen they can act as prooxidants that generate toxic oxygen species such as singlet oxygen and superoxide anion. Thus, furanocoumarins can interfere with cellular processes to cause toxicity in a wide variety of organisms, including insects (Berenbaum, 1991, 1995b). Over 200 furanocoumarins have been described from plants. Plant furanocoumarins occur in two structural configurations (Fig. 1): linear furanocoumarins (with the furan ring attached at the 6,7 positions of the benz-2-pyrone nucleus) can cross-link opposing strands in DNA helices as well as bind to proteins, whereas angular furanocoumarins (with the furan ring attached at the 7,8 positions of the benz-2-pyrone nucleus) bind to proteins but form only monoadducts with DNA. Linear furanocoumarins are known from approximately a dozen families, although they are most diverse and ubitquitous in Rutaceae and Apiaceae. Angular furanocoumarins are more narrowly distributed and are found only in a few genera in three plant families (Fabaceae, Rutaceae, Apiaceae); they are most frequently encountered in two tribes in the Apiaceae (Murray et al., 1982).

The biosynthesis of both linear and angular furanocoumarins begins with L-phenylalanine and involves several cytochrome P-450 monooxygenases (Fig. 1). Three P-450s catalyze in sequence the biosynthesis of bergaptol from

demethylsuberosin (6-prenylated umbelliferone) via (+)-marmesin and psoralen (Stanjek et al., 1999; Matern et al., 1999). Although these P-450s have been characterized biochemically, they have not yet been defined at the molecular level. Furanocoumarin biosynthesis, however, is clearly inducible by multiple forms of environmental stress, including insect damage (Zangerl and Berenbaum, 1998; Berenbaum and Zangerl, 1999); in *Apium graveolens*, furanocoumarin biosynthesis is stimulated by jasmonic acid and its analogs (Stanjek et al., 1997). The pattern of furanocoumarin response to insect damage in *Pastinaca sativa* is different from that elicited by mechanical damage (Zangerl and Berenbaum, 1990), raising the possibility that, as in some other plant–insect interactions, insect-derived oral secretions may contain compounds that influence induction of plant biosynthesis (Frey et al., 2000).

Few insects other than lepidopterans specialize on furanocoumarin-containing plants, and, within the Lepidoptera, specialization on these toxic plants is restricted to a handful of families (Berenbaum, 1983). Cytochrome P-450-mediated detoxification of furanocoumarins is associated with specialization on these plants in the Papilionidae, the swallowtail butterflies. Within the family, furanocoumarin-feeding is restricted to the genus *Papilio* within the subfamily Papilioninae; over 75% of these species are associated with furanocoumarin-containing plant hosts. Within the genus, P-450-mediated metabolism of furanocoumarins corresponds to the frequency of ecological exposure. Constitutive levels of activity (associated with host plants unsupplemented with furanocoumarins) against xanthotoxin, a linear furanocoumarin, are high in *Papilio cresphontes*, a specialist restricted to linear furanocoumarin-containing Rutaceae, the putative ancestral host plant family of the group. Constitutive activity is high as well in *P. polyxenes* and *P. brevicauda*, two specialists associated with furanocoumarin-containing Apiaceae. In contrast, P-450-mediated metabolism of xanthotoxin is undetectable in *P. troilus*, a specialist on host plants in the Lauraceae, all of which lack furanocoumarins; furanocoumarin metabolic activity is also not inducible by supplemental dietary furanocoumarins (Cohen et al., 1992).

The molecular basis of furanocoumarin resistance has been characterized at least in part in *P. polyxenes*. Transcripts of two cDNAs, *CYP6B1v1* and *CYP6B1v2*, accumulate in response to supplemental furanocoumarins (Cohen et al., 1992); that these cDNAs encode furanocoumarin-metabolizing P-450s was demonstrated by baculovirus-mediated expression in two different lepidopteran cell lines (Sf9, Tn5) (Ma et al., 1994) (Table 2). These P-450s metabolize linear furanocoumarins with high levels of activity; angular furanocoumarins such as angelicin and sphondin are metabolized poorly, if at all. Expression of CYP6B1 mRNA is tissue-specific, restricted to midgut and, to a lesser extent, fat body (Petersen et al., 2001) (Table 2). Consistent with its function in metabolizing plant allelochemicals, CYP6B1 is expressed only in larval feeding stages; no activity is detectable in eggs, pupae, or adults, which also lack furanocoumarin-metabolizing capabilities (Harrison et al.,

2001). Transcripts of a second P-450, *CYP6B3* (Hung et al., 1995), accumulate in response to a greater variety of linear and angular furanocoumarins than do *CYP6B1* transcripts, but CYP6B3 expressed in baculovirus-infected lepidopteran cells shows only low levels of furanocoumarin-metabolic activity (J.-C. Chen, unpublished).

Insights into regulation of CYP6B1 come from work with the *CYP6B1v3* gene (Prapaipong et al., 1994), with a coding sequence 98% identical to *CYP6B1v1* cDNA. A *cis*-acting regulatory element is necessary for transcriptional induction of P-450s in *P. polyxenes*. Nucleotides spanning the region from −136 to −119 have been identified as the xanthotoxin-responsive xenobiotic response element (XRE-xan) and are required for basal transcription and xanthotoxin inducibility (Prapaipong, 1995; Prapaipong et al., 1994). This element is conserved throughout the known *Papilio* P-450 genes (Table 5), consistent with a role in furanocoumarin regulation. The furanocoumarin inducibility of P-450 genes in other insects (Table 2), including those that rarely, if ever, encounter furanocoumarins, indicate that a search for this element in promoter sequences may be productive.

Members of the *P. glaucus* species group are exceptional in that they represent the most polyphagous species in an otherwise oligophagous family. All six species can utilize rutaceous plants, even when these plants are not within the normal host range (Scriber, 1988). *P. glaucus* and *P. canadensis* are two closely related generalists that are reported on a wide range of host plant families. Despite their similar appearance, they display consistent genetic, physiological, behavioral, and ecological differences (Scriber, 1988; Hagen, 1990; Hagen and Scriber, 1991,

1995). Geographical separation into northern *P. canadensis* and southern *P. glaucus* has led to different patterns of host plant use due to differences in the frequency of encounter. *P. glaucus* uses hoptree (*Ptelea trifoliata*), a rutaceous plant containing linear furanocoumarins (Murray et al., 1982), whereas *P. canadensis* rarely, if ever, encounters this host, although it can survive on its foliage in the laboratory (Scriber, 1988, 1995). No other reported host of either species is reported to contain furanocoumarins.

Furanocoumarin metabolism in *P. glaucus* is attributable, at least in part, to xanthotoxin-inducible *CYP6B4v1* cDNA and a closely related *CYP6B4v2* genomic DNA that differ in 7/500 amino acids (Hung et al., 1996, 1997). Baculovirus-mediated expression of CYP6B4v1 demonstrated that it metabolizes linear furanocoumarins at high rates (isopimpinellin, bergapten, xanthotoxin) and angular furanocoumarins at lower rates (angelicin, sphondin) (Hung et al., 1997) (Table 2). The metabolic capabilities of this P-450 are, in general, consistent with the frequency and distribution of furanocoumarins present in foliage of *P. trifoliata*, although differences between the overall metabolic profiles of caterpillars and the substrate profiles of CYP6B4v1 *in vitro* suggest that other P-450s may contribute to furanocoumarin metabolism. W. Li et al. (2001) succeeded in identifying two additional cDNAs (*CYP6B23* and *CYP6B24*) and five additional *CYP6B* gene sequences containing full-length or nearly full-length P-450 coding sequences and 5′ promoter sequences ranging from 400 bp to 1.7 kb (*CYP6B12*, *CYP6B16*, *CYP6B17*, *CYP6B20*, and *CYP6B21*) from *P. glaucus*. All of these P-450s are xanthotoxin-inducible (Table 2), but the extent to which they participate in furanocoumarin metabolism is unknown.

Although it rarely encounters furanocoumarins, *P. canadensis* can metabolize certain furanocoumarins at low levels (W. Li et al., 2001). In interspecific comparisons, metabolism rates for both linear and angular furanocoumarins are invariably higher in induced *P. glaucus* larvae than in induced *P. canadensis* larvae. From *P. canadensis*, W. Li et al. (2001) characterized two full-length cDNA sequences (*CYP6B25* and *CYP6B26*) and five gene sequences containing full-length or nearly full-length P-450 coding sequences (*CYP6B11*, *CYP6B13*, *CYP6B14*, *CYP6B15*, and *CYP6B18*), as well as the prematurely truncated open reading frames of *CYP6B19* and *CYP6B22*. As in *P. glaucus*, all of the CYP6B P-450s characterized in *P. canadensis* are xanthotoxin-inducible.

That this ability of xanthotoxin to cause accumulation of furanocoumarin-metabolizing P-450s is maintained in *P. canadensis* even though this species rarely, if ever, encounters furanocoumarins in its host plants suggests the furanocoumarin response cascade might be similar to that found in *P. glaucus*. Consistent with this suggestion is the high degree of similarity in promoter sequences in *CYP6B* genes in these two species. The proximal 5′ flanking sequence (translation start codon to −615) is highly conserved, with 91–98% identity, although the distal region is more variable. The xenobiotic-responsive elements to arylhydrocarbons

(XRE-AhR) and xanthotoxin (XRE-xan) (Prapaipong et al., 1994; Hung et al., 1996), are conserved among all these *CYP6B* genes (except for one position in the XRE-AhR sequence) (W. Li et al., in preparation) (Table 5).

Alignment of the deduced amino acid sequences of the 14 full-length or nearly full-length CYP6B subfamily members in *P. glaucus* and *P. canadensis* reveals that they share an extremely high degree of sequence identity, ranging from 92.8% to 99.8%. Comparison of the deduced protein sequences indicates that variations among these full-length sequences are confined to 64 out of 500 positions. There is, however, conservation of certain critical amino acids. In SRS1, one of the substrate recognition sites that define catalytic activities in P450s (Gotoh, 1992), Phe116 and His117 have been demonstrated to affect the integrity of the catalytic pocket and, thus, to influence the range of furanocoumarins metabolized (Chen et al. 2002). Both residues are conserved in the CYP6B proteins of *P. glaucus* and *P. canadensis*. However, the presence of at least eight differences within four of the substrate recognition sites determining P-450 catalytic properties (Gotoh, 1992; Straub et al., 1994; von Wachenfeldt and Johnson, 1995; Negishi et al., 1996; Roussel et al., 2000) suggests that some of these enzymes may differ from CYP6B1 in their range of furanocoumarin substrates or may even metabolize substrates other than furanocoumarin. This is not an unlikely scenario, given the broad host plant range of these two species. *In vitro*, however, CYP6B4 failed to metabolize representative alkaloids, coumarins, flavonoids, terpenoids, or phenylpropanoids that are naturally encountered within the host plant range (C. Hung, unpublished results).

A comparison of *P. glaucus* and *P. canadensis CYP6B* genes suggests that *P. canadensis* and *P. glaucus* are recently derived from a common ancestor that ostensibly possessed P-450 genes encoding furanocoumarin detoxification enzymes (Berenbaum et al., 1996). Conserved features in the promoter and coding regions of these genes, including the presence of insertions and deletions (W. Li et al., in preparation), most likely occurred prior to or concomitant with divergence of these species; unique features, including differences in substrate recognition sites and variability in promoter sequence upstream of a 640-bp conserved region, may have resulted from relaxed selection in the absence of furanocoumarin-containing hosts and may contribute to lower levels of induction as well as lower rates of metabolism of furanocoumarins in *P. canadensis*.

The isolation of a multitude of *CYP6B* genes from both species indicates that the genomes of both contain multiple closely related genes that are continuously differentiating. Analysis of the promoter and intron structure (W. Li et al., in preparation) indicates that these genes likely arose through repeated duplication of a single progenitor gene, followed by the insertion/deletion of sequences at several sites within the 5′ flanking and intron regions. The fact that *P. canadensis* maintains the ability to induce *CYP6B* genes even though it rarely if ever encounters furanocoumarins suggests that there may still be gene flow between these species in hybrid zones (Hagen, 1990; Scriber et al., 1991). Alternatively, if, in fact, these

species diverged long ago, the possibility exists that the mutation rate is low in regulatory elements or that elimination of P-450 genes from the genome is a slower process than expected in the absence of selection (Kimura et al., 1989; Gonzalez and Gelboin, 1989; Nebert, 1997); as well, the regulatory apparatus may be maintained for responses to other toxins ingested by these two species.

The patterns of evolutionary change in P-450s in *P. glaucus* and *P. canadensis* are paralleled in another pair of closely related polyphagous lepidopterans. *Helicoverpa zea* is a polyphagous noctuid that, despite its broad host range, rarely encounters furanocoumarins; nevertheless, like *P. glaucus* and *P. canadensis*, *H. zea* maintains furanocoumarin-inducible metabolism. From this insect, Li et al. (2000) cloned and sequenced *CYP6B8*, a full-length cDNA encoding protein with 51–99% identity with other members of the CYP6B subfamily. Like transcripts of *CYP6B1* and *CYP6B3* in *P. polyxenes* and *CYP6B* in *P. glaucus* and *P. canadensis*, transcripts of *CYP6B8* accumulate in response to dietary furanocoumarins. In a genomic study that parallels work in *P. glaucus*, X. Li et al. (2001) found a series of closely related genes. Four *CYP6B* genes exist as two pairs of duplicated paralogs with recent gene conversions at the 5′ end. In a comparison with *H. armigera*, a highly polyphagous congener that can hybridize under laboratory conditions with *H. zea*, three groups of orthologous *CYP6B* genes were found: *HzCYP6B8–HaCYP6B7*, *HzCYP6B27–HaCYP6B6*, and *HzCYP6B9–HaCYP6B2/B10*. The degree of divergence in the first two of these groups is extremely low: 1% (amino acid) and 4% (nucleotide) for *HzCYP6B8–HaCYP6B7* and 2% (amino acid) and 4% (nucleotide) for *HzCYP6B27–HaCYP6B6*. This is similar to the allelic variation for P-450s within species. Heliothine *CYP6B* genes share at least 80% identity in amino acids and coding nucleotides. Despite some divergence in coding sequence, the 5′ exon/intron splicing sequences are absolutely identical, and the 3′ intron/exon splicing sequences are also highly conserved. This high level of conservation throughout the gene suggests relatively recent gene duplication.

Despite the taxonomic distance between the groups, heliothine and papilionine P-450s share several similarities. All *Papilio* P-450 proteins characterized to date are furanocoumarin-inducible, as is CYP6B8 in *Helicoverpa* (Table 2). A striking number of amino acids are conserved in SRS1 and SRS4 in all CYP6B proteins. Among those absolutely conserved are Phe 116 and His 117, required for furanocoumarin metabolism in CYP6B1 (Chen et al., 2002). *P. glaucus* B4/B5 share almost identical nucleotide (coding) regions and amino acid sequences (Hung et al., 1996), as do *H. zea* paralogs *CYP6B8* and *CYP6B28*. The presence of multiple P-450s in two still-diverging pairs of polyphagous species raises the possibility that polyphagy may arise in specialized groups via extensive gene duplication. Such gene duplication could allow for rapid acquisition of new substrates; indeed, rapid gene duplication is thought to underlie the tremendous diversity of P-450s in the genome of the human (Nebert, 1997), arguably the most polyphagous species on the planet.

The degree to which polyphagy depends on a predisposition to gene duplication may be lineage-dependent. In Lepidoptera, for example, the vast majority of species (including the putative ancestors of the two pairs of polyphagous species examined here) are relatively oligophagous. In a lineage with relatively substrate-specific P-450s, gene duplication with subsequent acquistion of new function may be a mechanism for shifting from oligophagy to polyphagy. However, polyphagy may also reflect physiological adaptation via P-450s with broad substrate specificity; such appears to be the case, for example, in humans, in which individual P-450s can turn over dozens of biosynthetically and structurally unrelated substrates (Berenbaum, 1999). Behavioral adaptations are also a factor in the acquistion of the polyphagous habit. Again, in humans, a spectacularly broad diet may minimize the exposure of an individual to any particular group of dietary toxins. Whether there is any relationship at all between P-450 diversity and diet breadth, however, cannot be determined definitively until the P-450 inventories of a larger number of species have been determined.

In contrast with the evolution of polyphagy, the presence of highly conserved promoter elements that play a role in furanocoumarin-responsiveness as well as highly conserved features of substrate recognition sites in three species within the genus *Papilio* suggest that strong selection for specialization may manifest itself in the genome. Indeed, extensive investigation of *P. polyxenes*, a specialist on furanocoumarin-containing plants that experiences a much narrower and more predictable array of allelochemicals in its host plants, has yet to reveal extensive gene diversity. The key innovation in allowing species in the genus *Papilio* to utilize and diversify on furanocoumarin-containing plants may well have been the linkage between a promoter element allowing responsiveness and a coding sequence allowing rapid and efficient metabolism (Berenbaum et al., 1996; Stevens et al., 2000).

CONCLUSIONS

The field of chemical ecology, the study of the ways in which chemicals affect the distribution, abundance, and interaction of organisms, really did not gain a distinct identity until 1970, when a book appeared, titled *Chemical Ecology* (Sondheimer and Simeone, 1970). Shortly thereafter, in 1974, the *Journal of Chemical Ecology* was founded, "devoted to promoting an understanding of the origin, function, and significance of natural chemicals that mediate interactions within and between organisms." Following the first Gordon Conference organized around the subject of plant–herbivore interactions in 1980, the International Society for Chemical Ecology was organized. Today, membership in the society includes not only chemists and ecologists but a wide range of life scientists. As practiced today, the field of chemical ecology involves not only the fields of natural products chemistry

and ecology but also such subdisciplines of biology as behavior, evolution, genetics, and physiology.

In many subdisciplines within biology, the use of molecular tools and approaches has led to a tremendous explosion of productivity. These tools and approaches hold considerable promise for the field of chemical ecology. In particular, the possibility now exists to identify mechanisms underlying familiar and well-characterized ecological and behavioral phenomena—host plant specificity, mate choice, territoriality, allomonal defense, and the like. The enormous advantage of elucidating mechanisms is that it allows for a more complete understanding of complex phenomena as well as more refined ability to make predictions about newly observed phenomena. At the same time, the field of chemical ecology has much to offer to genome scientists; only those intimately familiar with the small molecules that affect ecology and behavior can begin to hazard a guess as to the function of the macromolecules that provide the blueprints for behavior and ecology. Chemical ecology has, since its inception, been an inherently multidisciplinary field. Traditionally, it has been a synthesis of a physical science (chemistry) and a biological science (ecology). At the beginning of the new century, it seems particularly apt to expand the multidisciplinary nature of the field to take advantage of ways to think about and new tools to tackle familiar research challenges.

Acknowledgments—I thank the International Society of Chemical Ecology for inviting me to travel to Brazil to present this paper; much of the original work presented here was funded by NSF IBN96-30442. Funding from the USDA Innovations Program, with a supplement from the Sloan Foundation, allowed me to organize and attend a workshop dedicated to exploring the future of chemical ecology in the 21st century. I also thank Weimin Li, Xianchun Li, Rebecca Petersen, Hugh Robertson, and Arthur Zangerl for assistance with tables, figures, and thoughts, and I thank Mary Schuler for over a dozen years of extremely productive collaboration.

(Received March 30, 2001; accepted January 13, 2002)

Abstract—We conducted defoliation experiments with 7- to 8-year-old clones of Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco var. *glauca*] to assess the role of monoterpenes as a resistance mechanism to western spruce budworm (*Choristoneura occidentalis* Freeman) defoliation. The grafted clones were derived from mature trees that showed resistance or susceptibility to budworm defoliation in the forest. All clones were exposed to either budworm defoliation or nondefoliation treatments in 1998 and 1999 under greenhouse conditions. We found that the total concentration of monoterpenes in current-year foliage varied greatly between two consecutive years in clones in the greenhouse and in their corresponding mature trees in the forest. Fractional composition of different monoterpenes was similar between different years and between clones and mature trees, indicating genetic control of this trait. Two different defoliation experiments were conducted to assess the importance of budburst phenology as a factor determining host plant resistance. In the 1998 experiment, budworm feeding was matched to the budburst of each individual plant. Monoterpene concentration was high in 1998, and budworm potential fitness was greater on clones from the resistant mature trees that had lower concentrations of total monoterpenes. In the 1999 experiment, budworm feeding was matched to budburst of the whole population of plants in order to mimic conditions similar to insects feeding on trees in the field. The concentration of monoterpenes was low in 1999, and budworm fitness was not related to monoterpenes. Total monoterpene concentration was negatively related to foliar nitrogen concentration, suggesting that C/N balance may affect monoterpene synthesis in needles. However, tree growth was not related to total monoterpene concentration. We concluded that

expression of differences in budworm resistance among Douglas fir genotypes might be caused by interactions among multiple resistance mechanisms such as needle monoterpenes and tree budburst phenology.

Key Words—Budburst phenology, *Choristoneura occidentalis*, herbivory, monoterpenes, plant-insect interactions, *Pseudotsuga menziesii*.

INTRODUCTION

Terpenes are the largest and most diverse group of plant secondary metabolites. At least 15,000 terpenoids have been described and perhaps thousands more are yet to be discovered (Gershenzon and Croteau, 1991). Monoterpenes (i.e., C_{10} hydrocarbons) are one of the major terpene groups and are widespread in plants, functioning as either deterrents or attractants to herbivores (Hedin et al., 1974; Kogan, 1975). They are also involved in numerous physiological and ecological interactions in forest ecosystems (Harborne, 1991; Gershenzon, 1994; Langenheim, 1994; Lerdau et al., 1995). Monoterpene concentration and composition in coniferous trees are influenced by tree genotype (von Rudloff and Rehfeldt, 1980; Gershenzon and Croteau, 1991; Hanover, 1992; Gershenzon, 1994) and environmental factors such as availability of nitrogen (Lerdau et al., 1995; McKinnon et al., 1998), water, and sunlight (Johnson et al., 1997). Further, monoterpene concentration and composition can change during tissue maturation (Wagner et al., 1989; Gambliel and Cates, 1995; Zou and Cates, 1995) and can vary among different tissues within the same tree (Latta et al., 2000).

The association between terpenes and resistance of host trees to insect herbivores has been investigated in several conifers (Annila et al., 1984; McClure and Hare, 1984; Redak and Cates, 1984; Hanula et al., 1985; Wilkinson, 1985; Cates et al., 1987; Cates and Redak, 1988; Cates and Zou, 1990; Clancy, 1991a; Clancy et al., 1992, 1993; Wagner and Zhang, 1993; Felipe et al., 1994; Tomlin et al., 1997; Manninen et al., 1998; Nault et al., 1999). However, the role of terpenes as a resistance mechanism remains controversial. Several studies have concluded that monoterpenes are an important mechanism of resistance to insect herbivores in conifers (McClure and Hare, 1984; Cates et al., 1987; Cates and Zou, 1990; Felipe et al., 1994; Tomlin et al., 1997), whereas other studies have not (Annila et al., 1984; Wilkinson, 1985; Clancy, 1991a, 1993, 2001; Clancy et al., 1992, 1993; Wagner and Zhang, 1993; Manninen et al., 1998; Nault et al., 1999). This controversy likely arises from the many influences on conifer monoterpene concentration and composition (e.g., tree genotype, ontogeny, environment, and genotype–environment interaction), the evolution of different resistance mechanisms for different host plant–insect systems, and the possible involvement of several mechanisms in host plant resistance.

Evidence for an important role of monoterpenes as a tree resistance mechanism is also mixed for the subjects of our study, Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco var. *glauca*] and western spruce budworm (*Choristoneura occidentalis* Freeman). Some monoterpenes, such as tricyclene, camphene, and bornyl acetate, have been reported to adversely affect western spruce budworm performance on Douglas fir (Cates et al., 1983; Redak and Cates, 1984; Cates and Zou, 1990; Zou and Cates, 1995). In contrast, other studies have found no difference in these monoterpene components between mature Douglas fir trees that showed resistance versus susceptibility to budworm defoliation in the forest (Clancy, 1991a, 2001; Clancy et al., 1993). Further, Clancy et al. (1992) and Clancy (1993) reported little influence of monoterpenes that were microencapsulated in an artificial diet on budworm performance in a three-generation bioassay unless components such as camphene, bornyl acetate, β-citronellol, and linalool were at extremely high concentrations that rarely occurred in forest trees.

The overall objective of this study is to further understand the role of monoterpenes as a resistance mechanism of Douglas fir to budworm defoliation. We used data on total monoterpene concentration and composition from resistant and susceptible mature trees and clones of these trees in the greenhouse to address these questions: (1) Does foliar monoterpene concentration and composition differ between tree genotypes that were resistant to budworm defoliation versus genotypes that were susceptible? (2) Does variation in monoterpene concentration affect budworm performance in a pattern consistent with field observations of tree resistance? (3) Is the influence of foliar monoterpenes on budworm performance mediated by the degree of synchrony between budworm feeding and tree budburst phenology? (4) Does budworm defoliation induce changes in monoterpene concentration and composition? (5) Does carbon allocation to monoterpene synthesis compromise allocation to tree radial growth?

METHODS AND MATERIALS

Douglas Fir Trees and Clones. Our experimental plant material consisted of clones derived from mature Douglas fir trees that differed in western spruce budworm defoliation under field conditions (Clancy et al., 1993). The mature Douglas fir trees were from sites on the Pike National Forest near Deckers, Colorado (105.23°W, 39.23°N, elevation 2573 m) and the Kaibab National Forest near Jacob Lake, Arizona (112.22°W, 36.71°N, elevation 2774 m). At the time the trees were identified (1988 and 1989), most of the trees at the sites had sustained moderate to severe budworm defoliation for at least several years, as determined from their growth form and general condition. We selected seven phenotypically resistant trees at the Pike National Forest site and five phenotypically resistant trees

at the Kaibab National Forest site by identifying trees with full crowns and little other evidence of budworm damage. These trees were visually distinct from other trees in the stand that were characterized as phenotypically susceptible based on their defoliated crowns. Each resistant tree was paired with a nearby (within 30 m) susceptible tree of similar size (height and dbh) and microsite (slope and aspect). In other words, the pairs of resistant and susceptible trees were matched as closely as possible to minimize any size-, age-, or microsite-related effects that could confound effects associated with different levels of herbivory. We deliberately chose pairs at each site that represented a range of size (i.e., age) classes. The age of the 24 trees ranged between 45 and 123 years [79.3 $\pm$ 4.1 years (mean $\pm$ SE)]; height ranged between 6.4 and 14.9 m (10.4 $\pm$ 0.5 m); dbh ranged between 15 and 40 cm (25.3 $\pm$ 1.3 cm). We measured radial growth increment on these trees over each 5-year interval between 1966 and 1990 on increment cores sampled at breast height (one sample per tree) with a binocular microscope equipped with an ocular micrometer (Clancy et al., 1993).

We cloned each of the 24 mature trees by whip-grafting branches collected from the lower third of the crown onto 1-year seedling rootstocks in 1991 and 1992. This is a common and widespread technique for reproducing mature tree characteristics in a smaller plant (Hartmann and Kester, 1983; Zobel and Talbert, 1984). Such cloning resulted in the fixation of the genotype and tissue developmental stage of mature trees but not tree environment. All cloned trees were grown in plastic pots (15-liter volume) containing a mixture of screened peat moss and vermiculite in the greenhouse; they were regularly watered and fertilized during the growing season. Cloned trees averaged 2.11 $\pm$ 0.03 cm (mean $\pm$ 1 SE, here and throughout) in base stem diameter (approximately 1 cm above the graft), 93.5 $\pm$ 1.6 cm in height, and 45.9 $\pm$ 0.7 cm in crown diameter (averaged over two directions) in spring 1998 before the start of the budworm defoliation experiments.

Experimental Design and Budworm Defoliation. The experiment had a completely randomized block design composed of six blocks, each containing 48 clonally propagated trees [i.e., 2 treatments (budworm defoliation versus control) $\times$ 2 traits (resistant versus susceptible)/pair $\times$ 12 pairs]. In total, 288 cloned trees were included in the experiments. However, 11 trees died before the experiment started; therefore, there were actually four to six replications of each treatment combination for each of the 12 pairs. In order to test the role of budburst phenology as an influence on budworm performance, we conducted the budworm defoliation experiment differently in 1998 and 1999. The budworm larvae used in our study were from our laboratory cultures of diapausing and nondiapausing western spruce budworms, maintained in the Entomology Laboratory at Rocky Mountain Research Station, Flagstaff, Arizona. The nondiapausing colony has growth rates and feeding behavior similar to a wild population (Leyva et al., 1995).

In the 1998 experiment, nondiapausing third- and primary fourth-instar budworm larvae (one larva to five terminal buds) were used to defoliate each cloned

tree when approximately 50% of its buds were in the fourth (i.e., columnar) budburst development stage. This stage is highly suitable for budworm feeding (Shepherd, 1983). Because budworm larval feeding was purposely matched to the fourth budburst stage of each clone, the effect of genetic variation in budburst phenology among trees on budworm feeding was minimized. In the 1999 experiment, diapausing second-instar larvae in hibernacula (one larva to four terminal buds) were introduced to the same clones that were defoliated by budworms in 1998. However, larvae were placed on all trees at the same date when approximately 50% of all terminal buds in the population were in the second (i.e., yellow) budburst stage (Shepherd, 1983). This schedule of larval introduction allowed genetic differences in budburst phenology among trees to influence the developmental stage of buds available for budworm feeding, as can occur in Douglas fir forests (Clancy et al., 1993). Our measurements of budburst phenology of nondefoliated clones in the greenhouse in 1998 revealed that clones of susceptible trees broke bud earlier than clones of resistant trees (Chen et al., 2001a), and the same pattern occurred for the mature trees in the forest (Clancy et al., 1993).

Other experimental procedures were the same in both years. Both defoliated and nondefoliated tree clones were caged with nylon "No-See-um" netting bags (The Rain Shed Corp., Corvallis, Oregon) that allowed approximately 80% of full light to penetrate in order to contain larvae and create similar growing conditions for all clones. The bags were not removed until 95% of the larvae pupated, which required approximately five weeks.

Budworm Bioassay. Most of the pupae were removed from defoliated tree clones within 24–48 hours of pupation. Male and female pupae were separately weighed (to the nearest 0.1 mg), and sorted into trays based on clone genotype. The pupae were refrigerated at 10°C for up to seven days until an adequate number of male and female pupae were collected from the same clone genotype for mating, which occurred in brown paper mating bags at room temperature (20°C). Female pupal weight was used to estimate the number of oocytes per female or potential fecundity (Wagner et al., 1987).

When about 10% of the moths had emerged in the mating bags, freshly clipped Douglas fir foliage was added for adult oviposition substrate. Once the foliage was added, the moths were allowed to mate and oviposit for 7–10 days. Next, the foliage was removed, and the number of next-generation (noted as F_1) egg masses larger than 4 mm was counted. Then, mating bags were frozen to kill the adult moths, and the unemerged pupae (i.e., dead) in each bag were counted and sexed to determine percent survival through the pupal stage and the number of female moths that had emerged. The collected F_1 egg masses were placed in Petri dishes, sealed inside plastic bags, and incubated in the laboratory (20°C) for 7–10 days to determine if the egg masses were viable (i.e., if $\geq$50% of the eggs in the mass hatched).

The measurement of budworm potential fitness was based on the following population growth model modified from Clancy (1991b):

$$\begin{aligned}\text{Number of } F_1 \text{ larvae } (N) = {} & [\text{number of parent generation (noted as } P_1) \text{ larvae}] \\ & * (P_1 \text{ proportion cohort survival to the adult stage}) \\ & * (P_1 \text{ average potential fecundity per female}) \\ & * (F_1 \text{ proportion of egg masses with viable eggs})\end{aligned}$$

This model estimated the number of first instars alive at the beginning of the F_1 generation, assuming that clones from the resistant and susceptible trees had equal population sizes at the beginning of the P_1 generation (i.e., we assumed that all populations started with a single P_1 larva). Cohort survival to the adult stage was based on survival through the larval and pupal stage (multiplied together) when we used data from the 1998 experiment. For the 1999 experiment, this value was based on survival through the pupal stage alone because the data on larval survival were unavailable due to the survival of some residual F_1 larvae on some trees from the 1998 experiment.

We acknowledge that our estimations of budworm potential fitness were inflated in 1998 (because of the lack of data on survival of first-instar larvae to the third or fourth instars) and in 1999 (because of the lack of reliable data on survival of second-instar larvae to the pupal stage). However, the lack of these data did not influence our comparisons between the potential fitness of budworms after feeding on clones of resistant and susceptible trees within each experimental year (i.e., the biases were consistent between the resistant and susceptible trees in each year).

Foliage Collection and Terpene Analysis. Current-year foliage was sampled from mature trees in late June of the 1989 and 1990 growing seasons, corresponding to the late-instar feeding period of the western spruce budworm (foliage was at the feather duster, or seventh developmental stage) (Clancy et al., 1993). One branch was clipped at random from the mid-crown area of the north, south, east, and west quadrants of each tree; the needles collected from these quadrants were pooled for each tree prior to chemical analysis. Although we have previously reported the foliar monoterpene data for the mature trees (Clancy et al., 1993; Clancy, 2001), this study is the first comparison of foliar monoterpenes in the parent trees and their corresponding clones.

Current-year foliage from the clonal trees in the greenhouse was sampled in 1998 and 1999 when late instars of the budworm were actively feeding on the defoliated trees, and the foliage was at the seventh (or feather duster) developmental stage (Shepherd, 1983). Two clusters of current-year foliage were clipped at random from the upper third of the crown. The foliage sampled from defoliated trees was not directly damaged by budworms. The foliage sampled in each year was pooled over the four to six trees from the same clone and treatment (i.e., budworm defoliation versus control). Therefore, no block effect was included in

the analysis of terpene data. A total of 48 pooled foliage samples were used for chemical analysis [i.e., 2 treatments (defoliated versus control) $\times$ 2 traits (resistant versus susceptible clones) $\times$ 12 pairs].

Foliage samples were sealed in plastic bags and temporarily stored in a freezer before being transferred to an ultralow freezer for long-term storage (up to seven months) at -60°C before being analyzed. Approximately 250 mg of needle tissue was extracted from each sample in 5 ml pentane. The extracts were analyzed with a Hewlett Packard 5890 series II gas chromatograph containing an HP-1 capillary column (30 m $\times$ 0.25 mm). Monoterpene concentrations were calculated on a fresh mass basis (Clancy et al., 1993) because foliage samples collected from the clonal trees were at the same phenological stage and were grown under similar environments; thus, they had little variation in moisture content. All chemical analyses were conducted by the Analytical Services Laboratory at Northern Arizona University.

Statistical Analysis. Since the sampled Douglas fir population from the Pike National Forest site (Colorado) was not genetically differentiated from the sampled population from the Kaibab National Forest site (Arizona) based on an isoenzyme study (Chen et al., 2001b), we treated the 12 pairs of trees from these two sites as one population for statistical analysis. We used a multivariate analysis of variance (MANOVA) to investigate the overall effect of tree pair (i.e., 12 pairs of resistant and susceptible mature trees from which clones were derived), trait (resistant versus susceptible), treatment (defoliation versus non-defoliation), and their interactions on variations in total monoterpene concentration and fractional composition (i.e., percentage) of different monoterpenes. After that, we performed a univariate analysis of variance (ANOVA) test with the three-way interaction term as the error term for each monoterpene component using the same model as described for the MANOVA. Since we measured multiple response variables (e.g., 11 different terpenes) from the same set of experimental units, we used a Bonferroni correction to the P value we accepted as indicating significant differences in the univariate ANOVAs in order to maintain the correct P value of 0.05 for the type I error rate over the whole set of univariate ANOVAs. For this study, we focused on the effects of trait, defoliation treatment, and their interaction because they were most relevant to our research questions. Spearman's rank correlation coefficient (SAS Institute, 1995) was used to compare the rank order of percent composition of different monoterpene components between years and between clones and mature trees.

Finally, we used linear regression to examine the association between: monoterpenes and budworm potential fitness in the 1998 and 1999 greenhouse experiments with clones; the most recent 5-year radial growth (1986–1990) of mature trees in the forest and total monoterpene concentration in 1989 and 1990; and total monoterpene concentration of clones and their corresponding mature trees.

RESULTS

Monoterpene Composition and Structure. Eleven monoterpenes were detected in the needles of cloned trees in greenhouse experiments. The rank order of monoterpene concentration in 1998 was bornyl acetate, camphene, limonene, β-pinene, α-pinene, unknown A, unknown C, myrcene, unknown B, tricyclene, and terpinolene (Table 1). Five monoterpenes, α-pinene, camphene, β-pinene, limonene, and bornyl acetate, accounted for approximately 78% of total monoterpenes in 1998 and 86% in 1999 (Table 1). Fractions of bornyl acetate and limonene increased from 1998 to 1999 ($P \leq 0.017$), fractions of camphene, β-pinene, and α-pinene did not change ($P \geq 0.239$), and unknown monoterpenes A, B, C, and terpinolene declined ($P \leq 0.002$) (Table 1). Based on Spearman's rank correlation coefficient, the rank order in concentration of monoterpenes in 1998 and 1999 was highly correlated ($\rho = 0.955$, $P < 0.001$), indicating high consistency of fractional composition over years.

The same 11 monoterpenes present in clones were also present in mature tree foliage (Table 1). The rank order of fractional composition of monoterpenes in mature trees was consistent between 1989 and 1990 (Spearman's $\rho = 0.734$, $P = 0.010$). Moreover, monoterpene fractional composition was similar between mature trees and clones ($\rho = 0.682$–0.902, $P = 0.021$–0.001, depending on years).

Total monoterpene concentration of clones was greater in 1998 than 1999 by approximately 245% ($P < 0.001$), whereas the total monoterpene concentration in mature trees was approximately 315% greater in 1990 than in 1989 ($P < 0.001$) (Table 1). Further, variation in total monoterpene concentration among individual ramets ($r = 0.164$, $P = 0.269$, $N = 48$) and mature trees ($r = 0.339$, $P = 0.104$, $N = 24$) was not significantly correlated between consecutive sampling years. Moreover, there was no clear relationship in total monoterpene concentration between mature trees and clones. For example, total foliar monoterpene concentrations were positively, but weakly, correlated between mature trees in 1989 and clones in both 1998 and 1999 ($P \leq 0.067$; Figure 1). However, this was not the case for mature trees in 1990 ($P > 0.338$) (data not shown).

Effect of Tree Resistance Trait and Treatment on Monoterpenes. Monoterpene concentration and fractional composition in foliage of clones differed among levels of the experimental factors in the 1998 and 1999 greenhouse experiments (MANOVA, $P < 0.001$) (Table 2). Tree pair and the interaction between pair and trait (resistant versus susceptible) were significant (MANOVA, $P \leq 0.002$) in both years, indicating that both concentration and fraction of monoterpenes differed among the clones from 12 pairs of trees and that the difference between the resistant and susceptible trees within each pair was not consistent.

In the 1998 experiment, trait (resistant versus susceptible) had a marginally significant overall effect on monoterpene concentrations (MANOVA, $P = 0.059$) (Table 2). Further univariate ANOVA for each monoterpene component

[a] The P value indicates whether there were differences between two sampling years.

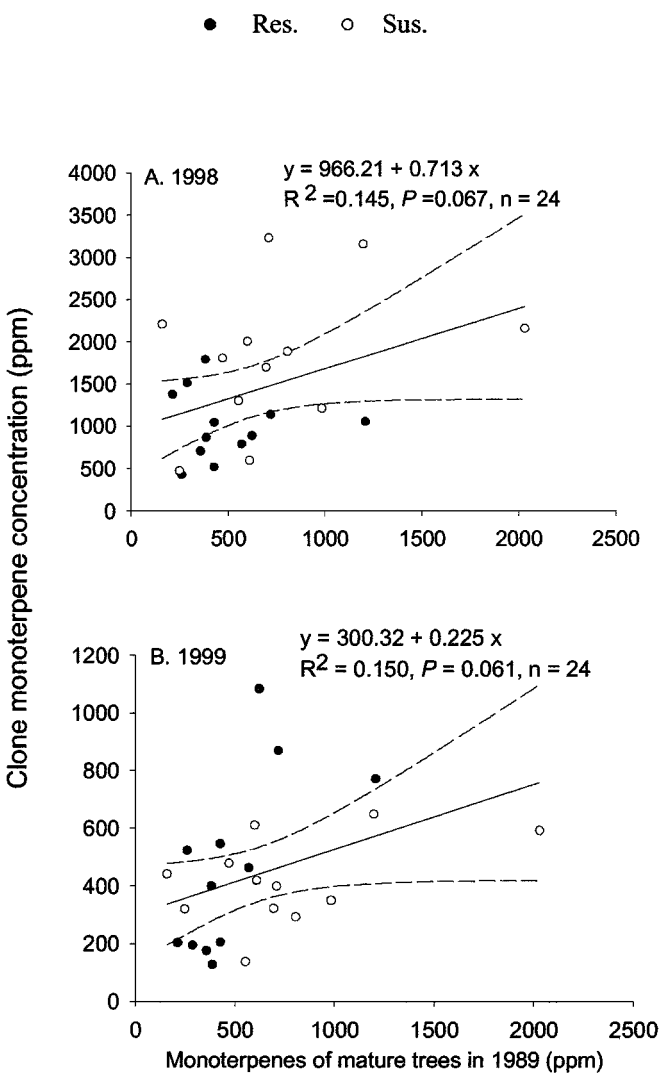

FIG. 1. Regression of foliar concentration (ppm fresh weight) of total monoterpenes in current-year foliage of clones derived from mature Douglas fir trees against concentrations in the original parent trees. All needles were at the seventh (i.e., feather duster) developmental stage when they were sampled. Clonal data is shown for 1998 (A) and 1999 (B) and is plotted against data from the parent trees for 1989. Data are shown for mature trees that appeared to be resistant (●) versus susceptible (○) to western spruce budworm defoliation. Dashed lines around the regression line indicate the 95% confidence limits for the mean response, and the equations for the regression lines and their associated statistics are shown on the graphs.

TABLE 2. RESULTS OF MULTIVARIATE ANALYSIS OF VARIANCE WITH WILKS' LAMBDA TEST FOR EFFECTS OF TREE PAIR, TRAIT, AND TREATMENT ON CONCENTRATION (FRESH-WEIGHT-BASED) AND FRACTIONAL COMPOSITION (% OF TOTAL MONOTERPENE CONCENTRATION) OF 11 MONOTERPENES FROM 1998 AND 1999 GREENHOUSE EXPERIMENTS WITH DOUGLAS FIR CLONES[a]

Source of variation	Wilks' lambda test (Num DF, Den DF)	*P*			
		1998		1999

[a] *P* value represents the probability for the null hypothesis of no overall effect from each source of variation.

indicated that clones from resistant trees generally had a lower concentration of monoterpenes than clones from susceptible trees (ANOVA, $P \leq 0.021$) (Table 3; Figure 2A). Moreover, clones of resistant trees had a lower average total monoterpene concentration (1181 ± 75 ppm) than clones from susceptible trees in 1998 (1798 ± 75 ppm) ($P < 0.001$; Table 3). In contrast, overall monoterpene fractional composition did not differ between clones from resistant and susceptible trees in 1998 (MANOVA, $P = 0.233$; Table 2). However, univariate ANOVA suggested that clones from resistant trees had a higher fraction of camphene and bornyl acetate and a lower fraction of β-pinene and unknown C than clones from susceptible trees ($P \leq 0.004$; Table 3) (Figure 2C). Budworm defoliation treatment in 1998 did not influence the overall concentration or fractional composition of monoterpenes (MANOVA, $P \geq 0.201$; Table 2). However, the univariate ANOVAs suggested a reduction in the fraction of myrcene and limonene in defoliated versus nondefoliated tree clones ($P \leq 0.005$; Table 3; Figure 3C).

Clones from susceptible trees had a greater ratio of total monoterpene concentration to nitrogen concentration (i.e., monoterpene/N ratio; 0.083 ± 0.005) than clones from resistant trees (0.054 ± 0.005) in the 1998 experiment ($P = 0.001$). Furthermore, budworm defoliation caused a marginal increase in the monoterpene/N ratio (0.075 ± 0.005) compared to the control (0.062 ± 0.005) in 1998 ($P = 0.088$). The interaction between tree trait and treatment did not influence the concentration or fractional composition of monoterpenes in 1998 (MANOVA, $P \leq 0.533$; Table 2) or the monoterpene/N ratio, indicating similar effects of defoliation on clones from resistant and susceptible trees. Univariate ANOVA also supported the absence of any significant trait × treatment interactions ($P \geq 0.033$; Table 3).

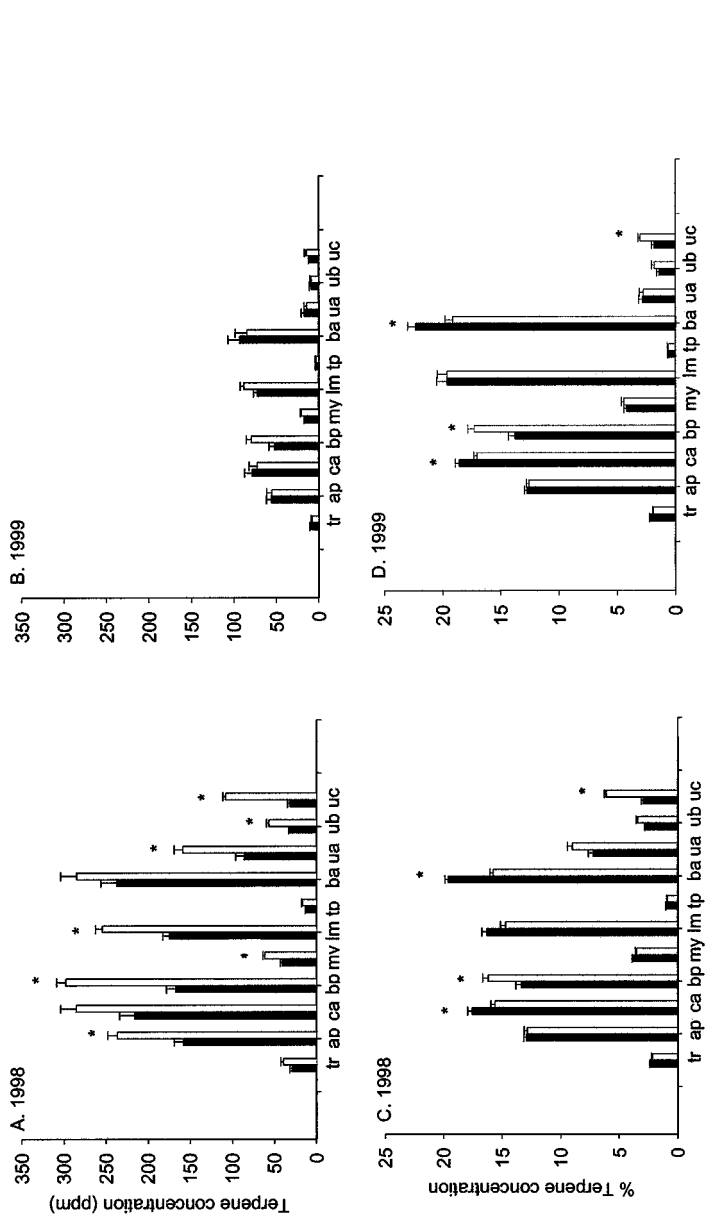

FIG. 2. Mean (+1 SE) concentration (A, B) and fractional composition (C, D) of 11 monoterpene components in Douglas fir needles sampled in the 1998 (A, C) and 1999 (B, D) greenhouse experiments for clones from mature Douglas fir trees that appeared to be resistant (■) versus susceptible (□) to western spruce budworm defoliation. Abbreviations represent 11 monoterpenes defined in Table 1. Asterisks (*) indicate there was a significant difference between the resistant and susceptible clones (ANOVA, Bonferroni adjusted $\alpha \leq 0.005$).

[a] The Bonferroni adjusted P value of $\alpha = 0.005$ (i.e., 0.05 divided by 11) was used to determine significance, in order to maintain the correct P value of 0.05 for the type I error rate over the whole set of univariate ANOVAs for the 11 individual terpene compounds.

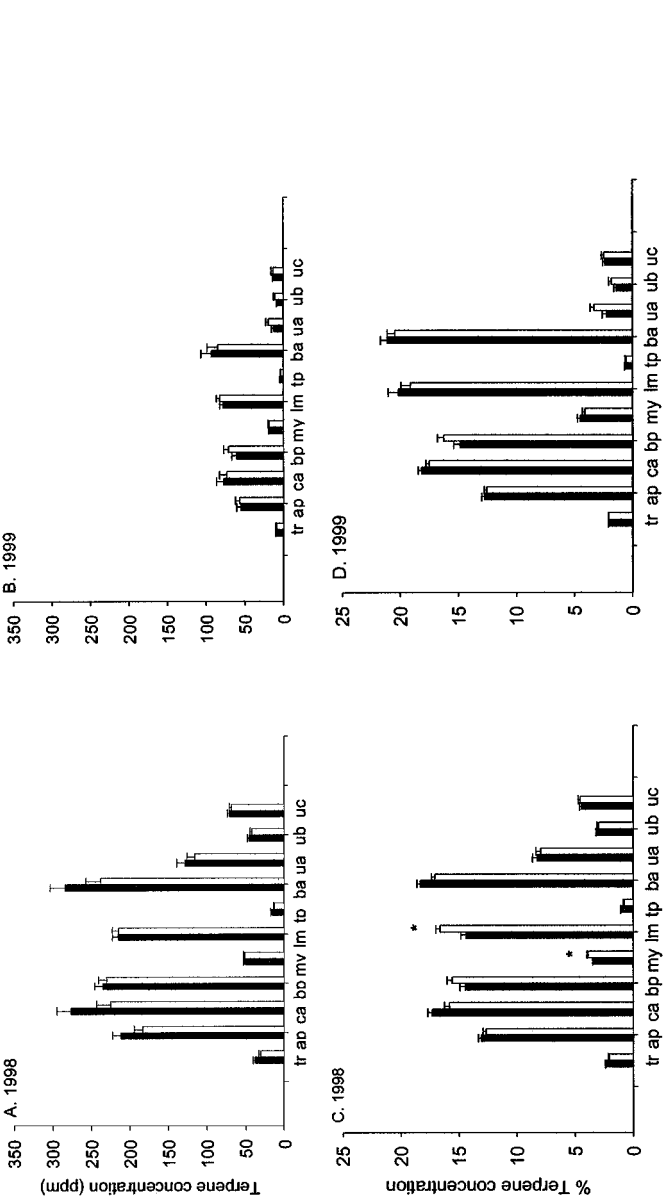

FIG. 3. Mean (+1 SE) concentration (A, B) and fractional composition (C, D) of 11 monoterpene components in Douglas fir needles sampled in the 1998 (A, C) and 1999 (B, D) greenhouse experiments for defoliated (■) versus nondefoliated (□) clones from mature Douglas fir trees (data pooled for resistant and susceptible clones). Abbreviations represented 11 monoterpenes defined in Table 1. Asterisks (*) indicate there was a significant difference between the defoliated and non-defoliated clones (ANOVA, Bonferroni adjusted $\alpha \leq 0.005$).

In the 1999 experiment, when total monoterpene concentration was 71% lower than in 1998, tree trait, defoliation treatment, and their interaction did not influence the concentration or composition of monoterpenes (MANOVA, $P \geq 0.219$; Table 2). Univariate ANOVAs also failed to detect significant effects on concentrations of individual or total monoterpenes ($P \geq 0.011$; Table 4; Figures 2B and 3B) or on the monoterpene/N ratio ($P > 0.509$). Likewise, the fractional composition of monoterpenes was unaffected by defoliation in 1999 ($P \geq 0.058$; Table 4; Figure 3D) and there were no detectable trait $\times$ treatment interactions ($P \geq 0.036$; Table 4). However, the univariate ANOVAs indicated there were significant differences between resistant and susceptible trees in the proportions of camphene, β-pinene, bornyl acetate, and unknown terpene C ($P \leq 0.005$; Table 4). Interestingly, the patterns were identical to those observed in the 1998 experiment (Figure 2C); resistant trees had higher percentages of camphene and bornyl acetate, whereas susceptible trees had higher fractions of β-pinene and unknown C (Figure 2D).

Effect of Monoterpenes and Terpene/N Ratio on Budworm Performance. In the 1998 experiment, when total monoterpene concentration was high and budworm feeding was matched to the budburst of each individual plant, budworm potential fitness declined as total monoterpene concentration increased ($P = 0.027$); approximately 20% of the variation in potential fitness was explained by total monoterpene concentration (Figure 4A). Individual terpenes that were negatively correlated with budworm fitness included myrcene ($P = 0.046$), limonene ($P = 0.029$), and unknown C ($P = 0.029$). Further, the monoterpene/N ratio was negatively related to budworm fitness in 1998 ($r = -0.481$, $P = 0.017$; Figure 4B).

In contrast, in the 1999 experiment, monoterpene concentrations were low and genetic differences among the clones in budburst phenology affected the quantity and quality of the buds and needles available for larval feeding. Under these conditions, budworm fitness was not related to total monoterpene concentration ($P = 0.567$), the fractional composition of monoterpene components (P values ranged from 0.124 to 0.954), or the monoterpene/N ratio ($P = 0.531$).

The monoterpene/N ratio was significantly higher in 1998 (0.069 ± 0.004) than in 1999 (0.011 ± 0.004) ($P < 0.001$). Although nitrogen concentration was not related to monoterpene concentration in each year, total monoterpene concentration declined exponentially as foliar N concentration increased for data pooled over both years (Figure 5). The higher monoterpene/N ratio in 1998 was caused by both higher total monoterpene concentration and lower nitrogen concentration compared to the data in 1999 (Figure 5).

Relationship between Monoterpene Concentration and Growth. Total monoterpene concentration was not correlated with the relative growth rates of the base diameter, crown, or height of the clones between the start of the experiments and the end of the 1998 growing season ($P \geq 0.814$; $N = 24$). Moreover, the five-year

TABLE 4. RESULTS FROM UNIVARIATE ANALYSIS OF VARIANCE TESTS (F TEST AND PROBABILITY VALUES) FOR EFFECTS OF TRAIT, TREATMENT, AND THEIR INTERACTION ON CONCENTRATION (FRESH-WEIGHT-BASED) AND FRACTIONAL COMPOSITION (% OF TOTAL MONOTERPENE CONCENTRATION) OF EACH MONOTERPENE COMPONENT OF DOUGLAS FIR CLONES IN 1999 EXPERIMENT WHEN BUDWORM FEEDING WAS MATCHED TO BUDBURST OF ENTIRE POPULATION OF PLANTS TO MIMIC CONDITIONS *similar to those* OCCURRING IN FOREST[a]

[a] The Bonferroni adjusted P-value of $\alpha = 0.005$ (i.e., 0.05 divided by 11) was used to determine significance, in order to maintain the correct P-value of 0.05 for the type I error rate over the whole set of univariate ANOVAs for the 11 individual terpene compounds.

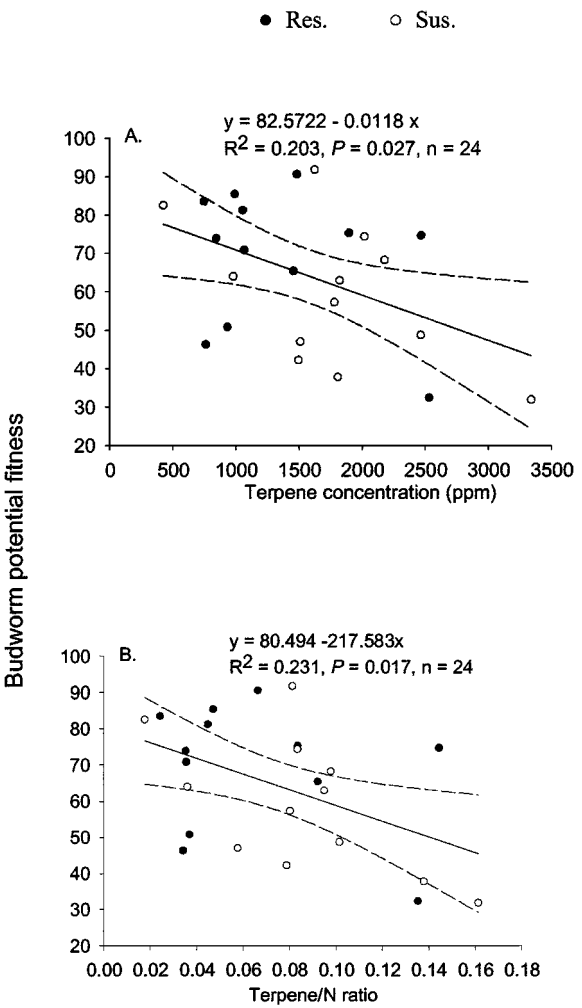

FIG. 4. Regression of western spruce budworm potential fitness against foliar concentration (ppm fresh weight) of total monoterpenes (A) and the ratio of total monoterpene concentration to foliar nitrogen (B) in the current-year foliage of clones derived from trees that appeared to be resistant (●) versus susceptible (○) to western spruce budworm defoliation. Data are from the 1998 experiment; needles were at the feather duster (seventh) developmental stage when they were sampled. Dashed lines around the regression line indicate the 95% confidence limits for the mean response, and the equations for the regression lines and their associated statistics are shown on the graphs.

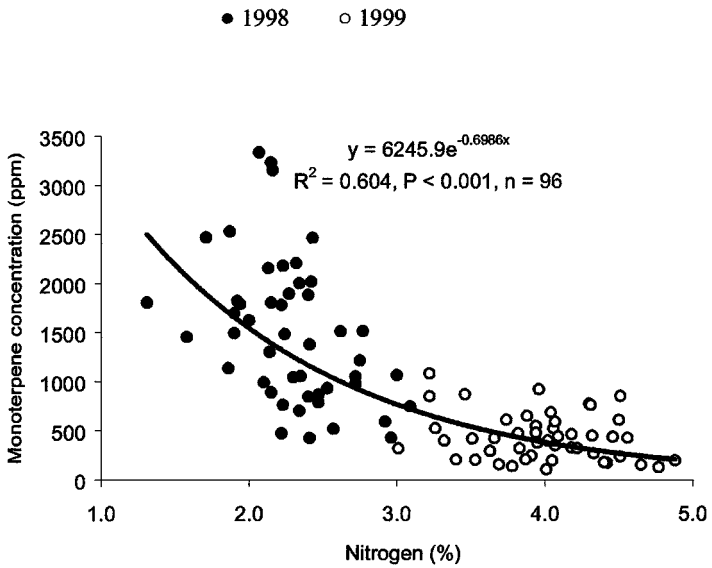

FIG. 5. Regression of foliar concentrations (ppm fresh weight) of total monoterpenes against nitrogen (% dry weight) in current-year foliage of Douglas fir clones. All needles were at the feather duster (seventh) developmental stage when they were sampled. Data are shown for the 1998 and 1999 experiments, pooled for the resistant and susceptible clones. The equation for the regression line and the associated statistics are shown on the graph.

radial growth rate of mature trees between 1986 and 1990 also was not related to the total monoterpene concentration of the mature trees in 1989 ($P = 0.902$) or 1990 ($P = 0.498$; $N = 24$).

DISCUSSION

Eleven monoterpenes were detected in current-year needles of Douglas fir clones sampled at Shepherd's (1983) feather duster (or seventh) developmental stage. They included the most common monoterpenes reported in other studies of Douglas fir, but did not include several monoterpenes, such as α-phellandrene, *cis*-β-ocimene, and 3-carene, that occurred at low concentrations in other studies (von Rudloff and Rehfeldt, 1980; Wagner et al., 1989; Zou and Cates, 1995). Compared with the relative percentage of major leaf monoterpenes of Douglas fir trees in the northern Rocky Mountains (von Rudloff and Rehfeldt, 1980), trees from southern Colorado and northern Arizona in our study had a much higher relative percentage of limonene, β-pinene, and myrcene, but a lower percentage of

tricyclene, camphene, bornyl acetate, and α-pinene. The rank order of concentration for different monoterpenes was highly correlated between the sampling years and between mature trees and their clones (Table 1), despite the variations in total monoterpene concentration over years (Figures 2A,B and 3A,B). These findings indicated remarkable consistency in fractional composition of monoterpenes.

We hypothesized that clones from resistant trees would have a higher monoterpene concentration than clones from susceptible trees based on the assumption that high monoterpene concentration would limit budworm defoliation. Testing this hypothesis with clones grown in a uniform greenhouse environment allowed us to eliminate environmental differences as a causal factor. Contrary to our hypothesis, clones from resistant trees had a lower total monoterpene concentration than clones from susceptible trees in the 1998 experiment (Figure 2A), and budworm potential fitness was greater after feeding on clones from resistant trees (Figure 4A). Thus, results from the 1998 experiment were not consistent with our field observations of resistance. This suggests that the ability of resistant mature trees to escape heavy budworm defoliation cannot be attributed to a greater genetic capacity for monoterpene biosynthesis in foliage. A difference in budburst phenology is a more likely explanation for the difference in budworm defoliation between the resistant and susceptible trees. For example, clones from resistant trees required about 90–110 more degree-days to reach the same budburst developmental stage than clones from susceptible trees (Chen et al., 2001a). This difference in budburst phenology among clones is consistent with differences in budburst phenology for mature trees in the forest (Clancy et al., 1993). Resistant trees are genetically predisposed towards later budburst that could cause poor food quality for the budworm if late budburst forces them to feed on old foliage (Clancy et al., 1993; Dodds et al., 1996).

The different results from the 1998 and 1999 experiments on the clones suggest a role of budburst phenology in regulating the influence of foliar monoterpenes on budworm performance. In 1998, we allowed budworms to feed on each clone when buds offered the best suitable food source. In this situation, genetic differences in total monoterpene concentration among clones influenced budworm fitness (Figure 4A). In contrast, in the 1999 experiment, we introduced larvae to all clones on one date when approximately 50% of the buds in the whole population were in Shepherd's (1983) second budburst stage that was just accessible for larval mining. With this approach, suitable buds available for larval feeding varied widely among clones because of genetic differences in budburst phenology (Chen et al., 2001a); the potential influence of genetic differences in monoterpenes among clones on budworm performance may have been overshadowed by differences in foliage quality associated with budburst and shoot development (Dodds et al., 1996).

Of course, an alternative explanation for the different results between the 1998 and 1999 experiments is that monoterpene concentration in 1999 was too

low to influence budworm performance (Figures 2B and 3B). This explanation implies that budworm larval performance may not be affected by total monoterpene concentration less than 1000 ppm. Nonetheless, our results raise an interesting possibility that mature trees classified as "resistant" to budworm defoliation in the forest could actually be "susceptible" in situations where the onset of budworm larval feeding coincides with their budburst. Thus, the mixed conclusions about the role of monoterpenes as a resistance mechanism against budworm defoliation in Douglas fir (Cates et al., 1983; Redak and Cates, 1984; Cates and Zou, 1990; Clancy, 1991a, 1993, 2001; Clancy et al., 1993) are perhaps not surprising, as factors such as budburst phenology may mediate the expression of this mechanism.

It is also noteworthy that there were consistent differences in 1998 and 1999 between the resistant and susceptible clones in the proportions of camphene, β-pinene, bornyl acetate, and unknown terpene C ($P \leq 0.005$; Tables 3 and 4). The resistant trees had higher percentage of camphene and bornyl acetate, whereas the susceptible trees had higher fractions of β-pinene and unknown terpene C (Figures 2C and D). This finding, to some extent, also agrees with the results of previous studies that camphene and bornyl acetate were highly toxic to several populations of budworm in Idaho, Montana, and New Mexico (Cates et al., 1983; Cates and Redak, 1988; Cates and Zou, 1990).

One or two years of budworm defoliation under our study conditions did not influence the total concentration or fractional composition of monoterpenes in either the 1998 or 1999 experiments with the clones (Figure 3). Furthermore, the large differences in total monoterpene concentration of clones (Figures 2A,B and 3A,B) and mature trees (Clancy et al., 1993) between two consecutive sample years could not be clearly explained by effects of defoliation. Moreover, defoliation had a similar effect on monoterpene concentrations of clones from resistant and susceptible trees. The lower monoterpene concentration of clones in 1999 compared to 1998 was probably caused by a decrease in tree carbon/nitrogen balance in 1999 (Figure 5) that reduced synthesis of monoterpenes and other carbon-based secondary metabolites (Bryant et al., 1983; Larsson et al., 1983; Mattson and Haack, 1987). The strong negative relationship between total foliar monoterpene concentration and nitrogen concentration for data pooled over two years of experiments support this view (Figure 5) and suggest that the carbon/nitrogen balance is important in regulating carbon allocation to monoterpenes in Douglas fir trees.

Many other traits of tree tissues can vary with budburst phenology and seasonal cycles of growth and dormancy (Mattson and Scriber, 1987; Clancy et al., 1988a,b, 1995). For example, positive correlations of growth and reproduction of insect herbivores with variation in one chemical constituent of their food do not prove cause and effect, because changes in the level of the chemical constituent in a plant may be accompanied by changes in the levels of nutrients, water, fiber, and numerous allelochemicals (Clancy, 1992). We recognize that the strong intercorrelations among many different characteristics in host plants make

it difficult to determine an herbivore's response to one specific trait, such as foliar monoterpenes. Moreover, it is impossible to maintain a constant level of monoterpenes (or other potentially confounding nutrients, etc.) throughout the duration of a greenhouse experiment because a plant's biochemical composition is continuously changing (Clancy, 1992). Thus, differences in resistance to budworm defoliation among Douglas fir genotypes are most likely caused by interactions or linkages among multiple resistance mechanisms such as monoterpenes, nutrients, and tree budburst phenology.

Finally, despite the high cost of monoterpene synthesis (Gershenzon, 1994), we found no evidence for a tradeoff between growth and monoterpene concentration in the clones and mature trees. The proportion of energy allocated to monoterpene synthesis was perhaps too small to compromise tree growth. On the other hand, perhaps high carbon allocation to monoterpenes reduced allocation to other tree uses of carbon (e.g., roots, leaves, mycorrhizae) that could not be detected by measuring stem radial growth at breast height (mature trees) or canopy size (clones).

In summary, our results suggest remarkable consistency in the percent composition of different monoterpenes in Douglas fir trees, in spite of much year-to-year variation in concentrations of these compounds. Moreover, genetic variation in budburst phenology among trees may mediate the influence of inherent differences in total monoterpene concentration on budworm fitness.

(Received March 1, 2001; accepted January 14, 2002)

Abstract—Condensed tannins have been considered to be important inducible defenses against mammalian herbivory. We tested for differences in condensed tannin defenses in *Acacia drepanolobium* in Kenya over two years among different large mammalian herbivore treatments [total exclusion, antelope only, and megaherbivore (elephants and giraffes) + antelope] and with four different ant symbiont species on the trees. We predicted that (1) condensed tannin concentrations would be lowest in the mammal treatment with the lowest level of herbivory (total exclusion), (2) trees occupied by mutualist ants that protect the trees most aggressively would have lower levels of tannins, and (3) if chemical defense production is costly, there would be a trade-off between tannin concentrations, growth, and mechanical defenses. Mean tannin concentrations increased from total exclusion treatments to wildlife-only treatments to megaherbivore + antelope treatments. In 1997, condensed tannin concentrations were significantly lower in trees occupied by the ant *Crematogaster nigriceps*, the only ant species that actively removed axillary buds. Contrary to our prediction, trees occupied by ant species that protect the trees more aggressively against mammalian herbivores did not have lower overall levels of condensed tannins. There was no consistent evidence of a trade-off between tannin concentrations and growth rate, but there was a positive correlation between mean thorn length and mean tannin

concentrations across species of ant inhabitants and across herbivore treatments in 1997. Contrary to our expectation, trees had higher tannin concentrations in the upper parts of the canopy where there is little herbivory by mammals.

Key Words—Induced defenses, condensed tannins, *Acacia*, mammalian herbivory, ants, mutualism.

INTRODUCTION

Plants show a wide variety of defenses against herbivory, including physical responses (such as thorn production; reviewed by Myers and Bazeley, 1991), chemical defense (e.g., McNaughton and Tarrants, 1983; Du Toit et al., 1990; Bryant et al., 1992; Ward et al., 1997), growth strategies (e.g., growing too tall for the leaves to be eaten, e.g., Milewski et al., 1991; Palo et al., 1993), and low nutrient content (Lundberg and Astrom, 1990). Of increasing interest to the ecologist are inducible defenses against herbivory. When the cost of defense is high and levels of herbivory are variable, plants are predicted to have inducible defenses (Rhoades, 1979; Young, 1987; Herms and Mattson, 1992; Karban et al., 1997), i.e., they produce the defense only when herbivory is initiated so as not to commit resources prior to the need for defense. Chemical defenses are important inducible defenses because they can be produced quickly or at least transported quickly from one part of the plant to another (Bryant et al., 1983; Karban and Baldwin, 1997). There is little consensus as to the general importance of plant secondary metabolites as inducible defenses (Herms and Mattson, 1992; Karban and Baldwin, 1997) because, by definition, inducible defenses are costly to produce, yet costs of production of these chemicals have not always been detected (Bryant et al., 1983; Herms and Mattson, 1992; Simms, 1992).

Most current theories of inducible plant defenses against herbivory are based on the notion that plants will produce defenses when the benefit to be derived from them outweighs the cost of their production (e.g., Rhoades, 1979; Van der Meijden et al., 1988; Herms and Mattson, 1992; Rosenthal and Kotanen, 1994). It is generally assumed that defense is costly because investments in defense come at the expense of investments in growth and reproduction (Briggs and Schultz, 1990; Palo et al., 1993; reviewed in Herms and Mattson, 1992). Due to the costs of defense, it is also frequently assumed that few plants invest simultaneously in more than one mechanism of herbivore deterrence and that defense traits are negatively correlated (reviewed by Zangerl and Bazzaz, 1992; Silvertown and Dodd, 1996).

African Acacias as Model Organisms for Tests of Inducible Defenses. African acacias evolved as savanna trees under intense pressure by mammalian herbivores (Ross, 1979; Scholes and Walker, 1993). *Acacia* trees have long thorns and high polyphenol (especially condensed tannin) contents, both of which are effective in deterring mammalian herbivores (Wrangham and Waterman, 1981; Cooper and

Owen-Smith, 1985, 1986; Furstenburg and van Hoven, 1994). Condensed tannins are generalized digestion inhibitors in mammals (Robbins et al., 1987; Waterman and Mole, 1994). Although condensed tannins may also be effective against insect attack, the importance of these organisms as agents of selection on defenses of African *Acacia* species is generally considered to be low (Cooper and Owen-Smith, 1985; Du Toit et al., 1990; Owen-Smith, 1993; Gowda, 1997; Rohner and Ward, 1997). Inducible thorn defenses against herbivory in *A. drepanolobium*, *A. seyal* (Young, 1987; Milewski et al., 1991), *A. tortilis* (Gowda, 1996a; Rohner and Ward, 1997), and *A. raddiana* (Rohner and Ward, 1997), as well as inducible polyphenol defenses in *A. raddiana* (Rohner and Ward, 1997), suggest that defenses are costly in *Acacia* species. This conclusion is reinforced by the experimental evidence that investment in thorn defenses in *A. drepanolobium* declined following removal of mammalian herbivores (Young and Okello, 1998). Thus, *Acacia* species may be model organisms for investigating the inducibility of defenses against mammalian herbivory. Furthermore, because they frequently have long thorns and high tannin concentrations, they may be suitable species for testing for the presence of possible trade-offs between investments in different types of defense.

Plants may concentrate their defenses in those structures or life-history stages that are most likely to be affected by herbivory (e.g., Palo et al., 1993). The most clear-cut division between accessible and nonaccessible parts of trees depends on the height of the tree relative to the maximum browsing height of nonarboreal herbivores (Palo et al., 1993; Gowda, 1996a). Younger *Acacia* trees have higher levels of mechanical defense and chemical defenses than older trees (Palo et al., 1993; Brooks and Owen-Smith, 1994; Gowda, 1996b; Rohner and Ward, 1997), and within trees, lower branches have longer thorns than higher branches (Young, 1987; Milewski et al., 1991; Young and Okello, 1998). This suggests that plants and plant parts that are more exposed to mammalian browsers invest more in defense, while larger trees normally escape mammalian herbivory and, thus, allow for more varied and flexible investments (including reproduction) and only produce stronger defenses when necessary (see also Brooks and Owen Smith, 1994; Rohner and Ward, 1997). Here, we investigate the effects of mammalian herbivory on condensed tannins in a common African *Acacia*, *A. drepanolobium*, and determine whether the level of defense is related to the probability of herbivory.

Ants as Acacia Defenses. Ants that live in the swollen thorns of *Acacia* species are frequently assumed to provide a form of defense against large mammalian herbivores because they swarm over the herbivores and bite them when they come into contact with the trees (e.g., Hocking, 1970; Coe and Beentje, 1991). Madden and Young (1992) showed that *A. drepanolobium* with more active ants had more foliage than did trees with less active ants and were less heavily browsed by immature (but not mature) giraffes.

Although several African *Acacia* species produce swollen thorns and are occupied by ants, *A. drepanolobium* is the only species known to be an obligate ant

TABLE 1. ANT SPECIES COMMONLY RESIDENT ON *Acacia drepanolobium* AND THEIR ROLES,[a] SUCCESSIONAL STAGE, AND EFFECT ON THE PLANT

Species	Interaction with tree	Successional stage	Ant behavior	Feeds on
Crematogaster mimosae	Mutualist	Late	Aggressive	
C. sjostedti	Non-Mutualist	Late	Timid	
C. nigriceps	Non-Mutualist	Early	Aggressive	Axillary shoots
Tetraponera penzigi	Non-Mutualist	Early	Timid	Extrafloral nectaries

[a] Data from Young et al. (1997).

host (Ross, 1979). Several ant species on *A. drepanolobium* are mutually exclusive (Hocking, 1970), and certain ant species appear to replace others in a successional process (Young et al., 1997) (Table 1). Two of the ant species found on *A. drepanolobium* respond aggressively when their branches are disturbed (*Crematogaster mimosae* and *C. nigriceps*). Because aggressive ants may reduce the threat of herbivory to the trees (Madden and Young, 1992), we predicted that there would be a reduction in tannin concentration in trees occupied by more aggressive ants. Two less aggressive ant species on *A. drepanolobium*, *C. sjostedti* and *Tetraponera penzigi*, may be less effective at protecting their trees from herbivory (Table 1) (Young et al., 1997). In addition, two species of ants have unusual behaviors. *C. nigriceps* ate virtually all of the axillary shoots at nodes with unswollen thorns on trees they occupied (Young et al., 1997). Unlike *A. drepanolobium* inhabited by other ant species, few trees occupied by *C. nigriceps* flower or set fruit. Trees occupied by *T. penzigi* were 2–9 times more likely to have at least some leaves with their nectaries eaten compared to trees without *T. penzigi*. Most of the nectaries were eaten on these trees and more than 90% of them lacked any active nectaries, whereas only 26–38% of other trees lacked active nectaries (Young et al., 1997).

The potential interactions between the effects of mammalian herbivory and ant occupancy on *A. drepanolobium* provide a unique opportunity to examine the relative effects of mammalian herbivores and ant mutualists on plant chemical defenses. We simultaneously examined the relative effects of mammalian herbivory and ant occupancy on tannin production in an experimental design with replicated 4-ha plots that either allowed (1) the entry of all large mammalian herbivores, (2) all large mammalian herbivores except megaherbivores (elephants *Loxodonta africana* and giraffe *Giraffa camelopardis*) to enter, or (3) excluded all large herbivores (Young et al., 1998). Within each of these plots, we sampled trees with each of the different ant occupants listed in Table 1.

We made the following predictions about condensed tannin concentrations in *A. drepanolobium*:

1. Trees from plots with higher levels of mammalian herbivory should have higher concentrations of condensed tannins in their leaves to defend themselves

against herbivory. Thus, the highest tannin levels should be found in the megaherbivores + antelope plots, followed by the antelope plots, and then the total exclusion plots.

2. More aggressive ant species (*C. nigriceps* and *C. mimosae*) may protect their trees from herbivory more than less aggressive species (*C. sjostedti* and *T. penzigi*). This should result in reduced tannin concentrations in the leaves of trees occupied by mutualist ant species.

3. Because inducible defenses are hypothesized to be costly to produce (Herms and Mattson, 1992; Zangerl and Bazzaz, 1992), there should be a trade-off between investments in chemical (tannins) and physical (thorn) defenses. Similarly, there may be a trade-off between growth rate and chemical defenses.

4. If *A. drepanolobium* is capable of investing differentially in different parts of the canopy according the probability of being eaten, we should find lower tannin levels high in the upper canopy where mammalian herbivory is low, with this effect being reduced in the megaherbivore plots.

METHODS AND MATERIALS

Research was conducted at the Mpala Research Centre in the Laikipia ecosystem (36°50′E, 0°15′N) in north-central Kenya. *Acacia drepanolobium* is the dominant tree species in the wooded grasslands on "black cotton" soils in this ecosystem, comprising approximately 95% of woody individuals (Young et al., 1997, 1998). There are 18 experimental plots (fenced in September 1995), each 4 ha in size and located in three blocks. Within each block, different forms of barriers and control of individual cattle herds create six mammalian herbivore treatment levels. The treatment levels are: (1) total exclusion, (2) cattle only, (3) nonmegaherbivore wildlife (antelope) only, (4) nonmegaherbivore wildlife (antelope) + cattle, (5) all wildlife, including megaherbivores (= elephants + giraffe) and antelope, and (6) all wildlife (megaherbivores and antelope) + cattle. This design has one replicate per block. Because cattle do not eat *Acacia* leaves (Young and Okello, 1998), we collapsed the treatment levels into three wild mammalian herbivore levels, allowing two replicates per block. The treatment levels we considered here were total exclusion, antelope, and antelope + megaherbivores (elephants and giraffes). Browsing species that occurred in the antelope plots were: Grant's gazelle (*Gazella granti*), eland (*Taurotragus oryx*), steinbuck (*Ramphicerus campestris*), and oryx (*Oryx beisa*). Antelope plots also included zebras, buffaloes, and hartebeests, but these grazers do not eat *Acacia* leaves and will not concern us here. Densities of large mammals were not controlled within the plots other than by restricting access (Young et al., 1998). Dung counts suggest that the antelope barriers reduce the presence of antelopes by 90% and that the megaherbivore barriers reduce the presence of elephants and giraffes by >80% (Young et al., 1998).

In July 1997, within each of the 18 plots, we collected undamaged leaves over a short time period approximately 1 m above the ground of one tree for each of the four ant species mentioned above. We sampled leaves at two heights (1 and 2 m) on trees occupied by the mutualist ant species, *C. mimosae*. In all but two cases, these were different trees. This procedure was repeated in 1998 on 90 new trees, each paired with a nearby tree from 1997 with respect to ant occupant and branch height. These 1998 trees also served as control trees for a leaf removal experiment.

The branches from which we sampled leaves in 1997 were also the basis of a leaf removal experiment. Each branch selected was randomly chosen from a simple forked pair of branches of similar length. After collecting leaves for our tannin analysis, we removed all remaining leaves from the leaf removal branch, while keeping its paired branch as a control.

In combination with the new trees sampled in 1998, this experiment had three levels: leaf removal, leaf control on the same tree, and (a separate) control tree. If trees invest preferentially in sections that have had leaves removed, then tannin concentrations should be highest in the leaf removal treatments in the following year. If tannins are invested at the level of the tree as a whole, leaf removal and leaf controls should have similar tannin concentrations that will be higher than in the control trees.

We also attempted to ascertain whether there were trade-offs between tannin production and investments in thorns and in growth. Mean thorn (=spine) lengths across multiple trees occupied by different ants species in these plots were taken from Young and Okello (1998). We also had mean thorn length measurements from a small number of thorns on each sampled tree. Growth rates of individual branches were measured as the difference between branch lengths in surveys in 1997 and 1998.

Leaves were air-dried prior to measurement of condensed tannins. All analyses were done simultaneously. We measured condensed tannins in the leaves using a standard acid–butanol protocol (Waterman and Mole, 1994). Following the recommendation of Hagerman and Butler (1989), quebracho was used as a standard (quebracho supplied by A. E. Hagerman, Miami University, Ohio, USA). All results are expressed as percent dry weight in quebracho equivalents (QE).

The data were analyzed in a randomized block ANCOVA with mammal treatment as a fixed factor and ant species and branch height class as random factors (error terms as for model III ANOVA). Height of tree and length of new growth on the sampled branch were used as covariates.

RESULTS

There was no correlation in condensed tannin concentration within trees between years ($r = 0.15$, $F = 2.14$, $P = 0.15$). For 89 unmanipulated trees for which we had data in both 1997 and 1998, we found no difference in tannin

TABLE 2. TANNIN CONCENTRATIONS IN 1997 AND 1998 ON TREES INHABITED BY *C. mimosae*[a]

Branch height	Mammalian treatment	Herbivory	Tannin concentration (% QE)
Low (1m)	Control	None	16.27 ± 1.63
	Antelope only	High	10.96 ± 1.83
	Megaherbivores + antelope	High	13.44 ± 2.43
High (2m)	Control	None	19.29 ± 1.59
	Antelope only	None	17.56 ± 2.12
	Megaherbivores + antelope	Low	17.12 ± 1.07

[a] Estimates of herbivore presence are based on dung counts of herbivores that can reach reference branches.

concentration between years (paired t test, $t = 0.76$, $P = 0.45$). In no analysis were there significant year effects. There were also no block effects. Overall, there was tremendous variation in tannin concentrations among samples (range 2–30% QE, coefficient of variation = 37%).

We only sampled higher branches on trees occupied by *Crematogaster mimosae* ($N = 47$ trees). Tannin levels from upper branches were 33% higher than on lower branches, even after controlling for the identity of ant occupant by using only trees occupied by *C. mimosae* (Table 2). This was true for both years, for all herbivore treatments, and in both experimental and control trees and branches. For all of the analyses that follow, upper and lower branches were analyzed separately, or only lower branches were analyzed.

Among lower branches, there were no differences in condensed tannin concentration among trees occupied by different ant species. However, there was a difference in condensed tannins among 1997 trees with different occupant ant species ($P = 0.03$, Table 3). Contrary to prediction 2, the lowest tannin levels were found in trees with a nonmutualist species, *C. nigriceps*, while trees with *C. mimosae*, a mutualist species, had the highest tannin levels (Figure 1). Scheffé *post hoc* tests revealed that there was a difference in tannin concentrations between

Source	*d.f.*	*F*	*P*
Block	2	1.20	0.31
Herbivores	2	0.36	0.87
Ant species	3	3.08	0.03
Herbivores × ant species	6	1.03	0.44
Tree height	1	3.87	0.05
Branch height	1	15.24	<0.001

[a] Dependent variable is condensed tannin concentration.

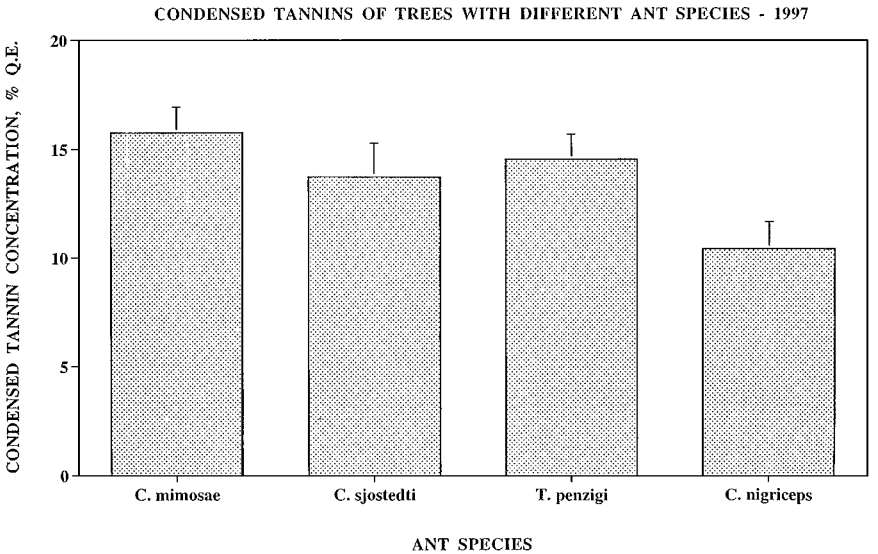

FIG. 1. Differences in mean condensed tannin concentrations (+SE) in *A. drepanolobium* among ant occupants for unmanipulated trees in 1997.

trees occupied by *C. nigriceps* and *C. mimosae* ($P = 0.03$) only. These two species swarmed more aggressively than *Tetraponera penzigi* or *C. sjostedti*. In 1998, there was no difference in condensed tannins among trees with different occupant ant species ($F = 0.67$, $P = 0.58$).

We found no effect of our leaf removal treatments ($F = 1.71$, $P = 0.18$). Paired t test comparisons that either controlled for within-tree variation (leaf removal vs. leaf control) or paired leaf removal vs. control tree or leaf control vs. control tree were not significant (range of $t = 0.22$–1.20, $P = 0.83$–0.23). Condensed tannin concentration in control tree leaves was 14.80 ± 0.64 (S.E.) % QE ($N = 89$), in leaf controls was 13.65 ± 0.74% QE ($N = 74$), and in the leaf removal treatment was 12.87 ± 0.83% QE ($N = 75$). There were no interactions between leaf removal treatments and either herbivore treatments ($F = 0.41$, $P = 0.80$) or ant treatments ($F = 0.67$, $P = 0.67$).

When both years were combined (180 different trees, no tree measured twice), there were no year or ant species effects, but there was a significant mammalian herbivore effect (Table 4). There appears to be a difference in these data between the confirmed mutualist (*C. mimosae*) and the other ants in terms of how tannin concentrations respond to mammalian herbivore treatments, resulting in a significant ant $\times$ herbivore treatment interaction ($F = 2.35$, $P = 0.006$). This interaction means that for trees without *C. mimosae*, the differences between mammalian herbivore treatments are consistent with prediction 1 ($P = 0.05$;

TABLE 4. PARTIAL TABLE FOR REDUCED ANOVA MODEL FOR ALL DATA FOR BOTH YEARS USING UNMANIPULATED TREES ONLY[a]

Source	*F*	*P*
Year	0.95	0.33
Herbivores	3.11	0.05
Ant species	2.08	0.13
Ant × year	1.89	0.16

[a] Dependent variable is condensed tannin concentration. The interaction term was included in this analysis because in the full ANOVA model with all interaction terms, this was the only interaction with $P < 0.25$. There were also no significant block effects ($P = 0.91$) in the full model.

Control $= 12.03 \pm 0.89\%$ QE, antelope only $= 12.98 \pm 1.07\%$ QE, megaherbivores + antelope $= 15.24 \pm 0.88\%$ QE). Data for each of the three ant species separately show this trend.

Within *C. mimosae* trees, the results are essentially reversed. Tannin levels are high on branches exposed to little or no herbivory (i.e., contra prediction 4), and low on branches subject to high herbivory (Table 2). We identified dung piles according to mammalian herbivore species and grouped these species according to whether they were tall enough to reach either the 1-m or 2-m branch height classes. Among individual plots, tannin levels were negatively correlated with the number of dung piles of species capable of reaching either the 1-m or 2-m branch height classes ($F = 5.82$, $P < 0.02$).

There was no correlation between tree height and tannin concentrations ($r = 0.11$, $F = 1.08$, $P = 0.30$) in 1997, although there was a positive correlation between branch height and tannin concentrations ($r = 0.37$, $F = 14.22$, $P < 0.001$).

Trade-Offs. Tannin concentration and thorn length were not correlated in 1997 ($r = 0.20$, $F = 2.61$, $P = 0.11$) or 1998 ($r = 0.074$, $F = 0.78$, $P = 0.38$). There was also no interaction effect between tannin concentration, thorn length, and either ant species (1997: $F = 0.29$, $P = 0.83$; 1998: $F = 0.39$, $P = 0.76$) or herbivore treatment (1997: $F = 0.51$, $P = 0.60$; 1998: $F = 0.15$, $P = 0.86$). When data for each ant species were analyzed separately, there was no correlation between tannin concentration and thorn length in 1997 and 1998 (range of $F = 0.06$–0.85, range of $P = 0.81$–0.25). However, contrary to prediction 3, greater mean tannin concentration was associated with greater mean thorn length across ant species in 1997 ($r = 0.99$, $F = 202.6$, $P = 0.005$) (Figure 2), but not in 1998 ($r = 0.15$, $F = 0.04$, $P = 0.85$).

For low branches (height = 1 m), and with data for each ant occupant species treated separately, we found a significant correlation between tannin concentration

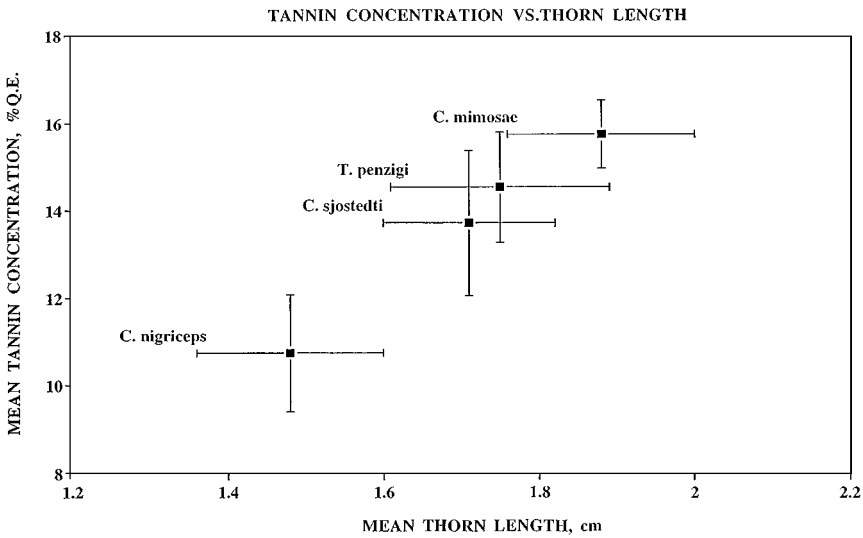

FIG. 2. Relationship between mean condensed tannin concentration and mean thorn length per tree averaged across ant treatments. Error bars represent ±1 SE for both tannin concentration (ordinate) and thorn length (abscissa).

and new branch growth for trees occupied by *T. penzigi* only. However, this correlation was positive ($r = 0.55$, $F = 11.34$, $P = 0.002$, $N = 28$). For high branches (height = 2 m), we had data for trees occupied by *C. mimosae* only. There was a nonsignificant negative trend between tannin concentration and branch growth, but this was not significant ($r = -0.33$, $F = 3.37$, $P = 0.08$, $N = 29$). Thus, there is no support for prediction 3, viz. that there is a trade-off between tannin production and growth.

DISCUSSION

Inducible Defenses. There was considerable variation in condensed tannin concentrations among *A. drepanolobium* individuals and in different parts of the canopies of individual trees. Similarly, there was high variation in thorn lengths within and among individuals (Young and Okello, 1998), which means that substantial sample sizes are necessary to reveal even moderate effect sizes. Some of the variation in tannin concentrations includes interyear differences within trees and differences among mammalian and ant treatments.

Our pooled results for 1997 and 1998 provide evidence for inducible tannin defenses across mammalian herbivore treatments in a manner that is consistent with prediction 1. However, this effect was small and was revealed only after

excluding trees occupied by one of the ant species. The absence of a strong effect of herbivore treatments may be due to the short time available for the production of inducible defenses (see also Young and Okello, 1998) or because these trees do not strongly respond to mammalian herbivory. In addition, tannin response to herbivory may be ephemeral (Furstenburg and van Hoven, 1994).

An additional consideration is that secondary compounds may not always be effective against mammalian herbivores. The condensed tannin concentrations found in *A. drepanolobium* in this study were relatively low, and it is uncertain whether they reached a threshold level necessary to deter ruminants as suggested by Cooper and Owen-Smith (1985). Further examination of the behavioral and physiological responses of local mammalian herbivores to different levels of tannin production is required to answer this question. We believe that the search for generalities regarding the inductive responses of trees to mammalian herbivory must necessarily focus on the abilities of the trees to respond in a timely manner and with tannin levels of sufficient concentration to act as a deterrent to further herbivory. Futhermore, optimal tree response strategies with regard to growth–defense relationships, as well as possible trade-offs between multiple defensive strategies (e.g., tannins and thorns), must be reconsidered (see below).

Ant occupants appeared to exert a greater effect on condensed tannins than mammalian herbivore treatments. It is possible that differences among ant treatments occurred because ants choose trees according to their tannin phenotypes. We consider this to be unlikely because ant species replace one another on trees (Young et al., 1997). Trees occupied by the two more aggressive ant species did not have lower tannin concentrations than trees occupied by the less aggressive ant species. This result is inconsistent with prediction 2. Trees occupied by one of the two aggressive species, *C. nigriceps*, did exhibit lower tannin levels (at least in 1997); this is the ant species that eats the axillary shoots of its host trees, and reduces the number of leaves per branch. One possibility is that the negative impact of the ant on the leaves reduces the resources available to the tree to invest in tannin defenses. An alternative explanation is that their destruction of axillary buds results in the production of larger, more nectariferous (observed), and physiologically younger (implied) leaves. "Younger" leaves may produce less tannin (Furstenburg and van Hoven, 1994).

There was also a significant ant $\times$ herbivore treatment interaction, with trees occupied by *C. mimosae* exhibiting a pattern in which shoots subject to less herbivory contained substantially more tannin than shoots subjected to more herbivory. This contradicts both prediction 1 and prediction 4. It is also curious that the antelope-only treatment had lower tannin concentrations than the total exclusion plots in 1998. Are there lower levels of tannins where herbivory is highest under certain circumstances because browsing causes a local decline in tannins? At first sight, such results might seem counterintuitive because it is usually assumed that tannins are produced in order to reduce herbivory and might be expected to

increase in concentration under high herbivory. However, other studies of African acacias have found that tannin concentrations decreased with herbivory. Du Toit et al. (1990) found that heavily browsed specimens of *A. nigrescens* had greatly reduced condensed tannin concentrations and may serve as "grazing lawns" (sensu McNaughton, 1983) for herbivores. They proposed the following mechanism for this phenomenon: Browsing reduces intershoot competition for nutrients through a reduction in the number of shoots and the release of apical dominance. The result is increased concentration of nutrients in the remaining shoots. Increased nutrient concentrations in the remaining shoots was recorded by them for *A. nigrescens* [but not *A. tortilis*; see also Gowda (1997)] and Teague (1989) for *A. karroo.* Du Toit et al. (1990) also showed that there was a strong positive correlation in *A. nigrescens* between leaf nitrogen concentration and the percentage of browsed shoots on a tree. This increased nutrient concentration, together with a release of apical dominance, stimulates growth. We note here that Young et al. (1997) found that *A. drepanolobium* trees occupied by *C. nigriceps* showed greater shoot growth than trees occupied by the other ant species. Furthermore, carbohydrate demands incurred by rapid regrowth cause substrate limitation of carbon-based secondary metabolite synthesis (Bryant et al., 1983, 1987; Danell and Huss-Danell, 1985). Hence, leaf condensed tannin concentrations decline. Reduced chemical defense and increased shoot nutrients increase the palatability of most woody plants (Bryant et al., 1983; Cooper and Owen-Smith, 1985; Danell and Huss-Danell, 1985; Cooper et al., 1988), thereby attracting increased browsing pressure. This hypothesis remains to be tested. We note here that another study (Rohner *and* Ward, 1997) found no reduction in secondary compounds in *A. raddiana* and *A. tortilis* that suffered unnaturally high levels of herbivory in Israel.

Our data certainly suggest that tannin responses are highly contingent effects. We tentatively suggest that some forms of browsing may sufficiently increase carbohydrate demands for regrowth and cause a trade-off with secondary metabolite synthesis and, thus, result in a subsequent decline of tannin concentrations. If browsing is not severe enough, or does not result in the release of apical dominance, intershoot competition will not be reduced and the process will not occur as outlined by Du Toit et al. (1990), and induced production of tannins may then occur in trees suffering herbivory.

Trade-Offs. There was no indication of trade-offs between investments into chemical or mechanical defense or between chemical defense and growth in *Acacia drepanolobium*. Indeed, across trees occupied by different ant species, mean tannin concentrations and thorn lengths were positively correlated in 1997 (Figure 3), in contradiction with prediction 3. Several issues arise concerning underlying assumptions when attempting to demonstrate trade-offs between thorn and tannin defenses in individuals within a population (see also Rohner and Ward, 1997):

1. Chemical and mechanical defenses may not be operating at a comparable time scale. Production of thorns is irreversible and may integrate a response over

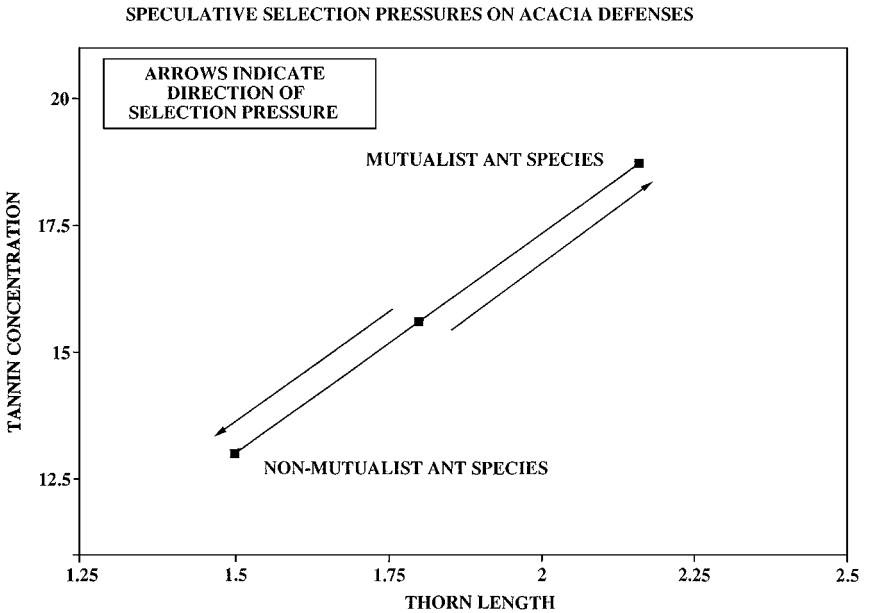

FIG. 3. Schematic diagram indicating how bidirectional selection by mutualist and non-mutualist ant species might result in a positive correlation between tannin and thorn production.

several years. Production of secondary metabolites, in contrast, is more variable on a shorter time scale (Cooper et al., 1988; Furstenburg and van Hoven, 1994). Indeed, in this study we found no significant correlations in tannin concentrations among years within trees. This difference in time scale between the production of thorn and chemical defenses may obscure correlations.

2. Phenotypic changes in response to herbivory can cause positive, rather negative, correlations. The negative impact of *C. nigriceps* on the trees (reduced leaf area and virtually eliminating reproduction) may cause the trees to be stressed, reducing their abilities to invest in both tannins and thorns. Conversely, a mutualist species such as *C. mimosae* may increase the tree's quality (e.g., by reducing herbivory), resulting in more resources being available to invest in both tannins and thorns against mammalian herbivory. These effects may result in bidirectional selection (Figure 3), causing the observed positive correlation.

3. If there is a small difference between good and poor individuals in the amount of resources acquired (allocated to total defense) and a large difference in the relative allocation of resources to tannin and thorn defenses, then a trade-off will occur (Van Noordwijk and de Jong, 1986) (Figure 4a). If there is a large difference between good and poor individuals in the amount of resources acquired (allocated

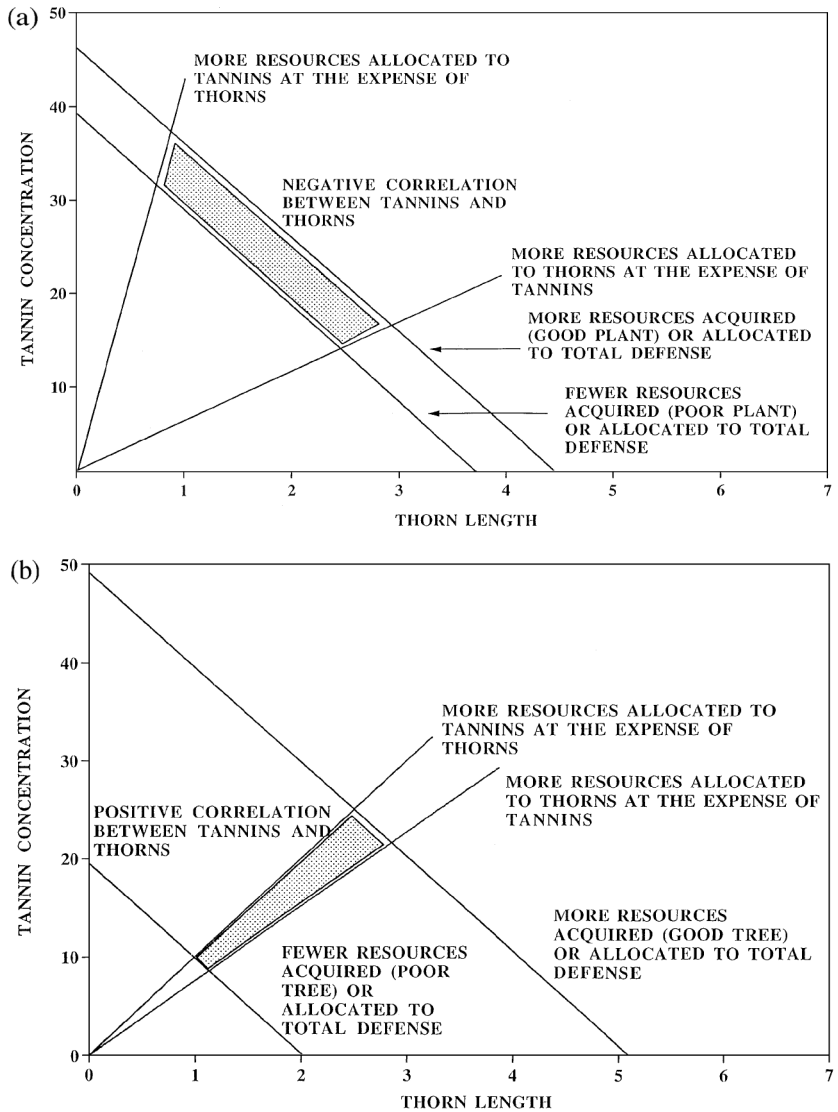

FIG. 4. (a) Schematic diagram indicating how a small difference between good and poor individuals in the amount of resources acquired (or allocated to total defense) and a large difference in the relative allocation of resources to tannin and thorn defenses will cause a trade-off (Van Noordwijk and de Jong, 1986). (b) Schematic diagram indicating how a large difference between good and poor individuals in the amount of resources acquired (or allocated to total defense) and a small difference in the relative allocation of resources to tannins and thorns will result in a positive correlation (Van Noordwijk and de Jong, 1986).

to total defense) and a small difference in the relative allocation of resources to tannins and thorns, a positive correlation will result (Van Noordwijk and de Jong, 1986) (Figure 4b).

The scenarios in Figures 3 and 4b are not mutually exclusive, i.e., large differences in resource availability may be induced by the activity of the ants which, if combined with low variability among plants in resource allocation, will result in the scenario outlined in Figure 4b. Further experimentation, such as ant removals combined with manipulation of resource availability, is needed to ascertain whether these explanations are appropriate for *Acacia drepanolobium*.

4. Defenses may not be costly to the plant. Inducible defenses were apparent for physical defenses in *A. drepanolobium*, *A. seyal* (Young, 1987), *A. tortilis* (Gowda, 1996a; Rohner and Ward, 1997), and *A. raddiana*, suggesting that thorn production is costly and resources are allocated differently when browsing levels are low. However, the results of Rohner and Ward's (1997) study on *A. tortilis* in Israel, Gowda's (1997) study on *A. tortilis* in East Africa, and the study by Du Toit et al. (1990) of *A. tortilis* in South Africa did not confirm this for secondary compounds.

Thus, it still is not clear whether condensed tannins can be considered as general defense compounds in *Acacia* species, whether they are effective inducible defenses (see review by Owen-Smith, 1993), and under which conditions such responses are likely to be expressed. Further research is needed to understand these relationships. Our original, admittedly simplistic, view of these compounds as defenses against herbivory certainly needs revision. Undoubtedly, such revision will need to incorporate more realistic models of physiological constraints to defense production and its relationship with investments in other traits such as growth.

DOES DECREASED MOWING FREQUENCY ENHANCE ALKALOID PRODUCTION IN ENDOPHYTIC TALL FESCUE AND PERENNIAL RYEGRASS?

(Received June 11, 2001; accepted January 16, 2002)

Abstract—Tall fescue, *Festuca arundinacea*, and perennial ryegrass, *Lolium perenne*, are widely infected with fungal endophytes (*Neotyphodium* spp.). The symbiosis between plant and fungus leads to synthesis of alkaloids that have been shown to be either toxic or act as feeding deterrents against insect pests. As cultural practices have the potential to regulate production of plant secondary metabolites, we evaluated the influence of mowing frequency on the levels of major alkaloids in tall fescue and perennial ryegrass in the greenhouse. Tall fescue and perennial ryegrass maintained in 15-cm-diam. pots were cut to 5-cm height weekly or biweekly. Samples were taken monthly and the alkaloids extracted and analyzed by reverse-phase LC-MS. In tall fescue, ergovaline, ergonovine, and ergocristine were identified, whereas only ergocristine was identified in perennial ryegrass samples. In tall fescue, we observed a trend showing higher levels in samples cut biweekly than in those cut weekly. A similar pattern was seen in some putative alkaloids that were not identified. In perennial ryegrass, ergocristine and two putative alkaloids followed a pattern similar to that of alkaloids in tall fescue. A survey of a few samples of perennial ryegrass using extractions specific to peramine and lolitrem B yielded evidence suggesting their presence as well as several other identified alkaloids. These data support the hypothesis that decreased mowing frequency enhances alkaloid production/accumulation in tall fescue and perennial ryegrass.

Key Words—Fungal endophytes, *Neotyphodium coenophialum*, *Neotyphodium lolii*, alkaloids, tall fescue, *Festuca arundinacea*, perennial ryegrass, *Lolium perenne*, mowing frequency.

INTRODUCTION

Tall fescue, *Festuca arundinacea* Schreb, and perennial ryegrass, *Lolium perenne* L., are widely infected by the fungal endophytes *Neotyphodium coenophialum* Morgan-Jones & Gams and *Neotyphodium lolii* Latch, Christensen & Samuels, respectively. These mutualistic symbioses lead to production of several alkaloids that provide infected plants with chemical defenses against herbivory (Prestidge et al., 1982). Livestock feeding on the endophyte-infected grass suffer toxicoses from alkaloid ingestion (Porter et al., 1974; Hoveland, 1993). At least 15 species of insects are affected by endophyte alkaloids (Siegel et al., 1990; Rowan et al., 1990; Breen, 1993). This chemical defense also extends to other organisms including nematodes (West et al., 1988) and fungi (White and Cole, 1985).

Tall fescue and perennial ryegrass are widely used turf grasses in home lawns, golf course fairways, driving ranges, and public parks. They sometimes require application of pesticides to manage insect pests. Heavy use of chemical pesticides in urban environments leads to increased health risks to pets, children, and adults. Not surprisingly, the use of many organophosphate and carbamate pesticides has been banned by the United States Environmental Protection Agency or is under review in order to implement the Federal Food Quality Protection Act. However, this has, led to a more intensive use of other pesticides, such as neonicotinoids, that are deemed safe, relative to organophosphates.

The potential of endophyte-mediated resistance offers a promising avenue of investigation (Clay, 1989). If pesticide use in urban environments could be reduced through cultural practices (fertilization, irrigation, clipping), this could lead to health and economic benefits for homeowners and managers of golf courses and recreational parks. There are indications that the alkaloid levels in endophyte-infected turf grasses can be manipulated by management practices. For instance, clipping has been shown to reduce alkaloid content in tall fescue (Belesky and Hill, 1997). This occurred as a function of nonstructural carbohydrates that were channeled from alkaloid synthesis to production of leaf matter. This led us to hypothesize that decreased mowing frequency would result in an increase in the level of endophytic alkaloids. Here we present results of a greenhouse study on the effect of mowing frequency on levels of major alkaloids produced in tall fescue and perennial ryegrass.

METHODS AND MATERIALS

Grass Management and Mowing Frequency. Six 15-cm-diam. cores of established stands of endophytic tall fescue, *F. arundinacea*, and endophytic perennial ryegrass, *L. perenne*, were taken from field plots established in 1999 at the Ohio Agricultural Research and Development Center. The cores were placed into 15-cm-diam. pots and transferred to a greenhouse in the fall of 2000. The

percentage of tillers infected by the endophyte was in the range of 30–100% with an average of 58% for the tall fescue, and 50–90% with an average of 77% for the perennial ryegrass (Grewal, unpublished data). Plants were maintained at 21°C day and 16°C night and a 16L:8D light cycle. Daylight was supplemented with artificial lighting as required. Plants were watered as a needed, and weekly applications of Peters Professional fertilizer [(20-20-20 N-P-K) (Scotts Company, Maysville, Ohio, USA] was provided. The plants were maintained in greenhouse for four weeks before sampling was initiated. The grasses were cut to 5-cm height either weekly or biweekly (every other week).

Sampling. Triplicate samples were collected monthly, starting one month after the first treatment. Sampling was limited as much as possible to a quarter section of the pot where the grass was cut at the soil level. We tried to avoid collecting from a previously sampled sector. Samples were immediately frozen in liquid nitrogen and lyophilized. Dried samples were ground to a powder in a Cyclotech 1093 mill and stored for analysis.

Alkaloid Extraction. A method described by Hill et al. (1993) with some modifications was used to extract alkaloids. Briefly, 100 mg of plant material were weighed and transferred into a liquid scintillation vial. One hundred nanograms of ergotamine were added as an internal standard. Nine ml of $CHCl_3$ and 1 ml of 0.01 N NaOH were added, and the sample was then agitated by wrist action for 30 min. The sample was filtered through Whatman 1 PS filter paper and loaded onto 5 ml solid-phase extraction columns prepared as described by Hill et al. (1993). The columns contained 0.5 g of Ergosil at the bottom and 1 g of Na_2SO_4 on top separated by Whatman No. 41 filter paper disks. Pigments were eluted with an aspirated manifold with 5 ml of acetone–chloroform (75:25), and the residual acetone–chloroform was removed with 1 ml of diethyl ether. A detachable Nylon 66 filter (22 μm) was attached to the syringe and the alkaloids eluted by slowly plunging 2 ml of methanol through. The sample was evaporated to dryness under N_2 flow and stored in the freezer untill analysis.

Separate extraction methods were attempted to see if they would be better suited for detection of peramine and lolitrem B in perennial ryegrass, as described by Ball et al. (1995). Only a few samples were subjected to these extractions. Chlorophylls remaining after the lolitrem extraction method were removed by passing the samples through an aminopropyl SPE column.

Data Collection. Samples were suspended in 100 μl of methanol, and analyzed on a Waters LC-MS system using a Novapak C_{18} (2 $\times$ 150 mm) column. The mobile phase was H_2O–methanol–acetonitrile plus 0.3% NH_4OH (60:10:20:10). The flow rate was 0.27 ml/min in a linear gradient for 48 min, changed to 10:10:70:10 at 52 min, and returned to the original composition untill 60 min. Peaks were detected with a Waters 996 Photodiode Array Detector, after which the flow was split in two with one part going through a Waters 474 Scanning Fluorescence Detector with excitation wavelength at 316 nm and emission

wavelength at 413 nm, and the other to the mass spectrometer. Splitting of the flow was done as a precautionary measure to avoid damage to the fluorometer cell by the pressure in the system. Positive ion electrospray spectra were recorded on a Waters ZQ instrument. Soft ionization of the electrospray results in production of quasimolecular ions $(M+H)^+$, where M represents molecular weight and H hydrogen.

Direct-phase chromatography of samples following Ball et al. (1995) was carried out as described by Gallagher et al. (1985) using a Supelco (2 × 150 mm) silica column and acetonitrile–CH_2Cl_2 (80:20) for 30 min. The excitation and emission wavelengths of the fluorescence detector were set at 265 nm and 440 nm, respectively.

Data Analysis. Quantification was based on the ergotamine internal standard. Repeated-measures (Statistica, StatSoft, Inc., Tulsa, Oklahoma, USA) analysis to look at the effect of time on alkaloid levels, and one-way ANOVA to compare samples from weekly and biweekly treatments at each sampling time were used. Replicates that could not be accurately determined due to interfering peaks in the chromatograms were excluded from analysis.

RESULTS

Alkaloids. Levels of major alkaloids and some of the unidentified putative alkaloids detected in tall fescue and perennial ryegrass are listed in Table 1. In tall fescue, we identified eight alkaloids, of which ergovaline, ergonovine, and ergocristine were the major ones. In addition, three unknown compounds were present in large quantities. In perennial ryegrass, ergocristine was the major alkaloid with two unidentified compounds. Evidence for eight more alkaloids was found using a method described by Ball et al. (1995).

Tall Fescue. The repeated-measures analysis of ergonovine indicated a significant effect by month (Figure. 1) ($F = 4.95$, $df = 3,12$, $P = 0.018$). Biweekly cutting resulted in higher levels of ergonovine ($F = 11.77$, $df = 1,3$, $P = 0.042$) by the second month.

The level of ergovaline in month 1 samples was higher in the grass subjected to weekly cutting than in grass clipped on a biweekly schedule ($F = 10.73$, $df = 1,3$, $P = 0.047$), but by month 2 the biweekly treatment showed a large increase over the weekly treatment ($F = 9.23$, $df = 1,4$, $P = 0.038$) (Figure 1). In the subsequent two months, a trend favoring biweekly mowing over weekly cutting was evident, but the differences were not significant due to large variation.

Like ergonovine, ergocristine levels showed an effect by month in the repeated-measures analysis ($F = 5.08$, $df = 3,12$, $P = 0.017$), but the cutting frequency was significant only at month 2 where weekly cutting gave higher values ($F = 6.81$, $df = 1,4$, $P = 0.059$). Levels remained high for the first three months and then decreased considerably in both treatments (Figure 1).

TABLE 1. ALKALOIDS AND PUTATIVE ALKALOIDS FOUND IN TALL FESCUE AND PERENNIAL RYEGRASS USING REVERSE-PHASE LC-MS ELECTROSPRAY IONIZATION[a]

Compound	$(M+H)^+$	Amounts (ng/g)
Tall fescue		
N-Formyl loline	183[b,c]	trace
N-Acetyl-loline	197	trace
Chanoclavine	257	<1
Ergonovine	326	71–490
Ergovaline	534	10–140
Ergocryptine	577	<1

[a] The amounts (ng/g dry weight) are relative to an ergotamine internal standard. The compounds are in order of increasing size of their quasimolecular ions with known alkaloids listed first. $(M+H)^+$ denotes molecular weight (M) and hydrogen (H).

[b] Alkaloids found using the methods of Ball et al. (1995) and direct phase chromatography.

The three putative alkaloids (Figure 2, unknowns A, B, and C) all showed significant effects by month (A: $F = 63.02, df = 3,12; P = 0.001$; B: $F = 4.20, df = 3,12, P = 0.030$; C: $F = 3.66, df = 3,12, P = 0.044$), as well as month × treatment interactions (A: $F = 14.80, df = 3,12, P = 0.001$; B: $F = 8.34, df = 3,12, P = 0.003$; C: $F = 6.37, df = 3,12, P = 0.008$). During the second month of the study, all of the unknowns showed higher levels in samples from the biweekly cutting at month 2 (A: $F = 55.40, df = 1,4, P = 0.002$; B: $F = 103.27, df = 1,3, P = 0.002$; C: $F = 14.69, df = 1,4, P = 0.019$). Biweekly treatment also resulted in higher levels of unknowns A and B at month 4 (A: $F = 9.26, df = 1,4, P = 0.038$; B: $F = 9.59, df = 1,3, P = 0.053$).

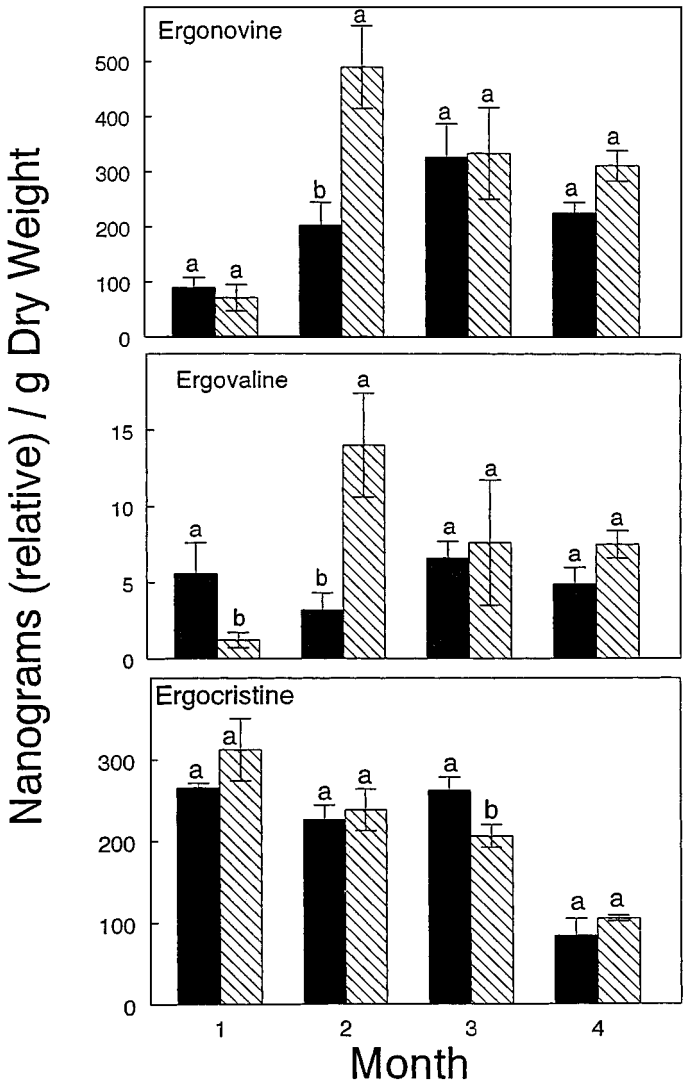

FIG. 1. Mean (±SE) levels of ergonovine, ergovaline, and ergocristine in tall fescue. Mowed weekly (■) or biweekly (▨). The same letters on the columns at each sampling date indicate no differences between treatments at $\alpha = 0.05$.

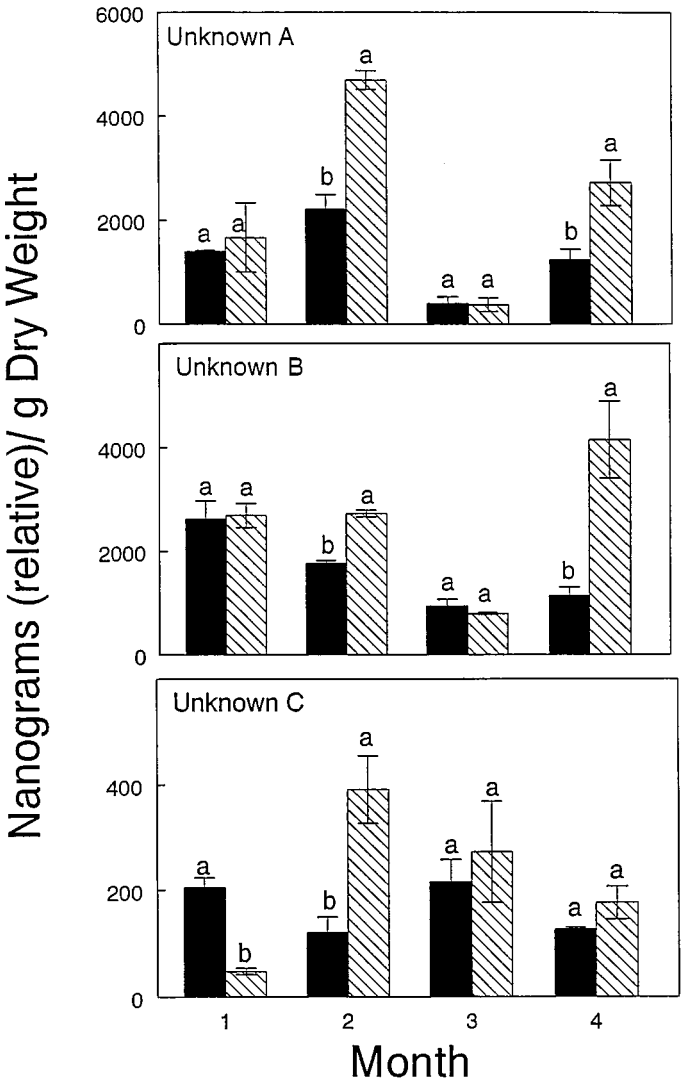

FIG. 2. Mean (±SE) levels of unknown A, unknown B, and unknown C in tall fescue. Mowed Weekly (■) or biweekly (▨). The same letters on the columns at each sampling date indicate no differences between treatments at $\alpha = 0.05$.

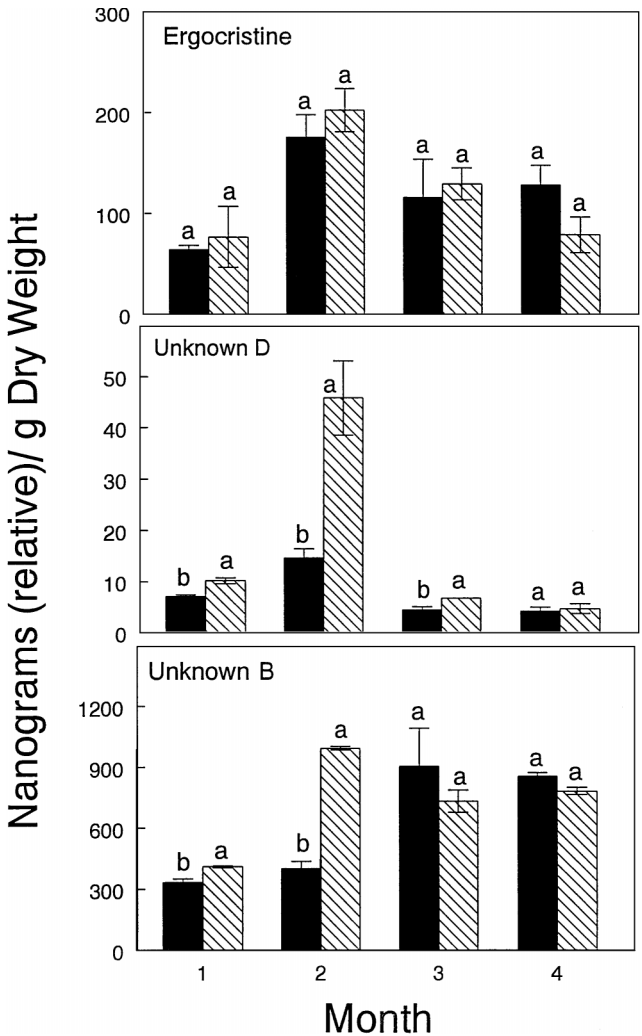

FIG. 3. Mean (±SE) levels of ergocristine, unknown D, and unknown B in perennial ryegrass. Mowed weekly (■) or biweekly (▨). The same letters on the columns at each sampling date indicate no differences between treatments at $\alpha = 0.05$.

Perennial Ryegrass. Only ergocristine was positively identified in the perennial ryegrass. Repeated-measures analysis indicated a main effect by month ($F = 8.17$, $df = 3,9$, $P = 0.006$), but no interaction. Biweekly treatments showed a slightly higher trend for the first three months over the weekly cutting (Figure 3). The level of ergocristine was similar to that in the tall fescue. For

unknown D, the repeated-measures analysis indicated a significant effect by month ($F = 8.17$, $df = 3,9$, $P = 0.005$) and month × treatment interaction ($F = 14.00$, $df = 3,3$, $P = 0.028$) (Figure 3). Levels of unknown D were higher in the biweekly treatment for the first three months (month 1: $F = 28.77$, $df = 1,3$, $P = 0.013$; month 2: $F = 17.17$, $df = 1,4$, $P = 0.014$; month 3: $F = 16.04$, $df = 1,2$, $P = 0.057$) (Figure 3).

Samples from biweekly treatments contained more of unknown B than those from the weekly mowing for the first two months (month 1: ($F = 18.14$, $df = 1,2$, $P = 0.051$; month 2: $F = 292.90$, $df = 1,2$, $P = 0.003$). Unknown B is the same compound as unknown B in the tall fescue based on the quasimolecular ion 572, its fragmentation pattern, and retention time in the chromatograph. In addition, traces of peramine, chanoclavine, and ergostine were observed in some of the samples, but they were either poorly resolved or not detected in others (data not shown). The identity of other unknown peaks remains to be elucidated. The presence of several known alkaloids was observed in the few samples extracted by using the method of Ball et al. (1997) (Table 1).

In weekly mowing treatments of both grasses, we observed an oscillating variation in the alkaloid levels. No evidence for this was seen in the biweekly mowing treatment.

DISCUSSION

Our results agree with those reported by others on the general composition of endophytic alkaloids in tall fescue and perennial ryegrass [(Porter et al., 1979; Lyons et al., 1986; Siegel et al., 1990)]. Ergovaline is generally considered to be the predominant alkaloid in tall fescue (Lyons et al., 1986). It was somewhat surprising that the levels of ergovaline that we found were low in comparison to the other identified alkaloids. However, the levels vary greatly depending on the endophyte–host combination (Siegel et al., 1990; Breen, 1993). Values as high as 8 mg/g dry weight for loline alkaloids in tall fescue have been reported (Jones et al., 1983). Ergovaline levels from 166 to 1083 ng/g dry wt plant tissue have been shown in tall fescue (Rottinghaus et al., 1991).

A common trend across all samples was the increased level of alkaloids in tall fescue samples subjected to biweekly mowing. Although differences in individual as well as in putative alkaloids were small, taken together they indicate a more consistent pattern. Small increases could have an important impact on herbivore performance if there were interactions between the alkaloids. Yates et al. (1989) reported synergistic interaction between perloline and ergocryptine on mortality of *Oniopeltus fasciatus* (Dallas). In fact, most clear-cut differences were seen at month 2. The exception to the trend was at month 1 where the weekly treatments sometimes had a higher alkaloid content than plants treated biweekly.

Alkaloids are more concentrated in the sheaths than in leaves. Rottinghaus et al. (1991) reported ergovaline levels in tall fescue up to three times higher in leaf sheaths than leaves. Our samples were not separated into sheaths and leaves, and the grass was cut to the soil level. Samples from weekly cuttings would be expected to have a higher sheath-to-leaf ratio. Had the data indicated higher alkaloid content in samples from weekly cutting, this would have reflected the sheath-to-leaf ratio. As our data indicate a higher level in biweekly treatments, this would argue that the differences would be even more pronounced if the sheath-to-leaf ratio were the same in the two treatments. This is consistent with the reduction of alkaloid levels as a result of clipping when clipped and nonclipped tall fescue were compared (Belesky and Hill, 1997). Belesky and Hill (1997) suggest that carbon from photosynthesis is used to build new leaf material, and is, thus, not available for alkaloid synthesis. This could also contribute to the low levels of ergovaline found.

The unknown compounds exhibited trends similar to the identified alkaloids. However, we cannot be certain that these were, in fact, alkaloids. The extraction method and the solid-phase extraction, although yielding alkaloids, do not necessarily exclude other compounds with similar properties, e.g., phenolic compounds and chlorophylls. It should be pointed out that the unknown with a pseudomolecular weight of 572 is not a $(M+K)^+$ adduct of ergovaline, based on the absence of the $(M+H)^+$ spectral ion at 534.

The methods used did not provide good data for peramine or lolitrem B in the perennial ryegrass. Preliminary results using methods developed for peramine and lolitrem B extraction and direct-phase chromatography gave indications of the presence of not only these compounds, but also of ergosine, perloline methyl ether, paxilline, lysergic acid, and lysergamide in the perennial ryegrass samples. Lysergamide (ergine) may arise from solvolytic cleavage of lysergic acid during the extraction (Agurell, 1966). These data suggest that it may be necessary to analyze samples using different extraction and chromatography procedures to get a more comprehensive picture of the alkaloid profile in these grasses, e.g., ethanolic extraction of turf grasses has been successfully used for analysis of ergosterol (Logendra and Richardson, 1997).

Results with the perennial ryegrass must be interpreted with some caution because of heavy infestation by the aphid *Rhopalosiphum padi.* Several species of aphids show no avoidance of alkaloids (Latch et al., 1985; Siegel et al., 1990). Tall fescue has been shown to be resistant to *R. padi* (Johnson et al., 1985) and was not attacked, although it was growing next to the infested perennial ryegrass. A difference in the composition of the alkaloids in the two grasses could be one explanation for this. Our efforts to control the aphids with judicious application of azidirachtin were moderately successful, as we tried to avoid possible complications arising from the use of a synthetic pesticide.

It is tempting to speculate that if the period between cuttings had been extended to three weeks, the differences might have been more pronounced. From the

standpoint of a homeowner or a golf course manager, however, that might be impractical. In many of the weekly treatments, we noticed oscillating fluctuations in the alkaloid levels. Oscillations usually result from negative feedback (Goldbeter and Dupont, 1990) and could indicate that synthesis of alkaloids is regulated by changes in metabolism resulting from cutting, as resources are allocated toward building of new leaf material at the expense of secondary metabolites. Oscillations were not seen in the biweekly treatment.

The results do suggest the possibility that management practices, such as mowing frequency, could have an impact on alkaloid levels, and, as a concequence, on insect pest control in turf grasses. Specific endophyte–host genotypes providing control over insect pests are becoming available. Replacing established lawns and golf course fairways might not always be economically feasible. However, overseeding is a viable alternative, provided the new seed can establish itself in an existing stand (Richmond et al., 2000). The inconsistent control of insects with the use of endophytes (Clay et al., 1985) may have its basis not only in the endophyte–host combination, but also in cultural practices such as mowing frequency.

Acknowledgments—We thank Dr. G. E. Rottinghaus, College of Veterinary Medicine, University of Missouri, for his generous gift of ergovaline, and Dr. A. R. Miller for his valuable advice. We also thank Drs. Douglas S. Richmond and Bert Bishop for their helpful advice in the statistical analysis of the data. This study was funded by the OARDC interdisciplinary grant.

DIFFERENTIAL ATTRACTIVENESS OF INDUCED ODORS EMITTED BY EIGHT MAIZE VARIETIES FOR THE PARASITOID *Cotesia marginiventris*: IS QUALITY OR QUANTITY IMPORTANT?

Abstract—Herbivore-induced plant volatiles can function as indirect defense signals that attract natural enemies of herbivores. Several parasitoids are known to exploit these plant-provided cues to locate their hosts. One such parasitoid is the generalist *Cotesia marginiventris*, which is, among others, attracted to maize volatiles induced by caterpillar damage. Maize plants can be induced to produce the same blend of attractive volatiles by treating them with regurgitant of *Spodoptera* species. We collected and analyzed the regurgitant-induced emissions of two plant species (cowpea and maize) and of eight Mexican maize varieties and found significant differences among their volatile emissions, both in terms of total quantity and the quality of the blends. In a Y-tube olfactometer, the odors of the same artificially induced plant species and Mexican varieties were offered in dual choice experiments to naïve mated females of *C. marginiventris*. Wasps preferred cowpea over maize odor and, in 3 of 12 combinations with the maize varieties, they showed a preference for the odors of one of the varieties. A comparison of the odor collection with results from the behavioral assays indicates that not only the quantity of the volatile emissions, but also the quality (composition) of the volatile blends is important for attraction of *C. marginiventris*. The results are discussed in the context of the possibility of breeding crop varieties that are particularly attractive to parasitoids.

Key Words—Induced plant volatiles, parasitoid, olfactometer, *Cotesia marginiventris, Spodoptera littoralis*, *Zea mays*, *Vigna unguiculata*, parasitoid attraction, odor variability.

INTRODUCTION

Herbivore-induced odors have been suggested to benefit plants in different ways (Vet and Dicke, 1992; Turlings and Benrey, 1998; Sabelis et al., 1999; Dicke and van Loon, 2000). Over the last 15 years, it has become evident that these odors are important for the attraction of natural enemies to the microhabitat of their prey (e.g., Dicke et al., 1990a; Turlings et al., 1990a; Steinberg et al., 1993; Du et al., 1998; Röse et al., 1998). The blend of odors released by plants after herbivore attack is variable, depending on the plant (species and variety) and the herbivore that feeds on it, although some compounds are common to many induced blends (for reviews see Dicke, 1994, 1999). It is known that European maize varieties and their wild ancestors differ considerably in quality and quantity of odors if induced to produce volatiles by treating scratched leaves with *Spodoptera littoralis* (Lepidoptera: Noctuidae) regurgitant (Gouinguené et al., 2001). We define differences in the quality of the odor blends as differences in the presence of specific compounds in the blend and/or the proportions among compounds. This variation among maize varieties could have important consequences for pest management, as biological control may be more effective for varieties that are highly attractive to natural enemies. This may be particularly true for countries in Latin America where the major pests of maize are leaf-feeding *Spodoptera* caterpillars (for review see Andrews, 1988).

Young *Spodoptera* caterpillars can be parasitized by *Cotesia marginiventris* (Hymenoptera: Braconidae), a common solitary endoparasitoid that attacks Lepidopteran larvae during the first and second instar (Jalali et al., 1987). *C. marginiventris* females are strongly attracted by the odors emitted by caterpillar-damaged maize seedlings (Turlings et al., 1990a, 1991a) and spend more time on caterpillar-damaged plants than on artificially damaged or unattacked plants (Loke et al., 1983). Maize plants infested with a *Spodoptera* larva parasitized by *C. marginiventris* produce more seeds than plants infested with a healthy caterpillar (Fritzsche Hoballah and Turlings, 2001), which could translate into a higher yield for maize cultivars that are particularly attractive to the parasitoid. Hence, it seems important to know which factors determine the attractiveness of the crop.

Here we report on how differences in induced volatile emissions among different plant genotypes may affect the attractiveness of these genotypes to parasitoids. We first compared the emissions of maize and cowpea and their attractiveness to *C. marginiventris*. The former plant species is known to release large amounts of induced volatiles (e.g., Turlings et al., 1998), while the latter releases relatively little, but can be quite attractive (Whitman and Eller, 1990). Furthermore, we investigated the attractiveness of eight Mexican maize cultivars. In Y-tube olfactometer, naïve *C. marginiventris* females were offered a choice between the odors of the two respective plant species or 12 paired combinations of the Mexican maize varieties. Comparison of the results from these behavioral assays with the

odor blends that were collected from the various plants revealed that for naïve wasps attractiveness is not simply a matter of quantity of volatiles, but that the quality of the blend is important as well.

METHODS AND MATERIALS

Growing and Treatment of Plants. Plants used in all experiments were grown in plastic pots (6 cm high, 8 cm diam.) in fertilized commercial soil (Coop) in a climate chamber (23°C, 60% relative humidity, and 16L:8D, 50,000 lumens/m^2). Two-week-old *Vigna unguiculata* (var. kpodii-guegue, obtained from IITA) Africa) and 10-day old *Zea mays* (var. Delprim and varieties obtained from CIMMYT, Table 1) plants were used for the experiments. To induce the plants to produce volatiles, we scratched two leaves (the second and third leaf of maize and first and second of cowpea) of each plant with a razor blade (an area of 2–4 cm^2/leaf) and subsequently applied on each damaged site 10 μl of regurgitant. Regurgitant was collected from fourth and fifth instar *S. littoralis* caterpillars (for the method, see Turlings et al., 1993a) and kept at −70°C until just before utilization. After treatment, plants were placed for 5 hr (plant species) and 6 hr (varieties), under three fluorescent lamps (Sylvania standard F36W 133-T8 cool white, 5000 lumens/m^2 at pot height), before they were used for the volatile collection and olfactometer experiments. It is known that 5–6 hr after treatment corn plants emit relatively large quantities of induced volatiles (Turlings et al., 1998).

Insects. *S. littoralis* caterpillars and eggs were supplied weekly by Syngenta (Stein, Switzerland). Eggs were incubated in Petri dishes (9 cm diam., 1.5 cm high) on moist filter paper. Emerged caterpillars were fed with artificial diet and kept in plastic-boxes (15 × 9 × 5 cm) under ambient laboratory conditions. This non-native host causes a similar reaction in plants as the natural host *S. frugiperda* (Fritzsche Hoballah, unpublished data).

The solitary endoparasitoid *C. marginiventris* that was used in the experiments originated from the USDA-ARS, Biological Control and Mass Rearing Research Unit. For the rearing of parasitoids, 25 young caterpillars (3–4 days old) were offered to a single mated female (4–7 days old) for 3 hr in a plastic box (9.5 cm diam., 5 cm high). The caterpillars were further reared on artificial diet in an incubator (25°C and 16L:8D) until cocoon formation. Cocoons were kept in Petri dishes until adult emergence. Emerging adults were sexed and kept in cages (30 × 30 × 30 cm) at a male–female ratio of 1:2, with distilled water on cotton and honey as a food source. The cages were kept in the laboratory under ambient light and temperature conditions.

Volatile Collection. After treatment and light exposure, plants were placed in a climate chamber (CMP4030, Conviron, Winnipeg, Canada) and the emitted volatiles were collected. The climate chamber was programmed at 20°C and with a light intensity of 14,500 lumens/m^2 (light provided by 28 lamps, 16 Sylvania 150-W VHO Cool White and 12 Sylvania 100-W Satin). Volatiles were collected from six plants simultaneously in an automated collection system as described by Heath and Manukian (1992) and Turlings et al. (1998). Glass cylinders (9.5 cm diam., 54 cm high) were placed over the plants and rested on a Teflon disk consisting of two halves with a hole in the middle for the stem of the plant. Air was pushed (1 liter/min) through a charcoal filter and introduced from the top of each cylinder over the plants. Super-Q traps (25 mg, 80/100 mesh, Alltech, Deerfield State) were attached laterally at the base of each cylinder. Traps were connected to an automated volatile collection system (ASU, ARS, Gainesville, Florida) through which the air was pulled out at 0.8 liters/min during 2 hr. The collection period was programmed with the use of the software TESS (Version 1.0, ARS, Gainesville, Florida). After each collection, volatiles were extracted from the traps with 150 μl methylene chloride, and 200 ng of *n*-octane and nonyl acetate were added as internal standards. Aliquots (3 μl) of the samples were injected on column, with an automated injection system into a Hewlett Packard model HP 6890 gas chromatograph equipped with a flame ionization detector. The apolar EC-1 capillary column (30 m × 0.25 mm ID, 0.25 μm film thickness, Alltech Associates) was held at 50°C for 3 min and then programmed at 8°C per min to 230°C, where it was maintained for 9.5 min. The column was preceded by a deactivated retention gap (10 m × 0.25 mm ID, Connex) and a deactivated precolumn (30 cm × 0.530 mm ID, Connex). Helium (24 cm/sec) was used as carrier gas. We collected and analyzed the odor of treated cowpea and maize plants ($N = 6$) as well as of 8 Mexican varieties ($N = 5$ for each variety). Hewlett Packard GC Chemstation software was used to quantify all major components by comparison to the known quantity of internal standards. Initial identification of most compounds was based on comparisons of retention times from previous studies (Turlings et al., 1998; Bernasconi et al., 1998). Conformation of identity by comparison of retention times with the synthetic samples was obtained for nerolidol (Fluka), (*E*)-β-farnesene (Denka

International), geranyl acetate (Fluka), (*Z*)-3-hexenol (Fluka), (*Z*)-3-hexenyl acetate (Sigma), linalool (Fluka), indole (Fluka), and β-myrcene (Sigma). A few compounds were identified only with the use of the Wiley library after mass spectrometry analysis (Agilent 5973, transfer line 230°C, source 230°C, quadrupole 150°C, ionization potential 70 eV, scan range 0–400 amu). These compounds are 2-hexenol, β-sesquiphellandrene, β-bisabolene, and cycloisosativene/α-ylangene. These identifications are regarded as tentative and are marked as such in the remainder of the text.

ANOVA and Student-Newman-Keuls *post-hoc* test were used to compare the total quantity of volatiles emitted among varieties (data ln-transformed). The Mann-Whitney test was used to compare differences in total emissions between plant species and among single compounds emitted by the different species and plant varieties. Tests were carried out with the program SPSS 10.0 for Windows.

Choice Experiments. A Y-shaped olfactometer was used to test the attractiveness of plant odors to *C. marginiventris* females. The system, based on a design by Sabelis and Van de Baan (1983), consisted of a central tube (13.5 cm long, 4 cm diam.) and two lateral arms (12 cm long, 4 cm diam.) ending with a glass frit (to create a homogeneous airflow and to prevent escape of test insects). The lateral arms tapered off into 0.5-cm tubes to which Teflon tubing was connected. Teflon tubes were used to introduce the odors into the Y-tube. To limit visual distractions for the insects, the Y-tube olfactometer was placed inside a white paper box, which was open on top (for illumination) and on the front side (for observation). An office lamp (60 W, 750 lumens/m^2) illuminated the olfactometer. A black and white striped pattern for visual orientation was placed under the Y-tube. Plants, treated and incubated in the same way as for volatile collections, were placed in plastic bags that were then heat-sealed. Humidified and purified (with activated charcoal) air was pushed into each bag via Teflon tubing and airtight connectors at pot height. The air passed over the plants and into the Teflon tubes connected with the arms of the olfactometer at a rate of 0.8 liters/min.

Wasps were used only one time and released singly at the base of the central arm of the Y-tube. In a first experiment, they were offered the odor of induced cowpea and maize (var. Delprim). In subsequent experiments, they had the choice between the odor of two different induced Mexican maize varieties. Twelve of the 36 possible combinations of the eight Mexican varieties were randomly chosen for these tests. It was not our goal to determine which of the eight varieties were the most attractive, but to establish if only the quantity or also the quality of the blends were important for the attraction of *C. marginiventris*. Naïve (no experience with hosts or plants) wasps were placed individually in the base of the olfactometer and observed for 10 min. If a wasp did not make a choice after this period, it was removed and recorded as a "no choice." Wasps that walked to the end of one of the arms and stayed there at least 5 secs were recorded as having made a choice for the odor offered through that arm. After four to seven individuals were tested,

the olfactometer was turned such that the direction of the arms was reversed and another four to seven wasps were tested. Each combination of odor sources was tested six to nine times with different plants and on different days. Each time the position of the two different odor sources was switched. A minimum of 67 and maximum of 94 wasps were tested in the 12 combinations of maize odor sources.

A binomial test was used to determine significant preferences for an odor. The number of wasps that chose the highest and lowest volatile emitting maize varieties on each experimental day was compared with a Wilcoxon signed rank test. This test was carried out using data of all experimental days to determine if the quantity (regardless of quality) of the odor was important for the attraction of the wasps.

RESULTS

Volatile Collection. The two plant species, cowpea and maize, differed dramatically in the quantities of volatiles emitted (Figure 1). The total amount of volatiles collected during the experiment was almost 53 times higher in maize (4141.35 ± 460.2 ng/2 hr) than in cowpea (77.9 ± 20.9 ng/2 hr) ($N = 6$, Mann-Whitney test: $P = 0.004$, $Z = -2.882$). The two plant species released several identical compounds, but cowpea did not release benzyl acetate, phenethyl acetate, 1-H-indole, (*E*)-β-caryophyllene, "β-sesquiphellandrene," or (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, and it released only traces of (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, α-(*E*)-bergamotene, (*E*)-β-farnesene, "β-bisabolene," and nerolidol (Figure 1). In contrast, cowpea emitted considerable amounts of (*E*)-2-hexenal and significantly more (*Z*)-3-hexenol than maize plants (Figure 1).

Among the Mexican maize varieties we also found differences in the total amounts of volatiles collected ($N = 5$, ANOVA: $df = 7$, $F = 10.589$, $P < 0.001$, Figure 2). Variety 1 emitted 14 times more than variety 8 (Figure 2). We compared the emissions of volatiles for the varieties that were shown to be differentially attractive to *C. marginiventris* (see below). Variety 4 released significantly more (*Z*)-3-hexenal, (*Z*)-3-hexenol, and phenethyl acetate than variety 7 (Figure 3A). Variety 4 did not release geranyl acetate or (*E*)-β-ocimene, and variety 7 did not release "cycloisosativene/α-ylangene" or "β-sesquiphellandrene" (Figure 3A). Variety 1 released significantly more (*Z*)-3-hexenyl acetate, (*E*)-4,8-dimethyl-1,3,7-nonatriene, benzyl acetate, phenethyl acetate, geranyl acetate, and "cycloisosativene/α-ylangene" than variety 6 (Figure 3B). Variety 6 did not release (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, benzyl acetate, or phenethyl acetate (Figure 3B). Variety 1 released significantly more linalool, benzyl acetate, phenethyl acetate, 1-H-indole, geranyl acetate, α-(*E*)-bergamotene, (*E*)-β-farnesene, and "β-sesquiphellandrene" than variety 5 (Figure 3C). Variety 5 did not produce "cycloisosativene/α-ylangene" (Figure 3C).

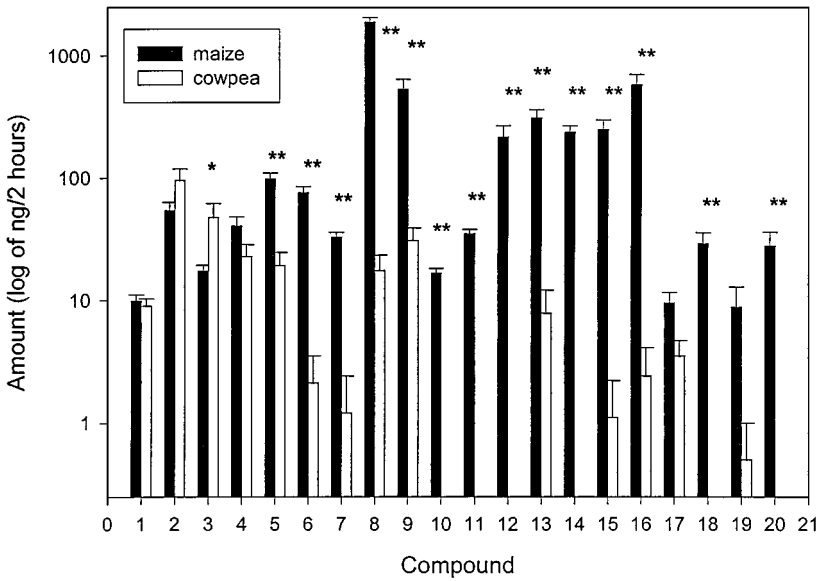

FIG. 1. Mean amount (±SE) of volatiles collected from cowpea and maize plants that were artificially damaged and treated with regurgitant of *Spodoptera littoralis* caterpillars. Collections started 5 hr after treatment and lasted 2 hr. Asterisks above bars indicate significant differences (Mann-Whitney test (two-tailed): $^{*}P < 0.05$, $^{**}P < 0.005$) in release of a specific compounds. The compounds are: **1**, 1-(*Z*)-3-hexenal; **2**, (*E*)-2-hexenal; **3**, (*Z*)-3-hexenol; **4**,"2–hexenol"; **5**, β-myrcene; **6**, (*Z*)-3-hexenyl acetate; **7**, (*E*)-β-ocimene; **8**, linalool; **9**, (*E*)-4,8-dimethyl-1,3,7-nonatriene; **10**, benzyl acetate; **11**, phenethyl acetate; **12**, 1-H-indole; **13**, geranyl acetate; **14**, (*E*)-β-caryophyllene; **15**, (*E*)-α-bergamotene; **16**, (*E*)-β-farnesene; **17**, "β-bisabolene"; **18**, "β-sesquiphellandrene"; **19**, nerolidol; **20**, (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (compounds within quotation marks were tentatively identified by comparison of their MS-spectra with those of the Wiley library).

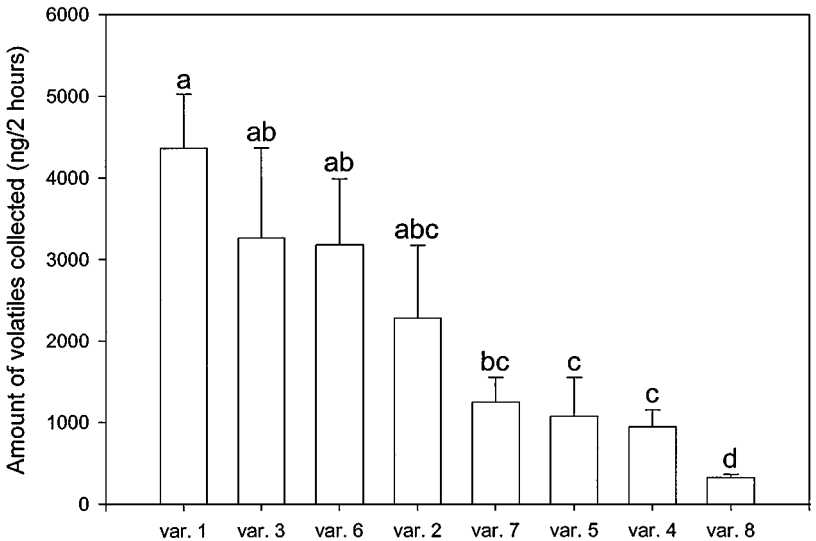
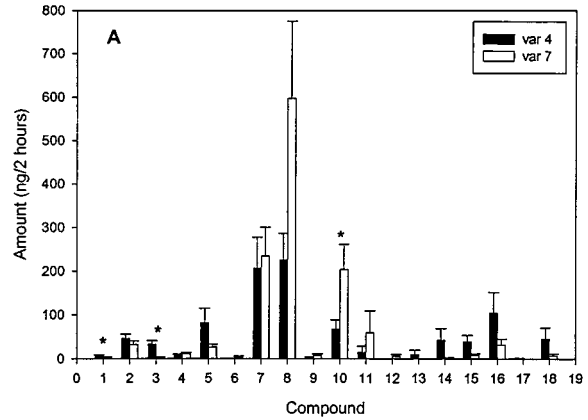
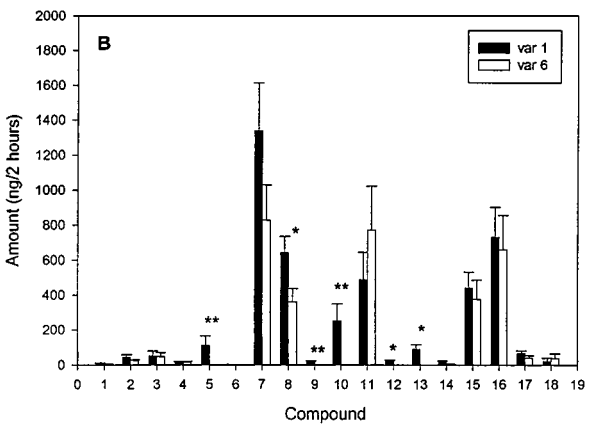
Choice Experiments. Cowpea odors were more attractive to *Cotesia marginiventris* than maize odors (Binomial test, $P = 0.007$, Figure 4). The parasitoids showed only a preference in 3 of the 12 combinations of Mexican maize varieties tested (Figure 4). In one case (var. 1 vs. var. 5), the wasps were attracted to the variety releasing more volatiles (Figures 2, 3C, and 4). However, in two cases (var. 4 vs. var. 7 and var. 1 vs. var. 6), the varieties tested released the same amounts of volatiles (Figures 2, 3A,B, and 4), and the preference must have been due to a difference in odor quality.

The number of wasps on each experimental day (89 experimental days in total) choosing the higher emitting maize variety on that day (mean ± SE wasps, 4.6 ± 0.25) was compared with the number of wasps on each experimental day choosing







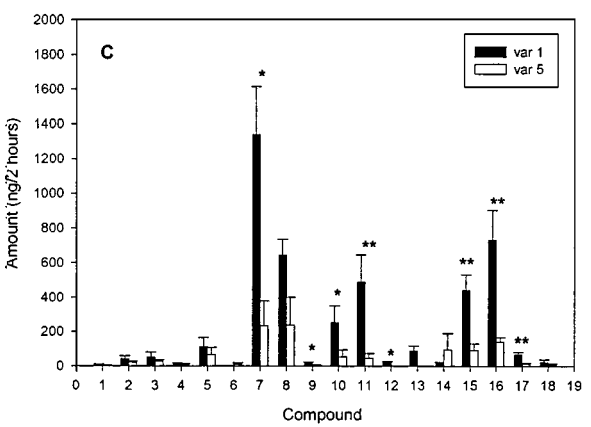


FIG. 2. Mean amount (±SE) of volatiles collected from different varieties of maize seedlings (10 days old) that were artificially damaged and treated with regurgitant of *Spodoptera littoralis* caterpillars. Volatiles were collected 6 hr after treatment, for 2 hr. Letters above bars indicate significant differences between varieties in the total amount released (Student-Newman-Keuls post hoc test after ANOVA: $df = 7$, $F = 10.589$, $P < 0.001$).

the lower emitting maize variety (3.8 ± 0.24 wasps). It revealed a marginally significant preference for the variety that emits larger amounts of volatiles offered in the dual choice test (Wilcoxon signed rank test: $P = 0.045$, $Z = -2.008$).

FIG. 3. Mean amount (±SE) of individual compounds collected from maize varieties that were artificially damaged and treated with regurgitant of *Spodoptera littoralis* caterpillars. Collections started 6 hr after treatment and lasted 2 hr. Asterisks above bars indicate significant differences (Mann-Whitney test (two-tailed): $^{*}P < 0.05$, $^{**}P < 0.005$, $^{***}P < 0.001$), between the two plant varieties (A: between varieties 4 and 7, B: 1 and 6, and C: 1 and 5). The compounds are: **1**, 1-(*Z*)-3-hexenal; **2**, (*E*)-2-hexenal; **3**, (*Z*)-3-hexenol; **4**, β-myrcene; **5**, (*Z*)-3-hexenyl acetate; **6**, (*E*)-β-ocimene; **7**, linalool; **8**, (*E*)-4,8-dimethyl-1,3,7-nonatriene; **9**, benzyl acetate; **10**, phenethyl acetate; **11**, 1-H-indole; **12**, geranyl acetate; **13**, "cycloisosativene/α-ylangene"; **14**, (*E*)-β-caryophyllene; **15**, (*E*)-α-bergamotene; **16**, (*E*)-β-farnesene; **17**, "β-sesquiphellandrene"; **18**, (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (compounds within quotation marks were tentatively identified by comparison of their MS-spectra with those of the Wiley library).

DISCUSSION

Difference in Induced Volatile Emission among Plant Species and Varieties. Differences in herbivore-induced odor emissions among plant species genotypes have been demonstrated in several studies (Takabayashi et al., 1991, 1994a; Loughrin et al., 1995; Geervliet et al., 1997; Halitschke et al., 2000; Ozawa et al., 2000). In maize, these differences can be considerable (Gouinguené, et al., 2001). The current study confirms that different plant species, but also different varieties, release qualitatively and quantitatively different blends of induced odors. The 11 most important compounds that were collected from induced maize plants are partially shared with other plant species for which induced volatiles have been studied (Table 2). The only compound released by all plant species is (*Z*)-3-hexenol, and in 12 of 14 cases, (*Z*)-3-hexenyl acetate and (*E*)-4,8-dimethyl-1,3,7-nonatriene are also shared (Table 2).

TABLE 2. VOLATILES COLLECTED FROM REGURGITANT-INDUCED MAIZE PLANTS, SHARED AMONG OTHER PLANT SPECIES[a]

(1998), Halitschke et al. (2000); cowpea: present study.

We found large qualitative and quantitative differences in induced odor blends between the plant species, maize and cowpea, and to a lesser extent among different maize varieties. Cowpea released almost exclusively green leaf volatiles, as was found by Whitman and Eller (1990), and maize released more indole, linalool, and a range of terpenoids that differed in the presence, proportion, and amount among varieties. Among maize varieties, the difference in total emission of volatiles was striking, with a 14-fold difference between lowest and highest emitting variety. When comparing the odors released by plants infested by *Pieris* larvae, Geervliet et al. (1997) showed differences in odor blends released by different plant species and cabbage varieties. Takabayashi et al. (1991, 1994a) found a qualitative and quantitative difference in volatile compounds emitted between two varieties of apple attacked by the same spider mite. In a comparison of *Spodoptera exigua*-infested leaves from different cotton varieties, naturalized cotton released seven times more volatiles than commercial cultivars (Loughrin et al., 1995). One constraint of using insects to induce odor emissions is that observed differences could be due simply to the fact that herbivores eat more or less of a specific plant species or variety. Using elicitors may allow for a more precise comparison. This was done by Halitschke et al. (2000), who treated the leaves of three genotypes of *Nicotiana attenuata* with methyl jasmonate and found a difference in the pattern of emitted compounds. The standardized treatment of the Mexican maize varieties in our study rules out any variable treatment effects. The results corroborate the tremendous variability in induced odor emissions in the genus *Zea* (see Turlings et al., 1998; Gouinguené et al., 2001).

Responses of Natural Enemies to Plant Odors. It is known that parasitoids show innate preferences to odors of specific undamaged plant species (Ngi-Song et al., 1996; Vaughn et al., 1996; Benrey et al., 1997). Furthermore, parasitoids show innate preferences for odors of specific plant varieties. For example, the parasitoid *Campoletis sonorensis* was attracted differentially to odors released by different cotton varieties (Elzen et al., 1986). In contrast, the parasitoid *Diaeretiella rapae*, did not distinguish among six grass varieties presented in a flight tunnel assay (Vaughn et al., 1996). If plants are damaged by herbivores, odors subsequently produced and released by the plants are considerably more attractive to parasitoids than odors of undamaged plants (Turlings et al., 1991b; Steinberg et al., 1993; Blaakmeer et al., 1994; Agelopoulos et al., 1995; Finidori-Logli et al., 1996; Bertschy et al., 1997; Cortesero et al., 1997; Röse et al., 1998). Choice experiments carried out in flight tunnels and in semi-field plots show that parasitoids have preferences for specific herbivore-attacked plant species (Drost et al., 1988; Geervliet et al., 1996; Du et al., 1998; De Moraes and Lewis, 1999).

Our study compared the attraction of *C. marginiventris* females to cowpea and maize and among maize varieties, focusing exclusively on odor cues. Cowpea odors were preferred over maize odors by naïve *C. marginiventris* females. This was somewhat surprising because cowpea released much less than maize. We had

expected the quantity of odors to be positively correlated with attractiveness, as is indicated by dose-dependent responses of natural enemies in several studies (Eller et al., 1988; Turlings et al., 1990a, 1991b; Ngi-Song et al., 1996; Vaughn et al., 1996; Weissbecker et al., 1999). Although the dual-choice experiments with maize varieties showed that, in general, *C. marginiventris* is more attracted to high releasing maize varieties, in a few combinations females showed preferences even if the quantities of odors produced by the two varieties did not differ. These results indicate that some compounds are more important than others for attraction of wasps, and that the proportions among compounds in the blend could play an important role. Cowpea released relatively larger proportions of green leaf volatiles as (*Z*)-3-hexenol, a very common compound among plant-induced volatiles (Table 2), than maize. Cortesero et al. (1997) analyzed the responses of *C. marginiventris* females to cotton plants and suggested that they primarily cue in on recently damaged plants, which are known to release green leaf volatiles. Other parasitoids like *Microplitis croceipes* and *Netelia heroica* are also attracted to green leaf volatiles, especially to different hexenols and hexenals, when they are offered individually in a flight tunnel (Whitman and Eller, 1990). The parasitoid *Aphidius rhopalosiphi* was strongly attracted to the two green leaf volatiles (*Z*)-3-hexenyl acetate and (*E*)-2-hexenal in Y-tube experiments (Wickremasinghe and Van Emden, 1992). These same chemicals are involved in the attraction of *C. glomerata* to infested or regurgitant-treated cabbage plants (Mattiacci et al., 1994). Green leaf volatiles are probably the most common volatiles released by plants damaged by herbivores (Table 2), which could explain why natural enemies without previous experience (naïve) are strongly attracted to them. (*Z*)-3-hexenol, which is shared by all plant species listed in Table 2, elicits strong responses in the two-spotted stinkbug predator *Perillus bioculatus*, while β-caryophyllene, a terpenoid shared by half of the plant species, elicited only weak responses (Weissbecker et al., 1999). Yet, the importance of specific plant volatiles and mixtures of volatiles has been suggested for the attraction of some natural enemies. The lacewing *Chrysopa carnea*, a predator of small insects, was caught more often in traps containing β-caryophyllene, than in traps that contained limonene, bisabolene, or caryophyllene oxide (Flint et al., 1979). In contrast, β-caryophyllene did not elicit antenna palpation by the parasitoid *Campoletis sonorensis*, whereas caryophyllene oxide did (Elzen et al., 1984). The EAG response of the two spotted stinkbug *Perillus bioculatus* was strong for a α-zingiberene and bicyclogermacrene mixture, but low/when these two compounds were offered singly to the predator (Weissbecker et al., 2000). The volatile compound borneol, extracted from garry oak, *Quercus garryana*, attracted the tachinid parasitoid *Cyzenis albicans* (Roland et al., 1995).

Innate Versus Learned Responses. Generally, naïve females respond poorly to odor cues, but a contact experience with hosts and/or host feces increases this responsiveness (Dmoch et al., 1985; Wardle and Borden, 1989; Whitman and Eller, 1990; Steinberg et al., 1992). These experiences can increase the insects'

motivation to search for a host, but this is also the result of associative learning of the encountered odors (Turlings et al., 1990b, 1993b; Vet and Groenewold, 1990). *C. marginiventris* females also show a dramatic increase in responses to herbivore-damaged maize plants in a flight tunnel after the females have contacted a host-damaged plant (Turlings et al., 1989, 1990b, 1993b). The olfactometer assays allowed us to better test odor preferences in naïve females. The strong responses to cowpea indicate that the innate preference is for the most common herbivore-attacked plant volatiles, the green leaf volatiles. Once a host is encountered, typical host-induced volatiles, like specific terpenoids, may be associated with host-presence, and the wasps will use these more reliable cues in searching for more hosts (Vet and Dicke, 1992). The fact that naïve females are less responsive to specific odor cues could explain why we found only three clear preferences among the 12 combinations tested in the Y-tube olfactometer. Nevertheless, the results suggest that *C. marginiventris* has some innate preference for certain odor blends. To reveal the key compounds in these blends, it would be useful to test the response of the parasitoids to plants that differ only in a single compound as suggested by Dicke and van Loon (2000).

Selection of Varieties and Wasps for Their Use in Biological Control. The selection of varieties that are highly attractive to parasitoids or selection of parasitoids that are particularly responsive to specific odors could be used to enhance biological control programs, as suggested by Loughrin et al. (1995) and Bottrell and Barbosa (1998). The exploitation of parasitoid associative learning in pest management has also been suggested (Wardle and Borden, 1985; Lewis and Martin, 1990; Papaj and Vet, 1990; Vet and Groenewold, 1990).

Some of the Mexican maize varieties tested here appear to be more attractive than others. Field studies will demonstrate if these differences in attractiveness are reflected in parasitism rates. The high genetic variability observed in odor emissions among maize lines (Gouinguené et al., 2001) make it an ideal plant to optimize its attractiveness.

In summary, we confirmed that there are qualitative and quantitative differences in herbivore-induced odor blends among maize varieties. Both quality and quantity of the volatile blends were important for the attraction of inexperienced *C. marginiventris*. Based on the results, we speculate that green leaf volatiles, which are the most common volatiles produced by herbivore-damaged plants, could be important for the attraction of naïve generalist parasitoids such as *C. marginiventris*. More specific compounds, such as terpenoids, could be learned associatively during host encounters. However, further studies will have to establish precisely which compounds are responsible for the observed differences in attractiveness and if such differences can be used to enhance biological control.

Acknowledgments—We are grateful to: Syngenta (Stein, Switzerland) for the weekly shipment of *S. littoralis* larvae and eggs; David Bergvinson for providing Mexican maize seeds; Donald Nordlund for

providing *C. marginiventris*; Katya Besomi, Claire Bonifay, Yves Borcard, Philippe Jeanbourquin, and Cristina Marazzi for assistance with rearing; and Martine Rahier for providing advice and infrastructure at the University of Neuchâtel. We thank Betty Benrey, Thomas Degen, Karl Gotthard, and Bernd Hägele for constructive comments on the manuscript and Jacqueline Moret for helping with statistical analyses. This study was supported by grants from the Swiss Centre of International Agriculture (ZIL) and the Swiss National Science Foundation (grants 31-46237-95 and 31-44459-95).

(Received May 14, 2001; accepted December 25, 2001)

Abstract—A previous study on the feeding responses of tsetse flies, *Glossina morsitans morsitans*, implicated the existence of allomonal barriers, both volatile and nonvolatile, on the nonpreferred host, waterbuck, *Kobus defassa*. In the present study, electroantennogram-active compounds in odors from waterbuck were compared with those of two preferred hosts of tsetse flies, buffalo, *Syncerus caffer*, and ox, *Bos indicus*. Odors from the three bovids were trapped on activated charcoal and/or reverse-phase (octadecyl bonded) silica and analyzed with a gas chromatography-linked electroantennographic detector (GC-EAD) and, where possible, identified by using gas chromatography-linked mass spectrometry (GC-MS) and chromatographic comparisons with authentic samples. The GC-EAD profiles (with *G. m. morsitans* antennae) of the odors of the two preferred hosts were comparable, comprising medium-chain, saturated or unsaturated aldehydes and phenols, with buffalo emitting a few more EAG-active aldehydes. Waterbuck odor gave a richer profile, consisting of fewer aldehydes but more phenolic components and a series of 2-ketones (C_8–C_{13}) and δ-octalactone. This bovid also emits moderate amounts of C_5–C_9 straight-chain fatty acids, some of which were detected in buffalo and ox only in trace amounts. However, these did not elicit significant GC-EAD responses. Waterbuck profiles from the antennae of *G. pallidipes* showed broad similarity to those from *G. m. morsitans*, although the composition of aldehydes and ketones was somewhat different, indicating species-specific difference in the detection of host odors. Certain waterbuck-specific EAG-active components, particularly the 2-ketones and lactone, constitute a candidate allomonal blend in waterbuck odor.

Key Words—*Glossina morsitans morsitans*, *G. pallidipes*, tsetse, buffalo, ox, waterbuck, host preferences, repellents, attractants, allomonal barrier.

INTRODUCTION

Blood-meal analyses of different species of tsetse flies (*Glossina* spp.) have shown varying degrees of specialization on specific groups of vertebrate hosts (Weitz, 1963; Vale, 1974a; Turner, 1987; Snow et al., 1988: Moloo, 1993; Clausen et al., 1998). For example, in the Luangwa valley of Zambia, *Glossina morsitans morsitans* and *G. m. centralis* derive over 90% of their blood meals from warthog (*Pharcochoerus aethiopicus*), hippopotamus (*Hippopotamus amphibius*), bushpig (*Potamochoerus porcus*), cattle (*B. indicus*), bushbuck (*Tragelaphus scriptus*), elephant (*Loxodonta africana*), and buffalo (*S. caffer*); other mammals in the area such as black rhinoceros (*Diceros bicornis*), zebra (*Equus burchelli*), giraffe (*Giraffa camelopardalis*), waterbuck (*K. defassa*), hartebeest (*Alcelaphus buselaphus*), and impala (*Aepyceros melampus*) are rarely fed on (Clausen et al., 1998). Similarly, in Lambwe Valley, Kenya, where *G. pallidipes* is the dominant species, over 80% of feeding is on bushbuck, buffalo, and bushpig, but none occurs on common game such as oribi (*Ourebia ourebia*), impala, waterbuck, reedbuck (*Redunca redunca*), and hartebeest (Turner, 1987). Vale (1974b) observed that very few *G. m. morstans* land and engorge on impala compared to ox, bushpig, and warthog. Similarly, in enclosures with ox, buffalo, eland (*Taurotragus oryx*), oryx (*Oryx beisa*), and waterbuck, *G. pallidipes* preferred to alight and engorge on buffalo or ox, followed by eland and oryx; few flies were associated with waterbuck, and none were seen to engorge (Grootenhuis, 1986; Grootenhuis and Olubayo, 1993).

Tsetse flies locate potential hosts beyond their visual range upwind (60–120 m) through odor-mediated anemotaxis, with visual cues becoming important at close range (≈10 m) (Vale, 1974b, 1977; Gibson and Torr, 1999). Near or on a host, thermal, tactile, and short-range or contact chemical stimuli induce a sequence of behaviors, including landing, probing, and feeding, which may contribute to host acceptability (Reinouts van Haga and Mitchell, 1975; Packer and Warnes, 1991; Van der Goes van Naters et al., 1998; Gikonyo et al., 2000). Some of the long-range kairomone components used by savanna tsetse fly species to locate their hosts are known. They include breath constituents, such as carbon dioxide, acetone, and 1-octen-3-ol (Hall et al., 1984; Vale and Hall, 1985), and phenolic microbial breakdown products (particularly, 4-cresol and 3-*n*-propylphenol) of host skin secretions and urine (Hassanali et al., 1986; Owaga et al., 1988; Bursell et al., 1988; Vale et al., 1988; Warnes, 1990; Saini et al., 1993). Different combinations of these attractants have been successfully deployed in the development of bait technologies for the control of *G. pallidipes* and *G. m. morsitans* (Vale et al., 1988; Brightwell et al., 1991; Willemse, 1991).

Madubunyi et al. (1996) found no significant differences in the phenolic composition and attractiveness to tsetse flies of urine samples derived from waterbuck, buffalo, and cattle. Therefore, Gikonyo et al. (2000) hypothesized that in nonpreferred vertebrates, key skin-derived kairomone components may be absent (or present in suboptimal amounts) or allomones may be present. Their observations of the responses of caged teneral *G. m. morsitans* on waterbuck and ox and on feeding membranes with and without smears of waterbuck sebum suggested the presence of both volatile and nonvolatile allomones on waterbuck skin. Our objective was to determine if the odor composition, particularly the GC-EAD profile, of waterbuck with respect to *G. m. morsitans* differs significantly from those of buffalo and ox. In addition, we compared the GC-EAD profiles of *G. m. morsitans* and *G. pallidipes* with respect to waterbuck odor.

METHODS AND MATERIALS

Host Animals. Waterbucks and buffaloes were born and reared at the Wildlife Disease Research Center, Kenya Agricultural Research Institute, Kabete, in an area free of tsetse flies. They were maintained on hay and concentrates (livestock feed pellets) and grazed freely within pens. Oxen were kept within pens at the International Centre of Insect Physiology and Ecology (ICIPE), Nairobi, and fed on hay and concentrates. The animals were maintained free of acaricides for more than one year.

Insects. G. m. morsitans and *G. pallidipes* were reared at the ICIPE insectary under a 12L:12D photoperiod, $25 \pm 2^{\circ}$C, $70 \pm 5\%$ relative humidity, and fed off rabbits' ears. *G. pallidipes* was also caught from the wild at Nguruman, southwest Kenya and maintained as above.

Odor Trapping. This was carried out conveniently with adsorbent sachets placed on the animals. Activated charcoal (350 mg, 80/100 mesh, Chrompack) and octadecyl bonded silica (450 mg, particle size 40 μm, J. T. Baker, Phillipsburg, New Jersey, USA), Soxhlet-cleaned with dichloromethane for 24 hr, and then dried at 40°C, were enclosed in sachets (4×4 cm) made of either filter paper (Whatman No. 1) or stainless steel mesh-wire sheet (250 mesh) folded from larger pieces (5×10 cm) and stapled securely together. Twenty such sachets were placed along mesh belts (8×41 or 126 cm) made from strips of the stainless steel mesh-wire sheet folded lengthwise in the middle (Figure 1). A strip of clean aluminum foil formed the outer part of the belt. Adsorbent sachets were arranged at intervals above the wire mesh along the inside of the belt, which was hemmed and stapled tightly on one side. The sachets were, thus, exposed to air on the inner side, and sealed by the aluminum foil on the other. The two ends of the belt (about 5 cm) were folded and stapled to provide a loop through which sisal twine (also Soxhlet cleaned with dichloromethane) would pass for tying the belt around an animal (Figure 2). The belts containing the sachets were Soxhlet cleaned with

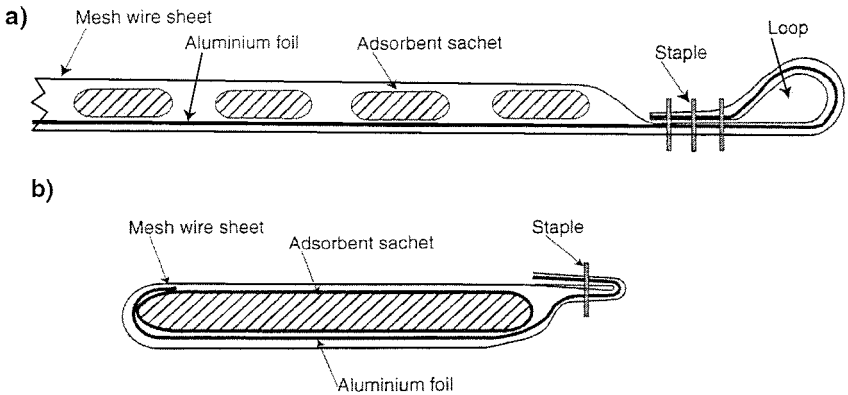

FIG. 1. Longitudinal (a) and cross-sectional (b) representation of adsorbent belt.

dichloromethane for 24 hr and then dried overnight at 40°C in a clean oven. The belts were transported wrapped lengthwise in aluminum foil and immediately tied around the neck and belly near the front and hind legs of animals restrained in a metallic crush (Figure 2). The belted animals were then released into pens to feed freely for the rest of the day. Because buffaloes tended to remove the belts tied round their bellies, only neck belts were used on them. All trapping was done from ca. 10:00–17:00 hr on sunny days when the average temperature was 26 ± 2°C and the relative humidity 40 ± 5%. Control belts were exposed to the air ambient around the crush for the same time taken to tie a single belt around an animal. After

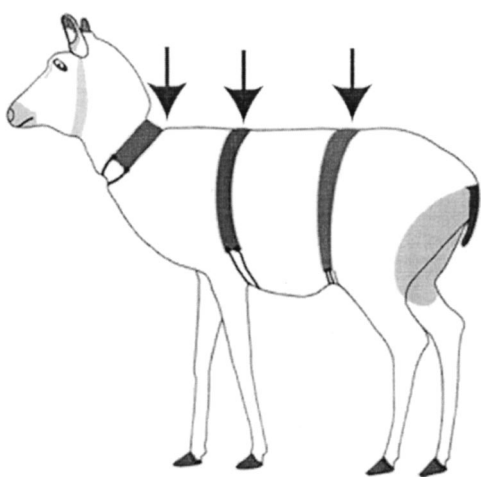

FIG. 2. Locations (arrows) of adsorbent belts on waterbuck.

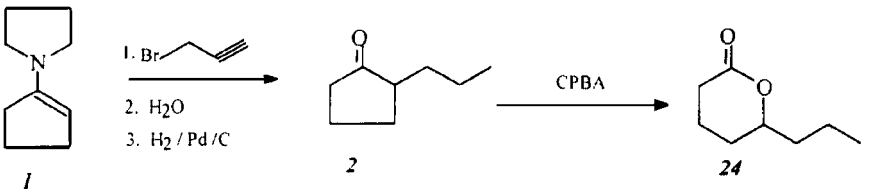

trapping, the animals were herded into the crush, and the belts removed, wrapped in clean aluminum foil, placed in a cool box, transported to the laboratory, and stored at −20°C.

Adsorbent from two sachets was pooled and eluted with 1 ml redistilled dichloromethane (over 99.9%; GC). The eluent was collected in a clean 4-ml vial, concentrated in ice under a gentle stream of clean nitrogen to 20 μl, and stored at −20°C.

Chemical Analyses. Gas chromatographic (GC) analyses were carried out on a Hewlett Packard (HP) model 5890 Series II gas chromatograph equipped with a splitless capillary injector system, a flame ionization detector (FID), and an HP 3396 Series II integrator. The GC oven was fitted with an HP fused silica capillary column (50 m × 0.2 mm × 0.33 μm) and temperature programmed at 40°C for 15 min, 8°C/min to 280°C, and held for 15 min. GC-MS analyses were carried out on a VG Masslab 12-250 mass spectrometer (EI, 70 eV) coupled to an HP 5790 Series A gas chromatograph, which was operated under the same conditions as the GC analyses. The synthetic standard chemicals were purchased from Aldrich Chemicals.

Electroantennographic Analyses (GC-EAD). Antennae were prepared from 3-day old adult female laboratory-reared *G. m. morsitans* and from laboratory-reared and field-trapped *G. pallidipes*. All flies had been fed two days earlier. A fly was held with fine forceps under a dissecting microscope and one of the antennae was gently pulled off with another forceps. The antenna was then cut with a scalpel at the base of the third broad segment into which a glass micropipet containing tsetse saline (Gee, 1976) was inserted. The micropipet with the antennal preparation was sheathed over a silver wire (0.5 mm diam) recording electrode on one arm of a micromanipulator (Syntech). The indifferent electrode was a similar glass micropipet, sheathed over a similar silver wire held on the other arm of the micromanipulator, and grounded through a wire. To complete the circuitry, the tip of the micropipet on the indifferent electrode was gently but firmly positioned on the intact end of the antennal preparation. The recording electrode was connected via a probe to a Universal AC/DC UN 05 amplifier (Syntech) and to a computer (PC) with an EAD card. The micromanipulator was positioned such that the antennal preparation was directly in the path of the effluent from the opening of the stimulus delivery tube connected to the GC.

GC-EAD was performed on an HP model 5890 Series II gas chromatograph equipped with an FID and an HP 3396 Series II integrator, and a splitter. The same conditions were employed as in the GC analyses. A makeup gas with a flow rate of 40 ml/min was added just before the split point to accelerate the effluent through 50-cm deactivated fused silica columns. The effluents for antennal detection were driven through a transfer line maintained at 150°C (Syntech THC-3) into a moistened air stream (25°C, 90% relative humidity, 4.0 ml/sec) and delivered over the antennal preparation via a stainless steel tube (5 mm ID). FID and EAD

SCHEME 1.

signals were monitored synchronously using a program on a GC-EAD interface card (Syntech) installed in a PC. Recordings were obtained from at least three antennae for each stimulus. EAG-active compounds were initially identified from their mass spectra and then confirmed by coinjections of authentic compounds and trapped odors into GC, GC-EAD runs on *G. m. morsitans* or *G. pallidipes*, and GC-MS comparisons.

Synthesis. δ-Octalactone (**24**), identified from waterbuck volatiles was prepared according to Scheme 1, adopted from Fieser and Fieser (1967) and Furniss et al. (1991). 1-Pyrrolidino-1-cyclopentene (**1**) was allowed to react with propargylbromide in acetonitrile, and the resulting 2-propylcyclopentanone (**2**) was converted to the lactone using *m*-chloroperbenzoic acid (CPBA). The structure of δ-octalactone (**24**) was confirmed by MS, ^{1}H and ^{13}C NMR spectra. The synthetic product (an enantiomeric blend) was EAG-active on both *G. m. morsitans* and *G. pallidipes* and coeluted in GC with the target peak in the waterbuck odor.

RESULTS

Odor Trapping and Composition. GC analysis of odor trapped from waterbuck body surface showed that activated charcoal and reverse-phase silica were equally effective, although the relative proportions of some peaks were different. Subsequent trapping employed reversed-phase silica. The GC profiles from the three body regions (Figure 2) were comparable. Odor profiles of volatiles from three different waterbucks were also similar and did not change significantly during a four-year period. Apart from some quantitative differences, odor profiles of buffalo and ox during the study period were also comparable.

GC-EAD Analyses. Fourteen EAG-active constituents on *G. m. morsitans* were detected in the reversed-phase silica- and activated charcoal-trapped volatiles from the waterbuck (Figure 3, Table 1). The antennae of insectary-reared *G. pallidipes* did not respond to any waterbuck odor constituents, but field-trapped *G. pallidipes* yielded 13 EAG-active peaks (Table 1). Eleven and 10 EAG-active constituents were detected by antennae of *G. m. morsitans* in (reversed-phase silica-trapped) volatiles of buffalo and ox, respectively (Figure 3, Table 1).

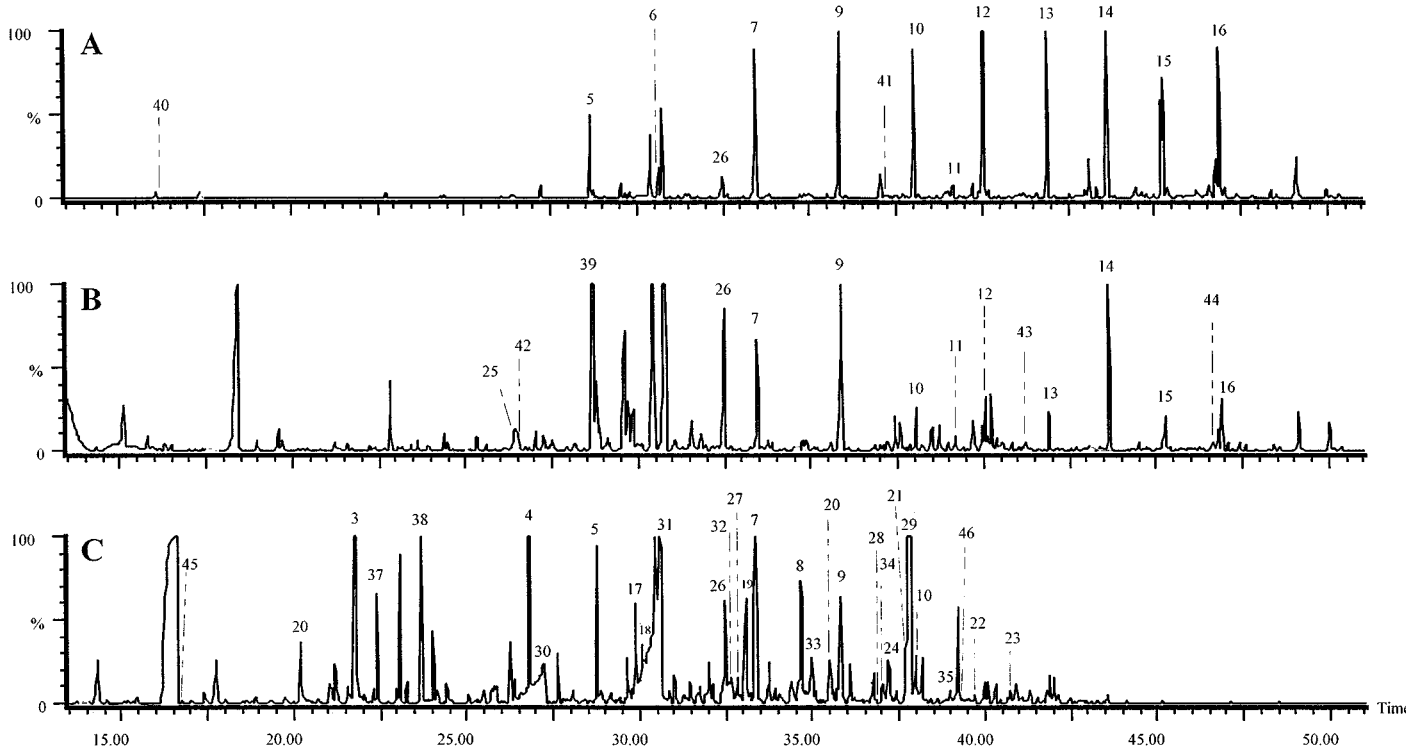

FIG. 3. Gas chromatograms of body odors from: buffalo (A), ox (B), and waterbuck (C). Numbered peaks refer to compounds in Table 1.

