(Received April 14, 2004; accepted August 10, 2004)

Abstract—Pectinate (feathery) antennae have high resistance to air flow, and therefore most of the air approaching an antenna is diverted around it and is not available for chemical sampling by the sensory hairs on that antenna. The small fraction (approximately 10–20%) of approaching air that passes through the air spaces or gaps in the antenna decelerates and the streamlines diverge as the air approaches the antenna. Sampling a small fraction of air that is decelerating and diverging has consequences for chemoreception that are described here for the first time. The behavior of the air is predicted from application of a fluid mechanical law: the principle of continuity. As this small fraction of air decelerates and flows through the air gaps in the antenna, it will be "stretched" in the plane perpendicular to the air flow. Therefore, the air may be sampled by the sensory hairs at a greater spatial resolution than expected from the distribution of the odorant molecules in the air upstream of the antenna. However, the slowing down of odorant-laden air as it passes through an antenna will not change the perceived temporal characteristics of the chemical stimulus (e.g., the rate of odorant filament encounter). This distortion or stretching of the air sample is expected to develop within about one antennal width upstream of the antenna, as verified by examining wakes of simple physical models.

Key Words—Antenna, insect, flow, chemoreception, pheromone, pheromone plume, spatial heterogeneity.

INTRODUCTION

The pectinate insect antennae have thousands to tens of thousands of sensory hairs arrayed in complex arrangements in three-dimensional space (e.g., Steinbrecht, 1970). Whereas such a large number of chemosensory hairs should facilitate the

* To whom correspondence should be addressed. E-mail: loudon@ku.edu

capture of odorant molecules from the air, Vogel (1983) noted that such a dense array of hairs would have a high resistance to air movement and, therefore, decrease the amount of air sampled by those hairs. This has been verified for the pectinate antennae of two insect species: only 10–20% of the approaching air passed through the pectinate antennae of the luna moth, *Actias luna* (L.) (Vogel, 1983) and the silkworm moth, *Bombyx mori* (L.) (Zhang, 2001; Zhang and Loudon, unpublished). A "trade-off" exists between the amount of air processed and the efficiency with which that air is sampled by the sensory hairs. For pectinate antennae, this small fraction of air is sampled with great efficiency (Loudon and Koehl, 2000). There will be additional consequences of this particular air flow pattern that have not been considered in the literature until now.

Some general features of this diverging and decelerating air flow pattern may be predicted by applying the fluid mechanical "principle of continuity." The principle requires that air approaching a pectinate antenna will decelerate and, thus, its streamlines will diverge (splay downstream). For air containing a spatially-heterogeneous odorant, divergence will distort the plume, affecting its interception by chemosensory structures. Odorants have a patchy distribution in natural environments, with filaments of concentrated odorant interspersed with clean air (Murlis and Jones, 1981; Murlis, 1986; Murlis et al., 1990). The filamentous nature of odorants is used during orientation to odor sources by some insect species (Vickers and Baker, 1994; Willis et al., 1994; Fadamiro and Baker, 1997; Baker et al., 1998; Vickers et al., 2001).

The principle of continuity is a statement of the conservation of mass applied to a moving fluid such as air or water. If only 10–20% of the air approaching a pectinate antenna passes through, then the approaching air must diverge (the streamlines will splay) (Figure 1A and B). By definition, a streamline is tangent to the local flow at every point, which means that a streamline will not be crossed even though it is not a solid barrier. Therefore, conservation laws may be applied to a volume enclosed within a set of streamlines (a "streamtube"), and the mass of air entering this volume must be identical to the mass of air leaving this volume during the same time period (if air moleculer are not created, destroyed, or accumulated within this volume). Air volume may be substituted for mass, assuming air of constant density (valid under these subsonic, biologically-relevant conditions). It follows that the product of cross-sectional area and average velocity will be constant at every downstream location (Figure 1A). Therefore, as the cross-sectional area increases (as the streamlines diverge), the average velocity will decrease. If the flow pattern is not changing over time, a streamline will indicate the path that will be traced by an individual fluid particle as it moves downstream in the flow (see Vogel 1994, for more explanation). Any patches or filaments of odorant will be distorted in space as each patch follows its own set of streamlines, slowing and diverging. The principle of continuity predicts that patches of odorant in air approaching a pectinate antenna will be stretched in the plane perpendicular to

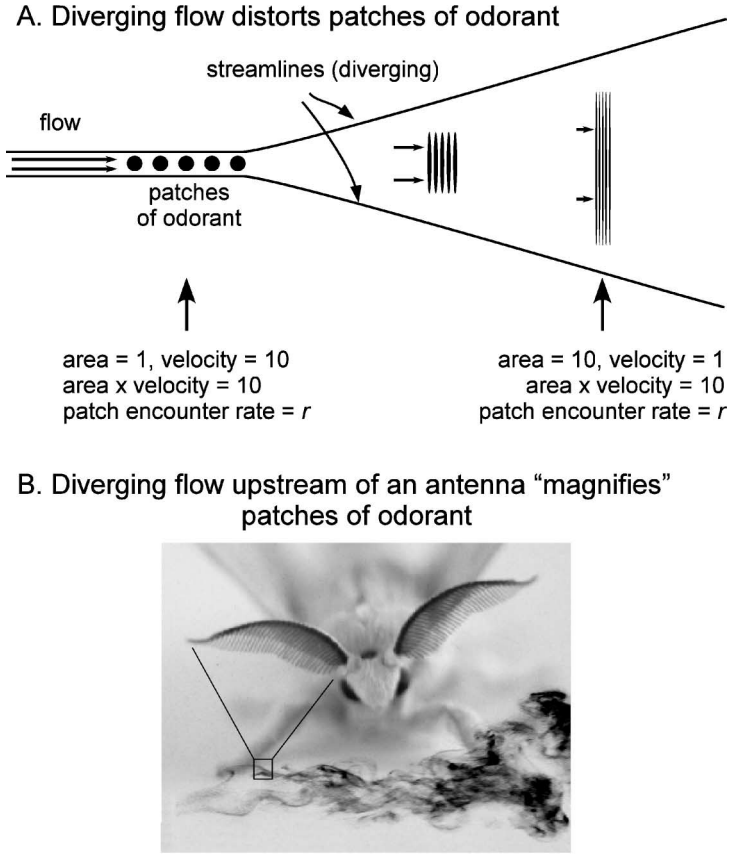

FIG. 1. (A) Patches of odorant, shown at left as black circles, become distorted in shape as the streamlines of the air diverge and the flow slows. Arrows indicate the direction of the air flow, with speed represented by arrow length. The representative values for area, velocity, and patch encounter rate demonstrate the predictions from the principle of continuity: the constant product of area × velocity (between streamlines) and the unchanging patch encounter rate. (B) The picture of the moth shows how an odorant plume will be magnified (stretched) as it is sampled by a pectinate antenna.

the direction of air flow and shortened in the direction of air flow (Figure 1A). A stretched, thinner patch of odorant will have the opportunity to strike a larger number of sensory hairs, but the patch encounter rate by an individual sensory hair is not expected to change. This is because the odorant patches are thinned and slowed by the same factor as they approach an antenna (Figure 1A).

Although the principle of continuity predicts that the air approaching a pectinate antenna will decelerate and diverge, it does not predict how far upstream of

the antenna this divergence will occur. The farther upstream the divergence occurs, the greater the opportunity for the thinner, stretched filaments (Figure 1A) to be eroded by diffusion and the less likely to be detected by the antennae as discreet filaments. It is not known where streamlines start to diverge upstream of a porous bluff body ("bluff" means nonstreamlined), such as a pectinate antenna.

In general, the location of the divergence upstream of a body will depend on the geometry and the magnitude of the Reynolds number (a dimensionless number characterizing the ratio of inertial to viscous effects in a fluid). The Reynolds number is defined as $Re = \rho L v/\mu$, where ρ is the density of the fluid, L is the characteristic length, v is the velocity, and μ is the kinematic viscosity of the fluid. The characteristic length of the object is usually measured perpendicular to the direction of flow, and the velocity of the fluid is measured with respect to the object's frame of reference (Vogel, 1994). Most of the literature on porous structures is for higher Reynolds number cases (Elder, 1959; Lau and Baines, 1968; Castro, 1971; Koo and James, 1973; Castro, 1976) in which the upstream divergence is extremely close to the body. For lower Reynolds numbers (relevant to insect antennae), diverging flow could develop farther upstream because of the increased importance of viscous effects.

To estimate where the flow diverges around porous structures for lower Reynolds numbers, we measured the flow around physical models of arrays of platinum wires. Because of the technical difficulties with accurate measurements of upstream streamlines, we measured downstream flow because it allowed us to identify unambiguously the fluid parcel that had moved through the porous array. These downstream measurements may be used to predict upstream streamlines because upstream and downstream flow patterns will be symmetrical for low Reynolds number flow ($Re < 1$). The downstream convergence will start to extend farther from the body than the upstream divergence as the Reynolds number increases above one (White, 1991). Therefore, measurements for this higher Reynolds number range ($Re > 1$) based on the downstream convergence will be a conservative estimate (in this case, overestimate) of the extent of the upstream divergence.

Dimensionless modeling was used (matching the Reynolds number of the physical model with the relevant Reynolds number for antennae) to enable comparison of the flow around the model array with air flow around insect antennae. A shift from air to water at the same Reynolds number range will not change the flow pattern geometry, which is the logic behind dimensionless modeling. The implications of the principle of continuity as described here are relevant for chemoreception in air or water.

