Abstract—The organization of termite societies depends predominantly on intraspecific chemical signals (pheromones) produced by exocrine glands, which induce and modulate individual behavioral responses. Here, the saliva-producing labial glands of termites were investigated with respect to their pheromonal role in communal food exploitation of termite colonies. From these glands, we identified for the first time hydroquinone (1,4-dihydroxybenzene) as a phagostimulating pheromone in the Australian termite species *Mastotermes darwiniensis*. Hydroquinone is released from the labial glands of termite workers and applied onto the food. It stimulates nestmates to feed at the spot of application and is, thus, employed to mark feeding sites. No synergistic effect with other identified labial gland compounds, such as glucose, inositol, and arbutin, was evident. Significantly, we show that termite species from all over the world, irrespective of taxonomic position and biological traits, produce and employ hydroquinone as phagostimulating signal. The use of the same chemical signal throughout an order is a unique phenomenon, not reported before in animals. Its possible biosynthetic pathway, ecological significance, and evolution are discussed.

Key Words—Termites, pheromones, feeding stimulation, labial glands, hydroquinone, arbutin.

INTRODUCTION

Termites are social insects living in highly organized communities of up to several million individuals. Communication among nestmates is essential for the coordinated functioning of a termite colony (Pasteels and Bordereau, 1998). This is achieved predominantly by intraspecific chemical signals (pheromones) produced by exocrine glands, which induce and modulate individual behavioral responses. Compounds from sternal and frontal glands regulating foraging, recruitment, alarm, and defense are well investigated (Pasteels and Bordereau, 1998; Kaib, 1999). The labial glands of termites have received only minor attention regarding the chemistry of their secretion and possible pheromonal role. These glands are located in the thorax, and the glandular ducts open into the oral cavity (e.g., Costa-Leonardo and Cruz-Landim, 1991; Kaib and Ziesmann, 1992). The aqueous labial gland secretion (contributing to the saliva) is released onto the substrate. The secretion contains numerous compounds and has diverse nonpheromonal functions. It has been reported to be defensive (Moore, 1968; Maschwitz and Tho, 1974; Olagbemiro et al., 1988), to play a role in nest construction and regulation of nest climate, and to function as a fungicide, social nutrient, and source of digestive enzymes (Noirot, 1969; Hewitt et al., 1971; Martin and Martin, 1978; Grassé, 1982; Brian, 1983; Hogan et al ., 1988; Veivers et al., 1982, 1991; Mednikova, 1991).

Behavioral data from previous studies suggested a pheromonal role of the labial gland secretion in *Reticulitermes santonensis* (France) and *Schedorhinotermes lamanianus* (East Africa). It appeared to contain a polar, heat-resistant chemical signal (Kaib and Ziesmann, 1992; Reinhard and Kaib, 1995, 2001 a,b; Reinhard et al., 1997a), that is released onto the food by feeding termite workers and stimulates nestmates to feed at the same site, thereby initiating clusters of feeding termites. Both termite species belong to the same family, Rhinotermitidae, but they differ in many aspects of their biology, such as habitat, nesting habits, and foraging and recruitment strategies (Harris, 1968; Becker, 1970; Schedel and Kaib, 1987; Kaib and Brandl, 1992; Brandl et al., 1996, Reinhard et al., 1997b). Nevertheless, both species appear to produce a chemically similar, if not identical, phagostimulating pheromone in their labial glands. Further studies using bioassays combined with thin-layer chromatography indicated that numerous other termite species possess the phagostimulating signal as well (Reinhard and Kaib, 2001a,b). The work presented here was undertaken to identify the chemical nature of the phagostimulating pheromone from labial glands of termites.

METHODS AND MATERIALS

Insect Species. Most experiments were first carried out with the Australian termite species *Mastotermes darwiniensis. M. darwiniensis* were collected near Darwin, Australia, and maintained in the laboratory in groups of ca. 1000 individuals in plastic containers with water and wood at 30°C, 90% relative humidity for the bioassays. Other termite species (Table 2 below) were collected in Australia and Africa, or provided from the laboratory cultures of the Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany, and the University of Bern, Switzerland. Cockroaches (*Periplaneta americana*) were taken from a laboratory culture of CSIRO Entomology, Australia.

Preparation of Samples. Labial gland extracts of termite workers and cockroaches were prepared by excising between 6 and 120 labial glands (depending on species size), without the gland reservoirs, as the latter do not contain the active signal (Kaib and Ziesmann, 1992; Reinhard et al., 1997a). Glands were extracted in distilled water (500 μl) for 12 hr at 4°C, then deep-frozen for 24 hr. Thereafter, the glands were removed. Saliva (100 μl) of *M. darwiniensis* was collected with glass microcapillaries from the oral cavity and extracted in distilled water (500 μl). For the gnawed filter paper extract, filter paper was offered to 50 *M. darwiniensis* workers in Petri dishes overnight, and the following morning excised pellets (corresponding to an area of ca. 5 cm^2) were extracted over glasswool in distilled water (1 ml). Extracts of clean filter paper were prepared as controls. All extracts were used for both feeding bioassays and chemical analyses. For bioassays with synthetic references, the compounds were dissolved in distilled water with or without the antioxidant BHT (2,6-bis(1,1-dimethylethyl)-4-methylphenol; butylated hydroxytoluene) added in 10% ratio. Solution series were prepared corresponding to the natural concentrations of the compounds in the labial glands of the respective species.

Bioassays. All biological experiments were conducted under red light illumination. Feeding behavior in termite workers can be recognized by the hypognathous head position and wriggling head movements while gnawing and tearing off food fibers (Reinhard and Kaib, 2001a,b). Feeding spots are recognized afterwards by marks or holes in the substrate due to removal of food particles by the feeding termites. Foraging arenas for the feeding choice tests were made of large Petri dishes (14.5 cm ID, 1 cm high). They were attached to the containers holding *M. darwiniensis*. In each test, two semicircles (2.5 cm diam.) of filter paper were offered, one treated with 25 μl extract (labial gland, saliva, gnawed filter paper extract) or a solution of synthetic chemicals, the other moistened with 25 μl distilled water (control). For each bioassay, the spatial distribution of the first 20 termites feeding on the two semicircles according to the behavior described above was determined during the test duration of ca. 1 hr. Termites arresting or aggregating without actually feeding were not considered. Tests were

replicated 20 times and analyzed with the sign test on an ordinal level of the data (Zar, 1974). For the other termite species tested, the bioassay set-up was modified with respect to size of nest containers and arenas, observation method (direct or recorded by IR-sensitive video techniques), and duration of tests. Tests in the field were conducted with colonies of *C. curvignathus* in Malaysia, using paper towels (10 × 40 cm) treated with 40 μg hydroquinone and untreated ones as control, offered in open plastic containers for 24 hr. The results were photographed.

Chemical Analysis. Chemical analyses were based on GC-MS investigation, with a Hewlett Packard 5890 gas chromatograph coupled to VG Trio 2000 mass spectrometer. 1,2-Dihydroxyphenol (Aldrich) was added to the extracts described above as an internal standard for quantification of the pheromone. After the extracts were concentrated to 30 μl under nitrogen and freeze-dried, the residues were taken up in *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA, Alltech, 50 μl), and pyridine (15 μl) and silylated at 90°C for 1 hr. The samples (1 μl) were injected on-column (Alltech EC 5, 30 m long × 0.32 mm ID, film thickness 0.5 μm), with helium as the carrier gas (flow rate 1 ml/min). The GC was operated using the following temperature program: 90°C for 6 min, a gradient of 20°C/min to 180°C, followed by a gradient of 10°C/min to 300°C, and isothermal for 20 min at 300°C. The effluent was subjected to positive-ion chemical ionization with NH_3 as reactant gas, and the monitored ions for the pheromone and internal standard were $[M+NH_4]^+$ and $[M+NH_4-H_2O]^+$. For general quantification of the remaining labial gland components, apart from the pheromone, Tri-Sil (Pierce, 20 μl) was added to the above samples and heated at 90°C for further 3 hr to ensure complete silylation. These components were quantified by gas chromatography (GC Varian 3300, on-column injection, Alltech EC 5, temperature program 60°C for 1 min, followed by successive gradients of 50°C/min to 150°C and 10°C/min to 280°C isothermal for 10 min).

RESULTS

In feeding choice tests with laboratory colonies of *Mastotermes darwiniensis*, semicircles of filter paper, onto which we applied extracts of labial glands of *M. darwiniensis* workers or water as control, were offered as food. Labial gland extract clearly stimulated feeding in *M. darwiniensis* (Figure 1a). Saliva extracts and extracts of filter paper pellets that *M. darwiniensis* workers had previously chewed and salivated upon (gnawed filter paper) also stimulated feeding significantly. For the chemical analyses, we used persilylated samples of labial gland extracts, saliva, and gnawed filter paper. For the first time in *M. darwiniensis* workers, we identified hydroquinone (1,4-dihydroxybenzene) in small amounts

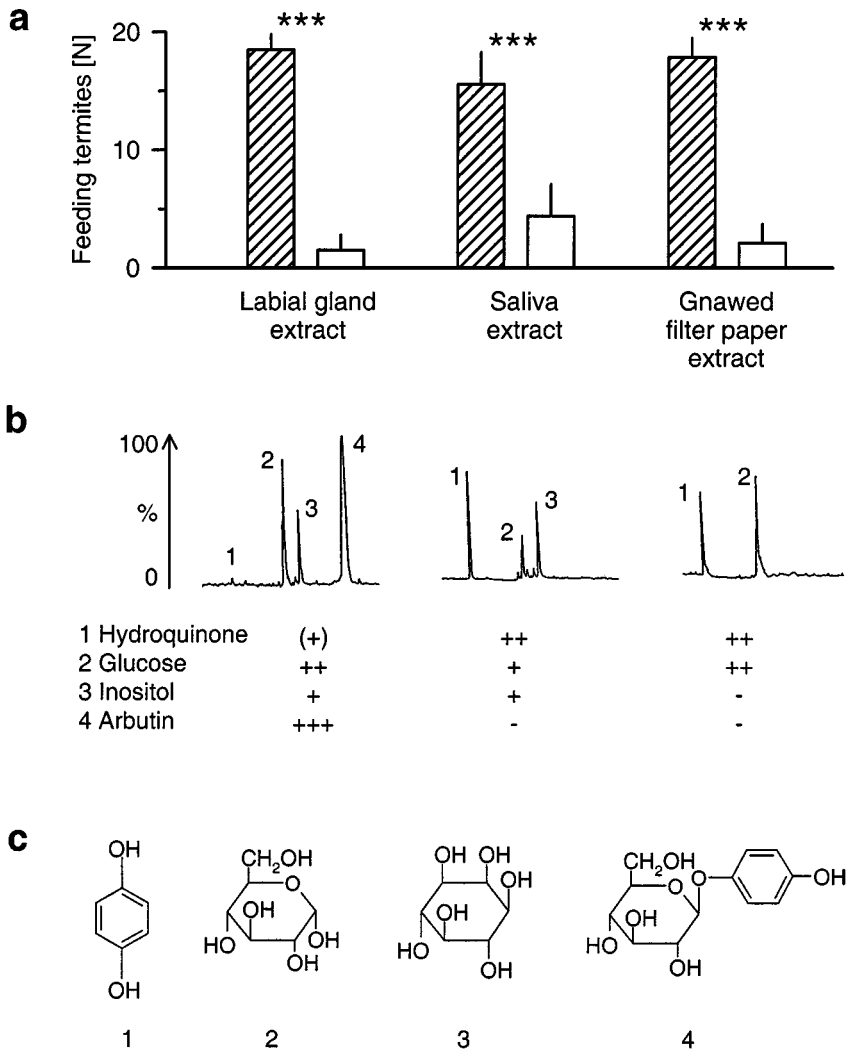

FIG. 1. Phagostimulating effect and chemical analysis of *Mastotermes darwiniensis* extracts. (**a**) Feeding choice tests with labial gland, saliva, and gnawed filter paper extract (25 μl extract per test). Mean distribution ($\pm$SD, $N = 20$) of the first 20 termites feeding on two semicircles of filter paper; hatched bars: semicircle treated with extract, empty bars: semicircle moistened with water as control. ***: significant difference at $P < 0.001$, sign-test. (**b**) Gas chromatograms of the above extracts (y axis: relative abundance) and ratio of identified compounds. $+++$: major component, $++/+$: minor components, $(+)$ trace component, $-$: not present. (**c**) Chemical structures of identified compounds.

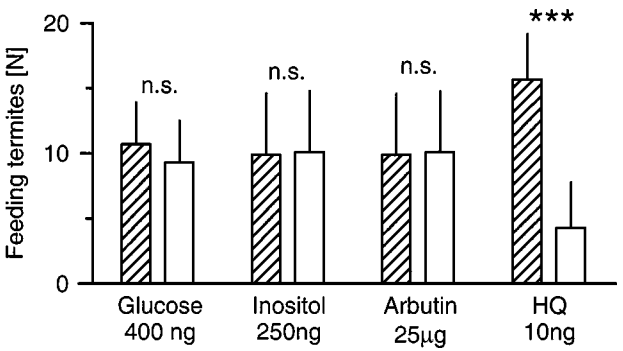

FIG. 2. Phagostimulating effect of labial gland components of *Mastotermes darwiniensis*. Compounds tested in naturally extractable concentrations (amount per labial gland) in a feeding choice bioassay. Mean distribution ($\pm$SD, $N = 20$) of the first 20 termites feeding on two semicircles of filter paper; hatched bars: semicircle treated with compound, empty bars: semicircle moistened with water as control. n.s.: no significant difference, ***: significant difference at $P < 0.001$, sign-test.

by gas chromatography–mass spectrometry (GC-MS) analysis of the labial gland extract (Figures 1b,c). We also identified glucose, an inositol, and arbutin (4-hydroxyphenyl-β-glucopyranoside) in labial gland extracts, corresponding to earlier preliminary results (Reinhard, 1998). The saliva and gnawed filter paper extracts contained glucose and an inositol, or glucose only, respectively. Arbutin was not detectable in the latter extracts, but hydroquinone was found instead as a major component (up to 0.64 μg/μl saliva). When each of the identified components was assessed individually at natural concentrations in the feeding choice test, only hydroquinone stimulated feeding in *M. darwiniensis* (Figure 2), corresponding to the activity of saliva and labial gland extracts. Mixtures of hydroquinone with other gland components were tested for phagostimulation, but a synergistic effect was not evident (Table 1). Thus, it was concluded that hydroquinone is the phagostimulating pheromone derived from the labial glands.

Tests with a concentration series of hydroquinone, from 1 ng to 10 μg per test, revealed that for *M. darwiniensis* it was effective as a phagostimulant only at 5–10 ng (Figure 3). At higher concentrations, the effect was diminished. However, when the synthetic antioxidant BHT was added in 10% ratio to hydroquinone, the phagostimulant proved to be effective at concentrations up to 10^3 times higher.

After analyzing the labial glands of a further 14 termite species from all major termite families collected throughout the world, we found that they all contained the same components: glucose, one or more inositols, arbutin, and a trace amount of hydroquinone (Table 2). On the other hand, labial glands of the cockroach

[a] Quantification of components with GC and GC-MS. G: glucose, I: inositol(s), A: arbutin, HQ: hydroquinone; mean concentration ($N = 3$) in nanograms per labial gland. Species-specific variation correlated with size of glands.

Periplaneta americana contained glucose and inositols, but lacked arbutin (or other glucosides) and hydroquinone. Laboratory feeding choice tests with selected termite species (numbers 2, 3, 6, 7, 9, 10, 11, 13 in Table 2), using 0.1–5 ng hydroquinone per test, as well as first field trials with a Malaysian species revealed that, without exception, hydroquinone works as a powerful phagostimulant (Table 2, Figure 4).

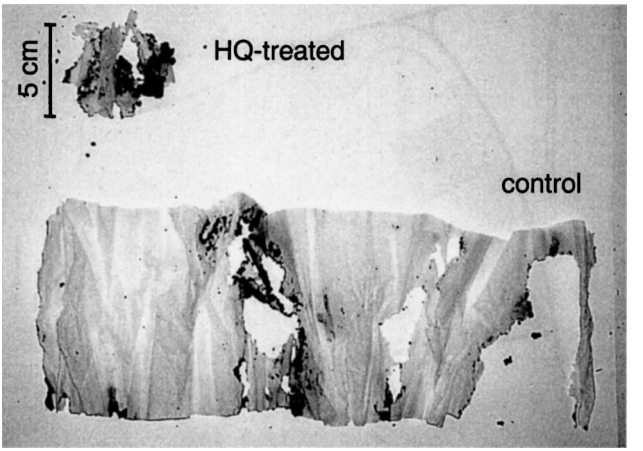

FIG. 4. Phagostimulating effect of hydroquinone on *Coptotermes curvignathus* (Malaysia) in the field. Above: paper treated with 40 μg hydroquinone (HQ), below: untreated paper (control).

DISCUSSION

Feeding bioassays with the Australian termite species *M. darwiniensis* demonstrated that a phagostimulatory signal, such as suggested for *R. santonensis* and *S. lamanianus* (Kaib and Ziesmann, 1992; Reinhard and Kaib, 1995; Reinhard et al., 1997a), also existed in the labial glands of *M. darwiniensis*. Subsequent chemical analyses and feeding bioassays identified hydroquinone as the phagostimulating pheromone from termite labial glands, even though present in only minute amounts. Verification of solubility, heat resistance, and TLC analyses of hydroquinone proved that its physicochemical properties corresponded to those suggested for the phagostimulant in previous studies (Kaib and Ziesmann, 1992; Reinhard et al., 1997a; Reinhard and Kaib, 2001a). Laboratory and field experiments evaluating quantitative data of food consumption in choice tests over a longer period of time have confirmed the phagostimulatory nature of hydroquinone (Reinhard et al., in press).

Hydroquinone seems to be effective only in the nanogram range. Its diminished effect at higher concentrations is possibly due to the oxidative formation of larger quantities of quinone (1,4-cyclohexadienedione) in the bioassay, which is generally known as an effective repellent and in some termite species is released as a defensive compound by soldiers (Moore, 1968; Olagbemiro et al., 1988). This assumption is supported by the fact that hydroquinone proved to be effective

at levels up to 10^3 times higher when the synthetic antioxidant BHT was added. Similar to other hydroquinone analogs tested, BHT alone does not have a significant phagostimulating effect (Reinhard et al., in press). Therefore, the increased effectiveness of hydroquinone in this experiment is indeed due to the antioxidative function of BHT.

The most remarkable aspect of the phagostimulating signal was revealed when the labial glands of termite species from all major termite families were analyzed. Independently of the phylogenetic classification, geographic origin, or living and feeding habits of these termite species, their labial glands contained hydroquinone as a phagostimulant. Interspecific sharing of single compounds within multicomponent pheromones occurs (Howard et al., 1976; Kaib et al., 1982; Borges et al., 1999), but the use of the same chemical signal throughout an order has not been reported before in animals. The labial glands of the cockroach *Periplaneta americana*, analyzed because cockroaches are assumed to be ancestors of termites (Kambhampati, 1995), lacked hydroquinone. The use of hydroquinone as phagostimulating pheromone seems to be a monophyletic trait of the Isoptera. Notably, however, the potency of hydroquinone as a phagostimulant for bark beetles, albeit at higher concentrations, has been known for some time (Norris, 1970, 1976).

This is the first report of the use of hydroquinone as a termite pheromone to organize communal food exploitation. As yet, we have not evaluated the amount of pheromone released by individual termites, nor do we know if other unidentified synergistic compounds or antioxidants are released simultaneously. Concerning the other compounds identified in the labial glands, the presence of inositols could be due to many factors, considering the numerous functions of inositols in cell biochemistry (Stryer, 1995; Berridge, 1997). Glucose and arbutin, on the other hand, may be associated with hydroquinone formation. While there is arbutin but little hydroquinone in the labial glands, there is significant hydroquinone and glucose but no arbutin in saliva and gnawed filter paper. Moreover, the termite diet consists mainly of carbohydrates (cellulose-derived) and aromatic compounds (lignin-derived), suggesting the following hypothetical pathway based on inducible enzymatic activities: termites acquire glucose, hydroquinone, and arbutin either directly in their food or via metabolism (Kreitsberg and Ekabsone, 1973; Noirot, 1992; Inoue et al., 1997; Oliver et al., 1998). Since hydroquinone itself is a slight irritant, and formation of the toxic quinone needs to be avoided, hydroquinone is stored as its stable conjugate arbutin, possibly synthesized by the enzyme phenol-β-glucosyltransferase (PGT) (Ahmad and Hokins, 1993). When required, arbutin can be readily broken down by the digestive enzyme β-glucosidase (Tokuda et al., 1997; Itakura et al., 1997), thus releasing hydroquinone. The trigger for β-glucosidase induction could be stimulants in the food and possibly hydroquinone itself, given the role of quinoid compounds in redox cycling, affecting cell signaling pathways (Brunmark and Cadenas, 1989; Schlatterer and Schaloske, 1996; Ambudkar, 2000).

The biological significance of the phagostimulating pheromone resides in the fact that food exploitation is a communal activity for all termite species. The phagostimulant promotes the formation of clusters of feeding termites, while successive application of saliva humidifies food and repeated biting enhances the mechanical break-up of its surface. In termite species that feed on dispersed food, such as the harvester termite *Hodotermes mossambicus*, the effect of the phagostimulant is not as obvious as in xylophagous termites, but nevertheless of importance. During the process of cutting long grass stems into pieces, the phagostimulant induces *H. mossambicus* workers to gather and bite into the same spot of the grass stem (Reinhard, 1998). Through such concentrated feeding efforts, a termite colony can exploit a food source faster and more efficiently.

It seems advantageous to use a simple chemical that is probably food-derived for such a frequently employed pheromone. Termites are herbivorous or humivorous, irrespective of the many different life and feeding traits within the group. All termites ingest similar compounds derived from cellulose and lignin, and they share basic digestive pathways (Abe, 1987; Noirot, 1992); therefore, food-derived signals are expected to be similar in all species. Furthermore, as termite species may share food sources, it can be advantageous to employ the same signal. Phagostimulation by hydroquinone appears to be an ancestral trait that has been strongly selected for in termites. We propose that this mechanism has evolved in concert with utilizing cellulose and lignin as a food source and has been developed into a strategy used by termites all over the world for organization of communal food exploitation.

Hydroquinone from termite labial gland secretion might also serve functions other than phagostimulation. For example, hydroquinone could be responsible for the fungicidal and aseptic effect demonstrated for the saliva of termites (Noirot, 1969; Grassé, 1982). Hydroquinone might also, serve a certain defensive role, acting as an irritant and repellent against intruders. It is notable that in termite species, in which the soldiers use the labial gland secretion for chemical defense, such as *Mastotermes*, *Odontotermes*, and *Macrotermes*, this secretion is composed of mixtures of benzo- and toluquinones (Moore, 1968; Maschwitz and Tho, 1974; Grassé, 1986; Olagbemiro et al., 1988). One could imagine that the production of quinones in the labial glands of the soldier caste has evolved out of the hydroquinone production in the worker caste.

These unanswered questions point to the most important consequence of the final identification of the phagostimulating pheromone in termites: our discovery opens up a whole range of new studies on function, biosynthesis, and evolution of hydroquinone, as well as on the application of the pheromone for termite control.

Acknowledgments—We thank H. Hertel and R. Leuthold for providing termites, and L. Kirton for help with trials in Malaysia. We are grateful to W. Francke, S. Mikus, and C. Claudianos for valuable discussions. Special thanks go to J. Ruther for advice and continued support during the entire project.

(Received April 26, 2001; accepted August 31, 2001)

Abstract— The responses of *Ixodes scapularis* (Acari: Ixodidae) nymphs and adults to extracts of cast larval skins were tested in a Petri dish bioassay. Assembly was elicited in nymphs and adults in the presence of skins, exudate from ticks, and filter paper exposed to ticks compared to untreated controls. Assembly was noted by 1 hr after exposure with little change between 1 and 24 hr. The assembly response increased in the presence of an increased number of skins. Similar assembly was elicited in nymphs and adults in the presence of cast larval skins and a saline (0.95% NaCl) skin extract. Methanol and hexane extracts were not attractive. When chemical standards were tested against nymphs, they responded to guanine, uric acid, hypoxanthine, xanthine, inosine, and hematin. Adults were tested against guanine, inosine, and xanthine, and all elicited significant assembly. Responses of nymphs increased significantly with increase in dose of uric acid and guanine. Responses of nymphs to a mixture of guanine, xanthine, and adenine (25:1:1 ratio) were similar to responses to cast skins. This study provides the first evidence of an assembly pheromone in *I. scapularis*.

Key Words—Assembly pheromone, tick, *Ixodes scapularis*, purines, guanine.

INTRODUCTION

Relatively little is known about the pheromonal regulation of behavior of the black-legged tick, *Ixodes scapularis* (Acari: Ixodidae) despite its public health importance as the primary vector of Lyme disease, human granulocytic ehrlichiosis, and human babesiosis in the United States (Spielman et al., 1985; Walker and

*To whom correspondence should be addressed. E-mail: sallan@gainesville.usda.ufl.edu

0098-0331/02/0100-0015/0 © 2002 Plenum Publishing Corporation

Dumler, 1996; Childs et al., 1998). Reports of pheromones in other *Ixodes* species are also limited. Graf (1975) reported that a water-soluble pheromone produced by female *I. ricinus* strongly attracted males and, to a lesser degree, females. This pheromone appeared to facilitate mate finding and mating through an assembly response. Evidence of a water-soluble pheromone inducing assembly has also been documented for *Ixodes holocyclus* (Treverrow et al., 1977), *Ixodes persulcatus* (Uspensky and Emelyanova, 1980) and *I. ricinus* (Hájkova and Leahy, 1982), however, these pheromones are yet to be characterized or identified.

Assembly pheromones typically induce formation of off-host clusters of various stages and sexes of ticks through arrestment of movement upon contact. These assemblies are best described in soft ticks and tend to occur in caves, under ledges, and in cracks and crevices in proximity to nests of the hosts. These assemblies are thought to enhance mating and host-finding success (Sonenshine et al., 1982). Pheromone-induced assembly was first described from *Argas* ticks by Leahy et al. (1973). Subsequently, this behavior has been reported from at least 14 species of soft ticks as well as from several hard ticks including *Hyalomma dromedarii* (Leahy et al., 1981), *Rhipicephalus appendiculatus, Amblyomma cohaerans* (Otieno et al., 1985), *Rhipicephalus evertsi* (Gothe and Neitz, 1985), and the above mentioned species of *Ixodes*. Assembly pheromones are present in the excreta and the aqueous and saline washings of ticks (Leahy et al., 1973; Gothe and Kraiss, 1982). Best described from several species of *Argas*, assembly pheromones appear to consist of guanine and other purines such as xanthine and hypoxanthine that are present in extracts of nitrogenous excreta of these ticks (Neitz and Gothe, 1984; Otieno et al., 1985; Gothe, 1987; Dusbábek et al., 1991a,b). The existence of similar pheromones has not been previously reported from *Ixodes scapularis* and the objective of this study was to determine if assembly pheromones are present in *Ixodes scapularis*.

METHODS AND MATERIALS

Ticks. Ticks were obtained from a laboratory colony maintained at the University of Florida. Adult ticks were fed on New Zealand white rabbits and immatures fed on rats. Ticks were held in screen-topped vials at $24 \pm 1^{\circ}$C and 93–96% relative humidity under a 16L:8D photoperiod.

Bioassay Procedure. Responses of ticks were evaluated in Petri dish bioassays modified from Leahy et al. (1973). Disposable plastic Petri dishes (100 mm diam.) were placed over similar-sized paper templates divided into six equal-sized sectors. Sectors of the templates were labeled from 1 to 6. Teflon discs of 1 cm diam. (Thomas Scientific, Swedesboro, New Jersey) were treated with treatment solutions or solvent (control) and placed in the center of sector 1. None of the other sectors in the Petri dish received a treatment or control disc. Treatments or

controls were placed on Teflon discs and the solvent allowed to dry before being placed in the Petri dish. After the disc was added to the dish, 10 ticks were added in the center of the dish and the dish placed in a high-humidity (>93% relative humidity) chamber. The location of ticks by sector was noted at 1, 2, and 24 hr after placement to evaluate the cumulative effect of the assembly. Initial bioassays determined that there was no location bias under these experimental conditions and that there was no significant difference in numbers of ticks present in any sector (data not presented).

Bioassays. Initial bioassays were conducted using cast skins collected from blood-fed larvae, filter paper exposed to blood-fed larvae, and the exudate from blood-fed larvae. Skins shed by emerged nymphs were collected from tick rearing vials within a week after being shed. Skins were collected using fine-tipped forceps or a paintbrush, and only whole skins were used for extracts. Filter paper strips (1 × 4 cm) were placed in tick rearing vials along with 10 freshly blood-fed larvae. After 30 days of exposure, filter strips were removed from the vials and evaluated in bioassays. Exudate from the sides of glass tick rearing vials was removed by scraping with forceps and collected for use in bioassays. Bioassays were conducted immediately after collection of skins, filter paper, or exudate. Bioassays were conducted by placing cast skins (10 or 25), folded contaminated filter paper strips, or exudate (0.5 mg) on a Teflon disc in the center of sector 1. Controls consisted of an untreated Teflon disc or clean filter paper.

Extracts of cast skins were made using solvents covering a range of polarities and bioassay responses compared to those using cast skins. Cast skins were placed in 500 μl of 0.95% NaCl, vortexed three times for 20 sec, allowed to sit for 10 min, and then all liquid was transferred to a separate vial. Skins were washed twice times with 100 μl of 0.95% NaCl, and washes were added to the original extract and reduced under N_2 to a concentration of 1 skin equivalent/μl. Similarly, skins were washed with methanol (HPLC grade) and the extract reduced to 1 skin equivalent/μl. An extract with hexane (HPLC grade) was also prepared following the protocol for the above extracts. Bioassays were conducted comparing responses of *I. scapularis* females, males, and nymphs to cast larval skins, saline, methanol, and hexane extracts and untreated controls. Treatments were tested at 10 and 20 skins or skin equivalents. All bioassays were replicated 15 times.

Responses of *I. scapularis* were tested to a series of compounds previously reported as potential components of an assembly pheromone in soft ticks (Dusbábek et al., 1991a,b). Compounds tested included guanine, uric acid, hypoxanthine, xanthine, inosine, adenine, and hematin (Sigma, St. Louis, Missouri). Compounds were diluted in 0.95% NaCl and tested at 0.5 mg, which was a dose eliciting response in the study by Dusbábek et al. (1991a). Controls consisted of 1 μl of 0.95% NaCl. Prior to bioassays, Teflon discs were treated with 0.5 mg of each compound,

discs were allowed to air dry, and then bioassays were conducted. Bioassays were replicated 10 times for nymphs and 15 times for adults.

Compounds eliciting significant responses were tested over a range of doses to examine dose–response relationships. Responses of *I. scapularis* nymphs to 0.05, 0.5, and 5 mg of guanine, uric acid, xanthine, and adenine were examined in Petri dish bioassays and replicated 10 times.

Mixtures of purines consisting of guanine, xanthine, and adenine in a 25:1:1 ratio elicited responses in *A. persicus* equivalent to the natural pheromone (Dusbábek et al., 1991a). Comparisons were made of responses of *I. scapularis* nymphs to concentrations of this purine mixture ranging from 10 to 0.001 mg.

Analysis. Data were transformed [log $(x + 1)$] prior to statistical analysis; however, original numbers are presented in tables and figures. Data were analyzed by ANOVA and differences between means located by paired *t* test.

RESULTS

Cast larval skins, tick-exposed filter paper, and tick exudate elicited more assembly response in nymphs than untreated controls (Table 1). Within 1 hr, there were more ticks in sectors with larval skins ($t = -5.93$, $df = 18$, $P < 0.001$), exposed filter paper ($t = -9.76$, $df = 18$, $P < 0.001$), and exudate ($t = -5.69$, $df = 18$, $P < 0.001$) compared to untreated controls. Similarly by 2 and 24 hr, there were more ticks in the sectors with larval skins ($t = -3.99$, $df = 18$, $P < 0.001$; $t = -4.8$, $df = 18$, $P < 0.001$, respectively), exposed filter paper ($t = -11.4$, $df = 18$, $P < 0.001$; $t = -13.5$, $df = 18$, $P < 0.001$, respectively), and exudate ($t = -6.39$, $df = 18$, $P < 0.001$; $t = -5.3$, $df = 18$, $P < 0.001$, respectively) than in the controls. There was no difference in tick response between 1 and 24 hr in Petri dishes containing larval skins ($t = -0.48$, $df = 18$, $P = 0.31$), exposed filter paper ($t = 0$, $df = 18$, $P = 0.5$), exudate ($t = 1.32$, $df = 18$, $P = 0.1$), or untreated controls ($t = 1.34$, $df = 18$, $P = 0.09$).

TABLE 1. ASSEMBLY OF *I. scapularis* NYMPHS IN PETRI DISH SECTORS[a]

	Ticks in treatment sector (zone 1) (%, mean ± SE)			
Time (hr)	Untreated control	Cast skins	Exposed filter paper	Exudate
1	8.0 (2.5)	36.1 (4.0)[b]	40.8 (2.1)[b]	30.0 (2.9)[b]
2	4.0 (1.6)	34.2 (7.3)[b]	38.5 (2.5)[b]	24.2 (2.6)[b]
24	4.0 (1.6)	40.0 (7.3)[b]	40.2 (2.1)[b]	24.0 (3.4)[b]

[a] Petri dishes contained cast larval skins (10), filter paper exposed to blood-fed larvae, or exudate from molting ticks or untreated controls. Each mean represents 10 replicates with 10 nymphs per replicate.

[b] Significantly different from the untreated control, paired *t* test, $P < 0.001$.

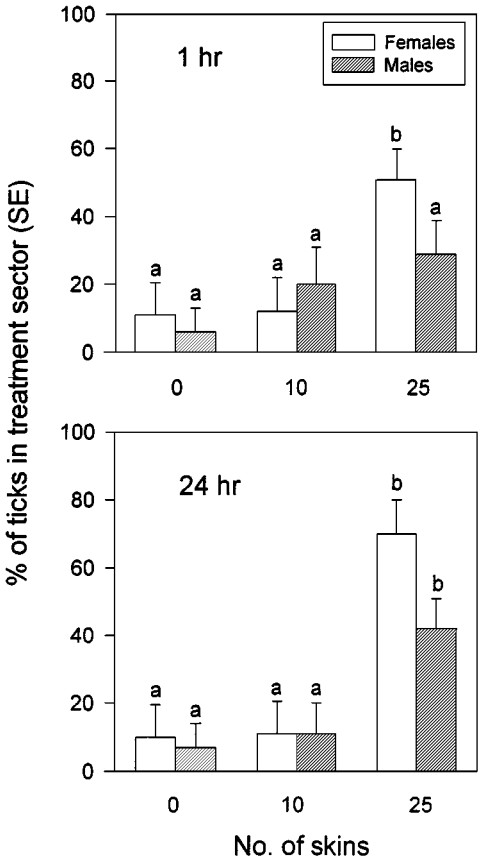

FIG. 1. Responses (mean ± SE) of adult *I. scapularis* to numbers of cast larval skins in Petri dish bioassays. Data are averages of 10 replications. Within each sex, bars marked by the same letter are not significantly different ($P > 0.05$).

Both male and female *I. scapularis* also responded to the presence of cast larval skins (Figure 1). In the presence of 10 larval skins, there was no difference after 1 hr in the number of male ($t = -0.6, df = 18, P = 0.27$) or female ($t = 0.24$, $df = 18$, $P = 0.40$) ticks in treatment sectors, nor was there a difference at 24 hr (male $t = 0.0$, $df = 18$, $P = 0.5$; female $t = 0.0$, $df = 18$, $P = 0.5$) compared to untreated controls. In the presence of 25 larval skins, there were more females in sectors with larval skins at both 1 hr ($t = -1.93$, $df = 18$, $P < 0.05$) and 24 hr ($t = -3.28$, $df = 18$, $P < 0.001$). There was no difference in numbers of males present in treatment sectors at 1 hr ($t = -0.89$, $df = 18$, $P = 0.19$) compared to untreated control sectors; however, there was a difference at 24 hr ($t = -1.4$, $df = 18$, $P < 0.05$).

TABLE 2. ASSEMBLY OF *I. scapularis* AFTER TWO-HOUR EXPOSURE TO CAST LARVAL SKINS, SALINE, OR METHANOL OR HEXANE EXTRACTS OF SKINS IN PETRI DISH BIOASSAYS[a]

Treatment	Ticks in treatment sector (zone 1) (%, mean ± SE)		
	Females	Males	Nymphs
Saline extract (95% NaCl)	64.3 (13.2)[b]	42.8 (13.7)[c]	45.0 (6.7)[b]
Methanol extract	10.0 (10.0)	10.0 (10.0)	10.0 (10.0)
Hexane extract	0.0 (0.0)	20.1 (13.1)	20.0 (13.3)
Cast skins	60.5 (13.3)[b]	40.5 (16.3)[c]	40.0 (7.3)[c]
Control	6.6 (6.6)	6.2 (6.2)	6.0 (3.1)

[a] Each treatment consisted of 20 skins or skin equivalents ($N = 10$).
[b] Significantly different from the untreated control, paired *t* test, $P < 0.001$.
[c] Significantly different from the untreated control, paired *t* test, $P < 0.05$.

Responses of ticks were similar to cast skins and to saline extracts of the skins (Table 2). More females were present in sectors with cast skins ($t = -3.85$, $df = 18$, $P < 0.001$) and the saline extract ($t = -3.02$, $df = 18$, $P < 0.001$) than the untreated controls. Similarly, responses of males and nymphs were greater to the cast skins ($t = -1.88$, $df = 18$, $P < 0.05$; $t = -4.29$, $df = 18$, $P < 0.001$, respectively) and the saline extract ($t = -2.37$, $df = 18$, $P < 0.05$; $t = -5.29$, $df = 18$, $P < 0.001$, respectively). Methanol and hexane extracts were not any more attractive than the controls ($P < 0.05$).

Assembly responses of nymphs were elicited by several of the purine standards tested (Table 3). More nymphs were present in sectors with guanine, uric acid, hypoxanthine, xanthine, inosine, and hematin compared to the solvent controls ($P < 0.05$). There was no significant response to adenine compared to the controls (Table 3). In general, responses increased slightly from 1 to 24 hr. After 24 hr, responses of nymphs to cast skins (40.0 ± 7.3%) were similar to responses to hematin ($t = 1.56$, $df = 18$, $P = 0.07$), xanthine ($t = 0.41$, $df = 18$, $P = 0.07$) and inosine ($t = 1.51$, $df = 18$, $P = 0.07$).

Similarly, responses of adults were also elicited by purine standards (Table 4). Uric acid, hypoxanthine, adenine, and hematin were also tested, but none of these elicited responses greater than the solvent controls ($P > 0.05$), and these data are not presented. More males and females were present in sectors with guanine, inosine, and xanthine compared to solvent controls (Table 4). Responses of females were similar to those obtained with cast skins (Table 2) and guanine ($t = 0.86$, $df = 18$, $P = 0.19$) and xanthine ($t = 0.86$, $df = 18$, $P = 0.18$); responses of males were similar between cast skins (Table 2) and guanine ($t = -0.86$, $df = 18$, $P = 0.19$), inosine ($t = 0.0$, $df = 18$, $P = 0.5$) and xanthine ($t = 0.0$, $df = 18$, $P = 0.5$).

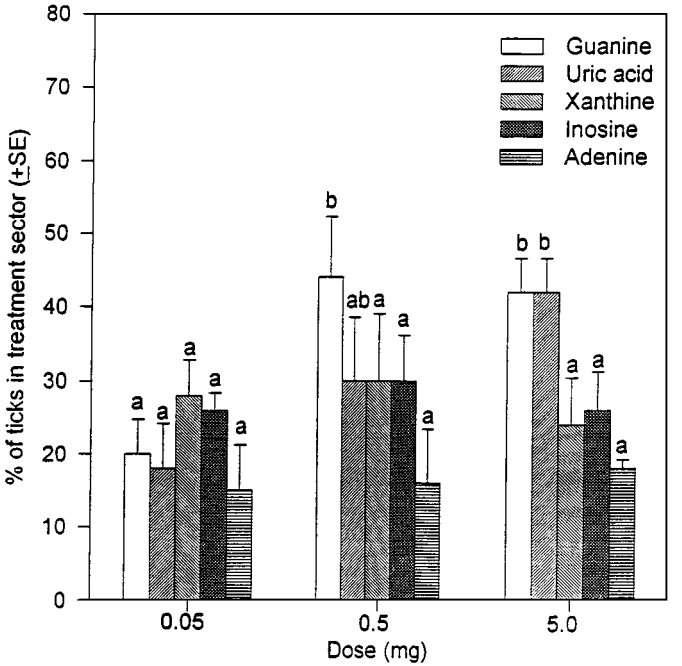

FIG. 2. Responses (mean ± SE) of *I. scapularis* nymphs to different concentrations of purines in a Petri dish bioassay. Data are averages of 10 means. Within each compound, bars marked by the same letter are not significantly different ($P > 0.05$).

Responses to several purine standards increased with dose when tested against nymphs (Figure 2). Differences in responses with increased dose were observed with guanine ($F = 5.51$, $df = 2, 29$, $P < 0.001$) and uric acid ($F = 3.43$, $df = 2, 29$, $P = 0.04$), but not with adenine ($F = 0.03$, $df = 2, 29$, $P = 0.96$), xanthine ($F = 0.20$, $df = 2, 29$, $P = 0.81$), or inosine ($F = 0.23$, $df = 2, 29$, $P = 0.29$).

Responses of nymphs to a range of concentrations of a mixture of guanine, xanthine, and adenine (25:1:1 ratio) differed (Figure 3) ($F = 2.55$, $df = 4, 74$, $P = 0.04$). Mixtures consisting of purines at 10.0, 1.0, and 0.1 mg elicited the highest responses (Figure 3). Responses of nymphs to cast skins were not different than responses to 10 mg and 1 mg (t test, $P > 0.05$) of purine mixtures, but were greater than other the other concentrations of purine mixtures tested (t test, $P < 0.05$).

DISCUSSION

This study provides clear evidence of an assembly pheromone in *Ixodes scapularis*. Similar to other reported assembly pheromones in ticks (summarized

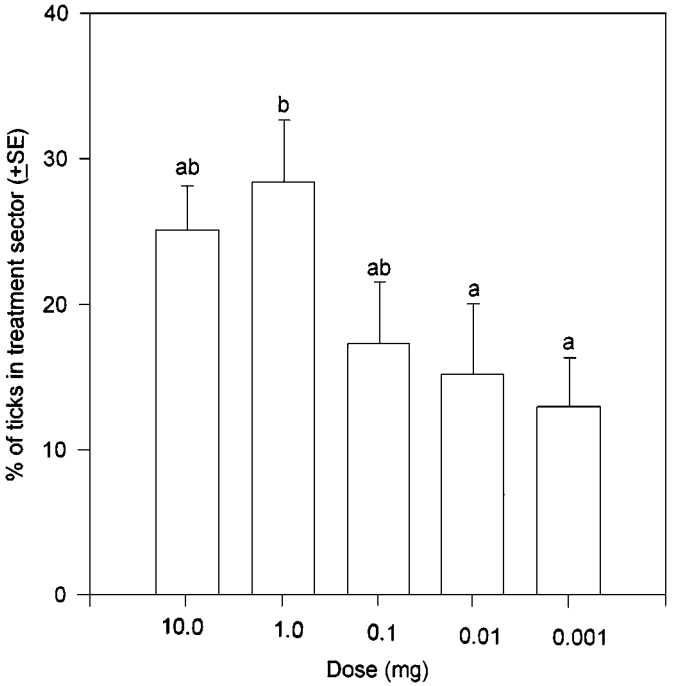

FIG. 3. Responses (mean ± SE) of *I. scapularis* nymphs to different concentrations of a mixture of guanine, xanthine, and adenine in a 25:1:1 ratio. Data are averages of 10 replicates in Petri dish bioassays. Bars marked by the same letter are not significantly different ($P > 0.05$).

in Sonenshine, 1991), arrestment responses were elicited by tick waste products (excreta and cast skins), responses could be elicited by saline but not organic solvent extracts, and responses were not stage-specific, with significant responses elicited from males, females, and nymphs. Additionally, equivalent assembly responses could be elicited in both nymphs and adults to several purine compounds previously identified as components of assembly pheromones in soft ticks (Dusbábek et al., 1991a).

Excretion of nitrogenous waste products by ticks generally occurs after blood-feeding and immediately after molting (thus contaminating the cast skins). Locations with an accumulation of excretory products are likely conducive to tick survival as these indicate successful completion of blood feeding and molting and have appropriate environmental conditions for tick survival (Otieno et al., 1985). Although there may be differences in sites of molting of different stages of *I. scapularis*, arrestment of tick movement in sites containing excretory products may result in assemblies of ticks of different stages since assembly pheromones are

nonspecific in activity. Although activity is nonspecific, there may be differences in quantities and mixtures of constituents produced between different stages. This study was conducted using cast skins from blood-fed larvae because of their use in previous studies and the ability to produce large numbers of them.

Nitrogenous waste products from ticks contain primarily guanine, other purines in lower concentrations and hematin (Hamdy, 1972, 1973). Dusbábek et al. (1991a) reported the relative abundance of guanine, xanthine, and hypoxanthine in excretory granules of five soft tick species. Several studies associated the observed assembly behaviors with excretory wastes of ticks (Leahy et al., 1973, 1975; George, 1981; Hájkova and Leahy, 1982; Otieno et al., 1985; Dobrotvorskii et al., 1991) as well as mites (Entrekin and Oliver, 1982; Arlian and Vyszenski-Moher, 1996). Aggregation in response to guanine was demonstrated in *Argas persicus* (Otieno et al., 1985), *Argas walkerae* (Neitz and Gothe, 1984), and *Argas persicus* (Hassanali et al., 1989). Response to guanine alone was reported by Gothe (1987) to be lower than to naturally occurring pheromone, supporting the idea that additional components may be present. Other compounds such as xanthine, hypoxanthine, and uric acid also elicited significant responses with response levels high in Otieno et al. (1985) (>75%). In addition to guanine, Dusbábek et al. (1991a) also reported significant assembly responses (>55%) of *A. persicus* males to xanthine, hypoxanthine, and inosine. Compounds tested that did not elicit assembly of ticks included adenine (Otieno et al., 1985; Dusbábek et al., 1991a), adenosine, guanosine, and uric acid (Dusbábek et al., 1991a). Several of these compounds, however, were reported to elicit assembly responses in *Sarcoptes* mites (adenine, uric acid) (Arlian and Vyszenski-Moher, 1996). Our data provide clear evidence that guanine, uric acid, hypoxanthine, xanthine, inosine, and hematin elicit assembly responses in *I. scapularis* in immatures and adults. However, whether any of these compounds occur in *I. scapularis* excreta and if so, their relative frequency, has yet to be determined.

Mixtures of purines appeared to elicit more assembly in the soft tick, *A. persicus*, compared to the purines alone (Dusbábek et al., 1991a). A mixture of guanine, adenine, and xanthine mixed in a ratio of 25:1:1 enhanced assembly of ticks equivalent to about 75% of the natural pheromone. Our data indicate that assembly of *I. scapularis* to a similar mixture of purines appears to be dose-dependent, and the highest responses to mixtures are equivalent to those of cast skins. The future identification of components and ratios in extracts may aid in further enhancement of assembly response in purine mixtures for *I. scapularis*.

Ixodes scapularis has emerged as a common suburban pest in the northeastern United States with the increased encroachment of communities into wooded areas (Lastavica et al., 1989; Carroll et al., 1992). Human risk for Lyme disease depends on the density of infected ticks as well as the degree of human–tick contact (Mather et al., 1989) with most risk associated with exposure to nymphs in summer (Spielman et al., 1985). Most tick control strategies are areawide and

do not specifically target ticks. The identification of assembly pheromones in *I. scapularis* can provide the basis for development of an alternative targeted control with the potential to reduce overall acaricide use and nontarget effects. The potential for such an approach was demonstrated by initial studies by Dusbábek et al. (1997), who reported the enhancement of efficacy of permethrin against immatures and adults of *A. persicus* when used in conjunction with guanine hydochloride.

Future research is needed to identify components in saline extracts containing the assembly pheromone and to determine a mixture of components equivalent in response to natural pheromone. Formulation of such components, in conjunction with an acaricide and perhaps also with volatile attractant compounds, may serve as the basis for development of a targeted control approach for *I. scapularis*.

(Received February 27, 2001; accepted September 2, 2001)

Abstract—The behavioral responses to urine and ovarian fluids from conspecific and heterospecific ovulated females were studied in mature Atlantic salmon (*Salmo salar*) male parr in a two-choice fluviarium. The males reacted differently to the stimulants. They spent more time in water scented by urine from salmon or brown trout (*Salmo trutta L.*) females compared to the time in water with ovarian fluids from salmon females. Furthermore, the males were attracted to salmon female urine (different from an indifferent reaction). Males exposed to urine of either species had higher plasma concentrations of testosterone (T) compared to unexposed controls. Measurement of the concentrations of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and its major metabolite 15-ketodihydroprostaglandin $F_{2\alpha}$ (15-ketodihydro-$PGF_{2\alpha}$) showed that the concentrations of the substances were higher in ovarian fluids of both species compared to those in urine. $PGF_{2\alpha}$ showed a greater difference between ovarian fluid and urine than its major metabolite. The results suggest that urine of both species, in contrast to ovarian fluid, contain substances that attract mature Atlantic salmon male parr and that the active substances are neither $PGF_{2\alpha}$ nor 15-keto-$PGF_{2\alpha}$.

Key Words—Atlantic salmon, *Salmo salar*, brown trout, salmonids, sex odorants, precocious males, behavior, attraction, steroid hormones, pheromones.

INTRODUCTION

Previous studies have shown that mature salmonid females release odorants that affect the endocrine status (priming effect) and behavior (releasing effect) of mature conspecific males (for terminology see Liley, 1982). It has been previously shown that urine contains substances with priming effects in rainbow trout (*Oncorhynchus mykiss*) (e.g., Scott et al., 1994) and in Atlantic salmon (*Salmo salar*) (e.g., Waring et al., 1996). The males showed increased plasma sex steroid hormone levels, and this was frequently combined with enhanced volumes of milt. Other studies have given various results concerning the behavior responses of salmonid males to urine and ovarian fluids. Emanuel and Dodson (1979) induced upstream movements of rainbow trout males following exposure to ovarian fluids. Furthermore, Honda (1980, 1982) showed that odorants in the ovarian fluid of Pacific salmon stimulated different reproductive behaviors in males, and species specificity was suggested. Recent studies have shown that mature masu salmon males were attracted to water scented with urine from ovulated females, while ovarian fluids had no effect (Yambe et al., 1999). These contradicting results suggest that substances with effects on the male behavior are present both in the ovarian fluids and female urine, but the active source varied between the studies.

Recently we observed that mature male parr of Atlantic salmon and brown trout (*Salmo trutta*) were primed by odorants from ovulated females of either species (Olsén et al., 2000). The ovulated female stimulants, composed of odorants from a mixture of ovarian fluid and urine, were not species specific in these closely related species. Later we observed that both urine and ovarian fluid increased plasma sex steroid levels in mature male Atlantic salmon parr (Olsén et al., 2001). Both stimulants contained prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), that has been proposed to have a priming effect in mature Atlantic salmon parr (Moore and Waring, 1996). We have also shown that the plasma sex steroid hormones and volumes of strippable milt are increased in mature brown trout parr after exposure to F-prostaglandins (A. Moore, K. H. Olsén, and H. Kindahl, unpublished data).

In view of the above results, further studies are needed to determine whether both female urine and ovarian fluid are a source of releaser odorants in salmonids. In the present experiment, we studied the behavior and endocrine responses of mature Atlantic salmon parr exposed to low concentrations of urine or ovarian fluid from conspecific ovulated females, or from ovulated females of anadromous brown trout. We aimed at answering the questions: Are there any differences in response to urine and ovarian fluid and do salmon parr males respond differently to stimulants from conspecific and heterospecific females?

METHODS AND MATERIALS

Collection of Female Stimulants. Urine and ovarian fluids were collected by catheters from anesthetized (2-phenoxy ethanol, 0.05%) ovulated Atlantic salmon and brown trout females (Atlantic salmon: 80–107 cm T.L., 5.4–14.1 kg, $N = 8$; brown trout: 60–85 cm total length, 2.4–7.4 kg, $N = 17$) at the Älvkarleby hatchery on the River Dalälven. Both urine and ovarian fluids were taken from each female. The urine and ovarian fluids were collected in 20-ml polythene tubes on ice, and then stored at -80° C. Care was taken to prevent contamination between the two fluid types and involved using separate catheters. It was easy to fill the tubes with ovarian fluid, but the amounts of urine were often less than 10 ml. Prior to freezing, 0.5–1.5 ml of both fluids from seven females were decanted into microfuge tubes for analyses of $PGF_{2\alpha}$ and 15-Keto-dihydro-$PGF_{2\alpha}$ concentrations in individual fish. The remainder of the ovarian fluid and urine samples was pooled into an ovarian fluid mix and a urine mix, respectively, and frozen in aliquots suitable for the experiments.

Experimental Procedure. On October 13, 1999, one week before the start of the experiment, male parr with running milt were collected at Älvkarleby salmon hatchery and transported to Uppsala University and placed in 400-liter rearing tanks. Aerated tap water was continuously supplied and the photoperiod followed the natural cycle. Fish were fed Astra EWOS salmon feed. Individual fish (29.7–75.5 g, $N = 36$) were tested in a fluviarium at the Department of Environmental Toxicology (Höglund, 1961; Olsén, 1987; Bjerselius et al., 1995a,b) during the period October 20 to November 30, 1999. The fluviarium is an artificial stream with a laminar flow of aerated tap water. Water, with or without test stimulants, was supplied to opposite halves of the fluviarium and mixed into the main stream of aerated tap water flowing to the test area at a total rate of 18 liters/min (9 liters in each half) (Bjerselius et al., 1995a). The temperature in the fluviarium decreased during the experimental period from 10.7 to 9.2°C. Individual fish were placed in the test area within the fluviarium measuring, $46 \times 33 \times 11.5$ cm (L × W × D), formed by inserting two fine-mesh plastic screens. The test stimuli were released from 12-liter stainless steel containers by means of two peristaltic pumps, at the rate of 60 ml/min through two separate magnetic valves. Female stimulants were supplied from one container and only water from the other. In control tests, water was supplied from both. To ensure good mixing into the main stream, the supply of test stimuli from the stainless steel containers were mixed with a small supply of constantly flowing tap water (100 ml/min) through the magnetic valves. The supply in the fluviarium was also directed upstream. The two magnetic valves automatically switched the supply between the two halves of the test area at regular 90-min intervals. Then 4 ml of female stimulants (either salmon urine, trout urine, salmon ovarian fluid, or trout ovarian fluid) was supplied to 11 liters of water in the stainless steel container. Mixing in the main currents of the fluviarium was tested

using a green dye, and this showed that there was a sharp boundary line between the green-dyed and the nondyed sides in the test area.

A video camera was placed above the test area, and the position of the fish was recorded once every 2 sec by means of a video-computer image analysis system (EthoVision, Noldus Information Tech., Wageningen, The Netherlands) (Bjerselius et al., 1995a,b; Olsén and Winberg, 1996). Two 20-W halogen lamps equipped with a red glass filter (RG 780, Melles Giro) that allowed only transmission of wavelengths longer than 750 nm (beyond the visual range of salmonid fish) (Bone et al., 1995) were used as a light source for the camera. A full test started at 16:30 hr and ended at 07:30 hr the next morning. No stimuli were added during the first six 90-min periods (16:30–01:30 hr), but started at 01:30 hr and lasted until 07.30 hr. The water going through the magnetic valves shifted sides in the fluviarium every 90 min from the start to the end of the experiment (16:30–07:30 hr). It was only during the last four 90-min periods (01:30–07:30 hr) that the pumps added water with female stimulants or only water (control). The pumps ran every alternate 15-min period, starting at 01:45 hr, thereby giving three 15-min periods of stimulant release over each 90-min period. The intermittent pumping was intended to mimic the pulsatile nature of urine release female salmon (Curtis and Wood, 1991).

To reduce the risk of disturbance, the experiments were performed during the night. The stainless steel containers and the silicone medical grade tubes that supplied stimulants were rinsed with tap water, 95% ethanol, and tap water again after each test. The fluviarium was drained after each test and brushed with water and 95% ethanol.

For each fluviarium test, we used data collected for the 15-min periods between 01:30 and 07:30 hr, which corresponded to those periods of stimulant release, in addition to the corresponding periods during 19:30–01:30 hr. Based on the observations collected during these periods, a reaction value (R_v) was calculated for the periods 19:30–01:30 hr and 01:30–07:30 hr, respectively. R_v was calculated according to the following equation (Olsén, 1986):

$$R_v = [(N_L - N_0)/(N_L + N_0)] \times 100$$

where N_L and N_0 during 01:30–07:30 hr represent the number of observations in each side of the test area when supplied with water containing female stimulants, or water only, respectively. During the period 19:30–01:30 hr, only water without help from the pumps passed through the magnetic valves. The arithmetic means of reaction values from identical tests are designated MR_v. A positive R_v during 01:30–07:00 hr means that the fish spent more time in the half of the fluviarium with the stimulant added than in the side with tap water added from the second stainless steel tank. A positive R_v during 19:30–01:30 hr means that the fish were more frequently observed in the half that was supplied through the magnetic valve that later (01:30–07:00 hr) was supplied with stimulant.

Blood Sampling. After each fluviarium test, blood was sampled from all fish as follows. For each sample, the male parr was first anesthetized (2-phenoxyethanol, 0.05%), weighed, and the volume of milt determined by collecting it in preweighed glass tubes following gentle abdominal pressure (Olsén and Liley, 1993). Blood was subsequently collected by severing the caudal peduncle and collecting the blood in heparinized tubes. The fish were humanely killed after blood sampling. Following centrifugation, the plasma was collected and stored at -80°C for future sex steroid determination. The testes were weighed for the determination of gonadosomatic index [GSI (gonad weight/body weight) $\times$ 100].

Hormone Measurements. Plasma levels of 11-ketotestosterone (11-KT), testosterone (T), and 17α,20β-dihydroxy-4-pregnen-3-one (17,20β-P) were measured by specific radioimmunoassay (RIA) according to the method described by Mayer et al. (1990).

The metabolite of prostaglandin $F_{2\alpha}$, 15-ketodihydro-$PGF_{2\alpha}$, was analyzed in unextracted media by RIA (Kindahl et al., 1976; Granström and Kindahl, 1982). The antiserum cross-reacted 16% against 15-keto-$PGF_{2\alpha}$, 4% against 13,14-dihydro-$PGF_{2\alpha}$, 0.4% against $PGF_{2\alpha}$, and 1.7% with 15-ketodihydro-PGE_2, a major metabolite of PGE_2. For other prostaglandins tested, the cross-reaction was $<$0.1%. The samples were diluted in a 0.25% bovine γ-globulin buffer. In most cases, 50 μl of media was diluted with 450 μl of the buffer. The practical detection limit of the assay was 300 pmol/liter. If necessary, the samples were diluted to allow accurate readings on the standard curve. The interassay coefficient of variation was 14%. Samples were reanalyzed if the coefficient of variation exceeded 10% for the duplicate determinations. The intraassay coefficient of variation was evaluated by analyses of 10 different pooled plasma samples in five separate radioimmunoassay tubes and was between 3.4% and 7.6% at different ranges of the standard curve.

The primary prostaglandin $F_{2\alpha}$ was analyzed in the media by a modified method according to Lindgren et al. (1974). The samples were diluted in the same way as for the analysis of 15-ketodihydro-$PGF_{2\alpha}$ as described above. The antiserum against $PGF_{2\alpha}$ cross-reacted 75% against $PGF_{1\alpha}$, 2% against $PGF_{2\beta}$, 1.5% against $PGF_{1\beta}$, and $<$0.1% for PGE_2, PGE_1, PGD_2, TXB_2, and 15-ketodihydro-$PGF_{2\alpha}$. The practical limit of detection for $PGF_{2\alpha}$ was 0.3 nmol/liter. The interassay coefficient of variation was 15% and the intraassay coefficients of variation varied between 7.3% and 12.5% at different ranges of the standard curve.

Statistical Analyses. Reaction values, plasma hormone concentrations, milt volumes, and GSIs were compared among treatments with a one-way ANOVA. In cases of significance, the ANOVA was followed by post tests. The behavior analyses were followed by Newman-Keuls multiple comparison test. Dunnett's test was used when comparing the plasma steroid hormone levels in males to different exposures with the concentrations in unexposed control males. The calculations were performed with GraphPad Prism (Motulsky, 1995, 1999).

Student's *t* test was used when the MR_{vs} from fluviarium tests were compared with the theoretically indifferent reaction, i.e., when $MR_v = 0$. MR_v is zero when the number of observations in each water quality is the same.

RESULTS

Behavior. ANOVA showed that there were significant differences in behavior among the different treatments ($F_{4,31} = 3.751$, $P = 0.0133$). Newman-Keuls test revealed differences between the responses to salmon urine and ovarian fluid from salmon ($q = 3.986$, $P < 0.05$) and between trout urine and salmon ovarian fluids ($q = 4.654$, $P < 0.05$) (Figure 1).

Males were attracted to female salmon urine (MR_v was different from an indifferent response when $MR_v = 0$) (Figure 1). No behavioral responses were observed with the other stimulants. Neither was there any preference for either of the two channels entering through the magnet valves to either side of the fluviarium before the supply of stimulants (within 90-min periods 3–6).

Blood Plasma Levels of Sex Steroids. A one-way ANOVA showed that there were significant differences in plasma T levels among the males undergoing different treatments ($F_{4,31} = 3.186$, $P = 0.0265$). The males that had been in contact with salmon or trout female urine had higher plasma concentrations of T than control males (Figure 2). Treated males were only compared with control males (Dunnett's test). No differences in plasma concentrations of 17,20β-P or 11-KT were observed among males given different treatments (17,20β-P: $F_{4,31} = 1.268$, $P > 0.05$; 11-KT: $F_{4,31} = 1.295$, $P > 0.05$).

Milt Volumes and GSI. No differences in volumes of strippable milt were observed between the controls and the fish exposed to the different female odors (milligrams of milt per gram of fish; mean $\pm$ SD; control: 28.3 ± 14.8, $N = 8$; salmon urine: 34.2 ± 12.9, $N = 7$; salmon ovarian fluid: 32.9 ± 9.4, $N = 7$; trout urine: 32.7 ± 16.8, $N = 7$; trout ovarian fluid: 25.4 ± 7.4, $N = 7$; $F_{4,31} = 0.60$, $P > 0.05$). There were also no differences in GSI (control: 9.1 ± 1.6, $N = 8$; salmon urine: 9.4 ± 1.4, $N = 7$; salmon ovarian fluid: 9.8 ± 0.8, $N = 7$; trout urine: 10.1 ± 1.8, $N = 7$; trout ovarian fluid: 9.0 ± 0.7, $N = 7$; $F_{4,31} = 0.94$, $P > 0.05$).

Prostaglandin Concentrations in Urine and Ovarian Fluid. Seven females of each species were analyzed. The median concentration of $PGF_{2\alpha}$ in the urine of salmon was 11.4 nmol/liter (range 5.4–16.1 nmol/liter). All samples of ovarian fluid from salmon contained $PGF_{2\alpha}$, with concentrations over 200 nmol/liter. In trout females, the median concentration of $PGF_{2\alpha}$ in urine was 0.4 nmol/liter (range 0.3–8.4 nmol/liter). In ovarian fluid, the concentrations of $PGF_{2\alpha}$ were greater than 200 nmol/liter in all but two samples, which had levels of 117 and 153 nmol/liter. The median concentration of 15-ketodihydro-$PGF_{2\alpha}$ in salmon

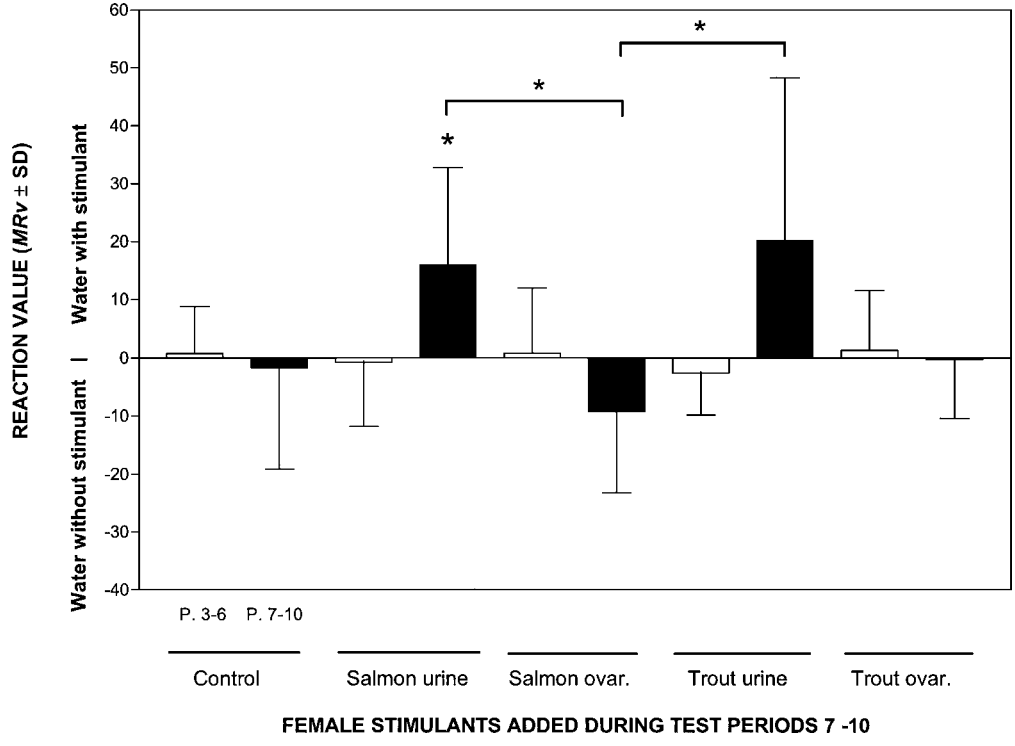

FIG. 1. Reaction value ($MR_v \pm$ SD) of mature Atlantic salmon male parr exposed to water scented by urine or ovarian fluid from conspecific or brown trout females. Only tap water was used in control tests. Positive MR_v means that the test fish is attracted to the stimulant. A significant difference between treatments is denoted by asterisk. An asterisk above the bar states that the MR_v was significantly different from an indifferent reaction when $MR_v = 0$. The open and solid columns represent the reaction values during the test periods 3–6 and 7–10, respectively. Seven fish were used for each treatment, except for controls which used eight. $^*P < 0.05$.

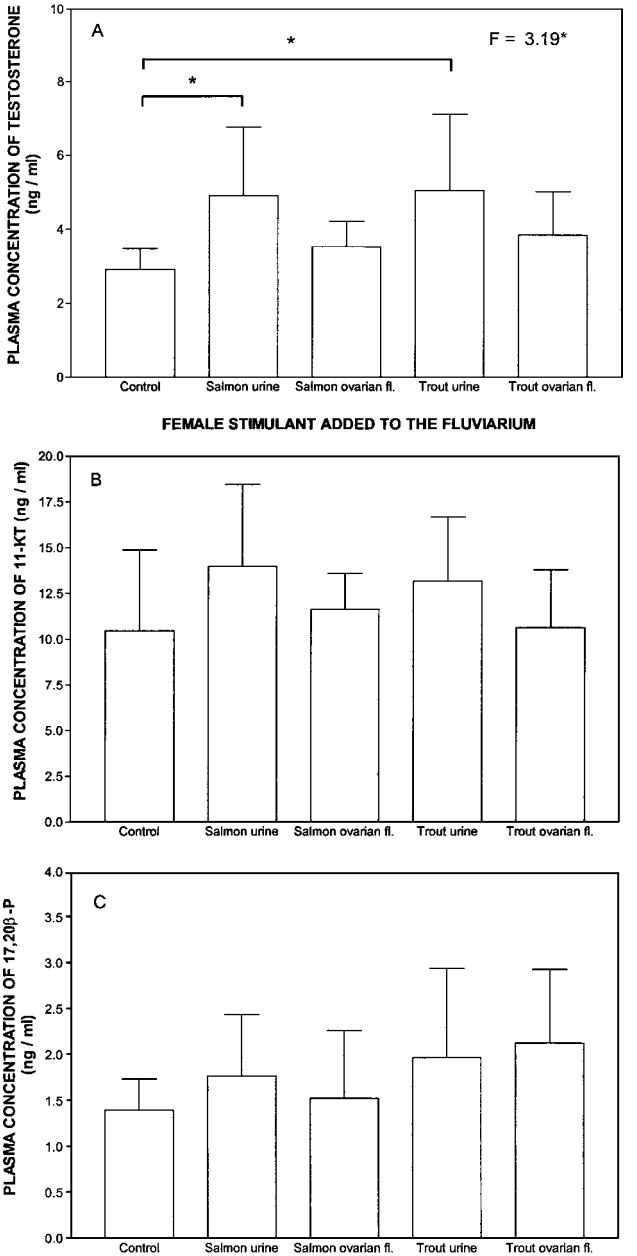

FIG. 2. Plasma steroid hormone levels are shown in mature Atlantic salmon male parr after exposure to urine or ovarian fluid from conspecific or heterospecific ovulated females or only to tap water (control) in fluviarium tests. The hormone levels after each exposure were compared to the control. The same number of fish used as in Figure 1. Values are mean $\pm$ SD, $^*P < 0.05$.

urine and ovarian fluid was 2.0 nmol/liter (range 1.3–5.5 nmol/liter) and 19.5 nmol/liter (range 15.6–48.0 nmol/liter), respectively. In trout females, the median concentration of the metabolite was 0.7 nmol/liter in urine (range 0.2–1.1 nmol/liter) and 2.6 nmol/liter in ovarian fluid (range 1.0–5.7 nmol/liter).

DISCUSSION

The present study shows that urine from ovulated females contains odorants that attract mature Atlantic salmon male parr. The ovarian fluids of both species were not attractive and, if anything, were somewhat repellent. The males that were exposed to urine of both species had higher plasma concentrations of T compared to the controls. These results are in agreement with those of Yambe et al. (1999) on masu salmon. They showed that attractants are present in the urine of ovulated females, but not in ovarian fluid. Furthermore, the male masu salmon were not attracted to the prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which also agrees with our results with salmon parr (Olsén et al., 2001). In contrast, $PGF_{2\alpha}$ has been shown to be a female attractant in Arctic charr (*Salvelinus alpinus*) (Sveinsson and Hara, 1995). Yambe and Yamazaki (2000) also found that juvenile masu males treated with methyl-testosterone were attracted to ovulated female urine. In the present study, the higher plasma concentrations of T were probably caused by the urine exposure. Previous studies have shown that exposure to female urine (Waring et al., 1996), or a mix of urine and ovarian fluid (Olsén et al., 2000), increases the plasma sex steroid levels and the volumes of strippable milt in mature Atlantic salmon male parr. Results have suggested that $PGF_{2\alpha}$ is the priming chemical in Atlantic salmon or is an important part of it (Moore and Waring, 1996; Olsén et al., 2001). In addition to urine, ovarian fluid also has a priming effect on salmon male parr, and both stimulants contain $PGF_{2\alpha}$ (Olsén et al., 2001). The dilution steps of urine and ovarian fluid in the present study should have resulted in low concentrations of $PGF_{2\alpha}$ in the fluviarium. We observed that the concentration of $PGF_{2\alpha}$ was at least 20 times higher in ovarian fluid than in urine of Atlantic salmon females. In brown trout, the concentration was 500 times higher in the ovarian fluids. In an earlier study, we observed that the concentration of $PGF_{2\alpha}$ in ovarian fluid of Atlantic salmon was about a 1000 times higher than in urine (500 nmol/liter vs 0.4 nmol/liter) (Olsén et al., 2001). Based on these measurements, the concentrations of $PGF_{2\alpha}$ should have been about 1 pM and 0.001–0.1 pM in the test area with ovarian fluid and urine, respectively. These concentrations are probably too low to be detected by males (Moore and Waring 1996; K. H. Olsén, P. W. Sorensen, and C. Murphy, unpublished data). The results suggest that $PGF_{2\alpha}$ is not the female urine attractant for Atlantic salmon male parr. The active attractants in our study appear to be present in significant concentrations only in the urine. The results also suggest that $PGF_{2\alpha}$ is not the priming chemical

that gave increased plasma testosterone concentrations after urine exposure but not after ovarian fluid.

To date, very few chemicals released by female fish that have an effect on the behavior of conspecific males have been identified. F-type prostaglandins induced reproductive behavior in goldfish (*Carassius auratus*) (e.g., Sorensen et al., 1989) and cobitid loach (*Misgurnus anguillicaudatus*) (Kitamura et al., 1994), and steroid glucuronides are active as releaser pheromones in the African catfish *Clarias gariepinus* (Resink et al., 1989). In masu salmon, the female attractant present in urine is not a free steroid or $PGF_{2\alpha}$ (Yambe et al., 1999).

At present, we do not know the chemical identity of the active attractants in Atlantic salmon and brown trout female urine. One candidate might be T, which is detected by the olfactory epithelium in mature male Atlantic salmon parr at concentrations as low as 10^{-14} M (Moore and Scott, 1991) and has been shown to act as an attractant to the males (Moore, 1991). Moore and Scott (1992) also referred to unpublished data that female urine induced positive rheotactic behavior in precocious Atlantic salmon male parr, similar to that induced by T. The next step in our study will be to analyze the release of different conjugated steroids in the urine of females and test their potency as attractants in mature male parr. Salmonids release both free steroid hormones and their metabolites in the urine (c.f. Scott and Liley, 1994).

In summary, the present study shows that urine from ovulated female salmon and possibly brown trout, contains a chemicals that attract mature male salmon parr and stimulates increased plasma testosterone levels. Ovarian fluid appears to not have such effects. Furthermore, we do not have any evidence that $PGF_{2\alpha}$ is the active substance.

Acknowledgments—The experiment was funded by The Swedish Council of Forestry and Agricultural Research (SJFR, to K.H.O) and by The Carl Trygger's Foundation for Scientific Research (to K.H.O.). Steroid antisera were kindly provided by Dr. R. W. Schulz (Utrecht University). We are indebted to Mr. Bjarne Ragnarsson and the rest of the staff at the Fisheries Research Station, Älvkarleby, for catching and letting us take samples from the adult fish. We also thank Mrs Katrin Lundstedt-Enkel for valuable assistance during some of the tests.

(Received March 1, 2001; accepted September 10, 2001)

Abstract—In many species, chemical signals are important in the context of intraspecific communication. European badgers (*Meles meles*) use the secretion of their subcaudal gland to mark both the environment and conspecifics. In this paper, we investigated the chemical composition of subcaudal gland secretions and how it varies among individuals according to group membership, season, sex, age, body condition, and reproductive status. We analyzed 66 samples by gas chromatography using a mass-spectrometer as detector. We found 110 different components, of which 21 were present in every profile. The chemical composition of the secretions proved to be highly individual-specific, but no single peak was found to be typical for one of the investigated categories (season, sex, etc.). Analyses of the relative area (% area) that every peak contributed to the overall profile area showed that, in general, group members have more similar profiles than do badgers from different groups. Composition varied over seasons and between sexes and was influenced by age, body condition, and reproductive status. We, therefore, conclude that the secretion not only encodes group membership and individuality as previously assumed, but might also convey information about fitness-related parameters.

Key Words—Badger, body odor, carboxylic acid, chemical communication, individuality, Mustelidae, chemical signal, scent-marking, semiochemistry.

INTRODUCTION

The subcaudal gland of the European badger (*Meles meles*) is a large skin gland, that is unique to this species (Brown and Macdonald, 1985). Sebaceous (holocrine) and sudiferous (apocrine) secretory tissues empty their pastelike secretion into a common lumen, the subcaudal pouch, which opens into the environment through a 20- to 80-mm-wide horizontal slit situated between the tail and the anus. In this paper, we report on the kind of information that is likely to be contained in the subcaudal secretion, and how chemical composition varies according to individuality, group membership, season, sex, and fitness-related parameters ("fitness"), such as age, body condition, and reproductive status.

Badgers use subcaudal gland secretions to scent-mark conspecifics (allomarking; Buesching et al., unpublished data), bedding material and other objects, the ground around their sett, paths, and latrines (object-marking; Buesching, 2000). A number of functions have been suggested for subcaudal scent-marking, including territorial signaling (Kruuk, 1978), group membership (Gorman et al., 1984), individual recognition (Kruuk et al., 1984), and fitness advertisement (Buesching and Macdonald, 2001). However, the chemical information encoded in subcaudal secretions is not yet fully understood. The only analytical study based on gas chromatography (Gorman et al., 1984) confirmed interindividual differences in the chemical profiles and showed the existence of group-specific characteristics in the scent profiles, thus suggesting that badgers can obtain information about individuality and the group membership of conspecifics from subcaudal scent-marks. Yet, despite significant sex- and fitness-related differences in the secretion color throughout the year (Buesching et al., 2002a), the above-mentioned study failed to show any sex- or fitness-related differences in the chemical profiles. One possible explanation for this result could be that Gorman et al. (1984) compared samples collected at different times of the year. Hence, possible sex- and fitness-related characteristics might have been obscured by overlying seasonal variation. The aim of the present study is, therefore, to compare samples collected within the same calendar month and to investigate whether differences in the chemical profiles can be related to season, sex, and "fitness."

METHODS AND MATERIALS

Study Animals and Collection of Samples. A total of 66 samples were collected from 35 females and 31 males during four trapping events between January and November 1998 from a badger population in Wytham Woods, Oxfordshire, England (Ordnance survey reference: SP462080; for detailed description of the study site see Kruuk, 1989). Cubs (i.e., individuals younger than 1 year) were not included in this study. Badgers were trapped following the methodology described

by MacDonald and Newman (2001). At first capture (usually as cubs), all individuals were tattooed with an individual number on the left inguinal region. Thus, after anesthesia with 0.2 ml ketamine hydrochloride (Vetalar, Pharmacia and Upjohns Ltd., Crawley, E. Sussex, UK) per kilogram body weight (Hunt, 1976), all badgers could be identified individually, sexed, and aged [category 1, cubs younger than 1 year (*excluded from this study*); 2, yearlings 1–2 years old; 3, adults 2–5 years old; 4, adults older than 5 years], and their body condition determined using a subcutaneous fat score originally developed for sheep (with 1 being emaciated and 5 being in very good condition; modified from Speedy, 1980). In males, reproductive status was determined by the degree to which the testes were descended from the body cavity into the scrotum (Woodroffe and MacDonald, 1995) and classified as 1, fully descended testes: in breeding condition; 2, intermediate: reproductive activity could not be determined unambiguously; and 3, completely retracted testes: not in breeding condition. In females pregnancy was determined by ultrasound scans (Kontron: external 5.0 MHz sector probe) in winter, and in spring, teats were measured for length and diameter to determine (recent) lactation (Cheeseman et al., 1987; Woodroffe, 1993), if no milk could be expressed.

Secretion was scooped out of the subcaudal pouch using a rounded stainless steel spatula. All samples were frozen immediately and stored in glass vials at -70°C for a maximum of one year until further analysis.

Gas-Chromatographic Analyses. Samples were analyzed using a Hewlett-Packard 5890A gas chromatograph (GC) with a polydimethylsiloxane column (25 m $\times$ 0.32 mm ID, 0.5-μm film thickness) and a Hewlett-Packard mass spectrometer (MS; HP5970 Series Mass Selective Detector) as detector.

After solvent extraction with hexane (approx. 1 g secretion in 0.2 ml hexane), the extract was left to settle for approx. 3 min. The supernatant was transferred into a second glass vial and mixed with one spatula tip of dried magnesium sulfate to trap the water content. The extract was filtered through a syringe filter (0.2-μm pore size) and injected directly into the column (1 μl; start temperature 40°C; temperature rise 8°C/min; end-temperature 200°C for 10 min with a solvent delay of 2 min). After each sample, the GC was heated to 240°C for 10 min, and after every four samples, a blank was run to ensure that no contamination was left in the column. Results were saved automatically using the Hewlett-Packard software G1034C version C.03.00, and, where possible, chemical compounds were identified by their retention times and mass spectra.

Statistical Analyses of GC Profiles. To compare different profiles, peaks were matched by their retention times and mass spectra. Injection of a mixture of nine standard acids (tetranoic, hexanoic, linoleic, octanoic, nonanoic, decanoic, undecanoic, dodecanoic, and hexadecanoic acid), and linoleic ethyl ester were used to validate retention times. Compounds were identified primarily from their mass spectra, and without confirmation these identities remain tentative. For some of the components (see Table 1), it was possible to confirm identities by comparison of

[a](*** = components with significant MS peak at 114; ??? as yet unidentified compounds).

GC times with those of authentic compounds. Some peaks (11, 13, 47, 75) could not be identified from mass spectra, and further analytical work is being carried out. The contribution of each peak to the overall area of the whole profile was calculated in percent (% area) and used for analyses. Peaks contributing less than 0.1% to the overall profile area were excluded from all analyses. If a certain peak could not be detected in a given profile, its % area was set as 0.001% to enable further statistical analyses, which would not accept values of zero. Independent samples were used for all analyses (i.e., no individual contributed more than one sample to the data set). Statistical analyses were carried out using Statistica for Windows (Release 4.5, StatSoft Inc. 1993).

RESULTS

In total we found 110 different components, of which 21 were present in all samples (Table 1); 16 components occurred only once in the data set, and 9 were

present in only two individuals. No pattern characterizing any of the categories investigated (sex, season, age, body condition, reproductive status) could be found in the presence/absence of any of the 89 peaks, which was not present in all individuals. Therefore, all analyses, except those concerning group similarities and average peak numbers, were restricted to the 21 shared peaks, which were present in every sample (the majority of which are carboxylic acids) and are listed in Table 1. However, due to overlap between peaks 77, 78, and 79, the respective % area of these three peaks—although present in every profile—could not always be clearly defined. Therefore, their values were combined in all further analyses, except those concerning average numbers of peaks per profile. Peak 83 proved to comprise two different components (heptadecanoic acid and a branched C_{18} acid), that were too similar in their retention times to be separated in this study and are, thus, combined in all analyses.

Compounds were identified primarily from mass spectra, and without confirmation these identities remain tentative. For some of the components (see Table 1), it was possible to confirm identities by comparison of GC retention times with those of authentic compounds. Some peaks (11, 13, 47, 75) could not be identified from their mass spectra. Although several of these components (marked with ??? in Table 1) show a significant peak at 114, they are not carboxylic acids, and their chemical structures are as yet unknown. Although the % area of several of the 21 shared peaks proved to be significantly correlated with one another, no correlation was significant for each of the investigated sex/season subsamples. Therefore, we separately performed all subsequent analyses for each peak.

Individuality. Chemical composition of subcaudal gland secretions proved to be highly individual-specific. The chemical profile of each badger consisted of a unique combination of 23–58 different peaks (average over all samples 33.4 ± 8.05, $N = 66$), and relative % area of all peaks varied highly between individuals (Table 1; Figure 1).

Group Membership. A cluster analysis (unweighted pair-group average) including all peaks (presence/absence and % area) occurring in more than one sample was performed on the secretions of 46 badgers from seven well-defined social groups (Figure 2). Results indicated greater similarities between the profiles of badgers from the same social group than from different groups, which is reflected in the tendency of group members to cluster closer together.

Due to the high number of variables and the influence of other parameters on the composition of subcaudal gland secretions (see below), this analysis can only reveal broad similarities. To investigate further group-related differences in the chemistry of subcaudal gland secretions we performed an ANOVA on the same data set, that showed that four peaks varied between groups (P5: $F\,(df\ 1,2)\ 7,43 = 3.240$, $P < 0.01$; P48: $F\,(1,2)\ 7,43 = 3.892$, $P < 0.005$; P50: $F\,(1,2)\ 7,43 = 2.321$; $P < 0.05$; P90: $F\,(1,2)\ 7,43 = 3.600$, $P < 0.005$).

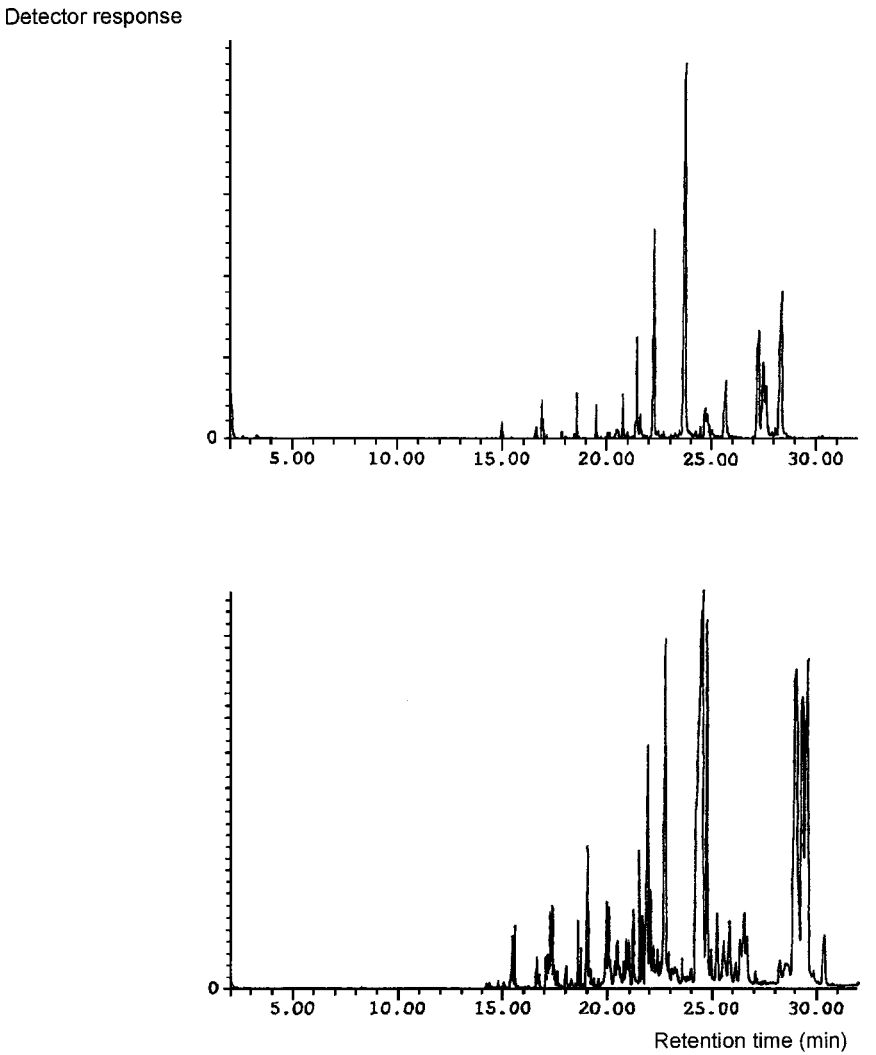

FIG. 1. Gas chromatography profiles of two female badgers of similar age illustrating interindividual variation (capture date: June 20, 1998).

Seasonal and Sexual Variation. The physiology of badgers is strongly influenced by season. The main mating season is between January and March during a post-partum estrous, and cubs are weaned around mid-April (Neal, 1990). A massive weight gain in autumn is followed by gradual decrease in body condition over winter, and badgers usually reach their minimal body weight around August

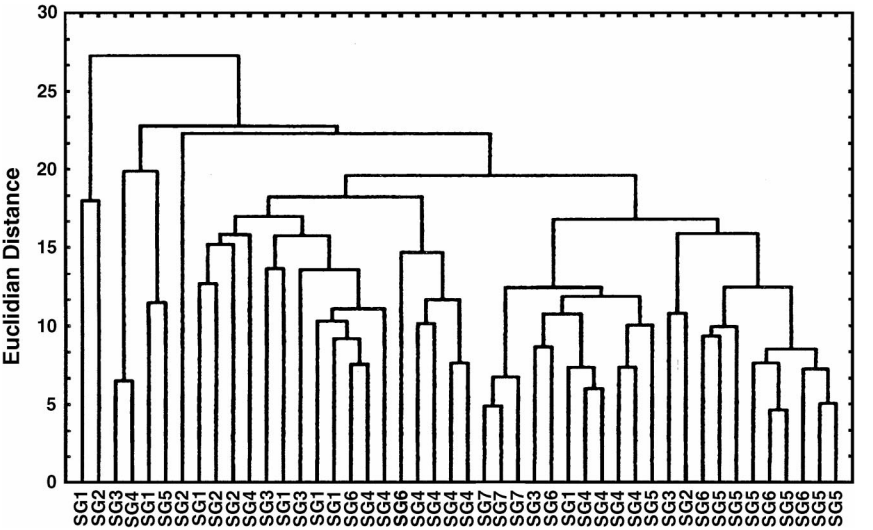

FIG. 2. Dendrogram of cluster analysis for 46 badgers from seven different social groups (SG = social group).

(Kruuk and Parish, 1983). It was noted that extracts derived from summer and autumn samples were far richer in residues (presumably proteins; Gorman et al., 1984), but at the same time much less concentrated in their chemical composition than those derived from winter and spring samples, this resulted in the need to condense by evaporation summer and autumn extracts to approximately 20% of their original volume. However, the experimental design of this study did not allow detailed quantitative analysis of the scent concentration in the samples.

To evaluate the effect of season on the composition of subcaudal gland secretions, we performed a two-way MANOVA with season and sex as factors, and corrected for age and body condition (= covariates). We employed contrast analyses to specify seasonal effects on male and female *secretions* and to test for sexual differences in the chemical composition over seasons (Table 2).

Chemical composition varied over season and between sexes (Table 2). Generally, profiles of female badgers comprised more peaks than did those of males ($x_{\text{females}} = 36.1, x_{\text{males}} = 30.7; U = 390.5, Z_{\text{adj}} = -1.956, P = 0.05$; Mann-Whitney-U test). However, while in males no seasonal differences were found in the number of peaks per profile, females had less complex profiles in spring than in winter ($U = 18$, $Z_{\text{adj}} = -2.583$, $P = 0.01$; Mann-Whitney-U test) and summer ($U = 15$, $Z_{\text{adj}} = -2.136$, $P < 0.05$; Mann-Whitney-U test).

In both sexes, the % area of peak 24 was lowest in winter and highest in autumn, and throughout most of the year it contributed less to the overall profile

TABLE 2. SIGNIFICANT RESULTS OF MANOVA WITH SEX AND SEASON AS VARIABLES[a]

area in males than it did in females. However, this difference was not significant in autumn. The % area of peak 43 showed only little seasonal variation, but was consistently higher in males than in females. This difference was most pronounced in winter ($F = 13.67$, $P < 0.001$). Whereas in females, the relative % area of peak 48 and peak 50 increased consistently throughout the year, in males they stayed on a low level from winter to summer and increased sharply towards autumn. Both peaks were always lower in males than in females. The relative % area of peak 68 showed seasonal variation only in females, but was consistently high in males. During winter, summer, and autumn, its contribution to the overall profile was lower in females than in males. However, in females its % area showed a marked increase in spring, thus reaching the same levels as in males. Strongest sexual differences were found in peak 77–79 (Figure 3). Whereas in females, its % area was low during winter and then climbed to a higher level from spring to autumn, in males it was highest in autumn and winter and reached a relative minimum in spring. Except during winter, these peaks contributed less to the profiles in males than in females. In females, peak 83 peaked in summer, but showed no variation among any other seasons. In males, its % area was lower in spring than in winter, and lower than in summer and autumn. In males, this pattern was also repeated in peak 95, whereas in females it was higher in winter than during other seasons.

Effects of Individual-Specific Parameters. Age showed a strong influence on the chemical composition of subcaudal gland secretions of badgers. The % area of peak 83 was positively correlated with age in both sexes (females: $N = 44$, $R = 0.443$, $P < 0.005$; males: $N = 43$, $R = 0.388$, $P = 0.01$; Spearman rank order correlation), with older (>5 years) individuals having larger % area

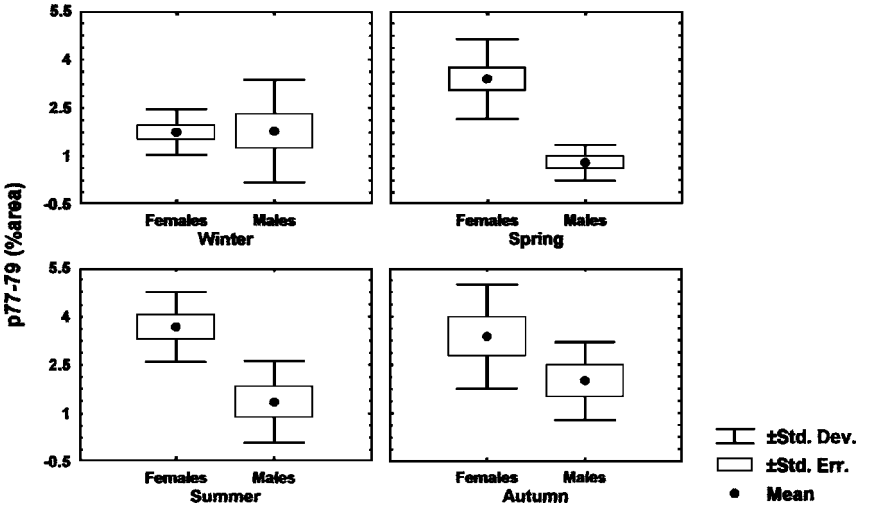

FIG. 3. Sexual differences over season in the % area of peaks 77–79.

than yearlings (females: $U = 15$, $Z_{adj} = -1.967$; $P < 0.05$; males: $U = 7$, $Z_{adj} = -2.061$, $P < 0.05$; Mann-Whitney U test; Figure 4). No relationship between age and average number of peaks per profile became apparent (females: $U = 17.5$, $Z_{adj} = -0.795$, $P = 0.427$; males: $U = 11$, $Z_{adj} = -0.851$, $P = 0.395$; Mann-Whitney U test).

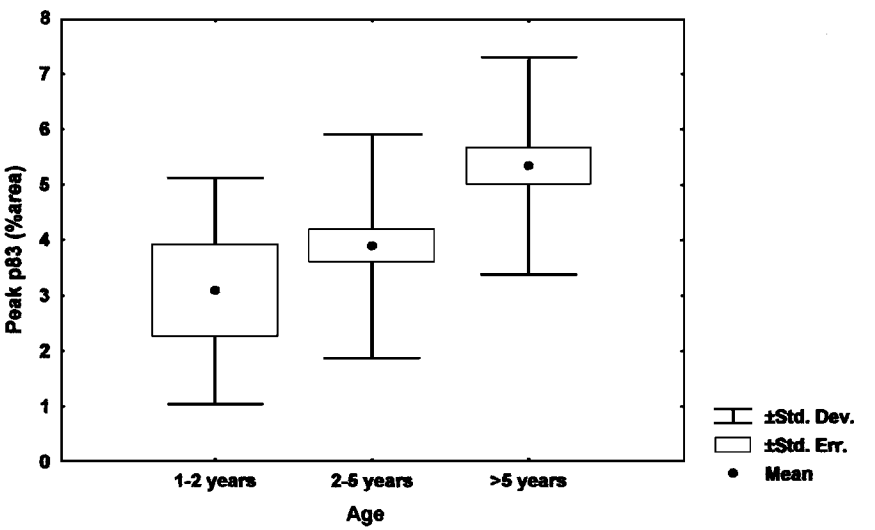

FIG. 4. Correlation between % area of peak 83 and age.

Body Condition was correlated with relative peak areas only in winter and summer. In females, peak 5 ($R = 0.844$, $P < 0.005$) and peak 50 ($R = 0.683$, $P < 0.05$) were positively correlated with body condition in winter, and peak 47 ($R = 0.845$, $P < 0.05$) and peak 75 ($R = 0.845$, $P < 0.05$) in summer. In males, peak 75 ($R = 0.648$, $P < 0.05$) and peak 89 ($R = 0.752$, $P < 0.05$) were correlated with body condition in winter, and peak 56 ($R = 0.850$, $P < 0.05$) and peak 89 ($R = -0.756$, $P < 0.05$; Spearman Rank correlation) in summer. While in females the number of peaks was not related to body condition, males in better body condition had fewer peaks per profile in winter ($N = 9$, $R = -0.684$, $P < 0.05$) and in spring ($N = 9$, $R = -0.872$, $P < 0.005$; Spearman rank correlation) than had thinner individuals, coinciding with the reproductive period.

Reproductive status had a significant influence on the chemical composition of subcaudal secretions in both sexes. In pregnant females, peak 83 contributed less to the overall profile area than it did in nonpregnant individuals ($U = 8$; $Z_{adj} = -2.066$, $P < 0.05$; Mann-Whitney U test; Figure 4), and it was smaller in lactating than in nonlactating females ($U = 9$, $Z_{adj} = -2.382$, $P < 0.05$; Mann-Whitney U test; Figure 5). By contrast, the relative % area of peak 21 ($U = 9$, $Z_{adj} = -2.382$, $P < 0.05$; Mann-Whitney U test; Figure 6) and peak 43 ($U = 13$, $Z_{adj} = -1.958$, $P = 0.05$; Mann-Whitney U test; Figure 7) were larger in lactating females.

In males, the degree of descent of the testes was correlated with the relative amount of peak 21 in winter ($N = 13$, $R = 0.598$, $P < 0.05$; Spearman rank order correlation), with males in breeding condition (i.e., with descended testes) having

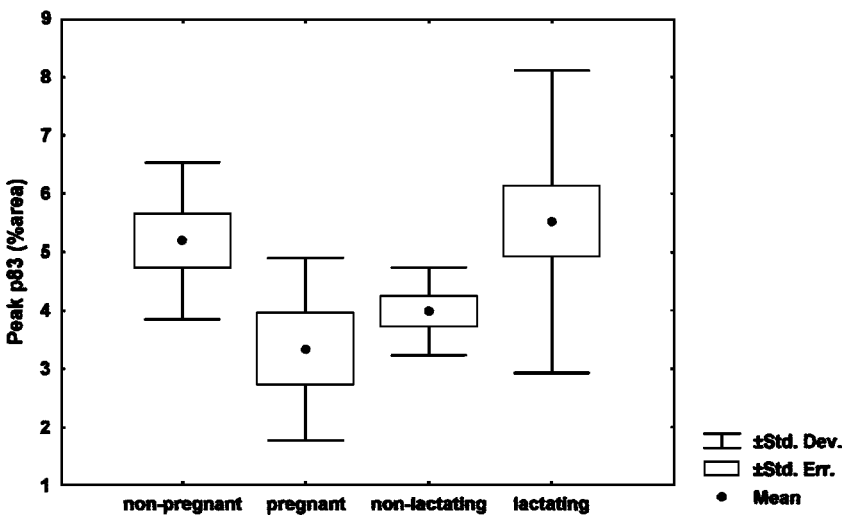

FIG. 5. Differences in % area of peak 83 in female badgers of different reproductive states.

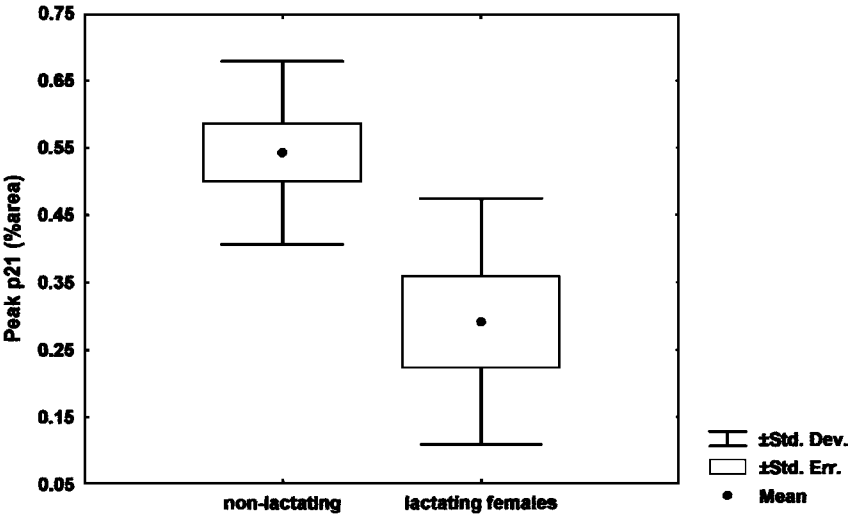

FIG. 6. Differences in % area of peak 21 between lactating and nonlactating females.

a larger % area of peak 21 than males with ascended testes ($U = 3$, $Z_{\text{adj}} = -1.984$, $P < 0.05$; Mann-Whitney U test; Figure 8).

Reproductive condition did not influence average peak numbers in either sex (females: pregnancy: $U = 11$, $Z_{\text{adj}} = -0.216$, $P = 0.829$; lactation: $U = 8$, $Z_{\text{adj}} = -0.494$, $P = 0.621$; males: $U = 8$, $Z_{\text{adj}} = -0.940$, $P = 0.347$).

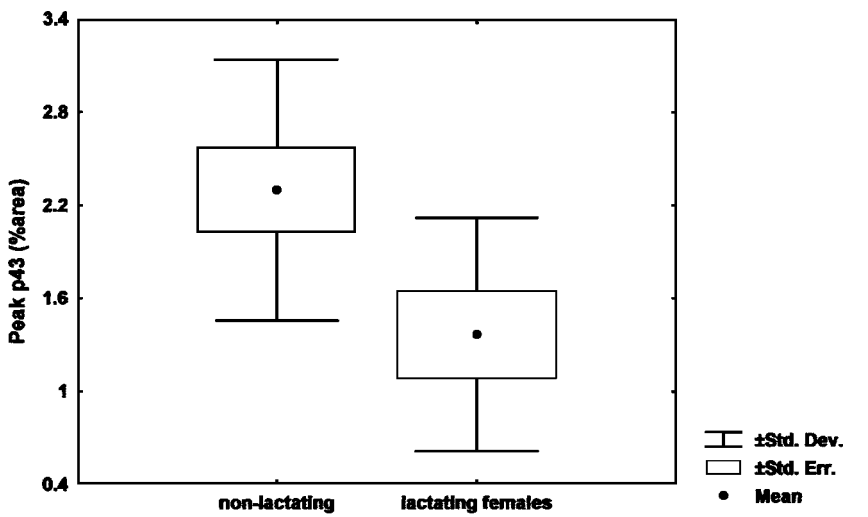

FIG. 7. Differences in % area of peak 43 between lactating and nonlactating females.

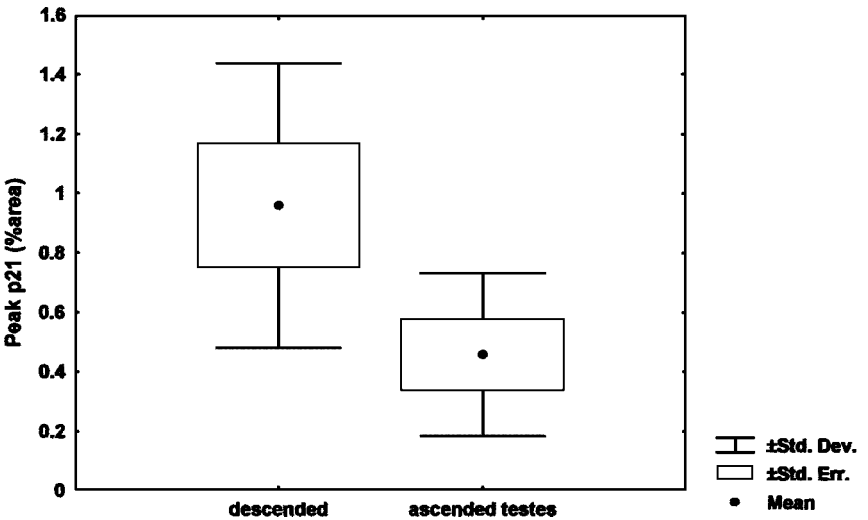

FIG. 8. Differences in % area of peak 21 between males in different reproductive states.

DISCUSSION

Subcaudal gland secretions of badgers are of high chemical complexity. In this study, we identified 21 components that were present in every sample, thus characterizing the species-specific odor. In many mammals, the exact composition of scent secretions has been shown to be of bacterial origin rather than primary gland products (Albone, 1984), and the subcaudal pouches of badgers have been shown to support a rich bacterial flora (Albone et al., 1978). Mutual allo-marking (i.e., two badgers pressing the openings of their subcaudal pouches against each other simultaneously) between group members is believed to facilitate the exchange of pouch bacteria, resulting in a group-specific composition of pouch bacteria, and hence leading to a group-specific smell (Albone et al., 1978; Gorman et al., 1984; Buesching, 2000).

The biological relevance of the chemical differences found in this analysis still remains to be tested. However, in a preliminary study (Buesching and Foster, unpublished data), investigating the behavioral reaction to secretion samples collected from unfamiliar (i.e., unfamiliar samples: from individuals of social groups separated from the focal group by the territories of at least four other groups), neighboring (i.e., familiar samples: from members from the territory adjacent to the territory of the focal group), and own social group (i.e., same group samples: from members of the focal group), it was found that badgers' reactions to the samples were dependent on the degree of their familiarity. Samples (presented as secretion smeared along the rim of a microfuge tube that was pushed completely

into the ground) were provided at one of the sett entrances of the focal sett in full view of an infrared video camera (for methods see Buesching, 2000). Samples were tested in random order [one sample per night; unfamiliar, familiar, same group, blank (i.e., empty microfuge tube), control (i.e., nothing)]. In this experiment, scent-marking activity was influenced by the treatment ($df = 4$, $F = 3.26$, $P = 0.02$; error $df = 45$; ANOVA), with badgers marking most in the presence of unfamiliar samples and least in control nights (unfamiliar > familiar > own > blank > control). Similarly, Kruuk et al. (1984) reported that a captive badger responded differently to the scent of familiar and unfamiliar subcaudal samples. However, it is as yet unclear which cues badgers use for discrimination. Testing the biological relevance of a common group odor remains difficult, as animals might become familiar with the individual odor profiles rather than extrapolate group characteristics (Kruuk et al., 1984).

Besides encoding group membership, the chemical composition of subcaudal gland secretions is also highly individual-specific. We found large interindividual variation in the contents and the relative amounts (i.e., % area) of all components, providing potential for individual recognition by scent (Gorman et al., 1984). Similar individual-specific compositions of scent secretions have been reported in other mustelids [e.g., mink (Brink et al., 1978), stoats (Erlinge et al., 1982), and weasels (Buglass et al., 1991)]. Badgers have been shown to be able to discriminate among samples collected from different individuals (Östborn, 1976; Kruuk et al., 1984), but it is as yet unclear if animals also use this potential for individual recognition under natural conditions. Nevertheless, the consistency of individual characteristics between years (Buesching et al., 2001b) and the use of subcaudal gland secretions as advertisement signals (Buesching, 2000; Buesching and MacDonald, 2001) are further indications that an important part of the information encoded in this signal relates to individuality. The chemical composition of subcaudal secretions is not stable but shows seasonal variation, reflecting the seasonal pattern in the secretion color (Buesching et al., 2002a), and significant variation in the composition of subcaudal gland secretions of individual badgers over time has been reported (Gorman et al., 1984; Buesching et al., 2002b). After correcting for the effect of season, we detected clear sexual differences in the relative amounts of eight of the 21 components present in every profile, again corresponding to the differences in color described elsewhere (Buesching et al., 2001a). Sex-related variation in the composition of scent secretions has been shown in several species [e.g., beavers (Gronneberg and Lie, 1984), capybaras (MacDonald et al., 1984), and peccaries (Waterhouse et al., 1996)] and is believed to serve as sexual advertisement.

Badgers are seasonal breeders (Ahnlund, 1980), and scent-marking activity is highest in winter (mating season) and spring (cub-rearing season) and lowest in autumn (Kruuk, 1978; Buesching, 2000; Buesching and MacDonald, 2001). Additionally, secretions are least concentrated in autumn, which coincides with

the time when badgers store the least amounts of secretion in their subcaudal pouches (Buesching et al., 2002a), indicating the importance of olfactory cues in the context of reproduction.

In both sexes, we detected differences related to reproductive status. Glandular activity is strongly influenced by hormonal status (Ebling, 1977), and many species use chemical signals to advertise reproductive activity (Taylor and Dewsbury, 1990). In several species, advertisement signals have been shown to include fitness-related information [e.g., primates (Pagel, 1994)]. The results of this study indicate that chemical composition of subcaudal gland secretions varies with age and body condition. Similar age-related differences in body odor have been reported, e.g., in humans (Chen and Haviland Jones, 1999). Body condition correlated with the chemical composition of subcaudal gland secretions only in winter and summer, and in female badgers body condition in summer proved to be a good predictor for pregnancy in the following winter (Woodroffe, 1995). As food availability (i.e., earthworms) is lower during these two periods than it is in spring and autumn (Kruuk, 1978), body condition in winter and summer might be a reliable indicator of individual fitness.

The interpretation of the results presented in this study is, however, complicated by several factors. First, the biological relevance of the chemical components in subcaudal gland secretions is unknown. Our analyses concentrated on 21 peaks, that are detectable in every profile, but other, possibly much smaller peaks might be more important to badgers. Second, in complex chemical mixtures, the ratio between a small number of components might be more important than the relative abundance of each individual compound (White and Chambers, 1989). Third, the analytical methods used in this study only detect volatile components soluble in hexane. As badgers possess a functional vomeronasal organ (Lüps and Wandeler, 1993), long chained, nonvolatile molecules might be of equal importance in encoding information (Buesching and Macdonald, 2001).

Acknowledgments—The study was carried out under English Nature license S/333/95 and home office license PPL 30/1216. Our special thanks go to the People's Trust for Endangered Species for their long-term support. We thank Dr. Julie Saxton for help with the ultrasound pregnancy scans and Pharmacia & Upjohns Ltd., Crawley, East Sussex, UK, for material sponsorship. Paul Blackwell, Tim Drye, and Paul Johnson gave valuable advice on the statistical analysis. The GC analyses were funded by a NERC grant to D.W.M. and Tristram Wyatt. While the study was carried out, C.D.B. held a Marie Curie student grant from the European Union.

Abstract—Individuality in body odors has been described in a variety of species, but studies on time-related variation in individual scent are scarce. Here, we use GC-MS to investigate how chemical composition of subcaudal gland secretions of European badgers (*Meles meles*) varies over days, seasons, and from year to year, and how secretions change with the length of time for which they are exposed to the environment. Samples were divided into subsamples—one was frozen immediately and the remaining ones frozen after 2, 6, 12, 24, and 48 hr, respectively—and many individual-specific characteristics of the scent-profiles remained stable over time. However, two components were negatively correlated with time, thus providing the possibility to determine the age of scent marks. The low variation found in scent profiles of samples collected from the same individual three days apart showed that the individual-specific scent is a true characteristic of the respective badger, and that trapping and subsequent sampling have little effect on the composition of subcaudal gland secretions. Long-term variation (i.e., over one year) in individual subcaudal scent profiles is not continuous, but periods of relative stability are followed by periods of rapid change, that can be related to badger biology. Annual variation between samples collected from the same individuals in winter 1998 and winter 1999, and in spring 1998 and spring 1999 was lower than seasonal variation. Therefore, the results of this study indicate the potential of an individual-specific scent

signature in the subcaudal gland secretions of badgers evidencing that individual recognition is of high importance in this species.

Key Words—Badger, body odor, individuality, individual variation, Mustelidae, chemical communication, scent-marking, semiochemistry, subcaudal gland, temporal variation.

INTRODUCTION

Individuality in body odors has been described in a variety of mammals (review in Brown and Macdonald, 1985). However, few studies examine how individual scent varies over time [e.g., brown hyaenas (Mills et al., 1980)]. In this study, we investigated how chemical composition of subcaudal gland secretions produced by individual badgers varies over time and how secretion changes with the length of time it is exposed to the environment.

The subcaudal gland of the European badger (*Meles meles*) consists of a pouch lined with several layers of apocrine and sebaceous cells (Stubbe, 1971) that opens in a 20 to 80-mm-wide slit between the anus and the root of the tail. Both sexes possess the gland and use its pastelike secretion for scent-marking. Subcaudal gland secretions contain mainly long-chained carboxylic acids, proteins, and water (Gorman et al., 1984). The characteristic smell is generated largely by bacteria in the pouch metabolizing the primary gland products (Kruuk et al., 1984). The color and amount of the secretion have been shown to follow a seasonal pattern and are influenced by sex and fitness-related parameters (Buesching et al., 2002a). Analytical gas chromatography and mass spectrometry studies proved that chemical composition is highly individual-specific (Gorman et al., 1984; Buesching et al., 2002b). Only 21 of the full complement of approx. 110 chemical components are present in every sample (average number of chemical components per sample $= 33.4 \pm 8.05$). Composition varies between seasons and between different badger groups, and is dependent on sex, age, body condition, and reproductive status (Buesching et al., 2002b). However, whereas visual and acoustic signals are received the moment they are emitted, and can thus, be matched immediately to other characteristics of the sender, chemical signals are persistent and are often used for delayed communication, implying that the receiver usually encounters scent marks only after the sender (i.e., the marker) has left the area. Therefore, to ensure effective communication and individual recognition, information-encoding components of chemical signals have to be reasonably stable over time in two respects: (1) composition of scent marks has to resist environmental influences to avoid loss of encoded information; and (2) composition of secretions produced by badgers has to remain similar over some period of time to enable individual recognition and the matching of individuals to scent marks.

In this paper, we report on how chemical composition of subcaudal gland secretions of individual badgers varies over days, seasons, and years; how sampling

affects individual scent composition; and how secretions change with the length of time they are exposed to the environment.

METHODS AND MATERIALS

Study Animals and Collection of Samples. All samples were collected from a badger population in Wytham Woods, Oxfordshire, England (ordnance survey reference: SP462080; for details about the study site see Kruuk, 1989; for details about the badger population see Macdonald and Newman, 2001) between January 1998 and June 1999.

For this study, badgers were trapped four times per year (winter: January/February; spring: May/June; summer: July/August; and autumn: November). For methodological details and classification of individual-specific parameters see Buesching et al. (2002b).

Gas-Chromatographic Analyses. For methodology see Buesching et al. (2002b).

Statistical Analyses of GC Profiles. For a detailed description of the methodology see Buesching et al. (2002b). In this study, the 21 peaks shared by every individual (i.e., present in every profile) are referred to as "shared peaks," whereas peaks that could not be detected in every profile are referred to as "rare peaks" (for details see Buesching et al., 2002b).

Variation in scent profiles of the same individual over time (i.e., between trapping events) was expressed as percentage change (%change) and calculated according to the following formula:

$$\%\text{change}_{\text{peak } x} \text{ in Interval } x = 100 * (\%\text{area}_{\text{peak } x} \text{ at trapping } 1 - \%\text{area}_{\text{peak } x} \text{ at trapping } 2)/(\%\text{area}_{\text{peak } x} \text{ at trapping } 1)$$

where Interval 1 is winter (= trapping 1)–spring (= trapping 2) 1998, Interval 2 is spring (= tr.1)–summer (= tr. 2) 1998, Interval 3 is summer (= tr. 1)–autumn (= tr. 2) 1998, Interval 4 is autumn 1998 (= tr. 1)–winter (= tr. 2) 1999, Interval 10 is winter 1998 (= tr. 1)–winter 1999 (= tr. 2), and Interval 20 is spring 1998 (= tr. 1)–spring 1999 (= tr. 2).

A measure for the change of the overall profile (= change rate) was obtained by calculating the mean % change over all peaks. Statistical analyses were carried out with the software program Statistica for Windows (Release 4.5, StatSoft Inc., 1993).

Changes of Secretion in the Environment. To investigate changes in the chemical composition of subcaudal gland secretions related to the length of time secretions had been exposed to the environment before freezing, six samples from three females and three males were collected on June 3, 1999. Each sample was divided into six equal-size subsamples, one of which was frozen immediately and

the others were left outside in the shade for 2, 6, 12, and 48 hr, respectively, before freezing. All samples were stored at −70°C for five months until further analysis.

Short-Term Changes. To assess how individual scent profiles change within a matter of days and to examine how trapping and subsequent secretion-sampling affect scent profiles of individuals, we compared the chemical composition of subcaudal gland secretions from one male and one female collected on the day of first capture May 31, 1998 and three days later June 2, 1998. For both animals, change rates and % change of all peaks were calculated and compared with the respective values from intervals 1 and 2. Secretions were frozen immediately after sampling and stored at −70°C for a period of five months prior to GC analysis.

Long-Term Changes. To evaluate long-term changes in the chemical composition of secretions from individual badgers, we analyzed scent profiles from four males and four females collected during six consecutive trappings between January, 1998 and January, 1999. All samples were frozen immediately and stored at −70°C for a maximum of eight months prior to GC analysis. To explore whether interindividual differences described in earlier studies (Gorman et al., 1984; Buesching et al., 2002b) are consistent over season, we performed a MANOVA (corrected for sex and season) comparing intra- and interindividual variability of the % area of all shared peaks.

We compared % change of all peaks and change rates over the whole profile during each interval to investigate whether chemical composition of gland secretions changes continuously over the year or whether periods of relative stability are followed by periods of rapid change. To examine if individual profiles vary at random over the course of one year, or if variation follows a regular seasonal pattern (i.e., profiles obtained from the same individual in the same season but in different years are more similar than profiles obtained from the same individual in different seasons within the same year), we compared scent-profiles from three females and four males from winter 1998 and winter 1999, and from seven females and four males from spring 1998 and spring 1999.

RESULTS

In the 112 samples analyzed for this study, we found 110 different chemical components, of which 21 were shared by every individual (i.e., shared peaks), the remainder being "rare peaks" (for details see Buesching et al., 2002b). Since, in several profiles, retention times for peaks p77, p78, and p79 were partly overlapping and thus could not be determined accurately, % areas of these three peaks were combined for all further analyses.

Changes of Secretion in the Environment. Although chemical composition of subcaudal gland secretions changed over time, no pattern in the presence or absence of peaks could be established, and the number of peaks per profile was not

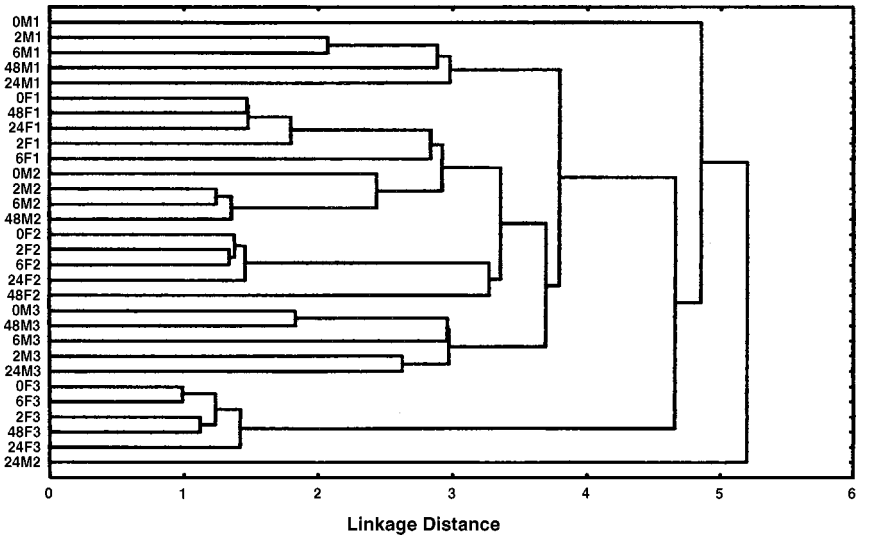

FIG. 1. Cluster analysis (including all peaks in the first part of the profiles up to p68) indicating that individuality is encoded mainly in the first part of the profile, which is stable over time ($M_{1,2,3}$ = male; $F_{1,2,3}$ = female; at intervals of 0, 2, 6, 24, and 48 hr).

correlated to the time span, for which samples were left in the environment before freezing ($P > 0.05$; Spearman rank correlation). Cluster analysis (single Euclidian distance, unweighted pair group average) revealed that the first part of the profiles (including all peaks prior to peak p68) was highly individual-specific and stayed relatively stable over time. Thus, samples of the same individual clustered closely together (Figure 1). However, cluster analysis including all peaks did not result in individual-specific clusters.

For statistical reasons, more detailed analyses were restricted to the shared peaks. Peak p90 ($N = 30$, $R = -0.378$, $P < 0.05$) and peak p91 ($N = 30$, $R = -0.395$, $P < 0.05$) proved to be negatively correlated with the time, for which the samples were left outside before freezing (Figure 2).

Short-Term Changes. As apparent from Figure 3, there is remarkably little change in individual profiles over short time periods. Comparison of secretions from the same individuals collected three days apart revealed that on the day of recapture % area of all shared peaks was within 33% (average % change for all peaks $14.66 \pm 13.99\%$; range: 0.258–32.526%) of its original value in both animals, and 95% of the rarer peaks were present in both of the respective profiles (Figure 3). Change rates were smaller among days than for the previous period, interval 1 ($U = 1126.5$, $Z_{adj} = -5.809$, $P < 0.001$; Mann-Whitney U test) and the following period, interval 2 ($U = 972$, $Z_{adj} = -6.319$, $P < 0.001$; Mann-Whitney U test).

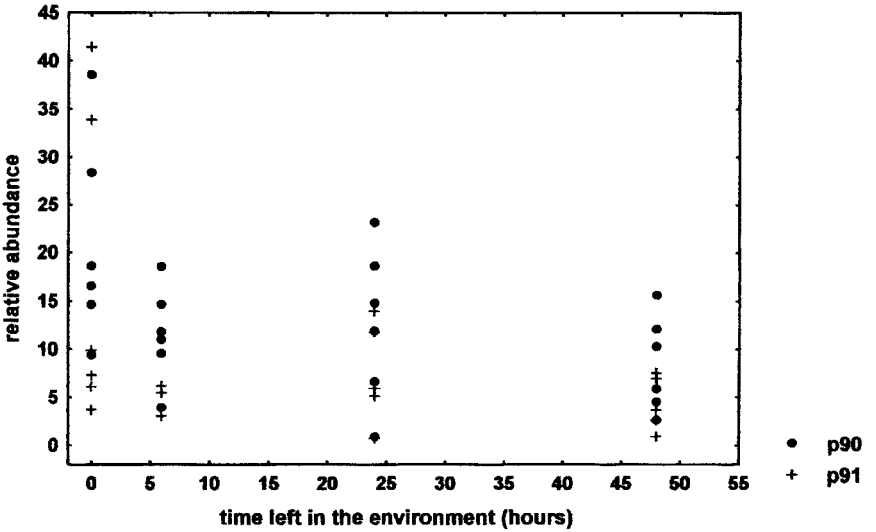

FIG. 2. Relative % area of peaks p90 and p91 are negatively correlated with the age of the scent-mark.

Long-Term Changes. Our results comparing intra- and interindividual variability in % area of all shared peaks indicate that approx. 42% of the shared peaks (8 of 19) show less variability within samples of the same individual (collected in different seasons) than between individuals (Table 1), indicating the existence of a unique scent signature in badgers. Comparative analyses of secretions collected from the same individuals in different seasons showed that change rates differ between sexes (Figure 4). Subcaudal scent profiles of female badgers change most between spring and summer (change $\text{rate}_{\text{interval2}} = 173.8 \pm 368.4\%$) and between autumn and winter (change $\text{rate}_{\text{interval4}} = 251.2 \pm 521.4\%$), but remain comparatively stable during the remaining intervals (change $\text{rate}_{\text{interval1}}$: $71.9 \pm 94.5\%$; change $\text{rate}_{\text{interval3}}$: $80.4 \pm 85.0\%$; $N = 4$). Thus, change rates in interval 1 appeared lower than in interval 2 ($U = 2415.5$, $Z_{\text{adj}} = -1.741$, $P = 0.08$) and were significantly lower than in interval 4 ($U = 1122$, $Z_{\text{adj}} = -1.935$, $P = 0.05$; Mann-Whitney U test). In contrast, male profiles show most pronounced changes between summer and autumn (change $\text{rate}_{\text{interval3}}$: $156.5 \pm 279.1\%$) and between autumn and winter (change $\text{rate}_{\text{interval4}}$: $121.4 \pm 204.3\%$) and show little change between winter and spring (change $\text{rate}_{\text{interval1}}$: $67.7 \pm 116.2\%$) and spring and summer (change $\text{rate}_{\text{interval2}}$: $99.6 \pm 328.5\%$; $N = 4$). Therefore, male change rates were lower in interval 1 than in interval 3 ($U = 1988$, $Z_{\text{adj}} = -3.316$, $P < 0.001$) and interval 4 ($U = 1722$, $Z_{\text{adj}} = -2.019$, $P < 0.05$) and also lower in interval 2 than in interval 3 ($U = 2197$, $Z_{\text{adj}} = -2.546$, $P < 0.05$; Mann-Whitney U test) (Figure 4).

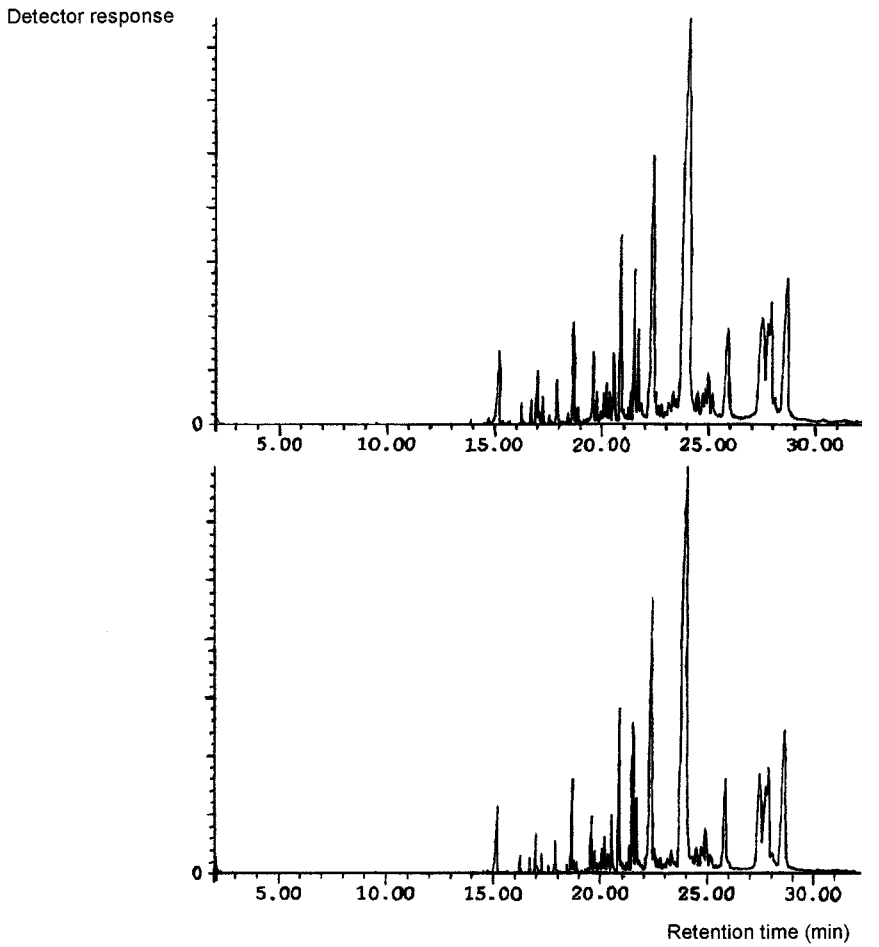

FIG. 3. Scent profiles of two samples from male 623 collected three days apart (the upper profile corresponds to the sample collected first).

To asses the pattern of change in individual peaks, we conducted a MANOVA using interval and sex as factors (Table 1). These analyses revealed that not all peak values change continuously, but that the rate of change differs between intervals. In peak p91 and p95, the pattern of seasonal change significantly differs between males and females (Table 2). Although the chemical composition of subcaudal gland secretions considerably varies with season, chemical composition of subcaudal gland secretions from the same individual collected in the same season of two different years is remarkably similar (Figure 4). On average, female composition changes 83.6 $\pm$ 92.3% between years in winter, but only 36.8 $\pm$ 38.3% in spring,

whereas male secretions change approx. $57.9 \pm 78.7\%$ between years in winter and $51.5 \pm 59.5\%$ in spring. In neither sex do annual winter and spring change rates differ from seasonal changes in interval 1 (winter: females: $F = 0.868$, $P = 0.768$, males: $F = 0.892$, $P = 0.765$; spring: females: $F = 0.728$, $P = 0.394$, males: $F = 0.143$, $P = 0.706$; F test). However, whereas in females both annual change rates are smaller than the average percentage change in interval 2 (winter: $F = 5.148$, $P < 0.05$; spring: $F = 15.106$, $P < 0.001$; F test) and interval 4 (winter: $F = 12.452$, $P < 0.001$; spring: $F = 23.964$, $P < 0.001$; F test), but not interval 3 (winter: $F = 0.006$, $P = 0.936$; spring: $F = 1.224$, $P = 0.269$; F test), in males annual change rates in winter and spring are smaller than seasonal change in interval 3 (winter: $F = 7.743$, $P < 0.01$; spring: $F = 11.003$, $P < 0.001$; F test) and interval 4 (winter: $F = 4.140$, $P < 0.05$; spring: $F = 5.264$, $P < 0.05$; F test), but not interval 2 (winter: $F = 1.422$, $P = 0.234$; spring: $F = 2.060$, $P = 0.152$; F test) (Figure 4). On average, 84.2% of all rare peaks were shared by the pairs of winter and spring profiles of the same individual recorded in different years.

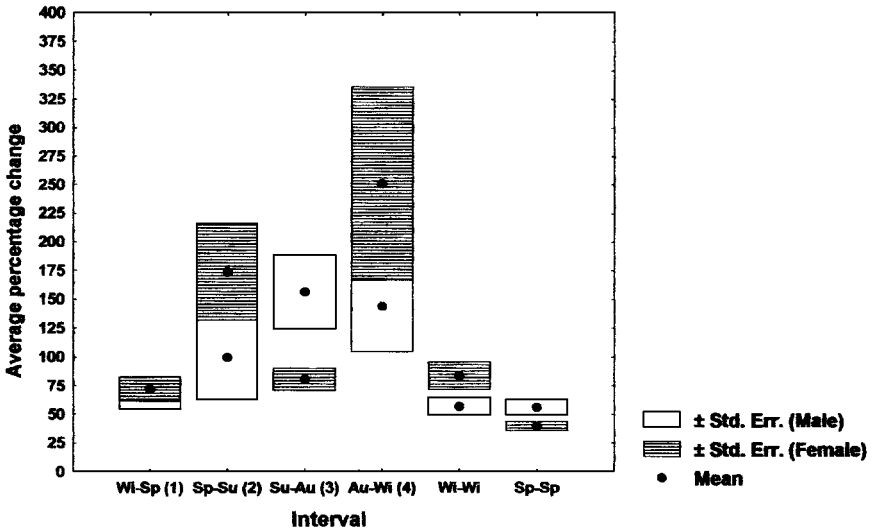

FIG. 4. Long-term average % change in gas chromatography profiles of the same individual.

DISCUSSION

Badgers rely heavily on their chemical senses and use subcaudal gland secretion to mark their environment and conspecifics (Kruuk, 1989). Subcaudal gland secretions contain mainly long-chain, nonvolatile carboxylic acids that are released slowly (Gorman et al., 1984). Thus, scent marks can be detected for some period after they have been deposited by the sender (i.e., the marking individual) and are, therefore, long-term signals suitable for delayed communication. Our results show that chemical composition remains relatively stable over time, when secretions are exposed to the environment. These findings are in concordance with Gorman et al. (1984), who stated that secretions smeared on glass slides and left in the lab for a period of five days did not change their composition appreciably.

Subcaudal scent-marking is believed to play an important role in territorial defense (Kruuk et al., 1984). By marking the territory with the scent of its owners, an asymmetry of context can be established between territory owner and intruder, as only residents will have had time for extensive scent-marking activity (Gosling, 1982). Thus, it is important that individual-specific information encoded in scent marks be resistant to environmental influences to enable matching scent marks to individuals. However, although chemical composition remained relatively stable over time, our results also show that % area of peaks p90 and p91 are negatively correlated with the time subcaudal gland secretions are left in the environment before freezing. Similar oxidation effects of scent marks have been described in

aardwolves (*Proteles cristatus*) (Sliwa, 1996), peccaries (Sowls, 1984), and brown hyaenas (Hyaena brunnea) (Mills et al., 1980), where secretion color changes over time of exposure to the environment. Klipspringers (*Oreotragus oreotragus*) have been shown to adapt their behavioral response to the age of the scent marks they encounter (Roberts, 1998). Including information about the age of the scent mark will help the receiver to decide if the scent mark is still relevant; this also benefits the sender by alerting receivers to recent scent marks. Information on the age of scent marks is especially important in the context of reproduction. In badgers, it has been shown that subcaudal secretions may include information about age, body condition, and reproductive status of the marking individual (Buesching et al., 2002a,b). Thus, highly increased marking frequencies during the reproductive season (Buesching and Macdonald, 2001) will provide accurate information about individual-specific parameters of the sender and will pinpoint locations that have recently been used by this animal.

Subcaudal samples collected three days apart from the same individual varied little in their chemical composition, indicating that trapping and sampling

have little effect on the individual-specific composition of badger subcaudal gland secretions. Despite the small sample size, these results reinforce that subcaudal scent is mainly determined by factors intrinsic to the badger and is, thus, a true characteristic typical for the respective individual. However, glandular activity and composition of gland secretions are under strong hormonal control (e.g., Ebling, 1977; Balakrishnan et al., 1984; Müller-Schwarze, 1983) and are also dependent on individual-specific parameters, such as sex, age, body condition, and dominance status (e.g., Atkeson and Marchington, 1982; Schilling and Perret, 1987; Buesching et al., 2002a,b). Additionally, chemical composition is often influenced by food sources. Thus, individual body odor is usually liable to changes over time. In badgers, color and volume of subcaudal gland secretions have been shown to vary with season and to depend on sex, age, body condition, and reproductive status (Buesching et al., 2002a). Gorman et al. (1984) showed that chemical composition of subcaudal gland secretions changes over time, although individuals can be recognized for a period of 80–160 days (Kruuk et al., 1984). Similarly, anal sac secretions of several mustelid species have been shown to be individual-specific and stable over time. For example, individual mink show similar patterns throughout the year (Brink et al., 1978), and in stoats, anal gland secretions of individuals remain similar for at least one month (Erlinge et al., 1982). In the individual-specific composition of subcaudal gland secretions of badgers, variation is not continuous, but periods of relative stability are followed by intervals of rapid change. In both sexes, change is lowest during the reproductive period between January and May, coinciding with a peak in scent-marking activity (Buesching, 2000; Buesching and Macdonald, 2001). Recognizing individuals during the breeding season is especially important in the context of mate choice and avoidance of incest. In badgers, dispersal is rare (Woodroffe and Macdonald, 1992), and females tend to mate with most males in their own social group (Macdonald et al., unpublished data), yet the degree of relatedness among members of the same social group is lower than expected (Evans et al., 1989).

Highest % change rates occur between autumn and winter. During this time, badgers switch their main food source from earthworms to cereals and nuts, and their metabolism changes from catabolic to anabolic (Neal, 1986). In autumn, scent-marking activities are lowest (Buesching, 2000; Buesching and Macdonald, 2001), reflecting a relative annual minimum in badger social behavior in general (Stewart, 1997).

The high degree of similarity in secretions of the same individual collected in the same season of two succeeding years indicates that variation in the chemical composition is not random, but highly individual-specific. Additionally, over 40% of all shared peaks showed less intra- than interindividual variability over the course of one year. In our opinion, these results, although derived from a relatively small sample size, indicate the existence of a unique individual-specific scent signature

in the subcaudal gland secretions of badgers. Thus, we suggest that, although badgers are often considered as primitively social mammals (Kruuk, 1989) due to their plasticity in social organization (Woodroffe and Macdonald, 1992) and their lack of truly cooperative behavior (Stewart, 1997), individual recognition is of high importance.

Acknowledgments—The study was carried out under English Nature license S/333/95 and home office license PPL 30/1216. Our special thanks go to the People's Trust for Endangered Species for their long-term support. We thank Dr. Julie Saxton for help with the ultrasound pregnancy scans, Upjohns Ltd., Pontypool, Gwent, UK, and Borger, Wausau, UK, for material sponsorship. Paul Blackwell, Tim Drye, and Paul Johnson gave valuable advice on the statistical analysis and C. Newman made helpful comments on an earlier draft of this paper. GC analyses were funded by a NERC grant to D.W.M and Tristram Wyatt. While the study was carried out, C.D.B held a Marie Curie student grant from the European Union.

(Received November 14, 2000; accepted April 1, 2001)

Abstract—The species of desert-dwelling ants of the *Cataglyphis bicolor* (Hymenoptera: Formicidae) group are difficult to distinguish by morphological features. Analysis of the secretion from the Dufour glands of workers of a number of colonies was undertaken to see if it provided a clear test of species. Linked 6c-ms showed in all samples straight and branched-chain alkanes, linear alkenes, ketones, aldehydes, acetates, and a group of C_{22} to C_{28} esters not previously identified in this genus. Contents of the Dufour glands of *C. savignyi* from Tunisia and Egypt were similar, and comprised straight and branched-chain alkanes, alkenes and small amounts of esters. *C. bicolor* from Tunisia contained compounds similar to *C. savignyi* but was distinguished from the latter by larger amounts of the esters. The major compound in the glands of *C. viaticus* was tridecane, in contrast to the pentadecane of other species. It also contained a branched alkane, 3-methyltridecane as a major component. Branched-chain esters and a wide variety of acetates were also found in this species. *C. diehlii* had a limited range of compounds, with branched alkanes almost completely absent and high proportions of pentadecene and dodecyl acetate. *C. bombycinus*, a sympatric species, but recognized as not belonging to the *bicolor* group by its different mandibular gland substances, was notable in having butanoate esters in its Dufour glands. Despite these differences among species, both the great variability of individuals from a single colony and the among between conspecific colonies make species diagnosis from a few individuals difficult, in contrast with postpharyngeal glands, which, as recently reported, give a clearer indication of species.

Key Words—Hymenoptera, Formicidae, Formicinae, exocrine secretion, hydrocarbons, esters, species specificity, species diagnosis.

INTRODUCTION

The ant genus *Cataglyphis* includes more than one hundred named taxa, with others yet undescribed, and is distributed in the Old World from Mauritania to the Gobi Desert. Almost all species thrive in open habitats, including deserts and dry salt plains. Because of their thermophilic and desert-dwelling behavior, they have been the subject of intensive research in neuroethology (Wehner, 1994) and physiology (Lighton and Wehner, 1993). Much of this work was carried out on "*Cataglyphis bicolor*", but during the course of this work it became apparent that this "*C. bicolor*" was either one species which varied slightly in external appearance from place to place or it was a group of closely similar species, and these were tentatively referred to as forms a, b, and c in Wehner et al., (1983).

Cataglyphis are unique among formicine ants in that the morphology of the male genitalia is diverse, making this genus easily distinguishable from others. However, anatomical similarities make the classification difficult at the species level. Because the morphological characters are lacking, neither can the species be diagnosed sufficiently nor can the phylogenetic relationships among species be easily inferred (Agosti, 1990). The work of Santschi (1929), who spent four decades in Tunisia concentrating on *Cataglyphis*, left a tangle of specific and subspecific names and synonyms. The work of Agosti (1990) supported by chemical studies of exocrine secretions of the groups (Keegans et al., 1992) and isozyme and *m* DNA analyses (Ready and Agosti, unpublished) have made possible the identification of some species of the group.

The Dufour gland is present in all females and workers of aculeate Hymenoptera, and although it has been shown to have a function (presumably secondary) in some individual species or genera, it has no known common function. Nevertheless, its contents have been found to be species-specific in many studies where closely related species have been compared. Usually the gland contains a mixture of linear hydrocarbons, terpenes, or oxygenated alkyl compounds.

Some chemotaxonomic studies have already been carried out on the Dufour gland contents of *Cataglyphis* species. The Dufour glands of *C. savignyi* from Egypt were shown to contain straight chain saturated and unsaturated hydrocarbons from C_{11} to C_{23}, together with some branched hydrocarbons with methyl groups at 3-, 5-, and 7-position. Oxygenated compounds (e.g., 2-ketones, 1-alcohols and branched chain aldehydes) were identified in trace quantities (Ali et al., 1988). Hefetz and Lenoir (1992) analysed Dufour glands of six *Cataglyphis* species from Israel, Tunisia, Spain, and the South of France. The major common feature was saturated hydrocarbons ranging from C_{11} to C_{19}. Minor amounts of corresponding alkenes and some oxygenated components in trace amounts were also observed. The main differences among species were expressed in the identity of the major components and the relative amounts of all components present in the secretion.

Our work, previously described for 10 species of *Cataglyphis* collected in Syria and Tunisia, showed that those species could be distinguished by their Dufour gland contents (Keegans et al., 1992). Five belonging to the bicolor group were similar. *C. niger* and *C. nodus* had pentadecane, tridecane, heptadecane, tetradecane, and tridecane in decreasing amounts as the major hydrocarbons. However, *C. niger* had equal quantities of 2-pentadecanone and 2-heptadecanone, whereas *C. nodus* had more 2-pentadecanone than 2-heptadecanone. The two types from Tunisia, called at that time *C. bicolor*-1 and *C. bicolor*-2, were similar to *C. niger* and *C. nodus* but also showed some differences. *C. bicolor*-1 had more tridecane (the major compound) and dodecanol than the other species but less pentadecanone than *C. niger* or *C. nodus*. The most obvious difference in *C. bicolor*-2 was the low amount of oxygenated compounds in its gland. *C. isis*, also from the bicolor group, was distinguished from the other four by the large amounts of dodecanol and tridecane it contained (Keegans et al., 1992).

We also discovered that the *bicolor* group has a distinctive feature in that the species examined all contain 2-methyl-1-hexanol, a new substance to exocrine secretions, as the major substance in their mandibular glands (Agosti et al., 1996). This substance was not found in any species outside the *bicolor* group.

For the present work, colonies of the *C. bicolor* group were collected at various sites in Tunisia and Egypt, identified only by a code (which referred to some morphological character, Table 1) or by the name of the place of collection. Samples of Dufour glands were taken from workers for chemical analysis. The code names were united with the new species names (*bicolor*, *diehlii*, *savignyi* and *viaticus*) derived from morphological examination of the male genitalia, after the analyses were finished. We describe the chemical examination and statistical analysis of the results of the analysis of Dufour glands here as they relate to these species and one more sympatric species, *C. bombycinus*, which was different and belongs to another *Cataglyphis* group.

MATERIALS AND METHODS

The ants were collected at sites in Tunisia and Egypt by D. Agosti during 1992. For location, see Wehner et al., (1994). The nests were brought live to Zürich where the workers were dissected. The Dufour glands were sealed in glass capillaries for transport to Keele as described by Morgan (1990). They were analyzed there by linked gas-chromatography-mass spectrometry (GC-MS), by the method of Morgan and Wadhams (1972).

The GC-MS was performed with a Hewlett-Packard 5890 gas chromatograph linked to a 5970B Mass Selective Detector, set to monitor m/z 35–350. The system was controlled by an HP Series 300 computer with HP 59970C ChemStation software. A fused silica capillary column (12 m $\times$ 0.32 mm; 0.25 μm) of 5%

*Samples were assigned to groups by the following characters: bdw, Large workers with head and alitrunk dark red to black, legs concolor to black; bdb, Alitrunk and dorsum of petiole with few white or yellowish, short erect hairs, which are less than half the length of the black, erect hairs on the occiput; and bb, Large workers with head and alitrunk bright red, legs sometimes slightly darker.

†For map, see Figure 1, also Wehner et al. (1994) or Agosti et al. (1996).

phenyl −95% methylsiloxane (non-polar phase) (SGE Milton Keynes) was used for chromatography. The samples were heated in the injector at 200°C for 3 min before crushing the glass capillary. The column was initially at 30°C for 2 min, then heated at 8°C min^{-1} to 250°C, and held at that temperature, to give a total run time of 40 min. The split valve was closed for the injection and opened 30 sec after injection.

Identification of the compounds was made with the aid of The Wiley- NIST mass spectral library (1994 version), and collections of spectra made in the laboratory. Final identification was made, wherever possible, by comparing retention times and mass spectra with commercially available materials (linear alkanes,

2-alcohols, and 2-alkanones) or in the cases of 2-tridecyl acetate, dodecyl decanoate, dodecyl tetradecanoate, and butyl oleate they were synthesized in the laboratory. Esters were prepared on a small scale by the method of Attygalle et al., (1987). For quantitative analysis, peak areas for each component in the chromatogram were determined by computer integration, and the percentage of each substance in the gland was calculated. For each compound, average percentage value and standard deviation were calculated for each colony and for each group of colonies identified by the same code. In the *t* test, data transformed by arcsin $[\sqrt{(\%/100)}]$ were used (Sokal and Rohlf, 1995).

RESULTS

Since the work was begun blind, a few mandibular glands of workers from each of the 25 colonies provided were examined first by GC-MS. In 23 out of 25 colonies, samples all contained 2-methyl-1-hexanol (Agosti et al., 1996), and these colonies were all placed in the *bicolor* group based on this evidence. Only the Gafsa and Kebili samples did not contain 2-methylhexanol; they both contained citronellol and citral (c.f. Keegans et al., 1992), and these colonies were assigned to the *bombycinus* group.

Altogether, 7057 chromatographic peaks from Dufour glands were identified and quantified for 195 workers from 25 colonies. For each of these colonies, the mean values of the area for each peak were calculated together with their standard deviations.

Table 1 gives the code names of the samples, the number of specimens analyzed per colony, their place of origin, and the species names assigned. The location of the sample sites are given in Figure 1.

C. savignyi, Tunisia (bdw)

Five colonies were analyzed. In each specimen but 3, the major compounds, beginning with the one in greatest quantity were pentadecane, tridecane, and undecane (Table 2). The substances found at highest retention times (peak numbers 84, 93, 94, 96–99, and 105 in Table 2) corresponded to long-chain esters. Some samples from locations t1 10b and t1 10c also contained some linear and branched ketones, mainly 2-pentadecanone and 2-heptadecanone, which in other samples were present in tiny amounts or were undetectable.

C. savignyi, Egypt

In general, the Dufour gland contents of the colonies collected in Egypt were similar to those of the same species samples collected in Tunisia. For example,

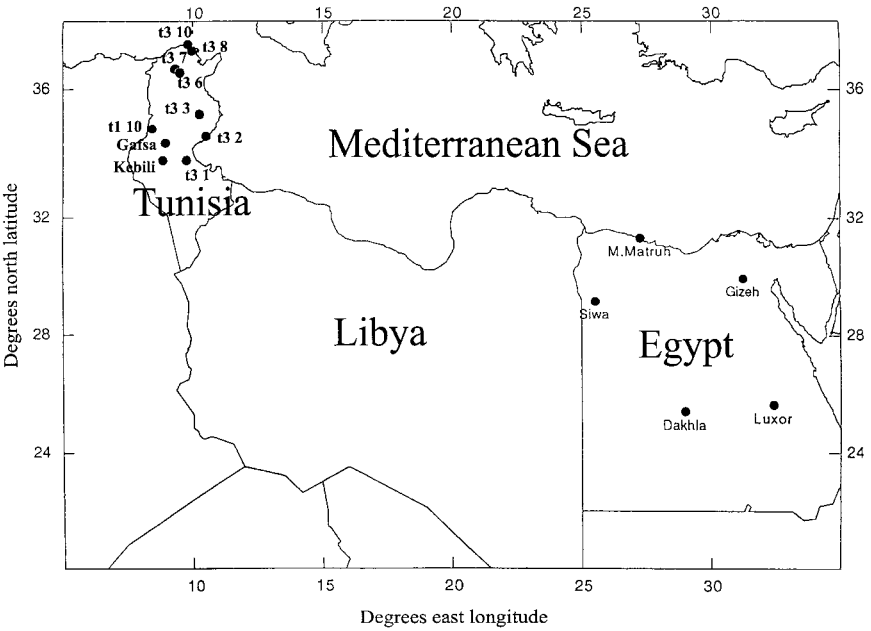

FIG. 1. The collection sites of nests of *Cataglyphis* ants in Tunisia and Egypt. The locations in Tunisia are explained in the text.

in all the Egyptian specimens, the order of the major compounds was pentadecane, tridecane, and undecane as in the Tunisian samples. However, undecane and tridecane were present in a significantly higher amount in the Tunisian samples (t test on the transformed data, respectively $t = 4.11$, $P < 0.001$ and $t = 4.44$, $P < 0.001$), while there was proportionally more of tetradecane and heptadecane in the Egyptian samples ($t = 7.55$, $P < 0.001$ and $t = 2.01$, $P = 0.048$, respectively). Moreover, in the Egyptian samples, the average percentage of branched hydrocarbons is almost twice the value found in the Tunisian specimens (13.5 and 7.4, respectively; t test on the transformed data $t = 4$, $P < 0.001$). No relevant differences were noted between the two samples for the non-hydrocarbon components.

C. bicolor (bdb)

The immediate difference noted in the bdb samples, collected across transect 3 in Tunisia, was their higher proportion of esters compared with the *savignyi* samples. All the esters identified were also found in the *savignyi* samples (Table 2), with the exception of those corresponding to peak numbers 85, 86, 102, and 103.

*Average values higher than 5.0% are written **bold**; when value is written in *Italic* the compound was not found in all the colonies (this does not apply to *C. diehlii* for which only one colony was available); when the value is underlined not all the individuals belonging to the same colony contained the compound in detectable amounts.
[1]Present as two isomers in some specimens.
[2]The peak also contains tridecyl tetradecanoate.
[3]Only present in one of the 9 specimens analysed (the same specimen for all the compounds indicated with this number.

However, some of the esters were present in much higher proportion, as dodecyl tetradecanoate (peak 104, 5.4%), dodecyl dodecanoate (peak 94, 4.1%), dodecyl decanoate (peak 84, 2.0%) and dodecyl 10-methyldodecanoate (peak 98, 1.3%) ($8.02 \leq t \leq 13.78$, $P < 0.001$). These esters were almost constantly present among all the samples analyzed (only one specimen out of 47 lacked both dodecyl dodecanoate and dodecyl tetradecanoate, one lacked decyl decanoate, and four lacked dodecyl 10-methyldodecanoate). Among the colonies, the average total proportion of esters varied from 4% to 22%. Despite this variation, the total percentage of esters in *C. bicolor* was higher than in the Tunisian *C. savignyi* (averages respectively, 16.08% and 4.68%; *t* test on the transformed data $t = 8.39$, $P < 0.001$).

With regard to the hydrocarbons, the average values were close among the Tunisian *savignyi* and the *bicolor* samples, with the exception of heptadecane which was in a lower amount in *bicolor* ($t = 5.70$, $P < 0.001$). By comparing the sympatric bdw and bdb samples collected on location 2 on transect 3, the same differences as reported above were noted.

C. viaticus (bb)

Samples given the code name bb contained the same hydrocarbons and esters as found in the other groups already described, but the percentage values were obviously different from the others (Table 2). First, all but 3 samples contained tridecane as the major component and pentadecane as second. Secondly, they all had a branched alkane, 3-methyltridecane, as an important component (*t* test for the above compounds against Tunisian *savignyi* and *bicolor*: $3.5 \leq t \leq 17.3$, $0.001 \leq P < 0.001$). Moreover, undecane and heptadecane were in lower amounts than in the Tunisian *savignyi* and in the *bicolor* samples ($5.30 \leq t \leq 9.6$; $P < 0.001$).

The amount of esters ranged among the colonies from 10 to 24%. However, compared to the *bicolor* samples, instead of dodecyl esters of tetradecanoic, dodecanoic, and decanoic acids dominating the esters (all in a significantly lower amount in the *viaticus* samples $3.57 \leq t \leq 9.93$, $P < 0.001$), there was a more complex mixture including more branched esters. Thus, the pattern of esters in the chromatogram looked quite different. The branched esters corresponding to the peak numbers 90–92 and 100, which all together gave 3.7% of the total, were only found in this species, while dodecyl x-methyldecanoate, corresponding to peak 89, whose average amount was 2.6%, was present only in traces in the Tunisian *savignyi* and in the *bicolor* samples. All these compounds were present in all the *viaticus* colonies analyzed. Four acetates were found (peak numbers 40, 41, 63, and 65), which were not found in the other samples, but their presence was variable both among colonies and among individuals belonging to the same colony (Table 2).

C. diehlii

One group of specimens, all belonging to the same colony, labelled diehlii from Methaoui in Tunisia was different from the others containing a simpler mixture of substances (Table 2). There was low consistency of composition in these nine specimens, as reflected in the larger standard deviation in Table 2, compared to all the other samples. As in the bb samples, the major component was tridecane ($t = 1.70$, n.s. in the comparison with the bb samples; $2.86 \leq t \leq 3.79$, $0.021 \leq P \leq 0.005$ in the comparison with bdb, bdw and Egyptian *savignyi*), but the amount of pentadecane and undecane was lower than in all the other samples analysed (respectively, $3.48 \leq t \leq 7.44$, $0.004 \leq P < 0.001$; $1.97 \leq t \leq 5.56$, $0.073 \leq P < 0.001$ in comparison with bdw, Egyptian *savignyi*, bdb and bb). Moreover a higher percentage of pentadecene was present (comparison with bb samples, $t = 2.96$, $P = 0.018$), despite the amount being variable among specimens. The unresolved peak of pentadecene and pentadecane was integrated by plotting single ion chromatograms for m/z values 210 and 212, respectively. Dodecyl acetate, only found in traces in the other samples, was present in a high average amount (15%), although it was absent in 2 out of the 9 analyzed glands. Tetradecyl acetate was also present in a high average amount (2.6%), but was missing in four out of the nine samples.

It is noteworthy that we found esters with a common ion at m/z 98 in their mass spectra in one specimen of this group. We determined these to be 2-methylhexyl esters of fatty acids. The esters with branched-chain acid portions gave clear strong ions at the branching points. For example, 2-methylhexyl 12-methylhexadecanoate had a weak molecular ion (M^+ 368, intensity 2%), and ions at m/z 311 (M-C_4H_7, 2%), 271 ($RCO_2H_2^+$, 20%), 270 (RCO_2H, 16%), 253 (RCO^+, 18%), 213 ($RCO_2H-C_4H_7$, 19%), 98 ($C_7H_{14}^+$ from the 2-methylhexanol, 53%) and 57 (C_4H_7, from both acid and alcohol parts, base peak). In 2-methylhexyl 13-methylheptadecanoate, the lower mass ions were unchanged and the high mass ions were shifted to 382 (M^+), 325, 285, 284, 267, and 227, respectively. Since all members of the *bicolor* group have the necessary enzymes to produce 2-methylhexanol in their mandibular glands, it is interesting to see this substance bound as esters in their Dufour glands. If similar esters are present in the other *bicolor* species, they are below our limit of detection.

C. bombycinus

The absence of 2-methyl-1-hexanol and the presence of citronellol and citral in the mandibular glands of the samples Gafsa bom and Kebili bom drew attention to these samples as not belonging to the group we had come to recognize as *bicolor*. As for most of the *bicolor* group, the major hydrocarbon was pentadecane (Table 2), but its average percentage was higher than in all the other samples analyzed

($2.22 \leq t \leq 11.82$, $0.032 \leq P < 0.001$). Tridecane was in a lower percentage amount than in all the other samples ($3.27 \leq t \leq 8.85$, $0.002 \leq P < 0.001$), and undecane was present in a low amount. Heptadecane was in a higher proportion than in all the *bicolor* samples ($7.43 \leq t \leq 32.18$, $P < 0.001$). Dodecyl acetate was found in about half of the samples, sometimes in high amounts; however, its proportion was lower than in the *diehlii* specimens ($t = 2.96$, $P = 0.016$). All together, the low standard deviation for the *bombycinus* indicated their homogeneity (Table 2), but the Gafsa sample lacked the traces of propionate esters present in the Kebili colony. The absence of further branching in peaks 26, 39, and 54, 3-methyl-2-tridecanone, 3-methyl-2-tetradecanone, and 3-methyl-2-pentadecanone (Table 2) cannot be excluded with as great a certainty as for the branched esters of *C. diehlii* above, and synthetic samples were not available. *C. bombycinus* is placed in the *bombycinus* group (Wehner et al., 1994).

DISCUSSION

Chemotaxonomy, or the use of chemical composition of an animal or plant, together with other criteria, to define a species has been in use for considerable time in particular cases. From a number of studies made of the secretion of the Dufour glands of ants (c.f. Morgan, 1992), it would appear that this secretion is relatively constant in composition and unique to each species. Because of the difficulty in diagnosing species in the large *Cataglyphis* genus, a chemotaxonomic study of exocrine secretions was undertaken (Keegans et al., 1992; Agosti et al., 1996). The group of large desert-dwelling *Cataglyphis* ants of Tunisia has been refined into five species (Wehner et al., 1994), four in the *bicolor* group (with 2-methyl-1-hexanol as their characteristic mandibular gland substance) and one in the *bombycinus* group (with citronellol and citral in the mandibular glands). Among the *bicolor* group species, *C. savignyi*, *C. bicolor*, and *C. viaticus* were quite similar for the composition of the Dufour's gland secretion, while *C. diehlii* was markedly differed from these three species showing (i) a much less complicated mixture and (ii) a high concentration of dodecyl acetate, a compound only found in low concentrations in some specimens of *C. viaticus* and in *C. bicolor*, and (iii) the presence of the 2-methylhexyl esters of long chain fatty acids, unique among the five species analyzed. Thus, the Dufour gland chemistry appears to be a clear diagnostic character for *C. diehlii*, while based on the postpharyngeal gland secretion, *C. diehlii* is not readily distinguishable from *C. bicolor*. Although less evident, differences between C. *savignyi*, *C. bicolor*, and *C. viaticus* were found in the concentration of the major constituents. As might be expected for insects so geographically separated, the glands of *C. savignyi* from Egypt and Tunisia were chemically differentiated, and since this difference is of an extent comparable to that observed between species, the chemistry of the Dufour gland does not appear

to be a reliable character for species identification if based on the description of the composition of allopatric populations. We have found for these closely related species the contents of the postpharyngeal gland (Oldham et al., 1999) to be a better separator than the Dufour gland contents.

In contrast to the differences in the mandibular glands between the *bicolor* group and *C. bombycinus*, the Dufour gland chemistry did not differ remarkably between them. However, the two groups were differentiated by the lack of the high molecular weight constituents, mainly long chain fatty acid esters, in *C. bombycinus*. It can be seen from Table 2 that in all the species, several of the minor components were absent in some of the analyzed specimens and sometimes in all the specimens sampled from the same colony. Although this sort of variability is generally not discussed in papers describing the composition of exocrine volatile secretion in insects, we know from direct experience it is a common situation. Moreover, even considerable deviations from the average values of concentration for several of the compounds are common. In this sense, we believe that the composition of just one volatile exocrine secretion is rarely a reliable and readily usable taxonomic character, but may prove to be useful for species determination if considered together with other chemotaxonomic and anatomical characters.

MAMMALIAN EXOCRINE SECRETIONS. XVII: CHEMICAL CHARACTERIZATION OF PREORBITAL SECRETION OF MALE SUNI, *Neotragus moschatus*

M. A. STANDER, B. V. BURGER,* and M. LE ROUX

Laboratory for Ecological Chemistry
Department of Chemistry
University of Stellenbosch
Stellenbosch 7600, South Africa

(Received April 3, 2001; accepted September 5, 2001)

Abstract—Gas chromatographic and gas chromatographic–mass spectrometric techniques were employed to identify 83 compounds, including alkanes, alkenes, aldehydes, 2-methylalkanes, carboxylic acids, 1-alkyl formates and alken-1-yl formates, benzoic acid, and cholesterol, in the preorbital secretion of the male suni, *Neotragus moschatus*. Dimethyl disulfide derivatization and lithium aluminum hydride reduction were used to determine the position of double bonds and to confirm the identity of the functional groups in some of the constituents of the secretion.

Key Words—Suni, *Neotragus moschatus*, semiochemicals, pheromones.

INTRODUCTION

Extensive research has been done on the role of the secretions of the preorbital glands of hoofed mammals or ungulates of the order Artiodactyla in their rutting and territorial behavior (e.g., Langguth and Jackson, 1980; Mossing and Damber, 1981; Frey and Hofmann, 1997; Marmazinskaya, 1997; Roberts, 1997, 1998; Arcese, 1999; Brashares and Arcese, 1999; Lawson et al., 2000, 2001), but in spite of the biological importance attributed to them, little is known about the chemical composition of preorbital secretions. Andersson (1979) has identified two ketones in the preorbital pouch secretion of the reindeer, *Rangifer t. tarandus*. Several heavy constituents such as cholesterol, lanosterol, fatty acids, and triglycerides were subsequently identified in this secretion (Sokolov et al., 1977). Cholesterol, benzaldehyde, and a homologous series of saturated γ-lactones have been identified

*To whom correspondence should be addressed. E-mail: lecus@maties.sun.ac.za

0098-0331/02/0100-0089/0 © 2002 Plenum Publishing Corporation

in the preorbital secretion of the muskox, *Ovibos moschatus* (Flood et al., 1989). The preorbital secretions of the bontebok, *Damaliscus dorcas dorcas*, and blesbok, *D. d. phillipsi*, contain, among other compounds, some unbranched primary alcohols, a few short-chain saturated and several long-chain saturated and unsaturated unbranched carboxylic acids and aldehydes, three long-chain δ-lactones, benzoic acid, 4-hydroxybenzoic acid, 4-hydroxybenzaldehyde, 2-heptanone, piperitone, dimethylsulfone, isopropyl tetradecanoate, isopropyl hexadecanoate, hexadecyl acetate, cholesterol, α-tocopherol, and squalene (Burger et al., 1999a).

With the exception of the female oribi, *Ourebia ourebi*, which does not produce a preorbital secretion (Mo et al., 1995), and the preorbital secretion of female klipspringer, *Oreotragus oreotragus*, which has not yet been investigated, the males and females of the other members of the subfamily Antilopinae produce qualitatively identical preorbital secretions. In sharp contrast, exploratory gas chromatographic–mass spectrometric (GC-MS) analyses of the preorbital secretions of suni, *Neotragus moschatus*, a dwarf antelope of the tribe Neotragini, revealed prominent qualitative and quantitative differences in the secretions of male and female animals. The suni was, therefore, selected for further study of its preorbital secretions in a continuing investigation of the role of preorbital secretions in the territorial behavior of South African antelope species.

METHODS AND MATERIALS

General. All Pyrex glassware was thoroughly cleaned with water and organic solvents and then heated at 500°C in an annealing oven to remove any trace of organic contaminants. Syringes and other apparatus that could not be heated to 500°C were cleaned with dichloromethane (Merck, Residue Analysis Grade). Preorbital secretions were extracted and the extracts diluted, where necessary, with this solvent.

Collection and Sample Preparation. Preorbital gland secretions were collected with a tubular PTFE scoop from male suni kept in pens (10 × 10 m) at the Tygerberg Zoo, Cape Town, South Africa. The scoop, with an inside diameter of 5 mm, was furnished with a PTFE plunger with which the collected material could be ejected into a 1-ml Reacti-Vial. Samples were taken at different times of the year as needed from six males bred from two unrelated lineages. To avoid the risk of losing animals, males were not trapped in the presence of pregnant females.

The organic constituents were extracted from the mucoid secretion by stirring the collected material with an appropriate quantity of dichloromethane, using a thin (ca.1 mm diam.) glass rod, centrifuging the resulting suspension at 3500 rpm for 15 min, and removing the organic fraction from underneath the supernatant mucoid layer with a 100-μl syringe. In a typical sample preparation, 108 mg of secretion was collected from the glands of a male and extracted with 120 μl of

dichloromethane to give 97 μl of extract. This extract was used without further concentration for quantitative determination of the volatile organic constituents. However, to avoid having to concentrate extracts for GC-MS analysis with the concomitant loss of volatiles, the organic material was mostly extracted with the smallest possible volume of solvent that still gave a separable solvent layer. Extracts were transferred to clean Reacti-Vials and stored at -30°C until used for analysis.

Analytical Methods. Instrumentation for the identification of the volatiles has been described in detail by Burger et al. (1996). GC and GC-MS analyses were done with the following capillary columns: (1) 40-m $\times$ 0.3-mm glass column coated with PS-089 (polarity equivalent to that of SE-52) at a film thickness of 0.25 μm, and (2) 30-m $\times$ 0.25-mm glass column coated with OV-240 at a film thickness of 0.25 μm. Helium was employed as carrier gas at a linear velocity of 28.6 cm/sec at 40°C. Samples were injected at an injector temperature of 220°C, thermally focused on the column at 30°C and analyzed using a temperature program of 2°C/min from 40°C to 270°C and holding the temperature at 270°C for 80 min. The flame ionization detector was operated at 280°C. Quantitative GC analyses were done with the same instrument and the PS-089 column, and data acquisition with Borwin Intuitive Chromatography Software (JMBS Developments, 38600 Fontaine, France) using hexadecanoic acid as external standard.

Low-resolution electron impact mass spectra (EI-MS) were obtained at 70 eV on a Carlo Erba QMD 1000 GC-MS instrument by using the columns and temperature program specified above. An ion source temperature of 100°C was used. Chemical ionization mass spectra, with methane as reactant gas [CI(CH_4)-MS], were obtained on an AMD 604 double-focusing mass spectrometer at a resolution of 1000 and a mass range of 100–500 atomic mass units.

Dimethyl Disulfide Derivatization. DMDS derivatization was carried out according to the method of Vincenti et al. (1987). A dichloromethane extract (18 μl) of the secretion was concentrated in a 1-ml Reacti-Vial with a slow stream of purified (activated charcoal) nitrogen. Residual dichloromethane was removed by the addition and slow evaporation of carbon disulfide 50 μl. This process was repeated three times. The residual material was dissolved in 50 μl carbon disulfide, and 5 μl of an iodine solution (60 mg iodine in 1 ml diethylether) as well as 50 μl dimethyl disulfide were added. The screw-capped vial was sealed using a PTFE-lined septum and left in the oven of a gas chromatograph at 60°C for 40 hr. The reaction was quenched with an aqueous solution of sodium thiosulfate (5%), and the DMDS derivatives were isolated by centrifuging the reaction mixture for a few minutes at 2000 rpm. The organic layer was transferred to a clean Reacti-Vial with a 100-μl syringe and concentrated to 5 μl for GC-MS analysis.

Lithium Aluminium Hydride Reduction. The organic constituents of the secretion were subjected to lithium aluminum hydride reduction to confirm the presence of reducible functional groups. A 7-μl aliquot of the extract was evaporated to dryness in a stream of nitrogen. The residual material was redissolved

twice in diethyl ether, evaporated to eliminate traces of dichloromethane, and then dissolved in diethyl ether (30 μl) and treated with a saturated solution of $LiAlH_4$ in ether (20 μl). The Reacti-Vial was closed using a PTFE-lined septum and heated for 5 min at 40°C, after which the reaction mixture was cooled and treated with cold water (30 μl), centrifuged, the organic layer transferred to a clean Reacti-Vial, and the resulting solution concentrated for GC-MS analysis.

Reference Compounds. Some of the compounds identified in the preorbital secretion of the male suni were available from previous research projects in this series, while others were obtained commercially. Unsaturated alcohols were purchased from Pherobank (Wageningen, The Netherlands). The following compounds were synthesized.

2-Methylicosane. A mixture of 1-bromohexadecane (2.78 g, 0.01 mol), 1-bromo-3-methylbutane (1.51 g, 0.01 mol), and sodium (0.92 g, 0.04 mol) was refluxed under argon until the Wurtz condensation started. The reaction went to completion within 3 hr. The unreacted sodium was destroyed with ethanol, whereafter water (5 ml) was added to the reaction mixture and the organic material extracted with hexane. According to GC-MS analysis, the extract contained 2,7-dimethyloctane (26%), 1-hexadecene (49%), 1-hexadecanol (6%), 2-methylicosane (18%), and dotriacontane (1%). EI-MS of 2-methylicosane: m/z 43 (85), 57 (100), 71 (66), 85 (45), 99 (18), 113 (8), 127 (6), 141 (5), 155 (4), and 253 (4%).

1-Alkyl Formates. A mixture of the primary alcohols, 1-butanol, 1-pentanol, 1-hexanol, 1-heptanol, 1-octanol, 1-nonanol, 1-decanol, 1-undecanol, 1-dodecanol, 1-tetradecanol, 1-hexadecanol, 1-octadecanol, 1-icosanol, 1-docosanol (15 mg each), and formic acid (420 μl) was heated overnight at 80°C and the products extracted with hexane for comparison with the constituents of the secretion.

Alken-1-yl Formates. A mixture of (*Z*)- and (*E*)-6-tridecen-1-yl formate, (*Z*)- and (*E*)-8-tetradecen-1-yl formate, and (*Z*)- and (*E*)-8-hexadecen-1-yl formate was prepared by heating the corresponding alkenols with formic acid and extracting the products from the reaction mixture as described above for the preparation of the saturated formates.

RESULTS AND DISCUSSION

The preorbital secretions of male and female suni differ both qualitatively and quantitatively, although they do contain a few constituents that are common to both. Male glands appear to be more productive than those of females, and the male secretion is also more complex. A series of related compounds forming the bulk of the female secretion could not be identified despite the availability of extensive 600-MHz NMR, HR-MS, and other physical data. Therefore, only the male secretion will be discussed here.

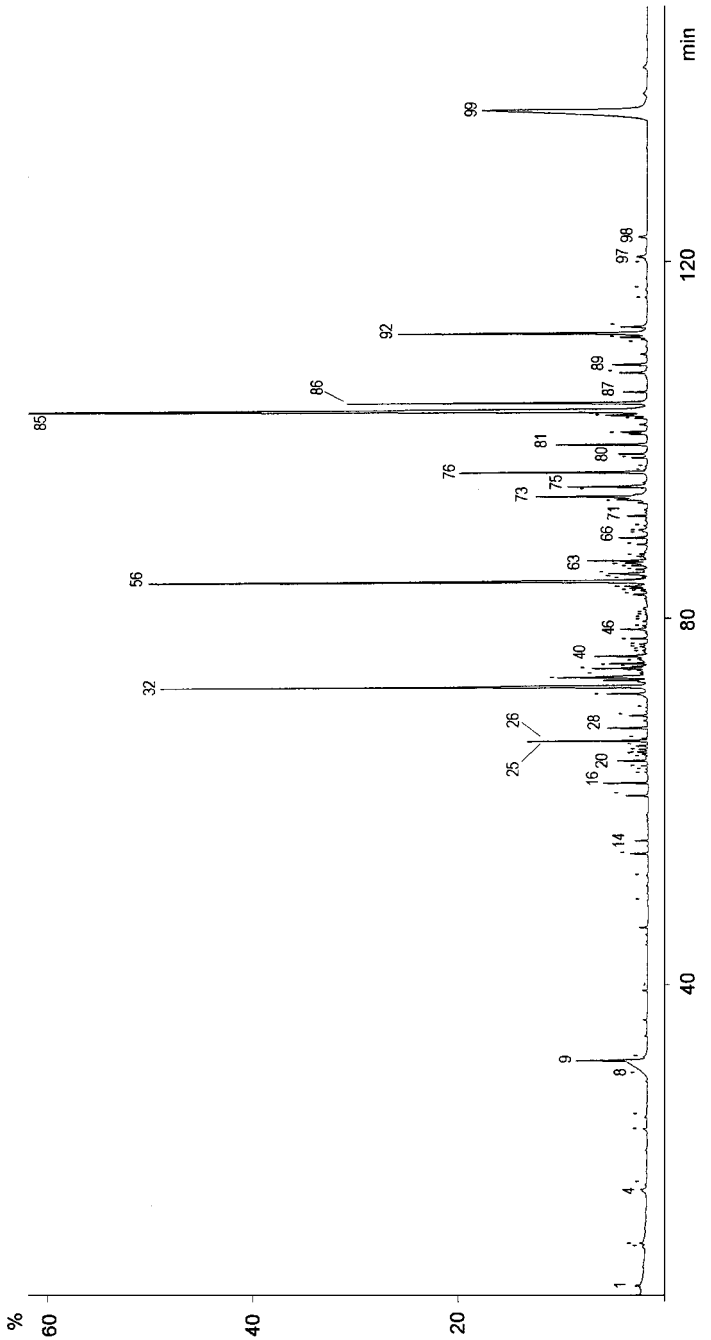

FIG. 1. Total ion chromatogram of an extract of the preorbital secretion of male suni, *Neotragus moschatus*. Glass capillary column coated with a 0.25-μm film of the apolar stationary phase PS-089, programmed at 2°C/min from 40°C to 270°C (hold).

A typical total ion chromatogram of the male secretion is shown in Figure 1. At the level of sensitivity at which the qualitative analyses were done, secretions from individual males were identical. Constituents from the male were tentatively identified by comparison of their mass spectra with mass spectral data in the NBS and Wiley mass spectral libraries. The identification of many compounds could be confirmed by coinjection of commercially available reference compounds or synthesized material. The molecular mass of some of the compounds and, therefore, their chain lengths were confirmed by CI(CH_4)-MS data.

There are two homologous series of alkanes present in the secretion. The first consists of long-chain, unbranched alkanes, the structures of which could easily be confirmed by GC coelution with reference compounds, and the second series contains saturated hydrocarbons with the typical EI mass spectra of isoalkanes. 2-Methylicosane was synthesized as a model compound to confirm interpretation of the mass spectral data. A series of unbranched, long-chain fatty acids, compounds that appear to be almost ubiquitous in the exocrine secretions of various antelope species, were also found in this secretion. These and the other compounds identified in the secretion are listed in Table 1.

Dimethyl disulfide derivatization and GC-MS analysis of the DMDS derivatives were used to determine the presence and position of double bonds in the unsaturated constituents of the secretion (Vincenti et al., 1987). The interpretation of the mass spectra of the DMDS derivatives was discussed in detail previously (Burger et al., 1996). Due to the complexity of the male secretion and extensive coelution of its constituents, almost none of the peaks in the chromatogram in Figure 1 represent pure compounds. With the exception of a few alkenyl formates identified using the PS-089 column, it was impossible to correlate the unsaturated constituents with their DMDS derivatives using the apolar PS-089 column. However, an OV-240 capillary column gave better separation of the large number of alkenes, saturated and unsaturated formic acid esters, and DMDS derivatives of the unsaturated compounds than the PS-089 column. The unsaturated compounds are listed in Table 1 in the order in which they eluted from the OV-240 column. Although these compounds do not necessarily elute in the same order from the less polar PS-089 column, the numbers are used in Figure 1 to indicate approximately where the different homologous groups of unsaturated compounds elute in the total ion chromatogram. In a few cases, DMDS derivatization showed both the *E* and *Z* isomers of the unsaturated alkenes and formates present in the secretion. It was, therefore, possible to assign *E* or *Z* configuration to the double-bond isomers based on the GC elution order of these compounds and their DMDS derivatives. The double-bond configuration of a few of the unsaturated constituents was also determined by GC retention time comparison with authentic samples. The elucidation of the stereochemistry of all unsaturated and chiral constituents of the secretion was not attempted. The stereochemistry of some of the unsaturated and

chiral constituents of the exocrine secretions of various South African antelope species will be dealt with in a future publication.

It is often difficult to differentiate between saturated and unsaturated long-chain alcohols, formates, and alkenes, especially if they are present in such small quantities that it is difficult to obtain pure spectra from a GC-MS analysis. These spectra often also lack diagnostic ions in the higher mass ranges. Furthermore, the preparative GC isolation of constituents is not feasible if they are present in low concentrations and only a limited quantity of secretion is available. Valuable diagnostic information was, however, obtained by lithium aluminum hydride reduction of the whole extract of the secretion of the male, which left some constituents intact, whereas carbonyl compounds, esters, etc., were reduced to compounds that coeluted with the reduction products of other reducible constituents. Information on the contribution of this experiment to the identification of some of the constituents of the secretion is included in Table 1.

Quantitative extraction of the volatile organic material from the secretion was not possible with small quantities of solvent. The widely varying quantities of secretion collected from individual males furthermore contained considerable proportions of water, as well as heavy material that does not pass through the GC column. It is, therefore, impossible to determine the average quantitative composition of the preorbital secretions of males with even reasonable accuracy. The quantitative results in Table 1 are nevertheless included to give at least an approximate indication of the quantities of most of the compounds present in a relatively large sample of secretion collected from a single male.

The suni is the fifth of several small South African antelope species belonging to the tribe Neotragini of which the chemical composition of the preorbital secretion

has been investigated. Of these antelope, the male klipspringer, *Oreotragus oreotragus*, (Burger et al., 1997) is unique in that the male preorbital secretion contains only eight short-chain, volatile organic compounds: four ketones and four esters. The female preorbital secretion of the klipspringer has so far not been investigated. As mentioned in the introduction, female oribi, *Ourebia orebi* (Mo et al., 1995), do not produce any preorbital secretion, although they possess an external structure that resembles that of the preorbital gland of the male. The preorbital secretions of male and female grysbok, *Raphicerus melanotis*, (Burger et al., 1996) and steenbok, *R. campestris*, (Burger et al., 1999b) have also been reasonably well characterized. Male and female secretions of the two *Raphicerus* species are qualitatively identical. Perhaps the most remarkable feature of members of this tribe is the large number of long-chain saturated and unsaturated formic acid esters present in all secretions investigated so far, with the exception of the klipspringer's preorbital secretion. The results from members of the tribe Neotragini are summarized in Table 2. Due to the large number of double-bond positional and configurational isomers present in some members of this tribe, it is impossible to include all relevant information in Table 2. However, there does not seem to be any indication that the position of double bonds in the unsaturated constituents and their stereochemistry could play a part in the territorial behavior of these animals.

One aspect that merits consideration in future research is the possibility that some constituents of the secretions are not secreted by the preorbital glands but are produced by different strains of the same bacterium or by different bacteria present in the glandular structures of the animals. This is supported by the observation that the secretions are more complex in the members of the tribe that produce secretion only very slowly, whereas the secretion of the male klipspringer, produced at a rate of about 5 mg/min, contains only eight simple compounds. In this case, microbial action probably cannot add to the secretion's complexity before it is deposited as a territorial mark and dries out.

Acknowledgments—Support by the University of Stellenbosch and the National Research Foundation, Pretoria, of research reported in this paper is gratefully acknowledged. The authors are indebted to Mr. John Spence, Director of the Tygerberg Zoo, Cape Town, for permission to collect secretions from suni in the zoo.

(Received March 30, 2001; accepted September 3, 2001)

Abstract—Changes in apple leaf chemistry after infestation by leafminers and their effect on both host location and host habitat location of the generalist parasitoid *Pholetesor bicolor* were investigated. Chemical analysis of leaf solvent extracts from healthy and leafminer-damaged leaves revealed that herbivory increased the amount of the triterpene squalene ($C_{30}H_{50}$), whereas quantities of all other identified compounds were similar in both plant treatments. To assess the response of parasitoids to host location cues, contact bioassays were conducted with naïve females. Results showed that parasitoids performed a characteristic ovipositional probing more often on the mine-damaged than on the healthy leaf. This behavior was triggered by a hexane extract of the mine-damaged leaf, but not by a healthy leaf extract. A synthetic mixture of the compounds identified in the extract triggered a similar response. A mixture devoid of squalene was not active, whereas squalene alone elicited the probing behavior. To assess the use of the identified compounds in habitat location, Y-tube olfactometer experiments were conducted with naïve and experienced females. Results showed that squalene is not involved in habitat location and has no priming effect on *P. bicolor*. While other triterpenes are known to mediate habitat location of parasitoids, this is the first report in which a plant triterpene is shown to mediate host location of a parasitoid. The biological and ecological functions of squalene on all three trophic levels are discussed.

Key Words—Squalene, semiochemicals, foraging behavior, leafminer parasitoid, apple plant, tritrophic.

INTRODUCTION

Upon insect herbivory, plants generally activate biochemical defenses. These defenses may act directly against herbivores (reviewed by Karban and Baldwin 1997) and/or elicit chemical signals that may attract natural enemies of the herbivore (reviewed by Price 1997). Several plant compounds induced by herbivore feeding have been identified and are most often used by parasitoids during the initial stages of host selection, i.e., for habitat location before landing (Rutledge, 1996). It is relatively unknown how parasitoids use plant chemicals after landing on an infested plant. In fact later stages of host selection, including host location, host acceptance, and oviposition (*sensu* Vinson, 1984) are most often mediated by semiochemicals directly produced by the arthropod host (Vinson, 1991; Vet and Dicke, 1992). There seem to be exceptions where plant derived chemical cues mediate host location of parasitoids. This includes foraging of parasitoids for non-concealed (Horikoshi et al., 1997) as well as concealed hosts (Keller and Horne, 1993; Horikoshi et al., 1997; Mattiacci et al., 1999).

Endophytic hosts such as leafminers impose a particular challenge for natural enemies. Parasitoids searching on a leaf for concealed hosts do not have direct contact with the herbivore. This investigation deals with the chemical signals involved in host location of *Pholetesor bicolor* Ness (Hymenoptera: Braconidae). This endoparasitoid belongs to a large community of natural enemies that parasitize apple leafminers of the genus *Phyllonorycter* (Lepidoptera: Gracillariidae). In Hungarian orchards, *P. bicolor* is considered a primary parasitoid of apple leafminers (Balázs et al., 1996). Because *P. bicolor* is well synchronized with its host (Balázs, 1992), it can be considered a potential biological control agent of *Phyllonorycter* species that cause economic damage in several major apple growing regions of the world (Dorn et al., 1999).

In a recent study on host location of *P. bicolor*, we obtained results indicating an innate response of parasitoids to the herbivore-damaged leaf, but not to the larva or host-derived material (Dutton et al., 2000). The response could be elicited by exposing females to a synthetic mixture of *n*-alkanes and squalene, which were identified from the herbivore-damaged mine area. *n*-Alkanes are important chemicals in both habitat and host location for various parasitoid species (Rutledge, 1996). However, in this system it remains unclear whether these compounds are produced by the plant after leafminer herbivory, which specific compound(s) are used by the parasitoid for host location, and whether they are used by the parasitoid as chemical cues for habitat location.

Habitat location of *P. bicolor* involves olfactory cues emitted by infested leaves (Dorn et al., 1999). Given that this parasitoid has no direct contact with the host upon landing on a leaf, it is possible that similar compounds mediate both habitat and host location. Furthermore, as a generalist parasitoid, *P. bicolor* may benefit from a previous contact exposure to the leaf enclosing its endophytic host

for the subsequent location of leafminers in the same habitat. Indeed, experience is known to increase parasitoid responses towards certain stimuli (i.e., priming) or even generate new ones (i.e., associative learning). For example, previous contact exposure to innately recognized semiochemicals enhances the searching ability of parasitoids used for biological control in greenhouses and the field (Hare et al., 1997; Grasswitz, 1998). *P. bicolor* prefers volatiles emitted by infested over noninfested plants only after prior exposure to plants damaged by leafminers (Lengwiler et al., 1994; Dorn et al., 1999). Presently, the effect of exposure to innately recognized contact cues on the subsequent habitat location of this parasitoid is unknown.

This study was designed to: (1) investigate the chemical response of apple leaves to leafminer herbivory, (2) identify the substance(s) mediating host location of *P. bicolor,* (3) assess the role of apple leaf chemicals for both host and habitat location, and (4) determine the impact of experience on contact cues for the subsequent parasitoid habitat location.

METHODS AND MATERIALS

Plant and Insect Rearing

Two-month-old apple seedlings (*Malus sylvestris* cv. Golden Delicious, Rosaceae) were used for rearing of insects and for preparation of leaf chemical extracts. Plants were grown in climatic chambers at 25°C daylight and 17°C night, 70% relative humidity and 16 L : 8 D photoperiod.

Insects were collected in apple orchards in South Tyrol (northern Italy). Parasitoids were reared in individual cages on four to five apple seedlings heavily infested with sap-feeder leafminers. At pupation, leaves were removed from plants and introduced in a separate cage in which the parasitoids were allowed to emerge. We used three to six-day-old honey-fed female parasitoids for all bioassays. Host location bioassays were conducted with mated naïve females, whereas habitat location experiments were conducted with females that were mated and then given an experience (see details below).

Plant Response to Herbivory

Leaf extracts were obtained by soaking overnight 45-50 apple leaves with 100 mines (2 mines per leaf) in 200 ml hexane. These herbivore-infested apple leaves are referred to as mine-damaged leaves. The hexane extract was filtered through 10 g silica gel (Supelco) that had been previously conditioned with 50 ml hexane, and concentrated first with a rotary evaporator (32 ± 3°C) and then under a stream of nitrogen (purity 99.96%) to 10 μl. The same extraction procedure was applied to healthy leaves that were of similar age and had the same leaf area surface as those with mines. Leaf area was measured with an area meter instrument (Licor 300A).

Ten separate sample extracts of each treatment (mine-damaged and healthy) were analyzed with an HP 5890 Series II Plus gas chromatograph, equipped with a flame ionization detector (300°C) and a nonpolar HP-1 (Crosslink Methyl Silicone Gum) capillary column (30 m × 0.25 mm × 0.25-μm film thickness). The oven temperature program was held at 100°C for 2 min, then increased to 300°C at a rate of 6°C/min, and held at 300°C for 15 min. The split/splitless injector (250°C) was operated in splitless mode throughout the analyses. The carrier gas was helium (purity 99.96%) at a pressure of 108 kPa (constant pressure). Samples of 1 μl were injected. To evaluate quantitative differences among treatments for the individual compounds identified, peak areas were analyzed using a *t* test with the appropriate Bartlett's test for homogeneity and Kolmogorov-Smirnov test for normality (Sokal and Rohlf, 1981). To quantify the compounds found in mine-damaged leaves and healthy leaves, three additional extracts of each treatment were analyzed with an internal standard (100 ng octylbenzene/μl). The quantities of each compound were calculated based on GC peak areas relative to the internal standard. A response factor for each identified compound in relation to the internal standard was calculated. Identification of compounds by coinjection with authentic standards was performed with gas chromatography–mass spectrometry (GC-MS). Analyses were done using a HP 6890 Series GC connected to an HP 5973 electron-impact (EI) MS. The chromatographic conditions were kept as described above. The MS temperature parameters were: 230°C at the source, 150°C at the quadruple, and 280° at the interface. The masses were swept at 23–600 mass units at a rate of 2.6 scans/sec.

Parasitoid Response to Contact Chemical Cues for Host Location

All behavioral contact assays were performed in a single choice Petri dish (10 cm diam.) arena. Parasitoids were placed individually in glass vials (2 cm diam. × 4 cm high) and the open end of the vial was positioned over the plant cue sources or over an extract treated filter-paper (1.3 cm diam.). Females that were observed performing the characteristic thrusting of the ovipositor, from here on referred to as probing, on the filter-paper for more that 5 sec were considered to respond positively to the treatment. Observations were conducted under laboratory conditions at 23 ± 2°C, 50 ± 10% relative humidity and 1000 ± 500 lux. Each treatment was bioassayed simultaneously with a control, and for statistical analysis a χ^2 test was performed between treatments and controls.

Experiment 1. Response to Healthy and Mine-Damaged Leaf Material. In order to elucidate whether the source of active compounds eliciting ovipositional probing of *P. bicolor* is specific to herbivore damage, female parasitoids were offered the following cue sources: (1) a 1.2-cm^2 piece of healthy lower-leaf epidermis (healthy), (2) a 1.2-cm^2 piece of lower-leaf epidermis damaged by one larva (mine-damaged), from which the larva and its by-products were

carefully removed, or (3) an empty Petri dish (control). The leaf area offered corresponded to the size of a fully developed mine. This reference area was used throughout the work for quantifying the compounds extracted from leaves and for calculating the concentrations of the synthetic mixture used in subsequent experiments.

The behavioral parameters recorded were the time spent walking, standing, and probing on the cue source offered. The parameters were recorded over a 20-min period with The Observer computer software (Noldus, 1991). Each behavioral parameter was analyzed by Kruskal-Wallis ANOVA followed by pairwise multiple comparisons between treatments using the Student-Newman-Keuls method (Sokal and Rohlf, 1981).

Experiment 2. Response to Healthy and Mine-Damaged Leaf Extracts. In order to examine whether host location is elicited by plant chemical cues, solvent extracts from both healthy and mine-damaged leaves were tested. Leaf epidermis from each plant treatment was carefully removed with tweezers and soaked separately in hexane (purity 99.7%) at 4°C for 24hr. The extract concentration applied to the filter-paper was made so that 10 μl were equivalent to 1.2 cm^2 mine-damaged or healthy leaf. Hexane alone was applied to the filter paper as a control.

Experiment 3. Response to a Mixture of n-Alkanes and/or Squalene. A mixture of the synthetic *n*-alkanes *n*-C_{27}, *n*-C_{29}, *n*-C_{30}, *n*-C_{31}, *n*-C_{32}, *n*-C_{33}, and squalene ($C_{30}H_{50}$) (Fluka Chemie AG, purity $\geq$ 99.5%) at quantities equivalent to 1.2 cm^2 mine-damaged leaf (see Table 1) was tested against a control (hexane). A dose–response test was carried out with the same reference mixture using a dilution factor of 10. The mixture of *n*-alkanes without squalene was tested, and subsequently a dose–response test of squalene was performed.

Parasitoid Response to Host Location Cues for Habitat Location

Two Y-tube olfactometer bioassays were conducted to examine: (1) whether the identified chemical cues identified in mine-damaged leaves are used by *P. bicolor* as olfactory stimuli for habitat location, and (2) whether a previous contact exposure to innately recognize plant-derived cues enhance habitat location of *P. bicolor* through priming (Hare et al., 1997).

The olfactometer consisted of a glass Y-shaped tube. Odor sources were placed in glass chambers (27 cm long $\times$ 2.5 cm diam.) which directly fitted to each of the two Y-tube arms. Humidified air (300 ml/min) entering the odor source chamber was filtered through a charcoal filter. Parasitoids were individually introduced in the central arm of the olfactometer and given a maximum of 10 min to make a choice for one of the two olfactometer arms. A choice was recorded when the female had crossed a line marked 20 cm after the junction of the two arms. Responses of *P. bicolor* in the olfactometer were analyzed with a χ^2 test

with null hypothesis of a 50 : 50 distribution over the two odor sources. Females that did not respond during the 10-min observation were not included in the analysis. To avoid a bias in arm preference, odor sources were reversed after every third tested female. The environmental conditions in the bioassay room were 23 ± 2°C, 50 ± 5% relative humidity and 1200 ± 50 lux provided with artificial light.

Experiment 4. Squalene and n-Alkanes as Olfactory Stimuli. In the Y-tube olfactometer females were given the choice between the synthetic mixture of squalene and *n*-alkanes identified in the mine-damaged leaves and pure solvent as control (blank). The mixture of compounds was tested at a concentration equivalent to 1.2 cm^2 mine-damaged leaf surface and at three higher concentrations (dilution factor of 10). The compounds in hexane were applied to a Teflon septum (1.3 cm diam.) and placed in one arm of the Y-tube. A similar septum with hexane (blank) was placed in the other arm of the Y-tube.

Prior to being tested, wasps were given 25 ± 5 min contact experience on leafminer-infested plants. Preliminary experiments showed that naïve parasitoids are not attracted to mine-damaged plants. Experienced wasps were placed individually in vials for 30 min before they were tested.

Experiment 5. Squalene and n-Alkanes as Priming Stimuli. In the Y-tube olfactometer, females were given the choice between one infested apple leaf containing five mines (mined leaf) or clean air (blank). Wasps were given either no experience (naïve) or a 25 ± 5 min contact experience on one of the following treatments: (1) a leafminer infested plant, (2) the hexane extract of mine-damaged leaf, (3) the synthetic mixture of squalene and *n*-alkanes, or (4) a healthy plant. The contact experience with leafminer infested or healthy plants was provided as in the previous experiment (see above). Experience on the leaf extract or the synthetic mixture was provided by offering the solution in a filter-paper as in the host location bioassays.

RESULTS

Plant Response to Herbivory. Eight major compounds were identified by GC-MS in extracts from apple leaves infested with the leafminer *P. pomonella* and from healthy apple leaves (Table 1). Among them, only squalene ($C_{30}H_{50}$) was found in the mine-damaged leaves in larger quantities than in the healthy leaves (Student's *t* test, t value $= 2.6$; $df = 9$; $P = 0.03$). Only one minor peak was not identified, and all other compounds consisted of long-chain hydrocarbons (*n*-C_{27}, *n*-C_{29}, *n*-C_{30}, *n*-C_{31}, *n*-C_{32}, *n*-C_{33}).

Experiment 1. Response to Healthy and Mine-Damaged Leaf Material. The behavior of *P. bicolor* offered mine-damaged or healthy leaf material is depicted in Figure 1. Wasps spent more time walking, standing, and probing on the mine-damaged leaf ($P < 0.05$, Kruskal-Wallis ANOVA) than on the healthy leaf.

TABLE 1. COMPOUNDS EXTRACTED WITH HEXANE FROM *Phyllonorycter pomonella* HERBIVORE-DAMAGED AND HEALTHY APPLE LEAVES (*Malus sylvestris*)[a]

Compound	Leaf		
	Herbivore-damaged	Healthy	*P*
Heptacosane *n*-C_{27}	10.7 ± 0.8	8.2 ± 0.7	n.s
Unknown	6.3 ± 1.1	4.0 ± 0.9	n.s
Squalene $C_{30}H_{50}$	32.3 ± 13.1	12.2 ± 4.7	<0.05
Nonacosane *n*-C_{29}	91.3 ± 8.9	77.4 ± 11.3	n.s
Triacontane *n*-C_{30}	8.7 ± 1.2	7.3 ± 0.8	n.s
Hentriacontan *n*-C_{31}	251.6 ± 36.3	228.8 ± 18.8	n.s
Dotriacontane *n*-C_{32}	5.9 ± 0.9	5.6 ± 0.6	n.s
Tritriacontane *n*-C_{33}	34.0 ± 5.5	34.2 ± 1.7	n.s
Total	440.8 ± 67.6	377.8 ± 39.5	n.s

[a] [Average amount (ng $\pm$ SE) extracted from 1.2 cm^2 leaf surface (*t* test between treatments, $N = 10$)].

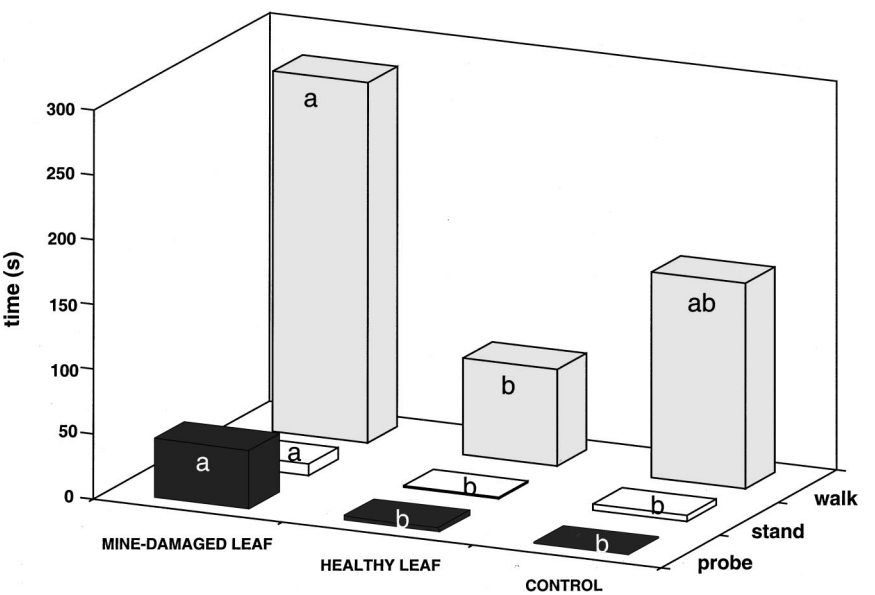

FIG. 1. Walking, standing, and probing activity of the parasitoid *P. bicolor* on mine-damaged and healthy apple leaf epidermis. Statistical differences in time duration spent for each activity on the different treatments are shown with different letters (Kruskal-Wallis ANOVA, $P < 0.05$).

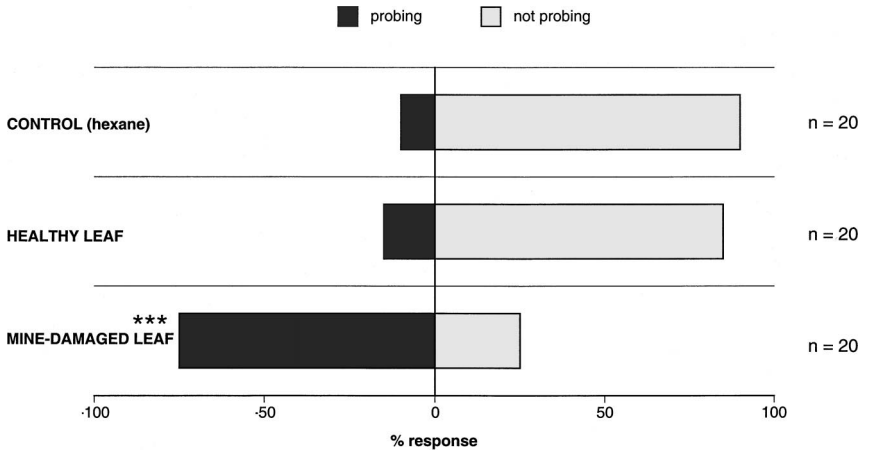

FIG. 2. Ovipositional probing response of *P. bicolor* females to hexane extracts of mine-damaged and healthy leaf epidermis. Mined-damaged vs. control: $^{***}\chi^2 = 14.7$, $df = 1$, $P < 0.001$.

In addition, no significant differences for probing and standing were observed between the healthy leaf and an empty arena (control). Only walking was similar on the mine-damaged leaf and on the control.

Experiment 2. Response to Healthy and Mine-Damaged Leaf Extracts. The ovipositional probing behavior of *P. bicolor* was triggered only by the hexane extract from mine-damaged leaves ($\chi^2 = 14.7$; $df = 1$; $P < 0.001$) (Figure 2). In contrast, the response of females to the extract from healthy leaves was similar to that of the control solvent, and substantially lower than the response to the mine-damaged leaves ($\chi^2 = 12.2$; $df = 1$; $P < 0.001$).

Experiment 3. Response to a Mixture of n-Alkanes and/or Squalene. The percent of females responding in the contact bioassay to the mixtures of synthetic compounds identified from the mine-damaged leaves is shown in Table 2. The mixture of *n*-alkanes and squalene elicited ovipositional probing behavior of *P. bicolor* at concentrations corresponding to quantities found in 1.2 cm^2 = 1 × ($\chi^2 = 20.1$, $P < 0.001$), 12 cm^2 = 10 × ($\chi^2 = 11.8$, $P < 0.001$), and 120 cm^2 = 100 × ($\chi^2 = 15.1$, $P < 0.001$) of mine-damaged leaf. The mixture of *n*-alkanes (1×) devoid of squalene did not trigger a response ($\chi^2 = 2.5$, $P > 0.05$). In contrast, squalene alone triggered a response over a range of concentrations from 30 ng to 3.1 μg. These quantities corresponded to those found in 1.2, 12, and 120 cm^2 surface area of mine-damaged leaves. The strongest response was obtained when females were offered 30 ng of squalene. This amount of squalene elicited a response that was significantly higher than to the solvent control, within the first 20 min of the bioassay.

TABLE 2. OVIPOSITIONAL PROBING RESPONSE OF FEMALE *Pholetesor bicolor* TO SYNTHETIC COMPOUNDS IDENTIFIED FROM *Phyllonorycter pomonella* HERBIVORE DAMAGED APPLE (*Malus sylvestris*) LEAVES[a]

Treatment	*n*	% females probing					
		20 min	χ^2	*P*	90 min	χ^2	*P*
Synthetic mixture (all compounds)							
0.1×	30	10	0.8	n.s.	23	2.9	n.s.
1×	30	30	5.1	≤0.05	70	20.1	≤0.001
10×	30	20	2.6	n.s.	50	11.8	≤0.001
100×	30	13	0.2	n.s.	57	15.1	≤0.001
1000×	30	7	0	n.s.	27	2.9	n.s.
synthetic mixture (1×) (excluding squalene)	30	3	0	n.s.	30	2.5	n.s.
Squalene (ng)							
3	30	7	0	n.s.	27	2.9	n.s.
15	30	7	0	n.s.	33	3.5	n.s.
30	30	30	4.0	≤0.05	63	16.1	≤0.001
310	30	13	0.2	n.s.	57	15.1	≤0.001
3100	30	20	2.3	n.s.	57	12.7	≤0.001
31000	30	7	0	n.s.	27	2.9	n.s.

[a][Concentration 1× corresponds to that given in Table 1 offered on a 1.3-cm^2 filter paper. The total observation time for each female was 90 min. χ^2 performed between treatment and control (hexane).]

Experiment 4. Squalene and n-Alkanes as Olfactory Stimuli. In the Y-tube olfactometer bioassay, no response of females towards the mixture of squalene and *n*-alkanes was observed (Figure 3), regardless of the concentration offered. This indicates that squalene is not used by *P. bicolor* as a chemical cue in habitat location.