Characterization of Waterbuck Odor. The 14 EAG *(G. m. morsitans)* active components of waterbuck odor (Figure 3A, Table 1) were identified by GC-MS, comparison of their mass spectral data with library data (NIST Registry of Mass Spectral Data), and GC coinjections as: **5**, (*E*)-2-heptenal, *m/z* (%) at 112 (4), 105 (6), 97 (8), 83 (66), 70 (36), 69 (35), 68 (33), 57 (51), 56 (46), 55 (68), 43 (35), 41 (100), 39 (52); **7**, nonanal; **9**, decanal; **10**, undecanal; **18**, 2-octanone; **19**, 2-nonanone; **20**, 2-decanone; **21**, 2-undecanone; **22**, 2-dodecanone; **23**, (*E*)-6,10-dimethyl-5,9-undecadien-2-one, 194 (0.4), 176 (1), 161 (1), 151 (10), 136 (10), 125 (6), 107 (12), 93 (7), 69 (46), 53 (6), 43 (100), 41 (35), 39 (7); **24**, δ-octalactone, 142 (1), 124 (5), 114 (12), 100 (8), 99 (100), 96 (9), 85 (6), 71 (73), 70 (55), 56 (40), 55 (68), 43 (57), 42 (75), 39 (26); **26**, 4-methylphenol, 108 (81), 107 (100), 90 (9), 79 (22), 77 (27), 63 (5), 53 (11), 51 (12), 39 (13); **28**, 3-*n*-propylphenol 136 (38), 121 (16), 108 (37), 107 (100), 91 (6), 77 (23), 65 (5), 51 (7), 39 (11); and **29**, 3-isopropyl-6-methylphenol, 150 (41), 136 (12), 135 (100), 121 (4), 115 (10), 107 (13), 91 (21), 77 (11), 65 (5), 51 (6), 41 (5), 39 (6). Of the 13 components active on *G. pallidipes*, 11 were similarly identified as: **5**, (*E*)-2-heptenal; **7**, nonanal; **8**, (*E*)-2-nonenal, 122 (5), 111 (9), 98 (19), 97 (16), 84 (32), 83 (66), 70 (85), 69 (56), 67 (23), 57 (55), 55 (92), 43 (93), 41 (100), 39 (52); **9**, decanal; **18**, 2-octanone; **19**, 2-nonanone; **23**, (*E*)-6,10-dimethyl-5,9-undecadien-2-one; **24**, δ-octalactone; **26**, 4-methylphenol; **27**, 2-methoxyphenol, 124 (85), 109 (100), 95 (2), 81 (65), 65 (7), 63 (7), 53 (22) 39 (11); and **28**, 3-*n*-propylphenol. Two minor components, **45** and **46**, active on *G. pallidipes*, which overlapped with other compounds, could not be identified. Additional EAG-inactive waterbuck odor components identified by GC-MS and comparisons with library mass spectra are listed in Table 1.

Characterization of Buffalo and Ox Odors. Nine of the 11 constituents of buffalo odor active on *G. m. morsitans* were identified and authenticated as: **5**, (*E*)-2-heptenal; **6**, octanal; **7**, nonanal; **9**, decanal; **10**, undecanal; **11**, (*E*)-2-undecenal, 165 (0.01), 147 (0.02), 121 (2), 97 (6), 83 (12), 70 (23), 57 (34), 55 (45), 43 (52), 41 (100), 39 (46); **12**, dodecanal; **26**, 4-methylphenol; and **28**, 3-*n*-propylphenol. Seven of the 10 active compounds from ox odor, on *G. m. morsitans*, were identified and authenticated as: **7**, nonanal; **9**, decanal; **10**, undecanal; **11**, (*E*)-2-undecenal; **12**, dodecanal; **26**, 4-methylphenol; and **28**, 3-*n*-propylphenol. The structures of five other minor components, **40** and **41** from the buffalo odor, and **42**, **43**, and **44** from ox odor, active on *G. m. morsitans*, could not be characterized because of coelution with other compounds. EAG-inactive components, prominent in the buffalo and ox odor collections, were also identified by GC-MS and comparisons with library spectra (Table 1).

DISCUSSION

The results of Gikonyo et al. (2000) on the behavior of teneral *G. m. morsitans* in small experimental cages on waterbuck and ox, and on feeding membranes with

and without smears of waterbuck sebum suggested the presence of volatile and short-range or contact allomones on waterbuck. Our results provide a chemical basis for discrimination between volatiles of waterbuck and those of buffalo and ox by tsetse flies. Of the known tsetse fly attractants (Hassanali et al., 1986; Owaga et al., 1988; Bursell et al., 1988), 4-methylphenol and 3-*n*-propylphenol were common to all the three bovids, albeit in varying relative amounts. Previously, these compounds were also found in the fermented urine of these animals (Madubunyi et al., 1996). In addition, different numbers of EAG-active, medium-chain (C_7–C_{11}) aldehydes were present in the odor of these animals. A notable difference in the GC-EAD profiles is the presence of δ-octalactone, 2-methoxyphenol (guaiacol), 3-isopropyl-6-methylphenol, and a series of (C_8–C_{13}) methyl ketones in waterbuck odor that were either not detected or present in trace amounts in the two preferred hosts. Guaiacol is moderately repellent to tsetse flies (Vale et al., 1988; Torr et al., 1996). Although we found only trace amounts (GC-EAD) of guaiacol in buffalo and ox volatiles, as did Bursell et al. (1988) and Torr et al. (1996), its amount was four times higher than 3-*n*-propylphenol in the waterbuck odor. A number of medium-chain 2-ketones are repellent or toxic to different insects, e.g., the maize weevil *Sitophilus zeamais* (Lwande et al., 1992), ants and termites (McDowell et al., 1988), and beet armyworm *Spodoptera exigua* (Lin et al., 1987). In field studies, several C_6 and C_7 methyl ketones reduced tsetse fly catches on electric nets, although some of the lower homologs (C_3–C_4) were attractive (Vale, 1980). The ketones in waterbuck odor together with guaiacol and the other two EAG-active constituents, acting additively or synergistically, could potentially constitute a long-range allomonal barrier. We are currently evaluating blends of these compounds for repellency.

Another distinctive feature in the odor chemistry of waterbuck compared to that of buffalo and ox is the presence of moderate amounts of C_5–C_9 straight-chain fatty acids. These, together with isopropyl-6-methylphenol, impart the cloying, musky smell of waterbucks (Estes, 1991; Mihok et al., 1991), which may also deter predators such as lion, leopard, and hunting dogs (Haltenorth and Diller, 1996). In our GC-EAD runs, none of the fatty acids elicited a discernible EAG response. Paradoxically, some of these acids reduced tsetse fly trap catches in the field (Vale, 1980), as did pentanoic and hexanoic acids (Torr et al., 1996). When added to targets baited with either a blend of known tsetse fly attractants or natural ox odor, pentanoic acid had no effect on the number of flies attracted, but did have a close-range effect on reduced trap entry. It also caused a small but significant reduction in feeding efficiency on the host (Torr et al., 1996). How then do we reconcile the effect of these compounds on tsetse behavior in these studies and lack of responses in our GC-EAD runs? Several possibilities exist. In the relative amounts present on the animal, the acids may not be behaviorally relevant to the fly, and the field results may represent an artifact resulting from relatively high doses used. On the other hand, a different set of receptors in the fly, perhaps located

in the tarsi, may be involved. Alternatively, the C_5–C_9 acids may act additively or in concert at the antennal receptors that results in an escape behavior closer to the animal where higher relative amounts of the longer chain homologs may be present. We are currently examining the validity of these alternatives.

The occurrence of a different combination of EAG-active aldehydes in waterbuck volatiles, compared to similar blends in the two preferred hosts, suggests a possible role for these compounds. Vale (1980) screened individual C_1–C_7 aldehydes in the field and found none to be reproducibly attractive. However, these compounds have not been tested in host-specific blends. Indeed, natural ox odor is 1.5–2 times more attractive than combinations of presently recognized attractants (carbon dioxide, phenols, and C_3–C_4 ketones) delivered at rates comparable to those emitted by ox (Torr et al., 1996), suggesting yet unidentified attractive constituents.

The GC-EAD profiles of waterbuck odor with *G. m. morsitans* and *G. pallidipes* antenna show that these related savanna species do not respond electrophysiologically to the same set of odor components. Although both species responded to (*E*)-2-heptenal, nonanal, and decanal, only *G. m. morsitans* responded to undecanal, and only *G. pallidipes* to (*E*)-2-nonenal. Moreover, *G. m. morsitans* responded to six 2-ketone odor components, only three of which elicited responses from *G. pallidipes*. Likewise, *G. pallidipes* was insensitive to 3-isopropyl-6-methylphenol, which elicited a distinct response from *G. m. morsitans.* These results indicate the olfactory uniqueness of each species and may partly account for the observed gradation of preferences for particular hosts. For instance, although waterbuck is generally avoided by *Glossina* species, it is comparatively more often fed on by *G. pallidipes* than *G. m. morsitans*. Interestingly, the former detected fewer 2-ketones in the present study.

Acknowledgments—We thank George Orinda of Kenya Agricultural Research Institute (Wildlife Disease Research Project) and his staff for maintaining the waterbucks and buffaloes. We are grateful to Onesmus Kaye, James Mbayi, and the late Willis Ouma for technical assistance. This research was funded by the European Union (EU) and German Academic Exchange Service (DAAD) through ICIPE to whom we are most grateful.

Abstract—Dietary leaf litter chemistry is known to play an important ecotoxicological role in the plant–mosquito interaction in subalpine flooded areas surrounded by vegetation because of differential larvicidal effects of insoluble polyphenols formed during the leaf decaying process. This dietary interaction was investigated through comparative evaluation of the role of toxic/nontoxic leaf litter in both larval foraging and feeding behavior, by using different samples of decomposed alder leaf litter and larval *Aedes aegypti* as experimental references. Track analysis showed significant differences in larval foraging behavior in the absence or presence of leaf litter. Comparative alimentary preference investigations and further track analysis suggested that larvae are unable to detect leaf litter toxicity. These characteristics of the larval behavioral feeding pattern suggested that: (1) decomposed leaf litter may be involved as an important attractive food source in the habitat selection and evolutionary history of culicids, and (2) preingestive behavioral mechanisms appear to be minimally involved in the differential larval dietary adaptation to toxic leaf litter. These results may have interesting consequences for culicid biological control.

Key Words—Feeding behavior, track analysis, dietary preferences, alder leaf litter, larvicidal activity, resistance, *Aedes aegypti*.

INTRODUCTION

The ability of phytophagous insects to tolerate plant secondary compounds is an important determinant of both ecological and evolutionary patterns in many terrestrial taxa (reviewed in Bernays and Chapman, 1994). These xenobiotics may act at two different steps in plant–insect dietary interactions. Before ingestion, they may act as deterrents, thus contributing to behavioral resistance (reviewed in Glendinning and Slansky, 1995; Bernays et al., 2000). After ingestion, they may induce digestive detoxification processes (Brattsten, 1992), thus allowing biochemical resistance. Polyphenols are among those vegetable xenobiotics that can act through either inhibition of feeding (reviewed in Appel, 1993) or direct toxicity against the midgut (reviewed in Barbehenn and Martin, 1994).

In subalpine mosquito breeding sites, polyphenols of dietary leaf litter originating from riparian vegetation were demonstrated to be involved in habitat choice (Rey et al., 2000) and evolutionary history (Rey et al., 2001a) of the detritivorous larval culicid fauna. Habitat selection among taxa and/or populations appeared to be the result of toxicity of these polyphenols versus the differential tolerance of the consumers to those dietary xenobiotics (David et al., 2000a; Meyran et al., 2002). The toxicity of leaf litter was effective after a complex 10-month decaying process in water, and correlated to the phenolic activity of an extractable cell wall fraction including ligninlike compounds (David et al., 2000b, 2001a). Ingested toxic leaf litter exerted deleterious effects on the midgut of larval mosquitoes (David et al., 2000a) and other larval Diptera (Rey et al., 1999a). The epithelial degenerative pattern was comparable to that generally described in the insect midgut in response to toxic dietary xenobiotics (e.g., vegetable polyphenols: reviewed in Steinly and Berenbaum, 1985; bacterio-insecticides: reviewed in Rey et al., 1998). Such acute larvicidal effects of dietary decomposed leaf litter may be used for a new insecticide strategy against anthropophilic, vector-competent, invasive culicid taxa (Rey et al., 2001b).

Comparative investigations among taxa and populations originating from vegetable environments with different polyphenol richness have revealed the involvement of biochemical mechanisms in the differential tolerance of culicid fauna to decomposed leaf litter. The ability of larvae to metabolize those dietary xenobiotics was correlated to levels of cytochrome P-450 monooxygenases (P-450) and esterases (David et al., 2000c, 2002).

Because leaf litter ingestion remains the starting point of this particular plant–mosquito chemical interaction, larval *Aedes* feeding behavior toward leaf litter was investigated in the current study. Our aim was to comparatively evaluate the role of decomposed toxic/nontoxic leaf litter in larval feeding behavior. This experimental approach will allow us to clarify whether behavioral factors may be involved in larval tolerance to toxic leaf litter.

METHODS AND MATERIALS

Insect and Plant Materials. The *Aedes*–alder (*Alnus glutinosa* (L.) Gaertn.) interaction was chosen as a reference for our investigations because of the predominance of this culicid genus in subalpine mosquito-breeding sites (Rey et al., 2000) surrounded by a canopy dominated by alder (Pautou and Girel, 2001). For convenience and to avoid variability inherent in field *Aedes* populations, experimentation was performed on a laboratory strain of *A. aegypti* L. raised under standard conditions (Rey et al., 1999b). Despite its tropical origin, *A. aegypti* is known to have a feeding mode and a dietary tolerance to alder leaf litter comparable to those of numerous subalpine *Aedes* taxa (David et al., 2000a; Chaton et al., 2001). Fourth-instars of equal size were used either after starvation for 20 hr in order to increase ingestion rate during feeding trials (Rashed and Mulla, 1989), or without starving.

Samples of alder leaf litter, taken from the same woodland submitted to periodic flooding in the Rhône-Alpes region (France) and known to have different toxicity levels (David et al., 2000b, 2001a), were assayed. Crude 10-month decomposed leaf litter, known to be toxic ($LD_{50} = 0.1$ g/liter) (David et al., 2000b) was used as the toxic sample. Two types of nontoxic samples were used: (1) crude one-month decomposed leaf litter, in which toxic polyphenols had not yet formed, and (2) autoclaved crude 10-month decomposed leaf litter, in which toxic polyphenols had been destroyed by heat (David et al., 2001a). In the preference bioassays, toxic and nontoxic samples were used with a fine texture (50–100 μm) obtained according to the technique of David et al. (2000b), except for one trial where toxic samples were used either with a coarse texture (>0.5 mm) or with a fine texture. In the track analysis experiments, fine leaf-litter suspensions, obtained by filtration of 500 mg crude leaf litter in 200 ml tap water, were used in order to increase video tracking quality.

Video Observation of Larval Feeding Behavior. To analyze their feeding behavior in the presence of leaf litter, 20 larvae were individually videotaped while feeding. Each larva was placed in a round glass dish (4 cm diameter) containing 2 ml of filtered tap water and a freshly cut 2-mm^2 piece of 10-month decomposed alder leaf litter. Each larva was allowed to acclimate for 5 min and then filmed for 5–30 min using a video camera (Canon EX1, 100-mm objective, macro mode). Images were recorded on a JVC SX120 videocassette and viewed on a Sony color monitor. After tape analysis, representative pictures of larval feeding behavior were selected using a video acquisition computer card and converted into black and white images.

Track Analysis. Because feeding by mosquito larvae requires ingestion processes and whole-body movements (reviewed in Merritt et al., 1992a,b), a track analysis of larval foraging behavior was performed on individual larvae placed into round glass dishes (18.6 cm diameter) containing 100 ml of filtered tap water

or filtrate of leaf-litter (i.e., toxic or nontoxic leaf litter sample). To avoid larval lighting disturbance (Olsson and Klowden, 1998), a 50-cm-high cylindrical sheet of white paper was put around the dish during experiments. Each larva was allowed to acclimate for 5 min in tap water, and then filmed for 1–5 min, depending on the number of recorded paths (1–5 paths/larva). The same larva was then transferred to leaf litter filtrate (toxic or nontoxic alternately) and filmed as previously described. All experiments were carried out under insectarium conditions and with constant white light, using a RCA black and white camera fitted out with a 35–200 objective mounted with a C-type adaptation ring. The paths followed by each larva were then analyzed with a SECAM acquisition video card and computed with Cible4 tracking and Harmony analysis software. Paths were automatically smoothed (average of five successive points) and all coordinates (25 frames/sec) were used.

Larval track was characterized by the linear speed (millimeters per second, excluding stop duration), the number of stops (per second), and the angular index (bearing variations along paths in degrees per second). Results were expressed as means (± standard deviation). Statistical analyses were done with Minitab sofware. Comparisons between absence/presence of leaf litter were obtained by paired data *t* test ($N > 75$, $df = N - 1$) because larvae were successively placed in two different situations (e.g., tap water and leaf litter filtrate). Comparisons between toxic/nontoxic leaf litter were obtained by a two-sample *t* test ($N_1 + N_2 > 75$, $df = (N_1 + N_2) - 2$) because different larvae were used for comparisons.

Dietary Preference Bioassays. Two hours before each bioassay, two homogeneous sets of 50 larvae were differently colored *in vivo* by using two alimentary dyes (E-122 for red, E-102 and E-131 for green) diluted in tap water. A clear Plexiglas container (35 × 24 × 13 cm), divided into two equal compartments by a sliding polystyrene divider (Figure 1) and containing 6500 ml of tap water, was allowed to stand for 30 min under insectarium conditions to equilibrate at 25°C. In order to prevent larvae from being attracted to dark substrates (see references in Clements, 1999) and from behavioral disturbance due to lighting effects (Olsson

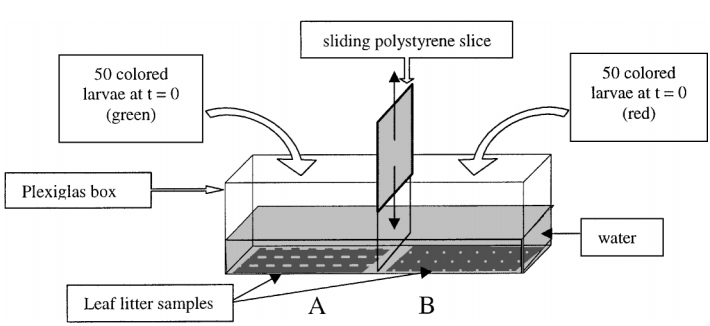

FIG. 1. Test arena for dietary preference bioassays.

and Klowden, 1998), a black sheet of paper was put under the Plexiglas box and a white one above the box. The effects of leaf-litter quality were compared by covering the floor of half the container with a toxic sample and the other half with a nontoxic sample (100 mg/assay) 10 min before introducing each set of 50 colored larvae into each compartment (Figure 1).

After allowing the larvae to disperse and equilibrate for 5 min in each compartment, the central polystyrene divider was pulled up, allowing the larvae to spread throughout the entire volume of water for 30 min. The central polystyrene divider was pulled down before identifying and counting the larval sets newly distributed into each compartment. Each assay was replicated three times.

Results were expressed as the percentage of total larvae present in the test arena (means ± SD). Statistical comparisons (one-way ANOVA) of the percentage of total larvae (without any distinction) present in each compartment after 30 min were made with Minitab software for each experiment.

RESULTS

Larval Leaf-Litter Feeding Behavior. Video observations of feeding larvae support the concept of arrestment in their food search strategy (Clements, 1999), as larvae randomly explore the aqueous environment before stopping at a leaf-litter piece which is recognized as a favorable food item. Moreover, the role of leaf litter as a direct food source is clearly demonstrated as larvae can be observed feeding directly on the leaf litter itself (Figure 2).

All observations show that larvae have a browsing feeding mode according to the terminology of Merritt et al. (1992a,b), and spend much time in shredding the

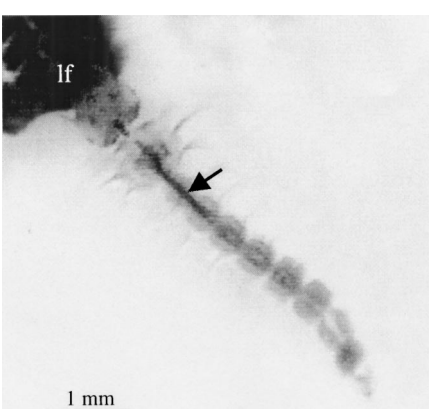

FIG. 2. *A. aegypti* larva browsing a piece of decomposed alder leaf litter (lf). Ingested leaf litter (arrow) is easily observable by transparency in the larval midgut.

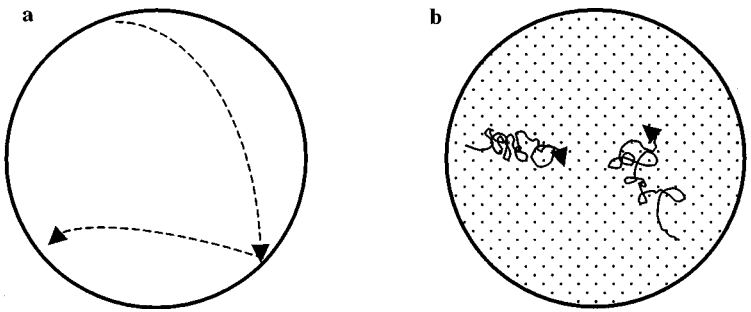

FIG. 3. Differences in larval *A. aegypti* track shapes in relation to food availability. Extensive search behavior, characterized by straight paths and high speeds are observed in filtered tap water (a), whereas intensive search behavior, expressed by curved paths associated with a slow gliding movement, can be observed in high food availability environment (b).

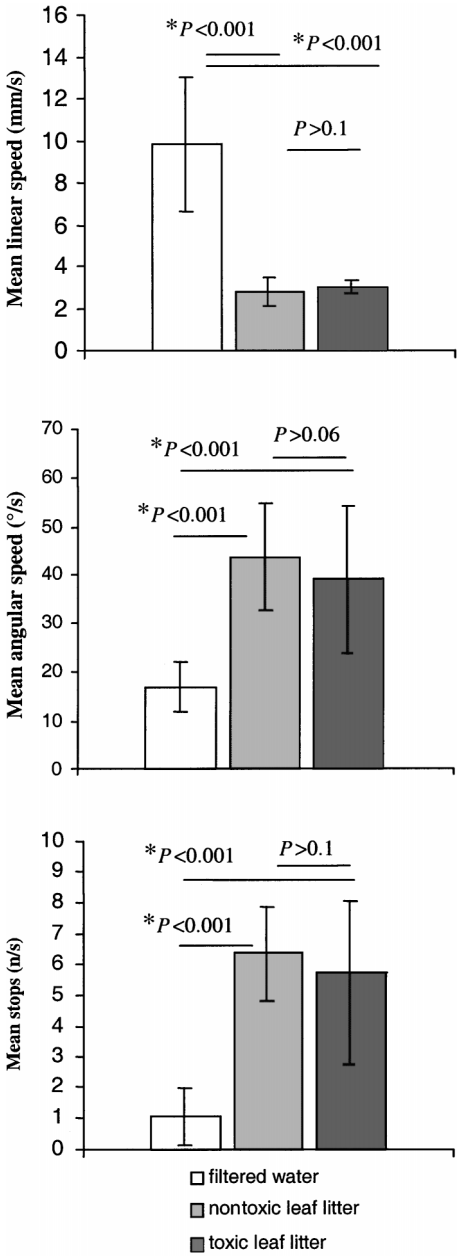
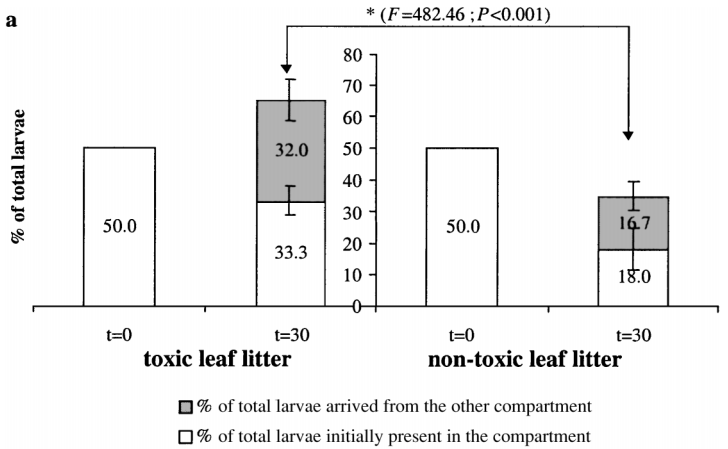
leaf litter piece. In the same way, because of the dark color of this food source, leaf-litter ingestion into the larval gut can be directly visualized through the larval body after 15 min of feeding (Figure 2). No postingestive regurgitation mechanisms, such as those reported for some larval Lepidoptera (Bernays et al., 1995), have ever been observed on leaf-litter feeding *Aedes* larvae.

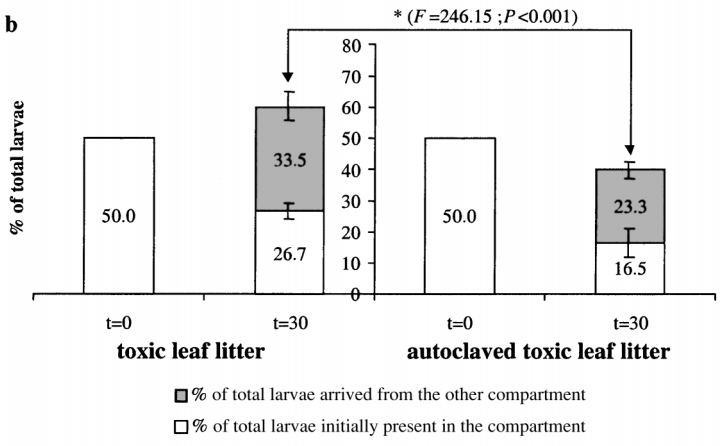
Track Analysis. As shown in Figures 3 and 4, track analysis results reveal differential larval behavior in relation to environmental food availability. Without any food source (i.e., in filtered tap water), larvae show straight trajectories (Figure 3a) with a high average linear speed, low number of stops per second, and low rate of turning (Figure 4). During this extensive search behavior, larvae increase their linear speed and to explore a maximum area. This rapid progression is powered by the whole abdomen together with the respiratory siphon and the ventral terminal brush.

The same larvae then placed in an environment of high food availability (i.e., in rough leaf litter filtrates) show an instantaneous change in their behavioral characteristics. Trajectory shapes become very curved (Figure 3b) with a low linear average speed associated with high angular speed and high number of stops per second (Figure 4). During this intensive search-behavior, larvae optimize their ingestion rate as their mouthparts generate the currents propelling them. These currents (called α currents; Widahl, 1992) allow larvae to glide while gathering alimentary particles. The trajectory characteristics of this behavioral pattern are not different in the presence of toxic or nontoxic leaf litter ($P > 0.1$, $P > 0.06$ and $P > 0.1$ for average linear speed, average angular speed, and average number of stops respectively: Figure 4).

Dietary Preferences. Toxic leaf litter appears to be preferred to nontoxic litter by larvae, either when starving them first (data not shown) or not (Figure 5).







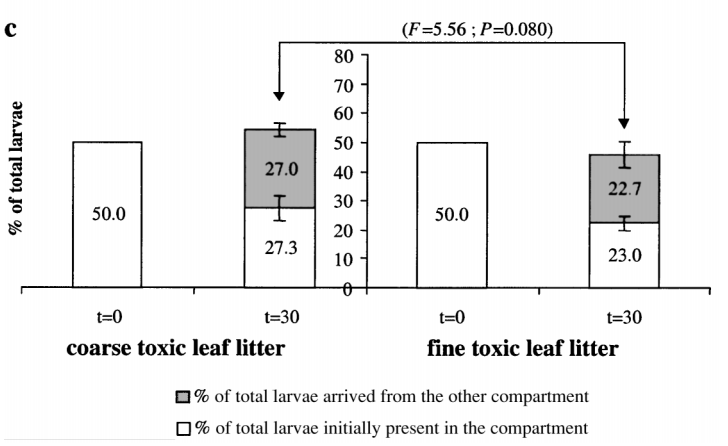


FIG. 4. Comparison of larval *A. aegypti* track characteristics in the absence of leaf litter (filtered water) and in filtrates of toxic and nontoxic leaf litter (mean ± SE). *P* values are given for all comparisons, $N > 75$, $df = -1$ or $(N + N_2) - 2$ for paired data *t* test and two-sample *t* test, respectively.

This was first demonstrated by the larval preference for crude 10-month decomposed leaf litter (i.e., including toxic polyphenols and with low mechanical resistance) versus crude one-month decomposed leaf litter (i.e., including no toxic polyphenols and with high mechanical resistance) (Figure 5a). In this case, more than 65% of total larvae were found in the toxic leaf litter compartment after 30 min of experiment. Moreover, among those 65% larvae found in the toxic leaf litter compartment, 32% were moving larvae originating from the nontoxic compartment, and 33.3% were arresting larvae originating from the toxic compartment.

Such a preference for toxic substrate was also found in the choice test between crude 10-month decomposed leaf litter (i.e., including toxic polyphenols and with low mechanical resistance) versus autoclaved 10-month decomposed leaf litter (i.e., where heat treatment destroyed toxic polyphenols and increased mechanical resistance) (Figure 5b). Thus, larval preference for toxic leaf litter appears to be related to its physical quality (i.e., related to the mechanical resistance to browsing) rather than to its chemical quality (i.e., related to the toxic polyphenol content).

Leaf-litter particle size does not seem to be a critical factor in larval dietary preferences, as coarse and fine pieces of toxic leaf litter appear to be equally attractive (Figure 5c), and both are browsed and ingested by larvae.

DISCUSSION

The current study suggests a role of leaf litter in structuring both feeding and foraging behavior of larval *Aedes* which appear unable to detect leaf-litter toxicity before ingestion. These behavioral characteristics of larval *Aedes* toward leaf litter may suggest a weak involvement of behavioral mechanisms in larval adaptation to the toxic polyphenols of dietary leaf litter. This may have important consequences in shaping the ecological and evolutionary patterns of *Aedes* populations in the subalpine mosquito breeding sites. It also reinforces the practicality of using decomposed alder leaf litter in a new larvicidal strategy.

Pattern of Leaf-Litter Feeding in Larval Aedes. Like numerous *Aedes* taxa, larval *A. aegypti* can have a browsing feeding mode focusing on a large spectrum of food sources (reviewed in Merrit et al., 1992a,b). Thus, it is not surprising that, as

←

FIG. 5. Comparison of larval *A. aegypti* dietary leaf litter preferences, obtained by larval distribution between two types of leaf litters after 30 min of experiment. Results are expressed by percentage of total larvae in each compartment (mean $\pm$ SE), between toxic (i.e., crude ten-month decomposed) and nontoxic (i.e., one-month decomposed) leaf litters (a), between toxic and nontoxic (i.e., toxic autoclaved) leaf litters (b), and between toxic leaf litter with coarse and fine granulometry (c). P and F values are given for each comparison (one-way ANOVA, $N = 3$, $^*P < 0.001$).

suggested by our trajectory results, the presence of leaf litter in the aquatic medium instantaneously generates intensive foraging behavior by larvae. Such differences in foraging behavior according to the presence/absence of food in the medium is commonly observed among larval mosquito taxa where food generally acts as an arrestant (reviewed in Clements, 1999). Alder leaf litter also may be recognized by the larvae as a phagostimulant during browsing (Chaton et al., 2001). This attests to the generalized flexible feeding strategy of *Aedes* larvae whose plasticity is shaped mainly through environmental cues of food availability (Eisenberg et al., 2000).

In subalpine *Aedes* breeding sites, the prominence of leaf litter as a food source for mosquito larvae is easily understood because of the important annual leaf input from the riparian vegetation into the water (Pautou and Girel, 2001). Leaf litter appears to be directly used as a food source by *Aedes* larvae rather than its microbial content. This is clearly shown by both our current video observations and previous histopathological investigations within the midgut (David et al., 2000a), and is consistent with that known for other culicid larvae in different lentic habitats (Léonard and Juliano, 1995).

Despite the prominent role of this food source in larval *Aedes* feeding mode, there is no behavioral evidence for immediate sensory discrimination of leaf litter toxicity by larvae, whether or not they have been starved. Such an absence of relation between food selectivity and starvation contrasts to that observed for other phytophagous insects (Bernays and Chapman, 1994). Moreover, this lack of food selectivity contrasts to that observed for other culicine taxa where feeding behaviors include chemotaxis and chemokinesis mechanisms (reviewed in Clements, 1999). Larval preference for toxic leaf litter may be due to its physical quality in relation to the degree of leaf decomposition. Together with the induction of toxicity within the leaf litter (David et al., 2000b), the decaying process may reduce the mechanical resistance of leaf material to larval browsing (Cummins and Klug, 1979), thus enhancing its edibility (Gessner, 1991). The absence of any deterrent effect of the leaf-litter toxic chemicals against larvae may be explained in two different ways: (1) the insolubility of these polyphenols in the aquatic medium (David et al., 2000b, 2001) preventing their accessibility to the larval sensory apparatus, and (2) the absence of elaborate mechanisms for larval recognition of those molecules. Thus, toxic polyphenols may contribute little to structuring the larval pattern of feeding in the leaf litter–*Aedes* interaction. This contrasts to that observed in numerous phytophagous insect–plant interactions (e.g., Orthoptera: Bernays et al., 1995; lepidopteran caterpillars: reviewed in Bernays et al., 2000) where the presence of plant secondary compounds can affect foraging activities and influence diet choice.

Ecotoxicological and Applied Consequences of Leaf-Litter Feeding Behavior. As larvae appear able to discriminate only the physical quality of the leaf litter, the involvement of behavioral mechanisms in the larval adaptation to toxic leaf

litter may be minimal. Thus, dietary adaptation to leaf-litter polyphenols may have proceeded mainly through metabolic changes. This biochemical resistance appears to be mediated by P-450 and esterase activities (Rey et al., 1999b; David et al., 2000c, 2002), which allow the larvae to tolerate toxic leaf litter after ingestion. This stands in contrast with that observed, for example, in phytophagous insects where adaptation to toxic dietary plant secondary compounds is primarily mediated at a preingestive behavioral step (reviewed in Glendinning and Slansky, 1995; Bernays et al., 2000).

Thus, in subalpine mosquito-breeding sites, the selection indirectly exerted by the riparian vegetation on larval culicine fauna through dietary leaf-litter polyphenols may have generated only postingestive adaptative responses. Because of the predominance of a polyphenolic-rich leaf litter in a given breeding site, the larvae may have no possible diet choice. Thus, the acquisition of metabolic detoxification processes may have appeared as the main way for larval tolerance to those ingested leaf-litter toxic polyphenols. Such a metabolic adaptation has been considered as the key innovation (Berenbaum et al., 1996) that may have promoted ecological diversification (David et al., 2000c) and shaped evolutionary history (Rey et al., 2001a) of mosquito taxa throughout the subalpine breeding sites surrounded by vegetation with different polyphenol richness.

The larval predilection for decomposed alder leaf litter, together with the fact that this toxic food cannot be recognized as deterrent by larvae, encourages us to propose the use of leaf litter as a new useful mosquito control agent against some anthropophilic taxa (Rey et al., 2001b). Contrary to many conventional insecticides, toxic alder leaf litter remains stable in the aquatic environment (David et al., 2000b, 2001) and is actively searched for and ingested by larvae. Further investigations are currently being performed in order to optimize this new promising larvicidal strategy.

Acknowledgments—This investigation was supported by a grant from Entente Interdépartementale pour la Démoustication (EID) Rhône-Alpes. We are thankful to C. Dahl who provided helpful comments on the manuscript and to J. Patouraux for technical assistance in dietary preference bioassays.

(Received February 5, 2001; accepted December 6, 2001)

Abstract—Phytotoxic assays, performed both *in vitro* and *in vivo* on leaves of *Phaseolus vulgaris*, with metabolites excreted by the fungus *B. cinerea* are evaluated. Exogenous application of the phytotoxin botrydial has been found to produce severe chlorosis and cell collapse and facilitated fungal penetration and colonization of plant tissue. The results also show a light-dependent action mechanism for the phytotoxin and seem to indicate that botrydial is a non-host-specific toxin involved in fungal infection of *B. cinerea*.

Key Words—Botryane, botrydial, chlorosis, phytotoxin, *Botrytis*, virulence factor.

INTRODUCTION

A substantial number of toxins, produced as mixtures of either related or unrelated substances, have been extracted from cultures of many different bacterial and fungal pathogens. In fact, the ability to produce one or more toxins and to use them as chemical weapons may be the decisive factor in the virulence of plant pathogens, and perhaps even their pathogenicity (Rudolph, 1990). A limited number of toxins, the so-called host-selective toxins, affect only plants of one specific genotype susceptible to the pathogen. At low concentrations, these toxins reproduce the symptoms of natural infections. By far, however, the majority of phytotoxins are nonselective and do not reproduce the patterns of resistance and susceptibility of

* To whom correspondence should be addressed. E-mail: isidro.gonzalez@uca.es

0098-0331/02/0500-0997/0 © 2002 Plenum Publishing Corporation

the host to the pathogen. These include all the bacterial phytotoxins described thus far and the majority of fungal toxins. Because these biologically active substances are broad-spectrum toxins that can affect many economically important crops, their total impact on agriculture has serious repercussions (Graniti, 1991).

Botrytis cinerea, the causative agent of the devastating gray mold disease in many economically important crops, produces characteristic metabolites with a botryane skeleton (Durán-Patrón et al., 1999). The role of these metabolites in the physiology of the fungus was hitherto unknown. Nevertheless, in previous work (Collado et al., 1996; Rebordinos et al., 1996; Durán-Patrón et al., 1997) we reported the phytotoxic effects of some of these compounds when they were assayed *in vitro* on leaf discs of *Nicotiana tabacum.*

Recently, the fungal metabolite botrydial was detected for the first time in plant tissues infected with isolates of *B. cinerea* (Deighton et al., 2001). The phytotoxin was produced in the soft rot regions of the infection. While it has not been ruled out that other toxins with a botryane skeleton may also be present in the tissues, the methodology of this particular study was applicable only to botrydial.

We have long felt that a greater understanding of the role of this toxin and its related compounds in the processes leading to disease onset and lesion expansion would be gained if the action mechanisms of the toxins involved were known. This paper describes experiments designed to determine the role of these compounds in the pathogenicity of the fungus *B. cinerea*. Phytotoxic assays with metabolites with the botryane skeleton (Figure 1) extracted from cultures of *B. cinerea* were studied. These assays were performed both *in vitro* and *in vivo* on leaves of *Phaseolus vulgaris*, as well as on different fruits. The effect of light on the action mechanism of botrydial was also studied.

METHODS AND MATERIALS

General. The strain *B. cinerea* Pers.: Fr. 2100 employed in this work was obtained from the Colección Española de Cultivos Tipos (CECT), Facultad de Biología, Universidad de Valencia, Spain. The procedures used for the isolation and purification of compounds **1–6** (Figure 1) have been described previously (Durán-Patrón et al., 1999). Pure metabolites were dissolved in 40% acetone (v/v) in 100 ml of water containing 10 μl of Tween 80. Solutions of different concentrations, ranging from 10 to 1000 ppm, were then prepared. Controls consisted of mixtures of aqueous acetone that had been used for dissolving the products.

Plant Material and Methods of Culture. Seeds of *Phaseolus vulgaris* genotypes N90598 (susceptible to *B. cinerea*) and N90563 Huron (resistant to *B. cinerea*) (Kelly et al., 1994) were obtained from J. D. Kelly, Michigan State University, East Lansing, Michigan, USA, and were grown in a standardized and quality controlled compost/sand mixture in individual pots in a greenhouse for two or three weeks at 25°C.

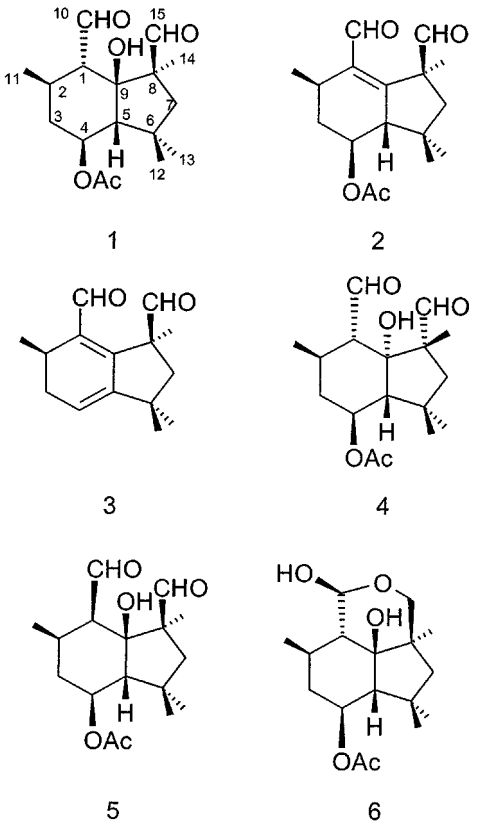

FIG. 1. Structures of compounds **1–6**.

Leaf Disc Assays. Leaves of *Phaseolus vulgaris* plants were sterilized with 10% bleach (v/v) for 3 min., washed four times with sterile water, dried between filter paper, cut into circles measuring 1 cm diam., and placed in Petri dishes (10 circles per dish) lined with Whatman paper wetted with sterile water. Each circle received a 10 μl droplet of pure compound solutions. The dishes were then incubated at 25–28°C in natural sunlight. Assays were carried out in duplicate.

The frequency of infection was ascertained by comparing the number of affected circles to the total number treated. The size of the damaged area was obtained by determining the affected surface area as compared with the total surface area, expressed in square millimeters.

Whole Plant Assays. Attached leaves were sterilized with an aqueous solution of 10% of ethanol (v/v), washed with sterile water, and dried between filter paper. In general, two *Phaseolus* plants were used per experiment. Five leaves per plant

were treated with a solution of the compound to be tested. Each leaf received five drops (10 μl) of control and five drops (10 μl) of the test solution. Two experiments were carried out for each compound and concentration. The plants were incubated at 25–28°C in natural sunlight for a minimum photoperiod of 12 hr. The diameter of the drops was identical in each case, and the total surface area of the drops was considered the treated area. The total treated area was considered to be 100%, and the affected area was calculated in relation to treated area.

Fruit Assays. Fruits (*Capsicum annuum*, *Licopersicom esculentum*, *Vitis vinifera*, *Phaseolus vulgaris*, *Fragaria vesca*, *Actinidia chinensis planchon*) were sterilized as described above and placed in Petri dishes lined with Whatman paper wetted with sterile water. Botrydial was dissolved to different concentrations (50–250 ppm) and was placed in 10 μl drops on the fruit surface. The treated fruit, five pieces per assay, was incubated at 25–28°C in natural sunlight. Two experiments were conducted for each type of fruit.

Inoculation Experiments. Sporulating fungal colonies of *B. cinerea* Pers.: Fr 2100 were first rinsed with an inoculating medium consisting of Gamborg's B5 obtained from Sigma Chemical CO (3.2 g/liter), sucrose (10 mM), and potassium phosphate buffer (0.01M, pH 6.4) and then filtered through cheesecloth to eliminate mycelial fragments. The conidial suspension was centrifuged, resuspended in an inoculating medium containing sucrose, and adjusted to approx. 10^5 conidia/ml. Five l-microliter droplets of conidial suspension were placed onto the leaf surfaces, and the leaves or plants were incubated in a chamber at 25°C in natural sunlight and with saturated air humidity.

The sunlight radiation was measured with the aid of a pyranometer (silicon cell pyranometer, SKS1110). An average total radiation of 514 W/m^2 and 360 W/m^2 was achieved, at plant level, for sunny and cloudy days, respectively.

RESULTS AND DISCUSSION

In an initial survey, we compared the activities of the phytotoxic metabolites produced by *B. cinerea in vitro* by incubating aliquots of solutions of the metabolites on leaf discs of *P. vulgaris* (genotype N90598) at concentrations of 1000, 500, 250, and 100 ppm. The more active metabolites were tested at concentrations under 100 ppm. The leaf circles were examined each day. The maximum phytotoxic effect was reached at different times for each metabolite, and remained constant thereafter. By the seventh day, the maximum effect for all metabolites had been reached (see Table 1; note that only those concentrations that gave a positive result are listed). Botryendial (**2**), botrydienal (**3**), and 8,9-epibotrydial (**4**) were highly phytotoxic; they produced chlorotic lesions at concentrations of 25, 25, and 50 ppm, respectively. Botrydial (**1**) had the highest level of activity; it caused a chlorotic effect even at a physiological concentration (1 ppm). Metabolites **5** and **6** were moderately active at a minimum concentration of 250 ppm.

Compounds **1**–**6** were tested in whole-plant assays with *Phaseolus vulgaris*, genotype N90598. Although the correlation between *in vitro* and *in vivo* experiments was generally good, the phytotoxic effect was more rapid *in vivo*, being noticeable after only a few hours (Tables 2 and 3). It is worth noting that all compounds assayed caused severe chlorosis and cell collapse. Botrydial (**1**) was active from 1 ppm and reproduced symptoms of plant disease in 70% of the treatments.

The results described above confirm those previously reported concerning the structure–activity relationships of compounds with the botryane skeleton

(Durán-Patrón et al., 1999). The biological activities of these compounds are related to the oxidation state of the C-10 and C-15 carbon atoms, as well as to the presence of a hydroxyl group on the C-9 carbon atom.

It was also observed that both sunlight radiation intensity and exposure period caused a significant difference in the time necessary for the lesions to appear. Botrydial (**1**), the most active compound, was shown to act rapidly and cause chlorotic lesions in the whole area of application at all the different concentrations assayed when the plant was exposed to bright sun light (514 W/m^2 average radiation; Table 3). In contrast, when the experiment was repeated in dim light (360 W/m^2 average radiation), the same effect took twice as long to occur. At the minimum active concentrations of 10 and 1 ppm, chlorosis took place after 120 hr in 80% and 70% of the treatments, respectively. Other highly active metabolites such as botryendial (**2**) and 8,9-epibotrydial (**4**) showed phytotoxic activity at higher concentrations after 2 and 3 hr, respectively. These experiments were carried out with two genotypes of *Phaseolus vulgaris*: genotype N90598, with well-characterized susceptibility to *B. cinerea*, and genotype N90563, with characterized resistance to the fungus. The results were similar in both cases.

In order to prove the light dependence of botrydial (**1**), the compound was applied at different concentrations (10–150 ppm) to leaves of *Phaseolus vulgaris*, which were then covered with aluminum foil. The leaves were examined every 2 hr for 12 hr and after 24 hr, and no chlorosis was evident. Nevertheless, once these same leaves were exposed to light, chlorosis was observed within 1–2 hr.

In another experiment, botrydial (**1**) was applied to the leaves of *P. vulgaris* at different concentrations, after which the plant was put in bright sunlight (514 W/m^2 average radiation). Once the lesion appeared, the leaf was covered with aluminum foil and the extent of the lesion was noted after 2, 4, 6, and 24 hr. No difference could be observed between the covered lesion and that of a leaf exposed to sunlight over the same time intervals.

As *B. cinerea* is a fungus that can affect all parts of the plant, including the fruit, we decided to observe the effect of this toxin on several fruits. When botrydial (**1**) was assayed on the surface of a fruit, a lesion in the fruit skin was observed in five of the six fruits studied. The exception was green pepper.

Finally, the effect of botrydial (**1**) on fungal penetration was studied on attached leaves of *Phaseolus vulgaris*. Botrydial was applied at different concentrations to the leaves, which were then inoculated with *B. cinerea*. The results showed that botrydial facilitates fungal penetration and colonization of plant tissue. In a typical experiment in which a 250 ppm solution of botrydial was used, 48 hr after the leaves had been inoculated with *B. cinerea*, the fungus had already started to grow, producing a lesion 43 mm in diameter. In contrast, in the inoculation experiment without botrydial, fungal penetration was slower, being visible only after 72 hr, and the diameter of the lesion was only 37 mm.

In conclusion, we have found that *B. cinerea* synthesizes a number of metabolites that reproduce some of the symptoms of the disease caused by this organism. As a result of our experiments, we have also obtained evidence that the action mechanism of the phytotoxin botrydial is light dependent.

Exogenous applications of the most active and abundant metabolite, botrydial (**1**), facilitate fungal penetration and colonization of plant tissue. These results, together with the recent discovery that botrydial is produced in infected plants (Deighton et al., 2001), suggest the involvement of this compound as a toxin in the pathogenesis of *Botrytis cinerea.* Furthermore, the fact that botrydial affects different crops and genotypes seems to indicate that this toxin and its related compounds are nonhost specific toxins that increase the extent of disease, and most likely are virulence factors. Further work is in progress to investigate the mechanistic aspects as well as the scope of the light dependent plant-toxin reaction.

Acknowledgments—This project was jointly financed by the European Union (Fair project no. PL97-3351). We thank Professor A. von Tiedemann (University of Rostock, Germany) for supplying *P. vulgaris* seeds.

Abstract—Larval red-legged frogs (*Rana aurora*) are known to exhibit antipredator behavior in response to both chemical alarm cues released from injured conspecifics and chemical cues of predators. In some cases, the response to predators is dependent on the predator's diet. In this experiment, we tested whether long-term exposure to predator chemical cues and alarm cues resulted in alteration of life history characteristics of red-legged frogs. We raised groups of tadpoles in the presence of chemical cues of predators that were either fed conspecifics or heterospecific caddis-fly larvae, chemical cues of injured conspecifics, or a no-cue control. Tadpoles raised in the presence of either a predator fed conspecifics or cues of injured conspecifics metamorphosed earlier and at a smaller size than those exposed to predators fed heterospecifics or the no-cue control. The result suggests that red-legged frogs exhibit a life history shift in response to predatory cues and that this response is dependent on the diet of predators.

Key Words—Alarm cues, amphibians, chemical cues, life history, predation, *Rana aurora*, red-legged frogs, rough-skinned newts, *Taricha granulosa*.

INTRODUCTION

Interactions among predators, prey, and factors that modify the strength of predator–prey interactions are important for determining the structure of many biological communities (e.g., Menge and Sutherland, 1976; Wellborn et al., 1996). Although many predators can reduce prey abundance, predator effects on prey survival can be modified through a variety of strategies employed by prey. Such strategies include alterations of behavioral responses (e.g., Sih, 1986; Kiesecker et al., 1996; Chivers et al., 1996b), changes in morphology (Appleton and Palmer, 1988; Bronmark and Miner, 1992; McCollum and VanBuskirk, 1996), and shifts in the timing of life-history events (e.g., Dodson and Havel, 1988; Skelly and Werner, 1990; Chivers et al., 1999). Prey that initiate antipredator strategies often have an increased probability of surviving predation events (e.g., Hews, 1988). However, antipredator strategies often take time and energy that would otherwise be available for other activities such as foraging and reproduction (Lima and Dill, 1990). As a result, there should be strong selection on prey to determine vulnerability to predation and to adjust antipredator response accordingly.

The vulnerability of prey to predators may also be influenced indirectly by the presence of heterospecifics that share the same predator. For example, apparent competition describes situations where the increase of one prey species negatively impacts another through increased predation intensity (Vandermeer, 1969; Levine, 1976; Abrams, 1987). Alternatively, increased heterospecific density may have positive effects on prey species when it decreases predation intensity as a result of predator switching (e.g., Murdoch, 1969; Abrams, 1987). In turn, selection should act to either sensitize or desensitize prey to cues of heterospecific predation events, depending on whether the presence of heterospecifics increases or decreases predation intensity.

Many aquatic prey animals, including amphibians, use chemical signals to assess predation risk (e.g., Petranka et al., 1987; Dodson et al., 1994; Kiesecker et al., 1996, 1999; Chivers and Smith, 1998). Cues may arise from the predators or they may be released by prey animals when they are captured by a predator (Chivers and Smith, 1998; Kats and Dill, 1998). However, the response of prey to predators may be context dependent. For example, many prey species only respond to chemical cues of a predator when the predator is fed a diet that contains conspecifics (e.g., Mathis and Smith, 1993; Wilson and Lefcort, 1993; Chivers et al., 1996a). Dietary cues of predators may be an effective way for prey to assess their vulnerability to the predators they encounter (Mathis and Smith, 1993; Wilson and Lefcort, 1993; Chivers et al., 1996; Stabell and Lwin, 1997). For example, Wilson and Lefcort (1993) found that tadpoles of the red-legged frog, *Rana aurora*, exhibit antipredator behaviors in response to predatory rough-skinned newts, *Taricha granulosa*, when newts are fed a diet of conspecifics, but not when newts are fed heterospecifics.

In this study, we raised tadpoles of the red-legged frog in the presence of chemical cues from predatory rough-skinned newts fed conspecifics, newts fed heterospecifics, injured conspecifics only, or a no-cue control. We tested whether tadpoles shifted aspects of the life history in response to potential predation risk. Specifically, we measured whether larval red-legged frog altered the timing of metamorphosis or size at metamorphosis in response to predation risk. While short-term behavioral decisions of prey to predatory chemical cues have been studied extensively, relatively little is known regarding life-history responses of prey to chemical cues that indicate increased predation risk (Chivers and Smith, 1998).

Red-legged frogs and rough-skinned newts can be found together in many of the same breeding habitats where their ranges overlap west of the Cascade–Sierra Nevada mountains from British Columbia, Canada, to northern California, USA (Stebbins, 1985). Rough-skinned newts are effective predators of red-legged frog larvae, although the presence of alternative prey may in some instances lower predation risk for red-legged frogs (Nussbaum et al., 1983; Wilson and Lefcort, 1993). Thus, the presence of newts alone may not accurately predict the level of predation that red-legged frog larvae may expect to experience. We predicted that red-legged frog larvae should only respond to cues of rough-skinned newts when they are associated with chemical cues that give a reliable indication of predation risk experienced by conspecifics.

METHODS AND MATERIALS

We collected *R. aurora* embryos on January 15, 1996, from a pond located 18 km south of Waldport, Oregon, USA. Embryos were collected and transported to a laboratory at Oregon State University where they were reared in 38-liter aquaria. After hatching, tadpoles were raised at approximately 16°C on a 12L:12D photoperiod and fed alfalfa pellets and fish food *ad libitum.* We began tests when all tadpoles reached Gosner (1960) stage 25.

Experiments took place in 24, 38-liter aquaria that were divided widthwise with a fiberglass mesh screen to create two compartments, each measuring 25 × 30 × 25 cm. One compartment of each tank contained a 24-cm-diam. opaque plastic chamber. The side of the chamber facing away from the other compartment was perforated with small (500 μm) holes to allow movement of chemical cues out of the chamber.

We placed 12 randomly selected tadpoles into each of the 24 test tanks, on the side opposite the large plastic chambers. The experiment consisted of four treatments in a randomized block design with six replicates. Treatments 1 and 2 were predator treatments. In treatment 1, tadpoles were exposed to chemical cues of one predatory rough-skinned newt (*T. granulosa*) that was fed caddisfly larvae;

treatment 2 tadpoles were exposed to chemical cues of a predatory *T. granulosa* that was fed conspecifics. Treatment 3 consisted of exposing tadpoles to alarm cues from injured conspecifics. Treatment 4 was a control where tadpoles were exposed to a blank control containing no cues. Within a given treatment, we rotated newts among each of the tanks so that tadpoles were exposed to all newts fed a particular diet.

Throughout the experiment, tanks were cleaned weekly. Newts were fed either three tadpoles or three caddisfly larvae each week. There was always at least one prey item available for each newt. We prepared the alarm cue stimulus by grinding a single tadpole with a mortar and pestle in 60 ml of distilled water. Ten milliliters of the solution was added to each of the six alarm cue treatment containers. Alarm cues were added to the tanks three days per week. On all occasions, the cues were introduced into the plastic chambers. Test tadpoles were fed ground rabbit chow *ad libitum.* All test animals that reached metamorphosis (Gosner stage 41) (Gosner, 1960) were removed from the aquaria, and their mass was determined to the nearest milligram.

Statistical Analysis. For each aquarium, we calculated the mean time tadpoles took to reach metamorphosis and their mean mass at metamorphosis. Because individual responses are not independent of one another, we used tank means for all statistical analyses. We used multivariate analysis of variance (MANOVA) to evaluate the treatment effects on the dependent variables: mean mass at metamorphosis and mean time to metamorphosis (Tabachnick and Fidell, 1989). After MANOVA, we used Bonferroni-adjusted univariate analysis of variance (ANOVA) on each response variable to interpret patterns uncovered by the MANOVA. Tukey (HSD) tests were used to compare treatment means where significant ($P < 0.05$) differences were found with the ANOVA.

RESULTS

The results of MANOVA revealed strong treatment effects on *R. aurora* life-history parameters (Table 1). We used univariate tests (ANOVA) and *post hoc* comparisons (Tukey tests) to interpret patterns of response of time and mass at metamorphosis due to our manipulations.

There were strong treatment effects on the timing of metamorphosis by red-legged frogs (Table 1, Figure 1). They responded to exposure to chemical cues of predatory newts fed conspecifics by initiating metamorphosis more than six days earlier than those exposed to chemical cues of newts fed caddisflies (Table 2, Figure 1). Moreover, frogs exposed to chemical cues of injured conspecifics initiated metamorphosis more than 7 days earlier than those exposed to control conditions (Table 2, Figure 1). Similarly, there were strong treatment effects on frog mass at metamorphosis (Table 1, Figure 1). Frogs exposed to predatory newts

Treatment	9.563	<0.001

[a] Response variables are mass at metamorphosis (mass) and time to metamorphosis (time). Significance level for univariate tests is 0.025 (Bonferroni-adjusted for two response variables).

fed conspecifics were 20% smaller than their counterparts exposed to newts fed caddisflies (Table 2, Figure 1). Additionally, mass at metamorphosis of frogs exposed to chemical cues of injured conspecifics was 14% lower than control animals (Table 2, Figure 1).

DISCUSSION

The results suggest that red-legged frogs alter aspects of their life history in response to chemical cues that indicate predation. Larval frogs initiate metamorphosis earlier and at a smaller size when exposed to cues that denote predation of conspecifics. By decreasing time to metamorphosis, larvae limit their exposure to predatory newts. However, this type of life-history shift likely incurs costs. For example, red-legged frogs that initiate metamorphosis earlier are also smaller. Smaller size at metamorphosis can decrease both reproductive success and survival in the terrestrial environment (e.g., Woodward, 1983). By metamorphosing earlier, frogs also may be exposed to higher levels of terrestrial predation and/or may experience slower growth rates. The cues responsible for initiation of metamorphosis are complex and need further investigation regarding the costs of early metamorphosis.

The experimental design provided insight regarding the specific mechanism responsible for the alterations of life history. Wilson and Lefcort (1993) showed that red-legged frog tadpoles do not initiate antipredator behaviors in response to cues of predatory newts unless newts are fed a diet of conspecifics. In this experiment, we

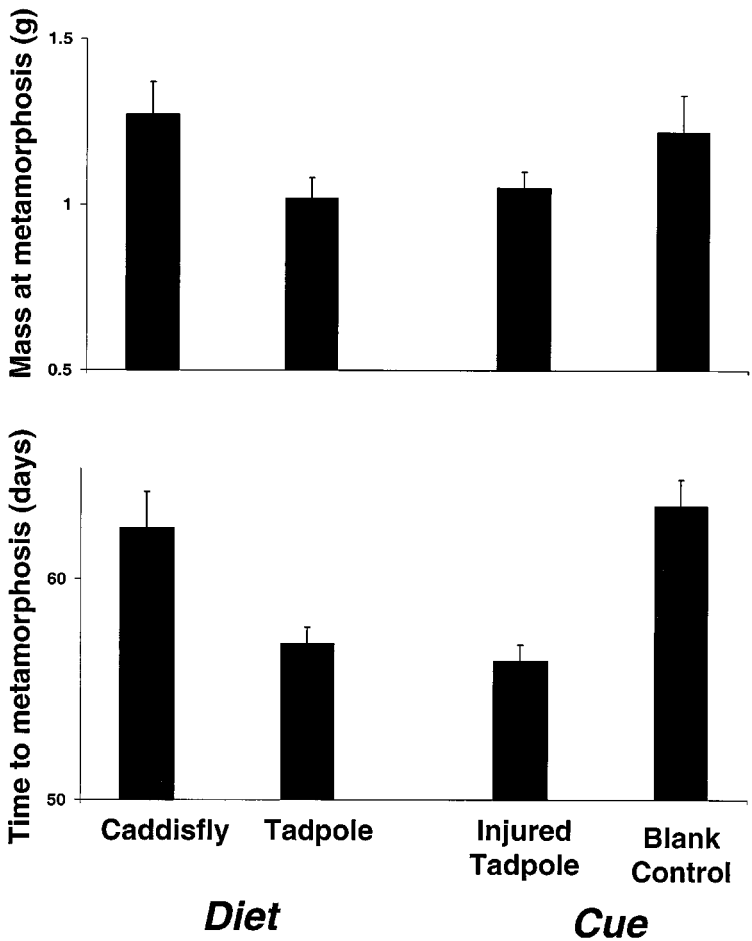

FIG. 1. Mean (+SE) time to metamorphosis (days) and mass at metamorphosis (grams) for *Rana aurora* exposed to chemical cues of predatory newts fed caddisflies, predatory newts fed conspecifics, injured conspecifics, or a blank control.

fed newts tadpoles in experimental chambers. Consequently, the predator stimulus likely resulted in a complex chemical array that included both chemical cues of the predator and injured prey cues. We know that predator stimuli and cues of injured conspecifics alone will induce change in life history. Furthermore, it is clear that exposure to predator cues in the absence of alarm cues will not induce life-history shifts. These results imply that the changes we observed are a direct response to the alarm cues of injured prey and not a reaction to the predator.

[a] Treatment 1 = predatory newts fed caddisflies; treatment 2 = predatory newts fed conspecifics; treatment 3 = injured conspecifics cues; treatment 4 = blank control.

The results parallel those found in other systems. For example, studies of behavioral responses and morphological changes indicate that prey species may only respond to chemical cues of a predator when the predator is fed a diet that contains conspecifics (Mathis and Smith, 1993; Wilson and Lefcort, 1993; Chivers et al., 1996a). The results presented here contribute to a growing body of evidence that suggests prey use chemical alarm cues released from injured conspecifics to alter aspects of their life history. For example, Crowl and Covich (1990) demonstrated that snails, *Physella virgata*, exposed to crayfish feeding on conspecifics were older at first reproduction than *P. virgata* exposed to crayfish not feeding on snails. Moreover, Chivers et al. (1999) showed that western toad tadpoles exposed to chemical cues of injured conspecifics initiated metamorphosis earlier than tadpoles not exposed to injured conspecifics. Future studies should examine the chemical nature of the stimulus that induces the changes (e.g., Wassersug, 1997; Kiesecker et al., 1999), and they should manipulate the timing and frequency of chemical stimuli to assess if alterations of life history can be induced by exposure to stimuli throughout development or whether exposure during certain stages is required to initiate life history shifts.

We expect that initiating antipredator responses by red-legged frog larvae must be costly and only used when predators are focusing their feeding on conspecifics. For example, why would red-legged frogs forgo responding to a potential predator when newts that are feeding on heterospecific caddisflies are still capable of consuming red-legged frog tadpoles? The foraging strategies employed by rough-skinned newts are unknown—whether they focus their feeding on the most abundant prey items or specialize their feeding on particular prey items regardless of relative abundance. However, the lack of response to newts fed heterospecifcs

suggests that the presence of alternative prey such as caddisfly larvae must result in decreased predation intensity on frog larvae. In natural ponds, abundance of heterospecific prey (e.g., caddisflies) varies dramatically between ponds and between years. If heterospecifics offer a release from predation by newts, then red-legged frog tadpoles may not be able to accurately assess predation risk by using cues of newts alone. Thus, using dietary cues of predators, as opposed to using cues directly released from the predators themselves, may provide a more accurate indication of vulnerability.

The ability of prey animals to assess risk and respond flexibly towards different degrees of predation has important ramifications. The failure of a prey animal to recognize and respond to a predator increases the probability that it will be captured during an encounter with a predator. However, a prey animal that gives an antipredator response upon encountering a nonpredator wastes time and energy that would otherwise be available for activities such as foraging and reproduction (Lima and Dill, 1990). Thus, there should be strong selective pressure for prey that can distinguish between predators that pose a risk and those that do not.

(Received May 14, 2001; accepted December 28, 2001)

Abstract—While chemoreception is involved in a wide variety of salamander behaviors, the chemosensory system that mediates specific behaviors is rarely known. We investigated the role of the vomeronasal system (VNS) in foraging behavior of the red-backed salamander (*Plethodon cinereus*) by manipulating salamanders' abilities to detect nonvolatile chemical cues emitted by potential prey. Subjects received one of three treatments: (1) impaired vomeronasal system, (2) sham manipulation, and (3) no manipulation. The role of the VNS in mediating foraging on motile prey (*Drosophila melanogaster*) was investigated under three light conditions (bright, dim, dark). Salamanders with impaired VNSs foraged less efficiently than either of the other experimental groups by displaying the longest latency to attack and the lowest rate of prey capture, especially in the absence of visual cues. A second experiment utilized freshly killed prey to determine whether the VNS takes on added importance in the absence of visual or tactile cues associated with moving prey. Animals with impaired VNSs showed a decreased foraging efficiency on stationary prey under both dark and light conditions. In addition, a mark–recapture study of VNS-impaired and sham salamanders in the field also indicated that salamanders with impaired VNSs consumed fewer stationary prey compared to shams. The study indicates that the VNS plays a substantial role in the foraging behavior of the plethodontid salamander, *P. cinereus*.

Key Words—Behavior, chemical senses, foraging, *Plethodon cinereus*, Plethodontidae, salamander, Urodele, vomeronasal system.

INTRODUCTION

Terrestrial salamanders are thought to rely primarily on vision while foraging, while olfaction plays a secondary role (Wake and Deban, 2000). However, there are few detailed studies examining the sensory mediation of salamander foraging behavior. Given that the olfactory system of terrestrial salamanders is well-developed and thought to play a role in feeding (Dawley and Crowder, 1995; Wake and Deban, 2000), the current study attempts to elucidate the role of specific olfactory cues in mediating foraging behavior.

The olfactory system of terrestrial salamanders is characterized by an elongate snout that houses paired and cartilaginous olfactory capsules. Within each of these capsules is a large medial olfactory sac, lined with olfactory epithelium [the nasal olfactory system (NOS)], and a small ventrolateral sac, lined with a specialized sensory epithelium [the vomeronasal system (VNS)] (Dawley and Bass, 1989). Most tetrapod vertebrates possess these two separate nasal chemosensory systems. Duvall (1980) described the NOS as being a "quantitative distance-sensing" system that responds to the presence of any pungent substance and initiates further investigation via the VNS, which is more of a "qualitative, or discriminating" system. While the division of function of the two chemosensory systems is not a simple one, the NOS is primarily responsible for the detection of volatile odorants (airborne chemical cues), while the VNS responds primarily to nonvolatile odorants (substrate-borne chemical cues) (Burghardt, 1980; Bertmar, 1981; Halpern, 1987). The functional roles of nasal chemosensory systems have been demonstrated in many tetrapods (reviewed by Halpern, 1992). For example, in lizards, electro-olfactograms (EOG), measures of summed neuronal activity, recorded from the olfactory mucosa in response to airborne odorants are considerably higher than the EOGs elicited by the same odorants from the vomeronasal olfactory epithelium. However, liquid delivery of the same airborne odorants to the vomeronasal olfactory epithelium results in significantly higher EOGs (Halpern, 1992). In our study, we focused on the VNS, by manipulating the ability of a tetrapod to detect and react to chemical cues associated with prey.

The VNS is variable among tetrapods. It ranges from being completely absent or vestigial in birds and some mammals, to being anatomically larger than the main olfactory system in most squamate reptiles (lizards and snakes) (Moulton and Beidler, 1967). In amphibians, the vomeronasal epithelium develops in a ventromedial (anurans) or ventrolateral (urodeles) diverticulum of the nasal cavity, termed the vomeronasal organ (Dawley and Bass, 1988).

Following the highly variable structure of the VNS among tetrapod taxa are diverse behavioral mechanisms by which molecules are transferred to the chemosensory epithelium (Graves, 1993). Mechanisms for chemical delivery to the VNS sensory epithelium include tongue flicking by squamate reptiles (Halpern and Kubie, 1980), flehmen in some mammals (Estes, 1972), and physical pumping of the

vomeronasal organ (Meredith and O'Connell, 1979; Eccles, 1982). Vomeronasal chemoreception among lungless salamanders (plethodontids) is mediated by contact of the nasolabial cirri (fleshy protuberances from the upper lip) to a substrate via "nose-tapping" (Arnold, 1972, 1976). Nonvolatile molecules in aqueous form are then transported from the nasolabial cirri up specialized grooves (the nasolabial grooves) via capillary action to the vomeronasal receptor epithelium in the ventral nasal cavity (Brown, 1968; Dawley and Bass, 1989).

In addition to variability in structure among tetrapods, the VNS also differs in function. In mammals, the primary function is to detect excreted sex hormones and their various breakdown products (Estes, 1972; Halpern, 1987). The VNS of squamate reptiles is responsible for the detection of prey, self, and conspecific cues, as well as for homing (Halpern, 1987; Graves, 1993). While chemical cues are important in the mediation of many salamander behaviors, rarely have researchers investigated the roles of specific chemical senses (i.e., NOS, VNS, and taste).

To investigate the role of the VNS in mediation of salamander behavior, we utilized the red-backed salamander, *Plethodon cinereus*, because the VNS of this species has been implicated in the detection of self, conspecific, prey, alarm cues released by both conspecifics and heterospecifics, and predator cues (Dawley and Crowder, 1995; Wake and Deban, 2000). Plethodontid salamanders are model organisms for studying the VNS, as the system can be easily manipulated by obstructing the flow of nonvolatile molecules up the nasolabial grooves (Dawley and Bass, 1989). However, the role of the VNS in mediation of plethodontid behavior has been directly investigated in only two studies. Graves (1994) found that the VNS is involved in the recognition of home areas by *P. cinereus*, while Jaeger (1981) found that *P. cinereus* that had been bitten on the snout by a conspecific and had at least one nasolabial groove scarred foraged less efficiently on nonmobile prey than *P. cinereus* that had been bitten on the tail.

Plethodon cinereus typically emerge from daytime refugia between dusk and a few hours after dusk, at which time they search the forest floor for prey, relying heavily upon visual cues. Despite these crepuscular tendencies, *P. cinereus* are considered nocturnal (Adler, 1969, 1970) and actively forage in the absence of visual cues (Placyk and Graves, 2001b). In addition, during the day, when less active, they typically seek shelter under logs and leaf litter, which can obscure or eliminate visual cues (Petranka, 1998). Therefore, we hypothesized that this species would rely heavily upon chemical cues, possibly nonvolatile chemical cues detected by the VNS, at night and from under cover objects during the day. David and Jaeger (1981) indicated that salamanders require chemical cues to locate prey in the dark, but did not investigate the role of the VNS specifically. We report here the results of laboratory and field experiments that addressed the questions: (1) What role do chemical cues play in the detection of motile prey under different lighting conditions? (2) What role do chemical cues play in the detection of stationary prey under different lighting conditions? (3) Can the function

of chemical cues in foraging behavior be demonstrated in natural populations of *P. cinereus*?

METHODS AND MATERIALS

General Methods. We collected 50 *P. cinereus* near the town of Big Bay, Powell Township, Marquette County, Michigan, USA. Specimens were placed individually in jars and transported to laboratory facilities at Northern Michigan University. Salamanders were housed individually in Petri dishes (9 cm diam.) lined with damp filter paper, and stored in a controlled temperature chamber at $18 \pm 0.5^{\circ}$C with a 12L:12D photoperiod. Snout–vent length (SVL) was measured to the nearest 0.02 mm with digital calipers, and individuals with SVLs below the estimated minimum adult size (<3.25 cm SVL), (Sayler, 1966) were excluded from experiments. Salamanders were fed *Drosophila melanogaster* (fruit flies) *ad libitum* and permitted to acclimate to laboratory conditions for a minimum of one week before trials were conducted. The acclimation period allowed the salamanders to become experienced with foraging on *Drosophila*. Salamanders that did not eat during the initial one-week acclimation period were not used. Before each experiment, animals were fed to satiation, then not fed again for seven days to provide approximately the same level of hunger for each individual.

Role of Vomeronasal System in Foraging on Motile Prey. The first experiment investigated the role of the VNS in foraging on motile prey, both in the presence and absence of visual cues. Three groups of 15 *P. cinereus* each were used. Thirty animals were anesthetized by placing them in a 30% ethyl alcohol and distilled water solution until they were flaccid when held or did not respond when nudged with a blunt probe (Fellers et al., 1994). Fifteen *P. cinereus* had their nasolabial grooves cauterized under a dissecting microscope with a heated inoculation loop to disrupt delivery of chemicals to the vomeronasal receptor epithelium (Dawley and Bass, 1989; Graves, 1994). Fifteen *P. cinereus* had both cheeks cauterized just posterior to the nasolabial grooves as a sham procedure to control for physical stress associated with the manipulations. The remaining 15 animals were unmanipulated controls. The treatment groups were termed VNX, sham, and control.

Light intensity was manipulated to simulate natural variation in illumination during various parts of the day. Incandescent bulbs of two intensities were used to simulate dim (7-W) and bright (100-W) light that might be experienced in the wild. Both lights were suspended approximately 1.33 m above the test arena to prevent any significant temperature change during the trials. Black light was used to simulate "night-time" conditions. Placyk and Graves (2001a) have shown that *P. cinereus* are unable to detect visual cues under such lighting. The black light was suspended approximately 70 cm above the test arena, as no significant temperature change was expected for this treatment. Temperature in the test arena

was monitored for the duration of each trial. The experimenter was concealed behind a blind to prevent detection of irrelevant visual stimuli. Test subjects were placed in a test arena (a Petri dish with a diameter of 14.5 cm) and permitted to acclimate for 1 min. To eliminate unfamiliar chemical cues, test arenas were washed with distilled water and a clinical detergent powder (Alconox) before each trial. Test arenas were swabbed with filter paper from the home Petri dish of each individual salamander prior to the start of each trial to provide moisture and to deposit familiar chemical cues to minimize escape behavior (Tristram, 1977) and to optimize foraging responses (Jaeger et al., 1981, 1983).

Following the 1-min acclimation period, 15 wingless *D. melanogaster* were added to each Petri dish to induce foraging behavior. Salamanders were tested under the different lighting conditions in random order to counter differences in behavior due to learning (Jaeger and Barnard, 1981; Jaeger and Rubin, 1982; Jaeger et al., 1995). Number of prey captured was recorded during the subsequent 15-min trials. The amount of time subjects spent moving after prey had been introduced to the test arena and latency until the initial attack were recorded. Additional dependent variables quantified included number of both successful and unsuccessful attacks and number of nose taps.

Since much of the data did not meet parametric assumptions, nonparametric statistical analyses were used for comparison purposes. Kruskal-Wallis one-way ANOVAs on ranks, with the three vomeronasal conditions as levels of the independent variable, were used to detect differences within each light condition. Friedman's ANOVAs, with the three light conditions as levels of the independent variable, were used to detect differences within treatment groups. If the Kruskal-Wallis and Friedman's ANOVAs indicated significant differences among treatments, we employed Kruskal-Wallis multiple-comparison Z-value tests and Tukey-Kramer multiple-comparison tests to investigate all pairwise differences, respectively (Roscoe, 1975; Sokal and Rohlf, 1995). Alpha was set at 0.05.

Role of Vomeronasal System in Foraging on Stationary Prey. The second experiment was designed to investigate the role of the VNS while foraging in the absence of visual and tactile cues. Two test groups composed of the 15 sham and 15 VNX individuals from experiment 1 were utilized. The normal salamander group was eliminated, as the data collected in experiment 1 and a previous study (Graves, 1994) indicated that the sham treatment is an appropriate control for the nasolabial groove cauterization treatment. Subjects were tested under dim light and black light. The bright light condition was eliminated, because subjects tested at this light intensity in the first experiment primarily exhibited escape behavior.

The home Petri dishes of each individual salamander were used as test arenas to facilitate concurrent testing of all subjects in each light condition. The larger test arenas did not allow us to test all individuals at once for each light condition. Twenty *D. melanogaster*, killed by freezing for 24 hr and, then thawed

for 1.5 hr, were scattered in each Petri dish (David and Jaeger, 1981). Test subjects were then placed individually into each dish and randomly exposed to one of the two light conditions for 6 hr, during which time the experimenter was not present. At the end of this period, the number of *D. melanogaster* remaining in each Petri dish was recorded.

The data were not normally distributed; therefore, nonparametric statistical analyses were employed. Mann-Whitney U tests were used to compare responses between the two groups within each light condition, and Wilcoxon signed-rank tests were used to compare responses to the two light intensities of individuals that were tested in both conditions (Roscoe, 1975; Sokal and Rohlf, 1995). Alpha was set at 0.05.

Role of Vomeronasal System in Foraging by Free-Ranging Salamanders. The third experiment was conducted at a field site located near the town of Big Bay, Powell Township, Marquette County, Michigan, to investigate the role of the VNS in foraging of free-ranging salamanders. Upon initial collection, *P. cinereus* were taken to the laboratory where they were weighed to the nearest 0.01 g with an electronic balance and measured for SVL to the nearest 0.02 mm. Salamanders were placed in one of two experimental groups of 25 subjects each. One group received the sham treatment, and the other had their VNS impaired by nasolabial groove cauterization as in experiment 1. Salamanders were marked individually by toe-clipping (Martof, 1953; Ott and Scott, 1999). On the day following their capture, subjects were released at the exact location from which they were collected. Surveyors' flags were numbered and placed at the locations to facilitate recapture.

At the end of the one-month trial period, release sites were searched and test subjects were recaptured. Recaptured salamanders were weighed, and their SVLs were recorded. They were euthanized via ventral application of a benzocaine-containing gel (Orajel regular, 7.5% benzocaine) (Chen and Combs, 1999) and placed in 10% formaldehyde after incisions were made in their sides so that the stomach contents would fix rapidly (Jaeger, 1972). Stomach contents were identified to the nearest taxonomic grouping (Bland, 1978), and stomach content volume was calculated with the formula for a cylinder (Jaeger, 1980). To take into account differences in diet due to environmental conditions (Jaeger, 1978, 1990), all salamanders were captured on the same day and collected again on the same day.

Statistical analyses consisted of *t* tests to compare changes in SVLs and weights among the treatment groups over the one-month trial period. In addition, a *t* test was used to compare stomach content volume of shams and VNX subjects. Mann-Whitney U tests were employed when data did not meet parametric assumptions. Chi-square tests of independence were used to compare the frequency of salamanders with particular prey types (sedentary prey, mobile prey) in their stomachs in relation to their treatment group (VNX or sham) (Roscoe, 1975; Sokal and Rohlf, 1995). Alpha was set at 0.05.

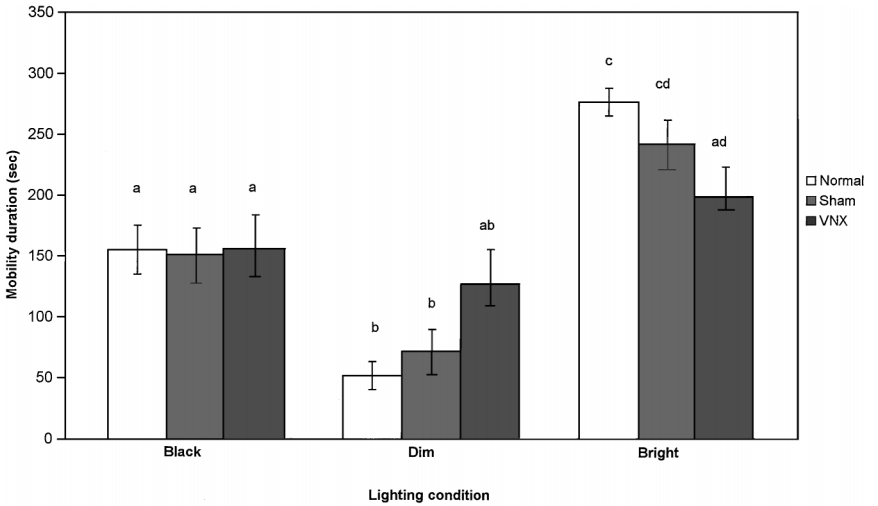

FIG. 1. Mobility duration (mean $\pm$ 1 SE) of normal, sham, and VNX treatment groups with equal sample sizes ($N = 15$) in bright, dim, and black light in the presence of mobile prey. Different letters indicate significantly different means ($P < 0.05$).

RESULTS

Role of Vomeronasal System in Foraging on Motile Prey. In terms of mobility, there was no significant difference in the amount of time moving in normal, sham, and VNX groups in either the black ($H_{(2,44)} = 0.19$; $P = 0.91$) or dim ($H_{(2,44)} = 3.34$; $P = 0.19$) light (Figure 1). However, there was a difference in the amount of time that the three groups spent moving in the bright light ($H_{(2,44)} = 7.81$; $P = 0.02$; Figure 1); VNX subjects moved less than normal individuals ($P < 0.05$), while sham subjects did not differ from either of the other two treatment groups ($P > 0.05$). Within treatment groups, normal ($Q_{(2,14)} = 28.13$; $P < 0.05$), sham ($Q_{(2,14)} = 19.0$; $P < 0.001$), and VNX ($Q_{(2,14)} = 11.29$; $P < 0.05$) salamanders exhibited different amounts of time moving under the three light conditions (Figure 1). Salamanders from the VNX group moved more in bright light than in dim ($P < 0.05$) but not more than in black light ($P > 0.05$). The amount of time the VNX salamanders spent moving in dim light did not differ from black light ($P > 0.05$). Salamanders from the normal and sham groups moved more in bright light than in either dim or black light and more in black light than in dim light ($P < 0.05$).

Latency to first attack differed among the treatment groups in black light ($H_{(2,44)} = 6.40$; $P = 0.04$; Figure 2). Multiple comparison tests showed that VNX salamanders exhibited a longer latency to attack than normal salamanders in black

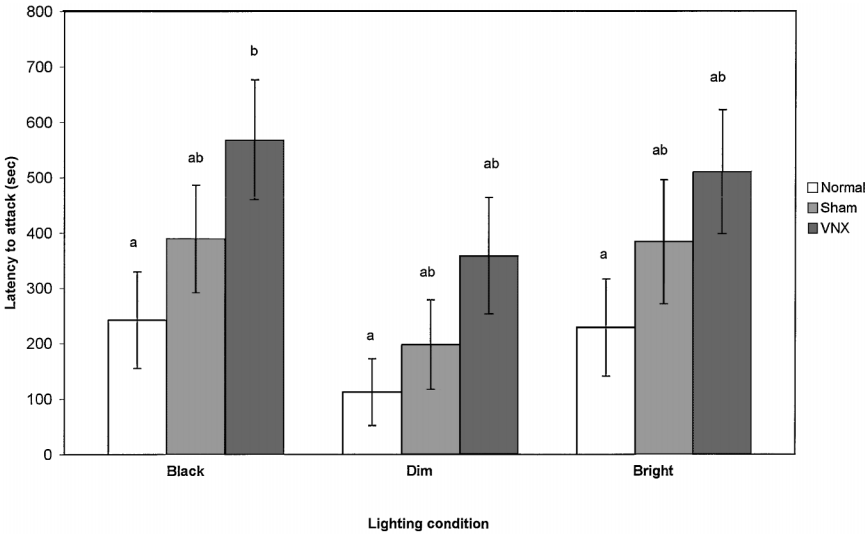

FIG. 2. Latency to attack mobile prey (mean $\pm$ 1 SE) for normal, sham, and VNX treatment groups with equal sample sizes ($N = 15$) in bright, dim, and black light. Different letters indicate significantly different means ($P < 0.05$).

light ($P < 0.05$), but there was no difference between the sham group and either the normal or VNX groups ($P > 0.05$). Conversely, the latency to first attack did not differ significantly among treatment groups in either the dim ($H_{(2,44)} = 2.37$; $P = 0.31$) or bright ($H_{(2,44)} = 2.88$; $P = 0.24$) light (Figure 2). Within treatment groups, there was no difference in latency to first attack under the three light conditions (Figure 2).

Regarding number of attacks, there were significant differences in the number of prey attacked among groups in black light ($H_{(2,44)} = 7.69$; $P = 0.02$), but not in dim ($F_{(2,44)} = 3.60$; $P = 0.16$) or bright ($H_{(2,44)} = 3.06$; $P = 0.22$) light (Figure 3). Specifically, VNX salamanders attacked less prey in black light than normal salamanders ($P < 0.05$), but sham salamanders did not differ in the number of prey they attacked in black light from either normal or VNX salamanders ($P > 0.05$).

The number of attacks on prey by normal ($Q_{(2,14)} = 17.81$; $P < 0.001$) and sham ($Q_{(2,14)} = 12.89$; $P < 0.05$) salamanders differed among light conditions (Figure 3) with each group attacking more prey in dim light than in either bright or black light ($P < 0.05$). However, the number of prey attacked by these two groups did not differ significantly between the bright and black light conditions ($P > 0.05$). There was a marginally significant difference in the number of times VNX salamanders attacked prey under the three light conditions ($Q_{(2,14)} = 4.05$;

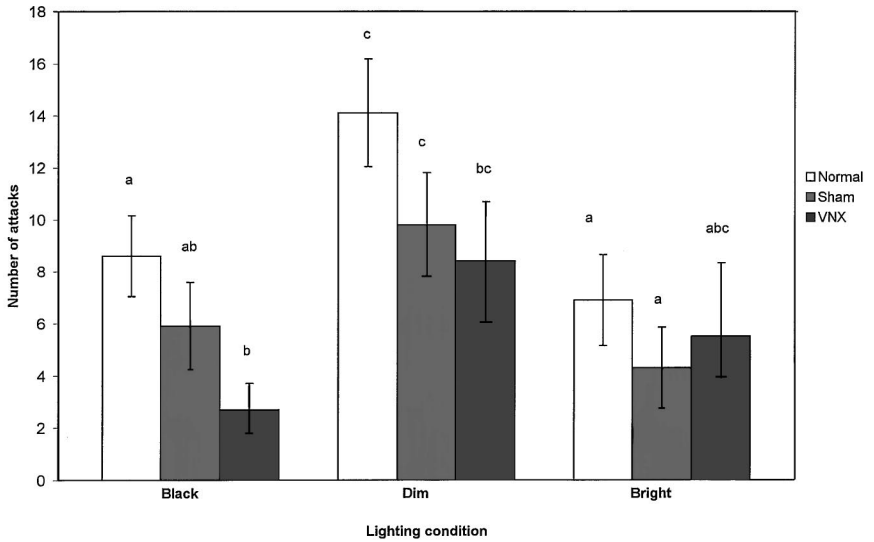

FIG. 3. Number of attacks on mobile prey (mean $\pm$ 1 SE) by normal, sham, and VNX treatment groups with equal sample sizes ($N = 15$) in bright, dim, and black light. Different letters indicate significantly different means ($P < 0.05$).

$P = 0.13$), with fewer prey being attacked in black light than in dim light. However, the number of prey attacked in bright light did not differ from those attacked in either dim or black light.

The number of prey eaten in black light differed among the three groups ($H_{(2,44)} = 6.36$; $P = 0.04$; Figure 4), with the VNX salamanders eating less prey than normal salamanders ($P < 0.05$). However, sham salamanders did not differ in the number of prey they ate under black light from either the normal group or the VNX group ($P > 0.05$). Additionally, the number of prey eaten by the three groups in the dim ($H_{(2,44)} = 3.58$; $P = 0.17$) and bright ($H_{(2,44)} = 2.38$; $P = 0.30$) light did not differ (Figure 4).

Within groups, both normal ($Q_{(2,14)} = 11.92$; $P < 0.05$) and sham ($Q_{(2,14)} = 10.02$; $P < 0.05$) salamanders ate different numbers of prey across the three light conditions (Figure 4), with fewer prey eaten in bright light than in dim light ($P < 0.05$), but no difference was exhibited between black light and the other light conditions ($P > 0.05$). In addition, VNX salamanders also differed in the number of prey they ate across the three light conditions ($Q_{(2,14)} = 8.22$; $P = 0.02$; Figure 4) with fewer prey eaten in bright light than in dim ($P < 0.05$) or black light ($P > 0.05$) and more prey eaten in dim light than in black light ($P < 0.05$).

Regarding nose taps, we found no difference in the number exhibited by groups in either black ($H_{(2,44)} = 0.13$; $P = 0.94$) and dim ($H_{(2,44)} = 4.31$;

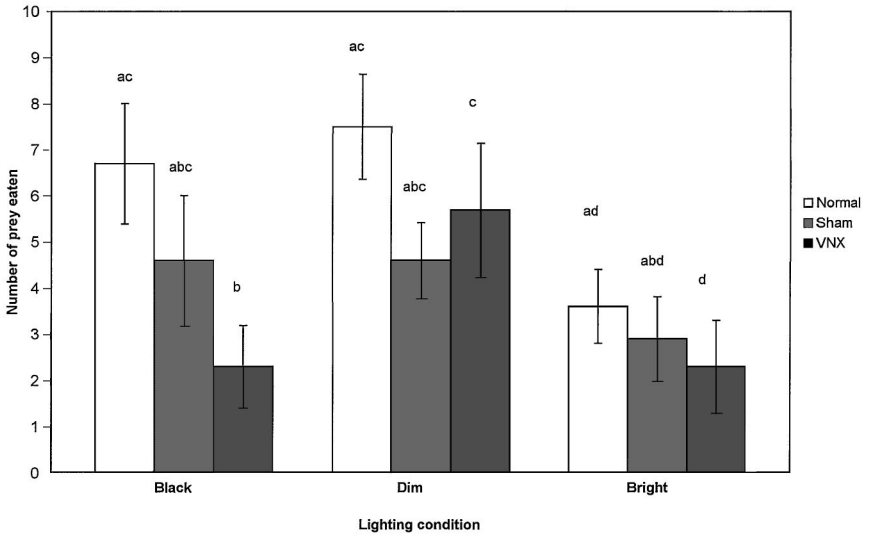

FIG. 4. Number of mobile prey eaten (mean ± 1 SE) by normal, sham, and VNX treatment groups with equal sample sizes ($N = 15$) in bright, dim, and black light. Different letters indicate significantly different means ($P < 0.05$).

$P = 0.11$) light, despite the large numerical difference in mean number of nose taps in the latter (Figure 5). However, the three groups did differ in the number of nose taps they exhibited in bright light ($H_{(2,44)} = 23.74$; $P < 0.001$; Figure 5), with VNX salamanders nose-tapping more than either the sham or normal salamanders ($P < 0.05$). The number of nose taps exhibited by normal salamanders ($Q_{(2,14)} = 12.54$; $P < 0.05$) and by sham salamanders ($Q_{(2,14)} = 9.42$; $P < 0.05$) differed across the light conditions, with each group nose tapping more in black light than in either dim or bright light (Figure 5). Although the VNX group exhibited a higher number of nose taps when compared to the normal and sham groups in all three light conditions, the number of nose taps for this group did not differ among those light conditions ($Q_{(2,14)} = 1.42$; $P = 0.49$; Figure 5).

Role of Vomeronasal System in Foraging on Stationary Prey. We found that a functional vomeronasal system may be important to *P. cinereus* when foraging on stationary prey. In both dim light ($Z = -2.33$, $P = 0.02$; $df = 28$) and black light ($Z = -3.74$; $P < 0.01$; $df = 28$), sham salamanders ate more stationary prey than VNX salamanders (Figure 6). In addition, while sham salamanders did not differ in the number of stationary prey they ate under the two lighting conditions ($Z = 0.8064$, $P = 0.41$, $df = 14$), the VNX salamanders ate less in black light than in dim light ($Z = 2.59$, $P < 0.01$, $df = 14$). Therefore, while visual stimuli coupled with chemical stimuli are important in dim light, a functional vomeronasal

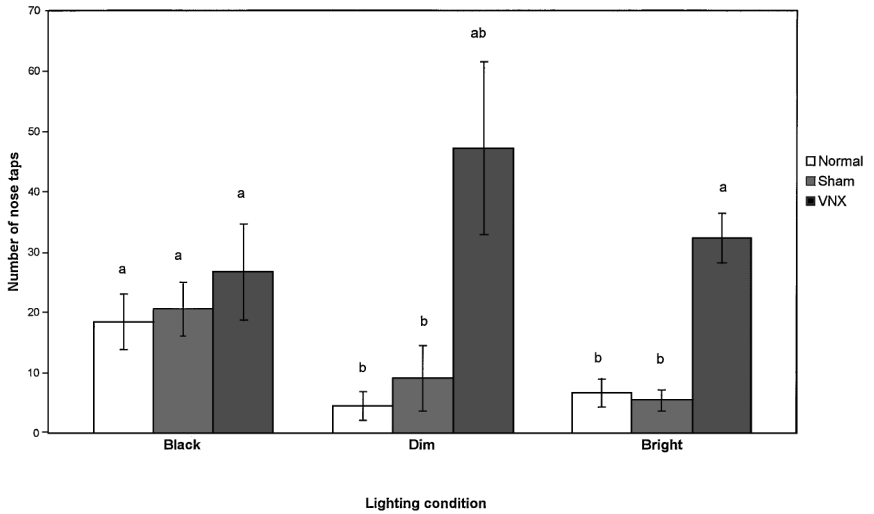

FIG. 5. Number of nose taps (mean $\pm$ 1 SE) exhibited by normal, sham, and VNX treatment groups with equal sample sizes ($N = 15$) in bright, dim, and black light in the presence of mobile prey. Different letters indicate significantly different means ($P < 0.05$).

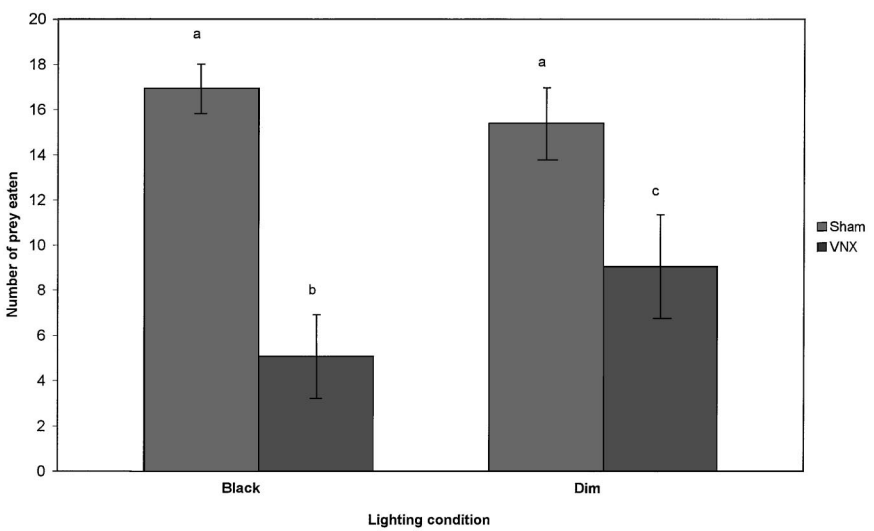

FIG. 6. Number of stationary prey eaten (mean $\pm$ 1 SE) by sham and VNX treatment groups with equal sample sizes ($N = 15$) in dim and black light. Different letters indicate significantly different means ($P < 0.05$).

system is essential for successful foraging on stationary prey in the absence of visual stimuli.

Role of Vomeronasal System in Foraging by Free-Ranging Salamanders. When examining the change in SVL ± SE (millimeters) among the groups over the one-month period, sham salamanders (1.7 ± 1.675) showed a marginally significant increase in SVL, while VNX salamanders (-2.44 ± 1.42) did not ($t = 1.897$; $P = 0.066$ $df = 37$). There was no difference in the change in weight ± SE (grams) ($t = 1.417$; $P = 0.165$ $df = 37$) between the sham (0.12 ± 0.105) and the VNX (-0.073 ± 0.089) group over the one-month test period. In addition, there was no difference between stomach content volumes (cubic millimeters) of the sham (28.69 ± 5.99) and the VNX (36.91 ± 10.91) groups ($U = 171.00$; $P = 0.612$; $df = 37$). However, upon comparing the stomach contents of each group, we found qualitative differences in prey composition and differences in the frequency of salamanders eating specific types of prey.

Arachnids (22%), coleopterans (23%), and arthropod eggs (21%) accounted for the majority of the 58 identifiable prey items found in the 18 recaptured sham salamanders' stomachs (Table 1). Coleopterans (26%), dipterans (14%), and arachnids (12%) comprised over 50% of the 83 identifiable prey items from the 21 recaptured VNX salamanders' stomachs, with arthropod eggs comprising a conspicuously low percentage of the total diet (1%) (Table 1). A χ^2 test of independence indicates that there is a relationship between the frequency of salamanders with stationary prey in their stomachs and treatment group ($\chi^2 = 5.39$; $P < 0.025$; $df = 1$), with sham salamanders (33%) eating more stationary prey than VNX salamanders (4%). However, there was no relationship between the frequency of salamanders with mobile prey items in their diet and treatment group, as 100% of the salamanders that had food in their stomachs ate mobile prey, regardless of treatment group.

DISCUSSION

Role of Chemical and Visual Cues in Detection of Motile Prey. We found that normal and sham animals moved significantly more in black light than in dim light, suggesting the combination of visual and chemical cues in dim light allowed them to use an ambush foraging strategy (remaining stationary waiting for prey to approach) (Placyk and Graves, 2001b). Conversely, VNX salamanders moved more than either the normal or the sham group in dim light, suggesting that impairment of the VNS disrupts this ambush foraging strategy in this light. In addition, all treatment groups moved more in bright light. This greater mobility is most likely associated with an aversion to bright light, as *P. cinereus* are adapted for life under the canopy, fallen logs, and leaf litter of secondary deciduous forests, where there is little or no direct light (Petranka, 1998). Furthermore, if bright light

[a] Prey items are ordered alphabetically starting at the phylum level.

increases the visibility of *P. cinereus* to predators and the chances of desiccation, it may be optimal for salamanders' fitness to avoid such conditions. Ducey and Brodie (1983) have shown that plethodontids will exhibit elevated levels of mobility when the threat of being preyed upon increases. However, none of this evidence explains

why normal salamanders moved more in bright light than the VNX treatment group. We postulate that this increase in mobility is either a spurious effect or has a biological interpretation that is not apparent.

Latency to first attack by normal, sham, and VNX salamanders did not differ among groups in dim or bright light. This suggests that VNX animals were able to locate and attack prey under dim light as quickly as the normal group, although VNX salamanders exhibited an increase in mobility to achieve this equivalent latency time. Conversely, Graves and Duvall (1985a) found that avomic prairie rattlesnakes, *Crotalus v. viridis*, never struck, located, or swallowed prey, whereas unimpaired subjects did. Vomeronasal-impaired *P. cinereus* from our experiment foraged on motile prey when they were available. Apparently, the loss of vomeronasal chemoreception in some species can be compensated for if alternative cues are available (Kardong, 1992; Graves et al., 1993). Under black light, latency to first attack was greater for VNX salamanders than for normal salamanders. This suggests that *P. cinereus* employ the VNS for prey location in the dark, but other sensory systems, such as nasal olfactory, taste, or tactile systems, may be used as well. Overall, the greatest mean latency to first attack across all nine light and salamander treatment combinations was exhibited by the VNX group under black light. This indicates that the VNS plays a role in initial prey detection by salamanders in the absence of visual stimuli.

Vomeronasal-impaired salamanders attacked and consumed fewer prey than normal salamanders in black light, but the difference was absent under dim or bright light. This indicates that a functional VNS is important to *P. cinereus* when foraging in the absence of visual cues, but when visual cues are available, the VNS plays a secondary role. In addition, since visual cues are available in dim and bright light, and since the chemical senses probably play no role in the consumption of prey once detected, one would expect any dependence on the VNS while foraging in lighted conditions to be minimal. The fact that there is no difference between the number of attacks and the number of prey consumed by the three groups in dim and bright light is contradictory to work that has been conducted with squamate reptiles. For example, both scincid lizards and the rattlesnake, *C. v. oreganus*, with impaired VNSs attacked but never swallowed the prey (Graves and Halpern, 1990; Alving and Kardong, 1996), and as described above, avomic *C. v. viridis* never attacked prey (Graves and Duvall, 1985a). These differences in foraging behaviors exhibited by avomic animals may be a result of the methodology used to impair the VNS in each experiment. The vomeronasal ducts that lead to the vomeronasal organ of both the scincid lizards (Graves and Halpern, 1990) and *C. v. viridis* (Graves and Duvall, 1985a) were either sealed with glue or sutured shut, thus preventing access of molecules to the vomeronasal receptors. *C. v. oreganus* were rendered avomic via bilateral lesions of the vomeronasal nerves (Alving and Kardong, 1996).

It is possible that chemical cues could have been transferred to the vomeronasal organ of the salamanders in our experiment if they entered the

nasolabial grooves above the cauterized portion of the groove. In addition, since the VNS of amphibians is located in a ventral pouch of the nasal cavity (Dawley and Bass, 1988), molecules may also reach the vomeronasal receptors from the throat via the internal nares. Therefore, our VNX salamanders may have still had partial use of their VNS (Dawley and Bass, 1989). It is also possible that the scincid lizards and rattlesnakes are more reliant upon chemical cues to differentiate between prey and nonprey, whereas *P. cinereus* may utilize a combination of sensory modalities when choosing appropriate prey.

Vomeronasal-impaired *P. cinereus* did not differ in the number of nose taps they exhibited across the three light conditions, but they nose-tapped significantly more in bright light than either normal or sham animals. Normal and sham salamanders did not differ from each other in the number of nose taps they exhibited in any light, but both nose-tapped more in black light than in either of the other two light conditions. This suggests an increase in chemosensory behavior in the presence of motile prey in the dark. Red spitting cobras (*Naja mossambica pallida*) exhibit increases in a chemosensory behavior (tongue-flicking) when visual cues are eliminated via blindfolds (Kardong et al., 1997). In addition, increases in chemosensory behavior coupled with high mobility, as seen with our salamanders in black light, have been demonstrated in studies conducted with lizards, suggesting that animals employing active foraging strategies (moving through the habitat searching for prey) rely primarily on chemical cues to find prey (Huey and Pianka, 1981; Cooper, 1994a,b, 1995). These results and those of Placyk and Graves (2001b) suggest that, in general, there may be an association between activity level and nose-tapping in plethodontid salamanders, whether visual stimuli are present or absent. The hypothesis that activity and chemosensory behavior covary, however, was not explicitly tested in our current experiments and requires more support.

Vomeronasal-impaired salamanders nose-tapped more than normal or sham animals under dim and bright light, but not under black light. The rate of nose-tapping by sham and normal salamanders in black light was similar to the rate exhibited by the VNX salamanders in all light conditions.

Impairment of the VNS resulted in an increased number of nose taps in the presence of motile prey in dim light (Figure 5). Since the ability to detect nonvolatile chemical cues is eliminated through cauterization of the nasolabial grooves (Dawley and Bass 1989), this increase in nose taps may be a futile attempt to illicit a chemosensory response from the vomeronasal system. In prairie rattlesnakes, mouth gaping and head shaking are believed to facilitate vomeronasal olfaction (Graves and Duvall, 1983). Graves and Duvall (1985b) found that VNX prairie rattlesnakes exhibited greater numbers of mouth gapes and head shakes than sham subjects when exposed to prey. The increase in nose taps among VNX salamanders may indicate that the animals did not exhibit a foraging response due to the lack of chemical signals, but behaved as they would in the absence of prey chemical cues. For example, Placyk (2000) found that, in the absence of prey, normal

salamanders exhibited a greater number of nose taps than when prey were present. Therefore, VNX salamanders that lack the ability to detect prey chemical cues efficiently may not express the foraging behavior typical of a salamander with an unmanipulated VNS.

In summary, the vomeronasal-impaired salamanders were not as effective at foraging on motile prey as salamanders with intact VNSs, especially in the absence of visual stimuli. Vomeronasal-impaired salamanders showed increased mobility under dim light, whereas control groups maintained an ambush foraging strategy. In addition, VNX salamanders exhibited an increase in latency to first attack and a decrease in both the number of attacks and the number of prey eaten in the absence of visual stimuli. Therefore, depending on environmental conditions, chemical cues are important for successful foraging by *P. cinereus*, and the results suggest that the VNS plays a significant role in the detection of those cues.

Role of Chemical and Visual Cues in Detection of Stationary Prey. Comparisons across light conditions showed that VNX salamanders consumed significantly less prey in black light than in dim light, while sham salamanders did not differ in this regard. Thus, the availability of visual cues influenced the successful capture of nonmotile prey items. In addition, comparisons across treatment groups showed that VNX animals ate less than sham salamanders in both dim and black light. This indicates that the VNS plays a role in foraging on stationary prey items. It has been shown previously that *P. cinereus* with at least one nasolabial groove damaged via aggressive confrontations with conspecifics forage less effectively on nonmotile prey (Jaeger, 1981). While this study provides a more systematic approach at attempting to impair the VNS, the results of Jaeger (1981) suggest that even minimal damage to the nasolabial grooves decreases the foraging abilities of *P. cinereus*. Regardless, it appears as though plethodontid salamanders forage more efficiently when multiple sensory systems are employed, as our results indicate that a combination of both visual and chemical cues resulted in the greatest foraging efficiency. This reliance on multiple sensory systems for foraging effectively has also been indicated in two other caudates (*Notophthalmus viridescens* and *Ambystoma tigrinum*), which require a combination of visual and chemical cues to exhibit high rates of foraging behavior (Martin et al., 1974; Lindquist and Bachmann, 1982).

Can Function of Chemical Cues in Foraging Behavior be Demonstrated in Natural Populations of Plethodon cinereus? A significant difference in the types of prey eaten by our two treatment groups was evident. The majority of identifiable prey items removed from the stomachs of sham salamanders were beetles, arachnids, and arthropod eggs. In comparison, beetles, flies, and arachnids comprised the highest percentage of identifiable prey removed from VNX salamander stomachs. Vomeronasal-impaired salamanders had only 1% of their identifiable stomach contents consisting of arthropod eggs, and this difference from the amount of arthropod eggs found in sham salamanders' stomachs was significant. Thus, a functional vomeronasal system might be important for successful foraging on

particular types of stationary prey items, as demonstrated in both our laboratory and field studies. Despite consuming few stationary prey, VNX animals compensated for this inability by taking more motile prey than salamanders with intact vomeronasal systems. This is indicated by the lack of difference between the stomach content volume of the two groups.

In spite of the differences in diet composition, VNX and sham groups did not show a significant change in SVL or weight over the one-month period. This contradicts Jaeger's (1981) study on free-ranging *P. cinereus*, which indicated that individuals who showed damage to one or both of their nasolabial grooves exhibited lower weight–length relationships than those that were uninjured. However, Jaeger (1981) failed to take into account that low body weights may have been the cause of nasolabial groove damage, rather than the result, as individuals with low weight–length ratios may have a high probability of losing fights and thus incurring nasolabial groove damage. Similar to our study, Graves et al. (1993) found that sham and VNX garter snakes, *Thamnophis sirtalis*, collected again after a three-week period, showed no significant difference in change in body mass change.

Implications for Natural Populations. Plethodon cinereus suffer damage to their nasolabial grooves as a result of fighting on a regular basis under natural conditions (Jaeger, 1981), with 11.8% of wild-caught adults having scar tissue on their nasolabial grooves. Jaeger et al. (1982), in a study of intraspecific aggression among *P. cinereus*, also showed that more bites were directed at the snout than at the tail. Our experiments provide empirical evidence that disruption of the vomeronasal system significantly decreased the ability of *P. cinereus* to forage on prey in the absence of visual cues, regardless of their initial weight/length relationships. It is possible that the decreased foraging efficiency exhibited by salamanders with damaged nasolabial grooves may result in a decrease in the fitness of those individuals, but such long-term effects could not be demonstrated over the relatively short period of time in which we conducted our studies.

Acknowledgments—We thank Nathan Forst and Peter Froiland for assistance in the collection of specimens. Gordon M. Burghardt, Joseph Gathman, and Mac Strand provided useful comments on the data analyses and interpretations. Rita Mehta and two anonymous reviewers have made this article much stronger through their extremely critical and useful comments. EVALUATION OF SYNTHETIC HYDROCARBONS FOR MARK–RECAPTURE STUDIES ON THE RED MILKWEED BEETLE

MATTHEW D. GINZEL* and LAWRENCE M. HANKS

Department of Entomology
University of Illinois at Urbana-Champaign
Urbana, Illinois 61801

(Received September 27, 2001; accepted January 1, 2002)

Abstract—This study evaluates the potential for using blends of synthetic hydrocarbons in mark–recapture studies of insects. To test the durability of hydrocarbons, we applied a blend of five straight-chain hydrocarbons (C_{24}, C_{25}, C_{26}, C_{28}, C_{30}) to detached elytra of the red milkweed beetle, *Tetraopes tetrophthalmus* (Forster) (Coleoptera: Cerambycidae), mounted the elytra on pins, and placed them in an exposed location outdoors. The amount of hydrocarbons on the elytra did not change over time, even after two months of exposure to sun and rain. Synthetic hydrocarbons applied to the elytra of living beetles did not significantly influence their longevity or mating success in a laboratory study, and the amounts of hydrocarbons did not change with age. The invariability of hydrocarbon ratios over time suggests that blends could provide a nearly infinite variety of ratios to mark individual insects uniquely and indelibly with a hydrocarbon "fingerprint." This technique offers a convenient, safe, and durable means of individually marking insects and may find application in field studies of larger bodied insects that are long-lived and sedentary.

Key Words—Dispersal, marking techniques, population dynamics, cuticular hydrocarbons, Cerambycidae, *Tetraopes tetrophthalmus.*

INTRODUCTION

Mark–recapture techniques are commonly used to estimate population densities of animals and study their dispersal behavior (Hagler and Jackson, 2001). For this research, it is essential that markings be easy to apply and detect, be durable, and have no adverse effect on the development, behavior, or longevity of subjects

(Southwood and Henderson, 2000). A variety of effective marking techniques have been developed, each with its own drawbacks. For example, materials most often used for marking insects (paints, dyes, physical tags) are easily detected, but can fade, rub off, or dislodge, and may inhibit movement of small insects or render subjects conspicuous to vertebrate predators (Southwood and Henderson, 2000; Hagler and Jackson, 2001). Mutilation marking for insects would involve clipping appendages or damaging the cuticle and would be appropriate only for heavily sclerotized insects or those with large wings (Hagler and Jackson, 2001). Application of many of these markers involves handling the insects, which subsequently may influence their dispersal behavior (Singer and Wedlake, 1981).

Fluorescent dyes can be applied as dusts to groups of insects (Crumpacker, 1974), but may have sublethal effects (Labrecque, 1975). Radioactive isotopes (e.g., ^{14}C and ^{65}Zn) were once popular for marking insects (Service, 1993) but have been replaced by trace elements of low toxicity, such as rubidium, that also have the advantage of persisting in tissues (Hagler and Jackson, 2001). Rubidium levels may rapidly decline, however, once the marked insect is removed from the Rb-containing host (Fleischer et al., 1986), and high levels of exposure can affect developmental rate of larvae and kill adults (Stimmann, 1973; Culin, 1986). These rare elements are also inconvenient markers because they require extensive sample preparation, and detection by rather costly atomic absorption spectrophotometry (Hagler and Jackson, 1998). Immunoproteins can be used to mark groups of small insects, but also involve relatively complicated laboratory assays and are rapidly degraded by rain or high humidity, limiting their utility for some field studies (Hagler and Jackson, 1998).

Our study examines the potential for using blends of synthetic long-chain hydrocarbons, which are structurally stable and nonvolatile, to mark insects for field research. Long-chain hydrocarbons occur naturally in the cuticular wax layer of insects and serve as contact pheromones in some species (Howard and Blomquist, 1982). We tested the durability of hydrocarbon markers with a field study, and also tested for negative affects on the mating success and longevity of our model insect, the red milkweed beetle, *Tetraopes tetrophthalmus* (Forster) (Coleoptera: Cerambycidae). This beetle is endemic to North America and common on its milkweed hosts (Yanega, 1996).

METHODS AND MATERIALS

We prepared a blend of synthetic hydrocarbons (Aldrich, Milwaukee, Wisconsin, USA) by mixing stock solutions of 0.05 g of tetracosane (C_{24}), pentacosane (C_{25}), hexacosane (C_{26}), octacosane (C_{28}), and triacontane (C_{30}) in 1 ml of hexane, and combining 20-μl aliquots of each standard in a 4:2:1:2:4 ratio, respectively. Preliminary analysis of hydrocarbon profiles of *T. tetrophthalmus* of both

sexes by gas chromatography – mass spectrometry revealed there were no major peaks that overlapped with those of the synthetic compounds.

To test the durability of hydrocarbon markers, we removed elytra from field-collected *T. tetrophthalmus* (sex not determined), mounted them individually on insect pins, and arrayed the pinned elytra on a square corkboard (30 cm^2). Half of the elytra were treated with 2 μl of hydrocarbon solution ($N = 25$), and the other half with 2 μl of hexane as a control ($N = 25$). The board was then placed flat on the rooftop of our laboratory building where it was exposed to full sunlight and weather. The board was left in place for 55 days between June 11 and August 5, 2000, during which time daily maximum temperatures averaged $29 \pm 3^{\circ}$C; there were 15 cloudless days, and 17.3 cm of rainfall (Illinois State Water Survey, Department of Natural Resources, University of Illinois at Urbana-Champaign).

We extracted hydrocarbons from the elytra after 0, 1, 7, 30, and 55 days ($N = 5$ elytra per date and treatment) by dipping them in 0.5 ml of hexane for 5 min (see Millar and Sims, 1998). We spiked extracts with 2 μl of a 0.01g/ml docosane solution as an internal standard (docosane does not naturally occur on the cuticle of *T. tetrophthalmus*). We quantified amounts of compounds (as fractions of the amount of internal standard) with a Hewlett-Packard 5973 mass spectrometer interfaced with a HP 6890 gas chromatograph, with an HP-5MS (cross-linked 5% phenyl-methyl siloxane) capillary column (30 m $\times$ 0.25 mm $\times$ 0.25 μm) in splitless mode, with helium as the carrier gas. The injection port was maintained at 250°C, and the oven temperature was ramped from 200 to 240°C at 5°C/min, then 240 to 250°C at 2°C/min. We tested for changes over time in the total amount of synthetic hydrocarbons (the five compounds combined) by one-way analysis of variance (ANOVA; SAS Institute, 2001) with day being the main effect, and tested for changes in relative proportions of individual compounds by two-way ANOVA with main effects being date and compound.

To determine whether our blend of synthetic hydrocarbons influenced longevity and mating success of *T. tetrophthalmus*, we placed six females and four males (collected from the field) in each of five aluminum screen cages (30 cm on a side), and applied 2 μl of hydrocarbon blend to the elytra of half of each sex, and 2 μl of hexane to the other half. To indicate treatments, we marked beetles with a dot of enamel paint of different colors (Testors, Phoenix Model Co., Brooksville, Florida, USA). In each cage, we provided a fresh milkweed umbel and foliage in water for food; cages were kept in the laboratory. We made hourly observations between 08:00 and 17:00 hr for as long as beetles lived to measure mating success (number of times mating) and longevity. In the field, *T. tetrophthalmus* are active from early morning to late afternoon (personal observations), and males and females may remain in copula for more than an hour (McCauley, 1982). The influence of hydrocarbon marking on mating success and longevity was tested by two-way ANOVA with main effects being chemical treatment and beetle sex, and cage as a random effect. To evaluate the durability of hydrocarbons on living beetles, we

extracted the hydrocarbon-marked beetles after they died, quantified amounts of hydrocarbons (as described above for elytra), and tested for changes in total amount of hydrocarbon with beetle age (time since marking) using one-way ANOVA.

We also determined whether *T. tetrophthalmus* was affected by the solvent hexane, by using an experiment of identical design to the above, but applying 2 μl of hexane to the elytra of half of the beetles of each sex, leaving the other half as controls (four cages per treatment), and testing the treatment effects on mating success and longevity by ANOVA. We present means $\pm$ 1 SE throughout.

RESULTS

The total amount of synthetic hydrocarbons (all five compounds combined) on the pinned beetle elytra declined by only ~25% over the two month period (0.12 ± 0.067, 0.11 ± 0.028, 0.11 ± 0.023, 0.079 ± 0.013 and 0.089 ± 0.00025 μg for 0, 1, 7, 30, and 55 days, respectively), but these differences were not statistically significant (ANOVA $F_{4,19} = 0.33,\ P > 0.86$). In addition, the relative proportions of the individual compounds were consistent over time, as indicated by the insignificant interaction term in the ANOVA ($F_{16,24} = 0.24,\ P = 0.99$; time effect $F_{4,24} = 1.19,\ P = 0.32$; compound effect $F_{4,24} = 9.44,\ P < 0.001$; Figure 1).

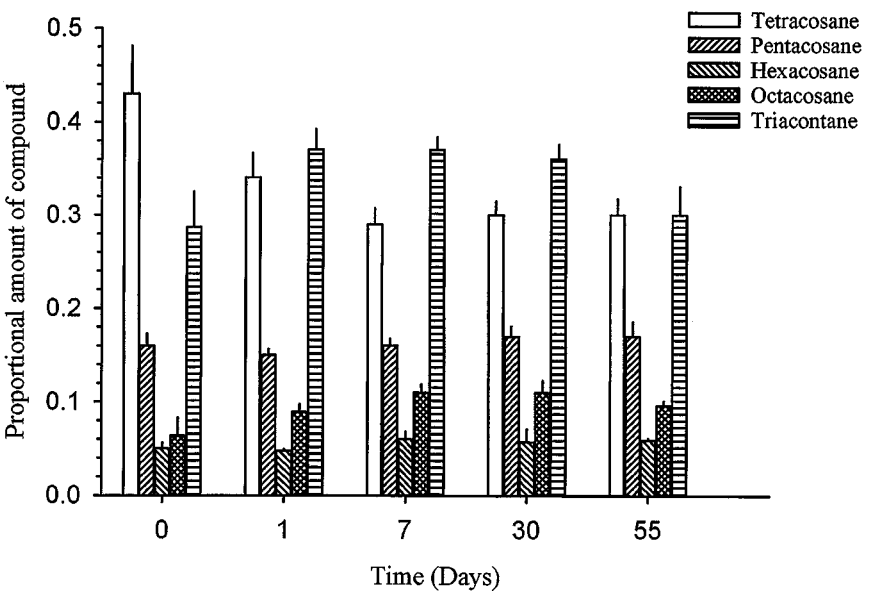

FIG. 1. Proportion of individual hydrocarbons to the total extracted from elytra of *T. tetrophthalmus* that had been exposed outdoors.

Male *T. tetrophthalmus* were observed to mate 0–18 times (average 5.9 ± 1.33), and females mated 0–13 times (average 4.44 ± 0.63) while caged in the laboratory, and the number of matings was not influenced by hydrocarbon treatment (ANOVA treatment effect $F_{1,40} = 0.23,\ P = 0.64$). Moreover, hydrocarbon treatment did not influence longevity: hydrocarbon- and hexane-treated beetles lived 12.7 ± 1.32 and 14.1 ± 1.40 days, respectively (ANOVA $F_{1,33} = 0.65,\ P = 0.43$). The total amount of synthetic hydrocarbons on marked beetles did not vary with their age, averaging 0.0365 ± 0.017 μg across treatments (day effect not significant; ANOVA $F_{6,13} = 0.94,\ P = 0.52$). As with the hydrocarbon-marked elytra, the relative proportion of compounds (individual peaks divided by the total) applied to living beetles did not vary among time periods of 0–4 days, 5–8 days, and 9 and 15 days (ANOVA interaction term $F_{8,14} = 0.68,\ P = 0.71$; time effect $F_{2,14} = 1.34,\ P = 0.27$; compound effect $F_{4,14} = 13.32,\ P < 0.001$).

Hexane alone did not affect mating success of *T. tetrophthalmus*, with hexane-treated and untreated beetles mating an average of 3.76 ± 0.86 and 3.12 ± 0.68 times, respectively (means not significantly different, treatment effect $F_{1,43} = 0.39,\ P = 0.53$). Solvent did not influence longevity: hexane-treated and untreated beetles lived 9.1 ± 1.34 and 9.9 ± 1.42 days, respectively (means not significantly different, treatment ANOVA $F_{1,32} = 0.15,\ P = 0.70$).

DISCUSSION

The amounts of synthetic hydrocarbons that we had applied to beetle elytra changed little over time, even after nearly two months of exposure to high temperatures, sunlight, and rain. This invariability of hydrocarbon ratios over time suggests that blends would provide a nearly infinite variety of ratios that could be used to uniquely and indelibly mark individual insects with a synthetic hydrocarbon "fingerprint." Hydrocarbon blends are easily applied in the field with a small paintbrush or can be applied to some insects by spraying; this labeling is unlikely to influence rates of predation. It takes only a few minutes to extract hydrocarbons from each insect, and analysis requires ~15 min per sample by gas chromatography. Hydrocarbon markers could also be quickly and easily detected, without harming marked insects, by solid-phase microextraction (Shirey, 1999). In a preliminary study, we detected synthetic hydrocarbon blends from the marked elytra of dead *T. tetrophthalmus* using a 7-μm polydimethylsiloxane fiber designed to extract high molecular weight compounds (Supelco, Bellefonte, Pennsylvania, USA). Finally, the synthetic hydrocarbons we used for marking are relatively inexpensive: a kit of straight-chain alkanes (C_5–C_{30}) costs ~US$200 (Aldrich, Milwaukee, Wisconsin, USA) and would yield more than 10 liters of solution per compound, enough for a career of mark–recapture experiments.

Our study confirmed that synthetic hydrocarbons applied directly to the elytra of *T. tetrophthalmus* did not adversely affect mating success or longevity;

however, sublethal effects of hydrocarbons or solvent may influence, for example, dispersal or reproduction. In particular, this technique is probably not suitable for marking soft-bodied insects because hexane may be more readily absorbed through their cuticles. Because cuticular hydrocarbons may play a role in chemical communication among insects (Howard and Blomquist, 1982), care also must be taken in selecting synthetic hydrocarbons that will not influence mating behavior and other intraspecific interactions. Marking insects with hydrocarbons that do not naturally occur on the cuticle, however, is unlikely to influence mating behavior.

We conclude that application of blends of synthetic hydrocarbons offers an effective, convenient, and inexpensive means of uniquely marking insects for long-term field studies of population size and dispersal, and is probably best suited for marking long-lived, large bodied, and heavily sclerotized insects, such as orthopteroids, coleopterans, hymenopterans, and lepidopterans. Because detection of the marker requires chemical analysis, the technique is probably best suited for relatively sedentary insects that would be recaptured at a greater rate and so would require smaller sample sizes. The technique could be extended by using as markers branched-chained hydrocarbons to provide a greater selection of synthetic markers or halogenated hydrocarbons that can be detected with greater sensitivity by electron-capture gas chromatography.

Acknowledgments—We thank P. F. Reagel and V. N. Pham for assisting in bioassays, and J. G. Millar, J. F. Tooker, and two anonymous reviewers for their constructive comments on the manuscript.

(Received August 6, 2001; accepted January 4, 2002)

Abstract—Male *Roptrocerus xylophagorum* (Ratzeburg) (Hymenoptera: Pteromalidae) exhibited courtship and mating behaviors including wing fanning, antennation, mounting, and copulation attempts when exposed to glass bulb decoys coated with a whole-body extract of females in hexane, acetone, or methanol. Activity of extract-treated decoys declined gradually over one week. Males responded much less strongly to freeze-killed female cadavers extracted with solvents than to unextracted cadavers; treatment of extracted cadavers with female extract restored male responses. The pheromone was found to be equally present over the surface of both the abdomen and head/thorax of females, and the origin of the pheromone could not be conclusively localized to any single body region. The activity of pheromone on females increased between day 1 and days 3–5 following eclosion; otherwise, pheromone activity was not significantly affected by either female age or mating. Males were arrested within the zone of a glass surface on which females had walked, suggesting that the pheromone might be substrate-borne. Recent exposure to females reduced male responsiveness, but responsiveness was fully restored after a few hours of male isolation from females. When hexane extracts of whole females were fractionated on silica gel, the pheromone's activity was largely recovered with the first, most nonpolar fraction. Female extracts and fractions were analyzed by coupled gas chromatography–mass spectrometry. Cuticular hydrocarbon alkanes were identified as the extract components whose concentrations correlated best with male responses. Evidence of the pheromone's long persistence, low volatility, low polarity, and presence over the insect's entire body surface further supported the hypothesis that the pheromone was composed of one or more cuticular hydrocarbons.

Key Words—parasitoid, sex pheromone, *Roptrocerus xylophagorum*, Pteromalidae, bark beetle, Scolytidae, cuticular hydrocarbons, semiochemicals.

INTRODUCTION

Sex pheromones are apparently widespread in the parasitic Hymenoptera and have been shown to occur in at least 16 families (Eller et al., 1984; Swedenborg and Jones, 1992a; Cormier et al., 1998). These pheromones mediate mate-finding and mating behaviors, including long-range orientation of males to females (Swedenborg and Jones, 1992a; Fauvergue et al., 1999; Jewett and Carpenter, 1999), concentration of male searching activity on substrates contacted by females (Kamano et al., 1989; Kainoh et al., 1991; Pompanon et al., 1997; Fauvergue et al., 1998), and short-range mate recognition and stimulation of male courtship behaviors (Vinson, 1978; Yoshida, 1978; Simser and Coppel, 1980; Takahashi and Sugai, 1982). Interest in parasitoid sex pheromones has been fueled in part by the practical needs of integrated pest management and the benefits offered by pheromone-baited traps as an efficient means for sampling and monitoring parasitoid populations in the field (Lewis et al., 1971; Powell, 1986; Reed et al., 1994; Jewett and Carpenter, 2001).

Roptrocerus xylophagorum (Ratzeburg) is an external parasitoid of the larvae and pupae of at least 12 economically important species of bark beetles (Coleoptera: Scolytidae) in North America, Australia, and Europe (Bushing, 1965; Mills and Schlup, 1989; Sullivan et al., 2000). My observations of male sexual behavior suggested the presence of a sex pheromone in this species; however, males did not demonstrate anemotaxis or other long-range orientation to live females in a Y-tube olfactometer. The following studies were devised to test the hypothesis that *R. xylophagorum* uses a close-range sex pheromone and to identify some of this pheromone's functional and chemical properties.

METHODS AND MATERIALS

Insects. Parasitoids were obtained from a stock culture initiated with insects from Alabama, Georgia, and Louisiana. Voucher specimens from this culture have been deposited at the University of Georgia Museum of Natural History. Parasitoids were collected daily from the window-illuminated side of a screen cage as they emerged from bolts of loblolly pine, *Pinus taeda* L., infested with the bark beetle, *Ips grandicollis* (Eichhoff) (Sullivan et al., 1999). Following collection, males and females were housed together in 250-ml Erlenmeyer flasks containing two to three light-duty paper wipers and stored in an incubator at 8°C, 40–90% relative humidity, and a 14L:10D photoperiod. Flasks were provisioned with honey and distilled water and removed from the incubator for approximately 1 hr daily to allow parasitoids to feed, take water, and mate. Male courtship behavior toward live females was observed inside the flasks or small glass enclosures and recorded.

Unless otherwise noted, parasitoid males and females utilized in bioassays had been collected from emergence cages three to five days previously. Ninety

percent of these females were found to have live spermatazoa in their spermathecae ($N = 30$). One day prior to use in bioassays, males were isolated from females into separate Erlenmeyer flasks held as above but at $25 \pm 2^{\circ}$C.

Bioassays. Male responses to surrogates of live females were observed in an olfactometer consisting of a glass tube (15 mm $\times$ 5 mm ID) sealed on one end with a disk of Teflon screening (0.1-mm mesh). Each female surrogate was mounted singly on an insect pin inserted lengthwise through a cork such that the surrogate was 6–9 mm from the cork's tapered end. Surrogates were either glass female "decoys" or the cadavers of freeze-killed female parasitoids. Glass decoys consisted of borosilicate glass bulbs (3–4 mm long $\times$ 1.5 mm diam.) constructed by melting the ends of Drummond 5-μl micropipets in a Bunsen burner (Figure 1). For cadaver surrogates, females were killed in a deep freezer and mounted lengthwise on insect pins by gluing their legs to the pin's shaft with a small amount of Elmer's Glue-All. After the glue had dried, extracts were applied to surrogates as a 10-μl aliquot delivered from either a micropipet or a Hamilton syringe. The extract was delivered as evenly as possible across the surface of each female surrogate. Normally, glass decoys were assayed two days following application of test extracts; cadavers were tested one day following mounting and application of test extracts to permit extraction solvents to evaporate completely. Unless noted otherwise, individual surrogate preparations were tested in four separate trials (each with a different male) and then replaced. No significant reduction in male responses was observed between the first and fourth trials with the same surrogate ($P = 0.136$, signed-rank test, $N = 201$).

At the beginning of each trial, a male parasitoid was gently aspirated into the glass tube using a length of flexible plastic tube ($\sim$30 cm long $\times$ 6 mm ID) sealed to the screened end of the glass tube. A mounted female surrogate was then presented to the male by inserting it into the open end of the glass tube. The surrogate's mounting cork was pushed firmly into the tube's mouth, thus stabilizing the surrogate within the glass tube and preventing male escape. The behavior of the enclosed male was then observed with a dissecting microscope under fluorescent laboratory lighting for 2.0 min.

For each trial, a response score was recorded as the sum of single points awarded for each of three observed behaviors: (1) climbing onto the surrogate while antennating its surface ("mounting"), (2) rapid vibration of the wings either while adjacent to or mounted on top of the surrogate ("fanning"), and (3) repeated thrusting of the exserted genitalia against the surrogate ("attempted copulation"). Males were tested once and then discarded. Individual experiments consisted of sequential assays of a related set of treatments grouped to allow statistical comparisons. Within each experiment, treatments were assayed in random order and with equal replicates of each treatment executed at any single testing session. Experiments were conducted between hours 4 and 11 of photophase at ambient laboratory conditions: $25 \pm 2^{\circ}$C and 30–60% relative humidity. Separate olfactometer tubes

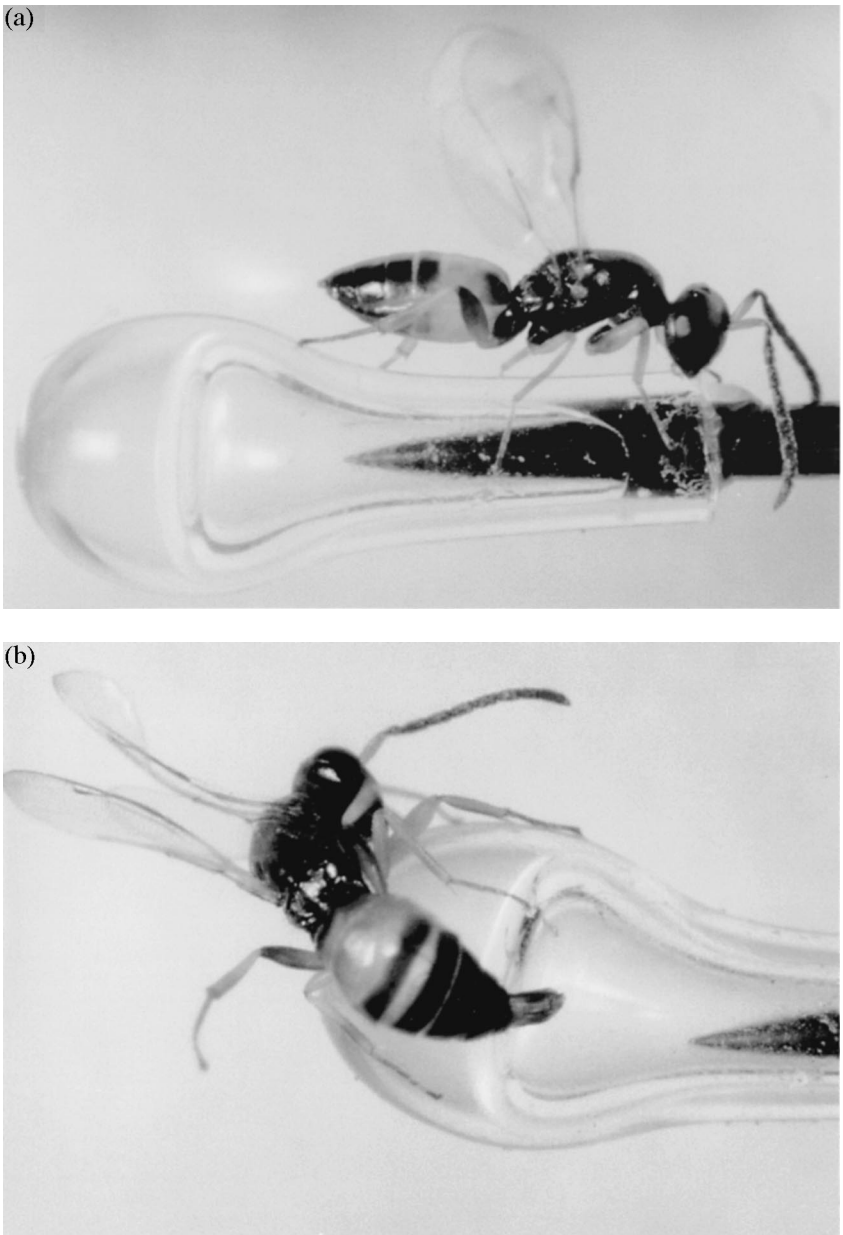

FIG. 1. Male *R. xylophagorum* exhibiting sexual behaviors in response to a glass bulb treated with a whole-body acetone extract of *R. xylophagorum* females: wing fanning (a) and copulation attempt (b).

were assigned to the different surrogate treatments, and olfactometer tubes were sonicated in a 1:1 acetone–ethanol mixture and oven dried for >2 hr at 120°C between test sessions. Experiments and treatments are described below.

Pheromone Stimulation of Male Sexual Behaviors. In the olfactometer, males ($N = 20$) were presented with female cadavers that were either (1) not manipulated, (2) extracted to remove all traces of pheromone, or (3) extracted and then treated with one female equivalent (1 FE) of female extract. Female extract was obtained by steeping 10 freezer-killed females in 50 μl acetone for 15 min, then rinsing the insects with another 50 μl acetone and combining the rinse with the original extract (1 FE = 10 μl extract). Cadavers used in treatments 2 and 3 above were further extracted: twice in 10 ml hexane, acetone, and 95% ethanol for >1 hr each with gentle agitation on a shaker table.

Pheromone Characteristics. In separate experiments, males were presented with: (1) glass decoys treated with either a hexane, acetone, or methanol extract (1 FE) of whole parasitoids, (2) decoys treated with sequential dilutions of a 1 FE acetone extract of whole females (1.0, 0.1, 0.01, 0.001, or 0.0001 FE), or (3) decoys that had been treated with a 0.01 FE acetone extract and then stored in a dark cabinet in the laboratory for 2–6 hr, or one, two, four, or seven days ($N = 20$, 20, and 32, respectively).

Source of Pheromone. Isolated body regions were extracted sequentially to distinguish between pheromone that may have spread across the entire body surface from its site of origin and that present in exocrine organs within or beneath the cuticle. The abdomens of 10 freezer-killed females were separated from heads/thoraces with a scalpel, and the two body regions were placed into separate vials and extracted three times in acetone: (1) 5 min with 100 μl, then (2) 15 min with 100 μl, and finally (3) thoroughly macerated with a glass rod and extracted with 1.0 ml for 15 min. Prior to application to decoys, extracts 1 and 2 were diluted 1/10 in acetone (0.1 FE = 10 μl). Extract 3 was spun at 2000 rpm in a clinical centrifuge to remove particulates and then used undiluted. In the olfactometer, males ($N = 20$–28) were presented with glass decoys treated with one of the three extracts of either body region. Each extraction was tested as a separate two-treatment experiment.

Effect of Female Mating and Age on Pheromone Production. Parasitoid pupae were dissected from *I. grandicollis*-infested pine bolts from the stock culture, placed into gelatin capsules, incubated in the dark at 29°C and 70–80% relative humidity, and inspected daily. On the day of eclosion, females were either extracted immediately or transferred in groups of up to eight individuals into housing flasks as described previously. Half of these flasks contained 3-5-day-old males ($N = 12$–15) collected from the emergence cage; the remaining flasks did not contain males. Flasks were maintained at 25 ± 2°C, 40–80% relative humidity, and a 14L:10D photoperiod for three to five days, and then the females were removed and extracted. To estimate the proportion of mated females in the mixed-sex flasks at the time of extraction, 18 females were dissected live and the spermathecae examined.

Individual parasitoids were extracted whole in acetone (2×100 μl) for 15 min (0.05 FE = 10 μl). Males ($N = 32$) were presented with glass decoys treated with the extract of: (1) a 1-day-old virgin male, (2) a 1-day-old virgin female, (3) a 3- to 5-day-old virgin female, (4) a 3- to 5-day-old female from a mixed-sex flask, or (5) a female that had naturally emerged three to five days earlier from a pine bolt in the stock culture. Eight decoys each bearing the extract of an individual insect were assayed per treatment (four males tested per decoy).

In a separate experiment, males ($N = 32$) were presented with cadavers of females that had emerged from culture bolts either 3–5 or 14–16 days earlier. Females in the 14 to 16 day category were removed from the 8°C incubator at five days and then maintained in culture flasks at 25 ± 2°C, 40–80% relative humidity, and a 14L:10D photoperiod for an additional 9–11 days. Females in the three to five-day category were kept consistently at 8°C prior to freezing and mounting.

Effect of Recent Female Contact on Male Responsiveness to Pheromone. Males were isolated from females for varying durations prior to being assayed for their response to decoys treated with 0.1 FE acetone extract of whole females. Male test subjects were held in housing flasks with ~50 females before being isolated into clean flasks. Males ($N = 30$) experiencing four different separation intervals were assayed: 0 hr (removed from mixed-sex flask immediately before each trial), 1–2 hr, 5–9 hr, and 18–36 hr. The same decoy was used in up to eight trials.

Activity of Fractions of Female Extract. A hexane extract of whole females was fractionated using low-pressure liquid chromatography, and the resulting fractions were bioassayed. A Pasteur pipet was plugged at its tip with silanized glass wool and then wet-packed with silica gel (1.0 g, 70–230 mesh, Merck grade 7754, conditioned >1 hr at 130°C) in 40% ethyl ether in hexane. The packed column was rinsed with 10 ml hexane prior to loading with sample (50 μl of a 100-μl hexane extract of 10 females, i.e., 5 FE). Fractions were eluted sequentially with 5 ml of hexane; 5% ether in hexane; 30% ether in hexane; ether; acetone; and methanol. Prior to application to decoys, each fraction was evaporated under nitrogen to a volume of 0.5 ml, and a portion of the original extract was diluted 1/10 in acetone (so that 10 μl = 0.1 FE for all extracts and fractions). Males ($N = 16$) were presented with glass decoys treated with each of the six fractions singly, the six fractions in combination (10 μl of each), or the original, unaltered extract.

Female Deposition of Pheromone on Surfaces. Ten females were confined for 0.5 hr inside a 4-cm-diam. plastic Petri dish bottom covered with a 15-cm-diam. glass plate. During this time, females walked across and/or stood motionless on the glass surface. Control glass plates were prepared similarly but with no females present. Two concentric circles were drawn on the reverse side of each plate: the inner circle marked the position of the dish rim and the outer was 7 cm diam. The Petri dish and females were removed, and the glass plate was suspended vertically against a white surface (dish side out). Within 1 hr of female removal, individual

male parasitoids were released onto the plate surface (inside the bottom third of the inner circle) and observed for 5 min. The total time each male spent in motion within the outer circle was measured with a stopwatch. Four female-exposed and blank plates were assayed with 6–10 males each.

Chemical Analyses. Portions (100 μl each) of the extracts and fractions utilized as decoy baits were concentrated under nitrogen to approximately 2–5 μl, and 1 μl was then injected splitless into a Hewlett-Packard 6890 gas chromatograph coupled to a model 5973 mass-selective detector (GC-MS). The column was a Hewlett-Packard HP-1 (polydimethylsiloxane; 50 m $\times$ 0.2 mm ID, 0.11-μm film thickness); the temperature program was 60°C for 1 min, then 10°C/min to 200°C, then 6°C/min to 310°C, then isothermal for 20 min. Each sample was spiked with two internal standards (11 ng 1,3,5-triphenyl benzene and 9 ng α-humulene) prior to concentration. Components of the extracts–fractions were identified by their mass spectra and retention time matches to known standards when available. Each component was quantified by dividing the integration area for one of its diagnostic ions by the integration area of a diagnostic ion of one of the internal standards. The following decoy baits were analyzed: acetone extract of 1-day-old virgin males, acetone extracts of 1-day- and 3- to 5-day-old virgin females, hexane extract of naturally emerged, presumably mated females, and all six silica gel fractions of the hexane extract.

Statistical Analyses. Response scores for the two to four males tested with each surrogate were averaged, and these means were utilized as individual data points in statistical analyses. Significant differences among treatment means were identified with the nonparametric Kruskal-Wallis ANOVA and Mann-Whitney rank sum tests. The Student-Newman-Keuls test was employed for all-pairwise comparisons among treatments ($\alpha = 0.05$; SigmaStat, 1997). Associations between the concentrations of bait constituents and male responses to those baits (i.e., the mean response score for that bait) were assessed with Spearman's rank order correlation (SigmaStat, 1997).

RESULTS

Male Sexual Behavior. Courtship behavior by males toward live females consisted of a characteristic succession of steps. A male would initiate courtship either after chance antennal contact with a female (during what appeared to be nondirected, random movements) or after coming within $\sim$2 cm of a female. The male would approach with accelerated, sinuous movements while fanning his wings almost continuously. He would then mount the female, typically from the side, while making constant antennal contact. Once on top, the male aligned his body above the female's with his head directly above hers. Sometimes the male would pivot his body several times before settling in the typical alignment. The

aligned male then initiated a predictable sequence of behaviors: (1) a brief burst of wing fanning, (2) a nodding motion of the head in which the mouthparts were extruded and stroked forward and upward above the female's antennae, and (3) a motionless pause approximately equal in duration to behaviors 1 and 2. Step 2 was often accompanied by sweeping movements of the male's antennae slightly towards one another and upward; occasionally the male's antennae would contact and noticeably move the female's antennae. This complete sequence was typically repeated two to five times and immediately followed either by male attempts at copulation or abandonment of the female. If copulation attempts failed, often the male would reposition himself above the female and recommence the sequence.

Bioassays. In the glass-tube olfactometer, males responded to female cadavers with wing fanning, mounting, and copulation attempts. Cadavers extracted with a series of organic solvents elicited relatively few male responses, but their activity was largely restored after treatment with 1 FE acetone extract (Figure 2). Males responded to extracted cadavers with mounting and antennation only; only the nonextracted and extract-treated cadavers elicited wing fanning and copulation attempts.

Glass bulb decoys treated with 1 FE extract likewise stimulated wing fanning, mounting, and copulation attempts (Figure 1). However, methanol extracts of females elicited significantly lower levels of response than either hexane or acetone extracts (Figure 3). Acetone extracts of females induced male responses in a dose-dependent manner within the concentration range of 0.0001 FE to 1 FE (Figure 4).

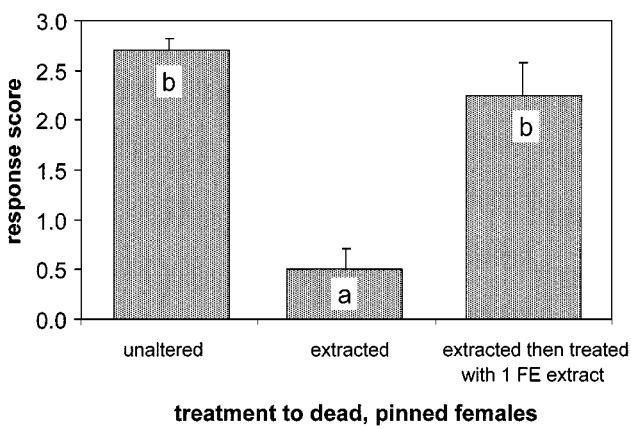

FIG. 2. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 20$) reacting to pin-mounted female cadavers that were either not manipulated, extracted repeatedly in organic solvents, or extracted and then treated with whole-body extract (1 FE) of a female. Means with the same letter are not significantly different (Student-Newman-Keuls test; $\alpha = 0.05$).

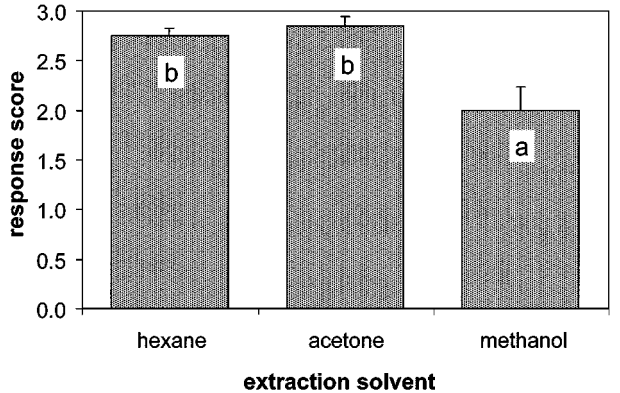

FIG. 3. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 20$) reacting to glass bulb decoys treated with either a hexane, acetone, or methanol extract (1 FE) of a female. Means with the same letter are not significantly different (Student-Newman-Keuls test; $\alpha = 0.05$).

Glass decoys treated with 0.01 FE acetone extract gradually lost activity over a seven-day period (Figure 5).

Male responses to decoys treated with the initial extracts of either abdomens or heads/thoraces of females were essentially identical, while decoys treated with the second consecutive extract of heads/thoraces had a marginally higher level of activity than the second consecutive extract of abdomens ($P = 0.053$; Figure 6).

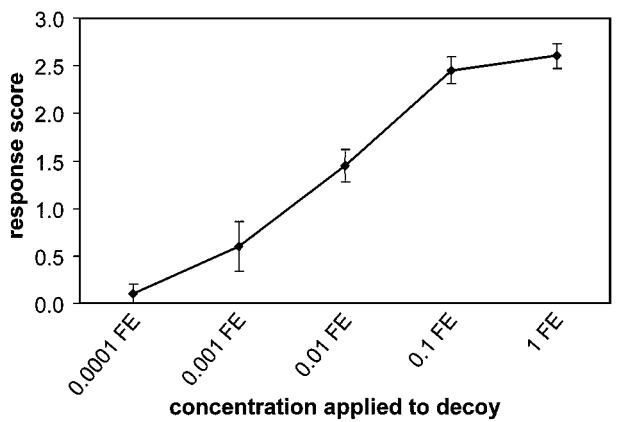

FIG. 4. Mean response scores (±SE) of individual male *R. xylophagorum* ($N = 20$) reacting to glass bulb decoys treated with the serial dilutions of an acetone extract of females (0.0001–1.0 FE).

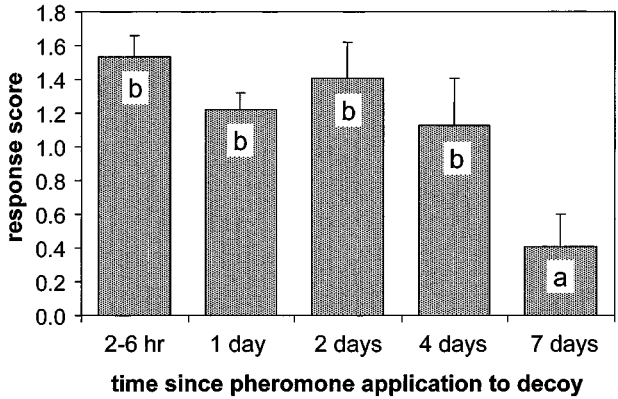

FIG. 5. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 32$) reacting to glass bulb decoys treated with female extract (0.01 FE) at different time intervals prior to testing. Means with the same letter are not significantly different (Student-Newman-Keuls test; $\alpha = 0.05$).

This difference in the activity of the second extracts was most visible in the number of males making copulation attempts: 12 for head/thorax-treated decoys vs. 1 for abdomen-treated decoys. Maceration and further extraction of the two body regions yielded extracts with relatively low levels of activity that did not differ significantly.

Live spermatozoa were found in the spermathecae of 12 of 18 females that had been housed with males for three to five days following eclosion in gelatin capsules. Extracts of these females, of 3- to 5-day-old virgin females from single-sex flasks, and of females naturally emerged from infested bolts elicited roughly similar

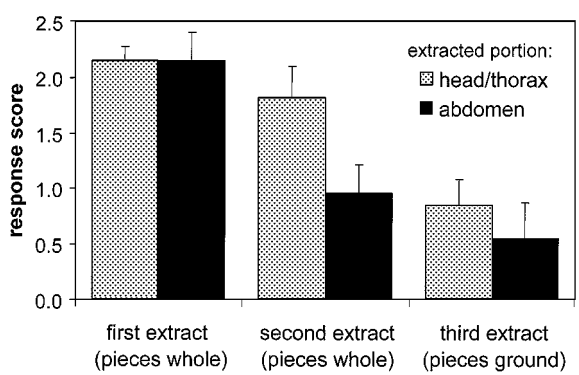

FIG. 6. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 20-28$) reacting to glass bulb decoys treated with one of three sequential extractions of either the head/thorax or abdomen of females (0.1 FE).

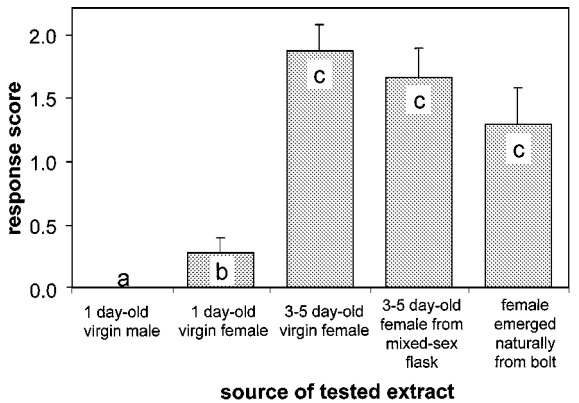

FIG. 7. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 32$) reacting to glass bulb decoys treated with the acetone extracts (0.05 FE) of 1-day-old virgin males, 1-day-old virgin females, 3- to 5-day-old virgin females, 3- to 5-day-old females that had been housed in mixed sex flasks, or females that had emerged naturally from host-infested pine bolts and were presumably mated. Insects in all treatments except the last had been isolated as pupae from host-infested bolts. Means denoted with the same letter are not significantly different (Student-Newman-Keuls test; $\alpha = 0.05$).

levels of male responses; simultaneously, these three treatments had significantly greater activity than extracts of either 1-day-old virgin males or females (Figure 7). Extracts of 1-day-old virgin females showed significantly greater activity than extracts from 1-day-old virgin males. Male response scores elicited by cadavers of females that had emerged from bolts either three to five days earlier (2.50 ± 0.23) or 14–16 days earlier (2.53 ± 0.15) did not differ significantly.

Mean response to extract-treated decoys was significantly lower for males removed from mixed-sex flasks immediately before bioassay than for males isolated from females 1–2, 5–9, or 18–36 hr prior to bioassay (Figure 8). Males isolated 1–2 hr prior to bioassay were intermediate in responsiveness between males with either longer or shorter periods of isolation.

Most of the activity present in female extract was recovered with the first hexane fraction on silica gel (Figure 9). Male responses did not differ significantly between decoys treated either with all six fractions or with the first fraction alone, indicating the absence of synergism between any of the fractions.

Males remained in motion within a 7-cm-diam. zone on a glass plate for significantly longer durations when females had previously been confined within the zone than when they had not (Figure 10; $P < 0.001$, Mann-Whitney rank-sum test). Half the males placed onto female-exposed plates exhibited wing-fanning behavior, and many such males exhibited accelerated, sinuous movements in and around female-contacted surfaces.

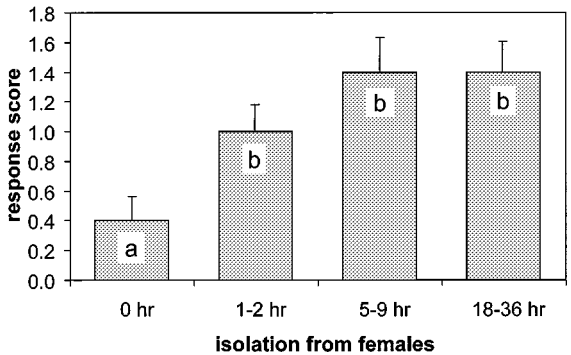

FIG. 8. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 32$) that had been removed from mixed-sex flasks at variable intervals prior to testing with glass decoys treated with female extract (0.1 FE). Means denoted with the same letter are not significantly different (Student-Newman-Keuls test; $\alpha = 0.05$).

Chemical Analyses. The 68 largest GC peaks in female extract (i.e., all peaks >0.2% the integration area of the largest peak) were quantified for the examined decoy baits, and identifications were made for 28 peaks exhibiting a strong degree of association (Spearman rank-order correlation coefficient >0.75) between their concentrations and male response scores to the individual baits (Table 1). Structures

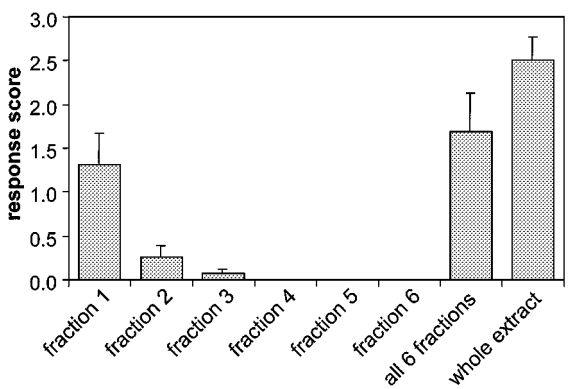

FIG. 9. Mean response scores (+SE) of individual male *R. xylophagorum* ($N = 16$) reacting to glass bulb decoys treated with a hexane extract of females, each of six LC fractions of the extract, or all six fractions simultaneously. Extract fractions were eluted sequentially with hexane (fraction 1), 5% ether in hexane (fraction 2), 30% ether in hexane (fraction 3), ether (fraction 4), acetone (fraction 5), and methanol (fraction 6). Extract and fractions were applied at 0.1 FE per decoy.

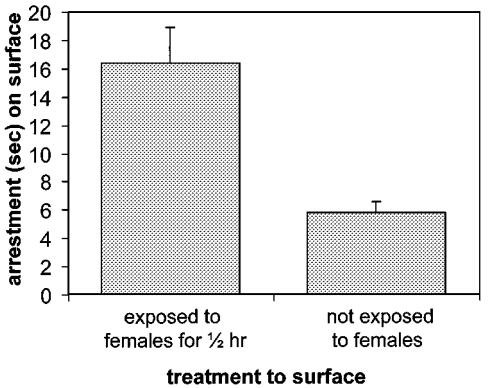

FIG. 10. Mean time (+SE) spent by male *R. xylophagorum* ($N = 29-40$) in motion within a 7-cm-diam. zone of a glass surface that had or had not been contacted by walking females. Male arrestment time differed significantly between the two treatments (Mann-Whitney test; $P < 0.001$).

were determined for all 28 of the correlating peaks based on retention times and interpretation of mass spectra (Blomquist et al., 1987; Carlson et al., 1998). These compounds consisted entirely of alkanes with a 27- to 33-carbon backbone and no, one, or two methyl branches.

DISCUSSION

Female *R. xylophagorum* apparently possess a sex pheromone capable of stimulating courtship behavior and mating in males. Removal of chemical cues from female cadavers by solvent extraction largely eliminated sexual behavior directed toward them, while restoration of chemical cues through the reapplication of female extracts restored male responses. Male response to the pheromone was minimally altered by the absence of visual and tactile cues normally associated with a female. Males responded with the complete courtship sequence (including body alignment and head nods) to pheromone-treated glass decoys, although these decoys differed substantially in color, shape, and texture from female parasitoids. However, the courtship sequence was often terminated at various stages prior to attempted copulation, and this likely resulted from the absence of receptivity signals or other cues from the female surrogate (Van Den Assem, 1986). Pheromone-based stimulation of male courtship behaviors (including wing fanning and copulation attempts) in the absence of normal visual/tactile cues associated with females has been reported in other parasitic Hymenoptera (Obara and Kitano, 1974; Kitano, 1975; Robacker et al., 1976; Vinson, 1978; Yoshida, 1978; Takahashi and Sugai, 1982; Shu and Jones, 1993).

TABLE 1. CONSTITUENTS OF FEMALE EXTRACT WITH STRONG ASSOCIATION BETWEEN THEIR CONCENTRATIONS AND RESPONSE SCORES OF MALE *R. xylophagorum* (SPEARMAN'S CORRELATION COEFFICIENT >0.75)

Kovats index	Compound name	Correlation coefficient[a]	% of cuticular hydrocarbons[b]	Gender association[c]

[a] Spearman's rank-order correlation coefficient between average male response score and quantity of compound identified in tested bait. Baits subjected to analyses included extracts of 1-day-old virgin males, 1- and 3- to 5-day-old virgin females, mated females, and six silica gel fractions of this latter extract.

[b] Percentage of total cuticular hydrocarbon composition identified in female *R. xylophagorum*. Only those hydrocarbons with correlation coefficient >0.75 are shown (88.3% of total).

[c] Gender association of individual compounds identified in the cuticular hydrocarbons of North American populations of *R. xylophagorum* (Espelie et al., 1996). Treatment abbreviations are F = only in females, F > M = female concentrations greater than four times those in males, F&M = present in roughly similar concentrations in both sexes, — = not reported in Espelie et al. (1996).

The courtship-stimulating pheromone may also mediate mate-finding in *R. xylophagorum*. Males coming into contact with residue deposited on a glass surface by walking females confined their movements to its vicinity for up to 45 sec while apparently searching for females. The residue likewise induced male wing fanning, a behavior, which, in addition to triggering receptivity in females (Kitano, 1975; Van Den Assem, 1986), may also enhance orientation toward sources of female odors (Vinson, 1972, 1978). Males of other parasitoid species exhibit similar, mate-finding-related behaviors (e.g., arrestment, accelerated movement, increased turning rate) on substrates previously contacted by females (Kamano et al., 1989; Pompanon et al., 1997; Fauvergue et al., 1998). Substrate-borne pheromone residues may concentrate searching by males in areas frequented by females, increasing the probability of sexual encounters. Although lacking the ability to attract males over long distances, substrate-borne sex pheromones can be adequate for ensuring a high rate of insemination for female parasitoids (Fauvergue et al., 1995).

The gradual recovery in male responsiveness to sex pheromone following removal from mixed-sex flasks indicated that male courtship behaviors can be temporarily inhibited by continuous contact with females or their environment. The inhibition in male responsiveness was possibly caused by habituation to the female's sex pheromone (Robacker et al., 1976; Askari, 1979) or may have been a reaction to unsuccessful courtship attempts with unreceptive females (Van Den Assem, 1986).

Sex pheromones in hymenopterous parasitoids originate in the abdomen (Tagawa, 1977; Vinson, 1978; Yoshida, 1978; Askari and Alishah, 1979), the head and/or thorax (Takahashi and Sugai, 1982; Kainoh and Oishi, 1993), or both regions (Vinson, 1972), and pheromone-producing glands have been identified in both the abdomen and head (Tagawa, 1977; Weseloh, 1980; Syvertsen et al., 1995; Jones, 1996). Parasitoid pheromones may have their origin in a localized gland but spread across the insect's entire body either passively or as a result of grooming (Tagawa, 1977). The results presented here suggest that the sex pheromone of *R. xylophagorum* was uniformly present across the body surface of females, but do not clearly identify a single body region as the site of pheromone production.

Mating by female parasitoids can cause an abrupt termination of male responses through an apparently copulation-induced change in the release rate or composition of the female pheromone (Fauvergue et al., 1995; McNeil and Brodeur, 1995; Pompanon et al., 1997; Schwörer et al., 1999). *Roptrocerus xylophagorum* males did not respond differently to extracts from virgin females than to extracts from females that had been housed with males, suggesting that mating does not alter pheromone presence on females. However, dissections of spermathecae indicated that some of the females from mixed-sex flasks had probably never mated, and their unintentional inclusion in the tests may have partially obscured changes in male responses.

Concentrations of pheromone on female *R. xylophagorum* apparently did not diminish with age, since males responded equally to cadavers of females that were either younger (3–5 days old) or older (14–16 days old) than the average life span of six to eight days (Samson, 1984; Matthews and Stephen, 1997). The life-long presence of active sex pheromone on female *R. xylophagorum* is not a unique phenomenon within the parasitic Hymenoptera (Vinson, 1978; Swedenborg and Jones, 1992b). There is little evidence to suggest that persistence of sexual attractiveness enhances the fitness of female *R. xylophagorum.* This species is reported to mate immediately after emergence and only once (Bushing, 1967), and the extreme infrequency with which I have observed apparently receptive *R. xylophagorum* females seems to corroborate this report. The persistence of pheromone on female *R. xylophagorum* might be an incidental consequence of the low volatility and high stability of semiochemicals produced earlier in life, and little or no active synthesis or release of pheromone may be necessary for the pheromone's activity to persist throughout the female's life span.

The only extract constituents possessing a strong quantitative association with male responsiveness were apparently cuticular hydrocarbons. All were long-chain alkanes removed from whole insects with relatively brief steeping in hexane and had been previously identified in the cuticular hydrocarbons of other insects (Blomquist et al., 1987; Carlson et al., 1998). Espelie et al. (1996) reported numerous qualitative and quantitative differences in the cuticular hydrocarbon composition of male and female *R. xylophagorum* and suggested that these differences might play a role in close-range mate recognition. Several of the compounds correlating quantitatively with male responsiveness in my study were previously identified by Espelie et al. (1996) as being associated primarily or uniquely with female *R. xylophagorum* (Table 1).

The bioassay results support the hypothesis that the sex pheromone is composed of cuticular hydrocarbons, which function as close-range sex pheromones in several orders of insects (Howard, 1993). As expected for cuticular hydrocarbons, the pheromone was apparently distributed over the entire body surface. It was highly nonpolar, eluting mainly with the first, hexane fraction on silica gel, and it exhibited significantly lower solubility in methanol relative to hexane and acetone. Likewise, the long persistence of the pheromone on objects was consistent with the typical stability and extremely low vapor pressure of long-chain, saturated hydrocarbons. Bioassays with synthetic hydrocarbons will be necessary to confirm the role of these compounds in mediating sexual behavior in *R. xylophagorum*.

Acknowledgments—I thank Ray Arnold and Jonny Fryar for maintaining the parasitoid colony during the study. Lori Nelson provided help with the interpretation of several of the hydrocarbon spectra. Karl Espelie, Chris Asaro, and Dan Slone provided critical reviews of the manuscript prior to its submission.

(Received April 24, 2001; accepted January 9, 2002)

Abstract—The Comstock-Kellog glands in adult females of certain acridid species, including the desert locust, *Schistocerca gregaria* have been implicated as a source of volatiles that play a role in mating behavior. A dichloromethane extract of the glands was analyzed for metabolites by gas chromatography, coupled gas chromatography–electroantennographic detection, and mass spectrometry. Coupled gas chromatography–electroantennographic detector (GC-EAD) analysis revealed a component that elicited an electroantennogram response from the antenna of adult male *S. gregaria*. The compound was identified by GC-MS as pentanoic acid. The levels of the compound in the gland extract varied with age of female locust; it was present in detectable amounts only in 14- to 16-day-old females. In bioassays, pentanoic acid significantly stimulated pre-mating behavior in male desert locust. These results are discussed in relation to the biology of the locust.

Key Words—Pheromone, mating behavior, *Schistocerca gregaria*, Acrididae, Comstock-Kellog gland, pentanoic acid, hexanoic acid, heptanoic acid, octanoic acid, nonanoic acid, decanoic acid.

INTRODUCTION

Acridids in the subfamily *Cyrtacanthacridinae* exhibit precopulatory behavior as part of their mating repertoire (Uvarov, 1966). These behaviors may involve various postures, nonlocomotory movements, and gestures. In the desert locust, *Schistocerca gregaria*, the behavior is generally characterized by a slow approach

of the male to the female, frequently interrupted by "freezing" in a semistilted posture, and rhythmic movements of the maxillary palps (Uvarov, 1977), antennation, antenna- and eye-cleaning, scanning, and body vibration (Inayatullah et al., 1994). Other male sexual behaviors may involve production of "short" and "long" bursts of sound by stridulation of both pairs of wings (Loher, 1959) or rapid vibration of the wings under the tegmina, described by some authors as stationary wing-fluttering (Uvarov, 1977).

In female locust of some species in the subfamily, precopulatory behavior may involve extrusion of the Comstock-Kellog glands (CKGs). These are a pair of membranous eversible organs with folded walls and glandular epithelium that are located at the anterior of the floor of the genital pouch (Thomas, 1965; Uvarov, 1966; Szopa, 1981). Over the years, there has been debate as to whether the glands function in mate attraction or in oviposition (Whitman, 1990). Nevertheless, experiments have been conducted on only a few species. The first experiment was conducted by Eisner et al. (1966), who showed that in the grasshopper *Romalea microptera*, secretions from the glands cause tanning of eggs and froth of the egg pod. In later experiments, excision of the glands from mature virgin females of another grasshopper, *Melanopus sanguinipes*, did not affect their coupling with males (Pickford and Gillott, 1972). Similarly, removal of the CKGs from females of *S. gregaria* did not affect their oviposition behavior and egg pod formation (Szopa, 1981). In these grasshopper species and the desert locust, results from experiments do not preclude the possibility that the glands may play a role in other aspects of the mating behavior. It has been suggested that in the desert locust the glands may release odors that attract males (Uvarov, 1966, 1977). Despite the speculated role of the CKGs, no chemical analysis has been carried out on secretions of the glands.

In the present study, we employed gas chromatography (GC), coupled GC-electroantennography, GC-mass spectrometry, and behavioral assays to determine (1) the chemical composition of the extract from the gland, (2) whether there is evidence of sensory detection of extract components, (3) whether there is evidence of behavioral response to physiologically active compounds, and (4) whether there are age-related variations in the amounts of the active components?

METHODS AND MATERIALS

Insects. Crowd-reared (gregarious) desert locusts, *S. gregaria*, were from the ICIPE colony that originated from a stock obtained from the Desert Locust Control Organization for Eastern Africa (DLCO-EA) in Addis Ababa, Ethiopia. The colony had been propagated in the insectary since 1991, and locusts were reared as described in Obeng-Ofori et al. (1993), Torto et al. (1994), and Njagi et al. (1996). Batches of 300–400 hundred locusts of both sexes (male to female ratio *ca.* 1:1) were bred in cages made of light aluminum sheets ($50 \times 50 \times 50$ cm) that had wire mesh ventilation ports (14×15 cm) on two sides and the top (Ochieng-Odero et al.,

1994). Locusts in each cage developed synchronously from one stage to the next and were all of the same age. Cages with locusts were kept in a temperature-controlled room maintained at 30–35°C and a light–dark cycle of 12:12 hr. The room was aerated by a duct system maintained at a negative pressure. Insects were fed *ad libitem* fresh wheat (*Triticum* sp.) seedlings and wheat bran, provided daily.

Gland Extracts. Female locusts, 1–3, 7–9, 14–16, and 20–22 days old after final molt and held in glass jars, were kept in a freezer at −15°C prior to dissection to remove the glands. The CKGs were located as illustrated by Szopa (1981), and for each age group, glands from 15 females were dissected out. The glands were extracted in 2 ml HPLC grade dichloromethane (99.9%; Aldrich Chemicals, Gillingham, UK) in a vial kept overnight (*ca.* 18 hr.) in a refrigerator at 4°C. The extracts were filtered through a clean glass wool plug in a Pasteur pipet, dried over anhydrous sodium sulfate, and stored in a freezer at −15°C until used. For each age group, five such extract samples were prepared.

Analysis of Extracts. Extracts were concentrated to 100 μl under a stream of nitrogen at 0°C. For GC analysis, 4 μl of each extract were injected onto the capillary column. In GC-EAD tests, we used 8 μl since the GC had a 1:1 ratio splitter to the EAD and the detector. The GC analyses were performed on a Hewlett-Packard (HP) 5890 Series II gas chromatograph equipped with a flame ionization detector and an HP capillary column (Carbowax 20 M, 50 m × 0.2 mm ID × 0.2 μm). Nitrogen was used as the carrier gas at a flow rate of 0.35 ml/min. In GC, GC-EAD, and GC-MS analyses, the column temperature was set at 60°C for 10 min, programmed at 5°C/min to 180°C and held for 5 min, then at 10°C/min to 220°C and held for 10 min. Chromatographic peaks for the GC analysis were integrated with an HP 3396 Series II integrator. GC-MS analysis was carried out on a VG Masslab 12-250 mass spectrometer (EI, 70 eV) coupled to an HP 5790 gas chromatograph. The identities of the components in the extracts were confirmed by GC-EAD and GC-MS analyses of authentic samples.

In GC-EAD analysis, preparation of the mature male locust antenna followed Torto et al. (1994). The FID and EAD signals were monitored synchronously by using a program on an EAD interface card (Syntech) installed in a PC (Harvard Professional Computer, American Megatrends Inc.). The FID signal was also plotted on an HP 3396 Series II integrator at 0.5 cm/sec.

Still Air Glass Jar Bioassay. The glass jar (6.5 cm ID and 19 cm high) had a perforated metal top covered with a wire mesh. A piece of wire mesh was placed inside at an inclined angle for climbing. The dispenser for the test material was a Pasteur pipet (11. 0 cm long × 0.5 cm ID at the wide end) with one end drawn to a short tapering tip (≅1.0 cm from the shoulder to the shank) with a tip diameter of 0.2 cm. A small ball of cotton wool plugged into the tip to a depth of 0.3 cm. Aliquots of 1.0 and 2.0 μl (equivalent to 0.5 and 1.0 μg of pentanoic acid, respectively) of a stock preparation of the acid (>99% pure; Aldrich Chemicals), in polyethylene glycol 200 (PEG) (Aldrich Chemicals)

(to slow down the evaporative release of the compound), were each pipetted onto the cotton wool plug. A sexually mature male or female locust (16–20 days old after final molt) or a sexually immature adult male (seven to nine days after final molt) was placed into the glass jar and left to settle at the bottom. After 2 min, a pipet with the test material was inserted through the wire mesh of the cover on top of the jar and pushed about 6.0 cm into it. At this point, the dispensing tip of the pipet was about 2.0 cm from the top of the slanting wire mesh strip. For the control, the cotton wool was impregnated with a similar volume of PEG, and in both cases, the behavior of the locust inside the jar was monitored for the subsequent 15–20 mins. The insects for control and treatment tests were drawn from the same batches of gregarious locusts reared as outlined above, and each was observed individually. Glass jars were thoroughly cleaned with a detergent and dried in an oven prior to reusing them to avoid contamination. Preliminary studies showed that in response to our treatment, locusts performed one of three types of behaviors:

1. An insect moved to within 1–2 cm from the tip of the pipet dispenser and stayed for a minimum of 5 min with the body halfway between the "stilted" and "crouching" postures (Uvarov, 1977). In the former posture, the locust raised its whole body above the wire mesh with the tibiae of the hind legs slightly folded such that the femora lay below and almost parallel to the top of the elytra. When crouching, the insect had its body pressed against the substrate with the hind femora and tibiae folded at an angle and pointing upwards. This was accompanied by vigorous mandibular and maxillary palp movements, preening of antennae with foretarsi, and, on rare occurrences, stationary wing-fluttering (see 3 below). Most of these activities are elements of the male precopulatory behavior (PCB) as described by Uvarov (1977) and are often elicited in sexually mature males prior to mounting females.

2. An insect moved to within 3–5 cm from the tip of the dispenser and stayed stationary in semistilted posture and/or almost crouching without noticeable movement of other body parts. This is interpreted as nonsexual behavior, possibly triggered by the presence of the dispenser in the field of vision of the locust and has been denoted as secondary arrestment (SAR) in this paper.

3. Stationary wing-fluttering (SWF) consisted of rapid movements of the elytra and the wings raised high above the abdomen as in flight while the insect perched on the wire mesh or on the wall of the jar. A bout of wing fluttering lasted for up to 4 secs and generated a low-pitched audible sound. This behavior is believed to be sexual, mainly with regard to mate attraction in some acridid species (Uvarov, 1977).

Five replicates were done for the control and the two doses of pentanoic acid for each of the three groups of locusts, immature males, and mature males and females. A replicate consisted of five insects. Each insect was observed individually in the glass jar only once and was not reused. The number of insects performing a given behavior was recorded and the percentage overall mean of the replicates

calculated for each group. For statistical analysis, data were transformed into arcsine and subjected to a multivariate analysis of variance (MANOVA, $\alpha = 0.05$; SAS Institute, 2000) to determine the dose effects on the behavior of the three groups of locusts. Differences between mean number of insects performing a behavioral activity for the different treatments were determined using paired Student's *t* test.

RESULTS

Gas chromatographic profiles of extracts of CKGs mainly included short-chain aliphatic acids including pentanoic (**1**), hexanoic (**2**), heptanoic (**3**), octanoic (**4**), nonanoic (**5**), and decanoic (**6**) (Figure 1). Pentanoic acid was present in

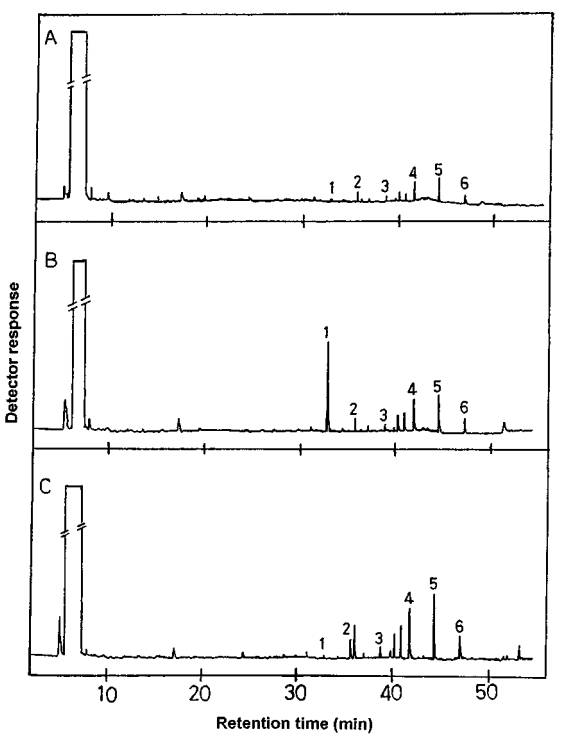

FIG. 1. Representative gas chromatograms of dichloromethane extracts of Comstock-Kellog glands of gregarious female desert locust ($N = 15$) of ages (A) 1–3 days, (B) 14–16 days, and (C) 20–22 days old after final molt showing the identified compounds: pentanoic acid (**1**), hexanoic acid (**2**), heptanoic acid (**3**), octanoic acid (**4**), nonanoic acid (**5**), and decanoic acid (**6**).

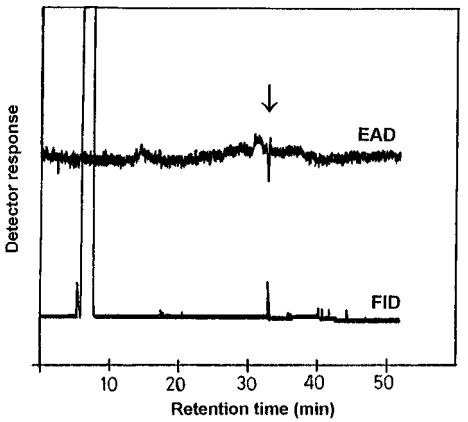

FIG. 2. Computer recorded GC-EAD response from antenna of adult male desert locust, *S. gregaria* to dichloromethane extract of Comstock-Kellog glands of conspecific adult females 14–16 days old after fledging (as in Figure 1). Compound **1**, identified to be pentanoic acid, was EAG-active (arrow).

moderately high amounts in CKG extracts from insects that were 14–16 days old, whereas in younger and older females, only trace amounts were detected. In GC-EAD tests, only pentanoic acid in volatiles from glands of female locusts that were 14–16 days old was EAG active (Figure 2).

In the glass jar bioassay, mature male locusts tended to behave differently (MANOVA, $P < 0.001$) from either the mature females or the immature males when exposed to pentanoic acid. The mature males exhibited strong precopulatory behavior when exposed to dispensers impregnated with 0.05 μg ($t = 15.1$, $df = 8$) and 0.1 μg ($t = 31.2$, $df = 8$) of the compound, whereas the immature males and the mature females did not exhibit the precopulatory behavior (Table 1). In addition, the mature adult males seem to have been more alert to other objects in their proximity than the other insects since a significant proportion ($t = 7.65$, $df = 8$; $P < 0.05$) of them reacted to the blank dispenser (control). On the other hand, all three groups of locusts exhibited secondary arrestment (SAR), which was only slightly significant ($t = 2.61$, $df = 8$; $P < 0.05$) between male and female mature adult locusts at 0.1 μg of pentanoic acid and between the immature adult male and mature adults of both sexes in the control. In essence, immature adult males and mature adult female locusts spent more time either moving up and down on the walls of the jar and climbing the wire mesh or, at some intervals, resting at the base of the jar or underneath the top cover.

Stationary wing-fluttering (SWF) behavior was observed in only a small proportion of mature adult male locusts ($t = 8.45$, $df = 8$; $P < 0.05$) that were exposed to the acid compared to the control (Table 1).

TABLE 1. BEHAVIORAL RESPONSES OF DESERT LOCUSTS TO PENTANOIC ACID (PA)[a]

	Activity (% of insects responding)[b]								
	Precopulatory behavior			Secondary arrestment			Stationary wing-fluttering

[a] Values are mean $\pm$ SE. Sexually immature adult male, Im-male; mature adult male, M-male; and mature adult female, M-female.

[b] Two-tailed t test for comparison between means: Differences between groups of locusts (rows) for each treatment; *significant ($P < 0.05$, $df = 8$), **highly significant ($P < 0.001$, $df = 8$), and ns = not significant. Differences between treatments for each group (columns) in each behavior activity with the same letter were not significant ($P > 0.05$, $df = 8$). $N = 5$ replicates with five locusts in each.

DISCUSSION

Our study suggests that pentanoic acid functions as a female-produced pheromone that elicits sexual behavior in male *S. gregaria*. There were variations in the relative amounts of pentanoic acid in the gland extracts. The maximum production of the acid was detected in 14- to 16-day-old females, which coincided with their sexual maturity. Under the rearing conditions in our insectary, a small proportion ($\leq$5% in a batch) of female locusts start mating when they were 12 days old after the final molt (fledging). The bulk of females ($\cong$95%) mate 13–15 days after fledging, and eggs are laid one to two days thereafter. In adult male desert locust, the onset of production of phenylacetonitrile, which is the key component of the aggregation pheromone, coincides with their sexual maturation (Mahamat et al., 1993; Deng et al., 1996). Thus, in addition to enlargement of oocytes in gregarious female locusts (Assad et al., 1997a,b), production of pentanoic acid may also increase at the onset of sexual maturity. Furthermore, production of pentanoic acid may influence mate recognition and mating. This is supported by the results of this study, which demonstrate that mature adult male locusts but not immature adult males respond to the odor of pentanoic acid with precopulatory behavior and stationary wing-fluttering when exposed to the acid.

Pentanoic acid, either on its own or in mixtures with other compounds, plays an important chemical ecological role in the behavioral repertoire of a number of insects. It is a sex pheromone for the wireworm, *Limonius californicus* (Mannerheim) (Jacobson et al., 1968) and an attractant for a dipteran *Olcella parva* (Adams) (Hibbard et al., 1997). A mixture of pentanoic acid and hexanoic acid has been used as a standard attractant for the adult rose chafer *Macrodactyla subspinosus* (Williams et al., 1990), and with phenylethanol, the blend is a lure for the onion flies *Delia antiqua* and *D. platura* (Ishikawa et al., 1984).

The results of the glass jar assays further showed that mature male locusts are more sensitive than immature males and mature females to the presence of innate objects in their surroundings. However, SAR was not largely influenced by the presence of pentanoic acid in the three groups. As suggested above, this was a behavioral reaction of the insects to the presence of the dispenser since, in its absence, locusts kept climbing up and down the wire mesh and/or walls of the glass jar.

Stationary wing-fluttering was exclusively observed in mature adult male locusts and was influenced by pentanoic acid, although not as markedly as PCB. There were also indications that there may be an optimum age during which most mature adult males perform this behavior. This behavioral activity is similar to, but more vigorous than, the stridulation of both wings that produces the “short sounds” in a male locust prior to jumping upon a female conspecific (Loher, 1959). However, despite wing-fluttering being a widespread phenomenon in acridids, its relation to sexual behavior has not been rigorously established (Uvarov, 1977).

In some cases, it is not clear whether it is the visual or acoustic or both components of the wing-fluttering that are important. In other insect species, for example the noctuids, wing-fluttering (fanning) may serve to create air movements that influence diffusion of a sex pheromone (Baker and Cardé, 1985). Thus, wing-fluttering in *S. gregaria* males may play a similar role since it has been documented that female *S. gregaria* are stimulated by a volatile substance that is produced by mature adult male conspecifics (Uvarov, 1966).

In summary, this is the first report to identify volatile chemicals from CKGs of gregarious mature adult females of the desert locust. The chemical signal was found to stimulate precopulatory behavior in conspecific mature adult males. The signal was more prominent in sexually mature females than in immature and older ones. However, it is possible that there may be other components of lower polarity that contribute to the specificity of the signal. Follow-up research will focus on identifying any other component(s) of the signal and determining whether the production is influenced by the phase status of the desert locust.

Acknowledgments—We thank Prof. A. Hassanali for critical review of an earlier version of the manuscript. We are also grateful to P. M. Njiru for technical assistance and the Locust Breeding Unit of the Animal Rearing and Quarantine Unit at ICIPE for the supply of locusts. This study is a contribution to the project on Locust Semiochemicals Research at ICIPE supported by funds coordinated by IFAD.

(Received October 4, 2001; accepted January 12, 2002)

Abstract—Male antennae of the Japanese beetle, *Popillia japonica*, possess olfactory receptor neurons (ORNs) cocompartmentalized in the same sensilla placodea, one tuned to the sex pheromone, (*R*)-japonilure, and the other to the detection of a behavioral antagonist, (*S*)-japonilure. In-depth electrophysiological experiments revealed mutual inhibitory and synergistic effects in ORNs stimulated simultaneously with the two semiochemicals. The olfactory system of *P. japonica* exhibited a remarkable ability to discriminate completely coincident strands of pheromone and behavioral antagonist from strands of the two semiochemicals temporally isolated (by 1.5–3 msec). The mutual inhibition was reflected mainly by the delay of onset or total lack of spikes and by the significant increase in the rise time of potentials generated by blends of (*R*)- and (*S*)-japonilure. In contrast, synergist ORNs showed no neural activity (spikes) when stimulated with either the sex pheromone or the behavioral antagonist, but showed clear responses to blends of the two semiochemicals. Evidence for mixture-suppressed responses was observed not only in the Japanese beetle, but also in the Osaka beetle, *Anomala osakana*, and the Oriental beetle, *Exomala orientalis*, thus suggesting that it is a common feature in the sensory physiology of scarab beetles.

Key Words—*Popillia japonica*, *Anomala osakana*, *Exomala orientalis*, Scarabaeidae, peripheral coding of semiochemicals, single sensillum recordings.

INTRODUCTION

Insects rely heavily on their highly sensitive and selective olfactory systems to perceive the world. Together with the discovery of sex pheromones (Butenandt et al., 1959), electrophysiological studies (Schneider, 1957) first began to reveal details of peripheral sensory physiology. With chemically pure pheromones available, the insect olfactory system became an experimentally favorable model for addressing basic questions in olfaction, given that antennal sensory neurons could be investigated by subjecting antennal preparations to a single stimulus. Experiments based on electroantennogram (Schneider, 1957) and single sensillum recordings (Schneider and Boeckh, 1962) highlighted the inordinate specificity and sensitivity of the insect olfactory system. While minimal structural modifications to pheromone molecules render them inactive (Kaissling, 1987), a single molecule of the native ligand is estimated to be sufficient to activate olfactory neurons in male antennae (Kaissling and Priesner, 1970). Given that the insect olfactory receptor neurons (ORNs) lie beneath a thick cuticle and are tightly enveloped by auxiliary cells, *in vivo* intracellular recordings at the periphery are technically difficult. On the other hand, the groundbreaking development of intracellular recording from insect brains (Matsumoto and Hildebrand, 1981) and optical measurements of glomerular calcium activities (Joerges et al., 1997) have attracted a great deal of attention and have given emphasis to elucidation of the function(s) of the antennal lobe and signal coding. Currently, it is widely accepted that insect antennae are merely "signal transducers" whose ORNs generate action potentials (spikes) that are transmitted directly to the antennal lobe, where primary processing and spatial and temporal coding take place.