METHODS AND MATERIALS

Physical Models and Flow Chamber. The physical model consisted of an array of platinum wires inside a fluid-filled enclosed chamber (with a glass top

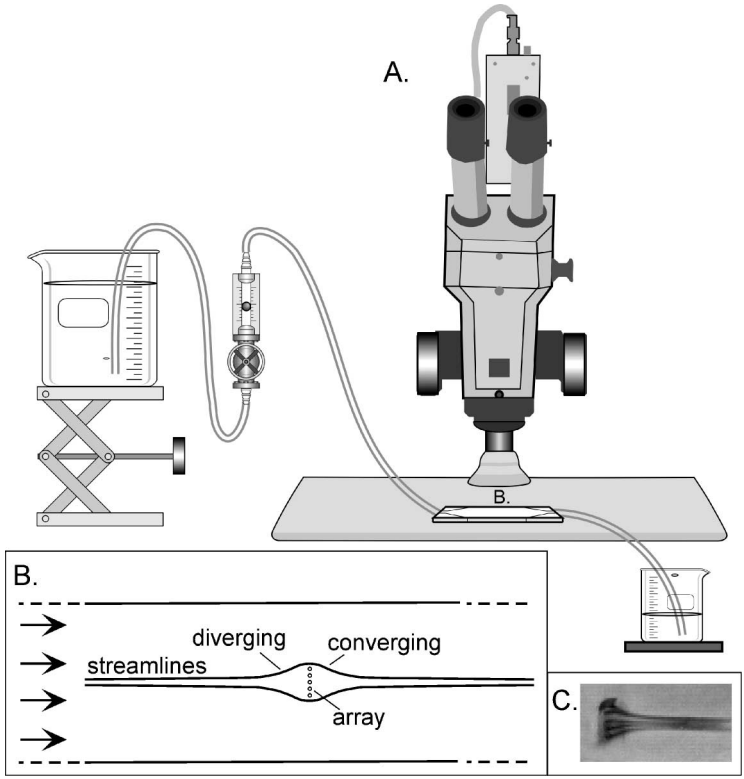

FIG. 2. Flow visualization technique: A—Experimental setup showing location of visualization chamber on microscope. B—Camera/microscope view of chamber showing array (5 parallel wires viewed end-on) and two hypothetical streamlines diverging upstream of the array (with symmetrical downstream convergence). C—Frame from videotape showing streaklines of marked thymol blue solution downstream of the array.

for viewing) (Figure 2). The array had five parallel wires (wire diam = 0.3 mm, length 3.0 mm, array width 4.28 mm). The platinum wires of the physical model were used as the anodes to mark the fluid at the array itself; a single platinum wire elsewhere in the chamber served as the cathode. The applied voltage was 1.7 V. This array was centered in a chamber of 3.0-mm height and 28-mm width (Figure 2A). Therefore, the wires completely spanned the height of the chamber to make the flow two-dimensional, and the array spanned 20% of the total cross-sectional area of the chamber. To generate higher resistance to flow (lower porosity) as a second treatment, a nylon mesh sheath was placed over the array of wires.

Gravity-driven flow of the solution through the chamber was controlled and measured by a flow meter (Manostat flow meter #2, New York). For each array

type, three different volumetric flow rates were tested, each corresponding to a different Reynolds number. For these Reynolds numbers, the flow was laminar (not turbulent). Three Reynolds numbers were used for each array type: 0.5, 1, and 3 (using chamber height, 3 mm, as characteristic length L). The volumetric flow rates were kept within 5% of the target flow rate. The complete range of fluid speeds inside the chamber ranged from 0.02 cm/sec to 0.138 cm/sec. The range of fluid temperatures was 19–23°C.

Physical Properties of Fluid Used for Flow Visualization

An aqueous solution of the pH indicator thymol blue (0.05 g thymol blue and 1.52 g NaCl in 500 ml water) was used to visualize the flow. This fluid can be "marked" electrolytically when titrated just below the pH at which it changes color from amber to blue (pH 8, Baker, 1966; Sparrow et al., 1970). We added salt (NaCl) to the original published recipe (only thymol blue in water) in order to increase the electrical conductivity of the solution and decrease the amount of hydrogen bubbles generated. The fluid was marked at the array of wires and the resulting streaklines in the chamber were videotaped (Panasonic WV-CL700 camera mounted on a Nikon Stemi SV6 dissecting microscope). The advantage of this flow visualization technique is that the marked fluid does not differ in physical properties from the unmarked fluid, and therefore will accurately represent its behavior. The marked fluid eventually reverts back to its original unmarked state; this change was imperceptible over the time period of our measurements. We tested this by repeatedly digitizing marked patches of fluid as the fluid moved downstream. The digitized areas did not change over the videotaping period (up to a minute). This was tested for three replicates for each of three different flow rates. The area of the marked fluid was not significantly affected by flow speed (ANCOVA, $P = 0.87$, $N = 9$) or distance downstream ($P = 0.98$).

The physical properties of the solution were determined within the range of fluid temperatures used in the experiments (19–23°C). The density of the solution was determined by weighing three 100 ml samples (in a 100 ml volumetric flask) at 20°C. The average density of the solution was 0.99923 ± 0.00056 g/ml (mean $\pm$ 1 SD, $N = 3$), 0.09% greater than pure water at that same temperature (0.99823 g/ml, Weast et al., 1988). Therefore, the density of pure water was used for the density of the thymol blue solution in all subsequent calculations. The viscosity of the solution was measured for three replicates at each of two temperatures (20°C and 25°C) using a Gilmont falling ball viscosimeter (Barnant Company, Barrington, IL) and it was always within 2% of the value reported for pure water (Weast et al., 1988). Comparable measurements performed on deionized water were of similar accuracy (within 3% of the published value for pure water). Therefore, the viscosity of pure water was used for the viscosity of the thymol blue solution in all subsequent calculations.

Video Analysis

Regular speed video (30 frames/sec) was digitized using motion analysis software (Motus, Peak Performance Inc., Englewood, CO). The distance between the two outermost streamlines ("width of marked fluid") was digitized at multiple locations (up to 18 locations; 3 replicates for each *Re* and resistance) downstream of the array at 1.2 or 0.25 mm intervals (the finer spatial scale was used for the less porous/higher resistance array). From these digitized points, we were able to calculate the change in width of the marked fluid as it moved farther downstream from the array. These widths were normalized to a 0–1 scale where "1" is the width of the marked fluid at the array for each porosity. When we were no longer able to measure further change in the width (successive widths differed by a pixel or less and no longer showed a monotonic trend), we considered the streamlines to have "converged" to a constant distance apart.

Statistical Analysis and Mathematical Manipulations

All statistics were performed with SAS software (version 8.2, SAS Institute Inc., Cary, NC). Exponential fits to the widths of the marked fluid (Figure 3) were calculated by using Excel's built-in exponential regression option after subtracting the constant asymptotic value (for large x). Streamlines around a sphere at low

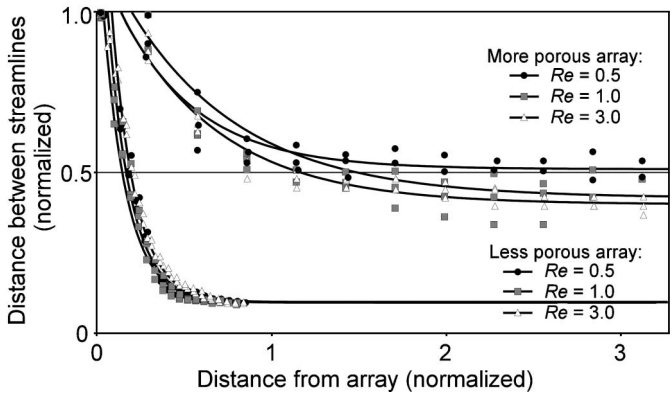

FIG. 3. Streamlines of the fluid that had passed through the array converged more rapidly downstream for the less porous array (with higher resistance to flow). The porosity (the normalized distance between streamlines far downstream of the array) did not differ within the Reynolds number range (0.5–3.0) for the less porous array, but decreased slightly with Reynolds number for the more porous array. Each symbol represents a single replicate, and the lines indicate best exponential fits to the data for each Reynolds number and array type. The distance between streamlines was normalized to the width of the marked fluid at the array, whereas the distance downstream was normalized to array width.

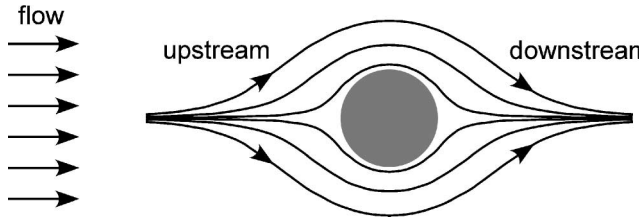

FIG. 4. Streamlines around a sphere at low Reynolds number (calculated from Stokes' equations) show the upstream/downstream symmetry expected for small bodies or in slow flow.

Reynolds number were calculated from Stokes' equations of the velocity flow field (Equation 3-214 in White, 1991) by a stepwise iterative simulation calculating the next position of a fluid particle from its current position and velocity vector (Figure 4).

RESULTS

Physical Modeling

The marked fluid downstream of the five-membered array (Figure 2C) was used to identify the locations of the streamlines of the fluid that had passed through the array (marked at the array elements). The distance between the two outermost streamlines decreased downstream of the array asymptotically to an approximately constant value (Figure 3). This value was compared to the distance between the same streamlines at the array. The streamline width ratio (width far downstream: width at array) was used to estimate the porosity of the array (the amount of approaching fluid that passes through the array). The average porosity of the high resistance array was $9.7 \pm 0.08\%$ (mean $\pm$ 1 SD, $N = 3$ *Re*) and the average porosity of the low resistance array was $44 \pm 6\%$ (mean $\pm$ 1 SD, $N = 3$ *Re*). The porosities were significantly different for the two different array resistances; the porosity of the low resistance array decreased slightly with increasing Reynolds number, whereas the porosity of the high resistance array was independent of Reynolds number for the range of parameters and resistances used (two-way ANOVA, $P < 0.001$ for array resistance, $P = 0.04$ for Reynolds number, $P = 0.04$ for the *Re* $\times$ resistance interaction term; $N = 3$ replicates for each of 3 Reynolds numbers for each resistance level).

Convergence took place within one array diameter downstream for the less porous array (entire *Re* range 0.5–3) and within two array diameters for the more porous array (entire *Re* range 0.5–3). That is, the distance between the outermost streamlines did not continue to decrease farther downstream.

DISCUSSION

It is not intuitive that a parcel of air approaching a pectinate antenna will be "stretched" in the plane perpendicular to flow, although this streamline divergence is mandated by the fluid mechanical principle of continuity. This divergence of the flow has important consequences for chemoreception by pectinate antennae because it will affect the spatial pattern with which the odorant molecules encounter the sensory hairs on an antenna. For pectinate antennae, the parcel of air will be stretched by a factor of $5x$–$10x$ because these antennae typically sample only about 10–20% of the approaching air. For example, a patch of odorant that is 1 mm^2 across (upstream) could be enlarged to 5–10 mm^2 across when it arrives at the sensory hairs. From the perspective of the sensory hairs, it appears as if the patch is magnified; i.e., a larger number of sensory hairs will encounter a patch of odorant than would be expected from the size of the patch upstream. Whether this stretching is two-dimensional (within the plane perpendicular to flow) vs. one-dimensional (along a single axis within that plane), is not known and could differ for antennae of different morphology. Note that simply changing the shape of an odorant patch (and not its volume) will not change the odorant concentration in that patch. The patch volume remains constant because as the patch is stretched in the plane perpendicular to flow, it will be shortened in the direction parallel to flow (Figure 1).

Over time, diffusion will reduce the differences in concentration between the odorant patches and the intervening clean air, making that air sample more homogeneous. The elongation and thinning of the patches that occurs during streamline divergence (e.g., Figure 1) will greatly increase the surface area of the patches and, therefore, the rate of homogenization of the air. If the streamline divergence is far upstream of an antenna, there will be more time for this diffusion-driven homogenization to occur, and the potential information in the filamentous odorant pattern could be lost or diminished far more rapidly. In addition, this homogenization may lower the concentration to a level below the detection threshold of the sensory array. To obtain an accurate picture of the extent to which a patchy or filamentous odorant pattern may linger or be obliterated, it is important to determine how far upstream of an antenna the streamline divergence will take place. The principle of continuity does not specify the location of streamline divergence, but only that it will occur.