Experiment 5. Squalene and n-Alkanes as Priming Stimuli. In the Y-tube, only females that had been given a previous contact experience on leafminer damaged plants preferred the volatiles emitted by the mine-damaged leaf versus the control ($\chi^2 = 15$; $P < 0.001$) (Figure 4). Neither a previous contact experience with the mine-damaged leaf extract nor a contact with the synthetic mixture, induced a preference towards the odor of the mined leaf.

DISCUSSION

Apple leaves infested by leafminers produce the triterpene squalene ($C_{30}H_{50}$) in quantities higher than noninfested leaves. Squalene elicits a characteristic ovipositional probing behavior of naïve *P. bicolor* which demonstrates that this chemical

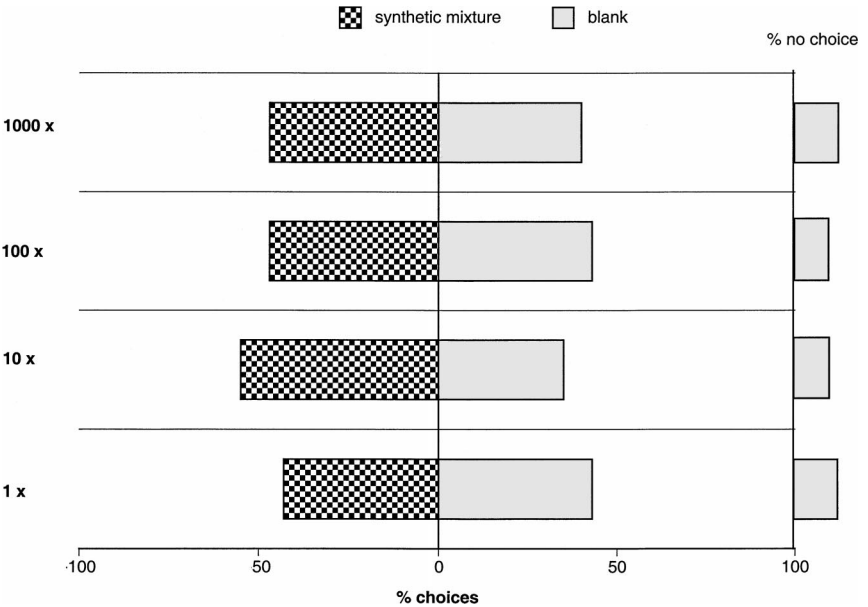

FIG. 3. Response of *P. bicolor* to the synthetic mixture of squalene and *n*-alkanes in the Y-tube olfactometer. Concentrations of synthetic mixture are indicated on the left side (dilution factor of 10). 1× corresponds to 1.2 cm^2 leaf area surface of mine-damaged leaf (see Table 1 for quantities). Percent females making no choice is indicated on the right side ($N = 30$ for each test).

is innately recognized and used by the parasitoid for host location after landing on a host-infested patch. Given that squalene cannot be synthesized by arthropods (Downer, 1985), we conclude that this compound is of plant origin. Its increased production seems to be induced by *Phyllonorycter pomonella's* herbivory. Previous reports have documented herbivore induction of terpenes in plants, and their use by parasitoids and predators for habitat location (for reviews see Rutledge, 1996 and Dicke, 1994). However, this specific triterpene has not been reported as a plant-derived semiochemical for parasitoids. Squalene in this system can be defined as a contact plant synomone for the parasitoid (sensu Dicke and Sabelis, 1988).

To our knowledge, this is the first record of squalene being extracted from apple leaves. The most closely related plant species from which squalene has been extracted is *Prunus persica* (L.) Batsch (Lin and Lin, 1992). Squalene is widely found in both plant and animal tissue, being a basic intermediate metabolite for the biosynthesis of sterols and triterpenes (Bonner, 1965). From the genesis of squalene through the mevalonate → geranyl pyrophosphate → farnesyl pyrophosphate

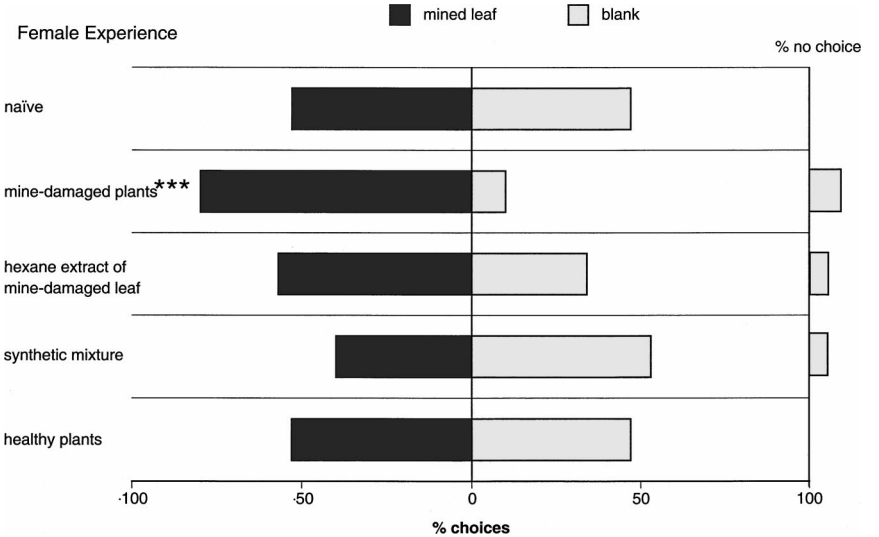

FIG. 4. Response of *P. bicolor* females to mine-damaged leaf in Y-tube olfactometer. Type of experience is indicated on left side. Percent females making no choice is indicated on the right side. Asterisks indicate a significant difference within a choice test: χ^2, $^{***}P < 0.001$ ($N = 30$ for each test).

pathway, and the subsequent steps leading to sterol production (squalene epoxidase → squalene 2,3-oxide), it is evident that squalene is an essential compound regulating plant growth (Yates et al., 1991; Simmen and Gisi, 1995). The increase of squalene in organisms such as plants, fungi, and mammals has been correlated to the exogenous inhibition of squalene epoxidase (Petranyi et al., 1984; Ryder and Dupont, 1985; Yates et al., 1991; Simmen and Gisi, 1995). The inhibition of squalene epoxidase in these organisms is shown to constrain the biosynthesis of sterols and consequently lead to growth inhibition. In our apple plant system, we observed both an increase of squalene (Table 1), and a decrease of plant growth in mine-damaged seedlings as compared to healthy seedlings (A. Dutton, personal observation). We can, therefore, hypothesize a possible direct effect of squalene on the first trophic level.

Given that squalene is an intermediate in the biosynthesis of other triterpenoids and sesquiterpenoids, it might indirectly affect the second trophic level. In fact, different plant species produce sesquiterpenoids and triterpenoids as defense compounds against pathogens (phytoalexins) and/or herbivores (Threlfall and Whitehead, 1988; Gershenzon and Croteau, 1991; Zook and Kuc, 1991). Although squalene itself has not been reported as a phytoalexin or as a toxin to herbivores, its involvement in phytoalexin biosynthesis in plant cell cultures after

fungal infection is known (Van Der Heijden et al., 1989). It would be of interest to determine if squalene has a behavioral effect on the leafminer or on other herbivore species.

Our results indicate a behavioral effect of squalene on the third trophic level. The almost threefold increase of squalene in mine-damaged leaves, with a mean value of 32 ng/1.2 cm^2 (Table 1) triggered the observed ovipositional probing behavior of the parasitic wasp *P. bicolor* (Table 2). A slightly higher amount of squalene was extracted from the mined leaf area (mean = 37 ng/1.2cm^2) (Dutton et al., 2000) as that extracted from the whole leaf (mean = 32 ng/1.2cm^2, Table 1). This indicates a possible localized increase in concentration of this substance at the site of herbivory. This finding coincides with our behavioral observation that parasitoids probe on the mined leaf area and not on healthy tissue. A similar localized response of plant compounds upon herbivory and a related parasitoid response were recently shown in the crucifer-*Pieris*-*Cotesia* tritrophic system (Horikoshi et al., 1997).

Several terpenes are known to be involved in habitat and host location of parasitoids (Rutledge, 1996). To our knowledge, this is the first report of squalene being involved in host location of a parasitoid. Behavioral effects of squalene in interactions among other organisms are known. For example, ticks of the genus *Dermacentor* ingest squalene from mammal blood and use the substance as an allomone to protect themselves against ant attack (Yoder et al., 1993). Furthermore, pollinating bats use squalene as a flower attractant (Ecroyd et al., 1995).

Enhanced responsiveness of parasitoids after a brief exposure to innately recognized cues has been demonstrated previously (Turlings et al., 1989; Lewis and Martin, 1990; Hare et al., 1997). In our system, exposing *P. bicolor* females to innately recognized cues such as squalene did not result in a subsequent attraction to leafminer infested leaves (Figure 5). However, we cannot rule out the possibility that this substance is used in associative learning (Vet et al., 1995). If such were the case, the parasitoid would need a previous exposure to the contact cue in association with plant volatiles. This can be supported by the fact that parasitoids exposed to contact and volatile cues (i.e., females given a contact experience on leafminer infested plants) subsequently were attracted to herbivore–plant volatiles.

In the Y-tube olfactometer experiments, we could not demonstrate a habitat location response to the mixture of squalene and *n*-alkanes. However, in a previous study (Lengwiler et al., 1994) and in the present experiments (Figure 4), we observed a significant attraction of parasitoids to herbivore induced leaf volatiles. It seems evident, therefore, that the volatile and contact cues used by *P. bicolor* for habitat and host location are different. In both cases the cues are of plant origin.

Acknowledgments—This project was supported by a TH grant (ETH Zurich). We thank A. Hern, C. Fornallaz, and A. Dutly for technical support with GC-MS analysis; R. Bosshard and P. Egli for

assistance with behavioral bioassays; M. Krebs and T. Christoffel for helping in rearing of plants and insects; and W. Völkl and A. Hern for their comments on an earlier draft of the manuscript.

Abstract—Silphinene sesquiterpenes are established chrysomelid antifeedants. In this work, nine silphinene analogs, 11β-acetoxy-5α-angeloyloxysilphinen-3-one (**1**), 11β-acetoxy-5α-tigloyloxysilphinen-3-one (**2**), 11β-acetoxy-5α-isobutyryloxysilphinen-3-one (**3**), 11β-hydroxy-5α-angeloyloxysilphinen-3-one (**4**), 11β,5α-dihydroxysilphinen-3-one (**5**), 11β,5α-diacetoxysilphinen-3-one (**6**), 5α,11β-diisobutyryloxysilphinen-3-one (**7**), silphinen-3,5,11-trione (**8**), and *O*-methyl-5-epicantabrenolic acid methyl ester (**10**), and a presilphiperfolane sesquiterpene (**9**) were tested against several divergent insect species, including the lepidopteran *Spodoptera littoralis*, the chrysomelid *Leptinotarsa decemlineata*, and five aphid species, and their antifeedant effects were compared with those of picrotoxinin, a GABA-antagonist, and thymol, an allosteric modulator for insect GABA receptors. All insects tested responded to at least one silphinene analog and/or GABA antagonist. Compound **3** and thymol were effective antifeedants against all species tested except *S. littoralis*, with varying potencies according to their feeding ecologies. The toxicity of these compounds was species-dependent and did not correlate with their antifeedant effect.

Key Words—Silphinene sesquiterpenes, picrotoxinin, thymol, GABA inhibitor, antifeedants, Colorado potato beetle, aphids.

INTRODUCTION

The role of insect taste on host-plant acceptance is basic to the understanding of insect–plant interactions (Bernays and Chapman, 1994). In most cases, antifeedant compounds play an important role in host-plant selection by phytophagous insects (Bernays and Chapman, 1977, 1994, 2000; Mitchell, 1994). The molecular basis of insect taste, however, remains unknown.

Gustatory studies carried out on western corn rootworm (*Diabrotica virgifera virgifera* LeConte, WCR) have shown a direct correlation between antifeedant potency and known antagonistic action at GABA (γ-aminobutyric acid)/glycine amino-acid neuroreceptors (Mullin et al., 1992, 1994; Chyb et al., 1995; Eichenseer and Mullin, 1997). These antagonists include isoquinoline and indole alkaloids and sesquiterpenes (picrotoxinin).

Tricyclic silphinene sesquiterpenes such as compounds **1**, **4**, and **5** (Figure 1) are strong antifeedants to the Colorado potato beetle CPB; (*Leptinotarsa decemlineata* Say) (González-Coloma et al., 1995, 1997). A comparative study between the western corn rootworm and CPB included these silphinenes among 15 compounds, such as alkaloids, terpenoids, and phenolics. The silphinene analogs and all the established GABA- and glycinergic compounds tested acted as antifeedants to both insect species, suggesting a shared molecular mechanism for antifeedant taste chemoreception in divergent Chrysomelidae species (Mullin et al., 1997).

Additionally, sesquiterpenes with strong antifeedant effects on *L. decemlineata*, such as drimanes and bisabolanes, are also active feeding inhibitors to the aphid *Myzus persicae* Sulz (Griffith and Pickett, 1980; Caprioli et al., 1987; Gutiérrez et al., 1997), indicating that CPB sesquiterpene antifeedants are good aphid-antifeedant candidates.

Here we studied the antifeedant effects of 10 silphinene sesquiterpenes against several divergent insect species, including the lepidopteran *Spodoptera littoralis* Bois, the chrysomelid *L. decemlineata*, and five aphid species with diverse host adaptations. The molecules tested are shown in Figure 1 and included 11β-acetoxy-5a-angeloyloxysilphinen-3-one (**1**),11β-acetoxy-5α-tigloyloxysilphinen-3-one (**2**),11β-acetoxy-5α-isobutyryloxysilphinen-3-one (**3**),11β-hydroxy-5α-angeloyloxysilphinen-3-one (**4**), 11β,5α-dihydroxysilphinen-3-one (**5**), 11β, 5α-diacetoxysilphinen-3-one (**6**), 5α,11β-diisobutyryloxysilphinen-3-one (**7**), silphinen-3,5,11-trione (**8**), the presilphiperfolane **9**, and silphinene *O*-methyl-5-epicantabrenolic acid methyl ester (**10**). Compounds **1–4**, **9**, and **10** are natural products, and their biological activities have been compared with those of the semisynthetic ones (**5–8**) to establish their structure–activity relationships. Their antifeedant effects have been compared with those of picrotoxinin, an established GABA-gated chloride channel antagonist (Klunk et al., 1983; Ozoe and Matsumura, 1986) and thymol, an allosteric modulator for insect GABA receptors

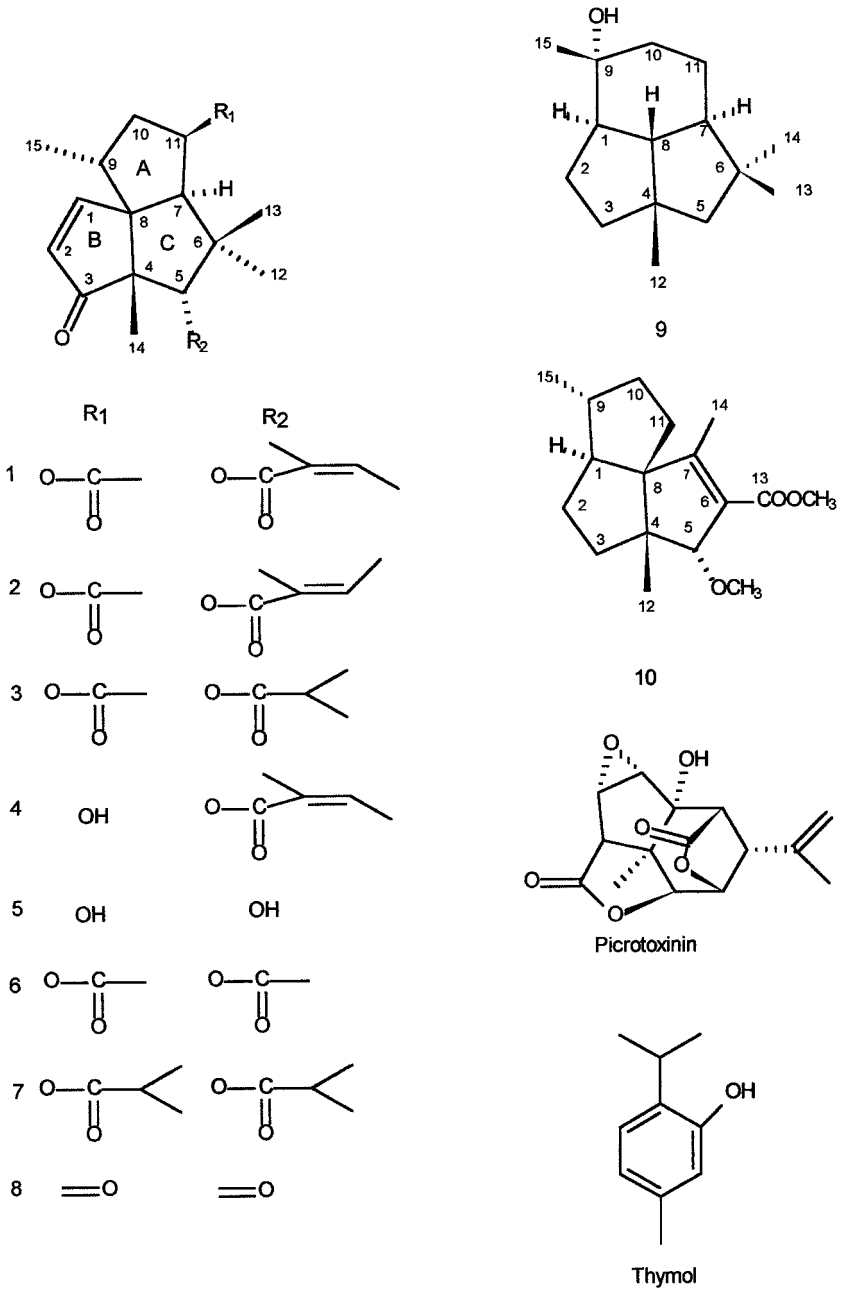

FIG. 1. Molecular structures of compounds **1–10**, picrotoxinin, and thymol.

(Priestley et al., 1999). The sesquiterpene farnesol was included as a positive control for aphid antifeedants (Gutiérrez et al., 1997).

METHODS AND MATERIALS

General Experimental Procedures

NMR spectra were measured on a Bruker AMX2 500-MHz spectrometer with pulsed-field gradient, using the solvent as internal standard ($CDCl_3$, at δ_H 7.26 and δ_C 77.0). Exact mass measurements and electronic impact–mass spectroscopy (EI-MS) results were recorded on an Autospect instrument at 70 eV. HPLCs were carried out on a Gilson-302, equipped with a 115 model UV detector and a Waters Prep-LC 4000 equipped with a diode-array detector. Silica gel from Merck (15111, 7741, 5550) and Aldrich (9,944-3) were used for column chromatography and TLC. Sesquiterpenes were visualized on TLC with a 25% H_2SO_4 solution.

Insects

S. littoralis, *L. decemlineata*, and the aphid colonies (*M. persicae*, *Diuraphis noxia*, *Rhopalosiphum padi*, *Metopolophium dirhodum*, and *Sitobion avenae*) were reared on artificial diet (Poitout and Bues, 1974) and their respective host plants (*Solanum tuberosum*, *Capsicum annuum*, and *Hordeum vulgare*) and maintained at $22 \pm 1^{\circ}$C, >70% relative humidity, and photoperiod of 16L:8D in a growth chamber.

Choice Feeding Assays

These experiments were conducted with *S. littoralis* L6 larvae, adult *L. decemlineata*, and apterous aphid adults. For *S. littoralis* and *L. decemlineata*, each treatment consisted of 5–10 Petri dishes with 2 or 4 insects each as described in González-Coloma et al. (1997). The uneaten leaf disk surfaces were measured according to Escoubas et al. (1993) with a computer interfaced scanner. Percent feeding reduction (%FR) was determined for each Petri dish by the equation $\%FR = [1 - (\text{treatment consumption/control consumption})] \times 100$ (Bentley et al., 1984). For the aphids, each treatment consisted of 20 boxes with 10 insects each as described in Gutiérrez et al. (1997). A settling inhibition index (%SI) was calculated for each compound [$\%SI = 1 - (\%T/\%C) \times 100$, where $\%T$ is percent aphids on treated surface, $\%C$ is percent aphids on control surface] (Gutiérrez et al., 1997). Compounds with FR or SI > 60% at an initial dose of 50 μg/cm^2 were tested in a dose–response experiment to calculate their relative potencies (EC_{50} values, the effective dose for 50% feeding/settling reduction), which was determined from linear regression analysis (%FR or %SI on log dose).

Oral Cannulation

This experiment was performed with preweighed newly emerged *S. littoralis* L6 larvae under the same environmental conditions as above. Each experiment consisted of 20 larvae orally dosed with 20 μg of the test compound in 2 μl DMSO (treatment) or solvent alone (control) as described in González-Coloma et al. (1998). At the end of the experiments (72 hr), larval consumption and growth were calculated on a dry weight basis (see González-Coloma et al., 1998 for details). An analysis of covariance (ANCOVA) was performed on biomass gains and food consumption with initial biomass as covariate (Raubenheimer and Simpson, 1992; Horton and Redak, 1993).

Hemolymph Injection

DMSO solutions of the test compounds (10 μg each per insect) were injected through the metepimeron suture of the thorax of 20 adult *L. decemlineata* beetles as described in González-Coloma et al. (1998). Toxicity symptoms and mortality were recorded up to three days after injection by maintenance of beetles on their respective potato leaf foods. Percent mortality was analyzed with contingency tables and corrected according to Abbott (1925).

Isolation of Compounds

Compounds **1–4** were isolated from *Senecio palmensis* Chr. Sm. (Asteraceae) (collected in Boca Tauce, Tenerife, July 1996, voucher number ORT 36393, Jardín Botánico de La Orotava, Tenerife). Dried aerial parts of *S. palmensis* (2.8 kg) were exhaustively extracted with EtOH. The ethanolic extract (1000 g, 35.7% yield of dry plant weight) was chromatographed on a silica gel (Si gel) vacuum liquid chromatography (VLC) column using an *n*-hexane–EtOAc–MeOH gradient (*n*-hexane–EtOAc, 100:0–50:50) to give fractions A–G.

Fraction D, 14.5 g (1.45% yield, *n*-hexane–EtOAc, 95:5) was subsequently purified by Si gel-VLC, Sephadex LH-20, Si gel-column chromatography (CC), and semiprep normal-phase HPLC chromatography using a 250- $\times$ 20-mm silica column (Inertsil Prep-Sil, 10 μm particle size) at a flow rate of 10 ml/min and an isocratic mixture of Cl_2CH_2–$CNCH_3$ (92:8) to obtain 2.0 g of a mixture of **1** and a minor compound (0.21% yield). Peaks were detected at 254 nm. One hundred milligrams of this mixture were further purified by semiprep reversed-phase HPLC chromatography using a 250- $\times$ 20-mm silica column (Kromasil C18, 5-μm particle size) at a flow rate of 20 ml/min and a $CNCH_3$–H_2O gradient (65:35–100:0) to obtain 56 mg of pure **1** (0.11% yield) and 4 mg of pure **2** (5.3×10^{-3}% yield). Peaks were detected at 235 nm.

Fraction E, 70 mg (1.8 g, 0.06% yield, *n*-hexane–EtOAc, 90:10) was purified by semiprep normal-phase HPLC chromatography using a 250- $\times$ 8-mm silica

column (Nucleosil, 10-μm particle size) at a flow rate of 1.5 ml/min and a *n*-hexane–EtOAc gradient (92:8–90:10) to obtain 10.9 mg of a mixture (0.01% yield). This mixture was further purified by a gradient (Cl_2CH_2–$CNCH_3$, 100:0–96:4) and a subsequent isocratic (Cl_2CH_2–$CNCH_3$, 97:3) HPLC elution to yield compound **3** (6.5 mg, 5.9×10^{-3}% yield). Peaks were detected at 254 nm.

Fraction F, 1.8 g (6.3×10^{-2}% yield, *n*-hexane–EtOAc, 90:10) were subsequently purified by VLC and Si gel CC and eluted with *n*-hexane–EtOAc mixtures. The eluate obtained with *n*-hexane–EtOAc 85:15 afforded 60 mg of **4** (2.1×10^{-3}% yield).

Compound **5** was generated from **1** by chemical hydrolysis (González-Coloma et al., 1997). Compound **5** (100 mg) was acetylated with Ac_2O-pyridine at room temperature for 24 hr to give a residue of 142 mg. This residue was chromatographed over silica-gel to yield compound **6** (128.2 mg, 95.95%). A mixture of **5** (10 mg), pyridine (0.1 ml), and isobutyric anhydride (0.4 ml) was kept at room temperature for 72 hr to afford the reaction product, compound **7** (11.3 mg, 72.1%), after purification over a silica-gel column. A mixture of **5** (10.6 mg), pyridine (0.2 ml), and Cornforth's reagent (0.5 ml) was kept at room temperature for five days. The excess of reagent was decomposed with EtOH, the solvent removed, and the residue chromatographed over silica-gel column eluting with hexane–EtOAc (60:40), to give compound **8** (6.0 mg, 58%).

Compounds **9** and **10** were previously isolated from *Artemisia chamaemelifolia* Vill. (Asteraceae) (Marco et al., 1996) and provided by Prof. J. A. Marco (U. de Valencia, Spain).

Identification of Compounds

Compounds **1**, **4**, and **5** were identified as *11β-acetoxy-5α-angeloyloxysilphinen-3-one, 11β-hydroxy-5α-angeloyloxysilphinen-3-one, and 11β,5α-dihydroxysilphinen-3-one* by comparing their spectra with previously published data (Jakupovic and Abraham, 1985; González-Coloma et al., 1995, 1997).

*11β-Acetoxy-5α-tigloyloxysilphinen-3-one (**2**).* 1.8 mg. oil; EI-MS (70 eV, *m/z*, rel. int., %); 374 (M^+) (1) HRMS *m/z* (rel. int., %): $[M]^+$ 374.2106 (1), for $C_{22}H_{30}O_5$ (calcd. 374.2093). ^{1}H NMR ($CDCl_3$, 500 MHz): δ_H 0.91 (3H, s, H-12), 0.94 (3H, d, $J = 6.2$ Hz, H-15), 0.95 (3H, s, H-13), 1.23 (3H, s, H-14), 1.59, (H, ddd, $J = 12.5, 6.0, 3.0$ Hz, H-10α), 1.83 (3H, d, $J = 7.0$ Hz, H-4′), 1.89 (3H, br s, H-5′), 2.10 (H, dd, $J = 13.0, 6.0$ Hz, H-10β), 2.18 (H, s, OCC$\underline{H}_3$), 2.24 (H, d, $J = 4.4$ Hz, H-7), 2.63 (H, m, H-9β), 5,27 (H, br t, $J = 3.3$ Hz, H-11α), 5.44 (H, s, H-5β), 6.15 (H, d, $J = 6.2$ Hz, H-2), 7.60 (H, d, $J = 6.2$ Hz, H-1), 7.0 (H, dq, $J = 7.0$ Hz, H-3′). ^{13}C NMR ($CDCl_3$, 50 MHz): δ_C 211.1 (s, C-3), 173.9 (s, C-1″), 168.0 (s, C-1′), 167.8 (d, C-1), 138.0 (d, C-3′), 131.9 (d, C-2), 86.3 (d, C-5), 76.1 (d, C-11), 63.7 (s, C-8), 61.5 (d, C-7), 57.0 (s, C-4), 42.6 (s, C-6),

RESULTS AND DISCUSSION

Compounds **1–4** were previously isolated from *Cineraria geifolia*, and Compound (**1**) from *S. palmensis* (Jakupovic and Abraham, 1985; González-Coloma et al, 1995). Compound **4** has also been obtained as the partial hydrolysis product of **1** (González-Coloma et al., 1997), and is being described here as a natural metabolite of *S. palmensis* for the first time. Silphinene derivatives **5–8** were synthesized to carry out structure–activity studies.

The antifeedant effects of compounds **1–10**, picrotoxinin, and thymol were species-dependent (Table 1). The polyphagous *S. littoralis* was moderately sensitive to silphinenes **6** and **8** and insensitive to the GABA antagonists. *L. decemlineata*, a specialist of some Solanaceae species (Mitchell and Harrison, 1985; Hsiao, 1986; Sinden et al., 1988), was strongly sensitive to all the sesquiterpenes and GABA antagonists. *M. persicae* (more than 40 host-plant families) and *R. padi* (the most polyphagous among the cereal aphids) (Blackman and Eastop, 1985) were sensitive to compound **3** and thymol. *S. avenae* and *M. dirhodum*, both specialists of grasses and cereals as secondary hosts (Blackman and Eastop, 1985), were moderately sensitive to silphinenes (*S. avenae* responded to **3** and **5**; *M. dirhodum* to **3**) or picrotoxinin (*M. dirhodum*), and thymol (both). *D. noxia*, with the most restricted host-range (restricted to wheat and barley) (Blackman and Eastop, 1985), was the most sensitive aphid to silphinene derivatives (**1**, **3**, and **4**), picrotoxinin, and thymol. A similar species-dependent pattern was observed for the aphid antifeedant farnesol. Compound **3** was the only silphinene derivative that maintained its antifeedant activity among all the species tested with varying potencies according to their feeding ecologies. These results are consistent with the model suggesting that differences in taste sensitivity to deterrent compounds could account for the difference in host range (Bernays and Chapman,1994; Bernays et al., 2000). The fact that

[a] na, not enough compound available.

the insects were sensitive to either a silphinene analog, thymol, and/or picrotoxinin supports the hypothesis of a shared molecular mechanism for antifeedant taste chemoreception in divergent insect species as proposed by Mullin et al. (1997).

L. decemlineata responded to most of the silphinene analogs, as expected from their structural similarities with **1** and their possible biogenetic relationship (Marco et al., 1996), allowing for the study of their structure–activity relationships (Table 1). When compared to **1**, analogs **2** and **3** were 4 and 10 times more active, respectively, **6** was similarly active; and **7**, **9**, and **10** were 6–20 times less active.

Small structural changes resulted in drastic differences in antifeedant activity, suggesting a high molecular selectivity for silphinene derivatives on CPB taste chemoreception. The increased activity of compounds **2** and **3** versus **1** and **6** demonstrated that a small change at the C-5 substituent (from an angelate in **1** or an acetate in **6**, to a tiglate in **2** or an isobutyrate in **3**) had a great impact on the antifeedant potency. The reduction in activity found for compounds **4**, **5**, and **7** in contrast to **1–3** and **6** showed the importance of the C-11 acetate. The lack of activity of **8** (with carbonyl groups in C-5 and C-11) in contrast with **5** suggests that hydrogen-bonding at C-5 (with a hydroxyl substituent) may play a role in the antifeedant effect of these molecules. The activity of the related silphinenes **9** and **10** indicated that structurally related tricyclic sesquiterpenes are good CPB antifeedant candidates for future studies.

The GABA modulators thymol and picrotoxinin were also CPB antifeedants, with thymol being seven times more active than picrotoxinin (Table 1). Silphinenes **1–3** and **6** were more active than both antagonists; **1**, **5**, and **7** were as active as thymol; while **4**, **9**, and **10** had similar activity levels to picrotoxinin. Silphinene **1** has 3D structural features similar to those of picrotoxinin (Mullin et al., 1997). Furthermore, **1** and **4** are GABA antagonists at mammalian receptors. (Bloomquist, 2001), **4** being threefold more active than **1**, and **5** essentially inactive. These results paralleled their rootworm antifeedant action and effects on excitation of galeal chemoreceptors (Mullin et al., 1997), supporting the hypothesis of a GABA-mediated taste regulation in chrysomelid insects. However, the CPB antifeedant effects of these compounds did not correlate with their mammalian GABA antagonist effect, probably due to the different pharmacology of mammal and insect GABA receptors (see Bloomquist, 2001)

Table 2 shows the toxic and postingestive effects of the test compounds to *L. decemlineata* and *S. littoralis*, respectively. Beetle mortality significantly increased when injected with compounds **3**, **5**, **6**, **9**, and thymol, with **6** being the most toxic, but their toxicity levels did not correlate with their antifeedant action, as previously described for the toxicity of **1**, **4**, and **5** (Gonzalez-Coloma et al., 1997; Mullin et al., 1997), indicating that these compounds could act on both the peripheral and central nervous system of insects. None of the test compounds had negative effects on *S. littoralis* biomass gain or consumption, probably due to metabolic detoxification and/or species-related target differences.

TABLE 2. TP INJECTED (10 μg/INSECT, 20 INSECTS) AND ORAL (20 μg/INSECT, 20 INSECTS), TEST COMPOUNDS ON ADULT *L. decemlineata* AND *S. littoralis* L6 *Larvae*[a]

P[f]		>0.05	>0.05

[a] Mortality data were corrected according to Abbott (1925).
[b] $\triangle$B = change in insect body weight (dry weight, mg).
[c] I = mg food consumed (dry weight, mg).
[d] Significantly different from the control, $P < 0.05$, contingency table analysis.
[e] na, not enough compound available.
[f] Treatment P-level, ANCOVA analysis with initial body weight as covariate.

In summary, based on the antifeedant effects of silphinenes, thymol, and picrotoxinin against a wide range of insect species, the structural similarities between silphinens and picrotoxinin and the action of these sesquiterpenes on mammalian GABA neuroreceptors suggest a shared GABA-mediated taste regulation in these insects. Therefore, the study of the molecular mode of action of this type of sesquiterpenes merits further investigation.

Abstract—The parasitoids *Trichogramma chilonis* (Hymenoptera: Trichogrammatidae) and *Cotesia plutellae* (Hymenoptera: Braconidae), and the predator *Chrysoperla carnea* (Neuroptera: Chrysopidae), are potential biological control agents for the diamondback moth, *Plutella xylostella* (Lepidoptera: Yponomeutidae). We present studies on the interactions between these bioagents and various host-associated volatiles using a Y olfactometer. *T. chilonis* was attracted to a synthetic pheromone blend (*Z*11–16:Ald, *Z*11–16:Ac, and *Z*11–16:OH in a 1:1:0.01 ratio), to *Z*11–16:Ac alone, and to a 1:1 blend of *Z*11–16:Ac and Z11–16:Ald. *C. plutellae* responded to the blend and to *Z*11–16:Ac and *Z*11–16:Ald. Male and female *C. carnea* responded to the blend and to a 1:1 blend of the major components of the pheromone, although no response was elicited by single compounds. Among the four host larval frass volatiles tested (dipropyl disulfide, dimethyl disulfide, allyl isothiocyanate, and dimethyl trisulfide), only allyl isothiocyanate elicited significant responses in the parasitoids and predator, but *C. plutellae* and both sexes of *C. carnea* did respond to all four volatiles. Among the green leaf volatiles of cabbage (*Brassica oleracea* subsp. *capitata*), only *Z*3–6:Ac elicited significant responses from *T. chilonis*, *C. plutellae*, and *C. carnea*, but *C. plutellae* also responded to *E*2–6:Ald and *Z*3–6:OH. When these volatiles were blended with the pheromone, the responses were similar to those elicited by the pheromone alone, except for *C. carnea* males, which had an increased

response. The effect of temperature on the response of the biological agents to a mixture of the pheromone blend and *Z*3–6:Ac was also studied. *T. chilonis* was attracted at temperatures of 25–35°C, while *C. plutellae* and *C. carnea* responded optimally at 30–35°C and 20–25°C, respectively. These results indicate that the sex pheromone and larval frass volatiles from the diamondback moth, as well as volatile compounds from cabbage, may be used by these natural enemies to locate their diamondback moth host.

Key Words—Olfactory responses, *Trichogramma chilonis*, *Cotesia plutellae*, *Chrysoperla carnea*, *Plutella xylostella*, Lepidoptera: Yponomeutidae, sex pheromones, larval frass, green leaf volatiles, cabbage.

INTRODUCTION

Semiochemicals help natural enemies locate and recognize their hosts or prey (Vinson, 1985; Lewis and Martin, 1990; Vet and Dicke, 1992). Therefore, knowledge of the nature of these chemicals and their functional roles is important in the design of programs that use parasitoids and predators as biological control agents. The diamondback moth (DBM), *Plutella xylostella*, is one of the most serious pests of cruciferous crops throughout the world (Talekar and Shelton, 1993). All stages of the DBM are attacked by numerous parasitoids and predators, the former being the most widely studied. Polyphagous egg parasitoids, *Trichogramma* and *Trichogrammatoidea*, have received attention in the development of strategies to control DBM (Tabone et al., 1999); *Trichogramma chilonis* Ishii is reported to be particularly effective (Miura and Kobayashi, 1998). Larval parasitoids are the most predominant and efficient, particularly those belonging to two major genera *Diadegma* and *Cotesia* (*Apanteles*). *C. plutellae* Kurdjumov (Hymenoptera: Braconidae) is effective in lowland areas of the tropics and subtropics where it is the only larval parasitoid that can survive (Talekar and Shelton, 1993; Verkerk and Wright, 1996; Liu et al., 2000). In this context, *C. plutellae* is a good candidate for the biological control of DBM (Talekar and Shelton, 1993). Lacewings, *Chrysoperla* spp., are one of the most effective general predators of soft-bodied insects feeding on eggs and young larvae (New, 1988), *Chrysoperla carnea* being important for corn borers and aphids. This predator and *C. plutellae* have been used in an integrated pest management program to control DBM in cabbage (Reddy and Guerrero, 2000a).

We have conducted experiments to establish activity of DBM sex pheromone and larval frass volatiles, as well as green leaf volatiles (GLVs) from cabbage, on natural enemies of the pest. To our knowledge, this is the first time that such a study has been carried out. The main components of the DBM pheromone are (*Z*)-11-hexadecenal (*Z*11–16:Ald) and (*Z*)-11-hexadecenyl acetate (*Z*11–16:Ac) (Chow et al., 1977; Tamaki et al., 1977). An 8:2 to 4:6 blend of them was highly attractive to males in the field (Koshihara et al., 1978). Addition of 1%

(*Z*)-11-hexadecenol (*Z*11–16:OH) increased captures of males (Koshihara and Yamada, 1980). GLVs from cabbage, *Brassica oleracea* var. *capitata* L., are 1-hexanol, (*Z*)-3-hexen-1-ol, 1-hexen-3-ol, hexanal, (*E*)-2-hexenal, hexyl acetate, and (*Z*)-3-hexenyl acetate (Reddy and Guerrero, 2000b). The larval frass volatile of DBM is a mixture of dipropyl disulfide, dimethyl disulfide, methyl propyl disulfide, and dimethyl trisulfide (Auger et al., 1989).

METHODS AND MATERIALS

Insects. T. chilonis were reared on eggs of DBM in 250-ml beakers under a 16L:8D photoperiod, 28 ± 1°C, and 60–65% relative humidity. Adults of *T. chilonis* emerged eight days after the eggs had been parasitized. They were collected daily, transferred to glass tubes (10 cm long × 2.5 cm ID), and supplied with a 20% honey–water solution. Females used for experiments were 3-days old, mated, and without previous oviposition experience. *C. plutellae* were reared on DBM larvae as described above, following Fan and Ho (1971). Parasitoid cocoons were collected in glass vials and kept in a clean Plexiglas cage (18 × 15 × 15 cm) until emergence. Adults were provided with a 20% honey–water solution. One-day-old, mated females, without oviposition experience, were used for experiments. Eggs of *C. carnea*, collected from a cabbage field, were placed individually in plastic cups (6 cm long × 3 cm ID) and reared on DBM larvae as described above. Newly emerged adults were collected daily, fed with honey, fructose, protinex, water (1:1:1:1 and by volume), and transferred to acrylic cages (28 cm diam.) for oviposition. Three-6-day-old males and females were used for experiments.

Chemicals. Test compounds were obtained from commercial sources (Table 1). The synthetic pheromone blend was prepared by mixing *Z*11–16:Ald, *Z*11–16:Ac, and *Z*11–16:OH in 1:1:0.01 ratio. All solutions (1:100 v/v) were prepared in hexane.

Bioassays. Experiments were conducted in a Y-tube olfactometer made of transparent Plexiglas (3 cm ID; stem 10 cm, arms 8 cm; stem-arms angle 130°) with each arm connected to a glass container (250 ml) holding the odor source. Filtered air (30 ml/min for the parasitoids; 1.2 liters/min for the predator) was drawn through the olfactometer by a pump connected to a flowmeter. A vapor trail was generated with $TiCl_4$ to verify the airflow through the olfactometer. Whatman filter paper (4 × 2 cm) impregnated with 10 μl of test solution, left to dry for 5 min, and introduced into one of the containers was used as the odor source. The other container held untreated filter paper of the same size. The olfactometer was disconnected from the containers and thoroughly washed in soap and water, rinsed in 70% ethanol, and dried in an oven at 120°C after every three runs. The apparatus was rotated 180° after five runs to exclude directional bias. Each insect was allowed

to respond for 10 min and was used only once. Insect behavior was recorded with the program The Observer (Noldus Information Technology, Wageningen, The Netherlands). Responses were considered positive when insects traveled at least 4 cm along the arm connected to test compounds. The mean percentage of time spent by parasitoids/predator in each arm of the olfactometer was recorded and the values analyzed using the Wilcoxon matched-pairs test (Statistica, Stat Soft Inc.). All experiments were conducted in daylight at $28 \pm 2^{\circ}$C and 60% relative humidity. To determine the optimum temperature for parasitoids/predator responses, tests were conducted at 15, 20, 25, 30, and 35°C using a blend of the DBM synthetic pheromone and (*Z*)-3-hexenyl acetate in 1:1 ratio.

RESULTS

Preliminary Y-olfactometer studies of *T. chilonis*, *C. plutellae*, and *C. carnea* indicated that hexane did not elicit any response from these insects. The parasitoids flew and/or walked towards the scent source, while the predator usually walked, hopped, or jumped since the olfactometer design did not allow them to fly.

Synthetic P. xylostella Pheromone. The responses of *T. chilonis*, *C. plutellae*, and *C. carnea* to pheromone blends and individual pheromone components are shown in Table 2. *T. chilonis* preferred the pheromone blend, the 1:1 blend of *Z*11–16:Ald and *Z*11–16:Ac, and *Z*11–16:Ac alone ($P \leq 0.001$) over the control,

[a] Asterisks indicate means significantly different from controls (Wilcoxon matched pair test, $N = 30$): $^{*}P \leq 0.05$; $^{**}P \leq 0.01$; $^{***}P \leq 0.001$.
[b] Pheromone blend was a mixture of Z11–16:Ald, Z11–16:Ac, and Z11–16:OH in 1:1:0.01 ratio.

while no preference was shown for *Z*11–16:Ald or *Z*11–16:OH alone. *C. plutellae* was attracted to the complete pheromone blend, the 1:1 blend of *Z*11–16:Ald and *Z*11–16:Ac, as well as the individual components other than *Z*11–16:OH, which had no effect. Similarly, *C. carnea* males and females preferentially responded to the ternary and binary pheromone blends, but not to the individual compounds.

P. xylostella Frass Volatiles. The responses of *T. chilonis*, *C. plutellae*, and *C. carnea* to DBM frass volatiles is presented in Table 3. *T. chilonis* females responded only to allyl isothiocyanate ($P \leq 0.01$), while the other volatile compounds failed to elicit significant responses. *C. plutellae* females responded to dipropyl disulfide ($P \leq 0.001$), whereas the other frass volatiles elicited responses at $P \leq 0.01$. *C. carnea* females showed preference for allyl isothiocyanate and dimethyl trisulfide ($P \leq 0.001$). These compounds also elicited smaller responses in males ($P \leq 0.01$ with allyl isothiocyanate, $P \leq 0.05$ with dimethyl trisulfide).

Cabbage GLVs. The response of *T. chilonis*, *C. plutellae*, and *C. carnea* to cabbage green leaf volatiles is shown in Table 4. Among the seven GLVs tested, only (*Z*)-3-hexenyl acetate elicited responses from the two parasitoids and the predator. In addition, *T. chilonis* was attracted by hexyl acetate ($P \leq 0.05$), and *C. plutellae* by (*E*)-2-hexenal and (*Z*)-3-hexen-1-ol ($P \leq 0.01$ and $P \leq 0.05$). When the pheromone was blended with the individual GLVs in a 1:1 ratio, the responses of *C. plutellae* and *C. carnea* were greater than those elicited by the pheromone or the single compounds alone.

Temperature. The responses of *T. chilonis*, *C. plutellae*, and *C. carnea* to blends of the pheromone and (*Z*)-3-hexenyl acetate in 1:1 ratio at different temperatures are presented in Table 5. For *T. chilonis* and *C. plutellae*, optimum responses were obtained at 30–35°C, although at 25°C the former also responded significantly. *C. carnea* males and females were mostly attracted at 20–25°C.

DISCUSSION

Among semiochemicals, sex pheromones play a prominent role in attracting parasitoids to the host (Nordlund et al., 1983; Noldus and van Lenteren, 1985; Colazza et al., 1997). In the present study, we demonstrate for the first time that DBM sex pheromone components, individually or as synthetic blends, are attractants for the parasitoids *T. chilonis* and *C. plutellae* and the predator *C. carnea*, three of the main natural enemies of the DBM worldwide.

Trichogramma spp. utilize a variety of semiochemicals including plant synomones and host kairomones to find their oviposition host (Nordlund et al., 1985). For instance, a synthetic blend of sex pheromone components of *Heliothis zea* (*Z*7–16:Ald, *Z*9–16:Ald and 16:Ald) increased rates of egg parasitization by *T. pretiosum* in greenhouse bioassays and field plots of cotton (Lewis et al., 1982).

[a]Asterisks indicate means significantly different from controls (Wilcoxon matched pair test, $N = 30$): $^{*}P \leq 0.05$; $^{**}P \leq 0.01$; $^{***}P \leq 0.001$.

These results were confirmed by Noldus (1988) in olfactometer bioassays. We have found that *T. chilonis* is attracted to the pheromone blend of the DBM and to one of the main pheromone components, *Z*11–16:Ac, alone or in combination with *Z*11–16:Ald, the other major component of the pheromone. Our results agree with those of Boo and Yang (2000), who reported that *T. chilonis* was attracted to the sex pheromone of *Helicoverpa assulta* and to a component of the pheromone blend *Z*11–16:Ac. The parasitoid was also attracted to *E*12–14:Ac, a component of the sex pheromone of *Ostrinia furnacalis* (Boo and Yang, 2000). However, contrasting results were obtained by Noldus and van Lenteren (1985), who reported that *Z*11–16:Ac is not always attractive to *Trichogramma* spp. Indeed, this chemical is also the main pheromone component of *Mamestra brassicae*, and elicited no responses in its parasitoid *T. evanescens*, in contrast to the response evoked by the sex pheromone released by calling female moths (Noldus and van Lenteren, 1985).

To our knowledge there are two reports on the response of *C. plutellae* to host plant volatiles. Bogahawatte and van Emden (1996) showed that female *C. plutellae* preferred the odor of the *Brassica* plant type on which they had developed, even over those volatiles from DBM-infested and damaged leaves of other *Brassica* plants. Potting et al. (1999) reported in wind-tunnel studies that this parasitoid uses stimuli from oilseed rape plants (*Brassica napus* cv. Falcon) in its in-flight searching behavior. An oviposition experience or contact with a host-damaged leaf prior to the bioassay significantly increased the response to these volatile cues. In our study, the DBM pheromone blend, as well as the two major components *Z*11–16:Ac and *Z*11–16:Ald, either individually or in a 1:1 blend, effectively attracted the braconid females.

We found that male and female *C. carnea* were also attracted to the DBM pheromone blend and to the pheromone blend devoid of *Z*11–16:OH. Similarly, two sex pheromone components of the pea aphid *Acyrthosiphon pisum* (Homoptera: Aphididae), (4a*S*,7*S*,7a*R*)-nepetalactone and (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol, elicited significant electroantennogram (EAG) responses in both sexes of the lacewing (Zhu et al., 1999). However, female antennae were more sensitive to the lactone than to the lactol. In contrast, (*E*)-β-farnesene, a common component of the aphid alarm pheromone, elicited a 30% higher EAG response than either of the two former pheromone components, and (−)-β-caryophyllene, a potent inhibitor of the pheromone, also had an attractant effect on the predator (Flint et al., 1979).

Larval frass of DBM contains dipropyl disulfide, dimethyl disulfide, methyl propyl disulfide, dimethyl trisulfide, and allyl isothiocyanate, the three disulfides being responsible for the host searching behavior of the parasitoid *Diadromus pulchellus* (Auger et al., 1989). We tested these compounds, except the noncommercially available methyl propyl disulfide, and found that all chemicals exhibited responses from *C. plutellae* and both sexes of *C. carnea*, but not *T. chilonis*. *T. chilonis* was only attracted by allyl isothiocyanate. Notice the high attractivity

shown by the polyphagous predator *C. carnea*. This preference may be acquired during early developmental stages (Corbet, 1985), since *C. carnea* were reared on DBM larvae. We did not test predator populations reared on other hosts. Regarding frass activity on *C. plutellae*, only one previous report has been found on *Cotesia* spp: *C. marginiventris* attracted to hexane extracts of *Spodoptera frugiperda* frass and actual frass of the armyworm (Loke and Ashley, 1984).

We have previously identified several GLVs [(*Z*)-3-hexenyl acetate, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, hexanal, 1-hexanol, 1-hexen-3-ol, and hexyl acetate] from cabbage (*B. oleracea* subs. *capitata*) (Reddy and Guerrero, 2000b). These chemicals induced attractant/arresting behavior in DBM in a wind tunnel and (*Z*)-3-hexenyl acetate enhanced the attractant effect of this synthetic pheromone blend in the field. When we tested these compounds in the olfactometer, they elicited strong responses in *T. chilonis*, *C. plutellae*, and both sexes of *C. carnea*, while (*E*)-2-hexenal and (*Z*)-3-hexenol also atttracted *C. plutellae*. The attraction was greater when the GLVs were mixed with the pheromone blend in 1:1 ratio (Reddy and Guerrero, 2000b).

There are many reports on the effect of GLVs of cruciferous plants on insect pests (Visser et al., 1979; Guerin et al., 1983; Katsoyannos and Guerin, 1984; Zhang et al., 1999). However, there are few studies on the effect of GLVs on the natural enemies of these insect pests. Among these studies, volatiles emitted by sorghum (*Sorghum bicolor* L.) in the vegetative and reproductive stages arrested *T. chilonis* females, while volatiles from pigeonpea plant (*Cajanus cajan* L.) elicited no effect in the vegetative phase of the plant, and were repellent in the reproductive stage (Romeis et al., 1997). Extracts from corn leaves and the catnip *Nepeta catania* exhibited significant EAG responses in two predatory species, *Coleomegilla maculata* and *C. carnea* (Zhu et al., 1999). While many of the corn volatiles [(α-terpineol, (*Z*)-3-hexenol, (*Z*)-3-hexenal, 1-octen-3-ol, 1-hexanol, β-farnesene, 2-phenylethanol, and β-caryophyllene) attracted equal numbers of both sexes of *C. maculata* in the field, *C. carnea* adults were only allured by 2-phenylethanol (Zhu et al., 1999). In a previous but contrasting report, β-caryophyllene was found to act as an attractant of *C. carnea* in the field (Flint et al., 1979).

In the present study, the standard deviations are relatively large. This could be due to an effect of the experimental design, since the experiments were carried out at different times of the day and the responses may vary accordingly.

In summary, our results show that the parasitoids *T. chilonis* and *C. plutellae* and the predator *C. carnea* are attracted to a variety of chemical cues associated with their host, the DBM. These cues include sex pheromone components of the host, either in a blend or alone, frass volatiles, and GLVs from the host plant. The attraction of volatiles can be greatly enhanced when the GLVs are combined with the pheromone blend of the host. It is likely that the natural enemies considered utilize all these volatile compounds to locate the host.

(Received May 1, 2001; accepted September 10, 2001)

Abstract—Soluble sugars are essential nutrients generally perceived as phagostimulants to most insects studied. However, tannins are known as digestibility reducers, hence deleterious to caterpillar development, and as deterrents as well. Previous work demonstrated that larvae of the polyphagous oblique-banded leafroller, *Choristoneura rosaceana*, performed better when reared on a control + 0.5% tannic acid diet than on the standard control diet and that larvae reared on a control + 5% glucose diet had slower development and reduced survival. This study was designed to elucidate the behavioral and neurophysiological components of the larval responses to tannic acid and glucose. *C. rosaceana* larvae were reared individually from the first to the sixth instar on one of four different artificial diets: (1) control; (2) control + 5% glucose; (3) control + 0.5% tannic acid; (4) control + 5% glucose + 0.5% tannic acid. After 14 days, larvae reared on the control + 5% glucose diet had not developed past the fourth instar, whereas a considerable proportion of larvae reared on the control + 0.5% tannic acid diet had already attained the pupal stage. Insects reared on the control or the control + 5% glucose + 0.5% tannic acid diet had intermediate development, with most larvae in the fifth instar. In addition, once the mid-sixth instar was reached, the feeding preferences to 25 and 300 mM glucose, 25 mM tannic acid, and 25 mM glucose + 25 mM tannic acid over water were assessed in two-choice tests. Feeding affected preference. Control-reared insects preferred feeding on treatments containing glucose and were not deterred by tannic acid. However, larvae that had been exposed to tannic acid during their development were deterred by tannic acid and their glucose discrimination was impaired. The sensitivity to glucose was also examined from neurophysiological recordings by

stimulating the sugar-sensitive cell (cell 1) on the lateral styloconic sensillum of the maxillary galea with increasing concentrations of glucose (1, 10, 25, 50, 100, 200, 300, and 500 mM). We also determined whether tannic acid was phagostimulatory, since insects develop relatively quickly on a diet containing this compound, by testing 1 mM tannic acid, 1 mM tannic acid + 300 mM glucose, and 300 mM glucose on the lateral styloconic sensilla. The traces indicated that 1 mM tannic acid was not detected by any of the four chemosensory cells in these sensilla. The combination of tannic acid and glucose produced no spikes from the sugar-sensitive cell, whereas a prominent spike activity resulted with 300 mM glucose. We concluded that, although *C. rosaceana* larvae develop faster on a tannic acid diet, this compound is not a phagostimulant. The converse is true for glucose; i.e., it stimulates the sugar-sensitive cell in the lateral styloconica in a concentration-dependent fashion. Previous dietary experience changes the sensory and behavioral responses of *C. rosaceana* to glucose. Our findings imply that not all compounds that are phagostimulatory are necessarily beneficial to an insect's fitness. Therefore, developmental studies should be interpreted in conjunction with behavioral and physiological data.

Key Words—Oblique-banded leafroller, tannic acid, glucose, electrophysiology, rearing diets, feeding preference, lateral styloconic sensillum, dose–response, chemoreception, induction.

INTRODUCTION

Prior feeding experience, i.e., an insect's rearing history, can be important in modulating the selection of a particular food or simply the responsiveness to a given chemical (Ma, 1972; Yamamoto, 1974). Changes in sensitivity of certain chemoreceptors have been documented following an induction of preference to a particular food or to an allelochemical (Blaney et al., 1986). Feeny (1976), Rhoades and Cates (1976), and Swain (1979) advanced the theory that tannins are polyphenolic resistance secondary compounds that are ubiquitous in angiosperms and that have antifeedent effects on phytophagous insects. There are two types of tannins: the hydrolyzable, such as gallic acid, which are esters of sugars, usually glucose, and condensed tannins, which are polymers of flavonols (Ayres et al., 1997). It has been assumed that tannins bind to proteins, acting as nutritional protein precipitating agents, thus reducing their digestibility (Feeny, 1976; Rhoades, 1979). Zucker (1983) highlighted the fact that not every tannin can bind with every protein or vice versa. In a classical study, Feeny (1968) showed that in the winter moth larvae, *Operophtera brumata*, pupal weight and growth rate significantly decreased when fed a diet with an addition of as little as 1% tannin that had been extracted from oak leaves. In the forest tent caterpillar, *Malacosoma disstria*, an addition to the diet of 0.5% tannic acid reduced survival and growth rates, and lethal deformations were detected in the pupae (Karowe, 1989). However, Bernays et al. (1980) found that tannic acid was a feeding stimulant in various species of Acridoideae and improved growth of the tree locust, *Anacridium melanorhodon*.

The indisputable role of sugars as nutrients to lepidopteran larvae has been emphasized in various nutritional studies (Harvey, 1974; Clancy, 1992). They are also important energy sources (Friend, 1958) for insects in their later larval stages (Harvey, 1974; Panzuto and Albert, 1997). Shaw et al. (1978) hypothesized that if an insect obtains enough energy compounds (sugars) from its diet, more dietary protein will be directed toward growth. In fact, there is often a direct relationship between adult weights and rates of larval development with increasing dietary levels of some sugars (Harvey, 1974). However, this is not always the case. Clancy (1992) explored the role of sugars in conjunction with varying nitrogen levels in the western spruce budworm, *Choristoneura occidentalis*. This insect performed best when reared on diets containing 6% sucrose, an amount reflecting the lower limit observed for host foliage. Savopoulou-Soultani et al. (1994) found that $>2.3\%$ glucose levels slowed down larval development of the grape berry moth, *Lobesia botrana*, also a tortricid. The oblique-banded leafroller, *Choristoneura rosaceana* is polyphagous and feeds on a wide range of conifers (Chapman and Lienk, 1971). It also feeds on members of the Rosaceae and is notorious for its preference for apples (Carrière et al., 1995). Carrière (1992) found that Red Delicious apples (*Malus domestica*), trembling aspen (*Populus tremuloides*), wild rose (*Rosa* sp.), and snowberry (*Shepherdia canadensis*) were the preferred host species, in that order. Dauphinais (1998) demonstrated that *C. rosaceana* performed better when reared on a control + 0.5% tannic acid diet than on the standard control diet. In addition, insects reared on a control + 5% glucose diet developed more slowly and larval survivorship decreased. Thus, elevated sugar levels seemed to be detrimental to insect growth. The present study is an attempt to elucidate the behavioral and neurophysiological components of these occurrences.

All caterpillars investigated to date are known to possess gustatory receptors to sucrose and glucose (Dethier and Kuch, 1971; Schoonhoven, 1987). Sugars are perceived by a cell, and in some instances by more than one cell (Dethier, 1973; Dethier and Kuch, 1971), usually on either the medial or the lateral styloconic sensilla of the galea (Schoonhoven, 1987). Spruce budworm larvae, *Choristoneura fumiferana* (Clem.), exhibit a strong phagostimulatory response to the sugars sucrose and glucose (Albert et al., 1982; Albert and Parisella, 1988; Albert and Bauce, 1994; Panzuto and Albert, 1997). As for tannins, many have assumed that they can be perceived by contact chemoreceptors (Bennet, 1965; Chan et al., 1978; Bernays, 1981). A receptor cell responsible for the detection of these compounds has not yet been found; however, tannins do reduce the responsiveness to other compounds by acting on other cells, such as the sugar-sensitive cells in two phytophagous caterpillars (Dethier, 1982).

In the present study, we used the oblique-banded leafroller, *Choristoneura rosaceana* (Harris) (Lepidoptera: Tortricidae) as a model system in an attempt to answer the following questions: (1) Do rearing conditions induce a feeding preference and/or a physiological change in responsiveness? (2) Can *C. rosaceana* detect

tannic acid with the styloconic sensilla of the galea? (3) Is glucose a phagostimulant or a deterrent? To answer these questions, behavioral and neurophysiological techniques were used to assess the response of *C. rosaceana* larvae to glucose and tannic acid when reared on four types of diet.

METHODS AND MATERIALS

Oblique-banded leafrollers, *Choristoneura rosaceana*, were obtained as egg masses from a lab colony at Agriculture et Agroalimentaire Canada located in St-Jean-sur-Richelieu, Québec, and maintained in an incubator at a temperature of 24°C, under a 16L:8D photoperiod and 60% relative humidity. Once the larvae emerged, they were transferred individually into Solo cups containing the pinto-bean-based artificial diet (Shorey and Hale, 1965) and three variations of this diet. Therefore, a total of four types of diets were used: (1) control diet, with no additions (Shorey and Hale, 1965); (2) control diet + 0.5% tannic acid; (3) control diet + 5% glucose; (4) control diet + 0.5% tannic acid + 5% glucose. The additions were achieved by measuring the total liquid volume of the preparation of the control standard diet, i.e., 5% glucose (= 67.5 g) and 0.5% tannic acid (= 6.75 g) of the final liquid volume (1350 ml). It is important to note that a 5% addition of glucose corresponds to 278 mM, whereas 0.5% tannic acid is a concentration of 2.94 mM. The insects were reared individually from the first through the sixth instars in Solo cups.

Development. A developmental assay similar to that of Dauphinais (1998) was used. Fourteen days following transfer of first instars onto the four types of diets, we inventoried the number of insects per developmental stadia for each diet. Insects reared on the control + 5% glucose diet never reached the sixth instar; hence, electrophysiology and two-choice cafeteria tests could not be performed on this group.

A 100-mg sample of ground pinto bean, a main ingredient of the control diet (Shorey and Hale, 1965), was used for the extraction of soluble sugars (Gougeon, personal communication). The sample was added to 5 ml of methanol–chloroform–water (MCW, 12:5:3, v/v/v), mixed with a vortex, and left to settle for 10 min. It was then centrifuged at 3500 rpm for 10 min; the resulting supernatant was collected, and HLPC was used to determine the type and concentration of soluble sugars. This was done to ensure that our addition of 5% glucose to the diets was the sole source of glucose present. Peaks from HPLC analysis revealed minimal amounts of the sugar alcohols mannitol and sorbitol. No glucose was found in the ground pinto bean.

Electrophysiology. Mid-sixth instar *C. rosaceana* larvae were selected from the Petri dishes and starved for 24 hr prior to an experiment. The head and the first three thoracic segments were severed from the rest of the body of a larva

and a glass microcapillary pipet containing insect saline (Schnuch and Hansen, 1989) was fitted into the opening and pushed into the walls of the hypopharynx to expose the mouthparts. Special care was taken to avoid damaging the gustatory nerve. This preparation was placed into an electrode under a compound microscope, with the animal ventral side up, to facilitate viewing and contact. A second glass micropipet was filled with a given test solution combined with 25 mM KCl and used to stimulate the lateral styloconic sensilla of the galea. Resulting action potentials were recorded for 1 sec on digital audio tape. Between each stimulation, the sensilla were allowed a 3-min rest period to avoid adaptation of the cells. Data were digitized using SAPID tools (Smith et al., 1990) and then visually analyzed by counting the number of neural impulses from the sugar, water and salt cells, which can be differentiated from one another based on their characteristic shapes and amplitudes. Direct current recordings were made to facilitate the task of distinguishing spike shapes, since the impulses were not distorted as in filtered recordings (Schnuch and Hansen, 1990).

All tests were performed on the lateral styloconic sensillum of the galea of 10–20 *C. rosaceana* larvae. This sensillum possesses a sugar-sensitive cell while the medial sensillum does not. All solutions were diluted in 25 mM KCl, an electrolyte that enables adequate electrical conductance. The solutions used to establish the dose–response curve for insects reared on the control diet were 1, 10, 25, 50, 100, 200, 300, and 500 mM glucose. The 200, 300, and 500 mM glucose data were not obtained in the same year; these were done later as a separate experiment to verify whether the curve would plateau at a concentration higher than 100 mM glucose, or whether there would be a further increase in firing frequency. The solutions for insects reared on the control diet + 0.5% tannic acid and the control diet + 0.5% tannic acid + 5% glucose were 25 and 300 mM glucose. Tannic acid at 1 mM and 1 mM tannic acid + 300 mM glucose were also tested on the lateral styloconica to verify whether tannic acid interfered with glucose perception by the sugar-sensitive cell. Preliminary tests were done to confirm that the medial styloconic sensilla did not respond to tannic acid.

Statistical analyses were done with Number Cruncher Statistical Software (J. L. Hintze, 865 East North, Kaysville, Utah 84037, USA). A one-way ANOVA ($P < 0.05$) was performed to determine whether the spike frequency of the sugar-sensitive cell in response to 100, 200, 300, and 500 mM glucose differed. A two-sample *t* test analysis ($P < 0.05$) was used to assess whether the sugar cell response differed between stimulation of 25 mM glucose and 300 mM glucose for each diet (control, control + 0.5% tannic acid, control + 0.5% tannic acid + 5% glucose). In addition, a one-way ANOVA ($P < 0.05$) verified for differences among the three diets for the responses to 25 mM and 300 mM glucose.

Behavior. A two-choice test such as that described in Albert and Bauce (1994) was used to measure feeding preferences of larvae. On the day prior to each experiment, about 10–30 mid-sixth instar larvae from each diet were isolated into

individual Solo cups and starved for 24 hr. They were then placed separately in an arena containing eight Millipore HA 0.45-μm cellulose discs (4 mm diam.). Four test discs were wetted with 15-μl aliquots of one of the test solutions (either 25 mM glucose, 300 mM glucose, or 25 mM tannic acid) and four control discs were wetted with 15 μl of distilled water. Test and control discs were placed in an alternating fashion. The discs were held in place with pins arranged in a circle over a styrofoam sheet. Each circle was covered with a 3.5-cm-diam. $\times$ 2-cm-high Solo cup. The styrofoam sheet was transferred to an incubator with the same growth conditions. The experiments lasted 12 hr. Only insects that ate $>50\%$ of the total disc area were considered for analysis. For each two-choice experiment, the percent mean consumption (MPCT) was calculated in the following manner: $MPCT = T/(T + C) \times 100$ and $MPCC = C/(T + C)$, where *MPCT* is the mean percentage consumption of the test discs (glucose or tannic acid), *MPCC* is the mean percentage consumption of the control discs (water), *T* is the proportion eaten of the test discs, and *C* is the proportion eaten of the control discs.

The solutions for the behavior experiments were 25 mM glucose vs. water, 300 mM glucose vs. water, and 25 mM tannic acid vs. water tested on insects reared on the diets (control, control + 0.5% tannic acid, and control + 0.5% tannic acid + 5% glucose). Glucose was tested at 300 mM since the addition of glucose at 5% to the diet corresponds to 278 mM. All chemicals, except for the tannic acid, were obtained from Sigma Chemical, St. Louis, Missouri, USA. Tannic acid was obtained from BDH, Toronto, Canada and contains 9% impurities.

Statistical analysis was done with Number Cruncher Statistical Software (J. L. Hintze, 865 East North, Kaysville, Utah 84037, USA). The data were analyzed using a nonparametric Mann-Whitney test ($P < 0.05$) to compare the percent mean consumption of the response of the treatment vs. water for each diet insects were reared on, since the data were not normally distributed. One-way ANOVAs ($P < 0.05$) were used to compare the means of the insects reared on the three types of diets, in response to both treatments (25 vs. 300 mM glucose). Finally, other one-way ANOVAs ($P < 0.05$) checked for differences among the treatments within each diet.

RESULTS

Development. When inventory was taken after a two-week period, *C. rosaceana* reared on the control diet presented individuals in a whole range of developmental stages but predominantly in the fifth instar (Figure 1A). Insects reared on a diet containing an addition of 5% glucose did not occur past the fourth instar and, in fact, the majority were arrested in the first instar (Figure 1B). An altogether different profile was exhibited for those insects reared on a control + 0.5% tannic acid diet: most insects had attained the pupal stage (Figure 1C).

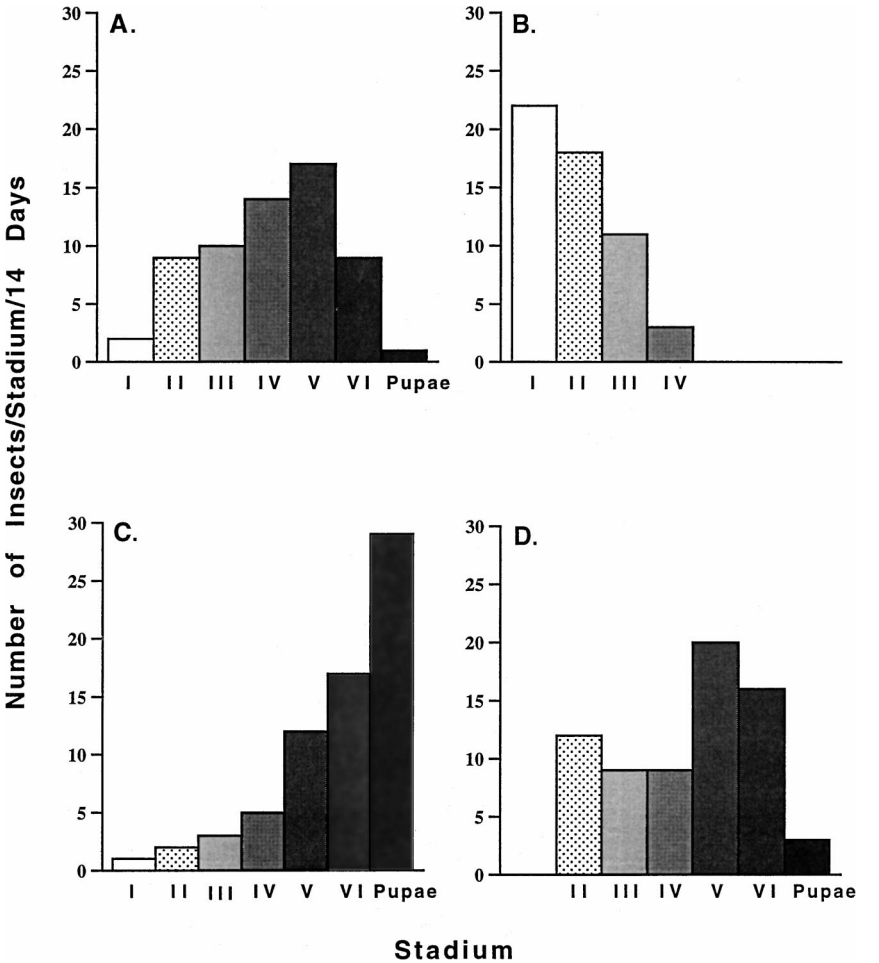

FIG. 1. Number of insects per stadium at 14 days for *C. rosaceana* reared on four different diets. A = control diet; B = control + 5% glucose; C = control + 0.5% tannic acid; D = control + 5% glucose + 0.5% tannic acid.

The combination diet (5% glucose + 0.5% tannic acid) revealed a pattern that was similar to the one seen in the case of the control diet, i.e., larvae were found in the whole range of developmental stages but mainly in the fifth instar (Figure 1D).

Electrophysiology. Three cells in the lateral styloconic sensillum responded to stimulation with the various solutions; these are identified by the characteristic shapes of their waveforms. Impulses from cell 1 (sugar cell) are monophasic,

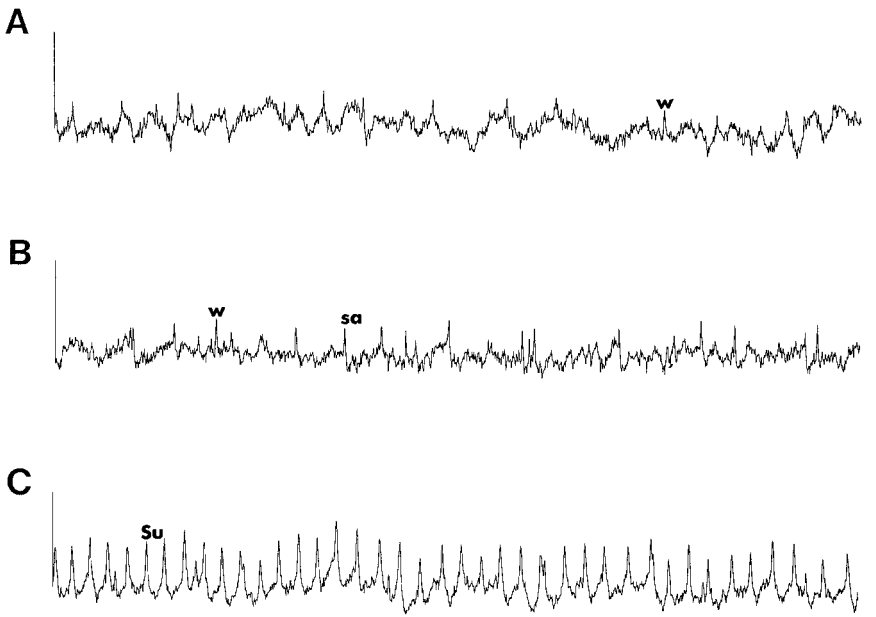

FIG. 2. Representative 1-sec traces showing the response of the lateral styloconic sensillum of sixth-instar *C. rosaceana* larvae to stimulation with: A, 1 mM tannic acid; B, 1 mM tannic acid + 300 mM glucose; and C, 300 mM glucose dissolved in 25 mM KCl. Su = sugar cell response; sa = salt cell response; w = water cell response.

slow spikes with a high amplitude (Figure 2C, Su). Cell 2 (salt cell) impulses are fast, biphasic spikes with a prominent negative flank (Figure 2B, sa). Impulses from cell 3 (water cell) are monophasic and slow, with a very low amplitude (Figure 2A, B, w).

Cell 1 (sugar cell) responded in a concentration-dependent manner to glucose (Figure 3). Maximum firing frequency was obtained at about 88 impulses/sec for animals reared on the control diet. Cell 1 showed a significant difference in response between 25 and 300 mM glucose for insects reared on the control and control + 0.5% tannic acid (Table 1). Alternatively, the control + 0.5% tannic acid + 5% glucose diet showed no significant difference between the same two glucose concentrations. The response from cell 2 (salt cell) and cell 3 (water cell) remained relatively stable at <20 impulses/sec and <5 impulses/sec, respectively (data not shown).

The one-way ANOVA comparing the cell 1 (sugar-sensitive cell) response to 25 mM glucose for *C. rosaceana* insects reared on the three diets revealed that the means were not statistically different ($F_{2,39} = 2.10$; $P = 0.136$). However, the response of this cell to 300 mM glucose showed a significant difference in mean

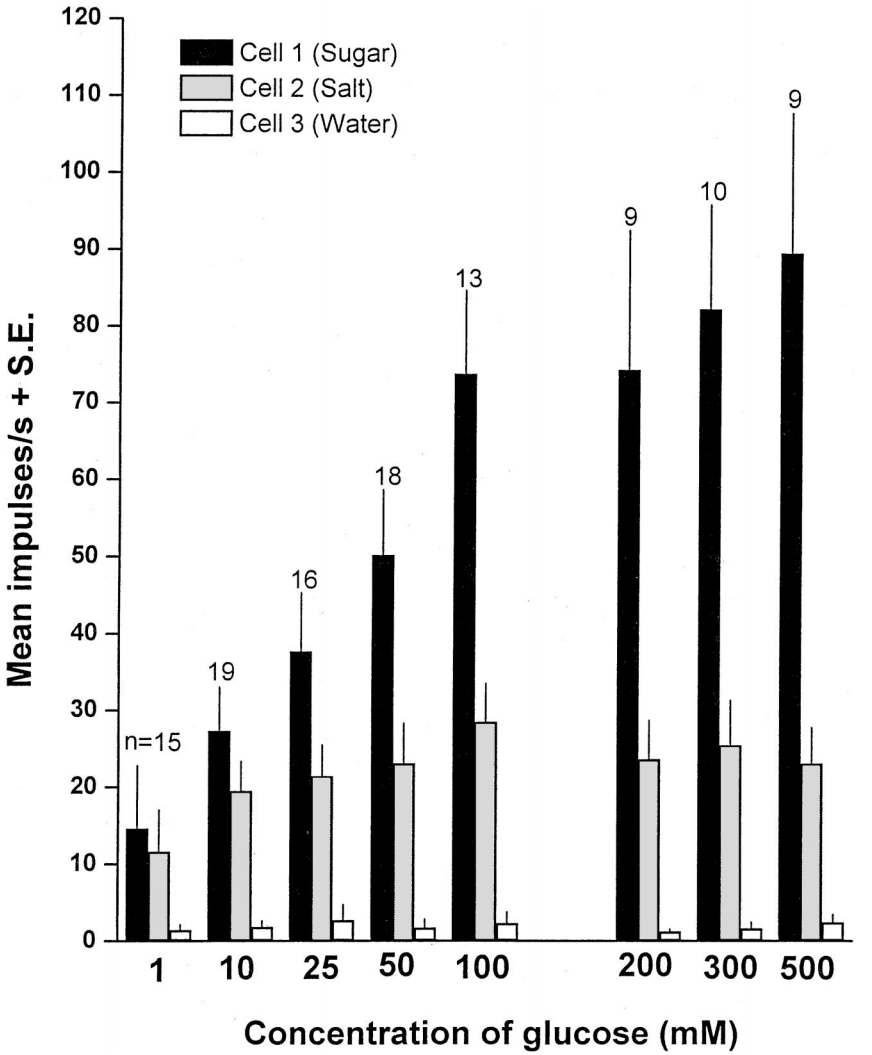

FIG. 3. Sensitivity in mean impulses/sec (+SE) of cells 1, 2, and 3 on the lateral styloconic sensillum of *C. rosaceana* larvae to stimulation with several concentrations of glucose dissolved in 25 mM KCl (N = sample size for each stimulus). Data for 200, 300, and 500 mM were collected in a separate experiment.

impulses per second depending on the type of diet ($F_{2,30} = 23.56$; $P < 0.001$). Insects reared on the control diet were significantly more sensitive to glucose stimulation (82 impulses/sec) as opposed to the responses from the other two diets which did not differ (approximately 60 impulses/sec) (Table 1).

TABLE 1. RESPONSE OF CELL 1 (SUGAR CELL) ON LATERAL STYLOCONIC SENSILLUM OF *C. rosaceana* LARVAE REARED ON DIFFERENT DIETS TO STIMULATION OF 25 AND 300 mM GLUCOSE DISSOLVED IN 25 mM KCl

Diet	Response (impulses/sec, mean ± SE)		
	25 mM glucose	300 mM glucose	*P* (*t* test)
Control	37.7 ± 7.66	82.4 ± 13.69	<0.001
Control + 0.5% tannic acid	34.4 ± 5.29	57.6 ± 7.89	0.001
Control + 0.5% tannic acid + 5% glucose	45.8 ± 13.12	63.7 ± 14.77	0.169

Stimulation of the lateral styloconic sensillum with 1 mM tannic acid in 25 mM KCl revealed traces possessing only background noise and a few cell 2 (salt-sensitive cell) and cell 3 (water-sensitive cell) spikes (Figure 2A). An addition of 300 mM glucose to the same amount of tannic acid showed a very similar response (Figure 2B). However, stimulation with 300 mM glucose (in KCl) alone resulted in a heightened activity of cell 1 (sugar cell) (Figure 2C).

Behavior. In the behavioral tests, *C. rosaceana* larvae reared on the control diet revealed a trend towards a preference for the test discs with glucose (25 or 300 mM glucose, or 25 mM glucose + 25 mM tannic acid) over water (Figure 4A). The only exception was the tannic acid vs. water test, where there was no preference. The highest percent mean consumption was obtained at ca. 75% with 300 mM glucose tested vs. water.

The diet containing the control + 0.5% tannic acid produced larvae that responded to 300 mM glucose but not to 25 mM glucose vs. water (Figure 4B). The percent mean consumption eaten for 25 mM glucose was about 55% as opposed to 78% for 300 mM glucose. In the response to tannic acid, there was a definite preference for water over 25 mM tannic acid and no difference between 25 mM glucose + 25 mM tannic acid vs. water.

The feeding response to both 25 and 300 mM glucose in control + 5% glucose + 0.5% tannic acid-reared insects shows a significant preference for glucose over water (Figure 4C). In both tests where tannic acid was tested over water (even in combination with 25 mM glucose) there was no preference for water.

DISCUSSION

Development. The results from the development study concur with prior work (Dauphinais, 1998) where it was observed that tannic acid-reared *C. rosaceana* larvae (control + 0.5% tannic acid) developed faster than those reared on control, control + 5% glucose + 0.5% tannic acid, and control + 5% glucose diets.

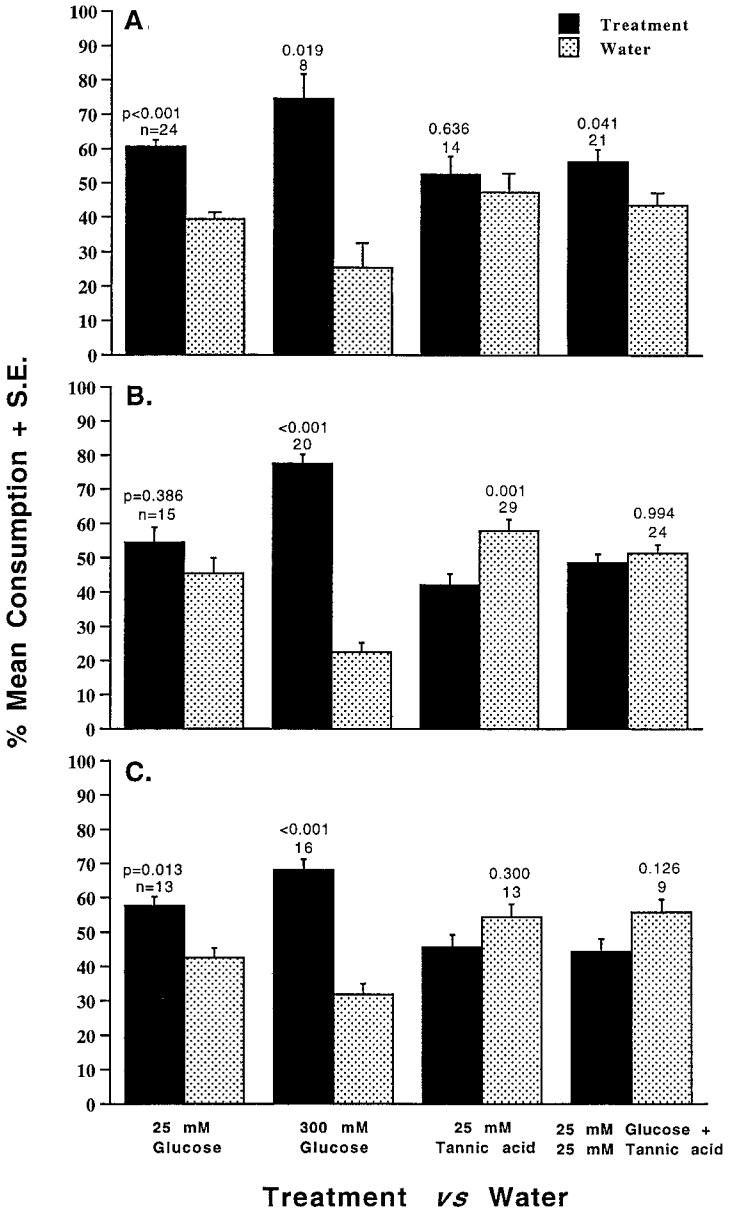

FIG. 4. Response in percent mean consumption (+SE) by *C. rosaceana* larvae reared on the control diet (**A**), control + 0.5% tannic acid diet (**B**), and the control + 0.5% tannic acid + 5% glucose diet (**C**) to a treatment vs. water. (n = sample size, p = probability value from nonparametric Mann-Whitney U test comparing the treatment *vs.* water response).

Most research on the effects of tannic acid on insects reveals its negative impact on various growth parameters including larval developmental time (Feeny, 1968, 1976; Rhoades and Cates, 1976; Rhoades, 1979; Karowe, 1989). Fundamentally, a prolonged stadium duration is not ideal since this is usually associated with increased risk of predation (Bernays, 1989) and asynchronization with the phenology of the insect's host plant (Moran, 1986). However, our finding that tannic acid supports the growth of a herbivore (Figure 1C) is not unique. The tree locust, *Anacridium melanorhodon*, makes use of the phenol gallic acid, or a derivative of it, isolated from the leaves of *Geranium endressi*, in the process of sclerotization of the cuticle. Tannic acid is hydrolyzed to gallic acid in the gut of locusts (Bernays, 1978; Bernays and Chamberlain, 1980). Furthermore, a plausible explanation to our finding that *C. rosaceana* develops more quickly on a tannic acid diet can be provided in Bernays' (1978) work wherein she describes the tree locust, *S. gregaria*, also reaps benefits from this phenolic compound. She suggests that in the hydrolysis process that occurs during the passage of tannic acid through the gut, gallic acid and glucose are released and probably utilized by the insect for its development.

As in Dauphinais's work (1998), we observe that a significant proportion of insects reared on a control + 5% glucose diet displayed an arrested development at the first stages and thus did not survive to pupation (Figure 1B). The artificial diet with 5% glucose represents a concentration of about 300 mM. However, the concentration of glucose in trees varies between 2 and 10% of dry weight, which corresponds roughly to between 10 and 50 mM in green leaves (Schoonhoven et al., 1998), suggesting that a control diet with 5% glucose addition is oversaturated with this sugar.

The developmental time for insects reared on the control + 5% glucose + 0.5% tannic acid diet was similar to that of the control diet (Figure 1A,D). Tannic acid might somehow mask the effects of glucose, maybe by complexing with the glucose molecules in the gut, therefore reducing the high concentration of glucose that was added to the diet to one where the nutritional value increases. This seems a reasonable argument since tannins are known to cross-link with nucleic acid and polysaccharides, such as cellulose and starch (Schoonhoven et al., 1998); nonetheless, we do not know whether the same process may be occurring with monosaccharides.

Electrophysiology. The response of the sugar-sensitive cell on the lateral styloconic sensilla of the galea of *C. rosaceana* is typically dose-dependent; i.e., as the concentration of glucose increases, there is a concomitant increase in the firing frequency of cell 1 (sugar-sensitive cell) (Figure 3). The sugar-sensitive cell of insects reared on the control diet exhibits a much more pronounced response to stimulation by 300 mM glucose than for insects reared on control + 0.5% tannic acid and control + 0.5% tannic acid + 5% glucose (Table 1). Compared to caterpillars reared on the control diet, caterpillars reared on the two other diets showed

a significantly lower chemosensory sensitivity to 300 mM glucose, about 80 impulses/sec as opposed to approximately 60 impulses/sec, respectively. Feeding on diets amended with tannic acid or glucose, especially at elevated concentrations, seems to alter the characteristics of chemoreceptors by decreasing their sensitivity to glucose. Sensitivity changes at the level of the peripheral chemoreceptors as a result of rearing insects on different diets are known (Blaney et al., 1986). For instance, in larvae of the tobacco hornworm, *Manduca sexta*, adding inositol or salicin to an artificial diet causes a reduction in the sensitivity of the cells responsive to these compounds (Schoonhoven, 1969).

Tannic acid did not act as a phagostimulant to *C. rosaceana* (Figure 2). In fact, addition of only 1 mM tannic acid to an otherwise stimulating 300 mM glucose solution resulted in response from only the salt-sensitive cell. Tannic acid may block the excitability of the sugar-sensitive cell, perhaps since, like other phenols, it possesses an aromatic ring (Denno and McClure, 1983), which is a rather bulky molecule when it comes in contact with sugar receptor sites. Dethier (1982) observed that tent caterpillars, *Malacosoma americanum*, do not possess a receptor that fires in response to tannic acid; however, this compound inhibited the sugar-sensitive cell in this insect. Whether it can stimulate a specific chemosensory neuron in a chemosensillum other than the lateral or medial styloconic sensilla is not known.

Behavior. We report another instance where feeding history has a subsequent effect on the behavior of an insect (Ma, 1972; Yamamoto, 1974; Städler and Hanson, 1978; Blaney et al., 1986); the feeding response of *C. rosaceana* to glucose, when presented in combination or alone, is altered due to feeding experience (Figure 4). Larvae reared on a standard control diet significantly prefer to feed on the various treatment discs containing glucose, whereas glucose discrimination is impaired in tannic acid-fed larvae where 25 mM glucose is not enough to elicit a preference. Interestingly, larvae that had not been exposed to tannic acid at any point in their development prior to the feeding tests showed a preference for discs containing tannic acid and glucose. Larvae fed a diet with an addition of 0.5% tannic acid were deterred by tannic acid. Similar results were found in Städler and Hanson's (1978) work with the tobacco hornworm, *Manduca sexta*, where they showed that the response to the deterrent was significantly reduced in larvae reared on the diet containing the deterrent. Some feedback mechanism may be involved in signaling to the insect that the choice is not nutritionally adequate. Insects are known to select a suitable host based on their internal state (Blaney et al., 1986).

Generally, consumption is reduced at very high concentrations of sugars (Ito, 1960; Schoonhoven, 1968; Chapman, 1974), which is not the case in our study. Larvae of *C. rosaceana* were stimulated to feed on glucose, even at 300 mM, which is uncommonly high considering that they do not encounter such high concentrations in the leaves of their hosts (Schoonhoven et al., 1998). As expected, the sugar-sensitive cell on the lateral styloconic sensilla responds in a

typical concentration-dependent fashion to glucose (Figure 3). However, what is remarkable in this study is that although larvae respond positively to very high concentrations of glucose, they develop poorly on a diet containing a 5% glucose addition (Figure 1B). Thus, very high concentrations were detrimental to development, as was the case in Clancy's (1992) work with the western spruce budworm, *C. occidentalis*.

In conclusion, notwithstanding the fact that tannic acid reduces instar duration, this compound is not a phagostimulant for *C. rosaceana* larvae. Quite the contrary, it may interfere with sugar binding at the receptor sites of the sugar-sensitive cell in the lateral styloconic sensilla. Glucose is highly phagostimulatory for these larvae; at high concentrations it elicits a response from the lateral styloconic sensillum of the galea even if deleterious effects are incurred in their development. Rearing conditions profoundly affect feeding preferences; 0.5% tannic acid and 5% glucose additions to the diet impair the response to sugar. Hence, both behaviorally and physiologically, tannic acid is not a phagostimulant for this insect. The sensory and feeding responses of *C. rosaceana* are definitely altered due to feeding experience. The interactions between tannic acid and glucose that we observe in our development, behavior, and electrophysiology tests suggest that we should be cautious in making general conclusions about the roles of specific compounds on the decision-making processes of feeding. The significance of these interactions may become more ecologically apparent once we obtain detailed information on the relative concentrations of tannins and glucose in the various host plants of this polyphagous species.

Acknowledgments—The authors thank NSERC for funding this work, Agriculture et Agroalimentaire Canada for providing the insect colony, and Julie Poulin for providing assistance with several of the feeding experiments. We extend special thanks to Dr. Karen Clancy for her excellent suggestions for improvement of the original manuscript.

Abstract—Peanut plants, *Arachis hypogaea*, infected with white mold, *Sclerotium rolfsii*, emit a blend of organic compounds that differs both quantitatively and qualitatively from the blend emitted from plants damaged by beet armyworm (BAW; *Spodoptera exigua*) larvae or from uninfected, undamaged plants. Attack by BAW induced release of lipoxygenase products (hexenols, hexenals, and hexenyl esters), terpenoids, and indole. The plant-derived compound methyl salicylate and the fungal-derived compound 3-octanone were found only in headspace samples from white mold infected plants. White mold-infected plants exposed to BAW damage released all the volatiles emitted by healthy plants fed on by BAW in addition to those emitted in response to white mold infection alone. When BAW larvae were given a choice of feeding on leaves from healthy or white mold-infected plants, they consumed larger quantities of the leaves from infected plants. Exposure to commercially available (*Z*)-3 hexenyl acetate, linalool, and methyl salicylate, compounds emitted by white mold-infected plants, significantly reduced the growth of the white mold in solid-media cultures. Thus, emission of these compounds by infected plants may constitute a direct defense against this pathogen.

Key Words—Peanut, plant defense, volatile induction, white mold, beet armyworm, *Spodoptera exigua*, *Sclerotium rolfsii*, *Arachis hypogaea*.

INTRODUCTION

Plants are attacked by a number of organisms during their life-span, including insect herbivores and disease-causing microorganisms. In response, they have evolved complex defense mechanisms to fend off their parasites. These mechanisms may be triggered by a specific organism and may be effective against present and future attacks by organisms of the same or different species. This phenomenon is known as cross-resistance and has been the subject of interest for many biologists since the 1970s (Karban and Baldwin, 1997). Another field that has received much attention, especially in the last decade, is the induction of what are now called indirect defenses (i.e., volatile emissions) in plants by feeding of herbivorous insects. Induced volatile compounds released by the plant attract natural enemies of the herbivore inflicting the damage (Dicke and Sabelis, 1988; Turlings et al., 1991).

It is clear that a thorough understanding of the plant's own defense mechanisms is required for their use against the pests that present a constant threat to our agricultural commodities. Although, in a typical field situation, plants are confronted with a wide array of antagonistic organisms, most studies on induced plant defenses have been conducted using plant–pathogen or plant–herbivore systems independent of one another. However, in recent years, many studies have suggested an interaction (or cross-talk) between the pathways involved in plant defense to pathogens and herbivorous insects. In many cases, it appears that induction of plant defenses by one type of organism interferes with plant defense against the other (Karban et al., 1987; Fidantsef et al., 1999; Stout et al., 1999; Bostock, 1999; Felton et al., 1999). Much remains to be learned about how plants defend against multiple stress factors. All studies conducted on this subject have focused on inducible direct defense compounds. It is still not known how plant indirect defenses against herbivores, consisting of volatile synomones, are influenced by the presence of phytopathogens, and how simultaneous attack of insects and phytopathogens on the plant may affect production of indirect defense substances.

In the present study, we tested the effect of peanut, *Arachis hypogaea* L. (Fabaceae), stem infection by the white mold fungus, *Sclerotium rolfsii* Sacc. (Mytosporic fungi), on the feeding preference of beet armyworm, *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae). We also evaluated and compared the emission of volatile compounds from peanut plants under attack by the white mold fungus and by beet armyworm. The emission of volatile compounds from *S. rolfsii* fungal cultures was also evaluted. Finally, we tested the effect of synthetic forms of the commercially available compounds identified from the volatile profile emitted by fungus-infected plants on the radial growth of laboratory cultures of *S. rolfsii*.

METHODS AND MATERIALS

Fungal Culture. S. rolfsii (strain 80) was grown on potato dextrose agar (PDA) Petri plates from original cultures provided by Dr. Tim Benneman (Coastal Plain Experiment Station, University of Georgia, Tifton, Georgia). Subsequent cultures were started, under sterile conditions, in our laboratory by placing sclerotia harvested from the original culture in the center of the PDA media plates. Culture plates were kept in a biological incubator with a 14L:10D cycle and maintained at 25°C and 6–70% relative humidity. To inoculate the experimental plants, fungal culture plugs were cut out of the agar plate with a #2 cork borer (5 mm diam.).

Plant and Insect Material. Georgia Green peanut seeds were provided by Drs. Tim Brenneman and Glen Raines (Coastal Plain Experiment Station, University of Georgia, Tifton, Georgia). Seeds were sown in pairs in 3.78-liter pots (16 cm diam.) containing a 1:1 (v/v) mixture of commercially available filter sand and Metromix 300 (Scotts-Sierra Horticultural Company, Marysville, Ohio). Plants were grown in an insect-free greenhouse with natural light, under Florida summer conditions (14L:10D light cycle). The greenhouse temperature was kept at 25–30°C. After emergence, seedlings were thinned to one individual per pot. Each plant received 100 ml of a 3.38 g/liter liquid fertilizer solution [20-20-20 (N-P-K)]; Peters, W. R. Grace, Fogelsville, Pennsylvania) every two weeks starting one week after emergence. Five-week-old peanut plants with six fully developed leaves on the main stem and three fully developed leaves on each of two secondary branches were used in all experiments.

Beet armyworm eggs were obtained from the rearing facilities at the USDA-IBPMRL, Tifton, Georgia. Larvae were reared on a pinto-bean artificial diet following the methodology described by King and Leppla (1984). Insects were kept in a biological incubator with a 14L:10D cycle at 25°C. Third-instar larvae were used in all experiments.

BAW Feeding on S. rolfsii-Infected Peanuts. The feeding preference of BAW larvae on old and young leaves of healthy and fungus-damaged plants was evaluated to determine whether insects were deterred from feeding on tissues of the *S. rolfsii*-infected plants. Peanut plants were infected with the fungus by distributing four culture plugs along the first three internodal spaces of the main stem. The plugs were positioned so the fungus was in direct contact with the stem. Fungal plugs were pressed against the stem so they remained in place. Each plant was then individually covered with a 3.78-liter plastic storage bag (Ziploc DowBrands L. P., Indianapolis, Indiana) to provide adequate humidity and temperature conditions for fungal growth and colonization of the plant's stem. The plants were incubated for three days, after which time lesions approximately 1 cm long could be observed at the point of fungal contact with the stem. After this incubation period, bags were removed from the plants 24 hr before being used for the experiment. *S. rolfsii* is a

nonsystemic pathogen, and only the stems of the plants were in contact with the fungus; therefore, the leaves used for the experiments were not infected.

The second-oldest (old) or newest (young) fully developed tetrafoliate leaves on the mainstem of an infected plant were paired with their counterparts from a healthy plant by confining them within Petri dish clip-cages. The leaves (four leaflets each), still attached to each of the plants, were placed side by side within a clip-cage (Alborn et al., 1996), so the caterpillars had equal access to them. Insects were deprived of food for 6 hr before the start of the experiment to ensure immediate feeding on the plant tissues. Young peanut leaves are larger than old leaves, so six third-instar larvae were confined with the young leaves, and three larvae of the same stage were confined to the old leaves. Caterpillars were removed from the leaves after 24 hr. Leaves exposed to the feeding were carefully labeled, removed from the plants, brought into the laboratory, and photocopied to estimate feeding damage. Leaf images were scanned and imported into an imaging software program (ImagePC beta version 1, Scion Corporation, Frederick, Maryland) to estimate leaf area eaten and leaf area remaining. These measurements were used to calculate the leaf area consumed by the insects on each of the treatments. Six replicates of this experiment were set up at one time in the greenhouse. This experiment was repeated twice for a total of 18 replicates.

Volatile Collections from Fungus and BAW-Damaged Peanuts. In this experiment, plant treatments consisted of control (uninfected/undamaged), BAW damage, fungus-infection, and fungus-infection plus BAW damage. Plants were inoculated with the fungus as described in the first experiment. BAW-damaged plants were exposed to feeding by six third-instar larvae within the volatile collection chambers three days after pathogen inoculation and 12 hr before the start of the first sampling period.

The aerial portion of the plant was contained within glass sleeves that rested on Teflon bases, with an opening that closed around the plant stem (Röse et al., 1996). Purified air was pumped in at the top of the chamber at a rate of 5 liters/min. Air within each of the chambers was sampled daily, at a rate of 1 liter/min, for four days in three consecutive periods: (1) 6:00 AM–12:00 PM, (2) 12:00 PM–6:00 PM, and (3) 6:00 PM–6:00 AM. Compounds emitted were collected at the downwind end of the chambers in adsorbent traps containing 25 mg Super Q (800–100 mesh) (Alltech, Deerfield, Illinois). All volatile collections were conducted in the greenhouse where plants were grown. The experiment was set up in duplicate and repeated three times on different days for a total of six replicates.

Volatile Collection from Fungal Cultures. To determine whether any of the volatile compounds collected from infected plants were also produced by the fungus directly, we collected and analyzed volatiles from culture plugs of the white mold at different stages of development. Five 1-cm-diam. plugs were made from *S. rolfsii* culture plates at 3, 5, 8, and 16 days after inoculation. Volatiles emitted from control, noninoculated PDA plates, were also collected and analyzed. Plugs

from each treatment were separately placed in Pyrex glass odor collection chambers, and volatiles were collected using a push–pull system previously described by Turlings et al. (1991). Volatiles were adsorbed by the Super Q traps described previously. Approximately 300 ml/min of purified and humidified air was passed over the culture plugs and through the collection traps for a 2-hr period. Air samples were obtained from plugs made from three different culture plates for each of the developmental times tested.

Sample Extraction and Analysis. Compounds from individual traps in the volatile collection experiments were eluted with 170 μl dichloromethane (GC/GC-MS Solvent, B&J, AlliedSignal, Inc), and then 400 ng each of *n*-octane and nonyl acetate were added to each eluted sample as internal standards. The samples were analyzed by gas chromatography with flame ionization detection (HP5890 gas chromatograph, HP7673 auto sampler, Hewlett Packard, Palo Alto, California) equipped with a 15-m $\times$ 0.25-mm-ID, 0.25-μm film thickness DB-1 capillary column (Quadrex, New Haven, Connecticut). The splitless mode injector system was set at 220°C, the column oven was held at 40°C for 1 min after injection and then programmed at 14°C/min to 180°C. The carrier gas used was helium at a flow average velocity of 19 cm/sec. For identification of compounds, selected samples were analyzed via GC-MS (HP 6890 gas chromatograph equipped with 30-m $\times$ 0.25-mm-ID, 0.25-μm film thickness HP-5 capillary column, interfaced to a 5973 Mass Selective Detector, Hewlett Packard, Palo Alto, California) in both electron impact and chemical ionization modes. The column was held at 40°C for 1 min after injection and then programmed at 10°C/min to 180°C. The carrier gas used was helium at a flow average velocity of 30 cm/sec. Isobutane gas was used as the reagent gas for chemical ionization, and the ion source temperature was set at 250°C. Individual compounds were identified by comparing their retention times to that of commercially obtained authentic samples and by comparing their mass spectra against those available in a database from the Environmental Protection Agency/National Institute of Standards and Technology.

Effect of Volatile Compounds from S. rolfsii-Infected Peanut on Radial Growth of Fungal Cultures. The effect of vapors from synthetic forms of 3-octanone, (*Z*)-3-hexenyl acetate, linalool, and methyl salicylate (Sigma-Aldrich Chemical Company, St. Louis, Missouri) on the radial growth of *S. rolfsii* on PDA culture plates was evaluated. These compounds were selected because they are present in the blend of compounds emitted by infected peanut plants and because they were commercially available. Three levels of the compounds, 3, 10, and 30 μl, were diluted in 100 μl hexane (GC/GC-MS Solvent, B&J, AlliedSignal, Inc) and loaded on to 5 $\times$ 11-mm sleeve stoppers made of natural red rubber (Wheaton, Millville, New Jersey). The loaded stoppers were allowed to equilibrate for 24 hr before using them for the experiments. The rubber stoppers were attached to the cover of the Petri dish by means of double-sided Scotch tape to prevent direct contact and contamination of the growth media. Two *S. rolfsii* sclerotia were placed in the

center of the bottom part of the plate containing the PDA media; thus, the fungus was exposed only to the vapors of the compounds emitted from the rubber stoppers for the duration of the experiment. Rubber stoppers loaded with 100 μl hexane were used in the control plates. This experiment was repeated on different days for a total of six replicates.

Statistical Analyses. Data for BAW feeding preference were analyzed by paired *t* test (Proc MEANS; SAS Institute, 1996). Data for volatile collections and the effect of volatiles on fungal radial growth were analyzed using ANOVA (Proc GLM; SAS Institute, 1996). Significant ANOVAs were followed by Tukey's mean separation test.

RESULTS

BAW Feeding on S. rolfsii-Infected Peanuts. BAW feeding was not negatively affected by infection of *S. rolfsii* on peanut plants. To the contrary, larvae consumed significantly more of the young and old leaves from fungus-infected plants than from healthy, noninfected plants (Figure 1). Fungal infection resulted in a 1.4- and 6.4-fold increase in BAW leaf area consumption for old and young leaves, respectively.

Volatile Collections from Fungi and BAW-Damaged Peanuts. Uninfected/uninfested control plants released small amounts of volatiles compared to the other treatments. Healthy and fungus-infected peanut plants exposed to BAW feeding started releasing volatiles within 24 hr. However, plants exposed to damage by *S. rolfsii* alone did not emit volatiles until the third day of collection. Volatile emission in all plants showed a diurnal pattern with peak release during period 2 (12:00–6:00 PM). Thus, data presented for this experiment are from 12:00–6:00 PM of the third day of collection.

Noninoculated control plants (Figure 2A) released relatively small amounts of volatiles, such as myrcene, β-ocimene, linalool, and (*E*)-4,8 dimethyl-1,3,7-nonatriene compared to those released by white mold-infected or BAW-damaged peanut plants. Plants infected with the white mold fungus alone released (*Z*)-3-hexenyl acetate, linalool, and relatively large amounts of (*E*)-4,8-dimethyl-1,3,7-nonatriene (Figure 2B), which were also present in emissions from BAW-damaged plants. Additionally, the compounds methyl salicylate and 3-octanone were only present in volatile emissions from plants that were infected by the fungus (Figure 2B) and not in those of plants damaged by BAW alone (Figure 2C). Noninfected peanut plants exposed to feeding by BAW released large amounts of lipoxygenase products, monoterpenes, indole, and sesquiterpenes (Figure 2C). The emission of volatiles from peanuts in response to BAW damage was not negatively affected by infection of white mold fungus on the plant. In fact, white mold-infected peanuts damaged by BAW (Figure 2D) released all the volatiles

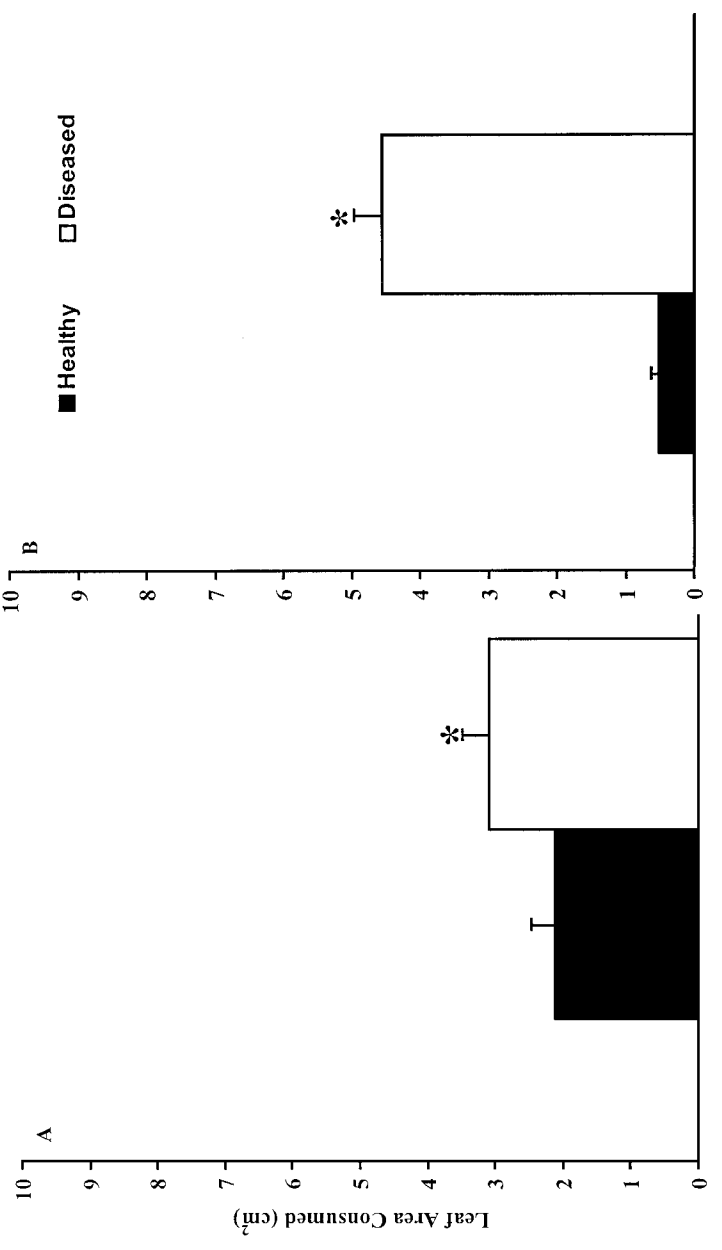

FIG. 1. Mean leaf area consumed by third-instar *Spodoptera exigua* larvae in paired-choice tests with healthy (dark bars) and white mold-infected (white bars) plants. (A) Old leaves and (B) young leaves. Error bars denote 1 SD and an asterisk denotes significant differences (paired t test, $P \leq 0.05$).

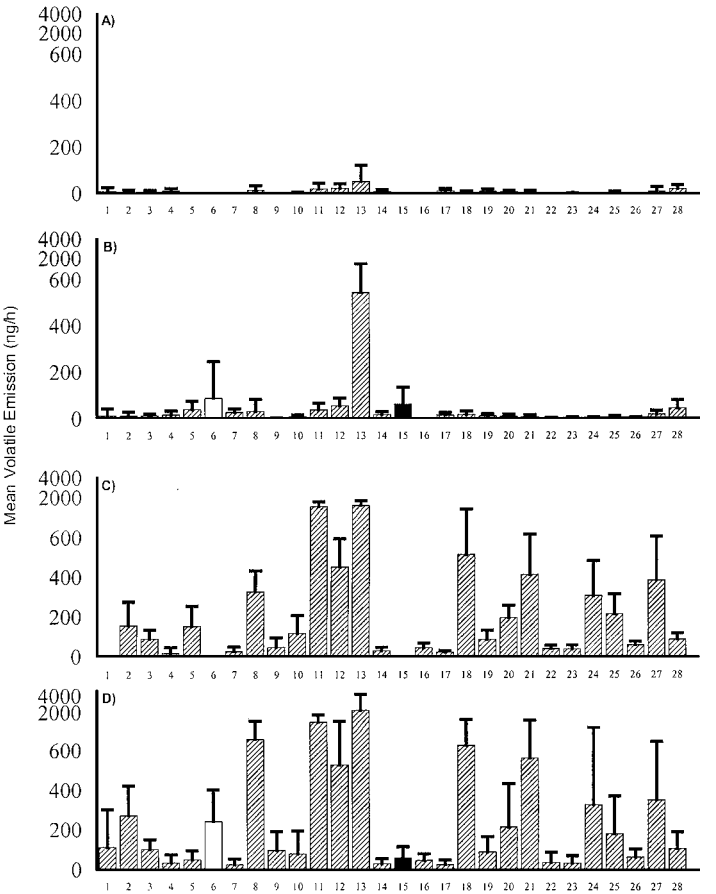

FIG. 2. Mean volatile emissions from peanut plants: (A) uninfected/undamaged, (B) white mold-infected, (C) BAW-damaged, and (D) white mold-infected + BAW-damaged. Compounds: (1) (*E*)-2-hexenal, (2) (*Z*)-3-hexen-1-ol, (3) α-pinene, (4) β-pinene, (5) 1-octen-3-ol, (6) 3-octanone, (7) (*Z*)-3-hexenyl acetate, (8) myrcene, (9) eucalyptol, (10) limonene, (11) β-ocimene, (12) linalool, (13) (*E*)-4,8-dimethyl-1,3,7-nonatriene, (14) (*Z*)-3-hexenyl isobutyrate, (15) methyl salicylate, (16) (*E*)-2-hexenyl butyrate, (17) (*Z*)-3-hexenyl butyrate, (18) indole, (19) *cis*-jasmone, (20) β-caryophyllene, (21) 2,6,-dimethyl-6-(4-methyl-3-pentenyl) bicyclo[3.1.1]hept-2-ene, (22) α-farnesene, (23) α-humulene, (24) germacrene-D, (25) β-farnesene, (26) naphthalene, (27) nerolidol, (28) (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Day 3, period 2 (12:00–6:00 PM). Bars across treatments headed with the same letter are not significantly different (Tukey's mean separation test, $P \geq 0.05$). Error bars are equivalent to 1 SD. No synthetic standards were available for compounds 21, 24, and 26; identification is based on National Institute of Standards and Technology library spectral match only.

typical of a healthy plant damaged by BAW. Furthermore, the amounts of some released compounds, such as (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, myrcene, and (*E*)-4,8-dimethyl-1,3,7-nonatriene, were higher than those emitted from noninfected plants in response to BAW feeding (Figure 2C). In addition, headspace collections from white mold/BAW-damaged plants also contained volatiles produced by plants in response to white mold infection alone (Figure 2B).

Volatile Collection from Fungal Cultures. Volatile profiles from *S. rolfsii* cultures showed the presence of one dominating volatile compound, which was identified as 3-octanone. The amounts of 3-octanone produced by the fungal culture plugs increased with age up until day 8, and ceased almost completely by day 16. Amounts of 3-octanone produced were 0.9 $\pm$ 0.4 ng/hr (mean $\pm$ SE), 1.8 $\pm$ 0.3 ng/hr, 4.3 $\pm$ 0.7 ng/hr, and 0.1 $\pm$ 0.2 ng/hr at days 3, 5, 8, and 16, respectively. This compound was recovered only from culture plates containing the fungus and not from non inoculated control PDA plates.

Effect of Selected Volatile Compounds from S. rolfsii-Infected Peanut on Radial Growth of Fungal Cultures. The growth rate of the fungus was significantly reduced by (*Z*)-3-hexenyl acetate, linalool, and methyl salicylate volatiles released from septa treated with 10 μl. Additionally, volatiles from 30 μl of linalool or methyl salicylate on a septum completely inhibited sclerotial germination and fungal growth (Figure 3). The *S. rolfsii*-produced compound 3-octanone did not prevent sclerotial germination and significantly reduced the growth of the fungus only at the highest dose of 30 μl tested.

DISCUSSION

Plant release of volatile compounds in response to attack by herbivores and the role of such compounds in attracting parasitoids of the herbivores have been studied extensively in recent years (Turlings et al., 1991, 1993; McCall et al., 1994; Loughrin et al., 1995; Röse et al., 1996, 1998; Paré and Tumlinson, 1997). In contrast, the emission of volatiles in response to pathogen invasion has been the subject of a limited number of studies (Croft et al., 1993; Doughty et al., 1996; Shualev et al., 1997; Chaudry et al., 1998; Buonaurio and Servili, 1999). All of these studies have examined the induction of plant volatile emission by either herbivore damage or pathogen infection on different plant systems or using excised plant parts. Thus, we have no clear knowledge of whether the regulation of volatile production in response to these organisms is affected in any way by the simultaneous attack of herbivores and phytopathogens on the same plant.

Data obtained from this study confirm that peanut plants release volatile compounds in response to attack by the white mold fungus. Furthermore, we present conclusive evidence that the volatile profile emitted by these plants differs qualitatively and quantitatively from profiles emitted from healthy plants and from

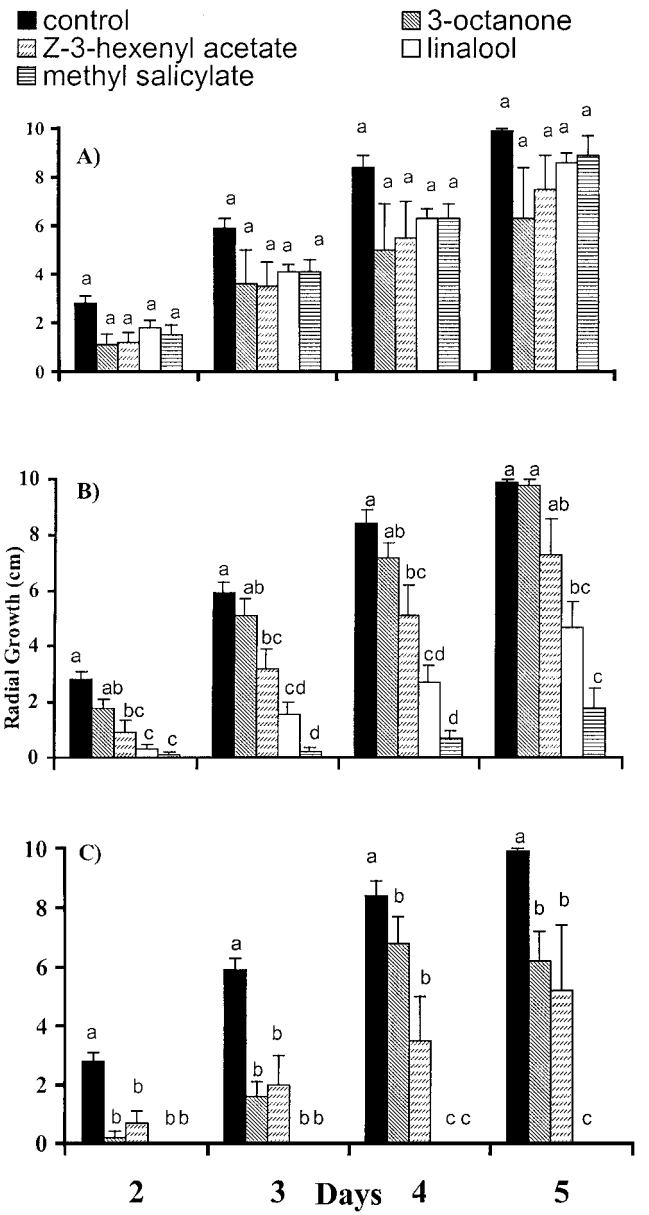

FIG. 3. Mean radial growth of *S. rolfsii* cultures exposed to volatile vapors from 3-octanone, (*Z*)-3-hexenyl acetate, linalool, and methyl salicylate: (A) 3 μl, (B) 10 μl, and (C) 30 μl of the synthetic forms of the compounds. Bars within days headed with the same letter are not significantly different (Tukey's mean separation test, $P \geq 0.05$). Error bars indicate 1 SD.

those emitted in response to BAW damage. Additionally, previous infection of the plant by the white mold fungus does not interfere with the emission of volatiles by the diseased plant in response to BAW attack; rather it seems to induce release of some compounds in relatively higher quantities.

The significant quantitative difference in the volatile profile of peanut plants attacked by either the fungus or the insect, added to the fact that emission of compounds was not suppressed when both organisms were simultaneously attacking the plant, provides a clear indication that the activation and regulation of plant biosynthetic pathways is dependent upon the type of threat perceived by the plant. Four major biosynthetic pathways are believed to be involved in the production of plant volatiles in response to damage by lepidopterous larvae (Paré and Tumlinson, 1997). The shikimic/tryptophan, mevalonate, Rohmer, and lipoxygenase pathways are all believed to be involved in the production of the different classes of volatile compounds released by plants under attack by insect herbivores (Paré and Tumlinson, 1997). The lipoxygenase (LOX) pathway, via jasmonate production, has been directly linked to direct plant defense responses to wounding and damage by herbivorous insects (Ryan, 1990; Farmer and Ryan, 1990; Farmer et al., 1992). Jasmonic acid and methyl jasmonate have also been found to induce volatile emissions similar to those resulting from herbivory in many plants (Boland et al., 1995; Dicke et al., 1999). Thus, it has been suggested that they mediate volatile production. In our study, the emission of volatiles from peanut plants previously infected with *S. rolfsii* indicates that, in this case, unlike direct defenses, volatile production is not compromised by pathogen infection. The latter may be an indication that peanut production of volatile compounds in response to insect and pathogen attack is not jasmonate-dependent. However, the precise combination and regulation of pathways activated in response to an individual or combination of stressors may vary widely among plant species. Therefore, the role of jasmonic acid and salicylic acid on the production and release of induced volatiles by plants in response to insect and pathogen attack needs to be investigated further. The dynamics of volatile emission in response to insect herbivores, phytopathogens, and their combined effect upon other plant species also merit additional attention.

Volatile compounds have been shown to affect pathogens in different ways. For example, the germination and growth of white mold are stimulated by the release of methanol and other volatile compounds emanating from moist peanut hay (Shokes et al., 1996). On the other hand, volatiles from ground-up healthy corn kernels resistant to *Aspergillus flavus* have been found to inhibit the growth and aflatoxin production in colonies of this pathogen (Zeringue et al., 1996). In cotton, however, the lipoxygenase-derived volatile (*E*)-2-hexenal inhibited, while α- and β-pinene stimulated the growth of this fungus (Zeringue and McCormick, 1989, 1990). Thus, the negative effect of (*Z*)-3-hexenyl acetate, linalool, and methyl salicylate volatiles on the growth of our *S. rolfsii* in laboratory cultures suggests that the production of these volatiles by the plant acts as a direct defense by

slowing the growth of the fungus and preventing additional sclerotial germination. However, since we were unable to quantify the headspace concentration of the compounds used, further experiments need to be conducted to confirm that the amounts are comparable to those produced by an infected plant and that in fact the growth of the fungus is hindered under natural conditions.

In the dual-choice feeding experiments, BAW preferentially fed on leaves from white mold-infected peanut plants. BAW and corn earworm, *Helicoverpa zea*, have been reported to feed more upon tomato plants that had been previously treated with benzothiadiazole–carbothionic acid *S*-methyl ester (BTH), an elicitor of systemic acquired resistance via the salicylic acid pathway (Stout et al., 1999). Tomato plants treated with BTH were found to have compromised direct defenses, based on expression of genes encoding for proteinase inhibitors (Fidantsef et al., 1999). In our study, the presence of methyl salicylate in headspace samples of white mold-infected plants indicates activity of the salicylic acid pathway in peanuts in response to *S. rolfsii* infection. Thus, the feeding preference observed in BAW towards leaves from white mold-infected peanut plants may be caused by a reduction in direct defenses of the plant due to fungal infection. Alternatively, the feeding preference of BAW for leaves from fungus-infected plants could be due to changes in the nutritional quality of the tissues caused by the pathogen infection. Different pathogen species have been found to either up- or down-regulate accumulation of photoassimilates (reviewed in Hatcher, 1995). Pathogen infections influence concentrations of compounds such as nitrogen, nonstructural carbohydrates, starch, protein, free amino acids, and amino acid composition, in their respective plant hosts (reviewed in Hatcher, 1995). Although most of the studies included in that review evaluated the effect of leaf-infecting pathogens on the suitability of plant tissue to insect herbivores, it is not inconceivable that a stem-infecting pathogen such as *S. rolfsii* can have similar consequences upon its hosts. However, this is an aspect that remains to be elucidated.

To our knowledge, this is the first in planta study in which the production of volatiles by a single host system in response to both insect herbivores and pathogens has been evaluated simultaneously. This is also the first time that the effect of previous pathogen infection on the production of plant volatiles in response to insect damage has been studied. The study of plant volatile defenses may improve our understanding of plant resistance mechanisms to disease and insect herbivores. The identification of specific pathogen- and herbivore-induced plant volatiles will greatly contribute to the development, improvement, and implementation of host-plant resistance and other control methods for insect and pathogen pests.

Acknowledgments—The authors thank Dr. Tom Kucharek (Department of Plant Pathology, University of Florida), Dr. Naoki Mori, and Barbara Dueben (USDA-ARS/CMAVE, Gainesville, Florida) for their invaluable advice and assistance throughout this project. We also thank Peggy Brennan, Carolina Briceño, and Tim Kirchner (USDA-ARS/CMAVE, Gainesville, Florida) for their technical support. Drs. Tim Brenneman and Glen Raines (Coastal Plain Experiment Station, University of

Georgia) provided the initial *S. rolfsii* culture and the Georgia Green peanut seeds used throughout this project. We also thank Drs. Heather McAuslane (Department of Entomology and Nematology, University of Florida), Raghavan Charudattan (Deparment of Plant Pathology, University of Florida), and Jack Schultz (Department of Entomology, Penn State University) for their comments on an earlier version of this manuscript. This project was funded in part by a Southern Area SARE Graduate Student Research Grant (GS00-001).

Abstract—The phagodepression activity of five furanocoumarins (FC), bergapten, xanthotoxin, psoralen, imperatorin, and angelicin, has been studied against larvae of Egyptian cotton leafworm *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae) using a leaf-disk choice bioassay. The dose range used was 0–10 μg/cm^2 for linear furocoumarins and 0–30 μg/cm^2 for angelicin, the angular furanocoumarin. Dose–feeding deterrency activity correlations were governed by various sigmoidal functions, except in the case of imperatorin and bergapten, which had dose–response curves showing irregular traces with two maxima. All five FCs induced various degrees of phagodepression in *S. littoralis*; at 3 μg/cm^2, the relative feeding deterrence was bergapten = xanthotoxin > psoralen = imperatorin = angelicin. Structure–activity correlations indicated that a methoxy group on C-5 or C-8 enhanced the activity. Comparison of experimental feeding deterrence of binary mixtures of imperatorin with xanthotoxin, bergapten, or psoralen at various relative concentrations with the calculated additive activity of each combination indicated that a proportion of 40% or more of imperatorin may exert a greater antifeedant effect on *S. littoralis* than the sum of individual compounds. The effect of angelicin also was examined in combination

with psoralen, both of which are present in *Psoralea* plants. Their mixtures yielded a clear synergistic effect in the 20–80% angelicin range (coactivity coefficient = 124–133). By contrast, the effect of angelicin on xanthotoxin was only additive. In the dose–response curves of imperatorin/bergapten combinations, synergism was found at >60% imperatorin relative concentration and 1 μg/cm^2, whereas lower proportions led to antagonism. The threshold between the two opposing effects was found to depend on the total FC concentration employed. Some natural systems contain FCs in the range of synergistic proportions recorded here and, thus, may have been produced by the host to increase its defensive effect at a lower metabolic cost.

Key Words—Furanocoumarins, synergism, *Pilocarpus goudotianus*, *Psorale glandulosa*, *Spodoptera littoralis*, feeding deterrence.

INTRODUCTION

Furanocoumarins (FC), tricyclic aromatic derivatives of the phenylpropanoid pathway, are defense metabolites of several species of plants chiefly from the Rutaceae, Apiaceae, and less commonly from the Asteraceae, Fabaceae, Pittosporaceae, Solanaceae, Thymeleaceae, Orchidaceae, and Moraceae (Dean, 1963; Murray et al., 1982). Linear and angular FCs (Berenbaum and Feeny, 1981) are toxic to plants (Fukushi, 1960; Macías et al., 1993), vertebrates and arthropods (Scott et al., 1976; Berenbaum, 1978; Ashwood-Smith et al., 1980; Berenbaum and Neal, 1985; Koenigs and Trager, 1998) and constitute an effective line of defense against insect herbivory predation (Berenbaum, 1981; Berdegué and Trumble, 1997) and possibly fungal attacks (Heath-Pagliuso et al., 1992; Oliva et al., 1999). Their role as phytoalexins has also been demonstrated (Zangerl, 1990; Masuda et al., 1998).

FCs elicit behavioral responses and physiological effects in herbivorous insects. They are repellents and feeding deterrents (Yajima et al., 1977; Yajima and Munakata, 1979; Klocke et al., 1989; Berdegué et al., 1997), and they act as phototoxins by ultraviolet radiation-promoted cycloaddition and cross-linking of DNA pyrimidines (Yajima et al., 1977; Berenbaum, 1978, 1985, 1991, 1995; Sastry et al., 1997). The combination of FC and UV light acting together against insects is consistent with the finding of these compounds in heliophilic plants. In addition, some linear FCs disrupt the detoxification capability of organisms by acting as suicide substrates for cytochrome P-450 monooxygenases, an enzyme system involved in detoxification processes in mammals (Labbé et al., 1987; Koenigs and Trager, 1998) and insects (Neal and Wu, 1994).

Selective pressure by some FCs on herbivorous insects has led to physiological adaptations that allow certain insects to consume FC-containing plants and even depend on these compounds for their reproduction and development (Nitao, 1989, 1990; Berenbaum et al., 1989; Degen et al., 1999). A good correlation was found between the diversity of FC chemistry in a given plant community and

herbivore specialization. Thus, generalists tend to exploit plants with a simpler FC composition (Berenbaum, 1981). However, these adaptations may depend on whether FCs are linear or angular (Berenbaum and Feeny, 1981).

Most FC-producing plants synthesize more than one of these compounds, and there are examples where several furano- and pyranocoumarins have been isolated from the same plant (e.g., Amaro-Luis et al., 1990). It is conceivable that the production of similarly structured materials in the same plant is an evolutionally advantageous response to a variety of environmental pressures that allows the plant to deter a wider spectrum of predators. It is also plausible that these secondary metabolites do not operate individually on the target but in concert, additively or synergistically. In the case of FCs, it has been shown that, in addition to their inherent toxicity, they may act synergistically or antagonistically when mixed with other plant secondary metabolites, FCs or otherwise. For example, mixtures of psoralen with xanthotoxin or bergapten resulted in reduced mortality of *Spodoptera exigua* reared on artificial diets mixed with these FCs and exposed to UVB radiation, suggesting an antagonistic effect (Diawara et al., 1993). In contrast, Brewer et al. (1995) found that mixtures of similar composition, but at lower combined concentration where psoralen was the minor component, caused greater mortality in *Spodoptera exigua* than the sum of individual FCs, suggesting a synergistic effect of psoralen. These results suggest that both the concentration of the mixture and the proportion of its individual components may affect the response of *S. exigua* to FCs. Additionally, synergism has been observed in mixtures of xanthotoxin with nonfuranocoumarins myristicin, safrole, and fagaramide (Berenbaum and Neal, 1985; Neal, 1989).

Feeding deterrence tests with *Spodoptera* spp. by FCs have never been performed with pairs of these compounds. Only mixtures of bergapten, xanthotoxin, and psoralen in amounts naturally found in petioles and leaves of *Apium graveolens* have been examined, but no systematic variation of their concentration was investigated. Although Berdegué et al. (1997) found apparent synergism, the contribution of each individual FC to the observed synergistic effect cannot be surmised from their data. If these and other FCs are to be deemed defense metabolites against generalist herbivores, it would be desirable to observe their effect in general mixtures of varying concentration.

Pilocarpus goudotianus (Rutaceae) is a rich source of a variety of coumarins (Amaro-Luis et al., 1990). Linear and angular pyranocoumarins and dihydrofuranocoumarins, as well as linear furanocoumarins, have been identified in ethanolic extracts of leaves in quantities that may cause toxicity in herbivores. *P. goudotianus* may rely on light-activated defenses because it grows in xerophytic areas of northwestern Venezuela and northern Colombia.

Spodoptera littoralis, a generalist herbivore is likely affected by FCs in the diet and might be sensitive to possible synergistic antifeedant effects. Thus, *Spodoptera* is a useful model to examine synergism among *P. goudotianus* furanocoumarins in reference to feeding deterrence. In particular, linear FCs (xanthotoxin, bergapten,

and imperatorin) were selected here based not only on being the most abundant FCs in *P. goudotianus*, but also because they are the most active feeding deterrents against *S. littoralis* (Calcagno, 1995). This activity was higher in chromatographic fractions that also contained imperatorin in addition to other FCs. *Psoralea*, plants contain a combination of linear and angular FCs whose possible synergistic interaction also needed to be examined. Thus, we set out to investigate the synergistic interactions of imperatorin and the other FCs in *P. goudotianus* as well as the linear–angular combinations in *Psoralea glandulosa*. Although chemical synergism in plants may result from the contribution of several compounds, methodological clarity requires that such effects should be investigated first by pairs of compounds.

METHODS AND MATERIALS

Compounds. The FC structures are shown in Figure 1. Angelicin and psoralen were isolated from *Psoralea glandulosa* collected from Cuesta La Dormida, Chile, in March 1994 (end of southern summer) according to an established procedure (Labbé et al., 1996). The three linear FCs bergapten, xanthotoxin, and imperatorin were obtained by hexane extraction and silica gel chromatography of aerial parts of several mature individuals of *Pilocarpus goudotianus*, collected in the deciduous dry forest of Curarigua, Lara State, in west-central Venezuela in May 1993 (end of dry season). Plant parts were transported to the laboratory in a cooler within 12 hr, air dried at 28–30°C for several days in the dark, and stored in paper bags at room temperature until used. This material was milled to fine particles just before solvent extraction. The antifeedant activity against *S. littoralis* of hexane,

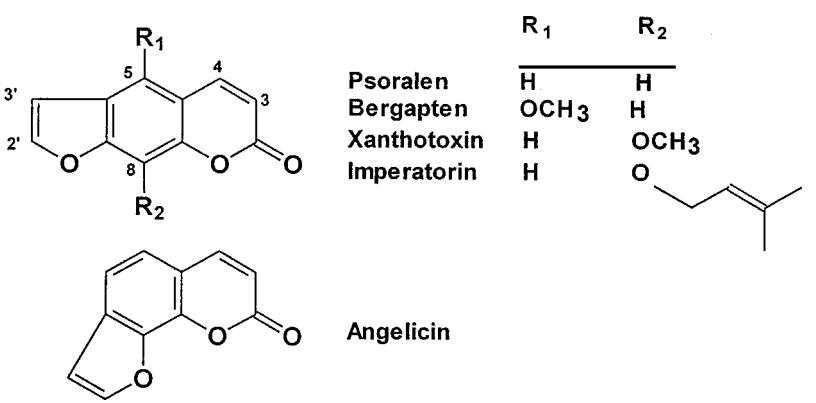

FIG. 1. Chemical structures of FCs examined in this study.

dichloromethane, and ethyl acetate extracts of this plant, which were obtained at room temperature using an ultrasound bath, were tested as described below. Only the hexane extract was found to contain the antifeedant activity. This extract (3×1 liter) of *P. goudotianus* dry leaves (200 g) was prepared by sonication at room temperature. The filtered solution was partitioned with methanol–water 9:1 (3×600 ml). After removing the methanol in a rotary evaporator at room temperature with protection from ambient light, the aqueous layer was extracted again with hexane. The crude residue (0.85 g) remaining after desiccation with anhydrous sodium sulfate, filtration, and evaporation was chromatographed through silica gel (30 g) and eluted with a hexane–dichloromethane gradient away from direct light. The fractionation was followed by antifeedant tests on larvae of *S. littoralis* (see below). The active fractions were gathered (0.34 g) and chromatographed again on the same stationary phase (15 g) using a hexane–ethyl acetate gradient. The final purification was performed using thick-layer chromatography on silica gel employing hexane–*t*-butyl methyl ether (1:2) and hexane–chloroform–methanol (8:4:0.3), and yielded three compounds. ^{1}H and ^{13}C NMR analysis showed these to be imperatorin (0.015%; mp 100–102°C, lit 102–103°C; Harkar et al., 1984), bergapten (0.009%; mp 190–193°C, lit 193–194°C; Yajima et al., 1977) and xanthotoxin (0.022%; mp 152–154°C, lit 151–152°C; Yajima et al., 1977). Upon exhaustion of the plant stock, bergapten and psoralen were purchased from Sigma Chemical Co. (St. Louis, Mo) and angelicin and imperatorin from Extrasynthese:HPLC (Genay, France) with bioactivities identical to the naturally derived compounds determined by parallel antifeedant bioassays. A stock acetone or acetone–chloroform solution, depending on compound solubility, of 1 mg/ml of each linear FC and 3 mg/ml of angelicin was prepared, from which aliquots were drawn to obtain the working concentrations, such that 10 μl of solution would contain 1–10 μg for linear FCs and 2–30 μg for angelicin. For binary mixtures, the total FC concentration was kept constant and bioassays were run employing various total concentrations in the range of 1–5 μg/cm^2 leaf disk.

Insects. Newly ecdysed fifth-instar larvae from laboratory cultures of *S. littoralis* were used for the antifeedant assays. Insects were reared on standard artificial diet (Poitout and Bues, 1974) at 25 ± 2°C, 60–70% relative humidity, 18 hr photophase, and maintained for several (>50) generations with eventual out-crossings in the insectary of CSIC-Barcelona, Spain.

Two-Way Feeding Bioassay. These were performed using the leaf disk method of Bellés et al. (1985) employing lettuce (*Lactuca sativa*) as feeding substrate at 30 ± 0.5°C in the dark for the length of the feeding period. Areas devoured by the larvae were determined by overlapping the disks on millimeter-squared paper. The feeding coefficient, FR_{50}, was calculated from the ratio of treated and control disk areas at the time 50% of the control disks had been consumed. FR_{50} varies from 0, i.e., no consumption of treated disks, to $FR_{50} > 1$ where acceptance of the treated disk indicates a net phagostimulant effect. Coactivity coefficients (CA) were used

to estimate synergism where CA is defined as:

$$CA = [(1 - FR_{50})_e/(1 - FR_{50})_c] \times 100$$

where $(1 - FR_{50})_e$ is the experimental feeding deterrence index and $(1 - FR_{50})_c$ is the calculated feeding deterrence index.

Mathematical Simulations and Statistical Methods. Computational calculations were performed with a Pentium III 500-MHz computer running Microsoft Excel 98 spreadsheet and Microcalc Origin v. 5.0 (Microcalc Software Inc., One Roundhouse Plaza, Northampton, Massachussetts) for plotting, curve fittings, and simulations. Tukey ($\alpha = 0.05$) tests for comparison of means were executed with SX v. 4.5 statistical package (Analytical Software, St. Paul, Minnesota)

RESULTS AND DISCUSSION

Activity of Individual FCs (Table 1). The phagodepression activity of FCs on *S. littoralis* might be expected to follow a linear dose–response curve. This is true for some FCs, particularly in the lower range of concentrations tested. For instance, dose–response correlations of psoralen and xanthotoxin in the range of 0–10 and 0–3 μg/disk, respectively, may be adjusted to a linear regression

[a] Values are mean ± SEM ($N = 6$). Values with the same letter do not differ significantly ($\alpha = 0.05$, Tukey). Comparisons are between rows: different compounds at the same concentration.

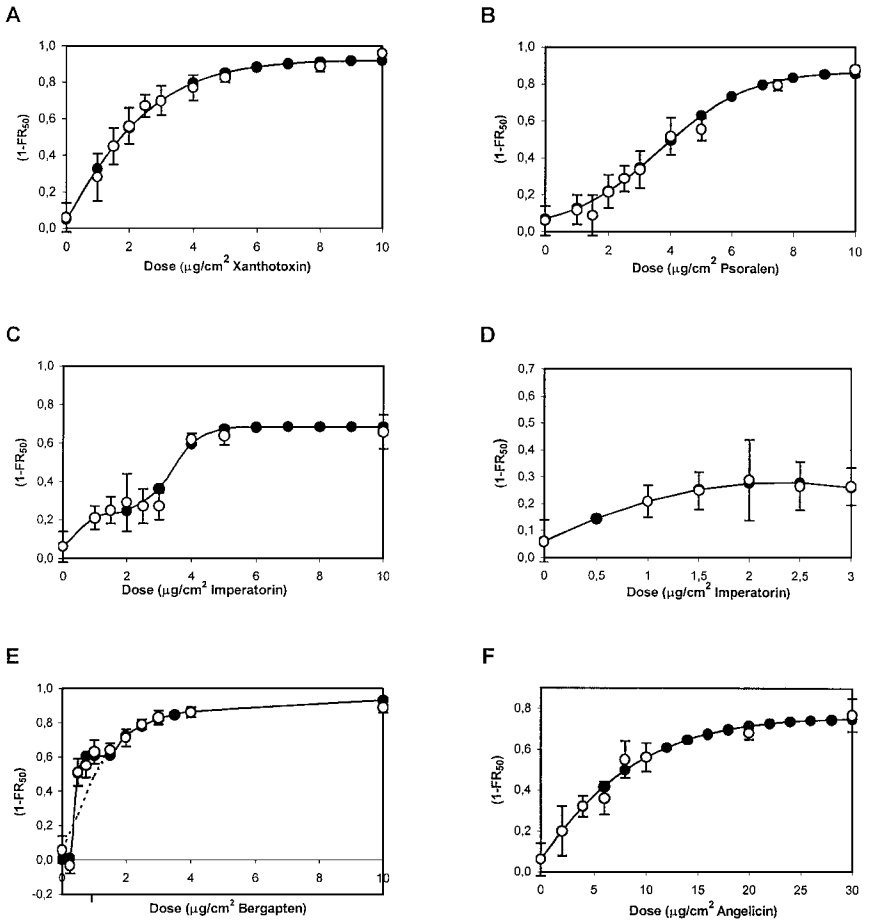

FIG. 2. Feeding deterrence dose–response plots and curve fitting models of individual furanocoumarins. (A): Xanthotoxin. (B): Psoralen. (C) and (D): Imperatorin. (E): Bergapten. (F): Angelicin. [(○) experimental; (●) calculated]. The value zero concentration is based on a control involving the insects being exposed to two sets of untreated disks. For comments and equations describing odd-shaped curves see text. Bars represent SEM.

(Figure 2). However, a better fit is obtained by representing the data as a sigmoid curve (Figure 2, Table 2). Recently, we showed that small variations in the shape of the dose–response curves may cause profound effects on the curves representing the sum of the activities of individual compounds (Alonso-Amelot and Calcagno, 2000). Therefore, computational curve fittings of dose–response correlations of individual FCs were obtained after equation and parameter choices, such that the

TABLE 2. COMPARISON OF SIGMOIDAL CORRELATIONS AND LINEAR REGRESSION OF DOSE/$(1 - FR_{50})$ ASSOCIATIONS IN XANTHOTOXIN AND PSORALEN IN THE APPARENTLY MORE LINEAR SECTION OF THE CURVES

Dose-deterrence activity correlation function		SUM |dif|[a]	
		Xanthotoxin[b]	Psoralen[c]
Boltzman sigmoidal growth	$\chi^2 = 0.0010$	0.46	
S-logistic sigmoidal growth	$\chi^2 = 0.0035$		1.34
Linear regression	$r^2 = 0.9777$	0.62	
	$r^2 = 0.9571$		1.86

[a] SUM $|\text{dif}| = \sum |[(1 - FR_{50})_e - (1 - FR_{50})_c]/(1 - FR_{50})_e|$, where $(1 - FR_{50})_e$ is the experimental feeding deterrence index and $(1 - FR_{50})_c$ is the calculated feeding deterrence index.
[b] Dosage: 0–3 $\mu g/cm^2$.
[c] Dosage: 0–10 $\mu g/cm^2$.

minimum deviation from the calculated and experimental points could be obtained. χ^2 and the sum of the module of differences between calculated and experimental values (equation 1) were used as criteria for the best fit. FR_{50} could not be employed as such because the greater the phagodepression, the lower the FR_{50}. Instead, $[1 - FR_{50}]$ inverted the scale and, thus, became amenable to additive calculations.

$$\text{SUM } |\text{dif}| = \Sigma|[(1 - FR_{50})_e - (1 - FR_{50})_c]/(1 - FR_{50})_e| \qquad (1)$$

All five of the FCs examined induced various degrees of phagodepression in *S. littoralis* (Table 1). Bergapten was the most active compound at lower dosages. Xanthotoxin, however, showed a steeper activity increment with concentration than psoralen, imperatorin, and angelicin, and reached a level of activity statistically undistinguishable from that of bergapten above 1.5 μg/disk. From 1.5 to 3.0 μg/disk, the relative feeding deterrence became bergapten = xanthotoxin > psoralen = imperatorin = angelicin. All compounds showed nonlinear dose–activity regressions, each one governed by a different equation (Table 3). The relative effect of substituents on the tricyclic FC system could be discerned by comparing their molecular structures (Figure 1). A methoxy group either on C-5 (bergapten) or C-8 (xanthotoxin) enhanced the activity relative to the unsubstituted system (psoralen) or a C-8 isoprenoxy group (imperatorin). This trend is similar to that reported by Muckensturn et al. (1981), except that we record comparable activities for psoralen and imperatorin.

Figure 2 also shows that dose–response curves in terms of $[1 - FR_{50}]$ progress towards asymptotic maxima. This suggests that the behavioral response of *S. littoralis* becomes saturated above a given threshold of FC concentrations. Beyond this limit, antifeedant tests become concentration-independent and, hence, experimentally useless.

TABLE 3. PARAMETERS OF BEST COMPUTATIONAL CURVE FITTING OF DOSE–RESPONSE PHAGODEPRESSION ACTIVITY CORRELATIONS OF INDIVIDUAL FUROCUMARINS ON *S. littoralis*

	Bergapten	Xanthotoxin	Psoralen	Imperatorin	Angelicin

χ^2	0.004	0.001	0.003	0.004	0.002

[a] Equation 2: $Y = [(A1 - A2)/[1 + (X/Xo)^P] + A2$; equation 3: $Y = (A1 - A2)/(1 + e^{(X-Xo)/dx}) + A2$; equation 4: $Y = A/(1 + e^{-K(X-Xc)})$; equation 5: $Y = 0{,}6843 - (A2 - A1)F/(1 + 10^{(X - \log X1)}) - [(A2 - A1)(1 - F)/(1 + 10^{(X - \log X2)})]$.

Imperatorin displayed a two-part dose–response curve. At lower concentrations the activity trend followed a pattern comparable to that of other FCs, reaching a plateau between 2 and 3 μg/disk. This was followed by a second, much higher plateau above 4 μg/disk, suggesting that more than one FC discrimination system assists the insect in its feeding choice. This abnormal behavior required a special treatment of imperatorin in its evaluation as synergist (see below). A complex equation (equation 5, Table 3) was necessary to accommodate all the data points. However, by using only the data below 3 μg/disk, it was possible to fit the recorded activity to a much simpler and accurate mathematical representation (equation 6; Figure 2D). Thus, imperatorin at concentrations below 3 μg/disk was used.

$$[1 - \mathrm{FR}_{50}] = 0.060 + 0.190X - 0.041X^2 \tag{6}$$

$r^2 = 0.9919$; $P < 0.0008$.

The dose–response curve of bergapten (Figure 2E) showed a similar inflection at 1.5 μg/disk that demanded a double mathematical treatment: a Gompertz sigmoid for those points in the $0 < X < 1.5$ μg/disk range (equation 7) and a logistic sigmoid fitting for points above this value (equation 2, Table 3).

$$Y = Ae^{-e^{-[K(X - X_c)]}} \tag{7}$$

where $A = 0.610$, $K = 12.169$, $X_c = 0.365$, and $\chi^2 = 0.001$.

The phagodepressant activity of angelicin has been examined in only a few polyphagous insects (Muckensturn et al., 1981) and has not previously been examined in *S. littoralis*. Its dose–response data followed a sigmoidal Boltzman distribution, in parallel with xanthotoxin, but at a much reduced level (equation 3, Table 3; Figure 2F).

Activity of Binary Mixtures. The expected feeding deterrence activity of binary mixtures of FCs was calculated by the algebraic sum of individual activities represented by their particular best-fit equations. The calculated composition of the mixtures was set at 10% intervals between 0 and 100% of one of the components, keeping their added concentration *K* constant. From the estimated result, the concentration range to be used experimentally was determined such that the total activity was at most 90% of the maximum activity in terms of $1 - FR_{50}$ (Alonso-Amelot and Calcagno, 2000). This procedure allowed us to detect any significant synergistic effect without reaching the 100% response level where the insect's sensory system would presumably become saturated. Estimated dosages for each FC combination were 2 μg/cm^2 for imperatorin–xanthotoxin, 3 μg/cm^2 for imperatorin–psoralen and angelicin–xanthotoxin, and 5 μg/cm^2 for angelicin–psoralen. Three dosages (*K*) were used for the imperatorin/bergapten combination (1, 2, and 3 μg/cm^2) to evaluate if the purported synergism was dose-dependent and to assess the effect on the total insect feeding behavior of the dose–response curve discontinuity of bergapten.

In the case of imperatorin–xanthotoxin, moderate synergism became evident only in the 40–75% imperatorin range (Figure 3A), but only the point at 40%, whose coactivity coefficient (CA) was 121, was statistically distinguishable from the additive value. Imperatorin–psoralen mixtures were studied at greater *K* (3 μg/cm^2) because of the lower activity of psoralen and the limitations imposed by the dose–response curve distortion above this value for imperatorin (Figure 2C). A correlation analogous to that of imperatorin–xanthotoxin was obtained (Figure 3B) with a similar zone of synergism. The maximum effect was found at 75% imperatorin (CA = 153).

In the smoothly distributed experimental points of the imperatorin–bergapten mixtures, two zones became apparent (Figure 4A). At $K = 1$ μg/cm^2, synergism occurs at >60% imperatorin, whereas lower imperatorin proportions lead to antagonism. The synergistic range is narrower (>80% imperatorin) at $K = 2$ μg/cm^2 and the recorded $1 - FR_{50}$ values in the plateau zone become undifferentiated from the addition curve. A similar behavior in the synergistic range was recorded for $K = 3$ μg/cm^2, but activities in the plateau were significantly antagonistic. In all three cases, the bergapten concentration where synergism was observed was only around 0.25 μg/cm^2, just below the activity threshold of this compound (Figure 2E). Thus, imperatorin must be a synergist for bergapten in this dose range.

Our data indicate that mixtures of linear FCs, xanthotoxin, psoralen, and bergapten with imperatorin at 40% or greater of the latter may exert a greater

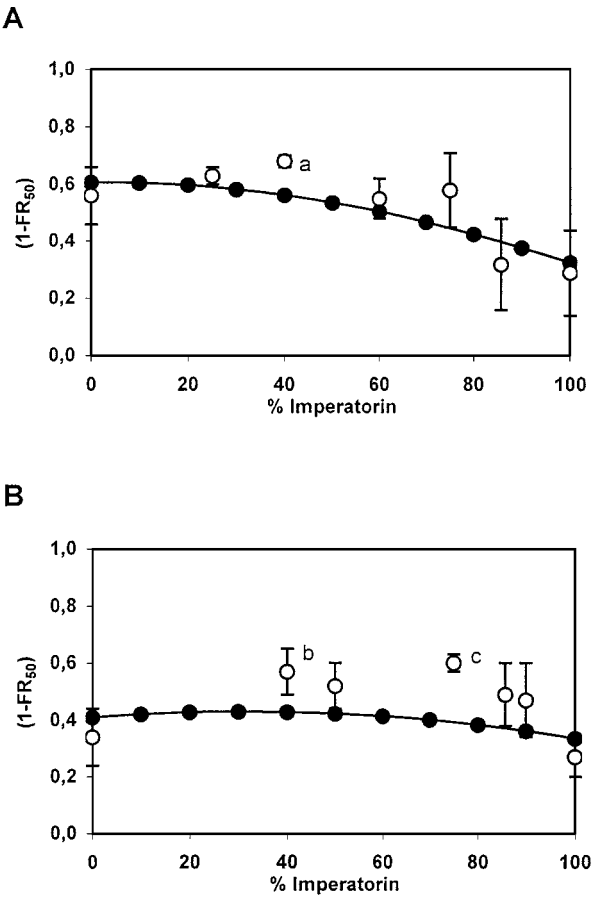

FIG. 3. Effect of binary mixtures of linear FCs in feeding deterrence activity on *S. littoralis*. Experimental (○) and calculated ((●) solid line) additive activities of mixtures of (**A**): imperatorin + xanthotoxin at $K = 2\mu g/cm^2$ and (**B**): imperatorin + psoralen at 3 $\mu g/cm^2$ showing moderate synergism in the 40–75% imperatorin range. antifeedant effect on a generalist herbivore such as *S. littoralis* than the individual compounds. This conclusion is in agreement with recent work on FC effects on *S. exigua*, although imperatorin was not examined (Berdegué et al., 1997). Conversely, xanthotoxin alone possessed a higher feeding deterrency activity against *Helicoverpa zea* than the FC mixture naturally found in *Pastinaca sativa* (Berenbaum et al., 1991), indicating a moderate antagonism. This also fits the

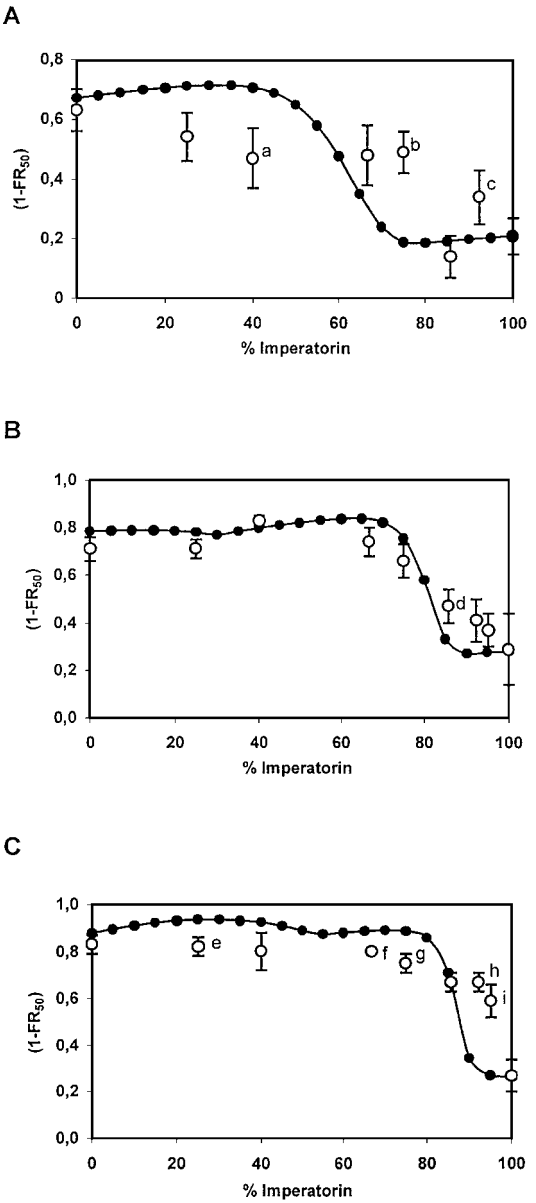

FIG. 4. Effect of binary mixtures of imperatorin and bergapten in feeding deterrence activity on *S. littoralis* at different total doses. Experimental (○) and calculated (●) additive activities of mixtures showing significant antagonistic and synergistic zones. Significant data points in lower captions ($\alpha = 0.05$, Tukey). portion of our dose–response regressions where antagonism occurs, such as in the imperatorin–bergapten combinations. This might well be the case with xanthotoxin in complex combinations such as those reported by Berenbaum et al. (1991) in *P. sativa*.

Thus, it might be advantageous for the parent plant to synthesize and accumulate various FCs, including imperatorin, to fend off generalist herbivorous insects. Because not only the presence but also the concentration and, more importantly, the proportions of these compounds appear to be essential in the synergistic effect, it will be necessary to determine quantitatively the relative amounts of these materials in a wide range of natural systems that find protection by use of FCs. Data at present are probably insufficient to draw conclusions in this regard, but some evidence is clearly suggestive. Studies on *Psoralea* showed the presence of linear and angular FCs at relatively constant ratios in various plant parts (e.g., Cappelletti et al., 1992). Their accumulation in whole fruits is reported at a 0.3–0.4 psoralen–angelicin ratio in *P. cinerea*, *P. onobrychys*, and *P. macrostachya*. This combination has been interpreted as a chemical defense of the reproductive organ. In the latter two species, although the total concentration of FCs varies with seed maturation, the psoralen–angelicin ratio changes only marginally (Innocenti et al., 1984; Cappelletti et al., 1992). This pattern, however, may not be universal within this genus, as *P. lacnostachys*, and *P. pustulata* contain these FCs in a 2.0–2.5 ratio (Innocenti et al., 1984).

This compound configuration in the natural systems led us to examine the possible synergistic effect that angelicin, the least active among the compounds examined, has in combination with psoralen. Mixtures yielded a clear synergistic effect in the 20–80% angelicin range (Figure 5A). At $K = 5\ \mu g/cm^2$, a 0.3–0.4 psoralen–angelicin ratio furnished a CA = 124–125. Similarly, a 2.0–2.5 psoralen–angelicin ratio produced a CA = 132–133, both corresponding to a detectable increase in feeding deterrence capacity. Therefore, there may be considerable latitude in the proportion of these compounds that may yield increased protection against herbivory by generalist insect herbivores.

There are some plants that also contain xanthotoxin and angelicin such as *Pastinaca sativa* (Berenbaum et al., 1991; Berenbaum and Zangerl, 1993). It is conceivable that synergism between these compounds could occur. However, using $K = 3\ \mu g/cm^2$ and varying the xanthotoxin–angelicin ratio, our tests indicated that feeding deterrence activity against *S. littoralis* was similar to the calculated additive curve (Figure 5B), so no synergism was in effect. This result is consistent with the behavior of *Papilio polyxenes* facing the same combination of xenobiotic chemicals in *P. sativa* (Berenbaum and Zangerl, 1993). The FC mixture was more toxic than the individual compounds, but feeding deterrence capacity was not greater. It is clear that the synthesis of selected FCs in one organism may be derived from the added protection that these compounds confer to the host plants as mixtures. Other

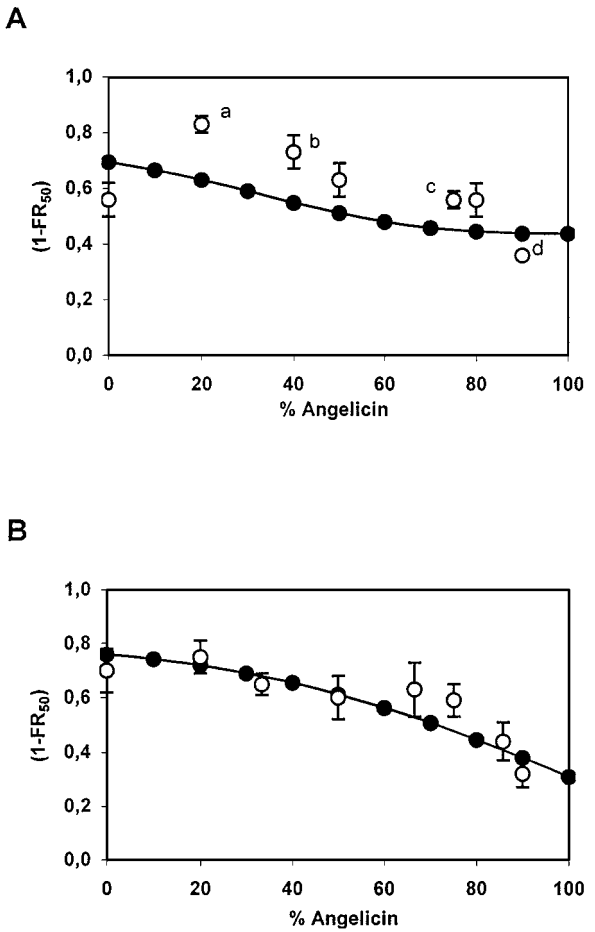

FIG. 5. Effect of binary mixtures of angular and linear FCs in feeding deterrence activity on *S. littoralis*. Experimental (○) and calculated ((●) solid line) additive activities of mixtures of (**A**) angelicin and psoralen at 5 μg/cm^2, showing clear synergism in the 20–80% angelicin range, significant data points in lower captions ($\alpha = 0.05$, Tukey); a: CA = 132; b: CA = 133; c: CA = 124; and (**B**) angelicin and xanthotoxin at $K = 3$ μg/cm^2 (showing no significant synergism). Bars represent SEM.

FC combinations, deemed nonsynergistic at present, may prove to be so in other insects.

Acknowledgments—The collection of *Pilocarpus goudotianus* specimens by Dr. L. D. Otero is greatly appreciated. The authors are grateful for the financial support of CONICIT of Venezuela

OVIPOSITION RESPONSES BY HESSIAN FLY, *Mayetiola destructor*, TO WHEATS VARYING IN SURFACES WAXES

(Received April 20, 2001; accepted September 13, 2001)

Abstract—Leaf waxes are known to contain oviposition stimulants for Hessian fly. In dual-choice tests comparing seedlings of each of three nonglaucous lines of wheat with its corresponding glaucous line, Hessian flies laid similar numbers of eggs on each genotype. However, when plants from these genotypes were tested at the flag-leaf stage, Hessian flies deposited 25–100% more eggs on the nonglaucous genotype compared to normal wax genotype in each pair. Leaf waxes extracted from the genotypes in one of these pairs (Avalon and nonglaucous Avalon) at the seedling and the flag-leaf stage and tested on paper leaf models elicited oviposition responses similar to those observed on the intact plants. Scanning electron microscopy showed differences in crystal density on nonglaucous and glaucous genotypes only at the flag-leaf stage. Gas chromatography–mass spectrometry of the leaf wax extracts showed that fly oviposition responses were associated with differences in the chemical composition of the waxes. This is the first report of Hessian fly oviposition responses varying among genotypes of wheat with different surface wax composition.

Key Words—Cecidomyiidae, host plant resistance, antixenosis, oviposition preference, plant surface wax, *Triticum aestivum*.

INTRODUCTION

The Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), is a major pest of wheat (*Triticum aestivum* L.) throughout many wheat growing areas of the world (Barnes, 1956; Ratcliffe and Hatchett, 1997). Hessian fly also infests several other cereal crops, including barley (*Hordeum vulgare* L.), rye (*Secale*

*To whom correspondence should be addressed. E-mail: sanforde@uidaho.edu

0098-0331/02/0100-0193/0 © 2002 Plenum Publishing Corporation

cereale L.), and triticale, and several noncereal grasses (Harris et al., 1996). This insect continues to be problematic for wheat production in most of North America, and during the last two decades has become increasingly important in the Pacific Northwest (Pike et al., 1993; Ratcliffe et al., 2000).

Resistant cultivars are the most effective control method for Hessian fly (Ratcliffe and Hatchett, 1997). Deployed resistance to the fly and all known sources of resistance depend upon antibiosis conditioned by single genes (Ratcliffe and Hatchett, 1997). The high level of mortality imposed on first-instar larvae by resistant varieties exerts a strong selection pressure on Hessian fly populations, resulting in the evolution of Hessian fly biotypes unaffected by resistant genes and posing a risk to the durability of resistant varieties (Ratcliffe and Hatchett, 1997; Ratcliffe et al., 2000). Resistance other than antibiosis could provide a means for increasing the durability of resistance to Hessian fly (Gould, 1986).

Harris and colleagues (Harris and Rose, 1989, 1990; Foster and Harris, 1992; Harris et al., 1993; Kanno and Harris, 2000a,b; Morris et al., 2000) have conducted extensive investigations of the oviposition behavior of Hessian fly. Their research has shown that host finding and oviposition by Hessian fly is influenced by visual, tactile, and chemical cues from the plant, especially the composition of plant surface waxes. Foster and Harris (1992) showed that Hessian flies lay significantly more eggs on paper strips impregnated with epicuticular wax extracts of wheat than on wax-free controls, or strips impregnated with epicuticular waxes from the nonhost, oats. Recently, Morris et al. (2000) reported that *n*-octacosan-1-aldehyde (1-octacosanal) and 6-methoxy-2-benzoxazolinone (MBOA) in wheat seedling surface waxes were major oviposition stimulants for a New Zealand population of Hessian fly.

If wax composition influences Hessian fly oviposition preference, it might be possible to alter wheat wax composition genetically to provide the crop with some protection against the fly. There are no reports of Hessian fly responses to wheat genotypes varying in surface waxes. Working on a group of winter wheat genotypes, Lowe et al. (1985) identified genotypes that lacked a waxy bloom. These were named nonglaucous (NG) Avalon, NG Brigand, and NG Virtue after their respective normal-wax or glaucous parental lines Avalon, Brigand, and Virtue. The NG lines were found to be resistant to the English grain aphid, *Sitobion avenae* F. (Aphididae) by Lowe et al. (1985). Mutations that reduce waxy bloom in wheat and other crops typically reduce the amount of wax (wax load) and the density of wax crystals on a leaf area basis, and alter wax chemical composition (Macey and Barber, 1970; Holloway et al., 1977; Avato et al., 1984; Eigenbrode et al., 1991; Eigenbrode and Pillai, 1998).

We obtained the three NG wheat genotypes and their glaucous counterparts used in the Lowe et al. (1985) study to examine their effects on oviposition by the Hessian fly. We hypothesized that oviposition would be altered on NG plants, either because of the lower loads of stimulatory waxes or because the waxes on NG

plants have altered amounts of oviposition stimulants and/or deterrents for the fly compared to normal wax plants. We examined this hypothesis using free-choice bioassays with plants at the seedling stage and the flag-leaf stage. We tested flag-leaf stage plants because the NG state in the lines we used is only detectable at this stage. We tested plants at the seedling stage because this is most vulnerable to the fly and because the effects of the wax mutations on seedling stage wax composition were unknown. We included a known nonhost, oats, as a negative control in the bioassays with intact seedlings. Based on results of the bioassays with intact plants, we extracted leaf waxes from one pair of wheat genotypes, applied them to paper leaf models, and conducted free-choice bioassays to examine the effect of wax chemistry on Hessian fly oviposition. We characterized the waxes used in this bioassay chemically using gas chromatography/mass spectrometry. Because fly oviposition also might be affected by the differences in crystalline morphology of the waxes on normal and NG types, we examined the surfaces of the plants with scanning electron microscopy (SEM).

METHODS AND MATERIALS

Insects. Hessian flies were obtained from a laboratory colony established with individuals collected from wheat in the summer of 1998 in Lewiston, Idaho. Biotypes GP, E, F, and G make up 83% of the Hessian fly field populations in Lewiston (Ratcliffe et al., 2000). The laboratory colony was determined to have similar frequencies of each biotype (R. Ratcliffe, personal communication). Hessian fly biotypes are characterized by their virulence against a number of resistance genes (Ratcliffe and Hatchett, 1997) and are not known to differ in their oviposition preference. The colony was maintained in the laboratory on the susceptible cultivar Centennial at $21 \pm 4^{\circ}$C, and 16L : 8D, using a method modified from Foster et al. (1988). When plants reached the two-leaf stage, they were infested with 50 mated female Hessian flies per cage over a five-day period. Mated females are distinguished from virgin ones by their characteristic calling posture (Bergh et al., 1990). After oviposition, eggs hatched and larvae developed on wheat plants. Adults emerged after ca. 28–30 days.

Wheat Genotypes. Three sets of winter wheat genotypes (Avalon, Brigand, Virtue, and NG variants from each genotype) and oats (cv. Coast Black) were tested for oviposition preference by Hessian fly. At maturity, the NG variants of each wheat genotype have a distinctly reduced waxy bloom. Seed of Avalon, Virtue, Brigand, and Coast Black oats was obtained from the USDA National Small Grains Collection, Aberdeen, Idaho. Seed of NG Avalon, NG Virtue, and NG Brigand was obtained from the John Innes Center, Norwich, England. Seed of all entries was increased in the greenhouse to obtain sufficient material for testing. For experiments, plants were grown in the greenhouse ($20 \pm 2^{\circ}$C, 16L : 8D) using

supplemental lighting provided by Son Agro 430-W high-pressure sodium lamps (Phillips, Somerset, New Jersey). Plants to be used at the flag-leaf stage were subjected to a six-week vernalization period (4°C, 8L : 16D).

Seedling Stage Bioassays. Free choice tests were conducted in the greenhouse (20 ± 2°C, 16L : 8D). In three separate experiments, comparisons were made between each glaucous wheat genotype and its NG variant. Experiments were arranged as randomized complete block designs with 10 replications (1 cage = replication). Plexiglas cages (51 × 50 × 51 cm) were used for tests. The bottom part of the cage was filled with soil mixture [6 : 1 ratio of Sunshine mix #1 (Sun Gro Horticulture, Bellevue, Washington) and sand], and seeds were planted directly in the soil. For the tests with Avalon and Virtue and their NG variants, each cage contained one row of each genotype (seven plants per row, rows spaced 10 cm, plants spaced 3.5 cm). Genotypes were assigned to rows randomly. When plants reached the three-leaf stage (Zadoks scale 12) (Zadoks et al., 1974), a single mated female obtained from the laboratory colony was released into each cage (09:00 hr) and allowed to oviposit for 6 hr. At the end of the oviposition period, all plants were cut at the base, and Hessian fly eggs were counted using a dissecting microscope. For the test comparing Brigand, Brigand NG, and oats, five mated females rather than one were released per cage, and each row contained eight plants per genotype rather than seven.

Flag-Leaf Stage Bioassays. The distinctly reduced waxy bloom on NG variants was only discernible on plants after vernalization and nearing emergence of the flag leaf. Although under field conditions most oviposition by Hessian fly occurs on seedlings, Painter (1951) reported that females lay eggs on the flag leaf of winter wheat plants, if available, during the oviposition period. For these reasons, we also conducted oviposition tests using flag-leaf stage wheat plants (Zadoks scale 50) (Zadoks et al., 1974). Each glaucous genotype and its NG variant was tested in a separate experiment in the greenhouse and under the same environmental conditions as for the seedling stage experiments. Plexiglas cages (92 × 50 × 51 cm) contained two potted plants (15-cm pots) each of the glaucous genotype and its NG variant. Plants were located randomly within a cage and each experiment had 10 replications. When plants reached the flag-leaf stage, eight mated females were released into each cage and allowed to oviposit for 24 hr, after which eggs were counted using a dissecting microscope. Eggs were counted separately on flag leaves and the entire plant.

Leaf Model Bioassays. Bioassays using leaf models impregnated with leaf wax extracts, as described by Harris and Rose (1990), were conducted to determine the role of epicuticular waxes in fly preference. We tested the activity of waxes extracted from Avalon and NG Avalon because Hessian fly discrimination between these two was stronger and more consistent than between the other two pairs of glaucous and NG genotypes. Leaf models consisted of 10- × 0.5-cm strips of yellow copy paper (Canary Yellow, Color Source, Boise Cascade, Boise, Idaho).

Waxes extracted from Avalon or NG Avalon (see extraction methods below) were dissolved in hexane and applied to the models at physiological concentration (PC) on a mass per leaf area basis. Physiological concentrations were determined by weighing extracted waxes from known leaf area samples of Avalon and NG Avalon plants. Leaf models treated with hexane served as controls. Acetate cages (14 cm diam. $\times$ 15.5 cm high) with a screen top were used for bioassays. The bottom part of the cage was covered with fine sand to a depth of ca. 8 mm and the inner sides were lined with blue paper (Morris et al., 2000). Just before the flies were introduced, the sand was moistened with 30 ml of water. For tests using flag-leaf wax extracts, five leaf model treatments were positioned randomly in each cage: models treated with wax extracts of Avalon glaucous or Avalon NG wax at Avalon PC (23 μg/cm^2), models treated with wax extracts of Avalon glaucous or Avalon NG wax at NG Avalon PC (13 μg/cm^2), and a hexane-treated model as a control. Ten female and two male Hessian flies were released in each cage (09:00 hr) and eggs were counted 6 hr later using a dissecting microscope. Tests using seedling wax were conducted similarly, but only three leaf model treatments were used in each cage: models treated with Avalon and NG Avalon seedling waxes at the same concentration (1.6 μg/cm^2) and a hexane-treated model as a control. This concentration was the average PC of waxes on Avalon and NG Avalon at the seedling stage, which are similar. Five female flies and two males were released per cage, and eggs were counted as described above. Cages were kept in a greenhouse at 20 $\pm$ 2°C. Each test was replicated 12 times.

Scanning Electron Microscopy. To characterize the morphology of the leaf surface waxes, scanning electron micrographs (SEM) of upper leaf surfaces of each genotype were taken at the Electron Microscopy Center, Washington State University, Pullman, Washington. In our experiments with flag-leaf-stage plants, and as previously reported for seedlings (Harris and Rose, 1989; Kanno and Harris, 2000a), the upper leaf surfaces of plants receive virtually all of the Hessian fly eggs. Samples were prepared for imaging as in Eigenbrode et al. (1998). Tissue samples of each genotype were taken from seedling and flag-leaf-stage wheat plants grown in the greenhouse. Samples (4 $\times$ 4 mm) were cut and placed on microscopy stubs and transferred into a drying chamber at -20°C. After two days, dried samples were sputter-coated with gold for nine, 10-sec intervals (for a total of 90 sec) at 10 mA. Micrographs for each genotype (glaucous and NG) and each developmental stage were taken at 15 kV at 5000$\times$ magnification.

Measuring Wax Crystal Density. SEM images of flag leaves were used to estimate the density of wax crystals on leaf surfaces of the test lines. Four replicate 100-μm^2 areas of the adaxial surfaces were randomly selected and the crystals were counted within them.

Gas Chromatography. Plant waxes were extracted from Avalon and NG Avalon at the seedling and flag-leaf stages with 20-sec hexane washes at room temperature. The relatively short duration of this extraction time was intended

to minimize extraction of internal plant constituents. To avoid extracting internal plant constituents, cut leaf ends were not immersed in the solvent during extraction. Waxes of all leaves of 20 plants within each developmental stage of each genotype were pooled. Each wax extract was analyzed underivatized and derivatized with *N*,*O*-bis(trimethylsilyl) acetamide (Sigma, St. Louis, Missouri), dissolved in hexane, and analyzed separately by gas chromatography–mass spectrometry (GC-MS). The samples were characterized by using a Hewlett-Packard (HP) 6890 GC equipped with a HP5973 quadrupole mass selective detector interfaced with HP Chemstation software. The GC-MS was equipped with an SP-1, fused silica capillary column (30 m × 0.2 mm ID) (Sigma-Aldrich) and operated in splitless mode with injector temperature at 320°C. The oven temperature program was 80°C for 1 min, 15°/min to 260°C, hold 10 min, then 5°C/min to 320°C, and hold 15 min. Identification of the components was based on mass spectra and retention times of authentic standards for some of the components (*n*-pentacosane, *n*-heptacosane, *n*-nonacosane, *n*-triacontane, and trimethyl-silyl esters and ethers of tetradecanoic acid, hexadecanoic acid, octadecanoic acid, hexacosanoic acid, *n*-docosan-1-ol, *n*-octacosan-1-ol, and *n*-triacontan-1-ol). Quantitation was based on the total ion count per peak, adjusted using response factors for standard alkanes, free fatty acids, primary alcohols, and wax esters (based on response of palmitic acid behenyl ester). Quantitation of fatty acids and alcohols was based on their TMS esters and ethers from the derivatized samples; all other components were quantified based on underivatized samples. Total wax load (micrograms per square centimeter of leaf area) was calculated based on the area of the leaves extracted for each sample. Because wax loads differed among the lines, relative composition (percentage of total load) of the wax components was calculated from the raw data. The ratio of percent composition for each component in NG Avalon and Avalon was also calculated for each component (percentage in NG Avalon to percentage in Avalon). Seedling waxes and flag-leaf waxes were analyzed in the same manner.

Morris et al. (2000) identified 1-octacosanal and MBOA as oviposition stimulants for the Hessian fly. To ensure that our methods were efficient for these known oviposition stimulants, we conducted pilot tests using our hexane extraction method (20 sec in hexane) and extraction with CH_2Cl_2 at 10°C for 60 secs (Morris et al., 2000). As another check on our methods, we included Otane seedlings (seeds courtesy of M. Harris, North Dakota State University, Fargo, ND). Otane is a widely grown wheat variety in which 1-octacosanal and MBOA were identified as oviposition stimulants for Hessian fly (Morris et al., 2000). These extracts were analyzed by GC-MS and compared.

Statistical Analysis. The numbers of eggs per female per plant for the plant bioassays and the numbers of eggs per strip for leaf model assays were compared with analysis of variance (ANOVA) using the GLM procedure in SAS (SAS Institute, Cary, North Carolina). For the Avalon seedling leaf model tests, two contrasts were conducted: (1) NG Avalon vs. Avalon and (2) wheat wax extracts vs. hexane

control. For the Avalon flag-leaf-stage leaf model tests, three contrasts were conducted: (1) NG Avalon vs. Avalon, including both high and low PCs; (2) high PC (23 μg/cm^2) vs. low PC (13 μg/cm^2), and (3) all wheat wax extracts vs. hexane control.

RESULTS

In tests with seedlings, Hessian fly females laid eggs only on wheat plants; no eggs were laid on oats. The mean number of eggs laid per female per plant was not different between NG wheat lines and the glaucous lines: Avalon lines ($F = 1.24$, $P = 0.31$), Virtue lines ($F = 1.40$, $P = 0.28$), and Brigand lines ($F = 1.41$, $P = 0.24$) (Figure 1).

In tests with flag-leaf-stage plants, Hessian fly laid more eggs per female per plant ($F = 20.31$, $P < 0.001$) and per flag leaf ($F = 10.84$, $P = 0.0026$) on NG Avalon than on Avalon, and more eggs per female per plant on NG Virtue than Virtue ($F = 7.64$, $P = 0.009$) (Figure 2). The number of eggs laid on the flag leaves of NG Virtue and Virtue did not differ ($F = 0.03$, $P = 0.859$) (Figure 2). The number of eggs laid per female per plant on NG Brigand and Brigand plants did not differ ($F = 1.29$, $P = 0.26$), but more eggs per female were laid on NG Brigand flag leaves than on Brigand flag leaves ($F = 15.77$, $P = 0.001$) (Figure 2).

The oviposition patterns by Hessian fly on paper leaf models treated with waxes from Avalon and NG Avalon were similar to those that occurred on the Avalon and NG Avalon intact plants. There were no significant differences in the number of eggs laid on leaf models treated with seedling wax extracts of NG Avalon and Avalon (Figure 3). Models treated with only hexane received fewer eggs than models treated with wax extracts ($F = 7.24$, $P = 0.002$). Models treated with NG Avalon flag-leaf wax extracts received twice as many eggs as models treated with waxes from Avalon flag-leaf wax extracts (Figure 4) ($F = 22.54$, $P < 0.001$). There was no effect of wax physiological concentration on the number of eggs laid within or across the wax extract ($F = 0.20$, $P = 0.6604$). Together, flag-leaf wax extract-treated models received more eggs than the hexane-only control ($F = 16.19$, $P < 0.001$).

Scanning electron micrographs of adaxial leaf surfaces of seedlings showed no visible differences in wax (Figure 5). Crystal densities on NG Avalon (273 ± 13) were similar to those on Avalon (286 ± 10). Crystal densities on NG Brigand (172 ± 34) were lower than those on Brigand (294 ± 25) (t test $P = 0.03$). Crystal densities on NG Virtue (299 ± 28) appeared to be higher than on Virtue (230 ± 28), but the difference was not significant ($P = 0.14$).

Waxes extracted from NG Avalon and Avalon apparently differed in chemical composition, but the differences appeared more pronounced between the flag-leaf waxes than between the seedling waxes (Table 1). Our data are from pooled samples

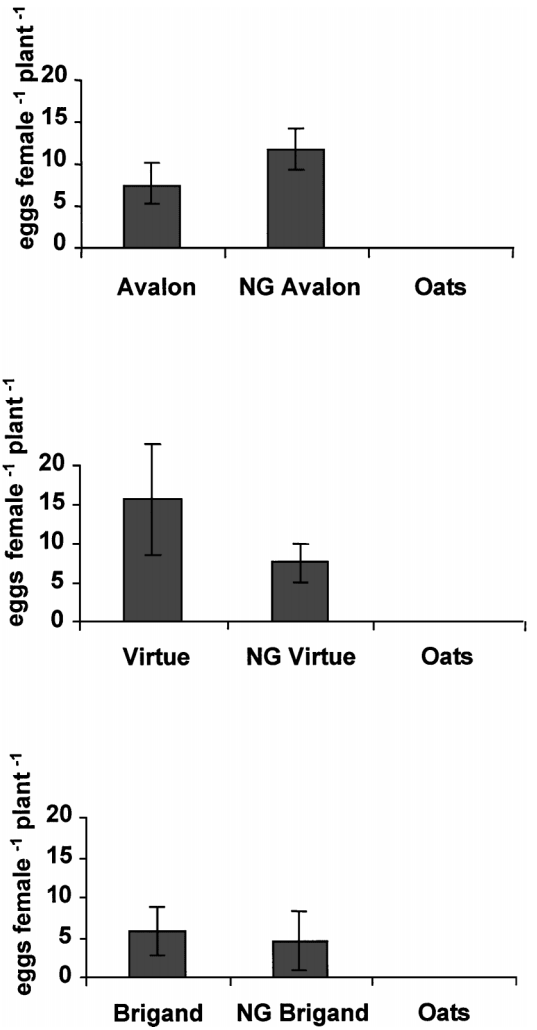

FIG. 1. Mean number of eggs laid per female Hessian fly per plant in choice tests in a greenhouse among seedling stage oats and wheat plants that vary in surface wax composition. NG = nonglaucous. Bars are standard errors of the means.

of 20 plants of each line at each developmental stage, but are not replicated, preventing statistical comparisons. Seedling waxes were dominated by hexadecanoic acid, 1-octacosanol, hentriacontane, and wax esters, but included 26 components, including six unidentified wax esters (each with a C_{28} chain length acid moiety).

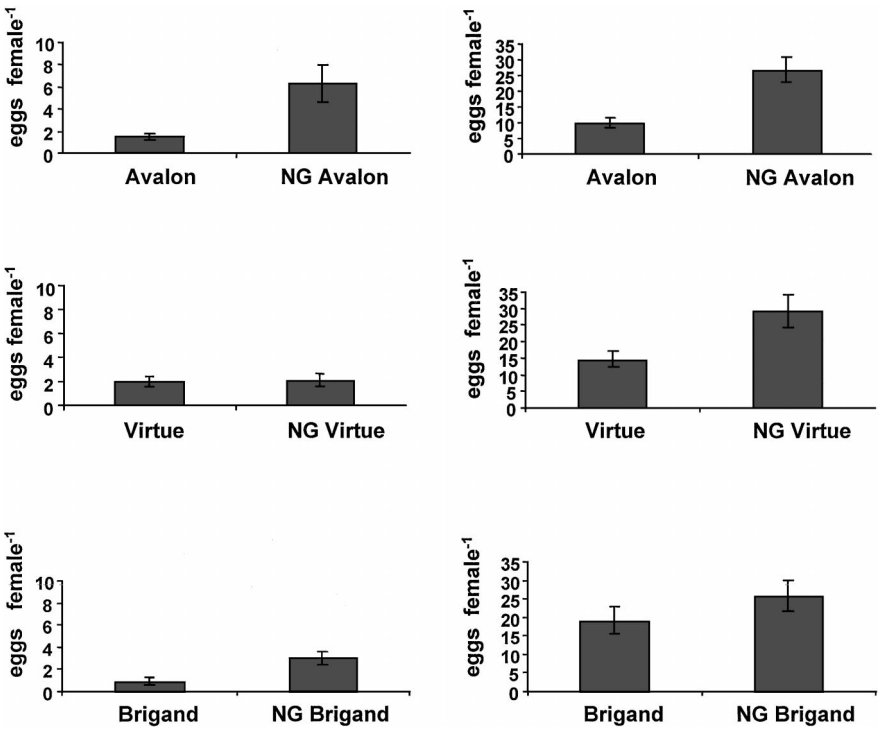

FIG. 2. Mean number of eggs laid per female Hessian fly in choice tests in a greenhouse among flag-leaf-stage wheat plants that vary in surface wax composition. Left panels show data from flag leaves of the plants; right panels show data from entire plants. Bars are standard errors of the means.

The percent compositions of all components were similar in Avalon and NG Avalon seedling waxes. The NG Avalon/Avalon ratio of percent composition for individual components ranged between 0.8 and 2.7. The largest NG Avalon/Avalon ratios were for tricosane and 3-methyl-tricosane, both of which were minor components (<1% of total wax based on GC-MS). 1-Octacosanal composition was similar in the two waxes (NG Avalon/Avalon ratio = 0.96). MBOA was detectable at trace levels in NG Avalon and Avalon seedling waxes.

Compared with seedling waxes, flag-leaf waxes had lower concentrations of free fatty acids (mean of 3.2% as compared with 21.1% on seedling waxes), detectable concentrations of β-diketones, a shift of the dominant hydrocarbon to *n*-nonacosane from *n*-hentriacontane, a nearly fivefold increase in wax esters, and a greater number of detectable components, including five to eight wax esters.

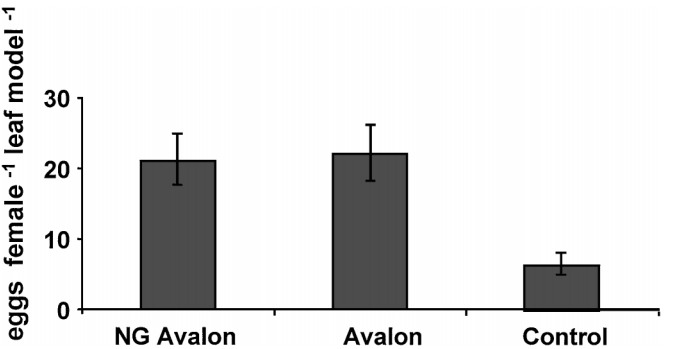

FIG. 3. Mean numbers of eggs deposited per female Hessian fly in choice tests in a greenhouse among paper leaf models treated with surface wax extracts of seedling-stage Avalon, seedling-stage NG Avalon (both at a concentration of 1.6 μg/cm^2), or hexane. Bars are standard errors of the means.

MBOA was not detected in flag-leaf waxes. The NG Avalon/Avalon ratio of percent composition for individual components ranged between 0 and 4.5. Altogether, 13 components were relatively higher and 19 components were relatively lower in NG Avalon flag-leaf waxes as compared with Avalon flag-leaf waxes. The largest ratios (>2) were for 9-octadecenoic acid (oleic acid), *n*-dodecanal, *n*-tetracosanol, and nonadecane-2,4-dione. Notably small NG Avalon/Avalon ratios (<0.05)

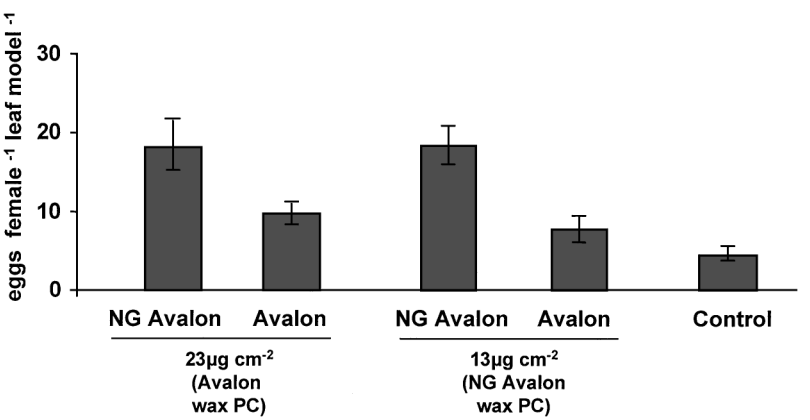

FIG. 4. Mean numbers of eggs deposited per female Hessian fly on paper leaf models treated with surface wax extracts of flag-leaf stage Avalon or flag-leaf stage NG Avalon. Treatments were NG Avalon and Avalon at the Avalon physiological concentration (23 μg/cm^2) per leaf area, NG Avalon and Avalon at the NG Avalon physiological concentration (13 μg/cm^2), and a control treated with hexane. Bars are standard errors of the means.

[b] Requires confirmation.
[c] Total load for all detected wax esters; acid moiety C_{28} for all wax esters detected; alcohol moiety variable and not always clearly determinable on the basis of mass spectra.
[d] tr = trace: concentration too low for reliable integration; identification based on detectable diagnostic ions and retention times of an authentic standard (MBOA) or of the same components present in other wax mixtures (diketones).

occurred for tritriacontane 14,16-dione, 7-hexyl 2-oxepanone, heneicosane, and 2-heptadecanone. All were minor components (<1% of total wax), except tritriacontane 14,16-dione and *n*-tetracosan-1-ol. The major component 1-octacosanol (>25% of each wax type) was 1.35-fold higher in concentration in NG Avalon than in Avalon. 1-Octacosanal content was slightly higher in Avalon flag-leaf waxes than on NG Avalon.

Seedling wax extracts of Otane were similar in composition to Avalon seedling wax extracts. However, whereas trace amounts of MBOA occurred in seedling waxes of Avalon and NG Avalon, Otane waxes contained 0.05% MBOA, regardless of the extraction method (hexane 20 sec or CH_2Cl_2 extraction at 10°C for 60 sec). Avalon and NG Avalon contained 1.49% and 1.43% 1-octacosanal, respectively (hexane extraction), or 1.43% and 1.70% 1-octacosanal, respectively (CH_2Cl_2 extraction), while Otane contained 2.42% 1-octacosanal (hexane extraction) or 2.87% 1-octacosanal (CH_2Cl_2 extraction).

DISCUSSION

This is the first report of Hessian fly oviposition responses varying among wheat lines known to have different wax composition. Three different NG variants received significantly more eggs than their glaucous wheat counterparts in dual-choice tests with plants at the flag-leaf stage. However, the same pairs of wheat lines tested at the seedling stage, before differences in glaucousness are apparent, received similar numbers of eggs. Oviposition responses to paper models treated with wax extracts of NG Avalon and Avalon mirrored oviposition responses to the intact plants; models treated with seedling wax extracts of the two lines received similar numbers of eggs, whereas models treated with flag-leaf wax extracts of NG Avalon received significantly more eggs than models treated with flag-leaf wax extracts of Avalon. These results confirm our hypothesis that wax variation in wheat influences Hessian fly oviposition and indicate that wax composition contributes to Hessian fly oviposition responses to the intact plants.

The differences in composition of NG Avalon and Avalon flag-leaf waxes as detected by GC-MS (Table 1) may help explain the greater numbers of eggs laid by Hessian flies on intact plants and models treated with flag-leaf waxes from NG Avalon. We did not carry out statistical comparisons of components. However, candidate components affecting oviposition include those apparently differing in relative percentage in Avalon and NG Avalon flag-leaf waxes. Thirteen components are present in higher concentrations in NG Avalon flag-leaf waxes (NG Avalon/Avalon ratio >1.05, Table 1) and are potential stimulants. Nineteen components are present in higher concentrations in Avalon waxes (NG Avalon/Avalon ratio <0.95) and are potential deterrents. Actual activities of these components are unknown. Other components not detected by GC-MS could also determine

Hessian fly oviposition response to the waxes. Fractionations coupled with additional bioassays are required to identify the active components.

Our study was influenced by prior work showing that Hessian fly oviposition is stimulated by extracted surfaces waxes of wheat seedlings (Harris and Rose, 1989, 1990; Foster and Harris, 1992), culminating most recently in identification of 1-octacosanal and MBOA as oviposition stimulants for the fly (Morris et al., 2000). We thought it possible that differences in the concentrations of these known stimulants would help explain fly responses to NG and glaucous Avalon wheats. 1-Octacosanal and MBOA were present in seedling waxes of Avalon wheats (Table 1), but at concentrations lower than those that occur in Otane wheat from which they were identified as stimulants (Morris et al., 2000; B. Morris, personal communication). Avalon and NG Avalon seedling waxes contained only a trace of MBOA, as compared with 0.05% in Otane seedling waxes. NG Avalon and Avalon seedling waxes contain similar amounts of the oviposition stimulant 1-octacosanal (Table 1), which may be consistent with the similar rates of oviposition on leaf models impregnated with these waxes. MBOA was not detected in Avalon or NG Avalon flag-leaf wax extracts, and 1-octacosanal was present in apparently higher concentrations in the less stimulating extracts of Avalon flag-leaf waxes than in the more stimulating extracts of NG Avalon flag-leaf waxes (Table 1). Therefore, our data indicate MBOA and 1-octacosanal apparently do not explain the different responses by an Idaho population of Hessian fly to NG Avalon and Avalon.

Morris et al. (2000) tested the behavioral activity of long-chain aldehydes other than 1-octacosanal (chain lengths between C_{22} and C_{29}) and reported that all stimulated oviposition by the Hessian fly more than a solvent control and that this activity was greatest for a chain length of 26 carbons. However, Avalon waxes apparently contain a slightly higher percentage of the C_{26} aldehyde than NG Avalon waxes (NG Avalon/Avalon ratio = 0.9, Table 1). The only *n*-alkanal in higher concentrations in NG Avalon waxes is *n*-dodecanal (C_{12}) (NG Avalon/Avalon ratio = 3.36). Morris et al. (2000) did not test *n*-dodecanal. Even if all aldehydes are presumed active, the total concentration of this class does not apparently differ between NG Avalon and Avalon flag-leaf waxes (1.48% on NG Avalon vs. 1.43% on Avalon). Moreover, if the small difference detected is real, it converts to 0.015 $\mu g/cm^2$ on our leaf model bioassay, well below the threshold (0.6 $\mu g/cm^2$) for oviposition response by the Hessian fly to pure 1-octacosanal bioassayed on paper models [threshold calculated from data presented in Morris et al. (2000)]. Thus, differences in *n*-alkanals do not appear to be sufficient to account for the observed greater oviposition on models treated with NG Avalon flag-leaf waxes as compared with Avalon flag-leaf waxes.

It is probable that the Hessian fly responds to mixtures of wax components during host selection. The host range of the flies includes several grasses other than wheat (Harris et al., 1996). Neither the candidate stimulants elevated in NG Avalon nor 1-octacosanal are unique to grasses (Walton, 1990). MBOA and other

benzoxazolinone derivatives also probably occur in waxes of various grasses; one benzoxazolinone derivative has been reported in waxes of corn (Hedin et al., 1993). Indeed, the Hessian fly oviposits on several other grasses, and some triticales stimulate more oviposition than Otane (Harris et al., 1996). Thus, host recognition by the fly cannot be based on presence or absence of these wax components alone. Rather, a combination of components must contribute, as is suggested by the report of Foster and Harris (1992) that combinations of fractions of wheat waxes applied to paper models synergistically stimulate Hessian fly oviposition.

The inconsistencies between our results and those of Morris et al. (2000) do not challenge the validity of their results. First, our conclusions are based on associations between behavior and wax composition, whereas Morris et al. (2000) used bioassay-guided fractionation to identify stimulants for the fly. Second, the concentrations of aldehydes and MBOA in Avalon waxes are lower than Otane waxes, possibly below threshold concentrations for oviposition activity. Third, Morris et al. (2000) used Hessian flies from New Zealand, whereas we used flies from Idaho, and the two populations may differ in their responses to wax constituents. Our results do show that the flies we tested are stimulated to oviposit by wheat wax components other than MBOA and 1-octacosanal.

Morphological attributes of the leaf surface are important stimulants for Hessian fly oviposition (Kanno and Harris, 2000b), and leaf wax structure has been shown to influence oviposition or feeding preference of other herbivores (Uematsu and Sakanoshita, 1989; Bodnaryk, 1992). However, we did not find evidence that wax morphology affected Hessian fly oviposition on our test lines. Seedling waxes did not differ in wax crystal structure and received similar numbers of eggs, and differences in crystal structure between glaucous and nonglaucous lines we tested were inconsistent. NG flag-leaf-stage plants received more eggs in bioassays, but did not differ consistently in crystal density. NG Avalon and NG Brigand had similar crystal densities to their glaucous counterparts, and NG Virtue flag-leaf waxes have greater crystal densities than glaucous types. It is possible that other physical attributes of the waxes that we did not measure influence fly oviposition. Nonetheless, because crystal structure is eliminated in the process of applying extracts to paper models, we can conclude that wax composition alone is an important component in host recognition by the fly and is capable of eliciting responses qualitatively similar to responses to intact plants (Figures 2–5).

Our results raise the possibility of manipulating wheat surface waxes genetically to reduce Hessian fly oviposition. However, the NG lines we examined only elicited reduced Hessian fly oviposition at the flag-leaf stage and not at the economically important seedling stage. If the functional wax characteristics can be discovered, suitable variation in seedling waxes could be sought by screening seedling waxes. In addition, wax production is developmentally regulated as evidenced by the distinct wax types of juvenile and mature wheat (Tulloch and Hoffman, 1973; Bianchi and Corbellini, 1977) (Table 1) and other grasses (Atkin and Hamilton,

1982; Blaker and Greyson, 1988). Surface wax variation in plants appears to depend to a considerable extent on regulatory genes as well as biosynthetic genes (Post-Beittenmiller, 1996; Jenks and Ashworth, 1999). Eventual manipulation of the regulatory genes for wax synthesis in wheat could allow wax variation that influences Hessian fly oviposition on flag leaves to be expressed in the seedling stage in order to influence fly oviposition preferences.

(Received March 6, 2001; accepted September 9, 2001)

Abstract—We determined variation in both the concentration and composition of terpenoids in needles and wood within nine Scots pine (*Pinus sylvestris*) provenances. Seedlings of different provenances representing a 1200-km N–S transect from Estonia to northern Finland were cultivated in Suonenjoki nursery field, central Finland, for seven years. Growth of seedlings and the number of vertical resin ducts in wood were also determined. α-Pinene and 3-carene were the major monoterpenes both in the needles and wood. The total monoterpene concentration was about five times higher in the needles than in the wood. A strong positive correlation was found between proportional quantities of several terpenes of the needles and wood, particularly for 3-carene, sabinene, and terpinolene. The needles contained both labdane-type and tricyclic resin acids, whereas the wood contained only tricyclic ones. The wood had a four times higher tricyclic resin acid concentration than the needles. The highest total monoterpene concentration in the needles and in the wood occurred in the most northern Muonio provenance and in the most southern Saaremaa provenance plants, respectively. The amount of high 3-carene genotype trees decreased among the northern provenances. The wood of the most northern Muonio provenance showed the lowest total resin acid concentration, but provenance did not affect total tricyclic resin acids in the needles. Korpilahti provenance trees from central Finland had the best growth in height. In addition, Korpilahti and Ruokolahti provenance trees showed largest radial growth of stem and smallest number of vertical resin ducts.

*To whom correspondence should be addressed.

0098-0331/02/0100-0211/0 © 2002 Plenum Publishing Corporation

The results suggest that especially the proportional quantity of 3-carene in the needles could be used in estimating the amount of this compound in the wood and vice versa.

Key Words—Terpenes, resin acids, wood, needles, provenance, *Pinus sylvestris*.

INTRODUCTION

Conifers have constitutive and inducible terpenoid-based defense mechanisms that deter insect herbivores and protect against pathogens. The epithelium cells of resin ducts secrete oleoresin, which consists of volatile (mono- and sesquiterpenes) and nonvolatile (resin acids) terpenoids. Terpenoids in needles and wood have an impact on herbivore performance (Leather, 1987; Gershenzon and Croteau, 1991; Manninen, 1999). In Scots pine needles, resin acids are known deterrents of *Schizolachnus pineti* (Homoptera: Lachnidae) (Kainulainen et al., 1996; Manninen et al., 1998b) and *Lygus rugulipennis* (Heteroptera: Miridae) (Manninen et al., 1998a), and also affect the host plant selection of *Neodiprion sertifer* (Hymenoptera: Diprionidae) (Larsson et al., 1986; Saikkonen et al., 1995; Manninen et al., 2000). If the cortical tissue of conifers is wounded, preexisting and induced resin form a physical barrier to seal the wound. Consequently, the concentrations of resin acids in cortical and woody tissues increase near the wound (Gref and Ericsson, 1985; Walter et al., 1989). Oleoresin compounds are an important resistance mechanism against stem-boring bark beetles and fungi associated with them (Bridges, 1987; Paine and Hanlon, 1994; Phillips and Croteau, 1999). Insect attack also induces monoterpene production in wood oleoresin (Valterová et al., 1995) and in phloem (Klepzig et al., 1996).

There is a great variation in the anatomy of oleoresin-producing structures in conifers. These structures range from the most simple isolated resin cells, typical for cedars (*Thuja* sp.), to multicellular resin blisters of true firs (*Abies* sp.), and finally to highly developed resin duct systems of pines (*Pinus*) (Lewinsohn et al., 1991; Phillips and Croteau, 1999). The resin ducts of Scots pine are located in the intercellular space of needle, bark, wood, and root tissues and are surrounded by oleoresin-secreting epithelium cells. In the wood, resin ducts run vertically, mainly among the tracheids of latewood and horizontally in the rays, these being also connected with each other (Wilson and White, 1986). The needles have only lateral resin ducts, and their number and distribution are variable (Esau, 1977).

The composition of oleoresin compounds is genetically controlled (Hiltunen et al., 1975; Gref, 1987; Baradat and Yazdani, 1988), but environmental factors (i.e., light, water, and nutrients) can affect the terpenoid concentrations of conifer needles (e.g., Gleizes et al., 1980; Gref and Tenow, 1987; McCullough and Kulman, 1991; Kainulainen et al., 1996). Terpenoid concentrations may vary among organs of a tree (Gershenzon and Croteau, 1991), between the same organs of individual

trees (Hiltunen et al., 1975; Gref, 1987), and between geographical location and different provenance of trees (Juvonen and Hiltunen, 1972; Muona et al., 1986; Nerg et al., 1994; Tognetti et al., 1997; Manninen et al., 1998b). Furthermore, the relative amount of the different compounds in the oleoresin varies considerably among different tissues of the same tree (Hrutfiord et al., 1974). Studies related to the chemical composition of needle and wood oleoresin within the same pine individuals are rare (Sjödin et al., 1996, 2000; Kleinhentz et al., 1999; Latta et al., 2000). The concentration and composition of oleoresin compounds in the wood has not been intensively studied either (Cown et al., 1992; Coppen et al., 1993).

Earlier, we studied the variation in chemical defense of different Scots pine provenances and whether such variation is related to the performance of insect herbivores damaging needles (Manninen et al., 1998b). The possible connection of wood terpenoids to old house borer (*Hylotrupes bajulus* L.) resistance will also be determined using Scots pine wood blocks originating from the same provenances. It would be a great advantage, if the resistance of Scots pine wood against wood-boring insects could be evaluated by analyzing terpenoid concentration and/or composition in the needles of the same pine individuals. Therefore, the present study aims at: (1) determining the concentration and composition both of needle and wood terpenoids in Scots pine seedlings, (2) finding out whether there is a relation between the concentration and/or composition of terpenoids in needles and wood, (3) determining differences in needle and wood terpenoid content among different provenances growing along a 1200-km north–south transect from Estonia to Finland, and (4) studying the relationships among the concentration of terpenoids, growth parameters, and the number of vertical resin ducts in the wood.

METHODS AND MATERIALS

Growth Conditions. In open pollinated stands of Scots pine (*Pinus sylvestris* L.), seeds were collected from seven geographical locations in Finland and two in Estonia along a 1200-km north–south transect. In the study, a total of nine provenances were used originating from Muonio (MUO) (North latitude 67°56′), Ylitornio (YLI) (66°20′ N), and Suomussalmi (SUO) (65°10′ N) in the north, from Kinnula (KIN) (63°32′ N), Korpilahti (KOR) (62°0′ N), and Ruokolahti (RUO) (61°26′ N) in central Finland, and from Tenhola (TEN) (60°3′ N), Rakvere (RAK) (59°18′ N), and Saaremaa (SAA) (58°22′ N) in the south. The seeds were sown in seedling beds containing peat as a growing medium at the Finnish Forest Research Institute at Suonenjoki Research Station in spring 1991. Plants were fertilized (Puutarhan Y-1 fertilizer, 10:7:14, N:P:K, Kemira) twice a season (120 kg/ha and 80 kg/ha) until spring 1993. In May 1993, 1000 seedlings from each of the nine provenances were planted at Suonenjoki Research Station in the nursery field and randomly divided into five replicate blocks. Every block contained 200 seedlings

representing one provenance. The seedlings were planted in four adjacent lines (50 seedlings in each line and distance between the lines was 0.8 m). The area of each block was 1000 m^2, and the area of the whole research field was 0.5 ha. The growing medium was sandy soil containing 1–3% of added peat.