In marked contrast to most insect species, females of the Japanese beetle, *P. japonica* (Coleoptera: Scarabaeidae), produce only a single pheromone compound, (*R*,*Z*)-(−)-(decen-1-yl)-octacyclopentan-2-one, (*R*)-japonilure (Tumlinson et al., 1977). The enantiomer of the Japanese beetle pheromone, (*S*)-japonilure, is used as a sex pheromone of the Osaka beetle, *Anomala osakana* (Leal, 1996). These two species share the same habitat in Japan and can detect each other's pheromone (Leal, 1996). This detection occurs within sensilla placodea on the antennae of each species. Each sensilla placodea contains a pair of ORNs. One of these ORNs responds to a species-specific pheromone, and the other responds to the pheromone of the other species (Wojtasek et al., 1998). In this study, we investigated the sensory physiology of scarab beetles by mimicking natural conditions where insects may encounter not only their own pheromone plume, but also the pheromones of other species, including behavioral antagonists. This study reveals that olfactory signals for behavioral attraction (sex pheromone) and olfactory signals for behavioral antagonism ("stop" signal) in the Japanese beetle are processed and encoded in the periphery before transmission to the antennal lobe.

METHODS AND MATERIALS

Insects. Eggs laid by field-collected beetles were transferred to wet sand in ice cream cups. After hatching, the grubs were transferred individually to ice cream cups filled with humus (Leal et al., 1994). Emerged adults were kept at 20°C (*Exomala orientalis*) or 25°C (*P. japonica*), 65–78% relative humidity, and under a 16L:8D photoregime. Adult *P. japonica* were fed on the artificial diet of the silkworm moth, *Bombyx mori* (Nihon Nosan Kogyo, Yokohama, Japan), whereas adult *E. orientalis* were provided with saturated sucrose solution on cotton.

Olfactory Stimuli. (*R,Z*)-(−)-(Decen-1-yl)-oxacyclopentan-2-one, (*R*)-japonilure, (*S,Z*)-(+)-(decen-1-yl)-oxacyclopentan-2-one, (*S*)-japonilure, (*R,Z*)-(−)-(octen-1-yl)-oxacyclopentan-2-one, *R*-buibuilactone, (*S,Z*)-(+)-(octen-1-yl)-oxacyclopentan-2-one, and (*S*)-buibuilactone were synthesized as previously described (Leal, 1999). The enantiomeric purity of these compounds, determined by gas chromatography with a cyclodextrin-based chiral column (Leal, 1991), was >99.6%. (*Z*)-7-Tetradecen-2-one and (*R,Z*)-(7,15)-(+)-hexadecadien-4-olide were prepared according to Leal et al. (1994) and Kuwahara et al. (1997), respectively.

Single Sensillum Recordings. Antennal preparations were obtained with beetles, and lamellae immobilized in microfuge tubes and dental wax, respectively (Nikonov et al., 2001). Extracellular contacts with ORNs were established by the insertion of either glass or tungsten electrodes under a stereomicroscope (300 × magnification), with the reference electrode placed in the abdomen. Sharp and low impedance glass electrodes (2–5 MΩ, tip 2–3 μm) were prepared from borosilicate glass capillaries (Word Precision Instruments, Inc.; M1B150F-4) with a PC-10 micropipet puller (Narishige, Tokyo, Japan). The glass electrodes were filled with a sensillar lymph solution (Kaissling, 1995), pH 6.5, containing (all in mM): glucose, (22.5), NaCl (25), KCl (171.9), KH_2PO4 (9.2), K_2HPO4 (10.8), $MgCl_2$ (3), $CaCl_2$ (1), HCl (1.5). The tungsten electrodes were electronically sharpened in KNO_2 solution. Electrical contacts were established by inserting an electrode through the cuticle adjacent to a single sensillum placodeum. The antennal preparations were continuously flushed with a charcoal-filtered and moistened air stream (0.4 m/sec) through a stimulus delivery glass tube (8 mmID) placed 10 mm away from the antennal preparation. The glass tube had 5 holes (2 mmID) for introducing stimulus pipets; holes were 1 cm apart, with the first and last ones at 5 and 9 cm away from the outlet, respectively. Each test compound was applied to a piece of filter paper (0.5 × 1 cm) that was dried for 10 min and inserted into a Pasteur pipet. Throughout the paper, the amounts of semiochemicals refer to the amount loaded on filter papers rather than the delivered (puffed) material. Stimulation was performed by inserting the tip of a Pasteur pipet into the hole 5 cm away from the outlet of the stimulus delivery glass tube (6 cm away from the preparation). Air was blown for 300 msec through the pipet by a stimulus controller (CD-02/E;

Syntech, Hilversum, The Netherlands). Simultaneous delivery of two stimuli was done by splitting the airflow into two pipets loaded with different compounds. The two pipets were placed in different holes, and the pipet with the first stimulus to be delivered was placed 5 cm away from the outlet. When glass electrodes were used, receptor generator potentials and spikes were recorded simultaneously. The signals were amplified (Nihon Kohden MEZ-8300; Tokyo, Japan) with bandpass filters of 0–300 Hz and 0.3–3.0 KHz for the receptor generator potentials and spikes, respectively. With tungsten electrodes, only spikes were recorded. Data were stored with Axotape 2.0.2 (Axon Instruments, Foster City, California, USA). Data files were displayed on a computer screen and viewed also on a Nihon Kohden memory oscilloscope VC-11 (Tokyo, Japan). Temporal descriptions of receptor potentials and spikes were done manually from the computer screen. One-tailed interrupted analysis (Zacks, 1971; Hudson, 1977) was used to compare the number of action potentials during a 5-sec prestimulus (for an analysis of spontaneous activity) and during (300 msec) and after (700 msec) the odor stimulation. The neural activity prior to exposure (prestimulus period) was compared with that during stimulation, and the t value obtained was compared to the tabled critical value (37%, $P < 0.05$). The results obtained were statistically processed (Zacks, 1971) and represented as diagrams.

In order to investigate the effect of the time interval on the "mutual inhibition," the relationship between the distance from the stimulus delivery and the antennal preparation was experimentally determined. This was done by stimulating mechanical receptors in the antennae ($N = 10$) with air delivered from 6 to 10 cm away from the antennal preparation (Figure 1) and recording the onset of responses. On the basis of the most linear part of the curve (6–9 cm), it was determined that stimuli delivered 1 cm apart were separated by 15 ± 2.7 msec. Considering the airflow (20 ml/sec) and the diameter of the stimulus delivery glass tube (8 mm), the nominal value is 25 msec/cm.

RESULTS

Colocalized ORNs in Pheromone Sensilla (Type A). In this study, a total of 217 sensilla from 49 male Japanese beetles were examined. Mapping of the antennae showed that the majority of the sensilla (68%) are the pheromone-sensitive sensilla placodea (Kim and Leal, 2000). As previously described (Wojtasek et al., 1998), these sensilla possess two ORNs, one tuned to the sex pheromone [(R)-japonilure] and the other responding to the behavioral antagonist [(S)-japonilure]. Although colocalized, these ORNs are readily distinguishable by their spike amplitudes, with the sex pheromone ORNs showing a larger amplitude than the behavioral antagonist ORNs. The dose–response curves for the pheromone detectors showed remarkable enantiomeric specificity and low threshold (1–10 ng). As previously observed (Wojtasek et al., 1998), the behavioral antagonist ORNs

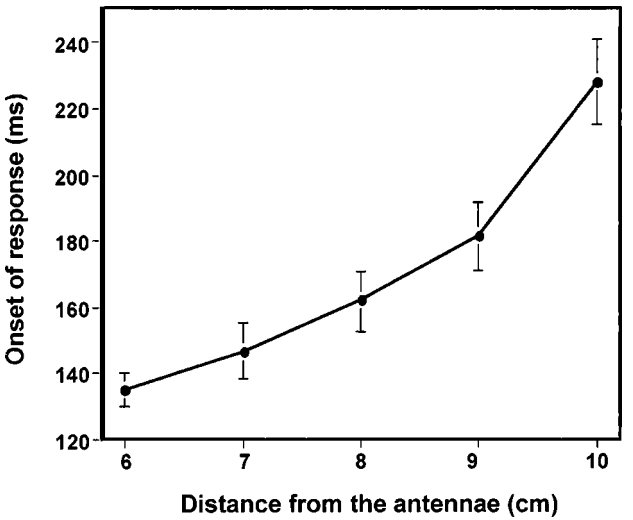

FIG. 1. Relationship between the onset of response ($N = 10$ for each point) in mechanical receptors in the antenna of the Japanese beetle and the distance from the stimulus delivery to the antennal preparation. On the basis of the most linear part of the curve (6–9 cm), stimuli separated by 1 cm were estimated to be temporally isolated by 15 ± 2.7 msec.

were completely silent when challenged with the sex pheromone. However, they were stimulated by the analog lactones (*R*)- and (*S*)-buibuilactone, when subjected to doses higher than their threshold to (*S*)-japonilure (10 ng).

Pheromone Sensilla with Indistinguishable Spike Amplitudes (Type B). In addition to the previously described pheromone sensilla [see above and Wojtasek et al. (1998)], a type of sensilla (14%) stimulated by either (*R*)- or (*S*)-japonilure was also identified. Type B sensilla showed a lower threshold (0.1–1.0 ng) than the other pheromone detectors. Contrary to the large and small spiking ORNs (type A), the amplitudes of the action potentials generated by the sex pheromone and behavioral antagonist in the neurons in type B sensilla were indistinguishable (Figure 2A). The same spike amplitude was observed when the sex pheromone and behavioral antagonist were puffed together or independently.

Sensilla Showing Mutual Inhibition (Type C). Given that the response of the male Japanese beetle is shut down by the behavioral antagonist (Tumlinson et al., 1977), the nervous activity was investigated when sensilla were challenged with a racemic mixture, i.e., the pheromone and behavioral antagonist in equimolar amounts. After observing the firing pattern or the lack of spikes when stimulated with a racemic mixture, the nervous activity generated by the sex pheromone and behavioral antagonist was recorded. Within the pheromone detectors (type A, 68%), a group of sensilla (type C, 36%) was found that showed no spikes when

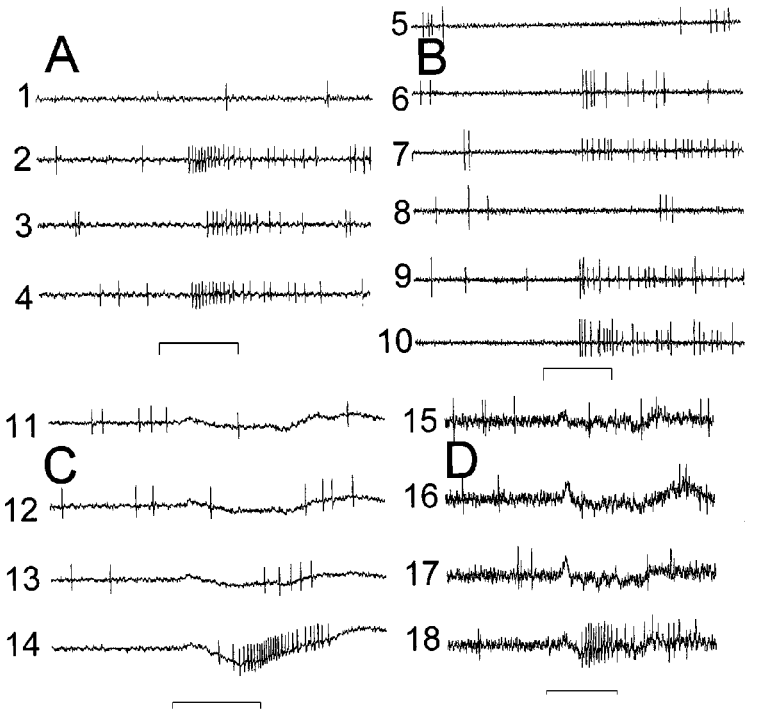

FIG. 2. Response characteristics to the sex pheromone, (*R*)-japonilure, and a behavioral antagonist, (*S*)-japonilure, in olfactory receptor neurons housed in sensilla placodea in the antennae of the Japanese beetle. (A) Recording from type B sensillum with ORNs stimulated by both semiochemicals isolated, or blended. Trace 1, air; 2, (*R*)-japonilure, 0.1 ng; 3, (*S*)-japonilure, 0.1 ng; 4, (*R*)- and (*S*)-japonilure, 0.1 ng of each. (B) Recording from a type C sensillum with larger and smaller spiking ORNs stimulated by the sex pheromone and the behavioral antagonist, respectively. The two neurons were mutually inhibited with blends of the two semiochemicals if their strands were coincident in time. Trace 5, air; 6, (*R*)-japonilure, 100 ng; 7, (*S*)-japonilure, 100 ng; 8, (*R*)- and (*S*)-japonilure, 100 ng of each; 9, (*S*)- and (*R*)-japonilure, (100 ng of each, separated by 60 msec; 10, (*R*)- and (*S*)-japonilure, 100 ng of each, separated by 60 msec. (C) Recording from type D sensillum showing synergist ORNs. Trace 11, air; 12, (*S*)-japonilure, 0.1 ng; 13, (*R*)-japonilure, 0.1 ng; 4, (*R*)- and (*S*)-japonilure, 0.1 ng of each. (D) Recording from the same sensillum in D after excising the antennae. Trace 15, air; 16, (*S*)-japonilure, 0.1 ng; 17, (*R*)-japonilure, 0.1 ng; 18, (*R*)- and (*S*)-japonilure, 0.1 ng of each. These recordings were obtained with tungsten electrodes, and the same patterns shown here were observed at least three times for each type of sensillum after offering the same set of stimuli randomly. The experiments were also replicated with different individuals ($N = 120$). The same experiments were repeated with glass electrodes by recording not only spikes, but also slow potentials. The lines below each set of recordings show the stimulus duration (300 msec).

challenged with a racemic mixture of japonilure (Figure 2B8). These sensilla had two ORNs, one tuned to the sex pheromone (Figure 2B, trace 6) and the other stimulated by the behavioral antagonist (Figure 2B, trace 7). Their dose–curve responses were indistinguishable from those of previously identified pheromone detectors (type A). When challenged with the racemic mixture, most of the type C sensilla (70.6%) showed a complete loss of activity, and the onset of the spikes was tremendously delayed. The other sensilla showed activity for the *R* ORNs, but the spike frequency decreased significantly and the onset of spikes was delayed. Mutual inhibition was observed when the two semiochemicals were delivered at the same time (racemic mixture), but when they were temporally isolated, the cells fired (Figure 2B, traces 9 and 10). This was done by delivering the two semiochemicals at 60-msec intervals. When the sex pheromone was delivered first, the nervous activity was initiated by the large spiking neurons (pheromone detectors) followed by the smaller ones (Figure 2B, trace 10), and when the behavioral antagonist was puffed first, the *S* ORNs responded with lower frequency, but the *R* ORNs showed only a few spikes (Figure 2B, trace 9).

Neuronal responses from the two ORNs were observed when the two stimuli were delivered at 60-, 45-, 30-, or 15-msec intervals either with the sex pheromone or behavioral antagonist delivered first. Mutual inhibition was not observed even when the two stimuli (sex pheromone and behavioral antagonist) were delivered from two pipets with the tips in close proximity, i.e., separated by ca. 1–2 mm (ca. 1.5–3 msec).

Next, the question of whether the ratio of the two semiochemicals is important for the mutual inhibition was considered. Neuronal activity was suppressed when the sensilla were challenged with racemic (1:1) mixtures of the two semiochemicals in the range of 10–10,000 ng. Mutual inhibition was observed with 100:1 and 10:1 mixtures, either with (*S*)- or (*R*)-japonilure being the major constituent. These data were particularly unambiguous when the tests were done in doses higher than the threshold response for the behavioral antagonist ORN (10 ng). At lower doses, the inhibition was not complete, but the onset of response was delayed and the frequency of spikes decreased ($P < 0.05$).

Sensilla Detecting Mixtures (Type D). Another type of sensilla fired only when stimulated with a mixture of the sex pheromone and behavioral antagonist (Figure 2C), but was silent when challenged with the same dose of either the sex pheromone or behavioral antagonist. Type D sensilla (9%) showed high sensitivity (threshold 0.1 ng), but their performances were restricted to the range of 0.1–10 ng. When challenged with higher doses, they responded to individual enantiomers, with (*R*)-japonilure stimulating the ORNs with slightly larger spike neurons. These sensilla showed the same synergistic effect when challenged with the two enantiomers in 10:1 ratios, particularly when at lower doses (0.1–1 ng). Because of the slight difference in spike amplitudes, it was not possible to determine whether the responses were due to one of the neurons or to a combination.

In order to investigate whether the mutual inhibitory and synergistic effects were related to any feedback from the brain, analogous experiments were conducted with excised antennae. The results (shown in Figure 2D) were obtained with the same antenna used for the experiments shown in Figure 2C. Although there was an increase in the noise, the responses with intact insect and excised antennae showed the same profile. This was the case with both mutual inhibition (data not shown) and the synergistic effect (Figure 2D).

Other Types of Sensilla. A small number of sensilla (2%) showed ORNs tuned either to the sex pheromone or the behavioral antagonist. Although the other enantiomer (antipode) did not elicit spikes, it generated a slow potential. Both the *R*- and *S*-type ORNs failed to respond to racemic mixtures (no spikes were observed), but they generated slow potentials. Another type of sensilla (1%) showed a basal firing (natural spikes), generated a slow potential when stimulated with (*R*)- and (*S*)-japonilure, but never generated spikes.

Mutual Inhibition in Other Species. The influence of semiochemical blends on the firing patterns of pheromone-detecting neurons was investigated in other scarab species. Preliminary experiments with field-collected ($N = 10$) Osaka beetle, *A. osakana*, showed a similar type of mutual inhibition. However, a laboratory colony of this species could not be established, and an in-depth investigation was not performed. As previously demonstrated (Wojtasek et al., 1998), the pheromone detectors in *A. osakana* were stimulated by (*S*)-japonilure and generated large spikes, whereas (*R*)-japonilure elicited nervous activity (with smaller spike amplitude) in colocalized neurons. The mutual inhibition was observed in the tested range (100–1000 ng) either with racemic or 10:1 mixtures.

In the Oriental beetle ($N = 25$), the sex pheromone, (*Z*)-7-tetradecen-2-one (Leal et al., 1994), stimulated a large spiking neuron (Figure 3A). In the same sensilla, there is a second neuron (smaller spiking amplitude), which was activated by the sex pheromone of another scarab species, *Heptophylla picea*, (*R*,*Z*)-7,15-hexadecadien-4-olide (Leal et al., 1996) (Figure 3B). A 1:1 mixture of the two pheromones (100 ng of each) had a major influence in the firing pattern of the pheromone detector in the Oriental beetle (Figure 3C). The onset of pheromone spikes was dramatically delayed, and the frequency was significantly lower. Conversely, the onset of spikes of the neuron detecting the interspecific pheromone was shorter, and the frequency was significantly higher. Furthermore, the slow potential generated by the mixture was quite different from the slow potential elicited by the two compounds independently, in particular the rise phase potential was significantly slower.

Electrical Signals Characteristics. An in-depth investigation of type C sensilla in the Japanese beetle was carried out to determine the effect of mutual inhibition on the electrical signals generated by the receptor cells. The parameters (Figure 3) characterizing the signature of the nervous activity (Kaissling, 1987), i.e., the onset of slow potential (t_0), the onset of spikes (t_1), the rise time (t_2), and the fall of the

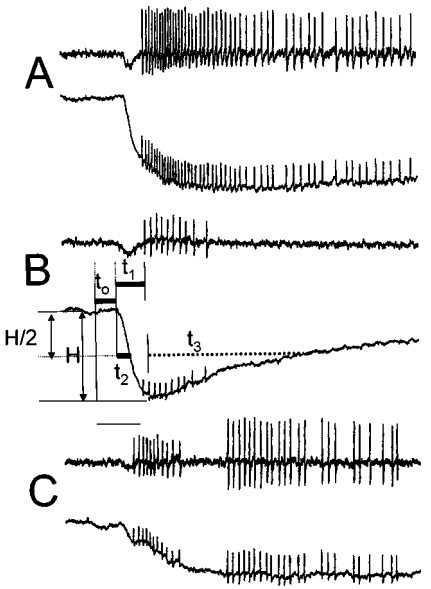

FIG. 3. Single sensillum recordings from pheromone-detecting sensilla placodea in the Oriental beetle obtained with a glass electrode. Two ORNs differing in their spike amplitudes are housed in these sensilla. They were stimulated by the sex pheromone of the Oriental beetle, (*Z*)-7-tetradecen-2-one (A, 100 ng), and the sex pheromone of the yellowish elongate chafer, *Heptophylla picea*, i.e., (*R*,*Z*)-7,15-hexadecadien-4-olide (B, 100 ng). There was mutual inhibition of the two ORNs by a blend of the two semiochemicals (C, 100 ng of each). Experiments were replicated with the same individual at least three times and with different individuals ($N = 9$). The lines below the recording in B show the stimulus duration (300 msec). Parameters used to evaluate the effect of mutual inhibition on the characteristics of the signals: t_0, onset of slow potential; t_1, onset of spikes; t_2, rise phase time; t_3, fall of the slow potential, and H, amplitude of the slow potential.

slow potential (t_3), were analyzed. The most striking influence was the onset of spikes (t_1, Table 1; Figure 2B, trace 8). Spikes generated by 10 and 100 ng of a racemic mixture were significantly delayed. In various experiments ($N > 80$), it was not possible to determine accurately if the spikes were delayed or the activity was completely lost. This was because the spike frequency was so low and the onset so delayed (e.g., Fig 2B, trace 8) that it was impossible to distinguish them from basal firing (spontaneous nervous activity).

Although there was no significant difference in the onset of the slow potential when the sensilla were subjected to individual compounds or a racemic mixture (t_0, Table 1), the rise time was significantly delayed with higher concentrations of the racemic mixture (t_2, Table 1). Contrary to the slow potential generated

TABLE 1. EFFECT OF SIMULTANEOUS STIMULATION WITH SEX PHEROMONE AND BEHAVIORAL ANTAGONIST ON ELECTRICAL SIGNALS GENERATED BY PHEROMONE-DETECTING SENSILLA (TYPE C) IN JAPANESE BEETLE ($N = 16$)

Stimulus	Amount (ng)	t_0 (ms)	t_1 (ms)	t_2 (ms)	t_3 (ms)
R	10	95 ± 9	95 ± 11	70 ± 7	280 ± 30
S	10	90 ± 9	50 ± 7	65 ± 8	220 ± 24
$R + S$	10	101 ± 13	180 ± 24	50 ± 6	201 ± 20
R	100	90 ± 10	58 ± 6	50 ± 8	217 ± 21
S	100	91 ± 11	33 ± 7	67 ± 7	305 ± 27
$R + S$	100	83 ± 12	150 ± 16 (S) 201 ± 18 (R)	151 ± 14	205 ± 25

either with the sex pheromone or behavioral antagonist, the rise potential with the racemic mixture showed two phases, a slow rise phase followed by a fast rise phase of the slow potential. The general effect was a significant delay of the rise phase as compared to individual semiochemicals. This delay in the rise phase of the slow potential was also observed in the silent sensilla (see above) that showed slow potential but no spikes.

DISCUSSION

Research was conducted to determine how the peripheral sensory system in the Japanese beetle perceives the environment, particularly with regard to the detection of the sex pheromone, (*R*)-japonilure, and a behavioral antagonist, (*S*)-japonilure. The latter is a sex pheromone of the Osaka beetle. These two species share the same habitat in parts of the Japanese archipelago, and the pheromone of one species is detected as a behavioral antagonist (stop signal) by the other (allospecies) (Tumlinson et al., 1977; Leal, 1996, 1998). Therefore, under natural conditions, these beetles encounter not only their own sex pheromone but also blends of the two semiochemicals. An in-depth investigation of the peripheral sensory physiology in the Japanese beetle antennae that mimicked natural conditions revealed an interesting feature of its olfactory system. Coding of the sex pheromone and behavioral antagonist can be achieved with the peripheral sensory system given that the antennae possess: (1) detectors activated only by a mixture of the two semiochemicals, (2) detectors specific for each enantiomer, and (3) detectors with neuronal activity decreased when they encounter a mixture of the two compounds. Therefore, the nervous activity sent to the antennal lobe already contains a signature characterizing the presence/absence of sex pheromone and/or behavioral antagonist.

Previously, synergist neurons have been identified in the antennal lobes in the brain of the earworm moth *Helicoverpa zea* (Christensen et al., 1991). The neurons

in the antennal lobes of *H. zea* were silent to the major pheromone constituent, (*Z*)-11-hexadecenal, and a behavioral antagonist, (*Z*)-9-hexadecenal, produced by the sympatric species, *Heliothis virescens*. However, the neurons responded only when the two semiochemicals were offered together (Christensen et al., 1991). A synergistic effect at the sensory neuronal level has been observed in the tobacco cutworm moth, *Spodoptera litura* (Aihara and Shibuya, 1977). Stimulation with a mixture (9:1) of the major sex pheromone constituent, (*Z,E*)-9,11-tetradecadienyl acetate, and a second constituent, (*Z,E*)-9,12-tetradecadienyl acetate, increased the frequency of spikes more than the major constituent alone (Aihara and Shibuya, 1977).

Although mutually inhibitory neurons have never been observed in insect antennae, there are a few examples of mixture interactions occurring among insect ORNs that would alter the information at the periphery before reaching the antennal lobe (Todd et al., 1992). In the summerfruit tortrix moth, *Adoxophyes orana*, the responses of an ORN to separately applied (*Z*)-11-tetradecenyl acetate concentrations are higher than those to the same concentrations of this compound when mixed with the major pheromone constituent, (*Z*)-9-tetradecenyl acetate (Den Otter, 1977). An interaction between plant odor and pheromone perception has been documented in the small ermine moth, *Yponomeuta evonymellus*. In this species, geraniol inhibits response to the sex pheromone, (*Z*)-11-tetradecenyl acetate (van der Pers et al., 1980). Inhibition of pheromone receptor activity by plant chemicals has also been found in the male wild silkmoth, *Antheraea pernyi* (Schneider et al., 1964) and silkworm moth, *B. mori* (Kaissling et al., 1989). In the cabbage looper moth, *Trichoplusia ni*, the binary mixture containing the major pheromone constituent, (*Z*)-7-dodecenyl acetate, and a behavioral antagonist, (*Z*)-7-dodecenol, did not elicit significant deviation from additivity in either olfactory receptor neuron. However, addition of dodecyl acetate to this blend resulted in a mixture that significantly reduced the observed response of both ORNs below that expected by the additive model (O'Connell, 1985; O'Connell et al., 1986). Responses to the major pheromone constituent, (*Z,Z,Z*)-3,6,9-nonadecatriene, in a type of sensilla in the mottled umber, *Erannis defoliaria*, were inhibited by the second constituent, (*Z,Z*)-3,9-*cis*-6,7-epoxy-nonadecadiene, which produces hyperpolarization (Hansson et al., 1990). A comprehensive study of the sensory physiology in normal and mutant *T. ni* showed that a single minor component could apparently hyperpolarize one cell while depolarizing another cell within the same sensillum (Todd et al., 1992). It has been also observed in the maxillary palp of *Drosophila melanogaster* that a particular odor can excite one neuron and inhibit another and that a particular neuron can be excited by one odor and inhibited by another (de Bruyne et al., 1999). However, mutual inhibition at the periphery is reported here for the first time.

It is conceivable that mixture or blend interactions in insect antennae may have been overlooked previously because the widely studied lepidopteran species have complex pheromone systems that may obscure this feature. Clearly, the

behavioral significance of the two semiochemicals in the biology of the Japanese beetle facilitated our studies. However, peripheral coding has not been observed in bark beetles, for which pheromones and behavioral antagonists are also clearly identified. Earlier studies indicate that the majority of the ORNs in the antennae of the bark beetle *Ips pini* were activated either by the aggregation pheromone, ipsdienol, or the behavioral antagonist, ipsenol (Mustaparta et al., 1977). Simultaneous stimulation with the two semiochemicals showed that ipsenol had no inhibitory effect on the receptor response to ipsdienol, leading to the conclusion that behavioral inhibition results from central integration of the information from separate receptor cells rather than a peripheral event (Mustaparta et al., 1977). Further studies with pure enantiomers and racemic mixtures indicate that there is no synergistic or inhibitory interaction of the enantiomers on the receptor cells in *I. pini* and *I. paraconfusus* (Mustaparta et al., 1980). Whether or not peripheral coding of sex pheromones and behavioral antagonists is a general feature in insect olfaction must await further studies, but the findings presented here suggest that it is the case in more than one species of scarab beetles. In this study, mutual inhibition was observed not only in the Japanese beetle, but also in the Osaka beetle, *A. osakana*, and the Oriental beetle, *E. orientalis*. A comprehensive investigation in the Japanese beetle sensory physiology showed not only mutual inhibition but also a synergistic effect.

The remarkable fine resolution of the olfactory system in the Japanese beetle allows discrimination of completely overlapped plumes of sex pheromone and behavioral antagonist from those derived from the two semiochemicals temporally isolated (1.5–3 msec). This is in agreement with the evidence in the literature that a behavioral antagonist must be emitted from the same point source as a pheromone to be optimally effective (Witzgall and Priesner, 1991; Liu and Haynes, 1992, 1993). *H. zea*, for example, can distinguish completely coincident strands of pheromone and behavioral antagonist from those whose strands are separated by only 1 mm [3 msec at 40 cm/sec wind (Baker et al., 1998)]. It has been pointed out that the ability to discriminate their conspecific pheromone strands from the strand of a nonconspecific female could have fitness advantages to males. This fine resolution would allow males to not be erroneously deterred by the presence of antagonistic compounds in a plume and to successfully locate and mate with their own females (Todd and Baker, 1999). Such fine resolution would likely be easily achieved at the periphery rather than by central processing of information. This might be the reason for cocompartmentalized ORNs that detect pheromones and behavioral antagonists (Baker et al., 1998; Todd and Baker, 1999).

It is not known unequivocally what happens to the activities of antennal neurons farther down the antennal nerve where there could potentially be interactive effects due to gap junctions or other interaxonal phenomena (Todd and Baker, 1999). The first line of evidence for mutual inhibition and synergist ORNs in scarab beetles prompted us to study the ultrastructure of sensilla placodea in

the Japanese beetle (Kim and Leal, 2000). Following assignment of pheromone-detecting sensilla placoda by single sensillum recording, their ultrastructures were studied. Each pheromone sensillum had two ORNs (Kim and Leal, unpublished) in agreement with the electrophysiological findings of two ORNs characterized by the spike amplitudes. The observation of two ORNs in all pheromone-detecting sensilla placodea traced by transmission electronic microscopy (TEM) led us to conclude that all types of sensilla have two ORNs, even when the discrimination on the basis of spike amplitude is not clear (types A and C).

The internal morphology of the pheromone-detecting sensillum placodeum in the Japanese beetle is similar to that of sensilla trichodea of moth antennae, except for near-cuticle structures. The outer and inner dendritic segments of ORNs are enclosed by three enveloping cells: thecogen, trichogen, and tormogen. High-magnification micrographs reveal that there are desmosomal contacts between the inner dendritic segments and the thecogen cells (Kim and Leal, 2000). If these desmosomal contacts function like gap junctions, electrical interaction between one ORN tuned to pheromone and a behavioral antagonist detecting ORN may lead to the peripheral mutual inhibition observed in the Japanese beetle.

Acknowledgments—We thank George Kamita and John Romeo for critical review of a previous version of the manuscript. We appreciate comments and suggestions from members of our group, in particular, Dr. Jong-yoon Kim. This research was supported in part by a program for promoting Basic Research Activities for Innovative Bioscience (BRAIN). Work in the United States was made possible through direct financial support from the department, college, and Chancellor's office at UCD.

Abstract—Twenty *ent*-labdane diterpenes, isolated from the aquatic plants *Ruppia maritima* and *Potamogeton natans*, were tested to detect their effects on aquatic organisms from different trophic levels. Toxicity tests were performed on aquatic producers (the alga *Selenastrum capricornutum*), and consumers including a rotifer (*Brachionus calyciflorus*), a cladoceran crustacean (*Daphnia magna*), and two anostracan crustaceans (*Thamnocephalus platyurus* and *Artemia salina*). Furano-*ent*-labdanes exhibited high toxicity toward all of these organisms. 15,16-Epoxy-12(*S*)-hydroxy-8(17),13(16),14-*ent*-labdatrien-20,19-olide had a high toxicity only toward the algae and the rotifers. It was inactive for the crustaceans.

Key Words—Potamogetonaceae, *Potamogeton natans*, *Ruppia maritima*, diterpenes, *ent*-labdane, aquatic organisms activity, antialgal activity, toxicity testing.

INTRODUCTION

The potential role of allelochemicals in agriculture and forestry has been extensively reported (Waller, 1987). This is in contrast to the chemical interactions

* To whom correspondence should be addressed. E-mail: antonio.fiorentino@unina2.it

0098-0331/02/0600-1091/0 © 2002 Plenum Publishing Corporation

between vegetal organisms in aquatic systems that have not been much studied, despite evidence of potential allelopathic interactions.

Schreiter (1928) was the first to hypothesize that aquatic plants could interfere with phytoplankton, citing a case in which phytoplankton growth decreased if there was a high presence of aquatic plants. Hasler and Jones (1949) observed a reduction of the algal population in ponds where some species of Potamogetonaceae were present. They confirmed their observation through an experiment using densely planted and plant-free silo-ponds, finding that microalgal growth was significantly less in the densely planted ponds than in the plant-free ponds. Fitzgerald (1969) indicated that some species of aquatic weeds could control the algal growth. Many other experiments also identified interactions between hydrophytae and microalgae (Kogan and Chinnova, 1972; Brammer, 1979; Godmaire and Planas, 1983), although allelopathy was not mentioned. Hootsmans and Blindow (1994) affirmed that the allelopathic limitation of algal growth could not be excluded, but suggested that the allelopathic effects might vary with regard to place and time and that they might be dependent on nutrient concentration and the relative age of the organisms.

The ability of some natural products to inhibit in vitro development of microalgae has been reported by our research group in recent years (DellaGreca et al., 1996, 1998), and we have shown that bioactive products isolated from *Pistia stratiotes* are released into the environment (DellaGreca et al., 1999).

In connection with a study of the allelopathic interactions among aquatic plants distributed in the Mediterranean basin and microalgae, and on the basis of the previously reported observations of Hasler and Jones (1949), we examined two species of Potamogetonaceae, which grow in the Volturno, the largest river of southern Italy. The first one, *Potamogeton natans*, commonly known as water tongue, is a freshwater species, while *Ruppia maritima*, commonly known as sea hay, lives at the mouth of the river in brackish waters. The phytochemical study of these plants led to the isolation of *ent*-labdane diterpenes, identified previously on the basis of their spectroscopic properties (DellaGreca et al., 2000; Cangiano et al., 2001).

The aim of this study was to determine the effect of the diterpene metabolites from Potamogetonaceae, not only on algae, but also on aquatic species from various taxonomic levels to provide a wider range of ecotoxicity information (Rand, 1995).

METHODS AND MATERIALS

General Experimental Procedures. NMR spectra were recorded at 400 MHz for ^{1}H and 100 MHz for ^{13}C on a Bruker AC 400 spectrometer in $CDCl_3$ or CD_3OD solutions, at 27°C. Proton-detected heteronuclear correlations were measured using HMQC (optimized for $^{1}J_{HC} = 145$ Hz) and HMBC (optimized for $^{1}J_{HC} = 7$ Hz). Optical rotations were measured on a Perkin-Elmer 343 polarimeter. IR spectra were determined in $CHCl_3$ solutions on a FT-IR Perkin-Elmer 1740 spectrometer. UV spectra were obtained on a Perkin-Elmer Lambda 7 spectrophotometer in

EtOH solutions. EI-MS spectra were obtained with a Kratos MS 80 apparatus. FAB mass spectra were obtained with a Kratos VG ZAB 2SE. The HPLC apparatus consisted of a pump (Shimadzu LC-10AD), a refractive index detector (Shimadzu RID-10A), and a Shimadzu Chromatopac C-R6A recorder. Preparative HPLC was performed using RP-8 (Luna 10 μm, 250 $\times$ 10 mm ID, Phenomenex), SiO_2 (Maxsil 10 μm, 250 $\times$ 10 mm ID, Phenomenex), or RP-18 (Kromasil 10 μm, 250 $\times$ 10 mm ID, Phenomenex) columns. Analytical TLC was performed on Merck Kieselgel 60 F_{254} or RP-18 F_{254} plates with 0.2 mm layer thickness. Spots were visualized by UV light or by spraying with H_2SO_4–AcOH–H_2O (1:20:4). The plates were then heated for 5 min at 110°C. Preparative TLC was performed on Merck Kieselgel 60 F_{254} plates, with 0.5 or 1 mm film thickness. Flash column chromatography (FCC) was performed on Merck Kieselgel 60 (230–400 mesh) at medium pressure. Column chromatography (CC) was performed on Merck Kieselgel 60 (70–240 mesh) or on Sephadex LH-20 (Pharmacia).

Plant Material. Plants of *Potamogeton natans* and *Ruppia maritima* were collected from the Volturno River, Italy, and identified by Professor Antonino Pollio at the Università Federico II of Naples. Voucher specimens (HERBNAPF065) were deposited at the Dipartimento di Biologia Vegetale of the Università Federico II of Naples.

Extraction and Isolation of Diterpenes from R. maritima (Figure 1). Air-dried plants (10 kg) were sequentially and exhaustively extracted with light petrol,

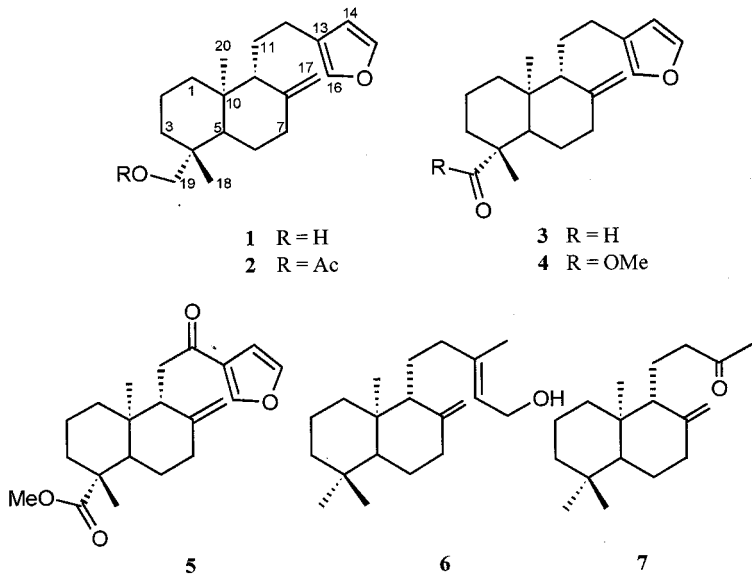

FIG. 1. *ENT*-Labdane-diterpenes isolated from *Ruppia maritima*.

EtOAc, and MeOH. The light petrol extract (36 g) was chromatographed on neutral Al_2O_3 (grade III), and elution with hexane–Et_2O (19:1) gave fractions A–D. Fraction A was purified on Sephadex LH-20 [hexane–$CHCl_3$–MeOH (4:1:1)] to give compound **1** (23 mg). Fraction B was chromatographed on silica gel eluting with hexane–$CHCl_3$ (4:1) to give pure **3** (31 mg) and **4** (37 mg). Fraction C was chromatographed on silica gel eluting with hexane–benzene mixtures. Hexane–benzene (49:1) gave crude **6**, which was purified by preparative TLC [hexane–benzene (9:1)]. The fraction eluted with hexane–benzene (9:1) was chromatographed by RP-18 HPLC [MeOH–MeCN (19:1)] to give compounds **2** (8 mg) and **7** (35 mg). Fraction D was chromatographed on Sephadex LH-20 with hexane–$CHCl_3$–MeOH (4:1:1) to give compound **5** (8 mg), which was purified by RP-18 HPLC [MeOH–MeCN (19:1)].

Extraction and Isolation of Diterpenes from P. natans (Figure 2). The air-dried and powdered plant material (13 kg) was sequentially and exhaustively extracted with light petrol, EtOAc, and MeOH. The light petrol extract (66 g) was

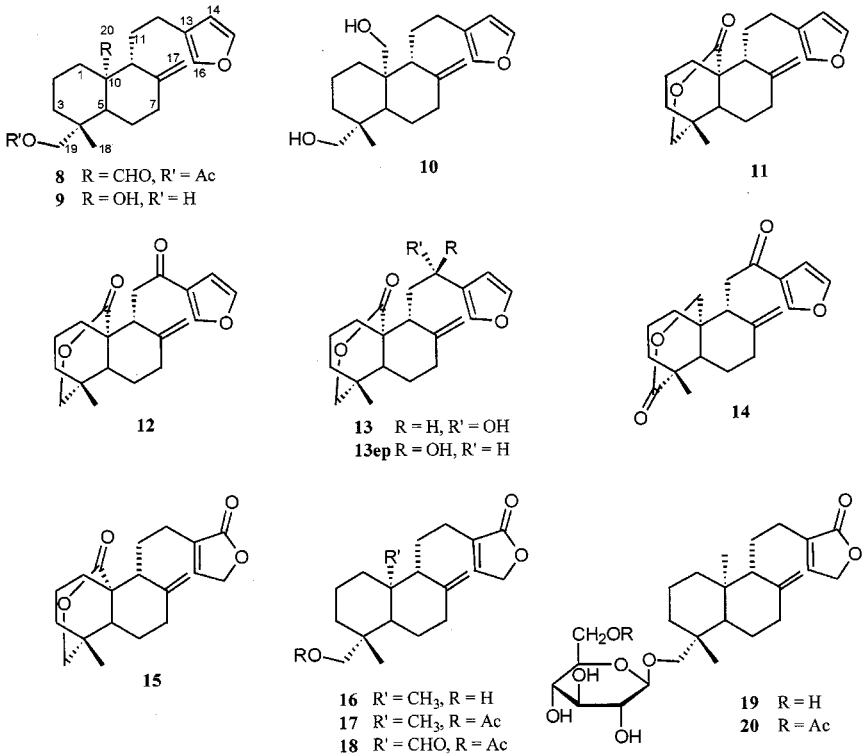

FIG. 2. *ENT*-Labdane-diterpenes isolated from *Potamogeton natans*.

chromatographed on silica gel eluting with hexane and EtOAc solutions to give fractions A and B. Fraction A, eluted with hexane–EtOAc (19:1), was chromatographed using hexane–EtOAc (17:3) as eluent to give pure compounds **8** (57 mg) and **11** (125 mg). Fraction B, eluted with hexane–EtOAc (17:3), was filtered on Sephadex LH-20 using hexane–$CHCl_3$–MeOH (3:1:1) as eluent; fractions 12–38 were purified by HPLC, using a preparative silica gel column and a mixture of hexane–*i*Pr_2O (3:1) as eluent, and gave pure **17** (15 mg) and **18** (11 mg); fractions 56–89 were purified by preparative TLC, using a mixture of benzene–EtOAc (19:1) as eluent, to give pure **12** (85 mg) and **14** (4 mg). The EtOAc extract (79 g) was chromatographed on silica gel eluting with hexane and EtOAc solutions to give fractions C–E. Fraction C, eluted with hexane–EtOAc (4:1), was chromatographed on Sephadex LH-20 with hexane–$CHCl_3$–MeOH (3:1:1). The elute obtained was purified by HPLC, using a preparative RP-8 column and a mixture of MeOH–H_2O (4:1) as eluent, to give pure **9** (11 mg) and **13** (35 mg). Fraction D, eluted with hexane–EtOAc (2:1), was chromatographed on preparative TLC [$CHCl_3$–EtOAc (3:1)] to give compound **10** (31 mg). Fraction E, eluted with hexane–EtOAc (3:1), was chromatographed on preparative TLC [benzene–EtOAc (3:2)] to give compounds **15** (13 mg) and **16** (51 mg). The methanolic extract (120 g) was treated with H_2O and EtOAc. The aqueous layer, concentrated to 500 ml, was chromatographed on Amberlite XAD-4. The fraction eluted with MeOH was chromatographed on Sephadex LH-20 [MeOH–H_2O (1:1)] to give a mixture of glycosides, which were separated on preparative RP-18 eluting with MeOH–H_2O (4:1) to give pure **19** (21 mg) and **20** (8 mg).

*Preparation of **13** and **13ep***. $NaBH_4$ (8 mg) was added to a solution of **12** (30 mg) in MeOH (2.5 ml), and the reaction mixture was stirred for 5 hr at room temperature. The hydride in excess was broken with AcOH (2 drops). The mixture was then directly purified by preparative TLC with $CHCl_3$–EtOAc (17:3) to give, besides the unreacted **12** (11 mg), compound **13** (5 mg) and 12(*S*)-hydroxy-15,16-epoxy-8(17),13(16),14-*ent*-labdatrien-20,19-olide (**13ep**, 11 mg).

Preparation of (R)- *and* (S)-*MTPA Esters of **13***. (*S*)-(+)-MTPA-Cl (5 μl) was added to a solution of pure **13** (1.5 mg) in dry pyridine (50 μl). After 4 hr at room temperature under magnetic stirring, ethyl ether (5 ml) and water (5 ml) were added to the reaction mixture. The organic layer gave a crude ester, which was purified by preparative TLC eluting with hexane–EtOAc (5:1). The ester (*R*)-MTPA had ^{1}HNMR ($CDCl_3$, 400 MHz) δ: 6.45 (1H, s, H-14), 5.95 (1H, d, $J = 10.5$ Hz, H-12), 5.01 (1H, s, H-17), 4.69 (1H, s, H-17), 4.18 (1H, dd, $J = 1.5$, 11.6 Hz, H-19), 4.01 (1H, d, $J = 11.5$ Hz, H-19), 2.65 (1H, m, H-11), 2.11 (1H, m, H-11), 0.90 (3H, s, H-18). (*S*)-MTPA of **13** was prepared by the same procedure. ^{1}HNMR ($CDCl_3$, 400 MHz) δ: 6.38 (1H, s, H-14), 5.91 (1H, dd, $J = 4.7$, 10.5 Hz, H-12), 5.02 (1H, s, H-17), 4.76 (1H, s, H-17), 4.14 (1H, dd, $J = 1.5$, 11.5 Hz, H-19), 3.98 (1H, d, $J = 11.5$ Hz, H-19), 2.75 (1H, m, H-11), 2.26 (1H, m, H-11), 0.89 (3H, s, H-18).

Preparation of (R)- *and* (S)-*MTPA Ester of* ***13ep***. The procedure used for the MTPA esters of **13** was also used for the preparation of (*R*)-MTPA and (*S*)-MTPA of **13ep**. The (*R*)-MTPA ester had ^{1}HNMR ($CDCl_3$, 400 MHz) δ: 6.29 (1H, s, H-14), 6.03 (1H, dd, $J = 4.7$, 10.5Hz, H-12), 4.99 (2H, s, H-17), 4.16 (1H, dd, $J = 1.5$, 11.5 Hz, H-19), 4.00 (1H, d, $J = 11.5$ Hz, H-19), 2.95 (1H, m, H-11), 2.23 (1H, m, H-11), 0.89 (3H, s, H-18). The ester (*S*)-MTPA had ^{1}HNMR ($CDCl_3$, 400 MHz) δ 6.41 (1H, s, H-14), 6.02 (1H, dd, $J = 4.7$, 10.5Hz, H-12), 5.01 (1H, s, H-17), 4.99 (1H, s, H-17), 4.16 (1H, dd, $J = 11.5$, 1.5 Hz, H-19), 4.00 (1H, d, $J = 11.5$ Hz, H-19), 2.85 (1H, m, H-11), 2.20 (1H, m, H-11), 0.88 (3H, s, H-18).

Toxicity Testing. Microbiotests independent of the culturing and/or maintenance of live stocks of test organisms, known as Toxkits™ (Creasel, Deinze, Belgium) were selected for this study (Persoone and Janssen, 1993; Persoone et al., 1993; Persoone, 1998a,b). The Toxkits for freshwater were used in accordance with conditions and media prescribed by OECD (1994), ISO (1987), AFNOR (1983), and US EPA (1991), following the standard operational procedure described for the respective Toxkit tests. There were: (1) the Algaltoxkit F (Creasel, 1996), a 0-72 hr algal growth inhibition assay with *Selenastrum capricornutum*; (2) the Rotoxkit F (Creasel, 1992), a 24 hr rotifer mortality test (test species: *Brachionus calyciflorus*); (3) the Thamnotoxkit F (Creasel, 1995), a 24 hr crustacean mortality test (test species: *Thamnocephalus platyurus*, anostraca); and (4) the Daphtoxkit F (Creasel, 2000), a 24 hr crustacean immobilization test (test species: *Daphnia magna*, cladocera).

The toxicity tests were conducted by exposing the organisms to solutions of varying concentrations of single chemicals of high purity as reported in our previous studies (DellaGreca et al., 2000, 2001b). In the present study, to the test battery we added a further bioassay with the anostracan *Artemia salina*, a marine species, to detect the impact of metabolites released by *R. maritima* and *P. natans* in proximity of the mouth of the river where salinity is substantially higher. The crustacean toxicity test to assess the mortality of *A. salina* was conducted by hatching these anostraca from cysts incubated for two days at 25°C in synthetic seawater in the dark. The solutions were prepared in five toxicant concentrations (twofold concentration increments) for each compound, each with three replicates of 10 animals in disposable multiwell plates (1 ml per well). After 24 hr in a 25°C incubator in the dark (Creasel, 1990), the number of dead crustaceans was counted.

Data Analysis. Raw data for all bioassays, except the algal test, were analyzed by using the Toxcalc Toxicity Data Analysis and Database Software, ver. 5.0 (Tidepool Scientific Software). Point estimations were calculated by concentration response regression with Probit Analysis as first choice and Trimmed Spearman-Karber as second, if Probit was not possible. If the raw data did not allow the respective LC/EC_{50} to be calculated at the highest tested concentrations, then these values were determined by a direct graphical method. Raw test data from Algaltoxkit were analyzed by a Microsoft Excel 5.0 program tailored for this test.

The algal median growth inhibition was estimated by integrating the mean values from time 0 to 72 hr (area under the curve). Inhibition (percentage) values were reported against log-transformed data of concentrations (micromoles per liter) to evaluate the slope, the trend of regression and the IC_{50} value.

RESULTS AND DISCUSSION

The structures of the 20 *ent*-labdane diterpenes tested in this research are reported in Figures 1 and 2. Plants of *R. maritima* and *P. natans* were air-dried and extracted with light petrol, ethyl acetate, and methanol. Chromatographic processes (CC, TLC, and HPLC) of the extracts of the first plant led to isolation of seven *ent*-labdanes (**1–7**). Five (**1–5**) of them have a furano ring in the skeleton, and one (**7**) is a *nor*-bis-diterpene. Compounds **1** and **4** had already been isolated from *Psiadia altissima* (Canonica et al., 1969) and *Daniella oliveri* (Haeuser and Lombard, 1961), respectively, while all the other compounds were isolated here for the first time from *R. maritima*.

Chromatographic processes of the extracts of the water tongue afforded six furano-*ent*-labdanes (**8**, **10**–**14**), six γ-lactone-*ent*-labdanes (**15**–**20**), two of them as glucosides (**19** and **20**), and one *nor*-diterpene (**9**) (Cangiano et al., 2001; DellaGreca et al., 2001a). All the furano diterpenes (**8**–**14**) were isolated for the first time from *P. natans*, except compound **11**, which had already been isolated by Smith et al. (1976) and is known as potamogetonin. To establish the configuration at C-12 of the compound **13**, 12-oxopotamogetonin (**12**) was reduced with $NaBH_4$ to give the natural **13** and its epimer **13ep** at C-12. Mosher's method (Dale and Mosher, 1973; Othani et al., 1991) was applied to both the products. The (*R*)-MPTA and (*S*)-MTPA esters showed differences in the chemical shifts in agreement with the *S* configuration for **13** and, consequently, the *R* configuration for its epimer (**13ep**). The lactonediterpenes (**15**–**20**) were isolated for the first time in *P. natans*, except for compounds **16** and **19**, known as andrograpanine (Fujita et al., 1984) and neoandrographolide (Chan et al., 1971), respectively, which were previously isolated from *Andrographys paniculata*.

All the natural products (**1**–**20**), and the synthetic **13ep**, were assayed in standard water against the green alga *Selenastrum capricornutum*, one of the organisms recommended for the standard algal assay procedure developed for aquatic systems (Pipe and Shubert, 1984) to measure the potentially adverse effect of chemicals on the aquatic environment. The toxicity is reported as IC_{50}, the inhibiting concentration that reduces algal growth by 50% (Table 1).

The tests revealed that the presence of the furano group in the molecule is important for the antialgal activity. Among all the furano diterpenes, the most toxic was compound **1**, showing an IC_{50} 0.8 μmol/liter. The free hydroxyl group at C-19 seems to be important for such activity; in fact, the acetylation of the C-19 position (compare **1** and **2**) increases the IC_{50} value (13.62 μmol/liter), retaining

TABLE 1. EFFECTS OF DITERPENES ON *Selenastrum capricornutum*, REPORTED AS IC_{50} WITH 95% CONFIDENCE LIMITS[a]

Compounds	IC_{50} (μmol/liter)	Compounds	IC_{50} (μmol/liter)
1	0.8 (0.43–1.41)	**11**	28.58 (23.85–36.63)
2	13.62 (10.95–16.96)	**12**	60.89 (57.8–62.8)
3	7.57 (6.90–8.33)	**13**	4.40 (3.11–6.21)
4	ND	**13ep**	ND
5	1.45 (1.07–2.0)	**14**	ND
6	ND	**15**	44.16 (25.11–61.9)
7	ND	**16**	217.13 (200.4–221.8)
8	58.27 (37.94–89.49)	**17**	696.25 (680.7–703.4)
9	2.84 (1.11–3.02)	**18**	NR
10	18.45 (13.73–24.81)	**19**	80.54 (68.52–94.70)
		20	53.70 (34.27–61.91)

[a] ND = not determined at highest concentration assayed; NR = no relation dose–response.

a dose–response relationship in compound **2,** but diminishing the activity. Compound **3** is a growth stimulant at low concentrations, and the toxic effect was revealed only by increasing the concentrations ($IC_{50} = 7.57$ μmol/liter). The toxicity of **4** was significant for concentrations higher than 9.5 μmol/liter, and its IC_{50} could not be found at the highest tested concentration (45 μmol/liter). The carbonyl group at C-19 decreases the activity of the chemicals unless another carbonyl is present at C-12 (compound **5**). Furthermore, the lactone ring between the C-19 and C-20 decreases the inhibitory effect. In fact, the IC_{50} of potamogetonin **11** was 28.58 μmol/liter, while the 12-oxo derivative **12** was biostimulating up to a concentration of 25.85 μmol/liter and became inhibiting at the highest concentration (60.89 μmol/liter). The activity becomes significant again because of the presence of a hydroxyl group at C-12, as shown by compound **13** with an IC_{50} of 4.40 μmol/liter. It is important to note that epimer **13ep** acts in a completely different way. It is only slightly active (20% inhibition) at the highest tested concentration (136.4 μmol/liter), indicating that the configuration of carbon 12 is fundamental to the biological activity. On the other hand, it is reported that the algal growth effect is dependent on the stereochemistry of the substrates (DellaGreca et al., 1990). The absence of the furano group (compounds **6** and **7**) reduces the activity of the chemicals considerably, and the oxidation of the heterocyclic ring to γ-lactone decreases the toxicity, as is evident from the comparison of compounds **11**, **16**, **17**, and **18** with the analogs **15**, **1**, **2**, and **8**. Furthermore, statistical analysis performed with Student's t test (comparison between averages) shows that the furano compounds are more toxic than lactones ($P < 0.01$).

The glucosylation of the lactone diterpenes (**19** and **20**) causes biostimulation at the low concentrations. These results can be explained by the fact that detoxification often occurs through glucosylation (Harborne, 1977).

TABLE 2. EFFECTS OF FURANO DITERPENES ON AQUATIC ORGANISMS REPORTED AS L(E)C_{50} WITH 95% CONFIDENCE LIMITS

Compounds	*D. magna* (EC_{50})[a]	*T. platyurus* (LC_{50})[a]	*B. calyciflorus* (LC_{50})[a]	*A. salina* (LC_{50})[a]

13ep	ND	ND	ND	ND

[a] In micromoles per liter. ND = not determined at highest concentration assayed.

To evaluate the impact of these diterpenes on other aquatic organisms, present in the same ecosystems as the investigated Potamogetonaceae, we tested the most active and abundant chemicals on consumers, including a rotifer (*Brachionus calyciflorus*), a crustacean cladoceran (*Daphnia magna*), and two anostracans (*Thamnocephalus platyurus* and *Artemia salina*). Acute toxicity of labdane diterpenes was detected by exposing the organisms to solutions of varying concentrations and counting the number of dead (*T. platyurus*, *B. calyciflorus*, and *A. salina*) or immobile (*D. magna*) organisms. We report the toxicity as LC_{50} or EC_{50}, the lethal or immobilizing concentrations that affect 50% of the exposed organisms (Table 2).

The activity of the diterpenes on *D. magna* is less than that on *S. capricornutum*. Compounds **2**, **3**, **13**, and **13ep** are completely inactive at the highest concentrations tested. The carbonyl group at carbon 20 and the absence of an oxygenated function at the carbon 12 (compounds **8** and **11**) seems to enhance the toxicity.

In contrast to the previously mentioned species, compounds **1** and **8** were very active on *T. platyurus*. The LC_{50} value of the first compound (0.84 μmol/liter) was comparable with its IC_{50} value for *S. capricornutum* (0.80 μmol/liter). Compounds **3**, **10**, **13**, and **13ep** were inactive at the tested concentrations, while *ent*-labdanes **2** and **12** showed high values of LC_{50}.

B. calyciflorus was sensitive to most of the tested compounds. Only compounds **12** and **13ep** were inactive for this invertebrate. The most toxic for rotifers was **13**, showing a LC_{50} of 1.48 μmol/liter. Diterpenes **2** and **3** also showed a high toxicity, with LC_{50} values lower than 7 μmol/liter. *A. salina*, already known as a resistant organism (Persoone, 1998), was not affected by exposure to these chemicals.

It should be noted that the synthetic **13ep** was active on all species tested, while its natural epimer **13** showed high toxicity values only for algae and rotifers. Treatment of **12** with $NaBH_4$ afforded the alcohol **13ep** in two-fold yield compared

to the epimer **13**. The absence of **13ep** in the plant allows one to suppose the involvement of an appropriate enzymatic system in the biosynthesis of **13** and a plausible specific role of this metabolite.

Except for compound **13ep**, no one compound was active or inactive toward all the organisms. Compound **3** was inactive for *D. magna* and *T. platyurus*, but had low of LC_{50} and IC_{50} values for *B. calyciflorus* and *S. capricornutum*. Compound **1** was highly toxic toward *T. platyurus* and algae, while showing high LC_{50} and EC_{50} values for *B. calyciflorus* and *D. magna*, respectively.

The biological activity of diterpenes is thoroughly reported in the literature. Singh et al. (1999) reviewed the biological activity of labdane diterpenes from 1987 to 1997. The antibacterial, antifungal, antiinflammatory, cytotoxic, and other biological activities detected in the labdane diterpenes have been widely discussed in relation to chemical structures. In recent years, the role of diterpenes in allelopathy has been supported (Macias et al., 1999, 2000), but so far the antialgal activity of these compounds has not been reported. The only exception is geniculol, an irregular diterpenoid isolated from an ecdophytic fungus of the *Geniculosporium* genus, which inhibits the growth of the green alga *Chlorella fusca* (König et al., 1999). The toxicity of the labdanes on other aquatic organisms also is but slightly known, and only the brine shrimp (*Artemia salina*) has been extensively employed in bioassays (Gray et al., 1998).

One of the factors supporting the use of algae and invertebrates in bioassays is their niche in aquatic ecosystems. If these organisms are adversely affected by a toxicant, then the surrounding ecosystem may also feel the effects, either directly or indirectly, from the lack of a food source. Algae and invertebrates occupy a low trophic level, and their disturbance may cause a chain effect throughout the ecosystem.

The results obtained from the phytochemical study of *P. natans* and *R. maritima* suggest that the high concentrations of the bioactive diterpenes found in these plants interfere with other aquatic organisms, thus playing a role in the equilibrium of the aquatic systems.

Abstract—Caribbean sponges of the genus *Ircinia* contain high concentrations of linear furanosesterterpene tetronic acids (FTAs) and produce and exude low-molecular-weight volatile compounds (e.g., dimethyl sulfide, methyl isocyanide, methyl isothiocyanate) that give these sponges their characteristic unpleasant garlic odor. It has recently been suggested that FTAs are unlikely to function as antipredatory chemical defenses, and this function may instead be attributed to bioactive volatiles. We tested crude organic extracts and purified fractions isolated from *Ircinia campana*, *I. felix*, and *I. strobilina* at naturally occurring concentrations in laboratory and field feeding assays to determine their palatability to generalist fish predators. We also used a qualitative technique to test the crude volatile fraction from *I. felix* and *I. strobilina* and dimethylsulfide in laboratory feeding assays. Crude organic extracts of all three species deterred feeding of fishes in both aquarium and field experiments. Bioassay-directed fractionation resulted in the isolation of the FTA fraction as the sole active fraction of the nonvolatile crude extract for each species, and further assays of subfractions suggested that feeding deterrent activity is shared by the FTAs. FTAs deterred fish feeding in aquarium assays at concentrations as low as 0.5 mg/ml (fraction B, variabilin), while the natural concentrations of combined FTA fractions were >5.0 mg/ml for all three species. In contrast, natural mixtures of volatiles transferred from sponge tissue to food pellets and pure dimethylsulfide incorporated into food pellets were readily eaten by fish in aquarium assays. Although FTAs may play other ecological roles in *Ircinia* spp., these compounds are effective as defenses against potential predatory fishes. Volatile compounds may serve other defensive functions (e.g., antimicrobial, antifouling) but do not appear to provide a defense against fish predators.

Key Words—Sponge, predation, chemical defense, Caribbean, *Ircinia*, terpenoids, volatiles, dimethylsulfide.

INTRODUCTION

Sponges produce a wide variety of marine natural products that often exhibit potent activity in pharmacological assays (Faulkner, 2000, and previous reviews cited therein). Yet, the roles that these metabolites play in sponge biology remain largely unknown. Because secondary metabolites in sponges are structurally complex and frequently present in high concentrations, it has been presumed their synthesis occurs at some metabolic cost to the organism, and for this cost, they should provide some benefit (Paul, 1992; Pawlik, 1993; McClintock and Baker, 2001). Sponge secondary metabolites may act to inhibit biofouling and overgrowth (Henrikson and Pawlik, 1995, 1996), inhibit the growth of microorganisms (Newbold et al., 1999; Zea et al., 1999), prevent damage caused by UV radiation (Paul, 1992), or act as allelopathic agents (Sullivan et al., 1983; Porter and Targett, 1988; Engel and Pawlik, 2000), but the most commonly hypothesized function is that of predator deterrence (Pawlik, 1993; Pawlik et al., 1995; Chanas et al., 1996; McClintock, 1997; Wilson et al., 1999; Waddell and Pawlik, 2000a,b).

In a previous study, we surveyed the crude organic extracts of 71 species of Caribbean sponges (Pawlik et al., 1995) and found that 63.4% contained metabolites that were unpalatable to the generalist predatory fish *Thalassoma bifasciatum* in aquarium assays. Among the least palatable were extracts from sponges of the genus *Ircinia*. Three species of *Ircinia—I. felix, I. strobilina*, and *I. campana*—are commonly found on tropical coral reefs, grassbeds, and in mangroves throughout the Caribbean (Zea, 1987; Schmahl, 1991).

Sponges of the genus *Ircinia* are well known for their strong, unpleasant garlic odor, which has recently been traced to a mixture of low-molecular-weight, volatile nitrogen- or sulfur-containing compounds, including dimethylsufide, methyl isocyanide, and methyl isothiocyanate (Duque et al., 2001). These volatile compounds exhibit antimicrobial activity in laboratory assays (Duque et al., 2001). In addition, furanosesterterpene tetronic acids (FTAs) have been isolated from *Ircinia* spp. (Cimino et al., 1972; Martínez et al., 1997) (Figure 1). These compounds reportedly have a variety of biological activities in various assay systems, including antimicrobial activity and the inhibition of Ca^{2+} transport (Beveridge et al., 1995), but their potential ecological functions have never been experimentally addressed.

Recently, Zea et al. (1999) reported that concentrations of FTAs in *Ircinia felix* were lower in the sponge surface than in internal tissues, greater in sponges found or transplanted to areas of lower light intensities, and greater in sponges that had been intentionally injured. Moreover, they reported that, when injured, *I. felix*

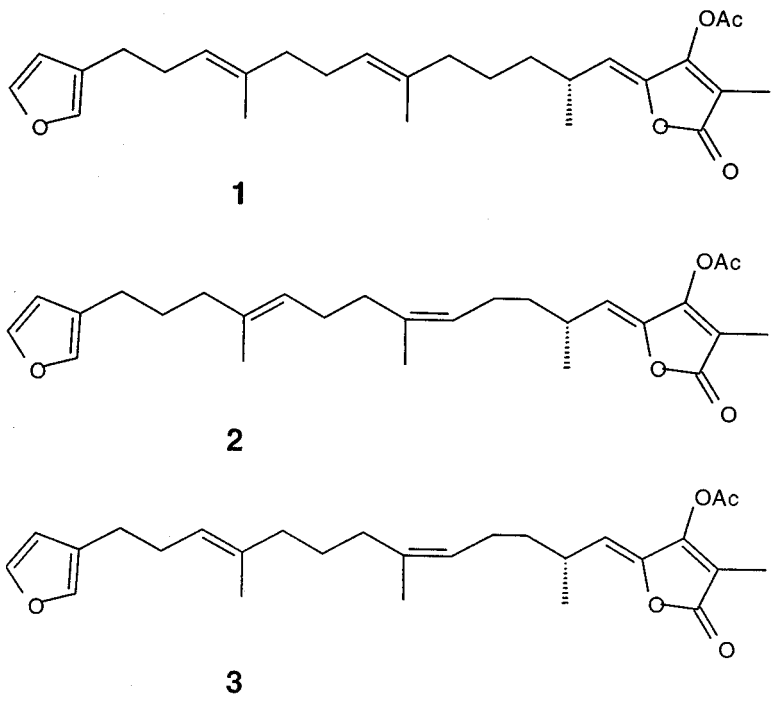

FIG. 1. Furanosesterterpene tetronic acids (FTAs, shown as acetate esters) from *Ircinia* spp. **1**, variabilin; **2**, strobilinin; **3**, felixinin.

did not release FTAs into the surrounding water column, suggesting that these nonpolar compounds were not involved in external ecological interactions such as chemical defense against potential predators, antifouling, or antiovergrowth (Zea et al., 1999). Instead, they suggested that the odor-causing, volatile compounds were responsible for chemical defense, either by direct action, or at a distance by signaling invasive organisms or potential predators of the presence of FTAs within the sponge tissue (Zea et al., 1999; Duque et al., 2001).

Considering the foregoing, we became interested in the relative antipredatory role of volatiles and FTAs from *Ircinia* spp. Standard techniques for isolating crude organic extracts, such as those used in Pawlik et al. (1995), result in the loss of highly volatile constituents, and to our knowledge, volatile metabolites of sponges have not previously been subjected to feeding assays. Specifically, we wanted to answer these questions: (1) Which nonvolatile components of the crude organic extracts of *Ircinia* spp. are responsible for the antipredatory effects described previously (Pawlik et al., 1995)? (2) Do the odor-causing volatile metabolites of *Ircinia* spp. also contribute to the antipredatory chemical defenses of these sponges?

METHODS AND MATERIALS

For experiments with nonvolatile crude organic extracts of sponges, samples of *Ircina felix* and *I. strobilina* were collected in August 1995 from reefs, mangroves, and seagrass beds from Acklins Island, Long Island, and Sweetings Cay, Bahamas, at 1–30 m depth. Samples of *I. campana* were collected October 1995 at Rodriguez Cay, Key Largo, Florida, at 1–2 m depth. Replicate specimens were obtained from geographically distinct locations to avoid collection of asexually reproduced clones. Samples were removed from the substrate by cutting the tissue with a sharp knife. Sponges were identified according to Zea (1987). Specimens were extracted immediately or frozen at -20°C until extraction.

Sponge tissue was chopped into cubes, tissue volume was measured by displacement, and the tissue was serially extracted in methanol and a 1:1 mixture of dichloromethane (DCM) and methanol (MeOH) (details in Pawlik et al., 1995; Chanas et al., 1996). The resulting crude extract was resuspended and divided into aliquots that were stored under nitrogen and kept at -20°C until use in aquarium or field assays. To separate compounds based on polar affinity, an aliquot of each crude extract was successively partitioned against water, hexanes, DCM, and *n*-butanol. The four partitions were tested for feeding deterrency in aquarium and field assays (see below).

Aquarium assays indicated that antifeedant activity was present in the hexanes and DCM partitions. Subsequent reverse-phase (C_{18}) thin-layer chromatography (TLC) of all the partitions using 9:1 MeOH–H_2O as the mobile phase revealed that these two partitions contained the same compounds. The hexanes and DCM partitions were combined as a nonpolar partition, and the *n*-butanol and aqueous partitions were likewise combined to form a polar partition, and both combined partitions were subjected to aquarium and field assays.

The combined nonpolar partition was dried and repartitioned between hexanes and acetonitrile. TLC analysis (as above) indicated nearly complete separation of at least two compounds into the acetonitrile repartition, with two pink-stained spots having R_f values of approximately 0.45 and 0.55, respectively. Both repartitions were subjected to aquarium assays, and the acetonitrile repartition was also assayed in the field.

Reverse-phase preparative TLC was used to isolate two fractions (A and B) from the acetonitrile repartition using 7:3 MeOH–H_2O as the mobile phase. Fractions A and B were further purified by using high-performance liquid chromatography (Spherisorb ODS-2 C_{18} column with a mobile phase of 65:34.7:0.03 acetonitrile–water–trifluoroacetic acid). Fraction A was a mixture of compounds, but fraction B was a single metabolite and was subjected to mass spectrometry (HP 5890 series II gas chromatograph coupled with an HP 5971 mass detector) and to ^{1}H and ^{13}C NMR spectroscopy using a 300-MHz Varian model NMR.

For assays of the naturally occurring volatile metabolites from *Ircinia* spp., individual specimens of *I. felix* and *I. strobilina* were collected in July 2000 at Sweetings Cay and Little San Salvador, Bahamas, from 14–18 m depth. For each species, sponge samples were drained of excess seawater and pureed in a blender. The resulting sponge slurry (125 ml) was stirred and slightly heated in a stoppered Erlenmeyer flask through which air was bubbled from an aquarium air pump. The air emerging from the flask was passed by airline tubing through an air-stone in a test tube containing distilled water (20 ml) chilled in a bath of ice in seawater. After several trials, the ratio of 125 ml of sponge slurry to 20 ml of distilled water produced an odor from the distilled water at 25°C that was approximately as strong as that of the slurry from which it was obtained. The distilled water containing the mixture of volatile metabolites was immediately used to make alginic acid food (see below) and subjected to aquarium fish feeding assays. Pure dimethylsulfide, at concentrations equivalent to 1, 10, and 100 times those found in the tissues of *Ircinia felix* was also subjected to aquarium fish feeding assays (Duque et al., 2001) (natural concentration was $\sim$0.3 μg/g of ash-free tissue dry weight, equivalent to 0.29 μl/liter, calculated from an average ash-free weight of 82 mg/ml of sponge; cf. Chanas and Pawlik, 1995).

Aquarium assays using the generalist reef predator, *Thalassoma bifasciatum*, were performed according to the methods detailed in Pawlik et al. (1995). Briefly, crude extracts, partitions, fractions, or pure compounds were incorporated at natural volumetric concentrations (or higher, for fractions A and B and for dimethylsulfide) into a food matrix composed of alginic acid and freeze-dried, powdered squid mantle. The matrix was extruded through a syringe into a 0.25 M solution of $CaCl_2$ to produce a hardened noodle that was then cut into food pellets. Treated and control pellets (lacking addition of extract or compounds) were offered to 10 replicate sets of three fish. A treated pellet was considered deterrent if it was not eaten after three or more attempts to take it into their mouths, by one or more fish or if it was ignored. Control pellets were eaten in all assays, as fish that would not eat control pellets were considered satiated and were not used in assays. For any single assay of 10 replicates, an extract was significantly deterrent if four or more pellets were rejected ($P < 0.043$, Fisher exact test, one-tailed).

Field assays were conducted as described in Chanas and Pawlik (1995) and Chanas et al. (1996) on nonvolatile crude extracts and all partitions of all three *Ircinia* spp. Field assays were conducted on shallow reefs near Key Largo, Florida, in May 1996, or in the Bahamas (most at Sweetings Cay) during July–August 1996 or 1997. Briefly, crude extracts, partitions, or fractions were incorporated at natural volumetric concentrations into a heated food matrix composed of carrageenan and freeze-dried, powdered squid mantle. The heated mixture was then poured into plastic molds crossed by lengths of cotton string that protruded from the ends of the molds. After the matrix had cooled and set, 1.0 $\times$ 0.5 $\times$ 5.0-cm strips were

sliced to size with a razor blade and removed from the mold. For each experiment, 20 treated strips and 20 control strips were prepared. One treatment and one control strip each were tied to a 50-cm length of three-strand nylon rope at a distance of approximately 4 and 12 cm from one end of the rope (the order was haphazard). Twenty ropes were deployed on the reef, with the end of each rope opposite the food strips attached to the substratum by inserting a piece of nonliving substratum through the rope twines. Within 1 hr, the ropes were retrieved and the amount of each strip eaten was recorded as a percentage decrease in the strip length (to the nearest 5%). The Wilcoxon paired-sample test (one-tailed) was employed to analyze the results after excluding pairs for which both control and treatment slices had been either completely eaten, or not eaten at all.

RESULTS

Food pellets containing natural concentrations of crude organic extracts of *Ircinia campana*, *I. felix*, and *I. strobilina* deterred feeding of *Thalassoma bifasciatum* in aquarium assays (Figure 2), and deterred feeding of a natural assemblage of reef fishes (Figure 3). Food pellets containing the water and *n*-butanol (BuOH)

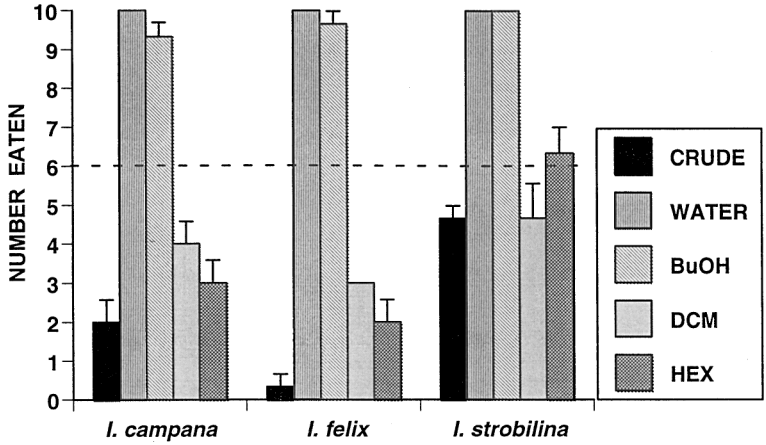

FIG. 2. Aquarium assay. Consumption by *Thalassoma bifasciatum* of food pellets containing natural concentrations of crude extracts and solvent partitions of the crude extracts from three *Ircinia* spp. For each species, assays were replicated with extracts and partitions from 3 sponge samples ($N = 3$: mean + SD is shown). BuOH = butanol partition, DCM = dicholormethane partition, HEX = hexane partition. For each assay, all 10 control food pellets were eaten. For any individual assay, extracts were considered deterrent if the number of pellets eaten was ≤ 6 ($P \leq 0.043$, Fisher exact test) as indicated by the dotted line on the graph.

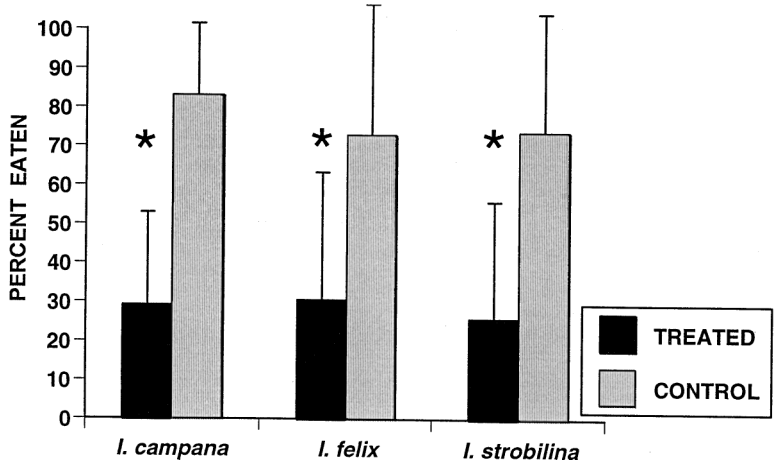

FIG. 3. Field assay. Consumption by reef fishes of paired control food strips and strips containing the natural concentration of the crude organic extracts from three *Ircinia* spp. Mean + 1 SD is indicated. For each assay, 20 pairs of food strips were deployed in the field. $^{*}P < 0.05$, Wilcoxon paired-sample test.

partitions of the crude extracts of all three species were palatable, and the compounds responsible for antifeedant activity were restricted to the dichloromethane and hexanes partitions (Figure 2). Field assays of the combined polar (water and BuOH) partitions and combined nonpolar (DCM and hexanes) partitions confirmed the results of the aquarium assays, with the activity restricted to the nonpolar partitions (Figure 4). Repartitioning of the combined nonpolar partitions between acetonitrile and hexanes further separated the activity: the acetonitrile repartition deterred feeding in field assays for each species, while the reconstituted remainder of the crude extract was not deterrent (Figure 5).

The acetonitrile repartition yielded two spots by TLC analysis, and these were separated and quantified by HPLC into fractions A and B for each of the three species of *Ircinia* (Table 1). Fractions A and B from *Ircinia felix* were subjected to aquarium assays at natural concentrations and at lower concentrations in order to ascertain the minimal effective concentration (Table 2).

Analysis of fractions A and B by HPLC revealed that fraction A was a mixture of compounds, but that fraction B was a single metabolite. Analysis of fraction B by GC-MS yielded a M′ of 429 with a base peak of 73. NMR data revealed the structure of fraction B to be that of the known FTA variabilin (**1**). Fraction A was not further separated or analyzed, but was most likely a mixture of the other FTAs present in the mixture isolated from *Ircinia* spp. (Cimino et al., 1972; Martínez et al., 1997) (Figure 1).

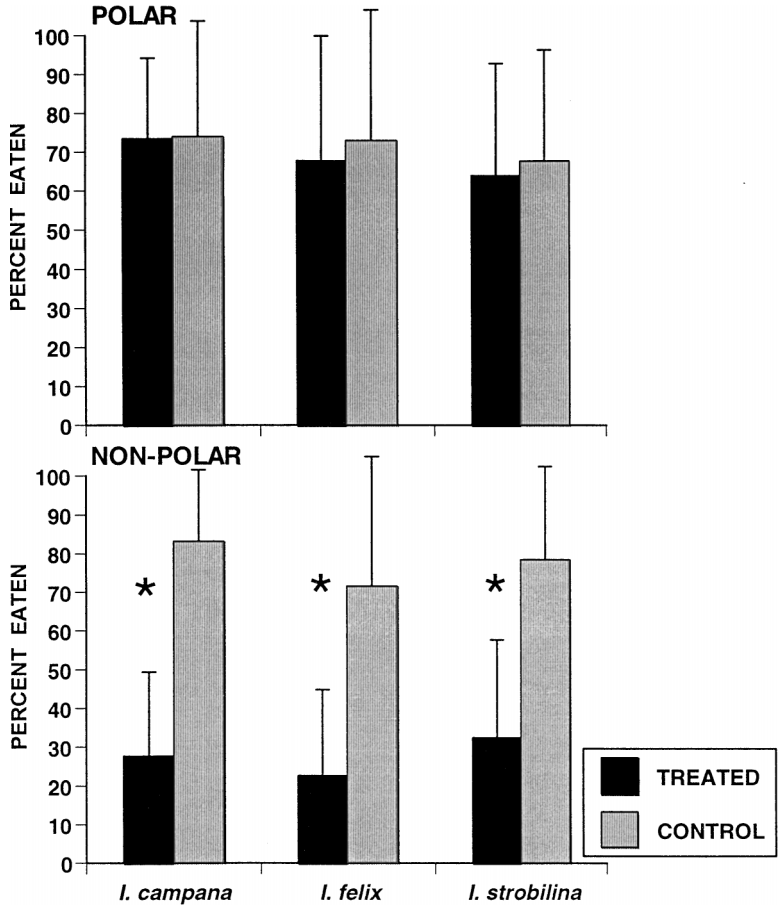

FIG. 4. Field assay. Consumption by reef fishes of paired control food strips and strips containing natural concentrations of recombined polar (water and BuOH) and nonpolar (DCM and hexanes) solvent partions of the crude organic extracts of three *Ircinia* spp. Data presented as in Figure 2.

Food pellets containing roughly natural concentrations of the volatile metabolites from *I. felix* and *I. strobilina* were readily eaten by *Thalassoma bifasciatum* in aquarium assays. Pellets exhibited odor at the same level of intensity as sponge slurry when presented to the fish. Food pellets containing 1, 10, and 100 times the natural concentration of dimethylsulfide as tissue of *Ircinia* spp. were also readily eaten by fish in aquarium assays, although these pellets did not have a noticeable smell at the time of the assays.

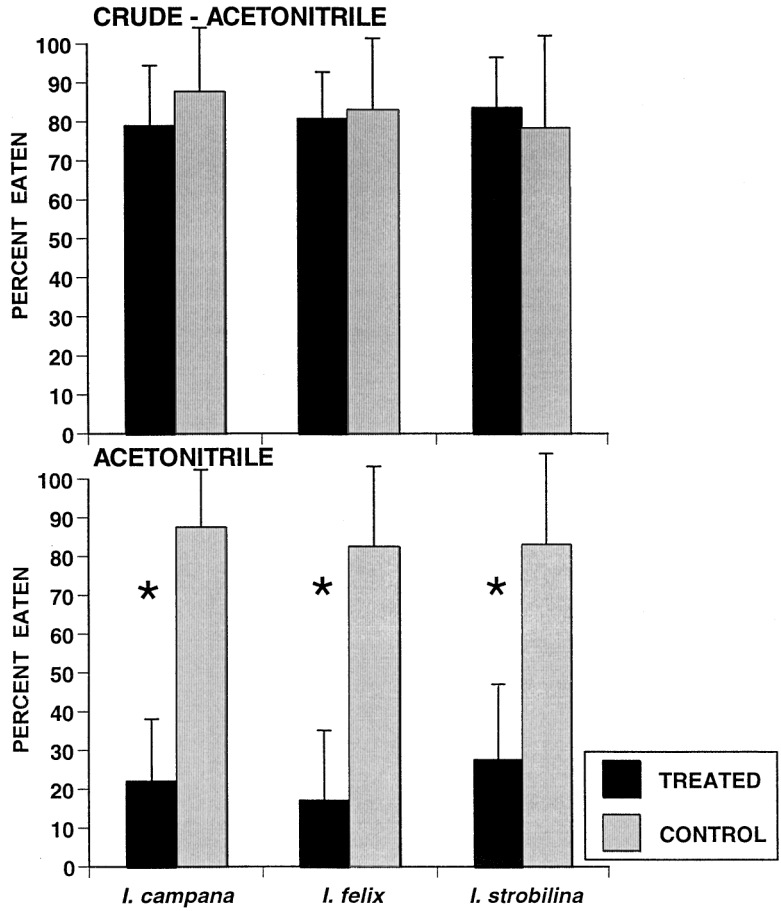

FIG. 5. Field assay. Consumption by reef fishes of paired control food strips and strips containing natural concentrations of the recombined crude extract minus the acetonitrile repartition and the acetonitrile repartition from the crude organic extracts of three *Ircinia* spp. Data presented as in Figure 2.

DISCUSSION

Since the initial survey of crude extracts of 73 species of Caribbean sponges for their capacity to deter feeding of the generalist predatory fish *Thalassoma bifasciatum* in aquarium assays (Pawlik et al., 1995), bioassay-guided fractionation using aquarium and field assays has resulted in the isolation and identification of several metabolites responsible for sponge chemical defenses against fish predators: amphitoxin from *Amphimedon compressa* (Albrizio et al., 1995), oroidin and

TABLE 1. CONCENTRATION OF FRACTIONS FROM *Ircinia* spp. THAT DETERRED FISH FEEDING IN AQUARIUM AND FIELD ASSAYS[a]

Species	Concentration (mg/ml)		
	Fraction A	Fraction B	Total
Ircinia campana	4.17	3.08	7.52
Ircinia felix	5.23	3.84	9.07
Ircinia strobilina	3.35	2.43	5.78

[a] Fraction B was identified as the FTA variabilin **(1)**, while fraction A contains a mixture of the other FTAs.

related metabolites from *Agelas* spp. (Chanas et al., 1996; Assmann et al., 2000), stevensine from *Axinella corrugata* (Wilson et al., 1999), and triterpene glycosides from *Erylus formosus* (Kubanek et al., 2000). The present study confirms that the metabolites of *Ircinia* spp. that deter feeding by predatory fishes are the FTAs and not the foul-smelling volatile metabolites, as suggested by Zea et al. (1999) and Duque et al. (2001). Because the technique for transferring the volatile metabolites from macerated sponge tissue to the assay food did not rely on a precise quantitative method, but rather a comparison of the intensity of the odor, it is possible that the concentration of volatiles transferred to the assay food were below natural levels or that some oxidation of the volatiles had occurred in the process. However, it is just as likely that volatile concentrations exceeded natural levels in replicate experiments. In any case, we observed no hesitation on the part of the assay fish

TABLE 2. AQUARIUM ASSAY: CONSUMPTION OF FOOD PELLETS BY *Thalassoma bifasciatum* CONTAINING EXTRACTS AND ISOLATED METABOLITES FROM *Ircinia felix*[a]

Sample	Concentration (mg/ml)	Treated pellets eaten

[a] Fish consumed all 10 control pellets in each assay. $N = 10$ replicates for assays of the crude extract. For any individual assay, samples are considered deterrent if the number of pellets eaten is ≤ 6 ($P \leq 0.043$, Fisher exact test).

in consuming food pellets made from volatile-treated assay food in replicate experiments performed with two *Ircinia* spp., and these pellets retained the sponge odor throughout the assay process. We have used *Thalassoma bifasciatum* as an assay fish for testing the defensive properties of secondary metabolites from marine organisms for over 15 years (Pawlik et al., 1987) and have found that deterrent metabolites will elicit avoidance behavior in assay fishes (repetitive mouthing, opercular flaring, followed by subsequent consumption) at concentrations that are a fraction of those that result in immediate rejection. In this study, fish responses to volatile-treated pellets were no different from those to control pellets (immediate consumption). Given that these bad-smelling volatiles do not deter fish feeding in aquarium assays, it appears that they neither act as direct natural deterrents nor serve to signal the fish of the presence of FTAs in the sponge tissue (Duque et al., 2001).

Concentrations of FTAs were greatest in *I. felix*, followed by *I. campana* and *I. strobilina* (Table 1), as was also reported by Martínez et al. (1997) for the same species from the Colombian Caribbean. Levels of FTAs for all three species were several-fold higher than required to deter predation by generalist fishes (Table 2). Although concentrations of FTAs were lower in the surface tissues than in the sponge interior of *Ircinia* spp. (Zea et al., 1999), surface concentrations exceeded those necessary to deter fish predation, and it is likely that any bites taken by generalist predatory fishes would include both surface and internal sponge tissues.

Despite the presence of FTAs, *Ircinia* spp. are subject to predation by specialist sponge predators. In their survey of the diets of Caribbean fishes, Randall and Hartman (1968) reported that *I. strobilina* was found in the guts of five spongivorous species and was the most abundant sponge in the guts of three, comprising 30%, 9%, and 5.6% of the gut contents of the tilefishes *Cantherhines macrocerus* and *C. pullus* and the queen angel, *Holacanthus ciliaris*, respectively. *Ircinia* spp. were also consumed by some seastars (Wulff, 1995; Waddell and Pawlik, 2000a), although avoided by hermit crabs (Waddell and Pawlik, 2000b). Clearly, some fish and invertebrate predators have circumvented the chemical defenses of *Ircinia* spp.

Although other possible roles of the odor-producing volatile compounds from *Ircinia* spp. (e.g., antifouling, antiovergrowth) have not been studied and cannot be ruled out, it may be possible that these compounds are produced as metabolic by-products. For example, dimethylsulfide is an apparent waste product of the digestion of phytoplankton by zooplankton (e.g., Dacey and Wakeham, 1986). Similarly, volatile metabolites may be waste products of the digestion of phytoplankton (Pile, 1997) or of endosymbiotic bacteria (Simpson, 1984) by *Ircinia* spp. Nevertheless, the broad spectrum of bioactivities of known marine isocyanide and isothiocyanate compounds (Duque et al., 2001) and the high level at which they are produced and released from *Ircinia* spp. is certainly suggestive of a functional role for these metabolites.

Abstract—Studies of chemoreception in crustaceans have shown that flesh-eating species can detect amino acids, nucleotides and derivatives, and amines, while most herbivorous and omnivorous species are additionally sensitive to carbohydrates. We used extracellular recording techniques to evaluate the effectiveness of a range of nitrogen-containing compounds (mostly amino acids), bile acids, and carbohydrates in stimulating chemoreceptor cells present in the second and third pereopods of the omnivorous crayfish *Procambarus clarkii*. When applied at a final concentration of $\sim$100 μM, effective stimuli were trehalose, leucine, cellobiose, glycine, sucrose, maltose, and ammonium (from most to least effective). The other 17 compounds tested, many chosen because they are potent stimuli for other crustaceans, were ineffective stimuli for *P. clarkii*. Concentration–response functions were determined for three single cells that were sensitive to ammonium, for five multiunit fibers sensitive to glycine, and for six multiunit fibers sensitive to leucine. Thresholds ranged from 10 nM to 10 μM, functions were generally linear when plotted against the log of the stimulus concentration, and there was little evidence of saturation. While *P. clarkii* is sensitive to only seven of 24 compounds tested, the compounds that proved stimulatory should serve as cues for location and identification of food items preferred by this omnivorous crustacean.

Key Words—Gustation, crayfish, chemoreception, taste, Crustacea, Procambarus.

INTRODUCTION

Crustaceans use chemoreception to locate odor sources (Devine and Atema, 1982; Weissburg and Zimmer-Faust, 1993), discriminate between odors (Derby et al., 1989), and communicate with conspecifics (Atema, 1986). The range of stimulatory compounds varies among species, but typically includes amino acids, nucleotides and derivatives, amines and, in some cases, carbohydrates. Compounds that stimulate crustacean chemoreceptor cells are typically those that possess the best signal properties, i.e., they are found at high concentrations within food items, but are present at much lower "background" levels in the environment. For example, most amino acids are found in millimolar concentrations within the invertebrate tissues consumed by flesh-eating crustaceans, but in seawater are present in low nanomolar concentrations (Carr, 1988). Consequently, amino acids are recognized as some of the most important chemosensory stimuli for crustaceans, and sensitivity to amino acids has been demonstrated in a wide range of crustacean species.

In contrast, chemosensory sensitivity to carbohydrates has been demonstrated in just a few crustaceans, where such sensitivity appears correlated with herbivorous or omnivorous feeding habits. Carbohydrates are important chemical stimuli for the porcelain crab *Petrolisthes cinctipes* and fiddler crabs (*Uca* species), which feed largely on microscopic algae, for the omnivorous ghost crab *Ocypode quadrata* and the crayfish *Orconectes rusticus* (Hartman and Hartman, 1977; Robertson et al., 1981; Trott and Robertson, 1984; Tierney and Atema, 1988; Rittschof and Buswell, 1989). Carbohydrate sensitivity, however, is not found in all omnivorous crustaceans; the crayfish *Austropotamobius torrentium* is insensitive to sugars (Bauer and Hatt, 1980), and crayfish are widely considered to be omnivores (Lorman and Magnuson, 1978; Momot et al., 1978). More species must be studied to determine whether sensitivity to carbohydrates is a reliable predictor of herbivorous or omnivorous feeding habits in Crustacea.

One class of compounds that has not been tested on crustaceans is the bile acids. Bile acids are potent olfactory stimuli for fish (reviewed by Hara, 1994), which release bile acids in their feces (Zhang et al., 2001). If crayfish were able to sense bile acids, they might be able to identify fecal matter better upon encountering it. Moreover, zebrafish appear to respond to bile acids with the use of a different transduction mechanism and set of receptors than is used for other odorants (Michel and Derbidge, 1997; Michel, 1999). If crayfish chemoreceptor cells can also respond to bile acids, comparative studies of their transduction mechanisms could be performed.

Here we used physiological methods to investigate the range of chemical stimuli for the walking legs (pereopods) of the crayfish *Procambarus clarkii*. Crustaceans use their pereopods for locomotion and feeding, and for food localization (Devine and Atema, 1982; Steele et al., 1999) and evaluation (Hazlett, 1968). We

assessed the pereopod's sensitivity to a variety of nitrogen-containing compounds (mostly amino acids), carbohydrates, and bile acids.

METHODS AND MATERIALS

Animals and Solutions. Adult, intermolt *Procambarus clarkii* were obtained from a local supplier, maintained in aerated, aged tap water, and fed chicken, spinach, or carrots every other day. Second and third pereopods were excised at the middle of the merus to expose the nerve as it emerges from the proximal end of the carpus. Pereopods were placed in a conventional olfactometer that allowed superfusion of the dactyl and propus with a 20 ml/min carrier flow of modified van Harreveld's saline (205.0 mM NaCl, 13.5 mM $CaCl_2$, 5.4 mM KCl, 2.6 mM $MgCl_2$, and 2.4 mM HEPES), while the nerve was suspended in a separate compartment filled with the same solution. Pereopods were perfused with modified van Harreveld's saline (vH) via a cannula inserted into the articular membrane of the dactyl–propus joint. This perfusion technique, however, may not have efficiently provided vH to the most distal regions of the appendage. Poor perfusion in this area could compromise the passive flux of ions from the animal that is likely to provide the chemosensory dendrites with an environment protected from osmotic stress (see Discussion). By superfusing the entire appendage in vH, we hoped to prevent osmotic damage to these dendrites and to provide them with an environment similar to that normally generated by such a passive flux of ions.

Stimuli were injected by hand in 100 μl volumes into the vH carrier flow and reached peak concentration approximately 1 sec later, after being diluted $\sim$23-fold (Figure 1). Except in investigations of concentration–response characteristics, all stimuli were injected at a concentration of 2.3 mM to reach a predicted peak concentration of 100 μM at the pereopod.

Equipment. Exposed nerves were teased into fascicles, and activity was monitored with a conventional suction electrode connected to a DHS-300 active differential headstage (CB Sciences, Milford, Massachusetts, USA) and ETH-250 amplifier (CB Sciences) set to AC mode. Data were digitized at 10 kHz with the use of a PowerLab 200 A/D converter (ADInstruments, Milford, Massachusetts, USA) and monitored, stored, and analyzed on an Apple Macintosh computer equipped with Chart software (ADInstruments). Responses were quantified with the use of the MLS 062 Spike Histogram Extension (an optional component of Chart), which counted the total number of spikes with amplitudes falling within a certain range, set to exclude noise and the large action potentials generated by most mechanosensory axons.

Identification of Chemosensory Bundles. Axon bundles were considered chemosensory if they responded to either a fish food extract or a defined mixture—both were tested on every bundle. Fish food extract was prepared by grinding 5 g

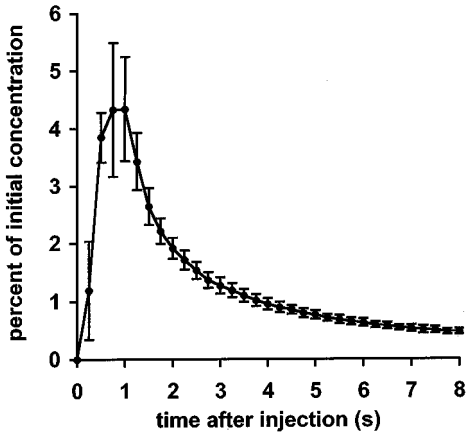

FIG. 1. Concentration profile of stimuli injected by hand into the olfactometer. Shown is the percent of the initial concentration of a 100 μl volume of 2 M NaCl injected into a carrier flow of 100 mM NaCl flowing at 20 ml/min, as determined by conductivity measurements. The stimulus concentration peaked within the olfactometer at 4.4% of the initial concentration. Mean values from 1–8 sec were fit best by the power function, $y = 4.12x^{-1.053}$ ($R^2 = 0.9988$; curve fitting was performed with Microsoft Excel). Based on this function, 60 sec after application of a stimulus, the stimulus concentration should be reduced to 1.3% of the peak concentration reached in the olfactometer. Bars show standard deviation, $N = 5$.

of Tetramin fish food (Tetra Sales, Blacksburg, Virginia, USA) in 100 ml of vH, mixing for 15 min, and filtering. Defined mixtures included all of the single compounds being tested, each at the same concentration as when they were applied individually.

Correction for Mechanosensory Activity. Most recordings included the activity of mechanoreceptor cells. When these cells generated large action potentials, their activity was excluded with the use of the MLS 062 Spike Histogram Extension. Remaining mechanoreceptor activity was excluded with two procedures. To eliminate activity induced by the carrier flow, the number of spikes occurring during the 5-sec period preceding the stimulus injection was subtracted from the number occurring during the 5-sec period following the injection. To eliminate responses elicited by the hand injection itself, responses to blank injections that occurred before and after injection of the stimulus were averaged and then subtracted from that elicited by the stimulus. Although necessary, this subtraction procedure likely led to small errors, mostly due to changes in the level of mechanoreceptor cell activity that tended to occur unpredictably as the procedure progressed. For example, if a non stimulatory compound is applied, but by chance evokes a greater mechanosensory response than the blanks, subtraction would yield a small, seemingly chemosensory response. Because of this problem, compounds

TABLE 1. COMPOUNDS INVESTIGATED IN INITIAL SURVEY AND TWO SUBSEQUENT INVESTIGATIONS

Initial survey	Second survey (11 bundles tested)
Nitrogen-containing compounds (18 bundles tested)	L-Arginine
Betaine	Glycine
L-Glutamate	L-Leucine
Glycine	L-Lysine
Ammonium chloride	*trans*-4-Hydroxy-L-proline
L-Serine	Mixture of all compounds used in the second survey
Taurine	Third survey (19 bundles tested)
Mixture of all N-containing compounds above	Cellobiose
Sugars (21 bundles tested)	β-Cyclodextrin
D-Glucose	D-Fructose
Lactose	D-Galactose
Maltose	D-Glyceraldehyde
Sucrose	Maltose
Mixture of all sugars above	D-Ribose
Bile acids (23 bundles tested)	Trehalose
Glycocholic acid	Mixture of all compounds used in the third survey
Taurocholic acid	
Taurodeoxycholic acid	
Mixture of all bile acids above	

were considered stimulatory only if they generated unambiguous responses upon visual inspection of the trace.

Compounds Tested and Protocols Used. We performed three surveys to explore the range of compounds that act as chemical stimuli for *Procambarus clarkii*. All chemicals were purchased from Sigma-Aldrich (St. Louis, Missouri, USA). The initial survey included nitrogen-containing compounds (mostly amino acids), sugars, bile acids, and mixtures of all the nitrogen-containing compounds, all the sugars, and all the bile acids (Table 1). Stimuli were applied in sets, e.g., all the sugars were tested, then all the bile acids, etc. The order of the sets was randomized as was the sequence of stimuli within each set. Stimulus blanks were applied between each set of stimuli to allow subtraction of mechanoreceptor cell responses. Fish food extract, or the defined mixture of all the single compounds, was also applied between each set of stimuli to assess viability. Data from a set of stimuli were excluded if the coefficient of variation of the two flanking viability checks exceeded 60%. This means that not all stimuli were tested on all axon bundles. For example, a bundle's responses to sugars would be excluded if they failed to meet the criterion for viability, but its responses to other sets of stimuli would still be included provided they met that criterion.

Initial results indicated that glycine was a potent stimulus. In the lobster *Homarus americanus*, glycine-sensitive cells are also often sensitive to hydroxyproline, arginine, lysine, and leucine (Tierney et al., 1988; Corotto et al., 1992;

Voigt and Atema, 1992). To determine if this might also be the case in *Procambarus clarkii*, we conducted a second survey that included those stimuli (Table 1). Early results also indicated that maltose was a potent stimulus. Our third survey included a range of carbohydrates to explore carbohydrate sensitivity further (Table 1). In the second and third surveys, data were again excluded if the coefficient of variation for the two flanking viability checks exceeded 60%.

By fitting the stimulus profile (Figure 1) to a power function, we determined that allowing 1 min between stimulus injections was sufficient to remove more than 98% of the injected stimulus. We, therefore, allowed 1 min to pass between stimulus applications. Any systematic effects from the remaining stimulus were eliminated by randomizing the order of stimulus presentation.

Quantification of Results. When analyzing multiunit recordings, investigators commonly express responses relative to that elicited by a standard stimulus, tested on all fibers. We chose not to employ this method because it results in all axon bundles being given equal weight regardless of the number of chemosensory axons they contain; fascicles containing few chemosensory axons, thus displaying low levels of activity, would influence the results just as much as fibers containing many chemosensory axons, which display greater levels of activity. Rather than expressing responses relative to that elicited by a standard stimulus, we chose to calculate the average number of action potentials elicited by a stimulus per bundle tested. This approach allows larger fascicles, with more chemosensory axons, to have a proportionally greater influence on our results than that of smaller, less representative fibers.

Concentration–Response Determinations. To determine concentration–response characteristics, we applied glycine, leucine, or ammonium at a predicted peak concentration of 100 μM to test for chemical sensitivity. We initially chose ammonium because we found that identifiable single cells were typically ammonium-sensitive. However, due to the rarity with which we encountered single units (see Results), we chose to evaluate the concentration–response characteristics of glycine and leucine with the use of multiunit recordings. After locating a chemically sensitive fiber, we allowed 5 min to pass and then applied an ascending concentration series, in log unit steps, beginning with a predicted, final concentration of 1 nM and ending with 1 mM.

Preliminary results of this study have been published in abstract form (Corotto and Gentilozzi, 2000).

RESULTS

Fifty-six nerve bundles displaying chemosensory activity were identified in this study. Fascicles typically responded to chemical stimuli with large numbers of action potentials from many different cells (Figure 2). Chemosensory spike

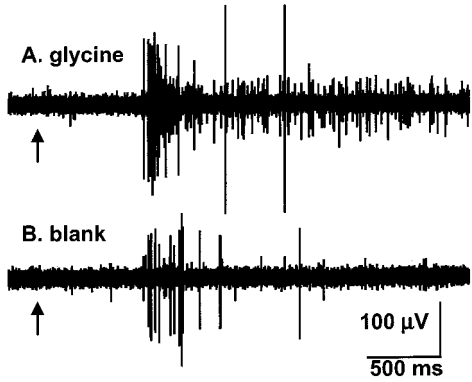

FIG. 2. Typical suction-electrode recordings obtained from nerves in the pereopods of *Procambarus clarkii*. (A) Injection of glycine at a predicted peak concentration of 100 μM elicited large amplitude action potentials from mechanosensory neurons and a sustained train of smaller spikes from many chemosensory cells. (B) Injection of a blank elicited only the mechanosensory response. Arrows indicate time of injection.

amplitudes ranged from being barely visible to $\sim$100 μV. Multiunit chemosensory responses were typically superimposed upon those of numerous mechanosensory axons, many of which possessed spike amplitudes of 100 μV or more. Of the 56 chemosensory bundles we studied, only seven appeared to display the activity of single chemosensory cells.

The most stimulatory single compound tested was the disaccharide trehalose (Figure 3). This is followed, in order of decreasing effectiveness, by leucine, cellobiose, glycine, sucrose, maltose, and ammonium. Unambiguous responses were not obtained from the other 17 single compounds tested (shown in Table 1, but omitted from Figure 3). A single, unambiguous response to the equimolar mixture of bile acids was obtained once (not shown), but single bile acids failed to evoke convincing responses from that fiber.

Of the seven single cells identified, six responded to ammonium and one to glycine. Thus, ammonium sensitivity dominated the small number of cells identifiable as single units, even though ammonium was the weakest chemosensory stimulus identified, eliciting the lowest average number of spikes per bundle (Figure 3).

Concentration–response functions from multiunit and single-unit recordings showed thresholds at predicted, final stimulus concentrations of 10 nM to 10 μM (Figure 4). Two of the three single-units displayed concentration–response functions that appeared roughly linear when plotted against the log of the stimulus concentration (Figure 4A). The third single unit generated fewer spikes to 1 nM ammonium than to 100 μM ammonium, indicating saturation. Multiunit responses

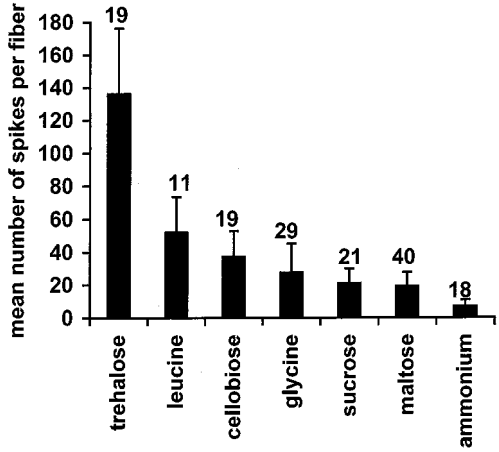

FIG. 3. Mean number of spikes per bundle elicited by chemical stimuli applied at a predicted peak concentration of 100 μM. Numbers above error bars indicate the number of axon bundles tested. In a few cases, both recognizable single cells and multiunit activity was present in the same recordings. These were analyzed separately and considered separate bundles. Bars show standard error of the mean.

to leucine and glycine generated concentration–response functions that showed little sign of saturation and were also approximately linear in form (Figure 4B).

DISCUSSION

The crayfish *Procambarus clarkii* proved a challenging subject for an electrophysiological investigation of chemoreception. Suction electrode recordings from axon bundles usually displayed the activities of large numbers of mechanoreceptor cells with only a small minority including chemoreceptor cell responses. When present, chemosensory responses typically consisted of the activities of large numbers of cells (Figure 2). In contrast, recordings obtained with similar techniques from the maxillipeds of the lobster *Homarus americanus* contain relatively few mechanoreceptor cell responses, abundant chemoreceptor cell responses, and the activities of single chemoreceptor cells are often identifiable (personal observations). While we had initially hoped to focus on the responses of single units, one advantage of multiunit recordings is that they allow one to study a vast number of cells, although it is impossible to determine the actual number. We identified seven single cells, and six of them were selective for ammonium, despite the fact that ammonium is the least effective of the compounds we identify as being stimulatory (Figure 3). This suggests that cells sensitive to ammonium are more easily identified as single units than cells sensitive to other

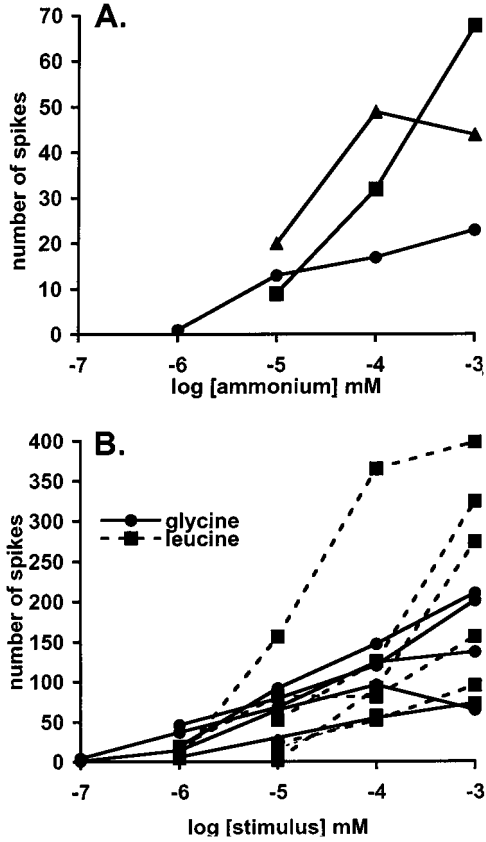

FIG. 4. Concentration-response functions of chemoreceptor cells from *P. clarkii*. (A) Responses of three single cells to different predicted peak concentrations of ammonium. (B) Responses of multiunit fibers to different predicted peak concentrations of glycine and leucine.

compounds. Perhaps ammonium-sensitive cells have larger axons, and, therefore, generate larger spikes in extracellular recordings, or perhaps they are bundled differently within the nerve. Regardless, the observation that most single cells were sensitive to a weak stimulus suggests that focusing entirely upon the responses of single cells may bias one's results towards stimuli that affect particular classes of cells most likely to be identified as single units in extracellular recordings.

Even though many of the compounds we tested are potent stimuli for other crustaceans, only seven evoked unambiguous physiological responses from the pereopods of *P. clarkii*. Neurophysiological and behavioral studies have shown

that sensitivity to taurine, betaine, hydroxyproline, serine, and especially glutamic acid is widespread in crustaceans (Levandowsky and Hodgson, 1965; Fuzessery and Childress, 1975; Robertson et al., 1981; Derby and Atema, 1982; Hatt, 1984; Laverack, 1988; Tierney and Atema, 1988; Voigt and Atema, 1992). None of these compounds is an effective physiological stimulus for the pereopods of *P. clarkii*. We cannot, however, exclude the possibility that behavioral studies, or neurophysiological studies of other appendages, might reveal sensitivity to these compounds. The stimulatory compounds we did identify seem, nevertheless, highly appropriate as cues for food localization and identification. Crayfish are omnivores (Lorman and Magnuson, 1978; Momot et al., 1978) with *P. clarkii* subsisting mostly on living plants and plant detritus along with smaller quantities of invertebrates (Penn, 1943; Ameyaw-Akumfi, 1977; Avault, et al., 1983; Feminella and Resh, 1989). It is within the body fluids of these invertebrates that *P. clarkii* is most likely to encounter the disaccharide trehalose (Fairbairn, 1958), the most stimulatory compound we identified. Other effective carbohydrates include cellobiose, maltose, and sucrose. Sensitivity to cellobiose and maltose is appropriate for an animal that feeds on plant detritus; these disaccharides are produced by the microbial degradation of cellulose and starch (Ljungdahl and Eriksson, 1985). Sucrose, another effective disaccharide, is the major sugar found in phloem sap (Mohr and Schopfer, 1995) and would be present in the fresh macrophytes that *P. clarkii* consumes. Other effective stimuli for *P. clarkii* include leucine, glycine, and ammonium. Leucine and glycine are common amino acids, and glycine, in particular, is found at high concentrations in the tissues of many invertebrates (Simpson et al., 1959; Awapara, 1962). Ammonium is a common metabolite and is also a potent stimulus for many crustaceans. Collectively, the stimulatory compounds we identified should render the animal highly sensitive to its natural food items, including invertebrates, plant detritus, and fresh macrophytes.

The particular compounds we identified as chemosensory stimuli for *P. clarkii* closely match those shown to stimulate feeding behavior in the crayfish *Orconectes rusticus*. In *O. rusticus*, the most powerful stimulants of feeding behavior are cellobiose, sucrose, glycine, and maltose (Tierney and Atema, 1988). All of these are effective physiological stimuli for *P. clarkii*. Similarly, monosaccharides are ineffective for both species. In contrast, physiological investigations of pereopods from the crayfish *Austropotamobius torrentium* show that this animal responds to a very different range of compounds. *A. torrentium* possesses three classes of chemoreceptor cells: one tuned to amino acids, one to amines, and one to pyridines (Bauer and Hatt, 1980). The most effective amino acid stimulant for *A. torrentium* is serine (Bauer et al., 1981; Hatt, 1984), an ineffective stimulus for *P. clarkii*. Sugars are ineffective stimuli for *A. torrentium* (Bauer and Hatt, 1980), but for *P. clarkii* some of the most potent stimuli are disaccharides. Additional studies on *P. clarkii* are necessary to assess its sensitivity to amines and pyridines, but even without testing those classes of compounds, it is clear that the pereopods

of the two species are sensitive to a different range of chemical stimuli. It would be interesting to know if these chemosensory differences are also paralleled by differences in dietary preference.

To our knowledge, this is the first investigation of bile acids as potential chemosensory stimuli for a crustacean; bile acids are especially potent odorants for fish (reviewed by Hara, 1994). Crayfish would likely encounter bile acids in fish feces (Zhang et al., 2001). We had thought that sensitivity to bile acids might aid crayfish in identifying fecal matter and, presumably, allow them to reject it as food. The three bile acids we chose to investigate, however, were not effective chemosensory stimuli for *P. clarkii*. We observed one unambiguous response to the mixture of all three bile acids but did not observe responses to the components. Since only three bile acids were included in this study, investigations with others are necessary before we can conclude that they are ineffective, in general, as chemosensory stimuli for *P. clarkii*.

In crustacean chemoreceptor cells, physiological thresholds for the most potent stimuli typically range from 1 to 100 nM (Fuzessery and Childress, 1975; Derby and Atema, 1982; Tierney et al., 1988; Corotto et al., 1992). Although values higher and lower than these have been noted (Laverack, 1963; Levandowsky and Hodgson, 1965; Fuzessery et al., 1978; Derby and Atema, 1982), unusually high thresholds may result from testing compounds that are not a cell's best stimulus. This is less of a problem with multiunit recordings because the compound being applied is likely to be the best stimulus for at least some of the cells being tested. Our findings indicate that *P. clarkii*'s thresholds may be slightly higher than the typical 1–100 nM range; two multiunit fibers responded to 100 nM glycine but not 10 nM glycine, and the other multiunit fibers had higher thresholds (Figure 4B). The three single cells we identified also had thresholds above 100 nM (Figure 4A). Exact concentrations, however, are difficult to predict when using conductivity measurements to determine the concentration of a diluted stimulus, as we did. Such measurements provide an estimate of the average concentration surrounding the pereopod, but turbulence within the olfactometer is likely to have distributed the stimulus in the form of small patches of higher and lower concentrations, so the actual concentration of a stimulus at a particular chemoreceptor cell may differ from that predicted. Nevertheless, our results are sufficient to conclude that the thresholds of chemoreceptor cells of *P. clarkii* are similar to, or perhaps slightly higher than those of most other crustaceans. Interestingly, chemoreceptor cells from the blue crab *Callinectes sapidus* lose some sensitivity as the animal moves from seawater to a freshwater environment (Gleeson et al., 1997). Apparently the accompanying osmotic stress causes shortening of the exposed chemosensory dendrites (Gleeson et al., 1996). Chemosensory dendrites in *P. clarkii* are presumably exposed as well, so we had thought that *P. clarkii*'s chemoreceptor cells might be forced to operate at unusually high thresholds given its freshwater environment. This is not the case. Similarly, response thresholds

of amino acid-sensitive cells in the crayfish *Austropotamobius torrentium* lie at approximately 300 nM for serine, the most potent amino acid stimulus (Bauer et al., 1981). In *Callinectes sapidus*, passive flux of ions from the animal provides a microenvironment surrounding the chemosensory dendrites that prevents complete osmotic lysis and allows chemoreception to occur, although responses are reduced in magnitude (Gleeson et al., 1997, 2000). A similar microenvironment may protect chemosensory dendrites in crayfish.

Of the seven compounds identified as stimulatory for *P. clarkii*, the most effective was the disaccharide trehalose. Trehalose elicited more than twice the average number of spikes per bundle as leucine, the next most effective stimulus (Figure 3). Trehalose sensitivity has been noted previously in the porcelain crab *Petrolisthes cinctipes* (Hartman and Hartman, 1977), the fiddler crabs *Uca pugilator* and *U. longisignalis* (Robertson et al., 1981; Weissburg and Zimmer-Faust, 1991), and the ghost crab *Ocypode quadrata* (Trott and Robertson, 1984). Because trehalose is such a potent stimulus for *P. clarkii*, we wonder if it might play a unique role as a chemical cue. Could invertebrate prey release enough trehalose by diffusion across their gills or body wall for crayfish to detect it at a distance? If not, what if the prey item were wounded? Crayfish, including *P. clarkii*, use chemosensory cues to locate distant odor sources (Kreider and Watts, 1998; Moore and Grills, 1999; Steele et al., 1999), and trehalose would seem to be an ideal chemical signal for indicating the presence of a nearby protein-rich meal in the form of a wounded invertebrate.

Abstract—The jasmonate (JA) and salicylate (SA) signaling pathways in plants provide resistance to herbivorous insects and pathogens. It is known that these pathways interact, sometimes resulting in antagonism between the pathways. We tested how the timing and concentration of elicitation of each pathway influenced the interaction between the jasmonate and salicylate pathways measured in terms of five biochemical responses and biological resistance to caterpillars and bacteria. The salicylate pathway had a stronger effect on the jasmonate pathway than did the reverse. The negative signal interaction was generated by two distinct paths in the plant. A negative interaction in the biochemical expression of the two pathways was most consistent in the simultaneous elicitation experiments compared to when the elicitors were temporally separated by two days. Herbivore bioassays with *Spodoptera exigua* also consistently reflected an interaction between the two pathways in the simultaneous elicitation experiments. The negative signal interaction reducing biological resistance to the herbivore was also demonstrated in some temporally separated treatment combinations where attenuation of the biochemical response was not evident. Concentration of the elicitors had an effect on the pathway interaction with consistent biochemical and biological antagonism in the high concentration experiments and inconsistent antagonism in the low concentration experiments.

The bacterial pathogen, *Pseudomonas syringae* pv. *tomato* (*Pst*), consistently showed reduced lesion development on plants with SA responses activated and, in some experiments, on JA-elicited plants. Resistance to *Pst* was not reduced or enhanced in dual-elicited plants. Thus, signal interaction is most consistent when elicitors are applied at the same time or when applied at high doses. Signal interaction affected the herbivore *S. exigua*, but not the pathogen *Pst*.

Key Words—Signal interaction, induced defense, jasmonate, salicylate, *Spodoptera exigua*, *Pseudomonas syringae* pv. *tomato*, polyphenol oxidase, tomato.

INTRODUCTION

Plants can be attacked by many organisms at a particular moment and over their lifetimes. They respond to this attack by inducing responses that can protect themselves against future herbivory. Two suites of responses that are important in plant resistance have jasmonic acid (JA) and salicylic acid (SA) as key signal components. Jasmonate-mediated responses and salicylate-mediated responses (also known as systemic acquired resistance, SAR) are necessary for plant resistance against insects and pathogens, respectively. Biochemical interactions in the expression of the JA and SA pathways can prevent the maximal simultaneous expression of each pathway (Felton and Korth, 2000). This has led researchers to ask under what conditions these signal interactions occur, as this will affect their ecological consequences. The biochemical interactions that occur to generate negative signal interactions may be influenced by the temporal pattern of induction and degree of elicitation (Doherty et al., 1988).

There are several ways in which the jasmonate and salicylate pathways are known to interact. SA itself interferes with JA signaling in at least three sites. The first site is before JA synthesis where 13*S*-hydroperoxylinolenic acid is converted to 12-oxy-phytodienoic acid by 13*S*-hydroperoxide dehydrase (Peña-Cortez et al., 1993; Doares et al., 1995a), the second is in the conversion of 12-oxy-phytodienoic acid to JA (Engelberth et al., 2001), and the third is after JA synthesis (Doares et al., 1995a). Compounds structurally similar to SA have also been shown to inhibit the JA pathway (Doherty et al., 1988). For example, acibenzolar-*s*-methyl (benzothiadiazole, BTH), a synthetic SAR inducer, is translocated in the plant and can, therefore, activate resistance systemically. Thus, while application of BTH does not result in increased endogenous SA, BTH apparently shares sufficient structural similarity to SA to have the same functional properties in vivo. The inhibitory effects of JA on the SA pathway are less well documented (but see Niki et al., 1998; Schenk et al., 2000). JA may interfere with salicylate biosynthesis in tobacco plants via a G-protein switch that is required for a plant's appropriate response to external stimuli (Seo et al., 1995).

The signal molecules (e.g., JA and SA) that initiate the plant responses and appear to be involved in generating the pathway interactions (Felton et al., 1999)

decay with time after elicitation (Niki et al., 1998). Jasmonate levels increased in mechanically wounded leaves of tomato plants sixfold within 90 min and then dropped over the next several hours (Doares et al., 1995b; Conconi et al., 1996). Salicylic acid levels increase in *Pseudomonas syringae* pv. *tomato* (*Pst*) -infected tomato plants and remained twofold higher for at least 48 hr (Oldroyd and Staskawicz, 1998). This suggests that the signaling interaction between the JA and SA pathways will be influenced by the timing of elicitation and that SA induction will influence JA induction more than the converse (Creelman and Mullet, 1997). However, these endogenous JA and SA measures are not directly comparable because the mechanical damage was a single pulse of stress and *Pst* infection was chronic. In addition, other components of the jasmonate and salicylate signal pathways may contribute to the signal interaction and be differentially responsive to the timing of elicitation (Felton and Korth, 2000).

Plants respond to natural damage and induction by elicitors in a dose-dependent manner (Karban and English-Loeb, 1988; Enyedi et al., 1992) and the jasmonate/salicylate signal interaction may be influenced by the degree to which each individual pathway is induced. It may be that heavy infection by a plant pathogen influences deployment of resistance to insects more than a mild infection. For example, Niki et al. (1998) examined antagonisms in expression of JA- and SA-inducible mRNA and proteins when tobacco leaf disks were floated in solutions containing the two elicitors. They found that the concentration of each elicitor negatively influenced the action of the other in a dose-dependent manner. Doherty et al. (1988) found an effect of timing in salicylic acid application on proteinase inhibitor production. Brief application of aspirin to cut tomato stems inhibited production of proteinase inhibitors by mechanical wounding, but only for 2-3 hr after the aspirin application. Doares et al. (1995a) found that aspirin inhibited systemin (a mobile systemic signal of octadecanoid induction in tomato plants) when applied either at high concentration (10 mM) for a short duration (30 min) or low concentration (1 mM) for a long duration (24 hr).

Given this antagonistic interaction in the expression of resistance, we studied how elicitor concentration and timing of application affect the biochemical expression of each pathway and resistance to insects and pathogens. To do this we first needed to (1) establish a concentration response and time course for the effects of BTH on tomato plants [JA concentration response–time course reported in Thaler et al. (1996)] and (2) test whether the interactions between the JA and SA pathways were due to the washing off of elicitor in the dual spray treatments. These preliminary experiments established the range of concentration and timing conditions where pathway interactions could occur and showed that pathway interactions were not result of interactions between elicitors at the leaf surface. (3) Based on these results, we determined how concentration and timing of elicitation influenced the interaction between the JA and SA pathways. Our hypothesis was that the negative interactions between the JA and SA pathways would be

weaker or not occur at lower concentrations of elicitor or when elicitation was temporally separated. (4) Lastly, we examined the effect of BTH on *Spodoptera exigua* caterpillars feeding on wild-type plants and jasmonate-deficient plants. The last experiment was conducted to demonstrate conclusively that the positive effect of BTH treatment on caterpillar growth (observed in 1 and 3 above) was indeed due to an effect of BTH on the jasmonate pathway. If so, the positive effect of BTH on herbivore performance seen in wild-type plants should not be detected in the jasmonate deficient plants.

We assessed this interaction between pathways by assaying plant defensive compounds: PPO (polyphenol oxidase), POD (peroxidase), and LOX (lipoxygenase) enzyme activities, and P4 (pathogenesis-related protein 4) and PINII (proteinase inhibitor) mRNA accumulation, as well as herbivore and pathogen performance: relative growth rate, gross growth efficiency, and leaf area consumed by *S. exigua* caterpillars, and lesion formation caused by *Pst*.

METHODS AND MATERIALS

General Protocols

Tomato plants (*Lycopersicon esculentum* cv. New Yorker) were grown in 4-in. pots containing UC soil mix in a greenhouse. Plants were grown until the four-leaf stage, after which the treatments were applied. JA and BTH were applied to plants using hand-held atomizers. The JA was prepared in aqueous suspension using acetone to help disperse it in water (1% acetone in water). BTH was dissolved in water. The solutions/suspensions were sprayed to runoff onto the desired portion of the plant, shielding the rest of the leaves. Control plants were sprayed with an equal amount of water with acetone.

Two days after the plants were treated, we measured the levels of hallmark indicators of each pathway to determine the level of activation of the SA- and JA-mediated responses. We measured P4 mRNA as a marker of BTH action, and PPO activity and PINII mRNA as markers for JA action. POD and LOX activity, other enzymes with defense-related activity, were also measured. The fourth youngest leaf (systemic, unelicited) was used in most cases, although the third leaf (local, elicited) was used for some experiments as noted in the figures. Thus, we tested for systemic induction unless stated. The terminal leaflet was collected for PPO, POD, and LOX assays unless *Pst* was inoculated on this leaflet, in which case one of the adjacent leaflets was used for biochemical analyses. The other adjacent leaflet was collected for the herbivore bioassay. The remainder of the leaf from four plants were collected and pooled for each P4 and PINII mRNA sample.

RNA Gel Blot Analyses. Abundance of P4 and PINII mRNA was determined by analysis of total RNA (20 μg) prepared from tomato leaves (Choi et al., 1994) according to the methods in Fidantsef et al. (1999). When both *pinII* and

*p*4 expression were measured, the blots were hybridized with the *pinII* probe and then stripped and hybridized with the *p*4 probe. Quantitation of hybridization was measured by exposing the probed blots to a screen that was scanned using a phosphor imaging system (Storm 860 scan, Molecular Dynamics, Inc., Sunnyvale, California, USA). The intensity of the bands produced was measured by drawing a box around the bands and measuring the counts in the area. Equal loading of RNA samples was verified by hybridization of the blots with a tomato cyclophilin DNA probe or by staining of rRNAs with ethidium bromide.

Enzyme Activity. PPO and POD activities were determined according to the methods described in Thaler et al. (1996). Briefly, we extracted the enzymes from weighed leaflets that were homogenized in ice-cold buffer and then centrifuged to obtain a clarified extract for enzyme analyses. For PPO the supernatant was added to a caffeic acid solution (2.92 mM in pH 8 K Phos buffer); for POD the supernatant was added to a guaiacol solution (2.92 mM in pH 8 K Phos buffer), and for LOX the supernatant was added to a linoleic acid suspension (0.4 mM linoleic acid in 0.1 M, pH 8, K Phos buffer with 0.1% Tween 20).

Herbivore Bioassays. Newly hatched *S. exigua* caterpillars were reared on artificial diet (Southland Products) for three to five days before the bioassays. Caterpillars were placed on a single leaflet in 90-mm Petri dishes lined with moist filter paper. The caterpillars were weighed at the beginning of the experiment and again at the end, after two to three days of feeding on the specified leaflets. The assays were terminated before the caterpillars could consume the entire leaflet. Relative growth rate (RGR) was calculated [(final weight-initial weight)/(initial weight $\times$ number of days)] (Waldbauer, 1968). The amount of leaf area consumed (AREA) was quantified using an acetate grid and gross growth efficiency (ECI) was calculated as [(final weight – initial weight)/area consumed)].

Bacterial Speck Disease Assay. Pseudomonas syringae pv. *tomato* isolated from field-grown tomatoes (isolate Pst23, gift of D. Cooksey, Department of Plant Pathology, UC Riverside) was incubated at 27°C for 48–72 hr on King's B medium, and colonies were suspended in sterile water. An aqueous suspension of 10^7 colony-forming units (CFU)/ml was gently painted on the terminal leaflet of the fourth leaf of intact plants with a cotton applicator, and the plants were incubated in the greenhouse. Seven days later, the number of lesions on the inoculated leaflet were counted. There is a strong correlation between the number and/or amount of lesions and bacterial populations (colony-forming units per square centimeter) (Craig Richael, personal communication).

Experimental Protocols

Concentration Response. Concentration response curves for the effects of JA and BTH in tomato were established. The effect of applications of four concentrations of JA on several defensive proteins was reported in Thaler et al. (1996).

BTH concentration response data are reported here. To standardize the treatment, we applied BTH to the third leaf (all leaflets) only. We measured P4 mRNA levels (total density, counts), PPO (ΔOD per gram per minute), POD (ΔOD per gram per minute) activity in the third leaf, and 24-hr RGR, AREA (square millimeters of leaf area consumed), and ECI of *Trichoplusia ni* (a generalist noctuid caterpillar) at 0, 0.3, 0.6, 1.2, and 2.5 mM BTH applications. The terminal leaflet was used for PPO and POD quantification, and the adjacent leaflet was used for the herbivore bioassay. Ten replicate plants were used for each of the five concentration treatments. P4 expression was also quantified at 0.0012, 0.012, 0.036, and 0.12 mM BTH application to establish the minimum concentration required for induction. In addition, we assayed *Pst* lesion formation at three concentrations (0, 0.3, and 1.2 mM) two days after plants were elicited ($N = 11$ plants per concentration). *Pst* was inoculated on the terminal and adjacent leaflets of the elicited leaf two days after BTH elicitation, and lesions were counted seven days later. We used linear regression to analyze the effect of BTH concentration on plant responses, insect performance, and lesions. Mortality of caterpillars slightly reduced sample sizes for RGR, AREA, and ECI.

Because we frequently found that plants sprayed with BTH supported relatively high growth of herbivores (see results), we tested for the effects of BTH on total leaf protein content in the elicited leaf. Total protein was assayed using the Bradford method as modified for plant protein by Jones et al. (1989). Ten replicates of each treatment were analyzed in the control, 0.3, 0.6, 1.2, and 2.5 mM BTH treatments. We used linear regression to analyze the effect of BTH application on plant protein content.

Time Course. To establish the timing of induction, we determined the effects of 1.2 mM BTH on local P4 mRNA induction 1, 4, and 8 days after treatment. The third leaf was elicited with BTH and extracted for P4 mRNA. One sample of each treatment was analyzed, with each sample consisting of elicited leaves pooled from four plants. We used linear regression to analyze the effect of BTH application on P4 mRNA accumulation.

Elicitor Runoff Experiment. Spraying plants with both elicitors simultaneously could possibly wash some elicitor off the plant and produce the antagonism that we observed. To evaluate this possibility, we simultaneously sprayed plants with each elicitor and water and compared the responses to each elicitor alone. The third leaf was sprayed with 1.5 mM JA alone, JA and water, 1.2 mM BTH alone, or BTH and water ($N = 8$ each treatment). The terminal leaflet of the third leaf was assayed for activity of PPO, and the rest of the leaf was collected for P4 mRNA accumulation analysis. Leaves from two plants were pooled for each P4 sample ($N = 3$ each treatment). This experiment was conducted concurrently with a trial where JA induced PPO, BTH induced P4 mRNA, and there was a significant reduction in PPO activity and P4 transcript accumulation when plants

were dually elicited compared to single elicitation with JA or BTH, respectively (data not shown). We used *t* tests to compare PPO activity in JA and JA + water treatments, and P4 mRNA abundance in BTH and BTH + water treatments.

Pathway Interaction Experiments. To examine the effect of the concentration and timing of elicitation on the antagonistic interactions between JA- and SA-mediated resistance, we conducted a series of experiments where we employed four general treatments: plants elicited with (1) water (control), (2) JA, (3) BTH, and (4) JA and BTH.

Simultaneous Elicitation. The third leaf of plants at the four-leaf stage was sprayed with the elicitors. Two concentrations of JA and BTH were used: low JA concentration = 0.5 mM (approx. 0.105 mg/plant) and high JA concentration = 1.5 mM (approx. 0.315 mg/plant) and low BTH concentration = 0.3 mM (approx. 1.0 μmol/plant) and high BTH concentration = 1.2 mM (approx. 3.0 μmol/plant). The two experimental combinations of our four treatments were: (1) high JA, high BTH, simultaneously (three trials) and (2) low JA, low BTH, simultaneously (4 trials). The low and high concentrations were chosen based on the concentration–response curves generated above. The low concentration treatment of our elicitors resulted in a full chemical response (i.e., without excess elicitor), while the higher concentration resulted in excess elicitor in the plant (i.e., more elicitor than necessary to get the maximum response).

Delayed Elicitation. In addition, two timing regimes were used to test the hypothesis that the negative interactions between the JA and SA pathways would not occur when elicitation of the respective pathways was temporally separated. These experiments consisted of treating plants first with jasmonate followed by BTH or first with BTH followed by jasmonate, and were conducted using the high and low concentrations of JA and BTH. The four experimental combinations of our four treatments were: (3) high JA, two-day delay, high BTH (1 trial); (4) high BTH, two-day delay, high JA (2 trials); (5) low JA, two-day delay, low BTH (2 trials); and (6) low BTH, two-day delay, low JA (2 trials). In these experiments, we assayed PPO, POD, and LOX enzyme activities, P4 and PINII mRNA accumulation, relative growth rate, leaf area consumed, and conversion efficiency of *S. exigua* caterpillars, and lesions formed in response to*Pst*. Sample sizes for each response variable are given in the figures. Not all chemical and biological assays were conducted during every trial; the specific information for each trial is presented in the figures and tables.

Factorial analysis of variance was used to analyze the effects of elicitor treatments on the respective response variables. The main effects are interpreted in a manner similar to a single-factor analysis if the JA × BTH interaction is not significant. In this case, the main effects indicate whether JA and BTH affect the response variable when applied alone, and these effects are simply additive in the dual-elicitation treatment. If the interaction is significant, then the main effects

are not independent and cannot be interpreted individually (Underwood, 1997). A significant interaction means that the effects of JA and BTH were not additive, i.e., the effect in the dual elicitation treatment (relative to control) is not the sum of the individually elicited treatments. Thus, there are two possible scenarios in which the two plant defense pathways negatively interact. The first is when both main effects are significant but operate in the opposite direction (e.g., JA decreases RGR, BTH increases RGR) and the interaction term is not significant (i.e., effects of JA and BTH are additive); the net result is an intermediate response in the dual elicited plants. The second scenario is a statistically significant interaction indicating that the expression of one response pathway influenced the expression of the other. In this case, inspection of the means indicates the nature of the interaction in dual-elicited plants compared to singly elicited plants. For example, if JA singly increases PPO, BTH singly has no effect, but together JA and BTH result in lower PPO activity than JA alone, then we expect a significant statistical interaction between elicitation by JA and BTH. Both of these scenarios are biologically relevant (see Discussion).

Data were log $x+1$-transformed where necessary to equalize variance and meet the assumptions of ANOVA. Untransformed means are presented in graphs. Although "trial" was always included in the analyses, trials of the same experimental treatments were pooled for graphical presentation because results across trials were consistent. Only one replicate of PINII mRNA per treatment was measured in each experiment and, therefore, was not statistically analyzed.

S. exigua Performance on Wild-Type and Jasmonate-Deficient Plants. If BTH benefits herbivores through its suppression of the jasmonate pathway, then herbivores should have increased performance on wild-type plants elicited with BTH, but not on jasmonate-deficient plants elicited with BTH. We tested this by examining herbivore performance on the jasmonate-deficient mutant defenseless-1 compared to its wild-type counterpart Castlemart (Howe et al., 1996). This mutant is deficient in its ability to synthesize jasmonic acid. Constitutive PPO activity is not different between the wild-type and jasmonate-deficient plants. PPO activity is induced in wild-type plants when they are damaged by *S. exigua* caterpillars, but not in jasmonate-deficient plants that are damaged by caterpillars (J. S. Thaler and M. Dicke, unpublished data). Wild-type and jasmonate-deficient plants were divided into two groups; one group was elicited with 1.2 BTH on the third leaf, and the other group was treated with the BTH carrier as the control. After three days, the terminal leaflet of the third leaf was excised, placed in a damp Petri dish, and one *S. exigua* neonate was added. This neonate was allowed to develop for three days, after which survivorship was scored and mass measured. This experiment was repeated three times with 12–20 plants per treatment per trial. Survivorship was pooled across trials and analyzed using a G test. Mass was analyzed using a two-way ANOVA for each plant type with BTH treatment and trial as the factors.

RESULTS

BTH Concentration Response. Tomato plants responded to BTH by inducing P4 at concentrations as low as 0.0012 mM, but the effect was 20-fold at 0.6 mM and 40-fold at 1.2 mM (regression: $R^2 = 0.737$, $F_7 = 19.631$, $P = 0.003$; Figure 1). POD was induced by BTH in a concentration-dependent manner ($R^2 = 0.299$, $F_{1,48} = 20.501$, $P < 0.001$; Figure 1). In contrast, the chemicals induced by jasmonate and herbivory did not respond to BTH. PINII (undetectable expression at all levels) and PPO were not induced by BTH at any concentration (PPO: $R^2 = 0.034$, $F_{1,48} = 1.704$, $P = 0.198$; Figure 1). These chemical responses were mirrored by the bioassays. Applications of BTH caused concentration-dependent reductions in *Pst* lesions ($R^2 = 0.107$, $F_{1,35} = 4.215$, $P = 0.048$; Figure 2). There was no effect of BTH application on the performance of *Trichoplusia ni* caterpillars (RGR: $R^2 = 0.012$, $F_{1,43} = 0.511$, $P = 0.479$, ECI: $R^2 = 0.299$, $F_{1,43} = 1.460$, $P = 0.234$; leaf area consumed: $R^2 = 0.020$, $F_{1,43} = 0.689$, $P = 0.352$; Figure 2).

The protein concentration of leaf tissue was reduced by BTH treatments compared to controls in a concentration dependent manner with the plants at the highest concentration of BTH containing 75% the protein of the control plants ($R^2 = 0.194$, $F_{1,46} = 11.105$, $P = 0.002$; Figure 1).

Time Course. P4 mRNA was present at low levels on the day of 1.2 mM BTH application (0.61 counts), at higher levels on the day after (1.21 counts), and at much higher levels on the fourth (48.52 counts), and eighth days (73.22 counts) ($R^2 = 0.953$, $F_{1,2} = 40.334$, $P = 0.024$).

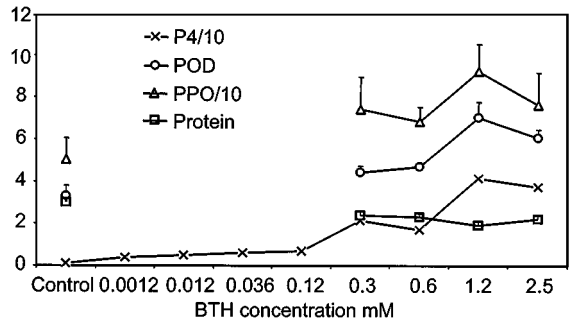

FIG. 1. Effect of different concentrations of BTH (benzothiadiazole) on the activity of chemical constituents of the plant. Relative expression (0-1) of pathogenesis-related protein mRNA expression (P4), peroxidase (POD, ΔOD/g/min), polyphenol oxidase (PPO, ΔOD/g/min), and total protein (mg protein/g tissue). P4 mRNA and POD activity were divided by 10 so they would fit on the same axis.

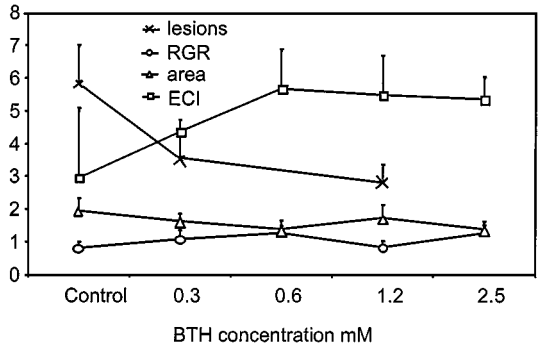

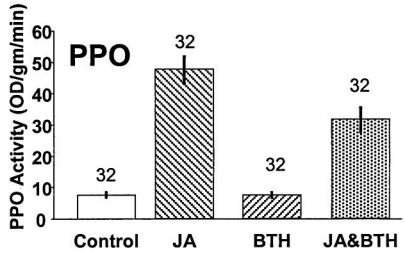

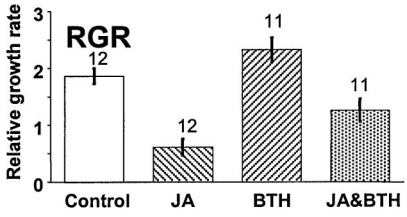

FIG. 2. Effect of different concentrations of BTH (benzothiadiazole) on the performance of the herbivore *Trichoplusia ni* and the pathogen *Pseudomonas syringae* pv. *tomato*. Herbivore performance was measured as relative growth rate (RGR), leaf area consumed (area), and gross growth efficiency (ECI). Performance of the pathogen was measured as the number of lesions formed (lesions). Lesion number was divided by 5 so it would fit on the same axis.

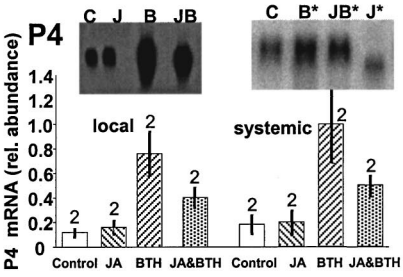
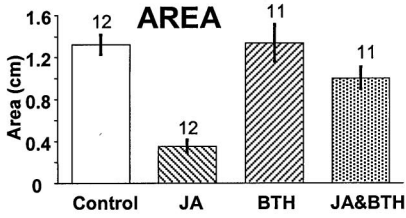


Elicitor Runoff Experiment. Spraying the plants with water at the same time as the JA was sprayed did not alter the effect of JA on PPO activity (mean $\pm$ SE ΔOD/g/min, JA: 17.06 ± 3.80, JA + water: 17.44 ± 5.22; $t = 0.059$, df $= 14$, $P = 0.954$). Spraying the plants with water at the same time as the BTH was sprayed did not change the effect of BTH on P4 mRNA accumulation (mean $\pm$ SE counts: BTH: $185{,}093 \pm 59{,}236$, BTH + water: $128{,}946 \pm 32{,}440$; $t = 0.831$, df $= 4$, $P = 0.453$).



Pathway Interaction Experiments, Biochemical Assays. Attenuation of herbivore responsive proteins in the dual-elicited plants was most consistent when JA and BTH were applied at the same time, regardless of concentration. Application of JA alone increased PPO activity in all experiments (Figures 3–8, Table 1). Application of BTH alone did not affect PPO activity in any of the experiments. The activity of PPO in the dual-elicited plants was reduced when the

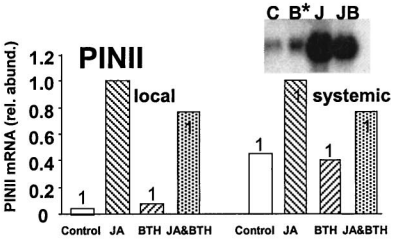


FIG. 3. Chemical and biological measures of resistance for plants in the simultaneous, high-concentration treatment. The four treatments are control plants, plants treated with 1 mM JA, plants treated with 1.2 mM BTH, and plants treated with 1 mM JA and 1.2 mM BTH simultaneously. Chemical measures are polyphenol oxidase (PPO), pathogenesis-related protein 4 (P4), proteinase inhibitor (PINII), peroxidase (POD), and lipoxygenase (LOX). Biological measures are relative growth rate (RGR), leaf area consumed (AREA), and gross growth efficiency (ECI) of the insect *Spodoptera exigua*, and lesion formation (*Pst*) caused by the bacteria *Pseudomonas syringae* pv. *tomato*. Numbers indicate sample size. Inset: representative mRNA blots. *Treatments that are in a different sequence than the labels on the figure axis. Bars indicate mean $\pm$ SE.

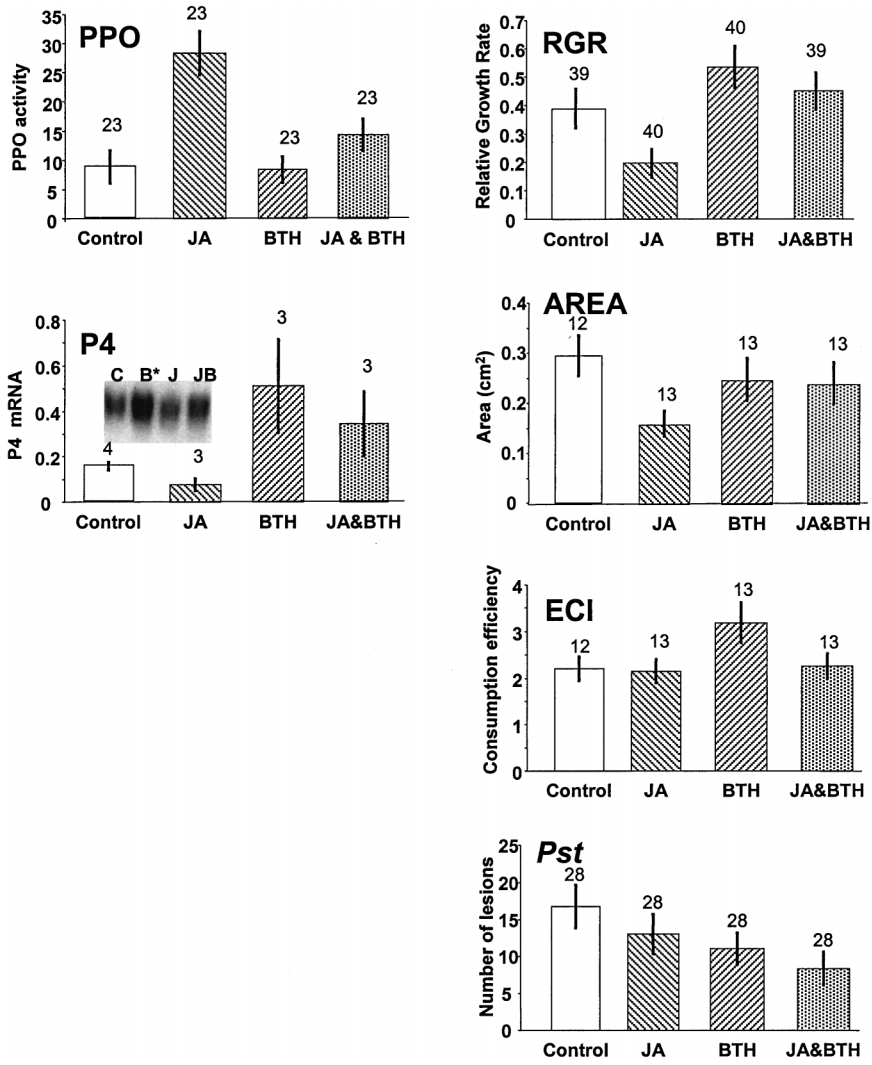

FIG. 4. Chemical and biological measures of resistance for plants in the simultaneous, low-concentration treatment. The four treatments are control plants, plants treated with 0.5 mM JA, plants treated with 0.5 mM BTH, and plants treated with 0.5 mM JA and 0.5 mM BTH simultaneously. Chemical measures are polyphenol oxidase (PPO), and pathogenesis-related protein 4 (P4). Biological measures are relative growth rate (RGR), leaf area consumed (AREA), and gross growth efficiency (ECI) of the insect *Spodoptera exigua*, and lesion formation (*Pst*) caused by the bacteria *Pseudomonas syringae* pv. *tomato*. Numbers indicate sample size. Inset: representative mRNA blot. *Treatments that are in a different sequence than the labels on the figure axis. Bars indicate mean ± SE.

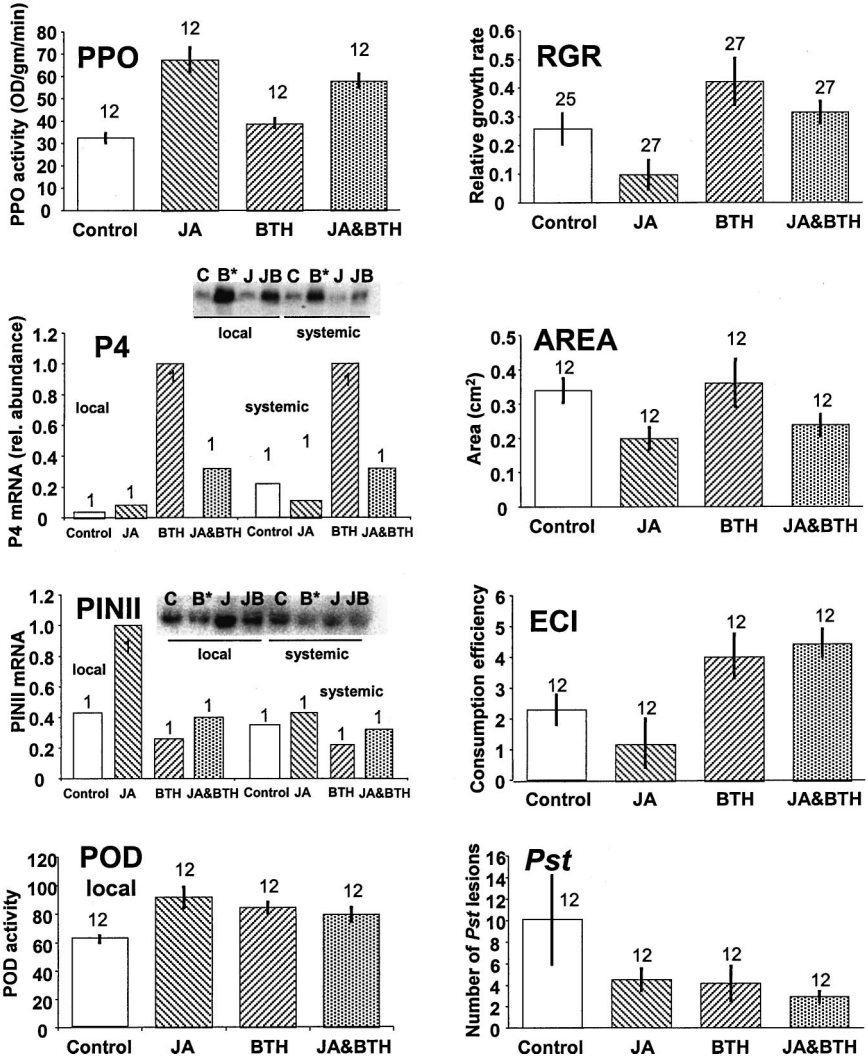

FIG. 5. Chemical and biological measures of resistance for plants in the JA-first, high-concentration treatment. The four treatments are control plants, plants treated with 1 mM JA, plants treated with 1.2 mM BTH, and plants treated with 1 mM JA and then 1.2 mM BTH 2 days later. Chemical measures are polyphenol oxidase (PPO), pathogenesis-related protein 4 (P4), proteinase inhibitor (PINII), and peroxidase (POD). Biological measures are relative growth rate (RGR), leaf area consumed (AREA), and gross growth efficiency (ECI) of the insect *Spodoptera exigua*, and lesion formation (*Pst*) caused by the bacteria *Pseudomonas syringae* pv. *tomato*. Numbers indicate sample size. Inset: representative mRNA blot. *Treatments that are in a different sequence than the labels on the figure axis. Bars indicate mean ± SE.

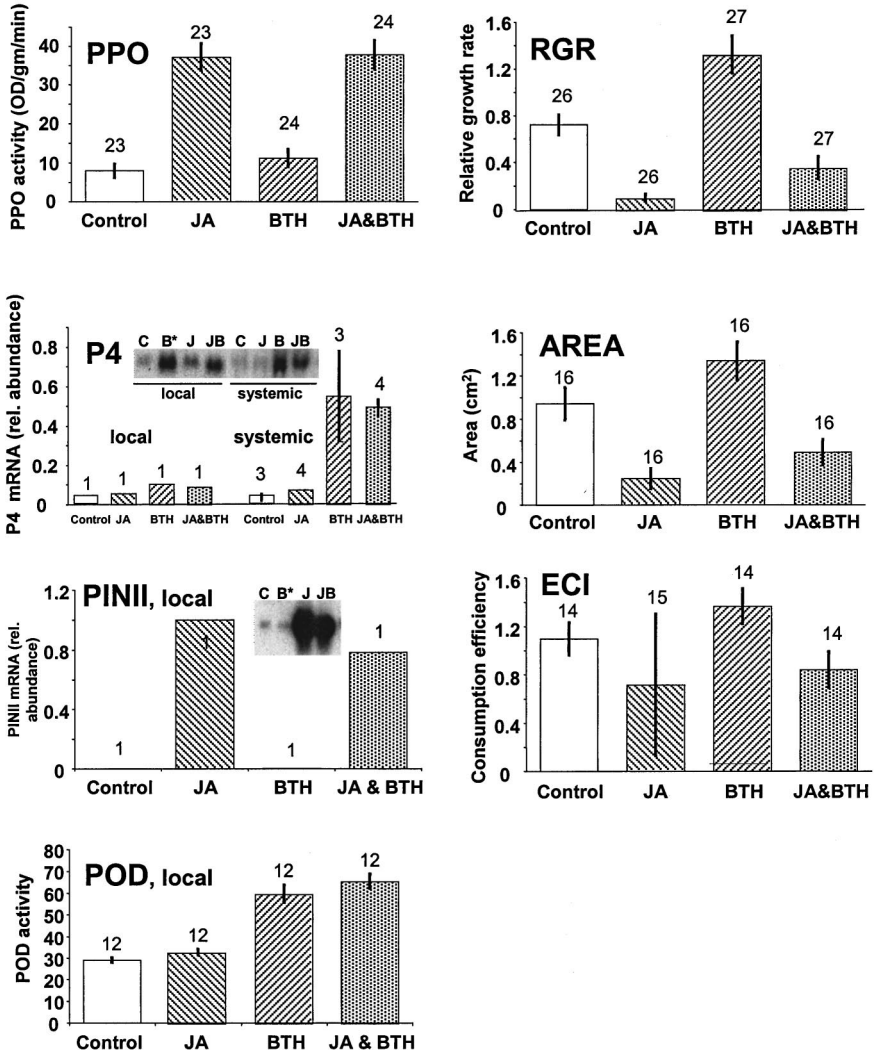

FIG. 6. Chemical and biological measures of resistance for plants in the BTH-first, high-concentration treatment. The four treatments are control plants, plants treated with 1 mM JA, plants treated with 1.2 mM BTH, and plants treated with 1.2 mM BTH and then 1.0 mM JA two days later. Chemical measures are polyphenol oxidase (PPO), pathogenesis-related protein 4 (P4), proteinase inhibitor (PINII), and peroxidase (POD). Biological measures are relative growth rate (RGR), leaf area consumed (AREA), and gross growth efficiency (ECI) of the insect *Spodoptera exigua*, and lesion formation (*Pst*) caused by the bacteria *Pseudomonas syringae* pv *tomato*. Numbers indicate sample size. Inset: representative mRNA blot. *Treatments that are in a different sequence than the labels on the figure axis. Bars indicate mean ± SE.

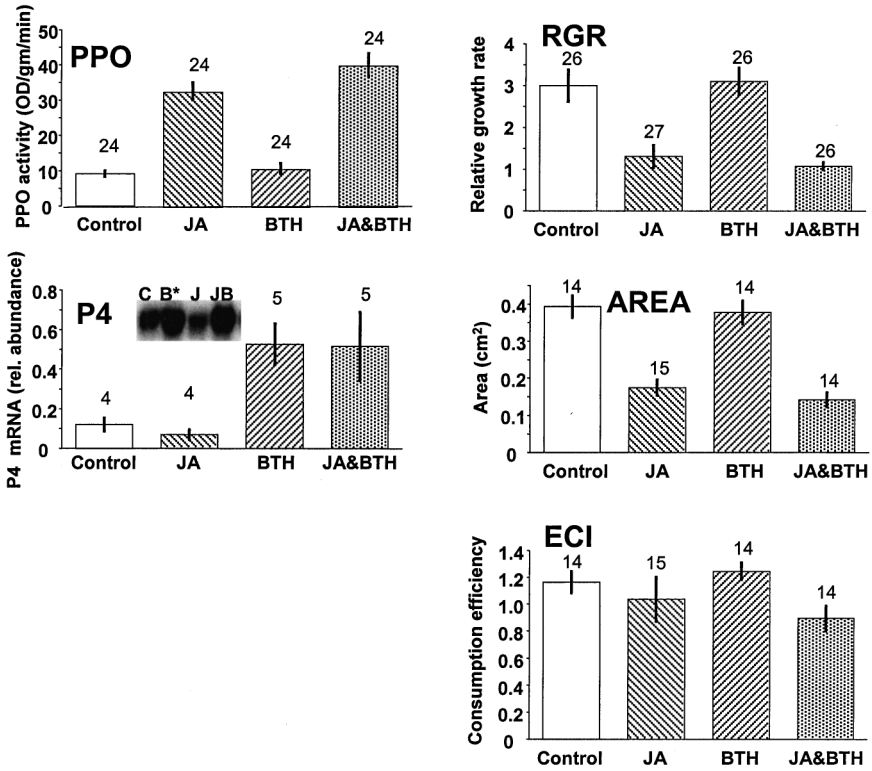

FIG. 7. Chemical and biological measures of resistance for plants in the JA-first, low-concentration treatment. The four treatments are control plants, plants treated with 0.5 mM JA, plants treated with 0.5 mM BTH, and plants treated with 0.5 mM JA and then 0.5 mM BTH 2 days later. Chemical measures are polyphenol oxidase (PPO), and pathogenesis-related protein 4 (P4). Biological measures are relative growth rate (RGR), leaf area consumed (AREA), and gross growth efficiency (ECI) of the insect *Spodoptera exigua*. Numbers indicate sample size. Inset: representative mRNA blot. *Treatments that are in a different sequence than the labels on the figure axis. Bars indicate mean ± SE.

two elicitors were sprayed at the same time compared to plants sprayed with JA alone, at both high and low concentrations (Figures 3 and 4). Activity of PPO was also reduced in the dual-elicited plants when JA was applied first at high concentration (Figure 5), but not when BTH was applied first at the high concentration (Figure 6), or when BTH or JA was applied first at the low concentration (Figures 7 and 8). JA alone increased expression of PINII, and BTH had

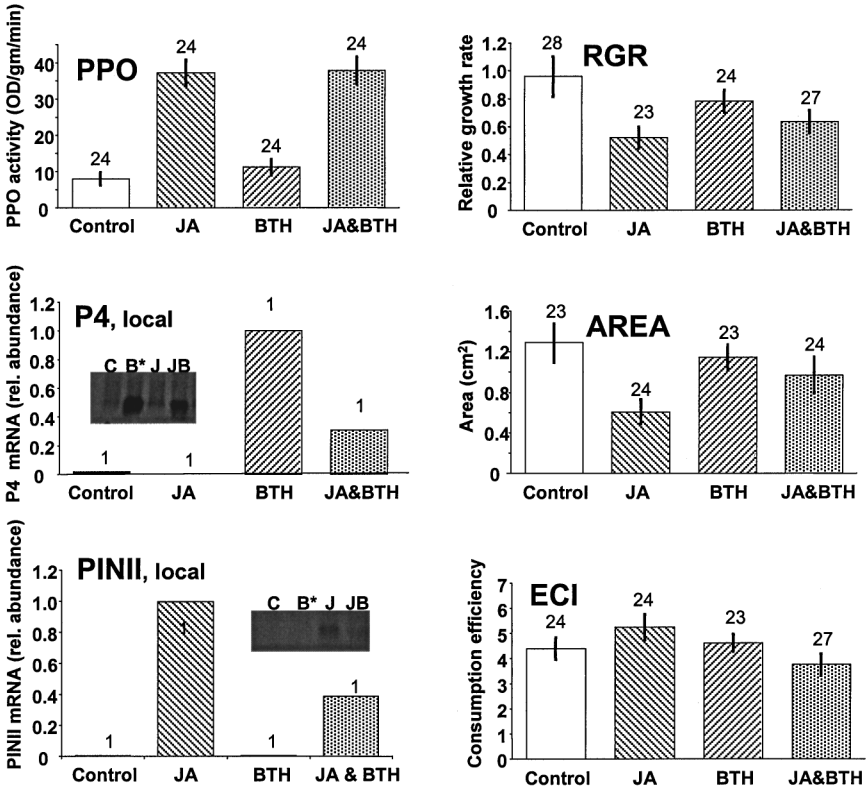

FIG. 8. Chemical and biological measures of resistance for plants in the BTH-first, low-concentration treatment. The four treatments are control plants, plants treated with 0.5 mM JA, plants treated with 0.5 mM BTH, and plants treated with 0.5 mM BTH and then 0.5 mM JA 2 days later. Chemical measures are polyphenol oxidase (PPO), pathogenesis-related protein 4 (P4), and proteinase inhibitor (PINII). no effect; these results were consistent across experimental trials. Expression of PINII was reduced in all dual-elicited plants, regardless of concentration or timing (Figures 3, 5, 6, and 8). JA alone increased LOX activity, and BTH alone had no effect on LOX in the simultaneous high experiment. Activity of LOX was reduced in dual elicited plants (JA: $F_{1,44} = 5.839$, $P = 0.020$; BTH: $F_{1,44} = 2.691$, $P = 0.1084$; JA × BTH: $F_{1,44} = 6.753$, $P = 0.013$).

[a] Trial is included as a factor in the experiments that were conducted more than once. All interactions were included in the model; non-significant interactions are not reported.

Attenuation in expression of BTH-responsive genes was less pronounced than the attenuation of JA-responsive proteins. Across all experiments, BTH alone increased expression of P4 mRNA accumulation, and JA had no effect (Figures 3–8, Table 2). Accumulation of P4 mRNA was not reduced in dual-elicited plants compared to BTH alone, although there was a non statistically significant trend in this direction in most of the experiments. This trend was observed in the simultaneous elicitation at both high and low concentration experiments: the high concentration

TABLE 2. ANOVA ON PATHOGENESIS-RELATED PROTEIN 4 mRNA EXPRESSION OF PLANTS IN CONTROL, JA, BTH, AND JA AND BTH GROUPS IN FOUR OF SIX CONCENTRATION (LOW = 0.5 mM JA, 0.3 mM BTH AND HIGH = 1.5 mM JA AND 1.2 mM BTH) AND TIMING (SIMULTANEOUS AND 2-DAY DELAYED ELICITATION) COMBINATIONS[a]

[a] Local and systemic samples were grouped for statistics. The two combinations not reported below were not statistically analyzed because only one replicate of each treatment was obtained.

of JA applied first, and experiments with the low concentration of BTH applied first. The P4 activity between the BTH alone and the BTH and JA treated plants was nearly identical in the high concentration BTH first and the low concentration JA first experiments. Activity of POD increased in local leaves sprayed with JA and BTH singly and these effects were not altered by dual spray at high concentration regardless of timing (Figures 3–5, Table 3); POD was not examined at low-concentration sprays.

Pathway Interaction Experiments: Bioassays. Like the chemical measures of resistance, attenuation of plant resistance to herbivores was consistently seen when JA and BTH were applied at the same time, regardless of concentration. Attenuation of resistance to herbivores was also seen in the high-concentration delayed-spray treatments, but not in the low-concentration delayed-spray treatments. Relative growth rate (RGR) and amount of foliage consumed (AREA) were influenced by elicitor treatment, whereas gross growth efficiency (ECI) was not. Applications of JA by itself reduced the RGR of *S. exigua* in all experiments (Figures 3–8, Table 4). BTH by itself increased the RGR of *S. exigua* consistently in high-concentration experiments, but only in the simultaneous elicitation low-concentration experiment. At the high concentrations of JA and BTH, RGR of *S. exigua* increased on dual-sprayed plants compared to plants sprayed with JA alone. At the low

[a] All interactions were included in the model; non-significant interactions are not reported.

concentration, the increase in RGR in the dual-sprayed plants was only seen when the elicitors were sprayed simultaneously.

JA alone reduced AREA in all experiments (Figures 3–8, Table 5). BTH alone increased AREA in the BTH-first, high-concentration experiment, but in the other experiments had no effect when applied singly. Dual-elicitation increased the amount of foliage consumed compared to the JA-treated plants in the simultaneous-elicitation experiments at both concentrations and when BTH was sprayed before JA at both concentrations. For dual elicitation to affect AREA, either a high concentration of BTH must be applied or BTH must be applied before the JA. JA tended to decrease ECI and BTH tended to increase ECI, but these patterns were only significant in a few cases (Figures 3–8, Table 6). JA and BTH did not interact in their effects on ECI. Effects on RGR and AREA but not ECI indicate that herbivore rate of consumption (and thus growth) were affected by JA, but the ability of the herbivore to convert food into herbivore biomass was not affected.

Pathway Interaction Experiments: Disease Assay. BTH consistently reduced the number of *Pst* lesions while JA was inconsistent in this effect (Figures 3–5, Table 7). Elicitation by JA alone reduced the number of lesions in the simultaneous high-concentration experiments, but not in the simultaneous low- or JA-first high-concentration experiment. When both elicitors were applied in the simultaneous high- and simultaneous low-concentration experiments, the fewest lesions were

the jasmonate-deficient plants treated with BTH (wild-type: BTH $F_{1,57} = 10.53$, $P = 0.002$, trial $F_{2,57} = 29.22$, $P < 0.001$; jasmonate-deficient: BTH $F_{1,58} = 0.028$, $P = 0.86$, trial $F_{2,59} = 72.19$, $P < 0.001$; Figure 9). More caterpillars died on the wild-type plants compared to the wild-type + BTH-treated plants (8/33 wild type, 2/35 wild type + BTH; $G = 3.7$, $P = 0.054$). There was no detectable difference in caterpillar mortality on the jasmonate-deficient plants (1/32 def-1, 4/33 def-1 + BTH; $G = 1.71$, $P = 0.19$). A functional jasmonate pathway is required for the positive effect of BTH on caterpillar performance, indicating that the mechanism of BTH action is through interference with the jasmonate pathway.

DISCUSSION

Our study has five key findings: (1) antagonism between the JA and SA pathways is observed in the both chemical and biological assays, although this was asymmetric, with the effects of BTH on the jasmonate pathway being more frequent than the effects of JA on the salicylate pathway. (2) Timing of elicitation influenced chemical responses and biological resistance, with simultaneous elicitation consistently showing a negative signal interaction. (3) Concentration of elicitation was most important in determining the chemical attenuation, with high concentration of elicitors consistently resulting in a negative interaction. (4) Temporal separation and/or low concentration of elicitors may reduce the negative signal

[a] ANOVA on the number of lesions formed by *Pseudomonas syringae* pv. *tomato* growing on plants in the Control, JA, BTH and JA BTH and groups in the high and low simultaneous elicitation experiments (low = 0.5 mM JA, 0.3 mM BTH and high = 1.5 mM JA and 1.2 mM BTH) and in the experiment where high concentration JA was applied 2 days before high concentration BTH. Trial is included as a factor in the experiments that were conducted more than once. All interactions were included in the model; non-significant interactions are not reported.

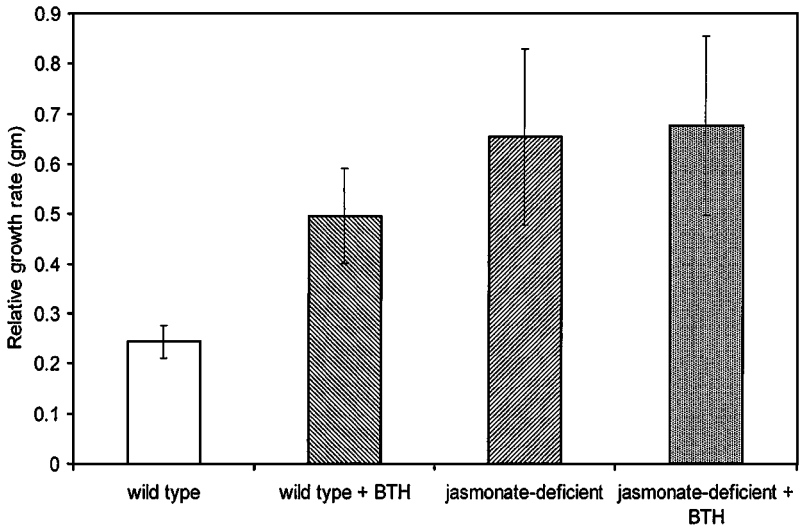

FIG. 9. Relative growth rate of *Spodoptera exigua* caterpillars [(final weight − initial weight)/(initial weight)] feeding on plants in four treatments: wild-type, wild-type treated with 1.2 mM benzothiodiazole (BTH), jasmonate-deficient, and jasmonate-deficient treated with 1.2 mM BTH. Bars indicate mean ± SE.

TABLE 8. SUMMARY OF ATTENUATION OF CHEMICAL EXPRESSION OF JASMONIC ACID AND SALICYLIC ACID PATHWAYS IN DUAL-ELICITED PLANTS[a]

	Simultaneous					JA first				BTH first			
	PPO	PINII	LOX	P4	POD	PPO	PINII	P4	POD	PPO	PINII	P4	POD
Low	Y	NT	Y	Y	NT	N	NT	N	NT	N	Y	Y	NT
High	Y	Y	Y	Y	N	Y	Y	Y	N	N	Y	N	N

[a] Markers of the jasmonate pathway are polyphenol oxidase (PPO), proteinase inhibitors (PINII), and lipoxygenase (LOX). Markers of the salicylate pathway are pathogenesis-related protein 4 (P4), and peroxidase (POD). Y = significant attenuation in the dual elicited plants compared to the singly elicited plants, N = no attenuation, NT = not tested.

interaction. (5) The negative signal interaction was observed more consistently in biological assays than in chemical assays, underscoring the importance of linking the chemistry of the putative plant defense with their apparent targets.

Effects of BTH on Plant Responses and Herbivore Performance. Elicitation of tomato plants by BTH affected production of primary and secondary plant metabolites. BTH induced the pathogenesis-related protein, P4, in a concentration-dependent manner starting two days after application and lasting for at least eight days. BTH treatment at the highest concentration reduced total protein concentration approximately 20% compared to the control. This is in contrast to the results of Inbar et al. (1998), who found no effect of BTH application on foliar protein in tomato. Thus, we found no support for the hypothesis that BTH elicitation benefits herbivores by increasing plant protein.

Effects of Concentration and Timing of Elicitors on Antagonistic Interactions Between Plant Defense Pathways. Concentration and timing of elicitation affected JA-mediated chemical responses and biological resistance in overlapping but not identical ways (Tables 8 and 9). The negative signaling interaction between the jasmonate and salicylate responses was seen in PPO and PINII, hallmark responses

TABLE 9. SUMMARY OF ATTENUATION OF BIOLOGICAL RESISTANCE TO HERBIVORES AND PATHOGENS IN DUAL-ELICITED PLANTS[a]

	Simultaneous				JA first				BTH first			
	RGR	AREA	ECI	Lesions	RGR	AREA	ECI	Lesions	RGR	AREA	ECI	Lesions
Low	Y	Y	N	N	N	N	N	NT	N	Y	N	NT
High	Y	Y	N	N	Y	N	Y	N	Y	Y	N	NT

[a] The measures of performance of the herbivore, *Spodoptera exigua*, were relative growth rate [RGR, (final weight - initial weight)/(initial weight)], leaf area eaten (AREA, mm^2 of foliage consumed), gross growth efficiency [ECI, (final weight - initial weight)/(area consumed)]. Y = significant attenuation in the dual elicited plants compared to the singly elicited plants, N = no attenuation, NT = not tested.

of the jasmonate pathway in tomato as well as herbivore performance. For PPO, the timing of the elicitors was important; the attenuation of induction was most consistently seen when the compounds were applied at the same time, irrespective of concentration. The attenuation in PINII expression was consistent, regardless of concentration–timing combination. Concentration of elicitors was only important for relative growth rate of *S. exigua* when the elicitor applications were separated in time. At high concentration, there was always attenuation, regardless of timing. At low concentration elicitation, there was only attenuation when the plants were elicited simultaneously, not when the applications were separated in time.

Pst was negatively affected by both JA and BTH, with no attenuation of resistance in the dual-elicited treatments. *Pst* is a complicated pathogen because it triggers SAR and jasmonate defenses through its release of coronatine into the leaf. Given that the JA and SA pathways interact with each other, even prior to exogenous induction, it is difficult to estimate the relative roles of the pathways on *Pst* performance.

Does Temporally Separating Elicitation of Pathways or Decreasing Concentration of Elicitor Reduce Negative Signal Interaction? In the broad sense, yes, the antagonism was less predictable in the experiments where the elicitors were used at low concentration and/or were separated in time. However, the predictions do not hold for each particular concentration and timing combination, and chemical attenuation does not always match the biological attenuation of resistance to herbivores. Our original hypotheses were based on the inhibition between the two pathways due to the action of JA and SA molecules per se. A complete understanding of how these interact awaits further discoveries of the components in each signaling pathway (Felton and Korth, 2000; McDowell and Dangl, 2000). Other plant hormones, such as ethylene, could also influence the interaction between the jasmonate and salicylate pathways (O'Donnell et al., 1996; Zhu-Salzman et al., 1998).

There was a greater effect of BTH on jasmonate-mediated responses than of JA on BTH-mediated responses. However, the trends for attenuation of P4 expression were similar to the trends for PPO activity. During simultaneous elicitation, attenuation is obtained regardless of elicitor concentration, but during temporally separated elicitation, elicitor concentration does influence whether P4 expression is attenuated in the dual-elicited plants. In contrast to these non statistically significant effects, Thaler et al. (1999) found attenuation of BTH-induced P4 by jasmonate spray. The Thaler et al. (1999) study differed from this work in several ways: the experiments were conducted in field-grown plants, entire plants were treated with both elicitors, and larger sample sizes were employed, allowing detection of smaller effects. The data presented here suggest that JA attenuates BTH action. However, this could also be partially explained by elicitor runoff. While the reduction in P4 expression in the BTH + water compared to the BTH-alone treatment was not significant, the reduction was of the same magnitude as when P4 expression in the BTH + JA and BTH-alone treatments are compared.

Paths of Signal Interaction. The signal interaction between the JA and SA pathways was detected acting through two distinct paths. In the first path (nonadditive) of antagonism between the JA and SA pathway, there was a statistically significant interaction between the effects of JA and BTH. For example, JA singly induced PPO, BTH singly had no effect on PPO, and there was reduced PPO activity in dual-elicited plants compared to plants elicited with JA alone (e.g., Figure 5, PPO; Table 1). In this case, BTH had no effect on constitutive PPO activity by itself, but interfered with the induction of the jasmonate pathway when JA was applied to the plant. These are nonadditive effects and reflect the more straightforward signal interactions reported in the literature where SAR activation reduces the expression of JA-mediated responses (indicated by PPO activity). Our elicitor runoff experiments suggest that this is an in vivo interaction and not an effect of the elicitors at the plant surface.

The second path (additive) occurred when the main effects of JA and BTH were both significant, with the means in opposite directions, and the interaction term was not significant. For example, JA singly decreased RGR, BTH singly increased RGR, and the RGR of herbivores on dual-elicited plants was intermediate (e.g., Figure 3, RGR; Table 4). In this case, PPO activity was not reduced in the BTH single elicitor treatment, but elicitation by BTH still had a positive effect on RGR. The effects of JA and BTH on RGR were additive but appeared independent of the PPO correlated suite of responses in tomato plants. In all of the timing–concentration scenarios where attenuation was seen in the dual-elicited plants, PPO activity was influenced via pathway 1 (nonadditively) and caterpillar RGR via pathway 2 (additively).

What Aspect of SAR Results in Attenuation of Caterpillar RGR? Previous work has established PPO activity in tomato plants as a good predictor of caterpillar performance (Broadway et al., 1986; Felton et al., 1989; Duffey and Felton, 1991; Stout et al., 1998). In this study, PPO activity is negatively correlated with herbivore performance with some exceptions. When we take the entire data set from this study and examine the relationship between PPO activity and RGR (the mean PPO and RGR from each treatment group in each experiment is the unit of replication), we find that PPO and RGR are inversely correlated ($F_{1,30} = 4.45$, $P = 0.041$, $R^2 = 0.13$). This indicates that increased PPO activity is correlated with reduced the performance of herbivores but that other jasmonate-related compounds not correlated with PPO activity are also important.

Many studies have found that SAR activation increases the performance of herbivores. In this study, we generally find that SAR activation increases the RGR of *S. exigua* caterpillars both when SAR is induced singly and when SAR and JA responses are induced in combination. Elicitation of SAR itself never reduced constitutive PPO activity, while it did increase the RGR of *S. exigua*. In dual SAR/JA-elicited plants in many experiments, SAR elicitation decreased PPO activity but it only increased RGR in the experiments where SAR elicitation alone

increased RGR. This suggests that SAR elicitation increases caterpillar performance independent of PPO correlated jasmonate responses. However, SAR elicitation increased caterpillar growth rate on the wild-type plants, but not on the jasmonate-deficient plants. This indicates that SAR elicitation does increase caterpillar growth through a jasmonate-dependent mechanism, possibly by preventing induction of the jasmonate pathway by the caterpillar during the three-day assay. At this stage we cannot distinguish between PPO simply being a variable correlate of JA-mediated responses and BTH preventing induction of PPO correlated responses that are induced when the bioassay organism is feeding on the plant.

(Received August 15, 2001; accepted February 7, 2002)

Abstract—The major fruit fly attractant component in the floral fragrance of *Bulbophyllum cheiri* (fruit fly orchid) is methyl eugenol (ME). In the lowland rain forest of Malaysia, the solitary and nonresupinate flowers of the fruit fly orchid attract only males of the ME-sensitive fruit fly species (*Bactrocera carambolae*, *B. papayae*, and *B. umbrosa*. During the morning, the fruit fly orchid flower is visited by many fruit flies, which can sometimes cover the whole flower. The number of visitors dwindles in the afternoon. Headspace analysis of the flower shows a high ME peak in the morning, a small one between 12:00 and 14:00 hr, and no detectable ME peak after 14:00 hr. The process of pollination in the wild is initiated by attraction of fruit flies to floral ME. The flower, with the aid of its specialized hinged see-saw lip (labellum), temporarily traps (<1 min) a fruit fly pollinator between its lip and column. Just prior to this, the fly is rewarded by the opportunity to feed on the floral attractant found on surfaces of petals, sepals, and lip. The pollinaria borne by two wild *B. papayae* males (caught on and near the fruit fly orchid flower) are identical in morphology and structure with those obtained from the flower. Many of the *B. papayae* males (17 of 22 analyzed) attracted to the fruit fly orchid already possessed both ME metabolites, *trans*-coniferyl alcohol and 2-allyl-4,5-dimethoxyphenol, in their rectal glands, indicating that they had previously consumed ME. In this orchid–fruit fly association, both organisms gain direct reproductive benefits: the orchid flower gets pollinated without having to offer nectar, while the fruit fly boosts its pheromone and defense system, as well as its sexual competitiveness by feeding on the ME produced by the flower.

Key Words—*Bulbophyllum cheiri*, fruit fly orchid, Orchidaceae, fruit flies, Tephritidae *Bactrocera* spp., methyl eugenol, floral scent, pheromone, synomone, pollination, coevolution.

INTRODUCTION

Many species of wild orchids have myophilous (fly pollinated) flowers. The genus *Bulbophyllum* (Orchidaceae) is characterized by its well-balanced see-saw lip (labellum), which is attached to the base of the floral column by a small springy hinge. The flowers produce foul-smelling scent to attract flies (Van der Pijl and Dodson, 1969). Of the many myophilous orchids, however, the involvement of tephritid fruit flies in pollination has not been mentioned (Kevan and Baker, 1983; Metcalf and Metcalf, 1992). Several species of *Bulbophyllum* are pollinated by flies (Christensen, 1994). In Brazil, milichiid female flies (*Pholeomyia* spp., Diptera: Milichiidae) pollinate three species—*Bu. involutum* Borba, Semir and F. Barros, *Bu. ipanemense* Hoehne, and *Bu. weddellii* (Lindl.) Rchb. f. (Borba and Semir, 1998b). In Queensland, *Bu. baileyi* F. Müell. flowers have a fruity odor (chemical identity unknown) and are reportedly visited by fruit flies—*Strumeta* (currently under *Bactrocera*) species (Symthe, 1969). More recently, it was shown that males of many fruit fly species [*Bactrocera* (formerly *Dacus*) spp., Diptera: Tephritidae] are attracted to flowers of the ginger orchid (*Bulbophyllum patens* King), particularly to the ginger essence of the floral scent zingerone, where they perform pollination. Zingerone attracts both the methyl eugenol (ME) attracted and the raspberry ketone (RK) attracted fruit fly species (Tan and Nishida, 2000). In order to better understand the coevolution between *Bulbophyllum* and fruit flies, it is necessary to search systematically for, and investigate, orchid flowers that release either ME or RK specifically to attract the male *Bactrocera* flies sensitive to these floral scent components.

One orchid species that has yet to be studied is *Bulbophyllum cheiri* Lindley (henceforth referred to as fruit fly orchid) that is found primarily in lowland rain forest of Malaysia. It belongs to the genus *Bulbophyllum* sect. Sestochilus (Breda) Benth. & Hook. f., and comprises 60–70 species worldwide. *Bu. cheiri* bears solitary flowers that resemble a closed hand with fingers almost meeting at the tips (Figure 1A) (Vermeulen, 1991). It possesses a slender lip that has a broad base, which is hinged to the column. In the wild, the flower is postured in order to position the movable see-saw lip in a higher plane than the column—a characteristic of a nonresupinate (not upside down) orchid flower. The flower is visited by fruit flies as soon as it blooms (Figure 1A) and occassionally has been observed to be completely covered with fruit flies. However, it never attracts other insects.