It is reasonable, as a first approximation, to assume that flow around a slightly porous structure (such as a pectinate insect antenna) might resemble flow around a solid object with the same outer dimensions. The velocity flow field around a solid sphere at low Reynolds number is a classic solution in fluid mechanics (Stokes' equations, Equation 3-214 in White, 1991; see streamlines calculated from these equations in Figure 4). However, flow through or around porous structures may sometimes exhibit complex or unexpected behavior, such as the pulsatile flow

generated by vortex shedding of a cylindrical array for certain combinations of geometry and flow conditions (Leonard, 1992), or the "pathological behavior" of the mathematical solutions for low Reynolds number flow through porous pipes (referring to lack of solutions, or multiple sets of double solutions, p. 148, White, 1991). In low Reynolds number flow, objects may have surprisingly large velocity boundary layers or may "feel" other objects or walls from very far away (Happel and Brenner, 1965; Loudon et al., 1994). The lack of published detail on streamline divergence upstream of porous objects in low Reynolds number flow supplied the motivation for making direct estimates of streamlines using physical modeling.

Theoretically, the distance between diverging (or converging) streamlines around an isolated body in an unbounded medium (Figure 4) will continue to approach a limit indefinitely, making it impossible to define a location at which divergence starts. In practice, however, it is useful to consider when most (90%) of the divergence (or convergence) has occurred. This definition is similar to the recommendation made by Vogel (1994, 2003) to use 90% of free stream velocity for identifying the depth of the velocity boundary layer (rather than the 99% definition used by fluid mechanical engineers). For example, streamlines passing closely around a solid sphere at low *Re* ($Re < 1$, streamlines passing within 5% of the sphere's diameter), will have converged 90% within one radius downstream of the sphere's surface (Figure 4, innermost streamlines).

Results from the physical modeling make it clear that most of the divergence of the air is likely to take place immediately upstream of a pectinate antenna for biologically relevant antennal morphologies and air flows. Therefore, there will be little chance for the increased homogenization of filaments and clean air caused by far-upstream diverging flow and distorted odorant patches. A pectinate antenna has porosity more similar to the "less porous" array used for these measurements, and, therefore, the divergence of the air is expected within about one array diameter upstream.

The experimental Reynolds number range (0.5–3) corresponds to cases of extremely slow flow or very small antennae, such as 1-mm wide antennae in air flows of a few cm/sec (calculated from the formula for *Re* given above, using $\rho/\mu = 15 \times 10^{-6}$ m^2/sec). For larger Reynolds number flow (larger antennae or faster air flow), the upstream divergence is expected to be even closer to the antenna (within one antennal width). No evidence was seen for complex or unexpected flow behavior; the streamlines converged smoothly downstream in a manner similar to streamlines downstream from a solid sphere in low Reynolds number flow (compare Figures 3 and 4).

Some pectinate antennae are flat (planar) and are held perpendicular to the oncoming air, similar to our experimental array (e.g., luna moth antennae, *A. luna*), whereas others are curved or bent in a "V" shape, such as antennae from gypsy moths [*Lymantria dispar* (L.)] and silkworm moths (*B. mori*), and are held with the

concave "V" oriented approximately upstream. While details of the streamlines passing through these antennae remain unexplored, experiments with curved or tilted screens placed in a flow field show that the streamlines approaching a screen surface tend to bend such that the flow always passes perpendicularly through the screen (Elder, 1959; Lau and Baines, 1968; Koo and James, 1973). In an analogous manner, the streamlines flowing through a curved or bent pectinate antenna are likely to deflect and pass through the mesh-like structure at right angles.

A physical model will capture the essential flow behavior at the antennal level if its Reynolds number (based on the whole antenna) and porosity are matched by the model, and if its geometry is similar. Therefore, the divergence pattern reported here will be most closely approximated by the flow approaching flat pectinate antennae, and will be similar to the flow approaching curved or "V" shaped pectinate antennae. Whereas the flow through an antenna could be affected by the presence of nearby surfaces including the head of the insect, we do not expect the streamlines to diverge in a qualitatively different manner from that described here. Flow through an antenna positioned into the flow is less likely to be affected by the proximity of the head.

The results presented in this paper are of interest when the odorants in the environment are of a patchy distribution and where the patches are much smaller than the antennae. If the odorant concentration is uniform everywhere (which is approximately true when the patch size greatly exceeds the size of the antenna), any divergence or mixing (within the patch) will have no effect on the odorant concentration at the sensory hairs. Sensory hairs on pectinate antennae are individually innervated (Steinbrecht, 1987, 1999) but are so small and close to each other that spatial heterogeneity in the odorant concentration at their spatial scale will only be meaningful in fast air flows, such as those generated during flying; i.e., for slow air speeds, the "random walks" taken by individual odorant molecules passing between sensory hairs exceed the distance between adjacent hairs (Loudon and Koehl, 2000). There is behavioral evidence for the importance of small scale sampling (within an antenna) by species with filamentous antennae (Liu and Haynes, 1992; Baker et al., 1998) although this is not yet demonstrated for an insect with pectinate antennae. How filamentous antennae stretch or distort an odorant pattern is not known, but the work of Schneider et al. (1998) with the sexually dimorphic antennae from *Manduca sexta* (L.) suggests that this small difference in antennal morphology will change the way in which chemicals are sampled. It is clear that pectinate antennae sample a "magnified" piece of the olfactory landscape, without much homogenization of this magnified patch. The prediction that the temporal pattern of filament interception will remain unchanged has recently been tested and verified by electroantennography on *B. mori* and *L. dispar* antennae (Bau, et al., in review).

Acknowledgments—This research was funded by a grant from the National Science Foundation to CL (IBN 9984475). We thank Bill McGregor and the Physics Shop for construction of the flow chamber with the platinum wire array. J. Botz, G. Miller, and two anonymous reviewers made constructive suggestions on the manuscript.

(Received August 12, 2003; accepted August 10, 2004)

Abstract—Mated female *Heliothis virescens* and *H. subflexa* were induced to produce sex pheromone during the photophase by injection of pheromone biosynthesis activating neuropeptide (PBAN). When injected with 1 pmol *Hez*-PBAN, the total amount of pheromone that could be extracted from glands of mated females during the photophase was similar to that extracted from virgin females in the scotophase. The PBAN-induced profile of pheromone components was compared between mated, PBAN-injected females and virgin females during spring and fall. Virgin females exhibited some differences in the relative composition of the pheromone blend between spring and fall, but no such temporal differences were detected in PBAN-injected, mated females. Because the temporal variation in pheromone blend composition was greater for virgin females than for PBAN-injected females, PBAN can be used to determine a female's native pheromone phenotype. This procedure has the advantages that pheromone glands can be extracted during the photophase, from mated females that have already oviposited.

Key Words—*Heliothis virescens*, *Heliothis subflexa*, sex pheromone, PBAN, temporal variation.

INTRODUCTION

The sex pheromones of many moths are 12–18 carbon unsaturated derivatives of fatty acids, with an oxygen-containing functional group. Species specificity of the pheromone signal is achieved by the presence of specific pheromone components,

*To whom correspondence should be addressed. E-mail: astrid_groot@ncsu.edu

and the relative amounts of these components in the pheromone blend. For example, most noctuid moths in the genera *Heliothis* and *Helicoverpa* use (*Z*)-11-hexadecenal (Z11-16:Ald) as the major component of their pheromone blends, but vary the types and relative amounts of minor components (e.g., Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Klun et al., 1980a,b, 1982; Teal et al., 1981, 1984; Pope et al., 1982, 1984; Ramaswamy et al., 1985; Vetter and Baker, 1984; Heath et al., 1991; Choi et al., 2002). The closely related *Heliothis virescens* (*Hv*) and *H. subflexa* (*Hs*) both produce small amounts of hexadecanal (16:Ald), (*Z*)-7-hexadecenal (Z7-16:Ald), and (*Z*)-11-hexadecenol (Z11-16:OH). In addition, *Hv* females produce tetradecanal (14:Ald) and (*Z*)-9-tetradecenal (Z9-14:Ald) that are generally not found in *Hs*, whereas *Hs* females produce (*Z*)-9-hexadecenal (Z9-16:Ald) and three acetates, (*Z*)-7-hexadecenyl acetate (*Z*7-16:OAc), (*Z*)-9-hexadecenyl acetate (*Z*9-16:OAc), and (*Z*)-11-hexadecenyl acetate (*Z*11-16:OAc). Whereas the acetates are completely absent in the glands of *Hv*, Z9-16:Ald can be found in trace quantities. Even though a number of studies have been conducted to determine the pheromone compositions of *Hv* (Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Klun et al., 1980; Pope et al., 1982; Heath et al., 1991) and *Hs* (Teal et al., 1981; Tumlinson et al., 1982; Klun et al., 1982; Heath et al., 1991), the female pheromone component emission ratios and rates, and the relative importance of various blend components to males, have not been fully resolved (Vickers, 2002).

Well-characterized pheromone systems in closely related, interfertile congeners offer a powerful tool for studying the genetic bases of both pheromone production and male response to different pheromone components. Understanding the genetic mechanisms underlying sex pheromone production can in turn enhance our understanding of the evolution of divergent sexual communication systems (e.g., Löfstedt, 1990, 1993; Butlin, 1995; Linn and Roelofs, 1995; Phelan, 1997; Coyne and Orr, 1998). Teal and colleagues (Teal and Oostendorp, 1995a,b; Teal and Tumlinson, 1997) recognized that *Hv* and *Hs* offer such a model: these are closely related species that can be hybridized (Laster, 1972; Prosholt and LaChance, 1974; Sheck and Gould, 1993, 1995, 1996), although their pheromone compositions differ. Recently, we initiated studies aimed at identifying genes that regulate the species-specific pheromone profiles of *Hv* and *Hs*. By hybridizing these species, followed by backcrossing to one of the parents, genes from one species have been introgressed into the genetic background of the other species. We used amplified fragment length polymorphism (AFLP) analysis to genotype each female (Sheck et al., unpublished), while her pheromone phenotype was determined by chemical analysis of the pheromone gland. Central to this approach were the requirements that each female be sampled for both DNA and pheromone, and that she produce viable progeny for the next round of genetic crosses. However, this approach is confounded by the temporal dynamics of pheromone production: females must mate and oviposit to produce progeny, but pheromone production is reduced

dramatically after mating. Preliminary data showed that in some backcrosses, the glands of less than half of the females contained more than 50 ng of pheromone (A. Groot, unpublished data), even though the glands were extracted during the scotophase, when the pheromone titer is maximal. When gland extracts contained less than 50 ng of total pheromone, we found it impossible to accurately analyze the amount of the minor pheromone components.