Sampling. In October 1998, 15 randomly selected 7-year-old trees from each provenance (three trees from each block) were cut. The heights of trees including the five latest annual growths were measured. For chemical analysis, current-year needles from the middle of a lateral branch of the uppermost whorl were collected. From the main stem of the fourth annual growth, disks about 5 mm thick were cut for chemical analyses, for vertical stem area, and resin duct number measurements. The samples were stored in a cooling bag during sampling. The chemical samples were then stored in a deep-freezer (-80°C). The samples for microscopy were stored in a freezer (-20°C) until preparation and analysis. For chemical analyses, the whole stem disk without bark was used forming one sample.

Chemical Analyses. For terpene analysis, frozen needles and stem disks were cut into small pieces and extracted at room temperature with *n*-hexane for 1 hr. The hexane was filtered into screw-cap tubes, and the residue washed two times with *n*-hexane and filtered. The filtrates were pooled into one sample. 1-Chlorooctane was used as an internal standard. Resin acids were extracted from freeze-dried needles and stem disks using the method described by Gref and Ericsson (1985). Heptadecanoic acid was used as an internal standard. Terpene and resin acid samples were analyzed by gas chromatography–mass spectrometry (Hewlett Packard GC-type 6890, MSD type 5973) using a 30-m-long HP-5MS capillary column (ID 0.25 mm, film thickness 0.25 μm, Hewlett Packard). Helium was used as a carrier gas. The temperature program for terpenes was from 50°C to 250°C and for resin acids from 50°C to 270°C. The heating rate was 5°C/min. SCAN technique (mass numbers from m/z 30 to 350 were recorded; signal ions in monitoring; 93, 133, 136, 161, 204 m/z) was used for terpene samples, and the technique of selected ion monitoring (SIM) (299, 301, 314, 316 m/z) for resin acid samples. Only tricyclic resin acids were quantified. For identifying other possible resin acids in extracts, the SCAN technique was used in separate runs. Individual terpenes and resin acids were identified by their mass spectra and retention times. They were quantified by means of peak areas by using pure standards for calibration. The response factor for each compound was determined in relation to the known amount of internal standard. Korpilahti provenance trees were selected in order to compare the composition of mono- and sesquiterpenes between needles and stem disks. Some of these compounds were identified using available pure compounds. When pure compound was not available, identification was based on comparison of mass spectra with Wiley Library and Kovats retention indices (Davies, 1990; Elias et al., 1997). The proportional quantity of different compounds was calculated on the basis of the peak areas.

Growth Measurements and Vertical Resin Ducts. A stem cross-section area was measured in the fourth annual shoot of the trees. The stem disk without bark was scanned and the cross-sectional area was analyzed with an image analysis software (NIH IMAGE/Scion IMAGE). For light microscopic study, wood samples (1×1 cm) were cut from each stem disk and softened in boiling water for 1 hr. Wet samples were deep-frozen and sections approximately 16 μm thick were cut with a cryomicrotome. The sections were mounted on slides and stained with a mixture of safranin and Alcian blue (1:2). The number of vertical resin ducts in the radial wood was assessed with a light microscope (Zeiss) and the image analysis software (NIH IMAGE). The resin ducts were counted from two to three samples (image area approx. 2.37×1.77 mm^2) selected within the third and second growth rings of each cross section. Means per tree were used in statistical analyses.

Statistical Analyses. The data were analyzed with one-way analyses of variance (ANOVA), and the means were separated with the Tukey B procedure. An arc-sin transformation was used for percentage data, and some variables were $\log(n + 1)$ transformed to stabilize the variances before statistical analyses. Correlations were determined by using nonparametric Spearman correlation. All analyses were done with the SPSS statistical software package.

RESULTS

Comparison of Needle and Wood Chemical Composition. α-Pinene and 3-carene were the major monoterpenes, both in the needles and the wood (Table 1). They constituted about 67% of total monoterpenes in the needles and 74% in the wood. The wood showed lower quantities of tricyclene, camphene, and bornylacetate than the needles, while sabinene, limonene + β-phellandrene, and terpinolene were more abundant in the wood than in the needles (Table 1). The total monoterpene concentration was about five times higher in the needles than in the wood (Figure 1). Detailed terpene analyses of Korpilahti provenance trees showed that almost all identified monoterpenes were found both in the needles and wood (Table 2). *trans*-Ocimene and borneol were detected in the needles only. Overall, the number of sesquiterpenes was higher in the needles than in the wood (Table 2). The main sesquiterpene in the needles and wood was germacrene D. The other dominating sesquiterpenes were β-caryophyllene and α-muurolene in the wood, and germacrene B in the needles (Table 2).

A strong positive correlation was found between the proportional quantity of all terpenes, except myrcene, in needles and in wood (Table 3). If the proportional quantity of 3-carene in the needles or wood was high, the proportional quantities of sabinene and terpinolene were simultaneously high (Table 1). The concentrations of individual monoterpenes in the needles also positively correlated with corresponding wood values, but this relationship was weaker than observed with

[a] SAA = Saaremaa, RAK = Rakvere, TEN = Tenhola, RUO = Ruokolahti, KOR = Korpilahti, KIN = Kinnula, SUO = Suomussalmi, YLI = Ylitornio, MUO = Muonio ($N = 15$). *F* (variance ratio) and *P* (significance) values from one-way analysis of variance are included. The provenances are ordered according the geographical distribution.

[b] Limonene and β-phellandrene were not separated from each other on HP-5MS column.

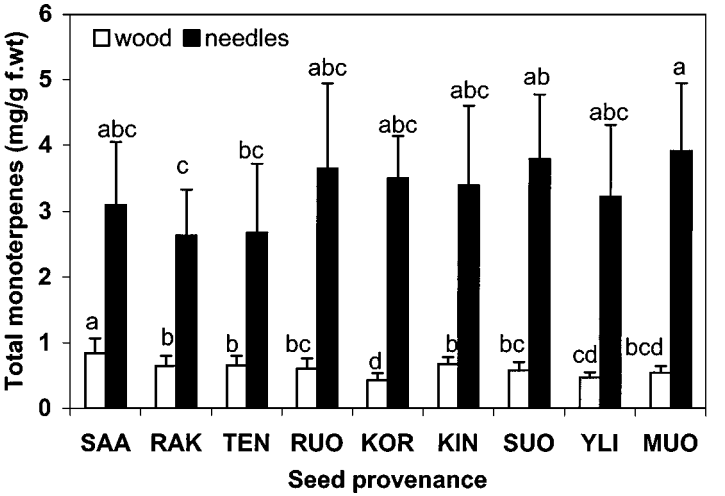

FIG. 1. Total monoterpene concentration (+SD) in wood and needles of Scots pine from nine different provenances growing in Suonenjoki nursery garden. Means followed by different letters are significantly different according to Tukey B procedure. Provenance names as described in Table 1. $N = 15$.

the proportional quantities (Table 3). No correlation was found between the total monoterpene concentration in needles and wood.

Pinifolic acid was the main resin acid in the needles of almost all trees, and isoabienol appeared to be the other main resin acid in the needles of several trees in each provenance (data not shown). Manoyl oxide acid occurred as the main resin acid in the needles of six pine individuals (two trees from SAA, three trees from RAK, and one from RUO) (data not shown). These above-mentioned labdane-type compounds were not found in the wood at all. Tricyclic resin acids, palustric + levopimaric and abietic acid, constituted about 80% of total resin acids in the wood (Table 4). The other tricyclic resin acids were found only in low quantities. The main tricyclic resin acids in the needles, palustric + levopimaric, dehydroabietic, abietic, and neoabietic acids, constituted about 75% of total tricyclic resin acids (Table 4). The total tricyclic resin acid concentration was four times higher in the wood than in the needles (Figure 2). The proportional quantities of different resin acids in the needles were only weakly related to the corresponding wood values, while no relationship was found between the resin acid concentrations of these different conifer tissues (Table 3).

Effects of Provenance on Needle and Wood Chemical Composition. The total monoterpene concentration in the needles or wood was highest in the northernmost MUO provenance and in the southernmost SAA provenance trees, respectively (Figure 1). In the needles, α-pinene concentration was lowest in TEN and

highest in MUO provenance trees, but its proportional quantity was similar in all provenances (Table 1). Although α-pinene concentration in the wood was at the same level in all nine provenances, its proportional quantity was higher in the MUO provenance trees compared to the SAA trees (Table 1). Actually, the proportional quantity of α-pinene in wood showed a clear increasing latitudinal gradient from south to north (Figure 3). The proportional quantity of 3-carene, both in needles and wood, was higher in SAA trees than in the northern MUO and YLI trees (Table 1), and in the case of wood samples, a clear decreasing latitudinal gradient from south to north was found (Figure 3). All trees from southern SAA and TEN provenances were high 3-carene ($\geq$10%) genotypes, and this genotype was rare among the northern provenance trees (Figure 4). Both the concentration and proportional quantity of limonene + β-phellandrene in wood (Table 1) were highest in the northern and central provenance trees, but terpinolene appeared to be more common in the southern provenance trees (Table 1). The quantity of camphene was higher in MUO than in SAA provenance trees.

The needles of trees from various Scots pine provenances contained a similar amount of total tricyclic resin acids (Figure 2). Abietic, levopimaric + palustric,

[a] SAA = Saaremaa, RAK = Rakvere, TEN = Tenhola, RUO = Ruokolahti, KOR = Korpilahti, KIN = Kinnula, SUO = Suomussalmi, YLI = Ylitornio, MUO = Muonio ($N = 15$). *F* (variance ratio) and *P* (significance) values from one-way analysis of variance are included. The provenances are ordered according the geographical distribution.

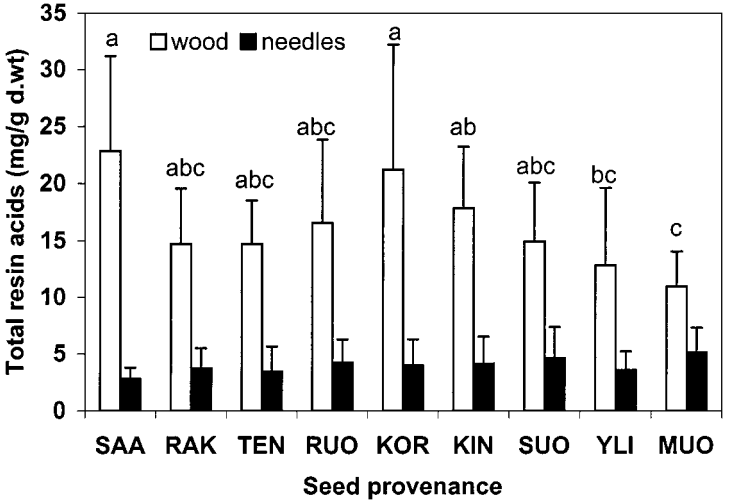

FIG. 2. Total resin acid concentration (+SD) in wood and needles of Scots pine from nine different provenances growing in Suonenjoki nursery garden. Means followed by different letters are significantly different according to Tukey B procedure. Provenance names as described in Table 1. $N = 15$.

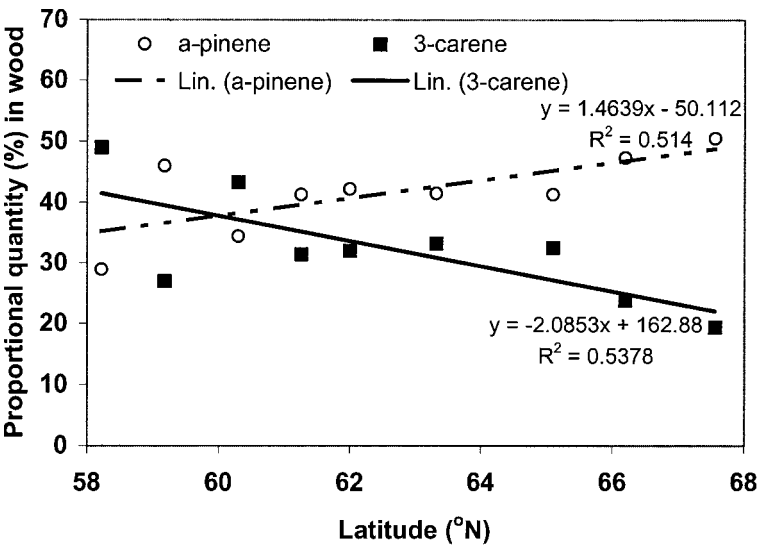

FIG. 3. Mean proportional quantity of α-pinene and 3-carene in Scots pine wood as a latitudinal gradient. Symbols represent results of different provenances at different latitudes. Linear relationship between the latitude and the proportional quantity of each compound is given.

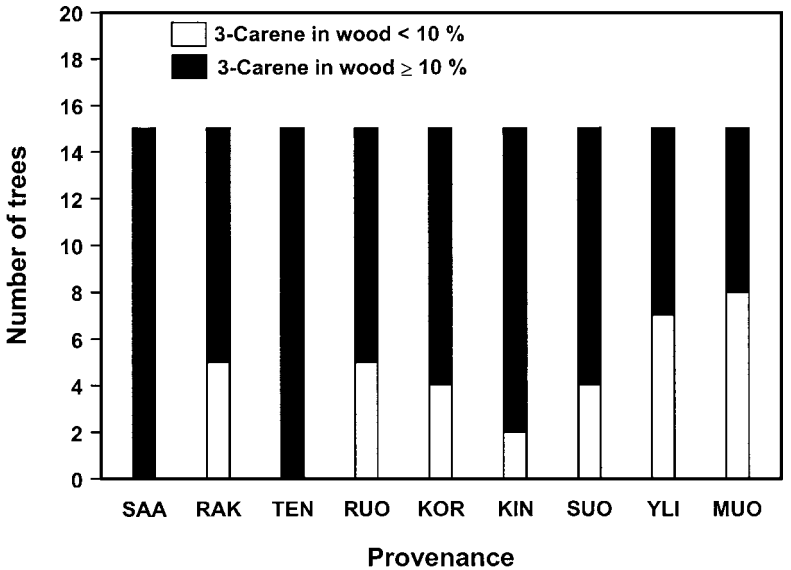

FIG. 4. The number of Scots pine trees with a low 3-carene proportion in wood (open part of bar) or with a high 3-carene proportion in wood (solid part of bar) in Scots pine from nine different provenances growing in Suonenjoki nursery garden. Provenance names as described in Table 1.

and neoabietic acid concentrations were lower in YLI provenance trees than in the other northern provenance trees. In contrast, the wood of MUO provenance trees showed significantly lower total resin acid concentration than the wood of SAA and KOR provenance trees (Figure 2). All individual resin acid concentrations in the wood, except isopimaric acid, were significantly affected by provenance. The trees from the southernmost SAA provenance and from central KOR provenance showed the highest abietic and levopimaric + palustric acid concentrations. The proportional quantities of different resin acids in the needles were similar in all the provenances (Table 4). In the wood, however, the proportional quantity of abietic acid was significantly higher in KIN and SUO provenance trees than in MUO provenance trees (Table 4).

Growth Measurements and Resin Ducts. The trees from KOR provenance showed the best growth in height of all provenances (data not shown), being significantly taller than trees from SAA, RAK, KIN, and YLI provenances. Pine trees originating from SAA had the smallest radial growth of stem. RUO and KOR trees had the best radial growth, but fewer vertical resin ducts per 1 mm^2 wood than pines from KIN provenance. The total monoterpene concentration in the wood positively correlated with the vertical resin duct number ($r = 0.188$, $P < 0.05$, $N = 132$) and negatively with the radial growth of stem ($r = -0.395$, $P < 0.001$,

$N = 132$). Tricyclic resin acid concentration in the wood did not correlate with the vertical resin duct number or with the radial growth of stem.

DISCUSSION

Needle and Wood Chemical Composition. Monoterpene composition in Scots pine needles and wood appeared to be fairly analogous, α-pinene and 3-carene being the major monoterpenes in both tissues. The monoterpene composition of needles was in accordance with many earlier Scots pine studies (Hiltunen et al., 1975; Chalchat et al., 1985; Muona et al., 1986; Sjödin et al., 1996). The monoterpene composition of wood has not been thoroughly studied so far, and comparisons between monoterpene compositions in needles and wood of Scots pine are rare (Sjödin et al., 1993, 1996, 2000). The proportional quantity of 3-carene in wood and in needles within same pine individuals was similar, which coincides with the findings of Sjödin et al. (1996). Thus, the present results suggest that needle analysis might be used to estimate the proportional quantity of 3-carene in the wood of Scots pine and vice versa. According to a correlation analyses, sabinene and terpinolene could also be used for this purpose. However, Latta et al. (2000) concluded that a high error is associated in that kind of prediction. In their study with Ponderosa pine, needles were the most variable tissue in monoterpene composition, and needle monoterpene composition weakly correlated with the composition of other tissues.

Proportional quantities of 3-carene, sabinene, and terpinolene were simultaneously high in both analyzed tissues. Similar results have been found earlier in cortical oleoresin studies (Yazdani et al., 1982; Baradat and Yazdani, 1988) leading to the suggestion that these three monoterpenes are formed by a common biosynthetic pathway. The low quantity of camphene in the wood agrees with the study of Sjödin et al. (1993). In low 3-carene trees ($<10\%$), α-pinene and limonene made up to 85% of total wood monoterpenes. This finding is also consistent with the earlier study of Sjödin et al. (1993).

Resin acid composition and concentration in Scots pine needles and wood were quite different, suggesting different biosynthetic mechanisms in the two tissues. Labdane-type pinifolic acid represented the major resin acid in most needle samples, and this is consistent with earlier studies (Gref and Tenow, 1987; Andersson et al., 1990; Danell et al., 1990). Another labdane-type resin acid, manoyl oxide acid, was infrequent in the needles [detected earlier with Scots pine trees growing in Scandinavia (Andersson et al., 1990) and elsewhere (Tobolski and Zinkel, 1982)]. In earlier studies, Scots pine seedlings originating from central Finland had abietic acid as the main tricyclic resin acid in the shoots (Manninen et al., 1998a) and needles (Kainulainen et al., 1996). In the present study, the same result was found with needles originating from KOR and KIN provenances.

In contrast, wood in the present study and Scots pine bark in the earlier studies (Tobolski and Zinkel, 1982; Gref and Ericsson, 1985) contained only tricyclic resin acids. Palustric + levopimaric acid made up to 35% of total resin acids in our study, which agrees with an earlier Scots pine study (Bridgen and Hanover, 1982). No strong correlation was detected between the proportional quantities of resin acids in needles and wood. Thus, it could be assumed that the resin acid composition of needles is not necessarily a good tool for estimating the corresponding composition in wood.

Effects of Provenance. Because all Scots pine seedlings were growing under similar environmental conditions in the Suonenjoki nursery, the observed differences in the needle and wood monoterpenes between provenances may mainly be due to genetical variation. Undisturbed growth of over five years in the nursery garden ensures that the effect of planting on terpenoids was minimized (Sallas et al., 1999). The variation of needle monoterpenes in Scots pines collected from different geographical locations in Finland has been evident in previous studies (Hiltunen et al., 1975; Muona et al., 1986). Individual trees in the present study could be characterized as high 3-carene trees ($\geq$10%) or low 3-carene trees ($<$10%) based on the limits set for needles (Hiltunen et al., 1975; Muona et al., 1986). The number of high 3-carene trees was smaller among the northern provenances than in southern ones. A similar north–south gradient of high 3-carene trees was found earlier with Scots pines growing in different parts of Finland (Hiltunen et al., 1975; Muona et al., 1986). Genetic isolation of the SAA and TEN provenances could explain why all trees from them were high 3-carene trees.

In the present study, the proportion of α-pinene in needles did not increase towards northern provenances, while shoots of the same provenances (Nerg et al., 1994) showed an increase. Higher total monoterpene concentration in the southern and coastal provenance trees than in the other provenance trees originating from more inland areas may indicate that the southern provenances represent a geographically isolated area. Geographical isolation of insular populations was also suggested to explain the distinctive low β-pinene concentrations in *Pinus nigra* in Western Europe (Rafii et al., 1996).

Muona et al. (1986) found that the proportional quantity of camphene in needles within the low 3-carene group in the natural stands was higher in northern Finland than in southern Finland. In our study, a similar trend was found in the wood samples only. In Sweden, in the most northern Scots pine populations, the majority of trees contained a high proportion of limonene in the cortex, while in southern populations a high proportion of sabinene was found (Yazdani and Nilsson, 1986). A similar north–south trend in the present wood results was found with limonene. Terpinolene in wood, together with 3-carene, had the highest concentrations in southern populations, suggesting that wood monoterpene composition is genetically controlled.

The total tricyclic resin acid concentration and the proportional quantities of individual tricyclic resin acids in Scots pine needles were independent of the provenance. This was also shown for shoots of the same pine provenances (Nerg et al., 1994). However, variations in resin acid composition in the needles and in the cortex between Scots pine provenances have been reported earlier (Tobolski and Zinkel, 1982). In our study, only the isopimaric acid concentration in needles was affected by provenance, consistent with the results of Hansson and Gref (1987). In contrast, wood resin acids showed more variation among provenances than resin acids in the needles. Thus, low resin acid concentration in the most northern MUO provenance may be genetically determined. Overall, among Scots pine varieties, Scandinavian ones had the highest total resin acid concentration in wood compared to other regions in Europe (Bridgen and Hanover, 1982).

The best growth of KOR provenance seedlings in the Suonenjoki location could be partly explained by the geographical proximity of the locations. In our long-term observations, trees from provenances closest to Suonenjoki, i.e., KIN, KOR, and RUO, have shown the best growth in Suonenjoki (Martti Vuorinen, personal communication). The differences in growth conditions, e.g., highest effective temperature sum in the original area of SAA provenance (Nerg et al., 1994), and differences in genetic factors may provide explanations for the smallest radial growth of stems originating from coastal SAA provenance. Although frost hardening is initiated according to the intrinsic attributes of genotypes, all provenances become hardy enough to tolerate the winter conditions in Suonenjoki (Repo et al., 2000).

The small number of vertical resin ducts in stems of KOR provenance may be associated with the fast growth of trees, when the same amount of resin ducts distributes over a larger area. This was also suggested by Blanche et al. (1992) with *Pinus taeda*. Another explanation for this finding may be the competition of resources between growth and differentiation (i.e., production of secondary metabolites) (Herms and Mattson, 1992). However, Bridgen and Hanover (1982) found no genetic variation in the resin duct density of Scots pines. In our study, monoterpene concentration in wood negatively correlated with radial growth of stem, but in maritime pine, the tree diameter showed no relation to the proportional quantity of different terpenes in wood (Kleinhentz et al., 1999). Wood resin acids did not correlate with the vertical resin duct density or growth of trees in our study, but resin flow of loblolly pine positively correlated with vertical duct density (Blanche et al., 1992). In addition, wood resin acids did not correlate with resin duct area in the study of Bridgen and Hanover (1982). However, Saikkonen et al. (1995) found a positive correlation between the total resin acid concentration and the proportional resin duct area of the needles. This could mean that resin acids in the wood are also located elsewhere than only in resin ducts. Horizontal resin ducts in wood were not analyzed in this study.

In conclusion, Scots pine needles and wood exhibit similar monoterpene composition. The proportion of 3-carene in needles especially may serve as an estimator for the 3-carene content in wood tissue and vice versa. Resin acid composition in the needles and wood is different, and resin acid concentration in the wood is much higher than in the needles. Needles are exposed more directly to, e.g., insect herbivores than wood and, thus, they may be constrained to produce a higher concentration of volatile monoterpenes than wood. Cortex and the cortical volatile oleoresin compounds are already a chemical barrier against external irritants threatening the wood. The effect of geographical provenance on needle and wood terpenoids is evident. Vertical resin duct numbers showed slight correlation with total monoterpene concentration in wood. Thus, the number of vertical resin ducts might not be useful tool to estimate the amount of oleoresin in wood tissue.

(Received June 29, 2000; accepted September 6, 2001)

Abstract—Allelopathy in rice (*Oryza sativa*, L.) effective against weeds has been found in about 3.5% of tested rice germplasm in both laboratory and field experimentation. However, the allelochemicals responsible for growth inhibition of rice-associated weeds have not yet been identified. In the literature, phenolic acids are often mentioned as putative allelochemicals. If phenolic acids commonly reach growth inhibitory concentrations in rice ecosystems, it must be expected that the degree of tolerance to phenolic acids will vary among traditional rice cultivars or plant species adapted to rice environments having inherently different phenolic acid concentrations. Phenolic acids concentrations are normally greater in submerged than in aerobic soils. A dose–response study, however, showed that seedlings of rice cultivars adapted to submerged anaerobic soils did not have higher level of tolerance against *p*-hydroxybenzoic acid than did seedlings of varieties adapted to aerobic upland soils. Moreover, traditional rice cultivars had no greater tolerance than did improved cultivars that were recently bred for traits other than tolerance of phenolic acids. Similarly, there were no differences in tolerance of *p*-hydroxybenzoic acid between two *Echinochloa* weed species adapted to either anaerobic or aerobic growth conditions. Thus, neither the rice cultivars nor weed species had evolved different tolerance levels against the phenolic acid. However, all rice cultivars had significantly greater tolerance of *p*-hydroxybenzoic acid than did either weed species. In a second experiment, the rates at which rice plants released phenolic acids into solution cultures were measured for at least one month, the time period of greatest allelopathic activity following planting under field conditions. The maximum release rate of phenolic acids during the first month of growth was approximately 10 μg/plant/day. At a conventional plant density, the release rate of phenolic acids would be approximately 1 mg/m^2/day. This order of release rate cannot provide concentrations

remotely close to phytotoxic levels determined for these rice cultivars and weed species. The results presented in this paper do not preclude the possibility that phenolic acids might be one component in a mixture of chemicals that, when present simultaneously, are allelopathic.

Key Words—Allelopathy, *Oryza sativa*, phenolic acids, phytotoxicity, rice, weed suppression.

INTRODUCTION

Allelopathy is the direct influence of a chemical released from one plant on the development and growth of other plants. Its potential as a natural means for weed suppression in agrosystems has long attracted interest. Allelopathy in rice effective against weeds has been found in about 3.5% of tested rice germplasm in both laboratory (Fujii, 1992; Navarez and Olofsdotter, 1996) and field experimentation (Dilday et al., 1998; Olofsdotter et al., 1999). Under field conditions, in three different growing seasons, some strongly allelopathic cultivars were capable of reducing *Echinochloa crus-galli* L. biomass by more than 50% compared to non-allelopathic rice cultivars (Olofsdotter et al., 1999). This biomass reduction was expressed as reduced biomass per plant, whereas germination and total number of plants were unaffected. Despite realized effects in the field, the allelochemicals responsible for growth inhibition of rice-associated weeds have not yet been identified.

In the literature on allelopathy, phenolic acids are often mentioned as putative allelochemicals and are perhaps the most commonly investigated compounds among potential allelochemicals. They are found in a wide range of soils, and their phytotoxic potential against various plants has been demonstrated under controlled conditions at concentrations greater than about 1 mM (Hartley and Whitehead, 1985; Dalton, 1999). Studies of mixtures of phenolic compounds, however, have shown that individual concentrations can be additive when evaluating for phytotoxic affects (Blum, 1996). This means that concentrations under 1 mM can become important when in mixture with other phenolic acids.

Phenolic acids are known root exudates of rice, and Mattice et al. (1998), suggested that allelopathy of rice against weeds was correlated with the amounts of phenolic acids released by living rice roots. Their work showed that rice cultivars that were allelopathic against ducksalad (*Heteranthea limosa*) released increased amounts of several isomers of hydroxybenzoic acid (HBA) and two isomers of hydroxyphenylpropanoic acid compared with nonallelopathic rice cultivars (Mattice et al., 1998). Phenolic acids have also been suggested to cause autotoxicity problems in double-cropped rice systems. Chou et al. (1977) attributed inhibited germination and poor early season growth of a second rice crop in Taiwan to phenolic acids arising from decomposing residues of a first rice crop. Alternatively, however, poor early season rice growth has also been associated with inhibition

of nitrogen (N) uptake, due either to the presence of aromatic acids such as 2-phenylpropanoic acid, 3-phenylpropanoic acid, and benzoic acid, all microbial metabolites in soil under highly reduced conditions (Tanaka and Nishida, 1998), or to biological N immobilization (Niranjan Rao and Mikkelsen, 1976; Witt et al., 2000).

Allelochemicals are often identified by testing for phytotoxicity under controlled conditions of a given chemical found in the plant or associated soil. Such studies need to consider not only the chemical composition sensu stricto but also the mixture of compounds, the dose, and the duration the plants experience under a given environment. In rice soils, for example, Kuwatsuka and Shindo (1973) isolated 13 different phenolic acids during decomposition of rice straw. They showed that *p*-coumaric acid was released in the highest amount. However, over time, during decomposition, release of all phenolic acids except *p*-HBA decreased considerably. The importance of these phenolics as allelochemicals in the rice ecosystem must be questioned, because the concentrations needed for phytotoxicity, as determined by Chou and Chiou (1979), far exceeded the concentrations commonly found in natural conditions (Tsutsuki and Ponnamperuma, 1987).

In another study, Hsu et al. (1989) evaluated the concentrations of phenolics needed to inhibit germination of lettuce (*Lactuca sativa*) and alfalfa (*Medicago sativa*). From their data, we calculated the ED_{50g}, which is the effective dose of phenolic acids required to inhibit germination of lettuce and alfalfa by 50%, respectively (Table 1). Salicylic and *p*-HBA were the strongest germination inhibitors but only at very high concentrations (200–350 mg/kg solution). Their data also allowed calculation of the time needed to reach 50% germination, which was lengthened by most phenolic acids tested (Table 1).

In fact, a phenolic acid typically has a concentration less than 5 mg/kg soil in submerged rice soils without amended rice straw. Amendment of rice straw (5 tons/ha) has been shown to raise the average level of phenolic acids seven-fold (Tsutsuki and Ponnamperuma, 1987), which would still be well below phytotoxic levels. However, soil is not a uniform medium, and there may be pockets with concentrations substantially higher than the bulk mean concentration (Foy, 1999; Dalton, 1999), such as the rhizosphere of living plants and the immediate vicinity of degrading plant tissues. In summary, additional evidence is necessary before phenolic acids can be considered as primary allelochemicals in rice.

Rice has been grown for several thousand years, and the evolution of traditional cultivars has been driven by local adaptation for site-specific climatic conditions, pest tolerance, and higher yield. As such, traditional rice varieties are expected to be adapted to the most important features in their growing environment. Therefore, it must be expected that traditional plant cultivars or plant species adapted to environments with inherently different phenolic acid concentrations would vary in their tolerance of phenolic acids if phenolic acid content indeed reaches growth inhibitory concentrations in parts of the soil. Similarly, the

capacity of weeds to develop specific adaptations to biochemical controls is well documented (Jordan and Jannink, 1997), and some insects have developed tolerance toward or have even acquired the capability to benefit from phenolic-rich substrates (Appel, 1993). In a second comparison among rice cultivars, modern varieties, derived from traditional cultivars and bred for higher yield, might be expected to have a lesser degree of adaptation to environmental stresses than the traditional cultivars, as plant characteristics not included in the selection procedure are in principle selected against (G. S. Khush, personal communication).

Under irrigated rice (anaerobic) environments, the average content of phenolic acids in the soil, at least during early crop growth stages, is considerably larger than under upland (aerobic) conditions because of the slower degradation of phenolic acids under anaerobic conditions (Shindo and Kuwatsuka, 1977; Hartley and Whitehead, 1985). It is not clear, however, whether phenolic acid concentrations are maintained at higher levels in lowland soils than in upland soils over longer periods of time. Leaching losses might be greater in lowland soils (Shindo et al., 1979), and the soil temperature can be higher in lowland soils, which would accelerate decomposition (Chou et al., 1981). Anaerobic microbial degradation of phenolic acids may also be delayed by reversible sorption of the phenolic acids to the soil (Blum, 1998). Such sorption, however, will also influence the magnitude and duration of phytotoxicity for these compounds (Cheng, 1995; Blum, 1998). Sorption of phenolic acids to soil, however, could occur in either situation in both lowland and upland soils and cannot explain differences between upland vs lowland.

If naturally occurring concentrations of phenolic acids are inhibiting growth and if plants have adapted to their environmental conditions, plants normally growing under anaerobic conditions should have a higher level of tolerance towards phenolic acids than plants adapted to aerobic conditions, and the degree of adaptation by lowland rice should be greater in traditional varieties than in modern varieties since it has not been a primary breeding objective.

While knowledge of interactions among phenolic compounds has gradually accumulated in aerated soils, virtually nothing has been done on phenolic compounds as allelopathic agents in irrigated rice soils. Knowledge gained in aerated soil is not always directly transferable to irrigated rice. The rice plant has different root processes than most other plants, and the anaerobic soil conditions also provide for potentially different biological and chemical environments. Hence, this study was set up under controlled conditions, first, to establish any differences in tolerance for *p*-hydroxybenzoic acid among weed species, traditional rice, and modern rice cultivars adapted to irrigated lowland or upland conditions. We selected *p*-hydroxybenzoic acid to represent phenolic acids, based on the phytotoxicity results of Hsu et al. (1989), the increased release of HBA in allelopathic rice (Mattice et al., 1998), the demonstrated phytotoxic nature of this acid when tested on a range of weeds (Reigosa et al., 1999), and the widespread belief that this particular phenolic acid is often involved in host plant resistance to weeds, pests, and diseases (Niemeyer, 1988). As a second objective, the amounts of phenolic acids released from living rice plants, allelopathic or not, were measured and compared with the tolerance levels of *p*-hydroxybenzoic acid in order to evaluate whether the amounts of naturally exuded *p*-hydroxybenzoic acid sufficed for allelopathic activity of rice, assuming additive effects of phenolic acids in mixture (Blum, 1996; Reigosa et al., 1999).

METHODS AND MATERIALS

Dose–Response Curves for p-Hydroxybenzoic Acid. Four rice cultivars and two weed species were chosen to represent cultivars and species adapted to either irrigated (anaerobic) or rainfed upland (aerobic) environments. The upland rice cultivars were Moroberekan and IRAT 216, representing traditional and modern (improved) japonicas, respectively. Cultivars adapted to irrigated and anaerobic conditions were represented by Mahsuri (traditional) and IR5 (improved), respectively, both indicas. *Echinochloa crus-galli* and *Echinochloa colona*, both of which can be suppressed by allelopathic rice cultivars (Olofsdotter et al., 1999; Pheng et al., 1999), were chosen as the weeds adapted to anaerobic and aerobic conditions, respectively. Seeds for all rice cultivars and both weed species were obtained from field soils maintained under representative growing conditions.

All seeds (20 per Petri dish) were sown on filter paper in a Petri dish placed inside a small growing box, closed with a removable plastic cover. A filter paper strip formed a liquid bridge from the surrounding box into the Petri dish. By this technique, an excess of test solution can be added to the box to ensure a sufficient amount of water to the test plants without drowning the seeds. Thirty milliliters of test solution was added to the surrounding box, outside the Petri dish, at the start of the experiment and 20 ml was added at day 4. Seven different concentrations of *p*-hydroxybenzoic acid were applied as the test solution in the plant box. Concentrations were chosen to cover the entire range of responses from virtually unaffected to severe inhibition or death. When log-transformed, concentrations were evenly spaced along the dose–response curve. Two weeks after seeding the plants were harvested, shoot and root length were measured for all germinating plants, and shoot and root dry matter were measured for each Petri dish. Germination of individual seeds was recorded from 2 days after seeding until all seeds had germinated. The experiments were replicated five times and repeated once over time.

Statistics. Plant growth (y) in response to a dose (z) can be described by a four-parameter logistic model (Streibig, 1988):

$$y = (D - C)/1 + \exp\left\{2b * \left[\log(\mathrm{ED}_{50}) - \log(z)\right]\right\} \quad (1)$$

where D denotes the upper and C the lower limit of response at low and high doses, respectively. ED_{50} defines the dose required to decrease the response by 50% relative to untreated and is equal to a response $(D + C)/2$. Parameter b is proportional to the slope of the curve at ED_{50}. If a phytotoxin has the same mode of action regardless of cultivar or weed, the dose–response curves would theoretically have the same slope. Such parallelism can be statistically tested by the F test.

Variation in this kind of experiment is rarely normally distributed. Therefore, data are typically transformed to provide a normal distribution. A suitable family $h(\lambda)$ of transformations was found by Box-Cox analyses (Box and Cox, 1964), and a transform-both-sides technique was used (Carroll and Ruppert, 1988). All statistical procedures were done in SAS.

Release Rates of Phenolic Acids from Living Rice Plants. Nine rice cultivars were selected for this experiment based on our previous rice allelopathy study (Olofsdotter and Navarez, 1996). Four nonallelopathic rice cultivars were selected: AUS196 (improved AUS), IR38 (improved indica), Mahsuri (traditional indica), Brown Gora, (traditional indica), all lowland rice. Five allelopathic cultivars were selected: Woo Co Chin Yu (traditional indica), IR64 (improved indica), Taichung Native1 (traditional indica), AC1423 (improved indica), and IR56 (improved indica), all lowland rice. The five allelopathic cultivars had different strengths of allelopathic activity toward weeds, and their correlation with the rate of phenolic release would test the significance of phenolics in weed-suppressing

allelopathy. Rate of phenolics release was monitored in four cultivars until 56 days after transplanting, and in another experiment the remaining five cultivars plus IR38 (control) were measured only until 28 days after transplanting, mirroring the most important time period of allelopathic weed control. The plants were grown in hydroponic solutions in the greenhouse, and the experiment was carried out in a randomized complete design with three blocks and repeated once over time.

Rice seeds were surface-sterilized with 2.6% sodium hypochloride for 20 min, rinsed three times with distilled water, and germinated in Petri dishes at room temperature. Twelve days after seeding, seedlings with uniform root length and shoot height were wrapped with foam, inserted into holes in a styrofoam float, and transplanted into the hydroponic solutions. Two seedlings were grown 10 cm apart in a 3.6-liter pail filled with hydroponic solution. The pails were wrapped with aluminum foil to inhibit algae growth and placed in a bench with cool water to avoid overheating. The nutrient/hydroponic solution (Yoshida et al., 1976) was changed every 2.5 days to ensure sufficient nutrients to the rice plants, and its pH was maintained at 5.5 daily by using 0.1 N NaOH throughout the experiment. The nutrient/hydroponic solution was kept at half strength for the first week after transplanting, and thereafter full-strength solution was used.

The hydroponic solution was first sampled two weeks after transplanting (WAT). Thereafter the solution was sampled weekly. Twenty-four hours before every sampling, the nutrient solution was replaced with 3.6 liters of solution with the same N concentration as before but in the form of NH_4Cl instead of NH_4NO_3 to avoid possible interference by nitrate in the determination of total phenolic compounds. At sampling, the plants were lifted out of the hydroponic solution, the solution stirred, and 500 ml removed for analysis. The release rates of phenolic compounds were determined through the amount of detected phenolics released by the plants during the previous 24 hr. The sample was filtered through Whatman No. 1 filter paper and analyzed for total phenols by using the 4-aminoantipyrine colorimetric method (Clesceri et al., 1989) with *n*-phenol (C_6H_5OH) as the standard. This method covers the phenolic compound range from 1 to 250 μg/liter with a sensitivity of 1 μg/liter. The minimum detectable quantity is 0.5 μg/liter. Obtained values represent a minimum amount of phenolic compounds present in the sample, as the reactivity with 4-aminoantipyrine varies by phenolic compound. Typical standard deviations for such an analysis are 12%, which should be considered when interpreting the data obtained (Clesceri et al., 1989).

Release rates of total phenolic compounds per day per plant were calculated as:

$$\mu\text{g phenol/plant} * \text{day} = (A/B \times 1000 * 3.6)/2 \qquad (2)$$

where A is the amount phenol measured per microgram of sample as determined from a calibration curve and B is the volume of the sample.

TABLE 2. PARAMETERS FOR NORMALIZED *p*-HYDROXYBENZOIC ACID DOSE–RESPONSE CURVES FOR ROOT LENGTH OF FOUR RICE CULTIVARS AND TWO WEED SPECIES

	D	−*b*	ED_{50}	*C*
Moroberekan	102	1.77	653	−1.1
	(86–118)	(0.95–2.60)	(540–767)	(−5.6–3.3)
Mahsuri	101	2.53	639	1.3
	(90–112)	(1.69–3.38)	(571–708)	(−0.5–3.2)
IR5	99	2.44	528	8.8
	(89–109)	(1.17–3.52)	(461–595)	(3.1–14.4)
IRAT 216	101	2.54	678	−0.3
	(90–113)	(1.64–3.44)	(600–756)	(−1.7–1.0)
Echinochloa crus-galli	101	1.53	334	0.4
	(80–121)	(1.09–1.97)	(264–409)	(−0.8–1.6)
Echinochloa colona	101	2.05	310	0.1
	(74–128)	(1039–2.72)	(241–380)	(−0.3–0.6)

[a] *D* denotes the upper and *C* the lower limit of response at low and high doses, respectively. ED_{50} is the dose required to decrease the response by 50% and is equal to a response $(D + C)/2$. The parameter *b* is proportional to the slope of the curve at ED_{50}. Confidence limits (0.05) for the estimated parameters are given in parentheses.

RESULTS

Dose–Response Curve for p-*Hydroxybenzoic Acid.* The dose–response equation (1) adequately described the dose–response relationship for root length of all rice cultivars and both weed species. The estimated parameters from normalized dose–response curves did not vary among rice cultivars (Table 2). Rice cultivars adapted to submerged anaerobic conditions did not have a higher level of tolerance against *p*-hydroxybenzoic acid than did upland varieties, and traditional varieties had no greater tolerance than did improved varieties. Similarly, there were no differences in tolerance of *p*-hydroxybenzoic acid between the two weed species adapted to either anaerobic or aerobic growth conditions (Table 2). This means that, parallel to the findings in rice, weed species have not evolved tolerance against the phenolic acid that reflects their growth environments.

When comparing all rice cultivars with both weeds, there was a significant difference in their tolerance of *p*-hydroxybenzoic acid. The two *Echinochloa* species had ED_{50} values only half of those of the rice cultivars (Table 2). Consequently *p*-hydroxybenzoic acid can selectively control the *Echinochloa* species at a concentration that does not affect rice. The slopes of the dose–response curves at ED_{50} (*b* parameter) did not differ significantly between all rice cultivars and the weeds, indicating a similar mode of action for growth inhibition both in rice and weeds. Root dry weight showed the same trends as did root length, and shoot length and shoot dry weight had smaller but similar levels of response (data not shown).

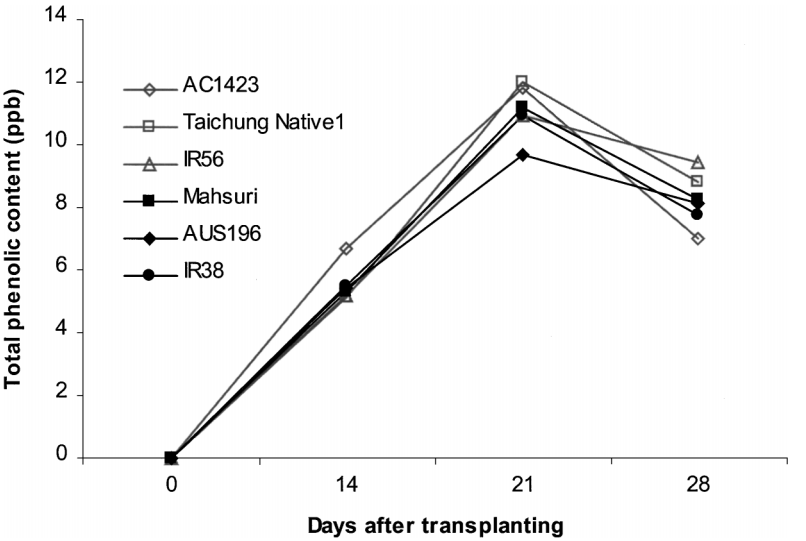

FIG. 1. Total phenolic acids released (μg/plant/day) for three allelopathic rice cultivars (open symbols) and three nonallelopathic rice cultivars (closed symbols) into hydroponic solution.

Release Rates of Phenolic Acids from Living Rice Plants. Allelopathic rice cultivars did not release higher amounts of phenolic acids than nonallelopathic cultivars (Figure 1). Similarly there were no differences in the amounts released from traditional rice cultivars compared to improved rice cultivars (Figure 2). All rice cultivars had an increasing release rate of phenolic acids until at least 14 days after transplanting, whereafter a slight decrease in the amount released occurred at 28 days after transplanting. For the cultivars that were studied until 56 days after transplanting, the amounts released increased after 28 days after transplanting.

The maximum release rate of phenolic acids from rice plants during the first month of growth, when allelopathy normally affects weed growth, was approximately 10 μg/plant/day (Figures 1 and 2). At a conventional plant density of 100 rice plants/m^2, the release rate of phenolic acids would be approximately 1 mg/m^2/day. Even if all phenolic acids were as phytotoxic as *p*-hydroxybenzoic acid, this release rate could not provide concentrations within one month remotely close to phytotoxic levels for the rice cultivars studied here (Table 2).

DISCUSSION

Dose–response relations with *p*-hydroxybenzoic acid presented in this paper agree with other studies on the magnitude of phytotoxicity of phenolic compounds

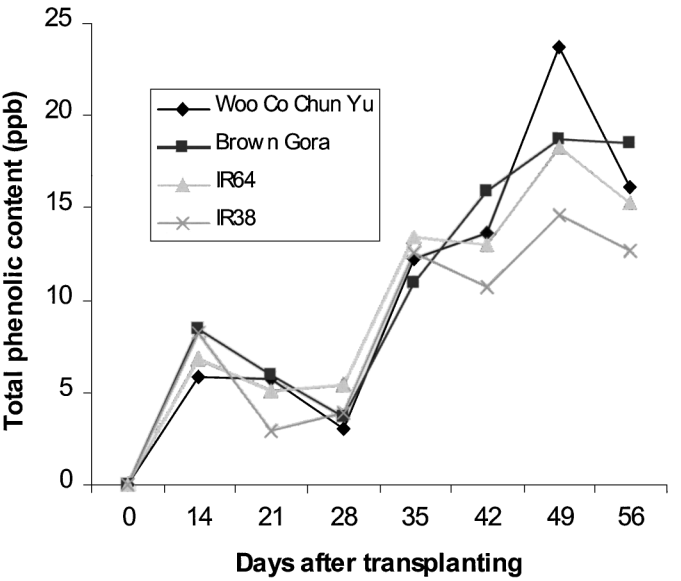

FIG. 2. Release of phenolic compounds (μg/plant/day) in traditional (Woo Co Chun Yu and Brown Gora) versus modern (IR64 and IR38) and allelopathic (Woo Co Chun Yu and IR64) versus nonallelopathic (Brown Gora and IR38) rice cultivars into hydroponic solution.

(Tanaka et al., 1990). As stated by Tsutsuki (1984), phenolic acids are phytotoxic at lower concentrations than are aliphatic organic acids, which are more common in decomposing rice straw than are phenolic acids and have often been evaluated for their autophytotoxic effects on rice (Gotoh and Onikura, 1971; Niranjan Rao and Mikkelsen, 1976). Our results indicate that it is unlikely that allelopathic interaction in rice is the effect of released phenolic acids alone, as the concentration needed for phytotoxic effects far exceeds the concentrations found in natural rice soils. Likewise, Gotoh and Onikura (1971) and Niranjan Rao and Mikkelsen (1976) found that released concentrations of aliphatic acids were too low to cause rice autotoxicity. However, rice autotoxicity (decomposing residues) may well involve wholly different processes than does rice allelopathy towards weeds (active root secretion).

The capacity of *p*-hydroxybenzoic acid to inhibit weed growth at concentrations that do not inhibit rice growth suggests that there has been an evolutionary drive in rice towards tolerance of phenolic acids. This could indicate that rice is better adapted than *Echinochloa* to grow under conditions of elevated phenolic acid concentrations, for example, in submerged (or lowland) rice soils during early growth stages. Such a selective response to phytotoxins is widely seen with herbicides (Streibig, 1988) and is often attributed to reduced uptake of the phytotoxin

(*p*-hydroxybenzoic acid in this case) or a more efficient metabolic degradation. However, the fact that the concentrations needed to inhibit *Echinochloa* growth are much higher than those exuded by rice cultivars again points towards a limited involvement of phenolic acids in allelopathic weed suppression under field conditions (Olofsdotter et al., 1999). Consequently the tolerance of rice cultivars to high phenolic acid concentrations is more likely to be an evolutionary response to phenolic acids formed during decomposition of plant residues than to phenolic acids exuded as allelochemicals.

It has been debated whether allelopathy under field conditions results from a single compound or a mixture of several phytotoxins (Einhellig, 1999). If a mixture of compounds is responsible for the observed growth inhibition of weeds, phenolic acids such as *p*-hydroxybenzoic acid could play a role in such a mixture. To fully establish the potential phytotoxicity of such mixtures, however, it is important to understand the joint action of these compounds. If allelopathy indeed results from mixtures of compounds, then evaluation of one phenolic acid at a time, as done here, cannot lead to proper identification of the causal agents or to determination of critical concentrations of all involved chemicals in field settings. Simultaneously, the results of this study will serve as a useful foundation for future studies of phenolic acid mixtures.

Nevertheless, our results raise some uncertainty regarding the role of phenolic acids in general and *p*-hydroxybenzoic acid in particular as a primary allelopathic agent of lowland rice against weeds. First, as described above, our measured rates at which phenolic acids are released from rice would require unrealistic quantities of time and plants in order to reach concentrations phytotoxic for weeds as determined in the dose–response curves. Second, the rate of phenol release does not differ between allelopathic and nonallelopathic rice cultivars. Third, dose–response curves do not indicate that traditional rice varieties are better adapted to phenolic acids than are improved varieties or that lowland rice varieties are better adapted than upland varieties. Fourth, the concentrations of phenolic acids released from all varieties into hydroponic solutions do not appear to notably exceed those resulting from straw decomposition (Chou et al., 1977; Tanaka, 1990), although differences in experimental design introduce some uncertainty in comparing data across studies. Thus, many weeds adapted to rice soils should tolerate the levels of exuded phenolic acids reported here, at least for short periods of time.

In this study, an admittedly limited numbers of rice cultivars and weed species were studied. However, the cultivars were chosen from previous allelopathy screenings (Navarez and Olofsdotter, 1996) to represent a wide range of allelopathic strength and a large genetic background. For the weed species, we selected some of the most troublesome weeds in rice cropping systems adapted to anaerobic (*E. crus-galli*) and aerobic (*E. colona*) growth conditions. The fact that the two species are both *Echinochloa* should make this comparison of aerobic and anaerobic conditions more valid.

Some limitations exist in synthesizing our results with other allelopathy studies. The tolerance levels of rice cultivars to *p*-hydroxybenzoic acid and their rates of phenolic acid release determined here cannot be compared with many equivalent measurements reported elsewhere for field settings. The type of extractant used in field studies will considerably affect the quantity of phenolic acids extracted, and there is no widely accepted method for isolating labile phenolic acids (Dalton, 1999). Soil moisture level and various interactions between phenols and soil components will affect phenolic acid activity (Foy, 1999; Huang et al., 1999; Schmidt and Ley, 1999). Phenolic acids degrade quickly in the field, and they can be leached (Tsutsuki, 1984), reducing their effective concentrations below exuded concentrations measured in solution cultures as in this study, which again suggests that the measured release rates for phenolic acids in this study cannot explain the allelopathy seen in rice. The correlation between phenolic acid content of rice and allelopathic activity of the same cultivars reported by Mattice et al. (1998) must, therefore, be explained either by the incidental correlation between phenolic acid content of the limited number of cultivars included in their study with their field suppressive activity, or it can be speculated that there might be genetic links between allelopathy and the phenolic acid content in rice, which per se do not link phenolic acid phytotoxicity with allelopathy.

Significant knowledge gaps remain in our understanding of rice allelopathy against weeds. Future studies must address the identification of allelopathic chemical(s) in rice as well as problems in translating laboratory results into field processes. Identification of allelochemicals in rice must also discern the true causal agents of allelopathy from a multitude of other chemicals that might be exuded from allelopathic cultivars, preferably without prior assumptions about which chemicals are active (Rimando et al., 1998).

Acknowledgments—The authors wish to thank DANIDA for financial support to this project.

Abstract—Optimal defense theory (ODT) predicts that plant defenses will be allocated to plant organs and tissues in proportion to their relative fitness values and susceptibilities to attack. This study was designed to test ODT predictions on the myrosinase–glucosinolate defense system in *Brassica juncea* by examining the relationships between the fitness value of *B. juncea* cotyledons and the levels and effectiveness of cotyledon defenses. Specifically, we estimated fitness value of cotyledons during plant development by measuring plant growth and seed production after cotyledon damage or removal at successive seedling ages. Cotyledon removal within five days of emergence had a significant impact on growth and seed production, but cotyledon removal at later stages did not. Consistent with ODT, glucosinolate and myrosinase levels in cotyledons also declined with seedling age, as did relative defenses against a generalist herbivore, *Spodoptera eridania*, as estimated by bioassay. Declines in glucosinolates were as predicted by a passive, allometric dilution model based on cotyledon expansion. Declines in myrosinase activity were significantly more gradual than predicted by allometric dilution, suggesting active retention of myrosinase activity as young cotyledons expand.

Key Words—*Brassica juncea*, cotyledon, glucosinolates, myrosinases, plant defense, plant fitness, secondary metabolites, optimal defense theory, *Spodoptera eridania*.

INTRODUCTION

Optimal defense theory (ODT) predicts that defenses should be allocated to plant tissues in proportion to the value of these tissues for plant fitness and their vulnerability to herbivore or pathogen attack (McKey, 1974; Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1979, 1983). The theory also predicts that defense allocation should change dynamically as fitness value and risk of attack of plant tissues change during plant development. We tested ODT predictions for the glucosinolate–myrosinase defensive system in cotyledons of *Brassica juncea* L.

Glucosinolates are nonvolatile nitrogen and sulfur-containing secondary metabolites derived from amino acid precursors (Louda and Mole, 1991). Glucosinolates are antibacterial, fungistatic, allellopathic, and toxic to some insects and mammals; however, they are also feeding stimulants for specialist insects such as flea beetles (Louda and Mole, 1991).

Hydrolysis of glucosinolates to glucose, sulfate, and volatile mustard oil products is catalyzed by enzymes known as myrosinases (thioglucoside glucohydrolases, EC 3.2.3.1). Myrosinases appear in all glucosinolate-producing plants studied, with the highest activity in seeds and seedlings (Bones, 1990; Rask et al., 2000). Myrosinase is located in special myrosin cells located throughout the plant (Xue et al., 1995), and glucosinolates are present in most cells. Damage to the integrity of the plant cell walls unites glucosinolates and myrosinases, allowing release of hydrolysis products (Cole, 1975; Feeny, 1977; Bones and Rossiter, 1996). Glucosinolate hydrolysis products are broadly biocidal, much more so than the intact glucosinolates. They are toxic to generalist insect herbivores (Seo and Tang, 1982; McCloskey and Isman, 1993; Borek et al., 1995, 1997, 1998; Li et al., 2000) and to crucifer specialist insects (Åhman, 1986; Wadleigh and Yu, 1988; Li et al., 2000) and have been implicated in defense against microbial diseases (Brabban and Edwards, 1995). Thus, glucosinolates and the myrosinase enzymes that catalyze their hydrolysis products appear to be important for full expression of binary glucosinolate-based defenses.

A few studies have documented the ecological importance of myrosinases for glucosinolate-based defenses. Newman et al. (1992) showed that thermally denaturing myrosinases in watercress, *Nasturtium officinale*, reduced defenses in this plant against arthropod herbivores. Recently, Li et al. (2000) showed that varying myrosinase activity and glucosinolate concentrations in *B. juncea* cotyledons significantly affected the area damaged by generalist *Spodoptera eridania* (Cramer) (Noctuidae) and specialist *Plutella xylostella* (L.) (Plutellidae) and the feeding frequency of *P. xylostella*.

Glucosinolates are categorized as a relatively inexpensive qualitative defense (Feeny, 1976; Rhoades, 1983) because their concentration in tissue is relatively

low. Chew and Rodman (1979) estimated the cost of glucosinolate synthesis at approximately 90 ATP and 12 $NADH_2$, which accounts for an isoleucine precursor and nine subsequent enzymatic steps to the glucosinolate product. However, the costs of maintaining glucosinolates for defense include synthesis, storage, compartmentalization, and possibly transport (Chew and Rodman, 1979; Gershenson, 1994; Bones and Rossiter, 1996; Hartmann, 1996). In addition, glucosinolate defense depends upon myrosinases, which may be the more costly component of the system. As evidence for this, *Brassica rapa* populations selected for high myrosinase activity produce less seed than low-myrosinase-activity genotypes (Siemens and Mitchell-Olds, 1988).

The glucosinolate-myrosinase system, therefore, has apparent metabolic costs, contributes to defense, and thus should be shaped towards optimal allocation by these opposing selective forces. Cotyledon tissue is particularly suitable for examining the optimality of glucosinolate defense allocations during plant development. Among the highest within-plant glucosinolate concentrations and myrosinase activities occur in cotyledons of *B. juncea* and *B. napus*, respectively (Bones, 1990; Bodnaryk, 1992). High allocations of defensive compounds to cotyledons is predicted by ODT because cotyledons are valuable storage organs for the growing seedling, the first photosynthetic tissue, and the first above-ground tissue available for terrestrial herbivore or pathogen attack. Flea beetle (*Phyllotreta cruciferae*) attack of *Brassica napus* and *B. rapa* is most detrimental at the cotyledon and first true leaf stage (Lamb, 1989). As the plant develops true leaves, the importance of cotyledons for plant fitness should decline, and ODT predicts that allocation of defenses to cotyledon tissues should also decline.

Many cotyledon studies have been performed on economically important *Brassica* crops, including *B. juncea* (Bodnaryk and Palaniswamy, 1990; Bodnaryk, 1992; Brandt and Lamb, 1993), but there is little reported on the important binary glucosinolate/myrosinase defense.

To test whether within-plant defenses are allocated to tissues in proportion to the specific tissue value, we measured the changes in the fitness value of *B. juncea* cotyledons during seedling development as determined by the effects of damage or cotyledon removal on ultimate plant height and seed production (tissue value estimation reviewed in Chew and Rodman, 1979; McKey, 1979; Krischik and Denno, 1983; Zangerl and Bazzaz, 1992). We compared these estimates of the fitness value of cotyledons with quantitative measurements of myrosinase activity and glucosinolate concentration in cotyledons during seedling maturation. We also measured the defenses of the cotyledons functionally through growth and feeding bioassays with a generalist herbivore. We hypothesized that estimates of the fitness value of cotyledons would decline during seedling development and predicted a similar decline in the levels of chemical defense, measured directly and in terms of response by an herbivore.

METHODS AND MATERIALS

Plants. Three *B. juncea* homozygous lines (designated 24, 41, and 9) were used in this study to broaden the domain of inference. Each was developed from the F_1 of a cross between the East Indian cultivar RLM514 and a breeding line from the University of Alberta (Thiagarajah and Stringam, 1993). Seed of these lines was provided by G. Stringam, University of Alberta, Edmonton, Alberta, Canada. Glucosinolate concentrations and myrosinase activity in these lines and their parental lines had been previously determined (Li et al., 2000, 2001). Glucosinolate profiles are >90% allyl and <10% 3-butenyl.

Seeds were hydrated on moistened filter paper-lined Petri dishes two days before sowing. All plants were grown in 15-cm-diam. pots in Sunshine Mix 1 potting soil (SunGro Horticulture, Bellevue, Washington), in a regulated greenhouse at $25 \pm 3^{\circ}$C, ambient humidity, with a supplemental 18L:6D photoperiod under metal-halide lighting (600 μmol PAR/m^2). Plants were watered daily by drip irrigation. One hundred forty-four plants of each line were used for chemical and biological assays. A second experiment to assess the effect of cotyledon damage on seed production and biomass included 70 plants of each line.

Insects. The generalist herbivore *S. eridania*, the southern armyworm, was used for bioassays. Insects were from a laboratory colony at the University of Idaho. The colony was reared on southern armyworm diet (Southland Products Inc., Lake Village, Alaska) in a growth chamber at 25°C with an 18L:6D photoperiod (light intensity 17.0 μEinstein/m^2/sec PAR, 400–700 nm).

Effects of Cotyledon Removal and Damage on Plant Growth and Seed Production. The effects of cotyledon damage or excision on plant fitness potential were investigated by damaging or removing cotyledons from plants at different times after plant germination and measuring plant growth (height and biomass at maturity) and seed production. The damage treatments were mechanical damage to both cotyledons with pliers (producing striated compression injury over the whole cotyledon surface) and removal of two cotyledons. The damage treatments were not intended to mimic insect damage, but to assess the effects of cotyledon injury or removal on subsequent plant growth and reproduction. Each of the treatments was applied 1, 5, or 10 days after germinating plants emerged from the soil. Plant height and total seed production were recorded at maturity. The small percentage (<1%) of undeveloped seed collected from mature plants was not included in our analysis. There were 10 replications; each replication included one randomly chosen plant of each of the three homozygous lines subjected to each of the six treatment combinations (2 damage types $\times$ 3 days applied), and an untreated control of each line, for a total of 210 plants. The plants were arranged on the greenhouse bench in a randomized complete block design.

Height and seed count data were compared with analysis of variance (ANOVA) based on a randomized design, with *B. juncea* line and treatment as main effects.

The analysis was conducted using PROC GLM and means were separated using the LSMEANS option (SAS Institute, Cary, North Carolina).

Myrosinase Activity and Glucosinolate Concentrations. Myrosinase activity was measured as in Li et al. (2000). Briefly, 20 half-cotyledons of each line were pooled and ground in 10 ml of pH 7.5 Tris EDTA buffer. Soluble proteins free of endogenous glucosinolates and sugars were obtained by filtration through a Sephadex G25 column. Exogenous sinigrin was added and glucose released by hydrolysis was measured colorimetrically using a glucose oxidase, peroxidase, 4-aminoantipyrine, and phenol reagent. Groups of extract samples were measured simultaneously in a microplate reader. Each sample was replicated twice in the plate. Absorbance at 490 nm was calibrated with a glucose standard curve included in each plate, and the signal for each extract sample was corrected for background absorbance with an extract without sinigrin control.

Glucosinolate concentrations were determined as in Li et al. (2000). Briefly, cotyledon halves were extracted in boiling methanol with PbBa acetate to precipitate phenolics and sulfate. Glucosinolates were then enzymatically desulfated and silylated with bis(trimethylsilyl)trifluoroacetamide (Sigma, St. Louis, Missouri). Trimethylsilyl derivatives were analyzed by gas chromatography with mass spectrometer detection using trimethylsilyl benzyl glucosinolate as an internal standard. Glucosinolates were identified by GC-MS (Hewlett Packard, HP 5890A gas chromatograph, coupled with a mass selective detector MSD 5972A; Agilent Technologies, Palo Alto, California) and a DB-5 capillary column (30 μm $\times$ 0.25 mm ID, 0.25-μm film thickness; J&W Scientific, Folsom, California). Glucosinolate compounds were identified based on standard mass spectra (provided by M. Morra, University of Idaho) and their relative retention times. Glucosinolate concentrations were quantified by GC with a flame ionization detector (HP 5890A), using a HP-5MS (30 μm $\times$ 0.25 mm ID, 0.25-μm film thickness; Agilent Technologies) or a SPB-5 (30 μm $\times$ 0.25 mm ID, 0.10-μm film thickness; Supelco, Bellefonte, Pennsylvania) capillary column.

Myrosinase activity and glucosinolate concentration data were analyzed similarly. Values from pooled samples of each line were used as a single observation, providing three observations for each estimate, except for day 5 (five days after emergence), which excluded line 9. ANOVA was performed on these data using a randomized design with cotyledon age as the class variable. Because secondary chemistry might change passively as the cotyledon expands, we also calculated an expected concentration based on simple dilution. This expected value was calculated by dividing the average mass of cotyledons on plants one day after emergence by the average mass of cotyledons at 5 or 10 days after emergence, respectively. These factors were then multiplied by the average glucosinolate concentration or myrosinase activity/unit mass on day 1 to estimate expected values at 5 or 10 days after emergence. Student's *t* test was used to examine whether

glucosinolate concentration or myrosinase activity 5 or 10 days after emergence differed significantly from this expected value.

Bioassay to Measure Cotyledon Defenses. Neonate larvae of *Spodoptera eridania* were placed five per cage in 2-oz clear plastic rearing cups with a layer of 6% water agar. The larvae were provided cotyledons from seedlings 1, 5, or 10 days after emergence daily from one of each *B. juncea* line. Despite differences in the size of cotyledons of different ages, the larvae never consumed an entire cotyledon before fresh tissue was provided. Old tissue and dead larvae were removed daily and recorded. After four days, surviving larvae were starved for one day, with access to water, and then weighed. There were 10 replications, totaling 50 caterpillars per line.

Caterpillar weights and survival at the end of the bioassay were analyzed with a two-factor ANOVA based on a completely randomized design with *B. juncea* line and cotyledon age as factors. Observations used in the analysis were the average weight of all surviving caterpillars in each rearing cup and the proportion of caterpillars surviving in each cup. No data were obtained for cotyledons from plants five days after emergence for *B. juncea* line 9. Because the effect of line and the line $\times$ day interaction were not significant, we also conducted single factor ANOVA for the effect of cotyledon age on weight and on survival, and separated the means with Tukey's HSD test at the 0.05 level. All statistical analyses were performed using PROC GLM and PROC MEANS in SAS (SAS Institute, Cary, North Carolina).

RESULTS

Effects of Cotyledon Removal and Damage on Plant Growth and Seed Production. Removal of cotyledon tissue from *B. juncea* seedlings affected both height at maturity and seed production (Table 1, Figure 1). Plants with removed cotyledons were shorter relative to controls (Figure 1A) and plant height was affected by treatment, line, and their interaction (Table 1). The effect of treatment was largely due to the reduced height of plants from which two cotyledons had been removed on either day 1 or day 5 (Figure 1A). The line effect and interaction were caused by a relative tolerance of line 23 (removal of two cotyledons from this line on day 1 did not significantly reduce height at maturity relative to undamaged controls) ($P = 0.066$, data not shown). Removing both cotyledons on day 5 only significantly reduced height of line 41 ($P = 0.003$) and not the other two lines (data not shown).

Plant seed production was affected by treatment and line but not by their interaction (Table 1). As was true for plant height at maturity, removal of cotyledons within five days of emergence substantially reduced seed production (Figure 1B).

In summary, plant height at maturity and seed production were reduced by cotyledon removal from seedlings one or five days after emergence. Cotyledon damage at any stage or cotyledon removal after day 5 did not significantly reduce growth or eventual seed production of *B. juncea* seedlings.

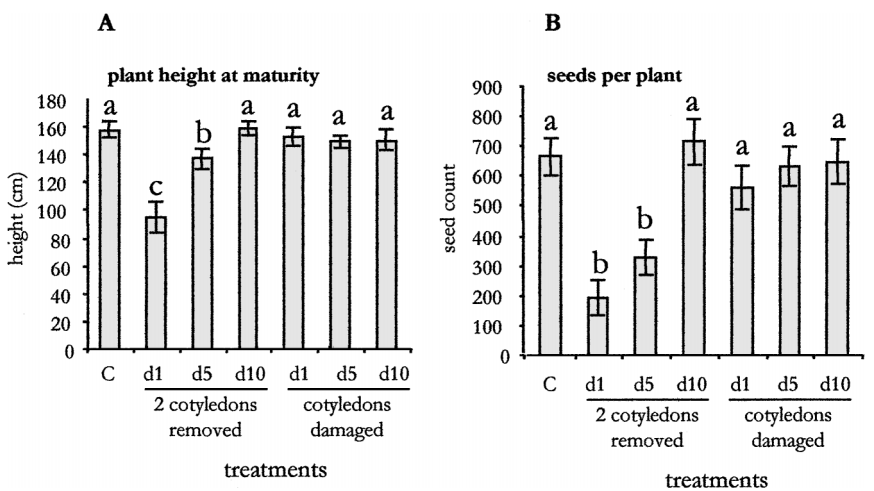

FIG. 1. Effects of cotyledon removal and damage at different seedling ages on *B. juncea* plant height at maturity (A), and per-plant seed production (B). In each panel, values with the same letter are not significantly different ($P \leq 0.05$); bars are SEM.

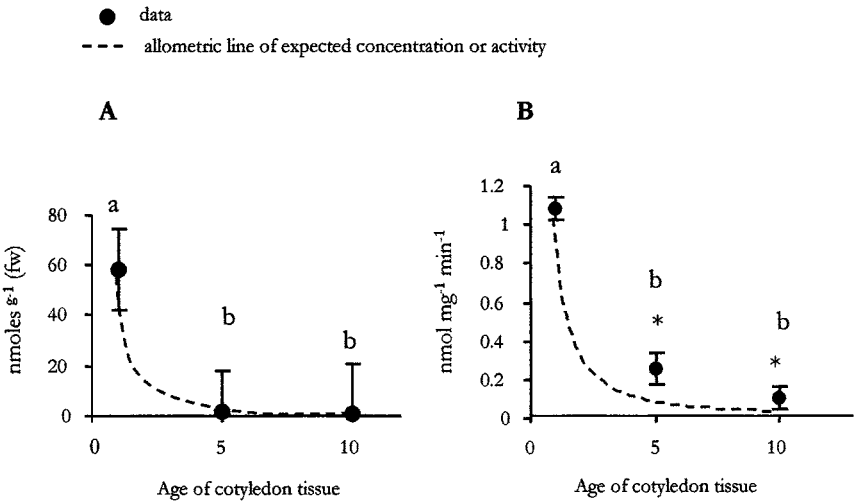

FIG. 2. Glucosinolate activities (A) and myrosinase concentrations (B) in cotyledons of *B. juncea* seedlings 1, 5, and 10 days after emergence. The data are for three *B. juncea* lines pooled. The allometric trendline shows expected specific activity of myrosinase or expected concentrations of allyl glucosinolate based on dilution due to cotyledon expansion (see text). In each panel, values with the same letter are not significantly different ($P \leq 0.05$). Asterisks show significant differences between observed values and those expected due to dilution ($P \leq 0.05$); bars are SEM.

Glucosinolate concentrations in cotyledons also decreased with seedling age (*df* 2,7; $F = 31.36$; $P = 0.001$) between day 1 and day 5 (Figure 2A). The falling concentrations were not different from those predicted from simple allometric dilution, suggesting that the growth of the cotyledon tissue rather than catabolism or active transport of glucosinolates served to alter defense concentrations.

Defensive Chemistry: Glucosinolate Concentrations and Myrosinase Activity. Myrosinase activity, in nanomoles of glucose released per microgram of fresh tissue per minute, was affected by the age of cotyledons (*df* 2,5; $F = 59.78$; $P = 0.0003$) (Figure 2B), decreasing with seedling age. Myrosinase activity was significantly higher than predicted from simple allometric dilution of myrosinase activity as cotyledons expanded ($P < 0.001$).

Bioassay to Measure Cotyledon Defenses. Weights of larvae fed cotyledons aged one day were lower than those aged 5 or 10 days (Figure 3A). Survivorship of *S. eridania* was lower when fed cotyledon tissue from 1-day-old seedlings than when fed cotyledons from 5 or 10-day-old seedlings (Table 2) (Figure 3B). Based on survival and growth rates of the generalist *S. eridania*, defenses in *B. juncea* cotyledons were highest in young cotyledons and declined as seedlings matured through 10 days (Figure 3). The caterpillars that survived on the

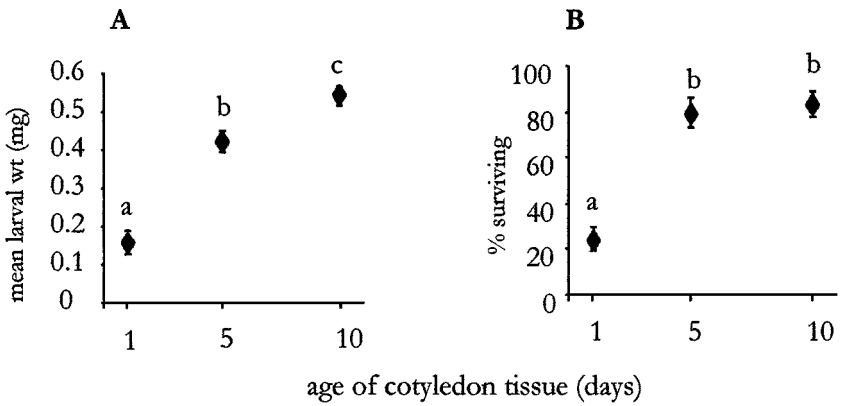

FIG. 3. Larval weights (A) and survival (B) of *S. eridania* fed *B. juncea* cotyledons from seedlings 1, 5, and 10 days after emergence. In each panel, values with the same letter are not significantly different ($P \leq 0.05$), bars are SEM.

treatments appeared not to eat or to eat little of the cotyledon tissues from 1-day-old plants and therefore did not gain weight. It could not be determined if reduced feeding was due to feeding deterrence or postingestive effects of the cotyledon tissues.

DISCUSSION

Attempts to confirm aspects of optimal defense theory have generated sizable literature (Simms, 1992; Zangerl and Bazzaz, 1992; Sagers and Coley, 1995; Zangerl and Rutledge 1996; Ohnmeiss et al., 2000) and include studies on glucosinolate-producing plants and plant parts during different growth stages

(Bodnaryk, 1992; Lamb et al., 1993; Palaniswamy and Lamb, 1993), as well as studies on myrosinase activity in different plant parts during development (Bones, 1990; Lenman et al., 1990; James and Rossiter, 1991; Falk et al., 1992; Xue et al., 1995). Our study examines three elements of ODT for plant tissues defended by the glucosinolate–myrosinase defensive system. We measured both glucosinolates and myrosinase simultaneously during cotyledon development of *B. juncea* and the actual level of defense of these tissues against herbivory using a bioassay with a generalist herbivore, and we estimated the fitness value of the cotyledon tissues in terms of plant growth and seed production.

Our data show allocation of the binary glucosinolate–myrosinase defense to cotyledon tissues is broadly consistent with the ODT prediction that within a plant the defenses are allocated to tissues in proportion to the tissue value. High initial myrosinase activity and glucosinolate concentrations in cotyledons occurred when these tissues were most critical for plant fitness, as estimated by the effects of removing cotyledons on plant height at maturity and seed production. As the value of cotyledons for plant performance (growth and seed production) declined, both components of this binary defense system also declined.

Consistent with these dynamics in defensive chemistry, *S. eridania* growth and survival were lowest when fed young cotyledons and increased with increasing age of the cotyledons eaten. Although the defensive characteristics responsible for this pattern cannot be determined from our experiment, it has been shown that allyl glucosinolate, the dominant one in the three *B. juncea* lines tested, is toxic to *S. eridania* neonate larvae ($LC_{50} = 6.73$ μmol/g diet) and that the myrosinase catalyzed hydrolysis product, allyl isothiocyanate has a higher toxicity ($LC_{50} = 3.42$ μmol/g diet) (Li et al., 2000). This suggests that the glucosinolate–myrosinase system contributes to *B. juncea* defense against *S. eridania* and that the decline of the system components in cotyledons as seedlings mature results in the observed declining defense of these tissues.

The dynamics of glucosinolate concentration in *B. juncea* cotyledons can be explained by a passive dilution with the expansion of young cotyledon tissues (our data, Bodnaryk and Palaniswamy, 1990). Thus, initial seed defense allocations apparently serve the tissue throughout its growth (Figure 3). This contrasts with conclusions of a similar study of glucosinolate dynamics in seedling *Brassica napus*, which also displays a rapid decline in seed glucosinolate concentrations in the first seven days of growth (Clossais-Besnard and Larher, 1991). These authors postulate that seedling glucosinolates are rapidly metabolized for subsequent plant growth, constituting a sink for carbon, nitrogen, and sulfur, serving two or more functions within the plant, aside from defense (see also Bones and Rossiter, 1996). The data presented by Clossais-Besnard and Larher (1991) do not permit examination for a possible passive dilution effect for *B. napus* seedlings.

Myrosinase activity levels did not decline as predicted by a passive allometric model, but remained somewhat elevated over expected levels, at a presumed

cost to plant fitness. Myrosinases occur in complexes and function using accessory components such as myrosinase-binding proteins and epithiospecifier proteins (Bones, 1990; Bones and Rossiter, 1996; Taipalensuu, 1996). During hydrolysis, an epithiospecifier protein (ESP) interacts with myrosinase to specify the reaction products of the glucosinolate–myrosinase interaction (Bones, 1990). *Brassica juncea* was found to have ESP activity (Cole, 1975). These accessory components must be accounted for in a quantitative analysis of the cost of defense. The elevation of myrosinase activity above allometric expectations could reflect changes in some of these associated factors, or through synthesis of additional myrosinase enzymes.

However they arise, levels of myrosinase activity above those expected from passive dilution may be adaptive for defense. 3-Indolylmethyl- and 4-hydroxy-3-indolylmethylglucosinolates can be induced approximately 3-fold and 1.5-fold, respectively, in *B. juncea* cotyledons (Bodnaryk, 1992). Myrosinase activity in *B. juncea* cotyledons is not induced by herbivory or mechanical damage (Byrne and Eigenbrode, unpublished data). Thus, the elevated levels of myrosinase activity in older cotyledons may complement these inducible glucosinolates in the event of pathogen or herbivore attack.

Our study on the dynamics of myrosinase and glucosinolates in *B. juncea* cotyledon tissue must be interpreted realizing that the test lines were developed from agronomic cultivars (Thiagarajah and Stringam, 1993) and that the greenhouse environment used for the test lacks some of the stresses likely to be important for plant growth and seed production in the field. Furthermore, our damage treatments do not model many types of herbivory, and feeding by different insects differs in its impact on plant fitness. Feeding by seven different insect species differed in its impact on seedlings of canola, *Brassica napus*, and mustard, *Sinapis alba* (Gavloski and Lamb, 2000). Nonetheless, tested patterns of defense allocation we have measured in *B. juncea* cotyledons appear qualitatively optimal.

Acknowledgments—We thank T. Mitchell-Olds for providing the myrosinase activity protocol and K. Falk for modifying it for our application. We also thank Q. Li for guidance during the project and S. Bentjen, M. Young, and C. Wallace for technical assistance. The manuscript was improved by critical reviews by G. Chang, H. Ding, P. Duetting, S. Emmert, C. Rutledge, J. McCaffrey, M. Morra, and D. Weaver. The research was supported by NSF/EPSCoR grant EHR 9350539 to the University of Idaho and was conducted as an undergraduate research project by S. K. W. (Received September 17, 2001; accepted October 22, 2001)

Abstract—Using a colorimetric procedure, we assessed the HCN-p of black cherry leaves (*Prunus serotina*) ingested by the eastern tent caterpillar, *Malacosoma americanum*, and the cyanide content of the bolus as it passed thorough the caterpillar's digestive tract and into the detritus pool. The mean HCN-p of leaves in our study area was 1902 ± 174 (SE) ppm. Young leaves found at the tips of growing branches, which the caterpillars preferred, had a significantly higher HCN-p (3032 ± 258 ppm) than older leaves found at the middle (1542 ± 243 ppm) or base of the shoot (1131 ± 159 ppm). Following a bout of overnight feeding on young leaves, the cyanide content of the foregut and midgut boluses of early sixth-instar caterpillars averaged 631 ± 161 ppm, and 14 ± 3 ppm, respectively, indicating that host-derived cyanide is rapidly depleted as the bolus transits the gut. Some cyanide, however, remains. In three studies, the mean cyanide content of fresh fecal pellets ranged from approximately 20 to 38 ppm, while the dried, compacted pellets ranged from 63 to 85 ppm. Food in the foreguts of mature caterpillars dispersing over the ground in search of pupation sites had 417 ± 99 ppm cyanide. The potential impact of this egested and caterpillar-transported cyanide on the consumer and detritivore communities is discussed.

Key Words—*Malacosoma americanum*, tent caterpillar, cyanide, *Prunus serotina*, black cherry, Lasiocampidae.

INTRODUCTION

During the spring of 2001, horse breeders in central Kentucky experienced an unprecedented loss of the current year's foals, a phenomenon that became know as mare reproductive loss syndrome (MRLS) (Kane and Kirby, 2001). After ruling out the involvement of infectious agents, a toxin was implicated and the investigators eventually focused on the possibility that the loss of foals was due to cyanide poisoning. The likely source of the cyanide was the black cherry tree *Prunus serotina*. Concurrent with the epidemic was a local population explosion of tent caterpillars, *Malacosoma americanum*, leading some to believe that the caterpillar was also involved in the problem (Kane and Kirby, 2001). Although reports of a link between the direct consumption of cherry leaves and the mortality of livestock have appeared in the scientific literature for over 100 years (e.g., Morse and Howard, 1898; Smeathers et al., 1973), there have been no studies implicating tent caterpillars in the process. Indeed, there have been no reports of any vertebrate suffering from cyanide toxicity after ingesting tent caterpillars or their fecal pellets. Nonetheless, *P. serotina*, a particularly cyanogenic species of cherry, is a favored host of *M. americanum* (Fitzgerald, 1995), and Peterson et al. (1987) showed that the defensive regurgitation of the newly fed caterpillar contained HCN derived from the cyanogenic precursor prunasin, which occurs in the leaves of the tree. When a leaf is mechanically damaged by a caterpillar, prunasin is converted to the cyanohydrin, mandelonitrile, which subsequently disassociates to form benzaldehyde and the toxin. The caterpillar itself is immune to ingested or inhaled cyanide and is presumed to detoxify it (Fitzgerald, 1995), but there have been no attempts to measure the amount of cyanide in the bolus as it passes through the digestive tract of the insect. Such information is particularly relevant to the possible involvement of caterpillar-transported or egested cyanide in MRLS, but it also has larger ecological implications because tent caterpillars may fall prey to small vertebrate predators, and the fecal pellets of the insects then enter the detritivore and decomposer food chains. We undertook the present study to determine the HCN-p of leaves of black cherry ingested by the eastern tent caterpillar, *Malacosoma americanum*, and the cyanide content of the bolus as it passed thorough the caterpillar's digestive tract and into the detritus pool.

METHODS AND MATERIALS

Study Site. The study was conducted during the spring and summer of 2001. Colonies of *M. americanum* and leaves of *P. serotina* used in the study were collected from various field locations in Cortland County, New York, as described below.

Chemical Analysis of Cyanide. Studies we conducted preliminary to our chemical assays indicated that the small samples we used (typically 3–6 mg)

could be efficiently and rapidly homogenized with a micro tissue-grinder (barrel length, 5 cm, barrel diameter, 0.3 cm) with no significant loss of cyanide. Although a previous study (Torres, et al., 1988) indicated that the most efficient extraction of cyanide from plant tissue occurs when the material is first ground to a powder in liquid nitrogen, test samples of leaves we processed with the micro tissue-grinder in our preliminary study had cyanide yields that were not significantly different from those we obtained by grinding the tissue in liquid nitrogen (paired t test, $T = -1.60$, $P = 0.15$, $N = 8$ pairs of leaf samples).

To prepare our samples for distillation, the material was placed in the bottom of the grinder and ground with 0.5 ml of 0.1 M phosphate buffer ($NaH_2PO_4 \cdot H_2O$, pH 6.8) (Brinker and Seigler, 1989, 1992) and chilled to approximately 4°C in an ice bath. The grinder was kept chilled up to the moment of grinding by parking it in another ice bath. The sample was ground until fully homogenized, a process requiring 5–10 sec depending on the nature of the material. The buffer was then transferred to the outer compartment of a Warburg flask (capacity = 18 ml), the center compartment of which was preloaded with a measured quantity of 1 M NaOH. The micro tissue-grinder was immediately rinsed with another 0.5 ml of chilled buffer, and the rinse was added to the flask. The flask was sealed and held in a temperature-controlled cabinet at 35°C for a minimum of 18 hr. During the distillation process, HCN volatilizing from the sample was trapped in the NaOH as nonvolatile CN^-. More detailed procedures for specific sample types (leaves, fecal pellets, and gut contents) are given below.

We used the colorimetric technique of Lambert et al. (1975) as modified by Brinker and Seigler (1989, 1992) to determine the quantity of cyanide in our samples. Briefly, an aliquot of the 1 M NaOH solution was transferred from the center well of the Warburg flask to a test tube, and the solution was adjusted to 0.1 M NaOH. Measured quantities of 1 M acetic acid sufficient to neutralize the NaOH, a succinimide–*N*-chlorosuccinimide oxidizing reagent, and a barbituric acid–pyridine coupling reagent were then added to the tube in succession. Following vortexing, the solution was allowed to develop for 10 min, and then the absorbance was read at 580 nm on a Spectronic 20 spectrophotometer. Standard curves relating absorbance to cyanide quantity were prepared following the procedures of Brinker and Seigler (1989).

Preparation of Samples. The HCN-p of variously aged leaves of *P. serotina* was determined. Vigorously growing branches, all bearing young expanding leaves at their apices were collected from three to five trees from four distinct field populations located in Cortland County, New York. Whole branches were cut from the trees, and the cut ends of the stems placed in containers of water to prevent wilting. Care was taken to collect no more branches at one time than could be processed within 1 hr of collecting to minimize the possibility that cutting the branch would induce the production of cyanide. A 3- to 6-mg section was cut from the blade of the youngest, partially expanded leaf located at the tip of the branch,

another from a leaf at the middle of the branch, and another from the oldest leaf found at the base of the branch. Sections were separately ground and sealed in Warburg flasks as described above.

It is not known if damage to cherry trees can induce the production of cyanide, as reported for other allelochemicals from other tree species. Since cutting branches necessarily involves some systemic disturbance, we conducted a preliminary study to determine the likelihood that our procedure induced cyanide production in our sample leaves. A young leaf from near the apex of a shoot was selected at random from a tree growing near our laboratory and cut in half with scissors. The cut half was taken immediately to the laboratory and a section excised, weighed, ground, and sealed in a Warburg apparatus as described above. Twenty-four hours later the half remaining on the tree was collected and treated in the same manner as the first half. To determine if this procedure induced cyanide production, we compared the cyanide content of the two halves. The experiment was replicated five times with leaves from different trees.

The cyanide content of food in the foreguts and midguts of fifth-instar caterpillars allowed to feed ad libitum overnight in the laboratory was determined. Caterpillars were maintained in colonies on wooden frames (Fitzgerald, 1995) and provided daily with freshly collected branches of *P. serotina*. The caterpillars of *M. americanum* are finicky feeders (Fitzgerald 1995), and care was taken to provide colonies with branches bearing the younger leaves the caterpillars prefer. Colonies were maintained at $21 \pm 2^{\circ}$C under a 10L:14D daylight fluorescent light regime with lights on at 08:00 hr. Caterpillars were collected from the colonies at 09:00 hr and immediately frozen. Samples of the bolus of the foregut and midgut were obtained for chemical assay by cross sectioning with a razor blade whole frozen caterpillars in the mid-thoracic and mid-abdominal regions. The bolus in the exposed gut was removed with a forceps. Dissection was carried out on a cold-table at approximately -10°C, allowing the bolus to be removed, weighed, and placed in the micro tissue-grinder while still frozen.

The cyanide content of the foregut bolus was measured at two different times to determine if loss of HCN occurs in this section of the digestive tract. Forty caterpillars maintained in a colony and allowed to feed ad libitum overnight, as described above, were collected at 09:00 hr. Half of the caterpillars were immediately frozen, the other half were placed individually in Petri plates and held without food until 16:00 hr, then frozen. The foregut was subsequently removed by allowing the cadaver to thaw to just above freezing, grasping it by the head, and pulling the head off and with it the attached foregut. This technique was used in preference to dissection because it produced a clean gut: the dense fat body that surrounds the gut of the sixth instar was left behind in the hemocoel. Once exposed, the gut was laid out on the cold table, cut at its junction with the midgut, a sample taken, weighed, ground, and sealed in a Warburg flask for distillation.

Full-grown sixth-instar caterpillars dispersing over the ground were collected over a nine-day period in early June from roadways at two different locations in Cortland County. Dispersal occurs when caterpillar are nearing pupation and in search of pupation sites (Fitzgerald, 1995). The caterpillars were frozen within 15–30 min of collection. The foregut was subsequently removed, weighed, and a sample taken for analysis as described in the preceding paragraph.

The cyanide content of fresh and dried fecal pellets was determined in three separate studies. For the first study, 15 fifth-instar caterpillars were housed overnight in Petri plates with fresh cherry leaves. In the morning, all food and fecal pellets were removed from the dishes and discarded. Fecal pellets produced by each of the 15 caterpillars over the next 2 hr were collected and frozen for later analysis. A separate group of 15 caterpillars was treated similarly, but the fecal pellets were allowed to dry for 4–6 hr after deposition before they were collected and frozen. Frozen pellets were subsequently placed directly in the micro tissue-grinder, ground, and their cyanide content collected by distillation in the Warburg apparatus. Because the cyanide content of the fecal pellet is small, sets of two pellets were used for each of the 15 replicates of each treatment.

In the above study, the fresh and dried fecal pellets were not weight-matched, and the data collected from the study could not be used to determine if the fecal pellets lost cyanide as they dried. Another study was conducted to examine this question. Following a bout of feeding, several hundred fresh fecal pellets produced by a whole colony of fifth-instar caterpillars were collected within 2 hr of egestion. A sample of 15 of these pellets was weighed, then allowed to dry at 30°C in the open for several hours. The pellets were reweighed after drying and the ratio of fresh to dry weight calculated. A second sample of weight-matched pellets from this same source was used to calculate the cyanide content of fresh and dry pellets. Fifteen sets consisting of two fresh pellets and 15 sets consisting of two dry pellets were assayed. ANOVA showed no significant difference between the initial mass of the fresh pellets in the two sets ($F = 0.0015$, $P = 0.96$).

In a third study, the cyanide contents of fecal pellets extracted directly from the rectums of frozen sixth-instar caterpillars collected from roadways while dispersing were determined as described above.

Although it would appear likely that all of the cyanide recovered from caterpillars and fecal pellets was produced from cyanogenic precursors found in the leaves of *P. serotina*, we set up a control study in which we assayed for cyanide in the foregut bolus and in fecal pellets of caterpillars reared on an acyanogenic variety of apple (*Malus*), which is a natural alternate host of the caterpillar (Fitzgerald, 1995). We used the same analytical procedures as outlined above for caterpillars fed the leaves of *P. serotina*.

Bioassay of Cyanide Toxicity. To assess the residual toxicity of host material processed by the caterpillar, we compared the knockdown power of HCN

emanating from macerated cherry leaves with that of HCN emanating from macerated fecal pellets. A gas chamber was prepared by gluing together the bottoms of two 50-mm × 9-mm tight-lid plastic Petri plates, then drilling a series of holes through the connected bottoms. Ten second- to third-instar nymphs of the milkweed bug *Oncopletus fasciatus* were placed in the upper section of the chamber and the chamber sealed with a top. Approximately 0.5 g of dried fecal pellets collected from under a colony of fourth-instar tent caterpillars fed young cherry leaves in the laboratory were ground with a mortar and pestle in 2 ml of the phosphate buffer. The slurry was poured into the top of a second Petri plate, spread into a thin layer, and the top used to seal the bottom section of the chamber. Thus, HCN emanating from the slurry in the bottom section of the chamber entered the section containing the bugs by passing through the connecting holes. The 10 bugs were observed continuously for the next 2 hr, and the time when individuals first collapsed was recorded. This procedure was repeated with a slurry prepared by grinding approximately 0.5 g of partially expanded terminal leaves and another slurry made from a basal leaf of approximately the same mass. We also observed the response of bugs sealed in a chamber changed with the phosphate buffer alone.

Statistics. All statistical tests were performed with Prostat or Sigmastat software.

RESULTS

The cyanide content of samples of 48 leaves of *P. serotina* collected from 16 trees is shown in Table 1. The mean cyanide content for all leaf samples collectively was 1902 ± 174 ppm. There was no significant difference in the cyanide content of the two halves of cut leaves removed from the tree at different times, indicating that the relatively minor disturbances to the leaves associated with collecting our samples for assay was unlikely to have had a significant influence on the cyanogenic potential of the leaves (paired *t* test, $T = 1.78$, $P = 0.15$). Although we found no

TABLE 1. MASS AND CYANIDE CONTENT OF *Prunus serotina* LEAVES FROM 16 TREES[a]

Location on branch	Leaves (N)	Leaf mass (mg)	Cyanide (ppm)	Total cyanide content of leaves (mg)
Terminal	16	52.7 ± 5.5	3032 ± 258	0.16 ± .02
Medial	16	600.0 ± 85.2	1542 ± 243	0.89 ± 0.17
Basal	16	327.4 ± 54.4	1131 ± 159	0.40 ± 0.11

[a] Leaves were collected June 20–27, 2001, from four locations in central New York State. Values are mean ± SE.

evidence of cyanide induction in leaves that had been mechanically severed, it remains to be determined if caterpillar feeding induces cyanide production.

All 20 of the foreguts of caterpillars allowed to feed ad libitum overnight on young cherry leaves and killed at 09:00 hr contained food. The midguts of 16 of these also contained food, but four others were empty and were not used in the analysis. The 20 foregut boluses contained 631 ± 162 ppm of cyanide. The 16 midgut boluses contained 14 ± 3 ppm of cyanide. The difference is highly significant (ANOVA, $F = 10.82$, $P = 0.002$).

A comparison of the mass and cyanide content of the foreguts of two groups of 20 caterpillars allowed to feed ad libitum overnight and killed at either 09:00 hr or 16:00 hr showed that the foregut and its food load had a mass equivalent to $12.5 \pm 0.1\%$ of the total body mass of those killed at 09:00 hr and $5.2 \pm 0.1\%$ of those killed at 16:00 hr. The difference is significant (ANOVA of arcsin $\sqrt{P}$ transformations, $F = 22.52$, $P < 0.001$). All but three caterpillars killed at 09:00 hr had food in their foreguts. Ten of those with full guts were randomly selected for analysis. Nine killed at 16:00 hr had completely empty foreguts, while only eight had sufficient food in the foregut for analysis. The cyanide content of the foregut boluses from caterpillars killed at 09:00 hr was 1059 ± 125 ppm and for those killed at 16:00 hr, 175 ± 46 ppm. The difference is significant, indicating that the depletion of cyanide occurs in the foregut (ANOVA, $F = 36.19$, $P < 0.001$). The presence of food in the foregut of some caterpillars that had not fed for at least 7 hr is consistent with a previous study showing that 6 hr after feeding, residual food remained in the foreguts of eastern tent caterpillars maintained at 23°C (Casey et al., 1988). The rate of food processing in tent caterpillars is temperature dependent, occurring most rapidly in larvae allowed to raise their body temperature by basking and not at all in caterpillars whose body temperature is less than 15°C.

Of the dispersing sixth-instar caterpillars collected from roadways, 5 were males and 25 females. The total body mass of the males was 0.67 ± 0.03 g and the females, 1.13 ± 0.03. Nine of the 30 caterpillars had empty foreguts. For the remainder, the mean mass of the foregut was 0.09 ± 0.01 g. On a percentage basis, the foregut of these 21 caterpillars constituted $11.1 \pm 0.1\%$ of their total body mass. The foregut boluses contained 417 ± 99 ppm of cyanide.

The fresh fecal pellets of one group of 15 caterpillars contained 37 ± 4 ppm of cyanide. The dry fecal pellets of another group of 15 caterpillars contained 86 ± 15 ppm of cyanide. The ratio of fresh to dry weight for fecal pellets collected from a whole colony following a feeding bout was 3.4. Fresh fecal pellets from this colony contained 21 ± 1 ppm cyanide, while dry pellets contained 63 ± 7 ppm. Based on these values, the ratio of cyanide in fresh to dried pellets was 3.1. When the total amounts of cyanide in the dry and fresh pellets was compared, there was no difference (ANOVA, $F = 2.09$, $P = 0.16$). This indicates that there is no significant loss of cyanide from the pellet during the drying process. Although the pH of the gut of the tent caterpillar is unknown, the guts of lepidopterous

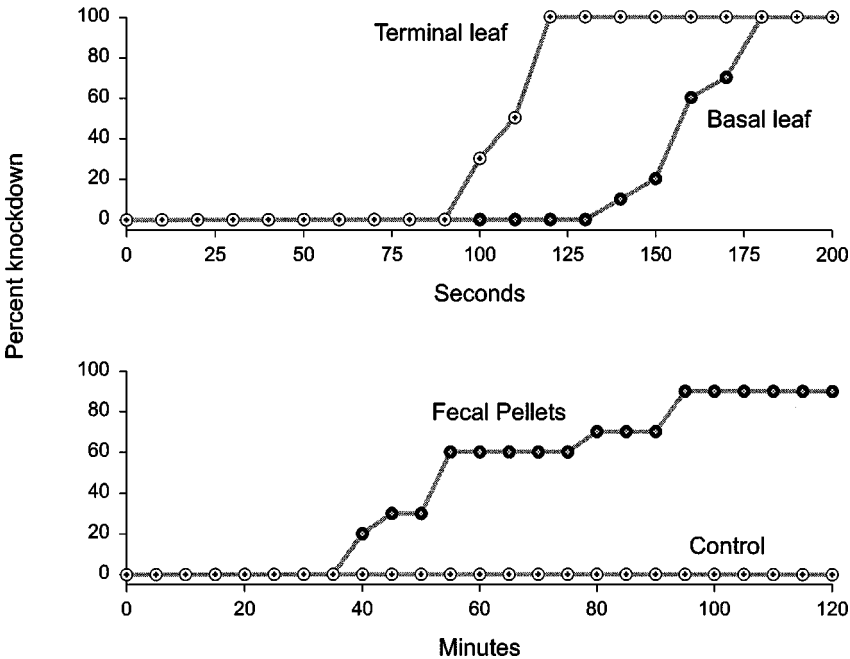

FIG. 1. Collapse of *Oncopeltus faciatus* nymphs in a gas chamber charged with slurries prepared from young or aged leaves of *Prunus serotina*, and from a slurry prepared from fecal pellets of *Malacosoma americanum* caterpillars reared on young leaves of *P. serotina*.

larvae typically have pH values of 8–12 (Chapman, 1998), and under such alkaline conditions, the HCN in the pellet or prepellet bolus should be converted to the relatively stable CN^-. It is also possible that pellets contain residual prunasin that is not converted to HCN until the pellet is homogenized. Fecal pellets taken directly from the rectum of 15 dispersing sixth-instar caterpillars had 19.8 ± 1.2 ppm cyanide.

The results of the bioassay with *Oncopeltus* is shown in Figure. 1. Consistent with our chemical analyses, knockdown took approximately 20–50 times longer when the bugs were exposed to a slurry of fecal pellets compared to slurries of leaves. Both the gut contents and the fecal pellets of tent caterpillars reared on *Malus* leaves were devoid of cyanide.

DISCUSSION

There have been several previous studies to determine the HCN-p of the leaves of *P. serotina*. Morse and Howard (1898) reported that in New Hampshire

the HCN-p of cherry leaves grouped into four classes, ranging from dry and woody to succulent, varied from 420 to 2120 ppm. Smeathers et al. (1973) indicated that the cyanide content of the leaves of *P. serotina* in Kentucky varied seasonally with an average 2472 ppm at the beginning of the season in April and 43 ppm at the end of the season in November, but that study provides no statistical measurement of variation. Peterson et al. (1987) sampled leaves on Long Island, New York. in May and June and found 1845 ± 154 (SE) ppm in young leaves and 1128 ± 202 ppm in mature leaves. Santamour (1998) reported that in Washington, D.C., from June to early September the HCN-p of *P. serotina* leaves was 2644 ± 236 (SE) ppm, but in November it declined to 209 ppm. He also reported that newly emerging leaves have an HCN-p of 7432, but gives no indication of sample size or variation. The broad variation in HCN-p found among and within trees in the present study (Table 1) is consistent with that reported in those studies. Aside from the singular measurement reported by Santamour (1998) for an emerging leaf, there have been no previous attempts to assess the HCN-p of the young tip leaves that eastern tent caterpillars prefer (Fitzgerald, 1995). Our study shows that these leaves are particularly cyanogenic. Under conditions of moderate infestation, these young leaves are likely to be completely harvested from a tree before the caterpillars turn their attention to the older leaves (Fitzgerald, 1995). During the first few larval stadia, the caterpillars are likely to subsist almost completely on these partially expanded leaves.

Our study shows that the amount of cyanide in the foregut bolus decreases over time and that food in the midgut is largely devoid of cyanide at the same time that cyanide is present in the foregut. These observations show that cyanide depletion increases with gut residency time. Although the results of our three studies indicate that the fecal pellets of tent caterpillars contain relatively small amounts of cyanide, the cyanide load of fecal pellets may vary more widely in caterpillars under field conditions. As shown by Casey et al. (1988), the rate at which food transits the caterpillar's gut and the rate of fecal pellet production are temperature-dependant processes. On cool, cloudy days, caterpillars process food slowly, and the bolus remains in the gut for an extended period. When the sun is available, the caterpillars bask and may achieve body temperatures approaching 40°C (Casey et al., 1988; Joos et al., 1988), causing food to transit the gut rapidly. The effect of such rapid transit on the cyanide content of egested material is unknown.

The mechanism by which the eastern tent caterpillar avoids the toxic effects of cyanide is unknown, but three mechanisms have been proposed for caterpillars in general. Rhodanese (thiosufate sulfur transferase) is commonly employed by animals to catalyze the conversion of HCN to thiocyanate (Conn, 1979). Rhodanese is widely distributed in insects, but its role in cyanide detoxification may be marginal to its role as a sulfur donor to proteins (Beesley et al., 1985). Although rhodanese occurs in only trace quantities in the larvae of *M. neustrium*, the

caterpillars are able to consume the highly cyanogenic leaves of *P. laurocerasus* (Parsons and Rothschild, 1964), suggesting that some other detoxification mechanism is involved. Studies by Witthohn and Naumann (1987) and Meyers and Ahmad (1991) indicate that detoxification of cyanide by L-3-cyanoalanine synthase may be the primary mechanism employed by insects. L-3-Cyanoalanine was found to occur in the adults of *M. neustrium* (Witthohn and Naumann, 1987), but it has not been looked for in the larvae of any species of tent caterpillar. Recently, Engler et al. (2000) reported that a species of tropical caterpillar metabolizes leaf cyanogens, preventing the release of cyanide in the body. The results of our study and that of Peterson et al. (1987), showing cyanide in the defensive regurgitations of the caterpillar, however, make sequestration an unlikely possibility in the tent caterpillar.

Eastern tent caterpillars leave their natal tree under two conditions—following premature defoliation of the host and when fully grown and ready to seek pupation sites (Fitzgerald, 1995). In the first instance, the caterpillars exhibit great reluctance to move off the host tree onto the ground. They repeatedly comb the branches of the tree in a fruitless search for food that may last for several days (Snodgrass, 1922; Fitzgerald, 1995). When the caterpillars finally leave the tree, their guts are almost certainly devoid of food. In the second instance, fully grown caterpillars that disperse in the sixth instar may carry cyanide-ladened food in their foreguts but, as our study shows, the total cyanide load is likely to be small.

Small amounts of cyanide survive transit through the gut of the caterpillar and are encapsulated in the fecal pellet. The fecal pellet undergoes dehydration and compaction in the rectum, so on a per-unit-mass basis, pellets are likely to contain more HCN than the midgut bolus itself. After deposition, the pellet dries rapidly and, again, on a per-unit-mass basis, its cyanide concentration increases. In addition to the HCN found in the fecal pellets as detected by our chemical assays, it is possible that the pellets may also contain unhydrolyzed cyanogenic glycoside, which may add to their toxicity in animals that have the ability to hydrolyze the glycosides after ingesting the pellet (Conn, 1979).

Our study shows that as leaf material passes from the tree to the caterpillar to the detritus pool, the cyanide content of the material is greatly reduced but not entirely eliminated. Although many organisms have some capacity to detoxify cyanide (Westley, 1973), it is not known whether the small amounts of cyanide that remain in the fecal pellet have any influence on consumers or detritivores. While the amount of cyanide per fecal pellet is small, colonies produce large quantities of pellets: approximately half of the energy ingested is voided as fecal pellets (Fitzgerald, 1995). However, the production of fecal pellets is likely to be relatively small if caterpillars abandon prematurely defoliated trees before achieving the last instar. A study of the related forest tent caterpillar (*M. disstria*), which may also feed on *P. serotina*, showed that approximately 82% of all the aspen

foliage consumed during the lifetime of the caterpillar was consumed by the last instar.

The oral LD_{50} of HCN for the mouse is 3.7 mg/kg (Sax and Lewis, 1989). In contrast to the small residue of cyanide in the fecal pellet, our study indicates that newly fed caterpillars may carry cyanide in their foreguts in quantities sufficient to poison small predators that are unable to neutralize the toxin. The most likely predators of eastern tent caterpillars are birds nesting in areas infested with colonies of the insect. Numerous studies have shown, however, that with few exceptions, birds reject tent caterpillars as a food source, after initially sampling them, because of their hairiness (Fitzgerald, 1995), but it remains a possibility that some find their way to nestlings. Unlike avian predators, small mammals, frogs, and toads that prey on insects are unlikely to climb trees to search for prey, but a naive predator might attack a sixth-instar caterpillar that is dispersing over the ground with potentially negative consequences. Small fish, too, might be poisoned from consuming recently fed tent caterpillars that have dropped into the water from nests in overhanging trees. Nothing is currently known of the fate of the fecal pellet after it reaches the ground, and it remains to be determined if the residual cyanide it contains has any significance for the small detritivores and decomposers that eventually attack it.

In addition to fecal pellets, colonies of caterpillars also send fragments of partially consumed leaves to the ground, but the quantities involved have not yet been measured. Moreover, it remains to be determined whether animals grazing under infested trees would consume the fallout of leaf fragments and fecal pellets along with grasses, and, if so, what influence the small quantities involved might have on them. Both Morse and Howard (1898) and Smeathers et al. (1978) found greatly reduced quantities of cyanide in dried leaves compared with fresh leaves. There have also been reports of tent caterpillars and fecal pellets dropping into water troughs, and it remains a possibility that some small amount of cyanide might be transferred to animals that drink from such troughs. Larger amounts of cyanide could potentially be transferred to grazers that ingested recently fed, dispersing caterpillars. Although it would seem most likely that grazers would reject the hairy and bitter caterpillars, the guts of some horses from areas experiencing MRLS were shown to contained the remains of caterpillars (T. Tobin, personal communication). Compared to the small amount of cyanide likely to be found in caterpillars moving over the ground, in the fallout under infested trees, or in water troughs visited by tent caterpillars, the highly cyanogenic leaves of cherry trees, or their small seedlings secreted among grasses, may pose a much greater potential threat to grazers and browsers.

Acknowledgments—We gratefully acknowledge the technical assistance of J. Battistia, R. Hazen, C. Liddy, I. Maffetore, and W. Mauck. L. Brattsten and T. Tobin provided helpful information during the progress of the investigation. C. Spink, B. Webb, A. Zipp, and two anonymous reviewers provided helpful comments on the manuscript.

Abstract—Goat feeding preferences for straw pellets flavored with ryegrass (*Lolium perenne*, cv. Belida) or white clover (*Trifolium repens*, cv. Huia) aromatic extracts, obtained by means of a cold aromatic extraction method, were assessed with cafeteria trials. Prior to the trials, odor differences between the two plant species, the two aromatic extracts, and the straw pellets sprayed with the two aromatic extracts were verified using sensory analysis performed by 30 human panelists. Since odor differences observed among fresh samples were still detectable in aromatic extracts and moistened pellets, the extraction method was considered effective in reproducing plant odors. Straw pellets sprayed with either distilled water (W) or ryegrass (R) or clover (C) aromatic extracts were used to assess flavor preferences of 12 female Rossa Mediterranea goats. Sprayed pellet preference was evaluated in two sessions conducted in two consecutive weeks. Each session consisted of three two-choice presentations performed on three consecutive days. In both sessions, food intake, proportion of food intake, time spent feeding, and proportion of time spent feeding were significantly affected by pellet type ($0.05 > P > 0.001$). In particular, straw pellets sprayed with ryegrass extract were highly selected compared to those sprayed with clover ($0.01 > P > 0.001$) or water ($0.01 > P > 0.001$). In addition, in the second session, the clover extract was preferred to distilled water ($0.05 > P > 0.01$). The results of this study gave two main indications: first, goat selectivity for ryegrass against clover was consistent even when straw pellets sprayed with odors of these plants were offered, and secondly, the addition of aromatic extracts to straw pellets increased the preference for pellets.

Key Words—Ryegrass, clover, goats, food preferences, flavor, aromatic extracts, cafeteria trials.

INTRODUCTION

In temperate grassland, goats actively select grasses over legumes. This results in increased clover content in goat-grazed pastures as compared with those grazed by sheep (Radcliffe and Francis, 1988; Bown et al., 1989; del Pozo and Wright, 1995). Lambs grazing after goats consume diets with higher clover content and show higher growth rates than those grazing after sheep (del Pozo and Wright, 1995). Goat selectivity for grasses as opposed to legumes is also consistent in short-term trials (De Rosa et al., 1997). Although levels of non-structural carbohydrates are equivalent between legumes and grasses, legumes contain a much lower proportion of water-soluble carbohydrate (Smith, 1973; Osbourn, 1980). The different dietary preferences observed in sheep and goats may be due to the fact that goats ingest plants with high non-structural carbohydrate content (Fedele et al., 1993), whereas plants with higher levels of secondary metabolites such as tannins, alkaloids, terpenes, and cyanogenic glycosides (e.g., legumes) are disliked (Narjisse, 1991; Morand-Fehr et al., 1993; Narjisse et al., 1996).

The forage preference is considered to be a function of taste, odor, texture (forage flavor), and postingestive effects on the animal (Provenza, 1995, 1996). Animals acquire preferences for nutritious foods and dislike foods with low nutrient content or high toxins levels (Provenza, 1995, 1996).

Goats learn to avoid condensed tannins from the current season's twigs of blackbrush (*Coleogyne ramosissima*) by associating the flavor of foods containing condensed tannins with aversive postingestive effects (Provenza et al., 1990). Sheep and goats appear to discriminate against monoterpenoid odor and taste, respectively, but this possibility has not been fully ascertained (Narjisse et al., 1996). Sheep regulate intake according to the flavor concentration of the feed, when flavor and toxicity are strongly correlated (Launchbaugh et al., 1993). In contrast, when they are not associated, animal intake relied on the maximum dose of toxin they had ingested (Launchbaugh et al., 1993). Sheep also more readily eat an unfamiliar feed associated with a familiar flavor or odor, whereas they avoid it when presented with a novel odor (Van Tien et al., 1998). Moreover, it has been shown that in sheep, hay palatability may be modified using different chemical compounds. The intake of wheaten hay was increased by the addition of butyric acid and monosodium glutamate, whereas it was reduced by MgO (Gherardi and Black, 1991; Gherardi et al., 1991). These results indicate that the flavor of the forage may play an important role in determining herbivore feeding preferences.

The present study aimed to evaluate the importance of flavor on feeding preferences of goats. We developed a cold aromatic extraction method for ryegrass

(*Lolium perenne*, cv. Belida) and white clover (*Trifolium repens*, cv. Huia) herbage that was effective in reproducing the corresponding plant's odor characteristics. Feeding preferences can be assessed by either long-term trials, comparing the proportion of a plant species in the diet as against its proportion in the sward, or cafeteria trials, directly testing preferences using two-choice presentations (Gordon, 1995). Goat feeding preferences for the aromatic extracts sprayed on straw pellets were assessed using cafeteria trials. The plants were chosen according to their different palatability as shown by Fedele et al. (1993) in field trials conducted in a Mediterranean grazing environment and by De Rosa et al. (1997) in cafeteria trials, who noted that ryegrass was highly selected, whereas clover was disliked by goats.

METHODS AND MATERIALS

Odor Differences between Ryegrass and White Clover. Prior to preparation of aromatic extracts from ryegrass and white clover, odor differences between the two plant species were verified using sensory analysis. Thirty human panelists, (students and staff members of the Department of Animal Production, University of Naples), were selected on the basis of their availability and motivation. Triangle tests were performed, offering each member two sets of three samples of herbage in the vegetative stage harvested just before use and chopped into 4- to 6-cm pieces. The weight of each sample was 30 g. Two samples were alike and one was different within each triangle test. Samples were presented in Teflon bags that lay on a layer of ice placed in Pyrex beakers to avoid olfactory bias and visual discrimination. Panel members were asked to identify the odd sample. Triangle tests were performed in a 25-m^2 room where the panel members were individually introduced to the person conducting the test. Three sessions of the triangle test were performed per panelist.

Preparation of Aqueous Aromatic Extracts. Samples from the two plant species were harvested and immediately frozen in liquid nitrogen in order to minimize degradation and/or transformation of odorous molecules. Frozen plants were powdered in liquid nitrogen and added to distilled water at 50, 100, or 200 g/liter. Powder and water were mixed for 48 hr at 4°C. Subsequently, the aqueous solution containing volatile components was centrifuged for 10 min at 7000 rpm and stored at −80°C until use. A sensory test was conducted to determine the concentration of the aromatic extract that most resembled the corresponding plant smell. Extracts were thawed overnight at 4°C and introduced in 50-ml flasks wrapped with aluminum foil. Human panelists were asked to associate, by sniffing, a series of different concentrations of aromatic extract (5, 10, and 20%) to the original plant species. For each plant species, panelists received three samples of extracts and a sample of corresponding herbage. Three sessions of this test (the similarity test) were performed. The panelists chose the 10% powder concentration for

both ryegrass and clover as most similar to the corresponding plant species (see Results). Therefore, this concentration was used for the successive experimental steps.

Subsequently, three triangle test sessions for aqueous aromatic extracts of ryegrass and clover were performed as described above to test whether odor differences between the two plant species were consistent in the corresponding aromatic aqueous solutions after the cold extraction.

Preparation of Samples Offered to Animals. Straw pellets are characterized by a low-intensity odor that is cosidered unlikely to interfere with the volatile components of an aqueous solution. Straw pellets are also known to be disliked by goats, so that any increase or decrease in consumption may be attributed to the effect of extract addition. Thus, the aromatic extracts to be offered to the goats were incorporated into straw pellets. Three sessions of triangular tests where the straw pellets were sprayed with ryegrass or clover aromatic extracts (50 ml of aqueous solution for 200 g of straw pellet) were performed.

Experimental Design. Twelve female Rossa Mediterranea goats were used in this experiment. The age and weight of the animals were 2–3 years and 35–45 kg, respectively. The goats were not pregnant or lactating, and all had previous experience of consuming both plant species.

The goats were equally divided into two groups and group-housed in two straw-bedded pens (4 $\times$ 2 m) with water available *ad libitum*. The animals were exposed to a three-week preliminary phase, during which they were offered straw pellets ad libitum in plastic baskets (50 $\times$ 34 $\times$ 15 cm) from 09:00 to 14:00 hr and, subsequently, mixed grass hay *ad libitum*.

In a subsequent two-week training phase, the animals were moved once a day into individual test pens (1.2 $\times$ 2 m) for 10 min where they received approximately 800 g of straw pellets in four plastic baskets placed in a wooden trough located 30 cm above floor level. An observer sat in front of each individual test pen to acclimate the animals to human presence. The goats in the adjacent test pens could not see each other. Thereafter, the animals were moved to the home pen where *ad libitum* mixed grass hay was offered. In the last two days of the training phase, straw pellets were sprayed with distilled water (50 ml/200 g).

Cafeteria Trials. During the preference tests, straw pellets sprayed (50 ml/200 g) with either distilled water (W) or ryegrass (R) or clover (C) aromatic extracts were used to assess goat flavor preference. The pellets were sprayed immediately prior to the start of the preference tests.

For each goat, sprayed pellet preference was evaluated in two sessions performed in two consecutive weeks. Each session consisted of three two-choice presentations conducted over three consecutive days. Two-choice presentations started at 09:00 hr and never continued past 12:00 hr. Five minutes before each presentation, the animals were moved to the individual test pens. The animals were offered two samples (sprayed pellets) simultaneously for 3 min in four adjacent

baskets (200 g/basket) filling all the through front. Two consecutive baskets contained sample 1 and two contained sample 2. On test days, each pair of samples (ryegrass–water, clover–water, and ryegrass–clover) was offered to four animals to avoid day effect. Three goats from the same group were simultaneously tested, always at the same time of day, with each animal getting a different pairing. Goats were used for only one two-choice presentation a day. Samples were assessed with the same frequency in each spatial (left–right) and temporal position (ryegrass–water, clover–water, ryegrass–clover), thereby minimizing the effects of position habits and order of presentation. Samples were weighed before and after each presentation in order to determine the total intake using an electronic digital scale. Six control baskets (two for each sample) were used to estimate the evaporative weight losses and the total intake was corrected accordingly. During the two-choice presentation an observer recorded feeding time (prehension time + mastication time) for each sample. For each session, the preference of the animals for each sample was determined by using the averages of time spent feeding, food intake, proportion of time spent feeding (time spent feeding on one sample/total feeding time), and proportion of food intake (intake from one sample/total intake) recorded in all the two-choice presentations where the sample was present (Morand-Fehr et al., 1987). After the two-choice presentations, the animal were moved to the home pen and fed with mixed grass hay *ad libitum*.

Statistical Analyses. Data were analyzed with a statistical package for social sciences (SPSS-PC+, version 3.1) (Norusis, 1989). Data obtained from human sensory evaluation were analyzed with the χ^2 one-sample test, where the expected frequencies of the odd samples (triangle tests) and of each concentration of aromatic extract (similarity tests) were 33.3%.

For the cafeteria data, the goat was used as the experimental unit. For each session of cafeteria trial, the variables collected (time spent feeding, food intake, proportion of time spent feeding, and proportion of food intake) were analyzed using the Friedman two-way analysis of variance by ranks test with pellet type (R, C, and W) as factor. When significant effects were recorded, the differences among the means were evaluated by the Wilcoxon matched-pairs signed-ranks test. The latter was also used to test session effect for each type of pellet.

RESULTS

Validation of Extraction Technique. Triangular tests performed on the two plant species, their aromatic extracts, and moistened pellets showed significant differences between clover and ryegrass odors ($P < 0.001$) (Table 1). Since odor differences observed between fresh samples were still detectable in aromatic extracts and moistened pellets, the extraction method can be considered effective in reproducing plant odors.

TABLE 1. DEGREE OF DISCRIMINATION OBSERVED DURING TRIANGLE TESTS OF RYEGRASS AND CLOVER OFFERED AS HERBAGE, AROMATIC EXTRACTS, AND SPRAYED STRAW PELLETS TO 30 PANELISTS

Sample	Comparison	Session	Proportion of correct responses	Significance[a] (P)
		I	0.83	<0.001
Herbage	ryegrass–clover	II	0.83	<0.001
		III	0.87	<0.001
		I	0.87	<0.001

		I	0.72	<0.001
Sprayed pellets	ryegrass–clover	II	0.75	<0.001
		III	0.80	<0.001

[a] χ^2 one-sample test; $df = 1$.

Similarity tests were conducted to evaluate the concentration of aqueous extracts that presented the odor closest to the corresponding plant (Table 2). Results indicated that a 10% powder concentration could be considered to be the most similar to the corresponding plant, since the choice of assessors for this concentration over the three sessions was 55.6% and 55.7% for ryegrass and clover, respectively ($\chi^2 = 7.02$, $df = 2$, $P < 0.05$ and $\chi^2 = 8.6$, $df = 2$, $P < 0.05$, respectively). Therefore, this concentration was used in cafeteria trials.

Cafeteria Trials. Food intake (Figure 1) was significantly affected by pellet type in both sessions ($\chi^2 = 6.5$, $df = 2$, $P < 0.05$ and $\chi^2 = 13.54$, $df = 2$, $P < 0.001$, respectively). In the first session, R consumption was higher than C and W

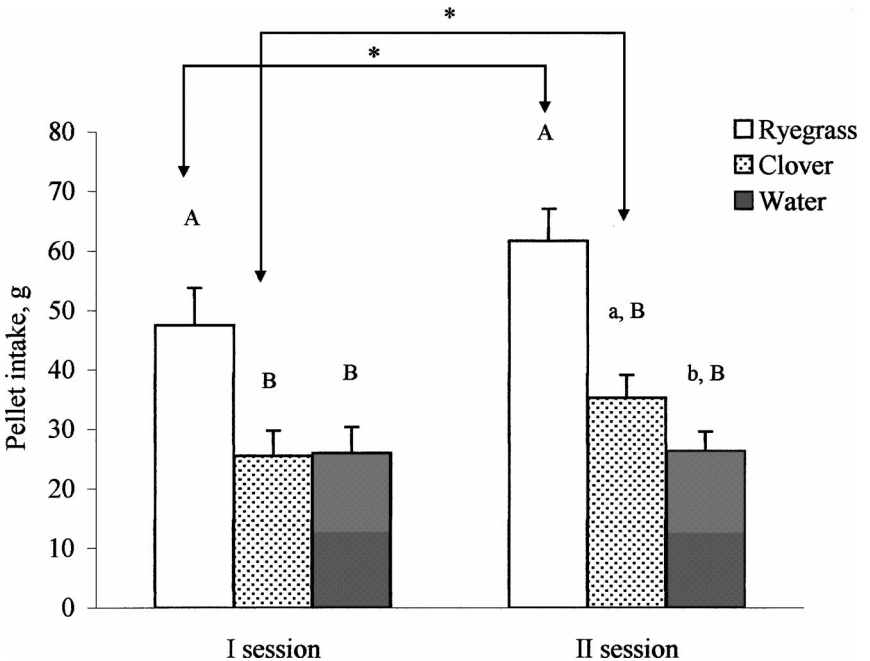

FIG. 1. Goat intake (mean + SE) of straw pellets sprayed with either distilled water or ryegrass or clover aromatic extracts in the two session cafeteria trial. A, B: means within sessions followed by a different letter are different at $P < 0.001$. a, b: means within sessions followed by a different letter are different at $P < 0.05$. $*$ means between sessions are different at $P < 0.05$.

($P < 0.001$). There was no difference between C and W. In the second session, goats showed a higher intake for R than for C and W ($P < 0.001$), as well as a higher ingestion of C than W ($P < 0.05$). A comparison between the two sessions showed higher intakes for R and C in the second trial ($P < 0.05$), but no differences between trials for W. Similar results were observed for the proportion of food intake except for the differences between trials (Figure 2).

For both sessions a significant effect of pellet type on time spent feeding ($\chi^2 = 6.5$, $df = 2$, $P < 0.05$ and $\chi^2 = 17.17$, $df = 2$, $P < 0.001$, respectively; Figure 3) was found. In fact, in the first session, the animals spent more time eating R than C and W ($P < 0.01$). There were no differences observed between C and W. In the second session, time spent feeding on R was higher than that spent on C and W ($P < 0.01$), whereas this variable was lower for W than for C ($P < 0.01$). A comparison between the two sessions showed higher levels of time spent feeding on W in the first session ($P < 0.05$). Accordingly, the proportion of time spent feeding showed a similar pattern (Figure 4).

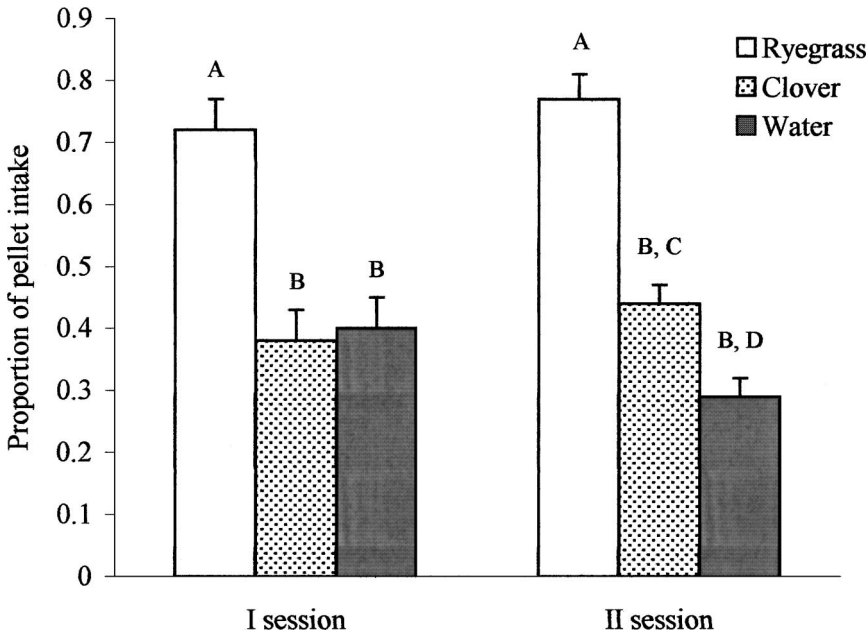

FIG. 2. Proportion of goat intake (mean + SE) of straw pellets sprayed with either distilled water or ryegrass or clover aromatic extracts in the two session cafeteria trial. A, B: means within sessions followed by a different letter are different at $P < 0.001$. C, D: means within sessions followed by a different letter are different at $P < 0.01$.

DISCUSSION

In this study, plant physical characteristics were removed by transferring the odorous molecules from ryegrass and clover to aqueous solutions. However, the aroma of the original sample extract may change during the extraction process and does not necessarily reproduce the characteristics of the original sample from which it was obtained (Moio et al., 1995). If such an odor distortion occurs during the preparation of extract, the aromatic aqueous phase offered to the animals may exhibit olfactory properties different from those of the original plant. Therefore, the first objective of this study was to develop an extraction procedure yielding extracts with odors close to those of the original plant. The results of sensory analysis indicate that the cold aromatic extraction technique from ryegrass and white clover may be effective in reproducing the corresponding plant odor characteristics. The importance of using a low temperature during the extraction process to attain a good representation of the extracts before sensory analysis has also been reported for wine (Moio et al., 1995), cheese, and tomato (Etievant et al., 1995).

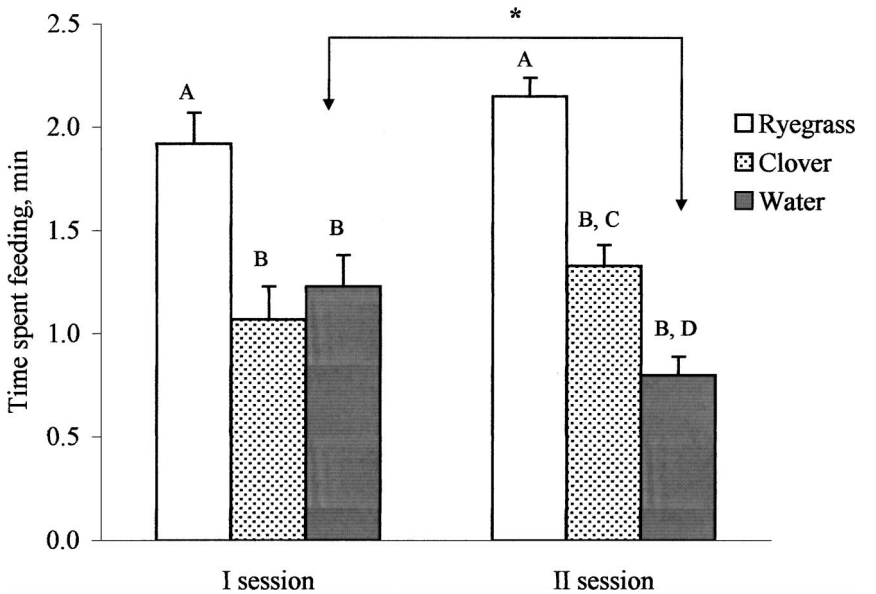

FIG. 3. Time spent feeding (mean + SE) by goats on pellets sprayed with either distilled water or ryegrass or clover aromatic extracts in the two session cafeteria trial. A, B and C, D: means within sessions followed by a different letter are different at $P < 0.01$. $*$ means between sessions are different at $P < 0.05$.

The results obtained in the cafeteria trials with the four dependent variables (time spent feeding, food intake, proportion of time spent feeding, and proportion of food intake) were generally similar. This study indicates that the addition of aromatic extract (ryegrass or clover) to straw pellets usually increased the preference for pellets. In particular, the intake of straw pellets sprayed with ryegrass extract was higher than those sprayed with water in both sessions, whereas for the clover extract this was observed only in the second session. These findings are in agreement with Provenza et al. (1996), who suggested that offering lambs the same food in different flavors influences food intake, as does offering different foods of similar or different nutritional value.

In field experiments, it has been found that ryegrass and white clover swards grazed by goats have more clover than those grazed by sheep (Penning et al., 1996; del Pozo et al., 1998). In a Mediterranean grazing environment, where the vegetation was exclusively herbaceous, Fedele et al. (1993) found that goats preferred grasses and had little interest in forbs and legumes. A preference for grasses over legumes was also confirmed in short-term trials (De Rosa et al., 1997). It has been suggested that goats prefer plants with high non-structural carbohydrate content (Fedele et al., 1993), whereas plants with higher levels of secondary metabolites,

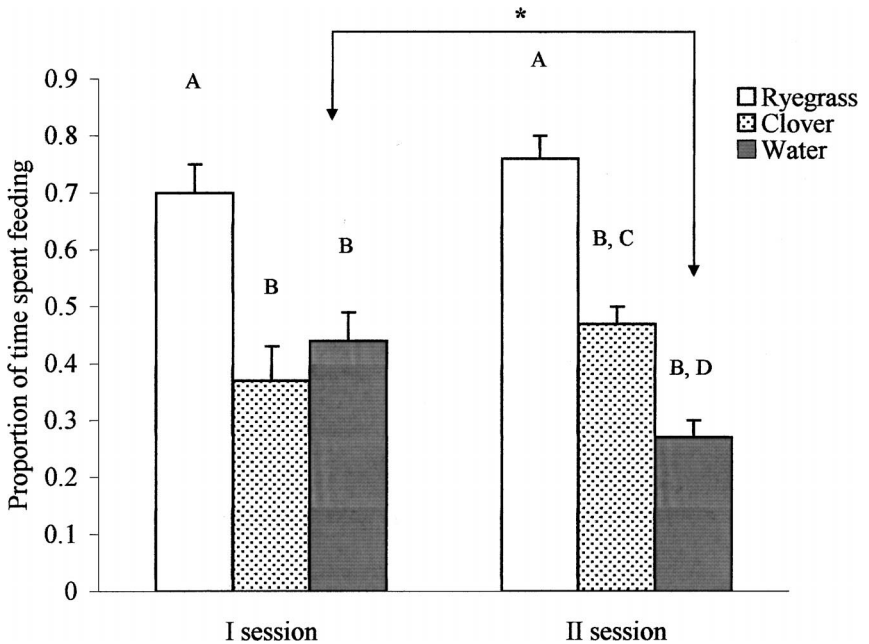

FIG. 4. Proportion of time spent feeding (mean + SE) by goats on straw pellets sprayed with either distilled water or ryegrass or clover aromatic extracts in the two session cafeteria trial. which are considered protective agents for plants against herbivores and pathogens (Provenza et al., 1988) such as tannins, terpenes, alkaloids, cyanogenic glycosides (e.g., legumes) are markedly disliked by goats (Narjisse, 1991; Morand–Fehr et al., 1993). In fact, removal of surface compounds with organic solvents increased tarbush (*Flourensia cernua*) intake by sheep (Estell et al., 1994), and terpenes on the leaf surface were related to diet preference (Estell et al., 1996). Accordingly, diet selection of goats was inversely correlated with tannins (Provenza and Malechek, 1984; Provenza et al., 1990). Goats were also able to taste monoterpenes (Narjisse et al., 1996) in pellets, and a positive (camphor) or negative (α-pinene, limonene) correlation between the content of these monoterpenes with juniper ingestion has been found (Riddle et al., 1996). Conversely, in lambs a detrimental effect of both camphor and α-pinene concentration on pellet intake has been reported (Estell et al., 1998). These findings are consistent with our results where the preference was higher for ryegrass extract than for clover, although the nutritional value of the two pellets was similar and the factor of plant physiological characteristics was removed. Therefore, only sensory cues (odor and taste) could be used by goats for

pellet discrimination, thus confirming that food flavor may play an important role in affecting goat preferences.

Food preferences depend on the functional interrelationship between flavor and postingestive effects of nutrients (Provenza et al., 1996). Animals discriminate among foods using taste, odor, and sight, which are a source of hedonic sensations (Provenza, 1996). They acquire preference for nutrients and for high levels of rapidly digestible nutrients and an aversion for toxins and foods deficient in specific nutrients (Provenza, 1995, 1996). It can be argued that in the present study goat selection was not based on postingestive effects, since short-term trials were performed. Thus, the data may reflect only the initial response of goats to the flavors of ryegrass and clover. The animals were exposed to these flavors after one week and the preference for ryegrass over clover was confirmed. The animals used in this study had experienced grazing in open rangeland, where they may have learned to associate a particular flavor with negative (or positive) postingestive effects in previous grazing activity. This hypothesis is supported by experimental evidence that young mammalian herbivores can still associate, even after as long as three years, negative (Burritt and Provenza, 1990; Distel and Provenza, 1991) or positive associations (Squibb et al., 1990; Distel and Provenza, 1991) with specific foods. It is likely that the goats generalized preferences and aversions to the flavored straw pellets on the basis of their past experiences with straw, clover, and ryegrass. Flavor generalizations have been demonstrated for food preferences (Ralphs et al., 1995) and food aversions (Launchbaugh and Provenza, 1993). This is especially likely to be the case given the limited amount of time the goats were tested. With more time and greater intake of the pellets, the postingestive effects of straw would likely have played a greater role in influencing food selection (Lawler et al., 1999; Villalba and Provenza, 2000). In addition, during the cafeteria trials, the goats ate limited amounts of the straw pellets, less than 50 g of each flavored pellet, and they were offered the foods briefly (3 min) on only six occasions. Food items that make up such a small part of the daily ration have relatively little postingestive influence on food preference (Villalba and Provenza, 2000).

Results from this study show that goat selectivity for ryegrass as opposed to clover is consistent, even when straw pellets sprayed with odors of these plants are offered. Further studies using gas chromatography–sniffing and gas chromatography–spectrometry analysis to determine the aromatic compounds responsible for grass–legume discrimination and preference are the next steps, because a better understanding of the mechanisms underlying food preferences may lead to strategies for altering diet selection.

Abstract—Floral scents often act as pollinator attractants. In the case of obligate and specific plant–pollinator relationships, the role of floral signals may be crucial in allowing the encounter of the partners. About 750 *Ficus* species (Moraceae) are involved in such interactions, each with a distinct species of pollinating wasp (Chalcidoidea, Agaonidae). Several species have been shown to release volatile compounds, but their role in pollinator attraction has rarely been simultaneously tested. We investigated the floral scents of four tropical fig species and combined chemical analysis with biological tests of stimulation of insects. Pollinators of three species were stimulated by the odor of their associated fig species and generally not by the odor of another species. The fourth actually comprised two distinct varieties. The main compound was often a different one in each species. Floral blends of different species always shared compounds, but ratios of these compounds varied among species.

Key Words—*Ficus*, Moraceae, volatile compounds, mutualism, fig wasps, bioassays.

INTRODUCTION

Floral scents are supposed to have evolved from herbivore deterrents (Pellmyr and Thien, 1986) and to act as pollinator attractants in numerous species (Williams

and Dodson, 1971; Groth et al., 1987; Dobson, 1994). Their chemical composition has often been studied (Pellmyr et al., 1991; Bergström et al., 1992; Moya and Ackerman, 1993; Pichersky et al., 1994; Bestmann et al., 1997), but the role of these odors in pollinator attraction has rarely been tested (but see Roy and Raguso, 1997). *Ficus* species (Moraceae) interact with their pollinators (Chalcidoidea, Agaonidae) in a species-specific mutualism, where each partner needs the other to reproduce (Janzen, 1979; Wiebes, 1979). Each pollinator species is associated with a single *Ficus* species. In this obligate and specific relationship, encounter with the partner is a crucial step, and recognition signals, thus, play an important role. *Ficus* species mainly live in tropical regions, and many species can cooccur in the same forest. In these regions, the density of individual species is often quite low. Therefore, signals emitted by a species must be efficient at long distances and specific, to allow the attraction of the associated pollinator. In several of the 750 *Ficus* species, figs have been shown to release volatiles when they are receptive (i.e., at the stage when pollination can occur) (Barker, 1985; Van Noort et al., 1989; Ware et al., 1993; Hossaert-McKey et al., 1994; Ware and Compton, 1994; Harrison, 1996; Gibernau et al., 1998; Grison et al., 1999). Biological tests have been performed with three species (*F. burtt-davyi*, *F. thonningii*, and *F. carica*), confirming for these species the role of fig scent in insect attraction (Van Noort et al., 1989; Hossaert-McKey et al., 1994; Ware and Compton, 1994; Gibernau et al., 1998), either with figs enclosed in bags (in these cases compounds were not identified), or with pentane extracts. In this work, we used a combination of biological tests with volatile compounds present in the fig headspace and performed chemical analysis of this blend. To our knowledge, this is the first time that tests have been performed on fig pollinators with volatile blends of known composition. Our aim was to investigate, in several tropical species, the role of fig scent in pollinator stimulation and in the specificity of the fig–fig wasp interaction.

METHODS AND MATERIALS

Study Species and Site. We studied four tropical fig species in Brunei (on the island of Borneo). For each species, odor released by receptive figs was collected and analyzed, and biological tests were performed. As often as possible (depending on wasp availability), tests were also done with pollinators of other fig species.

Figs are urn-shaped inflorescences, closed by imbricate covering bracts, forming the ostiole. Half of all fig species are monoecious, the other half gynodioecious. In monoecious species, when the inflorescence is receptive, it attracts females of a specific agaonid species, which enter the fig through the ostiole, lay eggs, and pollinate. Seeds and pollinators develop inside the fig. Several weeks later, male flowers inside the fig produce pollen and, at the same time, pollinators exit their galls and mate inside the fig. Female wasps will then leave the fig, loaded with

pollen grains. During this phase, they have to find a new fig of their associated species, in the receptive phase, to lay eggs. Because of the synchrony of figs on the same tree, pollinators have to fly away from their natal tree in order to be able to find a receptive fig. Their short life-span (2-3 days) (Kjellberg et al., 1988) makes this step critical for the accomplishment of their life cycle [see Janzen (1979) and Wiebes (1979) for more details on the fig–fig wasp cycle]. In gynodioecious species, female trees produce seeds, and hermaphrodite trees (which are functionally male) produce pollen and pollinators (Janzen, 1979; Kjellberg et al., 1987). In these species, as well, upon their exit from the natal fig, female wasps must fly away to find a new receptive fig. They may visit figs on either male or female trees.

Mature and secondary rainforests in Brunei contain 80 *Ficus* species (Corner, 1965). This study involved four of them (Table 1). Three are dioecious: *F. fulva*, *F. deltoidea* (both subgenus *Ficus*; associated pollinators: *Blastophaga compacta* and *Wiebesia* sp., respectively), and *F. condensa* (subgenus Sycomorus, associated pollinator: *Ceratosolen constrictus*), and one is monoecious: *F. microcarpa* (subgenus *Urostigma*; associated pollinator *Eupristina verticillata*). *Ficus fulva* and *F. condensa* are small trees, living in secondary forests (often along riverbanks for *F. condensa*) or in forest understorey (Corner, 1965). *Ficus microcarpa*, a banyan tree, is a hemiepiphyte found in the forest canopy or in mangroves. *Ficus deltoidea* can be found in the forest as an epiphyte, but the individuals studied here grow as shrubs in sandy soil.

Collection and Analysis of Volatile Compounds. Volatile compounds released by figs were collected by adsorption–desorption (headspace technique) (Turlings et al., 1991; Grison et al., 1999). Because of the necessity to obtain concentrated extracts, collections were not performed in situ. Branches bearing figs were cut and leaves removed (to prevent dehydration due to transpiration). They were then put in a bag with wet paper sheets during the transportation, which never lasted more than 90 min. For odor collection, branches were enclosed in polyethylene terephthalate (Nalophan) bags, which have been shown not to release volatiles, and put in a water-containing vase. Airflow was maintained through the bag by

TABLE 1. SPECIES AND SITES[a]

Species	Site	Latitude (°N)	Longitude (°E)
F. fulva female	Bandar Seri Begawan (museum and city)	4.9	114.9
	Labi Road	4.7	114.3
F. fulva male	Jalan Muara	5	115
F. condensa male	Bandar Seri Begawan (museum and city)	4.9	114.9
	Jalan Muara	5	115
F. deltoidea male	Tutong	4.7	114.3

[a]All sites were disturbed by human activity.

two pumps. Entrance and exit flow rates (controlled by flowmeters) were 400 and 300 ml/min, respectively. The bags were then pressurized so that pollution by external air was prevented. At the entrance of the bag, air was purified in a charcoal filter. At the exit, it went through a Porapak Q trap (25 mg, 80–100 mesh), where compounds were adsorbed.

Collection lasted 5–8 hr. Empty bags and bags containing branches without figs were used as controls. For each species, several collections were performed, depending on the fig phenology (*F. fulva* female: 10 samples, with figs from 3 trees; *F. fulva* male: 2 samples, with figs from 1 tree; *F. condensa* male: 18 samples, with figs from 9 trees; *F. deltoidea* male: 3 samples, with figs from 3 trees; *F. microcarpa*: 5 samples, with figs from 3 trees). During the period of our study, because of the tree phenology, collections of odors from female figs of *F. condensa* and *F. deltoidea* could not be performed. During the collections, numbers (mean $\pm$ SD) of figs in the sample were: for *F. microcarpa*, 950 $\pm$ 531 (mean $\pm$ SD diameter of figs 5.6 mm $\pm$ 0.6), for *F. fulva*, 415 $\pm$ 220 (diameter 12 mm $\pm$ 1.6), for *F. condensa* 255 $\pm$ 116 (diameter 15 mm $\pm$ 2.2) and for *F. deltoidea* 143 $\pm$ 126 (diameter 11 mm $\pm$ 3.6).

Compounds were eluted from Porapak Q with 150 μl of dichloromethane and stored at -20°C until used for chemical analysis or biological tests. Solutions obtained were either used for biological tests (see below) or combined to form a more concentrated solution (one per species) that was analyzed with a gas chromatograph–mass spectrometer (GC: Hewlett-Packard, MS: HP 5870; FID, column DB-5, 30 m, 0.25 mm ID, film thickness 0.25 μm, carrier gas: helium, oven temperature program: 50–180°C, 3°C/min). Noncombined solutions were not concentrated enough for GC or GC-MS analysis. Percentages of compounds in the scent are given on the basis of the chromatogram obtained. Component identification was based on computer matching with Wiley 138 and NBS 75K libraries and on GC retention times. Retention indices were calculated and compared to those in the literature (Adams, 1989). Unknown compounds were identified with a MS library. *Ficus fulva* male scent was not abundant enough to be concentrated and analyzed by GC-MS, and was entirely reserved for bioassays.

Bioassays. For biological tests, mature figs were collected before wasp emergence and kept in a cloth bag at ambient temperature. Emergence of pollinators occurred the same day or the following one, and experiments took place at that time. A drop (1.5 μl) of solvent (dichloromethane) or volatile sample (compounds collected by the headspace technique, in a solution with dichloromethane) was deposited on the top of a glass marble (15 mm diam.). The size of the marble overlapped with fig size, except for *F. microcarpa*, but the results suggest that the size of the marbles did not matter. After 1 min of solvent evaporation, a newly emerged pollinator was deposited on the marble. The length of time it stayed on the marble was recorded (with a maximum time of 10 min, after which the experiment was stopped; pollinators appeared to make their decision before that time),

as an estimate of the stimulation of the insect by the solvent or solution. The term "stimulation" will be used throughout this text as a synonym for the "arrestment" of the insect on the marble, during the time when it wanders and antennates on the surface of the marble. Pollinators attracted to a fig arrive on it, and then, if they are stimulated, they wander on the surface around the ostiole, sweeping it with their antennae for some time before they enter it. If not stimulated, they generally fly away quickly (Gibernau et al., 1998). Thus, the stage tested was the stimulation of the insect once on the fig (and not the attraction at a distance). For each marble, the solvent and then, with another insect, the volatile sample were tested. These bioassays were done outside to prevent contamination of air by previous experiments and to provide pollinators with appropriate temperature and humidity conditions.

Data were analyzed using Mann-Whitney rank-sum tests. For each species, series of control times were compared to series of assay times. Two-tailed probability values were considered. We used the Genmod procedure from the SAS statistical package (SAS, 1999) to test for the effect of the date of the experiment, and no effect was found (*F. fulva*: $F = 0.27$; $P = 0.95$; *F. condensa*: $F = 0.26$, $P = 0.97$; *F. deltoidea*: $F = 0.02$, $P = 0.88$; *F. microcarpa*: $F = 0.89$, $P = 0.35$). Biological tests performed with different volatile samples of the same species and with the same pollinators were, therefore, analyzed together (series of tests performed at different dates were pooled together). Bioassays were performed with volatile samples from male and female *F. fulva*, and male *F. microcarpa, F. deltoidea*, and *F. condensa*, with their associated pollinators. Cross-tests were also done with samples of volatiles from female *F. fulva*, male *F. microcarpa* and *F. condensa*, and pollinators associated with the other two species.

RESULTS

Bioassays showed that the pollinators remained longer on marbles that had received samples of volatiles from their host species than on controls ($P < 0.01$), for *F. condensa, F. microcarpa*, and *F. fulva* female (Figure 1a). Tests with volatile samples from *F. fulva* male ($P = 0.102$) and *F. deltoidea* ($P = 0.850$) were not significant. Durations of the stay on the marbles were highly variable. For the significant tests, durations (mean $\pm$ SD) on the marbles were 18 sec $\pm$ 57 and 74 sec $\pm$ 124 for the solvent and the samples, respectively. Cross-tests performed with samples of volatiles and pollinators of *F. microcarpa, F. fulva*, and *F. condensa* were not significant, except for the test with samples of volatiles from *F. fulva* female and pollinating wasps associated with *F. microcarpa* ($P = 0.002$) (Figure 1b).

For each species blend, 23–53 peaks were visible on the chromatogram. Among these, 89–100% were identified (for the less abundant compounds, identification was sometimes not possible). The identified volatile compounds released

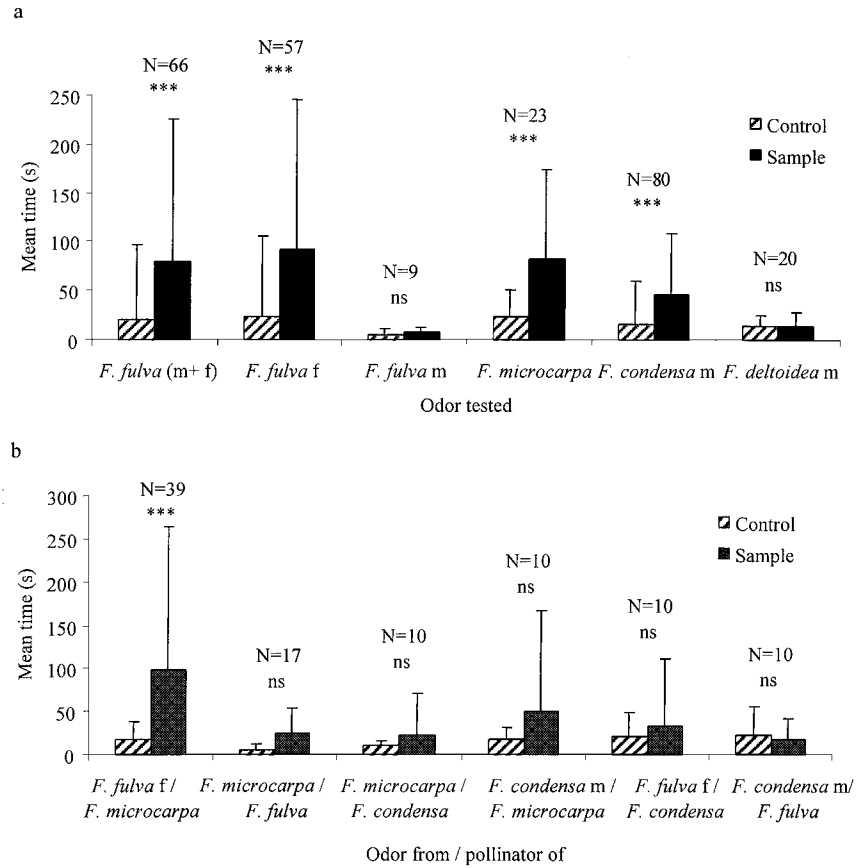

FIG. 1. Species-specific and crossed bioassays were performed with solutions of volatile compounds collected in the headspace of receptive figs of four tropical species (*F. fulva*, *F. condensa*, *F. microcarpa*, and *F. deltoidea*) and with fig pollinating wasps. The results and statistical analyses (Mann-Whitney two-tailed probability) are shown: (a) species-specific tests; (b) cross-tests (odor from one fig species tested with pollinator of another fig species). m: male, f: female, N: number of assays, ns: not significant, $^{***}P < 0.01$. *Note*. maximum time is 10 min.

by receptive figs from the four species mainly belonged to four chemical families: monoterpenes, sesquiterpenes, benzenoids, and aliphatic compounds. Each species blend comprised 9–16 compounds with an abundance greater than 1%, the total abundance of these compounds representing 90–96% of the blend. In each blend, one compound (or few compounds in the case of *F. deltoidea*), most of the time a sesquiterpene, was far more abundant than the others (Figure 2). These main

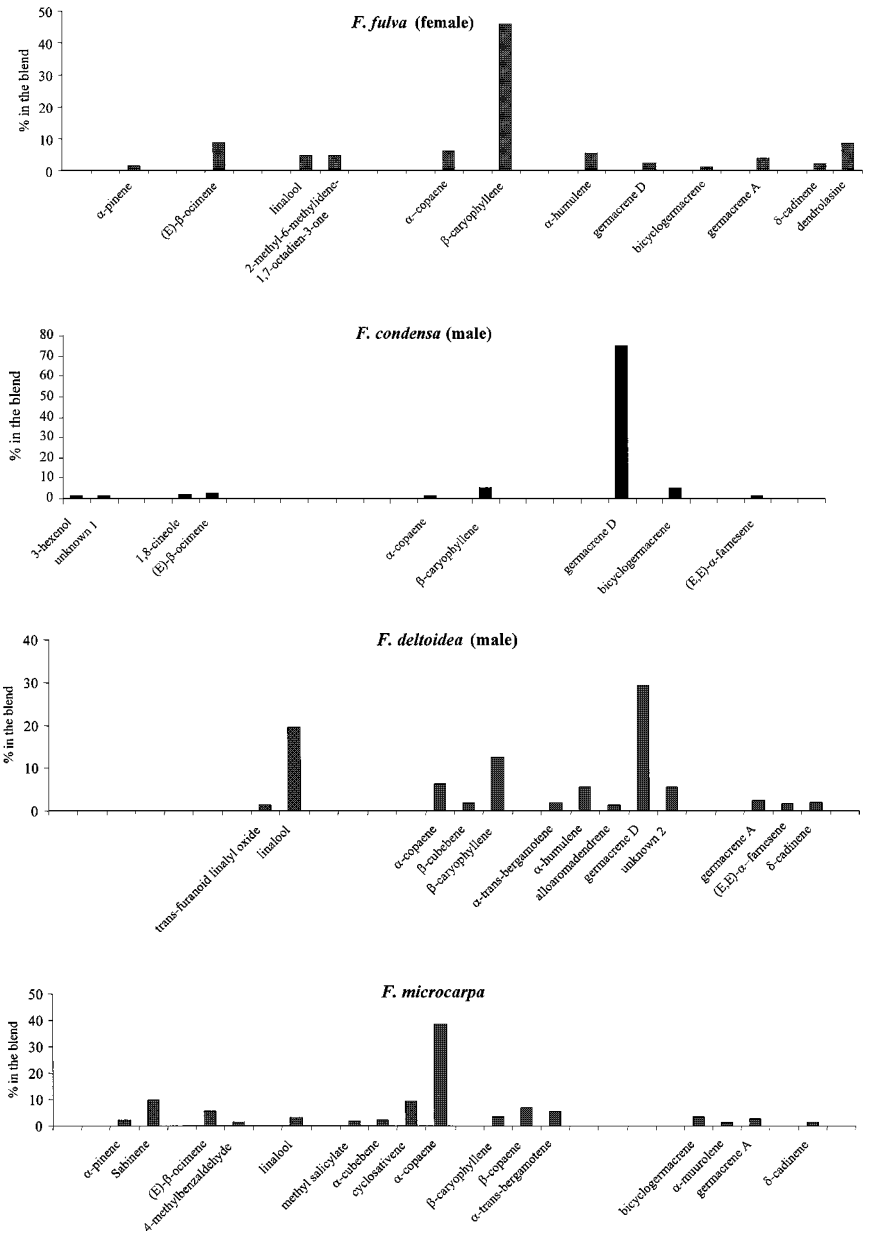

FIG. 2. Chemical composition of the scent present in the headspace of four tropical *Ficus* species: *F. fulva*, *F. condensa*, *F. microcarpa*, and *F. deltoidea*. Only compounds with an abundance >1% are represented.

compounds were β-caryophyllene in the *F. fulva* (female) blend, α-copaene in the *F. microcarpa* blend, and germacrene D in the *F. condensa* blend. In the case of *F. deltoidea* (male), linalool, germacrene D, and β-caryophyllene were the most abundant compounds in the fig fragrance. Most of the compounds were shared by two or more of the four species studied, but the composition of each species blend was unique (Figure 2).

DISCUSSION

Chemical Composition of Fig Floral Blend. Composition of the blend of *F. fulva* female was similar to that found in our previous study (Grison et al., 1999). In that study, we only identified linalool, β-ocimene, α-copaene, β-caryophyllene, α-humulene, and β-selinene. The first five compounds were present in the sample studied here, and we identified several additional compounds. This is probably due to differences in concentrations: the previous samples were less concentrated, and the sensitivity of the GC-MS did not allow us to identify some minor compounds. Odors from *F. condensa* (male) and *F. microcarpa* have different compositions from those found in our previous work, because the compounds identified then (Grison et al., 1999) were not present in the scents collected in this study. The previous collections also were done in Brunei, but during the drought, due to El Niño in May 1998. The situation for fig trees at that time was unusual, because pollinator populations were absent from the site when the study took place (Harrison, 2000). They came back only several months later [pollinators of *F. condensa* were first seen in the beginning of November 1999 (S. Patiño, personal communication)]. In the absence of pollination, figs seemed to stay receptive for two to three weeks, until aborted.

During the first study, collections were performed on morphologically receptive figs, but since no biological tests could be performed, it was not possible to determine if these figs were truly still receptive. Moreover, volatile emissions during this period may have been affected by the drought. Leaf fall frequently occurred, and even some figs pollinated before the drought aborted (E. Jousselin, personal communication). These data suggest that an environmental stress might have an impact on fig blend composition, and we cannot exclude the hypothesis of a high intraspecific chemical variability. This is highly improbable, however, because in this case, it would be difficult to understand how pollinators could recognize their partner. Some results on *F. carica*, the edible fig, indicate variability among trees in the proportions of the compounds present in the blend but strong similarities in the identities of the compounds of the blends (Grison-Pigé et al., 2001). Additional experiments in years when pollinators are present (such as in the present study) should help to answer the question of the influence of the drought

on fig scent in 1998 and explore the intraspecific variability of the scent of these tropical fig blends.

Specific Stimulation Induced by Floral Blend. The tests of contact stimulation with the associated pollinators were generally significant, even if the length of time that insects stayed on the marbles was variable. Pollinators of *F. fulva*, *F. microcarpa*, and *F. condensa* were clearly stimulated by the odor released by receptive figs of their mutualist. The substances we examined led to an arrestment response of the wasp: the insect stopped, antennated, and flew away after a while. Tests with *F. fulva* male scent showed a nonsignificant trend in the same direction. Solution of this scent was not abundant enough to allow more repetitions. Since compounds in the solution are volatile and since we showed in this study that they have an effect on their associated pollinating wasps, they might also be involved in long-distance attraction of insects. In this study, we did not attempt to distinguish between contact chemoreception and olfaction. Tests of attraction of pollinators at a distance, with a four-branched olfactometer (Vet et al., 1983) or using odor traps, are in progress to examine this. Previous studies with the *F. carica–B. psenes* system (Hossaert-McKey et al., 1994; Gibernau et al., 1998) showed that the same blend was responsible for the attraction of the pollinators of *F. carica* at long distance and for their stimulation once on the fig surface. Gibernau (1997) showed that the same three compounds are responsible for the insect reaction, at both steps. Van Noort et al. (1989) showed that pollinators of *F. burtt-davyi* were attracted to receptive figs by volatile chemical signals, as did Ware and Compton (1994) with pollinators of *F. thonningii*. Thus, data on several species from subgenera *Urostigma* (sections *Americana*, two species, *Conosycea*, one species and *Galoglychia*, two species), *Ficus* (section *Ficus*, subsections *Ficus*, one species, and *Eryosycea*, one species) and *Sycomorus* (one species) show that wasps are receptive to volatile chemical signals released by receptive figs of the appropriate species, at one or both of the two steps of pollinator arrival: distance attraction and stimulation once on the fig. Hence, in three of the four subgenera of genus *Ficus* [morphology (Berg and Wiebes, 1992), molecular phylogeny (Weiblen, 2000)], chemical stimulation of the specific pollinators, sometimes at long distance, has been demonstrated. This suggests that the importance of chemical signals as mediators of the encounter of the two partners is characteristic of the genus.

Tests performed with scent from figs of *F. deltoidea* were not significant. This could be due to the existence of different varieties that were identified in our sample of the species. Fig size and shape differed among individuals. These varieties could constitute good species. Indeed, our sample seemed to come from two different varieties (*F. deltoidea* var. *arenaria* and var. *borneensis*) that are pollinated by different wasp species (F. Kjellberg and J.Y. Rasplus, personal communication). A similar situation was observed by Bergström et al. (1992) on lady's slipper (*Cypripedium calceolus*, Orchidaceae), where three intraspecific taxa exist.

They are pollinated by different species of bees and emit different odors. However, these taxa are geographically distinct, whereas in the case of *F. deltoidea* the different morphs can be found at the same site. Thus, in the case of *F. deltoidea*, the two morphs are probably already reproductively separated, whereas in the case of *Cypripedium calceolus*, this speciation is presumably in process. In the genus *Narcissus* (Amaryllidaceae), Dobson et al. (1997) observed that one species could include different chemotypes, in relation with different major pollinators. Unfortunately, odors of the different morphs of *F. deltoidea* were not analyzed separately, because of the necessity to combine samples to have concentrated extracts for GC-MS analyses. Comparisons of the scents would be interesting, in order to test the hypothesis of the existence of chemotypes in this species or of sibling species in which differential pollinator attraction plays a role in reproductive isolation.

Specificity of Interaction. Crossed bioassays were performed with odors shown to be active on the specific pollinator (Figure 1). Odors of the species studied often shared several compounds (Figure 2), but in five of the six cross-tests performed, pollinators were not stimulated by the floral blend of a species other than their associated one. This suggests that several compounds of the blend contribute to the signal. Two nonexclusive hypotheses can be advanced. The first one is that not only are the identities of the molecules important, but also that their ratios must be part of the scent specificity. This was previously shown by Nordlander et al. (1986) on weevil attraction by pine volatiles and Roseland et al. (1992) on weevil attraction to the sunflower and was discussed by Visser (1986). The second one is that some compounds may be below the threshold of the GC-MS detection but may be responsible for wasp stimulation. This would reveal a keen coadaptation between the partners of the interaction (Guerin and Städler, 1982; Baur and Feeny, 1995). Which one of these hypotheses applies here has not yet been determined, and further bioassays are needed. This first experiment confirms the role of the chemical signal, which allows the specificity of the encounter, thus maintaining the association. To determine which step(s) (distance attraction or contact stimulation of the insect) guarantees in natura the specificity of the encounter, other types of bioassays are needed, for example, with a four-branched olfactometer (Vet et al., 1983). The role of fig scent as specific attractant of pollinators has been suggested by Van Noort et al. (1989) for *F. burtt-davyi* and by Ware and Compton (1994) for *F. burtt-davyi* and *F. thonningii*.

Odors are considered to contribute to reproductive isolating mechanisms in the genus *Catasetum* (Orchidaceae), where species having a specific odor also have a specific pollinator (Hills et al., 1972). In *Cimicifuga simplex*, evolution of the composition of the scent can be considered as an adaptation to pollination by a new guild of pollinators under variable environmental conditions (Pellmyr, 1986; Groth et al., 1987). In such a system, pollination morphs would probably evolve to distinct species. For one of the six tests (odor from *F. fulva* and pollinators of *F. microcarpa*), a significant difference was observed between the times the insects

stayed on the control and the sample-treated marbles (Figure 1). Pollinators of *F. microcarpa*, thus, seem to be at least somewhat stimulated by odor from *F. fulva* figs. This could be an effect of the common compounds of the scents of the two species: they share 8 of the 13 and 15 compounds (of abundance $>1\%$) constituting their respective odors. Other tests on receptive figs are necessary to determine whether this stimulation is strong enough to induce the insects to enter the fig and lay eggs inside. These two species belong to different subgenera and do not have the same natural habitats, but they can be found at short distances from each other (a few hundred meters, for example, in the city). At the moment, our observations in the field do not suggest that this breakdown of specificity really occurs. Breakdowns of specificity, however, have been observed for several *Ficus* species (Compton, 1990; Gibernau, 1997). Odors were not analyzed in studies of these breakdowns, but it would be interesting to compare them for a better understanding of the limits of their role as isolating mechanisms. These cross-tests were performed with species belonging to different subgenera, and it would be interesting to investigate the specificity of the stimulation by chemical signals for pollinators of more or less closely related species.

Combining bioassays and chemical analyses, we were able to show, for three tropical *Ficus* species, the role of the chemical signal as pollinator stimulant and the specificity of the stimulation. Chemical analyses strongly suggest the importance of compound ratios in the blend for recognition by specific pollinating wasp.

Acknowledgments—This work was supported by a Brunei Shell Environmental Studies Fellowship and by a grant "Dynamique de la Biodiversité et Environnement" from the French government. We wish to thank Ted C. J. Turlings for his kind support during our work on volatile collections. We are grateful to the Brunei Museum Director for providing access to the tree collection in the museum garden, to Dr. D. S. Edwards, Dr. A. A. Edwards, Dr. P. Becker, and the biology and chemistry department staff of Universiti Brunei Darussalam for their help during this work. We would like to thank Laurent Dormont, Mathilde Dufay, Marc Gibernau, Finn Kjellberg, and Doyle McKey for their helpful comments on the manuscript.

Abstract—The weevil *Oxyops vitiosa* is an Australian species imported to Florida, USA, for the biological control of the invasive weed species *Melaleuca quinquenervia*. Larvae of this species feed on leaves of their host and produce a shiny orange secretion that covers the integument. When this secretion is applied at physiological concentrations to dog food bait, fire ant consumption and visitation are significantly reduced. Gas chromatographic analysis indicates that the larval secretion qualitatively and quantitatively resembles the terpenoid composition of the host foliage. When the combination of 10 major terpenoids from the *O. vitiosa* secretion was applied to dog food bait, fire ant consumption and visitation were reduced. When these 10 terpenoids were tested individually, the sesquiterpene viridiflorol was the most active component in decreasing fire ant consumption. Fire ant visitation was initially (15 min after initiation of the study) decreased for dog food bait treated with viridiflorol and the monoterpenes 1,8-cineole and α-terpineol. Fire ants continued to avoid the bait treated with viridiflorol at 18 μg/mg dog food for up to 6 hr after the initiation of the experiment. Moreover, ants avoided bait treated with 1.8 μg/mg for up to 3 hr. The concentrations of viridiflorol, 1,8-cineole, and α-terpineol in larval washes were about twice that of the host foliage, suggesting that the larvae sequester these plant-derived compounds for defense against generalist predators.

Key Words—Antipredator defense, biological control of weeds, Curculionidae, generalist predator, *Melaleuca quinquenervia*, Myrtaceae, *Oxyops vitiosa*, plant defensive compounds, red imported fire ant, sequestration, *Solenopsis invicta*, terpenoids, viridiflorol.

INTRODUCTION

The Australian weevil, *Oxyops vitiosa*, Pascoe (Coleoptera: Curculionidae) was introduced in south Florida in 1997 for the biological control of the invasive weed *Melaleuca quinquenervia* (Cav.) S. T. Blake (Myrtaceae) (Center et al., 2000). This weevil species has since been established throughout the infested area of Florida. Larvae feed on young leaves and have a characteristic odor that resembles that of the foliage of their host tree. The bright orange larvae are diurnally active and feed exposed during all instars on the foliage, then drop to the ground, where they form a protective pupal cell in the soil (Purcell and Balciunas, 1994). The cuticle of the larvae is completely covered with a shiny, oily substance that may function in defense against generalist predators (Montgomery and Wheeler, 2000). However, the chemical nature of this defense has yet to be determined. Although few weevil species have been reported to produce defensive secretions (Pavis et al., 1992), similar integumental slime found on the sluglike sawfly larvae of *Caliroa cerasi* reduced the incidence of predation by generalist ants (Eisner, 1994).

The red imported fire ant, *Solenopsis invicta* Buren (Hymenoptera: Formicidae) constitutes one of the most invasive invertebrate predators in the southeastern United States, invading forests, pastures, croplands, and natural areas (Lofgren et al., 1975). This ant is among the most common invertebrate predators in the southeastern United States. (Elvin et al., 1983; Kharboutli and Mack, 1991). Generalist predators, including ants, have prevented the establishment or reduced the effectiveness of many weed biological control agents (Goeden and Louda, 1976), and this ant species, in particular, has been directly implicated in reducing the efficacy of *Tyta luctuosa*, a biological control agent of field bindweed (Ciomperlik et al., 1992).

Biological control efforts may benefit by recruiting agents that sequester plant defensive compounds that impart protection from generalist predators. Sequestration of plant defenses may be more common than appreciated by biological control practitioners, as this phenomenon is common among herbivores with narrow host ranges (Bowers, 1990). Several weed biological control agents are known to sequester plant defensive compounds, namely the pyrrolizidine alkaloids of the *Senecio jacobaea–Tyria jacobaeae* association (Aplin et al., 1968), the quinolizidine alkaloids of the Scotch broom–aphid association (Wink et al., 1982), and the bisanthraquinone hypericin obtained by the *Chrysolina* beetles from their host plant *Hypericum* (Rees, 1969). The purpose of this study was to determine the nature of the defensive secretions produced by the larvae of *O. vitiosa* toward the generalist predator *S. invicta*.

METHODS AND MATERIALS

Insects. Larvae of *O. vitiosa* were collected ($N = 20$) from a field site infested with *M. quinquenervia* in Ft. Lauderdale, Broward County, Florida. All larvae were weighed alive prior to analysis. Solvent washes were conducted on fourth instars by dipping each in 1 or 2 ml of chloroform ($CHCl_3$) for 15 sec. The $CHCl_3$ larval wash was filtered through glass wool and dried over sodium sulfate (Na_2SO_4) prior to analysis by gas chromatography.

Red imported fire ants were collected at the University of Florida, Ft. Lauderdale Research and Education Center, as described previously (Montgomery and Wheeler, 2000). Colonies, consisting of brood, eggs, and workers, were established in plastic boxes (20 × 12 cm) and provided with deionized water in a glass tube (45 × 4 mm) plugged with cotton. Ants were fed kibbled dog food (Pedigree Prime) freely for two to five days prior to each test. The food was removed 24–36 hr prior to each test. Newly collected ant colonies were used for each test.

Plants. Leaves were collected from the same location as the larvae described above. Tip leaves were clipped from young trees and brought to the laboratory where they were frozen (−10°C) for further processing. The leaf components were extracted by a modified microwave technique (Southwell et al., 1995; Degen and Stadler, 1998; Gomez et al., 1999). Fresh leaf samples (75–150 mg fresh weight) were immersed in 1 ml EtOH (95%) and irradiated with microwaves (750 W) for 60 sec. An aliquot (500 μl) of the EtOH extract was mixed with deionized water (500 μl), followed by 500 μl of $CHCl_3$. The sample was vortexed for 1 min and then centrifuged for 10 min at 10,000 rpm. An aliquot (200 μl) of the $CHCl_3$ layer was removed and dried over Na_2SO_4. Internal standards were added as 10 ng/μl each of *n*-tridecane and *n*-eicosane in 10 μl $CHCl_3$ to the extract prior to analysis by gas chromatography.

Chemicals. Terpenoids were purchased from commercial sources, except where mentioned, and were of the highest purity available. The list included the primary compounds reported by Brophy et al. (1989) and Ramanoelina et al. (1994). These included (+)-α-pinene (Chemical Purity = 98%), (−)-β-pinene (99%), α-terpinene (98%), (−)-limonene (92%), 1,8-cineole (100%), γ-terpinene (98%), terpinen 4-ol (97%), α-terpineol (98%), and *trans*-nerolidol (95%). Viridiflorol (86%) was extracted from *M. quinquenervia* foliage by one of us (I.A.S.).

Gas Chromatography. Samples were analyzed with either a Hewlett-Packard model 6890 or 5890 gas chromatograph. Data collection, storage, and analysis were conducted with the ChromPerfect data system. Helium at a linear flow rate of 37 cm/sec was used as a carrier gas. All samples were analyzed on three fused silica capillary columns [HP-5 (Hewlett Packard Company, Wilmington, Delaware), DB-17MS and a DB-WAXetr (J & W Scientific, Folsom, California); all 30 m × 0.32 mm ID, 0.25-μm-thick film]. Injector temperature was 200°C and FID temperature was 250°C. The oven temperature was held at 50°C for 2 min then increased

at 8°C/min to 250°C, where it was held for 5 min. Compounds were quantified relative to the peak areas of the internal standard and values were adjusted by calculation of their response factors relative to *n*-tridecane (Debbrecht, 1985).

Compound identities were confirmed by GC-MS using a Hewlett Packard 6890 instrument fitted with a HP-5MS (30.3 m × 0.25 mm, 0.25-μm film thickness) FSOT column with helium (36 cm/sec) as a carrier gas, injector port (split 1:50) at 250°C, mass selective detector (HP 5973) at 250°C (source) and 150°C (quad) with transfer line 280°C and ion source filament voltage of 70 eV. Component identification was made on the basis of mass spectral fragmentation, retention index with *n*-paraffins, and comparison with authentic constituents and mass spectral and retention matching with commercial (NIST, Wiley, and Adams) libraries.

Bioassay of Defensive Secretions. The material washed from the *O. vitiosa* larvae or select commercial terpenoids was dissolved in 50 μl of $CHCl_3$ and applied to kibbled dog food cut into 50-mg pieces. The solvent was allowed to dry for 0.5 hr in a fume hood under ambient conditions. The treated dog food bait was stored for 12–15 hr at 4°C. Each test consisted of offering the ants a choice between a solvent ($CHCl_3$)-treated control and either a crude larval wash or a select commercial terpenoid formulated individually or in a mixture. To determine the percentage loss of terpenoids during the experiment, treated dog food samples were $CHCl_3$-extracted before and after a 6-hr test and analyzed by GC. By comparing peak areas the concentration (mean ± SE) of each terpenoid was found to decrease during the experiment from 53.9% ± 2.5% for viridiflorol to 93.7% ± 0.9% for α-pinene.

Four choice tests were conducted, all under ambient conditions between 9 AM and 3 PM. For all tests, ant consumption was determined by comparing the dog food weight before and after each 6-hr test. Additionally, the number of ants visiting each dog food bait was counted at regular intervals. In study 1, choice tests were conducted between a $CHCl_3$-treated control and the crude *O. vitiosa* larval wash [1-larval equivalent (LE)] applied to a piece of dog food ($N = 10$). In study 2, choice tests were conducted between a $CHCl_3$-treated control and a mixture of the 10 major terpenoids found from GC analysis of the larval washes ($N = 6$). These were formulated to include the range of concentrations of each compound found in the crude larval washes (Table 1). Additional treatments consisted of 10-fold and 100-fold dilutions of these mixtures. One major *M. quinquenervia* terpenoid, β-caryophyllene, was not identified during this phase of the research and, thus, its repellent activity was not determined. In study 3, choice tests were conducted between a $CHCl_3$-treated control and the same 10 terpenoids tested individually at the highest concentrations tested in study 2 ($N = 4$). In study 4, choice tests were conducted between a $CHCl_3$-treated control and three different viridiflorol concentrations using the same concentrations as in study 2 ($N = 6$).

Statistical Analysis. All data, terpenoid extraction yields, *S. invicta* consumption, and the number of fire ants visiting each dog food bait, were analyzed with

TABLE 1. CONCENTRATION OF 10 TERPENOID COMPONENTS APPLIED TO KIBBLED DOG FOOD AND FED TO RED IMPORTED FIRE ANT WORKERS[a]

Compound	Concentration (μg/mg dog food)
1,8-Cineole	22.00
Viridiflorol	18.00

SAS (SAS Institute, 1990). The terpenoid yields of the leaf extracts and the larval washes were compared with an ANOVA for each terpenoid analyzed. The consumption and the fire ant activity data were analyzed with a Kruskal-Wallis test.

RESULTS

Chemical Analyses

Considerable quantitative and qualitative similarity was found in the chemical constituents from leaf extracts and larval washes (Table 2; Figure 1). However, some of the terpenoids analyzed (e.g., viridiflorol, 1,8-cineole, α-terpineol, limonene, terpinen 4-ol) were present in greater concentrations in the larval washes than in the leaf extracts. This suggests that as the *O. vitiosa* larvae consume *M. quinquenervia* foliage, they absorb and deposit the foliar terpenoids on their cuticle. The larval fresh weight averaged ($\pm$SE) 101.9 ($\pm$3.0) mg and the amount of material removed by washing each larva averaged 7.9 ($\pm$0.5) mg.

Bioassay of Larval Secretions

Study 1—Larval Washes. Fire ant consumption and visitation were significantly greater on the control dog food bait (treated with $CHCl_3$) compared with that treated with the *O. vitiosa* larval wash (Table 3). During the 6-hr test, the fire

	$\chi_1^2 = 14.438$; $P < 0.001$		$\chi_1^2 = 16.365$; $P < 0.001$		$\chi_1^2 = 16.351$; $P < 0.001$	

[a] Each piece of dog food (50 mg) was treated with one larval equivalent.

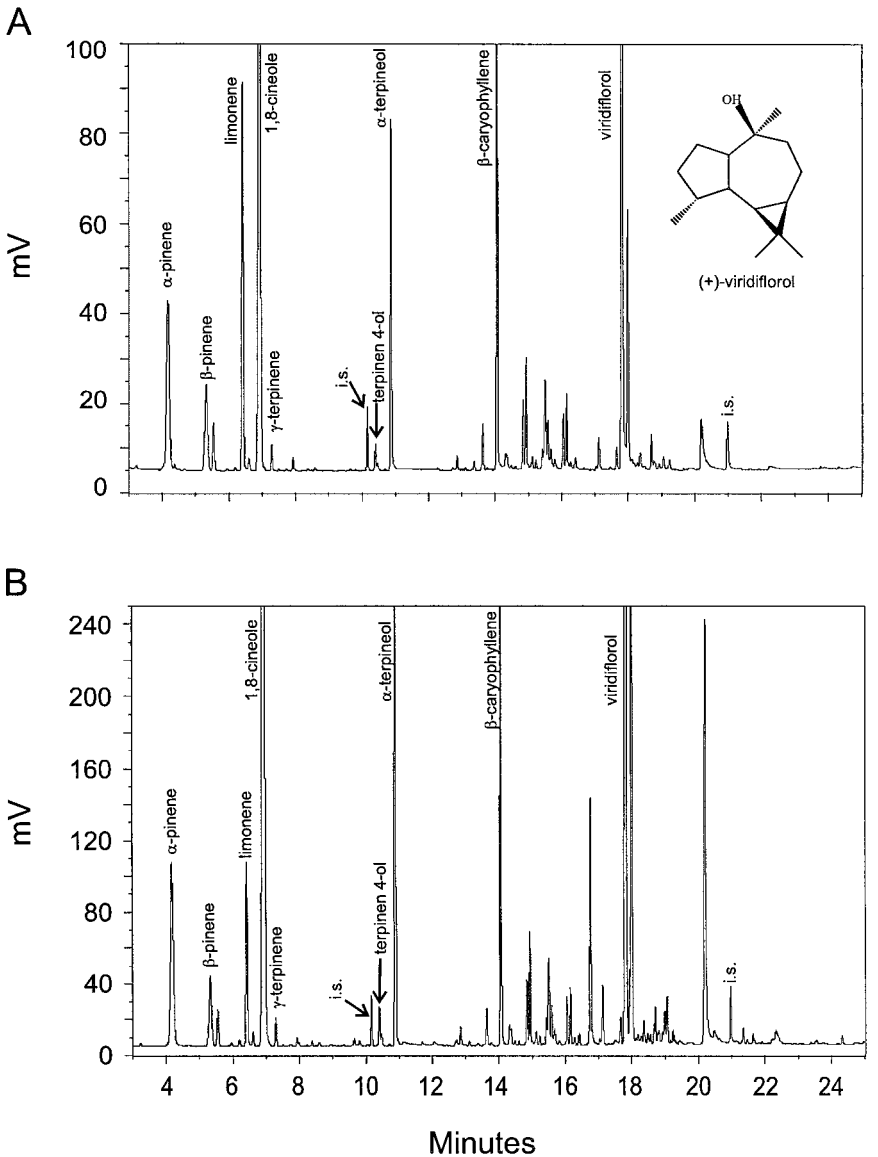

FIG. 1. Representative gas chromatograms of *M. quinquenervia* leaves (A) and *O. vitiosa* larval washes (B). Leaves were digested in 95% EtOH by 60-sec microwave irradiation. Larval washes consisted of dipping fourth-instar larvae in $CHCl_3$ for 15 sec. Internal standards *n*-tridecane and *n*-eicosane (10 ng/μl of each) were added to each sample.

ants consumed an average of 8.7 (±3.6) mg of dog food in the controls compared with 0.8 (±0.3) mg of dog food in the larval-wash treatment. Additionally, fire ants frequently visited the control dog food at both 3 and 6 hr after initiation of the experiment, whereas they were never observed visiting the larval wash-treated dog food (Table 3).

Study 2—Mixture of Terpenoids. Fire ant consumption and visitation of dog food were significantly lower following treatment with the mixture of the 10 terpenoids (about 1 LE) than with the solvent-treated controls. In the high ($\chi_1^2 = 8.932$; $P = 0.003$) treatment of the terpenoid mixture, consumption was significantly reduced compared with that of the solvent-treated dog food (Figure 2). Furthermore, fire ant visitation was reduced (Figure 3) during the 15-min observation period in the high ($\chi_1^2 = 9.466$; $P = 0.002$), intermediate ($\chi_1^2 = 8.425$; $P = 0.004$), and low ($\chi_1^2 = 8.366$; $P = 0.004$) treatments of the terpenoid mixture

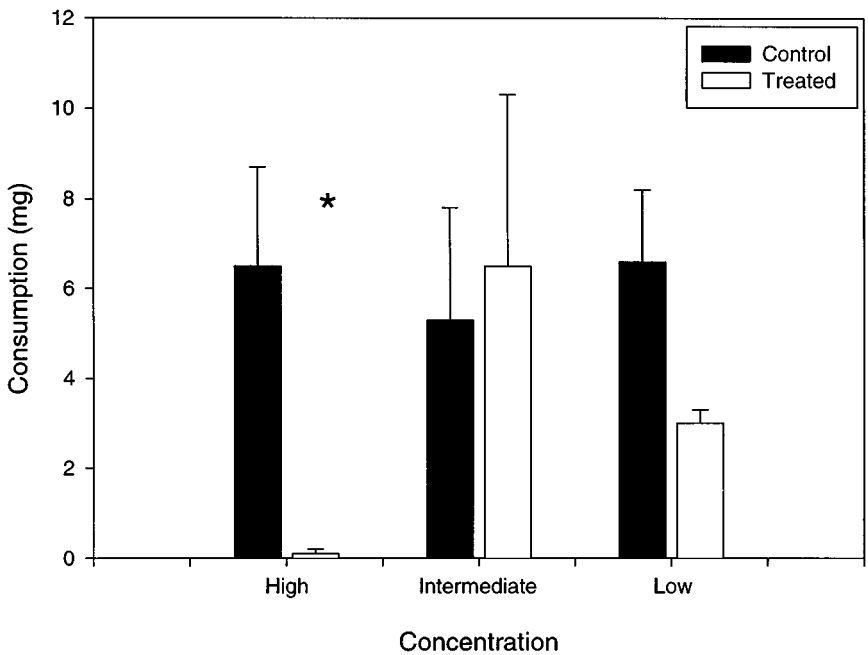

FIG. 2. Mean consumption (±SE) by *S. invicta* workers offered a choice between a dog food bait treated with $CHCl_3$ (control) and a mixture of the 10 major terpenoids occurring in $CHCl_3$ washes of *O. vitiosa* larvae. The high concentration approximated the amount washed from one larva (Table 1), whereas the intermediate and the low levels were 10-fold and 100-fold dilutions, respectively. Asterisk indicates significant differences between the control and treated means.

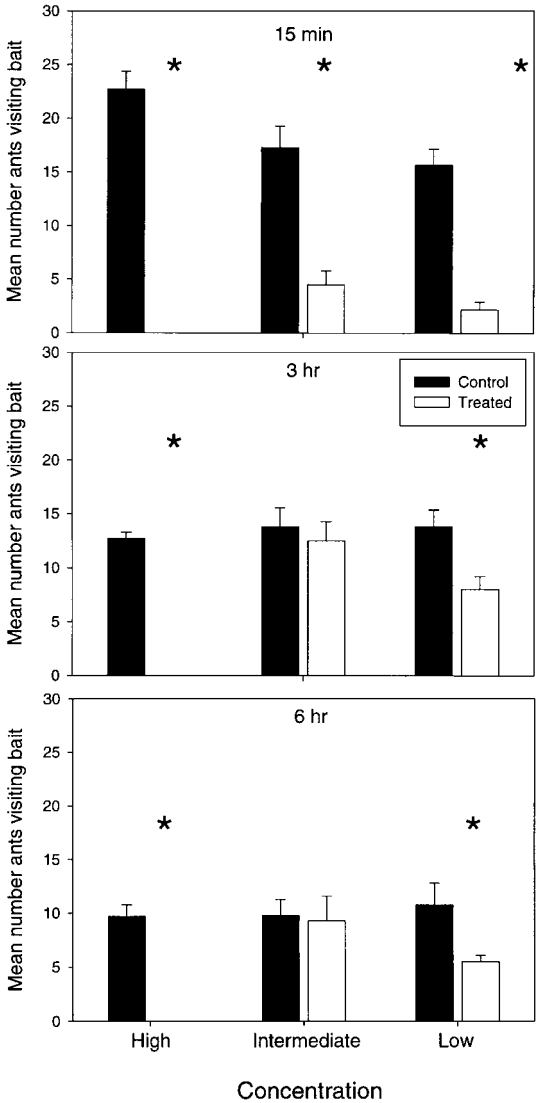

FIG. 3. Mean number (±SE) of *S. invicta* workers visiting dog food bait treated with $CHCl_3$ (control) and a mixture of the 10 major terpenoids occurring in $CHCl_3$ washes of *O. vitiosa* larvae. The high concentration approximated the amount washed from one larva (Table 1), whereas the intermediate and the low levels were 10-fold and 100-fold dilutions, respectively. The number of ants contacting each dog food bait was counted at 15 min, 3 hr, and 6 hr after the beginning of the experiment. Asterisks indicate significant differences between the control and treated means.

compared with the solvent-treated controls. Significant differences were also found 3 hr after the study began in the high ($\chi_1^2 = 9.542$; $P = 0.002$) and the low ($\chi_1^2 = 5.448$; $P = 0.020$) concentrations. Finally, fewer fire ants were observed visiting the terpenoid mixture-treated dog food at 6 hr after the study began on the high ($\chi_1^2 = 9.466$; $P = 0.002$) and the low ($\chi_1^2 = 6.226$; $P = 0.012$) concentrations.

Study 3—Individual Terpenoids. When each terpenoid was applied individually to the dog food, the only treatments that reduced fire ant consumption of bait were α-terpineol (Figure 4; 5.47 μg/mg; $\chi_1^2 = 5.333$; $P = 0.021$) and viridiflorol (18.0 μg/mg; $\chi_1^2 = 5.398$; $P = 0.020$). Fire ant visitation was reduced after 15 min (Figure 5) in those treated with 1,8-cineole (22.0 μg/mg; $\chi_1^2 = 3.607$; $P = 0.058$), α-terpineol ($\chi_1^2 = 4.083$; $P = 0.043$) and viridiflorol ($\chi_1^2 = 5.463$; $P = 0.019$).

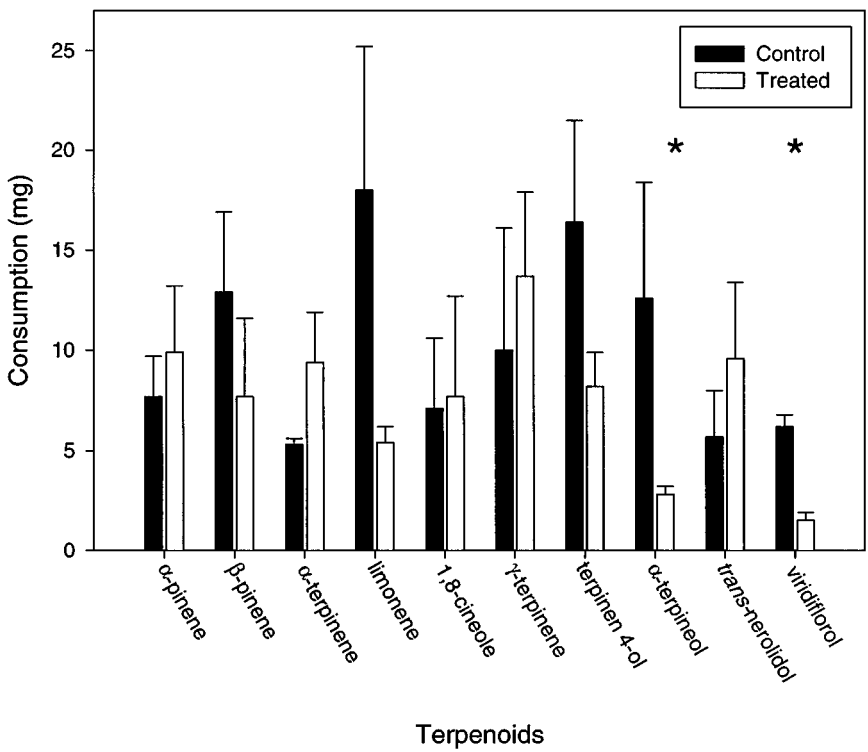

FIG. 4. Mean consumption (±SE) by *S. invicta* workers offered a choice between a dog food bait treated with $CHCl_3$ (control) and each of the 10 major terpenoids occurring in $CHCl_3$ washes of *O. vitiosa* larvae. Asterisks indicate significant difference between the control and treated means.

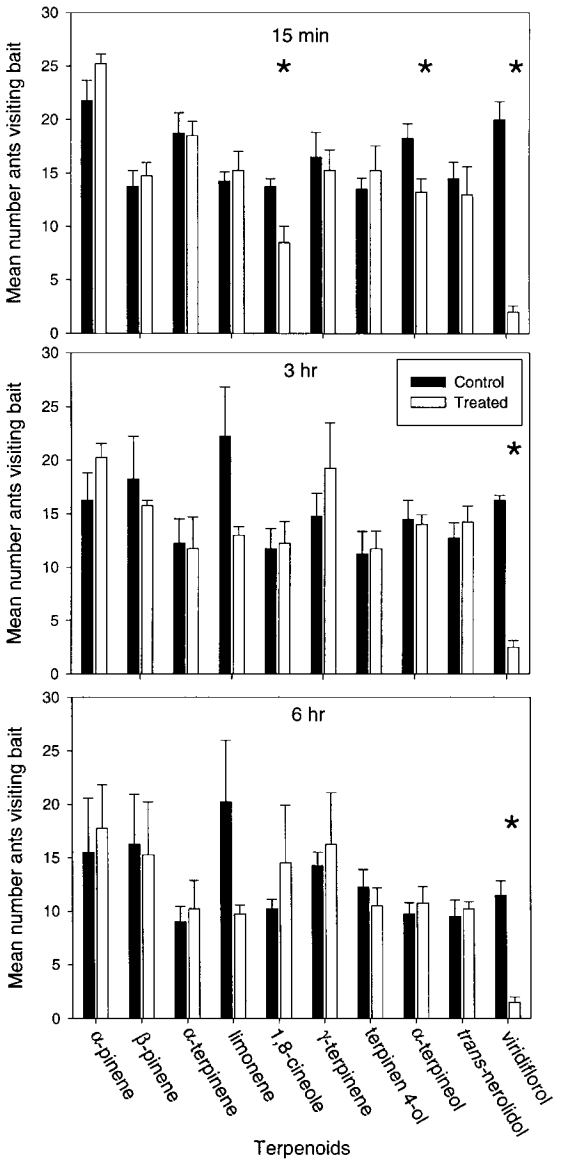

FIG. 5. Mean number (±SE) of *S. invicta* workers visiting dog food bait treated with $CHCl_3$ (control) and each of the 10 major terpenoids occurring in washes of *O. vitiosa* larvae. The number of ants contacting each dog food bait was counted at 15 min, 3 hr, and 6 hr after beginning the experiment. Asterisks indicate significant differences between the control and treated means.

After 3 hr ($\chi_1^2 = 5.398$; $P = 0.020$) and 6 hr ($\chi_1^2 = 5.600$; $P = 0.018$) fire ant visitations were reduced only on the viridiflorol-treated dog food bait.

Study 4—Viridiflorol. Viridiflorol tested alone was active over a range of concentrations at decreasing fire ant consumption and repelling ants. Compared with the solvent-treated controls, consumption was significantly reduced only by viridiflorol at the highest concentration ($\chi_1^2 = 4.395$; $P = 0.036$) tested (Figure 6). However, fire ant visitation to viridiflorol-treated bait was reduced at the highest ($\chi_1^2 = 9.466$; $P = 0.002$) and intermediate ($\chi_1^2 = 9.103$; $P = 0.003$) concentrations 15 min after the beginning of the study (Figure 7). This activity continued for 3 hr after the beginning of the study at the highest ($\chi_1^2 = 9.466$; $P = 0.002$) and intermediate ($\chi_1^2 = 3.480$; $P = 0.062$) viridiflorol concentrations. After 6 hr, a difference in activity was only found at the highest viridiflorol concentration ($\chi_1^2 = 7.174$; $P = 0.007$).

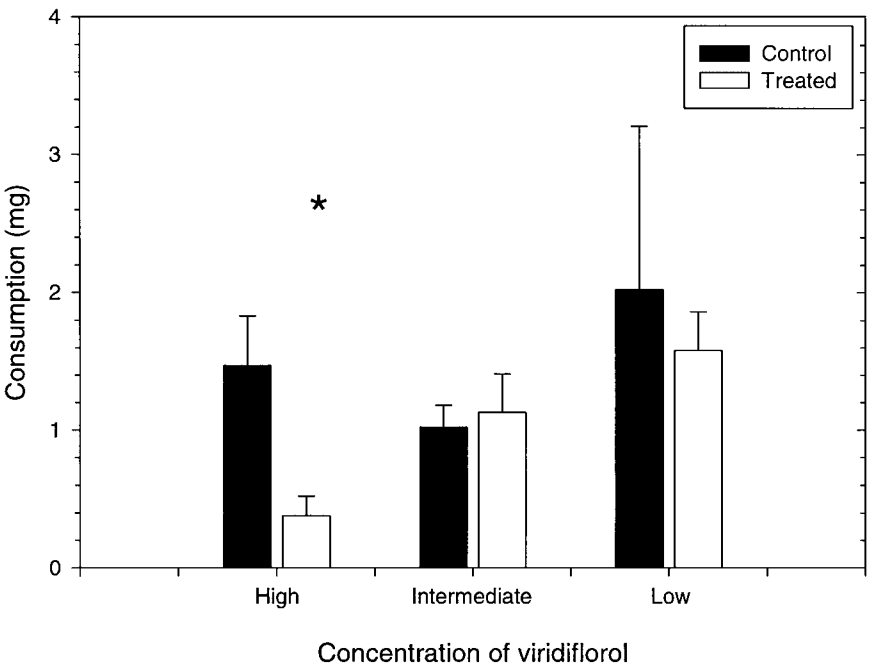

FIG. 6. Mean consumption (±SE) by *S. invicta* workers offered a choice between a dog food bait treated with $CHCl_3$ (control) and viridiflorol at high (18 μg/mg dog food bait), intermediate (1.8 μg/mg dog food bait), and low (0.18 μg/mg dog food bait) concentrations. Asterisk indicates significant difference between the control and treated means.

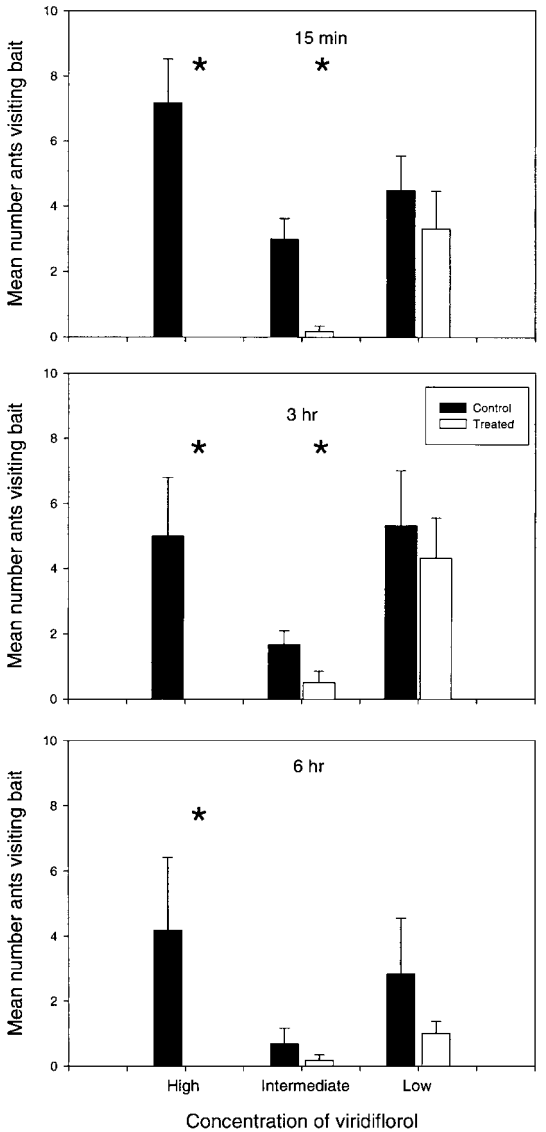

FIG. 7. Mean number (±SE) of *S. invicta* workers visiting dog food bait treated with $CHCl_3$ (control) and viridiflorol at high (18 μg/mg dog food bait), intermediate (1.8 μg/mg dog food bait) and low (0.18 μg/mg dog food bait) concentrations. The number of ants contacting each dog food bait was counted at 15 min, 3 hr, and 6 hr after beginning the experiment. Asterisks indicate significant differences between the control and treated means.

DISCUSSION

These results demonstrate the repellent nature of the larval secretions of the *M. quinquenervia* biological control agent *O. vitiosa* toward the red imported fire ant *S. invicta*. They indicate repellent activity from the crude larval washes, mixtures of the 10 major terpenoids contained in the larval washes, and individual compounds from this mixture. In all experiments, fire ant consumption and visitation to the treated baits significantly decreased compared with the solvent-treated controls. The repellency of the most active component, viridiflorol, was demonstrated throughout the duration of the experimental observations (6 hr). Additionally, 1,8-cineole and α-terpineol were repellent during the initial observation (15 min). Possibly limonene was also repellent, although variable, and thus was not statistically significant in these analyses.

In the larval secretions, the three most active compounds, viridiflorol, 1,8-cineole, and α-terpineol, were recovered at about twice the concentration extracted from the host foliage, suggesting that the larvae sequester these plant-derived compounds. In fact, nearly all of the 10 compounds investigated were in greater concentration (on a fresh mass basis) washed from the larvae compared with those measured in the leaf extracts. The most active ant repellents increased the most from the plant to the larvae, namely viridiflorol (2.0-fold), 1,8-cineole (2.1-fold), and α-terpineol (2.5-fold). The proportion of ingested terpenoids retained by larvae on the cuticle can be calculated and expressed as the conversion efficiency for each terpenoid (ECI_t), analogous to calculation of the food conversion efficiency (ECI_f) (Slansky and Scriber, 1985). The ECI_t values were estimated by: [larval mass (mean = 101.9 mg) $\times$ concentration of the terpenoid (μg/mg) washed from the larvae (from Table 2)]/[food consumed (mg) $\times$ concentration of the terpenoid (μg/mg) in the leaves (from Table 2)]. We used consumption (400 mg fresh mass) and food conversion efficiency (ECI_f; 7.3% fresh mass) results from a similar study of *O. vitiosa* larvae fed leaves of *M. quinquenervia* (Wheeler, unpublished data). To determine if select terpenoids were actively sequestered and deposited on the larvae, the conversion efficiency of each active terpenoid washed from the cuticle (ECI_t) can be compared with the conversion efficiency of the food (ECI_f). The results of these calculations generally suggest that more than half the quantity consumed of the most repellent terpenoids was retained and deposited on the larval cuticle. For example, the ECI_t values all exceeded 46% for viridiflorol (49.8%), 1,8-cineole (54.5%), and α-terpineol (63.9%). Moreover, with the exception of α-terpinene and terpinen 4-ol, which were present in barely detectable levels, the conversion efficiencies of the less-repellent terpenoids were considerably lower ($\leq$30%). These results are consistent with the interpretation that these terpenoids were actively sequestered, as these values were considerably greater than the conversion efficiency value for food ($ECI_f = 7.3\%$). A similar analysis was conducted, using the approximate digestibility (AD) of the

ingested terpenoid 1,8-cineole by a chrysomelid eucalypt-feeder, *Paropsis atomaria* (Olivier) (Ohmart and Larsson, 1989). Our calculations also suggest that sequestration was selective as the ECI_t values were greatest for the most repellent compounds. Similar selectivity was found with the larvae of other species where the most emetic iridoid glycoside, catalpol, was selectively sequestered compared with the less-emetic aucubin (Bowers and Collinge, 1992; Bowers et al., 1993). However, our calculations need to be confirmed with a more direct determination of the terpenoid budgets. Finally, our intention was to test the terpenoids at physiological concentrations. Thus, as the most repellent compounds were the most abundant terpenoids washed from the larvae, they were also tested at higher concentrations. Possibly, α-terpinene and γ-terpinene would be equally active if tested at higher concentrations.

Ant foraging activity was similar in studies 1–3, where typically more than 10 ants was reported on the control bait during each observation and 5 mg of the control bait was consumed. However, a decrease in the number of foraging ants was observed in study 4, resulting in less than 10 foragers reported during all observation periods and less than 2 mg of bait consumed by foragers. Similar variability in foraging activity occurred in a subsequent study (Wheeler et al., unpublished data). Several factors may influence ant activity including degree of satiation. However, the food was always removed from the ant colonies 24–36 hr prior to each test. Possibly seasonal or colony phenology changes influenced foraging activity. However, these factors were minimized as all the studies were conducted during July and August 2000. Moreover, studies were always conducted from 9 AM to 3 PM at ambient temperatures that varied only slightly on the days of the tests, with mean (range) temperatures between 27.3°C (22.8–31.7°C; study 3) and 28.6°C (23.3–33.9°C; study 4). Thus, it is unclear why consumption and foraging activity were lower during study 4.

Terpenoids are well known ant repellents (Shorey et al., 1992) that, when sequestered (e.g., cardenolides, cucurbitacins), may be repellent against many predatory types (Bowers, 1990). Several terpenoids have shown activity against both herbivorous and predaceous ant species. For example, plant foliar terpenoids may either repel (Hubbell et al., 1984; Howard et al., 1989) or be toxic to leaf-cutting ants (Howard et al., 1988). Additionally, insect-produced terpenoids from chrysomelid larvae also repel *S. invicta* (Blum et al., 1978). The plant sesquiterpene farnesol may be applied as a band around citrus tree trunks to exclude Argentine ants *Linepithema humile* (Mayr) for several months (Shorey et al., 1996). Numerous compounds with a range of volatilities have been reported to have ant repellent activity (Shorey et al., 1992); however, to our knowledge, this is the first report of repellent activity at physiological concentrations of the terpenoids viridiflorol, 1,8-cineole, and α-terpineol.