Males of *Bactrocera dorsalis* Hendel, *B. carambolae* Drew & Hancock, *B. papayae* Drew & Hancock, and *B. umbrosa* Fabricius are all attracted to ME and are known to be serious pests to many fruit species in tropical and subtropical

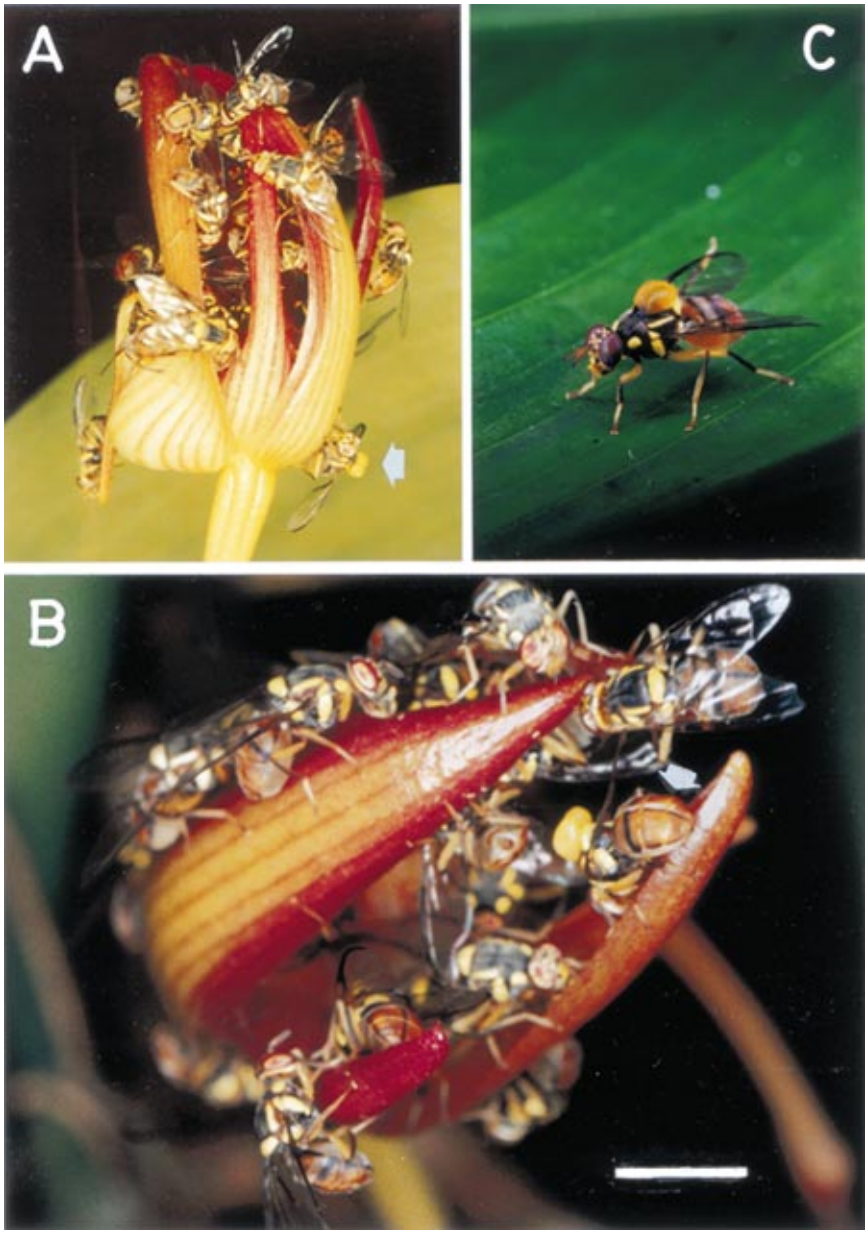

FIG. 1. (A) Male fruit flies of *Bactrocera papayae* lapping on synomone containing methyl eugenol of a fully blossomed flower of the fruit fly orchid (*Bulbophyllum cheiri*). Note: a fruit fly bearing a pollinarium at the base of the medial sepal (white arrow); and a fruit fly facing downwards on the slender tip of the movable see-saw lip (left bottom). (B) A close-up view of fruit flies lapping on the surface of *Bulbophyllum cheiri* flower. Note: posterior view of a male of *Bactrocera papayae* bearing a pollinarium on a lateral sepal (white arrow). Bar = 5.0 mm. (C) A frontal view of a male *Bactrocera papayae* bearing a pollinarium of *Bulbophyllum cheiri* consisting of two pairs of pollinia of approximately equal length, on its thoracic dorsum (The pollinarium remained stuck to the fly for over one month until death in captivity).

regions. When males are fed ME from either natural or synthetic sources, they convert it into its analog(s), which are used to boost their sex pheromone system (Tan and Nishida, 1996). Over 200 species from as many as 32 plant families have been reported to contain ME in shoots, blossoms and/or leaves (Tan and Toong, unpublished data).

Unlike many other orchids, the flower of the fruit fly orchid does not produce nectar to attract bees, wasps, or butterflies, but instead attracts only certain species of *Bactrocera* fruit flies through a mildly scented fragrance resembling that of ME. This paper reports the results of a study on *Bu. cheiri* and its association with fruit flies. The research had three goals: (a) chemical analysis of the attractant in the flower that lures fruit flies, (b) behavioral observations of fruit flies on the orchid flowers, and (c) qualitative analysis of rectal glands from male fruit flies attracted to the fruit fly orchid.

METHODS AND MATERIALS

Plants and Flowers. Orchid plants were originally collected from the Tenom Orchid Center, Tenom, Sabah, and from Pulau Kapas, W. Malaysia. Plants were grown in two localities in Penang—Tanjung Bungah and USM Campus. Flowers used for chemical analyses were covered with a clear plastic bag one day before blooming.

Collection of Fruit Flies. Fruit flies visiting the orchid flower were collected in a clear plastic bag, transferred into vials, and identified to their respective species. For rectal gland extraction, male flies were collected as they landed on a nylon stocking covering a mini wire cage over a fruit fly orchid flower. The rectal gland was removed under a dissecting microscope after cold immobilization. Each gland was homogenized in 20 μl of redistilled ethanol in a small V tube by using a fine glass rod. After centrifugation, a 1-μl aliquot was subjected to gas–liquid chromatographic and GC-MS analyses to qualitatively determine and confirm the presence of ME analogs in comparison with authentic compounds.

Pollinarium Removal by Fruit Fly. The process of pollinarium removal by a male *B. papayae* was observed in a large field cage ($2.1 \times 2.1 \times 2.1$ m^3). A plant bearing a bud was placed into the cage. On the day when the flower bloomed, a sexually mature male fruit fly was released into the cage for observation. The observation was repeated with another flower.

Identification of Pollinarium. Whenever possible, a fly bearing a pollinarium when found on or near an orchid flower was collected. The morphology and size of pollinarium on two flies were checked against those picked from *Bu. cheiri* and *Bu. patens* flowers, both under a dissecting microscope and scanning electron microscope (SEM). The dimensions of a single pollinarium stuck to the dorsum of a fly were measured from the SEM micrographs. To determine how long the

pollinia remained on the flies, two of the four wild flies caught bearing pollinaria were isolated and kept in a cage containing water and fly food sources, which were changed regularly, for observation.

Instruments. The volatile components were analyzed by GC-MS by using a HP 5989B mass spectrometer coupled with a HP 5890 series II plus gas chromatograph equipped with a HP-5 capillary column (30 m $\times$ 0.32 mm, 0.33-μm film thickness) programmed from 60° (2 min holding) to 240°C at a rate of 10°C/min, total ion monitor. Quantification of volatile chemicals was done on a HP 5790A gas chromatograph with the same program conditions as above by comparing the FID intensities with those of the standard sample of known concentrations using a HP 3396 integrator.

Extraction of Floral Fragrance. Flowers of *Bu. cheiri* were initially collected from Tenom, Sabah. Five flowers of *Bu. cheiri* were extracted with ethanol (ca. 10 ml/flower $\times$ 2). The combined ethanolic solution was filtered (Advantec filter paper No. 2), concentrated under reduced pressure ($\sim$20 mm Hg, below 30°C), and partitioned between an 8:1:1 mixture of hexane, benzene, and ethyl acetate (10 ml $\times$ 2) and water (5 ml). The organic layer was dried over anhydrous sodium sulfate and evaporated under partial vacuum to yield an oily material (26 mg), a portion of which was analyzed by GC-MS.

Headspace Analysis of Floral Fragrance. A flower of *Bu. cheiri* was wrapped with a small plastic bag with an air inlet and a small Porapak Q column outlet. A small stream of air was passed through the bag continuously for several hours. The column was changed every 2 hr and washed with dichloromethane (5 ml). The extract from each 2-hr period was concentrated and analyzed by GC.

Quantification of Fruit Fly Attractants. Quantification was performed for two separate flowers (sample 1: collected on August 28, 1996, one day after blooming without exposure to flies; and sample 2: collected on April 15, 1988, within 2 hr of blooming). Floral lip, column, petals, and medial and lateral sepals were separated from each *Bu. cheiri* flower. They were individually weighed, soaked in ethanol, and subjected to GC quantification.

Authentic Samples. Methyl eugenol (ME, 3,4-dimethoxyallylbenzene) was purchased from Tokyo Chemical Industries Co. Ltd. Pure (>96%) chemicals synthesized and used for comparison were 2-allyl-4,5-dimethoxyphenol, *trans*-coniferyl alcohol, and *Z*-3,4-dimethoxycinnamyl alcohol (Tan and Nishida, 1998).

RESULTS

Fruit Fly Species. When the flower first bloomed in the morning, many fruit flies were attracted to it (Figure 1A). At certain times in the morning, the flower was literally covered with fruit flies. They were generally seen lapping on the petals and sepals. The process of pollinarium removal and pollination was difficult to observe due to the arrangement of petals and sepals, which completely cover the column

cavity. A few flies were generally observed to visit and lap on the flower in late afternoon and evening; and all would leave just before sunset at ca. 19:30 hr. One of the flies attracted early in the morning was seen to be carrying the pollinarium (pollinium and viscidium) of the flower (Figure 1B). In captivity, the pollinarium remained stuck to the fruit fly (Figure 1C) for over a month until the fly died.

All visitors to the fruit fly orchid flower were male *Bactrocera* fruit flies. When the flower was covered with a screen, flies would land on the latter. The majority of the 276 flies collected belonged to *B. papayae*; while 1 *B. carambolae*, 17 *B. umbrosa*, and 2 individuals with intermediate characteristics between *B. carambolae* and *B. papayae* were identified. All species belonged to the ME-sensitive group of *Bactrocera* fruit flies.

Pollinarium Removal. Normally, a fly visiting a flower first lands on one of the lateral sepals, extends its proboscis, and begins lapping the surface. It eventually ends up on the lip. When it moves onto the see-saw lip, which is on a higher plane than the floral column, it laps and continues moving slowly along the lip. As the fly moves towards the column and nears the hinge, the lip suddenly tilts towards the column and, simultaneously, topples the fly head first into the column cavity. Presumably, the shallow groove and the basal flank of the lip ensure that the fly does not fall on its side. In the small enclosed space, the fly struggles to free and upright itself by moving backwards because it is squeezed between the closed lip and the floral column. As it retreats, it pushes the lip away from the column and at the same moment the thoracic dorsum touches the visidium and removes the pollinarium, which adheres dorsally to the fly's thorax (Figure 1C). The pollinia borne by wild *B. papayae* males showed identical characteristics to those removed from the fruit fly orchid. In captivity, two wild *B. papayae* males, bearing a pollinarium each, showed normal feeding and grooming activities in a cage. The pollinarium was not observed to fall from the flies.

Rectal Gland Components. Many of the male *B. papayae* flies attracted to the fruit fly orchid flower that was enclosed within a mini cage already possessed ME analogs. Chemical analysis of the rectal glands showed that 17 of the 22 flies had varying quantities of *trans*-coniferyl alcohol and 2-allyl-4,5-dimethoxyphenol. The identities of both compounds were confirmed through GC-MS analysis and comparison with authentic samples. These chemicals were not detected in the remaining five individuals ($<25\%$).

Comparison of Pollinarium. Each pollinarium has four pollinia—a larger outer pair that enclose a smaller inner pair of almost equal lengths. They differ in size and morphology from those removed from flowers of *Bu. patens*, in which each pollinarium had only one pair of pollinia. Figure 2 shows the SEM micrograph of pollinia of *Bu. cheiri* on the thoracic dorsum of a male *B. papayae.* The average dimensions (width $\times$ length $\times$ height) of pollinaria borne on native flies (two each) for *Bu. cheiri* and *Bu. patens* were $1.22 \times 1.27 \times 0.72$ mm and $0.92 \times 0.90 \times 1.52$ mm, respectively.

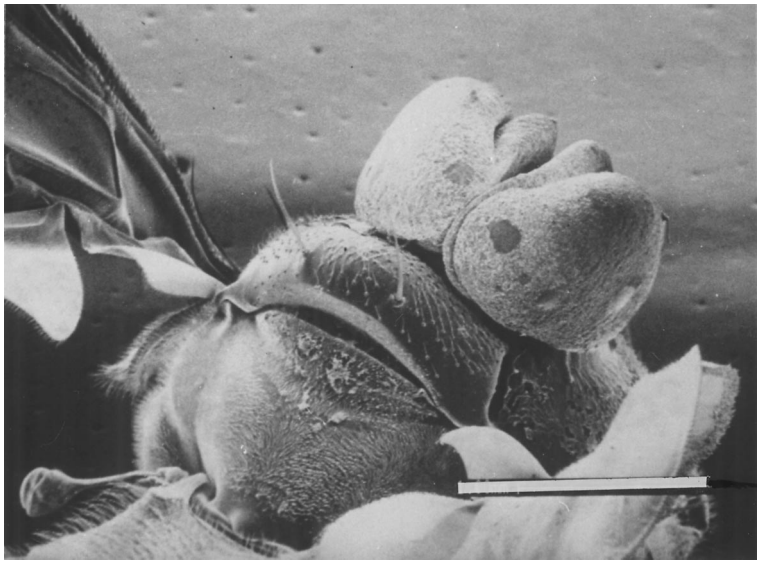

FIG. 2. Scanning electron micrograph of *Bulbophyllum cheiri* pollinarium on the thoracic dorsum of a fruit fly. Note: the four pollinia—two outer and larger pollinia enclosing a pair of smaller pollinia. Bar = 1.00 mm.

Chemical Analyses of Bu. cheiri Floral Scent. The major peak in the gas chromatogram of a *Bu. cheiri* floral extract had a retention time of 11.7 min and was identified as methyl eugenol (ME) (Figure 3) [MS: m/z(%) 178(100), 163(33), 151(9), 147(33), 107(22), 105(19), 103(19), 77(9)]. Also detected in individual

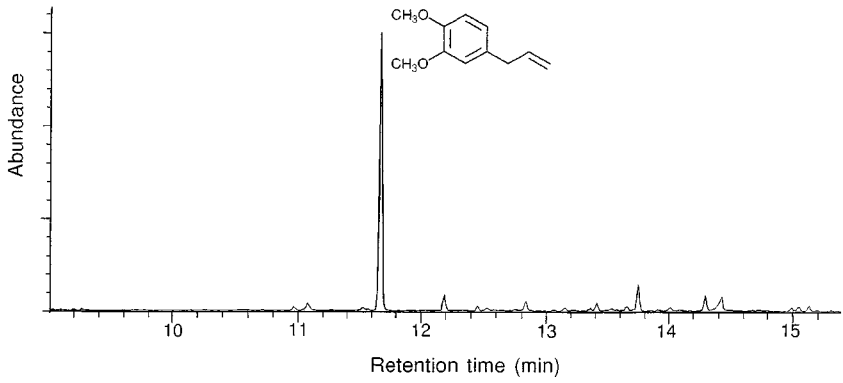

FIG. 3. Gas chromatogram of floral extract of a *Bulbophyllum cheiri* flower. The major peak is methyl eugenol.

TABLE 1. METHYL EUGENOL CONTENT IN INDIVIDUAL FLORAL PARTS OF TWO *Bulbophyllum cheiri* FLOWERS[a]

	Content (μg)		Fresh weight (mg)		Concentration (ppm)	
Floral part	A	B	A	B	A	B
Lateral sepals	310	35	413	321	750	107
Medial sepal	104	7	189	151	550	44
Petals	96	11	143	125	669	91
Lip	35	6	66	59	526	95
Column	40	6	174	139	230	41
Total	585	65	985	795	average 594	82

[a] Flower A was collected on April 15, 1998, within 2 hr after blooming; and flower B was collected on August 28, 1996, one day after blooming and not exposed to flies.

flowers were much smaller quantities of related phenylpropanoids such as eugenol (in one of the flowers), 1,2-dimethoxy-4-(1-propenyl)-benzene (retention time 12.8 min), a trimethoxypropenylbenzene (13.7 min), and a dimethoxypropenylphenol (14.3 min). The structure of the trimethoxypropenylbenzene could not be determined due to the small quantities available for further chemical analyses. The latter compound gave the same retention time and MS fragmentation pattern as 2-allyl-4,5-dimethoxyphenol, but its identity from other possible positional isomers has not been established due to the small amount of sample available.

The contents of ME in each floral part, given in Table 1, show that the lateral sepals contained the highest quantities. In the headspace analysis, ME was the major component in the first collection period (10:00–12:00 hr), declined in the second (12:00–14:00 hr), and was not detectable in the third 2-hr collection. Although the floral parts of a flower that has just bloomed contain much higher quantities of ME than those of a flower collected after one day of blooming, the latter contained larger quantities of dimethoxypropenylphenol.

DISCUSSION

The presence of ME analogs in the rectal glands of some flies attracted to the fruit fly orchid flower showed that they had previously fed on ME. Males of *B. papayae* that had fed on ME produced *trans*-coniferyl alcohol and 2-allyl-4,5-dimethoxyphenol, while those not exposed to ME did not (Nishida *et al*., 1988). These compounds are known to boost the pheromone and defense systems of *B. papayae* and *B. dorsalis*, thereby benefiting the male flies (Tan and Nishida, 1996).

After feeding on natural sources of ME, fruit flies did return to feed on ME released by the fruit fly orchid flower. When *B. papayae* males were exposed to a

high concentration of a pure ME source (isolated in a small-wire cage to prevent feeding) for over 1 hr in the laboratory, they did not respond to any subsequent ME source offered to them for one week. However, exposure for <1 hr did not cause this temporary habituation. Using a capture–mark–release–recapture technique and clear traps with an isolated ME source within a small-wire cage in the field, marked native *B. papayae* males were recaptured daily (Tan, 1985) or weekly (Tan and Serit, 1994) after being exposed to ME in an enclosed space for <1 hr. This ability of a ME-sensitive fruit fly to return repeatedly to a source of ME ensures its effectiveness and reliability as a pollinator.

Among the ME-sensitive fruit fly species, *B. papayae* and *B. umbrosa* are endemic in the forest, while *B. carambolae* is normally found in urban and cultivated areas. Sensitivity to ME varies from species to species. In the field, male *B. papayae* can be attracted to a spot containing ca. 1 ng of ME, but not *B. umbrosa* and *B. carambolae* (Tan, unpublished data). The relative content of ME in a freshly opened fruit fly orchid flower is high (>50% peak area) when compared with other orchid species: *Cattleya araguaiensis* Pabst, *Cattleya leopoldii* Lem., *Epidendrum nocturnum* Jacquin, *Gymnadenia conopea* (L.) R. Br., *Odontoglossum pulchellum* Lindl., *Oncidium sarcodes* Lindl., *Pescatorea dayana* Rchb.f., *Phalaenopsis violacea* Witte (Malaya type), *Rangaeris amaniensis* (Kraenzl.) Summerh., and *Zygopetalum crinitum* Lodd, which had ME from minor to 9% peak area of total floral volatiles (Kaiser, 1993). Using headspace–GC analysis, it was found that the fruit fly orchid flower releases ME into the environment at high levels during the morning, and this diminishes to undetectable quantities in the afternoon. Furthermore, ME contents were greatly reduced in the various floral parts when extracted a day after blooming. The high levels of ME account for the mild scent of *Bu. cheiri* flowers as opposed to it being "not scented" (Vermeulen, 1991), and to the high number of *B. papayae* males attracted to flowers during the morning hours.

It was suggested that ME-sensitive *Bactrocera* species are evolutionarily more advanced than RK-sensitive species (Tan, 2000a). The former consume and convert exogenous sources of ME to produce pheromonal and allomonal components, thus spending less metabolic energy, whereas the latter produce endogenous components and then sequester RK to boost the pheromonal and defense system (Tan, 2000b). Thus, the coevolution of *Bu. cheiri* and ME-sensitive *Bactrocera* species, especially *B. papayae*, has probably reached its peak. In this case, the flower does not only need to fully display its petals and sepals to ensure pollination, but it also possesses a similar defense system to that of the fruit fly through the production of ME analogs. The presence in the orchid flower of an allyldimethoxyphenol similar to that found in the rectal gland of most ME-sensitive fruit fly species is interesting. Male fruit flies use it as one of the components to attract other male fruit flies and to deter vertebrate predation (Nishida *et al.*, 1988; Tan and Nishida, 1998). Is this compound in the flower used primarily as an allomone to deter phytophagous vertebrate and, thus, protect the flower, i.e., to prevent unwelcome intruders from

damaging the precious floral reproductive organs, or is it one of the synomonal components? Without actual botanical and ecological evidence, the answer at this stage remains subjective.

An evolutionary trend from many to few pollinator species per plant species was observed in comparisons of ancestral versus recently derived monophyletic taxa in Orchidaceae (Tremblay, 1992). Further, reduction in the number of pollinator species per plant species is suggested to be a mechanism that may reduce the cost of pollen transfer. Taking this view, *Bu. patens*, with flowers that attract both the ME- and RK-sensitive *Bactrocera* species through zingerone, may be an ancestral species to *Bu. cheiri.* Therefore, floral synomone containing zingerone is probably the divergent point for *Bulbophyllum* species producing either RK or ME as attractants to lure fruit flies as efficient pollinators. As such, one would expect to find more species of wild orchids belonging to the genus *Bulbophyllum* that either produces RK or ME. A case in point is another *Bulbophyllum* species, *Bu. ecornotum*, which has a RK floral fragrance (Tan, 2000b). The flower of *Bu. ecornotum* is presently under going chemical analyses.

After attracting flies by the fragrance it releases, *Bulbophyllum* flowers ensure the removal and deposition of the pollinarium by its floral lip, which has been modified and adapted to a well-balanced structure of hinged see-saw lip that provides a floral mechanism to assist in pollination by flies. However, details of the fly's "temporary capture in a precise position" by the flower vary from one species of *Bulbophyllum* to another, depending largely on the design of the lip. In the fruit fly orchid flower, the adaxial end of its lip is broad, has high side-walls, and a shallow groove to ensure that a fruit fly always remains in an upright position when tipped head first into the column cavity. In this way, the pollinarium, when removed, is stuck on to the thoracic dorsum of the fly. In *Bu. patens*, the lip mechanism functions the same way in assisting pollination by tilting suddenly through an imbalance caused by the shifting of the fly's weight while feeding on the lip (Tan and Nishida, 2000). However, in *Bu. macranthum* the attracted fly (species not reported) slips from the glassy surface of the lateral sepal into the lip and then suddenly is tilted back, sending the fly abdomen-first into the column cavity. In this case, the pollinarium, when removed, sticks to the upper part of the fly's abdomen, and the fly, temporarily stuck to the floral stigma, extricates itself after releasing its grip on the lip (Ridley, 1890). Females of *Pholeomyia* spp. (unidentified), attracted by a fragrance of unknown identity, remove pollinarium via the movable lip mechanism by using wind assistance in *Bu. involutum*, *Bu. ipanemense* and *Bu. weddellii* (Borda and Semir, 1998b).

Hybridization has been observed between two sympatric *Bulbophyllum* species—*Bu. weddellii* and *Bu. involutum*, which have synchronous flowering and share the same species of pollinators in Brazil (Borba and Semir, 1998a). However, in Sabah, East Malaysia, hybridization between *Bu. cheiri* and *Bu. patens* is

unlikely—the former flowers in April–June, October, and December, and shares the same habitat in lowland forest at altitude 0–100 m with *Bu. patens*, which flowers in February and April (Vermeulen, 1991). While these two orchids are sympatric, with partially synchronous flowering (i.e., in April), and share a common ME-sensitive fruit fly species, *B. papayae*, as pollinator in the forest, hybridization through the transfer of pollinia by the ME-sensitive *Bactrocera* species will not occur for two reasons. First, the differences in pollinium size and shape may not allow for successful interspecific pollination; second, the ME-sensitive flies such as *B. papayae*, which are attracted at nanogram levels compared with zingerone at microgram levels, will be lured to the flowers of *Bu. cheiri* due to abundant ME released as a floral synomone (Tan and Nishida, 1998, 2000), leaving *Bu. patens* to attract only the RK-sensitive *Bactrocera* species found in the forest during the short overlap of flowering seasons in April.

In conclusion, this investigation shows a strong association between *Bu. cheiri* and male flies of the ME-sensitive *Bactrocera* species that results in mutual reproductive benefits through the release of ME in the floral fragrance. While the male fruit flies may find and consume ME from other plant sources to boost their pheromonal and allomonal systems, it is obvious that *Bu. cheiri* is entirely dependent on the male fruit flies for its pollination. Unfortunately, this unique association will be impacted by the current usage of ME in the management of pest fruit fly species in the agricultural sector. Therefore, the potential threat to the survival of *Bu. cheiri* in the rain forest must be seriously looked into before an eradication or suppression program for the ME-sensitive fruit fly species is implemented over a vast area.

Acknowledgments—We thank A. Lamb, Agricultural Research Station, Tenom, Sabah, and S. T. Tan, USM, for assistance and orchid plants, and our respective universities for providing research facilities. This work was supported by the Malaysian Government IRPA MPKSN/IRPA grant 01-02-05-6004.

(Received May 22, 2000; accepted February 12, 2002)

Abstract—The allelopathic potential of *Ageratum conyzoides* was investigated under different environmental stress conditions, including nutrient deficiency, physical damage, 2,4-D treatment, competition with *Bidens pilosa*, infection with *Erysiphe cichoracearum*, and feeding by *Aphiids gossypii*. The inhibitory effects of *A. conyzoides* volatiles on peanut (*Arachis hypogaea*), redroot amaranth (*Amaranthus retroflexus*), cucumber (*Cucumis sativus*), and ryegrass (*Lolium multiforum*) increased when plants were grown under nutrient-deficient conditions or in competition with *B. pilosa*; however, there was no difference with physical damage or 2,4-D treatment. Phytoinhibitory effects decreased under fungal infection and aphid feeding. Volatiles from *A. conyzoides* plants infected with *E. cichoracearum* or exposed to *A. gossypii* feeding inhibited or killed fungi and insects. Precocenes and their derivatives, monoterpenes, and sesquiterpenes were the major volatile components of *A. conyzoides*.

Key Words—*Ageratum conyzoides*, allelopathy, environmental stress, volatile allelochemicals, chemical constituent, and phytochemistry.

INTRODUCTION

The allelopathic potential of many plants is intensified by exposure to various environmental stresses (Einhellig, 1987, 1996) and induces phytochemical variation (Josep and Joan, 1997; Kong et al., 2000). Several studies have shown that the

* To whom correspondence should be addressed. E-mail: chkong@scau.edu.cn

0098-0331/02/0600-1173/0 © 2002 Plenum Publishing Corporation

amount of allelochemicals produced and released by plants is correlated to environmental factors (Dick, 1994; Loughhrin et al., 1995; Rose et al., 1995; Pare and Tumlinson, 1997; Agrawal, 1998). As a result, an increasing number of studies have focused on the relationship between environmental variation, plant chemical response, and the ecological function of plant allelochemicals.

Ageratum conyzoides is a perennial plant that grows in tropical and subtropical regions and is spread widely in natural and managed ecosystems. Its allelopathic potential has been demonstrated in previous studies (Kong et al., 1998a,b, 1999) and is achieved by releasing volatile allelochemicals into the environment (Kong et al., 1998a). Further research has shown that the allelopathic potential and major allelochemicals of *A. conyzoides* vary in different habitats, and that allelopathic synergism exists among *A. conyzoides* allelochemicals (Kong et al., 1998b, 1999). In this paper, the allelopathic potential and volatile chemicals from *A. conyzoides* were studied when plants were grown under various environmental stresses, including: nutrient deficiency, physical damage, treatment with 2,4-D, competition with *Bidens pilosa*, infection with the fungus *Erysiphe cichoracearum*, and feeding by the *Aphiids gossypii*.

METHODS AND MATERIALS

Culture of A. conyzoides. Plants were grown at the Ecological and Meteorological Experimental Station of South China Agricultural University (Guangzhou, China). Plots (4×5 m^2) were selected with two different fertility levels (Table 1). Fertility level 1 was regarded as containing sufficient nutrients to adequately support *A. conyzoides* growth (based on four years of observation and investigation), while fertility level 2 was considered nutrient deficient.

Black, ripe seeds of *A. conyzoides* were collected from uncultivated individuals growing at the experimental station during the summer of 1998. Seeds were dried in sunlight (48 hr) and stored in a sealed glass jar. In 1999, seeds were sown on different treatment plots and thinned to 600 plants/m^2 at the two-leaf stage. Sowing was done in October, and sampling of the above-ground portions of plants for chemical analysis was done in December.

Environmental Conditions. Except for conditions of nutrient deficiency, *A. conyzoides* was grown in fertility level 1 plots. Nutrient-deficient plants were

TABLE 1. ORGANIC MATTER AND SOIL FERTILITY

	Organic matter (g/kg)	Total N (g/kg)	Available N (mg/g)	Total P (g/kg)	Available P (mg/kg)	Total K (g/kg)	Available K (mg/kg)
Level 1	22.03	1.71	40.79	0.23	13.80	12.90	102.50
Level 2	6.12	0.29	10.88	0.49	0.15	6.06	22.01

grown in fertility level 2 soils. The above-ground portions of plants were collected at the peak flowering stage for chemical analysis.

A. conyzoides plants exposed to stresses other than nutrient deficiency were grown in fertility level 1 soils under nutrient-sufficient conditions as described below.

For physical damage, 50% of above-ground plant tissue was removed at the preflowering stage (60 days). Samples for chemical analysis were collected at the peak flowering stage (about 20–25 days after damage).

For 2,4-D stress, A solution of 2,4-D (250 μg/ml) was sprayed onto leaves and stems at the preflowering stage. The amount of spraying was 200 ml/m^2, half of the level used to control *A. conyzoides* in agricultural areas of South China. Plant samples for chemical analysis were collected at peak flowering stage (about 15–20 days after treatment).

For *B. pilosa* competition, seeds of *A. conyzoides* and *B. pilosa* were sown together on October 5. At the two-leaf stage, seedlings were thinned by hand to 300 plants/m^2 for each species. Samples for chemical analysis were collected at peak flowering stage as above.

For *E. cichoracearum* infection, *E. cichoracearum*-infected *A. conyzoides* plants were selected from the experimental station and planted into a plot containing healthy *A. conyzoides* at the preflowering stage. Most healthy plants showed visible signs of infection after 10 days. Plants for chemical analysis were collected at peak flowering stage.

For *A. gossypii* feeding, 1000 aphids were discharged evenly onto *A. conyzoides* plants at the beginning of the flowering stage. Plant samples for chemical analysis were collected after about 10 days when most leaves had been fed upon.

Collection of Volatiles. The above-ground portion of *A. conyzoides* (approx. 5.0 kg) was collected from each treatment plot on the sampling date. Samples were immediately placed into a vacuum desiccator equipped with a liquid nitrogen cold trap and pumped to 133 Pa. The oily volatiles were removed from the cold trap by injector after approx. 10 hr. Yields (volatile weight per plant, milligrams per gram fresh weight), bioassay, and chemical analyses were immediately determined.

Bioassays. Peanut (*Arachis hypogaea*), redroot amaranth (*Amaranthus retroflexus*), cucumber (*Cucumis sativus*), and ryegrass (*Lolium multiforum*) were used to bioassay for growth inhibition by *A. conyzoides* volatiles. Fungi included sheath blight (*Rhizoctonia solani*), cucumber gray mold (*Botrytis cinerea*), and Chinese cabbage sclerotinia rot (*Sclerotinia sclerotiorum*). The insects tested were red flour beetle (*Tribolium confusum*), Oriental armyworm (*Mythimna separata*), and northern mosquito (*Culex pipiens*). The biological actions on insects and fungi were evaluated by using the methods of Robertson and Preisler (1992). The inhibitory effect of volatiles on plant growth was evaluated following Kong et al. (1999). Uniform, germinated seedlings (30 seedlings with radicle lengths approx. 1 mm) from each of the bioassay plant species were placed into Petri dishes (10 cm diam.) containing filter paper and a thin layer of quartz sand in the bottom. The paper and

sand was moistened with Hoagland's nutrient solution (2.5 ml). The five uncovered dishes containing the various bioassay species were placed into a controlled environmental chamber (3 m^3) with a source of *A. conyzoides* volatiles. The rate of allelochemical volatilization was maintained at 200 mg/hr (monitored by gas chromatography) with proper air displacement pressure. Ordinary air served as the control for these experiments. Plants were grown for one week at $25 \pm 2^{\circ}$C under a 12L:12D photoperiod. Fresh weight, chlorophyll content, and peroxidase (POD) activity were determined for both treated and control plants. Chlorophyll content was determined using the technique developed by Baziramaberga et al. (1994) and POD activity was determined by the method of Hammerschmidt et al. (1982). All determinations were replicated three times under identical conditions.

Qualitative and Quantitative Analyses. Volatiles were analyzed by gas chromatography–mass spectrometry (GC–MS) on a Hewlett-Packard 5972 GC/MSD. Samples (1 μl) were injected onto an HP-5 bonded stage fused-silica capillary column (30 m $\times$ 2.5 mm) using the split mode. The initial oven temperature (70°C) was maintained for 2 min following injection. The temperature was then increased to 150°C at a rate of 20°C/min and then to 180°C at a rate of 10°C/min. After maintaining the column at 180°C for 5 min, the oven temperature was raised to 250°C at 15°C/min. Mass spectra were repetitively scanned from 35 to 450 amu every 2 sec. Ionization was elected in the electron impact mode (EI) at 70 eV. Volatiles were identified by peak matching against standards in the NIST 92 Computer Library or spectral similarity to an authentic reference compound (Aldrich Chemical Co.). The relative amounts of volatiles were calculated by integration of all peaks with areas greater than 0.1%.

Data Analyses. Impact effects were evaluated by the method of Williamson and Richardson (1988). The response index (RI) was determined as follows:

$$\text{If } T \geq C, \text{ then } RI = 1 - C/T; \qquad \text{If } T < C, \text{ then } RI = T/C - 1$$

where T is the treatment response and C is the control response. RI values range from $+1$ to -1, with positive values indicating stimulation and negative values indicating inhibition relative to controls. Absolute values of RI varied directly according to impact effects. A t test was used to analyze results of experiments evaluating impact effects of volatiles on plants, fungi and insects.

Quantification of the volatile chemical components was obtained from independent GC-MS measurements. Data are presented as means $\pm$ SEM. ANOVA with Duncan's multiple-range test was used to analyze the data.

RESULTS

Allelopathic Potential under Stress. Volatiles from *A conyzoides* inhibited the growth and development of peanut, redroot amaranth, ryegrass, and cucumber (Figure 1). Inhibition of plant growth was significantly different under nutrient

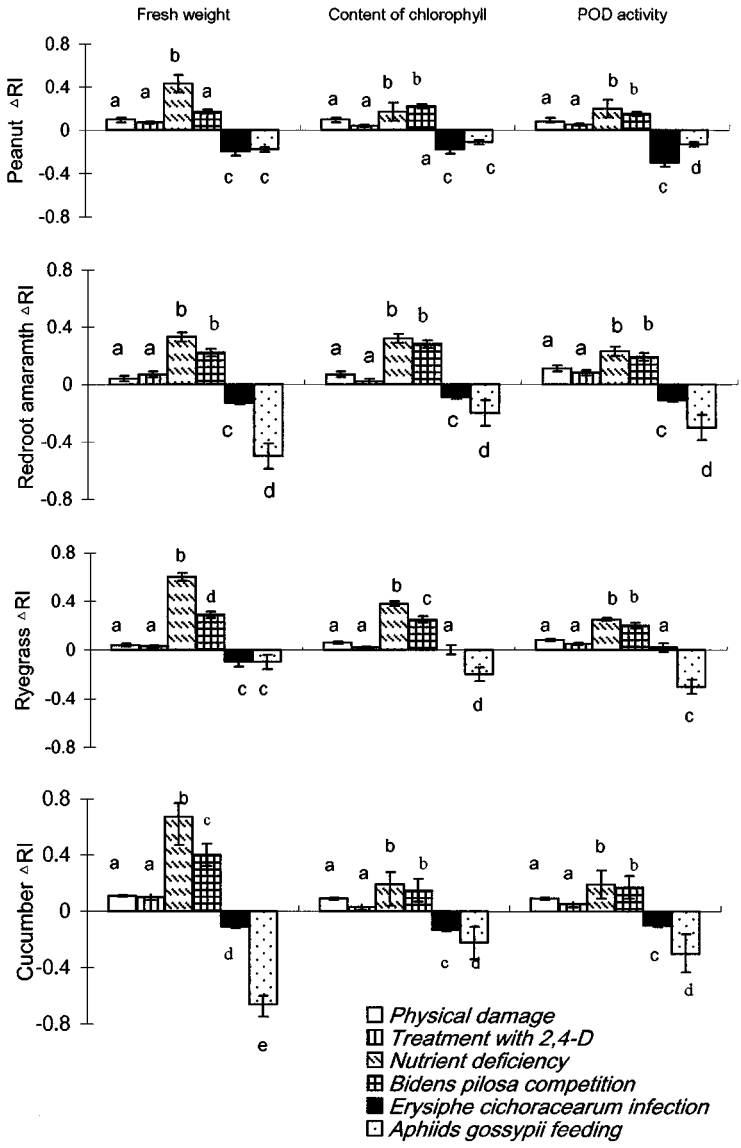

FIG. 1. Inhibitory effects of the volatiles from *A. conyzoides* on plants tested with different stress factors. ($^{\triangle}$RI = control RI—treatment RI, control was nutrient sufficiency.)

deficiency and *B. pilosa* competition. Significant differences in allelopathic potential were not observed in response to nutrient sufficiency (control), physical damage, or treatment with 2,4-D. The allelopathic potential of *A. conyzoides* was enhanced under conditions of nutrient deficiency and *B. pilosa* competition.

The absolute amounts of volatiles from *A. conyzoides* increased greatly while the inhibitory effects of these chemicals on plant growth decreased dramatically under *E. cichoracearum* infection and aphid feeding by *A. gossypii*. It is possible that allelochemicals produced in response to *E. cichoracearum* infection and *A. gossypii* feeding not only inhibit the growth of neighboring plants, but also defend plants against microbial infection and insect feeding. To test this, some common insects and fungi were exposed to volatiles produced by *A. conyzoides* either infected with *E. cichoracearum* or subjected to aphid feeding by *A. gossypii*. The volatiles had significant inhibitory or killing effects on the insects and fungi tested (Figure 2). Volatiles produced by *A. conyzoides* in response to infection by *E. cichoracearum* inhibited the growth of *Rhizoctonia solani*, *Botrytis cinerea*, and *Sclerotinia sclerotiorum*. Similarly, *A. conyzoides* exposed to *A. gossypii* produced volatiles that killed *Tribolium confusum* (adult), *Mythimna separata* (the third larva), and *Culex pipiens* (the fourth larva). However, purified precocene II, the major component of *A. conyzoides* volatiles in both control and stressed plants, was less effective at inhibiting the growth of fungi or killing of insects. Obviously, There may be other allelochemicals with antifungal and antiinsect activity produced by *A. conyzoides* infected by *E. cichoracearum* or fed on by *A. gossypii*.

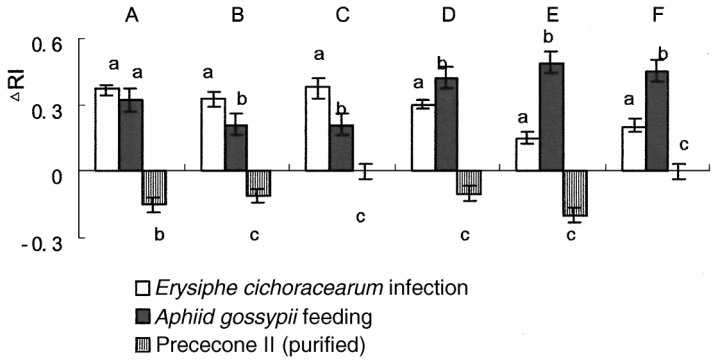

FIG. 2. Inhibitory and killing effects on tested insects and fungi of the volatiles from *Ageratum conyzoides* growing under *Erysiphe cichoracearum* infection and *Aphiid gossypii* feeding. (A: *Rhizoconia solani* B: *Botrytis cinerea* C: *Sclerotininia sclerotiorum* D: *Tribolium confusum* (adult) E: *Mythimna separata* (the third larve, Compared to control, all treatments delayed molting 24 h) F: *Culex pipiens* (the forth larve). The treatment concentrations to *M. separata* were 1000 μg.g^{-1}, and to *C. pipiensis* were 100 μg.g^{-1}, the others were 500 μg.g^{-1}. other remarks were the same as Fig. 1 footnote.)

Impact of Environmental Stress on Volatile Constituents. When exposed to different environmental stresses, *A. conyzoides* demonstrated different biological actions as demonstrated above. These actions were correlated with varying volatile compositions. Qualitative and quantitative analysis of volatile constituents was accomplished by GC-MS and showed significant variation in response to the various stress factors (Table 2). Precocenes and their derivatives (2H-benzopyran), monoterpenes, and sesquiterpenes were the main constituents. Control plants, those subjected to physical damage and treatment with 2,4-D, showed weak allelopathic potential and were characterized by precocene I and II levels of around 57 and 37 mg/g fresh wt, respectively; β-caryophylene levels of control plants were approximately 26 mg/g fresh wt. Under nutrient-deficient conditions and/or *B. pilosa* competition, *A. conyzoides* elicited a stronger alleopathic response and produced significantly higher levels of both precocenes and β-caryophllene. Precocene levels decreased in response to *E. cichoracearum* infection (i.e., precocene I) and aphid feeding (precocene II), while β-caryophllene levels did not change significantly. The levels of various mono and sesquiterpenes significantly increased in response to these stresses. These differences resulted in differential allelopathic effects and biological actions on insects and fungi.

DISCUSSION

There were significant differences in plant growth inhibition and biological actions on the fungus and aphids tested in response to phytochemical changes in *A. conyzoides* exposed to various biotic and abiotic stresses. It is unclear how *A. conyzoides* may release these volatile allelochemicals into the environment; however, this research documents that *A. conyzoides* can produce more and different volatile allelochemicals under adverse conditions—particularly under nutrient deficiency, competition with *B. pilosa*, infection with *E. cichoracearum*, and aphid feeding by *A. gossypii*. Physical damage and treatment with 2,4-D did not affect the allelopathic potential of *A. conyzoides* or the concentration of the major compounds present, i.e., anthropogenic factors did not seem to induce *A. conyzoides* to produce higher levels of allelopathic phytochemicals.

Allelopathic capability could be an adaptive mechanism and strengthen the ability to compete with other plants under adverse conditions (Tang, 1995). Although the allelopathic potential of *A. conyzoides* was related to environmental stress, not all stress factors intensified the plants' allelopathic potential. Only a few natural environmental stress factors induced and/or regulated the production of allelochemicals and caused changes in the qualitative and quantitative characteristics of the phytochemical constituents. The main ecological functions of volatiles from *A. conyzoides* infected with *E. cichoracearum* or exposed to aphid feeding may not be for inhibition of neighboring plant growth; infection and aphid feeding

were more harmful to *A. conyzoides* than competition with neighboring plants. In fact, many kinds of allelochemicals not only interfere with neighboring plant growth, but also affect the behavior and development of insects and fungi. Allelochemicals have multiple ecological functions (Seigler and Price, 1976; Saiki and Yoneda, 1981; Berenbaum, 1985; Romeo, 1998). They may serve as antiherbivore, antifungal, and/or antibacterial compounds, phytotoxins, attractants, internal regulators of growth and development, seed germination stimulants, and inhibitors, etc. Our results suggest that the allelopathic potential of *A. conyzoides* is correlated with its growth conditions, and the categories and amounts of volatile allelochemicals from *A. conyzoides* could be induced by a few of these natural stress factors.

MICROBE INHIBITION BY *Tribolium* FLOUR BEETLES VARIES WITH BEETLE SPECIES, STRAIN, SEX, AND MICROBE GROUP

HOLLY R. PRENDEVILLE and LORI STEVENS*

(Received October 27, 2000; accepted February 12, 2002)

Abstract—*Tribolium* flour beetles produce defensive compounds, including quinones, putatively aimed at deterring predators and inhibiting microbes. Here we examine how effective the defensive secretions of *Tribolium confusum* and *T. castaneum* are at inhibiting growth of various microbes and how this varies with species, geographic strain, and sex of the beetles. We explore differences at both the kingdom and species level of common flour microbes in their susceptibility to defensive compounds. Beetle species and strains vary in their ability to inhibit microbial growth. In addition, microbes vary in their sensitivity to the beetles' defense compounds. The capability to suppress microbial growth is likely under stabilizing selection with optimum quinone production varying among populations and may be dependent on several environmental factors including temperature, humidity, and predators.

Key Words—*Tribolium confusum*, *Tribolium castaneum*, microbe inhibtion, defense compounds, benzoquinones, Coleoptera, Tenebrionidae, beetle-microbe interactions.

INTRODUCTION

Flour beetles, genus *Tribolium*, are an agricultural pest commonly found in flour silos (Sokoloff, 1974). Their habitat is rich in microbial competitors such as bacteria, yeast, and fungi (Abramson et al., 1980; Borjesson et al., 1989; Yezerski et al., 2000). Presumably, to both inhibit microbe growth and deter predators (Dettner, 1993; Eisner et al., 1998), *Tribolium* produce and store defensive secretions in the form of a foul-smelling yellow fluid. The secretion of *T. confusum* consists of

ethyl-1,4-benzoquinone (EBQ) and methyl-1,4-benzoquinone (MBQ); while that of *T. castaneum* contains EBQ, MBQ, and small quantities (<1%) of 2-methoxy-1,4-benzoquinone (Pappas and Morrison, 1995; Unruh et al., 1998; Yezerski et al., 2000). Benzoquinones are toxic and nonspecific elements of chemical defense in many insects (Blum, 1981). In excess, these benzoquinones turn the beetles' flour medium pink and cause developmental abnormalities in larvae and pupae (Chapman, 1926; Happ, 1968; Sokoloff, 1974, 1977). Previous studies have shown that benzoquinones inhibit the growth of yeast, bacteria, and fungi (Söderhall and Ajaxon, 1982; Nishina and Uchibori, 1991), in addition to deterring other insects and predators (Dettner, 1993; Eisner et al., 1998).

Benzoquinones are produced only in adult beetles, from a pair of prothoracic and postabdominal glands that are reservoirs for benzoquinones [for morphological description of *T. confusum* see Happ (1968) and for *T. castaneum*, see Roth and Stay, (1958)]. An individual beetle can be characterized by its internal, or glandular, amount and the external amount that reflects the nonvolatized residue from excretion. Internal and external quinone quantities are known to vary among species, geographic strains within species, and sexes (Pappas and Morrison, 1995; Unruh et al., 1998; Yezerski et al., 2000). The genetic basis of this variation has been examined for *T. confusum*; internal amounts of benzoquinones are genetically variable, whereas external amounts are largely determined by nongenetic factors (Yezerski, 1990).

In this paper, we examine the efficacy of compounds produced by *Tribolium* flour beetles to inhibit the growth of microorganisms that commonly occur in flour. We investigate whether the zone of inhibition from an individual beetle varies among geographic strains within a species and between the sexes. We also investigate whether microbes vary in their susceptiblity to the beetles' defensive secretions.

METHODS AND MATERIALS

Beetles. To investigate intra- and interspecific variation, we examined *T. confusum* strains b-+ and b-Pak, and *T. castaneum* strains c-sm and c-+ (see Yan and Norman, 1995, for description). Beetles were raised in stock jars with 100 g of single-sifted standardized (SSS) flour medium per 200 adults. The flour medium, SSS, is fine, sifted whole-wheat flour, sterilized by heating to 55°C for at least 24 hr, and supplemented with 5% dry weight, powdered brewer's yeast. Beetle colonies were maintained at 70% relative humidity and 29°C in dark incubators. Individuals were sexed as pupae, and individually placed into 1-dram vials containing 1 g SSS. Beetles were assayed at 31–52 days after eclosion.

Microbes. We examined effects of four yeast species [*Rhodotorula glutinis* (RG), *Saccharomyces microellipsoides* (SM), *Pichia anomala* (PA), *Cryptococcus albidus* (CA)]; and two bacteria species [*Bacillus subtillis* (BS) and *Bacillus*

licheniformis (BL)]. Microbe species were obtained from the USDA Agricultural Research Service Culture Collection (http://www.ars.usda.gov/is/np/systematics/contents.htm). We cultivated microbe cultures from lyophilized preparations by suspending pellets in 10- × 75-mm tubes with 0.5–0.7 ml of liquid yeast medium (YM). The YM agar was prepared according to a protocol outlined by the USDA: 3 g of yeast extract, 3 g of malt extract, 5 g of peptone, 10 g of glucose, 1 liter of distilled water, and 20 g of agar. Cultures were initially grown for three weeks in 15-ml Corning centrifuge tubes with 10 ml of YM broth at ambient temperature, approximately 26°C. We refreshed microbe suspensions every two to three weeks by adding 1–2 ml of culture solution to 10 ml of fresh YM broth. After addition of YM broth, cultures were allowed to grow for a minimum of three days prior to plating. We transferred all microbe suspensions with filtered pipet tips to minimize contamination.

Microbe lawns were grown on YM agar in Petri dishes to test for their sensitivity to compounds. Yeast medium agar was poured into 100-mm plates, allowed to congeal overnight, and plates were either used the next day or refrigerated until needed to reduce the risk of contamination. Plates were inoculated by the addition of 0.8–0.9 ml of one of the six microbe suspensions. The plate was immediately swirled to ensure even microbe lawn growth, then the suspension was allowed to absorb into the plate for 10–20 min.

Assay. To determine an assay for microbe inhibition from a single beetle, pilot assays investigated potential techniques that would cause excretion of compounds in the prothoracic and postabdominal glands. The pilot assays included: (1) grinding a beetle onto a filter paper disk with a glass rod and placing the disk on an inoculated plate; (2) placing a live beetle upside down on the agar (beetles often cannot turn themselves over; therefore, the effect is localized); (3) freezing a beetle for 1 hr at −4°C and then placing it on a Petri dish; and (4) placing a beetle frozen at −80°C for 5–15 min on an inoculated plate. Freezing triggered release of a yellow substance from the thorax and abdomen, at the location of the glands that produce quinones. The −80°C freezing protocol was chosen because it was easy, consistent, and did not involve a solvent. Inoculated plates with previously frozen beetles were placed in a dark drawer at ambient temperature for 24 hr, after which we measured the area of inhibition. A zone of inhibition is the area around a beetle where a microbe lawn or colony is not visible to the unaided eye. The zone was measured by placing a Petri dish on a 1-mm-square sheet of graph paper and counting the number of squares. Thus, the assay represents the zone of inhibition for a single beetle and includes the total (internal + external) defensive secretions produced by that beetle.

We quantitatively assayed five of the six microbes with a total of 401 beetles; however, we only assayed RG with b-+ and were unable to assay b-Pak with BL because of contamination. Sample sizes for each microbe–beetle combination ranged from 16 to 28, with a mean of 21.

Statistical Analysis. Area of inhibition was square-root-transformed prior to statistical analysis to achieve a normal distribution of the values. Analysis of variance was carried out with the statistical program JMP (SAS Institute, 1995) on a Macintosh computer. The analysis is a nested ANOVA. Beetle strains are nested within species, and microbe species nest into bacteria and yeast groups, and the design is unbalanced. Thus, orthogonal contrasts were used to test for main effects and interactions. Contrasts were generated a priori to allow us to investigate the effect of beetle sex, species, and strain in addition to microbe group with a controlled experiment-wise error rate.

RESULTS

All beetle strains examined inhibited microbial growth, and all microbe species were sensitive to beetle secretions (Figure 1, Table 1). A zone of inhibition

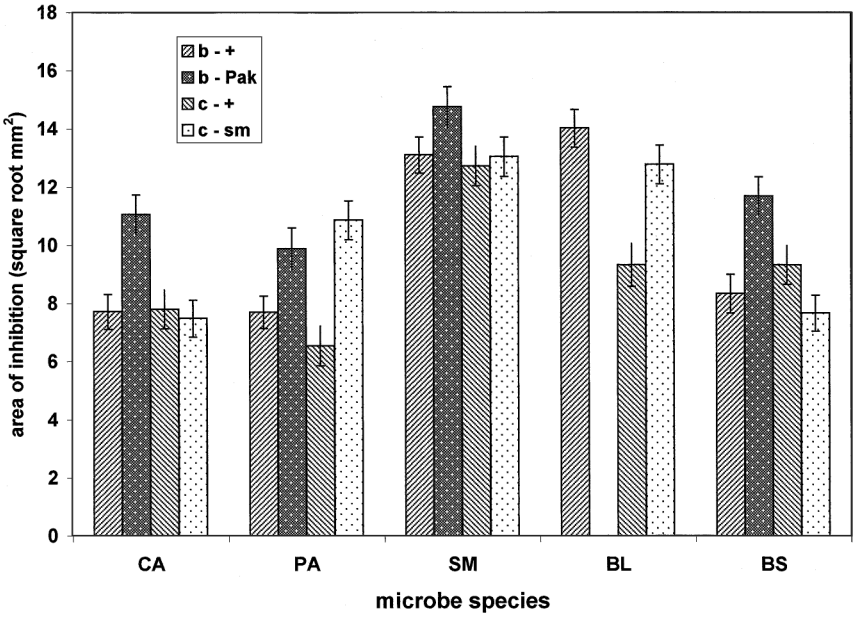

FIG. 1. Area of inhibition (square root transformation of mm^2) of microbe growth for two genetic strains of *Tribolium confusum* (b-+ and b-Pak) and two of *T. castaneum* (c-sm and c-+). The origin of the beetle strains is described in the text. Microbes from two kingdoms, yeast and bacteria, were examined. Results are presented for three species of yeast (*Cryptococcus albidus*, CA; *Pichia anomala*, PA and *Saccharomyces microellipsoides*, SM) and two of bacteria (*Bacillus licheniformis*, BL, and *B. subtillis*, BS).

[a] Orthogonal contrasts examined main effects and interactions, significant interactions ($P < 0.05$) are shown.

was visible around the beetles even weeks after the beetles were placed onto Petri dishes. The main effects from the ANOVA are shown (Table 1), along with the statistically significant interactions ($P < 0.05$). Beetle sex, species, and strain significantly affected the area of inhibition, as did the microbe group and strain (Table 1). The mean zone of inhibition from female beetles was larger than from males. On average, *T. confusum* had a larger zone of inhibition than *T. castaneum*. This is because strain b-Pak has such high values rather than that *T. confusum* has an overall greater zone of inhibition (Figure 1). Both sets of strains within beetle species were significant, suggesting a wide potential range of adaptation within species. On average, the zone of inhibition for bacteria was larger than for yeast (main effect 3: bacteria vs, yeast, $F = 9.85$, $P < 0.01$); however, the suppression of the yeast species SM was significantly greater than one of the two bacteria species tested. Thus, microbe species vary in their sensitivity to compounds produced by *Tribolium* beetles, but the pattern of sensitivity does not reflect phylogeny at the yeast and bacteria level.

Of the 27 interaction terms, eight were significant ($P < 0.05$) (Table 1). These are a priori tests, based on the hierarchical nesting of the groups examined, so multiple comparisons are controlled for. Four of the eight interactions include the strain of *T. castaneum* (2b, Table 1), four include the microbe group (3, Table 1), and three include sex (1, Table 1). The interactions indicate when an effect has a different order or magnitude. For example, the strain of *T. castaneum* (c-+ vs

c-sm) × species of bacteria (BL vs BS) interactions indicates that the zone of inhibition of c-+ relative to c-sm is significantly different for the two bacteria species. Overall, the statistical analysis reveals that the microbes are inhibited by the beetles and that several factors affect the level of inhibition; however, the taxonomy or phylogeny of the groups examined does not control the level of inhibition.

DISCUSSION

Tribolium beetles produce compounds that inhibit the growth of microbes commonly found in their flour medium (Figure 1, Table 1). Biochemical analysis has detected only benzoquinones in these secretions; however, our assay tested the ability of whole beetles to inhibit microbial growth rather than explicitly testing the quinones. Beetles vary both between species and between genetic strains within species in their capability to suppress microbe growth. Microbes vary at the kingdom and species level in their sensitivity to the beetle's defense compounds.

Tribolium confusum and *T. castaneum* are believed to have evolved as inhabitants of bark, decomposing plants, food caches of Hymenoptera, and rodent nests (Sokoloff, 1974). Present populations of *Tribolium* are cosmopolitan and commonly found in flour mills and grain silos. In these habitats, *Tribolium* encounter and consume microorganisms (Thatcher et al., 1953) and, in so doing, increase their fitness (Sinha, 1966; Wicklow and Stevens, 1997). However, high benzoquinone quantities cause abnormal development in larvae and pupae, as well as death in adults (Chapman, 1926; Happ, 1968; Sokoloff, 1974, 1977). Beetles are attracted to flour containing fungi and bacteria (Van Wyk et al., 1959) and are deterred from flour with high quantities of quinones (Loconti and Roth, 1953).

The variation in the ability to inhibit microbe growth suggests that quantities of defense secretions result from stabilizing selection combined with environmental factors at the individual or population level. Populations in different environments may be selected for distinct quinone levels if microbe growth or predators vary among environments. Temperature and humidity may affect microbe growth and, thus, climate may indirectly affect quinone levels. Stabilizing selection may occur for this trait with a beetle strain finding a balance between permitting the growth of beneficial microbes, controlling harmful microbes, deterring predators, and reducing harm to the beetle itself.

(Received May 1, 2001; accepted February 16, 2002)

Abstract—We proved that the leafminer moth *Phyllonorycter emberizaepenella* (Lepidoptera: Gracillariidae) reproduces by parthenogenesis of the thelytoky type. Despite a complete absence of males, parthenogenetically reproducing females diurnally demonstrated the calling posture normally used for releasing signaling compounds. Two compounds, which we collected from a calling female, were identified as potential sex pheromone components: (8*E*,10*E*)-8,10-tetradecadienyl acetate and (8*E*,10*E*)-8,10-tetradecadienol, the latter occurring only in trace amounts. In field experiments, no males were attracted to traps baited with either the potential sex pheromone or with virgin females. Both the pattern of behavior and the chemical characteristics of the pheromone of *Ph. emberizaepenella* species were similar to those known for Lepidoptera with the usual amphimictic mode of reproduction. Theoretical speculations that in thelytoky, where there is no need to find a sexual partner, the individuals would obtain certain advantages due to reduction in their sexual behavior, were, thus, not confirmed for *Ph. emberizaepenella*.

Key Words—Thelytoky, diurnal rhythm, communication behaviour, (8*E*,10*E*)-8,10-tetradecadienyl acetate, (8*E*,10*E*)-8,10-tetradecadienol, Lepidoptera, Gracillariidae.

INTRODUCTION

The parthenogenetic mode of reproduction in animals has a number of drawbacks and advantages when compared with amphimixis. One potential advantage is the absence of mate finding (Gilyarov, 1982; Went, 1984). However, from the viewpoint of the theory of optimality (Rozen, 1969), for altering the genetic program (including that of sex pheromone production and calling behavior), certain energy expenses are needed, and these are justified only when there will be a benefit greater than the cost of carrying out these modifications. With this in mind, the detailed investigation of both chemical and behavioral elements related to "searching" for a sexual partner in parthenogenetically reproducing animals is of interest.

Insects are convenient objects for such studies, especially species that use chemical communication while locating their mates. The aim of this study was to verify the parthenogenetic reproduction of the widespread leafminer moth *Phyllonorycter emberizaepenella* that was reported earlier (Būda et al., 1991) but never confirmed, as well as to elucidate the sexual behavior of this moth and to determind whether it releases potential sex pheromones during the calling.

METHODS AND MATERIALS

Insects

Common honeysuckle shrubs, *Lonicera xylosteum* L. leaves with *Ph. emberizaepenella* (Z.) (Lepidoptera, Gracillariidae) mines were collected at the end of October 1989 and 1996–1998 and held in an outdoor container on moistened peat moss until the following spring. Specimens were collected from Vilnius (Žemieji Paneriai) and from four other localities in Lithuania. The maximum distance between collection sites was 300 km. In addition, nondiapausing individuals were collected at the beginning of June 1999. The leaves with pupae were placed in 28-ml glass vials, three mines per vial, and held under an artificial 16L:8D photoperiod. A daylight lamp of 1000 W (type DRF, for greenhouses) was used. The temperature was maintained nearly constant during the scotophase, with irregular fluctuations within the range $14 \pm 1^{\circ}$C. Within 2 hr of the start of the photophase, it was gradually raised to $20 \pm 1^{\circ}$C, kept constant until 2 hr before the end of the photophase, and then gradually decreased, reaching 14°C when the next scotophase began. Following emergence, the adults were collected daily just after the onset of the photophase, then sexed and placed into individual holding vials (28-ml volume), and provided with a solution of 5% of sucrose in water.

Parthenogenetic Mode of Reproduction

Three 2-day-old virgin females of *Ph. emberizaepenella* were placed in individual containers together with green branches of the honeysuckle and were left to

oviposit for one day. The branches were steeped in Knop's solution (Grodzinskii and Grodzinskii, 1973). This food source was sufficient for the complete development of the progeny.

Diurnal Rhythm of Female Calling Behavior

At emergence, 32 virgin females were placed in individual glass vials and their behavior was observed over a four-day period. During experiments, females were provided with a solution of 5% of sucrose in water. Observations were made every 30 min during the last 2 hr of the scotophase until the 8th hour in the photophase, and hourly during the remaining period of a photocycle. Observations during the scotophase were made using a 4.5-V red lamp light. Females were classified as calling when the abdomen was raised clearly above the wings (Figure 1B).

Collection of Compounds

Compounds released from calling females were collected using the solid phase microextraction (SPME) technique (Borg-Karlson and Mozuraitis, 1996). The SPME fiber (100-mm polydimethylsiloxane) was purified at 225°C for about 10 min in a GC injector before being placed a few millimeters away from the abdominal tip of a calling female for 2–4 hr at the beginning of the calling period. Then the SPME fiber was inserted in a glass tube (1.75-ml volume), containing undecyl acetate (10 ng) and pentadecyl acetate (100 ng) on the inner wall as internal standards, and the sorption continued for another 15 min at 22°C. The volatiles from 12 females were collected individually during their calling and noncalling periods and analyzed one by one in this way.

Chemical Analyses

The signaling compounds were identified by using the Finnigan SSQ 7000 GC-MS system, including a Varian 3400 GC. One DB-5 and one DB-Wax silica capillary column (30 m $\times$ 0.25 mm ID, 0.25-μm film thickness) were used with a temperature program of 70°C (1 min), increased by 10°C/min to 140°C, then by 1°C/min up to 150°C, by 2°C/min up to 170°C, by 5°C/min up to 200°C, and thereafter maintained constant at 200°C for 17 min. The split/splitless injector temperature was 225°C, and the splitless period was 30 sec. Helium was used as the carrier gas with an inlet pressure of 5 psi. Electron ionization mass spectra were determined at 70 eV with the ion source at 150°C. When the sample had been injected, the desorption of the sex pheromone components and of the internal standards from the SPME fiber was checked by subsequent injection into a split/splitless injector of a second GC for 30 sec of splitless time at an injector temperature of 225°C. Total desorption of the compounds occurred during the first injection.

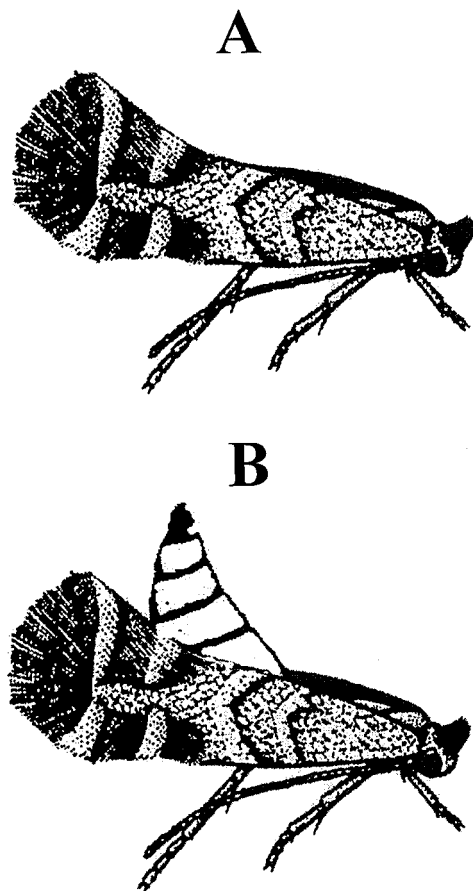

FIG. 1. Postures of virgin *Phyllonorycter emberizaepenella* females: (A) resting, (B) calling.

The volatiles collected from females during their calling and noncalling periods were compared chromatographically, and only those coming exclusively from calling periods were analyzed. The compounds selected for analysis were identified by comparison of their mass spectral data and GC-retention times with the corresponding data of synthetic standards.

Chemicals

All isomers of 10,12-tetradecadienols and their acetates used as GC-MS standards were available from previous research, whereas the 8,10-tetradecadienols and

their acetates were synthesized at the Department of Chemistry, Organic Chemistry, The Royal Institute of Technology, Stockholm. The synthetic intermediates as well as the products were characterized with a Bruker AM 400 spectrometer (NMR spectra were recorded in $CDCl_3$), and the GC-MS system is described in the section above (Chemical Analyses).

8-Bromooctanol (**2**; Figure 2) was prepared according to Rossi *et al.* (1981), Gardette *et al.* (1983), and Tellier (1990). 8-Hydroxyoctyl-triphenylphosphonium bromide (**3**; Figure 2) was synthesized as in Vinczer *et al.* (1987). (8*E*,10*E*)-8,10-tetradecadienol (**4**; Figure 2) and (8*Z*, 10*E*)-8,10-tetradecadienol (**5**; Figure 2) were made according to Lo and Shiao, (1986). The products were obtained in a mixture of **4** (40%) and **5** (60%). *ZZ* and *EZ* isomers were not detected by GC-MS. Isomers **4** and **5** were separated by chromatography on silica gel impregnated with 15% $AgNO_3$. Finally, 99.0% isomerically pure **4** was derived from a urea inclusion complex, and **5** was obtained in 99.2% purity by crystallization from pentane at -30°C.

*(8*E*,10*E*)-8,10-Tetradecadienol **4***. ^{1}H NMR: δ: 5.97 (m, 2H, $-$CH=C$\underline{\text{H}}$-C$\underline{\text{H}}$=CH$-$), 5.54 (m, 2H, $-$C$\underline{\text{H}}$=CH-CH=C$\underline{\text{H}}-$), 3.61 (t, $J = 6.6$ Hz, 2H, $-$C$\underline{\text{H}}_2$-OH), 2.02 (m, 4H, $-$C$\underline{\text{H}}_2$-CH=), 1.24–1.54 (m, 12H), 0.89 (t, $J = 5.7$ Hz, 3H, $-$CH$_2$-C$\underline{\text{H}}_3$). *(8*Z*,10*E*)-8,10-Tetradecadienol **5***. ^{1}H NMR: δ: 6.28 (dd, $J = 11.0$, 14.8 Hz, 1H, $-$C^{8}H=C^{9}H-C$^{10}\underline{\text{H}}$=C^{11}H$-$), 5.93 (dd, $J = 10.9$, 11.0 Hz, 1H, $-$C^{8}H=C$^9\underline{\text{H}}$-C^{10}H=C^{11}H$-$), 5.63 (dt, $J = 7.3$, 15.0 Hz, 1H, $-$C^{8}H=C^{9}H-C^{10}H=C$^{11}\underline{\text{H}}-$), 5.31 (dt, $J = 7.4$, 10.8 Hz, 1H, $-$C$^8\underline{\text{H}}$=C^{9}H-C^{10}H=C^{11}H$-$), 3.61 (t, $J = 6.5$ Hz, 2H, $-$C$\underline{\text{H}}_2$-OH), 2.06-2.16 (m, 4H, $-$C$\underline{\text{H}}_2$-CH=), 1.28-1.65 (m, 12H), 0.89 (t, $J = 7.2$ Hz, 3H, $-$CH$_2$-C$\underline{\text{H}}_3$). EI-MS [m/z (relative intensity)]: 210 (M^+, 34), 192 (6), 135 (8), 122 (7), 121 (18), 111 (7), 110 (15), 109 (17), 108 (7), 107 (13), 98 (10), 97 (10), 96 (43), 95 (33), 94 (13), 93 (25), 91 (7), 83 (9), 82 (38), 81 (75), 80 (21), 79 (38), 77 (8), 69 (10), 68 (25), 67 (100), 55 (31), 54 (33), 43 (12), 41 (28).

*(8*E*,10*E*)-8,10-Tetradecadienyl Acetate (**6**; Figure 2).* Pyridine (2 ml) and acetic anhydride (0.5 ml) were added to compound **4** (0.200 g, 0.95 mmol) at room temperature, and the mixture was left in a refrigerator overnight. The next day it was poured into ice-water and extracted with hexane. The extract was dried and chromatographed to yield **6** (0.205 g, 91%). No loss in isomeric purity was observed. ^{1}H NMR: δ: 5.97 (m, 2H, $-$CH=C$\underline{\text{H}}$-C$\underline{\text{H}}$=CH$-$), 5.54 (m, 2H, $-$C$\underline{\text{H}}$=CH-CH=C$\underline{\text{H}}-$), 4.01 (t, $J = 6.5$ Hz, 2H, $-$C$\underline{\text{H}}_2$-COO$-$), 2.08 (m, 4H, $-$C$\underline{\text{H}}_2$-CH=), 2.04 (s, 3H, C$\underline{\text{H}}_3$-COO$-$), 1.22-1.50 (m, 12H), 0.88 (t, $J = 5.6$ Hz, 3H, $-$CH$_2$-C$\underline{\text{H}}_3$). EI-MS [m/z (relative intensity)]: 252 (M^+, 44), 192 (33), 163 (7), 149 (14), 136 (9), 135 (27), 124 (7), 123 (7), 122 (14), 121 (40), 110 (28), 109 (21), 108 (16),

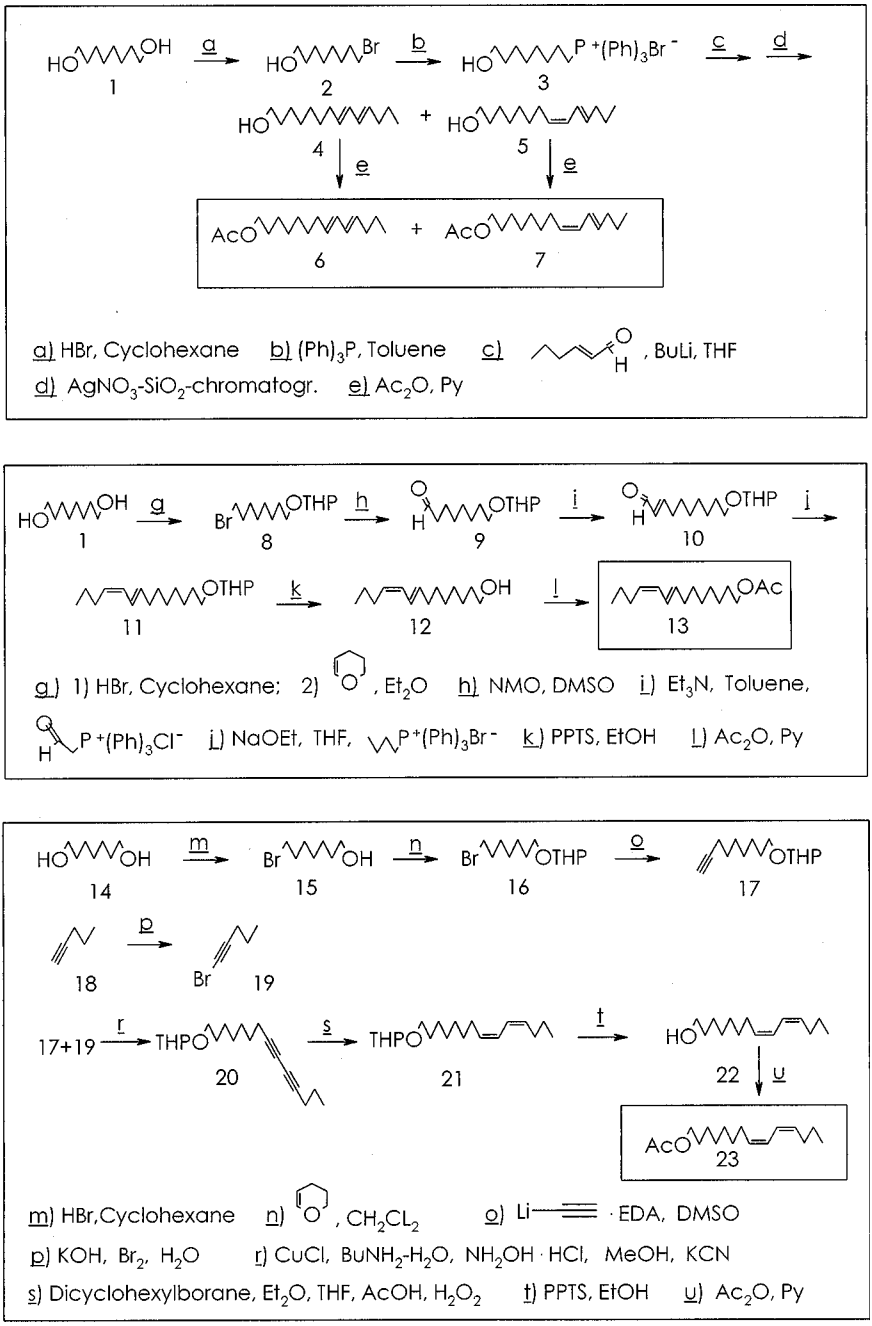

Fig. 2. Schemes of the syntheses of 8,10-tetradecadienols and their acetates.

107 (22), 97 (8), 96 (44), 95 (33), 94 (23), 93 (38), 91 (8), 83 (7), 82 (38), 81 (72), 80 (35), 79 (7), 78 (8), 69 (10), 68 (22), 67 (100), 66 (8), 55 (28), 54 (24), 43 (51), 41 (24).

*(8Z,10*E*)-8,10-Tetradecadienyl Acetate (**7**; Figure 2).* Acetylation of **5,** as described above for **4**, gave **7** in 88% yield. Minor isomerization products were separated by liquid chromatography on $AgNO_3$/silica gel to yield 99% isomerically pure acetate **7**. ^{1}H NMR: δ: 6.28 (dd, $J = 11.0, 14.8$ Hz, 1H, $-C^8H{=}C^9H$-$C^{10}\underline{H}{=}C^{11}H-$), 5.93 (dd, $J = 10.9, 11.0$ Hz, 1H, $-C^8H{=}C^9\underline{H}$-$C^{10}H{=}C^{11}H-$), 5.65 (dt, $J = 7.3, 15.0$ Hz, 1H, $-C^8H{=}C^9H$-$C^{10}H{=}C^{11}\underline{H}-$), 5.30 (dt, $J = 7.4, 10.8$ Hz, 1H, $-C^8\underline{H}{=}C^9H$-$C^{10}H{=}C^{11}-$), 4.02 (t, $J = 6.6$ Hz, 2H, $-C\underline{H}_2$-COO–), 2.10 (m, 4H, $-C\underline{H}_2$-CH=), 2.03 (s, 3H, $C\underline{H}_3$-COO–), 1.26–1.40 (m, 12H), 0.90 (t, $J = 6.8$ Hz, 3H, $-CH_2$-$C\underline{H}_3$). EI-MS [m/z (relative intensity)]: 252 (M^+, 37), 192 (33), 163 (7), 149 (18), 136 (9), 135 (25), 124 (7), 122 (15), 121 (42), 110 (29), 109 (19), 108 (15), 107 (22), 97 (8), 96 (43), 95 (35), 94 (25), 93 (38), 91 (7), 83 (8), 82 (42), 81 (77), 80 (35), 79 (63), 78 (7), 77 (8), 69 (9), 68 (23), 67 (100), 66 (7), 55 (31), 54 (26), 43 (53), 41 (28).

8-Bromo-1-(2-tetrahydropyranyloxy)-octane (**8**; Figure 2) was synthesized as described by Miyashita et al. (1977). 8-(2-Tetrahydropyranyloxy)-octanal (**9**; Figure 2) was made based on Ando et al. (1988). 4-(*E*)-10-(2-Tetrahydropyranyloxy)-2-decenal(**10**, Figure 2) was made according to Ando et al. (1985). (8*E*,10*Z*)-1-(2-Tetrahydropyranyloxy)-8,10-tetradecadiene (**11**, Figure 2) was synthesized based on the methods published by Vinczer et al. (1988).

*(8*E*,10*Z*)-8,10-Tetradecadienol (**12**; Figure 2).* Deprotection of **11** (2.2 g, 7.5 mmol) was performed in EtOH (25 ml) at 55°C for 6 hr in the presence of pyridinium tosylate (188 mg, 0.75 mmol) as a catalyst. Evaporation of the ethanol and chromatography yielded a crude product from which 0.86 g (55%) 97% isomerically pure **12** was obtained after crystallization from pentane. Chromatography on $AgNO_3$-impregnated silica gel enriched the isomeric purity up to 99.5%. ^{1}H NMR: δ: 6.32 (dd, $J = 10.9, 15.0$ Hz, 1H, $-C^8H{=}C^9\underline{H}$-$C^{10}H{=}C^{11}H-$), 5.95 (dd, $J = 10.6, 10.9$ Hz, 1H, $-C^8H{=}C^9H$-$C^{10}\underline{H}{=}C^{11}H-$), 5.64 (dt, $J = 7.0, 15.1$ Hz, 1H, $-C^8\underline{H}{=}C^9H$-$C^{10}H{=}C^{11}H-$), 5.30 (dt, $J = 7.5, 10.9$ Hz, 1H, $-C^8H{=}C^9H$-$C^{10}H{=}C^{11}\underline{H}-$), 3.63 (t, $J = 6.9$ Hz, 2H, $-C\underline{H}_2$-OH), 1.90–2.22 (m, 4H, $-C\underline{H}_2$-CH=), 1.21–1.72 (m, 12H), 0.93 (t, $J = 7.6$ Hz, 3H, $-CH_2$-$C\underline{H}_3$). EI-MS [m/z (relative intensity)]: 210 (M^+, 49), 192 (13), 176 (13), 167 (8), 135 (9), 125 (8), 123 (17), 122 (7), 121 (25), 110 (17), 109 (23), 107 (15), 98 (9), 97 (18), 96 (47), 95 (35), 94 (24), 93 (19), 91 (17), 87 (10), 85 (12), 83 (8), 82 (44), 81 (82), 80 (24), 79 (64), 71 (23), 70 (7), 69 (15), 68 (24), 67 (100), 66 (9), 55 (25), 54 (32), 41 (17).

*(8*E*,10*Z*)-8,10-Tetradecadienyl acetate (**13**; Figure 2).* The alcohol **12** was acetylated in the manner described above for compounds **6** and **7**. Acetylation gave **13** in 87% yield. Minor isomerization products were separated by chromatography on $AgNO_3$-impregnated silica gel to yield 99.5% isomerically pure acetate

13. ^{1}H NMR: δ: 6.32 (dd, $J = 10.9, 15.0$ Hz, 1H, $-C^8H{=}C^9\underline{H}\text{-}C^{10}H{=}C^{11}H-$), 5.95 (dd, $J = 10.6, 10.9$ Hz, 1H, $-C^8H{=}C^9H\text{-}C^{10}\underline{H}{=}C^{11}H-$), 5.64 (dt, $J = 7.0, 15.1$ Hz, 1H, $-C^8\underline{H}{=}C^9H\text{-}C^{10}H{=}C^{11}H-$), 5.30 (dt, $J = 7.5, 10.9$ Hz, 1H, $-C^8H{=}C^9H\text{-}C^{10}H{=}C^{11}\underline{H}-$), 4.05 (t, $J = 6.8$ Hz, 2H, $-C\underline{H}_2\text{-}COO-$), 1.90–2.16 (m, 4H, $-C\underline{H}_2\text{-}CH{=}$), 2.04 (s, 3H, $C\underline{H}_3\text{-}COO-$), 1.30–1.70 (m, 12H), 0.91 (t, $J = 7.3$ Hz, 3H, $-CH_2\text{-}C\underline{H}_3$). EI-MS [$m/z$ (relative intensity)]: 252 (M^+, 39), 192 (32), 149 (12), 136 (8), 135 (26), 123 (7), 122 (14), 121 (40), 110 (28), 109 (19), 108 (15), 107 (21), 97 (7), 96 (42), 95 (32), 94 (20), 93 (36), 91 (8), 83 (7), 82 (36), 81 (72), 80 (34), 79 (58), 69 (8), 68 (21), 67 (100), 55 (30), 54 (24), 43 (52), 41 (27).

7-Bromoheptanol (**15**; Figure 2) was obtained by a procedure similar to the one described above for 8-bromooctanol, **2**. For 7-Bromo-1-(2-tetrahydropyranyloxy)-heptane (**16**; Figure 2), the alcohol **15** was protected as its THP–ether by the usual method, which gave **16** in 95% yield. ^{1}H NMR: δ: 4.57 (t, $J = 3$ Hz, 1H), 3.31–3.86 (m, 4H, $-C\underline{H}_2\text{-}O-$), 3.63 (t, $J = 6.6$ Hz, 2H, $-C\underline{H}_2Br$), 1.30–1.81 (m, 16H). 1-(2-Tetrahydropyranyloxy)-8-nonyne (**17**; Figure 2) was prepared according to Rossi et al. (1981); Gardette et al. (1983).

*1-Bromo-1-pentyne (**19**; Figure 2).* Potassium hydroxide (67.2 g, 1.2 mol) was dissolved in water (370 ml). Bromine (32 g, 0.2 mol) was added dropwise at 0°C during 30 min, and 1-pentyne (**18**) (13.0 g, 0.19 mol) was then added to the solution, while the temperature was maintained at 0°C. The reaction mixture was stirred for 14 hr at room temperature. The product was extracted with a pentane–diethyl ether mixture (1:1), and the extract was dried and concentrated. Distillation gave 23.9 g of **19,** an 85% yield. ^{1}H NMR: δ: 2.18 (t, $J = 7.0$ Hz, 2H, $-C\underline{H}_2\text{-}C{\equiv}$), 1.54 (td, $J = 7.3, 14.3$ Hz, 2H, $-C\underline{H}_2-$), 0.98 (t, $J = 7.4$ Hz, 3H, $-C\underline{H}_3$).

1-(2-Tetrahydropyranyloxy)-8,10-tetradecadiyne (**20**; Figure 2) was obtained by a procedure described by Svirskaya et al. (1980); Chisholm et al. (1985); De Jarlais and Emken (1987). (8*Z*,10*Z*)-1-(2-Tetrahydropyranyloxy)-8,10-tetradecadiene (**21**; Figure 2) was synthesized according to Svirskaya et al. (1980); Chisholm et al. (1985); De Jarlais and Emken, (1987).

*(8Z,10Z)-8,10-Tetradecadienol (**22**; Figure 2).* Compound **21** (1.78 g, 6.1 mmol) was added to pyridinium tosylate in ethanol (25 ml). The mixture was warmed at 55°C for 4 hr. Evaporation of the ethanol, followed by chromatography, yielded 1.2 g (80%) of **22** with an isomeric purity of 97%. After crystallization from pentane at −20°C, no isomers were detected by GC. ^{1}H NMR: δ: 6.28 (m, 2H, $-CH{=}C\underline{H}\text{-}C\underline{H}{=}CH-$), 5.47 (m, 2H, $-C\underline{H}{=}CH\text{-}CH{=}C\underline{H}-$), 3.65 (t, $J = 6.7$ Hz, 2H, $-C\underline{H}_2\text{-}O-$), 2.18 (m, 4H, $-C\underline{H}_2\text{-}CH{=}$), 1.56 (m, 2H), 1.26–1.46 (m, 10H), 0.94 (t, $J = 7.3$ Hz, 3H, $-C\underline{H}_3$). EI-MS [m/z (relative intensity)]: 210 (M^+, 26), 192 (8), 135 (12), 122 (7), 121 (19), 111 (8), 110 (18), 109 (15), 108 (8), 107 (12), 98 (12), 97 (11), 96 (45), 95 (34), 94 (14), 93 (25), 91 (7), 83 (9), 82 (42), 81 (84), 80 (22), 79 (42), 77 (8), 69 (10), 68 (27), 67 (100), 55 (33), 54 (35), 43 (11), 41 (31).

*(8Z,10Z)-8,10-Tetradecadienyl acetate (**23**; Figure 2).* The acetylation procedure described above gave the acetate **23** in 92% yield. No isomerization occurred during the acetylation. ^{1}H NMR: δ: 6.28 (m, 2H, —CH=C<u>H</u>-C<u>H</u>=CH—), 5.56 (m, 2H, —C<u>H</u>=CH-CH=C<u>H</u>—), 4.08 (t, $J = 6.7$ Hz, 2H, —C<u>H$_2$</u>-O—), 2.17 (m, 4H, —C<u>H$_2$</u>-CH=), 2.08 (s, 3H, C<u>H$_3$</u>COO—), 1.34–1.67 (m, 12H), 0.94 (t, $J = 7.4$ Hz, 3H, —C<u>H$_3$</u>). EI-MS [m/z (relative intensity)]: 252 (M^+, 24), 193 (8), 192 (43), 163 (7), 149 (13), 136 (10), 135 (26), 124 (6), 123 (7), 122 (14), 121 (39), 110 (27), 109 (18), 108 (16), 107 (22), 97 (8), 96 (40), 95 (35), 94 (24), 93 (40), 91 (9), 83 (8), 82 (40), 81 (81), 80 (35), 79 (66), 78 (7), 77 (8), 69 (11), 68 (23), 67 (100), 66 (8), 55 (32), 54 (37), 43 (54), 41 (28).

Trapping Tests

The trapping tests using virgin calling females were carried out in the vicinity of Vilnius in eastern Lithuania from April 20 to May 20, 1990. Two-day-old virgin calling females were placed in a 30-ml wire mesh cylinder containing a sponge with a solution of 5% of sucrose in water that was replaced every two days. The container was placed in an opaque white Atracon A delta trap containing an exchangeable bottom (11 × 18 cm), coated with Pestifix glue. Ten traps, each containing one female, were placed about 1 m above the ground on a branch of common honeysuckle shrub with a distance of >10 m between traps and inspected daily. Females were replaced by young females when they reached age 10 days of or were found to be not calling.

The field tests of potential synthetic sex pheromone components were carried out at the same locality in the vicinity of Vilnius from May 19 to June 15, 2000. The compounds were dissolved in hexane (Merck p.a.) and, either alone or in binary mixtures, soaked from the inside into the walls of red rubber tube dispensers (18 × 15 mm). Samples of 200 μg 8*E*,10*E*–14:OAc/dispenser; 0.2 μg 8*E*,10*E*–14:OH/dispenser; 200 μg 8*E*,10*E*–14:OAc + 0.2 μg 8*E*,10*E*–14:OH/dispenser and 50 μl hexane/dispenser (as a control) were tested. Five replications of each lure were used. In order to diminish the impact of biotopic variation on the trapping results, all traps of one replication set were moved to the location of traps of another replication set every five days.

RESULTS

Biological Characteristics of Ph. emberizaepenella Sample. After the winter diapause, 172 moths were obtained from pupae collected in the autumn of 1989 (42% of the pupae were infected by parasites and 12% died due to other causes). In all, 748 moths emerged from the mined leaves collected in the autumns of 1996–1998, and 82 moths emerged from the pupae collected in the summer of 1999. All of the adult moths were females. In addition to the individuals obtained from

pupae, we collected 134 moths outdoors from April 20 through May 20, 1990 with an entomological net, and even in this group all specimens were females. Under laboratory conditions the average length of life of the adult female was 15 ± 5 days ($N = 37$).

Parthenogenetic Mode of Reproduction. Normally developed caterpillars emerged from unfertilized eggs laid by virgin females of *Ph. emberizaepenella*. Host plant twigs with leaves containing offspring of three *Ph. emberizaepenella* females remained suitable as food sources for the larvae long enough to allow them to form typical pupae. Seventeen adults of the F_1 generation were obtained from the pupae, and all of them were females.

Calling Behavior of Females. By observing the behavior of virgin females in nature, we established that they preferred to stay on the underside of the host plant leaves, where they remained stationary, while exhibiting the calling posture. The most typical elements of this posture were the following: wings slightly spread and lowered, abdominal tip dorsally curved and distal abdominal segments protruded, and antennae placed along the wings (Figure 1B).

Under laboratory conditions, females started to call on the second day after emergence. The peak of activity was registered 0.5–3 hr after the beginning of the light phase. Nearly 100% of the females ($N = 37$) were active during the calling peak. The total duration of the active period within the group of 2- to 4-day-old females was about 6 hr/day (Figure 3).

Chemical Identification of Compounds Collected from Calling Females. Two compounds were found to be specific for the calling periods of virgin

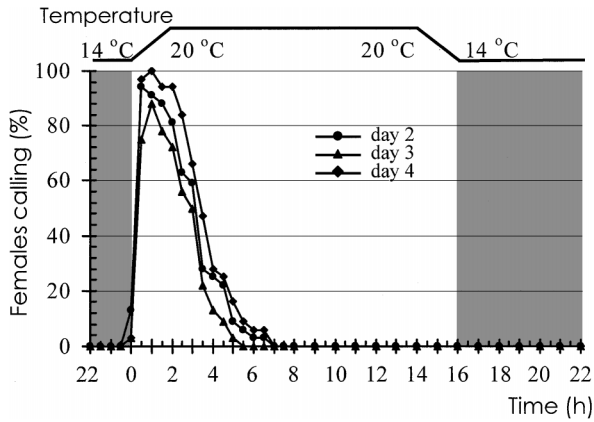

FIG. 3. Diurnal rhythm of calling activity of virgin *Phyllonorycter emberizaepenella* females under laboratory conditions. Shaded areas: scotophase, white area: photophase. The females were not found calling during the first day after emergence. $N = 32$ females in each day of the observation.

Ph. emberizaepenella females, when GC-MS chromatograms from calling and noncalling periods were compared (Figure 4AB). One of these compounds showed m/z 61 but not m/z 60, typical diagnostic ions of acetates and fatty acids, respectively. The diagnostic ion, m/z 192 (M-60), indicated di-unsaturation and a chain length of C_{14}. In addition, the well-expressed molecular ion m/z 252 ($M^{+\cdot}$) confirmed that the compound was a tetradecadienyl acetate and indicated that the double bonds were conjugated (Figure 5A).

The second compound showed a fragmentation pattern similar to that of the tetradecadienyl acetate. The presence of the diagnostic ions m/z 31 and m/z 210 ($M^{+\cdot}$) instead of m/z 61 and m/z 252 ($M^{+\cdot}$), respectively, indicated that the second compound was a tetradecadienol (Figure 5B).

In all unsaturated sex pheromone components identified from species of the genus *Phyllonorycter*, double bonds occurred only at even positions (Mozūraitis et al., 1999; Arn et al., 2001). Therefore, we compared the retention times of the two compounds collected from the calling females with those of synthetic 8,10- and 10,12-tetradecadienols and their acetates. This comparison showed that the volatiles released by the *Ph. emberizaepenella* females were 8*E*,10*E*–14:OAc and 8*E*,10*E*–14:OH (Table 1). A comparison of the mass spectra of the compounds collected from calling females with those of synthetic standards confirmed the results of the GC analyses.

Volatiles from all 12 calling females contained a trace amount of 8*E*,10*E*–14:OH relative to the acetate, detected only by using the most abundant diagnostic ions m/z 67, m/z 81 and m/z 210 ($M^{+\cdot}$) (Figure 5B).

Trapping Experiments. During the trapping period, which was about twice as long as the average lifetime of adult females, neither traps containing virgin calling females nor lures made up with potential sex pheromones captured any males, in spite of the large number of moths of this species in the habitat. These facts indicated that the probability of finding a male among moths of the first generation of this population was extremely small, close to zero. Consequently, 8*E*,10*E*–14:OAc and the corresponding alcohol have to be considered as potential sex pheromone components of this leaf-miner species.

DISCUSSION

The development of adults from unfertilized eggs, as well as the absence of males in both generations, confirmed the previous report (Būda et al., 1991) on parthenogenesis of *Ph. emberizaepenella* species. When only females develop from unfertilized eggs, the term thelytoky is applicable for characterizing the parthenogenesis. Regular thelytoky is rare among the Lepidoptera, but it has been found in some species belonging to the families Psychide, Tineidae, and Lymantridae (reviews: Cockayne, 1938; Suomalainen, 1950; Went, 1984). As far

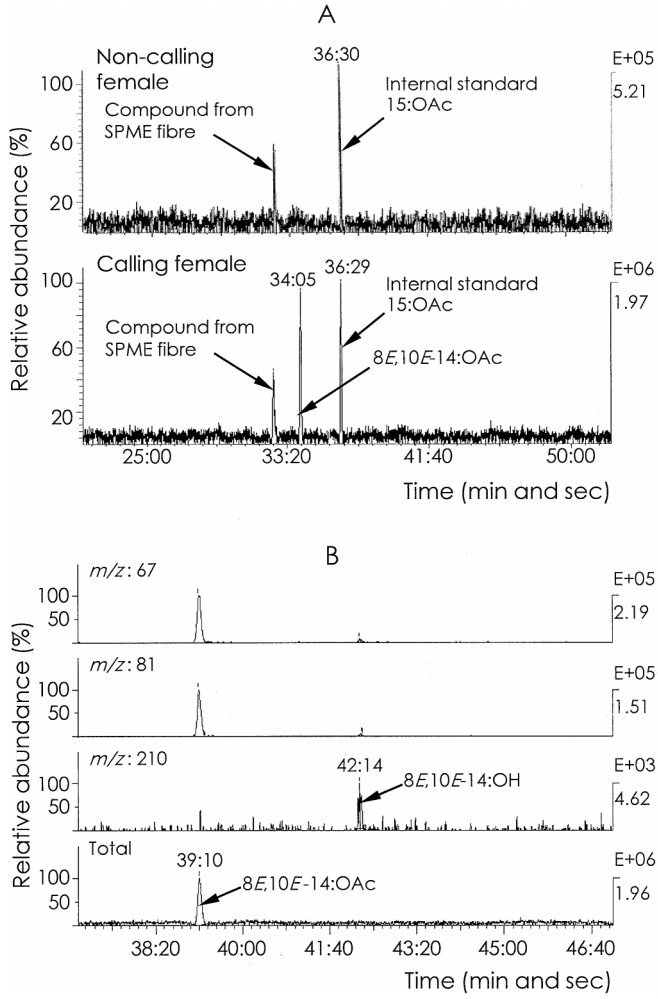

FIG. 4. Total and selected ion chromatogram records of volatiles collected from one *Phyllonorycter emberizaepenella* female. (A) Total ion chromatogram in the range m/z 30–400; Noncalling and calling indicate that volatiles were obtained during noncalling and calling periods of a female, respectively; DB-5 fused silica capillary column (30 m $\times$ 0.25-mm ID, 0.25-μm film thickness). (B) Selected ion chromatograms where m/z 67 and m/z 81 ion fragments indicate unsaturation; m/z 210 is the molecular ion characteristic of tetradecadienols; Total represents chromatogram in the ion range m/z 30–400; HP-Wax fused silica capillary column (30 m $\times$ 0.25 mm ID, 0.25-μm film thickness); m/z indicates the ratio of the mass of the ion to the number of charges on it. The numbers at the upper-right corner of the chromatograms, for example, E+05 5.21, represent the number of counts related to the abundance of the ions formed and E+05 5.21 has to be read as 5.21×10^5.

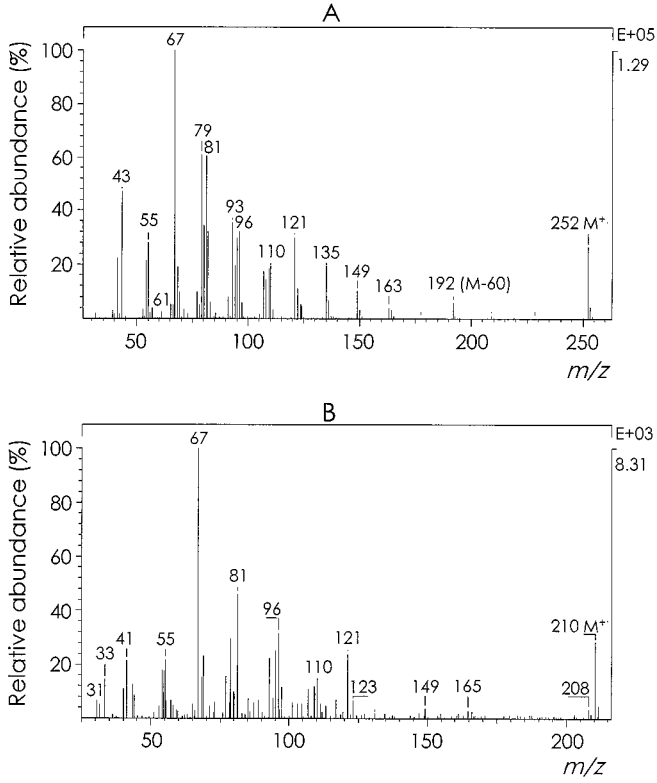

FIG. 5. Mass spectra of the compounds obtained only during calling periods of *Phyllonorycter emberizaepenella* females: (A) 8*E*,10*E*-14:OAc; (B) 8*E*,10*E*-14:OH; *m*/*z* indicates the ratio of the mass of the ion to the number of charges on it; $M^{+\cdot}$ represents the molecular ion; the number at the upper-right corner of the mass spectrum, e.g., E+0.5 1.29, represents the number of counts related to the abundance of the ions formed and E+0.5 1.29 has to be read as 1.29×10^5.

as we know, *Ph. emberizaepenella* is the first case of thelytokous parthenogenesis found in the Gracillariidae family.

Ph. emberizaepenella females demonstrated a calling posture similar to that of other species of the same genus that we have investigated: *Ph. ulmifoliella* (Hb.) (Mozūraitis et al., 1997), *Ph. acerifoliella* (Z.) and *Ph. heegerella* (Z.) (Mozūraitis et al., 2000), and *Ph. sorbi* (Frey.) and *Ph. strigulatella* (Lien *et* Z.) (Mozūraitis, 2000). This posture is also similar to that of the pyralids, *Ephestia* (=*Anagasta*) *kuehniella* (Z.) (Traynier, 1968) and *Plodia interpunctella* (Hb.) (Brady and Smithwich, 1968).

TABLE 1. RETENTION TIMES OF COMPOUNDS OBTAINED FROM CALLING *Phyllonorycter enberizaepenella* FEMALES, AND SYNTHETIC 8,10- AND 10,12-TETRADECADIENOLS AND THEIR ACETATES, WHEN PASSING THROUGH TWO CAPILLARY COLUMNS

Compound	Retention time (min:sec)	
	Polar column (HP-wax)	Unpolar column (DB-5)
From female		
(8*E*,10*E*)-8,10-tetradecadienyl acetate	39:10	34:05

(10*E*,12*E*)-10,12-tetradecadienyl acetate	39:47	34:18
(10*Z*,12*Z*)-10,12-tetradecadienol	42:53	26:43
(10*Z*,12*E*)-10,12-tetradecadienol	42:11	25:35
(10*E*,12*Z*)-10,12-tetradecadienol	42:43	26:31
(10*E*,12*E*)-10,12-tetradecadienol	42:30	26:15

A distinct diurnal rhythm of the calling behavior was established on the basis of the calling posture. *Ph. emberizaepenella* females were active after the start of the light period of a day, which is a common calling time for other species of the same genus [*Ph. ulmifoliella* (Mozūraitis et al., 1997); *Ph. ringoniella* (Matsumura) (Boo and Jung, 1998); *Ph. acerifoliella* and *Ph. heegerella*, (Mozūraitis et al., 2000), *Ph. sorbi* and *Ph. strigulatella* (Mozūraitis, 2000)] and for some species of other families (Dreisig, 1986; McNeil, 1991, Tóth et al., 1995).

Both compounds identified from calling *Ph. emberizaepenella* females were new for the family Gracillariidae, but their chemical structures corresponded to the general pattern of the structures determined for sex pheromones of other *Phyllonorycter* species. These compounds were aliphatic C_{12}–C_{14} straight-chain, saturated, mono- or di-unsaturated acetates or alcohols, with *Z* or *E* double bonds occurring in positions 4, 8, 10, and 12 (Mozūraitis et al., 1999; Arn et al., 2001).

Assuming that both compounds were collected from virgin females only during calling periods, and their chemical structures corresponded to the general pattern of the ones determined for sex pheromones from other *Phyllonorycter* species, it is possible that 8*E*,10*E*–14:OAc alone or in a binary mixture with a

corresponding alcohol is a sex pheromone conponent of *Ph. emberizaepenella* species.

All these characteristics of chemical communication of *Ph. emberizaepenella* females are very similar or even identical to those of Lepidoptera with the usual amphimictic mode of reproduction. In spite of the parthenogenetic reproduction during which complete reduction of sexual behavior might be expected, the females of this leafmining species exhibited the calling posture and released potential sex pheromone with the diurnal rhythm of such behavior that is inherent in the process. Why do parthenogenetically reproducing females still call and synthesize and release potential sex pheromone in the absence of males?

A reduction of sexual behavior involves changes in the physiology of an organism. From the viewpoint of the theory of optimality (Rozen, 1969), these changes are justified only when they are more beneficial than the cost of carrying out all necessary modifications. The benefit of the absence of male finding would include both resources and time saved from biosynthesis of a sex pheromone, sex pheromone release, and exposure to potential natural enemies such as egg parasitoids that use moth sex pheromones to locate resources. While the costs include those for turning off sex pheromone biosynthesis and calling behavior.

The greatest benefit would be achieved by turning off both calling behavior and biosynthesis of sex pheromones. Unfortunately, there are no data available on these processes in the family Gracillariidae. Thus, our discussion must be based on knowledge of other lepidopteran taxa.

In most investigated lepidopteran species, sex pheromone biosynthesis requires pheromone biosynthesis activating neuropeptide (PBAN) or PBAN-like compounds (Ramaswamy, 1997; Tillman et al., 1999). To turn off production of a single peptide would not be complicated or costly if its role is not multifunctional. However, in some species, pheromone glands are able to produce sex pheromone through the diel period without the presence of PBAN, and this competence is achieved as a result of developmental–metamorphic events (Tang et al., 1989, 1991). The prediction of a mechanism and the cost of switching off sex pheromone biosynthesis in these species is unclear.

Calling in Lepidoptera is usually controlled by neural outputs from the brain or other neuronal centers (Sasaki et al., 1983; Itagaki and Corner, 1986; Tang et al., 1987; Christensen et al., 1994). Thus, the stopping of calling behavior should not be costly. However, more complex regulation of pheromone release occurs in two migratory noctuid moth species. In the true armyworm moth, *Pseudatelia unipunctata* (Haworth), juvenile hormone (JH) must be continuously present to maintain calling behavior once initiated (Cusson and McNeil, 1989a), and the same hormone is important for ovarian development (Cusson and McNeil, 1989b). The similar function of JH has been demonstrated in black cutworm moth, *Agrotis ipsilon* (Hufnagel) (Gadenne et al., 1993; Picombon et al., 1995). Turning off calling by inhibiting production of JH would lead to termination of ovarian development, thus

disturbing reproduction. In such an event, the cost for termination of calling and sex pheromone production obviously would overcome the benefit, and it is most likely that females would continue to release signaling compounds despite the complete lack of males. Possibly, similar regulation of pheromone release might occur in parthenogenetically reproducing *Ph. emberizaepenella* species.

The theoretical speculation that in thelytoky, individuals obtain advantages due to a reduction in their sexual behavior when there is no need to find a sexual partner clearly needs re-examination.

Acknowledgments—We thank Dr. G. Aulin-Erdtman for valuable discussions and language revision of the manuscript and two anonymous reviewers for valuable comments and kind suggestions. This study was supported by the Agricultural and Forest Research Council (Sweden) and by the Swedish Institute.

(Received March 14, 2001; accepted February 2, 2002)

Abstract—Host-recognizing kairomones for the stinging behavior of the parasitic wasp, *Anisopteromalus calandrae*, were identified on host azuki bean weevil larvae, *Callosobruchus chinensis* (L.). The kairomones were extracted with acetone from Chinese green beans, from which emerged wasps and host weevils had been removed. The kairomones are a mixture of triacylglycerols and fatty acids, each of which is separately active, and with no observable synergistic effect between them. These compounds are known to be constituents of an oviposition-marking pheromone of host azuki bean weevils. However, they differ from the previously reported saturated hydrocarbons and diacylglycerols of the kairomone that another parasitic wasp, *Dinarmus basalis*, uses for the host recognition of *C. chinensis*. Thus, *A. calandrae* and *D. basalis* selectively utilize different constituents of the oviposition-marking pheromone of *C. chinensis* as host-recognizing kairomones.

Key Words—*Anisopteromalus calandrae*, parasitic wasp, oviposition-marking pheromone, host-recognizing kairomone, azuki bean weevil, *Callosobruchus chinensis*.

INTRODUCTION

The azuki bean weevil, *Callosobruchus chinensis* (L.) (Coleoptera: Bruchidae) is a serious pest of stored *Vigna* legumes, such as azuki beans (*V. angularis*), cowpea beans (*V. catiang*), and Chinese green beans (*V. radiata*). The physiology

and ecology of this multivoltine insect has been widely researched, and it had also been used as a test insect against insecticides. Consequently, the chemical ecology of this weevil has been well studied, including that of oviposition-marking pheromones (Ohshima et al., 1973; Sakai et al., 1986; Honda and Ohsawa, 1990), a copulation-release pheromone (Tanaka et al., 1981), and oviposition stimulants (Ueno et al., 1990; Matsumoto et al., 1994; Tebayashi et al., 1995).

The parasitic wasp, *Anisopteromalus calandrae* (Howard) (Hymenoptera: Pteromalidae), is an important natural parasite of larvae of the maize weevils, *Sitophilus zeamais* Motschulsky, a major pest of stored corn, *Zea mays* L. (Williams and Floyd, 1971; Arbogast and Mullen, 1990; Smith, 1992). This wasp also attacks several other bruchid weevils, including azuki bean weevils (Utida and Nagasawa, 1949; Okamoto, 1971, 1972), rice weevils, *S. oryzae* (L.) (Press et al., 1984; Cline et al., 1985), granary weevils, *S. granarius* (L.) (Ghani and Sweetman, 1955; van den Assem et al., 1984), and Mexican bean weevils, *Zabrotes subfasciatus* Bohman.

Adults of *A. calandrae* are sexually dimorphic; females are entirely black and ca. 2.5 mm in length while males have partly milk-white abdomens and are ca. 2.0 mm in length. When an azuki bean or Chinese green bean containing host larvae is presented to a female, the following sequential behaviors are observed: the female walks and examines the surface of the bean with antennal tapping, bends her abdomen vertically, stings her ovipositor through the surface of the bean (stinging behavior), and lays an egg on the surface of the larva. Stinging behavior is only observed when females locate beans that contain host larvae.

We previously reported that another parasitic wasp, *Dinarmus basalis* (Rondani) (Hymenoptera: Pteromalidae), utilizes the oviposition-marking pheromone of its host azuki bean weevil as a host-recognizing kairomone (Kumazaki et al., 2000). This prompted us to search for similar kairomone(s) in *A. calandrae*, which paratitizes the same larvae. Here, we report that *A. calandrae* utilizes different constituents of the oviposition-marking pheromone of its host azuki bean weevils as host-recognizing kairomones.

METHODS AND MATERIALS

Host and Wasp. Azuki bean weevils and *A. calandrae* were obtained from colonies maintained at Fujii's laboratory, but which had been subsequently reared for several generations on Chinese green beans, *Vigna radiata* (L.) in Suzuki's laboratory. Although Chinese green beans are smaller than azuki beans (ca. 60 mg/bean), azuki bean weevils developed well in this host. The rearing method of the weevil host and *A. calandrae* is reported elsewhere (Kumazaki et al., 2000). Both sexes of wasps were introduced into plastic Petri dishes (9 cm ID $\times$ 20 mm high) containing Chinese green beans in which host larvae were present (ca. 18 days old). Both insect species were reared at 25°C, 60% relative humidity, and 16L:8D

photoregime. Wasps began to emerge 16–18 days after being exposed to infested beans. The newly emerged wasps (not sexed) were either assayed or used for further reproduction.

Prior to the bioassay, 1- to 3-day-old mated, female wasps were individually released into glass Petri dishes (18 mm ID × 13 mm high; mini P, Tsukuba Flat Co.) on an acrylic plate and conditioned overnight. Only females that showed stinging behavior (2 hr) when presented to a bean with host larvae were bioassayed.

Bioassay. In preliminary studies, the active kairomone(s) eliciting the stinging behavior could be extracted with acetone from beans containing host larvae. In addition, the behavior was observed only when the extract was applied to a fresh bean. Based on these observations, the bioassay in this study was conducted as follows. Two fresh green beans were used for each trial; one was treated with 5 μl [1 mg bean equivalent (BE)] of the test sample, and the other was treated with 5 μl of acetone as a control. After evaporation of the solvent, the beans were placed ca. 1 cm apart on a filter paper (3 × 3 cm) inside an 18-mm glass Petri dish. A mated, 2- to 4-day-old female wasp (described above) was released. Her stinging behavior was observed for 15 min, and the number of stings on each bean was recorded. The assay was repeated 15 times for each sample with a different female. Samples were diluted 10-fold with acetone when necessary. Total number of the stinging behaviors for each sample was compared to the control using Wilcoxon's sign test ($P < 0.05$) (Sokal and Rohlf, 1973).

Analytical Methods. Gas chromatography (GC) was performed with three capillary columns: a fused silica CP-Sil 19 CB column (25 m × 0.25 mm, 0.2 μm; Chrompack, Middelburg, The Netherlands), a heat-resisting MP65HT column (25 m × 0.25 mm, 0.1 μm; Quadrex, New Haven, Connecticut, USA) with a Hewlett-Packard 5890 (Palo Alto, California, USA) gas chromatograph, or a bonded-phase FFAP column (25 m × 0.25 mm, 0.25 μm; Quadrex) with a Hitachi 263-30 gas chromatograph (Hitachi, Ltd., Tokyo, Japan), with nitrogen as the carrier gas. The column temperatures were raised from 100 to 230°C at 4°C/min for analyses of fatty acid methyl esters (FFAP and CP-Sil columns; the injector and detector temperature was set at 250°C) and from 300 to 365°C (held for 10 min) at 5°C/min for analyses of triacylglycerols (MP65HT column; the injector and detector temperature was set at 400°C). Mass spectra were measured with a Hitachi M-80B GC mass spectrometer (MS) coupled with a Hitachi 367-0200 gas chromatograph equipped with an Al-clad methylsilicone capillary column (25 m × 0.22 mm, 0.10 μm, Quadrex) (EI, 70 eV). Mass spectra of methyl esters were obtained by GC-MS (column temperature: 120–270°C programmed at 4°C/min) and those of triacylglycerols were measured by the direct inlet method, using helium as the carrier gas. Thin layer chromatography (TLC) was performed with precoated silica gel $60F_{254}$ plates (E. Merck, Darmstadt, Germany). The developing solvent was a mixture of hexane–ether (7:1, v/v) or hexane–ether–acetic acid (70:30:1, v/v). Spots were detected by exposing the sample to iodine vapor or

spraying with 0.02% rhodamine 6G ethanol solution, followed by UV (365 nm; fluorescent spots). The infrared (IR) spectrum was measured with a JASCO IRA-1 spectrometer (Japan Spectroscopic Co. Ltd., Tokyo, Japan) as a liquid film.

Extraction and Fractionation of Kairomone(s). As described above, the kairomone(s) was (were) extracted with acetone only from beans that had contained host larvae. The selection of beans previously infected by host weevils is important as extracts from uninfected beans were not active. The kairomone(s) was (were) extracted from the green beans (2.6 kg, 30 mg/bean) with acetone (2.5 liters $\times$ 2) at room temperature for two days. The extract was dried, and the major part of the residue (40 of 50 g) was partitioned with ether and water. Half of the active layer (14.8 of 30 g) was chromatographed on a silica gel (SiO_2) column (125 g, 3.5 cm ID $\times$ 37 cm, Wako-gel C-200, Wako, Tokyo, Japan) with a stepwise elution of 1.5 liters each of hexane, hexane–ether (90:10 and then 50:50 v/v), ether, and methanol. Only the 10% ether in hexane fraction (10.8 g) was active, and this was checked by TLC (hexane–ether 7:3, v/v) to give three spots (R_fs $= 0.85$, 0.64, and 0.11), in which the last two spots (the R_f 0.11 spot was tailing) were considered to be triacylglycerols (TGs) and fatty acids (FAs), respectively. The fraction was submitted to Florisil column chromatography (WAK Florisil, Wako) to separate the seven fractions of lipids, according to the method of Carroll (1961). The column (150 g, 3.2 cm ID $\times$ 31 cm) was successively eluted with 1.5 liters each of hexane (fraction 1, 0.04 g), hexane–ether [95:5 (fraction 2, 1.0 g), 85:15 (fraction 3), 75:25 (fraction 4), and 50:50 (fraction 5, 1.2 g)], 2% methanol in ether (fraction 6, 1.6 g), and 4% acetic acid in ether (fraction 7, 3.2 g). Fractions 3 and 4 were combined, because they yielded spots with the same R_f value (0.65) in TLC. This combined fraction (named fraction I, 3.2 g,) and fraction 7 were separately active.

Extraction of Triacylglycerols and Fatty Acids from Chinese Green Beans. Because we used previously infected Chinese green beans, it is possible that the source of the TGs and FAs were derived from green beans. To investigate this possibility, 200 g of crushed fresh green beans were extracted with acetone (200 ml $\times$ 2) for 24 hr. After evaporation of the solvent, the residue was partitioned with ether and water. The ether layer (0.47 g) was submitted to SiO_2 column chromatography (5 g, 10 mm ID $\times$ 14 cm) with stepwise elution of hexane, hexane–ether (90:10, 50:50 v/v), ether, and methanol (50 ml each). TGs and FAs were eluted in 10% ether in hexane (390.7 mg) and analyzed with Florisil column chromatography (5 g, 10 mm ID $\times$ 14 cm). The column was successively eluted with 50 ml each of hexane, hexane–ether (95:5, 85:15, 75:25, and 50:50 v/v), 2% methanol in ether, and 4% acetic acid in ether.

Surface Hexane Washing from Previously Infected Green Beans. Approximately 40 g of green beans were placed into each of five 9-cm plastic Petri dishes, and ca. 150 adult host weevils were added to each dish. After eight days, all of the adult weevils had died and were removed with a sieve, but the hatched larvae had invaded the beans. The surfaces of these beans were washed with hexane for

30 sec, and the TGs and FAs were identified with TLC. The same total volume (200 g) of fresh green beans that had not been invaded by weevils were extracted with hexane for 30 sec as a control.

Synthesis of Triacylglycerols. TGs were synthesized by the following two methods. For method A, commercially obtained 1-monoacylglycerols or 1,3-diacylglycerols (Wako) were treated overnight at 60°C with the desired acyl chlorides in the presence of pyridine. The crude TGs were purified by SiO_2 column chromatography and eluted with 10% ether in hexane. The following nine TGs were prepared (acronyms and yields are given in parentheses): 1-oleoyl-2,3-dipalmitoylglycerol (1O2P3P, 26.4 mg, 94.1%), 1,3-dioleoyl-2-palmitoylglycerol (1O2P3O, 36.7 mg, 89.6%), 1,2-dioleoyl-3-palmitoylglycerol (1O2O3P, 22.1 mg, 76.5%), 1,2-dilinoleoyl-3-palmitoylglycerol (1L2L3P, 10.0 mg, 78.1%), 2-linoleoyl-1-oleoyl-3-palmitoylglycerol (1O2L3P, 4.6 mg, 59.6%), 1,3-dioleoyl-2-stearoylglycerol (1O2S3O, 35.3 mg, 50.0%), 2-linoleoyl-1-oleoyl-3-stearoylglycerol (1O2L3S, 10.4 mg, 73.2%), 2-linoleoyl-1,3-dioleoylglycerol (1O2L3O, 6.9 mg, 65.0%), and 1,2-dilinoleoyl-3-oleoylglycerol (1L2L3O, 4.4 mg, 55.2%).

For method B, three TGs were prepared according to Golding et al. (1993). 2,2-Dimethyl-1,3-dioxolane-4-methanol (100 μl, 0.8 mmol, Wako) was dissolved in 1.5 ml pyridine, to which excess acyl chlorides were added. This was stirred overnight at 60°C. The crude monoacylesters of 2,2-dimethyl-1,3-dioxolane-4-methanol were treated by SiO_2 column chromatography and eluted with 10% ether in hexane to yield pure esters. The acetonides of the esters were cleaved by treating with trifluoroacetic acid in 80% THF aqueous solution and stirring at 0°C in (Leblanc et al., 1986). The crude 1-monoacylglycerols were purified by SiO_2 column chromatography and then reacted with acyl chlorides (two molar equivalents) as described in A: 1-palmitoleoyl-2,3-dipalmitoylglycerol (1P'2P3P, 6.1 mg, 13.4%), 1-linoleoyl-2,3-dipalmitoylglycerol (1L2P3P, 30.3 mg, 17.4%), and 3-oleyl-1,2-distearoylglycerol (1S2S3O, 55.9 mg, 6.2%).

Some acyl chlorides were prepared by the reaction of the desired acids with oxalyl chloride. For example, palmitic acid (20 mg, 0.08 mmol) was dissolved in dry benzene (1 ml), to which equimolar oxalyl chloride was added, and the mixture was refluxed for 1 hr. After benzene and oxalyl chloride were removed, palmitoyl chloride (21.7 mg) was obtained. Palmitoleoyl chloride and stearoyl chloride were prepared in the same way.

RESULTS

Chemical Analysis of Active Fraction 7. Kairomonal activity was found only from fraction 7 (active at 10^{-2} BE) and Fraction I (active at 10^{-1} BE). No synergistic effect was observed between the fractions because their mixture did not

enhance the activity (Table 1). In view of their TLC (hexane–ether 7:3, v/v) and Florisil column chromatographic behaviors, the chemicals were considered to be FAs ($R_f = 0.13$, tailing) and TGs ($R_f = 0.65$), respectively.

Fraction 7 was treated with diazomethane to yield methyl esters, which were analyzed by GC and GC-MS and compared with the authentic samples. Ten peaks were detected and identified (Table 2). The fraction 7 (3.2 g) obtained from 1.04 kg green beans, with emerged weevil removed, had a 10^{-2} BE (active dose) of 30.9 ng FAs. Thus, the absolute amount of each acid in 10^{-2} BE of fraction 7 was calculated on the basis of the GC peaks (Table 2). The most abundant acid was palmitic acid (40.8%). Kairomonal activity of authentic acids or their mixtures was assayed

TABLE 2. FATTY ACID COMPOSITION OF ACTIVE FRACTION

Fatty acid	Composition (%)	Absolute amount (ng)[a]
Lauric acid	0.1	0.03
Myristic acid	0.8	0.25
Pentadecanoic acid	0.1	0.03
Palmitic acid	40.8	12.61
Palmitoleic acid	0.7	0.22

Chemical Analysis of Active Fraction I. Another active fraction (Fraction I) was comprised of TGs. Its IR spectrum showed the following frequencies: 2940, 2860, 1750 (ester C=O), 1470, and 1160 cm^{-1}. No OH stretching frequency was observed. In TLC, fraction I gave a spot with $R_f = 0.64$ (trioleoylglycerol, $R_f = 0.64$) (hexane–ether 7:3, v/v).

Fraction I showed the activity at a dose of 10^{-1} BE, which contained 309 ng of TGs. An aliquot of fraction I was hydrolyzed with KOH in ethanol–water overnight at room temperature. The acidic fraction was analyzed by GC and GC-MS, after methylation with diazomethane. The GC profile was very similar to that of the methyl esters of fraction 7. The aqueous layer, upon evaporation of ethanol and water after neutralization, was heated with potassium hydrogen sulfate ($KHSO_4$) to confirm the presence of glycerol, using the acrolein test (Hayashi, 1991). The characteristic pungent odor of acrolein confirmed the presence of glycerol.

The MS spectrum of the TGs (fraction I) was measured with the direct inlet method, and the following fragments were detected; *m/z* 57 (base peak), 237, 239, 261, 263, 265, 267 (fatty acid residues), 336, 338, 340, 549, 551, 571, 573, 575, 579, 601, 603, and 605 (residues leaving FAs from TGs) (Murata and Takahashi, 1973).

Direct GC analysis of the TGs involved in fraction I was conducted using an MP65HT capillary column. The column temperature was 300–360°C programmed at 5°C/min. A total of 13 peaks were observed from the gas chromatogram (Figure 1), which were separated on the basis of total number of carbons that constituted the FAs of the TGs. They were C_{48} (2.5%), C_{50} (33.1%), C_{52} (50.0%), and C_{54} (14.4%), compared with those of the synthetic TGs (Table 4). The major components of the TGs were PPO (24.2%) and POO (26.3%). In this column, TGs with the same total number of carbons as those of FAs, but with different carbon positions, could not be distinguished. For example, 1,2-dipalmitoyl-3-oleoylglycerol (1P2P3O), and 1,3-dipalmitoyl-2-oleoylglycerol (1P2O3P) yielded one peak.

TGs and FAs from Chinese Green Beans. Florisil column chromatography separated 153 mg TGs and 124.1 mg FAs from 5 and 15% ether in hexane and 4% acetic acid in ether fractions, respectively. These fractions were obtained from 200 g (ca. 60 mg/bean) of crushed green beans and were calculated as 45.9 μg TGs and 37.3 μg FAs per bean, or 765 μg TGs and 620.5 μg FAs per g beans.

TGs and FAs in Surface Hexane Washings of Green Beans from Which Weevils Were Removed. The hexane washing from the beans oviposited by weevils produced 72.5 mg or 38.5 μg/bean of hydrocarbons (the main component), TGs and FAs, which were identified with TLC (hexane–ether 7:3, v/v). Conversely, the hexane washing from the fresh bean control (no weevil oviposition) produced almost no residue (0.3 mg).

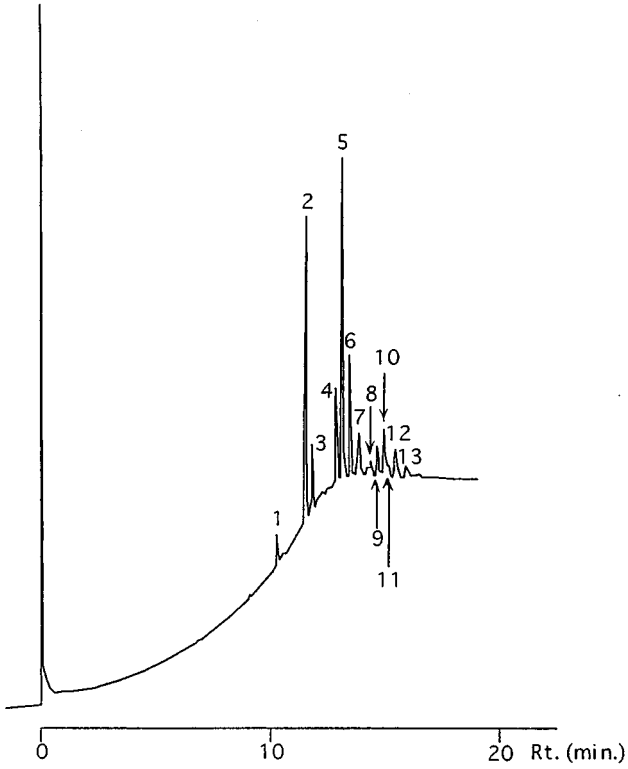

FIG. 1. Gas chromatogram of the active triacylglycerols (fraction I). Condition: MP65HT capillary column; 300–365°C (10 min) at 5°C/min.

DISCUSSION

The host-recognizing kairomones for the parasitic wasp, *A. calandrae*, were demonstrated to be comprised of fatty acids (FAs) and triacylglycerols (TGs). Both fractions separately elicited kairomonal activity, but no synergistic effect was observed. The activity of the FAs (fraction 7) was more than 10^{-2} mg BE (30.9 ng), whereas for the TGs (Fraction I) it was more than 10^{-1} mg BE (309 ng). Thus, fraction 7 was ten times more active than Fraction I. Fraction 7 was composed of 10 carboxylic acids, of which palmitic acid was main component (40.8%). Individual acids or a mixture of five major acids were inactive, but the complete acid mixture was active. This suggests that minor acids were required for activity.

The FAs constituting the TGs in fraction I were characterized, although their attaching positions to glycerol were not determined. The carbon numbers

constituting the FA component of the TGs in this fraction ranged from C_{48} to C_{54}, in which C_{52} (50.0%) was the major components.

Azuki bean weevils secrete an oviposition-marking pheromone to prevent multiple oviposition for a bean, which consists of FAs, hydrocarbons, and TGs (Oshima et al., 1973; Sakai et al., 1986; Honda and Ohsawa, 1990) in a ratio of ca. 1:4.7:2. Of these three constituents, the FA fraction is composed of palmitic (21.6%), stearic (11.5%), oleic (45.5%), linoleic (10.7%), and linolenic (4.1%) acids and 7.4% other acids; the TG fraction comprises a mixture of C_{48} (1.0%), C_{50} (18.9%), C_{52} (47.7%), C_{54} (31.7%), and C_{56} (0.4%) (Honda and Ohsawa, 1990). In the present study, the active kairomones for *A. calandrae* were also comprised of FAs and TGs and are almost the same constituents as for those of the host pheromone. Although TGs and FAs were components of the control fresh green beans (765 and 620.5 μg/bean, respectively), the major fractions of the separated kairomones are thought to be insect-derived, because the amount of TGs and FAs obtained from previously infected green beans was calculated to be 3120 μg/g

beans, i.e., ca. 4–5 times more than those obtained from the control beans. In addition, hexane washing of surface green beans yielded almost no residue. Thus, the major part of the kairomones must be derived from the host pheromone.

We previously reported that other pteromalid wasp, *Dinarmus basalis*, utilizes the saturated hydrocarbons (and diacylglycerols) of the oviposition-marking pheromone of azuki bean weevils as a host-recognizing kairomone (Kumazaki et al., 2000). Thus, the two pteromalid wasps selectively utilize different constituents of the oviposition-marking pheromone of azuki bean weevils as host-recognizing kairomones. For *D. basalis*, TGs as well as diacylglycerols were active. Moreover, both saturated hydrocarbons and diacylglycerols (triacylglycerols) were required for activity in this wasp, whereas in *A. calandrae*, FAs and TGs were separately active, and no synergistic effect was observed between them. *D. basalis* mainly parasitizes azuki bean weevils, whereas *A. calandrae* also attacks other bruchid species. The narrower host range of *D. basalis* compared to *A. calandrae* might be because both constituents of its host pheromone are necessary to search for, or recognize, its host larvae. It would be interesting to know whether FAs and TGs can independently promote stinging behavior.

Abstract—Interactions between male *Nauphoeta cinerea* cockroaches are characterized by an elaborate ritual that leads to a stable dominant–subordinate hierarchy between two individuals. Chemical signals involving volatile sex pheromones and cuticular hydrocarbons play an important role in establishing and maintaining dominance status. The present study was performed to identify cuticular hydrocarbons in two- and three-times dominant or subordinate individuals obtained by forcing dyadic encounters. Two methods, i.e., solid-phase microextraction (SPME) and organic solvent extraction, were used to isolate cuticular hydrocarbons. A total of 23 peaks of cuticular hydrocarbons were identified. Analysis showed quantitative differences in hydrocarbon profiles of three-times dominant and subordinate individuals according to extraction method and dominance status. Dominant individuals were characterized by higher proportions of the monomethylalkanes 11- and 13-MeC_{36}, 13- and 15-MeC_{38}, and 11-, 13-, and 15-MeC_{35}, while subordinate individuals had higher proportions of the following monomethylalkanes: 7-, 9-, and 11-MeC_{31}, 5-MeC_{31}, 3- and 8-MeC_{32}, and 9-, 10- , 11-, and 12-MeC_{32}. Discussion focuses on the reliability of hydrocarbons as indicators of dominance status and on their correlation with physiological processes.

Key Words—Dominance status, Hydrocarbon profiles, SPME, cockroaches, *Nauphoeta cinerea*.

INTRODUCTION

Social stability in many orders of insects depends on the outcome of agonistic encounters that confer dominant individuals with special rights with regard to water, food, shelter, and mating. Numerous studies have concentrated on the elaborate agonistic interactions between mature male *Nauphoeta cinerea* cockroaches (Ewing, 1967, 1972, 1973; Ewing and Ewing, 1973; Bell et al., 1979; Bell and Gorton, 1978; Breed et al., 1980; Schal and Bell, 1983). Depending on population density, these encounters determine either hierarchy (high density) or territoriality (low density). Various interrelated aspects of this behavior have been studied, including the role of volatile sex pheromones, importance of posture, and physiological impact of dominance versus subordination on physiological activity.

Based on early reports by Ewing (1967) indicating that dominant males respond to subordinates before making contact, it was speculated that volatile signals are involved in these interactions. After more than 30 years of study, a great deal of data has been gathered on volatile sex pheromone in male cockroaches (Sreng, 1990; Sirugue et al., 1992; Moore et al., 1995). The presence of a sex pheromone called "seducin" was first demonstrated in the abdominal region of male *N. cinerea* in 1966 by Roth and Dateo (1966), but its origin from the sternal glands was not elucidated until 1979 (Sreng, 1979), and its exact chemical composition was not determined until 1990 (Sreng, 1990). Various studies have shown that sex pheromone plays a fundamental role in male–male agonistic behavior and dominance status (Breed et al., 1980; Smith and Breed, 1982; Schal and Bell, 1983; Moore, 1988, 1989, 1997; Sreng, 1991; Moore et al., 1995, 1997). The great variability in the proportion of the three components identified in the sex pheromone (Sreng, 1990) suggests that each male has a characteristic blend (personal odor) depending on its status in the group. However, in a detailed study of ontogenetic and social factors involving paired comparison of the ratios of the three sex pheromone components, Moore et al. (1995) showed that only the ratio between 2-methylthiazolidine and 3-hydroxy-2-butanone differed significantly between subordinate and dominant males. The study of volatile sex pheromones is obviously subject to chemical and physical limitations. Another factor to consider is the effect of male status on the level of biosynthesis activity in glandular cells and on storage in glandular epithelium or reservoir (Sreng, 1985).

Behavioral studies have shown that male posture plays an important role in mating competition between male cockroaches. Since cockroaches live in darkness, vision plays little role in the perception of posture. This was confirmed by Schal and Bell (1983) by eye-painting experiments. In a report describing the discovery

of male abdominal glands, Sreng (1979) also noted that males assumed a special stance, or calling posture, when releasing sex pheromone produced by the sternal glands. Release of sex pheromone can be enhanced by expanding the abdomen to expose the glandular orifices situated at the anterior portion of abdominal segments (Sreng, 1979, 1984, 1985, 1990, 1991, 1993). This position, also termed the aggressive posture (Ewing, 1967, 1972; Bell and Gorton, 1978), is normally associated with dominant males (Ewing, 1967; Moore et al., 1995) and is adopted immediately after winning an encounter. Only dominant males display the calling posture releasing sex pheromone that determines access to receptive females and mating success (Breed et al., 1980; Schal and Bell, 1983; Sreng, 1991; Moore et al., 1995). The same posture has been observed in the same context in many species of Oxyhaloinae (Fraser and Nelson, 1984; Leibensperger et al., 1985; Sreng 1993; Clark and Moore, 1995).

Physiological correlates of agonistic behavior in male cockroaches have received less attention than sex pheromone or posture. In one study, it was shown that stress induced by domination could cause death in subordinate males (Ewing, 1967). Electrophysiological recordings showing high ventral nerve cord activity in subordinate males confirmed that agonistic behavior led to profound physiological changes (Ewing and Ewing, 1973). Several authors demonstrated that physiological changes probably involve sex pheromone (Moore et al., 1995) as well as cuticular hydrocarbons. Previous studies in a variety of species have demonstrated that the proportion of cuticular hydrocarbons depends on physiological status [Arnold and Régnier (1975) in flies; Antony and Jallon (1981) and Jallon et al. (1982) in drosophila; Bonavita-Cougourdan et al. (1991) in wasps; and Schal et al. (1991) and Everaerts et al. (1997) in cockroaches].

The main purpose of this study was to identify cuticular hydrocarbons in male *Nauphoeta cinerea* cockroaches and determine their correlation with dominant versus subordinate status. Secondarily, we compared the efficiency of conventional solvent extraction and solid-phase microextraction (SPME) for cuticular hydrocarbon extraction.

METHODS AND MATERIALS

Animals. The cockroaches used in this study were obtained from mixed-age and mixed-sex colonies of *Nauphoeta cinerea* (Blaberidae, Oxyhaloinae) reared in an aquarium ($60 \times 40 \times 20$ cm) at $26 \pm 1^{\circ}$C and 70% relative humidity with a reversed 12L:12D photoperiod. Insects were allowed free access to dry dog food and water. After removal from the colony, newly emerged males were isolated in round plastic boxes (10 cm diam.) pending behavioral tests at the age of 12 days. To enable identification during behavioral tests, a number tag was attached with an adhesive used by beekeepers to mark queens. Tagging was performed on the pronotum of each animal to avoid contamination during extraction.

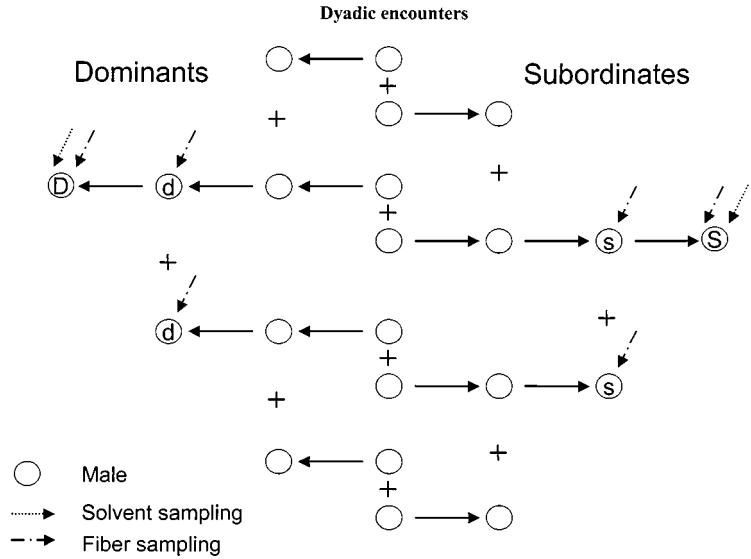

FIG. 1. Behavioral experiment used to obtain two-times dominant (d) or subordinate (s) individuals and three-times dominant (D) or subordinate (S) individuals by forcing dyadic encounters. Arrows indicate the sampling techniques used.

Behavioral Tests. Dyadic agonistic encounters were carried out as follows: In the first test, two untried males were placed in a new plastic dish. Hierarchy was established by observing the outcome of the encounter. The male that continued to move about the dish with its body high off the ground and abdomen extended was declared the winner (dominant), while the male that ran away and assumed the crouched rocklike posture with its legs folded up and antenna on the ground was declared the loser (subordinate) (cf. Ewing, 1967). In the second and third tests, winners were confronted with winners and losers with losers. In this way, we obtained two-times and three-times winners and losers, i.e., two-times dominant (d), two-times subordinate (s), three-times dominant (D), or three-times subordinate (S) (Figure 1).

Extraction of Cuticular Hydrocarbons. Hydrocarbons were sampled using solid phase microextraction (SPME) and pentane extraction (Figure 1). Since SPME involves solventless recovery and concentration of substances on silica fibers coated with various stationary phases, it can be repeated more than once on the same animal. In this study, SPME was used twice, i.e., once on two-times dominant and subordinate males and once on three-times dominant and subordinate males. In contrast, since pentane solvent extraction requires destruction of the specimen, it was used only on three-times dominant animals.

SPME was performed using a Supelco 5-7308 fiber (polydimethylsiloxane phase, 30 μm thickness). During sampling, cockroaches were anesthetized with carbon dioxide and restrained with five staples placed over the body of the animal in order to expose the usually hidden glandular part of the third sternite (Sreng, 1984). Care was taken not to damage the animal physically. After cleaning by deabsorption in the GC injector at 250°C for 30 min, the fiber was rubbed gently against the sternal gland for 1 min. Similar SPME techniques have been used to study pheromone production in ants and weevils (Malosse et al., 1995; Monnin et al., 1998).

To enhance comparability with SPME, which involved only the sternite 3, pentane extraction was performed on a fragment of abdominal cuticle removed with microsurgical scissors. After wiping off adjacent tissue (hemolymph and fat body) with a paper towel, the cuticule fragment was placed in pentane for 20 min at room temperature. The resulting extracts were stored at −20°C pending analysis. Prior to analysis extracts were dried under a nitrogen stream in a conical vial and resuspended in 10 μl of pentane.

Chemical Analysis. SPME samples and pentane extracts were analyzed by gas chromatography (GC). The chromatograph was a Delsi Nermag DN 200 equipped with a flame ionization detector, split/splitless injector (splitless mode, 15 sec), and a capillary column (Chrompack CPSil. 5 WCOT: 25 m long × 0.25 mm diam., 0.25 μm). It was coupled with an Enica 31 integrator. Oven temperature was programmed from 150°C for 5 min to 250°C at 10°C/min, then to 320°C at 5°C/min (final time, 15 min). The carrier gas was helium at 1 bar. SPME samples were injected by desorbing the fiber in the injection port for 15 min at 250°C. Individual insect pentane extracts (2 μl) were injected in the chromatograph.

Hydrocarbons were identified by gas chromatography–mass spectrometry (GC-MS), performed on a Hewlett Packard 5890 coupled with a 5989A mass spectrometer. The capillary column and temperature program were the same as those used for GC. The system was programmed with a HPUX MS Chemstation controller. Analyses were performed in the electron impact mode (EI, 70 eV) and chemical ionization mode (CI, methane).

Data Analysis. Twenty-three peaks, representing a single component or mixture of components, were selected for analysis. Any peak causing integration problems due to background noise was discarded. Compounds with similar retention times were combined. As described by Bagnères et al. (1991), peak areas given by the integrator were corrected as a function of chain length using the following correction factor: $K = 0.042X + 0.11$, where X is the number of carbon atoms per molecule of the substance. Statistical analyses were conducted on the proportion of each peak in relation to the overall number of peaks obtained in each specimen as calculated with a Microsoft Excel 5 spreadsheet.

Comparison of SPME and pentane extraction was carried out on data from eight three-times dominant or subordinate individuals (set A). Principal component

analysis (PCA) was performed by using the Le Statoscope software package. The most representative hydrocarbons on factorial axes, i.e., those for which the squared values of the correlation coefficient between the variable and axes were from 0.65 to 1, were chosen for study. Hydrocarbon selection was also assisted by the Wilcoxon signed rank test (for paired samples).

To further analyze the correlation between hierarchy status and cuticular hydrocarbon profile, a second PCA was carried out using corrected data from a table designed to eliminate the possible effects of extraction technique on the dispersion of the individuals on the factorial plane. The correction table was constructed as follows. For each and every compound (j), we compared its mean value for fiber extraction (F), let it be $m_F(j)$, and its mean value for the eight pentane extractions (P), let it be $m_P(j)$. Each x_j value was then replaced by [$(x_j - m_F(j))$ or $(x_j - m_P(j))$], depending on which extraction technique had been used. A Mann-Whitney U test was carried out on the factorial coordinates of the first axis of this PCA. To assess the role of compounds, we performed the Friedman nonparametric test, with extraction mode as blocks and dominance status as factors.

Another PCA, using hydrocarbon data from 29 SPME (set B), was performed to confirm the correlation between cuticular profile and dominance status. Eight of the 29 tests involved the same animal tested after the second and third encounters, i.e., when they were two- and three-times dominant or subordinate (Figure 1). A Kruskal-Wallis test with the factorial coordinates was carried out to clarify the distribution of individuals according to profile on the first axis. Mean values for each status were introduced in the PCA as supplementary variables and encoded as follows: DOM = three-times dominant individuals, dom = two-times dominant individuals, SUB = three-times subordinate individuals, sub = two-times subordinate individuals. Again, to assess the role of each compound the Kruskal-Wallis test was individually applied to all compounds.

RESULTS

Chemical Analysis. The 23 peaks identified in *Nauphoeta cinerea* cockroaches contained a variety of hydrocarbons, including normal alkanes from C_{25} to C_{33}, monomethylalkanes from C_{26} to C_{39}, dimethylalkanes from C_{34} to C_{37}, and one trimethylalkane of C_{36} (Figure 2, Table 1).

Comparison of Extraction Techniques. PCA using the eight three-times dominant or subordinate individuals (set A), using both SPME and solvent extraction, demonstrated a clear-cut difference between the two techniques. Individuals were separated along a linear combination (axis δ) of the first and second axes, accounting for 59.4% of total variance (Figure 3a). Pentane extracts projected on the positive side of axis δ, whereas all SPME but one (rDF) projected on the negative side. Pentane extracts were characterized by a higher proportion of cholesterol (cholest-5-en-3-ol, peak s5) and n-C_{33} (peak a13) (Figure 3b, upper right area),

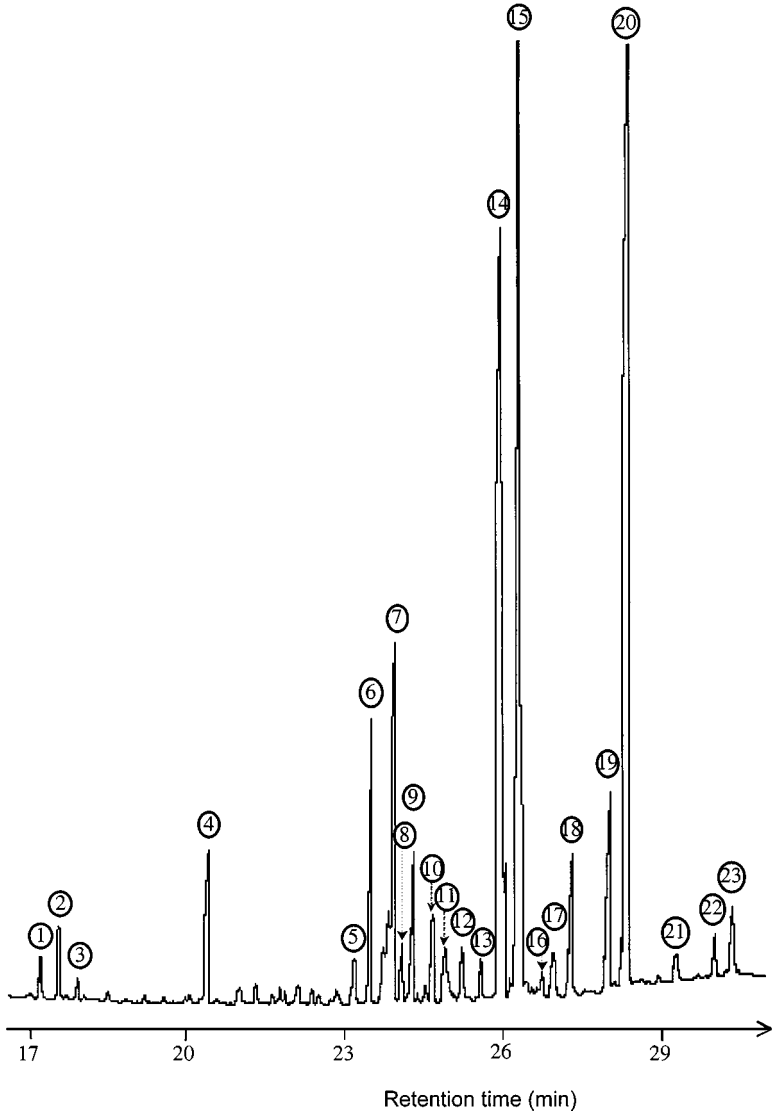

FIG. 2. Gas chromatogram of the cuticular hydrocarbons of a dominant male. Each peak corresponds to one compound or mixture of several compounds listed Table 1.

whereas SPME samples were characterized by a higher proportion of monomethylalkanes with C_{25} (13-MeC_{25}, peak m2), C_{31} (7-, 9-, 11-MeC_{31}, peak m7, 5-MeC_{31}, peak m8), C_{32} (3-, 8-MeC_{32}, peak m10) and dimethylalkanes with C_{33} (11-, 21-DimeC_{33}, peak d15) (Figure 3b, lower left area). According to the Wilcoxon signed

rank test, peaks a1, a4, m7, m8, m10, and d12 were discriminant at the 5% level, and peaks m2, m3, s5, a13, and d15 were discriminant at the 1% level.

Correlation between Status and Hydrocarbon Profile. A second PCA was performed after correction of set A data to eliminate the effect of extraction technique (Figure 4a). Dominant individuals (negative side) and subordinate individuals (positive side) were separated on the first axis in all but three cases (uSP, kDF, qDF, for nomenclature see legend). A Mann-Whitney test with the factorial coordinates on the first axis confirmed nonrandom separation ($z = 59$, $P < 0.05$). Dominant

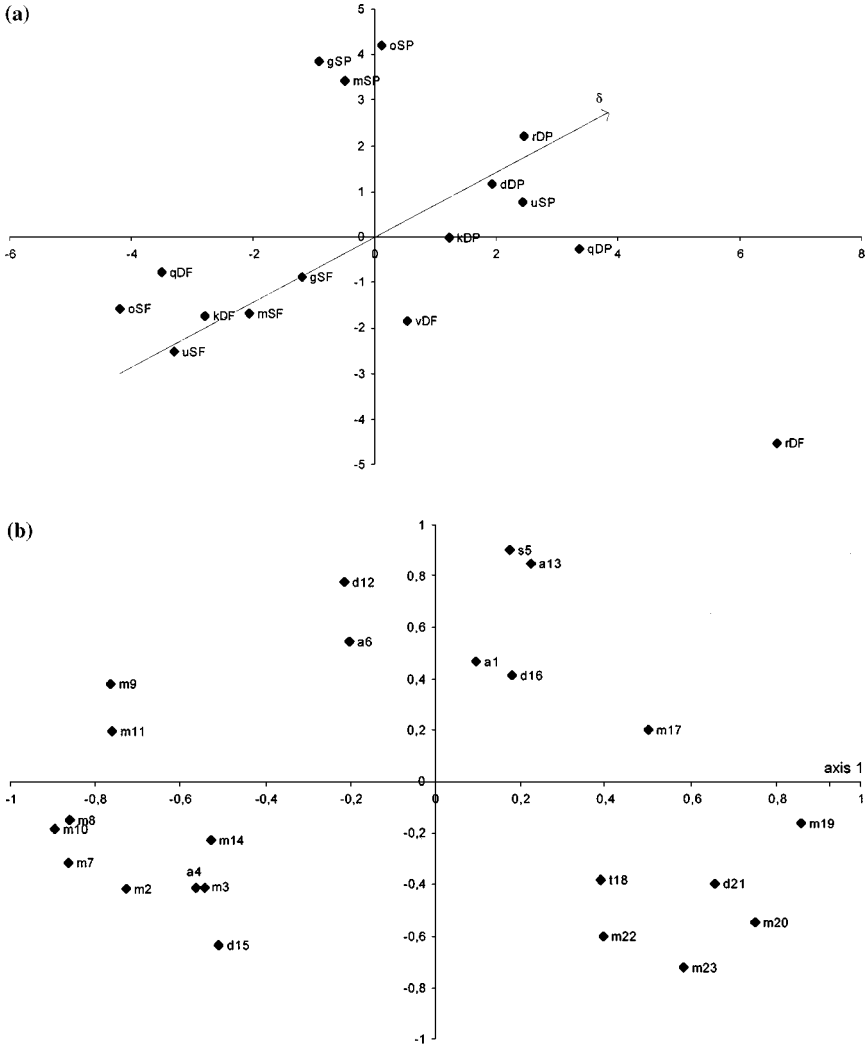

FIG. 3. (a) Principal component analysis of 23 variables (proportions of hydrocarbons) from eight three-times dominant individuals and eight three-times subordinate individuals (set A, $N = 16$). Projection was performed on factorial plane 1–2. Axis 1 accounts for 34.7% of total variance and axis 2 for 24.7%. Axis δ discriminates the two types of individuals. Solvent (xxP) and fiber (xxF) samples from three times dominants (xDx) or subordinate (xSx) individuals were compared. The letter in front of the status designates the individual insect. (b) Projection of the hydrocarbons on axes 1 and 2. Abbreviations: alkanes, a; monomethylalkanes, m; dimethylalkanes, d; trimethylalkane, t; cholesterol, s.

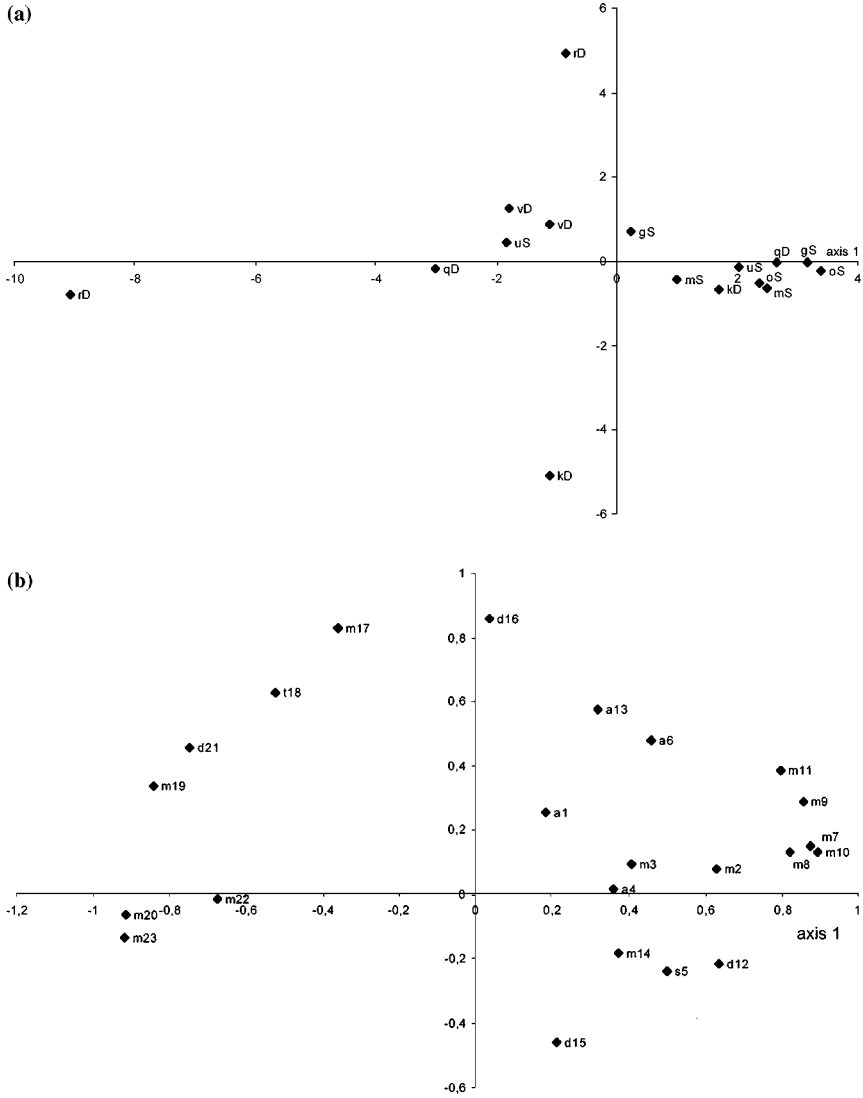

FIG. 4. (a) Principal component analysis of 23 variables (proportions of hydrocarbons) using corrected data from the same eight three-times dominant individuals and eight three-times subordinate individuals as in Figure 3 (corrected set A, $N = 16$). Projection was performed on factorial plane 1–2. Axis 1 accounted for 40.4% of total variance and axis 2 for 15.0%. Dominance status of three times dominant (xD) or subordinate (xS) individuals were compared. The letter in front of the status designates the individual insect. (b) Projection of the hydrocarbons on axes 1 and 2. Abbreviations as in Figure 3.

individuals were characterized by a higher proportion of monomethylalkanes: 11-, 13-, 15-MeC_{35}, peak m19; 11-, 13-MeC_{36}, peak m20; and 13-, 15-MeC_{38}, peak m23; whereas subordinate individuals were characterized by a higher proportion of monomethylalkanes: 7-, 9-, 11-MeC_{31}, peak m7; 3-MeC_{31}, peak m9; 3-, 8-MeC_{32}, peak m10; and 9-, 10-, 11-, 12-MeC_{32}, peak m11 (Figure 4b). The Friedman nonparametric test indicated that peaks m2, s5, and m9 were discriminant for dominance status at the 5% level.

The PCA performed on set B data corresponding to tests on two- and three-times dominant or subordinate individuals also showed a significant difference between dominant and subordinate individuals. As shown in Figure 5a, the four groups (D, d, S, s) lined up in their logical order on the first factorial axis accounting for 56.20% of total variance. Three-times dominant individuals were in the most negative position. Despite the four exceptions (ls, vD, kD, qD), the Kruskal-Wallis test indicated nonrandom distribution of individuals ($K = 8.27$, $P < 0.05$). This finding was confirmed when dominance level (DOM, dom, sub, SUB) was projected as supplementary variables (Figure 5b). The compounds characterizing dominant individuals were the same as in the previous PCA plus a mixture of monomethylalkanes (11-, 13-, 15-MeC_{35}, peak m19). In contrast, subordinate individuals were characterized by four mixtures involving 7-, 9-, 11-MeC_{31} (peak m7) and 3-, 8-MeC_{32} (peak m10) as previously described and monomethylalkanes 5-MeC_{31} (peak m8) and 9-, 10-, 11-, 12-MeC_{32} (peak m11). The Kruskal-Wallis test showed that peaks m7, m11, and m14 were discriminant at the 5% level.

DISCUSSION

Qualitatively, the cuticular hydrocarbon profiles obtained in dominant and subordinate males using SPME and pentane extraction were identical. Both methods extracted a total of 23 peaks. Differences between SPME and pentane extraction profiles were observed with regard to the proportion of some peaks compounds. Pentane extracted more cholesterol, peak s5, and *n*-alkane *n*-C_{33}, peak a13, whereas SPME extracted more monomethylalkanes 13-MeC_{25}, peak m2; 7-, 9-, 11-MeC_{31}, peak m7; 5-MeC_{31}, peak m8; 3-, 8-MeC_{32}, peak m10; and dimethylalkane 11, 21-$DimeC_{33}$, peak d15. These differences could be due to chemical affinities of the fiber and pentane as observed even when solvents with the similar polarity are used.

Quantitative differences in the hydrocarbon profiles could also be due to the methodological differences between the two extraction techniques. Unlike the solvent, the fiber is applied directly to the target and, thus, all compounds obtained came from the sternal gland. There was no contamination by adjacent tissue. Residual tissue (e.g., fat, hemolymph, and muscle) clinging to the sample after dissection for solvent extraction may be a source of cholesterol.

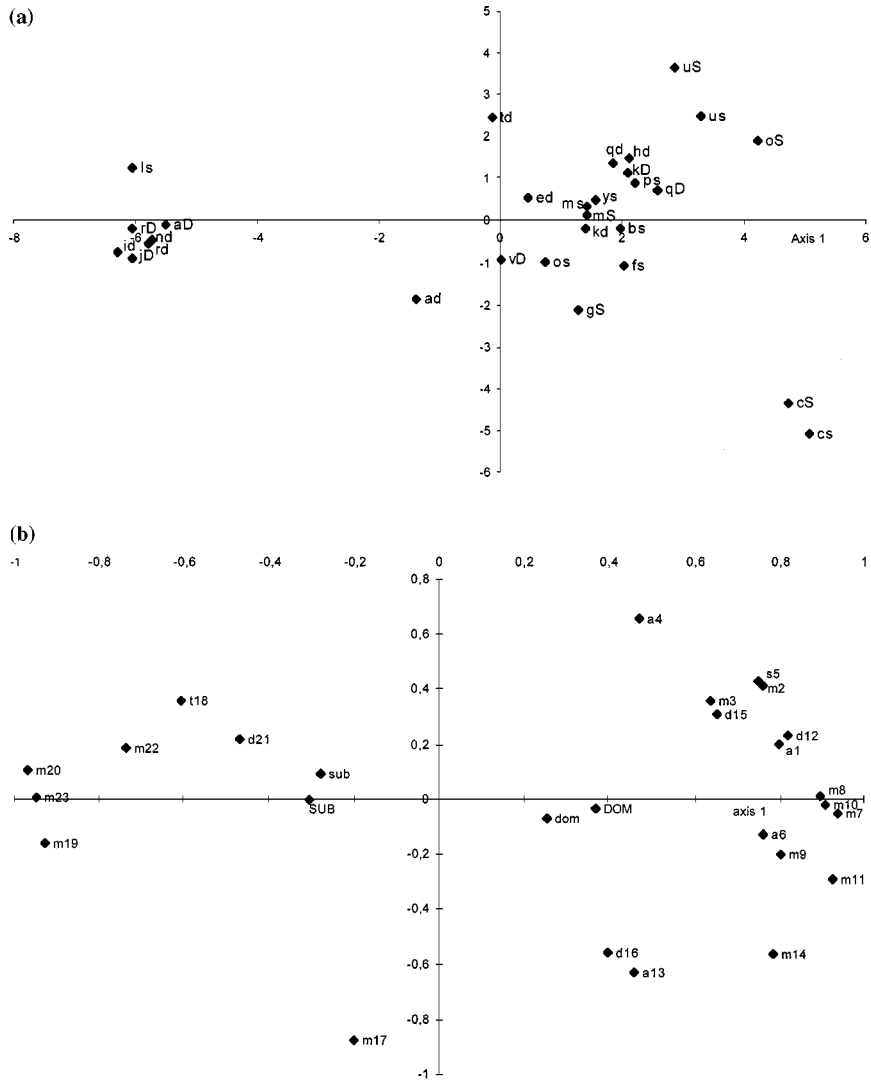

FIG. 5. (a) Principal component analysis of 23 variables (proportions of hydrocarbons) obtained in 29 SPME from 13 individuals sampled once or eight individuals sampled twice (set B). Projection was performed on factorial plane 1–2. Axis 1 accounted for 56.2% of total variance and axis 2 for 14.3%. Samples of three (xD)- or two (xd) -times dominant individuals and three (xS)- or two (xs) -times subordinate individuals were compared. The letter in front of the status designates the individual insect. (b) Projection of the hydrocarbons on axes 1 and 2. Abbreviations as in Figure 3. Mean values for each status were introduced in the PCA as supplementary variables and were encoded as follow: DOM = three-times dominant individuals, dom = two-times dominant individuals, SUB = three-times subordinate individuals, sub = two-times subordinate individuals.

After eliminating the extraction mode effect, we observed a strong correlation between cuticular hydrocarbon profile and individual status (first PCA axis, 40.4% of variance). Dominant individuals were characterized by higher proportions of 11-, 13-MeC_{36}, peak m20; 13-, 15-MeC_{38}, peak m23; and 11-, 13-, 15-MeC_{35}, peak m19; whereas subordinate individuals were characterized by higher proportions of 7-, 9-, 11-MeC_{31}, peak m7; 3-MeC_{31}, peak m9; 3-, 8-MeC_{32}, peak m10; and 9-, 10-, 11-, 12-MeC_{32}, peak m11. These differences could allow individuals meeting for the first time to recognize each other by antennal palpation (Ewing, 1967). In subsequent encounters, individuals manifest dominant or subordinate behavior without making contact, probably by means of volatile substances (Breed et al., 1980).

Two previous studies, i.e., Moore et al. (1995) and Moore (1997), showed that the ratio between two sex pheromone components varied according to individual status. Everaerts et al. (1997) stated that dominant males present a hydrocarbon profile different from that of subordinate males even though separation of these two categories was not clear-cut. These findings and our study suggest that both cuticular hydrocarbon profile and sexual pheromone blend are involved in establishing and maintaining dominance status. This conclusion is further supported by the similar behavior observed during agonistic encounters establishing individual status and mating rituals. In both cases, males expand the abdomen to expose the sternal gland where sexual pheromone is produced (Ewing, 1967; Sreng, 1979).

Laboratory tests show that the outcome of an encounter involving an untried male, regardless of its aggressive potential, depends mainly on the status of the opponent, especially if the latter has already been dominant (Ewing, 1967; Manning and Johnstone, 1970; Breed et al., 1980; Schal and Bell, 1983). Thus physiological changes induced by these agonistic encounters, such as modifications of the chemical signature, could be essential in establishing the dominance status.

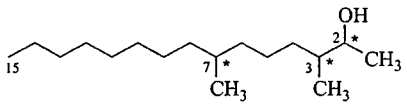
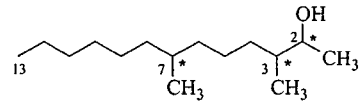
(Received October 10, 2001; accepted February 9, 2002)

Abstract—3,7-Dimethyl-2-undecanol, 3,7,9-trimethyl-2-tridecanol, and 3,7,11-trimethyl-2-tridecanol were synthesized as racemic mixtures in moderate yields. The alcohols are known precursors of the female sex pheromones of the pine sawfly species *Diprion nipponica*, *Macrodiprion nemoralis*, and *Microdiprion pallipes*, respectively. Stereoisomeric mixtures of 3,8,12-trimethyl-2-tridecanol, *erythro*-(2*R*,3*R*,11*R*/*S*)-3,11-dimethyl-2-tetradecanol, 3,5-dimethyl-2-tetradecanol, and 5,7-dimethyl-2-tetradecanol, structurally related to sex pheromone alcohol precursors of pine sawfly species, were also synthesized in moderate yields. The key reaction in the syntheses was the ring opening of γ-butyrolactones by using different alkyl lithiums as nucleophiles.



Key Words—Sex pheromone, pine sawfly, synthesis, *Diprion nipponica*, *Macrodiprion nemoralis*, *Microdiprion pallipes.*

INTRODUCTION



We have long been interested in the sex pheromones of pine sawflies, and our work has thus far included identification, syntheses, and biological activities of such chemical substances (for recent examples see Bergström et al., 1998; Karlsson and Hedenström, 1999; Larsson et al., 2001; Wassgren et al., 2000). In the northern hemisphere, some pine sawfly species are severe pests on pines (Smith, 1993). Consequently, our interest is to monitor and to control pine sawfly populations by using mass trapping or mating disruption techniques (for two recent examples see Rieske

FIG. 1. The sex pheromone precursor alcohols **1**–**5** identified so far in females of pine sawfly species. The syntheses of compounds **3**–**5** as stereoisomeric mixtures are presented in this paper.

et al., 2001; Martini et al., 2002). Several structurally similar sex pheromone precursor alcohols have been identified in females of pine sawfly species (Anderbrant, 1993; Bergström et al., 1995, 1998; Tai et al., 1998; Wassgren et al., 2000; Larsson et al., 2001). As sex pheromone, most of the pine sawfly species employ esters of *erythro*-(2*S*,3*S*,7*S*)- or *threo*-(2*S*,3*R*,7*R*)-3,7-dimethyl-2-pentadecanol (**1**, diprionol, Figure 1). From virgin female extracts of the pine sawfly *Neodiprion sertifer*, only the precursor alcohol **1** has been isolated and no trace of the behavioral active ester was found (Wassgren et al., 1992). So far, little is known about the pheromone biosynthesis in pine sawfly species, and no production site has been found for the pheromone or the precursor alcohol. The alcohol **1** has been found in different parts of the female *N. sertifer* (Wassgren et al., 1992) and probably is stored and then esterified just before emission, as suggested earlier (Jewett et al., 1976).

The sex pheromone precursors identified in female pine sawfly species are basically methyl-branched long-chained 2-alcohols that may be divided into two structural groups. One group is based on different lengths of the carbon chain,

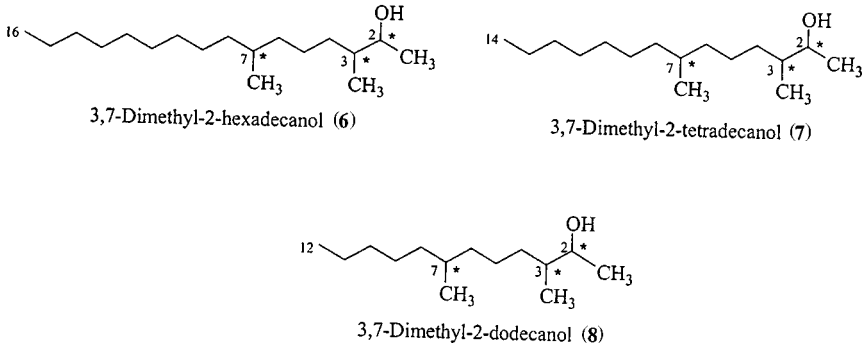

FIG. 2. Lower and higher homologs identified in females of pine sawflies *N. sertifer* (**6** and **7**) and *D. pini* (**6**–**8**) together with the species specific sex pheromone precursor, alcohols **1** and **2**, respectively.

with methyl branching on carbons 3 and 7 (3,7-dimethyl-2-pentadecanol (**1**); 3,7-dimethyl-2-tridecanol (**2**); and 3,7-dimethyl-2-undecanol (**3**); Figure 1). From female extracts of the pine sawflies *N. sertifer* (Hedenström et al., 1992; Wassgren et al., 1992) and *Diprion pini* (Bergström et al., 1995), some minor (1–5%) pheromone components were identified (3,7-dimethyl-2-hexadecanol (**6**); 3,7-dimethyl-2-tetradecanol (**7**); and 3,7-dimethyl-2-dodecanol (**8**); Figure 2). These minor compounds gave a GC-EAD response but showed no activity in field tests performed with either pine sawfly species (Wassgren et al., 1992; Bergström et al., 1995). The other structural group is based on the same 13-carbon chain length but includes yet another methyl branching on a carbon different from carbons 3 and 7, i.e., on carbon 9 or 11 (3,7,11-trimethyl-2-tridecanol, (**4**); and 3,7,9-trimethyl-2-tridecanol (**5**); Figure 1). The propionate of 3,7,11-trimethyl-2-tridecanol (**4**), and the acetate of 3,7,9-trimethyl-2-tridecanol (**5**), have been found to be the sex pheromones of *Microdiprion pallipes* (Bergström et al., 1998; Nakamura and Mori, 1999; Larsson et al., 2001) and *Macrodiprion nemoralis* (Karlsson and Hedenström, 1999; Wassgren et al., 2000), respectively.

To confirm the structure of future pheromone candidates that likely will be found in other pine sawfly species, we need access to an extensive library of structurally related compounds for screening their mass spectra and gas chromatography (GC) retention times and relating the observed variation to the differences in structure. As part of this work, we previously synthesized some structural analogs of diprionol, representing a third group of compounds with one methyl group missing [(2*S*,3*S*)-3-methyl-2-pentadecanol (**9**); (2*S*,7*S*)-7-methyl-2-pentadecanol (**10**); and (2*S*,6*S*)-2,6-dimethyl-1-tetradecanol (**11**); Figure 3] (Hedenström et al., 1992). The biological activity of the acetates of compounds **9**–**11** have been tested on the pine sawfly *N. sertifer* in Sweden (Anderbrant et al.,

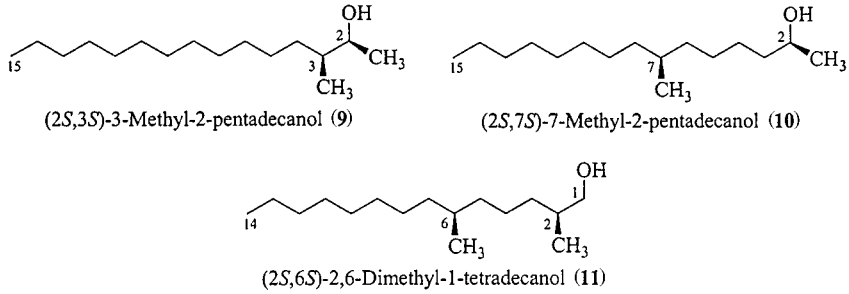

FIG. 3. The acetates of stereoisomeric pure diprionol analogues **9**–**11**. In a field study performed in Sweden on the pine sawfly *N. sertifer*, no biological activity was found.

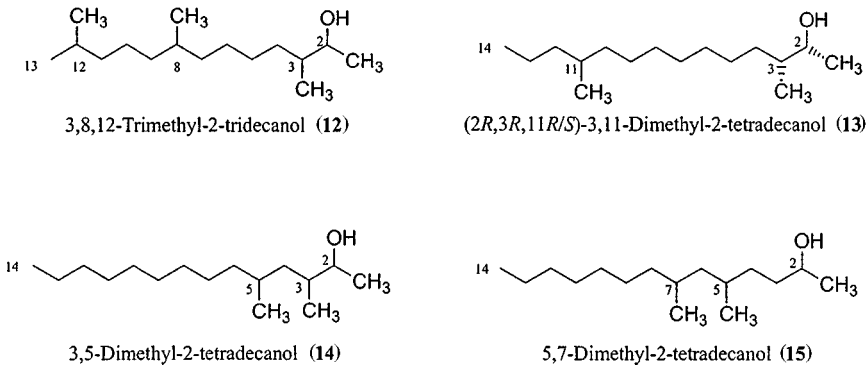
in personal communication). None of the analogous acetates showed any activity in the field. In field experiments performed in Japan on the same species (Tai et al., 1992), both the *erythro*-(2*S*,3*S*) and the *threo*-(2*S*,3*R*) isomers of analog **9** were active.

We present in this paper the syntheses of some novel substances. One compound, 3,8,12-trimethyl-2-tridecanol (**12**); (Figure 4), which is structurally related to compounds **4** and **5** (Figure 1), and three others represent a new, fourth group of compounds that are structurally related to sex pheromones of pine sawflies. This group has the same 14-carbon chain length but a variation in the attachment of the two methyl groups [*erythro*-(2*R*,3*R*,11*R*/*S*)-3,11-dimethyl-2-tetradecanol (**13**); 3,5-dimethyl-2-tetradecanol (**14**); and 5,7-dimethyl-2-tetradecanol (**15**), Figure 4].

We also present here the syntheses of the 16 stereoisomeric mixtures of 3,7,11- and 3,7,9-trimethyl-2-tridecanol, compounds **4** and **5**, respectively, by somewhat



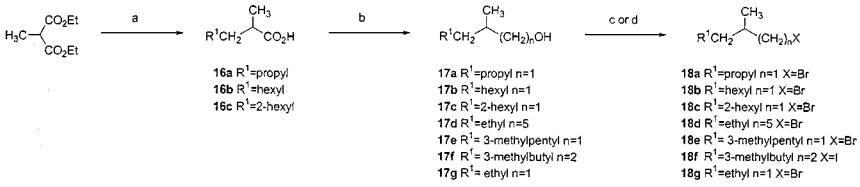


FIG. 4. Stereoisomeric mixtures of methyl-branched, long-chained alcohols **12**–**15** that are structurally related to sex pheromone precursors in pine sawfly species. Their syntheses are presented in this paper.

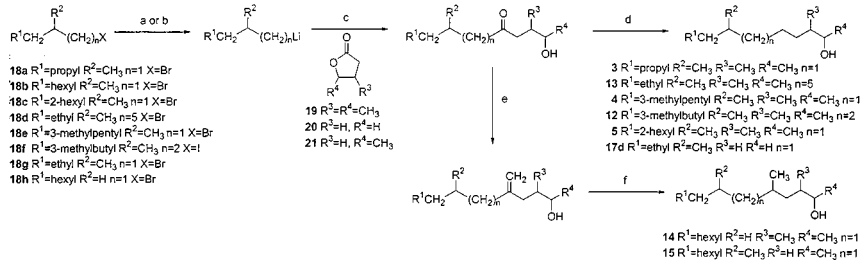
different procedures from those previously published (Karlsson and Hedenström, 1999; Larsson et al., 2001). The synthesis of 3,7-dimethyl-2-undecanol (**3**) as an eight stereoisomeric mixture is also presented. The propionate of this compound was recently identified as the sex pheromone of *Diprion nipponica* (Tai et al., 1998).

METHODS AND MATERIALS

General Chemical Procedures and Instruments

Unless otherwise stated, commercially available chemicals were used. 2-Methyl-1-pentanol (**17g**), 3,7-dimethyl-1-octanol (**17f**), γ-butyrolactone (**20**), and 4-methyl-γ-butyrolactone (**21**) were purchased from Aldrich and distilled prior to use. 3,4-Dimethyl-γ-butyrolactone (**19**) was prepared according to Hedenström et al. (1992). The *trans–cis* ratio was 65:35 according to GC [iso 115°C, retention time: *cis* (minor): 4.15 min; *trans* (major): 5.34 min]. The analytical and spectral data were identical to those reported in Hedenström et al. (1992). Dry acetone (Na_2CO_3), diethyl ether ($LiAlH_4$), diethyleneglycole (NaOH), pyridine (CaH_2), and THF (K and benzophenone) were distilled from the indicated drying agents. Reactions sensitive to moisture and/or oxygen were carried out under argon. Preparative liquid chromatography was performed on straight-phase silica gel (Merck 60, 230–400 mesh, 0.040–0.063 mm, 10–50 g/g of product mixture) by using a gradient elution technique with an increasing concentration of distilled ethyl acetate in distilled cyclohexane or of distilled diethyl ether in distilled pentane. Thin-layer chromatography (TLC) was performed to monitor the progress of the reactions on silica gel plates (Merck 60, precoated aluminum foil), using ethyl acetate (20 or 40%) in hexane as an eluant, and plates were developed by means of ultraviolet irradiation and/or by spraying with vanillin in sulfuric acid and heating at 120°C. Unless otherwise stated, GC analyses were carried out by using a capillary column [J & W DB-Wax, 30 m $\times$ 0.32 mm ID, $d_f = 0.25\ \mu m$, carrier gas He (103 kPa), split ratio 1:30]. Mass spectral analyses were carried out on a Saturn 2000 GC/MS/MS instrument, coupled to a Varian 3800 GC instrument, using a capillary column [VA-5MS, 30 m $\times$ 0.32 mm ID, $d_f = 0.25\ \mu m$, carrier gas He (60 kPa), split ratio 1:20]. Boiling points are uncorrected and are, unless otherwise stated, given as air bath temperatures (bath temperature/millimeters if mercury) in a bulb-to-bulb apparatus (Büchi GKR-51). IR spectra were recorded as concentrated substance between NaCl or KBr plates with a Perkin Elmer 782 or Perkin Elmer 16PC FT-IR spectrometer. NMR spectra were recorded in $CDCl_3$ with tetramethylsilane as an internal standard using either a Jeol EX270 (270 MHz ^1H and 67.8 MHz ^{13}C) or a Bruker DMX 250 (250 MHz ^1H and 62.9 MHz ^{13}C) instrument. Optical rotation was measured on a Perkin Elmer 241 polarimeter using a 1-dm cell. Elemental analyses were performed by Mikro Kemi AB, Uppsala, Sweden.

SCHEME 1. a) 1) Na(s), EtOH, Δx 2) butylbromide, heptylbromide or 1-bromo-2-methylhexane, Δx 3) KOH, EtOH/H_2O, Δx 4) Δx; b) $LiAlH_4$, Et_2O; c) Br_2, PPh_3, CH_2Cl_2, 0°C 4 hr; d) I_2, PPh_3, imidazole, 0°C, 2 hr.



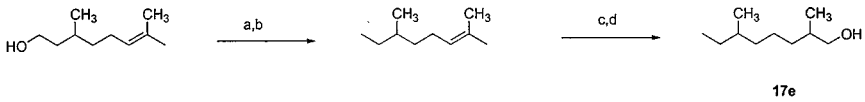
*Synthesis of 3,7-Dimethyl-2-Undecanol (**3**)*

*2-Methylhexanoic Acid (**16a**) (Scheme 1).* The compound was prepared by malonic ester synthesis using the method in Karrer et al. (1930) but from 1-bromobutane. The acid obtained was pure as judged by GC. Bp 120–122°C/14 mm Hg [bp 109–110°C/17 mm Hg for (*S*)-2-methylhexanoic acid (Terashima et al., 1979)]. $n_D^{20} = 1.4249 \pm 0.0002$ [$n_D^{20} = 1.4195$ (Lide, 1999)]. IR data were similar to data for (*S*)-2-methylhexanoic acid (Terashima et al., 1979). The ^{1}H NMR spectral data were identical to those reported in the literature (Lubell et al., 1990) for (*R*)-2-methylhexanoic acid.

*2-Methyl-1-Hexanol (**17a**) (Scheme 1).* This compound was obtained from the above prepared 2-methylhexanoic acid (**16a**) via $LiAlH_4$ reduction (Edlund et al., 1996). It was obtained (16 g, 0.137 mol, 94%) in a >99.5% purity, as judged by GC. Bp 164–165°C/760 mm Hg [bp 112–113.5°C/100 mm Hg (Wender et al., 1950)]. n_D^{20} was identical to that reported in the literature (Mori and Horikiri, 1996) for (*R*)-2-methyl-1-hexanol. IR and ^{1}H NMR spectral data were identical to those reported in the literature (Decicco and Grover, 1996) for (*S*)-2-methyl-1-hexanol.

*1-Bromo-2-Methylhexane (**18a**) (Scheme 1).* This was prepared as described below for 1-bromo-2-methylnonane (**18b**) but from 2-methyl-1-hexanol (**17a**). Distillation {bp 72°C/10.6 mm Hg [bp 90–92°C/40 mm Hg (Manabe et al., 1985)]} gave the pure product as judged by GC (19.3 g, 0.108 mol, 80%). $n_D^{20} = 1.4509 \pm 0.0002$ [$n_D^{25} = 1.4460$ (Manabe et al., 1985)]. IR and ^{1}H NMR data were similar to data in Kurosawa et al. (1997) for (2*S*)-1-bromo-2-methylhexane.

*3,7-Dimethyl-2-Undecanol (**3**) (Scheme 2).* A mixture of stereoisomers was prepared with the preparative procedure used for 3,7-dimethyl-2-dodecanol (Bergström et al., 1995) with slight modification. 3,4-Dimethyl-γ-butyrolactone (**19**), (*trans–cis* 65:35) and 1-bromo-2-methylhexane (**18a**) were used as starting materials, and before adding the bromide to 3.5 equivalents of lithium in Et_2O, the oxide on the surface of the metal was removed with one equivalent of *t*-butanol at 10°C, the Et_2O was removed, and the metal was washed twice with dry Et_2O. Thereafter, we followed the method described in Bergström et al. (1995). The compound was obtained in a 30% yield, and the *threo–erythro* ratio was 65:35 as analyzed



SCHEME 2. a) Li(s), Et_2O, -10°C, 2 hr; b) *t*-Bu-Li, *n*-pentane/Et_2O, -78°C, 1 hr; c) 1) Add to the lactone in Et_2O at -78°C, 4 hr; 2) H_20; d) $(NH_2)_2$, KOH, diethyleneglycol, 180°C, 1 hr, 220°C, 2 hr; e) 1) CH_2PPh_3, benzene, ambient temp., 16 hr; 2) H_2O; f) Pd/C, H_2, MeOH, ambient temp., 72 hr.

by GC [iso 140°C, retention times for the propionate: *threo* (2*S*,3*R* and 2*R*,3*S*, minor): 8.30 min; *erythro* (2*S*,3*S* and 2*R*,3*R*, major): 8.61 min]. Bp 98°C/0.68 mm Hg. $n_D^{20} = 1.4451 \pm 0.0002$. IR (neat): 3355, 2959, 2924, 2858, 1464, 1378, 1094, 1002, 924, 889, 728, 665 cm^{-1}. ^1H NMR and MS data were similar to published data (Tai et al., 1998) for (2*S*,3*R*,7*R*/*S*)-3,7-dimethyl-2-decanol. ^{13}C NMR (62.9 MHz) δ: 14.13, 14.17, 14.49, 14.52, 19.28, 19.33, 19.62, 19.75, 20.27, 20.28, 23.02, 24.63, 24.66, 24.72, 24.75, 29.30, 29.33, 32.67, 32.68, 32.71, 32.77, 32.88, 32.97, 36.66, 36.84, 37.28, 37.37, 39.76, 39.79, 40.01, 40.04, 71.36, 71.45, 71.74, 71.80 ppm. Anal. calcd for $C_{13}H_{28}O$: C 77.9%, H 14.1%; found: C 77.9%, H 14.2%.

*Synthesis of 3,7,11-Trimethyl-2-Tridecanol (**4**)*

*2,6-Dimethyl-1-Octanol (**17e**) (Scheme 3).* The 2,6-dimethyloct-2-ene-1-tossylate was prepared similar to Bergström et al. (1998), but starting from citronellol. The tossylate was obtained in quantitative yield, the purity was checked by IR and ^1H NMR, and it was used without further purification. The tossylate (19.1 g, 61.5 mmol) in dry Et_2O (110 ml) was added dropwise to $LiAlH_4$ (2.60 g, 68.5 mmol) in dry Et_2O (50 ml) at ambient temperature. The reaction was heated to reflux for 3.5 hr (no starting material remained according to TLC), cooled to 0°C, and quenched with water (2.6 ml) and 15% aqueous NaOH (2.6 ml) followed by

SCHEME 3. a) TsCl, pyridine, 5°C, 4 hr; b) 1) $LiAlH_4$, Et_2O, Δx 3.5 hr; 2) H_2O; c) 1) SeO_2, EtOH 2) $NaBH_4$, EtOH, 2 hr; d) RaNi, H_2, MeOH/H_2O, 72 hr.

H_2O (2.6 ml). After refluxing for 1 hr, the precipitate was filtered, and the solution was dried ($MgSO_4$). The Et_2O was distilled off through a column, and the residual oil was chromatographed (eluted with pentane and distilled off through a column) and distilled to give 6.47 g (46.2 mmol, 75%) of the pure alkene (>99% as judged by GC). Bp, n_D^{20}, IR and ^{1}H NMR spectral data were identical to those reported by Mori and Harashima (1993) for (6*R*)-2,6-dimethyl-2-octen. ^{13}C NMR data were similar to those of Naoshima et al. (1988) for (6*S*)-2,6-dimethyl-2-octen]. MS (EI) data were similar to Rossi and Salvadori (1979) for (6*R*)-2,6-dimethyl-2-octen.

The alkene (2.06 g, 14.7 mmol) was added to a solution of SeO_2 (1.23 g, 11.1 mmol) in EtOH (210 ml) and refluxed. A mixture of the allylic alcohol and the α,β-unsaturated aldehyde was formed and after 30 hr, MeOH was added and the selenium residues removed by filtration. Evaporation of the solvent was followed by extraction with Et_2O (3 × 50 ml). The combined organic phases were washed with aqueous saturated Na_2CO_3 and dried ($MgSO_4$). Liquid chromatography and removal of solvent yielded a mixture of the allylic alcohol and the α,β-unsaturated aldehyde (1.17 g, 7.58 mmol, 52%). This was dissolved in absolute EtOH (30 ml) and added drop by drop to a suspension of $NaBH_4$ (0.41 g, 10.7 mmol) in EtOH (80 ml) at 5°C. After 3.5 hr, TLC indicated no aldehyde, and H_2O (115 ml) and brine (50 ml) were added. Extraction with Et_2O (3 × 100 ml) and drying ($MgSO_4$) of the combined extracts gave after liquid chromatography and distillation {bp 70°C/3 mm Hg [bp 100–103°C/10 torr (Webb, 1961)]} 0.99 g (6.33 mmol, 84%) of the unsaturated pure alcohol. $n_D^{20} = 1.4590 \pm 0.0002$ [$n_D^{22} = 1.4541$ for (*E*)-(6*R*)-2,6 dimethyl-2-octen-1-ol (Mori and Harashima, 1993)]. IR data were similar to Mori and Harashima (1993) for (*E*)-(6*R*)-2,6-dimethyl-2-octen-1-ol. ^{1}H NMR and MS (EI) spectral data were identical to those of Ghisalberti et al. (1991) for (6*R*)-2,6-dimethyl-2-octen-1-ol. Compound **17e** was obtained as a mixture of isomers by RaNi reduction of 2,6-dimethyl-2-octen-1-ol according to Högberg et al. (1992). Bp 90°C/6.8 mm Hg [bp 60°C/1 mm Hg for (2*R*,6*R*)-2,6-dimethyl-1-octanol (Cheskis et al., 1988)]. $n_D^{20} = 1.4249 \pm 0.0002$ [$n_D^{20} = 1.4371$ for (2*R*,6*R*)-2,6-Dimethyl-1-octanol (Cheskis et al., 1988)]. The IR and ^{1}H NMR spectral data were identical to those reported by Chênevert and Desjardins (1996) for (2*R*,6*R*)-2,6-dimethyl-1-octanol.

*1-Bromo-2,6-Dimethyloctane (**18e**) (Scheme 1).* This was prepared as below for 1-bromo-2-methylnonane (**18b**) but from 2,6-dimethyl-1-octanol (**17e**). Distillation {bp 70–72°C/8 mm Hg [bp 45°C/0.7 mm Hg for (2*R*,6*R*)-1-bromo-2,6-dimethyloctane (Cheskis et al.,1988)]} gave the pure product, as judged by GC. $n_D^{20} = 1.4530 \pm 0.0002$ [$n_D^{20} = 1.4565$ for (2*R*,6*R*)-1-bromo-2,6-dimethyloctane (Cheskis et al., 1988)]. The IR, ^{1}H NMR, and MS (EI) spectral data were identical to those reported by Cheskis et al. (1988) for (2*R*,6*R*)-1-bromo-2,6-dimethyloctane.