Several approaches can be used to obtain pheromone before females mate, without interfering with subsequent mating and oviposition. These include (a) headspace collection and analysis, (b) solid phase microextraction (SPME) analysis, or (3) non-debilitating microdissection and extraction of a portion of a virgin female's pheromone gland. However, all are laborious, time-consuming, expensive, or preclude storage of many samples prior to pheromone analysis. Because pheromone biosynthesis activating neuropeptide (PBAN) stimulates sex pheromone production in female moths (Raina et al., 1989), it appeared promising for determining the pheromone phenotype of individual females by stimulating pheromone production *after* oviposition. Indeed, a common assay of its activity is to induce pheromone production during the photophase, when the pheromone titer is normally minimal in nocturnal moths (reviews: Rafaeli, 2002; Rafaeli and Jurenka, 2003). Furthermore, Teal et al. (1993) demonstrated that PBAN-injected *Hv* and *Hs* females were induced to produce sex pheromone during the photophase; Teal and Oostendorp (1995b) extended these observations to *Hv-Hs* hybrid females. However, only Z11-16:Ald, the major sex pheromone component, was analyzed by Teal and colleagues. Because our genetic analysis required quantification of all the pheromone components, it was important to establish whether PBAN elevated production of all pheromone components in naturally occurring ratios.

Several studies have examined variation of the pheromone blends in virgin *Hs* and *Hv* females. Pope et al. (1982) determined the temporal variation in the pheromone blend emitted by *Hv* throughout the night, and Heath et al. (1991) examined the periodicity of both pheromone gland content and its emission in both *Hv* and *Hs*. Both studies found variation in the alcohol/aldehyde ratios during the scotophase, and maximal pheromone titers and release between the 4th and 8th hour of the scotophase, although *Hs* seemed to produce maximum amounts of pheromone earlier in the scotophase than *Hv* (Heath et al., 1991). Pheromone production and composition may vary not only during the night, but also during the flight season. In this study, we aimed to determine whether the blend composition in PBAN-induced mated females at a given sampling time was similar to that found in untreated virgin females, and whether any differences between the two types of females were comparable in magnitude to differences across sampling times among virgin females. We compared the amount of pheromone produced, as well as the pheromone profile, in the glands of both *Hs* and *Hv* during two periods: spring and fall.

METHODS AND MATERIALS

Insects. Hv and *Hs* were reared on artificial diet as described in Sheck and Gould (1993, 1995). Pupae were separated by sex, and placed under a reversed light cycle (14L:10D, lights off from 04:00 to 14:00). Newly eclosed adults were collected daily and placed in plastic containers (diameter 11 cm, height 8 cm) with sugar water.

Pheromone Gland Extractions: Virgin Females. In April and May, 2002 (denoted "spring treatment"), the glands of 14 *Hs* and 7 *Hv* females were dissected 2–4 d after eclosion and 4–7 hr into the scotophase. The glands were placed in conical vials containing 50 μl hexane and 20 ng of 1-pentadecanol acetate as internal standard. After 20–60 min, the glands were removed and the extracts were stored at -20°C until analysis. Variation of pheromone composition was evaluated by repeating these extractions in September and October 2002 (denoted "fall treatment"), during which glands of 12 *Hs* females and 18 *Hv* females were dissected in a similar way.

PBAN-Injections and Pheromone Gland Extractions: Mated Females. Upon eclosion, single *Hs* and *Hv* females were confined with conspecific males. The mating buckets were checked daily for oviposition, and females were allowed an additional 4 d to oviposit before they were injected with PBAN. Males were kept in the mating buckets the entire period, which allowed for multiple matings.

A stock solution of *Hez*-PBAN (Peninsula Laboratories, San Carlos, CA) (200 pmol/μl in 50% methanol and 1 N HCl) was diluted in saline (Kurtti and Brooks, 1976) within 24 hr of injection to 1pmol/μl. Females were injected during the photophase with 1 pmol PBAN in 1 μl, using a 10 μl syringe (Hamilton, Reno, NV) with a 31 gauge needle that was inserted ventrally between the 8th and the 9th abdominal segments. One hr after injection, the pheromone glands were dissected and extracted as described for virgin females. This procedure was conducted in the spring and in the fall, in the same periods as the virgin females. A total of 37 mated *Hs* females were subjected to this procedure (23 and 14 in the spring and fall, respectively), while a total of 23 mated *Hv* females were used and analyzed (9 and 14 in spring and fall, respectively).

Gas Chromatography (GC) and GC-Mass Spectrometry (MS). The hexane extracts were reduced to 0.5–1.5 μl under a gentle stream of N_2. Each sample was injected into a pulsed splitless injector held at 240°C in an HP6890 GC (Agilent, Palo Alto, CA), and separated using a 30 m $\times$ 0.25 mm $\times$ 0.5 μm Stabilwax column (Restek, Bellefonte, PA) programmed from 60°C (with a 2 min hold) to 180°C at 30°C/min, then to 230°C at 2°C/min, during which all the pheromone components eluted. The column was then heated to 245°C at 20°C/min and held at 245°C for 5 min to clean it before the next analysis. The FID detector was held at 240°C. The amount of each pheromone component was calculated relative to the 20 ng of internal standard. The components we quantified were: 14:Ald, Z9-14:Ald, 16:Ald,

Z7-16:Ald, Z9-16:Ald, Z11-16:Ald, Z7-16:OAc, Z9-16:OAc, Z11-16:OAc, and Z11-16:OH. Most chromatographic analyses did not separate Z7-16:Ald from Z9-16:Ald. Therefore, we combined the peak areas of these compounds and denoted the combination as Z7/9-16:Ald, even though Z7-16:Ald is present only in low amounts in both species, and Z9-16:Ald is present in relatively large amounts in *Hs*.

The chemical identities of all pheromone components were confirmed by GC-MS. Aliquots of these extracts were injected into an HP5890 GC, and separated using a 30 m $\times$ 0.25 $\times$ 0.5 μm DB-Wax column or a DB-225 column (both from J&W Scientific, Folsom, CA) temperature programmed from 60°C (with a 1 min hold) to 230°C at 10°/min and held for 10 min. The eluted compounds were detected with an HP5972 mass selective detector, and mass spectra were compared to those of known standards injected in the same manner. Further GC-MS analysis of the 14-carbon aldehydes was conducted on a G1800A GCD (Agilent, Palo Alto, CA) equipped with a 60 m $\times$ 0.25 mm $\times$ 0.25 μm DB-23 column, programmed from 130°C (1.5 min hold) to 170°C at 6.5°/min, then to 210°C at 2.5°/min, and to 240°C at 10°/min, followed by an 11 min hold.

Statistical Analyses. First, the total amount of pheromone extracted from the pheromone glands of virgin and PBAN-injected mated *Hs* and *Hv* at the two sampling periods was compared between species, treatments (virgin vs. PBAN-injected, mated females) and periods (spring vs. fall). The total amounts of pheromone were log-transformed and subjected to 3-factor analysis of variance (ANOVA) in which the factors species, treatment, and period were treated as fixed. ANOVA was carried out using the GLM procedure of SAS (SAS, 2002). Specific comparisons between virgin females and PBAN-injected mated females were carried out as appropriate, depending on the presence of interaction between treatments and the other two factors. To test for differences in variability among individuals in the total pheromone amounts, a generalization of the Lev1:med test (Conover et al., 1981; Boos and Brownie, 1989) was used to test for main and interaction effects of the factors species, treatment, and period, on the measure of variation corresponding to the average absolute deviation from the median. This test is robust to non-normality of the data, and is essentially a 3-factor ANOVA on $Z_{ij} = |Y_{ij} - median_i|$, where Y_{ij} is the total pheromone for the jth individual in the ith group, and $median_i$ is the median of the ith group, a group being one of the eight species-treatment-period combinations.

Second, the impact of PBAN on ratios of pheromone components was tested. The relative percentage of each of the components was calculated by setting the total amount of all pheromone components to 100%. The three C_{16} acetates were summed and treated as one component, the sum of acetates, to reduce the number of comparisons. All values were then log-transformed to stabilize the variance. When we compared *Hv* with *Hs*, large differences were found between the means and the variances of most pheromone components. Therefore, only intraspecific differences were analyzed further. Within each species, the following comparisons

were made, using multivariate ANOVA (MANOVA): (a) Differences in overall pheromone composition between treatments, (b) Differences in overall pheromone composition between periods, and (c) Interaction effects between treatments and periods. These overall comparisons were followed by a univariate ANOVA for each component separately, with separation of means using Tukey's adjustment for multiple comparisons. Comparisons between virgin females and PBAN-injected mated females in the same period were of primary interest, but comparisons across periods were also of interest to provide information about the magnitude of temporal differences.

RESULTS

Our GC and GC-MS results confirmed the presence of 14:Ald and Z9-14:Ald in *Hs* females (data not shown). The retention times of each of these two compounds on both polar (Stabilwax) and non-polar (HP-1) GC columns were coincident with the retention times of the respective authentic sample. The parent ions of 14:Ald and Z9-14:Ald were not detected, but for 14:Ald, *m/z* 194 ($M^+ - 18$) and 168 ($M^+ - 44$) were diagnostic. The mass spectrum of Z9-14:Ald showed $M^+ - 18$ at *m/z* 192, which is characteristic of C_{14} monounsaturated aldehydes. Based on these results, together with the earlier identification by Klun et al. (1982), we are confident that both 14:Ald and Z9-14:Ald were present in *Hs* females.

Injection of 1 pmol of *Hez*-PBAN into mated, post-oviposition *Hs* and *Hv* females during the photophase resulted in a total amount of extractable pheromone in the range of that found in virgin females during the scotophase (Table 1). The only significant effects were the Species × Period and Species × Treatment × Period interactions ($P = 0.004$ and $P < 0.001$, respectively). Pheromone glands of virgin *Hs* females in the spring contained significantly more pheromone than those of PBAN injected, mated *Hs* females in the same period, but the difference between virgin *Hs* females in the spring and fall (i.e., a temporal effect) was of similar magnitude to the treatment difference in the spring (Table 1). In contrast to the significant temporal effect for virgin *Hs* females, the PBAN-induced pheromone titers in mated females of both species were not influenced by the sampling period. More importantly, the amount of pheromone extracted during the photophase from glands of mated, post-oviposition females injected with PBAN was sufficient, i.e., $\gg$50 ng, for accurate analyses of pheromone blend composition.

Analysis of absolute deviations from the median using the Lev1:med test (Conover et al., 1981; Boos and Brownie, 1989) yielded a marginally significant ($P = 0.058$) treatment main effect. Mean absolute deviations presented in Table 2 suggest that variation in the amount of pheromone produced among females of the same species within a period was higher in virgin females than in PBAN-induced mated females. Values in Table 1 for the coefficient of variation also suggest that PBAN reduced variation in pheromone titers.