The ecological host range of this biological control agent *O. vitiosa* may be influenced by the availability of foliar compounds that serve as effective repellents

against generalist predators. Larvae may escape from predators on plant species that have the compounds that can be sequestered for antipredator defense (Jeffries and Lawton, 1984). Even though oviposition and larval development may occur on test plants in the laboratory, in field conditions, where natural enemies like fire ants are abundant, host use may be restricted to plant species that provide compounds that can be sequestered and impart defense against generalist predators. Although field observations indicated that this species was only collected on *M. quinquenervia* (Balciunas et al., 1994), quarantine host testing indicated that neonates complete development on the Australian myrtaceous species *Callistemon rigidus* and *C. viminalis* (Balciunas and Buckingham, 1996). Additionally, third instars previously fed *M. quinquenervia* will feed on the North American *Myrica cerifera* (Balciunas and Buckingham, 1996; Wheeler, unpublished data). Additional chemical variation in the *O. vitiosa* host range exists in the different *M. quinquenervia* chemotypes, both of which occur in Australia (Ireland, 1999) and Florida (Dray and Wheeler, unpublished data). The two *M. quinquenervia* chemotypes have distinct terpenoid profiles; one has primarily *trans*-nerolidol and only small concentrations of the primary components found in the present study. Different larval diets influenced the cuticular waxes of *Manduca sexta* when fed different plant species or an artificial diet (Espelie and Bernays, 1989) and these differences influenced the susceptibility of the larvae to ant predation (Cornelius and Bernays, 1995). The protection *O. vitiosa* larvae derive from these plant species and chemotypes and its ecological significance are the subject of an additional series of studies (Wheeler et al., unpublished data).

Predators are well-known antagonists of arthropods used for biological control of weeds (Crawley, 1989; Julien and Griffiths, 1998), and predation is so common that it may be assumed that it likely influences the establishment of all agents (Goeden and Louda, 1976). In general, natural enemies, including predators, parasitoids, and diseases interfere with approximately half of biological control projects (Goeden and Louda, 1976). *Oxyops vitiosa* is apparently well protected from one of the most common invertebrate generalist predators in the southeastern United States (Montgomery and Wheeler, 2000). However, recent observations indicate that another predator, the pentatomid, *Podisus mucronatus* Uhler, with relatively long mouthparts may penetrate the integumental defenses of *O. vitiosa* larvae (Pratt, unpublished data). Different mouthpart sizes have allowed heteropteran predators with long mandibles [e.g., *Nabis americoferus* (Carayon) (Heteroptera: Nabidae) or *Podisus maculiventris* (Say)] (Heteroptera: Pentatomidae) to utilize otherwise well-defended prey compared with predators with shorter mandibles (e.g., coccinelids) (Olmstead and Denno, 1993). Nonetheless, *O. vitiosa* has become well established in Florida (Center et al., 2000). Several factors may contribute to its success, among them is their integumental terpenoid defense.

ANTIMICROBIAL ACTIVITY OF EXOCRINE GLANDULAR SECRETION OF *Chrysomela* LARVAE

JÜRGEN GROSS,* LARS PODSIADLOWSKI, and MONIKA HILKER

Institut für Biologie
Freie Universität Berlin
Grunewaldstr. 34, D-12165 Berlin, Germany

(Received January 8, 2001; accepted October 17, 2001)

Abstract—The exocrine glandular secretions of leaf beetle larvae of the taxon *Chrysomela* are well-known defensive devices used against some generalist predators. Salicylaldehyde is the major repellent component of secretions emitted by larvae of *Chrysomela vigintipunctata* and *C. lapponica*, which feed on salicin-rich Salicaceae. In this study, we examined whether salicylaldehyde is also active against the entomopathogenic fungus *Metarhizium anisopliae*. The germination and growth of this fungus was strongly inhibited when salicylaldehyde was applied directly onto the blastospores. The salicylaldehyde concentration of the larval secretions of the tested willow feeding *Chrysomela* larvae was much higher than the one necessary to display this antifungal activity. Additionally, salicylaldehyde was shown to reduce germination and growth of *M. anisopliae* via the gas phase over a distance of 45 mm. Further studies on the antimicrobial activity of the salicylaldehyde-containing secretions of *Chrysomela* larvae revealed that they act nonspecifically against prokaryotic (*Escherichia coli*) and eukaryotic cells (*Saccharomyces cerevisiae* and *Trichoplusia ni*). All antimicrobial and cytotoxic effects detected proved to be due to salicylaldehyde. The larval secretions of the birch-feeding allospecies of *C. lapponica*, that do not contain salicylaldehyde, but mainly carboxylic acids and their esters, showed no detectable effects on bacteria or fungi and no cytotoxic effects against insect cells. The results are discussed with respect to their ecological relevance.

Key Words—*Chrysomela vigintipunctata*, *Chrysomela lapponica*, larval secretion, antimicrobial activity, cytotoxicity, entomopathogens, *Metarhizium anisopliae*, salicylaldehyde, carboxylic acids, carboxylic esters.

INTRODUCTION

Larvae of the leaf beetle taxon *Chrysomela* discharge a defensive secretion from nine pairs of dorsal glands when disturbed. *C. vigintipunctata* and *C. lapponica* larvae feeding upon willows (Salicaceae) use phenolic glycosides (e.g., salicin) from their host plants as precursors to produce salicylaldehyde, the main component of their secretion (Wallace and Blum, 1969; Pasteels et al., 1988; Gross and Hilker, 1995). This secretion is highly effective for defense against some generalist predators (Pasteels et al., 1986; Palokangas et al., 1992; Rank et al., 1996). While mammals feeding upon salicin-rich willows and poplars metabolize salicylalcohol, the aglycone of salicin, to salicylic acid, (Nahrstedt, 1990), *Chrysomela* larvae oxidize salicylalcohol to salicylaldehyde (Pasteels et al., 1983). Salicylic acid is known as an antimicrobial agent (Falbe and Regitz, 1991), but no detailed knowledge is available about the antimicrobial activity of the respective aldehyde.

In *C. lapponica*, both an allospecies feeding upon Betulaceae and one feeding upon Salicaceae are known (Gross, 1997). Larvae of birch- and alder- (Betulaceae) feeding *Chrysomela* species produce isobutyric and 2-methylbutyric acids and esters of these in their glands. Like the secretions containing salicylaldehyde, this secretion acts as repellent against generalist predators (Blum et al., 1972; Hilker and Schulz, 1994).

In this study, we examined whether the larval secretions of *C. vigintipunctata* and *C. lapponica* with salicylaldehyde as major component show activity against fungal disease in addition to their repellent character against generalist predators. Furthermore, the larval secretion of the *C. lapponica* allospecies feeding upon Betulaceae was tested for its effects against fungal pathogens. The entomopathogenic fungus *Metarhizium anisopliae*, that we used in our assays, is well known as one of the most frequently occurring fungal pathogens of Chrysomelidae (Humber, 1996). Larvae of *C. vigintipunctata* and *C. lapponica* not only release their secretions when attacked by predators, but also emit secretions when disturbed by conspecific larvae or when host plant leaves are fluttered by the wind. Thus, they almost live in a cloud of volatiles produced by their own secretions. The volatiles of the secretion might prevent fungal spores from germinating on, and penetrating into, the larval cuticle. Therefore, we tested salicylaldehyde as the major component of the exocrine secretion of willow feeding larvae for its antifungal activity via the gas phase.

In order to evaluate the range of activity of the larval secretions towards microorganisms, we examined not only the activity of the secretion towards a fungal entomopathogen, but also the effects of the secretions towards other microorganisms, such as yeast and bacteria. Furthermore, we studied whether the secretions exhibit cytotoxic effects against insect cells.

METHODS AND MATERIALS

Leaf Beetles. Larval secretions containing salicylaldehyde as the main component were obtained from willow-feeding third-instar larvae of *Chrysomela vigintipunctata* and *C. lapponica*. Larvae of *C. vigintipunctata* were collected from *Salix fragilis* in the area of Marianske Lazne, Czech Republic. *C. lapponica* larvae were collected from *S. borealis* in Finnish Lapland near the Kevo Subarctic Research Institute. Larval secretion containing no salicylaldehyde, but carboxylic acids and their esters were obtained from birch-feeding second- and third-instar larvae of *C. lapponica*. They were collected in the Czech Republic from *Betula pubescens*. Larvae were reared in the laboratory in small plastic boxes ($15 \times 15 \times 6$ cm) at 15°C and a 16L:8D photoperiod (Czech specimen) or constant light (Finnish specimen). They were fed with leaves of their natural host plants.

Samples. For collecting exocrine secretions from larvae for chemical analyses and antimicrobial assays, larvae were disturbed with forceps. The secretory fluid emerging from the glandular openings was collected using sterile glass capillaries (samples for GC-MS analyses and microtiter plate experiments) or small disks of sterile filter paper (5 mm diam., samples for assays on agar plates). For some experiments, synthetic salicylaldehyde (Roth) was used instead of the larval secretion.

GC-MS Analysis. The chemical composition of larval secretions from *C. vigintipunctata* and *C. lapponica* was analyzed in earlier studies (see Introduction for references). Nevertheless, we analyzed the chemical composition of larval secretions from those populations that were examined for their antimicrobial activity, since the chemical composition of larval secretions may vary between populations of a species and between the host plants the larvae fed upon (e.g., Rowell-Rahier and Pasteels, 1986; Gross and Hilker, 1995; Soetens et al., 1998). Coupled gas chromatography–mass spectrometry was used for analyses. Secretions that were stored in calibrated glass capillaries were dissolved in specific volumes of dichloromethane. Dodecane (0.1 μg/μl; Aldrich) was added as an internal standard. One microliter of each solution was injected splitless into a gas chromatograph (Fisons GC 8060, Thermoquest, injector temperature 240°C), equipped with a 30 m $\times$ 0.32 mm $\times$ 0.25 μm DB-5 column (Fisons). The temperature program started at 40°C, was held for 4 min, and raised to 280°C at 10°C/min. Helium (Air Liquide) was used as the carrier gas (inlet pressure 10 kPa). The gas chromatograph was coupled to a quadrupole mass spectrometer (Fisons MD 800; Thermoquest). EI mass spectra were recorded at 70 eV. Structures of the identified components were confirmed by coinjection of synthetic samples. The following secretion components were quantified: benzaldehyde (Fluka); salicylaldehyde (Roth); 2-phenylethanol (Sigma); hexyl isobutyrate, (*Z*)-3-hexenyl isobutyrate, and hexylbutyrate (Aldrich); and 2-phenylethyl isobutyrate and 2-phenylethyl

2-methylbutyrate (synthesized as described by Hilker and Schulz, 1994; purity >98%). Quantitative data for each component were obtained by analyses of the secretions from five larvae of each secretion type considered in this study (*C. lapponica* on birch, *C. lapponica* on willow, *C. vigintipunctata* on willow).

Assay of Cytotoxicity Towards Insect Cells: MTT Assay. The cytotoxicity of larval secretions and pure salicylaldehyde towards insect cells was determined using the MTT assay as designed by Mosmann (1983). We used cells of *Trichoplusia ni* (Lepidoptera: Noctuidae). In MTT assays, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) (Sigma) is used as coloring agent for detection of live fungal cells, as described below. To conduct this assay, cells were grown in Grace's insect medium (GIM, Life Technologies) supplemented with 10% fetal bovine serum. A volume of 5 ml of a culture with an initial cell number of 2×10^5 cells/ml was filled into a culture-flask (25 cm^2 cultivation area), and subcultured every two to three days. To determine cytotoxic effects of the samples, each 200 μl of a cell suspension was transferred into wells of one row of 96-well microtiter plates. The cell number was adjusted to 5×10^4 cells/well. After one day, the cells were attached at the bottom of the plate and medium was replaced by 200 μl test solution (= GIM containing 0.05 μl larval secretion or different concentrations of salicylaldehyde: 11.7, 1.17, 0.12, and 0.01 μg/μl; these concentrations are equivalent to 10, 1.0, 0.1, and 0.01 μl salicylaldehyde/ml medium). The microtiter plates were covered by a lid that left about 0.75 mm between samples and lid. To quantify the distance over which volatiles of larval secretions or salicylaldehyde show cytotoxic effects, one row at 9 mm distance, and a second row at 90 mm distance from the wells containing test solutions were filled with cells and medium. Each test solution was assayed on a separate plate, as the volatile samples also affect neighboring wells. For control, 200 μl GIM was applied as above. After 24 hr of incubation at room temperature, 20 μl MTT solution (5 mg/ml medium) was added and incubation was continued for 4 hr. The yellow MTT invades into the cells. The tetrazolium ring of MTT is cracked by mitochondrial dehydrogenases that are active only in living cells. Blue crystals of formazan are formed. The medium was then replaced by 100 μl isopropanol (Merck) containing 0.1% HCl (Merck) and incubated for 10 min at room temperature. Isopropanol destroys the cells and dissolves formazan. Absorbance of the resulting blue solutions was read at 560 nm using a microtiter plate reader (Titertek).

Assaying of Antibacterial Activity. Lytic Zone Assay. Lytic activity of larval secretions and salicylaldehyde was monitored with a lytic zone assay against *Micrococcus luteus*. Agar plates were prepared according to Mohrig and Messner (1968): A volume of 5 ml of sterile *M. luteus* agar was added to Petri dishes (9 cm diam.) (1% Agar L11, Oxoid; 5 mg/ml freeze-dried *M. luteus*, Sigma; 0.1 mg/ml streptomycin sulfate, Serva; in 67 mM potassium phosphate buffer, pH 6.4). Samples were applied onto disks of sterile filter paper (5 mm diam.) that were placed on the agar surface. The tested samples per filter paper disk were (a) secretion of

one larva of *C. vigintipunctata* or *C. lapponica* of each allospecies. The secretion was directly sucked onto the filter paper when the larva released the secretion after disturbance; (b) 5 μl of salicylaldehyde dissolved in dichloromethane (0.5 μl salicylaldehyde in 4.5 μl dichloromethane), and (c) 5 μl dichloromethane for control. Due to the high volatility of the samples, each sample was placed on a different agar plate. During incubation, the turbid agar was cleared by lytic activity of the samples forming clear zones. After a 24-hr incubation at 37°C, filter paper disks were removed. It was recorded whether clear zones appeared at the places where filter paper disks had been located.

Inhibition Zone Assay. Activity of larval secretions and salicylaldehyde against *Escherichia coli* was measured by an inhibition zone assay using a lipopolysaccharide-defective, streptomycin- and ampicillin-resistant mutant of *E. coli* K12 strain D31 (Faye and Wyatt, 1980). Petri dishes (9 cm diam.) were filled with 5 ml agar suspension (2.5% nutrient broth I, Merck; 1% Agar L11, Oxoid; and 0.1 mg/ml streptomycin sulfate, Serva) containing 2×10^4 viable bacteria. Samples were applied at the same concentrations and the same conditions as described above for lytic zone assay. After incubation of the agar plates (24 hr, 37°C), filter paper disks were removed and diameters of inhibition zones were determined.

Antifungal Activity. Inhibition Zone Assay. Toxic effects of larval secretions and salicylaldehyde towards yeast were quantified by an inhibition zone assay (Vilcinskas and Matha, 1997). Yeast (*Saccharomyces cerevisiae*, strain 211) was grown in a liquid medium containing 0.2% glucose (Merck), 0.1% yeast extract (Difco Laboratories) and 0.05% peptone (Sigma) for 24 hr at 37°C. Test plates were prepared as described by Gross et al. (1998). Then 1 g agar (Agar Bacteriological No. 1, Oxoid) was dissolved in 100 ml yeast medium, 1 ml sodium phosphate buffer (0.1 M, pH 7) was added, and the medium was sterilized. Finally, 2 ml of yeast suspension was added to the medium and 5 ml was filled in each Petri dish (9 cm diam.). Samples were applied at the same concentrations and same conditions as described above for the lytic zone assay. Inhibition zones were determined after 24 hr at 37°C.

Colorimetric Fungus Assay. In order to study whether salicylaldehyde affects the germination ability of blastospores and the growth and survival of hyphae of *M anisopliae*, we modified the MTT assay (see above). Conidia from stationary cultures of *Metarhizium anisopliae* (strain 8C-D2202) were used to inoculate nutrient broth (25 g Standard I, Merck, and 20 g glucose, Merck, dissolved in 1 liter distilled water and sterilized). Blastospores were harvested after four to six days of incubation, using a miracloth filter (Calbiochem) to remove mycelia. Blastospores were washed by centrifugation and resuspended in fresh medium. The density was determined (Bürker counting chamber) and adjusted to 2×10^6 spores/ml. The wells of a 96-well microtiter plate were filled with 100 μl (2×10^5 spores) of this suspension. After 30 min the blastospores had sedimentated to the bottom and medium was exchanged with 200 μl fresh medium containing

0.5 mg/ml MTT and different concentrations of salicylaldehyde (11.7 μg/μl, 1.17 μg/μl, 0.12 μg/μl, and 0.01 μg/μl; these concentrations are equivalent to 10 μl, 1.0 μl, 0.1 μl, and 0.01 μl salicylaldehyde/ml medium). For control, only 200 μl of medium containing 0.5 mg/ml MTT was applied under the same conditions as described above. With respect to the volatility, samples were always tested on separate plates and all plates were covered with lids (distance between lid and plate: 0.75 mm). The plates were incubated for 48 hr at room temperature. During this time blastospores could germinate and grow hyphae. After incubation, the medium was replaced with 200 μl isopropanol (Merck) containing 0.1% HCl (Merck). The hyphae in each well were mechanically disrupted by mixing the fluid with a 200-μl pipet. After a 10-min incubation at room temperature, 100 μl from each well was transferred to empty wells of a fresh microtiter plate. As described above, the staining agent MTT colors only living cells. Absorbance was read at 560 nm using a microtiter plate reader (Titertek).

Quantification of Distance Effects: Colorimetric Fungus Assay. To quantify the antifungal effect of volatile salicylaldehyde over distance, we modified the colorimetric fungus assay with *M. anisopliae*. In one row of a 96-well microtiter plate; each of six wells was filled with 0.5 μl salicylaldehyde, all others were filled with 200 μl blastospore suspension (2×10^5 spores/well) in fresh medium (see Colorimetric Fungus Assay) with MTT (0.5 mg/ml). The plate was covered with a lid, incubated for 48 hr at room temperature and viability was determined as described above. To prevent errors due to edge effects, the viability of the blastospores in edge wells was not recorded.

Statistical Analysis. Differences between the concentrations of the quantified compounds of larval secretions, between the diameters of lysis and inhibition zones, and between absorbance measured in fungal colorimetric assays were evaluated by the Mann-Whitney U test (Sachs, 1992). Multiple comparisons of data were confined to Bonferroni correction. Differences between absorbance of colored suspensions of the cells in the MTT test for cytotoxicity were evaluated by one-way ANOVA and post-hoc Scheffé tests.

RESULTS

Composition of Larval Secretions and Quantification of Constituents. The composition of larval secretions of *C. vigintipunctata* feeding upon *S. fragilis* did not differ from the literature (Pasteels et al., 1982; Soetens et al., 1998). The secretion is composed mainly of salicylaldehyde and shows traces of benzaldehyde (Table 1). GC-MS analyses of the larval secretion of *C. lapponica* feeding either upon *B. pubescens* or *S. borealis* also revealed the presence of known components for these species. Secretions of *C. lapponica* larvae feeding upon birch contained neither benzaldehyde nor salicylaldehyde, but did contain isobutyric and

TABLE 1. CONCENTRATIONS OF COMPOUNDS IN THREE DIFFERENT SECRETION TYPES OF *Chrysomela* Larvae ($N = 5$) DETECTED AND QUANTIFIED BY GC-MS ANALYSES[a]

	Concentration (μg/μl, mean $\pm$ SD)		
	C. lapponica		*C. vigintipunctata*
Compound	*Betula*	*Salix*	*Salix*
Benzaldehyde	0	0.20 ± 0.21^a	0.07 ± 0.02^a
Salicylaldehyde	0	58.36 ± 31.08^a	81.50 ± 9.68^a
2-Phenylethanol	0	0.11 ± 0.11	0
Hexyl isobutyrate	0.76 ± 0.12^a	0.01 ± 0.01^b	0
(*Z*)-3-Hexenyl isobutyrate	0.88 ± 0.03	0	0
2-Phenylethyl isobutyrate	0.84 ± 0.11^a	0.05 ± 0.05^b	0
2-Phenylethyl 2-methylbutyrate	1.01 ± 0.14^a	0.02 ± 0.02^b	0

[a] Different letters indicate significant ($P < 0.05$) differences between columns. Mann-Whitney U test.

2-methyl butyric acid and several esters. Secretions of *C. lapponica* larvae feeding on *S. borealis* contained salicylaldehyde as the major component and small amounts of benzaldehyde and carboxylic acid esters (Table 1) (Hilker and Schulz, 1994; Gross, 1997).

Direct and Distance Effects of Cytotoxicity. The results of the cytotoxicity assays with the larval secretions and salicylaldehyde are presented in Table 2. When applied directly onto the cell cultures of *T. ni*, concentrations of synthetic salicylaldehyde of 0.12 μg/μl and higher exhibited significant cytotoxicity. Direct application of 0.05 μl of the *C. vigintipunctata* larval secretion also resulted in cytotoxic activity. However, cytotoxic effects were not caused by application of the secretion of birch-feeding *C. lapponica* larvae. High concentrations (11.7 μg/μl) of synthetic salicylaldehyde showed a cytotoxic effect via the gas phase over a distance of 90 mm; concentrations of 1.17 and 11.7 μg/μl also caused a cytotoxic effect over a distance of 9 mm compared to the respective control. The *C. vigintipunctata* larval secretion inhibited the growth of insect cells over a distance of only 9 mm.

Antibacterial Activity. Neither salicylaldehyde nor the larval secretions showed activity in the lytic zone assay with the gram-positive bacterium *Micrococcus luteus* (Table 3). In contrast, secretions of the willow-feeding leaf beetle larvae showed a significant growth inhibition of the gram-negative bacterium *Escherichia coli*. The tested synthetic sample of salicylaldehyde, which is the main component of the secretions of both willow feeding leaf beetle species, had also, a strong inhibitory effect. The larval secretion of the birch-feeding allospecies of *C. lapponica*, which does not contain any salicylaldehyde, caused no growth inhibition of *E. coli* (Table 3).

Antifungal Activity. The antifungal activity of larval secretions and salicylaldehyde as measured by the inhibition zone assay with the yeast *Saccharomyces*

[a]Mean values and standard deviations ($N = 6$) of the lytic/inhibition zone diameters caused by synthetic salicylaldehyde and by exocrine secretions of larvae of *Chrysomela lapponica* feeding upon birch (*Betula pubescens*), and of *C. lapponica* and *C. vigintipunctata* feeding upon willow (*Salix* ssp.). Glandular secretion of one larva was collected with filter paper disks and placed onto agar plates. Volumes of 5 μl salicylaldehyde dissolved in dichloromethane (0.5 μl salicylaldehyde in 4.5 μl dichloromethane) or 5 μl dichloromethane (control) were applied to filter paper disks and placed onto agar plates.

[b]Significant ($P < 0.05$) difference from control within a treatment.

cerevisiae are shown in Table 3. Germination and growth of the fungus were inhibited by both the exocrine secretions of the willow-feeding larvae and synthetic salicylaldehyde, but not by the secretion of birch-feeding larvae of *C. lapponica*.

The antifungal activity of salicylaldehyde as measured by the colorimetric fungus assay with the entomopathogenic fungus *Metarhizium anisopliae* is presented in Figure 1A. Since mitochondrial enzymes of living hyphae produce the blue color formazan from MTT, high absorbance values mean high germination and growth rates of *M. anisopliae*. A concentration of 0.12 μg/μl salicylaldehyde reduced the germination and growth of the fungus by more than 50% when compared to the control (Figure 1A). The level of salicylaldehyde in the larval secretion of willow feeding *Chrysomela* larvae is much higher (see Table 1). In order to reach such a 50% reduction of germination and growth, a much higher concentration of the common fungicide nystatin (1.0 μg/μl) was necessary (Figure 1B).

Distance Effect of Antifungal Activity. Results of the colorimetric fungus assay for quantification of a distance effect of antifungal activity of salicylaldehyde via the gas phase are given in Figure 2. At a distance of 9–36 mm from wells containing 0.5 μl salicylaldehyde, germination of blastospores of *M. anisopliae* and growth of hyphae were strongly inhibited. At a distance of 45 mm from wells containing salicylaldehyde, a weaker, but still significant reduction of fungal activity was recorded (Mann-Whitney U test, Bonferroni corrected, $P < 0.0004$). At greater distances, inhibition of fungal blastospore germination and growth could no longer be detected.

DISCUSSION

The present study shows that larval exocrine secretions from willow-feeding leaf beetles exhibited antibacterial, antifungal and cytotoxic activities. Salicylaldehyde, the major component of the secretion of willow-feeding larvae, was shown to display these activities (Figures 1 and 2; Tables 2 and 3). Larvae are protected from the cytotoxic activity of their own secretion by a cuticular lining of the glandular reservoirs that store the secretions (Garb, 1915; Hinton, 1951; Oldham et al., 1996; Gross et al., 1998).

The results of our study show that secretions of willow feeding larvae act nonspecifically against a wide range of microorganisms. We consider the antifungal activity of the exocrine larval secretions to be of particular ecological significance. Fungal attack occurs when fungal hyphae penetrate the cuticle at the larval body surface, which is where the exocrine secretion may display its antifungal activity. Glands releasing the antifungal secretion are distributed segmentally on the larval body from the mesothorax to the seventh abdominal segment and thus, may, protect

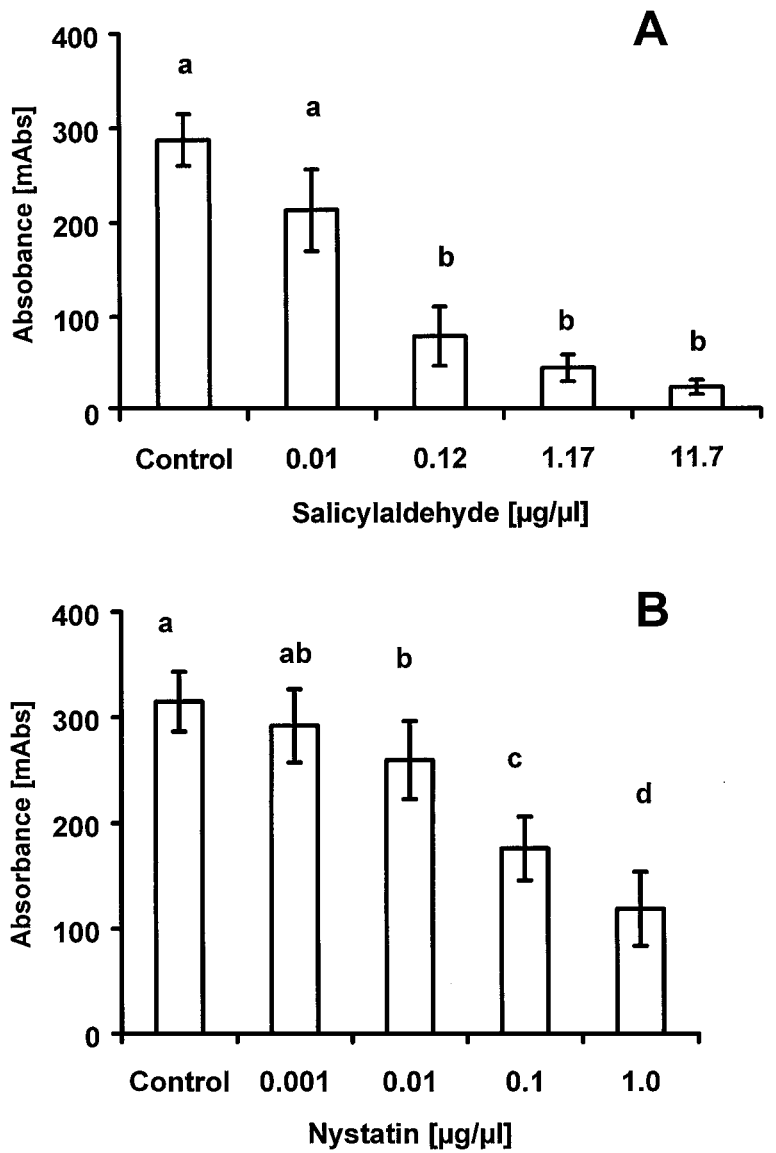

FIG. 1. Results of the colorimetric fungus assay. Mean values and standard deviations ($N = 6$) of photometrically measured absorbance (mAbs) of coloring produced by *Metarhizium anisopliae* after treatment with different concentrations ($\mu g/\mu l$) of (A) salicylaldehyde and (B) nystatin. Less coloring means reduced activity of mitochondrial enzymes and, thus, reduced blastospore germination and hyphal growth. Mann-Whitney U test (Bonferroni corrected); different letters indicate significant ($P < 0.005$) differences.

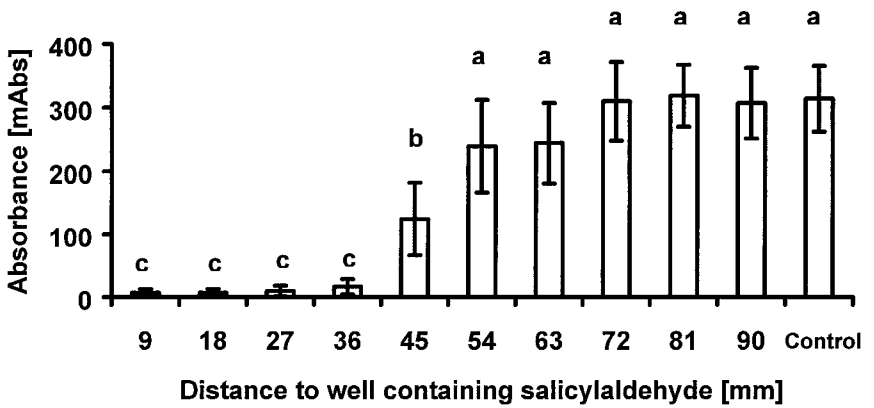

FIG. 2. Quantification of antifungal effects of salicylaldehyde via the gas phase using the modified colorimetric fungus assay with blastospores of the entomopathogenic fungus *Metarhizium anisopliae*. Mean values and standard deviations ($N = 18$) of photometrically measured absorbance (mAbs) of coloring produced by *M. anisopliae*. Distance between wells containing 0.5 μl salicylaldehyde to measured wells extend from the left to the right. Mann-Whitney U test (Bonferroni corrected); different letters indicate significant ($P < 0.0004$) differences.

a large part of the larval surface from fungal penetration. Pathogenic bacteria may only invade the larval body orally or via injuries. Larval secretions may be unable to act against bacteria at feeding sites, unless volatiles in the secretion also show activity at contaminated feeding sites.

The range of activity of the secretion via the gas phase was not tested for bacteria, but towards insect cells and the entomopathogenic fungus *M. anisopliae*. Cytotoxic activity of secretions of willow-feeding larvae was obvious when applied directly onto insect cells and was also detected over a distance of 9 mm via the gas phase (Table 2). However, salicylaldehyde exhibited antifungal activity via the gas phase over a distance of 45 mm (Figure 2). This range of activity was recorded when the microtiter plate with wells containing 0.5 μl salicylaldehyde was covered with a lid. The antifungal activity range of the secretion containing salicylaldehyde is expected to be much lower in a natural environment. Nevertheless, since paired larval glands are located on nine larval segments, even antifungal activity via the gas phase over much shorter distances might be sufficient to effectively protect these larvae from fungal attack. During larval development, *C. lapponica* or *C. vigintipunctata* larvae grow from approximately 2 mm to approximately 9 mm length.

The antimicrobial effects of the larval secretion of *C. vigintipunctata*, as measured by inhibition zone assays, were stronger than those of the secretion of

C. lapponica larvae feeding on willow (Table 3; Mann-Whitney U test: $P < 0.001$). For the inhibition zone assays, larval secretions had been collected on filter paper that was then placed onto agar plates in order to examine whether the secretion released by one larva is sufficient to show antimicrobial effects. We did not measure the volume of secretion released by each larva. The larvae of *C. vigintipunctata* from which secretion was obtained for the bioassays were larger than those of *C. lapponica* and may have released more secretion than the *C. lapponica* larvae. Even though concentrations of salicylaldehyde in larval secretions of *C. vigintipunctata* and willow feeding *C. lapponica* were not significantly different (Table 1), higher amounts of salicylaldehyde due to larger secretion volumes might explain the stronger activity of the larval secretion of *C. vigintipunctata* detected by the inhibition zone assays.

The volume of secretion and the concentration of salicylaldehyde within the secretion are known to decrease when larvae of *C. vigintipunctata* are transferred from a salicin-rich willow like *S. myrsinifolia* to *S. caprea*, a willow species with a very low concentration of phenolic glucosides (Julkunen-Tiitto, 1986; Soetens et al., 1998). Volumes (salicylaldehyde concentrations) of secretions ranged from 0.103 μl $\pm$ 0.029 (526 μg/μl $\pm$ 190) on *S. myrsinifolia* to 0.047 μl $\pm$ 0.019 (0.83 μg/μl $\pm$ 0.35) on *S. caprea* (Soetens et al., 1998). Willow beetle larvae that feed on Salicaceae with small contents of salicin suffer an increased risk of predation by some generalist predators (Matsuda and Sugawara, 1980; Pasteels et al., 1986; Palokangas et al., 1992), but they might also benefit from the low salicylaldehyde concentrations of their secretions due to a decreased rate of detection by specialist predators, that use salicylaldehyde as a kairomone for finding prey (Pasteels and Gregoire, 1984; Rank, 1994; Köpf et al., 1997; Sears et al., 2001). However, the results of the present study indicate that a reduced concentration of salicylaldehyde in the larval secretion decreases the defensive efficacy against pathogen attacks (compare Figure 1A).

In contrast to the willow-feeding allospecies of *C. lapponica*, the secretion of the birch-feeding larvae, that did not contain salicylaldehyde, was inactive against microorganisms and insect cells. These differences between secretions of birch- and willow-feeding allospecies are supported by our field observations. Fungal infections of larvae have never been observed in larvae of the willow-feeding Finnish population. In contrast, when recording larval mortality of the birch-feeding Czech population during a rainy season, 30% of the larval groups (about 30 larvae per group) were found dead with obvious fungal infection of several larvae within a group (unpublished data). During a five-year study of natural enemies of the willow-feeding allospecies of *C. lapponica* in Russia, only 2% of pupal mortality had been caused by microbial infections (Zvereva and Kozlov, 2000). Pupae may be protected against microbial infection by the salicylaldehyde-containing larval secretion that evaporates from the glandular reservoirs of the larval exuvia that remains attached to the pupa.

Only three species of the taxon *Chrysomela* feed on Betulaceae: *C. interrupta* and *C. mainensis* feed on alder (Brown, 1956), and one allospecies of *C. lapponica* feeds on birch (Letzner, 1876). The exocrine larval secretions of these *Chrysomela* species on Betulaceae are well known to repel generalist predators (Hilker and Schulz, 1994). We suppose that the larval secretions of all these *Chrysomela* species feeding on Betulaceae do not exhibit any antimicrobial effects because of their chemical similarity (Termonia and Pasteels, 1999). Further studies are needed to elucidate whether, and how, these Betulaceae feeding *Chrysomela* species balance the disadvantage of being unprotected against pathogens by other positive effects that might have favored the specialization of these beetles on birch or alder (Termonia et al., 2001).

Acknowledgments—This study was funded by the Deutsche Forschungsgemeinschaft (Hi 416/9-1,2) and the state of Berlin for NaFöG-fellowship. We would like to thank the Ministry of Ecology in the Czech Republic for permission to collect leaf beetles in protected areas. We are grateful to Dr. Seppo Neuvonen, Kevo Subarctic Research Institute, Finland, for collecting and sending leaf beetles, and Dr. Hong Yang, Wuhan University, China, for the gift of *Trichoplusia ni* cells. We thank Nina Fatouros and Frank Müller for their help in GC-MS analyses. Many thanks are also due to Dr. Joachim Ruther, Berlin, and two anonymous reviewers for their critical comments on an earlier version of this manuscript.

CHARACTERIZATION AND TOXICITY OF *Amanita cokeri* EXTRACT

DENNIS C. DREHMEL and WILLIAM SCOTT CHILTON*

Department of Botany
North Carolina State University
Raleigh, North Carolina 27695

(Received May 24, 2001; accepted October 5, 2001)

Abstract—The nonprotein amino acids 2-amino-3-cyclopropylbutanoic acid and 2-amino-5-chloro-4-pentenoic acid were isolated from the mushroom *Amanita cokeri*. The cyclopropyl amino acid is toxic to the fungus *Cercospora kikuchii*, the arthropod *Oncopeltus fasciatus* (milk weed bug), and the bacteria *Agrobacterium tumefaciens*, *Erwinia amylovora*, and *Xanthomonas campestris*. Toxicity to bacteria was reversible by addition of isoleucine to the medium. No toxicity was observed for 2-amino-5-chloro-4-pentenoic acid.

Key Words—Basidiomyces, *Amanita*, *Lepidella*, 2-amino-3-cyclopropylbutanoic acid, 2-amino-5-chloro-4-pentenoic acid, *Oncopeltus*, *Cercospora*, *Agrobacterium*, *Erwinia*, *Xanthomonas*.

INTRODUCTION

The mushroom genus *Amanita* Pers. per Hook. has a reputation for having a high ratio of species toxic to humans. Those of section *Phalloidae* sensu Drehmel (Drehmel et al., 1999; Moncalvo et al., 2000), containing cyclopeptide amatoxins, are the most deadly. Amanita species of section *Amanita* subsection *Amanita* sensu Drehmel are characterized by the less deadly, neurotoxic amino acids ibotenic acid and muscimol. Amanita species of section *Lepidella* (Gilb.) Corner & Bas, which lack amatoxins and neurotoxic amino acids, are characterized by the presence of unsaturated, C_5–C_7 nonprotein amino acids containing unsaturation or cyclopropyl groups and, often, chlorine (Table 1). Cyclopropyl amino acids are of interest because 2-amino-3-cyclopropylpropionic acid has been shown to be "a potent antagonist" of *Escherichia coli* (Meek and Rowe, 1955) and can inhibit germination of spores from *Pyricularia oryzae* Cav. (Ohta et al., 1986).

Very little is known about the edibility or human toxicity of species in section *Lepidella* or whether nonprotein amino acids of this section play a role in defense of the carpophore. Earlier studies have shown toxicity of 2-amino-4,5-hexadienoic acid from *A. smithiana* to guinea pigs (Chilton and Tson, 1973). The amino acid fraction of *A. smithiana* also damages renal epithelial cells (Pelizzari et al., 1994). The amino acid fraction of *A. abrupta*, containing 2-amino-4,5-hexadienoic acid and 2-amino-4-pentynoic acid, also causes liver damage in mice (Yamaura et al., 1986). The 2-amino-4-chloro-4-pentenoic acid isolated from *A. pseudoporphyria* had antibacterial activity against a number of human pathogens (Moriguchi et al., 1987).

A common mushroom of section *Lepidella* in the southeastern United States is *Amanita cokeri* (Gilb. & Kuhner) Gilb. In view of the previously reported

biological activity of nonprotein amino acids of section *Lepidella*, we have tested potential antimicrobial and antiinsect defensive effects of the two major nonprotein amino acids of this mushroom, 2-amino-3-cyclopropylbutanoic acid (Chilton and Drehmel, 2001) and 2-amino-5-chloro-4*E*-pentenoic acid, chemically characterized in the present study.

METHODS AND MATERIALS

General Characterization. Fresh fruiting bodies of *A. cokeri* were collected in August 1998 in Wake County, North Carolina (Duke University herbarium number HN5914). They were processed by brushing away dirt, weighed, and extracted in a blender with 70% ethanol in water. A 1-ml sample of the extract was evaporated to dryness in a Speed Vac to determine the solids concentration. The solids were redissolved in distilled water to achieve a standard of 0.1 mg/μl. Amino acids of these samples were analyzed by cellulose thin-layer chromatography (TLC), paper chromatography (PC), and high-voltage paper electrophoresis (HVPE). TLC and PC were developed with 1-butanol–water–acetic acid (BAW, 12:3:5). Amino acids were detected by ninhydrin reagent.

Isolation of Amino Acids. Total amino acids in mushroom extracts were absorbed on a Dowex $50H^+$ column (1×10 cm) and eluted with dilute ammonia. The total amino acid fraction was further fractioned by descending preparative PC (BAW 12:3:5), allowing the solvent front to drip off the end of the paper for better resolution. Individual amino acids of interest were redissolved off of the PC. The purity of the amino acids isolated was verified by TLC or PC and by HVPE using ninhydrin detection. The structure of the nonprotein amino acids isolated was verified by NMR and mass spectroscopy.

Toxicity Tests. Standard test solutions of both total and individual amino acids were prepared to a concentration of 0.1 mg/μl. Standard solutions were also prepared of two well-studied toxins from plants: DIMBOA (2,4-dihydroxy-7-methoxy-1,4-benzoxazin-3-one), from corn seedlings, and tenulin, a sesquiterpene lactone from bitter sneeze weed (*Helenium amarum* [Raf.] H. Rock). All of these standard solutions, including the standard solution of the unrefined extract, were used in three types of toxicity tests that were targeted toward bacteria, fungi, and arthropods.

Bacteria. The bacterial organisms used were *Agrobacterium tumefaciens* (Smith & Townsend) Conn, *Erwinia amylovora* (Burrill) Winslow, Broadhurst, Buchanan, Krumwiede, Rogers & Smith, and *Xanthomonas campestris* pv. *zinniae* (Pammel) Dawson. A liquid culture of the bacteria and soft agar was applied to a culture plate of hard agar incorporating nutrient broth. Treated 3MM paper disks were applied, and the zone of inhibition was observed after 48 hr. The paper disks (7 mm diam.) were treated in a two-step process. First, to each disk was applied

10 μl of 95% ethanol, which was allowed to dry in the sterile laminar flow hood. Second, to each disk was applied 1 μl (100 μg of test substance), 3 μl (300 μg) or 10 μl (1 mg) of a test solution, which was also allowed to dry. Each culture plate had a negative control disk that had been treated with ethanol only. Many culture plates had one or two positive control disks treated with DIMBOA or tenulin.

Fungi. Toxicity to the fungal plant pathogen *Cercospora kikuchii* (Matsumoto & Tomoyasu) M. W. Gardner was studied in two ways. In one method, the same general approach as with the bacteria was used. Instead of a liquid culture of bacteria, plugs of *Cercospora* were dispersed into 1 ml of sterile distilled water using glass beads in a glass tube vibrated by a Vortex machine. The resultant hyphal fragment inoculum was pipetted onto a potato dextrose agar (PDA) culture plate and allowed to dry in a sterile laminar flow hood. Treated disks were applied as above with the bacterial testing. In a second method, plugs were removed from a PDA plate and replaced with plugs of *Cercospora*. Again, test disks were treated and placed on the PDA plate, but in this case they were applied exactly on top of the *Cercospora* plugs.

Insects. Milkweed bugs (*Oncopeltis fasciatus* Dallas) in the third or fourth instar, or newly hatched, were housed in a 1-liter flask covered with a paper towel and supplied with raw, shelled suflower seeds and water in a 1.5-ml microcentrifuge tube fitted with a paper wick. Tested substances were dissolved in the water supply. A negative control group with no test substance was used in each experiment. In tests with third or fourth instar insects, a positive control was used with DIMBOA added to the water. Dosing schedules are noted below. With medium sized insects, the effects of both short- and long-term water deprivation also were studied. In one test with insects of various ages, the insects were given a choice between treated and untreated water to gauge the relative appeal of each.

RESULTS

Both TLC and PC of the total amino acid fraction of *Amanita cokeri* showed the presence of two prominent high R_f, low-polarity amino acids in the valine–leucine region of the chromatogram. We have previously shown (Chilton and Drehmel, 2001) that the higher R_f amino acid giving a normal ninhydrin reaction is 2-amino-3-cyclopropylbutanoic acid. Treatment of the lower R_f amino acid with ninhydrin gave an initial yellow-brown color, shifting gradually to purple, characteristic of β,γ- and γ,δ-unsaturated amino acids. The lower R_f amino acid was purified by ion exchange chromatography and preparative PC. Positive FAB MS gave a pseudo molecular ion doublet at $M + H = 150$, 152 in the 3:1 ratio of a mono-chloro compound. Similarly, negative ion FAB MS gave $M - H = 148$, 150, indicating that the elemental composition must be $C_5H_8ClNO_2$. The NMR

TABLE 2. ZONE OF INHIBITION RESULTS FOR BACTERIA (DIAMETER OF ZONE IN MILLIMETERS)

Bacteria tested	Unfractionated extract (1 mg)	Cyclopropy/AA (0.3 mg)	DIMBOA (1 mg)	Tenulin (1 mg)

Erwinia amylovora	26	28	nt	20
Xanthomonas campestris	14	16	nt	nt

spectrum in D_2O (α-CH, 3.64 ppm, t; β-CH_2, 2.64 ppm, q; γ-CH, 5.63 ppm, q; δ-CH 6.15 ppm, d, $J = 10$ Hz) indicates that this compound is 2-amino-5-chloro-4*E*-pentenoic acid, previously isolated by Yoshimura et al. (1999) from *A. castanopsidis*.

Results of the zone of inhibition (ZOI) tests using three different bacteria, *A. tumefaciens*, *E. amylovora*, and *X. campestris* pv. *zinniae*, were positive for the unfractionated standard extract, the total amino acid fraction, and purified 2-amino-3-cyclopropylbutanoic acid (Table 2). However, purified 2-amino-5-chloro-4-pentenoic acid did not show any zone of inhibition. For all three bacteria tested, it was possible to reverse the toxicity of 2-amino-3-cyclopropylbutanoic acid by adding isoleucine to a disk in close proximity to the disk with 2-amino-3-cyclopropylbutanoic acid. The toxicity reversal was evident in the space around the isoleucine and between the two disks but did not extend beyond this space. 2-Amino-3-cyclopropylbutanoic acid remained toxic in the space on either side of its disk and in the space away from the disk with isoleucine. This demonstrates that 2-amino-3-cyclopropylbutanoic acid acts as an antimetabolite with respect to isoleucine (Scannell and Pruess, 1975). Neither leucine nor valine demonstrated any zone of reversal in the double disk test.

Results for the test on the PDA plate with the dispersed fungus *Cercospora kikuchii* showed that there was no zone of inhibition using either unfractionated amino acids or 2-amino-3-cyclopropylbutanoic acid from *A. cokeri*. However, in the test where the treated disk was placed on top of the fungal plug, the fungal growth area at the 2-amino-3-cyclopropylbutanoic acid-treated disk was less than half (46%) of the fungal growth area at the untreated disk after a five-day period.

The unfractionated extract of *A. cokeri* was lethal to both milkweed bug neonates and later instars. In the case of the former, four populations of approximately 25 eggs each were split into two groups where one received untreated water and the other received water with 19 mg of unfractionated dried extract dissolved in 1.5 ml water in a microcentrifuge tube. Water was replenished as needed, usually every day or two to make up for consumption and evaporation. On day 5 and day

10, the resupply contained additional extract for the test group in the same dose as the initial dose. Thus, the total possible dose to the end of the early development test group was 57 mg. However, as noted below, many did not survive long enough to be exposed to this amount. At one week, there were differences between the two groups. The control group was bigger and more active, and more of the insects had progressed to later instars. Many in the test group were motionless. On day 10 before the third treatment with the extract, at least half of the test group was dead. At the two week mark, most of the test group were dead. The untreated group was mostly in the third instar and very large compared to the remaining couple of insects in the test group. All treated milkweed bugs (population = 49) were dead by day 18. Meanwhile, the untreated group was entirely healthy and proceeding to the fourth instar. To check whether death was due to dehydration, because the test insects found the treated water undesirable, approximately 50 insects were given the choice between treated and untreated water after being without water for two days. The numbers of insects at each water supply were counted every 15 min. The total number of visits to the treated water was slightly higher than that for untreated water.

As another check on possible antifeedant properties of *A. cokeri* amino acids, a total of 34 milkweed bugs of third and fourth instar were tested in five groups. There were six in a negative control group (no treatment), seven in a positive control group (treatment with DIMBOA), seven in the test group given *A. cokeri*-treated water, seven in a group given no water at all, and 7 in a group given no water for six days and untreated water after that. The DIMBOA group received one treatment of 9 mg in the water, and the test group received two treatments (day 0 and day 5) of 33 mg each in the water for a total dose of 66 mg. In all cases other than day 5 of the test group, the resupply water given every day or two was only water. After one week, six of seven of the DIMBOA group were dead, and all in the other groups were alive, although the test group with *A. cokeri*-treated water appeared lethargic. After a week and a half, all of the group denied water were dead, although prior to death many of the insects remained active and were climbing the walls of the flask.

After two weeks, the group with the *A. cokeri*-treated water had difficulty walking and in some cases even had difficulty in standing. Movement was sluggish and awkward or not at all. All of the untreated group had achieved full adulthood, while only two of the test group had. All bugs in the group that had been denied water for six days only were active. After three weeks, all of the untreated group remained active adults, in contrast to the *A. cokeri*-treated group where only one survived. The bugs in the group denied water for only six days remained active and showed no signs of difficulty in movement as was seen with the *A. cokeri*-treated group. Of the lethal conditions used in testing medium-sized insects, the treatments may be compared by the time to greater than 50% death of the test population: for DIMBOA, 4 days; for no water, 9 days; for *A. cokeri* extract, 17 days.

DISCUSSION

The hallmark of the nonprotein amino acids of *Amanita* section *Lepidella* is the presence of unsaturated norvalines and norleucines. Hatanaka (1992) has suggested that all of the acyclic unsaturated and chlorinated C-5 amino acids of Table 1 may arise by desaturation of norvaline followed, in some cases, by hydrogen chloride addition and hydroxylation. The C-6 series may be related to the C-5 amino acids by α-homologation of the type that converts the valine precusor α-ketoisovaleric acid into the leucine precursor α-ketoisocaproic acid in primary metabolism (Lehninger, 1975). The 3-cyclopropylpropionic acid could arise via one carbon addition across the double bond of 2-amino-4-pentenoic acid. However 3-cyclopropylbutanoic acid of *A. cokeri* must have a different origin.

The four microorganisms used to test toxicity of the two nonprotein amino acids of *A. cokeri* are common soil or phylloplane-inhabiting bacteria and fungi not known to be pathogenic or saprophytic on *A. cokeri*. Consequently, they were considered unlikely to have evolved resistance to the unusual amino acids of this mushroom. While no toxicity was detected for 2-amino-5-chloro-4-pentenoic acid, 2-amino-3-cyclopropylbutanoic acid inhibited growth of all four microorganisms. Toxicity of this amino acid was reversed in each case by isoleucine but not by leucine or valine. This suggests that replacement of the isoleucine β-ethyl group by a β-cyclopropyl group converts it into an isoleucine antimetabolite.

The milkweed bug, a narrow host range insect, is also unlikely to be adapted to defensive compounds of *A. cokeri*. Colonies of this insect are commonly maintained indefinitely on a more readily available diet of sunflower seeds. Addition of the 2-amino-3-cyclopropylbutanoic containing amino acid fraction of *A. cokeri* to their drinking water caused the death of all insects prior to the reproductive stage. This may be due to an antimetabolte mechanism similar to that observed with the microorganisms or by reduced water intake caused by the insects' perception of the added amino acid, or by a combination of these mechanisms. While there may be some antifeedant effects underlying the lethality of the amino acid fraction of *A. cokeri*, direct toxicity is implied by four observations. Both small and larger sized insects were observed to drink frequently and on a regular basis from treated water. When given a choice between treated and untreated water, the insects chose each in nearly equal numbers. In the tests with older insects, death by dehydration was much faster than death of insects given water containing *A. cokeri* amino acids. *A. cokeri*-treated insects demonstrated a difficulty in walking and climbing not seen in either short- or long-term dehydrated insects.

We conclude that aqueous ethanolic extracts of *A. cokeri* contain at least two nonprotein amino acids, 2-amino-3-cyclopropylbutanoic acid and 2-amino-5-chloro-4-pentenoic acid, both of which have been isolated previously form *A. castanopsidis* (Yoshimura et al., 1999). Aminocyclopropylbutanoic acid was

toxic against the three bacteria, a fungus, and an insect used in the bioassays. Toxicity toward the microorganisms is probably due to this cyclopropyl amino acid acting as an isoleucine antimetabolite. The total amino acid fraction of *A. cokeri* is lethal to milk weed bugs (*Oncopeltus fasciatus*) in both early and late stages of development. The mechanism for this is direct toxicity rather than as a drinking deterrent causing death by dehydration. Since the amino acids were not fractionated in this test, it is not known whether one of these two nonprotein amino acids is responsible, or possibly, some other, unrecognized component of the extract.

(Received May 10, 2001; accepted October 5, 2001)

Abstract—Caulerpenyne (CYN) contents was measured in two Chlorophyceae algae, *Caulerpa taxifolia* and *Caulerpa racemosa*, between July 1999 and July 2000. Sampling was performed at three stations exhibiting increasing levels of competition with the seagrass *Posidonia oceanica*. Significant differences were observed as a function of the *Caulerpa* species, the season, and the level of competition. CYN concentrations were always greater in *C. taxifolia*, regardless of either season or level of competition (35–80 times greater, according to the season). For a given species, maximum concentrations were recorded in autumn (September/November) and minimum values occurred in spring (April/May). CYN contents decreased with increasing level of competition, whereas frond length increased over this same gradient. It would appear that when the algae are in competition with *P. oceanica*, *Caulerpa* is more inclined to accelerate vegetative growth (competition for light) than to produce secondary metabolites.

Key Words—*Posidonia oceanica*, *Caulerpa taxifolia*, *Caulerpa racemosa*, competition, caulerpenyne.

INTRODUCTION

The genus *Caulerpa*, which belongs to the Class Ulvophyceae, is made up of approximately 1000 species, most of which are found in temperate and tropical waters. *Caulerpa taxifolia* (Vahl) C. Agardh and *Caulerpa racemosa* (Forsskål) J. Agardh are currently spreading throughout the Mediterranean. *C. racemosa* is generally considered to be a Lessepsian immigrant, as are *C. scalpelliformis* and *C. mexicana* (Boudouresque et al., 1996; Piazzi et al., 1997). Conversely, the

presence of *C. taxifolia* within the Mediterranean is most probably due to the accidental release of this alga from a public aquarium. It was observed for the first time in Monaco in 1984 (Meinesz and Hesse, 1991). Its distribution, which was on the order of 1 m^2 when initially discovered and 3 ha in 1990 (Meinesz et al., 1993), was estimated to be between 8000 and 10,000 ha in 2000 (Gravez et al., 2000) with six countries being affected (Monaco, France, Spain, Italy, Croatia, and Tunisia). *C. racemosa* has also spread rapidly within the Mediterranean. Since it was first discovered in the western basin (Livorno, Italy), the area that this alga covers has increased from 3000 m^2 in 1993 to over 300 ha in 1997 (Piazzi et al., 1997), which represents a 1000-fold increase.

Among the many secondary metabolites produced by algae belonging to the genus *Caulerpa*, caulerpenyne (CYN) is the most abundant cytotoxic sesquiterpenoid to be released. In *Caulerpa taxifolia* (Vahl) C. Agardh, this molecule makes up 0.2% (in spring) to 13% (in summer) of the alga's frond wet weight (Amade et al., 1994), values that are much higher than those observed in other *Caulerpa* species (Guerriero et al., 1994). In *C. taxifolia* and *C. racemosa* (Forsskål) J. Agardh, CYN, thought to be the most active substance, is involved either in the chemical defense of the plant against herbivore pressure or within the framework of interspecific competition (antifeedant and antifouling effects) (Lemée et al., 1993, 1997).

A variety of toxic effects due to CYN have been demonstrated in several organisms at different stages of their growth. The most harmful effect is on sea urchin eggs, which are killed by CYN (Lemée et al., 1993). This molecule, therefore, represents a potential danger to organisms living in proximity to either of these two *Caulerpa* species. The *C. taxifolia* strain from the Mediterranean contains higher CYN concentrations than the tropical strain (Guerriero et al., 1992). In addition, it exhibits exceptional growth in the Mediterranean in terms of both its population densities and the length of its fronds (Meinesz and Hesse, 1991).

The phases of vegetative growth in *P. oceanica* and *C. taxifolia* are reversed (Boudouresque et al., 1995; De Villèle and Verlaque, 1995). Thus, the leaves of *P. oceanica* are larger in winter and spring than the fronds of *C. taxifolia*, the period during which the growth of the latter species is at a minimum (Meinesz et al., 1993, 1995). Conversely, it is in summer and autumn that fronds of this alga reach their maximum length of 65 cm (see Meinesz and Hesse, 1991). During this period, the biomass of *C. taxifolia* can exceed 10 kg wet weight/m^2 (Meinesz and Hesse, 1991; De Villèle and Verlaque, 1995).

The aim of the present study was to assess the interspecific competition between either *C. taxifolia* or *C. racemosa* and the seagrass *Posidonia oceanica* (L.) Delile. This impact was assessed by quantifying the levels of CYN in the two *Caulerpa* species under different conditions of competition. *P. oceanica* is a key species in Mediterranean coastal ecosystems (Pergent, 1992), and regressions of

these seagrass beds are not without consequence, both from an ecological and economic point of view. Although a certain number of studies have quantified the impact of *C. taxifolia* on *P. oceanica* seagrass beds (Verlaque and Fritayre, 1994; De Villèle and Verlaque, 1995; Boudouresque et al., 1995; Francour et al., 1995), the same is not true of the impact of *P. oceanica* on these two *Caulerpa* species (Ceccherelli et al., 2000).

METHODS AND MATERIALS

Sampling of *C. taxifolia* was performed every two months, from July 1999 to July 2000, at the Cap Martin site (Alpes Maritime, France), at a depth of 10.0 m, and at the Antignano site (Livorno, Italy) for *C. racemosa*, at a depth of 2.0 m (Figure 1). For each site, three levels of competition were considered (Figure 2): **Station 0**—absence of *P. oceanica*; **Station 1**—simple contact between *P. oceanica* and either *C. taxifolia* or *C. racemosa* (boundaries), in which the fronds of *Caulerpa* just touch the sheath and leaves of *P. oceanica*; and **Station 2**—strong interaction between *P. oceanica* and either *C. taxifolia* or *C. racemosa* (mixed population), in which the fronds of *Caulerpa* penetrate inside foliar shoots and rhizomes, between sheaths and leaves of *P. oceanica*.

The sampling stations at each site were within the same meadow and exhibited similar biological/physical and chemical characteristics (shoot density, sediment,

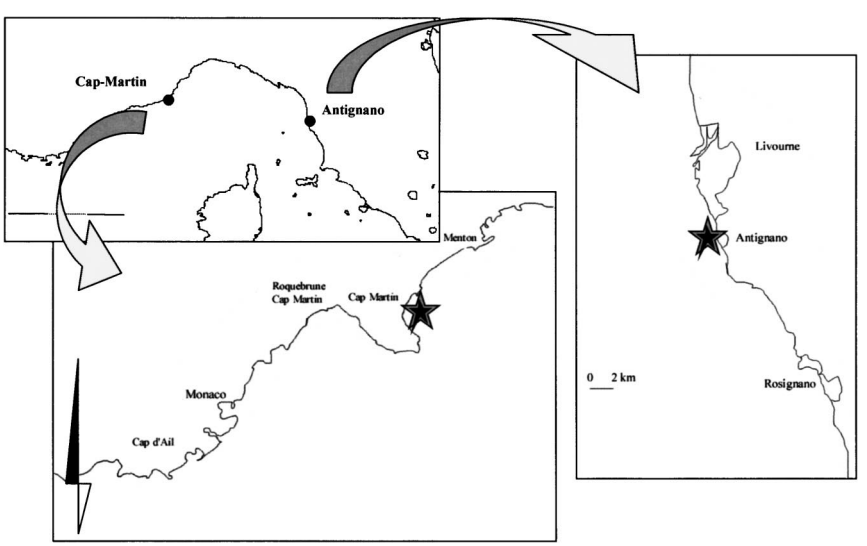

FIG. 1. Location of the sampling sites: Roquebrune-Cap Martin (France) for *Caulerpa taxifolia* and Antignano (Livorno, Italy) for *Caulerpa racemosa*.

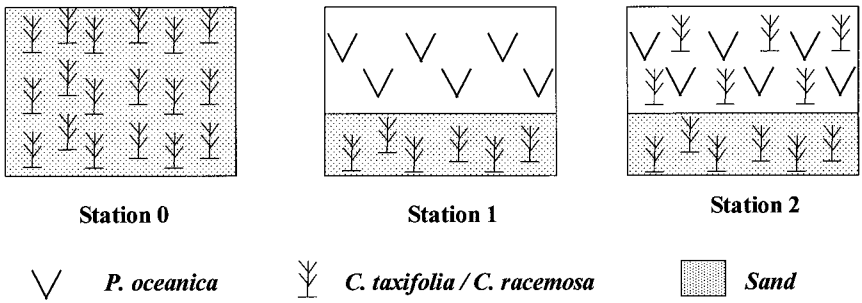

FIG. 2. Diagrams representing the three levels of competition between *P. oceanica* and the two *Caulerpa* species.

depth, temperature, salinity, hydrodynamics, etc.). The only difference between stations involved the presence and/or density of *C. taxifolia*.

Five samples were taken from each station. The algae were subsequently processed according to the protocol described by Amade et al. (1996). Briefly, they were rinsed in fresh water and stored at –20°C in methanol at a concentration of 5 g wet weight of *Caulerpa* in 50 ml of MeOH (MeOH, 95–98% Chromanorm; HPLC quality) in order to avoid any degradation of the CYN.

Extraction of CYN was performed directly in MeOH. To ensure the total diffusion of the CYN present within the syncytium, samples were sonicated for approximately 5 min. CYN measurements were performed using high performance liquid chromatography (Amade et al., 1996). Thus, 10 μl of sample was injected into a glass column of 5 μm silica (100 $\times$ 3 mm, Chrompack) and eluted with a MeOH–water solvent mixture (8:2) at a speed of 0.5 ml/min. As the retention time of CYN is on the order of 2.8 min, the injection time for each sample was set at 6 min. Measurements were performed at a UV wavelength of 254 nm, sensitivity = 0.32. The HPLC pump (Waters 600), equipped with an automatic injector (Waters 717), was monitored by specific software (Millennium Waters software) that also controlled the PAD data acquisition (Photodiode Array Detector Waters 996). This system allowed CYN peaks to be identified during elution, both in real time and under the measurement conditions. Three replicates were performed for each sample to assess the analytical dispersion. The standard curve, drawn up by using purified CYN, allowed the determination of CYN levels in the samples (Amade et al., 1994). A direct relationship between HPLC peaks and CYN levels was thus obtained.

Once normality (Shapiro and Wilks test) and variance homogeneity (Bartlett test) were tested, a one-way ANOVA was performed (as there exists a positive relationship between season and station) coupled with a Tukey multiple comparisons test in order to compare frond length. When the data were not normal (e.g., CYN levels), a nonparametric Kruskal-Wallis test was used coupled with a

Neuman-Keuls-Shapiro test in order to detect differences (Zar, 1984). The software Statgraphics Plus (v. 2.1) for Windows was used.

RESULTS

Variations in Caulerpenyne Content. CYN concentrations varied according to season (Kruskal-Wallis test; $P < 0.01$). For *C. taxifolia* (Figure 3), a maximum CYN production was observed in fall (September), followed by a decrease to reach minimum values in spring (March/May), and this regardless of the level of competition.

For a given season, CYN concentrations also varied as a function of competition (Kruskal-Wallis test; $P < 0.01$), and a decrease in CYN was observed with increasing levels of competition. In July, for example, station 0 exhibited values of 3.70 ± 0.68 mg CYN/g wet wt, whereas values were on the order of 1.99 ± 0.75 mg CYN/g wet wt and 1.42 ± 0.57 mg CYN/g wet wt for stations 1 and 2, respectively (Figure 3).

The severe storms that hit western Europe in December of 1999 caused exceptional hydrodynamic conditions on the Ligurian and Tuscan continental shelves. This phenomenon brought with it the erosion of 3–5 cm of substrate, as was clearly seen by the laying bare of the matte in the *P. oceanica* beds. In light of its shallow root system (rhizoids of 0.5–1 cm in length), *C. racemosa* was uprooted and a drastic reduction in its bottom cover was observed throughout the sampling site. Only a few individuals present within the rhizomes of *P. oceanica* escaped: the study of competition at this site was, therefore, stopped prematurely. Nevertheless, as was observed for *C. taxifolia*, the trend was toward a decrease in CYN levels with

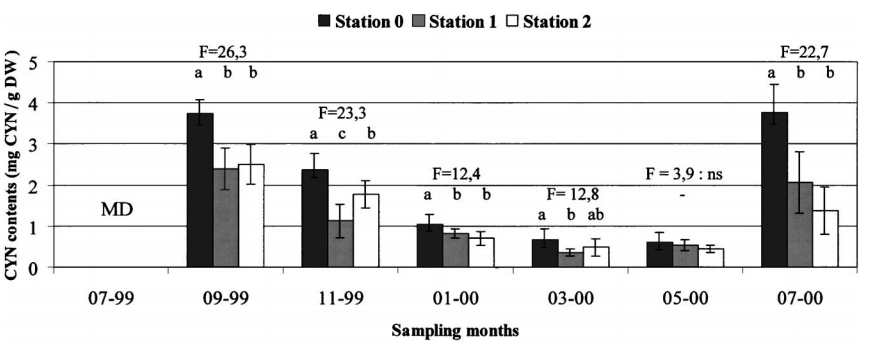

FIG. 3. CYN concentrations in *C. taxifolia* as a function of both season (fronds and stolons combined) and level of competition. No data are available for July 1999 (MD: missing data). Also shown are the ANOVA (or Kruskal-Wallis) test results (ns: nonsignificant). Tukey (or NKS) test is presented when ANOVA (or Kruskal-Wallis) test is significant. Values that do not differ at the 0.01 level are noted with the same letter.

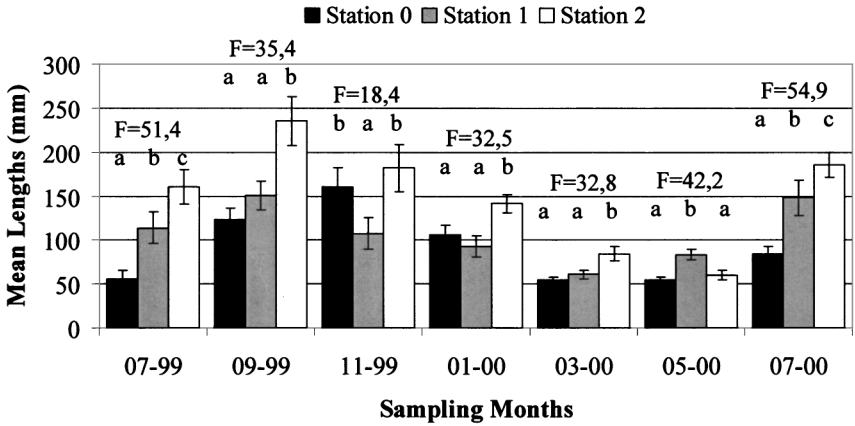

FIG. 4. Mean frond lengths for *C. taxifolia* as a function of both season and level of competition. Also shown are the ANOVA (or Kruskal-Wallis) test results (ns: nonsignificant). Tukey (or NKS) test is presented when ANOVA (or Kruskal-Wallis) test is significant. Values that do not differ at the 0.01 level are noted with the same letter.

increasing levels of competition. Indeed, in October 1999, CYN concentrations went from 0.07 ± 0.010 mg CYN/g wet wt for the station without competition to 0.03 ± 0.006 mg CYN/g wet wt for the station with a high level of competition, which represents a decrease of 42%. The station presenting intermediate competition levels generated values of 0.06 ± 0.01 mg CYN/g wet wt.

The mean CYN values were much higher in *C. taxifolia* than in *C. racemosa*. For example, in November 1999 values at the stations presenting no competition were on the order of 2.37 ± 0.41 mg CYN/g wet wt and 0.03 ± 0.014 mg CYN/g wet wt, respectively. There was, therefore, 80 times more CYN in *C. taxifolia*.

Variation in Frond Length. The frond length in *C. taxifolia* varied as a function of season (Figure 4), with a maximum autumn value (September–November) and a minimum in spring (March–May) (one-way ANOVA, $P < 0.01$). The longest fronds (one-way ANOVA; $P < 0.01$) were those in close contact with the *P. oceanica* seagrass beds (maximum level of competition). Thus, in July 2000, the algae in contact with *P. oceanica* exhibited mean frond lengths of 185.5 ± 13.9 mm vs 84.5 ± 8.1 mm where no such competition occurred; the station presenting moderate competition levels exhibited an intermediate value of 148.1 ± 20.3 mm.

Similar results were recorded for *C. racemosa*, with frond length also varying as a function of season (maximum length in November) and the largest fronds being those in the closest contact with *P. oceanica* (Figure 5). For example, in October 1999, fronds in close contact with *P. oceanica* exhibited a mean length of 19.13 ± 2.64 mm, followed by a value of 17.19 ± 1.82 mm for moderate contact, and finally 14.94 ± 1.85 mm in the absence of interspecific competition.

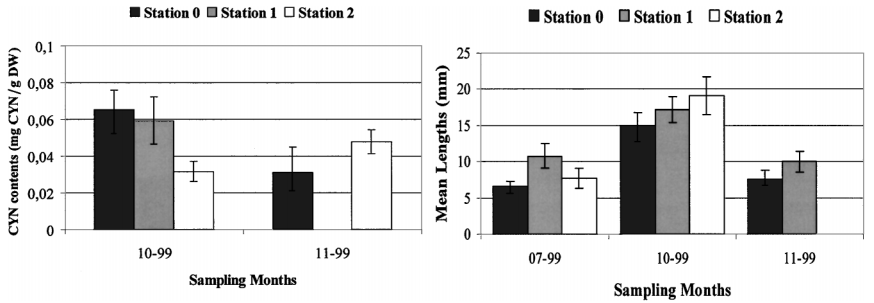

FIG. 5. CYN concentrations and mean frond lengths in *C. racemosa* as a function of both season (fronds and stolons combined) and level of competition.

DISCUSSION

The seasonal variations in CYN concentrations observed in *C. taxifolia* confirm previous results (Amade et al., 1996). As pointed out by Lemée et al. (1997), these variations help to explain the maximum and minimum toxicities observed for *C. taxifolia* in summer/fall and in spring, respectively.

Interspecific competition also appears to affect CYN levels, with those individuals experiencing maximum competition levels presenting the lowest CYN concentrations. Moreover, individuals under conditions of intense competition exhibited longer maximum frond lengths, which is a classical phenomenon in plants, termed phototropism.

Although these trends were less evident than in *C. taxifolia*, there appears to be a decrease in CYN levels in *C. racemosa* between October and November. Further studies over a longer time period will need to be undertaken to confirm these results. In addition, there was a great difference in CYN concentrations between the two algae. Values differed by a factor of 35–80, depending on the season, for a given level of competition.

We detected a variation in the length of the fronds in *C. taxifolia* throughout the year 1999/2000, with maximum lengths in early autumn and a minimum in spring. This evolution is similar to that observed in *P. oceanica*, but presents a lag period of approximately three months. Indeed, leaf lengths in *Posidonia oceanica* exhibited maximum values in June–July and minimum values in winter (Wittman, 1984; Pergent and Pergent-Martini, 1988). This tends to confirm the hypothesis of competition for light between these two photoautotrophs; growth of the *Caulerpa taxifolia* fronds corresponds to the plant's response in the acquisition of this resource. Studies involving another invasive species, namely *Sargassum muticum*, have revealed that the indigenous algal community is altered as a result of, or in response to, an interspecific competition for both nutrients and light

(Stæhr et al., 2000.). It, therefore, appears that this phenomenon often occurs when several species compete for the same ecological niche.

Variations in the seasonal growth of *Caulerpa taxifolia* appear to be widespread within the Mediterranean. Such variations have also been reported by Meinesz et al. (1993) and Belsher et al. (1994), who described minimum growth in winter and spring and maximum values in summer and autumn. It seems that such seasonal variation also exist in the frond lengths of *C. racemosa* (Piazzi et al., 1997).

In summary, this study shows that CYN concentrations in *C. taxifolia* exhibit seasonal variations with maximum values in autumn and minimum values in spring. A similar trend is observed for mean frond lengths. There appears to be a direct relationship between frond length and CYN concentration. Althouth a number of parameters may be implicated, the most likely reason for these significant physiological modification in *C. taxifolio* is the presence of *P. oceanica.* Results suggest that the presence of this phanerogam leads to a decrease in CYN production with a concomitant increase in frond length. Similar observations were made for *C. racemosa*, although these last results need confirmation.

The decrease in CYN concentrations, with the concomitant increase in frond length, under conditions of competition with *Posidonia oceanica* could be the result of a modified metabolism in the alga. The increased energy allocated to growth of fronds (nutrient resources, light) would be at the cost of another function (e.g., production of secondary metabolites). If this hypothesis were to be confirmed, the production of secondary metabolites, thought to intervene under conditions of competition, would not be the strategy adopted by *C. taxifolia* when competing with *Posidonia oceanica*. Instead, this alga would appear to use an "exploitation"-type (e.g., use of light) rather than an "interference"-type competitive strategy (e.g., synthesis of active molecules) (Barbault, 1997; Ramade, 1990).

Acknowledgments—The authors thank Pr. F. Cinelli and Dr. L. Piazzi, Dipartimento di Scienze dell'Uomo e del'Ambiente, Università di Pisa, Pisa, Italy, for their valuable collaboration in locating a site (Antignano, Italy) with the invasive species *Caulerpa racemosa*, as well Miss L. Ferrat for help in sampling. We also thank Dr. M. Johnson for proofreading the English. MYCORRHIZAL COLONIZATION AND PLANT GROWTH AFFECTED BY AQUEOUS EXTRACT OF *Artemisia princeps* var. *orientalis* AND TWO PHENOLIC COMPOUNDS

K. W. YUN* and S. K. CHOI

Department of Oriental Medicine Resources
Sunchon National University

(Received July 13, 2000; accepted September 10, 2001)

Abstract—The effects of an aqueous extract of *Artemisia princeps* var. *orientalis* and two phenolic compounds on mycorrhizal colonization and plant growth have been investigated. Greenhouse studies showed that the inhibitory effect of the extract on mycorrhizal colonization and plant growth increased in proportion to the concentration of the extract. When the mycorrhizal test plants were treated with an increasing concentration of phenolic compounds, the mycorrhizal colonization in roots of the test plant and the plant growth were decreased. There were strong indications that mycorrhizal fungi mitigated the inhibitory influence of shoot extract of *A. princeps* var. *orientalis* and phenolic compounds.

Key Words—*Artemisia princeps* var. *orientalis*, aqueous extract, caffeic acid, *p*-coumaric acid, mycorrhizal fungi, plant growth.

INTRODUCTION

It has been reported that *Artemisia princeps* var. *orientalis* exhibits allelopathic effects via aqueous extracts (Kil and Yun, 1992), residues (Yun and Kil, 1992), and volatile constituents (Yun et al., 1993). Yun (1991) identified benzoic acid and 16 phenolic compounds as water-soluble allelochemicals of *A. princeps* var. *orientalis*.

Phenolic substances have been identified as allelopathic inhibitors more often than any other class of chemicals. They are readily soluble in water and easily leached from plant tissue (Horsley, 1977). Some have been reported to interfere with ontogenic processes, energy transfer processes, and nutrient uptake

*To whom correspondence should be addressed. E-mail: ykw@sunchon.sunchon.ac.kr

or transport. Corcoran et al. (1972) found that several tannins, benzoic acid, and cinnamic acid inhibit gibberellic acid-induced growth. Einhellig and Kuan (1971) showed that scopoletin inhibits photosynthesis in tobacco. Caffeic acid and *p*-coumaric acid are widely known as allelochemicals (Rice, 1984). There has been a report that leaf area expansion of cucumber seedlings is inhibited by ferulic and *p*-coumaric acid, depending on the concentration and the reduction in leaf expansion because of reduced hydrostatic pressure for cell expansion (Blum et al., 1985).

Plant–mycorrhizal fungus association enhances uptake and transport of soil nutrients to the plant via fungus (Cox et al., 1975; Allen, 1991). Siqueira et al. (1991) suggested that declines in arbuscular mycorrhizal (AM) fungal populations in the field can negatively affect the growth of crop plants. Tinker (1978) reported that vesicular arbuscular mycorrhizae aid host plants in the acquisition of phosphorus and certain micronutrients. However, allelochemicals can also adversely affect the normal functioning of mycorrhizal fungi associated with their root systems (Olsen et al., 1971; Theodorou and Bowen, 1971), thus reducing the beneficial effects of AM fungi.

The purpose of the present study is to examine the effect of an aqueous extract of *A. princeps* var. *orientalis* and two phenolic compounds on mycorrhizal colonization and plant growth of three plant species.

METHODS AND MATERIALS

Preparation of Aqueous Extract. Aqueous extract was prepared as follows; 100 g of dry shoots of *A. princeps* var. *orientalis* were soaked in 1 liter of distilled water at 20°C. After 24 hr, it was filtered through a sieve and the filtrate was considered as 100% extract. The extract was then diluted to reduce concentration to 50% and 10% with distilled water.

Mycorrhizal Fungal Materials. Seeds of three test plants, *Digitaria sanguinalis*, *Plantago asiatica*, and *Oenothera odorata*, were germinated in Petri dishes, and the seedlings transplanted into pots filled with plant-growth substrate (vermiculite–perlite–autoclaved soil 8:2:1). When the plants were 2 months old, they were inoculated with mycorrhizal fungi according to the procedure of Little and Maun (1996). The procedure consisted of growing corn seedlings in soil containing mycorrhizal fungi. When the seedlings were 2 months old, the presence of mycorrhizal fungi was ascertained. The corn roots with mycorrhizal fungi were washed, weighed into 5-g batches, and placed at 5-cm depth in new plastic pots (Yun and Maun, 1997).

Phenolic Compounds. Gas chromatography was used to identify and analyze the water-extractable phytotoxic substances of *A. princeps* var. *orientalis*. Benzoic, phenylacetic, salicylic, *t*-cinnamic, *p*-hydroxybenzoic, vanillic, gentisic, *o*-hydroxycinnamic, protocatechuic, syringic, *p*-coumaric, ferulic, and caffeic acids

and *m*-hydroxybenzone, catechol, phloroglucinol, *p*-phenylbenzaldehyde were detected in the leaf aqueous extract of *A. princeps* var. *orientalis* (Yun, 1991). Among these acids, caffeic acid and *p*-coumaric acid were chosen for the study, because these two phenolic acids were consistently detected in *A. princeps* var. *orientalis* extracts. Chemicals were purchased from Sigma Co. (St. Louis, Missouri; USA). Each acid was diluted to 5×10^{-5}, 5×10^{-4}, and 5×10^{-3} M.

Effect of Aqueous Extract on Mycorrhizal Fungal Colonization and Plant Growth. The three test plants, *Digitaria sanguinalis, Plantago asiatica*, and *Oenothera odorata*, are representative weed species in South Korea and did not occurr with *A. princeps* var. *orientalis*. They were inoculated with mycorrhizal fungi and placed in the greenhouse maintained at 25°C during the day and 18°C at night. Plants were allowed to grow for an additional two months in order to ensure that their roots had been colonized by mycorrhizal fungi. The plants were then exposed to the aqueous extract treatments, which consisted of the addition of 40 ml of 10, 50, and 100% shoot extracts of *A. princeps* var. *orientalis* to the soil in each pot. Extracts were added every two days for one month. Distilled water was used for the control plants. Six replications were used.

After 30 days, the experiment was terminated. Plants were taken out of the pots and washed carefully to remove plant-growth substrate from roots. Shoot and root lengths and dry weight were recorded. A 2 g sample of the root of the test plants was taken from each plant to determine mycorrhizal colonization. The root samples were stained in Chlorazol Black-E stain (Brundrett et al., 1984). Percent colonization of the stained root was determined by the magnified-intersection method (McGonigle et al., 1990).

Effect of Acids on Mycorrhizal Fungal Colonization and Plant Growth. The same experimental procedure as described above was followed, except that the two phenolic compounds, caffeic acid and *p*-coumaric acid, instead of the aqueous extract were used. The test plant was *Digitaria sanguinalis*.

RESULTS

The Effects of Aqueous Extract of Artemisia princeps var. orientalis on Mycorrhizal Colonization and Plant Growth. The effect of the shoot extract of *A. princeps* var. *orientalis* on mycorrhizal fungal colonization in the root of the three test plants is shown in Table 1. In *Digitaria sanguinalis*, arbuscular vesicular mycorrhizal (AM) colonization decreased with an increase in the concentration of aqueous extract. In *Digitaria sanguinalis*, the uncolonized area and hyphal colonization were not significantly altered by the three concentrations. However, the percent vesicular colonization decreased significantly, with an increase in the percent concentration of the aqueous extract. *Plantago asiatica* was more susceptible to the extracts. The uncolonized area increased significantly, and

[a] Percent colonization by vesicles, hyphae and arbuscules and percent uncolonized (UNC) roots were determined according to the method of McGonigle et al. (1990). Values in a column followed by the same letter are not significantly different at $P < 0.05$ according to Duncan's multiple range test.
[b] Nonmycorrhizal means no-inoculation of plants by mycorrhizal fungi.

vesicular mycorrhizal colonization of the root was inhibited significantly by the extract. In the case of *Oenothera odorata*, vesicular, hyphal, and arbuscular mycorrhizal colonizations were significantly inhibited by the extract, and the inhibition was concentration-dependent.

The shoot and root elongations of the three test plants treated with aqueous extract of shoots of *A. princeps* var. *orientalis* are shown in Table 2. Shoot and root elongations of *Digitaria sanguinalis* were inversely proportional to the extract concentrations especially at the 50 and 100% concentrations. Mycorrhizal fungi mitigated the injurious effects of aqueous extracts on the elongation of shoots at all three concentrations and elongation of roots at 50 and 100% concentrations. The shoot and root elongation of *Plantago asiatica* was also influenced by different concentrations of aqueous extracts. A significant decrease in shoot elongation occurred at 50 and 100% concentrations, while root elongation decreased significantly from control only at 100% concentration of extract. In the case of *Oenothera odorata*, shoot elongation was significantly higher in the 100% extract compared with nonmycorrhizal control. None of the other treatments differed significantly. The root elongation decreased significantly at 50 and 100% aqueous extracts. The colonization of roots by AM fungi was beneficial to both *P. asiatica* and *O. odorata* for decreasing the allelopathic impact of *A. princeps* var. *orientalis*. Mycorrhizal fungi association significantly increased the dry weight of all three species compared with the nonmycorrhizal control. Mycorrhizal plants exposed to the three concentrations of aqueous extract were not significantly different in their dry weight from the nonmycorrhizal control, suggesting that mycorrhizal fungi did mitigate the harmful effects of allelopathy. However, the beneficial effect of AM fungi seen in the mycorrhizal control was lost.

Effects of Phenolic Compounds on Mycorrhizal Colonization and Plant Growth. Percent root colonization of *Digitaria sanguinalis* by mycorrhizal was inhibited by the two phenolic compounds, caffeic acid and *p*-coumaric acid (Table 3). The uncolonized area of nonmycorrhizal plants exposed to caffeic and *p*-coumaric acids was significantly higher than mycorrhizal plants. As the concentration of these two acids was increased, there was an increase in percent uncolonized area. Similar results were also observed for colonization by mycorrhizal hyphae. *Digitaria sanguinalis* treated with caffeic acid and *p*-coumaric acid had the lowest mycorrhizal colonization when the highest concentration (5×10^{-3} M) of each acid was used. Percent colonization by vesicles showed an increase at intermediate concentrations of caffeic acid. However, at the highest concentration, vesicular colonization was not significantly different from control (Table 3). Inoculation of *D. sanguinalis* plants by mycorrhizal fungi increased shoot elongation and dry weight compared to nonmycorrhizal controls (Table 4). However, root elongation was not altered. Exposure of plants to *p*-coumaric acid did not show a clear-cut effect on shoot elongation. There was no change in shoot elongation at 5×10^{-5} M concentration but as the concentration increased there was a slight decline. The

p-coumaric acid exhibited a decline in shoot elongation with an increase in concentration. The root elongation was not affected by any of the four concentrations of both caffeic and *p*-coumaric acids. The two acids had a clear negative impact on the dry weight of *D. sanguinalis* plants. As the concentrations of the two acids were increased, there was a decrease in dry weight (Table 4).

DISCUSSION

The present study demonstrates the effects of shoot extracts of *Artemisia princeps* var. *orientalis* and different concentrations of caffeic and *p*-coumaric acids on root mycorrhizal colonization, shoot and root elongations, and dry weight of the weedy plant species.

We emphase four main contributions of this study. First, as expected, the inoculation of plants by arbuscular mycorrhizal fungi increased the dry weight of all three species of weeds compared to nonmycorrhizal controls. Several studies show that mycorrhizal fungi provide additional nutrients, especially phosphorus to the host (Allen, 1991). The fungal hyphae make connections with the root hair and colonize a greater volume of soil than the roots of nonmycorrhizal plants. Second, the shoot extracts of *A. princeps* var. *orientalis* and phenolic compounds were clearly inhibitory to the dry weight per plant of all three species. Kil and Yun (1992) reported similar inhibitory effects of the aqueous extract of *A. princeps* var. *orientalis* on seed germination and seedling growth of six plant species. The only difference was that in this study, mycorrhizal inoculated plants were treated with the aqueous extracts, while Kil and Yun (1992) applied the extracts to nonmycorrhizal plants. In this study, the extract of *A. princeps* var. *orientalis* inhibited mycorrhizal fungal colonization in *Plantago asiatica* and contributed to a decline in plant growth. Similarly, although mycorrhizal colonization of *Oenothera odorata* was inhibited by the extract, the shoot elongation of the plant was not affected. The degree of inhibition effect of the extract on mycorrhizal plants is smaller than that on nonmycorrhizal plants. This is similar to the first study, clearly demonstrating the effect of allelopathic interference on the function of mycorrhizae (Nilsson et al., 1993). Caffeic acid showed a stimulatory effect on hyphal mycorrhizal colonization at 5×10^{-5} M, but it produced an inhibitory effect at 5×10^{-4} and 5×10^{-3} M. The inhibition of hyphal mycorrhizal colonization by *p*-coumaric acid was proportional to the concentration. Wacker et al. (1990) found that ferulic acid led to an inhibition of mycorrhizal colonization of asparagus by *Glomus fasciculatum*, and it was dependent upon the concentration. Kil et al. (1989) reported that *p*-coumaric acid showed an inhibitory effect on seed germination and nonmycorrhizal seedling growth of *Lactuca sativa* at concentrations of 5×10^{-5}, 5×10^{-4}, and 5×10^{-3} M. Seedling growth of mycorrhizal plants was less inhibited than that of nonmycorrhizal plants by *Empetrum* extract (Nilsson et al., 1993). Nilsson et al.

(1993) proposed that the spread of mycorrhizal infection and uptake of nutrients by roots and mycorrhizae were more sensitive to the extract than seed germination and radicle growth. Pedersen et al. (1991) showed caffeic and methylenedioxycinnamic acids reduced mycorrhizal infection of *Glomus fasciculatum* in asparagus and that it could influence the decline of plant growth. Third, the beneficial effects of colonization by mycorrhizal fungi were lost when mycorrhizal plants were treated with shoot extracts of *A. princeps* var. *orientalis* and higher concentrations of caffeic and *p*-coumaric acids. Siqueira et al. (1991) suggested that VAM fungal inoculation reduced herbicide-induced leaf injury and alleviated the phytotoxic effects. Herbicide effects were dependent on soil-applied concentrations and the presence of VAM, and VAM effects were dependent on the kinds of herbicide and the concentration of the herbicides. Finally, we emphasize the mitigating effects of mycorrhizal fungi on the deleterious effects of allelopathy. A plant colonized by AM fungi was better equipped to survive the inhibitory impact of extracts of allelopathic plants and phenolic acids.

The results of this study lead to the conclusion that the aqueous extract of *Artemisia princeps* var. *orientalis* and two phenolic acids inhibit mycorrhizal fungal colonization and plant growth, and the degree of inhibition of mycorrhizal colonization and plant growth by the aqueous extract and the two phenolic acids showed similarities.

(Received March 1, 2001; accepted October 8, 2001)

Abstract—The European rabbit (*Oryctolagus cuniculus*) uses the secretion of the chin gland in the maintenance of social status. Previous work has concentrated on secretion collected directly from the animal. In this study, the analysis was conducted by collecting scent marks made by free-ranging animals. Scent marks were found to be concentrated at the center of the area controlled by a social group, and at the boundaries between two adjacent social groups. Only the mark from dominant animals could be identified. Marks were also collected from the skin of rabbits, where they had been placed by the dominant individual. The mark found on the head of a subordinate animal may, in the future, be used to identify the dominant animal of the social group, who placed the mark.

Key Words—Rabbit, *Oryctolagus cuniculus*, social structure, glandular secretion, gas chromatography, GC-MS, behavior, olfactory communication, field studies.

INTRODUCTION

The majority of the work that has been conducted to examine the constituents of mammal scent gland secretions has been undertaken on the whole secretion. Animals have been trapped and the secretion collected directly from the site of production. There are few studies where the animals were allowed to scent mark and the mark itself collected for examination. Where such attempts have been made, the volatile components of the mark are often not the focus of the study (e.g., Singer

et al., 1986, 1989; Belcher et al., 1990). The difficulty with using whole secretions is that there is no guarantee that the signal that an animal receives in a field situation is composed of the entire secretion. It may be that only part of the secretion is used to pass on a message, and it follows that the signaling portion of the secretion will be obtained during studies of the volatiles from field collected scent marks.

Another difficulty with previous semiochemical studies is that limited data are available on the semiochemical profiles of free-ranging animals. Most of the animals examined have been kept in cages (e.g., Brownlee et al., 1969; Black-Cleworth and Verberne, 1975; Goodrich et al., 1990a,b; Hudson and Distel 1990; Swaisgood et al., 1999) or living in controlled environments, such as enclosures (e.g., Mykytowycz, 1958, 1979; Mykytowycz and Hesterman, 1970; Müller-Schwarze et al., 1974; Gassett et al., 1996, 1997; Kappeler, 1998; Miller et al., 1998; Burger et al., 1999). Most of these animals have been fed artificial diets. There is no guarantee that the secretions exuded by captive animals are the same as those produced by animals in the wild. In more recent years, there has been a reversal of this trend, with more studies of wild animals reported (e.g., Cantoni et al., 1996; Kazanehdari et al., 1996; Siller-Zubiri and MacDonald, 1998; Sliwa and Richardson, 1998; Bel et al., 1999; Lawson et al., 2000).

The solution to both of these problems is to collect and analyze scent marks made by members of a wild population, preferably one that is well studied and where all individuals are known and recognizable. European rabbit (*Oryctolagus cuniculus*) populations are ideal, as social groups have a relatively small home range size, strict social structure, and home range fidelity, and individuals show clear scent-marking behavior. This means that it is possible to know exactly which individuals are available to mark at a given location.

Rabbit Environmental Scent-Marking Behavior. In many species of mammals, there is a vast difference between the amount of scent mark placed at or near territorial boundaries compared with marking behavior throughout the hinterland (e.g., Johnson, 1973; Peters and Mech, 1975; Roper et al., 1993; Bel et al., 1995; Bowen and Cowan, 1980; Rosell and Nolet, 1997; Rosell et al., 1998; Sillero-Zubiri and MacDonald, 1998; Sliwa and Richardson, 1998). If scent marks are for defending territory, they should be left preferentially at territory borders (Johnson, 1973). This will create a "wall of smell" to fend off intruders, and as an individually distinctive signature of territory occupancy (Gorman and Mills, 1984; Gorman, 1990). This would, then, produce an "olfactory bowl" (Peters and Mech, 1975), with a changing odor gradient as the high concentration of marks at the boundary decreased towards the center of the territory (Bowen and Cowan, 1980). Indeed, there will most likely be a positive feedback, and the number of border marks will be even higher than would be predicted due to overmarking from adjacent groups (Sillero-Zubiri and MacDonald, 1998).

An alternative approach to this mark placement is seen in the Eurasian badger, *Meles meles*, in which, once inside the territory, marking density is inversely related

to distance from the main set. In this case, an incoming intruder that has passed the territory boundary will be progressively more likely to meet a scent mark, and, thus, become aware of territorial ownership (Roper et al., 1993). The rabbit could adopt either of these two approaches.

Previous studies on rabbit chin gland secretion have used whole secretion for the analysis, either from swabs of the chin region of live rabbits (Hayes et al., 2001a,b) or from excised glands (Goodrich and Mykytowycz, 1972). As stated above, this may be different from a scent mark deliberately placed by a rabbit and utilized by the rabbit population in the field. Rabbits scent mark objects throughout their territory (Mykytowycz and Gambale, 1969) and have been shown to mark any novel object placed into their environment (Mykytowycz, 1967, 1968, 1972; Johnson, 1973). Mykytowycz (1965) said that the marking behavior of rabbits probably saturates their territory with smell. It has been suggested that different classes of rabbits mark differentially at a particular location. Dominant males mark the entire territory of the social group but appear to concentrate on the boundaries with neighboring groups (Mykytowycz, 1968). In addition, a male is much more likely than a female to apply a scent mark to a latrine site (Mykytowycz and Gambale, 1969).

In the breeding season, much of the time spent above ground by female rabbits is on, or near, the warren (Bell, 1980). Lockley (1961) found that females seldom move more than 15 m from the warren entrance, usually much less. (There is, however, some question as to the validity of this result, and the small size of this distance may have been an artifact of the experimental design.) When young are present in a burrow, the mother will seal up the entrance, then urinate, defecate, and chin-mark the opening (Mykytowycz, 1968). Thus, females are thought to concentrate their scent marking behavior at the entrances of holes where their young are located (Gibb et al., 1978). It has, therefore, been suggested that the scent marks found throughout the territory of a rabbit social group will not be uniform, but that there will be structuring of these marks, in relation to environmental cues, such as the position of warrens and other social groups.

Scent Marking on Other Rabbits. The dominant male in a social group will scent mark the other individuals in his social group. He does this with both urine and chin gland secretion (Mykytowycz, 1968; Bell, 1980). The dominant male has been observed to chin-mark juveniles and females, but no chin-marking of subordinate males has ever been observed (Bell, personal communication). By swabbing regions of an animal other than the chin, it is proposed that a scent mark different from that seen on a swab of the chin region of the donor individual can be obtained. It is also predicted that there will be no mark on the head of the dominant male, as no other animal can or will chin-mark him.

The present study sought to examine the chin gland secretion of the wild rabbit by collecting it on “chinning poles” located throughout the field site. Differences among the marks on these poles were examined by comparing chromatograms

produced. It was hypothesized that there would be structuring in the locations and content of these marks, with marks from different classes of rabbits being found in different places within the territory. In addition, swabs were collected from the tops of the heads of the rabbits and compared to the swab from the chin and to the secretion of other animals in the social group.

METHODS AND MATERIALS

Environmental Marking. The wild population of rabbits (*Oryctolagus cuniculus*) used for this study were located at Hope Farm, Cattai National Park (150°52′E, 33°33′S), in the northwest of Sydney, Australia. This population consists of about 150 adult animals, and up to about 300 juveniles, in an area of approximately 20 ha.

To examine the scent mark itself, as opposed to secretion manually expressed from the chin gland, chinning poles were placed in the field site so that wild individuals could mark them. A series of 149 tomato stakes (90 cm) were located in lines throughout the site. The chinning poles were placed at 1 m intervals across the area in lines that crossed at least one boundary between adjacent social groups. These social group boundaries were determined by examining the location of scratch marks and by behavioral observations (such as displacement behavior, chasing, etc.). Some pole lines also extended beyond the territory of an individual social group and into communal feeding areas. The pole lines were assigned a letter from A to K, and the poles within each line given a number from 1 to 26 (Figure 1). In addition, 25 chinning poles were placed at all the active entrances of seven of the warrens within the sampling area. Each warren pole was indicated by the warren number and a letter from a to e (Figure 1). A total of 174 chinning poles were, therefore, located on the site.

A double layer of aluminum foil was placed around each pole at two heights, 10 and 70 cm from the ground. The underlayer of foil prevented contact between the top layer and the stake. The top, sample layer could, thus, be removed for analysis, while the underlayer remained. The sample layers of foil at 10 cm were considered to be experimental, as this is well within the height that an adult rabbit can easily reach to scent mark. The sample layers at 70 cm are too high to be reached by a rabbit in normal activity and were used as controls. The foil layers at these two heights experienced the same environmental conditions, but layers at 70 cm could not be scent marked by a rabbit. Although aluminum foil is not a natural substrate, and the interaction of the substrate with the secretion may differ from that seen with more usual surfaces, rabbit chin secretion is placed on many different substrates by wild rabbits, from sticks and grass to stones and piles of feces (Mykytowycz, 1968). It was assumed that aluminum foil would simulate a valid substrate for the current analysis.

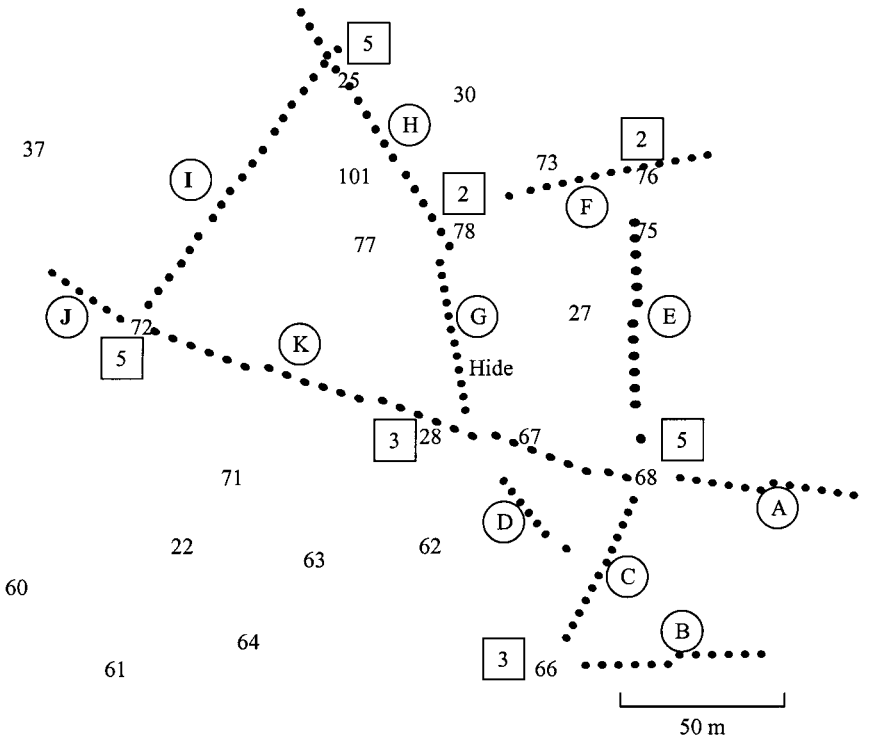

FIG. 1. A map of the central portion of the Cattai field site where the chinning poles were located. Numbers indicate warrens where trapping occurred. Chinning pole lines are shown, with the letter indicated in a circle. Each dot represents a separate pole. The boxed number near a warren number indicates the number of poles located at warren entrances. The position of the observation hide is shown.

Samples were taken from every pole for five days, in late October and early November 1996 (October 29, 1996, November 5–8, 1996). This is late in the breeding season of rabbits at the Cattai site. There was no rainfall during this period, and observations during spotlighting and from a hide suggest that no other mammal species are likely to have contaminated the samples by also marking the poles. Therefore, the samples collected from these poles are attributable to rabbit scent marks.

The sample layer of foil was removed from the poles early in the morning of the sampling day. The foil was placed in an airtight headspace vial (10 ml), and the vial was closed with an airtight Teflon-faced rubber seal. The foil on the chinning pole was replaced, that is, the foil was left on the pole for 24 hr. Control

foil samples were also collected from each pole on each sampling occasion and treated in the same manner to compare with the experimental foil samples.

The foil samples were returned to the laboratory, and prepared in the same way as used previously for cotton swabs of the rabbit chin region (Hayes *et al*., 2001a). This dynamic headspace sampling trapped the volatile components of the secretion onto a sample of Tenax TA in a trap. The traps were analyzed on the PTV-GC to ascertain the volatile components. Analysis was conducted using a Hewlett Packard 5890 Series II gas chromatograph (GC) equipped with a flame ionization detector and fitted with a silica capillary column (SGE, model BP-1, 25 m long $\times$ 0.22 mm ID and 0.1-μm film thickness). Data were acquired under the following GC conditions inlet temperature: 200°C, carrier gas: nitrogen at 23 cm/sec, split ratio: 1:20, detector temperature: 260°C, temperature program: initial temperature 45°C, initial time 5 min, rate 8°C/min, final temperature 250°C, final time 10 min.

The resultant chromatograms were compared to those previously obtained, and peak numbers assigned as previously discussed (Hayes et al., 2001a). The chromatograms were compared specifically with swabs taken from animals belonging to the relevant social groups. The data (relative areas under each peak) were analyzed by Bray-Curtis similarity cluster analysis to determine if any groups were formed.

Marks on Rabbits. Swabs were taken from the top of the head of all animals trapped, in a manner similar to that used for collection from the chin region (Hayes et al., 2001a). The fur was not clipped from the top of the head. The cotton bud was swabbed 20 times over the area with a firm pressure. The swab was then placed into an airtight vial, stored in a freezer at -20°C, and analyzed by dynamic headspace gas chromatography (see above and Hayes et al., 2001a). The chromatogram produced was compared to the chin swab from the donor, as well as the swab from the chin of the dominant male from the same warren. The head region was chosen for collection, as an animal presumably cannot chin-mark its own head. Therefore, any mark that was collected from this area was assumed to have been placed there by another individual.

Social status of the wild animals was determined in several ways. For those social groups that lived near the observation hide, direct observations of displacement behavior and other agonistic interactions were possible. For rabbits from other parts of the site, indirect methods of assessment had to be employed. These included: body mass, encrustation of the chin region, the size and date of descent of the testes (since testes are withdrawn into the body outside of the breeding period), and knowledge of other rabbits living in the social group. Thus, a dominant male was the largest male trapped on the warren, with the largest testes, that descended early in the breeding season, and with a large amount of secretion encrusted in the chin region. An animal that was subordinate was taken as a small animal, living in a warren with larger males. The testes of this rabbit were small and descended late in the breeding season; the rabbit also had little or no encrustation on the chin.

Head and chin swabs were examined from 10 pairs of dominant males and subordinate individuals, each pair from a different social group. The chromatograms were examined to determine whether or not the head swabs of the subordinates resembled the chin swabs from the dominant animals more than chin swabs from themselves.

RESULTS

Environmental Marking. Only 23 of the 174 poles located on the site showed a chromatogram that differed significantly from control samples (ANOVA, $F = 350.3$, $P \ll 0.001$). The chromatograms obtained from the other poles are indistinguishable from both a sample of aluminum foil and a control sample. Of those that were marked, 20 had a mark on every collection, while the other three showed marks on four of the five collection days. Of the 870 poles that were available for marking across the experiment, only 112 ever showed a mark. This is significantly different to random when compared to a Poisson distribution ($\chi^2 = 86.4$, $P < 0.001$)

Although there were some minor variations within the control chromatograms, they all contained significantly fewer peaks (4.22 ± 0.23) than the samples considered to have been marked (17.6 ± 0.69). The chromatogram of a control sample is illustrated in Figure 2. However, the 23 poles that regularly showed a scent mark over the five collection days contained many peaks that did not occur in the control (Figure 3). The additional peaks had retention times mostly between 15 and 20 min. There were 17 compounds found at least once in the experimental marks, but never in the controls (Table 1). Of these, eight occur in all of the samples.

The swabs from the rabbits show the presence of siloxane compounds that are not present in the blank swabs. While these compounds are generally considered to be contaminants, exactly why these peaks do not appear in the blank samples is not clear. As they do not occur in the control or blank samples, they have tentatively been included in subsequent analyzes, although their exact relevance is not certain.

All the poles that showed a scent mark included 2-phenoxyethanol as one of the constituents. This compound has been shown to be associated with social status in the European rabbit, only occurring in the secretion of a dominant male and never in the secretion of subordinate animals (Hayes et al., 2001b). As all marks contain this compound, there is no evidence for marking by any individual other than the dominant male.

A K-means cluster analysis distinguishes the scent marks into two groups with a squared distance between the clusters of 13.998 (Table 2). The 10 most important peaks in assigning a sample to a cluster are listed (Table 3).

There was no correlation between the marks on poles and the chromatograms of chin swabs taken from animals on the same warrens. The signals from specific

TABLE 1. COMPOUNDS FOUND IN EXPERIMENTAL SAMPLES BUT NOT IN CONTROLS[a]

Compound number	Compound name
7	
14	1,3-dimethylbenzene
16*	siloxanes
38	α-pinene
20*	benzaldehyde
39*	siloxanes
41*	siloxanes
40	
22*	1,2,4-trimethylbenzene
23	
24	
25*	2-ethylhexanol
50	4-methyl-1-undecane
26	
29*	hydrocarbon
51	
45*	2-phenoxyethanol

[a] Starred compounds occur in all of the samples, compounds without a name could not be positively identified. The compound number refers to previous studies on the European rabbit (Hayes et al., 2001a).

TABLE 2. SAMPLE CLUSTERS[a]

Cluster 1		Cluster 2	
c3	i9	e12	h4
c6	i18	f12	h6
f9	k11	f13	h11
g13		g1	w66c
i1		g3	w76a
i3		g5	w78a
i8		h2	

[a] Samples that showed a scent mark could be subdivided into two clusters by a K-means cluster analysis, with a squared distance between the clusters of 13.998. The letter in a sample name refers to the chinning pole line, and the number refers to its position along that line. Sample names starting with a "w" are those poles that are located on a warren, referred to by warren number.

TABLE 3. TEN MAJOR COMPOUNDS USED TO ASSIGN POLES TO ONE OF TWO CLUSTERS IDENTIFIED

Compound number	Compound name
12	dimethylbenzene
15	xylene
16	siloxanes
17	siloxanes
18	2,4,6-trimethyloctane
20	benzaldehyde
39	siloxanes
22	1,2,4-trimethylbenzene
25	2-ethylhexanol
28	1-methyl, 4-isopropylbenzene

poles do not look like signals from individual rabbits. A cluster analysis of chin swabs and pole marks separates these two groups of chromatograms as being different from each other.

The location of marked poles is not random (Figure 4) ($G_H = 16.212$, $P < 0.005$) (Sokal and Rohlf, 1995). There are more marked poles close to warrens

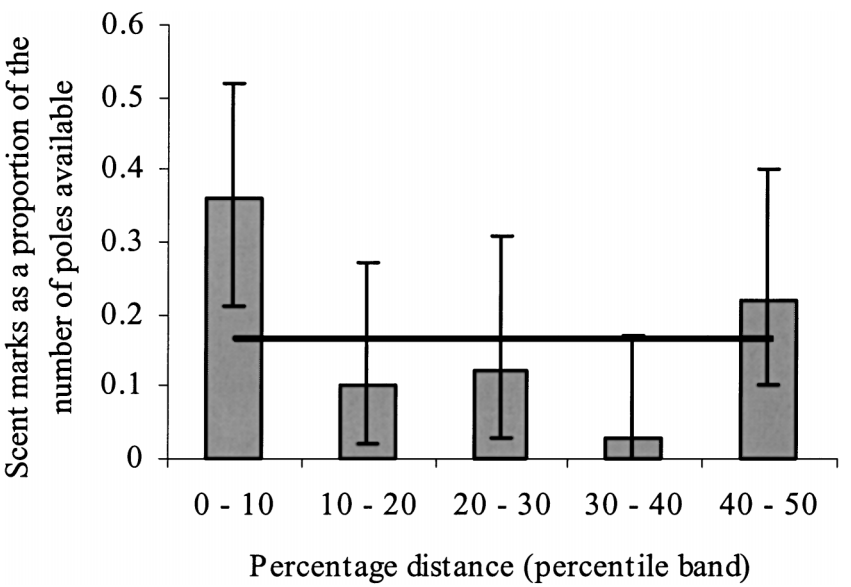

FIG. 4. Percentage distance of marks between two warrens as a proportion of the number of poles available. The dark line is a plot of the mean value (error bars are 95% confidence limits of the binomial distribution).

than there are in other parts of the territory, and the number of marks located midway between adjacent warrens also is higher than the mean level of marking throughout the territory. This location corresponds to the boundary between social groups as ascertained from the scratch marks observed on the site. The numbers of marks found on warrens and midway between groups are statistically homogeneous ($G_H = 1.698$). The rabbits are actively scent marking at the warrens and at the edge of their group territory more than they are at other locations within the territory.

Marks on Rabbits. There is a large difference between the head and chin swabs from a dominant individual (Figure 5). The number of peaks detected from a head swab (9 ± 1.0) is less than that detected from a chin swab (22 ± 2.1). Both the animals shown have very little signal on their head, but the signal collected at the same time from the chin has many more peaks in the chromatogram. This is also true of the other eight dominant male head swabs examined. 2-Phenoxy ethanol, the dominant signaling compound, was never detected from the head swab of a dominant animal.

There is also a difference between the head and chin swabs of subordinates and females. In this case, however, there are many more peaks identified from the head than from the chin (Figure 6).

In a comparison among the pairs of 10 subordinate and dominant individuals, each pair from the same warren showed that the signal from the head of the subordinate was similar to the chin signal from the dominant male (Figure 7). It was not the same as the signal from the donor's own chin swab. MDS analysis (Clarke and Warwick, 1994) groups together the swabs from the dominant's chin and the subordinate's head more closely than the swabs from the subordinate's chin and head (ANOSIM: Global $R = 0.478$, $P < 0.001$) (Figure 8).

DISCUSSION

Environmental Marking. While it is clear that a specific set of poles has been marked, it is not possible to recognize the signal of the dominant male on the chinning poles located on his warren. However, the data support the hypothesis that there is structuring of the marking behavior on the warren. There are more marks located on poles that are placed next to active warren entrances or distributed in this immediate vicinity. There are also more scent marks found at the proposed boundary between adjacent social groups. This produces an olfactory bowl, similar to that seen in the wolf (*Canis lupus*) (Peters and Mech, 1975).

There was no evidence of scent marks on poles from any individuals other than the dominant male (as determined by presence of 2-phenoxy ethanol); the scent mark of the dominant females present was not detected on the poles at warren entrances, as was hypothesized. This may be due to the nature of the female scent mark. If the mark of a female were overmarked by the dominant male in her social

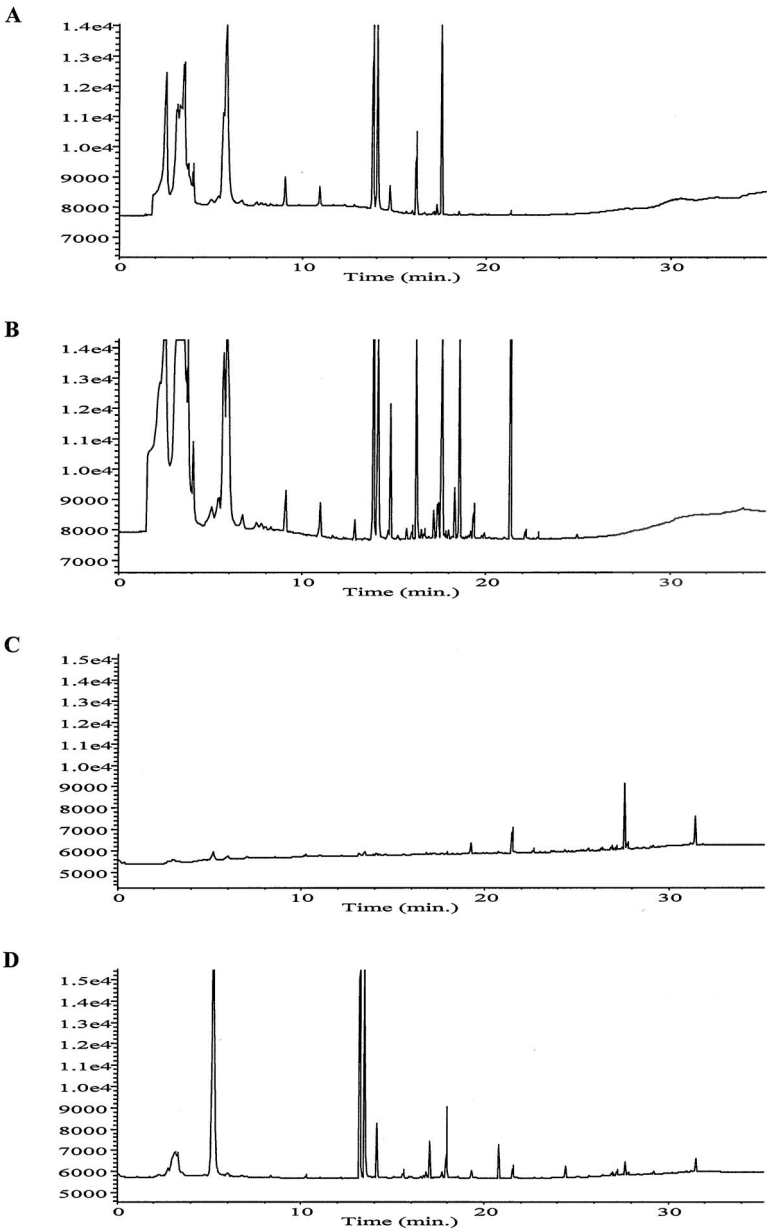

FIG. 5. A comparison of the head and chin swabs of dominant male rabbits showing the reduced presence of volatiles on the head suggesting a lack of a scent mark. Chromatograms are: (A) O + Bk/O 12/12/96 head; (B) O + Bk/O 12/12/96 chin; (C) R + W/G 7/9/95 head; and (D) R + W/G 7/9/95 chin.

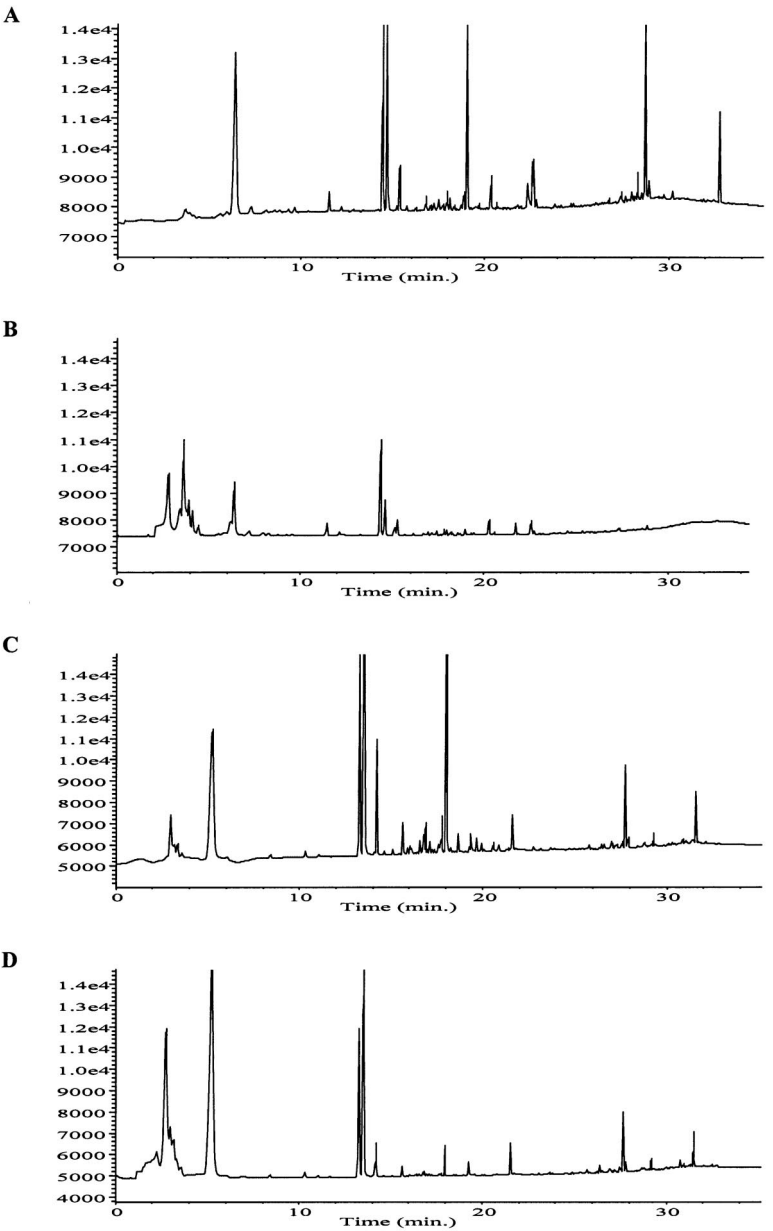

FIG. 6. A comparison of swabs from the head (A and C) and chin (B and D) of some subordinate rabbits. Note that the signal from the head contains more peaks than that from a swab of the chin region. Chromatograms are: (A) Pi + Bk/Pu 30/10.95 head; (B) Pi + Bk/Pu 30/10/95 chin; (C) Pu + W/G 6/10/95 head; and (D) Pu + W/G 6/10/95 chin.

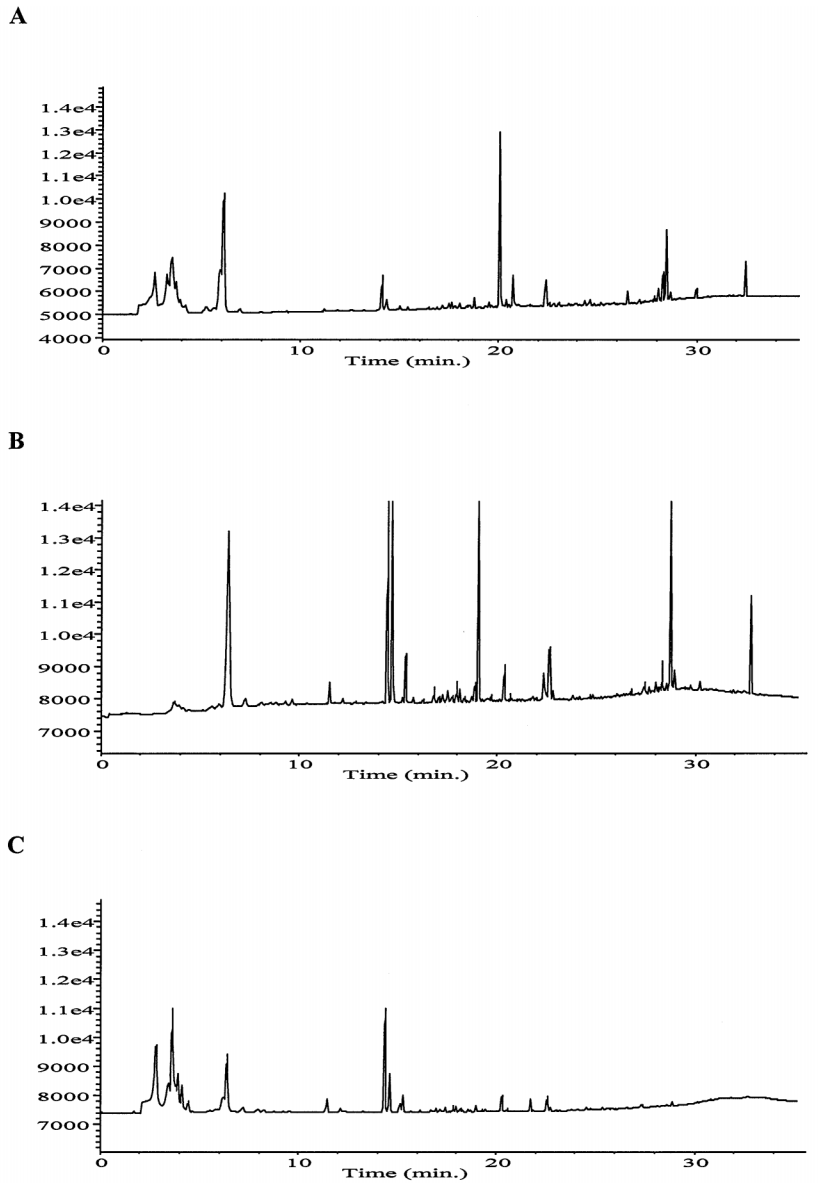

FIG. 7. A comparison between the head and chin swabs of dominant and subordinate rabbits from the same warren. The top chromatogram (A) is from the chin swab of the dominant individual (R + Bk/O 15/11/95). The lower chromatograms are from the head (B) and chin (C) from the subordinate individual (Pi + Bk/Pu 30/10.95).

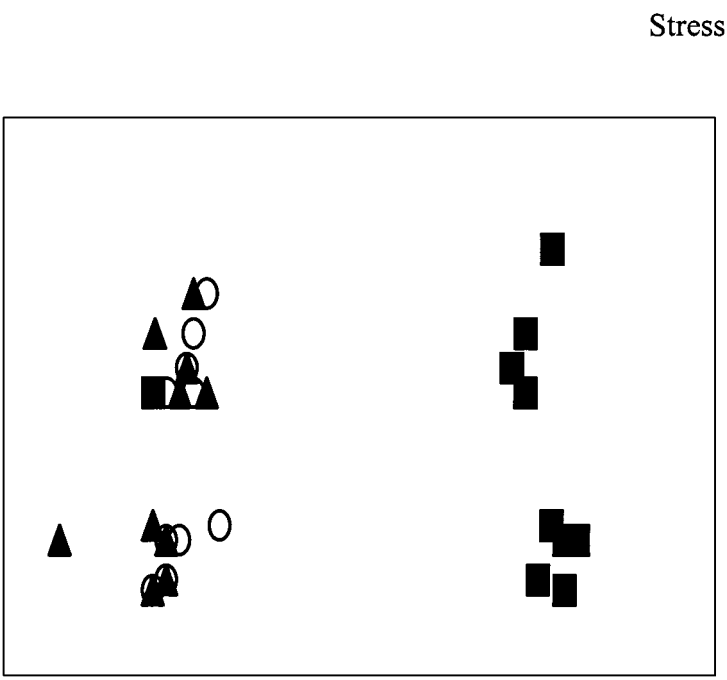

FIG. 8. The two-dimensional MDS ordination of the 30 samples, based on square root transformed abundances and a Bray-Curtis similarity matrix. Distinct clusters emerge showing grouping of the swabs from the dominant's chin and the subordinate's head against swabs from the subordinate's chin. ○ = samples from dominant chin swabs; ■ = samples from subordinate chin swabs; ▲ = samples from subordinate head swabs.

group, then her mark would almost certainly not be detected because there is much more secretion from the gland of a male than from a female and it appears to be more concentrated (Mykytowycz, 1965; Mykytowycz and Dudzinski, 1966). The marking behavior of the male may, thus, be masking the female marking. This does not mean that the female's mark is undetectable to a rabbit, merely that the techniques employed in the present study do not detect them.

It is reported that females mark at the entrances to burrows that contain their unemerged kittens (less than 28 days old) (Mykytowycz, 1968; Gibb et al., 1978). We know from trapping at this site that there were kittens living below ground in the warrens in question during the period of study. If the reported female marking occurred at Cattai, then it must be that we are unable to detect the female's mark. Since the females are suggested to mark the dirt immediately adjacent to the warren entrance, it is probable that the pole is not marked. The other marking behaviors of the female at the warren entrance, i.e., urination and defecation (Mykytowycz, 1968) may play a more significant role.

The scent marks detected on the poles across the site can be divided into two groups, and these clusterings are distinguishable statistically. The patterns seen are not due to differences in the presence or absence of compounds, but are related to changes in the relative proportions of the constituents. The poles belonging to each group are also geographically clustered. The two clusters are not just the marks from two individuals. These groupings cover several social groups, with dominant males trapped from four or five separate warrens within the area covered by each cluster. Previous work at this site has shown that the deme size is 100 m (Richardson, unpublished results), approximately the difference between these two groups. It is possible that these clusters represent a deme, and within this group the animals are more closely related to one another than they are to animals from outside the area. If the difference is genetically determined, then this pattern of distribution would not be incompatible with movement of the males at these population densities (Richardson et al., 2001). This relatedness may show in the similarity of the chin secretion, as detected on the poles. However, any conclusions about these data should be drawn carefully, and further investigation is required before anything can be ascertained with confidence.

The placement of the chin marks in the rabbit territory did not agree with expectation. Marks were preferentially located at the boundary, and the placement was inversely related to distance from the center of the territory. This does not conform to the proposal set forth by Mykytowycz (1965), in which he suggested that rabbits would mark in a random manner, such that the environment would be saturated with scent. There is also nonrandom marking of a restricted set of poles. Once a pole has been marked, that pole continues to be marked throughout the period of the experiment. Marking sites were overmarked.

One explanation for the observed distribution of the chin marks is that the rabbit's marking behavior is highest on the warren, then as distance increases away from the core territory, the frequency of marking decreases. That is, the frequency of marks is inversely proportional to distance from the warren. To this must be added a boundary effect at the edge of the territory controlled by a social group. Although the amount of marking by members from each group individually is low, the numbers of marks on both boundaries add together, and the observed frequency is, therefore, artificially high. Another explanation could be that rabbits make a choice about where to mark. Individuals mark preferentially on the warren and at the edge of the area controlled by the social group. Marking that occurs between these two extreme locations is at a much lower frequency than that seen at either one. This pattern is seen in badgers (Roper et al., 1993).

These two explanations rely on different perceptions of space by the rabbits. The first sees the core territory as being most important. As you move further away from this area, the need to alert others of the ownership of the site is reduced. The further from the core zone one is, the less important this communication becomes. The second hypothesis has the rabbits perceiving the whole of the controlled

territory as being important; however, it is principally at the edge of this territory that warnings to others to stay away need to be placed. Any rabbits that occur within the social group's boundaries must either belong to the social group or have had to cross a boundary to enter and must consequently have encountered the message. Invaders will also be progressively more likely to encounter a message the further they penetrate into the territory.

Data from the published literature suggests that the second hypothesis is more likely to be accurate. Dominant males are known to chin mark at the entrances to warrens (Mykytowycz, 1968), as are females (Gibb et al., 1978). Wild rabbits are known to concentrate activities on the edge of the territory controlled by the social group, including paw-scraping, defecation, and chin marking (Mykytowycz, 1968; Bell, 1980; Cowan and Bell, 1986). Thus, the rabbits "know" where the centers and boundaries of their territories are and actively defend them both.

A further explanation may be that animals do not choose where they will place their scent marks, but merely mark wherever they are. Thus, the observed distribution of marks is a product of where animals are spending the majority of their time, rather than the result of specific decisions to mark the warren and boundaries of their territory. This explanation would seem unlikely, as dominant male rabbits are observed to actively tour the extent of their territory (Mykytowycz, 1968) and, thus, seem to be making a decision to mark in these locations.

Several of the pole lines were extended into communal feeding areas (line A, B & J), where no social group is in control, and no marks were detected on these poles. Thus, in the communal areas used by all animals from adjoining territories, no one animal is in control, and no individual leaves a scent mark. This also raises the interesting point that rabbits are believed, as reported above, to mark any novel object placed within their sphere of influence (Mykytowycz, 1967, 1968, 1972; Johnson, 1973). However, as the present study shows, the majority of poles placed within the group territory were not marked. The explanation for this may be that previous studies have all considered animals kept in cages or enclosures. The restricted space available in these systems may have affected the behavior.

The marks that occur at the entrances to warrens are likely to serve a different function. Instead of being a message to warn members of another social group that they are entering an area already under the control of a group, they may serve as an intragroup message.

It is not possible for the experimenter to distinguish the scent marks collected on the poles from one another, except in a fairly superficial way into two broad groups. This means that if the marks found on a warren are carrying a different message from those found at the boundaries, it is not detectable by current analytical methods. This lack of distinctiveness may be due to the method of collection. Samples were collected onto aluminum foil, a substance that has vastly different properties from the usual materials that are used to carry a rabbit's scent mark. The highly reflective surface of the foil, and the much higher heat conductivity may

well mean that some components of the secretion will not adhere to the surface or that some of the constituents may be lost more quickly than would occur from a more typical surface (Reigner and Goodwin, 1977). However, animals on this site come above ground no earlier than about 1 hr before sunset. Since the foil was collected from all poles before 9:00 AM, the samples were not exposed to sunshine for a very long period, and there seems to be little time for this evaporation to occur. In addition, for at least some of the more common constituents of rabbit chin gland secretion, aluminum foil is suitable and it retains the compounds as well as a biological substrate (Hayes, unpublished data).

Another explanation may be that the marks on poles might actually not be different from each other. Rabbits may produce two types of signals from the chin gland. One may be used to mark the territory and establish that this area belongs to a dominant individual. This is the signal found on the chinning poles. The other could be used to mark individuals as belonging to that group. This signal would need to be individually identifiable; a generic dominant signal would not suffice. This second type of signal would be that collected from a chin swab and also from the head of other animals in the social group (see below). There is no histological evidence of two separate glands in the chin region that would allow this division of the signal; however, there are three types of cells (Lyne et al., 1964), and, thus, it is possible that there is more than one type of signal produced by the dominant male.

The marks on poles and the head and chin swabs were collected from the same habitat at the same time, and yet the swabs from an animal's skin show the full complexity of peaks, while all the poles show a depauperate signal. Either this difference detected among the samples is trivial, an artifact of the collection technique, or it reveals something more important: that there are two types of mark produced by the rabbit chin gland.

Marks on Rabbits. Dominant male rabbits are known to place their scent marks on other individuals in their social group (Bell, personal communication, Mykytowycz, 1968). It is possible to identify the secretion of the dominant male from the swab taken from the head of a subordinate individual. It is also possible to ascertain the social status of an individual without reference to any behavioral observation, but instead from the pattern of secretion found on its head and chin. If an animal is dominant, then his chin swab will contain more peaks than the swab from his head. No other animal is dominant to him, and, thus, there is none that places a scent mark upon his head. If, on the other hand, the animal is a subordinate individual, then the swabs collected will show the opposite pattern. The head swab (the mark of the dominant individual) will be more complex than the swab from under the chin.

It is also possible to determine the composition of the secretion from the dominant individual in a social group without having to trap this male, simply from the swab of the head of a subordinate animal. Since dominant animals are notoriously

trap-shy (Mykytowycz, 1964; Sunnocks, 1998), this gives the opportunity to collect this information from any social group, whether or not the dominant individual is trapped. A mark that is collected from the head of a rabbit is the scent mark of the dominant male of that social group, unless the donor animal is the dominant male, and then no mark is detectable on the head.

There is a structuring of the location of scent marks through the territory controlled by a rabbit social group. There are significantly more marks placed near the warren and at the borders with other social groups, than there are throughout the rest of the territory. This suggests that the rabbits are using a semiochemical message to defend the core of the territory, and the boundaries.

Acknowledgments—The authors thank C. Herlihy and K. Stephenson for technical and field assistance. This research was carried out under UWS ACEC Permit No. ARP97-2 (part of ARP92-13). The authors also thank the NSW National Parks and Wildlife Service for permission to conduct this research at Hope Farm, Cattai National Park. Financial support was provided by the Co-operative Research Centre for Biological Control of Vertebrate Pest Populations.

(Received August 31, 2000; accepted October 5, 2001)

Abstract—The cuticular lipids of the wheat stem sawfly *Cephus cinctus* (Hymenoptera: Cephidae) were investigated as part of a chemical ecology project with this species. The major cuticular lipids were *n*-alkenes and *n*-alkanes. Alkenes were the most abundant and exhibited dramatic sexual dimorphism. (*Z*)-9-Tricosene accounted for about half of the total hydrocarbon in males but was nearly absent from females. The dominant alkenes in females were (*Z*)-9-pentacosene and (*Z*)-9-heptacosene. The alkane profiles were similar in both sexes, with *n*-tricosane being the most abundant, followed by *n*-pentacosane and *n*-heptacosane. In both sexes, there were minor amounts of alkanes and alkenes with other chain lengths and *n*-alkadienes of 29 and 31 carbons. In males, about one tenth of the surface lipids consisted of (*Z*)-9-alkene-1, ω-diol diacetates with 22-, 24-, and 26-carbon chains. The same compounds were also detected from females but in much smaller amounts. The structures of these novel diacetates were proven by synthesis. By analogy to methyl oleate, a well-studied food lipid, the alkenes and diacetates were expected to undergo slow oxidation in air to release specific aldehydes and other volatile products, and these were generally detected in volatiles collected from living sawflies.

Atmospheric oxidation of the diacetates was also demonstrated in the absence of sawflies. One product from the diacetates, 9-acetyloxynonanal, was shown in other research to be particularly active electrophysiologically and was also attractive in the field. Aldehydes from the alkenes also showed strong electrophysiological activity. The concept of volatile pheromones originating from heavy, unsaturated cuticular lipids is discussed.

Key Words—*Cephus cinctus*, wheat stem sawfly, pheromone, cuticular lipid, hydrocarbon, alkene, alkane, (*Z*)-9-docosene-1,22-diol diacetate, (*Z*)-9-tetracosene-1,24-diol diacetate, (*Z*)-9-hexacosene-1,26-diol diacetate, aldehyde, oxidation.

INTRODUCTION

The wheat stem sawfly *Cephus cinctus* Norton (Hymenoptera: Cephidae) remains an important pest of wheat in the northern Great Plains, and the chemical ecology of this species is now being investigated with the goal of finding new management tools. Aspects of this research have included the chemical identification, electrophysiological activity, and attractiveness of volatile compounds from the sawfly (Cossé et al., 2002). Compounds from sawfly volatiles collections that elicited strong electrophysiological responses included 9-acetyloxynonanal, nonanal, tetradecanal, phenylacetic acid, and other aldehydes and carboxylic acids. 9-Acetyloxynonanal was attractive to both sexes in preliminary field tests (Cossé et al., 2002).

In another sawfly species, *Pikonema alaskensis* (Rohwer) (Hymenoptera: Tenthredinidae), the volatile long-range pheromone also includes aldehyde components, and these originate in an unusual way, through the oxidation of essentially nonvolatile cuticular lipids (Bartelt and Jones, 1983). The cuticular lipids of *C. cinctus* were, therefore, studied to explore whether such a mechanism might operate in this species. The results suggest it does. This report includes a survey of the cuticular lipids of *C. cinctus*, the synthesis of three novel constituents to prove structure, and a discussion of the production of volatile pheromone components from unsaturated lipids by oxidation.

METHODS AND MATERIALS

Extracts and Collections of Volatile Compounds. Hexane extracts of whole, individual sawflies were prepared in Montana by one of us (D.K.W.) and sent to Peoria for analysis. The insects were field collected as prepupae and handled as described by Cossé et al. (2002). Individual adult sawflies were extracted for either 20 min or 24 hr in ca. 0.5 ml hexane, and the sex and age of each insect was recorded. Because mating occurs soon after emergence in the field, the chosen age

categories emphasized the younger insects: 1, 2, 3, 4, and 5 hr after emergence, 1–2 days old, and 5–6 days old. Some sawflies were also extracted before emergence; these were removed from the wheat stem stubs after they had eclosed from their pupae but before they had chewed through the plug in the stem. A total of 23 extracts of individuals were analyzed by GC-MS and compared. Later, additional hexane extracts were prepared in Peoria from insects received from Montana. These included 1 sec dips and 24 hr soaks of groups of 10–25 male or female sawflies.

The collection of volatiles from living sawflies was described by Cossé et al. (2002). The GC-MS data files for these previous volatiles collections were studied further for additional information.

Instrumentation. The details of the GC-MS system were given by Cossé et al. (2002). Briefly, the HP 5973 Mass Selective Detector was interfaced to an HP 6890 GC. Cuticular lipid samples were analyzed on a thin-film DB-1 GC column (15 m length, 0.25 mm ID, 0.1 μm film thickness; J & W Scientific, Folsom, California). The oven program started at 50°C for 1 min, increased at 10°C/min to 300°C, and remained at 300°C for 5 min. The inlet and transfer line were held at 300°C and 250°C, respectively. The usual MS scanning range was 40–550 amu (EI, 70 eV). The Wiley mass spectral library with 275,821 spectra (Wiley, 1995) was available on the MS data system. Quantitation of cuticular components was done by the external standard method on an HP 5890 Series II gas chromatograph equipped with flame ionization detector. High-performance liquid chromatography (HPLC) was used to separate geometrical isomers of alkenes and of one alkenediol diacetate. The system consisted of a Waters M6000 pump, Waters R401 differential refractometer detector, and $AgNO_3$-treated column. The $AgNO_3$ column was prepared from a 25-cm $\times$ 4.6-mm-ID silica column (Alltech, Adsorbosphere, 5 μm) by the method of Heath and Sonnet (1980). The elution solvent was 0.25% 1-hexene in hexane for alkene hydrocarbons and benzene for the alkenediol diacetate. HPLC on a silica column (Alltech, Econosphere Silica 5μ) was also used to separate the sawfly-derived alkenediol diacetates from the other cuticular lipids (10% ether in hexane). Infrared spectra of purified synthetic alkenediol diacetates were obtained as thin films on KBr plates using a Nicolet Impact 410 FT-IR spectrometer. The proton NMR spectrum was obtained at 400 MHz for a synthetic alkenediol diacetate on a Bruker Avance 400 instrument. The solvent was deuterobenzene, and the shifts were measured relative to TMS.

Dimethyl Disulfide Derivatives. Dimethyl disulfide (DMDS) adducts were prepared from the sawfly-derived olefinic lipids and the synthetic alkenediol diacetates so that locations of double bonds could be determined (Carlson et al., 1989). Briefly, the samples were evaporated to dryness under a stream of nitrogen, and DMDS and 5% iodine in ether were added (equal volumes, about 25 μl each). The samples were heated at 45°C for 1–2 hr, then diluted with hexane and worked up with aqueous sodium thiosulfate to destroy the iodine catalyst. The hexane layer, which contained the products, was dried over sodium sulfate, evaporated under

nitrogen, resuspended in about 10 μl of hexane, and analyzed by GC-MS. The MS scanning range for these was 40–650 amu.

Synthesis of Alkene-1, ω-Diol Diacetates. Three alkenediol diacetates (**8**, **9**, and **10**) were synthesized by one of us (R.J.P.), using standard methods, to confirm chemical identifications (Figure 1). The Wittig reaction was the key synthetic step, and most of the reactions in Figure 1 involved the creation of the required Wittig salts and aldehydes from commercially available starting materials and the addition or removal of protecting groups. The Wittig salts (**1–4**) were prepared from 9- or 11-carbon bromohydrins (Aldrich, Milwaukee, Wisconsin) by refluxing with triphenylphosphine in acetonitrile, followed by solvent removal and trituration with dry ether to remove impurities. For two of these (**1** and **2**), the hydroxyl group

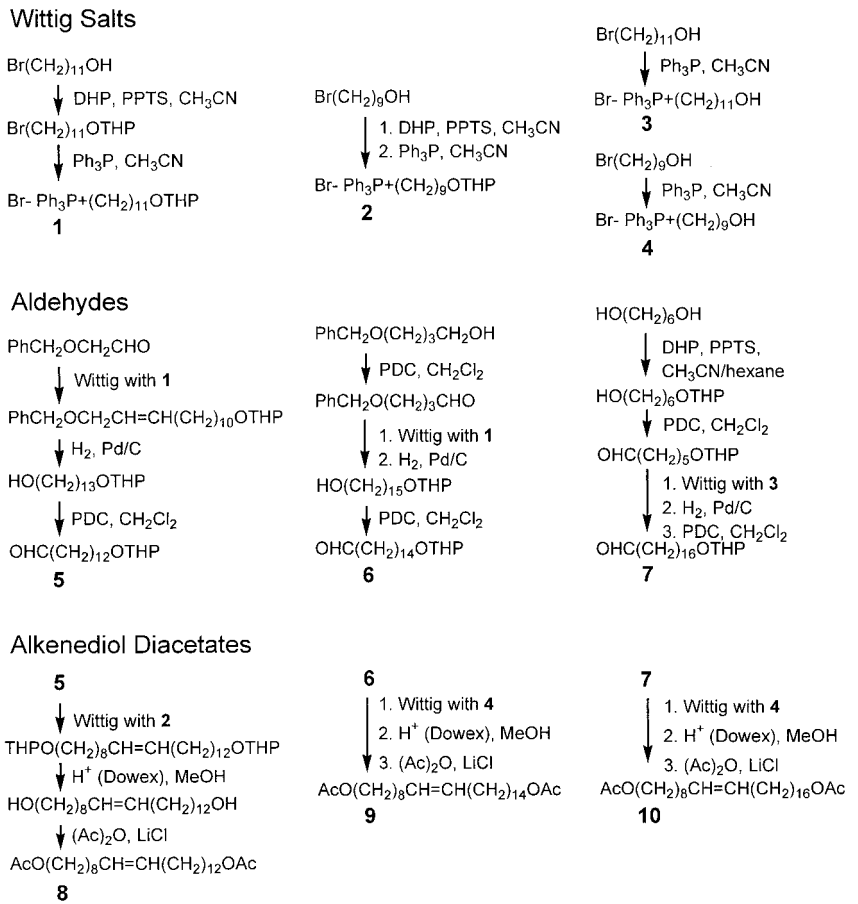

FIG. 1. Synthesis of the 9-alkene-1,ω-diol diacetates by Wittig routes (see text for abbreviations).

was protected as a tetrahydropyranyl (THP) ether before salt formation by reaction with 2,3-dihydropyran (DHP) in acetonitrile, using pyridinium *p*-toluene sulfonate (PPTS) as catalyst (Miyashita et al., 1977).

The carbon chains of the aldehydes (**5**–**7**) were all built up from smaller fragments with Wittig reactions (Sonnet, 1974). For **5** and **6**, two- and four-carbon benzyl-ether aldehydes were condensed with the 11-carbon THP Wittig salt. The four-carbon aldehyde was not commercially available but was made from its alcohol by oxidation with pyridinium dichromate (PDC) (Corey and Schmidt, 1979). Hydrogenation of these Wittig products over 10% palladium on carbon both removed the benzyl protecting group (but not the THP group) and reduced the double bond (Greene and Wuts, 1991). The free hydroxyls were subsequently oxidized to aldehydes with PDC. To make aldehyde **7**, the six-carbon diol was first converted to a mono-THP ether in a biphasic mixture of acetonitrile and hexane; the reactants were primarily in the more polar (acetonitrile) phase, but the mono ether migrated to the hexane phase, reducing the chance of further derivatization to the diether. The free hydroxyl was then oxidized to an aldehyde, and the aldehyde was condensed with hydroxy Wittig salt **3**. The double bond of the resulting 17-carbon product was hydrogenated over palladium on carbon, and the final aldehyde was formed by PDC oxidation of the alcohol.

The final Wittig condensations with the prepared aldehydes involved either the protected (THP) or hydroxy salts; both gave the expected products, although the yields in either case were only fair. The THP groups were removed in MeOH under acid catalysis (provided by Dowex 50W-X4 ion-exchange resin, which was later easily removed by filtration) (Beier and Mundy, 1979). Finally, the free alkenediols were acetylated with acetic anhydride, using lithium chloride as the Lewis acid catalyst (Sabitha et al., 1999).

The synthetic requirement was only to obtain enough material for chromatographic and spectral comparison with the natural material. Reactions were not optimized for yield, and in most cases, intermediates were used in subsequent reactions without purification. Overall yields were less than 1% from the starting materials, but the desired final products were distinct and readily recognizable in the reaction mixtures.

Reactions were monitored by mass spectrometry. Mass spectral and GC retention data for the syntheses in Figure 1 are summarized in Table 1. Mass spectra were not obtained for the Wittig salts **1**–**4**. The THP ether and diol intermediates for **9** and **10** were not analyzed by GC-MS but were converted directly to the diacetates before analysis. Synthetic **8**–**10** consisted of both *E* and *Z* isomers, which were separable by GC. Synthetic **10** was investigated further so that the proper configuration could be assigned to each GC peak. HPLC on the $AgNO_3$/silica column was used to separate the geometrical isomers, and infrared spectra were then obtained for these. A proton NMR spectrum was also acquired for the more abundant isomer.

TABLE 1. GC RETENTION TIMES AND MASS SPECTRAL DATA FOR INTERMEDIATES AND FINAL PRODUCTS IN SYNTHESIS OF 1,ω-ALKENEDIOL DIACETATES (SEE FIGURE 1)

Compound and (GC retention in min.)	Mass spectral fragments [m/z] and (relative abundance)

[a] *Z* and *E* isomers with nearly identical mass spectra. The spectral data correspond to the earlier, larger GC peak (*Z* isomer) in each case.

Other Standards. Samples of 8-acetyloxyoctanal and 10-acetyloxydecanal were prepared for comparison of GC retention times and mass spectra with components in sawfly volatile collections. The commercially obtained 8- and 10-carbon diols were converted to mono-THP ethers as described above, oxidized with PDC to mono-THP aldehydes, then deprotected and acetylated. The 13-, 15-, and 17-carbon aldehyde acetates were obtained by ozonolysis (see Cossé et al., 2002) of alkenediol diacetate samples. The saturated aldehydes of 6–14 and 16 carbons were either commercially available (6–14 carbons, Aldrich) or were prepared by ozonolysis of appropriate alkene hydrocarbons. Octanoic, nonanoic, decanoic, and phenylacetic acids were obtained commercially (Aldrich). Synthetic *E* and *Z* alkenes and various other alcohols, hydrocarbons, and 2*E*-alkenals were on hand from other research.

Laboratory Oxidation of Alkenediol Diacetates. Preliminary study of light-induced, abiotic oxidation of alkenediol diacetates was performed using a Suntest CPS solar simulator (Atlas, Gainesville, Florida), with the system set up as described by McGuire et al. (2000). Purified (HPLC) samples containing about 500 ng of synthetic **10** or natural male alkenediol diacetates were evaporated to dryness on the inside of quartz cuvettes. Cuvettes were capped and sealed with Teflon tape and placed in the solar simulator. The outside of the treated cuvette was in direct contact with the cooled (15°C) instrument surface. Samples were exposed for 2 hr

to light irradiation similar in intensity and wavelength composition (300–1100 nm) to sunlight. As a control, a sample of synthetic **10** was set up identically but without the light. All samples were resuspended in hexane after 2 hr and then analyzed by GC-MS.

RESULTS AND DISCUSSION

Cuticular Hydrocarbons. The cuticular hydrocarbons were the major compounds in the sawfly hexane extracts (Figure 2, Table 2). Both sexes had large amounts of *n*-alkanes and *n*-alkenes, primarily with odd numbers of carbons. The *n*-alkane profiles were similar between sexes, with tricosane being most abundant and with smaller amounts of 25-, 27-, 29-, and 31-carbon alkanes. There were traces of the intervening even-chain compounds and also the 21- and 33-carbon alkanes. No branched alkanes were detected.

The *n*-alkenes were the most abundant class of hydrocarbons, and their profiles differed dramatically between sexes. In males, the 23-carbon alkene accounted for about half of the total hydrocarbon. In females, this alkene was far less

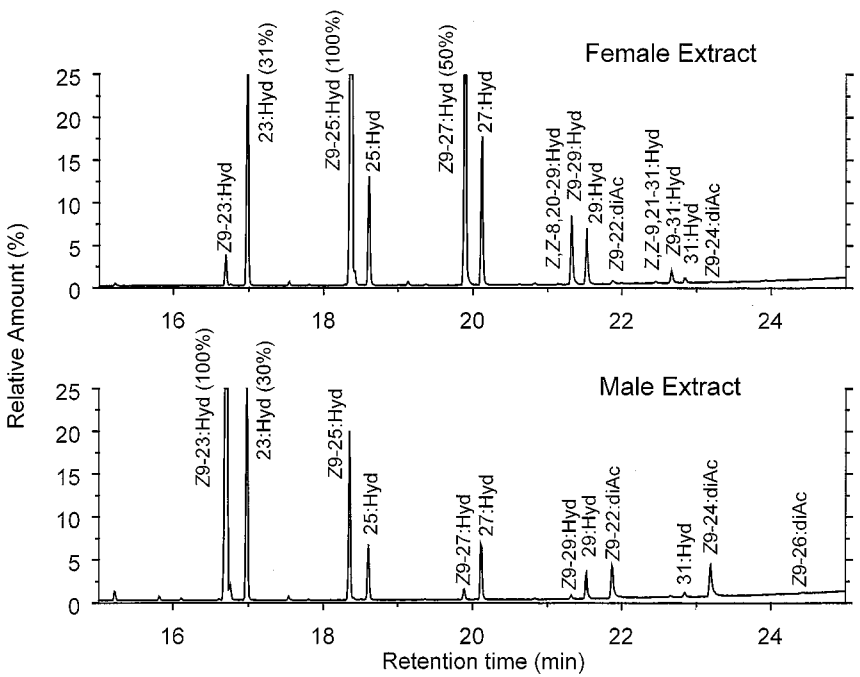

FIG. 2. Gas chromatograms of extracts from female and male *C. cinctus*. Selected hydrocarbons (:Hyd) and diacetates (:diAc) are labeled. Relative areas of off-scale peaks are shown in parentheses.

[b] ND denotes not detected.

abundant, and the 25- and 27-carbon alkenes were dominant instead. There were smaller amounts of alkenes with 21, 29, and 31 carbons in both sexes and also the intervening even-chain compounds. In both sexes, the double bonds were almost exclusively in the nine position for all chain lengths, based on mass spectra of the DMDS derivatives. The 23-carbon alkenes from both sexes did have trace amounts of 7-alkene (<1% as much as the 9-isomer). The observed molecular ions (alkene molecular weights plus 94) and the key fragment ions (from cleavage between the carbons with the thiomethyl groups) are given in Table 2. By comparison to *E* and *Z* synthetic standards (underivatized) on the $AgNO_3$ HPLC

column, all of the sawfly alkenes had the *Z* configuration. No branched alkenes were detected.

In females, hydrocarbon mass spectra indicated the presence of small amounts of alkadienes of 29 and 31 carbons (molecular ions at $m/z = 404$ and 432, respectively). The mass spectra of the DMDS derivatives were interpreted according to Carlson et al. (1989). Fragments listed in Table 2 represent the molecular ion (addition of two equivalents of DMDS), the loss of 94 (one DMDS) as a neutral molecule, and subsequent cleavage at the remaining DMDS site as with the alkenes (yielding four ions, representing the saturated and unsaturated side of each double bond). These spectra determined the double bonds to be in the 9 and 21 positions from one end of the chain for both dienes. (However, rules of nomenclature require that the 29-carbon compound be named as 8,20-nonacosadiene so that the locant numbers are as small as possible). GC retention times were consistent with straight chains and *Z* configurations at the double bonds (Bartelt et al., 1986). These dienes were also detected from males, but in smaller amounts.

The total amount of hydrocarbon per sawfly was about 15 μg, with males and females having very similar quantities. Extraction for 20 min or 24 hr gave comparable profiles and amounts, although the longer soak also extracted fatty acids (primarily palmitic and oleic) and sterols from the insects. Even a 1 sec rinse gave essentially the same profiles, indicating that the compounds were present on the immediate surface. The lipid profiles and amounts were consistent in major features for all ages between 1 hr and 5 days. In contrast, adults removed from wheat stubs before natural emergence had the typical amount of alkane but only about 10% of the usual amount of alkene. Apparently, biosynthesis of alkenes is intense around the time of emergence. Finally, younger females (several hours to 1 day old) had larger amounts of the alkadienes than older ones, with the 29-carbon diene amounting to as much as 0.5% of the total hydrocarbon rather than less than 0.05%. This difference was not seen in males. The female in Figure 2 was less than 1 day old at the time of extraction.

Diacetate Lipids. Initial comparison of chromatograms revealed two compounds in male extracts (approximately 1 μg of each per male) that were far less abundant in females (Figure 2, retention times of 21.9 and 23.2 min). The mass spectrum of the first of these indicated a molecular weight of 424 (Figure 3), which was not consistent with a hydrocarbon. (A fully saturated hydrocarbon of 30 carbons would have a molecular weight of 422; thus oxygen was probably present in the sawfly compound to account for the higher molecular weight). Several subtle features in the mass spectrum gave important information about the structure. The first was a fragment at m/z 61 (19% of base peak), which is characteristic for an acetate group (McLafferty, 1980). Examination of library spectra of acetates indicated that the m/z 61 peak is most intense when the acetate group is at or near the end of the carbon chain and is distant from other functional groups or branches. Second, the spectrum of the sawfly compound lacked the characteristic peaks that

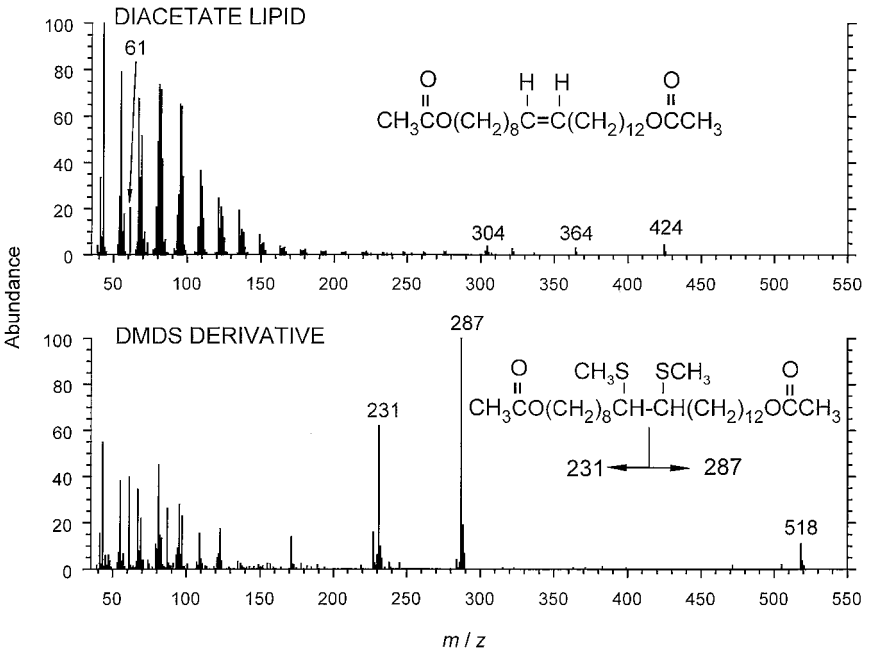

FIG. 3. EI-mass spectrum of 22-carbon diacetate lipid from male *C. cinctus* (top) and EI-mass spectrum of the DMDS derivative of this lipid, showing origins of major fragments (bottom).

would be expected if the acetates were secondary; for example, an acetate on the second carbon of a chain leads to a prominant spectral peak at *m*/*z* 87 due to chain cleavage adjacent to the acetate. Finally, there were fragments at *m*/*z* 364 and *m*/*z* 304 that corresponded to two consecutive losses of 60 from the molecular ion (believed to represent the loss of two acetic acid molecules). Taken together, this evidence suggested a lipid chain of 22 carbons with an acetate group on each end. However, the molecular weight for a saturated chain would be 426 instead of 424; thus a double bond was probably present in the chain. The DMDS derivative formed readily (molecular ion at *m*/*z* 518 = 424 + 94), and the fragment ions (*m*/*z* 231 and 287) were consistent with a double bond being present in the 9 position of the original lipid (Figure 3).

The data for the second lipid were analogous, with molecular weight of 452 and key fragments at *m*/*z* 61, 332, and 392. The DMDS adduct gave key MS ions at *m*/*z* 231, 315, and 546, consistent with a 24-carbon diacetate, again with the double bond in the 9 position. Closer inspection of the gas chromatograms revealed a third, still later-eluting member of this series, about 10% as abundant as the first two. Its mass spectrum included ions at *m*/*z* 61, 360, 420, and 480, and the MS

ions of its DMDS derivative included 231, 343, and 574. These data indicated a 26-carbon diacetate, once more with the double bond in the 9 position. There was no evidence for other double-bond positional isomers. Close examination of female-derived extracts and their DMDS derivatives by GC-MS revealed that the same three compounds were present but at much lower levels (about 10% of the amounts in males, see Figure 2).

Synthetic Alkenediol Diacetates. Synthetic alkenediol diacetates were prepared to confirm the proposed structures and to establish double-bond configuration of the natural material. The mass spectral data (Table 1) supported that the synthetic reactions proceeded as shown in Figure 1 because the synthetic intermediates and products had the expected molecular weights and reasonable fragmentation patterns. For example, THP ethers were readily recognized by their mass spectra (Table 1) because of the base peak at m/z 85 and a moderately intense ion at m/z 101, due to cleavage on either side of the ether oxygen. The molecular ion and an M-1 ion were usually seen for the THP ethers, but the intensity for both was low (ordinarily $<1\%$). The M-85 peak was similarly small but was still reliably present and served as further confirmation of molecular weight. Example details for one THP ether alcohol and one THP ether aldehyde are given under the intermediates for compound **5** in Table 1; for other THP ethers, only key ions are listed. Analogously to THP ethers, benzyl ethers had spectral peaks at m/z 91 and 107. The THP ether bromides (intermediates for **1** and **2**) had characteristic spectra because of the bromine isotopes. For the di-THP diether precursor of **8**, the molecular ion was not seen, but the M-85 fragment was present, and there was another ion corresponding to two losses of a deprotonated THP group (m/z 340). After deprotection, the free diol exhibited a small molecular ion and ions corresponding to one and two neutral losses of water. Features of the mass spectra of alkenediol diacetates were discussed above.

Patterns in GC retention times supported the mass spectral interpretations and synthetic expectations. For example, the Wittig reactions always gave two products (the *E* and *Z* isomers) that were separated by about 0.1 min but had nearly identical mass spectra. Catalytic hydrogenation always collapsed the E/Z peak doublet into a single peak of still higher GC retention time. Also, oxidation of a THP ether alcohol to the corresponding THP ether aldehyde consistently decreased the GC retention time (Table 1).

By GC of synthetic **8–10**, the earlier-eluting isomer was always the more abundant one; this was expected to be the *Z* isomer because the Wittig reaction conditions favor production of *Z* double bonds (Sonnet, 1974). Compound **10** was analyzed further by AgNO3 HPLC to confirm this. The more abundant isomer eluted later than the less abundant one (24–26 ml vs. 20–21 ml, based on GC analysis of HPLC fractions), which also supported that the more abundant isomer was *Z* (Heath and Sonnet, 1980). The IR spectra further corroborated this conclusion. The more abundant isomer was a liquid at room temperature and had key IR

absorbances (cm^{-1}) indicative of an olefin (3003, w, =C–H), hydrocarbon chain (2925 and 2854, both s, $-CH_2-$), and acetate group (1741, s, C=O; 1365, m, 1240, s, and 1037, m, other acetate-related peaks), but the spectrum did not indicate presence of an *E* double bond. On the other hand, the less abundant isomer was a solid at room temperature and had corresponding absorbances at 2918, 2850, 1732, 1369, 1247, and 1041; it also had the absorbance (962, m) that confirmed the *E* double bond. The proton NMR spectrum of the more abundant isomer supported the structure for synthetic **10** as drawn in Figure 1, but it gave no further information about double-bond configuration because the olefinic protons had the same shift and the coupling constant could not be observed: δ 5.56 (2 H, m, =C$\underline{H}$–), 4.04 (4 H, m, O–C$\underline{H}_2$–), 2.17 (4 H, m, =CH–C$\underline{H}_2$), 1.74 (6 H, s, C$\underline{H}_3$(C=O)O), 1.2–1.6 (40 H, other –C$\underline{H}_2$–, m).

Comparison of Natural and Synthetic Alkenediol Diacetates. Based on same-day comparisons of GC retention times, each natural alkenediol diacetate matched exactly the *Z* isomer of the corresponding synthetic compound for all three chain lengths. They also matched with respect to mass spectra and with respect to GC rentention times and mass spectra of the DMDS derivatives.

Compounds in Nature Related to Diacetates. This is believed to be the first report of natural alkenediol diacetates, but related compounds are known. Beeswax contains saturated 1,ω-diols of 24–28 carbons and esters of these, but the acid moieties have 16–24 carbons instead of just two (Tulloch, 1971). Free 1,ω-alkanediols of 22, 24, and 26 carbons have been isolated from various plants (Chatterjee and Chakraborty, 1967; Austin et al., 1969; Rizvi and Sultana, 1972; Amparo-Lopez et al., 1976; Hatam et al., 1990). 1,16-Hexadecanediol diacetate has been reported in the defensive secretion of the gulf fritillary butterfly (M. Blum, personal communication). Recently Oliver et al. (2000) and Doss et al. (2000) isolated 3-hydroxypropanoyl esters of (*Z*)-9-docosene-1,22-diol and (*Z*)-9-tetracosene-1,24-diol from bruchid weevils. The compounds are potent plant growth regulators, and callus tissue develops on legume pods exposed to these compounds during oviposition by female beetles.

Oxidation of Cuticular Alkenes. "Spontaneous" oxidation of unsaturated lipids has been studied extensively, especially in relation to rancidity of food oils, and much is known about the chemical mechanisms involved (reviewed by Frankel, 1998). Oxidation is complicated and involves cascades of free-radical reactions. It can be light induced (photooxidation) or simply occur by exposure to molecular oxygen under ambient conditions (autoxidation) if triggered by trace catalysts or reactive species such as free radicals. Once initiated, the reactions tend to be self-sustaining. Both mechanisms generally lead to the same volatile products, but proportions can differ. The major volatile products are usually aldehydes.

One food-related lipid, methyl oleate, provides a reasonable predictive model for the nonenzymatic oxidation of the alkenes and cuticular alkenediol diacetates of *C. cinctus*. Methyl oleate is like the sawfly compounds in having just one *Z* double

bond that is distant from other functional groups or chain ends. The mechanism for oxidation of methyl oleate to volatile products (Frankel, 1998) suggests a specific series of compounds that would result from the oxidation of particular alkenes, and occurrence of these compounds in the volatile collections from sawflies would support that such a mechanism is operating.

The oxidation scheme and expected products from (*Z*)-9-tricosene, the only abundant alkene in *C. cinctus* males, are summarized in Figure 4. The initial reaction is the formation of allylic hydroperoxides (four positional isomers). The hydroperoxides decompose either thermally or catalytically (e.g., by metal ions) into alkoxyl radicals, and these can then react in a number of ways, including cleavage into volatile products. Scission on either side of the radical group (indicated by "A" or "B" in Figure 4), yields a specific free aldehyde plus an intermediate that reacts further to give a characteristic hydrocarbon, alcohol, or other aldehyde. This general scheme is shown at the bottom of Figure 4, and the expected products from each of the hydroperoxide isomers are summarized at the upper right. By analogy to methyl oleate (Frankel, 1998), nonanal and tetradecanal should be the most abundant products.

The compounds actually detected in volatile collections are shown in bold print in Figure 4; relatively large and intermediate quantities are indicated by ** and *, respectively. The compounds were identified by mass spectrum and GC retention time, relative to authentic standards. The more abundant products are also indicated in the total ion chromatogram in Figure 5, which represents a volatile collection from male sawflies.

Nonanal and tetradecanal were, in fact, the most abundant of the expected oxidation products from males. Octanal and decanal were clearly present but were less abundant. Amounts were still smaller for the other compounds noted in bold in Figure 4. Some of the products expected but not found (heptanal, heptane, heptanol, octane) are relatively volatile and would have occurred too near the solvent front of the GC run to yield sharp peaks and be easily detected. Others, such as 2-undecenal, were probably present, but small amounts and coelution with more abundant compounds prevented positive identification. The heavier (15- and 16-carbon) 2-alkenals were not detected. Their lower volatilities would have reduced the amounts collected. Furthermore, these compounds are especially prone to further oxidation, and remaining in the oxidizing lipid mixture instead of evaporating out would have enhanced their degradation.

Female sawflies have very little 23-carbon alkene but have large amounts of the 25- and 27-carbon alkenes. Oxidation of these would be analogous to tricosene. All of the scission products with 11 or fewer carbons (Figure 4) would be expected from any of the 9-alkenes, but those of 12 or more carbons expected from 9-tricosene would be replaced by homologs with two or four additional carbons if the parent alkene is 9-pentacosene or 9-heptacosene. Hence, there was relatively little tetradecanal from females, but hexadecanal was abundant instead (Cossé

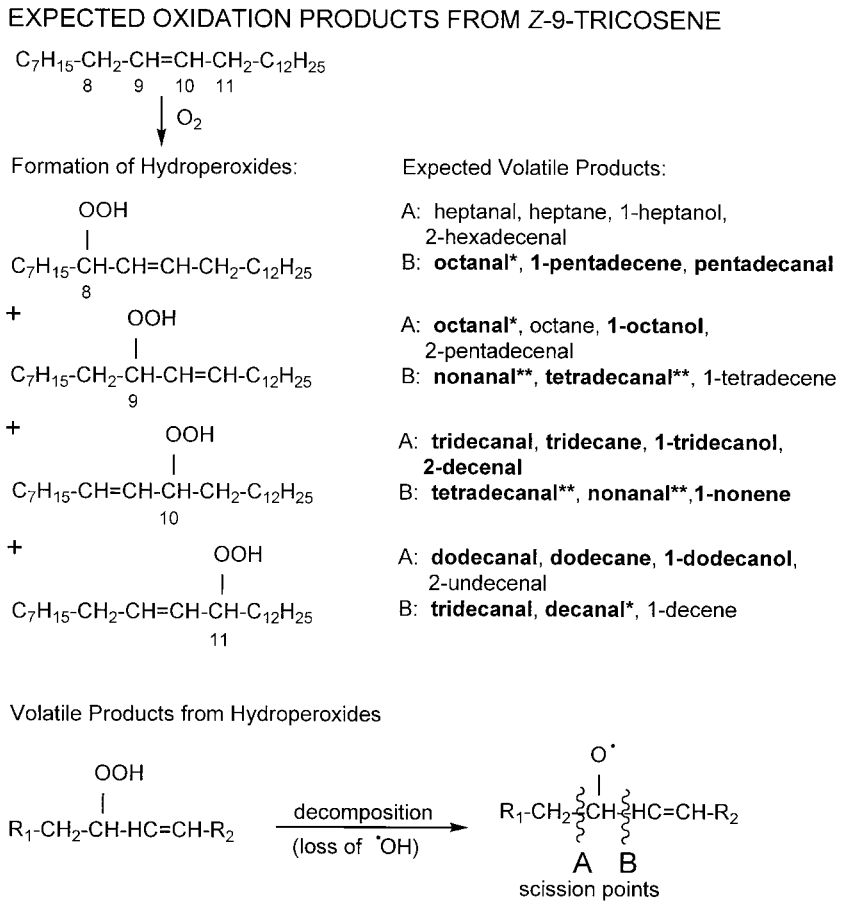

FIG. 4. Expected products from the autoxidation of (*Z*)-9-tricosene, based on the process for methyl oleate (Frankel, 1998). Compounds in bold print were detected in volatile collections from male sawflies. High and intermediate relative abundance denoted by ** and *, respectively.

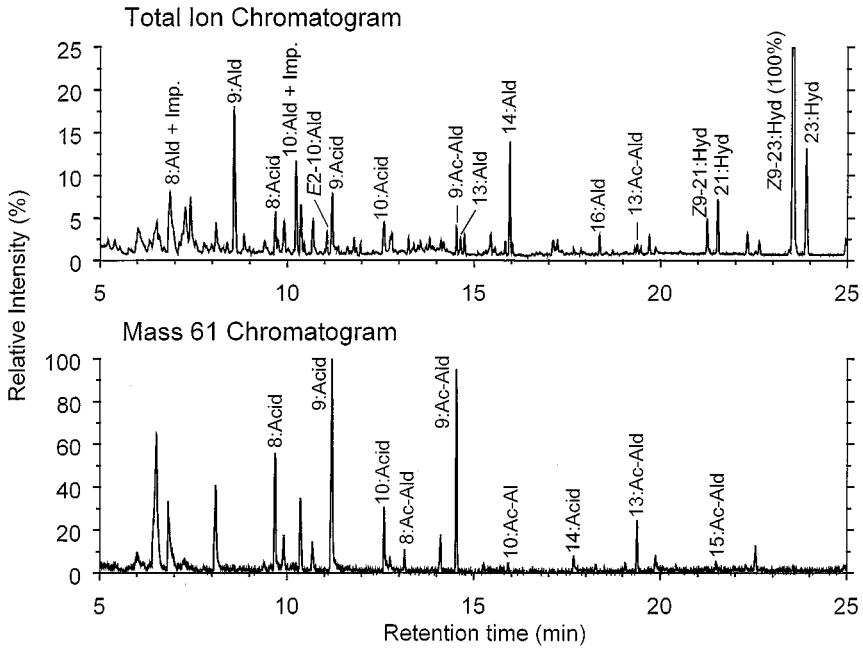

FIG. 5. GC-MS chromatograms of a volatile collection from male *C. cinctus*. The upper trace is total ion chromatogram. The lower trace is for mass 61 only, which shows the acetyloxyaldehydes (and also the carboxylic acids) very clearly. Peaks are labeled as aldehydes (:Ald), hydrocarbons (:Hyd), carboxylic acids (:Acid), or acetyloxyaldehydes (:Ac-Ald). Nonbiological impurities are denoted by "Imp."

et al., 2002). The 18-carbon aldehyde was observed in the collections of volatiles but in smaller amounts. Its lower volatility probably reduced its abundance in the collections.

The observed product patterns support the formation of the volatiles by a mechanism like that described for methyl oleate. Further oxidation of these aldehydes would yield carboxylic acids, and those of 8, 9, and 10 carbons were found consistently in the volatile collections from sawflies (Cossé et al., 2002) (Figure 5), although these may have other, as yet unexplained sources as well. The emission of phenylacetic acid from sawflies is not, however, accounted for by the oxidation mechanism.

The amounts of oxidation products collected from the sawflies were minute relative to the amounts of alkene present. The most abundant aldehydes from males were nonanal and tetradecanal, but typical collected amounts were only 50 and 15 ng/day per male, respectively, while males have about 7 μg of the parent 9-tricosene. Monounsaturated compounds such as methyl oleate oxidize

only 1–2% as rapidly as the polyunsaturated analogs (Frankel, 1998); thus, the minor yields of volatile products from alkenes is not surprising. Nevertheless, the levels of volatiles observed are still sufficiently high to be detectable to sawfly antennae. Intriguingly, even though the intact alkenes were not found to elicit electrophysiological responses (Cossé et al., 2002), the male–female dimorphism in alkenes could still lead to behavioral recognition of sexes at a distance by way of the aldehyde (or other) oxidation products.

Dienes. The alkadienes, which are more abundant in females, would release additional, unique oxidation products. These would include dodecanedial and unsaturated aldehydes of 20, 21, and 22 carbons with a double bond in the 12 position. None of these compounds were detected, but the amount of diene starting material that was present was extremely small.

Oxidation of Alkene-1,ω-diol Diacetates. By analogy to the alkenes, the alkenediol diacetates of 22, 24, and 26 carbons would all be expected to produce 9-acetyloxynonanal, and each diester would also generate a unique, heavier homolog from the other end of the lipid chain (Figure 6).

The mass spectral data files for collections of sawfly volatiles were examined for these compounds by extracting single-mass chromatograms for *m*/*z* 61 (for

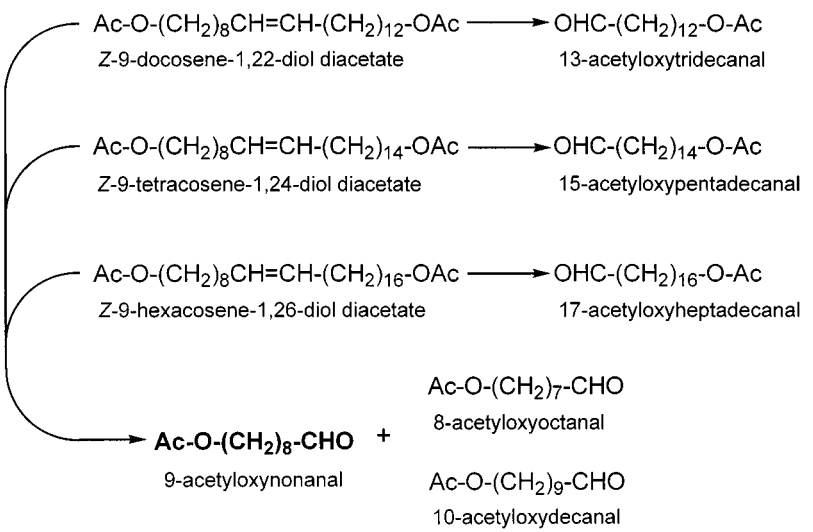

FIG. 6. Acetyloxyaldehydes expected from the oxidative cleavage of the alkenediol diacetates of *C. cinctus*. The major product would be 9-acetyloxynonanal because it can be derived from all three parent lipids, and acetyloxyaldehydes with 13-, 15-, and 17-carbon chains would result from the other ends of the parent lipid chains. Analogs of these acetyloxyaldehydes having one additional or one fewer carbon would also be expected (see text), but only those related to 9-acetyloxynonanal were likely to be detectable.

example, Figure 5). This approach revealed compounds containing the primary acetate group without interference from many other functional classes. (Simple aldehydes, alcohols, and hydrocarbons do not exhibit the *m*/*z* 61 fragment. Organic acids do show up, however, because there is always an isotope peak or protonated fragment corresponding to the major ion at *m*/*z* 60). 13-Acetyloxytridecanal was readily found in samples in which 9-acetyloxynonanal was prominent (about 20% as abundant as the major product, Figure 5). The 15-carbon homolog was sometimes detectable but was even less abundant, probably because of lower volatility. 17-Acetyloxyheptadecanal was never found, presumably because of still lower volatility and the much smaller amount of precursor. All four of these aldehyde acetates (of 9, 13, 15, and 17 carbons) were detected when the crude hexane extract of sawflies was ozonized, and the 13-carbon homolog clearly stimulated antennae (Cossé et al., 2002).

8-Acetyloxyoctanal and 10-acetyloxydecanal were also detected in volatiles collections but not from the lipid ozonolysis experiment. These compounds would be expected if the alkenediol diacetates oxidized according to the scheme for the alkenes and methyl oleate (but not from ozonolysis). Thus the pattern of aldehyde acetates observed in volatiles collections further supported the idea that they were formed by "weathering" of cuticular lipids. Interestingly, in tests with the synthetic standards, 8-acetyloxyoctanal and 10-acetyloxydecanal were clearly active by GC-EAD. Analogs with one additional and one fewer carbon would also be expected for the acetyloxyaldehydes with 13-, 15-, and 17-carbon chains, but these would have been present at extremely low levels and were not detected.

Under laboratory conditions, the amount of 9-acetyloxynonanal emitted from male sawflies was small (1–10 ng per sawfly per day) (Cossé et al., 2002) relative to the amounts of precursor alkenediol diacetates present in males (about 2 μg), but it was roughly proportional to the amounts of aldehydes apparently derived from 9-tricosene, further supporting a similar origin. In addition, the relatively greater production of 9-acetyloxynonanal from male sawflies than females (Cossé et al., 2002) was consistent with the greater amounts of the alkenediol diacetates present in males.

These qualitative and quantitative relationships strongly suggest that the alkenediol diacetates are the precursors to 9-acetyloxynonanal, a key compound in the sawfly volatiles collections that elicited intense antennal activity and had demonstrable activity in field tests (Cossé et al., 2002), and furthermore, that passive oxidation of the cuticular lipids could account for the amounts obtained in our volatiles collections from living sawflies.

Laboratory Oxidation of Alkenediol Diacetates. The synthetic alkenediol diacetate **10** was free of detectable acetyloxyaldehydes prior to artificial sunlight exposure. However, after 2 hr of irradiation, and as expected from our chemical model (Figure 6), 8-acetyloxyoctanal, 9-acetyloxynonanal, 16-acetyloxyhexadecanal, and 17-acetyloxyheptadecanal could be readily detected and were 0.09%, 0.4%,

0.3%, and 0.9% as abundant as the recovered starting material **10** (calculated from peak areas in the total ion chromatogram). 10-Acetyloxydecanal and 18-acetyloxyoctadecanal were not detected. An HPLC preparation of natural alkenediol diacetates, which contained **8** and **9** in an 8:1 ratio, was also free of detectable acetyloxyaldehydes before the light treatment. After 2 hr of light exposure, the results were analogous to synthetic **10:** 8-acetyloxyoctanal, 9-acetyloxynonanal, 12-acetyloxydodecanal, 13-acetyloxytridecanal, and 15-acetyloxypentadecanal were detected and were, respectively, 0.1%, 0.6%, 0.2%, 0.8%, and 0.2% as abundant as starting compound **8**. The experiment with synthetic **10** without exposure to light gave results similar to when the light was used, but the amounts of the acetyloxyaldehydes were lower (the acetyloxyaldehydes with 8-, 9-, 16-, and 17-carbon chains were 0.03%, 0.2%, 0.1%, and 0.4% as abundant as the starting material, respectively).

Although this experiment was preliminary, it clearly demonstrated that the biologically active acetyloxyaldehydes can be produced from the alkenediol diacetates in the absence of living sawflies. Furthermore, the amounts of acetyloxyaldehydes produced, relative to the amounts of parent alkenediol diacetates, were remarkably similar to those encountered with living sawflies (e.g., low nanogram quantities of acetyloxyaldehydes emitted per sawfly per day versus low microgram quantities of alkenediol diacetate present on the cuticle). Based on the GC-EAD studies of Cossé et al. (2002), the amounts of acetyloxyaldehydes produced by this process are large enough to be biologically relevant.

Behavioral and Environmental Enhancement of Oxidation Reactions. Certain features of sawfly biology would favor the oxidation of cuticular lipids. The insects are most active when the weather is warm (microclimate as hot as 35°C) and sunny (D. K. Weaver, unpublished). The oxidation reactions are accelerated by both heat and sunlight (Frankel, 1998, and our preliminary experiment). Sawfly grooming behavior (D. K. Weaver, unpublished) could distribute pheromonal precursors over the cuticle in a way that enhances oxidation rates. Thus it is possible that the reactions may be biologically (behaviorally) controlled even if there is no direct enzymatic mediation. The abiotic oxidation of unsaturates is complicated to study, especially in the early stages of the process, because it can be triggered or influenced by so many factors. These include the presence of trace amounts of metal ions, ketones, hydroperoxides, and other reaction-initiating substances, the action of ultraviolet light, and the effect of temperature (Frankel, 1998). On the other hand, involvement of enzymes has not been ruled out, and resolving this issue will be essential to understanding this pheromone system.

Pheromones Produced by Oxidation. The oxidation of relatively nonvolatile cuticular lipids is known to release volatiles with pheromonal activity in other hymenopterans. For example, females of the yellowheaded spruce sawfly, *P. alaskensis*, possess a series of (*Z*,*Z*)-9,19-alkadienes of 28–37 carbons that is absent in males (Bartelt et al., 1982). All of these dienes have a common oxidation

product, (*Z*)-10-nonadecenal, that is highly attractive to males in the field (Bartelt and Jones, 1983). Similarly, in the parasitic wasp, *Macrocentrus grandii* Goidanich (Braconidae), the females have a series of (*Z*,*Z*)-9,13-alkadienes of 27–41 carbons that the males lack (Swedenborg and Jones, 1992). With these dienes, the common oxidation product is (*Z*)-4-tridecanal, and as with *P. alaskensis*, the aldehyde is clearly attractive to males in the field. In laboratory wind-tunnel bioassays, as little as 17 pg of this aldehyde elicited dramatic upwind orientation.

C. cinctus differs in two important ways from the above examples. First and most obviously, the males are the major source of the key compounds (e.g., the diacetate lipids and the derived aldehyde acetates) instead of the females. Second, *both* sexes do have measurable amounts of the compounds, unlike the usual pattern with insect sex pheromones. Although the pheromone research on *C. cinctus* is in its early stages, the pheromone biology of the species already appears to be quite atypical and may provide a useful model for comparison in the future.

The existence of oxidation-derived pheromones in insects has not been frequently explored. The distinctive alkenediol diacetates of *C. cinctus* and their chemical relationship to the acetyloxyaldehydes through oxidation made this connection between nonvolatile precursors and volatile pheromones very clear, but as demonstrated with the alkenes, very typical compounds can also release volatiles that could be every bit as important biologically as the more esoteric ones. The reported examples of biologically active oxidation products are from the Hymenoptera, but it seems likely that the phenomenon could occur far more widely.

Acknowledgments—Useful discussions and helpful advice concerning lipid oxidation were generously provided by Dr. Hal Gardner, USDA-ARS-NCAUR. We are grateful to Dr. Dave Weisleder of NCAUR for obtaining the NMR spectrum and to Mr. John Salch of NCAUR for acquiring the IR spectra. Dr. Robert Behle of NCAUR allowed us to use the solar simulator in his laboratory.

Abstract—Volatiles collections and cuticular extracts of the wheat stem sawfly, *Cephus cinctus* Norton (Hymenoptera: Cephidae), were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) in order to detect possible pheromone components of this species. Volatiles collections from male and female sawflies contained the same 13 GC-EAD-active compounds that stimulated both male and female antennae. GC-EAD-active compounds were identified by mass spectrometry, and the identities were verified by acquiring or synthesizing authentic standards with identical GC retention times and mass spectra. 9-Acetyloxynonanal gave the strongest EAD response. Additional GC-EAD-active compounds included 13-acetyloxytridecanal, aldehydes with 9–16 carbon chain lengths, acids with 8–10 carbon chain lengths, and phenylacetic acid. The last was instantly detectable by human nose when several males were allowed to interact, but not from isolated insects. On a per-insect basis, grouped males overall released higher amounts of the GC-EAD-active compounds than grouped females. Notable quantitative differences between the sexes were relatively higher amounts of 9-acetyloxynonanal, phenylacetic acid, and tetradecanal from males and hexadecanal from females. In the absence of an absolute, qualitative difference between sexes, these relative differences might be im-

portant for sex recognition. Field bioassay demonstrated the attractiveness of 9-acetyloxynonanal for male and female *C. cinctus*. The major compounds of male and female cuticular extracts showed no GC-EAD activity, but ozonolysis of extracts gave dramatically increased amounts of GC-EAD-active material. Hence, double-bond-containing cuticular compounds are suggested as precursors of the aldehydic pheromone components.

Key Words—Sawfly, aggregation pheromone, 9-acetyloxynonanal, phenylacetic acid, gas chromatographic–electroantennographic detection, cuticular extracts, *Cephus cinctus*, Cephidae, Hymenoptera.

INTRODUCTION

The wheat stem sawfly, *Cephus cinctus* Norton (Hymenoptera: Cephidae), has been a major pest of wheat, *Triticum aestivum* L, in the northern Great Plains of the United States and the Canadian prairies since cultivation began (Weiss and Morrill, 1992). In Montana, the insect has been estimated to cause annual losses in excess of $25 million in recent years (Blodgett et al., 1996, 1997), and losses in the entire area impacted by the wheat stem sawfly are estimated to exceed $100 million (US Department of Agriculture, 2000). The biology of the insect is described in Ainslie (1920), and population dynamics are given in Holmes (1982). Briefly, short-lived adults emerge from wheat stubble in the spring and fly to cereals or other grasses, where they oviposit into the interior of growing stems. The larvae feed and develop cryptically within the stem during the summer. When crop maturity is reached and the host plant desiccates, the larvae descend to the base of the plant and girdle the stem near the soil interface, resulting in lodged plants. The mature larva seals the tip of the cut stem with a uniform plug and then descends to near the root where it overwinters as a mature larva within a translucent hibernaculum. Dispause is broken in the spring, and metamorphosis is completed. Adults chew a hole in the plug at the tip of the cut stem and move to the surrounding green vegetation.

The female-produced sex pheromones of sawflies belonging to the family Diprionidae and one species belonging to the family Tenthredinidae are well documented (Anderbrant 1999 and references therein). In addition, studies on several species belonging to the family Pamphiliidae have shown that female-produced sex pheromones are used for mate location (Borden et al., 1978). However, no studies have been published on pheromones in the remaining 11 families of hymenopteran sawflies, including Cephidae. Understanding the chemical ecology of *C. cinctus* could lead to new and environmentally friendly approaches for reducing agricultural damage, especially since insecticides are ineffective against larvae inside the wheat stem and adult emergence is difficult to predict (Morrill et al., 1992).

This paper and the companion paper (Bartelt et al., 2002) describe the identification, electrophysiological, chemical, and behavioral aspects of pheromonal communication in the wheat stem sawfly.

METHODS AND MATERIALS

Insects. Overwintering stage prepupae of *C. cinctus* were collected at several field sites in Montana. After the 1998 harvest, collections were made in September and October in Broadwater and Cascade counties, and again in March and April, 1999, from the same sites. Stubble was removed from these heavily infested fields with a shovel and taken to the laboratory. The uninfested residue was separated from the sawfly-cut stems, and stems containing sawfly larvae were rinsed to remove the soil, spotted dry with a paper towel, and stored in lots of 100 in plastic Ziploc bags. To allow the larvae to complete diapause, bags containing fall-collected larvae were stored at 4°C for at least 100 days, while material collected in late winter and early spring was refrigerated until used. Upon arrival in Peoria, Illinois, sawfly-containing wheat stems were placed individually into glass vials capped with a moist piece of cloth-covered cotton. Adults emerged at 25°C under a 16L:8D photoperiod regime using a fluorescent light source.

Initial Cuticular Extracts. Groups of 25 male and 25 female sawflies were killed by freezing when 1–3 days old and cuticular extracts were obtained by soaking insects for 20 min in 1 ml hexane. Hexane extracts were stored at −20°C.

Volatiles Collections. Volatiles collections were made from individuals or groups of two to five male or female insects. The 1- to 3-day-old adults were placed in 75-ml silanized (dichlorodimethylsilane) (Bartelt and Zilkowski, 1998) Pyrex glass tubes fitted with corks at both ends, into which Super Q porous polymer (80–100 mesh, Alltech, Deerfield, Illinois) traps were inserted. The Super Q traps were prepared from 10-cm × 0.5-cm-ID glass tubing. A piece of stainless steel screen (325 mesh) was sealed into one end by heating. Traps were filled to a depth of 0.5 cm with Super Q and topped with a plug of silanized glass wool. Newly prepared and used traps were conditioned by several rinses of CH_2Cl_2 followed by hexane and dried under a gentle stream of nitrogen. Traps used to collect volatiles from male and female insects were kept separated. Insects had access to water from 2 ml cotton plugged vials, which were placed inside the collection tubes. Volatiles collections from tubes with water vials, but without insects, served as controls. A vacuum was applied to one of the Super Q traps so that volatiles from the tube were drawn into the trap. The second Super Q trap then served as a filter for incoming air. The tubes were kept under fluorescent light in an incubator (16L:8D) at 27°C and 40% relative humidity with an airflow through the tubes adjusted to 30 ml/min. Two- to three-day volatiles collections were started 2–3 hr into the photophase. To extract volatiles from the Super Q traps, each trap was rinsed with 250 μl hexane. Samples were concentrated to approx. 10 μl under a gentle stream of nitrogen and 1 μl was analyzed. Approximately 160 volatiles collections were made.

Solid-phase microextraction (SPME) was used as a second volatiles collection method. Individuals and groups of up to five adults were placed in the above-mentioned silanized Pyrex glass tubes. The upwind end of a glass tube was

covered with nylon mesh and the downwind end was fitted with a cork, into which a glass tube (0.4 cm ID) with a side arm was inserted. A SPME fiber (100 μm polydimethylsiloxane. Supelco) was inserted though a septum placed into the other end of the tube, extending past the side arm junction. Vacuum was applied to the side arm so that air from the outside passed though the tube with the sawflies and then over the SPME fiber. Volatiles collections were made 2–3 hr into the photophase at 25°C for 30 min with airflow of 10 ml/min. Insects could not contact the SPME fiber.

Electrophysiology. Coupled gas chromatographic–electroantennographic (GC-EAG) analyses were made by methods and equipment generally described by Cossé and Bartelt (2000).

Pheromone Identification. Volatiles collections were analyzed by gas chromatography with flame ionization detection (GC-FID), coupled GC-mass spectrometry (GC-MS), and GC-EAD. The GC was a Hewlett Packard 6890 instrument fitted with a 30-m EC-1 capillary column (0.25 mm ID, 0.25 μm film thickness, Alltech). Temperature programs were from 50°C to 275°C at 10°C/min. (GC-FID) or from 50°C to 275°C at 15°C/min. (GC-EAD). Injector temperatures were maintained at 250°C, and the GC-EAD effluent interface from the post-colum splitter was kept at 275°C. Injectors were fitted with SPME injector liners (Supelco, Bellefonte, Pennsylvania) for SPME analysis. Mass spectrometry was performed by using a Hewlett Packard 5973 instrument (electron impact, 70 eV). Chemical ionization spectra (methane) were obtained on a Finnigan 4535 quadrupole mass spectrometer with GC inlet. Most EAD-active compounds were identified by searches of the mass spectral library (Wiley, 1995). Identifications were confirmed with authentic standards that had the same GC retention times and mass spectra.

Ozonolysis of cuticular extracts was done as described by Beroza and Bierl (1967), and the products were compared with the compounds in the volatiles collections. Samples were ozonized in 0.5 ml dichloromethane for about 2 min at −70°C. Ozone was formed by electrical discharge through a stream of oxygen. The gas was bubbled gently through the solution until a faint bluish color developed, indicative of excess ozone. Ozonides were reduced with excess triphenylphosphine. Samples were analyzed by GC-MS and GC-EAD.

Chemicals. Nonanal and (*Z*)-9-dodecen-1-ol acetate were purchased from Bedoukian (Danbury, Connecticut), and the remaining commercially available chemicals used in this study were obtained from Aldrich Chemical Co. (Milwaukee, Wisconsin).

Synthesis of 9-Acetyloxynonanal. A solution of (*Z*)-9-dodecen-1-ol acetate (100 mg, 0.44 mmol) in 5 ml hexane was cooled in a dry ice–ethanol bath. Ozone was bubbled through the solution until a faint bluish color developed, indicative of excess ozone. The solution was purged with N_2 until the blue color disappeared. The reaction mixture was reduced by adding dimethylsulfide (0.66 mmol) and allowed to warm to room temperature. After addition of 0.5 ml H_2O and separation

of layers, the organic phase was dried (Na_2SO_4) and evaporated (N_2) to remove propanal and excess dimethylsulfide, followed by dilution by hexane. Part of this sample was used for subsequent field studies.

Field Trial with 9-Acetyloxynonanal. Synthetic 9-acetyloxynonanal was applied in six selected doses (0.3, 1, 3, 10, 100, or 1000 μg) to rubber septa in Peoria, Illinois, and sent to Montana, where they were stored at -80°C until use. Septa without added compound were the seventh (control) treatment. Beginning on June 23, 1999, a 15-day field test was conducted by one of us (D.K.W.) at a site 17 km northwest of Three Forks, Montana, near the county line between Jefferson and Broadwater counties (46°2.19′N, 111°38.39′W). The test was conducted as the sawfly population was beginning to decline. The field site consisted of a fence line that separated a standing crop of wheat (to the west) from a fallow field (to the east) that had been moderately infested with wheat stem sawflies during the 1998 growing season. This field was the source of the sawflies that would infest the growing crop. Prevailing winds were westerly; thus, movement into the new crop would generally be upwind. Twenty-one traps were spaced at 30-m intervals along this fence line. Each trap consisted of a 10-cm $\times$ 10-cm square of #20 mesh metal hardware cloth, coated with Tangle-Trap on both sides. The trap was stapled to a 60-cm wooden stake driven into the ground so that the bottom of the sticky surface was approximately 5 cm above the soil substrate. A rubber septum trap bait was penetrated with a paper clip and attached to the center of the upwind side of the sticky surface. Daily insect counts were taken and the trapped insects were removed. Lures were replaced and the traps were re-randomized every three days. Each of the seven dose treatments was replicated three times in the random trap array. The trap catch data were analyzed by Poisson regression, a method that is appropriate for small counts, using the Statistix analysis package (Analytical Software, 1998). Details of the models are given in the Results section.

RESULTS

Cuticular Extracts. GC-EAD analyses of male and female cuticular extracts were obtained with male and female antennae. As shown in Figure 1, GC-EAD analyses of female cuticular extracts and the simultaneously recorded EAD of male antennae showed no activity with any of the higher molecular weight compounds, such as the major cuticular hydrocarbons (Bartelt et al., 2002). However, compounds of lower molecular weight did stimulate male antennae. Similar results were obtained with female antennae and with male cuticular extracts and male and female antennae. Further research was focused on the analysis of volatiles collections due to the EAD activity of compounds of lower molecular weight.

Volatiles Collections from Individual Insects. Initial GC-EAD profiles of Super Q-collected volatiles from individual males and females revealed variable

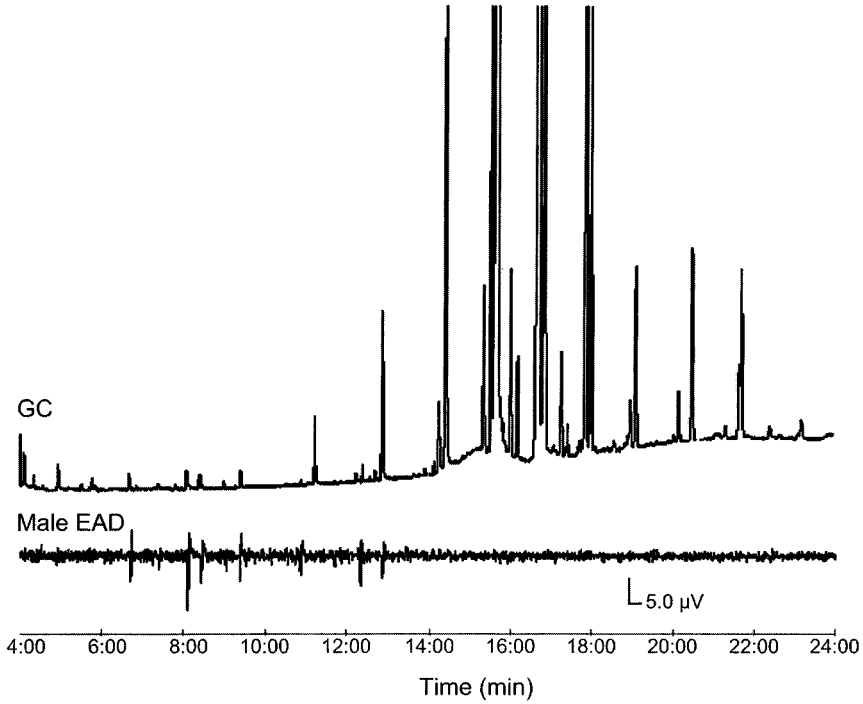

FIG. 1. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of a typical male antenna to a cuticular hexane extract of female *C. cinctus*.

and relatively small amounts of insect-specific material during two- to three-day collection periods. In male-collected volatiles, the major compounds were nonanal and (*Z*)-9-tricosene (Bartelt et al., 2002). The same compounds, at lower amounts, were present in female-collected volatiles. With males, these compounds were present at 43 ng ($\pm$14 SD, $N = 8$) and 96 ng ($\pm$76 SD, $N = 8$) per sawfly per day, respectively. From females, collected amounts of nonanal were 26 ng ($\pm$13 SD, $N = 5$) per sawfly per day. Amounts of (*Z*)-9-tricosene from females were smaller (e.g., Figure 2), because females have less of this hydrocarbon than males (Bartelt et al., 2002). These initial male and female collections consistently elicited a notable depolarization on both male and female antennae (Figure 2). In addition to the depolarization elicited by the compound eluting at 10.42 min, several smaller depolarizations were noted. However, these depolarizations were less consistent, which was probably due to the variable and relatively small amounts of insect-specific material.

Identification of 9-Acetyloxynonanal. The mass spectrum of the compound giving the relatively strong depolarization (10.42 min) is shown in Figure 3. No

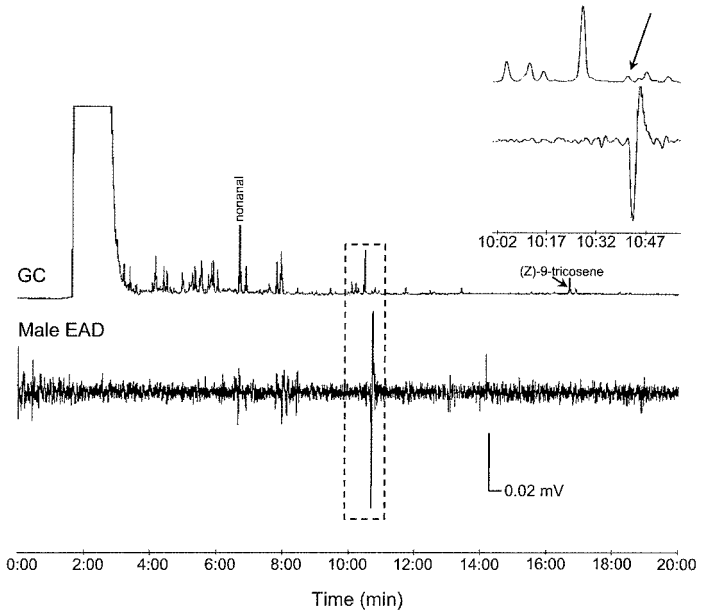

FIG. 2. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of a typical male antenna to a volatiles collection from an individual female *C. cinctus*. Arrow in cutout denotes the location of 9-acetyloxynonanal.

molecular ion was visible, and the mass spectral library did not provide a probable identification. However, the fragment at *m*/*z* 61 was informative and suggested that the compound was a primary acetate. The largest significant ion in the chemical ionization (CI) mass spectrum had *m*/*z* 201, suggesting it was the protonated molecular ion; thus, the molecular weight was 200. The CI spectrum also had two major fragments. The first (*m*/*z* 141) represented a loss of 60 from the molecular ion and corresponded to a neutral loss of acetic acid, as would be anticipated for an acetate. The second fragment (*m*/*z* 123) represented an additional loss of 18, corresponding to a loss of water. Together, these features suggested the presence of three (or more) oxygen atoms for a possible molecular formula of $C_{11}H_{20}O_3$, with two sites of unsaturation. If two oxygens and one site of unsaturation were accounted for by an acetate function, then one additional oxygen and one double-bond equivalent would remain to be explained. Example spectra from the mass spectral library gave some guidance: in primary acetates with another functional group, the *m*/*z* 61 fragment peak is relatively large, as in the sawfly compound, only when the two functional groups are distant from each other in the structure. Thus, a nine-carbon chain with an acetate group on one end and an epoxy, aldehyde, or ketone group near the other end was suggested.

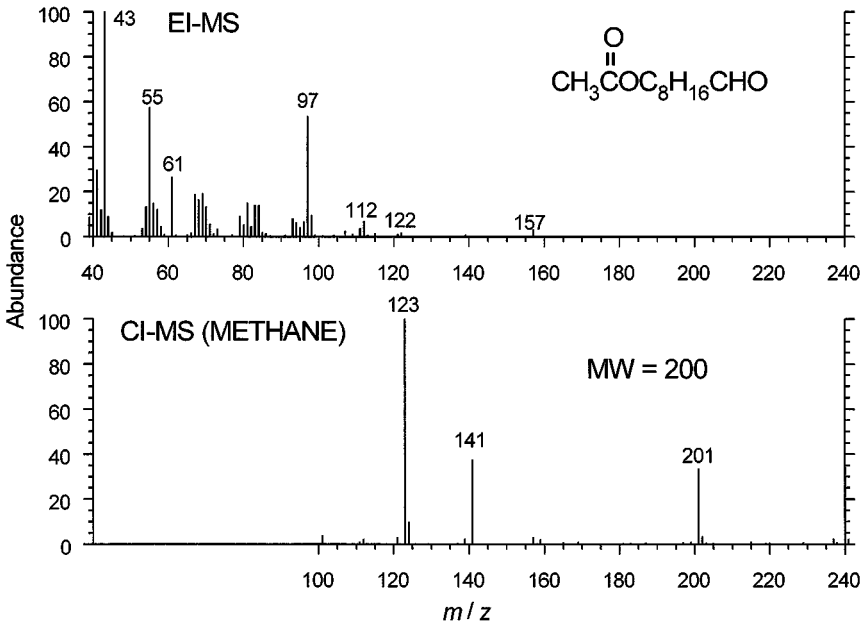

FIG. 3. Electron impact and chemical ionization mass spectra for 9-acetyloxynonanal.

Amounts of this compound collected from males and females were variable and were in the range of 1–5 ng per sawfly per day, with lower amounts produced by females overall. The amounts of material on hand were so small that other spectra or microchemical tests were not deemed feasible. The approach for continuing was to synthesize model compounds for comparison of mass spectral details and GC retention times. 9-Acetyloxynonanal was the first compound prepared because it was accessible in a single step (ozonolysis) from (*Z*)-9-dodecen-1-ol acetate, which was on hand as an example moth pheromone. Fortuitously, the synthetic and natural compounds matched perfectly, by GC retention time and mass spectrum. A larger amount of this compound was synthesized for subsequent laboratory and field use.

Volatiles Collections from Groups of Insects. Single males appeared odorless to the human nose and stayed relatively inactive when placed in collection tubes. However, placing several males together in a collection tube almost instantly triggered wing fanning of all the males, which was accompanied by the release of a relatively strong, distinctive odor. This odor was absent with single females and barely detectable with grouped females. Due to the detectable odor of grouped males, additional GC-EAD analyses were performed on volatiles from groups of insects, pooling collections to increase amounts of compound to be analyzed.