*3,7,11-Trimethyl-2-Tridecanol (**4**) (Scheme 2).* This was prepared as above for 3,7-dimethyl-2-undecanol (**3**) but starting from 3,4-dimethyl-γ-butyrolactone (**19**), (*trans–cis* 65:35) and 1-bromo-2,6-dimethyloctane (**18e**). It showed by GC

a *threo–erythro* ratio of 62:38 [iso 120°C, retention times: *erythro* (2*S*,3*S*,7*R*/*S*, 11*R*/*S* and 2*R*,3*R*,7*R*/*S*,11*R*/*S*, minor): 31.33 min; *threo* (2*S*,3*R*,7*R*/*S*,11*R*/*S* and 2*R*,3*S*,7*R*/*S*,11*R*/*S*, major): 31.83 min]. Bp 95°C/0.65 mm Hg. $n_D^{20} = 1.4508 \pm 0.0002$. IR (neat): 3358, 2961, 2926, 2872, 1462, 1377, 1099, 1003, 925, 888, 666 cm^{-1}. ^1H NMR and ^{13}C NMR spectral data were identical to those reported by Larsson et al. (2001). MS (EI) *m*/*z* (relative intensity): 227 (5%), 224 (M^+-H_2O, 3), 196 (3), 168 (2), 140 (9), 125 (87), 111 (46), 97 (55), 85 (70), 83 (55), 71 (90), 69 (80), 57 (100), 55 (73), 45 (84), 43 (55), 41 (72).

*Synthesis of 3,7,9-Trimethyl-2-Tridecanol (**5**)*

*2,4-Dimethyloctanoic Acid (**16c**) (Scheme 1).* This compound was prepared as 2-methylhexanoic acid (**16a**) above but from 1-bromo-2-methylhexane (**18a**). We obtained 9.1 g (0.053 mol, 57%) of the acid as a racemic mixture of *syn–anti* (45:55) products. Bp 127–130°C/9 mm Hg. $n_D^{20} = 1.4300 \pm 0.0002$. IR, ^1H NMR, and ^{13}C NMR spectral data were identical to those reported by Decicco and Grover (1996) for (2*R*,4*S*)- and (2*S*,4*S*)-2,4-dimethyloctanoic acid).

*2,4-Dimethyl-1-Octanol (**17c**) (Scheme 1).* This compound was obtained from the acid **16c** *via* $LiAlH_4$ reduction as for **17a**. The alcohol (3.1 g, 0.053 mol, 86%) was obtained as a racemic mixture of *syn–anti* (45:55) products and in >99.2% purity as judged by GC. Bp 130°C/9.9 mm Hg [bp 90°C/3 mbar for (2*R*,4*S*)-2,4-dimethyl-1-octanol (Karlsson and Hedenström, 1999)]. $n_D^{20} = 1.4332 \pm 0.0002$. IR (neat): 3342, 2958, 2925, 2879, 1463, 1379, 1038 cm^{-1}. ^1H NMR and ^{13}C NMR were similar to those reported by Karlsson and Hedenström (1999) for (2*R*,4*S*)- and (2*S*,4*S*)-2,4-dimethyl-1-octanol).

*1-Bromo-2,4-Dimethyloctane (**18c**) (Scheme 1).* This was prepared as **18b** but from 2,4-dimethyl-1-octanol (**17c**). Distillation {bp 110°C/6 mm Hg [bp 90°C/7 mbar for (2*S*,4*S*)-1-bromo-2,4-dimethyloctane (Karlsson and Högberg, 2000)]} gave the pure product as judged by GC. $n_D^{20} = 1.4569 \pm 0.0002$. IR (neat): 2958, 2927, 2871, 1459, 1379, 1228, 665, 654 cm^{-1}. ^1H NMR data were similar to those of Karlsson and Högberg (2000) for (2*S*,4*S*)-1-bromo-2,4-dimethyloctane. Anal. calcd for $C_{10}H_{21}Br$: C 54.3%, H 9.6%; found: C 53.9%, H 9.5%.

*3,7,9-Trimethyl-2-Tridecanol (**5**) (Scheme 2).* This was prepared as above for 3,7-dimethyl-2-undecanol (**3**) but starting from 3,4-dimethyl-γ-butyrolactone (**19**), (*trans–cis* 65:35) and 1-bromo-2,4-dimethyloctane (**18c**). It showed a *threo–erythro* ratio of 64:36 analyzed by GC [CP-Wax 52CB, 30 m × 0.25 mm ID, $d_f = 0.25$ μm, carrier gas He (110 kPa), split ratio 1:30, 80°C, 0 min, then programmed 1.0°C/min up to 250°C, retention times: *erythro* (2*S*,3*S*,7*R*/*S*, 9*R*/*S* and/or 2*R*,3*R*,7*R*/*S*,9*R*/*S*, minor): 57.63 min; *erythro* (2*S*,3*S*,7*R*/*S*,9*R*/*S* and/or 2*R*,3*R*,7*R*/*S*,9*R*/*S*) and *threo* (2*S*,3*R*,7*R*/*S*,9*R*/*S* and/or 2*R*,3*S*,7*R*/*S*, 9*R*/*S*): 58.86 min; *threo* (2*S*,3*R*,7*R*/*S*,9*R*/*S* and/or 2*R*,3*S*,7*R*/*S*,9*R*/*S*, major): 59.97 min]. Bp, ^1H NMR and ^{13}C NMR spectral data were identical to those

reported by Karlsson and Hedenström (1999). $n_D^{20} = 1.4510 \pm 0.0002$. IR (neat): 3354, 2957, 2926, 2872, 1461, 1378, 1097, 1066, 1002, 923, 728 cm^{-1}. MS (EI) *m*/*z* (relative intensity): 227 (1%), 166 (2), 154 (2), 139 (7), 125 (40), 111 (40), 97 (39), 85 (58), 83 (49), 71 (67), 69 (72), 57 (100), 55 (59), 45 (64), 43 (53), 41 (74).

*Synthesis of 3,8,12-Trimethyl-2-Tridecanol (**12**)*

*1-Iodo-3,7-Dimethyloctane (**18f**) (Scheme 1).* Preparation of this compound was according to Marshall and De Hoff (1987) but from 3,7-dimethyl-1-octanol (**17f**). Distillation gave the pure product as judged by GC. Bp and n_D^{20} were identical to those reported in Schlenk (1973). IR and ^{1}H NMR data were similar to data reported in Nagai (1976).

*3,8,12-Trimethyl-2-Tridecanol (**12**) (Scheme 2).* This was prepared as for 3,7-dimethyl-2-undecanol (**3**) above but starting from 3,4-dimethyl-γ-butyrolactone (**19**) (*trans–cis* 65:35) and 1-iodo-3,7-dimethyloctane (**18f**). It showed a *threo–erythro* ratio of 65:35 by GC [iso 120°C, retention times: *erythro* (2*S*,3*S*,8*R*/*S* and 2*R*,3*R*,8*R*/*S*, minor): 28.20 min; *threo* (2*S*,3*R*,8*R*/*S* and 2*R*,3*S*,8*R*/*S*, major): 28.99 min]. *Synthesis of 3,5-Dimethyl-2-Tetradecanol (**14**)*

*3,5-Dimethyl-2-Tetradecanol (**14**) (Scheme 2).* This alcohol was prepared in a slightly modified manner from the below 5,7-dimethyl-2-tetradecanol **15** and started from 3,4-methyl-γ-butyrolactone (**19**), (*trans–cis* 65:35) and 1-bromononane (**18h**). To improve the yield of the Wittig reaction by preventing cyclization of the ketoalcohol to the hemiketal, the isolated ketoalcohol was acetylated quantitatively according to the method of Byström et al. (1981) before performing the Wittig reaction. 3-Methyl-5-methylene-2-tetradecanol so obtained as a mixture of isomers was >95% chemically pure. IR (neat): 3374, 3072, 2959, 2926, 2855, 1718, 1643, 1458, 1378, 1090, 722 cm^{-1}. ^{1}H NMR (270 MHz) δ: 0.85 (3H, d, $J = 6.9$ Hz), 0.88 (3H, t, $J = 6.7$ Hz), 1.17 (3H, d, $J = 6.3$ Hz), 1.20–1.60 (14H, m), 1.60–1.90 (2H, m), 1.80 (1H, bs disappears when shaken with D_2O), 1.90–2.10 (2H, m), 2.12–2.30 (1H, m), 3.60–3.80 (1H, m), 4.75 (2H, d, $J = 9.9$ Hz) ppm. The compound was obtained as a mixture of stereoisomers after hydrogenation. The diastereomeric ratio as propionates was 32:19:17:32 [DB-5, 30 m × 0.32 mm ID, $d_f = 0.25$ μm, carrier gas N_2 (103 kPa), split ratio 1:30, 170°C, 1 min, then programmed 0.5°C/min up to 200°C, retention times for the propionate isomers: 17.7, 18.4, 18.9, and 19.2 min]. *Synthesis of 5,7-Dimethyl-2-Tetradecanol (**15**)*

*2-Methylnonanoic Acid (**16b**) (Scheme 1).* This was prepared as for **16a** but starting from 1-bromoheptane. The acid was obtained in a 51% yield and >99.5% pure as judged by GC. Bp 76–77°C/0.5 mm Hg [bp 88–90°C/0.5 mm Hg (Nikishin et al., 1974)]. $n_D^{20} = 1.4249 \pm 0.0002$ [$n_D^{25} = 1.4312$ for (*R*)-2-methylnonanoic acid (Levene and Marker, 1932)]. IR data and ^{1}H NMR data were similar to Nikishin et al. (1974).

*2-Methyl-1-Nonanol (**17b**) (Scheme 1).* The compound was obtained from the acid **16b** via $LiAlH_4$ reduction, as above for **17a**, in 92% yield and was pure as judged by GC. Bp 56–57°C/1.5 mm Hg [bp 90°C/22 mm Hg for (*S*)-2-methyl-1-nonanol (Högberg et al., 1992)]. $n_D^{20} = 1.4123 \pm 0.0002$ [$n_D^{20} = 1.4381$ for (*S*)-2-methyl-1-nonanol (Högberg et al., 1992)]. IR and ^{1}H NMR data were similar to Högberg et al. (1992) for (*S*)-2-methyl-1-nonanol.

*1-Bromo-2-Methylnonane (**18b**) (Scheme 1).* The compound was prepared from 2-methyl-1-nonanol (**17b**) (8.06 g, 0.051 mol), which was added dropwise to a solution of triphenylphosphine (17.1 g, 0.111 mol) and bromine (3.4 ml, 0.067 mol) in CH_2Cl_2 at 0°C. The mixture was stirred overnight at ambient temperature. The solvent was evaporated, the residue was triturated with pentane, and the triphenylphosphine oxide was removed by filtration. Evaporation of the solvent, flash chromatography of the remaining oil and distillation {bp 76°C/8 mm Hg [bp 70°C/3 mm Hg (Hedenström et al., 1992)]} gave the pure product (9.91 g, 0.045 mol, 88%). $n_D^{20} = 1.4530 \pm 0.0002$. IR (neat): 2955, 2923, 2868, 2852, 1458, 1377, 653, 622, 602, 592 cm^{-1}. ^{1}H NMR (250 MHz) δ: 0.88 (3H, t, $J = 6.6$ Hz), 1.00 (3H, d, $J = 6.6$ Hz), 1.18–1.49 (12H, broad), 1.72–1.84 (1H, m) 3.32 (1H, dd, $J = 9.8$, $J = 6.2$ Hz), 3.40 (1H, dd, $J = 9.8$, $J = 5.0$ Hz) ppm.

*5,7-Dimethyl-2-Tetradecanol (**15**) (Scheme 2).* This stereoisomeric mixture was prepared using the procedure for 3,7-dimethyl-2-dodecanol (Bergström et al., 1995) with a slight modification. An amount of 4.56 g (20.6 mmol) of 1-bromo-2-methylnonane (**18b**) was added dropwise to 50 mmol finely cut lithium in

20 ml Et_2O at $-5^\circ C$. After stirring for 2 hr, the alkyl lithium was cooled to $-100^\circ C$ and added dropwise to a stirred solution of 1.73 g (17.3 mmol) of 4-methyl-γ-butyrolactone (**21**) in 40 ml of Et_2O at $-100^\circ C$. From the recovered unreacted lithium metal, the alkyl lithium produced was calculated to be 14 mmol (68%). After checking the progress of the reaction by TLC, the reaction was quenched after 5 hr at $-100^\circ C$ with water (44 mmol) in THF, and the mixture was allowed to reach ambient temperature overnight. Thereafter, 150 ml of water and 150 ml of Et_2O were added, and the organic phase was separated. The water phase was extracted with Et_2O (3×150 ml), and the pooled organic phases were washed with brine (100 ml) and dried ($MgSO_4$). Evaporation of the solvent left a yellow oil, which was purified by flash chromatography to give 1.99 g (8.2 mmol) of the ketoalcohol. The identity of the product was checked by IR and ^1H 60 MHz NMR, and the ketoalcohol was used in the next step without further purification or characterization. To the ketoalcohol in 50 ml of dry benzene at ambient temperature was added a dark red solution of an ylide [prepared by refluxing 14.32 g (40 mmol) of flame-dried methyltriphenylphosphoniumbromide in dry benzene (35 ml) and 31 ml of BuLi (1.3 M in *n*-hexane)]. The reaction was stirred overnight and then poured onto ice and water (400 ml). The organic phase was separated, the water phase was extracted with Et_2O (3×150 ml), the combined organic phases were washed with aqueous 0.5 M HCl (100 ml) and aqueous saturated $NaHCO_3$ (100 ml), and dried ($MgSO_4$). The residue gave, after solvent evaporation and flash chromatography, 0.90 g (3.8 mmol) of pure 7-methyl-5-methylene-2-tetradecanol >95% as judged by GC. IR (neat): 3337, 3070, 2956, 2923, 2851, 1643, 1457, 1375, 889, 602 cm^{-1}. ^1H NMR (270 MHz) δ: 0.83 (3H, d, $J = 6.6$ Hz), 0.88 (3H, t, $J = 6.7$ Hz), 1.21 (3H, d, $J = 5.9$ Hz), 1.20–1.40 (14H, m), 1.50–1.70 (2H, m), 1.75 (1H, bs disappears when shaken with D_2O), 1.75–1.83 (1H, m), 2.00–2.18 (2H, m), 3.73–3.87 (1H, m), 4.74 (2H, d, $J = 18.8$ Hz) ppm. 0.83 g (3.47 mmol).

An amount of 0.83 g (3.47 mmol) of this unsaturated alcohol was dissolved in dry methanol, and 0.07 g of 10% Pd/C was added. The reaction mixture was hydrogenated at 1 atm for 72 hr. After removal of the catalyst and solvent, the remaining oil was purified by flash chromatography and distillation to give 0.68 g (2.80 mmol, total yield 16% based on the 4-methyl-γ-butyrolactone (**4**) as a mixture of stereoisomers. The diastereomeric ratio judged by GC as propionates was 23:25:27:25 [iso 140°C, retention times for the propionate isomers: 13.9, 14.4, 15.6, and 15.9 min]. (64), 85 (38), 83 (83), 71 (45), 69 (100), 57 (96), 55 (88), 45 (54), 43 (59), 41 (78). Anal. calcd for $C_{16}H_{34}O$: C 79.3%, H 14.1%; found: C 79.6%, H 14.1%.

RESULTS AND DISCUSSION

Employing essentially the same synthetic methodology that we used previously, the mixture of stereoisomers of compound **3** was prepared, as shown in Schemes 1 and 2. Racemic 2-methylhexanoic acid (**16a**) was prepared using the malonic ester synthesis sequence according to the method described (Karrer et al., 1930), and after subsequent lithium aluminum hydride ($LiAlH_4$) reduction, 2-methyl-1-hexanol (**17a**) was obtained (Scheme 1). The alcohol was converted by way of the bromide **18a** into the alkyl lithium, which was reacted with a racemic mixture of diastereomers of 3,4-dimethyl-γ-butyrolactone (**19**) to give a ketoalcohol. When exposed to Huang-Minlon reduction, this gave the desired alcohol 3,7-dimethyl-2-undecanol (**3**) as an eight stereoisomer mixture with a *threo–erythro* ratio of 65:35 (Scheme 2).

In the same way, the mixtures of the 16 stereoisomers of 3,7,11-trimethyl-2-tridecanol (**4**) (*threo–erythro*, 65:35), of 3,8,12-trimethyl-2-tridecanol (**12**) (*threo–erythro*, 65:35), and of 3,7,9-trimethyl-2-tridecanol (**5**) (*threo–erythro*, 64:36) were prepared from a racemic mixture of diastereomers of 3,4-dimethyl-γ-butyrolactone (**19**) and alkyl lithiums obtained from 2,6-dimethyl-1-octanol (**17e**) 3,7-dimethyl-1-octanol (**17f**), and 2,4-dimethyl-1-octanol (**17c**), respectively. 2,6-Dimethyl-1-octanol (**17e**) was prepared from citronellol via tossylation, $LiAlH_4$ reduction, allylic oxidation of the obtained 2,6-dimethyl-2-octene with SeO_2, followed by $NaBH_4$ reduction and hydrogenation (RaNi, H_2) to give the desired alcohol (Scheme 3). 2,4-Dimethyl-1-octanol (**17c**) was prepared via the malonic ester synthesis as above but from 1-bromo-2-methylhexane (**18a**), and after subsequent $LiAlH_4$ reduction of the acid **16c**, the alcohol **17c** was obtained (Scheme 1).

To prepare *erythro*-3,11-dimethyl-2-tetradecanol (**13**) as a mixture of two of the possible diastereomers, the following steps were used: racemic 2-methyl-1-pentanol (**17g**) was converted via the bromide **18e** into the alkyl lithium, which was reacted with γ-butyrolactone (**20**) to give a ketoalcohol, after Huang-Minlon reduction, gave the racemic 6-methyl-1-nonanol (**17d**) (Scheme 2). The alkyl lithium, obtained as above but through the alcohol **17d** and the bromide **18d**, was reacted with the pure enantiomer of *cis*-(3*R*,4*R*)-3,4-dimethyl-γ-butyrolactone (**19**) and the ketoalcohol obtained was reduced as above to give compound **13** as two *erythro*-diastereoisomers without any detectable amount of *threo*-diastereomers (Scheme 2).

The alcohols 3,5-dimethyl-2-tetradecanol (**14**) and 5,7-dimethyl-2-tetradecanol (**15**) were prepared as stereoisomeric mixtures from 1-nonyl lithium and 3,4-dimethyl-γ-butyrolactone (**19**) and from 2-methylnonyl lithium and 4-methyl-γ-butyrolactone (**21**), respectively, as above (Scheme 2). Both 1-nonyl

lithium and 2-methylnonyl lithium were prepared for the bromide **18a** but via 1-bromononane (**18h**) or the acid **16b**, the alcohol **17b**, and the bromide **18b**, respectively (Scheme 1). The resulting ketoalcohols were reacted with two equivalents of phosphorus ylide, and the obtained methylene group was hydrogenated to give the products **14** and **15**, respectively (Scheme 2). The alcohols **14** and **15** were converted to the corresponding propionates and analyzed by GC for their diastereomeric ratios, which were found to be 32:19:17:32 and 23:25:27:25, respectively.

In conclusion, we have presented the syntheses of an eight-stereoiomeric mixture of 3,7-dimethyl-2-undecanol (**3**), the precursor of the sex pheromone of *Diprion nipponica* (Tai et al., 1998) and the syntheses of the 16 stereoisomeric mixtures of 3,7,11- and 3,7,9-trimethyl-2-tridecanol (compounds **4** and **5**), the precursors of the sex pheromones of *M. pallipes* (Bergström et al., 1998; Nakamura and Mori, 1999; Larsson et al., 2001) and *M. nemoralis* (Karlsson and Hedenström, 1999; Wassgren et al., 2000), respectively. The propionate and acetate esters of these mixtures of stereoisomers (compounds **4** and **5**) have been tested in field studies and shown to efficiently catch males of *M. pallipes* (Bergström et al., 1998; Nakamura and Mori, 1999) and of *M. nemoralis* (Wassgren et al., 2000). Whether the propionate ester of the eight stereoiomeric mixture of 3,7-dimethyl-2-undecanol (**3**) is capable of catching males of the species *Diprion nipponica* remains to be investigated in field tests. We also have presented the syntheses of some new substances that are structurally related to sex pheromones of pine sawfly species and the biological activities of these substances have not yet been established.

It is important to have access to fast and trustworthy analysis methods for elucidation of pheromone candidates found in different species of insects such as, pine sawflies. Access to libraries of several structurally similar compounds is, therefore, essential for the screening of, for instance, their mass spectra and GC retention times so that structural differences may be recorded and compared with those obtained from the natural source. This work will contribute to such a library, which can be used when identifying new compounds found in pine sawfly species in the future.

Acknowledgments—Financial support from the City of Sundsvall (Sundsvalls Kommun), the Swedish Council for Forestry and Agricultural Research (SJFR), the Swedish Natural Science Research Council (NFR), and the Commission of the European Communities, Agriculture and Fisheries (FAIR), specific RTD programe, contract FAIR1-CT95-0339, "Pine sawfly pheromones for sustaiable management of European forests" This study does not necessarily reflect the Commission's view and in no way anticipates its future policies.

DEFINING A SYNTHETIC PHEROMONE BLEND ATTRACTIVE TO MALE *Heliothis subflexa* UNDER WIND TUNNEL CONDITIONS

NEIL J. VICKERS*

Department of Biology
University of Utah
Salt Lake City, Utah 84112

(Received August 15, 2001; accepted February 16, 2002)

Abstract—*Heliothis subflexa* males were flown in a wind tunnel to a variety of combinations of synthetic pheromone components admixed on a filter paper disk. Blends containing (*Z*)-11-hexadecenal (*Z*11–16:Ald, 1000 ng), (*Z*)-9-hexadecenal (*Z*9–16:Ald, 500 ng) and (*Z*)-11-hexadecenol (*Z*11–16:OH, 10–500 ng) elicited upwind flight and source contact in 52–69% of males. All these compounds have previously been isolated and identified from female *H. subflexa* gland extracts and volatile pheromone emissions. Males were not attracted by blends in which *Z*9–16:Ald was omitted (0% source contact). Similarly, blends lacking *Z*11–16:OH were unattractive to male *H. subflexa* (3% or less source contact). Males were extremely sensitive to the presence of *Z*11–16:OH; however, responding in high numbers (57–69% source contact) to blends containing a dosage of 1% (10 ng) or greater *Z*11–16:OH. Males were unresponsive to blends in which *Z*9–16:Ald was replaced with a variety of dosages of (*Z*)-9-tetradecenal, a secondary component of a closely-related congeneric species, *Heliothis virescens*. Another compound present in the blend emitted by conspecific females, (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac), did not inhibit *H. subflexa* males (69% source contact) when added to the three-component mixture (1:0.5:0.1) at a ratio of 0.1 (100 ng) with respect to *Z*11–16:Ald. These results indicate that *Z*9–16:Ald and *Z*11–16:OH are required in addition to *Z*11–16:Ald to elicit significant levels of upwind flight in *H. subflexa* males. The effects of *Z*11–16:Ac are more subtle, but at the dosage tested in these experiments, this compound does not have an antagonistic effect on upwind flight and source location by *H. subflexa* males.

Key Words—Moths, Heliothine, Lepidoptera, Noctuidae, sex pheromone, behavior.

INTRODUCTION

The pheromone communication system of *Heliothis subflexa* (Guenée) (Lepidoptera: Noctuidae) has been studied largely because of the close relationship of this innocuous species to its agriculturally important sister species, *Heliothis virescens*. The ability of these two species to interbreed is an interesting biological phenomenon that has been examined as a potential control method for *H. virescens*. Sterile hybrid male offspring result from interspecific mating of *H. subflexa* females with *H. virescens* males (Laster, 1972), and hybrid females backcrossed to *H. virescens* males continue to produce infertile male offspring. The introduction of such sterile males into the environment was tested as a method for suppressing the *H. virescens* population (Proshold et al., 1983).

The contents of the pheromone gland of *H. subflexa* females have been examined in some detail (Teal et al., 1981; Klun et al., 1982; Heath et al., 1991; Teal and Tumlinson, 1997). The chemicals present in volatile collections included: (*Z*)11-hexadecenal (*Z*11–16:Ald), (*Z*)-9-hexadecenal (*Z*9–16:Ald), hexadecenal (16:Ald), (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac), (*Z*)-9-hexadecenyl acetate (*Z*9–16:Ac), (*Z*)-7-hexadecenyl acetate (*Z*7–16:Ac), (*Z*)-11-hexadecenol (*Z*11–16:OH), and (*Z*)-9-hexadecenol (*Z*9–16:OH) (Teal et al., 1981; Heath et al., 1991). Klun et al. (1982) reported the presence of small amounts of tetradecanal (14:Ald), (*Z*)-9-tetradecenal (*Z*9–14:Ald), (*Z*)-7-hexadecenal (*Z*7–16:Ald), and hexadecenyl acetate (16:Ac) in addition to those compounds reported by Teal et al. (1981), with the exception of Z9–16:OH. Comparisons with volatiles extracted from *H. virescens* pheromone glands revealed that *H. virescens* females did not manufacture any compounds that had an acetate terminal moiety (Roelofs et al., 1974; Tumlinson et al., 1975; Klun et al., 1980a; Pope et al., 1982; Vetter and Baker, 1983; Teal et al., 1986; Teal and Tumlinson, 1997). In addition, *H. virescens* females do not emit either *Z*9–16:OH or *Z*11–16:OH, even though both compounds can be found in gland extracts (Teal et al., 1986; Heath et al., 1991). It seems doubtful that *H. subflexa* females produce any of the shorter chain C_{14} aldehydes (14:Ald and *Z*9–14:Ald) emitted by *H. virescens* females as reported in the study of Klun et al. (1982). These compounds have not been found in any other analyses of *H. subflexa* female pheromone gland production (Teal et al., 1981; Heath et al., 1991). The compounds present in the pheromone glands of both *H. virescens* and *H. subflexa* females are summarized in Figure 1.

Initial field-trapping experiments revealed that most males were captured when *Z*11–16:Ald, *Z*9–16:Ald, *Z*11–16:Ac, *Z*9–16:Ac, and *Z*7–16:Ac were present on the pheromone lure (Teal et al., 1981). Subsequently, Heath et al. (1990) reported that *Z*11–16:OH was a critical component of the pheromone, required in combination with 16:Ald, *Z*11–16:Ald, *Z*9–16:Ald, *Z*9–16:Ac, and *Z*11–16:Ac,

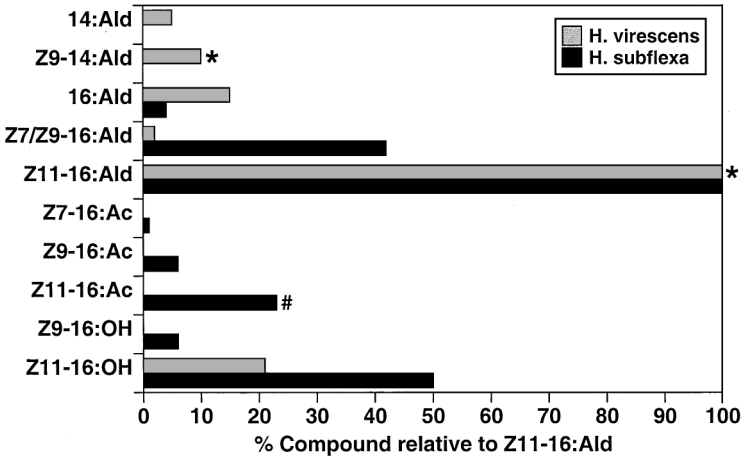

FIG. 1. A comparison of the compounds detected in the pheromone gland of *H. virescens* and *H. subflexa* females (data from Teal and Tumlinson, 1997). Female *H. subflexa* do not produce any of the shorter C_{14} aldehydes (14:Ald, *Z*9–14:Ald). Female *H. virescens* do not produce any of the C_{16} acetates including *Z*11–16:Ac (#), a potent antagonist of *H. virescens* males (Vickers and Baker, 1997). Compounds forming part of an attractive pheromonal blend for *H. virescens* males are indicated (*). While *Z*11–16:OH is present in the pheromone gland of *H. virescens* females, it does not appear to be emitted and utilized by conspecific males.

for attraction of males under field conditions. Because *H. virescens* and *H. subflexa* are sympatric throughout much of their range in the eastern United States, we predicted that males would exploit the differences in female gland emissions with behavioral requirements for distinct pheromonal blends under wind-tunnel conditions. The purpose of the current study was, therefore, to determine which volatile constituents of the female *H. subflexa* pheromone gland are essential for the attraction of conspecific males.

METHODS AND MATERIALS

Insects. A colony of *H. subflexa* was established in January 1999 from pupae and eggs sent to the University of Utah from North Carolina State University. This colony had been initiated from insects collected in the field during summer/fall of 1998. Neonate larvae were reared on a corn–soy blend diet (A. Sheck, personal communication) in individual 30-ml medicine cups fitted with cardboard lids (WLM Inc.). Once the larvae had pupated, they were removed from the cups,

and pupae were separated into males and females. Male pupae for experimental use were placed in an environmental chamber (Percival Scientific, Boone, Iowa, USA) at 25°C, 60% relative humidity, and 14L:10D reversed light cycle and allowed to eclose. Males were aged daily and cohorts of aged males were keep in plastic containers. Males between the ages of 3 and 10 days were utilized in wind-tunnel experiments. On the day of experimentation, males were placed into 5- × 6-cm (W × H) cylindrical wire screen cages. The cages were inverted to prevent escape from the open end and were placed into a larger plastic container. The container was then returned to the environmental chamber prior to the onset of scotophase before being moved to the darkened wind tunnel room during the third hour of scotophase. Individual cages were removed from the container and placed on one side of the wind tunnel. Males were afforded a period of at least one hour to acclimate to the conditions in the wind tunnel prior to being flown between 3 and 6 hr of scotophase. Individual males were released by inverting their cage on a platform, allowing each male to take flight from the now open cage end. The platform intersected the pheromone plume, being positioned in the horizontal center of the wind tunnel, 50 cm from the downwind end and 19 cm above the wind-tunnel floor.

Wind Tunnel. The working section of the wind tunnel was 2.5 × 1.14 × 1.14 m (L × H × W). Wind speed varied between 0.45 and 0.61 m/sec. Temperature in the wind-tunnel room varied between 21.1 and 22.2°C with ambient relative humidity of 12.8–55.2%. The wind tunnel was illuminated by a single red incandescent light bulb above the downwind end and a single white incandescent bulb at the upwind end, both controlled by rheostats. The plume was vented to the exterior of the building at the downwind end of the wind tunnel via a large exhaust duct.

Pheromone Components. Stock solutions of individual compounds were maintained at −20°C. Dilutions were made volumetrically in hexane until a concentration of 100 ng/μl was achieved for *Z*11–16:Ald and *Z*9–16:Ald, and dilutions of 10 ng/μl were obtained for *Z*9–16:Ald, *Z*11–16:OH, *Z*11–16:Ac, and *Z*9–14:Ald (the latter compound was also diluted to 1 ng/μl). The purity of each solution was established by injection of a small volume onto a Shimadzu GC 17A gas chromatograph equipped with a 30-m DB-5 capillary column (0.25 mm ID). All compounds were >95% pure. Each blend was created by admixing the appropriate volumes of the required single compounds directly onto a circular filter paper disk (Whatman No. 4, 1-cm diam.). All compounds in a given blend were loaded in a ratio with respect to *Z*11–16:Ald, which was always present at 1000 ng (denoted 1). For example, to achieve a ratio of 1:0.5 *Z*11–16:Ald and *Z*9–16:Ald (or 50% *Z*9–16:Ald), 500 ng *Z*9–16:Ald was added onto a filter paper disk already impregnated with 1000 ng *Z*11–16:Ald. The hexane was allowed to evaporate in the fume hood. The disk was held by a small alligator clip mounted on a wire post with a heavy rubber cork base. The holder, when complete with the filter paper

[a] A ratio of 1 indicates that the compound was loaded at a dosage of 1000 ng.

disk, measured 24.5 cm tall. The distance between the odor source and takeoff platform in the wind tunnel was 1 m.

Experimental Design. Treatments were presented in a randomized complete block design. Groups of three to five males were flown to each treatment on any given day. The treatments presented in each experiment are shown in Table 1.

Data Analysis. The behavioral responses of males were categorized according to the following sequential series: (1) Flight: male exited cage and initiated flight in the wind tunnel. (2) Lock-on: male exhibited narrow turns perpendicular to wind line in the area of the take off platform at height of pheromone plume. (3) Upwind: male proceeded upwind in characteristic zig-zag flight at height of pheromone plume. The distance of flight toward the source was noted. Random upwind flight lacking characteristic orientation behaviors and outside the vicinity of the plume (along walls or ceiling) was not included as upwind flight. (4) Close approach: oriented upwind flight continued to within 5cm of pheromone source. (5) Source: male landed on filter paper source or clip holding source.

Percentages of males performing each behavior were calculated and subjected to a χ^2 2 × 2 test of independence with Yates' correction (Steel and Torrie, 1961). Significance was determined at the $P < 0.05$ level.

RESULTS

The series of blends tested and ratios utilized in experiment 1 (Table 1) was based upon previous field-trapping data and the known constituents of female *H. subflexa* pheromone gland constituents (Figure 1) (Teal et al., 1981; Klun et al., 1982; Heath et al., 1990, 1991; Teal and Tumlinson, 1997). The first experiment (Figure 2) clearly demonstrated that both *Z*9–16:Ald and *Z*11–16:OH were essential components of the pheromone blend. The two blends that lacked either of these compounds elicited very low levels of upwind flight, and virtually no males located the source in response to either blend. The addition of *Z*11–16:Ac to a blend containing *Z*11–16:Ald, *Z*9–16:Ald, and *Z*11–16:OH increased the number of males contacting the source, but this difference was not significantly greater compared to the blend in which this compound was omitted.

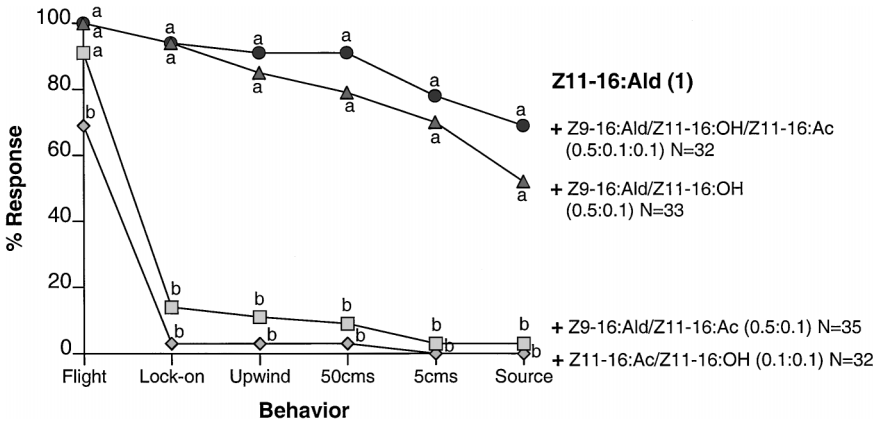

FIG. 2. Test of a series of blends on behavioral responses of *H. subflexa* males. The performance of each male in a sequential series of behaviors was noted: male took flight (Flight); male oriented to the pheromone plume (Lock-on), male initiated upwind flight (Upwind), upwind flight sustained to within 50 cm of source (50 cms) or 5 cm (5 cms), male lands on odor source (Source). The ratios utilized in this first experiment were based upon the data from female gland analyses (Teal and Tumlinson, 1997, summarized in Figure 1). *Z*11–16:Ald was held constant in each test mixture, with other compounds varying as indicated. Both *Z*9–16:Ald and *Z*11–16:OH were required to elicit significant and high levels of upwind flight and source location. Symbols in the same behavioral category having no letters in common are significantly different according to a χ^2 2 × 2 test of independence with Yates' correction. ($P < 0.05$)

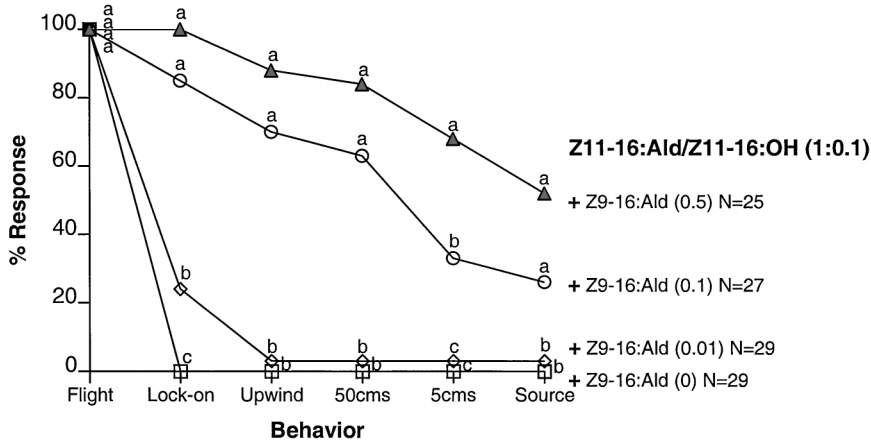

FIG. 3. Behavioral responses of *H. subflexa* males to a series of blends that contained varying dosages of *Z*9–16:Ald relative to constant dosages of *Z*11–16:Ald (1000 ng) and *Z*11–16:OH (100 ng). Significant levels of upwind flight and source location were attained only when the ratio of *Z*9–16:Ald was 0.1 (100 ng) or greater with respect to *Z*11–16:Ald. Behavioral and statistical details as for Figure 2.

The initial observation of the importance of *Z*9–16:Ald was confirmed in a second experiment (Table 1, Figure 3). When *Z*11–16:Ald and *Z*11–16:OH were held constant at a ratio of 1:0.1, males failed to respond to the blend lacking *Z*9–16:Ald. Upwind flight and source location were not significantly enhanced by the presence of a small amount of *Z*9–16:Ald (0.01 or 1%). Significant levels in all orientation categories were achieved with the addition of 10% *Z*9–16: Ald. When the amount of *Z*9–16:Ald was increased to 50%, more males reached within 5 cm of the source, but there was no statistical difference between 10% and 50% Z9–16:Ald treatments for males contacting the odor source.

In experiment 3, the ratio of *Z*11–16: Ald to *Z*9–16:Ald was held constant at 1:0.5 and the amount of *Z*11–16:OH was varied (Table 1, Figure 4). Males showed no signs of attraction to blends that lacked *Z*11–16:OH, confirming the result from experiment 1. However, addition of a small amount of *Z*11–16:OH improved attraction. Source location was improved to 69% when only 1% *Z*11–16:OH was added to the binary mixture of *Z*11–16:Ald and *Z*9–16:Ald. Increasing the amount of *Z*11–16:OH (10%, 50%) neither enhanced nor inhibited upwind flight and source location compared to the Z11–16: Ald treatment.

In experiment 4, responses of males to blends in which *Z*9–16:Ald had been replaced with varying dosages of *Z*9–14:Ald were tested (Table 1, Figure 5). Males were not attracted by blends in which this substitution had been effected.

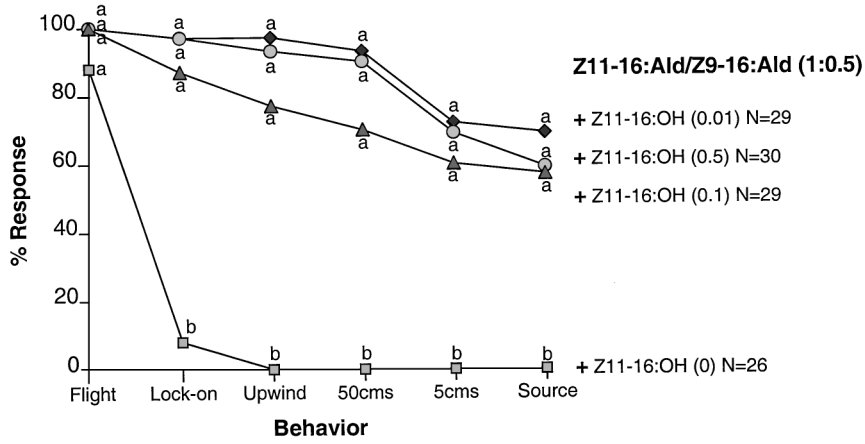

FIG. 4. Behavioral responses of *H. subflexa* males to a series of blends that contained varying dosages of *Z*11–16:OH relative to constant dosages of *Z*11–16:Ald (1000 ng) and *Z*9–16:Ald (500 ng). Males did not respond to a blend in which *Z*11–16:OH was excluded. However, males were sensitive to the presence of this compound in the mixture and responded at low dosages (10 ng, ratio 0.01). Increasing the dosage (100 ng, ratio 0.1; or 500 ng, ratio 0.5) neither elevated nor diminished male response levels. Behavioral and statistical details as for Figure 2.

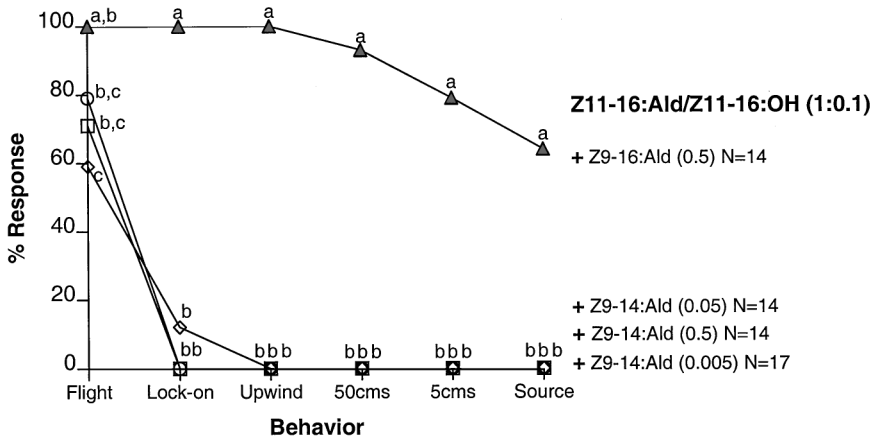

FIG. 5. Effects of replacing *Z*9–16:Ald with varying dosages of *Z*9–14:Ald on behavioral responses of *H. subflexa* males. Amounts of *Z*11–16:Ald and *Z*11–16:OH were held constant at a ratio of 1:0.1. Males were not attracted to any blend in which *Z*9–16:Ald was replaced with *Z*9–14:Ald, the secondary component of the closely-related congeneric species, *H. virescens*. Behavioral and statistical details as for Figure 2.

DISCUSSION

Male *H. subflexa* were attracted to filter paper sources impregnated with a mixture containing *Z*11–16:Ald, *Z*9–16:Ald (10% or greater), and *Z*11–16:OH (1% or greater). These compounds have previously been identified in pheromone gland extracts from *H. subflexa* females (Teal et al., 1981; Klun et al., 1982; Heath et al., 1991; Teal and Tumlinson, 1997). At least 10% *Z*9–16:Ald was required to elicit significant levels of upwind flight and source location (Figure 3), whereas dosages as low as 1% *Z*11–16:OH (Figure 4), exceeded the behavioral threshold for this compound. Field-trapping studies led Teal et al. (1981) to conclude that male *H. subflexa* did not require the presence of *Z*11–16:OH, but a subsequent field study (Heath et al., 1990) revealed that this compound was essential for attraction. Our results concur with those of Heath et al. (1990) in clearly demonstrating that male *H. subflexa* require the presence of *Z*11–16:OH in the pheromone blend. Furthermore, males appeared to be extremely sensitive to the presence of this compound. Addition of as little as 10 ng (1%) *Z*11–16:OH relative to *Z*11–16:Ald (1000 ng) resulted in 68% upwind flight and source location compared to 0% source location when *Z*11–16:OH was excluded from the test blend (Figure 4). The threshold for behavioral responses to this compound is, therefore, below the 10 ng dosage tested in these experiments. No significant improvement or deterioration in the ability of males to locate the pheromone source was noted as the dosage of *Z*11–16:OH was increased to 500 ng (50%). The precise release rates of the test compounds from the filter paper substrate utilized in these experiments, however, are not known. Heath et al. (1990) found that release ratios in excess of 3.5% *Z*11–16:OH resulted in decreased trap capture of *H. subflexa* males. The formulations used in that study were based upon known release rates of compounds from rubber septa (Heath et al., 1986).

The composition of the *H. subflexa* pheromonal mixture is interesting when potential interactions with other species are considered. Avoidance of attraction between *H. subflexa* and *H. virescens* has obvious biological significance given the ability of these two species to hybridize and the reduced fitness of the offspring (in the form of male sterility) (Laster, 1972). The apparent lack of *Z*9–14:Ald in the *H. subflexa* pheromone gland (Teal et al., 1981; Heath et al., 1991) would prevent the attraction of *H. virescens* males, which require the presence of this compound in small amounts (Vickers et al., 1991). Even if female *H. subflexa* were to produce 0.5% of this compound relative to *Z*11–16:Ald, as reported by Klun et al. (1982), the additional presence of *Z*11–16:Ac [63% reported by Klun et al. (1982), 41% by Teal et al. (1986)], which has been shown to be a potent inhibitor of *H. virescens* males even at a loading of 1% (Vickers and Baker, 1997), would prevent the cross-attraction of *H. virescens* males. It is unlikely that male *H. subflexa* would be attracted to *H. virescens* females for two reasons: (1) the small amount of *Z*9–16:Ald relative to *Z*11–16:Ald produced by *H. virescens*

females [1.6% reported by Klun et al. (1980), 1.7% by Teal et al. (1986)] may be insufficient to attract *H. subflexa* males because the upwind flight threshold for this compound is between 1% and 10% (Figure 3), and (2) even though *Z*11–16:OH can be extracted from female *H. virescens* pheromone glands (Klun et al., 1979, 1980a; Teal et al., 1986), it is not released by calling females (Pope et al., 1982; Teal et al., 1986; Heath et al., 1991). Indeed, field results have indicated that no cross-attraction occurs between traps baited with synthetic pheromone blends of *H. virescens*, *H. subflexa*, and a third related North American species, *Helicoverpa zea* (Klun et al., 1982).

The presence of *Z*11–16:OH in female *H. virescens* pheromone glands has been debated for a number of years. Klun et al. (1980a) first reported the presence of *Z*11–16:OH, but other studies were unable to isolate this compound (Pope et al., 1982). Teal et al. (1986) identified *Z*11–16:OH in gland extracts but did not detect it in volatile emissions from calling females or extruded pheromone glands. According to biosynthetic schemes, *Z*11–16:OH is a precursor of the major pheromone component and is rapidly converted to *Z*11–16:Ald by an alcohol oxidase in the pheromone glands of both *H. virescens* and *H. zea* (Teal and Tumlinson, 1986, 1987). Vetter and Baker (1983) demonstrated that the addition of *Z*11–16:OH to an attractive blend was not deleterious to *H. virescens* male behavior until loading exceeded 3%, with lower concentrations having no observable effect. In other studies, small amounts of *Z*11–16:OH were shown to increase trap catches of *H. virescens* males (Sparks et al., 1979; Ramaswamy et al., 1985). Recent results indicate that *Z*11–16:OH does not have a clear inhibitory effect on males tested from laboratory populations (N. J. Vickers, unpublished observations).

An obvious possibility to further diminish the likelihood of interspecific attraction is the use of *Z*9–14:Ald released by *H. virescens* females as an antagonist by *H. subflexa* males. However, preliminary experiments have revealed that *H. subflexa* males are neither attracted nor repelled when this compound is combined with an otherwise attractive blend (N. J. Vickers, unpublished observations). In addition, *Z*9–14:Ald cannot be used in place of *Z*9–16:Ald at any dosage tested thus far (Figure 5). This contrasts with *H. zea* where substitution of the usual secondary component, *Z*9–16:Ald, with small amounts of *Z*9–14:Ald can be achieved without significantly impacting the levels of upwind flight and source location (Vickers et al., 1991). Despite the current lack of evidence for a clear antagonist, it is apparent from on-going experimentation involving *H. subflexa*/*H. virescens* hybrids in our laboratory that mating between *H. virescens* females and *H. subflexa* males is difficult to achieve (in contrast to the reciprocal cross), perhaps indicating other pre- or postmating reproductive isolation mechanisms.

Another possible interspecific interaction might occur between *H. subflexa* and *H. zea*. Although there is no evidence for hybridization with this more distantly related heliothine moth, male *H. zea* require a mixture of two compounds, *Z*11–16:Ald and *Z*9–16:Ald, both of which are present in the *H. subflexa* pheromone

gland. However, *H. zea* males are antagonized by the presence of two other compounds present in the pheromone blend emitted by *H. subflexa* females, *Z*11–16:Ac (Fadamiro et al., 1999) and *Z*11–16:OH (Teal et al., 1984; Quero and Baker, 1999). Conversely, male *H. subflexa* are not attracted to *H. zea* females because they do not emit *Z*11–16:OH (Klun et al., 1979, 1980b; Pope et al., 1984) even though this compound is abundantly present in pheromone gland extracts (see above, Teal et al., 1984, 1989).

There are several other compounds present in the pheromone gland of *H. subflexa* females that were not tested in this series of experiments. These include 16:Ald, *Z*7–16:Ac, *Z*9–16:Ac, and *Z*9–16:OH (Teal et al., 1981). These compounds may play important roles in the pheromone-mediated behavior of *H. subflexa* males, and their potential behavioral effects will be examined in future experiments. The current study reveals the minimum pheromonal requirement by *H. subflexa* males to be *Z*11–16:Ald, *Z*9–16:Ald, and *Z*11–16:OH. Behavioral observations suggest an optimal ratio of 1:0.5:0.01–0.1. The effects of *Z*11–16:Ac upon *H. subflexa* male behavior remains somewhat ambiguous. It may play a pivotal role under field conditions where the background chemical "noise" from other species may have a significant impact upon blend discrimination.

Molecular analysis of heliothine moth phylogeny utilizing nuclear DNA (Cho et al., 1995; Fang et al., 1997) and morphologically based surveys (Mitter et al., 1993) have revealed that *H. virescens* and *H. subflexa* belong within the monophyletic *virescens* group. The requirement by males of these two species for pheromone blends that differ markedly in their secondary component characteristics provides an excellent opportunity to explore the underlying changes in the male olfactory system accompanying this divergence in blend preferences.

VARIATION IN A FEMALE SEXUAL ATTRACTIVENESS PHEROMONE CONTROLS MALE MATE CHOICE IN GARTER SNAKES

MICHAEL P. LEMASTER* and ROBERT T. MASON

(Received September 6, 2001; accepted February 2, 2002)

Abstract—Male red-sided garter snakes (*Thamnophis sirtalis parietalis*) display a courtship preference for larger females during the breeding season. Utilizing behavioral experiments and chemical analyses, we tested the hypothesis that males can discriminate among females of varying size solely by means of the sexual attractiveness pheromone, a previously characterized sex pheromone composed of a homologous series of long-chain saturated and ω-9 *cis*-unsaturated methyl ketones contained in the skin lipids of females. When presented with skin lipid extracts from large and small females, a greater proportion of males displayed courtship behaviors to large female extracts. This demonstrates that there is an intrinsic property of the female skin lipids that allows males to differentiate among large and small females. Analysis of the sexual attractiveness pheromone revealed that the necessary variation exists for this pheromone to function as a reliable indicator to males of female body size. Specifically, we observed a strong correlation between female snout–vent length and the relative concentration of saturated and ω-9 *cis*-unsaturated methyl ketones composing the pheromone; smaller females expressed pheromone profiles higher in saturated methyl ketones, while larger females expressed pheromone profiles dominated by unsaturated methyl ketones. The results of this study suggest that male red-sided garter snakes utilize compositional variation in the female sexual attractiveness pheromone to differentiate among potential mates of varying size.

Key Words—Mate choice, sexual attractiveness pheromone, qualitative variation, methyl ketones, red-sided garter snake, *Thamnophis sirtalis parietalis*.

INTRODUCTION

In many vertebrate species, individuals of one or both sexes actively select among potential mates during the breeding season in an effort to optimize their reproductive success (Andersson, 1994). Individuals often discriminate among potential mates based on variation in the expression of a particular morphological trait. For example, females of some bird species differentiate among males based on variation in visual traits [e.g., color intensity (Hill, 1990), tail length (Møller, 1988)], whereas female frogs may utilize variation in auditory traits [e.g., call rate (Sullivan, 1983), call pitch (Ryan, 1980)]. Chemical traits, such as pheromones (Karlson and Lüscher, 1959), represent an additional type of morphological trait by which potential mates might be evaluated.

The occurrence of chemically mediated mate choice is relatively common in insects, where chemical communication is considered the dominant modality for controlling reproductive behavior in many species (Bell and Cardé, 1984). Unlike insects, however, few studies have documented chemically mediated mate choice in vertebrates (e.g., Verrell, 1985; Reece-Engel, 1988; Martín and López, 2000). This paucity of studies is primarily due to the multicomponent sensory nature of vertebrates where a combination of sensory inputs (e.g., visual, tactile, chemical) is often responsible for mediating a particular behavior (Albone, 1984). Such diversification makes it difficult to establish effective bioassays for measuring behavioral responses of individuals to isolated chemical cues to determine to what extent such cues are utilized.

Snakes offer an excellent model system in which to investigate the chemical mediation of mate choice in vertebrates. More than most vertebrates, snakes rely extensively upon the production and perception of specific sex pheromones for the coordination of reproductive behavior (reviewed in Mason, 1992; Mason et al., 1998). Hence, there is an increased probability that mechanisms evolved to select among potential mates will be chemical in nature [mate choice in snakes (Hawley and Aleksiuk, 1976; Luiselli, 1996)]. In addition, snakes are much like insects in that they respond to isolated chemical cues with stereotypical, robust behaviors (Brown and MacLean, 1983; Mason and Crews, 1985). Thus, behavioral bioassays can be constructed with relative ease to test the responses of snakes to chemical cues from potential mates when presented in isolation.

Annual aggregations of red-sided garter snakes (*Thamnophis sirtalis parietalis*) at underground hibernacula in Manitoba, Canada, are unique natural phenomena, representing the highest concentrations of snakes in the world (Gregory, 1984). Mating in these populations occurs directly at the hibernacula following spring emergence, with virtually all females [>95% (Garstka et al., 1982)] mating within one day of emerging from winter dormancy. During this period, it is not uncommon to observe 10–100 males courting a newly emerged female, forming what are termed "mating balls" (Gregory, 1974, 1977). Males do not randomly associate

with females, but instead display a courtship preference for larger females (Hawley and Aleksiuk, 1976; Shine et al., 2001).

It has been hypothesized that the cue utilized by male red-sided garter snakes to differentiate among potential mates is the sexual attractiveness pheromone (Garstka et al., 1982; Gregory, 1984; Mason, 1992). Composed of a homologous series of saturated and ω-9 *cis*-unsaturated methyl ketones (Mason et al., 1989, 1990), this pheromone is sequestered in the skin lipids of females during the breeding season and is primarily responsible for eliciting male courtship behavior (Noble, 1937; Garstka et al., 1982). Indeed, if a male does not detect this pheromone on the dorsal surface of a female, then courtship behavior will not be initiated and mating will not occur (Mason, 1993). Thus, variation in the expression of the sexual attractiveness pheromone by females of varying size may directly influence male courtship behavior, leading to the mating preference observed in this species.

Here, we report a study designed to investigate the role of the female sexual attractiveness pheromone in mediating male mate choice in the red-sided garter snake. Our two major aims in this study were: (1) to determine whether males can discriminate among females of varying size based solely on chemical cues in the skin lipids, and (2) to evaluate whether the sexual attractiveness pheromone contains the necessary variation to function in male mate choice. To this end, we conducted behavioral experiments testing the courtship response of males to large and small females and skin lipid extracts from large and small females. Further, we collected pheromone samples from females of varying size and examined the quantity and quality of pheromone expressed by individual females.

METHODS AND MATERIALS

Study Population

Red-sided garter snakes utilized for this study were captured at a field site near the community of Inwood in the Interlake region of Manitoba, Canada (50°31.58′N; 97°29.71′W) during May 2000. This site is located at an abandoned gravel quarry containing a single overwintering hibernaculum possessing in excess of 10,000 red-sided garter snakes during the winter months (R. T. Mason, unpublished data). Adult females in this population attain an average snout–vent length (SVL) of 55–60 cm and a mean mass of 70–85 g, while adult males are much smaller, attaining an average SVL of 45–50 cm and a mean mass of 35–40 g (Shine et al., 1999).

Behavioral Experiments

Experimental Animals. Unmated large female adult red-sided garter snakes (SVL $>$ 60.0 cm; $N = 35$) and small female adult red-sided garter snakes

(SVL < 50.0 cm; $N = 35$) were collected at the hibernaculum immediately upon emergence. We established the SVL criteria for large and small females based on the results of Hawley and Aleksiuk (1976), who found that female red-sided garter snakes with SVL > 60 cm were twice as likely to be courted by males than females with SVL < 50 cm. Adult males ($N = 380$; SVL $\pm$ SD $= 52.4 \pm 2.54$) were collected from naturally occurring mating balls located around the hibernaculum. We focused our collection on larger males (SVL > 50.0 cm), as larger males show an increased ability to differentiate between females based on size compared to smaller males in this species (Shine et al., 2001). Animals were segregated by sex and size in cloth bags and held at ambient temperatures until testing, after which the animals were returned to the hibernaculum and released.

Testing Conditions. Behavioral experiments were carried out in outdoor arenas measuring $1 \times 1 \times 1$ m and constructed of nylon fabric attached to metal posts inserted in the ground. Arenas of this type do not appear to alter male reproductive behaviors compared to the behaviors observed in the wild, and as a result such arenas have been used extensively in the study of snake reproductive ecology (e.g., Mason and Crews, 1985; Shine et al., 1999; Moore et al., 2000). To avoid any confounding effects due to weather conditions, an array of four arenas was established, allowing for groups of trials to be carried out simultaneously. Testing days and times of day (10:00 hr to 16:00 hr) were chosen so that all experiments were conducted under similar ambient conditions (mostly sunny skies with light winds and temperatures of 15–20°C), which correspond with conditions when red-sided garter snakes are most active (M. P. LeMaster, personal observation).

Experiment 1. To verify that males in our study population exhibited a courtship preference for larger females, we first tested the behavioral response of males to large and small females using a simultaneous choice test design (e.g., Mason and Crews, 1985). Briefly, we introduced 10 randomly chosen males into an arena and allowed them to acclimatize for 5 min. We then placed into each arena simultaneously a large and small female. The snakes were allowed to interact undisturbed for 5 min, after which time the number of males actively courting each female size was recorded. A total of 16 tests were performed with unique male and female snakes used in each trial.

Male courtship behavior was assessed by using an ethogram of male garter snake mating behavior (Table 1). Similar ethograms are routinely used in field and laboratory studies with garter snakes (e.g., Crews et al., 1984; Moore et al., 2000). To prevent females from mating during the trials, a condition that drastically reduces further male courtship advances (Garstka et al., 1982), we placed adhesive tape across the female cloaca. The tape was then removed immediately upon completion of each trial.

Experiment 2. This experiment utilized behavioral trials to determine whether chemical cues contained within the skin lipids of females are sufficient for male mate discrimination. For each trial, we introduced 10 randomly chosen males into

TABLE 1. ETHOGRAM OF COURTSHIP BEHAVIOR FOR MALE RED-SIDED GARTER SNAKES, *Thamnophis sirtalis parietalis*[a]

Courtship score	Description of behavior
1.0	Male investigates female with increasing tongue-flick rate
2.0	Male chin-rubs dorsal surface of female and aligns body with female
3.0	Male actively tail searches and attempts cloacal apposition with female
4.0	Male copulates with female

[a] Modified from Crews et al. (1984). A behavioral score of 2.0 or greater only occurs in a reproductive context and is, therefore, indicative of sexual behavior for males of this species.

an arena and allowed them to acclimatize for 5 min. We then randomly placed in with the males one of four treatments: (1) a small female, (2) a large female, (3) filter paper containing a small female skin lipid sample, or (4) filter paper containing a large female skin lipid sample. Male snakes were allowed to interact with the female or filter paper undisturbed for 5 min, after which the number of males actively courting the treatment was recorded. For filter paper treatments, a male had to be rapidly tongue-flicking and chin-rubbing the filter paper for it to be considered actively courting. A total of 38 trials were performed using small ($N = 9$) and large ($N = 9$) female snakes and skin lipid samples from small ($N = 10$) and large ($N = 10$) female snakes. Unique males and females were used in each behavioral trial.

Skin lipid samples were collected from large and small females by rubbing down the dorsal surface of the donor snake with filter paper wetted with 100% hexane. Care was taken to prevent contamination from cloacal gland secretions (Mason et al., 1989). For each skin lipid sample collected, a unique female was used that was independent of females used in the behavioral trials. To control for surface area differences in the two groups of females, we rubbed down the length of the large females once with the filter paper and rubbed down the length of the small females three times. We established this protocol based on prior knowledge that hexane extracts from large females yield three times the amount of skin lipids compared to small females and that multiple rubbing of a female does not affect male behavior towards the subsequent skin lipids extracted (M. P. LeMaster, unpublished data). To verify that similar quantities of skin lipids were laid down for each female size, we compared the average skin lipid amount laid down on the filter papers for each female size upon completion of the trials [skin lipids (milligrams) = weight of treated filter paper − weight of blank filter paper].

Chemical Analysis

Pheromone Collection. Adult, sexually attractive female red-sided garter snakes of varying size (SVL range 48.0–74.2 cm; $N = 20$) were collected

immediately upon spring emergence from the hibernaculum. The size range of females collected corresponded with the size range of females used in our behavioral experiments. The animals were killed with an overdose of brevital sodium. Each snake was then placed dorsal side down in a 500-ml glass beaker and covered with 25–50 ml of 100% hexane (C_6H_{12}) for 12 hr (Mason et al., 1989, 1990). Care was taken to keep the head and cloaca out of the hexane to avoid possible contamination by internal body fluids. After removal of the animals, the excess solvent was removed under reduced pressure by rotoevaporation at 35°C. The resulting residues were weighed on a digital scale (Mettler AT400), resuspended in fresh hexane (1–2 ml), and sealed in 9-ml glass vials with polyethylene-lined caps for storage at −20°C.

To isolate the methyl ketones composing the sexual attractiveness pheromone, we fractionated the skin lipid extracts using column chromatography as described by Mason et al. (1989). Briefly, we loaded the skin lipid extracts onto glass columns (350 mm long × 22 mm ID) packed with alumina (activity III) and eluted the columns with hexane and ethyl ether ($C_4H_{10}O$) solutions of increasing polarity. For each sample, the fraction containing the appropriate methyl ketones [fraction 5 (Mason et al., 1989)] was collected, and the excess solvent was removed by rotoevaporation (35°C). The resulting methyl ketone residues were weighed on a digital scale (Mettler AT400) and resuspended in 1 ml fresh hexane. Samples were then placed in 9-ml glass vials with polyethylene-lined caps and stored at −20°C until further analysis.

Pheromone Analysis. Multicomponent pheromones, such as the sexual attractiveness pheromone of the red-sided garter snake, can show variation in both the quantity and quality of pheromone expressed. To examine variation in the quantity of pheromone expressed by female snakes of varying size, we calculated the amount of methyl ketones expressed per unit skin surface area (micrograms per square centimeter) for individual females. This was accomplished by dividing the weight of the isolated methyl ketone residues extracted from a female by the total skin surface area of the female. A general index of skin surface area for each female was determined by multiplying the snout–vent length of a female by its circumference at mid-body (Mason et al., 1990).

To examine variation in the quality of pheromone expressed by females, we determined the number of unique methyl ketones expressed by individual females and calculated the relative contributions of saturated *versus* monounsaturated methyl ketones to the individual pheromone profiles. The methyl ketones present in the pheromone extracts were identified utilizing a Hewlett Packard 5890 Series II gas chromatograph fitted with a split injector (280°C) and a Hewlett Packard 5971 Series mass selective detector. Aliquots (1 μl) of the methyl ketone fractions were injected onto a fused-silica capillary column (HP-1; 12 m × 0.22 mm ID; Hewlett Packard) with helium as the carrier gas (5 cm/sec). Oven temperature was initially held at 70°C for 1 min, increased to 210°C at 30°C/min, held at 210°C for 1 min,

increased to 310°C at 5°C/min, and finally held at 310°C for 5 min. Once the methyl ketones were identified, we calculated the relative concentrations of saturated and monounsaturated methyl ketones in each sample by using peak integration [e.g., percent relative concentration of saturated methyl ketones = (area under saturated methyl ketone peaks/total area of all methyl ketone peaks) × 100]. Identification of compounds and peak areas were determined utilizing ChemStation software (Version B.02.05; Hewlett Packard) interfaced with the gas chromatograph/mass spectrometer.

Statistics

Statistical analyses were performed using Jandel SigmaStat Version 2.0 software package (Jandel Corporation). The numbers of males courting large females compared to small females when presented simultaneously were examined by using χ^2 analyses. Differences in the proportion of males courting large and small females and large and small female skin lipid samples were initially analyzed by using a χ^2 test of proportions, with Tukey-type multiple comparison tests then used to perform pairwise comparisons among the four treatments (Zar, 1984). Finally, the relationship between the size of the female (SVL) and various quantitative and qualitative measures of pheromone expression were examined utilizing Pearson product moment correlation tests (Sokal and Rohlf, 1995). Level of significance for each test was set at $P < 0.05$.

RESULTS

Behavioral Experiments

Experiment 1. The average SVL ± SD of small females used in the simultaneous choice tests was 46.2 ± 2.70 cm, whereas the average SVL ± SD for large females was 63.0 ± 2.57 cm. This resulted in an average ± SD difference between small and large females presented to males during individual trials of 16.84 ± 3.93 cm. Over the 16 trials conducted, a greater proportion of males was observed courting the larger female over the smaller female following the 5-min interaction period ($\chi^2 = 56.47$, 1 *df*, $P < 0.001$; 64.3% of males courted large females vs. 11.9% of males courting small females) (Figure 1). We pooled the data for analysis after a heterogeneity χ^2 test showed no significant difference in male courtship preference among the individual trials conducted ($\chi^2 = 7.09$, 15 *df*, $P > 0.5$).

Experiment 2. When presented with the four treatments, male garter snakes responded with stereotypical courtship behaviors including increased tongue-flick rate, chin rubbing along the dorsum of the female (or filter paper), and body alignment with the female (or edge of filter paper). Overall, we observed significant variation in the proportion of males actively courting the various treatments

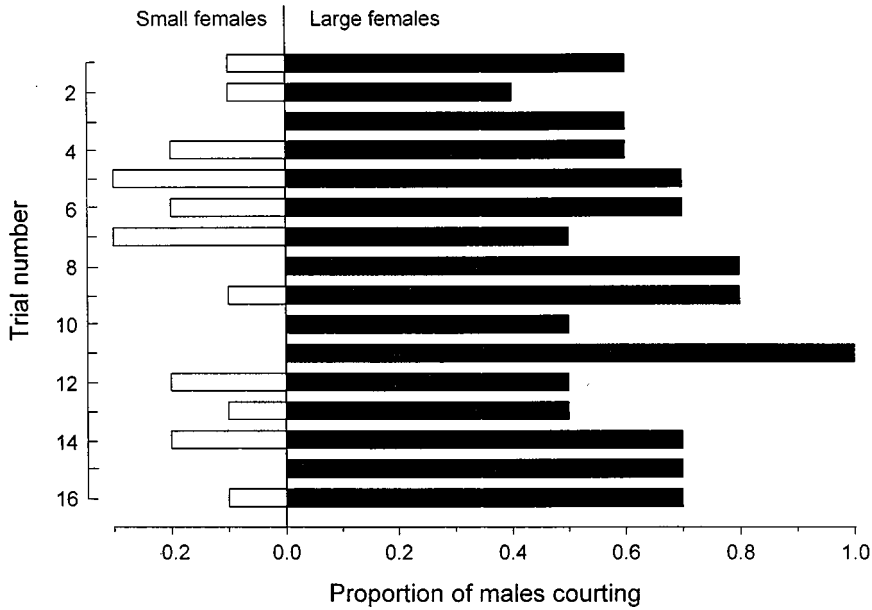

FIG. 1. Results of simultaneous choice tests in which a large and a small female red-sided garter snake (*Thamnophis sirtalis parietalis*) were placed in an outdoor arena with 10 courting males. After 5 min, the number of males that courted either female was recorded.

after the 5-min interaction period ($\chi^2 = 66.48$, 3 *df*, $P < 0.001$; Figure 2). Pairwise analysis revealed that a significantly greater proportion of males directed courtship behavior to large females and filter paper containing large female skin lipids than to small females and filter paper containing small female skin lipids (multiple comparison tests; $q = 10.4$–19.4; $P < 0.001$ for all tests). However, little difference was observed in the proportion of males displaying courtship behavior to large females and large female skin lipid extracts (multiple comparison test; $q = 3.23$; $P > 0.10$) and to small females and small female skin lipid extracts (Multiple comparison test; $q = 2.59$; $P > 0.20$).

When we examined the amount of skin lipids placed on the treated filter papers, we found no difference between filter papers containing large female skin lipid samples and filter papers containing small female skin lipid samples (large female average $\pm$ SD $= 3.0 \pm 2.4$ mg, small female average $\pm$ SD $= 3.2 \pm 2.0$ mg; ANOVA, $F_{1,18} = 0.041$, $P = 0.842$). In addition, there was no difference in SVL $\pm$ SD between large females presented to males and large female skin lipid donors (test female $= 66.1 \pm 3.63$ cm, donor female $= 66.7 \pm 4.66$ cm; t test: $t = 0.308$, $P = 0.762$) or between small females and small female skin lipid

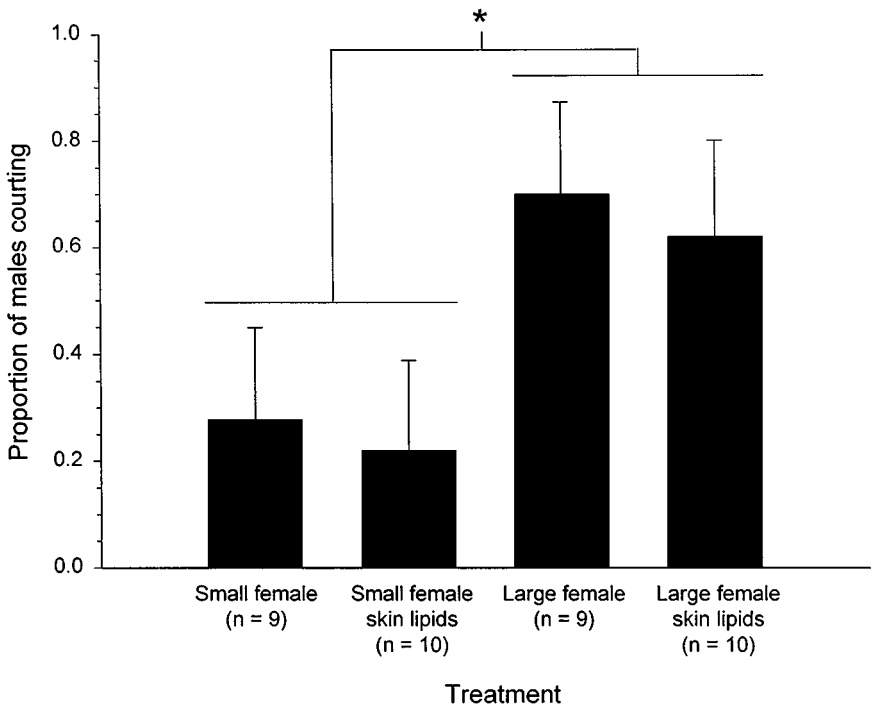

FIG. 2. Proportion (mean ± SD) of male red-sided garter snakes (*Thamnophis sirtalis parietalis*) displaying courtship behavior to large and small females and skin lipid samples from large and small females.

donors (test female = 46.7 ± 4.60 cm, donor female = 44.2 ± 3.16 cm; t test: $t = 1.379$, $P = 0.186$).

Pheromone Analysis

Pheromone Quantity. The hexane extractions of individual females yielded an average ± SD of 21.3 ± 7.5 mg of skin lipids per female. Subsequent fractionation of the lipids yielded an average ± SD methyl ketone fraction of 1.4 ± 1.1 mg/female. Overall, the methyl ketones accounted for an average ± SD of 6.1 ± 3.4% of the skin lipids collected from the female snakes. After accounting for variation in skin surface area, individual females were found to vary widely in the quantity of methyl ketones expressed on their dorsal surface (range = 1.8–16.4 μg/cm^2; Table 2). There was not, however, a significant relationship between the female SVL and the amount of methyl ketones extracted per unit of surface area (Pearson product-moment correlation: $r = 0.169$, $N = 20$, $P = 0.476$).

TABLE 2. QUANTITATIVE AND QUALITATIVE VARIATION IN EXPRESSION OF SEXUAL ATTRACTIVENESS PHEROMONE AMONG INDIVIDUAL FEMALE RED-SIDED GARTER SNAKES, *Thamnophis sirtalis parietalis*[a]

Individual female	Snout-vent length (cm)	Methyl ketone expression ($\mu g/cm^2$)	Unique methyl ketones observed	Relative (%) methyl ketone concentrations	
				Saturated	Unsaturated
1	48.0	5.6	17	75.1	24.9

20	74.2	5.3	16	25.2	74.8

[a] Female snakes are arranged according to snout-vent length (small to large).

Pheromone Quality. Complete GC-MS analysis of the methyl ketone fractions revealed the presence of 18 unique long-chained methyl ketones (Figure 3). Nine of these were identified as long-chain saturated methyl ketones, while the remaining nine had mass spectra in accord with long-chain ω-9 *cis*-unsaturated methyl ketones (Mason et al., 1990). The saturated methyl ketones ranged in size from 394 mass units to 506 mass units, whereas the unsaturated methyl ketones ranged in size from 420 mass units to 532 mass units. Individual females were found to vary in the number of methyl ketones expressed in their skin lipids, ranging from pheromone profiles composed of 10 unique methyl ketones to pheromone profiles composed of all 18 unique methyl ketones (Table 2). However, when we plotted the number of unique methyl ketones present against the SVL of the females, a significant relationship was not observed (Pearson product-moment correlation: $r = -0.338$, $N = 20$, $P = 0.144$).

The relative contribution of the saturated and unsaturated methyl ketones to the overall pheromone profiles varied extensively among females (Table 2).

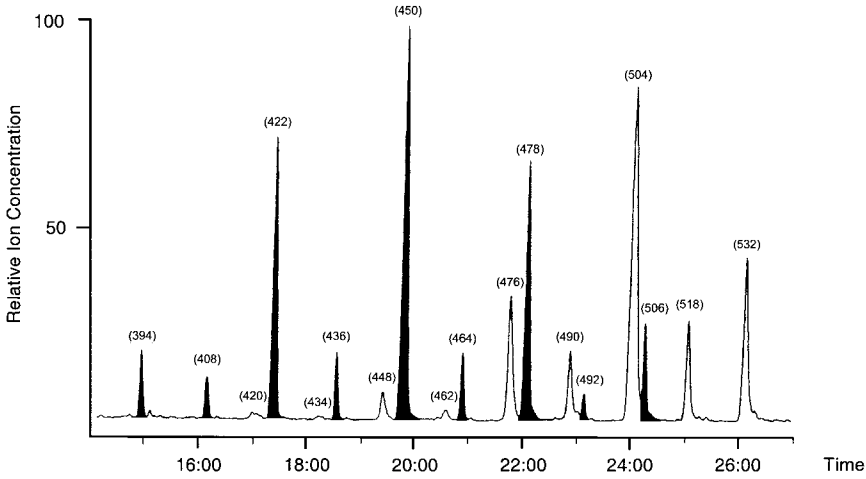

FIG. 3. Gas chromatogram of the female sexual attractiveness pheromone profile for the red-sided garter snake, *Thamnophis sirtalis parietalis*. Pheromone profiles are composed of saturated (shaded peaks) and unsaturated (open peaks) methyl ketones. The numbers over the peaks represent the molecular weights of individual components.

For example, one female expressed a pheromone profile composed of 75.1% saturated methyl ketones and 24.9% unsaturated methyl ketones, whereas a second female expressed a profile composed of 7.4% saturated methyl ketones and 92.6% unsaturated methyl ketones. Saturated methyl ketones composed (average $\pm$ SD) $44.2 \pm 24.5\%$ of the total methyl ketones in the pheromone profiles, and unsaturated methyl ketones composed $55.8 \pm 24.5\%$. When we plotted the SVL of the females against the relative contribution of unsaturated methyl ketones to the pheromone profiles, a significant correlation was observed (Pearson product moment correlation: $r = 0.788$, $N = 20$, $P < 0.001$; Figure 4). This relationship showed that smaller females express pheromone profiles comprised predominantly of saturated methyl ketones, while larger females express profiles composed predominantly of unsaturated methyl ketones.

DISCUSSION

The results of this study demonstrate that adult red-sided garter snakes are able to discriminate among females of various size based solely on chemical cues contained within the skin lipids of the female. Males displayed a courtship preference for large females over small females when presented both simultaneously and in isolation, and continued to demonstrate a similar preference when visual, tactile, and behavioral cues from the females were removed through the use of skin lipid

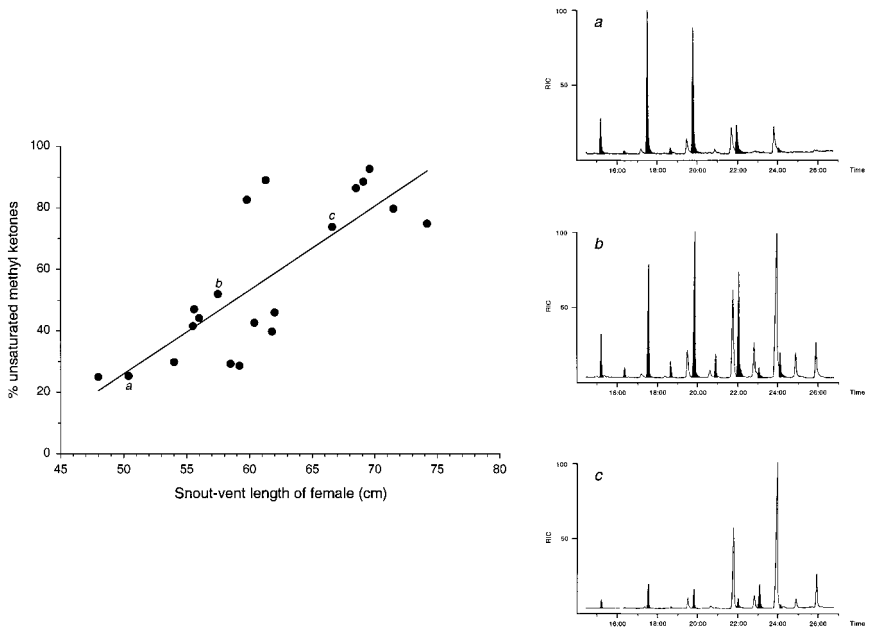

FIG. 4. Regression of the percent relative concentration of unsaturated methyl ketones composing the sexual attractiveness pheromone profile on snout-vent length for female red-sided garter snakes, *Thamnophis sirtalis parietalis*. Small females express pheromone profiles consisting predominantly of saturated methyl ketones (a), mid-size females express profiles consisting of equal proportions of saturated and unsaturated methyl ketones (b), and large females express profiles consisting predominately of unsaturated methyl ketones (c).

extracts. Furthermore, we observed size-specific variation in the chemical structure of the female sexual attractiveness pheromone, suggesting that this pheromone represents the skin lipid-borne cue responsible for mediating male mate choice in this species. Previous studies have documented chemically mediated mate choice in a variety of vertebrates [e.g., mammals: lemmings (Huck and Banks, 1982), rabbits (Reece-Engel, 1988), amphibians: salamanders (Verrell, 1985; Marco et al., 1998), reptiles: lizards (Martín and López, 2000)] but have focused exclusively on the behavioral responses of individuals to chemical cues. To our knowledge, this study represents the first attempt to provide empirical evidence towards the identification of a chemical cue responsible for mediating mate choice in a vertebrate species.

Our results from the behavioral experiments confirm previous studies documenting a courtship preference by male red-sided garter snakes for larger females during the breeding season (Hawley and Aleksiuk, 1976; Garstka et al., 1982; Shine et al., 2001). Similar courtship preference by males for larger females has been observed in other reptiles including lizards (e.g., Olsson 1993; Cooper and Vitt, 1997; Whiting and Batemen, 1999) and snakes (e.g., Luiselli, 1996). One potential benefit incurred by male red-sided garter snakes for choosing a female of larger body size is an increase in the number of offspring sired. Fecundity has been shown to increase with body size in a variety of animals (reviewed in Andersson, 1994), and this appears true for red-sided garter snake populations in Manitoba, where larger females are observed producing larger clutches of young (Gregory, 1977; R. T. Mason, unpublished data).

We are confident that our bioassay results represent a true measure of male courtship preference for skin lipids from larger females. When male red-sided garter snakes were presented with skin lipid extracts from both large and small females, we observed courtship behavior closely mimicking what was observed with the actual females, including chin-rubbing and body alignment (with edge of filter paper). These behaviors are only observed in a reproductive context (Mason, 1993), confirming that we were measuring a courtship response and not some other male behavior (e.g., aggregation). Furthermore, analysis of the treated filter papers showed that similar amounts of skin lipids were transferred to the filter papers from the large and small snakes. Potentially, variation in the total amount of skin lipids transferred for the two female sizes could have driven the male courtship preference observed. Instead, our results suggest that there is some intrinsic property of the female skin lipids that allows for males to differentiate among large and small females.

The observed relationship between the SVL of females and the methyl ketone group ratios demonstrates that the sexual attractiveness pheromone can function as a reliable indicator to males of female body size. Indeed, the observed uniform shift in methyl ketone group ratios as females increased in size conforms well with the observed uniform change in male courtship behavior displayed to females of varying size when tested in the field (Hawley and Aleksiuk, 1976). In addition,

the pattern of variation we observed in pheromone composition is concordant with what would be expected for such variation to function in male mate selection. Although both saturated and unsaturated methyl ketones are required to elicit full male courtship behavior in red-sided garter snakes, unsaturated methyl ketones appear to be the more biologically active. When presented in isolation, unsaturated methyl ketones elicit a five-fold increase in male response over saturated methyl ketones (Mason et al., 1989). Accordingly, higher levels of unsaturated methyl ketones in the pheromone ratios of larger females, as observed in this study, are a likely explanation for why males find these females more attractive.

Why larger females express higher levels of unsaturated methyl ketones is unclear. The production and expression of this pheromone appears to be under hormonal control [estrogen (Crews, 1976; Crews et al., 1984)], suggesting that variation in the release rate of hormones and/or sensitivity of target cells to the hormones may explain the variation. For example, larger females produce a greater number of follicles in the fall [hence, greater numbers of offspring (Gregory, 1977)], which may translate into higher levels of estrogen circulating in the blood during the period of pheromone biosynthesis. Alternatively, females of varying size may differ in the organization of biosynthetic pathways involved in methyl ketone production. Future studies are necessary to resolve the underlying mechanism(s) responsible for the observed variation in methyl ketone production.

We might have expected to find variation in the quantity of sexual attractiveness pheromone expressed by female red-sided garter snakes of varying size or variation in the presence or absence of individual methyl ketones. Similar mechanisms of mate choice have been observed in insects (reviewed in Andersson, 1994). For example, female rattlebox moths (*Utetheisa ornatrix*) prefer to mate with males producing higher quantities of a courtship pheromone (Dussourd et al., 1991), whereas female Oriental moths (*Grapholita molesta*) preferentially court males expressing a food-related chemical in their pheromone blend (Löfstedt et al., 1989). However, we did not observe a correlation between female body size and either of the two measures in the expression of the sexual attractiveness pheromone, suggesting that such variation is not utilized by male red-sided garter snakes to differentiate among females.

Although the results from this study strongly suggest that male red-sided garter snakes differentiate among females of varying size by utilizing size-specific variation in the female sexual attractiveness pheromone, we can not rule out the possibility that additional cues may assist males in mate choice for this species (Shine et al., 2001). For example, male garter snakes searching for sexually attractive females in the field are initially attracted to movement (Joy and Crews, 1988; Holtzman, 2001). Thus, males might initially respond to perceived areas of greater movement (i.e., larger female moving through grass or action of larger mating ball) and then confirm their choice by sampling the skin lipid composition of the female once contact is made. In addition, tactile cues may provide additional

relevant information to the male. When a male initially comes in contact with a female, he proceeds to chin-rub up and down the female, turning back at the head and tail before finally coming to rest with his head resting behind the female's head (Noble, 1937). Males perform this behavior to detect quickly whether the female is mated by means of postcopulatory pheromones deposited near the cloaca (Shine et al., 2000), but males might also be able to judge the size of the female based on distance covered. Further studies are required to determine to what extent these additional cues may be utilized.

Acknowledgments—We thank the Manitoba Department of Natural Resources, Dave Roberts, and Al and Gerry Johnson for assistance in the field. We also thank Thomas Roberts, Rick Shine, Heather Waye, Adam Jones, and two anonymous reviewers for useful comments concerning this manuscript and William Gerwick for the use of his GC-MS system. (Received January 30, 2001; accepted February 12, 2002)

Abstract—The volatile constituents in anal gland secretions of two sympatric *Mustela* species, the Siberian weasel (*M. sibirica*) and steppe polecat (*M. eversmanni*), were studied by the headspace technique, followed by gas chromatography–mass spectrometry (GC-MS) analysis. Nine sulfur-containing compounds were identified. They were 2,2-dimethylthietane, (*Z*)- or (*E*)-2,4-dimethylthietane, (*E*)-2,3-dimethylthietane, 2-ethylthietane, (*E*)-2-ethyl-3-methylthietane, (*Z*)-2-ethyl-3-methylthietane, 2-propylthietane, 3,3-dimethyl-1,2-dithiacyclopentane, and (*Z*)-3,4-dimethyl-2,2-dithiacyclopentane. Among them, (*E*)-2-ethyl-3- methylthietanes, (*Z*)-2-ethyl-3-methylthietanes, and (*Z*)-3,4-dimethyl-1,2-dithiacyclopentane were present in the polecat but not in the weasel. The predominant compound was 2,2-dimethylthietane in the weasel and (*E*)- or (*Z*)-2,4-dimethylthietane in the polecat. These differences were consistent between the two species, regardless of sex and age and, therefore, could possibly be used for species recognition. In the weasel, 2-ethylthietane was found only in the female, and the relative abundance of several compounds was significantly different between males and females. In the polecat, although no sex-specific volatile compounds were found, males and females differed in the relative abundance of several of the compounds. In both species, the relative abundance of some compounds varied with age. We conclude that these volatile compounds can be used to communicate information about species, sex, and age.

Key Words—Anal gland secretion, volatile compounds, Siberian weasel, *Mustela sibirica*, steppe polecat, *Mustela eversmanni*.

INTRODUCTION

Chemical communication plays a vital role in mammalian social interactions, such as recognition of species, sex, age, dominance status, and physiological and reproductive condition (e.g., Müller-Schwarze, 1974; Brown, 1979; Sun and Müller-Schwarze, 1999). Our current knowledge of animal chemical communication has been mainly garnered through two inseparable approaches: chemical analysis of secretion materials and behavioral bioassays. Chemical analysis of secretions can provide insight into what information is available and how it is coded and, therefore, can narrow or generate new hypotheses for behavioral bioassays (Sun, 1996).

Carnivores, rodents, and ungulates are among the most intensively studied mammalian groups for chemical communication (see Brown and Macdonald, 1985). The chemical composition of the anal gland secretion of small carnivores is of particular interest to researchers. In the *Mustela* genus, chemical analysis has been conducted in the domestic American mink (*M. vison*) (Sokolov et al., 1980; Brinck et al., 1978, 1983), stoat (*M. erminea*) and domestic ferrets (*M. putorius furo*) in New Zealand (Crump, 1980a,b; Crump and Moors, 1985), and mountain weasel (*M. nivalis*) and ferret (*M. putorius*) (Brinck et al., 1983). These efforts have resulted in the identification of 18 major volatile compounds unique to *Mustela*. They are 2-pentylthietane ($C_8H_{16}S$), 3-propyl-1,2-dithiolane ($C_6H_{12}S$), indole (C_8H_7N), and *o*-aminoacetophenone (C_8H_9NO), six isomers of $C_5H_{10}S$, four isomers of $C_6H_{12}S$, and four isomers of $C_5H_{10}S_2$. Among them, two are nitrogen-containing compounds: indole (in all *Mustela* species) and *o*-aminoacetophenone (only in *M. erminea*), and the remaining are all sulfur-containing compounds. These 18 compounds apparently are unique to *Mustela* and have not been found in other genera in the family Mustelidae, such as *Martes martes* (Brinck et al., 1983), *Lutra lutra* (Gorman et al., 1978; Brinck et al., 1983) and *Meles meles* (Brinck et al., 1983). Comparisons of these volatiles from the anal gland secretions of various *Mustela* species show that the presence or absence or relative proportion of isomers of $C_5H_{10}S$, $C_6H_{12}S_2$ and $C_5H_{10}S_2$ is species specific. This provides cues for species recognition among sympatric species.

Findings in intersexual or individual variation in the chemical composition of anal gland secretions may also indicate the possibility for sex and individual recognition within a *Mustela* species. For example, the chromatographic peak profile of the anal gland secretion in the mink is characteristic of the individual and not affected by season (Brinck et al., 1978). In stoats, highly volatile components in the anal gland secretion also demonstrate a stable individual pattern (Erlinge et al., 1982). Sexual dimorphism in the chemical composition of anal gland secretion varies with species. American minks show no specific sex differences over the four seasons (Brinck et al., 1978). Secretions from female stoats during the breeding season, however, contain compounds not present in the male in the breeding season

(Crump, 1980a). This implies that other unidentified compounds may also be involved in sex recognition.

Siberian weasels (*Mustela sibirica fortanieri*) and steppe polecats (*Mustela eversmanni admirata*) distribute sympatrically in farmlands in northern China. They overlap in their activity range and rodent diet (Gao, 1987). Thus, both interspecific and intraspecific recognition is important for the two species. Since secretions from the anal gland have already been identified as a source of information for recognition in *Mustela*, chemical analyses of the volatile compounds may allow us to pinpoint the components involved. In this study, we characterized the volatile components of the two *Mustela* species and explored their potential roles by examining species-, sex-, and age-related differences in these compounds.

METHODS AND MATERIALS

Collection and Separation of Volatile Compounds. Anal glands were removed fresh from Siberian weasels (70 males and 50 females) and steppe polecats (40 males and 20 females) captured legally by fur trappers in several farmlands in central northern China in January 2000. They were immediately frozen and transferred to the laboratory and stored at -20°C until use.

For both species, we used the baculum to estimate the age of males. Animals with a baculum weight <250 mg were classified as juveniles and >350 mg as adults (Sheng and Lu, 1976; Gao, 1987). For females, we used body weight to estimate the age. Those weighing >500 g were classified as adults and <350 g as juveniles (Sheng and Lu, 1976; Gao, 1987). We found no juvenile female steppe polecats and, thus, this age group was not included in our study.

Each anal gland was punctured, and secretion material was squeezed into a 1.5-ml vial. Secretions from individuals of the same species, sex, and age group were pooled into larger vials, each containing samples from at least five individuals. These pooled samples were used for chemical analysis.

For each pooled sample, we filtered 150 mg of secretion material and placed it into a 100-ml glass entrainment jar, which was waterbathed at a constant temperature of $55 \pm 1^{\circ}$C. A headspace sample was collected using Porapak Q (100 ± 2 mg, mesh 80–100). Volatiles trapped on the porous Porapak Q were released by solvent desorption. Porapak Q was packed individually into a glass tube (8 cm long $\times$ 3 mm ID) and kept in place with silanized glass wool plugs. The Porapak Q tube was immersed in ice-water (0°C) for better retention of the volatiles. Volatile chemicals from the headspace of the secretion samples were drawn onto the polymer for 10 hr by using Porapak Q-filtered nitrogen gas at a flow rate of 100 ml/min. At the end of entrainment, trapped volatiles were eluted from Porapak Q with 5 ml of redistilled dichloromethane. The dichloromethane solutions were later condensed to 1/8 volume (0.625 ml) by a gentle stream of N_2 gas and were used for the following analysis.

Gas Chromatography–Mass Spectrometry (GC-MS). Analytical GC-MS was performed on a Shimadzu GC-MS QP5050A instrument. The GC was equipped with a 30-m glass capillary column (0.25 mm ID) coated with SE54. Helium was used as the carrier gas at a flow rate of 0.5 ml/min. The temperature of the injector was set at 250°C, and the split ratio was set at 1:10. The oven temperature was programmed as 50°C for 5 min, then increased at 10°C/min to 220°C, and finally held at 220°C for 10 min. Electron impact was used for ionization, which was set at 70 eV and 250°C.

We searched the literature to determine which reference substances should be used for parallel analyses. This led to our identification of 2,2-dimethylthietane (**1**), 2-ethylthietane (**4**), and 3,3-dimethyl-2,2-dithiacyclopentane (**8**), which had been identified in the mink by using a similar method (Brinck et al., 1978, 1983; Sokolov et al., 1980). (The number that follows each compound corresponds to the number in Table 1 below.) The GC profile and mass spectrum of 2-propylthietane (**7**) was compared with that of a commercially available authentic chemical compound. We used the mass spectra available in the literature to aid in the identification of the following compounds: (*Z*)-or (*E*)-2, 4-dimethylthietane (**2**), (*E*)-2,3-dimethylthietane (**3**) (Crump, 1980b), (*E*)-2-ethyl-3-methylthietanes (**5**), (*Z*)-2-ethyl-3-methylthietanes (**6**) (Crump and Moors, 1985), and (*Z*)-3,4-dimethyl-1, 2-dithiacyclopentane (**9**) (Crump, 1980b; Sokolov et al., 1980; Brinck et al., 1983).

We used the method developed by Sun and Müller-Schwarze (1998) to quantify the relative abundance of the nine compounds. We converted the peak area of a particular compound into the percentage of the summed peak areas of all nine compounds in a sample. We then used a two-tailed independent *t* test to test for the difference in these compounds between species, sexes, and age groups. The level of significance was set at 0.05. Because we had four samples for each specific sex or age group, the degree of freedom was 6 for all tests.

RESULTS

Volatile Compounds in Anal Gland Secretions. Typical GC chromatogram profiles of volatiles from anal gland secretions in male steppe polecats and female Siberian weasels are shown in Figure 1. Mass spectral information of the numbered peaks is given in Table 1. Using headspace sampling and subsequent GC-MS analysis, we identified nine volatiles in the anal gland secretion of the two species: 2,2-dimethylthietane (**1**), (*Z*)-or (*E*)-2,4-dimethylthietane (**2**), (*E*)-2, 3-dimethylthietane (**3**), 2-ethylthietane (**4**), (*E*)-2-ethyl-3-methylthietanes (**5**), (*Z*)-2-ethyl-3-methylthietanes (**6**), 2-propylthietane (**7**), 3,3-dimethyl-1,2-dithiacyclopentane (**8**), and (*Z*)-3,4-dimethyl-1,2-dithiacyclopentane (**9**) (Table 1).

The GC chromatogram shows nine volatile constituents in the secretion of the steppe polecat (Figure 1A). Compounds **1–4** (Table 1) have a molecular mass of

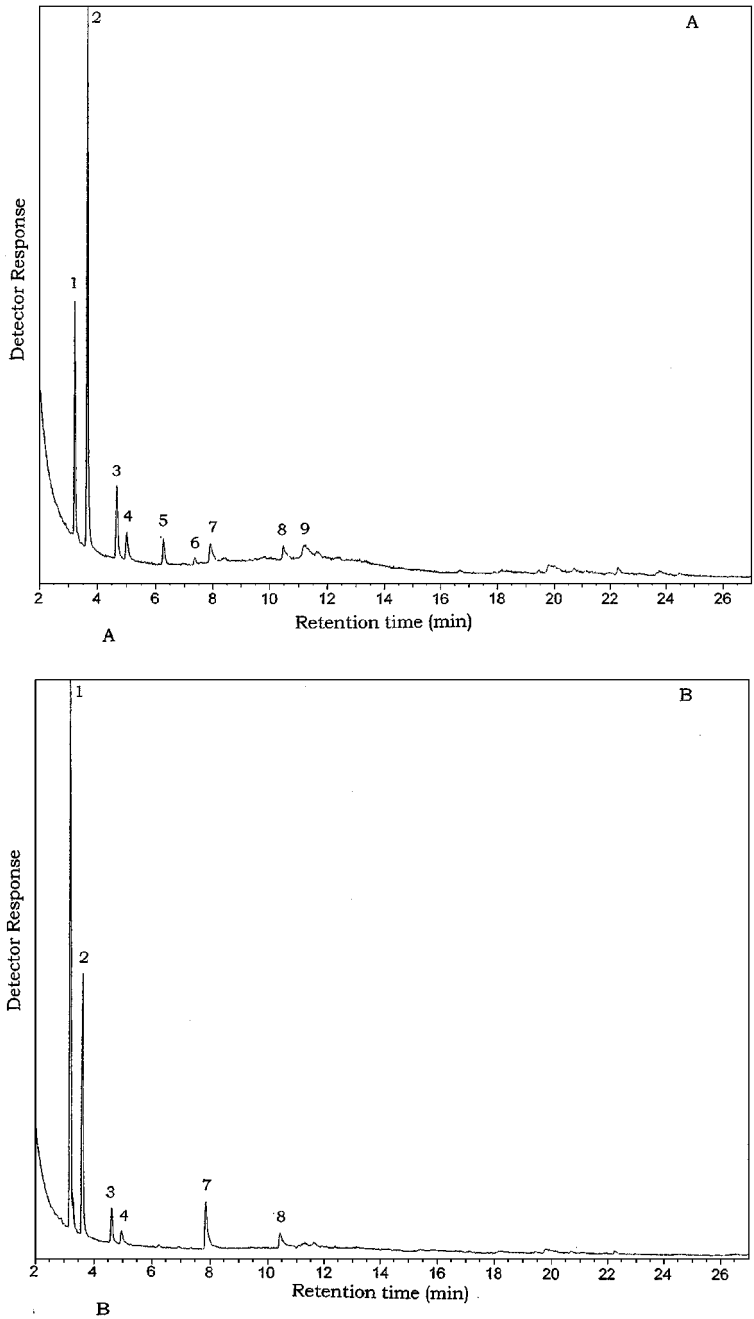

FIG. 1. Gas chromatogram of the anal gland secretion from male adult steppe polecats (*Mustela eversmanni admirata*) (A) and female adult Siberian weasels (*Mustela sibirica fortanieri*) (B).

TABLE 1. MS DATA AND COMPOUNDS IDENTIFIED IN ANAL GLAND VOLATILES OF SIBERIAN WEASEL OR STEPPE POLECAT

Compound	Mass spectrum data [*m*/*z* values (ion intensities)]	Identification
1	102(48), 87(28), 74(28), 69(25), 68(18), 67(15), 60(25), 56(82), 41(100)	2,2-dimethylthietane
2	102(32), 87(3), 74(1), 73(1), 69(4), 68(2), 67(3), 60(100), 61(16), 59(22), 56(31), 45(26), 41(45)	*Z*- or *E*-2,4-dimethylthietane
3	102(30), 87(12), 74(7), 73(7), 69(8), 67(8), 61(15), 60(100), 59(20), 56(28), 41(45)	*E*-2,3-dimethylthietane
4	102(64), 87(42), 74(49), 73(52), 69(14), 68(24), 67(18), 61(13), 60(100), 59(12), 56(29), 55(50), 45(89), 41(100)	2-ethylthietane
5	116(59), 101(22), 87(59), 74(16), 73(42), 69(27), 68(8), 67(51), 60(39), 59(19), 55(70), 45(77), 41(100)	*E*-2-ethyl-3-methylthietanes
6	116(37), 86(6), 84(13), 74(100), 70(19), 69(26), 60(2), 59(27), 56(18), 55(45), 45(29), 41(98)	*Z*-2-ethyl-3-methylthietanes
7	116(55), 88(43), 87(79), 86(26), 74(13), 73(73), 69(45), 67(50), 56(52), 55(51), 41(100)	2-propylthietane
8	134(20), 86(2), 70(10), 69(99), 67(8), 59(14), 57(4), 56(4), 55(13), 53(11), 41(100)	3,3-dimethyl-1,2-dithiacyclopentane
9	134(31), 86(12), 85(13), 70(24), 69(100), 57(42), 55(32), 41(87)	*Z*-3,4-dimethyl-1,2-dithiacyclopentane

102 ($C_5H_{10}S$). Compounds **1** and **4** have GC and MS data identical to peaks identified as 2,2-dimethylthietane and 2-ethylthietane by Brinck et al. (1978, 1983) in a parallel analysis of the anal gland secretion of the mink. Compounds **2** and **3** show mass spectra that are superimposable on those of (*Z*)- or (*E*)-2,4-dimethylthietane and (*E*)-2,3-dimethylthietane found in the domestic ferret (Crump, 1980b) and mountain weasel (Brinck et al., 1983). GC retention time sequence shows that compound **2** is (*Z*)- or (*E*)-2,4-dimethylthietane and compound **3** is (*E*)-2, 3-dimethylthietane. Compounds **5**, **6**, and **7** all have a molecular mass of 116 ($C_6H_{12}S$) (Table 1). Compound **7** and authentic synthetic 2-propylthietane have identical GC and MS data, whereas the MS data of compounds **5** and **6** correspond to (*E*)- and (*Z*)-2-ethyl-3-methylthietane identified in the stoat (Crump and Moors, 1985). The GC and MS data of compounds **8** and **9** show that they both have a molecular mass of 134 ($C_6H_{12}S_2$) (Table 1). The presence of ions at *m*/*z* 41, *m*/*z* 69, and *m*/*z* 134 and the absence of an ion at *m*/*z* 29 indicate that they are most likely isomers of 3,3-dimethyl-1,2-dithiacyclopentane. The GC and MS data of compound **8** are similar to those of 3,3-dimethyl-1,2-dithiacyclopentane (Sokolov et al., 1980). The absence of ions at *m*/*z* 102 and 94 in the MS of compound **9** agrees with that observed by Crump (1980b) for (*Z*)-3, 4-dimethyl-1,2-dithiacyclopentane in the ferret.

Interspecific Differences. In the Siberian weasel, the gas chromatograms and mass spectra of anal gland secretions of both sexes and two age groups had six peaks (Figure 1B) corresponding to 2,2-dimethylthietane (peak 1), (*Z*)- or (*E*)-2,4-dimethylthietane (peak 2), (*E*)-2,3-dimethylthietane (peak 3), 2-ethylthietane (peak 4), 2-propylthietane (peak 7), and 3,3-dimethyl-1,2-dithiacyclopentane (peak 8).

(*E*)-2-Ethyl-3-methylthietanes (peak 5), (*Z*)-2-ethyl-3-methylthietanes (peak 6), and (*Z*)-3,4-dimethyl-1,2-dithiacyclopentane (peak 9) were present in the polecat but not in the weasel. Several compounds, although present in both species, showed a consistent difference in relative abundance between the two species. 2,2-Dimethylthietane was the dominant component in the weasel (male: $t = 5.022$, $P = 0.004$; female: $t = 4.038$, $P = 0.006$), while in the polecat (*Z*)- or (*E*)-2,4-dimethylthietane was the dominant component (male: $t = 4.975$, $P = 0.002$; female: $t = 2.455$, $P = 0.048$). For males, 2-ethylthietane occurred only in the polecat but not in the weasel. The polecat also had a higher level of (*E*)-2,3-dimethythietane ($t = 3.272$, $P = 0.017$) and a lower level of 3,3-dimethy-1,2-dithiacyclopentane ($t = 3.490$, $P = 0.012$) than the weasel. For females, the polecat had a higher level of 2-ethylthietane and a lower level of 2-propylthietane ($t = 3.811$, $P = 0.009$) than the weasel (Table 2).

Intraspecific Differences. In terms of *sex difference*, in Siberian weasels, 2-ethylthietane (peak 4) only occurred in females and was undetectable in males. Furthermore, the relative abundance of (*Z*)- or (*E*)-2,4-dimethylthietane (peak 2) and (*E*)-2,3-dimethylthietane (peak 3) was significantly higher in females than in males ($t = 4.954$, $P = 0.003$ and $t = 2.927$, $P = 0.026$, respectively).

TABLE 2. COMPARISON OF ANAL GLAND VOLATILES BETWEEN SEXES AND CONSPECIES IN SIBERIAN WEASEL AND STEPPE POLECAT[a]

Component	Adult Siberian weasel		Adult steppe polecat	
	Males	Females	Males	Females
1	$78.37 \pm 26.33^{\dagger\dagger}$	$55.68 \pm 21.22^{\dagger\dagger}$	15.99 ± 3.88	14.14 ± 5.09

[a] Mean of percent peak area (%) $\pm$ SD, $N = 4$. †:$P < 0.05$; ††:$P < 0.01$ between the two species of the same sex (marked only in the weasel data); *:$P < 0.05$; **:$P < 0.01$ between the two sexes of the same species (marked only in the female data).

Furthermore, 3,3-dimethyl-1,2-dithiacyclopentane (peak 8) was more abundant in males than in females ($t = 3.27$, $P = 0.017$; see Table 2).

In the steppe polecat, five compounds showed quantitative differences between the two sexes. (*E*)- and (*Z*)-2-Ethyl-3-methylthietanes (peaks 5 and 6), 3,3-dimethyl-1,2-dithiacyclopentane (peak 8), and (*Z*)-3,4-dimethyl-1,2-dithiacyclopentane (peak 9) were all higher in females ($t = 2.990$, $P = 0.034$; $t = 2.371$, $P = 0.046$; $t = 2.450$, $P = 0.043$; and $t = 3.318$, $P = 0.012$, respectively), whereas 2-propylthietane (peak 7) was higher in males ($t = 2.762$, $P = 0.038$). However, no sex-specific compound was observed (Table 2).

In terms of *age difference*, in male Siberian weasels, adults had a higher level of 2-propylthietane (peak 7) and 3,3-dimethyl-1, 2-dithiacyclopentane (peak 8) than juveniles ($t = 2.978$, $P = 0.034$ and $t = 3.097$, $P = 0.026$, respectively). In female weasels, adults had a higher level of (*Z*)- or (*E*)-2,4-dimethylthietane (peak 2), (*E*)-2,3-dimethylthietane (peak 3), and 2-propylthietane (peak 7) than juveniles ($t = 2.608$, $P = 0.041$; $t = 2.990$, $P = 0.032$ and $t = 3.582$, $P = 0.014$, respectively). Juveniles, however, had a higher level of 3,3-dimethyl-1, 2-dithiacyclo pentane (peak 8) than adults ($t = 3.049$, $P = 0.026$).

In male steppe polecats, adults had a lower level of 2-ethylthietane (peak 4) and (*E*)-2-ethyl-3-methylthietanes (peak 5) in comparison with those in juveniles ($t = 2.976$, $P = 0.383$ and $t = 2.901$, $P = 0.0371$, respectively; Table 3).

DISCUSSION

Our results show that all volatiles detected in the anal gland secretion of the Siberian weasel and steppe polecat were sulfur-containing compounds, as previously reported in other *Mustela* species (Sokolov et al., 1980; Crump, 1980a,b; Brinck et al., 1983; Crump and Moors, 1985). A unique aspect that has not been previously reported, however, is that four isomers of $C_5H_{10}S$ occurred in either Siberian weasels or steppe polecats. Whether this similarity in the anal gland secretions is due to their close phylogenetic relationship or to the similarity in microbial communities is yet unknown.

Three compounds [two isomers of 2-propylthietane and (*Z*)-dimethyl-1,2-dithiacyclopentane] occurred only in steppe polecats. 2,2-Dimethylthietane was dominant in the Siberian weasel, while (*Z*)- or (*E*)-2,4-dimethylthietane was most abundant in the steppe polecat. The two species also differed significantly in the relative abundance of 2-ethylthietane, (*E*)-2,3-dimenthythietane, 3,3-dimethy-1,2-dithiacyclopentane, and 2-propylthietane for males or females or both. These consistent qualitative and quantitative differences between the two sympatric species provide unambiguous recognition cues between them.

Nitrogen-containing indole, detected previously in other *Mustela* species, was not found in the two species we studied. This can probably be attributed to the headspace sampling technique: our sampling apparatus may fail to trap indole,

which is less volatile than the nine compounds we identified. In fact, we only found three sulfur-containing compounds (2,2-dimethylthietane, 2-ethylthietane, and 3,3-dimethyl-1,2-dithiacyclopentane) in the anal gland secretion of the mink using our sampling method (unpublished data). In contrast, Brinck et al. (1983) detected indole, in addition to these three compounds in solvent extracts from mink secretions. Thus, the headspace technique appears to be insensitive for detecting relatively heavy volatiles.

Intraspecific communication is suggested to be the main function of the anal gland secretion in mustelids (Erlinge et al., 1982; Brinck et al., 1983). Our study demonstrates that there is a wealth of information contained in the anal gland secretion that can be used for age and sex recognition in the two *Mustela* species. It seems that the coding for sex information takes two forms, either by the presence or absence of sex-specific compounds, such as 2-ethylthietane in female Siberian weasels, and/or by the difference in relative abundance of some compounds between males and females. We failed to find any age-specific compounds.

The sex or age difference in the composition of secretions is generally regulated by hormones (Ebling, 1977). For example, female-specific compounds are only found in stoats during the breeding season (Crump et al., 1980a). In ferrets, production of anal gland secretion is suppressed during estrus (Crump et al., 1980b). Quinaldine is only found in the urine of male red foxes, *Vulpes vulpes* (Jorgenson et al., 1978), and sex hormones significantly affect some volatile constituents in the anal gland secretion of the wolf, *Canis lupus* (Raymer et al., 1985). The hormonal difference between males and females or between adults and juveniles may be responsible for the qualitative and quantitative differences in the volatile compounds in our study.

One obvious caveat is that not all volatiles in anal gland secretions were detected due to methodological limitations (e.g., indole). Additionally, nonvolatiles may also play a significant role (e.g., Sun and Müller-Schwarze, 1998). Whether these nine volatiles are exclusively involved in these recognitions should be ultimately confirmed through behavioral bioassay in the future.

ANNOUNCEMENT

19TH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY AUGUST 3–8, 2002, HAMBURG

The 19th annual ISCE meeting will be held at the Department of Chemistry, University of Hamburg, Germany. The conference will begin on the evening of August 3, 2002 (Saturday) and end on the evening of August 7 (Wednesday). The meetings will be hosted by Wittko Francke.

There will be four symposia covering aspects of chemical ecology in symbiosis, molecular biology, insect-plant relationship, and pheromone chemistry.

Both oral and poster presentations are invited from participants. Contributed papers fitting to the symposia are particularly welcome.

Participants are encouraged to arrive on Saturday, August 3, and attend the Social Lecture given by Prof. Dr. Jerrold Meinwald followed by a mixer that evening. The concluding banquet will be held Wednesday evening, August 7.

Further Information may be obtained on the meetings web site http://isce2002.chemie.uni-hamburg.de

Mini-Review

CONSTRAINTS ON EFFECTIVENESS OF CYANOGENIC GLYCOSIDES IN HERBIVORE DEFENSE

ROSLYN M. GLEADOW* and IAN E. WOODROW

School of Botany, The University of Melbourne
Victoria, Australia 3010

(Received January 20, 2002; accepted March 15, 2002)

Abstract—Cyanogenesis is the process by which hydrogen cyanide is released from endogenous cyanide containing compounds. Many cyanogenic plants release HCN in sufficient quantities to be toxic and, as a result, tend to be avoided by herbivores. However, there are many exceptions with some herbivores either immune to the cyanogenic status of the plant, or in some cases attracted to cyanogenic plants. This has led to a certain degree of scepticism regarding the role of cyanogenic glycosides as defense compounds. In this review, we examine evidence showing that differences in the effectiveness of cyanogenic glycosides in deterring herbivory can usually be reconciled when the morphology, physiology, and behavior of the animals, together with the concentration of cyanogenic glycosides in the host plant, are taken into account. Cyanogenic glycosides are not effective against all herbivores, and not all cyanogenic plants release enough cyanide to be considered toxic. Nevertheless, they do form part of the broad spectrum of toxic and distasteful compounds that herbivores must accommodate if they are to feed on cyanogenic plants.

Key Words—Cyanide, herbivory, defense, toxic compounds, diet selection, plant secondary metabolites, cyanogenesis.

INTRODUCTION

Over 2500 plant species have the capacity to release hydrogen cyanide from endogenous cyanide-containing compounds (Conn, 1981; Jones, 1988; Seigler, 1998). Many of these cyanogenic plants are capable of releasing HCN in sufficient

0098-0331/02/0700-1301/0 © 2002 Plenum Publishing Corporation

quantities to be toxic and, as a result, are often avoided by herbivores (Nahrstedt, 1985; Jones, 1998). Nevertheless, there has been a certain amount of controversy over the effectiveness of cyanogenesis as a herbivore defense system (e.g., Hruska, 1988), which has become all the more important to resolve with the recent "engineering" of cyanogenesis into the otherwise acyanogenic *Arabidopsis thaliana* (Tattersall et al., 2001). In this review, we examine studies of cyanogenesis in relation to herbivory and argue that conflicting data can generally be reconciled when the morphology, physiology, and behavior of the herbivores, together with the concentration of cyanogenic glycosides in the host plant, are taken into account.

CYANOGENESIS

The most common cyanogens found in plants are glycosides of α-hydroxynitriles (i.e., cyanohydrins) (Figure 1) (Møller and Poulton, 1993; Lechtenberg and Nahrstedt, 1999; Møller and Seigler, 1999). In cyanogenesis, the sugar moiety is cleaved from the cyanogenic glycoside in a process catalyzed by one or more β-glucosidases (Figure 2). The resulting cyanohydrin is relatively unstable and degrades, either spontaneously or enzymatically, to produce HCN and an aldehyde or a ketone (Conn, 1981). Autotoxicity is prevented by spatial separation—either at the subcellular or tissue level—of the degradative enzymes and the cyanogenic glycoside (e.g., Saunders et al., 1977; Frehner and Conn, 1987; Poulton, 1988; Swain et al., 1992). Tissue disruption, as might happen when tissue is chewed by a herbivore, is necessary for HCN to be released (Nahrstedt, 1985).

Cyanogenic compounds also function in the metabolism and transport of nitrogen (Lieberei et al., 1985; Selmar et al., 1988; Selmar, 1993; Gleadow et al., 1998) and the control of germination (e.g., Esashi et al., 1996). These roles do not, however, need to be seen as an alternative to their role in herbivore defense. Just as some plants store nitrogen as inactive Rubisco (Woodrow, 1994), cyanogenic plants may store nitrogen in a toxic form for the dual purpose of defense.

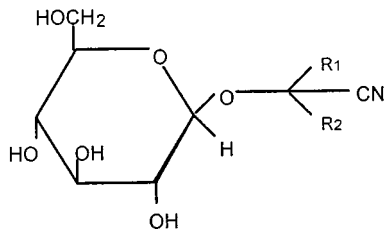

FIG. 1. General structure of cyanogenic glycosides. The aglycone is typically derived from one of the hydrophobic protein amino acids: tyrosine, phenylalanine, valine, leucine, or isoleucine. The glycoside is usually a monoglycoside, although there are a number of diglycosides and one triglycoside (Lechtenberg and Nahrstedt, 1999).

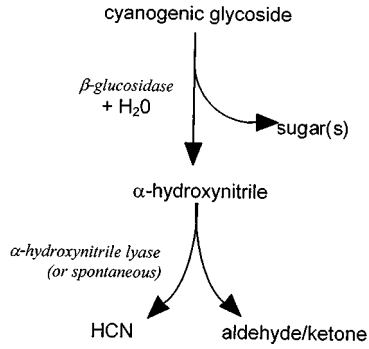

FIG. 2. Degradation of cyanogenic glycosides is a two-step process. First, the molecule is cleaved, resulting in the production of a sugar and a cyanohydrin. The cyanohydrin is unstable and is further degraded, either spontaneously or in the presence of an α-hydroxynitrile lyase, to produce hydrogen cyanide and a carbonyl group (Poulton, 1988).

ASSOCIATION BETWEEN CYANOGENIC PLANTS AND POISONING

The association between certain plants and acute poisoning in humans and domestic animals is well known. There are many well-documented examples of deaths and serious illness from consumption of cyanogenic plants in humans (e.g., Cock, 1982; Cardoso et al., 1998; Banea-Mayambu et al., 2000), cattle (e.g., Robinson, 1930; Finnemore et al., 1935; Boyd et al., 1938; Hopkins, 1995; Zentek, 1997), sheep (e.g., Robinson, 1930; Cooper-Driver et al., 1977; Crush and Caradus, 1995), koalas (e.g., Pratt, 1937), goats (e.g., Webber et al., 1985), and other grazing mammals (e.g., Harborne, 1982; Saucy et al., 1999). Moreover, grazing mammals do not usually eat large quantities of cyanogenic food when alternatives are available (e.g., Jones, 1962; Cooper-Driver et al., 1977; Jones, 1988; Crush and Caradus, 1995; Caradus and Forde, 1996). Many insects and mollusks also tend to avoid cyanogenic plants (e.g., Cooper-Driver and Swain, 1976; Keymer and Ellis, 1978; Dritschilo et al., 1979; Dirzo and Harper, 1982; Foulds, 1982; Schreiner et al., 1984; Nahrstedt, 1985, 1988; Jones, 1988; Kakes, 1989; Patton et al., 1997; Schappert and Shore, 1999b,c; Gleadow and Woodrow, 2000a,b; Magalhaes et al., 2000).

Many of the examples involve studies that are not necessarily conclusive (see, for example, the discussion of Dritschilo et al., 1979, in Hruska, 1988). Nevertheless, there are many cases where it is quite reasonable to attribute feeding patterns to the cyanogenic glycoside content of the plant. Patton et al. (1997), for example, fed leaves from a range of species of *Prunus* to Japanese beetles (*Popillia japonica*) in a fully replicated, no-choice experiment. They found a strong negative correlation between the concentration of the cyanogenic glycoside prunasin in the

leaves and the feeding intensity of the beetles. Moreover, in a parallel study, they incorporated the cyanogenic diglycoside, amygdalin, into artificial diets and found a similar relationship.

Despite evidence documenting the deterrent effect of cyanogenic glycosides, there are a number of studies in which glycosides are shown to have little or no effect on herbivores (e.g., Scriber, 1978; Ferriera et al., 1997; Glander et al., 1989). Indeed, in some cases, plant cyanide production actually acts as a phagostimulant rather than an inhibitor (e.g., Calatayud et al., 1994; Calatayud and Le Rü, 1996; Mowat and Clawson, 1996).

Nearly all of the variability in the effectiveness of cyanogenic glycosides in defense can be explained by four confounding factors. First, the concentration of the cyanogenic glycosides may be below the threshold toxicity. Second, the animal feeding on the species under examination may be a specialist that has evolved mechanisms to cope with high levels of HCN in the diet. Third, the cyanogenic plant might normally be consumed as part of a mixed diet and, therefore, might not be toxic. Fourth, the mode of feeding may be such that the animal does minimal damage to the leaf, thereby limiting the mixing of the cyanogenic glycoside with the degradative β-glucosidases.

CONCENTRATION EFFECTS

Many studies of the effectiveness of cyanogenic compounds in herbivore defense only tested for the presence or absence of cyanogenic glycosides. Natural populations of plants, however, vary widely in cyanogenic glycoside concentration (e.g., Nass, 1972; Hughes, 1991; Thomsen and Brimer, 1997; Schappert and Shore, 1999a,b; Buhrmester et al., 2000; Gleadow and Woodrow, 2000b, Goodger et al., 2002), which in turn, impacts on the degree of herbivory (Feeny, 1976). Gleadow and Woodrow (2000a), for example, detected a significant inverse correlation between the concentration of cyanogenic glycosides in the young leaves of *Eucalyptus cladocalyx* and the amount of damage by herbivores. Similarly, Schappert and Shore (1999b) found that the concentration of cyanogenic glycosides was important not only in the selection of *Turnera ulmifolia* as a source of food, but also as an oviposition site for *Euptoieta hegesia*.

Cyanogenic glycoside concentration also varies with leaf age and environmental conditions (e.g., Patel and Wright, 1958; Bernays et al., 1977; Caradus et al., 1990; Gleadow et al., 1998; Gleadow and Woodrow, 2000a). A particular plant may be innocuous under one set of conditions, but lethal under another (see Bernays et al., 1977). Studies that show little or no influence of cyanogenic glycosides on feeding preferences could be testing plants that are essentially nontoxic to the herbivore. This has been particularly well documented in *Sorghum*, which

is highly toxic to grazing stock when young, but becomes suitable for pasture as plants mature (Martin et al., 1938; McBee and Miller, 1980; Haskins et al., 1987).

SPECIALISTS VERSUS GENERALISTS

Cyanogenesis appears to be an effective inhibitor of feeding by infrequent or opportunistic herbivores rather than by specialists (Compton and Jones, 1985; Nahrstedt, 1985; Hughes, 1992; Schappert and Shore, 1999c, 2000). For example, the feeding and reproductive behavior of the specialist clover weevil (*Sitona lepidus*) is the same on both cyanogenic and acyanogenic *Trifolium repens* (Mowat and Clawson, 1996). *Phenacoccue manihot*, which feeds on *Manihot esculenta*, actually uses the presence of linamarin as a phagostimulant (Calatayud and Le Rü, 1996). By contrast, the generalist-feeding insects *Schistocerca gregaria* and *Sodptera littoralis* avoid feeding on cyanogenic plants (Cooper-Driver and Swain, 1976; Schwarz et al., 1996).

Schappert and Shore (1999c) studied the abundance and diversity of herbivores on populations of *Turnera ulmifolia* in detail on Jamaica. They found that the number of herbivore taxa in any particular population was inversely proportional to the cyanogenic glycoside content of the leaves. However, the amount of herbivory was similar in all populations (1–9% leaf area lost), and most of the damage to cyanogenic plants came from a relatively small suite of insects. Thus, in *T. ulmifolia*, cyanogenesis appears to deter generalist herbivores, but not specialists (Schappert and Shore, 1999c).

Specialist herbivores appear to have evolved mechanisms to tolerate cyanogenic glycosides (e.g., Feeny, 1976; Provenza et al., 1992). Some even use them as a source of nitrogen, as do some fungi (e.g., Birk et al., 1996; Osbourne, 1996). Larvae of the neotropical butterfly, *Heliconius sara*, do this by sequestering the cyanogens from the leaves of the host plant (*Passiflora auriculata*), preventing the release of cyanide. The cyanogen is then metabolized within the insect, and the nitrogen is recovered and used in protein synthesis (Engler et al., 2000). Other specialist herbivores retain the sequestered cyanogenic glycosides and employ them in defense against predators (Nahrstedt, 1985, 1988; Hughes, 1991; Engler et al., 2000). For example, larvae of *Eupitoiea hegesia* take up cyanogenic glycosides from their host plant (*Turnera ulmifolia*) and become distasteful to common predators such as *Anolis* lizards (Schappert and Shore, 1999b). A more complex story is seen in *Lotus corniculatus* (Nahrstedt, 1988). While some snails (e.g., *Helix aspersa*) are deterred from feeding on cyanogenic *L. corniculatus*, larvae of *Zygaena trifolii* are not. These larvae both synthesize and sequester cyanogenic glycosides from *L. corniculatus*, increasing their resistance to predators, similar to *Eupitoiea hegesia*. However, a specialist predator on *Z. trifolii*, *Apanteles*

zygaenarum, is itself able to tolerate HCN, circumventing the complex defense mechanism employed by the *Z. trifolii* larvae (Nahrstedt, 1988).

Specialist herbivores gain a competitive advantage by feeding on plants that are unpalatable to other animals (Edwards, 1989; Bryant et al., 1992). This is well illustrated by the feeding preferences of three sympatric species of bamboo lemur in Madagascar (Glander et al., 1989). The golden bamboo lemur (*Hapalemur aurens*) feeds heavily on the cyanogenic shoots of *Cephalostachym* cv. *viguieri*, consuming up to 12 times the calculated lethal dose of HCN per day. The distribution of the golden bamboo lemur overlaps with that of two other bamboo lemurs (*H. griseus* and *H. sium*), which preferentially feed on the acyanogenic *C. perrieri* and acyanogenic parts of *C. viguieri* (Glander et al., 1989). While the mechanism by which the golden bamboo lemur tolerates such high concentrations remains unknown, it is clear that food preferences have contributed to the sympatric distribution of these primate species.

Most omnivorous mammals are generalists and, in general, are susceptible to cyanide poisoning. The dose required to cause acute poisoning varies with body size and species. The rate of ingestion is also important, as animals can detoxify the cyanide over time (Cock, 1982). Humans are generalists and can only tolerate about 1.4 mg HCN/kg body weight, or about 50–200 mg/day (Harborne, 1982), compared with sheep, which can tolerate about 2.5 mg/kg (Jones, 1972). Unlike other generalists, humans consume many highly cyanogenic plants—two thirds of all crop plants have at least some cyanogenic parts (Jones, 1998)—but because foods are processed before consumption, we do not consume large quantities of the cyanogenic glycosides themselves. Processed food has the added benefit of becoming sweeter through the production of glucose (Jones, 1998; Cardoso et al., 1998).

DIET SELECTION

In practice, animals are unlikely to overingest toxins if they are given a choice in their diet (Provenza et al., 1992). Cyanogenic plants frequently have a bitter taste that is known to deter herbivores (Nahrstedt, 1985). Humans, too, can detect the bitter taste of intact cyanogenic glycosides such as linamarin and lotaustralin, (King and Bradbury, 1995; Jones, 1998). Farmers in Malawi use the degree of bitterness as an indicator of the degree of toxicity of *Manihot esculenta* (Chiwona-Karltun et al., 1998, 2000), although the flavor may be modified by the presence of various organic acids (King and Bradbury, 1995).

Hungry animals are generally less discriminating in their choice of food (e.g., Bernays et al., 1977; Crush and Caradus, 1995; Caradus and Forde, 1996). Webber et al. (1985), for example, documented a case where a herd of 50 goats in western Victoria, Australia, was exposed to large amounts of *Eucalyptus cladocalyx* leaves when a tree was felled. With little alternative pasture due to a drought, the goats

fed ravenously on the young leaves resulting in the death of over half the herd, even after veterinary treatment (Webber et al., 1985).

Results of no-choice feeding experiments may, therefore, seriously underestimate the degree of avoidance that occurs in the field. Young nymphs of *Zonocerus variegatus*, for example, will eat *Manihot esculenta* leaves in captivity when there is no alternative, but do not feed on them at all in the field (Bernays et al., 1977). Even the older, more cyanide-tolerant instars of *Z. variegatus* only feed extensively on *M. esculenta* when they are deprived of other food, resulting in reduced growth rates (Bernays et al., 1977). In binary choice experiments, animals usually choose to eat the acyanogenic plants, thereby avoiding cyanide poisoning. For example, when voles (*Arvicola terrestri*) were offered a choice between cyanogenic and acyanogenic *Trifolium repens*, they consistently preferred the acyanogenic morph. When they were offered only cyanogenic plants (no-choice), they consumed them, but their overall food intake was reduced (Saucy et al., 1999; Viette et al., 2000).

History of exposure to cyanogenic glycosides can also affect feeding patterns (Jones, 1988; Viette et al., 2000). Increased tolerance to amygdalin develops over time in the insect *Spodoptera frugiperda* and is related to improved detoxification of the aglycone (Ferreira et al., 1997). By contrast, habituation to the cyanogenic glycosides amygdalin and salicin by another insect, *Diatraea saccaralia*, has been attributed to the decreased synthesis of endogenous β-glucosidases in the midgut (Ferreira et al., 1997). Similarly, in a controlled experiment, Keymer and Ellis (1978) observed that the mollusks *Helicella itala* and *Cochlicella acuta* ate more leaves on their second exposure to cyanogenic *Lotus corniculatus* than in the first phase of the experiment. The mechanism for this is not clear, particularly as mollusks are known to produce a range of endogenous cyanogenic β-glucosidases (Freeland and Janzen, 1974). Nevertheless, it does illustrate a degree of habituation by the herbivore.

In most animals, gaseous HCN combines with thiosulfate to form less toxic thiocyanate in a process catalyzed by rhodanese (thiosulfate cyanide sulfur transferase, EC 2.8.1.1; Figure 3). Humans and other mammals that regularly consume highly cyanogenic foods increase the production of the rhodanese, and can, therefore, tolerate higher concentrations of cyanide (McMahon et al., 1995). The amount of protein in the diet affects this degree of tolerance. This is particularly true for proteins high in cysteine, as they provide the sulfur essential for the thiosulfate production (Conn, 1991). Problems do arise, however, in humans from long-term ingestion of HCN including hyperthyroidism, goiter, cretinism, tropical ataxic neuropathy, konzo, and tropical diabetes (Cock, 1982; McMahon et al., 1995; King and Bradbury, 1995; Banea-Mayambu et al., 1997). Similar disorders have also been noted in sheep grazing on highly cyanogenic *Trifolium repens* in New Zealand (Crush and Caradus, 1995). As a result of diet selection, food processing and detoxification, acute poisoning from food in humans is rare, even in Africa where consumption rates of *Manihot esculenta* are high (Cock, 1982).

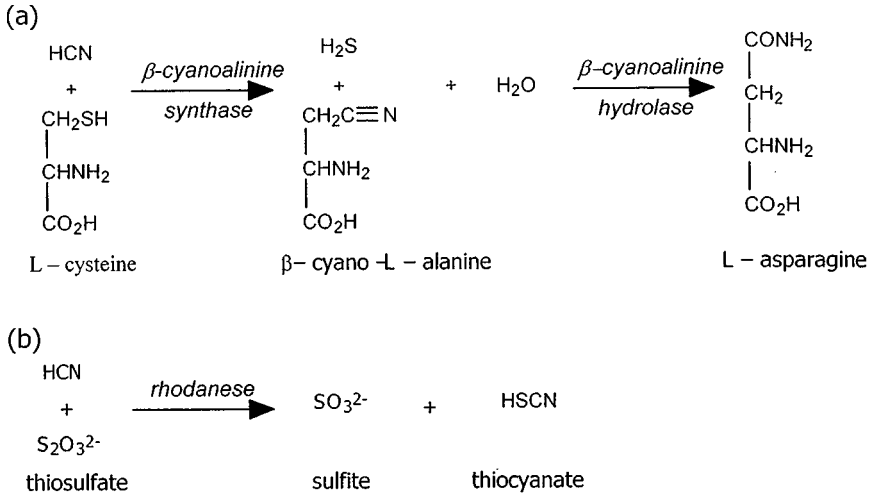

FIG. 3. Detoxification of cyanide by (a) β-cyanoalanine synthase and (b) rhodanese. The former is common in plant tissue and also occurs in some insects. The latter pathway is most commonly found in mammals and microoganisms, but it is also found, to a smaller extent, in plant tissues (Conn, 1981; Manning, 1988).

MODE OF FEEDING

In natural systems, cyanogenesis only occurs when a cyanogenic glycoside is mixed with the appropriate degradative enzymes, for example, when the tissue is chewed. Mammals tend to consume whole leaves (Cork, 1996) and almost inevitably consume β-glucosidases along with the cyanogen. Different orders of insects, however, have different types of mouthparts, which affect their feeding style. Generally, they have either sucking mouthparts (e.g., Hemiptera, Homoptera) or chewing mouth parts (e.g., Coleoptera, Hymenoptera, Orthoptera). If the insect herbivore has sucking mouthparts, then there is minimal tissue disruption, thereby avoiding the defense process. On the other hand, insects that chew leaves tend to mix the cyanogenic glycoside with the degradative enzymes, which are separated at either the cellular or tissue level in the plant (Frehner and Conn, 1987; Poulton, 1988). This difference in mouthparts could explain the difference between, for example, aphids (*Macrosiphum euphorbiae*, Hemiptera) and sawflies (*Strongylogaster impressata*, Hymenoptera), which show neutral and discriminatory feeding behavior, respectively, on polymorphic *Pteridium aquilinum* (Schreiner et al., 1984). One notable exception to this hypothesis is the field study by Dritschilo et al. (1979), who found that aphids fed preferentially on acyanogenic *Trifolium repens*.

The length of the stylus of sucking insects may also determine feeding patterns. Fully mature cassava burrowing bugs (*Cyrtomenus bergi*, Hemiptera) are able to feed effectively by penetrating beyond the outer layers of the root, which are particularly high in linamarin, while the young insects, bearing a shorter stylus, are deterred from feeding (McMahon et al., 1995).

CONCLUSION

The effectiveness of cyanogenesis as an herbivore deterrent is not universal, and this has led to some degree of scepticism. However, variation in the ability to deter herbivores can usually be explained in terms of the concentration of the cyanogenic glycosides themselves, the availability of alternative foods, whether or not the herbivore is a specialist, and the mode of feeding. Cyanogenic glycosides are not effective against all herbivores, and not all cyanogenic plants release enough cyanide to be considered toxic. Nevertheless, they do form part of the broad spectrum of toxic and distasteful compounds that herbivores must overcome if they are to feed on cyanogenic plants.

Abstract—Gas chromatographic and mass spectroscopic analyses of extracts of cantharidin-containing meloid, clerid, and staphylinid beetles revealed the presence of minor to significant amounts of palasonin, previously only known from seeds and fruits of the Indian shrub *Butea frondosa* (Leguminaceae). Unlike (*S*)-(−)-palasonin (>99% ee) from *B. frondosa*, the insects produce palasonin of low ee with the (*R*)-(+)-enantiomer (0–50% ee) prevailing. The ee of palasonin from individual specimens of predatory insects (*Trichodes apiarius*), which acquire their chemical protection from cantharidin-producing insects, may vary considerably. The absolute configuration of (*S*)-(−)-palasonin, previously deduced from indirect chemical and spectroscopic methods, was confirmed by X-ray crystal structure analysis of a cyclic imide derived from (*S*)-(−)-palasonin and (*S*)-(−)-1-(4-nitrophenyl)-ethylamine.

Key Words—Cantharidin, palasonin, *Butea frondosa*, Meloidae, Cleridae, Staphylinidae, canthariphilous insects.

INTRODUCTION

The terpenoid cantharidin represents one of the most famous defensive compounds from insects. Blister beetles (Meloidae) and false blister beetles (Oedemeridae) are

the only insect species that are able to synthesize this unusual vesicant, insecticide, antifeedant (Carrel and Eisner, 1974; Carrel et al., 1986), and powerful inhibitor of protein phosphatase 2A (PP2A) (Matsuzawa et al., 1987). Since the dynamics of protein phosphorylation and dephosphorylation by protein kinases and protein phosphatases control metabolic activities, cantharidin affects one of the most important regulatory elements of cellular signal transduction (Cohen, 1989). Besides the meloids and oedemerids, other insect orders, collectively called cantharidphilous insects, utilize cantharidin for protection (Dettner, 1997). These insects are not able to produce cantharidin by themselves but are attracted over distances to sources of the toxin and become protected after uptake of the compound from the hemolymph of living or dead meloids, oedemerids, or other cantharidin sources (Frenzel et al., 1992; Dettner, 1997; Hemp and Dettner, 2001). In several species, male-produced cantharidin is transferred during copulation to the female, for incorporation into the eggs (Holz et al., 1994; Eisner et al., 1996).

A structurally related toxin, namely (−)-palasonin, which lacks one of the two angular methyl groups of cantharidin, was isolated in 1967 from seeds of the Indian shrub *Butea frondosa* Koenig ex Roxb. (Leguminaceae), also known as "flame of the forest" due to its brightly orange colored flowers (Raj and Kurup, 1967). Palasonin was found to be effective against ascarids, stomach worms of sheep, oxyurids of mice, and hook worms of dogs (Mehtar and Parasar, 1966). The biochemical mechanism of the antihelminthic action of palasonin is based upon inhibition of glucose uptake affecting the energy generating mechanisms and motor activity of the parasite (Kumar et al., 1995). Like cantharidin, palasonin also inhibits PPA2, albeit with much lower efficiency (Liu et al., 1995).

Although both compounds share the same unique, angularly methylated oxabicyclo skeleton, the toxins have never been reported to cooccur in either plants or insects. However, recent analyses of species from the families Meloidae (Dettner et al., 2001), Cleridae, and Staphylinidae gave the first evidence for simultaneous presence of cantharidin and palasonin in the hemolymph and tissues of individual insects. Since palasonin is a chiral compound, we not only thoroughly documented the occurrence of the two toxins in cantharidin-producing and cantharidin-utilizing insects, but also investigated the absolute configuration and enantiomeric excess (ee) of the compound.

METHODS AND MATERIALS

Collection of Insects

Specimens of Hycleaus lunata Pall. (Meloidae) were caught in 1996 by Prof. Dr. G. Gäde (Rondebosch, South Africa) and transported to Bayreuth by Prof. Dr. E. Zebe (Münster), where they were frozen. Specimens of *Trichodes apiarius* (L.) (Cleridae) were caught from yellow colored composite blossoms at

Saint Jean du Gard (Southern France, Département Gard) on May 30, 1993 by K. Dettner. Rove beetles of *Eusphalerum minutus* (F.) (Staphylinidae) were collected from *Ranunculus* blossoms by K. Dettner near Bayreuth-Seulbitz (Northern Bavaria, Germany) on May 10, 1996.

Extraction of Beetles

Insects were extracted following a standard protocol. Prior to extraction, dry body weight was determined for all samples. Whole specimens, reproductive organs of beetles, eggs, or larvae were treated in small test tubes with 50–300 μl 6N hydrochloric acid (HCl) at 120°C for 4 hr in order to dissolve all body structures and release bound material. Following hydrolysis, equivalent amounts of $CHCl_3$ (50–300 μl) were added and samples were vigorously shaken on a Vortex mixer for 30 sec. Layers were separated by centrifugation at 2000*g* for 3 min. The lower organic phase was filtered, transferred to a vial, and covered with water (10–50 μl). Samples were taken from the lower $CHCl_3$ layer and directly analyzed by GLC-MS.

Isolation of (−)-Palasonin from Seeds of Butea frondosa

Powdered seeds of *Butea frondosa* (140 g) were placed into a Soxhlet apparatus (500 ml) and defatted with low boiling petrol ether (40–60°C, 800 ml) for 24 hr. The seed powder was soaked over night at room temperature in a mixture of *i*-propanol and conc. HCl (500:5 ml). Solids were removed by suction followed by concentration of the solution under reduced pressure and acidification with 2N HCl. Palasonin was thoroughly extracted from the aq. solution with $CHCl_3$ (3×20 ml). After removal of the solvent, the crude brown oil was redissolved in ether (10 ml) and coated onto silica gel (1 g). The solid support was placed into a Soxhlet apparatus (100 ml) and continuously extracted for 16 hr with a mixture of petroleum ether–ether (1:3, v/v). After removal of the solvents, the crude residue (ca. 1.3 g) was recrystallized from low boiling petroleum ether (40–60°C) and yielded 0.47 g of (−)-palasonin. Spectroscopic data and the chiroptical properties (CD and ORD) were in agreement with the literature (Peter et al., 1974).

1-(4-Nitrophenyl)-Ethylimide of (−)-Palasonin

Crystalline (−)-palasonin (0.26 g, 1.42 mmol) isolated from seeds of *Butea frondosa* and (*S*)-(−)-1-(4-nitrophenyl)-ethylamine (0.18 g, 1.08 mmol) were mixed in a small reaction vial (4 ml) and heated to 140°C for 30 min. After cooling, the product was dissolved in CH_2Cl_2 (20 ml) and successively washed with 1N NaOH (15 ml), 1N HCl (15 ml), and water (15 ml). After removal of solvents, the crude product was purified by chromatography on silica gel using a binary

solvent of petroleum ether (40–60°C) and ether (3:5 v/v) for elution. Recrystallization of the condensation product from petroleum ether–ether (3:1 v/v) afforded the imide as colorless needles. Yield: 0.10 g (21%). Mp: 111°C. $[\alpha]_{589}^{26} = 78.8°$ ($c = 0.025$ g/ml, methanol). ^{1}H NMR (acetone-d_6) δ [ppm]: 1.34 (s, 3H); 1.61–1.73 (m, 2H), 1.75–1.83 (m, 1H), 1.79 (d, $J = 7.0$, 3H), 1.95–2.01 (m, 1H), 2.59 (s, 1H), 4.56 (d, $J = 4.9$, 1H), 4.61 (d, $J = 5.5$, 1H), 5.43 (q, $J = 7.1$, 1H), 7.61 (d, $J = 8.85$, 2H), 8.18 (d, $J = 8,85$, 2H). ^{13}C NMR (acetone-d_6) δ [ppm]: 16.1, 17.0, 24.7, 28.9, 49.8, 53.7, 56.7, 81.5, 83.3, 124.2, 128.6, 148.6, 148.5, 177.3, 181.7. IR (KBr) ν [cm^{-1}]: 3050, 1751, 1699, 1516, 1343, 1392, 858. MS (70 eV) *m/z* (%): 330 ($M^{+\bullet}$, 100), 312(20), 300(15), 285(20), 262(60), 244(15), 208(15), 151(60), 113(40), 82(40), 70(60). HR-MS *m/z* [M^+]: calcd. for $C_{17}H_{18}N_2O_5$ 330.121572; found 330.121643.

Crystal Structure Determination

The intensity data for the compound were collected on a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K$_\alpha$ radiation. Data were corrected for Lorentz and polarization effects, but not for absorption [COLLECT, Data Collection Software; Nonius B.V., Netherlands, 1998 (Otwinowski and Minor, 1997)]. The structure was solved by direct methods (SHELXS; Sheldrick, 1990) and refined by full-matrix least-squares techniques against Fo^2 (SHELXL-97; Sheldrick, 1993). The hydrogen atoms were located by difference Fourier synthesis and refined isotropically. All nonhydrogen atoms were refined anisotropically (Sheldrick, 1993). XP (Siemens Analytical X-ray Instruments, Inc.) was used for structure representations.

Crystal Data for 1-(4-Nitrophenyl)-Ethylimide of (−)-Palasonin

$C_{17}H_{18}N_2O_5$; Mr = 330.33 g/mol, colorless prism, size 0.18 × 0.10 × 0.08 mm^3, monoclinic, space group $P2_1$, $a = 11.3905(8)$, $b = 6.5844(6)$, $c = 12.0322(8)$ Å, $\beta = 117.016(4)°$, $V = 803.9(1)$ Å^3, $T = -90°$C, $Z = 2$, $\rho_{\text{calcd.}} = 1.365$ g/cm^3, μ (Mo-K$_\alpha$) = 1.02 cm^{-1}, $F(000) = 348$, 3134 reflections in $h(-14/14)$, $k(-7/8)$, $l(-15/15)$, measured in the range $3.40° \leq \Theta \leq 27.40°$, completeness $\Theta_{\max} = 99.1\%$, 3134 independent reflections, 2573 reflections with $F_o > 4\sigma(F_o)$, 289 parameters, 1 restraints, $R1_{\text{obs}} = 0.085$, $wR2_{\text{obs}} = 0.112$, $R1_{\text{all}} = 0.115$, $wR2_{\text{all}} = 0.120$, GOOF = 1.149, Flack parameter of 1.7(16), largest difference peak and hole: 0.207/−0.236 e Å^{-3}. Detection of Cantharidin and Palasonin and Chiral Analysis

Detection. Five microliters of each beetle extract was injected by using split/splitless injection in a capillary gas chromatograph (GCQ system, Finnigan MAT) equipped with a HT5 fused silica capillary column (bonded phase, SGE; 25 m × 0.32 mm ID, 0.1 μm phase thickness) connected to an ion trap system (GCQ). Electron impact ionization (70 eV) of all samples investigated provided mass spectra with characteristic fragment for palasonin ($M^{+\bullet}$: 182, *m/z* = 114, 82) and cantharidin ($M^{+\bullet}$: 196, *m/z* = 128, 96).

Chiral Analysis. The chiral analysis of palasonin was performed on a TraceMS (Thermoquest, Egelsbach, Germany) equipped with a silica column coated with Lipodex E (Macherey & Nagel, Düren, Germany) (25 m × 0.25 mm, 0.32 μm). The GC injection port was operated at 220°C and the transfer line at 270°C. The oven temperature was programmed from 80°C to 200°C at 5°C/min, with an initial isothermal time of 5 min and a final isothermal time of 10 min. Helium was used as a carrier gas at 3 ml/min and the sample was injected in the splitless mode. Mass spectra were measured in electron impact (EI) mode at 70 eV. Spectra were usually taken in the full scan mode (*m/z* 50–250, one scan per second). In cases of a very low abundance of cantharidin or palasonin, only the two most relevant fragments at *m/z* 82 and *m/z* = 114 were monitored (SIM mode).

RESULTS

Cantharidin and Palasonin in Insects. Blister beetles protect their eggs with cantharidin. The compound is synthesized by the beetles, sometimes only by the males, which transfer it to the females during copulation, for incorporation into the eggs (McCormick and James, 1987). Using both unlabeled cantharidin and stable-isotope-labeled cantharidin combined with mass spectroscopy for analysis, it was demonstrated that such an interindividual cantharidin transfer at copulation and paternal endowment of this toxin into the offspring is a rather common phenomenon among cantharophilous insects (Holz et al., 1994; Eisner et al., 1996). These studies were greatly facilitated by the rather unique mass spectrum of cantharidin, which displays, among others, two highly abundant even numbered fragments at *m/z* = 128 (80%) and *m/z* = 96 (100%), respectively (Figure 1, insert). In continuation of these studies, we recently observed in several specimens of meloid beetles of the genus *Hycleus* minor amounts of another compound that displayed a similar mass spectrum with two major even-numbered fragments that were shifted to lower masses by 14 mass units (Dettner et al., 2001). The compound displayed a quasimolecular ion at $[M+H]^+ = 183$ (cantharidin: $[M+H]^+ = 197$) and two even-numbered fragments at *m/z* = 114 (80%) and *m/z* = 82 (100%). The identity of the fragments, established by high-resolution and linked-scan techniques,

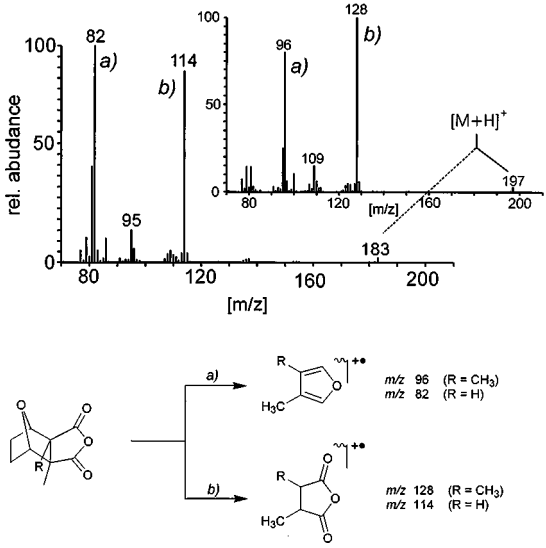

FIG. 1. Mass spectra of cantharidin (insert) and palasonin (main spectrum) from insect extracts. Both compounds are cleaved into the same type of fragments. Methyl-substituted furans (path *a*) and methyl-substituted succinic acid anhydride (path *b*) represent the two most prominent fragments of cantharidin or palasonin.

is outlined in Figure 1 and confirms previous work (McCormick et al., 1986; McCormick and James, 1987).

Due to these characteristic features, the compound was readily identified as palasonin, previously only known to occur in seeds and fruits of the Indian shrub *Butea frondosa*. Within *Hycleus* specimens, there were found 22–321 ng palasonin/mg dry weight (Dettner et al., 2001). Direct comparison of the minor component with authentic palasonin established its identity.

Chiral Analysis of Palasonin. Unlike cantharidin, palasonin is a chiral compound. The lack of the second methyl group introduces dissymmetry and, hence, it is important to know which, and to which extent, individual enantiomers are present in the insects. However, owing to the very low concentration of palasonin in the extracts, only highly sensitive gas chromatographic methods using chiral stationary phases promised to be successful. Optimum results were obtained on an enantioselective capillary column coated with octakis-(3-*O*-butanoyl-2,6-di-*O*-pentyl-γ-cyclodextrin (Lipodex E) that separated racemic palasonin into the two enantiomers with high efficiency ($\alpha = 1.13$).

Figure 2 shows the gas chromatographic separation of palasonin enantiomers from an extract of *Hycleus lunata* Pall a cantharidin-producing meloid. (−)-Palasonin eluted first and the (+) enantiomer second, as established by comparative

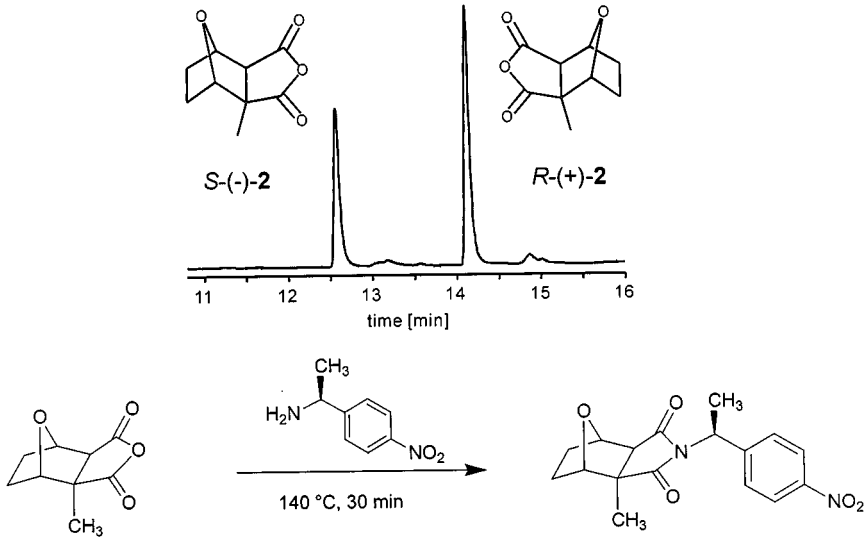

FIG. 2. Gas chromatographic separation of palasonin enantiomers. Palasonin of low ee from an extract of a *Hycleus* sp. is separated on a fused silica column coated with a modified cyclodextrin (Lipodex E). Separation factor: $\alpha = 1.13$.

injection with (−)-palasonin from seeds of *Butea frondosa*. The presence of both enantiomers in the extracts of the meloid beetle *Hycleus lunata* was not unique but proved to be representative for all other hitherto examined palasonin-containing insects. Integration of the peak areas demonstrated that all insect species (Table 1) produced both enantiomers of palasonin with only low to moderate preference for the (+)-enantiomer.

Particularly interesting is the result of the analysis of palasonin from two individuals of the clerid beetle genus *Trichodes apiarius* (L.). One specimen contained almost racemic material, while the other had accumulated (*R*)-(+)-palasonin of 32% ee. Remarkably, this also represents the first record of cantharidin within the beetle family Cleridae. In contrast to palasonin from insects, crude (−)-palasonin obtained from different collections of seeds of *Butea frondosa* proved always to be optically pure (>99% ee).

Absolute Configuration of (+)- and (−)-Palasonin. The absolute configuration of (*S*)-(−)-palasonin from seeds of *Butea frondosa* was originally deduced from its CD spectra and by indirect chemical methods (Peter et al., 1974). The configurational assignment was based on conversion of (−)-palasonin into a secondary alcohol followed by reaction of this intermediate with the anhydride of α-phenylbutyric acid (Horeau, 1961). This empirical method is based on the reaction of secondary alcohols with the above anhydride to give (+)- or

TABLE 1. SPECIMEN ANALYSIS[a]

Toxin origin	Plant or insect species	Cantharidin–palasonin ratio	Palasonin (*S*)-(−) (%)	Palasonin (*R*)-(+) (%)	Palasonin ee (%)

[a] In *Hycleus lunata* and *Trichodes apiarius* specimens, one individual per sample was analyzed; in *Eusphalerum minutum* four individuals per sample were analyzed.

(−)-α-phenylbutyric acid, depending on the relative size of the substituents flanking the secondary alcohols. Although this indirect method generally proved to be reliable, a direct approach via a crystal structure analysis of a palasonin containing a structural element of known absolute configuration is preferred owing to the unequivocal identification of additional asymmetric centers in the molecule. Palasonin readily reacts with primary amines to give crystalline cyclic imides. A naturally occurring imide of palasonin and (*S*)-(−)-phenylalanin was isolated from seeds of *Butea frondosa* (Barua et al., 1970; Guha et al., 1990). To obtain crystals suitable for structure analysis, we reacted (−)-palasonin (>99% ee; isolated from seeds of *Butea frondosa*) with either (*R*)-(+)- or (*S*)-(−)-1-phenyl-ethylamine. Although the expected imide was formed in good yield, no suitable crystals could be obtained after chromatographic purification. Better results were obtained by reacting (−)-palasonin with 1-(4-nitrophenyl)-ethylamine (Baumgarten and Peterson, 1960) (Figure 3). The additional nitro group in the *p*-position should enhance the

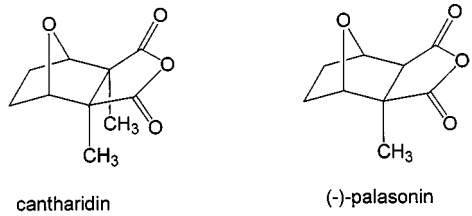

FIG. 3. Reaction of (−)-palasonin from *Butea frondosa* with (*S*)-(−)-1-(4-nitrophenyl)-ethylamine.

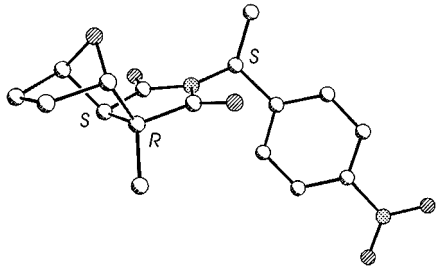

FIG. 4. Molecular structure of the cyclic imide derived from (*S*)-(−)-1-(4-nitrophenyl)-ethylamine and (−)-palasonin as determined by X-ray crystal structure analysis.

tendency of the product to crystallize due to the strongly enhanced intermolecular interactions.

As expected, (−)-palasonin readily reacted with 1-(4-nitrophenyl)-ethylamine to give a cyclic imide that spontaneously crystallized upon removal of the solvent. Recrystallization from a binary mixture of hexane/ether (3:1 v/v) afforded the pure imide. The compound crystallized as monoclinic colorless prisms.

The three-dimensional architecture of the imide is shown in Figure 4. Since the absolute configuration of the asymmetric center next to the aromatic nucleus is known due to the use of (*S*)-(−)-1-(4-nitrophenyl)-ethylamine, the absolute configuration of (−)-palasonin follows as depicted in Figure 4 and unequivocally confirms previous indirect assignments.

DISCUSSION

Cantharidin is an exceedingly powerful toxin that is used by many insects but is only produced by members of two insect families, the meloids and the oedemerids. All canthariphilous and other cantharidin-containing species acquire the toxin from dead or living cantharidin-producing or other cantharidin-containing insects. Specimens of the pollen-feeding staphylinid beetle *Eusphalerum minutum* were regularly found in cantharidin traps, which indicates that they are canthariphilous (Dettner, 1997). Since females of the canthariphilous ceratopogonid *Attrichopogon lucorum* were observed attacking living *E. minutum* by piercing membranes and sclerites of these rove beetles (Klinker, 1983), the presence of palasonin in predatory canthariphilous ceratopogonid flies was expected. Concerning clerid beetles, the search for cantharidin in the genus *Trichodes* hitherto was negative (Juanjie et al., 1995). Therefore, the presence of both anhydrides within certain species of this widespread and abundant beetle family is remarkable. Although it was reported that members of Cleridae are canthariphilous (Bologna and Havelka, 1984; Hemp et al., 1999), specimens of *Trichodes apiarius* were never

observed within cantharidin traps, but occur in various yellow-colored composite blossoms (Dettner, unpublished observations), where they probably feed on cantharidin producing oedemerid and meloid beetles.

Recent analyses of extracts from meloid beetles clearly demonstrated for the first time that palasonin does occur in insects, sometimes even in substantial amounts (Dettner et al., 2001). In general, palasonin was found as a minor or trace compound along with cantharidin as the major toxin (Table 1). As shown by chiral analysis, the insect-derived palasonin is of moderate to very low enantiomeric purity, while the (*S*)-(−)-palasonin from *Butea frondosa* is an optically pure compound. Owing to this major and significant difference between the insect-derived and the plant-produced product, an uptake of palasonin from a hitherto unknown plant source in the environment of meloids and oedemerids appears to be highly unlikely. Hence, it follows that at least the cantharidin-producing meloid beetles must be able to synthesize palasonin *de novo* or by degradation of cantharidin (see below). Moreover, since the various cantharidin-producing specimens of *Hycleus lunata* Pall. generate palasonin with a different ee (Table 1), acquisition of this compound from randomly selected sources by canthariphilous and cantharidin-tolerant predatory insects will inevitably lead to an accumulation of palasonin with varying ee in different individuals of the same species. This phenomenon was observed with two specimens of the canthariphilous genus *Trichodes apiarius* (L.) (Table 1).

Although the mechanistic details of the biosynthesis of cantharidin and/or palasonin are not known, two alternative routes can be envisaged for the origin of palasonin. In the insects, the compound could originate directly from cantharidin (Figure 5, route A) or derive from cyclization of a previously demethylated "12-*nor*-farnesol" (Figure 5, route B) along the pathway analogous to that of cantharidin.

Thus, an oxidative attack onto one of the two angular methyl groups of cantharidin ($-CH_3 \rightarrow -CH_2OH \rightarrow -CHO \rightarrow -COOH$) could finally generate an angular carboxylic acid moiety that, in turn, could readily decarboxylate to palasonin. Owing to the high symmetry of the molecule, a selective functionalization of a distinct methyl group might be difficult and could account for the low ee of palasonin in insects (Figure 5, route A). Alternatively, the oxidative demethylation may occur earlier, on the level of farnesol, the sesquiterpene precursor of cantharidin (Carell et al., 1986) (Figure 5, route B). After oxidative transformation of the two terminal methyl groups into a dicarboxylic acid, one carbonyl group could be lost by decarboxylation. The resulting *nor*- intermediate might be further processed to palasonin, analogous to the pathway to cantharidin. This route might also be operative in seeds or fruits of *Butea frondosa*, since no traces of cantharidin were found along with the main constituent (*S*)-(−)-palasonin. The almost exclusive production of the (*S*)-enantiomer by the plant tissue is also not congruent with the very low ee and the absolute configuration of insect-derived

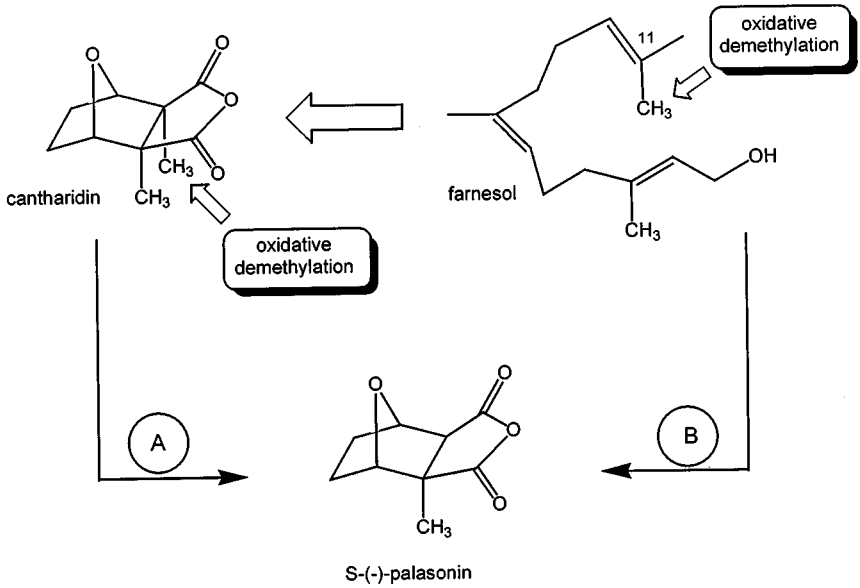

FIG. 5. Alternative biosynthetic routes to palasonin. According to sequence A palasonin is produced by oxidative degradation (demethylation) of cantharidin. Sequence B assumes an early oxidative "demethylation" of farnesol followed by cyclization of the resulting intermediate to palasonin analogous to the biosynthesis of cantharidin (McCormick et al., 1986).

(*R*)-(+)-palasonin and may additionally support an alternative pathway. Although preliminary feeding experiments with larvae of *Oedemera femorata* and synthetic deuterium-labeled 12-*nor*-farnesol precursors demonstrated a successful conversion into labeled palasonin, the amount of the metabolite was too low to assess its configuration and ee (Duetemeyer, 1997; Fietz, 2001). A final decision in favor of a route via late oxidative demethylation (route A) or via demethylation of an early precursor of cantharidin (route B) is, as yet, not possible and awaits further experimental results. Nevertheless, the rather widespread occurrence of palasonin in cantharidin-producing and cantharidin-utilizing insects is unexpected and surprising. Whether or not the compound has a specific ecological function remains to be established and requires further analyses with special emphasis on tissue specific distribution in the insects, its flux between male and female individuals, and, especially, its transfer into eggs for protection of the next generation.

Acknowledgments—We thank Prof. Dr. G. Gäde (Rondebosch) and Prof. Dr. E. Zebe (Münster) for their help in collecting and transporting meloid beetles. Furthermore, the helpful advice of C. Holz, V. Seidl, S. Schramm (all Bayreuth), and Dr. N. Oldham (Jena) is acknowledged.

(Received December 26, 2001; accepted March 12, 2002)

Abstract—Graminivorous species of grasshoppers develop lethal lesions in their midgut epithelia when they ingest tannic acid, whereas polyphagous grasshoppers are unaffected by ingested tannins. This study tests the hypothesis that polyphagous species are defended by higher activities of antioxidant enzymes (constitutive or inducible) in their guts than are graminivorous species. Comparisons were made between four antioxidant enzymes: superoxide dismutase (SOD), catalase (CAT), ascorbate peroxidase (APOX), and glutathione transferase peroxidase (GSTPX). Enzyme activities were measured in the gut lumens and midgut tissues of *Melanoplus sanguinipes* (polyphagous) and *Aulocara ellioti* (graminivorous). The results of this study do not support the hypothesis that *M. sanguinipes* is better defended by antioxidant enzymes than is *A. ellioti*, nor are these enzymes more inducible in *M. sanguinipes* than in *A. ellioti* when insects consume food containing 15% dry weight tannic acid. Instead, tannic acid consumption reduced SOD, APOX, and GSTPX activities in both species. This study reports the first evidence that SOD is secreted into the midgut lumen in insects, with activities two- to fourfold higher than those found in midgut tissues. The spatial distribution of GSTPX and APOX activities observed in both species suggests that ingested plant antioxidant enzymes may function as acquired defenses in grasshoppers. In addition, the results of this study permit the first comparison between the antioxidant enzyme defenses of Orthoptera and Lepidoptera. Most notably, grasshoppers have higher SOD activities than caterpillars, but completely lack APOX in their midgut tissues.

Key Words—Grasshopper, Orthoptera, Acrididae, graminivorous, polyphagous, herbivore, *Melanoplus*, *Aulocara*, antioxidant enzyme, superoxide dismutase, catalase, ascorbate peroxidase, glutathione transferase peroxidase.

INTRODUCTION

The ingestion of tannic acid by graminivorous grasshoppers (Orthoptera: Acrididae) greatly increases mortality, a result of the formation of ulcerlike lesions through the midgut epithelium (Bernays, 1978; Bernays et al., 1980). By comparison, the consumption of similar amounts of tannic acid by polyphagous grasshoppers produces neither lesions nor increased mortality (Bernays, 1978; Bernays and Chamberlain, 1980; Bernays et al., 1980). The formation of midgut lesions has been attributed to the direct interaction of tannins with the midgut epithelia of grasshoppers (Bernays, 1978) and caterpillars (Steinly and Berenbaum, 1985). Another possible mode of action of ingested tannins is oxidative stress in epithelial tissues. For instance, in some caterpillars the consumption of low-molecular-weight phenols causes elevated levels of oxidative damage to proteins and lipids in midgut tissues (Summers and Felton, 1994; Bi and Felton, 1995), as well as midgut lesions (Lindroth and Peterson, 1988).

Ingested phenolic compounds can act as antioxidants or prooxidants, depending on the physicochemical environment of an insect's gut lumen. If ingested phenols do oxidize, they can produce oxidative stress by two primary mechanisms. The oxidation of phenols produces reactive oxygen species (ROS; Table 1) (Canada et al., 1990), including hydrogen peroxide in the gut lumens of caterpillars (Barbehenn et al., 2001). Hydrogen peroxide is relatively stable and permeates cell membranes (Grisham, 1992). However, its decomposition (via the Fenton reaction) produces highly reactive hydroxyl radicals. Cytotoxicity can result from hydroxyl radical damage to DNA, lipids, and proteins (Hanham et al., 1983; Imlay et al., 1988, Halliwell and Gutteridge, 1999). Secondly, quinones (oxidation products of phenols) may also be cytotoxic and can cause the formation of gut lesions (Gant et al., 1988; Zheng et al., 1997; Thiboldeaux et al., 1998). Ingested tannins appear to oxidize in the gut lumens of grasshoppers (Barbehenn et al., 1996), suggesting that, if antioxidant defenses were inadequate, oxidative stress could produce lesions in the midgut epithelium.

Little is known about the antioxidant enzyme defenses of grasshoppers. Previous work on antioxidant enzymes in insects has been done primarily on caterpillars

TABLE 1. ENZYME-CATALYZED REMOVAL OF REACTIVE OXYGEN SPECIES

Reactive oxygen species[a]	Antioxidant enzyme
$2\,\mathbf{O_2^-} + 2\,H^+ \rightarrow H_2O_2 + O_2$	Superoxide dismutase
$2\,\mathbf{H_2O_2} \rightarrow 2\,H_2O + O_2$	Catalase
$AA + \mathbf{H_2O_2} \rightarrow DHA + 2\,H_2O$	Ascorbate peroxidase
$\mathbf{ROOH} + 2\,GSH \rightarrow ROH + H_2O + GSSG$	Glutathione transferase peroxidase

[a] AA = ascorbic acid, DHA = dehydroascorbic acid, GSH = glutathione, GSSG = glutathione disulfide, ROOH = hydroperoxide.

(e.g., Ahmad et al., 1987; Pritsos et al., 1988; Aucoin et al., 1991; Berenbaum, 1991; Felton and Duffey, 1992; Barbehenn et al., 2001). A variety of antioxidant enzymes protects caterpillar tissues and extracellular fluids from oxidative damage. Among the most widely studied enzymes for detoxifying ROS (including lipid peroxides) are superoxide dismutase (SOD), catalase (CAT), ascorbate peroxidase (APOX), and glutathione transferase peroxidase (GSTPX) (Table 1). Two types of evidence have supported the hypothesis that these enzymes serve a defensive role in insect herbivores that feed on plants containing high levels of potential prooxidants. First, antioxidant enzyme activities are high in the tissues of some insect species that feed on such host plants (Pritsos et al., 1988; Lee and Berenbaum, 1990; Aucoin et al., 1991; Felton and Duffey, 1992), and second, in some species, some antioxidant enzymes are induced by ingested prooxidants (Pritsos et al., 1988; Lee and Berenbaum, 1989, 1990; Ahmad and Pardini, 1990; Aucoin et al., 1991; Lee, 1991).

Relatively little attention has been focused on the antioxidant defenses in the gut lumens of insects. Studies on the antioxidant enzymes of caterpillars commonly have examined enzyme activities in whole-body homogenates, providing no information on antioxidant defenses in the gut lumen. However, it is in the gut lumen that ingested phenolic compounds may become extensively oxidized (Barbehenn and Martin, 1994; Barbehenn et al., 1996). Previous work on antioxidant enzymes secreted into the midgut lumens of caterpillars has measured the activities of CAT, APOX, and dehydroascorbate reductase (Felton and Duffey, 1991; Mathews et al., 1997; Barbehenn et al., 2001). This study extends work on antioxidant enzymes to grasshoppers, and examines their activities in both the midgut tissues and gut lumen.

If antioxidant enzyme defenses are strengthened in species of insect herbivores that feed on plants that are rich in potential prooxidants, then polyphagous insects would be expected to have evolved higher antioxidant enzyme activities than have graminivorous insects. Insects that feed on mature grasses ingest far lower allelochemical concentrations, as well as a far lower diversity of these chemicals, compared to insects that feed on dicots (Bernays and Barbehenn, 1987). Secondly, the antioxidant enzymes of polyphagous insects might be more effectively induced by the consumption of potential prooxidants than are those of graminivorous species.

The purpose of this study was twofold: (1) to test the hypothesis that polyphagous grasshoppers are better protected from oxidative stress by antioxidant enzymes, either constitutive or induced, than are graminivorous grasshoppers; and (2) to compare the activities of a suite of antioxidant enzymes in grasshoppers and caterpillars. Two grasshopper species (*Melanoplus sanguinipes* and *Aulocara ellioti*) were compared to test the first hypothesis. *M. sanguinipes* is a polyphagous species in the subfamily Melanoplinae and is tannin tolerant (Bernays et al., 1980). *A. ellioti* is a member of the graminivorous subfamily Gomphocerinae and is

assumed to be tannin sensitive like other graminivorous species examined (Bernays et al., 1980). Four antioxidant enzymes were examined in the gut lumens and tissues of *M. sanguinipes* and *A. ellioti*: SOD, CAT, APOX, and GSTPX. To test the extent of antioxidant enzyme inducibility in the two grasshopper species, enzyme activities were compared after feeding each species control or tannic acid-treated wheat leaves. This study provides the first examination of grasshopper antioxidant enzyme activities, and these values are compared with the enzyme activities from previous studies on larval Lepidoptera.

METHODS AND MATERIALS

Insects

Eggs of *M. sanguinipes* were obtained from a nondiapause colony (USDA, Bozeman, Montana, USA). Insects were reared on romaine lettuce (*Lactuca sativa* var. *longifolia*) and wheat bran as previously described (Barbehenn et al., 1996). Third-instar nymphs of *A. ellioti* were collected in central Wyoming, USA, and reared to adulthood in Ann Arbor, Michigan, USA, in the same conditions as *M. sanguinipes*, with the exception that the host plant was seedling wheat (*Triticum aestivum*). Adult females were used for all experiments, unless otherwise noted. Each experimental insect was placed in a separate ventilated plastic container (470 ml) in an incubator (28°C; 16L:8D) for 2–2.5 days. Insects were assigned at random to feed on control or treated wheat leaves. Seedling wheat leaves were cut and treated with 13 μl of 70% acetone (control) or 13 μl of a 70% acetone solution of tannic acid (Sigma, lot 64F-0049) to give a final concentration of 15% dry weight. Fresh leaves were provided daily, and these were usually completely consumed. In some instances, *A. ellioti* exhibited reduced consumption rates on tannin-treated wheat, and in these cases the level of tannin was reduced to 10% dry wt.

Sample Collection

Each insect was chilled at -20°C for 10 min and dissected. The entire gut was removed from the body, rinsed in distilled water (2–3 sec), blotted dry, and the Malpighian tubules removed. Samples of foregut and midgut contents were weighed in tared microcentrifuge tubes flushed with N_2, and extracted by shaking (10 sec) in N_2-purged buffer containing 50 mg/ml hydrated insoluble polyvinylpolypyrolidone (PVP). The midgut contents included the portion of the food bolus that extended into the anterior hindgut. Extracts of gut contents were incubated for a minimum of 5 min on ice with occasional mixing to remove tannic acid. Midgut tissues, including the caeca, were blotted dry on a paper towel, weighed, and homogenized in N_2-purged buffer (without PVP) in a hand-held

glass tissue homogenizer (20 strokes). Sample extracts were centrifuged (8000*g*, 4° or 22°C, 3–5 min), and kept under a N_2 atmosphere on ice until analyzed. Samples were assayed within 1 hr from the time of collection, unless otherwise noted. Sample sizes are presented in Tables 2–5 below. All buffers were purged of O_2 by bubbling them with N_2 (1 min/ml), unless otherwise noted. Reagents for all assays were purchased from Sigma Chemical Co. or ICN Pharmaceuticals.

Enzyme Assays

Superoxide Dismutase. Dissected gut contents were extracted in 350 μl of sodium phosphate buffer (pH 7.0, 50 mM). Midgut tissues were homogenized in 200 μl of phosphate buffer and centrifuged. Centrifuged extracts were stored at -75°C as they were collected. Thawed supernatant solutions were ultrafiltered to remove low-molecular-weight antioxidants. Sample supernatant solutions (150 μl from gut contents; 100 μl from tissues) were placed in 10,000 molecular-weight cutoff ultrafilters (Millipore Centrifree 0.5). The extracts were reduced to approximately 10 μl by centrifugation of the ultrafilters (8000*g*, 4°C). The retentate (containing SOD) was resuspended with 250 μl of N_2-purged buffer (pH 7.0) and filtered again. The washing process was repeated a second time, after which the retentate was reconstituted to a final volume of 200 μl with phosphate buffer. Sample retentates and SOD standards were stored in microcentrifuge tubes under N_2 at -75°C without loss of activity. Frozen solutions of purified SOD (Sigma) were stable for at least one month. Thawed samples were kept on ice until analyzed. Boiled samples were analyzed to control for nonenzymatic activity. No SOD activity was observed in boiled samples.

The SOD reaction mixture was composed of 145 μl of carbonate buffer (pH 10.2; 62.5 mM with 0.125 mM EDTA), 20 μl of catalase (prepared as 1.3 enzyme units (EU) ml of 50 mM phosphate buffer, pH 7.0), 15 μl of sample extract, and 20 μl of epinephrine (13.6 mM in 100 mM HCl) to start the reaction. The rate of change absorbance at 490 nm was measured with a Biorad Benchmark microplate reader. Kinetic measurements were made using three different dilutions of each sample extract with pH 7.0 phosphate buffer (range = 5–100% of original sample extract concentration). Dilutions were chosen to fall within the linear region in regressions of percent inhibition of the browning reaction versus milligrams of protein in the reaction mixture. One unit of SOD activity was defined as the mass of protein (milligrams) corresponding to a 50% inhibition of the rate of epinephrine oxidation (Misra and Fridovich, 1972; Munkres, 1990). SOD activity was expressed as enzyme units/per milligram of protein. Protein concentrations in the samples were measured with the modified Bradford assay (Stoscheck, 1990), using Bradford reagent and bovine serum albumin as a standard.

Catalase. Samples of foregut and midgut contents from male and female *M. sanguinipes* were extracted in 400 μl of phosphate buffer (pH 7.0, 66 mM).

Tissues were homogenized in 200 μl of buffer. The reaction mixture was composed of 665 μl of potassium phosphate buffer (pH 7.0, 66 mM), 25 μl of sample extract, and 10 μl of 3% hydrogen peroxide. Change in absorbance was measured at 240 nm over a 30-sec period using a Zeiss spectrophotometer. The protein concentration in each extract was measured as described above. CAT activity was expressed as micromoles of hydrogen peroxide reduced per minute per milligram of protein, using an extinction coefficient of 39.4 M^{-1} cm^{-1} (Aebi, 1984). CAT activity in *A. ellioti* was measured as described above, with the exception that females were fed wheat treated with 10% tannic acid (dry wt), 50 mM phosphate buffer was used for extraction and the reaction mix, and 400 μl of buffer was used to homogenize tissues. Rapid bubble formation was observed in cuvettes containing high levels of CAT (e.g., gut tissues), consistent with the formation of O_2 by this enzyme. Negligible CAT activity was observed in boiled samples.

Ascorbate Peroxidase. Samples from the foregut and midgut lumen were extracted in 400 μl of potassium phosphate buffer (pH 7.0, 50 mM) containing 0.5 mM ascorbic acid. Midgut tissues were homogenized in 400 μl of buffer. Samples of seedling wheat (16–21 mg fresh wt) from plants fed to the insects were homogenized in 500 μl of buffer (50 strokes). The reaction mixture was composed of 75 μl of supernatant solution, 646 μl of potassium phosphate buffer (containing 0.5 mM ascorbic acid), and 18 μl of hydrogen peroxide (0.3% in double-distilled water). The rate of change in absorbance at 290 nm was measured with a Zeiss spectrophotometer. Reaction rates were measured in boiled samples (10 min) to correct for nonenzymatic ascorbate oxidation. Protein levels in the samples were measured as described above, and enzyme activity was expressed as micromolar ascorbate oxidized per minute per milligram of protein, using a molar extinction coefficient of 2.8 mM^{-1} cm^{-1} (Asada, 1984). No enzyme activity was measurable using cumene hydroperoxide as the substrate.

Glutathione Transferase Peroxidase. Samples were extracted or homogenized in potassium phosphate buffer (pH 7.0, 50 mM), containing 1 mM EDTA. Foregut and midgut contents were extracted in 150 μl of buffer, and tissues were homogenized in 150 μl of buffer. Wheat leaf samples were collected and homogenized as described above. The reaction mixture consisted of 20 μl of supernatant solution, 20 μl of glutathione reductase (1.67 EU/ml), 100 μl of buffer (pH 7.0, containing 1.0 mM GSH and 0.2 mM NADPH), and 50 μl of cumene hydroperoxide (1.4 mM in buffer) (Ahmad and Pardini, 1990; Weinhold et al., 1990). The rate of decrease in the absorbance at 340 nm was measured for 4 min using a Biorad microplate reader. Boiled samples (10 min) and reaction mixtures lacking certain reagents were assayed as controls. The average reaction rate in boiled samples ($N = 5$–6/type) was subtracted from the rates in active samples to correct for the nonenzymatic oxidation of NADPH. The reaction rate was negligible in the absence of added glutathione or cumene hydroperoxide, and autoxidation of NADPH was negligible in the absence of added samples. Protein levels were

measured as described above, and GSTPX activity was expressed as nmol NADPH oxidized per minute per milligram of protein, using a molar extinction coefficient of 6220 M^{-1} cm^{-1}. Although GSTPX activity was measured promptly in fresh extracts, full activity was recovered after storage at $-75^{\circ}C$ (two weeks).

Statistical Analyses

All analyses were performed using SAS (version 8e; PROC MIXED) (SAS Institute, 2000). Comparisons between means were made using differences of least square means (SAS Institute, 2000).

RESULTS

Antioxidant Enzyme Activities

Superoxide dismutase. Overall, SOD activities were similar in *A. ellioti* and *M. sanguinipes* (Table 2 and Table 6 below). Tannin consumption decreased SOD activity in both species ($P = 0.018$). However, activity levels in the midgut tissues of *M. sanguinipes* were unaffected by tannic acid consumption (94.8% of control levels). By comparison, SOD activities in the midgut tissues of *A. ellioti* were reduced to 73.4% of control levels. SOD activity varied across sites in the gut in a similar fashion within each species: maximal activity was found in the midgut lumen, followed by the foregut lumen, and similar lower levels were found in

Midgut tissue	0	181.8 ± 42.5^{defg}	10
Midgut tissue	15	235.9 ± 59.7^{g}	9

[a] Data are presented as mean $\pm$ SE. Means followed by nonoverlapping letters are statistically different ($P < 0.05$).

the midgut tissues (Table 2). SOD activities were three- to fourfold higher in the midgut lumens of grasshoppers than in their midgut tissues (Table 2).

Catalase. Overall, CAT activities were similar in *A. ellioti* and *M. sanguinipes* (Tables 3 and 6). CAT activity was unaffected by tannin consumption in both species at each site in the gut (Table 3 and Table 6 below). Within different sites in the gut, however, CAT activity varied between the species: CAT activity in the foregut of *M. sanguinipes* was higher than that in *A. ellioti* ($P = 0.020$), but the reverse was true for CAT activity in the midgut lumen ($P = 0.016$) (Table 3). The greatest CAT activity was present in midgut tissues and midgut lumen contents in *A. ellioti*. The lowest levels of CAT activity were present in the foregut contents, which varied from as little as 14% of midgut lumen levels (*A. ellioti* controls) to 51% of midgut lumen levels (*M. sanguinipes* controls).

Ascorbate Peroxidase. APOX activities were similar in *A. ellioti* and *M. sanguinipes* (Table 4 and Table 6 below). Tannic acid consumption reduced APOX activity ($P = 0.030$) (Tables 4 and 6). This effect was most pronounced in the midgut lumen of *M. sanguinipes*, in which APOX activity in insects fed tannic acid was 21% of control levels (Table 4). A similar treatment effect was observed in *A. ellioti.* APOX activities were substantially higher in the foreguts of both species than in their midgut lumens. No APOX activity was found in the midgut tissues of either species. APOX activity in the seedling wheat leaves consumed by *M. sanguinipes* and *A. ellioti* was 1007.0 ± 128.8 ($N = 3$) and 1017.9 ± 103.3 μM/min/mg ($N = 5$), respectively.

TABLE 4. ASCORBATE PEROXIDASE (APOX) ACTIVITIES IN *Aulocara ellioti* AND *Melanoplus sanguinipes* FED WHEAT LEAVES WITH OR WITHOUT TANNIC ACID[a]

Species and site	Tannic acid in diet (%)	APOX activity (μM/min/mg protein)	N
A. ellioti

Midgut contents	15	42.3 ± 14.6^{a}	8
Midgut tissue	0	0.0 ± 0.0	8
Midgut tissue	15	0.0 ± 0.0	9

[a] Data are presented as mean $\pm$ SE. APOX activity in wheat leaves consumed was 1007.0 ± 128.8 ($N = 3$) and 1017.9 ± 103.3 ($N = 5$) in experiments on *M. sanguinipes* and *A. ellioti*, respectively. Means followed by nonoverlapping letters are statistically different ($P < 0.05$).

Glutathione Transferase Peroxidase. M. sanguinipes maintained higher GSTPX activities in its foregut and midgut lumens than did *A. ellioti* ($P < 0.001$) (Tables 5 and 6). By comparison, GSTPX activities in the midgut tissues were remarkably similar across species and treatments (Table 5). GSTPX activity in control insects decreased along the length of the gut, dropping over 50% from the foregut to the midgut lumen in both species. Tannin consumption reduced GSTPX activity in both species, most strikingly in the gut lumens. GSTPX activity in the foregut lumen was reduced to 7.2% and 10.4% of control levels in *A. ellioti* and *M. sanguinipes*, respectively. In the midgut lumen, tannic acid consumption reduced GSTPX activities to 39.6 and 78.8% of control levels in *A. ellioti* and *M. sanguinipes*, respectively. GSTPX activity in the seedling wheat leaves consumed by *A. ellioti* was 46.0 ± 11.1 nmol/min/mg ($N = 3$).

Comparison of Orthoptera and Lepidoptera

Table 7 summarizes examples of SOD, CAT, APOX, and GSTPX activities previously measured in caterpillars. Among the quantitative differences between Orthoptera and Lepidoptera, the most striking is the higher activity of SOD in grasshoppers; activities in grasshopper midgut tissues (Table 2) range from 10- to 50-fold greater than in the midgut tissues and whole body homogenates

TABLE 5. GLUTATHIONE TRANSFERASE PEROXIDASE (GSTPX) ACTIVITIES IN *Aulocara ellioti* AND *Melanoplus sanguinipes* FED WHEAT LEAVES WITH OR WITHOUT TANNIC ACID[a]

Species and site	Tannic acid in diet (%)	GSTPX activity (nmol/min/mg)	*N*

[a] Data are presented as mean $\pm$ SE. GSTPX activity in wheat leaves consumed by *A. ellioti* was 46.0 ± 11.1 nmol/min/mg ($N = 3$). Means followed by nonoverlapping letters are statistically different ($P < 0.05$).

of caterpillars. Among the qualititative differences that are evident, the most notable is the absence of APOX from the midgut tissues of grasshoppers (Table 4), but its presence in the midgut tissues and whole body homogenates of caterpillars. CAT activities in grasshopper gut tissues and gut fluids (Table 3) are in the range of those found in the midgut tissues and whole-body homogenates of caterpillars (Table 7). APOX activities present in the gut lumens of the grasshoppers in this study also lie within the broad range measured in caterpillars (Tables 4 and 7). GSTPX activities in grasshopper midgut tissues fall at the low end of the range of GSTPX activities found in caterpillar whole-body homogenates (Tables 5 and 7).