TABLE 1. AMOUNT OF PHEROMONE EXTRACTED FROM THE GLANDS OF VIRGIN FEMALES, AND MATED FEMALES INJECTED WITH 1 PMOL PBAN AFTER THEY HAD OVIPOSITED FOR 4 DAYS[a]

Source	Period	*N*	Total pheromone per female (ng), mean ± SEM (CV)	
H. subflexa	Spring	13	Virgin	414 ± 72 (63) **a**
		23	Mated + PBAN	201 ± 21 (50) **b**
	Fall	13	Virgin	166 ± 41 (90) **b**
		14	Mated + PBAN	231 ± 28 (46) **ab**
H. virescens	Spring	7	Virgin	196 ± 44 (59) **A**
		9	Mated + PBAN	260 ± 37 (43) **A**
	Fall	18	Virgin	317 ± 46 (61) **A**
		14	Mated + PBAN	279 ± 35 (47) **A**

[a]Within a species, means without a letter in common differ significantly ($P < 0.05$), using Tukey's procedure for multiple comparisons on log-transformed total amounts. ng: nanogram, SEM: Standard error of the mean, CV: Coefficient of variation.

When comparing the overall profiles per species using MANOVA, a significant difference was found between virgin females and PBAN-injected mated females, averaged over periods, for both *Hv* and *Hs* (Table 3). Overall pheromone profile differences between periods were not found in *Hv*, but were significant in *Hs*. Overall interaction effects between treatment and periods were found for both *Hv* and *Hs* (Table 3).

To determine which components contributed to these overall differences, results of separate analyses on each component are presented in Table 3. In *Hv*, significant treatment main effects were found for 14:Ald and Z11-16:OH (see Table 3 and Figure 1). Examining the means for these components showed that,

TABLE 2. VARIATION, MEASURED BY THE MEAN ABSOLUTE DEVIATION FROM THE MEDIAN, IN TOTAL PHEROMONE AMOUNTS EXTRACTED FROM THE GLANDS OF VIRGIN FEMALES, AND MATED FEMALES INJECTED WITH 1 PMOL PBAN AFTER THEY HAD OVIPOSITED FOR 4 DAYS

Source	Period	*N*	*z* mean ± SEM[a] (ng)	
H. subflexa	Spring	13	Virgin	175 ± 53
		23	Mated + PBAN	82 ± 13

[c] Absent in *Hv* females.

although statistically significant, the difference in the relative percentages was small for 14:Ald, i.e., 0.8%. The difference in Z11-16:OH between virgin and PBAN-injected *Hv* was bigger (6.7%), which is due to the relatively high amount of Z11-16:OH in virgin *Hv* females in spring.

In *Hs,* significant differences were found for all components except Z11-16:OH (Table 3). The percentages of 14:Ald, 16:Ald, and Z11-16:Ald were significantly lower in fall than in spring, whereas the percentages of Z9-14:Ald and Z7/9-16:Ald were significantly higher in fall than in spring (see Figure 1). Also, significant differences were found between virgin *Hs* females and PBAN-injected, mated *Hs* females (Table 3). Despite these differences, the relative percentages of the different compounds found in virgin or PBAN-injected mated *Hs* females overlapped in at least one of the periods (Figure 1).

DISCUSSION

Our results demonstrate that mated *Hs* and *Hv* females injected with 1 pmol PBAN during photophase produced pheromone at levels and ratios comparable to those produced by virgin females during the scotophase. It is likely, based on dose-response studies (Raina et al., 1989; Abernathy et al., 1996), that injection of more PBAN would have stimulated mated females to produce more pheromone.

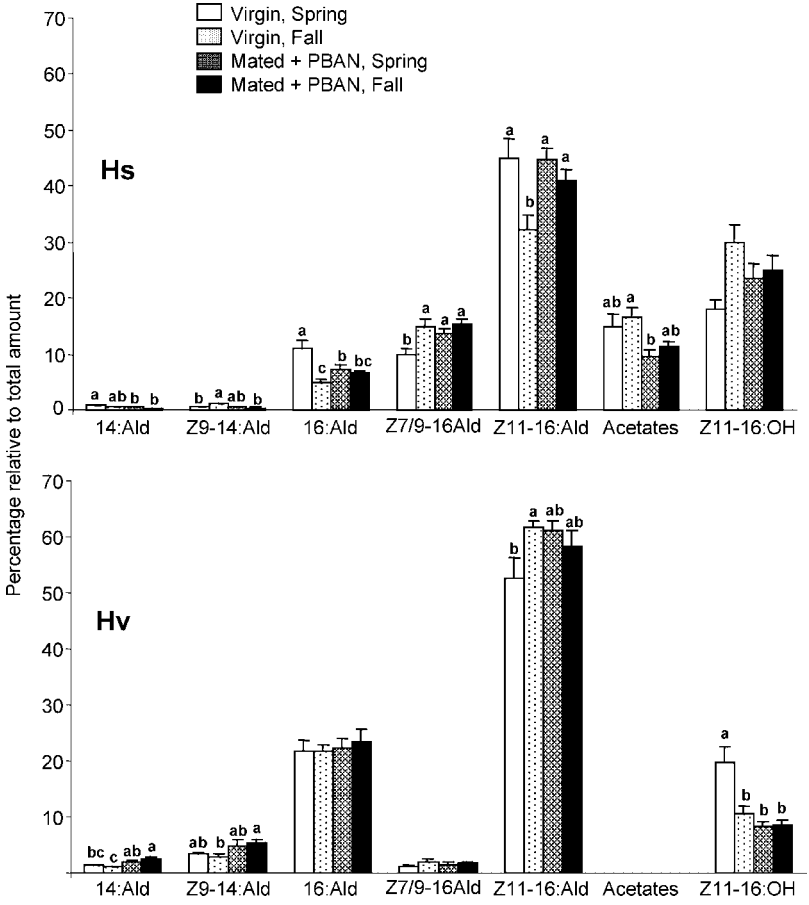

FIG. 1. Pheromone profiles (mean ±SEM) of *H. subflexa* (***Hs***, upper graph) and *H. virescens* (***Hv***, lower graph) when the relative abundance of each component is calculated as a percentage of the total amount of pheromone. Different letters within each component indicate significant differences ($P < 0.05$), using a Tukey adjustment for multiple comparisons. No letters: not significant. See text for further explanation.

Our results also demonstrate that PBAN-induced mated females produce and accumulate pheromone of comparable blend quality to that of virgin females. This is not surprising given our current understanding of the enzymatic steps affected by PBAN. In most species, including *H. zea*, PBAN appears to affect steps in or prior to fatty acid synthesis (e.g., Jurenka et al., 1991; Jurenka, 1996; Teal et al., 1996; reviews: Tillman et al., 1999; Rafaeli, 2002; Rafaeli and Jurenka, 2003). In

some species, reduction of the fatty acyl moiety to alcohol appears to be controlled by PBAN (Arima et al., 1991; Ozawa et al., 1993; Fabrias et al., 1994). One study using *Sesamia nonagrioides* (Mas et al., 2000) found an activation by PBAN of acetyl transferase, converting alcohols to acetates. In heliothines, it appears that PBAN controls either the biosynthesis of fatty acids, their reduction, or both.

Pheromone composition is usually reported either relative to the mass of the major component (here, Z11-16:Ald), or as a percentage of each component relative to the total mass of pheromone recovered. The first approach, expressing the secondary components as a percentage of the main component, may facilitate comparisons between species that differ in the number of secondary components. The second approach, expressing all components as a percentage of the total amount of pheromone produced, can show intraspecific treatment effects on the main component. We calculated and analyzed the relative amounts of the different pheromone components in both ways. Because similar trends emerged, we have shown only the pheromone profiles in which all components are expressed as a percentage of the total amount of pheromone produced.

The fact that we found statistically significant differences in the relative amount of 14:Ald produced in both species may not be biologically significant, because the quantities produced were very low. The overall significant difference in Z11-16:OH between virgin *Hv* and PBAN-induced mated *Hv* females, and the overall significant difference in the amount of acetates produced between virgin *Hs* and PBAN-injected mated *Hs* females, are harder to explain. However, the difference in relative percentages of these components between virgin females and PBAN-induced mated females was no greater than the difference between periods (i.e., temporal changes) for virgin females of the same species.

We did not find any of the acetates in *Hv* females, in agreement with previous analyses of *Hv* (Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Klun et al., 1980; Pope et al., 1982; Heath et al., 1991). However, acetate esterases, which convert acetates to alcohols (Bjostad and Roelofs, 1983; Roelofs and Wolf, 1988; Wolf and Roelofs, 1989), appear to be present in both *Hv* and *Hs*. When Teal et al. (1989) applied acetate esters to the surface of the pheromone glands of both *Hs* and *Hv* females, they found more of the corresponding alcohols and aldehydes in *Hv* than in *Hs*. Whether acetyl transferases that convert alcohols to acetate esters (Bjostad and Roelofs, 1983; Morse and Meighen, 1986) are present in *Hv* as well remains to be determined.

Both species had Z11-16:OH, but it was present in much higher amounts in *Hs* than in *Hv*. In *Hs*, this alcohol has been found to be an essential component for the attraction of conspecific males (Heath et al., 1991; Vickers, 2002), whereas *Hv* females apparently do not emit this compound (Teal et al., 1986; Heath et al., 1991).

We confirmed an earlier report by Klun et al. (1982) that 14:Ald and Z9-14:Ald were present in *Hs* females. Because other studies did not find these compounds in *Hs* (Teal et al., 1981; Tumlinson et al., 1982; Heath et al., 1991),

it was questionable whether they were produced by *Hs* at all (Vickers, 2002). Not only did we consistently find both compounds in both virgin and PBAN-injected mated *Hs* females, but the percentage of 14:Ald relative to the main component was similar to that found in virgin *Hv* females. In *Hv,* these compounds, especially Z9-14:Ald, are essential for attracting conspecific males (Vickers et al., 1991). *Hs* males do not seem to be attracted or repelled by Z9-14:Ald (Vickers, 2002), although receptor cells responding to Z9-16:Ald also respond to Z9-14:Ald in *Hs* (Baker et al., 2004).

Z7/9-16:Ald were almost absent in *Hv*, but present in relatively large amounts in *Hs*. Z9-16:Ald is one of the major pheromone components that provides species-specificity; *Hs* males are not attracted to a blend lacking this component (Vickers, 2002), whereas attraction of *Hv* males is independent of the presence or absence of Z9-16:Ald (Tumlinson et al., 1982; Teal et al., 1986; Vickers et al., 1991). Z9-16:Ald can be formed through Δ9-desaturase acting on the 16:acid, or through Δ11-desaturase acting on the 18:acid (e.g., Choi et al., 2002). A Δ11-desaturase is present in both species, because it is involved in formation of the major pheromone component, Z11-16:Ald (Jurenka, 1996; Choi et al., 2002). We hypothesize that in *Hv,* low amounts of Z9-16:Ald are formed through Δ11-desaturase acting on the 18:acid, whereas *Hs* females possess a Δ9-desaturase which allows them to produce Z9-16:Ald through 16:acid as well. We are currently investigating whether *Hv* and *Hs* differ in how the Δ9-components are produced.