TABLE 1. WHEAT STEM SAWFLY (*Cephus cinctus*) VOLATILES IDENTIFIED FROM GROUPED SAWFLIES WITH ELECTROPHYSIOLOGICAL ACTIVITY ON MALE AND FEMALE ANTENNAE AND THEIR RELATIVE ABUNDANCE

Peak	Compound[a]	Relative abundance (mean ± SD)[b]	
		Per male/day	Per female/day
1	Nonanal[c]	100 ± 0	100 ± 0
2	Octanoic acid	29 ± 10	27 ± 6
3	Decanal	66 ± 9	63 ± 26
4	Phenylacetic acid	53 ± 43	3 ± 3
5	Nonanoic acid	53 ± 18	47 ± 12
6	Decanoic acid	35 ± 12	40 ± 31
7	Dodecanal	12 ± 1	10 ± 2
8	9-Acetyloxynonanal	10 ± 6	3 ± 2
9	Tridecanal	9 ± 2	7 ± 3
10	Tetradecanal	35 ± 20	14 ± 8
11	Pentadecanal	5 ± 1	9 ± 4
12	Hexadecanal	19 ± 13	32 ± 8
13	13-Acetyloxytridecanal	trace	trace

[a] Identification is based on comparison of mass spectra and retention times of the natural materials with those of authentic synthetic standards.
[b] Two- to three-day volatiles collections of groups of 5 males or females ($N = 5$).
[c] Male: 74 ng (±3 SD), Female: 37 ng (±7 SD).

GC analyses of volatiles from groups of females and the simultaneously recorded EAD activity of male and female antennae revealed 12 compounds (Table 1), that consistently stimulated the antennae (Figure 4). The same 12 compounds were present in volatiles collected from groups of males, and subsequent GC-EAD analyses confirmed their activity on male and female antennae (Figure 5).

The GC profiles differed notably between the sexes. Groups of males produced relatively more of the EAD-active compounds than groups of females on a per sawfly basis. The distinct odor released by grouped males was identified as phenylacetic acid, which was clearly more abundant with volatiles from males than from females. Ratios of aldehydes also differed. Male volatiles collections showed a relatively higher abundance of tetradecanal, whereas female collections showed higher amounts of hexadecanal. In addition. 9-acetyloxynonal was approximately three times more abundant in male collections than in female collections.

SPME-Collected Volatiles. The profile of SPME-collected volatiles from the first 30 min after placing five males together is shown in Figure 6. In males, the most abundant compounds were nonanal and tetradecanal. In females (not shown), hexadecanal replaced tetradecanal as the abundant larger aldehyde. GC-EAD profiles

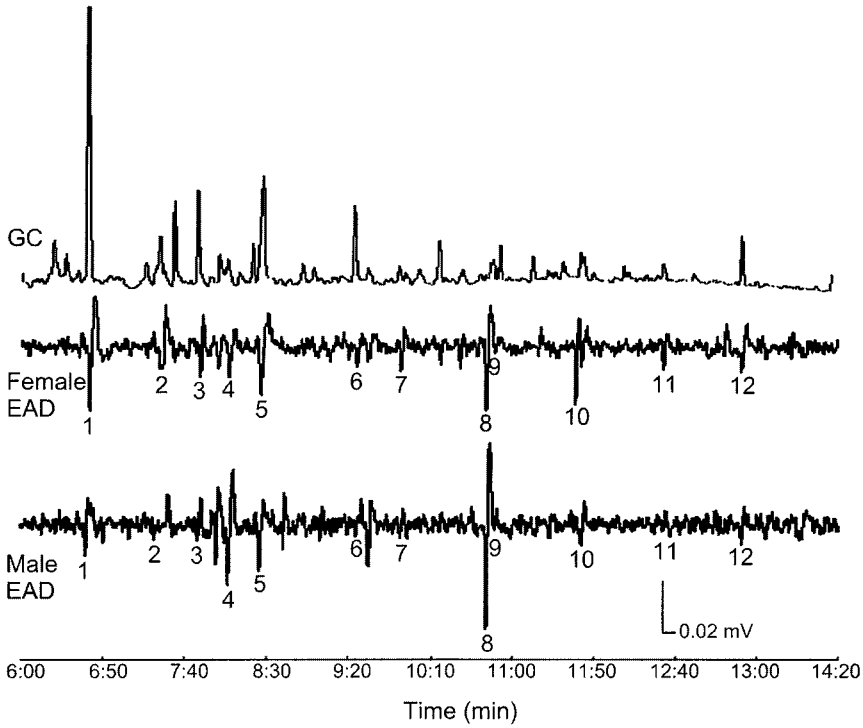

FIG. 4. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of typical male and female antenna to volatiles collection on Super Q from a group of five female *C. cinctus*.

of SPME-collected volatiles confirmed the EAD-activity of the 12 compounds collected with Super Q.

Ozonolysis of Cuticular Extracts. The extract shown in Figure 1 showed relatively small amounts of EAD-active materials. However, this same extract showed a dramatic increase in EAD-active compounds after ozonolysis. The presence of these EAD-active compounds was confirmed by GC-MS and GC-EAD analysis (Figure 7). The most abundant compound after ozonolysis was nonanoic acid. 13-Acetyloxytridecanal, which was present in trace amounts in some of the volatiles collections and was without detectable antennal activity, consistently stimulated male and female antennae in ozonized extracts (peak 13, Figure 7).

Field Trial with 9-Acetyloxynonanal. The trap catch totals and means for the various doses of 9-acetyloxynonanal are shown in Table 2. The sex ratio was nearly 1:1, with 179 females and 164 males being captured. No pattern could be discerned between sex ratio and trap treatment; thus, the data were pooled over sex. The

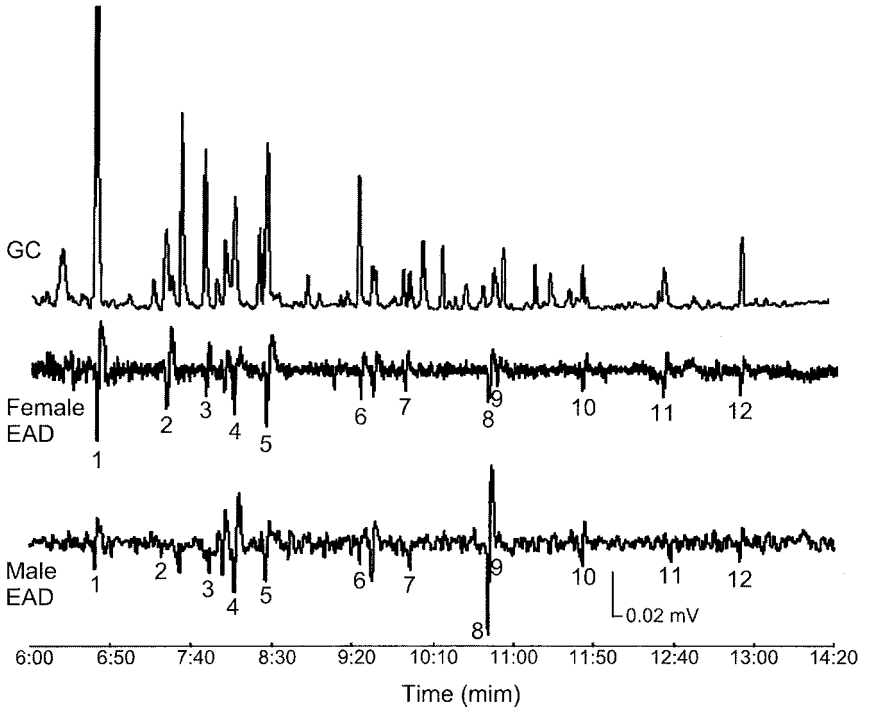

FIG. 5. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of typical male and female antenna to volatiles collection on Super Q from a group of five male *C. cinctus*.

initial Poisson regression model applied to the trap catch data (315 observations) included terms for differences among days of the experiment (14 *df*), differences among treatments (6 *df*), and the constant term (1 *df*). The resulting likelihood ratio statistic (G^2) for the model was 409.6 (294 *df*, $P < 0.0001$, compared to the χ^2 distribution). Thus the overall residual variance was larger than expected for a Poisson process. Examination of residuals revealed that two of the catches for the 1000-μg treatment were inconsistently large: 59 sawflies in one trap on day 2 and 13 sawflies in one trap on day 5. When these two data points were removed as outliers, the model fitted adequately ($G^2 = 303.9$, 292 *df*, $P = 0.30$), and conditional tests (Fienberg, 1977) for differences among treatments or days were then justified. The overall test for differences among treatments was highly significant ($G^2 = 147.2$, 6 *df*, $P < 0.00001$). Differences among days were also highly significant ($G^2 = 146.4$, 14 *df*, $P < 0.00001$). Averaged over all treatments and replications, mean daily trap catches for the 15 days of the study ranged from

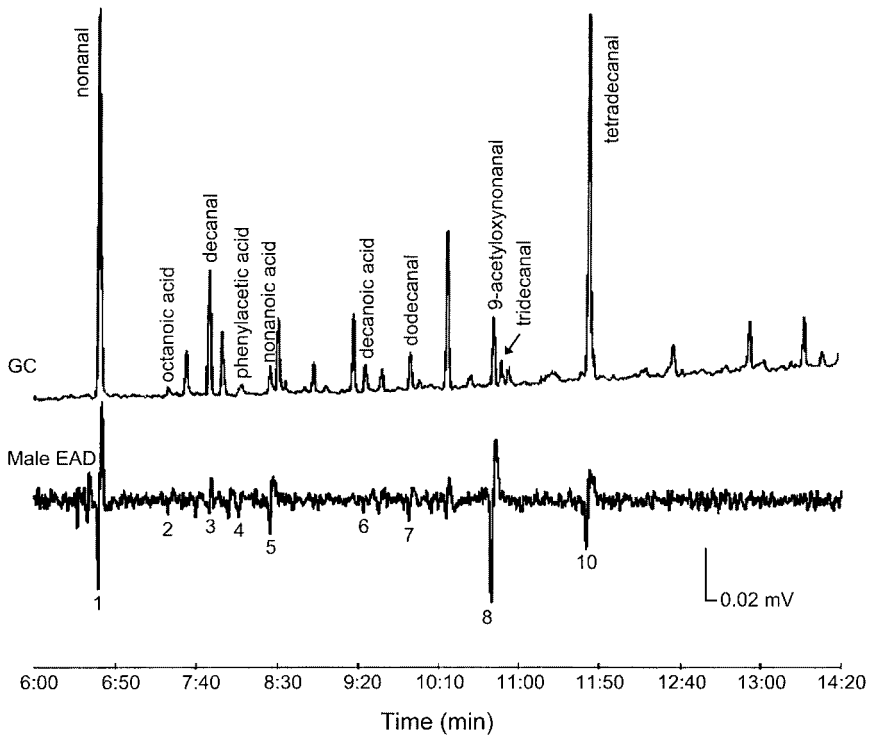

FIG. 6. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of a typical male antenna to volatiles collected with solid phase microextraction (SPME) of the first 30 min when five male *C. cinctus* were grouped together.

0.11 to 1.23; it was necessary to allow for differences among days in the model. Daily sawfly activity is greatly influenced by weather conditions (temperature, wind, and cloud cover; D. K. Weaver, personal observation).

Differences among treatments were further explored. A linear relationship was fitted for log catch versus log dose; a separate term (1 *df*) was simultaneously fitted for the control because the logarithm for dose = 0 would be meaningless. The linear trend was highly significant ($G^2 = 107.4$, 1 *df*, $P \ll 0.00001$), and the value of the slope corresponded to a 1.70-fold increase in trap catch for each 10-fold increase in septum dose. Deviations from the linear trend were also significant ($G^2 = 11.45$, 4 *df*, $P = 0.022$), but these were relatively minor and did not suggest that any simple curve would describe the data better than the straight line. A series of 1-*df* comparisons were made between individual doses and the control to define the response threshold. As shown in Table 2, all doses

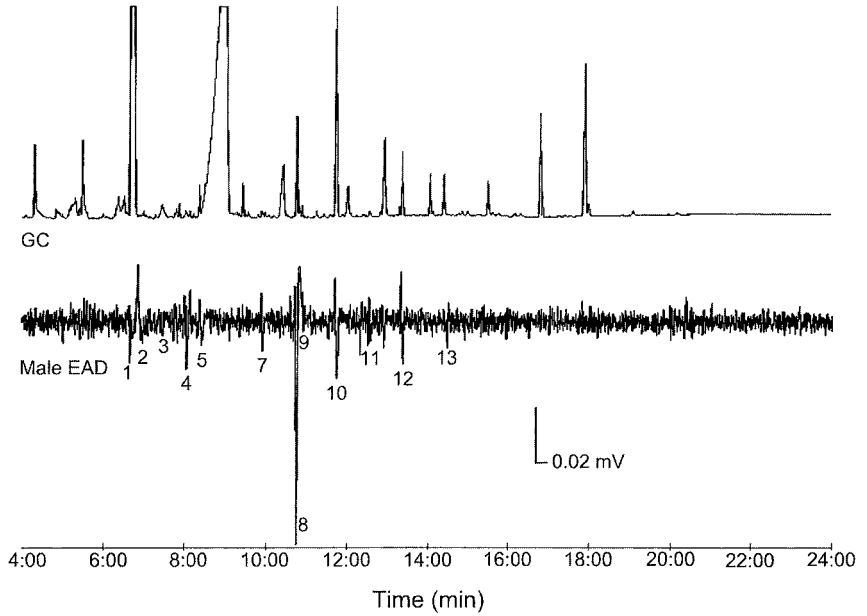

FIG. 7. Simultaneously recorded gas chromatogram (GC) and electroantennogram responses (EAD) of a typical male antenna to a cuticular hexane extract of female *C. cinctus* after ozonolysis.

of 9-acetyloxynonanal ≥ 3 μg/septum were significantly more attractive than the control. This data set demonstrated a consistent, although fairly subtle, field activity of 9-acetyloxynonanal. Although the highest dose, 1000 μg, was clearly the most active, activity became detectable at 3 μg.

TABLE 2. SUMMARY OF FIELD TRAPPING EXPERIMENT WITH 9-ACETYLOXYNONANAL

Septum dose (μg)	Total catch (N)	Mean catch	G^2 for difference from control (P value, 1 df)
0 (control)	12 (45)	0.27	
0.3	20 (45)	0.44	2.02 (0.16)
1	15 (45)	0.33	0.33 (0.57)
3	33 (45)	0.73	10.19 (0.0014)
10	39 (45)	0.87	15.05 (0.0001)
100	43 (45)	0.95	18.54 (0.00002)
1000	106 (43)[a]	2.47	94.18 ($\ll$0.00001)

[a] Two outlier data points were removed, which had values of 59 and 13 (see text).

The conclusion from the analysis was that the effect of 9-acetyloxynonanal was real, even after two of the highest trap catches had been removed as outliers. An alternative analysis that would legitimately make use of all trap data (but that would probably be more complex than Poisson regression) would be expected to demonstrate the effect of the compound even more strongly.

DISCUSSION

Both males and females release the same EAD-active compounds. Although there was no evidence for any sex-specific compounds, overall release of EAD-active compounds was higher with grouped males than with grouped females. This was especially noted for phenylacetic acid, which was instantly detectable by the human nose when male sawflies were put together. In addition, male and female volatiles collections differed in the ratios of 9-acetyloxynonanal, tetradecanal, and hexadecanal. In the absence of qualitative differences, these different male and female ratios might be important clues for sex recognition.

The EAD-active 9-acetyloxynonanal is part of the pheromone of *C. cintus*. This compound alone attracted both male and female sawflies in the field bioassay. However, as is evident from our results, the complete pheromonal system of *C. cintus* appears to be more complicated. Our volatiles collections showed that males and females release 13 EAD-active compounds and, with the exception of phenylacetic acid, all could be derived through oxidation of cuticular compounds (Bartelt et al., 2002). Higher molecular weight compounds in male and female cuticular extracts showed no GC-EAD activity and the relatively small amounts of compounds of lower molecular weight showed relatively weak EAD responses. However, extracts after ozonolysis showed dramatically increased amounts of aldehydic GC-EAD-active compounds and absence of the unsaturated, higher-molecular-weight materials, giving credibility to the notion of an oxidative origin of the GC-EAD active compounds. In particular, unsaturated cuticular compounds could function as the precursors for the EAD-active compounds by oxidative cleavage of their double bonds (Bartelt et al., 2002). One might expect the oxidation of cuticular monoolefins to be a relatively slow process. However, EAD-active materials could be detected within minutes rather than hours using SPME, suggesting that an oxidative system might be fast enough to be significant to the sawflies' sexual communications under field conditions.

A multitude of factors can trigger and influence the abiotic oxidation of unsaturated cuticular compounds, making this a complicated process to study (Bartelt et al., 2002). For example, the action of ultraviolet light and the effect of temperature, as well as premating behaviors such as wing fanning and rubbing of the abdomen (D. K. Weaver, personal observations) could all influence this oxidation and will need further attention. Preliminary experiments showed that

abiotic oxidation of alkenediol diacetates, present on the cuticle of the insects, could yield the biologically active acetyloxyaldehydes (Bartelt et al., 2002). However, enzymatic involvement in *C. cinctus* pheromone system has not been ruled out, especially with regard to the occurrence of phenylacetic acid.

All the pheromones of sawfly species have thus far been reported as being female-produced. For example, sex attraction in the genera *Diprion* and *Neodiprion* depends to a large extent on esters derived from various optical isomers of female-produced 3,7-dimethyl-2-pentadecanol and from homologous alcohols with carbon chains of different length (Anderbant, 1999, and references therein). A different pheromone system has been reported for the tenthredinid, *Pikonema alaskensis* (Rohwer), still female-produced, but derived from the oxidation of sex-specific straight-chain hydrocarbon dienes found on the cuticle of the insects (Bartelt and Jones, 1983; Bartelt et. al., 1983). Although restricted to one sex, the oxidative component in the pheromone system of *P. alaskensis* resembles that of *C. cinctus*.

Field observations have shown that males form in-flight aggregations and that female sawflies near these active aggregations are rapidly recognized by male *C. cinctus*, and synthetic 9-acetyloxynonanal released from rubber septa can induce this aggregation (D. K. Weaver, unpublished). Furthermore, from the electrophysiological data, it is likely that more dramatic responses would result if additional antennally active compounds were included in the trap baits. Finally, trap design was a critical issue in this study. A number of trap types were tried (D. K. Weaver, unpublished) but were unsuccessful either because the insects would not enter a trap with interior shadows or because the trapping surface was so large and accessible that frequent accidental captures overwhelmed the treatment effects. While the trap design employed here was suitable for the present study, future improvements would be desirable.

9-Acetyloxynonanal has not been reported as an insect attractant before, but this and other acetyloxyaldehydes were analytically useful as cleavage products of epoxides in a method to locate the double-bond position in long-chain acetates (Bierl-Leonhardt et al., 1980). The mass spectrum of 9-acetyloxynonanal reported by Bierl-Leonhardt et al. (1980) did not agree with ours. However, this discrepancy might be due to a typographical error in the above-mentioned paper, as the published spectrum was also inconsistent with the spectra of homologous aldehyde acetates in that report.

The behavioral role of phenylacetic acid has yet to be determined. Its presence was noted in volatiles collections from both sexes, and its odor was instantly detected by the human nose when males were grouped together. Phenylacetic acid has not been reported as an insect attractant. Laboratory bioassays have shown that female *C. cinctus* were attracted to volatiles emitted from groups of males, but not to volatiles from single males (D. K. Weaver, unpublished). Whether this attraction to groups of males is due to the release of phenylacetic acid or due to a threshold effect is not clear and will need further study.

Individually, none of the identified EAD-active compounds would account for recognition of females by males. Therefore, future research will focus on more behaviorally driven assays of collections in order to collect a possible distinct female-specific chemical signal. In addition, emphasis will be given to elucidate the behavioral significance of additional EAD-active compounds and the importance of different ratios of EAD-active volatiles between the sexes.

(Received January 16, 2001; accepted September 22, 2001)

Abstract—By means of electroantennographic detection and gas chromatography-mass spectrometry, the sex pheromone of *Argyrotaenia sphaleropa* was identified as a mixture of (*Z*)-11-tetradecenal, (*Z*)-11,13-tetradecadienal, (*Z*)-11-tetradecenyl acetate, and (*Z*)-11,13-tetradecadienyl acetate in the ratio of 1:4:10:40. Best trap catches were obtained with mixtures of (*Z*)-11-tetradecenal and (*Z*)-11,13-tetradecadienal in the ratio of 1:4 to 1:9.

Key Words—Pheromones, *Argyrotaenia sphaleropa*, (Z)-11-tetradecenal, (Z)-11,13-tetradecadienal.

INTRODUCTION

The native leafroller *Argyrotaenia sphaleropa* (Meyrick) is an important pest of deciduous fruit crops and grapes in Uruguay. The species occurs in the south of Brazil, Argentina, Bolivia, and Peru. (Bentancourt and Scatoni, 1995). Three to four insecticide sprays per season are necessary to control this pest, but in the case of conventional orchards, the organophosphate insecticide sprays (5-8 per season) aimed at controlling the codling moth (*Cydia pomonella*) also control this leafroller.

*To whom correspondence should be addressed.

0098-0331/02/0200-0425/0 © 2002 Plenum Publishing Corporation

However, in orchards where mating disruption of the codling moth is part of the integrated pest management system, this leafroller has become a severe pest. Under these conditions, monitoring is the key tool for rational control. Malt-baited traps have been used, but operating these traps under practical conditions is difficult, time consuming, and not always reliable. Therefore, it was decided to identify the pheromone of this leafroller and to develop a monitoring system based on pheromones. A first attempt to identify the pheromone of *A. sphaleropa* was undertaken by the Japanese International Cooperation Agency (JICA) (Nunez, unpublished data). The work of this group was seriously hampered by the fact that no living insects were allowed to be imported into Japan. Biomonitoring of purification procedures [electroantennography (EAG) gas chromatography–electroantennographic detection (GC-EAD)] and/or wind-tunnel experiments, therefore, could not be performed. Based on GC-MS only, they tentatively identified three compounds: tetradecyl acetate (14:Ac), (*Z*)-11-tetradecenyl acetate (*Z*11–14:Ac), and (*Z*,*E*)-9-11-tetradecadienyl acetate (*Z*9,*E*11–14:Ac). However, when field-trapping experiments were carried out with the above-mentioned compounds in various ratios and quantities, no male moths were trapped. Hence, it was concluded that the identification either was incomplete or that the proposed structure(s) for one (or more) of the compounds identified was (were) incorrect.

Within the framework of the European Commission (Cooperation with nonmember countries, Project CI*-CT94-0006), a joint project TNO-INIA was undertaken to characterize the sex pheromone of *A. sphaleropa*.

METHODS AND MATERIALS

Rearing of Insects. A. sphaleropa was reared on a synthetic diet (Shorey and Hale, 1965) under reversed long-day conditions. (14L:10D) at 24°C and 60% relative humidity. Two cultures both at INIA and at TNO were maintained simultaneously. Adults were maintained on a mixture of water and honey. To avoid degeneration of the culture, fresh material was collected regularly in the field and introduced into the laboratory culture.

Pheromone Extraction. Field experiments with female-baited traps had indicated that most *A. sphaleropa* moths were trapped shortly after midnight and, therefore, this period was considered to be the period of maximum pheromone production. Pheromone glands were clipped during or shortly after this period. Females 2–3 days old were anesthesized with carbon dioxide, and by gently pressing the abdomen, the pheromone gland was extruded and could be clipped without any appendages. The dissected glands were collected in hexane (10–20 μl/gland) and shaken regularly for 10–15 min. The hexane extract was kept at -20°C.

Electroantennography (EAG). Based on the findings of the Japanese workers, *A. sphaleropa* was subjected to EAG, using a series of 21 monounsaturated and

8 double unsaturated tetradecenyl acetates (10-μg samples on filter paper pads); samples were freshly prepared; the purity of the compounds was >97% by GC analysis. The experiment was repeated with 1-μg samples per filter paper pad.

Gas Chromatography–Electroantennographic Detection (GC-EAD). A gas chromatograph (GC) was fitted with capillary columns at the end of which an effluent splitter (1:15) was installed. To achieve proper elution of the compounds, 30 ml N_2 /min was introduced between the column and the splitter (makeup gas). Five percent of the compounds eluting from the column were fed to the FID, whereas 95% of the compounds were transferred by means of capillary tubing through the heated outlet of the GC into a mixing chamber. The outlet of the mixing chamber (glass tubing; 1 cm diam.) was directed towards the antennae. By blowing air into the mixing chamber, the compounds eluting from the column were blown across the antennae (Venturi effect). The linear air velocity at the antennae was 0.6 m/sec. The signals derived from the antennae and from the flame ionization detector (FID) were simultaneously fed to a computer linked to a display and a printer. The traces on the display of the two signals enabled us to correlate directly the EAD signals with the FID signals (Syntech, Hilversum, The Netherlands). Amounts of *ca*. 4 female equivalents (FE) were injected on to a DB-23 column (25 m $\times$ 0.53 mm ID; He carrier gas at 6 ml/min; makeup gas 30 ml/min; split ratio 1:15; oven temperature 170°C; injection port 200°C; detector 225°C; outlet 200°C). The same experiments were repeated on a CPSil-5 column (25m $\times$ 0.53 mm ID; temperature programmed from 120°C to 220°C at 10°C/min; 5 min isotherm at 220°C) and on a CPWax-52 column (temperature programmed for 7 min at 165°C and increased to 200°C at 10°C/min; 5 min isotherm at 200°C); the other conditions were as mentioned above.

Gas Chromatography–Mass Spectrometry (GC-MS). A VG-250S mass spectrometer fitted with either a CPWax-52 or CPSil-5 column was used (50 m $\times$ 0.32 mm ID; $df = 1$ μm). MS spectra were run on a CPSil-5 column (temperature programmed from 80°C to 250°C at a rate of 15°C/min or on a CPWax-52 column (190°C). Both EI and CI mass spectra were recorded. For CI spectra, methane was used and the ion source set at 200°C. In a later stage, the ion source temperature was set at 100°C.

Field Evaluations. Wing-type traps with replaceable sticky bottoms were loaded with different amounts and different ratios of the pheromone blends on polyethylene or rubber dispensers. Each treatment had two to five replicates, and traps were randomly installed. The distance between traps was at least 25 m to avoid interferences. Traps were rotated every week, and the trapped insects were counted. Virgin female traps were used as a control and were baited with two virgin females. These females were replaced twice a week.

For statistical analysis, captures were grouped per period of evaluation, transformed to square root, and analyzed by ANOVA followed by Duncan test ($\alpha = 0.05$).

RESULTS

The EAG experiments with the series of mono- and double-unsaturated tetradecenyl acetates indicated that (*Z*)-11-tetradecenyl acetate (*Z*11–14:Ac) evoked the most intensive EAG amplitude. EAG amplitudes evoked by the other two compounds, tentatively identified by the Japanese group (Nunez, unpublished data) as tetradecanyl acetate (14:Ac) and (*Z*,*E*)-9,11-tetradecadienyl acetate (*Z*9,*E*11–14:Ac) were far less intensive (10 μg on filter paper pads). When 1-μg samples were tested, *Z*11–14:Ac still evoked the highest EAG amplitude, whereas at this concentration, 14:Ac and *Z*9,*E*11–14:Ac barely gave EAG responses. This suggested that *Z*11–14:Ac might be part of the pheromone, whereas the findings with regard to 14:Ac and *Z*9,*E*11–14:Ac suggest that these compounds are not part of the pheromone complex.

Injection of 4 (FE) of *A. sphaleropa* on the DB-23 column gave four reproducible AD responses with retention times (R_ts) of 2.05, 2.38, 2.53, and 3.40 min, respectively. The EAD active fraction eluting at 2.05 min from the DB-23 column was collected in a chilled capillary and reinjected on a CPWax-52 column (Burson and Kenner, 1969). On the latter column, its R_t was 5.14 min. Under the same conditions, *E*11–14:Ald and *Z*11–14:Ald eluted at 5.03 and 5.16 min, respectively. Comparison of the MS of the natural compound with the MS of synthetic *Z*11–14:Ald, recorded on a CPWax-52 column, confirmed the natural compound to be a monounsaturated 14:Ald ($M = 220$). Based on these data, it was concluded that this compound was *Z*11–14:Ald.

The R_t of the EAD response at 2.38 min on the DB-23 column corresponded with the R_t of *Z*11–14:Ac. Both its EI and CI mass spectra (CPSil-5 column) confirmed the compound to be a monounsaturated 14:Ac ($M = 254$). Both mass spectra of the natural compound were in full agreement with the mass spectra of synthetic *Z*11–14:Ac.

The compound eluting from the DB-23 at 2.53 min was collected in a chilled capillary and re injected on a CPSil-5 column (Burson and Kenner, 1969). On this column, its R_t was 2.23 min. The EI spectrum (on CPSil-5) showed a strong fragment at m/z 54. This fragment is typical for conjugated diene systems with a terminal double bond (Ando et al., 1985, 1988). Its CI mass spectrum showed the molecular weight to be 208. Combining these data leads to the conclusion that this compound might be an 11,13–14:Ald. The EI spectrum of synthetic *Z*11,13–14:Ald (kindly provided by Dr. T. Ando, Tokyo University of Agriculture and Technology, Tokyo, Japan and Dr. A. Cork, NRI, Chatham, UK.) gave a 100% match with the EI spectrum of the natural compound. As the amounts of some of the compounds in the natural extract were extremely low, determination of the configuration of 11,13–14:Ald based on R_t was impossible. We, therefore, used the GC-EAD technique. Injection of a very low dose of *E*- and *Z*11,13–14:Ald on CPSil-5 and DB-23 indicated that the EAD response to the *Z* isomer was

consistently much higher than to the *E* isomer. Based on these data, it was concluded that the 11,13–14:Ald had the *Z* configuration. The compound eluting from the DB-23 column at 3.40 min was collected in a chilled capillary and reinjected on a CPSil-5 column (Burson and Kenner, 1969). On the latter column, its R_t was 4.15 min. Its EI and CI spectra (on CPSil-5) suggested this compound to be a double unsaturated 14:Ac [$M = 252$; M-60 (acetate) $=192$]. A major fragment, m/z 54 (see also *Z*11,13–14:Ald), indicated that the compound might be a conjugated diene system with a terminal double bond and could be either *Z*- or *E*11,13–14:Ac. Comparison of the EI spectrum of synthetic *Z*11,13–14:Ac (kindly provided by Dr. J. Klun, USDA, Beltsville, Maryland) with the spectrum of the natural compound confirmed this hypothesis.

Determination of the configuration was performed by GC-EAD. The same procedure was followed as was used for the determination of the configuration of 11,13–14:Ald. However, the responses to *Z*11,13–14:Ac and *E*11,13–14:Ac were low. Based on biosynthetic considerations, it was assumed that the 11,13–14:Ac had the same configuration as the 11,13–14:Ald, i.e., the *Z* configuration. This leads to the same conclusion that the pheromone of *A. sphaleropa* consists of a mixture of *Z*11–14:Ald, *Z*11,13–14:Ald, *Z*11–14:Ac, and *Z*11,13–14:Ac (ratio of 1:4:10:40). GC-EAD of a synthetic mixture as mentioned above on both a CPSil-5 and a DB-23 column gave a complete match with the natural extract.

Field Evaluation of Different Pheromone Blends. The results of a first field experiment are summarized in Table 1. Dispensers loaded with 1 mg of a blend of *Z*11–14:Ald and *Z*11,13–14:Ald in a ratio of 1:4 show the highest attraction, comparable to traps baited with two females. Addition of *Z*11–14:Ac and of *Z*11,13–14:Ac to this blend seems to inhibit attraction. This might be due to the fact that *Z*11–14:Ac inhibits attraction or due to the lower concentration

TABLE 1. *Argyrotaenia sphaleropa* MOTHS CAPTURED PER TRAP[a]

Pheromone blend tested				Dose (mg)	Average catch/ trap
*Z*11–14:Ald	*Z*11,13–14:Ald	*Z*11,13–14:Ac	*Z*11–14:Ac		
1	4	20	10	2	10.6d
1	4	20	10	1	6.2d
1	4	20	10	0.5	2.6d
1	4			1	115.0ab
	1		3	1	22.6cd
1	4		10	1	49.0bc
Virgin female traps (2 per trap)					125.0a

[a] Average number caught between January 20 and February 15, 1996. Traps loaded with different pheromone blends in polyethylene dispensers, three replicates. Means followed by the same letter are not significantly different ($P > 0.05$, Duncan's test).

of the diene when *Z*11–14:Ac is added: 1 mg of the blend of *Z*11–14:Ald and *Z*11,13–14:Ald (ratio 1:4) contains 0.8 mg of the diene, whereas 1 mg of the blend *Z*11–14:Ald, *Z*11,13–14:Ald, and *Z*11–14:Ac (1:4:10) contains 0.27 mg of the diene. To determine more precisely the role and the most attractive ratio of the two aldehydes, a new series of blends was tested, using polyethylene and rubber dispensers (Table 2). The results in Table 2 show that *Z*11,13–14:Ald is attractive alone. However, its attractiveness is increased by adding *Z*11–14:Ald. The best ratio *Z*11–14:Ald, *Z*11,13–14:Ald seems to be 1:9. This ratio is even slightly more atractive than two virgin females. For the same pheromone rate and ratio, the differences of moths captured with rubber or polyethylene dispensers are not significant. As this experiment was carried out at the end of the flight period of *A. sphaleropa*, catches are lower than those reported in Table 1.

DISCUSSION

Of the compounds tentatively identified by the Japanese workers as part of the pheromone of *A. sphaleropa*, only the presence of *Z*11–14:Ac could be confirmed. The presence of tetradecyl acetate and of (*Z*,*E*)-9,11-tetradecadienyl acetate (*Z*9,*E*11–14:Ac) could not be confirmed. Comparison of the mass spectrum provided by the Japanese workers (Nunez, unpublished data), to which they tentatively assigned *Z*9,*E*11–14:Ac as the structure, with that of synthetic

[a]R, rubber dispenser; P, polyethylene dispenser. Means followed by the same letter are not significantly different ($P > 0.05$, Duncan's test).

*Z*9,*E*11–14:Ac (from our own stock) showed some marked differences. The mass spectrum of the compound isolated by the Japanese workers showed a strong *m*/*z* 54 fragment, whereas the mass spectrum of *Z*9,*E*11–14:Ac did not. This fragment is typical for conjugated diene systems with a terminal double bond (Ando, et al., 1985,1988). The mass spectrum provided by the Japanese workers to which they assigned *Z*9,*E*11–14:Ac as the structure looked similar to the mass spectrum of *Z*11,13–14:Ald. Therefore, it might well be that the Japanese workers were dealing with the correct compound, but that an incorrect structure was assigned to it. *Z*11,13–14:Ald and *Z*11,13–14:Ac have not been found before as part of a pheromone blend, whereas the *E* isomers of these compounds have been found as part of the pheromone of *Acleris minuta* (Schwarz et al., 1983). Moreover, in field screening tests, *E*11,13–14:Ald has been shown to be attractive for a number of *Acleris* sp. (Ando et al., 1987).

Although it was found that the major compound (*Z*11,13–14:Ald) was attractive alone, trap catches increased with mixtures of two pheromone compounds relative to either component alone. Binary mixtures as sex pheromones are well known, and this has repeatedly been established for Tortricidae (Roelofs and Cardé, 1974; Persoons and Ritter, 1975; Ritter and Persoons, 1976), where it seems to be more the rule than the exception. However, binary mixtures are also found in other moth families (Mayer and McLaughlin, 1991). In those cases where synergistic effects of binary pheromone mixtures have been observed, the individual compounds are barely and often not attractive at all in field experiments.

FIELD VERIFICATION OF PREDATOR ATTRACTION TO MINNOW ALARM SUBSTANCE

BRIAN D. WISENDEN* and TRAVIS A. THIEL

Biology Department
Minnesota State University, Moorhead
Moorhead, Minnesota 56563

(Received April 16, 2001; accepted September 11, 2001)

Abstract—Fishes such as minnows in the superorder Ostariophysi possess specialized alarm substance cells (ASC) that contain an alarm cue. Alarm substance can only be released by damage to the epidermis; thus, the release of alarm substance is a reliable indicator of predation risk. When nearby minnows detect the cue, they adopt a range of antipredator behaviors that reduce their probability of predation. Predator–predator interactions afford prey an opportunity to escape and, thus, a fitness benefit that maintains alarm substance calls over evolutionary time. Here, we present data from a simple field experiment verifying that nearby predators are attracted to minnow alarm substance because it signals an opportunity to pirate a meal. Fishing lures were baited with sponge blocks scented with either (1) water (control for sponge odor and appearance), (2) skin extract from non-ostariophysan convict cichlids (superorder Acanthopterygii, *Archocentrus "Cichlasoma" nigrofasciatus*) to control for general injury-released cues from fish, or (3) skin extract from fathead minnows (superorder Ostariophysi, *Pimephales promelas*). Predator strike frequency on each sponge type was 1,1, and 7 for water, cichlid, and minnow cues, respectively. These data provide the first field test using fish predators of the predator-attraction hypothesis for the evolution of Ostariophysan alarm substance cells.

Key Words—*Schreckstoff*, alarm substance, alarm pheromone, minnow, predator attraction, evolution, chemical signal, predator–prey, Ostariophysi.

INTRODUCTION

Predation, and risk of predation, influences the evolution of behavior and morphology of virtually all animals because predation is the final arbiter of natural

selection (Lima and Dill, 1990). Chemical cues mediate predator–prey interactions in aquatic habitats for organisms ranging from ciliates to mammals (Wisenden, 2001). Chemical cues released by predators, or from conspecifics that have been injured or frightened, are used by prey to detect and evade predators (Smith, 1992, 1999; Kats and Dill, 1998; Chivers and Smith, 1998; Wisenden, 2000).

Predators cause physical damage and injury to their prey in the process of capture, handling, and ingestion. Consequently, chemical cues from injured prey are often released during a predator attack, and these cues serve as public information about predation risk. Most aquatic taxa, from ciliates to amphibians, exhibit antipredator behavior in response to injury-released chemical cues from conspecifics (Chivers and Smith, 1998).

Fishes in the superorder Ostariophysi, i.e., minnows, catfish, characins, and suckers, represent about 64% of all freshwater fish species (Nelson, 1994). One character that unites this group is the presence of specialized epidermal cells that contain an alarm substance; hence, the cells are referred to as alarm substance cells (ASCs). These cells lack an external duct. The cell contents are released only when the skin is damaged. Predator attacks on Ostariophysans release alarm substance into the surrounding water and warn nearby prey of predation risk. Alarm substance is potent. Minnow skin elicits overt antipredator behavior when diluted to 1 cm^2 skin per 58,000 liters (Lawrence and Smith, 1989), or the equivalent volume of a sphere with a radius of 3.7 m. The behavioral response to this cue significantly reduces the probability of predation risk (Mathis and Smith, 1993).

ASCs have caught the attention of evolutionary ecologists. It is not readily apparent how the alarm signaling function of ASCs provides a selfish benefit to the signal sender, and thereby provides a mechanism for these cells to be maintained by natural selection (Smith, 1992; Williams, 1992). The only evolutionary mechanism for ASCs for which there is experimental support is the predator-attraction hypothesis (Smith, 1992). In a laboratory experiment, northern pike *Esox lucius* were more attracted to ASC–minnow skin extract than skin extract without ASCs (Mathis et al., 1995). Similarly, in a field experiment, dytiscid predaceous diving beetles were more attracted to traps scented with minnow skin with ASCs than traps scented with minnow skin that lacked ASCs (Mathis et al., 1995). Chivers et al. (1996) showed in staged predation events in laboratory aquaria that fathead minnows in the grasp of a small pike have a significant chance of escape if a second, slightly larger, pike is allowed to interfere. Fathead minnows receive a selfish fitness benefit by investing in ASCs because ASCs attract secondary predators, not because they warn conspecifics of predation risk. The studies by Mathis et al. (1995) and Chivers et al. (1996) make important contributions to the understanding of the evolution of chemical alarm signaling in this ecologically important group of fishes. No other experiments

have been conducted to verify these findings, and importantly, they have not been verified with fish predators in the field. In this study, we report the results of a simple field experiment that provides further support for the secondary predator-attraction hypothesis.

METHODS AND MATERIALS

We conducted our experiment on Lake Ida, approximately 25 km north of Alexandria, Minnesota, USA (46°00′ N, 95°25′ W). Potential minnow predators in Lake Ida are: northern pike, *Esox lucius*; walleye, *Stizostedion vitreum vitreum*; largemouth bass, *Micropterus salmoides*; yellow perch, *Perca flavescens*; black crappie, *Poxomis nigromaculatus*; several types of bullhead catfish, *Ameiurus melas, A. nebulosus, A. natalis*; and perhaps bluegill sunfish, *Lepomis machrochirus*.

We fished for 4 hr on January 27 and 4 hr on February 11, 2001. Ice cover at the time of data collection was about 80 cm thick. We drilled six holes about 25 cm in diameter with a gas-powered auger and spaced the holes about 8 m apart. We used a depth sonar to standardize water depth below all holes at about 3 m. We fitted each hole with an ice-fishing tip-up. A tip-up has a small platform and an upright stand connected to an arm that extends over the hole. The arm was equipped with a reel of anti-freezing line followed by a 1.1 m length of transparent monofilament line "leader." A lure was attached to the end of the leader. At the other end of the arm there was a piece of springy metal attached to a fluorescent orange flag. The flag was flexed against the reel of line in such a way that when a fish tugs on the line the flag is released, signaling a strike. In addition, a broad metal paddle was attached to the arm designed to catch any wind movement, causing the arm to bob up and down and jig the line. Jerky vertical motion on the line attracts fish to the lure. All holes were about 300 m from shore and equally exposed to wind. By using wind-powered tip-ups, we standardized the visual presentation of test stimuli among treatments.

Each tip-up was fitted with a fluorescent green, 1/32 oz (0.9 g) teardrop style jig and a small block of cellulose sponge ($1 \times 1 \times 0.7$ cm). The sponge block was soaked with one of three test solutions: (1) dechlorinated tap water to control for the odor and appearance of the sponge and background attractiveness of the jig lure, (2) skin extract of a tropical fish (convict cichlid, *Archocentrus "Cichlasoma" nigrofasciatus*) to control for general chemical cues released from injured fish, or (3) skin extract of fathead minnows, *Pimephales promelas*. Convict cichlids are not in the Ostariophysi (superorder Acanthopterygii) and, therefore, do not possess Ostariophysan ASCs. Skin extracts for each species were prepared using the same protocol. We used five cichlids (mean $\pm$ SE $= 6.8 \pm 0.8$ cm, $N = 5$)

and 11 minnows (mean $\pm$ SE $= 6.5 \pm 0.17$ cm, $N = 11$) to make the skin extract solutions. We killed each fish by a blow to the head, then carefully filleted the skin from each flank. Skin fillets were measured, then placed in chilled dechlorinated tap water. The total area of skin collected was 68.44 cm^2 and 66.97 cm^2 for cichlids and minnows, respectively. To simulate a predator attack we macerated the skin fillets with a conventional hand-held blender. The solution was filtered through polyester wool to remove scales, connective tissue, and suspended tissue particles. Dechlorinated water was added to bring the total volume of each skin extract to 32 ml. We made 64 sponge blocks of each odor type. Each sponge block was infused with 0.5 ml of dechlorinated water, cichlid skin extract, or minnow skin extract. Therefore, cichlid and minnow cues were of equivalent strength, based on 1.0 cm^2 of skin extract per sponge for each species cue. We froze the sponges at -20°C until needed. Conspecifics exhibit an alarm reaction to skin extract that has been frozen for both fish species used in this experiment (Lawrence and Smith, 1989; Wisenden and Sargent, 1997).

Of the six holes fished each day, two were assigned water sponges, two were assigned cichlid sponges, and two were assigned minnow sponges. We replaced the sponges with fresh ones every 30 min. We also rotated locations so that each sponge type was used at every location during each test day. We recorded the number of times that the tip-up arms showed a clear tip, i.e., the tip of the arm pulled into the hole, and the number of times the indicator flags were released.

We analyzed the data by using a chi-square goodness of fit test. Conventional wisdom maintains that a chi-square test cannot be used if more than 25% of the cells contain frequencies less than 5. However, this oft-repeated rule of thumb is overly conservative and unnecessary (Haldane, 1943; Snedecor and Cochran, 1980, p. 77).

RESULTS

Over the course of 48 hole-hr of fishing effort, holes with the minnow-sponges received seven predator strikes, of which six released the flag, while holes with the cichlid-sponges and water-sponges received one strike (and flag release) each ($\chi^2 = 8.0$, $P < 0.02$). Tip-ups baited with the scent of injured minnows were more attractive to predators than general chemical cues released by an injured non-Ostariophysan fish ($\chi^2 = 4.5$, $P < 0.05$). Predator attraction to the cichlid cue was not different from water ($P \cong 1$).

The time between replacement of the sponge and strike on the lure varied and did not seem related to treatment type. Lures scented with minnow skin were struck 6–24 min (mean $\pm$ SE $= 14 \pm 6$ min, $N = 4$) after sponge replacement. The single strike on the cichlid-scented lure occurred 4 min after sponge replacement. Strike time was not recorded for the water-scented strike.

DISCUSSION

The first conclusion from this experiment is that chemosensory cues are important in eliciting strike behavior. Because minnows are small fishes and fall prey to a wide variety of predators, it is reasonable to infer that fish large enough to trip the tip-up flag were minnow predators. The second conclusion is that not all scents are equally effective. The strike frequency on the cichlid cue was the same as for the water cue, indicating that general substances released from injured fish (amino acids, proteins, lipids, etc.) do not automatically elicit a strike response from predators. Minnow scent was clearly preferred by predators, consistent with predictions from chemical alarm signaling theory (Smith, 1992; Mathis et al., 1995; Chivers et al., 1996). Therefore, this study provides the first field verification from fish predators of the predator-attraction hypothesis for the evolution of ASCs. The predator species that struck the scented lures could not be observed through the ice; however, Lake Ida is best known for its pike fishery during the ice-fishing season. None of the fish striking the scented lures were landed because the sponge block was on the jig hook. Nevertheless, fish large enough to release the tip-up flag would be large enough to eat a fathead minnow or interrupt a predation event by attempts of piracy or cannibalism.

The precise chemistry of the alarm cue contained in minnow skin cells is not completely understood. A nucleotide, hypoxanthine-3(N)-oxide, has long been thought to be the active ingredient in the alarm cue/predator attractant (unpublished PhD thesis by Argentini in 1976, after Smith 1999). Laboratory (Pfeiffer et al., 1985; Mathis et al., 1995) and field (Brown et al., 2000) tests confirm the biological activity of hypoxanthine-3(N)-oxide.

An alternative explanation for the differences in strike frequency is that predators may have preferred minnow cue because minnow cue is familier to them. Cichlids are tropical fish and allopatric to the fish species in Lake Ida. However, there is no evidence to suggest that the chemical cues released by cichlids should differ qualitatively from those typical of general non-Ostariophysan fishes. Cichlids are in the same order, Perciformes, and ecologically similar to centrarchids (sunfish, bass), which are abundant in Lake Ida. The most likely explanation of the differences in strike frequency in the current experiment is that skin from minnows produces a more potent cue, with perhaps better dispersing properties than an equivalent area of cichlid skin. The presence of ASCs in minnow skin is the most likely cause of this.

(Received April 17, 2001; accepted September 10, 2001)

Abstract—In this study we conditioned fathead minnows (*Pimephales promelas*) to recognize the odor of a perch (*Perca flavescens*) by exposing them to perch odor coupled with minnow alarm cue. We then staged encounters between the predator and prey in order to assess whether the predator odor training had any effect on survival of the prey. We tested for a survival effect in the presence and absence of shelter. Our results indicate that fish trained with alarm signals to recognize predators gained a survival benefit during staged encounters with a predator and that habitat characteristics influenced the survival of conditioned fish.

Key Words—Predator recognition, predator training, chemical alarm signals, predator–prey interactions, survival, habitat, shelter, fathead minnow, *Pimephales promelas*, yellow perch, *Perca flavescens*.

INTRODUCTION

Alarm signaling is the situation in which an animal that encounters a hazard produces a response, the signal, that could make other individuals aware of danger (Smith, 1992). The signal(s) produced can include the sender's escape response or, alternatively, a chemical, sound, visible movement, or other change that may be detected by the receiver (Chivers and Smith, 1998). Many species of aquatic organisms release chemical alarm signals upon being attacked or captured by a predator (Chivers and Smith, 1998; Mirza and Chivers, 2001).

Chemical alarm signals have been shown to be important in facilitating learned recognition of predation risk by prey animals. For example, Chivers and Smith

(1995a,b) showed that fathead minnows (*Pimephales promelas*) learned the identity of dangerous habitats when they detected alarm signals in conjunction with specific habitat odors. Göz (1941) and Magurran (1989) showed that European minnows (*Phoxinus phoxinus*) learned to recognize the odor of a pike (*Esox lucius*) when the pike odor was paired with a minnow alarm signal. Similar studies have demonstrated that fathead minnows learned to recognize the sight or odor of a pike when the pike cues were paired with a conspecific alarm signal (Chivers and Smith, 1994a,b). Several authors provide similar findings in other fishes (Suboski, 1990; Chivers et al., 1995; Berejikian et al., 1999; Yunker et al., 1999; Mirza and Chivers, 2000) as well as in invertebrates (Wisenden et al., 1997; Rochette et al., 1998).

Despite the numerous studies that have documented the importance of alarm cues in learned recognition of unknown predators, only two studies have directly tested whether prey animals that are conditioned to recognize predators have a higher survival upon encountering the predator (Berejikian et al., 1999; Mirza and Chivers, 2001). The results of these studies are mixed. There is a clear need to conduct live predation trials to assess the validity of the current research paradigm (see review Mirza and Chivers, 2001).

The primary objective of the current study was to test whether fathead minnows that are conditioned to recognize predatory yellow perch (*Perca flavescens*) gain a survival benefit during a staged encounter with the predator. A secondary objective was to examine the importance of specific habitat characteristics in determining whether a survival effect was observed. We conducted live predation trials in both the presence and absence of artificial shelter. Minnows conditioned to recognize predators may seek shelter and hence be able to gain a survival benefit over those minnows that do not have shelter available. However, shelter may conceal the location of the predator; hence minnows that are tested in the presence of shelter may be more vulnerable to attacks by the predator.

METHODS AND MATERIALS

Fish Collection and Maintenance. In the fall of 2000, we collected adult yellow perch from Blackstrap Lake, in central Saskatchewan, Canada. The perch were transported to the University of Saskatchewan and held in 150-liter aquaria at 19°C and on a 14L:10D cycle. Prey animals may recognize an unknown predator that has recently fed on conspecifics (see review Chivers and Mirza, 2001). Consequently, we maintained the perch on a diet of brook stickleback (*Culaea inconstans*) prior to collecting stimuli from them.

Fathead minnows that were naïve to perch were obtained from Briarwood Pond, Saskatoon, Saskatchewan. The minnows were held in a 625-liter holding tank at 17°C and on a 14L: 10D cycle. The minnows were fed daily with commercial fish flakes.

Collection of Test Stimuli. Perch odor was prepared by placing two adult perch (≈15 cm standard length) in a 37-liter aquarium for 12 hr. The aquarium was aerated but not filtered. Perch were not fed in the stimulus aquarium. The water was frozen in 60-ml portions, the quantity of perch odor used for each trial.

Skin extract was obtained from five adult fathead minnows that were killed by a single blow to the head, in accordance with the guidelines set by the Canadian Council on Animal Care. Minnow skin fillets (total = 15 cm^2) were placed in 100-ml of chilled glass-distilled water. The skin was homogenized, filtered through filter floss to remove any visible particles, and diluted in distilled water to make a final volume of 150 ml. The extract was frozen in 10-ml lots, and 5 ml were used for each trial. The procedure was repeated to create a "control" extract from six green swordtails (*Xiphophorus helleri*). Swordtails were used as a control because they are phylogenetically distant and allopatric from minnows.

Experimental Protocol. Groups of five adult minnows (*ca.* 4.0−5.0 cm standard length) were placed into separate 37-liter aquaria (50 × 25 × 30 cm) that were filled with 20 liters of dechlorinated tap water. Each aquarium was supplied with an airstone and its sides were covered to prevent disturbance by an observer. The minnows were allowed to acclimate for approximately 22 hr and then were exposed to either perch odor paired with minnow skin extract (experimental treatment) or perch odor paired with swordtail skin extract (control treatment). The perch odor and skin extracts were introduced via a plastic tube. We used a syringe to remove 60 ml of tank water via the tube and retained it. We then slowly injected this into the tube, followed by the 5 ml of skin extract. The stimuli were flushed into the tanks with the 60 ml of tank water. The stimulus was added at a rate of approximately 1 ml/sec. We predicted that minnows would learn to recognize perch odor based on its association with conspecific skin extract, and hence should have a higher survival upon subsequently encountering a perch.

The day following the conditioning trials we removed the test fish from their tanks and conducted the survival trials. We tested the survival of trained and nontrained minnows during staged encounters with perch (*ca.* 15 cm standard length) in 400-liter test aquaria (180 × 45 × 45 cm). Test trials were completed in both the presence and absence of shelter; hence we used a 2 × 2 design, crossing predator training with shelter. Shelter was simulated by hanging 72 strands of twine from each of two pieces of floating Styrofoam measuring 45 × 60 cm. This shelter resembles submergend vegetation in that it visually obstructs the environment but allows the fish to move through it. For treatments done without shelter, two plain square pieces of Styrofoam were placed on the top of the tank to keep the light conditions consistent. Twelve perch were each tested four times, once under each of the different treatment conditions, for a total of 48 trials. The order of treatments was randomized.

Prey animals may recognize any unknown predator that has recently fed on conspecifics of the prey (reviewed by Chivers and Mirza, 2001). Consequently,

prior to each test, the perch were fed stickleback for a minimum of three days and then were starved for three days. Perch were placed into test aquaria at least 2 hr before the start of the trial. Each trial began when the group of five fathead minnows was placed into the test aquaria with the perch. Minnows were introduced into the tank at the maximum possible distance from the perch. For each trial, we recorded the number of minnows surviving after 1 hr. Each aquarium was drained and washed between trials to ensure no alarm cues were present from the previous trial.

We used a series of Wilcoxon signed rank tests to assess effects of the conditioning treatments and shelter treatments on minnow survival (Siegel and Castellan, 1988). The family-wise error rate was assessed and controlled using the modified Bonferroni test following Keppel (1982). The modified Bonferroni test specifies that corrections to the family-wise error rate be introduced only when the number of comparisons exceeds $k - 1$, where k is the number of treatments (Keppel, 1982). In this experiment, there were a total of four treatments. Since the analysis was restricted to four preplanned comparisons, the rejection probability (P) was set at 0.0375 for each comparison (Keppel, 1982).

RESULTS

Both predator training and the presence of shelter had an influence on minnow survival. In the presence of weeds, there was no difference between the survival of minnows conditioned with conspecific extract versus swordtail extract ($T = 23$, $N = 9$ corrected for ties, $P > 0.95$; Figure 1). In contrast, in the absence of weeds, minnows conditioned with conspecific extract survived longer than those conditioned with swordtail extract ($T = 28$, $N = 7$ corrected for ties, $P = 0.016$; Figure 1).

There was no difference in survival for swordtail-conditioned minnows in the presence versus absence of weeds ($T = 22$, $N = 8$ corrected for ties, $P = 0.641$; Figure 1). Minnows conditioned with conspecific extract did not survive longer in the absence of weeds than in the presence of weeds ($T = 25.5$, $N = 7$ corrected for ties, $P = 0.062$; Figure 1).

DISCUSSION

Our results show that fathead minnows can be conditioned to recognize the odor of a perch and that this recognition can translate into increased survival during encounters with the predator. The learned recognition occurs after a single pairing of perch odor with minnow alarm cue. Previous studies have documented that fathead minnows can learn the identity of pike cues in a similar manner (Chivers and Smith, 1994a,b). Complimentary results have been found in several

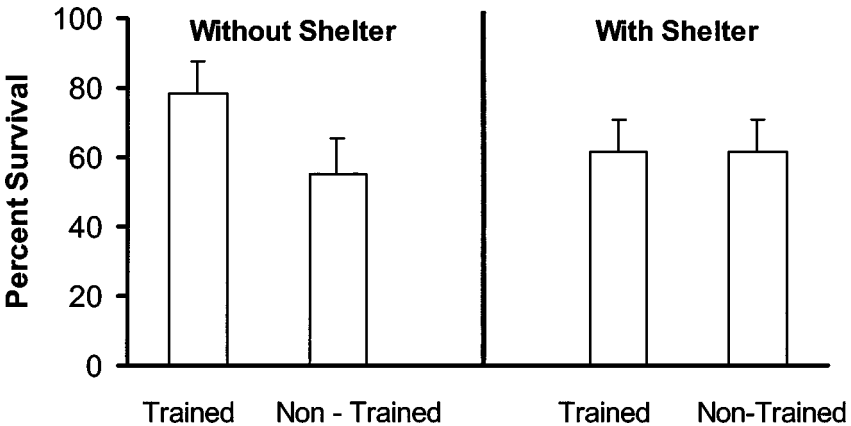

FIG. 1. Mean (+SE) percent survival of trained (conditioned with conspecific skin extract) and nontrained (conditioned with swordtail skin extract) minnows in the presence and absence of shelter during staged encounters with perch.

other species, but whether the conditioning effect translates into increased survival remains untested in most systems.

In our study, we conditioned the prey to recognize the odor of the predator but not the sight of the predator. As such, our results provide empirical evidence of the survival consequences of chemically mediated antipredator responses. Additional studies should examine whether prey conditioned to recognize the sight of a predator gain a survival benefit, and if so, whether the magnitude of the survival effect is dependent on visual versus chemical conditioning.

Only two other studies have tested the survival consequences of conditioning with chemical alarm cues. Mirza and Chivers (2000) showed that juvenile brook charr (*Salvelinus fontinalis*) conditioned to recognize predatory chain pickerel (*Esox niger*) had a greater probability of escaping attacks than nontrained fish. Berejikian et al. (1999) conditioned juvenile chinook salmon (*Oncorhynchus tshawytscha*) to recognize cutthroat trout (*Oncorhynchus clarki*) and then staged encounters between the predator and prey. They observed no survival effect in their first experiment and in their second experiment found that trained fish had a higher survival but that the rearing environment had a significant influence on the result. Fish that were raised in a complex environment, with both overhead and submersed structure, and then conditioned to recognize the trout did not survive better than nontrained controls when stocked in a natural stream. In contrast, fish that were raised in a barren tank environment and then conditioned to recognize predators had higher survival than those that were not trained. Berejikian et al. (1999) speculated that the absence of a survival effect in fish raised in a complex environment may result from the fact that fish from such an environment have a

greater propensity to enter cover, the location where predatory cutthroat trout are most likely to occur.

The results of Berejikian et al. (1999) demonstrate the importance of considering the rearing environment when assessing the potential survival benefit of alarm cue conditioning. The rearing environment may have influenced minnow survival in our study. We collected minnows from Briarwood Pond, a stormwater retention pond with little weed cover. We found an effect of predator recognition training in the absence of weeds but not in the presence of weeds. It is possible that altering the rearing conditions can influence the outcome. For example, minnows reared in an environment with high weed cover could exhibit different types of antipredator defenses that might result in higher survival in the presence of weeds.

It seems clear that fishes and other prey animals can be conditioned to recognize the characteristics of unknown predators based on a single association of the predator cues with alarm signals (reviewed in Chivers and Smith, 1998). Ours is among only a few studies to test specifically whether prey conditioned with alarm cues to recognize predators gain a survival benefit. Moreover, our study is the first to document that habitat characteristics of the testing environment can influence the survival of predator-conditioned fish. We suggest that future work should examine if and when alarm cue conditioning translates into a survival benefit for prey. This should include conducting studies designed to manipulate the rearing conditions and the habitat conditions under which the predator–prey encounter takes place. Habitat variables that could be manipulated include turbidity of the water, presence and density of shelter, and color and type of substrate. Experiments should also employ predators with different hunting strategies. To consider that the survival of prey is dependent exclusively on particular habitat characteristics may be ignoring the possibility of habitat dependence by the predator. Future experiments should also condition prey to recognize visual and chemical cues of predators both singly and together. We need to conduct live predation trials under various conditions in order to assess the potential importance of alarm cue conditioning under natural conditions.

Acknowledgments—We thank Mike Pollock, Reehan Mirza, Carrie Hindman, Jamie Hindman, and Pam Gazdewich for assisting in fish collection and in conducting the experiment. Reehan Mirza and two anonymous reviewers provided helpful comments on earlier versions of this manuscript. Funding was provided by NSERC of Canada and the University of Saskatchewan. The research presented here was approved by the University Committee on Animal Use and Supply (University of Saskatchewan Animal Care Protocol # 19920077).

CALL FOR PAPERS

SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Aquatic Chemical Ecology". Publication is planned for late summer/early fall 2002. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special issue should do so by February 1, 2001.

Please send the original and two copies of the manuscript (including illustrations) and the names and addresses of three potential reviewers to:

(Received July 9, 2001; accepted November 14, 2001)

Abstract—Four EAG-active components (A–D) were found in the solvent extract of virgin females of the clear-winged tussock moth, *Perina nuda*. The most abundant component (B, ca. 250 ng/female) was identified as (3*Z*,6*S*,7*R*,9*Z*)-6,7-epoxyhenicosa-3,9-diene by GC-MS analyses of the extract, chemical derivatization, and comparative chiral HPLC. Minor components also elucidated were (3*Z*,9*Z*)-*cis*-6,7-epoxyicosa-3,9-diene, (A); (3*R*,4*S*,6*S*,7*R*,9*Z*)-3,4-6,7-diepoxyhenicos-9-ene, (C); and its 3*S*,4*R*,6*S*,7*R* isomer, (D); with amounts of 0.4, 5, and 8 ng/female, respectively. Component B showed weak attractiveness to male moths in the field. The attractiveness was significantly enhanced by addition of component(s) C and/or D. No males were captured with either the antipode of component B or its mixtures with the minor components. In this field test, noctuid *Hypocala rostrata* males were also attracted with the synthetic *P. nuda* pheromone.

Key Words—Sex pheromone, *Perina nuda*, Lymantriidae, (3*Z*,6*S*,7*R*,9*Z*)-6,7-eopxyhenicosa-3,9-diene, (3*R*,4*S*,6*S*,7*R*,9*Z*)-3,4-6,7-diepoxyhenicos-9-ene, (3*S*,4*R*,6*S*,7*R*)-3,4-6,7-diepoxyhenicos-9-ene, sex attractant, *Hypocala rostrata*, Noctuidae.

INTRODUCTION

The tussock moth *Perina nuda* (Fabricius) (Lepidoptera: Lymantriidae) is distributed in the Ryukyu Islands (Japan), Taiwan, Malaysia, and India (Inoue, 1982; Azuma, 1996). Adults show remarkable sexual dimorphism. The female has a yellowish body and wings similar to those of the tussock moth species of the genus *Euproctis*. The male has clear wings and a blackish body like those of the cicada.

In Lymantriidae, the sex pheromone chemicals that have been identified are diverse and include hydrocarbons, ketones, epoxides, and esters with and without methyl branches and unsaturation (see Arn et al., 1992, 1997; Gries et al., 1997a,b; Wakamura et al., 2001a,b). In the case of the genus *Euproctis*, different chemicals have been identified from different species. Moreover, no common component has been found (Wakamura et al., 2001a). The sex pheromone component(s) of *P. nuda* are also interesting in terms of pheromone diversity.

Larvae of this insect feed on leaves of the Malayan banyan, *Ficus micromorpha* L.f. ("Gajumaru" in Japanese) (Inoue, 1982; Azuma, 1996). In Okinawa, *P. nuda* larvae have occasionally defoliated the Malayan banyan, especially the horticultural variety that lines streets (Azuma, 1996). Furthermore, human contact with the urticating hair of the caterpillar can cause skin irritation. In Okinawa, insecticide has been sprayed against this species on urban Malayan banyans, but it is often ineffective against severe defoliation.

Chemical identification of the sex pheromone component(s) of *P. nuda* can also improve protection of the Malayan banyan by detecting early moth occurrence that will probably be followed by severe defoliation. This report deals with the identification of sex pheromone components and attractiveness of the synthetic compounds in the field.

METHODS AND MATERIALS

Insects. P. nuda pupae were collected from a horticultural variety of the Malayan banyan found on the streets of Naha, Okinawa on January 14, 2000. Last-instar larvae of this species pupate on the upper surface of the leaves by spinning rough silk cocoons, and the pupae are easy to collect at the outbreak site with forceps. Pupae were treated with 1% sodium hypochlorite solution to wash away the cocoon silk and larval urticating hair, in order to avoid risk of skin irritation. Pupae were sexed and maintained at 25°C and 16L:8D in separate containers until emergence in the laboratory.

Extraction. Solvent extracts of sex pheromone glands were obtained from 1-day-old virgin females at around 30 min after lights-on, since calling behavior was frequently observed at this time. The tip containing the pheromone gland was

excised from the female abdomen with fine tweezers and soaked in hexane (5–10 tips/0.5 ml) for ca. 15 min. This was filtered through a small wad of cotton to obtain an extract. Tips were rinsed with the same volume of hexane twice, and the rinses were added to the extract.

Column Chromatography. Column chromatography was carried out on 200 mg of Florisil (100–200 mesh, Floridin Co.) or silica gel (particle size 75–150 μm, Wako gel, C-200, Wako Pure Chemical Ind. Co., Osaka, Japan) in a Pasteur pipet. Substances were eluted successively with 1 ml each of hexane and 5%, 20%, and 50% ether in hexane.

Gas Chromatography (GC) and Electroantennographic Detection (EAD). GC analyses were conducted on a Hewlett-Packard (HP) 5890II gas chromatograph equipped with a flame ionization detector (FID). An HP-1 or HP-INNOWax fused silica column (15 m $\times$ 0.25 mm ID $\times$ 0.25 μm film thickness) was used at a column head pressure at 55 kPa. Injection was made directly into the capillary column through a cool on-column injector programmed at oven temperature plus 3°C. Temperature program (TP) for the column oven was 50°C for 1 min, 50°C to 150°C at 20°C/min, 150°C to 260°C at 5°C/min, and then final temperature for 5 min [abbreviation for this TP: 50(1)-20-150(0)-5-260(5)]. An electroantennographic (EAG) response was obtained simultaneously with the FID recording. The electroantennographic detector (EAD) was set up according to Struble and Arn (1984), with a minor modification in the column split system.

Coupled Gas Chromatography–Mass Spectrometry (GC-MS). GC-MS analyses were conducted with an HP6890 gas chromatograph interfaced to a Jeol JMS SX-102A double-focusing magnetic sector mass spectrometer (EI mode, 70 eV) and operated with an HP model 715/64 computer. The carrier gas was helium. An HP-1 or HP-Innowax column (15 m $\times$ 0.25 mm ID $\times$ 0.25 μm film thickness; HP) was operated at constant flow mode (1.6 ml/min, ca. 70 cm/sec), with initial column head pressure at 35 kPa. Samples were injected through a cool on-column injector as described above. TP for the column oven was 50(1)-20-150(0)-5-240(5). In certain analyses, a mixture of normal alkanes with even numbers of carbon atoms from icosane (C_{20}) to tricosane (C_{30}) were coinjected for calculation of Kováts retention indices (KI) (Kováts, 1965). These hydrocarbons were eluted at approximate equal intervals from both HP-1 and HP-INNOWax columns.

High-Performance Liquid Chromatography (HPLC). HPLC involved a Jasco PU-980 liquid chromatograph equipped with an integrator (System Instrument Chromatocorder 21J), an RI detector (Labo System RI-98SCOPE), and a Chiralpak AD column (0.46 cm ID $\times$ 25 cm, Daicel Chemical Ind. Co., Ltd., Tokyo, Japan). For the monoepoxide, 0.1% 2-propanol in hexane was used at a rate of 0.45 ml/min, while 0.5% 2-propanol in hexane was used at the same flow rate for the diepoxide. Injection was made through a Rheodyne 7125 loop injector as 10 μl of hexane solution.

Diimide Reduction. Polyenyl compounds were partially or completely hydrogenated according to the method described by Yamaoka et al. (1976). A solution of a polyenyl compound concentrated to about 10 μl in a 1-ml taper-bottomed vial was combined with 10 μl each of hydrazine and hydrogen peroxide solution in ethanol (N_2H_4: 0.3 ml of hydrazine hydrate in 10 ml of ethanol, H_2O_2: 0.04 ml of 31% H_2O_2 in 10 ml of ethanol). The mixture was maintained at 65°C for 1 hr for complete hydrogenation or 55°C for 1 hr for partial hydrogenation. For some other analyses, the reaction was quenched by the addition of 100 μl of 1% HCl solution, and the mixture was immediately extracted with 200 μl of hexane three times. The hexane extract was passed through a short column of ca. 0.1 g of powdered Na_2SO_4 and then concentrated to ca. 10 μl.

Dimethyl Disulfide (DMDS) Adducts. Since yields of direct DMDS derivatization of epoxymonoene were low at the nanogram scale in preliminary experiments, epoxymonoenes were reduced with $LiAlH_4$ before being subjected to DMDS derivatization. About 200 μl of 1 mmol/ml $LiAlH_4$ solution in ether was added to the solution of test material in ca. 100 μl of THF at 0°C, and the mixture was stirred at room temperature overnight. After the reaction had ceased, 100 μl of 1% HCl was added, and the mixture was extracted with 400 μl of hexane three times. Extracts were combined, passed through a layer of powdered Na_2SO_4 (ca. 100 mg), and chromatographed on 200 mg of silica gel in a Pasteur pipet. The fraction eluted with 1.0 ml of 15% ether in hexane was collected after elutions with 1.0 ml each of hexane and 5% ether in hexane.

As in the method described by Buser et al. (1983), 20 μl of DMDS and a very small crystal of iodine were added to ca. 10 μl of hexane solution of the test material in a 100-μl capillary tube with one end sealed. The other end was then sealed, and the capillary was kept at 55°C for 2 hr. After the addition to 100 μl of 5% $Na_2S_2O_3$ solution in distilled water, the products were extracted with 100 μl of hexane three times. The extracts were combined and concentrated to ca. 4 μl, and 0.6 μl of the solution was injected through a cool on-column injector into the GC-MS equipped with an HP-1 column in which the TP was 50(1)-25-200(0)-5-270(5).

Chemicals. *cis*-6,7-Epoxyhenicosane and its *trans*-isomer were obtained from (*Z*)-henicos-6-ene and its *E* isomer, respectively, by oxidation with *m*-chloroperoxybenzoic acid (MCPBA) in dichloromethane. (*Z*)-Henicos-6-ene was synthesized from tetradecyl tosylate and 1-heptyne by an acetylene coupling reaction in HMPA and subsequent hydrogenation over Lindlar catalyst as in Hendry et al. (1975). A part of the *Z* isomer was isomerized to (*E*)-henicos-6-ene by heating in a sealed tube at 60°C for 12 hr with 2,2′-azobis(2-methylpropionitrile) and thiophenol in benzene as in Sgoutas and Kummerow (1969). Geometric isomers were purified by chromatography on SiO_2 impregnated with 16.7% of $AgNO_3$ to $>$99% purity.

(3*Z*,9*Z*)-*cis*-6,7-Epoxyhenicosa-3,9-diene (**1b**) was synthesized from the corresponding (3*Z*,6*Z*,9*Z*)-triene by oxidation with MCPBA (Ando et al., 1993), and pure enantiomers were separated by successive achiral and chiral preparative HPLC (Qin et al., 1997). (*Z*)-*cis*-3,4-*cis*-6,7-Diepoxyhenicos-9-ene (**2**) was prepared by further oxidation of **1b** with MCPBA. Separation of the resulting positional isomers and stereoisomers was also accomplished by preparative HPLC (Yamamoto et al., 1999; Yamazawa et al., 2001).

Dose-Response Relations of EAG Responses. Dose–response curves were measured with the GC-EAD system. A single antenna was used for a series of measurements that ranged from low to high dosages of synthetic compound or extract. Since considerable variation was observed in raw EAG voltage when different antennae were used, the EAG responses were normalized to 1.0 at 10 ng of the 6*S*,7*R* isomer of **1b** (6*S*-**1b**), which was injected immediately after a series of measurements from low to high concentrations.

Field Attraction. A tent-shaped sticky trap (white type, SE trap of Sankei Chem. Co., Kagoshima, 29 × 32 × 8 cm high) with a 24-cm × 30-cm sticky plate was used for field attraction. Synthetic chemicals were applied to the terminal ca. 1 cm^2 area of a 1-cm × 4-cm piece of filter paper (Toyo No. 2, Toyo Roshi Kaisha, Tokyo) as ca. 50 μl of hexane solution. Immediately after the solvent evaporated, the paper pad was suspended about 2 cm above the sticky plate in the trap at about 07:00 hr (attraction of *P. nuda* males occurred around 08:00–09:00 hr). A filter paper pad of the same size was treated with the same volume of hexane as an unbaited control. Trap catches were counted in the afternoon, and the used filter paper pads were removed. Traps were placed on steel rods about 1 m above the ground at 5-m intervals. Trap locations were exchanged in every repetition to cancel out any possible effect of trap locations.

For one test, blends of synthetic chemicals were impregnated in rubber septa (gray halo-butyl isoprene blend elastomer septa, 8 mm outside diam., 19 mm high, West Co., Singapore) by applying ca. 0.3 ml of the hexane solution into the depression. Rubber septum lures were continuously used from late October to early December. Trap locations were exchanged at three- or four-day intervals. Trap catches were counted at intervals of one to three days and pooled for one trap per week, resulting in six replications.

Trap data (X) were transformed to $\sqrt{X + 0.5}$ and subjected to two-way layout ANOVA where zero data (mean = 0) were omitted. The means were ranked by Tukey's method when ANOVA was significant at the 5% level (Figures 6–8 below). Means accompanied by the same letter are not significantly different, and the same letter was given to the zero data when the confidential range of the mean contained zero ($\sqrt{0 + 0.5}$).

Field tests were conducted in Naha, Okinawa, from late October to early December 2000. The population level of *P. nuda* became considerably lower than

expected from observation of the trend of the previous season (September 1999 to January 2000). We were unable to collect larvae or pupae for virgin female traps or to evaluate the effect of the minor component **1a**.

RESULTS

GC and GC-EAD Analyses of the Pheromone Extract. When the accumulated crude extract from 100 virgin females was concentrated to ca. 50 μl and 1 female equivalent (FE)/0.5 μl of the extract was injected into the GC-EAD system, one weak and three distinct EAG-active components (A–D) were observed together with a number of FID peaks (Figure 1). The remaining crude extract was chromatographed on the Florisil column. Components A and B were eluted with 5% ether in hexane (5% fraction), and components B, C, and D were eluted with 20% ether in hexane (20% fraction) (Figure 1). A trace amount of component B in the 20% fraction was probably due to a tailing effect. In separate GC analyses, the amounts in the extracts were estimated to be 0.4, 250, 5, and 8 ng/FE for components A, B, C, and D, respectively, by comparison of FID peak size of 100 ng of tetracosane as an internal standard.

Identification of Components A and B. About 0.3 FE of the 5% fraction was injected into the GC-MS to measure mass spectra, and two corresponding peaks were observed. The mass spectrum for component B (Figure 2B) showed a molecular ion at *m*/*z* 306 (relative intensity 12.9%, base ion: *m*/*z* 67), and diagnostic fragment ions were observed at *m*/*z* 290 (M−16, 4.3%) and *m*/*z* 288 (8.2%, M−18), which suggested an unsaturated epoxide. The mass spectra of the product by complete hydrogenation with diimide at 65°C for 1 hr showed a molecular ion at *m*/*z* 310 (7.7%, base ion: *m*/*z* 83) and fragment ions at *m*/*z* 294 (M−16, 6.3%) and 292 (M−18, 1.1%), which indicated that the component was an epoxide (e.g., McLafferty, 1973). The diagnostic ions at *m*/*z* 239 ($[\overset{\diagup\,\diagdown}{\mathrm{CH}\text{—}\mathrm{CH}}\,\mathrm{C_{14}H_{29}}]^+$, 86%) and *m*/*z* 113 ($[\mathrm{C_5H_{11}}\,\overset{\diagup\,\diagdown}{\mathrm{CH}\text{—}\mathrm{CH}}\,]^+$, 38%) indicated the functional group at the 6,7 position. The KI value on the polar column (HP-INNOWax) was 2499, which was similar to that for the authentic *cis*-6,7-epoxyhenicosane (2498) but apparently different from that for the *trans* isomer (2475). Component B was, thus, considered to be *cis*-6,7-epoxyhenicosadiene. Since the mass spectra of the original component B showed two mass unit smaller fragment ions at *m*/*z* 237 and *m*/*z* 111 than the hydrogenated compound, the double bonds were considered to be located on either side of the epoxide group (Ando et al., 1993).

To determine the position of the double bonds in component B, a 5% fraction (ca. 10 FE) was treated with diimide at 55°C for 1 hr to obtain a mixture that

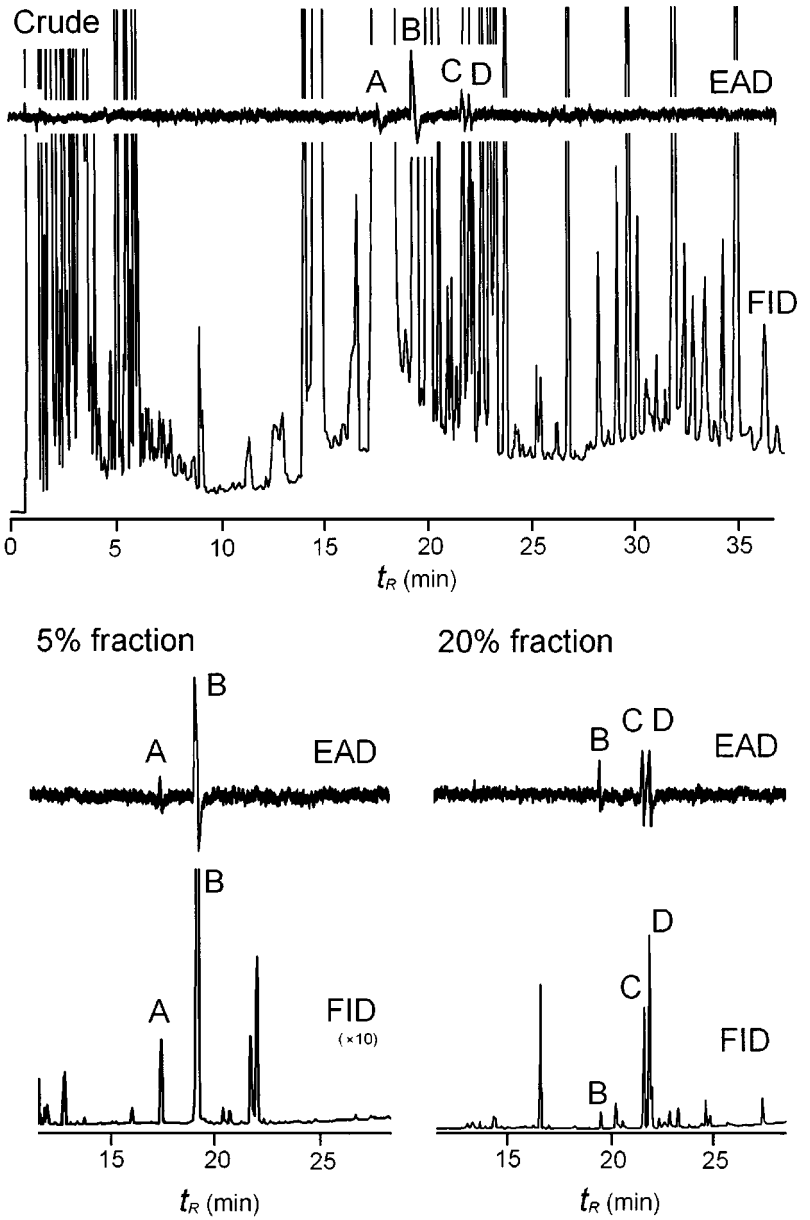

FIG. 1. GC-EAD chromatograms of crude extract of virgin *P. nuda* females and 5% and 20% ether-in-hexane fractions from Florisil column chromatography.

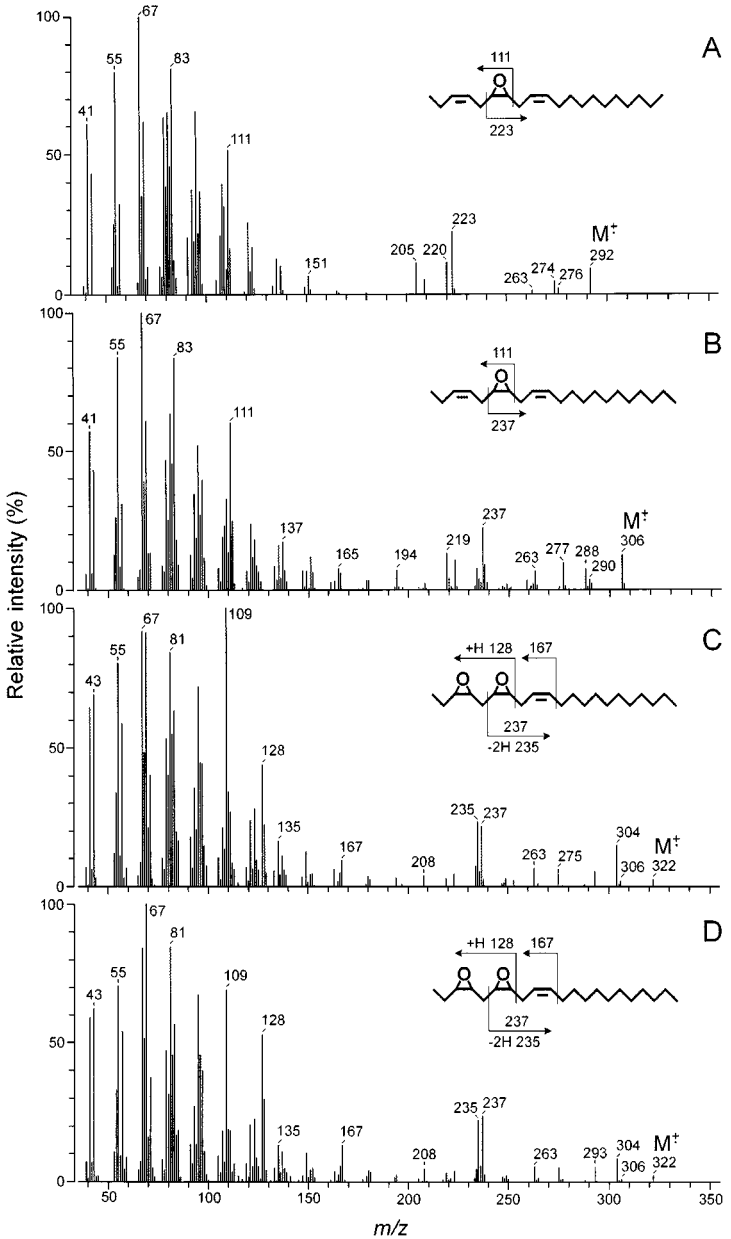

FIG. 2. EI mass spectra of EAG-active components A–D in the extracts of virgin *P. nuda* females. JEOL JMS SX-102A at 70 eV.

contained monounsaturated epoxides. These epoxides were then reduced with $LiAlH_4$ to corresponding alcohols. The unsaturated alcohols were treated with DMDS, and the DMDS adducts were analyzed by GC-MS. Two expected adducts were detected: the mass spectrum of one product showed the molecular ion at *m*/*z* 404 (17.9%) and a diagnostic fragment ion at *m*/*z* 215 {$[CH_3(CH_2)_{10}CHSCH_3]^+$, 100%}, which indicated that one olefin position was at the 12th carbon atom from the end (9th carbon from the opposite end). The partner ion expected at *m*/*z* 189 was not observed, probably because of the effect of the alcohol group. The other product also gave a molecular ion at *m*/*z* 404 (15.0%, base *m*/*z* 75) and the diagnostic ion at *m*/*z* 89 [$(CH_3CH_2CHSCH_3)^+$, 30%], which indicated a double bond at the third carbon. This implied that the original component B included a 3,9-diene system.

Almost all the epoxides that have been identified as sex pheromone components from lepidopterous insects possess a *Z* configuration (see Arn et al., 1992, 1997). The only known exception is posticlure, (6*Z*,9*Z*,11*S*,12*S*)-11,12-epoxyhenicosa-6,9-diene, a sex pheromone component of *Orgyia postica* (Walker) (Lepidoptera: Lymantriidae) (Wakamura et al., 2001b). As expected, component B and the authentic (*Z*,*Z*)-*cis*-6,7-epoxyhenicosa-3,9-diene (**1b**) showed almost identical mass spectra and KI values on both nonpolar HP-1 (KI 2220) and polar HP-INNOWax (KI 2555–2556) columns. Therefore, component B was considered to be an epoxydiene **1b**, although there remains a slight possibility of another geometric isomerism.

The mass spectrum of minor component A (Figure 2A) showed a molecular ion at *m*/*z* 292 (10.1%, base: *m*/*z* 67), and a similar series of fragment ions to those for component B, but the *m*/*z* values in the high mass region were 14 mass units smaller than those of component B. These similarities suggested that component A is (*Z*,*Z*)-*cis*-6,7-epoxyicosa-3,9-diene (**1a**), an analog of component B.

Identification of Components C and D. Components C and D in the 20% fraction of the Florisil column showed almost the same mass spectra (Figure 2C,D). In both spectra, the ion that appeared at *m*/*z* 322 was considered to be a molecular ion. Significant fragment ions at *m*/*z* 306 (M–16) and 304 (M–18) indicated an epoxide group in the molecule. However, the KI values for these components on both nonpolar HP-1 (KI 2369 and 2387) and polar HP-Innowax (KI 2909 and 2948) columns (Table 1) were larger than expected for monoenyl C_{22} epoxides (KI ~2320 for HP-1, ~2655 for HP-INNOWax). This suggested the presence of an additional polar functional group such as an epoxide.

Based on the homology in the chemical structure of component B, (9*Z*)-*cis*-3,4-*cis*-6,7-diepoxyhenicos-9-ene (**2**) and (3*Z*)-*cis*-6,7-*cis*-9,10-diepoxyhenicos-3-ene were the most likely candidates for components C and D. In the GC-EAG analyses, diastereomers of **2** (racemic mixtures) evoked more intensive EAG response than the other candidates (Figure 3B). In the GC-MS analyses of the

TABLE 1. KI VALUES OF COMPONENTS C AND D AND SYNTHETIC *cis,cis*-DIEPOXYHENICOSENES[a]

Compounds	HP-1	HP-Innowax
EAG-active components in VF extract		
Component C	2369	2906
Component D	2387	2945
Synthetic diepoxyhenicosenes[b]		
9*Z*(3*S**6*R**)	2369	2908
9*Z*(3*S**6*S**)	2387	2946
6*Z*(3*S**9*R**)	2389	2953
6*Z*(3*S**9*S**)	2397	2966
3*Z*(6*S**9*R**)	2371	2904
3*Z*(6*S**9*S**)	2396	2954

[a] KI values were measured with a GC-MS system. See text for GC conditions.

[b] Synthetic diepoxyhenicosenes are presented by abbreviation: e.g., 9*Z*(3*S**6*R**) is a racemic mixture of (3***S***,4*R*,6*R*,7*S*,9*Z*)-3,4-6,7-diepoxyhenicos-9-ene and its antipode, the 3*R*,4*S*,6*S*,7*R*,9*Z* isomer.

synthetic diepoxy compounds that include (6*Z*)-*cis*-3,4-*cis*-9,10-diepoxyhenicos-6-ene (Yamazawa et al., 2001), two diastereomers of **2** showed similar mass spectra and identical KI values to components C and D (Table 1). Components C and D were, thus, estimated to be two diastereomers of **2**.

Stereochemistry of Components B–D. To determine chirality of component B, ca. 20 FE (5 μg) of 5% fraction was injected into the HPLC equipped with a chiral column. Component B was eluted as a single peak at $t_R = 15.98$ min. This value was almost identical to that for the 6*S*,7*R* enantiomer, but smaller than that for the 6*R*,7*S* enantiomer (16.67 min), as shown in Figure 4. The identity was confirmed by coinjection of 20 FE of 5% fraction and 10 μg of the racemic mixture. Component B was, thus, considered to be (3*Z*,6*S*,7*R*,9*Z*)-6,7-epoxyhenicosa-3,9-diene [(6*S*)-**1b**]. This conclusion was also supported by the GC-EAG analyses (Figure 3A). The dose–response curve of the enantiomers of (6*S*)-**1b** was equivalent to that of the 5% fraction of the virgin female extracts, while the enantiomer (6*R*)-**1b** elicited significantly less antennal response.

The 20% fraction of another 140 FE of extracts was injected onto HPLC, and eluates were fractionated at 0.50-min intervals from $t_R = 20.00$ min. In the RI monitor, small and unclear peaks were observed at around $t_R = 22.33$ min and $t_R = 24.46$ min (Figure 5A). The racemic mixture of two diastereomers of **2** (ca. 20 μg) was also fractionated under the same conditions. Three peaks were observed in the RI monitor: the (3*S*,4*R*,6*R*,7*S*) isomer (3*S*6*R*)-**2** at $t_R = 20.19$ min, the (3*S*,4*R*,6*S*,7*R*) isomer [(3*S*6*S*)-**2**] at $t_R = 22.33$ min, and the (3*R*,4*S*,6*S*,7*R*)

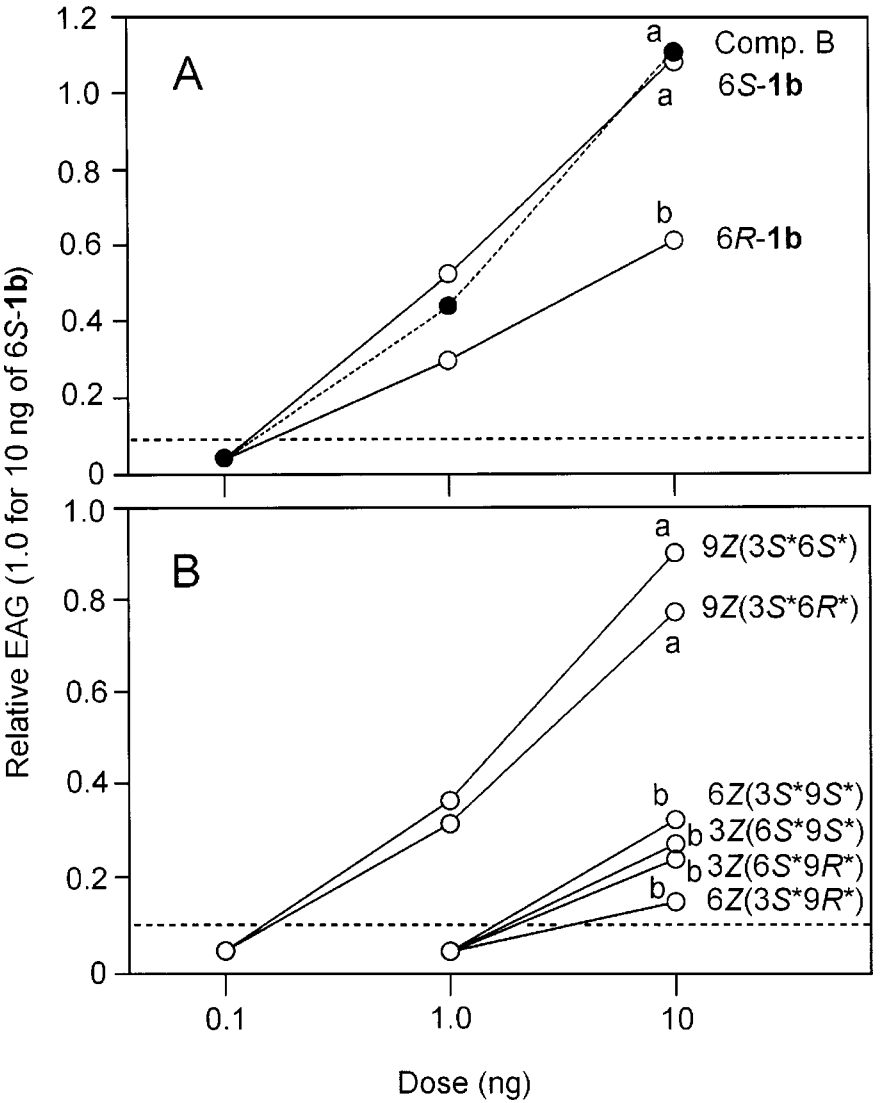

FIG. 3. EAG responses to authentic (3*Z*,6*S*,7*R*,9*Z*)-6,7-epoxyhenicosa-3,9-diene [(6*S*)-**1b**], its enantiomer [(6*R*)-**1b**], and component B in the virgin female extract (A) and to authentic diepoxymonoene isomers (racemic mixture) (B). For abbreviations, see footnote to Table 1. EAG values are normalized to 1.0 for 10 ng of (6*S*)-**1b**. Values indicated are means for six replications for (6*S*)-**1b**, (6*R*)-**1b**, 9*Z*(3*S**6*S**) [= (3*S*6*S*)-**2** + (3*R*6*R*)-**2**] and 9*Z*(3*S**6*R**) [= (3*S*6*R*)-**2** + (3*R*6*S*)-**2**]. The other isomers had three replications. Values accompanied by the same letter are not significantly different by Tukey's test ($P > 0.05$). Horizontal dashed lines indicate noise levels.

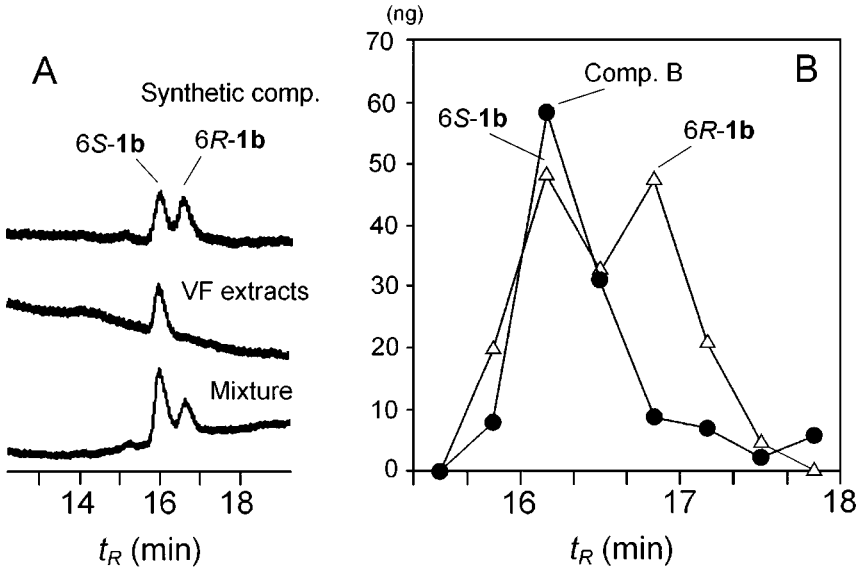

FIG. 4. HPLC analyses of component B in the 5% fraction of the virgin female extracts and synthetic *cis*-6,7-epoxyhenicosa-3,9-diene (**1b**: racemic mixture) (A) and quantitative GC analyses of the HPLC fractions (B). Solid circles and open triangles represent the amounts of compounds in the HPLC fractions of the 5% fraction of virgin female extracts and synthetic **1b**, respectively.

isomer [(3*R*6*S*)-**2**] and (3*R*,4*S*,6*R*,7*S*) isomer [(3*R*6*R*)-**2**] at $t_R = 24.56$ min as a slightly broad peak.

In order to determine the amounts of the components in the fractions, GC analyses were done on the HP-1 column (Figure 5B). Before injection, 100 ng of docosane was added to the HPLC fractions of the 20% fraction as an internal standard and concentrated to ca. 100 μl. Two hundred nanograms of docosane was added to the HPLC fraction of the authentic components. Components C and D were detected in the HPLC fractions from $t_R = 24.00$ to 25.50 min and from $t_R = 22.00$ to 23.00 min, respectively. Authentic (3*S*6*R*)-**2** and its enantiomer were detected in the fractions from $t_R = 20.00$ to 21.50 min and from $t_R = 24.00$ to 25.50 min, respectively. In contrast, authentic (3*S*6*S*)-**2** and its enantiomer were observed in the fractions from $t_R = 22.00$ to 23.50 min and from $t_R = 24.50$ to 25.50 min. Components C and D were, thus, confirmed to be (3*R*6*S*)-**2** and (3*S*6*S*)-**2**, respectively.

Field Attraction of P. nuda. Field tests were conducted at Naha, Okinawa, from late October to early December 2000. Male catches were observed mainly from 08:00 to 09:00 hr. Apparently, more *P. nuda* males were captured with

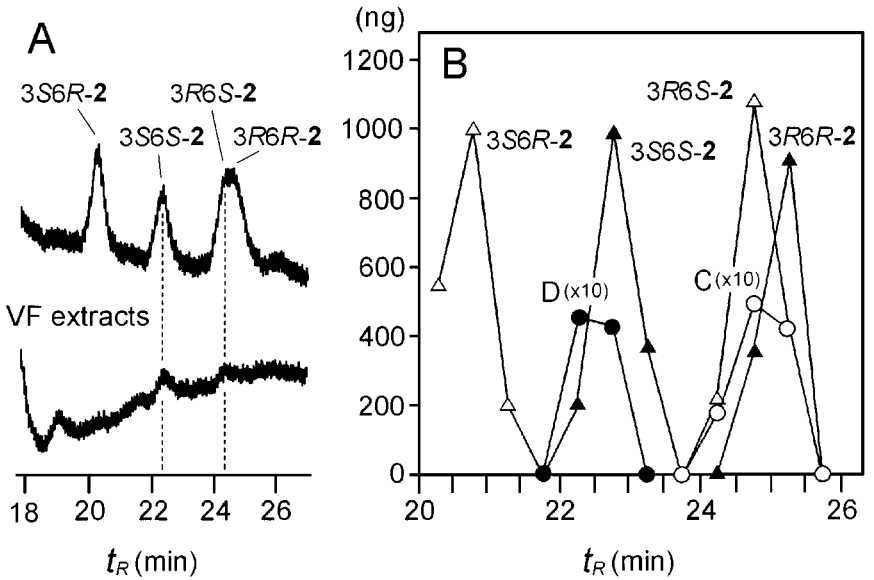

FIG. 5. HPLC analyses of components C and D in the 20% fraction of the virgin female extracts and a mixture of authentic isomers of diepoxyhenicosene (**2**) (A) and quantitative GC analyses of the HPLC fractions (B)

500:20:30 μg/rubber septum blends of (6*S*)-**1b**, (3*R*6*S*)-**2**, and either (3*S*6*S*)-**2** or (3*R*6*R*)-**2** than with the other blends, although the difference was not always significant (Figure 6). A small number of males was captured with (6*S*)-**1b** alone, but there were no captures with the blends containing (6*R*)-**1b**. To determine which minor diepoxide component is synergistic, 50:2 or 50:3 μg/paper pad blends of (6*S*)-**1b** and one stereoisomer of diepoxide components (**2**) were examined. Significantly more males were captured when either (3*R*6*S*)-**2** or (3*S*6*S*)-**2** was blended with (6*S*)-**1b**, whereas blends of (6*S*)-**1b** with either (3*S*6*R*)-**2** or (3*R*6*S*)-**2** were equivalent to (6*S*)-**1b** alone (Figure 7A). However, the synergistic effect of single diepoxide components did not increase when the two diepoxide components were blended together in a subsequent test (Figure 7B). In this test, no males were captured with the single diepoxide components (3*R*6*S*)-**2** or (3*S*6*S*)-**2**. A small number of males were captured with (6*S*)-**1b** alone (Figure 8A,B). These observations confirmed that (6*S*)-**1b** and either one or both of the minor diepoxides, (3*R*6*S*)-**2** and (3*S*6*S*)-**2**, are the sex pheromone components of *P. nuda.*

Field Attraction of Noctuid Hypocala rostrata. H. rostrata (Fabricius) (Lepidopera: Noctuidae) males were frequently captured with the traps baited with the synthetic compounds loaded on rubber septa (Figure 8). Captures were similar to those of *P. nuda* (Figure 6): they apparently occurred with formulations

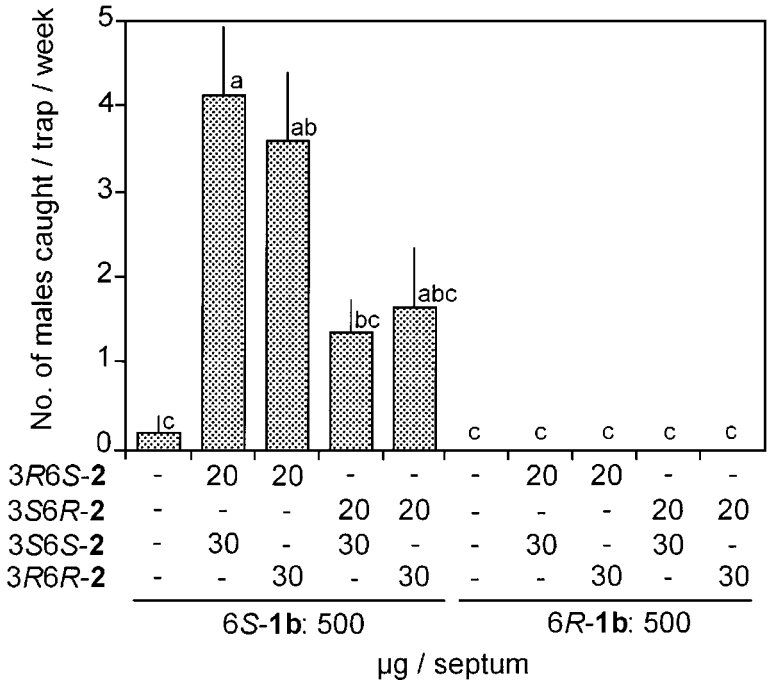

FIG. 6. Captures of male *P. nuda* with blends of stereoisomers of (3*Z*,9*Z*)-*cis*-6,7-epoxyhenicosa-3,9-diene (**1b**) and (9*Z*)-*cis*-3,4-*cis*-6,7-diepoxyhenicos-9-ene (**2**). Values are means and standard errors (SE) of pooled catches for one trap for six weeks (= 6 replications) from October 26 to December 2, 2000. Means capped with the same letter are not significantly different ($P > 0.05$; see text for details of statistical analyses). (6*S*)-**1b** and (6*R*)-**1b** are 6*S*,7*R* and 6*R*,7*S* isomers of **1b**, respectively, and (3*R*6*S*)-**2**, (3*S*6*R*)-**2**, (3*S*6*S*)-**2**, and (3*R*6*R*)-**2** are (3*R*,4*S*,6*S*,7*R*), (3*S*,4*R*,6*R*,7*S*), (3*S*,4*R*,6*S*,7*R*), and (3*R*,4*S*,6*R*,7*S*) isomers of **2**, respectively.

that contained (6*S*)-**1b**. Formulations with antipode failed to yield any captures. Captures with (6*S*)-**1b** combined with either (3*R*6*S*)-**2** or (3*S*6*S*)-**2** were greater than with (6*S*)-**1b** alone but the difference was not significant.

DISCUSSION

Four EAG-active components in the extracts of abdominal tips of *P. nuda* females were identified as (3*Z*,9*Z*)-6,7-epoxyicosa-3,9-diene (**1a**), (3*Z*,6*S*,7*R*,9*Z*)-6,7-epoxyhenicosa-3,9-diene [(6S)-**1b**], (3*R*,4*S*,6*S*,7*R*,9*Z*)-3,4-6,7-diepoxyhenicos-9-ene [(3*R*6*S*)-**2**] and its (3*S*,4*R*,6*S*,7*R*,9*Z*) isomer [(3*S*6*S*)-**2**], by means of chemical analyses including GC-MS, chemical derivatization, syntheses, and

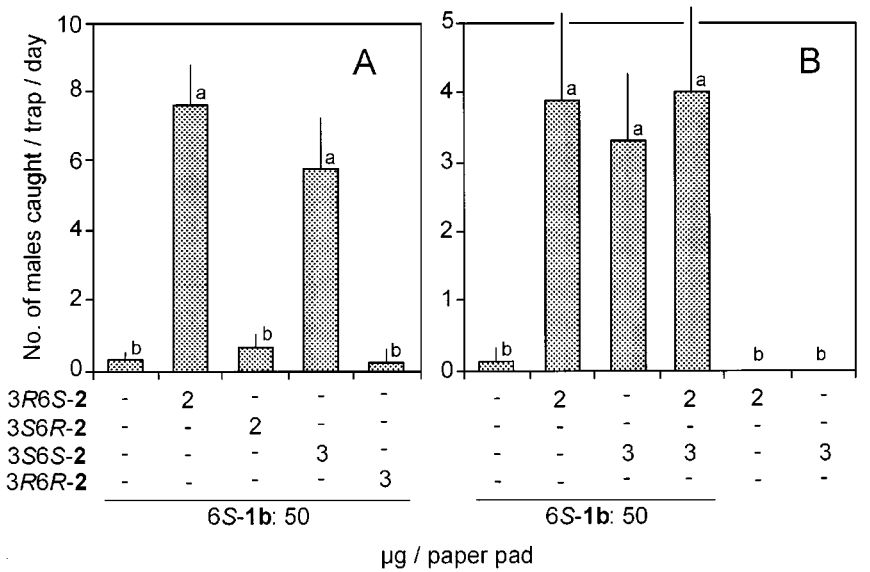

FIG. 7. Captures of male *P. nuda* with blends of (3*Z*,6*S*,7*R*,9*Z*)-6,7-epoxyhenicosa-3,9-diene [(6*S*)-**1b**] and stereoisomers of (9*Z*)-*cis*-3,4-*cis*-6,7-diepoxyhenicos-9-ene (**2**). Values are means and SE for one trap for five days (= 5 replications) for every five days between November 16 and 23 (A) and from November 26 to 30 (B) 2000. For abbreviations of compounds and statistical analyses, see Figure 6 legend.

chiral HPLC. (6*S*)-**1b** was shown to be an essential component for male attraction in the field experiment, and either or both diastereomers of **2** were synergistic (Figures 7 and 8). These C_{21} components were, thus, confirmed to be sex pheromone components of *P. nuda*. However, details of the stereochemistry of the minor C_{20} component **1a** and the attractiveness of blends of synthetic compounds that include enantiomers of **1a** to compete with that of virgin females are still unknown.

Both diastereomers found in the extract of the sex pheromone gland elicited equal male antenna responses (Figure 3B) and equally increased male catch when blended with **1b** (Figure 7B). It is interesting that the two diepoxide diastereomers act neither additively nor synergistically, but the presence of either is equivalent to the presence of both in male attraction. Similar redundancy between enantiomers has been observed in a lymantriid, *Euproctis pseudoconspersa*, in which females release the *R* enantiomer (Ichikawa et al., 1995), and the male antenna show significantly greater EAG responses to the *R* than the *S* enantiomer (Wakamura et al., 1996). In the field, however, slightly more males were attracted with the *R* enantiomer (Japan: Wakamura et al., 1996; China: Zhao et al., 1998).

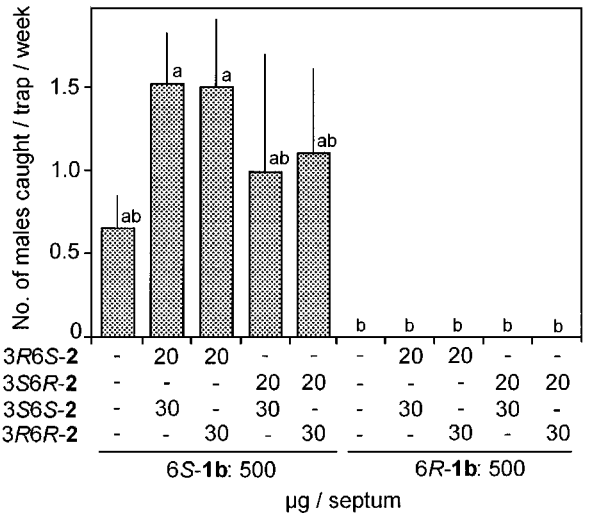

FIG. 8. Captures of male *Hypocala rostrata* with blends of stereoisomers of (3*Z*,9*Z*)-*cis*-6,7-epoxyhenicosa-3,9-diene (**1b**) and (9*Z*)-*cis*-3,4-*cis*-6,7-diepoxyhenicos-9-ene (**2**). Values are means of pooled catches for one trap for six weeks (= 6 replications) from October 26 to December 2, 2000. For abbreviations of compounds and statistical analyses, see Figure 6 legend.

In *Trichoplusia ni* (Hübner) (Noctuidae), a neurophysiological study suggested that redundancy occurs at the receptor level on neighboring dendrites (Todd et al., 1995). In *P. nuda*, chirality of one epoxide group at the 6,7 position in **1b** and **2** seems to be strictly discriminated both in production by the female (Figures 4 and 5) and in response by male antenna (Figures 3, 6, and 7), while that at the 3,4 position does not in either or both sexes. It is also interesting that redundancy might occur in biosynthesis in the female pheromone gland and/or in perception by receptors on male antenna.

Males of a noctuid moth *Hypocala rostrata* (Fabricius) were also captured with the blends containing (6*S*)-**1b** (Figure 8). This species and *P. nuda* probably share (6*S*)-**1b** as a sex pheromone component. Capture of *H. rostrata*, however, occurred during the night (the exact time is unknown) and contrasted to the morning captures of *P. nuda*. The mating time is probably different for these two species. It would be interesting to study whether the diepoxide compounds have any effect on male catches of *H. rostrata*.

The major component (6*S*)-**1b** has been identified as a sex pheromone component from *Tetanolita mynesalis* (Walker) (Noctuidae) (Haynes et al., 1996). In field screening tests conducted in Canada, males of *Idia americalis* (Guenée), *Bleptina caradrinalis* (Guenée) (both Noctuidae), *Xanthorhoe munitata* Hübner, *X.*

abrasaria aquilonaria (Herrich-Schäffer), and *X. ferrugata* (Clerck) (all Geometriidae) were captured with blends containing (6*S*)-**1b** (Millar et al., 1991). In Japan, males of *Paragabora flavemacula* (Oberthür) (Noctuidae) were captured with the corresponding racemic mixture (Ando et al., 1993). Probably this is the first case in which (6*S*)-**1b** was found in families other than Noctuidae and Geomtriidae.

Diepoxide pheromone components were first identified from *Leucoma salicis* L. (Lymantriidae): (3*Z*)-*cis*-6,7-*cis*-9,10-diepoxyhenicos-3-ene (Gries et al., 1997a). The absolute configuration has not been determined. The minor diastereomers (3*R*,6*S*)-**2** and (3*S*,6*S*)-**2** are, therefore, probably newly recognized compounds as sex pheromone components in Lymantriidae as well as in Lepidoptera. The addition of these findings has certainly increased the diversity of known pheromone chemicals in Lymantriidae.

In this study, we used only chiral compounds for the field tests, so the activity of the racemic mixture still needs to be evaluated. Limited amounts of chiral compound compelled us to use small filter paper sheets instead of rubber septa as release devices. In our experience, the filter paper-sheet may release larger amounts of chemicals than rubber septa, but effective duration is too short for monitoring use (effective for only one or two days with *P. nuda*). Daily trap catches seemed several times greater with ca. 50 μg of chemicals treated on filter paper pads (Figures 8) than with 550 μg on rubber septa (Figure 6), although direct comparison was inadequate. Nevertheless, this suggested that more captures would occur when larger amounts of chemicals are loaded on rubber septa.

Acknowledgments—We thank Dr. S. Sugi for identification of *H. rostrata* and Dr. T. Akino for critical reading of the manuscript. The manuscript was edited by Mr. S. Glushkoff.

(Received February 20, 2001; accepted November 10, 2001)

Abstract—Our objective was to identify the sex pheromone of *Lymantria lucescens* and *Lymantria serva* (Lepidoptera: Lymantriidae), whose larvae defoliate, respectively, *Quercus* spp. in temperate regions and *Ficus* spp. in the subtropics. Coupled gas chromatographic-electroantennographic (GC-EAD) detection analyses of pheromone gland extracts revealed one EAD active compound produced by female *L. lucescens* and by female *L. serva*. This was identified as 2-methyl-(*Z*)-7-octadecene (2me-*Z*7-18Hy) by retention index calculations on DB-5, DB-23, and DB-210 columns and by comparative GC-mass spectrometric (MS) and GC-EAD analyses of the insect-produced candidate pheromone and synthetic 2me-*Z*7-18Hy. In field experiments, traps baited with 2me-*Z*7-18Hy captured male *L. lucescens* near Toyota City, Japan, and male *L. serva* in Taipei, Taiwan. Allopatric distribution of *L. lucescens* and *L. serva* seems to allow both species to use the same sex pheromone without compromising its specificity.

Key Words—Lymantriidae, *Lymantria lucescens*, *Lymantria serva*, sex pheromone, reproductive isolation, 2-methyl-(*Z*)-7-octadecene, (+)-disparlure, (−)-disparlure, (+)-monachalure, (−)-monachalure, (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane, (7*S*,8*R*)-*cis*-7,8-epoxy-2-methyloctadecane, (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane, (7*S*,8*R*)-*cis*-7,8-epoxy-octadecane.

INTRODUCTION

Lymantria lucescens (Lepidoptera: Lymantriidae) is a temperate species present on the islands of Hokkaido, Honshu, and Kyushu of Japan (Inoue, 1957), and in Korea (Nam and Kim, 1981; P.W.S., unpublished). Larvae feed on oak trees, *Quercus* spp. (Fagaceae). *Lymantria serva* is a subtropical species known to occur in Taiwan (Kishida, 1992), southern China (Collenette, 1933; Zhao, 1982), including Hong Kong (R. Kendrick, personal communication 1999), Nepal (Kishida, 1995), and India (Gupta, 1992). In Taiwan, it appears to have two generations per year. Larvae feed on several species of *Ficus* (Moraceae).

Schaefer and Kishida (1999) captured male *L. lucescens* in sticky traps baited with (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [(+)-disparlure], (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane [(+)-monachalure], and 2-methyl-(*Z*)-7-octadecene (2me-*Z*7-18Hy), sex pheromone components of the nun moth, *L. monacha* (Bierl et al., 1975; Klimetzek et al., 1976; Grant et al., 1996; Gries et al., 1996). Either or all of these compounds could be pheromone components of *L. lucescens*. No attractant was known for *L. serva.*

A moderate population density of *L. serva* in Taipei, Taiwan (1996–1999) and an outbreak population of *L. lucescens* near Toyota City, Japan (2000) allowed us to field collect larvae and to laboratory-rear them to adults for pheromone analyses. We report identification and field testing of the sex phermone of *L. lucescens* and *L. serva.*

METHODS AND MATERIALS

Experimental Insects. Between 1996 and 1999, *L. serva* larvae or pupae were collected on *Ficus microcarpa* in a schoolyard in Taipei, Taiwan and either hand-carried or shipped to the USDA Quarantine Facility in Newark, Delaware, USA. From these shipments, two mated females were reared and their egg masses obtained. Because neonate larvae fed only reluctantly on ornamental *Ficus* spp., they were offered and accepted lichens from local Newark tree trunks before feeding on *Ficus microcarpa*, which they preferred over *F. elastica*. Despite these diet adjustments, larvae developed slowly, and only a few specimens reached the adult stage.

Between May 27 and 28, 2000, near Toyota, Japan, 326 intermediate stage larva *L. lucescens* were collected on foliage of oak trees, including *Quercus variabilis*, *Q. serrata*, and *Q. glauca* (all new host records). Larvae of the gypsy moth, *Lymantria dispar*, and pink gypsy moth, *L. mathura*, were feeding concomitantly on the same trees. Larvae of *L. lucescens* were reared to adults at Tokyo University of Pharmacy and Life Science, and in the Quarantine Facility in Newark.

Extraction and Analyses of Pheromone. Abdominal tips with pheromone glands of calling, 2- to 3-day-old females were removed and extracted for

15–30 min in HPLC grade hexane. Ampuoles with the supernatant of pheromone extracts and male pupae were sent by courier to Simon Fraser University.

Aliquots of <0.5 female equivalents (FE) (*L. serva*) and >1 FE (*L. lucescens*) of pheromone gland extracts were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975) with a Hewlett Packard (HP) 5890A gas chromatograph equipped with a fused silica column (30 m $\times$ 0.25 or 0.32 mm ID) coated with either DB-210, DB-5, or DB-23 (J&W Scientific, Folsom, California, USA). GC-EAD analyses were replicated twice (*L. serva*) and three to five times (*L. lucescens*) with each of these fused silica columns. GC-mass spectra of synthetic or insect-produced compounds in full-scan electron ionization mode were obtained from a Varian Saturn II Ion Trap GC-MS fitted with the above-referenced DB-5 column.

Field Experiments. Field experiments were conducted in 2000 in the Botanical Garden of Taipei (25°2′N, 121°30′E) and in a mixed oak forest near Toyota (35°8′N, 137°11′E). Delta-type traps made from two-liter milk cartons (Gray et al., 1984) were coated with Tanglefoot (The Tanglefoot Company, Grand Rapids, Michigan, USA), and suspended from trees $\sim$2 m above ground in complete randomized blocks with trap spacings of 15–20 m. Traps were baited with gray sleeve stoppers (The West Company, Lionville, Pennsylvania, USA) impreganted with test chemicals in HPLC grade hexane.

Experiments 1 and 2 and 3–8 were conducted with *L. serva* and *L. lucescens*, respectively. Although 2me-*Z*7-18Hy was the only EAD-active candidate pheromone component in both species, experiments also assessed other conceivable candidate pheromone components in combination with 2me-*Z*7-18Hy or singly, including disparlure (the corresponding epoxide of 2me-*Z*7-18Hy; experiments 1, 2, 7), 2-methyl-(*Z*)-7-heptadecene (2me-*Z*7-17Hy, the lower homolog of 2me-*Z*7-18Hy; experiment 3), and (*Z*)-7-octadecene (*Z*7-18Hy, the straight chain equivalent of 2me-*Z*7-18Hy; experiment 4). Both (+)- and (−)-monachalure, which are components in the volatile blend of *L. monacha* (Gries et al., 1996), were tested as potential synomonal repellents for *L. lucescens* (experiment 6). Experiment 5 tested increasing quantities of 2me-*Z*7-18Hy, and experiment 8 tested diel periodicity of response by male *L. lucescens* to pheromone-baited traps.

Various treatments in several experiments did not attract any male moths. Despite transformation, trap catch data were not normally distributed and were, thus, analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Bonferroni (Dunn) *t* test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS AND DISCUSSION

GC-EAD analyses of pheromone extract of female *L. serva* and *L. lucescens* (Figure 1) revealed a single component that consistently elicited responses from

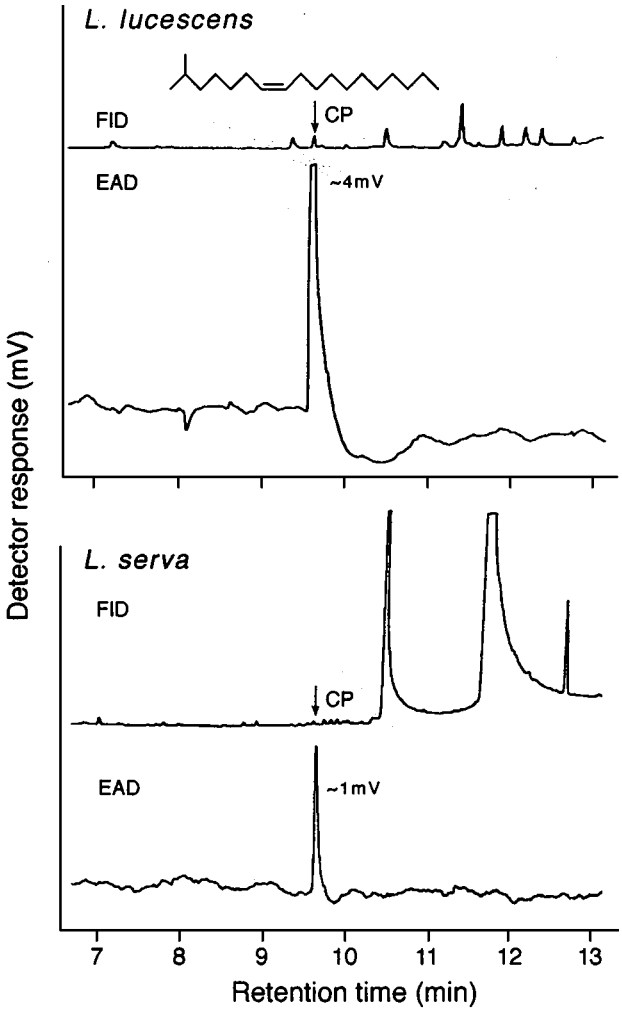

FIG. 1. Top: Flame-ionization detector (FID) and electroantennographic detector (EAD: male *L. lucescens* antenna) responses to >1 female equivalent (FE) of pheromone gland extract from female *L. lucescens*. Bottom: FID and EAD (male *L. serva* antenna) responses to <0.5 FE of pheromone gland extract from female *L. serva*. Chromatography: splitless injection; injector and FID detector: 240°C; DB-23 column; temperature program: 100°C (1 min), then 10°C/min to 200°C (5 min).

male antennae. Retention indices (Van den Dool and Kratz, 1963) and a mass spectrum of this compound in gland extracts of female *L. lucescens* indicated that it was 2-methyl-(*Z*)-7-octadecene (2me-*Z*7-18Hy). Identical retention and mass spectrometric characteristics as well as comparable EAD activity of the candidate pheromone (CP in Figure 1) and of synthetic 2me-*Z*7-18Hy confirmed this structural assignment.

In field experiments 1 and 2 with *L. serva* (Figure 2), 2me-*Z*7-18Hy, but not disparlure, attracted males. The attractiveness of 2me-*Z*7-18Hy was not affected by addition of either (+)-, (−)-, or (+)- plus (−)-disparlure (Figure 2, experiment 2). In experiments 3–5 with *L. lucescens* (Figure 3), 2me-*Z*7-18Hy attracted males, whereas 2me-*Z*7-17Hy or *Z*7-18Hy were not behaviorally active (experiments 3, 4). Increasing doses of 2me-*Z*7-18Hy resulted in increasing attractiveness of the lure (experiment 5). Addition of (+)- monachalure or (+)-disparlure to 2me-Z7-18Hy decreased attractiveness of the lure, whereas addition of (−)-monachalure or (−)-disparlure had no behavioral effect (Figure 4, experiments 6, 7). Male *L. lucescens* were captured in pheromone-baited traps between 20:00 and 23:00 hr (Figure 5, experiment 8).

Laboratory analyses of pheromone extract and field experiments provide conclusive evidence that 2me-*Z*7-18Hy is the single-component sex pheromone of both *L. serva* and *L. lucescens*. In GC-EAD recordings of pheromone extracts and in field experiments, it was the only compound that elicited antennal responses and attracted male *L. serva* and *L. lucescens*.

Considering that 2me-*Z*7-18Hy and (+)-disparlure are synergistic pheromone components in both *L. monacha* from Bohemia, Czech Republic (Grant et al., 1996; Gries et al., 1996) and *L. fumida* from Honshu, Japan (Schaefer et al., 1999), disparlure and other conceivable candidate pheromone components (2me-*Z*7-17Hy, *Z*7-18Hy) were also field-tested, but were found not to be attractive. On the contrary, (+)-disparlure reduced attraction of male *L. lucescens* to 2me-*Z*7-18Hy (Figure 4, experiment 7). We conclude that male *L. lucescens* are repelled by synomonal (+)-disparlure from *L. fumida* during synchronic communication periods (Figure 5), and by synomonal (+)-monachalure from *L. monacha* despite allochronic communication periods of *L. monacha* and *L. lucescens* (Figure 5).

The single-component sex pheromone (2me-*Z*7-18Hy) of *L. lucescens* differs from that of all other congeners and, when tested by itself, did not cross-attract any other lymantriid moth (this study; Schaefer et al., 1999; Gries et al., unpublished). With the specificity of 2me-*Z*7-18Hy, and with synomonal repellency of (+)-disparlure from *L. fumida* and (+)-monachalure from *L. monacha*, male *L. lucescens* may not have experienced selective pressure to evolve the ability to recognize (−)-disparlure as a reinforcing synomonal repellent (Figure 4, experiment 7).

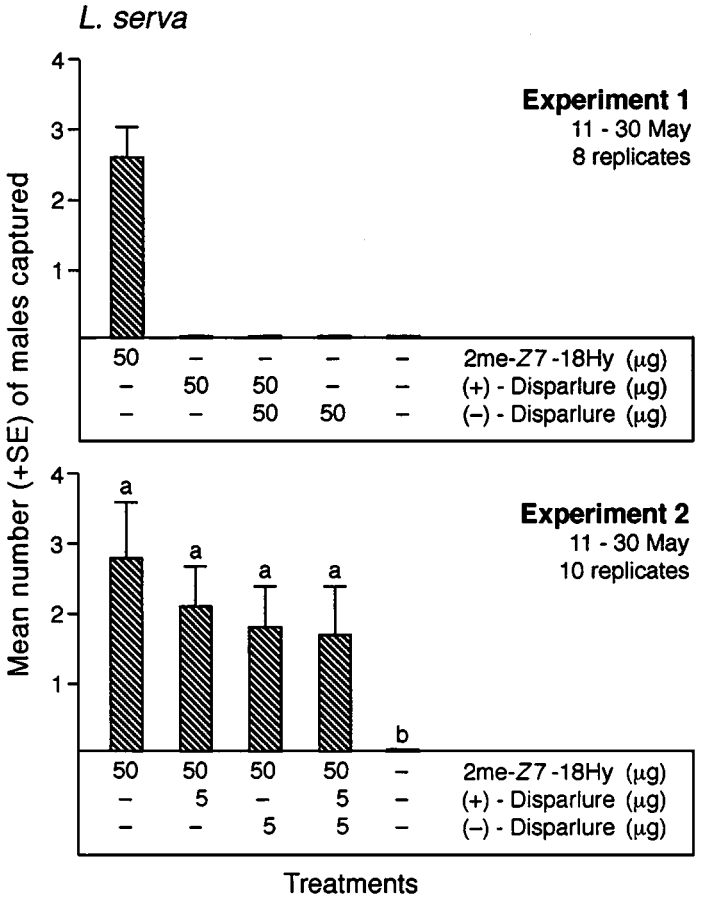

FIG. 2. Captures of male *L. serva* in experiments 1 and 2 in sticky Delta traps baited with test chemicals singly and in combination. Botanical Garden, Taipei, Taiwan. In experiment 1, attractiveness of only one treatment did not warrant statistical analyses of data. In experiment 2, bars with different superscript letters are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Student-Newman-Keuls test) (Zar, 1984), $P < 0.05$.

Allopatric distribution of *L. lucescens* and *L. serva* seems to allow both species to use the same sex pheromone without compromising specificity. Response to sex pheromones from congeners seems to be affected by both the composition of the lymantriid community and communication channels of its member species. Synchronous communication periods of *L. fumida* and *L. lucescens* (Figure 5) may explain the reduced attraction of male *L. lucescens* to pheromonal

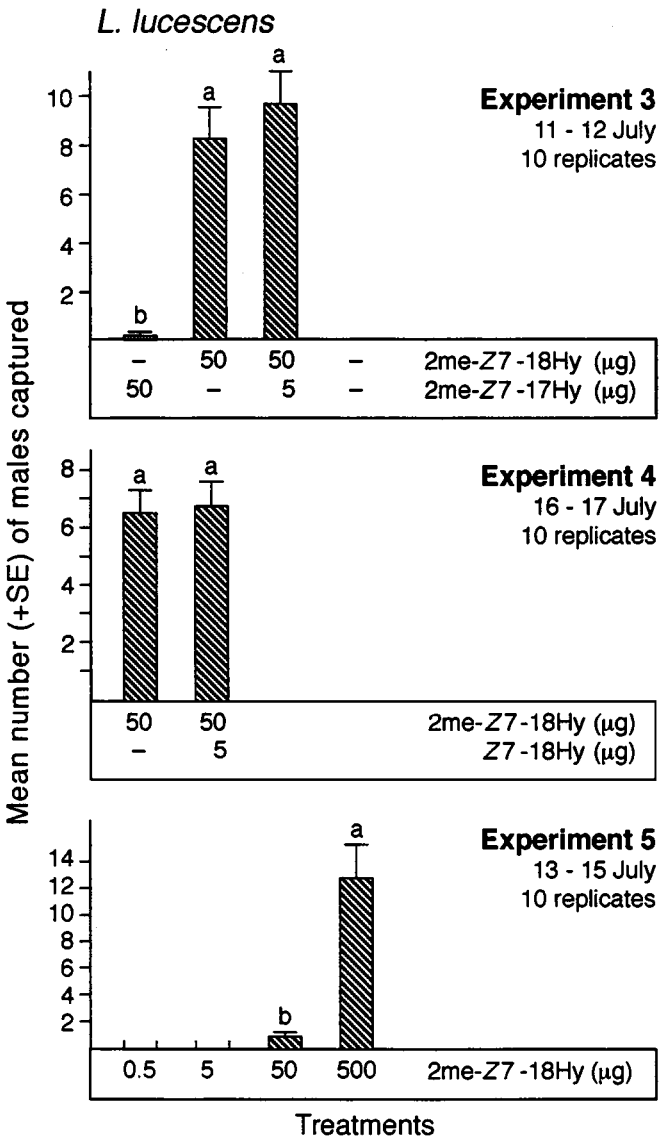

FIG. 3. Captures of male *L. lucescens* in experiments 3–5 in sticky Delta traps baited with candidate pheromone components singly and in combination. Oak (*Quercus* spp.) forest near Toyota City, Honshu, Japan. In each experiment, bars with different superscript letters are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Student-Newman Keul's test) (Zar, 1984), $P < 0.05$.

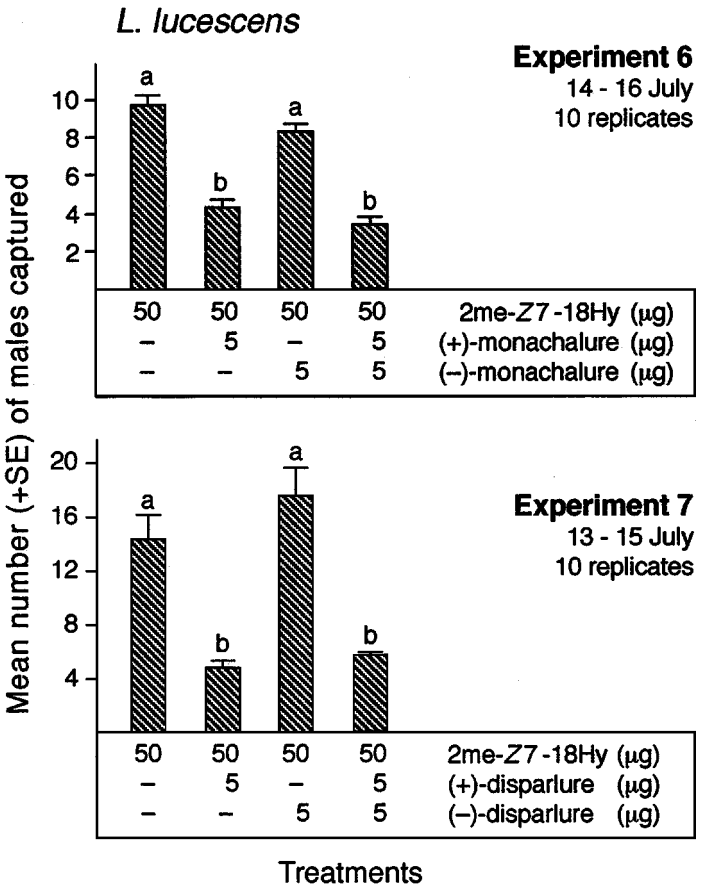

FIG. 4. Captures of male *L. lucescens* in experiments 6 and 7 in sticky Delta traps baited with the pheromone 2me-*Z*7-18Hy singly and in combination with candidate synomonal repellents. Oak (*Quercus* spp.) forest near Toyota, Honshu, Japan. In each experiment, bars with different superscript letters are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Student-Newman Keul's test) (Zar, 1984), $P < 0.05$.

2me-*Z*7-18Hy in the presence of (+)-disparlure (Figure 4, experiment 7), the major pheromone component of *L. fumida* (Schaefer et al., 1999). With no such effect observed in the experiment with *L. serva* (Figure 2), there is not likely a congener in the *L. serva* community in Taiwan that uses (+)-disparlure as a pheromone component within the communication period of *L. serva.* If true, our data support the hypothesis that community composition is a "biology factor" that affects

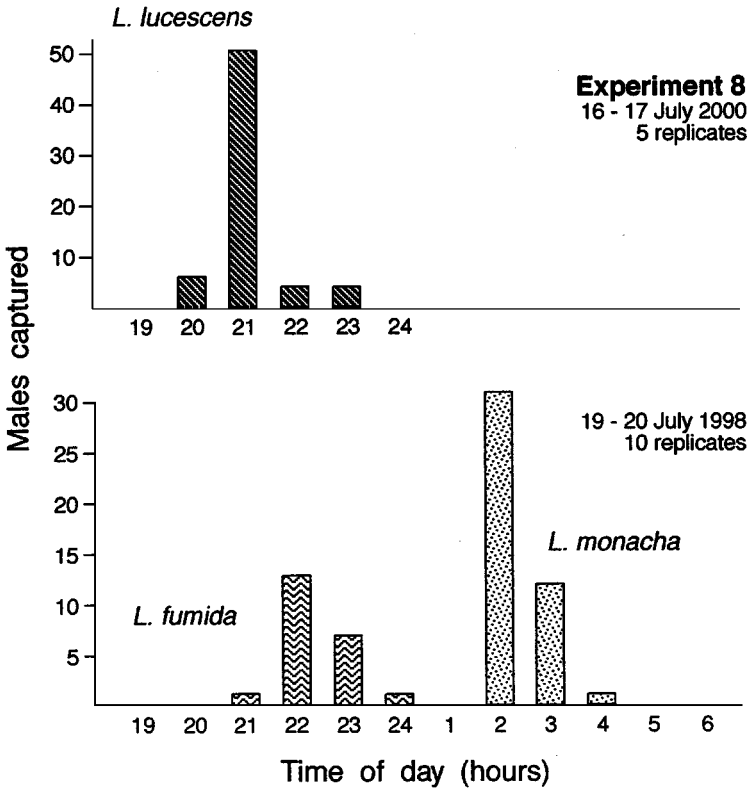

FIG. 5. Top: Hourly recording of captures of male *L. lucescens* in sticky Delta traps ($N = 5$) spaced 50 m apart and baited with 2-methyl-(*Z*)-7-octadecene (500 μg). Oak forest near Toyota, southern Honshu, Japan. Bottom: Representative hourly recording of captures of male *L. fumida* and male *L. monacha* in sticky Delta traps baited with either (+)-disparlure (50 μg) and 2-methyl-(*Z*)-7-octadecene (5 μg) (for *L. fumida*) or with (+)-monachlure (50 μg), (+)-disparlure (5 μg), and 2-methyl-(*Z*)-7-octadecene (5 μg) (for *L. monacha*). Larch forest near the City of Morioka, northern Honshu, Japan. Traps with baits for *L. fumida* ($N = 10$) or *L. monacha* ($N = 10$) were alternated at 15- to 20-m intervals (adapted from Schaefer et al., 1999).

recognition and evolution of intra- and interspecific communication signals in the Lepidoptera (Linn and Roelofs, 1995).

Acknowledgments—We thank Susan Barth for technical assistance. This research was supported, in part, by grants from Global Forest (GS-18-1999-15), the Department of Food and Agriculture, California (98-0508), and the Japanese Ministry of Education, Science, Sports and Culture (fund 12440220). This paper is contribution No. 179 of the Taiwan Forestry Research Institute.

(Received May 25, 2001; accepted November 12, 2001)

Abstract—Laboratory and field investigations were carried out to investigate the nature and role of the male pheromone emitted by the Dynast beetle *Scapanes australis* and to develop a mass trapping technique against this major coconut pest in Papua New Guinea. We report the biological data obtained from natural and synthetic pheromone, previously described as an 84:12:4 (w/w) mixture of 2-butanol (**1**), 3-hydoxy-2-butanone (**2**), and 2,3-butanediol (**3**). EAG recordings from natural and synthetic pheromone and a pitfall olfactometer were poorly informative. In contrast, extensive field trapping trials with various synthetic pheromone mixtures and doses showed that **1** and **2** (formulated in polyethylene sachets in 90:5 v/v ratio) were necessary and sufficient for optimum long-range attraction. Beetles were captured in traps baited with racemic **1** plus **2**, with or without a stereoisomer mixture of **3** (2.5- to 2500-mg/day doses). Plant pieces, either sugarcane or coconut, enhanced captures by the synthetic pheromone, which was active alone. Traps with the pheromone caught both sexes in a 3:2 female–male ratio. A pheromone-based mass trapping led to the capture

of 2173 beetles in 14 traps surrounding 40 ha of a cocoa-coconut plantation. The captures followed a log-linear decrease during the 125-week trapping program. The role of the male pheromone and its potential for crop protection are discussed.

Key Words—Coleoptera, Scarabaeidae, *Scapanes*, aggregation pheromone, EAG, field trapping, coconut pest.

INTRODUCTION

Scapanes australis Bsdv. (Coleoptera, Scarabaeidae, Dynastinae) is a 4- to 6-cm long horned beetle and a major coconut pest endemic in Papua New Guinea (PNG), the Solomon Islands, and Indonesia (Irian Jaya); (Bedford, 1976; Dechambre, 1995). The adults mine galleries to feed in the bases of fronds where they hide during daytime. Given their size, they frequently destroy the growth point in young coconut palms. On bigger palms, the damage attracts black palm weevils (BPW), *Rhynchophorus bilineatus* (Montr.), which lay eggs. The weevil larvae cause new damage, leading inevitably to the death of the palms. In East New Britain (ENB) province of PNG, the combined *S. australis*–BPW attacks are so common that coconut replanting has become impossible for the last 20 years. Neither chemical nor biological control of *S. australis* has been effective to date because of cost, the risks to human health, and the lack of efficient pathogens and predators (Beaudoin-Ollivier et al., 1999). A prospective way of reducing *S. australis* primary damage is to eliminate the adults by selective trapping with attractants. Great hopes have been placed in this system, for pheromones have been recently identified in the Dynastinae *Oryctes monoceros* (Oliv.) and *Oryctes rhinoceros* (L.) (Gries et al., 1994; Hallet et al., 1995; Morin et al., 1996), which are now used in South-Eastern Asia (Ho, 1996; Chung, 1997). More recently, a particular male calling behavior has been described in *S. australis* (Prior et al., 2000): at nightfall, the males move to the gallery entrance, take up a special position with the abdomen and rear legs raised outwards while the head is in the gallery, and emit a liquid secretion, rhythmically smeared onto the pygidium by crossing the rear legs. In field assays with caged insects on young coconut palms, attraction of both sexes to calling males was evidenced. The attraction was assumed to be elicited by a pheromone from the male secretion. The solid phase microextraction (SPME) associated with a specific protocol allowed the identification of three highly volatile compounds that characterized the male secretion (Rochat et al., 2000a). These were **1**: 2-butanol [= *sec*-butanol; in a 67:33 (*R*)-(−):(*S*)-(+) ratio], **2**: acetoin (= 3-hydroxy-2-butanone), and **3**: 2,3-butanediol [in a 43:17:40 (*R*, *R*)-(−):(*S*, *S*)-(+):*meso* ratio], emitted in a 84:12:4 w/w ratio in the headspace. We examined the pheromone properties of the male secretion and of synthetic **1–3**. The ecological role of the pheromone and its potential for pest control are discussed.

METHODS AND MATERIALS

Synthetic Chemicals

(±)-2-Butanol (>99% GC purity; Aldrich Chemical Co., Gillingham-Dorset, UK), acetoin (>97% GC; crystallized mixture of dimer and monomer; Fluka Chemie AG, Buchs, Switzerland), and (±)-2,3-butanediol (>98% GC; mixture of (2*R**,3*R**) and *meso* forms; Aldrich Chemical Co., Gillingham-Dorset, UK) were used for laboratory and field experiments. Acetoin was heated to melt. A reference 90:5:5 (v/v) **1:2:3** mixture was designed using SPME to reproduce the headspace ratio (84:12:4, w/w) obtained from the male secretion (Rochat et al., 2000a). Ethanol (96%: EtOH) and ethyl acetate (EtAc) (>99% GC; Ajax Laboratory Chemicals, Australia) were used to prepare the kairomone mixtures A–C. A is a 50:50 (v/v) EtOH:EtAc mixture. B is based on a 42:47 (v/v) EtOH:EtAc mixture plus 11% of 14 compounds identified in the volatiles released by sugarcane and coconut (described under reference G in Rochat et al., 2000b). C is a 375:375:50:25:75:25:75 mixture of EtOH, EtAc, hexanol, guaiacol, 2-phenylethanol, phenol, and ethyl propionate. All minor compounds were commercial products as reported in Rochat et al. (2000b).

Collection and Preparation of the Natural Pheromone

Several types of samples were prepared in an initial process to study the pheromone.

Effluvia Collection. Effluvia were collected by passing a stream of purified air over activated charcoal (75 ml/min) into a 1-liter glass flask containing one insect (*S. australis* ssp. *grossepunctatus* (Stern.); CCRI Keravat Station, ENB, PNG). They were adsorbed onto 350-mg Supelpak-2 (Supelco). As it was not possible to maintain a calling male in the flask, collections were carried out in 3-hr sessions on several consecutive evenings, with one male extracted from its gallery while calling. For comparison, effluvia were collected at the same time from flasks containing one female or no insect (control). The adsorbent was rinsed with 1.1 ml dichloromethane. The samples were used in electroantennography.

Wiping Beetle Abdomens with Filter Papers. The filter papers were washed in a Soxhlet apparatus with hexane (Sigma, HPLC grade) prior to use. One paper was held with tweezers and wiped once over the tip of the abdomen of a calling male, then placed immediately in a sealed tube with 1 ml solvent: acetone or dichloromethane (HPLC grade). Samples were taken on several consecutive evenings from calling males artificially settled in coconut plants in the laboratory (PNG). The wiping operations were counted to establish a stimulus concentration: the number of filter papers per microliter of solvent. Although females did not adopt a calling behavior, samples were also taken from them for comparison.

Control samples (unwiped filter papers) were prepared. Two independent series of wipings were performed: one with 40-mm^2 papers on *S. a. grossepunctatus* individuals (CCRI Keravat Station, ENB) and used in electroantennography. The other one with 100-mm^2 papers on *S. a. australis* individuals (CCRI Steward Research Station, Madang) and used in olfactometry.

Capillary Collection of Male Secretion. Because organic extracts obtained by wiping and effluvia collections did not reveal male-specific compounds by gas chromatography (GC) and triggered weak EAG responses, the secretion emitted by 10 calling males (*S. a. grossepunctatus*; laboratory, France) was collected directly in 10-μl capillary glass tubes. These tubes were stored in a tight vial and kept at -12°C during the collection sessions (Rochat et al., 2000a). Male secretion from the various individuals were pooled, stored at -40°C, and used as a stimulus.

Olfactometer Experiments

These experiments were conducted at CCRI Steward Research Station on *S. a. australis* individuals (tested and bait) by using a two-choice pitfall olfactometer (45 cm diameter $\times$ 20 cm high) adapted from Rochat et al. (1991). The pits consisted of 600-ml glass beakers (15 cm high $\times$ 6.5 cm diam.). Beetles, collected from family palm plantations were kept in aerated plastic boxes with sugarcane pieces. Tests lasted 30 min. They were conducted during the 4 hr after nightfall using two olfactometers simultaneously in the laboratory ($27 \pm 1^\circ$C; $70 \pm 5\%$ relative humidity). Coconut stem pieces (10×5 cm) with an artificial gallery were placed in the pits when required. Responses of both sexes ($22 < N < 125$) in the following five experiments were recorded: 1, one male in coconut versus blank control; 2, one male in coconut versus coconut (control); 3, one female in coconut versus blank control; 4, coconut without insect versus blank control; and 5, one filter paper wiped with the male secretion versus an unwiped filter paper (control). Wiping procedures were done before the olfactometer tests and the filter papers were stored in 1 ml acetone at -10°C. The rareness of females found in the coconuts (Prior et al., 2000) explains the lower number of replicates performed with females and the use of some individuals two or three times in certain experiments (Figure 1). A test beetle was responding when it fell into one pit (choice). The repartition of the choices was compared using one-tailed binomial tests at 5%. The calling activity of the bait males was recorded in experiments 1 and 2. The proportions of responding beetles to calling and to noncalling bait males were compared using χ^2 tests.

Electroantennography

Electroantennograms were recorded from *S. a. grossepunctatus* individuals by using the same equipment as described for *O. rhinoceros* (Morin et al., 1996).

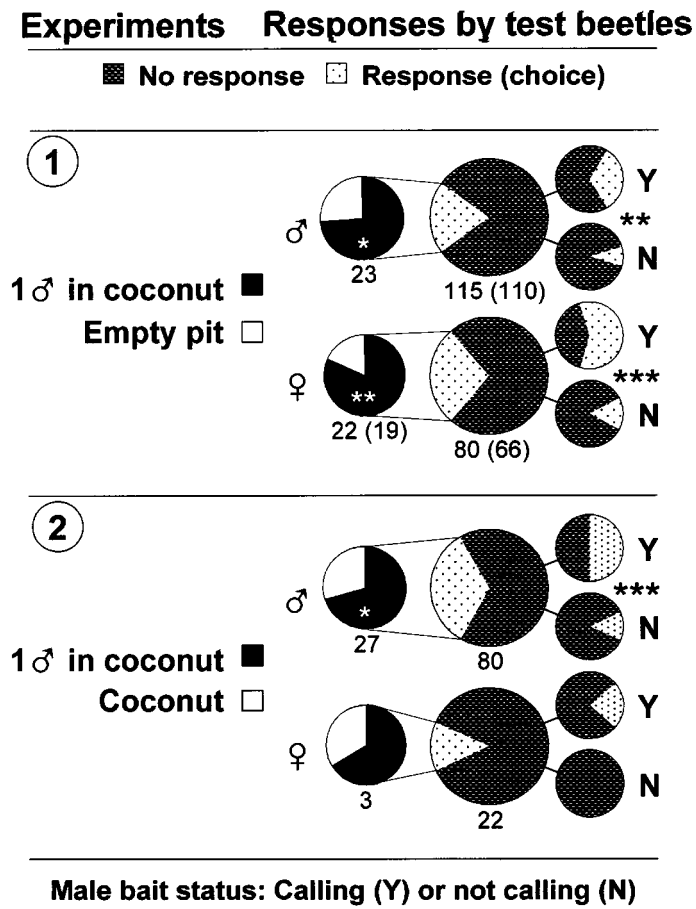

FIG. 1. Responses of *Scapanes a. australis* in five experiments (1–5) carried out in a two-choice pitfall olfactometer after 30 min. (CCRI Steward Research Station, Madang, PNG; April 1997–April 1998). Values under the pie charts (left to right) indicate the numbers of responses, of replicates and of individuals used (in parentheses). In experiments 1 and 2, the proportions of responding beetles to calling and to noncalling bait males are significantly different with $^{**}P < 0.01$ and $^{***}P < 0.001$ (χ^2 tests on contingency tables). The number of responses to the treatment is significantly greater than to the control at: $^{*}P < 0.05$, $^{**}P < 0.01$ and $^{***}P < 0.001$ (one-tailed binomial test).

A special restraining device held the insect vertically. Recording was carried out on antennae in situ. The three antenna lamellae were separated and a glass electrode was placed on the central lamella, while the reference electrode was pushed into the eye. The antenna was flushed with a permanent moistened airstream (400 ml/min).

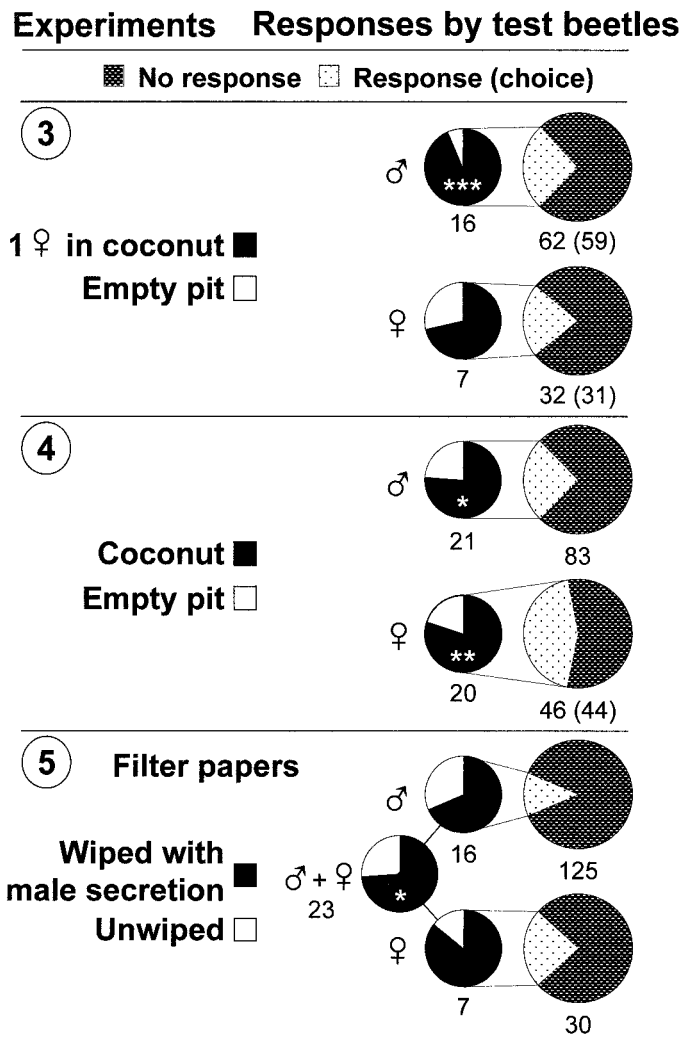

FIG. 1. Continued.

Three experiments were carried out. Experiment 6 compared the activities of various solvent extracts obtained from the effluvia collections and the wipings of abdomens on antennae from four males and four females. Experiment 7 established the responses to increasing doses of male secretion. Experiment 8 determined the responses to increasing doses (0.1, 1, 10, 100, and 1000 μg) of **1–3**, characteristic of the male secretion. The compounds were presented as 1-μl appropriate hexane solutions (hexane as control). Male secretion (10 μl) was used for comparison. As

it is an aqueous (natural) solution, a water control was also included. Experiments 7 and 8 were done only on female antennae ($N = 5$) due to a lack of males. Aliquots of the stimuli to be studied were deposited on filter papers inserted in Pasteur pipets just prior to the stimulation. The antennal responses were expressed as percentages of the amplitude measured in response to 10 μg *cis*-3-hexenol (relative EAGs) used as a reference (hexane solution). The samples were tested at a rate of 1 μl, representing 0.1 insect/wipe (wipings) and 0.1 insect/hr (effluvia). The male secretion was tested at doses of 0.1 (1 μl of a 10% solution in distilled water), 1, and 10 μl.

Statistical Analyses. The relative EAG responses were used for the calculations (STATITCF, 1991). In experiment 6, the responses to the male and female extracts were compared with the responses to the corresponding controls within each sex by Student's *t* tests. Data were processed by a one-way ANOVAs followed by a Newman-Keuls test at 5% (experiment 7) or by Dunnett's tests at 5% (experiment 8; solvent as control). The responses to the male secretion and to the water control were compared by Student's *t* tests for paired data.

Field Trapping Experiments

Semiochemical Dispensers. The characteristics of the semiochemical dispensers are listed in Table 2. They were stored at -10°C and weighed (mg precision) prior to, and at the end of, each replicate or experiment to determine the actual daily release rates of the chemicals. Details of the experiments are presented in Tables 1 and 2. All experiments were done in ENB and targeted *S. a. grossepunctatus*, except for experiments 10 and 14, done on the PNG mainland and targeting *S. a. australis*. The traps (standard) consisted of 18-liter plastic buckets with two large vents (10 $\times$ 15 cm) in the sides, with an inner plastic container (17 cm diam. $\times$ 19 cm high) perforated and fixed to the lid of the bucket (Kakul et al., 1999). All treatments (except as indicated) included three to four split sugarcane pieces. Sugarcane and one live male settled in a large sugarcane stalk when used were placed in the inner container and the semiochemical dispensers were hung outside. Traps were suspended 1 m from the ground on wood poles, or shading *Gliricidia sepium* (Jacq.), or cocoa trees after optimization (Kakul et al., 1999). Soapy water was poured into the bottom of the bucket to stop beetles from escaping. No insecticide was used. The traps were spaced 50 m apart except in experiments 10 and 14 (spaced 15 m apart). Two blocks were 100 m distant at minimum. Sugarcane was renewed and the treatments were rerandomized at each replicate (Table 1).

Chronology and Experimental Choices. To fit with the large amounts (up to 50 μl/hr) of male secretion emitted on calling, which was initially assumed to be pure pheromone, we first sought to achieve high diffusion ($\approx$1 g/day i.e., $\approx$40 mg/hr) of the synthetic **1:2:3** mixture, which was obtained with open flasks

TABLE 1. GENERAL CHARACTERISTICS OF NINE FIELD EXPERIMENTS TO TRAP *Scapanes australis* USING SYNTHETIC SEMIOCHEMICALS IN PAPUA NEW GUINEA FROM AUGUST 1998 TO FEBRUARY 2000

Experiment	Place	Date	Treatments compared[a]	Experimental design	Checks	Variable analyzed[b]

[a] Pheromone means a lure based on synthetic compounds **1** (2-butanol), **2** (3-hydroxy-2-butanone), or **3** (2,3-butanediol), identified in the secretion emitted by calling *Scapanes australis* males (Rochat et al., 2000a). See Table 2 for composition of pheromone lures. SC : Sugarcane. Co : coconut. A, B and C are synthetic mixtures based on ethanol plus ethyl acetate (at least 70% of the total and in a ca. 50:50 v/v ratio) plus various minor compounds identified as volatiles from palm and sugarcane decaying tissues (Rochat et al., 2000b).

[b] (Σ) cap.: (Sum of) captures; exp.: experiment.

[c] Mixed cocoa and coconut industrial plantation.

[d] Mixed coconut and betelnut (*Areca catechu L.*) palm family plantation.

(experiments 9 and 10). To avoid loss and contamination of the chemicals, the flasks were placed in the field only during the 3 hr covering the activity periods of the species (Prior et al., 2000). Captures were recorded only at that time. As the male secretion later proved not to be pure pheromone (Rochat et al., 2000a and unpublished), the suitability of heat-sealed polyethylene (PE) sachets to release the **1:2:3** mixture at lower doses was tested (experiment 11). The role played by each of compounds **1–3** was studied in experiment 12. The **1:2:3** mixture formulated in RS (Table 2) was kept as a reference, and all possible combinations of **1–3** were prepared by removing one or two components. Lures without **1** were formulated in PE sachets, whose characteristics were adjusted in the laboratory to obtain the desired diffusion rates (Table 2). Dose–capture effect was studied extensively with the **1:2:3** (experiment 13) and the **1:2** mixtures (experiments 15 and 16), both formulated in RS. In experiment 14, we studied the effect of removing the inner plastic containers from standard bucket traps. Finally, the effect of a coattractant with the pheromone was investigated (experiment 17). Two plant material (coconut bulb and sugarcane; ca. 250 g) and the synthetic chemical mixtures A–C, known as palm odor mimics in the palm weevil, *Rhynchophorus palmarum* (L.), (Rochat et al., 2000b and unpublished) were compared for their ability to increase *S. australis* response to the pheromone.

Statistical Analysis. Most data were processed by two-way ANOVAs (F1: bait; F2: replicate) on $\mathrm{Ln}(x + 1)$ transformed data (Table 1) (STATITCF, 1991). The means were compared by Newman-Keuls tests at 5%. Due to very low captures, elementary data were pooled in experiments 10, 14, and 16 and processed similarly or with a Student's t test.

Long-Term Mass Trapping Effect on S. australis grossepunctatus Population

This was estimated by recording the captures of beetles in 14 traps installed at the border of a 40 ha area at CCRI Tavilo Research Station (TRS) during 125 weeks (April 3, 1998–August 24, 2000). The traps were the standard devices previously described. The baits were one live male settled in a sugarcane piece during the first 60 weeks, then two synthetic pheromone dispensers (RS) filled with **1:2:3** mixture and releasing about 100 mg/day. The male baits were checked every one to two weeks, replaced when dead, and the sugarcane renewed. Pheromone dispensers were replaced when necessary.

RESULTS

Olfactometer Experiments. Regardless of the type of experiment or the sex tested, ca. 75% of the beetles did not respond in the olfactometer tests, exhibiting weak or no locomotor activity. Considering the beetles that responded

(Figure 1), both sexes responded to coconut without insect (male: $P = 0.013$; female: $P = 0.006$; experiment 4) and to one male in coconut (male: $P = 0.017$; female: $P = 0.002$; experiment 1) versus blank controls. Males, but not females, responded to one female in coconut ($P < 0.001$; experiment 3) versus a blank control and to one male in coconut ($P = 0.026$; experiment 2) versus coconut. In the two experiments where one male was used as bait, the proportions of responses (whatever the choice) were greater when the bait male adopted a calling behavior than when it did not (one male in coconut versus blank: male: $\chi^2 = 9.56$, 1 *df*, $P < 0.01$; female: $\chi^2 = 15.19$, 1 *df*, $P < 0.001$; one male in coconut versus coconut: male: $\chi^2 = 11.55$, 1 *df*, $P < 0.001$; experiments 1 and 2), except for females tested with one male in coconut versus coconut with a limited number of replicates ($\chi^2 = 0.84$, 1 *df*, $P > 0.05$; experiment 2). A nonsignificant trend for a preference for the filter papers wiped with male secretion versus the unwiped filter papers was observed for both sexes (male: $P = 0.10$; female: $P = 0.14$). The effect of the male secretion proved to be significant when analyzing the responses by both sexes pooled ($P = 0.017$; experiment 5).

Electroantennography. The wiping and effluvia extracts of male origin always triggered relative EAGs of greater amplitudes than the corresponding controls. The differences were significant in most cases (Figure 2). The EAG responses elicited

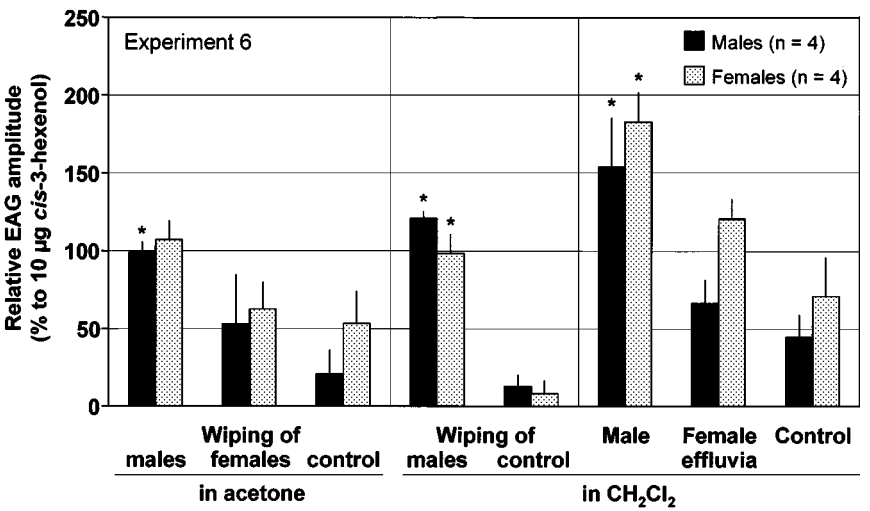

FIG. 2. Mean relative (% response to 10 μg *cis*-3-hexenol) electroantennogram responses of male and female *S. australis grossepunctatus* to wipings of male secretion (0.1 insect/wipe) and male effluvia (0.1 insect/hr) in 1-μl samples with respect to wipings and effluvia of females and corresponding solvent controls (experiment 6). *The differences with the corresponding controls are significant (Student's *t* tests at 5%).

by the extracts of female origin were not significantly different from the control. The profiles of responses by male and female antennae were similar (Figure 2). The male secretion released a log-linear dependent EAG response on the female antenna [$F(1,13) = 25.2$, $P < 0.001$; $r^2 = 0.66$], each dose releasing a significantly greater EAG than the lower one. The responses were greater than to pure air (control: 0.19 ± 0.04) at any doses. The mean relative EAG to 10 μl male secretion (0.94 ± 0.05) was of the same level as those recorded to extracts from wipings of males at 0.1 insect/wipe doses (1.07 ± 0.12 and 0.98 ± 0.12). A weak dose–response effect was recorded to acetoin: $F(5,20) = 5.52$, $P < 0.01$, and to 2,3-butanediol: $F(5,20) = 3.95$, $P < 0.05$, in the range tested (0.1 to 1000 μg on filter paper; Figure 3). Only the relative EAGs recorded to the highest dose tested were significantly greater than to hexane. The mean relative EAGs to every dose of acetoin and 2,3-butanediol were lower than to 1 μl male secretion. A more marked dose effect was recorded to 2-butanol: $F(5,20) = 57.38$, $P < 0.001$ (Figure 3). Relative EAGs to the 100 and 1000 μg doses were significantly greater than to hexane. One microliter of male secretion elicited a relative EAG intermediary with

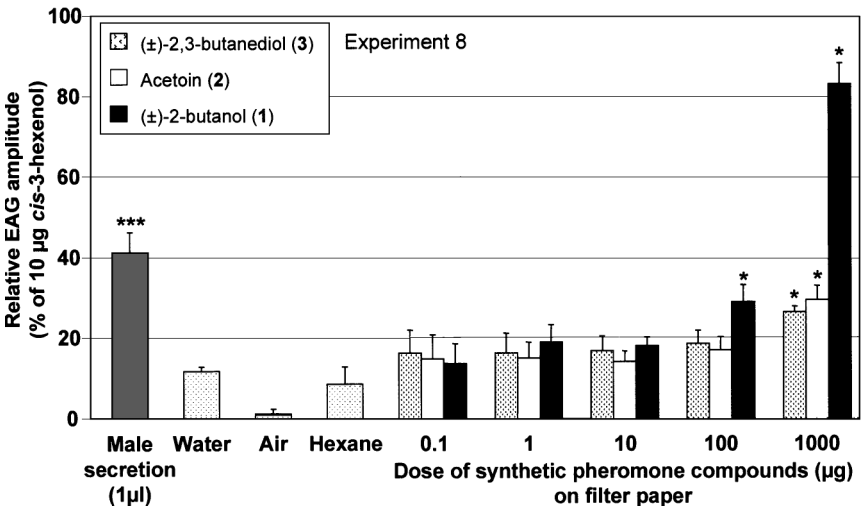

FIG. 3. Mean relative (% response to 10 μg *cis*-3-hexenol) electroantennogram responses of female *Scapanes australis grossepunctatus* ($N = 5$) to increasing doses of the synthetic components identified in the male secretion: **1**: (±)-2-butanol, **2**: acetoin, and **3**: (±)-2,3-butanediol (mixtures of stereo-isomers) diluted in hexane relative to 1 μl male secretion and controls (experiment 8). Doses are amounts put on a filter paper in 1 μl solution. Lines associated with bars represent the standard errors of the means. Synthetic chemicals: bars topped by one asterisk indicate responses different from the control (hexane; Dunnett's test at 5% after one-way ANOVAs). Male secretion is compared to distilled water by a Student's *t* test for paired data. ***Difference significant at $P < 0.001$.

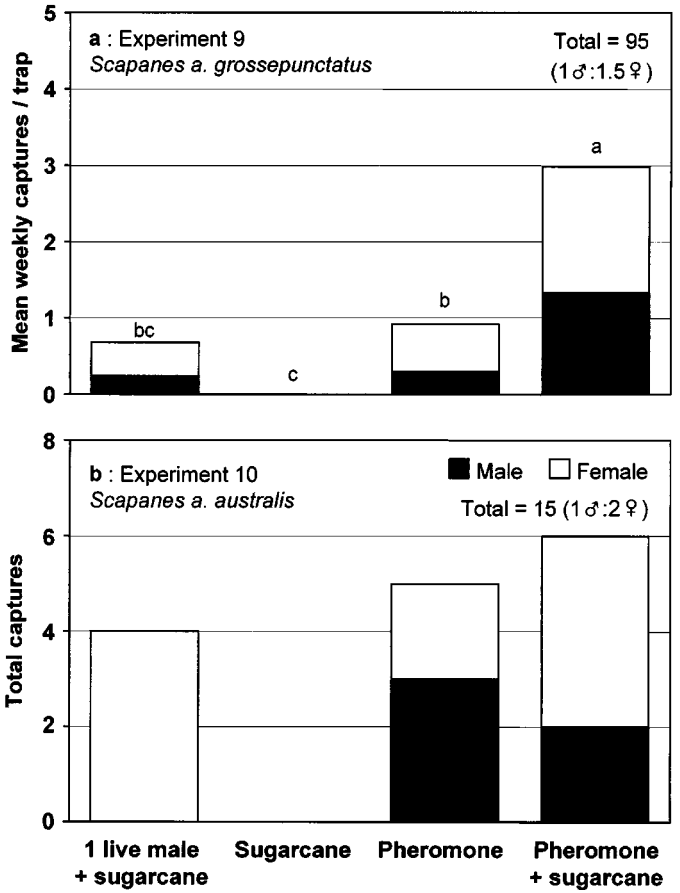

FIG. 4. Responses of *Scapanes australis* to traps baited with sugarcane, synthetic pheromone [90:5:5 v/v mixture of (±)-2-butanol, acetoin, and (±)-2,3-butanediol emitted at ca. 2.5 g/day from open polyethylene flasks], or both compared to traps baited with one live male in sugarcane. (a) Responses by *S. a. grossepunctatus* in CCRI Tavilo Research Station (experiment 9); (b) responses by *S. a. australis* in Malas (experiment 10). Treatments associated with same letters do not differ in effect based on ANOVAs followed by Newman-Keuls test at 5%. See Tables 1 and 2 for other data about experiments.

100 and 1000 μg 2-butanol, lower than in previous experiments but greater than the water control ($t = 6.74$, 4 *df*, two-tailed test, $P < 0.01$).

Field-Trapping Experiments. The actual release rates of the semiochemical dispensers used are detailed in Table 2. In experiment 9 (Figure 4a), the bait and replicate effects were significant: $F(3,77) = 22.02$, $P < 0.001$ and

$F(2,77) = 4.13$, $P < 0.05$, respectively. Both factors interacted: $F(6,77) = 4.41$, $P < 0.001$, the captures by the second replicate were twice as abundant as the others. **1:2:3** + SC caught more beetles (4×) than only SC (no capture) and male + SC control. Captures by only **1:2:3** were different from zero. Captures by only **1:2:3** and male + SC control were equivalent. The **1:2:3** mixture was emitted at a mean dose of 2500 mg/day. Captures in experiment 10 followed the same pattern as in experiment 9 (Figure 4b) with a similar pheromone release, but they were weak and no significant effect of the bait could be disclosed: $F(3,31) = 1,40$, $P > 0.2$.

In experiment 11 (Figure 5), the bait and replicate effects were significant: $F(3,77) = 13.95$ and $F(2,77) = 18.49$, respectively, $P < 0.001$. Both factors interacted, $F(6,77) = 4.56$, $P < 0.001$, due to contrasted levels of captures during the three replicates. **1:2:3** + SC either released by open flasks (103 mg/day) or the RS (61 mg/day) caught as many beetles and more (2×) than SC + **1:2:3** released

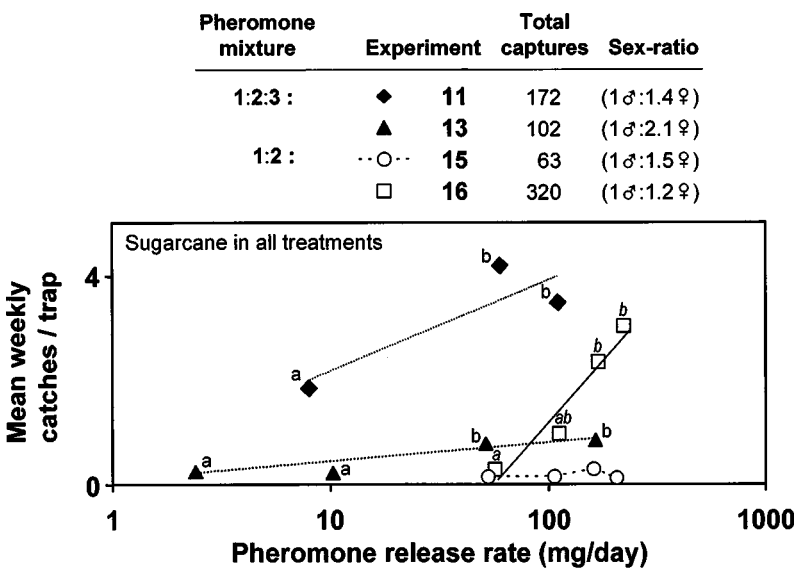

FIG. 5. Responses of *Scapanes australis grossepunctatus* to traps baited with various doses of ternary [**1:2:3**: (±)-2-butanol, acetoin, and (±)-2,3-butanediol in 90:5:5 v/v ratio] or binary [**1:2:** (±)-2-butanol and acetoin in 90:5 v/v ratio] synthetic pheromone mixtures plus sugarcane pieces during four experiments in East New Britain (PNG). The pheromone was formulated in heat-sealed polyethylene sachets except for the highest dose in experiment 11, a modified open polyethylene flask. See Table 2 for actual release rates and detail about dispensers. Experimental characteristics are given in Table 1. Within each experiment, doses associated with same letters led to equivalent captures based on an ANOVA followed by Newman-Keuls test at the 5% level.

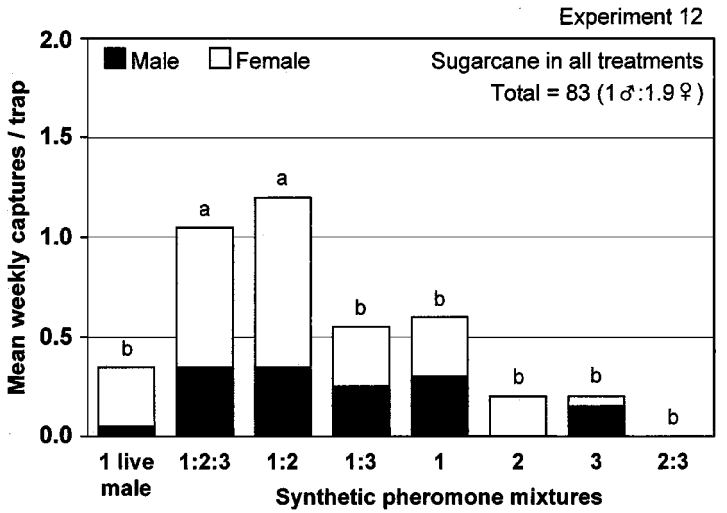

FIG. 6. Responses of *Scapanes australis grossepunctatus* to traps baited with various mixtures of synthetic (±)-2-butanol **(1)**, acetoin **(2)**, and (±)-2,3-butanol **(3)** obtained by removing one or two components from the complete mixture in 90:5:5 (v/v) ratio with respect to traps baited with one live male in sugarcane [experiment 12: CCRI Tavilo Research Station (TRS)]. Pheromone lures were formulated in heat-sealed polyethylene sachets (Table 2). Treatments associated with same letters do not differ in effect based on an ANOVA followed by Newman-Keuls test at 5%. See Table 1 for other data.

by the small sachet (8 mg/day). All treatments with **1**:**2**:**3** caught more beetles than the male + SC control. Release by the PE sachets was much less variable than by the open flasks.

In experiment 12 (Figure 6), the bait effect was significant: $F(7,124) = 7.34$, $P < 0.001$. Absence of **1** in the synthetic baits resulted in very low captures. The combinations of **1:2** + SC and **1:2:3** + SC caught more (2×) beetles than all other baits, including the male + SC control. The latter group had statistically equivalent effects. Addition of **3** to either **1** or **1:2** did not increase the captures. Baits with **1** emitted mean pheromone doses ranging from 53 to 71 mg/day.

In experiment 14, only 71 beetles (1 male: 1.4 females) were caught during 105 days in 16 traps. The captures were greater in traps with than without (0.43 vs 0.16 beetle/trap/week) the inner plastic boxes ($t = 2.63$, 12 *df*, $P = 0.011$, one-tailed test). The pheromone was emitted at 48 mg/day.

In the dose–response experiments (Figure 5), the dose effect was significant: $F(3,165) = 5.75$, $P < 0.001$ in experiment 13 (**1:2:3** mixture). The two lower doses (2.4 and 10 mg/day) had equivalent effects, with smaller captures than the two higher doses (52 and 165 mg/day). A trend for a log-linear relationship was

observed between the captures and the pheromone dose released. With **1:2** mixture, no effect of the dose (207, 162, 107, and 53 mg/day on an average) was recorded: $F(3,33) = 0.82$, $P > 0.5$ during experiment 15; but a dose effect was observed in experiment 16: $F(3,165) = 7.92$, $P < 0.001$. The two higher doses (223 and 171 mg/day) had equivalent effects, with greater catches than the lowest one (57 mg/day). The fourth dose (112 mg/day) had an intermediary effect. A log-linear relationship was observed between the mean weekly captures per trap and the mean daily pheromone release: $F(1,2) = 129.7$, $P < 0.01$; $r^2 = 0.98$. Eighty percent of the beetles were captured during the second week (significant replicate effect: $F(3,165) = 44.17$, $P < 0.001$).

In experiment 17 (Figure 7), the coattractant added to the pheromone (67 mg/day) had a significant effect on the captures: $F(5,85) = 15.92$, $P < 0.001$. Coconut allowed significantly greater captures (70% total) than any other bait (6×). The other baits added to the pheromone did not improve the captures obtained with the pheromone alone, especially the synthetic mixtures A–C, emitted at a mean dose of 325 mg/day.

Long Term Mass Trapping. A total of 2173 beetles were removed from the treated area during 125 weeks in the 14 traps monitored (Figure 8). The weekly

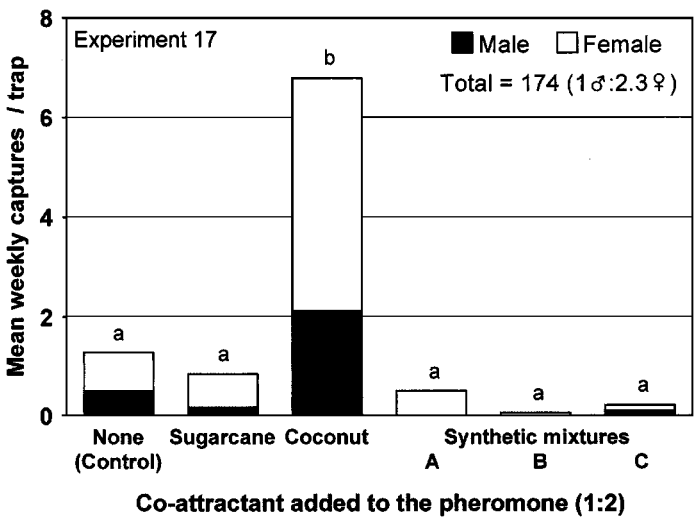

FIG. 7. Coattractant effect of coconut and sugarcane pieces and of three synthetic chemical mixtures (A–C) known for pherosynergistic properties in palm weevils (*Rhynchophorus* spp.) compared to synthetic *Scapanes australis* pheromone [**1:2:** 90:5 v/v mixture of (±)-2-butanol and acetoin] emitted at 67 mg/day (experiment 7, Sikut, East New Britain). Treatments associated with same letters do not differ in effect based on an ANOVA followed by Newman-Keuls test at 5%.

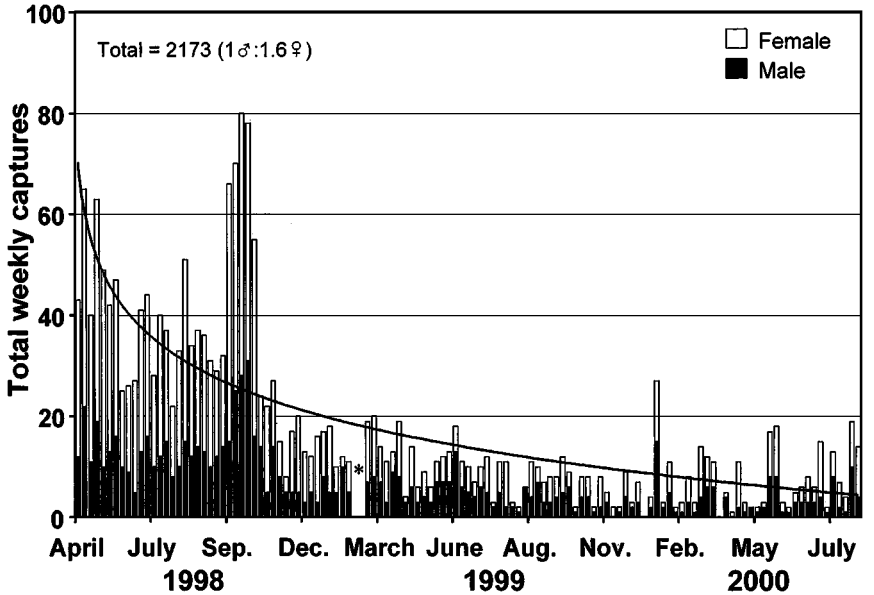

FIG. 8. Weekly captures of *Scapanes australis grossepunctatus* by 14 traps baited with either one live male or two dispensers of synthetic pheromone [**1:2:3:** 90:5:5 v/v mixture of (±)-2-butanol, acetoin, and (±)-2,3-butanediol emitted at about 100 mg/day] plus sugarcane pieces in a 40-ha area of cocoa-coconut plantings in CCRI Tavilo Research Station during continuous monitoring from April 3, 1998, to August 24, 2000. The curve is a log-linear fitting of the total captures versus the time from the beginning. *Indicates no trapping during 2 weeks.

captures dropped 30 weeks after the installation of the monitoring system, from 43 ± 15 (mean $\pm$ SD) in the initial 30 weeks to 14 ± 5 beetles in the next 30 weeks. The captures followed a log-linear relationship with time along the period of monitoring: $F(1,121) = 150.81$, $P < 0.001$, $r^2 = 0.55$. A marked peak of captures that could not be correlated with a change in the baits put in the traps was observed in October 1998.

DISCUSSION

Field trapping with synthetic compounds unambiguously demonstrated that 2-butanol and acetoin are key components of the male pheromone of *S. australis grossepunctatus*, acting for long-range attraction on both sexes. It established the basis for the development of the pheromone-based mass trapping as a new control method against this pest.

The two-choice pitfall olfactometer gave the first clue of an attraction of both sexes to males placed on coconut pieces, mainly to calling males, suggesting the emission of a volatile pheromone. However, the experiments were not conclusive, especially due to the high proportion of beetles that did not respond. Definite evidence for attraction to calling males was obtained a few months later by field trapping (Prior et al., 2000). The response to the male secretion was also weak and again not conclusive. The use of a suboptimal dose might have contributed to that result since the pheromone was diluted in a solvent that was itself as volatile as its major component. As the beetles did not respond to the **1:2:3** reference mixture in further olfactometer experiments (unreported), our olfactometer device and test procedure might have not been appropriate to the species, although good responses to pheromones were recorded in the same device from two other large palm beetles: *O. rhinoceros*, another Dynast (Saïd et al., unpublished data), and the weevil, *R. palmarum* (Rochat et al., 1991). In contrast to the two latter species, *S. australis* has developed a complex behavior sequence associated with sex communication and selection (Prior et al., 2000), the optimal realization of which was probably not possible in our laboratory conditions.

Electroantennography, especially coupled with gas chromatography, has been used as an efficient tool to disclose the pheromones of most scarab species studied to date (review in Leal, 1998), as well as *Oryctes* spp. (Gries et al., 1994; Hallet et al., 1995; Morin et al., 1996). *S. australis* appears to be an exception. Indeed, both the natural and the synthetic male pheromone compounds elicited EAGs of weak amplitudes with a low signal-to-noise ratio. The significant EAGs from the natural pheromone samples supported the existence of a male pheromone, but attempts to concentrate the extracts led to a loss of the EAG activity. This was logical, due to the high volatility of 2-butanol, the major pheromone component, undetermined at that time. GC-EAG recordings from the extracts did not reveal consistent EAGs from any compound (unreported). EAGs from the synthetic pheromone components greater than the control could only be recorded at very high doses (1 mg/filter paper), likely not relevant in natural situations. The existence of highly sensitive olfactory neuroreceptors to pheromones has been described in several scarab beetles [e.g., *Anomala cuprea* Hope (Leal and Mochizuki, 1993), *O. rhinoceros* (Morin et al., 1996; Renou et al., 1998), and *Phyllopertha diversa* Waterhouse (Hansson et al., 1999; Nikonov et al., 2001)]. The low threshold of response to the synthetic pheromone measured in field trapping suggests the existence of such receptors in *S. australis*, but electroantennography did not reveal them, and single sensillum recordings would be necessary for confirmation.

In field trapping experiments, *S. a. australis* individuals were captured by the synthetic pheromone designed from the analyses of *S. a grossepunctatus* male secretion (experiments 10 and 14). However, captures were limited and did not seem to reflect the beetle abundance in the experimental plots, as estimated by the

number found in palm galleries (Beaudoin-Ollivier, unpublished). This and the lack of responses to the **1:2:3** mixture in the olfactometer may reflect a difference in *S. a. australis* male pheromone composition with respect to *S. a. grossepunctatus* that could not be verified. As *S. a. australis* is not a pest in the PNG mainland, investigations were not pursued to clarify that point, and the following refers to *S. a. grossepunctatus*.

The synthetic mixture of 2-butanol, acetoin, and 2,3-butanediol, which reproduced the specific bouquet emitted by the male secretion, attracted beetles from both sexes. The combination of 2-butanol and acetoin was necessary and sufficient to obtain captures equivalent to those by the ternary mixture. The two compounds are actual pheromone components with long-range activity. In contrast, 2,3-butanediol seemed not to be involved in long-range attraction. It may play a role in short-range recognition or be involved in the specificity of the pheromone message.

As initially reported, beetles always responded to the racemic chemicals and stereoisomer mixtures used. This agreed with the composition of the natural pheromone: a mixture of enantiomers and stereoisomers (Rochat et al., 2000a). The specificity of the pheromone message remains puzzling since it relies on the use of short-chain chemicals, that are not optically pure. While acetoin and 2,3-butanediol are commonly produced by microorganisms, 2-butanol appears to be a less common molecule in nature (Robinson et al., 1999). The specificity of the message could rely on the large amount of chemical emitted (160 μg $\mathbf{1}+\mathbf{2}+\mathbf{3}$ on average) (Rochat et al., 2000a and unpublished) during the brief period of calling (1 hr) (Prior et al., 2000) associated with a specific adaptation of the olfactory apparatus, although the latter was not evidenced by electroantennography. Beetles were captured by 2.4- to 2600-mg/day doses. No sign of inhibition was detected at the higher doses. The capture at given doses depended on the experiment and likely on the population level in and around the experimental plots. Differences in the dose–capture relationships were not correlated with the presence or absence of 2,3-butanediol, which confirmed the lack of long range activity of this compound.

More females (average: 60%) than males were caught in the synthetic pheromone than in the male-baited traps in all experiments. The proportion was the same during the 125-week mass-trapping campaign. This sex ratio is opposite to that of the beetles found in the galleries in coconut palms (Prior et al., 2000). Females were considered rarer and more mobile than males. The use of synthetic pheromone clearly contradicted the first assessment and confirmed the second. The male pheromone is an aggregation one according to the classical definition (Nordlund and Lewis, 1976). However, calling males had a marked territorial behavior and got rid of all males in their vicinity by fighting (Prior et al., 2000). Individuals were scattered but certainly not aggregated on trees. Males were mostly alone or with one, rarely two, females. Groups comprising more than two males

on the same palm were rare, and males were then settled in separate galleries (Prior et al., 2000). Considering these ecological elements, the male pheromone was probably originally a sex pheromone. Males might have evolved to respond to their own sex signal to gain possession of a suitable mating and feeding site from fighting rivals.

Although captures from the only synthetic pheromone were observed, the presence of plant material enhanced trap catches. As earlier experiments with only plant controls led to no catch at all, the effect is likely synergistic. In a comparative experiment, coconut, a natural host plant of the beetle, appeared more efficient than sugarcane. As using coconut material was not possible on a large scale, sugarcane, much cheaper and easier to handle, was used in most experiments. It was accepted by the live males, and the level of captures obtained over 2.5 years with sugarcane appears to be acceptable from a pest control perspective. In contrast, the synthetic chemical mixtures that exhibited interesting pherosynergistic properties in certain palm weevils were not active on *S. australis*. Either the dose used was not optimal or the beetle does not use the same chemical signature to recognize its host plants. The results may, nevertheless, constitute a basis for further investigations aimed at identifying plant pherosynergists active in *S. australis*.

The 125-week campaign carried out in the TRS plantation indicated that mass trapping can severely depress the local *S. australis* population. The pheromone-based mass trapping provides success for controlling females, which is of special importance in any pest control program and particularly in the present case since the breeding sites where they spend the most time are difficult to access (Beaudoin-Ollivier et al., 1999). It is also targeting the males that are primarily damaging the palms. Our various experiments also reveal that outbreaks of adults occur during the year (intense peaks of catches in experiments 11 and 16 and in the long-term monitoring), for which detection and rapid elimination are important to improve the control of this pest. The trapping components (traps and attractants) have been optimized (Kakul et al., 1999 and unpublished). Despite rather large active doses, the synthetic pheromone is cheap, and its formulation is easy. Great hopes are riding on a decisive breakthrough in controlling *S. australis* after the severe coconut recession that has occurred PNG in recent years. The optimal trap layouts and the impact of the method on the damage level in coconut plots are currently being investigated as is the development of simultaneous trapping of both *S. australis* and BPW, for which a pheromone is already available (Oehlschlager et al., 1995).

Acknowledgments—We thank Rosa Perez Martin (INIA, Madrid, Spain) for dispenser calibrations and laboratory studies, Enzo Casagrande (AgriSense-BCS Ltd., Pontypridd, United Kingdom) for investment in dispenser technology and preparation, Charles Descoins (INRA, Versailles, France) and Dominique Mariau (CIRAD-CP, Montpellier, France) for support in this project, and all the workers and technicians from CCRI, without whom the field work would not have been possible.

(Received July 10, 2001; accepted November 19, 2001)

Abstract—Using gas chromatography with flame ionization detection (FID) and electroantennographic detection (EAD) in parallel, and employing chiral and achiral capillary columns, three constituents of the abdominal sex-attracting secretion of male *Kheper nigroaeneus* dung beetles were found to elicit reproducible EAD responses in male and female *K. nigroaeneus* antennae. One of these constituents is present in the secretion in such a small quantity that it could not be detected by FID, and it was not identified. The other constituents were identified as 3-methylindole (skatole) and (*R*)-(+)-3-methylheptanoic acid.

Key Words—Scarabaeinae, *Kheper nigroaeneus*, dung beetle, sex attractant, sex pheromone, insect semiochemicals, EAD, electroantennographic detection.

INTRODUCTION

The coprophagous fauna associated with the mammals of Africa plays an important role in the recycling of nutrients and in the destruction of the habitat of many dung breeding flies (Heinrich and Bartholomew, 1979). During the summer months when dung beetle activity reaches its peak, hardly any flies are found in game reserves with normal herbivore populations. In contrast, areas a few kilometers outside these reserves, where the cultivation of land or other farming practices have resulted in a decrease in the dung beetle population, the indigenous people are often plagued by swarms of flies. Similar problems are experienced in Australia,

where cattle were introduced without the associated insect fauna, resulting in the deterioration of pastures (Waterhouse, 1974) and the uncontrolled increase of the fly population (Hughes, 1970).

Based on their nesting behavior, dung beetles of the subfamily Scarabaeinae can be divided into three groups (Halffter and Matthews, 1966; Bornemissza, 1969). The paracoprids construct their nests under the dung pad by excavating tunnels in which dung is packed, the endocoprids excavate a chamber in the dung pad itself, forming brood-balls within this chamber, and the telecoprids detach a portion of dung from the pad, rolling it some distance from the dung source before burying it. The majority of species of dung beetles found in southern Africa are crepuscular paracoprids (87%), although the diurnal telecoprids are also numerous, even if represented by fewer species (12%) (Ferreira, 1972). The telecoprid genus *Kheper* is confined mainly to the hot Lowveld areas of Natal and the Transvaal, extending into tropical Africa.

Telecoprid behavior is considered to have evolved from competition for dung, as dung is the meeting place of the sexes and is vital for mating success. Dung beetles, are attracted to dung and arrive by the hundreds at fresh dung where they either immediately start feeding or burrow into the dung. Within a few minutes, they distinguish between the sexes, determine the state of maturity of the opposite sex, and enlist the cooperation of the selected partner in molding and rolling a brood-ball. If the male has been unsuccessful in finding a female in or on the dung pad, he might fly away and start secreting a sex attractant or start constructing a dung ball on his own. The male *K. nigroaeneus* first buries a brood-ball before assuming the typical secretion-producing stance at the entrance to the burrow in which the ball has been buried, or even when he is not in possession of a dung ball (Edwards and Aschenborn, 1988). Supporting his body on the front two pairs of legs, the male raises his abdomen and lowers his head so that his body is at a relatively steep angle. Repeated rapid extension of the hind legs results in the extrusion of a white proteinaceous material from tiny openings in a depression on either side of the first abdominal sternite. The secretion is supplied from a glandular complex underlying the depressions. The movement of the hind legs results in the secretion being broken up into tiny particles between brushes on the tibia and comblike structures on the abdomen of the male. Small puffs of secretion are, thus, released into the air. Amputation of one of the hind legs of a beetle results in thin-strand fibers resembling cotton wool being formed on that side of its abdomen. The tibial brushes are rudimentary in the females. When the presence of an attracted female is detected by a calling male, he challenges the female by raising his forelegs and advancing on her. Her reaction is a submissive lowering of the forelegs, followed by antennal contact and acceptance by the male. If the male has not already prepared and, in the case of *K. nigroaeneus*, buried a dung ball, the male detaches a portion of dung from the pad and proceeds to roll both the dung and the female clinging to it and compacting the dung, away from the dung pad.

Once the dung ball is buried, copulation occurs below the soil, the male returning to the surface after a few days, while the female remains below to lay an egg and to brood the developing larva (Tribe, 1975, 1976).

The abdominal secretions produced by *Kheper* species consist of a visible proteinaceous material that acts as a pheromone-disseminating carrier material for minute quantities of a complex mixture of volatile organic compounds. A comparison of the secretions of *K. lamarcki*, *K. nigroaeneus*, and *K. subaeneus* revealed that similar, but not identical, proteins with molecular masses of ca. 15 kDa are the major constituents of the proteinaceous fractions of each of these secretions (Burger et al., 1990). The major volatile constituents of the secretion of *K. lamarcki* were found to be hexadecanoic acid, 2,6-dimethyl-5-heptenoic acid, and (*E*)-nerolidol (Burger et al., 1983). The volatile fractions of the secretions of these *Kheper* species are, in fact, complex mixtures, each containing at least 150 constituents such as, among others, hydrocarbons, straight- and branched-chain fatty acids and methyl and ethyl esters of these, and other fatty acids. The volatile compounds present in the secretions of these three species are similar, but only a few are common to two or all three of the species. The secretions of these insects contain many chiral long-chain compounds. Because the enantiomers of these compounds cannot be separated with the current technology, it was decided to suspend attempts to identify all the volatile constituents of the secretions in favor of the identification of the EAD-active constituents. In this paper, identification of two EAD-active constituents of the abdominal secretion of male *K. nigroaeneus* is presented.

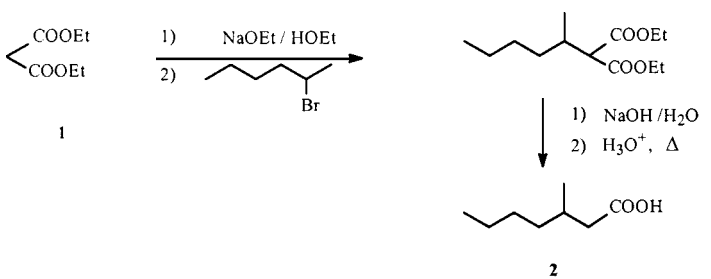
METHODS AND MATERIALS

Collection and Purification of Carrier Material. The pentane, dichloromethane, and chloroform used for extraction purposes were of residue analysis grade (Merck). All Pyrex glassware used in the handling of the material was heated to 500°C in an annealing oven to remove any traces of organic material. Spatulas, syringes, etc., used in handling the secretion, were cleaned by rinsing with the dichloromethane specified above.

Adult *K. nigroaeneus* dung beetles were trapped in Mkuzi Game Reserve in Kwazulu Natal, South Africa, during the early summer months by baiting pitfall traps (Tribe, 1976) with fresh horse dung. On arrival in Stellenbosch, one hind leg was removed from all male beetles. A small percentage of the beetles died within a week or two after removal of a leg. This was, however, the best method to prevent dispersal of the secretion that, if not brushed off, collects at one side of the abdomen. The male and female beetles were kept at subtropical temperatures in greenhouses, the floors of which were covered with about 15 cm of moist sandy soil. Permits were granted for the collection and removal from the game reserve of 150 males and a small number of females annually for the duration of this project.

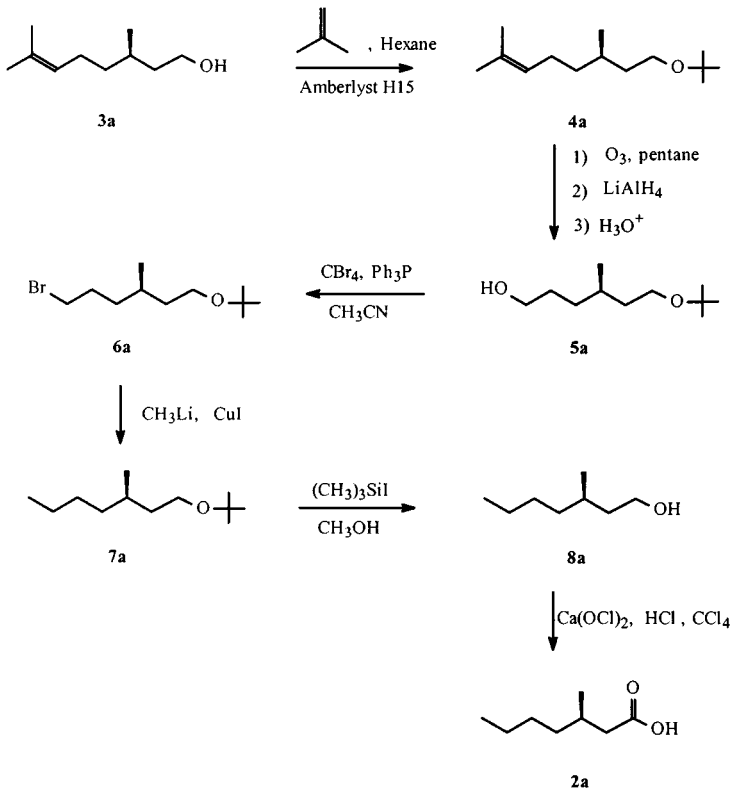
When disturbed, male dung beetles immediately stop secreting the attractant to investigate, and they may even disappear underground together with a female. Males observed to assume the attractant secreting posture were, therefore, fenced off from other beetles with aluminum strips. In some cases, the production of secretion continued for up to 2 hr. Without touching the body of the secreting male, the secreted material was removed periodically from its incapacitated side with ophthalmic forceps to prevent contamination with dust particles and the evaporation of the pheromone from the carrier material. In the meantime, the vial with material already collected was kept cool in an icebox. Tiny dust and dung particles picked up from the abdomen of the insects by the emerging secretion were carefully removed from the secretion under a microscope. Only about 5–10% of the males produced secretion in captivity, and in most instances, secretion production lasted only a short while and yielded too little material for gas chromatographic analysis of the secretion from individual insects. Small samples, therefore, had to be pooled for analysis. However, when secretion production was kept up for longer periods, it was possible to analyze the secretion from individuals. In a typical sample preparation, 3 mg of the secretion was sonicated for 1 min with 50 μl of chloroform in a Reacti-Vial, after which the suspension was centrifuged at 3000 rpm for 10 min. The white carrier material was concentrated in the upper layers of the solvent, while the remaining dust particles were precipitated. The solvent, containing soluble organic material, was carefully removed from between these two layers of solid material with a 100-μl syringe. The process was repeated a number of times, and extracts were pooled and concentrated for analysis of the volatile components of the secretion.

Analytical Methods. Gas chromatographic determinations were carried out with a Carlo Erba 4160 gas chromatograph with parallel flame ionization and electroantennographic detection (FID/EAD). The instrument was equipped with a 40 m $\times$ 0.3 mm glass capillary column coated with OV-1701-OH at a film thickness of 0.4 μm. Helium was used as carrier gas at a linear velocity of 28.5 cm/sec at 40°C, and a temperature program of 2°C/min from 40°C to 250°C was employed. Chiral gas chromatographic analyses were done on a glass column (25 m $\times$ 0.3 mm) coated with 10% heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV-1701-OH at a film thickness of 0.25 μm, using H_2 as carrier gas at a linear velocity of 50 cm/sec. The instrumentation for gas chromatographic analysis of dung beetle secretions with FID and EAD recording in parallel, with the use of dung beetle antennae as sensing elements has been described by Burger and Petersen (1991). In short, an antenna was inserted lengthwise into the air duct, as this arrangement produced a less noisy baseline than positioning the antenna sideways in the airstream, a position in which the club of the antenna is subjected to the effect of the turbulent mixing of the effluent and ambient air. The antenna was protected against heat radiation from the gas chromatograph by a heat shield cooled with water at 18°C. Electrical responses in the antenna were recorded via Ag–AgCl electrodes placed in



pipets filled with saline solution containing NaCl (7.5 g/liter), $CaCl_2$ (0.21 g/liter), KCl (0.35 g/liter), and $NaHCO_3$ (0.2 g/liter), as well as polyvinylpyrrolidone K90 (Fluka, 49 g/liter) to increase its viscosity (Van der Pers, 1980). Antennal responses were amplified with a Murphy Developments AMS-025 amplifier and were recorded on an Omniscribe recorder.

Mass spectra were recorded on a Carlo Erba QMD 1000 quadrupole mass spectrometer with the column and gas chromatographic conditions specified above. ^{1}H and ^{13}C NMR spectra of synthetic compounds and intermediates were recorded at 299.905 MHz and 75.42 MHz, respectively, at 25°C on a Varian VXR 300 NMR spectrometer.



3-Methylheptanoic acid was isolated from extracts of the abdominal secretion by preparative gas chromatography on a glass column (40 m × 0.6 mm) coated with the apolar phase PS-255 at a film thickness of 1.0 μm. A 1:10 effluent splitter was used, and fractions were collected in $CDCl_3$ for NMR analysis. ^{1}H NMR ($CDCl_3$): $\delta = 2.357$ (dd, 1H, C**H**H-2, $^2J_{2a,2b} = 15.0$ Hz, $^3J_{2a,3} = 5.9$ Hz); 2.153 (dd,1H, CH**H**-2, $^2J_{2b,2a} = 15.0$ Hz, $^3J_{2b,3} = 8.0$ Hz); 1.96 (m, 1H, C**H**-3); 1.45–1.15 (m, 6H, C$\mathbf{H}_2$-4,5,6); 0.894 (t, 3H, C$\mathbf{H}_3$-7, $^3J_{7,6} = 6{,}7$ Hz); 0.970 (d, 3H, C$\mathbf{H}_3$-8, $^3J_{8,3} = 6.6$ Hz).

Reference Compounds. 3-Methylindole and starting compounds were purchased from Sigma-Aldrich (Cape Town, South Africa).

Racemic 3-methylheptanoic acid (**2**) was synthesized from diethyl malonate according to Scheme 1. Diethyl malonate (**1**) (23.22 g; 145 mmol) was deprotonated with a solution of sodium ethoxide prepared from sodium (3.22 g; 140 mmol) and absolute ethanol (100 ml), and then alkylated with 2-bromohexane (23.11 g; 140 mmol) (Vogel, 1978). The resulting diethyl ester was saponified by refluxing it with a solution of potassium hydroxide (20 g) in water (30 ml), after which the reaction mixture was acidified and refluxed until the evolution of carbon dioxide had ceased. The conventional isolation procedures gave *rac*-3-methylheptanoic acid (**2**) as a colorless oil (12.94 g; 64%); ^{1}H NMR ($CDCl_3$): $\delta = 2.356$ (dd, 1H, C**H**H-2, $^2J_{2a,2b} = 14.9$ Hz, $^3J_{2a,3} = 6.0$ Hz); 2.145 (dd, 1H, CH**H**-2, $^2J_{2b,2a} = 14.9$ Hz, $^3J_{2b,3} = 8.1$ Hz); 1.96 (m, 1H, C**H**-3); 1.44–1.14 (m, 6H,

SCHEME 2. Synthesis of (*R*)-(+)-3-methylheptanoic acid.