The effect of tannic acid consumption on APOX activity in grasshoppers and caterpillars was similar: activity is reduced in the midgut fluids of both Orthoptera and Lepidoptera (*O. leucostigma* and *M. disstria*) (Tables 4 and 7). GSTPX activity is also reduced in grasshoppers and some caterpillars by ingested phenols (tannic acid and quercetin, respectively) (Tables 5 and 7). By comparison, SOD activity is increased in caterpillars by ingested quercetin (Table 7), but is reduced or unaffected by tannin consumption in the examined grasshoppers. CAT activity is unaffected by ingested tannic acid in species of Lepidoptera and Orthoptera (Tables 3 and 7). The specific effects of ingested tannic acid on SOD and GSTPX activities have not been measured in caterpillars.

[a] Data for mid- and final-instar larvae are reported when available. ND = not determined. NS = not statistically significant.
[b] CAT activities are proportional to substrate concentration and may not be completely comparable between studies.
[c] Published in Berenbaum (1991) as mol/mg/min, but presumably is μmol/min/mg.
[d] Note corrected values here.
[e] GSTPX assays used cumene hydroperoxide, with the exception of Peric-Mataruga et al. (1997), which used *t*-butyl hydroperoxide.

DISCUSSION

The results of this study demonstrate that the superior defenses of polyphagous grasshoppers against the effects of ingested tannic acid are not the result of consistently elevated activities of four of the major antioxidant enzymes. Contrary to the main hypothesis, few cases were observed in which *M. sanguinipes* was found to have greater enzyme activities than *A. ellioti*. Among the antioxidant enzymes measured in *A. ellioti* and *M. sanguinipes*, only GSTPX in the foregut and midgut lumen was consistently higher in the tannin-tolerant species. In addition, SOD activities in *M. sanguinipes* gut tissues were unaffected by tannic acid, whereas tannic acid reduced SOD activity in *A. ellioti* tissues. CAT activity was also higher in the foregut lumen of *M. sanguinipes* than in this region of *A. ellioti*. However, the opposite pattern exists for CAT activity in the midgut lumen, where its activity was higher in *A. ellioti* than in *M. sanguinipes*. Enzyme activities in the polyphagous and graminivorous grasshopper species are remarkably similar in many cases, most notably in the tissues of the midgut.

The results of this study also show that antioxidant enzymes are not induced to a greater extent in a polyphagous grasshopper than in a graminivorous species. None of the enzymes examined in either species was significantly induced by tannic acid during a two-day period. On the contrary, lower enzyme activity was associated with tannin consumption, where a significant treatment effect was observed (SOD, APOX, and GSTPX). Ingested tannic acid had a strong inhibitory effect on APOX activity in the midgut fluids of both species. GSTPX activity was also strongly inhibited in the foreguts of both species. Among the enzymes studied, only CAT activity was unaffected by tannic acid in all cases.

In this study it is assumed that the pattern of tannic acid sensitivity observed in examined graminivorous grasshoppers is shared by *A. ellioti* (Bernays et al., 1980). Although this assumption was not tested, an examination of the morphological features found in strictly graminivorous grasshoppers confirmed that *A. ellioti* has both the flattened mandibles and shortened posterior midgut caeca that are typical of graminivorous species (Isely, 1944; Chapman, 1988; Barbehenn, personal observation). Care must also be taken in generalizing from results on the nondiapause strain of *M. sanguinipes*; elevated levels of some detoxification enzymes have been found to arise as artifacts of laboratory rearing in this variety (Isman et al., 1996). The midgut tissues of grasshoppers, particularly those of the midgut caeca, contain the highest detoxification enzyme activities in the body (Feng and Isman, 1994). In this study, it is assumed that these tissues also represent a key site at which the capabilities of antioxidant enzyme defenses can be compared among grasshopper species.

Two distinct sources of antioxidant enzymes in the gut lumens of grasshoppers are apparent: secretion by the midgut and ingestion. The results of this study suggest that luminal SOD and CAT activities are due to enzymes secreted by the

midgut, whereas luminal APOX and GSTPX activities are due to ingested plant enzymes. The spatial pattern of SOD and CAT activity (i.e., higher activity in the midgut lumen than the foregut lumen, and activity in midgut tissues) is consistent with their secretion into the midgut lumen by midgut tissues. The foregut is lined with an impermeable cuticle (Maddrell and Gardiner, 1980), precluding enzyme secretion. However, if antioxidant enzymes were secreted into the midgut lumen, regurgitation into the foregut would provide a source of these enzymes in the foregut. For example, regurgitated gut fluid from the midgut provides digestive enzymes to the foregut (e.g., Evans and Payne, 1964; Ferreira et al., 1990). Secretion of antioxidant enzymes in the saliva cannot be ruled out as an additional enzyme source.

The results of this work also suggest that ingested plant antioxidant enzymes are functional in grasshopper gut fluids. Unlike SOD and CAT, the spatial distribution of GSTPX and APOX activities in the guts of grasshoppers is characterized by maximal activity in the foregut lumen. In the case of APOX, the absence of activity in midgut tissues suggests that it is either inactive at this site or is not synthesized in grasshoppers. On the other hand, the activities of APOX and GSTPX in seedling wheat are sufficiently high to account for their activities in the foreguts of *M. sanguinipes* and *A. ellioti*. APOX activity in wheat is approximately fourfold higher than that found in grasshopper foregut lumens. Similarly, GSTPX activity in wheat leaves ranges from fourfold higher than the maximal (foregut) activity in *A. ellioti* to roughly twofold higher than the maximal (foregut) activity in *M. sanguinipes* (assuming similar enzyme levels across seedling wheat used in separate experiments).

Previous work on plant enzymes ingested by insects has focused on defensive enzymes, such as polyphenol oxidase and guaiacol peroxidase (Duffey and Felton, 1989; Felton et al., 1989; Felton and Duffey, 1991). A considerable body of evidence demonstrates that ingested enzymes also play beneficial roles in the gut lumens of insects. For instance, previous work on ingested fungal enzymes demonstrates that they play an essential role in cellulose digestion in a variety of saprophagous plant-feeding insects (Martin, 1987). The physicochemical conditions in grasshopper gut fluid are conducive to the continued activity of ingested plant enzymes, which function in an acidic pH (ca. 4–6) in the plant (Schultz and Lechowicz, 1986). The pH of grasshopper gut fluid (ca. 6–7) (Barbehenn et al., 1996; Appel and Joern, 1998) is far more favorable for continued plant enzyme activity than the high pH conditions commonly found in caterpillars (ca. 8–12) (Dow, 1984; Appel and Martin, 1990). Do the more extreme conditions in Lepidoptera preclude the acquisition of plant antioxidant enzymes, selecting for the secretion of endogenous APOX in caterpillars? Cofactors necessary for the function of APOX (ascorbate) and GSTPX (glutathione) are present in grasshopper gut fluid in adequate concentrations to permit enzyme activity. Ascorbate is present in the midgut and foregut lumens of both grasshopper species examined at levels

of 300–5000 μM (Barbehenn, in preparation), compared to 500 μM in the APOX assay reaction mixture. Glutathione is present in the midgut and foregut lumens of both species at levels of 200–800 μM (Barbehenn, in preparation), compared to 1000 μM in the GSTPX assay reaction mixture. The potential importance of acquired antioxidant enzymes in insect herbivores needs further work.

If APOX is not present in grasshopper midgut tissues, then what controls hydrogen peroxide levels in these insect tissues? Mathews et al. (1997) propose that CAT is inefficient at reducing hydrogen peroxide to low levels because of its high K_m and that APOX better serves this role. It is possible that CAT could effectively reduce hydrogen peroxide to low levels, despite its high K_m, if high activity levels of this enzyme were produced. However, CAT activities in the grasshoppers examined in this study are not higher than those found in Lepidoptera (Table 7). It is also possible that other, unmeasured enzymes function in grasshoppers and that these are measured in assays intended to measure the degradation of hydrogen peroxide by CAT. This limitation of the assay performed cannot be addressed in this study, although the rapid production of gas bubbles in the "CAT" reaction mixtures is consistent with the activity of CAT.

Neither SOD nor GSTPX has been examined in the gut lumens of Lepidoptera, to my knowledge. SOD would likely be even more useful for catalyzing the dismutation of superoxide in the high pH midguts of larval Lepidoptera; at the high pH of caterpillar gut fluids, the stability of superoxide anion radical is on the order of 100,000-fold greater than in the mildly acidic pH of grasshopper gut fluids (Rosen et al., 1999).

In conclusion, the relative susceptibilities of graminivorous and polyphagous grasshoppers to fatal midgut lesions from ingested tannic acid do not appear to be determined by variation in the activities of the antioxidant enzymes examined in this study. Several alternative hypotheses may be proposed: (1) antioxidant enzymes that were not measured in this study differ between the two species, (2) low-molecular-weight antioxidants are more important than antioxidant enzyme activities, and (3) antioxidant defenses do not explain the relative susceptibility of grasshoppers to develop gut lesions (i.e., a mechanism other than oxidative stress is at work). Additional enzymes that might be examined in grasshopper tissues include ascorbate free radical reductase, quinone reductase, glutathione reductase, and in the lumen and tissues, thioredoxin reductase, dehydroascorbate reductase, and glutathione peroxidase. Low-molecular-weight antioxidants play a critical role in protecting tissues and extracellular fluids from oxidative stress, and compounds such as ascorbate, glutathione, and α-tocopherol could vary among grasshopper species independent of the activities of antioxidant enzymes, such as those measured in this study. In addition, the basis for proposing an antioxidant defense hypothesis to explain the taxonomic variation in grasshopper midgut lesions would be strengthened by an examination of levels of ROS and oxidative stress (biomarkers) in tannin-tolerant and -sensitive grasshoppers.

Acknowledgments—Professor Michael M. Martin made excellent suggestions to improve this paper. I also thank Scott Schell for identifying and collecting *A. ellioti*. This work was supported by the National Science Foundation (IBN-9974583).

(Received October 8, 2001; accepted March 12, 2002)

Abstract—Many plant secondary compounds induce detoxification activity in herbivorous insects. Although inducibility may be advantageous as a means of reducing costs associated with maintenance of metabolism, another benefit of inducibility is that it may allow insects to tailor their detoxification profiles to multiple substrate toxins in their diets. The parsnip webworm, *Depressaria pastinacella*, must contend with many types of furanocoumarins, toxins present in abundance in all of its host plants. Previous studies have documented that cytochrome P-450s are responsible for metabolism of furanocoumarins in this species and that this overall activity is inducible. In this study, we examined the effects of ingestion of single furanocoumarins on metabolism of multiple furanocoumarins and the ability of webworms to adjust their metabolism profiles to match artificial diets with furanocoumarin content differing qualitatively and quantitatively from the average content found in their principal host. That detoxification rates of newly molted sixth instars prior to feeding did not differ from those of actively feeding fifth or sixth instars suggests that constitutive activities of furanocoumarin-metabolizing enzymes are maintained in the absence of substrates. All of the induction assays in this study were performed with ultimate instars. Each of the furanocoumarins assayed was found to induce metabolism of five different furanocoumarin substrates; however, the induction profile was independent of the inducing agent. Consistent with this finding, webworms were incapable of matching their detoxification profiles to diets with different furanocoumarin compositions. Thus, the profile of detoxification within individuals of this species appears to be genetically fixed, although there is considerable variation in profiles among individuals.

Key Words—Detoxification, induction, *Depressaria pastinacella*, furanocoumarins, substrate matching, development, cytochrome P-450, oligophage.

INTRODUCTION

A wide range of secondary plant compounds induce detoxification activity in herbivorous insects (Brattsten et al., 1977; Cohen, 1989; Nitao, 1989; Snyder and Glendinning, 1996). Insects encounter these secondary compounds, which are produced by plants as a defense mechanism against herbivores (Rosenthal and Berenbaum, 1991), when they ingest plant tissue (Slansky, 1992). Inducibility may enable insects to limit their potential costs of maintaining suites of detoxification enzymes and to tailor their detoxification profile specifically according to their exposure to dietary toxins.

Cytochrome P-450 monooxygenases (P-450s) are heme-based proteins involved in the oxidative metabolism of exogenous and endogenous chemicals. Numerous studies have examined the effects of plant allelochemicals on the induction of P-450 enzymes during larval development of many insects (Ahmad, 1986; Snyder et al., 1995; Stevens et al., 2000). In these studies, P-450 activity was reported to be highest in actively feeding larvae and significantly lower in nonfeeding larvae. Ahmad (1986) and Stevens et al. (2000) noted that P-450 activity was highest when the larvae were mid-stage. Moreover, some allelochemical-metabolizing P-450 genes have in their promoter region sequences showing a high level of identity with ecdysone response elements (Li et al., in preparation), suggesting the possibility of hormonal regulation of allelochemical metabolism. This would be consistent with past observations of adaptive regulation, such as lack of P-450-mediated metabolism activity in nonfeeding stages (egg, pupa, and adult) of *Papilio polyxenes* (Harrison et al., 2001). As well, some insect P-450 genes possess regulatory elements that appear to respond specifically to host-plant allelochemicals (e.g., XRE-xan in *CYP6B1* in *Papilio polyxenes*; Berenbaum, 2002), further suggesting specificity of regulation.

In addition to the potential benefit that inducibility can afford as a cost-saving measure, it may also provide benefits as a means of adjusting detoxification capacity to multiple substrates. Although most herbivorous insects must contend with a suite of secondary compounds that may or may not be biosynthetically related (Berenbaum and Zangerl, 1996), studies of inducibility have typically focused on single secondary compounds or several compounds administered singly (Muehleisen et al., 1989; Snyder et al., 1993; Snyder and Glendinning, 1996). Efficient food utilization by herbivores encountering multiple secondary compounds may necessitate adjustments of multiple detoxification reactions to match intake rates of each secondary compound. Such adjustments have been observed with respect to nutrient digestion. Kamin-Belsky and Wool (1993) tested the effects of different diets on the induction of digestive enzymes in *Ephestia cautella* (Walker) larvae. Ten diets that differed in nutritional composition were fed to larvae, and their ability to induce digestive enzymes was assayed. The pattern of correlations

among the different classes of digestive enzymes was diet-dependent, suggesting that enzyme activities could be modulated independently. In another study, Hinks et al. (1991) demonstrated that adult grasshoppers (*Melanoplus sanguinipes*) that consumed a diet consisting of oats or kochia exhibited a higher level of trypsin and chymotrypsin activity than those fed wheat, which contains more soluble protein than oats or kochia. However, only proteolytic enzymes were assayed, and it is not known whether enzymes for digestion of other substrates (e.g., carbohydrates) were independently modulated.

To date, no studies have been published that document matching of detoxification activities to multiple secondary compounds via the mechanism of independent induction. However, there is suggestive evidence that such a mechanism exists. The oligophagous insect *Depressaria pastinacella* (the parsnip webworm) feeds almost exclusively on wild parsnip (*Pastinaca sativa*), a biennial umbelliferous weed that was introduced from Europe about 300 years ago (Schery, 1972) and is now found throughout eastern North America in a variety of habitats such as roadsides, railroads, open fields, and waste places (Fernald, 1950; Thompson, 1977). The caterpillar, also introduced from Europe, feeds primarily on the fruits and flowers of wild parsnip. In order to utilize wild parsnips, the parsnip webworm must contend with a variety of furanocoumarins, secondary compounds produced mainly by species in the Apiaceae (=Umbelliferae) and Rutaceae that are known for their phototoxic properties (Berenbaum, 1991). Individual wild parsnip plants vary in the relative concentrations of these furanocoumarins, with generally high production of xanthotoxin and bergapten and low production of isopimpinellin and sphondin (Berenbaum and Zangerl, 1998). Webworms rely on cytochrome P-450s to detoxify host plant furanocoumarins (Nitao, 1989). Berenbaum and Zangerl (1998) have shown that webworm populations vary in their ability to metabolize furanocoumarins and that the frequencies of detoxification phenotypes of webworms generally match the frequencies of furanocoumarin chemotypes in the plant population with which they are associated. It has also been shown that furanocoumarin intake has a significant effect on growth rate, nutritional efficiency, and development of *D. pastinacella* (Berenbaum et al., 1989) and that there may be a material cost of detoxification (Berenbaum and Zangerl, 1994).

To determine whether inducibility might serve to reduce detoxification costs in *D. pastinacella*, we tested whether furanocoumarin detoxification rates in *D. pastinacella* larvae decrease following their molt from penultimate to ultimate instar and prior to feeding. To determine whether *D. pastinacella* can adjust their furanocoumarin-metabolizing enzyme levels based on the furanocoumarin content of their diet, we examined furanocoumarin metabolism as a function of larval feeding on diets containing individual furanocoumarins or mixtures of furanocoumarins.

METHODS AND MATERIALS

Postmolt Detoxification Capacity. To determine the effect of a molt on the metabolism of furanocoumarins, fifth- and sixth-instar *D. pastinacella* larvae were collected from a field of wild parsnip plants near a railroad track in west Champaign County, Illinois, USA (5 km NW of the city of Champaign). Fifteen fifth and 15 sixth instars were transferred to plastic cups (29.6 ml capacity; Solo, Urbana, Illinois, USA) with fresh parsnip from the same field. An additional 15 late fifth instars were placed in cups without food to ensure that they would not feed as sixth instars. After 24 hr, the webworms were weighed and dissected in cold sucrose medium (Cohen et al., 1989). The guts were removed, washed of their contents, and homogenized in 0.1 ml of phosphate buffer (pH 7.8, 0.1 M) before being frozen in liquid nitrogen. The phosphate buffer contained PMSF and leupeptin to inhibit protease activity and glycerol to allow the tissue to be frozen without damage. Once all larvae had been dissected, the homogenates were thawed, and 0.7 ml of reaction buffer (phosphate; pH 7.8; 0.1 M), containing a NADPH regenerating system (NADP, glucose-6-phosphate, and glucose-6-phosphate dehydrogenase) and (10 μl/0.7 ml) furanocoumarin mixture (with furanocoumarin levels representative of relative proportions normally encountered by the webworms; bergapten = 7.314 μg, isopimpinellin = 6.5 μg, xanthotoxin = 10.36 μg, and sphondin = 3.42 μg), was added to each reaction. Each assay was incubated for 15 min at 30°C, and then 0.2 ml of 2M HCl was added to stop each reaction. To each vial, 0.5 ml of ethyl acetate was added, and each sample was thoroughly vortexed before being centrifuged for 5 min. Approximately 200 μl of the ethyl acetate layer was removed and analyzed by normal-phase high-pressure liquid chromatography (Waters, Milford, Massachusetts, USA, with an Alltech, Deerfield, Illinois, USA, Absorbosphere column, 150 mm long × 4.6 mm ID, 5-μm particle size). The mobile phase consisted of 55% cyclohexane, 42% isopropyl ether, and 3% butanol flowing at 1.5 ml/min and detection was at 254 nm. Samples (20 μl) were automatically injected by a Waters WISP. Metabolism rates were expressed as nanomoles of furanocoumarin metabolized per minute per gram of larva. Statistical analyses were performed using the SPSS statistical package (SPSS, 1999).

Induction by Individual Furanocoumarins. To determine whether individual furanocoumarins differentially induce metabolism of several different furanocoumarin substrates found in wild parsnips, ultimate (sixth) instar webworms from a laboratory colony (constituted from local populations) were fed artificial diets lacking furanocoumarins (Nitao and Berenbaum, 1988) or containing one of the following furanocoumarins at a concentration of 13.9 mM fresh wt: bergapten (0.3% fresh wt), sphondin (0.3% fresh wt) (synthesized by Dr. William Wulff, University of Chicago), psoralen (0.26% fresh wt), and angelicin (0.26% fresh wt) (Indofine, Somerville, New Jersey, USA); all of these naturally occur in its host plants (Murray et al., 1982). The larvae were permitted to feed

for 24 hr, after which they were weighed prior to dissection for metabolism assays.

Webworms were dissected in cold sucrose medium (Cohen et al., 1989), and the guts were removed. After the guts were washed of their contents, they were placed in a 1.5-ml microcentrifuge tube containing 100 μl of phosphate buffer (pH 7.8, 0.1 M). The phosphate buffer contained PMSF and leupeptin to inhibit protease activity. One-fifth of a single gut homogenate, as measured by volume, was used to assay metabolism of each furanocoumarin substrate, thereby allowing the assay of all five furanocoumarin substrates (angelicin, sphondin, bergapten, xanthotoxin, and psoralen) in each larva. The homogenate aliquot was added to 1 ml of reaction buffer (phosphate; pH 7.8; 0.1 M) that contained the NADPH regenerating system (NADP, glucose-6-phosphate, and glucose-6-phosphate dehydrogenase) and 10 μg of furanocoumarin. Each assay was incubated for 30 min at 30°C. The remainder of the procedure was the same as described. Metabolism rates were expressed as nanomoles of furanocoumarin metabolized per minute per gram of larva.

Three larvae were assayed per diet. Because rates of metabolism of the five substrates were obtained from each larva, they represent repeated measures and were analyzed by repeated measures analysis of variance with diet as the main between-subjects factor (SPSS, 1999).

Induction by Multiple Furanocoumarins. In order to determine whether webworms can adjust their metabolic profiles to match precisely the phytochemical profile of the food they consume, we first determined the average concentration of furanocoumarins in fruits of *Pastinaca sativa* from four Midwestern populations (using data from Berenbaum and Zangerl, 1998). Averaging across these populations allowed us to estimate an average chemical phenotype, characterized by high levels of xanthotoxin (3 μg/mg), intermediate levels of bergapten (1.5 μg/mg), low levels of isopimpinellin (0.5 μg/mg), and very low levels of sphondin ($<$0.2 μg/mg). We then set out to create furanocoumarin profiles that differed both quantitatively and qualitatively from the average chemical phenotype. One mixture was designed to contain all four furanocoumarins present in the average phenotype but to vary in the proportional representation of each furanocoumarin in the mix. A second mixture was designed to differ qualitatively from the average phenotype in that only half of the compounds in the mixture would be present.

To create these mixtures, furanocoumarins were isolated from seeds of *P. sativa* that were collected in the Phillips Tract, a university-owned natural area 3 km northeast of Urbana, Illinois. The seeds were macerated in a blender with ethyl acetate, and the homogenate was filtered through glass wool and concentrated in a rotary evaporator. For isolation of furanocoumarin fractions, 200 g of thin-layer silica (M. Woelm, Eschwege, Germany) was mixed with hexane to produce a thin slurry. The slurry was then poured into a glass Büchner funnel with a fritted

glass filter. A vacuum was applied to the funnel, and the silica was packed until the hexane level was just at the top surface of the silica. A filter paper disk was placed on top of the silica to ensure that the surface would not be disturbed by addition of the sample or elution solvents. Hexane was added to the concentrated extract until the solution became flocculent (furanocoumarins are not readily soluble in hexane). The extract was then poured onto the filter paper and loaded into the top layer of silica with additional hexane. A mixture of cyclohexane (55%), isopropyl ether (42%), and *n*-butanol (3%) was used to separate the furanocoumarins from other constituents, and the resolving bands were visualized with the aid of a short-wave ultraviolet lamp, which causes the furanocoumarins to fluoresce. By collecting fractions at different stages of the elution, extracts were produced with different furanocoumarin profiles. These fractions were analyzed by normal-phase HPLC as described above. Fractions were consolidated in different amounts to produce two distinct furanocoumarin mixes. One mix, the qualitatively different mix, contained large amounts of bergapten and xanthotoxin with effectively no isopimpinellin or sphondin. The other mix, the quantitatively different mix, contained all four furanocoumarins, but in proportions different from the average phenotype: approximately equivalent concentrations of all four furanocoumarins ($1\ \mu$g/mg $\pm$ $0.5\ \mu$g/mg) (Figure 1).

To ensure a wide range of genetic variation, webworms were collected as pupae from four populations in central Illinois (two in Kankakee County, one in Champaign County, and one in Douglas County) and maintained as separate populations according to the methods of Berenbaum and Zangerl (1998) to obtain fifth instars to be reared on a semidefined artificial diet lacking furanocoumarins. Two artificial diets were prepared. The first contained 0.1% (fresh wt) of the qualitatively different furanocoumarin mixture and the second contained 0.1% (fresh wt) of the quantitatively different furanocoumarin mixture. Each sixth instar was weighed and placed into a plastic cup (29.6 ml capacity; Solo). A preweighed amount of solidified diet (mean weight = 0.731 g) was added to the cup. A total of 50 webworms were placed on each diet type and allowed to feed for two days. Care was taken to ensure that equal numbers of larvae from each population were represented in each treatment. After feeding, the larvae were weighed, and the remaining diet and frass were dried completely in a desiccator before their mass was recorded. As a standard, an uneaten diet sample was dried down in a desiccator to determine the wet to dry mass conversion. These values were used to obtain information on performance of the larvae on the two different types of diets with respect to growth rates and efficiency of utilization.

After feeding on the diets for two days, the webworms were dissected as described above, except that the guts were placed in phosphate buffer containing glycerol (20%) to allow the tissue to be frozen in liquid nitrogen and stored at -80°C. The guts were later thawed 10 at a time on ice and homogenized in the microcentrifuge tube with a glass pestle, refrozen in liquid nitrogen, and stored

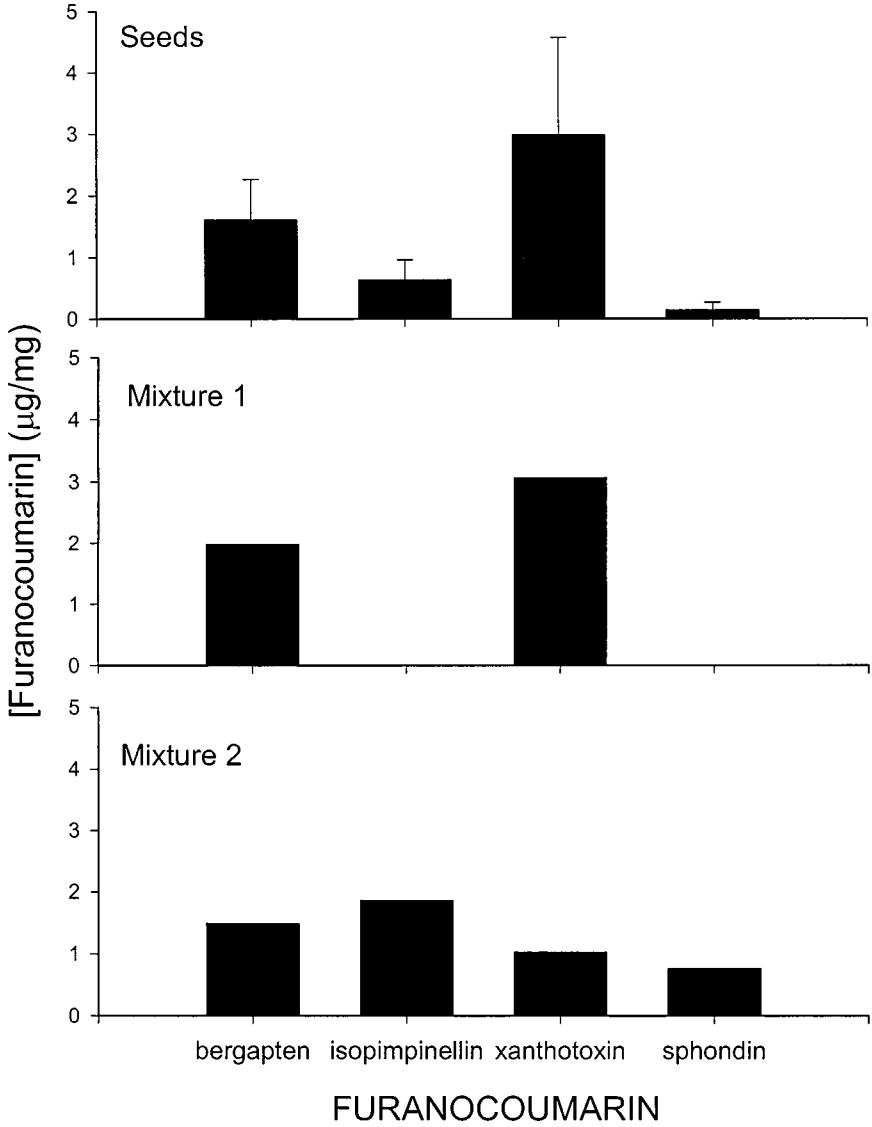

FIG. 1. Furanocoumarin concentrations of artificial diet treatment diets and seeds of wild parsnip.

at −80°C until the metabolism assays were performed. A preliminary experiment confirmed that the freezing, thawing, homogenization, and refreezing of the sample do not affect the rates of furanocoumarin metabolism measured.

The homogenates were allowed to thaw at room temperature. Once thawed, 1 ml of reaction buffer containing a mixture of furanocoumarins (10 μg/ml), representative of relative proportions normally encountered by the webworms, was added (bergapten = 7.314 μg, isopimpinellin = 6.5 μg, xanthotoxin = 10.36 μg, and sphondin = 3.42 μg). The assay was otherwise performed as described above, except that the entire gut homogenate was used in a single assay and the reaction was run for 25 min. Metabolism rates were expressed as nanomoles of furanocoumarin metabolized per caterpillar.

Dry diet samples and dry frass samples (three from each treatment) were randomly chosen for analysis of unmetabolized furanocoumarins. The diet samples were ground to a powder using a modified Wig-L-Bug (Dental Manufacturing Co., Chicago, Illinois, USA). To each diet sample 1 ml of ethyl acetate was added, and to each frass sample 0.5 ml of ethyl acetate was added. These samples were allowed to extract in solvent 24 hr before being analyzed by HPLC as described above.

The effects of diet on growth, consumption, and food utilization efficiency were examined by performing analysis of covariance according to Raubenheimer and Simpson (1992). To determine whether diet type altered furanocoumarin metabolism, we performed a repeated measures analysis of variance with diet and webworm population origin as main effects and metabolism rates of each of the four furanocoumarins as the within-subjects repeated measures effect. Population origin was not significant in this model and so a reduced model combining populations was also evaluated. Unmetabolized furanocoumarins passing into the frass were compared to rates of metabolism to determine whether there was a correlation between the two variables. To determine which factors among initial larval mass, consumption, and metabolism influence final larval mass on each diet, we performed multiple regressions with furanocoumarin metabolism expressed in nanomoles per minute. All statistical analyses were performed using the SPSS statistical package (SPSS, 1999).

RESULTS

Postmolt Detoxification Capacity. Metabolism of xanthotoxin and sphondin did not differ among feeding fifth instars, feeding sixth instars, and freshly molted sixth instars (Figure 2; $P = 0.581$ for xanthotoxin and $P = 0.933$ for sphondin). Thus, overall detoxification activity is not reduced in *D. pastinacella* during the intermolt period.

Induction by Individual Furanocoumarins. All four of the furanocoumarins administered individually in the diet increased rates of furanocoumarin metabolism (Figure 3). Angelicin metabolism was negligible in larvae fed control diet, making

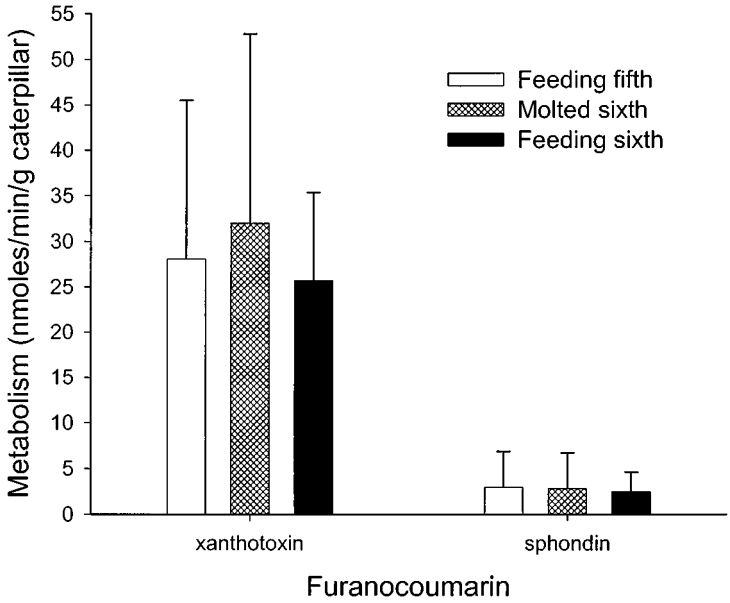

FIG. 2. Mean metabolism rates (+SD) of xanthotoxin and sphondin in feeding fifth-instar larvae, freshly molted sixth-instar larvae, and feeding sixth-instar larvae of parsnip webworms ($N = 15$ for each stage). There were no significant treatment differences for metabolism of xanthotoxin (ANOVA, $df = 2,42$; $F = 0.551$; $P < 0.581$) or sphondin (ANOVA, $df = 2,42$; $F = 0.069$; $P = 0.933$).

calculations of proportional increase impossible. For the other furanocoumarins, induction was as much as 27-fold (for angelicin induction of sphondin metabolism) or as little as 0.6-fold (for sphondin induction of psoralen metabolism). Repeated-measures analysis of variance (Table 1) confirmed that diet type significantly affects furanocoumarin metabolism and that webworms metabolize the furanocoumarins at different rates (significant within-subjects effect, $P < 0.001$). The interaction between diet type and metabolism ($P = 0.005$) suggests that not only is furanocoumarin metabolism affected by diet, but the rates of metabolism of the different furanocoumarins relative to one another are also altered by diet. This effect, however, appears to result solely from the difference between control and furanocoumarin diets, as the interaction disappears when the data from the control diet are omitted from the analysis (interaction P in that model is 0.114). Overall, rates of metabolism were highest for psoralen, intermediate for xanthotoxin and bergapten, and lowest for angelicin and sphondin.

Induction by Multiple Furanocoumarins. The effects of the two different diet types with a mixture of furanocoumarins were indistinguishable with respect to

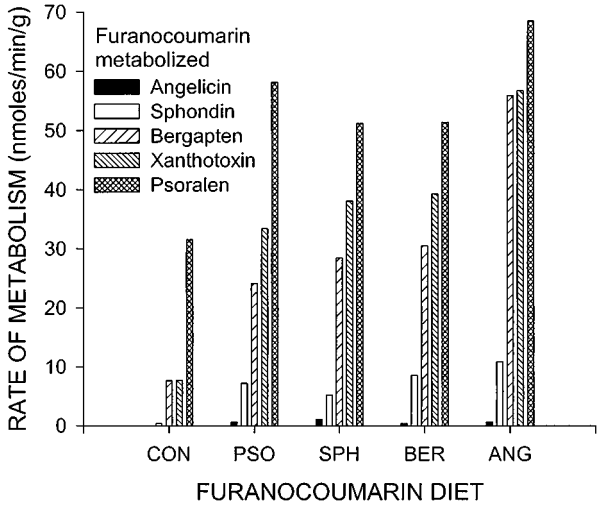

FIG. 3. Mean rates of metabolism of angelicin, sphondin, bergapten, xanthotoxin, and psoralen by parsnip webworms fed diets containing a single furanocoumarin or a diet containing no furanocoumarins ($N = 3$ for each diet).

growth and feeding (Table 2). Analyses of covariance (Table 3) suggest that final larval mass was not affected by diet type with initial larval mass as a covariate and that larval mass gain was not affected by diet with consumption or net consumption (consumption minus frass) as a covariate. An effect of diet type on consumption

TABLE 1. REPEATED-MEASURES ANALYSIS OF VARIANCE OF DIET-INDUCED FURANOCOUMARIN METABOLISM IN *Depressaria pastinacella*[a]

Factors	Sums of squares	*df*[b]	*F*	*P*
Between-subject effects				
Diet type	6,351	4	12.56	0.001
Error	1,265	10		
Within-subject effects				
Metabolism	26,923	2.002	133.5	<0.001
Metabolism × Diet type	3,340	8.006	4.14	0.005[c]
Error	2,017	20.016		

[a] Diet type was a main between-subjects effect and metabolism of each of the five furanocoumarin substrates was a repeated (within-subjects) effect.

[b] The assumption of sphericity was not met in these data; therefore, adjustments to the degrees of freedom were made, and the Greenhouse-Geisser tests are reported (SPSS, 1999).

[c] This interaction becomes nonsignificant ($P = 0.114$) when the control is dropped from the analysis.

TABLE 2. MASS OF *Depressaria pastinacella* LARVAE BEFORE AND AFTER FEEDING AND ABSOLUTE AND NET AMOUNTS (MINUS FRASS) OF DIET CONSUMED

Variable	Diet mixture 1	Diet mixture 2
Larval mass (fresh wt, mg)		
Initial	30.4 ± 6.0	32.6 ± 6.9
Final	75.0 ± 9.4	74.9 ± 9.9
Diet consumed (dry wt, mg)	36.6 ± 5.7	36.0 ± 6.7
Net diet consumed (dry wt, mg)	17.7 ± 3.2	17.2 ± 3.9

was observed, however, with larvae eating less of the diet containing all four furanocoumarins (adjusted means were 35.3 mg vs. 37.4 mg). In the absence of dietary sphondin and the near-absence of isopimpinellin, regressions of larval final mass versus initial mass, consumption, and metabolism (Table 4) yielded significant relationships for all three independent variables. For larvae fed the diet containing all four furanocoumarins, however, only consumption and metabolism were predictive of final larval mass.

Repeated measures analysis (Table 5) revealed a significant effect of diet type, with diet containing only two of the furanocoumarins eliciting higher overall rates of metabolism. The analysis also yielded a significant repeated measures effect (i.e., the metabolism rates were different among the four furanocoumarins). The lack of a significant interaction, albeit only marginally nonsignificant, between diet and the repeated measure ($P = 0.06$), however, indicates that the webworm larvae were unable to adjust their metabolism profiles to match what they consumed. That this interaction was close to significant suggests that there may have been

[a] The assumption of sphericity was not met in these data; therefore, adjustments to the degrees of freedom were made appropriate to the Greenhouse-Geisser (SPSS, 1999).

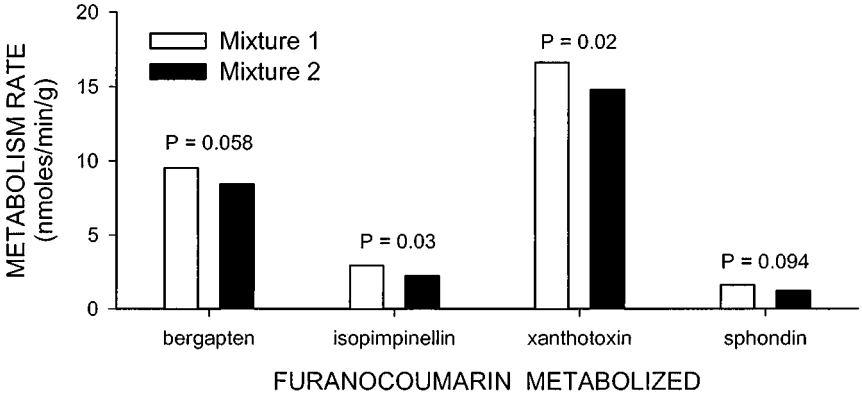

FIG. 4. Mean metabolism rates of bergapten, isopimpinellin, xanthotoxin, and sphondin in parsnip webworms fed a diet containing a mixture of furanocoumarins qualitatively different from that encountered in nature (essentially lacking isopimpinellin and sphondin, $N = 44$) and a diet containing a mixture of furanocoumarins similar to that encountered in the host plant but lower in overall quantity (wild parsnip) ($N = 48$).

a slight degree of adjustment, but it is clear from the comparison between what was eaten (Figure 1) and the differences in metabolism profiles (Figure 4) that any such adjustment was small. Moreover, this inability to adjust metabolism seems to be geographically widespread; a similar repeated-measures model including also webworm population origin (as a fixed main effect) yielded no effect of population nor any interaction of population with the repeated measure or diet (all $P > 0.5$).

The difference in furanocoumarin content that was ingested as diet and eliminated in the frass was correlated with the metabolism rate of individual furanocoumarins in only two instances. As might be expected, the decline in bergapten between its ingestion and elimination in frass was positively correlated with bergapten metabolism ($r = 0.339$, $P = 0.018$, $N = 48$), but it was also correlated with xanthotoxin metabolism ($r = 0.404$, $P = 0.004$, $N = 48$). These relationships held only for larvae feeding on the quantitative diet, which contained all four furanocoumarins. The lack of correlation between metabolism rates and disappearance rates for other furanocoumarins is likely due to imprecision in quantifying furanocoumarins in diet and frass samples, which are not entirely homogeneous.

DISCUSSION

Previous studies have shown that enzymatic activity increases from one larval stage to the next, with a significant decline right before molting. The results from this study indicate that metabolism rates in actively feeding *D. pastinacella*

remain constant from fifth to sixth instar and do not decline between stages. This maintenance of rates prior to feeding that are indistinguishable from those of actively feeding larvae suggests that, if there are costs of detoxification, they are not sufficient to warrant down-regulation. A possible explanation as to why metabolic activity does not change during the intermolt period is that webworms are never in a situation where they are in an environment free of furanocoumarins. Because of the specialized feeding preferences and sedentary habits of the parsnip webworm, which spins a silken web within the plant reproductive structures on which it feeds, the caterpillar is in constant contact with high levels of furanocoumarins not only through ingestion but also possibly through cuticular absorption (e.g., for black swallowtails, see Petersen et al., 2001). In fact, larvae fed diets lacking furanocoumarins nevertheless maintain rates of furanocoumarin metabolism that are high relative to other species not specialized on furanocoumarin-containing plants (Berenbaum and Zangerl, 1994). Reducing rates of furanocoumarin metabolism may thus expose webworms to the toxic effects of their hostplants.

Inducibility is unlikely to function as a means to tailor detoxification rates to dietary intake. Sixth-instar parsnip webworms did not adjust their pattern of metabolism to one particular furanocoumarin or to a mixture of furanocoumarins in their diet. Diet type had no significant effect on the rates of metabolism of furanocoumarins relative to each other but did affect overall rates of metabolism. This lack of a significant interaction suggests that the dietary furanocoumarins tested do not differentially induce furanocoumarin metabolism, a result that is consistent with the finding that webworms cannot adjust their metabolism profiles to match precisely what they are eating, irrespective of whether the furanocoumarin levels differ quantitatively or qualitatively from average host-plant levels.

That the addition of furanocoumarins to artificial diet does not alter the webworm's pattern of metabolism suggests that this trait may be largely genetically fixed in an individual. That is not to say that the trait is uniform among individuals, although correlations between metabolism rates of the substrates were all significant ($P \ll 0.05$) and positive. Xanthotoxin and bergapten metabolism rates were highly correlated ($r = 0.961$), but correlations between rates of metabolism of these two substrates and isopimpinellin ($r = 0.79$ and 0.857, respectively) were lower and were lower yet with sphondin ($r = 0.568$ and 0.577, respectively), suggesting substantial variation in metabolism profiles among individuals. The variation among individuals may be due to the presence of alternative alleles in populations that code for enzymes with differing metabolism rates and substrate specificities. That distinct P-450 enzymes occur in webworm populations is indicated by the less than perfect correlations between metabolism rates of some of the furanocoumarins, the exception being the correlation between xanthotoxin and bergapten metabolism. The lack of flexibility within individuals might occur if the genes coding for the furanocoumarin-metabolizing P-450s share the

same regulatory apparatus. The fact that any one of the furanocoumarins found in webworm hosts can induce metabolism of all of the furanocoumarins lends credence to the possibility at least of a common regulatory response element. Alternatively, the level of dietary furanocoumarins administered, albeit within the range of what the insect encounters in its hosts, may have been sufficiently high to induce maximum capacity for all of the substrates; if that were the case, exposure to lower levels of furanocoumarins might have produced differences in metabolism profiles.

The results from these experiments suggest that individual webworms can adjust their furanocoumarin metabolism quantitatively, but not qualitatively. There may be limited genetic variation for induction in extant webworm populations that restricts individuals to specific patterns of metabolism. The initial population of webworms that was introduced from Europe may have represented only a small proportion of the entire range of ancestral phenotypes; whether independent induction occurs in ancestral European populations remains an open question.

Abstract—The parsnip webworm, *Depressaria pastinacella*, exhibits limited physiological resistance to furanocoumarin toxins in its principal host, the wild parsnip, *Pastinaca sativa*. These insects are typically found attacking individual plants low in furanocoumarins, relative to others within populations. They also feed preferentially on parthenocarpic fruits, which are lower in furanocoumarin content than are normal fruits. However, in a previous study with artificial diets, they did not appear to discriminate between high and low concentrations of furanocoumarins. In this study, the ability of webworms to distinguish between diets differing in furanocoumarin content was examined with an artificial diet containing wild parsnip and in green parsnip fruits with and without supplemental furanocoumarins. Larvae showed no preference for high or low furanocoumarin diets containing equal amounts of freeze-dried parsnip fruit powder. When given a choice between otherwise similar wild parsnip fruits, webworms strongly preferred fruits that were not augmented with furanocoumarins in one plant but showed no preference or only a weak preference for nonaugmented fruits in four other plants. In order to identify chemical constituents other than furanocoumarins that might determine feeding preferences, we compared the chemical profile of parthenocarpic fruits (which are preferred) to that of normal fruit. Octyl butyrate, a known deterrent to webworms, is highly correlated with furanocoumarin content, occurs in all plants, and differs significantly among normal and parthenocarpic fruit, suggesting that webworms may be able to avoid furanocoumarins by virtue of their behavioral response to octyl butyrate.

Key Words—Behavior, furanocoumarins, insect, parsnip webworm, *Depressaria pastinacella*, wild parsnip, *Pastinaca sativa*.

INTRODUCTION

Specialist herbivores generally feed on a limited number of host plants, often within a single family (Bernays and Graham, 1988) and, therefore, tend to encounter a narrow range of plant secondary compounds. Because specialist herbivores typically do not encounter the variety of secondary plant compounds that generalist herbivores do, they may lack the discriminative feeding behaviors that allow insects with a broader diet range to choose among plants (Bernays and Chapman, 1994).

Depressaria pastinacella, the parsnip webworm, is a specialist herbivore that feeds preferentially on the fruits and flowers of *Pastinaca sativa*, the wild parsnip (Zangerl and Berenbaum, 1993). *D. pastinacella* encounters a suite of furanocoumarins while feeding on the fruits and flowers of *P. sativa*, and the concentration of the furanocoumarins varies among plants as well as within individual umbels (Berenbaum and Zangerl, 1986, 1998). Within wild populations of *P. sativa*, *D. pastinacella* successfully attacks individual plants with lower amounts of furanocoumarins, suggesting either an ability to detect and avoid high concentrations of these chemicals or early differential mortality (Zangerl and Berenbaum, 1993). Ovipositing moths appear to be incapable of distinguishing among hosts based on suitability for their offspring, instead preferentially laying their eggs on larger plants (Zangerl and Berenbaum, 1992). The most conspicuous selective feeding behavior in parsnip webworms involves larval preference for parthenocarpic fruits (fruits without viable seeds). These fruits are preferred despite their low nutritional value compared to normal fruits (Zangerl et al., 1991). Zangerl et al. (1991) reported that between 2.5 and 13 empty fruits were consumed for every filled fruit consumed, depending on the plant from which fruits were taken. They also found that the number of empty fruits that the webworms consumed is negatively correlated with feeding efficiency and growth rate. This decrease was attributed to the low nutritional value of parthenocarpic fruits; filled fruits are 1.6 times higher than parthenocarpic fruit in nitrogen and caloric content, but they are also higher in their furanocoumarin content. These results suggest that webworms prefer parthenocarpic fruits because of their reduced furanocoumarin content, but it is still unclear whether furanocoumarins or other chemical constituents directly mediate this feeding choice.

If preference by *D. pastinacella* larvae is governed directly by furanocoumarin content, it was not apparent in an earlier artificial diet study (Berenbaum and Zangerl, 1992). Sixth-instar *D. pastinacella* larvae that were given the choice between artificial diet supplemented with high and low levels of xanthotoxin, bergapten, sphondin, or a mixture of all three furanocoumarins showed no preference. Moreover, they did not show an ability to discriminate between these diets even when there was a fourfold difference in furanocoumarin level (Berenbaum and Zangerl, 1992). One possible explanation for this lack of discriminatory behavior is that, due to the variation in furanocoumarin concentration that *D. pastinacella* encounters, caterpillars may not invest as much energy in discriminative behavior

because their metabolic capabilities may be more important in determining their interaction with their host plant. Alternatively, the bioassay results may be misleading.

A problem with the study conducted by Berenbaum and Zangerl (1992) is that they tested the effects of only three furanocoumarins and only in artificial diet. There are at least seven furanocoumarins present in green tissues of wild parsnip (Berenbaum and Zangerl, 1996), and there may be interactions among furanocoumarins that provide cues for webworms to consume a particular diet. Alternatively, the inability of webworms to discriminate between high and low furanocoumarin levels reported by Berenbaum and Zangerl (1992) may be due to a failure to consider responses to other chemicals, correlated with furanocoumarins, acting as kairomones. Indeed, Carroll and Berenbaum (in press) demonstrated that octyl acetate, correlated with furanocoumarin content in fruits (Carroll et al., 2000), is an attractant for parsnip webworms. Moreover, components of artificial diets can themselves influence the feeding behavior of caterpillars toward allelochemicals (Shields and Mitchell, 1995; Huang and Renwick, 1997).

In this study, we determined whether webworms can differentiate between artificial diets with high and low furanocoumarin content in a matrix of freeze-dried plant material and between parsnip fruits with and without supplemental furanocoumarins. We also compared chemical components other than furanocoumarins in preferred and nonpreferred plant tissues to determine if other chemicals may act as kairomones.

METHODS AND MATERIALS

Choice between Plant-Containing Artificial Diet with High or Low Furanocoumarin Content. Furanocoumarin assessment by webworms may require the presence of other plant constituents. To test this possibility, we presented webworms with a choice between artificial diets that contained the same amount of freeze-dried wild parsnip material but different amounts of furanocoumarins.

An artificial diet was prepared according to Nitao and Berenbaum (1988), except that all of the wheat germ and cellulose powder and half of the Wesson's salt mix, sucrose, and vitamin-free casein were replaced with freeze-dried ground powder of wild parsnip buds, flowers, and fruits collected in Champaign County, Illinois, USA, in late May 2001. Half of this diet was further modified by the addition (0.1% fresh wt) of a 94.1% pure mixture of furanocoumarins (containing 1.8% imperatorin, 33.4% xanthotoxin, 53.8% bergapten, 0.51% sphondin, and 4.4% isopimpinellin) isolated from seeds of wild parsnip by the method described in Cianfrogna et al. (2002). This mixture is similar in composition to that of wild parsnip seeds except that the amount of imperatorin is underrepresented. Sixth instars for this experiment were collected from wild parsnip along a railroad track in Kankakee County, Illinois (approximately 127.5 km NE of Champaign, Illinois).

Webworms were transferred to plastic cups, one per cup (29.6 ml capacity; Solo, Urbana, Illinois, USA), containing a preweighed cube of each diet. Once half or more of either diet had been consumed (as judged by eye), the webworms were weighed again, and each diet sample was placed into a new cup and frozen at -20°C. At the end of the experiment, the diet samples were dried in a desiccator and, once the diet samples were at a constant dry weight, all masses were recorded. A preweighed diet cube at the beginning of the experiment was also dried to obtain a wet to dry mass conversion. These values were used to evaluate larval performance on each diet with respect to growth rates, efficiency of utilization of ingested food, as well as diet preference. All larvae readily fed on the plant-containing diet.

To confirm that the furanocoumarin content of diet supplemented with furanocoumarins was higher in furanocoumarin content than the unsupplemented diet, we analyzed content of nine randomly selected samples of each diet type remaining after feeding. Each dried diet sample was ground to a fine powder using a modified Wig-L-Bug (Dental Manufacturing Co., Chicago, Illinois, USA). Furanocoumarins were extracted from the ground diet samples in 0.5 ml of ethyl acetate. After 1 hr, the samples were centrifuged for 5 min, and 0.2 ml of the ethyl acetate layer was removed for analysis by normal-phase high-pressure liquid chromatography (HPLC) (Waters, Milford, Massachusetts, USA, with an Alltech, Deerfield, Illinois, USA, Adsorbosphere column, 150×4.6 mm, 5-μm particle size). Samples (20 μl) were injected by a Waters Intelligent Sample Processor (WISP 710B, Waters). The mobile phase consisted of 55% cyclohexane, 42% isopropyl ether, and 3% butanol flowing at 1.5 ml/min, and detection was at 254 nm.

To determine which of three factors—initial larval mass, amount of control diet consumed, and amount of furanocoumarin diet consumed—influenced final larval mass, we performed multiple regression analysis. To determine whether webworms exhibited a preference between diets, a one-sample *t* test was performed in which the average proportion of diet consumed that contained no furanocoumarins was compared to 0.5, the expected proportion resulting from random choice. All statistical analyses were performed using a SPSS statistical package (SPSS, 1999).

Choice between Filled P. sativa Fruits Treated or Not Treated with Furanocoumarins. In order to determine whether *D. pastinacella* larvae can distinguish among green fruits of *P. sativa* with differing furanocoumarin levels, we presented webworms with fruits to which additional furanocoumarins had been added topically and untreated fruits from the same umbel. Primary umbel fruits of five wild parsnip plants were collected from a roadside population in Kankakee County, Illinois (approximately 127 km NE of Champaign, Illinois). Parsnip fruits are schizocarps, consisting of two mericarps, each of which typically contains a single seed. Parthenocarpic fruits, which contain two empty mericarps, were separated from filled fruits with the aid of an illuminator and reserved with a sample of fully filled fruits for chemical analysis (see below); all half-filled fruits (one mericarp empty) were discarded. Fifty filled fruits from each plant were treated with a furanocoumarin mixture dissolved in acetone (the same mixture of furanocoumarins as

used in the previous experiment), and 50 filled fruits from each plant were treated with acetone alone. Fruits were treated by passing a mixture of furanocoumarins in acetone over them in a Büchner funnel. Solvent was removed by applying suction to the funnel and subjecting the fruits to a constant flow of air for 2 min. To confirm that the fruits had been appropriately supplemented, they were placed under a UV light (long wavelength). Because furanocoumarins fluoresce under UV, the treated fruits fluoresced yellow, whereas the untreated fruits did not. Each fruit was then individually marked with a permanent marker to distinguish between the treated and untreated fruits. A line was drawn on the edge of each untreated fruit starting at the stigma end and extending along both margins halfway to the opposite end of the fruit. For the treated fruits, a line was drawn with a permanent marker on the edge of the fruit starting with the carpophore end and going halfway to the distal end. Once the fruits had been marked, they were thoroughly mixed (100 fruits in all) and placed into Petri dishes (14 cm) with 15 sixth-instar webworms. The experiment was replicated five times, each time with fruits from a different plant. To maintain humidity, we placed a plastic cap containing 1.2 ml of water in each dish. When about half of the fruits had been eaten (approximately 24 hr), the webworms were removed and the uneaten fruits were counted. To determine which fruits the webworms preferred, Pearson chi-square analysis was performed.

To confirm that the supplemental furanocoumarins remained on the fruit for the duration of the experiment, we took four treated and four untreated fruits that had not been eaten from each of the five replicates. The untreated fruits were dipped in acetone to remove any small amounts of furanocoumarins that might have been transferred through webworm feeding and were allowed to air-dry. All fruits were cut widthwise across the vittae and soaked in 0.5 ml of ethyl acetate for 30 min. Samples were centrifuged for 2 min before approximately 0.2 ml of the ethyl acetate was removed from each sample and analyzed by HPLC as described above.

Chemical Differences between Normal (Filled) and Parthenocarpic Fruit. To determine which chemicals might influence webworm preference for parthenocarpic fruits, we analyzed the quantities of 33 constituent chemicals in filled and parthenocarpic fruit from the fruits collected for the previous experiment. Prior to analysis, we confirmed in feeding trials that webworms preferred the parthenocarpic fruits over filled fruits from the same umbel. Three parthenocarpic and three filled fruit samples were analyzed per umbel. Each of the three samples consisted of three fruits, which were broken apart with forceps in 0.3 ml of water before being homogenized with a ground glass tissue grinder inside a 1.5 ml microfuge tube. Once the fruits were homogenized, 0.2 ml of ethyl acetate containing 0.01% hexadecane as an internal standard was added to each tube. Homogenates were thoroughly vortexed before being centrifuged at maximum speed (13,000*g*) for 2 min. One microliter of each extract was analyzed by gas chromatography (Hewlett Packard 5890) for separation and quantification of chemical constituents (Alltech, SE-30, 30-m capillary column, 0.32 mm, ID, 0.25 μm film thickness; temperature program: 60°C, 5 min, 5°/min, 175°C, 2°/min, 200°C, 5°/min, 290°C, 1 min).

Compounds were identified by injecting a representative sample into a Hewlett Packard gas chromatograph—mass spectrophotometer. Additionally, confirmation was made by retention time for compounds with authentic standards (Aldrich, Milwaukee, Wisconsin, USA).

RESULTS

Choice between Plant-Containing Artificial Diet with High or Low in Furanocoumarin Content. HPLC analysis showed that adding furanocoumarins to the artificial diet containing freeze-dried parsnip increased furanocoumarin level threefold over the control artificial diet containing parsnip ($T = 6.94$, $df = 16$, $P = 0.00$). Despite this large difference in furanocoumarin concentration, webworms exhibited no preference ($T = 0.668$, $df = 37$, $P = 0.508$), and the amounts of each diet consumed did not affect larval growth, as evidenced by nearly identical partial regression slopes (0.200 and 0.206, Table 1).

Choice between Filled P. sativa Fruits Treated or Not Treated with Furanocoumarins. On average, augmentation raised furanocoumarin levels in treated fruits by 20% ($T = 2.77$, $df = 4$, $P = 0.025$). Pearson chi-square analysis indicated that parsnip webworms showed a marginal preference for untreated fruits in one of the plants analyzed ($P = 0.046$), a distinct preference for untreated fruits from another plant ($P < 0.001$), and a marginally nonsignificant preference for untreated fruits in one plant ($P = 0.069$). Webworms exhibited no preference in two other plants ($P = 0.546$ and $P = 0.826$). HPLC analysis confirmed that the differences in furanocoumarin content between treated and untreated fruits in the two plants for which no preference was exhibited were similar to those from plants in which a preference was shown.

TABLE 1. MULTIPLE REGRESSION OF RELATIVE CONTRIBUTIONS OF AMOUNT OF ARTIFICIAL PARSNIP DIET CONSUMED WITH OR WITHOUT ADDITIONAL FURANOCOUMARINS TO FINAL LARVAL MASS (DEPENDENT VARIABLE) OF *Depressaria pastinacella*[a]

	Regression Coefficients		Standardized Regression Coefficients

[a] Peaks are in integrator units with each unit having a value of 0.125 μV-sec.
[b] Identified both by mass spectrum and retention time against standard.
[c] Given only for compounds that differed significantly between fruit types based on paired *t* test. n.s. Not significant.

Chemical Differences between Normal (Filled) and Parthenocarpic Fruit. A significant difference in peak area between filled and empty fruits was found for 21 of the 33 peaks recorded. Of the 33 peaks, 21 were present in all plants assayed and 19 were positively correlated with furanocoumarins (Table 2). Of

the 12 constituents that were different between fruit types, present in all plants, and correlated with furanocoumarin content, we identified three as octyl butyrate, myristicin, and decanal. The correlations between total furanocoumarin content and octyl butyrate and myristicin content were significant and positive (0.953 and 0.790, respectively; Figure 1), whereas the correlation involving decanal was considerably lower (0.616).

DISCUSSION

The parsnip webworm does not sequester furanocoumarins in its body for defense against predators; rather, it relies on rapid cytochrome P-450-mediated metabolism of furanocoumarins (Berenbaum and Zangerl, 1992). Ever since Verschaffelt's (1910) demonstration that *Pieris* spp. consume nonhost tissues treated with sinigrin, a glucosinolate component of their cruciferous host plants, there has been an expectation that highly oligophagous insects detect and recognize host plants by virtue of their distinctive chemistry (Städler, 1992). Demonstrations of such unequivocal responses to diagnostic host chemicals, however, are less frequent than might be expected. Although species that sequester host-plant chemicals for defense often display distinct feeding preferences for those chemicals, not all sequestering species are immune to the negative effects of these chemicals. Young monarch butterfly larvae, for example, experience reduced growth and survival associated with feeding on latex and cardenolides in *Asclepias humistrata* (Zalucki et al., 2001). Oligophages that do not sequester chemicals to which they are presumably well adapted may nevertheless be adversely affected by high concentrations (Siemens and Mitchell-Olds, 1996) and might be expected to avoid high concentrations.

When, in the first choice experiment, webworms were presented with a threefold difference in furanocoumarin content of artificial diets containing host-plant tissue, they exhibited no preference. This lack of preference is consistent with the only other study of furanocoumarin feeding preference by webworms (Berenbaum and Zangerl, 1992). However, the experiment reported here more closely resembles the situation confronting webworms in nature because more of the furanocoumarins commonly found in green wild parsnip tissues were assayed [five of seven rather than three of seven in Berenbaum and Zangerl (1992)], and the assay was performed in the context of other wild parsnip chemicals. More realistic yet is the choice test involving whole green fruits with and without supplemental furanocoumarins. The results of this experiment suggest that webworms are generally not able to detect differences in the levels of furanocoumarins and behave in a way that minimizes their exposure to these toxins. Instead, detection of furanocoumarins, if it occurs at all, appears to depend on the fruit characteristics peculiar to the plants from which they are taken. Shields and Mitchell

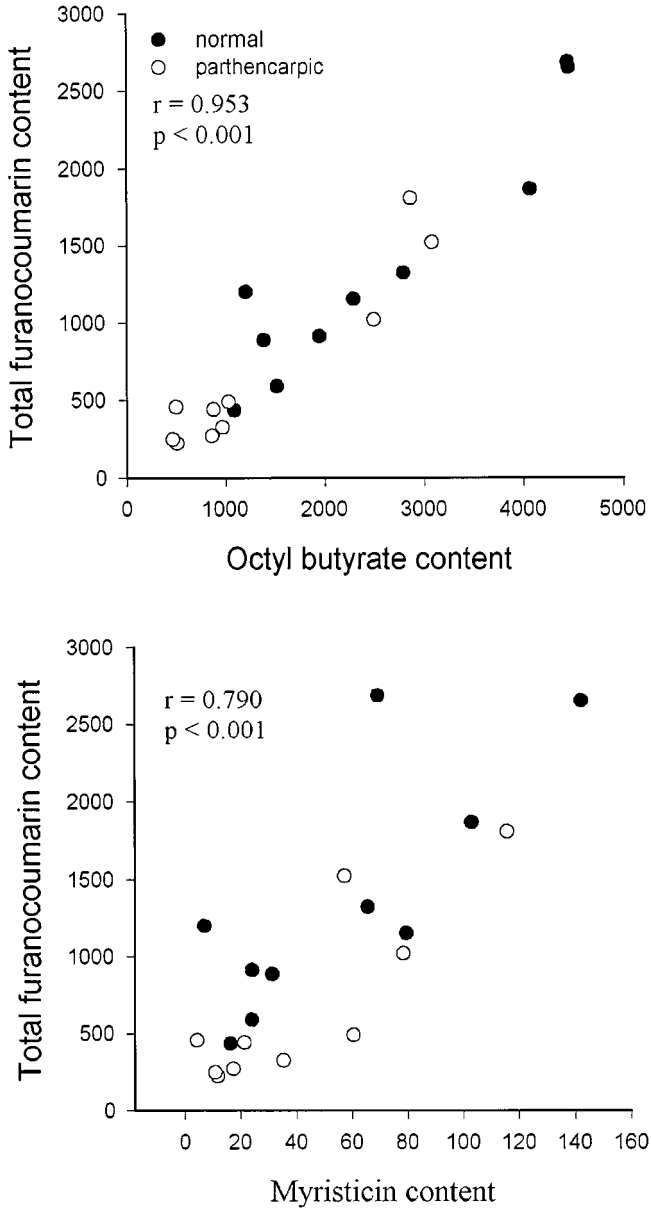

FIG. 1. Correlations between total furanocoumarin content and octyl butyrate and myristicin in filled and parthenocarpic fruits of wild parsnip. Contents are expressed as areas in integrator units.

(1995) similarly reported that the deterrent properties of sinigrin, a glucosinolate, to crucifer-feeding caterpillars are dependent upon the presence or absence of stimulatory sugars and sugar alcohols.

Although webworms exhibit a distinct preference for parthenocarpic fruit (Zangerl et al., 1991), which are lower in furanocoumarins, it appears unlikely from the choice experiments in this study and in an earlier one (Berenbaum and Zangerl, 1992) that furanocoumarins are independently assessed and avoided. If other compounds can be detected that are highly correlated with furanocoumarins, webworms may use them as cues to assess furanocoumarin levels. Such compounds would be expected to differ between parthenocarpic and normal fruit, and, presumably, should be present in all parsnip plants. Using these criteria, we narrowed the number of candidate chemical constituents detected by gas chromatography from 33 to 12, of which three have been positively identified. Of these, octyl butyrate is known to be a feeding deterrent for the parsnip webworm (Carroll and Berenbaum, in press). The high correlation ($r = 0.953$) between furanocoumarin content and octyl butyrate content detected in this study suggests that webworms could precisely assess furanocoumarin content of fruits indirectly by assessing octyl butyrate content. Another possible candidate that may explain feeding preference is myristicin, which is also correlated with furanocoumarin content and may be harmful by inhibiting activity of the cytochrome P-450s involved in metabolism of furanocoumarins (Berenbaum and Neal, 1985). Other chemical constituents that were not quantified or those such as decanal or the other nine unidentified constituents might be responsible for the feeding behavior in parsnip webworm, but further work is needed to make such a determination.

This study suggests that feeding behaviors of insect herbivores, including those with a restricted host range, may not be guided directly by those plant constituents that pose a potential risk for the insect. The level of host-plant toxins indicated by the level other detectable host-plant constituents may allow webworms to feed on the most suitable plants or plant parts. That webworms cannot consistently avoid higher furanocoumarin content in the presence of other plant constituents but can avoid them in intact plants suggests that the covariance of furanocoumarins with other plant constituents may ultimately govern feeding choice. To the extent that this phenomenon occurs in other herbivorous insects, choice studies, even those involving spiked plant parts, may lead to erroneous conclusions because they do not preserve the correlations between the chemical of interest and other plant constituents that exist in plants and affect feeding behavior.

(Received July 12, 2001; accepted March 13, 2002)

Abstract—The parasitic wasp *Trogus pennator* (Hymenoptera: Ichneumonidae) attacks larvae in two genera of Papilionidae, *Eurytides* and *Papilio*, on plants in a variety of families. The female wasps' responses to food plants, feeding damage, and frass were examined in a series of experiments designed to test the hypothesis that parasitic wasps that specialize on host taxa and seek their hosts in a variety of habitats exhibit fixed responses to host-derived cues and more flexible responses to cues associated only with the hosts' food plants. Naive *T. pennator* females showed no preferences when offered either a choice between two papilionid food plants or a choice between a food plant and a plant not used for food by Papilionidae. After experience with hosts in the presence of a particular food plant, however, wasps preferred that plant. Naive wasps did prefer plants damaged by host larvae over plants damaged by nonhost (saturniid) larvae and also preferred methylene chloride extracts of host frass over extracts of frass from saturniid larvae fed on the same plant species, results indicating that the responses of *T. pennator* females to host-derived cues are innate. The chemical compositions of the extracts of frass from several papilionid and one saturniid species were also examined, and the significance of the finding that no host-specific patterns were detected among the major components of the extracts is discussed.

Key Words—Ichneumonidae, Papilionidae, host-finding behavior, learning, feeding damage, semiochemicals, frass, flight chamber.

INTRODUCTION

Parasitic wasps in the genus *Trogus* Panzer (Ichneumonidae) lay their eggs in the larvae of swallowtail butterflies (Lepidoptera: Papilionidae) and emerge as adults from the remains of the host pupae (Mitchell, 1979, 1981). The North American species *T. pennator* (Fabricius) is widespread in the United States, although it is most common in the southeastern states, and is relatively polyphagous, attacking nearly all the papilionids in its range, including *Eurytides marcellus* (Cramer) and at least five *Papilio* species (Heinrich, 1962; Mitchell, 1983; Sime and Wahl, 2002). These hosts feed on a variety of plants, although with the exception of the generalist *P. glaucus* L., each species tends to specialize within plant families (Feeny, 1991). *Trogus pennator* has been reared from larvae feeding on eight plant families, suggesting that it does not discriminate among its hosts' food plants (Sime, 2001).

The host-finding behavior of *T. pennator* has been studied under natural conditions in the Ocala National Forest, Florida, USA, where the usual host is the zebra swallowtail, *E. marcellus* (Sime, 2001), which feeds on species of pawpaw (Annonaceae: *Asimina*). By following females as they searched for host larvae, it was established that the wasps discriminate between *Asimina* and other plants, that they are attracted to plants damaged by hosts, and that they spend more time searching on damaged than on intact plants. While that study provided valuable information about the behavior of undisturbed wasps in a natural environment, it left several important questions unanswered. The evidence indicated that the wasps rely at least in part on vision to identify *Asimina* plants, but it was not possible to determine whether they also respond to plant odor, as do most parasitic wasps (Vinson, 1984). It was also not possible to establish whether the wasps recognize feeding damage on the basis of odor, or whether they can distinguish the feeding damage of their hosts from that left by other lepidopteran larvae.

To discover the nature of the cues involved in orienting to plants, laboratory experiments were conducted to determine whether wasps are attracted to plant odor and whether the sources of useful odors include intact plants as well as plants chewed by host larvae. To establish a chemical basis for their arrestment behavior, the responses of wasps to chemical extracts of host frass were examined and an attempt was made to isolate and identify active compounds.

Another shortcoming of the previous field study was that it was not possible to know whether the observed attraction to plants had been learned, as is the case for many parasitic wasps (Vet et al., 1995). No information was available on the life experiences of the wasps observed, although presumably all had encountered hosts, which were abundant at the site. Because the host range of *T. pennator* and the food plants of its hosts are well known, an investigation of learning and cue specificity in this species provides an opportunity to test ideas concerning the evolution of host range in parasitoids. Gauld (1988) and Vet and Dicke (1992)

have hypothesized that for parasitoids specializing on particular host taxa, host range is a function of the distribution of chemical compounds used to find and identify hosts. This hypothesis requires, first, that innately attractive cues exist (i.e., the wasps are attracted to them regardless of experience and environment), and second, that the parasitoids are able to use these cues to discriminate hosts from nonhosts. For *T. pennator*, this hypothesis predicts that the females use compounds characteristic of papilionid larvae to find and recognize these hosts. Responses to hosts are expected to be fixed, but responses to plant-derived cues may be more flexible. This hypothesis was tested in the present study by investigating whether plant- and host-derived chemical cues were innately attractive or learned and by comparing responses to odors produced by papilionid and non-host larvae.

METHODS AND MATERIALS

Sources of Insects and Plants. Most of the *Trogus pennator* females used in these experiments were the offspring of adults caught in the Ocala National Forest, Florida, in late March and early April of 1995, 1997, and 1998. A few were netted at patches of *Asimina triloba* (L.) (a food plant of *E. marcellus*) along the James River near Buchanan, Virginia, USA, in July of 1996 and 1998. The wasps were raised on larvae of *E. marcellus*, also collected in Florida, that had been exposed to female wasps in captivity and maintained on cuttings of *A. speciosa* Nash and *A. triloba*. Adult wasps were kept for up to several weeks at room temperature with unlimited access to water and a honey-water solution. They were refrigerated (at 4°C) for up to a week at a time when not needed for experiments. Females were intermittently allowed to attack *E. marcellus* larvae as necessary to maintain the colony.

Several other species of Papilionidae were reared for use in experiments. Larvae of *Papilio troilus* L., taken from a laboratory colony maintained on the Cornell campus (Carter et al., 1999), were reared on foliage clipped from sassafras trees [*Sassafras albidum* (Nutt.)] in Ithaca, New York, USA. Larvae of *Papilio polyxenes* Fabricius, also taken from a local colony, were reared on leaves from potted carrot plants (*Daucus carota* L.) (Brooks, 2000). The offspring of *Papilio glaucus* L. females caught in the Ithaca area were reared on ash (*Fraxinus americana* L.). In addition, a nonpapilionid species, *Callosamia promethea* (Drury) (Saturniidae), was reared for use as a control. This species was chosen because it is readily available and because, like *P. troilus* and occasionally *P. glaucus*, it feeds on sassafras, thus introducing a control for the effects of food plant on host odors. The *C. promethea* larvae were the offspring of moths obtained as pupae from an amateur supplier in New Jersey and were reared on the leaves of local sassafras trees under the same conditions used to rear *P. troilus*.

All insects were bred and reared in a climate-controlled chamber (16L:8D, 30/16°C day/night, and 80–85% relative humidity). Wasps used in experiments

requiring naive females had no contact with hosts or with any plant matter between the time of their emergence and the time of the experiment. The pupae from which they emerged had been cleaned of silk and plant residue and placed on clean paper towels in a nylon-screened cage.

Voucher specimens of butterflies, moths, and wasps were deposited in the Cornell University Insect Collection (lot no. 1240).

Responses to Plants and Feeding Damage: Flight-Chamber Experiments. The flight chamber was a wooden cage screened with nylon mesh (185 × 92 × 92 cm). Plant samples were placed at one end and separated from each other by a cardboard partition projecting 50 cm into the cage. The wasps were released from vials at the opposite end of the chamber. A 50-cm-diam. fan was placed just outside the plant end of the chamber. Wind speeds were maintained at 1.0 m/sec at the plants, grading down to 0.5 m/sec at the release site, as measured by a handheld anemometer (Davis Instruments, Hayward, California, USA). The assembly was housed in a rooftop greenhouse on the Cornell University campus that was maintained at 24°C. Experiments were conducted near midday on sunny days in midsummer, using the sun as the main light source. The plants were placed in the southern end of the flight chamber to take advantage of the wasps' phototactic responses.

Twigs were cut shortly before each trial (except when exposed to host larvae as described below) and were kept in small vials of water during the trials. The positions of the two cuttings were switched with every fifth wasp. A wasp that did not cross into the partitioned area within 10 min was considered nonresponsive and excluded from the data set. The numbers of wasps that chose each plant species or treatment were compared with binomial probability functions (Conover, 1999).

The first two flight-chamber experiments (1a and 1b) tested whether the wasps learn the odor of swallowtail food plants by comparing the responses of naive and experienced females to a choice of sassafras (the food plant of a host, *P. troilus*) and maple (*Acer platanoides* L.). Maple was chosen as the alternate because it is not fed on by any swallowtails, because it is a common tree in swallowtail habitats in the eastern United States, and because its lobed leaves resemble those of sassafras in gross outline, thus providing a control for visual preferences. Discrimination by naive females would indicate an innate preference. Alternatively, if only wasps with experience attacking hosts in the presence of sassafras favored the food plant, then a learned response would be indicated.

In experiment 1a, females were tested before and after they had experience attacking hosts. The wasps were reared from *E. marcellus* larvae collected in Florida in spring 1996. The naive trials were conducted with 2-week-old mated wasps between June 30 and July 2. After the last trial, the wasps were placed in cages containing *P. troilus* larvae feeding on sassafras, which they attacked immediately. The experienced trials were conducted July 3–6.

Experiment 1b controlled for the age of the wasps. The wasps had been reared from *E. marcellus* larvae collected in Florida in spring 1997. When they

were 2 weeks old, the females were divided into two sets, one of which stayed naive while the other—the experienced set—was placed for a few hours on June 27 and 28 in boxes with first- and second-instar *P. troilus* feeding on sassafras cuttings. The two groups of wasps were tested concurrently from June 29 to July 2.

Experiment 2 tested for an innate preference among different swallowtail food plants. Week-old, mated, naive females were offered a choice of sassafras and *Asimina triloba*, the food plants of *P. troilus* and *E. marcellus*, respectively, the most common hosts of *T. pennator* in the southeastern United States. The wasps were reared from *E. marcellus* larvae collected in Florida in spring 1997 and raised on *Asimina*. Any food-plant effects carrying over from the hosts or pupae were, thus, expected to bias the experiment towards *Asimina*.

Experiment 3 tested whether host damage is innately attractive by examining the responses of naive wasps to a choice of sassafras leaves chewed by *P. troilus* larvae and sassafras leaves that had never been exposed to caterpillars. The naive wasps used in experiment 2 were refrigerated for four days and used again in this experiment. The unexposed sassafras leaves were mechanically damaged with scissors to control for effects of damage unrelated to larval feeding. The "chewed" leaves were exposed to *P. troilus* larvae overnight; the larvae were removed from the leaves 10 min before the start of the experiment.

Experiment 4 expanded on experiment 3 by testing whether the wasps are more attracted to the feeding damage of their hosts than to the damage of other lepidopteran larvae. Naive wasps were offered a choice between sassafras leaves chewed by *P. troilus* and sassafras leaves chewed by the saturniid *C. promethea*. As in experiment 3, the larvae fed on the leaves overnight and were removed from them 10 min before the start of the experiment. Fourth and fifth instars of both species were used, so the amount of damage inflicted on the leaves was similar in the two treatments. The female wasps were reared from *E. marcellus* larvae collected in Florida in spring 1998; they emerged over several days in mid-June and were tested 10 days after emergence.

Responses to Frass Extracts. Methylene chloride extracts of frass were prepared from the following species: *E. marcellus* (35 g frass collected), *P. troilus* (49 g), *P. glaucus* (7 g), *P. polyxenes* (5 g), and *C. promethea* (60 g). The larvae were reared on plant cuttings inserted into plastic vials and placed in plastic boxes. Each morning, frass that had accumulated in the bottom of the box was transferred to a container of CH_2Cl_2 and ground with a glass rod to increase the efficiency of extraction. The extracts were refrigerated at 0°C. After collection was complete (usually after several days), the extracts were filtered under low vacuum through glass wool and Whatman No. 1 filter paper. They were then evaporated under reduced pressure at 40°C to a concentration of 0.25 g frass equivalent/ml.

To test for arrestment responses to these extracts, the time females spent searching in the vicinity of the extract was measured. The extract was presented on a cotton swab in the center of a Petri dish lid (9 cm diam.), supported by a small

piece of green plastic sponge (2 cm square × 0.5 cm high). The swab contained 2–3 drops of extract, which at the given concentration was roughly equal to the amount of frass produced by a fourth- or fifth-instar caterpillar in a few hours of feeding. The Petri lid was centered on the floor of a plastic box (35 × 27 × 60 cm), and the wasps were released into the box from a glass jar placed at one end of the box. Searching time was recorded as the time spent actively antennating the substrate while within the lid; time spent grooming or resting was excluded. Both experiments were carried out in the climate chamber described above.

The first experiment compared the time that naive wasps spent searching at extracts from *P. troilus* and from the nonhost *C. promethea*. The trials were paired such that each wasp spent 5 min with one extract and then 5 min with the other (the order of presentation of extracts varied randomly from wasp to wasp). The average times spent at the extracts were compared with a two-tailed paired *t* test. The wasps originated in Florida and had been reared from *E. marcellus* larvae collected in spring 1998.

To get a better idea of the extent to which these responses were particular to swallowtail frass, a second experiment was conducted which tested the wasps' responses to extracts from the three *Papilio* species (*P. troilus*, *P. polyxenes*, and *P. glaucus*) and the *C. promethea* control. Each wasp spent 4 min with each of the extracts in succession, the order of presentation being varied at random. The wasps used in this experiment had been caught in Virginia at *Asimina* patches and were assumed to have had experience in the field with *E. marcellus* and possibly *P. troilus*. Because the wasps switch readily between host species in the laboratory (K.R.S., personal observation), such experience was not expected to affect the outcome of the experiment.

Characterization of Frass Extracts. The preceding experiments compared the arrestant activities of the *C. promethea*, *P. troilus*, *P. polyxenes*, and *P. glaucus* frass extracts. The *E. marcellus* extract was simply tested against the solvent with a bioassay identical in design to the paired experiment described above. Following the biosassays, the compositions of the papilionid and nonpapilionid extracts were characterized and compared.

Each extract was fractionated on an open column containing 30 g silica gel (Si-60, 32–63 μm). Five fractions were collected, corresponding to five additions of 250 ml solvent: pentane, pentane–methylene chloride (1:1), methylene chloride, methylene chloride–ether (1:1), and ether. The *P. troilus* extract was analyzed in detail. Each of its five fractions was bioassayed in paired experiments like those described above, comparing the searching activities elicited by the fraction and a solvent control. When the third fraction was identified as active, it was tested against a recombination of the five fractions (controlling for concentration) in order to determine the extent to which activity was limited to that fraction. Fractions of the *E. marcellus*, *P. glaucus*, *B. philenor*, and *C. promethea* extracts comparable to the third fraction of the *P. troilus* extract were prepared using the same procedures

to fractionate the original CH_2Cl_2 extracts. The eluting samples were monitored with thin-layer chromatography using a solvent system of equal portions hexane and ethyl acetate.

These fractions were analyzed using a Hewlett-Packard HP5890 gas chromatograph coupled to an HP 5970B mass-selective detector. The GC employed helium as carrier gas, with a flow rate of 1 ml/min, and was fitted with an HP-1 capillary column. Injections were splitless. The temperature program started at 60°C, rising at a rate of 10°/min to 260°C, then holding for 5 min at 260°C. The major components of the samples were identified by matching EI spectra recorded at 70 eV to spectra in the Wiley library.

Finally, to facilitate identification of active compounds, the active fraction of the *P. troilus* extract was further split into three subfractions (A, B, C). The fractionation procedures were like those described above except that the solvent system consisted of successive additions of 250 ml hexane–chloroform (1:4), chloroform, and chloroform–ethyl acetate (1:1). Each of the three resulting subfractions was bioassayed against chloroform.

RESULTS

Responses to Plants and Feeding Damage: Flight-Chamber Experiments. The outcomes of experiments 1a and 1b were similar (Table 1), with the less conclusive results of 1a possibly indicating effects of age. Naive females did not discriminate between maple and sassafras leaves, but the wasps that had attacked *P. troilus* larvae feeding on sassafras tended to fly towards sassafras. These results

Experiment 4	Sassafras damaged by *P. troilus*	Sassafras damaged by *C. promethea*	
Wasps favoring each treatment (*N*)	14	6	0.05

indicate that responses to plants *not* damaged by hosts are learned. Assuming that differences in visual cues were minimized between the two treatments, these experiments also show that odor plays a role in plant recognition. Because color and shape cues in the leaves were not strictly controlled for, however, the possibility that visual cues contributed to the wasps' responses cannot entirely be eliminated.

Naive wasps did not discriminate between two common swallowtail food plants, *Asimina* and sassafras (Table 2, experiment 2). Because the wasps used had been reared from *E. marcellus* larvae feeding on *Asimina*, this experiment also shows that neither the host nor its food plant biases the preferences of a naive wasp.

Experiment 3 indicated that naive wasps favor leaves damaged by hosts over mechanically damaged leaves, while experiment 4 showed that naive wasps prefer leaves damaged by a host over leaves damaged by another lepidopteran species (Table 2). Since there were no differences in the appearances of the leaves used in these treatments, it may be concluded that the wasps were responding to odors associated with host damage.

Responses to Frass Extracts. Naive wasps searched longer at a methylene chloride extract of the frass of *P. troilus* (a host) than at an extract from *C. promethea* (a nonhost) (Figure 1). Arrestment responses to extracts of the frass of *P. troilus*, *P. glaucus*, and *P. polyxenes* were similar, and all were significantly greater than responses to the extract from *C. promethea* (Figure 2). Because both the *P. troilus* and the *C. promethea* larvae had fed on sassafras, both experiments show that the wasps respond to odors in frass that are peculiar to host larvae.

Characterization of Frass Extracts. The preceding experiments showed that the methylene chloride extracts of the frass of *P. troilus*, *P. glaucus*, and *P. polyxenes* larvae elicit an arrestant response in *T. pennator*. Similarly, an extract from *E. marcellus* was searched significantly longer than a solvent control (Table 3). Bioassays of the five fractions of the *P. troilus* extract indicated that

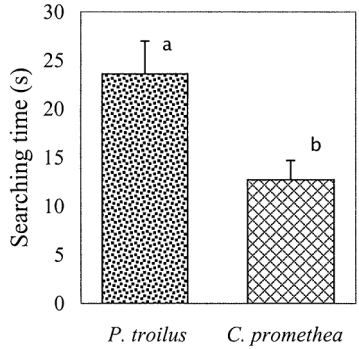

FIG. 1. Mean searching times of naive female wasps at methylene chloride extracts of frass from a papilionid host, *P. troilus*, and from the saturniid moth *C. promethea* ($N = 17$, $P < 0.01$). Both species were reared on sassafras foliage.

nearly all of the arrestant activity could be attributed to fraction 3 (Table 3): the wasps searched significantly longer at fraction 3 than at the solvent control, and its activity was comparable to that of the recombined fractions. Of the three subfractions prepared from fraction 3, only the middle one (3B) elicited greater activity than the solvent control.

A number of compounds were identified in fraction 3 of frass extracts from *C. promethea*, *P. troilus*, *E. marcellus*, and *P. glaucus* (Table 4). Concentrations of compounds in fraction 3B of *P. troilus* proved insufficient to make reliable identifications.

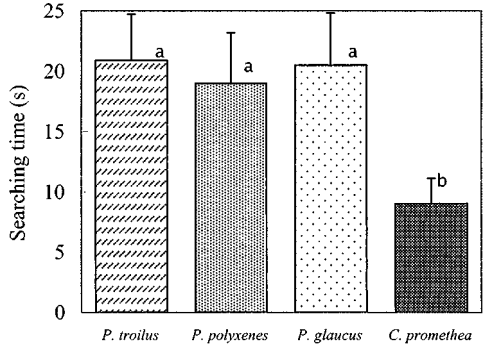

FIG. 2. Mean searching times of female wasps at methylene chloride extracts of frass from three host *Papilio* species and the saturniid *C. promethea* ($N = 24$, $P < 0.05$).

DISCUSSION

The flight-chamber experiments, although limited in the number of plant species tested, provide evidence that *T. pennator* females emerge without preference for the food plants of swallowtails over other plant species or for particular swallowtail food plants over others. The Ocala National forest is at the southern edge of the geographical range of sassafras (Brown and Kirkman, 1990). The wasps used in these experiments therefore came from a population whose members do not normally encounter sassafras, although they may encounter *P. troilus* larvae feeding on another lauraceous plant, *Persea borbonia* L. (Lederhouse et al., 1992). That they can learn to associate the odor of sassafras with the presence of host larvae indicates considerable flexibility in their capacity to recognize plants, as would be expected in a widespread species that attacks hosts feeding on a diverse array of plant families (Vet and Dicke, 1992). The attraction to undamaged plants observed in the flight chamber also helps explain the observation that in the field, female *T. pennator* approach and search food plants lacking feeding damage significantly more often than they approach damaged plants (by a ratio of about 2:1) (Sime, 2001). While the field observations suggested that vision plays

a role in plant recognition, the flight-chamber experiments show that the odor of undamaged plants can also be learned.

One consequence of the attraction of naive wasps to odors associated with feeding damage is that they need not land on and search plants at random before their first encounters with host larvae, but instead can rapidly come to focus on the host's food plant. Field data for female *T. pennator* indicate that the feeding damage of *E. marcellus* larvae on *Asimina* plants is detected at distances of at least 1 m (Sime, 2001); studies of other species, conducted in flight chambers or

wind tunnels, have also provided evidence that feeding-damage odor is involved in medium-range (on the order of meters) orientation (e.g., Geervliet et al., 1994). The attraction of naive wasps to the so-called plant-host odor complex has been observed in many species of Braconidae (Turlings et al., 1990; Steinberg et al., 1992; Udayagiri and Jones, 1993; Reed et al., 1995; Geervliet et al., 1996) and Ichneumonidae (Lecomte and Thibout, 1986; Vinson and Williams, 1991). Other studies have found that the odor of lepidopteran feeding damage is species specific and that parasitoids can distinguish host odors from those of nonhosts (Blaakmeer et al., 1994; Agelopoulos et al., 1995; DeMoraes and Mescher, 1999), although such discrimination is not always observed (McCall et al., 1993; Geervliet et al., 1996).

It has also often been shown that naive wasps are attracted to the frass of their hosts (Lewis and Jones, 1971; Hendry et al., 1973; McKinney and Pass, 1977; Lewis and Tumlinson, 1988; Vet and Dicke, 1992; Suiter et al., 1996). It is usually assumed that the wasps are able to distinguish the frass of their hosts from that of other species, but most studies of frass do not test responses to nonhosts or distinguish compounds of plant origin from those modified by digestion and metabolism in the larvae (Ramachandran et al., 1991). The finding that *T. pennator* females favored *P. troilus* frass over *C. promethea* frass when both species were reared on sassafras indicates that the frass of two species feeding on the same food plant can differ in odor and that the wasps recognize the difference. Furthermore, swallowtail frass is recognized and about equally attractive regardless of food plant. In the four-way experiment, the *Papilio* species had fed on Lauraceae (*P. troilus*), Apiaceae (*P. polyxenes*), and Oleaceae (*P. glaucus*). To this list may be added Aristolochiaceae: a separate study showed that a methylene chloride extract of the frass of *Battus philenor* (L.) larvae feeding on *Aristolochia* was as attractive to *T. pennator* females as was an extract from *P. troilus* (Sime, 2002). Whereas the Lauraceae and Apiaceae resemble each other in odor and essential oil content, and the Aristolochiaceae share some of these chemical qualities, the Oleaceae are chemically very different (Feeny, 1991).

The chemical basis of frass discrimination is difficult to pinpoint. None of the compounds or classes of compounds identified in the active fraction of the frass extracts (Table 4) is characteristic of swallowtails, and there appears to be as much overlap in frass composition between *C. promethea* and any given swallowtail as there is among swallowtail species. Even if any of these compounds should prove attractive to *T. pennator*, it is unlikely that any one compound would provide a basis for distinguishing host from nonhost. Two bases for host discrimination are possible, and neither can be rejected with the available evidence. Critical compounds that characterize swallowtails might be among the minor, unidentified constituents of the extracts. Alternatively, the wasps may respond not to the presence or absence of particular compounds, but instead to a particular blend of compounds; such blends have been found to be critical for recognition of host odors associated with feeding

damage (Turlings et al., 1990, 1991; Tumlinson et al., 1992, 1993; Agelopoulos and Keller, 1994; Geervliet et al., 1994). The observation that the wasps searched at the *C. promethea* extracts at all merits mention, for it indicates that, despite their evident preference for swallowtail frass, the wasps may also have generalized responses to the odors of frass. The compounds eliciting the arrestment response would, thus, appear to include a combination of swallowtail-specific cues plus more general cues of either caterpillar or plant origin. Finally, the possibility that *C. promethea* frass contains deterrent compounds should not be dismissed, as it was not accounted for in the design of these experiments.

These results suggest a general caveat for the interpretation of data concerning the semiochemical content of frass. Although many evidently attractive compounds have been identified in the frass of lepidopteran larvae (Tumlinson et al., 1992; Rutledge, 1996), the ecological roles of these compounds have not always been clearly demonstrated. It is usually not known whether any are individually characteristic of the host or if they are simply components of attractive blends used to identify hosts. The distribution of identified attractant compounds within Lepidoptera is not known; in many systems it would be useful to know which appear in the frass of other lepidopteran larvae feeding on the same or similar plants. Compounds widespread in Lepidoptera cannot by themselves permit host recognition.

Although the active compounds or blends that permit *T. pennator* females to distinguish papilionid larvae from nonhosts were not identified, the work reported here provides evidence that hosts differ chemically from nonhosts and that this difference is discerned by wasps with no prior experience of hosts. Odors associated with both host-damaged leaves and host frass were distinguished from odors produced by a saturniid feeding on the same plants. These findings indicate that the host range of *T. pennator* is a function of attractive compounds shared by and unique to swallowtail larvae, and they are consistent with the hypothesis that the chemical similarity of hosts is an essential parameter of the host range of taxonomic specialists (Gauld, 1988; Vet and Dicke, 1992). One alternative explanation for restricted host ranges is that host range is a function of responses to habitat or food plant (Gauld, 1988). Because *T. pennator* is not known to attack other Lepidoptera that share food plants with the Papilionidae, this hypothesis cannot provide a complete explanation of its host restriction; moreover, it is invalidated by the finding that responses to plant odors are learned. Another possible explanation is that host range may be a function of physiological compatibility (Brodeur and Vet, 1995). This hypothesis is compatible with the two behavioral hypotheses but would be more compelling had no support been found for the others. Possible physiological mechanisms underlying host range have not been studied in *Trogus*. However, given the evidence found in this study for behavioral correlates with host range, it is unlikely (at least among the potential host species studied) that physiology is an important determinant of host use.

Acknowledgments—J. Brooks, J. Carpenter, M. Carter, P. Feeny, C. Heinz, M. McDonald, S. Murphy, C. Tauber, M. Tauber, and S. van Nouhuys helped in the field and laboratory and in the preparation of this manuscript. M. Haribal analyzed GC-MS data, and A. Attygalle (Cornell University Department of Chemistry) provided access to GC-MS instrumentation. J. Clutts (Lake George Ranger District, Silver Springs, Florida) permitted work in the Ocala National Forest. This work was funded by National Science Foundation Research Grants IBN-9119674 and IBN-9420319 to Paul Feeny and IBN-9600094 to K.R.S. and P. Feeny, and by grants from the Rawlins Fund (Department of Entomology, Cornell) and the Andrew Mellon Foundation to K.R.S. The author was also supported by a Liberty Hyde Bailey Fellowship (Cornell University College of Agriculture and Life Sciences) and a National Science Foundation Graduate Research Fellowship.

(Received September 8, 2001; accepted March 20, 2002)

Abstract—This study describes the chemical ecology of a tritrophic interaction among species endemic to the island of Hawaii, USA: a tree (*Sophora chrysophylla*: mamane), an endangered bird (*Loxioides bailleui*; palila), and moth larvae (*Cydia* spp.). Palila and *Cydia* both specialize on the seed embryos of mamane but avoid eating the seed coats. Palila actively seek out and feed mamane embryos and *Cydia* larvae to their nestlings. Because mamane embryos contain potentially toxic levels of alkaloids, including broadly toxic quinolizidine alkaloids, and because insects often sequester alkaloids from their food plants, we focus on the questions of why palila forage upon mamane embryos and why they supplement their diet with *Cydia* larvae. Our data show that mamane embryos contain high amounts of potentially toxic alkaloids, but are well balanced nutritionally and contain lipids, carbohydrates, proteins, amino acids, and minerals at levels that are likely to be sufficient for maintenance and breeding. Mamane seed coats contain lower levels of alkaloids and nutrients, somewhat

0098-0331/02/0700-1393/0 © 2002 Plenum Publishing Corporation

higher levels of phenolics, and much higher levels of nondigestible fiber. Taken together, these results suggest that palila have evolved tolerance to high levels of alkaloids and that they forage upon embryos primarily because of their availability in the habitat and high nutritional reward. Our data also suggest that *Cydia* are used by palila because they are readily accessible, nontoxic, and nutritious; the larvae apparently do not sequester alkaloids while feeding upon mamane seeds. Our results are interpreted with respect to the likelihood of current and historical coadaptive responses in this ecologically isolated and simplified island setting.

Key Words—Coadaptation, *Cydia*, Hawaii, *Loxioides bailleui*, mamane, nutrition, palila, quinolizidine alkaloids, seed predation, secondary metabolites, *Sophora chrysophylla*, toxins.

INTRODUCTION

During much of the year, the US federally listed endangered bird palila (*Loxioides bailleui*; Drepanidinae) feeds primarily on developing seeds of mamane [*Sophora chrysophylla* (Salisb.) Seem; Fabaceae]; both species are endemic to the Hawaiian Islands and occur together in the subalpine dry forest of Mauna Kea Volcano on the island of Hawaii, USA. Palila adjust their breeding according to annual variation in the timing and abundance of mamane seeds (van Riper, 1980a; Pratt et al., 1997; Hess et al., 2001; Banko et al., 2002a). Palila feed on mamane by tearing open the pods, extracting immature seeds from their seed coats, and consuming some or all of the embryos. Mamane embryos also are fed to developing young by day 3, but as early as day 2 (van Riper, 1980a), and this diet is supplemented by insect larvae, mamane flower parts, and a few other items (Banko et al., 2002a). The only other species that we have observed eating mamane seeds are larvae of specialist moths, *Cydia* spp. (Lepidoptera: Tortricidae), upon which both adult and nestling palila commonly feed as a supplement to mamane (Banko et al., 2002a). Because whole seeds of mamane and other species of *Sophora* have been reported to contain levels of quinolizidine alkaloids (QAs) that are potentially lethal to vertebrates (Kadooka et al., 1976; Murakoshi et al., 1984), and because insects feeding upon alkaloid-containing plants often sequester toxic levels of plant metabolites, the ability of palila to specialize upon these resources is especially intriguing.

This study addressed some questions related to the specialized feeding behavior, primarily from the bird's perspective, but also from the plant's and insect's perspectives. We had three goals. The first was to describe the chemical makeup of mamane seed coats and embryos as a means of understanding the nutritional and secondary chemical factors that induce palila to consume embryos but discard seed coats. In particular, we wanted to know if embryos at the stage consumed by palila are relatively less toxic or more nutritious than the seed coats. The second goal was to compare the nutritional composition of mamane embryos with the

nutritional requirements of wild birds as a means of understanding why palila might exhibit such dietary restriction. That is, considering nutritional parameters alone, are mamane seeds particularly well balanced in composition, especially with regard to rearing young on such a restricted diet? Our third goal was to determine the chemical composition of *Cydia* larvae as a means of explaining why palila might also exploit this resource. Are *Cydia* larvae simply an accessible, nontoxic source of nutrition for palila, or do the insects sequester mamane toxins within their bodies at levels potentially toxic to birds? If the latter, why are palila able to feed upon these larvae?

If significant levels of QAs or other secondary metabolites are present in mamane embryos, we predicted that embryos must represent a profitable and nutritionally balanced reward. This would be particularly true if there are costs associated with the bird's ability to tolerate high levels of secondary chemicals in the embryo. Second, based upon the lack of aposematic coloration, we predicted that *Cydia* larvae would not sequester alkaloids and, thus, would likely represent to palila a relatively nontoxic and readily exploitable nutritional resource. Cryptic coloration such as that exhibited by *Cydia* is rarely found in insects that sequester toxins from their food plants (cf., Montllor et al., 1990).

We focused on QAs because of their widely reported effects upon organisms ranging from bacteria to insects to vertebrates. QA biosynthesis from lysine via cadaverine to sparteine/lupanine takes place in the aerial green parts of legumes (Wink et al., 1982; Wink, 1987b) followed by translocation via the phloem to other plant parts (Wink and Witte, 1991), where they accumulate predominantly in the vacuoles of epidermal and subepidermal cells (Wink et al., 1984). Especially rich in alkaloids are the seeds, which can contain up to 8% dry mass (Wink, 1993).

It has been shown experimentally that pure QA or QA mixtures are broadly biologically active (for review of the older literature see Kinghorn and Balandrin, 1984) in that they inhibit the multiplication of potato-X virus (Wink, 1987a) and the growth of gram-negative and gram-positive bacteria (Wink, 1984a; Tyski et al., 1988) and certain fungi (Wippich and Wink, 1985). QAs deter feeding of a number of herbivores (nematodes, insects, molluscs, mammals) or are directly toxic or mutagenic to them (Cantot and Papineau, 1983; Bentley et al., 1984; Wink, 1984b; Dreyer et al., 1985; Johnson and Bentley, 1988; Matsuda et al., 1989; Knauer et al., 1995; Zhao et al., 1998; for review see Wink, 1992, 1999). Toxic effects are probably due to inhibition of Na^+ and K^+ ion channels to interactions with the nicotinic and muscarinic acetylcholine receptors, and to inhibition of protein synthesis (Wink and Twardowski, 1992; Wink et al., 1998; Wink, 2000). By targeting several phylogenetically conserved receptor sites, QAs provide a defense against a broad spectrum of herbivores and microorganisms (Wink, 1998a,b).

METHODS AND MATERIALS

Study Site

We collected mamane seeds and *Cydia* larvae in subalpine forest on the western slope of Mauna Kea, Hawaii (Figure 1), where over 90% of the palila population has become concentrated since before 1975 (van Riper et al., 1978; Jacobi et al., 1996; Gray et al., 1999). The forest on the western slope extends

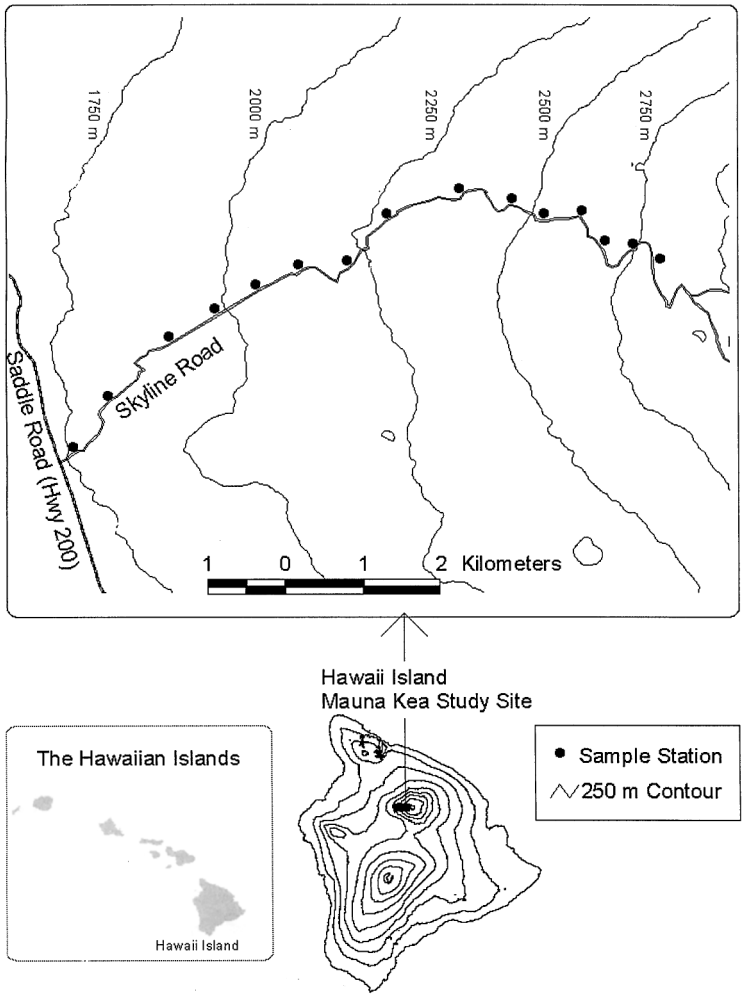

FIG. 1. Map of the study area on the western slope of Mauna Kea, Hawaii.

from about 1750 to 2900 m elevation and is cool and dry, receiving an average of 511 mm of rain annually (Juvik et al., 1993). The study area is dominated by only two tree species: mamane, which occurs in single-species stands over a portion of the western slope, and naio (*Myoporum sandwicense*), which generally dominates mamane in mixed stands (Scott et al., 1986; Hess et al., 1999). Tree heights rarely exceed 8 m. Where mamane and naio occur together, canopy cover may exceed 60%, but overall the forest resembles an open-canopy woodland, due largely to the long history of browsing by introduced feral sheep (*Ovis aries*) and mouflon sheep (*O. musimon*). These and other ungulates, such as cattle (*Bos taurus*) and goats (*Capra hircus*), severely browse mamane trees and seedlings. In recent years, however, populations of browsing ungulates have been reduced, and the understory is filling in with young mamane and naio as well as several other endemic shrubs and small trees (Hess et al., 1999). Endemic and alien grasses and other herbaceous species occur throughout the area, but ground cover tends to be most dense at intermediate and lower elevations of the forest. Wildfire has not occurred within our study area for decades and possibly not for a century or longer, but fire is a natural, if infrequent, feature of this ecosystem.

Seed Collection and Preservation

We collected mamane seeds during August 4–18, 1999, along an elevation gradient extending from 1750 to 2820 m. Palila occur throughout the area where we collected, and August represents a time when, in most years, all age classes of birds, including nestlings and fledglings, are consuming mamane seeds. However, by August the mamane seed crop has largely matured (pods have turned brown) and immature seeds (in green pods) are becoming increasingly scarce (van Riper, 1980b; Banko et al., 2002b). We arbitrarily picked 6–34 full-sized, green pods from 75 trees ($>$2 m tall $\times$ $>$2 m wide) at 15 stations (5 trees/station) separated by 76 m of elevation. Pods ($N = 1236$) contained 1–10 expanded seeds each, but some seeds were partially or entirely eaten by *Cydia* larvae or were destroyed by microorganisms or other agents. We extracted seeds that were expanded ($\geq$3 mm across the broad surface of the pod), removed their seed coats, and flash-froze (liquid nitrogen) the embryos and seed coats in separate vials within an hour of collection. Samples were stored at -70°C until shipped in liquid nitrogen to Berry College, Georgia, USA, for freeze-drying and analysis.

Cydia Collection and Preservation

We collected 200 *Cydia* larvae from mamane pods between 2000 and 2500 m elevation during September 21–November 2, 1995. Specimens were flash-frozen in liquid nitrogen within 5 min of being extracted and were stored at -70°C until shipped in liquid nitrogen to Berry College for freeze-drying and analysis. In

order to determine if alkaloids within whole *Cydia* are mainly associated with gut contents, we collected a second group of 209 larvae during May 13–July 19, 2000 using similar methods, but fasted them for 24 hr prior to flash-freezing.

Sample Preparation and Storage

Immediately upon receipt from Hawaii, embryos, seed coats, and *Cydia* larvae were freeze-dried, ground to pass a #40 mesh screen, and stored in a desiccating chamber at -20°C.

Nutritional Analyses

We analyzed freeze-dried embryo, seed coat, and *Cydia* samples for: (1) total reducing sugars by ethanol extraction followed by the anthrone assay (Smith, 1981), (2) total nonstructural carbohydrate by α-amylase extraction followed by the anthrone assay (Spiro, 1966; Smith, 1981), (3) total lipids by petroleum ether extraction (Williams, 1984), (4) amino acids by hydrolysis followed by ion-exchange chromatography (Moore and Stein, 1951) using a LC5000 Biotronic amino acid analyzer, (5) mineral nutrients by acid hydrolysis followed by inductively-coupled plasma emission spectroscopy, and (6) total nitrogen by acid hydrolysis and direct N detection (Williams, 1984). Total protein was estimated three ways: (1) by using the Bradford assay (Jones et al., 1989), (2) by summing total amino acids, and (3) by multiplying total nonalkaloidal nitrogen by 6.25 (Williams, 1984).

Secondary Chemical Analyses

QA Extraction and Sample Clean-Up. Freeze-dried embryo, seed coat, and *Cydia* samples were extracted by weighing subsamples (500 mg) into 40 ml centrifuge tubes, to which 15 ml 0.1 N HCl was added, followed by a 5-hr room-temperature incubation. The sediment was suspended using an ultrasound bath, followed by centrifugation at 4800 rpm for 10 min. The supernatant was collected, and the pellet was reextracted with another 15 ml 0.1 N HCl. Following a second centrifugation, the supernatant was collected, combined with the first extract, and made alkaline with 6 N NaOH (to pH 13). Total volume of the alkaline extracts was determined by weighing, and aliquots (18 ml) were placed on an Extrelut NT 20 (Merck) column for solid–liquid extraction. The aqueous phase was allowed to adsorb onto the column, then three sequential 20-ml aliquots of Cl_2CH_2 were added and allowed to elute. The combined Cl_2CH_2 eluates were collected and reduced to dryness in a rotary vacuum evaporator. The residue was collected in about 5 ml Cl_2CH_2 and transferred quantitatively into a test tube (10 ml). After the Cl_2CH_2 was removed at room temperature under nitrogen, the alkaloidal residue was taken up with 0.5–7.5 ml of methanol and was stored at -20°C.

QA Qualitative GLC-MS Analysis. A bulk seed embryo extract (containing all alkaloids) was analyzed qualitatively by using a Carlo-Erba 4160 GC coupled to a Finnigan MAT 4500 quadrupole mass spectrometer, and with a Supelco OV-1 microcapillary column (30 m long $\times$ 0.25 mm ID; 0.25-μm-thick coating). The following conditions of analysis were employed: injection volume: 1 μl; split ratio: 1:20; carrier gas: He; flow rate: 1 ml/min; injector temperature: 250°C; temperature program: 120°C, 3 min isothermal, 120–312°C at 10°C/min, 10 min isothermal. The electron impact mass spectra were recorded at 45 eV ionization energy by an INCOS data system. Major GLC peaks were identified by comparison of their MS spectra with published data and with an authenticated library of MS spectra.

QA Quantitative GLC Analysis. Bulk embryo, seed coat, and *Cydia* extracts were analyzed quantitatively for major alkaloids by using an HP5890A gas chromatograph, equipped with a flame ionization detector and an OV-1 column identical to that used for qualitative GLC assays. Conditions of analysis were: injection volume: 4–10 μl; split ratio: 6.5:1; injector temperature: 300°C; carrier gas: He at 10 psi; temperature program: 120°C, 3 min isothermal, 120–312°C at 10°C/min. Cytisine (Sigma) was used as an external standard (0–3.5 mg/ml, slope = 0.2495, $R^2 = 0.990$). Major alkaloid peaks in routine GLC assays were identified by reference to the qualitative GLC-MS chromatographic data.

Total Phenolics. Embryo, seed coat, and *Cydia* samples were analyzed for total phenolics by using ethanol extraction followed by the Prussian blue colorimetric assay (Budini et al., 1980; Graham, 1992).

Statistical Treatment

All quantitative analyses were run in triplicate, and the results are reported as percent of dry mass plus or minus one standard deviation, except for trace minerals, which are reported in parts per million. Because variances associated with these determinations were an estimate of measurement error (individual samples were bulked prior to analysis to achieve sufficient sample size), statistical comparisons among the three tissue types were not appropriate (Sokal and Rolhf, 1981). The data were intended to be interpreted in an exploratory fashion, rather than being used to test any a priori hypotheses.

RESULTS

Identification of Major QAs

Based upon qualitative GLC-MS data, we confirmed the identity of about 15 compounds in the alkaloidal extract of mamane embryos (Table 1; Figure 2), primarily QAs and the bipiperidyl alkaloid ammodendrine. Major constituents

[c] Phthalate is a contaminant from the laboratory solvent and is not an alkaloid.

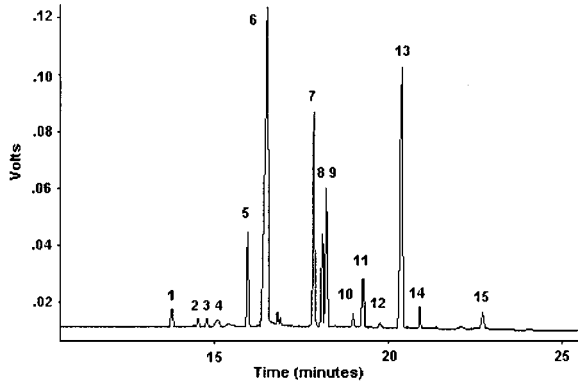

FIG. 2. Sample GLC chromatogram showing the separation of the 15 most important compounds in a sample of mamane seed embryos. Numbered peaks correspond to compounds identified via GLC-MS and listed in Table 1 [note that phthalate (peak 14) is a contaminant from the laboratory solvent and is not an alkaloid]. For conditions of analysis, see the text.

TABLE 2. CARBOHYDRATE, LIPID, AND PROTEIN CONTENT OF MAMANE EMBRYOS, SEED COATS, AND *Cydia* LARVAE

Nutrient	Percent of dry mass ± 1 SD		
	Embryos	Seed coats	*Cydia*
Total reducing sugars	4.92 ± 0.52	6.32 ± 0.43	0.77 ± 0.57
Total other nonstructural carbohydrates	12.42 ± 0.33	15.87 ± 0.71	4.10 ± 5.00
Total lipids	29.69 ± 0.05	0.18 ± 0.10	62.24 ± 2.85
Total protein via Bradford assay	32.81 ± 2.31	11.69 ± 1.24	41.01 ± 2.46
Total protein via total amino acids	27.12 ± 0.59	9.97 ± 0.32	
Total protein via total N	26.29 ± 0.07	9.92 ± 0.21	

included cytisine, 5,6 dehydrolupanine, lupanine, and anagyrine, which together comprised about 88% of the total alkaloids. These data confirm the presence of significant levels of QA alkaloids in mamane embryo tissues fed upon by palila.

Comparison of Mamane Embryos and Seed Coats

Nutrients. In comparison with seed coats, embryos contained slightly less nonstructural carbohydrate and trace minerals, but much higher levels of total lipids, total protein (by all three measures), and most major minerals (Tables 2 and 3). Reflecting their higher level of total protein, mamane embryos were much

Histidine	0.70 ± 0.00	0.27 ± 0.01
Lysine	1.74 ± 0.04	0.72 ± 0.02
Argininine	2.69 ± 0.09	0.61 ± 0.03

higher than seed coats in all amino acids measured (Table 4). Amino acid profiles for embryos were relatively balanced, ranging from glutamate at 5.5% to methionine at 0.28% dry mass. We detected no nonprotein (toxic) amino acids in our analysis. Embryos were much lower than seed coats in nondigestible fiber (9.47% vs. 57.55%, respectively, based upon subtraction of all measured nutrient and secondary chemical constituents from 100%).

Secondary Metabolites. In comparison with seed coats, mamane embryos contained much higher levels of all major alkaloids as well as several other individual metabolites (Table 5); embryos also contained about four times greater levels of total alkaloids (about 4% of dry mass). The results suggest the opposite for total phenolics; embryos were nearly eight times lower in total phenolics than seed coats, which contained about 4% of dry mass (Table 5).

Comparison of Mamane Embryos and Cydia Larvae

Nutrients. In comparison with mamane embryos, whole *Cydia* larvae contained slightly lower amounts of total sugars, but higher amounts of total lipid and total protein (Table 2). There was essentially no digestible fiber in *Cydia*, in that our estimates of major nutrients exceeded 100% when summed. Due to insufficient sample material, we did not assay *Cydia* for minerals.

TABLE 5. ALKALOID AND TOTAL PHENOLIC CONTENT OF MAMANE EMBRYOS AND SEED COATS AND *Cydia* LARVAE FROZEN IMMEDIATELY FOLLOWING COLLECTION

Alkaloid	Percent of dry mass ± 1 SD		
	Embryos	Seed coats	*Cydia*
Sparteine	0.07 ± 0.01	0.00 ± 0.00	0.001 ± 0.000
Ammodendrine	0.02 ± 0.01	0.01 ± 0.00	0.000 ± 0.000
N-Methylcytisine	0.05 ± 0.01	0.05 ± 0.01	0.002 ± 0.000
Cytisine	1.56 ± 0.1	0.2 ± 0.03	0.002 ± 0.000
5,6-Dehydrolupanine	0.56 ± 0.07	0.11 ± 0.02	0.001 ± 0.000

Matrine	0.18 ± 0.04	0.07 ± 0.01	0.001 ± 0.000
Anagyrine	1.01 ± 0.16	0.4 ± 0.01	0.001 ± 0.000
Baptifoline	0.06 ± 0.01	0.01 ± 0.00	0.000 ± 0.000
Total alkaloids	4.29 ± 0.05	1.08 ± 0.01	0.087 ± 0.010
Total phenolics	0.57 ± 0.13	4.31 ± 0.10	2.84 ± 0.33

Secondary Metabolites. In comparison with mamane embryos, the sample of freshly collected *Cydia* larvae contained much higher amounts of total phenolics (about 5 times higher; Table 5). These levels (about 3%) were similar to the levels found in mamane seed coats. These larvae contained much lower levels of alkaloids, however. Total alkaloid content was 0.087% of dry mass, which was about 50 times lower than mamane embryos. Sparteine, *N*-methylcytisine, cytisine, 5,6-dehydrolupanine, rhombifoline, lupanine, matrine, and anagyrine were found at levels of 0.001–0.002% of dry mass (Table 5), along with numerous apparent breakdown products at similarly low levels (data not shown). Residual alkaloids and breakdown products were largely eliminated with fecal matter, as total alkaloid levels were reduced to a level (0.019%) about 8 times lower during the 24-hr fasting period. The only identifiable alkaloid in the sample of starved *Cydia* was sparteine at 0.002% of dry mass. Altogether, alkaloid levels in fasted larvae were about 200 times lower than levels in seed embryos, suggesting that these insects do not sequester alkaloids in their tissues while feeding upon mamane.

DISCUSSION

General Observations. Why do palila feed commonly on mamane embryos while consistently excluding seed coats? Embryos at the stage consumed by palila contained high levels of several different alkaloids, including the highly toxic QA cytisine, which exceeded 1.5% of seed dry mass. They contained about 4% total alkaloids, whereas seed coats had lower levels of the same major alkaloids (about 1% total alkaloids). The major compound (cytisine) and the overall concentration

TABLE 6. TOTAL DAILY ALKALOID INTAKE BY PALILA FORAGING ON MAMANE SEEDS COMPARED WITH LITERATURE REPORTS FOR TOXICITY IN ANIMALS

Parameter			Value
Palila body mass (kg)[a]			0.0377

of alkaloids in mamane embryos are comparable to *Sophora secundiflora* Lag. ex DC (mescalbean), a species with well-known broad toxicity (Keller, 1975; Keller et al., 1976). While the toxicity of *S. secundiflora* has been attributed to synergism among alkaloids and toxic amino acids (Izaddoost et al., 1976; Hatfield et al., 1977), we found no toxic amino acids in mamane. Because embryos contained levels of alkaloids known to cause severe neurological symptoms and death in humans and other animals, it is likely that palila have evolved a tolerance to the alkaloids. Based upon an estimated daily consumption rate of 300 seeds per adult palila (US Geological Survey, unpublished data), we calculated a total daily alkaloid intake of about 12,000 mg/kg body mass (Table 6). This value far exceeds oral LD_{50} estimates for small granivorous animals such as mice. The tolerance of palila to such high levels of alkaloid may be the product of intestinal uptake followed by detoxification in the liver (with consequent effects on relative liver size), nonabsorption from the gut (unlikely because QAs are lipophilic under alkaline conditions of the gut and should diffuse into the body), or active export via P-glycoprotein-type ABC transporters.

Relative to embryos, seed coats had higher levels of phenolics, but lower levels of most major nutrients and higher levels of fiber. Thus, it is likely that seed coats are rejected because of lower overall nutritional value, coupled perhaps with a negative influence of phenolic-based secondary metabolites. Phenolic compounds, such as tannins and phenolic glycosides that may be found in the seed coats of legumes, can have both direct deterrent effects through toxicity or astringency and indirect effects upon digestion via their ability to bind to complex molecules such as proteins (cf., Levey and Cipollini, 1999). To avoid seed coats, palila must

spend time and effort extracting the embryos. After the pod has been torn open, the exposed portion of the seed coat is removed before the embryo is extracted; the remainder of the seed coat is left in the pod, which is discarded after the embryo has been consumed. However, palila in the hand are capable of removing the seed coat in an entirely different manner. When presented with an intact seed that has been removed from the pod, a hand-held palila takes the seed in its bill, orients the long axis of the seed with the long axis of its bill, and bites through the seed coat (P. Banko, personal observation). The bird then rotates the seed inside its bill with its tongue, causing the seed coat to neatly peel away in one piece and fall from the side of the bird's bill. The exclusion of the seed coat appears to be purposeful and not an accident of sloppy eating.

Are mamane embryos a particularly well-balanced food for palila? Based upon our understanding of avian nutrition (cf., Robbins, 1993), mamane embryos seem well balanced nutritionally and contain relatively low levels of fiber and high levels of carbohydrate, lipid, and protein (a ratio of about 1:2:2), as well as relatively balanced profiles of essential amino acids and minerals. For example, based on our estimate of daily seed consumption, the amount of nitrogen and protein consumed is, respectively, about 14 and 9 times that required for maintenance in granivorous birds (Table 7). While variation in digestive efficiency is not considered in these estimates, and we do not have an estimate of nitrogen and protein requirements for palila, it is unlikely that palila have difficulty obtaining sufficient protein or other nutrients from mamane seeds. Although we did not assay minor

TABLE 7. DAILY PROTEIN AND N INTAKE BY PALILA FORAGING ON MAMANE SEEDS, WITH RESPECT TO PROTEIN AND N REQUIREMENTS FOR MAINTENANCE IN GRANIVOROUS BIRDS

Parameter	Value
Dry mass per embryo (g)	0.0356
N in dry embryo (%)	4.77
Protein in dry embryo (%)	32.81
Total N per embryo (g)	0.0017
Total protein per embryo (g)	0.0117
Total N in 300 embryos (g)	0.5098
Total protein in 300 embryos (g)	3.5041
Palila body mass (kg)[a]	0.0377
Required N intake per day per bird (g)[b]	0.0364
Required protein intake per day per bird (g)[b]	0.3961
Ratio of consumed/required N	13.9973
Ratio of consumed/required protein	8.8465

organic constituents, such as vitamins, mamane embryos are particularly well balanced nutritionally, thus largely explaining why palila rely so heavily on mamane embryos for their daily diet and for rearing their offspring. We hypothesize that palila evolved specialization on mamane as a result of food competition with other seed-eating honeycreepers (Drepanidinae) in relatively simple habitats that were dominated by only a few tree species.

Why do palila commonly supplement their diets with *Cydia* larvae? In addition to being found conveniently inside mamane pods, the data suggest that these insects are relatively nontoxic sources of lipid, protein, and other nutrients and, thus, represent occasional but relatively high-quality resources for the bird. Adults likely seek out *Cydia* to feed to their chicks, as the incidence of *Cydia* mandibles is high in nestling and fledgling fecal samples (US Geological Survey, unpublished data). Relatively nontoxic nutritious foods would be important to the survival and development of birds that were susceptible to alkaloid toxicity. The frequency of *Cydia* mandibles is also higher in fecal samples collected from adults than from juvenile birds that are independent of parental care, suggesting that experience may be helpful in finding pods containing larvae. For example, birds may learn to identify pods that contain *Cydia* by the presence of silk caps that are spun by the larvae over their emergence holes, and they may learn that some trees support larger infestations of larvae than do others. Although *Cydia* larvae have a much higher level of phenolics than do seed embryos, total phenolics in the insects were close to the level found in seed coats. Thus, our conclusion that phenolics might induce palila to reject seed coats must be tempered by an understanding of the relative nutritional rewards. Assuming that the phenolics within *Cydia* bodies are of mamane origin and have similar antinutritional effects when consumed by palila regardless of the food source, seed coats should be nonetheless less nutritious than are *Cydia* larvae.

The data suggest that *Cydia* larvae break down the alkaloids in the course of digestion, as evidence of alkaloids and breakdown products is found primarily in insects containing material within the gut. We found no evidence that *Cydia* larvae sequester significant quantities of these alkaloids in their bodies, thus supporting our prediction that crypsis should be associated with a lack of toxin sequestration. Furthermore, crypsis may reduce predation by palila since pods often contain larvae that have consumed one or more embryos and are, thus, relatively exposed to foraging birds. *Uresephita polygonalis virescens* (Lepidoptera: Crambidae), an indigenous or possibly endemic moth whose aposematically colored larvae feed upon mamane foliage, is more likely to sequester alkaloids, based upon studies of a congener, *U. reversalis*, which feeds upon a QA-containing legume (Montllor et al., 1990). Historically, *U. polygonalis* larvae were major prey of adult palila apparently on Mauna Loa (Perkins, 1903, 1913), where the birds are now extinct (Scott et al., 1986). *U. polygonalis* is presently rare on Mauna Kea and is probably seldom eaten by palila, even though the birds forage generally for insects and

spiders on mamane foliage and branches in addition to extracting *Cydia* from pods (US Geological Survey, unpublished data).

Questions Resulting from This Analysis. Are nonspecialist birds and other generalist seed predators more susceptible to mamane seed alkaloids than are palila and *Cydia*? In other words, is there any evidence for evolved tolerance in these specialist species? Because the palila is a US federally listed endangered species, which limits work with captive birds, it be may difficult to compare its tolerance to QA alkaloids with that of related bird species in side-by-side feeding trials. Nevertheless, controlled feeding trials with other species might indirectly address part of the question. We have been unable to find published reports on oral toxic effects of QAs on wild birds; however, four 10- to 14-day-old, hand-reared house finches (*Carpodacus mexicanus*) convulsed and died within about 10 min of ingesting mashed mamane seeds (C. Kuehler, Keauhou Bird Conservation Center, personal communication). Assuming that a suitable laboratory diet can be developed, feeding trials with *Cydia* and related moth species are a promising possibility.

Palila and *Cydia* forage heavily upon certain trees and lightly upon others (US Geological Survey, unpublished data); therefore, work is needed to determine what factors influence selection among individual mamane plants. Are seeds of preferred individuals particularly high in certain required nutrients (lipids, carbohydrates, protein, essential amino acids, etc.), or are they particularly low in certain toxic secondary metabolites? Do *Cydia* compete with palila for mamane seeds, and what are the consequences of this interaction? Answers to these questions may help explain the evolutionary impact on mamane of seed predation by palila and *Cydia*. It is possible that individual mamane trees vary in their seed alkaloid profiles due to both genetic and environmental effects. For example, samples of seeds collected from two different individual plants in Hawaii have been reported to contain virtually no cytisine, instead being dominated by anagyrine, *N*-methylcytisine, and baptifoline (Pena and Cassels, 1996), whereas our bulk sample derived from many individuals was dominated by cytisine. Considering possible inter-individual variation, future research might focus on relating levels of alkaloids and other chemical constituents of seeds with foraging preferences of palila and rates of *Cydia* seed predation within individual mamane trees. If secondary chemistry substantially influences palila foraging and moth oviposition patterns, we would expect strong selection pressure for seed embryo toxicity in mamane. Such a result may indicate that palila are able to reduce their exposure to toxins by adjusting their foraging behavior. In any case, our general conclusion is that continued study of the palila–mamane–*Cydia* triad holds promise for heightening our understanding of plant–animal coadaptation and for understanding the management implications of such interactions. These interacting species can be studied in a relatively simple and isolated environment, where one can better account for factors that might confound or obscure patterns in more diverse environments.

Acknowledgments—We acknowledge the Palila Restoration Project staff and interns for field assistance to P.C.B., A. Tei and A. Backhaus for laboratory assistance to Michael Wink, Ann Wolf for conducting mineral analyses, Zvi Harduf for conducting amino acid analyses, Dennis LaPointe and Donald Gardner for reviewing the manuscript, and Kathy Patrick and Ian and Megan Cipollini for continued support and encouragement to M.L.C. Access to the study area was permitted by Hawaii Division of Forestry and Wildlife. Field work and a portion of the laboratory work was supported by US Army Garrison, Hawaii.

A LECTIN-LIKE WHEAT GENE RESPONDS SYSTEMICALLY TO ATTEMPTED FEEDING BY AVIRULENT FIRST-INSTAR HESSIAN FLY LARVAE[1]

(Received August 20, 2001; accepted March 12, 2002)

Abstract—Through gene-for-gene interactions, wheat plants respond to specific biotypes of Hessian fly upon the initiation of first-instar larval feeding. Leaves of plants containing the *H9* resistance gene responded to avirulent biotype L larvae with rapid changes in the levels of several mRNA transcripts and initiation of an incompatible interaction. A low-copy gene, *Hfr-1* (Hessian fly-response gene 1), responded with increased mRNA levels for two days before returning to preinfestation levels by day five. *Hfr-1* mRNA was constitutively expressed in uninfested control plants as well as in plants infested with virulent larvae. The cDNA sequence was similar to a maize gene encoding a β-glucosidase aggregating factor (BGAF), to jacalin-like mannose-binding lectins, and to several plant genes that respond to microbial infections. The potential roles of *Hfr-1* in defending wheat against Hessian fly damage are discussed.

Key Words—Wheat, *Triticum aestivum* L., Hessian fly, β-glucosidase aggregating factor, BGAF, jacalin-like lectin, defense response, resistance, PR gene, incompatible interaction, Genbank number AF483596.

INTRODUCTION

Genetic interactions between the Hessian fly [*Mayetiola destructor* (Say)] and wheat (*Triticum aestivum* L. em Thell.) operate on a gene-for-gene basis (Hatchett and Gallun, 1970; Gallun, 1978), much like the well-documented, race-specific

interactions between microbial pathogens and plants (Bent, 1996). Over 29 resistance genes that protect wheat against 16 biotypes of the Hessian fly have been characterized in wheat and related species (Delibes et al., 1997; Ratcliffe and Hatchett, 1997). The wheat–Hessian fly interaction is very specific; although a wheat genotype may harbor one or more of these resistance genes, the plant becomes resistant only when its resistance gene is able to mediate recognition of the specific biotype of Hessian fly larvae that has infested. Thus, a wheat genotype can be resistant, participating in an incompatible interaction with a biotype of larvae that is avirulent on that wheat genotype. However, the same wheat genotype can become susceptible by participating in an incompatible interaction with a different larval biotype that is virulent on that wheat genotype. The resistant/susceptible phenotype of the plant and the avirulent/virulent phenotype of the insect are interdependent. Plants undergoing incompatible interactions with Hessian fly larvae show little sign of stress or yield loss. However, compatible interactions result in drastic changes in the physiology and development of the wheat plant.

Compatible wheat/Hessian fly interactions (larvae virulent and wheat susceptible) are characterized by the ability of first-instar larvae to feed, grow, and mature between the leaf sheaths near the crown of seedlings, or just above the nodes of older jointed wheat plants. Systemic symptoms in susceptible seedlings include a generalized increase in leaf sheath cell permeability within five days of larval feeding initiation (Shukle et al., 1992), followed by stunting of the plant and chloroplast accumulation, which become evident about five days later (Cartwright et al., 1959; Robinson et al., 1960). A single virulent larva is sufficient to produce these plant symptoms, which become irreversible after four days of larval feeding (Byers and Gallun, 1972). These symptoms are thought to result from injected larval secretions that fail to trigger resistance responses, rather than from consumption of plant material. After five days of larval feeding, the first molt occurs and the second instars are no longer mobile or able to inject secretions into the plant. By this time, changes in the physiology of the plant have provided an environment where nutrients are delivered to the larvae and they are protected by the stunted leaf sheaths.

During incompatible interactions (larvae avirulent and wheat resistant), first-instar Hessian fly larvae fail to increase in length (C. Williams, unpublished data) and die within three to five days of hatching (Painter, 1930). Despite repeated attempts to feed [sites evident in electron micrographs (Grover, 1995)], avirulent larvae fail to establish a permanent feeding site, continue to migrate downward as the plant leaves elongate, and are unable to effect plant stunting and other physiological changes that make the wheat plant a hospitable host for the virulent larvae. In some incompatible interactions, a hypersensitive response develops in the plant (Shukle et al., 1992), but it is unclear whether recognition results in production of insecticidal compounds. However, the plant's ability to detect avirulent larvae does not result in systemic resistance to future infestation. Subsequent feeding by

virulent larvae (tested up to three days after first attempted feeding by the avirulent larvae) leads to obviation of resistance, allowing survival of both virulent and the avirulent larvae that first infested the plant (Grover et al., 1989; J. Stuart, personal communication). The ability of both virulent and avirulent larvae to survive during mixed infestations suggests that avirulent larvae do not induce systemic toxin production. Thus, resistance mechanisms may be highly localized at the attempted feeding sites of avirulent larvae and may not prevent nearby virulent larvae from initiating systemic changes in the plant that result in obviation of resistance.

The complex interactions between the wheat plant and first-instar Hessian fly larvae offer opportunities for molecular analysis of signaling pathways and gene regulation. Biochemical analyses reveal that during a compatible interaction, feeding by virulent larvae results in increased concentrations of carbohydrates in the leaf and crown (Refai et al., 1955; Wellso et al., 1989, 1990) and increased concentrations of Rubisco in the leaf sheath and crown (Shukle et al., 1992). These affected plant tissues are at or near the larval feeding sites. In contrast, little or no visible change is apparent in plants participating in an incompatible interaction after infestation by avirulent larvae, and the biochemical responses are not well defined. The only available molecular information about the resistant plant response documents an increase in 5- and 11-kDa proteins of unknown function that were detected one to two days after attempted feeding by avirulent first-instar larvae. Both proteins were no longer detected by day 5 (Shukle et al., 1992).

Feeding by chewing insects, such as *Manduca sexta* and *Spodoptera littoralis* larvae, results in expression of plant wound-response genes [proteinase inhibitors, polyphenol oxidases (Green and Ryan, 1982; Stout et al., 1996) and leucine aminopeptidase (Pautot et al., 1993)] in addition to a novel set of plant genes (Korth and Dixon, 1997). Although limited information is available about plant responses to insects with piercing mouth-parts, such as the Hessian fly larvae, a few studies have focused on responses to phloem-feeding insects. These insects inflict minimal physical damage to the plant and consequently do not induce wound responses. However, interactions between *Arabidopsis* and the green peach aphid result in dramatically increased expression of pathogenesis-related (PR) genes (Moran and Thompson, 2001) known to be associated with salicylic acid (SA) -dependent responses to microbial pathogens. Whiteflies feeding on tomatoes induce SA-independent, jasmonic acid (JA)/ethylene-dependent genes (Walling, 2000). In addition, silverleaf whiteflies feeding on squash plants induce genes that previously had not been linked to plant–insect interactions: a M20B metallopeptidase-like gene and a β-glucosidase-like gene (van de Ven et al., 2000).

Although the gene-for-gene interactions between wheat and the Hessian fly are genetically well defined at the level of plant phenotypes, lack of information about the defense response at the molecular level led us to search for genes that respond to Hessian fly infestation. We identified *Hfr-1*, a gene whose mRNA levels increased rapidly during an incompatible interaction within 22 hr of egg hatching

and returned to normal within five days. The expression profile of *Hfr-1* corresponded with the critical period in which the first-instar larvae are attempting to establish feeding sites by injecting substances into the plant. Structural similarities between *Hfr-1* and a maize gene encoding a β-glucosidase aggregating factor (BGAF), mannose-binding lectins, and a wheat gene that responds to a chemical elicitor of systemic acquired resistance (SAR), are suggestive of involvement in plant defense against insect attack.

METHODS AND MATERIALS

Insects, Plant Tissues and Infestations. Hessian fly biotype L flies (virulent to wheat resistance genes *H3*, *H5*, *H6*, and the *H7H8* combination, but avirulent to the *H9*-containing variety of wheat used in these experiments) and *vH9* flies (virulent to the *H9*-containing variety of wheat) were maintained in a 4°C cold room as purified laboratory stocks by the USDA-ARS Crop Production and Pest Control Research Unit, Purdue University. According to the methods outlined by Cartwright and LaHue (1944), the fly stocks are increased each year and selected for virulence on appropriate wheat genotypes: biotype L is selected on *H5* wheat, which is resistant to all biotypes maintained in the laboratory except for biotype L, and *vH9* is selected on *H9* wheat. Although wild populations of Hessian fly are composed of mixtures of biotypes, genetically purified insect stocks were used for these experiments so that clearly defined compatible and incompatible interactions could be studied. All wheat plants used in these experiments were of identical genotype, containing the *H9* gene for Hessian fly resistance [variety Iris (Patterson et al., 1994)]. Wheat seedlings were grown in flats of soil in a growth chamber at 20°C and 12-hr photoperiod until they reached the two-leaf stage (7–10 days after germination). During infestations, about 100 newly emerged adult female Hessian flies of biotype L (avirulent on wheat containing *H9*) or *vH9* flies (virulent on *H9* wheat) were allowed to mate and oviposit for 24 hr on flats containing 300 seedlings (Maas et al., 1989). Leaves of each plant were inspected after infestation to ensure the presence of eggs. Plants were grown in chambers at 20°C throughout tissue collection. No other insects or pathogens were apparent on the experimental plants.

RNA Isolation for Differential Display. One week after infestation, leaves were collected above the larval feeding sites, and total RNA was isolated with the kit CLONsep 2 (Clonetech Laboratories, Inc., Palo Alto, California, USA). Differential display experiments were conducted according to the directions in the RNAimage kit 2 (Genhunter Corporation, Nashville, Tennessee, USA). The two *H9* Iris wheat samples used in differential display were of identical age and genotype, but one was infested with *vH9* flies and the other was infested with biotype L flies. Thirty-six unique fragments were identified from reactions of eight primer pairs. Excised cDNA fragments were purified with the Wizard PCR Prep

DNA Purification System (Promega Corporation, Madison, Wisconsin, USA) and were cloned with the pGEM-T System I (Promega). All DNA sequencing utilized infrared fluorescent dye-labeled SP6 and T7 primers on a LiCor Long Reader 4200.

Isolation of a Near Full-Length cDNA. To generate the near full-length *Hfr-1* cDNA clone (UPW1Hfr1a), the partial cDNA sequence, from the 583-bp clone UPW1Hfr1b obtained by differential display of the 3′ end of the *Hfr-1* mRNA, was used as a template for the design of primers. These primers were amplified toward the 5′ end of the mRNA, following the directions of the Smart RACE (Rapid Amplification of cDNA Ends) cDNA amplification kit (Clontech). A total of 1283 bp of sequence was obtained for *Hfr-1* cDNA (Genbank number AF483596). From this sequence, the forward primer (5′-ACGCACACACACAATCCT-3′) and the reverse primer (5′-CAACACCCAGGAACGTACTA-3′) were designed to amplify a 1090-bp fragment from within the 1283-bp of sequence. This amplicon included all of the *Hfr-1* open reading frame. Amplified fragments were isolated from gels by using the Wizard PCR prep DNA purification System (Promega) and were ligated into the pGEM-T Vector (Promega). Plasmid DNA was isolated by using the Wizard SV Plus Miniprep Kit (Promega). The 1283 bp of sequence and the 1090-bp near full-length cDNA clone (UPW1Hfr1a) were used in BLAST inquiries. The 583-bp partial cDNA clone (UPW1Hfr1b) was used to generate a probe for radioactive blot experiments.

Blot Hybridization. For Northern analysis, leaves were collected over a period of eight days, starting three days after infestation (two days before egg hatch), and total RNA was isolated with the Totally RNA kit (Ambion, Inc., Austin, Texas, USA). RNA samples (10–15 μg) were separated on 1.2% formaldehyde–0.8% Agarose denaturing gels in 10$\times$ MOPS buffer (Maniatis et al., 1982). RNA was transferred to Hybond N^+ membranes (Amersham Pharmacia Biotech, Piscataway, New Jersey, USA), hybridized with ^{32}P-labeled *Hfr-1* and 28s rDNA probes. The *Hfr-1* probe was the 583-bp partial cDNA clone (UPW1Hfr1b) encompassing nucleotides 770 through 1283 of the *Hfr-1* sequence. A 650-bp fragment of the barley 28s ribosomal DNA gene was used to detect wheat rRNA in quantification experiments. This clone was kindly provided by J. Anderson (USDA-ARS, West Lafayette, Indiana, USA). The RNA blots were processed according to the Hybond directions. Blots were washed twice with 2$\times$ SSC, 0.1% SDS at 65°C for 30 min. Blots were exposed to Biomax MR film (Eastman Kodak Company, Rochester, New York, USA) with Biotech L-Plus intensifying screens (Fisher Scientific, Pittsburg, Pennsylvania, USA) for three to seven days.

For Southern analysis, genomic DNA was isolated (Osborn et al., 1987) from seedlings of Iris wheat. DNA samples (15 μg) were digested with various restriction enzymes and separated on 0.8% agarose gels in 1$\times$ TBE (Maniatis et al., 1982), blotted onto Hybond N^+ membranes (Amersham Pharmacia Biotech) and processed according to the manufacturer's instructions with a ^{32}P-labeled *Hfr-1* partial cDNA clone.

Sequence Analysis. Database searches were conducted at the NCBI BLAST site (http://www.ncbi.nlm.nih.gov/BLAST/) with the BLASTx option to compare DNA sequences and with the tBLASTx option for deduced translated protein sequences derived from the experimentally determined *Hfr-1* cDNA sequence. Amino acid sequence alignments were performed with Vector NTI Suite (Informax, Inc., Bethesda, Maryland, USA). The program SignalP V1.1 was used to inspect the deduced *Hfr-1* sequence for a potential signal peptide sequence (http://www.cbs.dtu.dk/services/SignalP/#submission). Protein domain analysis was conducted with ProDom (http://prodes.toulouse.inra.fr/prodom/doc/prodom.html).

RESULTS

Response to Infestation. The studies presented here investigated changes in *H9* Iris wheat gene expression during the first 136 hr of attempted feeding by first-instar Hessian fly larvae. All plants included in the study were of identical genotype: homozygous for *H9*, a gene that confers resistance to biotype L but not to the *vH9* strain of Hessian fly. Both compatible and incompatible interactions were studied in *H9* Iris wheat tissue, thus eliminating any variability imposed by use of multiple wheat genotypes.

Seedlings were grown to the two-leaf stage and then divided into three treatment groups. The first group of plants was not infested. Observations of the second group, which was infested with adult *vH9* Hessian flies, confirmed that symptoms of a classical compatible interaction, leading to larval growth and plant stunting, were present by 14 days after infestation. The third group, which was infested with adult biotype L Hessian flies, produced an incompatible interaction leading to larval death and normal plant growth that was indistinguishable from the uninfested controls. Eggs were oviposited on the top surface of the first and second leaf, and both genotypes of larvae hatched simultaneously over a period of a few hours during the morning of the fifth day after infestation. Plant dissections indicated that within a few hours of the first hatch, first-instar larvae had crawled to the base of the culm within the lower leaf sheaths just above the roots. Larvae attempted to feed on the leaf sheath of the second leaf (counting from the bottom toward the top of the plant) and on all tissues that were fully enclosed by sheaths of the first two leaves, including the leaf blade and sheath of immature leaves as well as meristematic tissues. Although Hessian fly larvae begin feeding within a few hours of hatching, they are not synchronous in their establishment of feeding sites at the crown of the plant. Moreover, larval feeding cannot be observed without destroying the plant since it occurs between the leaf sheaths. Thus, the first posthatch time point was taken 22 hr after the prehatch time point, with the exact time of first feeding being unknown. Leaf blades, rather than regions surrounding larval feeding sites, were collected at various times so that systemic gene expression could be monitored.

Expression of Hfr-1. To identify wheat genes responding to attempted-feeding by first-instar Hessian fly larvae, partial cDNA clones were isolated by differential display (Liang and Pardee, 1992). In a comparison of sequences that were differentially expressed between leaves of *H9* Iris wheat plants undergoing compatible versus incompatible interactions, eight primer–pair combinations yielded 36 differentially displayed bands. Several bands representing sequences shorter than 400 bp were not cloned, and 18 sequences returned no BLAST similarities.

A 583-bp cDNA fragment, corresponding to the 3′ end of a differentially expressed wheat gene, referred to here as *Hfr-1* (Hessian fly-response gene 1), was cloned and used as a probe in expression experiments. Northern blot analysis confirmed increased levels of *Hfr-1* mRNA in response to the initiation of feeding by avirulent first-instar larvae on *H9* Iris wheat plants (incompatible interaction; Figure 1). In contrast, the *Hfr-1* gene was expressed at a low constitutive level in leaves of *H9* Iris wheat plants that were either infested with *H9* virulent larvae or were uninfested (compatible interaction and "U"; Figure 1).

After the initiation of avirulent larval feeding, the level of *Hfr-1* mRNA increased in leaf blades for approximately 48 hr and then began to decrease. These avirulent first-instar Hessian fly larvae residing at the base of resistant plants did not increase in length, and they began to die within three days of initiation of feeding, corresponding well with the expression profile of *Hfr-1*. In contrast, only a slight

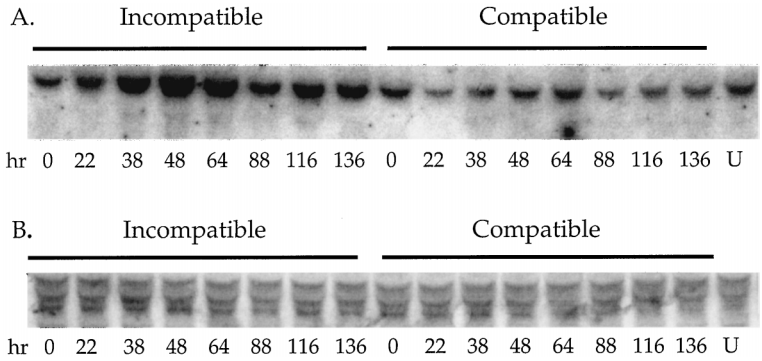

FIG. 1. Accumulation of *Hfr-1* mRNA in response to feeding by Hessian fly larvae. Northern blot analysis was performed on total RNA from leaves of the wheat variety *H9* Iris after infestation by avirulent biotype L (incompatible interaction) and *H9* virulent fly (compatible interaction). "U" indicates mRNA from uninfested control plants. Samples in lanes marked "0" were taken before eggs hatched, but no more than 22 hr before the initiation of larval feeding (time 0). Subsequent samples were taken at the indicated number of hours after the time 0 sample. (A) The blot was hybridized with a ^{32}P-labeled partial cDNA clone of *Hfr-1* (UPW1Hfr1b). (B) The blot was stripped of the *Hfr-1* probe and then rehybridized with a ^{32}P-labeled barley 28s rDNA clone to indicate relative levels of RNA in each lane.

elevation in the level of *Hfr-1* mRNA was observed, during the first 48 hr, in *H9* Iris wheat plants infested with virulent larvae (compatible interaction; Figure 1). Even 10 days after infestation, *Hfr-1* mRNA levels remained low and similar to uninfested controls during this compatible interaction (data not shown). Since the variety Iris is hexaploid (containing three distinct wheat genomes), the mRNA detected by Northern blot analysis may have been contributed by orthologous genes from any of the genomes rather than exclusively by the gene corresponding to the clone UPW1Hfr1b.

Genomic Copies of Hfr-1. Southern blot analysis revealed that *Hfr-1* is a low-copy sequence. DNA from the hexaploid wheat cultivar, Iris, was digested with enzymes that had no restriction site within the *Hfr-1* partial cDNA clone UPW1Hfr1b. The low number of resulting bands (Figure 2) was consistent with only one or a few copies of the *Hfr-1* gene in each of the three wheat genomes. Surprising results from nulli-tetrasomic analysis revealed that *Hfr-1* sequences

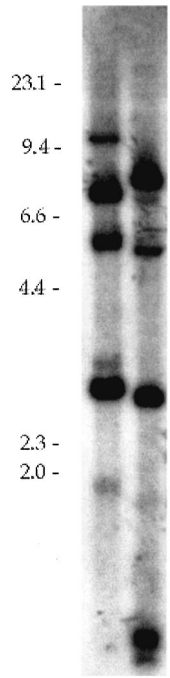

FIG. 2. Genomic copies of *Hfr-1* in hexaploid wheat. *H9* Iris genomic DNA (15 μg/lane) was digested with EcoR I or Dra I restriction enzymes. These enzymes did not cut within the sequence of the *Hfr-1* partial cDNA clone (UPW1Hfr1b). DNA was separated on a 0.8% agarose gel, blotted, and hybridized with the ^{32}P-labeled partial cDNA clone of *Hfr-1*.

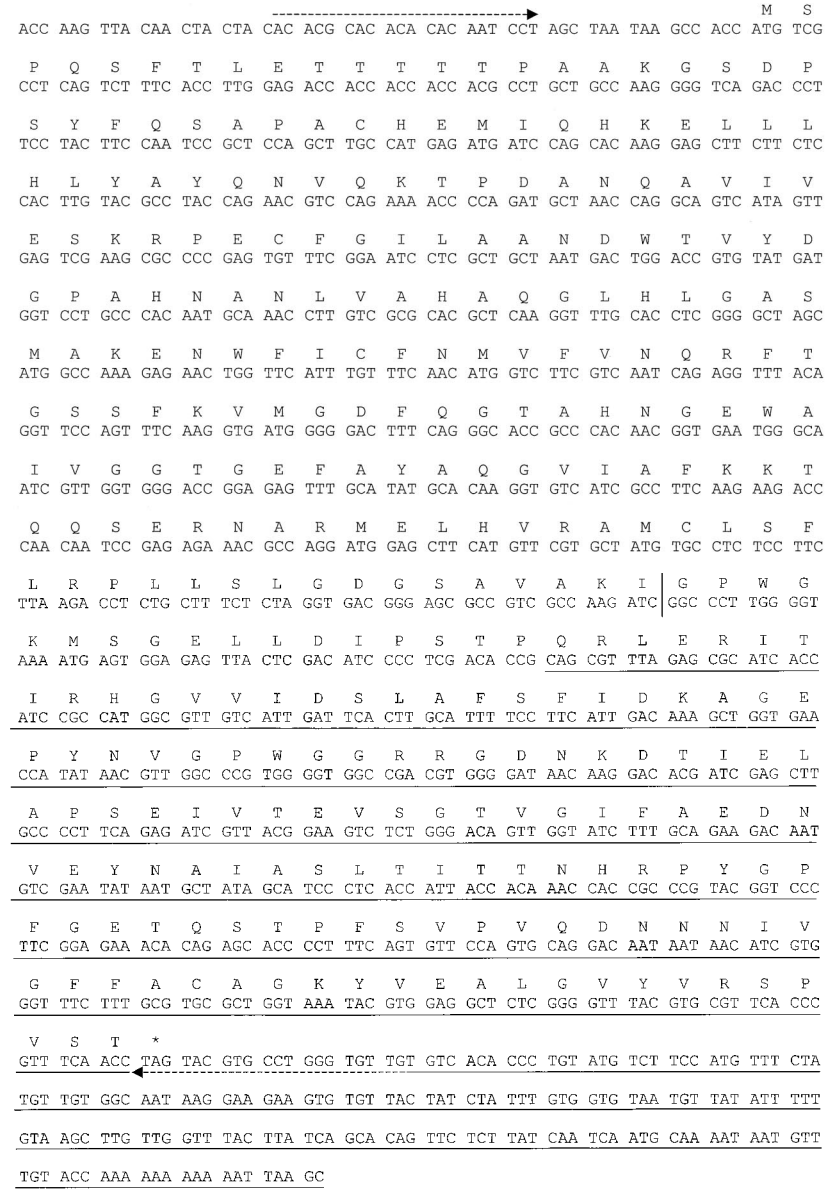
were present in only two of the three genomes of the hexaploid line Chinese Spring, with one copy on chromosome 4A and the other on chromosome 7D (Devos and Williams, unpublished results). The banding pattern for restriction digests of Chinese Spring wheat was identical to what was seen for Iris wheat, suggesting that only two loci containing *Hfr-1* sequences were present in the line that was used here for expression studies.

Characterization of Hfr-1 cDNA Sequence and Deduced Amino Acid Sequence. A near full-length cDNA sequence of *Hfr-1*, generated by 5′-RACE, was characterized by DNA sequence analysis. The sequence was 1283 bp long (Genbank number AF483596), including a 5′-untranslated region of 54 bp, a 3′-untranslated region of 194 bp, and a 1035-bp open reading frame encoding a 37.7-kDa protein of 345 amino acids (Figure 3). The predicted protein lacked signal peptide sequences and transmembrane domains.

Database searches and sequence comparisons revealed that the deduced amino acid sequences for the *Hfr-1* gene and the wheat chemically induced gene, *Wci-1* (Genbank number AAC49284.1), were 68% identical (Figure 4a). The chemical benzothiadiazole (BTH) is an analog of salicylic acid. In addition to causing increases in mRNA levels of *Wci-1* and other wheat genes, BTH is an inducer of systemic resistance to powdery mildew, leaf rust, and *Septoria* leaf spot in wheat (Gorlach et al., 1996). The Hfr-1 deduced amino acid sequence was 42% identical to the deduced amino acid sequence encoded by a barley mRNA that is induced by jasmonic acid (Genbank number AAA87042.1) (Lee et al., 1996), a signaling molecule involved in plant abiotic stress and pathogen attack (Farmer and Ryan, 1992; Sembdner and Parthier, 1993). A maize β-glucosidase aggregating factor (BGAF; Genbank number AAF71261.2), which may play a role in defense against insects (Blanchard et al., 2001), was 44% identical to the Hfr-1 deduced amino acid sequence. The similarity between the Hfr-1 deduced amino acid sequence and proteins from rice (Genbank number BAB19404.1), crocus (Genbank number AAG10403.1), hedge bindweed (Genbank number AAC49564), Jerusalem artichoke (Genbank number AAD11577.1), and others that have demonstrated mannose-binding jacalin-related lectin activity (Bourne et al., 1999), strongly suggests a functional role in defense against insects.

The Hfr-1 deduced amino acid sequence appeared to have two domains (Figure 4b). BLAST searches and ProDom analysis indicated that within the first 200 amino acids of the N-terminus lies a domain found in several disease resistance-response proteins of unknown function (ProDom family number 011170; Figure 4b). The sequence from amino acid 201 through 345, at the C-terminus, resembled lectins and myrosinase-binding proteins (ProDom family numbers 000864 and 336299). However, the N-terminal domain that is present in the wheat, maize, and barley proteins is not found in the proteins known to function as lectins (Blanchard et al., 2001). Thus, the Hfr-1 sequence contained a disease resistance-response domain fused to the N-terminus of an entire lectin



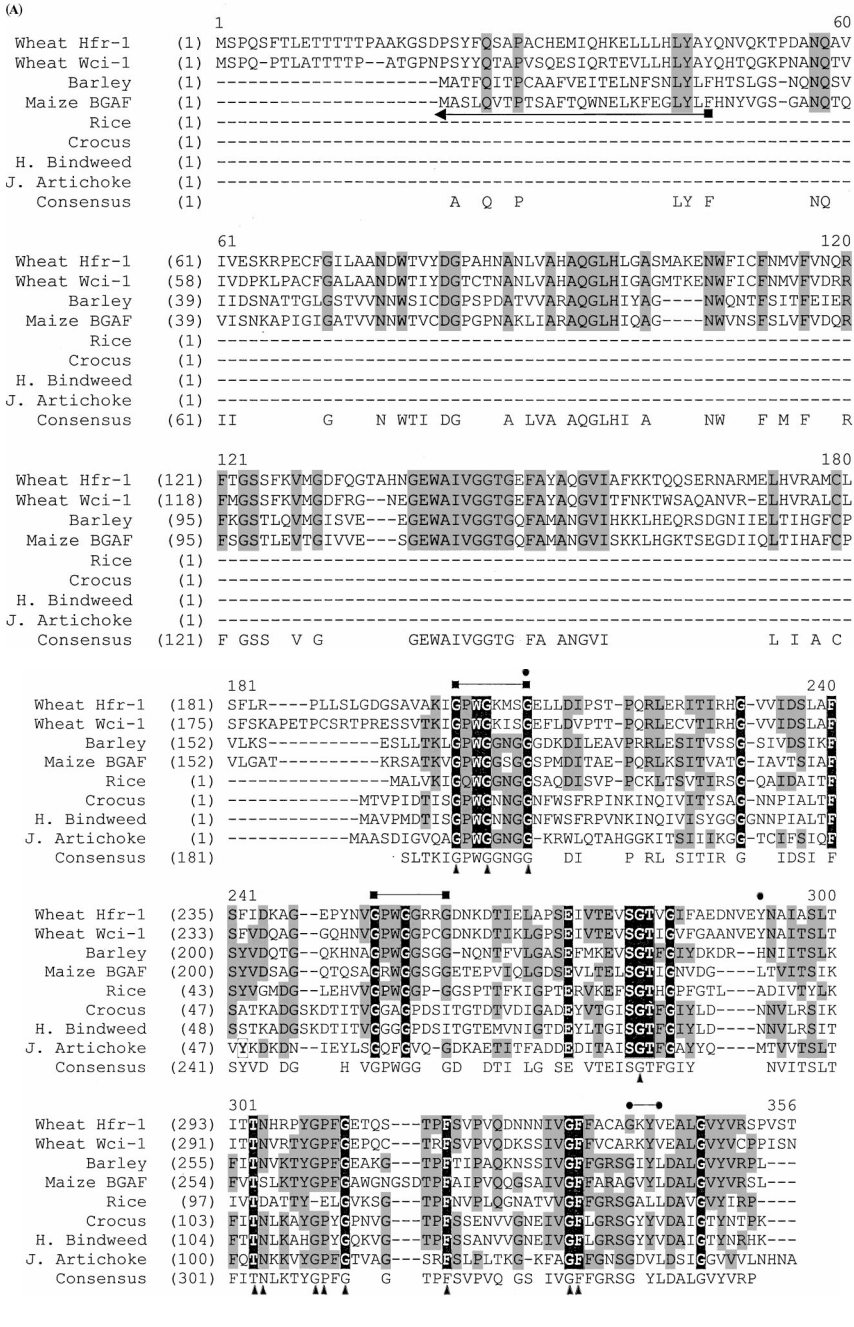


FIG. 3. Nucleotide and deduced amino acid sequence of *Hfr-1*. The near full-length nucleotide sequence of the *Hfr-1* cDNA is shown with the deduced amino acid sequence above each codon. The nucleotide coordinates are indicated to the left. The termination codon is indicated with an asterisk. The sequences corresponding to the forward and reverse primers for the clone UPW1Hfr1a are indicated with dashed arrows. The sequence of the clone UPW1Hfr1b, which was used for blot hybridizations, is underlined. The N-terminal and C-terminal amino acid domains are separated by a vertical line.

protein sequence. Mannose-binding jacalin-like lectins, the class most similar to the C-terminus of the Hfr-1 deduced amino acid sequence, contain a fair amount of sequence diversity. However, all proteins that have been shown to exhibit mannose-binding lectin activity have 12 invariant amino acid residues, also invariant in the Hfr-1 sequence (Figure 4a), that are necessary for the integrity of the β prism fold (Bourne et al., 1999). Some of the residues known to exhibit mannose-binding lectin activity, as well as the residues of the β-glucosidase-binding sites of BGAF, are highly conserved across this group of related proteins (Figure 4a).

Elements of the N-terminal domain of Hfr-1 are found in several *Arabidopsis* defense-response genes that are identified in database searches. Part of this N-terminal domain is cleaved from BGAF to produce the active protein (Blanchard et al., 2001). Similarly, a small polypeptide is cleaved from the N-terminal end of the mannose-binding lectins to produce the mature proteins (Zhang et al., 2000) (Figure 4a). These cleavage sites are not classical signal peptide sites, but they were determined experimentally. It is unknown whether, like related proteins, the N-terminal domain of the Hfr-1 sequence is cleaved in vivo. However, a comparison of the C-terminal portion of the deduced Hfr-1 protein sequence, starting at amino acid 203 (Figure 4a), with the β prism region of known mannose-binding jacalin-like lectins revealed that identity varied from 41% with jackfruit (Genbank number AAA32679) to 33% with Jerusalem artichoke (Genbank number AAD11577) and 30% with hedge bindweed (Genbank number AAC49564).

DISCUSSION

Because wheat and the Hessian fly interact in a gene-for-gene manner, the response of a given plant genotype may result in either a compatible or an incompatible interaction, depending on the genotype of the infesting larvae. Likewise, a single Hessian fly genotype may be virulent on some lines of wheat and avirulent on others, depending on the genotype of the host plant. Thus, the outcome of an interaction is determined by the ability of the plant to recognize and defend against the invader, coupled with the insect's effectiveness in avoiding recognition. The success and failure of larval recognition, mediated by the *H9* resistance gene in these experiments, resulted in up- and down-regulation of different sets of genes (C. C. Collier and C. E. Williams, unpublished results) and markedly different plant phenotypes. The plant phenotype resulting from the compatible interaction was distinct, characterized by systemic stunting of the leaves. However, during incompatible interactions, typically no visual phenotypic change in the plant is noted. It has been unclear whether the resistant wheat plant passively blocks the effect of larval secretions, leaving the insect to die of starvation, or actively mounts a local defense. Obviation of resistance during mixed infestations (Grover et al., 1989) suggests

that systemic induction of toxin production is not a major component of the plant's response to avirulent larvae. However, the increased expression of the *Hfr-1* gene in leaf blades demonstrated that recognition of avirulent first-instar larvae initiated an active response that may involve local and systemic defense mechanisms. The increased *Hfr-1* gene expression during the incompatible interaction corresponded to the period when first-instar larvae were attempting to feed. *Hfr-1* mRNA levels returned to low expression at a time when avirulent larvae appeared dead.

This study focused on wheat–Hessian fly interactions during the first 136 hr of infestation, which corresponded to the period when first-instar larvae were injecting substances into the plant and attempting to establish feeding sites. During this period, *Hfr-1* mRNA, which is similar to the mRNA sequence for a *BGAF* gene from maize, increased in abundance. The maize BGAF protein is capable of forming large complexes with β-glucosidases. Since BGAF does not interfere with β-glucosidase activity, it may protect an endogenous plant β-glucosidase that activates 2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA), a major defense compound active against insect pests of maize and wheat (Gianoli and Neimeyer, 1998), from proteolytic enzymes in larval saliva (Blanchard et al., 2001). Genes responsible for accumulation of DIMBOA are located on wheat chromosome 4A (Neimeyer and Jerez, 1997), the same chromosome that includes one of the two copies of *Hfr-1* in Chinese Spring wheat (K. M. Devos and C. E. Williams, unpublished results).

Saliva from several insects has been shown to contain β-glucosidase (Mattiacci et al., 1995; Miles, 1999). Although it is not a major component, β-glucosidase is detectable in the saliva of virulent second-instar Hessian fly larvae

FIG. 4. Sequence conservation. (A) Alignment of the deduced amino acid sequences for *Hfr-1* and sequences encoded by related genes (Genbank numbers: wheat Wci-1, AAC49284.1; barley JA-induced gene, AAA87042.1; maize BGAF, AAF71261.2; rice lectin, BAB19404.1; crocus lectin, AAG10403.1; hedge bindweed lectin, AAC49564.1; Jerusalem artichoke lectin, AAD11577.1). Multiple sequence alignment was constructed with ClustalW. The first four sequences are substantially longer than the last four, which are known to function as mannose-binding jacalin-like lectins. Residues that are identical in at least four of the eight sequences are highlighted in gray. Residues that are invariant are highlighted in black. The arrow with a black square indicates the N-terminal sequence that is cleaved to activate the BGAF protein. The two bars with black squares indicate the regions of BGAF that bind β-glucosidase. These sites are partially conserved in the other sequences. Black circles indicate regions of the four jacalin-like lectins that bind mannose. The 12 amino acid positions indicated by black triangles are conserved in all mannose-binding lectins (modified from Figure 1 in Bourne et al., 1999). (B) Domains of the Hfr-1 deduced amino acid sequence. The N-terminal region that shares sequence similarity with disease resistance response genes spans amino acids 44–179. The C-terminal mannose-binding jacalin-like lectin domain spans amino acids 195–348 and the region that is similar to myrosinase-binding proteins spans amino acids 286–348.

and may be more abundant in the first-instar larval saliva that is injected into plant tissues. Because of greatly increased larval size over first-instars, the contents of saliva from virulent second-instar Hessian fly larval only have been analyzed (Grover et al., 1988). However, it is the first-instar rather than the second-instar larvae that pierce and inject substances into plant tissues. Second instars no longer need to or are capable of piercing, because in order for the larvae to survive, the relevant changes in plant cell permeability had to be initiated through a compatible interaction during the first instar. β-Glucosidases activate stored cytokinins (Brzobohaty et al., 1993) and defense molecules such as salicylic acid (Wallner and Walker, 1975), which is an inducer of *Hfr-1* expression (J. M. Meyer and C. E. Williams, unpublished results). Because they also hydrolyze cell wall polysaccharides (Wallner and Walker, 1975), β-glucosidases from larval saliva may contribute to partial cell wall degradation and permeability in the wheat–Hessian fly interaction. Similar to the silverleaf whitefly, which may produce elicitors in nymphs but not in adults for the *SLW1* and *SLW3* genes of squash plants (van de Ven et al., 2000), components of Hessian fly larval saliva may vary according to feeding strategy at different instars. Alternatively, a larval genotype may vary the components of its saliva, depending on whether the plant is resistant or susceptible (once the plant's defense is compromised), much like hemipteran salivary protein profiles that can change in response to different host plant substrates (Habibi et al., 2001). Thus, the *Hfr-1* gene sequence is similar to a gene encoding a protein that agglutinates cell-damaging β-glucosidases. However, the Hfr-1 deduced amino acid sequence, as well as that of Wci-1 and BGAF, share so many structural elements and active sites with lectins that their *in vivo* functions may be more closely aligned with lectin activity than with agglutination of β-glucosidases.

The sequence similarity between the mannose-binding jacalin-like lectins and the C-terminal domain of the deduced amino acid sequences of Hfr-1, plus the wheat Wci-1, maize BGAF and barley sequences shown in Figure 4a, strongly suggested that all belong to the same superfamily of lectins. Although Hfr-1, Wci-1, BGAF, and the barley sequences contained N-terminal regions that are not found in the sequences that are known to function as lectins, much of the C-terminal sequence corresponding to the β prism fold was conserved. The β prism sequence is divergent among active lectins, allowing agglutination of a wide variety of glycoproteins. However, 12 amino acids, essential for proper folding, are conserved among all mannose-binding lectins (Bourne et al., 1999). All 12 of these amino acids were present in Hfr-1, Wci-1, and the barley sequences, and only one of the 12 was missing from BGAF. Most plant lectins target foreign glycans rather than endogenous plant carbohydrates (Peumans et al., 2000), and several are implicated in resistance to insects. The mannose-binding snowdrop lectin binds to the mid-gut of the brown planthopper and the green leafhopper (Foissac et al., 2000), preventing nutrient absorption. In addition, snowdrop lectin acts as a feeding deterrent for these insects. Experiments are underway to determine whether

the protein encoded by *Hfr-1* has lectin activity. No discrete function has been assigned to molecules sharing the domain that is part of the N-terminal sequence of Hfr-1 and the other lectin-like proteins from monocots. Further experimentation will determine whether this domain contains cleavage sites similar to those needed for production of the mature forms of the BGAF protein and the mannose-binding lectins (Blanchard et al., 2001; Zhang et al., 2000).

In conclusion, the rapid increase in expression of *Hfr-1* mRNA was similar to the expression profiles of plant defense–response genes during incompatible interactions between microbial pathogens and their monocot hosts: wheat (Rebmann et al., 1991; Schaffrath et al., 1997; Molina et al., 1999), barley (Hahn et al., 1993; Mouradov et al., 1994), oat (Lin et al., 1996), and maize (Morris et al., 1998). Related defense–response genes, such as *PR-1*, that are characteristic of responses to microbial attack are also induced during interactions involving *Arabidopsis* and phloem-feeding aphids (Moran and Thompson, 2001). Furthermore, Russian wheat aphids feeding on wheat cause rapid increases in expression of the PR proteins chitinase, peroxidase, and β-glucanases (van der Westhuizen and Pretorius, 1998; van der Westhuizen et al., 1998). Thus, responses to diverse organisms share common elements. Defense–response genes are not limited to a standard set of genes or pathways, however. Four pathogen-response signaling pathways are prominent in addition to other less well-characterized pathways that lead to novel gene expression (reviewed in Walling, 2000). Some elicitors activate novel genes involved in systemic species-specific responses, such as genes responding to whitefly feeding on squash (van de Ven et al., 2000). Although induction of an *Hfr-1*-like gene during plant defense has not been reported previously, related jasmonate-induced genes have been noted in barley (Chaudhry et al., 1994). The timing of *Hfr-1* expression plus its sequence similarity to lectins and other genes implicated in insect resistance suggested that it may play a role in defending wheat against infestation by Hessian fly larvae.

Acknowledgments—Valuable discussions with L. Walling, J. Anderson and S. Goodwin are gratefully acknowledged. Special thanks go to F. Maas III for providing *H9* seed and Hessian fly stocks. (Received November 13, 2001; accepted March 9, 2002)

Abstract—Major urinary proteins (MUPs) are present in high levels in the urine of mice, and the specific profile of MUPs varies considerably among wild-caught individuals. We have conducted a detailed study of the polymorphic variation within a geographically constrained island population, analyzing the MUP heterogeneity by isoelectric focusing and analytical ion exchange chromatography. Several MUPs were purified in sufficient quantities for analysis by electrospray ionization mass spectrometry and MALDI-TOF mass spectrometry of endopeptidase Lys-C peptide maps. The results of such analyses permitted the identification of three new MUP allelic variants. In each of these proteins, the sites of variation were located to a restricted segment of the polypeptide chain, projecting to a patch on the surface of the protein, and connected to the central lipocalin calyx through the polypeptide backbone. The restriction of the polymorphic variation to one segment of the polypeptide may be of functional significance, either in the modulation of ligand release or in communication of individuality signals within urinary scent marks.

Key Words—Major urinary proteins, mouse, MALDI-TOF mass spectrometry, protein purification, isoelectric focusing.

INTRODUCTION

The urine of house mice (*Mus domesticus*) contains a high concentration of protein, virtually all of which consists of members of an 18- to 19-kDa protein family termed "major urinary proteins," (MUPs). These MUPs are lipocalins (Flower et al., 1993), characterized by an archetypical eight-stranded β-barrel (Bocskei et al., 1992; Lucke et al., 1999; Zidek et al., 1999), enclosing a hydrophobic cavity. A generic role of the lipocalin family is the binding of small hydrophobic ligands (Flower et al., 1993, 2000), and in this respect, the MUPs are typical. Thus far, five endogenous MUP ligands have been reported; 2-*sec*-butyl-4,5-dihydrothiazole, 3,4-dehydro-*exo*-brevicomin, α- and β-farnesene, and 6-hydroxy-6-methyl-3-heptanone (Bocskei et al., 1992; Bacchini et al., 1992; Robertson et al., 1993; Novotny et al., 1999; Timm et al., 2001). All of these ligands are semiochemicals and are known to elicit primer pheromonal effects (Jemiolo et al., 1985, 1986).

Until recently, the necessity of protein binding for the activity of these ligands has not been understood, but we have provided direct behavioral and biochemical evidence that MUPs slow the release of semiochemicals from deposited urine samples (Hurst et al., 1998; Beynon et al., 1999). However, a simple role of ligand binding and release does not explain the observation that MUPs are encoded by a large, multigene complex and that urine from individual mice contains several MUPs, each a discrete gene product. Although there is some variation in ligand binding capability between different MUPs (Marie et al., 2001; Robertson et al., 2001), differential ligand release kinetics seems inadequate as an explanation for MUP diversity, since many MUPs show similar ligand binding properties. We have shown that protein fractions, depleted of natural volatile ligands by aging or by competitive displacement, elicit a strong countermarking response (Humphries et al., 1999) and, thus, MUPs or nonvolatile MUP–ligand complexes communicate chemical information in their own right. This is consistent with the hypothesis that proteins act as a stable signal of an animal's presence and are the medium through which scent marks evince the presence of a different individual. The growing evidence for other roles of MUPs in chemical signaling is also relevant. Brennan et al. (1999) suggested that these proteins provide one component of the strain recognition signal, and Mucignat-Caretta et al. (1995) showed that MUPs interact with receptors in the vomeronasal organ to exert an effect on puberty acceleration in females, even without the ligands. We have suggested that the MUPs, possibly in combination with ligands, have the ability to be used to communicate individuality within a mouse population (Beynon et al., 1999), and we recently provided direct evidence to support this hypothesis (Hurst et al., 2001).

Most of the information relating to MUPs has derived from studies of the proteins from relatively few inbred mouse strains (Robertson et al., 1996 and references therein). Since each strain is genetically homogeneous, it must be considered as a single snapshot of the wild mouse genome and, as such, yields little

information on the extent of genetic diversity in the wild house mouse. Accordingly, we have embarked on a study of the MUPs from wild mice. Our initial screen of a small number of wild mice from several sites in the UK yielded clear evidence of a hitherto unsuspected degree of polymorphism (Robertson et al., 1997; Pes et al., 1999; Payne et al., 2001). In this study, we have focused on MUP diversity from a single island population of mice to establish further the degree of polymorphism, particularly in a geographically and, therefore, genetically constrained population. The Isle of May (54 ha) in the Firth of Forth, approx. 10 km from the Scottish mainland, is uninhabited (except for wardens and a small number of researchers during the summer months) and contains a population of between a few hundred and a few thousand mice that vary cyclically over the year (Triggs, 1991). Indeed, until the introduction of a small number of mice from another island in 1982, the May mice were homozygous for over 70 loci, including the major histocompatibility complex (Berry and Peters, 1977; Berry et al., 1991). Subsequently, the new alleles penetrated rapidly through the population and reached equilibrium within three years (Figueroa et al., 1986; Jones et al., 1995). This rapid penetration may have been aided by the lack of territorial division in this population, leading to considerable genetic mixing. In contrast to the strongly territorial behavior normally seen among house mice living commensally in the built environment, competitive behavior appears to be virtually absent among feral males from the Isle of May (Gray and Hurst, 1998), and individual home ranges overlap extensively (Hurst, unpublished data). However, even within such an isolated and freely mixing population, where overall genetic variation is low, we should expect relatively high variation among individuals in cues that are used for individual recognition and perhaps also to recognize close relatives. Further identification of the sites of variation between the MUPs expressed by different individuals may indicate whether variation lies largely at the ligand-binding site (suggesting that individuality may be signaled through differential binding and release of volatile ligands) or lies on the surface of the protein for direct receptor-mediated detection. This paper reports detailed characterization of the MUPs expressed by different individuals within the Isle of May population and provides evidence for several new allelic variants not previously encountered.

METHODS AND MATERIALS

Chemicals. Acetonitrile, triflouroacetic acid, and methanol, all HiPerSolv grade, were obtained from BDH (Poole, England). Formic acid, NaCl, β-mercaptoethanol, EDTA, Tris, and trichloroacetic acid, all AnalaR grade, were obtained from BDH. Peptides (des-Arg bradykinin, neurotensin, ACTH, and insulin B-chain), horse heart myoglobin, Coomassie blue, Bistris, and α-cyano-4-hydroxycinnamic acid were obtained from Sigma (Poole, England). The Coomassie

Protein Plus assay including BSA standard was obtained from Pierce & Warriner, Chester, UK. The endoprotease Lys-C (sequencing grade) was obtained from Roche (Lewes, England).

Mice and Urine Collection. Male wild mice were captured from the population living on the Isle of May. The mice were housed individually in cages (30 × 13 × 12 cm) on peat substrate with shredded paper nest material and ad libitum food (Teklad Mouse/Rat diet 9609; Banting and Kingman, Hull, UK, and wheat grain) and water. Urine, voided in response to the mouse being held by the scruff of the neck, was collected into 1.5-ml Eppendorf tubes and frozen immediately. Many samples were no greater than 10–20 μl, which precluded exhaustive analysis.

Isoelectric Focusing (IEF). Isoelectric focusing was performed using Immobiline dryplates pH 4.2–4.9 (AP Biotech) on the Multiphor flatbed system cooled to 10°C with a Multitemp III thermostatic circulator (AP Biotech). Samples were diluted 1:10 in water, and 5 μl was loaded onto the gel at 200 V, 5 mA, and 15 W for 200 vh. Sample applicators were removed and the gel run at 3500 V, 5 mA, and 15 W for 14.8 kVh. The gel was stained with Coomassie Brilliant Blue in a Hoefer automated gel stainer.

Ion Exchange Chromatography (IEC). Urinary proteins were purified by high-resolution anion exchange chromatography on the SMART chromatography platform (AP Biotech). Prior to chromatography, 10 μl urine was desalted on micro Sephadex G25 spin columns and filtered through a 0.22-μm filter. Protein concentration of the desalted urine was measured (Coomassie Protein Plus assay). Fifteen micrograms of urinary protein was applied to a MiniQ PC 3.2/3 column (240 μl bed volume, Pharmacia) equilibrated with 20 mM Bistris buffer, pH 5.5, at a flow rate of 120 μl/min. Following sample application, the column was washed with 5 column volumes of 20 mM Bistris buffer, pH 5.5. Bound protein was eluted with a linear gradient of NaCl from 0 to 150 mM in the same buffer in 20 column volumes. Protein peaks, identified by absorbance at 280 nm, were collected. Peak fraction sizes were typically 60 μl, containing 1–3 μg of protein.

Electrospray Ionization Mass Spectrometry (ESI-MS). Peak fractions from IEC were desalted into 0.2% (v/v) formic acid on Microcon-10 concentrators (Millipore, Watford, England). Desalted samples were diluted 1:10 in 50% (v/v) acetonitrile–0.1% (v/v) formic acid. All analyses were performed on a VG Quattro mass spectrometer, upgraded to Quattro-II specifications (Micromass, Manchester, UK), fitted with an electrospray ionization source. Samples were introduced into the mass spectrometer as a continuous infusion at 5 μl/min. Raw data, gathered between *m/z* 700 and 1400, were subsequently refined and transformed to a true mass scale using Maximum Entropy software. Raw data were processed between 18,400 and 19,000 Da. The instrument was calibrated using a 2 pmol/μl solution of horse heart myoglobin in 50% (v/v) acetonitrile–0.1% (v/v) formic acid run after each sample. The calibration spectrum also served to determine the peak width parameter (0.75 Da) during Maximum Entropy processing.

Lys-C Digestion. The proteins in peak fractions from ion exchange chromatography were denatured in 4 M guanidinium thiocyanate for 1 hr and desalted into Lys-C digestion buffer (25 mM Tris, 1 mM EDTA, 2 mM β-mercaptoethanol, pH 8.5) on Microcon-10 concentrators. Sequencing grade Lys-C was added in a 1:100 (w/w) ratio. Digestion took place overnight at 37°C, and the reaction was stopped by the addition of 1 μl formic acid. A reference peptide digest of uMUP-I from BALB/C was prepared by digesting purified uMUP-I (IEC on the SMART system) as described above.

MALDI-TOF MS. Peptides were analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (PE Biosystems Voyager Elite, Warrington, UK), equipped with a 2-m linear and a 3-m reflectron flight mode and a delayed extraction function. A pulsed nitrogen laser emitting at 337 nm was used as a desorption/ionization source. In all experiments, mass spectrometry was performed in reflectron mode with positive ion detection. Instrument parameters were as follows: accelerating voltage 20 kV, grid voltage 73.5%, guide wire voltage 0.05%, and pulse delay time 175 nsec. Laser energy was ca. 1500. External mass calibration was performed with a mixture of des-Arg bradykinin, neurotensin, adrenocorticotrophic hormone, and insulin β-chain (50 nM each in 50% acetonitrile–0.1% triflouroacetic acid). To 1 μl of digested protein or peptide calibrants, 1 μl of α-cyano-4-hydroxycinnamic acid (saturated in 50% acetonitrile–0.1% triflouroacetic acid) was added, and 1 μl of the mixture was spotted onto the target. Signal-averaged mass spectra for 80–256 laser shots were collected, and data were analyzed using the PE Biosystems GRAMS/386 software.

RESULTS AND DISCUSSION

We have previously examined in detail the MUP allelomorphs from two inbred laboratory strains of mice: BALB/C and C57BL/6J (Robertson et al., 1996) in which we were able to reconcile urinary protein expression with known cDNA sequences and provide evidence, purely from protein analysis, for new gene products for which no cDNA sequences were known. These inbred strains, BALB/C and C57BL/6J, can be construed as two snapshots of the wild mouse genome, and our data provided evidence for at least 14 proteins potentially or actually expressed in these two strains. Further work on limited numbers of wild-caught specimens yielded clear evidence for remarkable diversity in MUP profiles (Pes et al., 1999; Payne et al., 2001), suggesting many as yet uncharacterized variants of these proteins. Accordingly, we embarked upon a systematic study of MUP expression in mice sampled from a closed, island population. In addition to yielding further information on MUP polymorphism, these samples were informative in studies on MUP pattern complexity within a closed but natural population, the results of which will be reported elsewhere. In this paper, we describe the isolation and characterization of the most abundant MUPs found in this population.

Survey of MUP Expression in Isle of May Mouse Urine Samples. Charge and exact mass are valuable parameters in the screening for novel MUPs (Robertson et al., 1997). Isle of May mouse urine samples separated on linear SDS–polyacrylamide gel electrophoresis showed a strong protein band at 18 kDa and little or no other protein constituents. When electroblotted to nitrocellulose, the 18 kDa band reacted strongly with an anti-MUP polyclonal antiserum (results not shown). Accordingly, we assumed that the detectable proteins in a mouse urine sample were predominantly MUPs, an assumption that has been repeatedly validated. For rapid initial screening of samples derived from Isle of May mice, urinary proteins from 17 wild caught animals were analyzed by IEF using the method described in Payne et al. (2001) (Figure 1). Whereas all individuals from any inbred mouse strain would have completely identical profiles in IEF (a BALB/C sample is included in the figure for comparison), the profiles of these 17 wild mice differed among individuals, although there was evidence of widespread expression of common protein subtypes. Between four and 10 bands were expressed in each of the Isle of May urine samples, but there was considerable overlap of protein expression in these individuals—a total of only 11 different bands could be discerned. By comparison with analyses of urine samples from mainland-caught mice, the patterns were much more similar among individuals, which may reflect the limited number of founder animals, or genetic bottlenecks due to poor overwinter survival

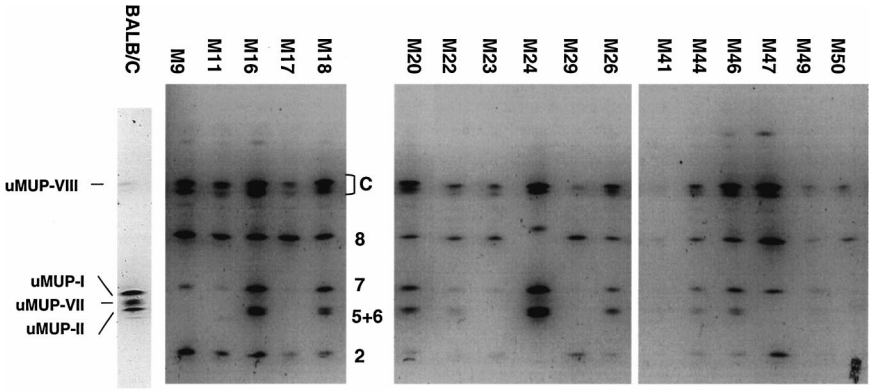

FIG. 1. Isoelectric focusing of MUPs from 17 wild mice from the Isle of May. Isoelectric focusing was performed using Immobiline dry plates, pH 4.2–4.9 (AP Biotech) on the Multiphor flatbed system (AP Biotech). Samples were diluted $1 + 9$ in water, 5 μl was applied and the gel was run at 3500 V, 5 mA, and 15 W for 14.8 kVh. A sample of urine from a BALB/C inbred mouse was included for comparison. Bands identified by analysis of proteins purified by ion exchange chromatography are labeled for cross-reference elsewhere in the paper. Known MUP variants from BALB/C urine are labelled with the standard nomenclature.

that is a feature of this geographically constrained population (Berry and Peters, 1977; Berry et al., 1991; Jones et al., 1995; Payne et al., 2001).

Chromatographic Separation of MUPs from Isle of May Mice. For further characterization of the proteins, MUPs from the wild-caught May mice and from inbred BALB/C and C57BL/6J mice were purified by high-resolution IEC (MiniQ column, SMART chromatography platform). A representative elution profile for one Isle of May mouse (M22), and the profiles from the well-characterized inbred strains BALB/C and C57BL/6J are given in Figure 2. A low loading (15 μg of protein) was necessary for reproducible and high-resolution separation of these mixtures of very similar proteins. The M22 mouse sample contained 11 discernible protein peaks, all eluting between 2.8 and 4.9 ml, thus displaying greater complexity than inbred mice (seven and five peaks for BALB/C and C57BL/6J, respectively). The first six and last three peaks were well separated, whereas the proteins at $V_e = 3.76$ ml and 3.86 ml overlapped and probably contained more than one protein each, as both were irregularly shaped with shoulders. The large, complex peak between $V_e = 3.76$ and 3.86 ml is a persistent feature of urine samples from Isle of May mice but is not present in either inbred strain. When comparing the peak elution volumes (V_e) to those of the inbred mice proteins, some overlap was found. Five peaks ($V_e = 2.97$, 3.38, 3.50, 3.76, and 4.82 ml) were matched by similar peaks in BALB/C ($V_e = 2.98$, 3.40, 3.49, 3.73, and 4.84 ml), and four May peaks ($V_e = 3.50$, 3.63, 3.76, and 4.82 ml) matched to equivalents in C57BL/6J ($V_e = 3.48$, 3.61, 3.77, and 4.83 ml), indicating the presence of proteins of similar charge in the three different samples.