Because there was considerable similarity in blend composition between virgin and PBAN-injected mated females, we conclude that PBAN can be used in determining ratios of pheromone components in backcross females. PBAN injection has several major advantages over other possible methods, because glands can be extracted during the photophase, from relatively old (>6 d old) and/or mated females, which makes this method time- and age-independent.

Acknowledgments—We thank Rick Santangelo for outstanding technical assistance, and Dorit Eliyahu for helping with PBAN injections. This research was supported in part by grants from NSF Population Biology 0235400 and the W. M. Keck Center for Behavioral Biology, and by the Blanton J. Whitmire Endowment at North Carolina State University.

(Received June 6, 2004; accepted August 10, 2004)

Abstract—Production of the male specific compound, 6,10,13-trimethyltetradecyl isovalerate by the predatory stink bug *Eocanthecona furcellata* (Wolff) was dramatically affected by rearing conditions. Male bugs kept isolated after eclosion produced an average of 1,948 ng of 6,10,13-trimethyltetradecyl isovalerate per bug, whereas male bugs reared in groups of 5–8 bugs produced an average of only 4 ng of 6,10,13-trimethyltetradecyl isovalerate per bug. Same-sex or mixed-sex pairs of bugs produced less than 50 ng per bug. Male bugs kept isolated for 1 wk and then grouped for 1 wk produced 3 ng of 6,10,13-trimethyltetradecyl isovalerate per bug, whereas male bugs grouped first and then isolated produced 135 ng of 6,10,13-trimethyltetradecyl isovalerate. A total of 11 minor components in relative amounts of less than 1% of the major 6,10,13-trimethyltetradecyl isovalerate were found in the sternal gland secretion. These included 6,10,13-trimethyltetradecanol, acetate, propionate, and butyrate esters of 6,10,13-trimethyltetradecanol, and isovalerate or valerate esters of homologs of 6,10,13-trimethyltetradecanol.

Key Words—*Eocanthecona furcellata*, Pentatomidae, 6,10,13-trimethyltetradecyl isovalerate, 6,10,13-trimethyltetradecyl acetate, 6,10,13-trimethyltetradecyl propionate, 6,10,13-trimethyltetradecyl butyrate, sternal gland, rearing conditions.

INTRODUCTION

In the study of semiochemicals from the predatory stink bug *Eocanthecona furcellata* (Wolff), 6,10,13-trimethyltetradecyl isovalerate extracted from sternal glands (SG) was found to be present in only 5% of mature virgin male bugs (Ho et al., 2003). In a related species, *Perillus bioculatus* (Fabricius), production of 6,10,13-trimethyltetradecyl isovalerate as an attractant pheromone was highest when males were starved first and then fed. It was proposed that stimulation of isovalerate production after feeding occurred in order to attract conspecifics to food sources (Aldrich et al., 1986). In another report (Aldrich and Lusby, 1986), a subset of male bugs of *Mineus strigipes* Herrich–Schaeffer and *Oplomus severus* Breddin with SG setae never produced a detectable amount of secretion, but starvation for 2–3 d after ecdysis followed by feeding was the most effective way of stimulating secretion.

In our initial attempts to obtain enough of the SG secretion from *E. furcellata* for bioassays, starving followed by feeding failed to stimulate the secretion of SG compounds from *E. furcellata*. Because 6,10,13-trimethyl-1-tetradecanol from the SG of *Stiretrus anchorago* (Fabricius) was found to be an aggregation pheromone (Kochansky et al., 1989), and SG of males of the male predatory stink bug *E. furcellata* produce compounds similar to that of *S. anchorago*, we hypothesized that the SG secretion of *E. furcellata* may be an aggregation pheromone as well. We further postulated that isolated bugs should produce more aggregation pheromone than bugs in groups because isolated bugs would use the chemical to attract conspecifics. The male-specific SG secretion may also have a role as a sex pheromone to attract female bugs. Thus, we hypothesized that male bugs grouped with females should produce minimal SG secretion to attract the opposite sex, whereas males grouped with males would still produce more SG secretion.

In this report, the amount of 6,10,13-trimethyltetradecyl isovalerate from SGs of virgin male bugs reared under different conditions, including being reared in isolation or in groups, and being reared in single or mixed sex pairs, was quantified and compared. Furthermore, because relatively large amounts of SG secretion could be collected from male bugs reared in isolation, other minor compounds in the SG secretion, mainly homologs of the major compound—6,10,13-trimethyltetradecyl isovalerate, were also identified.

METHODS AND MATERIALS

Insects. Bugs were reared on blowfly larvae, *Chrysomya megacephala* (Fabricius) (Diptera: Calliphoridae) in the laboratory under a 14:10 L:D regime at 23 $\pm$ 3°C and 70% relative humidity. The bugs were fed on alternate days *ad libitum*. Blowfly larvae were purchased from a fishing supply store. The colony was

maintained as described earlier in the literature (Chu and Chu, 1975a,b). Nymphs were kept in transparent plastic cups of 7 cm height $\times$13 cm diam. cup in groups of 10 bugs per cup. Adults were kept under different conditions as described later in this paper. The cups were covered with cheesecloth and a sugar–water impregnated cotton ball was placed at the top of the cup as the water source for the bugs.

Bugs Under Different Conditions. For the group-reared treatment, adults of the same sex were kept in groups of 5–8 bugs in 7 cm height $\times$13 cm diam. cup containers after eclosion. For the isolated rearing treatment, adults were kept individually in 250 ml transparent ice-cream cups after eclosion. For tests with pairs of bugs, two bugs, either both males of the same age or one male and one female of the same age, were kept in 250 ml ice-cream cups after eclosion. All these bugs were analyzed for the contents of the SG secretions 2 wk after eclosion.

To test the effects of grouping on previously isolated bugs, five bugs were kept individually for 1 wk and then brought together in a 7 cm height $\times$13 cm diam. cup for 1 wk before the extraction of SG compounds. For the converse test of grouped and then isolated adults, the bugs were kept in groups of five in the 7 cm height $\times$13 cm diam. cup for 1 wk, and then isolated individually in the 250 ml ice cream cups for 1 wk.

Extraction of Sternal Gland Contents of Adults. The bugs from various treatments were anesthetized with CO_2, and the ventral surface was washed with 40 μl of hexane. The extracts were analyzed by gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS). The amount of 6,10,13-trimethyltetradecyl isovalerate was quantified vs. benzophenone as an internal standard as described by Ho et al. (2003).

Chemical Analysis. The extracts were analyzed by splitless coupled GC–MS with a Thermo Quest Trace GC, interfaced with a Finnigan Trace MS (electron impact ionization, 70 eV). The GC was held at 60°C for 1 min, then programmed at 10°C/min to 300°C, with injector and transfer line temperatures of 200 and 250°C, respectively. A DB-1 column (30 m $\times$ 0.32 mm ID, J & W Scientific, Folsom, CA) was used in the GC–MS analyses with helium carrier gas.

Hydrolysis of 6,10,13-Trimethyltetradecyl Isovalerate. Ten micrograms of 6,10,13-trimethyltetradecyl isovalerate (authentic sample from Dr. J. R. Aldrich) were hydrolyzed in 200 μl of ethanol and 20 μl of 1N NaOH at 50°C for 8 hr. The hydrolyzed product, 6,10,13-trimethyltetradecanol, was extracted into hexane and analyzed by GC-MS, then used for esterification as described below.

Formation of Esters of 6,10,13-Trimethyltetradecanol. Acetyl chloride (50 μl) was added to a solution of 6,10,13-trimethyltetradecanol (1 μg) in hexane at 0°C. After 5 min, water was added to the reaction mixture, and the product was extracted with hexane. After filtration through anhydrous $MgSO_4$, the extract was concentrated for GC-MS analysis. Analogous procedures were used to esterify aliquots of the 6,10,13-trimethyltetradecanol solution with propionyl chloride, isobutyryl chloride, butyryl chloride, and valeryl chloride, respectively.

TABLE 1. AMOUNT OF 6,10,13-TRIMETHYLTETRADECYL ISOVALERATE FOUND IN THE SG OF VIRGIN MALE *E. furcellata* REARED UNDER DIFFERENT CONDITIONS. PAIRS OF TREATMENTS WERE COMPARED WITH *t*-TESTS

Rearing condition	Amount of 6,10,13-trimethyltetradecyl isovalerate (ng) (mean ± SE)	*P*
Grouped	4 ± 3 ($N = 20$)	$P < 0.001$
Isolated	1948 ± 525 ($N = 27$)	
Grouped first, then isolated	135 ± 109 ($N = 24$)	$P = 0.07$
Isolated first, then grouped	3 ± 3 ($N = 19$)	
Paired with another male	22 ± 13 ($N = 12$)	$P = 0.57$
Paired with another female	48 ± 43 ($N = 15$)	

RESULTS

Amounts of Isovalerate from Bugs Reared under Different Conditions. The amounts of 6,10,13-trimethyltetradecyl isovalerate produced by male bugs reared in isolation, in pairs, or in groups are shown in Table 1. Almost 500 times as much isovalerate was extracted from bugs reared in isolation as compared to bugs reared in groups (*t*-test, $P < 0.001$). Although the mean amount of isovalerate that was produced by bugs that were grouped first and then isolated was more than 40 times greater than the mean amount produced by bugs that were isolated first and then grouped, the two groups were not significantly different ($P = 0.07$), probably due to the extreme variability in the amounts produced per bug. There was also no difference in the mean amount of isovalerate recovered from males paired with other males or with females ($P = 0.57$).

Identification of Homologs of 6,10,13-Trimethyltetradecyl Isovalerate. Several compounds with mass spectra similar to that of 6,10,13-trimethyltetradecyl isovalerate were found in the SG extracts. Spectral data, possible structures, percentage relative to the most abundant compound, 6,10,13-trimethyltetradecyl isovalerate, and Kovats retention indices are listed in Table 2, and a chromatogram of the gland extract is shown in Figure 1. Detailed identification data are presented in subsequent paragraphs.

Peak 1: The compound gave a base peak of m/z 97, a molecular ion at m/z 256, and an M-18 peak (m/z 238), very similar to the mass spectrum of 6,10,13-trimethyltetradecanol in the SG secretion of *Oplomus dichrous* (Aldrich and Lusby, 1986). The mass spectrum and GC retention time matched those of an authentic standard generated by hydrolysis of 6,10,13-trimethyltetradecyl isovalerate, confirming the structure.

Peak 2: The mass spectrum of this compound was similar to that of 6,10,13-trimethyltetradecyl isovalerate, but its GC retention time was shorter. A prominent fragment at m/z 61 (McLafferty, 1980) suggested that it might be the acetate analog

of 6,10,13-trimethyltetradecyl isovalerate, and the identification was confirmed with an authentic standard.