C**H**$_2$-4,5,6); 0.894 (t, 3H, C**H**$_3$-7, $^3J_{7,6} = 6.6$ Hz); 0.969 (d, 3H, C**H**$_3$-8, $^3J_{8,3} = 6.6$ Hz).

(*R*)-(+)-*3-Methylheptanoic acid* (**2a**) was synthesized from (*R*)-(+)-3,7-dimethyl-6-octen-1-ol [(*R*)-(+)-β-citronellol] according to Scheme 2. Isobutene was slowly introduced into a suspension of Amberlyst H-15 (2.88 g) in a solution of (*R*)-(+)-3,7-dimethyl-6-octen-1-ol (**3a**) [9.91 g; 63.5 mmol, 98% pure, $[\alpha]_D^{19}$ + 5.3° (neat)] in hexane (100 ml) at room temperature for 12 hr (Alexakis et al., 1988). Removal of the catalyst and solvent gave a colorless oil (13.47 g) containing 99.9% (GC-MS) of (*R*)-(+)-8-*tert*-butoxy-2,6-dimethyl-2-octene (**4a**); $[\alpha]_D^{25}$ + 3.26° (neat). MS: *m*/*z*(%) = 156(6), 138(4), 137(5), 123(6), 109(7), 95(28), 81(67), 69(97), 57(100), 55(48), 43(35), 41(94). ^{1}H NMR ($CDCl_3$): $\delta = 1.599$ (d, 3H, C**H**$_3$-1, $^4J_{1,3} = 1.4$ Hz); 5.102 (m, 1H, =C**H**-3, $^3J_{3,4} = 7.1$ Hz, $^4J_{1,3} = {}^4J_{3,9} =$ 1.4 Hz); 1.980 (m, 2H, C**H**$_2$-4); 1.46–1.21 (m, 2H, C**H**$_2$-5); 1.62–1.47 (m, 1H, C**H**-6); 1.62–1.47 (m, 1H, C**H**H-7); 1.46–1.21 (m, 1H, CH**H**-7); 3.33 (m, 1H,

C**H**H-8); 3.38 (m, 1H, CH**H**-8); 1.679 (d, 3H, C**H**$_3$-9, $^4J_{9,3} = 1.4$ Hz); 0.890 (d, 3H, C**H**$_3$-10, $^3J_{10,6} = 6.5$ Hz); 1.185 (s, 9H, (C**H**$_3$)$_3$). ^{13}C NMR ($CDCl_3$): $\delta = 25.72$ (q, C-1), 131.01 (s, C-2), 124.98 (d, C-3), 25.51 (t, C-4), 37.30 (t, C-5), 29.66 (d, C-6), 37.77 (t, C-7), 59.80 (t, C-8), 17.62 (q, **C**H$_3$-9), 19.72 (q, **C**H$_3$-10), 72.51 (s, C-1′), 27.62 (q, 3**C**H$_3$).

Ozone was passed through a solution of the unsaturated ether (**4a**) (13.42 g; 63.3 mmol) in pentane (100 ml) until a sharp color change from colorless to blue was observed (Marvel and Nichols, 1941). Reduction of the ozonide with lithium aluminum hydride at –10°C, the usual work-up, and column chromatography on silica gel gave (*R*)-(+)-6-*tert*-butoxy-4-methyl-1-hexanol (**5a**) (7.02 g, 59%) in 99.2% purity (GC-MS); $[\alpha]_D^{25} + 1.95°$ (neat). MS: *m*/*z*(%) = 173(2), 132(6), 131(15), 115(28), 97(49), 69(40), 59(38), 57(100), 55(78), 43(23), 41(55). ^{1}H NMR ($CDCl_3$); $\delta = 3.627$ (t, 2H, OC**H**$_2$-1, $^3J_{1,2} = 6.6$ Hz); 1.72–1.47 (m, 2H, C**H**$_2$-2); 1.47–1.26 (m, 2H, C**H**$_2$-3); 1.72–1.47 (m, 1H, C**H**-4); 1.72–1.47 (m, 1H, C**H**H-5); 1.47–1.26 (m, 1H, CH**H**-5); 3.382 (qd, 1H, C**H**H-6, $^2J_{6a,6b} = 14.7$ Hz, $^3J_{6a,5a} = 8.6$ Hz, $^3J_{6a,5b} = 6.7$ Hz); 3.360 (qd, 1H, CH**H**-6, $^2J_{6b,6a} = 14.6$ Hz, $^3J_{6b,5a} = 8.6$ Hz, $^3J_{6b,5b} = 7.0$ Hz); 0.938 (d, 3H, C**H**$_3$-7); 1.185 [s, 9H, (C**H**$_3$)$_3$]. ^{13}C NMR ($CDCl_3$): $\delta = 63.37$ (t, C-1), 30.20 (t, C-2), 33.05 (t, C-3), 29.72 (d, C-4), 37.67 (t, C-5), 59.53 (t, C-6), 19.72 (q, **C**H$_3$-7), 72.52 (s, C-1′), 27.61 (q, 3**C**H$_3$).

Bromination of the alcohol (**5a**) (6.80 g; 36.20 mmol) with tetrabromomethane (14.37 g; 43.33 mmol) and triphenylphosphine (10.42 g; 39.72 mmol;) in acetonitrile (40 ml) (Christol et al., 1978; Slagle et al., 1981) gave (*R*)-(+)-1-bromo-6-*tert*-butoxy-4-methylhexane (**6a**) as a colorless oil (8.74 g, 96.4%) in 86% purity (GC-MS); $[\alpha]_D^{25} + 3.46°$ (neat). MS: *m*/*z* (%) = 237(3), 235(3), 179(9), 177(10), 150(2), 148(2), 137(9), 135(10), 123(6), 121(7), 109(6), 107(7), 97(92), 69(85), 59(88), 57(100), 56(77), 55(92), 43(86), 41(95). ^{1}H NMR ($CDCl_3$): $\delta = 3.354$ (t, 2H, C**H**$_2$-1, $^3J_{1,2} = 7.0$ Hz); 1.98–1.76 (m, 2H, C**H**$_2$-2); 1.49–1.21 (m, 2H, C**H**$_2$-3); 1.72–1.42 (m, 1H, C**H**-4); 1.69–1.50 (m, 2H, C**H**$_2$-5); 3.396 (qd, 1H, C**H**H-6, $^2J_{6a,6b} = 14.3$ Hz, $^3J_{6a,5a} = 8.9$ Hz, $^3J_{6a,5b} = 6.9$ Hz); 3.354 (qd, 1H, CH**H**-6, $^2J_{6b,6a} = 14.9$ Hz, $^3J_{6b,5a} = 8.8$ Hz, $^3J_{6b,5b} = 6.9$ Hz); 0.900 (d, 3H, C**H**$_3$-7, $^3J_{7,4} = 6.6$ Hz); 1.85 [s, 9H, (C**H**$_3$)$_3$]. ^{13}C NMR ($CDCl_3$): $\delta = 34.29$ (t, C-1), 30,41 (t, C-2), 35.57 (t, C-3), 29.35 (d, C-4), 37.87 (t, C-5), 59.53 (t, C-6), 19.72 (q, **C**H$_3$-7), 72.49 (s, C-1′), 27.62 (q, 3**C**H$_3$).

Treatment of the bromide (**6a**) (7.35 g; 29.3 mmol) with lithium dimethylcuprate in ether at 0°C (Johnson and Dutra, 1973) and isolation of the product in the usual manner gave (*R*)-1-*tert*-butoxy-3-methylheptane (**7a**) as a colorless oil (4.04 g, 74%) in 85% purity (GC-MS). MS: *m*/*z* (%) = 171(2), 113(3), 84(3), 71(28), 69(7), 59(25), 57(100), 56(18), 55(17), 43(35), 41(43). ^{1}H NMR ($CDCl_3$): $\delta = 3.370$ (qd, 1H, C**H**H-1, $^2J_{1a,1b} = 14.9$ Hz, $^3J_{1a,2a} = 8.8$ Hz, $^3J_{1a,2b} = 6.0$ Hz); 3.344 (qd, 1H, CH**H**-1, $^2J_{1b,1a} = 14.9$ Hz, $^3J_{1b,2a} = 8.7$ Hz, $^3J_{1b,2b} = 6.5$ Hz); 1.62–1.46 (m, 2H, C**H**$_2$-2); 1.70–1.46 (m, 2H, C**H**-3); 1.46–1.05 (m, 6H, C**H**$_2$-4,5,6); 0.899 (t, 3H, C**H**$_3$-7, $^3J_{7,6} = 6.6$ Hz); 0.871 (d, 3H, C**H**$_3$-8,

$^3J_{8,3} = 6.6$ Hz); 1.185 [s, 9 H, (C**H**$_3$)$_3$]. ^{13}C NMR ($CDCl_3$): $\delta = 59.88$ (t, C-1), 37.87 (t, C-2), 25.65 (d, C-3), 36.88 (t, C-4), 29.21 (t, C-5), 23.01 (t, C-6), 14.17 (q, C-7), 19.78 (q, **C**H$_3$-8), 72.42 (s, C-1′), 27. 63 (q, 3**C**H$_3$).

Treatment of the *tert*-butoxy ether (**7a**) (3.21 g; 17.2 mmol) with iodotrimethylsilane (6.18 g; 30.91 mmol) in dichloromethane (50 ml) (Jung and Lyster, 1977) gave (*R*)-3-methyl-1-heptanol (**8a**) (2.24 g) in quantitative yield and 86% purity (GC-MS). MS: *m*/*z*(%) = 112(2), 97(3), 84(52), 83(25), 70(77), 69(37), 57(38), 56(67), 55(98), 43(100), 44(38), 41(87). ^{1}H NMR ($CDCl_3$): $\delta = 3.654$ (t,2H, OC**H**$_2$-1, $^3J_{1,2} = 6.6$ Hz); 1.66–1.48 (m,2H, C**H**$_2$-2); 1.69–1.48 (m,1H, C**H**-3); 1.47–1.11 (m,6H, C**H**$_2$-4,5,6); 0.896 (t, 3H, C**H**$_3$-7, $^3J_{7,6} = 6.7$ Hz); 0.894 (d, 3H, C**H**$_3$-8). ^{13}C NMR ($CDCl_3$): $\delta = 61.28$ (t, C-1), 40.01 (t, C-2), 27.35 (d, C-3), 36.82 (t, C-4), 29.20 (t, C-5), 22. 97 (t, C-6), 14.12 (q, C-7), 19.66 (q, **C**H$_3$-8).

Oxidation of the alcohol (**8a**) with various reagents such as chromic acid and permanganate gave the acid (**2a**) in very poor yields. The best results were obtained with calcium hypochlorite as oxidizing agent (Kabalka et al., 1990). Concentrated hydrochloric acid (7 ml) was, thus, added dropwise to a stirred suspension of hypochlorite (8.8 g; 61.5 mmol) in water (40 ml) giving a bright yellow solution. A mixture of *tert*-butanol (30 ml) and tetrachloromethane (20 ml) was added, followed by the addition of (*R*)-3-methyl-1-heptanol (**8a**) (1.87 g; 14.4 mmol) in *tert*-butanol (10 ml) over a period of 4 min. The reaction mixture was stirred for 5 hr, and the organic material extracted exhaustively with tetrachloromethane. The combined extracts were washed with a solution of sodium metabisulfite until it was colorless. The organic acid was extracted with sodium carbonate, and this basic solution was extracted thoroughly with ether to remove all non-acidic products. The water layer was carefully acidified with hydrochloric acid and the organic acid extracted with ether. The usual work-up procedures gave (*R*)-(+)-3-methylheptanoic acid (**2a**) as a colorless oil (1.14 g, 55%) in 99.3% purity (GC-MS); $[\alpha]_D^{25} + 4.94^\circ$ (neat); 96.2% ee by gas chromatography on heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin. MS: *m*/*z* (%) = 144(3), 129(8), 115(3), 101(7), 87(55), 85(28), 84(33), 73(20), 69(22), 61(26), 60(100), 56(20), 55(38), 45(27), 43(75), 42(26), 41(65). ^{1}H NMR ($CDCl_3$): $\delta =$ 2.355 (dd,1H, C**H**H-2, $^2J_{2a,2b} = 14.9$ Hz, $^3J_{2a,3} = 5.9$ Hz); 2.144 (dd, 1H, CH**H**-2, $^2J_{2b,2a,} = 14.9$ Hz, $^3J_{2b,3} = 8.1$ Hz); 1.96 (m, 1H, C**H**-3); 1.46–1.11 (m, 6H, C**H**$_2$-4,5,6); 0.894 (t, 3H, C**H**$_3$-7, $^3J_{7,6} = 6.7$ Hz); 0.968 (d, 3H, C**H**$_3$-8, $^3J_{8,3} = 6.6$ Hz). ^{13}C NMR ($CDCl_3$): $\delta = 190.40$ (s, C-1), 41.56 (t, C-2), 30.16 (d, C-3), 36.37 (t, C-4), 29.11 (t, C-5), 22.78 (t, C-6), 14.07 (q, C-7), 19.72 (q, **C**H$_3$-8).

(*S*)-(−)-*3-methylheptanoic acid* was synthesized in an analogous manner from (*S*)-(−)-β-citronellol in 51% yield, 99.2% purity (GC-MS), and 96.8% ee; MS: *m*/*z*(%) = 144(3), 129(9), 115(10), 101(7), 87(55), 85(38), 84(33), 73(20), 69(21), 61(25), 60(100), 56(19), 55(36), 45(26), 43(73), 42(25), 41(65), 39(30).

RESULTS AND DISCUSSION

A typical FID gas chromatogram of an extract of the abdominal secretion of the male *K. nigroaeneus* is shown in Figure 1. A faster programming rate and the injection of more material were found to produce a better signal-to-noise ratio in the EAD recording. Dung beetle antennae survived in EAD experiments for more than 12 hours. Figure 2 shows the first part of a gas chromatographic analysis with EAD and FID recording in parallel at a programming rate of 4°C/min. A female antenna was used as the EAD-sensing element in this analysis. Although male and female antennae mostly produced reproducible and qualitatively similar results, a few examples of male and female antennae responding reproducibly to a few other long-chain constituents of the secretion were encountered over a period of several years. Because these EAD analyses could not be reproduced with other antennae, identification of these compounds could not be verified by EAD analyses of the synthetic compounds. However, they were always long-chain fatty acids such as hexadecanoic acid and/or the methyl or ethyl esters of long-chain acids. It is difficult to explain these results, and this phenomenon was not investigated in more detail.

One explanation for the presence of a large number of long-chain alkanes, alcohols, fatty acids, etc., in the abdominal secretion could be that these compounds augment the pheromone disseminating capacity of the proteinaceous carrier material. However, the fact that the antennae of the male and female dung beetles on occasion seemed to respond to some of these compounds could indicate that, depending on circumstances, they possibly have a semiochemical function.

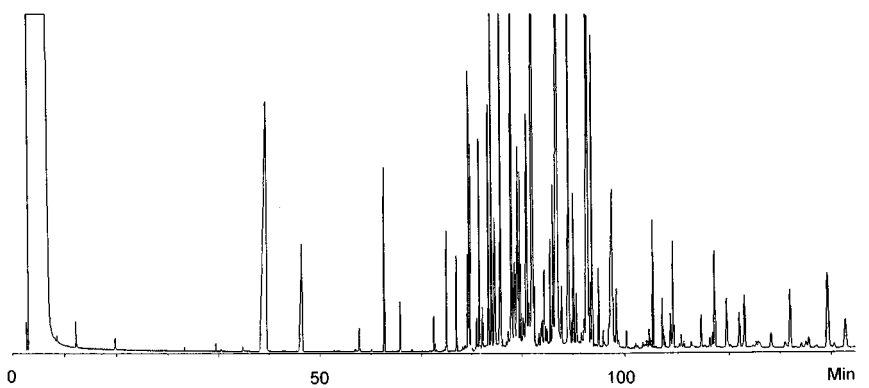

FIG. 1. Total ion chromatogram (GC-MS) of an extract of the male abdominal secretion of the dung beetle *Kheper nigroaeneus.* Gas chromatographic conditions: 40 m × 0.3 mm-ID glass column coated with OV-1701-OH at a film thickness of 0.375 μm and programmed at 2°/min from 40° to 250°C (hold); injector temperature 220°C; FID 250°C.

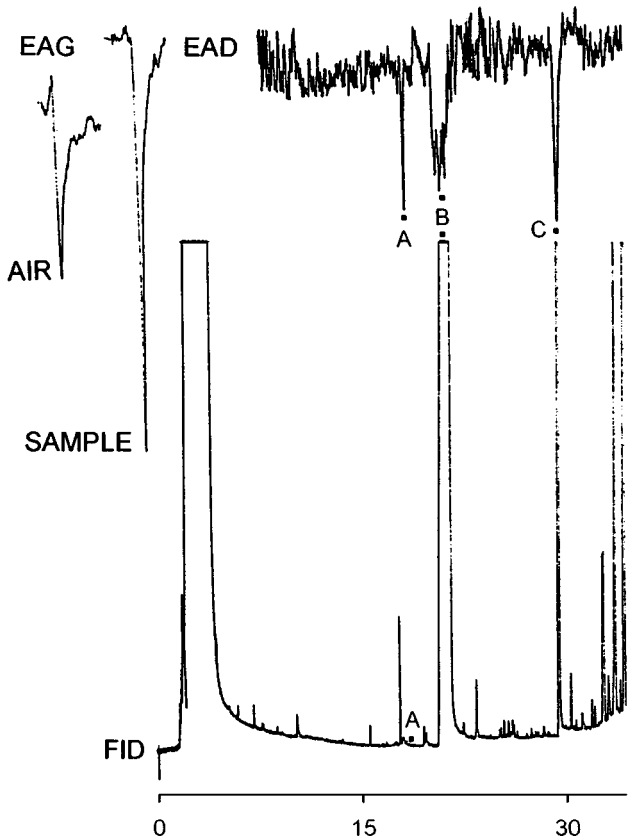

FIG. 2. First part of a gas chromatogram of an extract of the male abdominal secretion of the dung beetle *Kheper nigroaeneus* obtained by EAD/FID recording in parallel using a female antenna as detector element. Corresponding peaks in the EAD and FID chromatograms are indicated with a dot. Gas chromatographic conditions as in Figure 1 but with a programming rate of 4°C/min from 40° to 250°C (hold); EAD interface line 250°C; antenna and humidified air at 22°C. Assignment of EAD-active constituents: A = unidentified; B = (*R*)-(+)-3-methylheptanoic acid; C = skatole.

Although some of these long-chain compounds are common to the four *Kheper* species that were investigated, it is noteworthy that there were clearly large qualitative and quantitative differences in their secretions. This could be construed as evidence that the volatile constituents of the secretions are involved in the transmission of chemical signals. It is also possible, however, that the EAD and gas chromatographic techniques used in this study were not suitable for the detection of such long-chain compounds.

Constituent A, eluting at 18.55 min in the gas chromatographic analysis of the volatile organic fraction of the abdominal secretion shown in Figure 2, gave reproducible EAD responses, but was invisible in FID gas chromatograms despite relatively large samples having been used for the analysis. The low concentration in which this compound is present in the secretion and the fact that it was impossible to collect large enough quantities of abdominal secretion so far has precluded its identification.

Constituent B, eluting at 20.92 min, was initially identified as 5-methylheptanoic acid. However, it was found that the retention time and mass spectra of synthetic 5-methylheptanoic acid are different from those of the natural compound. 5-Methylheptanoic acid, furthermore, did not elicit any EAD response in the antennae of male or female *K. nigroaeneus*. All the available abdominal secretions and extracts of the secretion accumulated over more than eight years were combined for preparative gas chromatography, and enough material was isolated for ^{1}H NMR analysis of this acid, which was identified as 3-methylheptanoic acid.

Racemic 3-methylheptanoic acid (**2**) was synthesized from diethyl malonate (**1**) and 2-bromohexane according to Scheme 1. (*R*)-(+)-3-Methylheptanoic acid (**2a**) was synthesized from (*R*)-(+)-3,7-dimethyl-6-octen-1-ol [(*R*)-(+)-β-citronellol] (**3a**) according to Scheme 2 and was found to have mass and ^{1}H NMR spectra identical to those of the natural compound. This synthetic enantiomer was found to be EAD active. The *S* enantiomer was synthesized from (*S*)-(−)-β-citronellol according to an analogous synthetic route and was found to be EAD inactive. The two enantiomers are separable on a capillary column coated with a mixture of the stationary phase OV-1701-OH and heptakis (2,3,6-tri-*O*-methyl)-β-cyclodextrin, the *S* enantiomer eluting first from this column. Finally, a gas chromatographic analysis with FID and EAD detection in parallel and using this chiral column confirmed the EAD activity of the second eluting *R* enantiomer.

The third EAD-active constituent of the secretion, C, eluting at 29.21 min in the gas chromatogram shown in Figure 2, was identified as 3-methylindole (skatole), which has also been identified as a constituent of the abdominal secretion of *K. lamarcki*. Synthetic 3-methylindole was found to be EAD active.

One of the goals of this research was the development of a pheromone-based monitoring system for some of the *Kheper* species as a possible method to evaluate certain aspects of the ecological status of areas where these dung beetles are found. So far, all attempts at devising a field test with which the constituents of the secretion could be evaluated have been unsuccessful. The primary source of attraction is dung, and in tests with constituents of the secretion of *K. lamarcki*, for example, no dung beetles were attracted to pitfall traps baited with hexadecanoic acid, 2,6-dimethyl-5-heptenoic acid, (*E*)-nerolidol, and skatole. In the case of *K. lamarcki*, initial indications that more females than males are attracted to pitfall traps baited with dung plus these compounds than to traps baited only with dung proved to be statistically insignificant. In this regard, however, it must also be taken

into consideration that the ratio of males to females constantly changes due to the fact that the females stay underground for a while after mating. The sex ratio could also be influenced by other factors, such as the localized availability of dung and differences in the texture and moisture content of the soil in different parts of the area where the tests were done.

(Received December 20, 2000; accepted October 27, 2001)

Abstract—The male attractant pheromone of the scarab beetle *Holotrichia reynaudi*, an agricultural pest native to southern India, was extracted from abdominal glands of females with hexane and analyzed by gas chromatography–mass spectrometry. Field testing of the candidate chemicals, indole, phenol, and anisole, both alone and as binary mixtures, led us to conclude that anisole was the major component of the sex pheromone. Neither male nor female beetles were attracted to indole or phenol on their own. Similarly, when indole and anisole were combined, the attractiveness of the solution did not increase over that obtained with anisole alone. However, combination of phenol and anisole did alter the attractiveness of anisole, with fewer male beetles attracted to the binary mixture than to anisole on its own. The behavior of female beetles was not altered by any of the chemicals tested. Anisole is also the sex pheromone of *H. consanguinea*, making this the first known example of two melolonthine scarabs sharing the same pheromone.

Key Words—Coleoptera, Scarabaeidae, Melolonthinae, *Holotrichia reynaudi*, anisole, indole, phenol, pheromone.

INTRODUCTION

In recent years, there has been a variety of studies examining the chemical ecology of white grubs injurious to agricultural crops. As a result, the sex pheromones of a number of species from the subfamilies Melolonthinae and Rutelinae have been successfully identified (Leal, 1998). These include the pheromones used by the melolonthine species *Costelytra zealandica* (Henzell and Lowe, 1970), *Holotrichia parallela* (Leal et al., 1992), and *Holotrichia consanguinea* (Leal et al., 1996).

Sex pheromones may play an important role in maintaining the reproductive isolation of closely related species. Despite this, beetles from two genera of rutelines have been found to share either the same pheromone or a complex of pheromones. Leal et al. (1994) observed that *Anomala albopilosa sakishimana* and *Anomala cuprea* shared the same pheromone complex. Similarly, Potter (1980) reported that *Cyclocephala lurida* (formerly *C. immaculata*) and *Cyclocephala borealis* appeared to share the same pheromones. In both cases, reproductive isolation was maintained by either temporal or spatial means. Although a number of rutelines have been observed sharing the same pheromones, no similar observations have been made in the melolonthines. This paper reports the first known record of the same phenomenon in the Melolonthinae.

Holotrichia is a genus of the melolonthine scarabs that occurs across the Indian subcontinent and through southeast and east Asia. A number of species, including *H. reynaudi* and *H. consanguinea*, are major agricultural pests in India. Leal et al. (1996) identified anisole as the pheromone used by *H. consanguinea*. In this paper, we report that *H. reynaudi* also uses anisole as a sex pheromone.

METHODS AND MATERIALS

Analytical Procedures. Gas chromatography–mass spectrometry (GC-MS) was carried out on a VG Trio-2000 instrument (VG Biotech, Altrincham, UK), equipped with a split/splitless injector and nonpolar DB5-MS column (30 m $\times$ 0.25 mm; 0.25 μm). The column was held at 40°C for 2 min, then raised to 260°C at 10°C/min, where it was held for 6 min.

Extracts. Abdominal glands were excised from four calling females and placed in a screw top vial containing 2 ml of solvent (hexane). The vial containing the glands was air freighted to Australia for analysis along with 2 ml of the original hexane, which acted as a blank.

Field Testing. Behavioral responses to the candidate pheromones, anisole, indole, and phenol were evaluated over two years at the International Centre for

Research in the Semi Arid Tropics (ICRISAT) near Hyderabad, in the southern Indian State of Andhra Pradesh. Indole and anisole were also tested at Mahbubnagar (approximately 100 km southwest of Hyderabad) in 2000. In 2000, field testing of anisole and indole was completed at ICRISAT over five nights, June, 7–8 and June, 12–14. In 2001, anisole and phenol were tested at ICRISAT over four nights, June, 4–7. The test site at ICRISAT, in both 2000 and 2001, was an area of approximately 1500 m^2 in which eight distinct patches of *H. reynaudi*'s host tree (*Zizyphus mauritiana*) were growing. The trees had a maximum height of approximately 2 m. Testing was carried out at Mahbubnagar over one night (June 16, 2000). The test site consisted of a U-shaped border to a commercial peanut field surrounded by another of *H. reynaudi*'s host trees, *Butea monosperma*.

At ICRISAT, in 2000, anisole, indole, anisole + indole, or a control (empty vial) was assigned to each patch of trees, giving two replicates of each treatment. Phenol was not tested until 2001, as it was not clearly evident in the initial samples (see Results and Discussion for details). The location of each chemical was rerandomized each night. The anisole, indole, and phenol were purchased as laboratory reagents in India (anisole from s.d. fine-chem pvt. Ltd., indole from Loba Chemie, Bombay; phenol from Qualigens Fine Chemicals, Glaxo India Limited) and were undiluted. Approximately 5 g of each of the candidate chemicals was placed in a 20-ml glass vial. This was approximately the quantity of anisole soaked onto sponges and placed into trees by J. N. Vijayvergia (personal communication) in on-farm beetle-management trials with *H. consanguinea* in Rajasthan. The glass vials were taped to the stem of the host tree approximately 10 min before the anticipated time of beetle emergence. In the case of the anisole + indole mixture, equal quantities of the two compounds were mixed together by weight. Each pheromone station was separated by at least 10 m. The attractiveness of each compound was assessed by counting the number of beetles attracted to each vial. The sex ratio was also recorded. A similar sampling procedure was adopted at Mahbubnagar. Beetle flights around the anisole and the anisole + indole trees during the period of attractiveness of the chemicals were too intense (>200 beetles) for accurate counts to be made. A funnel trap baited with anisole was also placed in the middle of the field at this site.

In 2001, field tests at ICRISAT compared the attractiveness of anisole, phenol, anisole + phenol and empty (clean) vials to *H. reynaudi* beetles. Beetle attraction was monitored with water traps, which consisted of plastic bowls 10 cm deep × 35 cm diam. Two 30-cm-high aluminum baffles, slotted to give a right angle fit, were attached to the top of each bowl. The glass vials, into which the test compounds were placed, were accommodated in the top center of the baffle. The bowl contained 4–5 cm of water + one drop of detergent. Data were analyzed by using ANOVA following a log $(x + 1)$ transformation. Means were separated using least significant differences.

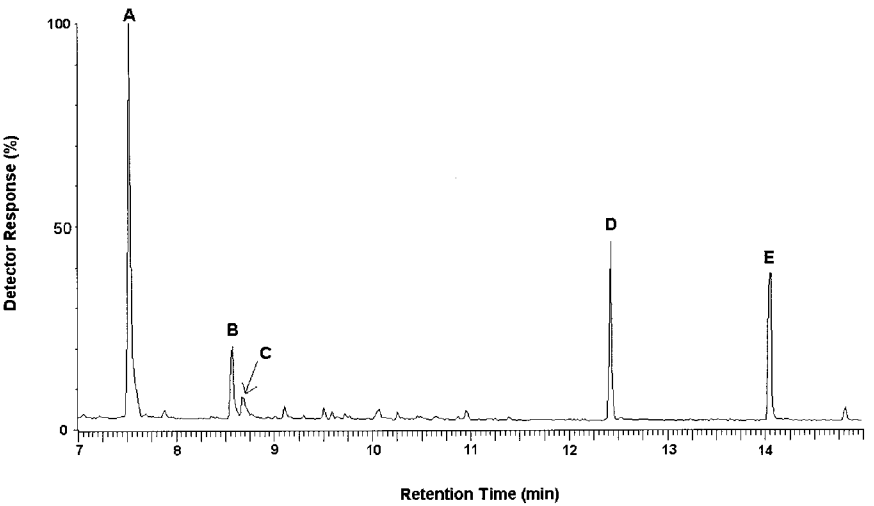

FIG. 1. GC-MS output from crude extracts taken from the abdominal glands of *H. reynaudi*. Peak A, anisole; B, dimethyltrisulfide; C, phenol; D, naphthalene; E, indole.

RESULTS AND DISCUSSION

GC-MS analysis of the crude extracts from the abdominal glands gave a clean profile (Figure 1). There were a number of relevant peaks. These were identified as indole (E), methoxybenzene (anisole, A), and phenol (C). They were the same as those identified by Leal et al. (1996) in the crude gland extracts taken from the closely related species, *H. consanguinea.* There were two additional peaks, naphthalene (D) appeared in both the solvent and the extract, suggesting that it was a contaminant. The other peak (B), was dimethyltrisulfide. As it was not possible to freight the samples in a frozen or chilled form, the gland tissues had started to decay by the time analysis was undertaken. This compound is a common component of volatiles emitted from animal wastes, biocultures, and anaerobically decomposing animal tissue (see, for example Niedziella et al., 2000). No record of the connection of this material with insect semiochemical phenomena has been found.

Early samples freighted to Australia, on which the synthetic formulation for field testing was based, had been insufficiently concentrated to reveal phenol in the original total-ion-current chromatograms. The samples had, however, been transported more carefully, and generation of mass chromatograms corresponding to phenol (*m*/*z* 94) and dimethyltrisulfide (*m*/*z* 126) from raw data acquired earlier from these samples revealed traces of phenol and the absence of dimethyltrisulfide. Although phenol has previously been identified as the pheromone used by

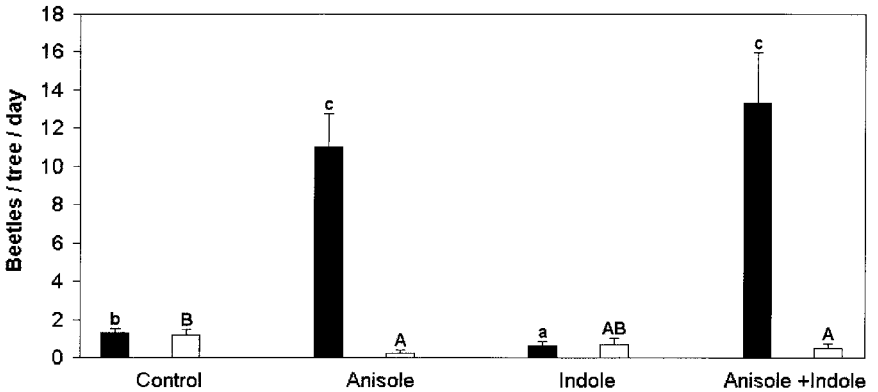

FIG. 2. Number of *H. reynaudi* beetles attracted to vials containing anisole, indole and a mixture of anisole + indole. Solid bars represent the number of male beetles and open bars represent the number of female beetles. Bars of the same color marked with the same letter are not significantly different at $P < 0.05$ using least significant differences.

Costelytra zealandica (Henzell and Lowe, 1970), field testing was, of necessity, confined to anisole and indole in 2000.

The results of the field testing at ICRISAT in 2000 demonstrated that anisole was highly attractive to male *H. reynaudi* (Figure 2). After emerging from the soil, male beetles flew towards the trees baited with vials containing anisole and the mixture of anisole + indole. More male beetles were attracted to these trees than to control trees or trees baited with indole alone [$F(3,36) = 64.97$, $P < 0.001$]. When the males reached the vials containing anisole, they flew around them and attempted to either copulate with the vials or with other male beetles. This activity commenced at about 19:10 hr (dusk) and continued for approximately 15 min before the beetles commenced feeding. By comparison, no male beetles were observed flying or displaying sexual behavior around the control vials or the vials containing indole alone.

In 2001, similar results were recorded with large numbers of male beetles being caught in the traps baited with anisole (Figure 3). Male beetles were also caught in the traps baited with anisole and phenol. However, the numbers were smaller than those in the traps baited with anisole alone [$F(3,60) = 11.11$, $P < 0.001$]. This observation was interesting because it makes little sense for a female beetle to produce a compound that repels members of its own species. Explanations for this may include that the concentration of phenol emitted from the vials was excessive and, therefore, masked the attractiveness of the anisole. No beetles were caught in the traps baited with phenol alone.

The behavior of the male beetles in the presence of anisole was similar to that observed in males seeking a mate. The normal pattern is for males to emerge

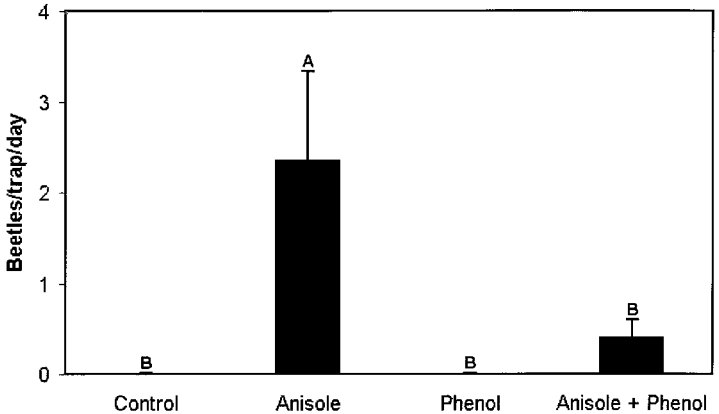

FIG. 3. Number of male *H. reynaudi* beetles attracted to vials containing anisole, phenol, and a mixture of anisole + phenol. No female beetles were caught. Bars marked with the same letter are not significantly different at $P < 0.05$ using least significant differences.

from the soil and fly around searching for calling females. If successful, copulation usually commences within five minutes of emergence from the soil. Males that are unable to find a mate continue to patrol in an attempt to find a calling female before settling to feed after approximately 15 min.

Although the number of females attracted to the candidate chemicals differed in 2000 [$F(3,36) = 3.55$, $P = 0.02$] (Figure 2), the number of females was low in all treatments. In 2001, no females were caught. Importantly, the behavior of female beetles was unchanged by the presence of the candidate compounds. In both the presence and absence of the candidate chemicals, female beetles emerged from the soil and commenced calling in an attempt to attract male beetles. Although mating usually commences within 5 min of emergence, females located close to the vials containing anisole were observed calling unsuccessfully for periods in excess of 10 min before ceasing, while males attempted to mate with either the vials containing anisole or each other less than 1 m away.

The field bioassay conducted at Mahbubnagar gave almost identical results to those obtained at ICRISAT. Large numbers of beetles (>200) were attracted to the trees baited with anisole, while low numbers of beetles were observed on the control and indole trees. Regular checks of the sex of the beetles flying around the trees baited with anisole showed that all of the beetles were male. Similarly, all of the beetles captured ($N = 47$) in the funnel trap baited with anisole were male.

Sex pheromones can be defined as compounds emitted by individuals of one sex that attract members of the opposite sex, resulting in the location of the emitter, and subsequently, mating (Baker, 1989; Tamaki, 1985). From our observations,

anisole can be regarded as a sex pheromone because it is released by females, and males show a clear sexual response to it. When vials containing anisole were placed on the trees, male beetles were observed orienting towards the vials after emerging from the soil. When they reached the vials, the beetles landed on or close to the vial and buzzed their wings vigorously before everting their genitalia and attempting to mate with either the vial or other male beetles in their vicinity.

Anisole has also been identified as the sex pheromone used by *H. consanguinea* (Leal et al., 1996), a species closely related to *H. reynaudi*, found in northern India. However, unlike *H. reynaudi*, where only male beetles were attracted to anisole, anisole was equally attractive to both male and female *H. consanguinea*, resulting in large aggregations of both male and female beetles. In northern India, this behavior is exploited for management of the pest, by spraying trees with insecticide prior to adult emergence (Yadava and Sharma, 1995), killing beetles of both sexes and reducing subsequent crop damage. More recently, this has been combined with the use of anisole to further concentrate the beetles and reduce the number of trees sprayed (Yadava, personal communication). On the basis of the data reported here, the prospects are limited for a similar approach with *H. reynaudi.*

From an evolutionary perspective, we believe that there are advantages for female beetles to release sex pheromones that attract members of the opposite sex only. Sex-specific pheromones may limit competition for males from other female beetles attracted by the semiochemical and, therefore, increase the probability of successful mating. This view is supported by Leal et al. (1996), who believe that, in the evolution of functional communication in scarab beetles, sex-specific signaling has evolved later than signals that attract beetles from both sexes. In this sense, *H. reynaudi* would be considered more advanced than *H. consanguinea* because the semiochemical used as a pheromone has developed a sex-specific function, attracting only male beetles.

The use of the same pheromone or complex of pheromones has previously been observed in closely related species from the subfamily Rutelinae. However, there are no similar reports in the melolonthines. Leal et al. (1994) observed that *Anomala albopilosa sakishimana* and *Anomala cuprea* shared the same pheromone. Similarly, Potter (1980) observed that *C. lurida* and *C. borealis* appeared to share the same pheromones. In both cases, reproductive isolation was maintained using either temporal or spatial means.

Although both *H. consanguinea* and *H. reynaudi* are endemic to India, there are no reports in the literature of them occurring sympatrically. As *H. reynaudi* is found in southern India and *H. consanguinea* is found in northern India, reproductive isolation is maintained through spatial separation, and as a result there is unlikely to be significant selective pressure for the pheromone system of either species to evolve further.

Acknowledgments—We thank the Australian Centre for International Agricultural Research for funding this work through project CS94/50 and Manaiah, Babu Rao and Md. Khaja for providing technical assistance.

Abstract—Flour beetles are cosmopolitan and common pests in grain stores and flour mills. Their ability to exploit a wide variety of stored products has contributed to their status as major pests of stored food. Although it was previously reported that the same aggregation pheromone, 4,8-dimethyldecanal (DMD), is shared by three flour beetles species (*Tribolium castaneum*, *T. confusum*, and *T. freemani*), the volatiles released by the other *Tribolium* species associated with stored products have not yet been examined. In the present study, the volatiles produced by males and females of eight *Tribolium* species were examined by solid phase microextraction (SPME). SPME samples were analyzed by gas chromatography coupled to mass spectrometry (GC-MS). Experiments were conducted to identify volatiles emitted by the adults of different *Tribolium* species and to determine whether DMD is a common aggregation pheromone. We observed that DMD is not a common pheromone of the eight species tested, but is common to *T. castaneum*, *T. confusum*, *T. freemani*, and *T. madens*. Two other volatiles were detected, 1-pentadecene, which is shown here to be a common semiochemical of flour beetles, and 1,6-pentadecadiene, which was detected in five species (*T. audax*, *T. brevicornis*, *T. destructor*, *T. freemani*, and *T. madens*).

Key Words—Tenebrionidae, *Tribolium*, aggregation pheromone, epideictic pheromone, 4,8-dimethyldecanal, 1-pentadecene, SPME, GC-MS.

INTRODUCTION

Worldwide losses of stored products due to postharvest insect attack are estimated to be 15% annually, and tremendous costs are involved in protecting commodities against insect infestations (Reichmuth et al., 1997). Tenebrionid flour beetles (*Tribolium* spp.) are common pests of numerous stored products. Their occurrence results in contamination and substantial economic damage due to loss of the product and a decrease in nutritional value (Sokoloff, 1974). Pesticides have been widely used to control pest infestations. However, many stored product pests are now resistant to many insecticides (Georghiou and Lagunes-Tejeda, 1991), and for some insecticides registrations have not been renewed due to safety hazards. Therefore, new methods of pest management are needed. The application of insect semiochemicals might represent a way to reduce the level of damages caused by stored product insects to acceptable levels.

Although many studies have examined chemical communication in flour beetles, only a few have identified the volatiles released by the adults and investigated their role as pheromones (Keville and Kannowski, 1975; Suzuki et al., 1975, 1984, 1987; Suzuki, 1980; Faustini and Burkholder, 1987). An aggregation pheromone, 4,8-dimethyldecanal (DMD), which is used in pheromone trapping systems (Hussain et al., 1994), has been identified in *T. castaneum* and *T. confusum* (Suzuki, 1980) and later also in *T. freemani* (Suzuki et al., 1987). Although other semiochemicals produced by flour beetles have been identified, currently only DMD is used to monitor flour beetles in stored product facilities.

The *Tribolium* genus can be subdivided in five species groups (Hinton, 1948; Sokoloff, 1974, Howard, 1987). Beetles of more than one species may occur in sympatry (Sinha and Watters, 1985). Interspecific attraction was observed between species belonging to the same or a different species group. However, cross-attraction was not reciprocal for all species tested (Suzuki et al., 1987, 1988a; Faustini et al., 1982). This phenomenon could lead to imperfect pre-reproductive isolation between some species. Moreover, within the *castaneum* species group, sterile hybrids are observed between *T. castaneum* and *T. freemani* (Nakakita et al., 1981). Hybrids are even observed between *T. audax* and *T. madens* (Sokoloff, 1972), two species belonging to distinct species groups (sensu Howard, 1987). Although *T. confusum* belongs to a different species group from *T. castaneum* and *T. freemani*, evidence indicates that *T. castaneum*, *T. confusum*, and *T. freemani* males produce the same aggregation pheromone (4,8-dimethyldecanal, DMD) (Suzuki, 1980; Suzuki et al., 1987). However, the response to the pheromone of the different species, and also of populations of the same species, depends upon the chirality of the molecules (Levinson and Mori, 1983; Suzuki and Mori, 1983; Barak and Burkholder, 1984/85; Boake and Wade, 1984; Suzuki et al., 1987). In addition, *Tribolium* species have other semiochemicals, such as quinones and cuticular hydrocarbons, in common (Lockey, 1978; Markarian et al., 1978; Wirtz

et al., 1978; Howard, 1987). Until now the role of these compounds and their potential utilization to monitor flour beetles has not been examined.

In the present study, we examined the production of volatile compounds by males and females of eight *Tribolium* species belonging to three species groups (sensu Howard, 1987): the *brevicornis* group: *T. audax* and *T. brevicornis*; the *castaneum* group: *T. castaneum*, *T. freemani*, and *T. madens*; and the *confusum* group: *T. anaphe*, *T. confusum*, and *T. destructor*. Our aims were to identify the volatile semiochemicals emitted by adults of the different species and to observe whether DMD was a common aggregation pheromone of flour beetles.

METHODS AND MATERIALS

Insects. Eight *Tribolium* species originating from different geographic areas were used (Table 1). Beetles were cultured in a dark incubator at $28 \pm 3^{\circ}$C and $65 \pm 5\%$ relative humidity with wheat flour and brewer's yeast (10/1, w/w) as rearing medium. Beetles were sexed as pupae by morphological characters (Ho, 1969) and maintained individually (to ensure their virginity) in small vials (5.5 cm^3) with 0.5 g of the medium. One-month-old adults were used in the experiments.

Volatile Collection: Sample Technique. To identify the volatiles emitted by virgin male and female *Tribolium*, we used a glass vial (10 cm^3) where one adult was placed with 0.2 g of wheat bran as feed. Vials were sealed with a rubber septum and kept in an incubator at $28 \pm 3^{\circ}$C and $65 \pm 5\%$ relative humidity. Volatile semiochemicals secreted by the adult were sampled after four days. For that purpose, glass vials were maintained at 35°C, and volatiles were sampled for 30 min by solid phase microextraction (SPME) with a polydimethylsiloxane (PDMS) fiber (100 μm, Supelco, Sigma-Aldrich, Belgium) previously conditionned for 1 hr at 250°C. Moreover, the SPME fiber was systematically reconditioned before each analysis. Since a preliminary set of 10 SPME samplings performed with males of *T. castaneum* revealed no qualitative differences, only three males and three

TABLE 1. *Tribolium* MCLAY (COLEOPTERA, TENEBRIONIDAE) SPECIES USED AND THEIR ORIGIN

Species	Common name	Origin, Year
T. anaphe (Hinton)	—	Nigeria, 1956
T. audax Halstead	American flour beetle	Canada, 1969
T. brevicornis (LeConte)	Giant flour beetle	USA, unknown
T. castaneum (Herbst)	Red flour beetle	USA, 1960
T. confusum DuVal	Confused flour beetle	Germany, 1967
T. destructor Uyttenboogaart	Dark flour beetle	Ethiopia, 1968
T. freemani (Hinton)	Kashmir flour beetle	Japan, 1980
T. madens (Charpentier)	Black flour beetle	Yugoslavia, 1959

females of each species were investigated. A vial with 0.2 g of wheat bran was used as control.

SPME and GC-MS: Analytical Method. GC-MS analyses were performed on a mass spectrometer Hewlett-Packard 5972 coupled to a Hewlett-Packard 5890 Series II gas chromatograph (splitless mode at 250°C) fitted with a Hewlett-Packard HP-5 MS column (30 m × 0.25 mm; 1 μm). The temperature program was from 40 to 200°C at 8°C/min and from 200 to 280°C at 20°C/min. Helium was used as carrier gas at 1.0 ml/min. Mass spectra were recorded in the EI mode at 70 eV (scanned mass range: 35–400 amu). The interface and the source were maintained at 280°C and 250°C, respectively. Identifications were performed by comparing the recorded mass spectra with those of the Wiley 275.L computed data base and by determination of the retention times and mass spectra interpretations of pure DMD (Biosystèmes, France) and 1-pentadecene (Sigma-Aldrich, Belgium). Quantification of DMD was carried out by integration of the peak areas by using an external standard method. For calibrations, solutions of known amounts of DMD in *n*-hexane were injected in analytical conditions identical to that of SPME analyses.

RESULTS

DMD is not a common semiochemical of the genus *Tribolium*; it is produced in *T. castaneum*, *T. confusum*, *T. freemani*, and *T. madens* (Table 2). Two other volatiles were detected, 1-pentadecene, which is shown here to be a common semiochemical of flour beetles, and 1,6-pentadecadiene, which was detected in five species (*T. audax*, *T. brevicornis*, *T. destructor*, *T. freemani*, and *T. madens*) (Table 3).

TABLE 2. PRODUCTION OF 4,8-DIMETHYLDECANAL (DMD) BY *Tribolium* MALES AND FEMALES[a]

Species	DMD (ng/beetle)	
	Male	Female
T. anaphe	nd[b]	nd
T. audax	nd	nd
T. brevicornis	nd	nd
T. castaneum	0.71 ± 0.12 ($N = 3$) a	nd
T. confusum	0.18 ± 0.01 ($N = 3$) b	nd
T. destructor	nd	nd
T. freemani	0.12 ± 0.02 ($N = 3$) b	nd
T. madens	0.22 ± 0.17 ($N = 3$) b	nd

[a] Three males and three females were sampled for each species. Volatiles were trapped with a SPME fiber during 30 min.
[b] nd = not detected. Values followed by the same letter are not significantly different (Tukey's test, $P > 0.05$).

TABLE 3. PRODUCTION OF 1-PENTADECENE AND 1,6-PENTADECADIENE BY *Tribolium* MALES AND FEMALES[a]

Species	1-Pentadecene			1,6-pentadecadiene	
	Male (N)	Female (N)	Estimated quantity (ng)	Male (N)	Female (N)
T. anaphe	2	3	0.73 ± 0.35	nd	nd
T. audax	3	2	0.46 ± 0.26	3	2
T. brevicornis	3	2	1.93 ± 0.28	3	2
T. castaneum	1	nd	0.21	nd	nd
T. confusum	1	1	0.49 ± 0.41	nd	nd
T. destructor	1	1	0.09 ± 0.05	nd	1
T. freemani	3	3	0.21 ± 0.07	1	3
T. madens	3	2	0.12 ± 0.01	3	2

[a] Three males and three females were sampled for each species. Volatiles were trapped with a SPME fiber during 30 min.
N = number of adults that releazed the compound, nd = not detected.

Typical chromatograms (total ion current) of the SPME sampling of the volatiles released by flour beetles are illustrated in Figure 1. The peaks at 16.15 min (retention time, t_R) and 18.70 min correspond to DMD and 1-pentadecene, respectively. Both the recorded mass spectra and retention times were identical to those of the authentic compounds. In addition, their fragmentation patterns were indistinguishable from those in the Wiley 275.L data base. Although the molecular ion (M^+ 184) of DMD has never been observed, a characteristic ion was obtained at m/z 140. It corresponds to a fragmentation resulting from the McLafferty rearrangement due to the β–cleavage of the aldehyde group.

An additional constituent (RRT = 1.016; 1-Pentadecene as reference) detected mainly in *T. brevicornis* and in lower proportions in *T. audax*, *T. destructor*, *T. freemani*, and *T. madens* showed a mass spectrum identical to that of *cis*-cyclododecene from the Wiley 275.L computed library. Nevertheless, the injection of a reference mixture of *cis*- and *trans*-cyclododecene (Fluka, Belgium) did not corroborate this interpretation. To establish the identity of the molecule, 250 flour beetles (*T. brevicornis*) were extracted with 50 ml peroxide-free diethyl-ether. After concentration to 500 μl under a gentle stream of nitrogen, the ethereal extract was submitted to GC-MS analysis. A well-resolved peak with both RRT (1.012) and fragmentation pattern similar to that observed during SPME analysis was observed. The molecular peak $M^+ = 208$ indicated a pentadecadiene isomer. The peak was attributed to 1,6-pentadecadiene (Suzuki et al., 1975; Wirtz et al., 1978; Howard, 1987). Although it was observed here in only five *Tribolium* species, it was previously observed as a common chemical of the same eight species examined here (Howard, 1987).

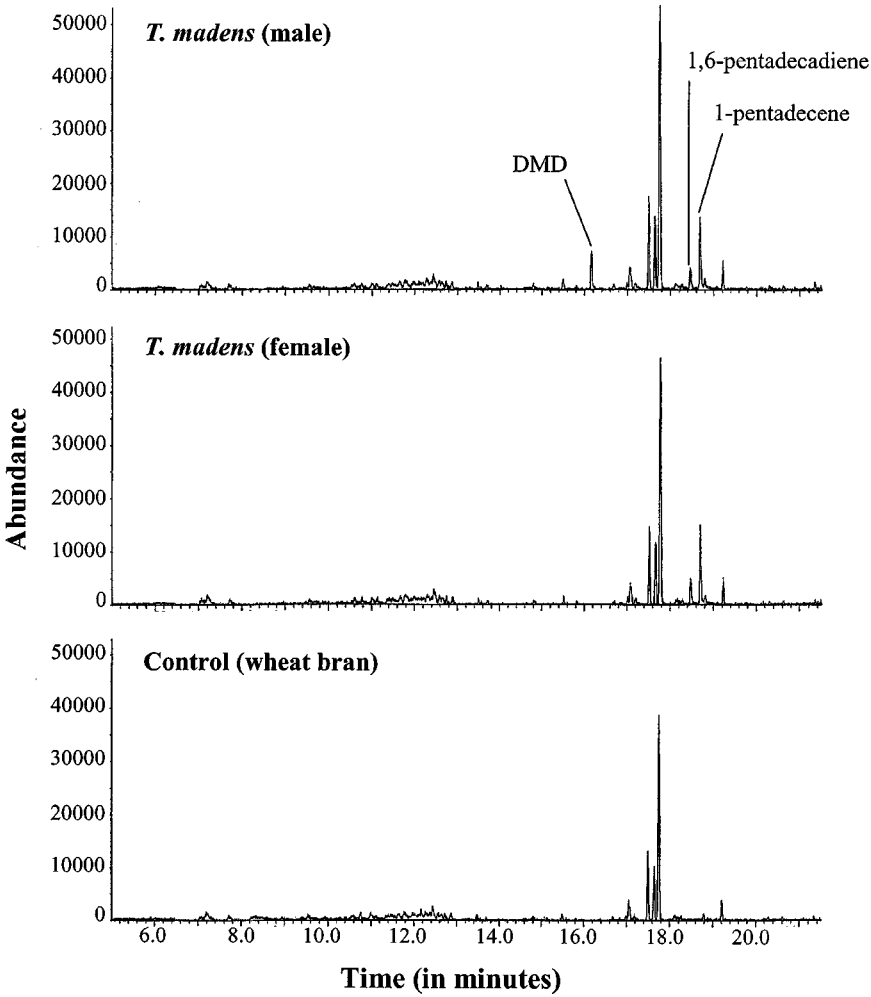

FIG. 1. Typical chromatogram (total ion current) of the PDMS SPME sampling of the volatiles released by male and female *Tribolium madens*. 4,8-Dimethyldecanal (t_R = 16.15 min), 1,6-pentadecadiene (t_R = 18.48 min), 1-pentadecene (t_R = 18.68 min). The other unidentified compounds are generated by the wheat bran.

The volatiles released by males and females of the eight species are shown in Tables 2 and 3. The values presented in the tables are an estimation of the quantities of the volatiles released by the adults by comparison of the area of the peak in insect volatiles to that of a known amount of DMD and of 1-pentadecene. Not all of the three semiochemicals were released by adults of each species. Furthermore, the species differed in the quantity of compounds they released.

DMD has been identified previously in *T. castaneum*, *T. confusum*, and *T. freemani* and is now reported for the first time in *T. madens* males. However, it was not secreted by female beetles. One-way ANOVA showed that males of the three species differ in the quantity of DMD secreted ($F_{3,8} = 6.80$, $P = 0.014$). However, there were no significant differences among *T. confusum*, *T. freemani*, and *T. madens* (Tukey's test, $P > 0.05$).

We observed that 1-pentadecene was released from all species (Table 3). However, it appeared that this compound was not secreted by all individuals of a species and that the production was highly variable among individuals. The 1,6-pentadecadiene ($t_R = 18.48$ min) was detected in adults of *T. audax*, *T brevicornis*, *T. destructor*, *T. freemani*, and *T. madens*, but was not found systematically in each replicate of each species.

DISCUSSION

Since the identification of the same aggregation pheromone for three *Tribolium* species (Suzuki, 1980; Suzuki et al., 1987), DMD has been considered a common volatile in flour beetles. A synthetic pheromone mostly composed of the (4*R*,8*R*) isomer was, thus, commonly used to trap the confused and the red flour beetles in stored product commodities. Indeed, we observed that DMD is not a common volatile of *Tribolium* flour beetles. It was produced only by males of four of the eight species tested.

Hussain (1993) observed that, in *T. castaneum*, DMD was released also by young females (<2 days old) and by larvae and pupae. We used 1-month-old insects in our experiments. This could explain the absence of DMD production by females. The quantities of DMD detected with our sampling method are much smaller than those reported by Hussain (1993) and Bloch Qazi et al. (1998). Working with a Super-Q column, these authors had observed that, on average, a single *T. castaneum* male produces 633 ng/24 hr and 163 ng/48 hr, respectively. In high-density conditions (2000 males in a 500-ml Erlenmeyer flask for 40 days), Suzuki and Sugawara (1979) observed that about 3.17 ng of DMD was secreted by one adult per day. Hussain (1993) observed that DMD production decreases while population density increases.

Ethyl- and methyl-benzoquinones are secreted by adult flour beetles (Alexander and Barton, 1943; Markarian et al., 1978; Howard and Mueller, 1987; Hussain, 1993; Pappas and Wardrop, 1996). Quinones were trapped with a Super-Q column connected to an aeration chamber containing one adult red flour beetle by Hussain (1993). We did not trap any quinones in our experiments. Quinones are released by adult flour beetles in stressful (Tschinkel, 1975) or overcrowded conditions (Faustini and Burkholder, 1987). Either the PDMS fiber (apolar phase) was not suitable to trap quinones (polar molecules), or our sampling conditions were not stressful to the insects. In order to differentiate between these hypotheses,

we used a Carboxen-PDMS SPME fiber, which is suitable for polar compounds. Moreover, vials containing one *T. castaneum* male (unstressful conditions) or 25 unsexed *T. castaneum* adults (stressful conditions) were sampled. Sampling was conducted as described above. By using the PDMS fiber, DMD was detected in both kind of samples, but quinones were not. Ethyl- and methyl-benzoquinones were easily detected with the Carboxen-PDMS fiber in the stressful conditions (25 adults), but no detectable amounts of quinones were observed in the unstressful conditions (1 male). DMD was not detected with that fiber. Both hypotheses can, thus, explain our results: PDMS fiber is not suitable to detect quinones, and stressful conditions are necessary to bring about the release of quinoid compounds. An interesting observation is that, contrary to Hussain (1993), DMD was detected even in stressful conditions.

The unsaturated hydrocarbon 1-pentadecene has been observed in studies examining cuticular lipids and defensive secretions of flour beetles (Keville and Kannowski, 1975; Tschinkel, 1975; Suzuki et al., 1975, 1988b; Lockey, 1978; Markarian et al., 1978; Wirtz et al., 1978; Hebanowska et al., 1990). In *T. confusum*, 1-pentadecene was believed to bring the sexes together and induce copulation because, although it was produced by males and females, only males appeared to be affected (Keville and Kannowski, 1975). However, it was first hypothesized that 1-pentadecene was used to facilitate the absorption of quinones by *Tribolium* enemies (Endt and Wheeler, 1971). Suzuki et al. (1975) observed that 1-pentadecene was repellent to *T. castaneum* and *T. confusum* adults at very low concentrations (0.1–10 μg/21-mm disk). Considering the amount of 1-pentadecene used by Keville and Kannowski (1975) (2–2.5 mg/6 mm disk) and the quantity of 1-pentadecene secreted by adults of the confused flour beetle (3 μg/beetle/3 hr) (Endt and Wheeler, 1971), the repellent hypothesis seems to be more likely. We, thus, hypothesized that 1-pentadecene may function as an epideictic (spacing) pheromone to flour beetles and a defensive secretion against *Tribolium* enemies. However, its exact function is not yet established. In this study, we observed that 1-pentadecene was produced by males and females of all species tested, except *T. castaneum* males. However, this volatile has been previously observed in the male red flour beetle (Howard, 1987; Hussain, 1993). Therefore, 1-pentadecene could be considered a common volatile of *Tribolium* flour beetles.

Our findings increase knowledge on chemical communication in *Tribolium* flour beetles and have implications in integrated pest management of these stored-products insects. Hitherto, DMD has been considered a common aggregation pheromone of flour beetles and is used in pheromone traps (Barak and Burkholder, 1984/85; Hussain et al., 1994). However, in flour beetles, the efficiency of the pheromone trap depends on the isomeric composition of the synthetic compound, on the target species (Levinson and Mori, 1983; Suzuki and Mori, 1983; Barak and Burkholder, 1984/85; Suzuki et al., 1984, 1987), and even on the population of the species (Boake and Wade, 1984). Although it was not produced by every adult, we observed that 1-pentadecene was a common volatile to flour

beetles. Therefore, it could be used as an alternative semiochemical to DMD, which is restricted to some species. Behavioral experiments are still needed to determine its precise role in *Tribolium* chemical communication and to determine its potential use in monitoring and/or controlling flour beetles in stored products. If its repellent role is confirmed, 1-pentadecene could instead be used as a protectant of stored products against *Tribolium* flour beetles.

Acknowledgments—We are grateful to H. Nakakita, C. Reichmuth, and A. Sokoloff for providing us the cultures of *Tribolium* and to A. Bozsik, R. Plarre, T. Wyatt, and the anonymous referees for their comments on a previous version of the manuscript. L. Arnaud is a fellow from the FNRS (Fonds National de la Recherche Scientifique).

(Received September 10, 2001; accepted November 17, 2001)

Abstract—Individual analysis of the female sex pheromone of the adzuki bean borer, *Ostrinia scapulalis*, has shown that the sex pheromone of this species comprised (*E*)-11-tetradecenyl acetate (E11–14:OAc) and (*Z*)-11-tetradecenyl acetate (Z11–14:OAc) at variable blend ratios. The pheromone blend could be tentatively categorized into three types with respect to the proportion of *E*11–14:OAc: E type (94–100%, median 99.2%), Z type (0–16%, median 3.0%), and intermediate type (I type, 48–85%, median 63.7%). In addition to the identity of components, the blend ratios in the three types were similar to those of the E strain, Z strain, and hybrid of the European corn borer, *O. nubilalis*, respectively. This finding suggests that two closely related but morphologically distinct species, *O. scapulalis* and *O. nubilalis*, share almost the same sex pheromone communication systems. The significance of this similarity in the two sibling species is discussed.

Key Words—*Ostrinia scapulalis*, sex pheromone, (*Z*)-11-tetradecenyl acetate, (*E*)-11-tetradecenyl acetate, *Ostrinia nubilalis*, polymorphism.

INTRODUCTION

The adzuki bean borer *Ostrinia scapulalis* (Lepidoptera: Crambidae) is one of the seven *Ostrinia* species currently found in Japan and is an important pest of the adzuki bean plant *Vigna angularis*, cowpea *V. sinensis*, and hop *Humulus lupulus*. *Ostrinia scapulalis* is morphologically similar to the European corn borer *O. nubilalis* but is distinct in the following aspects: (1) The middle tibia of *O. scapulalis* males are large, while those of *O. nubilalis* males are small (Mutuura and Munroe, 1970). (2) *O. nubilalis* is found mainly in Europe and North America but not in Japan, while *O. scapulalis* is found mainly in Asia including Japan and Eastern Europe (Frolov, 1998; Ishikawa et al., 1999). (3) Although both *O. nubilalis* and *O. scapulalis* are polyphagous, the host range of *O. scapulalis* is much narrower. In particular, *O. scapulalis* does not feed on maize and other Gramineae plants (Hattori and Mutuura, 1987), while *O. nubilalis* is an important pest of maize. In Asia, another congener, *O. furnacalis* (Asian corn borer), occupies the niche of maize pest.

Huang et al. (1997) identified the female sex pheromone of *O. scapulalis* from a population collected at Matsudo, located in the central part of Japan. The pheromone was found to be a 3:97 blend of (*E*)- and (*Z*)-11-tetradecenyl acetate, the same blend as that of the Z-strain European corn borer *O. nubilalis* (Klun et al., 1973, 1975). During the course of a continuing study, however, we found a case where progenies of a female *O. scapulalis* collected at the same location produced a pheromone of opposite blend ($E:Z = 99:1$), similar to that of the E-strain *O. nubilalis* (Kochansky et al., 1975; Klun et al., 1975). Furthermore, we found a case where a single mother of *O. scapulalis* collected at Matsudo produced female offspring of variable pheromone blends. We report here these findings on the variation of the sex pheromone in *O. scapulalis*, in comparison with that of the European corn borer *O. nubilalis*.

METHODS AND MATERIALS

Insects. Since morphological identification of *Ostrinia* female moths to species level is impractical, the following procedure was undertaken to prepare *O. scapulalis* families: Wild female moths of *Ostrinia* spp. were captured with an insect net at Matsudo (35.8°N, 139.9°E), Japan in September 1995. They were placed individually in plastic cups (9 cm diam. × 4.5 cm) with a cotton pad soaked with 5% sucrose solution, brought to the laboratory, and kept in an environmental chamber maintained at 25°C with a 15L:9D regime. Most of the females produced fertile eggs on the surface of the cups within a few days. Eggs produced by each female were treated separately as one family, with the mother's identity noted. Larvae were reared on a general diet for insects (Insecta LF, Nihon Nosan Co., Yokohama). The pupae obtained were sexed based on the morphology of terminal abdominal segments and maintained separately. Identification of the offspring

to species was based on the morphology of male moths (Mutuura and Munroe, 1970; Y. Yoshiyasu, unpublished). More than half the families were found to be *O. scapulalis*, the remainder being *O. furnacalis* and *O. orientalis*.

Sex Pheromone Analyses. The abdominal tip, which includes a sex pheromone gland, of a 3-day-old female moth was cut during the calling period in the late scotophase and immersed for 30 min in 5 μl redistilled hexane. The extract was concentrated to less than 2 μl under a dry nitrogen stream and analyzed with a gas chromatograph (Shimadzu GC 14-B) fitted with a split/splitless injector, a flame ionization detector, and a fused silica capillary column (DB-Wax, 30 m $\times$ 0.25 mm ID, J&W Scientific). The oven temperature was maintained at 100°C for 2 min, and programmed at 5°C/min to 240°C. The carrier gas was nitrogen, and the splitless injection time was 2 min. The ratio of the two pheromone components was calculated based on the peak areas.

RESULTS

Pheromone gland extracts from individual *O. scapulalis* females comprised E11–14:OAc and Z11–14:OAc at various blend ratios. The patterns of variation in pheromone blend differed from family to family among the eight examined (Figure 1). All females in two families (MD5202 and MD5208) produced a Z11–14:OAc-dominant pheromone (hereafter referred to as Z type). In contrast, almost all females in MD5304 produced an E11–14:OAc-dominant pheromone (E type). Moreover, analysis of females in families MD5211, MD5301, and MD5305 indicated females that produce pheromones with blends intermediate to the Z and E types (I type). Within the families analyzed, MD5300, MD5301, and MD5305 comprised the three pheromone types, MD5205 and MD5211 comprised Z and I types, and MD5304 comprised E and I types (Figure 1).

By comparisons of the pheromone blend distribution patterns in all families, the proportion of E11–14:OAc in Z type was estimated to range from 0 to 16% (median 3.0%, but see below). Similarly, the percentage range of E11–14:OAc in E type was estimated to be very narrow: 94–100% (median 99.2%). The proportion of E11–14:OAc in the I type appeared to extend from 48 to 85%, with a median at 63.7%. Although a female in MD5300 produced a pheromone blend near 35% E11–14:OAc, we cannot assign this blend either as Z type or I type from the available information.

DISCUSSION

The sex pheromone polymorphism in *O. scapulalis* appears to be similar to that in a sibling species, the European corn borer *O. nubilalis*. Since the discovery of extreme sex pheromone polymorphism in *O. nubilalis* in 1970s, scientists from various research fields have utilized this insect as a model for their studies. Thus,

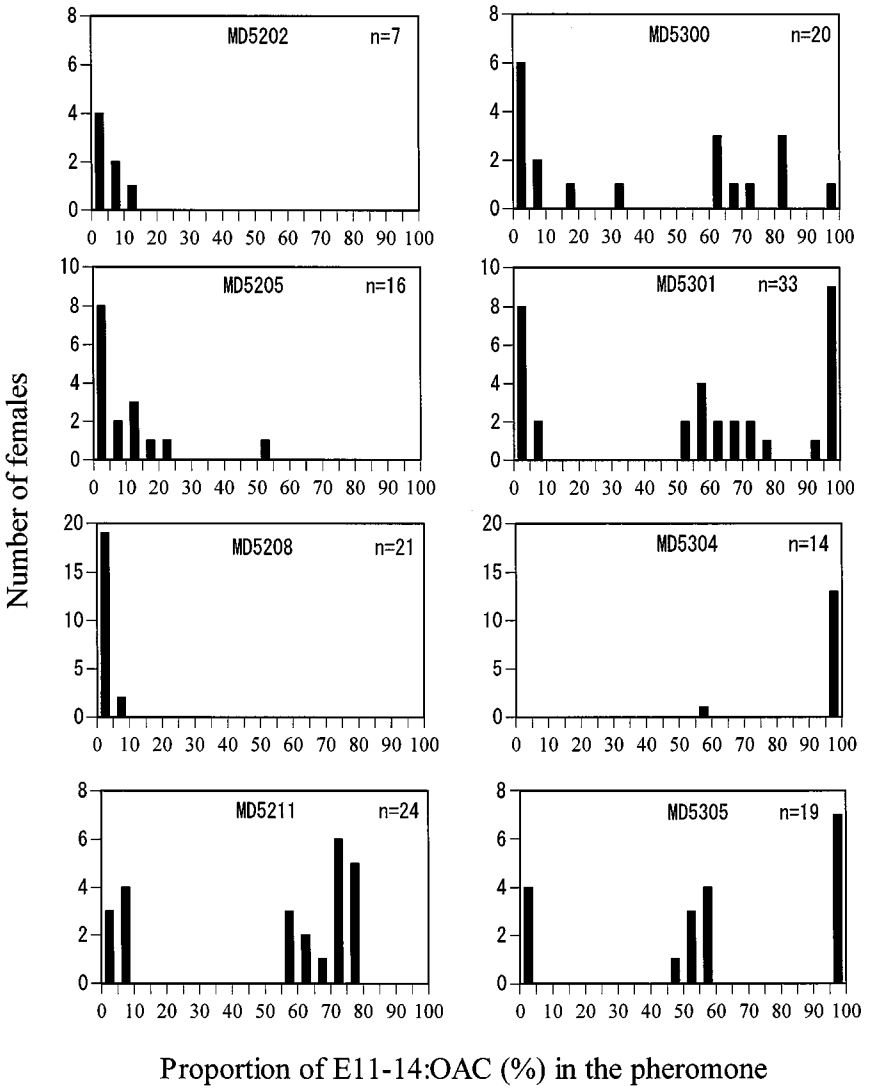

FIG. 1. Female sex pheromone blend of daughters from eight families of the adzuki bean borer, *Ostrinia scapulalis*. The female sex pheromone of *O. scapulalis* comprised (*E*)- and (*Z*)-11-tetradecenyl acetates (E11– and Z11–14:OAc), and the blend ratio is expressed by the proportion of E11–14:OAc.

understanding of various features of this phenomenon, e.g., genetic control of the sex pheromone blend in females and that of behavioral responses in males (Klun and Maini, 1979; Roelofs et al., 1987; Linn et al., 1997), have increased greatly.

The patterns of variation in the pheromone blends in *O. scapulalis* families strongly suggest that the variation has a genetic basis. The blend of pheromones in *O. nubilalis* is controlled by two codominant alleles ***E*** and ***Z*** at a single autosomal locus (Klun and Maini, 1979; Roelofs et al., 1987). The percentage ranges of E11–14:OAc in the E-type and Z-type *O. scapulalis* are similar to those in the corresponding two types in *O. nubilalis* (genotypes are ***EE*** and ***ZZ***, respectively). Moreover, the percentage range of E11–14:OAc in the I-type *O. scapulalis* (48–85%) is also similar to that of the hybrid *O. nubilalis* (***ZE***). It is, therefore, likely that the pheromone blend in *O. scapulalis* is under the same genetic control as that in *O. nubilalis*. This has to be confirmed through the establishment of pure *O. scapulalis* cultures of the Z and E types and crossing experiments that use these cultures.

The geographic variation in frequency of the pheromone types in natural *O. scapulalis* populations is of interest. The *Ostrinia nubilalis* Z strain predominates throughout Europe and North America, while the E strain is observed in southern Switzerland and northern Italy in Europe, and in northeastern North America (Klun et al., 1975; Anglade et al., 1984; Peña et al., 1988). Hybrid *O. nubilalis* are found only in limited regions where the two strains occur sympatrically (Roelofs et al., 1985; Peña et al., 1988; Klun and Huettel, 1988; Glover et al., 1991). In contrast, three pheromone types of *O. scapulalis* are found sympatrically in most regions of Japan (Takanashi, unpublished data), and in our main research area at Matsudo, the I type appears to be dominant.

Since *O. scapulalis* and *O. nubilalis* share practically identical sex pheromone communication systems, hybridization between the species would be expected if they occur sympatrically. Available distribution information on *O. scapulalis* and *O. nubilalis* suggests that although the two species occur largely allopatrically, cooccurrence is observed in some regions, mainly in Eastern Europe (Frolov, 1998; Ishikawa et al., 1999). To make the situation more complex, it has been suggested that populations of *O. nubilalis*, and probably those of *O. scapulalis*, are substantially differentiated geographically and in their use of host plants (Frolov, 1995, 1998). In laboratory experiments, hybridization between *O. nubilalis* and *O. scapulalis* occurred only in certain combinations of the parental populations (Frolov, 1994). Therefore, it does not seem relevant to discuss reproductive isolation between the two species as a whole; rather, careful investigations of geographic and host-associated differentiation, as well as sex pheromone types, in the populations are required.

It would be of interest to know the origin of similarity in the female sex pheromones of *O. scapulalis* and *O. nubilalis*: whether the pheromone polymorphisms in the two species were acquired independently or not. To answer this

question, we must clarify the sex pheromones and phylogenetic relationships among all extant *Ostrinia* species worldwide. Analyses of sex pheromones and phylogeny of all *Ostrinia* species in Japan, is currently in progress in our laboratory (Ishikawa et al., 1999; Kim et al., 1999), and this should contribute to the understanding of this interesting phenomenon.

Acknowledgments—We thank Dr. A. N. Frolov of the All Russian Institute of Plant Protection for information on the state of reproductive isolation between *Ostrinia nubilalis* and *O. scapulalis*. We thank Mr. D. Kageyama of our laboratory for help in insect rearing. Y. Huang was a postdoctoral research fellow sponsored by the Japanese Society for Promotion of Science. This research was supported by a Grant-in-Aid for Scientific Research No. 07306003 from the Ministry of Education, Sports and Culture of Japan.

EXPERIMENTAL EVIDENCE OF AN AGE-SPECIFIC SHIFT IN CHEMICAL DETECTION OF PREDATORS IN A LIZARD

MEGAN L. HEAD, J. SCOTT KEOGH,* and PAUL DOUGHTY

School of Botany and Zoology
Australian National University
Canberra, ACT 0200, Australia

(Received June 1, 2001; accepted November 12, 2001)

Abstract—The risk posed by predation is one of the most fundamental aspects of an animal's environment. Avoidance of predators implies an ability to obtain reliable information about the risk of predation, and for many species, chemosensory cues are likely to be an important source of such information. Chemosensory cues reliably reveal the presence of predators or their presence in the recent past. We used retreat site selection experiments to test whether the Australian scincid lizard *Eulamprus heatwolei* uses chemical cues for predator detection and avoidance. Both adult and juvenile lizards were given the choice of retreat sites treated with scents from invertebrate predators, as well as sympatric and allopatric snake predators. Some of the snake predators were known to eat *E. heatwolei*, while others did not pose a predation threat. All invertebrate predators posed a risk to juveniles, but not adults because of their size. We found that juvenile *E. heatwolei* avoided predator odors more strongly than adults. Juveniles avoided both invertebrate predators and snakes, and the strongest response was toward the funnelweb spider, the only ambush predator used in this experiment. This result may demonstrate the importance of predator ecology in the evolution of predator detection mechanisms, with chemical cues being more useful in detecting sedentary predators than active predators. Adult lizards showed no avoidance behavior toward predator odors. This result suggests an age specific shift in predator avoidance behavior as lizards get older and become too large for many predators. However, adults showed no response to the odor from the red-bellied black snake, a known predator of adult *E. heatwolei*. This finding further demonstrates the importance of predator ecology when examining communication between predators and prey. Chemical cues, which are persistent long after predators have vacated the area, may not be useful in detecting the red-bellied black snake, a wide-ranging active forager.

Key Words—Behavioral ecology, chemical ecology, predator avoidance, ontogenetic shift, reptile, lizard.

INTRODUCTION

Recognition of and response to predator odors is common and widespread throughout the animal kingdom. Avoidance of predator chemical cues has been demonstrated in mollusks, arthropods, fish, amphibians, mammals, and to a much lesser extent in echinoderms, reptiles, and birds (Kats and Dill, 1998). While most prey are capable of using multiple sensory mechanisms for predator detection, there appear to be important advantages to using chemical cues (Kats and Dill, 1998). Chemical cues reliably reveal the presence of predators (or their presence in the immediate past) without the need to actually confront the predator (Van Damme and Castilla, 1996). The ability to detect predators chemically is particularly advantageous for organisms whose activity patterns or environment preclude the effective use of other sensory systems (Petranka et al., 1987).

Chemical identification of predators by lizards has received little attention. Given their well-developed chemosensory systems, the potential for chemosensory-based predator avoidance behavior appears to be considerable (Dial, 1990), although Simon et al. (1981) found no evidence for chemical detection of snake predators by the phrynosomatid *Sceloporus jarrovi.* Detection of predators via chemical cues has been reported in a number of other lizard species. These studies have shown that these lizards can detect snake predator odors, as well as distinguish between the odors of predatory snakes and nonpredatory snakes (e.g., Thoen et al., 1986; Dial et al., 1989; Cooper, 1990; Dial, 1990; Dial and Schwenk, 1996; Van Damme and Quick, 2001). Differences among populations in response to snake predator odors have been demonstrated for a number of lizards. In some species, populations living sympatrically with predators respond more vigorously to predator scent than do populations living allopatrically with the same predator (e.g., Thoen et al., 1986; Van Damme and Castilla, 1996; Downes and Shine, 1998; Downes and Adams, 2001). Moreover, age related differences in thermoregulatory behavior in response to snake predator odors have been reported in *Lacerta vivipara*, with juveniles basking less than adults when exposed to the scent of a predator (Van Damme et al., 1995). Other studies have examined lizard response to predators at different ages (e.g., Phillips and Alberts, 1992). These studies, however, concentrated on whether chemical detection of predators is innate or learned, and did not focus on age specific shifts in predator avoidance behavior.

The southern water skink, *Eulamprus heatwolei*, is a medium-size (<110 mm snout-vent length, SVL) diurnal scincid lizard that occurs in southeast Australia. They are insectivorous and can often be found basking on logs on the forest floor of sclerophyll riparian zones. To examine differences in the responses of adult and juvenile *Eulamprus heatwolei* to predator odors, we conducted retreat site

selection experiments involving a range of chemical stimuli from potential snake and invertebrate predators. Snake predator odors were obtained from snake species that are known to eat lizards and are sympatric with our population of *E. heatwolei*. To test whether lizards respond to snake odor in general or only those that naturally pose a predation threat, we also included two snake species that are allopatric with our lizard population and are not known to eat *E. heatwolei*.

In all previous studies on chemosensory based antipredator behavior, the chemical stimuli have been derived from snakes alone. No studies on lizards have used chemical stimuli from invertebrate predators, even though many arthropods are predators of small lizards, and several arthropods and lizards may be involved in cross predation (where vertebrates are sequentially the prey and later the predator of the same species of invertebrate) (McCormick and Polis, 1982). By using invertebrate predators, we have the opportunity to examine age-specific shifts in antipredator behavior as well as to examine the difference in lizard responses to vertebrate and invertebrate predator odors by both adults and juveniles. We predicted that adult lizards would not avoid invertebrate odors and may even be attracted to them, whereas juveniles should avoid these odors, as they pose a predation threat. All lizards were expected to avoid odors from sympatric, but not allopatric snakes.

METHODS AND MATERIALS

Lizards were collected in late September and early October 2000 from the Tidbinbilla Nature Reserve (Canberra, ACT, Australia, 800 m elevation). This capture period occurred immediately after spring emergence before mating began. Juveniles were caught from the field at the same time and from the same locations as adults. Based on their size, juveniles were most likely born the previous season, making them approximately 1 year old. The lizards were brought back to a laboratory at the Australian National University where they were measured, weighed, and their sex determined via hemipene eversion.

Adult lizards were housed individually in plastic boxes (43L $\times$ 32W $\times$ 23H cm) and juveniles four or five to a box. All boxes contained a bark substrate, water bowl, and a ceramic tile for shelter. A 40-W light bulb was placed at one end of the box to allow lizards to thermoregulate naturally. The light bulb was turned off at night so they experienced a natural photoperiod. During the day, when the light bulb was on, temperatures ranged from 33°C under the light bulb to 25°C at the opposite end of the cage. All lizards were provided with food (*Tenebrio* larvae and dog food) and water ad libitum.

Lizards were tested with seven potential predator species, including four snakes and three invertebrates, as well as an odorless control. Species were chosen in order to test lizard response against a range of predators that presented different threats (Table 1). Three species of elapid snakes were used. *Pseudechis*

[a] The predator has been recorded to eat *Eulamprus* species.

porphyriacus (red-bellied black snake) is a major threat to both adults and juveniles (Shine, 1987). *Drysdalia coronoides* (white-lipped snake) is a major threat to juveniles, but not adults because adults are too large for them to eat (Shine, 1981). *Rhinocephalus nigrescens* (small-eyed snake) does not occur at our study site, but is known to eat *Eulamprus* spp. elsewhere (Shine, 1984; Swan, 1990). It can be regarded as an elapid control to test whether *E. heatwolei* are responding to cues of actual predators and not just a general elapid odor. *Liasis maculosus* (children's python) preys mostly on mammals and sometimes on lizards. It does not overlap *E. heatwolei* in distribution and should not pose a threat (Shine and Slip, 1990; Swan, 1990). Thus, this snake can be used as a snake control to test whether *E. heatwolei* are responding to actual predator odors or a general snake odor.

A number of invertebrates have been recorded to prey on skinks (McCormick and Polis, 1982; Daniels and Heatwole, 1984). However, there are no reports on whether lizards are able to detect invertebrate predators via chemical cues. We tested adult and juvenile *E. heatwolei* with the odors of three sympatric invertebrates that are common at our study site and have been reported to eat small skinks (Daniels and Heatwole, 1984). They all pose a threat to juveniles, but not adults. Scolopendromorpha (centipedes) are active foragers that live under moist logs. *Hadronyche* sp. (funnelweb spiders) are ambush foragers that build their funnels only in moist rotting logs. Sparassidae (hunstman spiders) are generally arboreal, but sometimes forage on the forest floor.

This experiment was designed to test whether adult and juvenile *E. heatwolei* could detect predators via chemical cues and whether there was any difference in the way the two size (and age) classes of lizards responded to predator odors. A total of 14 adult (87–96 mm SVL) and 14 juvenile (43–61 mm SVL) lizards were tested for 12 nights with various combinations of predator odors. The experimental design consisted of a linked paired-comparison design (David, 1988, p. 100). This design allowed us to balance the experiment by judges as well as by comparisons. The experiment was repeated twice for adults and juveniles, for a total of 24 nights. Each pair of odors was tested six times, and for any two lizards, there are four pairs of odors that are compared by both lizards. Each night, lizards were removed from their home boxes and placed in plastic test boxes at 17:00 hr. Four hours later, the tile under which a lizard was sleeping was recorded. Trials were run in two 12-day blocks, the first from January 25 to February 5 and the second from March 1 to 12.

Test boxes ($30 \times 15 \times 7$ cm) contained a bark substrate and two retreat sites. Retreat sites consisted of two ceramic tiles (11×11 cm) placed at either end of a test cage. Tiles were raised 1 cm off the bottom of the cage with sticks to allow lizards to crawl underneath them. A paper towel treated with the odor of one of the seven predator treatments or the control was placed under each tile. Paper towels were placed on the floor of the predators' cage for three days to obtain their odors. Paper towel used for the odorless control was handled in the same way as

for predators except that it was not placed with a predator prior to being used. Cages and tiles were washed with detergent (Morning Fresh) and dried between all trials.

To test whether preferences were the same for both size classes, we compared the fit of a model allowing different preferences for both size classes and a model with the same preferences for both size classes. If the model allowing different preferences fit the data better than the alternative model, then the size classes were analyzed separately by using the Bradley-Terry model. The Bradley-Terry model is a parametric test that allows treatments to be ordered according to preference and is specifically designed for experiments consisting of paired comparisons (David, 1988). Likelihood ratio tests were used to determine whether the data conformed to the Bradley-Terry model and whether the Bradley-Terry model fit better than a no-preference model. If the Bradley-Terry model fits the data better than the no preference model, then it shows that there were strong preferences between the treatments (De'ath and Moran, 1998). A model of no preference also was tested against the data. If both models fit the data, then the model of no preference was retained.

Our analysis represents a novel application of the Bradley-Terry model. Additionally, this model is more appropriate for our analysis than statistics such as chi-square goodness of fit tests. This model uses information from all comparisons within an experiment, simultaneously, rather than information from each of the comparisons separately (Cowling, Head, and Stapley, personal observation).

RESULTS

A significant difference existed between adult and juvenile avoidance of predators ($\chi^2 = 23.469$, $df = 7$, $P \leq 0.005$). Juveniles avoided most of the treatments, while adults showed no preference among treatments (Figure 1). For the adults, the no-preference model fit the data just as well as the Bradley-Terry model (no preference: $\chi^2 = 8.857$, $df = 7$, $P = 0.263$; Bradley-Terry: $\chi^2 = 23.919$, $df = 21$, $P = 0.296$), therefore, the no preference model was retained. This result indicates that either adults could not detect the odors of potential predators, or if they could, they did not respond (Figure 1a). For juveniles, the no preference model did not fit the data as well as the Bradley-Terry model ($\chi^2 = 29.059$, $df = 7$, $P < 0.001$), whereas the Bradley-Terry model fit the data well ($\chi^2 = 14.557$, $df = 21$, $P = 0.845$), indicating a well-ordered hierarchy of juvenile preferences. Juveniles preferred tiles treated with the odor of the small-eyed snake over the odorless control, while all other vertebrate and invertebrate predator odors were avoided in comparison to the control (Figure 1b). The odor avoided most was that of the funnelweb spider. The probability of juveniles choosing the control over the funnelweb spider was 0.835 (Table 2).

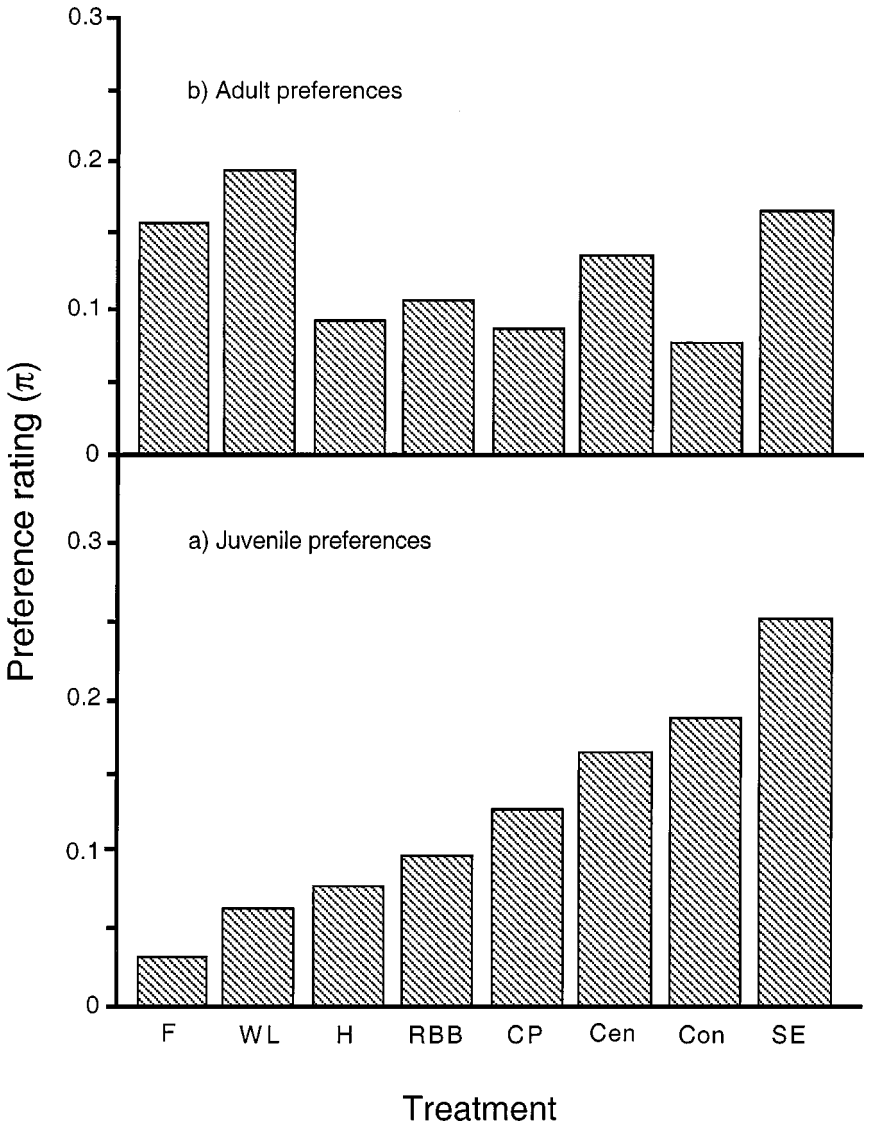

FIG. 1. Juvenile (a) and adult (b) preference ratings (π) obtained from the Bradley-Terry model. F = funnelweb spider, WL = white-lipped snake, H = huntsman spider, RBB = red-bellied black snake, CP = childrens' python, Cen = centipede, Con = odorless control, SE = small-eyed snake.

DISCUSSION

Our results indicate that adults and juveniles respond differently to the chemical cues of a variety of predators and nonpredators. Adults showed no preferences between predators and nonpredators, indicating that either they could not detect predator odors or they did not avoid detected odors because they were no longer a threat. Juveniles, on the other hand, avoided all but one of the predator treatments in comparison to the control. This is the first study to show a reptile antipredator response to invertebrate predator odors. Specifically, juvenile *E. heatwolei* avoided the funnelweb spider over all other treatments.

Our knowledge of the specific chemicals that mediate antipredator responses in lizards is poor. However, evidence suggests that these chemicals are most likely lipids that originate from the integument of the predator (Dial, 1990). Integumentary lipids are thought to play an important role in communication among predator conspecifics (Simon, 1983). These substances also may be deposited on the substrate, and they have low volatility, so it is not unrealistic to expect that prey species may be able to detect these chemicals later in the absence of the predator (Schwenk, 1995).

Chemical Detection of Predators. Chemoreception is believed to be an important mechanism for detecting the presence of predators when other cues are

not available, such as in nocturnal species like geckos (Dial et al., 1989; Dial and Schwenk, 1996), or in low-visibility habitats, such as for tadpoles in turbid water (Schley and Griffiths, 1998). Low-visibility habitats also may include structurally complex habitats where prey may approach predators or be approached by them without detecting them visually. In such environments, more mobile animals such as active foragers may encounter predators at a greater rate (Anholt et al., 1996). *Eulamprus heatwolei* is an active forager that inhabits a complex habitat and uses chemoreception in social interactions. Thus, we expected that *E. heatwolei* would use chemoreception to avoid retreat sites treated with predator odors.

Adult *E. heatwolei* did not respond to red-bellied black snake odors. This result may seem surprising, as this snake species is sympatric with the lizards and is known to prey upon *E. heatwolei*. However, the ability of an individual to detect a predator is not dependent solely on aspects of the prey's ecology, but also on the behavior and ecology of the predator. For chemical cues to be useful in assessing predation risk, they must provide reliable information about the presence and identity of a predator. For example, the American toad, *Bufo americanus*, showed no response to odors of a known predator, the garter snake, *Thamnophis sirtalis* (Heinen, 1994). A lack of response may be because the substrate is likely to be permeated with the predator odors regardless of whether it is in the immediate vicinity; thus, chemicals do not provide a reliable cue. However, *Bufo cognatus* and *Bufo microscaphus* were both able to detect snake predator odors (Flowers and Graves, 1997). In this example, predator odor was a reliable cue because the snakes revisited the same foraging area daily. Chemical cues are most likely to be useful in detecting slow-moving predators that are confined to certain areas, such as ambush foragers (e.g., Gelowitz et al., 1993). Chemical information about fast moving and wide-ranging predators such as the red-bellied black snake may not be as reliable, because the chemicals will probably linger long after the snake has gone. Responding to the odors of predators that have left the area would incur unnecessary costs (Kats and Dill, 1998).

The only predator in our study that is naturally confined to a small area is the funnelweb spider, which waits at the entrance of its burrow for prey to come close. Because of its small size, the funnelweb is not a threat to adult *E. heatwolei* (in fact, observations suggest that adults may prey on funnelweb spiders). However, they do pose a predation threat to juveniles (Daniels and Heatwole, 1984). Retreat sites treated with the odor of funnelweb spiders were avoided by juvenile *E. heatwolei* more than any other scent, suggesting that chemical cues are a reliable means of detecting the risk of predation by this spider.

It is known that phylogeny can influence the distribution of chemical discrimination of prey, but there also is evidence that foraging mode affects the use of prey chemical discrimination independent of phylogeny (Cooper, 1994a). Changes in prey chemical discrimination are linked to changes in foraging mode, and this may show that prey chemical discrimination is adaptively matched to foraging mode

(Cooper, 1994b). Is chemical detection of predators also influenced by foraging mode? Published data suggest that it is. Like prey detection, the detection of predators by chemosensory means has been reported only in active foragers (however, no studies of chemical predator detection in iguanian ambush foragers have been reported) [e.g., eublepharids (Dial et al., 1989); lacertids (Thoen et al., 1986)].

A number of reasons could explain why this could be the case. First, lizards may simply be taking advantage of an already well-developed sense and applying it to other aspects of their ecology. Second, lizards that are active foragers may have other aspects of their ecology in common that influence the use of chemical predator detection. Third, foraging mode may have direct implications on the use of chemical signals for predator detection. Finally, any combination of the above may be true. Iguanian lizards may have little to gain from detecting predator odors because they tend to be sedentary species that escape predators by fleeing to known shelters rather than leaving the area. Furthermore, major predators of ambush foragers are likely to be active foragers (Cooper, 1994a). Detection of active foragers via chemical cues may not be as useful as the detection of ambush predators because odors are persistent and do not reliably indicate the location of fast-moving or wide-ranging predators. Active foraging lizards, on the other hand, are likely to encounter ambush predators, and chemical cues are likely to be reliable for detecting these predators because they are sedentary.

Our results for *E. heatwolei* support the idea that chemical detection of predators is not solely dependent on foraging mode. Adults of this actively foraging lizard species did not distinguish between the odor of predators and the control. This result is probably not a response to the inability to detect predators, but because the predator odors presented were derived from active foragers. This indicates that the absence or presence of chemical detection of predators is not the result of the lizards foraging mode directly, but that chemical cues are more useful in detecting ambush predators than active foragers and that ambush predators are more likely to pose a predation threat to active foragers. The fact that juvenile *E. heatwolei* responded most strongly to the odor of an ambush forager also supports this idea.

It has been suggested here and elsewhere (Downes and Shine, 1998) that chemical detection of predators is, in part, dependent on the ecology of the predator in question. While this idea makes intuitive sense, it remains to be demonstrated. Our study supports this idea; however, it is necessary to conduct experiments that explicitly test this hypothesis. Testing prey with the odors of numerous predators that pose an equal predation threat but differ in aspects of their ecology, such as foraging mode, may provide valuable information on this problem.

Another aspect of chemical predator detection that has been neglected is whether chemical cues are used by prey that themselves are ambush foragers. This has been looked at in the use of chemicals for foraging but not for predator

detection. Addressing this issue is pivotal to our understanding of the evolution of chemical communication. It is necessary that even negative results be published in this area if we are to gain an accurate picture of the use of chemical signals and the selection pressures that act on this mode of communication.

Age-Specific Changes in Predator Avoidance Behavior. Although not responding to predator cues appropriately can be lethal, an excessive or unnecessary response also can have detrimental effects for prey (Beldon et al., 2000). Similarly, if predators are not uniformly risky to prey, prey may respond more strongly to predators that pose a greater threat (Kats and Dill, 1998). For example, many amphibians respond only to predators that have consumed conspecifics (e.g., Wilson and Lefcort, 1993). Other evidence suggests that individuals may differ in their response to predators. For example, prey populations that experience lower predation pressures in response to different predators or predator densities respond less vigorously to predator odors (e.g., Ducey and Brodie, 1991; Mathis et al., 1993). Differential responses also may occur within populations because of changing predation pressures on different life stages. Such a phenomenon may lead to a change in antipredator responses during ontogeny (e.g., Wahle, 1992; Anholt et al., 1996). The more specific the information on potential risk, the more useful it may be in behavioral decision making.

Juvenile *E. heatwolei* avoided predator odors more than adults. Similar results have been demonstrated for other species. Some garter snakes show ontogenetic shifts in antipredator behavior in response to visual predator stimuli (Herzog et al., 1992). In lobsters, small individuals increased shelter use in response to predator odors, whereas large lobsters responded to these odors with aggressive displays (Wahle, 1992). In the common lizard (*Lacerta vivipara*), juveniles refrained from basking in the presence of predator odors, whereas adult basking behavior remained the same as in control tests (Van Damme et al., 1995). The study by Van Damme et al. (1995) differs from ours, however, in that juveniles in their study were inexperienced hatchlings and were compared to adults from the field. In our study, juveniles were caught in the field at the same time and from the same location as adults and so, presumably, would have been exposed to similar predators. Thus, previous experience is less likely to be a factor determining adult and juvenile response.

A change in antipredator response with individual size is not surprising because smaller individuals often are more vulnerable to predation than larger individuals (McCormick and Polis, 1982). This difference in predator threat is not only because more predators can eat smaller individuals, but also because a number of important antipredator mechanisms are associated with age and size. For instance, smaller individuals may not have developed a full array of defensive mechanisms present in larger individuals. Such is the case in some tadpoles, which become toxic as they increase is size (Anholt et al., 1996). In reptiles, relatively small individuals also may be less able to defend themselves because of lower stamina associated with anaerobic and aerobic capacity (Pough, 1977, 1978) and be less

able to run away from predators because size is often positively correlated with speed (Garland, 1985). Younger individuals also may be less familiar with their environment (Burger, 1990).

In conclusion, the ability of lizards to detect predators via chemical cues is not only dependent on their own ecology but also on the ecology of the predator in question. Predators must pose a sufficient threat and cues must be reliable for chemosensory mechanisms of predator detection to be an advantage. This holds true not only for different prey species or populations, but also for different life stages within a species.

Acknowledgments—For help in the field, lab, and workshop, we thank J. Stapley, S. Dennis, E. Wilson, A. Muir, and B. Phillips. For predators, we thank Ross Bennet (Australian Reptile Centre), Terry Murphy, and Dave Rowell. For help with the statistical analyses, we thank A. Cowling from the ANU Statistical Consulting Unit. All work carried out as part of this project was done under the approval of the Australian National University Animal Experimentation Ethics Committee (F.BTZ.01.99) and with research permits from Environment ACT (permit number LT1999008). We thank the staff at Tidbinbilla Nature Reserve for their help and cooperation. Grants from the Australian Research Council to J.S.K. and P.D. provided financial support. The manuscript was improved by the constructive criticism of Sharon Downes and other members of the Keogh Lab.

BROOK CHAR (*Salvelinus fontinalis*) CAN DIFFERENTIATE CHEMICAL ALARM CUES PRODUCED BY DIFFERENT AGE/SIZE CLASSES OF CONSPECIFICS

REEHAN S. MIRZA* and DOUGLAS P. CHIVERS

(Received August 31, 2001; accepted November 5, 2001)

Abstract—A wide diversity of aquatic organisms release chemical alarm cues when captured by a predator. For most animals, it is not known whether the specific chemicals that comprise the alarm cue are conserved as prey animals age. In this study, we tested whether brook char (*Salvelinus fontinalis*) can differentiate alarm cues produced by individuals of different ages/sizes. In separate laboratory experiments we exposed small brook char and large brook char to chemical alarm cues from small brook char, large brook char, and a control of swordtails (*Xiphophorus helleri*). Both small and large brook char responded with antipredator behavior to chemical alarm cues from both small and large char, but not to those from swordtails. Small char responded with a greater response intensity to cues of small char than to cues of large char. In contrast, large char responded with a greater response intensity to cues of large char than to cues of small char. These results suggest that chemical(s) that act as the alarm cue for fish of different age/size classes may be: (1) identical and that there may be other chemical(s) that allow the test fish to distinguish between cues from fish of different ages/sizes, or (2) the cues are not identical, but similar enough to be recognized.

Key Words—Brook char, alarm cue, ontogenetic shift, antipredator behavior, Salmonidae.

INTRODUCTION

A wide diversity of aquatic organisms release chemical alarm cues when captured by a predator (reviewed in Chivers and Smith, 1998). Chemical alarm cues serve to warn nearby individuals of potential threat in the vicinity. Individuals warned by

alarm cues may gain a survival benefit by avoiding or evading the predator during an encounter (Mathis and Smith, 1993; Wisenden et al., 1999; Mirza and Chivers, 2001a).

The importance of chemical cues may be heightened in situations where visual cues are limited, such as at night, in highly structured habitats, or in areas of high turbidity (Smith, 1992). Furthermore, chemical cues function well in aquatic media because a large number of compounds can dissolve in water, giving a large number of potential chemical cues to be detected (Kleerekoper, 1969; Hara, 1994). Although controversy exists concerning the function of chemical alarm cues (Magurran et al., 1996; Smith, 1997; Brown and Godin, 1999), there exists considerable evidence for the antipredator function of alarm cues for both signal senders and receivers (Smith, 1992; Chivers and Smith, 1998). Thus, chemical cues provide reliable information to assess predation risk (Kats and Dill, 1998; Wisenden, 2000).

The use of alarm cues to assess predation risk may change as animals age. Many organisms undergo ontogenetic shifts in diet and/or habitat during their life cycle (Werner and Gilliam, 1984). For example, many fishes commonly undergo an ontogenetic shift from feeding predominantly on invertebrates to piscivory (Werner and Gilliam, 1984; Olsen, 1996; Brown et al., 2001). In regard to chemical alarm cues, we do not know if the chemical(s) that comprise the cue are conserved with age. Moreover, we do not know if prey animals respond to the same chemical alarm cue with the same intensity at different stages in the life cycle.

Previous studies have demonstrated that prey animals respond with antipredator behavior to chemical alarm cues from similar age/size conspecifics (reviewed in Chivers and Smith, 1998; Summey and Mathis, 1998). However, little work has examined whether chemical alarm cues are conserved with age/developmental stage. Belden et al. (2000) found that juvenile western toads (*Bufo boreas*) recognize and avoid areas labeled with chemical cues from snakes (*Thamnophis sirtalis concinnus*) fed juvenile conspecifics, but not from snakes fed conspecific tadpoles.

We examined whether small and large brook char (*Salvelinus fontinalis*) could differentiate alarm cues produced by individuals of different size/age. We exposed small and large char to chemical alarm cues from injured small char, injured large char, and injured swordtails (*Xiphophorus helleri*). Swordtails represent a generalized injured fish cue to which char do not respond with antipredator behavior (Mirza and Chivers, 2000, Mirza and Chivers, 2001a,b). Small char were $\sim$5 months old whereas large char were 1 year older. We employed fish of a different age/size, but all individuals were juveniles. Brook char typically reach sexual maturity at age 3 and have a life-span that ranges from 5 to 8 years (Scott and Crossman, 1973). If the chemical(s) that comprise the cues are conserved with age, we predict that both small and large char should respond to injured cues from each other with the same intensity. If the chemicals are not conserved, then

responses should be age specific (small char should respond to small char, but not large char and vice versa).

METHODS AND MATERIALS

Fish Maintenance. We obtained one group of juvenile brook char from the provincial hatchery in Ft. Qu'Appelle, Saskatchewan, Canada, in May 2000 and a second group of juvenile char in May 2001. The two groups were kept in separate 350-liter artificial stream tanks at 14°C on a 14L:10D photoperiod. Fresh dechlorinated water was introduced into each holding tank at a rate of 1 liter/min. Char were fed daily on a combination of commercial trout pellets and frozen brine shrimp, *Artemia* spp.

Preparation of Stimulus. Skin extracts were prepared from 10 small brook char (mean ± SD, 4.30 ± 0.31 cm standard length), 2 large brook char (7.6 and 8.2 cm), and 8 swordtails (4.91 ± 0.32 cm). Fish were humanely killed with a single blow to the head in accordance to guidelines set by the Canadian Council on Animal Care. A fillet of skin was removed from both sides of each fish and placed in 100 ml of chilled glass-distilled water. Approximately 25 cm^2 of skin was collected from each of the three groups. Skin was homogenized, filtered through filter floss to remove the larger particles, and then diluted in distilled water to make a final volume of 400 ml. Each char was exposed to the equivalent of 1 cm^2 of skin. Lawrence and Smith (1989) report that for fathead minnows (*Pimephales promelas*) 1 cm^2 of minnow skin provides an active space of 58,000 liter, which is equivalent to a cube 3.9 m on a side. The active space created by 1 cm^2 of char skin is unknown. Stimuli were pipetted into sample bags in 25-ml aliquots and frozen at –20°C until used.

Response of Small Char to Conspecific Alarm Cues. We exposed individual small brook char (mean ± SD, 4.86 ± 0.09 cm, $N = 19$) to three treatments: (1) skin extract from small brook char, (2) skin extract from large brook char, and (3) skin extract from swordtails. Each char received each of the three treatments, and the presentation of the stimuli was randomized. There was a 24-hr period between each successive treatment for each char.

Each test chamber was set up as a gravity flow-through system (modified from Petranka et al., 1987). Water flowed into one of two 60-liter header tanks, then spilled over into a 113-liter test chamber (measuring 54 × 44 × 36 cm), and finally down the drain at a rate of 1 liter/min. A single plastic tube ran into one of the two header tanks for introduction of chemical stimuli. Each test chamber was subdivided into two compartments by an opaque barrier with screen mesh at either end. The barrier was 12 cm from the long wall of the tank. This created an observation area of 54 × 32 × 36 cm. Behind the barrier, two small powerheads were used to create a circular flow in the tank. Each test chamber contained a single

centrally located shelter object constructed from a ceramic tile (20 × 10 cm) with three glass legs (7 cm). A single plastic tube was situated at the right hand side of the chamber for introduction of food. A grid of 9- × 9-cm squares was constructed on the front of the barrier to quantify movement of fish in the tank (Figure 1).

Fish were allowed to acclimate in the test chambers for 24 hr prior to trials. Each trial was 18 min in length and consisted of an 8-min pre- and 8-min poststimulus period, with a 2-min stimulus introduction period in between. Dye trials indicated that it took approximately 1.5 min for the stimulus to enter the test chamber from the header tank. At the beginning of both the pre- and poststimulus periods, approximately 5 ml of previously frozen brine shrimp was introduced into the tank. The food was added to stimulate activity and remained in the water column for only a few minutes. Char were observed to forage predominantly in the water column, rather than pick food off the bottom. The water flow was switched over to the second header tank after the prestimulus period to allow introduction of the chemical stimulus. Tanks were drained and cleaned out between successive trials. Test fish were held in the test tanks until exposed to all three treatments.

During both the pre- and poststimulus periods, we recorded the number of line crosses and the number of feeding bites. We also recorded occurrence of motionlessness (stationary for a minimum of 30 sec on either the bottom or in the water column). A line cross was recorded when 75% of the fish's body crossed from one grid square to another. We measured the length of each fish and converted the number of line crosses into number of body lengths moved. This was done in order to allow comparison of movement between fish of different sizes. Changes between the prestimulus and poststimulus periods for each response variable were calculated, and the difference in changes between pairs of treatments was analyzed by using Wilcoxon sign rank tests (Siegel and Castellan, 1988). The family-wise error rate was assessed and controlled by using the modified Bonferroni test (Keppel, 1982). The modified Bonferroni test specifies that corrections to the family-wise error rate be introduced only when the number of comparisons exceeds $k - 1$, where k is the number of treatments (Keppel, 1982). The comparisons must be based on a priori predictions. In this experiment, there were three treatments; thus, the family-wise error rate was held to $P = 0.033$. Occurrence of motionlessness was compared with a Cochran Q test (Siegel and Castellan, 1988). Based on predictions of reduced activity and reduced foraging of brook char to conspecific alarm cues found in our previous studies (Mirza and Chivers, 2000, 2001a,b), we conducted one-tailed tests.

Response of Large Char to Conspecific Alarm Cues. In this experiment, we exposed large brook char (9.90 ± 0.36 cm, $N = 19$) to chemical alarm cues from injured large char, injured small char, and injured swordtails. Each char was tested individually and received each of the three treatments in a randomized order. The experimental setup, procedure, and analysis were identical to that used in experiment 1.

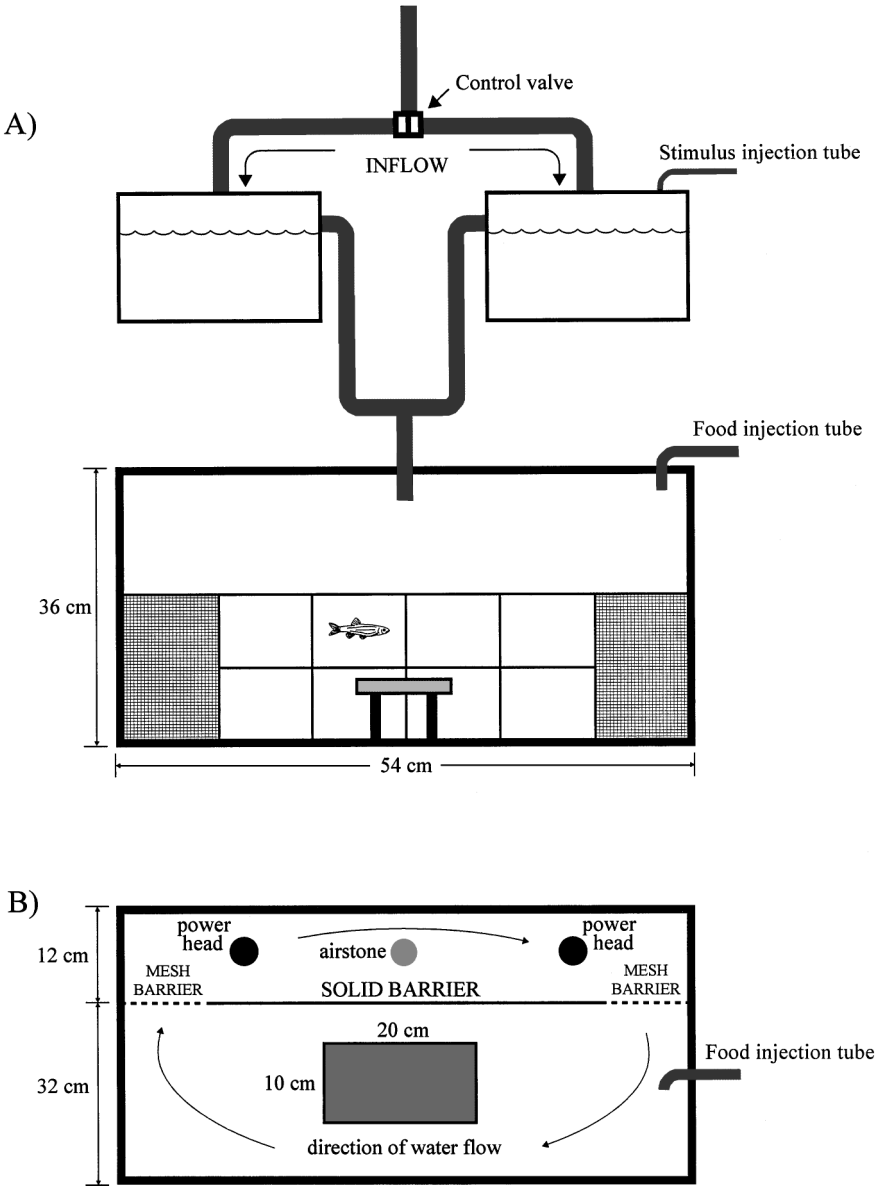

FIG. 1. Schematic diagram representing the gravitational flow-through apparatus used in experiment 1 illustrating front (A) and top (B) views.

RESULTS

Response of Small Char to Conspecific Alarm Cues. Results of the Wilcoxon sign rank tests revealed that small char reduced their activity (number of body lengths moved) in response to small char cues ($Z = -3.42$; $P < 0.001$) and to large char cues ($Z = -2.86$; $P = 0.002$) when compared to swordtail cues. Moreover, small char showed a greater reduction in movement in response to cues from small char than to cues from large char ($Z = -2.03$; $P = 0.021$; Figure 2).

Small char reduced their number of feeding strikes when exposed to small char skin extract and large char skin extract compared to exposure to swordtail

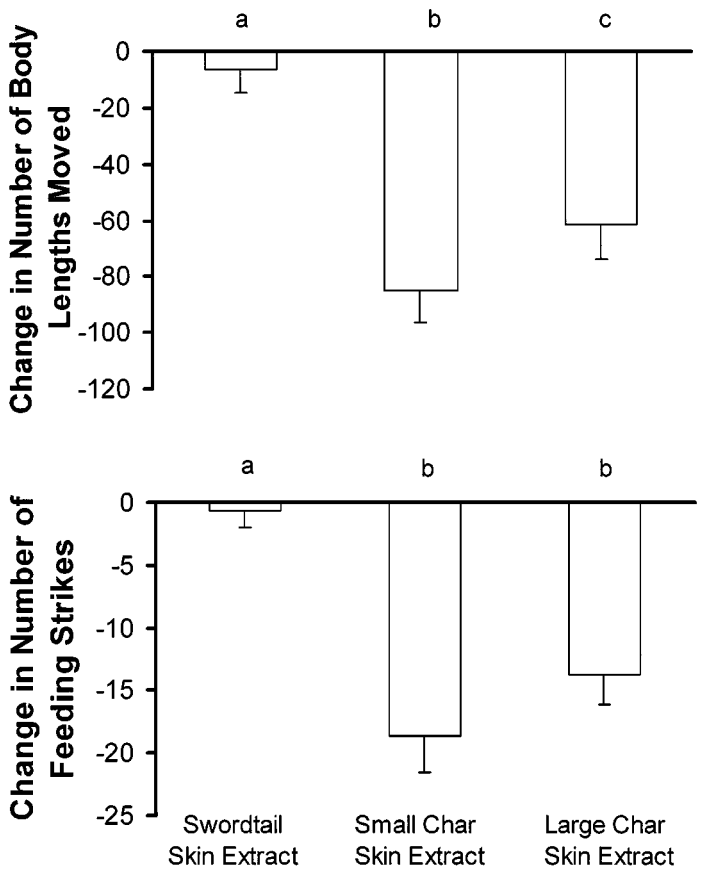

FIG. 2. Mean (+SE) of changes in number of body lengths moved (top) and number of feeding strikes (bottom) for small brook char exposed to skin extract from small brook char, large brook char, and swordtails. Different letters over bars denote significant differences at $P < 0.05$ (see text for details).

skin extract ($Z = -3.52$, $P < 0.001$; $Z = -3.29$, $P < 0.001$). There was a non-statistically significant trend for small char to reduce foraging strikes in response to cues of small char than to cues of large char ($Z = -1.83$, $P = 0.034$; Figure 2).

Small char were motionless in 9 of 19 trials when exposed to small char skin compared to 6 of 19 trials when exposed to large char skin and 1 of 19 trials when exposed to swordtail skin (Cochran's $Q = 9.8$, $P = 0.004$).

Response of Large Char to Conspecific Alarm Cues. When compared to responses to the control swordtail cues, large char reduced their activity in response to both cues of large char ($Z = -2.98$; $P < 0.002$) and to cues of small char ($Z = -2.33$; $P = 0.010$). Moreover, large char reduced activity to a greater extent in response to large char cues than to small char cues ($Z = -1.87$; $P = 0.031$; Figure 3).

Char reduced their number of feeding strikes when exposed to large char cues and small char skin cues when compared to exposure to swordtail cues ($Z = -2.63$, $P = 0.005$; $Z = -2.02$, $P = 0.014$). However, there was no significant difference in the level of reduction in foraging activity for large char exposed to large char cues compared to exposure to cues of small char ($Z = -0.78$, $P = 0.218$; Figure 2).

Large char were motionless in 8 of 19 trials when exposed to large char skin extract compared to 3 of 19 trials when exposed to small char skin extract and 2 of 19 trials when exposed to swordtail skin extract (Cochran's $Q = 7.75$, $P = 0.011$).

DISCUSSION

Our results indicate that brook char are capable of distinguishing between alarm cues produced by individuals of different ages/sizes. Small brook char responded to conspecific alarm cues produced by both small and large individuals. However, there was a significantly greater reduction in activity when char were exposed to alarm cues from conspecifics of the same age/size than from older/larger individuals. Conversely, older/larger char reduced activity significantly more in response to alarm cues from large char than small char. Given that predators are often specific in the size of prey that they consume, it is adaptive for prey to respond most strongly to alarm cues of individuals that are the same size as the sender.

Ours is one of the first studies to examine how responses to alarm cues change through ontogeny. In another study, Belden et al. (2000) examined whether conspecific alarm cues were conserved in amphibians that underwent metamorphosis. They exposed juvenile western toads to chemical cues of red-spotted garter snakes fed either juvenile conspecifics, snakes fed larval conspecifics (tadpoles), water conditioned by juvenile toads, or water conditioned by earthworms. Juvenile toads avoided areas labeled with chemical cues from snakes fed juvenile conspecifics, but not to chemical cues from snakes fed tadpoles or the other two treatments. Previous work had shown that western toad tadpoles respond to alarm

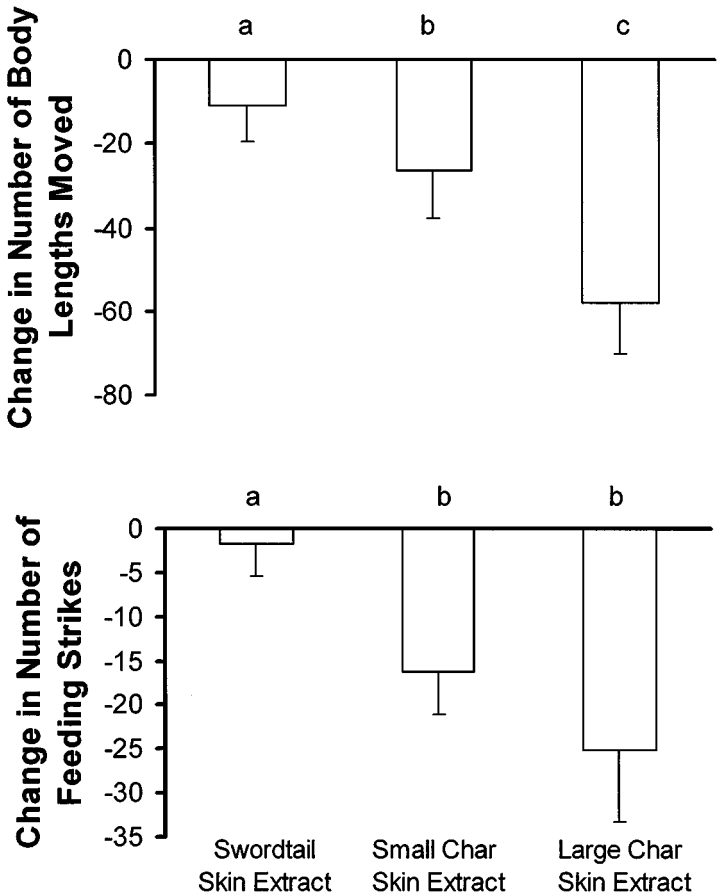

FIG. 3. Mean (+SE) of changes in number of body lengths moved (top) and number of feeding strikes (bottom) for large brook char exposed to skin extract from small brook char, large brook char, and swordtails. Different letters over bars denote significant differences at $P < 0.05$ (see text for details).

cues from conspecific tadpoles (Hews and Blaustein, 1985; Hews, 1988; Kiesecker et al., 1996). Belden et al. (2000) suggest that the lack of response to snake-fed-tadpole cues may be the result of the lack of conservation of the alarm cue between larval and juvenile forms, differential processing of larval and juvenile alarm cues in the gut of the predator, or an inability of juveniles to detect the chemical cue due to changes in chemoreception attributed to metamorphosis. Alternatively, a lack of response may be due to larval and juvenile toads not being members of the same prey guild.

Several studies have documented that salmonid fishes (salmon, trout, and char) use chemical alarm cues to assess their level of predation risk. (Brown and Smith, 1997; Berejikian et al., 1999; Mirza and Chivers, 2000, 2001a,b). However, little is known about the chemical nature of salmonid alarm cues. In one study, Mirza and Chivers (2001b) demonstrated cross-species reactions to chemical alarm cues among three different species of salmonids (rainbow trout, *Oncorhyncus mykiss*; brown trout, *Salmo trutta*; and brook char). For all of the species, the responses to cues of conspecifics were of greater intensity than to cues of heterospecifics. Mirza and Chivers (2001b) concluded that the chemical(s) that act as the alarm cue may be: (1) identical and that there may be chemical(s) that allow the fish to distinguish between conspecifics and heterospecifics, or (2) that the chemical(s) that act as the cue are not identical but are similar enough to be recognized.

In this study, we found that both small and large char responded to alarm cues produced by each other, but that the intensity of the response was lower for different sized individuals. Consequently, these results indicate that the chemical(s) that act as the alarm cue for fish of different age/size classes may be similar but not identical. Alternatively, the chemical(s) may be identical, and there may be other chemicals present that allow the test fish to distinguish among individuals of different ages/sizes. The level of complexity and specificity of chemical alarm cues among salmonid fishes appears to be sophisticated and requires further study.

Acknowledgments—We thank Jerry Banks and the Ft. Qu'Appelle hatchery for providing the char. The study was funded by grants to D. P. Chivers from NSERC of Canada and the University of Saskatchewan. The research described was approved by the University Committee on Animal Use and Supply at the University of Saskatchewan (Animal care protocol #19920077).

Abstract—We used solid-phase microextraction of headspace samples followed by gas chromatography and mass spectrometry to identify and quantify the major volatile compounds produced by the buds and corollas of *Ipomopsis aggregata* (Polemoniaceae), and we compared them to a sympatric, confamilial plant species, *Polemonium foliosissimum*. The two species have distinct floral morphologies and pollinators, but share a common predispersal seed predator that oviposits under the calyces of buds. *Ipomopsis aggregata* buds emitted fewer compounds than the corollas. The buds of *I. aggregata* were dominated by α-pinene and, to a lesser extent, β-pinene. The corollas of *I. aggregata* emitted a mixture of 10 compounds. Like the buds, *I. aggregata* corollas produced relatively high concentrations of α-pinene as well as caryophyllene. In addition, the emission of four terpenoids, three esters, and one ketone added to the volatile bouquet of the corollas. *Polemonium foliosissimum* buds also emitted fewer compounds than the corollas. The buds of *P. foliosissimum* were dominated by β-pinene and, to a lesser extent, α-pinene. The corollas of *P. foliosissimum* were also dominated by β-pinene along with three terpenoids, three alcohols, one ester, and two aldehydes. Comparing *I. aggregata* and *P. foliosissimum*, bud samples from both species produced considerable amounts of α- and β-pinene. *Ipomopsis aggregata* emitted more α-pinene than β-pinene, while *P. foliosissimum* emitted more β-pinene. The corollas of the two species, however, differed in their volatile bouquet. The partition of volatiles between *I. aggregata* and *P. foliosissimum* buds and corollas and differences in volatile

production between *I. aggregata* and *P. foliosissimum* are consistent with selection pressures exerted by organisms interacting with these plants.

Key Words—Floral volatiles, *Ipomopsis aggregata*, Polemoniaceae, *Polemonium foliosissimum*, pollinators, seed predators.

INTRODUCTION

Floral and vegetative fragrances mediate insect identification of plants (Williams, 1983; Robacker et al., 1988; Harborne, 1993). Volatile odors guide pollinators to nectar and pollen rewards or mating sites (e.g., Dodson et al., 1969; Borg-Karlson et al., 1985; Heath et al., 1992; Dobson et al., 1996; Raguso et al., 1996; Roy and Raguso, 1997), advertise vegetative or floral food for herbivores (e.g., Liu et al., 1988; Hopkins and Young, 1990), and serve as oviposition cues for insects (e.g., Dorsett and Pike, 1995; Jallow et al., 1999). Intra- and interspecific variation in volatiles help insects choose among individual plants of the same species (Pellmyr, 1986; Groth et al., 1987; Tollsten and Bergström, 1989) and among individual plants of different species (Dodson, 1970; Williams and Dodson, 1972; Knudsen et al., 1993; Dobson et al., 1996). Yet, floral odors have received little attention compared to studies that examine floral color, size, and shape as cues for visiting insects (for reviews see Faegri and van der Pijl, 1979; Jones and Little, 1983; Proctor et al., 1996). The paucity of studies on volatile odors as attractants may be due, in part, to the difficulty in identifying and quantifying odors produced by plants (for a review see Raguso and Pellmyr, 1998). Nonetheless, insects often use variation in floral odor at both long and short distance intervals to choose plants and may exert phenotypic selection on floral scent production. Here, we explore differential volatile production within and between two plant species in relation to known insect visitors.

Limited work has shown that the volatile odors emitted by plants vary at several levels, including variation among floral parts within individuals (e.g., Meeuse et al., 1984; Dobson et al., 1990, 1996), among individuals within species (e.g., Galen and Kevan, 1980; Chang et al., 1988; Galen and Newport, 1988), and among species (e.g., Knudsen et al., 1993; Dobson et al., 1996). For example, flower parts, such as petals, sepals, anthers, pollen, and/or nectar, often differ in fragrance chemistry and intensity and may signal to insects the location of food or oviposition sites within plants (e.g., Dobson et al., 1990, 1996, 1999). Scent polymorphisms within species may attract different suites of pollinators, resulting in assortative mating based on scent preference (e.g., Galen and Kevan, 1980; Galen and Newport, 1988). In addition, scent variation among closely related species may result in reproductive isolation (e.g., Dodson, 1970; Williams and Dodson, 1972).

Despite the documented variation in floral-scent chemistry, similarities in floral scents among closely related plants species are striking. Closely related plants

often produce similar suites of chemical compounds, although the distribution of compounds does not necessarily follow phylogenetic branches (e.g., Becerra, 1997). The macroevolutionary importance of scent (or chemical) production may be critical to understanding the evolution of host shifts by generalist pollinators and phytophagous insects and to understanding the evolution of plant–insect interactions in general (Ehrlich and Raven, 1964).

Plants in the family Polemoniaceae provide a unique opportunity to test the importance of differential volatile production in attracting various insect visitors. The Polemoniaceae include a diversity of vegetative and floral forms with a wide-ranging assemblage of pollinators, nectar robbers, herbivores, and seed predators (for a review see Grant and Grant, 1965). A wealth of studies have investigated how interacting organisms respond to variation in vegetative and floral diversity in the family (e.g., Brody, 1992; Galen, 1983, 1996, 1999; Brody and Mitchell, 1997; Campbell et al., 1997); however, the importance of volatile odors has been virtually ignored (but see Galen and Kevan, 1980; Galen and Newport; 1988; Dorsett and Pike, 1995). Here, we examine intraspecific and interspecific variation in volatile-odor production of the buds and corollas of two members of the Polemoniaceae, *Ipomopsis aggregata* and *Polemonium foliosissimum*.

The plant and floral morphologies of *I. aggregata* and *P. foliosissimum* are distinct. *Ipomopsis aggregata* produce a single stalk with numerous red, trumpet-shaped flowers that are pollinated primarily by hummingbirds (*Selasphorus platycercus* and *S. rufus*) (Waser, 1978) and are nectar robbed by bumblebees (*Bombus occidentalis*) (Irwin and Brody, 1998, 1999). To the human nose, *I. aggregata* floral corollas range in smell from sweet (like applesauce) to unscented, and the buds often smell pungent. In contrast, *P. foliosissimum* produce multiple stalks with purple, campanulate flowers that are pollinated primarily by bumblebees (*Bombus* spp.) (Zimmerman, 1980). The petals of *P. foliosissimum* flowers usually smell sweet (like sweet clover), and the buds smell pungent or skunky (Dorsett and Pike, 1995). Despite the visual dissimilarity of the two species, they share a common predispersal seed predator, *Hylemya* sp. (Anthomyiidae) (Zimmerman et al., 1984). *Hylemya* lays its eggs under the sepals of buds on both species. The eggs hatch after approximately 14 days, and the larvae burrow into the developing fruits and eat the seeds before they disperse. *Ipomopsis aggregata* and *P. foliosissimum* are the sole hosts for *Hylemya*. We hypothesized that because *I. aggregata* and *P. foliosissimum* share this seed predator, their buds may produce similar volatiles as attractants. However, because the species differ in their primary pollinators, we hypothesized that the corollas may produce distinct odors.

Our objective was to identify, quantify, and compare the volatile odors produced by *I. aggregata* and *P. foliosissimum*. We collected buds (plus gynoecium) and corollas (plus anthers) of *I. aggregata* and *P. foliosissimum* and identified and quantified their major volatiles using solid-phase microextraction (SPME)

followed by gas chromatography (GC) and mass spectrometry (MS). We addressed the following questions: (1) Do the buds and corollas of *I. aggregata* differ in the quality and quantity of volatile compounds produced? (2) Do the buds and corollas of *P. foliosissimum* differ in the quality and quantity of volatile compounds produced? (3) Do *I. aggregata* and *P. foliosissimum* differ in the quality and quantity of volatile compounds produced?

METHODS AND MATERIALS

Study System. We collected plant material from sympatrically growing populations of *I. aggregata* and *P. foliosissimum* around the Rocky Mountain Biological Laboratory (RMBL), Gunnison County, Colorado, USA. Collections were made in July and August 1999 during the peak blooming of both species. Additional collections were made in July 2001 to further identify unknown peaks.

SPME Sampling and Gas Chromatography of I. aggregata. We used the Supelco SPME portable field sampler to collect floral volatiles and then injected the SPME fiber directly into a gas chromatograph for separation and identification of compounds. The portable field sampler has a 75-μm-thick fiber coated with carboxen/polydimethylsiloxane as the stationary phase (no. 504831, Supelco, Sigma-Aldrich Co., Bellefonte, Pennsylvania). Fibers were conditioned initially for 30 min at 280°C, and after each GC injection, the fiber was desorbed at 250°C for 5 min in the GC injection port.

To analyze *I. aggregata* buds, we collected samples from six plants (12 buds per plant) and placed samples from the same plant into cleaned 4 ml glass headspace vials. To analyze *I. aggregata* corollas, we collected six 1 to 2-day-old corollas from each of nine plants into cleaned headspace vials. The vials were sealed with a predrilled PTFE septum. We collected all samples between approximately 0900 and 1100 at similar ambient conditions. In no case were samples pooled; therefore, we could assess plant-to-plant variation in volatile production. We realize that sampling excised tissues for volatiles could introduce physiological artifacts, such as interruption of the flow of metabolic precursors to the sites of volatile emission. However, to sample the volatiles emitted by *individual* floral parts, excision of tissues was essential, and it has been used in other studies identifying volatiles in individual floral parts (e.g., Dobson et al., 1996).

We allowed samples to equilibrate in the vials for approximately 15 min. The septum-piercing needle of the field sampler was then driven through the predrilled septum, and the fiber was injected into the sample vial. Care was taken to ensure that the fiber was extended fully but did not touch the plant tissue or sides of the vial. In all samples, we included 2 μl of 2,2,4-trimethylpentane or geraniol as internal standards (neither of these chemicals are emitted naturally by *I. aggregata* or *P. foliosissimum*). We adsorbed volatiles onto the fiber for approximately 30 min

at 27°C. The fiber was then retracted into the septum-piercing needle sleeve, withdrawn from the sample vial, and introduced into the GC.

We used an HP 402 gas chromatograph with a 30-m nonpolar SPB1 (polydimethylsiloxane) capillary column and flame ionization detector. Starting temperature was 40°C. Injector temperature was 200°C, and detector temperature was 250°C. We held the column temperature at 40°C for 4 min, ramped the temperature to 200°C at 10°C/min, then held the temperature constant at 200°C for 5 min. We did not ramp the temperature above 200°C because preliminary work found no active compounds above 200°C. We used helium as the carrier gas at 20 ml/min, with nitrogen makeup (40 ml/min). As controls, we included runs of the 2,2,4-trimethylpentane and geraniol standards to ensure that the chemicals were not adding extra peaks to the chromatographs. We also controlled for ambient contaminants with blank runs of SPME fibers adsorbed in clean, empty vials.

To correlate fragrance components with GC peaks, we first timed the arrival of various fragrances at the GC detector to the human nose. Then, to identify the chemicals produced by the floral parts, we ran standards of known volatiles obtained from Sigma Aldrich Inc., including α- and β-pinene, cineole, citronellol, coumarin, ethyl acetate, farnesol, geraniol, limonene, linalool, myrcene, and phenylethyl alcohol. We compared the retention times of the standard peaks to those in our floral samples. We confirmed uncertain peaks by augmentation and GC-MS.

SPME Sampling and Gas Chromatography of P. foliosissimum. We also used SPME to identify volatiles produced by *P. foliosissimum* buds and corollas. For buds, we collected samples of 12 buds per plant from each of 12 plants. For corollas, we collected samples from three plants, 10 corollas per plant. We collected 12 buds and 10 corollas per sample for *P. foliosissimum*, as opposed to 6 buds and 6 corollas for *I. aggregata*, because of differences in size between the buds and corollas of the two species. We did not include an internal standard in the corolla samples because we could not find a reliable standard that we also were sure was not covering any sample peaks. We used the same techniques for SPME, GC, and GC-MS as described above for *I. aggregata*.

Data Analyses. To test for differences in total volatile production by the buds and corollas of *I. aggregata*, we added the areas of all peaks from a sample and divided by the area of the standard peak for that sample. We then used ANOVA with floral structure (bud or corolla) as the independent variable and standardized total volatiles emitted (square-root transformed) as the response variable.

To compare relative quantities of the *individual* volatile compounds emitted by bud and corolla samples, we calculated the mean percent composition of each chemical emitted by the different structures. This was accomplished by dividing individual peak areas by the total area of all volatiles emitted on a chromatograph for each species. To compare these volatiles statistically, we standardized the GC peaks from *I. aggregata* buds and corollas and from *P. foliosissimum* buds by dividing the area of each peak on the chromatograph by the area of the standard peak

(2,2,4-trimethylpentane or geraniol). To test for differences in volatile emissions between *I. aggregata* buds and corollas, we used MANOVA with floral structure (bud or corolla) as an independent variable and standardized peak areas (square-root transformed) for each chemical detected as response variables.

In addition, to compare the volatiles emitted by *I. aggregata* and *P. foliosissimum* buds, we used MANOVA with plant species as the independent variable and standardized peak area (square-root transformed) for each chemical detected as response variables. Finding significant MANOVAs (see Results below), we then used univariate ANOVAs to determine which chemical emissions differed between *I. aggregata* buds and corollas and between *I. aggregata* and *P. foliosissimum* buds. Using MANOVA followed by univariate ANOVAs decreases the type I error rate (Rencher, 1995). Because we did not add an internal standard to the *P. foliosissimum* corolla samples, we could only compare qualitative differences between *P. foliosissimum* buds and corollas and between *I. aggregata* and *P. foliosissimum* corollas.

RESULTS

Ipomopsis aggregata Volatiles. The buds of *I. aggregata* emitted three volatile compounds, while the corollas emitted the same three compounds as the buds along with seven additional compounds (Table 1). The three compounds we detected from *I. aggregata* buds were the monoterpenes α-pinene (93.17%) and β-pinene

TABLE 1. COMPOSITION OF VOLATILES FROM *I. aggregata* BUDS AND COROLLAS COLLECTED BY SPME FOLLOWED BY GC

Compound	From buds (%, mean ± SE)[a]	From corollas (%, mean ± SE)[b]
1. Esters		
3-hexen-1-ol-acetate	0	9.46 ± 2.04
Butyl butanoate	0	0.94 ± 0.26
Hexenyl butanoate	0	2.12 ± 0.95
2. Monoterpenoids		
α-pinene	93.17 ± 1.30	23.23 ± 7.58
β-pinene	5.01 ± 0.94	2.25 ± 1.04
β-myrcene	0	8.69 ± 2.63
Unidentified 1	0	2.07 ± 0.59
3. Sesquiterpenoids		
Copaene	0	9.06 ± 2.25
Caryophyllene	1.82 ± 0.41	25.93 ± 5.12
4. Ketones		
2-methyl-6-methenyl-1,7-octodien-3-one	0	16.25 ± 4.81

[a] $N = 6$.
[b] $N = 9$.

(5.01%) and the sesquiterpene caryophyllene (1.82%). In total, the buds emitted approximately one half fewer volatiles than the corolla samples (bud versus corolla standardized mean $\pm$ 1 SE: 0.13 ± 0.10 vs. 0.28 ± 0.06); however, this difference was not statistically significant ($F_{1,13} = 3.77$, $P = 0.07$).

The dominant peaks from *I. aggregata* corollas were the terpenoids caryophyllene (25.93%) and α-pinene (23.23%) and the ketone 2-methyl-6-methenyl-1, 7-octodien-3-one (16.25%) (Table 1). Minor constituents in the corollas included three esters (4-hexen-1-ol-acetate, butyl butanoate, and hexenyl butanoate) and four terpenes (β-myrcene, β-pinene, copaene, and one unidentified monoterpene) (Table 1).

Analyses contrasting the relative emissions of the volatiles from the buds and corollas of *I. aggregata* showed that the buds and corollas emitted different floral fragrances (MANOVA: $F_{10,4} = 23.09$, $P = 0.0042$). This result is driven primarily by the buds emitting only three volatile compounds that we could detect (α- and β-pinene and caryophyllene), while the corollas emitted 10 compounds (dominated primarily by α-pinene and caryophyllene). We then compared the three compounds that the buds and corollas shared: α-pinene, β-pinene, and caryophyllene. The buds and corollas differed in the amounts of these compounds emitted (MANOVA: $F_{3,11} = 5.79$, $P = 0.013$). Specifically, the corollas emitted almost 100 times more caryophyllene than the buds (ANOVA: $F_{1,13} = 14.17$, $P = 0.0024$). However, the buds and corollas did not differ in the amount of α-pinene (ANOVA: $F_{1,13} = 0.57$, $P = 0.46$) or β-pinene (ANOVA: $F_{1,13} = 0.0308$, $P = 0.86$) emitted.

Polemonium foliosissimum *Volatiles.* From *P. foliosissimum* buds, we detected four compounds; the largest peaks included the monoterpenes α-pinene (25.91%) and β-pinene (60.50%). The volatile compounds 2-ethyl-1-hexanol (4.15%) and caryophyllene (9.44%) were minor constituents of the total area measured in the buds' GCs.

In the corolla samples, we detected the four compounds that were emitted from the buds along with six additional compounds (Table 2). As with the buds, the dominant peaks included the monoterpenes α-pinene (24.87%) and β-pinene (40.99%). In addition, the aldehyde benzeneacetaldehyde (9.88%) and the sesquiterpene caryophyllene (6.60%) added to the volatile bouquet. Minor constituents in the corolla samples included three alcohols (1-hexanol, 2-ethyl-1-hexanol, and phenylethyl alcohol), one sesquiterpenoid (copaene), one ester (benzeneacetic acid methyl ester), and one aldehyde (benzaldehyde) (Table 2).

Qualitative comparison of the bud and corolla samples showed that the two produced different relative amounts of volatile compounds (Table 2). The bud and corolla samples produced similar relative amounts of α-pinene (25.91% vs. 24.87%), 2-ethyl-1-hexanol (4.15% vs. 3.31%), and caryophyllene (9.44% vs. 6.60%). However, the buds emitted proportionally more β-pinene (60.79%) than the corollas (40.99%). Finally, six compounds were unique to the corolla samples, including two alcohols (1-hexanol and phenylethyl alcohol), one sesquiterpene

TABLE 2. COMPOSITION OF VOLATILES FROM *P. foliosissimum* BUDS AND COROLLAS COLLECTED BY SPME FOLLOWED BY GC

Compound	From buds (%, mean ± SE)[a]	From corollas (%, mean ± SE)[b]
1. Alcohols		
1-hexanol	0	2.46 ± 0.51
2-ethyl-1-hexanol	4.15 ± 0.84	3.31 ± 0.86
Phenylethyl alcohol	0	3.56 ± 1.92
2. Esters		
Benzeneacetic acid methyl ester	0	1.15 ± 0.35
3. Monoterpenoids		
α-pinene	25.91 ± 0.79	24.87 ± 5.53
β-pinene	60.50 ± 1.08	40.99 ± 2.28
4. Sesquiterpenoids		
Copaene	0	2.78 ± 2.07
Caryophyllene	9.44 ± 1.21	6.60 ± 4.29
5. Aldehydes

[b] $N = 3$.

(copaene), one ester (benzeneacetic acid methyl ester), and two aldehydes (benzaldehyde and benzeneacetaldehyde) (Table 2).

Comparison of Ipomopsis aggregata and Polemonium foliosissimum Volatiles. Ipomopsis aggregata and *P. foliosissimum* buds both emitted α-pinene, β-pinene, and caryophyllene, although in different amounts (MANOVA: $F_{3,14} = 4.88$, $P = 0.016$) (Tables 1 and 2). Relative to other compounds, *I. aggregata* buds emitted more α-pinene than *P. foliosissimum* ($F_{1,16} = 1124.32$, $P < 0.001$), whereas *P. foliosissimum* buds emitted more β-pinene ($F_{1,16} = 1067.53$, $P < 0.001$) and caryophyllene ($F_{1,16} = 24.21$, $P < 0.001$). In addition, the alcohol 2-ethyl-1-hexanol was unique to *P. foliosissimum* buds.

The corollas of *I. aggregata* and *P. foliosissimum* both emitted α- and β-pinene, although the *P. foliosissimum* corollas emitted proportionally more β-pinene than the *I. aggregata* corollas (Tables 1 and 2). In addition, both species also emitted copaene and caryophyllene, but *I. aggregata* corollas emitted proportionally more of both of these compounds than *P. foliosissimum* corollas (Tables 1 and 2). In addition, both species emitted six different compounds unique to each (Tables 1 and 2). In particular, *I. aggregata* may be distinguished by esters (butyl and hexenyl butanoate) and dominant amounts of caryophyllene and a ketone (2-methyl-6-methenyl-1,7-octodien-3-one) producing an overall applelike fragrance; while the corollas of *P. foliosissimum* may be distinguished by aldehydes, in particular, producing a sweet-clove fragrance.

DISCUSSION

Ipomopsis aggregata and *P. foliosissimum* buds and corollas emitted several similar compounds; however, the relative amounts of each compound differed between species and among flower parts. The buds of *I. aggregata* emitted the fewest compounds, dominated by α-pinene, β-pinene, and caryophyllene. The volatile bouquet from the corolla samples of *I. aggregata* was more complex than the buds, emitting 10 volatile compounds. Like the buds, volatiles from *I. aggregata* corollas were dominated by α-pinene and caryophyllene; however, the corollas were also characterized by unique ketones (2-methyl-6-methenyl-1,7-octodien-3-one), terpenoids (such as copaene and β-myrcene), and esters (3-hexen-1-ol-acetate, butyl butanoate, and hexenyl butanoate). In comparison, the buds of *P. foliosissimum* were dominated by β-pinene and, to a lesser extent, α-pinene, caryophyllene, and 2-ethyl-1-hexanol. The corollas of *P. foliosissimum* were also dominated by β-pinene along with a mixture of terpenoids (such as caryophyllene), alcohols, esters, and aldehydes. The dominance of β-pinene emitted by *P. foliosissimum* buds and corollas matches findings of Dorsett and Pike (1995). In addition, most of the volatiles emitted by *I. aggregata* and *P. foliosissimum* are also commonly found in a wide variety of angiosperm species (Knudsen et al., 1993).

Peak area in gas chromatography is sensitive to methodology, e.g., peak areas may vary depending on the adsorbents used in headspace collection and also the stationary phase in the chromatograph. Therefore, we cannot be certain that the peak areas collected by SPME quantitatively represent realized volatile production by the floral parts. However, similar peak patterns were obtained from *I. aggregata* and *P. foliosissimum* by using a dynamic headspace technique (flow-through air over a volatile trap containing Tenax GC and activated charcoal) (Dorsett and Pike, 1995; Dorsett and Irwin, unpublished data), and recent comparisons have shown that SPME is more sensitive than other headspace techniques to a wide range of volatile compounds, especially those at low concentrations, although SPME is less sensitive to other compounds, such as benzenoids (Faldt et al., 2000). Therefore, even though SPME fiber types in a static sampling environment may be somewhat limiting chemically, the fiber used here was probably adequate to detect the types and quantities of compounds emitted by *I. aggregata* and *P. foliosissimum*, especially since we were most interested in relative comparisons among floral structures and between plant species and not in absolute emission of volatiles.

The finding that all of the volatiles emitted by the buds of *I. aggregata* and of *P. foliosissimum* were also emitted by the corollas is not uncommon. Different floral parts on the same plant may emit the same compounds in variable quantities (e.g., Dobson et al., 1990, 1996). For example, in the plant *Papaver rhoeas* (Fabaceae), pollen odors differ from flower odors primarily in the proportions of volatiles produced (Dobson et al., 1996). In general, the biochemical pathways responsible for the production of volatile compounds in buds and corollas may be

similar, resulting in similar emissions of volatiles. Furthermore, insects visiting the plants may not distinguish among different scents emitted by different floral parts. Therefore, the bouquet of whole-flower, whole-plant, and even whole-patch scents may be important in attracting visiting insects and animals to the plants (Beker et al., 1989; for a review see Raguso, 2001). Consequently, natural selection in some species may act on buds and corollas in a similar fashion, resulting in similar volatile emissions.

We detected variation in relative floral scent production not only between *I. aggregata* and between *P. foliosissimum* floral structures (i.e., between buds and corollas) but also among individual *I. aggregata* and individual *P. foliosissimum* (see Tables 1 and 2, variation around mean compound emission). Variation in relative compound production among samples may be due to abiotic conditions, such as small differences in temperature and relative humidity at the time of sample collection (Robacker et al., 1983, 1988). Furthermore, biotic conditions, such as plant genotype (Chang et al., 1988), flower age (Robacker et al., 1988), selection by mutualistic pollinators (Galen and Kevan, 1980; Galen and Newport, 1988), and/or induction by antagonistic herbivores (Turlings et al., 1998), could cause variation in relative scent production. We are currently investigating the degree to which abiotic and biotic conditions influence scent emission among individual *I. aggregata* and *P. foliosissimum*.

The bud samples for both *I. aggregata* and *P. foliosissimum* showed large pinene peaks. High concentrations of monoterpenes, such as α- and β-pinene, attract herbivorous and seed-eating insects in some systems (e.g., Chang et al., 1988; Jallow et al., 1999), but repel them in others (Harborne, 1993). The predispersal seed-predator fly, *Hylemya* sp., uses *I. aggregata* and *P. foliosissimum* as its sole hosts, ovipositing eggs in the developing buds of both species. *Hylemya* may use high concentrations of α- and/or β-pinene, perhaps in association with the combined bouquet of other compounds, as an identifier to find oviposition sites. Preliminary studies indicate that variation in pinene levels in *P. foliosissimum* affects *Hylemya* oviposition (B. Dorsett and N. Brown, unpublished data), and *Hylemya* oviposit on other nonhost Polemoniaceae with similar pinene signatures as *I. aggregata* and *P. foliosissimum* buds (B. Dorsett and R. E. Irwin, unpublished data). We found that *I. aggregata* buds produced relatively more α-pinene than β-pinene, while *P. foliosissimum* buds produced more β-pinene than α-pinene. It is not known how variation in the ratio of α- to β-pinene affects *Hylemya* attraction and larval success. Variation in the ratio of α- to β-pinene between *I. aggregata* and *P. foliosissimum* could play a role in reported *Hylemya* preference for *P. foliosissimum* over *I. aggregata* (Zimmerman et al., 1984); however, further manipulative studies of pinene are needed to test its importance in *Hylemya* attraction.

Despite similar volatile emissions by the buds of *I. aggregata* and *P. foliosissimum*, the volatiles emitted by the corollas of the two species were distinct. The corollas of *I. aggregata* were characterized by esters, terpenoids, and

ketones creating an apple-sweet odor, while the corollas of *P. foliosissimum* were characterized by terpenoids, alcohols, and aldehydes creating a sweet-clover odor. It is not surprising that *I. aggregata* and *P. foliosissimum* emit different odors from their petal tissue, as the two species have different primary pollinators. *Ipomopsis aggregata* is pollinated primarily by hummingbirds, while *P. foliosissimum* is pollinated primarily by bumblebees. Although there is little evidence to suggest that hummingbirds use odor to locate flowers (for a review see Faegri and van der Pijl, 1979; Proctor et al., 1996), there is increasing experimental work suggesting that corolla odors play a role in the attraction of insect pollinators (Williams, 1983; Galen and Newport, 1988; Pellmyr, 1986; Dobson et al., 1999; Pelz, 1997; for a review see Raguso, 2001) as well as other insect visitors (i.e., Galen, 1983; Baldwin et al., 1997). For example, foraging bee pollinators use floral odors at close distance for orientation and floral selection, landing, and feeding (e.g., von Frisch, 1923; Lunau, 1992), and bumblebees bring odors from rewarding flower species back to the nest to convey to other nest members information about foraging success (Dornhaus and Chittka, 1999). Increased pollinator attraction based on fragrance chemistry drives the potential for positive directional selection on fragrance variation (Galen and Newport, 1988; Pellmyr, 1986; Pelz, 1997). It is possible that bumblebee pollinators could act as a strong selective agent on petal-tissue odors in *P. foliosissimum*.

The reason that *I. aggregata* maintains sweet-smelling flowers, even in the absence of selection by hummingbird pollinators, remains a mystery. It may be that the volatiles are merely by-products of essential biochemical pathways or that the volatiles are nonadaptive and occur in *I. aggregata* populations due to drift or phenotypic plasticity. Alternatively, it may be that the sweet odor is selected for in rare years where *I. aggregata* experiences pollination by bumblebees (primarily *B. appositus*) (Pleasants and Waser, 1985). In years where hummingbird densities are low in *I. aggregata* populations, nectar accumulates high in the tubular corollas of *I. aggregata* flowers, allowing *B. appositus* queens to skim nectar from flowers that reach a certain threshold. In the last two decades at the RMBL, there have been two seasons (1981 and 1997) where *B. appositus* queens were the primary pollinators of *I. aggregata* and were shown to be highly effective pollinators (Mayfield, Waser, and Price, unpublished data). Because bumblebees may rely on floral scents to locate and land on flowers, as described above, these rare bumblebee years could maintain sweet-smelling flowers in *I. aggregata* populations.

In summary, the corollas of *I. aggregata* are characterized by a more complex mixture of floral volatiles than the buds, although both are dominated by α-pinene. Additionally, buds of *P. foliosissimum* produce a volatile bouquet similar to that of *I. aggregata* buds, although the buds of the two species emit different ratios of α- to β-pinene. However, the corollas of *P. foliosissimum* emit different compounds from those of *I. aggregata*. The partition of volatiles between *I. aggregata* and *P. foliosissimum* buds and corollas and differences in volatile production between

I. aggregata and *P. foliosissimum* are consistent with selection pressures exerted by organisms interacting with these plants. More comparative studies on plants in the same family will help to elucidate whether similarities and differences in odor production are related to interacting organisms, phylogenetic relationships, and/or similar biochemical pathways. Our next step in this system is to experimentally manipulate the emission of volatile odors by the buds and corollas of *I. aggregata* and *P. foliosissimum* to examine the microevolutionary and macroevolutionary importance of odor emission to mutualistic and antagonistic visitors.

Acknowledgments—We thank R. Jagger in the Chemistry Department at Western State College for the use of his lab facilities and gas chromatograph, P. Flanagan and N. Brown for help in the field and lab, and A. Brody for her insight into the study system. Comments from A. Brody, E. Bruno, R. Raguso, B. Taylor, and two anonymous reviewers improved the manuscript. (Received April 5, 2001; accepted November 8, 2001)

Abstract—Learning of host-induced plant volatiles by *Cotesia kariyai* females was examined with synthetic chemicals in a wind tunnel. Wasps were preconditioned by exposure to volatiles and feces simultaneously. A blend of four chemicals, geranyl acetate, β-caryophyllene, (E)-β-farnesene, and indole, which are known to be specifically released from plants infested by host larvae *Mythimna separata* (host-induced blend), elicited a response in naive *C. kariyai*, but did not enhance the response after conditioning. A blend of five chemicals, (E)-2-hexenal, (Z)-3-hexen-1-ol, (Z)-3-hexen-1-yl acetate, β-myrcene, and linalool, which are known to be released not only from plants infested by the host larvae, but also from artificially damaged plants or undamaged ones (unspecific blend), elicited little response in naive wasps, but significantly enhanced the wasps' response after conditioning. With a blend of the above nine chemicals, wasps could learn the blend at lower concentrations than they did in the nonspecific blend. Hence, both the host-induced and nonspecific volatile compounds appear to be important for *C. kariyai* females to learn the chemical cues in host location.

Key Words—*Cotesia kariyai*, associative learning, wind tunnel, conditioning, host-induced plant volatiles, blend, synthetic chemicals, host location.

INTRODUCTION

Cotesia kariyai Watanabe (Hymenoptera: Braconidae) is a dominant parasitoid species of the common armyworm *Mythimna separata* (Walker) (Lepidoptera: Noctuidae). The wasp is a gregarious, endoparasitoid of second to early sixth

*To whom correspondence should be addressed. E-mail: parasite@sakura.cc.tsukuba.ac.jp

instars of *M. separata* (Sato and Tanaka, 1984) and suppresses their population density in agricultural fields (Hirai, 1984). *M. separata* is widely distributed in Australia, New Zealand, and Asian tropic and temperate zones. In these areas, *M. separata* is an important pest of various Graminae crops (Kanda, 1991).

C. kariyai females use chemical cues of host and host-plant complex origin to find their hosts (Takabayashi and Takahashi, 1986; Takabayashi et al., 1991, 1995). *C. kariyai* has an innate preference for host-induced plant volatiles in Y-tube olfactometer bioassays: they prefer volatiles from plants infested with young host larvae to those from uninfested plants (Takabayashi et al., 1995). *C. kariyai* shows intensive antennation behavior in response to host by-products, such as feces, feeding traces, exuviae, and substances on the larval body surface that contain 2,5-dialkyltetrahydrofurans as kairomones (Takabayashi and Takahashi, 1986; Ohara et al., 1996). However, naive *C. kariyai* shows no response to the odor flow of host feces and the host itself in an Y-tube olfactometer (Takabayashi et al., 1995).

C. kariyai females have an ability to learn to associate host-induced plant volatiles with host feces (Fukushima et al., 2001). Wasps increased their flight response to host-induced plant volatiles in a wind-tunnel bioassay after conditioning, during which wasps were exposed simultaneously to host feces and volatiles. Many studies have revealed that parasitoids can learn to associate with their hosts various stimuli derived from plants (Turlings et al., 1993; Godfray, 1994; Vet et al., 1995).

Despite many papers on behavioral responses related to learning in parasitoids, there are few that focus on the plant components that parasitoids can learn (Turlings et al., 1991; Du et al., 1998; Vet et al., 1998). We have identified volatiles emitted from host-infested corn plants (Takabayashi et al., 1995). In this study, we classified the induced chemicals into two groups: (1) host-induced volatiles or volatiles that were specifically released from plants infested by host larvae *M. separata*, and (2) nonspecific volatiles or volatiles that were released not only from plants infested by the host larvae, but also from artificially damaged or undamaged plants. By using synthetic chemicals, we investigated which group of volatiles could be learned by *C. kariyai* under laboratory conditions.

METHODS AND MATERIALS

Insects. A colony of *C. kariyai* and its host, *M. separata*, were obtained from a stock culture at the University of Tsukuba. Both species were maintained at $25 \pm 1^{\circ}$C, $60 \pm 20\%$ relative humidity with a 16L: 8D photoperiod (on: 05:00 hr, off: 21:00 hr). Host larvae were reared on artificial diet in a similar manner as described by Kanda (1991). To maintain the wasp colony, third- to fifth-instar *M. separata* larvae were exposed to female wasps for oviposition. After wasp egression, cocoon masses were individually kept in glass test tubes (2 cm diam. $\times$ 20 cm

long) and emerging adult wasps were allowed to mate, which generally occurs right after emergence of the wasps. One day after emergence, females were transferred to a plastic cage (15 × 17 × 24 cm) with wet cotton on the bottom and honey on the wall. One- to 5-day-old females were used in all experiments.

Chemicals. We used nine commercially available chemicals to prepare the synthetic blends, including geranyl acetate, β-myrcene (Nakarai Chemicals, LTD., Kyoto, Japan), β-caryophyllene, (E)-β-farnesene, indole, (E)-2-hexenal, (Z)-3-hexen-1-ol, (Z)-3-hexen-1-yl acetate, and linalool (Wako Pure Chemical Industries, Ltd., Osaka, Japan). These compounds were released in relatively higher dosages from host-induced plants, and/or artificially damaged ones than nondamaged ones (Takabayashi et al., 1995).

Three types of blends were prepared by dissolving different kinds of synthetic chemicals in (1 ml) hexane. The amounts of each compound were determined based on their relative percentage amounts in the headspace of the corn plants infested by first/second-instar *M. separata* (Takabayashi et al., 1995). We called a blend of four chemicals that are specifically released from the plants infested by first/second-stadium host larvae [i.e., geranyl acetate, β-caryophyllene, (E)-β-farnesene, and indole] the host-induced blend (Figure 1A). We called a blend of five chemicals that are released not only from plants infested by first/second-stadium host larvae but also from artificially damaged or undamaged plants [i.e., (E)-2-hexenal, (Z)-3-hexen-1-ol, (Z)-3-hexen-1-yl acetate, β-myrcene, linalool] the nonspecific blend (Figure 1B). Furthermore, we called a blend of the above nine chemicals a mixed blend. Each blend was diluted to concentrations of 10^{-1} to 10^{-5} times with hexane, and these dilutions were used for conditioning and odor source.

Conditioning. Conditioning of *C. kariyai* to a blend together with their antennal contact to host feces was performed in a Petri dish (9 cm diam.). Each blend (10 μl), which was the same blend as used for the odor source of the wind tunnel bioassays, was applied to filter paper (1 × 1 cm) and placed in a Petri dish after evaporation of the solvent. Two sheets of nylon gauze were placed over the filter paper, thus preventing the wasps from contacting the filter paper directly. A fecal pellet excreted within 24 hr by fifth/sixth-stadium host larvae was placed on the nylon gauze. Female wasps were released into the Petri dish and the dish capped. When the wasps encountered the feces, they showed a characteristic antennal contact response. A female was allowed to contact the host feces for 1 min. After conditioning, the female was carefully collected with an insect aspirator and placed in another rearing cage (15 × 17 × 24 cm) until the wind-tunnel bioassay.

Bioassay. A wind tunnel (50 × 50 × 150 cm) was used to observe flight responses of wasps within 2 hr of conditioning. Flight responses were tested at a wind speed of 20–30 cm/sec at 25 ± 1°C, 60 ± 20% relative humidity and ca. 2200 lux. As an odor source, a filter paper (2 × 4 × 4 cm triangular) treated with a blend (20 μl) was placed on a stage (15 × 15 cm, 16 cm high) in a wind tunnel. Each conditioned female was introduced into a Petri dish (4 cm diam.) and

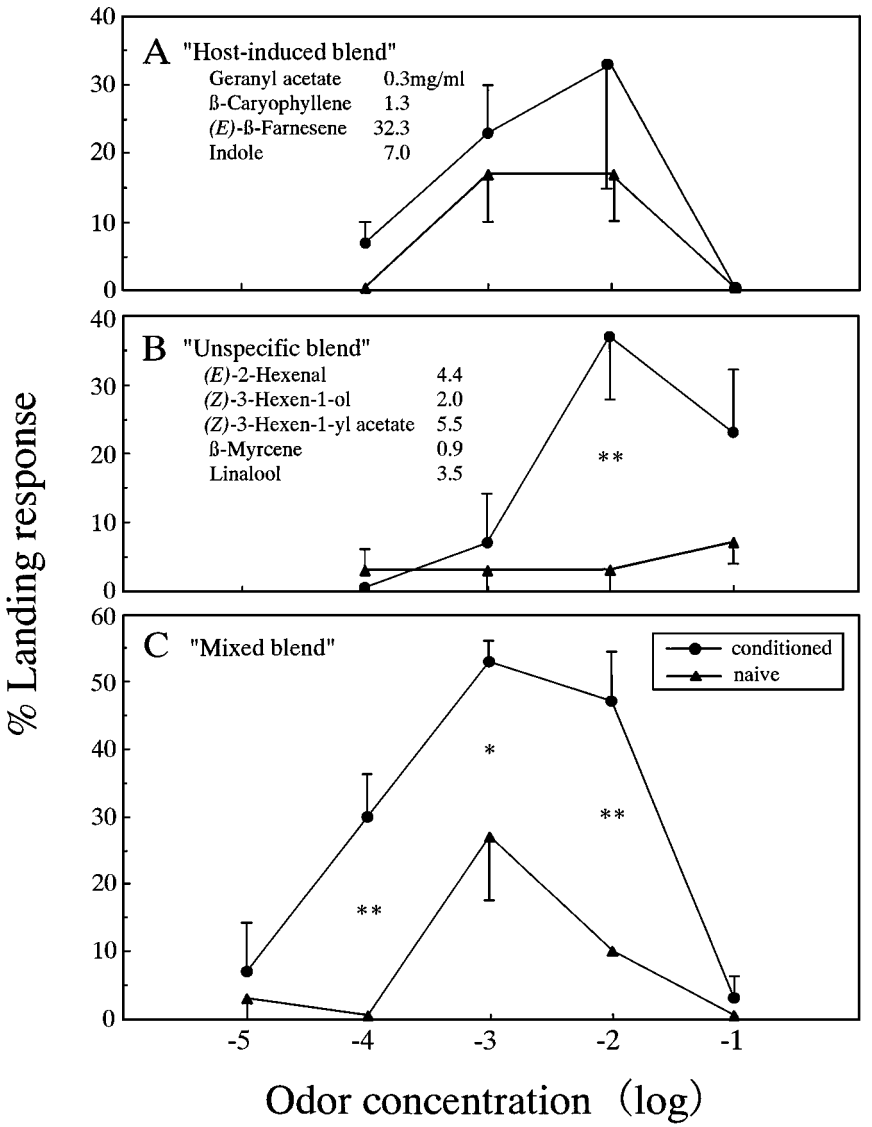

FIG. 1. Effect of a previous experience on subsequent flight response to (A) host-induced blend, (B) nonspecific blend, and (C) mixed blend by *Cotesia kariyai* in a wind tunnel. Dose–response was investigated at 10^{-1} to 10^{-5} concentrations. Error bars represent SE of three replicates (10 females $\times$ 3). Asterisks indicate significant difference by chi-square test ($^{*}P < 0.05$; $^{**}P < 0.01$).

released from a stage (8 × 8 cm, 20 cm high) at 15 cm downwind from the odor source. This distance was based on the previous work of Fukushima et al. (2001). Response of naive and conditioned females to different concentrations of the same blend was tested on the same day. The behavior of females was observed until they landed on the source or on the stage less than 5 cm away from the source within 5 min. When a female did not show any flight response during the test, she was considered to be not attracted by the odor source. A total of 30 females for each treatment were tested on three different days (10 females × 3).

RESULTS AND DISCUSSION

While the naive female *C. kariyai* responded to the host-induced blend (0–17%) (Figure 1A), they responded less to the nonspecific blend (3–7%) (Figure 1B). Responses were stronger to a mixed blend (27%) than to the other two blends at 10^{-3} concentration (Figure 1C). The response of naive wasps to the host-induced blend and to the mixed blend was not significantly different at each concentration ($P > 0.05$). These data suggest that there is little or no synergistic effect of the nonspecific blend to the host-induced blend on naive *C. kariyai* innate response.

The response of conditioned *C. kariyai* to the host-induced blend was not significantly higher than that of naive females at all concentrations ($P > 0.05$) (Figure 1A). By contrast, the response of conditioned females to the unspecific blend (37%) was higher than naive females (3%), but only at the 10^{-2} concentration of the blend ($P < 0.05$) (Figure 1B). Finally, the landing response of conditioned females to the mixed blend (30, 53, and 47%) was higher than that of naive females (0, 27, and 10%) between the 10^{-4} and 10^{-2} concentrations of the blend ($P < 0.05$) (Figure 1C). These data indicate that the wasp could learn the nonspecific blend and the mixed blend and that conditioned wasps responded to a lower concentration with the mixed blend than with the nonspecific blend. Thus, the host-induced blend would have a synergistic effect on learning response. Examples of synergistic effects of plant components have been previously reviewed in oviposition and feeding behavior in lepidopterous insects (Bernays and Chapman, 1994).

The maximum observed landing rate in *C. kariyai* is about 50% in our wind-tunnel experiment (Figure 1C). Naive insects showed a relatively high response (17%) to the host-induced blend when compared to the unspecific blend (Figure 1A); learning would, therefore, have less effect on the response to this blend, or the increase in responsiveness might not be detected under our experimental conditions. In contrast, the nonspecific blend elicited a low response in the naive wasps (Figure 1B), and the learning would therefore have more of an effect on the response to this blend.

C. kariyai was shown to learn blends of several synthetic chemicals from whole plant volatile components (Figure 1B,C). Similarly, other parasitoids can

learn some synthetic chemicals from whole plant volatiles [e.g., *C. marginiventris*, (Turlings et al., 1991); *Aphidius ervi*, (Du et al., 1998); *Leptopilina heterotoma*, (Vet et al., 1998)]. For example, *C. marginiventris* can learn a blend of 11 chemicals, i.e., (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, α-*trans*-bergamotene, (*E*)-β-farnesene, (*E*)-nerolidol, and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, when the wasps experienced the blend with host feces (Turlings et al., 1991). In *A. ervi*, previous experience with the plant–host complex increased the flight responses of females to single synthetic chemicals such as linalool, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexen-1-yl acetate, (*E*)-β-ocimene, and 6-methyl-5-hepten-2-one that are part of the volatile blend emitted by host-infested plants (Du et al., 1998). *L. heterotoma* also learns single plant component such as (*Z*)-3-hexen-1-ol associated with oviposition into the host (Vet et al., 1998).

Different mixtures of plant volatile components will influence the wasps' responses. In *C. marginiventris*, when host-induced plant volatiles were divided into four fractions according to volatility and the responses of the naive wasps to different blends of the four fractions were compared, fractions that contained indole and several sesquiterpenes were highly attractive to wasps in a wind tunnel (Turlings and Fritzsche, 1999). We divided volatiles from host-infested plants into a host-induced blend and a nonspecific blend and found that the responses of *C. kariyai* females were different for the two blends. Several major host-induced volatile compounds that were not commercially available were not tested. However, since the mixed blend used in this study elicited responses from both naive and conditioned wasps equivalent to their response to the infested leaf extract (Fukushima et al., 2001), our results using synthetic chemicals may partly explain the natural phenomena. Further study using complete blends of host-induced plant volatiles need to be done.

It is well-accepted that plants infested by herbivores attract carnivorous natural enemies of herbivores (Takabayashi and Dicke, 1996; Dicke and Vet, 1999). Special attention has been paid in plant–carnivore interactions to volatile compounds that are specifically produced by plants in response to herbivory (herbivore-induced plant volatiles) (Dicke, 1999; Turlings and Fritzsche, 1999). However, in the natural habitat, when *C. kariyai* finds host feces on a plant, the insect is surrounded not only by host-induced plant volatiles, but also by nonspecific ones. If the host density is low and the concentration of host-induced volatiles is accordingly low, associative learning of nonspecific volatiles with antennal contact with host feces would favor the wasp in the next host–microhabitat finding, rather than ignoring a potential habitat. A similar situation was discussed by Powell et al. (1998), in which *A. ervi* responded to an undamaged plant in a wind tunnel after experiencing the plant/host complex.

In our study, the role of each component was not determined. It would be necessary to test the learning response to each individual compound and also

to the blend with the individual compounds removed. These data would further elucidate the degree of specificity of the learned response and may help to reveal the role of volatile chemicals in parasitoid learning.

(Received May 2, 2001; accepted November 7, 2001)

Abstract—Larvae of the diamondback moth, *Plutella xylostella*, a crucifer specialist, refuse to feed on a crucifer, *Barbarea vulgaris*, because of the presence of a feeding deterrent, which is extractable with chloroform. We isolated a feeding deterrent from *B. vulgaris* leaves, by successive fractionations with silica-gel, ODS, i.e., C_{18} reversed phase, and Sephadex LH-20 column chromatographies, and ODS-HPLC, guided by a bioassay for feeding deterrent activity. The structure of the compound was determined to be a monodesmosidic triterpenoid saponin, 3-*O*-[*O*-β-D-glucopyranosyl-(1→4)-β-D-glucopyranosyl]-hederagenin, based on FAB-MS, ^{1}H- and ^{13}C-NMR spectra, and hydrolysis experiments. When the compound was applied to cabbage leaf disks at greater than 0.18 μg/mm^2, consumption of the disks by third instars was less than 11% of control disks treated with the solvent alone. Furthermore, all first instars died on the disks treated with the same concentrations. Because the concentration of the compound in the fresh leaves of *B. vulgaris* was comparable to the effective dose in the cabbage leaf disk tested, we conclude that the unacceptability of *B. vulgaris* to *P. xylostella* larvae is primarily due to this saponin.

Key Words—*Barbarea vulgaris*, Brassicaceae, diamondback moth, feeding deterrent, 3-*O*-[*O*-β-D-glucopyranosyl-(1→4)-β-D-glucopyranosyl]-hederagenin, host plant resistance, insect-plant interactions, Lepidoptera, *Plutella xylostella*, triterpenoids, saponins.

INTRODUCTION

The diamondback moth, *Plutella xylostella* L. (Lepidoptera: Plutellidae), a worldwide pest on cruciferous crops, is a typical crucifer specialist. The intimate relationship between crucifers and *P. xylostella* is mainly mediated by glucosinolates and their breakdown products, isothiocyanates, which stimulate oviposition of the adults and feeding of the larvae (Thorsteinson, 1953; Gupta and Thorsteinson, 1960a,b; Hillyer and Thorsteinson, 1969). However, most, but not all, crucifers containing glucosinolates are suitable hosts for *P. xylostella*; the wintercress, *Barbarea vulgaris* R. Br. (Brassicaceae), is a rare exception.

B. vulgaris is a biennial or perennial herbaceous plant of European origin and has recently been naturalized in Japan. The leaves of *B. vulgaris* contain (2*R*)- and (2*S*)-glucobarbarin and glucobrassicin, as major glucosinolates that stimulate the oviposition of *Pieris rapae*, another crucifer specialist (Huang et al., 1994). *P. xylostella* adults also preferably lay eggs on this plant, probably being stimulated by the glucosinolates. Despite the presence of glucosinolates, hatched larvae refuse to feed on the plant and cannot develop to the second instar (Idris and Grafius, 1996). In a previous study, we found strong feeding deterrent activity to *P. xylostella* larvae in a chloroform-extract of *B. vulgaris* leaves (Serizawa et al., 2001).

We now report the isolation and identification of a triterpenoid saponin from the leaves of *B. vulgaris* that strongly deters feeding of *P. xylostella* larvae. To our knowledge, this is not only the first feeding deterrent to *P. xylostella* found in the family Brassicaceae, but also the first oleanane-type saponin found in this family.

METHODS AND MATERIALS

Insects and Plants. Larvae of the diamondback moth, *Plutella xylostella*, a strain susceptible to insecticides, were maintained on radish seedlings at 25°C and 12L:12D following the method of Yamada and Koshihara (1978). *Barbarea vulgaris* var. *variegata* (Chiltern Seeds) and the cabbage, *Brassica oleracea* L. cv.YRSE, were grown in a greenhouse without any application of insecticides.

Isolation of Feeding Deterrent. Isolation of the feeding deterrent from *B. vulgaris* leaves was performed by a series of column chromatographies and ODS-HPLC, guided by successive bioassays of the fractions (Figure 1). Fresh leaves of *B. vulgaris* (2.8 kg) were homogenized in MeOH (14 liters), extracted overnight at room temperature, and filtered. After evaporation of MeOH, the aqueous residue was extracted with $CHCl_3$. The $CHCl_3$ extract (38.1 g) was chromatographed on silica gel (Kieselgel 60, Merck; 500 × 55 mm ID), eluted

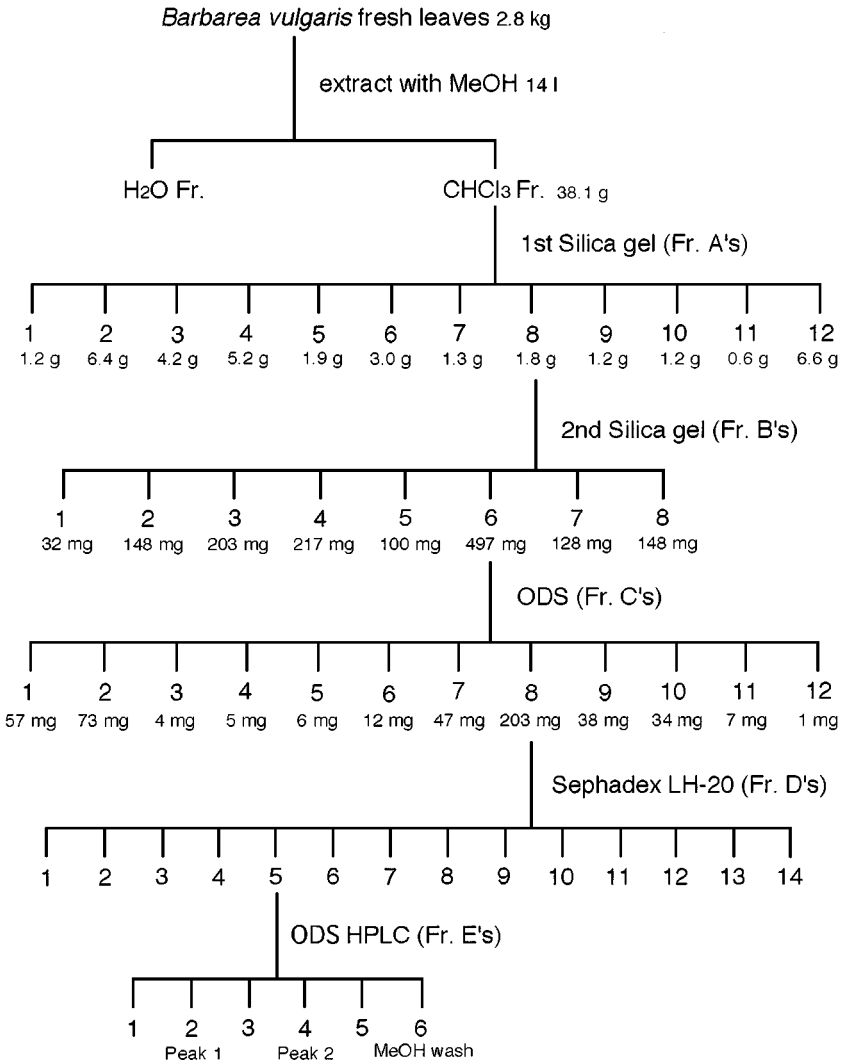

FIG. 1. Schematic diagram of the procedure for isolating the feeding deterrent from *B. vulgaris*.

successively with 0, 5, 10, 15, 20, and 100% MeOH in $CHCl_3$, and the eluate was collected (initially 100 ml/subfraction). Each subfraction was analyzed by TLC (plate, 5554, Merck; solvent system, $CHCl_3$–MeOH–H_2O, 32:9:1; development, spraying with 10% H_2SO_4 followed by heating), and subfractions showing similar spotting patterns were combined, providing 12 fractions (Fr. A-1 to A-12).

The solvents corresponding to the fractions are as follows: A-1, 100% $CHCl_3$, 1500 ml; A-2, 100% $CHCl_3$, 3500 ml; A-3, 5% MeOH/$CHCl_3$, 1000 ml; A-4, 5% MeOH/$CHCl_3$, 4000 ml; A-5, 10% MeOH/$CHCl_3$, 1000 ml; A-6, 10% MeOH/$CHCl_3$, 2000 ml; A-7, 10% MeOH/$CHCl_3$, 2300 ml; A-8, 10% MeOH/$CHCl_3$, 700 ml and 15% MeOH/$CHCl_3$, 2000 ml; A-9, 15% MeOH/$CHCl_3$, 1500 ml; A-10, 15% MeOH/$CHCl_3$, 2500 ml; A-11, 20% MeOH/$CHCl_3$, 2000 ml; A-12, 100% MeOH, 2500 ml. The most active fraction, A-8, was applied again to a silica gel column (Kieselgel 60, Merck; 200 $\times$ 25 mm ID) and successively eluted with 0, 5, 10, 12.5, 15, 20, and 100% MeOH in $CHCl_3$. The eluate was collected (50 ml/subfraction), analyzed by TLC, and combined into eight fractions (Fr. B-1 to B-8) in a manner similar to the first separation. The solvents corresponding to the B fractions are as follows: B-1, 100% $CHCl_3$, 400 ml, 5% MeOH/$CHCl_3$, 400 ml, and 10% MeOH/$CHCl_3$, 100 ml; B-2, 10% MeOH/$CHCl_3$, 300 ml; B-3, 12.5% MeOH/$CHCl_3$, 150 ml; B-4, 12.5% MeOH/$CHCl_3$, 200 ml; B-5, 12.5% MeOH/$CHCl_3$, 50 ml and 15% MeOH/$CHCl_3$, 50 ml; B-6, 15% MeOH/$CHCl_3$, 350 ml; B-7, 15% MeOH/$CHCl_3$, 500 ml; B-8, 20% MeOH/$CHCl_3$, 400 ml and 100% MeOH 400 ml. The active fraction, B-6, was chromatographed on ODS (Cosmosil, Nacalai; 100 $\times$ 30 mm ID), successively eluted with 150 ml of 30, 40, 45, 50, 55, 60, 65, 70, 80, 90, and 100% MeOH in H_2O, and 100% $CHCl_3$, providing 12 fractions (Fr. C's). The active fraction, C-8, was applied to Sephadex LH-20 (Pharmacia, 1000 $\times$ 25 mm ID) and eluted with 80% MeOH, providing 14 fractions (50 ml/fraction) (Fr. D's). The active fraction, D-5, was fractionated by ODS-HPLC (column, SenshuPak ODS-4253-D, 250 $\times$ 10 mm ID; column temperature, 40°C; solvent, 80% MeOH, 3 ml/min; detection, UV 210 nm). Fr. D-5 showed a major peak 1 (retention time, 10.1 min), that was designated as compound **1,** and a minor peak 2 (retention time, 14.9 min). The peak area of peak 2 was about 1/20 that of peak 1. Six fractions (Fr. E's) corresponding to prepeak 1, peak 1, postpeak 1, peak 2, postpeak 2, and the MeOH wash of the column were collected separately for the bioassay.

*Chemical Identification of Compound **1***. Compound **1** was obtained from Fr. D-5 by preparative HPLC (column, Cosmosil 5C18AR, 250 $\times$ 20 mm ID, Nacalai; solvent, 82% MeOH; flow rate, 7 ml/min; detection, RI). The yield of compound **1** was 124 mg out of 151 mg of Fr. D-5.

FAB-MS, ^{1}H-NMR, ^{13}C-NMR, and Optical Rotation. For structural analysis of compound **1**, a fast atom bombardment mass spectrum (FAB-MS) was obtained using a Jeol HX-110 mass spectrometer. ^{1}H- and ^{13}C-NMR spectra were recorded on a Jeol A-500 spectrometer. Optical rotation was measured on a JASCO DIP-360 polarimeter.

Methanolysis and GLC Analysis of Methyl Glycoside. Compound **1** (2 mg) was dissolved in 1 N HCl/MeOH (1 ml) and heated to 95°C for 2 hr. After cooling, the acidic solution was neutralized with Ag_2CO_3. $AgCl_2$ and Ag_2CO_3 were centrifuged off, and the supernatant was analyzed by TLC with authentic hederagenin

(Extrasynthese) (solvent system, $CHCl_3$–MeOH, 19:1) and methyl glycoside (solvent system, $CHCl_3$–MeOH–H_2O, 15:6:1). The supernatant described above was dried under a N_2 current, and the residue was dissolved in trimethylsilyl imidazole (0.2 ml) to convert the methyl glycosides into TMS ethers. After incubation at 95°C for 10 min, the solution (1 μl) was analyzed by GLC (Shimadzu GC-14A with FID) to identify the sugar. Sugar standards were treated in the same manner. GLC conditions were as follows: column, DB-1, 0.25 mm × 30 m, J & B Scientific; carrier gas, helium; linear velocity in column, 300 mm/sec; split ratio, 1/40; column temperature, 170°C; injection port temperature, 250°C; FID detector temperature, 250°C.

Bioassays with Third-Instar Larvae. Fractions from *B. vulgaris* and the purified compound **1** were dried in vacuo, dissolved in 80% MeOH, and applied topically to both sides (25 μl on each side) of cabbage leaf disks (19 mm diam., ~100 mg). For controls, solvent (80% MeOH) alone was applied to leaf disks. After evaporation of the solvent, the disks were placed individually at the center of moist filter paper set in a plastic container (60 mm diam. × 30 mm high) and three third instars of *P. xylostella* were gently transferred onto the leaf disks. The containers were closed with a lid and kept at 25°C and a 12L:12D cycle. After 24 hr of incubation, the disks were scanned with a digital image scanner (ES-2000, Epson) and the area consumed was measured by using imaging analysis software (NIH image). Assays were performed with five replicates.

Bioassays with First-Instar Larvae. Cabbage leaf disks were treated with various concentrations of compound **1** dissolved in 80% MeOH or the solvent alone (control) as described above. Each disk was set on moist filter paper (25 mm diam.) in a glass dish (28 mm diam. × 15 mm high). Five first instars within 12 hr of hatching were transferred gently onto the leaf disk with a fine brush. The dishes were sealed with Parafilm and kept at 25°C and a 12L:12D cycle. After 24 hr of incubation, the survival of *P. xylostella* larvae was examined under a microscope. Larvae that did not move after being touched with a pinhead were counted as dead. Assays were performed with 10 replicates.

Statistical Analysis. The significance of the difference of the consumption or survival rate between the test and the control samples was analyzed by an independent *t*-test (two-way) using commercial software (Statistica, StatSoft).

*Quantification of Compound **1** in* B. vulgaris *Leaves.* Fresh matured leaves of *B. vulgaris* were weighed and extracted three times with 10 volumes of 80% MeOH (v/w). The 80% MeOH extract (3 ml) was loaded on a Sep-Pak Plus C18 cartridge (Waters) that was equilibrated with 80% MeOH, and eluted with 80% MeOH (10 ml × 3). The whole eluate was dried in vacuo, and the residue was dissolved in 1 ml of 80% MeOH–0.1% CH_3COOH solution, and 100 μl of the solution [10 mg fresh weight equivalent (FWE)] was analyzed by analytical HPLC (Intersil ODS-2, 250 × 4.6 mm ID; column temperature, 40°C; solvent, 80% MeOH–0.1% CH_3COOH; flow rate, 0.6 ml/min; detection, UV 210 nm). Compound **1** eluted at

a retention time of 10.1 min. Concentration was calculated based on the peak area of the sample compared with purified compound **1**.

RESULTS

Isolation of Feeding Deterrent. In a previous paper, we reported that the $CHCl_3$ fraction of the MeOH extract of *B. vulgaris* leaves showed strong feeding deterrent activity against larvae of *P. xylostella* (Serizawa et al., 2001). To isolate the feeding deterrent, we fractionated the $CHCl_3$ fraction by several chromatographic steps guided by no-choice bioassays (Figure 1). After the first silica gel chromatography, when applied at a high dose to cabbage leaf disks (1120 mg FWE/disk), Fr. A-2, A-7, and A-8 showed strong ($P < 0.001$), Fr. A-3 moderate ($P < 0.01$), and Fr. A-6 and A-9 weak ($P < 0.05$) feeding deterrent activity (Figure 2A). When the fractions were applied at a low dose (140 mg FWE/disk),

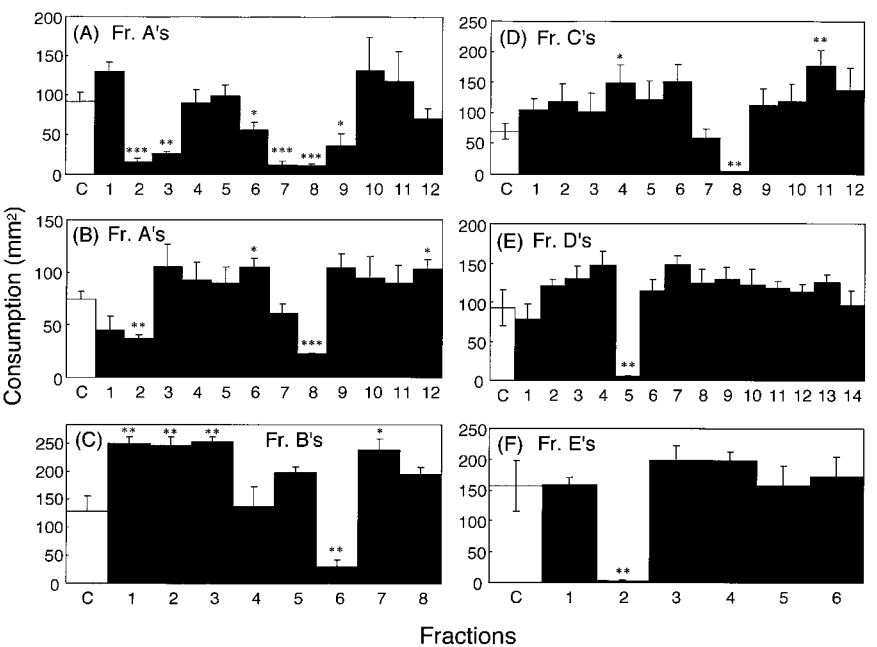

FIG. 2. Effects of *B. vulgaris* fractions on the feeding of *P. xylostella* larvae. The doses applied to cabbage leaf disks were 1120 (A), 140 (B), 700 (C), and 1400 mg FWE (D, E, F). Control disks were treated with 80% MeOH alone. Open and solid bars indicate consumption of control and test disks, respectively (means ± SE, $N = 5$). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

only Fr. A-8 ($P < 0.001$) and Fr. A-2 ($P < 0.01$) showed significant feeding deterrent activity (Figure 2B). We further purified only the most active fraction, A-8, on a second silica gel column, finding feeding deterrent activity in Fr. B-6 ($P < 0.01$) at 700 mg FWE/disk (Figure 2C). When this fraction was separated on an ODS column, feeding deterrent activity was found only in Fr. C-8 at 1400 mg FWE/disk ($P < 0.01$) (Figure 2D). Separation of this fraction on a Sephadex LH-20 column resulted in isolation of only one active fraction, D-5 (1400 mg FWE/disk, $P < 0.01$) (Figure 2E). After purification of Fr. D-5 by ODS-HPLC, only Fr. E-2 showed feeding deterrent activity ($P < 0.01$) at 1400 mg FWE/disk (Figure 2F).

*Chemical Identification of Compound **1***. Compound **1** was purified from Fr. D-5 as a white powder by a preparative ODS-HPLC. Optical rotation, FAB-MS, ^{1}H-NMR and ^{13}C-NMR spectra of compound **1** were as follows. $[\alpha]_D^{25} + 38.7^\circ$ ($c = 1.4$, pyridine). Negative ion FAB-MS (glycerol matrix) *m/z*: 795.4535 ([M–H]$^-$; $C_{42}H_{67}O_{14}$ requires 795. 4531), 633 ([M–glc-H]$^-$), 471 ([M–2glc-H]$^-$). ^{1}H-NMR δ (C_5D_5N): 0.93 (6H, s, C-25-H and C-29-H), 0.96 (3H, s, C-24-H), 1.00 (3H, s, C-30-H), 1.02 (3H, s, C-26-H), 1.25 (3H, s, C-27-H), 3.28 (br. d, $J = 11$, C-18-H), 3.69 (br.d, $J = 11$, C-23-Ha), 3.85 [ddd, $J = 2, 4, 9$, C-5′-H], 3.96 [ddd, $J = 2, 6, 9$, C-5″-H], 4.00 (dd, $J = 8, 9$, C-2′-H), 4.04 (dd, $J = 8, 9$, C-2″-H), 4.14 (dd, $J = 9, 9$, C-4″-H), 4.18 (2H, dd, $J = 9, 9$, C-3′-H and C-3″-H), 4.20 (dd, $J = 4, 10$, C-3-H), 4.25 (dd, $J = 6, 12$, C-6″-Ha), 4.29 (dd, $J = 9, 9$, C-4′-H), 4.41 (dd, $J = 2, 12$, C-6′-Ha), 4.49 (dd, $J = 2, 12$, C-6″-Hb), 4.52 (dd, $J = 4, 12$, C-6′-Hb), 5.04 (d, $J = 8$, C-1′-H), 5.14 (d, $J = 8$, C-1″-H), 5.47 (br. s, C-12-H). ^{13}C-NMR δ (C_5D_5N): 13.6 (C-24), 16.1 (C-25), 17.5 (C-26), 18.2 (C-6), 23.6 (C-16), 23.7 (C-30), 23.8 (C-11), 25.7 (C-2), 26.1 (C-27), 28.3 (C-15), 30.9 (C-20), 32.9 (C-7), 33.2 (C-22), 33.2 (C-29), 34.2 (C-21), 36.9 (C-10), 38.6 (C-1), 39.8 (C-8), 41.9 (C-18), 42.2 (C-14), 43.3 (C-4), 46.4 (C-19), 46.6 (C-17), 47.7 (C-5), 48.1 (C-9), 62.1 (C-6′), 62.3 (C-6″), 64.7 (C-23), 71.4 (C-4″), 74.6 (C-2″), 75.2 (C-2′), 76.3 (C-5′), 76.7 (C-3′), 78.0 (C-3″), 78.3 (C-5″), 81.3 (C-4′), 82.4 (C-3), 104.9 (C-1″), 105.3 (C-1′), 122.5 (C-12), 144.8 (C-13), 180.1 (C-28).

The molecular formula of compound **1** was established to be $C_{42}H_{68}O_{14}$ by high-resolution FAB-MS. The ^{1}H-NMR spectrum of compound **1** showed signals of six tertiary methyl groups [δ 0.93 (6H), 0.96, 1.00, 1.02, and 1.25], one trisubstituted olefinic proton (δ 5.47), and two sugar anomeric protons (δ 5.04 and 5.14). The ^{13}C-NMR spectrum revealed the presence of six saturated quaternary carbons (δ 30.9, 36.9, 39.8, 42.2, 43.3, and 46.6), a pair of olefinic carbons (δ 122.5 and 144.8), one carboxylic acid carbon (δ 180.1), three hydroxymethyl carbons (δ 62.1, 62.3, and 64.7), and two sugar anomeric carbons (δ 104.9 and 105.3). These spectral data indicated that compound **1** is a glycoside of olean-12-ene type triterpene carboxylic acid, having a hydroxymethyl group on the aglycone and two hexosyl groups as sugar moieties.

The methanolysate of compound **1** showed two spots that gave the same R_f values as hederagenin (solvent system, $CHCl_3$–MeOH, 19:1; $R_f = 0.31$) and

methyl glucoside (solvent system, $CHCl_3$–MeOH–H_2O, 15:6:1; $R_f = 0.26$) on TLC. Methyl glucoside was also identified by GLC as a TMS ether. The ^{13}C-NMR spectrum of compound **1**, and the signals of the aglycone moiety were consistent with the data reported for a hederagenin 3-*O*-glycoside (Kohda et al., 1990), indicating compound **1** is a glucobiosyl hederagenin. The HMBC spectrum was examined to determine the sugar linkage of compound **1**. The HMBC correlations, observed between the signals of C-3-H (δ 4.20) and C-1′ (C-1 of inner glucosyl group, δ 105.3), C-1′-H (δ 5.04) and C-3 (δ 82.4), C-4′-H (δ 4.29) and C-1″ (C-1 of terminal glucosyl group, δ 104.9), C-1″-H (δ 5.14) and C-4′ (δ 81.3), indicated a cellobiosyl group is linked to C-3 of hederagenin. From these data, compound **1** was identified as 3-*O*-[*O*-β-D-glucopyranosyl-(1 $\rightarrow$ 4)-β-D-glucopyranosyl] hederagenin, which has been reported only in the mature fruits of *Fatsia japonica* (Figure 3) (Aoki et al., 1976).

*Effect of Compound **1** on Feeding of Third-Instar Larvae.* Figure 4 shows the effect of compound **1** on feeding of third instars. Compound **1** deterred feeding of the larvae dose-dependently. The consumption of the cabbage leaf disks treated with 25 μg or more of compound **1** was less than that of the control ($P < 0.001$). Remarkably, the mean consumption of the disks treated with 50 and 125 μg was only 11% and 5%, respectively, of that of the control.

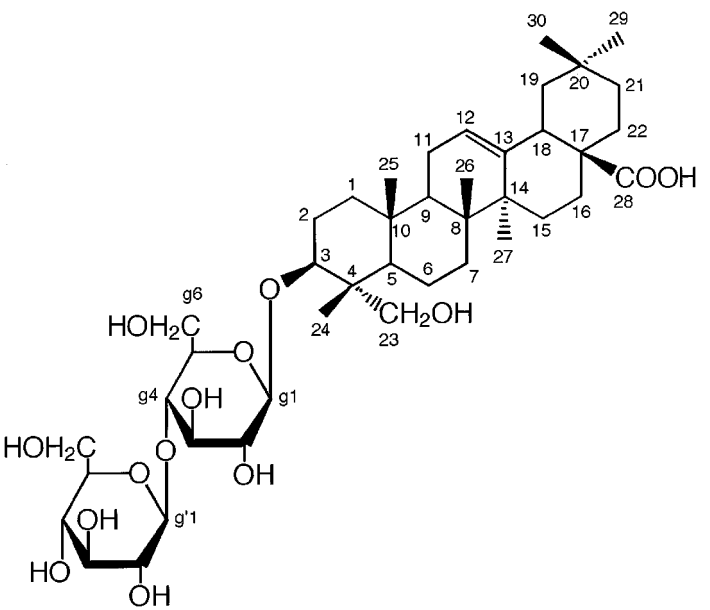

FIG. 3. Structure of the feeding deterrent (compound **1**) isolated from *B. vulgaris*.

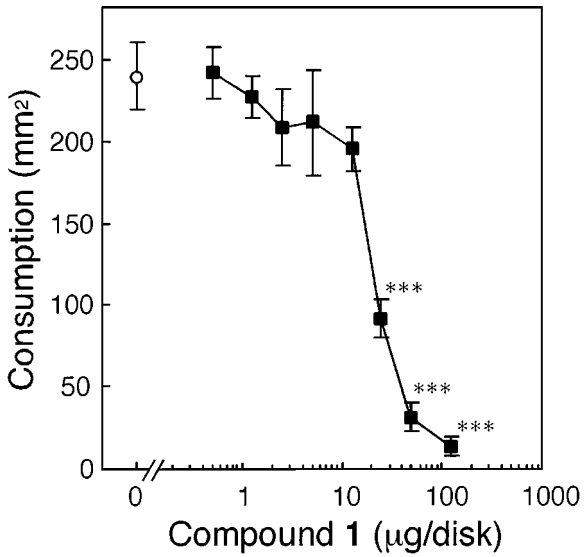

FIG. 4. Dose–response effect of compound **1** on the feeding of third-instar larvae. Data represent the consumption of the test (■) and control (○) leaf disks (mean ± SE, $N = 5$). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

*Effect of Compound **1** on Survival of First-Instar Larvae.* Figure 5 shows the effect of compound **1** on the survival of the first instars. Compound **1** reduced the survival rate dose-dependently. The survival rates on the disks treated with 5 μg or more of compound **1** were significantly lower than the control value. Only 6% of the larvae could survive on the disks treated with 12.5 μg of compound **1**, and all larvae died on the disks treated with more than 50 μg.

*Quantification of Compound **1** in* B. vulgaris *Leaves.* The concentration of compound **1** in the fresh mature leaves of *B. vulgaris* was estimated as 1.1 ± 0.3 mg/g (mean ± SD, $N = 4$).

DISCUSSION

We isolated and identified a triterpenoid saponin, 3-*O*-[*O*-β-D-glucopyranosyl-(1→4)-β-D-glucopyranosyl]-hederagenin (**1**), as a feeding deterrent to the diamondback moth, *Plutella xylostella*, from the winter cress, *Barbarea vulgaris*. It shows strong deterrence to this insect. Although a number of feeding deterrents to *P. xylostella* have been reported from various plant species, none has been found in the family Brassicaceae. Furthermore, few saponins have been reported from the family Brassicaceae (Hostettmann and Marston, 1995). To our knowledge,

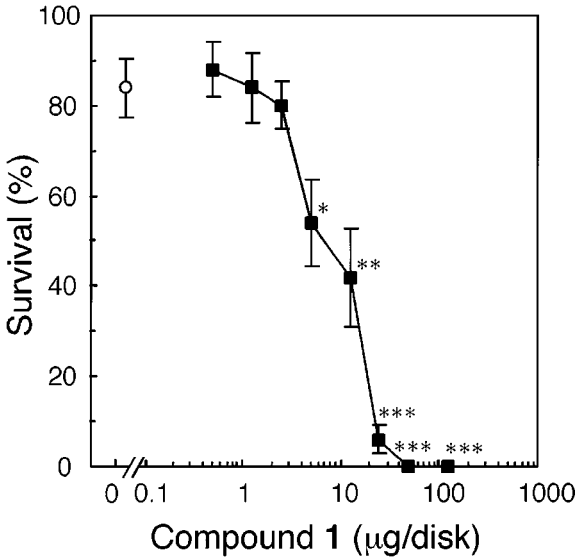

FIG. 5. Dose–response effect of compound **1** on the survival of first-instar larvae. Data represent the survival rate on the test (■) and control (○) leaf disks (mean ± SE, $N = 10$). $^{*}P < 0.05$; $^{**}P < 0.01$; $^{***}P < 0.001$.

this is the first feeding deterrent to *P. xylostella* and the first oleanane-type saponin isolated from this family.

On leaf disks of *B. vulgaris*, the third instars of *P. xylostella* consumed less than 10% of those of cabbage, and none of the first instars developed to the second instar (Serizawa et al., 2001). When the cabbage leaf disks (average weight = ∼100 mg) were treated with 50 μg or more of compound **1**, similar effects were found on both third and first instars. Because the effective dose of compound **1** on cabbage leaf disks (>0.5 mg/g) is comparable to that found in the fresh leaves of *B. vulgaris* (1.1 mg/g), we conclude that compound **1** alone is sufficient to inhibit the feeding of *P. xylostella* larvae on *B. vulgaris*. Other feeding deterrents present in Fr. A-2, A-3 and A-7 may also contribute.

The ED_{50}, i.e., 50% effective dose of compound **1,** for the third instars was estimated to be 20 μg/disk (0.07 μg/mm^2). In no-choice feeding deterrent bioassays similar to our experiment, several quassinoids isolated from *Picrasma ailanthoides* (Simaroubaceae) showed strong activity at 50–200 μg/disk (0.16–0.64 μg/mm^2) against the third instars (Daido et al., 1993), and 14-deoxyandrographolide isolated from *Andrographis paniculata* (Acanthaceae) showed minimal activity at 100 μg/disk (0.32 μg/mm^2) against the fourth instars (Hermawan et al., 1997). The activity of compound **1**, thus, is as strong as that of feeding deterrents reported previously.

Glucosinolates present in crucifers generally function in defense against nonadapted insects. However, crucifer specialists counteradapt and even utilize glucosinolates as key stimulants for host selection. Other classes of secondary compounds in the restricted genera of crucifers have been found to deter feeding of some crucifer specialists: cucurbitacin E and cucurbitacin I in *Iberis amara* against the flea beetle, *Phyllotreta nemorum* (Nielsen et al., 1977), 2-*O*-β-D-glucopyranosyl cucurbitacin E in *Iberis amara* against the cabbage butterfly, *Pieris rapae* (Sachdev-Gupta et al., 1993a), and cardenolides in *Erysimum cheiranthoides* against *P. rapae* (Sachdev-Gupta et al., 1993b). Feeny (1977) referred to such substances as "a second line of chemical defense" in contrast with glucosinolates, "the first line of chemical defense". *B. vulgaris* contains glucosinolates (Huang et al., 1994) and is favorably selected for oviposition by *P. xylostella* in the field (Idris and Grafius, 1996). Therefore, compound **1** apparently functions as "the second line of chemical defense" against *P. xylostella* larvae.

Besides *P. xylostella*, some crucifer specialists, such as the pollen beetle, *Meligethes* sp. (Merker and Nilsson, 1995), and the flea beetle, *Phyllotreta nemorum* (Nielsen, 1996, 1997a,b, 1999), cannot infest *B. vulgaris*, suggesting the presence of unidentified feeding deterrents or toxins to these insects in this plant. It will be of interest to see whether compound **1** also deters their feeding or growth. *B. vulgaris* is, however, a good host for *P. rapae* (Huang et al., 1994), indicating that the feeding deterrent activity of compound **1** is species-specific to some extent.