Ion exchange chromatography identified more charge variants than IEF, although for the major proteins, the results of the two analyses correlated well. Chromatographically purified MUPs from M18 and from BALB/C were analyzed by IEF, and the peaks that could be identified are labeled in Figure 1. The BALB/C MUPs had been previously identified and were labeled according to the proposed nomenclature (Robertson et al., 1997). When the remainder of the Isle of May samples were analyzed by high-resolution IEC, similarly complex elution profiles were obtained, with 6–11 peaks expressed in each sample. These elution traces are not shown, but representative profiles are summarized in Figure 3. Because a constant amount of protein was applied to the column for each individual urine sample, comparison of the expression of different peaks was possible. The chromatographic traces revealed differences between almost every animal. Two proteins were found in a single individual: peak 1 was seen only in M15 and peak 9 was only expressed in M24. The V_e of these two proteins differed from the nearest groups by more than 2 SD and are, therefore, likely to be separate proteins. At the other extreme, several peaks (2, 3, 6, 7, 8, 11) were present in over 50% of the samples analyzed, the cluster proteins were found in all mice tested, and peaks 2, 7, and 8 were observed in all but one individual. Many individuals share the major proteins (2, 3, 5, 6, 7, 8, cluster, 11). Of the major proteins, peaks 5 and 6 demonstrated the

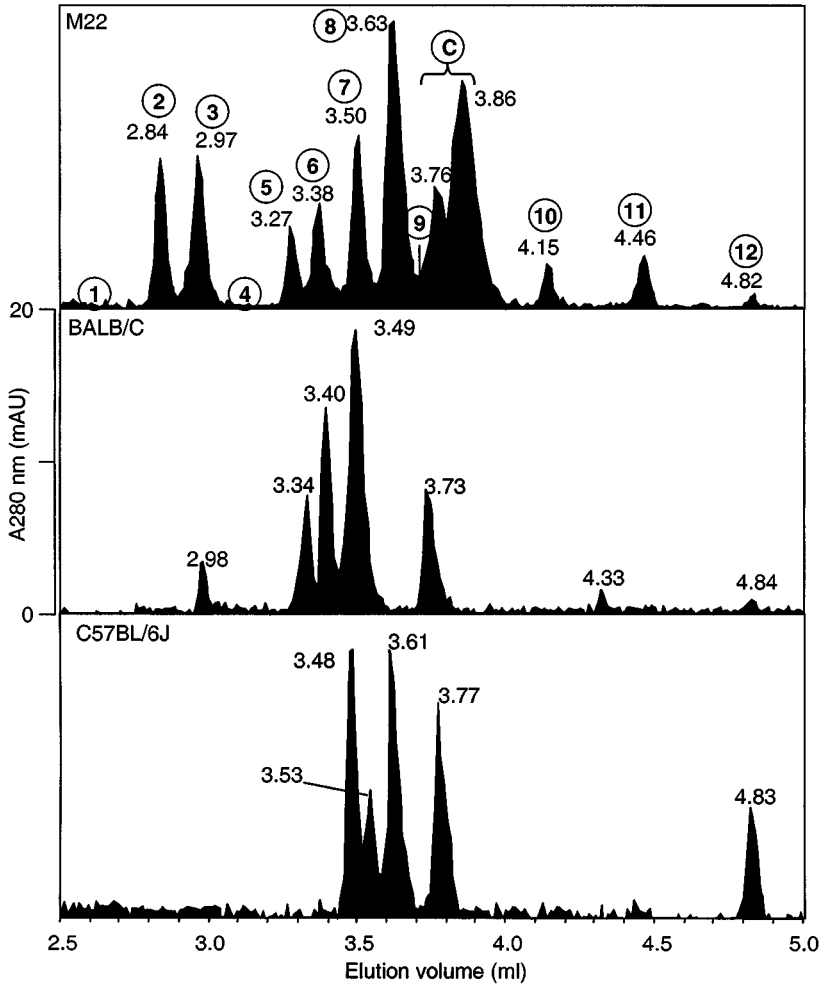

FIG. 2. Purification of MUPs from the M22 wild mouse. Urine samples from Isle of May mouse M22, BALB/C, and C57BL/6J were desalted into 20 mM Bistris buffer, pH 5.5, and 15 μg of protein was applied to a MiniQ column ($V_t = 240$ μl). Bound proteins were eluted with a linear salt gradient from 0 to 150 mM NaCl in 20 column volumes of the same buffer. The black areas define $A_{280\,nm}$. All three panels are displayed at the same scale, and each peak is annotated with the peak number and elution volume in milliliters.

greatest variability among individuals, but there was more pronounced variability in expression of the minor components. At present, we have no knowledge of the ability of mice to perceive differences in the relative concentrations of MUPs in a urine sample, and the significance of such variability is unknown.

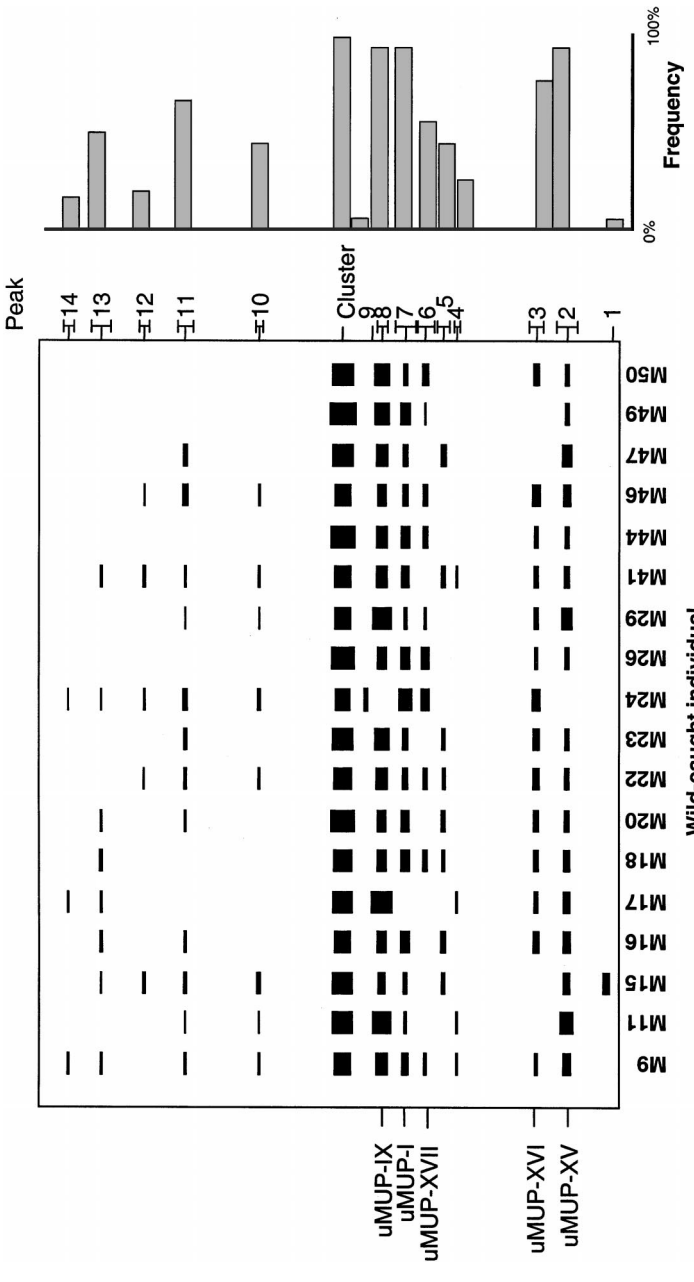

FIG. 3. Summary of IEC of MUPs from wild-caught mice from the Isle of May. MUPs from 18 Isle of May mice were purified by ion exchange chromatography on the SMART system, as described for M22 (see Figure 2 legend). Peaks from the different Isle of May mice were grouped according to V_e and are represented as bands at the average peak elution volume of the group. The width of the band represents the relative peak area (calculated as a percentage of the total peak area). The error bars to the right of the figure represent the mean $V_e \pm 2$ SD of each protein peak. The standard deviations of the elution volumes in the groups varied from 0.005 to 0.020 ml, which is comparable to that achieved from multiple runs of BALB/C (S.D. 0.01–0.02 ml for peaks 1–7, $N = 6$). The peaks between 3.69 and 3.88 ml are not completely resolved in any of the samples and are, therefore, presented as one cluster. Protein from groups annotated with an uMUP name are those that have been previously identified in inbred mouse strains or which were characterized as novel proteins by ESI-MS and peptide fingerprinting. The frequency of expression of each of the peaks is summarized to the right of the figure.

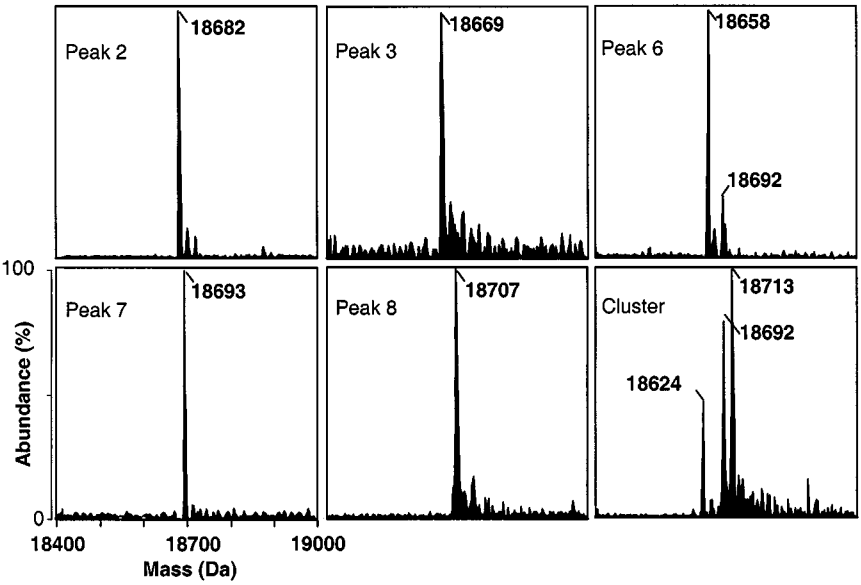

FIG. 4. Electrospray mass spectrometry analysis of purified M22 MUPs. IEC purified M22 urinary proteins were desalted into 0.2% formic acid and analyzed on a VG Quattro mass spectrometer, upgraded to Quattro-II specifications, fitted with an electrospray ionization source. Raw data, gathered between m/z 700 and 1400, were subsequently refined and transformed to a true mass scale using Maximum Entropy software. Raw data were processed between 18,400 and 19,000 Da. All six panels are displayed at the same scale.

Electrospray Ionization Mass Spectrometry of Purified Intact Proteins. To establish that the previously unseen species on IEF and IEC were new MUPs, the more abundant proteins were isolated by IEC of urine samples derived from individuals M9, M16, M18, M22, and M41. The major peaks (2, 3, 6, 7, 8, and the cluster mixture) were separately desalted into 0.2% formic acid and analyzed by electrospray ionization mass spectrometry (Figure 4). Each of the five main chromatographic peaks contained a predominant species, as assessed by accurate mass measurement (peak 6 contained a trace of a protein of mass 18,692 Da, possibly slight contamination from peak 7). The same chromatographic peaks from all five mice contained proteins of identical masses (mean $\pm$ SD): peak 2 was $18{,}682 \pm 0.3$ Da ($N = 5$), peak 3 was 18,668 Da (mean, $N = 2$), peak 6 was $18{,}658 \pm 0.9$ Da ($N = 3$), peak 7 was $18{,}693 \pm 0.5$ Da ($N = 5$), and peak 8 was $18{,}707 \pm 0.4$ Da ($N = 5$). From each mouse, the cluster contained protein species of three or four distinct masses, of which two (18,692 and 18,713 Da) had previously been observed in MUPs isolated from inbred animals (Robertson et al., 1997), and which could be reconciled to known cDNA sequences. It has not

proved possible to resolve the individual proteins in this cluster, and they have not been studied further.

Two of the proteins in the chromatographically pure peaks exhibited masses that were identical to the masses of proteins expressed in the urine of inbred mice (peak 7, 18,693 Da and peak 8, 18,707 Da) and that eluted in the same positions on IEC. The 18,693-Da peaks from BALB/C (uMUP-I) and Isle of May mice (peak 7) eluted at 3.49 ml and 3.50 ± 0.02 ml (mean $\pm$ SD), respectively, and the 18,707 Da peaks from C57BL/6J (uMUP-IX) and Isle of May mice (peak 8) eluted at 3.61 ml and 3.62 ± 0.01 ml, respectively. These proteins were, thus, indistinguishable on the basis of mass and charge, and we conjectured that these are the products of the same genes (subsequently proven by peptide mass fingerprinting, below).

Knowledge of the overall charge (isoelectric focusing and ion exchange chromatography) and intact protein mass are valuable parameters for the identification of new polymorphic variants of the proteins. However, these global parameters do not provide information on the site of protein sequence variation nor, indeed, do they exclude the possibility that these variants could be derived through posttranslational modifications. To characterize the new proteins further, we used MALDI-TOF peptide mass fingerprinting. The purified proteins were denatured and digested to limit peptides with the endopeptidase Lys-C, which cleaves specifically at the carboxyl side of lysyl residues. The resultant limit peptide mix was analyzed by MALDI-TOF mass spectrometry (Figure 5). Endopeptidase Lys-C is particularly valuable for the analysis of MUPs, since the limit digestion products (labeled L1 to L11 for the uMUP-I endopeptidase Lys-C limit peptides) were mostly large enough to be displaced from the chemical (mainly matrix) noise in the MALDI-TOF spectrum below 800 Da. All of the limit peptides, with the exception the two tripeptides L3 and L6, were observed and 96% (156/162) of the sequence was, thus, accounted for. As the protein sequence for uMUP-I was known (Genbank accession M16355), the peptide masses could be matched to that of the theoretical digest pattern for this protein, used as a reference for peptide mapping (Figure 6).

When comparing the peptide masses found for the five Isle of May MUPs to those of the BALB/C uMUP-I peptides, most of the Lys-C peptides were present in all samples. Those peptides corresponding to amino acid sequences from 1 to 28 (L1–L2) and 76 to 131 (L7–L9) were identical in all five MUPs analyzed. A further two peptides (L10 and L11) were variably present, due to a known amino acid polymorphism (Lys_{140} to Glu_{140}) that modifies a Lys-C site (Robertson et al., 1997) and, thus, in some proteins, the peptide (L10 + L11 − 18Da) was apparent. All other sequence variability in these proteins was located in peptides L4 and L5. For the Lys-C digest of the 18,682-Da protein (peak 2, expressed by all but one of the May mice), the expected 2095.9-Da L5 peptide was not present in the spectrum. Instead, a smaller 2047.4-Da peptide was present in the spectrum and is likely to correspond to the L5′ peptide arising from a $Phe_{56} \rightarrow Val_{56}$ mutation, as seen in uMUP-VII from BALB/C (Genbank accession X00907) (Kuhn et al., 1984;

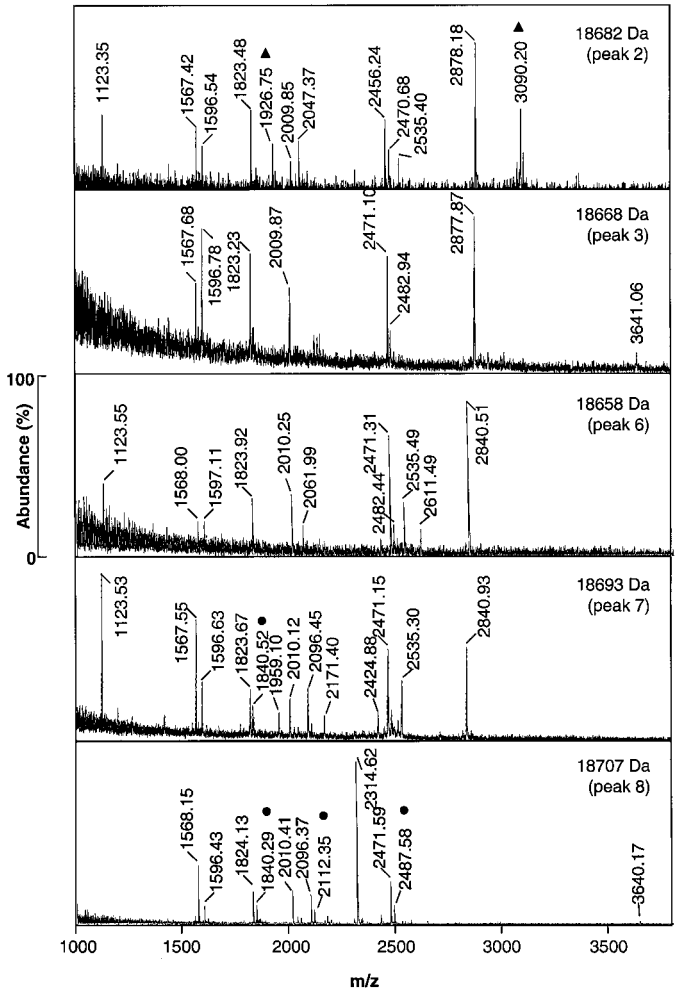

FIG. 5. MALDI-TOF mass spectrometry analysis of Lys-C digested purified M22 urinary proteins. Ion exchange chromatography-purified proteins were denatured in 4 M guanidine thiocyanate and desalted into Lys-C digestion buffer (25 mM Tris, 1 mM EDTA, 2 mM β-mercaptoethanol, pH 8.5) and digested with Lys-C overnight at 37°C. The peptides were analyzed on a PerSeptive Voyager Elite MALDI-TOF MS in reflectron mode. (**A**) Peak 2 (18682 Da), (**B**) Peak 3 (18669 Da), (**C**) Peak 6 (18658 Da), (**D**) Peak 7 (18693 Da), and (**E**) Peak 8 (18707 Da). Peaks marked with a closed circle are +18.003 Da peaks representing the oxidized methionine variant of the parent peak at lower mass. This serves as a useful confirmation of the presence of methionine in these peptides and their assignment to the peptide map. Peaks marked with a triangle are derived from autolysis of endopeptidase Lys-C (L1: 3090.49 Da and L2: 1926.83 Da).

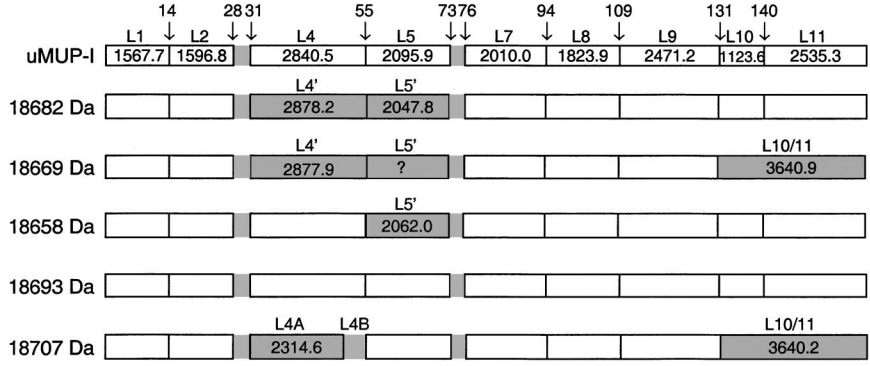

FIG. 6. Comparison of peptides obtained from Lys-C digestion of May mouse urinary proteins with that of a theoretical uMUP-I digest. A theoretical Lys-C digest of the protein sequence for uMUP-I was calculated using MassLynx software (Micromass, Manchester, UK) and compared with the MALDI-TOF results for the five Isle of May mouse peaks peaks. Lys-C peptides are numbered L1–L11. Some peptides are too small to be seen on the MALDI-TOF (L3, L6, and L4B). Blank boxes represent M22 peptides identical to the uMUP-I peptide. Peptide masses corresponding to known mutations found in inbred mice were also seen: $Asn_{50} \rightarrow Lys_{50} = 2314.2$ Da L4A and 559.4 Da L4B peptides, $Phe_{56} \rightarrow Val_{56} = 2047.9$ Da L5′ peptide, and $Lys_{140} \rightarrow Glu_{140} = 3640.8$ Da L10/11 peptide.

Robertson et al., 1997; Marie et al., 2001). Assuming that this was the L5′ peptide, an additional mass change had to account for the difference in the protein mass (10.7 Da smaller that uMUP-I). The 2840.5-Da L4 peptide was not present in the spectrum, but a prominent ion at 2878.2 Da was seen. This is 37.7 Da larger than the uMUP-I L4 peptide, and could, therefore, be a mutated L4′ peptide. The only single mass change of 38Da would be consequential to a Val to His mutation. Peptide L4′ contains two valyl residues, and it is not possible to be specific about which has been mutated. However, a Val to His mutation would also make the protein more cationic and less able to bind to the cation exchange column, which is exactly what is observed (Figure 2). The evidence clearly points to a new allelic variant, and this new protein was termed uMUP-XV according to the suggested nomenclature.

For the Lys-C digests of the 18,668-Da protein (peak 3, expressed by 14/18 males sampled), the L4, L5, L10, and L11 peptides of uMUP-I were not observed. All Lys-C peptide spectra for this protein contained ions at 3641 Da, which corresponds to the L10/11 peptide arising from the deletion of a Lys-C site by the mutation of Lys_{140} to Glu_{140}, as previously seen in the BALB/C protein uMUP-VIII [20]. The 2877.9-Da fragment is likely to be the L4′ peptide that was present in the digest of peak 2 material. Taking all these mass differences into account, peptide L5 would be expected to be 2037 Da. However, no peptide of this mass was present in any spectrum examined. It may be that L5′ in this protein contains

an additional Lys-C cleavage site that renders it too small for analysis. However, the implication is clear, inasmuch as there must be a further amino acid change in L5, which is the only peptide not accounted for. No peptides of the correct mass (i.e., the mass that would account for the remaining protein mass difference) were seen, and no substitution to Lys, thus generating an additional Lys-C cleavage site, could account for the mass differences or any observed peaks in the spectra. This too must be a new protein and is designated uMUP-XVI.

Lys-C digests of the 18,658-Da protein (peak 6, expressed by 10/16 males sampled) had only the L5 peptide mass peak missing, and the difference in protein mass must reside in this peptide. A 2062-Da peak was seen in the MALDI-TOF spectra, 34 Da smaller than the uMUP-I L5 fragment. This protein was termed uMUP-XVII. The third new MUP (uMUP-XVII) differed from uMUP-I at only one peptide: L5, by a decrease in mass of 34 Da. A number of single amino acid substitutions could account for this mass difference, of which a Phe→Ile/Leu substitution was deemed the most likely change. First, this was the only mutation that required a single base change. Second, the position at which the mutation occurred was F56, at which we had previously observed another mutation to valine (Kuhn et al., 1984; Robertson et al., 1997). Finally, the predicted average mass of the protein containing this mutation was 18,559 Da, in close agreement with the observed mass of 18,558 Da. This residue is directed in the central calyx of the MUP structure, and we have demonstrated that the F56V variant demonstrates altered binding of fluorescent probes (Marie et al., 2001). Thus, uMUP-VII from BALB/C, uMUP-X from C57BL/6J, and now uMUP-XVII from Isle of May mice are all variant at this position. All the amino acids at this position are hydrophobic, consistent with their disposition towards the hydrophobic central calyx. UMUP-XVII eluted at the same position on ion exchange chromatography as uMUP-VII from BALB/C, further evidence for the absence of amino substitutions that would evince a charge shift (such as Arg to Glu).

MALDI-TOF mass spectrometry of the Lys-C digest of the 18,693-Da protein (peak 7, expressed in all 17 samples, Figure 3), matched exactly that of uMUP-I. This protein had the same overall charge (i.e., it eluted at the same volume in IEC), the same mass, and resulted in the same Lys-C peptides as uMUP-I, suggesting that it was the same protein. Similar data were obtained for the 18,707-Da protein (peak 8, expressed in all but one of 17 samples, Figure 3), which was identical to uMUP-IX with respect to overall charge, mass, and pattern of Lys-C peptides. These two proteins, initially characterized in inbred mouse strains were, thus, also present in this wild population.

From the five purified proteins mapped by MALDI-TOF mass spectrometry, three new MUPs were identified, each containing at least one mutation. Our previous investigations of MUPs in wild house mice have revealed a much higher degree of heterogeneity than in inbred mice, both as to the number of MUPs expressed per mouse and profile differences between mice even from the same population

(Robertson et al., 1997; Pes et al., 1999; Payne et al., 2001). Although the degree of MUP molecular heterogeneity in Isle of May mice is less than that from other wild mainland populations (Payne et al., 2001), and the extent of sharing of the major protein peaks is substantial, individual MUP profiles were generally more complex than inbred mice, and there was substantially more individual variability in the expression of minor MUP species. This is consistent with selection pressure to maintain a high level of heterozygosity at the MUP loci as predicted.

Although roles for MUPs in ligand release (Hurst et al., 1998) and in direct signaling (Humphries et al., 1999; Brennan et al., 1999) have been established, neither function offers an explanation for the considerable polymorphisms in the MUP family or the combinatorial diversity that ensues from coexpression of multiple proteins in a single urine scent mark. We have proposed that the patterns of MUPs in a scent mark might provide a nonvolatile, stable, and complex label of ownership of the scent mark and, thus, deliver the complex olfactory signal of health, sexual status, and relatedness in the context of an individual animal (Beynon et al., 2001; Malone et al., 2001). We have shown that MUPs contribute to individuality signaling in urine deposits (Hurst et al., 2001) although we do not yet know the relative contribution of the major and minor protein species to this process. This would imply a receptor, or family of receptors, for the MUPs, and the evidence for such a receptor is accumulating. Analysis of the primary sequence of uMUPs, whether from cDNA sequences, where there is direct proof of expression, or of new proteins that we have analyzed by mass spectrometry indicates that much of the heterogeneity resides in endopeptidase LysC limit peptides L4 and L5 (Figure 7).

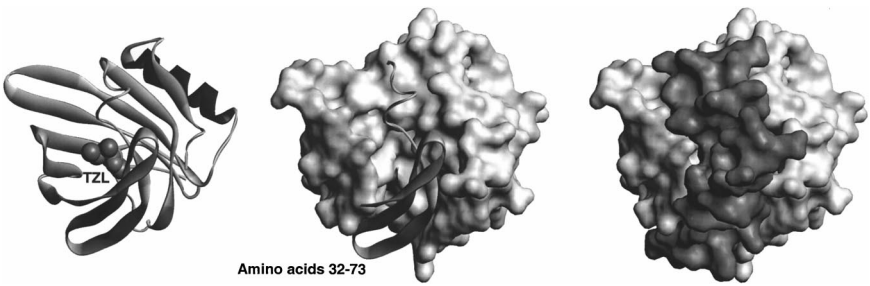

FIG. 7. Three-dimensional structure of MUP showing location of polymorphic variation. The structure of MUP [1MUP.PDB (Bocskei et al., 1992)] was used to generate these views of the protein. The left hand panel is a simple ribbon representation, showing the secondary structure and the approximate position of the ligand 2-*sec*-butyl-4,5-dihydrothiazole [although the disposition of this ligand has recently been revised (Zidek et al., 1999)]. Center panel: the segment of the polypeptide chain representing amino acids 32–73 (Lys C peptides L4 and L5, see text) is displayed in ribbon structure, superimposed on a space filling representation of the remainder of the protein. The right hand panel is a space filling representation in which the L4–L5 segment is shaded darker.

This area of the protein forms an extended patch on the surface of the protein, extended into a beta configuration. In such an extended conformation, the residues both protrude into the central cavity and towards solvent. If there were a selection for amino acid diversity directed to this patch of the surface, it might also lead to changes in cavity residues, which might, therefore, be consequential to the surface effects. Our initial analyses of the kinetics of ligand release have indicated that there are no major differences in the overall release–time curve when a comparison is made of urine or MUP samples derived from different strains and containing different proteins (Robertson et al., 2001). However, such studies do not reflect the environment proximal to a putative MUP receptor, and it is not unreasonable to consider coupling between externally facing residues that interact with a receptor and internally facing cavity-forming residues, such that the binding of the former alters cavity binding characteristics and ligand release.

Acknowledgments—This work was funded by grants from the BBSRC to R.J.B. and J.L.H. and a grant from NERC to J.L.H. The help of Samantha Gray in collecting wild mice from the Isle of May is gratefully acknowledged.

HERITABLE VARIATION OF SEX PHEROMONE COMPOSITION AND THE POTENTIAL FOR EVOLUTION OF RESISTANCE TO PHEROMONE-BASED CONTROL OF THE INDIAN MEAL MOTH, *Plodia interpunctella*

GLENN P. SVENSSON,* CAMILLA RYNE, and CHRISTER LÖFSTEDT

(Received September 27, 2001; accepted March 5, 2002)

Abstract—The short-term evolutionary effect of pheromone-based mating disruption on the mating ability of the Indian meal moth, *Plodia interpunctella*, was investigated. Three independent selection lines were established, and the mating ability of moths in plastic tents treated with high doses of pheromone and in control tents was compared for two consecutive generations. In addition, the heritability of the sex pheromone blend, measured as the ratio of two major pheromone components (*Z*,*E*)-9,12-tetradecadienyl acetate and (*Z*,*E*)-9,12-tetradecadienol, was estimated. Based on a mother–daughter regression analysis including 21 families, the heritability of the pheromone blend was 0.65 ± 0.14, indicating a potential for evolutionary change of the character. However, no increase in mating ability of females in pheromone-treated tents or alteration of the pheromone blend was observed in any selection line when compared with control lines, indicating no or weak selection on the pheromone blend as well as other traits influencing mating ability of this species under the created mating disruption conditions. Factors contributing to the lack of selection effects are discussed.

Key Words—Indian meal moth, *Plodia interpunctella*, Lepidoptera, Pyralidae, sex pheromone blend, mating disruption, heritability, selection.

INTRODUCTION

Mate-signaling in Lepidoptera is often achieved by sex pheromones produced by females to attract conspecific males. Application of synthetic sex pheromones for mating disruption is a successful method for population control of several moth

species (reviewed by Cardé and Minks, 1995). However, treatment by synthetic pheromones could theoretically result in strong selection leading to evolutionary change of the pheromone communication channel, which could reduce the efficiency of the control method. The potential for development of resistance towards pheromone-based mating disruption would depend on the heritable variation of traits involved in pheromone production and perception. Although sex pheromone systems in moths are often strongly canalized, substantial variation in pheromone-related characters has been revealed in several species (reviewed by Löfstedt, 1990).

Phenotypic variation in pheromone communication systems within and between populations is rarely taken into account when using pheromone-based control strategies, i.e., only the major pheromone component(s) or the average multicomponent blend are used as disruptants in field applications. It can be hypothesized that in species showing large phenotypic variation in pheromone-associated traits, females producing high amounts of pheromone may have a higher chance to attract searching males under mating disruption conditions than females producing low amounts of pheromone. Similarly, females producing skewed ratios of pheromone components compared to the applied synthetic background may be recognized more easily by the males. Evidence for increased emission rates in females after long-term exposure to high doses of pheromone has been reported from both field and laboratory studies (Haynes and Baker, 1988; Shani and Clearwater, 2001). So far, no correlated effect on pheromone blend production has been observed (Haynes and Baker, 1988; Shani and Clearwater, 2001). However, many studies have shown that single pheromone components disrupt mating less efficiently compared to more complex blends (Minks and Cardé, 1988), indicating that additional components produced by females may be exploited by males in a pheromone-permeated atmosphere, and that there is a potential for selection for altered blends under mating disruption conditions.

The heritability (h^2) of a character is measured as the fraction of the total phenotypic variance that is attributable to additive genetic factors (Falconer and Mackay, 1996), i.e., how much of the variance observed is subject to selection. Thus, estimates of heritability can be used to predict responses to selection and the potential for evolutionary change of characters. The genetic basis for pheromone production and perception has been examined in several moth species (e.g., Roelofs et al., 1987; Hunt et al., 1990; Foster et al., 1996; LaForest et al., 1997). Significant heritability has been reported for both female pheromone blend composition (Collins and Cardé, 1989) and titer (Collins et al., 1990), as well as male response to sex pheromones in the pink bollworm moth, *Pectinophora gossypiella* (Collins and Cardé, 1990). Heritability studies have also been performed on the communication system of the red-banded leafroller moth, *Argyrotaenia velutinana* (Roelofs et al., 1986; Sreng et al., 1989), the black cutworm moth, *Agrotis ipsilon* (Gemeno et al., 2000), and the cabbage looper moth, *Trichoplusia ni* (Gemeno et al., 2001).

Although selection studies have been performed on pheromone communication traits in several moth species (e.g., Collins and Cardé, 1989; Sreng et al., 1989; Collins et al., 1990; Liu and Haynes, 1994; Shani and Clearwater, 2001), in most cases only one selection line has been analyzed, which makes it impossible to distinguish true selection effects from effects caused by genetic drift. To be able to separate these mechanisms, several independent selection lines have to be analyzed.

The Indian meal moth, *Plodia interpunctella*, is a serious indoor pest on stored products. The first pheromone component identified in this species was (*Z*,*E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12–14:OAc) (Kuwahara et al., 1971). Later, Kuwahara and Casida (1973) and Sower et al. (1974) identified (*Z*,*E*)-9,12-tetradecadienol (*Z*9,*E*12–14:OH) as a second pheromone component, and Vick et al. (1981) showed that by adding the alcohol to the acetate, trap catch of males increased significantly. Recently, Teal et al. (1995) and Zhu et al. (1999) identified (*Z*,*E*)-9,12-tetradecadienal (*Z*9,*E*12–14:Ald) and (*Z*)-9-tetradecadienyl acetate (Z9–14:OAc) as additional pheromone components of the species. Phenotypic variation in both pheromone titer and ratios of individual components within the pheromone blend has been observed in this species (Zhu et al., 1999). Small-scale mating disruption experiments have recently been performed on *P. interpunctella* (Ryne et al., 2001). Mating was suppressed by up to 93% using different doses and composition of pheromones. However, mating disruption was not complete in any of the trials, indicating that some females may be easier to find by males against a background of synthetic pheromone.

In the present study, we investigated: (1) if the variation observed in pheromone blends produced by female *P. interpunctella* is heritable, and (2) if there is a potential for rapid evolution of resistance to synthetic pheromones due to a shift in the pheromone blend.

METHODS AND MATERIALS

Insects. Males and females of *P. interpunctella* were obtained from a laboratory culture maintained at the Department of Ecology at Lund University for 35 generations. This culture was established from a laboratory culture at the Danish Pest Infestation Laboratory at Lyngby, Denmark. About 100 males and 100 females from the Central Science Laboratory, Slough, England, were incorporated into the culture after ca. 20 generations. Larvae were reared on an artificial diet described by Zhu et al. (1999) at 24°C and 60% relative humidity. Pupae were separated according to sex and placed in a 17L:7D photoperiod at 22°C and 60% relative humidity.

Chemicals and Dispensers. The synthetic compounds *Z*9,*E*12–14:OAc, *Z*9,*E*12–14:OH and *Z*9–14:OAc were all purchased from Bedoukian Research Inc., Danbury, Connecticut, USA, and *Z*9,*E*12–14:Ald was synthesized from *Z*9,*E*12–14:OH at the Department of Chemistry, Royal Institute of Technology, Stockholm, Sweden. A blend containing *Z*9,*E*12–14:OAc, *Z*9,*E*12–14:Ald,

*Z*9,*E*12–14:OH, and *Z*9–14:OAc, in the ratio 100:11:18:12 (Zhu et al., 1999), was used as disruptant. A controlled-release system (MSTRS) described by Mafra-Neto and Baker (1996) was used for emission of pheromone.

Gland Extract Analysis. Pheromone gland extracts of individual female *P. interpunctella* (2–4 days old) were dissected 1–3 hr into the scotophase and extracted in 5 μl of hexane with internal standard (2.5 ng/μl of *Z*8–13:OAc). Extracts were analyzed on a Hewlett Packard (HP) 5890 Series II gas chromatograph equipped with a flame ionization detector (FID) and a HP-INNOwax capillary column (30 m $\times$ 0.25 mm ID, 0.25-μm film thickness). Hydrogen was used as carrier gas. Samples were injected in the splitless mode, and the injector temperature was 225°C. The column temperature was maintained at 80°C for 2 min after injection and then linearly increased to 230°C at a rate of 10°C/min.

Heritability Estimate. To test the potential for evolutionary change of the sex pheromone blend, the heritability of the ratio of two major components, *Z*9,*E*12–14:OAc and *Z*9,*E*12–14:OH, was estimated. The two additional components in the pheromone blend, *Z*9,*E*12–14:Ald and *Z*9–14:OAc, were not included in the analysis, as these were not reliably quantified in all females. Sex pheromone production of female *P. interpunctella* stops after mating. However, after oviposition, which normally occurs two to three days after mating, about 50% of the females initiate calling again and may attract males for remating (personal observations). The repeatability of the pheromone blend in females has been shown to be high in the different moth species investigated so far (Barrer et al., 1987; Du et al., 1987; Witzgall and Frérot, 1989; Svensson et al., 1997). Assuming that this is also the case for *P. interpunctella*, a female should produce the same pheromone blend after oviposition as before mating.

Pairs of 1- to 2-day-old males and females were placed in 250-ml plastic jars with artificial diet for mating. After oviposition, pheromone glands were dissected from calling females and analyzed as described above. Larvae originating from matings were kept in jars with artificial diet. Component ratios were analyzed in three or four daughters per family. Mean component ratios of daughters were then plotted against their corresponding mothers and heritability was estimated as twice the slope of the standardized mother–daughter regression line according to Falconer and Mackay (1996).

Selection Effects in Pheromone-Permeated Air. Experiments were performed in transparent plastic tents (2.5 $\times$ 2.5 $\times$ 2.5 m) in a greenhouse at Lund University, Sweden. The tents were purchased from the Central Science Laboratory, Slough, England. Control and treatment tents ($N = 2$) were placed in separate chambers to avoid chemical interference. Conditions during the experiments were: 22–28°C and 28–44% relative humidity. Passive ventilation was provided by creating two net-covered holes (10 $\times$ 15 cm) on opposite walls of each tent. In treatment tents, a MSTRS device was placed at 1 m height and programed to release pheromone every 15 min 24 hr/day. No MSTRS were used in control tents. The four-component

disruptant was diluted in 95% ethanol to correspond to a release rate of 50 μg/min of *Z*9,*E*12–14:OAc. The studies by Mafra-Neto and Baker (1996) and Ryne et al. (2001) were used as guidelines to choose the concentrations released from MSTRS devices. Those studies resulted in suppression of mating by up to 93% and 100% for *P. interpunctella* and almond moths, *Ephestia cautella*, respectively (Mafra-Neto and Baker, 1996; Ryne et al., 2001). Before each experimental period, pheromone was emitted from MSTRS for 48 hr to build up sufficient background concentrations of the disruptant. Between experimental periods, treatment tents were ventilated.

Virgin moths were released into control tents and pheromone-treated tents (10 males and 10 females per tent) and recaptured individually after 24 hr. The density used should be relevant to those under natural indoor conditions, as this species often aggregates. Females from control tents were dissected and checked for the presence of spermatophores, indicating successful mating. Females from treatment tents were put individually into plastic jars with artificial diet for oviposition. After two weeks, the presence of larvae in jars was scored and the mating frequency was estimated. The mating ability of moths from these selection families, as well as unselected moths randomly sampled from the laboratory culture, was then estimated in control tents and treatment tents for two consecutive generations. Only females from selection families in treatment tents were placed in jars for oviposition, i.e., females from selection families in control tents as well as females from the laboratory culture in control and treatment tents were dissected and checked for spermatophores. Up to 16 families originating from mated females in treatment tents were used in the next generation. In total, three independent selection lines were created and run in the same way as described above.

Differences in mating frequencies between moths in pheromone-treated tents and control tents in the initial generation of each selection experiment were analyzed by unpaired *t* tests. In consecutive generations, one-way ANOVAs followed by Tukey's test were applied both within and between lines. Mating frequencies were arcsin $\sqrt{x}$-transformed before analysis. In addition, virgin female offspring from five families in the second generation of each selection line as well as virgin females from the laboratory culture were randomly sampled and the ratio of *Z*9,*E*12–14:OAc and *Z*9,*E*12–14:OH was analyzed. Differences in component ratios between selection lines and unselected moths from the laboratory culture were compared using unpaired *t* test on arcsin $\sqrt{x}$-transformed values.

RESULTS

Heritability Estimate. In total, 21 families were analyzed for pheromone component ratios. Based on a mother–daughter regression, heritability ($\pm$SE) of the sex pheromone blend was estimated to be 0.65 ± 0.14 (Figure 1), calculated as twice

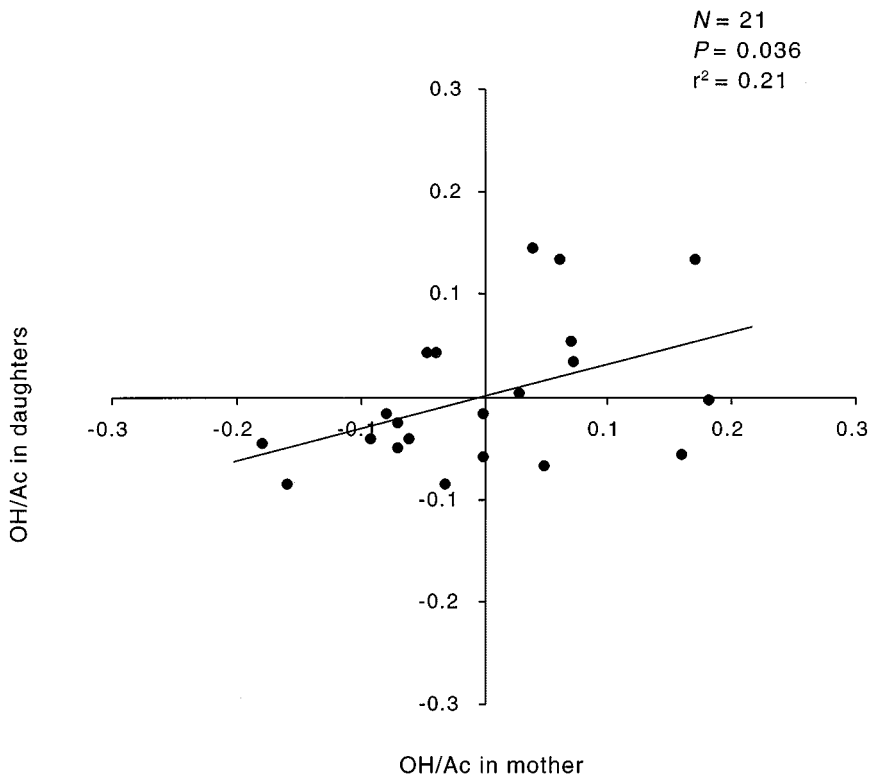

FIG. 1. Mother–daughter regression on ratios of *Z*9,*E*12–14:OH and *Z*9,*E*12–14:OAc based on pheromone gland extracts from 21 families of *P. interpunctella*. Axes intersect at the mean values of all mothers and all daughters. Heritability equals twice the slope (0.325) of the regression line.

the slope of the regression line (slope significantly different from zero, $P = 0.036$). The curve fit was relatively poor ($r^2 = 0.21$). Fifty-four percent (21 of 39) of the mated females initiated calling after oviposition and could be used for gland analysis. Pheromone was absent or found in very small amounts in glands of mated females not performing calling behavior after oviposition. A paired *t* test on ratios of the two pheromone components used in the heritability estimation revealed no difference between mated mothers and the corresponding virgin daughters (0.30 ± 0.02 vs 0.31 ± 0.02, $T = 0.28$, $P > 0.05$). This indicates that the heritability estimate based on parent-offspring regression was not affected by altered pheromone blends produced by mated mothers. In contrast, both pheromone components were produced in smaller amounts in mated mothers compared to their virgin daughters (*Z*9,*E*12–14:OAc: 0.71 ± 0.13 ng vs. 1.62 ± 0.23 ng, $T = 3.47$,

$P < 0.01$; $Z9,E12$–14:OH: 0.21 ± 0.04 ng vs. 0.51 ± 0.08 ng, $T = 3.49$, $P < 0.01$). Therefore, no heritability estimates of quantities of individual components could be performed using parent–offspring regressions.

Selection Effects in Pheromone-Permeated Air. Mating frequencies of moths in pheromone-treated tents and control tents in different generations from three independent selection lines as well as unselected moths are shown in Figure 2. Significant mating disruption in treatment tents compared to control tents was achieved in all experiments. However, the mating frequency in pheromone-treated tents did not differ between selection lines and unselected moths within any generation as would be expected if selection for increased mating ability in pheromone-permeated air had occurred. Mating frequencies of both selection lines and unselected moths remained at a high level in untreated tents throughout the experiments (Figure 2). However, statistical differences in mating frequency were found between selection lines (Figure 2). Thus, data could not be pooled. No difference in ratios of $Z9,E12$–14:OAc and $Z9,E12$–14:OH could be detected between unselected females and selection line females (Figure 3).

DISCUSSION

The present study focused on the short-term evolutionary effect of pheromone-based mating disruption on the mating ability of *P. interpunctella*. By combining heritability and selection studies, we tried to evaluate the potential for resistance development towards mating disruption strategies via evolutionary change of the pheromone blend. The heritability of the ratio of the two major components was estimated to be 0.65, indicating that a significant proportion of the phenotypic variation was due to additive genetic factors and that there should be potential for an evolutionary change of the character. Significant heritability of pheromone component ratios has been reported for other moth species (Table 1). Although the pheromone blend showed high heritability, no significant shift in component ratio

TABLE 1. ESTIMATED HERITABILIY OF TRAITS INVOLVED IN PHEROMONE COMMUNICATION IN MOTHS

Species	Parameter	h^2	Reference
Agotis ipsilon	Pheromone titer	0.56–1.15	Gemeno et al. (2000)
	Blend ratio	0.56–1.09	Gemeno et al. (2000)
Argyrotaenia velutinana	Blend ratio	0.41–0.64	Sreng et al. (1989)
Pectinophora gossypiella	Pheromone titer	0.71	Collins et al. (1990)
	Blend ratio	0.50	Collins and Cardé (1989)
	Male response	0.16	Collins and Cardé (1990)
Plodia interpunctella	Blend ratio	0.65	Present study
Trichoplusia ni	Pheromone titer	0.20–1.13	Gemeno et al. (2001)

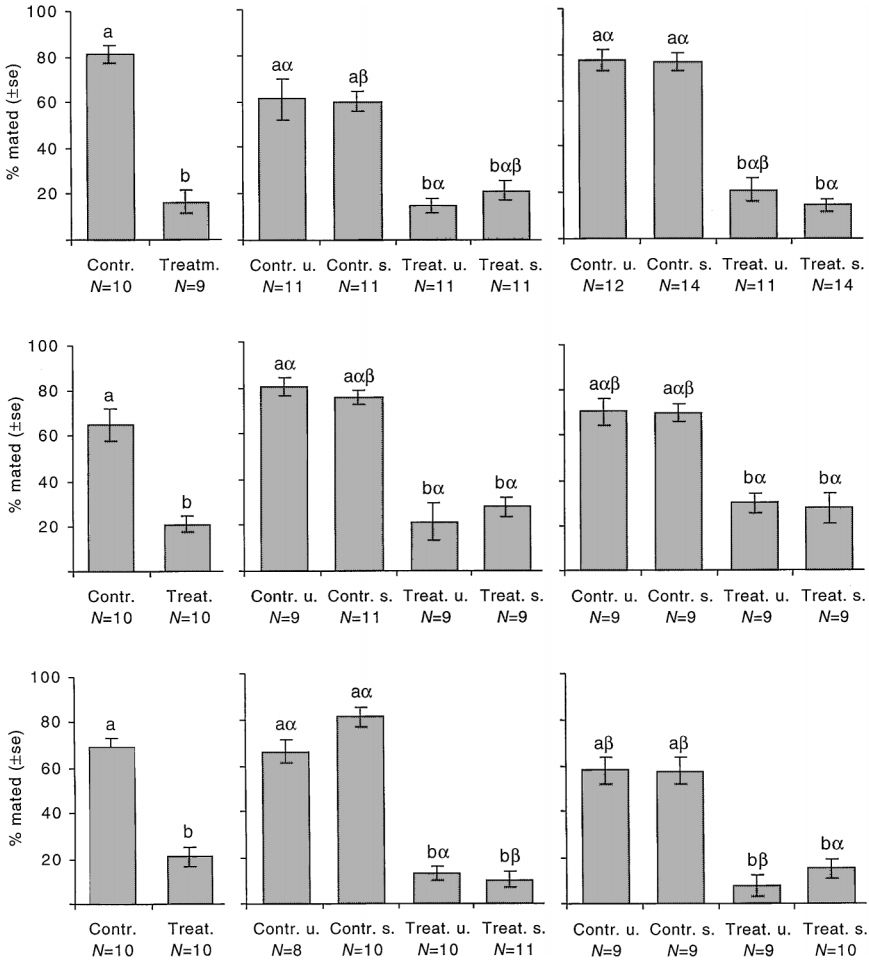

FIG. 2. Effect of selection on mating ability of *P. interpunctella*. Mating frequencies (mean ± SE) of moths from three separate selection lines (s) and of unselected moths from the laboratory culture (u) estimated in control tents or in treatment tents with disruptive doses of sex pheromone for three generations. Bars with different letters are significantly different (one-way ANOVA followed by Tukeys test, $P < 0.05$). English letters show significant differences between groups within each generation of the same line. Greek letters show significant differences within the same generation of one group, e.g., unselected moths in control tents, between lines.

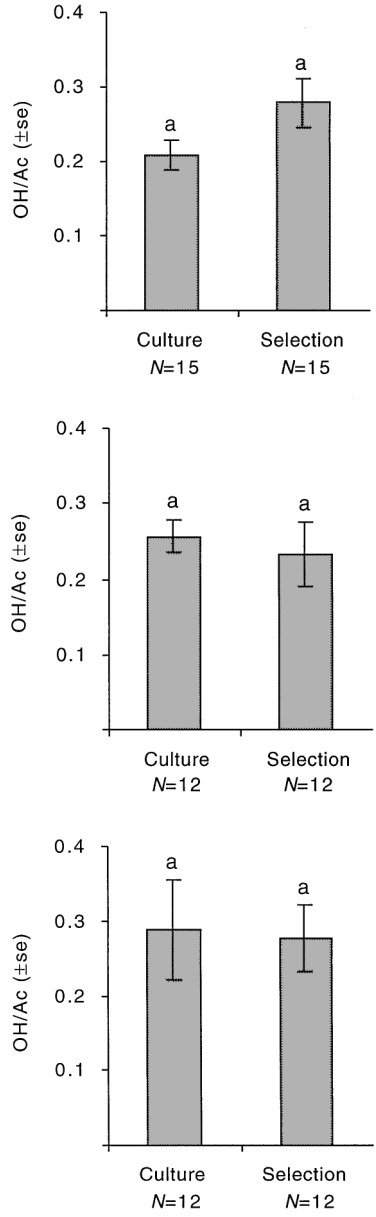

FIG. 3. Ratios (mean ± SE) of *Z*9,*E*12–14:OH and *Z*9,*E*12–14:OAc analyzed from pheromone gland extracts of *P. interpunctella*. Female offspring from the second generation of selection from three independent selection lines were analyzed as well as unselected females from the laboratory culture. Component ratios did not differ between groups in any experiment (unpaired t test, $P > 0.05$).

could be observed in third-generation females from three independent selection lines when compared with unselected females from the laboratory culture. Furthermore, no increase in mating ability under mating disruption conditions was observed in any selection line when compared to control moths. Since mating frequencies of selection lines in control tents were as high as for unselected moths, the lack of selection effect could not be attributable to overall lowering of mating due to inbreeding. Instead, our data indicate weak or no selection on the pheromone blend as well as other traits influencing mating ability of this species under the mating disruption conditions created in this study. The coefficient of the parent–offspring regression curve was relatively low, showing that the curve explained only a small fraction (21%) of the variation found in pheromone component ratios. As the curve fit was poor, the heritability may have been overestimated. The relatively small sample size and maternal effects could be factors explaining the low r^2 value.

Few studies have investigated how selection may affect the potential for resistance development towards synthetic pheromones in moths. Torres-Vila et al. (1997) performed a selection experiment on the European grape vine moth, *Lobesia botrana*. Mating in olfactometers permeated with high doses of the major sex pheromone component, (*E*,*Z*)-7,9-dodecadienyl acetate, significantly increased after only one generation of selection. However, the correlation between mating ability and pheromone production was not evaluated in that study. Furthermore, Torres-Vila et al. (1997) used only the major component of the sex pheromone as disruptant, whereas a multicomponent blend was used for disruption in the present study, which may have limited the potential for resistance development. Shani and Clearwater (2001) analyzed the effect on pheromone production in *E. cautella* females exposed to high doses of pheromone. Although females from the selection population produced significantly more pheromone compared to the nondisrupted population after seven generations of selection, overall pheromone production declined drastically in the disrupted population as well as the nondisrupted population during the selection experiment. However, the effect on pheromone production was not associated with an increased mating ability of the disrupted population in pheromone-permeated air when compared with the nondisrupted population (Shani and Clearwater, 2001). Haynes and Baker (1988) showed that *P. gossypiella* females from a population exposed to high doses of synthetic pheromones emitted significantly more pheromone during 1985 compared to 1982 and 1983. Although the increase in pheromone emission observed in these two studies was minor and would probably not result in effective resistance to mating disruption, it could be a result of this new selection pressure imposed on the populations.

In the majority of cases where selection effects on moth pheromone communication systems have been shown (e.g., Collins and Cardé, 1989; Sreng et al., 1989; Collins et al., 1990; Shani and Clearwater, 2001), only one selection line has been used, which makes it impossible to separate true selection effects from

effects caused by genetic drift. This is clearly shown in the study by Sreng et al. (1989) where a two-way selection scheme was carried out to change the ratio between two pheromone components of *A. velutinana*. One "high-ratio" line and one "low-ratio" line were run for three generations of selection and then maintained by random mating for six additional generations. Whereas no change in composition of the pheromone blend occurred in the low-ratio line after the selection pressure was removed, the blend in the high-ratio line continued to change in the same direction and at almost the same rate as during the intense selection. Genetic drift is the most probable cause for this asymmetry in change between the two lines.

The only clear evidence so far of a change in a pheromone communication system via selection is in the cabbage looper moth, *Trichoplusia ni* (Liu and Haynes, 1994). A mutation occurred in a laboratory culture of this species, causing a dramatic change in the composition of the pheromone produced by mutant females compared to the wild type (Haynes and Hunt, 1990). The mutant colony was split into two colonies and reared separately. Initially, the mutant blend attracted low numbers of conspecific males (Haynes and Hunt, 1990), but after 49 generations of rearing, the male response towards the altered pheromone increased to the same level as to the normal blend. As this change occurred in both colonies, it should reflect a true selection effect and not an effect caused by genetic drift. Recently, a selection experiment was performed on the mating ability of mutant and wild-type *T. ni* in the field under mating disruption conditions using the normal pheromone blend as disruptant (Evenden and Haynes, 2001). Interestingly, for each generation of selection, the relative proportion of mutant females increased in treatment cages compared to control cages. After four generations, the proportion of the mutant phenotype was significantly greater in treated cages compared to control cages. Thus, mating disruption programs using the average pheromone blend may select for females producing skewed blends and this would increase the potential for evolution of resistance to mating disruption.

The fact that we analyzed three independent selection lines without finding any effects on pheromone composition or mating ability suggests that there was at least a limited potential for resistance development to mating disruption in a few generations' time. However, the possibility that resistance towards mating disruption can evolve after more generations of selection cannot be ruled out. As shown by Haynes and Hunt (1990), it may take substantial numbers of generations before any selection effects are observed. Thus, our results are difficult to interpret.

The potential for development of resistance towards mating disruption via selection for altered blends or higher pheromone production in females may be small in natural populations, as pheromone communication systems in moths are often strongly canalized, i.e., genetic correlations among individual components can limit rapid changes of the pheromone blend in response to selection. Genetic correlations of components involved in the pheromone blends of normal and mutant *T. ni* have been investigated by Gemeno et al. (2001). As the strains differ in the

pattern of genetic correlations, they will evolve differentially even when the same selection pressure is imposed. Although large variation in component ratios was found in *P. interpunctella*, the pheromone components were highly correlated to each other ($r^2 \approx 0.90$), indicating a limited potential to change the blend by selection.

Attempts to change the pheromone blend by selection have been performed on *P. gossypiella* (Collins and Cardé, 1989) and *A. velutinana* (Roelofs et al., 1986), two species which utilize geometric isomers as main pheromone components. Statistically significant changes of isomeric ratios were obtained by selection in both species, but they were small. Although large heritable variation in pheromone component ratios was found among females in our laboratory culture of *P. interpunctella*, the results do not support the hypothesis of resistance development towards mating disruption via selection for altered blends. In addition, a broad response window in male moths to pheromone blends may further decrease the probability of such a scenario. However, no data are available on male response to different ratios of the investigated pheromone components of *P. interpunctella*.

A more probable route to resistance may be via point mutations with major effects on the communication channel. Although the chance of finding and evaluating the effect of such rare mutations is strongly limited in laboratory as well as natural populations, the studies on wild-type and mutant colonies of *T. ni* (Haynes and Hunt, 1990; Liu and Haynes, 1994; Evenden and Haynes, 2001) show that changes of the communication channel can occur and may lead to evolution of resistance to mating disruption.

The doses used in our experiments may have been too high to mimic large-scale mating disruption conditions, making it hard to extrapolate our data to future control programs. However, males could probably use other cues than sex pheromone to locate mates in pheromone-permeated air. McNeil (1992) proposed that if there is heritable variation in the ability to exploit other cues than those associated with long-range sex pheromones, selection could increase the chance of locating a mate under mating disruption conditions. *Plodia interpunctella* has a complex mating system involving long-range male attraction to sex pheromones emitted by females as well as short-range communication by olfactory and acoustic cues (McLaughlin, 1982; Trematerra and Pavan, 1995). The relatively high population density of moths in our small-size tent experiments should facilitate short-range communication. However, this was not reflected in any selection effect on mating ability. In addition, insects were removed from the tents after 24 hr, which may have resulted in a limited selection effect compared to if they would have been removed after several days.

To summarize, in spite of significant heritable variation in pheromone production of *P. interpunctella*, we found no evidence for resistance evolution towards mating disruption due to a shift in the pheromone blend. However, due to the few generations of selection conducted in this study, we cannot rule out the possibility

that resistance can evolve after more generations of selection. Long-term selection studies in pheromone-permeated air using independent lines are needed to get a better picture of how populations are affected by high doses of synthetic pheromone to facilitate the development of safe strategies of pheromone-based control of moths.

Acknowledgments—We thank Rickard Ignell, Karin Johnson, and Christian Olsson for technical assistance and Rickard Unelius and Ellen Santangelo for synthesis of the aldehyde. This study was funded by MISTRA, the Swedish Council for Forestry and Agricultural Research (SJFR), the Cerealia Foundation R&D and the Knut and Alice Wallenberg Foundation.

(Received June 15, 2001; accepted March 18, 2002)

Abstract—Studies to determine possible differences in the pheromone communication system of three different populations of the corn stalk borer *Sesamia nonagrioides* (Lef.) in France, Spain, and Greece were carried out. The two main pheromone components (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac) and (*Z*)-11-hexadecenol (*Z*11–16:OH), were detected in all analyses with very small differences in the three populations. Among the minor components, analyzed by GC-MS on concentrated gland extracts from French and Greek origin females, (*Z*)-11-hexadecenal (*Z*11–16:Ald) was detected in minor amounts. Wind-tunnel and field studies revealed similar a male response in the three populations to pheromone glands extracts and synthetic pheromone regardless of the

female/male origin. The results do not support the assumption of the existence of different pheromone types of the corn stalk borer *S. nonagrioides* due to geographic isolation.

Key Words—*Sesamia nonagrioides*, Lepidoptera, Noctuidae, sex pheromones, (*Z*)-11-hexadecenyl acetate, (*Z*)-11-hexadecenol, (*Z*)-11-hexadecenal, dodecyl acetate, geographic variation.

INTRODUCTION

The corn stalk borer *Sesamia nonagrioides* (Lef.) (Lepidoptera: Noctuidae) is considered the most serious corn pest in many countries distributed across southern Europe between the 45°N parallel and northwest Africa. The insect completes a variable number of generations annually, from two in southern France to up to four in Morocco (Anglade, 1972).

The sex pheromone of *S. nonagrioides* was identified by Sreng et al. (1985) as a mixture of (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac) (**1**) and (*Z*)-11-hexadecenol (*Z*11–16:OH) (**2**). The two compounds tested separately or as a 90:10 blend were attractive to males in laboratory bioassays, but traps baited with the two-component blend were not effective. The same authors reported that hexadecyl acetate (16:Ac) was present in the pheromone gland extract, but no biological activity was established. Later, the isolation of two additional components, (*Z*)-11-hexadecenal (*Z*11–16:Ald) (**3**) and dodecyl acetate (12:Ac) (**4**), was reported (Mazomenos, 1989). The four-component blend **1** + **2** + **3** + **4** in a 69:8:8:15 ratio increased male attractiveness to the pheromone traps.

Field trials conducted in France and Spain with pheromone traps to monitor moth populations indicated that traps baited with the four-component blend **1–4** in 69:8:8:15 ratio were less attractive than traps baited with virgin females. In addition, high numbers of other sympatric moth species were also captived by these traps (Perdiguer et al., 1992; Frérot et al., 1997a).

An improved formulation for male attractiveness and selectivity was developed by Sans et al. (1997) as a mixture **1–4** in a 77:8:10:5 ratio, based on wind-tunnel and field tests in Spain. However, the new formulation was again less effective than virgin females in field tests carried out in southern France (Frérot et al., 1997a). In this context, genetic differences between Spanish and French populations from certain geographic areas have been shown, and insect movements usually occur through the Atlantic or Mediterranean coast but not across the Pyrenees (Bues et al., 1996). In several noctuid species, differences in the pheromone composition produced by the females and the male responses to pheromone blends of different geographic populations have been well documented (Cardé and Baker, 1984; Phelan, 1993).

We report here comparative studies aimed at determining: (1) possible differences in the sex pheromone communication system of three *S. nonagrioides*

populations in France, Spain, and Greece; (2) male response of the three populations both to natural and synthetic pheromone in wind tunnel and field tests; and (3) cross-mating behavior among the three populations.

METHODS AND MATERIALS

Insects. Moths used in this study were derived from artificially reared colonies maintained in each laboratory. The composition of the artificial diet used in the French and Spanish laboratories has been described by Poitout and Bues (1970). In Greece, the larvae were reared on a diet described by Tsitsipis et al. (1983). Larvae and pupae were maintained at $27 \pm 1^{\circ}$C with a 16L:8D regime and relative humidity of $60 \pm 5\%$. Moths were separated by sex upon emergence and kept in $30 \times 30 \times 30$-cm screen cages in separated chambers until use. Insects at the pupal stage were exchanged among the collaborating groups.

Behavior Studies. Wind-tunnel bioassays were conducted in the three laboratories. The type of wind tunnel and conditions used were $150 \times 35 \times 35$-cm glass tunnel at 25–27°C and 65% relative humidity in Greece; $140 \times 70 \times 40$-cm Plexiglas tunnel at 25–27°C and 80% relative humidity in France, and $180 \times 55 \times 50$-cm glass tunnel at 24–26°C and 65% relative humidity in Spain. In all cases, air from the pheromone-free room was generated by a centrifugal fan and filtered to provide laminar airflow. The air speed through the tunnels was 50 cm/sec. The air inside the tunnels was vented outside via an exhaust tube at the downwind end of the tunnels. Red light (2.5–3 lux) that allowed observation and recording with CCD cameras illuminated the tunnels. Males, 2–3 days old and placed individually in screen cages, were transferred to the test room before the onset of the dark period. Wind-tunnel tests were run 5 hr after lights off when the peak of sexual activity occurred (Babilis and Mazomenos, 1992). The following sequences of behavior were recorded: wing fanning and taking flight, close approach (ca. 10 cm), and contact with the source. Only those males arresting at the pheromone source for a period of 5 sec or more were recorded as contact with the source. The pheromone baits were hung 15 cm apart. Males were introduced in the tunnel 1.2–1.6 m downwind of the pheromone bait, and each test lasted 5 min. The behavior responses of males from the three populations tested were compared using χ^2 homogenity test ($P \leq 0.05$).

Pheromone Sources. Pheromone glands and gland extracts obtained from calling females, as well as the synthetic pheromone adsorbed on a filter paper (Whatman No. 1; 1.5×1.5 cm), were used as baits for the wind-tunnel tests.

Synthetic Chemicals. Synthetic pheromone components were obtained from the Sociedad Española de Desarrollos Químicos, S.A (SEDQ) (Barcelona, Spain). The components were found to be 96–98% pure by GC analysis.

Gland Extraction. The pheromone was collected from the pheromone gland of calling virgin females during the dark period, 5 hr after lights off. Each time, five glands were removed with forceps and extracted in 200 μl of solvent for 30 min. The solvents used were pentane, hexane, and methylene chloride. The extracts were concentrated under a gentle stream of nitrogen and used for behavior studies or analyzed by GC-MS. If they were not immediately used, the extracts were stored at -20°C.

Solid-Phase Microextraction (SPME). For the SPME technique, the fiber used for pheromone collection was a 7-μm polydimethyl siloxane (Supelco Inc., Bellefonte, Pennsylvania, USA). The fiber was gently rubbed on the surface of the gland of a calling female for few minutes, and the chemicals adsorbed on the fiber were directly analyzed by GC or GC-MS (Frérot et al., 1997b).

GC and GC-MS Analyses. GC and GC-MS analyses of gland extracts from the three colonies were carried out in each laboratory. Particular attention was paid not only to the detection of major pheromone components of the extracts but also to the presence of other possible minor components that might contribute to increase male attraction. Electron impact ionization (EI) mass spectra (70 eV) were obtained under SCAN or SIM mode. The following instruments and conditions were used: In Greece, an HP-5890 Series II gas chromatograph interfaced to a Fisons VG Trio 1000 mass spectrometer was used with a DB-5 (J&W Scientific) fused silica capillary column 60 m $\times$ 0.25 mm ID, programmed at 50°C for 2 min, to 250°C at 5°C/min for 1 min, and then to 280°C at 2°C/min. In France, a Delsi-300 gas chromatograph interfaced with a Nermag R30-10 mass spectrometer and with a DB-5 (J&W Scientific) capillary column 25 m $\times$ 0.32 mm ID was used. The GC conditions were injection at 120°C and programmed to 260°C at 10°C/min. In Spain, a Fisons gas chromatograph coupled to a Fisons MD-800 mass selective detector with a HP-1 (Hewlett Packard) capillary column 30 m $\times$ 0.20 mm ID was utilized. The GC conditions were injection at 100°C and programmed to 250°C at 5°C/min, and then to 280°C at 10°C/min. Compounds in the gland extracts and SPME fiber were identified by comparison of the retention times and mass spectra with those of authentic standards.

Field Tests. Field trials were conducted in Catalonia (northeast Spain), Aude (southern France), and Kopais (central Greece). The experimental design, type of traps (Universal Moth Traps), and pheromone dispensers used were the same for the three countries. Rubber septa (Aldrich Ltd, No 10070-6), used as dispensers, were loaded with 100 μg of the two pheromone blends of $\mathbf{1}+\mathbf{2}+\mathbf{3}+\mathbf{4}$ in 69:8:8:15 and 77:8:10:5 ratios. Dispensers were prepared in Greece and mailed to the other groups. Funnel traps were installed at 1.5 m height, 1 m from the corn margin at the four corners of each field. Baited traps were in operation from April until late October, the traps were rotated clockwise weekly, and males captured were recorded and removed. Pheromone dispensers were renewed every two months.

Statistics. For statistical analysis, trap captures within sites were analyzed by using the paired t test ($P \leq 0.05$). The day effect was eliminated by averaging the trap captures for each of the two blends tested. Prior to analysis, the data were $[\log_{10}(x + 1)]$ transformed.

RESULTS

Male Response to Pheromone Glands and Gland Extracts from Calling Females. These studies were carried out to establish whether females attract nonsympatric males. A series of tests were done with excised pheromone glands from calling French females as the attractant source for Spanish, Greek, and French males. Almost all males tested (86–100%) initiated flight, and among them 52–72% successfully contacted the source (Table 1). Among the three populations, Spanish males displayed a higher response in all behavioral steps than the other two strains, but no significant differences were observed.

The effect of gland extracts from calling females on males' response was also studied in two independent series of experiments when extracts of 1 and 4 female equivalents (FE) were used as baits. Males of the three populations were similarly attracted (Table 1). The proportion of males that displayed close approach or made contact with the pheromone source was higher in 4 FE bait compared to the 1 FE bait. No difference was detected at the same concentration; i.e., males from different geographical origins showed the same responses.

TABLE 1. PERCENTAGE OF *Sesamia nonagrioides* MALES RESPONDING IN WIND TUNNEL TO FEMALE PHEROMONE GLANDS AND PHEROMONE GLAND EXTRACTS[a]

Pheromone source	Males origin	Behavior steps[b]		
		Take off	Close approach	Landing
Experiment 1 (pheromone gland)				
French	French	86[a]	68[b]	52[c]
French	Greek	95[a]	72[b]	64[c]
French	Spanish	100[a]	76[b]	62[c]
Experiment 2 (gland extract, 1 FE)				
French	Greek	95[a]	54[b]	27[c]
Greek	Greek	96[a]	58[b]	31[c]
Experiment 3 (gland extract, 4 FE)				
Spanish	Spanish	77[a]	77[b]	77[c]
Spanish	Greek	91[a]	76[b]	65[c]

[a] Glands and extracts were obtained from calling females of the three populations ($N = 20$, experiment 1; $N = 15$, experiment 2; $N = 30$, experiment 3).

[b] For each experiment, values within the same type of behavior and with the same letter are not significantly different (χ^2 homogenity test, $P \leq 0.05$).

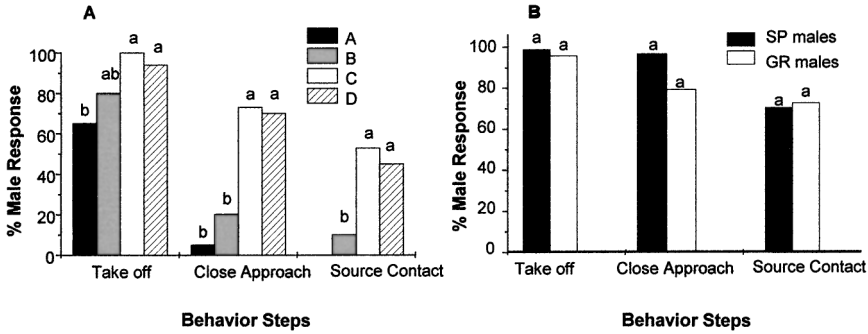

FIG. 1. Percentage of response of male *Sesamia nonagrioides* of three geographic populations (French, Spanish, and Greek) to 1 mg of various combinations of the synthetic pheromone components: **(A)** French males responded to A = **1**; B = **1** + **2** in 90:10; C = **1** + **2** + **3** in 90:10:5; D = **1** + **2** + **3** + **4** in (69:8:8:15) ($N = 20$); **(B)** Spanish and Greek males responded to **1** + **2** + **3** in 84:15:1 ratio ($N = 15$).

Male Response to Synthetic Pheromone Components. The effect of various combinations of the synthetic pheromone components on males' behavior from the three populations was also studied. French males showed a low response when exposed to component **1**. The addition of component **2** at a ratio of 90:10 induced more males to orient to the source, with a low percentage landing on the source. The three-component blend (**1** + **2** + **3**), in a 90:10:5 ratio, elicited a maximal male response, while the four-component blend of **1** + **2** + **3** + **4** in a ratio of 69:8:8:15 did not improve male attraction (Figure 1A). The response of Greek and Spanish males to the three-component pheromone blend (**1** + **2** + **3**) in an 84:15:1 ratio, was similar. (Figure 1B).

Identification of Pheromone Components in Gland Extracts of Females of Three Populations. The components **1**, **2**, and 16:Ac were present in all pheromone gland extracts of the three populations in variable ratios, when the data produced by the three groups were compared. The variance among the three populations was lower when the extracts were analyzed under the same conditions by one specific group (Table 2). Aldehyde **3** was detected in minor amounts directly by GC-MS on relatively concentrated gland extracts obtained from French and Greek origin females. Moreover, 12:Ac was detected in all three populations, and in some of the analyses, 14:Ac was present.

GC and GC-MS analyses using the SPME technique revealed the presence of **1**, **2**, and the saturated 16:Ac with small differences among the three populations. The ratio of the three components (**1**, **2**, and 16:Ac) identified from French, Spanish, and Greek females was 96:3:1, 96.5:1.5:2, and 95.5:3:1.5, respectively.

[c] Not detected (limit of detection was 200 pg).

Field Trials with Synthetic Pheromone Blends. Field experiments were conducted in each country to assess male response to two pheromone blends: A, $\mathbf{1} + \mathbf{2} + \mathbf{3} + \mathbf{4}$ in a 69:8:8:15 ratio and B, $\mathbf{1} + \mathbf{2} + \mathbf{3} + \mathbf{4}$ in a 77:8:10:5 ratio dispensed on rubber septa. In all countries, traps were set up from early May to the middle of October 1998, so that the two generations per year of the insect in France and the three generations per year in Spain and Greece were covered. The mean numbers of moths trapped in each generation and each country for the two-pheromone blends were not significantly different (Table 3).

[a] A: 69:8:8:15 and B: 77:8:10:5 for $\mathbf{1} + \mathbf{2} + \mathbf{3} + \mathbf{4}$. The comparative field studies were conducted in France, Spain, and Greece, during 1998. Means followed with the same letter in each row and for each country are not significantly different (*Paired t test*, $P \leq 0.05$).

DISCUSSION

The components *Z*11–16:Ac, *Z*11–16:OH, and 16:Ac were unambiguously detected in all French, Spanish, and Greek extracts. However, analyses of the pheromone gland extracts from females of the different populations revealed differences regarding the occurrence of certain minor pheromone components, as well as the ratio of the chemicals present in the blend. The presence of *Z*11–16:Ald in trace quantities was detected by GC-MS in Greek and French origin female extracts. The detection of *Z*11–16:Ald in trace quantities, after treatment of the pheromone gland with PBAN and subsequent derivatization with pentafluorobenzyl hydroxylamine hydrochloride (Mas et al., 2000) and by SPME headspace volatiles collected from French female pheromone glands incubated in physiological solution (Améline, 1999), has been described elsewhere. The presence of this compound in small quantities and its possible biosynthesis during release makes its detection and quantification difficult and sometimes ambiguous. The fourth component of the blend, 12:Ac, was detected only by one group, and in some cases, 14:Ac was detected in gland extracts and SPME collections. 12:Ac, 14:Ac, and 16:Ac were not attractive to males when tested individually; neither did they improve male attractiveness when added to the blend (Ameline, 1999). No other minor active components were detected.

Minor differences in the ratio of the two major components *Z*11–16:Ac and *Z*11–16:OH were also observed. Studies on pheromone components of other lepidopteran species demonstrated high levels of repeatability in the ratio of the compounds emitted by individual females for geometric isomers, while the variance for other components was high (Barrer et al., 1987; Witzgall and Frérot, 1989).

Wind-tunnel experiments revealed no significant difference of male responses to various pheromone sources despite the different origin of male. The results with the synthetic pheromone components revealed that *Z*11–16:Ald is essential for male attraction, while 12:Ac does not increase male attraction. These results agree with those reported by Sans et al. (1997), in that 12:Ac is not essential for male response in wind tunnel experiments. In this context, single-sensillum studies have revealed the existence of different receptor cells tuned to compounds **1**, **2**, and **3**, but not **4** (Guerrero et al., in preparation).

Furthermore, wind-tunnel and field experiments indicated that males of the three populations responded equally well to a relatively broad range of pheromone blends, suggesting that the *S. nonagrioides* male response window is wider than the variability observed in female pheromone production. Similar male response has been reported for other moths (Haynes and Baker, 1988; Löfstedt, 1990).

Variation in the pheromone composition of several lepidopteran species from different geographic populations is well documented (Cardé and Baker, 1984; Phelan, 1993). In our case, although some variations in the pheromone composition between the three populations of *S. nonagrioides* were detected, the

wind-tunnel and field results do not support the assumption of the existence of different geographic pheromone types of the corn stalk borer. Our combined data suggest that new and improved formulations should be developed for monitoring or mating disruption experiments, particularly focusing on improving the stability and slow release of the minor pheromone components.

Acknowledgments—This research was partially supported by the Commission of the European Union, Agriculture and Fisheries (FAIR, CT96-1302). The IIQAB-CSIC group also gratefully acknowledges CICYT (AGL2000-1695-C02-01) and Comissionat per a Universitats i Recerca (1997SGR 00021) for financial support. Thanks are also given to Dr. Jaume Castellà (SEDQ) for providing us with the synthetic pheromone components.

(Received September 8, 2001; accepted March 16, 2002)

Abstract—Screening tests of synthetic lepidopteran sex pheromones were carried out at orchards in the Mekong Delta over an approximately two-year period starting from December 1998. Monoenyl acetates with a C_{10}–C_{14} chain attracted six species distributed mainly in Southeast Asia: *Adoxophyes privatana*, *Archips atrolucens*, and *Meridemis furtiva* in the Tortricidae family, and *Argyrogramma signata*, *Spodoptera pectinicornis*, and *Zonoplusia ochreata* in the Noctuidae family. These were in addition to three other noctuid species that had been attracted during previous field examinations within a temperate zone. Furthermore, male moths of three species belonging to the Cosmopterigidae, Gelechiidae, or Batrachedridae family were also caught by traps baited with acetates. Trienes with a C_{18}–C_{21} chain and their monoepoxides, which are stereotypes of pheromones secreted by females in the Geometridae family, failed to attract any geometrid male, but attracted three Noctuidae species and four Arctiidae species.

Key Words—*Adoxophyes privatana, Archips atrolucens, Meridemis furtiva, Argyrogramma signata, Spodoptera pectinicornis, Zonoplusia ochreata*, Tortricidae, Noctuidae, Plusiinae, Arctiidae.

INTRODUCTION

Sex pheromones have been identified in female moths of about 500 species (Arn et al., 1992, 1997). Some are used as tools for integrated pest management (Cardé and Minks, 1995; Wakamura, 1992). The largest chemical group of lepidopteran pheromones is composed of unsaturated C_{10}–C_{18} straight-chain compounds with a functional group at the terminal position (type I), and they are biosynthesized from saturated fatty acids. The pheromones of the second group consist of unbranched C_{17}–C_{23} (3*Z*,6*Z*,9*Z*)-trienes, (6*Z*,9*Z*)-dienes, and their monoepoxy derivatives (type II), which lack a terminal functional group and are probably biosynthesized from linolenic acid and linoleic acid (Millar, 2000). Additionally, field screening of the synthetic pheromones and their analogs has revealed specific male attractants of more than 1200 lepidopterous species (Arn et al., 1992, 1997). Most of these species are cosmopolitan or are distributed within a temperate zone, and knowledge of the sex pheromones and the attractants of tropical species is limited. We are interested in developing sex pheromones of tropical species for a new pest control program in Vietnam. We started screening tests of chemicals in both types I and II at the end of 1998 in order to gain information on the mating communication systems of the tropical species and to compare the results in Southeast Asia with those of past field tests, particularly with a survey conducted in Japan. This paper deals with two-year tests conducted at orchards in the Mekong Delta. The results are informative for pheromone research in Vietnam, since specific attraction for males of 19 species was found, including some moths from groups in which no sex pheromones or sex attractants have been identified.

METHODS AND MATERIALS

Chemicals. The chemical structures of synthetic lures are abbreviated as follows; *Z* = *Z* double bond, *E* = *E* double bond, epo = *cis*-epoxy ring, number before hyphen = position of a double bond or epoxy ring, number after hyphen = carbon number of a straight chain, OAc = acetate, OH = alcohol, Ald = aldehyde, and H = hydrocarbon. Seven monoenyl acetates (*Z*5–10:OAc, *Z*5–12:OAc, *Z*7–12:OAc, *Z*9–12:OAc, *Z*9–14:OAc, *Z*11–14:OAc, and *E*11–14:OAc), three monoenyl alcohols (*Z*7–12:OH, *Z*11–14:OH, and *E*11–14:OH), and two dienyl acetates (*Z*9,*E*11–14:OAc and *Z*9,*E*12–14:OAc) with >97% purity were supplied by Shin-etsu Chem. Co., Ltd. (Tokyo, Japan). Monoenyl aldehyde (*Z*11–14:Ald) was prepared from *Z*11–14:OH by oxidation with pyridinium chlorochromate. Four trienes (*Z*3,*Z*6,*Z*9–18:H, *Z*3,*Z*6,*Z*9–19:H, *Z*3,*Z*6,*Z*9–20:H, and *Z*3,*Z*6,*Z*9–21:H) and 12 epoxydienes (racemic mixtures of epo3,*Z*6,*Z*9–18:H, *Z*3,epo6,*Z*9–18:H, *Z*3,*Z*6,epo9–18:H, and their C_{19}–C_{21} homologs) with >95% purity were synthesized from linolenic acid as previously described (Ando et al., 1993).

Field Tests. One milligram of each chemical (single-component lure) or one milligram of a mixture of two chemicals (two-component lure) dissolved in *n*-hexane (about 100 μl) was applied to a white rubber septum (8 mm OD, Aldrich Chemical Co., Ltd.), which was not specially coated with any antioxidants or stabilizers. After vaporization of the solvent, the septum was placed in a sticky trap (30 $\times$ 27 cm bottom plate with a roof, Takeda Chemical Ind., Ltd., Osaka, Japan). Each lure was replicated twice, and four extra traps with a septum including no chemicals were used as control. Traps were set 1.5 m above the ground.

In Cantho City, Vietnam, screening tests were carried out at orchards of Chinese apple, guava, and logan from December 1998 to November 1999 (test 1), and at other orchards of plum and guava from January to December in 2000 (test 2). Each lure was replaced every two months. Captured moths were counted once a week.

The activity of the following 28 lures was examined in test 1; *Z*7–12:OAc and its mixtures with *Z*9–14:OAc (9:1, 5:5, and 1:9), *Z*9–14:OAc and its mixtures with *Z*11–14:OAc (9:1, 5:5, 1:9, and 0:10), *E*11–14:OAc and its mixtures with *Z*11–14:OAc (9:1, 5:5, and 1:9), *Z*11–14:OH and its mixture with *Z*11–14:OAc (5:5), *E*11–14:OH, *Z*9,*E*11–14:OAc and its mixture with *Z*9–14:OAc (5:5), *Z*9,*E*12–14:OAc and its mixture with *Z*9–14:OAc (5:5), *Z*3,*Z*6,*Z*9–18:H, *Z*3,*Z*6,*Z*9–19:H, and each of their monoepoxy derivatives. In test 2, the activity of the following 28 lures was examined; *Z*5–10:OAc and its mixtures with *Z*7–12:OAc (9:1, 5:5, 1:9, and 0:10), *Z*5–12:OAc and its mixtures with *Z*7–12:OAc (9:1, 5:5, and 1:9), *Z*9–12:OAc and its mixtures with *Z*7–12:OAc (9:1, 5:5, and 1:9), *Z*7–12:OH and its mixtures with *Z*7–12:OAc (9:1, 5:5, and 1:9), *Z*11–14:Ald and its mixtures with *Z*11–14:OAc (5:5 and 0:10), *Z*3,*Z*6,*Z*9–20:H, *Z*3,*Z*6,*Z*9–21:H, and each of their monoepoxy derivatives.

Identification of Insects. Some parts of attracted moths were sent to Japan for species identification by Prof. Toshiya Hirowatari (species in the families Tortricidae, Cosmopterigidae, Gelechiidae, and Batrachedridae), Dr. Shigero Sugi (species in the families Noctuidae and Arctiidae), and Dr. Masashi Nomura (species in the subfamily Plusiinae).

RESULTS AND DISCUSSION

Overview of Discovered Attractants. For field trials in the first year (test 1), chemicals with a C_{14} chain were exclusively selected as lures among pheromone components in type I in order to attract tortricid and noctuid males. These compounds have been frequently identified from pheromone glands of the females (Arn et al., 1992, 1997). Since lepidopteran pheromones are generally composed of multiple components (Arn et al., 1992, 1997), we made some two-component lures in addition to single-component lures. The mixing ratio was limited to one

(5:5) or three (1:9, 5:5, and 9:1) to reduce the total number of traps. In test 1, *Z*7–12:OAc, only one chemical with a different chain length attracted several species. Based on this result, attraction by the mixtures including *Z*7–12:OAc as a common component was mainly evaluated in the next year (test 2). Among the chemicals in type II, trienes and epoxydinenes with a C_{18}–C_{21} chain were systematically evaluated for their activity in test 1 and test 2 without mixing with each other.

The field tests at orchards in the Mekong Delta successfully revealed the species-specific male attraction of 19 lepidopteran species. Table 1 shows the attractants, the main flight seasons, and the total number of captured moths. While the sex pheromones of two species and an attractant of one species have already been reported, attractants of six taxonomically identified species, and probably those of 10 other taxonomically unidentified species, were first found in this study.

Attraction of Tortricid Species. Tetradecenyl compounds unsaturated at the 11 position have been identified as key pheromone components of many species in the Tortricidae family (Arn et al., 1992, 1997). Our field tests showed the attraction of three tortricid species by *Z*11–14:OAc and its mixtures (Table 1). Among the tested lures, the best attractant for *Adoxophyes privatana* was a 9:1 mixture of *Z*11–14:OAc and *Z*9–14:OAc and that for *Archips atrolucens* was a 5:5 mixture of *Z*11–14:OAc and *E*11–14:OAc, while *Meridemis furtiva* was most strongly attracted by traps baited only with *Z*11–14:OAc. These three species have been recorded in Southeast Asia, but not in Japan (Inoue et al., 1982). *A. privatana* is a species closely related to *Adoxophyes honmai* and *Adoxophyes orana*, pests of tea and fruit trees. The *A. privatana* males were caught by the lure including the same monoenyl acetates as pheromones of the other two species (Tamaki et al., 1971a,b; Meijer et al., 1972), but the composition ratio was quite different from those of the latter pheromones. In the genus *Archips*, sex pheromones have been identified in seven species, and sex attractants have been discovered for 17 species (Arn et al., 1992, 1997). For the specific attraction of these species, *Z*11–14:OAc is an important common component. This characteristic was also indicated in the tropical *Archips* species, *A. atrolucens*. The attraction of males in the genus *Meridemis* has not been reported previously. In this screening, specific attraction was not found for the lures including *Z*11–14:OH, *E*11–14:OH, and *Z*11–14:Ald.

Attraction of Other Microlepidopteran Species. The traps baited with *Z*11–14:OAc also captured many males of a species in the Cosmopterigidae family. Because the taxonomy of microlepidopteran insects in Southeast Asia has not been sufficiently established, the genus of this species has not yet been identified. Another unidentified gelechiid species was specifically attracted to *Z*9–14:OAc, and a 9:1 mixture of *Z*7–12:OAc and *Z*9–14:OAc was the best attractant for *Batrachedra* sp. (Batrachedridae, Table 1).

Attraction of Noctuid Species by Type I Pheromones. Monoenyl acetates attracted six species in the Noctuidae family (Table 1). Attraction of the following

[a] Captured males in test 1 from December 1998 to November 1999 (*), and in test 2 from January to December 2000 (**).
[b] Tortricinae.
[c] Plusiinae.
[d] Amphipyrinae.
[e] Hypeninae.
[f] Ophiderinae.
[g] Herminiinae.
[h] Lithosiinae.

three species was also achieved: *Argyrogramma signata* (Plusiinae) by *Z*5–10:OAc, *Zonoplusia ochreata* (Plusiinae) by a 5:5 mixture of *Z*7–12:OAc and *Z*5–12:OAc, and *Spodoptera pectinicornis* (Amphipyrinae) by *Z*7–12:OAc. While *Z. ochreata* is also distributed in Japan, the other two are tropical species (Inoue et al., 1982). Additionally, this screening showed the male attraction of three other noctuid species in the Plusiinae subfamily: *Chrysodeixis eriosoma*, *Ctenoplusia agnata*, and *Ctenoplusia albostriata*. Their larvae are defoliators of vegetables (Inoue et al., 1982), and their sexual communication has been reported. Sex pheromones of many Plusiinae species include *Z*7–12:OAc as a key component (Arn et al., 1992, 1997). Table 2 shows the results of field attraction in the Mekong Delta by *Z*7–12:OAc and its mixtures with related compounds. The sex pheromone of *C. eriosoma* is composed of *Z*7–12:OAc and *Z*9–12:OAc (Benn et al., 1982), and the 9:1 mixture was the best attractant in this test. *C. agnata* in Vietnam was attracted most strongly by the single-component lure of *Z*7–12:OAc, whereas *Z*7–12:OAc and *Z*9–12:OAc have been previously identified in this species, and the 10:1 mixture was the best lure in Japan (Sugie et al., 1990). The same mixture in a 9:1 ratio caught few males in this test, indicating that the Vietnamese and Japanese strains have different systems for sexual communication. The highly specific attraction of *C. albostriata* attained by a mixture of *Z*7–12:OAc and *Z*5–10:OAc in Vietnam coincided well with the results of field tests in Japan (Inomata et al., 2000). The differences in optimum attractants shown in Table 2 seemed to be sufficient to prevent the cross-attraction of heterospecific males.

Figure 1 shows the monthly data of captured males of three Plusiinae species in test 2: *C. eriosoma*, *C. agnata*, and *C. albostriata*. The monthly average temperature in Cantho City is almost constant, around 27°C throughout the year, but there are two seasons based on rainfall. The dry season, from January to March, is suitable for the cultivation of vegetables. The rainy season starts in April, when many vegetables fields are changed to paddy fields. The above-mentioned species do not have a diapause system, and it was expected that continuous and overlapping generations would occur throughout the year. However, male catches from April to July were rarely observed. Their flights were observed primarily in the dry season and, interestingly, in the latter half of the rainy season. We plan to examine the ecological aspects of Plusiinae pests in detail using pheromone traps.

Attraction of Noctuid Species by Type II Pheromones. Field screening with C_{18}–C_{21} chain compounds in type II showed the attraction of three more Noctuidae species: *Hypena* sp. by *Z*3,*Z*6,epo9–21:H; *Luceria* sp. by *Z*3,*Z*6,epo9–18:H; and *Zanclognatha* sp. by *Z*3,epo6,*Z*9–19:H (Table 1). Although only genera were determined for these species, sex pheromones and attractants have not been reported for any other species in the former two genera. Among the *Zanclognatha* species, it has been reported that males of *Z. lunaris* were attracted to disparlure, a methyl-branched epoxyalkane (Minyailo et al., 1977). They belong to the subfamilies Hypeninae, Ophiderinae, and Herminiinae, which are recognized as

[a] Each lure was replicated twice using two traps except for four traps of control.
[b] Values were calculated with the data from October 11 to November 1 for *C. eriosoma, C. agnata,* and *Z. ochreata,* and from January 12 to February 2 for *C. albostriata.* Numbers within each column followed by a different letter are significantly different at $P < 0.05$ by Duncan's multiple-range test.

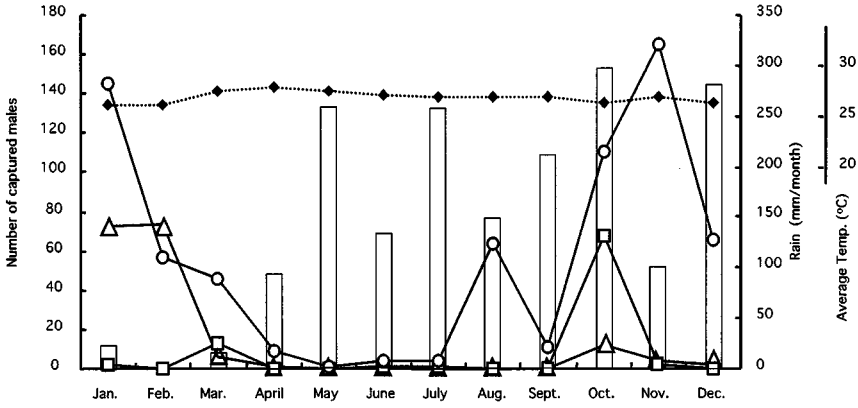

FIG. 1. Monitoring of three Plusiinae species by pheromone traps in orchards in the Mekong Delta (Cantho City, Vietnam) in 2000. Monthly totals, which were captured by two traps baited with the following lures, are shown; *Chrysodeixis eriosoma* by the 9:1 mixture of Z7–12:OAc and Z9–12:OAc (□), *Ctenoplusia agnata* by Z7–12:OAc (○), and *Ctenoplusia albostriata* by the 9:1 mixture of Z7–12:OAc and Z5–10:OAc (△). Temperature and rainfall were indicated by ♦ and open bars, respectively.

Noctuidae groups in Quadrifinae that secrete chemicals of type II as a pheromone component (Ando et al., 1993; Millar, 2000).

Attraction of Arctiid Species. Compounds of type II, which had attracted many species in the Geometridae family in Japan, did not attract any geometrid males in Vietnam. Instead, their field evaluation in Vietnam showed the attraction of four arctiid species (Table 1), whereas no arctiid males had been attracted in the same screening tests in Japan (Ando et al., 1993, 1995). Although their species names are unknown, they belong to the subfamily of Lithosiinae, which includes many tropical species, and *Cyana* and *Schistophleps* were assigned as their genera. Sex pheromones and attractants have not been reported for any species in Lithosiinae (Millar, 2000).

In conclusion, these results indicate the usefulness of field trials with synthetic lures in pheromone research of tropical species. Screening tests with known pheromone components provide leads to possible sex pheromones for other species, not only in the same group, but also in a different group for which sex pheromones have not been reported, as well as information about pheromone differences between geographically isolated populations. Although we captured male moths of some pest species of vegetables, our attempt to attract harmful pests in orchards was not successful. One of the main reasons might be the limited selection of test chemicals and their combination. We are going to evaluate lures, including other synthetic pheromone components, for example, aldehydes and compounds with a

C_{16} chain, in different fields in the Mekong Delta. Pheromone research may allow us to obtain a better understanding of the taxonomy of lepidopteran species from Vietnam.

(Received May 14, 2001; accepted March 2, 2002)

Abstract—In the sequential courtship behavior of the German cockroach, *Blattella germanica* (Dictyoptera: Blattellidae), females feed on the tergal gland secretions from the male tergites. The phagostimulative components in the male secretions were composed of a complex mixture of oligosaccharides and phospholipids. Besides seven oligosaccharides previously identified, two new trisaccharides, *O*-α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-glucopyranoside and *O*-α-glucopyranosyl-(1→4)-*O*-α-glucopyranosyl-(1→1)-*myo*-inositol, were characterized as the sugar components of the secretions. The activity of the sugar components was compared in combination with the lipid fraction. Individual oligosaccharides exhibited the activity either alone or synergistically with the phospholipids. A complex mixture of these primary substances in the tergal gland secretions, thus, serves as a pheromonal phagostimulant in the precopulatory behavior, strongly eliciting feeding response in the female cockroach.

Key Words—*Blattella germanica*, German cockroach, tergal gland, male courtship pheromone, phagostimulant, oligosaccharides, phospholipids.

INTRODUCTION

The courtship behavior of the German cockroach, *Blattella germanica* (L.), has been studied by many researchers, and the involvement of chemical cues in the sequential steps of precopulatory behavior has been suggested (Sikord, 1918; Wille, 1920; Gould and Deay, 1937; Roth and Willis, 1952, 1954; Ishii, 1972; Liang and Schal, 1993). In an encounter, the male touches the female with his antennae and raises his wings upward in response to a contact chemical factor on the female cuticular surface (female sex pheromone) (Nishida and Fukami, 1983; Schal et al., 1990). The male simultaneously turns around 180° and displays his abdominal tergal glands to the female. While the female feeds on the tergal secretions (male sex pheromone), the male pushes his abdomen under the female and clasps her genitalia with his left phallomere to accomplish genital connection. Although the male secretions have been chemically analyzed in the past (Brossut et al., 1975; Sreng, 1979), the pheromonally active compounds in the secretions have not been known until recently. We have characterized a series of oligosaccharides and polar lipids as the two main classes of male courtship pheromone components in the tergal glands (Nojima et al., 1999a). Further investigation of the secretions led to the isolation of additional oligosaccharide components. We describe here the structural elucidation of these compounds, and overview the chemical composition and pheromonal activity of the sugar components.

METHODS AND MATERIALS

Insects. Blattella germanica (L.) were raised under conditions described in a previous paper (Nojima et al., 1996). Newly emerged adults were reared separately, and sexually mature unmated males and females were used for tergal gland extraction and behavioral bioassay, respectively.

Phagostimulant Assays. The polyethylene glycol (PEG) film method was employed for the phagostimulant assay (Nojima et al., 1996). A test sample (in male equivalency) was applied to a micro cover glass plate as a mixture with 40 μg of PEG 70,000 (Wako Pure Chemical Industries, Ltd., Osaka, Japan). The test female (6 days old) was allowed to contact the film for 1 hr. The activity of a test material was recorded as the percentage of PEG films with bite marks (Nojima et al., 1996). For the qualitative assays, each sample was tested using 60–90 insects, and the results were analyzed by Fisher's exact probability followed by the sequential Bonferroni test (Rice, 1989). For the quantitative assays, expressed by the male equivalent per 40 μg PEG spot (ME/PEG), the median effective concentrations (EC_{50}) of active materials were evaluated by probit analysis on the correlation between concentration of the material and phagostimulative responses (Sakuma, 1998).

Spectral Instrumentation. Optical rotations were measured with a Jasco DIP-370 digital polarimeter. High-resolution fast atom bombardment (FAB) mass spectra were recorded with a Jeol HX221A mass spectrometer using dithiothreitol and thioglycerol matrix for a positive mode and triethanolamine matrix for a negative mode. ^{1}H and ^{13}C NMR spectra including the H-H COSY, C-H COSY, and HMBC spectra were measured with a Bruker ARX-500 spectrometer (^{1}H, 500 MHz; ^{13}C, 125 MHz) in D_2O. The chemical shifts were referenced to 3-(trimethylsilyl)-propionic acid sodium salt for D_2O (acetone was used as a secondary internal standard in D_2O: $^{1}H = 2.23$ ppm and $^{13}C = 33.07$ ppm at 27°C).

Extraction and Fractionation of Pheromone Components. Pheromone components were extracted from the eighth tergal glands (TG-8) by the method previously described (Nojima et al., 1999a). A portion of the phagostimulative methanol layer was fractionated by a reverse-phase column (Sep-Pak Vac cartridge C18, 10 g; Waters Associates), eluting in a sequence with 150 ml each of water-methanol-formic acid in ratios of 100:0:1, 40:60:1, 20:80:1, and 0:100:0 (v/v). The water eluate was fractionated into 16 subfractions by preparative HPLC with two Radial Pak cartridges (100 × 8 mm ID, packed with μ-Bondapak NH_2; Waters) eluted with 36% water in acetonitrile (2.0 ml/min) (Figure 1A).

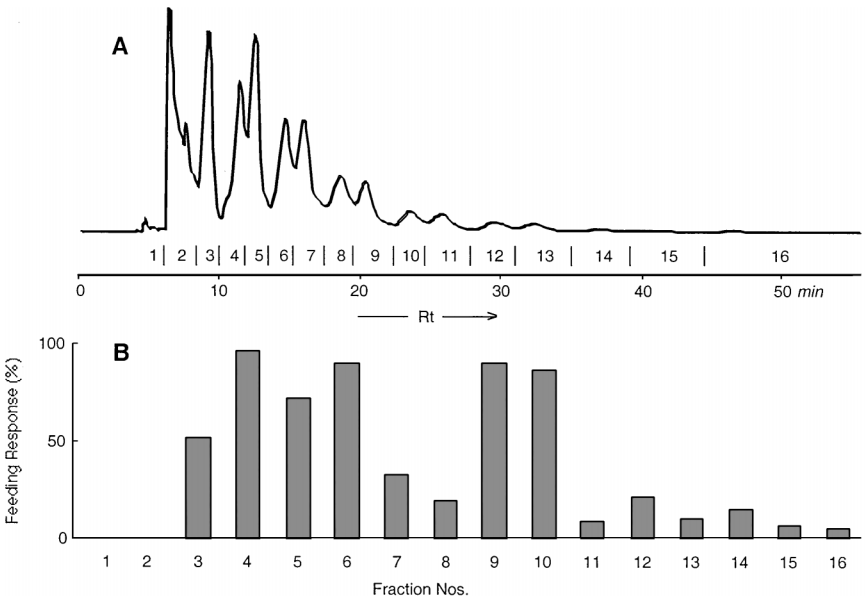

FIG. 1. (A) Liquid chromatogram of the sugar fraction on an aminopropylsilyl bonded silica gel column eluted with 36% water in acetonitrile, 2.0 ml/min, refractive index detection. (B) Feeding response of the virgin females of *Blattella germanica* to each sugar subfraction at a concentration of 1.0 ME/PEG ($N = 90$).

Chemicals. Maltotriose (**IIIa**) and glucosyl trehalose (**IIIb**) used for phagostimulant assay were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan) and Hayashibara Biochemical Laboratories, Inc. (Okayama, Japan), respectively. Pure samples of compounds **IIIc** and **IIId** were isolated from S-5 and S-6 (Figure 1A), respectively, by preparative HPLC with an ODS column (YMC PAK ODS A-323, 250 mm × 10 mm ID, YMC Co., Ltd., Kyoto, Japan) eluting with water 1.0 ml/min. The retention times of **IIIc** and **IIId** were 20.6 and 16.8 min, respectively.

RESULTS

Isolation of Oligosaccharides. Pheromonal secretions that induced feeding behavior in female *B. germanica* were extracted from the TG-8 segment of approximately 10,000 male cockroaches (Nojima et al., 1999a). A methanol-soluble fraction (636 mg) was separated into four fractions on a reverse-phase cartridge column, and the activity was recovered from fractions eluted with water (containing 1% formic acid) (sugar fraction, 398 mg) and with methanol (lipid fraction, 202 mg), respectively. A mixture of these two fractions synergistically exhibited phagostimulant activity (EC_{50} 0.0063 ME/PEG) close to that of the crude extract (EC_{50} 0.0047 ME/PEG) (Nojima et al., 1999a). The sugar fraction was subjected to HPLC with an aminopropylsilyl-bonded silica gel column and separated into 16 subfractions (S-1 to S-16) (Figure 1A). S-3, S-4, S-5, S-6, S-9, and S-10 individually exhibited more than 50% response to the females at 1.0 ME/PEG (Figure 1B). The activity of these subfractions was remarkably enhanced by mixing with the lipid fraction in the same equivalency (e.g., S-4 alone: EC_{50} 0.17 ME/PEG; S-4 + lipid fraction: EC_{50} 0.019 ME/PEG; S-5 alone: EC_{50} 0.69 ME/PEG; S-5 + lipid fraction: EC_{50} 0.016 ME/PEG; lipid fraction alone: EC_{50} 0.14 ME/PEG). Nine oligosaccharides with phagostimulant activity were isolated from subfractions S-3, -4, -5, -6, -8, and -10 by means of successive HPLC. Table 1 summarizes the subfractions from which each compound was isolated, $[\alpha]_D$ values, approximate contents (micrograms per gland), and phagostimulant activity of the saccharides isolated from the tergal glands.

Identification of Oligosaccharides. The identity of seven oligosaccharides from male tergal glands was reported in an earlier paper (Nojima et al., 1999a). These compounds were classified into two homologous series: D-maltose (**IIa**), D-maltotriose (**IIIa**) and D-maltotetraose (**IVa**) [maltooligosaccharides], and *O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-glucopyranoside (**IIIb**), *O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-glucopyranoside (**IVb**), *O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-glucopyranoside

(**Vb**) and *O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-*O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-glucopyranoside (**VIb**) [oligoglucosyl trehaloses with (1→4)-α-D-glycosidic linkages]. The Roman numerals represent the number of hexose units. Additionally, we have isolated two saccharides (**IIIc** and **IIId**) not homologous to the above series. Compound **IIIc** was found to be the most abundant sugar constituent in TG-8 (Table 1).

The molecular formula of **IIIc** was determined to be $C_{18}H_{32}O_{16}$ by FAB-MS (positive m/z 505 $[M+H]^+$, 527 $[M+Na]^+$, 543 $[M+K]^+$; negative m/z 503 $[M-H]^-$) and ^1H and ^{13}C NMR spectral data. From the correlation spectroscopy (H-H COSY and C-H COSY), each NMR signal was assigned as shown in Tables 2 and 3. The chemical shifts and coupling constants of the anomeric carbons and protons indicated the presence of three α-glucopyranose units in compound **IIIc**. Two glucose units were found to form an α,α-trehalose structure, to which another α-glucose was attached, by comparing the NMR spectra with those of α,α-trehalose (Tables 2 and 3). The glucosidic linkage between trehalose and glucose was determined to be positioned at C-6′ by HMBC experiment (a correlation observed between H-1″ and C-6′). Consequently, **IIIc** was identified to be *O*-α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-glucopyranoside (Figure 2). The ^{13}C NMR resonances and optical rotation of **IIIc** agreed with those reported in the literature (Koto et al., 1986; Ajisaka and Fujimoto, 1990; Kurimoto et al., 1997).

Compound **IIId** was found by the accurate mass measurement (HRFAB-MS: negative m/z 503.1604 $[M-H]^-$ (Δ mmu −0.8)] to have the molecular formula $C_{18}H_{32}O_{16}$. From the H-H COSY, H-C COSY, and HMBC spectra, each signal was assigned as shown in Tables 2 and 3. Anomeric protons and carbons were

[a] a, b: δ-values with the same letters are interchangeable. ND: not determined due to high multiplicity and signal overlapping.

found as two doublet proton resonances at δ_H 5.20 (H-1′) and 5.42 (H-1″) ($J_{H\text{-}1,2}$ of both were 4 Hz) and two carbon resonances at δ_C 103.24 (C-1′) and 102.44 (C-1″). The H-H COSY spectrum clearly showed that the two anomeric protons correlated with two sets of six protons, respectively, suggesting two hexose units in **IIId**. The coupling constants of $J_{H\text{-}2,3}$, $J_{H\text{-}3,4}$, and $J_{H\text{-}4,5}$ of both hexosyl residues were large ($J = 10$ Hz). These characteristics, together with the coupling constants of the anomeric protons, implied that both hexoses were α-glucopyranoses. The remaining proton signals were observed in the range δ_H 4.22–3.32. The H-H COSY correlation suggested that the other constituent was a cyclitol. The coupling constants of $J_{H\text{-}1,6}$, $J_{H\text{-}3,4}$, $J_{H\text{-}4,5}$, and $J_{H\text{-}5,6}$ were 10 Hz, whereas $J_{H\text{-}1,2}$ and $J_{H\text{-}2,3}$ were 3 Hz. These data indicated that H-4, H-5, and H-6 methines of the cyclitol were in the axial position and located in the vicinal diaxial geometry, whereas H-1 and H-3 were in the axial position and located in the vicinal axial–equatorial geometry, and H-2 was in the equatorial position and located in the vicinal diaxial geometry. These characteristics implied that the cyclitol was *myo*-inositol. The position of the glucosidic linkages of two glucoses and *myo*-inositol were elucidated by an HMBC spectrum. In the spectrum, anomeric protons H-1″

[a] a, b: δ values with the same letters are interchangeable.

(δ_H 5.42) and H-1′ (δ_H 5.20) were found to correlate with the carbons C-4′ (δ_C 79.69) and C-1 (or C-3) (δ_C 82.57), respectively. These data indicated that two glucosyl residues connected with an α-1,4-glucosidic linkage to constitute a maltose moiety, and the maltosyl residue connected to the C-1 (or C-3) position of *myo*-inositol in an α-glucosidic linkage (Figure 2). This was supported by ^{13}C resonances, which showed that the C-1 (or C-3) of *myo*-inositol residue and the C-4′ of glucose residue in **IIId** were shifted to down field ($\Delta\delta_C = 9$ and 7), compared with those of *myo*-inositol and trehalose, respectively (Table 3). Since the C-1 and C-3 are completely equivalent in the symmetrical structure of *myo*-inositol, it was not possible to determine the bonding position of the *myo*-inositol moiety with the maltosyl residue by the NMR spectroscopy. Thus, compound **IIId** was concluded to be *O*-α-glucopyranosyl-(1→4)-*O*-α-glucopyranosyl-(1→1)-*myo*-inositol (Figure 2). The absolute configuration of **IIId** remains to be clarified.

Phagostimulant Activity. The phagostimulant activity of maltooligosaccharides (**IIa**, **IIIa**, and **IVa**) and oligoglucosyl trehaloses with (1→4)-α-D-glucosidic linkages (**IIIb**, **IVb**, **Vb**, and **VIb**) has been previously reported (Nojima et al., 1999a) (see also Table 1 for male equivalent-based EC_{50}). We compared the activity of four isomeric trisaccharides (**IIIa**, **IIIb**, **IIIc**, and **IIId**) individually and in combination with the lipid fraction (at 0.1 ME/PEG) as shown (Figure 3). Maltotriose (**IIIa**) exhibits distinct activity by itself even without the lipid fraction.

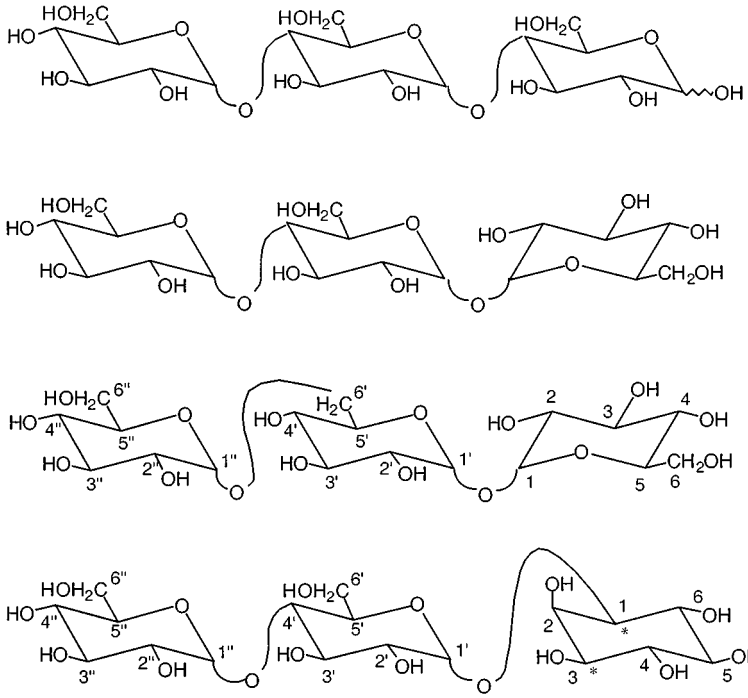

FIG. 2. Chemical structures of phagostimulative oligosaccharides isolated from the 8th tergal glands of *Blattella germanica* males: Maltotriose (**IIIa**), *O*-α-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl α-D-glucopyranoside (**IIIb**), *O*-α-D-glucopyranosyl-(1→6)-α-D-glucopyranosyl α-D-glucopyranoside (**IIIc**), *O*-α-glucopyranosyl-(1→4)-*O*-α-glucopyranosyl-(1→1)-*myo*-inositol (**IIId**).

In contrast, **IIIb**, **IIIc**, and **IIId** elicited only weak feeding responses from females, and showed significant activity in a synergistic action with the lipid fraction.

DISCUSSION

The sugar fraction of the tergal secretions was found to consist of glucose oligomers, which serve as the male courtship pheromone, stimulating female feeding responses, particularly when mixed with the phospholipid fraction (Nojima et al., 1999a). The sugar components were classified into three groups: reducing sugars (maltooligosaccharides **IIa**, **IIIa**, **IVa**), nonreducing sugars with (1→4) or (1→6) linkages (oligoglucosyl trehaloses **IIIb**, **IIIc**, **IVb**, **Vb**, **VIb**), and a *myo*-inositol-containing pseudotrisaccharide (**IIId**). Maltotriose (**IIIa**) exhibited the highest activity among the test compounds (Nojima et al., 1999a). There was a tendency for maltooligosaccharides to be more active than the corresponding

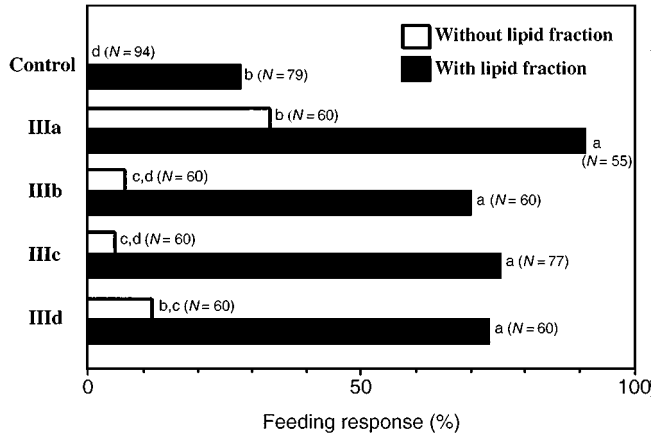

FIG. 3. Phagostimulant activity of trisaccharides (**IIIa**, **IIIb**,**IIIc**, and **IIId**) contained in the male tergal glands of *Blattella germanica* in combination with the phospholipid fraction at a concentration of 0.1 ME/PEG. Different letters indicate statistical differences between samples (Fisher's exact probability tests followed by the sequential Bonferroni test, $P < 0.05$).

oligoglucosyl trehaloses, although **VIb** was a potent phagostimulant among the latter (Table 1). Phospholipids appeared to synergize the activity of individual sugar components greatly, but in varying amplitudes. Although **IIIb**, **IIIc**, and **IIId** elicited only weak feeding responses from females, these compounds showed significant phagostimulant activity in a synergistic action with the lipid fraction (Figure 3). Considering its abundance in the tergal secretions (Table 1), **IIIc** appears to serve as an important sugar component in the courtship pheromone. In addition to these nine oligosaccharides, tergal secretions contained a series of other sugar components, as seen in the liquid chromatogram (Figure 2A). Trehalose (ca. 2 μg/gland) and *myo*-inositol (ca. 1 μg/gland) were found to be prominent components in the sugar subfraction S-3. Trehalose appeared to be a contaminant from the hemolymph, whereas *myo*-inositol was likely from the glands (Nojima et al., 1999a). Other components in the tergal secretions need to be identified in order to clarify the whole profile of the complex oligosaccharide mixture.

Oligoglucosyl trehaloses are known to be produced enzymatically from corresponding maltooligosaccharides by several maltooligosyl trehalose synthases isolated from microorganisms (*Arthrobacter* sp. Q36 and *Sulfolobus acidocaldarius*) (Nakada et al., 1995, 1996). It is interesting that tergal sugars coincidentally include both the substrates as well as rearranged products. However, an involvement of similar enzymes or microbial association in the biosynthesis of the tergal secretions remains to be clarified. Trisaccharide **IIIc** has recently been identified in the body of the silverleaf whitefly, *Bemisia argentifolii*, as a major soluble and possible

storage carbohydrate (Hendrix and Salvucci, 2001). To the best of our knowledge, this is the first report of the *myo*-inositol containing pseudotrisaccharide (**IIId**) isolated in nature.

The counterpart lipid fraction was composed predominantly of phosphatidylcholines (lecithins), and the synergistic activity could be substituted by yolk lecithin (Nojima et al., 1999a). The lipid fraction was found to contain phosphatidylethanolamines as well (unpublished data).

Sugars and lipids are well known as general dietary phagostimulants among cockroaches, including *B. germanica* (Tsuji, 1965, 1966; Nojima et al., 1996). In this pheromone system, the sugar and lipid components showed a synergistic action. Synergistic actions between dietary components are widely known among insects (Dethier, 1972). Male tergal secretions of *B. germanica*, thus, primarily play a behavioral role to induce female feeding behavior, which is basically the same as a general response toward dietary foods (Nojima et al., 1999b).

Male tergal glands are widespread among cockroach species (Roth, 1969). The gland secretions assist in settling the female in an appropriate position for the genital connection in the mating sequence (Roth and Willis, 1952, 1954). The secretions are thought to play various pheromonal roles, such as an attractant, arrestant, phagostimulant, sedative, or excitant (Roth and Dateo, 1966; Roth, 1969; Birch, 1974; Sreng, 1993). Although the tergal substances could serve as an aphrodisiac pheromone (Birch, 1974), the above evidence in the pheromone system of *B. germanica* suggests that the female's persistence in the secretions is merely attributed to the phagostimulant nature of tergal secretions and the ingenious structure of TG-8 (Nojima et al., 1999b). It is a peculiar case of a courtship pheromone presented as a glandular gift inducing feeding behavior in females. Similar nuptial feeding is commonly seen in crickets and often in other species (Engelmann, 1970; Gwynne, 1983, 1997); a beetle, *Neopyrochroa flabellata*, presents cantharidin on the head during courtship in a similar process (Eisner et al., 1996).

The tergal glands of species of the genus *Blattella*, which occur on both seventh and eighth tergites or only on the seventh tergite, are characteristic and rich in variety (Roth, 1969). *B. germanica* males have glands both on the seventh and eighth tergites. Differences in chemical composition of secretions and behavioral roles between these two glandular organs in *B. germanica* need to be clarified. A systematic study of the chemistry and function of secretions in the courtship behavior could provide a key to understanding the evolution of this unique glandular gift widely developed in the Blattaria.

Acknowledgments—The authors express their gratitude to Dr. K. Tsuzaki of Hayashibara Biochemical Laboratories, Inc., for providing authentic samples of oligoglucosyl trehaloses. We thank Professor W. L. Roelofs for reviewing the manuscript. This study was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan (No. 08406010).

Book Review

Marine Chemical Ecology. 2001. Edited by James B. McClintock and Bill J. Baker. CRC Press, Boca Raton, Florida. $129.95. 610 pp. ISBN 0-8493-9064-8

This compendium is meant to provide a "high-resolution snapshot" of marine chemical ecology at the beginning of the 21st century. Some 38 authors have prepared 18 chapters that range from ecological and evolutionary perspectives to detailed studies of specific interactions. Many of the recognized gurus in the field have contributed with a few conspicuous absences (Faulkner, Fenical, Hay).

The book is in four sections with Chapters 1–3 examining distributions of secondary metabolites in major animal phyla and discussions of marine natural products from both ecological and evolutionary perspectives. The attempt at this broad overview is laudable, and I found the chapters readable and reasonable. Marine chemical ecology has lagged significantly behind terrestrial chemical ecology, and attempts at such syntheses are needed. Chapters 4–10 are organismal in approach and include work on benthic invertebrates, meroplankton and holoplankton, algal/herbivore interactions, antarctic organisms, spatial patterns of algal chemical defense, resource allocation, and surface colonization. While detailed in nature, they are engaging enough for the terrestrial chemical ecologist to follow and wonder about.

The third section, Chapters 11–15, focuses on cellular and physiological aspects. Physiological consequences of natural products ingestion, exploitation of chemical gradients by algae and bacteria, chemical cues for larval settling and metamorphosis, prey attraction, chemoreception, and UV absorbing compounds are the topics considered. The work of major researchers in the fields is represented in these cafeteria-style offerings. The final three chapters venture into potential practical applications of marine chemical ecology. The two well-known areas of biomedical prospecting and antifoulant development provide the central thrust here. The final chapter focuses on the enormous diversity of known compounds from microorganisms and the need to focus on new methods for their isolation and cultivation.

While this book is certainly no "Harborne" (Introduction of Ecological Biochemistry, now in its 4th edition), in that it is neither concise, nor focused on the

0098-0331/02/0700-1495/0 © 2002 Plenum Publishing Corporation

major phenomena operating in marine (as opposed to terrestrial systems), it does fill a major void. The science is high caliber, the chapters are eminently readable and well-edited, a lot of excellent science will be prompted by what is included, and there is something for the tastes of nearly everyone. One does get, as the book jacket claims, "an integrated perspective of the current state of the this discipline, and its future. It is worth the money and needs to be on the book shelves of those working in this exciting and growing discipline. It could also probably be used successfully as a text for graduate courses.

(Received June 22, 2001; accepted April 11, 2002)

Abstract—Hot water-extraction was performed on decomposed leaf litter in order to solubilize the toxic fraction involved in the dietary interaction against mosquito larvae in subalpine breeding sites. The toxic fraction was partially extracted by water with an optimum temperature of 60°C and recovered in an insoluble form. Phytochemical characterization was achieved through differential enzymatic hydrolyses, using the laccase mediator delignifying system, and aluminum chloride chelation monitored by standard bioassays; comparative spectrophotometric analyses in ultraviolet light after solubilization in acetyl bromide; and comparative reversed-phase high-performance liquid chromatography of the phenolic aldehydes after alkaline nitrobenzene oxidation. The results suggested the involvement of ligninlike compounds in the toxicity of the isolated fraction. Toxicity of this fraction appeared far stronger than that of the crude leaf litter. The involvement of this ligninlike fraction in the dietary toxicity of leaf litter against larval mosquito was then investigated.

Key Words—Leaf litter, larvicidal activity, ligninlike compounds, hot-water extraction, *Aedes aegypti*.

INTRODUCTION

Plant–insect dietary interactions are often mediated by polyphenols that are among the most ubiquitous vegetable xenobiotics (review in Bennett and Wallsgrove, 1994). These plant secondary compounds act as chemical barriers in ecological and evolutionary patterns of terrestrial herbivorous insects (review in Ayres et al., 1997) and aquatic detritivorous Arthropoda (Newman, 1991).

Recently, foliar polyphenols were found to be involved in a particular dietary interaction between the detritivorous aquatic arthropodan fauna and the leaf litter of the arborescent vegetation decomposing in the water of the subalpine mosquito breeding sites (Rey et al., 1996). Owing to their differential biocidal effects against larval Diptera (Rey et al., 1998a; David et al., 2000a) and planktonic Crustacea (Pautou et al., 2001), leaf litter polyphenols are involved in niche differentiation of these aquatic populations and are considered as bioindicators (Rey et al., 2000). Such a chemical interaction was investigated by using either tannic acid (a commercially available standard polyphenolic mixture) (Nishizawa et al., 1982) or crude decomposed alder leaf litter originating from the mosquito breeding sites. The toxicity of those polyphenols is exerted against the midgut epithelium of consumers (Rey et al., 1999; David et al., 2000a), thus leading to pathological effects stronger than those obtained after treatment with the bacterioinsecticide *Bacillus thuringiensis* (Rey et al., 1998b). Because the biocidal properties of crude alder leaf litter are also stronger than those of tannic acid, the possible use of this vegetable leaf detritus was suggested for integrated larval mosquito control (Rey et al., 2001).

Preliminary ecotoxicological analyses have indicated that dietary toxicity was undetectable in green leaves and that the settling of the leaf litter toxicity required a 10-month long decaying process in the water of the mosquito breeding site, under complex seasonal environmental factors (David et al., 2000b). However, the possible generation pattern of the toxic molecules (i.e., de novo generation or strip mining from a complex preexisting matrix) during the decaying process was still unknown.

Fractionation procedures at room temperature using water, organic solvents, and a detergent allowed us to isolate an insoluble toxic residue corresponding to a cell-wall fraction associated with high phenolic activity (David et al., 2000b). Additional enzymatic and alkaline/acid hydrolyses did not affect either toxicity or phenolic activity of the cell-wall fraction, contrary to diverse chemical oxidations, suggesting the possible involvement of ligninlike compounds in the toxicity (David et al., 2001). During these characterization steps, laboratory treatments monitored by a standard larval mosquito bioassay have indicated that the toxicity of the decomposed leaf litter was heat-sensitive (David et al., 2000b), but the origin of this heat sensitivity (i.e., through extraction or breakdown of the toxic molecules) remained unknown.

In this work, we considered a possible solubilization of the toxic fraction using hot water. Once extracted, the following objectives were explored: (1) determine the relative stability of the aqueous extract and the evolution of its larvicidal properties under controlled conditions; (2) check the ligninlike hypothesis of David et al. (2001); (3) evaluate the relative toxicity of this fraction to that of the crude leaf litter, in order to check the efficiency of the extraction procedure and the real larvicidal potentialities of the toxic molecules.

METHODS AND MATERIALS

Plant and Insect Material. Extraction and characterization of the toxic fraction was investigated on 10-month decomposed poplar leaf litter samples known for their acute toxicity toward larval mosquitoes (David et al., 2000b) and collected in a woodland submitted to periodic flooding in the Rhône-Alpes Region of France (Pautou and Girel, 2001). Experimentation was carried out either on crude leaf litter or on a standard lignin fraction purified from crude leaf litter according to the procedure of Alibert et al. (1969). All fractions were air-dried and preserved deep frozen until use.

Toxicity controls of all crude material and extracted or treated fractions were performed on *Aedes aegypti* L. fourth-instar larvae (Bora-Bora strain) raised in our laboratory (Rey et al., 1999) and used as a standard for bioassays.

Hot Aqueous Extraction of Toxic Fraction. Extraction of the toxic fraction was performed on 150 mg dry crude leaf litter maintained under gentle stirring in 30 ml distilled water for 1 hr at constant temperature. Temperatures assayed varied from 20° to 100°C. The remaining solid residue was discarded after separation from the aqueous extract by centrifugation (5000 rpm for 5 min), then filtered through one layer of Whatman No. 4 filter paper (pore size 25 μm).

Toxicity and Stability Checking of Aqueous Extract. Toxicity of the aqueous extract was checked using the standard *A. aegypti* bioassay design of David et al. (2000a,b, 2001). The assay was conducted at 25°C on homogenous samples including 20 same-sized larvae, in glass vials containing 10 ml of aqueous extract buffered to pH 7.5. Larval mortality was measured after 4 hr of exposure and the results corrected by Abbott's formula (Abbott, 1925). In order to investigate the relative importance of the concentration (C) versus dose (q) of the aqueous extract in the larval toxic response, the initial extract was diluted from C to C/2 and C/4, and the bioassay volume was increased from 5 to 10 and 20 ml, thus supplying the same dose to the larvae. Then the bioassay volumes of the C/4 solution were reduced from 20 to 10 and 5 ml, thus dropping the dose available for the larvae from q to q/2 and q/4.

The persistence of toxicity in the aqueous extract was monitored by successive bioassays performed daily during a week on 10-ml aliquots. At the same time, stability of the aqueous extract was checked by visual observation.

Separation and Phytochemical Characterization of an Insoluble Fraction in the Aqueous Extract. A dense fraction was progressively observed within the aqueous extract, which separated little by little with time from the solution as it was cooling down and until the extract was totally cloudy. This insoluble fraction (IF) was isolated from 24-hr-old aqueous extracts either by centrifugation (5000 rpm for 30 min) or by filtration through a 0.45-μm filter (Millipore, type HV). To check toxicity, the supernatant and filtrate obtained with 10 ml aqueous extract (corresponding to about 50 mg dry crude leaf litter) were used directly for bioassays, whereas the filtered IF and pellet were resuspended in 10 ml water before being bioassayed.

In order to check the involvement of ligninlike molecules in the toxicity according to the hypothesis of David et al. (2001), the IF was submitted to several characterization tests: differential enzymatic degradation and chelation with aluminum chloride ($AlCl_3$) (Jurd, 1962) monitored by toxicity controls; spectrophotometric analysis in ultraviolet light after solubilization in acetyl bromide (Johnson et al., 1961), which appears as the most feasible, specific, and reproducible direct method for lignin characterization (Alibert and Boudet, 1979; Fukushima and Dehority, 2000); and reversed-phase high-performance liquid chromatography (HPLC) analysis of the phenolic aldehydes after alkaline nitrobenzene oxidation (Hartley, 1970). This chemical degradative procedure is frequently used for lignin characterization because it provides, in satisfactory yield, the three major monomeric units of lignins (review in Lapierre et al., 1995). HPLC is a routine technique for qualitative and quantitative characterization of these phenolic aldehydes (Villeneuve et al., 1982).

Chelation with 0.05% $AlCl_3$was performed at 20°C and pH 7 for 1 hr on the IF recovered from 10 ml of aqueous extract. Enzymatic degradation of the IF was performed according to the procedure of David et al. (2001), using an enzymatic mix made with 10 mg caylase (caylase 345, Cayla S.A., Toulouse, France) and 1 mg pectolyase (Sigma), to solubilize the polysaccharide and pectin compounds, 1 mg β-glycosidase (2.5 units/mg, Sigma) and 5 μl esterase (4.16 units/ml, Sigma), to break down glycosidic and ester linkages, respectively. The IF recovered from 10 ml aqueous extract was treated with 1 ml enzymatic mix for 60 min at 30°C. After enzymatic treatment, the supernatant was removed by centrifugation (10,000 rpm for 5 min). The insoluble residue was water-rinsed and centrifuged (10,000 rpm for 5 min) before resuspension in 10 ml water for standard bioassay.

Laccase digestion was performed through a laccase-mediator delignification system using *N*-hydroxybenzotriazole (HBT) as a chemical mediator. Highly purified laccase from the white rot fungus *Pycnoporus cinnabarinus* and HBT were from M. Asther. The IF recovered from 10 ml aqueous extract was resuspended in 1 ml HBT solution (0.1%) buffered to pH 5 with 0.05 M sodium tartrate/tartric acid. The reaction was initiated by dissolving 30 units of solid laccase in the reaction medium and digestion was conducted for 6 hr at 30°C with strong agitation

every hour for regular oxygen supply. The supernatant was then removed by centrifugation (10,000 rpm for 5 min). The residual pellet was rinsed in water, then resuspended in 10 ml water before standard bioassay.

Before comparative spectrophotometric analysis using an Uvikon 933 spectrophotometer, samples of standard lignin fractions and of hot-water-extracted IF were treated for 30 min at 70°C with 25% acetyl bromide in acetic acid. Excess reagent was removed by adding 7.5 M hydroxylamine hydrochloride. Samples were diluted with a blank solution to give an absorbance between 1.5 and 2.5.

Phenolic aldehydes were obtained from 10 mg standard lignin fractions and 5 mg IF after alkaline nitrobenzene oxidation following the procedure of Hartley (1970). The aldehyde fraction was purified by successive extractions with diethyl ether, first at pH 12, in order to eliminate nitrobenzene, and then at pH 8.5, in order to extract the phenolic aldehydes. For HPLC analysis, a reversed-phase system, including a Waters Spherisorb 5 μm ODS-2 column (250 $\times$ 4.6 mm ID, Alltech, Deerfield, Illinois, USA) was used. The column was equipped with a 5-mm precolumn, a Dionex 4500i gradient pump, Shimadzu SIL-9A (autoinjector), Shimadzu SPD 6A (UV detector), and Shimadzu Workstation Class CR-10 (integration software). The mobil phase consisted of ultrapure water with 0.01% orthophosphoric acid and methanol (HPLC grade). The column was eluted with a 30-min isocratic 70:30 water–methanol solution at a flow rate of 1 ml/min. Samples of 20 μl were injected in the column and phenolic aldehydes were detected at 280 nm.

Toxic Efficiency of the Insoluble Fraction. In order to determine the toxicity–dose relation and, thus, the toxic efficiency of the hot-water-extracted IF, the amount of organic material fed to larvae in bioassays was accurately estimated by the determination of carbon in IF samples using a CHONS Microanalyser (NA 1 500 from Carlo Erba Strumentazione).

RESULTS

Optimal Conditions for Hot Aqueous Extraction of the Toxic Fraction. As shown in Figure 1, toxicological comparison of the aqueous extracts obtained at different temperatures revealed a gradual increase in toxicity when the extraction was performed between 20° and 60°C, in parallel with a gradual decrease in the toxicity of the residues. When extraction was performed between 60° and 100°C, toxicity progressively decreased in the aqueous extracts, and no remaining toxicity was observed in the residues. Thus, 60°C was the optimal temperature for an efficient water extraction of the toxic molecules from decomposed leaf litter.

Instability of Aqueous Extract and Toxicity of Insoluble Fraction. For five days after the extraction process, aqueous extracts stored at either 4°C or 20°C always gave 100% larval mortality (data not shown), thus indicating that storage

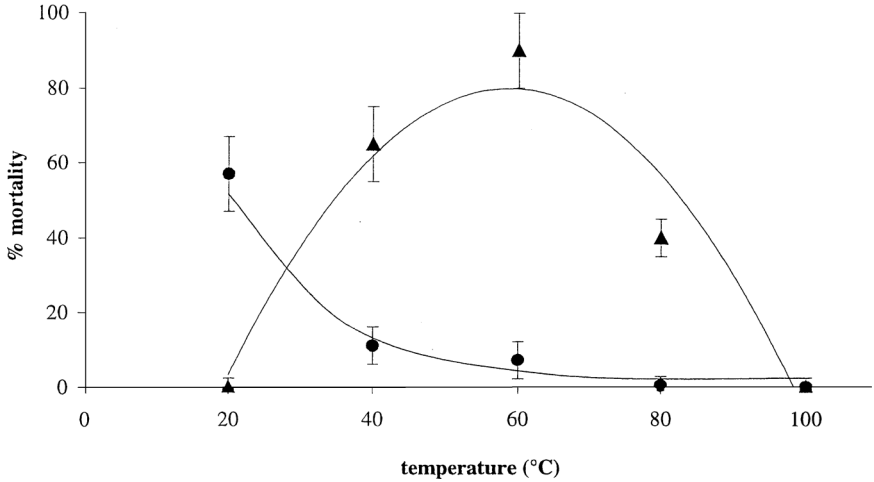

FIG. 1. Effect of temperature on the aqueous extraction of the toxic fraction from crude leaf litter (▲, toxicity of the aqueous extract; ●, toxicity of the residue; % mortality ± SE calculated from triplicate runs).

conditions did not affect the extract toxicity. However, as early as the first day of storage, the initial clear solution became cloudy, and an insoluble phase appeared and gradually increased. The progressive precipitation of an insoluble phase in the medium could explain the relative increase of the aqueous extract toxicity [i.e., from 80% to 100% larval mortality after a five-day storage (data not shown)]. Such an increase in toxicity may be related to the bioavailability increase of this toxic fraction for larval ingestion. The importance of bioavailability of the toxic molecules in the bioassay medium was clearly indicated by comparison of the effect of different concentrations of this toxic fraction for a given dose (Figure 2a) versus the effect of different doses for a given concentration (Figure 2b). This comparison showed that larval response depends on the overall dose of toxic fraction available in the bioassay solution, rather than on its concentration. Moreover, the larvicidal effect was lost in the filtrate or supernatant of filtered or centrifuged aqueous extracts, in contrarst to the whole extract or pellet, in which the whole toxicity was recovered (data not shown). All these results are in agreement to suggest a larval bioavailability of the toxic molecules in the aqueous medium in an insoluble form.

Characterization of the Toxic Insoluble Fraction. Enzymatic digestion of the toxic IF with the enzyme mix of David et al. (2001) did not alter the larvicidal effect (Table 1). In contrast, the toxicity of this fraction was entirely lost after the action of the laccase-mediator delignification system, whereas laccase and HBT alone had no larvicidal effect. These results suggest that lignins are good candidates for the toxicity. Moreover, since toxicity was not observable after treatment with $AlCl_3$,

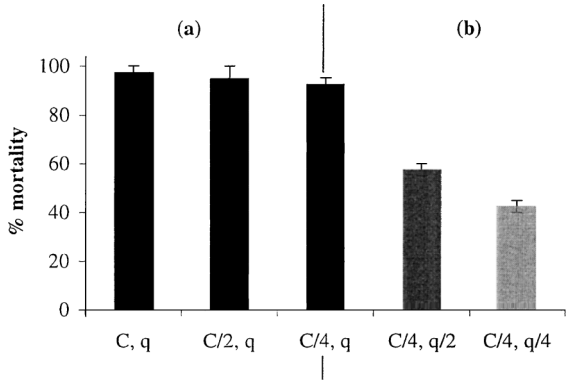

FIG. 2. Larvicidal effect (% mortality ± SE calculated from triplicate runs) of aqueous extract depending on (a) the concentration (ranging from C to C/4) and (b) the dose available (ranging from q to q/4 in 10 ml of bioassay medium.

which is a well-known hydroxyphenolic complexing agent, it may be concluded that OH phenolic groups are specifically involved in the larvicidal effect.

The UV spectra obtained with the standard lignin fraction and the toxic IF appeared to be similar, particularly between 270 and 290 nm (Figure 3). This suggests that part of the lignin constituents of the decomposed leaf litter were extracted by our hot-water procedure.

The presence of ligninlike molecules in the IF was also confirmed by HPLC profiles of the aldehydes after alkaline nitrobenzene oxidation (Figure 4). However, comparison of the respective profiles of standard lignin fractions and toxic IF (Figure 4) showed some differences in the aldehyde composition with maintenance of the relative proportion of *p*-hydroxybenzaldehyde (18 vs. 12 μmol/g, respectively in the standard lignin fraction and in the IF) and disappearance of vanillin and syringaldehyde from the IF.

TABLE 1. EFFECTS OF ENZYMATIC AND $AlCl_3$ TREATMENTS ON TOXICITY OF INSOLUBLE FRACTION

	Toxicity (% mortality)		
Control	Enzymatic mix[a]	Laccase[b]	$AlCl_3$
100	100	0	0

[a] The enzymatic mix was made of caylase, pectolyase, β-glycosidase and esterase.

[b] The laccase was used in the presence of the chemical mediator HBT. Each trial was repeated three times, SE < 5% is not shown.

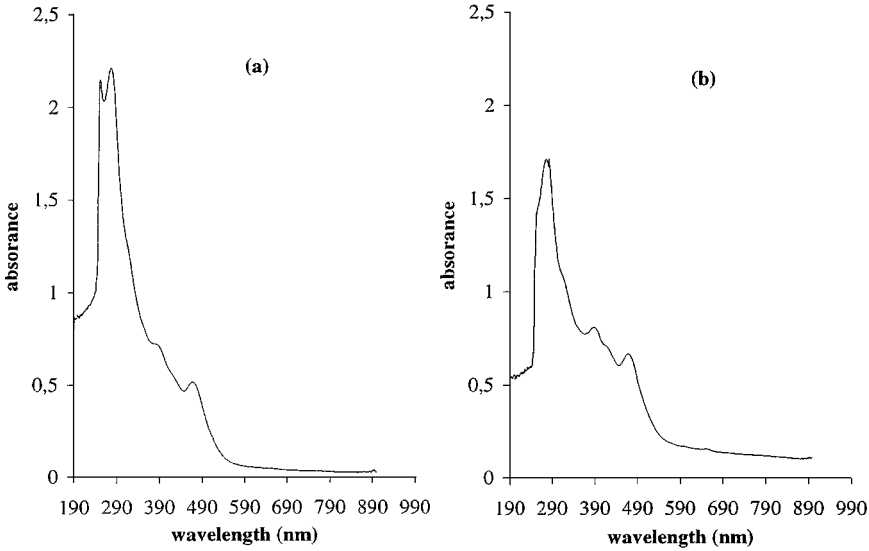

FIG. 3. Comparative spectrophotometric profiles of (a) standard lignin fraction and (b) toxic insoluble fraction after solubilization in acetylbromide 25% in acetic acid. The samples were diluted with acetic acid to give an absorbance between 1.5 and 2.5.

Larvicidal Activity of the Insoluble Fraction. Comparison of the toxic effects of different amounts of IF in the bioassay medium (Figure 5) revealed a larvicidal effect detectable using amounts as low as 18 μg. This toxicological effect increased sharply between 40 and 70 μg to reach a maximum at nearly 80 μg. Under such experimental conditions, an LD_{50} (dose generating 50% mortality) of almost 50 μg was observed, thus indicating the very strong toxic power of the IF.

DISCUSSION

The toxic fraction of decomposed leaf litter involved in the dietary interaction against larval mosquitoes in subalpine breeding sites was previously assessed as a heat-sensitive, insoluble, phenolic, cell-wall fraction indirectly recognized as associated with ligninlike compounds (David et al., 2000b, 2001). The current phytotoxicity-based, gentle, hot-water extraction procedure allowed us to purify, with an acceptable efficiency, an unstable fraction showing strong toxicity. The intrinsic water insolubility, together with some phytochemical characteristics of this fraction, allowed us to recognize it as a true ligninlike fraction, and its involvement in the dietary toxicity of the decomposed leaf litter in subalpine mosquito breeding sites may be questionned.

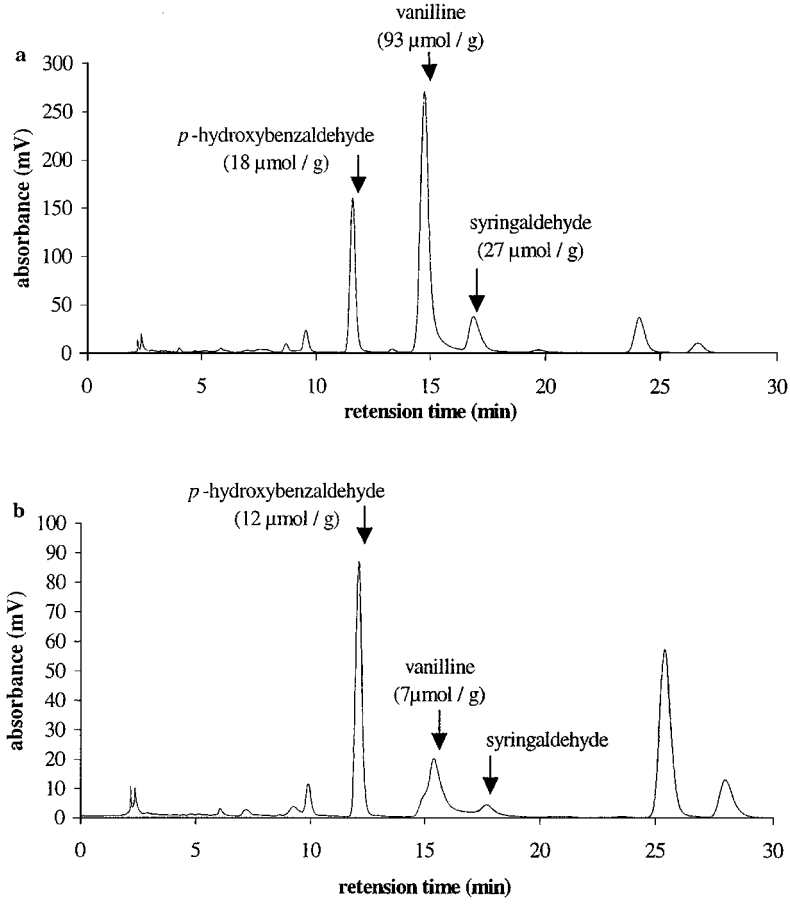

FIG. 4. Comparative HPLC profiles of standard lignin fraction (a) and toxic insoluble fraction (b) after alkaline nitrobenzene oxidation. Peaks identified are indicated on the chromatogram. The amount of each aldehyde (per gram of dry material) is indicated in parentheses.

Characterization of Ligninlike Compounds in the Insoluble Toxic Fraction. Whereas the preliminary characterization of ligninlike compounds in the larvicidal fraction of the decomposed leaf litter by David et al. (2001) was indirect, because it was performed on a nonextracted insoluble cell-wall fraction, the current analysis involves a temporarily solubilizable fraction that allowed the concentration of toxic molecules. The efficiency of our hot-water extraction procedure is evident when the toxicity of extracted IF ($LD_{50} = 50\mu g/10$ ml) is compared to that of the cell-wall fraction ($LD_{50} = 4$ mg/10 ml) found by David et al. (2000a).

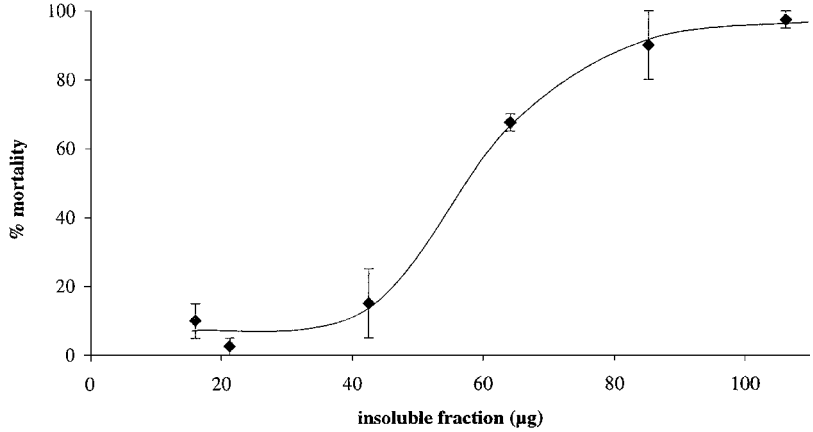

FIG. 5. Dose–response of *A. aegypti* larvae (% mortality ± SE calculated from triplicate runs) to the toxic effect of the IF. The amount of insoluble fraction fed to the larvae in the 10-ml bioassay was estimated by the determination of carbon.

Insolubility of the toxic leaf-litter molecules at ambient temperature in both water and organic solvents (not shown) is the first characteristic in favor of a ligninlike hypothesis. This water-insolubility is accompanied by a lack of toxicity in the water leached from immersed leaf litter during a 10-month decaying process in subalpine mosquito breeding sites (David et al., 2000b). In the same way, preliminary data correlate the toxicity of decomposed leaf litter to a water-insoluble phenolic fraction that is bound to the cell wall (David et al., 2000b). Solubilization of these toxic molecules in water has necessitated concomitant heat treatment, similar to some lignin forms (Lai and Sarkanen, 1971). Their instability at high temperature, which has also been reported through previous analysis of the cell-wall fraction (David et al., 2001), suggests the particular features of these ligninlike compounds. However, whereas these toxic molecules can be optimally extracted at 60°C, they progressively precipitate after this extraction step, thus finally revealing a water-insolubility typical of lignin compounds.

This toxic insoluble fraction is difficult to characterize directly, as generally observed for lignins (Higuchi, 1971), thus requiring the use of degradative reactions. The reactions used in the present study are typically employed in the characterization and structural exploration of lignin molecules (review in Lapierre et al., 1995).

The occurrence of resistant bonds in these biopolymers is responsible for the poor yields of most of the enzymatic degradative procedures performed on lignins. However, laccases from white-rot fungi [e.g., *Pycnoporus cinnabarinus*, which produces high levels of laccase (Sigoillot et al., 1999; Cameron et al., 2000; Herpoël et al., 2000)] are one of the best natural lignin degrading agents

(Reid, 1995; Herpoël et al., 2001). Their efficient in vitro use necessitates the presence of a mediator that is oxidized by the enzyme. This activated mediator then oxidizes the lignin molecules, which subsequently fragment (Sealey et al., 1998). The suppression of toxicity in the IF treated by laccase is strongly suggestive of the ligninlike nature of the larvicidal molecules in the decomposed leaf litter. A ligninlike character is also suggested by our inability to cancel the toxicity of the IF treated with the enzymatic mix of David et al. (2001), which solubilizes nonlignin cell-wall components and glycosidic and ester linkages (Wallace and Fry, 1994). Insensitivity to $AlCl_3$ treatment is further indirect evidence of the involvement of ligninlike molecules. $AlCl_3$ is known to complex phenolic hydroxyl groups (Jurd, 1962) in plant polyphenols in general, and lignins in particular.

More direct evidence that demonstrates the involvement of ligninlike molecules in this larvicidal effect was found by comparing the UV absorption spectra of the standard lignin fraction to that of the IF after treatment with acetyl bromide to solubilize lignin (Johnson et al., 1961). The similarity between these two UV spectra suggests that lignin compounds were extracted from decomposed leaf litter by hot water. The presence of lignin in the IF was also confirmed by thioacidolysis (data not shown), another method used to characterize lignin (Lapierre et al., 1986). Comparison of the monomeric units obtained after nitrobenzene oxidation suggests that hot water enhances the preferential solubilization of some forms of lignins—the *p*-hydroxybenzaldehyde units in particular (arising from the coumarylic alcohol) that differ from the native lignins in which three monomeric units (i.e., *p*-hydroxybenzaldehyde, vanillin, and syringaldehyde) were present.

Possible Involvement of Ligninlike Compounds in the Larvicidal Effect of Decomposed Leaf litter. The involvement of a ligninlike fraction in the dietary toxicity of decomposed leaf litter against larval mosquitoes is plausible. Lignins constitute the most stable and dominant components in decomposed vegetable material because of their resistance to most of the biotic and abiotic processes involved in leaf litter processing (Criquet et al., 2000). Moreover, lignins are known to have deleterious effects against phytophagous consumers—indirectly, through decreasing the digestibility of plant cell-walls, and directly through their own biocidal properties [e.g., against some larval Coleoptera (review in Wainhouse et al., 1990)]. However, characterization of these toxic, ligninlike molecules is still poorly documented. This is not surprising, given the tremendous variety of lignin compounds existing in nature and the difficulties in characterizing them. For example, several lignans with insecticidal properties against larval Lepidoptera have been isolated from herbaceous perennial plants (see references in Taniguchi et al., 1989).

Although further phytochemical investigation is necessary to establish the characteristics of ligninlike compounds that may be involved in leaf litter toxicity against larval mosquitoes, ecological considerations of the pattern of generation of

this toxicity during the leaf litter decaying process may give some preliminary information on these molecules. Contrary to what is generally observed in toxic leaf detritus, where dietary toxicity persists from the green leaf (Valiela et al., 1979), the larvicidal effect of leaf litter gradually appears during a 10-month long decaying process in a given water environment. This pattern of toxicity, previously related to the gradual increase of an insoluble phenolic fraction within the decomposing leaf litter (David et al., 2000b), is currently related to the ligninlike fraction. However, the evolutionary pattern of this fraction during the decomposing process may be either quantitative, through gradual enrichment of preexisting lignins, or qualitative, through alteration of the monomeric composition and possible maturation of these lignins into more condensed forms.

The toxicological interest of ligninlike compounds as larvicidal molecules in the aquatic subalpine mosquito breeding sites comes from their strong water-stability together with their variability in the oxidation state. As they are known to be the most recalcitrant components of decomposed leaf litter, lignins may behave as relatively stable molecules in the aquatic medium together with a bioavailability for detritivorous consumers that is better than toxic water-soluble polyphenols. Such a strong and durable toxicologic yield has been shown by comparison of the larvicidal effects of crude decomposed alder leaf litter versus tannic acid in the aquatic medium (David et al., 2000b; Rey et al., 2001). The involvement of oxidative processes in the leaf-litter larvicidal effects against mosquito has been previously suggested by David et al. (2001), as generally observed in insects fed phenolic-containing vegetable (review in Johnson and Barbehenn, 2000). Autooxidation of phenolic groups may result in the formation of superoxide radicals and other reactive species (Appel, 1993), leading to a direct oxidative stress of the larval digestive system. This is supported in our experiments using the laccase mediator delignifying system, which prevents the larvicidal effect of IF. Indeed, ^{13}C NMR analysis of the structure of residual lignins before and after laccase mediator treatment in kraft pulps (Sealey and Ragauskas, 1998) have shown that, among other modifications, this system selectively oxidizes free phenolic groups in lignins. Since our hot-water extracted ligninlike molecules lose their toxicity after action of the laccase mediator delignifying system, their toxicity may be associated with oxidative processes occuring in the larval gut (Barbehenn and Martin, 1994). Characterization of the chemical modifications induced by the laccase mediator system would be indicative of the lignin fraction or lignin substituents involved in the toxicity. Further analyses of such processes are now in progress in our laboratory.

Acknowledgments—This investigation was supported by a grant from Entente Interdépartementale pour la Démoustication Ain-Isère-Rhône-Savoie. We thank I. Thiery (Institut Pasteur, Paris) for supplying *A. aegypti* strain, J. Patouraux and G. Girard for technical assistance. We also thank B. Chabbert (INRA, Reims) for thioacidolysis analysis and valuable comments.

(Received March 7, 2002, accepted April 20, 2002)

Abstract—We determined concentrations of peramine, the only alkaloid produced by *Neotyphodium*-infected (E+) Arizona fescue plants (of the four major types typically assayed in infected grasses), in a long-term field experiment. Four plant genotypes with (E+) and without (experimentally removed, E−) their respective haplotypes (two haplotypes in two plant genotypes) of *Neotyphodium* were grown in the field under manipulated soil moisture and nutrients. Peramine production required the presence of the endophyte; plants without their endophytes did not contain peramine. Whereas the endophyte was necessary for peramine production, levels of peramine did not vary by *Neotyphodium* haplotype within plant genotypes. Furthermore, peramine levels did not differ among soil moisture and nutrient treatments, and growth and reproductive measures of the host grass explained little of variation in peramine levels. Instead, peramine levels differed significantly between plant genotypes harboring the same endophyte haplotype, suggesting that plant genotype, rather than endophyte haplotype or environment, largely determines levels of peramine in Arizona fescue. The results suggest that whereas the endophyte is required for peramine production, the plant genotypic background in which the endophyte is embedded, rather than endophyte haplotype or environmental factors, mostly influences peramine levels within this population of Arizona fescue.

Key Words—Alkaloids, Arizona fescue, endophyte, environment, host, genotype, native grasses, mutualism, *Neotyphodium*, peramine.

INTRODUCTION

Symptomless, systemic, and asexual fungi in cool season grasses are generally viewed as plant mutualists because they often increase the resistance of their hosts to herbivores, root-feeders, and pathogens and increase competitive abilities (e.g., Clay, 1988, 1990; Saikkonen et al., 1998). Because the asexual endophyte is dependent on the host grass for dissemination to offspring plants, increases in host fitness should result in commensurate increases in endophyte fitness (e.g., Wilkinson and Schardl, 1997; Schardl and Clay, 1997). The primary mechanism of increased resistance to natural enemies of the host plant, as well as some aspects of increased competitive abilities, such as allelopathy (Peters and Zam, 1981; Matthews and Clay, 2001), is fungal-related alkaloids (e.g., Siegel and Bush, 1996; Bush et al., 1997; Schardl and Clay, 1997). The asexual, systemic endophyte in the genus *Neotyphodium*, as well as its closely related sexual form, *Epichloë*, may produce varying levels of alkaloids within four major groups—pyrrolizidine alkaloids (lolines), peramine, ergot alkaloids and indolediterpenoids (lolitrem) (Porter, 1994; Siegel and Bush, 1996; Bush et al., 1997). Whereas fungal alkaloids are the primary route for endophyte-related benefits to the host grasses, they may also represent a source of significant costs (Siegel and Bush, 1996; Faeth and Bultman, 2002; Faeth and Fagan, 2002). Alkaloids are nitrogen-rich compounds. Thus, fungal production of these compounds may compete with host growth and reproduction, especially when resources such as nitrogen are limiting, although nutrient demand for alkaloid synthesis may be partially offset if systemic endophytes increase nutrient uptake by roots (e.g., Malinowski and Belesky, 1999). Furthermore, alkaloids themselves may be toxic to the host (Faeth, 2002; Faeth and Bultman, 2002), as has been shown for constitutively produced alkaloids in plants (e.g., Karban and Baldwin, 1997). Thus, alkaloid production is expected to vary with available resources. In E+ domesticated grasses, alkaloid levels sometimes vary with soil moisture and nutrients (Arechavaleta et al., 1989; Agee and Hill, 1994; Roylance et al., 1994; Malinowski et al., 1998) and temperature (Huizing et al., 1991).

Although alkaloid levels may be influenced by environmental factors, the types and levels of alkaloids appear to depend mostly on endophyte species, strain, or genotype (Siegel et al., 1990; Leuchtmann, 1992, 1997; Bush et al., 1993; Christensen et al., 1993; Leuchtmann et al., 2000) and less so on host grass genotype and environment (e.g., Siegel et al., 1990; Leuchtmann et al., 2000). Endophyte species or genotype influences alkaloid production in both infected agronomic (e.g., Siegel et al., 1990; Bush et al.,1993; Christensen et al., 1993) and native grasses (Siegel et al., 1990; Leuchtmann et al., 2000). Endophytic fungal genes for alkaloid production have been identified in some infected domesticated grasses (Wilkinson et al., 2000). However, artificial transfer of endophytes from one host grass species to another suggests that species and genotypic background of the host grass may also influence alkaloid production (Siegel et al., 1990).

Natural variation in alkaloid levels among grass species and within and between populations has been documented for some infected native grasses (e.g., Siegel et al., 1990; Leuchtmann et al., 2000; Jones et al., 2000; Faeth and Fagan, 2002). Variation is often great, ranging from very high and toxic levels of certain alkaloids to none at all (e.g., Leuchtmann et al., 2000; Jones et al., 2000; Faeth, 2002; Faeth and Bultman, 2002). However, the relative contributions of endophyte and plant genotype and local environmental factors to this wide variation in alkaloid levels of E+ native grasses are largely unknown. To our knowledge, there are currently no studies of infected native grasses that simultaneously test host and endophyte genotype and environmental factors.

We determined how endophyte haplotype and plant genotype and environmental factors affect production of peramine in *Neotyphodium*-infected (E+) Arizona fescue as part of a long-term field experiment. In this experiment, two different genotypes of *Neotyphodium* (i.e., haplotypes) were removed from one half of the ramets of infected maternal genotypes, and the infected (E+) and uninfected (E−) clones of each plant genotype were grown under varying soil moisture and nutrient conditions. We predicted that alkaloid amounts should vary mainly by endophyte haplotype and, to a lesser extent, by maternal plant genotype and available resources. In terms of the latter, we predicted that alkaloids should increase in nutrient rich environments because fungal production of these compounds may represent costs to the host plant (e.g., Marks et al., 1991; Faeth and Fagan, 2002).

METHODS AND MATERIALS

Study Plant and Endophyte. Festuca arizonica (Vasey), Arizona fescue, in the subfamily Pooideae, is a dense, perennial bunch grass that reproduces by seed (USDA, 1988) and is native and widespread in the Southwest United States and in northern Mexico (Kearney and Peebles, 1960). Arizona fescue grows in semiarid Ponderosa pine–bunchgrass communities above 2000 m elevation (Kearney and Peebles, 1960), where soils are low in nutrients and seasonal and yearly droughts are common (Schulthess and Faeth, 1998). The asexual, systemic endophyte, *Neotyphodium starrii*, is common in Arizona fescue populations in Arizona, infecting 60–100% of host plants (Lopez et al., 1995; Schulthess and Faeth, 1998). At least three distinct genotypes of *Neotyphodium* have been isolated from Arizona fescue throughout the Southwest (e.g., White and Cole, 1987; An et al., 1992; C. Schardl, personal communication). *Neotyphodium* in *F. arizonica* populations from Arizona most closely resembles *N. starrii* (White and Morgan-Jones, 1987; White et al., 1993), and we use this convention here. *N. starrii* grows intercellularly in aboveground tissues of Arizona fescue, especially in the leaf sheath tissue (White, 1987; Schulthess and Faeth, 1998). *N. starrii*, like all other *Neotyphodium* species and some species of *Epichloë*, is transmitted by growing into culms and then into

developing seeds. Although *N. starrii* will sporulate under restricted conditions in culture (White and Morgan-Jones, 1987), it is vertically transmitted in nature (Faeth and Fagan, 2002), as are other *Neotyphodium* endophytes (e.g., Clay, 1990; Schardl and Clay, 1997). *Neotyphodium* in Arizona fescue produces only the alkaloid peramine (Faeth and Fagan, 2002; N.S. Hill, personal communication; M.R. Siegel, personal communication), one of the four types of alkaloids known and typically assayed from *Neotyphodium*-infected grasses, and at levels varying from zero to 2.3 μg/g in Arizona populations (Faeth and Fagan, 2002).

Neotyphodium-infected Arizona fescue plants were removed in spring 1997 from an isolated population at Merritt Draw, a drainage meadow on the Mogollon Rim (elevation 2500 m), Arizona. Four maternal plants were randomly selected in 1997 from a pool of about 50 E+ plants in the population. Infection was determined initially by a modified tissue print immunoassay (Gwinn et al., 1991) and later confirmed by staining seeds from each plant after each growing season and examining them for the presence of *Neotyphodium* hyphae (Saha et al., 1988; Schulthess and Faeth, 1998). Haploid, asexual *Neotyphodium starrii* is represented by two distinct haplotypes in the Merritt Draw population, based upon four microsatellite DNA loci from 27 sampled plants (Sullivan and Faeth, 2001; T. J. Sullivan, unpublished data). Two of the four plants harbored one haplotype (termed A) and two harbored the other (termed B). Haplotypes of the experimental plants were confirmed by microsatellite DNA analyses of multiple loci (Sullivan and Faeth, 2001). Other populations of *Neotyphodium*-infected Arizona fescue in Arizona can be represented by a single *Neotyphodium* haplotype [e.g., Flagstaff, Arizona population (Sullivan and Faeth, 2001)] or up to six different haplotypes within a single population [e.g., Clint's Well, Arizona population (Sullivan and Faeth, 2001)].

Field Experiment and Sampling. We sampled living leaf tissue for peramine assays from 172 adult Arizona fescue plants as part of a larger experiment designed to test the effects of infection on growth and performance under varying resource environments while controlling for the effects of endophyte haplotype and plant genotype. In brief (details of this experiment are in Faeth and Fagan, 2002), the four E+ maternal plants, two harboring haplotype A and two harboring haplotype B (termed A-1, A-2, and B-1, B-2, respectively) were split into ramets and treated hydroponically with low levels of the fungicide propiconazole to remove the endophyte (M. Marlatt and C. West, personal communication). Fungicide treatment removes *Neotyphodium* from about 50% of ramets (E−); the remaining infected ramets of one genotype (genotype A) served as fungicide-treated, but infected controls (hereafter, termed E + F) such that any spurious effects of the fungicide on alkaloid levels could be tested. Other ramets were treated hydroponically but without fungicide and, thus, remained infected (hereafter E+). After hydroponic treatment, all ramets were planted individually into 16-oz. cups with native soil and continually split and repotted as they grew for about one year in the greenhouse

to provide cloned replicates. Infection status after cloning and growth in the field was confirmed as described above.

Removal of the endophyte strictly controls for plant genotype but does not control for endophyte haplotype. To strictly control for endophyte haplotype, reciprocal inoculations of endophytes from endophyte-removed maternal plants is necessary. While inoculations of uninfected, new seedlings under sterile laboratory conditions are possible for agronomic (e.g., Latch and Christensen, 1985; Christensen, 1995) and a few native grasses (e.g., Meijer and Leuchtmann, 2001), inoculations of adult ramets has thus far only recently been accomplished with the related *Epichloë* endophyte (Johnson-Cicalese, et al. 2000), but not *Neotyphodium*. Inoculation at the seedling stage does not control completely for plant genotype because each seedling is, at best, a full sibling due to the genetic contribution of the male parent. Moreover, inoculations of one haplotype into a maternal plant genotype may result in haplotype-genotype combinations that would not normally occur in nature because the endophyte is strictly maternally transmitted. We note that our experiment using endophyte-removed maternal ramets with known endophyte haplotypes to test how endophyte and plant genotype and varying environments affect alkaloid production is the first, to our knowledge, for a native grass.

We assumed that the maternal plants, two of which harbored haplotype A and two haplotype B, differed genetically from each other. This assumption is reasonable since Arizona fescue forms distinct bunches, outcrosses to produce seed, and does not reproduce by rhizomes (USDA, 1988). All four of the selected maternal plants were at least 10 m from each other. Obviously, plants with different endophyte haplotypes originated from different maternal lines because *Neotyphodium* is maternally transmitted. Maternal plants with the same haplotype are, at worst, half-sibs and probably less related than half-sibship because of outcrossing and very low dispersal distances of seeds from maternal plants ($<$2 m, S. H. Faeth, personal observation).

After growing for one year in the greenhouse, the plants were transplanted into a plot (1 m apart, randomly assigned) at the Arboretum of Flagstaff (elevation 2500 m), where Arizona fescue is the dominant native grass, in June 1998. The arboretum is fenced (4 m high) to exclude livestock and large native grazers (elk and deer) but subjected to herbivory from small vertebrates and invertebrate herbivores and root-feeders. All transplanted plants were approximately the same size ($\sim$10 tillers each). Before planting, the plot was disked to remove native vegetation, which was mostly Arizona fescue and a few other native grasses and forbs. Each plant was randomly assigned one of the following treatments: (1) ambient water and ambient nutrients, (2) supplemental water (1000 ml/plant every three days), (3) added nutrients (1.5 g/liter; 30 N–15 P–30 K fertilizer, every two weeks, and (4) added water (every three days) plus supplemental nutrients (every two weeks). Treatments began immediately after transplanting in 1998 and continued during the next two growing seasons (May–September of 1999 and 2000). All

genotype, infection status, and treatment combinations, including E + F plants, were replicated five times for a total of 180 plants. Eight plants died during the course of the experiment and, thus, 172 plants were sampled for peramine. Ambient precipitation at the arboretum is typically low from April through June each year ($\bar{X} = 16$ mm/month, 50-year average) until summer rains begin in July and August and then again in October and November ($\bar{X} = 38$ mm/month, 50-year average) until winter precipitation begins in December. Soil moisture measurements in the 2000 growing season showed that ambient soil moistures were ~20% saturation from April to June) and increased to 40% saturation in July and August, when summer rains began. Supplemental water treatments increased soil moisture to ~80% saturation throughout the growing season. Likewise, ambient soil nutrients are low (~1–2 ppm N) in native soils at the arboretum (Schulthess and Faeth, 1998), and the level of fertilizer used significantly increases nitrogen content of Arizona fescue plants (Saikkonen et al., 1999). The plot (except for a circular area around each plant to allow aboveground expansion) was covered with a weed barrier (Dalen Co.) that permits water and nutrient penetration but prevents weed growth and hence unwanted plant competition. The barrier was then covered with commercial Ponderosa pine bark chips.

We sampled living leaf tissue from the 172 plants in September 2000 (the end of the growing season but before plants senesced) when plants were harvested in connection with the larger experiment. At this time, growth and reproductive parameters of each plant were also determined. In brief (see Faeth and Fagan, 2002, for details), above- and below-ground mass, mass of seeds, and growth rate were determined. The latter was estimated by dividing final above-ground volume by the above-ground volume at the beginning of growing season. We could not determine any seasonal variation in peramine because the design of the larger experiment did not allow for periodic tissue removal. Tissue samples were placed on dry ice in the field and returned to the laboratory where they were kept frozen and then lyophilized and ground into a fine powder.

Determination of Peramine Levels. All peramine analyses were conducted at the University of Kentucky by LPB. Briefly, peramine was extracted from 150 mg samples and concentration determined by thin-layer chromotography (TLC) modified from Fannin et al. (1990). Then 1200 μl of 80% ethanol was added to the sample in a microcentrifuge tube, the sample was mixed and sonicated, and shaken for 1 hr. After 1 hr, tubes were again mixed, sonicated, and centrifuged. Five hundred microliters of supernatant was removed and taken to dryness in a stream of nitrogen. The residue was dissolved in 50 μl ethanol and 10 μl applied to a reversed-phase TLC plate. The spot was placed about 2.5 cm from one edge of the plate. Development was done in two directions. The edge of the plate opposite the origin was immersed in 0.1% H_3PO_4, pH 7.25, and 60% methanol, and the solvent was allowed to migrate to the top of the plate. The plate was then removed and a strip of adsorbent, 14 mm wide from the edge to the plate towards

the origin, was removed. After drying, the plate was developed in 0.6 M NaCl in 50% methanol removed from the tank, and sprayed with van Urk's reagent. After it was thoroughly dry, the plate was scanned in a Shimadzu High-Speed Thin-layer Chromato-Scanner (model CS-920) at 600 nm in the reflectance mode. The amount of peramine present was determined from a standard calibration curve for each run with authentic peramine. Peramine concentrations are expressed as micrograms per grams of dry mass of the plant.

Statistical Analyses. Peramine levels were not detected in any of the endophyte-removed (E−) plants, even in trace amounts. Therefore, statistical tests for differences between E+ and E− plants were irrelevant. For the E+ plants, we used ANOVA (Systat, 2000; GLM procedures), with plant genotype nested within endophyte haplotype, to test for differences in peramine concentrations based upon haplotype and treatment and their interaction. We also tested for any extraneous effects of the fungicide by comparing peramine levels for E+ and E + F plants (genotype A-1) with a two-factor (fungicide/no fungicide and treatment) ANOVA. All assumptions of ANOVA (e.g., homogeneity of variances) were tested and met. We used Tukey HSD tests to compare differences among levels of factors, when significant.

We used linear multiple regression analyses (Systat, 2000) to determine relationships between peramine content (dependent variable) and growth and reproductive parameters (independent variables). We first used a full multiple regression analysis where all independent variables and the constant were included in the regression model. We then used a backward stepwise regression where each independent variable was removed in a reverse direction from the full model to determine which variables contributed significantly to the regression model.

RESULTS

No peramine was detected (assays were sensitive to 0.003 μg/g) in any of the endophyte-removed plants for any genotype and treatment. Peramine levels did not vary between the E + F fungicide control plants ($\bar{X} = 0.87$ μg/g, SE $= 0.08$) and E+ plants ($\bar{X} = 0.97$ μg/g, SE $= 0.10$) of genotype A ($F = 1.17$, $df = 1,30$ $P = 0.29$), indicating that fungicide treatment did not spuriously alter peramine levels. We expected no differences because the field plants were removed by one year of regrowth, splitting, repotting in the greenhouse, and then >2 years of growth in the field.

For the E+ plants, peramine concentrations did not vary by *Neotyphodium* haplotype (Table 1, no endophyte haplotype effect; haplotype A, $\bar{X} = 0.76$ μg/g SE $= 0.07$; haplotype B, $\bar{X} = 0.82$ μg/g, SE $= 0.08$). Peramine levels did not vary by treatment (Table 1, no treatment effect; Figure 1) nor did haplotype interact significantly with the treatments (Table 1, no treatment haplotype effect).

TABLE 1. ANALYSES OF VARIANCE OF EFFECT OF *Neotyphodium* HAPLOTYPE, PLANT GENOTYPE NESTED WITHIN HAPLOTYPES, AND TREATMENTS ON PERAMINE LEVELS[a]

Source of variation	*df*	Sum of squares	Mean square	*F* ratio	*P*
Endophyte haplotype	1	0.07	0.07	0.46	0.50
Plant genotype within haplotype	2	5.02	2.51	17.51	<0.001
Treatment	3	0.84	0.28	1.96	0.13
Treatment x haplotype	3	0.29	0.10	0.68	0.57
Error	62				

[a] Results are for E+ Plants only because E− (endophyte-removed) had no detectable alkaloids.

Different plant genotypes with the same *Neotyphodium* haplotype varied in peramine levels (Table 1, Figure 2A,B). Plant genotype A-1 had higher peramine levels than did plant genotype A-2 harboring the same haplotype A (Figure 2A). Conversely, plant genotype B-1 had lower peramine levels than did plant genotype B-2 (Figure 2B).

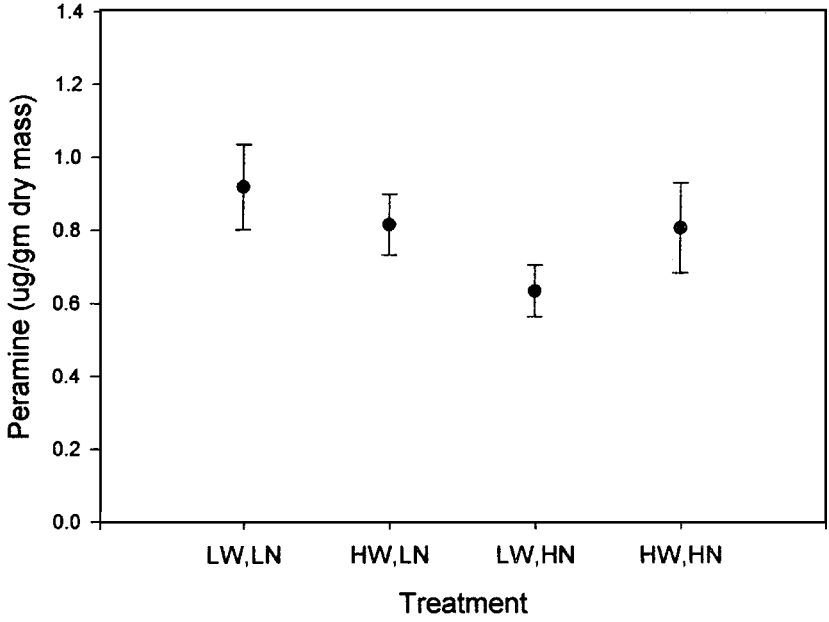

FIG. 1. Peramine concentrations (mean ± SE) of *Neotyphodium*-infected Arizona fescue plants in four water and nutrient treatments (LW,LN = ambient water and nutrients; HW, LN = supplemented water, ambient nutrients; LW,HN = ambient water and supplemented nutrients; HW,HN = supplemented water and nutrients).

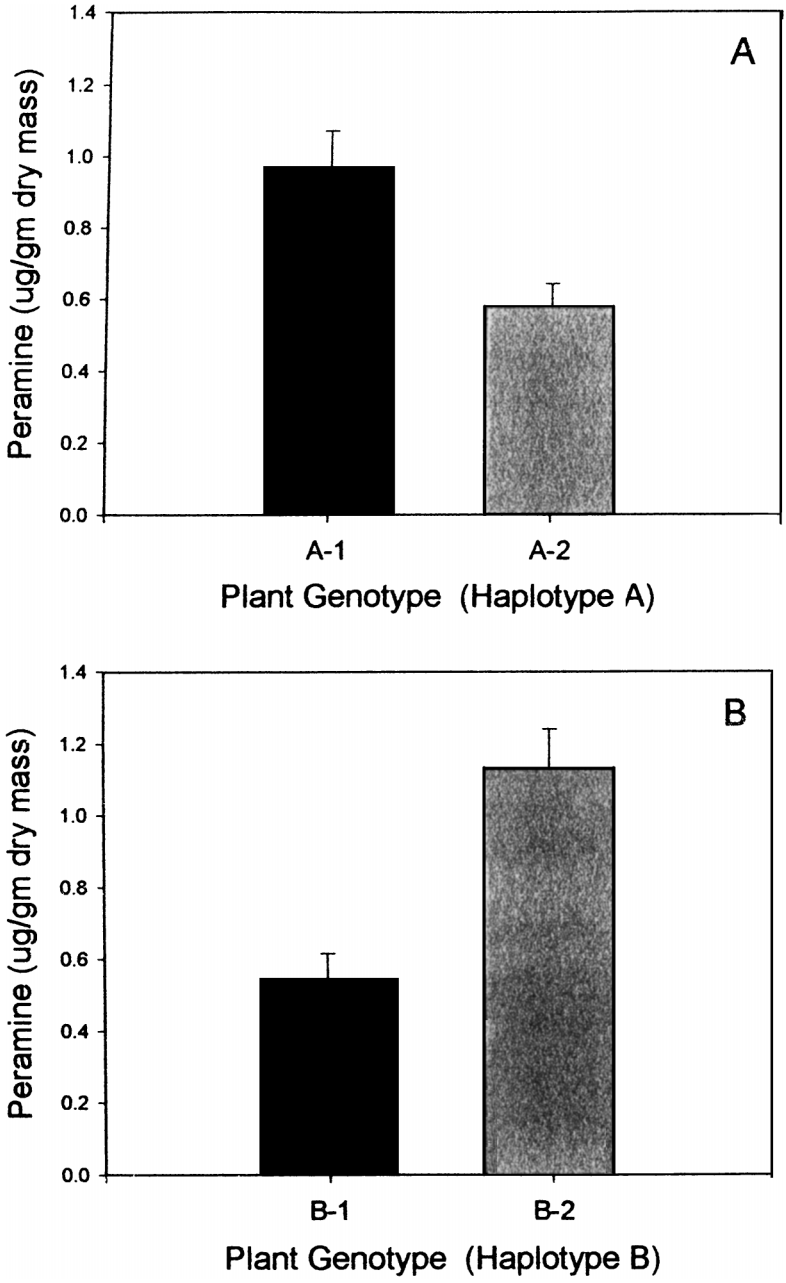

FIG. 2. Peramine concentrations (mean ± SE) of Arizona fescue by genotypes harboring *Neotyphodium* haplotype A and haplotype B.

The full multiple-regression analyses indicated that variation in peramine content was related to host grass growth and reproduction parameters ($F = 2.59$, $df = 5,48$, $P = 0.04$), but the full regression model explained only 13% ($R^2 = 0.131$) of the variation in peramine amounts. Of the five growth and reproductive parameters, only growth rate (as measured by change in above-ground volume from the beginning to the end of the growing season) was significant ($P = 0.003$). Stepwise removal of the other four variables did not affect the overall model. The regression of peramine content with growth rate only showed that peramine levels were positively related to growth rate in the final growing season ($F = 5.10$, $df = 1, 76$, $P = 0.027$), but the regression explained only 6% of the variation in peramine content ($R^2 = 0.06$).

DISCUSSION

The results show that the presence of *Neotyphodium* is necessary for production of the alkaloid peramine in Arizona fescue; plants with their endophyte removed produce no detectable peramine under any environmental conditions. The metabolic origin of alkaloids in endophyte-infected grasses has not always been clear because systemic fungal endophytes in culture may not produce alkaloids, and occasionally alkaloids have been found in host grasses after fungi have been apparently removed (Siegel et al., 1990). Furthermore, some grasses themselves appear capable of producing constitutive alkaloids and other allelochemicals (Chapman, 1996).

Whereas the qualitative production of peramine requires the presence of *Neotyphodium* in Arizona fescue, our results suggest that the host grass genotype, not the endophyte haplotype, determines the quantitative production of alkaloids. Both *Neotyphodium* haplotypes produced different levels of peramine depending on their maternal grass hosts. These results contrast with other studies of alkaloids in E+ grasses where endophyte strain or species is thought to largely dictate alkaloid types and levels (e.g., Siegel et al., 1990; Christensen et al., 1993; Leuchtmann et al., 2000), although many of these cases involved among-host species comparisons. Siegel et al. (1990) found that some endophyte strains in different plant genotypes or species produce different alkaloids, also suggesting that host plant genotype influences alkaloid levels.

Caution is necessary in interpreting the results because we have tested only two *Neotyphodium* haplotypes within two plant genotypes within the same population. Furthermore, identification of endophyte as the same haplotypes via microsatellite DNA, or for the matter, via isozymes, does not necessarily mean those endophytes are genetically identical in peramine-related genes (e.g., Roylance et al., 1994). Including more maternal plant genotypes and endophyte haplotypes from other Arizona fescue populations may complicate the pattern, and additional experiments determining the alkaloid levels of purported haplotypes in

axenic cultures are necessary to confirm our results. We also caution that infected plants could produce other alkaloids besides peramine and be different from the four major groups routinely tested for in endophyte-infected grasses. However, previous experiments and observations on vertebrate (Schulthess and Faeth, 1998; Saikkonen et al., 1999) and invertebrate herbivores (Lopez et al., 1995; Tibbets and Faeth, 1999; Saikkonen et al., 1999; Faeth and Fagan, 2002) suggest this possibility is remote, at least at levels at which herbivores would be negatively affected.

Nevertheless, the results suggest that the widely varying levels of peramine found within the Merritt Draw population of E+ Arizona fescue, and perhaps other populations, may result mostly from the genotypic background of the host. The *Neotyphodium* endophyte is transmitted asexually by hyphae growing into seeds, and, thus, remains genetically uniform within offspring of a maternal plant. Alternatively, genetic recombination during sexual reproduction of the host probably results in many different host genotypes with the same, or very few different, endophyte haplotypes in the host populations. Sullivan and Faeth (2001) found that four populations of Arizona fescue range from a single to six different *Neotyphodium* haplotypes. Multiple haplotypes within the same population apparently result from historical hybridization events between *Neotyphodium* and its sexual ancestor, *Epichloë* (e.g., Schardl et al., 1994; Tsai et al., 1994) or more recent colonization events of E+ seeds or plants with different haplotypes. The latter mechanism, however, seems unlikely given the low dispersal of Arizona fescue. Additional studies are necessary to determine whether these other haplotypes influence peramine levels within and between populations, or if plant genotype remains the dominant factor in determining peramine concentrations.

Our prediction that peramine levels should increase with available resources, particularly nitrogen, was not supported. In agronomic E+ grasses, increased nitrogen (Bacon, 1993; Agee and Hill, 1994), especially under moderate water stress (Belesky et al., 1989; Arechavaleta et al., 1992), may increase alkaloid levels. However, we found no effect of soil moisture or nutrients on peramine production, and no interaction of these abiotic factors with plant genotype (Table 1).

There are several explanations for the lack of effects of soil moisture and nutrient on peramine levels. First, we could not determine seasonal variation because of the design of the experiment, and peramine levels were determined only at the end of the growing season. Whereas levels of peramine at the end of the growing were not affected by the treatments, peramine concentrations may have been related to soil moisture or nutrients earlier in the growing season or in previous years of the study. Seasonal variation in alkaloids occurs for some E+ domesticated (e.g., Belesky et al., 1987; Roylance et al., 1994; Ball et al., 1995; Belesky and Hill, 1997) and native (e.g., Leuchtmann et al., 2000) grasses, although alkaloids levels usually are cumulative seasonally, and the highest levels occur at the end of the growing season (Siegel and Bush, 1996; Leuchtmann et al., 2000). Therefore, we would expect that peramine levels at the end of season should correspond

in relative levels to earlier in the season, even though absolute levels may vary seasonally. Second, we sampled leaf material, which constitutes the bulk of the plants. Alkaloid levels may also vary among plant parts and tissues (e.g., Ball et al., 1997; Belesky and Hill, 1997; Justus et al., 1997; Leuchtmann et al., 2000). It is possible that soil moisture and nutrients may have affected the amounts of peramine in other, nonsampled tissues. However, relative amounts of alkaloids in different plant tissues are usually positively related (e.g., Leuchtmann et al., 2000). A third explanation is that moisture and nutrients were not limiting to plant growth. Thus, peramine production was not altered because host plant stress or nutrient limitation did not occur. However, plants in the supplemented water and nutrient had significantly increased plant growth and reproduction (Faeth and Fagan 2002, Faeth and Sullivan, unpublished). Furthermore, previous experiments using Arizona fescue and the same nutrient manipulations as here, showed increased nitrogen content of the plant (Saikkonen et al., 1999). Therefore, we expected peramine levels, if affected by water stress or nutrient limitation, should have increased in the supplemented nutrient treatments, especially those subjected to low levels of water availability (e.g., Arechavaleta et al., 1992). The results, however, suggest that plant genotype, not environmental factors, explains most of the variation in peramine in E+ Arizona fescue in their semiarid and low-nutrient habitats. Peramine production may be so low, or even nonexistent in some E+ Arizona fescue plants (Faeth and Fagan, 2002), that it would rarely compete with host plant growth and reproduction. If infection increases nutrient uptake by Arizona fescue in their normally poor soils, as demonstrated by Malinowski and Belesky (1999) for E+ tall fescue, then nutrient demand for alkaloid synthesis may also be reduced. This scenario, of course, assumes that alkaloid production is costly to the host, either in terms of production, opportunity, or storage costs (e.g., Bazzaz and Grace, 1997) or autotoxicity to the host (e.g., Karban and Baldwin, 1997). In general, the actual cost of plant defense via allelochemistry is still debated (e.g., Purrington, 2000; Hamilton et al., 2001).

The lack of environmental effects on peramine levels and the low levels of peramine in *Neotyphodium*-infected Arizona fescue found here, as well as in a survey of other E+ Arizona fescue plants in this population (Faeth and Fagan, 2002), suggests that peramine production may entail relatively low costs to the host grass. Some E+ Arizona fescue plants in this population have no detectable peramine or other alkaloids (Faeth and Fagan, 2002). However, the low peramine levels also suggest few alkaloid-related benefits for the host. Deterrence of herbivory via alkaloids is considered the primary avenue for endophyte-related benefits to the host grass, which has been frequently demonstrated for E+ domesticated (e.g., Clay, 1988, 1990; Cheplick and Clay, 1988; Breen, 1994) and a few native grasses (e.g., Jones et al., 2000; Brem and Leuchtmann, 2001). Siegel and Bush (1996) and Rowan and Latch (1994) indicated that peramine alkaloid is generally deterrent and toxic to invertebrate herbivores, but only at levels greater than 3.0 μg/g.