Peak 4: Because of the distinct ion at m/z 75, characteristic of fragmentation of a propionate ester (McLafferty, 1980), and a mass spectrum similar to that of 6,10,13-trimethyltetradecyl isovalerate, peak 4 was identified as 6,10,13-trimethyltetradecyl propionate, again confirmed with an authentic standard.

Peak 6: The fragment ion at m/z 89, characteristic of a butyrate or isobutyrate ester (McLafferty, 1980), and an otherwise similar mass spectrum to that of 6,10,13-trimethyltetradecyl isovalerate, suggested that this compound was 6,10, 13-trimethyltetradecyl butyrate or isobutyrate. The peak was confirmed as 6,10,13-trimethyltetradecyl butyrate with a standard.

Peaks 8 and 9: The mass spectra of peaks 8 and 9 were similar to that of 6,10,13-trimethyltetradecyl isovalerate, but these peaks had different retention times, suggesting that they might be isomers. The valerate ester of 6,10,13-trimethyltetradecanol was synthesized, but its retention time (19.08 min) was slightly different than that of peak 8 (19.01 min) and peak 9 (19.13 min). Thus, these

two compounds appear to be isomers of 6,10,13-trimethyltetradecyl isovalerate, but the exact structures are unknown.

Peaks 3, 5, 7, 10, 11, and 12: These six components had similar mass spectra in the lower mass ranges to that of 6,10,13-trimethyltetradecyl isovalerate, but different fragment ions in the higher mass ranges. All of these peaks had a significant *m/z* 103 fragment ion, typical of isovalerate or valerate esters. For peak 3, an ion at *m/z* 255 and a molecular ion of *m/z* 312, as compared with the analogous ion of *m/z* 283 and molecular ion of *m/z* 340 of the 6,10,13-trimethyltetradecyl isovalerate, suggested that peak 3 might be the isovalerate or valerate ester of an alcohol with similar structure but two methylene units fewer than 6,10,13-trimethyltetradecanol. Similarly, for peaks 5 and 7, with significant ions at *m/z* 269, and molecular ions of *m/z* 326, the compounds are proposed to be isovalerate or valerate esters of an alcohol with one methylene fewer than 6,10,13-trimethyltetradecanol. For peaks 10 and 11, which gave ions with *m/z* 297 and 354, the compounds are proposed to be the isovalerate or valerate ester of an alcohol with one methylene unit more than 6,10,13-trimethyltetradecanol. Similarly, for peak 12, with ions of *m/z* 311 and 368, the compound was suggested to be the isovalerate or valerate ester of an alcohol with two methylene units more than 6,10,13-trimethyltetradecanol.

These isomers with different chain lengths were further grouped into three series of homologs according to the Kovats retention indices. Peaks 3 and 7 were homologs of peak 9 (IVb) with one or two methylene units less than peak 9 (Kovats indices are 2016, 2120, and 2217, respectively). Peaks 5 and 11 were homologs of peak 8 (IVb) with one methylene unit less and one unit more than peak 8 (Kovats indices are 2101, 2299, and 2205, respectively). Peaks 10 and 12 are homologs of IV with one or two more methylene units than IV (Kovats indices are 2263, 2367, and 2163, respectively).

Thus, the evidence suggests that these six compounds are isovalerate or valerate esters of homologs of 6,10,13-trimethyltetradecanol, with extra or fewer methylene units in the carbon backbone, but their exact structures remain to be fully elucidated.

DISCUSSION

Amount of 6,10,13-Trimethyltetradecyl Isovalerate Produced by Bugs Reared under Different Conditions. Production of SG secretions of some asopine hemipterans was stimulated by first starving and then feeding adult bugs after eclosion (Aldrich and Lusby, 1986; Aldrich et al., 1986). In contrast, in our study, we found that rearing density was the key factor affecting the production of the SG secretion, with isolated bugs producing more than two orders of magnitude more of the isovalerate ester than bugs reared in groups. The dramatic decrease in production of the isovalerate ester in the SG secretion from grouped bugs in

comparison to isolated bugs may be triggered by a variety of cues, such as physical contact with other bugs, or visual, olfactory, or acoustic signals. This remains to be explored further experimentally.

A comparison of the amount of isovalerate from bugs grouped first and then isolated with that from bugs isolated first and then grouped suggested that a period of isolation stimulated the production of SG secretion, even in bugs that were initially held in a group before being isolated. However, comparison of the amount of isovalerate from male bugs paired with either a male or a female indicated that the sex of the companion did not affect the production of SG secretion. Thus, even though SG secretion is only produced by male bugs, and they are the only sex to possess the setiferous patches on the ventral abdominal surface for release of the pheromone, the pheromone may be an aggregation pheromone for attracting both sexes, rather than being for sexual attraction alone. Possible roles for the SG secretion currently are being tested in bioassays in our laboratory.

6,10,13-Trimethyltetradecanol and the corresponding isovalerate have been found from the SG of several asopine stink bugs (Aldrich and Lusby, 1986; Aldrich et al., 1986), and the alcohol alone was demonstrated to be an aggregation pheromone of *S. anchorago* (Kochansky et al., 1989). Our results showing that isolated bugs produce much more of the SG secretion than grouped bugs support the hypothesis of the SG secretion being used for aggregation purposes.

Homologs of 6,10,13-Trimethyltetradecyl Isovalerate. Of the minor compounds found in the SG secretion, only 6,10,13-trimethyltetradecanol has been reported before (Aldrich and Lusby, 1986; Kochansky et al., 1989). All the homologs of the isovalerate, including the acetate, propionate, butyrate, valerate, and isovalerate esters with different alcohol chain lengths, have never been reported from natural sources. Although the amounts of the homologs were small (less than 1% relative to the major isovalerate), it is possible that they have a biological function.

There were actually two series of homologs of the major isovalerate ester. In the first series, the acid portion of the esters were variable, and the structures in this series were confirmed as acetate, propionate, and butyrate esters of 6,10,13-trimethyltetradecanol (peaks 2, 4, and 6). In the second series, the acid portion was constant (isovaleric or possibly valeric acid), whereas the alcohol portion appeared to have a variable chain length, although the structures of these peaks (peaks 3, 5, 7, 10, 11, and 12) have not yet been confirmed. It remains unclear whether this plethora of minor homologs of the main component represents imprecision in the biosynthesis of the major compound, or whether these trace components of the SG secretion indeed have a biological function.

In conclusion, we demonstrated that rearing conditions can have a profound effect on the production of stink bug SG secretions. The generality of this observation is being studied for other bugs. In particular, if it is indeed a fairly general phenomenon that a simple change in the rearing conditions can dramatically

increase pheromone production for a variety of bug species, it will make it easier to collect sufficient quantities of secretions for identification and bioassays. As a case in point to be noted, the method of collecting relatively large amounts of the SG secretion and the identification of the homologs of isovalerate in the resulting SG secretion has accelerated studies on the function of the SG secretion that are currently in progress in our laboratory.

Acknowledgments—The authors are grateful for a grant from the National Science Council, Taiwan, R. O. C., in support of this work. Helpful discussion with Dr. J. G. Millar of University of California Riverside is much appreciated.

(Received March 5, 2004; accepted September 22, 2004)

Abstract—Extracts of female sex pheromone gland of the carpenterworm moth, *Holcocerus hippophaecolus* Hua, a pest of sandthorn, *Hippophae rhamnoides* L. were found to contain (*E*)-3-tetradecenyl acetate (E3-14:Ac), (*Z*)-3-tetradecenyl acetate (Z3-14:Ac), (*Z*)-7-tetradecenyl acetate (Z7-14:Ac), the corresponding alcohols, E3-14:OH, Z3-14:OH, Z7-14:OH, and (*E*)-9-tetradecenyl acetate (E9-14:Ac). Electroantennographic (EAG) analysis of these chemicals and their analogs demonstrated that Z7-14:Ac elicited the largest male EAG response, followed by E3-14:Ac. In field trials, traps baited with either Z7-14:Ac or E3-14:Ac alone caught no male moths, whereas a combination of these two components in a 1:1 ratio caught more males than control traps. Addition of Z7-14:OH and Z3-14:OH or the alcohols plus E9-14:Ac did not enhance trap catches. We conclude that the sex pheromone of *H. hippophaecolus* is composed of Z7-14:Ac and E3-14:Ac. Optimal ratios and doses of these two components, and the possible role of other minor components, remain to be determined.

Key Words—*Holcocerus hippophaecolus*, sex pheromone, (*E*)-3-tetradecenyl acetate, (*Z*)-7-tetradecenyl acetate, Lepidoptera, Cossidae.

INTRODUCTION

The carpenterworm, *Holcocerus hippophaecolus* Hua (Lepidoptera: Cossidae) is a destructive forest pest, widely distributed throughout northern and western regions of China, including Inner Mongolia Autonomous Region, Ningxia Autonomous Region, Shanxi, Shaanxi, Gansu, and Liaoning provinces. Its primary host is the sandthorn plant (*Hippophae rhamnoides* L.). Sandthorns have been planted widely

* To whom correspondence should be addressed. E-mail: zhangzn@panda.ioz.ac.cn

in China (>1.4 million ha), often in single-species plantations, to prevent soil erosion and desertification (Tian and Tang, 1997). The fruits of sandthorn are processed for juice and traditional Chinese medicines. Currently, the sandthorn carpenterworm infests sandthorn plantations totaling 50,000 ha in area, often at high levels. In Liaoning Province, for example, infestation levels of sandthorns by *H. hippophaecolus* can reach 85% (Zhou, 2002; Luo et al., 2003). The damage is so severe and extensive that the sandthorn carpenterworm is considered a major threat to the continued existence of sandthorn plantations in China.

Larvae of *H. hippophaecolus* burrow in the root crowns of sandthorns, resulting in a high probability of plant mortality. Chemical insecticides are ineffective due to the cryptic nature of *H. hippophaecolus*. In addition, the indiscriminate use of insecticide can lower the quality of sandthorn. Thus, an alternative strategy for monitoring and controlling sandthorn carpenterworms is urgently needed.

Sex pheromones have been identified for three related Cossidae species: *Cossus cossus* L. (Capizzi et al., 1983), *Cossus mongolicus* Ersch (Qi et al., 1990), and *Holcocerus insularis* Staudinger (Zhang et al., 2001). Attractants for *H. hippophaecolus* have not been reported. In this paper, we report identification of the sex pheromone for *H. hippophaecolus*. Field trapping studies using blends of synthetic compounds were conducted to develop an efficient trap lure that can be used to monitor this important pest of sandthorns in China.