Finally, we point out that compound **1** can be utilized to develop novel methods to control *P. xylostella* on cruciferous crops. Because of the outstanding ability of *P. xylostella* to develop resistance to a wide spectrum of insecticides, alternative control methods are now in great demand (Talekar and Shelton, 1993). Compound **1** or its derivatives might be used as repellents to protect susceptible cruciferous crops from infestation. Resistant cruciferous crops harboring compound **1** could be developed via various breeding techniques, e.g., traditional crossing, somatic hybridization, or genetic engineering. Because *B. vulgaris* belongs to the family Brassicaceae, it may be relatively easy to introduce pathways for the biosynthesis of compound **1** into cruciferous crops. Indeed, intertribal somatic hybrids between *B. vulgaris* and *Brassica napus* have already been generated (Fahleson et al., 1994). Furthermore, because *B. vulgaris* has been used as a vegetable and medicinal plant (Senatore et al., 2000), compound **1** is likely to be safe for humans.

Acknowledgments—We thank Dr. Hubert Wojtasek for critical comments on the manuscript.

(Received June 28, 2000; accepted October 31, 2001)

Abstract—Secretions from the metathoracic glands (MTG) of the black locust bug, *Lopidea robiniae* (Uhler) (Heteroptera: Miridae) contained six major compounds, including (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, (*E*)-2-octenal, (*E*)-2-octen-1-ol (*E*)-2-heptenal, and (*Z*)-3-octen-1-ol. Males and females did not differ significantly in the relative compositions of identified compounds. In feeding trials, six bird species [robin (*Turdus migratorious*), blue jay (*Cyanocitta cristata*), brown thrasher (*Toxostoma rufum*), killdeer (*Charadrius vociferus*), starling (*Sturnus vulgaris*), and house wren (*Troglodytes aedon*)] demonstrated feeding aversions towards *L. robiniae*, implying that black locust bugs are chemically defended. Bugs discharged the liquid contents of their MTG when attacked, thereby producing a strong and distinct odor. Some birds immediately ejected bugs out of their mouth after biting them, suggesting that the MTG secretion was a deterrent.

Key Words—Aldehydes, alcohols, chemical defense, Heteroptera, Miridae, *Lopidea robiniae*, *Robinia pseudoacacia*, (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, (*E*)-2-octenal, (*E*)-2-octen-1-ol, (*E*)-2-heptenal, (*Z*)-3-octen-1-ol.

INTRODUCTION

The mirids are the largest family of Heteroptera, numbering over 1900 species in North America (McPherson, 1989) and 10,000 species worldwide (Schuh and Slater, 1995). Mirids predominately use crypsis and agile escape maneuvers, such

0098-0331/02/0300-0601/0 © 2002 Plenum Publishing Corporation

as taking flight, dropping, and feigning death, to avoid predation (Aldrich, 1988). Although adults have metathoracic scent glands, (MTG) and the nymphs and some adults possess dorsal abdominal scent glands (DAG), the chemical ecology of only a few species has been examined (Aldrich, 1988; Millar et al., 1997; Millar and Rice, 1998; McBrien and Millar, 1999).

A common genus in the family Miridae is *Lopidea*, with more than 60 species occurring solely in the Western Hemisphere throughout much of North and Central America. *Lopidea* are different from other mirids in that most are relatively large (>5.0 mm) and are brightly colored with red, orange, or yellow on a black background, creating striking patterns (Asquith, 1993). For insects, large size and conspicuous coloration is often associated with chemical defense (Pasteels et al., 1983).

The black locust bug, *Lopidea robiniae* (Uhler), is common in the eastern United States and is found nearly everywhere its host tree, black locust, *Robinia pseudoacacia* L., grows. Adults are typically 6.0–6.5 mm in length and 2.1 mm in width. Males and females are aposematically colored orange–yellow with a broad black stripe that runs along the mid-dorsum from the tip of the head to the end of the abdomen (Knight, 1941). The nymphs are also aposematic with black wingpads on an orange–red body. Our observations suggest that, in Illinois, black locust bugs overwinter in the egg stage and hatch in early spring after their host tree produces new growth. In the fall, we have observed adults aggregating on goldenrod plants. In central Illinois, adults first appear in mid-June and become scarce by middle to late September. The adults emit a conspicuous odorous secretion when disturbed.

Interestingly, the black locust bug appears to be involved in a mimicry relationship with the adult stage of the locust leaf miner beetle *Odontota dorsalis* (Thurnburg) (Chrysomelidae). The larvae feed on black locust and the adult beetles closely resemble the black locust bug in color, pattern, and size. Additionally, both species occur at the same time of year and can be found together on the same plant where their ranges overlap.

In this paper, we identify the volatile chemical components and glandular source of the secretion in the black locust bug. Additionally, we examine the palatability of *L. robiniae* against various avian predators and provide evidence that the bugs are chemically defended and that the secretion functions as a feeding deterrent against predators.

METHODS AND MATERIALS

Insect Collection and Care

Adult black locust bugs, *Lopidea robiniae* (Uhler), were collected on black locust trees, *Robinia pseudoacacia* L., in and near Normal, Illinois, USA, from late July to mid-September 1998. Thereafter, the bugs were maintained until

needed in 2-liter translucent plastic jars at 25°C under a 14L:10D photoperiod and fed daily with fresh cuttings of black locust twigs and leaves, with the base of the twig inserted into a vial of water. Black locust bugs readily emit their secretions in response to even mild disturbances (see below). Therefore, during collecting, maintaining, and testing, the bugs were handled in an extremely gentle manner.

Chemical Analysis

Twenty *L. robiniae* adults were separated by sex using a dissecting microscope, then placed individually into glass GC autosampler vials (12 × 32 mm; Hewlett-Packard) and sealed with a Teflon-lined aluminum crimp cap. Before sealing the vials, the adults therein were agitated by gently poking them with a probe. Undisturbed male and female insects were also individually isolated in vials to serve as controls. We used solid-phase microextraction (SPME) (100 μm polydimethylsiloxane fiber; Supelco Inc., Bellefonte, Pennsylvania) to sample volatiles from individual vials. Sampling time was 30–45 min. Volatiles obtained from SPMEs of individual bugs were analyzed using a gas chromatograph (GC) (Hewlett-Packard model 5890 Series II) equipped with split/splitless injector run in splitless mode. The injector port was purged after 30 sec. Compounds were separated using a 30-m × 0.25-μm ID DB-5 column (J & W Scientific, Folsom, California) with a temperature program of 50°C for 1 min, followed by a ramp of 50°C to 250°C at 10°C/min, and remaining at 250°C for 6 min. Individual compounds were detected by flame ionization.

Mass spectra were obtained with a Hewlett-Packard 5973 MSD mass spectrometer. We introduced samples through a DB-SMS capillary column (30 m × 0.25 mm ID, 1.0-μm film) using a temperature program of 50°C for 1 min, followed by a ramp of 50°C to 250°C at 10°C/min, and remaining at 250°C for 6 min.

Authentic standards of (*E*)-2-hexenal (99%), (*Z*)-2-hexenal (97%), (*E*)-2-hexen-1-ol (96%), (*Z*)-2-hexen-1-ol (95%), (*E*)-3-hexen-1-ol (98%), (*Z*)-3-hexen-1-ol, (98%) (*E*)-2-heptenal (99%), (*Z*)-2-heptenal (97%), (*Z*)-3-octen-1-ol (94%), (*E*)-2-octenal (99%), (*Z*)-2-octenal (97%), (*E*)-2-octen-1-ol (96%), and (*Z*)-2-octen-1-ol (95%) were purchased from Aldrich Chemical Co., Milwaukee, Wisconsin. Relative concentrations of individual secretion components were determined from GC peak areas, after compensating for biases for alcohols and heavier compounds inherent in SPME sampling (Bartelt, 1997).

Behavioral Response toward Threats

We used a 3-mm-diam. wooden dowel to examine the behavioral response of *L. robiniae* to threats. Ten wild adults were individually tested in the field on a warm sunny day (33–35°C) by moving the tip of the dowel several times to within

0.5 cm of the insect, at a rate of 2 cm/sec, then catching the insects in a net, and finally, holding the insects between the fingers.

Predator Feeding Trials

We tested six bird species for their ability to feed on black locust bugs. Birds were obtained as nestlings and raised in the laboratory on a diet of various arthropods and cat food supplemented with bird vitamins, earthworms, fruit, snails, and small fish. The specific diet approximated the natural diet of each bird species. In all cases, birds were tested only after they had developed the ability to feed independently and discriminate among food items. All the birds had experienced a variety of both palatable and chemically defended prey in the week prior to testing. For the robin (*Turdus migratorious*), brown thrasher (*Toxostoma rufum*), and blue jay (*Cyanocitta cristata*), this included several encounters with black locust bugs; hence, these birds had already experienced *L. robiniae*. In contrast, the killdeer (*Charadrius vociferus*), starling (*Sturnus vulgaris*), and the house wrens (*Troglodytes aedon*) had never encountered black locust bugs when tested and hence were naive vis-à-vis this insect.

The birds were starved for 2–4 hr prior to testing, and each was tested independently in 0.3- to 1.0-m^3 cages. Generally, each bird was offered a series of live *L. robiniae* adults until the bird refused to attack further offerings. Then the bird was offered alternative live palatable arthropods (crickets, *Acheta domesticus* L., and/or mealworms, *Tenebrio molitor* L.) of approximately the same mass as the black locust bugs. In some trials, birds received bugs and palatable prey in alternation. In addition to these tests using solitary birds, we also introduced bugs into a 1-m^3 cage containing a group of six wrens. Each test was completed within 48 min. After the trials, birds were released in appropriate habitats.

Blue Jay, Brown Thrasher, and American Robin. During the trials, each bird was offered a series of live *L. robiniae* by placing individual bugs in a Petri dish in the cage until the bird rejected at least four in a succession. Then, each was offered a series of five mealworms and three crickets.

Killdeer. The killdeer was first given a control third-instar *A. domesticus* cricket to demonstrate hunger. Then, individual *L. robiniae* were offered successively until the bird no longer consumed the bugs. When this occurred, the bird was then offered another control cricket to verify that the bird was not simply satiated. If the control was eaten, another treatment was then offered. Uneaten bugs were removed 4 min after placing them in the cage with the bird. This protocol was continued until the bird repeatedly ate the control insects, but repeatedly rejected the bugs, at which time the experiment was ended.

European Starling. This bird was tested with a protocol identical to that of the killdeer (above) except that mealworms were used as controls. With this predator,

we also recorded time to attack (the time from introduction of each insect until the bird pecked at the insect).

House Wren. A Petri dish containing seven live black locust bugs was placed into the bird's cage. Ten minutes later (when the wren had stopped attacking the bugs), a second Petri dish was added that contained four black locust bugs, four small crickets, and one mealworm. Eleven minutes later a third Petri dish containing five black locust bugs was added.

In a second experiment, we tested six wrens held communally in a 1-m^3 cage. A Petri dish containing 15 live black locust bugs was placed on the floor of the cage. Nine minutes later we added a Petri dish containing five crickets and four mealworms. Fourteen minutes later, we added a third dish containing 10 crickets and 10 black locust bugs.

Source of Volatiles

We examined *L. robiniae* adults under a dissecting microscope to determine the presence and location of external gland orifices. We then tested four locations as the possible source of the bugs' odorous secretion: mouth, anus, MTG, and DAG. Two adult males and two adult females were chilled to 10°C. One of each sex was glued ventral side up onto cardstock. The remaining two adults were dewinged using small scissors and glued ventral side down. All bugs were then allowed to warm to room temperature, viewed under a dissecting microscope, and poked or pinched with tweezers to elicit expulsion of the secretion. Slivers of filter paper (ca. 3.0 mm^2) were then placed on the MTG opening, dorsal abdomen, beak, or anus to absorb any ejected fluids, which were then examined for the presence or absence of odor.

RESULTS

Chemical Analysis. No volatiles were obtained from SPME of nonagitated adult male or female *L. robiniae*. Agitated bugs released a blend of at least six different volatiles (Figure 1) that were tentatively identified by matching mass spectra to library spectra. Chemical identification of five of these compounds was confirmed by comparing mass spectra and GC retention times (Table 1, Figure 2) to commercial standards. The sixth compound (peak 4) was identified as (*Z*)-3-octen-1-ol. It matched the authentic standard with respect to both GC retention time and mass spectrum. An authentic standard of (*E*)-3-octen-1-ol was not available for comparison, but by analogy to the hexen-1-ols, the (*E*)- and (*Z*)-3-octen-1-ols should be easily separable by GC, with the *E* isomer eluting first. There was no evidence for the *E* isomer from the bugs.

The relative concentrations of the six identified volatiles were not significantly different between males and females (six separate two-sample *t* tests,

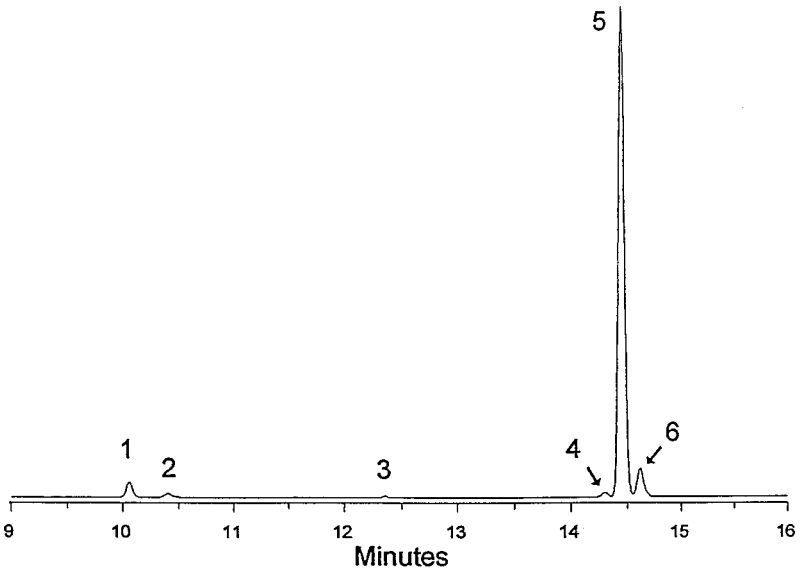

FIG. 1. Gas chromatogram of the metathoracic gland volatiles from a male black locust bug, *Lopidea robiniae*.

each $P > 0.05$). Averaged over both sexes ($N = 12$), the relative mean percentages and standard errors for the six compounds identified were: (*E*)-2-octenal, 75.5% ± 3.3; (*E*)-2-octen-1-ol, 15.5% ± 2.5; (*E*)-2-hexenal, 5.6% ± 1.8; (*E*)-2-hexen-1-ol, 2.0% ± 0.8; (*Z*)-3-octenol, 1.2% ± 0.3; (*E*)-2-heptenal, 0.2% ± 0.06.

TABLE 1. COMPOUNDS IDENTIFIED FROM *L. robiniae* (BLACK LOCUST BUG) SECRETIONS AND MS IONS

GC peak[a]	Identification	Major MS ions (percentages)
1	(*E*)-2-Hexenal	98 (M^+, 26), 83 (61), 70 (23), 69 (76), 57 (48), 55 (86), 42 (60), 41 (100)
2	(*E*)-2-Hexen-1-ol	100 (M^+, 2), 82 (22), 71 (11), 67 (18), 57 (100), 44 (17), 41 (40)
3	(*E*)-2-Heptenal	112 (M^+, 6), 97 (12), 83 (92), 70 (46), 69 (44), 68 (42), 57 (60), 56 (55), 55 (85), 43, (38), 41 (100)
4	(*Z*)-3-Octen-1-ol	128 (M^+, 1), 110 (14), 95 (15), 81 (63), 68 (53), 67 (43), 55 (100), 41 (51)
5	(*E*)-2-Octenal	126 (M^+, 0.4), 125 (0.9), 108 (4), 97 (14), 83 (61), 70 (90), 69 (46), 57 (58), 55 (100), 42 (42), 41 (100)
6	(*E*)-2-Octen-1-ol	128 (M^+, 1), 110 (8), 95 (12), 85 (8), 82 (24), 81 (29), 68 (31), 67 (26), 57 (100), 55 (47), 43 (41), 41 (56)

[a] Peak numbers correspond to those in Figure 1.

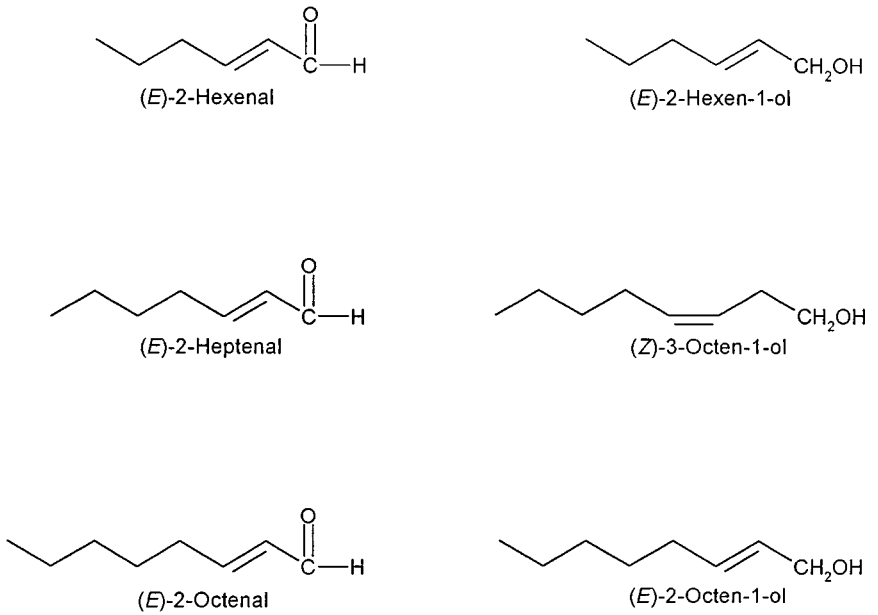

FIG. 2. Compounds identified in *Lopidea robiniae* (black locust bug) male and female metathoracic gland secretions.

Several other minor compounds were noted during GC-MS analysis, but were not identified.

Behavioral Response towards Threats. Nine of 10 adult *L. robiniae* showed defensive behavior when approaching dowels were about 6.0 cm away by quickly crawling away from the dowel to the opposite side of the leaf or stem. Pursuing the bug further with the dowel elicited escape by flight (7 of 10) or dropping (3 of 10), but failed to cause them to expel perceivable volatiles. Four of the 10 bugs secreted when simply caught in the insect net. Five of the remaining six bugs secreted when held between the fingers.

Predator Feeding Trials. All six species of bird tested showed some form of aversion to feeding on black locust bugs, although the exact response varied among individual birds (Table 2). The three birds that had previously encountered black locust bugs (jay, thrasher, robin) consumed only 2 of 15 bugs offered, yet ate 23 of 24 palatable crickets and mealworms. The killdeer and starling, which had not previously experienced *L. robiniae*, initially consumed the bugs, then abruptly stopped and refused all subsequent bugs. The killdeer vomited and the starling gagged (see below). The solitary house wren was also naive yet refused to eat a single black locust bug. Bugs that were attacked by birds emitted their secretion, producing a distinct odor in and near the cage.

TABLE 2. FEEDING RESPONSE OF SIX BIRDS TO BLACK LOCUST BUGS (*Lopidea robiniae*), CRICKETS (*Acheta domesticus*), AND MEALWORMS (*Tenebrio molitor*)

Predator	Bugs (*N*)		Mealworms (*N*)		Crickets (*N*)	
	Offered	Consumed	Offered	Consumed	Offered	Consumed
Blue Jay[a]	5	1	5	5	3	3
Thrasher[a]	5	1	5	5	3	3
American robin	5	0	5	5	3	2
Killdeer[b]	22	12	—	—	10	10
European starling[c]	17	12	8	8	—	—
House wren	16	0	1	1	4	2

[a] Only the first bug encountered was consumed. All subsequent bugs were rejected.
[b] The killdeer ate the first 12 bugs offered, then vomited. Afterwards, it refused all subsequent bugs offered, but ate all crickets offered.
[c] The starling gagged after consuming 12 bugs and 6 mealworms.

The blue jay attacked and swallowed the first bug 46 sec after it was introduced. One minute later we introduced a second bug, which was immediately seized and quickly flung from the beak. At 3 min from the start of the trial, a third bug was offered and was likewise seized and ejected. At 4 min, a fourth bug was introduced; 32 sec later the jay bit and dropped this insect. At 6 min, a fifth bug was introduced. For 5 min, the jay ignored this bug as well as the three previously ejected bugs, which remained in the cage. At 11 min, five mealworms and three crickets were introduced at 1-min intervals. The jay immediately attacked and consumed each, but continued to ignore the bugs remaining in the cage.

The thrasher attacked and swallowed the first bug 3 sec after it was offered. One minute later, a second bug was offered. It was seized within 2 sec and immediately flung from the mouth. Five seconds later the bird picked up the bug again, held it in its mouth for 4 sec and dropped it. At 2 min, a third bug was offered and was immediately seized and dropped. At 3 min, a fourth bug was offered. The thrasher landed next to the bug as if to attack, but turned and flew away. At 4 min, a fifth bug was introduced. The thrasher again landed near the bug, lowered its head as if to attack, then flew away. At 10 min, five mealworms and three crickets were offered at 1-min intervals; all were immediately attacked and consumed. The bird continued to ignore the remaining black locust bugs.

The robin immediately attacked and dropped the first bug offered. During the next 40 sec, it seized and dropped the bug three additional times. At 2 min from the beginning of the trial, a second bug was introduced and was ignored by the robin. At 3 min, a third bug was introduced, and it was immediately seized and dropped. At 4 and 5 min, a fourth and fifth bug were introduced and were ignored. At 10 min, five mealworms and three crickets were introduced at 1-min intervals. The robin quickly consumed the mealworms and two crickets, but continued to ignore the bugs remaining in the cage.

The killdeer ate the first control cricket, demonstrating that it was hungry. The bird was then offered 12 bugs in a row, but was hesitant to eat the first four, which were not eaten until 35–145 sec after they were introduced. However, the next eight were readily attacked and consumed, and each bug expelled its secretion, producing a strong odor. The thirteenth bug offered was rejected, and the second control was then subsequently offered and eaten immediately by the bird. The fourteenth bug was also rejected. The bird then vomited (after consuming 2 crickets and 12 bugs). Thereafter, the bird rejected all subsequent bugs (Table 2), and would (1) bob its head toward its prey as if to attack and then quickly withdraw without touching the prey, (2) actively pace around the bug, or (3) completely ignore the bugs. When a bug flew onto the killdeer's back, it quickly turned its head, bit and released the bug (without harming it), and then began biting the paper on the bottom of the cage. In contrast, the bird immediately consumed all 10 control crickets and, on one occasion, the bird stepped past three moving bugs to get to a cricket.

The starling demonstrated mild aversion towards adult *L. robiniae*. It consumed 12/17 bugs offered vs. 8/8 mealworms (Table 2), but the time to attack was significantly longer for *L. robiniae* (190.9 ± 21.0 sec) than for mealworms (2.3 ± 0.3 sec) (two sample *t* test, $P < 0.001$; $df = 7$). During the trial, the starling showed aversive behavior toward *L. robiniae*, such as ejecting bugs out of the beak and running toward newly introduced bugs, staring at them from 2 cm away, and then turning away. Near the end of the trial, the bird exhibited a gagging reflex by opening its mouth wide and thrusting its head and neck forward. It then closed its beak and swallowed, which suggests the bird was nauseated and possibly vomited into its esophagus or mouth.

The solitary wren attacked four bugs in quick succession, immediately flinging each bug away. During the next 4 min, it inspected bugs without attacking them. Four minutes into the test, the wren picked up and dropped a bug, then immediately wiped its beak on the floor of the cage. At 10 min, a second Petri dish was added, that contained four small crickets, four black locust bugs, and one mealworm. Within 15 sec, the wren ate two crickets and the mealworm. At 21 min, a third Petri dish was introduced that contained five live black locust bugs. The wren inspected these bugs, but did not attack.

When 15 black locust bugs were placed in a cage containing six house wrens, all birds quickly approached and attacked the bugs. By 5 min after the start of the test, 23 attacks (=bites) had occurred. In 19 of these attacks, the bug was rejected; however, one individual bird consumed four bugs. At 9 min, five small crickets and four mealworms were added to the cage. By 14 min, two mealworms, five crickets, and one of the remaining black locust bugs were eaten. At 23 min, 10 small crickets and 10 black locust bugs were added. By 24 min, nine crickets but no black locust bugs had been eaten. At 27 min, the experiment was concluded with a total consumption of 5 bugs, 2 mealworm, and 14 crickets.

Source of Volatiles. When adult male and female *L. robiniae* were disturbed, an odorous liquid emerged from the MTG openings suggesting that the MTG was the source of the scent. In contrast, filter paper slivers placed on the mouth, anus, or dorsal abdomen of disturbed adults acquired no scent.

DISCUSSION

Chemistry of Lopidea robiniae Secretion. We identified three unsaturated alcohols and three unsaturated aldehydes in the defensive secretion of adult *L. robiniae*. True bugs commonly produce six- and eight-carbon unsaturated (*E*)-alkanes and (*E*)-alcohols (Blum, 1981; Aldrich, 1988; McBrien and Millar, 1999). Hence, the compounds identified in *L. robiniae* represent, for the most part, typical hemipteran exocrine products. Four of the six identified compounds, [(*E*)-2-hexenal, (*E*)-2-hexen-1-ol, (*E*)-2-octenal, and (*E*)-2-octen-1-ol] are common in insect exudates. (*E*)-2-Hexenal is found in the defensive secretions of ants (Crewe et al., 1972), beetles (Tschinkel, 1975), cockroaches (Farine et al., 1997), and in true bugs (Percy et al., 1980; Knight et al., 1984; Hamilton et al., 1985; Staddon et al., 1987; Aldrich, 1988; Borges and Aldrich, 1992; Farine et al., 1992a,b; Leal et al., 1994; Krall et al., 1999; McBrien and Millar, 1999). (*E*)-2-Hexen-1-ol has similarly been identified in the defensive secretions of ants (Crewe et al., 1972), cockroaches (Wallbank and Waterhouse, 1970), and in the pheromone or defensive secretions of numerous Heteroptera (Hamilton et al., 1985; Aldrich, 1988; Smith et al., 1991; Farine et al., 1992a,b; McBrien and Millar, 1999). (*E*)-2-Octenal has been identified in cockroaches (Wallbank and Waterhouse, 1970; Farine et al., 1997), and numerous species of Heteroptera (Percy et al., 1980, Blum, 1981; Knight et al., 1984; Hamilton et al., 1985; Staddon et al., 1987; Aldrich, 1988; Borges and Aldrich, 1992; Farine et al., 1992a,b; Aldrich et al., 1995; Leal et al., 1996; Krall et al., 1997; McBrien and Millar, 1999). (*E*)-2-Octen-1-ol has been found in cockroaches (Wallbank and Waterhouse, 1970; Farine et al., 1997), sawflies (Boeve et al., 1997), and several Heteroptera (Aldrich and Yonke, 1975; Percy et al., 1980; Staddon et al., 1987; Farine et al., 1992a,b; Aldrich et al., 1993; Leal et al., 1996; Krall et al., 1997). (*E*)-2-Heptenal occurs less frequently in insects, relative to the other structurally similar chemicals identified in our research, and has been reported in at least one tenebrionid beetle, *Eleodes beamri* (Tschinkel, 1975) and in the heteropteran families Pentatomidae (Blum et al., 1960) and Cydnidae (Roth, 1961). Trace amounts of both stereoisomers of 3-octen-1-ol (e.g., $<1\%$ total secretion) have been found in cockroaches (Farine et al., 1997); however, this compound appears to be exceedingly rare among terrestrial arthropods and, to our knowledge, has never been reported as a primary constituent of any insect defensive secretion.

It is interesting to note that four of the compounds identified in this research are frequently found in a mixture in other Heteroptera. For example,

(*E*)-2-hexenal, (*E*)-2-hexen-1-ol, (*E*)-2-octenal, and (*E*)-2-octen-1-ol are present in the pheromone/defensive secretions of two members of Pyrrhocoridae (Farine et al., 1992a,b). (*E*)-2-Hexenal, (*E*)-2-octenal, and (*E*)-2-hexen-1-ol, are found in the pentatomid *Acrosternum pennsylvanicum* (Aldrich et al., 1995) and are part of a complex defensive secretion in the scutellerid bug *Hotea gambiae* that functioned to deter conspecific competitors and oviposition by parasitoids (Hamilton et al., 1985). Likewise, the former two aldehydes are extremely common in pentatomids (Aldrich et al., 1995; McBrien et al., 2001; Ho and Millar, 2001). The frequent cooccurrence of these compounds suggests a common enzymatic origin, and Blum (1981) has suggested that the alcohols may simply represent precursors to their aldehyde analogues.

Function of L. robiniae Secretion. Our results suggest that *L. robiniae* is chemically defended and that the volatiles found in the MTG secretion of *L. robiniae* function in antipredator defense. We base these conclusions on the following: (1) The secretion is discharged in direct response to threats. (2) Both sexes produce the same major components in the secretion, suggesting that they do not function as sexual pheromones. (3) Adults are brightly colored, implying an aposematic warning function (Pasteels et al., 1983; Guilford, 1990). (4) Adult black locust bugs occasionally aggregate, a trait often associated with chemically defended insects (Pasteels et al., 1983). (5) The types of compounds identified in the MTG secretion (short-chain aldehydes and alcohols) are volatile, highly odorous, and are known to have toxic or irritating effects (Eisner, 1970; Hamilton et al., 1985; Griffin and Segall, 1989; van Iersal et al., 1997). Hence, they are ideally suited to serve as alerting or punishing substances (Blum, 1981; Whitman et al., 1990) and can effectively deter predators (Blum, 1981; Hamilton et al., 1985; Aldrich, 1988; Gunawardena and Herath, 1991; Gunawardena and Bandumathie 1993; Krall et al., 1999). Finally, (6) Several predators tested in this study demonstrated feeding aversions towards *L. robiniae*. For example, after sampling a single bug, the jay and the thrasher rejected all others. The robin and several wrens refused to eat a single bug. Two birds exhibited symptoms of toxicosis after consuming black locust bugs: the killdeer vomited and the starling gagged. The most telling response was seen in the robin and the solitary wren: both birds eagerly attacked the first bugs offered, but then immediately ejected the bugs from their beaks, suggesting that the secretion itself was unpleasant. After biting bugs, the solitary wren wiped its beak on the floor of the cage, and the killdeer bit paper. These behaviors suggest that the secretion was irritating or unpleasant and that the birds were attempting to remove the offending secretion from their mouths.

It is interesting that the bird predators we tested displayed inter- and intraspecific variation in response to black locust bugs; some birds refused to attack, some ate only one bug, and some consumed several bugs. Some bugs were killed during the attacks, whereas other bugs survived relatively unscathed. Such differences in predator response to a single prey species are frequently observed in predator–prey

interactions (Brower, 1984; Whitman et al., 1985; Krall et al., 1999). Variability in predator response and prey survival is important for the evolution and continued maintenance of antipredator defenses in prey. It suggests that even limited or low-impact defenses would have selective advantages against timid predators. It also suggests that even a well-defended prey species would continue to experience selective pressure from naive, more aggressive, or less sensitive predators.

Chemicals in defensive secretions can function in different ways (Whitman et al., 1990), and it remains to be determined exactly how the compounds identified in this research facilitate prey rejection by bird predators. Defensive chemicals can be noxious Class I compounds, which poison, harm, or irritate predators, or relatively innocuous Class II compounds, which typically are not toxic themselves but function as chemical warning signals for other toxic compounds (Brower, 1984). Our observations suggest that secretions from *L. robiniae* may work on both levels. For example, the secretion appeared to be an immediate repellent to the robin and the solitary wren, which repeatedly spit out bugs without consuming them. Alternatively, the killdeer seemed little affected by the "taste" of the bug and appeared to consume them (at first) with impunity. However, this predator later vomited, suggesting that the black locust bug may possess internal toxins in addition to a secretory defense. Indeed, many chemically defended insects, exclusively or in addition to the use of volatile secretions, employ slower-acting, high-molecular-weight internal toxins, which are often sequestered directly from toxic host plants (Duffey, 1977; Blum, 1981; Aldrich, 1988; Bowers and Farley, 1990; Aldrich et al., 1997; Aliabadi and Whitman, 2001). Black locust trees contain a number of potent toxins, including the phytotoxin robin, the glycoside robitin, the alkaloid robinine, and numerous phenolics (Lewis and Elvin-Lewis, 1977; Duke, 1985; Bruneton, 1999). The consumption of black locust bark, leaves, or seeds causes serious neurointenstinal reactions in humans (especially children) and livestock (Kingsbury, 1964; Tampion, 1977; Stevens, 1980; Duke, 1985; Harborne and Baxter, 1993). Several Heteroptera appear to sequester defensive compounds from host material (Aldrich, 1988; Aliabadi and Whitman, 2001), presumably for chemical defense. Possibly, black locust bugs, which are thought to feed almost exclusively on black locust, may sequester plant toxins for their defense. Hence, *L. robiniae*, like many other chemically defended insects, might posses a paired defense mechanisms: an initial defense that warns or deters, backed up by an internal defense that is the primary basis for their unpalatability.

Sequestration of host plant toxins might explain the apparent mimicry relationship between the black locust bug and the locust leaf miner. At present it is not known which species is the model or the mimic, if the relationship is Batesian or Mullerian, or even if a true mimicry relationship exists. However, it is possible that both species sequester defensive substances from their common host plant.

In addition to a primary defensive role, the MTG secretions of some true bugs also function as sexual, aggregation, alarm, or dispersal pheromones (Aldrich,

1994, 1996; McBrien and Millar, 1999). This is true in the Miridae, where sexual pheromones from the MTG gland are known for a number of species (Knight et al., 1984; Thislewood et al., 1989; Aldrich, 1988, 1996; Millar et al., 1997; McBrien and Millar, 1999). Although *L. robiniae* occasionally aggregate, it is not yet known if their MTG secretions exhibit pheromonal activity.

(Received May 25, 2001; accepted November 6, 2001)

Abstract—Crop plants have to cope with phytochemical variability along with other environmental stresses. Allelochemicals affect several cellular processes. We tested the effect of toxic aqueous leachates from *Sicyos deppei*, *Acacia sedillense*, *Sebastiania adenophora*, and *Lantana camara* on the radicle growth and cytoplasmic protein synthesis patterns of *Zea mays* (maize), *Phaseolus vulgaris* (bean), *Cucurbita pepo* (squash), and *Lycopersicon esculentum* (tomato). 2D-PAGE and gel scan densitometry analysis were used to detect differences in cytoplasmic root protein pattern expression. High-, medium-, and low-molecular-weight cytoplasmic proteins were affected by the different aqueous leachates. Crop plant responses were diverse, but in general, an increase in protein synthesis was observed in the treated roots. Maize was the least affected, but both the radicle growth and also the protein pattern of tomato were severely inhibited by all allelopathic plants. The changes observed in protein expression may indicate a biochemical alteration at the cellular level of the tested crop plants.

Key Words—Allelochemical stress, allelopathy, mode of action, *Sicyos deppei*, *Acacia sedillense*, *Sebastiania adenophora*, *Lantana camara*, *Zea mays*, *Cucurbita pepo*, *Phaseolus vulgaris*, *Lycopersicon esculentum*, protein synthesis, phytochemical variability.

INTRODUCTION

Secondary plant metabolites that mediate interactions among different organisms are known as allelochemicals. These metabolites are released into the environment

* To whom correspondence should be addressed. E-mail: rcruz@ifisiol.unam.mx

by different routes and belong to several chemical groups, including terpenes, alkaloids, phenolics, and flavonoids (Larcher, 1995). Plants, as sessile organisms, encounter an array of biotic and abiotic environmental constraints such as phytotoxic compounds, which can affect different cellular processes on target organisms. Effects on physiological processes are well known (Einhellig, 1995) and include disruption of membrane permeability (Galindo et al., 1999), ion uptake (Yu and Matsui, 1997), inhibition of electron transport in both the photosynthesis and respiratory chains (Calera et al., 1995a; Rimando et al., 1998; Abrahim et al., 2000), alteration of enzymatic activity (Calera et al., 1995b; Friebe et al., 1997; Politycka, 1999; Romagni et al., 2000), and inhibition of cell division (Cruz-Ortega et al., 1988; Anaya and Pelayo-Benavides, 1997).

Environmental stresses (biotic and abiotic) have also been shown to induce the synthesis of new proteins in plants. These proteins might have evolutionary value for survival under adverse environmental situations. Synthesis of such stress-induced proteins has been well documented under stress by salinity, drought, heat shock, cold, anaerobiosis, metal toxicity, and pathogenicity (Cruz-Ortega et al., 1997; Riccardi et al., 1998; Seki, 2001), but there are few reports about allelochemical stress (Baziramakenga et al., 1997; Koitabashi et al., 1997).

The plants from El Eden Ecological Reserve (Quintana Roo, Mexico) tested in this study were previously evaluated in our laboratory for their phytotoxic effects on other plants (Anaya and del Amo, 1999). Currently, we are conducting biodirected fractionation studies to determine the chemical nature of the active metabolites. As a part of this project, we screened the changes induced in root cytoplasmic protein synthesis pattern of maize, bean, squash, and tomato by the aqueous leachates, with the aim of contributing to the knowledge of the modes of action of the stress produced by the phytotoxic compounds.

METHODS AND MATERIALS

Phytotoxic Plants. Leaves from *Acacia sedillense* L. Rico (Fabaceae), *Sebastiania adenophora* Pax & K. Hoffm. (Euphorbiaceae), and *Lantana camara L*. (Verbenaceae) were collected at El Eden Ecological Reserve in Quintana Roo, Mexico. *Sicyos deppei* G. Don (Cucurbitaceae) leaves were collected in some crop fields in the Mexico basin.

Plant Material. Seeds of maize (*Zea mays* L., cv. Chinampero, Poaceae), squash (*Cucurbita pepo* L. cv. Criolla, Cucurbitaceae), and bean (*Phaseolus vulgaris* L. var. Flor de mayo, Fabaceae) were obtained from a local market at Tulyehualco, Mexico, D. F. Tomato seeds (*Lycopersicon esculentum,* var. Pomodoro, Solanaceae) were obtained from Sun-Seeds, Parma, Idaho, USA.

Bioassays. Seeds were germinated in Petri dishes containing aqueous leachate (1% w/v) of each phytotoxic plant with 1% agar as substrate. Aqueous leachates were prepared by soaking dried leaves (2 g/100 ml) in distilled water for 3 hr

and were mixed with agar (2%) for a final aqueous leachate concentration of 1%. Leachates were filtered through Whatman No. 4 paper and then through a Millipore membrane (0.45 μm). Osmotic pressure was measured by using a freezing-point osmometer (Osmette A, Precision System, Inc.); all values ranged from 15 to 17 mosm/liter. Bioassays were conducted under sterile conditions in a laminar hood. Controls contained only distilled water and agar. Ten seeds were placed on each Petri dish and kept in the dark at 27°C. Twenty-five Petri dishes were used per treatment and per crop plant. The terminal 0.5 cm of the primary root was excised after 48 hr from maize, squash, and beans seedlings and after 72-hr from tomato seedlings. Roots were frozen in liquid nitrogen and kept at −70°C until use. For root growth response, experiments were conducted in a complete randomized experiment design with four replicates. Primary root lengths were measured after 48 and 72 hr, and data were analyzed by ANOVA.

Cytoplasmic Protein Extraction, Gel Electrophoresis, and Densitometry Analysis. Cytoplasmic proteins were extracted and purified from roots of control and treated plants. The terminal 0.5 cm of the primary root from 300 treated and control seedlings was homogenized in liquid nitrogen with a mortar and pestle and suspended (1:4 w/v ratio) in a cold homogenization buffer [50 mM K_2HPO_4 and 50 mM of KH_2PO_4, pH 6.8, 1 mM phenylmethylsulphonyl fluoride (PMSF)]. The homogenate was centrifuged at 300*g* for 10 min to pellet the nuclear fraction, and the supernatant was centrifuged at 12,000*g* for 10 min at 4°C. Proteins from the supernatant were extracted into phenol, precipitated with methanol, and redissolved in an isoelectric focusing (IEF) medium (ampholyte solution at pH 4–7) as described by Hurkman and Tanaka (1988). Protein content was determined by the Bradford method (1976).

Two-dimensional gel electrophoresis (2D-PAGE) was performed according to O'Farrell (1975). For the first dimension, 10 μg of protein was loaded at the basic end of the gels (capillary tubes, Bio-Rad). Isoelectric focusing was conducted for 30 min at 300 V, and then for 4 hr at 750 V. After extrusion, gels were either frozen at −70°C or loaded onto a second dimension of 12% polyacrylamide resolving gel. Gels were run in a mini-protein apparatus (Bio-Rad), fixed, and silver stained according to Morrisey (1981). Controls and treated gels were analyzed by GelScan XL (release 2.1) densitometry. Total area and absorbance of protein spots on the gels were determined, adjusted for background, and assessed for any change in size.

RESULTS

Aqueous leachates (1%) of the four phytotoxic plants affected maize (*Zea mays*) radicle growth differently, with *S. deppei* leachate causing 39% ($P < 0.001$) growth inhibition, while *A. sedillense*, *S. adenophora*, and *L. camara* had no

TABLE 1. RADICLE GROWTH AND CYTOPLASMIC PROTEINS ALTERED IN *Zea mays*, *Cucurbita pepo*, *Phaseolus vulgaris*, AND *Lycopersicon esculentum* BY AQUEOUS LEACHATES (1%) OF *Acacia sedillense*, *Sebastiania adenophora*, *Lantana camara*, AND *Sicyos deppei*

Crop plant	Allelochemical plant	Radicle growth (%)	Proteins (Number)

[a] $P < 0.001$.

significant effect (Table 1). Although the leachate of *S. deppei* inhibited maize root growth, no change was observed in cytoplasmic protein synthesis (results not shown). In contrast, *A. sedillense*, *S. adenophora*, and *L. camara* caused several changes in its cytoplasmic protein synthesis pattern (Figure 1). Twenty-one proteins were altered by *A. sedillense* leachate, with 18 increased (proteins 1–11, 14–18, 20, and 21), 1 decreased (protein 19), and 2 repressed (proteins 12 and 13). *S. adenophora* leachate affected 14 proteins, with 9 increased (proteins 1, 2, and 6–12), 2 decreased (13 and 14), and 3 induced (3–5). Ten proteins were altered by *L. camara*, with 7 decreased (proteins 1, 3, and 6–10) and only 3 increased (2, 4, and 5) (Table 1, Figure 1). These results indicate that maize responds differently to various phytochemical stresses caused by different leachates. Analysis of cytoplasmic proteins revealed that different aqueous leachates affected the same proteins differently (Table 2). For example, a protein with apparent molecular weight of 57 kDa, and pI of 5.5 was repressed with *A. sedillense* leachate but decreased with *L. camara*. Another protein (27 kDa, pI 6.4) increased with *A. sedillense*, *S. adenophora*, and *L. camara* leachates. Three low-molecular-weight proteins, 18 (pI 6.1), 16 (pI 5.8), and 15 (pI 5.7) kDa, were induced only with *S. adenophora* leachate (Table 1, Figure 1D, proteins 2–4).

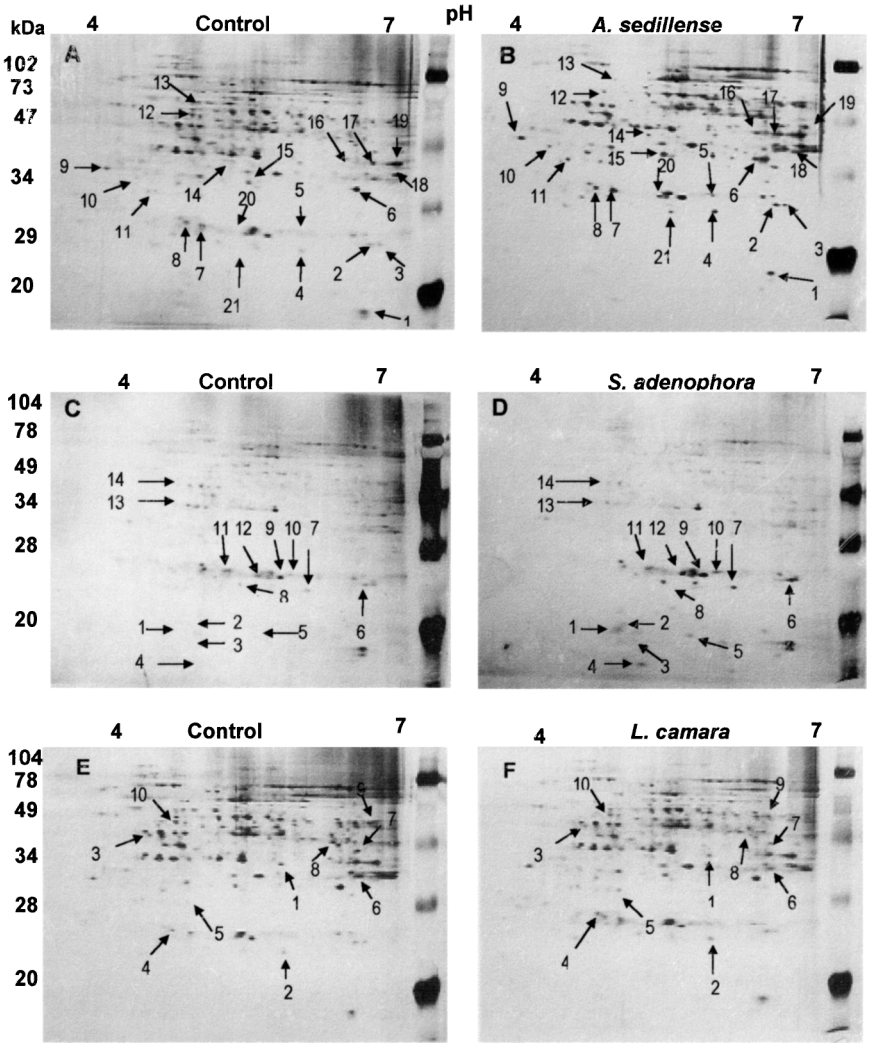

FIG. 1. 2D-PAGE of cytoplasmic root proteins from control maize seedlings (A, C, and E) and those subjected to the aqueous leachates: *A. sedillense* (B); *S. adenophora* (D), and *L. camara* (F). Ten micrograms of the proteins were loaded into each gel. Arrows indicate those proteins that were altered and detected by gel scanning. Gels represent the mean of at least three replicates. Molecular masses in kilodaltons (kDa) are indicated.

TABLE 2. PROTEINS OF SAME MOLECULAR WEIGHT AND pI ALTERED IN ROOTS OF *Zea mays* BY AQUEOUS LEACHATES OF *Acacia sedillense*, *Sebastiania adenophora*, AND *Lantana camara*[a]

Protein (kDa)	pI	*A. sedillense*	*S. adenophora*	*L. camara*
57.0	5.5	E		D
30.0	5.5	I		I
29.0	6.0	I	I	
28.0	6.8	I	I	
27.0	6.4	I	I	I

[a] I = increased; D = decreased; E = repressed.

Table 1 shows that *L. camara* inhibited squash (*Cucurbita pepo*) radicle growth by 30% ($P < 0.001$), while *S. adenophora* had a stimulatory effect (49%) ($P < 0.001$). No significant effect was observed with *A. sedillense* and *S. deppei* leachates. All four leachates also differently affected the protein synthesis in squash (Figure 2). *A. sedillense* and *L. camara* caused the most changes (a total of 19, and 18 proteins, respectively; Figure 2D, H, Table 1). Of the 19 proteins altered by *A. sedillense*, 16 increased (proteins 1, 4–8, and 10–19) and three decreased (2–4) (Table 1). Of the 18 altered by *L. camara*, 12 increased (6, and 8–18), 4 decreased (1, 3, 5, and 7), and 2 were repressed (2 and 4). In contrast, *S. adenophora* leachate, which significantly stimulated radicle growth, induced fewer changes in cytoplasmic proteins: 9 were altered with 4 increased (1–3, and 7) and 5 decreased (4–6, 8, and 9). *S. deppei* altered 13 proteins with 6 increased (5, 8–11, and 13), 4 decreased (3, 6, 7, and 12) and 3 repressed (1, 2, and 4) (Fig. 2b, F, Table 1). Table 3 shows that the same protein was differently affected by the different aqueous leachates. A16-kDa protein (pI 6.2) decreased with *S. deppei* and *L. camara* but increased with *A. sedillense*. The expression of a 15-kDa (pI 6.0) protein was repressed, increased, and decreased by *S. deppei*, *A. sedillense*, and *L. camara*, respectively.

As in maize and squash, aqueous leachates affected *P. vulgaris* radicle growth differently. *S. deppei*, *L. camara*, and *A. sedillense* leachates inhibited it 70%, 41%, and 25% ($P < 0.001$), respectively, while *S. adenophora* did not have any effect (Table 1). Although *S. deppei* strongly inhibited root growth in beans, it did not affect the expression of proteins. *A. sedillense* increased the expression of 16 proteins, and *L. camara* leachate altered 15 proteins: 5 proteins increased (2, 8–11), 9 decreased (3–7, 12–15), and one induced (1). *S. adenophora* altered 10 proteins, including 7 that increased (3, 5–10) and 3 that decreased (1, 2, and 4) (Table 1, Figure 3B, D, F). Two cytoplasmic proteins were differently affected by leachates. The expression of a 24-kDa (pI 5.8) protein was increased by *A. sedillense* but decreased by *S. adenophora*, while a 26-kDa (pI 5.9) protein was increased by both *A. sedillense* and *L. camara* (Figure 3B, F).

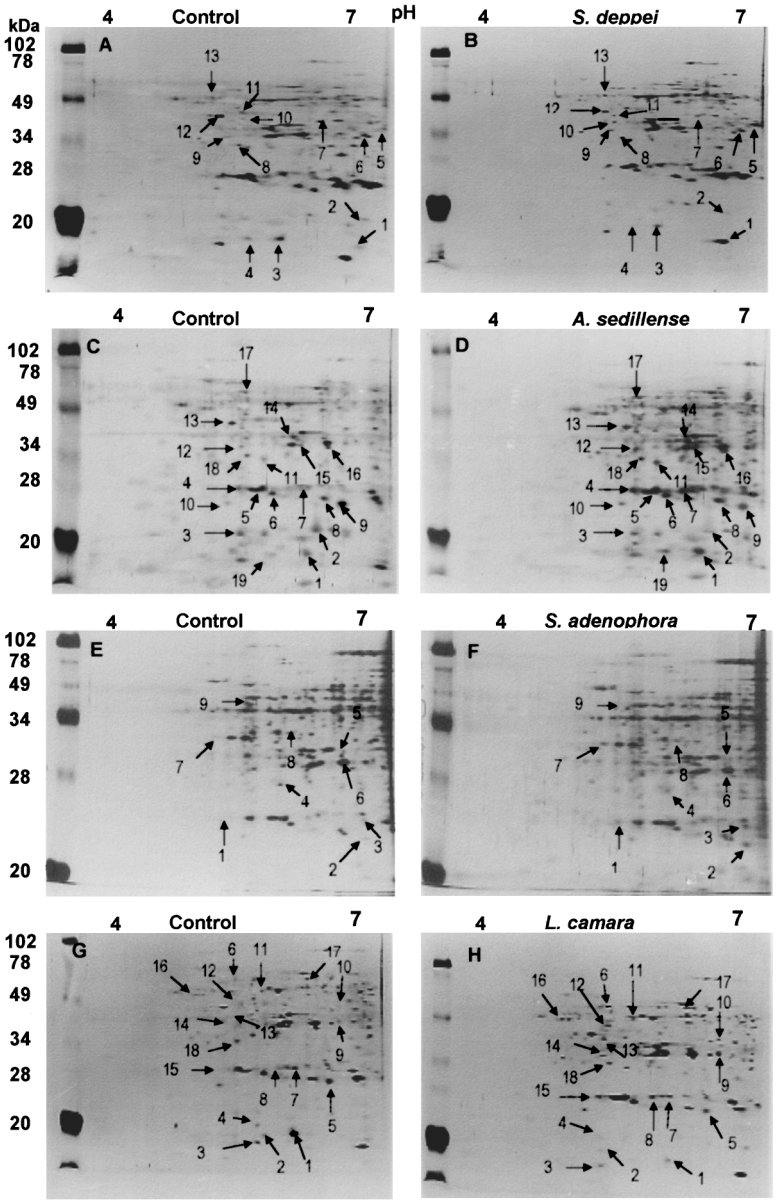

FIG. 2. 2D-PAGE of cytoplasmic root proteins from control squash seedlings (A, C, E, and G) and those subjected to the aqueous leachates: *S. deppei* (B), *A. sedillense* (D); *S. adenophora* (F); and *L. camara* (H). Ten micrograms of the proteins were loaded in each gel. Arrows indicate those proteins that were altered and detected by gel scanning. Gels represent the mean of at least three replicates. Molecular masses in kilodaltons (kDa) are indicated.

TABLE 3. PROTEINS OF SAME MOLECULAR WEIGHT AND pI ALTERED IN ROOTS OF *Cucurbita pepo* BY AQUEOUS LEACHATES OF *Sicyos deppei*, *Acacia sedillense*, *Sebastiania adenophora*, AND *Lantana camara*[a]

Tomato (*Lycopersicon esculentum*) seedlings were the most sensitive to phytochemical stress. All aqueous leachates significantly ($P < 0.001$) inhibited radicle growth, ranging from 81% for *S. deppei* and *L. camara*, to 70% for *S. adenophora* and 60% for *A. sedillense* (Table 1). The aqueous leachates also similarly affected the number of protein expressed in tomato, with a total of 11 each for *S. deppei*, *S. adenophora*, and *L. camara*; and 14 for *A. sedillense* (Table 1, Figure 4), with nearly an equal number of proteins increasing and decreasing for each leachate. Eight proteins were differently affected by leachates in tomato. For example, a high-molecular-weight protein (70 kDa, pI 5.5) was repressed by *A. sedillense* but was decreased by *L. camara*. A 34-kDa (pI 6.9) protein decreased under *S. deppei* but was increased by *A. sedillense* and *S. adenophora* (Table 4, Figure 4).

TABLE 4. PROTEINS OF SAME MOLECULAR WEIGHT AND pI ALTERED IN ROOTS OF *Lycopersicon esculentum* BY AQUEOUS LEACHATES OF *Sicyos deppei*, *Acacia sedillense*, *Sebastiania adenophora*, AND *Lantana camara*[a]

Molecular masses in kilodaltons (kDa) are indicated.

DISCUSSION

The metabolic stress response is an ubiquitous defense mechanism activated when cells are confronted with unfavorable environmental conditions. Induction leads to the expression of proteins known as stress proteins, which are thought

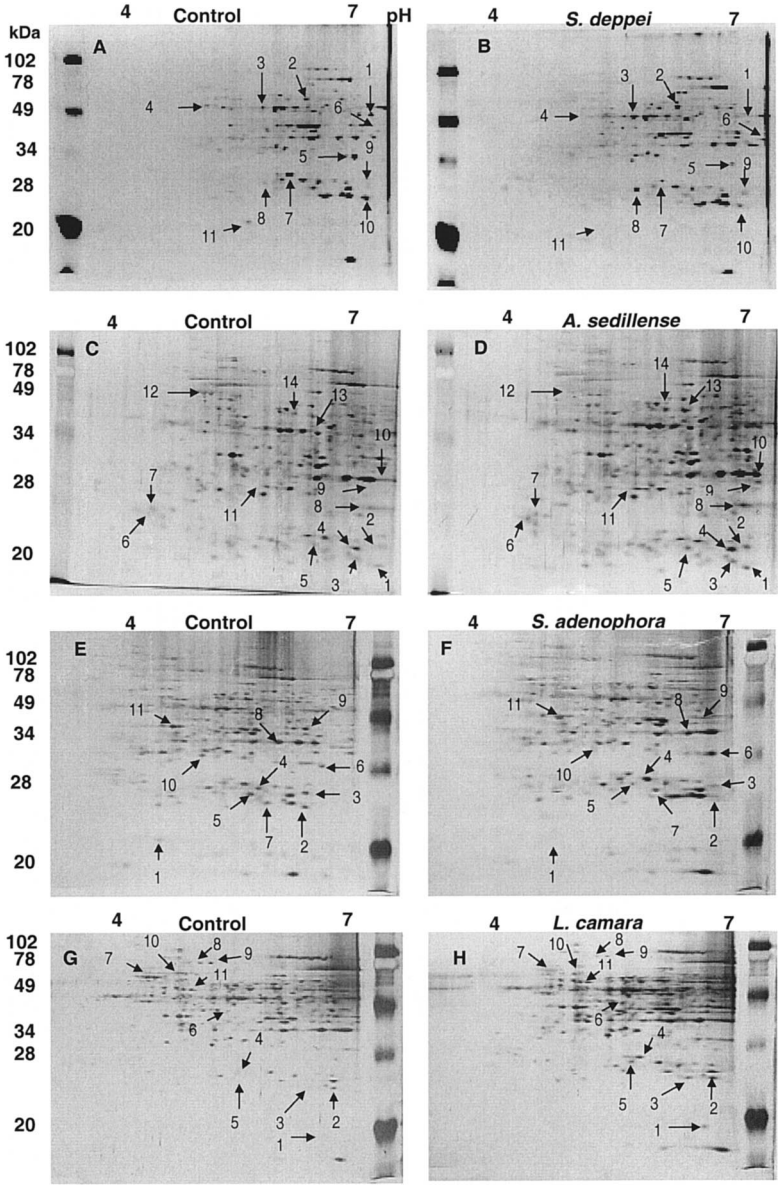

FIG. 4. 2D-PAGE of cytoplasmic root proteins from control tomato seedlings (A, C, E, and G) and those subjected to the aqueous leachates: *S. deppei* (B), *A. sedillense* (D); *S. adenophora* (F); and *L. camara* (H). to protect the cell. Stress and signaling inside the cell lead to protein expression changes, the activation of new biochemical pathways, and repression of others that are characteristic of the unstressed state (Bohnert and Sheveleva, 1998). The allelochemicals produced by the plants reported in this study, most of them of unknown chemical nature, may cause stress. Dayan et al. (2000) asserted that determination of the mode of action of allelochemicals is a challenging endeavor due to the multitude of potential molecular targets. However, this seemingly overwhelming task also presents an opportunity to discover new sites of action. In this sense, the present study adds to our understanding.

The effects of the leachates on the crop plants investigated varied in both radicle growth and cytoplasmic protein synthesis. Maize was the most chemical stress tolerant crop plant (inhibited by only *S. deppei*), and tomato the least (inhibited by all allelochemical plants). All the crop plants exhibited changes in the expression of their root cytoplasmic proteins. Overall there was a general increase in protein expression, some reduction, and little induction or repression. *A. sedillense* and *L. camara* leachates affected the largest number of proteins, resulting in a general increase in protein expression. *S. deppei* affected the least and produced a significant change only in tomato. *L. camara* caused a significant inhibition of radicle growth of *C. pepo*, but resulted in the highest decrease of proteins in *P. vulgaris*.

It is possible that the proteins that increased or were induced in response to the treatments are stress proteins that are related to defense mechanisms. They may be formed as a response to allelochemical stress, as are heat shock proteins (HSPs), pathogenic-related proteins (PR), or salinity and dehydration proteins (osmotin, LEA, dehidrins, among others) (Vierling, 1991; Bray, 1993; Van Loon et al., 1994). Proteins whose expression either decreased or were repressed may be those involved in "housekeeping processes," such as cell division or elongation, cell wall formation, or vesicle trafficking. Riccardi et al. (1998) reported a decrease in the expression of certain proteins when maize leaves were subjected to water stress. Sequencing of these peptides showed they were enzymes of the Krebs cycle and glycolysis, such as triose-phospho isomerase, enolase, and NAD-malate-dehydrogenase. Baziramakenga et al. (1997) found that some phenolic acids alter the incorporation of ^{32}P into DNA and RNA and reduce the uptake of [^{32}S] methionine into root soybean seedlings proteins.

S. deppei inhibited radicle growth significantly in maize and beans, but interestingly it did not modify the protein synthesis pattern. In a previous study, we observed that *S. deppei* caused plasma membrane disruption in root tips and plasmolized cells in the peripheral zone of beans and bottle gourd roots (Cruz-Ortega et al., 1998), suggesting that it may be altering membrane processes. It would be interesting to study the effects of this plant on electrolyte leakage and enzyme activities.

This study is one of the first describing changes in protein synthesis patterns caused by allelochemicals from phytotoxic plants. The proteins that were

significantly affected are currently being microsequenced to understand their function. In addition, isolation and identification of the major phytotoxic compounds are underway so that we can test the effects of individual compounds.

EFFECTS OF WATER DEFICIT STRESS, SHADE, WEED COMPETITION, AND KAOLIN PARTICLE FILM ON SELECTED FOLIAR FREE AMINO ACID ACCUMULATIONS IN COTTON, *Gossypium hirsutum* (L.)

ALLAN T. SHOWLER*

Kika de la Garza Subtropical Agricultural Research Center, USDA-ARS
2413 E. Highway 83, Bldg. 201
Weslaco, Texas 78596

(Received July 26, 2001; accepted October 17, 2001)

Abstract—Leaves of cotton plants, *Gossypium hirsutum* L., stressed by water deficit, reduced daylight, and weed competition, or treated with a kaolin wettable powder formulation were analyzed for levels of 17 free amino acids (FAAs) using reversed-phase high-performance liquid chromatography. Water deficit stress resulted in heightened free proline levels (49.9-fold, $P < 0.001$) that were correlated with diffusive resistance (seconds per centimeter). Five other FAAs increased, and the amounts of total free essential (for insect growth and development) amino acids and total FAAs also increased ($P \leq 0.05$). Cotton grown in 50% shade accumulated significantly more free arginine than control plants. In a small-plot weed competition assay, four FAAs increased and three FAAs decreased in association with weed competition, but because free proline levels were not altered and free arginine levels increased, other stresses aside from water deficit, possibly including shading by tall weeds, appear to have caused the changes. In a small-plot kaolin particle film assay, five FAAs were lower in cotton foliage sprayed weekly with kaolin. Because free proline was unaffected and free arginine was lower, it is possible that kaolin's reflectivity heightened light reception. The responses of free proline and arginine to the treatments used in these assays demonstrate that types and degrees of some stresses to cotton can be characterized by accumulations of certain FAAs. The study also demonstrates how some FAA levels can indicate degrees of cotton stress resulting from weed competition and from kaolin particle film application. Porometry and leaf water potential measurements assisted in corroborating some findings of the study.

Key Words—*Gossypium hirsutum*, cotton, free amino acids, water deficit, kaolin, weed competition, plant stress.

INTRODUCTION

Moisture deficit stress in plants has been shown to induce changes in plant free amino acid (FAA) accumulations (Bussis and Heineke, 1998). Changes of other stress-inducing parameters have also been associated with altered FAA contents, including soil or water salinity (Martinez et al., 1994), weed competition (Showler et al., 1991), and viral (Showler et al., 1990), bacterial (Meon et al., 1978), fungal (Nemec, 1995), and nematode (Doney et al., 1970) infections. Proline appears to be the FAA that reflects water deficit stress the most consistently by accumulating to significantly higher levels (Gzik, 1996).

Shading significantly decreased cotton leaf photosynthetic rate and nonstructural carbohydrate concentration, increased concentrations of chlorophyll and mineral nutrients, and reduced boll numbers (Zhao and Oosterhuis, 1998, 2000). Intermittent shade was shown to cause stomates to reacclimate within 4 min to changing light conditions to compensate for associated changes in transpiration rates (Bauer et al., 1997). Similar to water deficit, light reduction in cotton could be associated with distinctive FAA patterns.

Kaolin is a white, nonporous, nonswelling, nonabrasive, fine-grained platy aluminosilicate mineral [$Al_4Si_4O_{10}(OH)_8$] that disperses in water and is chemically inert over a wide pH range. Coating-grade kaolin is $>$90% pure and has a high brightness quality of $>$85% (Harben, 1995). Application of kaolin to crops has been shown to reduce damage caused by some plant pathogens and insects (Glenn et al., 1999), including the boll weevil, *Anthonomus grandis* Boheman (Showler, 2001a), an important pest of cotton. Kaolin can act as a physical barrier that makes the host plant visually or tactilely unrecognizable, and insect movement and feeding can also be hindered by the particles; the hydrophobic quality prevents pathogen propagules from contacting the leaf surface (Glenn et al., 1999). In addition to its possibilities for suppression of pest injury to crops, studies have shown how kaolin does not reduce photosynthesis in apple, peach, and pear, with particle levels up to 3000 μg/cm^2 on the leaf surfaces, and canopy temperatures significantly declined because of infrared radiation reflection from the leaf surfaces (Glenn et al., 1999).

This study was conducted to identify FAAs that are influenced by water deficit and shade stresses in cotton, *Gossypium hirsutum* L., and to interpret FAA levels observed in weed competition stressed and in kaolin-coated plants using FAA measurements from the water deficit and shade assays.

METHODS AND MATERIALS

Water Deficit Assay, Part 1. Eighty 7.6-liter pots with Sunshine mix No. 1 nursery potting soil ($\sim$75% sphagnum peat moss, perlite, dolomitic limestone, and gypsum; Sungro Horticulture, Bellevue, Washington) were each planted on May 3, 2000, with five cotton (var. C-208) seeds. Seedlings were thinned to three

per pot, and 200 ml of Peters Professional (Scotts-Sierra Horticultural Products Company, Marysville, Ohio) water-soluble general purpose 20-20-20 N-P-K fertilizer at 15.8 g/liter of water was applied to each pot at the two true leaf stage in this and all other greenhouse assays in the study. All pots were irrigated with 1 liter of water every week until the cotton plants reached the four true leaf stage. Then, four groups of 20 pots/group were maintained on separate irrigation regimes: 4000 ml water/week (saturation), 1500 ml/week, 1000 ml/week, and 750 ml/week, each delivered at one time per week. All the pots were placed in 4-cm-deep plastic dishes to retain any water, especially in the saturated regime, that might have run through the soil and out the holes in the bottom of the pots. After one week, irrometers for monitoring soil moisture in the pots were discontinued because the periodically dry soil in most pots prevented an adequate soil moisture–irrometer interface. The cotton plants were grown to the 7- to 10-mm-square diameter stage, then on June 19, 2000, an LI 1600 Steady State Porometer (Li-cor, Inc., 1989) was used to measure diffusive resistance and transpiration rates from upper (top four fully expanded) leaves on 17 of the plants in each water regime (changing cloud cover prevented further measurements). Twenty-five upper leaves grown in 2001 under approximately the same conditions were excised and their water potentials measured with a Model 610 (PMS Instrument Co., Corvallis, Oregon) pressure bomb on June 21, 2001. On the same day, 1 g fresh wt from the distal halves of upper cotton leaves (0.5 g from each of four leaves) from each pot ($n = 20$) was excised and homogenized with 10 ml 0.1 N HCl using a Virtishear homogenizer (Virtis, Gardiner, New York). At least 5 g homogenate from each sample was placed in separate 10-ml tubes and centrifuged at 10,000 rpm for 30 min. Samples were stored at -80°C.

One milliliter of supernatant from each sample was filtered through a 0.5-μl filter fitted to a 5-ml plastic syringe. Samples were placed in the autosampler of an Agilent 1100 Series (Agilent Technologies, Atlanta, Georgia) reversed-phase high-performance liquid chromatograph (HPLC) with a binary pump delivering solvent A [1.36 g sodium acetate trihydrate + 500 ml purified HPLC grade water + 150 μl triethylamine (TEA) + sufficient acetic acid to bring the pH to 7.2 ± 0.05] and solvent B [1.36 g sodium acetate trihydrate + 100 ml purified HPLC grade water (acetic acid added to this mixture to bring the pH to 7.2 ± 0.05) + 200 ml acetonitrile + 200 ml methanol] at 0.3 and 0.45 ml/min on a concave gradient through an Eclipse XDB-C8 4.6 mm 10×15 cm C_{18} fluorescence column (Agilent Technologies). Absorbances at 262 and 338 nm were monitored on a variable wavelength detector for 40 min per sample. The autosampler measured and mixed 6 μl sodium borate buffer (0.4 N, pH 10.2 in water), 1 μl 9-fluorenylmethylchloroformate (FMOC), and 1 μl ophthalaldehyde (OPA) derivatizing agents, and 2 μl of sample, then injected 2 μl for chromatographic separation of FAAs. Identification and quantification of derivatized FAAs were achieved by calibrating with a standard mixture of amino acids. Peak integration accuracy was enhanced by manual establishment of peak baselines using Agilent software.

Water Deficit Assay, Part 2. In the greenhouse, C-208 cotton was grown in 7.6-liter pots as described in part 1. Upon reaching the four true leaf stage, cotton plants received 1000, 750, 500, and 250 ml water/week ($n = 20$), and 20 pots of cotton were irrigated with 1000 ml water biweekly. Each dose of water was delivered in one irrigation weekly or biweekly. Twenty other cotton pots were provided 1000 ml water/week, but alfalfa, (*Medicago sativa* L.) seedlings were also grown at a density of 3/cm^2 in order to observe effects of competition for limited water. At the 7- to 10-mm-diam. square stage, 1 g of leaf material was excised, homogenized, stored, and analyzed for FAA content as described in part 1. Diffusive resistance and transpiration rate measurements were taken from the upper leaves of one plant in each pot by using a porometer. Water potential measurements were not taken because of broken instrumentation.

Shade Assay. In a greenhouse (to better control potential effects of other environmental parameters that could also affect FAA levels), October 11–November 28, 2000, 20 pots of C-208 cotton plants at the four leaf stage were covered with 50% shade cloth suspended 3.5 m overhead and along all four sides. Twenty control pots were not shaded. All received 1500 ml water each week beginning at the four-leaf stage. Water potential of one upper leaf from 25 plants grown in 2001 under approximately the same conditions was measured with the pressure bomb on June 15, 2001. Plant heights were recorded from 25 plants in each treatment on November 27, 2000, and FAA sample collection and analyses were as described in the water deficit assay, part 1. Porometry measurements were not taken because full sunlight is recommended (Li-cor, 1989).

Weed Competition Assay. A field at the USDA-ARS Kika de la Garza Subtropical Agricultural Research Center in Hidalgo County, Texas, was divided into twelve 0.028-ha plots and planted to Deltapine 436 RR cotton (this variety was planted because glyphosate was used to eliminate weeds on the rows) on March 6, 2000. In a randomized design, six of the 12 plots received a topical application of pendamethalin at 924 g-active ingredient (ai)/ha at planting; a rolling cultivator, glyphosate spot treatments, and hand-roguing were used thereafter to maintain weed-free plots. Weeds were permitted to grow freely in six weedy plots. Weed dry biomass was determined on April 18 and June 1 with two 0.5-m^2 quadrats per plot. The weeds were clipped at the soil surface, separated by species, oven dried for 48 hr at 60°C, and then weighed.

On May 15, 2000, when the cotton plants were squaring, the porometer was used to measure diffusive resistance and transpiration rates on five upper leaves in each of the 12 plots. On the same day, fifteen 1-g samples of leaf material were excised from each treatment and placed on ice until arrival at the lab within 5 min. The samples were homogenized, stored, and analyzed for FAA accumulations as described in the water deficit assay, part 1. Heights of five cotton plants in each plot were recorded (from soil level to uppermost leaf) on May 15, 2000. On July 12, two 4-m sections of row in each plot were hand-harvested, ginned, and the lint

weighed to determine yield. Water potentials of two upper leaves grown in 2001 under approximately the same conditions in each of the six treatment replicates were measured with the pressure bomb on June 26, 2001.

Kaolin Particle Film Assay. A field at the USDA-ARS Kika de la Garza Subtropical Agricultural Research Center, Hidalgo County, Texas, was arranged in a randomized design with sixteen .012-ha plots, and planted to C-208 cotton on March 6, 2000; pendimethalin (924 g ai/ha) was applied for weed control on the same day. Weeds were controlled thereafter using a rolling cultivator and hand-roguing, and irrigation occurred once at preplanting. Eight of the plots were not treated with kaolin (check), and eight plots were given a double application of 22.7 kg Surround WP (Engelhard, Iselin, New Jersey) per 378 liters of water from a tractor-mounted spray boom weekly from April 11 until mid-June 2000.

Kaolin particle deposition on the cotton leaves was determined by excising 20 leaves at random from each treatment. Kaolin particles were washed with methanol into preweighed plastic dishes (a 6-mm flat ox-hair paint brush was used to dislodge particles adhering to leaf surfaces), the methanol was evaporated off, and the dried particles plus dish were weighed. The upper surface area of each leaf was measured with a model 3100 Area Meter (Li-cor, Lincoln, Nebraska). The mass of kaolin collected was divided by two times the leaf area on one side to give the mass of kaolin deposited per square centimeter leaf surface area. Porometry measurements were not taken because the presence of particles on the leaf surfaces can reduce accuracy (Idso et al., 1987). Water potentials of two upper leaves from each of the eight treatment replicates grown in 2001 under approximately the same set of conditions were measured with the pressure bomb on June 26, 2001.

On May 19, 2000, when the cotton plants were blooming, two sets of three upper leaves per plot were collected, placed on ice, and taken to the lab within 5 min. Each three-leaf sample was used to obtain 1.0 g of leaf material that was homogenized, stored, and analyzed for FAA contents in the same manner as described for the water deficit assay, part 1. Heights of 200 cotton plants were measured from soil level to uppermost leaf, on May 15, 2000. On July 7, two 4-m sections of row in each plot were hand harvested, ginned, and the lint weighed.

Statistical differences among the treatments in these experiments were detected by using the two-sample *t* test or ANOVA (randomized design) and Tukey's HSD for mean separation (Analytical Software, 1998).

RESULTS

Water Deficit Assay, Part 1. Seventeen FAAs could be detected by using a FAA standard of alanine, arginine, aspartic acid, cystine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine,

TABLE 1. FREE AMINO ACID[a] (FAA) CONCENTRATIONS (± SE) IN COTTON, *Gossypium hirsutum* L. (VAR. C-208), UPPER LEAVES RESULTING FROM CONTINUOUSLY WATER-SATURATED POTTING SOIL, AND 1500, 1000, AND 750 ml WATER PER WEEK

FAA	Concentration[b] (pmol/μl extract)

Valine	118.4 ± 6.0 c	303.7 ± 39.1 b	311.2 ± 53.0 b	452.7 ± 34.2 a
Total essential FAAs	2,362.4 ± 111.9 b	5,259.8 ± 490.3 a	5,264.2 ± 646.8 a	6,397.2 ± 405.2 a
Total FAAs	7,499.6 ± 449.7 b	11,775.0 ± 879.7 a	11,723.0 ± 958.3 a	13,552.2 ± 633.4 a

[a] Free cysteine/cystine, leucine, lysine, methionine, and tyrosine were detectable but not present in the cotton extracts analyzed.
[b] Means followed by different letters in the same row are significantly different ($P \leq 0.05$), $n = 20$.

threonine, tyrosine, and valine. Of the 17 detectable FAAs, 12 were found in cotton leaf extract: alanine, arginine, aspartic acid, glutamic acid, glycine, histidine, isoleucine, phenylalanine, proline serine, threonine, and valine (Table 1), although histidine and phenylalanine appeared to be absent in some samples. Of the 10 amino acids essential for insect growth and development (Vanderzant, 1958), six were detected in cotton: arginine, histidine, isoleucine, phenylalanine, threonine, and valine.

The four moisture regimes were associated with significant ($P \leq 0.05$) differences in all detectable FAA concentrations, except glutamic acid. Arginine ($F = 26.08, df = 5$), aspartic acid ($F = 3.64, df = 5$), glycine ($F = 3.47, df = 5$), and threonine ($F = 4.94$, $df = 5$) levels were lower ($P \leq 0.05$) in the plants irrigated with 4000 ml/week than the plants irrigated with 1500, 1000, and 750 ml/week.

Six (50%) of the detectable FAAs in cotton foliage, arginine, histidine, phenylalanine, proline, threonine, and valine, increased with higher water deficit stress. In the case of threonine, the difference between saturated and 750 ml/week watering regimes was relatively low and the difference was marginal (1.2-fold, $F = 1.76$, $df = 3$, $P = 0.163$), but the five other FAA accumulations increased 3.1 times (phenylalanine, $F = 12.0$, $df = 3$, $P \leq 0.05$) to 49.9 times (proline, $F = 19.56$,

$df = 3$, $P \leq 0.05$). Levels of free isoleucine and serine were highest in the 1500 ml/week regime, and lower with each drier regime, but lowest in the water saturated regime.

Total free essential amino acids in the saturated and 1500, 1000, and 750 ml/week regimes comprised 31.5%, 44.7%, 44.9%, and 47.2% of the total FAA accumulations, respectively. Free arginine comprised 36.5%, 44.6%, 51.3%, and 54.1% of the detectable free essential amino acids, respectively.

Diffusive resistance in the 750 ml/week regime cotton was 31 times that of cotton grown in water saturated soil ($F = 14.60$, $df = 3$, $P \leq 0.05$) (Table 2). Similarly, 1000 ml/week and 1500 ml/week regime cotton were found to have 24.2 times

TABLE 2. DIFFUSIVE RESISTANCE, TRANSPIRATION RATES, AND WATER POTENTIALS OF COTTON LEAVES ON PLANTS IN WATER DEFICIT, SHADE, WEED COMPETITION, OR KAOLIN PARTICLE FILM ASSAYS[a]

No kaolin			8.5 ± 0.3

[a] Values are means ± SE. Means compared only within each assay; means followed by different letters are significantly different ($P \leq 0.05$). Leaf water potential measurements were taken on plants grown in 2001 under approximately the same sets of conditions. —, no data taken.
[b] $n = 25$.
[c] $n = 17$.
[d] $n = 6$.
[e] Water deficit and shade assays, $n = 25$; weed competition assay, $n = 6$; kaolin particle film assay, $n = 8$.

($P \leq 0.05$) and 16.6 times ($P \leq 0.05$) higher diffusive resistances as compared to water saturated cotton. Transpiration rate (micrograms of water per square centimeter per second) in the water saturated cotton, inversely influenced by diffusive resistance, was 5.1 ($F = 137.58$, $df = 3$, $P \leq 0.05$), 4.7 ($P \leq 0.05$), and 9.4 times ($P \leq 0.05$) that of the 1500, 1000, and 750 ml/week cotton, respectively. Water potentials in the 750 and 1000 ml/week regime leaves were $\geq$63% ($F = 333.57$, $df = 3$, $P \leq 0.05$) higher than in the 1500 ml/week and saturated regimes (Table 2).

Water Deficit Assay, Part 2. In relation to the 1000 ml/week regime, the highest levels ($P \leq 0.05$) of five FAAs occurred in the biweekly regime: arginine (6.4-fold, $F = 26.08$, $df = 5$), glycine (3.7-fold, $F = 3.47$, $df = 5$), proline (16.0-fold, $F = 26.64$, $df = 5$), serine (3.1-fold, $F = 5.93$, $df = 5$), and valine (4.3-fold, $F = 24.17$, $df = 5$) (Table 3). Free essential amino acids and total FAA accumulations in the biweekly regime were also significantly ($P \leq 0.05$) higher (2.4 times, $F = 25.35$, $df = 5$; 1.6 times, $F = 17.04$, $df = 5$, respectively) than in the 1000 ml/week regime. Among the FAA responses to the 1000, 750, 500, and 250 ml/week regimes, six followed one of two nonlinear patterns. The first, reflected by free arginine, histidine, proline, and valine, increased from the 1000 to 750 ml/week regimes, stabilized from 750 to 500 ml/week, and increased from 500 to 250 ml/week. The second pattern, reflected by aspartic acid, glutamic acid, and threonine, decreased from 1000 ml/week to the lowest levels at 750 ml/week, and increased from 750 to 250 ml/week. Total free essential amino acids generally conformed to the first pattern and total FAAs resembled the second pattern.

From 1000 to 250 ml/week, levels of six FAAs increased ($P \leq 0.05$): arginine (5.8-fold, $F = 26.08$, $df = 5$), glycine (2.8-fold, $F = 3.47$, $df = 5$), histidine (6.2-fold, $F = 22.42$, $df = 5$), phenylalanine (3.5-fold, $F = 25.19$, $df = 5$), proline (17.2-fold, $F = 26.64$, $df = 5$), and valine (3.6-fold, $F = 24.17$, $df = 5$). Total free essential amino acids and total FAAs increased ($P \leq 0.05$) by 3.4-fold ($F = 25.35$, $df = 5$) and 1.5-fold ($F = 17.04$, $df = 5$), respectively.

The 1000 ml/week + alfalfa seedlings resulted in concentrations of aspartic acid, glutamic acid, histidine, proline, serine, threonine, valine, total free essential amino acids, and total FAAs that were most similar to 750 or 500 ml/week levels (Table 3). Concentrations of glycine and phenylalanine in the 1000 ml/week + alfalfa regime were most similar to accumulations in 1000 ml/week cotton.

Percentage of total free essential amino acids to total FAAs was lowest in the 1000 ml/week regime (10.6%), highest in the 1000 ml biweekly regime (24.9%), and second highest in the 250 ml/week regime (23.9%). The percentage of total free essential amino acids in the 1000 ml/week + alfalfa regime (17.6%) was most similar to that of the 750 ml/week regime (17.0%). Free arginine was the predominant free essential amino acid, except in the 1000 ml/week foliage where free isoleucine levels were 1.2 times higher ($P \geq 0.05$) than levels of free arginine.

Diffusive resistance in the 1000-ml biweekly regime cotton was 2.3-fold higher ($F = 50.74$, $df = 5$, $P \leq 0.05$) than the 1000 ml/week regime cotton

TABLE 3. FAA CONCENTRATIONS IN COTTON, *Gossypium hirsutum* L. (VAR. C-208), UPPER LEAVES RESULTING FROM 1000, 750, 500, AND 250 ml WATER WEEKLY, 1000 ml WATER BIWEEKLY, AND 1000 ml WATER WEEKLY WITH THREE ALFALFA SEEDLINGS PER SQUARE CENTIMETER

[a] Values are means ± SE. Means followed by different letters in the same row are significantly different ($P \leq 0.05$), $n = 20$.

(Table 2). Reductions of water in the weekly irrigation regimes reflected increases in diffusive resistance, which at 250 ml/week was 1.9 times higher ($F = 50.74$, $df = 5$, $P \leq 0.05$) than that of cotton grown at 1000 ml/week. The Pearson correlation value for diffusive resistances and free proline accumulations was 0.98 ($P = 0.024$). Cotton irrigated in the 1000 ml/week regime had a transpiration rate 5.9 times ($F = 33.49$, $df = 5$, $P \leq 0.05$) that of cotton in the 1000-ml biweekly regime, and 2.3 times ($P \leq 0.05$) that of cotton in the 250 ml/week regime. Diffusive resistance and transpiration rates of cotton in the 1000 ml/week + alfalfa regime were approximately the same as those in the 750 ml/week cotton.

Shade Assay. Cotton plants grown under 50% shade were taller (45%, $t = 6.51$, $df = 48$, $P < 0.001$) than unshaded plants (Table 4). In conditions of full sunlight, accumulations of free aspartic acid and arginine were 1.2 times ($t = 2.40$, $df = 38$, $P = 0.021$) and 0.5 times ($t = 8.96$, $df = 38$, $P < 0.001$), respectively, the amounts found in the shaded leaves (Table 4). There were no differences among any of the other detectable FAA levels. Leaf water potentials were not higher in the shaded cotton (Table 2).

Weed Competition Assay. Total weed biomass was comprised of pigweed, *Amaranthus palmeri* S. Wats., (36.1%) (average percentages from April 18 and June 1); *Brachiaria texana* (Buckl.) Blake, (55.7%); ragweed, *Ambrosia*

[a] Free cysteine/cystine, leucine, lysine, methionine, and tyrosine were detectable but not present in the cotton extracts analyzed.
[b] Values are means ± SE. Means followed by different letters in the same row are significantly different ($P \leq 0.05$), $n = 15$.

artemisiifolia L., (6.8%); ground cherry, *Physalis heterophylla* Nees, (1.1%); and spurge, *Euphorbia* sp., (0.4%). On May 15, when cotton leaves were excised for FAA analysis, weed coverage of soil surface area was 85%. Weed dry biomass was 22.4 ± 3.3 g/0.5 m^2 and 111.7 ± 19.8 g/0.5 m^2 on April 18 and June 11, respectively, so the dry biomass of weeds on May 15, assuming linear increase over time, would be ≈68 g/0.5 m^2.

Cotton grown in the weedy habitats, as compared to weed-free cotton, had higher levels (1.4- to 12.4-fold) of five FAAs: arginine, glycine, histidine, phenylalanine, and isoleucine (Table 5). Of those, four were significantly different: arginine (12.4-fold, $t = 6.19$, $df = 28$, $P < 0.001$), histidine (7.3-fold, $t = 4.19$, $df = 28$, $P < 0.001$), isoleucine (1.8-fold, $t = 2.50$, $df = 28$, $P = 0.018$), and phenylalanine (2.2-fold, $t = 4.29$, $df = 28$, $P < 0.001$). Total free essential amino acids and total FAAs were more abundant in the weedy cotton foliage (5.5 times, $t = 6.26$, $df = 28$, $P < 0.001$; 1.5 times, $t = 5.01$, $df = 28$, $P < 0.001$). The predominant FAAs in the weedy cotton were arginine (44.8%), aspartic acid (21.5%), and glutamic acid (16.7%). The four free essential amino acids that were more abundant in weedy cotton foliage comprised 52.7% of the total FAAs accumulated.

TABLE 6. COTTON HEIGHTS AND LINT YIELDS FROM WEED COMPETITION AND KAOLIN PARTICLE FILM ASSAYS[a]

Assay	Treatment	Height (cm)[b]	Yield lint (kg/ha)[c]
Weed Competition	Weedy	27.7 ± 1.1 b	48.8 ± 24.8 b
	Weed-free	38.0 ± 0.9 a	460.7 ± 32.4 a
Kaolin	Check	52.6 ± 0.9	515.3 ± 25.0
	Kaolin	50.6 ± 0.6	520.5 ± 18.4

[a] Values are means $\pm$ SE. Means followed by different letter within each assay are significantly different ($P = 0.05$).
[b] Weed competition assay: $n = 30$, sampling date May 15, 2000; kaolin particle film assay: $n = 200$, sampling date May 18, 2000.
[c] Hand harvested and manually ginned. Weed competition assay, $n = 12$; kaolin particle film assay, $n = 16$.

In cotton grown in weed-free habitats, three FAAs were 1.2-fold higher than in weedy habitats: aspartic acid ($t = 4.38$, $df = 28$, $P = 0.001$), glutamic acid ($t = 3.37$, $df = 28$, $P = 0.002$), and threonine ($t = 3.28$, $df = 28$, $P = 0.003$), and the most abundant FAAs in weed-free cotton foliage were aspartic acid (39.6%), glutamic acid (30.6%), and alanine (9.7%). The combined total of free essential amino acids in weed-free cotton foliage was 14.7% of the total FAA content.

The diffusive resistance of leaves in the weedy plots was 2.8 times ($t = 2.20$, $df = 10$, $P = 0.052$) that of the weed-free habitat cotton foliage. Weed-free cotton transpired 1.6 times faster than weedy cotton ($t = 3.83$, $df = 10$, $P = 0.003$). Water potentials were not different among treatments (Table 2).

Cotton in the weed-free plots grew 1.4 times higher ($t = 7.24$, $df = 58$, $P < 0.001$) than weedy cotton by mid-May (Table 6). Lint yield was 9.4 times higher in weed-free plots than in weedy plots ($t = 10.10$, $df = 10$, $P < 0.001$).

Kaolin Particle Film Assay. Four hours after application, kaolin density ranged from 189.9 to 522.8 μg/cm^2, with a mean of 363.0 ± 18.7 μg/cm^2 ($n = 20$). Particle density after one week ranged from 135.5 to 470.1 μg kaolin/cm^2 with a mean of 319.9 ± 20.8 μg/cm^2 ($n = 20$).

Cotton leaves from control and kaolin-treated plots contained the same variety of detectable FAAs (Table 7) as the other assays. The application of kaolin was associated with significant reductions in free alanine (27.0%, $t = 2.88$, $df = 30$, $P = 0.007$), arginine (67.2%, $t = 3.17$, $df = 30$, $P = 0.004$), isoleucine (62.4%, $t = 2.74$, $df = 30$, $P = 0.010$), phenylalanine (36.0%, $t = 3.40$, $df = 30$, $P = 0.002$), threonine (61.0%, $t = 3.21$, $df = 30$, $P = 0.003$), total free essential amino acids (51.4%, $t = 3.22$, $df = 30$, $P = 0.003$), and total FAAs (15.2%, $t = 3.41$, $df = 30$, $P = 0.002$).

The percentage of detectable free essential amino acids declined from 19.8% in the check to 11.4% in the kaolin-treated leaves. Cotton growing in the check plots

Valine	136.1 ± 11.0	136.3 ± 9.1
Total essential FAAs	1,597.3 ± 253.5 a	7,76.9 ± 22.3 b
Total FAAs	8,048.2 ± 348.5 a	6,828.3 ± 82.1 b

[a] Free cysteine/cystine, leucine, lysine, methionine, and tyrosine were detectable but were not present in the cotton extracts analyzed.
[b] Values are means ± SE. Means followed by different letters in the same row are significantly different ($P \leq 0.05$), $n = 16$.

did not differ in height or lint yield per hectare from kaolin-treated cotton (Table 6). Differences in diffuse resistances, transpiration rates, and water potentials were not detected between the two treatments (Table 2).

Overall, each of the 12 detectable FAA accumulations in cotton foliage was significantly altered as a result of one or more treatments in the various assays. However, only free arginine levels were significantly altered by all four treatments: water deficit, shade, weed competition, and application of kaolin particle film.

DISCUSSION

FAA levels peculiar to the different treatments appear to represent stress-specific FAA profiles for some cotton varieties and possibly other cotton varieties and other species of plants. Showler et al. (1991) demonstrated that late-season weedy habitats were associated with changes in 16 FAAs in sugarcane stalks. The same study showed that soil-incorporated aldicarb caused a significant change in free proline, and addition of phytophagous nematodes (*Criconemella*, *Meloidogyne*, *Paratrichodorus*, *Pratylenchus*, *Rotylenchulus*, and *Helicotylenchus* spp.) to

sugarcane plots resulted in differences in free cysteine, histidine, proline, and serine accumulations. Similarly, virus-induced stress in sugarcane, for example, was associated with reductions in nine FAAs (Showler et al., 1990).

Water Deficit Stress. The higher levels of some FAAs, especially proline, in association with water deficit stress is consistent with findings in other plants, including soybeans, *Glycine max* (L.) Merr. (McQuate and Connor, 1990); wheat, *Triticum aestivum* L. Pers. (Gusev and Gordon, 1968); sugar beets, *Beta vulgaris* L. (Gzik, 1996); maize, *Zea mays* L. (Ranieri et al., 1989); cowpea, *Vigna unguiculata* L. (Labanauskas et al., 1981); tomato, *Lycopersicon esculentum* Mill. (Rhodes et al., 1986); and jack pine, *Pinus banksiana* Lamb. (Cyr et al., 1990). In corn seedlings, drought treatment caused an increase in total FAA content and a consistent rearrangement of the amino acid pool with increased accumulation of free alanine, arginine, valine, aspartate, serine, threonine, and tyrosine. The lower amounts of free glutamic acid, glycine, and methionine likely resulted from a strong decrease in glutamate.

Rhodes et al. (1986) exposed suspension culture cells of water-deficit-adapted tomato to polyethylene glycol and found a 300-fold elevated free proline pool, primarily the consequence of a 10-fold rise in proline synthesis via the glutamate pathway. Using ^{15}N labels, they determined that ornithine was an unlikely precursor for proline and suggested that the rate of proline synthesis in unstressed cells only slightly exceeds the rate required to sustain both protein synthesis and proline pool maintenance with growth. Mechanisms restricting free proline oxidation and oxidation of other FAAs can operate at different rates governed by the degree to which water deficit stress is imposed on cotton.

Fernandes (1991) interpreted the accumulation of large pools of free proline and other FAAs in water-deficit-stressed rice as being an indication of disruption in the pathway to synthesis, or increase in the degradation of proteins. Chiang and Dandekar (1995) concluded that the higher free proline levels in *Arabidopsis thaliana* (L.) Heynh tissues with low water content resulted from increased biosynthesis. Barnett and Naylor (1966) determined that water-deficit-stressed *C. dactyla* accumulated 10 to 100 times more free proline than the controls and suggested that because proline turns over more slowly than other FAAs during water deficit stress, it may function primarily as a storage compound. Alternatively, Bussis and Heineke (1998) found that hydroponic potatoes subjected to water deficit stress induced by polyethylene glycol were able to grow in dry conditions by accumulating organic solutes for use in osmoregulation. Osmoregulation in the tubers occurred in two phases: during the first two days hexoses were accumulated, and after seven days, osmotic adjustment was due mostly to the accumulation of FAAs, especially proline (150 times the amount in unstressed controls). Osmotic stress in *A. thaliana* induced a rapid accumulation of free proline through *de novo* synthesis from glutamate, and during recovery from osmotic stress, accumulated free proline was oxidized to glutamate and the first step of

this process was catalyzed by proline oxidase (Verbruggen et al., 1996). Golan-Goldhirsh et al. (1989) suggested that free proline acts as a compatible solute, a readily utilizable source of energy, and a sink for soluble N. They also indicated that free proline accumulation in plant cells under osmotic stress is not the result of damage, but accompanies survival and growth, and that plants originating in dry climates tend to have higher levels of free proline than plants in wetter climates. Gadallah (1995) demonstrated that proline sprayed on cotton plants counteracted the effects of water deficit stress and significantly increased chlorophyll content, chlorophyll stability to heat, leaf relative water content, and dry matter content. FAA accumulations associated with disease and nematode infections of plants might result from osmotic disruption, but also for other reasons, including xylem injury repair (Cohn and Orion, 1970), syncytial wall formation of nematode-induced root galls (Lewis and McClure, 1975), cell wall formation (Epstein and Cohn, 1971), and blockage of protein synthesis (Chowdhury et al., 1985).

Diffusive resistance reflected the rates of free proline accumulation. In cotton, as in other plant species, free proline levels appear to indicate water deficit stress. In both water deficit assays, elevated concentrations of arginine, histidine, and valine were detected at the highest stress levels, which suggests that FAA "profiles" might be characteristic of certain kinds of stress in cotton foliage. Competition with alfalfa seedlings resulted in a 2.9-fold increase ($P \leq 0.05$) in free proline and lower transpiration; both are characteristics of water deficit stress in plants (Rhodes et al., 1986).

The differences in FAA concentrations and diffusive resistances in cotton grown on the 1000 ml/week irrigation regime in parts 1 and 2 might have resulted from differences between seasons when the two assays were run. The changes in rates of accumulation with increasing water deficit observed in part 2 supports other findings that show nonlinear FAA accumulations with increasing levels of stress (Parrott et al., 1969). The significant difference only between the sets of the two driest and two wettest treatments demonstrates that leaf water potentials dropped with increasing conditions of water deficit. However, changes in free proline levels did not occur at corresponding rates. On the surface, it appears that free proline might not influence osmoregulation, but drawing firm conclusions based on correlating water potential measurements taken from other plants at a different time of year is difficult.

Shade Assay. The taller cotton plants under shade conforms to the findings of Ballaré and Casal (2000). Makus (1993) found that protein N in *Amaranthus* sp. was higher in conditions of reduced light, possibly enabled by accumulations of free arginine. Durzan (1971) found that free arginine in jack pine and spruce was higher in shade, and orthogonal comparisons over shade indicated a highly significant fit of arginine N with increased shade. Reduced free aspartic acid in combination with higher amounts of free arginine agrees with the trends

TABLE 8. RATIOS OF FAA CONCENTRATIONS IN WEED-FREE COTTON:WEEDY COTTON AND COTTON IN FULL DAYLIGHT:SHADED COTTON

	Ratios[a]	
	Weed-free	No shade
FAA	weedy	shade
Alanine	1.04	0.85
Arginine	0.08[a]	0.49[a]
Aspartic acid	1.20[a]	1.23[a]
Glutamic acid	1.19[a]	1.02
Glycine	0.72	1.02
Histidine	0.14[a]	1.25
Isoleucine	0.57[a]	1.32
Phenylalanine	0.46[a]	1.02
Proline	1.02	1.23
Serine	1.12	1.02
Threonine	1.22[a]	0.98
Valine	1.10	0.80
Total essential FAAs	0.65[a]	0.92
Total FAAs	0.18[a]	1.05

[a] $P \leq 0.05$ between weedy and weed-free, and between shaded and unshaded; weed competition assay, $n = 15$, shade assay, $n = 20$.

shown in the weed competition assay (Table 8). The observation in this study that unbound arginine was the only source of detectable FAA N to increase suggests that shade probably increased protein N rather than FAA-N. Free proline levels were not altered by weed competition or shade, which indicates neither stress involved water deficit. The relatively small (≈7%) difference between leaf water potentials indicates that water deficit stress is not reducing relative water content of the foliage. Being that the weed competition assay was conducted in field plots and the shade assay occurred in a greenhouse, other environmental parameters (e.g., pest damage, sunburn, herbicide residual, competition for root space, nutrient deprivation) might have acted singly or in combination to cause seven FAAs other than arginine and aspartic acid to accumulate to different levels in the field plots. The smaller increase of free arginine grown in 50% reduced daylight as compared to the larger increase in the weedy cotton foliage might be further evidence of the influence of other stresses on free arginine under field conditions.

Arginine is synthesized in plants from ornithine, and it appears to serve as an endogenous source of N (Ludwig, 1993) and a substrate for protein synthesis (Durzan, 1971). In dicots, such as cotton, increased stem growth in conditions of

shade is often observed (Morgan and Smith, 1970). Shargool et al. (1988) demonstrated that enzymes of arginine metabolism such as arginase and urease increase during seed germination, a time of rapid growth. Plants can use either ornithine decarboxylase or arginine decarboxylase to produce the polyamine precursor putrescine. Arginine and putrescine biosynthesis both occur in active photosynthetic tissues; the primary enzymes of the arginine pathway (from glutamate to citrulline) are chloroplastic, whereas the terminal step from citrulline to arginine is carried out in the cytoplasm (Borell et al., 1995). In cotton, shade decreased the photosynthesis rate but increased concentrations of chlorophyll (Zhao and Oosterhuis, 1998). Research on effects of shade on FAA levels is needed to demonstrate the physiochemical cause for the association of shade with elevated free arginine levels in cotton foliage.

Weed Competition Stress. Shainsky and Rose (1995), studying Douglas fir, *Pseudotsuga menziessi* [Mirb.] Franco, and red alder, *Alnus rubra* [Bong.], found that competition among plants accounted for 44% of the variation in FAA accumulations. They concluded that FAAs, storing surplus N in light-limited plants, increased as a result of competition. This study showed that some competition with alfalfa seedlings for finite water may have caused a 2.9-fold increase ($P < 0.001$) in proline over cotton grown without alfalfa seedlings. However, the lack of significant difference in free proline levels indicated that in the weedy and weed-free plots, water deficit was not a cause of stress, and this was supported by the similar water potentials found in the two treatments. A primary difference between the cotton planted with alfalfa seedlings and the cotton grown with weeds is that the former did not cover any of the cotton canopy whereas the weed canopy cast shade on the cotton canopy throughout each day. The primary difference in terms of FAAs was the 12.4-fold elevation of accumulated arginine in the weedy cotton. In addition to being a precursor to proline (Shargool et al., 1988), arginine is thought to serve under some conditions as a store of N and for biosynthesis of secondary products such as polyamines (Ludwig, 1993). Shading, whether caused by other plants or nonvegetative structures, causes increased upward growth (Morgan and Smith, 1970; Ballaré and Casal, 2000), which requires polyamines for protein construction. However, the shorter cotton in the weed competition plots as compared to the taller shaded cotton in the greenhouse appears to be a result of thigmomorphogenesis induced by the mechanical perturbation of wind (Jaffe and Forbes, 1993). Nutrient depletion and rhizosphere restriction might have also contributed to lower field cotton heights.

The lower transpiration rates in weedy cotton agrees with the effects of both water deficit and light reduction in plants (Zhao and Oosterhuis, 1998), and weeds can conceivably cause each or both conditions. These findings might help to explain the FAA levels detected in another crop. Showler et al. (1991) found less free proline and free arginine (45% and 55%, respectively) in sugarcane stalks. The samples were taken in late October, after the weed growth had died and formed a

dense mat that retarded water evaporation from the soil. In the weed-free habitats where soil moisture could evaporate more freely, free proline levels were higher. Weed-free sugarcane stalks had more free arginine, possibly because weed pressure had earlier reduced the sugarcane stand density (Showler and Reagan, 1991). The more dense sugarcane growth in the weed-free regimes probably resulted in greater shading from other sugarcane plants.

Kaolin Particle Film Effects. Free proline accumulations were unaffected by kaolin, so the particle film did not induce water deficit stress to the cotton, and this conclusion was corroborated by the lack of significant difference among the leaf water potentials observed in each treatment. Soybeans dusted with kaolin had lower transpiration rates and used less water as a result of increased global and long-wave radiation reflection and reduced emissivity of kaolin-treated leaves (Baradas et al., 1976). Stanhill et al. (1976) showed that grain sorghum and cotton treated with kaolin used less water than untreated plants. Heightened light reception or photosynthetic activity might be associated with free arginine reductions in foliage coated with kaolin. However, Makus (2000) did not find a difference in cotton canopy light intensity as a result of kaolin application. Glenn et al. (1999) found that kaolin application (up to 3000 μg/cm^2 leaf surface) did not reduce apple, pear, and peach leaf photosynthetic activity, but neither did they report any increase.

Whether photosynthesis was enhanced by kaolin sprays or not, there was a reduced need for free arginine. If free arginine serves as an endogenous source of N, then the smaller pools of free arginine suggest that the plant was building nitrogenous molecules using more alternative sources of N. Accumulation of free arginine in the absence of elevated levels of free proline appears to be an indicator of shade stress, much like elevated free proline levels indicate water deficit stress.

Although transpiration rate and diffusive resistance reflected levels of water deficit stress, the accuracy of the porometer is heavily influenced by cloud cover, relative humidity, and wind speed (Idso et al., 1987). Quantification of FAAs is more complex and time-consuming than porometry, but it circumvents those parameters that can cause spurious variation in porometer measurements, and permits stress assessment when plant stomates are either open or closed. Furthermore, porometry alone was not useful in distinguishing between light reduction and water deficit stress effects.

This study shows that characteristic associations between selected FAA levels and stress factors were useful in analyzing stress levels associated with weed competition and foliar coverage with kaolin. It also shows that total detectable free essential amino acid accumulations were significantly heightened by water deficit and weed competition stresses, whereas kaolin-treated cotton had significantly less total free essential amino acids than controls. The beet armyworm, *Spodoptera exigua* (Hübner), has been reported to oviposit more on stressed cotton (Ruberson et al., 1994) possibly because free essential amino acid content is higher (Showler 2001b) in water stressed plants. Research focusing on physiochemically mediated

relationships between plant stresses and phytophagous pests might provide new approaches to developing plant resistance and tolerance to some pests.

Acknowledgments—Thanks to Raúl Cantú, Jaime Cavazos, Robert Campos, Francisco Garcia, Jesse de Anda, Raúl Vallejo, Nancy Rivera, and Martín Porras for laboratory and greenhouse assistance; to Dave Eckert for HPLC setup and calibration; and to Paul Counce and Donald Hendrix for critical reviews.

ANNOUNCEMENT

19TH ANNUAL MEETING OF THE INTERNATIONAL SOCIETY OF CHEMICAL ECOLOGY AUGUST 3–8, 2002, HAMBURG

The 19th annual ISCE meeting will be held at the Department of Chemistry, University of Hamburg, Germany. The conference will begin on the evening of August 3, 2002 (Saturday) and end on the evening of August 7 (Wednesday). The meetings will be hosted by Wittko Francke.

There will be four symposia covering aspects of chemical ecology in symbiosis, molecular biology, insect-plant relationship, and pheromone chemistry.

Both oral and poster presentations are invited from participants. Contributed papers fitting to the symposia are particularly welcome.

Participants are encouraged to arrive on Saturday, August 3, and attend the Social Lecture given by Prof. Dr. Jerrold Meinwald followed by a mixer that evening. The concluding banquet will be held Wednesday evening, August 7.

Further Information may be obtained on the meetings web site http://isce2002.chemie.uni-hamburg.de

CALL FOR PAPERS

SPECIAL ISSUE ON AQUATIC CHEMICAL ECOLOGY

There will be a special issue of the *Journal of Chemical Ecology* devoted entirely to papers dealing with "Aquatic Chemical Ecology." Publication is planned for late summer/early fall 2002. The issue will consist of invited mini-reviews and contributed papers. Those wishing to submit a paper for consideration for this special issue should do so by March 15, 2002.

Please send the original and two copies of the manuscript (including illustrations) and the names and addresses of three potential reviewers to:

(Received July 26, 2001; accepted December 15, 2001)

Abstract—Pyrrolizidine alkaloids (PAs) are known to protect Arctiidae moths and Danainae and Ithomiinae butterflies against the orb-weaving spider *Nephila clavipes* (Araneae, Araneidae, Tetragnathinae), which liberates adults of these insects unharmed from its web. We tested against this spider the role of eight PAs and one derived structure [an 89:11 mixture of the 12-membered macrocyclic diester free base integerrimine and senecionine and the respective N-oxide; two hydrolysis products from this mixture (the necine base retronecine, its respective N-oxide, and a mixture of integerriminic and senecionic necic acids); the 12-membered macrocyclic senkirkine; the 9-*O*-monoester free base senecioylretronecine and its respective N-oxide; and the 9-*O*-monoester free base callimorphine (a PA biosynthesized only by insects from retronecine)]. The mixture integerrimine–senecionine N-oxide seems to be more active than the respective free base [$LibD_{50}$ (liberation dose 50) = 0.042 and 0.153 μg/dry weight of prey, respectively], but the difference in activity between the N-oxide and free base of the 9-*O*-monoester senecioylretronecine was slight ($LibD_{50}$ = 0.167 and 0.104, respectively). Senkirkine, an otonecine base PA that does not form N-oxide and is not found in insects, was the less active, showing the highest $LibD_{50}$ (0.354). The difference in antipredator activity between N-oxides and free bases from macrocyclic diesters and monoesters may be correlated with physicochemical properties of these molecules in interaction with the *Nephila* receptors. For the active structures, there was a significant correlation between dosage and antipredator activity. Both forms of retronecine and a necic acid mixture were inactive, supporting the hypothesis that PAs biosynthesized by insects from retronecine were originally produced and stored in order to optimize chemical defense. Comparison of dose/activity data with reported amounts of

PAs in butterflies suggested that, in general, PA-specialist insects are protected against predation by *Nephila*.

Key Words—Senecionine, integerrimine, retronecine, senkirkine, senecioyl-retronecine, callimorphine, *Nephila clavipes*, N-oxide, free base, sequestration, chemical defense, dose–activity, Araneae, Tetragnathinae, pyrrolizidine alkaloids.

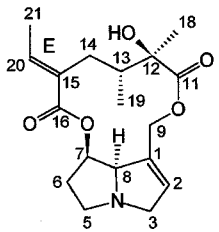
INTRODUCTION

Chemical defense against predators due to storage of plant secondary compounds occurs widely in insects (see Brower, 1984; Bowers, 1990; Brown and Trigo, 1995; Hartmann and Witte, 1995; Hartmann and Ober, 2000; Trigo, 2000 and references therein). In a classical study, Brower et al. (1967) verified that adults of the monarch butterfly, *Danaus plexippus* (Nymphalidae, Danainae), were protected against predation by birds due to cardenolides sequestered from their larval host plants *Asclepias* (Asclepiadaceae). Other compounds active against predation were later found to be sequestered from host plants by insects, including iridoid glycosides, quinolizidine alkaloids, aristolochic acids, diterpenes, pyrazines, and pyrrolizidine alkaloids (PAs).

The defensive activities of PAs against predators have been studied since 1980 and are demonstrated against invertebrate and vertebrate predators such as spiders (Eisner, 1982; Brown, 1984, 1985, 1987; Masters, 1990; Eisner and Eisner, 1991; Trigo et al., 1993, 1996a; Orr et al., 1996; Gonzalez et al., 1999), ants (Dussourd et al., 1988; Hare and Eisner, 1993), lizards (McLain and Shure, 1985; Masters, 1992), and birds (Cardoso, 1997; Masters, 1992). The activity against visually oriented predators may be involved in the evolution of aposematic coloration of Ithomiinae, Danainae, and Arctiidae (Brower, 1984).

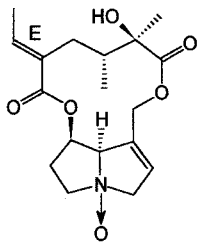
The most studied PA–prey–predator system involves the liberation of PA-protected arctiid moths and ithomiine and danaine butterflies by the orb-weaving spider *Nephila clavipes*, a Neotropical spider found in forest gaps and corridors, which are flight paths for insects (Robinson and Mirick, 1971). *N. clavipes* preys on bees, wasps, moths, and butterflies, but discriminates aposematic Ithomiinae and Danainae butterflies and Arctiidae moths, liberating them unharmed from the web (Belt, 1888, p. 317; Vasconcellos-Neto and Lewinsohn, 1984). Eisner (1982) was the first to show that PAs were responsible for liberating an insect (the arctiid *Utetheisa ornatrix*) without harm by *N. clavipes*. Other authors confirmed this chemical role (Brown, 1984, 1985, 1987; Masters, 1992; Trigo et al., 1993, 1996a). No studies were done on PA structure and dosage versus activity in relation to *N. clavipes* (but see Masters, 1992 for dose–activity relations in vertebrate predators).

In this paper, we report experiments to test the relative activity of some different types of alkaloids against *Nephila clavipes*. The questions addressed in the



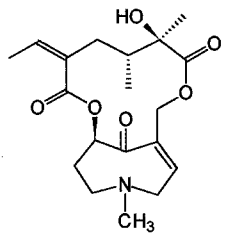
PAs to be bioassayed were: (1) Since N-oxides are the main PAs in plants and insects, and the latter have the capacity to N-oxidize dietary free bases (Hartmann and Witte, 1995), would there be difference in their activity? In order to ascertain this, we bioassayed a 1,2-unsaturated 12-membered macrocyclic diester, a 9-*O* monoester, their respective N-oxides, and also an otonecine 12-membered macrocyclic diester that does not form an N-oxide. (2) What chemical functions in the molecules give activity to PAs? Would insect PAs be biosynthesized to optimize chemical defense? To answer these questions, we bioassayed, in addition to the above PAs, the hydrolysis products from the first (a necine base and its respective N-oxide, and necic acids), and callimorphine free base, an insect PA biosynthesized from retronecine by several arctiid moths (Hartmann and Witte, 1995).

METHODS AND MATERIALS



Sources of PAs. We used for the bioassays free bases and N-oxides of a mixture (89:11) of integerrimine and senecionine [henceforward ISFB (Figure 1, **1a**) and ISNO (**1b**)], senkirkine [SKK (**2**)], the necine base, retronecine [RTFB (**3a**) and RTNO (**3b**)], the mixture of necic acids, integerriminic:senecic acids [ISAC (**4**)], the free base and N-oxide of 9-*O*-senecioylretronecine [SRFB (**5a**) and SRNO (**5b**)], and callimorphine free base [CLFB (**6**)].

ISFB, with two geometric isomers at C_{20}–C_{21}, was isolated from aerial parts of *Senecio brasiliensis* L. (Asteraceae: Senecioneae) from southeast Brazil. These 1,2-unsaturated macrocyclic diesters, also isolated from this species by Hirschmann et al. (1987) and Klitzke and Trigo (2000), are characteristic of Senecioneae plants. They are sequestered by several arctiid moths for defense and as chemical communication precursors (see for reviews Brown and Trigo, 1995; Hartmann and Witte, 1995; Trigo, 2000). The alkaloids were extracted according to Trigo et al. (1996a,b) and chromatographed over silica gel, eluting with a gradient of $CHCl_3$–MeOH from 99:1 to 90:10. The resulting mixture of integerrimine–senecionine was analyzed by GC-MS (Witte et al., 1993), ^{1}H, ^{13}C, COSY and HETCOR NMR (300 and 500 MHz). The ^{1}H NMR spectral comparison was done following data from Segall and Dallas (1983), Roitman (1983), and Logie et al. (1994) for ISFB and from Urones et al. (1988) for ISNO [the N-oxidation methodology for all compounds followed Craig and Purushothaman (1970)]. The ^{13}C signals were compared with Roeder (1990) for both ISFB and ISNO.



RTFB and ISAC were obtained by the hydrolysis of ISFB in a basic medium as previously described by Nishida et al. (1991). When necessary, RTFB was purified as above with $CHCl_3$–MeOH 3:1 over a basic alumina column. The structures were identified by the methods cited above. The ^{1}H NMR spectral comparison was done following data from Culvenor et al. (1965) for RTFB, Bohlmann et al. (1986) for RTNO, and Niwa et al. (1992, 1994) for ISAC. The ^{13}C signals for retronecine and

6. Callimorphine free base (CLFB)

FIG. 1. Pyrrolizidine alkaloids and derivatives used for *Nephila clavipes* bioassays.

its N-oxide were compared with Roeder (1990), and for ISAC they were assigned by HETCOR and DEPT analysis.

SRFB was obtained by the coupling of RTFB with senecioic acid regioselectively at C-9, following methodology developed by Nishimura et al. (1987), using dichloromethane instead of toluene as solvent. CLFB was obtained by the same methodology, using instead of senecioic acid (±)-2-acetoxy-2-methylbutanoic acid, synthesized from (±)-2-hydroxy-2-methylbutanoic acid refluxed 24 hr in acethylchloride. We obtained CLFB as a mixture of diastereoisomers at the

C-2′ position (see Figure 1). The ^{1}H NMR spectral comparison was done following data from Bohlman et al. (1986) for SRFB and SRNO, and L'Empereur et al. (1989) for CLFB. The ^{13}C signals for CLFB were also compared with L'Empereur et al. (1989), and for SRFB and SRNO they were assigned by HETCOR and DEPT analysis.

Bioassays with Nephila clavipes. The experiments with female *Nephila clavipes* (L.) (Araneae, Tetragnathinae) were carried out from March to May, in 1995, and in 1997–2000 at two sites: Serra do Japí, Jundiaí, São Paulo, and Instituto Agronômico de Campinas, Campinas, São Paulo. All experiments were performed between 09:00 and 16:00 hr. Only healthy female spiders were used, that is, spiders that responded immediately and in their typical way (Robinson and Mirick, 1971) when any prey was tossed onto their web. Spiders already feeding on any prey were not used. Each spider was used only once a day.

Workers of *Apis mellifera* L. (Apidae), with their stings intact, were killed by freezing, had their wings removed, and were used as carriers of tested PAs in the bioassays. Ten microliters of different amounts of the compounds soluble in MeOH [6.50×10^{-4}, 2.61×10^{-3}, 1.04×10^{-2}, 4.18×10^{-2}, 1.67×10^{-1}, 6.68×10^{-1}, and 2.67 μmol/bee or 3.82×10^{-5}, 1.54×10^{-4}, 6.14×10^{-4}, 2.46×10^{-3}, 9.82×10^{-3}, 3.93×10^{-2}, and 1.57×10^{-1} μmol/mg dry weight of bee (mean dry weight 17 mg)] were coated topically onto each bee with a microsyringe. The concentrations were based on the mean amount of PAs in Ithomiinae butterflies ($\approx$200 μg or 6.68×10^{-1} μmol; see Brown, 1985) and increased (once) or decreased (five times) in a geometric ratio of 4. ISAC was bioassayed only at the highest concentration. The bee was offered to the spider, whose response in relation to the prey was recorded (prey or liberate, see also Robinson and Mirick, 1971; Vasconcellos-Neto and Lewinsohn, 1984). When the spider preyed on the alkaloid-treated bee, the trial was finished. If the spider liberated a bee, another one treated with 10 μl of pure MeOH was offered immediately and the trial was valid only if the spider preyed on it. Each amount of alkaloid or derivative was tested at least 10 times.

Statistical Analyses. The 50% liberation dosages ($LibD_{50}$) were calculated by the linear regression of the probit of the percentage of liberated individuals *versus* log of micromoles per milligram of dry weight of the bees (Finney, 1971; Haddad, 1986). The regression lines were compared using analysis of covariance (ANCOVA) with a post hoc Tukey test (Sokal and Rohlf, 1995).

RESULTS

Neither RTFB nor RTNO showed activity against predation by *N. clavipes*: no dosage incited 50% liberation by spiders. At high concentration (3.93×10^{-2} μmol/mg), these compounds showed around 20% liberation (Table 1). ISAC

[a] The numbers in parentheses represent the percent liberated. NT = not tested. The concentrations that elicited ≥50% of liberation by the spider are shown in bold.

[b] ISFB = integerrimine–senecionine free bases; ISNO = integerrimine–senecionine N-oxides; SKK = senkirkine; RTFB = retronecine free base; RTNO = retronecine N-oxide; ISAC = integerriminic: senecionic acids; SRFB = 9-*O*-senecioylretronecine free base; SRNO = 9-*O*-senecioylretronecine N-oxide; CLFB = callimorphine free base.

TABLE 2. LIBERATION DOSE 50 ($LibD_{50}$) OF PAS IN *Nephila clavipes* BIOASSAYS

PA	Concentration		Regression lines	P^a
	μmoles/mg dry weight prey	μg/mg dry weight prey		
ISFB (**1a**)	5.0×10^{-4}	0.153	$y = 1.121x + 8.744$	a
ISNO (**1b**)	1.0×10^{-4}	0.042	$y = 1.406x + 10.516$	b
SKK (**2**)	1.0×10^{-3}	0.354	$y = 1.032x + 8.110$	c
SRFB (**5a**)	4.0×10^{-4}	0.104	$y = 1.251x + 9.199$	a,d
SRNO (**5b**)	7.0×10^{-4}	0.167	$y = 0.937x + 7.979$	a,c,d

[a] ANCOVA: the slopes had no significant differences; different letters denote significant differences in the intercept at 5% level.

also did not have antipredator activity. At the highest concentration tested (3.93×10^{-2} μmol/mg), only 1 of 12 preys was liberated by *N. clavipes*; due to the inactivity of this mixture, bioassays with smaller concentrations were not done (Table 1).

The other six bioassayed PAs were effective against predation by *N. clavipes*; all of them had at least one concentration that elicited 50% prey liberation by the spider (Table 1). For five, the $LibD_{50}$ was calculated, decreasing in the following order: ISNO > SRFB > ISFB $\cong$ SRNO $\gg$ SKK (Table 2); it is interesting to note that SRFB had a higher activity than SRNO. For CLFB, no $LibD_{50}$ was calculated since the synthetic yield was very low (around 20%), and there was not enough material to carry out more bioassays. At a concentration of 2.46×10^{-3} μmol/mg, 80% of the treated bees were liberated (Table 1); this is similar to the results obtained for SRFB and higher than those for SRNO (Table 1).

The line regression statistical analysis by ANCOVA showed that all five analyzed PAs had no significant differences in the slopes, and the intercept of ISNO was significantly higher than the others, representing the highest activity against predation (Table 2). SKK showed the lowest intercept, representing the lowest activity (Table 2).

DISCUSSION

Are There Differences between the Activity of N-Oxides and Free Bases? Our data showed that, for the macrocyclic diester mixture IS, the N-oxide was more active than the free base, but for senecioylretronecine it was not. The high activity of N-oxide in relation to its respective free bases was also found by other authors. Dussourd et al. (1988) topically applied monocrotaline in its free base and N-oxide forms on alkaloid-free eggs of *Utetheisa ornatrix* and observed that the latter was more active against predation by the beetle *Coleomegilla maculata* (Coccinellidae). Hare and Eisner (1993) repeated these bioassays against the ants *Leptothorax longispinosus* and found the same result. Moreover, ants with previous

contact with N-oxides preyed upon fewer alkaloid-free eggs in subsequent trials than ants with previous contact with free bases. However, Dreyer et al. (1985) found ambiguous results: senecionine N-oxide applied in a diet was 1.7 times more active than the respective free base against feeding by the pea aphid *Acyrthosiphon pisum*, but for riddelliine and monocrotaline, an inverse response was found.

We propose that the activities of free bases and N-oxides against *N. clavipes* are closely related to their intrinsic physicochemical features in relation to the spider receptors. The macrocyclic diester IS has a more rigid conformation than the 9-*O*-monoester SR, with few degrees of freedom, restricting its conformational possibilities. The free rotation around the C_9-O_{10}-C_{11} links in SR allows more conformational possibilities. For IS, the N-oxide is more active than the free bases. We hypothesize that this might be related to a restricted conformation, which could activate more efficiently the O on the N. This activation could facilitate the interaction of PA–spider receptors better than in free bases where this activation could not occur. For SR, there seems to be no difference in antipredation activity between free bases and N-oxides. Again, we hypothesize that the high degrees of freedom in the ester linkage would promote a loss of specificity at the N site when it is N-oxidized. The speculation calls for bioassays with more different PA structures and chemical calculations for these molecules, such as *ab initio*, semiempirical, or molecular orbital methods, to obtain physical and chemical parameters for a QSAR analysis.

Senkirkine, a macrocyclic PA that does not form an N-oxide and has as necine base (otonecine) with an N-methyl group (Hartmann and Witte, 1995), was less effective against predation by *N. clavipes*. Frei et al. (1992) found that senkirkine was more strongly genotoxic to *Drosophila melanogaster* than senecionine. This alkaloid is a more derived PA in plants, along the same biosynthetic pathway as senecionine (Hartmann and Dierich, 1998). These authors suggest that the diversity of structures formed from senecionine N-oxide, such as senkirkine, offers an excellent strategy for plant defense, increasing the escape success from local herbivory by generating populations with more deterrent or unpalatable PAs. However, nothing is known about insect incorporation of senkirkine, and its role as a defensive compound in this taxa; we can speculate that maybe the spider receptors are not able to recognize it.

What Chemical Functions in the Molecules Give Activity to PAs? Both retronecine and its N-oxide were ineffective against predation by *N. clavipes*. Dreyer et al. (1985) also found that retronecine was ineffective for deterrence against pea aphids and suggested that the function ester might be necessary for PA biological activity. More evidence for the importance of the ester function is that the acid mixture ISAC did not have activity against predation by spiders when tested alone. Moreover, specialist PA-sequestering butterflies have the capacity to produce specific insect PAs linking a plant necine base (probably formed by hydrolysis of ester PAs in insects) with a necic acid biosynthesized by the insect, which already

possesses an ester function. The insect PA activity in chemical defense is not clear, but we hypothesize that the biosynthesis of specific alkaloids could be an optimization of PA use in chemical defense against predators. Thus, the cost of sequestration of retronecine, ineffective against predation, could be compensated for by the biosynthesis of specific insect PAs, such as callimorphine, that protected insects against predation by *N. clavipes* better than RT. Hartmann et al. (1990) suggested that the production of insect PAs is linked to pheromone production by males, since the metabolic pathway to produce these involves hydrolysis of plant ester alkaloids. Nevertheless, since both males and females seem to produce these alkaloids (Hartmann et al., 1990), more studies must be done to clarify the biosynthetic pathway.

Unpalatability Spectrum Involving PAs. For six PAs bioassayed in this work, there was a positive correlation between dosage and antipredator activity against *N. clavipes.* Within any insect population or species, the degree of individual unpalatability can vary (Brower et al., 1968; Bowers, 1981). The chemical content of plants could be a critical determinant of the degree of protection conferred to insects that sequester host plant chemical compounds (Ritland, 1994). In an unpalatable insect population, the result of this chemical variation is a palatability spectrum (Brower et al., 1968; Brower, 1984). This phenomenon also results in automimicry as described by Brower et al. (1967), when more palatable insects are perfect mimics of less palatable individuals of the same species.

Nephila clavipes, like other predators, could test many individual potential prey items and reject the less palatable ones. Variation in defensive chemical quantity could determine which individuals would be killed and eaten and which would be liberated alive, as has been shown to occur with monarch butterflies, *Danaus plexippus* (containing different concentrations of cardenolides) in relation to the predator black-backed oriole, *Icterus abeillei* (Fink and Brower, 1981). These predators could act as selective agents on individual chemical variation. The results found in this work confirm this; prey with lower PA dosages were relatively more accepted than prey treated with higher dosages.

Brown (1985) determined the variation in PA concentration in 41 Ithomiinae species in the field. The range varied from 3 to 77 μg/mg of dry weight. All of these presented a higher average PA amount than that necessary to promote at least 50% liberation by *N. clavipes.* These data suggest that Ithomiinae butterflies in the field are protected against predation by *N. clavipes,* even though these butterflies present PA mixtures with structures different from IS, normally a mixture of intermedine and lycopsamine (Brown 1985, Trigo et al., 1996a,b). The data in Vasconcellos-Neto and Lewinsohn (1984) confirm this hypothesis, since *N. clavipes* liberated alive almost all Ithomiinae and Danainae butterflies offered to them. Our data showed that the PA amount that protects butterflies from predation by *N. clavipes* could be relatively low. The remaining PA found in butterflies could be used for other functions: in males for pheromone biosynthesis and a gift to females during

mating, and in females for transfer to eggs (Brown 1984, 1985, 1987; Trigo and Brown, 1990).

Acknowledgments—We are indebted to Ronaldo Alloise Pilli (IQ, UNICAMP) for the NMR analysis, and to the Prefeitura Municipal de Jundaí, Jundiaí, SP, and the Instituto Agronômico de Campinas, Campinas, SP, for permission to work in their areas. TEMPORAL MODULATION OF PYRROLIZIDINE ALKALOID INTAKE AND GENETIC VARIATION IN PERFORMANCE OF *Utetheisa ornatrix* CATERPILLARS

KATHERINE C. KELLEY,* KELLY S. JOHNSON, and MITZI MURRAY

(Received January 26, 2001; accepted January 12, 2002)

Abstract—Foraging on a variety of different food items allows individuals to balance nutrient intake, but it also may dilute toxins present in single items of the diet. The distinction between nutrient balancing and toxin dilution becomes less clear, however, for organisms that sequester potentially toxic compounds for their own benefit. Additionally, specific dietary components chosen may or may not affect metabolic rate, growth, and other measures of fitness. Using the arctiid moth *Utetheisa ornatrix*, we (1) evaluated the temporal pattern of larval feeding behavior when presented with diet enriched with the pyrrolizidine alkaloid (PA), monocrotaline, (2) estimated the cost of ingesting PAs by measuring larval nutritional performance on diets containing different amounts of usaramine, and (3) investigated the magnitude of genetic effects on the performance of families raised on diets of different usaramine concentrations. We demonstrate that an herbivorous insect can temporally vary its intake of sequestered allelochemical. Individuals combined a preference for intermediate amounts of monocrotaline with temporal modulation of the specific amount of PA ingested on a given day. Using usaramine, we found little evidence for a cost of ingesting PAs, except among some family groups. Measures of digestive and metabolic efficiency showed no consistent reduction in performance on higher alkaloid diets. Only when larvae in family groups were fed a single concentration of PA over more than one instar was there any evidence for a cost of ingestion. Additionally, there were large genetic components to both growth and an individual's growth response to dietary alkaloid. These results suggest that while genetic variation in performance on alkaloid-rich diets exists, modulation of intake rate by caterpillars may be an important mechanism to reduce effects on the growth and fitness of individuals.

Key Words—Pyrrolizidine alkaloid, larval diet choice, nutritional performance, larval growth, genetic effects, *Utetheisa ornatrix*, Arctiidae.

INTRODUCTION

Animals actively choose among different kinds of prey or food items during foraging (reviewed by Pyke et al., 1977; Stephens and Krebs, 1986; Waldbauer and Friedman, 1991). This diet mixing may achieve some optimal nutritional balance [e.g., marine invertebrates: (Rapport, 1980; Pennings et al., 1993); insects (reviewed by Simpson and Simpson, 1990); vertebrates (Leeson and Caston, 1991; Dearing and Schall, 1992)]. Alternatively, a diverse diet may dilute the impact of ingested toxins (Freeland and Janzen, 1974; Westoby, 1978). Interestingly, these two hypotheses may not be mutually exclusive for organisms that sequester plant allelochemicals for their own benefit.

While a physiological cost of ingestion and sequestration of secondary compounds is usually assumed and only sometimes demonstrated (reviewed by Bowers, 1992; Camara, 1997), there also can be fitness benefits to acquiring plant compounds (Boppré, 1986, 1990; Eisner and Meinwald, 1987). For many sequestering insects, the benefit is limited to a reduction in mortality (e.g., Eisner, 1980; Brower et al., 1984). For Lepidoptera specializing on host plants with pyrrolizidine alkaloids (PAs), however, the sequestration of alkaloids has a positive impact on reproductive success as well (Conner et al., 1981; Eisner and Meinwald, 1987; Dussourd et al., 1988, 1989). For this group of insects, PAs simultaneously might be considered nutrients (dietary component increasing survivorship, fecundity, etc.) and toxins (dietary component reducing survivorship, fecundity, etc.).

If an alleolochemical can be simultaneously nutritive and toxic, then its intake might influence the foraging behavior of those herbivore specialists that sequester their host's defensive compound(s). In the process of foraging, these specialists should not rely on a simple decision rule that identifies the allelochemical as a stimulant or deterrent for feeding. A more complex self-regulation of allelochemicals might balance the rate of intake, which is important for avoiding a toxic dose of the compound, with the cumulative intake, which determines the potential benefit an individual might accrue from sequestration of the compound. While several strategies might be employed to balance these, no study has detailed both the rate (intake per day) and rhythm (temporal variation in rate) of foraging decisions of these organisms to illustrate some of the strategies that might be employed.

The ornate moth [*Utetheisa ornatrix* (L.), Arctiidae] is an herbivore specialist that sequesters pyrrolizidine alkaloids from its *Crotalaria* hosts. The species is found on both native *Crotalaria* species and introduced ones (*C. pallida*, previously *C. mucronata*, and *C. spectabilis*). The introduced plants contain usaramine and monocrotaline, respectively, as their primary alkaloids; neither contains the alkaloid of the other (Dussourd et al., 1988). The PAs of *Crotalaria* could reduce some components of *U. ornatrix* fitness because of their general biological activity (Hartmann, 1991), yet both usaramine and monocrotaline are known to have a significant and positive impact on adult reproductive success in *U. ornatrix* (Conner

et al., 1981). Thus, PAs might be simultaneously toxic and nutritive to the larval *U. ornatrix* that sequester them.

We tested whether larvae of *U. ornatrix* actively regulate their intake of the pyrrolizidine alkaloid, monocrotaline, through temporal modulation of feeding behavior. Additionally, we estimated the cost of ingesting PAs by measuring the performance of larvae reared on diets containing different amounts of usaramine. Finally, we investigated the magnitude of genetic effects on the performance of families raised on different diets. If there are substantial physiological costs to ingesting pyrrolizidine alkaloids, larvae should prefer diets that minimize their alkaloid intake. If there is only a minimal cost to processing the allelochemical, then larvae should prefer diets that maximize their alkaloid intake. Finally, finding a family effect on the performance of larvae reared on different diets would suggest genetic variation in the physiological ability of larvae to process alkaloids and an opportunity for selection on this trait.

METHODS AND MATERIALS

Quantification of Alkaloids in Seed Powder. To measure seed alkaloid content, we modified the field test of Culvenor and Fitzgerald (1963). Dried *C. pallida* seeds were ground to a fine powder. The powder (2.7 g) was extracted in 50 ml ammoniacal chloroform (6.71 ml NH_4OH in 993.29 ml chloroform) for several hours. The extract was filtered and partitioned with 6 ml 2 N H_2SO_4. For total alkaloids, zinc dust was added to a 2-ml aliquot of the H_2SO_4 layer for several hours to reduce the N-oxides. A second 2-ml aliquot provided a measure of free base PA. The amount of precipitate formed 24 hr after addition of 6 drops of silicotungstinic acid was compared (visual determination of cloudiness) to a standard curve generated using known quantities of monocrotaline (equivalent to 0.51, 0.55, 0.84, 1.1, 1.7, and 3.3% dry wt).

The total alkaloid content of the seed powder was estimated to be between 1.1 and 1.7% dry wt. The concentration of free base (as opposed to N-oxide) in the seed powder was 0.06–1.1%, or roughly half. Based on these data, the concentration of PA in the four seed powder diets prepared (see below) was 0.017–0.026, 0.066–0.10, 0.13–0.20, and 0.26–0.41%. For simplicity, we will use only the larger estimated value.

Two-Choice Trials with Usaramine-Containing Seed Powder. Newly hatched larvae were reared on an alkaloid-free wheat germ and soy protein-based artificial (control) diet for 8–12 days (i.e., to the fourth or fifth instar). Then, larvae were transferred to small individual containers with loosely fitting lids and offered equal quantities of two test diets. Test diets contained 0% (control), 1.5%, 12%, and 24% dry wt of seed powder and were offered as paired choices (0% vs. 0.026% PA, 0.026% vs. 0.20% PA, and 0.20% vs. 0.41% PA). Varying the amount of seed

powder in artificial diet has been employed as a means of manipulating PA intake in numerous studies of alkaloid sequestration and use in *Utetheisa* (e.g., Conner et al., 1981; Dussoud et al., 1988). The seed powder replaced equivalent portions of indigestible cellulose, so the nutrient and water contents of the test diets did not vary (except with regard to differences specifically associated with the seeds). Larval feeding preferences were determined by comparing the amount (wet wt) of each diet consumed over 24 and 48 hr periods. Consumption was calculated by subtracting the wet mass of uneaten diet from the initial of amount of diet offered. Control (uneaten) portions of diet, weighed before and after trials, showed that water loss was negligible (less than 4% after 48 hr) and did not differ by diet. Twelve to fifteen larvae per trial were assayed.

The amount of diet eaten by larvae in each of the two-choice trials was analyzed with ANOVA. Effects in the model included individual, diet, time (24 and 48 hr after initially offered), and the interaction between diet and time. A significant interaction term would indicate that the rate of consuming a given diet changes over time and, therefore, suggest some modulation of feeding behavior in response to the diets available. Analyses were conducted with the GLM procedure (SAS Institute, 1989).

Four-Choice Trials with Monocrotaline. Larvae were reared on control diet until they approached the molt to the final (fifth) instar. At the premolting stage (head capsule slipped and gut emptied), larvae were weighed and placed in individual plastic boxes with four equal-sized (wet mass) diet cubes containing 0%, 1%, 4%, and 8% dry wt monocrotaline (free-base form; Sigma Co.). The pH of these diets ranged from 4 to 7 and was similar to that of natural caterpillar diets (Schultz and Lechowicz, 1986; Johnson and Felton 1996). Field-collected *C. spectabilis* contain a range (2.3–5.4% dry wt.) of monocrotaline (Johnson et al., 1985), so 8% represents approximately twice the concentration encountered by larvae in the wild. Diet cubes in the box were haphazardly assigned to one of four positions. The amount consumed from each was monitored daily for four days. All diet cubes in the arena were replaced when at least 70% of any one of the four had been consumed. Trials were performed with 22 individual larvae in two test groups, to accommodate the availability of appropriately aged larvae.

The amount of four monocrotaline diets eaten by larvae over a four-day trial was analyzed both with a repeated measures and randomized complete block design ANOVAs. To evaluate day and diet effects on individual feeding behavior, a repeated measures ANOVA was conducted with test group and sex as the between-subject effects. The Huynh-Feldt epsilon estimate approached unity for some within-subject effects ($0.78 < \epsilon < 1.05$); therefore, only multivariate tests of hypotheses were considered (SAS Institute, 1989). To further evaluate diet preferences and changes over the four-day period, randomized complete block designs were employed. Two individuals with missing data had to be excluded from this analysis to make the designs complete. This enabled multiple-range tests

[Ryan-Einot-Gabriel-Welsh (SAS Institute, 1989)] among diets or days, while still accounting for the nonindependence of observations made on each individual.

The final analyses of the four-choice experiment investigated the relationship between food and monocrotaline intake over time. Preliminary linear regression was conducted to evaluate whether intake of food or monocrotaline on a given day depended on the amount ingested on the previous day. Because intake rates appeared to oscillate, similar analyses were made to evaluate the dependence of changes in feeding (or the difference between days) on the previous day's intake. Correlation analyses indicated that food and alkaloid intake were related, so multiple regression analyses were performed using the change in intake on a given day as dependent variables, and both food and PA intake from all previous days in the trial as predictor variables. In the multiple regression, stepwise addition of predictor variables was employed. The variance inflation factors (VIF) for all multiple regression equations were less than 5; therefore multicollinearity, or intercorrelation among the predictor variables, was not large enough to affect the analyses (Stevens, 1996).

Nutritional Performance Study with Usaramine-Containing Seed Powder. Standard nutritional budgets were calculated for larvae fed diet containing *C. pallida* seed powder (0%, 0.10%, and 0.41% PA). Caterpillars were reared on control diet to the premolt stage for the fifth instar (10–15 days). Larvae were weighed, housed individually, and provided with preweighed cubes of treatment diet (15 larvae per treatment). Food was replenished daily as needed. Uneaten diet and frass were collected and refrigerated every other day. For each individual, pupation date and weight on the third day after pupation were recorded, then sex was determined using gross morphology. All uneaten diet, frass, shed skins, and silk were dried to constant weight and weighed to the nearest 0.1 mg. Indices were calculated on a wet-weight basis.

To improve normality, all three nutritional indices were arcsin transformed, growth rate was square-root transformed, and frass production was natural-log transformed. No transformation improved the skewed distribution of duration to pupation, so the variable was used untransformed.

Two separate multivariate analyses of covariance (MANCOVA) were performed, one on the nutritional indices and another on the six variables that comprise these indices, to test for multivariate effects of the diet treatments, family, gender, and the interaction between family and diet with initial weight as a covariate. The first analysis was conducted to provide results comparable to similar studies, while the second was performed to identify the specific changes in nutritional performance that contributed to effects on the calculated indices. The multivariate analyses were followed by univariate analyses (ANCOVA) to examine which variables contributed to significant multivariate effects. In these analyses, a diet effect would indicate changes in nutritional performance as a result of the amount of seed powder in the diet, a family effect would provide evidence of a genetic basis for the

response of the particular performance variable, a gender effect would imply males and females have different nutritional performances, and a family × diet interaction would demonstrate genotypes responded differently to the diet treatments.

Significant effects of diet on performance variables were further examined with multiple comparisons of least squares means. Because the experiment was not designed to test for genetic effects on nutritional performance, the power of the family and family × diet tests was not high. Type III sums of squares were employed because of the unbalanced design.

Genetic Effects on Performance with Usaramine-Containing Seed Powder. In a larger study, measures of growth were analyzed for seven full-sib families. Up to 60 larvae from each family were reared on control diet until approximately the third instar, then transferred to individual containers with experimental diet containing 0%, 0.10%, or 0.41% PA. Food was replenished daily as needed, and individuals were put in fresh containers when frass accumulated or mold appeared. Each individual was weighed at the time of transfer and at pupation so weight gain and growth rate could be calculated. Families were composed of all individuals that reached pupation (mean = 45, range = 19–56).

Pupal weight, weight gained, and growth rate were analyzed with a MANCOVA using initial weight as a covariate. The main effects included in the model were family, diet, and the family × diet interaction. This model was similar to that used for the previous experiment, although sex was not included. Analyses were conducted with the GLM procedure with type III sums of squares employed because of the unbalanced design; mean squares (MS) are reported.

RESULTS

Diet Choice Trials. In each of the two-choice trials, larvae always preferred the diet with more alkaloid (0% vs. 0.026% PA: MS = 0.068, $F_{1,39} = 26.27$, $P < 0.001$; 0.026% vs. 0.20% PA: MS = 0.064, $F_{1,33} = 45.32$, $P < 0.001$; and 0.20% vs. 0.41% PA: MS = 0.150, $F_{1,39} = 31.06$, $P < 0.001$). In two trials, larvae reduced their consumption of diet with less seed powder during the second 24 hr period (diet × time interactions, 0% vs. 0.026% PA: MS = 0.012, $F_{1,39} = 4.74$, $P = 0.036$; and 0.20% vs. 0.41% PA: MS = 0.025, $F_{1,39} = 5.26$, $P = 0.027$).

The pattern of larval feeding in the four-choice trial with monocrotaline differed among days and among diets (Table 1). Larvae consumed more diet with 1% or 4% alkaloid than diets with 0% or 8% (MS = 26,423, $F_{3,283} = 5.30$, $P = 0.001$). While this trend of preference for intermediate diets was observed on all days individually, only on the first day was there a significant difference in larval feeding (data not shown). The repeated measures analysis also showed other effects on larval feeding. The two groups tested ate different amounts of alkaloid on the four days tested (day × group interaction) and marginally differed in their feeding

preferences among days (day × diet × group), but showed no difference in feeding behavior overall (group between-subject effect, Table 1). Males and females fed similarly (sex between-subject effect, Table 1), both on different days and diets (interaction terms with sex), although there was some evidence of differences in their behavior when feeding on the diets on separate days (day × diet × sex interaction).

There was a strong negative relationship between the change in intake on a given day and the amount ingested the previous day (Figure 1). For example, most larvae decreased food intake on day 2 from day 1, then increased intake on day 3, while larvae were evenly split in their changes on day 4. Examination of the intake plots reveals that for both food and alkaloid intake and on all days (except alkaloid on day 2), larvae that ingested a large quantity ate considerably less the next day, while larvae that ate only a small amount reduced their consumption only slightly. This pattern was the consequence of individuals varying their food and alkaloid intake from day to day (Figure 2) apparently modifying the amplitude of the variation according to at least the previous day's intake. The multiple regression analyses demonstrate that intake of food and alkaloid were related, with both acting as significant and independent predictors of larval feeding behavior (Table 2). The amount of food ingested depended on the amount of food ingested the day before and usually the previous day's alkaloid intake as well. The amount of alkaloid consumed depended on the amount of food eaten the first day and

[a] The following abbreviations were used: food = food intake on given day, pa = alkaloid intake on given day. R^2, *F*, and *P* refer to the model overall, not the predictor variables. Predictors left in the model were significant at the 0.15 level.
[b] Not significant at 0.05 level.

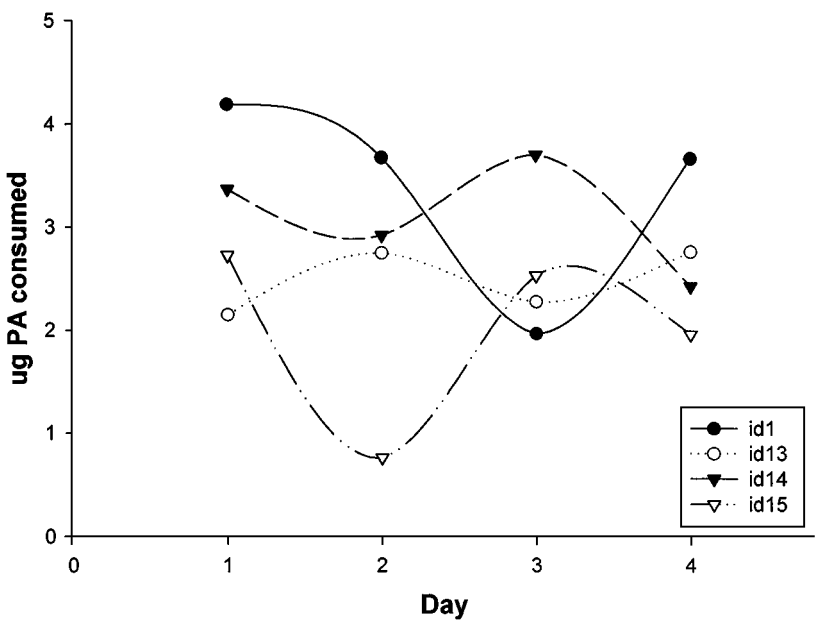

FIG. 2. Alkaloid intake of four representative larvae over the four day trial, showing both the oscillation of intake among days and variation in amplitude of those oscillations.

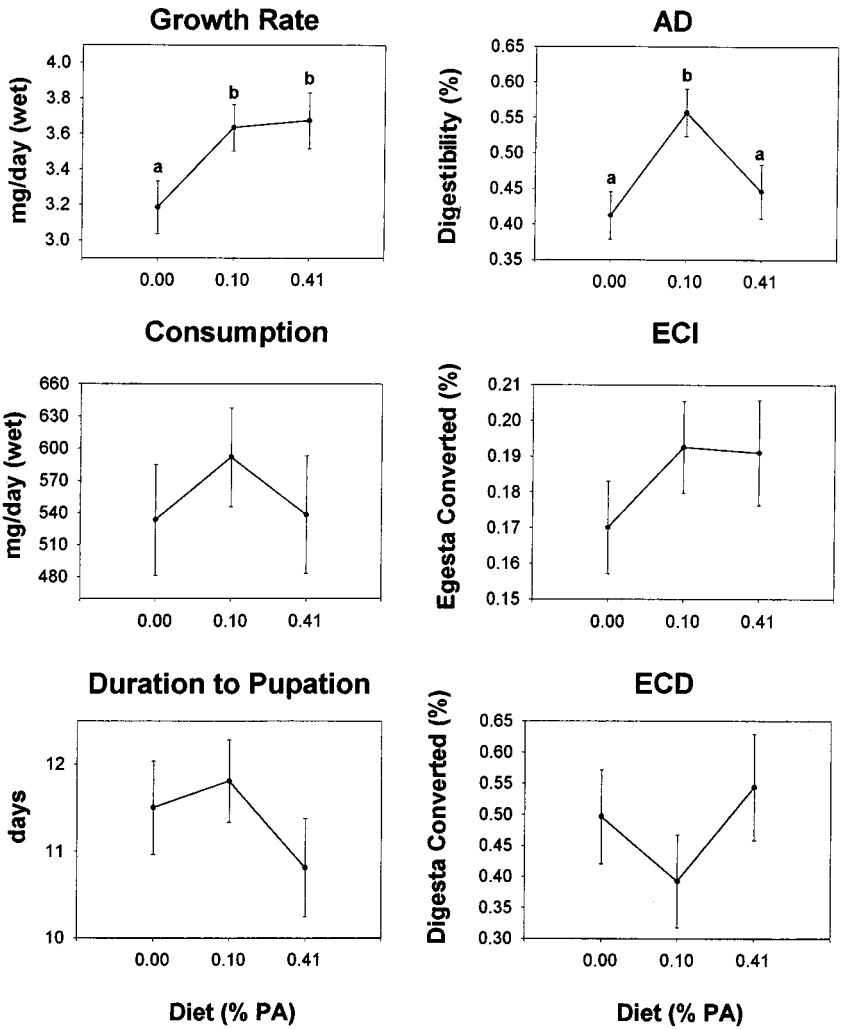
usually the amount of alkaloid ingested the previous day. Both the simple and multiple regression techniques indicate that the cyclical nature of feeding became more pronounced (stronger negative relationships) and more predictable (higher R^2 values) over time.

Performance Experiments. The first multivariate analysis, using standard performance indices (ECI, ECD, etc.), detected a weak, nonsignificant effect of diet (Wilk's lambda $= 0.434$, $F_{6,24} = 2.14$, $P = 0.086$). The univariate analyses showed the effect of diet was limited to (Figure 3) approximate digestibility (AD) was significantly higher on the seed-powder diet with 0.10% PA, in comparison to either the control (seedless) or 0.41% PA diets. The efficiency of converting ingested food to biomass (ECI) was higher on both seed-powder diets, in comparison to the seedless diet, but not significantly so. The efficiency of converting digested food (ECD) mirrored the response of AD, as would be expected, but the treatments did not differ significantly. The only other notable effect on the performance indices was a weak family effect on AD, suggesting the presence of genetic variation in the ability of larvae to digest a given diet. Neither sex effects, nor family $\times$ diet interactions were detected for the performance indices.

The second multivariate analysis, using measured performance variables, detected a family effect (Wilk's lambda $= 1.79$, $F_{20,57} = 1.79$, $P = 0.045$), but no diet effect. This family effect was found for several variables, including pupal weight (MS $= 6739.1$, $F_{4,21} = 7.38$, $P < 0.001$), total growth (MS $= 3790.8$, $F_{4,21} = 7.38$, $P < 0.001$), growth rate (MS $= 0.884$, $F_{4,21} = 4.95$, $P = 0.006$), and frass production (MS $= 0.252$, $F_{4,21} = 4.76$, $P = 0.007$), but not for duration of the final instar and consumption. Although no effect of diet was detected for the performance variables overall, the univariate analyses showed diet had a weak effect on pupal weight (MS $= 2914.4$, $F_{2,21} = 3.19$, $P = 0.062$), total growth (MS $= 1639.4$, $F_{2,21} = 3.19$, $P = 0.062$), and growth rate (MS $= 0.625$, $F_{2,21} = 3.50$, $P = 0.049$). In particular, larvae reared on the two seed-powder diets grew significantly faster than those reared on seedless diet (Figure 3). This increased growth rate contributed to a shorter duration to pupation for those reared on the diet with the most amount of seeds and occurred in spite of reduced consumption by larvae on the same diet (Figure 3). Weak sex effects were detected only for total growth (MS $= 1552.8$, $F_{1,21} = 3.02$, $P = 0.097$), and final weight (MS $= 2760.5$, $F_{1,21} = 3.02$, $P = 0.097$), with males tending to gain more weight during the final instar and have greater mass at pupation.

Examination of the growth of seven families showed that diet affected pupal weight, weight gain, and growth rate individually and was a main effect in the MANCOVA (Figure 4). Additionally, there were large family and family $\times$ diet effects on all measures of growth (for all $P < 0.001$, data not shown). Some families grew consistently faster than others, while families clearly differed in the diet on which they grew the best.



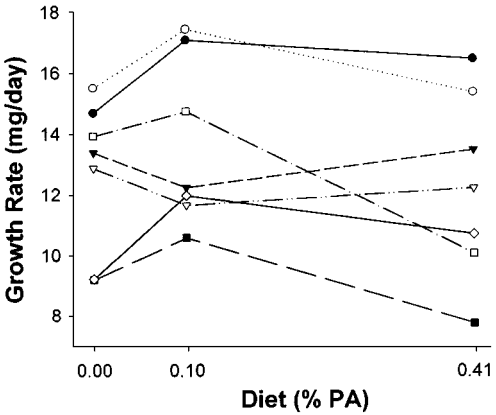


FIG. 3. The responses of three performance variables and the nutritional indices to each of the three diet treatments. Least-squares means and their standard errors are presented. Means with different letters were significantly different. The following definitions were used, after Scriber and Slansky (1981): $ECI = G/F \times 100$, $AD = (F - E)/F \times 100$, $ECD = G/(F - E) \times 100$, $RGR = G/TW$, $RCR = F/TW$ where E = weight of feces, F = weight of food eaten, G = weight gained, T = duration of feeding in days, W = mean weight calculated from initial and final weights. ANCOVA results for AD were: initial weight covariate, MS = 0.019, $F_{1,14} = 2.21$, $P = 0.159$; family effect, MS = 0.025, $F_{4,14} = 2.95$, $P = 0.058$; sex effect, MS = 0.019, $F_{1,14} = 2.24$, $P = 0.156$; diet effect, MS = 0.045, $F_{2,14} = 5.34$, $P = 0.019$; diet × family interaction, MS = 0.012, $F_{8,14} = 1.34$, $P = 0.301$. ACOVA results for growth rate were: initial weight covariate, MS = 0.00067, $F_{1,21} = 0.00$, $P = 0.952$; family effect, MS = 0.884, $F_{4,21} = 4.95$, $P = 0.006$; sex effect, MS = 0.326, $F_{1,21} = 1.83$, $P = 0.191$; diet effect, MS = 0.625, $F_{2,21} = 3.5$, $P = 0.049$; diet × family interaction, MS = 0.240, $F_{8,21} = 1.34$, $P = 0.278$.

DISCUSSION

The diet choice trials demonstrated that *U. ornatrix* larvae actively discriminate among diets with different concentrations of both *Crotalaria* seed powder and monocrotaline. Regardless of the combination offered, larvae in the two-choice trials always ate more of the diet with more PA. However, in the four-choice trials with monocrotaline, larvae consumed more diet with intermediate amounts of PA. These data may be interpreted in two ways. First, larvae may respond more to usaramine than monocrotaline. Second, a low concentration of alkaloid may elicit consistent phagostimulatory behavior, whereas the availability of more alkaloid might elicit more selective behavior. We suspect that the two-choice trials did not test the limits of PA diet choice, considering that the highest concentration of PA in the seed powder diet (0.41%) was less than half that available in the lowest monocrotaline diet (1%). Unfortunately, the constraint of holding nutrient and water content constant in the diet prohibited adding more seed powder, because the total amount of cellulose had been replaced with seed power in the 0.41% diet. That seed powder and monocrotaline are phagostimulants, at least at lower concentrations, is consistent with the observation that pyrrolizidine alkaloids typically act as feeding stimulants in specialists that sequester them (Brown, 1984; Boppré, 1986, 1990; Wink and Schneider, 1990; Bogner and Eisner, 1991).

A Varied Strategy of Dietary Self-Regulation. The four-choice self-selection trial using moncrotaline demonstrated that *U. ornatrix* consumed more diet with

an intermediate amount of alkaloid, but further analyses also revealed a pattern of temporal modulation of dietary alkaloid intake. Individuals varied both their total food and alkaloid intake in an oscillatory manner, with a given larva displaying a consistent amplitude in the oscillation of its consumption. Moreover, the multiple regression analyses clearly showed that changes in alkaloid consumption from one day to the next were dependent on alkaloid intake from previous days, an effect that was distinguishable from and independent of the changes in total food intake. In other words, the results show that the strategy of dietary self-regulation in *U. ornatrix* combines a preference for intermediate alkaloid diets with modulation of the specific amount of alkaloid ingested on a given day.

The observed dependence of feeding behavior on prior intake could be interpreted as a mechanism to obtain a proper balance of nutrients (Rapport, 1980). In particular, the behavior we observed is similar to compensatory feeding in response to dietary deficiencies in protein, carbohydrates, or other essential nutrients (Simpson and Simpson, 1990; Slansky, 1994). Among other insects that sequester for defense, it has not been clear whether there are compensatory responses to ensure that they acquire sufficient quantities from their diet. However, some pyrrolizidine alkaloid specialists actively seek sources of alkaloid (Boppré, 1986; Bogner and Eisner, 1991). We believe our results provide the first demonstration of oscillatory self-regulation of required dietary allelochemical intake in an herbivorous insect. The behavior suggests an active balancing of alkaloid as a nutritive component of the diet.

An alternative interpretation of the observed temporal modulation of alkaloid intake is that the behavior comprises a "dilution strategy" for regulating daily alkaloid intake to avoid autotoxicity (Freeland and Janzen, 1974). If so, then there should be a cost to the ingestion of alkaloids for *U. ornatrix*. Many alkaloids are toxic to a wide range of organisms (Hartmann, 1991) and deterrent to many generalist herbivores (Speiser and Rowell-Rahier, 1991). There certainly are metabolic costs of alkaloid ingestion in some insects (Cresswell et al., 1992), and there may be some cost of PA ingestion for *Creatonotos transiens* (Wink and Schneider, 1988), a PA specialist related to *U. ornatrix*. Based on this evidence, we anticipated finding some decline in the measures of metabolic efficiency, as a result of feeding on diets with alkaloid.

Are There Costs to Alkaloid Intake? Contrary to our expectation, the metabolic efficiency of larvae restricted to diets of low, medium, and high *Crotalaria* seed powder did not differ in a manner that would suggest a cost to ingesting alkaloid. In fact, growth rate and final pupal weight rose as the amount of seed powder in the diet increased. There was no reduction in the efficiency of converting ingested food into biomass (ECI, a combined measure of digestive and metabolic efficiency), or in the efficiency of converted absorbed food into biomass (ECD, metabolic efficiency). There was an increase in approximate digestibility at the intermediate seed powder

concentration and a complementary reduction in ECD at that concentration, but the effect was not linear with respect to concentration and, thus, is difficult to interpret. The only clear concentration-dependent effect of diet was on growth rate. Interestingly, the increase in growth rate on high alkaloid diet was due largely to a shortened development time. Typically, toxic effects reduce growth by extending development time, lowering pupal weight, or both. The pronounced effect on duration indicates a complex trade-off between growth, development time, and pupal mass in *U. ornatrix*.

In spite of the lack of evidence for metabolic costs in the nutritional performance experiment, feeding on a high alkaloid diet did have a negative impact on some genotypes in the population. In the longer-term growth study (three versus one stadia), which comprised a larger sample size of both individuals (318 vs. 48) and families (7 vs. 5), there were large family and small diet effects on growth and pupal weight, with families differing in their performance on the diet presented. Not all families grew faster on the seed powder diets, and most had reduced growth on the highest seed powder diet. These data indicate the presence of genetic variability in the tolerance to dietary alkaloid and are similar to performance and genetic measures of *Junonia coenia* Hubner (Nymphalidae) (Camara, 1997), a butterfly that sequesters iridoid glycosides.

Several caveats are worth mentioning given the lack of evidence for a metabolic cost in the nutritional performance study. First, gravimetric estimations of metabolic costs are sometimes criticized for being insensitive (Schmidt and Reese, 1986; van Loon, 1991). While we agree such assays may not detect a small metabolic cost, we believe the analyses are sufficiently precise to detect a large cost of feeding on alkaloids. Such a large effect would have been consistent with the toxin dilution hypothesis. Second, the concentration of alkaloid in the seed powder diet may not have been high enough or administered over a sufficient duration in the nutritional performance study to detect a metabolic cost. Third, the high quality of the artificial diet, or even the addition of non-PA components of the seed powder, may have offset any negative effects of increasing the PA content of diet. Additional studies that take these limitations into consideration might well detect a small metabolic cost of alkaloid intake in *U. ornatrix*.

We conclude that *U. ornatrix* appears to be well adapted to deal with the moderate levels of alkaloid encountered in its diet. Any negative effects of dietary alkaloid on growth are modest and only apparent after a longer duration of exposure or for some genotypes within the population. The pattern of temporal modulation of intake rate suggests larvae may have fairly sophisticated feeding behaviors that help maximize lifetime accrual of PA, while minimizing the potentially negative effects associated with ingesting too much PA within a short period of time. Because *U. ornatrix* larvae are highly mobile and frequently feed on both high-alkaloid seed pods and low-alkaloid leaf tissues, it is likely that they can detect and modulate

their intake to minimize negative effects. More information about the amount of variation in alkaloid content normally encountered in the field, and the genetic and behavioral responses of *U. ornatrix* to this variation, is needed to better determine whether self-regulation of dietary alkaloids occurs under natural conditions and to what extent it affects components of fitness.

Acknowledgments—We thank Mary Chamberlin and several anonymous reviewers for comments on the manuscript. Jason Wolf and Butch Brodie provided generous advice and some materials for working with *U. ornatrix*. Tom Parchman collected *U. ornatrix* adults for the laboratory colony. Archbold Biological Station and Mark Deyrup provided facilities for research and kindly permitted the collecting of animals. Stephanie Miller and Mike Sweeney assisted with larval rearing. Don Miles and Willem Roosenburg gave statistical advice. NSF (DBI-97501137) provided funding (to K.C.K.). The PACE and Honors Tutorial Programs of Ohio University supported the undergraduates.

(Received March 14, 2001; accepted December 5, 2001)

Abstract—The biochemical responses to varying levels of localized heat damage to stems and crowns were studied in *Pinus pinaster* trees in Galicia, Spain. The objective was to ascertain the utility of secondary metabolites (total polyphenols, condensed tannins, astringency, free and esterified phenolic acids) and pigments (chlorophylls and carotenoids) as chemical indicators of localized fire damage. The study involved three levels of girdling by trunk heating (0%, 60%, and 75%), three levels of crown scorching (0%, 50%, and 75%), and all combinations of those trunk and crown treatment levels. Secondary metabolites and pigments were analyzed in needles before, during, and up to 8 months after fire treatments. High levels of polyphenols, condensed tannin, and pigments occurred in situations where the sole treatment was 75% crown scorching. Low levels of hydroxycinnamic acids were the result when the treatment was 75% trunk girdling. These responses occurred in the first two months after fire. Thereafter, normal values were observed. Low values of chlorophyll a/b ratio and high levels of free protocatechuic and esterified syringic acids were found to be long-term indicators of trunk girdling damage combined with crown scorching.

Key Words—*Pinus pinaster*, fire effects, needles, secondary metabolites, pigments, indicators.

INTRODUCTION

Phenolic compounds are a group of secondary products that are almost universally present in higher plants (Harborne, 1980). The phenylpropanoids are a biosynthetic group formed in part via the shikimate pathway. A wide range of environmental stress factors affect this route (Rhodes, 1985). Temporary limitation of photosynthesis due, for example, to short-term drought or temperature extremes, leads to a decrease in carbon gains proportional to the duration of the unfavorable conditions. If these are too severe or prolonged, it takes longer for the plant to reactivate photosynthesis through its repair mechanisms after conditions have improved, if it recovers at all. This situation is referred to as the after-effect of stress (Larcher, 1995).

Fire, as a stress factor, may induce metabolic changes in leaves. Knowing the extent and nature of the metabolic changes in plants is important for the use of prescribed fire. Various effects of fire on trees have been identified. Biophysical parameters may change in forest species affected by direct heat application to the trunk or by prescribed fire, so that it is possible to predict tree survival from these changes (Bará et al., 1990, 1992, 1994).

Leaf composition can be related to flammability. Owens et al. (1998) observed the relationship between susceptibility of *Juniperus* communities to prescribed fires and the composition of volatile oils. Several biochemical changes in trees may occur as a result of fire damage, depending upon the level of crown scorching. These changes affect the relative vigor of damaged trees and appear to increase the attraction of insects and disease to fire damaged trees (Chambers et al., 1986). Studying the effect of a lightning strike on bark beetle susceptibility indicators in loblolly pine, Blanche et al. (1985) found that α-pinene, a primary attractant to beetles, increased by 71% after a lighting strike while the amount of myrcene in oleoresin, a precursor to *Ips* beetle pheromones, increased by 335%. In contrast, they found limonene, which is toxic to bark beetles, decreased, as did the level of β-pinene, a mountain pine beetle repellent. We noted increases in myrcene and α-pinene and decreases in β-pinene in needles of *Pinus pinaster* trees (relative to control trees) six months after they were affected by wildfire (Alonso et al., 1993b). Jakubas et al. (1994) found that secondary metabolite contents (phenolic glycosides, monoterpenes, and resin acids) were lower in burned than in unburned, lodgepole pine bark. Burned bark also contained more crude protein. Low levels of plant secondary metabolites in dead and burned bark may explain why elk and some insects preferentially utilize these trees. High levels of free proline and low levels of hydroxyproline were observed in *Pinus pinaster* trees affected by prescribed fire (Rozados et al., 1992, 1993). Fleck et al. (1996) observed in fire treated *Quercus ilex* that shoot foliage exhibited enhanced photosynthesis, leaf conductance, and Rubisco activity (particularly under high temperatures, irradiance, and vapor pressure deficit conditions) compared with foliage sampled from the lower

canopy in an undisturbed, contiguous stand (control). Higher values of astringency, total polyphenols, condensed tannins, free gallic and *p*-hydroxybenzoic acids, esterified gallic, protocatechuic and syringic acids, and lower free protocatechuic and esterified vanillic acids were observed in needles of *P. pinaster* trees affected by prescribed fire than were found in control trees. In the roots of the same trees, free protocatechuic and *p*-hydroxybenzoic acids were higher, and total polyphenols and esterified protocatechuic acid were lower (Alonso et al., 1998). Significantly more total chlorophyll and carotenoids (per gram of dry leaf tissue) were found in the first leaves that developed from affected trees after a fire than in leaves from unburned oaks (Trabaud and Methy, 1988).

Controlled crown and trunk heat injury treatments of ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) revealed effects of fire on xylem pressure potential, stomatal conductance, and transpiration (Ryan, 1993). Localized heating applied to the trunk of *Pinus halephensis* Mill. determined ecophysiological and morphological responses to fire injury (Ducrey et al., 1996). Rigolot et al. (1994) found that sap flux density and net photosynthesis were the most sensitive indicators of pending tree death. Mortality was nil until girdling exceeded 90% of the circumference. Although partial defoliation reduced stem diameter growth, partial girdling had no effect. The content of free protocatechuic acid was lower and esterified gallic, protocatechuic, and *p*-coumaric were higher than the control in 1-year-old *Pinus pinaster* seedlings after heat application to the trunk (Alonso et al., 1993a).

Many aspects of tree response to fire remain unknown. The aim of this study was to quantify the response of maritime pine (*Pinus pinaster* Ait.) to fire induced crown scorching and trunk girdling and to relate any chemical changes and their timing with the type of fire damage and/or the level of fire injury.

METHODS AND MATERIALS

Experimental Site. The experiment was conducted in an 18-year-old *P. pinaster* stand (dbh 18 cm, height 10.1 m, and density 2500 trees/ha) located in Cotobad (Pontevedra) in the northwest of Spain (700 m elevation, 38% slope). The substrate was granitic, the understory mixed heather (*Calluna vulgaris* and *Erica* spp.) and leguminosae (*Ulex* sp.), the mean annual precipitation of 1800 mm is well distributed throughout the year with a short dry summer season, and mean annual temperature of 10.5°C. The site occurs in clime VI (V) of Allúe's (1990) classification.

Localized Fire Treatments and Sampling. A completely randomized factorial experimental design (45 trees and 5 replicates by treatment) was used to study the effect of localized heat application to *P. pinaster* trees. Three levels of girdling by trunk heating (0%, 60%, 75%), three levels of crown scorching (0%, 50%, 75%), and the combination of both trunk and crown treatments were considered.

A gas flame was used to generate the heat necessary to damage the trunk cambium. The heat reached the trunk through a metal band fastened to the western side of the trunk. The metal band was 16.5 cm wide and 1.5 mm thick, and long enough to cover 60–75% of the perimeter of the tree (appropriate to the assigned treatment), with the lower edge of the band located approximately 35 cm above the forest floor. In the zone where the metal band was to be used, the bark was shaved slightly to reduce its fissures and roughness, thereby achieving a tighter contact between surfaces and a greater uniformity of heat conduction.

Crowns were scorched using a gas flame. The flame was applied to leaves and small branches at a distance of 50 cm for a few minutes until the desired level of healthy crown remained. Crown scorching was always done from below to simulate surface fire action. Leaf surface sheen (caused by melting wax), was used as an indicator of needle death.

All trees were treated between March 4 and 8, 1996. Before application of each treatment, 1-year-old needle samples were collected from the apex of a south-facing fourth whorl branch in four of the five trees treated February 16. We conducted another sampling immediately after treatment on March 12 and additional sampling on March 27, May 9, July 9, and November 6, 1996. Only green needles (not affected directly by heat application) were sampled. Pigment concentrations from fresh needles and other biochemical parameters were quantified from freeze-dried needles.

Analytical Methodology. Needle astringency was measured with hemoglobin derived from fresh bovine blood as a binding substrate in protein precipitation of tannins according to the method of Schultz and Baldwin (1981). Condensed tannins were measured with H_2SO_4/vanillin reagent (Scalbert et al., 1989), and total polyphenols with Folin Ciocalteau reagent (Dominguez, 1987). All of these determinations were made with methanol–water extracts (50:50 v/v), with the addition of $KHSO_3$ to prevent oxidation of phenolic compounds during the extraction (Peng and Jay-Allemand, 1991). Free and esterified phenolic acids (gallic, protocatechuic, *p*-hydroxybenzoic, vanillic, syringic, *p*-coumaric and ferulic) were analyzed by HPLC in 0.1% $KHSO_3$ water extract (Alonso et al., 1993a, 1998).

Pigments were extracted in dimethyl sulfoxide at 60°C during 8 hr immediately after the samples arrived at the laboratory (Hiscox and Israelstam, 1979). Spectrophotometrical readings were made in filtered solutions at 663, 646 and 470 nm (Lichtenthaler and Wellburn, 1983).

Statistical Analysis. Analysis of variance was undertaken for one between factor (treatment), including nine levels, and one within factor (sampling date) with one preburn and five postburn levels using a probability level of $P \leq 0.05$. Preplanned comparisons were made to evaluate differences between treatments by sampling dates throughout the period of study. Comparison of treatments included the effect of crown scorching only, crown scorching with 60% girdling by trunk heating, crown scorching with 75% girdling by trunk

heating only, girdling by trunk heating with 50% crown scorching, girdling by trunk heating with 75% crown scorching, and simultaneous and similar damages to trunk and crown.

RESULTS AND DISCUSSION

Fire Damage to Crowns

Crown damage resulted in increases in needle polyphenols (Figure 1A) and condensed tannins (Figure 1B). This effect was observed two months after the fire in all trees subjected to crown scorching. Trees with 75% crown scorching had higher polyphenol and condensed tannin levels than control trees for the postfire treatment dates. Trees damaged only by crown scorching at a 75% level exhibited an increase in free gallic acid 20 days after treatment (Figure 1C), and this effect could still be detected two months later. Trees with 75% crown scorching showed higher levels than control trees.

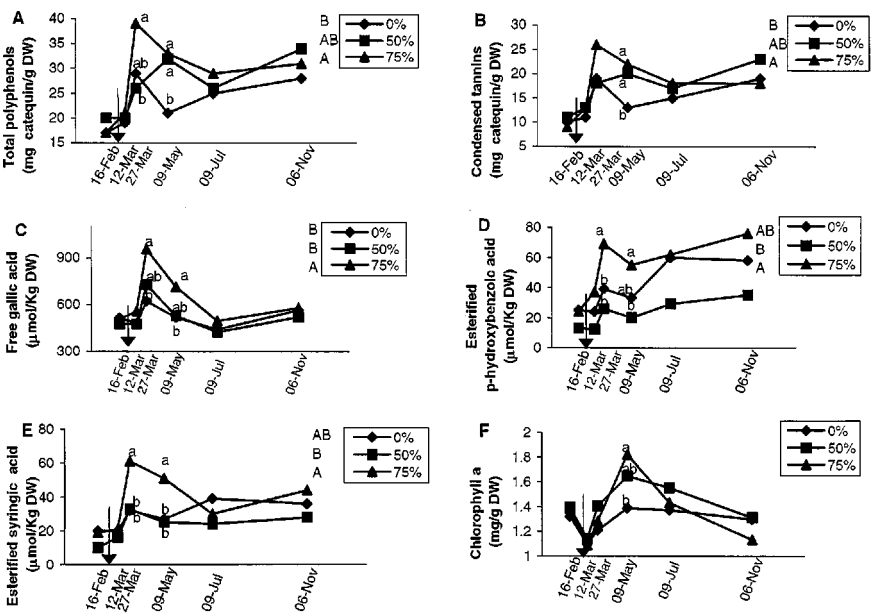

FIG. 1. Effects of different percentages of crown scorching on needle total polyphenols (A), condensed tannins (B), free gallic acid (C), esterified *p*-hydroxybenzoic acid (D), esterified syringic (E), and chlorophyll *a* (F). The vertical arrow refers to fire treatment date (March 4–8). Different lowercase show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatment ($P \leq 0.05$).

Twenty days after treatment, a high level of esterified *p*-hydroxybenzoic acid was observed in trees with 75% crown scorching compared to the levels in control trees (Figure 1D). Esterified syringic acid increased 20 days after treatment with 75% crown scorching and continued to rise until analysis two months later (Figure 1E). Thereafter, the level appeared to stabilize. Two months after fire treatment, the chlorophyll *a* content was significantly higher in trees with 75% crown scorching than in control trees, while trees with 50% of the crown affected had values intermediate between control and trees with 75% crown affected (Figure 1F). This effect disappeared in later samplings. The same result was obtained for chlorophyll *b*, total chlorophyll, and carotenoids (data not shown). In a previous study conducted on the same species two months after a mild intensity prescribed fire, high levels of polyphenols, tannins, and free gallic acid were noted in comparison to control trees (Alonso et al., 1998). In that study, the prescribed fire also affected a high percent of crown volume.

It can be concluded that 50% crown scorching by fire in *P. pinaster* trees does not modify the level of metabolites found in green needles. However, when 75% crown scorching occurs, increases in needle metabolite levels can be seen two months after treatment. Changes in phenolic acid levels occur 20 days after treatment. This suggests that secondary metabolism is activated to produce defense compounds, such as polyphenols, that might play a defensive role (Harborne, 1994; Hammerschmidt and Schultz, 1996) and may be enhanced as a consequence of crown scorch. Later, primary metabolism is enhanced to restore the photosynthetic activity that was diminished by crown scorching. Decreases in photosynthesis have been correlated with decreases in chlorophyll content by the action of phenolic compounds (Rama et al., 1997). These transitory effects indicate that irreversible changes did not occur, since carbon balance seemed to be restored four months after crown fire treatment. Total polyphenols, condensed tannins, and pigments may be good chemical indicators of crown damage alone. Furthermore, it is important to point out that severe crown scorching produces only temporary changes in these biochemical parameters. Botelho et al. (1998) suggested that relatively intense prescribed burns that result in severe crown scorching had a temporary and negligible impact upon growth rate (diameter at breast height and total height). Defoliation has little effect on survival until almost all of the foliage is removed in pine: young vigorous pines can survive fire-caused defoliation of more than 80% (Rigolot et al., 1994).

Fire Damage to Trunks

Twenty days after the fire treatment to the trunk, there was an increase in esterified gallic acid in trees with 75% trunk girdling (Figure 2A). Damage to only the trunk caused decreases in esterified *p*-coumaric acid in the trees with 75% trunk girdling two months after treatment (Figure 2B). For the same trees,

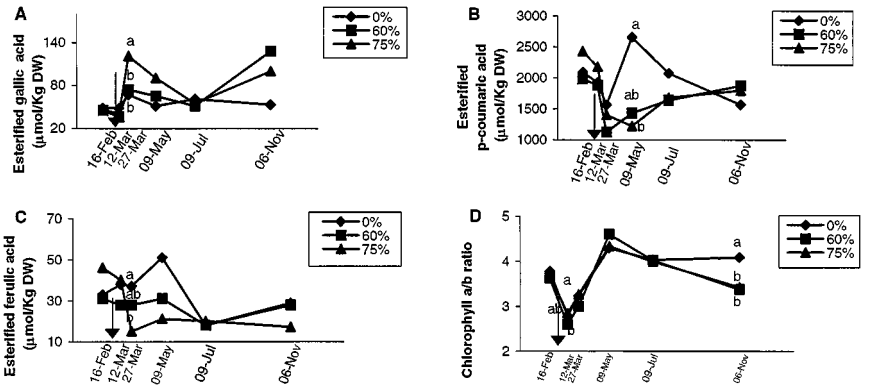

FIG. 2. Effects of different percentages of trunk girdling on needle esterified gallic acid (A), esterified *p*-coumaric (B), esterified ferulic acid (C), and chlorophyll *a*/*b* ratio (D). The vertical arrow makes reference to fire treatment date (March 4–8). Different lowercase show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatment ($P \leq 0.05$).

esterified ferulic acid decreased 20 days after treatment (Figure 2C). Ferulic acid is a precursor of coniferyl alcohol, the principal component of lignin in gymnosperms (Haslam, 1993). Fire injury to trunks may induce an increment in lignin production to repair damaged tree tissues, by utilization of ferulic acid and reducing its esterification.

In the final sampling, eight months after treatment, chlorophyll *a*/*b* ratios showed significant decreases for both fire treatments compared to control trees (Figure 2D). A 60% trunk girdling in *P. pinaster* trees was not sufficient to change metabolite levels in green needles, but 75% trunk girdling induced a specific decrease in hydroxycinnamic acids two months after the treatment. The chlorophyll *a*/*b* ratio may be useful for revealing long-term effects in treatment levels applied to tree trunks.

In another study, 1-year-old *P. pinaster* seedlings exposed twice to trunk heating showed decreases in electrical conductivity only in the damaged zone of the trunk (Bará et al., 1990). In the same seedlings, an increase in esterified gallic acid was observed four months after the second treatment, while the levels of esterified *p*-coumaric and ferulic were higher than those in control trees (Alonso et al., 1993a). However, in this study, esterified *p*-coumaric and ferulic acids levels were lower than those in control trees when trunk girdling alone was applied, suggesting different metabolic responses in young and mature trees. Vega et al. (1998), in a *P. pinaster* stand treated with prescribed burning, found that bark showed a high capability to effectively protect cambium for diameters ranging

from 9 to 40 cm. In these situations, temperature levels measured in the cambium, 25 cm above ground, were much lower than those registered on the outer bark surface (28.6°C instead of 662.9°C). This can explain why few changes were observed in severe trunk-affected trees. In a similar experiment where localized heating was applied to the trunks of young *P. halepensis*, Ducrey et al. (1996), found that the threshold for destruction of the cambium, in absence of any damage to foliage, occurred when 80–100% of the circumference of the base of the trunk was destroyed. They also observed that the behavior of partially burned pines was not significantly different from controls for all physiological variables studied (sap flux density, micro variations in trunk diameter, electrical resistance, photosynthesis, and stomatal conductance).

Combined Fire Damage to Trunks and Crowns

Trees with 50% Crown Scorching, Additional Trunk Girdling. In the most affected trees, a high level of astringency appeared immediately after fire. Fifteen days later the same results appeared in all trunk-damaged trees. In general, trees with 75% trunk girdling showed higher values than trees with 0% trunk girdling (Figure 3A). In the same trees, free protocatechuic acid, the most abundant phenolic acid in *P. pinaster* needles (Alonso and Bará, 1989), increased with 75% trunk girdling two months after fire treatment. This difference remained for eight months after fire treatment. In general, all trees with trunk damage showed higher values than trees with 0% trunk girdling in postfire dates (Figure 3B).

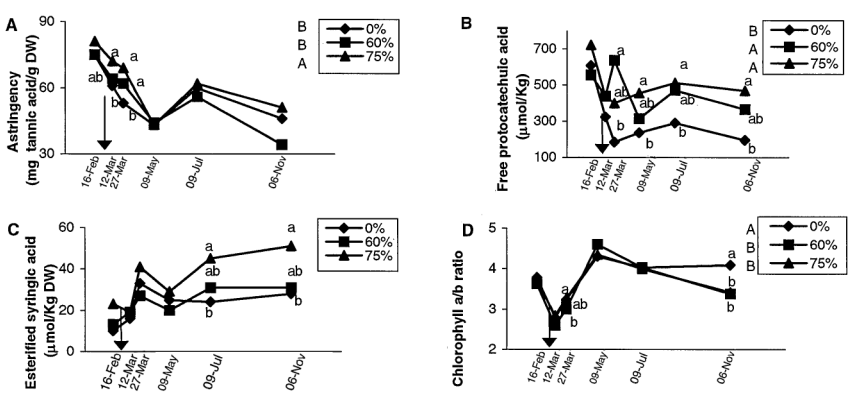

FIG. 3. Effect of different percentages of trunk girdling in trees with 50% crown scorching on needle astringency (A), free protocatechuic acid (B), esterified syringic (C), and chlorophyll *a*/*b* ratio (D). The vertical arrow makes reference to fire treatment date (March 4–8). Different lowercase letters show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatments ($P \leq 0.05$).

Esterified syringic acid level in trees with 75% trunk girdling was higher than in trees with 0% trunk girdling. This increase was detected four months after fire treatment and persisted to the end of the experiment (Figure 3C). Trees with 60% trunk girdling showed lower chlorophyll *a*/*b* ratios than trees with 0% trunk girdling 20 days after fire treatment. In November, all trees with trunk girdling showed lower values than trees with 0% trunk girdling. In general, all trunk-girdled trees had lower values than trees with 0% trunk girdling at post-fire treatment dates (Figure 3D).

Trees with 75% Crown Scorching, Additional Trunk Girdling. In cases where trees were subjected to 75% crown scorching combined with 75% trunk girdling, lower values in needle astringency than those in trees with 0% trunk girdling were observed for postfire data (Figure 4A). A decrease in esterified syringic acid for all trees with damage to the trunk 20 days and two months after fire treatments was noted and, in general, in postfire data in comparison to trees with 0% trunk girdling (Figure 4B). This is an inverse effect from that seen in trees with 50% crown scorching and additional 75% trunk girdling (Figure 3A,C).

Two months after fire treatment, levels of chlorophyll *b* decreased in trees with 60% trunk girdling relative to trees with 0% trunk girdling. In the final sampling, trees with 75% trunk girdling showed higher values than those with 0% trunk girdling (Figure 4C). All the trees with trunk girdling showed lower values for chlorophyll *a*/*b* ratios than trees with 0% trunk girdling in the final sampling (Figure 4D).

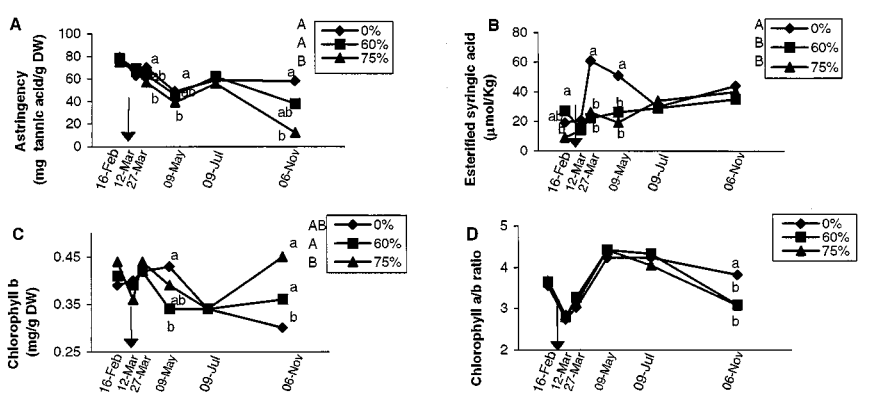

FIG. 4. Effect of different percentages of trunk girdling in trees with 75% crown scorching on needle astringency (A), esterified syringic acid (B), chlorophyll *b* (C), and chlorophyll *a*/*b* ratio (D). The vertical arrow refers to the fire treatment date (March 4–8). Different lowercase letters show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatment ($P \leq 0.05$).

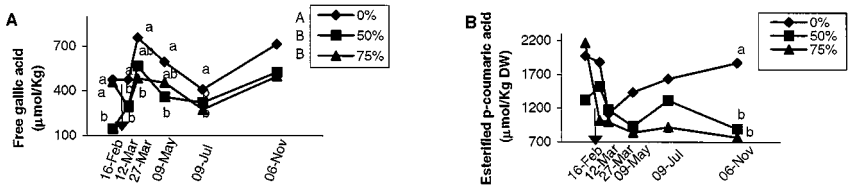

FIG. 5. Effect of different percentages of crown scorching in trees with 60% trunk girdling on needle free gallic acid (A) and esterified *p*-coumaric acid (B). The vertical arrow refers to fire treatment date (March 4–8). Different lowercase letters show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fore treatment ($P \leq 0.05$).

Trees with 60% Trunk Girdling, Additional Crown Scorching. In these trees, girdling in combination with 75% crown scorching produced a decrease of free gallic acid immediately after fire treatment, with the effect observable for four months. The trees showed lower free gallic acid values in needles than trees with 0% crown scorching (Figure 5A). The same trees contained less esterified *p*-coumaric acid in needles than the trees with 0% crown scorching in the final sampling (Figure 5B).

Trees with 75% Trunk Girdling, Additional Crown Scorching. We observed an increase in free vanillic acid in trees with 75% crown scorching two and four months postfire compared to trees with 0% crown scorching. In general, trees with 75% crown scorching showed higher free vanillic acid content than the trees with 0% crown scorching (Figure 6).

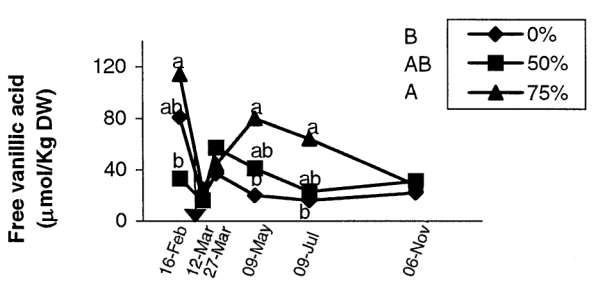

FIG. 6. Effect of different percentages of crown scorching on trees with 75% trunk girdling on needle free vanillic acid. The vertical arrow refers to fire treatment date (March 4–8). Different lowercase letters show significant differences between fire treatments on each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatment ($P \leq 0.05$).

In combined fire damage to trunk and crown, we observed characteristic needle astringency and esterified syringic acid changes. When additional trunk damage was applied to low-level crown damaged trees, these parameters increased, and the same parameters decreased if trunk damage was added to the trees with 75% crown scorching. This may indicate that, when damage exceeds a determined level, the tree does not react to activate the production of defense compounds and their levels diminish. Beyond eight months after fire treatment, the chlorophyll *a*/*b* ratio dropped, indicating a decrease in the efficiency of the conversion to energy and suggesting the presence of shadelike chloroplast in the needles. This finding is common to all girdled trees, with or without crown scorch, but is not observed in trees that are only crown scorched, suggesting a direct relationship between trunk girdling and long-term changes in the photosynthetic apparatus.

Simultaneous and Similar Damage to Trunks and Crowns

Twenty days after fire treatments, we noted high levels of esterified gallic acid in the most affected trees (75% trunk girdling and 75% crown scorching) compared to control trees. In July, this effect was observed in all affected trees. The mean of the postfire data in most affected trees was higher than that found in control trees (Figure 7A). Chlorophyll *a* content in mildly affected trees (60% trunk girdling and 50% crown scorching) showed higher values than control trees 20 days after fire treatment. Two months after fire, all treated trees showed higher chlorophyll *a* content than control trees (Figure 7B). Similar results were obtained for total chlorophyll.

In conclusion, polyphenols, condensed tannins, and pigments may reflect crown scorching damage alone, while hydroxycinnamic acids can be useful indicators of trunk damage. The chlorophyll *a*/*b* ratio seems to be a long-term

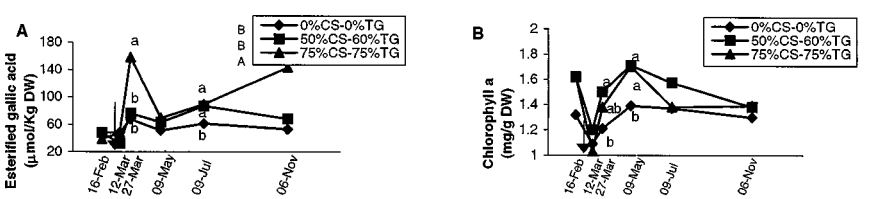

FIG. 7. Effects of different percentages of simultaneous and similar damages to trunk and crown on needle esterified gallic acid (A), and chlorophyll *a* (B). The vertical arrow refers to fire treatment date (March 4–8). CS: crown scorch, TG: trunk girdling. Different lowercase letters show significant differences between fire treatments in each sampling date ($P \leq 0.05$). Different capital letters indicate significant differences between treatments, considering the set of data after fire treatment ($P \leq 0.05$).

indicator of trunk damage, both alone or combined with crown scorching. Esterified syringic acid variations can reflect crown scorching, but this changes with additional trunk heating levels. Metabolic changes produced by both crown scorching and trunk heating show up in the first two months after fire. Thereafter, values return to normal. When both trunk and crown are affected by fire, some metabolites show variations that are detectable four and even eight months after fire. Under the conditions of this study, irreversible physiological disruption was not detected eight months after treatment, showing the potential use of mild intensity prescribed burns for *Pinus pinaster.* Nevertheless, the timing of fire treatment can also be important. Defoliation in summer can be particularly damaging because this is a time of rapid assimilative storage, while in winter the carbohydrate reserves are greater. Therefore, the conclusions of this study are limited to winter fires and any extrapolation to fire treatments carried out in summer must be avoided.

Acknowledgments—The authors acknowledge support given to this research work by the European Commission through the Environment Programme contract EV5V-CT94-0473. We are grateful to Dr. Salvador Bará for giving us the original idea to develop this topic, to Professor Ted Robak for reviewing the manuscript, to Maria Ignacio for laboratory work, and to Antonio Arellano for field assistance. We acknowledge to D. Jose Luis Gonzalez, veterinarian of Pontevedra Slaughter House for the supply of fresh steer blood used for astringency determinations.

(Received October 10, 2001; accepted December 17, 2001)

Abstract—*Oxytropis lambertii* has been considered to be one of the major locoweeds responsible for livestock poisoning on rangelands, but there has been much confusion as to its taxonomic identity. The objective of this study was to conduct a field survey of several populations of each of the three varieties [var. *lambertii* Pursh; var *bigelovii* A. Gray; var. *articulata* (E. Greene) Barneby] to document the presence or absence of the locoweed toxin, swainsonine. Swainsonine was found at detectable levels (>0.001% dry weight) in only five populations of var. *bigelovii* in the southwest portion of its distribution in southern Utah, Arizona, and southwestern New Mexico, USA. No swainsonine was detected in populations in the northeast areas of its distribution (eastern Utah, Colorado, northeastern New Mexico, USA). The other varieties, *articulata* and *lambertii*, also did not contain swainsonine. It is suspected that a plant fungal endophyte may be responsible for the high variability in swainsonine content in populations of *O. lambertii*.

Key Words—Lambert locoweed, crazyweed, *Oxytropis lambertii*, swainsonine, livestock poisoning, toxic plant, poisonous plant.

INTRODUCTION

Locoweeds (*Astragalus* and *Oxytropis* spp.) cause widespread poisoning of livestock in the western United States (Kingsbury, 1964). Much of the early toxicological research was conducted on the complex of species then called *Aragallus lambertii* (Marsh, 1909), which included both the white-flowered and the lavender-flowered groups of plants. Later Marsh (1919) referred to the white locoweed as

* To whom correspondence should be addressed. E-mail: mralphs@cc.usu.edu

0098-0331/02/0400-0701/0 © 2002 Plenum Publishing Corporation

Astragalus lambertii. Butcher et al. (1953) were first to point out that the plant with which Marsh conducted most of his early toxicology research was indeed the white flowered *O. sericea*. Taxonomists have separated the two species based on the color of their flowers (*O. sericea* is white to slightly yellow; *O. lambertii* is purple violet or lavender) and the dolabriform (ox head-like) pubescence that is unique to *O. lambertii* (Barneby, 1952; Welsh, 2001).

The confusion in taxonomy complicates the question as to whether *O. lambertii* is really a locoweed and whether it has been responsible for poisoning livestock. Literature reviews of the locoweeds all include *O. lambertii* as one of the major locoweeds (Marsh, 1919; Kingsbury, 1964; James et al., 1981; Ralphs and James, 1999). However, there is no empirical evidence of poisoning attributable to *O. lambertii*. The objective of this research was to document the presence of the locoweed toxin swainsonine in *O. lambertii*.

METHODS AND MATERIALS

A literature review was conducted of the toxicology and chemistry literature for any reference to swainsonine in *O. lambertii*. A widespread field survey of *O. lambertii* populations was conducted and laboratory analysis performed to determine the presence or absence of swainsonine. Voucher specimens are held in the S. L. Welsh Herbarium in the Bean Natural History Museum, Brigham Young University, Provo, Utah.

Known populations of each of three varieties representing the entire geographical distribution of that variety were sampled in June 2000 (Table 1). Ten individual plants were collected at each site. Half of each plant was pressed for identification. The other half was air dried in a forced air oven for 48 hr at 60°C and then ground through a cyclone grinder. Samples were analyzed for the locoweed toxin swainsonine by the procedures described by Gardner et al. (2001). Detection limit of swainsonine was 0.001% of dry weight. Swainsonine concentration was compared by one-way analysis of variance to determine differences between locations.

RESULTS AND DISCUSSION

There are few reports in the literature of *O. lambertii* containing swainsonine (Table 2). Molyneux et al. (1989, 1991) reported the presence of swainsonine in *O. lambertii* by using a thin-layer chromotography technique. Later samples from the Henry Mountains in southeast Utah, and from Livermore, Colorado, showed swainsonine levels of 0.031 and 0.007%, respectively (Molyneux, unpublished data). Fox et al. (1998) reported *O. lambertii* from western and northern New Mexico contained swainsonine. Braun (1999) also reported swainsonine in

[a] Presence detected by thin-layer chromotography.

O. lambertii taken from different pastures in 1998 and 1999 (Ralphs et al., 2001). Samples of *O. lambertii* collected from another research location in northeastern New Mexico also did not contain swainsonine (Ralphs, unpublished data).

There are three varieties of *O. lambertii*. Variety *bigelovii* A. Gray is separated from the other two by having stipitate pods (slender stalklike base). It occurs from southeastern Wyoming, southward through the foothills and mountains of Colorado and New Mexico, and westward into eastern Utah and Arizona. Variety *lambertii* Pursh is separated from var. *articulata* (E. Greene) Barneby by its longer calyx teeth, about one third as long as the tube and shorter flowers, <18 mm. It occurs on prairies from North Dakota to Kansas with a few populations in eastern Wyoming. Variety *articulata* has short calyx teeth, about one fifth as long as the tube, and flowers 18–25 mm long. It occurs in southwestern Kansas, western Oklahoma, the Texas panhandle, and northeastern New Mexico (Welsh, 2001).

Variety *bigelovii* is the most widespread of the three varieties. Ten populations were sampled in Colorado, Utah, Arizona, and New Mexico (Table 1). Three populations of var. *articulata* were sampled in Oklahoma and Kansas. Three populations of var. *lambertii* were sampled in Wyoming, South Dakota, and Nebraska.

The locoweed toxin is a trihydroxy indolizidine alkaloid, swainsonine (Figure 1) (Molyneux and James, 1982). Detectable levels of swainsonine were found in only five of the 10 populations of *bigelovii* located in the southwestern geographical areas of its range (Table 3). The other five populations in its eastern range did not contain detectable levels. The other two varieties also did not contain detectable levels of swainsonine.

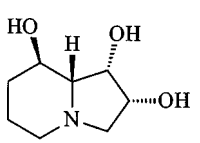

FIG. 1. The toxic alkaloid swainsonine found in locoweeds.

TABLE 3. LOCATIONS IN 2000 SURVEY WHERE *O. lambertii* CONTAINED SWAINSONINE (MEAN ± SE)

Location	Mean (%)	Range (%)
Flagstaff, AZ	0.054 ± 0.027	0.022–0.106
Winston, NM	0.038 ± 0.035	0–0.068
Springerville, AZ	0.026 ± 0.021	0–0.065
Kingston, NM	0.016 ± 0.013	0–0.043
Kanab, UT	0.008 ± 0.016	0–0.047

Four of the five southwestern populations of *bigelovii* containing swainsonine were in the vegetative or bud stage of growth when they were harvested in June (Table 1), indicating they flowered later in the summer. The Kanab, Utah, population that contained swainsonine had flowered early in the spring. The remainder of the *bigelovii* populations and the other two varieties were in the flower and pod stages when harvested, indicating they were spring-flowering plants. The summer monsoonal precipitation pattern, in which the majority of the annual precipitation occurs as summer thunder storms, is responsible for the summer-flowering populations. Although summer thunderstorms are common in areas of the other varieties and populations, there is sufficient winter and spring precipitation to support spring-flowering populations. The presence of swainsonine in both spring- and summer-flowering plants suggests precipitation patterns and subsequent flowering times do not influence presence of swainsonine.

Of the *bigelovii* populations containing swainsonine, the Flagstaff, Arizona, summer-flowering samples had the highest concentrations, while the spring-flowering samples at Kanab, Utah (100 miles away) had the lowest concentrations. Intermediate concentrations occurred in samples from Springerville, Arizona, and Kingston and Winston, New Mexico. Not all of the plants collected at these five locations contained swainsonine. Flagstaff was the only location in which all plants contained it. At Kanab, Utah, only half of the plants contained detectable levels of swainsonine. The range in concentration at each location was fairly large (Table 3).

There is a discrepancy between the presence of swainsonine in previous studies and our results. Fox et al. (1998) reported *O. lambertii* at Ocate, New Mexico, contained swainsonine, while our samples from Ocate did not contain swainsonine at detectable levels. Molyneux (unpublished data) found swainsonine in a sample from Livermore, Colorado, which is near our Ft. Collins, Colorado, population that did not contain swainsonine. Braun's (1999) sample from Colfax County, New Mexico, contained very small amounts of swainsonine (0.0006%), while our Colfax County sample was below the detectable limit (<0.001%).

It appears that the presence of swainsonine in *O. lambertii* is not genetic. Varieties *articulata* and *lambertii*, and half of var. *bigelovii* did not contain detectable

levels. Furthermore, there were individual plants within most collection sites that did not contain swainsonine, ruling out environmental influences.

It has been suggested that swainsonine in locoweeds may be produced by endophytes. Swainsonine is also produced by the fungus *Rhizoctonia leguminicola* in moldy forages (Broquist et al., 1984) and the fungus *Metarhizium anisopliae* (Hino et al., 1985). Braun (1999) found a fungal endophyte tentatively identified as *Alternaria nova* in toxic locoweed species, and reported a near perfect association between the presence of the endophyte and swainsonine in locoweed species. Recent research suggests that the fungus *Rhizoctonia leguminicola* was misclassified and should be in the phylum Ascomycota, which also contains *Alternaria nova* (McGinn et al., 1999). Analysis of our samples for the fungal endophyte showed a strong correlation ($r = 0.92$) with the presence of swainsonine (Gardner et al., 2002). The endophyte infection was limited to the five populations of variety *bigelovii* that contained significant levels of swainsonine, but there were a few plants infested by the endophyte that did not contain swainsonine and a few plants containing swainsonine in which the endophyte was not detected. Further research is needed to determine if swainsonine in locoweed is produced by an endophyte or if the stress from the endophyte augments swainsonine synthesis. This may explain why some populations or individual plants within a population do not contain it.

It is curious to note that the populations of *O. lambertii* var. *bigelovii* at Ft. Collins, Colorado, and at Capulin, Sophia, and Ocate, New Mexico, that did not contain swainsonine are growing together with *O. sericea*, which does contain fairly high levels (0.04–0.11) (Ralphs et al., 1993, 2001). The opportunity for infection by endophytes between these species would seem possible.

In summary, some populations of *O. lambertii* var. *bigelovii* in the southwest areas of its distribution contained swainsonine (Kanab, Utah; Flagstaff and Springerville, Arizona; Kingston and Winston, New Mexico). However, populations in the northeastern areas of its distribution did not contain detectable levels. Populations of the other two varieties, *O. lambertii* var. *articulata* and *lambertii*, also did not contain detectable levels of swainsonine. However, previous research showed some of the northern populations did. There is some evidence that swainsonine is produced by an endophyte. It is likely that other populations of *O. lambertii* may contain the endophyte and produce swainsonine. Further research will be conducted to confirm the presence of endophytes and their contribution to swainsonine.

Abstract—Many lizards are capable of identifying food using only chemical cues from food surfaces, but almost nothing is known about the types of compounds that are effective stimuli. We experimentally studied lingual and biting responses by a lacertid lizard, *Podarcis lilfordi*, to single representatives of three major categories of food chemicals, sucrose as a carbohydrate, pure pork fat as a mixture of lipids, and bovine gamma globulin as a protein. In 60-sec trials in which stimuli were presented on cotton swabs, the lizards detected all three stimuli, exhibiting more tongue-flicks, licks, or bites, or a greater tongue-flick attack score (TFAS; overall measure of response strength to prey stimuli) than to deionized water. The initial response to all stimuli was tongue-flicking, but the lizards discriminated among the types of chemical stimuli. After preliminary tongue-flicks, the lizards responded to sucrose solutions by licking at high rates, to pure pork fat by biting, and to protein by a combination of additional tongue-flicks and biting. Biting is a feeding response to prey or solid plant material. Licking is a feeding response to sugars in nectar or ripe fruit. Its frequency increased with sucrose concentration. Our data suggest that lizards can identify several types of chemicals associated with food and direct feeding attempts to sources of such chemicals in the absence of visual cues.

Key Words—Behavior, chemical senses, tongue-flicking, food chemicals, Squamata, Lacertidae, *Podarcis lilfordi*.

INTRODUCTION

Food flavors, based on a combination of olfactory and gustatory responses to chemical properties of food, are extremely important to evaluations of food by humans. Many other animals are able to locate and evaluate foods on the basis of perceptual qualities associated with classes of compounds, such as the sweetness of sugars and the bitterness of alkaloids. For many snakes and lizards, for which flavors might be determined jointly by vomerolfaction, olfaction, and gustation, very little is known about the importance of particular categories of food chemicals in stimulating chemosensory investigation and feeding responses.

Lizards that are active foragers (Cooper, 1995, 1997, 2000a) or include substantial quantities of plants in the diet (Cooper, 2000b,c; Cooper et al., 2000a). They are able to identify food using only chemical cues sampled by tongue-flicking, but little is known about the types of chemicals to which they respond or the precise chemical senses that mediate these responses. Only two recent studies document behavioral responses to certain types of food chemicals by lizards (Stanger-Hall, et al., 2001; Cooper and Pérez-Mellado, 2001a), and another study presents evidence that at least one lizard species is capable of rejecting chemically defended plant foods (Schall, 1990).

The major candidates for positive response to foods are proteins, lipids, and carbohydrates. Responses by lizards to proteins in food have not been studied, but specific glycoproteins from earthworms can elicit strong responses by garter snakes (Burghardt et al., 1988; Wang et al., 1988). The omnivorous lacertid lizard *Gallotia caesaris* responds strongly to lipids in pure pork fat and to sucrose, but the responses to these chemicals differ qualitatively (Cooper and Pérez-Mellado, 2001a). When responding to fat, the lizards tongue-flick at increased rates and frequently bite the stimulus source.