Therefore, benefits of infection to the host related to herbivore deterrence via endophyte-related peramine seem improbable in E+ Arizona fescue. These low levels of peramine, and sometimes the complete absence of alkaloids, are not uncommon in many E+ native grasses (Leuchtmann et al., 2000). Lack of herbivore deterrence in E+ Arizona fescue has been demonstrated for vertebrate (Schulthess and Faeth, 1998; Saikkonen et al., 1999) and a suite of invertebrate (Lopez et al., 1995; Tibbets and Faeth, 1999; Saikkonen et al., 1999; Faeth, 2002) herbivores. Other possible benefits of peramine to the host include allelopathy and inhibition of pathogens or seed predators (e.g., Faeth and Bultman, 2002; Faeth, 2002), although preliminary tests (Faeth, et al., 2001; Faeth, 2002) and the low levels of peramine again suggest that these benefits to the host are unlikely.

E+ Arizona fescue, like many other *Neotyphodium*-infected native grasses (e.g., Leuchtmann et al., 2000), displays wide variation in alkaloid levels within and between populations (Faeth and Fagan, 2002). The observed variability of peramine within populations appears related to reshuffling of plant genotypes at each transmission event of a limited number of relatively static endophyte haplotypes.

Acknowledgments—We thank C. Brillhart, R. DiSilvertro, N. Fuller, C. Hamilton, C. Hayes, J. Horne, W. Marussich, L. Morse, K. Neil, J. Rambo, L. Taft, and M. Triplett for their assistance in the field and laboratory assistance. We are grateful to M. Marlatt and C. West for technical advice on hydroponic removal of endophytes. We also thank the staff at The Arboretum of Flagstaff, especially J. Maschinski, for access and preparation of field sites. The USDA Forest Service, Blue Ridge Station, also provided generous access to field sites. T. Dowling and A. Leuchtmann made helpful comments on earlier versions of the manuscript. The research was supported by NSF grants DEB 9727020 and DEB 0128343 to S.H.F.

(Received December 11, 2001; accepted April 18, 2002)

Abstract—The sap beetle, *Colopterus truncatus* (Coleoptera: Nitidulidae), is one of the primary vectors of the oak wilt pathogen, *Ceratocystis fagacearum*, in the north-central United States. Field behavioral assays utilizing various release rates and blends of three methyl-branched hydrocarbon aggregation pheromone components showed that flight responses of this beetle were similar in Illinois and Minnesota populations. In both locations, both sexes of the beetle responded synergistically to a combination of the three-component pheromone and fermenting whole-wheat bread dough. Further, *Colopterus truncatus* preferred a high release rate over a low release rate of the three-component blend. In both locations, the response of *C. truncatus* to a simplified version of the pheromone consisting of (2*E*,4*E*,6*E*)-3,5-dimethyl-2,4,6-octatriene (**1**) and (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene (**3**) was not significantly different from the response to the three-component blend. An experiment in Illinois with all possible combinations of the components demonstrated that the decatetraene (**3**) was the crucial component in the blend; of all treatments, the maximal response was elicited by **3** + dough. Chipped bark, phloem, and xylem from northern pin oak, *Quercus ellipsoidalis*, was not attractive to *C. truncatus* in Minnesota. During a weekly survey over two seasons in Minnesota, *C. truncatus* flew in response

0098-0331/02/0800-1527/0 © 2002 Plenum Publishing Corporation

to the three-component pheromone between early April and early July, with the maximum responses coming on May 4, 2000 and April 20, 2001. During both years, more than 98% of the beetles were trapped between April 14 and June 1. During the same survey, *Glischrochilus* spp. (Nitidulidae) flew during longer periods of the summer, particularly in 2001. The sex ratio of *C. truncatus* responding during all experiments was female-biased (1.8:1, female–male), which is characteristic of other male-produced coleopteran aggregation pheromones. Other sap beetles that play a minor role in the pathobiology of *C. fagacearum* also responded in experiments conducted in Minnesota. *Carpophilus brachypterus* Say was cross-attracted to the two- and three-component blends of the *C. truncatus* pheromone and dough, whereas two *Glischrochilus* spp. were attracted to all treatments that contained dough.

Key Words—*Colopterus truncatus*, oak wilt, *Ceratocystis fagacearum*, aggregation pheromone, Coleoptera, Nitidulidae, sap beetle, *Glischrochilus* spp., *Carpophilus brachypterus*, methy-branched hydrocarbons, monitoring, phenology.

INTRODUCTION

Oak wilt, *Ceratocystis fagacearum*, Bretz (Hunt), is a fungal disease that annually kills many oak trees (Fagaceae: *Quercus* spp.) across a large area in the eastern and north-central United States (Tainter and Baker, 1996). For example, by the mid-1990s, aerial photographs recorded 3000 oak wilt infection centers (areas) in Minnesota that contained 100,000 recently killed trees (French, 1995). This disease has had a significant effect on the vegetative composition of natural, periurban, and urban forests and is the disease of most concern to forest health specialists in 5 of the 22 states in which it occurs (Billings, 2000).

One way in which new oak wilt infection centers are established in the landscape is through the dispersal of oak wilt spores during the feeding and reproductive activities of sap beetles (Coleoptera: Nitidulidae). These insects are attracted to and aggregate on oak wilt fungal fruiting tissues (mats) that occur on oaks recently killed by the pathogen (Lin and Phelan, 1992; Cease and Juzwik, 2001). The beetles feed, mate, and oviposit on the mats from which oak wilt fungal propagules are ingested and accumulate on the cuticular surfaces of the adults and larvae (Curl, 1955; Jewell, 1956; Juzwik, 1983). Spore-laden sap beetles also aggregate, feed, mate, and oviposit in sap fluxes associated with fresh wounds on uninfected oak trees, thereby propagating the disease (Jewell, 1956). The response of sap beetles to wounded oak tissue can be remarkably rapid; some species may be attracted to experimentally created wounds within 15 min (J.J., personal observation). In one study, up to 78% of sap beetles that responded to wounds carried viable oak wilt spores in or on their bodies (Juzwik et al., 1999). Behaviors associated with exposure to inoculum and the visitation of fresh wounds have led to the identification of two sap beetles, *Colopterus truncatus* (Randall) and *Carpophilus sayi* (Parsons),

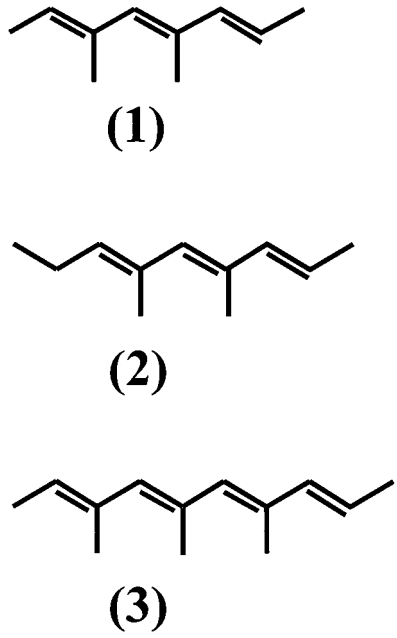

FIG. 1. Hydrocarbon components of the male-produced *Colopterus truncatus* aggregation pheromone: (**1**) (2*E*,4*E*,6*E*)-3,5-dimethyl-2,4,6-octatriene, (**2**) (2*E*,4*E*,6*E*)-4,6-dimethyl-2,4,6-nonatriene, and (**3**) (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene.

as the primary vectors of oak wilt in the north-central United States (Juzwik et al., 1999; Cease and Juzwik, 2001).

In order to improve our understanding of the life history of *C. truncatus*, we investigated the response of this insect and associated sap beetles to semiochemicals in oak forests of Illinois and Minnesota. Little is known about the chemical ecology of the response of *C. truncatus* to oak wilt mats or to wounded oaks in the field. However, a three-component, male-produced aggregation pheromone was recently isolated and identified from *C. truncatus* (Cossé and Bartelt, 2000). Three methyl-branched hydrocarbons, (2*E*,4*E*,6*E*)-3,5-dimethyl-2,4,6-octatriene (**1**), (2*E*,4*E*,6*E*)-4,6-dimethyl-2,4,6-nonatriene (**2**), and (2*E*,4*E*,6*E*,8*E*)-3,5,7-trimethyl-2,4,6,8-decatetraene (**3**) (Figure 1), elicited electroantennographic activity from male and female antennae, and when combined with fermenting whole-wheat bread dough as a trap bait, synthetic hydrocarbon **2**, the combination of **1** and **3**, and the combination of **1**, **2**, and **3**, all elicited flight responses from both sexes that significantly exceeded the response to dough alone (Cossé and Bartelt, 2000). The nonatriene (**2**) was the most abundant of the three components; volatiles collected from males indicated emission rates of 1.8:100:3.3 for **1**, **2**, and

3, respectively. However, Cossé and Bartelt (2000) did not unequivocally establish the relative significance of the components for the flight response of *C. truncatus*, particularly in light of the differences in volatility of components **2** and **3** after they had been loaded on rubber septa for slow release in the field.

In this study, we report new information on the chemical ecology of *C. truncatus* and other sap beetles associated with oak wilt. The specific goals of this study were to: (1) determine and compare the responses of *C. truncatus* to its pheromone at two different locations in the north-central United States; (2) optimize the blend and release rate of the *C. truncatus* synthetic aggregation pheromone components and explore the potential of specific synergy of the pheromone with oak tissue; and (3) determine the flight period of *C. truncatus* in oak forests in Minnesota to more clearly define the high risk seasonal period for overland transmission of oak wilt.

METHODS AND MATERIALS

Semiochemicals and Baits. As attractants, we used the synthetic aggregation pheromone components for *C. truncatus* [**1**, **2**, and **3** (Cossé and Bartelt, 2000) (Figure 1)] combined with fermenting whole-wheat bread dough or oak chips. Our standard attractant for *C. truncatus* consisted of dough in a plastic cup (see below) and 3.5, 500, and 280 μg each of the all *E* isomers of **1**, **2**, and **3**, respectively, applied in hexane to a rubber septum. Solution concentrations were quantified by capillary GC using an internal standard, and all pheromone components were formulated at the USDA-ARS laboratory in Peoria (Cossé and Bartelt, 2000). With these initial amounts of **1**, **2**, and **3** loaded on a septum, laboratory analyses have indicated that the proportions released during the first day from a trap are very close to those emitted by male beetles (Cossé and Bartelt, 2000). In two experiments, the treated septa were placed within 1.5 ml polyethylene Eppendorf microcentrifuge tubes each with a single pinhole in the lid (low release rate). Otherwise, the treated septa were pinned directly to the trap (high release rate).

The synthetic compounds had ca. 80% chemical purity and after passage through silica gel with hexane to remove polar contaminants, the remaining impurities were small amounts of *Z* isomers. The *Z* isomers result both as artifacts of synthesis and from slow isomerization of the *E* isomers, and there is presently no simple, large-scale method available for their removal. However, with other nitidulids, small amounts of *Z* isomers have not significantly reduced trap catch (Bartelt, 1999).

When compound **3** is synthesized (Bartelt et al., 1990), about 1–2% of the product consistently is compound **1** (which arises because a Wittig-Horner condensation does not quite go to completion). When a 100:1 mixture of **3** and **1** is applied to a rubber septum, **3** and **1** are released with an initial ratio of about 5:1 instead of 100:1 because of the impurity and because of their different boiling

points (Cossé and Bartelt, 2000). Thus, synthetic **3** on a rubber septum will deliver both **3** and **1** into the air at approximately the same ratio as from the male beetles (3.3:1.8). No complication of this sort arises with **2** because neither **3** nor **1** are produced in its synthesis, nor is **2** produced in the synthesis of **1** or **3**.

For one experiment (IV), samples of **1**, **2**, and **3** were purified further so that they could be tested individually and in all possible combinations. Synthetic **3** was purified by HPLC on a $AgNO_3$-coated silica column (Heath and Sonnet, 1980), using 0.5% 1-hexene in hexane as the solvent. The procedure removed all traces of **1** and a substantial fraction of the *Z* isomers [final chemical purity 90%, by capillary GC, instrumentation as in Cossé and Bartelt (2000)]. The major triene **2** was similarly purified to >90% by HPLC; the purity of minor triene **1** was 81%. After HPLC purification, this sample was free of compounds **2** and **3**.

Fermenting whole-wheat bread dough (dough) was used in these experiments because it is an attractive food bait to a variety of nitidulid species and because it has also been shown to act as a synergist for all nitidulid pheromones tested (Bartelt, 1997). Dough was prepared in the laboratory between 2 and 6 hr before use and consisted of whole-wheat flour, table sugar, water, and baker's yeast (3:1:3–4:0.1). Approximately 10–15 ml of dough was placed in a 35-ml plastic cup, and the cup was placed in the trap.

To test for the possibility of attraction of *C. truncatus* to volatiles produced by oaks, tissue was collected from a healthy northern pin oak, *Quercus ellipsoidalis* (E. J. Hill), in mid-April 2001. Live branches (<6 cm diam.) were cut and chipped using a chipper/shredder. All branch chips were mixed together and stored in heavy plastic bags in a −55°C freezer until they were placed in the field.

Traps and Field Sites. All studies used wind-oriented funnel traps (Dowd et al., 1992), which were hung from tree branches or posts ca. 1–1.5 m above the ground. Traps were placed at least 10 m apart. In one experiment, the traps were slightly modified to hold approximately 300 ml of oak chips. In Illinois, all studies were conducted in a single mixed hardwood forest near East Peoria (40.7°N latitude, 89.8°W longitude), while in Minnesota, four separate northern red/white oak (*Quercus rubra* L./*Quercus alba* L.) forests near Minneapolis-St. Paul were used as field sites. All four Minnesota field sites were separated by at least 5 km: Carlos Avery Wildlife Management Area (45.4°N latitude, 93.0°W longitude), a private residence in Columbus township (45.2°N latitude, 93.1°W longitude), Katherine Abbott Park in Mahtomedi (45.1°N latitude, 93.0°W longitude), and a private residence in Lake Elmo (45.0°N latitude, 92.9°W longitude). If more than one block was located at a site, blocks were separated by at least 100 m.

Field Bioassays. Six experiments were conducted in this study. They took place in Illinois in 2000 and in Minnesota in 2000 and 2001.

Experiment I. A study was conducted from late March to mid-April, 2000 in Illinois to establish the importance of the dough coattractant and to determine which of two pheromone release rates was most attractive to *C. truncatus*. The

experiment consisted of: (1) a high release rate of **1** + **2** + **3**, (2) a low release rate of **1** + **2** + **3**, (3) dough, (4) a high release rate of **1** + **2** + **3** + dough, (5) a low release rate of **1** + **2** + **3** + dough, and (6) an unbaited control. The experiment was initiated on March 24 with two completely randomized blocks (six traps per block), and the traps were emptied semiweekly until April 18. Treatment locations were rerandomized within blocks and dough baits were replaced after each trap was emptied. Pheromone baits were replaced weekly, but the replacement was staggered so that it was done in just one of the blocks after each trap check. Thus, after March 28 pheromone baits of two ages were always present, and in principle, changes in bait attractiveness over time would not be completely confounded with day effects.

Experiment II. Experiment I (Illinois) was duplicated in 2000 in Minnesota with the additional goal of monitoring the seasonal flight periodicity of *C. truncatus*. The same six treatments and the same trap type from experiment I were used. Experiment II was initiated on April 14 in a completely randomized block design in each of four field sites. Traps were emptied, rerandomized, and rebaited weekly until November 3. Traps were not baited in a staggered fashion as described in experiment I.

Experiment III. In 2001, the response to different treatments and the seasonal flight periodicity of *C. truncatus* were again monitored in Minnesota. This experiment consisted of: (1) a high release rate of **1** + **2** + **3** + dough, (2) dough, and (3) an unbaited control. The experiment was initiated on April 5 and continued until November 9. Sites, rebaiting, and rerandomization schedules were the same as in 2000.

Experiment IV. In 2000, in a second experiment in Illinois, the effects of **1**, **2**, and **3** on the response of *C. truncatus* were studied. In this case, the compounds were released individually and in all possible combinations. The amounts of each component loaded on the septa were 3.5, 500, and 280 μg, respectively, no matter what combination was tested. Based on the results of experiment I, high release rates of **1**, **2**, and **3** were always combined with dough. The experiment consisted of: (1) **1** + dough, (2) **2** + dough, (3) **3** + dough, (4) **1** + **2** + dough, (5) **1** + **3** + dough, (6) **2** + **3** + dough, (7) **1** + **2** + **3** + dough, and (8) dough alone control. The experiment was established as two completely randomized blocks, each with eight traps, in the same woodlot used for experiment I. Traps were set on posts at a height of 1 m and were baited fresh at ca. 07:00 AM on mornings with a favorable weather forecast (i.e., temperature $>15^{\circ}$C, with minimal wind and cloud cover). As peak flight activity of *C. truncatus* occurs in mid- to late afternoon (R.J.B., personal observation), traps were emptied either near dusk or early the following morning. Treatment locations were rerandomized within blocks each day. Seven replications of the experiment were run between April 21 and May 5, 2000, and each replication was of short duration to ensure that the component ratios and emission rates of the pheromone components would be essentially stable throughout the study.

Experiment V. Based on the results of experiment IV in Illinois, an experiment was conducted in 2001 in Minnesota (same four sites) to compare responses of *C. truncatus* to the high release rate of **1** + **2** + **3** and to the high release rate of **1** + **3**. As in experiment IV, the amounts of **1**, **2**, and **3** loaded on the septa were always 3.5, 500, and 280 μg, respectively. However, in this instance, component **3** also consisted of 1–2% of component **1**. The experiment consisted of: (1) **1** + **2** + **3** + dough, (2) **1** + **3** + dough, (3) dough, and (4) an unbaited control. Traps were hung from trees at a height of 1.5 m, baited fresh between 07:00 and 10:00 AM on days with a favorable weather forecast (as above), and emptied 24 hr later. This experiment was conducted for eight days between April 28 and May 31.

Experiment VI. An experiment was conducted in 2001 in Minnesota to compare responses of *C. truncatus* to oak chips (i.e., their volatiles) with responses to oak chips plus the high release rate of **1** + **3**. The experiment consisted of: (1) **1** + **3** + 300 ml oak chips, (2) 300 ml oak chips, and (3) an unbaited control. The experiment was set up as completely randomized blocks in each of the four previously described sites. Traps were placed, emptied, rebaited, and rerandomized on the same schedule and dates as in experiment V. The oak chips were replaced daily, and the previous day's chips were always moist when they were removed from the traps, increasing the likelihood that volatiles were still being released.

Statistical Analyses. Data were tabulated by species and sex, with the exception of experiment II, in which the sexes of responding *C. truncatus* were not determined. Nitidulid beetles other than *C. truncatus* were also tallied in the Minnesota experiments. Data from all experiments were analyzed by Friedman's nonparametric two-way ANOVA. Data from experiment IV also were analyzed by standard two-way ANOVA, after transformation of the trap-catch counts by log $(X + 1)$, because several linear contrasts were of particular interest. When F statistics were significant, means were compared using LSD (Bonferroni's method) with an experiment-wise $\alpha = 0.05$. Since trap catches of *C. truncatus* dropped off dramatically after mid-June in Minnesota, statistical analyses of responses of this species in 2000 and 2001 were only carried out on data collected during the mid-April to the mid-June periods. In some cases, analyses of trap catches of other nitidulid species spanned the entire trapping season. Voucher specimens from Minnesota trap catches were deposited in the University of Minnesota Insect Collection.

RESULTS

Experiment I. The high release rate of **1** + **2** + **3** + dough was the most attractive treatment to *C. truncatus* (Friedman's $\chi^2 = 367.1$, $df = 5$, $P < 0.001$; Figure 2A). The high release rate of **1** + **2** + **3** and dough were clearly synergistic; without the dough, *C. truncatus* did not respond to the high release rate of **1** + **2** + **3**, and dough alone attracted about one sixth the mean number of *C. truncatus* that responded to the combined treatments. There was no difference

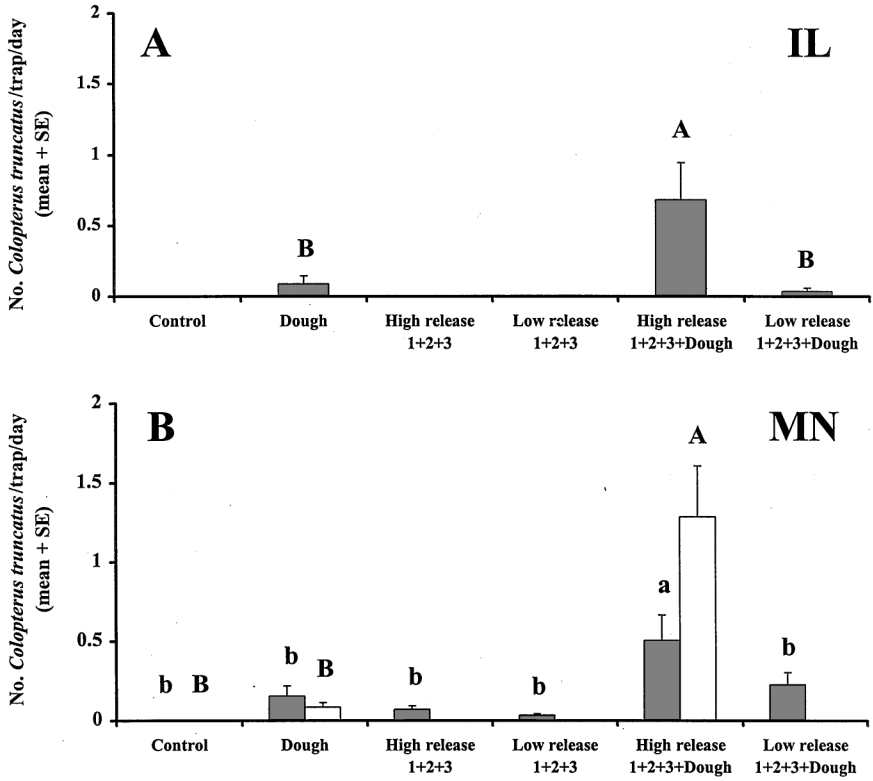

FIG. 2. Flight response of *Colopterus truncatus* to high and low release rates of synthetic aggregation pheromone components **1** + **2** + **3**, with and without dough, from (A) March 24 to April 18, 2000 in Illinois (experiment I) and from (B) April 4 to June 15, 2000, (dark bars) and April 5 to June 15, 2001 (open bars) in Minnesota (experiments II and III). Responses to treatments are significantly different if histogram bars within a year are marked with different letters.

between the responses of *C. truncatus* to dough alone and to dough combined with **1** + **2** + **3** released at the low rate. Overall, trap catches were too low to take advantage of the information from staggered pheromone replacement. Both sexes of *C. truncatus* (31 females and 21 males) responded in this experiment, and the sex ratio was not significantly different among treatments ($\chi^2 = 0.07$, $df = 5$, $P = 0.97$). No *C. truncatus* were collected in control traps.

Experiments II and III. *Colopterus truncatus* responded to the two release rates of its aggregation pheromone in Minnesota as it did in Illinois (Figure 2B). In 2000, the high release rate of **1** + **2** + **3** combined with dough was clearly the most attractive treatment to *C. truncatus* (Friedman's $\chi^2 = 3{,}414.9$, $df = 5$, $P < 0.001$;

Figure 2B). In experiments II, III, V, and VI, there were no significant effects for site or the site × treatment interaction for any of the taxa that responded. In experiments I and IV, only one site was used. As in Illinois, the responses of *C. truncatus* to dough alone and to the high release rate of **1** + **2** + **3** alone were low and did not differ significantly from one another or from the response to the unbaited trap. However, when the dough and high release rate of aggregation pheromone were combined, the response increased more than threefold above the response to the high release rate of **1** + **2** + **3** alone, indicating that the treatments were synergistic. Both treatments involving the low release rate of **1** + **2** + **3** elicited responses that were not significantly different from the response to the unbaited trap. However, when the low release rate of **1** + **2** + **3** was combined with the dough, the response was only exceeded by the comparable high release rate treatment. In 2001, the high release rate of **1** + **2** + **3** + dough was the most attractive treatment to *C. truncatus* (Friedman's $\chi^2 = 363.7$, $df = 2$, $P < 0.001$; Figure 2B). Although the numbers of trapping days were nearly identical, overall *C. truncatus* trap catch was nearly twice as great in 2001 (385) when compared to 2000 (206). Both sexes of *C. truncatus* responded in 2001 (the only year sex ratio data were collected); 247 females and 138 males were captured, and the sex ratio did not vary across treatments ($\chi^2 = 0.28$, $df = 2$, $P = 0.59$). No *C. truncatus* were collected in control traps during either year.

Two other nitidulid beetles, *Glischrochilus quadrisignatus* (Say) and *G. fasciatus* (Olivier), responded to the treatments in experiments II and III in a different way than did *C. truncatus* (Figure 3). In both years, these species responded to all traps containing dough at a higher level than those without dough (2000: Friedman's $\chi^2 = 3{,}722$, $df = 5$, $P < 0.001$; 2001: Friedman's $\chi^2 = 588.1$, $df = 2$, $P < 0.001$). No synergism was found, and there was no discernible response to either release rate of **1** + **2** + **3** alone. Hence, there was no evidence for cross-attraction of *G. quadrisignatus* and *G. fasciatus* to the pheromone of *C. truncatus*. The total pooled trap catch for *G. quadrisignatus* and *G. fasciatus* was nearly twice as great in 2000 (542) when compared to 2001 (337). Two other sap beetles, *Carpophilus sayi*, and *Epuraea corticina* Erichson were trapped in experiments II and III, but not in sufficiently high enough numbers to analyze.

Seasonality in Experiments II and III. There was a definite seasonality to the flight activity of *Colopterus truncatus* in Minnesota. In both years, adult activity was initiated in mid- to late April, peaked between late April and early May, and largely disappeared by early and mid-June (Figure 4A). Continued monitoring until November caught only three additional *C. truncatus*, one on September 15, 2000, and one each on August 24 and 31, 2001. The maximum flight responses came on May 4 (2000) and April 20 (2001), and during both years, more than 98% of the beetles were trapped between April 14 and June 1.

The seasonal pattern of flight activity of *G. quadrisignatus* and *G. fasciatus* (both species pooled) was different than *C. truncatus* (Figure 4B). In 2000, these

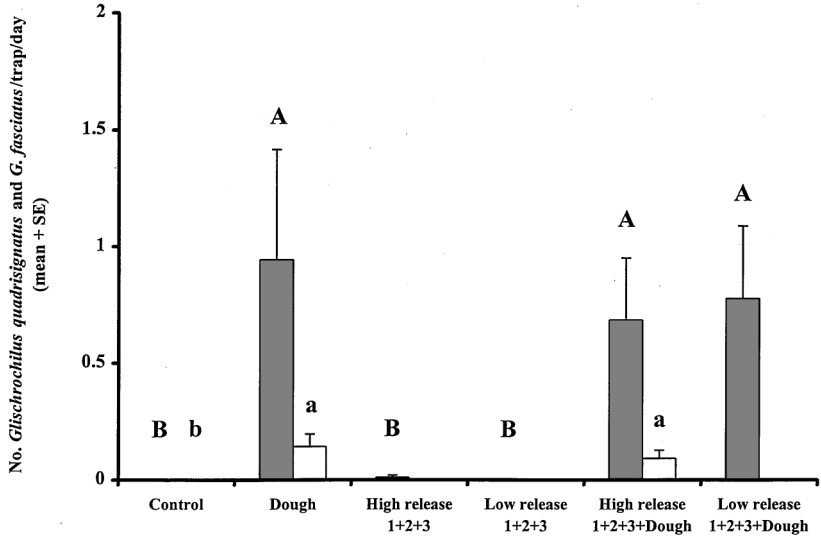

FIG. 3. Pooled flight responses of *Glischrochilus quadrisignatus* and *G. fasciatus* to high and low release rates of synthetic *Colopterus truncatus* aggregation pheromone components **1** + **2** + **3**, with and without dough, from April 4 to June 15, 2000 (dark bars) and April 5 to June 15, 2001 (open bars) in Minnesota (experiments II and III). Responses to treatments are significantly different if histogram bars within a year are marked with different letters.

species were abundant in the spring and their presence continued at a low, but discernible level throughout the rest of the year, showing a pattern somewhat similar to *C. truncatus*. In 2001, there was no large spring peak, and the abundance varied throughout the remainder of the year, peaking in mid- to late July. While there was a large amount of variation in trap catches during both years of the study, *G. quadrisignatus* and *G. fasciatus* were generally more abundant than *C. truncatus*, and they did not show the same distinct limited seasonality in Minnesota.

Experiment IV. The effect of all possible combinations of **1** + **2** + **3** on *C. truncatus* in Illinois, showed a strong treatment effect, using either the Friedman's nonparametric two-way ANOVA (Friedman's $\chi^2 = 2{,}104.2$, $df = 7$, $P < 0.001$) or the standard two-way ANOVA with data transformed using $\log(X + 1)$ ($F = 21.7$, $df = 7{,}49$, $P < 0.001$) (Figure 5). The day × treatment interaction was not significant ($F = 1.3$, $df = 42{,}49$, $P < 0.185$), indicating that relationships among treatments were fairly consistent from day to day. Individual block effects were allowed to vary from day to day in the analysis (i.e., the day × block interaction was fitted); this precaution allowed for the possibility that the *C. truncatus* population density changed in different ways over

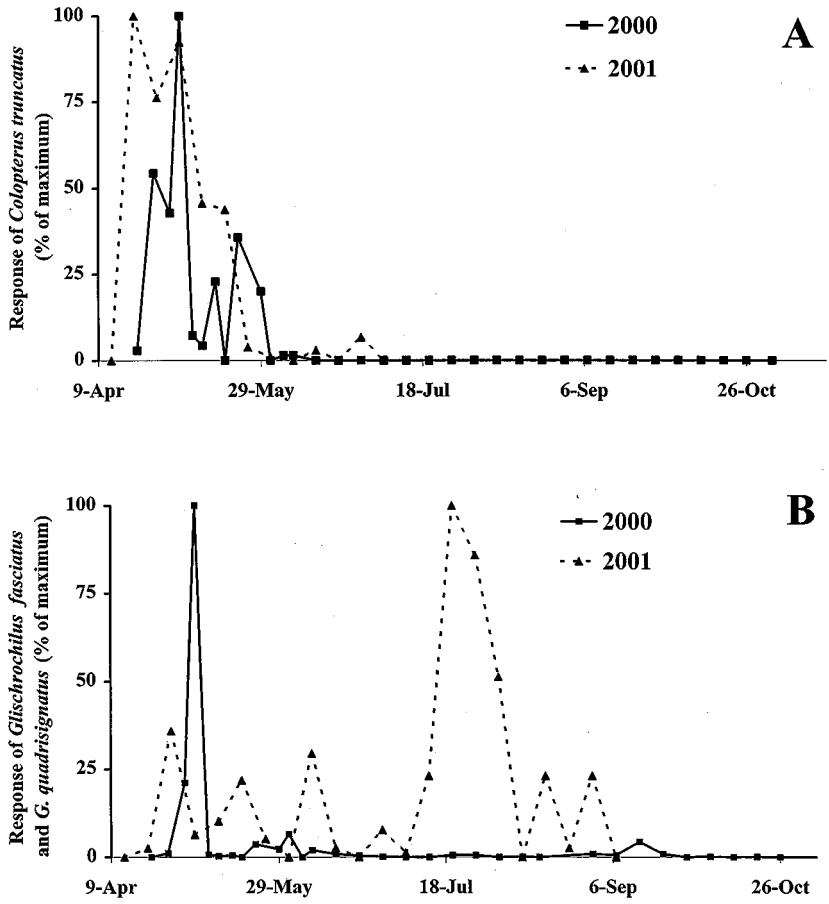

FIG. 4. Relative seasonal flight responses of (A) *Colopterus truncatus* to all treatments in experiments II and III from April 4 to November 3, 2000, and April 5 to November 9, 2001, in Minnesota and (B) *Glischrochilus quadrisignatus* and *G. fasciatus* to all treatments in experiments II and III from April 4 to November 3, 2000, and April 5 to November 9, 2001, in Minnesota. Of the 591 *C. truncatus* trapped in 2000 and 2001, only three beetles were trapped after early July (September 15, 2000; and August 24 and 31, 2001—both females). Maximum trap catch per week in 2000 was 40 beetles (May 4), whereas maximum trap catch per week in 2001 was 97 beetles (April 20). For *Glischrochilus* spp., maximum trap catch per week in 2000 was 136 beetles (May 11), whereas the maximum trap catch per week in 2001 was 76 beetles (July 18).

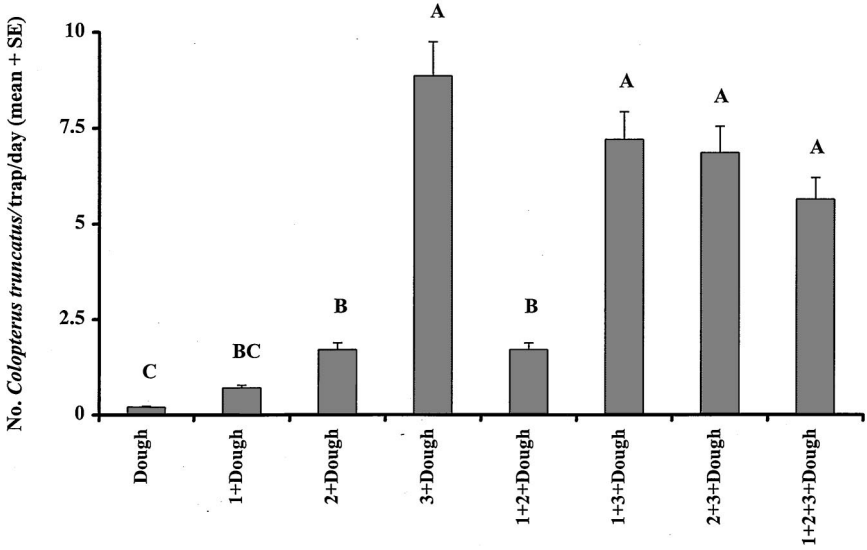

FIG. 5. Flight response of *Colopterus truncatus* to high release rate of all possible combinations of synthetic aggregation pheromone components **1**, **2**, and **3** with dough (experiment IV) in Illinois. Responses to treatments are significantly different if histogram bars are marked with different letters.

time in different areas of the site. The dominant effect in the experiment was that trap catches were dramatically higher whenever compound **3** was present in the bait (the linear contrast for the presence versus absence of **3** was significant, $F = 135.7$, $df = 1,49$, $P < 0.001$). On the other hand, the corresponding contrasts for **1** and **2** were not significant ($F = 0.0009$, $df = 1,49$, $P = 0.973$; $F = 1.932$, $df = 1,49$, $P = 0.170$, respectively), although the response to **2** plus dough was nominally more attractive than and significantly different from the response to the dough control (Figure 5). The higher-order effects for interactions among treatments were significant ($F = 3.595$, $df = 4,49$, $P = 0.012$), but these were minor when compared with the contrast for **3**. That the interaction was significant at all was due to catches for **3** being somewhat lower when **2** was also present versus when **2** was absent, for unknown reasons. This trend was not significant when the means were considered just two at a time with LSD tests. Overall, 291 female and 171 male *C. truncatus* were captured in experiment IV. The sex ratio did not differ significantly among treatments ($\chi^2 = 6.2$, $df = 7$, $P = 0.52$).

Experiment V. In Minnesota, the responses of *C. truncatus* to the high release rate of $\mathbf{1} + \mathbf{2} + \mathbf{3} +$ dough and to the high release rate of $\mathbf{1} + \mathbf{3} +$ dough were not significantly different (Friedman's $\chi^2 = 1{,}453.2$, $df = 3$, $P < 0.001$; Figure 6A). Both pheromone-containing treatments were more attractive than the

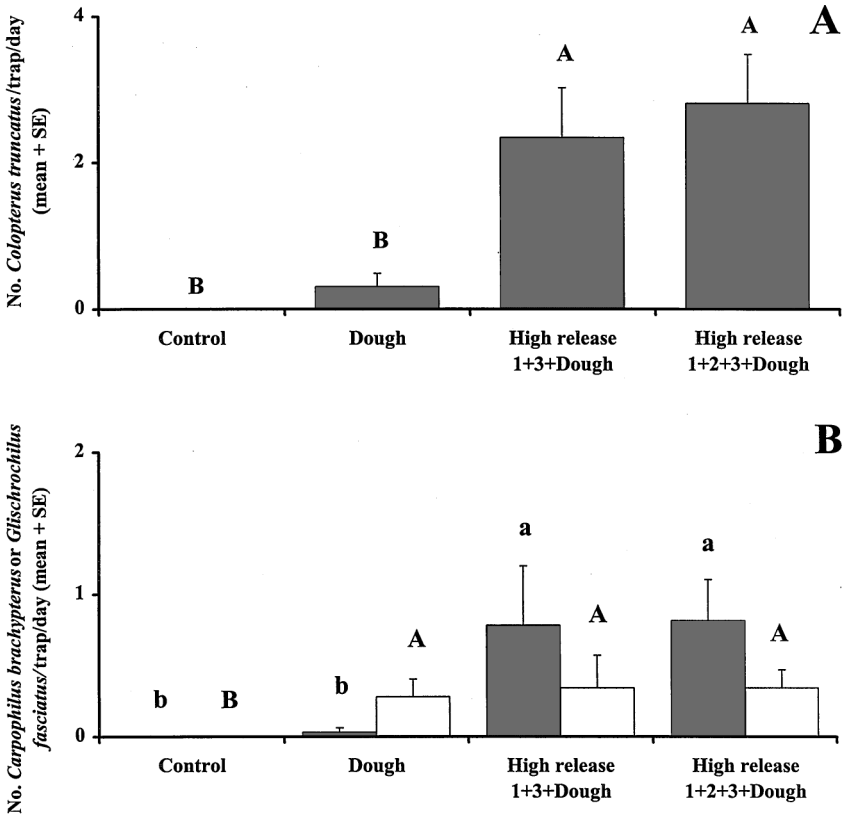

FIG. 6. Flight responses of (A) *Colopterus truncatus* and (B) *Carpophilus brachypterus* (shaded bars) and *Glischrochilus fasciatus* (open bars) to high release rate of synthetic *Colopterus truncatus* aggregation pheromone components **1** + **2** + **3** + dough, high release rate of **1** + **3** + dough, dough alone, and unbaited control in Minnesota (experiment V). Responses to treatments are significantly different if histogram bars within a species are marked with different letters.

dough alone or unbaited control treatments. Of the 182 beetles in the traps, there were 117 females and 65 males, and the sex ratio was not significantly different among treatments ($\chi^2 = 0.48$, $df = 3$, $P = 0.79$).

Two other nitidulids, *Carpophilus brachypterus* (Say) (52 beetles caught) and *Glischrochilus fasciatus* (31 beetles caught), also responded to treatments in experiment V (Figure 6B). *Carpophilus brachypterus* responded to the treatments similarly to *Colopterus truncatus* (albeit at lower levels), with a significant and similar response to both pheromone–dough combinations (Friedman's $\chi^2 = 813.8$, $df = 3$, $P < 0.001$; Figure 6B). *Glischrochilus fasciatus* responded

to the treatments differently than *C. truncatus* and *C. brachypterus*. With *G. fasciatus*, there were no significant differences among the responses to traps containing dough (Friedman's $\chi^2 = 269.1$, $df = 3$, $P < 0.001$; Figure 6B). Although some *G. quadrisignatus* were collected in this study, the catches (18 beetles) were too low to discern any pattern in the response.

Experiment VI. The high release rate of **1** + **3** + oak chips was the most attractive treatment to *C. truncatus* (Friedman's $\chi^2 = 147.0$, $df = 2$, $P < 0.001$). Overall trap catches in this experiment were quite low: no beetles were caught in either the control or oak chips-alone treatments, and more than 75% of the traps baited with **1** + **3** + oak chips were empty. Of the 16 *C. truncatus* caught in the traps baited with **1** + **3** + oak chips, there were 12 females and 4 males. No other sap beetles were caught in this experiment.

DISCUSSION

Both Illinois and Minnesota populations of *C. truncatus* responded similarly to the low- and high-release rate formulations of **1** + **2** + **3** with dough and to dough alone. Both populations preferred the high release rate formulation. Since the low release rate pheromone formulation keeps the ratios of emitted volatiles constant for a longer period of time than the high release rate (i.e., the unenclosed septum) formulation (R.J.B., unpublished data), our trapping results suggest that the sustained emission of the constant ratio of pheromone components is not the most important factor in the attraction of *C. truncatus*. Rather, they suggest that the total amount of components emitted was the most important factor in trap catch.

In both Illinois and Minnesota populations, there was no difference in the response to the combination of **1** + **2** + **3** with dough or the combination of **1** + **3** with dough. In contrast to earlier work in Illinois on *C. truncatus* (Cossé and Bartelt, 2000), this study showed directly in Illinois, and by inference in Minnesota, that component **2** was not necessary for, and in fact perhaps reduced, the attraction of *C. truncatus*. Even though component **2** was the most abundantly produced of the three male-specific hydrocarbons investigated in this study, it was component **3** that dominated the response. Component **3** had not been tested alone in previous behavioral studies, but it did show considerable electrophysiological activity when presented alone to male and female antennal preparations (Cossé and Bartelt, 2000). Although there were no apparent differences in the responses of Illinois and Minnesota populations of *C. truncatus* to various release rates and blends of the aggregation pheromone, there may be differences in the seasonal pattern of response to aggregation pheromone (see below).

Since *C. truncatus* and other nitidulids have a relatively rapid and strong response to fresh wounds in oak trees (Juzwik et al., 1999; J.J., personal observation), we hypothesized that the volatiles produced by oak tissue would synergize the *C. truncatus* aggregation pheromone. Based on the evidence shown here

(experiment VI), volatiles produced from chipped oak tissue are not attractive, and these volatiles likely do not synergize the pheromone. Trap catches in experiment VI were quite low, and are probably explained by a low-level response to the pheromone without the dough synergist as observed in experiments I and II. The oak tissue in our experiments might not have been attractive to *C. truncatus* because the process of chipping might produce different volatiles (or different amounts of volatiles) than those normally encountered by nitidulids when searching for fresh sap-laden wounds on living trees. Further work is needed to identify and characterize the volatiles of wounded oaks, how they change over time, and when they are most attractive to nitidulids searching for feeding, mating, and ovipositional sites. Preliminary chemical analyses, however, show that volatiles from individuals within an oak species are quite variable and suggest that this work will be difficult (R.J.B., unpublished data).

Since sap beetles aggregate on oak wilt mats (Cease and Juzwik, 2001), it is possible that oak wilt mat volatiles synergize the aggregation pheromone emitted by *C. truncatus* and other species while on mat tissue. Volatiles from laboratory cultures of oak wilt have been described and are attractive to sap beetles (*C. truncatus* was not tested) in wind-tunnel bioassays (Lin and Phelan, 1992). Further study on the relationship between oak wilt mat volatiles and nitidulid pheromones will be conducted when a stable *Ceratocystis fagacearum* volatile formulation is available for field tests.

The distinct seasonality shown by *C. truncatus* in our study is very important in understanding and managing the overland spread of oak wilt. Peak production of oak wilt mats (Campbell and French, 1955) and the window of peak susceptibility to infection (Prey and Kuntz, 1995) both occur during the spring in Minnesota (Juzwik et al., 1985). Our results show that in Minnesota, *C. truncatus* is attracted to pheromone + dough-baited traps in April, May, and June, but very few *C. truncatus* are caught in the same traps with the same baits later in the summer and in the fall. Skalbeck (1976), when trapping with fermenting dough and *Ceratocystis fimbriata* baits over two years in three Minnesota forest types, also found *C. truncatus* only in the spring and early summer, with the peak abundance in April and May. In another instance in Minnesota, of 40 *C. truncatus* trapped in response to combinations of dough and (2*E*,4*E*,6*E*,8*E*)-7-ethyl-3,5-dimethyl-2,4,6,8-decatetraene, 95% of the trap catch flew before July 6 (one male and one female were trapped in September) (R.J.B., unpublished data). However, McMullen and Shenefelt (1961), Levesque and Levesque (1992), Dowd and Nelsen (1994), and Cossé and Bartelt (2000) have all reported trapping *C. truncatus* in flight during the fall to various stimuli in Wisconsin, Quebec (Canada), Illinois, and Illinois, respectively. Climatic differences between Minnesota and these other north-central areas may influence the life history, and, specifically, the flight behavior of *C. truncatus*.

Sampling *C. truncatus* from oak wilt mats in Minnesota has revealed that it is univoltine. Adults disperse in flight for mating in the spring and early summer,

larvae only occur in the mats in spring and early summer, and adult densities are approximately eight times higher in the mats in the fall than in the spring (J.F.K., unpublished data). As the fall cohort of oak wilt mats is newly formed each fall, it is likely that *C. truncatus* has flown to the mats at this time. These adults are also likely to feed on these mats and are less likely to disperse from them again through flight. Rather, they are more likely to drop to the litter layer on the forest floor to overwinter. Further work in Minnesota needs to be done to determine whether *C. truncatus* flies selectively in the spring and early summer in response to synergized synthetic pheromone (as a mating and feeding response) and selectively in the early fall to mat odors (as a feeding and preoverwintering response). Alternatively, *C. truncatus* may fly in response to pheromone in the fall, but at much lower densities or it may reach the mats in the fall by crawling to them. It should be noted that the seasonally restricted flight behavior of *C. truncatus* in Minnesota is not unique among sap beetles. Some species in the genus *Carpophilus* also show strong seasonal flight activity periods in California (Bartelt et al., 1994), South Carolina (Bartelt et al., 1995), and Australia (James et al., 1994), while species of *Colopterus* and *Cryptarcha* show a similar seasonal pattern in Texas (Appel et al., 1986).

As with other nitidulid pheromones (Bartelt, 1997; Zilkowski and Bartelt, 1999), the *C. truncatus* aggregation pheromone is cross-attractive to other species. In our experiments in Minnesota, as was the case in previous work in Illinois (Cossé and Bartelt, 2000), *Carpophilus brachypterus* responded to the synergized *Colopterus truncatus* pheromone. Since the decatetraene (**3**) is the main component of the aggregation pheromone of *Carpophilus brachypterus* (Williams et al., 1995), the response of *Carpophilus brachypterus* is most likely due to pheromone component similarity, reflecting the close phylogenetic relationship between the genera *Colopterus* and *Carpophilus* within the subfamily Carpophilinae (Downie and Arnett, 1996). The effect could also be interpreted as a kairomonal response. *Carpophilus brachypterus* may benefit by locating wounds in oaks or mats originally colonized by *Colopterus truncatus* and signaled by aggregation pheromone production by *C. truncatus*. Since *Carpophilus brachypterus* has been collected from oak wounds (Vogt, 1950; Norris, 1956), this chemically guided ecological relationship seems plausible. However, our review of the literature and a reexamination of summary data in Skalbeck (1976) suggests that *C. brachypterus* has not been collected to date from oak wilt mats (T.C. Skalbeck, personal communication). *Glischrochilus quadrisignatus* and *G. fasciatus* (subfamily Cryptarchinae) responded equally to all treatments containing dough. Thus, these species respond to food volatiles (Lin and Phelan, 1991), but do not show a kairomonal response to the *C. truncatus* aggregation pheromone.

One interesting outcome from these experiments is that female *C. truncatus* consistently responded to the *C. truncatus* aggregation pheromone in both Illinois and Minnesota at nearly twice the rate that males did. The sex ratio of *C.*

truncatus trapped in all experiments from both locations was approximately 1.8:1 (female–male) (Minnesota 1.8:1; Illinois 1.7:1). In the previous study with aggregation pheromone components of *C. truncatus* in Illinois, Cossé and Bartelt (2000) also reported female-biased sex ratios between 1.1 and 1.7:1. In other studies with sap beetles, Petroski et al. (1994) recorded a sex ratio of 1.2:1 in *Carpophilus obsoletus* Erichson responding to its aggregation pheromone in the field, whereas Bartelt et al. (1994) reported sex ratios "close to" 1:1 in five *Carpophilus* spp. and in *Haptoncus luteolus* (Erichson) responding to aggregation pheromones in the field. In the latter study, the sex ratios for four of the *Carpophilus* spp. and for *H. luteolus* were nearly 1:1 in date fruits, which are the hosts colonized by the beetles. The sex ratio of a sample of *C. truncatus* collected in oak wilt mats in Minnesota was also nearly 1:1 (1.1:1, $N = 128$; J.F.K., unpublished data).

In other coleopteran aggregation pheromone systems with a male-produced attractant, the sex ratio of beetles responding behaviorally to pheromone or the magnitude of the electrophysiological response to pheromones also tends to be female biased. Indeed, aggregation pheromones may, in part, serve a sex pheromone function (Borden, 1985). Female-biased responses have been reported in bark beetles (Scolytidae), e.g., the California five-spined ips, *Ips paraconfusus* Lanier (Wood et al., 1967, 1968; Byers, 1983), and the pine engraver, *Ips pini* (Say) (Seybold et al., 1992; Miller et al., 1990, 1995, 1996; Miller and Borden, 1990, 2000; Miller, 2000) and in grain beetles (Bostrichidae, Cucujidae, and Silvanidae), e.g., the larger grain borer, *Prostephanus truncatus* (Horn) (Birkenshaw and Smith, 2000), the rusty and flat grain beetles, *Cryptolestes ferrugineus* (Stephens) and *C. pusillus* (Schönherr) (Chambers et al., 1990), and the saw-toothed grain beetle, *Oryzaephilus surinamensis* (L.) (White and Chambers, 1989). See Millar et al. (1985 a,b) and Pierce et al. (1988) for counter-examples with grain beetles. In the initial case of the isolation and identification of an aggregation pheromone from an insect (*I. paraconfusus*, Wood et al., 1967, 1968), the sex-specific production and the female-biased responses caused the investigators to view the signals as sex attractants. Since female *C. truncatus* are attracted at a greater rate than males in our study, this nitidulid example lends additional support to the hypothesis that male-produced aggregation pheromones evolved secondarily from their initial roles as sex pheromones to attract females (Raffa et al., 1993; Phillips, 1997; Plarre and Vanderwel, 1999).

A parallel can be made between sap beetles that colonize, develop on, and emerge from oak wilt mats (or wounds) and bark beetles that undergo similar activities in phloem in tree stems and branches. In the cases of both *C. truncatus* and *I. paraconfusus*, the sex ratios of the arriving insects (simulated by response to baited traps) do not appear to match the sex ratios of those that emerge from the developmental substrate. For example, the sex ratio of *I. paraconfusus* responding to the immediate source of naturally produced or synthetic pheromones in

various field studies ranges from 1.8 to 5.6:1 (Struble and Hall, 1955; Gara, 1963; Wood et al., 1967, 1968; Byers, 1983), whereas the sex ratio of insects emerging from ponderosa pine logs has been reported as approximately 1.2:1 (Gara, 1963; Cameron and Borden, 1967) and 1.3:1 (Struble and Hall, 1955). Similarly, with *C. truncatus* we have an arriving sex ratio of 1.8:1 and a sex ratio of 1.1:1 in the colonized oak wilt mats. Further investigation is needed to determine the sex ratio of *C. truncatus* that develop and emerge from oak wilt mats and wounds in oaks. However, higher differential mortality of males during dispersal has been offered as a potential explanation for this sex ratio difference in *I. paraconfusus* (Cameron and Borden, 1967), and this hypothesis may apply to the sex ratio difference for *C. truncatus* as well.

Finally, a number of conclusions with practical implications for monitoring the flight of *C. truncatus* and for managing overland spread of oak wilt can be drawn from this work. Experiments I and II demonstrated that the most attractive bait for *C. truncatus* is the high release rate of pheromone compounds with the bread dough coattractant. Further, experiment V showed that it is unnecessary to add synthetic **2** to the pheromone baits for monitoring *C. truncatus*. Thus, the simplest effective approach to preparation of pheromone baits would be to use synthetic **3**, without bothering to remove the **1** that is invariably present as a synthetic artifact. Since the two- and three-component blends of the *C. truncatus* aggregation pheromone are equally attractive, the less expensive two-component blend can be used effectively as a monitoring tool. As we recorded no response of *C. truncatus* or other sap beetles to 300-ml aliquots of oak chips (experiment VI), operational studies in the future might explore whether landowners, resource managers, or arborists could chip woody debris from uninfected oak trees and leave the chips on site without attracting nitidulid oak wilt vectors to the general area and accelerating overland transmission of the disease. Finally, land managers should be aware that the critical period of flight activity for *C. truncatus* in Minnesota occurs conservatively between early April and early July, and in order to limit the overland spread of oak wilt, pruning and other management activities that wound oaks should be avoided during this time. In a future study, a similar critical period needs to be defined for the other primary oak wilt vector, *Carpophilus sayi*.

Acknowledgments—We thank Bruce W. Zilkowski of the National Center for Agricultural Utilization Research for doing the HPLC purification of components **1**, **2**, and **3**; Roger D. Moon of the University of the Minnesota Department of Entomology for assistance with statistical analyses; and Julie A. Tillman of the University of Minnesota Department of Horticulture for assistance with graphics. We also thank Thomas W. Phillips of the Oklahoma State University, Department of Entomology and Thomas C. Skalbeck of the University of Minnesota Department of Entomology for helpful discussions. The Minnesota studies were funded in part by a grant from the Minnesota Environment and Natural Resources Trust fund as recommended by the Legislative Commission on Minnesota Resources—project title, "Development and Assessment of Oak Wilt Control Strategies: Life Histories of Principal Insect Vectors of the Oak Wilt Fungus" to J.J. and S.J.S., by Multistate Research Project W-189, "Biorational Methods for Integrated Pest Management: Bioorganic and Molecular Approaches," by a Dayton-Wilkie

Grant for Natural History Research to J.F.K., and by the H. Chiang scholarship to J.F.K. The work described in this paper is a portion of a MS thesis by J.F.K. and is a contribution of the Minnesota Agricultural Experiment Station (Project MN-17-070).

(Received November 13, 2001; accepted April 21, 2002)

Abstract—We investigated two strains of *Enterobacter agglomerans* that differ in their ability to metabolize uric acid for (1) attractiveness to sugar-fed Mexican fruit flies, and (2) production of volatile chemicals that may be responsible for the attractiveness. The two strains were cultured on a medium that contained uric acid as the primary nitrogen source to simulate bird feces, a natural substrate for this bacterium. Active cultures of both strains were more attractive than uninoculated uric acid medium to both sexes of sugar-fed flies in wind-tunnel bioassays. The uricase(+) strain was more attractive than the uricase(−) strain to males and to females <9 days old, but not to older females. Volatiles found by solid-phase microextraction in greater amounts in headspace above active cultures of both strains than above uninoculated medium were ammonia, dimethyldisulfide, 3-methylbutanol, 2-phenylethanol, 2,5-dimethylpyrazine, and trimethylpyrazine. The uricase(+) strain produced more ammonia, dimethyldisulfide, and trimethylpyrazine than the uricase(−) strain. An additional chemical, 3-hydroxybutanone, appears to be produced exclusively by the uricase(+) strain. The uricase(−) strain produced more 2-phenylethanol than the uricase(+) strain. Differences in volatiles are consistent with the generally greater attractiveness of the uricase(+) strain compared with the uricase(−) strain as ammonia, 3-hydroxybutanone, and trimethylpyrazine have been demonstrated attractive to sugar-fed Mexican fruit flies.

Key Words—Attractants, Diptera, Tephritidae, *Anastrepha ludens*, ammonia, pyrazines, 3-methylbutanol, 3-hydroxybutanone, solid-phase microextraction.

INTRODUCTION

Bird droppings are a well known natural food for many species of tephritid fruit flies (Christenson and Foote, 1960; Malavasi et al., 1983; Hendrichs and Hendrichs, 1990; Hendrichs and Prokopy, 1990). Experiments in which egg production by fruit flies was enhanced when bird feces were added to nitrogen-deficient diets indicated that bird feces may be an important natural source of organic nitrogen to fruit flies (Christenson and Foote, 1960; Hendrichs et al. 1993a,b). However, the principal organic nitrogen in bird feces is uric acid, and fruit flies are unable to metabolize uric acid without assistance from symbiotic microbes (Hendrichs et al., 1993b). Therefore, either the flies themselves or the bird feces must contain the necessary symbionts. Further, it has been shown that the odor of bird feces is attractive to various fruit flies (Prokopy et al., 1992, 1993; Epsky et al., 1997; Robacker et al., 2000). It was demonstrated by addition of antibiotic that bacterial utilization of the feces is largely responsible for their attractiveness to the apple maggot fly (*Rhagoletis pomonella* Walsh) (Prokopy et al., 1993).

In an effort to tie these studies together, Lauzon et al. (1998, 2000) investigated whether the bacteria responsible for making bird feces attractive also serve a role as symbionts that help fruit flies utilize nitrogen from uric acid in the bird feces. MacCollom et al. (1992, 1994) previously had demonstrated that *E. agglomerans* isolates from the apple maggot fly and from its environment were attractive to adult apple maggot flies. Lauzon et al. (1998) isolated several species of bacteria from bird feces and apple foliage and found that two species, *Enterobacter agglomerans* and an atypical strain of *Escherichia coli*, were highly attractive to the apple maggot fly, while other species were not attractive. Further investigation revealed that some strains of *E. agglomerans* isolated from bird feces were not attractive to the flies. These results indicated intraspecific variation in strains of *E. agglomerans* that manifested as phenotypes that were either attractive or nonattractive to the apple maggot fly. Closer examination revealed that the strains differed in their abilities to metabolize various purines and purine degradation products including uric acid, and that this ability was positively related to their attractiveness (Lauzon et al., 2000). Gel electrophoresis indicated that the purine metabolizing strains produced a protein that was characterized as a uricase. Further, they showed that the uricase was synthesized constitutively by the bacteria, i.e., in the absence of uric acid, and that additional uricase production could be induced by uric acid.

As discussed above, the *E. agglomerans* strains that were attractive or nonattractive to the apple maggot fly later proved to be uricase(+) or uricase(−), respectively. Attractiveness to the Caribbean fruit fly (*Anastrepha suspensa* Loew) of one of these *E. agglomerans* strains [later determined uricase(+) by C.R.L.] was demonstrated, ammonia and 3-methylbutanol were identified in volatiles produced by the bacteria, and both chemicals were demonstrated attractive to the flies (Epsky et al., 1998). However, no data were reported for a uricase(−) strain in that study.

Lauzon et al. (1998) suggested identification of volatiles produced by attractive and nonattractive strains of *E. agglomerans*. Such research should further understanding of metabolic differences between strains as well as help to determine which volatiles produced by bacteria are most important for attraction of fruit flies. The research described in this paper was conducted to determine if uricase(+) and uricase(−) strains of *E. agglomerans* differ in attractiveness to the Mexican fruit fly, *Anastrepha ludens* Loew, and if differences in attractiveness can be traced to differences in volatiles produced by the strains. Volatile collection from headspace above bacteria cultures was done with solid-phase microextraction (SPME), a technique used successfully to identify attractive principals produced by numerous bacteria (Robacker and Flath, 1995; Robacker and Bartelt, 1997; Robacker et al., 1998, 2000). Our results showed that both *E. agglomerans* strains are attractive to the Mexican fruit fly, that the uricase(+) strain is more attractive than the uricase(−) strain, that volatiles produced by the two strains differ both qualitatively and quantitatively, and that these differences in volatiles are consistent with observed differences in attractiveness.

METHODS AND MATERIALS

Insects and Test Conditions. Flies were from a culture that originated from yellow chapote fruit (*Sargentia greggii* Coult.), a native citrus host of the fly, collected in Nuevo Leon, Mexico, in 1997. Mixed-sex groups of 20–25 flies (overall sex ratio was 1:1 but individual cups varied) were kept in 473-ml cardboard cartons with screen tops until used in tests. Cups were provisioned with separate sugar and water sources but no protein. Laboratory conditions for holding and testing flies were $22 \pm 2^{\circ}$C, $50 \pm 20\%$ relative humidity, and photophase from 06:30 to 19:30 hr. All tests were conducted between 09:00 and 16:00 hr with 5- to 27-day-old flies. Previous work demonstrated that attraction of Mexican fruit flies to odors of aqueous bacterial cultures was maximum for sugar-fed, protein-deprived flies compared with other feeding regimens, and uniform between 08:30 and 16:30 hr under these temperature and relative humidity conditions for flies between 5 and 15 days posteclosion (Robacker and Garcia, 1993). However, responsiveness decreased by about 50% as flies aged from 15 to 30 days.

Bacterial Cultures. In preliminary work, the two strains of *Enterobacter agglomerans*, designated as uricase(+) and uricase(−), were inoculated individually into tryptic soy broth (Difco Laboratories, Detroit, Michigan, USA). The uricase(+) strain contained a protein characterized as a uricase (Lauzon et al., 2000) that was not present in the other strain. The tryptic soy broth cultures were held under identical conditions, and their growth was monitored and compared over a 24-hr period. Both strains were found to have similar growth rates and were kept under the same growth conditions for all subsequent work.

To prepare bacterial cells for plating, the two strains were grown individually in tryptic soy broth for 18 hr at 28°C. Cells were centrifuged for 20 min at 5000 rpm at room temperature. The supernatant was expelled, and the remaining pellet of cells received approximately 2 ml of sterile distilled water and was vortexed gently to disrupt the pellet. Each cell suspension received additional sterile water and was centrifuged as described earlier. The supernatant was discarded, and this washing procedure was repeated two more times. The final pellet of cells for each strain was adjusted by addition of sterile water to an optical density of approximately 0.550 at 550 nm using a UV-VIS spectrophotometer (Shimadzu Scientific Instruments, Inc., Kyoto, Japan).

A growth medium was prepared that contained uric acid as its primary nitrogen source. Medium was made by combining the following ingredients, per 100 ml of distilled water: 1.6 g phenol red broth (BBL, Becton Dickinson Co., Cockeysville, Maryland, USA); 0.1 g glucose (Sigma Chemical Co., St. Louis, Missouri, USA); 0.1 g dipotasium hydrogen phosphate (J. T. Baker, Phillipsburg, New Jersey, USA); and 1.8 g grade A agar (BBL). This mixture was autoclaved at 121°C at 15 psi for 15 min. The sterilized medium was tempered to approximately 50°C and poured into sterile Petri dishes (plates) containing 1.2 g uric acid (Sigma). Each plate was swirled gently to distribute the uric acid evenly within the medium. The resulting uric acid medium was allowed to solidify, then plates were individually inoculated with 0.1 ml of one of the bacteria strain cell preparations using the spread plate technique. Inoculated and uninoculated plates were sent via overnight delivery service to the USDA-ARS laboratory in Weslaco, Texas, USA.

Wind-Tunnel Bioassay. Bioassays were conducted in a Plexiglas wind tunnel with the dimensions of $0.3 \times 0.3 \times 1.2$ m. Each end of the wind tunnel was screened to allow airflow. The downwind end contained a baffle system to create a uniform airflow through the chamber. Air was pulled through the chamber at 0.4 m/sec by an exhaust fan connected to the downwind end. The top of the chamber had two circular openings (12.8 cm diam.) with Plexiglas covers, located at each end of the chamber, to allow easy access to the chamber's interior. A 75-W "soft white" light bulb (General Electric Co., Cleveland, Ohio, USA) in a reflecting lamp was positioned 17 cm above the downwind end of the chamber. The purpose of this light was to minimize random flying into the upwind end of the chamber by using the flies' positive phototactic reaction. Overhead lighting was provided by two banks of four fluorescent "cool white" lights each (F40CW, General Electric).

Attractiveness of plates containing either active cultures or uninoculated medium was assessed. Plates had been incubated for 2–9 days at 30–32°C prior to testing. Most assays were conducted using incubations of 6–9 days because observations indicated that uric acid utilization was maximum during this period (judged by disappearance of uric acid crystals in medium). To conduct a trial, a plate bottom containing the active culture or uninoculated medium was placed on the floor of the chamber below the opening at the upwind end. One cup of flies was

placed under the downwind opening. Flies were given 5 min to leave the cup, fly or walk upwind, and contact the plate. Upwind movement was scored if flies passed a point two thirds of the distance from the release cup to the plate. An exhaust fan was run for 5 min after each trial to refresh the air in the bioassay room.

Quantification of Volatiles from Cultures. Volatiles in the headspace above active bacterial cultures and above uninoculated medium were quantified by gas chromatography (GC). Plates used in these analyses were selected from every batch of inoculations that were used for bioassays. Incubation times ranged from 2 to 9 days at 30–32°C. Volatiles were sampled using SPME with a polydimethylsiloxane (PDMS) -coated fiber (100 μm coating) (Supelco, Inc., Bellefonte, Pennsylvania, USA). The fiber was inserted into the headspace through a small hole drilled into the side of each plate just prior to volatiles collection. The hole was only slightly larger than the fiber sheath to minimize escape of volatiles from the plate. Sampling time was 1 hr at 30–32°C. On-column injection of volatiles was by thermal desorption from the SPME fiber at 220°C in a 10-cm retention gap (0.53 mm ID deactivated fused silica) connected to the analytical column by a GlasSeal connector (Supelco). The analytical column was a DB-1 (60 m $\times$ 0.32 mm ID, 5-μm film thickness) (J & W Scientific, Folsom, California, USA). For most analyses, column oven temperature was 100°C for 10 min then programmed at 5°C/min to 210°C. However, some analyses were conducted beginning at 50°C after we discovered that 3-methylbutanol and dimethyldisulfide were coeluting in analyses that began at 100°C. No uninoculated controls were conducted for analyses that began at 50°C. Carrier gas was helium at a linear velocity of 30 cm/sec. Analyses were conducted using a Shimadzu GC-17A (Shimadzu Scientific Instruments, Inc., Columbia, Maryland, USA) equipped with both flame ionization (FID) and flame thermionic (model FTD-17) detectors. Detection was by FID for most plates, to analyze ammonia and organic chemicals that did not contain nitrogen. Detection was by FTD for others, to analyze organic chemicals containing nitrogen. GC peak areas were measured using Millennium 2010 Chromatography Manager software (Waters Corporation, Milford, Massachusetts, USA).

Identification of Volatiles Produced by Bacteria. Volatiles produced by bacteria were identified by gas chromatography–mass spectrometry (GC-MS). Two volatile collection methods were used. The first method was to collect volatiles in the headspace above cell suspensions in water. Bacterial cells were scraped from the surface of the medium from one plate each of uricase(+) and uricase(−) strains with a metal spatula and rinsed from the spatula into 1 ml of reverse-osmosis water. The two plates were from the same batch and were incubated for 8 days prior to cell collection. Except during transit to Illinois for GC-MS analysis ($<$24 hr) and during volatiles sampling, cell scrapings were kept at −20°C. Volatiles were collected by SPME with a PDMS fiber (100-μm coating). The fiber was inserted through a septum into the headspace above 0.5 ml of cell suspension in a 2-ml vial for 30 min at room temperature. NaCl and NaOH were added to the vials

to increase the headspace concentrations of organic compounds and basic compounds, respectively (Robacker and Bartelt, 1997).

The second method of volatiles collection was conducted when we discovered that a peak routinely observed by GC-FID analysis of plates containing active cultures was not present in vials with scraped cells. The method described above in which volatiles were sampled directly from plates was then used for GC-MS analysis of one plate each of the uricase(+) and uricase(−) strains incubated for eight days.

Thermal desorption from the PDMS fiber was conducted as described above. The analytical column for GC-MS was a DB-1 fused-silica capillary column (30 m × 0.32 mm ID, 5-μm film thickness). Linear velocity of helium carrier gas was 60 cm/sec. Column oven temperature was 50°C for 1 min, then programmed at 10°C/min to 200°C. GC-MS data were acquired using a Hewlett Packard 6890 GC (Hewlett-Packard Company, San Fernando, California, USA) with an HP 5973 mass selective detector (electron energy = 70 eV) over a mass range of 20–300 amu, at 2 scans/sec. GC-MS identifications were based on computer matching of unknown spectra with those in the Wiley 275K Mass Spectral Database (John Wiley & Sons, New York).

Chemical Attractiveness Bioassay. Cage-top bioassays as described in Robacker and Flath (1995) were used to test attractiveness of two chemicals identified in bacterial volatiles, 3-hydroxybutanone and 2-phenylethanol. The chemicals (both >99%) were obtained from Aldrich Chemical Company, Inc. (Milwaukee, Wisconsin, USA). Four quantities of each chemical were tested: 100 ng and 1, 10, and 100 μg. 3-Hydroxybutanone and 2-phenylethanol were prepared in water and methanol, respectively. The bioassay was conducted by placing two filter paper triangles (3 cm/side) containing 10 μl of test chemical solution and two papers containing 10 μl of appropriate solvent (water or methanol) near the corners on top of an aluminum-screened cage (30 cm/side) containing 180–200 adult flies. The papers containing test chemicals were positioned diagonally from each other on the cage top as were the papers containing solvent. The papers were raised 5 mm above the cage top using plastic rings to ensure that olfaction was solely responsible for responses. The number of flies beneath each paper was counted once each minute for 10 min following application of test chemicals. Bioassays were conducted using flies of two feeding regimes. First, the four concentrations of each chemical were bioassayed in random order using flies that were sugar-fed and protein-starved from eclosion. Sugar cubes were removed just prior to bioassays. In most cases, sugar cubes were not replaced, and the same cages were used as sugar-starved flies for bioassays of the same chemical solutions two days later. Each concentration of each chemical was assayed 10–18 times with both sugar-fed and sugar-starved flies.

Statistical Analyses. Attractiveness of the two strains of bacteria in wind-tunnel bioassays was analyzed using SuperANOVA (Abacus Concepts, 1989). For

analysis, proportions of flies to move upwind or contact the plates in each bioassay were transformed by arcsin of the square root because means were highly correlated with variances (Snedecor and Cochran, 1967). Proportions of 0 were replaced with $1/4n$. Separate analyses were conducted for males and females of different age groupings. Effect of bacteria strain on production of volatiles was also tested by analysis of variance of GC area counts using SuperANOVA. Separate analyses were conducted for each chemical. Means separations were done by Fisher's protected least significant difference method (LSD) in all ANOVA's. Paired *t* tests were used to analyze results of cage-top bioassays evaluating attractiveness of individual chemicals. For paired *t* tests, the total of 10 counts of flies at filter papers containing test chemicals were compared with the total at papers containing solvent for each bioassay.

RESULTS AND DISCUSSION

Attractiveness of Uricase(+) and Uricase(−) Strains. More females of ages 5–9 days posteclosion moved upwind toward plates containing cultures of either strain of *E. agglomerans* than plates containing uninoculated medium, and more moved upwind toward the uricase(+) strain than the uricase(−) strain ($F = 13.0$; $df = 2,62$; $P < 0.001$) (Table 1). More of these females also contacted plates containing the uricase(+) strain than uninoculated medium ($F = 3.8$; $df = 2, 62$; $P < 0.05$). More females of ages 10–27 days posteclosion moved upwind toward ($F = 7.0$; $df = 2,67$; $P < 0.01$) and contacted ($F = 5.0$; $df = 2,67$; $P < 0.01$) plates containing cultures of either strain than plates containing uninoculated medium. The number of these females to move upwind toward or contact plates

TABLE 1. ATTRACTION OF SUGAR-FED MEXICAN FRUIT FLIES TO PETRI PLATES CONTAINING TWO STRAINS OF *E. agglomerans* IN A WIND TUNNEL[a]

Fly group	Bacteria strain	Trials *N*	Upwind movement	Contact with plate
Females	Uninoculated medium	16	3.5 ± 1.8 a	1.1 ± 0.8 a
5–9 days old	Uricase(−)	26	14.9 ± 2.7 b	4.6 ± 1.5 ab
	Uricase(+)	26	21.9 ± 2.7 c	8.1 ± 2.1 b
Females	Uninoculated medium	16	3.1 ± 1.2 a	0.4 ± 0.4 a
10–27 days old	Uricase(−)	29	12.8 ± 2.9 b	5.0 ± 1.4 b
	Uricase(+)	29	13.6 ± 3.1 b	7.2 ± 2.6 b
Males	Uninoculated medium	32	3.9 ± 1.0 a	1.1 ± 0.7 a
	Uricase(−)	55	7.7 ± 1.2 b	2.1 ± 0.6 a
	Uricase(+)	55	14.1 ± 1.8 c	5.3 ± 1.2 b

containing the uricase(+) strain was not significantly different from the number responding to plates containing the uricase(−) strain. These analyses do not prove that females of the two age groups are significantly different from each other. No actual comparison of the age groups was possible because the experiment was not designed for this test.

Data for males of different ages were combined because analyses indicated that age (5–9 days vs. 10–27 days posteclosion) did not significantly affect responses of males to the *E. agglomerans* cultures. More males moved upwind toward plates containing either strain of *E. agglomerans* than plates containing uninoculated medium and more moved upwind toward the uricase(+) strain than the uricase(−) strain ($F = 13.3; df = 2,132; P < 0.001$; Table 1). More males also contacted plates containing the uricase(+) strain than either uninoculated medium or the uricase(−) strain ($F = 6.0; df = 2,132; P < 0.01$).

Because a wide range of incubation times were used in this work, we examined effects of incubation time on wind-tunnel bioassay results. We could not determine if incubation time affected overall attractiveness of the cultures because incubation time was confounded with time of year when tests were conducted and with batch of flies tested. Effect of incubation time on attractiveness of the two strains relative to each other was not confounded because each strain was tested equally with each fly batch, at all times of the year, and with all incubation times. Partitioning the data in Table 1 by incubation time (2- to 5-day vs. 6- to 9-day incubations), uricase(+) plates were more attractive than uricase (−) plates to younger females and to males of all ages, and uricase(+) and -(−) plates were about equally attractive to older females, regardless of incubation time. Thus, no effects of incubation time on relative attractiveness of the two strains were observed.

These results show that both strains of *E. agglomerans* were attractive to female and male Mexican fruit flies. They also show that the uricase(+) strain was more attractive than the uricase(−) strain, except to mature females. The results differed from those reported for *R. pomonella*, in which isolates of *E. agglomerans* that were found to be uricase(−) in later research (Lauzon et al., 2000) were not more attractive than uninoculated controls (Lauzon et al., 1998). No differences in response with sex or age were reported in studies with *R. pomonella*.

Chemical Identifications and Quantifications. GC-FID and GC-FTD analyses of headspace above active cultures in plates revealed about 100 chemicals in the headspace. It was decided that only peaks with areas of at least 1 mV (about 50 peaks), peaks found in at least three samplings, and peaks found in significantly greater amounts in at least one of the two strains than in the uninoculated controls, would be considered for further analysis. Two exceptions were ammonia and dimethyldisulfide, both of which had mean peak areas below 1 mV. Ammonia was analyzed because it is known to be attractive, and neither FID nor FTD are sensitive to it (it is not carbon based) such that peaks less than 1 mV represent high concentrations. For example, comparable peak sizes were obtained for ammonia and

TABLE 2. GAS CHROMATOGRAPHIC PEAK AREAS OF CHEMICALS IN HEADSPACE OF PETRI PLATE CULTURES OF TWO STRAINS OF *E. agglomerans* SAMPLED BY SOLID-PHASE MICROEXTRACTION[a]

Chemical	Peak area [mV (mean ± SE)]		
	Uninoculated medium	Uricase(−) strain	Uricase(+) strain
Ammonia[b]	0.06 ± 0.02 (8) a	0.13 ± 0.02 (12) b	0.20 ± 0.03 (11) c
Dimethyldisulfide[b]	0.00 ± 0.00 (8) a	0.53 ± 0.11 (8) b	0.96 ± 0.10 (7) c
3-Hydroxybutanone[b]	0.071 ± 0.05 (8) a	0.10 ± 0.10 (16) a	4.3 ± 1.1 (16) b

2-ethylhexanol despite actual concentrations of 1.8 mg/ml and 30 ng/ml, respectively, in a suspension of duck feces (Robacker et al., 2000). Dimethyldisulfide was analyzed because its GC peak overlapped with that of 3-methylbutanol in initial analyses.

GC-FID and GC-FTD quantifications of ammonia, dimethyldisulfide, and the other peaks remaining under consideration are shown in Table 2. Although actual headspace concentrations of the chemicals were not determined, concentrations of chemicals determined from comparable peak sizes in previous studies of volatiles produced by bacteria were in the range known to be attractive to the Mexican fruit fly (Robacker and Flath, 1995; Robacker and Bartelt, 1997; Robacker et al., 2000).

Both bacteria strains produced more ammonia, dimethyldisulfide, 3-methylbutanol, 2-phenylethanol, 2,5-dimethylpyrazine, and trimethylpyrazine than uninoculated controls (Table 2). The uricase(+) strain produced more ammonia, dimethyldisulfide, 3-hydroxybutanone, and trimethylpyrazine than the uricase(−) strain. In fact, the low amounts of 3-hydroxybutanone found in determinations for the uricase(−) strain and uninoculated medium may represent carryover from previous samplings of the uricase(+) strain, suggesting that 3-hydroxybutanone is not produced by the uricase(−) strain. The uricase(−) strain produced a 2-phenylethanol peak 8 × bigger than that produced by the uricase(+) strain. All of theses chemicals except 3-hydroxybutanone had been identified previously from bacterial odors (Gow, 1954; Drew and Fay, 1988; Lee et al., 1995; Robacker and Flath, 1995; DeMilo et al., 1996; Robacker and Bartelt, 1997; Epsky et al., 1998; Robacker et al., 1998). 3-Hydroxybutanone had been identified previously from yeasts and is known to be attractive to the sap beetle *Carpophilus humeralis* (F) (Coleoptera: Nitidulidae) (Phelan and Lin, 1991; Nout and Bartelt, 1998).

As with attractiveness experiments, data in Table 2 were partitioned to compare emissions of the various chemicals for incubations of 2–5 and 6–9 days. Patterns and amounts of emissions did not vary appreciably by incubation time within this range. Epsky et al. (1997) showed that more ammonia was produced by bird feces incubated for one day compared with longer incubations. Unfortunately, neither our current work nor Epsky et al. (1998) investigated volatiles produced by *E. agglomerans* incubated for shorter periods than two days.

As discussed in the introduction, Epsky et al. (1998) found 3-methylbutanol and ammonia in headspace above tryptic soy agar cultures of a uricase(+) strain of *E. agglomerans*. They reported that 3-methylbutanol and ammonia were the two most abundant volatiles in the headspace and specifically that 3-methylbutanol accounted for >85% of the volatiles detected by GC-MS (ammonia was not analyzed by GC-MS). Although 3-methylbutanol was not the largest peak we observed (Table 2), previous work showed that detection of this chemical in tryptic soy broth cultures of two bacteria species by SPME (Robacker and Bartelt 1997) was much less efficient than by adsorption onto charcoal (Lee et al., 1995; DeMilo et al., 1996), a method similar to that used by Epsky et al. (1998). It also is possible that cultures of the uricase(+) strain in tryptic soy agar may produce more 3-methylbutanol than cultures in uric acid medium. Thus, we do not dispute the statement by Epsky et al. (1998) concerning the abundance of 3-methylbutanol. These authors also speculated that 3-methylbutanol may be an important attractant produced by the uricase(+) strain of *E. agglomerans*, although they did not report volatiles produced by a uricase(−) strain. We have no evidence to refute that 3-methylbutanol may contribute to attractiveness of the uricase(+) strain under some conditions or with some species of fruit flies. However, in our work, 3-methylbutanol cannot account for the greater attractiveness of the uricase(+) strain because the uricase(−) strain produced just as much of this chemical (Table 2).

Bioassays of 3-Hydroxybutanone and 2-Phenylethanol. Attractiveness of 3-hydroxybutanone and 2-phenylethanol in cage-top bioassays was significant by paired *t* tests ($P < 0.05$) for several test quantities evaluated with several groups of sugar-fed and sugar-starved males and females as follows: 3-hydroxybutanone—fed males at the 1 μg test quantity, fed females at 0.1 and 100 μg, and starved females at 100 μg; and 2-phenylethanol—fed males at 10 μg, and starved males and starved females at all test quantities. No dose–response relationships were evident, so data were combined over test quantities, then partitioned into separate analyses for flies <10 days posteclosion versus flies ≥10 days posteclosion.

Results of the age analyses are shown in Table 3. 3-Hydroxybutanone was significantly attractive to 3- to 9-day-old flies including fed males, fed females, and starved males. This is the first report of attractiveness to sugar-fed Mexican fruit flies of a nonpheromonal chemical that does not contain protonizable nitrogen. 3-Hydroxybutanone was not significantly attractive to flies aged 10–14 days

TABLE 3. COUNTS OF SUGAR-FED OR -STARVED MEXICAN FRUIT FLIES OF TWO AGE GROUPS AT SOLVENT BLANKS (S) OR TEST CHEMICALS (T) IDENTIFIED FROM HEADSPACE ABOVE CULTURES OF *E. agglomerans*, USING CAGE-TOP BIOASSAYS

	Counts (mean ± SE)					
	3–9 days old			10–14 days old		
	Trials (*N*)	T	S	Trials (*N*)	T	S
3-Hydroxybutanone						
Fed males	40	38.2 ± 4.4^a	31.2 ± 3.1	20	32.8 ± 4.4	34.4 ± 3.8
Fed females	40	34.3 ± 3.5^a	26.4 ± 2.0	20	28.6 ± 2.5	27.5 ± 1.9
Starved males	16	37.8 ± 4.5^a	30.8 ± 3.3	24	48.7 ± 4.6	45.5 ± 3.7
Starved females	16	26.9 ± 3.8	23.0 ± 2.5	24	39.2 ± 4.2	32.4 ± 2.3
2-Phenylethanol						
Fed males	28	26.8 ± 3.6	22.1 ± 2.8	16	36.9 ± 3.9	35.5 ± 3.2
Fed females	28	23.4 ± 2.8	20.1 ± 2.0	16	35.0 ± 2.3	32.8 ± 2.3
Starved males	16	47.6 ± 4.6^a	34.2 ± 3.5	24	58.0 ± 4.7^a	40.5 ± 2.7
Starved females	16	38.4 ± 4.3^a	30.5 ± 3.7	24	41.0 ± 3.0^a	31.8 ± 2.7

[a] The mean response to a chemical was significantly different from the response to solvent by paired *t* test ($P < 0.05$).

posteclosion. As discussed for age groups responding to the plates, these analyses do not prove that flies of the two age groups are significantly different from each other because the experiment was not designed for this comparison. 2-Phenylethanol was significantly attractive to starved males and starved females of both age groups. It was not significantly attractive to sugar-fed flies.

Relationship Between Bacterial Volatile Emissions and Strain Attractiveness. Emission of three chemicals in greater amounts by the two strains of *E. agglomerans* than by uninoculated medium is consistent with the greater attractiveness of the bacteria to sugar-fed Mexican fruit flies compared with attractiveness of the uninoculated medium. These chemicals, ammonia, 2,5-dimethylpyrazine, and trimethylpyrazine (Table 2), have been reported attractive to sugar-fed Mexican fruit flies (Robacker and Warfield, 1993; Robacker and Flath, 1995; Robacker and Bartelt, 1997; Robacker et al., 2000). The other three chemicals produced in significantly greater amounts by both strains, dimethyldisulfide, 3-methylbutanol, and 2-phenylethanol, were not attractive in tests with sugar-fed Mexican fruit flies here (Table 3) or previously (Robacker and Flath, 1995; Robacker and Bartelt, 1997). However, Epsky et al. (1998) demonstrated that 3-methylbutanol was attractive to *A. suspensa*. 2-Phenylethanol, while not attractive to sugar-fed Mexican fruit flies, was highly attractive to sugar-starved flies (Table 3). This suggests that if sugar-starved flies had been used to evaluate attractiveness of the two bacteria strains, the uricase(−) strain may have been somewhat more attractive because of the high emissions of 2-phenylethanol. It also is possible that some combination

of dimethyldisulfide, 3-methylbutanol, and 2-phenylethanol with other chemicals in the bacterial odor may enhance attraction even though these chemicals were not attractive to sugar-fed flies by themselves. In that regard, Epsky et al. (1998) showed that a combination of 3-methylbutanol and ammonia was more attractive than either chemical alone to *A. suspensa*.

Emission of four chemicals in greater amounts by the uricase(+) strain than by the uricase(−) strain is consistent with the greater attractiveness of the uricase(+) strain to sugar-fed males and 5- to 9-day-old sugar-fed females (Table 1). Three of these chemicals, ammonia, 2,5-dimethylpyrazine, and trimethylpyrazine (Table 2), are attractive to sugar-fed Mexican fruit flies, as discussed above. The fourth, 3-hydroxybutanone, is attractive to sugar-fed males and 3- to 9-day-old sugar-fed females (Table 3). The lack of attractiveness of 3-hydroxybutanone to sugar-fed females 10 days posteclosion or older (Table 3) is also consistent with the lower attractiveness of the uricase(+) strain to 10- to 27-day-old sugar-fed females (Table 1). However, sugar-fed males 10 days posteclosion or older also were not attracted to 3-hydroxybutanone (Table 3), but no corresponding decrease in attractiveness of the uricase(+) strain to older males occurred in this case.

This is not the first time that production of volatiles and attractiveness to the Mexican fruit fly by different strains of the same bacterium have been investigated. Previously, Robacker et al. (1998) showed that four different strains of *Bacillus thuringiensis* produced widely different amounts of eight volatile chemicals known to be attractive to this fly. However, in that case, aqueous filtrates of the four strains did not differ in attractiveness as each contained enough of several of the chemicals to compensate for lesser amounts of some of the others.

Metabolic Capabilities, Attractiveness, and Symbioses. The medium used to culture *E. agglomerans* in this work was designed to simulate bird feces in that uric acid was the primary nitrogen source. We expected that only the uricase(+) strain would utilize uric acid efficiently. As a consequence, we also expected that the uricase(−) strain would utilize other biochemicals either more or less efficiently than the uricase(+) strain as different enzyme systems were induced to metabolize the usable nutrients. It follows that the greater amounts of ammonia, dimethyldisulfide, 3-hydroxybutanone, 2,5-dimethylpyrazine, and trimethylpyrazine (Table 2) produced by the uricase(+) strain were the result of this strain's metabolic capability on this special medium and may account for its greater attractiveness to *R. pomonella* (Lauzon et al., 1998) and *A. ludens*. Conversely, the greater amount of 2-phenylethanol produced by the uricase(−) strain (Table 2) may reflect this strain's metabolic capability. As discussed above, the uricase(−) strain may possibly be more attractive than the uricase(+) strain to sugar-hungry flies that respond strongly to 2-phenylethanol (Table 3) and less strongly to ammonia and at least some other nitrogen containing compounds (Robacker et al., 2000).

E. agglomerans strains are known to grow on variable and numerous substrates (Lauzon et al., 1998). In part, this is why biochemical identification of this bacterium can be a challenge. Thus, it was not surprising that *E. agglomerans* strains isolated from different sources possessed different metabolic capabilities (Lauzon et al., 2000). Results reported here (Table 2) and elsewhere (Robacker et al., 1998) indicate that different strains of the same bacterium can produce different volatile metabolites even when cultured on the same medium. It also is known that the same strain can produce different volatiles or at least different amounts of the same chemicals when grown on different substrates (Epsky et al., 1998). This was the reason we used a special uric acid medium to test differences between uricase(+) and -(−) strains of *E. agglomerans*. Further, it has been demonstrated that different species or strains of bacteria can produce many of the same chemicals (Robacker et al., 1998). In this case, it is possible that the same compounds could be produced by either identical or different metabolic pathways depending on the precursor available to the bacteria and perhaps other environmental factors. Incubation time or stage in the growth cycle of the bacteria is another factor that can affect utilization of substrate and production of volatile metabolites (Epsky et al., 1997). Thus, the dynamic and plastic nature of bacterial metabolism must be taken into consideration when trying to interpret insect response to bacterial odors. We also discussed that insects may respond differently to bacterial odors depending on their physiological condition related to age (Table 1) and nutritional state (Robacker and Garcia, 1993; Robacker and Moreno, 1995). All of this complicates evaluation of insect attraction to bacterial odors.

Despite nonuniformities in bacterial odor production and fly responses, there is reason to suspect that some bacteria form close symbiotic relationships with insect hosts, an idea that has been bandied about for decades but not proven. The close physical association between *E. agglomerans* and several tephritids, the presence of this bacterium in the natural food of these flies and on their host plants, and attraction by these tephritids to specific strains of the bacterium suggest this bacterium performs an important role in the life cycle of tephritids. The chemical profiles characteristic of the various strains of *E. agglomerans*, coupled with responses by fruit flies of specific physiological states, may give us some idea of the contributions these bacteria make to insect survival and perhaps provide insight to the needs flies have at distinct physiological times in their adult life.

Acknowledgments—We thank Robert Bartelt (USDA ARS, Peoria, Illinois) for conducting GC-MS analyses and Maura Rodriguez, Noemi Martinez (both USDA ARS, Weslaco, Texas, USA), and Sarah Potter (Cal State, Hayward, California, USA) for additional technical assistance. We thank Robert Bartelt, Tracey Leskey (USDA ARS, Kearneysville, West Virginia, USA), and Peter Teal (USDA ARS, Gainesville, Florida, USA) for reviews of the research report. KAIROMONE STRAINS OF *Euclytia flava* (TOWNSEND), A PARASITOID OF STINK BUGS[1]

J. R. ALDRICH* and A. ZHANG

USDA-ARS Chemicals Affecting Insect Behavior Laboratory
Agricultural Research Center-West
Beltsville, Maryland, USA 20705

(Received January 4, 2002; accepted April 18, 2002)

Abstract—Tachinid flies commonly use the pheromones and allomones of stink bugs (Pentatomidae) as host-finding kairomones. Pheromone-baited traps for predaceous (*Podisus* spp.) and phytophagous (*Euschistus* spp.) pentatomids were used to obtain tachinid parasitoids in order to study the semiochemical relationships between these parasitic flies and their stink bug hosts. Gas chromatography–electroantennogram detector (GC-EAD) experiments and field tests were conducted to determine if pheromone strains of the tachinids, *Euclytia flava* and *Hemyda aurata*, occur in nature and to determine if the EAD-active compound, (*E*)-2-octenal (a common allomone compound of Heteroptera), affects attraction of tachinid parasitoids to synthetic *Podisus* pheromones. Addition of (*E*)-2-octenal to *Podisus* spp. synthetic pheromones in field traps tended to suppress attraction of the bugs, whereas (*E*)-2-octenal decreased, did not affect, or increased pheromonal attraction of tachinid parasitoids depending on the host species pheromone being tested and the habitat type in which the traps were deployed. Evidence from GC-EAD experiments of *E. flava* associated with different stink bug hosts suggested that kairomone-strains of this tachinid parasitoid coexist naturally. The significance of cryptic kairomone strains of parasitoids for classical biological control is discussed, and the mechanisms whereby parasitoids evolve kairomonally mediated host-shifts is considered.

Key Words—Pheromone, allomone, *Hemyda*, *Gymnosoma*, hexenal, linalool, α-terpineol, methyl (*E*,*Z*)-2,4-decadienoate, host shift, speciation.

INTRODUCTION

Stink bugs, as the name implies, emit secretions unpleasant to humans and invertebrates alike—from metasternal glands (adults) or dorsal abdominal glands (nymphs)—to defend themselves (Aldrich, 1995b). Pentatomids and other true bugs (Hemiptera: Heteroptera) also produce pheromones from a variety of glandular sources (Aldrich, 1995b; McBrien and Millar, 1999). However, heteropteran chemical defense and communication are not without risks because many parasitoids exploit their allomones and pheromones as host-finding kairomones, especially scelionid wasps (egg parasitoids) and tachinid flies (parasitoids of nymphs and adults) (Mattiacci et al., 1993; Aldrich, 1995b; Bruni et al., 2000). Here we describe our efforts to understand the semiochemical relationships between tachinid fly parasitoids and their predaceous (*Podisus* spp.) and phytophagous (*Euschistus* spp.) pentatomid hosts.

In Maryland, *Podisus maculiventris* (Say) (called the spined soldier bug) is a common bivoltine general predator (McPherson, 1982), while the sympatric species, *P. neglectus* Westwood (= *P. fretus*), is a relatively uncommon univoltine specialist predator of pine sawfly larvae (Hetrick, 1959; Thomas, 1992). These (and other) *Podisus* males have enlarged dorsal abdominal glands from which they selectively release pheromones to attract conspecific females. Conspecific males also go to calling males, probably to find potential mates without advertising themselves to parasitoids, and nymphs walk to the pheromone, perhaps because pheromone emission is associated with prey (Aldrich, 1995b). The attractant pheromones of *P. maculiventris* and *P. neglectus* each contain (*E*)-2-hexenal and benyzl alcohol as major constituents, but the pheromones differ in their principal monoterpenoid component; in *P. maculiventris* α-terpineol is the essential synergist for the other essential synergist, (*E*)-2-hexenal (Aldrich et al., 1984a), whereas in *P. neglectus* linalool replaces α-terpineol as an essential synergist (Aldrich et al., 1986). Adult *Podisus* females possess glands homologous to the hypertrophied male pheromone glands; however, in females these glands are tiny, and produce a unique array of chemicals (Aldrich et al., 1984b). In addition, *Podisus* nymphs produce chemically distinctive exocrine secretions from dorsal abdominal glands (Aldrich, 1995b).

Euschistus is a New World genus of phytophagous stink bugs, several of which are agricultural pests that are all the more important nowadays because of their immunity to *Bt* endotoxins expressed in genetically modified crops (Bacheler, 1998). In North America, the genus *Euschistus* includes several species whose males produce an attractant pheromone (presumably from gland cells scattered in the abdominal epidermis) with one dominant compound, methyl (*E*,*Z*)-2,4-decadienoate (Aldrich et al., 1991b). Synthetic methyl (*E*,*Z*)-2,4-decadienoate attracts females, males, and nymphs of several *Euschistus* spp. Minor pheromone components that may account for species-specificity of *Euschistus* pheromones

have yet to be discovered despite attempts to do so (Aldrich et al., 1995). As in *Podisus* spp., secretions presumed to be allomones are produced in metasternal scent glands (adults) and dorsal abdominal glands (nymphs) of *Euschistus* spp., and the secretions from these glands are chemically similar to those of other stink bugs (Borges and Aldrich, 1992).

Large numbers of one tachinid parasitoid, *Euclytia flava* (Townsend), can be captured alive in traps baited with synthetic pheromones mimicking the male-produced pheromones of either *P. maculiventris* or *P. neglectus* (Aldrich, 1995a). A second tachinid parasitoid, *Hemyda aurata* Robineau-Desvoidy, is commonly attracted to, but will not usually enter, traps baited with these pheromones; however, substantial numbers of this tachinid can be reared from field-collected *Podisus* adults. Female tachinid parasitoids of stink bugs usually lay macro-eggs on adult hosts (McPherson et al., 1982), but late-stage nymphs are also attacked (Buschman and Whitcomb, 1980; Eger and Ables, 1981; Panizzi and Slansky, 1985). Indeed, both *E. flava* and *H. aurata* were significantly attracted to a synthetic blend mimicking the allomone of spined soldier bug nymphs (Aldrich, 1995b). *Euclytia flava* was occasionally collected in traps baited with the main *Euschistus* pheromone component methyl (*E*,*Z*)-2,4-decadienoate (Aldrich et al., 1991b) and, in the laboratory, females of this fly oviposited on a variety of pentatomids, actually preferring to lay on exotic species when given a choice between exotic and native bugs (Aldrich, 1995a). Therefore, we consider *E. flava* to be more of a generalist parasitoid (Oetting and Yonke, 1971; Buschman and Whitcomb, 1980; Jones and McPherson, 1980; Aldrich, 1995a) than is *H. aurata* (Eger and Ables, 1981; McPherson et al., 1982), which we have not encountered in or around traps baited with methyl (*E*,*Z*)-2,4-decadienoate (Aldrich et al., 1991b).

In the experiments described here we sought to explore the electrophysiological sensitivity of tachinid flies to the various exocrine secretions of preferred and nonpreferred hosts. Preliminary gas chromatography–electroantennogram (GC-EAD) experiments, using chilled preparations similar to those for apple maggot flies (Zhang et al., 1999), indicated that preparations of *E. flava* antennae could be maintained for hours and that their antennae were more sensitive to the essential *Podisus* pheromone components than were those of the bugs themselves. Furthermore, *E. flava* antennae were extremely sensitive to the common stink bug defensive compound (Aldrich, 1995b), (*E*)-2-octenal (Figure 1A below). Specific objectives of the research were to determine if kairomone strains of *E. flava* or *H. aurata* occur in nature and to determine if (*E*)-2-octenal affected attraction of tachinid parasitoids to synthetic *Podisus* pheromones.

MATERIALS AND METHODS

Chemical Standards and Treatments. Standards of the following compounds were purchased or prepared: (*E*)-2-hexenal (**1**), (*E*)-2-octenal (**3**), (*E*)-2-nonenal

(**6**), (*E*)-2-decenal (**8**), (*E*,*E*)-2,4-octadienal (**18**), methyl (*E*,*Z*)-2,4-decadienoate (**19**) (Bedoukian Research, Inc., Danbury, Connecticut, USA); hexanal (**10**), 1-hexanol (**11**), hexanoic acid (**15**), (*E*)-2-hexenoic acid (**14**), benzaldehyde (**12**), benzyl alcohol (**2**), *n*-dodecane (**7**), *n*-tridecane (**9**), linalool (**16**) (Aldrich Chemicals, Milwaukee, Wisconsin, USA); α-terpineol (**4**) (Fisher Scientific Company, Fair Lawn, New Jersey, USA); tetradecanal (**17**) (= myristyladehyde) (Fluka Chemika, Buchs, Switzerland). (*E*)-4-Oxo-2-hexenal (**5**) was synthesized according to Ward and VanDorp (1969), and hexyl hexanoate (**13**) was prepared by the standard acid-chloride procedure. Standard solutions for GC-EAD were prepared as follows: (*E*)-2-octenal and (*E*)-2-decenal; α-terpineol, linalool and (*E*)-2-octenal standards; (*E*)-2-octenal, linalool, α-terpineol and methyl (*E*,*Z*)-2,4-decadienoate; and methyl (*E*,*Z*)-2,4-decadienoate alone (10 ng each standard/μl CH_2Cl_2; the same solution was used for all data presented in Table 1 below).

Three-component blends were prepared to mimic the natural pheromones of *P. maculiventris* and *P. neglectus* as follows. (*E*)-2-Hexenal, racemic α-terpineol, and benzyl alcohol were mixed in a molar ratio of 1:0.843:0.061, respectively. Batches of 40 ml of pheromone (17.6 ml hexenal, 21.4 ml α-terpineol, 1 ml benzyl alcohol) were normally prepared. A 20% (v/w) formulation of pheromone in plasticized polyvinyl chloride (PVC) was prepared by mixing 107 g of powdered PVC (Tenneco, Piscataway, New Jersey, USA) with 53 ml of dioctyl phthalate (Aldrich Chem.), then adding the pheromone (Fitzgerald et al., 1973). The pheromone–PVC mixture was poured into test tubes (to the top), heated at 110°C for 30 min, removed from the tubes, and stored in sealed vials in a freezer until use (PM treatment). Pheromone for *P. neglectus* (PN treatment) was prepared in a similar manner except linalool (Aldrich Chem.) was substituted for α-terpineol (Aldrich et al., 1986). (*E*)-2-Octenal was formulated separately by adding 20 ml of the standard to PVC prepared as described above (O treatment). Methyl (*E*,*Z*)-2,4-decadienoate (Bedoukian Res.) inhibits plasticization of PVC; therefore, this treatment was prepared as a 1:2 solution in heptane (E treatment).

Trapping. Traps were made of transparent cylindrical containers having either white or transparent lids (20.2 × 19.7 cm; Pioneer Plastics, Inc., Dixon, Kentucky, USA) by cutting two holes (9 cm diam.) in opposite sides, and covering each hole with an inwardly projecting screen funnel. The containers were turned upside-down, so that the normal top of the container became the trap bottom, small drainage holes were made in the bottom, and the bottoms were held in place by two elastic cords hooked into each screen funnel. Traps were hung from branches about 1.7 m from the ground, at least 25 m apart, along power line cuts or dirt roads at Beltsville Agricultural Research Center-East (BARC-East; 39°2′N/76°55′W). Ten to 20 traps baited with ~350 mg of *P. maculiventris* pheromone-PVC material were deployed in mid-March each spring from 1999 through 2001 in deciduous

forest tracts at the BARC-East to harvest adult spined soldier bugs emerging from overwintering and to collect tachinids. These traps were monitored every one to two days, and rebaited every three to four days through July, after which bugs and tachinids became scarce.

In 1999, an experiment was conducted from May 21 through June 28 to test pheromones of *P. maculiventris* and *P. neglectus*, with and without (*E*)-2-octenal added, using traps deployed in deciduous and coniferous forest tracts at BARC-East (see Aldrich et al., 1986). The protocol for this experiment was similar to that described above. Six traps were deployed per treatment (four treatments: PM, PN, PM+O, PM+O) in each area (48 traps total), alternating treatments. For treatments that included (*E*)-2-octenal, a ~350 mg slice of PVC containing (*E*)-2-octenal was included in the trap with the PM or PN material.

In 2001, as part of another study to test different formulations of methyl (*E*,*Z*)-2,4-decadienoate, 20 traps were baited every two to three days by applying 10 μl of the heptane solution containing this methyl ester to gray rubber septa (5 × 9 mm; Thomas Scientific, Philadelphia, Pennsylvania, USA), plus 10 heptane-baited control traps. These traps were deployed as above at BARC-East and monitored regularly from August 31 through October 15.

Insects. Podisus maculiventris adults caught in pheromone-baited traps were brought to the laboratory and maintained in groups of 10–15 bugs per $^1/_2$-pint ice cream carton provided with mealworm pupae (Rainbow Mealworms, Inc., Compton, California, USA), fresh green beans (Leguminosae: *Phaseolus vulgaris* L.), and water (Aldrich and Cantelo, 2000). To collect *H. aurata* puparia, holes were punched in the bottom of the containers to allow larvae that emerged from bugs to escape predation by crawling through the holes into a Petri dish underneath the carton.

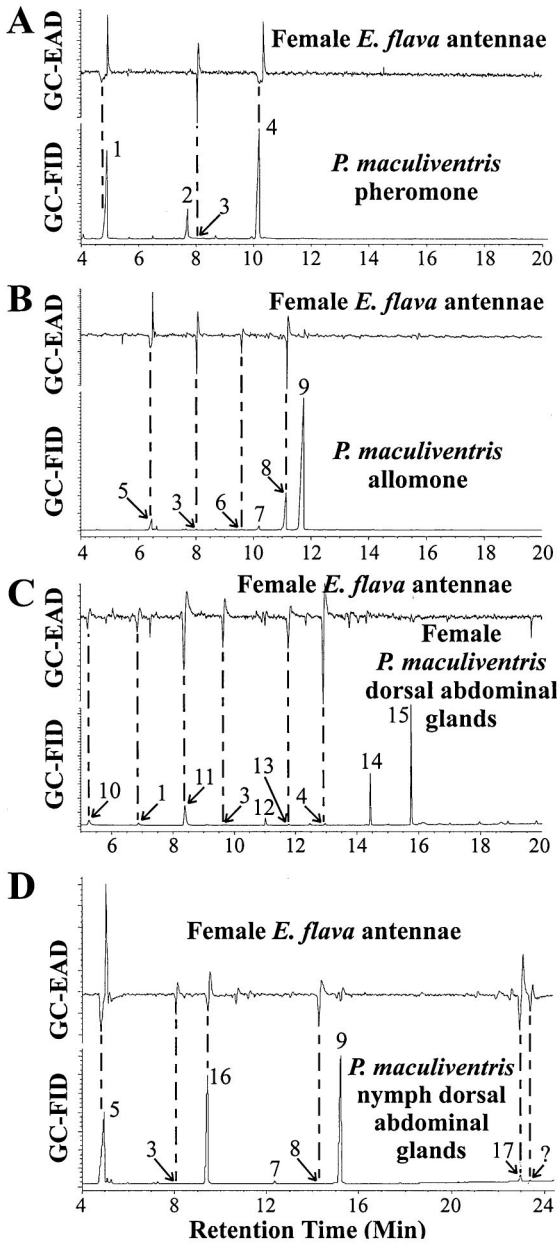
Colonies of *E. servus* and *E. tristigmus* were started from adults collected in May and June, 2000 and 2001, from Empress trees (Scrophulariaceae: *Paulownia tomentosa* (Thunb.) Steud.) at BARC-East and reared as described earlier (Aldrich et al., 1995). Trapped *Euschistus* spp. were also brought to the laboratory and held separately from the laboratory colonies to collect emergent tachinids.

Most *E. flava* used for GC-EAD experiments were collected in or around pheromone-baited traps, but a few individuals of this species were reared from *P. maculiventris* caught in PM- or PM+O-baited traps. One *E. flava* female was collected on October 11, 2001, in a trap baited with methyl (*E*,*Z*)-2,4-decadienoate, and this *Euschistus*-associated fly was used for GC-EAD. For *H. aurata* associated with *P. maculiventris*, approximately equal numbers of flies were reared from wild spined soldier bugs as were collected on or around PM- or PM+O-baited traps. For *P. neglectus*-associated *H. aurata*, all flies used for GC-EAD were collected on or around PN- or PN+O-baited traps. *Gymnosoma* sp. used for GC-EAD were both field-collected and reared from wild *E. tristigmus*.

Field-collected flies were caught in cotton-stoppered shell vials and transported to the laboratory in a cooler. Field-collected and laboratory-reared tachinids were segregated according to their associated host, confined in plastic pint containers provided with water and honey, and held in an insectary until use (16L:8D cycle, ~65% relative humidity, and ~25°C). Regardless of the source of tachinids, care was taken not to anesthetize the flies for fear that this might adversely affect antennal response; instead, flies were briefly chilled prior to killing for GC-EAD experiments.

Volatile Extracts. Dorsal abdominal and metasternal glands (DAGs and MGs, respectively) from *P. maculiventris* adults were excised from CO_2-anesthetized bugs submerged in tap water and extracted in CH_2Cl_2 as follows: 1 pair of DAGs/~300 μl solvent (male), 5 pairs of DAGs/~50 μl solvent (females), and 1 MG/~200 μl solvent (male or female). The contents of the nymphal DAGs are shed with the exuviae, and the secretion extracted from fresh exuviae has been shown to match the secretion obtained from live nymphs (Aldrich et al., 1991a; Borges and Aldrich, 1992); therefore, the fifth-instar exuviae from ~20 *P. maculiventris* nymphs that had molted to adults within 24 hr were collected and extracted in ~500 μl CH_2Cl_2. *Euschistus servus* pheromone extracts were obtained by aeration using Super Q adsorbent (Alltech Associates, Inc., Deerfield, Illinois, USA) as recently described (Borges et al., 2001).

Gas Chromatography–Electroantennogram Detector Analysis. The GC-EAD system used was as previously described (Zhang et al., 1997; Zhang et al., 1999) with some modifications. A Hewlett Packard 6890 gas chromatograph equipped with a 60-m × 0.25-mm-ID, 0.25-μm film-thickness DB-5 or DB-WAXetr capillary column (J&W Scientific Inc., Folsom, California, USA) in the splitless mode with nitrogen as carrier (2 ml/min) was used for GC (50°C for 2 min, then programmed to 230°C at 10°C/min and held for 10 min). Antennal recordings were made using a holder constructed from a piece of acrylic plastic (8 cm long × 0.8 cm wide × 0.6 cm thick) into which two 1.25-mm-diam. wells were drilled near the end of the plastic about 3 mm apart with a notch cut between the two wells to allow airflow. Each well was filled with 0.9% NaCl solution, and gold wires immersed in each saline-filled well electrode were connected to a high-impedance 1:100 amplifier with automatic baseline drift compensation. The EAD preparation was made using the whole head of a fly immersed in one well with the tips of the antennae making contact with the saline in the other well via a short lateral capillary tube inserted in the side of the other well. The antennal preparation was cooled to ~5°C inside a condenser by circulating near 0°C water from a benchtop refrigeration unit (RTE-100, Neslab Instruments, Inc., Portsmouth, New Hampshire, USA). The flame ionization and electrophysiological output signals (effluent split in 1:1 ratio) were recorded using Hewlett-Packard ChemStation software.



Compound Identification. Samples were analyzed by gas chromatography–mass spectrometry (GC-MS) on an HP 6890 GC coupled to an HP 5973 Mass Selective Detector using the same type of GC column and conditions as listed above except with helium as carrier gas. Identifications based on mass spectrometry were verified by chromatographic comparison to known standards, some of which were also used for GC-EAD experiments

Statistical Analysis. Analysis of variance was performed with the MIXED procedure (SAS Institute Inc., 1997) on the raw data counts. Treatments labeled with the same letter are not significantly different at the 0.05 significance level (Figures 3 and 4 below).

RESULTS

In general, tachinid EAD preparations remained active for four to eight GC runs (~30 min/run) and were extremely repeatable with low background noise after the first or second GC run. In contrast, antennal preparations of *Podisus* and *Euschistus* bugs (not shown) were relatively insensitive and unstable.

Representative GC-EAD runs of *E. flava* female antennal preparations to the array of *P. maculiventris* exocrine gland extracts are shown in Figure 1. The initial GC-EAD experiments showed that this tachinid is not equally sensitive to all components of the male-produced spined soldier bug pheromone (Figure 1A). Responses to the essential components, (*E*)-2-hexenal (**1**) and α-terpineol (**4**), were so extreme that apparent overload occurred as evidenced by the unusual initial deflection of the EAD signal, whereas benzyl alcohol (**2**) elicited almost no antennal response. A strong EAD response was consistently observed to a barely FID-detectable component of the male DAG secretion that was then identified as (*E*)-2-octenal (**3**) (Figure 1A). The *P. maculiventris* adult allomone (Figure 1B) elicited strong *E. flava* antennal responses to (*E*)-4-oxo-2-hexenal (**5**), (*E*)-2-octenal (**3**), (*E*)-2-nonenal (**6**), and (*E*)-2-decenal (**8**), but little or no response was elicited by either dodecane (**7**) or tridecane (**9**). In DAG extracts from *P. maculiventris* females (Figure 1C), the relatively minor components, (*E*)-2-octenal (**3**) and (*E*)-2-decenal (**8**), elicited strong antennal responses in *E. flava* [stronger than that for (*E*)-2-hexenal (**1**)], and a heretofore unknown component of this gland (Aldrich et al., 1984b), hexyl hexanoate (**13**), was strongly EAD-active. The more abundant components, hexanal (**10**) and 1-hexanol (**11**), elicited weak and strong EAD responses, respectively; while *E. flava* antennae were insensitive to the major components, hexanoic (**14**) and (*E*)-2-hexenoic (**15**) acids. Finally, GC-EAD experiments with the *P. maculiventris* exuvial extract (Figure 1D) corroborated the *E. flava* antennal responses to those compounds in common with components of adult exocrine gland secretions and demonstrated that *E. flava* is highly sensitive to linalool (**16**) as well as tetradecanal (**17**). No obvious differences in antennal

responses were observed for antennal preparations of male *E. flava* to these extracts (not shown).

The relative sensitivity of *E. flava* antennae to (*E*)-2-octenal (**3**) versus (*E*)-2-decenal (**8**) was tested by GC-EAD using a 10 ng/μl CH_2Cl_2 solution (Figure 2A). *Euclytia flava* antennae appeared to be more sensitive to (*E*)-2-octenal than (*E*)-2-decenal; therefore, it was decided to use (*E*)-2-octenal in the subsequent field experiment.

The captures of *Podisus* adults in traps baited with pheromone alone or pheromone plus (*E*)-2-octenal are shown in Figure 3. Only *P. maculiventris* adults were caught in PM- or PM+O-baited traps, and only *P. neglectus* were caught in PN-baited traps; there was no crossover attraction between pheromones. Significantly more *P. maculiventris* adults were caught in PM− and PM+O-baited traps in deciduous forest than coniferous forest but, within a given habitat and treatment, the captures of males and females were not significantly different (Figure 3A,B). Addition of (*E*)-2-octenal to the PM treatment tended to decrease the captures of spined soldier bug adults; this suppression was significant for males trapped in the deciduous forest habitat (Figure 3A), and females trapped in coniferous forest (Figure 3B). *Podisus neglectus* was caught solely in coniferous forest, and only about a tenth as many individuals were caught as the number of *P. maculiventris* caught in deciduous forest (Figure 3). Inclusion of (*E*)-2-octenal with the PN-treatment suppressed attraction of *P. neglectus* adults, significantly so for females (Figure 3B).

The responses of *E. flava* adults to the chemical treatments tested in the field are shown in Figure 4. In both deciduous and coniferous forest habitats, significantly more *E. flava* were caught in traps baited with PM or PM+O than in traps baited with PN or PN+O. In addition, more *E. flava* were captured within the deciduous forest site than the coniferous forest site. Addition of (*E*)-2-octenal to the PM treatment tended to reduce attraction of *E. flava* adults in the deciduous forest area (significant for males) (Figure 4A), but this trend was not evident for traps in the coniferous forest area (Figure 4B). Conversely, addition of

FIG. 1. Gas chromatogram–electroantennogram detector experiments for antennal preparations of *Euclytia flava* females caught in traps baited with *Podisus maculiventris* pheromone to *P. maculiventris* exocrine gland extracts of: (A) male dorsal abdominal gland (attractant pheromone), (B) adult metasternal gland extract (allomone), (C) female dorsal abdominal glands extract, and (D) fifth-instar nymph dorsal abdominal glands (A, B, and D run with DB-5 GC column; C run with DB-WAXetr column; other conditions as described in text; **1** = (*E*)-2-hexenal, **2** = benzyl alcohol, **3** = (*E*)-2-octenal, **4** = α-terpineol, **5** = (*E*)-4-oxo-2-hexenal, **6** = (*E*)-2-nonenal, **7** = dodecane, **8** = (*E*)-2-decenal, **9** = tridecane, **10** = hexanal, **11** = 1-hexanol, **12** = benzaldehyde, **13** = hexyl hexanoate, **14** = hexanoic acid, **15** = (*E*)-2-hexenoic acid, **16** = linalool, and **17** = tetradecanal).

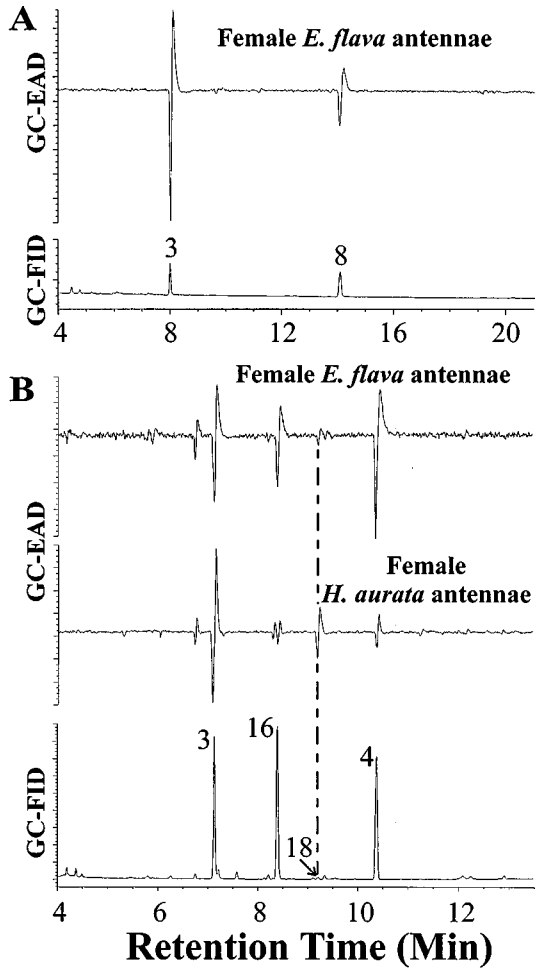

FIG. 2. Gas chromatogram-electroantennogram detector experiments for *Podisus maculiventris*-associated females of (A) *Euclytia flava* antennae to (*E*)-2-octenal (**3**) and (*E*)-2-decenal (**8**) standards (~10 ng each; DB-5 column) and (B) *E. flava* and *Hemyda aurata* antennae to (*E*)-2-octenal (**3**), linalool (**16**) and α-terpineol (**4**) standards (10 ng/μl CH_2Cl_2; ~3 μl/injection; DB-WAXetr column).

(*E*)-2-octenal to the PN treatment tended to increase attraction of *E. flava* females trapped both in the deciduous and coniferous forest sites (Figure 4). Significantly fewer *E. flava* males were attracted to both PN and PN+O treatments in each forest type.

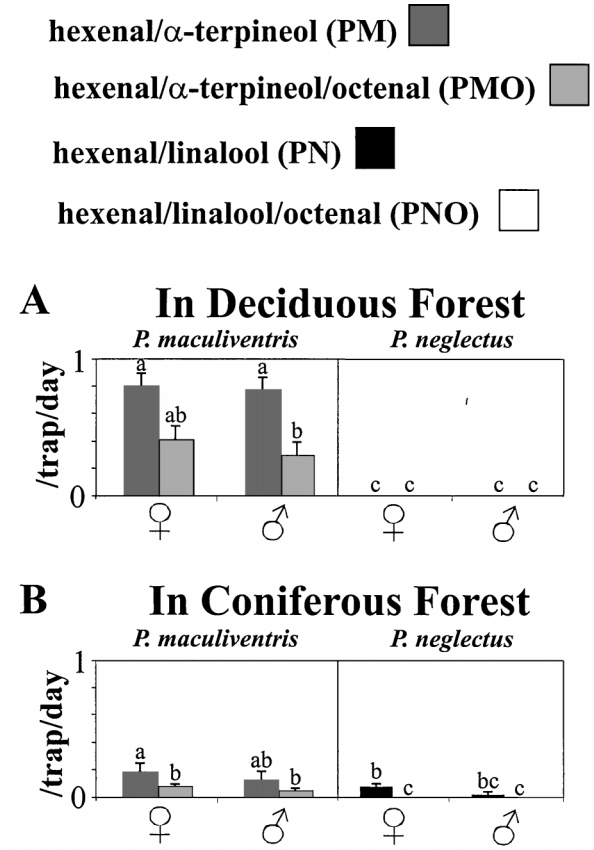

FIG. 3. Attraction of *Podisus* spp. to traps baited with pheromones (PM and PN) and with pheromones plus (*E*)-2-octenal (PMO and PNO) deployed in deciduous and coniferous forest tracts from May 21 through June 28, 1999 (6 traps/treatment/forest type; other details described in text; within a forest type, bars with different letters are significantly different at the 5% level).

Typical EAD traces for *E. flava* and *H. aurata* antennae toward a standard solution of (*E*)-2-octenal (**3**), linalool (**16**), and α-terpineol (**4**) are shown in Figure 2B (no differences noted between female and male flies). In addition to the clear responses to these known host volatiles, other responses were consistently observed to unknown compounds present in the standard solution, one of which was tentatively identified as (*E*,*E*)-2,4-octadienal (**18**).

Table 1 presents the relative antennal responses (calculated as amplitude ratios) of *H. aurata* and *E. flava* associated with particular stink bug species. The

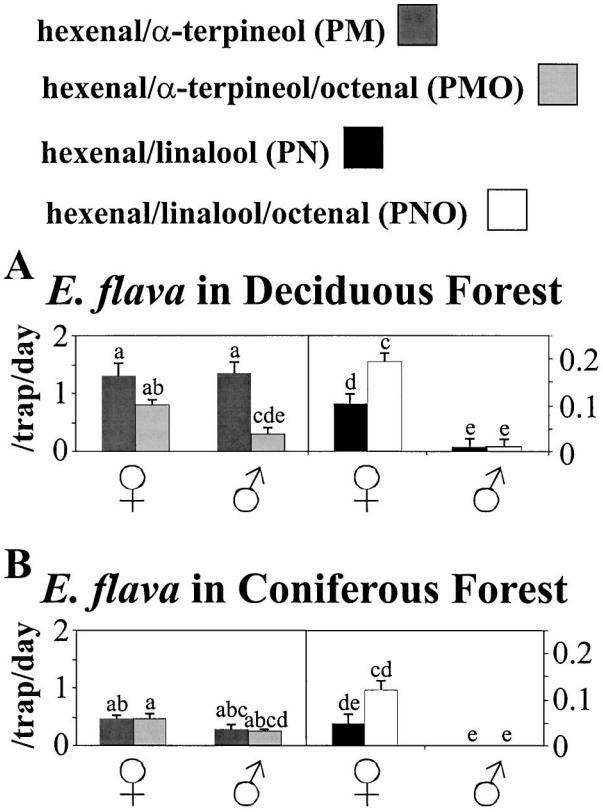

FIG. 4. Attraction of *Euclytia flava* to traps baited with pheromones (PM and PN) and with pheromones plus (*E*)-2-octenal (PMO and PNO) (conditions as for Figure 3).

outstanding difference in EAD-responses between *H. aurata* and *E. flava* is the relatively greater sensitivity of *H. aurata* to (*E*)-2-octenal versus the pheromone monoterpenoids; the (*E*)-2-octenal/α-terpineol ratio for *H. aurata* is >5 times that for *E. flava* from traps baited with *Podisus* pheromones. EAD data for *E. flava* from *P. maculiventris* and *P. neglectus* pheromone-baited traps do not indicate significant differences between these populations of flies; 2.12 ± 0.34 and 1.95 ± 0.13 for α-terpineol/linalool, respectively, and 0.73 ± 0.05 and 0.69 ± 0.05 for (*E*)-2-octenal/α-terpineol, respectively. In contrast, the *E. flava* individual collected in a *Euschistus* pheromone-baited trap was almost totally insensitive to linalool (Figure 5A), yielding an α-terpineol/linalool ratio of 14.91 ± 2.46 (Table 1). However, this fly exhibited sensitivities to α-terpineol and (*E*)-2-octenal comparable to those of *Podisus*-associated *E. flava* as indicated by its (*E*)-2-octenal/α-terpineol

TABLE 1. RATIOS OF ANTENNAL RESPONSES TO KAIROMONE COMPONENTS FOR TACHINIDS, *Euclytia flava* AND *Hemyda aurata*, OBTAINED FROM PHEROMONE-BAITED TRAPS OR BY REARING FROM FIELD-COLLECTED *Podisus maculiventris*

Species	Source[a]	*N* (Replicates)	α-Terpineol/linalool (mean ± SEM)	(*E*)-2-Octenal/α-terpineol (mean ± SEM)

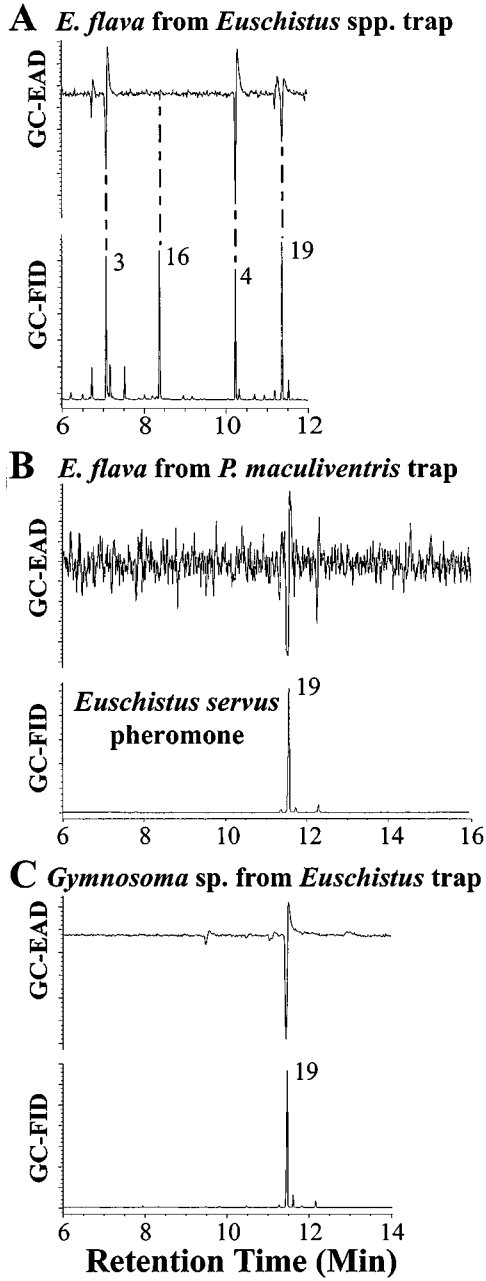
E. flava	PN/PNO traps[b]	7 (17)	1.95 ± 0.13	0.69 ± 0.05
E. flava	E trap[c]	1 (7)	14.91 ± 2.46	1.00 ± 0.07



[a] Pheromone codes as defined in text; SSB = spined soldier bug.
[b] Data are presented for flies collected during the 1999 season; EAD data (not shown) for *H. aurata* field-collected in 2000, and *E. flava* reared from SSB in 2000 and 2001, are consistent with these data.
[c] Collected October 11, 2001, in trap baited with methyl (*E*,*Z*)-2,4-decadienoate.

EAD ratio of 1.00 ± 0.07 (Table 1), and its antennae were sensitive to methyl (*E*,*Z*)-2,4-decadienoate (Figure 5A). An *E. flava* female from a PM-baited trap appeared to be relatively insensitive to *Euschistus servus* pheromone (Figure 5B), while a common *Euschistus* tachinid parasitoid (*Gymnosoma* sp.) is highly sensitive to methyl (*E*,*Z*)-2,4-decadienoate (Figure 5C). Reexamination of the EAD data for *E. flava* in the 1999 season revealed that 16 of 19 flies (Table 1; PM/PMO flies) exhibited low response ratios for α-terpineol/linalool (range: 0.88–2.46; mean ± SEM: 1.55 ± 0.09), whereas 3 of these 19 flies were much less sensitive to linalool resulting in higher α-terpineol/linalool ratios (range: 3.29–9.45; mean ± SEM: 4.93 ± 0.78).

DISCUSSION

Despite revelations, largely based upon *Drosophila* research (Benzer, 1967; Pascual and Preat, 2001), of the genetic foundations for insect (and all animal) behavior, the mechanism whereby a "simple" insect parasitoid acquires, retains, and passes on kairomone messages remains mysterious. In this study we have attempted to partially elucidate this process by electrophysiologically examining the peripheral chemosensory responses of tachinid parasitoids behaviorally associated with particular pentatomid hosts.

Affect of (E)-2-Octenal. The extreme electrophysiological sensitivity of the tachinid parasitoids, *Euclytia flava* and *Hemyda aurata*, to one of the most common defensive compounds of Heteroptera, (*E*)-2-octenal (Aldrich, 1995b), inspired the field experiment to determine if inclusion of this compound with synthetic *Podisus* pheromones would alter attraction of these parasitoids or the *Podisus* bugs themselves. The results in this regard are clear for the bugs; inclusion of

(*E*)-2-octenal tended to counteract attraction of both *P. maculiventris* and *P. neglectus* adults to pheromone. The affect of adding (*E*)-2-octenal to pheromone is less obvious for the tachinids. When (*E*)-2-octenal was added to the pheromone of *P. maculiventris*, attraction of *E. flava* was depressed or unaffected, whereas traps baited with (*E*)-2-octenal and *P. neglectus* pheromone tended to attract more *E. flava* females. It seems possible that these unusual results are somehow due to the fact that *P. neglectus* is a rare species compared to the spined soldier bug so that, although (*E*)-2-hexenal and linalool are strongly EAD-active, the synergism between these compounds at the central nervous system level is weak, resulting in the kairomonal effect of (*E*)-2-octenal being dominant. For *H. aurata*, the EAD data clearly indicate that this species is much more sensitive at the peripheral level to (*E*)-2-octenal than is *E. flava*. Unfortunately, *H. aurata* seldom entered the traps used in this study, so future tests using more effective traps need to be conducted to clarify this situation.

Tachinid Kairomone Strains. The seemingly conflicting affect of (*E*)-2-octenal on the attraction of *E. flava* could be interpreted as evidence that kairomone-strains of this parasitic fly exist based on differential sensitivity to (*E*)-2-octenal. However, this seems unlikely based on the near identical EAD sensitivities to key kairomone compounds for flies associated with either *P. neglectus* or *P. maculiventris*.

The evidence that kairomone strains of *E. flava* actually do exist in nature based on the pheromones of *Podisus* and *Euschistus* pentatomids is more convincing. The pheromones of these stink bugs are chemically dissimilar (Aldrich, 1995b), suggesting that cross-attraction is improbable. Furthermore, prior data from the same field site used for the present study verified that *Euschistus* adults are acceptable, albeit nonpreferred hosts for *E. flava* (Aldrich et al., 1991b). The observation that an *E. flava* female collected in a *Euschistus* pheromone-baited trap was almost totally EAD-insensitive to linalool, combined with the finding that an *E. flava* female collected in a *P. maculiventris* pheromone-baited trap only weakly responded to *E. servus* pheromone by GC-EAD, is direct evidence for coexisting kairomone strains of this tachinid. Reexamination of the EAD data for *E. flava* showed that a few flies caught in *P. maculiventris* pheromone-baited traps were anomalous in that they were relatively insensitive to linalool, although not so insensitive as the *Euschistus*-associated individual. Apparently ample chemosensory

FIG. 5. Gas chromatogram–electroantennogram detector experiments for (A) antennae of a *Euclytia flava* female collected in a *Euschistus* spp. pheromone-baited trap to (*E*)-2-octenal (**3**), linalool (**16**), α-terpineol (**4**) and methyl (*E*,*Z*)-2,4-decadienoate (**19**) standards (10 ng/μl CH_2Cl_2); (B) antennae of *E. flava* female collected in a *Podisus maculiventris* pheromone-baited trap to a pheromone extract of *Euschistus servus* male pheromone; and (C) antennae of female *Gymnosoma* spp. reared from *E. tristigmus* to methyl (*E*,*Z*)-2,4-decadienoate (**19**) (10 ng/μl CH_2Cl_2) (DB-WAXetr column for all GC runs; $\sim$3 μl/injection).

variation exists in the population of *E. flava* for natural selection of kairomone-strains of parasitoids. Similarly, Dietrick and Bosch (1957) observed that, "The larvaevorid fly *Trichopoda pennipes* Fabr. [Tachinidae], a parasite of hemipterous insects, apparently exists in the United States in at least three host-determined strains." Our preliminary GC-EAD experiments with host-associated strains of *T. pennipes* (Zhang and Aldrich, unpublished data) are consistent with the results presented here for *E. flava*, together suggesting that the intensity of a tachinid's antennal response toward particular host volatiles is directly proportional to host acceptability.

Summary and Significance. Clearly the tachinid parasitoids studied here, especially the generalist *E. flava*, have thoroughly subverted both the defensive and communicative chemical systems of their hosts to become "evolutionary boomerang" signals known as kairomones (Blum, 1974). However, the results of an earlier study of *E. flava* parasitism, also made possible by "pheromone-harvesting" wild flies, showed that this semiochemical exploitation is not unidirectional because native host species secrete repellent or masking compounds that confer some degree of immunity (lacking in exotic species) to oviposition by tachinids (Aldrich, 1995a).

From a practical point of view, application of today's GC-EAD technology may help avoid future mistakes in classical biological control, such as the errant attempt to control the cosmopolitan stink bug, *Nezara viridula* L., in Hawaii with what may have been a kairomonally incompatible strain of a *Trichopoda* parasitoid (references in Pickett et al., 1996). Of longer range practical and theoretical interest is the question of how parasitoid host-shifts evolve, for if this process were known better it might be possible to devise artificial selection regimes, incorporating appropriate semiochemicals, to more quickly recreate this normally slow natural process. Such artificial selection could be used to create kairomone-strains of physiologically competent endemic beneficials that would recognize alien hosts. Theoretically, this "nonclassical" biocontrol approach should exploit the vulnerability of exotic species, which lack the coevolved antiparasitoid defenses of native host species (Hokkanen and Pimentel, 1989).

Acknowledgments—We thank Carolyn Smith for technical and statistical assistance, and Dr. Norman Woodley (USDA-ARS Systematic Entomology Laboratory) for tachinid fly species determinations. We are also grateful to Drs. James Oliver and Murray Blum for reviewing the manuscript and for their supportive interaction over the years. One of us (J.R.A.) wishes to dedicate this paper to the memory the late Dr. H. H. Ross who helped kindle an early interest in the line of research pursued here.

FIELD RESPONSE OF *Ips paraconfusus*, *Dendroctonus brevicomis*, AND THEIR PREDATORS TO 2-METHYL-3-BUTEN-2-OL, A NOVEL ALCOHOL EMITTED BY PONDEROSA PINE

DENNIS W. GRAY*

Department of Ecology and Evolution
State University of New York
Stony Brook, New York 11794–5245, USA

(Received October 10, 2001; accepted April 16, 2002)

Abstract—Methylbutenol (MBO) is a major component of the aggregation pheromone of the European spruce beetle *Ips typographus* and also has been found to be emitted in large amounts by several species of pine native to western North America. This study investigates the influence this signal may have on the behavior of North American bark beetles and examines whether MBO functions as a defensive compound for emitting pines. The response of two North American bark beetles (*Ips paraconfusus* and *Dendroctonus brevicomis*) and their predaceous beetles (Trogositidae and Cleridae) to MBO, pheromone, and monoterpenes in varying release rates was investigated in the field using Lindgren funnel traps. MBO exhibited no repellent properties when tested alone, nor did MBO appear to have any effect on the aggregation response of these bark beetles and their predators to their pheromones. These results provide no support for a defensive function of MBO.

Key Words—Bark beetle, methylbutenol, MBO, 2-methyl-3-buten-2-ol, pheromone, *Ips paraconfusus*, *Dendroctonus brevicomis*, Cleridae, Trogositidae, Scolytidae, monoterpene, predator, plant defense, Ponderosa pine, *Pinus ponderosa*.

INTRODUCTION

Among the insect pests of conifers, the bark beetles of the family Scolytidae are by far the most important and destructive. During outbreaks, bark beetles may kill large numbers of trees within a given stand, and timber losses caused by bark

* E-mail: denwgray@life.bio.sunysb.edu

0098-0331/02/0800-1583/0 © 2002 Plenum Publishing Corporation

beetles during single outbreaks can range into the billions of board feet (Miller and Keen, 1960; Furniss and Carolin, 1977). The destructive potential of bark beetles stems largely from their use of chemical cues and signals that allow them to choose weakened hosts and to coordinate mass attacks. Understanding the ecological chemistry of bark beetle behavior and the role of volatile compounds in modulating this behavior is crucial to both basic questions in plant–insect interactions and to developing protocols for minimizing the economic impacts of these insects.

The chemical mediation of bark beetle behavior has received extensive study for more than 30 years; and researchers have described several distinct phases of these attacks (Stark, 1981; Wood, 1982). The initial attack on a tree is made by a small number of pioneer beetles that alight upon the bark and begin burrowing tunnels into the bole. Host choice at the initial selection phase has been ascribed to attraction to host volatiles (Rudinsky et al., 1971; Miller and Borden, 1990), visual cues (Henson, 1962), or random landing behavior (Burnell, 1977; Moeck et al., 1981). These pioneer beetles then begin emitting aggregation pheromones that attract conspecific beetles to the source (Byers, 1988). Some species such as *D. pseudostugae* and *D. frontalis* are capable of producing pheromones immediately upon landing (Renwick and Vité, 1968; Vité and Renwick, 1968; Ryker et al., 1979), whereas others such as *Trypodendron lineatum* and *I. paraconfusus* appear to produce pheromones after tunneling and feeding on the host (Wood and Bushing, 1963; Pitman et al., 1965; Chapman, 1966; Borden and Slater, 1969). Emission of these aggregation pheromones results in a mass attack that can overwhelm the tree's resin defenses and even lead to its death. The pheromones are sometimes synthesized by the bark beetle by using host monoterpenes as precursors (Hughes, 1974, 1975; Hendry et al., 1980; Byers, 1981) or are synthesized *de novo* by the bark beetle (Ivarsson et al., 1993; Seybold et al., 1995). Following the successful mass attack, some species enter a third phase in which the bark beetles begin emitting different pheromones that repel additional beetles from the attacked host. Schlyter et al. (1989) showed that the production of ipsenol by *Ips typographus* inhibited the aggregation response of this insect. Emission of the antiaggregation pheromones has been interpreted as a mechanism for preventing overcrowding and competition for larval food resources.

Although the role of insect-derived pheromones in mediating bark beetle behavior has received extensive study (Borden, 1985), the role of host volatiles in mediating bark beetle behavior is less clear. Host monoterpenes have been shown to both attract (Rudinsky et al., 1971; Miller and Borden, 1990; Hobson et al., 1993) and inhibit the attraction (Hayes et al., 1994) of bark beetles. Green leaf volatiles have also been shown to inhibit the attraction (Wilson et al., 1996), and volatiles present in non-hosts have been shown to disrupt the response of bark beetles to attractant-baited traps (Huber and Borden, 2001).

Recently 2-methyl-3-buten-2-ol (MBO) was discovered to be a major component of the volatiles emitted by several species of pine native to western North

America (Harley et al., 1998). For example, in ponderosa pine, *Pinus ponderosa* Laws, MBO emissions exceeded the emission of monoterpenes by a factor of 2–10, and represented an energetic investment of 0.5% of the tree's net photosynthetic carbon assimilation (Lerdau and Gershenzon, 1997; Schade et al., 2000). However, unlike monoterpenes, MBO is not stored in plant tissues and is instead emitted immediately upon production (Harley et al., 1998). Such a large investment of energy and carbon into MBO production, relative to monoterpene production, by MBO-emitting pines suggests that this compound may serve a biological function to the emitting plant and that insect pests (and/or their predators) may use MBO for host (prey) detection.

In addition to its synthesis by some North American pines, MBO production also occurs in the European spruce bark beetle, *Ips typographus*, and is used by this insect as part of its aggregation pheromone (Bakke, 1977). The MBO produced by *I. typographus* is synthesized *de novo* by the insect (Lanne et al., 1989) and not sequestered from its host plant, Norway spruce (*Picea abies*), which does not manufacture MBO. In fact, no MBO emitting plants have yet been discovered in Europe where two bark beetles (*Ips typographus* and *Orthotomicus erosus*) use MBO as parts of their pheromone systems (Bakke, 1976; Giesen et al., 1984; Harley et al., 1998). A complete survey of the pines native to Europe has shown that none manufacture MBO (Harley et al., 1998; Gray unpublished data). In contrast, in North America, where several pines produce MBO, MBO has not been reported as a major component of the pheromone system of any North American bark beetle. It has, however, been reported as a minor pheromone component for *Polygraphus rufipennis* and may possess anti-attractant properties for *Dendroctonus rufipennis* (Werner and Holsten, 1995).

The large energetic investment in MBO production made by MBO producing pines, the appearance of MBO as a bark beetle pheromone, and some indications that MBO possesses anti-attractant properties, led to the hypothesis that in North America MBO may function as a defensive compound protecting emitting trees against bark beetle attack. MBO might serve as a defensive compound in two fashions: directly by influencing bark beetle behavior or indirectly by attracting predators and parasitoids to the emitting tree. Since it is not stored in plant tissues or manufactured in the wood, any direct defensive properties exhibited by MBO probably influence host location and acceptance behavior rather than larval survival.

MBO may have repellent properties similar to those found for 4-allylanisole (Hayes et al., 1994; Hobson, 1995), or it may inhibit landing behavior similar to the landing inhibition that Schlyter et al. (1987b) observed for *I. typographus* in response to high MBO concentrations. MBO might also inhibit the aggregation response of bark beetles. Such a response was shown by Birch and Wood (1975) when they observed that the pheromones of *I. pini* inhibited the aggregation response of *I. paraconfusus* and vice versa. In addition to these potential direct influences, MBO may benefit an emitting tree indirectly by attracting predators

and parasitoids. In Europe, bark beetle predators have been shown to be attracted to MBO (Bakke and Kvamme, 1981), and in North America the pheromones of several bark beetles have been shown to attract the predators of bark beetles (Kohnle and Vité, 1984; Mizell et al., 1984; Herms et al., 1991).

To help elucidate the function of MBO emissions, we examined the response of two North American scolytid bark beetles (*Ips paraconfusus* and *Dendroctonus brevicomis*) and predatory beetles in the families Cleridae and Trogositidae that feed on bark beetles to differing MBO release rates alone or in the presence of attractive monoterpenes or bark beetle pheromone. *I. paraconfusu*s is a marginally aggressive *Ips* found in North America that feeds on a broad range of pines (including *P. ponderosa*) and occasionally attacks and kills live trees. *D. brevicomis* is one of the most aggressive tree-killing bark beetles in North America (Furniss and Carolin, 1977), and feeds predominantly on *P. ponderosa*. The impact of MBO on bark beetle and predatory beetle behavior was examined by using field trapping experiments; insect capture rates were then used to determine whether MBO aids either plant defense against herbivores or insect location of suitable trees.

METHODS AND MATERIALS

Field-trapping experiments were conducted in the central Sierra Nevada mountains of California at the UC Berkeley Blodgett Forest Research station (38°53′, 42.9″N, 120°37′, 57.9″W). Lindgren funnel traps (Lindgren, 1983) were placed in small clearcuts located in compartments 260 (1999), and 400 (2000). These sites were logged the previous year and the slash was piled and burned the previous winter in compartment 260 or treated with a rotary masticator the previous fall in compartment 400 prior to conducting the trapping studies. The trapping sites were surrounded by second-growth mixed-conifer forest (approximately 80 years old) containing Douglas fir (*Pseudotsuga menziesii*), Ponderosa pine (*Pinus ponderosa*), sugar pine (*Pinus lambertiana*), incense cedar (*Calocedrus decurrens*), and white fir (*Abies concolor*) in roughly equal proportions, and scattered individuals of California black oak (*Quercus kellogii*). In both years and at both sites, trees within 1 km of the trapping sites were observed to be attacked and killed by bark beetles.

The experiments conducted were fully factorial designs with two levels of attractant bait (presence or absence) and four levels of MBO release. Each attractant bait by MBO release rate combination was replicated once within the trapping array ($N = 2$) and additional replication was achieved by sampling repeatedly through time. Sampling durations ranged from one to seven days depending on bark beetle flight intensity. Longer sampling durations were used during periods of low bark beetle activity to avoid having to analyze sampling periods with no captures in any treatment. MBO and monoterpenes were released from 2 ml microcentrifuge tubes suspended from the middle of the Lindgren funnel trap. Release rates were

TABLE 1. DESCRIPTION OF TREATMENTS, METHYLBUTENOL RELEASE RATES, AND MBO-EMITTING DEVICES USED IN EXPERIMENTS

Treatment	Nominal release rate (mg/day)[a]	Design
None	0	NA
Low	2.5	2-ml polypropylene Eppendorf tube fitted with a 5-ul capillary tube inserted through the cap
Medium	5	Two 2.5 mg/day releasers
High	50	2-ml polypropylene Eppendorf tube with a 1.59-mm hole drilled in cap
Very high	1000	2-ml polypropylene Eppendorf tube without cap

[a] Nominal release rates were determined by measuring weight lost from emitting devices held at 25°C in the laboratory.

varied by drilling holes of various sizes in the cap of the microcentrifuge tube, fitting a glass microcapillary tube in the cap, or leaving the tube uncapped. MBO releasing devices were constructed to achieve release rates corresponding to the MBO release rates shown to influence the behavior of *Ips typographus* by Schlyter et al. (1987a). Nominal release rates of these devices were determined by measuring volatilization gravimetrically from devices held at 25°C. Release rates and device descriptions are shown in Table 1. These release rates fall within the range of MBO levels that bark beetles are likely to encounter from phytogenic sources in the field. Leaf level MBO emission rates have been measured as high as 3.44 mg MBO/g needle tissue/day in Ponderosa pine (Gray, unpublished data), thus allowing a single fascicle to equal the release rate of the lowest MBO-emitting device. At the other end of the scale, canopy-level MBO emission rates have been measured between 172 and 344 mg MBO/m^2/s (Baker et al., 1999, 2001; Schade et al., 2000).

Sixteen eight-unit funnel traps were arrayed in four groups of four traps (Figure 1), with a spacing of 6 m between traps within a trap group and 12 m between traps in adjacent trap groups. Each trap within a group contained the same level of attractant bait, but contained a device releasing MBO at a different rate (Table 1). The collecting cups were filled with soapy water in which the captured insects drowned. This prevented captured predatory beetles from consuming the captured bark beetles. At the end of each sampling period, the traps within each group and the groups within the array were rotated clockwise to minimize the effect of trap position on the results. Captured insects were frozen or preserved in ethanol until identified and counted.

Three experiments tested whether MBO affected the behavior of bark beetles or their predators and whether MBO mediated the response of bark beetles or their predators to pheromone signals. In experiment 1, a multicomponent *Ips paraconfusus* lure (Phero Tech Inc., Delta, British Columbia) containing ipsenol, ipsdienol, and *cis*-verbenol was used as the attractant bait, and the MBO release

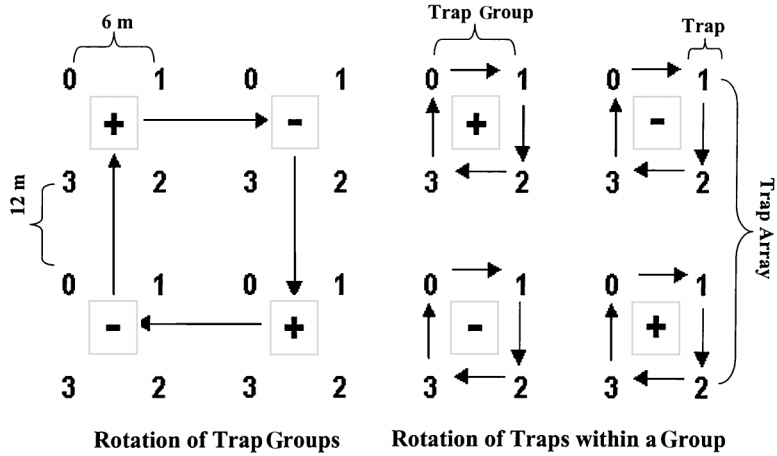

FIG. 1. Funnel trap layout and rotation scheme. Numbers 0–3 represent increasing MBO release rates as specified for each experiment. The +/− symbols denote the presence or absence of attractant bait (pheromone or monoterpenes) in traps within a trap group. Traps were spaced 6 m apart within a trap group and 12 m between traps in adjacent groups.

rates used were none, low, medium, or high (Table 1). Experiment 2 also used the *Ips paraconfusus* lure, but replaced the low MBO release rate with the very high treatment. Experiment 3 used a multicomponent *Dendroctonus brevicomis* lure (Phero Tech Inc., Delta, British Columbia) containing *exo*-brevicomin, frontalin, and myrcene as the attractant bait; and the MBO release rates were none, medium, high, and very high (Table 1).

A fourth experiment tested whether MBO affected the behavior of bark beetles or their predators to attractive host monoterpenes in the absence of a pheromone signal. In this experiment, host monoterpenes previously shown to be attractive to bark beetles (Rudinsky et al., 1971; Borden, 1985; Miller and Borden, 1990) were used instead of pheromones as the attractive bait. The MBO release rates were none, medium, high, and very high (Table 1). Monoterpenes were released from open-top 2 ml polypropylene microcentrifuge tubes at the following nominal rates: α-pinene = 0.47 g/day, β-pinene = 0.49 g/day, myrcene = 0.24 g/day.

Insects captured in the funnel-trap collection cups were collected at the end of each sampling period and frozen or preserved in ethanol until they were identified and counted. Scolytid bark beetles were identified to species, and all other captured insects were identified to family. The effects of attractant bait and MBO release rate on captures per sampling period were analyzed by three-way ANOVA using the GLM procedure of SAS (1990). The sampling period was included in the model as a covariate to take into account differences in sampling period duration (one to seven days) and differences in climatic conditions across samplings periods

such as temperature, cloud cover, and wind that may alter bark beetle activity levels (Bennett and Borden, 1971; Coster et al., 1978; Borden, 1981). Data were $\log_{10}(X + 1)$ transformed to meet the ANOVA assumptions of normality and homoscedasticity (Sokal and Rohlf, 1995).

RESULTS

In experiment 1, the addition of pheromone bait to traps increased the capture rate of *Ips paraconfusus* by a factor of more than 100. However, the addition of MBO did not alter the magnitude or pattern of captures across traps (Table 2, Figure 2). Predatory beetles in the families Cleridae and Trogositidae were not influenced by either *Ips paraconfusus* pheromone or MBO release rate (Table 2).

Similar results were observed in experiment 2 despite the addition of a much larger MBO release rate treatment. Pheromone bait increased bark beetle captures by a factor of more than 100; however, no effect of MBO release rate on captures of *Ips paraconfusus* could be detected (Table 3, Figure 3). No influence of either

pheromone or MBO release could be detected on the capture rates of predatory clerids or trogositids (Table 3).

In experiment 3, the addition of *D. brevicomis* pheromone caused a significant increase in *D. brevicomis* and trogositid captures. On the other hand, MBO release rate did not change *D. brevicomis* or trogositid capture rates in either the presence or absence of pheromone (Table 4, Figure 4). Neither pheromone nor MBO release rate changed the capture rates of predacious clerid beetles (Table 4).

In experiment 4, where host monoterpenes were used as the attractant bait, the number of bark beetles captured during the trapping period was quite low, and no differences were seen among treatments. Analysis of the predatory beetles captured showed that neither monoterpenes nor MBO release rate affected clerid or trogotidid captures (Table 5, Figure 5).

DISCUSSION

The results of the trapping experiments did not support the hypothesis that MBO emissions from Ponderosa pine provide protection against bark beetle attack. The data showed no indication that *I. paraconfusus* or *D. brevicomis* were repelled by MBO alone, or by MBO in combination with host monoterpenes or bark beetle pheromone. Similarly, the major insect predators of these bark beetles were not attracted by MBO, suggesting that MBO does not provide an indirect defense.

Despite the lack of evidence that MBO possesses defensive properties, it should be noted that this study examined only two of the many species of bark beetle found in North American pine forests. While *I. paraconfusus* is one of the most aggressive *Ips* in North America and attacks a wide range of pines, it is much less aggressive than its European congeners (especially *I. typographus*). Nonetheless, *I. paraconfusus* is an aggressive killer of pole-size trees and the tops of mature trees, especially *P. ponderosa* in the central Sierra Nevada mountains where this study was conducted (Furniss and Carolin, 1977). *D. brevicomis*, on the other hand, is one of the most destructive bark beetles present in North America and frequently attacks healthy trees. However, since both species of pine (*P. ponderosa* and *P. coulteri*) attacked by *D. brevicomis* produce MBO (Harley et al., 1998), its failure to respond to MBO may indicate an adaptation to feeding on these hosts. If, in fact, MBO has a defensive function, it likely has its effect on those bark beetle species that do not feed on MBO-producing trees, and this may help account for host specificity among bark beetle species. Perhaps MBO production excludes *P. ponderosa* from the host range of Scolytids that feed on non-MBO-producing

conifers (*A. concolor*, *P. menziezii*, *C. decurrens*, and *P. lambertiana*). However, scolytid species that feed exclusively on non-MBO-producing conifers have not been screened for their response to MBO.

A spatial discontinuity also exists between the site of MBO production and bark beetle attack. MBO production only occurs in the photosynthetic tissues, whereas bark beetles attack the non-photosynthetic trunks. For this reason, it is possible that bark beetles never encounter strong MBO plumes emanating from potential host trees. However, insects feeding on the foliage or reproductive structures

of MBO-emitting pines would certainly encounter MBO. No such insect has yet been tested for its response to MBO.

Acknowledgments—The author wishes to thank Blodgett Forest Research Station, its staff, and Allen H. Goldstein for providing field sites and logistical support for this research. Robert Heald provided invaluable assistance in selecting trapping locations, and special thanks go to Ken Hobson and Stephen Reay for their stimulating discussions on bark beetle biology. Manuel Lerdau, Ken Hobson, and Ken Raffa provided valuable comments on previous versions of this manuscript. The author also wishes to thank Ralph Mattle for assistance in designing and constructing field gear. The comments of two anonymous reviewers were greatly appreciated. This work was made possible by a NASA Earth System Science Fellowship to D. Gray.

(Received October 22, 2001; accepted April 17, 2002)

Abstract—Leafy spurge (*Euphorbia esula* L.), a plant introduced into the Great Plains of North America from Europe, has become a serious economic and ecological threat to the productivity of agricultural and natural areas. Cattle, the predominant livestock species on the Great Plains, as well as common wild ruminant species in this region appear to consume little if any leafy spurge. This is likely because they experience a toxic response after consuming small amounts of this plant, and they consequently learn to avoid it. Domestic sheep and goats can consume considerable amounts of leafy spurge and are used to help control it, but even these species may suffer a toxic response at high levels of intake. Toxic diterpene ingenols have been isolated from leafy spurge tissues, but compounds in this plant have not been evaluated with respect to their capacity to induce food aversion learning in ruminants. We conducted bioassay-guided fractionations of leafy spurge in an attempt to isolate toxic and aversive compounds. These bioassay-guided fractionations led to identification of ingenol and one of its diesters as two toxic compounds in leafy spurge that are potentially aversive to cattle.

Key Words—*Euphorbia esula*, leafy spurge, ingenol, diterpene, toxic, aversive, cattle.

INTRODUCTION

Leafy spurge (*Euphorbia esula* L.) is a serious invasive weed on lands with both native and introduced vegetation on the northern Great Plains of North America. Although domestic sheep and goats usually graze this perennial forb, it appears to be aversive and toxic to cattle, and is a serious threat to cattle production (Johnston and Peake, 1960; Hein and Miller, 1992; Heemstra et al., 1999). Domestic sheep may also experience toxicity from leafy spurge ingestion at high levels of intake, after ingestion of particular plants or plants growing at certain locations (Johnston and Peake, 1960; Kronberg and Walker, 1999). Little is known about which species of wildlife eat or avoid leafy spurge, but it is generally considered to have a negative impact on wildlife habitat (Belcher and Wilson, 1989). With cattle, the predominant species of grazing livestock in North America, their avoidance of leafy spurge may be one important reason why this introduced plant from Eurasia has spread across two million acres of range and pasture lands in the continental United States. It is considered the worst noxious weed on these lands, with an economic impact in the millions of dollars annually (Leitch et al., 1996). Leafy spurge has high protein and low fiber levels during its early growth stages (Fox et al., 1991). However, it is not utilized as feed by cattle because it contains aversion-inducing chemicals that cause negative feedback after they ingest small amounts of it. Thus, they learn to avoid it (Kronberg et al., 1993). Extracts of leafy spurge were shown to cause skin irritation and weak tumor promotion, but not solitary carcinogenic activity (Seip and Hecker, 1982). Ingenol (Seip and Hecker, 1982) and several diterpene derivatives such as 3-*O*-(2*E*,4*Z*)-decadienoylingenol (*Euphorbia* factor E1), 3-*O*-(3,4,6)-decatrienoylingenol, and 3-*O*-(3,4,6,8)-dodecatetraenoylingenol were identified and shown to mediate irritant activity (Hecker, 1978). Ingenol and ingenol esters appear to induce toxicity because of their ability to mimic the function of diacylglycerol and activate protein kinase C (Hasler et al., 1992; Winkler et al., 1993). Protein kinase C is a phosphorylating enzyme that mediates cellular signal transduction for a large group of hormones and cellular effectors (Winkler et al., 1993). Other diterpenes, such as jatrophane and lathyrane derivatives, were also found in leafy spurge (Manners and Davis, 1987; Onwukaeme and Rowan, 1992).

Leafy spurge has been studied chemically and ecologically, but has had little evaluation of its aversion-inducing capacity for cattle or other ruminants. Ingenols are suspected as aversion-inducing compounds in leafy spurge, and ingenol 3-monobenzoate was found to be aversive to rats (Kronberg et al., 1995). Our study focused on the identification of aversive toxins in leafy spurge to further understand their impact on cattle. Bioassay-guided fractionations led to the identification of two compounds—ingenol and its ester—that are likely responsible for some of the aversion that cattle develop to leafy spurge.

METHODS AND MATERIALS

Plant Material. Air-dried spurge was used throughout the study. Aerial parts of *Euphorbia esula* in the seed-ripening growth stage were collected in June 1995 near Veblen in northeastern South Dakota. Plants were air-dried and ground through a 2-mm screen. Ground plant material (3.6 kg) was extracted with cold 90% methanol (6 × 6 leters). The aqueous methanol extract was concentrated under reduced pressure at 40°C and partitioned with petroleum ether (40–60°C, 6 × 1 liter), chloroform (6 × 1 liter) and acetone (6 × 1 liter). A thick viscous layer, formed at the interface of the chloroform and aqueous phases, was collected separately and designated as the middle layer.

Evaluation of Middle Layer and Petroleum Ether Extracts for Aversive Response from Cattle

Three groups of yearling cattle (5/group) were trained for a one-week period to eat for 30 min in the morning from feed boxes within individual pens. They were held off feed, but not water, overnight during this period and allowed ad libitum intake of grass hay as a group only after the morning training period. A test period immediately followed the training period. At the same time as the training period, the cattle were given oat silage as a novel feed in feed boxes within individual pens for 30 min. After consuming about 700 g of the novel feed, one group was treated with the petroleum ether extract and the other with the middle layer residue at a dosage of 0.059 g/kg body wt and 0.176 g/kg body wt, respectively (materials orally dosed in gelatin capsules), and the control group was given empty capsules. On the following day at the same time, the cattle were again offered the same novel feed for 30 min. The amount of feed consumed by each animal was recorded. Novel feed consumption on both days of the test period was compared using a repeated-measures design and PROC GLM (SAS, 1991) to determine if the cattle had an aversive response to the novel feed on the second day. Treatment group was the between-animal effect, and postgavage response was the within-animal effect. When appropriate, individual means were compared with the protected LSD procedure (SAS, 1988).

Screening of Aversive/Toxic Effect of Petroleum Ether Fractions on Rats and Brine Shrimp

The middle layer did not induce aversions in cattle, but the petroleum ether extract induced strong aversions, so this extract was investigated as follows. The petroleum ether extract (20 g) was subjected to fractionation on silica gel (G60, 300 g) using flash column chromatography (5 × 50 cm) and developed with 100%

TABLE 1. TOXIC AND AVERSIVE EFFECTS OF FRACTIONS FROM LEAFY SPURGE (*Euphorbia esula* L.)

Fractions	Solvent	%	Aversive effect[a,b]	Toxic effect[b,c]
1–4	Pet.ether–ethyl acetate	8:2	–	–
5, 6	Pet.ether–ethyl acetate	75:25	–	–
7, 8	Pet.ether–ethyl acetate	65:35	–	++++
9, 10	Pet.ether–ethyl acetate	50:50	+	++++
11	Pet.ether–ethyl acetate	25:75	+	++++
12	Pet.ether–ethyl acetate	25:75	++++	++++
13	Ethyl acetate	100	++++	++++
14, 15	Methanol	100	–	–

[a] Aversive effect measured as reduction of novel fluid intake by rats.
[b] + = 25% aversive/cytotoxic activity; ++ ++ = 100% aversive/cytotoxic activity.
[c] Toxic effect measured as percentage of brine shrimp killed.

petroleum ether with a gradient increase in polarity with ethyl acetate (Table 1). One-liter fractions were collected, concentrated with a rotary evaporator, and evaporated to dryness under nitrogen. Fifteen fractions were collected. Aversive activity of fractions 1–15 was tested with rats (dosage 30 mg/rat) to measure their response to each fraction and compare them among fractions (Kronberg et al., 1995). Data on their aversive activity for rats was coupled with data from the brine shrimp toxicity assays to determine if these were consistent with cytotoxic effects of compounds in leafy spurge. For the brine shrimp toxicity assays, 0.25 mg of each extract was added to 8-ml vials ($N = 4$) and dissolved in 20 μl of DMSO (dimethyl sulfoxide) and mixed. The brine shrimp assays were conducted as outlined by Anderson et al. (1991).

Isolation and Identification of Aversive/Toxic Compounds

Combined fractions 12 and 13 (1.21 g) were subjected to a second step of purification using flash column chromatography (5 liters, 1:1, petroleum ether–ethyl acetate) and afforded 10 fractions (500 ml each) of which fractions 8 (32.5 mg) and 9 (25.6 mg) were finally purified with normal-phase HPLC using Econosil, 5μ (4.5 × 250 mm) and Econosil 10μ (22 × 250 mm) columns. HPLC columns were developed with a gradient system using hexane and a gradual increase in percentage of isopropanol. Compounds 8.5 (3.0 mg) and 9.4 (2.0 mg) were isolated from fractions 8 and 9, respectively. Structural elucidation was achieved using spectroscopic techniques. Nuclear magnetic resonance experiments were conducted with a Bruker DRX 400 spectrometer. Mass spectra were recorded using EI and CI techniques with a Finnigan 995633. Infrared spectra were recorded on a Bio-Rad FTS-60A infrared spectrophotometer.

Cytotoxicity Assays

Evaluation of the isolated compounds for cytotoxicity was made with bovine lymphosarcoma cells (CRL-8037 BL-3, American Type Culture Collection). The culture medium was Eagle's MEM with 0.1 mM nonessential amino acids and Earle's BSS (90%) and fetal bovine serum (10%). Two milligrams of each of the isolated compounds from leafy spurge was dissolved in 400 μl dimethyl sulfoxide (DMSO). Either zero, 1, 5, 10, 25, and 50 μl of DMSO alone (control) or 0, 1, 5, 10, 25, and 50 μl of DMSO plus one of the isolated compounds were incubated with 2 ml of the cells for 18 hr at 37°C. Aliquots of cells were withdrawn after 18 hr and stained using a two-step acridine orange (AO) technique: 200 μl of cell suspension (1–2 $\times$ 10^6/ml) treated for 30 sec with 200 μl of a buffer containing 0.1% Triton and 0.08 N HCI followed by staining with AO staining buffer (6 μg AO/ml). The metachromatic AO-stained cells were measured for green flourescence (510–530 nm band-pass filter) for amounts of DNA and red fluorescence (630 nm long-pass filter) for amounts of RNA.

Evaluation of Ingenol and Ingenol 3-Benzoate for Aversive Response from Cattle

Seip and Hecker (1982) found 99 mg of ingenols in 20 kg of air-dried leafy spurge. Therefore, we assumed that 0.0005% of air-dried leafy spurge was ingenol. Previous work (Kronberg et al., unpublished data) indicated that 0.3% of body weight is an aversive dosage of air-dried leafy spurge for cattle, so treated calves were dosed with 0.0148 mg of ingenol or ingenol 3-benzoate/kg body wt. Ingenol and ingenol 3-benzoate were purchased from LC Laboratories (Woburn, Massachusetts, USA). Ingenol, the parent compound, has weak affinity for protein kinase C while ingenol 3-benzoate has considerable affinity for protein kinase C and, therefore, likely has greater toxicity to cattle. Ingenol 3-benzoate is similar to ingenol esters found in leafy spurge. The gavage solution was made by initially solubilizing 25 mg of each ingenol with 5 ml of ethanol. Fifty milliliters of deionized water was then added to each solution, and these mixtures were gavaged. Control animals received an equivalent amount of ethanol and water.

Calves were trained and managed as described for the initial cattle trial. They were given 907 g of millet as a novel feed for 15 min in the first test period for ingenol, and 907 g of sugar beet pulp pellets for 15 min in the second test period for ingenol 3-benzoate. After consuming some of the novel feed, calves were gavaged with either ingenol or ingenol 3-benzoate in the ethanol–water solution. On the morning of the following day, they were offered novel feed again to determine if they formed an aversion to it. One calf (I4) was gavaged with ingenol a second time shortly after it ate a significant amount of novel feed, indicating that ingenol had not elicited an aversion. Because of the small amounts of ingenol and ingenol 3-benzoate available, the number of calves was limited, as was the number of days

that they were treated with the compounds. Novel feed consumption on both days of the test period was compared using a repeated-measures design and PROC GLM (SAS, 1991) to determine if the cattle had an aversive response to the novel feed on the second day. Treatment group was the between-animal effect, and postgavage response was the within-animal effect. When appropriate, individual means were compared with the protected LSD procedure (SAS, 1988).

Specroscopic Data

Compound 8.5. EI-MS *m*/*z* 348, 330 (M^+-18), 313, 295 (313-18), 246, 236, 214 (100%) and 197. IR ($CHCl_3$) 3450, 2930, 1685. Compound 9.4. EI-MS *m*/*z* 552, 538, 496, 382, 368, (100%), 348, 330, (348-18), 313, 295 (313-18), 246, 236, 214, 183, and 43 and 197. IR ($CHCl_3$) 3450, 2930, 1720, 1685. UV abs (MeOH) 214 nm.

RESULTS AND DISCUSSION

Initial screening for aversive activity showed the petroleum ether and chloroform extracts and the middle layer to be aversive to rats. Further screening of the middle layer and petroleum ether extracts on cattle showed no aversive response from cattle to the middle layer, but strong aversion to the petroleum ether extract ($P < 0.01$; Figure 1). Chromatographic separation guided by rat aversion trials and brine shrimp assays showed fractions 12 and 13 (Table 1) to have the greatest aversive and toxic effects. Further separation of the combined fractions 12 and 13 by column chromatography provided 10 fractions. Fractions 8 and 9 of the second separation constituted more than 80% of the combined original fractions 12 and 13. Preparative HPLC using normal-phase gradient analysis was conducted and monitored at a wavelength of 220 nm. All fractions were collected. HPLC purifications afforded compounds 8.5 and 9.4 as the major compounds in fractions 8 and 9.

Detailed 1D NMR (H^+, ^{13}C, and DEPT) and 2D NMR (GCOSY, HMBC, HMQC, and NOESY) experiments were conducted for compounds 8.5 and 9.4.

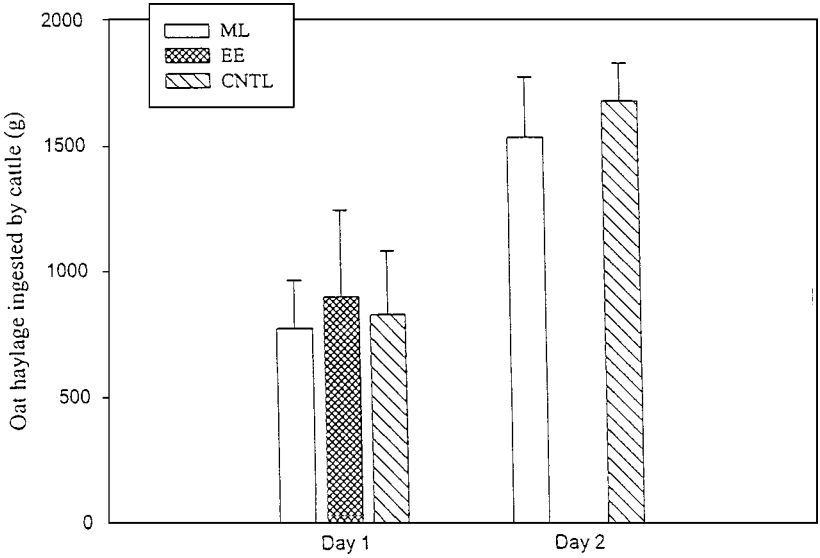

FIG. 1. Ingestion by cattle of a novel-tasting feed before and after receiving different portions of the original methanol extract of leafy spurge in gelatin capsules. The portions were a thick viscous layer at the interface between the chloroform and aqueous layers named the middle layer (ML) and the petroleum ether extract (pEE). A third group of control cattle (CNTL) received an empty gelatin capsule.

Mass spectral analysis of the two compounds showed evidence of a diterpenoid structure with molecular ion peaks at m/z 331 and 348. Mass spectral analysis showed a molecular ion peak for compound 8.5 at m/z 348 and fragments of m/z 313 and 295, which are characteristic of ingenol (Seip and Hecker, 1982). Compound 9.4 showed a molecular ion peak at m/z 330 and fragments of 313, 295, 183 and 43, which are characteristic of the ingenane skeleton and fragments of dodecanoate and acetate (m/z 183 and 43, respectively). The latter fatty acids were shown clearly from the m/z fragments of 43 and 183 corresponding to acetyl and dodecayl radicals, respectively. Figure 2 illustrates the structures of compounds 8.5 and 9.4.

H^+ and ^{13}C NMR data corresponded well with published data for the diterpene ingenol (Seip and Hecker, 1982). ^1H-^1H connectivities were confirmed from COSY and NOESY experiments. DEPT experiments assigned carbon shifts for all protonated carbons. A heteronuclear multiple bond correlation (HMBC) assigned shifts at δ 139.42 and 143.25 to quaternary carbons C-2 and C-6, respectively. NMR, MS, and IR data are in full agreement with published literature (Seip and Hecker, 1982). Therefore, compound 8.5 is identified as ingenol. NMR data for compound 9.4 could not be completed with this experiment,

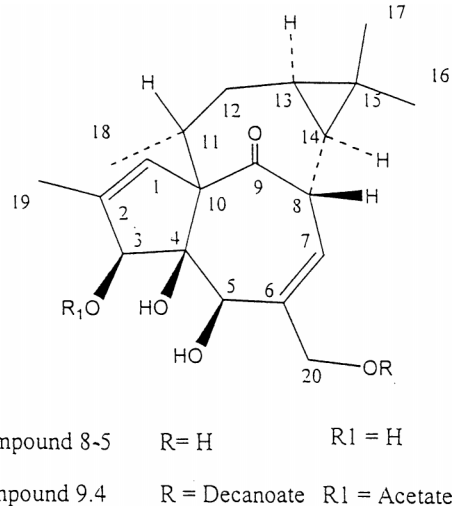

FIG. 2. Aversive diterpene ingenol (compound 8.5) and diester derivative (compound 9.4).

but the identity of it was established from mass spectral analysis. Moreover, alkaline hydrolysis of compound 9.4 followed by comparison of the diterpene part showed a complete match with ingenol in TLC and HPLC analysis. Therefore, compound 9.4 was tentatively identified as ingenol-20-dodecanoate, 3-acetate by comparison with published data (Seip and Hecker, 1982). Further NMR analyses are in progress to establish the positions of the diester derivatives of ingenol.

Compounds 8.5 and 9.4 showed toxicity to lymphosarcoma cells at 10 μl or more of DMSO plus a compound (Figures 3 and 4). The cell assay showed little difference in the cytotoxicity of compound 8.5 (ingenol, the parent diterpene alcohol) and compound 9.4 (ingenol diester derivative). Ingenol and its esters vary considerably in their biological activity (Hirata, 1975; Hirota et al., 1980). Ingenol has lower activity than some of its esters, but will still bind to protein kinase C and activate the enzyme (Hasler et al., 1992). Ingenol has been shown to be active in different cell systems with effects similar to those of the phorbol esters in respect to morphological change, cell to cell communication, epidermal growth factor binding, arachidonic acid metabolite release and ornithine decarboxylase activity (Hasler et al., 1992).

For the first trial with ingenol, change in intake of novel feed by treated and control cattle from the first to second days was similar ($P = 0.41$), and the ingenol treatment elicited an aversion in only one animal (Figure 5). This calf decreased intake of the novel feed by 83% from the first to second days. One calf that did not show an aversion from the initial ingenol treatment was dosed again and avoided

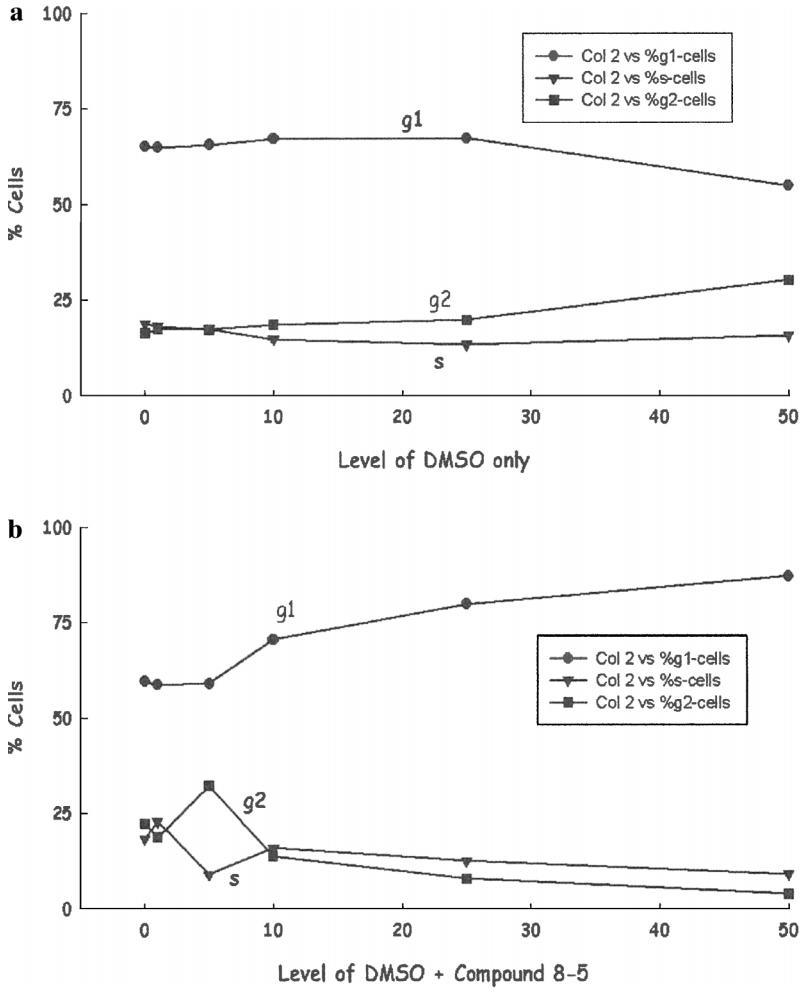

FIG. 3. Cell cycle analysis based on percent of bovine lymphosarcoma cells in each of three phases of the cell cycle: lag phase (g1), exponential phase (g2), and stationary phase (s). Effect on cell cycle when different amounts of DMSO was added to the lag phase of growing cells (a) and when different amounts of compound 8.5 dissolved in DMSO was added to the lag phase of growing cells (b).

the novel feed after a second treatment with ingenol. These results are consistent with work indicating that ingenol, the parent alcohol, is less toxic than some of its esters (Hasler et al., 1992). However, we recently determined that the air-dried leafy spurge from our South Dakota site contained at least 0.0074% ingenol. This

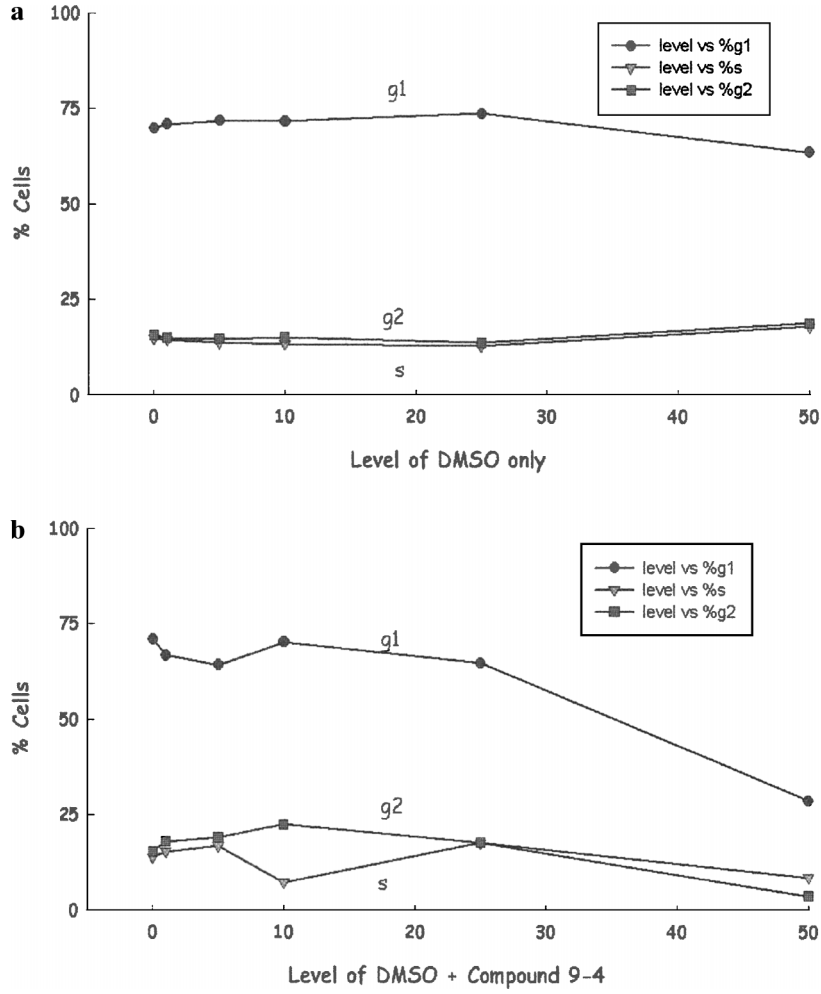

FIG. 4. Cell cycle analysis based on percent of bovine lymphosarcoma cells in each of three phases of the cell cycle: lag phase (g1), exponential phase (g2), and stationary phase (s). Effect on cell cycle when different amounts of the DMSO was added to the lag phase of growing cells (a) and when different amounts of compound 9.4 dissolved in DMSO was added to the log phase of growing cells (b).

level is considerably higher than our assumption of 0.0005% of air-dried leafy spurge that we used when determining our dosage rate for both aversion trials. Ingenol may have elicited more aversion had we used a higher dosage based on this level of ingenol in leafy spurge.

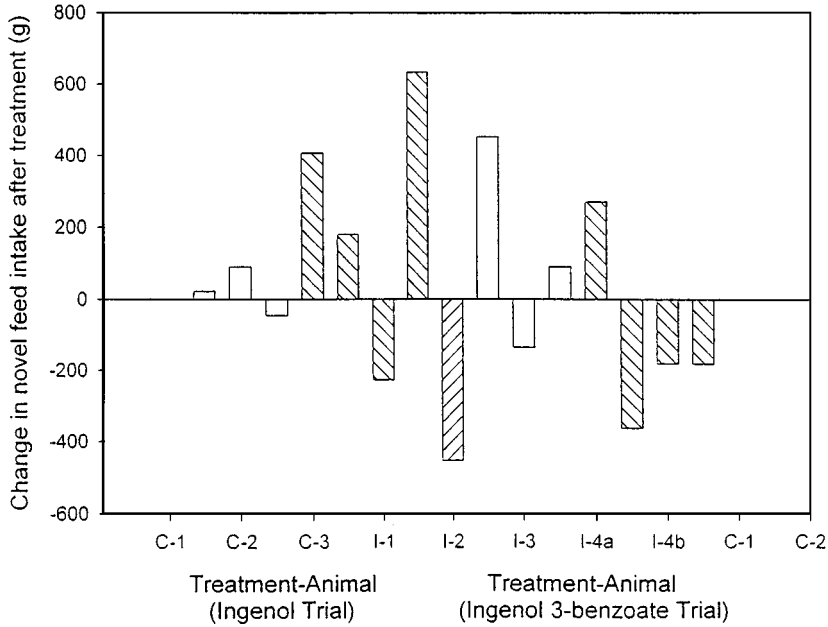

FIG. 5. Change in intake of a novel feed by cattle after gavage with ingenol (or ingenol 3-benzoate) in ethanol and water or only ethanol and water (control). Animals with "I" before their number were gavaged with ingenol or ingenol 3-benzoate (separate trials for each ingenol). Animals with "C" before their number were gavaged with only ethanol and water. Animal 940 did not show an aversion to the novel feed after the first time it was gavaged with ingenol (intake indicated at I-4a), so it was dosed again and its intake following the second gavage of ingenol is indicated by I-4b.

The esters are more lipophilic than the parent ingenol and, therefore, more likely to be absorbed through the intestinal mucosa. Ingenol 3-benzoate is similar to other ingenol esters that are in leafy spurge or possibly created by microbial metabolism of ingenols in the rumen of cattle. Hubert et al. (unpublished data) observed that extracts of 6-hr-long fermentations of leafy spurge and cattle ruminal digesta are more toxic to brine shrimp than are extracts of mixtures of leafy spurge and cattle ruminal digesta are more toxic to brine shrimp than are extracts of mixtures of leafy spurge and cattle ruminal digesta that were not allowed to ferment. One dose of ingenol 3-benzoate elicited an aversion in three of four calves tested (novel feed intakes decreased 89, 33, and 80% from the first to second day for these three calves). However, there was no significant difference ($P = 0.30$) between the control and treated cattle with respect to their change in novel feed intake from the first to second day (Figure 5). Kronberg and Walker (unpublished data) observed that air-dried leafy spurge did not elicit a feed aversion in one of five yearling cattle

gavaged with air-dried leafy spurge after ingesting a novel feed. If some cattle do not experience aversions to leafy spurge after one exposure, then it is logical that not all cattle will experience an aversion from a single dose of ingenol that is similar to that in leafy spurge. The response of cattle to ingenol 3-benzoate was similar to that observed with rats (Kronberg et al., 1995). Rats formed an aversion to a novel fluid when they received a gastric infusion of ingenol 3-monobenzoate that followed their initial drink of the novel fluid (Kronberg et al., 1995).

This study helps define toxic and aversive compounds in leafy spurge that are probably, at least in part, responsible for the toxic and aversive effect that leafy spurge has on cattle. In view of the widespread distribution of leafy spurge on the northern Great Plains and its negative impact on cattle production in the region, understanding the chemical interaction between cattle and leafy spurge is important. Furthermore, given that sheep and goats will ingest substantial amounts of leafy spurge and that cattle may ingest small amounts, it is of considerable importance to elucidate the overall environmental risk factors for the potential cumulative toxicity of these cocarcinogenic compounds. Several reports have suggested that direct or indirect exposure of people and livestock to such plants or plant parts may lead to a potential risk of cancer by conditional carcinogenesis (Upadhyay et al., 1978; Hecker, 1981, 1987a,b; Zayed et al., 1998; Vogg et al., 1999). This clearly indicates the necessity to investigate the overall toxicity of leafy spurge on livestock, especially in areas highly infested with this noxius weed.

Acknowledgments—The authors are grateful to Donald P. Evenson for conducting the cytotoxicity assays and Kjersten Grong for helping with the brine shrimp toxicity assays. Gary D. Manners, James A. Pfister, and Frederick D. Provenza are thanked for their helpful reviews of the manuscript. This work was funded by the USDA's NRICGP, grant 95-37315-2091, start-up funding for Fathi T. Halaweish from Department of Chemistry & Biochemistry, South Dakota State University, and the Ethel Austin Martin Pilot Project Fund at South Dakota State University.

Abstract—Howler monkeys, *Alouatta* spp., are the most folivorous of neotropical primates (Platyrrhini), although Amazonian red-handed howlers (*Alouatta belzebul*) are relatively frugivorous. The feeding ecology of a free-ranging group of *A. belzebul* was monitored at a site in eastern Brazilian Amazonia over a ten-month period (November 1997 to August 1998). The first half of the study period encompassed the peak of the wet season, during which the study group's diet was predominantly frugivorous (scan sample records: 53.5% fruit, 40.8% leaves), and the second half, the transition from wet to dry season, characterized by a marked shift to folivory (18.9% fruit, 77.9% leaves). This shift was accompanied by a marked increase in mature, as opposed to flush leaves, which are relatively rich in secondary compounds. Ingestion of soil from termitaria was recorded on a total of 26 occasions, all of which occurred during the second half of the study period. Soil from termitaria was relatively rich in elements such as Ca and Na and in organic carbon, in comparison with that from the forest floor. The extent to which the monkeys ingested soil for their mineral supplements, or as an aid for the digestion of leaves, in particular the absorption of secondary compounds, remains unclear. The marked correlation with the observed patterns of folivory

suggests that the latter function may have been the primary motive for geophagy in this species.

Key Words—Geophagy, soil geochemistry, howler monkey, *Alouatta belzebul*, folivory, Amazonia, detoxification.

INTRODUCTION

The systematic ingestion of soil has been observed in a wide range of vertebrates, including a number of primate species. Among primates, geophagy is apparently most common in arboreal folivores such as the Old World colobines (*Colobus*: Oates, 1978; *Presbytis*, Davies and Baillie, 1988), and the New World genus *Alouatta* (Hirabuki and Izawa, 1990; Izawa, 1993; Julliot and Sabatier, 1993; Bicca-Marques and Calegaro-Marques, 1994). Geophagy has been recorded in neotropical primates as diverse ecologically as spider monkeys (*Ateles*: Izawa, 1993), sakis (*Pithecia*: Setz et al., 1999), bearded sakis (*Chiropotes*: Ferrari, 1995), titi monkeys (*Callicebus*: Müller et al., 1997), and tamarins (*Saguinus*: Heymann and Hartmann, 1991), but appears to be less frequent overall than in howler monkeys, *Alouatta*.