In contrast, lizards responding to concentrated sucrose solutions exhibit no elevation in tongue-flick rate or likelihood of biting (Cooper and Pérez-Mellado, 2001a). Instead, they lick the stimulus source at high rates after preliminary tongue-flicks, the rate of licking increasing with sucrose concentration. In studies of food chemical discrimination, the omnivorous lacertid *Podarcis lilfordi* licked in response to stimuli from nectar-producing flowers and licked nectar in the field (Cooper and Pérez-Mellado, 2001b), also suggesting a specific response to sugar. The only other evidence regarding responses to carbohydrates by lizards is that some individuals of the polychrotid lizard *Anolis carolinensis* preferred to eat crickets dusted with a dextrose/aspartame powder, and one licked the residue of this powder in a food bowl after eating a cricket (Stanger-Hall et al., 2001).

Evidence that lizards can use chemical cues to avoid chemically defended foods is limited to responses to the alkaloid quinine. *Cnemidophorus murinus*, an omnivore, avoids eating plants in its natural habitat that contain high concentrations of alkaloids (Schall and Ressell, 1991) and rejects experimental food that has been treated with a low concentration of quinine (Schall, 1990). Some individuals of *A. carolinensis*, an insectivore, exhibited aversive responses to crickets treated with quinine solution and showed aversive responses to crickets treated with quinine powder (Stanger-Hall et al., 2001). The signs of aversion included spitting the crickets out prior to swallowing and regurgitation. The lizards significantly avoided eating crickets treated with quinine powder.

We studied lingual and biting responses by *P. lifordi* to single representatives each of protein, lipid, and carbohydrate stimuli presented on cotton swabs. *Podarcis lilfordi* eats a wide range of invertebrate prey, occasional vertebrate food, and diverse plant species (Salvador, 1986; Pérez-Mellado and Corti, 1993). Plant parts and products consumed that are likely to contain high concentrations of sugars are fruits and nectar (Pérez-Mellado and Corti, 1993). *Podarcis lilfordi* is an excellent subject for studies of responses to types of food chemicals due to its broad diet, its abundance, and existing knowledge about its responses to food chemicals (Cooper and Pérez-Mellado, 2001b, 2001c). These lizards can discriminate between odorless and odorous control substances and surface chemicals from prey and plant foods by lingually sampling them (Cooper and Pérez-Mellado, 2001b).

We predicted that animal protein and the complex lipid mixture in pure pork fat would elicit strong responses indicated by tongue-flicking and biting and that the sucrose found in plant foods eaten by these lizards (Pérez-Mellado and Corti, 1993) would elicit licking. We also examined the effects of sucrose concentration on rates of tongue-flicking and licking and observed responses to sucrose by the lacertid species, *Lacerta perspicillata*, which is insectivorous (Barbadillo et al., 1999). The goals of the study were to assess the importance of protein to food chemical discrimination by lizards, to extend previous findings for lipids and a carbohydrate to another species, and to determine whether the licking response to sucrose was limited to species that eat plants.

METHODS AND MATERIALS

Subjects and Maintenance. Adult *P. lilfordi* were collected on the islet of Aire, offshore from Menorca, Balearic Islands, Spain, and adult *L. perspicillata* were collected in a quarry near Ciutadella on Menorca. Both were transported to a laboratory on Menorca. They were housed individually in transparent plastic terrarria ($40.5 \times 25.0 \times 26.5$ cm). The side walls of terraria were covered with white paper to reduce disturbance to the lizards by movements of the experimenters and

by other lizards. Each terrarium contained a floor of indoor–outdoor carpet and a water bowl. The natural regional light cycle was maintained by light through a window, and additional light and heat were provided by incandescent heat lamps, one suspended above the ends of each cage to permit thermoregulation. Ambient temperatures during testing were 30.9–32.2°C. Body temperatures were not measured during this experiment, but some lizards measured in these conditions at other times voluntarily attained temperatures of over 35°C, slightly warmer than the body temperature of most individuals during spring (Salvador, 1998). The lizards were fed mealworms and continuously provided water in the laboratory but were not fed for 24 hr prior to testing. All tests were conducted while lizards were active from 09:00 to 14:00 hr.

Experimental Procedures. All observations were made for responses during 60-sec trials to chemicals presented on the cotton tips of wooden applicators (15 cm). To begin a trial, an experimenter slowly moved the cotton swab to a position 1.0–1.5 cm anterior to a lizard's snout. A trial began when the lizard directed the first tongue-flick to the swab and continued for 60 sec unless the lizard bit the swab, at which time the trial was terminated. In each trial, the experimenter recorded the number of tongue-flicks, occurrence of and latency in seconds to a bite, and number of licks.

These variables and the tongue-flick attack score (TFAS) were analyzed. The tongue-flick attack score (Burghardt, 1967, 1970a; Cooper and Burghardt, 1990) is a composite variable that combines tongue-flicking and biting data to give a single index of response strength. For experiments having repeated-measures designs, TFAS(R), it is equal to the number of tongue-flicks if the lizard does not bite the swab. If a lizard bites, TFAS(R) has two components, one being based on latency to bite and the other on tongue-flicks. The term (60 minus latency to bite in seconds) is added to a term expressing a maximum number of tongue-flicks (Cooper and Burghardt, 1990). The latency term gives heavier weight to bites at shorter latency because bites at short latency indicate rapid identification of food. The other term is the maximum number of tongue-flicks by that individual in any one of its trials (Cooper and Burghardt, 1990). The tongue-flick term assures that bites are more heavily weighted than any number of tongue-flicks because bites reflect predation attempts.

In an experiment designed to detect responses to major categories of organic compounds found in prey, the stimuli tested were sucrose as a carbohydrate, pure pork fat as a complex mixture of lipids (mainly triglycerides), and bovine gamma globulin (Sigma G7516) as a protein. The fat and protein stimuli are not those from normally consumed foods. They were selected for this first study because they are readily available and inexpensive, and in preliminary trials they were found to elicit responses observed to whole foods. Sucrose is appropriate as a major contributor to the sweetness of ripe fruits and nectar although free frutose may also contribute. Deionized water was used as an odorless control stimulus.

To prepare stimuli, swabs were either dipped into deionized water or a saturated sucrose solution (6.27 M), inserted into pure pork fat, or immersed in water and then brought into contact with crystalline protein.

Twenty individuals of *P. lilfordi* were tested in a repeated-measures (randomized blocks) design. Each individual was tested in all four conditions in which the sequence of stimuli tested was varied among individuals in a partially counterbalanced order to preclude any sequential bias that might have occurred if the same sequence of stimuli were used for each individual. The minimum intertrial interval was 0.5 hr.

The effects of sucrose concentration on number of tongue-flicks, tongue-flick attack score, and number of licks were examined in an experiment having an independent-groups design in which 21 individuals of *P. lilfordi* were tested at each concentration. The concentrations of sucrose in deionized water solution were 6.27 M (saturated), 1.57 M, 0.39 M, 0.10 M, 0.02 M, 0.01 M, and 0.00 M (pure deionized water). The two highest concentrations are unlikely to be encountered in nature but are included to examine the full range of responses. Due to the independent-groups design, the tongue-flick attack score must be calculated slightly differently. TFAS is the same as TFAS(R) with the exception that the tongue-flick term for individuals that bite is the maximum number of tongue-flicks performed by any individual in the experiment. Responses by six adult *L. perspcillata* to a saturated sucrose solution were observed. We studied effects of variation in concentration only for sucrose, in part because we lacked time for additional studies during a brief visit to Menorca. In addtion, responses to protein were not as clear-cut as the licking response to sucrose, and the pork fat is a mixture of substances.

Statistical Anaylsis. Some data from both experiments were analyzed nonparametrically due to intractable heterogeneity of variance and/or nonnormality. For the experiment on responses to representatives of major categories of organic compounds, data for the continuous variables were analyzed using Friedman two-way analysis of variance. Where main effects were significant, differences among pairs of conditions were tested for significance using nonparametric multiple comparisons procedures described by Zar (1996). Data on the number of individuals that bit were analyzed using a Cochran Q test. Paired comparisons of the numbers of individuals that bit were made using sign (binomial) tests. Raw probabilities are reported for these tests, but significance tests were conducted by a sequential Bonferroni procedure to adjust for the number of tests (Wright, 1992).

Tongue-flicks in the experiment on sucrose concentration were analyzed by parametric analysis of variance for a single-factor experiment having an independent-groups design after variances were found to be homogeneous using Hartley's F_{max} tests (Winer, 1962). Paired comparisons for this variable were made using Newman-Keuls procedures. Data on number of licks from the experiment on effect of sugar concentrations were analyzed using Kruskal-Wallis analysis of

variance for continuous variables, followed by Dunn's tests for signficance of difference between pairs of sucrose concentrations when the main effect was found to be significant. An additional analysis of differences in the proportions of individulas that licked at least once between pairs of 1/4, 1/16, and 1/64 saturated solutions was conducted using Fisher exact probability tests (Zar, 1996) with Bonferroni adjustments as above. Except where indicated otherwise and justified by directional prediction, all significance tests were two-tailed, with $\alpha = 0.05$.

RESULTS

Responses to Chemical Types. All individuals of *P. lilfordi* tongue-flicked in every trial, with the greatest mean number of tongue-flicks in response to protein, but none of the stimuli elicited large numbers of tongue-flicks (Table 1). The number of tongue-flicks varied among stimuli ($\chi^2 = 8.36$, $df = 3$, $P < 0.040$). The only significant difference between pairs of conditions was that there were fewer tongue-flicks in the sucrose condition than in the deionized water condition ($P < 0.05$). There were marginally fewer tongue-flicks in the sugar condition than in the protein condition ($P = 0.063$).

The latency to bite varied among conditions, the mean being much shorter in the fat condition than in all others (Table 1). The main stimulus effect was significant ($\chi^2 = 13.61$, $df = 3$, $P < 0.004$). Latency to bite was shorter in response to fat than to deionized water ($P < 0.05$) and sucrose ($P < 0.01$). There was a nonsignificant trend for latency to bite less in response to fat than protein ($0.05 < P < 0.10$). No other differences among pairs of stimuli were significant, but latency to bite was substantially less in response to protein than to sucrose ($0.05 < P < 0.10$). Results

TABLE 1. NUMBERS OF TONGUE-FLICKS AND INDIVIDUALS THAT BIT[a]

Variable	Sucrose	Pork fat	Gamma globulin	Deionized water
Tongue-flicks				
Mean	3.1	3.9	10.2	7.0
SE	0.5	0.6	3.3	1.5
Number that bit	11	20	14	11
Latency to bite (sec)				
Mean	42.8	5.1	24.7	34.8
SE	20.7	4.5	27.0	28.7
TFAS(R)				
Mean	24.5	68.7	48.8	33.3
SE	5.1	3.3	5.0	6.4

[a] Twenty adult *Podarcis lilfordi* were used in 60-sec trials with cotton swabs bearing a saturated sucrose solution, pure pork fat, bovine gamma globulin, or deionized water.

for the number of individuals that bit swabs (Table 1) had the same pattern of significance as did latency to bite. The stimulus effect was significant ($Q = 17.25$, $df = 3$, $P < 0.001$). More individuals bit in the fat condition than in the sucrose ($P = 0.008$) and deionized water conditions ($P = 0.003$). The difference between the fat and protein conditions closely approached, but did not attain, significance after Bonferroni adjustment ($P < 0.042$ vs. adjusted $\alpha = 0.0123$). Differences among the other pairs of stimuli were not significant.

Variation among conditions in TFAS(R) was substantial (Table 1). The main effect was highly significant ($\chi^2 = 16.49$, $df = 3$, $P < 0.001$). TFAS(R) was greater in the fat condition than in the sucrose ($P < 0.05$) and deionized water ($P < 0.01$) conditions. It was also greater in the protein condition than in the sucrose ($P < 0.01$) and deionized water ($P < 0.05$, one-tailed) conditions. The remaining differences between pairs of stimuli were not significant.

Numbers of licks (Table 1) varied dramatically among conditions. Licks began only after at least one tongue-flick. Lizards licked swabs bearing sucrose rapidly, with a mean of over twice per second, but none licked swabs bearing protein. Four of 20 individuals licked swabs bearing fat. Only one individual licked a swab in the water condition, but it licked 75 times. Numbers of licks differed among conditions ($\chi^2 = 55.43$, $df = 3$, $P < 0.001$). There were more licks in the sugar condition than in the fat, protein, and deionized water conditions ($P < 0.001$ each). No other differences between pairs of stimuli were significant.

All *L. perpicillata* initially tongue-flicked swabs bearing sucrose and then licked the swabs. Numbers of licks were 36.00 ± 14.74 (SE), with range 1–103.

Sucrose Concentration and P. lilfordi. Tongue-flicks varied among sucrose concentrations ($F = 2.46$; $df = 6, 140$; $P < 0.028$; Table 2). The number of tongue-flicks in response to saturated sucrose was less than in the other conditions

TABLE 2. TONGUE-FLICKS AND TONGUE-FLICK ATTACK SCORES (TFAS)[a]

	Concentration (M)						
Variable	6.27	1.57	0.39	0.10	0.02	0.01	0.00

Mean	118.4	21.0	21.3	2.4	0.0	0.0	0.0
SE	7.4	4.7	0.8	2.4	0.0	0.0	0.0

[a] Adult *Podarcis lilfordi* were used in 60-sec trials with cotton swabs bearing aqueous sucrose solutions of varying concentration. $N = 21$ for each concentration.

($P < 0.05$ each), but no other differences between pairs of concentrations were significant. TFAS differed among conditions ($F = 2.77$; $df = 6, 140$; $P < 0.015$; Table 2). The only difference in TFAS between pairs of concentrations was the greater TFAS in the 0.39 M versus 0.02 M solution ($P < 0.05$). Nevertheless, there was a trend for TFAS to be greater at the higher sucrose concentrations; the three highest TFAS scores occurred at the three highest concentrations.

The number of licks increased with the concentration of sucrose (Table 2; $\chi^2 = 100.09$, $df = 6$, $P < 0.001$). By far the greatest numbers of licks were performed in response to the 6.27 M sucrose solution, more than in all other conditions ($P < 0.05$ each). The only other difference among conditions was that the 1.57 M solution elicited more licks than each of the three solutions having the lowest concentrations ($P < 0.05$ each), none of which elicited any licking.

There were substantial differences in responses between the 1.57 M and the 0.39 and 0.10 M solutions that were not revealed in the ordinal analysis. In response to the 1.57 M solution, 14 of 21 individuals licked at least once, whereas only four and one did so in response to 0.39 M and 0.10 M solutions. A greater proportion of individuals licked in the 1.57 M group than in the 0.39 M (Fisher $P = 0.004$) and 0.10 M (Fisher $P = 0.001$) groups. A greater proportion of individuals licked in the 0.10 M group than in the combined groups at the three lower concentrations (binomial test with equal probability of licking in each group, $P = 0.008$).

DISCUSSION

Chemical Types. Podarcis lilfordi can detect and discriminate among major types of organic compounds from foods using only chemical senses. Sucrose as a representative carbohydrate, pure pork fat as a mixture of lipids, and bovine gamma globulin as a protein all elicited elevated responses by *P. lilfordi* that differed significantly among chemical types. Pork fat and sucrose elicited the strongest feeding responses; the most marked response to protein was elevated TFAS(R). It may be concluded that the lizards are capable of identifying a variety of chemicals associated with food and responding to them by investigative and feeding behaviors.

Podarcis lilfordi discriminated pork fat from sucrose and water, and exhibited a different feeding behavior in response to lipids from sucrose. Because any natural source of concentrated lipids is likely to indicate the presence of prey or plant food, feeding attempts upon detection may be adaptive even in the absence of visual cues. Lizards discriminated between bovine gamma globulin and sucrose, but there was no clear statistical evidence for discrimination between protein and pork fat. Although 70% of lizards bit in protein trials, this response was not significant because many individuals bit in all conditions. This unusual behavior for lizards may be a response to visual properties of the swabs and motion (Cooper and Pérez-Mellado, 2001b).

That protein and lipids elicit strong responses is adaptive because both are closely linked to nutritious foods. In garter snakes, specific proteins from natural prey elicit the strongest responses (Burghardt et al., 1988; Wang et al., 1988). Furthermore, some snakes tongue-flick and bite more in response to chemical cues from preferred prey than from species that are less preferred or not eaten (Burghardt, 1970b, Arnold, 1981; Cooper et al., 1990, 2000b). Response strength by lizards presumably varies among proteins within and between source species and may do so among individual lipids and lipid mixtures, emphasizing the need for future tests using chemicals from species eaten by the lizards.

After a few tongue-flicks to sucrose, lizards switched to licking, a feeding response. This change in behavior from investigation to consumption indicates rapid identification. Licking is a specific response to sucrose and likely to other sweet carbohydrates. Licking upon detecting sugar may be adaptive for omnivorous and herbivorous lizard species that frequently consume nectar or ripe fruits. The licking response was first observed for *P. lilfordi* responding to surface chemicals from nectar-producing flowers and in the omnivorous *G. caesaris* responding to a sucrose solution (Cooper and Pérez-Mellado, 2001a,b). However, that the insectivorous *L. perspicillata* licks swabs bearing sucrose hints that this behavior may be widespread in lacertids and perhaps other lizards, rather than limited primarily to omnivores and herbivores.

Licking may be an efficient means of consuming nectar and is frequently observed when *P. lilfordi* feeds on flowers in the field (Pérez-Mellado, personal observations). Occasional licks in response to pork fat suggest that licking might be a feeding response to soft or fluid substances that can be ingested without biting. In this study, excess fat could be ingested by licking. No licks occurred when excess fat was removed by wiping on a paper towel (Cooper and Pérez-Mellado, unpublished data).

Sucrose Concentration. Efforts to consume sucrose by licking appear to increase with concentration. Licking in nature would be likely to occur in response to sugars concentrated in nectar and ripe fruits. The shift from tongue-flicking to licking indicates identification of sucrose as food, which occurs more rapidly at the higher concentrations (Cooper and Pérez-Mellado, 2001a). In this, *P. lilfordi* differs from *G. caesaris*, which exhibits no variation in tongue-flick rates over a wide range of sucrose concentrations (Cooper and Pérez-Mellado, 2001a).

In a related experiment, *Gallotia caesaris* licked at a rate similar to that by *P. lilfordi* when responding to saturated sucrose but at much higher rates to 0.39 M and 0.10 M solutions (Cooper and Pérez-Mellado, 2001a). These differences might indicate that *G. caesaris* is more sensitive to sucrose or that sugar is a more important component of the diet than for *P. lilfordi*, possibly due to scarcity. Another possibility is that the two species do not differ intrinsically, and the apparent difference is an artifact of differences in experimental design. In the present study each

individual was tested only once, but each *G. caesaris* was tested at six different concentrations (Cooper and Pérez-Mellado, 2001a).

Chemical Senses. The senses that mediate food chemical discriminations by lizards are poorly known, but the major candidates are vomerolfaction, olfaction, and gustation. In garter snakes of the genus *Thamnophis* (Halpern and Frumin, 1979) and in the iguanid lizard *Dipsosaurus dorsalis* (Cooper and Alberts, 1991), vomerolfaction is required to discriminate between chemical cues from food and control chemicals. In contrast, *P. lilfordi* can locate hidden fruit using only airborne chemical cues (Cooper and Pérez-Mellado, 2001c), suggesting that olfaction also has a role in identificaiton of food by some lizards. Typically, the vomerolfactory system responds to large, nonvolatile molecules sampled by tongue-flicking (Halpern, 1992). However, vomerolfactory response to airborne volatiles cannot be excluded without experimentation.

The other chemical sense likely to participate in evaluation of food is gustation, but its function has been controversial in lizards (Schwenk, 1985). However, most lizards have taste buds on the tongue and oral mucosa (Schwenk, 1985), and substances that are sweet and bitter to humans elicit responses by *A. carolinensis* having blocked vomerolfaction (Stanger-Hall et al., 2001). Although *Anolis* lizards appear to have less well developed olfactory systems than most lizards, olfaction was not excluded in the experiment.

Some lingual behaviors provide presumptive evidence about sensory roles. When responding to sucrose, *G. caesaris* tongue-flick initially, contacting the anteroventral tip of the tongue with the swab, thereby indicating vomerolfactory sampling (Cooper and Pérez-Mellado, 2001a). They rapidly switch to licking, where the dorsal surface of the tongue that contains taste buds is brought into contact with the swab. Because licking did not occur in trials with prey surface chemicals or fat, but only in response to sucrose, it may be a specific response to carbohydrates, especially to those having a sweet taste.

ABILITY OF HONEYBEE, *Apis mellifera*, TO DETECT AND DISCRIMINATE ODORS OF VARIETIES OF CANOLA (*Brassica rapa* AND *Brassica napus*) AND SNAPDRAGON FLOWERS (*Antirrhinum majus*)

GERALDINE A. WRIGHT, BETHANY D. SKINNER, and BRIAN H. SMITH*

(Received April 16, 2001; accepted December 5, 2001)

Abstract—Honeybees (*Apis mellifera*) use odors to identify and discriminate among flowers during foraging. This series of experiments examined the ability of bees to detect and discriminate among the floral odors of different varieties of two species of canola (*Brassica rapa* and *Brassica napus*) and also among three varieties of snapdragons (*Antirhinnum majus*). Individual worker honeybees were trained using a proboscis extension assay. The ability of bees to distinguish a floral odor from an air stimulus during training increased as the number of flowers used during training increased. Bees conditioned to the odor of one variety of flower were asked to discriminate it from the odors of other flowers in two different training assays. Bees were unable to discriminate among flowers at the level of variety in a randomized presentation of a reinforced floral odor and an unreinforced floral odor. In the second type of assay, bees were trained with one floral variety for 40 trials without reinforcement and then tested with the same variety or with other varieties and species. If a bee had been trained with a variety of canola, it was unable to differentiate the odor of one canola flower from the odor of other canola flowers, but it could differentiate canola from the odor of a snapdragon flower. Bees trained with the odor of snapdragon flowers readily differentiated the odor of one variety of a snapdragon from the odor of other varieties of snapdragons and also canola flowers. Our study suggests that both intensity and odor quality affect the ability of honeybees to differentiate among floral perfumes.

Key Words—*Apis mellifera*, *Brassica napus*, *Brassica rapa*, *Antirhinnum majus*, proboscis extension assay, floral odors, olfactory learning, honeybee.

INTRODUCTION

The scent of a flower is a mixture of many volatile compounds that varies with respect to genotype, stage of development, and local environmental conditions (Dobson, 1994; Dudareva and Pichersky, 2000). The number, structure, and concentration of volatile chemicals emitted by individual flowers vary substantially among species of plants (Dobson, 1994; Dudareva and Pichersky, 2000). Genetic variation within a species may also modify the amount and type of compounds in the odor profile, producing varieties that are perceptually different to humans. This has been shown for the rose, *Rosa hybrida* (Dobson et al., 1987; Kim et al., 2000), oilseed rape or canola (Robertson et al., 1993), and other species of plants including snapdragons (*Antirhinnum majus*) (Dudareva et al., 2000), *Narcissus* (Dobson et al., 1997) and *Clarkia brewerii* (Nam et al., 1999). Flowers common to the same plant may also exhibit quantitative differences in volatile compounds (Schiestl et al., 1997; Dudareva and Pichersky, 2000) that vary diurnally and developmentally (Faegri and van der Pijl, 1979; Matile and Altenburger, 1988; Tollsten and Bergstrom, 1988; Jakobsen and Olsen, 1994; Dudareva et al., 2000) and with respect to their pollination status (Tollsten and Bergstrom, 1989; Schiestl et al., 1997).

This amount of variation in floral odorants is likely to have evolved to attract specific pollinators to flowers (Faegri and van der Pijl, 1979; Pellmyr and Thien, 1986; Metcalf, 1987; Dobson, 1994; Olesen and Knudsen, 1994). Pollinators, such as honeybees, use odors to discriminate among flowers while foraging (Waller et al., 1974; Pham-Delegue et al., 1986). Honeybees forage by selecting flowers that have similiar shape, color, and odor (Free, 1963; Chittka et al., 1999). Flowers are often accepted or rejected based ultimately on their odor (Faegri and van der Pilj, 1979; Dobson, 1994). Odors improve the floral constancy of honeybees by providing them with specific additional cues that aid in flower identification and memory (Dobson, 1994; Chittka et al., 1999). However, each individual flower may not be identical to other flowers of the same species or even others on the same plant. After feeding from a nutritionally acceptable flower, bees must be able to generalize among the odor cues presented by flowers of the same species. They must also be able to differentiate their target flower from others present in the environment. Their ability to distinguish acceptable flowers from nutritionally unacceptable flowers will directly affect the efficiency and fitness of the colony of honeybees (Chittka et al., 1999) and may also affect the fitness of the plants they pollinate (Odell et al., 1999).

It is important, therefore, to examine the characteristics of a flower's odor that individual honeybees use to identify acceptable flowers. Can bees discriminate among flowers that contain the same compounds in different concentrations, or is it essential that the odor profile contain compounds that are different from one another for bees to efficiently discriminate among flowers? To begin to answer these questions, we chose to examine the olfactory learning behavior of honeybees when

they were trained to respond to two types of well-studied flowers: canola flowers (*Brassica rapa* and *Brassica napus*) and snapdragons (*Antirhinnum majus*). As much is known about honeybee olfactory learning, we used the honeybee as a model generalist pollinator, even though it does not often forage on snapdragons, as the individual flowers are too difficult for workers to open. Both types of flowers have distinct odors, and the volatile components of the perfumes of both the flowers of canola (Tollsten and Bergstrom, 1988; Robertson et al., 1993; Butcher et al., 1994; Jakobsen et al., 1994; Blight et al., 1997; McEwan and Smith, 1998; Omura et al., 1999) and the flowers of snapdragons (Odell et al., 1999; Dudareva et al., 2000) have been previously identified and quantified. In addition, varieties of both types of flowers have been shown to contain many of the same compounds present at different concentrations (Roberston et al., 1993; Odell et al., 1999). A given variety may also contain compounds that are unique to that variety. Both types of variation in odor composition produce unique perfumes, so these differences could have large impacts on the ability of bees to differentiate among the odors of each type of flower.

Presently, an extensive literature has developed about the learning and discrimination of pure odors and simple mixtures by honeybees (Menzel, 1990; Smith, 1998; Chandra et al., 2000; Chandra and Smith, 1998). Our objective in this study is to apply the same types of conditioning procedures used previously to evaluate how honeybees discriminate natural floral perfumes (Pham-Delegue et al., 1989, 1993, 1997). This type of research ensures that the results generated from laboratory studies of pure odorants generalize to studies of honeybees and their olfactory learning in their natural environment. In the present study, we trained individual bees to the scent of one variety of our chosen floral species and then examined their responses to the same variety and to different varieties. With this type of assay, we tested the ability of bees to discriminate and/or generalize among the odors of different flowers after conditioning with one flower type. We were particularly interested in examining generalization with respect to inter- and intraspecific relatedness of the flowers and the similarity of their floral perfumes.

METHODS AND MATERIALS

Flowers. Two varieties (from Svalöf Weibull Seed Ltd., Saskatoon, Saskatchewan, Canada) of each canola species, *Brassica rapa* and *Brassica napus*, were grown over a two-month period between May and July 1999 or June and August 2000 in a field at the Waterman Agricultural and Natural Resources Station, Ohio State University. Two varieties of *B. rapa*, Horizon and Valleyview (Svalöf Weibull Ltd.), hereafter referred to as BR1 and BR2, and one variety of *B. napus*, Bullet (Svalof Weibull Ltd.), hereafter referred to as BN, were selected for testing. The canola flowers were isolated from pollinators in the field by 1.3- $\times$ 1.3-m

exclosures covered with screening to keep worker bees from pollinating the flowers. The exclosures were moved periodically to randomize sampling across the flowers. Inflorescences were collected in the morning and early afternoon, and the stems were placed in water. Selection of flowers from the inflorescences was random, but all flowers selected were fully opened.

Three varieties of ornamental snapdragon (*Antirhinnum majus*) studied at Purdue University (Dudareva et al., 2000; Murfitt et al., 2000; Kolosova et al., 2001) were grown in the greenhouse from April 2000 from plants obtained from N. Dudareva. These varieties were called Pale hybrid, Potomac Pink, and Maryland True Pink (henceforth PH, PP, and MTP). Previous studies of volatile emissions from these hybrids and other snapdragons have indicated that volatile emissions peak for this species of flowers on the fifth day after anthesis (Dudareva et al., 2000). Therefore, flowers chosen for training bees were between four and six days after anthesis. The flowers were collected in the morning on the day of testing.

The canola flowers were clipped by the petiole from inflorescences and placed in new 10-cc glass syringes. The syringes were modified to deliver the headspace volatiles from the flowers by attaching the needle end via 1/16-in. tubing to a mini-solenoid valve (Lee Co.) that controlled air flow from an aquarium air pump (Tetratec DW 96-2). The syringe was closed on the open end with a silicon stopper that had a modified, glass Pasteur pipet forced through the middle. The snapdragon flowers were placed in an Erlenmeyer flask with a tubulation arm, and the opening of the flask was fitted with a modified silicon stopper. The silicon stopper had a glass Pasteur pipet forced through it that was attached to an air supply via tubing in the same manner as the syringes for the canola flowers. The tubulation arm was modified by excising the narrow tip of a Pasteur pipet from the rest of the pipet and attaching it to the tubulation arm with putty. The narrow end of the pipet from both the flasks and the syringes faced outward, and it was aimed approximately 3–4 cm from the bee testing platform. Bees were unable to view the flowers within the syringe and the flasks. Both types of odor delivery device were washed three times with distilled, deionized water after use and allowed to dry, and each was specifically reused for the same variety of flower each time.

Honeybees. Individual bees were collected over two summers: 1999 and 2000. During the 1999 season, worker honeybees (*Apis mellifera*) were collected from the hive entrance as they left to forage between 8 and 10 AM. They were trapped individually in glass vials and cooled on ice. When they were quiescent, each bee was placed individually in a restraining harness as described by Bitterman et al. (1983) and by Smith (iris.biosci.ohio-state.edu/honeybee). Each bee was fed 0.4 μl of a 1.25 M sucrose solution and left for 2 hr. During the 2000 season, worker honeybees were collected from the hive entrance as they were leaving to forage between 1 and 5 PM. Each bee was fed 2–3 μl of a 1.5 M sucrose solution and left on the laboratory bench at 22°C overnight. The next morning, the bees were tested for motivation by touching one antenna with sucrose and observing

the subsequent proboscis extension. Bees that did not extend their proboscis were not used in the experiment.

Conditioning Protocol. Honeybees readily learn to associate odorants with sucrose reinforcements (Bitterman et al., 1983; Menzel, 1990). All experiments utilized the proboscis extension response (PER) assay to evaluate the olfactory learning behavior of individual bees restrained as described above. Three different experimental protocols were used to test their ability to detect and discriminate floral volatiles.

Relative Detectability of Odor of Different Floral Varieties. Bees were placed in a conditioning arena and conditioned to discriminate a floral odor from an air background stimulus. Individual bees were trained as described in Smith (1998), with an intertrial interval of 5 min. Each bee received conditioning to the odor of one species of flower in the following pseudorandomized, 12 trial sequence: F – A – A – F – A – F – F – A – F – A – A – F, where F = flower and A = air (Smith et al., 1991). The floral odors were paired with a 0.4-μl droplet of 1.5 M sucrose. The air stimuli were not reinforced. On a given trial, each bee was recorded as having responded if it extended its proboscis during the first 3 sec of odorant delivery.

Each of the varieties of canola was separated into three treatments: 1 flower per syringe, 5 flowers per syringe, and 10 flowers per syringe. This arrangement was designed to test if differences in concentration of odor were detected by the bees and reflected in their ability to discriminate the odor stimulus from the air stimulus. Snapdragon flowers were tested with only one flower per flask.

Discrimination of Floral Odors. Two protocols were employed to examine the ability of bees to discriminate among floral odors from the species and varieties of canola and snapdragon chosen for this experiment. The first utilized the same 12 trial, pseudorandomized sequence as above. One floral odor was paired with sucrose and the other was not reinforced. The following pairs of flowers were tested, with the underlined species of each pair receiving reinforcement: Pair 1: BR2 × BR1; Pair 2: BR1 × BN; Pair 3: BN × BR2; Pair 4: PH × BR1; and Pair 5: PH × PP. The responses of individual bees to each exposure of odor was scored as above.

The second means of examining discrimination utilized a paradigm developed to study latent inhibition in honeybees (Chandra et al., 2000). This protocol exposes individual bees to 40 unreinforced training trials with an odorant, during which a bee is stimulated with an odor, but no sucrose reinforcement is given. We switched to this conditioning paradigm because we could make use of an automated, odorant delivery system described in detail in Chandra et al. (2000). The automation facilitated delivery of a large number of trials. After the 40 training trials, each bee was tested in a seven-trial acquisition test with either the same odorant or a different odorant. Each trial presented the odorant reinforced with 0.4 μl of 1.5 M sucrose.

In this training paradigm, repeated presentation of a specific odorant over 40 trials without reinforcement leads to a slower than normal rate of learning to that odorant during the posttraining test phase (Chandra et al., 2000). In essence, the bees learn to ignore the stimulus during the pre-training phase. Alternatively, if a bee is pre-trained with one odorant and then post-tested with a novel odorant that is perceptually different from the original odorant, the rate of learning to the novel odorant should not be affected by the previous training with the original odorant (Chandra et al., 2000). We used this technique with the floral odors with the expectation that bees would show faster rates of acquisition during the test phase to a different test flower if they could readily differentiate the odor of a test flower from the odor of the training flower.

In this experiment, the delivery of the floral odor was the same as for the forward pairing, utilizing a syringe for canola flowers and an Erlenmeyer flask for snapdragons. In the canola treatments, the syringes contained 10 flowers each and were replaced with fresh flowers every 50 min. In the snapdragon experiment, the flasks contained three flowers, and they were also replaced every 50 min. During the acquisition trials, a separate syringe or flask was used to test each individual bee. The bees were "inhibited" to one species of a flower's odor, and then tested with one of four treatments: the same flower species; the same species, but a different variety; a different species; and a species from a different family. These treatments were used for all species of canola; for the snapdragons, only the PH variety was inhibited, and it was tested against itself, two other varieties, and *B. rapa* 1. In this way, we sought to examine the bees' ability to discriminate floral odors across different taxonomic levels.

Statistical Analyses. For the forward pairing experiment, the total number of responses for each stimulus was summed, and the sum for the unreinforced air stimulus was subtracted from the sum for the reinforced floral odor. This difference was tested in a Student's t test against the expected value of zero given an equal number of responses to odor and air (i.e., the odor was not detectable). This was repeated across the species for each of the treatments of 1, 5, and 10 canola flowers versus the air stimulus and the snapdragon versus the air stimulus. As this test was calculated for 10 different treatments at the $\alpha = 0.05$ level, a Bonferroni method of controlling for experiment-wise error rate was used to evaluate the significance levels of each of the comparisons (Sokal and Rohlf, 1995), where $\alpha'' = \alpha/n$, and n is the number of comparisons.

This type of analysis was also used to evaluate the same training procedure used for the simple discrimination test, where one floral odor was paired with sucrose and the other was unreinforced.

For the experiment in which each species of canola was inhibited in the latent inhibition protocol, the responses of each individual bee for each trial was summed at the end of the seven acquisition trials for each bee. A separate one-way ANOVA was employed to examine the differences in the sums among the treatments after

inhibition for each flower used during training (Sokal and Rohlf, 1995). The least-squares differences were compared for the responses to the test flower versus the responses to the training flower (Sokal and Rohlf, 1995).

RESULTS

Relative Detectability of Odor of Different Floral Varieties. Bees were unable to discriminate any of the canola odors from air when only one flower was present in a syringe (Table 1, Figure 1). They were able to discriminate the odor of BR1 and BN from air when 5 and 10 flowers were placed in each syringe (Table 1, Figure 1). They were only able to discriminate BR2 from air for the 10 flower treatment (Table 1). In contrast, the odor of a single snapdragon flower appeared to be easily discriminated from the air stimulus for each snapdragon variety tested (Table 2, Figure 2).

Discrimination of Floral Odors. In the discrimination protocol, the bees were unable to discriminate the odor of BR2 from BR1 ($df = 11, t = -1.86, P = 0.09$) (Figure 3a), BR1 from BN ($df = 11$, $t = 0.00$, $P = 1.0$) (Figure 3b), BN from BR2 ($df = 9$, $t = -0.81$, $P = 0.434$) (Figure 3c), or PH from PP ($df = 9$, $t = 0.88$, $P = 0.399$) (Figure 3d). The only pairing of flowers that bees were able to discriminate in this paradigm was PH with BR1 ($df = 9$, $t = 3.28$, $P < 0.009$) (Figure 3e).

The latent inhibition protocol showed a similar trend for the canola species. Separate one-way ANOVAs indicated that responses to the test flowers during the seven post-training acquisition trials were different when either BR1 or BN was used to produce inhibition (Table 3, Figure 4). The inhibited flower had the smallest response during the test trials in all cases (Figure 4), which is consistent with previous studies using this technique (Chandra et al., 2000). The other varieties and species of canola had slightly greater responses during the test, and the snapdragon odor provoked the greatest number of responses (Figure 4). The comparison of the inhibited species to each of the other tested species (Table 3) failed to reveal a difference among the inhibited canola species/varieties and the tested canola species/varieties (Table 3), indicating that individual honeybees could not easily discriminate among these varieties. The responses during the test after inhibition to BR1 and BN were significantly different only for the comparison between the inhibited odor and the snapdragon odor.

A one-way ANOVA for the PH snapdragon also demonstrated that the responses across each species during the test were significantly different from the inhibited flower ($df = 3, 80$, $F = 5.87$, $P < 0.001$) (Figure 4). This occurred in the same pattern as was seen for the canola, where the inhibited flower showed the lowest response, the other varieties of snapdragon a slightly greater response, and the canola flower provoked the greatest response during the test (Figure 4). The least-squares difference confirmed that significant differences occurred for the comparisons of the inhibited odor to each of the test flower odors (Table 3). Therefore, it appeared that individual honeybees could discriminate among the odors of each variety of snapdragons and the canola variety, BR1, after conditioning to the pale hybrid snapdragon.

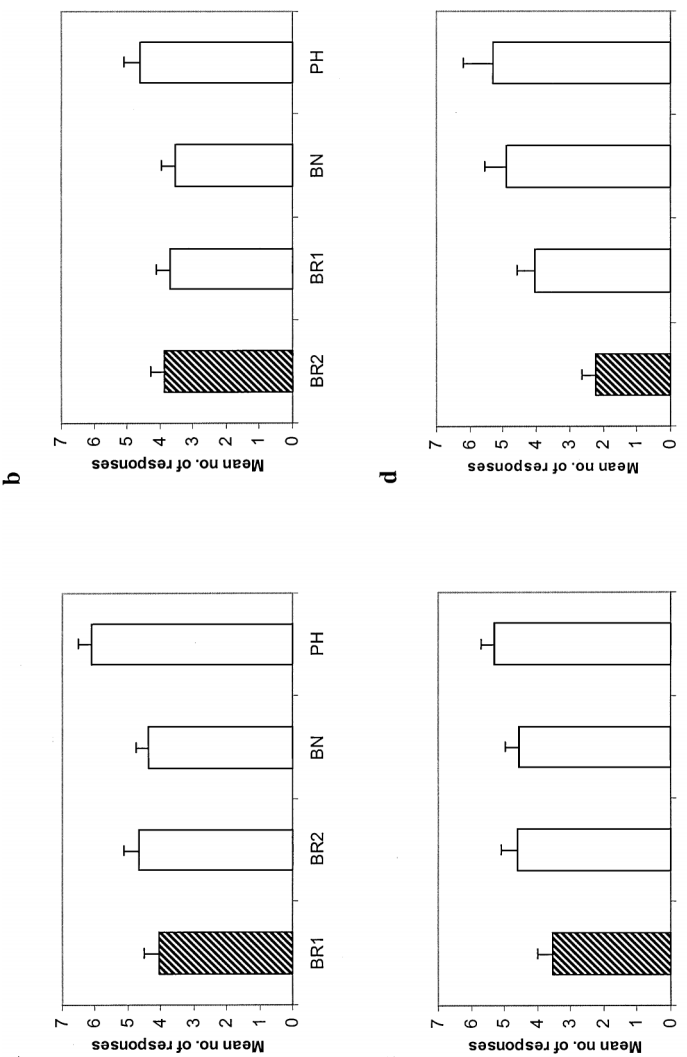

FIG. 4. PER (mean + SE) of honeybees to four different flower types during seven test trials after inhibiting to one flower type (the striped bar indicates the inhibition flower). Ten flowers per treatment were used for each canola variety; three flowers per flask were used for snapdragons: (a) inhibition to *B. rapa* 1 ($N = 112$), (b) inhibition to *B. rapa* 2 ($N = 160$), (c) inhibition to *B. napus* ($N = 143$), and (d) inhibition to pale hybrid snapdragons ($N = 84$).

DISCUSSION

Detectability and Discriminability of Floral Odors. The intensity of an odor stimulus produced by flowers may play an important role in initially attracting pollinators and in causing them to seek out perceptually similar flowers (Faegri and van der Pilj, 1979; Dobson, 1994). Many plant species produce floral arrays where individual flowers are arranged closely together, perhaps to influence pollinator perception and recognition among species of plants by increasing a given plant's impact on an animal's sensory apparatus. In addition, some species of plants have individual flowers that produce odor volatiles in greater concentrations than the individual flowers of other plant species (Dobson, 1994). Evidence from laboratory-based experiments suggests that odorant concentration affects both the detection and memory of odorants by honeybees, as more intense odors are generally learned faster and are more readily distinguished from other odors (Bhagavan and Smith, 1996; Pelz et al., 1997). Until now, the ability of bees to learn the odors of living flowers at natural intensities has not been often studied (Gerber et al., 1996).

To examine the effect of flower odor intensity on the rate of acquisition by honeybees, we trained individual bees to the odor of 1, 5, and 10 canola flowers. Our first experiments examined the ability of honeybees to discriminate the scent of *B. napus* or *B. rapa* flowers paired with sucrose reinforcement from an unreinforced, "background" air stimulus. We designed the first set of experiments as an assay of detectability, where we expected that if the stimuli represented by the flowers of the same unpollinated, developmental stage were approximately equal, then the odorant stimulus would increase in proportion to the number of flowers used.

The acquisition curves for honeybees showed that discrimination of the floral odor stimulus from the air stimulus increased as the number of flowers per treatment increased. When 10 flowers were placed in each modified syringe, the bees could clearly distinguish between a floral odor stimulus and an air stimulus for each variety. This suggests that 10 flowers of each variety produce a stimulus that is above the threshold of detectability for honeybees. At the level of one flower per syringe for each variety of canola, no difference is seen between the acquisition curves for floral odor versus air. Differences in detectability among varieties began to occur at the level of five flowers per syringe at which the second variety of *B. rapa* was not significantly distinguished from an air stimulus. This may be due to a weaker concentration of odor produced by these flowers, as the other two varieties were detectable when five flowers were present. We repeated this experiment with one snapdragon flower per flask for each variety of snapdragon; it was clear for all the varieties that the odor produced by a single flower was strong enough for them to discriminate the floral odorant from an air stimulus. A comparison of the responses to canola flowers with the responses to snapdragon flowers indicates that snapdragons produce odors that are more detectible than

individual canola flowers, as the threshold for detectability for a given snapdragon flower was reached using only one flower, regardless of variety.

We then examined the ability of honeybees to differentiate flowers of one variety reinforced with sucrose from flowers of different varieties that were not reinforced. Bees were unable to discriminate between flowers of different varieties and among the different species of canola (Figure 3a–d). However, when asked to differentiate the odor of a snapdragon flower from the odor of canola flowers, they successfully learned the discrimination task. Therefore, in general, the discrimination of floral varieties of *Brassica* was not detectable in this assay. The only case in which bees were able to discriminate among the odors of different floral varieties was when they were asked to choose between the odor of a snapdragon flower and the odor of a canola flower.

Previous experiments using pure odorants in this same 12-trial assay demonstrated that honeybees can easily discriminate different odors (Menzel, 1990). Lack of discrimination in our use of this assay may only imply that the discrimination task required of the bees is difficult. In the field, individual worker honeybees may experience hundreds of flowers on a single foraging trip. With more experience (i.e., more exposures to a specific target conditioned stimulus), honeybees might demonstrate the ability to discriminate among the odors of similar flowers.

To address this possibility, we decided to utilize an assay that repeatedly presented the odor of a particular flower 40 times without reinforcement (Chandra et al., 2000). In this assay, individual bees are exposed to a discrete odor stimulus 40 times at 5-min intervals. The bees are then tested during a post-test acquisition phase, during which the same or a different odor stimulus is presented with reinforcement. The mean response to each type of test stimulus can then be compared.

We expected that the rate of acquisition during the test phase would be proportional to the similarity of the odor of the test flower to that of the training flower. If a novel odor is perceptually similar to the pre-exposed odor, then it will be learned more slowly than a perceptually dissimilar odor. When bees were pre-exposed to the odors of BR1, BR2, or BN, the acquisition responses were lowest during the test phase for each of these flower types, which is consistent with Chandra et al. (2000). The lack of significantly faster acquisition to the other canola species and varieties indicates that they were not easily discriminable from any given pre-exposed variety of canola in this assay. Thus, in general, the *Brassica* species used in our experiments are relatively difficult to discriminate, even though the odors they produced are all detectable by honeybees.

Not surprisingly, *Brassica* odors are discriminable from snapdragons; the response to the odor of a snapdragon was significant for BR1 and BN. Interestingly, none of the responses during the test were significantly different for the individuals inhibited with BR2. As shown in the previous section, intensity of an odor stimulus, at least as indexed by the number of flowers, can strongly affect the ability of bees to discriminate among odors. The rate of acquisition of individual bees to five

flowers of BR2 during the training was slower than the rate of acquisition of five flowers of either BR1 or BN. This suggests that the odors of BR2 were not as intense as the odors of the other flowers used during training. The inability of bees to discriminate BR2 and the snapdragon flowers during the test after pre-exposure with BR2 also supports the idea that the odor of BR2 flowers was less intense than the odor of the other flowers.

When bees were inhibited with the odor of the PH snapdragon, they clearly demonstrated the ability to discriminate among other snapdragons and other species of flowers during the test. Thus, individual flowers of this group are relatively more discriminable than was the case for the *Brassica* species. This could be a result of both the intensity of the odor produced by the snapdragons and the types of compounds found in the floral perfume. The intensity of the snapdragons appeared to be greater than the intensity of the canola flowers, as indicated by our assay of the rate of learning of individual honeybees. Differences in the intensity and/or quality of the floral perfumes may therefore have allowed bees to differentiate among the snapdragons more readily during the test phase after pre-exposure to the odor of the pale hybrid snapdragon.

Qualitative Variation in Floral Volatiles. The discriminability of floral varieties is likely to be related to the chemical composition of their odors. The volatile compounds of both of the floral types chosen for this series of experiments have been identified in previous studies. The main types of compounds reported from the *Brassica* species are organic sulfides, C_4 substituted compounds, aliphatic and aromatic aldehydes, and mono- and sesquiterpene hydrocarbons (Robertson et al., 1993). Short-chain alcohols, ketones and acids were also detected (Robertson et al., 1993).

One report of the volatiles of five varieties of *B. napus* showed that they contain about 75–83% of compounds in common (Robertson et al., 1993). Comparisons across studies have revealed that qualitative differences are greater between *B. napus* (Tollesten and Bergstrom, 1988; Robertson et al., 1993; Butcher et al., 1994; Jakobsen et al., 1994; Blight et al., 1997; McEwan and Smith, 1998) and *B. rapa* (Omura et al., 1999). Six of 97 compounds from *B. rapa* (sum reported from all studies of *B. napus* cited before) were reported in common with *B. napus* (Omura et al., 1999). However, the method used to sample floral headspace significantly affects the amount and type of compounds reported (Dobson, 1994; Agelopoulous and Pickett, 1998; Raguso and Pellmyr, 1998), and the sampling procedures were quite different among all the studies examined. More compounds might be found in common among the species if a comparison were made of their volatiles using the same sampling procedures.

Snapdragons have been reported to contain substantially fewer compounds than canola flowers. The following constituents have been reported and identified from all of the varieties that we studied: methyl benzoate, *trans*- and *cis*-β-ocimene, myrcene, linalool, *trans*- and *cis*-methyl cinnamate, *cis*-3-hexenyl

acetate, acetophenone, dimethoxytoluene, diphenyl ether, and nerolidol (Odell et al., 1999; Dudareva et al., 2000; Murfitt et al., 2000; Kolosova et al., 2001). Other minor components have not yet been identified (Dudareva, personal communication).

Qualitative differences occur in both the species and varieties of canola flowers and in the varieties of snapdragons. The only compounds reported in common among snapdragons and canola flowers are *trans*-β-ocimene, myrcene, and linalool from *B. napus* (Robertson et al., 1993) and from some varieties of snapdragons (Odell et al., 1999; Dudareva et al., 2000). It is clear from our discrimination assay that bees have difficulty distinguishing among canola flowers; it is also clear that they were able to distinguish among snapdragon varieties. The differences in detectability and discriminability seen for these two types of flowers must be related to volatiles given off by the flowers. Previous hypotheses about the selection behavior of foraging honeybees propose that bees select flowers based on their ability to detect and respond to individual volatile components of a floral perfume (Pham-Delegue et al., 1986, 1989, 1993, 1997; Henning et al., 1992; Wadhams et al., 1994; Blight et al., 1997; Le Métayer et al., 1997). These studies typically isolate the volatiles from flowers, separate them into fractions, and then assay the response of both free-flying or restrained honeybees. This type of analysis predicts that certain compounds found in flowers, including canola and sunflowers, are more attractive and more easily learned by honeybees than others present in the perfume. It would also predict that differentiation among floral perfumes would result from qualitative differences among perfumes.

We were particularly interested in examining the ability of bees to discriminate among flowers that may exhibit subtle differences in their entire perfume. Our results for the tests of the ability of bees to discriminate the varieties of snapdragons show that flowers that have the same volatile components can be perceptually different. Other studies of bee discrimination among perceptually similar flowers have suggested that bees can distinguish among flowers that produce all of the same compounds, where each compound is present at slightly different concentrations in the floral headspace of individual flowers or plants (Beker et al., 1989; Ayasse et al., 2000). An experiment by Beker et al. (1989) tested the ability of free-flying bees to discriminate among the varieties of *Majorana syriaca*, and also showed that they were able to distinguish among different varieties, even though the chemical components of the perfumes of both varieties were mostly the same (Dudai et al., 1988; Beker et al., 1989). The solitary bee, *Andrena nigroaenea*, was shown to differentiate among individual flowers of the orchid, *Ophrys sphegodes*, based on variation in the quantities of the odor components found among individual flowers (Ayasse et al., 2000). In this case, the variation of individual odor components caused subtle differences in the floral perfume from flower to flower (Schiestl et al., 1997; Ayasse et al., 2000), which the bees apparently perceived as unique to individual flowers, and so were deceived into pollinating the orchid without

reinforcement. The inability of bees to distinguish *Brassica* floral odors from each other suggests that although they may have only 75% of their compounds in common, their odors are perceptually similar to honeybees. Thus, the perceptual similarity of the perfumes of flowers may not only be related to the number of compounds in common, but may also be a function of the relative concentration of certain key components of the floral odor (Pham-Delegue et al., 1989, 1993; Blight et al., 1997).

Differentiation by Honeybees among Floral Perfumes. Our study suggests that both intensity and odor quality affect the ability of honeybees to differentiate among floral perfumes. Other factors may also influence discrimination. The general intensity of the floral perfume and the intensity of individual odor components may contribute equally to the differences in perceptual qualities that arise among similar flowers. In addition to the contribution of the presence of individual compounds in a perfume, the number of compounds and the chemical similarity of the compounds may also affect the ability of bees to discriminate among flowers.

Studies of honeybee olfactory learning behavior typically do not utilize live flowers; indeed, few studies have examined honeybee learning and discrimination at concentrations that are similar to the intensities encountered in individual flowers (Pelz et al., 1997). Training honeybees to discriminate among odors presented at biologically relevant concentrations rigorously examines their true ability to differentiate among floral odors. Further examination of the characteristics of the odors of individual flowers may provide clues about which features of the odors of individual flowers bees learn and remember.

Acknowledgments—We gratefully acknowledge the assistance of Amanda Mosier during the training of the bees, and the assistance of Mark Schmittgen, Joe Latshaw, and Satish Chandra during the canola cultivation. Howard Love of Svalof Weibull Ltd. kindly donated the seeds of the canola varieties, and Natalia Dudareva donated individuals of her snapdragon varieties and commented on the manuscript. Support for this work was provided by awards to B.H.S. from NIH NCRR (9 R01 RR14166) and from the Ohio State University College of Biological Sciences and Office of Research.

(Received June 15, 2001; accepted December 5, 2001)

Abstract—Adult females of *Xestobium rufovillosum* de Geer demonstrated anemotactic orientation when exposed to an odor plume containing volatiles generated by wood-decaying fungi (*Coriolus versicolor*, *Donkioporia expansa*) and decayed oak wood (*Quercus petraea*, *Quercus robur*). They did not orient towards undecayed oak wood, beech (*Fagus sylvatica*), or pine wood (*Pinus sylvestris*). Although all insects tested showed anemotactic orientation, responses were nonlinear with respect to insect age. Adult females more readily oriented upwind when they were between 10 and 16 days old. Oviposition choice bioassays showed that ovipositing females would preferentially oviposit on extract-treated cellulose paper discs that had been treated with various strains of the wood-decaying fungus, *Donkioporia expansa*. HPLC-fractionated mycelial extracts were attractive to ovipositing deathwatch beetles, whereas HPLC-fractionated fungal broth extracts were repellent to ovipositing females. The implications of these results are discussed in the context of timber pest management in historically important buildings.

Key Words—Deathwatch beetle, *Xestobium rufovillosum*, Coleoptera, Anobiidae, *Quercus sp*., host selection behaviour, chemo-orientation behaviour, oviposition, timber pest, wood-decaying fungi, *Donkioporia expansa*.

INTRODUCTION

The presence of deathwatch beetles in historic buildings is reported across Europe (Fisher, 1937). It has been estimated that nearly all pre-19th century buildings containing oak timbers in England have been previously or are currently infested with deathwatch beetle (Hickin, 1963). Most evidence suggests that the beetle prefers to infest building timbers when the timber has been or is currently infested by wood-decaying fungi (Fisher, 1940; Hickin, 1974). Casual observations in buildings infested by deathwatch beetles showed that adult beetles were often found near timber-decaying fungi and that a greater number of emergence holes were found in and around fungally decayed timber (B. V. Ridout, personal communication). Unfortunately, little is known about the deathwatch beetle in its natural forest habitat. It is said that the beetle can be found in a range of tree species but that it is mainly found in the decaying parts of oak and willow trees (Fisher, 1937). The beetle is unknown to attack healthy living trees without fungal decay present (Fisher, 1940). Deathwatch beetle adults do not feed, and they live for approximately one to two months (Fisher, 1938).

The influence of decayed wood on deathwatch beetle development has been partially established (Fisher, 1940, 1941). Previous experimentation showed that deathwatch beetles demonstrated host selective oviposition preferences when given a choice between two blocks of oak timber that varied in their age (Belmain et al., 1998). Specific chemical compounds that may be important to the beetle's host selection behavior are unreported.

Generally, short-lived insects demonstrating strong host-specificity require well-developed chemoreceptors to ensure their offspring's survival (Akers and Wood, 1989). It was expected that wood-decaying fungi or decaying wood could be attractive to deathwatch beetle adults. The effects of wood-decaying fungi may be important to oviposition selection (host recognition) and/or chemoorientation (host finding). Experiments were designed to test whether walking deathwatch beetles would anemotactically orient towards airborne volatiles generated by wood-decaying fungi and timber as well as to investigate the effects of fungal extracts upon oviposition behavior.

METHODS AND MATERIALS

Adult deathwatch beetles were collected daily on emergence from a laboratory-maintained culture (21°C, 75% RH) or weekly from a deathwatch beetle-infested building (Bishopstone Church, Wiltshire, UK) at the beginning of the emergence season during April. The females used in experiments had been previously exposed to males for five days in the laboratory to allow mating to occur, but they had yet to commence ovipositing. Insects were sexed by the methods of Harris (1959) and Goulson et al. (1993).

Chemoorientation to Airborne Volatiles. The volatile odors tested were generated from pieces of European oak (*Quercus petraea*, *Quercus robur*), American oak (*Quercus rubra*), European pine (*Pinus sylvestris*), and beech wood (*Fagus sylvatica*). The wood was either of known dendrochronological age or had been decayed for standard periods of time from 4 to 20 weeks by the fungi *Fistulina hepatica*, *Coniophora putenana*, and *Donkioporia expansa* or was sound undecayed wood (Table 1). Volatiles generated from three strains of *Donkioporia expansa* grown on potato dextrose agar and *Coriolus versicolor* grown on oak wood were also tested. A blank "no odor" source was used to conduct control experiments. Odor sources were placed 30 cm away from a one-speed small domestic-use fan (fan radius = 10 cm). The amount of wood or fungus placed in front of the fan varied among experiments. Efforts were made to standardize exposed surface areas among samples; however, the amount of volatiles generated for each sample remained unknown. Smoke-generating capsules showed that air currents traveled from the fan in a straight pathway for approximately 2.5 m. Deathwatch beetles

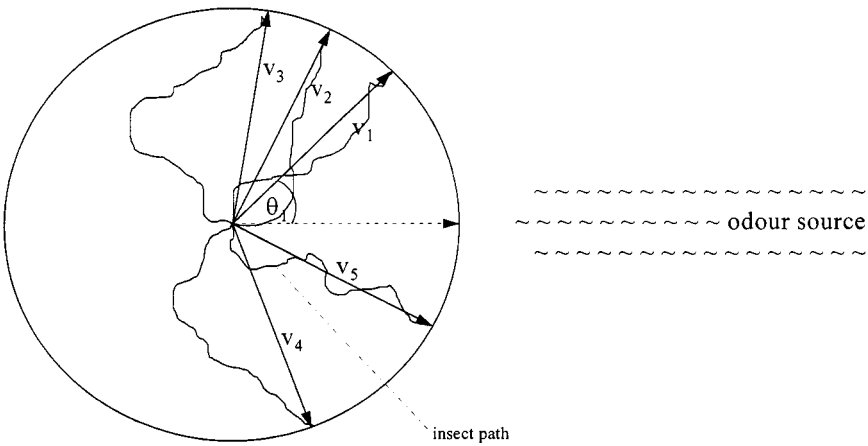

FIG. 1. Model diagram of five vectors made by the movements of five deathwatch beetles, from the center of the paper to the edge of the paper, in separate experimental trials.

were placed 1.5 m downwind from the odor source in the center of a piece of filter paper (radius = 16 cm) (Figure 1). Experiments comprised replicates of five insects of the same physiological state placed in five different standard orientations of 0°, 90°, 180°, 240°, and 300°, i.e., the insect placed at 0° would be head-first into the wind (and odor), whereas another would be rotated 180° so it was tail-first into the wind. Continual observation of each insect commenced after the individual insect was placed on the center of the paper (time zero). The insect path during the experiment was mapped, noting where the insect left the paper (end of trial). The time to complete the experiment was recorded. Trials where the insect had not left the paper after 60 min were aborted. All laboratory experiments were conducted under even lighting conditions at 21 ± 1°C and 35 ± 5% RH. Insects from Bishopstone Church were tested after five days in the laboratory against 24 odor sources (Table 1). Adult females from the laboratory culture were tested at known times after their emergence against four odor sources (o1341, ocv20, dwb frass, control).

The insect response to a volatile is represented by a vector. This vector was created by drawing a straight line from the center of the paper (the point where the insect was placed at the start of the experiment) to the point at the edge of the paper where the beetle departed (Figure 1). Therefore, each vector is of the same magnitude, i.e., the radius of the filter paper (16 cm), whereas the angle between the vector and the odor source varied.

Oviposition Preference Bioassay. Different strains of the wood-decaying fungus, *Donkioporia expansa*, were obtained from Belgium (MUCL), The Netherlands (CBS), and Great Britain (FPRL) (Table 2). Fungi were grown in liquid media, and

extracts of mycelial and broth fractions in hexane and ethylacetate were fractionated by HPLC by collaborators in Dublin, Republic of Ireland (D. M. X. Donnelly and I. Nesbitt). Fractions were dried, weighed and diluted in hexane to a concentration of 1000 ppm. Fungal exudates that were collected from different fungal strains and fungally derived purified compounds were similarly tested at 1000 ppm.

An aliquot (100 μl) of a extract was applied to cellulose paper discs (2 cm diameter) (Whatman) and allowed to dry. The discs treated with the extract were placed individually in a Petri dish (8.5 cm diameter) along with a solvent only (hexane) control disc. One mated female deathwatch beetle was placed in each Petri dish, and the number of eggs oviposited on the discs was counted daily until insect death ($N = 10$). The experimental arenas were kept in a dark quiet room at $21 \pm 1^{\circ}$C and $35 \pm 5\%$ RH. Participation in the experiment was determined by the oviposition of at least one egg.

RESULTS

Chemoorientation to Airborne Volatiles. Responses of adult females to volatiles varied according to their age and the source of the volatile. For example, the mean time taken for the insects to move from the center of the paper to the edge of the paper was shown to be less for samples of decayed oak (ohEde4, ohEde8) and living fungus (ocv20, Ade1, Ade2, Ade3) than for samples of European pine

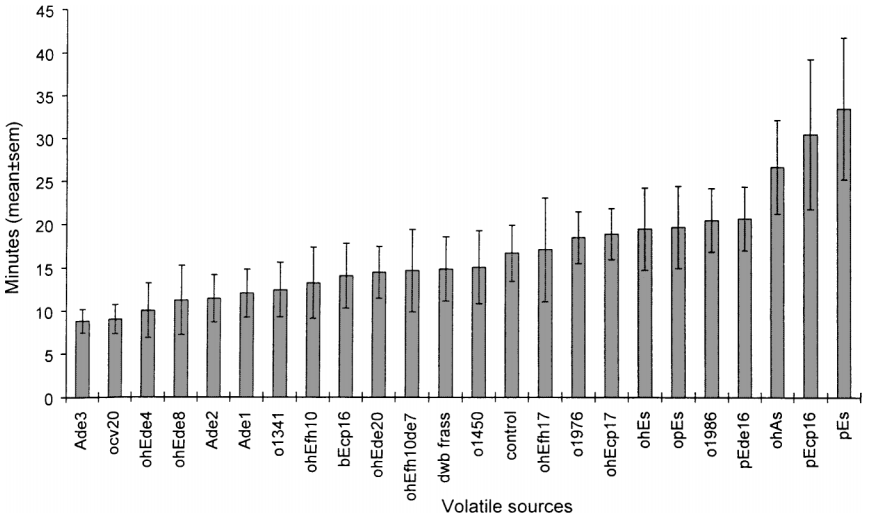

FIG. 2. Time (minutes) taken for deathwatch beetle mated females (collected from Bishopstone Church) to complete the chemoorientation experiment by leaving the edge of the filter paper when originally placed in the center of the disc ($N = 5$).

(pEs, pEcp16) and undecayed oak (ohAs) (Mann-Whitney U tests, $P < 0.05$; Figure 2). The effects of insect age on beetle response to three odors (o1341, ocv20, and dwb frass) showed no difference in the mean time taken to complete experiments among the insect ages tested (Mann-Whitney U tests, $P > 0.05$).

The mean vector angle for an experiment ($N = 5$) was shown to vary among experiments according to the source of the volatile odor and insect age. The mean angle was smaller (20°–40°), that is, the insect moved more directly towards the source when the odor source was from living fungi (ocv20, Ade1, Ade2, Ade3), old oak (o1341, o1450), or decayed oak wood (ohEfh10de7, ohEfh10, ohEcp17, ohEde20, ohEfh17) when compared with the mean angle (55°–110°) from modern oak (o1976, o1986), undecayed oak (ohAs, ohEs, opEs), beech (bEcp16), or pine (pEs, pEde16, pEcp16) (Mann-Whitney U tests, $P < 0.05$) (Figure 3). The mean vector angle varied with insect age when the volatile odor source was from o1341 (Figure 4) and ocv20 (Figure 5) (Mann-Whitney U tests and Kruskal-Wallis, $P < 0.05$). These two odor sources showed that the mean vector angle initially decreased with insect age until insects were approximately 11 days old and that the mean vector angle increased with insect age after insects were older than 14 days. Insect age had no effect on the mean vector angle when the odor source was generated from deathwatch beetle frass (dwb frass) (Figure 6) or in the control (no odor) experiment (Mann-Whitney U tests and Kruskal-Wallis, $P > 0.05$).

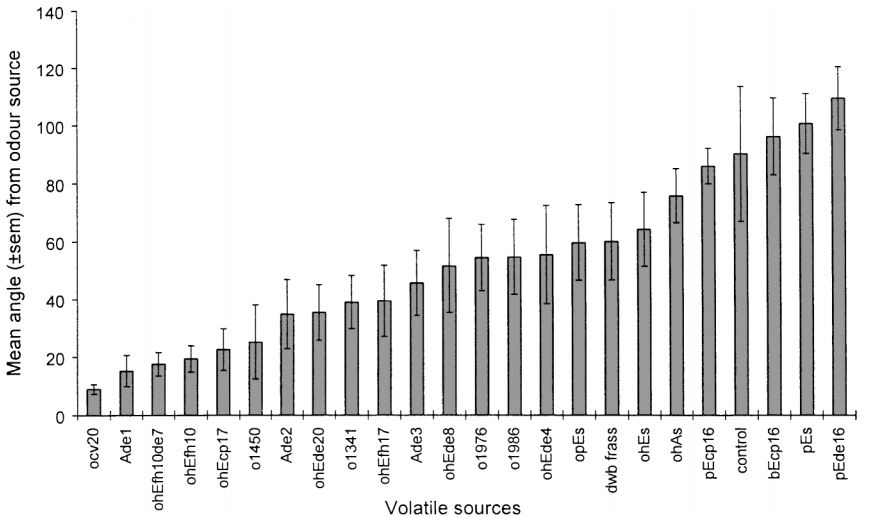

FIG. 3. Mean vector angle of vectors generated by wild mated female deathwatch beetles exposed to airborne volatiles in chemoorientation experiments ($N = 5$).

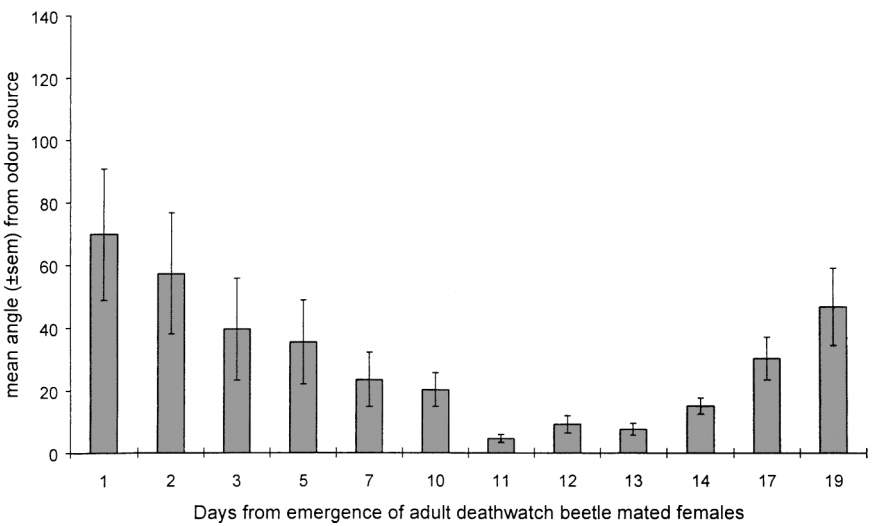

FIG. 4. Mean vector angle of vectors generated by mated female deathwatch beetles that emerged from a laboratory culture. Insects of known age were exposed to airborne volatiles from oak wood cut down in the year 1341 ($N = 5$).

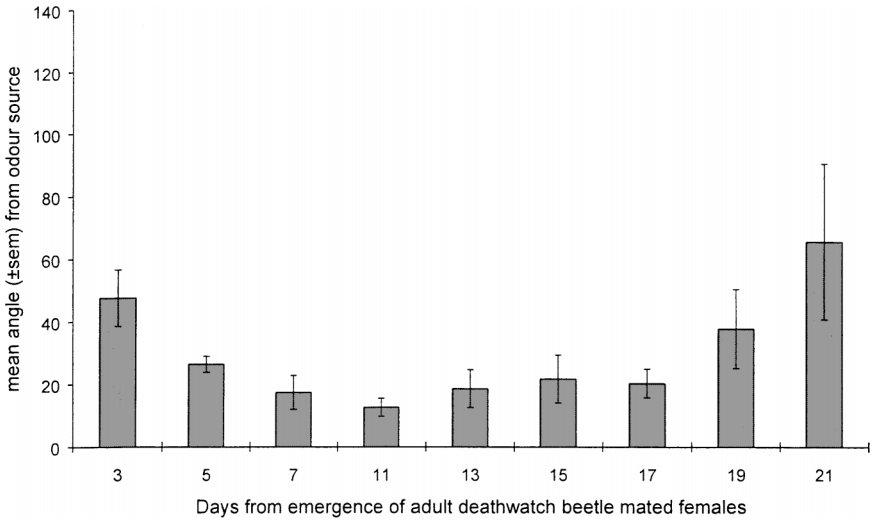

FIG. 5. Mean vector angle of vectors generated by mated female deathwatch beetles that emerged from a laboratory culture. Insects of known age were exposed to airborne volatiles from oak wood infected with *C. versicolor* ($N = 5$).

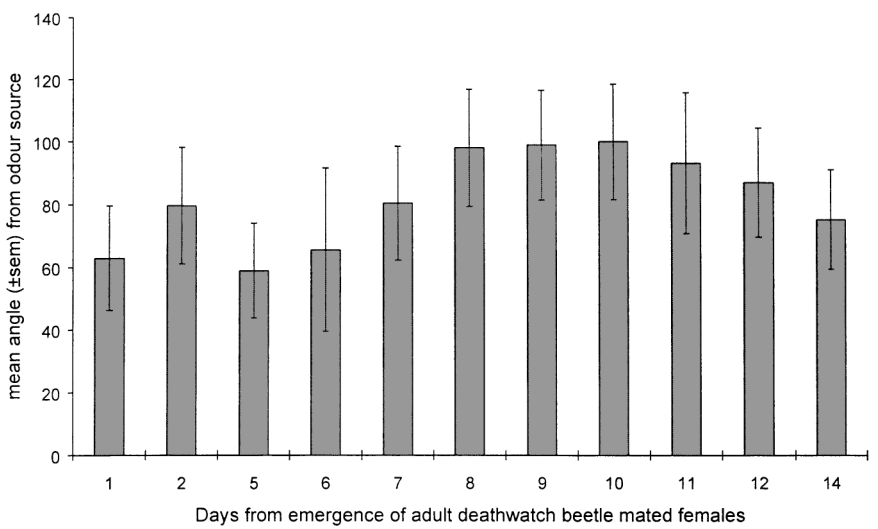

FIG. 6. Mean vector angle of vectors generated by mated female deathwatch beetles that emerged from a laboratory culture. Insects of known age were exposed to airborne volatiles of deathwatch beetle frass from laboratory insect culture wood ($N = 5$).

Variance of the mean vector angle was shown to indicate strength of insect response. High variance, as in the control experiment, indicated a lack of a directed response to the odor source as insects did not uniformly orient upwind, downwind, or across wind, i.e., insects did not orient to the wind and left the paper in the direction of their standard angle of orientation. High variance and high mean angle, therefore, indicated there was no insect response to a volatile. Low variance of the mean vector angle showed that odor sources were either attractive (when the mean angle was small) or repellent (when the mean angle was high). Linear and nonlinear regression models showed no correlation between variance and mean angle ($r^2 < 0.35,\ P = 0.05$). Variance among experiments that showed a low mean vector angle (0°–40°) was less than the variance among experiments that showed a high mean vector angle (55°–110°) (F tests at $P = 0.05$), indicating that insects demonstrated a less variable response to attractive odors than unattractive odors.

Oviposition Preference Bioassay. Some fungal extract-treated discs were preferentially oviposited upon, when compared to the control (no treatment) disc, whereas other extract-treated discs were avoided with insects ovipositing all their eggs on the control disc (Table 3, Figure 7). In some experiments, the extract

[a] 1000 ppm, Wilcoxon matched-pairs signed-ranks test on the mean number of eggs per disc, $N = 10$. An attractive response was when eggs were preferentially laid on the treated disc. A repellent response was when eggs were preferentially laid on the untreated control disc. No discrimination was when a significant preference could not be determined.

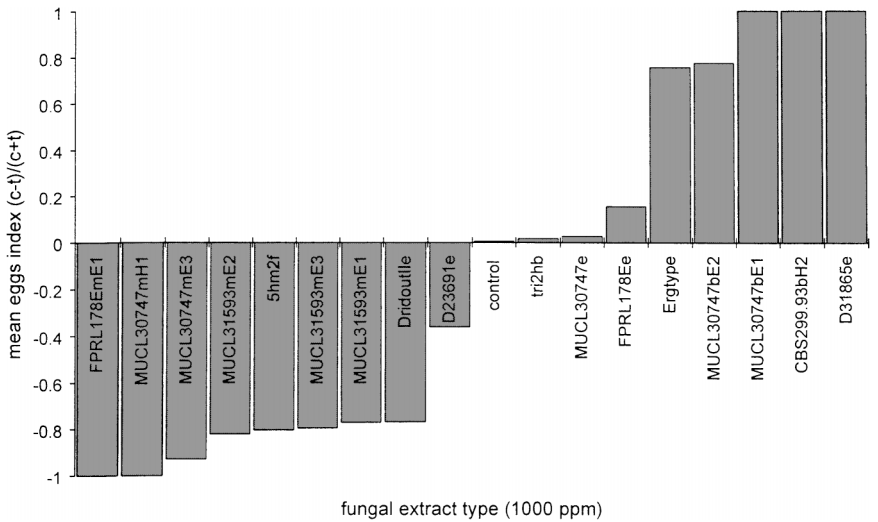

FIG. 7. Oviposition preference choice test bioassays ($N = 10$) using extracts of the wood decaying fungus *Donkioporia expansa* on cellulose discs showing an oviposition index that compares the mean number of eggs oviposited on control discs as opposed to treated discs; -1 shows all eggs were oviposited on the treated disc and $+1$ shows all eggs were oviposited on the control disc.

did not influence oviposition behavior as eggs were laid on treatment and control discs in a similar fashion to that when two control discs were present. Generally, mycelial fractions were found to be attractive, whereas broth fractions were found to be repellent when tested at the same concentration (Table 3). Fungal exudates appeared to have no significant effect on oviposition behavior.

In order to compare among experiments the variable oviposition response to the extracts, indices were calculated by the formula $(C - T)/(C + T) =$ oviposition index, where C and T represent the number of eggs laid on the control and treatment discs, respectively. Similar results were shown among experiments in the relative magnitude of oviposition response to the extract when oviposition indices were calculated from the mean number of eggs laid on the control and treatment discs (Figure 7).

DISCUSSION

The chemoorientation behavior of female deathwatch beetles would suggest that walking adult deathwatch beetles can orient upwind to potential host volatiles (Hansell, 1985; Visser, 1988). The observed differences in the strength of response

to various volatile sources could have been due to the particular volatiles associated with the source samples, or it could have been due to the amount of volatile produced or both (Heinzel and Böhm, 1984; Visser and Thiery, 1986; Akers and Wood, 1989). The similarity of insect response among odor sources of a similar nature would argue that the volatile composition was very important to the overall chemoorientation behavior demonstrated. For example, decayed oak samples and living fungal samples were attractive despite potential differences in volatile concentration or composition among odor sources. Similarly, undecayed oak and pine odors did not elicit an upwind orientation response. It is unknown what particular compounds or ratio of compounds were important for this chemoorientation behavior, but there may be combinations of compounds that could cause chemoorientation, as several different volatile sources demonstrated similar insect orientation behaviors (Visser, 1983; Miller and Strickler, 1984).

Volatiles from decayed oak and living fungi showed that insects readily walked upwind, regardless of their initial physical orientation to the wind at the commencement of the experiment, and variability among insect responses was relatively low as opposed to the control (no odor). Pine wood and undecayed wood produced a less definite insect response in that beetles tended to walk across the wind, downwind, or behaved similarly to those in the control experiment where insects walked off the paper in the direction of their initial orientation to the wind. Therefore, the experiment was inconclusive in determining whether some odors were repellent or simply unattractive (Heinzel and Böhm, 1984; Preiss and Kramer, 1986). However, variance of the mean angle was higher among experiments with a large angle from the odor source as opposed to experiments with a low angle from the odor source. This relative increase in variability among experiments of high angle suggests that some insect responses (low mean variance) were caused by repellent odors, whereas some insect responses (high mean variance) may indicate insects did not react to the odor. Choice-preference experiments using choice olfactometers (Ponsonby and Copland, 1995; Potting et al., 1995; Steinberg et al., 1992) could perhaps define a repellent volatile mix as opposed to a volatile mix that elicits no response.

Adult females appeared to have an optimal period when they were most responsive to volatile odors. Although insects of all ages did orient to attractive volatiles, the response was more directed when insects were at the age when oviposition usually occurred (10–16 days old). This could argue that, to some extent, chemoorientation behavior is physiologically driven as responsiveness to volatiles from the same odor source varied with insect age (Bell et al., 1995).

It was already known that deathwatch beetles demonstrate oviposition preferences when given a choice between two blocks of timber (Belmain et al., 1998). The oviposition bioassays using fungal extracts additionally showed that deathwatch beetles can at least partially select oviposition sites by contact chemoreception of fungally derived compounds. Fungally decayed oak contains decomposition

products, such as methylfuroate and dimethoxybenzene, as well as some uncharacterized furan compounds (Esser and Tas, 2001). Further experiments are required to assess whether the deathwatch beetles respond to any of these compounds. Concentration and the relative ratios of compounds in extracts could affect the overall oviposition response (Ridgway et al., 1990).

Many insects have demonstrated both host selection behavior from a distance (host plant finding) and on contact with the surface of the host (host plant recognition) (Bell et al., 1995). Chemoorientation has been argued to be a common insect trait as primitive insects such as cockroaches demonstrated both temporal and spatial processing of olfactory information (Bell and Kramer, 1979). It should, therefore, not be surprising that the deathwatch beetle is also capable of host selection using chemoorientation and oviposition selection to determine its optimal host in order to increase offspring fitness. The identification of beetle-attracting compounds could lead to improved pest control in deathwatch beetle-infested buildings through trap-baiting (Day and Sjogren, 1994) or monitoring as part of an integrated pest management (IPM) strategy (Simmonds et al., 2001). Research on the identification of chemoreceptors on the insect and subsequent electrophysiological experiments (Blaney et al., 1987; Blaney and Simmonds, 1990) would help confirm host selection behavior of the deathwatch beetle.

Acknowledgments—This research has been conducted as part of the Wood Care Project which received funding from the European Union Environmental Initiative Programme (Project 4.20.5.6396; contract EV5V-CT94-0517). We thank our project partners for fruitful exchange of ideas and information: John Fidler (Architectural Conservation, English Heritage, UK); Brian Ridout (Ridout Associates, UK); Dervilla Donnelly, Hubert Fuller, and Ian Nesbitt (University College Dublin, Ireland); Petra Esser, Jan de Jong, Piet van Staalduinen, and Albert Tas (TNO Building and Construction Research, The Netherlands). Fungal extracts and compounds were supplied by Ian Nesbitt, fungally decayed wood by Petra Esser, and Dendro-dated wood by Brian Ridout. The deathwatch beetle culture was donated by Michael Pallaske (Remmers Bauchemie GmbH, Germany). We thank the parish of Bishopstone, UK, for continued support of our research.

Abstract—*Lavandula stoechas*, a native plant of Greece, is rich in essential oil and fenchone is its major constituent. We examined the effect of the essential oil and its main constituents on soil metabolism and microbial growth. Addition of the essential oil or fenchone to soil samples induced a remarkable increase in soil respiration. This was accompanied by an increase in the soil bacterial population of three orders of magnitude. This sizable population was not qualitatively similar to that of the control soil samples. One bacterial strain dominated soil samples treated with *L. stoechas* essential oil or fenchone. By use of the disk diffusion assay, we evaluated the capacity of three bacterial strains that we isolated from the soil samples, as well as *Escherichia coli* and *Bacillus subtilis* (reference strains), to grow in the presence of the essential oil and three of its main constituents (fenchone, cineol, α-pinene). The substances tested did not inhibit the growth of the strain found to dominate the bacterial populations of treated soil samples; they severely inhibited *B. subtilis*. The other two isolated strains could also grow in liquid cultures in the presence of different quantities of essential oil or fenchone. Addition of fenchone at the end of the exponential phase increased the cell numbers of the strain that dominated the bacterial populations of treated soil samples, indicating use of the substrate added. On the basis of these results, we propose a scheme of successional stages during the decomposition process of the rich-in-essential-oil litter of aromatic plants that abound in the Mediterranean environment.

Key Words—*Lavandula stoechas*, soil metabolism, microbial growth, essential oil.

INTRODUCTION

Aromatic plants make a remarkable contribution to the flora and vegetation of the Mediterranean environment. Common among them are representatives of the family Lamiaceae (Kokkini et al., 1989). A distinctive feature of this family of plants is their production of essential oils, which are mixtures of low-molecular-weight isoprenoids. The antimicrobial activity of these compounds is widely known (Janssen et al., 1987; Bennett et al., 1994; Sivropoulou et al., 1995, 1996, 1997; Amaral and Knowles, 1998; Karamanoli et al., 2000).

Despite the fact that essential oils characterize the fragrant Mediterranean environment, their function is not known. In this environment, decomposition is limited by unfavorable combinations of temperature and rainfall (Vokou, 1992). If the antimicrobial activity of essential oils held for soil microorganisms as well, decomposition would be critically affected, as biological constraints (essential oils inhibiting microorganisms) would function on top of physical ones. Therefore, our goal has been to understand how essential oils, known to possess antimicrobial activity, affect soil microorganisms and, concomitantly, the decomposition process.

Results of our previous research showed that soil respiration was activated in the presence of *Coridothymus capitatus* and *Satureja thymbra* essential oils. The increase of soil respiration was found to be a primary rather than secondary effect. The essential oils from these plants did not kill some soil microorganisms, thereby providing substrate easily decomposable to others (Vokou et al., 1984) but directly activated soil bacteria.

We further examined the effect of a number of individual essentail oil constituents on soil respiration and found that the compounds tested (oxygenated or not) resulted in increased CO_2 release from soil samples collected from the area where these aromatic plants grow. The observed differences were mostly of a temporal nature. Some were immediately effective, while others required a time lag (Vokou and Margaris, 1988). Given these responses, we examined the effect of essential oils of largely different chemical composition from both indigenous and nonindigenous aromatic plants on soil samples of different origin. The essential oils tested were rich in phenols, carvacrol, and/or thymol (from *Origanum vulgare* subsp. *vulgare*, *C. capitatus*, and *S. thymbra*), in carvone–dihydrocarvone (*Mentha spicata*), in 1,8-cineol–camphor (*Rosmarinus officinalis*), and in linalool–linalyl acetate (*Lavandula angustifolia*, an introduced species). The soil samples were collected from beneath wild growing aromatic plants, from open spaces without a shrub layer, and from areas not exposed to essential oils (e.g., from cultivated fields). In spite of their different chemical composition, all of the essential oils activated soil respiration. Moreover, soils not previously exposed to essential oils responded similarly to those supporting aromatic plants (Vokou and Liotiri, 1999). These studies suggest that the antimicrobial activity of essential oils is not

expressed against all soil microorganisms. Some can metabolize them and use them as carbon and energy sources.

The ability of some bacteria to use volatile organic compounds (VOC), including essential oils, has been well documented. They can degrade monoterpenes, such as α- and β-pinene, carene, limonene, γ-terpinene, and *p*-cymene (Dhavalikar and Bhattacharya, 1966; Gibbon and Pirt, 1971; Griffiths et al., 1987; Stumpf et al., 1990; Harder and Probian, 1995; Misra et al., 1996; Harms et al., 1999; Kleinheinz et al., 1999) or oxygenated compounds, such as camphor (Gunsalus and Marshall, 1971). The bacteria are both Gram-negative (e.g., *Pseudomonas*, *Alcaligenes*) and Gram-positive (e.g., *Mycobacterium*, *Nocardia*). As stated by Misra and Pavlostathis (1997), although monoterpenes are easily degraded in liquid as well as soil–slurry systems under aerobic conditions, "much remains to be studied for a more complete understanding of the behavior of monoterpenes in the natural environment."

The aims of the present work are (1) to provide additional experimental evidence in support of our hypothesis that essential oils increase always soil respiration, and (2) to examine how changes in the soil microbial population shift toward microorganisms resistant to essential oils, able to use them as carbon and energy sources, and facilitate the decomposition process of aromatic plant litter. Towards these aims *Lavandula stoechas* (Lamiaceae) was used. This plant is native in Greece and has a wide occurrence across the country. Its essential oil is dominated by the oxygenated compound fenchone. Neither the essential oil nor fenchone, its major constituent, have been studied for their effect on soil microorganisms.

METHODS AND MATERIALS

Essential Oil and Constituents. Plant material of *L. stoechas* was collected in the wild from Halkidiki, N. Greece. Leaves were separated and water distilled in a Clevenger apparatus for 2.30 hr. The essential oil extracted from leaves was analyzed by gas chromatography (Varian 3700) by using previously described conditions (Vokou et al., 1993). Major constituents were identified on the basis of retention times and by cochromatography of authentic samples.

The crude essential oil and its constituents fenchone, cineol, and α-pinene (Aldrich Chemical Co., Milwaukee, Wisconsin) were used in the experiments.

Soil Respiration Studies. Soil samples were collected from the upper soil layer ($<$5 cm) in an area with Mediterranean vegetation, close to Thessaloniki University campus. The soil was air-dried and sieved ($<$1 mm). Soil respiration was determined by using the method described in Vokou and Liotiri (1999). In brief, soil samples (150 g dry wt) were put in airtight containers (aluminum cylinders with approximately 1 liter capacity), 30 ml of distilled water added to the soil samples, and a 50-ml beaker with 20 ml 1M KOH was placed on the top of the

soil in each container. Respiration was estimated under the following conditions: (1) from soils treated with *L. stoechas* essential oil, (2) from soils treated with fenchone (major constituent of the essential oil), (3) from untreated soils, and (4) from a control without soil but containing the beaker with KOH. In the treated soils, 0.1 ml of either essential oil or fenchone was added. Three replicates were used for each treatment. Experiments were conducted at room temperature (20–27°C). CO_2 absorbed by KOH was estimated by titration with 0.1 ml HCl after seven days based on previous studies (Vokou et al., 1984; Vokou and Margaris, 1988; Vokou and Liotiri, 1999). The essential oil or fenchone was added repeatedly in the same soil samples at the same quantity, on a weekly basis.

Counts, Isolation, and Identification of Bacterial Strains. We examined soil samples treated with essential oil, soil samples treated with fenchone, and control soil samples. The soil dilution plate method on Oxoid nutrient agar was used, and the number of bacterial colonies was counted. Three replicates were used for each treatment.

Pure cultures of bacterial strains were obtained. Isolated bacterial strains were examined for colony morphology (visual), cell morphology (light microscope), Gram reaction, and response to biochemical tests. Biochemical tests for each isolated strain were repeated twice and gave identical results. For bacterial identification, the commercially supplied systems MICROBACT 12A (for strains negative to oxidase) and MICROBACT 12B (for strains either positive or negative to oxidase) were used, as well as Bergey's Manual of Determinative Bacteriology (Holt et al., 1994).

Bacterial counts and bacterial composition of untreated soils and those treated with *L. stoechas* essential oil and fenchone were compared.

Disk Diffusion Assay. The tolerance against *L. stoechas* essential oil and its constituents, fenchone, cineol, and α-pinene, of the three isolated bacterial strains from soil samples and of *Bacillus subtilis* (NCIMB 3610) and *Escherichia coli* (NCIMB 8879), purchased from the National Collection of Industrial and Marine Bacteria (NCIMB, Aberdeen, Scotland), were tested. The latter two bacteria are standard reference strains routinely used for the evaluation of antimicrobial compounds and shown to be sensitive to various essential oils (Sivropoulou et al., 1995).

The essential oil and each constituent were examined at four different quantities: 1, 5, 10, and 15 μl. Filter paper disks (Whatman No. 1, 5 mm diameter), containing the essential oil or individual constituents were applied to the surface of agar plates previously seeded with 0.2 ml of the test organisms. There were four replicates for each treatment. Plates were incubated overnight at 30°C. The diameters of the resulting zones of inhibition were measured in millimeters. The net zones of inhibition were calculated after subtraction of the diameter (5 mm) of the paper disk.

Bacterial Cell Growth. Well-isolated, single bacterial colonies were grown overnight at 37°C in nutrient broth. Two sets of experiments were done to monitor

bacterial growth. In the first set, the growth of two bacterial strains isolated from the soil and *E. coli* were followed in presence of *L. stoechas* essential oil or fenchone, added at quantities of 0.1, 0.25 and 0.5 ml in tubes of nutrient broth (150 ml); control tubes for each strain were also used. The nutrient broth was inoculated with appropriate aliquots of the cultures of these bacteria so that their optical densities (OD_{600}) were similar. We monitored the growth of each culture by measuring optical density (OD_{600}) at 30-min intervals for 8 hrs. In the second set, the potential of the same two soil bacterial isolates and *E. coli* to grow in nutrient broth enriched with fenchone added at the end of the exponential phase of their growth was monitored. Fenchone was tested at 0.2 and 0.5 μl/ml and bacterial growth was monitored as above. Experiments were repeated twice and yielded essentially the same results.

Statistical Analysis. SPSS was used for statistical analyses. To estimate whether the effect of treatments was significant, analysis of variance was conducted followed by multiple LSD comparisons; *t* test was run in case of two-sample comparisons.

RESULTS

L. stoechas is a rich-in-essential-oil aromatic plant; the yield from its leaves was 2.3 ml/100 g dry wt. The chemical composition of its essential oil was found to be similar to that previously described for the species from a population at Halkidiki (Kokkalou 1987), from where we also took our samples. The main constituents were fenchone (41%), cineol (29%), and α-pinene (1.6%).

Addition of *L. stoechas* essential oil or fenchone increased the CO_2 released from treated soil samples compared to the control ($P < 0.001$) (Figure 1); soil respiration was maintained at high levels with repeated additions. There was no significant difference in soil respiration between the effect of *L. stoechas* essential oil and fenchone.

Bacterial counts from control soil samples and those treated with *L. stoechas* essential oil or fenchone are consistent with the observed increase in soil respiration. The counts rose by approximately three orders of magnitude in the presence of *L. stoechas* essential oil or fenchone (Table 1). The difference between bacterial counts from treated soil samples and the control was significant ($P < 0.001$).

Three Gram-negative bacterial strains were isolated and tentatively identified from treated soils (Table 2) including *Aeromonas hydrophila* (strain I), *Pseudomonas putida* (strain II), and *Vibrio alginolyticus* (strain III). However, we consider these identifications as tentative (particularly those for *A. hydrophila* and *V. alginolyticus*) because the substrate preferences do not fit well with the substrates that we used. For this reason, we will continue to refer to the isolates as strains I, II, and III.

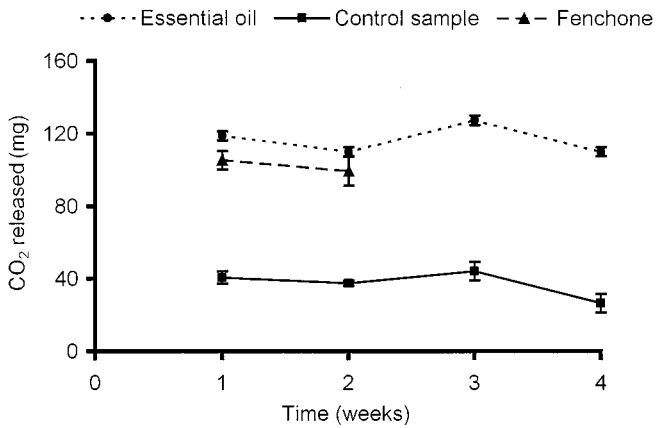

FIG. 1. Soil respiration in control samples and those treated with 0.1 ml of *L. stoechas* essential oil or fenchone. Values represent CO_2 released per week and were taken one week after *L. stoechas* essential oil or fenchone was added to soil samples (150 g dry wt).

Strain I was the most abundant in soils treated either with *L. stoechas* essential oil or fenchone. In fact, strain I accounted for 95% of the microbial population in soil treated with essential oil, for 78% in soil treated with fenchone, but only 13% in control soil (Table 1). Criteria used to assign bacterial counts to this strain included visual (morphology of the colony) and microscopic (light microscope); assignment was facilitated by the greenish color of strain I colonies that clearly differentiated it from all other strains.

The ability of the three isolated bacterial strains and two reference strains, *Escherichia coli* and *Bacillus subtilis*, to grow in the presence of *L. stoechas* essential oil (Figure 2a), the oxygenated monoterpenoids fenchone (Figure 2b) and cineol (Figure 2c), and the nonoxygenated monoterpene α-pinene (Figure 2d) was evaluated. None of the compounds affected the growth of strain I. The essential oil and the two oxygenated compounds, at quantities ≥ 5 μl, had a weak effect on

the growth of strain II (maximum inhibitory zone, 5 mm), whereas α-pinene was inactive. Their effect on strain III was similar; maximum inhibition was recorded in presence of 15 μl of the essential oil. *E. coli* responded similarly to strains II and III in most treatments, but fenchone and cineol considerably inhibited its growth at the maximum quantity tested (15 μl). *B. subtilis* was the most sensitive strain. The

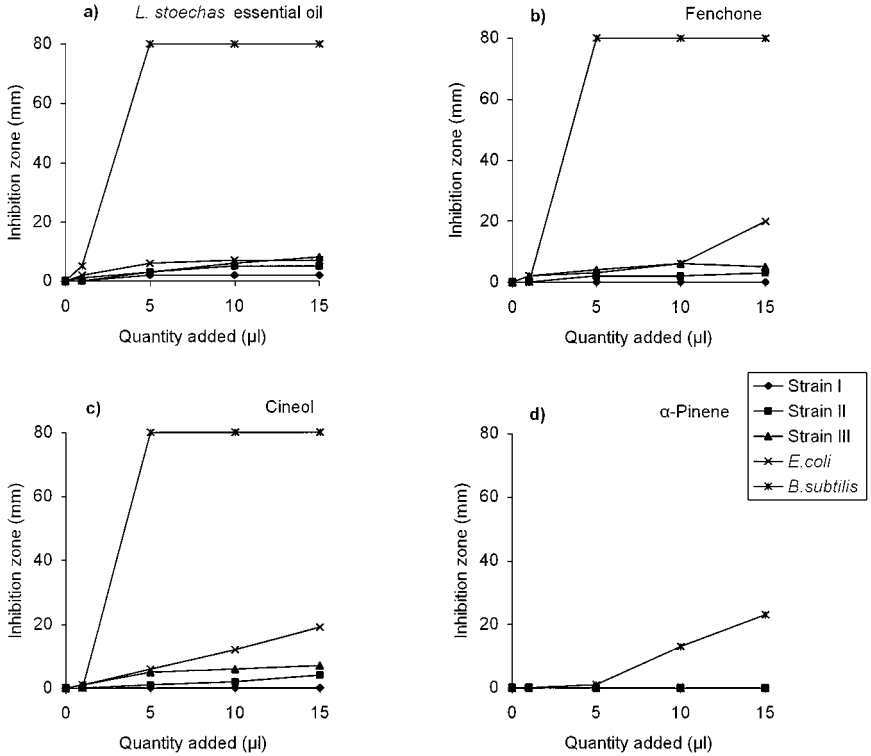

FIG. 2. Antimicrobial activity of (a) *L. stoechas* essential oil, (b) fenchone, (c) cineole, and (d) α-pinene, applied at four different quantities, against strains I, II, and III, *E. coli*, and *B. subtilis.*

essential oil, fenchone, and cineol entirely inhibited its growth at quantities ≥ 5 μl. α-Pinene, which was inactive against all other bacterial strains, was inhibitory at quantities ≥ 10 μl. Two-way ANOVA was run on data taken after addition of the maximum quantity (15 μl) with bacterial strains and compounds used as factors; both bacterial strains and compounds had significant effects. Multiple LSD comparisons showed that all differences in inhibition among species were significant. Differences among compounds were significant except between fenchone and cineol, the two oxygenated compounds.

The liquid-phase assays, designed to test a compound's activity when added either at the beginning or the end of the exponential phase of microbial growth, relied on the results of the disk diffusion assays to choose both the compound and the bacterial strains to be tested. Fenchone was chosen as the most inhibitory of the three compounds tested; strains I and II were selected as the most resistant

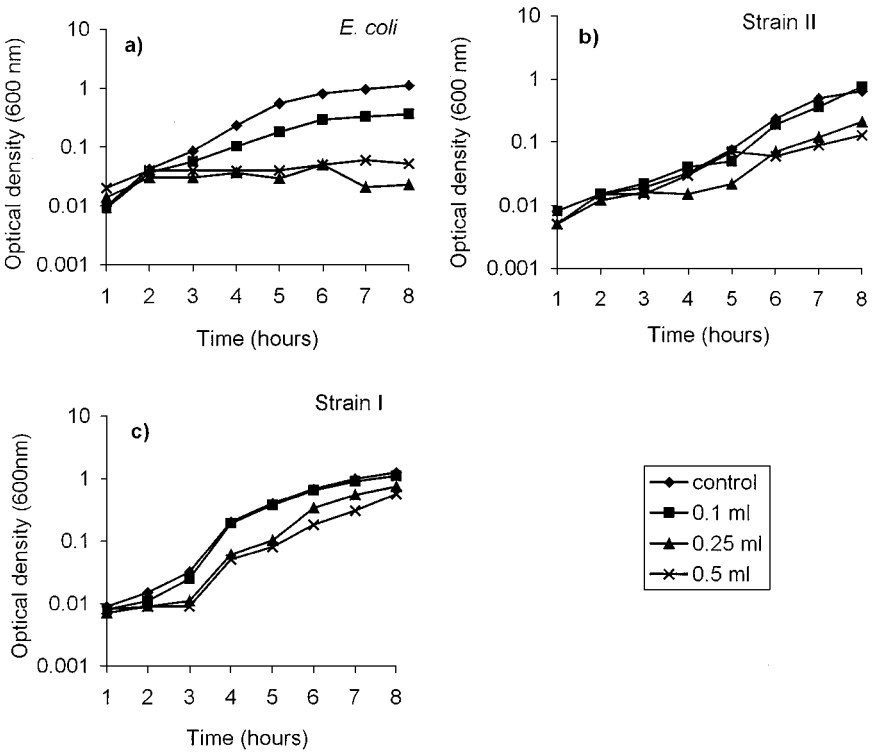

FIG. 3. Time- and concentration-dependent effect of fenchone on the growth rate of *E. coli* (a), strain II (b), and strain I (c). Quantities of fenchone were added to 150 ml of culture medium. Experiments were repeated twice. Each value in the graphs is the average of two; individual values differed by less than 3% from the mean.

soil bacterial strains. For the sake of comparison, the essential oil and *E. coli* were also examined. Results of the assay with fenchone and *L. stoechas* essential oil, added at the beginning of the exponential phase are given in Figures 3a–c and 4a–c, respectively. At the end of the experimental period (8 hr), strains I and II continued to grow in the presence of fenchone (Figure 3b,c), and growth curves were similar to controls. This was not the case for *E. coli*, which was substantially inhibited in presence of 0.25 and 0.5 ml of fenchone (Figure 3a). The growth of *E. coli* in presence of the essential oil was similar (Figure 4a). Strains I and II grew under all quantities examined, but strain I at a lower rate in the case of the highest quantities (Figure 4b,c).

When added at the end of the exponential phase of microbial growth, strain I continued to grow in the presence of fenchone, in contrast to strain II and *E. coli* (Figure 5). When a microbial population reaches the stationary phase of its growth,

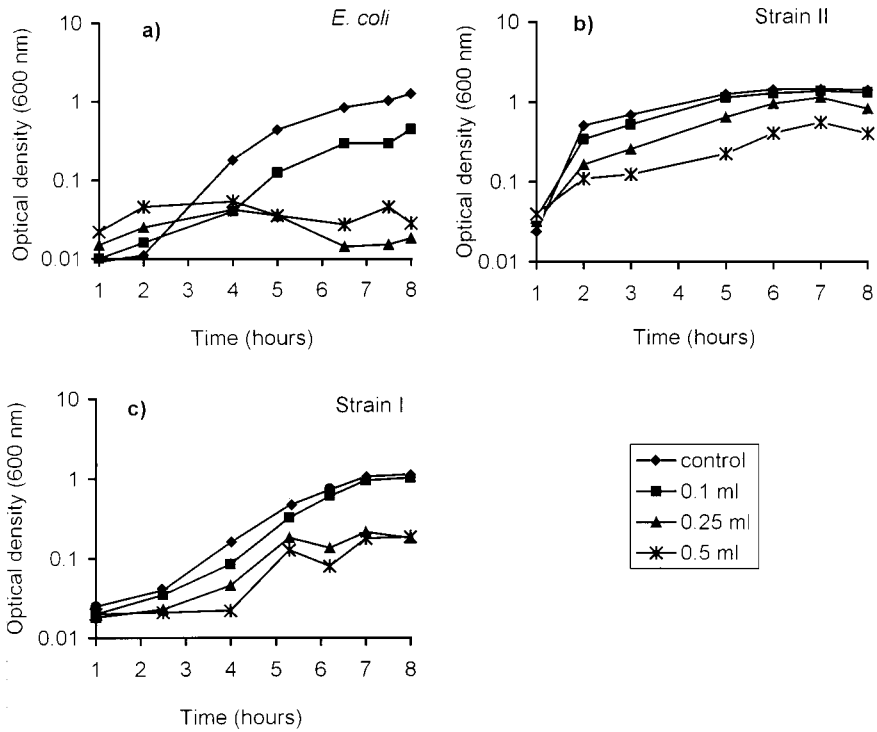

FIG. 4. Time- and concentration-dependent effect of *L. stoechas* essential oil on the growth rate of *E. coli* (a), strain II (b), and strain I (c). Quantities of essential oil were added to 150 ml of culture medium. Experiments were repeated twice. Each value in the graphs is the average of two; individual values differed by less than 3% from the mean.

it means that it has consumed all carbon and energy sources of the culture medium. Further increases in population size, after a substrate (fenchone, in this case) is added, indicates use of this substrate.

DISCUSSION

Addition of *L. stoechas* essential oil to soil samples induced a remarkable increase in soil respiration. Fenchone induced a similar response. These results are consistent with other studies using different essential oils (Vokou et al., 1984; Vokou and Liotiri, 1999) or individual compounds (Vokou and Margaris, 1988) and support the contention that essential oils, irrespective of their chemical composition, have the potential to increase soil respiration.

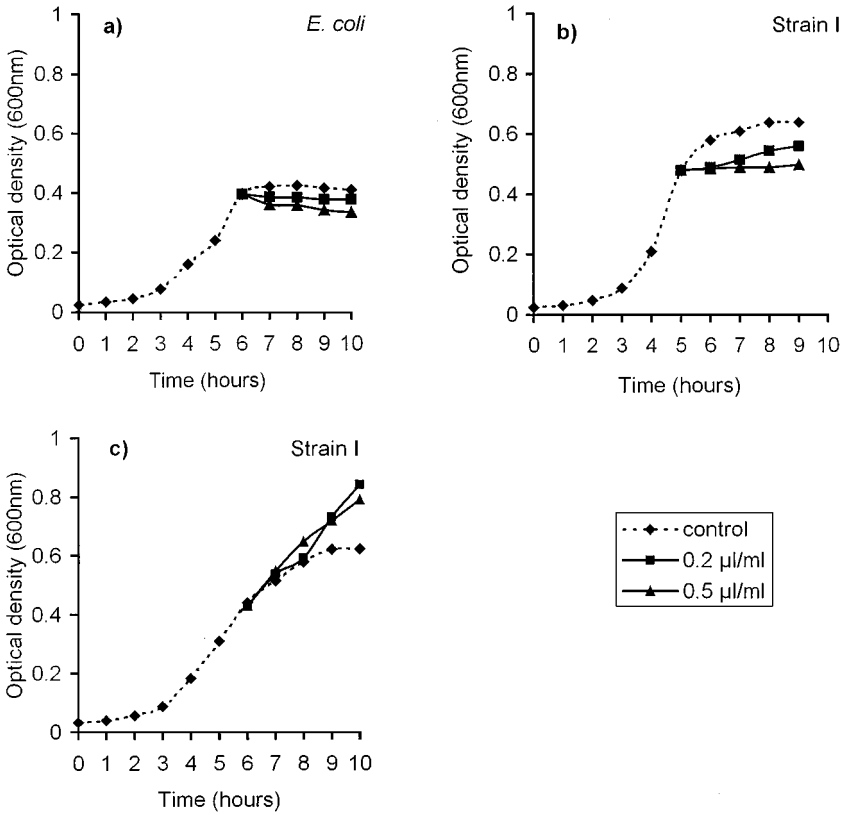

FIG. 5. Growth rate *E. coli* (a), strain II (b), and of strain I (c) before and after addition of fenchone (two quantities tested); the compound was added when populations reached the stationary phase of their growth. Experiments were repeated twice. Each value in the graphs is the average of two; individual values differed by less than 3% from the mean.

Activation of soil respiration in the presence of *L. stoechas* essential oil or fenchone was accompanied by an increase in the soil bacterial population, of approximately three orders of magnitude. This suggests that increased soil respiration can be attributed to increased bacterial populations in the soil and their concomitant metabolic activity. This population was qualitatively different from control soil samples. One bacterial strain in particular (I, Table 2) had an overwhelming participation in treated soils. These results support our working hypothesis that essential oils shift the microbial population balance in soil favoring particular bacterial strains.

Strain I, dominant in treated soils, was most resistant in the disk diffusion assays. The overall rank of bacterial resistance to monoterpenoids was: strain I > strain II ≥ strain III ≥ *E. coli* > *B. subtilis*. Of the compounds tested, fenchone and cineol were far more inhibitory than α-pinene. Oxygenated and nonoxygenated monoterpenoids repeatedly have been reported to differ in activity. Hydrocarbons (such as α-pinene) have been found to be far less active than oxygenated compounds (Sivropoulou, 1996; Karamanoli et al., 2000).

E. coli and *B. subtilis* have often been target organisms in assays examining the antimicrobial activity of various monoterpenoids (Pellecuer et al., 1980; Janssen et al., 1984; Yun et al., 1993; Sivropoulou et al., 1995, 1996). *B. subtilis* has always proved to be most sensitive, as in this study. In contrast, different patterns of response by *E. coli* strains have been reported, even when testing the same compounds.

Pseudomonas strains have been found to be resistant to essential oils and their individual constituents, (Janssen et al., 1984; Kivanç and Akgül, 1986; Kubo et al., 1992; Sivropoulou et al., 1996), and also able to use isoprenoids as a carbon and energy source (Dhavalikar and Bhattacharya, 1966; Gibbon and Pirt, 1971; Gunsalus and Marshall, 1971). However, this does not always hold true, as sensitive strains have been reported (Kivanç and Akgül, 1986; Karamanoli et al., 2000).

Strain II, tentatively identified as *Pseudomonas putida*, which we isolated from the treated soil samples, was only weakly affected. In fact, long ago it was found that this bacterial strain could degrade camphor (Gunsalus and Marshall, 1971), an oxygenated isoprenoid that is also present in *L. stoechas* essential oil. The authors reported that prominent among the organisms capable of attacking hydrophobic residues were soil saprophytic bacteria of the genus *Pseudomonas*. Inducible hydrogenases were found in *P. putida*, the model system that they studied. Some of these enzymes were not formed until other primary carbon sources were exhausted. This may explain why some essential oils and individual constituents do not cause an immediate effect, but require a certain period of time before increasing soil respiration (Vokou et al., 1984; Vokou and Margaris, 1988). The genes encoding the camphor catabolic enzymes were mapped on transmissible plasmids (Gunsalus and Marshall, 1971). If widespread, this genetic arrangement might provide a mechanism by which diverse compounds found in nature (i.e., isoprenoids) could be catabolized. With the results of this work, we cannot argue that *P. putida* can also metabolize fenchone. However, we can classify it among the bacteria resistant to *L. stoechas* essential oil and its constituents.

The striking participation of strain I in the treated soils, its ability to grow on/in solid and liquid media in presence of isoprenoids, and the fact that addition of fenchone at the end of the exponential phase of its growth caused further increases in its population size all indicate that it is able to biodegrade these secondary

metabolites. From the latter experiment, we can confidently state that strain I is resistant to fenchone and can use it as both a carbon and energy source.

On the basis of these results, we contend that essential oils determine the successional stages during the decomposition process of the litter of aromatic plants. Bacteria (e.g., strain I), able to use essential oils as carbon sources, must be among the initial colonizers of the rich-in-essential-oil litter (Vokou, 1992) from these plants. Activated in autumn, after the first rainfalls that follow the dry Mediterranean summer, these bacteria grow using essential oils as their carbon and energy sources. Among the later colonizers must be bacterial strains inhibited by these toxic substrates; they do not establish in the litter until the initial colonizers begin consuming the essential oils. Given that strains II and III were only weakly affected and were present in treated soil samples, we suggest that they may also participate in rather early successional stages. Whether the similar soil respiration response, induced by essential oils in all soil types that we have studied to date, is due to the same or a different spectrum of microorganisms is not known. This will be one of the directions of our future research, to understand the interactions between aromatic plants and soil microorganisms.

(Received April 16, 2001; accepted December 5, 2001)

Abstract—The secretion of the paracloacal glands of the American crocodile (*Crocodylus acutus*) contains over 80 lipophilic compounds, including saturated and unsaturated long-chain alcohols along with their formic, acetic, and butyric acid esters, and several isoprenoids. Most of these compounds were identified on the basis of mass spectra, obtained by GC-MS. In addition, identification of the major components was supported by infrared spectra obtained by GC-FTIR. Major differences are indicated in the composition of the paracloacal gland secretion of *C. acutus* and that of another crocodylid, the African dwarf crocodile (*Osteolaemus tetraspis*).

Key Words—American crocodile, *Crocodylus acutus*, paracloacal glands, fatty esters, formates, mass spectrometry, GC-FTIR.

INTRODUCTION

While insect chemical ecology has made great strides in the last five decades, much less is known about many comparable aspects of vertebrate chemical ecology (Eisner and Meinwald, 1995). The crocodilians, a small but fascinating group of ancient vertebrates, have aroused the curiosity of chemical ecologists in the last decade, with primary attention being paid to the chemical composition of their skin

gland secretions (Weldon and Wheeler, 2000). The study of crocodilian ecology and behavior, however, has lagged behind that of most other tetrapods. This circumstance can be attributed in part to the difficulties inherent in studying responses to chemicals by these large and, for adults at least, dangerous reptiles in field or seminatural settings. We have studied the chemistry of the secretion produced in the paracloacal glands of the American crocodile (*Crocodylus acutus*, Crocodylidae) in the hope that knowledge of this chemistry will ultimately contribute to an understanding of crocodilian chemical ecology. These glands in crocodilians are thought to produce pheromones involved in the nesting and/or mating activities (Weldon and Ferguson, 1993).

Previous analyses of lipids from the paracloacal glands of crocodilians have occasionally led to the characterization of unusual compounds, thus reflecting some novel biosynthetic capabilities of these reptiles (Weldon and Wheeler, 2000). For example, a unique 19-carbon aromatic ketone, named dianeackerone, and a family of related steroidal esters were found to be major glandular products of the African dwarf crocodile (*Osteolaemus tetraspis*, Crocodylidae) (Whyte et al., 1999; Yang et al., 1999, 2000). Two stereoisomers of dianeackerone occur in varying ratios in adults of this species, but this compound was not detected in immatures.

We report here the results of an analysis by gas chromatography–mass spectrometry (GC-MS) of the paracloacal gland secretion of another crocodylid, *C. acutus*. This species occurs in freshwater and brackish coastal habitats in Mexico, Central America, northern South America, Cuba, Jamaica, Hispaniola, and in the tip of southern Florida. Our study revealed that the glandular secretion of this species is composed largely of formate, acetate, and butyrate esters of C_{12}–C_{20} straight-chain alcohols, along with the alcohols themselves. Interestingly, formate esters have not previously been reported in reptiles. This is the first detailed report of the skin gland lipids of *Crocodylus*, the most speciose genus of crocodilians.

METHODS AND MATERIALS

Paracloacal gland secretions of *C. acutus* were obtained from one adult male [total length (TL) = 3.0 m], one adult female (TL = 2.5 m), six juvenile males (TL = 1–1.5 m), five juvenile females (TL = 0.7–1.1 m), and five unsexed hatchlings (TL = 0.5–0.6 m) maintained at Cypress Gardens (Plant City, Florida), Gatorama (Palmdale, Florida), and the St. Augustine Alligator Farm (St. Augustine, Florida). The adults we sampled, which had been housed together for 2.8 years, are within the size range of reproductively active, free-ranging *C. acutus* (Kushlan and Mazzotti, 1989); they had copulated, although neither egg-laying nor nesting behavior had been observed. Most secretion donors hatched from eggs laid by captive females from Florida; one juvenile female was reared from an egg laid by a female from Jamaica. Animals at Cypress Gardens were fed rats and chicken necks, those at Gatorama were fed a commercial feline food

(Nebraska Brand, Central Nebraska Packing Company, North Platte, Nebraska) containing primarily horse meat, and those at the St. Augustine Alligator Farm were fed nutria (*Myocastor coypu*).

The secretions were collected by manually pressing the region around the cloacal opening, causing the walls of the cloaca to flare outward, exposing the openings of the gland ducts. Additional pressure applied to the glandular region resulted in the discharge of yellow secretions from the glands. These exudates were collected in capillary tubes that were broken off into glass vials. A few milliliters of CH_2Cl_2 were added to the vials, which were stored on dry ice.

Determination of Position of Double Bonds. Dimethyl disulfide (DMDS) derivatization was carried out according to a reported procedure (Attygalle and Morgan, 1986).

Reference Compounds. Fatty acids and alcohols, cholesterol, cholesta-3,5-diene, citronellol, pentadecane, and squalene were purchased from Sigma-Aldrich. Cholesteryl and alkyl formates were synthesized by the uncatalyzed reaction of each alcohol with an excess of formic acid (Burger et al., 1996). Acetates were synthesized by treating each alcohol with an excess of acetic anhydride and pyridine (Zhdanov and Zhenodarova, 1975). The reaction of the alcohols with butyryl, caproyl, and capryl chloride in CH_2Cl_2 afforded the corresponding butyrates, caproates, and caprylates, respectively (Ihara et al., 1990; Madden and Prestwich, 1994). 2,3-Dihydrofarnesol was prepared following a literature procedure (Kaplay et al., 1980).

Analytical Procedures. Gas chromatography was performed on a Hewlett-Packard (HP) 5890 instrument equipped with a splitless injector, and either a flame-ionization detector, a HP 5965A IR detector, or a HP 5970 mass selective detector. The samples were injected in the splitless mode. Analyses were performed using a 25-m $\times$ 0.22-mm fused silica-column coated with SE-54. The oven was programmed from 40°C (2 min) at 7°C/min to 280°C (30 min). To investigate the possible presence of nonvolatile compounds, we undertook a direct analysis of unfractionated secretion samples by NMR spectroscopy, as well as by electrospray ionization–mass spectrometry. No additional compounds were found with these methodologies.

RESULTS AND DISCUSSION

An exploratory survey of the paracloacal gland secretions of 21 crocodilians by thin-layer chromatography showed the presence of bands consistent with aliphatic esters in most taxa, including *Crocodylus* spp. (Weldon and Tanner, 1991). Analyses by GC-MS have revealed the structures of these esters in alligators (*Alligator* spp.) and caimans (*Caiman* spp. and *Paleosuchus* spp.) (Shafagati et al., 1989; Dunn et al., 1993; Ibrahim et al., 1998). The present study confirms the presence of many aliphatic acetates in *C. acutus*, and demonstrates the occurrence

of formates (characterized by *m/z* 47 ions) and butyrates (characterized by *m/z* 89 ions) as well. Moreover, the ester derived from 1-hexadecyl alcohol is the main component of the caproic acid esters; 1-hexadecyl caproate (*m/z* 117 and 224 ions) is also abundant in the secretions of the Chinese alligator (*A. sinensis)* (Dunn et al., 1993). Our analytical results are presented in Tables 1 and 2 and Figures 1 and 2.

We observed significant quantities of formate esters derived from C_{13}–C_{18} alcohols; the major formates were those of C_{16}, C_{17}, and C_{18} monounsaturated alcohols. The presence of formates is interesting since they have not been reported previously from crocodilians or from any other reptiles. While formates are known from ants (Lopez et al., 1993), beetles (Attygalle et al., 1992), and caterpillars (Attygalle et al., 1993), to the best of our knowledge they have not been reported among vertebrates except in the preorbital gland secretions of three species of African antelopes (Burger et al., 1981, 1996, 1999; Mo et al., 1995). The alcoholic moieties of these esters range, among the three antelope species, from 9 to 28 carbons. As Burger et al. (1981) noted, the mass spectra of formates are very similar to those of the corresponding aliphatic alcohols, but are distinguished from them by the presence of a low-intensity peak at *m/z* 47, corresponding to an $HCO_2H_2^+$ (protonated formic acid) fragment.

We observed free alcohols in the *C. acutus* ranging from 10 to 18 carbons, including the terpene citronellol, which was found only in the secretion of the hatchlings. A similar array of alcohols has been reported in some alligatorids, e.g.,

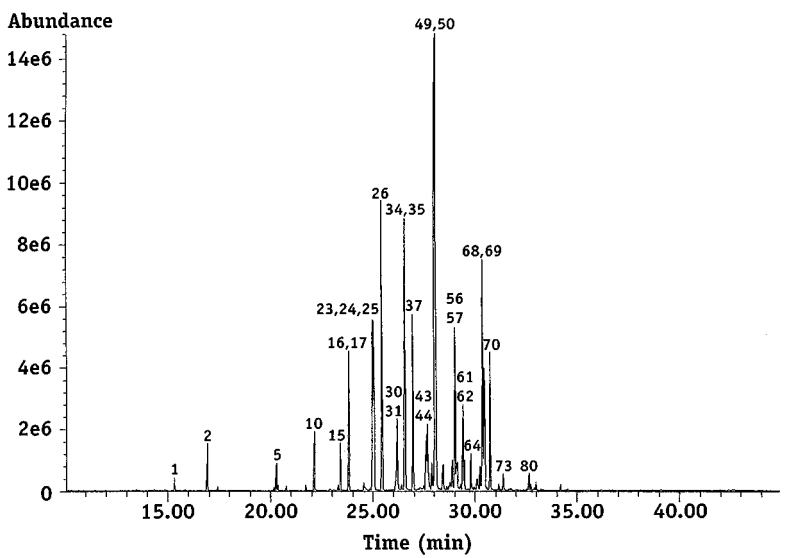

FIG. 1. A reconstructed gas chromatogram obtained from the paracloacal gland secretion of hatchling *Crocodylus acutus*. Peak numbers refer to components listed in Table 1.

TABLE 1. COMPONENTS FOUND IN PARACLOACAL GLAND SECRETION OF *Crocodylus acutus*[a]

No.	Compound	Molecular formula	NMM	Characteristic ions observed (*m/z*)	R_t (min)
1	Citronellyl formate	$C_{10}H_{19}OCHO$	184	138, 123, 95, 81, 69, 41	15.33

the Chinese alligator (*A. sinensis*) (Dunn et al., 1993) and caimans (*Paleosuchus* spp.) (Shafagati et al., 1989), although citronellol has been described only from several caimans. 2,3-Dihydrofarnesyl acetate, a known paracloacal gland component of the brown caiman (*Caiman crocodilus fuscus*) (Wheeler et al., 1999), accounted for up to 4% of the secretion of immature crocodiles, but was not detected in the adult samples.

Interestingly, we did not find free formic, acetic, or butyric acids in any of the secretions, based on the derivatization of the total sample with pentafluorobenzyl bromide/triethylamine (Attygalle, 1998). Five C_{14}–C_{18} fatty acids, which are routinely encountered from vertebrate integumentary organs, were observed in immature *C. acutus*, and a significant amount of oleic acid (~5%) was found in the adult male; we failed to detect free fatty acids in hatchling *C. acutus*. Thirteen fatty acids ranging from C_{14} to C_{20} were reported from the skin glands of *Crocodylus* spp. by Navajas Polo et al. (1988a,b). It should be noted that these investigators combined, for their studies, the paracloacal and gular (throat) glands of both *C. acutus* and the Cuban crocodile (*C. rhombifer*) thus our results are not directly comparable with theirs. We were also unable to confirm the presence of an intriguing lactone related to 10-hydroxystearic acid described in an earlier report (Navajas Polo, 1982) from the macerated and steam-distilled skin glands of the aforementioned mixed species.

Squalene was the major hydrocarbon we detected in *C. acutus*. This compound was especially abundant in the adult female; it was either present in reduced

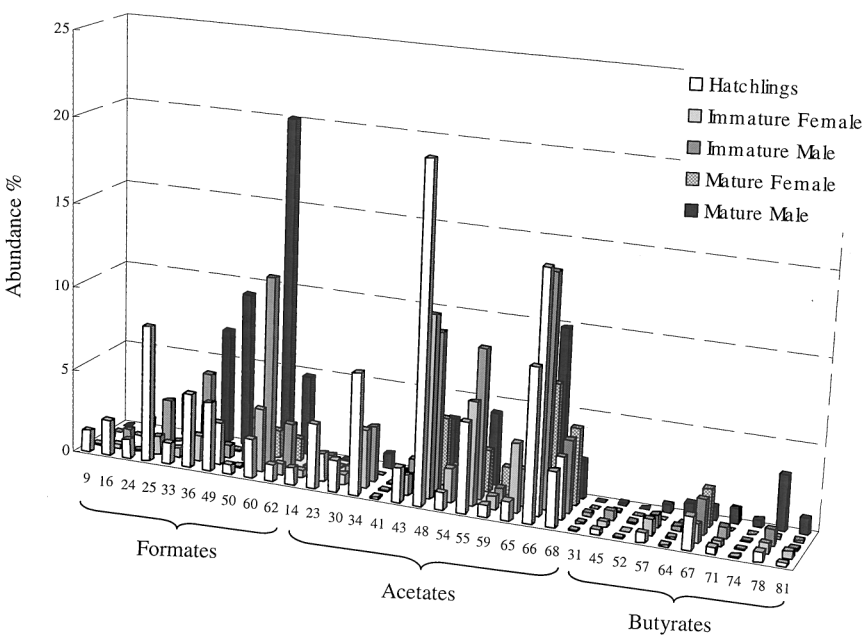

FIG. 2. Distribution of the alkyl and alkenyl esters (formates, 9–62; acetates, 14–68; and butyrates, 31–81) found in average abundance >0.2% in the paracloacal gland secretion of *Crocodylus acutus*, expressed as a percentage of the total secretion. Percentages are listed in Table 2; numbers refer to components listed in Table 1. Crocodile hatchlings were not sexed.

quantities or was entirely absent in the male or immature females. The abundance of squalene in our adult female is consistent with the appearance of an intense band corresponding to hydrocarbons in the thin-layer chromatogram of a female *C. acutus* secretion sample examined in the earlier survey of paracloacal gland lipids by Weldon and Tanner (1991).

All our compound identifications are based on the mass spectra obtained by GC-MS and comparison with synthetic standards. In addition, the identification of the major components was supported by infrared spectra obtained by gas chromatography–Fourier transform IR spectroscopy. Gas-phase FTIR spectra proved particularly helpful in recognizing formate, acetate, and butyrate peaks. Thus, the carbonyl group stretching vibrations appeared characteristically at 1740–1748 cm^{-1} in the gas-phase FTIR spectra of C_{13}–C_{18} formates, whereas that of acetates and butyrates appeared at 1761–1762 and 1753–1754 cm^{-1}, respectively. FTIR spectra were also useful for the assignment of the *Z* configuration to the double bonds in the unsaturated esters and alcohols. Double-bond positions in 9- and 11-octadecenyl acetate, 8- and 10-heptadecenyl acetate, 7- and 9-hexadecenyl acetate, 9-octadecenyl formate, 8-heptadecenyl formate, and 7-hexadecenyl formate were determined by the DMDS derivatization method (Buser et al., 1983; Francis and Veland, 1981).

We did not observe in *C. acutus* either dianeackerone or the related steroidal esters characteristic of the confamilial *Osteolaemus tetraspis* (Whyte et al., 1999; Yang et al., 1999); conversely, neither the aliphatic esters, alcohols, nor squalene that we have observed in *C. acutus* have been found in *O. tetraspis*. These results, foreshadowed by earlier TLC studies (Weldon and Tanner, 1991; Weldon and Wheeler, 2000), demonstrate substantive chemical differences in the paracloacal gland products of *Crocodylus* and *Osteolaemus*. While further analyses of the glandular products of *Crocodylus* will be needed to assess the range of chemical variation within the Crocodylidae, we can anticipate that the deeper task of deciphering the biological significance of these chemically complex secretions will remain a challenge for some time to come.

Acknowledgments—We are grateful to K. Bartel, B. Schwedick (Cypress Gardens, Plant City, Florida), A. Register, P. Register (Gatorama, Palmdale, Florida), J. Brueggen, J. Darlington, J. Heil, S. Huber, D. Kledzik, W. Puckett, and T. Rexroad (St. Augustine Alligator Farm, Florida) for allowing access to animals in their collections. (Received August 30, 2001; accepted December 5, 2001)

Abstract—The preference of juvenile Arctic char [*Salvelinus alpinus* (L.)] for odors from siblings and nonsiblings with different major histocompability complex class II (MHC) genotypes was studied in two-choice fluviarium tests. In the first part of the study, test fish demonstrated no preference for water scented by a sibling with a MHC genotype different from its own versus water scented by a MHC identical nonsibling. When both donors were siblings with different MHC genotypes, however, the test fish chose the water scented by the fish with the same MHC type as the test fish. The results suggest that odors with information about kinship are dependent on MHC but also on other, unknown factors. In the second part of the study, we observed that fish isolated since fertilization did not show any behavioral discrimination towards siblings, based on MHC genotype. One reasonable explanation for this result is that Arctic char learn to discriminate between odors from individuals of different MHC types.

Key Words—Arctic char, fish, chemical signals, MHC, kin discrimination, siblings, odors.

INTRODUCTION

The ability to discriminate between kin and nonrelated individuals has been demonstrated in various taxonomic groups of animals, including fish (Fletcher and Michener, 1987; Hepper, 1991; Olsén, 1992; Brown and Brown, 1996). Hamilton (1964) suggested that an individual's fitness is not only composed of its own fitness, but also involves the fitness of close relatives, i.e., the inclusive fitness theory. The ability to recognize kin makes it possible for an animal to act toward relatives in a way that increases its fitness, i.e., kin selection is possible (Wilson, 1975). Direct kin recognition mechanisms are composed of inherited and/or acquired components. Waldman (1987, 1991) suggested that direct recognition is composed of series of events. An individual presents labels (often odors, phenotype) that are detected by a second individual and these labels are compared with a template that is innate or learned. Recognition occurs if the fit of the label to the template is over a certain threshold and, if the social context is appropriate, a behavioral discrimination occurs.

Juvenile salmonids are capable of discriminating between water scented by siblings and fish from other sibling groups of the same population (Quinn and Busack, 1985; Olsén, 1989; Brown et al., 1993). They are more attracted to water with sibling odor than to water with odors from nonkin, even if both odor donors are unfamiliar to the test fish. These results demonstrate that the discrimination is based on direct recognition by phenotypic matching. Recent studies have also shown that the fish need experience with conspecifics during some early learning period, to establish a template by which other individuals can be compared (Winberg and Olsén, 1992; Olsén and Winberg, 1996).

The function behind kin recognition and discrimination in salmonid fish is not fully understood. It has been observed, however, that the level of aggression in pure sibling groups is lower than in groups of mixed relationship (Brown and Brown, 1993a,b; Olsén et al., 1996; Olsén and Järvi, 1997). The size of feeding territories was also larger in the mixed kin groups (Brown and Brown, 1993a,b). Attraction to sibling specific odors may also indicate that the fish prefer to school with related individuals (Olsén, 1989). Recent studies have also shown that the growth rate in pure sibling groups was greater and more even, compared to groups of mixed relationship (Brown and Brown, 1993a, 1996). These studies give support to the idea that juvenile salmonids benefit from the ability to discriminate between kin and non-kin.

The substances used for kin discrimination in juvenile salmonids are not known. In an elegant electrophysiological study (EOG), Moore and collaborators (Moore et al., 1994) showed that juvenile Atlantic salmon release odors containing information about kinship in the urine. Further more, juvenile Arctic char are attracted to water scented by urine or intestinal content from individuals from the same population (Olsén, 1987). We recently demonstrated that the odors released

by juvenile Arctic char and used in kin discrimination are significantly influenced by the major histocompability complex (MHC class II) (Olsén et al., 1998). MHC molecules (class I and II) are used for recognition of antigens and self-reference is required for the recognition of nonself substances (Klein, 1986). Our results correspond well with studies with mice (*Mus musculus*) that show abilities to discriminate between the odors of conspecifics with disparate MHC genes. The odors are present in the urine (Yamazaki et al., 1976, 1979; Singh et al., 1987, 1988; Potts et al., 1991), and the recognition ability is probably based on a familiar imprinting process of kin odors (Penn and Potts, 1998a). Mice may use this information for kin recognition and/or to increase the heterozygosity of MHC genes that may result in increased resistance towards parasites (e.g., Beauchamp et al., 1988; Potts et al., 1991; Manning et al., 1992; Lewis, 1998; Penn and Potts, 1998b; Eggert, 1999). Our recent study with juvenile Arctic char also indicated that genes from another part of the genome are involved in the production of cues used for kin discrimination when the fish cannot rely on information from the MHC class II (Olsén et al., 1998). We observed that a test fish did not show any preference when choosing between water scented by a sibling with no MHC class II genes in common and a nonsibling that shared one allele with the test fish. However, the test fish preferred the water from a sibling if both donors had no MHC-alleles in common with the test fish. Similar results showing the significance of other factors than MHC have been obtained from studies with rodents (Lennington et al., 1988; Brown et al., 1989; Schellink et al., 1993; Eggert et al., 1996). The MHC may be a major genetic factor that influences the odors of individuality, but there are other factors such as diet, social status, and the animal's bacterial flora that, together with inherited components, are of importance for the odor identity, as has been shown for rodents (e.g., Brown et al., 1996; Schellink et al., 1997; Zavazava and Eggert, 1997).

In the present study, we continue our previous work concerning the influence of MHC genes on kin discrimination in Arctic char. What happens if the test fish have to choose between odors from an MHC-like nonsibling (both alleles in common) and an MHC-different sibling? Further, by using test fish kept in isolation since fertilization, we want to ascertain whether the behavior discrimination of MHC is an innate response or might be based on learning.

METHODS AND MATERIALS

Fish. We created two full-sibling families, by using two pairs of wild Arctic char caught in Lake Hornavan, Lapland, Sweden, just before the spawning period in the autumn of 1995. Before the artificial fertilization was done, ten adult individuals of each sex were MHC characterized to obtain suitable sibling groups. The mature adults were placed in tanks at a hatchery close to Lake Hornavan (Sälla Fiskodling, Porjus).

Within 1 hr of fertilization, egg lots from the two pairs, family 1 and family 2, were each divided by volume into two equal groups. In addition, single eggs from both families were individually placed in compartments, each with its own water inlet and outlet (Olsén and Winberg, 1996). The eggs that were isolated were transported to Uppsala on the same day as they were fertilized. We incubated the rest of the eggs of the four groups (1A, 1B, 2A, 2B) in separate hatching boxes and placed each box at the upstream end of separate troughs to avoid contact with odors from conspecifics. Yolk sac fry from these four groups were transported to Uppsala University during the spring of 1996 and placed in equivalent boxes in separate troughs supplied with aerated Uppsala tap water. Later, we transferred fish groups to fiberglass holding tanks. In all groups, the fish remained healthy throughout the experimental period and mortality was negligible. All fish were fed daily with the same kind of Astra-EWOS granulated food pellets (EST40) in the amount of 1–2% of the body fresh weight.

Fluviarium Tests. Experiments were conducted during the period November 19, 1997, to January 20, 1998, in a modified standard fluviarium (Höglund, 1961; Olsén and Höglund, 1985; Olsén, 1986, 1989), which is a two-choice maze with a laminar flow of aerated tap water (see Figure 1 in Olsén et al., 1998). Water from two identical 12-liter donor aquaria (A1 and A2) was supplied to opposite halves of the fluviarium and mixed into the main water current flowing downstream to the test area. We placed one test fish in the test area, measuring $46 \times 33 \times 11.5$ cm (length $\times$ width $\times$ depth), limited upstream and downstream by two fine-mesh plastic nets. During the experiments, the flow (range during the entire study: 380–410 ml/min; no significant difference in flow during a test between the two channels) from the two donor aquaria was switched automatically between the two halves of the test area at regular 90-min intervals. The donor aquaria were continously supplied with aerated tap water at a rate of 440–450 ml/min. The flow rate of the water in the fluviarium was 19 liters/min (9.5 liters/min on each half) and the water temperature in the fluviarium and in the donor aquaria was 7.7–9.9°C. There was no difference in water temperature between the two donor aquaria, and the temperature difference between the aquaria and the fluviarium water was always less than 1.0°C. We placed a video camera 33 cm above the test area and recorded the position of the test fish once every 2 sec by means of a video-computer-based image analysis system (Bjerselius et al., 1995; Olsén and Winberg, 1996). A flat rack of infrared 468 diodes, transmitting wavelengths longer than 750 nm (beyond the visual range of salmonide fish) (Bone et al., 1995), were placed under the test area and used as light sources for the camera. To prevent external disturbances, fluviarium tests were run after the ordinary working hours for most people at the department. A test started at 17:00 hr and ended at 05:00 hr the next morning. Between the experiments, we washed the test area, the donor aquaria, tubes and electromagnetic valves with water and 95% ethanol. In addition, we brushed the aquaria with a solution of ethanol and acetic acid (97:3).

In each fluviarium test, data from the last 60 min in each of the eight 90-min periods in a complete test were used to calculate a reaction value (*Rv*). *Rv* was calculated according to Olsén (1986) using the following equation:

$$Rv = [(N1 - N2)/(N1 + N2)] \times 100,$$

where $N1$ and $N2$ represent the number of observations in each side of the test area with water scented by a individual placed in A1 and A2, respectively (a *Rv* of 100 would imply a complete preference for water from A1 and a $Rv = -100$ a complete preference for A2). The test fish always had the same MHC genotype as the fish in A1, except in control tests where the odor donors in the two aquaria had the same MHC class II genotype. The arithmetic means of reactions values from identical tests are designated M*Rv*.

MHC Matching Experiment. To test if the recognition and the following behavioral discrimination is a matching process influenced by MHC-based olfactory cues available to the test fish, 36 juveniles from two sibling groups were selected, all with a body mass between 8.4 and 10.7 g. The two sibling groups chosen shared MHC alleles between the clutches. On October 10, 1997, we placed the fish in diagonally divided troughs measuring 45 × 25 × 25 cm (length × width × depth). As the fish were placed in the troughs, a small piece of the caudal fin was cut for analyzing their individual MHC genotype. There were two fish in each trough, separated by a transparent partition which allowed both visual and chemical, but not physical, contact. The 18 troughs were continuously supplied with aerated tap water. All fish were in good condition and were fed once per day. The lights turned on at 05:00 hr and off at 17:00 hr, respectively. Individuals that had been isolated since fertilization were not moved to these troughs, but were maintained in their original compartments. The size of the test fish isolated since fertilization varied between 7.8 and 13.4 g ($N = 6$).

We ran four types of tests in the fluviarium (experiments 1–4, see below). The test fish and the donors were always from different troughs, and they were all changed between tests. In experiments 1–3, we used each test fish with three different combinations of donors ($N = 5$). One test fish of each belonged to groups 1A (genotype *fh*), 2A (*fd*), and 2B (*fd*). Two test fish belonged to 1B (both *fh*). To reduce the risk of recognition by familiarity, neither of the donors were from the same original rearing group as the test fish (e.g., from 1A) and the test fish and one of the donors in the triplet were not from the same diagonally divided trough. The differences in weight between the two donors were the same in the different experiments (mean ± SD; experiment 1: 0.9 g ± 0.6; experiment 2: 0.9 g ± 0.6; experiment 3: 0.9 g ± 0.7; $N = 5$ for all). Fish isolated since fertilization were used only as test fish and only once (experiment 4). Three test fish of each belonged to sibling group 1 (one fish *fh* and two *dd*) and 2 (one fish *fd* and two *ah*). The same pair of donors was used only once. The weight of the donors varied between

9.1 and 12.9 g ($N = 12$) and the mean difference in weight between the pair of donors used was 1.2 g $\pm$ 0.7 ($N = 6$).

We placed fish in the donor aquaria and in the fluviarium 30 min before the test started, and the following experiments were performed: (1) In the control test all three individuals belonged to the same sibling group. The two donors, one in each aquarium, were MHC-II identical. (2) A test fish was exposed to water scented by a MHC-identical sibling (identical to the test fish) and a MHC-different sibling. The experiments is designated as "full sibs, same MHC vs. full sibs, different MHC." (3) Water was scented by a nonsibling and a sibling. The test fish had the same MHC genotype as the nonsibling, but was different from the sibling odor donor. Designated as "non-sibs, same MHC vs. full-sibs, different MHC." (4) The test fish had been isolated since fertilization. The donors were siblings to the test fish and one sibling had the same MHC genotype as the test fish, the other sibling had different MHC genotype.

Tissue Preparation and PCR. A small tissue sample, 20–30 mg, was taken from the caudal fin of each fish. We immediately put the cut fins (approx. 6 mm^2) in a freezer (-20°C). This procedure did not cause any great harm to the fish, and it was possible to use them later in behavioral experiments. First, we took a random sample from the different groups (1A, 1B, 2A, 2B) to examine what genotypes were present. All fish placed in physical isolation were analyzed before the fluviarium test. Genomic DNA was extracted and purified according to Laird et al. (1991).

The complete exon 2 of a MHC class II gene encoding the hypervariable antigen binding site (315 bp) was amplified by the polymerase chain reaction (PCR) using standard procedures, 100 ng of DNA template in 25 μl PCR reactions (Perkin Elmer). MHC class II was chosen because the greater number of DNA sequences from related salmonid species (Hordvik et al., 1993) for this loci facilitated the design of specific PCR primers and development of a genotyping method. The conditions of the PCR were as follows: denaturation for 2 min at 94°C, followed by 30 cycles of denaturation for 30 sec at 94°C, annealing for 30 sec at 56°C, and primer extension for 30 sec at 72°C. The final extension was for 10 min at 72°C. When run on an agarose gel, the PCR products showed one distinct band corresponding to 315 bp and high DNA homology (96%) to salmon cDNA (M. Grahn and J. Lohm, unpublished data). The PCR was performed on a Perkin-Elmer-Cetus 9600 instrument. The two primers used to amplify the class II B exon were MG7 (5′-TAATCTGACAAAACAATGA-3′) and MG14 (5′-GCGGGCGGCGCGGGGCGCGGGCAGGGCGGCGGGGGCGGGCCACC TGTCTTGTCCAGTATG-3).

Denaturing Gradient Gel Electrophoresis. To detect allelic differences within and between individuals, we used denaturing gradient gel electrophoresis (DGGE), which is used to separate different DNA fragments of the same length based on sequence differences (Fischer and Lerman, 1983; Myers et al., 1987). The combination of PCR and DGGE has previously been used to study MHC class II B gene

variation in primates and provides an easy and reliable method for MHC typing in new and less well-studied species compared to serological typing or restriction fragment length polymorphism, RFLP (Knapp et al., 1997).

DGGE was performed by using 5%, 19:1 acrylamide–bisacrylamide, polyacrylamide parallel gels containing 1× TAE buffer and a gradient of urea and formamide. Denaturant concentrations in the gels ranged from 30% to 60% (Myers et al., 1987). Electrophoresis was performed in 1× TAE buffer heated to 60°C in electrophoresis cells and a buffer tank (C.B.C. Scientific Company, Inc.). A volume of 10–15 μl PCR products per lane was electrophoresed between 5 hr and 6 hr at 180 V. The gels were stained with ethidium bromide (0.2 μg/ml 1× TAE) for 15 min and the DNA was visualized with a UV transilluminator (UVP, inc Transilluminator, Nagle Company).

Sequencing. To verify that the DNA sequences of identical DGGE bands were the same among unrelated individuals, the DGGE fragments were sequenced by direct sequencing. Desired DGGE fragments were cut out from the gel, mixed with 160 μl dd H_2O, extracted by keeping the samples for 1 hr at −80°C, 1 hr at 25°C, 1 hr at −80°C, 2 hr at 4°C and used as template in a PCR with the primers and annealing temperatures as above. The PCR products were ethanol precipitated, dissolved in 15 μl dd H_2O and used as sequencing template. Fragments were sequenced in both directions using the primers MG 7 and ÅL1002 (Langefors et al., 2000). Sequences were then analyzed in a ABI PRISM 310 (Perkin Elmer).

Statistics. Experiments 1–3 were compared with repeated-measures ANOVA followed by Tukey-Kramer multiple comparison test. Student's t test ($t = \mathrm{M}Rv/\mathrm{SD}/\sqrt{N}$) was used to compare the M*Rv* for each experiment with the theoretically indifferent reaction when $\mathrm{M}Rv = 0$. M*Rv* = 0 when the number of observations in each water quality is the same. All calculations were performed with GraphPadTM Instat.

RESULTS

To test if fish preferences were affected by MHC genotype, we used triplets of genotyped fish. The genotypes of the char in family 1 were *df*, *dd*, *fh*, and *dh* and in family 2 *df*, *fh*, *ad*, and *ah*. The alleles designated with the same letters in both families (i.e., d, f, and h) showed the same DNA sequences in both families (data not shown). The repeated measures ANOVA revealed significant differences between the reaction in the control test, the test with MHC-different siblings as donors (experiment 2, "non-sibs, same MHC vs. full-sibs, different MHC"), and the test with donors from two different sibling groups with the non-sibling MHC-like the test fish (experiment 3, "non-sibs, same MHC vs. full-sibs, different MHC")($F_{2,8} = 5.44$, $P < 0.05$; Figure 1). The Tukey-Kramer multiple comparisons test showed that there was a significant difference between the reactions in

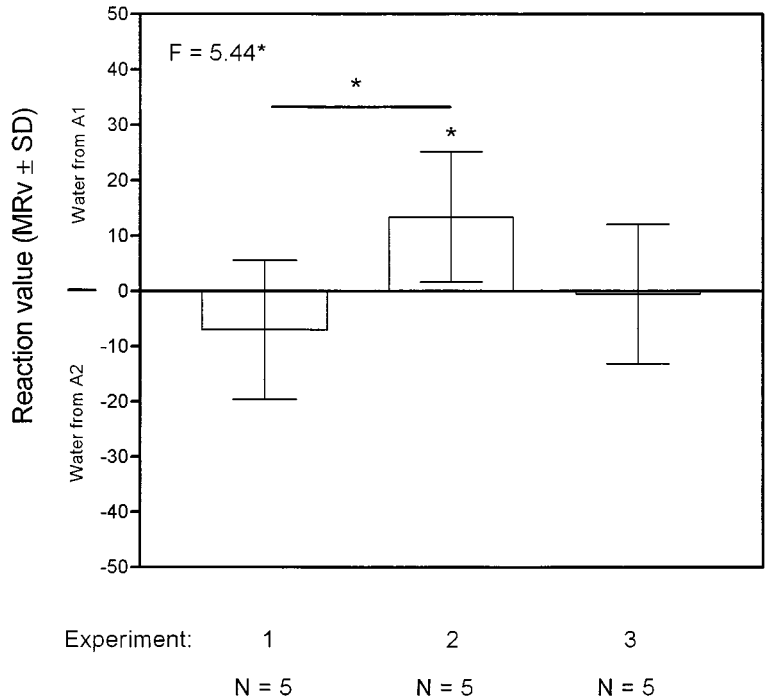

FIG. 1. Reaction value (M*Rv* ± SD) of juvenile Arctic char exposed to water scented by an unfamiliar fish in each channel (see Figure 1 in Olsén et al., 1998). M*Rv* is a measure of preference and a positive M*Rv* means that the fish is attracted to water from aquarium 1 that contained a fish with the same MHC genotype as the test fish. Experiment 1: water scented by MHC-identical siblings that were MHC-different or similar to the test fish (control test); experiment 2: "Full sibs, same MHC vs. full sibs, different MHC"; experiment 3: "non-sibs, same MHC vs. full-sibs, different MHC." The results of the different experiments were compared with repeated measures ANOVA followed by Tukey-Kramer multiple comparison test. Student's *t* test ($t = \mathrm{M}Rv/\mathrm{SD}/\sqrt{N}$) was used to compare the M*Rv* for each experiment with the theoretically indifferent reaction when $\mathrm{M}Rv = 0$. $\mathrm{M}Rv = 0$ when the number of observations in each water quality is the same. $^{*}P < 0.05$.

control tests and when the fish chose between siblings of different MHC genotype ($q = 4.41$, $P < 0.05$). The Student's *t* test showed that only in experiment 2 was the M*Rv* different from the theoretically indifferent reaction when M*Rv* = 0 ($t_4 = 2.56$, $P < 0.05$, one tailed). The results show that the test fish preferred water scented by an MHC-identical sibling, but no significant preference was observed during a choice between an MHC-like nonsibling and a sibling that was different. Test fish that had been isolated since fertilization showed no significant preference between water scented by MHC-like and nonlike siblings (Figure 2).

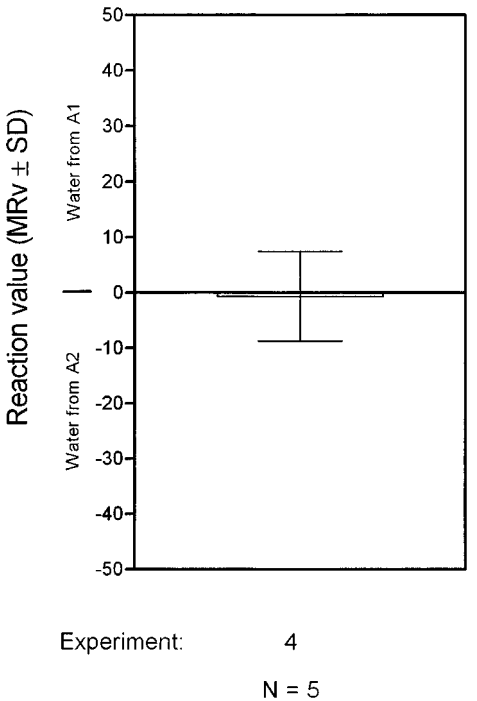

FIG. 2. In experiment 4, the test fish had been isolated since fertilization. An MHC-identical sibling scented one side of the test area and an MHC-different sibling scented the other side. For further details see Figure 1.

DISCUSSION

In the present study, we have demonstrated that juvenile Arctic char are not able (or not sufficiently motivated) to discriminate between odors from a sibling and a nonsibling when the sibling donor has a different MHC class II genotype compared to the test fish and where the nonsibling donor was identical. We also observed, as in a previous study (Olsén et al., 1998), that in tests using only siblings, the test fish prefer to be in water scented by an MHC class II-identical donor. The previous study showed also that a nonsibling with one MHC allele in common with the test fish gave no significant preference, but attraction to sibling-scented water was observed when both donors were different from the test fish but had one allele in common with each other. The results suggest that the test fish is probably guided by both MHC class II-linked odors plus odors dependent on other genes. If only MHC class II was responsible for the odors, the test fish should have chosen the water scented by the MHC-like nonsibling. The test fish had problems in choosing,

which led to an indifferent response. A likely candidate for this influence is genes in the MHC class I region, which, unlike all other vertebrates, is unlinked to the class II region in teleost fish (Sato et al., 2000). Class I genes encode membrane proteins on the outside of all cells (transplantation antigenes), and class II genes are responsible for the production of the polypeptides on the surface of B lymphocytes and macrophages that are important for the process of self-recognition capacity in other lymphocytes (Klein, 1986; Gardner et al., 1991). If the test fish used overall genetic similarity as a cue, it should have preferred the water scented by the sibling donor in all situations. This was not the case. Experiments with rodents have also shown that both MHC and other genes may have an influence on the animals' individual odors, which can be used as information about kinship (Lennington et al., 1988; Brown et al., 1989; Boyse et al., 1991; Schellink et al., 1993). Learning, as demonstrated by foster nursing, is also an important part of the mechanism (e.g., Boyse et al., 1991; Penn and Potts, 1998a). The results with isolated char also suggest that the ability to discriminate between odors from MHC class II-identical and nonlike siblings is learned. However, we can not rule out the possibility that the fish recognized the differences, but were not motivated enough to demonstrate a behavior discrimination. We know from previous studies that young Arctic char learn the odors used in sibling discrimination, and that social interactions are important and result in a more permanent ability to discriminate. (Winberg and Olsén, 1992; Olsén and Winberg, 1996).

The next step in the present study of behavioral discrimination of juvenile Arctic char will be to investigate the importance of the class I MHC regions. Furthermore, it is also of interest to analyze the significance of the commensal microflora on the odors released and detected by conspecifics. In rats, the odors of individuality have been shown to be dependent on commensal bacteria (Singh et al., 1990), and a recent study has shown that fish emit odors that are dependent on an intact bacterial flora (Ringelberg and van Gool, 1998).

(Received April 5, 2001; accepted December 5, 2001)

Abstract—Ovipositing insects may avoid aquatic sites where there is high predation risk to their offspring, but the proximate mechanisms that mediate avoidance behavior are poorly resolved. We conducted an experiment to determine whether mosquitoes would reduce oviposition rates in pools containing chemicals of the mosquitofish (*Gambusia affinis*), a voracious predator that is widely employed to control mosquitoes. Experimental treatments consisted of outdoor pools that contained known concentrations of fish chemicals (low, medium, or high) or no fish chemicals (control). The pools were arranged in a randomized block design, and the number of mosquito larvae in each pool served as the response variable to estimate relative oviposition rate. Members of the *Culex pipiens* complex were the main colonizers of the pools. The mean number of larvae per pool differed among treatments ($P = 0.026$) and was about three times greater in control pools compared with those receiving medium and high concentrations of fish chemicals. Pairwise comparisons indicate that only medium and high treatments differed significantly from controls, suggesting that a threshold concentration exists below which mosquitoes cannot reliably detect predators. Our data suggest that the effectiveness of *Gambusia affinis* in controlling mosquitoes may be compromised if adult mosquitoes respond to fish stocking by shifting to nearby breeding sites that lack fish. We discuss issues concerning the use of *Gambusia* in biological control programs within the context of these new findings.

Key Words—Chemical cues, predation, mosquitoes, *Culex pipiens*, *Culex quinquefasciatus*, fish, *Gambusia affinis*, oviposition, predator avoidance, predator detection.

INTRODUCTION

Chemically mediated avoidance is an adaptation used by prey to detect and evade predators. Weldon (1990), Chivers and Smith (1998), and Kats and Dill (1998) reviewed studies showing that fish, amphibians, reptiles, mammals, a bird, and a broad array of invertebrates have evolved chemosensory mechanisms for detecting predators. Common responses to predator chemicals include increased refuge use (e.g., Kats et al., 1988), marked changes in rate of movement (e.g., Williams and Moore, 1985; Mathis et al., 1993; Ode and Wissinger, 1993; Chivers et al., 1996; Huryn and Chivers, 1999), reduced foraging (e.g., Petranka and Hayes, 1998), reduced courtship behavior (Stein, 1979), and predator avoidance (Flowers and Graves, 1997). Prey respond more strongly to sympatric predators than allopatric predators (Mathis et al., 1993) and when natural exposure to a predator is high versus low (Kats et al., 1988). These findings suggest that natural selection may adapt prey to local predator regimes.

Kats and Dill (1998) list only 16 studies that provided evidence for chemically mediated detection of predators by insects, and almost all involve the larvae of aquatic species responding to aquatic predators. Mechanisms for predator detection by insects may involve tactile, visual, or chemical cues. Where chemical cues are involved, responses to predators are often influenced by the predator's diet. For example, mayfly and damselfly larvae are more likely to respond to fish chemicals if the fish recently consumed conspecific prey (Chivers et al., 1996; Huryn and Chivers, 1999).

Many aquatic insects have complex life cycles that include a relatively sedentary, aquatic larval stage and a volant adult stage. While searching for oviposition sites, insects may encounter an array of microhabitats or isolated habitats (e.g., individual ponds) that vary with respect to future offspring survival. Components of habitat quality that may influence offspring fitness are the density of competitors, the risk of predation, and the seasonal duration and productivity of the habitat.

Selection should favor individuals that can assess habitat quality and choose microhabitats for ovipositing that maximize offspring survival. The few studies that have addressed this question indicate that ovipositing mosquitoes and phantom midges will avoid pools containing egg or larval predators such as notonectids, odonates, tadpoles, and fish (Chesson, 1984; Petranka and Fakhoury, 1991; Blaustein and Kotler, 1993; Ritchie and Laidlaw-Bell, 1994; Stav et al., 1999). However, the proximate cues by which ovipositing insects detect predators are poorly resolved.

Petranka and Fakoury (1991) demonstrated that mosquitoes and phantom midges greatly reduced ovipositing rates in experimental pools that contained caged sunfish (*Lepomis*) that were not visible to ovipositing females. The mechanism by which mosquitoes detect fish was not determined, but chemosensory detection seemed most likely based on the experimental design. Here, we examine

whether ovipositing mosquitoes can detect the presence of a predatory fish (*Gambusia affinis*) using only chemical cues. We also examined whether female mosquitoes can use the relative concentration of predator chemicals to gauge predation risk.

METHODS AND MATERIALS

We collected mosquitofish (*Gambusia affinis*) from a pond in Mecklenburg County, North Carolina, to condition water with predator chemicals. We used three sets of plastic pools (1.3 m diameter; 0.15 m deep) for fish husbandry and water conditioning. These included a set of maintenance pools for feeding and raising fish, a set of clearing pools to allow fish to empty their guts, and a set of conditioning pools to condition the test water with fish chemicals. Pools were placed near the partially shaded edge of a field in Asheville, North Carolina, and were exposed to natural temperature fluctuations. Fish were fed and allowed to reproduce in maintenance pools that contained dechlorinated water, leaf litter, and *Elodea densa*, which provided cover and oxygenated the water. We added aquarium salts and adjusted the pH to slightly above seven with baking soda to reduce physiological stress on the fish.

We maintained fish on a regular feeding schedule of tropical fish food flakes. We did not use natural prey because many organisms use chemicals from injured conspecifics to detect predators (e.g., Chivers et al., 1996; Laurila et al., 1997; Chivers and Smith, 1998; Huryn and Chivers, 1999), and we did not want to confound the effects of predator chemicals with those from injured prey. Newborns were separated from adults to prevent cannibalism (Lloyd et al., 1986).

We began adding fish chemicals to test pools (see below) on July 7, 2000, and the experiment ran for 18 days. Prior to conditioning water that was added to test pools, we transferred fish into clearing pools containing an equal mixture of dechlorinated tap water and water filtered from other holding pools. We allowed the fish to fast and clear their guts for one day before being transferred to the conditioning pools.

We conditioned water with fish chemicals by maintaining 10 adults and 20 juvenile fish in a wading pool that contained only aged tap water and aquarium salts. We replaced 10 fish in the conditioning pools daily with fish taken from the clearing pools. These were returned to the maintenance pools for feeding and rotated through the clearing and conditioning pools as the experiment progressed. Water that was withdrawn to add to test pools was replaced daily with dechlorinated water (about 25% of the total volume) and replacement water was conditioned with fish chemicals for about 12 hr before being added to test pools.

We used a randomized block design to examine the response of mosquitoes to four experimental treatments (see below): a control that lacked fish chemicals, and low, medium, and high levels of water conditioned with fish. We set up 40 plastic

pools (1.0 × 0.2 m) in two rows in a partially shaded area of a field within 3 m of tree cover. There were 10 blocks (replicates), and the four experimental treatments were randomly assigned within each block. Each pool was filled to a depth of 10 cm, and 20 g of leaf litter was added to provide nutrients for larval growth and to attract ovipositing mosquitoes. A dead branch was placed on the side of each pool as a perch site for the females. Pools were seeded with invertebrates and microorganisms by adding 0.5 liters of water from a local vernal pond. Water from the pond was placed in a large bucket, mixed, and haphazardly assigned in 0.5-liter increments to the pools. These conditions provided an array of natural background chemicals and organisms to increase realism.

The treatments consisted of adding 2 liters of water twice daily that contained different ratios of conditioned and unconditioned water. The respective volumes (in liters) of unconditioned and conditioned water for treatments were 2:0 in control, 1.5:0.5 at low concentration, 1:1 at medium concentration, and 0:2 at high concentration. Conditioned water was taken from the conditioning pool containing 30 unfed *Gambusia affinis*, while unconditioned water was from similar pools that lacked fish and contained only dechlorinated water. Because fish chemicals will decompose with time through bacterial decay, we added 2 liters of water each day in early morning and late afternoon. The estimated dilution ratio for the high treatment was 20:1 (ratio of volume of water in pools/total volume of conditioned water added daily).

The aquatic phase of the mosquito life cycle includes four larval instars followed by a pupal molt (Gillett, 1972). Because mosquito eggs are difficult to locate in pools, we used the number of mosquito larvae as an estimate of the number of eggs laid. We terminated the experiment after the first pupa was sighted and two weeks after the first sighting of mosquito larvae. We retrieved larvae from pools by filtering out coarse debris and then filtering all water through fine-mesh plankton nets. We preserved samples in 70% ethanol and removed and counted all mosquito larvae using dissecting microscopes. We identified the fourth-instar larvae to genus and species complex.

We analyzed data by using Statistical Analysis System (SAS Institute, 1989). Preliminary analyses revealed that the assumptions of normality and homogeneity of variances were violated and could not be corrected using data transformations. We subsequently used ranked data in the analysis (PROC rank of SAS) with a general linear model. The Ryan-Einot-Gabriel-Welsch multiple range test was used for pairwise comparison of the means. The REGW test controls for a type I experimental error.

RESULTS

Early-instar larvae could not be identified, but all fourth-instar larvae identified were members of the *Culex pipiens* complex. Two sibling species (*C. pipiens*

and *C. quinquefasciatus*) occur in western North Carolina and cannot be separated by larval characteristics (King et al., 1944). Because our pools may have contained both species, we refer to all larval forms as *Culex* spp.

The mean number of *Culex* larvae per pool was highest in the control ($\bar{X} = 27.2$) and low ($\bar{X} = 38.1$) treatments and markedly lower in the medium ($\bar{X} = 8.4$) and high ($\bar{X} = 9.2$) treatments (Figure 1A). The high mean and SE for the low treatment was due to one extreme value ($N = 300$ larvae), with the second highest value for any pool being 77 larvae. Means for ranks, which better reflect central tendency, progressively decreased with the relative concentration of fish chemicals (Figure 1B).

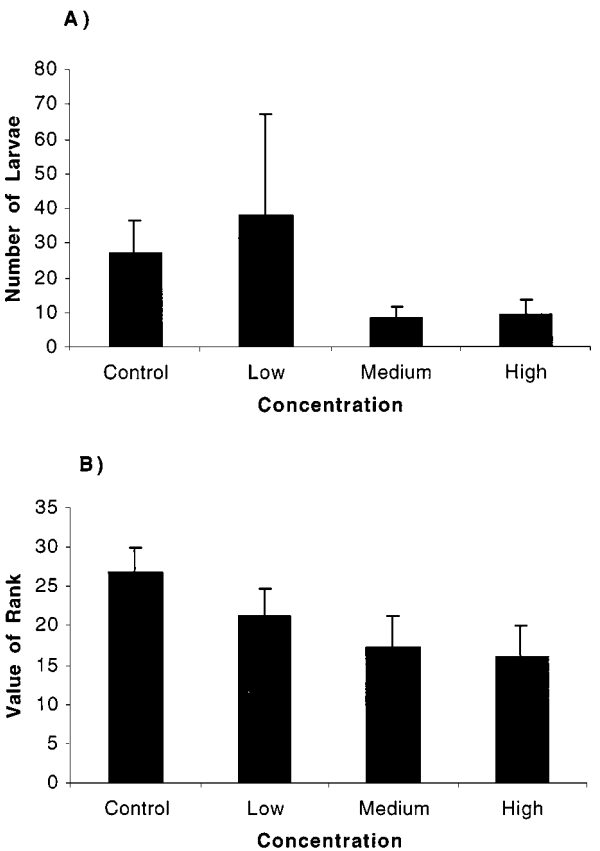

FIG. 1. Response of ovipositing mosquitoes to low, medium, or high concentrations of *Gambusia affinis* chemicals. Controls lacked fish chemicals. Bars are means +1 SE. (A) Graph is based on raw data, and (B) on ranked values.

TABLE 1. SUMMARY STATISTICS OF ANOVA FOR EFFECTS OF TREATMENTS ON NUMBER OF MOSQUITO LARVAE IN POOLS[a]

Source	*df*	Mean square	*F*	*P*
Blocks	9	313.75	4.86	0.0006
Treatments	3	232.18	3.60	0.026
Error	27	64.52		
Total	39			

[a] The analysis was conducted using ranked values. Blocks correspond to replicates.

ANOVA revealed a significant block effect ($P = 0.0006$) and significant treatment effect after the block effect was removed ($P = 0.026$; Table 1). The significant block effect was due to higher numbers of larvae in replicates that were near a shaded building that may have served as a diurnal resting site for mosquitoes. Pairwise comparisons using the REGWQ test revealed that the means for the control and low treatments did not differ significantly; however, means for medium and high concentrations differed significantly from controls.

DISCUSSION

This research is the first to demonstrate that ovipositing insects can use chemosensory mechanisms to assess predator risk to offspring. Grostal and Dicke (1999) recently demonstrated similar behavior in acarine mites, suggesting that the phenomenon may occur across a diverse array of arthropods. Kairomones or semiochemicals emitted from predators (sensu Nordlund, 1981) normally are used by prey to minimize their encounters with dangerous community associates (Kerfoot and Sih, 1987; Kats and Dill, 1998). This study extends this phenomenon by demonstrating that ovipositing females may use kairomones to make behavioral decisions that affect encounter rates of future offspring with predators. Statistically, our data only show evidence of a threshold response. However, the consistent decline in rank means with relative chemical concentration suggest that *Culex* females may be capable of making graded responses to predation risk. Dilution ratios of unconditioned water to conditioned water were as high as 80:1 in our experiment. The use of a wider range of concentrations in future studies may reveal statistically significant evidence of a graded response.

Prey species are more likely to evolve chemically mediated avoidance of predators when visual detection of predators is limited (Kats and Dill, 1998; Petranka and Hayes, 1998). In addition, prey must possess suitable behaviors and chemosensory mechanisms to detect and respond to predators. Mosquitoes appear to meet all of these requirements since many species are crepuscular or

nocturnal and rely heavily on chemosensory mechanisms when selecting oviposition sites. After mating and taking a blood meal, a hemolymph-borne hormone triggers the female to start searching for a suitable oviposition site and to become receptive to chemical signals from the site (Klowden and Blackmer, 1987). Females oviposit on mud or the water's surface (e.g., *Culex* spp.) after sampling the substrate for chemical composition using receptors on the tarsi, antennae, and tip of the proboscis (Davis, 1976; Bentley and Day, 1989).

Evidence now suggests that mosquitoes use chemosensory information to assess several parameters that reflect habitat quality for offspring, including the availability of nutrients, presence of competitors and predators, and the overall quality and permanence of the water (Davis, 1976; Angerilli, 1980; Chesson, 1984; Bentley and Day, 1989; Petranka and Fakhoury, 1991; Blaustein and Kotler, 1993; Edgerly et al., 1998). The neural mechanisms by which these are integrated to make appropriate behavioral decisions are unknown, as is the extent to which individuals can balance conflicting signals.

Chemically mediated avoidance of fish has been demonstrated for a taxonomically diverse group of prey (Kats and Dill, 1998), but the kairomones involved in avoidance have not been identified or characterized. Clearly, this remains a major challenge for fully understanding predator-specific responses and evolutionary interactions between predator and prey. Identifying kairomones associated with fish may prove to be particularly challenging because these may be omitted from the fish or from members of the microflora that inhabit the slime that covers the body.

Although we were unable to quantify chemical concentrations, the small volumes of conditioned water that we added to pools daily resulted in concentrations of chemicals that were presumably well within the range that occurs in nature. *Gambusia affinis* inhabits sluggish habitats such as swamps and roadside ditches, and forms schools that may contain hundreds of individuals. Schooling behavior produces a patchy environment in which predation risk may vary locally depending on the location of schools. Female mosquitoes could avoid *Gambusia* at several spatial scales. For example, females could use the strength of fish chemicals to avoid local sites in ponds with dense schools. Alternatively, females might strongly avoid ponds with *Gambusia* and seek out ponds that lack fish (Ritchie and Laidlaw-Bell, 1994).

Researchers have questioned the use of mosquitofish as biological controls, especially when introduced as exotics to supplement native species. Moyle (1976) showed that mosquitofish introduced in 1922 into southern California subsequently reduced populations of native fish throughout the state due to competition, predation, and hybridization. *Gambusia affinis* preys on amphibian eggs and larvae and could be contributing to certain anuran declines (Grubb, 1972; Gamradt and Kats, 1996; Komak and Crossland, 2000). Despite its reputation as being an effective predator on mosquitoes, Courtenay and Meffe (1989) concluded that *Gambusia* is generally ineffective as a biological control agent. For example, *Gambusia* had

a positive impact on controlling mosquitoes in only four of 20 countries where it was introduced for mosquito control or other reasons.

Many mosquitoes such as *Culex pipiens* and *C. quinquefasciatus* breed in small, fish-free habitats such as artificial containers (King et al., 1944), a pattern that may reflect adult choice more so than exclusion from fish ponds because of direct predation (lethal effects). Thus, one explanation for the ineffectiveness of *Gambusia* in controlling mosquitoes is that ovipositing mosquitoes may seek out fish-free habitats that adjoin large bodies of water containing *Gambusia*. The active avoidance of habitats with high predation risk to offspring may ultimately act to sustain high densities of mosquitoes near areas stocked with *Gambusia*. This hypothesis is supported by Ritchie and Laidlaw-Bell (1994), who found that ovipositing *Aedes taeniorhychus* strongly avoided sites with high densities of *Gambusia holbrooki* and shifted to adjoining habitats with few or no predatory fish.

We encourage research to more carefully examine the importance of nonlethal effects and adult choice of oviposition sites when designing mosquito control programs involving predators. We also encourage researchers to consider both evolutionary and ecological interactions between predator and prey when designing biological control programs.

Acknowledgments—We thank Tim Forrest for his assistance in identification of the larval samples and Mark O'Donoghue for supplying *Gambusia affinis*.

INTERNET PROGRAMS FOR DRAWING MOTH PHEROMONE ANALOGS AND SEARCHING LITERATURE DATABASE

JOHN A. BYERS*,†

Department of Crop Science
Swedish University of Agricultural Sciences
SE-230 53 Alnarp, Sweden

(Received March 27, 2001; accepted December 7, 2001)

Abstract—An Internet web page is described for organizing and analyzing information about lepidopteran sex pheromone components. Hypertext markup language (HTML) with JavaScript program code is used to draw moth pheromone analogs by combining GIF bitmap images for viewing by web browsers such as Netscape or Microsoft Internet Explorer. Straight-chain hydrocarbons of 5–22 carbons with epoxides or unsaturated positions of *E* or *Z* geometrical configuration with several alternative functional groups can be drawn by simply checking menu bars or checkboxes representing chain length, *E*/*Z* unsaturation points, epoxide position and chirality, and optional functional groups. The functional group can be an aldehyde, alcohol, or ester of formate, acetate, propionate, or butyrate. The program is capable of drawing several million structures and naming them [e.g., (*E*,*E*)-8,10-dodecadien-1-ol and abbreviated as *E*8*E*10–12:OH]. A Java applet program run from the same page searches for the presently drawn structure in an internal database compiled from the Pherolist, and if the component is found, provides a textarea display of the families and species using the component. Links are automatically specified for drawn components if found in the Pherolist web site (maintained by H. Arn). Windowed links can also be made to two other JavaScript programs that allow searches of a web site database with over 5900 research citations on lepidopteran semiochemicals and a calculator of vapor pressures of some moth sex pheromone analogs at a specified temperature. Various evolutionary and biosynthetic aspects are discussed in regard to the diversity of moth sex pheromone components.

INTRODUCTION

During the last few years, the Internet has become accessible to most scientists throughout the world. The quantity of information available through the Internet, or World Wide Web, is likely to grow, improve in quality, and become ever more important to research productivity and education (Byers, 1999; Zenger and Walker, 2000). Web pages are composed of hypertext markup language (HTML) code and are interpreted by web browsers such as Netscape Communicator and Microsoft Internet Explorer (IE), accounting for 37% and 61%, respectively, of 9394 visitors to the menu page, www.vsv.slu.se/cec/h.htm (during 2000, eXTReMe Tracking). JavaScript is a language, originating from Netscape Comm. Corp., that can be loaded from a web page and run by browsers to achieve a moderate level of interactivity and data processing (Goodman, 1996). Java applets (Sun Microsystems Inc.) are separately compiled programs that are called into action by the HTML or JavaScript code and run by the browser or associated software to yield a true program environment, although with security constraints so that only the screen image can be manipulated (Lemay and Perkins, 1997; Vanhelsuwé et al., 1997; Cadenhead, 1999). The use of java applet programs makes it possible to achieve full interactivity and advanced graphical applications. However, by clever use of bitmapped images, JavaScript can also produce interesting visual effects.

From 1975 to 1991 in the *Journal of Chemical Ecology*, there were 619 articles published on Lepidoptera, which accounted for 29% of the journal's reports (Byers, 1992). During the subsequent nine years, 1992–2000, this figure dropped slightly to 25% of 1840 articles. For all insect pheromone papers (1993–2000), BIOSIS Previews cites 3775 articles with 45.3% on Lepidoptera (nearly all on moths). Due to this large interest in lepidopteran pheromones, it was desirable to make a web page that draws and names most moth pheromone components and analogs by simply selecting checkboxes or buttons controlled by JavaScript code. I also wanted the web page to run a Java applet that would immediately tell the user if the drawn compound was a known pheromone component of one or more species in the Pherolist (Arn et al., 1992; Arn, 2000), the well-known web site covering moth pheromone components (www-pherolist.slu.se/index.html). If a known component is drawn, then the page should allow the user to save time by linking automatically to the specific component in the Pherolist. Another goal was to link the page to a searchable web database on moth literature citations (Byers, 2000) and a calculator of moth analog vapor pressures. The final objective was to discuss the diversity of double bond positions of moth sex pheromone components (Pherolist) and analogs

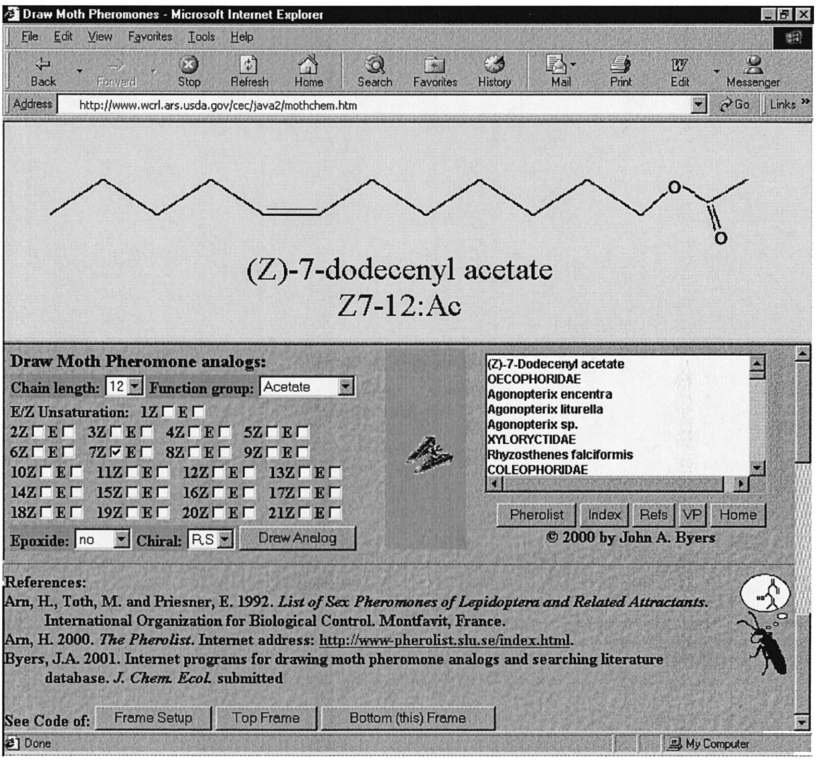

FIG. 1. Internet browser view of frames of web page that draws moth pheromone analogs in top frame based on user input in the bottom frame. Functions of various buttons and textboxes are explained in the text.

(program drawn) in regard to evolutionary and biosynthetic aspects. The web page is at the Internet address: www.wcrl.ars.usda.gov/cec/java2/mothchem.htm (Figure 1).

METHODS AND MATERIALS

The JavaScript code for drawing moth pheromone analogs is found in web frames that can be viewed by Netscape and IE by right-clicking on the frame and selecting "view source." Alternatively, the code for each frame can be viewed from pop-up windows (three buttons at bottom of lower frame, Figure 1).

To draw a molecule, the user selects a chain length from 5 to 22 from a drop-down menu with only one option selection allowed (Figure 1, lower frame). The

same input method is used for selecting the epoxide position and chirality as well as the functional group: either none, an aldehyde, alcohol, or esters of formate, acetate, propionate, and butyrate. A pair of checkboxes for each possible carbon position in the chain can be checked to designate geometrical configuration (*E* or *Z*) of double bonds. Only one box of a pair can be checked. After input is selected, the "draw analog" button is clicked. Several possible error messages may occur if an *E*/*Z* or epoxide position checkbox is selected outside the chain length or is next to position 1 of a functional group. Furthermore, adjacent positions cannot both be unsaturated nor can they be next to or within an epoxide, as these structures are chemically unlikely. Chains with unsaturation at the end opposite the functional group cannot be designated *E* or *Z* (but are delta).

The program then takes the input data and converts them to variables whose values are used to control the drawing of a molecule in the upper frame (Figure 1). The drawing is composed of an appropriate permutation of 22 bitmapped GIF images with transparent backgrounds. These are scaled according to the viewer's screen resolution and displayed from left to right such that the molecule is drawn from the highest numbered carbon toward the functional group. Six of the GIF images represent carbon–carbon bonds, 6 are for epoxides, and 10 are for different configurations of the 6 possible functional groups. The variables are also used to construct the IUPAC name, e.g., (*E*,*E*)-8,10-dodecadien-1-ol, and a short name, *E*8*E*10–12:OH. A further abbreviated name, e.g., e8e1012oh, is made and searched for in an internal database array of about 420 names. If found, as it would be in this case (codlemone), the abbreviation serves as the prefix of the HTML file name in the Pherolist in order to allow automatic linking to this file. The 420-name internal database was made by a BASIC program that extracted pheromone components (and female-produced analogs that could be drawn) from the 544 HTML files (1.5 MB) concerning components that are in the Pherolist as of June 2000.

Another feature found at the right of the lower frame (Figure 1) is a Java applet that is represented by a scrollable text area. The applet consists of a database of component names and the corresponding insect families and species that have or are attracted to the components as extracted from the Pherolist by the BASIC program. Initially the text area informs the user of the purpose of the text area and gives credits to the Pherolist. The data of the applet consists of an array of nonredundant names of families and species in no particular order, but simply as they were encountered in the 544 HTML Pherolist files on chemicals. Each of these files has the component name, as found between the beginning and ending HTML tags of the title, e.g., <TITLE>(E,E)-8,10-dodecadien-1-ol</TITLE>. Similarly, there are unique text strings that indicate the families, genera, and species reported to be attracted to or produce the component. However, the resulting extracted file was larger than 64 KB, the maximum size for a method in Java (version 1.2.2), so the information was indexed using numbers for the array of nonredundant

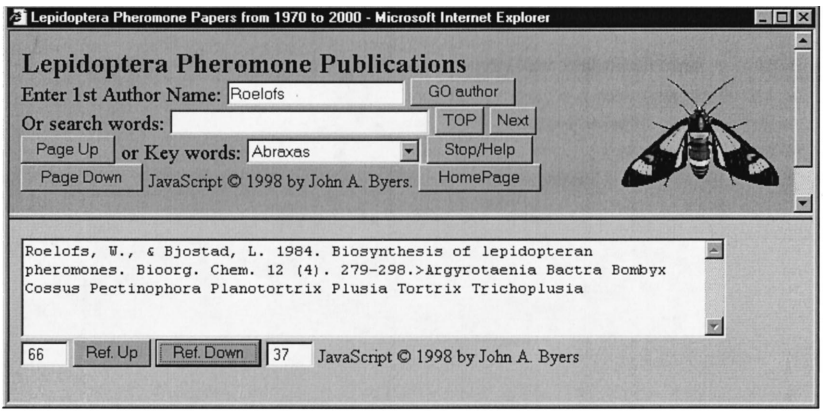

FIG. 2. Internet browser view of frames of a JavaScript database show a search for a specific citation from among currently 5912 references on semiochemicals of Lepidoptera.

species/families mentioned above. This allowed 420 components to be compared to 1716 species and families in the Java applet. Thus, when the user draws a component, e.g., (*E*,*E*)-8,10-dodecadien-1-ol, the Java applet searches its database and shows the names of all families and species attracted by this component (e.g., three subfamilies of Tortricidae and 13 species).

Another feature is a button ("Refs") that, when clicked, allows the user to open a pop-up window with two frames of a web database of citations on over 5900 papers of lepidopteran semiochemicals (Figure 2). A BASIC program similar to that reported earlier (Byers, 1992) reformatted the database, which served as input to another BASIC program that fused templet files of HTML and JavaScript code with the reformatted data to produce 92 web pages with self-searching capability by using JavaScript code and "cookies." Cookies are browser files maintained on the user's hard drive that store information that normally would vanish when the user moved to another web page. None of the literature web pages has more than 30 KB of data since it was found that data strings larger than 32 KB caused browsers to incompletely load the page. To update the list of citations, the entire database must be reformatted by the BASIC program into 30-KB blocks such that no first author is split between pages. The BASIC applications were programmed with Microsoft QuickBASIC version 4.5, while the Java applet (small application) was done with the Sun Microsystem' 1.2.2 package.

Still another feature is a button ("VP") that displays a window with a JavaScript coded calculator of vapor pressures of a few unsaturated acetate esters as well as saturated aldehydes, alcohols, hydrocarbons, and fatty acids with 10 or more carbon chain lengths (Figure 3). A compound is selected from a pop-up menu on the left and a temperature is entered on the right so that the vapor

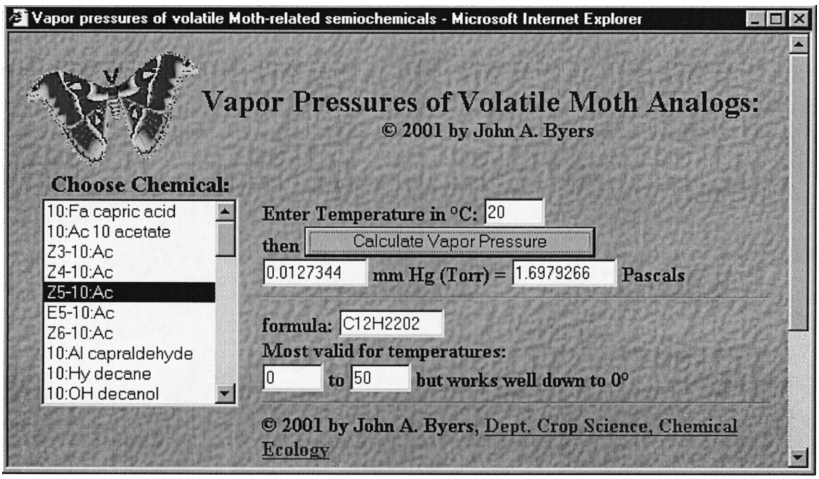

FIG. 3. Internet browser view of a pop-up window of a JavaScript web page for calculating vapor pressures of some moth pheromone components and fatty acids at different temperatures.

pressure (V) can be calculated from the equation, $V = 10^{(-0.2185\,A/K)+B}$, where V is in millimeters of mercury (torrs), A is molar heat of vaporization in calories per gram mole, K is temperature in degrees Kelvin, and B is a constant (Schlessinger, 1971). Exponential regression was used on the data of Olsson et al. (1983) to obtain vapor pressure equations for some moth acetate esters. Vapor pressures can also be estimated from boiling points at partial pressures according to the methods of Hass and Newton (1971).

RESULTS AND DISCUSSION

Operation of the web page for drawing unsaturated straight-chain hydrocarbons with various functional groups is user-friendly. Only two drop-down menu bars and possibly a few checkboxes need to be selected to draw and name the majority of natural moth pheromone components (Figure 1). The program can draw the 43 unbranched hydrocarbons with no functional group, 71 epoxides, 82 aldehydes, 66 alcohols, 167 acetate esters, and 10 other esters listed in the Pherolist. Thus, about 83% of the 528 currently listed components (produced or attractive) in the Pherolist can be drawn (16 additional analogs containing chlorine, fluorine, or nitrogen are considered unnatural). During the extraction of compound names from the Pherolist, names with "methyl," "chlor," "fluor," "one," "oate," "yn," "2-ol," "iso," "nitr," and "valer" were excluded to simplify the drawing function. Of the

71 epoxides known, all but one have one epoxide per compound and these are all *cis*-configured, being either of two chiral forms, *R,S* and *S,R*, so it was possible to include these components (Millar, 2000; Pherolist). However, the chiralities of about half of the aliphatic epoxides (all *cis*) have not been determined. Although chemists have made *trans*-configured epoxides, they have not been discovered in moths (Millar, 2000; Pherolist). One important group that was excluded contains 48 methyl-branched analogs. This group was not considered since the structures are often chiral and, thus, naming becomes more complex. The remaining 49 excluded names were: "one" (16), "oate" (13), "2-ol" (8), "iso" (6), and "valer" (1).

The program also can draw several million unused or undiscovered analogs. For example, considering 14-carbon acetate esters, there are 23 different singly unsaturated compounds, 200 doubly unsaturated ones, and 816 triply unsaturated ones (*E*, *Z*, or delta) (Byers, unpublished). Even more compounds are possible when four (1568), five (1232), and the maximum of six unsaturations (256) are considered. However, further unsaturation in a molecule would make it less stable due to chemical alteration by hydrogenation or geometric isomerization. Natural selection would not favor the evolution of a less stable pheromone component that otherwise would require continuous production of large quantities to be effective. Naturally occurring longer chain hydrocarbons have been reported with up to three unsaturations and rarely four, e.g., (*Z,Z,Z,Z*)-3,6,9,11-nonadecatetraene in *Alsophila pometaria* (Geometridae) (Wong et al., 1984) and (*Z,Z,Z,Z*)-7,13, 16,19-docosatetraen-1-ol isobutyrate in *Euproctis chrysorrhoea* (Lymantiidae) (Leonhardt et al., 1991), but none have been found with five. Theoretically, 10 unsaturations can fit within a 22-carbon chain acetate ester and be named by using the program. An analysis of the 294 unbranched naturally occurring aldehydes, acetate esters, and alcohols (Pherolist) shows that many possible permutations of unsaturations have not been reported in the Lepidoptera. There were 125 components with one unsaturation (42%) and 130 components with two unsaturations (44%). Of the latter, 77% have one single bond in between the unsaturations (conjugated), while 5% have two single bonds between the unsaturations, and 18% have more than two single bonds between. Only 16 components (5%) have three unsaturations and none have four unsaturations (only a few straight chain hydrocarbons have four).

The number of different components reported in moths to date (about 528) appears strikingly few when compared to the several million unsaturated *E* and *Z* analogs potentially available as sex pheromone components. For example, there are 1039 possible 14-carbon chain acetate ester components with one, two, or three unsaturations (*E*, *Z*, or delta) (Byers, unpublished data), but only 42 of these have been identified in moths (Pherolist; Byers, unpublished data). The limitation to essentially 1039 possible analogs may indicate this is a sufficiently large number to allow any species to evolve a unique blend from among these. However, there may not have been enough evolutionary time for speciation events to create more

divergence and use of more structures. The limitation to three or less unsaturations in components may also be due to chemical constraints such as increased instability with desaturation.

The enzyme systems for desaturation and chain-shortening involved in moth component biosynthesis (Bjostad et al., 1981; Roelofs and Wolf, 1988; Tillman et al., 1999) may have evolved in response to the inherent stability of mono- and di-unsaturated hydrocarbons as compared to less stable multiunsaturated alternatives. Probably the most obvious hypothesis to account for the relatively few unsaturations in a moth component is that the fatty acid precursors (oleic, linoleic, and linolenic acids) have one, two, or three unsaturations, respectively. However, as mentioned above, a few moths biosynthesize aliphatic chains with four unsaturations, and many odd- and even-numbered carbon bond positions can be unsaturated by the Δ5, 9, 10, 11, 12, and 14 desaturases and chain-shortening enzymes that have been discovered so far (Bjostad et al., 1981; Roelofs and Wolf, 1988; Foster and Roelofs, 1988, 1996; Zhao et al., 1990; Jurenka, 1997; Tillman et al., 1999). If there are constraints on the evolution of biosynthetic enzymes, there could also be limits on the ability of antennal receptors to discriminate among higher numbers of unsaturated bonds (and constraints on the evolution of more complexity).

The limited numbers of unsaturated positions in moth analogs might also be due to some disadvantage in using molecules with increased volatility due to higher numbers of unsaturated bonds. The double bond length between carbons is shorter than in a single bond (also the H—C bonds are shorter on double bond carbons), which makes the molecule smaller in area and, thus, more volatile (Morrison and Boyd, 1973). There are few data on vapor pressures of moth acetate esters with multiple unsaturations. Olsson et al. (1983) found that *Z*9–14:Ac (16 carbons) has a vapor pressure of 7*E*-4 mm Hg at 30.5°C, which is similar to 14-carbon myristic acid [3*E*-4 mm (Schlessinger, 1971)]. Thus, comparing 18-carbon fatty acids as models for 18:Ac, the differences in vapor pressures among 18-carbon fatty acids with none, one, two, or three unsaturations (stearic, oleic, linoleic, and linolenic acid) appear to be only about 2.5-fold using methods of Schlessinger (1971) and Hass and Newton (1971). Moth species have used pheromone components commonly with chain lengths from 18 down to 10, representing a decrease in volatility for saturated fatty acids of about 54-fold, for alcohols of about 33-fold, and for aldehydes of about 122-fold (Schlessinger, 1971; Hass and Newton, 1971). It seems doubtful that the modest increases in volatility by increasing desaturation would prevent evolution toward use of components with further unsaturation. However, no data were found to ascertain the effect of adding more than three double bonds on vapor pressures of moth pheromone components.

Ultimately, there is no selection pressure or fitness benefit to making a pheromone component more complex (more unsaturations or groups) once a unique species-specific structure has evolved. It is, however, apparently easier to combine two simpler components into a unique blend than to increase the

structural complexity of a single component pheromone to achieve specificity. It is expected that there would be costs to maintain unnecessarily complex systems for biosynthesis and reception when simpler ones suffice.

In moth pheromone components, two unsaturated bonds are always separated by at least one saturated bond, and position 1 is never unsaturated in aldehydes, alcohols, and acetate esters due to a maximum of four carbon bonds, keto–enol tautomerism, and dipole moments, respectively (Morrison and Boyd, 1973). Of the different moth 14-carbon acetate esters with two double bonds, the average number of saturated bonds separating two unsaturated bonds is 1.7 ± 0.66 (95% CL, $N = 20$, Pherolist). Theoretically, if two unsaturated bonds in a 14-carbon chain acetate ester are located in all possible ways such that they are separated by at least one single bond, then the average number of single bonds separating unsaturated bonds would be four (calculated from BASIC code: FOR W = 10 TO 1 STEP -1: FOR X = 1 TO W: C = C + X: D = D + 1: NEXT: NEXT: AVE = C/D). This expected average separation distance of four single bonds is much larger than the observed 1.7 bonds. Of the twenty 14:Ac components, 15 have one bond separation (conjugated), three have more than two bonds, and only one has two bonds between unsaturations (as does the fatty acid 9,12-linoleic acid).

It is also of interest to note that pheromone components and analogs have been identified from relatively few moth species (1683 species from 50 families, Pherolist). In North America alone there are over 65 moth families (Borror and DeLong, 1971), and the number of species worldwide is estimated to approach 185,000 (Holloway et al., 1987). The limited number of species with identified pheromone components is probably because most work has focused on pests, and these species are a small fraction. Secondly, once certain components are known, their subsequent discovery in other species is more likely because standards are more easily obtained and analytical methods for isolation and identification have already been developed. For example, an unknown exotic structure might not pass through the gas chromatographic columns in use, might occur in trace amounts, or have no comparable GC-MS standards (for identification) or commercial sources (for field bioassay).

The web site, linked closely with the Pherolist and reference database, should provide an educational experience for learning about moth pheromone components and aid in research. If a drawn pheromone component is on the Pherolist and the “Pherolist” button is clicked, a pop-up window links automatically to the compound’s web page in the Pherolist. Another button (“Index”) pops up a window displaying the main index of compounds of the Pherolist. As mentioned earlier, the button “Refs” opens a window of a database of over 5900 citations on lepidopteran semiochemicals, and this page links to several other citation databases on semiochemicals of Coleoptera (2256 citations), Hymenoptera (1724 citations), and other insects (2348 citations). The vapor pressure calculator (“VP” button) can aid in predicting appropriate release rates of components in the lab and field

in ratios depending on the mole percent in solution times the vapor pressure. For example, if components A:B have a mole percent ratio of 1:10 in solution and vapor pressure ratios of 1:100, then component B will have a 1000-fold higher release rate than A.

Acknowledgments—The study was supported in part by a grant from the Swedish Council for Forestry and Agricultural Research (SJFR). I am grateful to Heinrich Arn for introducing me to the Pherolist during his visits to Sweden. Ashraf El-Sayed, Miryan Coracini, Göran Birgersson, and Marie Bengtsson provided helpful advice.

(Received February 10, 2000; accepted December 9, 2001)

Abstract—Bats should benefit from recognition of their roost-mates when colonies form stable social units that persist over time. We used Y-maze experiments and gas chromatography–olfactometry (GC-O) to evaluate whether female big brown bats *Eptesicus fuscus* (Chiroptera: Vespertilionidae) use chemical cues to distinguish among conspecifics. In dual-choice Y-maze experiments, females chose the scent of another female from their own roost over a conspecific female from a different roost in a majority of trials. Analysis of total body odors using GC-O suggests that individuals from a given colony may share a more common odor signature with roost-mates than with non-roost-mate conspecifics. Using four principle components derived from 15 odor variables, discriminant function analysis correctly assigned most individuals to the correct colony.

Key Words—Big brown bat, Chiroptera, colony recognition, *Eptesicus fuscus*, female philopatry, gas chromatography–olfactometry, olfaction.

INTRODUCTION

Chemicals potentially provide discrete information about an animal's physical and social environment (Albone, 1984; Dusenbery, 1992). Olfactory cues may function at the individual and species level for the detection of predators and prey,

* To whom correspondence should be addressed. E-mail: kunz@bu.edu

for advertisement of social and reproductive status, as territorial markers, and for kin-recognition (e.g., Eisenberg and Kleiman, 1972; Halpin, 1986; Loughry and McCracken, 1991; Ylönen, 1994; Ferkin and Johnston, 1995).

Because many bats are highly gregarious and form stable social units (Kunz, 1982; McCracken and Wilkinson, 2000), olfactory cues may convey important information about individual or group identity (Bloss, 1999). Olfaction is important in mother–infant recognition in *Tadarida brasiliensis* (Gustin and McCracken, 1987; Loughry and McCracken, 1991), *Plecotus auritus* (De Fanis and Jones, 1995a), and *Pipistrellus pipistrellus* (De Fanis and Jones, 1996). Harem-males in *Phyllostomus discolor* respond to odors from other males (Höller and Schmidt, 1993), and *Noctilio leporinus* (Brooke and Decker, 1993, 1996), *Pipistrellus pipistrellus* (De Fanis and Jones, 1995b), *Mops condylurus*, and *Chaerephon pumilus* (Bouchard, 1998) appear to use olfactory cues to recognize roost-mates.

Recent advances in the genomics of the olfactory receptor protein (OR) have revealed a large homology among mammals (Glusman et al., 2001). Given the structural and biochemical similarities in the olfactory systems of animals as diverse as humans and insects (Acree and Bloss, 1996), and the number of odors perceived by humans that induce biological activity in other organisms (Acree and Bloss, 1996), human olfaction potentially offers a valuable tool for investigating the ecology of animals that rely on chemical cues. Because humans share the same transduction system with other mammals and are likely to detect similar odors, chemicals detected by humans should include volatiles that are biologically important to both.

Olfactory-induced behavior in mammals is elicited when mixtures of chemicals reach the olfactory epithelium (Dusenbury, 1992). The present model for humans is that all chemicals in mixtures that contribute to behavior cause some perception when experienced separately (Lawless and Heymann, 1999). Although many of the chemicals detected by humans do not influence the behavior of animals, chemicals that do affect their behavior are likely to be among those detected by humans. Using gas chromatography–olfactometry (GC-O), humans can be asked about perceptions of chemicals derived from animals, although perceptions of animals cannot be measured directly without employing invasive procedures.

This study was designed to use behavioral assays to evaluate whether female big brown bats (*Eptesicus fuscus*) respond to the odors from colonymates over non-roostmate conspecifics. If females respond to olfactory cues from colony members, we predicted that these individuals should respond to the odors to which they are most familiar. We used GC-O to test for colony-specific odors. GC to separates overall body odor into its component chemicals and employes human olfaction to identify volatiles with possible odor-induced activity.

METHODS AND MATERIALS

The big brown bat, *Eptesicus fuscus* (Pallisot de Beauvois, 1796) is one of the most common and widely distributed bat species in North America (Kurta and Baker, 1990). Females form relatively stable maternity colonies that reestablish annually following hibernation and generally persist throughout the warm months. Maternity colonies are comprised primarily of females and their young and vary in size from a few dozen to several hundred individuals. Males are generally solitary and roost separate from females. In eastern North America, females usually roost in buildings and give birth to twins in mid-June. In western North America, females more commonly roost in tree cavities and give birth to singletons (Kurta, 1999).

Maternity colonies were located in southern New Hampshire (Milford) and central and eastern Massachusetts (Sherborn, Harvard, Sterling) and sampled during June and July from 1996 to 1998. Banding records were used to assess roost fidelity during the three-year study. Colonies were located in barns and consisted of approximately 30–75 adult females and their pups. Adult females were captured using either a hand net or harp trap (Kunz and Kurta, 1988) as individuals returned from their predawn foraging bouts between 04:00 and 07:00 hr. Nonvolant young were captured by hand from the maternity roost. Body mass and length of forearm were measured for each bat, and a numbered, lipped alloy band (Lambournes, Ltd., Leominster, England) was attached to the forearm of each bat for identification. Males were banded on the right forearm and females were banded on the left.

Odor samples were collected from several adult females from five different maternity roosts. Upon capture, a sterile cotton swab was rubbed 10 times over the head, chin, chest, genital area, and wings of individual females to collect odor samples. Swabs were placed in 3.5-ml amber septum vials with Teflon-lined screw caps. The tips of all swabs were bathed in 2 ml of ethyl acetate to prevent odor degradation. Four blank swabs (no odor) were treated in the same manner and used in the chemical analysis to verify that all odors were from the individual bats and not from the cotton swabs. All vials were concentrated to a volume of 0.2 ml before analysis.

We conducted behavioral tests to evaluate whether a female preferred the odor from a member of her own colony to that of a conspecific from a different colony. In a Plexiglas Y-maze (36.5-cm-long base with 31- $\times$ 6- $\times$ 6-cm arms; Figure 1), the odor swab from a colony member was placed in one arm and a swab from a noncolony member was placed in the other arm. A coin toss determined swab placement. Females to be tested were introduced individually into the base of the Y-maze, and the amount of time that each subject spent in each arm of the maze was recorded during a 5-min trial. Because only the odor swabs were presented to the females, their preferences could not be based on auditory or visual cues. Females were never tested with their own scent or tested more than twice. Between

trials, the maze was washed with ethyl alcohol to remove potentially confounding odors from previous trials.

Results of the behavioral assays were analyzed using a one-tailed binomial test (Zar, 1984; see Loughry and McCracken, 1991). When the difference in time spent in each arm of the maze was less than 30 sec, or the female did not move from the third arm of the maze, the choice was treated as a tie and excluded from subsequent analysis (Loughry and McCracken, 1991).

Each odor sample was analyzed using gas chromatography–olfactometry (GC-O) (Acree, 1997). With GC-O, gas chromatography was used to separate the components of a chemical mixture before being diluted in the humidified air of an olfactometer and blown into the face of a human detector or "sniffer." The sniffer assigned a descriptor to the perceived odor and recorded a chromatographic retention time. With the exception of a few diastereoisomers, the retention time is distinctive for each chemical. Because the odor of most chemicals is unique, when two chemicals share the same odor as well as the same retention time, they are assumed to be the same (Acree, 1997). This made it possible for us to compare the presence or absence of like chemicals across samples. GC-O involves little sample preparation time and is often more sensitive than standard methods of chemical detection such as gas chromatography–mass spectometry (GC-MS) (Pollien et al., 1999). Because a human sniffer was used, only chemicals that have odors sensed by humans were detected using GC-O. Thus, a large group of odorless chemicals was ignored, simplifying analysis and comparison across samples.

All samples were analyzed using a GC-O system designed by DATU, Inc. (Geneva, New York). One of us (J.M.B) served as the sniffer, so that descriptors assigned to each odor could be consistent across all samples. Each sample was analyzed by GC-O in duplicate, and only those responses that occurred in both runs

were used for making colony comparisons. Samples were coded so that colony affiliation was unknown at the time of analysis.

Samples were injected (splitless mode) on a 0.25-mm × 10-m OV-101 (HP1) column held at 35°C for 5 min and then programmed at 6°C/min to 225°C in a HP 5890 modified by DATU, Inc. The effluent was sniffed in a 5-liter/min air flow at approximately 75% relative humidity, and all responses were standardized in Kovats retention indices using C_7–C_{18} normal parafins (Acree, 1997).

The presence and character of each odor was recorded as the mean retention index for the response with a single descriptor. Fifteen odors were detected and measured for each sample. In addition, the duration of odor detection was recorded by the sniffer and used as a semiquantitative measure for each odor. The duration of time that a sniffer detects an odor corresponds to the range of retention indices (peak width) over which a odor is eluted. This peak width is roughly associated with the amount of the chemical that produced the odor in the sample. Factors that may have biased these measurements include: (1) overestimation of the most polar odor caused by peak broadening on methyl silicon, (2) differences in the odor thresholds of bats and humans, and (3) selective loss of volatiles in the sampling procedure. Nevertheless, using presence or absence, an odor description and a semiquantitative measure of the amount of odor were recorded for each of 15 chemicals.

Principle component analysis was first used to collapse the 15 odor variables, followed by discriminant function analysis of the first four principle components. Cross-validation was used to estimate error rates and to control for the potential bias associated with using the same set of observations to classify as well as to generate the discriminant function (Johnson and Wichern, 1992). Principle component analysis and discriminant function analysis were conducted using the SAS statistical package (SAS Institute Inc., 1990).

The average retention index and odor descriptor for each of the 15 chemicals analyzed in this study were then compared to published OV-101 retention indices and descriptors for known compounds found on the Flavornet database (Acree and Arn, 1997). When the retention index and descriptor were identical or similar, a possible odor match was indicated. A literature search for these chemicals was conducted to determine if there was published evidence that would suggest biological activity in other systems.

RESULTS

Female big brown bats (*Eptesicus fuscus*) selected one arm of the Y-maze (difference in time spent between arms >30 sec) during 127 trials using 117 different individuals. Individual females spent more time in the arm of the maze that contained the odor from their own colony-mate in a majority (77%; $N = 98$) of trials (one-tailed binomial test; $P < 0.001$).

Our banding records indicate that many adult females and female young-of-the-year return each summer to the same maternity roost. Of 108 adult females banded in 1996, 70 were recaptured as adults at the same colony in 1997 and, among these, 34 were recaptured in 1998. Twenty-two of the 182 female pups banded in 1996 returned to their natal colony as adults in 1997. Among these 22 females, 17 females showed signs of lactation. The following year, 10 of these females were recaptured and showed signs of lactation or postlactation. Fourteen of the 230 female pups banded in 1997 were recaptured as adults in 1998, and 10 were reproductively active. Only four pups were recaptured at a colony other than the colony of initial capture. Two were individuals who moved from the Milford A to Milford B roost. The other two were adult females banded at Harvard in 1996. One was captured at Milford A, and the other was captured in Milford B in 1997. Switching between roosts was extremely rare, and those recorded may represent errors in the recording of band numbers.