METHODS AND MATERIALS

Insects. Roots of sandthorn infested with larval *H. hippophaecolus* were collected from Jianping county, Liaoning Province, in the spring of 2003. The roots were kept at 25 ± 1°C and 20 ± 1°C during light and dark hours, respectively, at 65 ± 5% RH, under 16L:8D photoperiod. Pupae were collected from soil and kept under the same conditions until moth emergence. Upon emergence, male and female moths were held at room temperature under a 16L:8D photoperiod. The antennae of male moths were used for electroantennographic (EAG) analyses whereas the abdominal tips of females were used for pheromone extraction and identification.

Chemicals. Semiochemicals (>98% purity) used in analytical work, EAG analysis, and lures for field trials were supplied by Plant Research International (Wageningen, The Netherlands). Reagents and solvents were obtained from Fisher Chemicals (New Jersey, USA), and dimethyl disulfide (DMDS) was obtained from ACROS Organics (New Jersey, USA).

Pheromone Extracts. Observations of 1-d-old virgin female moths for 24 hr revealed that their calling period was generally 2.5–5.5 hr into the scotophase. During this period, 84% of females were calling. The pheromone glands of calling females were extruded by gently pressing the abdominal tips, and then excised with a small blade. The single excised gland was immersed in 10 μl hexane containing

delta13–14:OH (1 ng) as internal standard for 20 min at room temperature and then immediately analyzed by gas chromatography (GC) or gas chromatography–mass spectrometry (GC–MS). The remaining extract was transferred into a clean conical glass vial and kept at −20°C for additional analysis.

Derivatization with Dimethyl Disulfide. Pheromone extracts were reacted with DMDS (Leonhardt and DeVilbiss, 1985). A mixture of 50 μl DMDS and 5 μl iodine-diethyl ether solution (0.06%) was added to an extract containing 12 FE (female equivalents) and kept at 40°C overnight. After the addition of 10 μl hexane and 20 μl of aqueous sodium thiosulfate (5%), the mixture was stirred and the hexane layer was transferred into a small vial, and concentrated under nitrogen prior to analysis by GC–MS.

Chemical Analysis. GC analyses of sex pheromone gland extracts were performed on an HP 5890 II GC with a flame ionization detector (FID) and a splitless injector using nitrogen as carrier gas. The GC conditions were as follows: BP-20 column (50 m × 0.25 mm i.d., Scientific Glass Engineering Pty. Ltd., Australia); temperature program, 50°C for 1 min to 150°C at 25°C/min, then 4°C/min to 200°C, hold for 10 min, finally 5°C/min to 210°C and hold for 30 min. The GC–MS analyses of pheromone gland extracts were performed on an HP 6890 GC interfaced with an HP 5973 mass selective detector using a 60 m × 0.22 mm i.d. HP-INNOWAX column. The temperature program was the same as that used in the GC analyses. Analyses of the DMDS derivatives were carried out on the same GC–MS instrument with a DB-5MS column (30 m × 0.25 mm i.d., J&W Scientific, USA). The column temperature was 100°C for 1 min then programmed at 10°C/min to 230°C, and hold for 20 min.

Electroantennograms. Dissected antennae from 1- to 3-d-old males were used for EAG measurements. Previously described methods (Fang and Zhang, 2002) were used for determining EAG responses to a series of monounsaturated 14-carbon alcohols and acetates. An aliquot of hexane solution of each tested compound was deposited onto a filter paper strip (5 mm × 30 mm). After allowing the solvent to evaporate at room temperature, the filter paper was inserted into a Pasteur pipette. A stimulus was introduced as a short puff (2 ml air) into a purified, humidified air stream from the Pasteur pipette, through a stainless steel tube positioned 9 cm from the antennae. The duration of each puff was kept at about 0.1 sec. Solvent blank puffs (filter paper and hexane) served as the controls. To compensate for possible deterioration of the antennal preparation, a stimulation with a reference compound, (*E*)-5-tetradecenol (E5-14:OH) (1 μg), preceded each test stimulus puff. Relative response to a test compound was expressed as a percentage relative to the response to E5-14:OH.

Field Trials. Trapping tests were carried out in Jianping County, Liaoning Province from June 15 to July 7, 2003. Semiochemicals were dissolved in hexane and loaded onto gray rubber septa (The West Company, Phoenixville, PA) at a dose of 500 μg/septum. After the solvent had evaporated, 2 × 100 μl aliquots

of dichloromethane were added to each septum to help the chemical permeate into the septum. Sticky traps, similar to the Pherocon 1C trap (Trécé Inc., Salinas, CA), were constructed from two pieces of cardboard (42 × 28 cm). All traps were hung on branches of *Hippophae rhamnoides* at 1.5–1.8 m above ground level. Seven synthetic chemical blends and a blank control were tested in a completely randomized block design with five replicate blocks. Traps were spaced 50 m apart and the trap positions were rotated to minimize the effects of habitat heterogeneity. Captured mothes were recorded and removed daily.

Statistical Analysis. Differences among the EAG responses to different compounds were analyzed by one way ANOVA. Values for field traps were compared with the Bonferoni test. All data were analyzed with a statistical program for Windows 11.0 (SPSS Inc., 2001).

RESULTS

Analysis of Sex Pheromone Gland Extracts. Sex pheromone gland chemicals of female *H. hippophaecolus* were identified and quantified by GC–MS and GC. The GC–MS analyses of the gland extracts revealed that the mass spectra of peaks I, II, III, and IV were consistent with those of monounsaturated 14-carbon acetates with a comparatively strong fragment at m/z 194 (27–30% of the base peak, loss of acetic acid), and a small but distinct fragment at m/z 61 (1–8%, $CH_3COOH_2^+$) (Figure 1, Table 1). The mass spectra of peaks V, VI, and VII contained diagnostic ions at m/z 194 (10–12% of the base peak, loss of H_2O) and m/z 31 (12–14%, CH_2OH^+). This suggested that the compounds were monounsaturated 14-carbon primary alcohols. After the comparison of the relative intensities of five diagnostic ions $[(m_1/z)/(m_2/z)]$: 54/55, 67/68, 81/82, 81/95, and 95/96 with literature data on positional isomers of 14-carbon acetates and alcohols (Horiike et al., 1990, 1991; Zhang et al., 2001) we determined the identities of the seven compounds as follows: peak I and II were 3-tetradecenyl acetates (3-14:Ac), peak III was a 7-tetradecenyl acetate (7-14:Ac), peak IV was a 9-tetradecenyl acetate (9-14:Ac); peak V and VI were 3-tetradecenols (3-14:OH), and peak VII was a 7-tetradecenol (7-14:OH).

Double bond locations of the pheromone components were further confirmed by analyses of their DMDS derivatives. Analyses revealed the existence of DMDS adducts derived from 7-14:OH (diagnostic ions at m/z 145, 161, and 306 [M^+]); 3-14:OH (diagnostic ions at m/z 105, 201, and 306 [M^+]); 3-14:Ac (diagnostic ions at m/z 87, 147, 201, and 348 [M^+]); 7-14:Ac (diagnostic ions at m/z 143, 145, 203, and 348 [M^+]); and 9-14:Ac (diagnostic ions at m/z 117,171, 231, and 348 [M^+]). The DMDS derivatives of E3-14:Ac and Z3-14:Ac and the corresponding alcohols could not be separated efficiently by DB-5MS column in our GC–MS system.

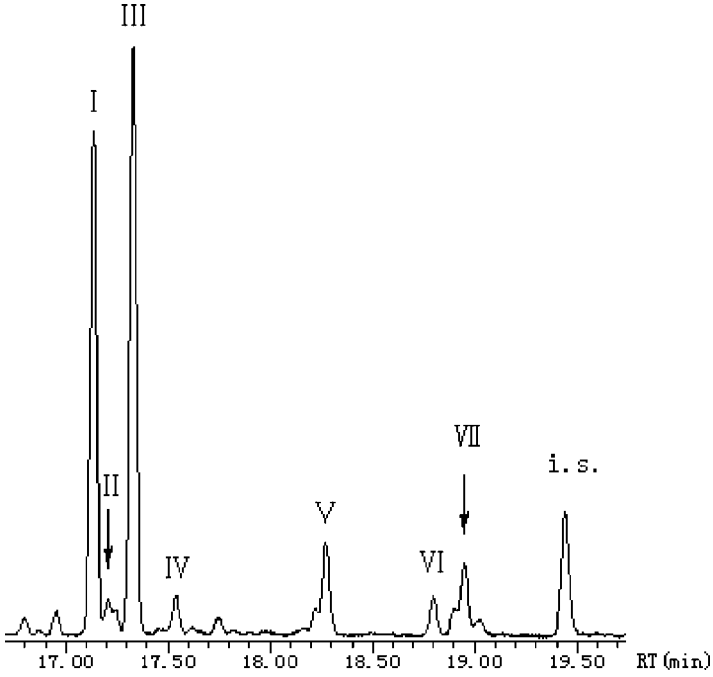

FIG. 1. Total ion chromatogram of GC–MS analysis of a single-gland extract from a female *H. hippophaecolus*. Identities of components are as follows: (I) E3-14:Ac; (II) Z3-14:Ac; (III) Z7-14:Ac; (IV) E9-14:Ac; (V) E3-14:OH; (VI) Z3-14:OH; and (VII) Z7-14:OH. Internal standard (i.s.): delta-13-14:OH (1 ng).

The configurations of monounsaturated 14-carbon compounds in the pheromone gland were first determined by a comparison of their retention times with those of standard compounds on a BP-20 GC column. However, the separation for Z7-14:Ac and E7-14:Ac was still poor, whereas the other components were well separated and were determined to be Z3-14:OH, E3-14:OH, Z3-14:Ac, E3-14:Ac, and E9-14:Ac. In GC–MS analyses, a more polar column, HP-INNOWAX was used. With this column, all possible isomers in female extracts were separated and the configurations of all monounsaturated 14-carbon compounds, including Z7-14:Ac, in the gland extracts were determined (Table 2). In the analyses of the single gland extracts, we found that the two gland components, E3-14:Ac and Z7-14:Ac were detected in calling females but not in noncalling ones. In calling females, the titer of Z7-14:Ac varied from 8.3 to 52 ng, whereas the titer of E3-14:Ac varied from 6.4 to 60.9 ng. Relative amounts of E3-14:Ac and Z7-14:Ac were equal, whereas for other components, the relative amounts were much lower than that of Z7-14:Ac (Table 2).

TABLE 1. MASS SPECTRAL DATA FOR CHEMICALS IN SEX PHEROMONE GLAND EXTRACTS

Component	Identity	Relative intensity of major ions (m/z)
I	3-14:Ac	194 (27) [M^+–60], 152 (10), 110 (23), 96 (66), 95 (37), 82 (71), 81 (57), 68 (67), 67 (65), 61 (1) [$CH_3COOH_2^+$], 55 (39), 54 (60), 43 (100) [$O{=}C^+CH_3$]
II	3-14:Ac	194 (27) [M^+–60], 152 (11), 110 (24), 96 (62), 95 (39), 82 (71), 81 (60), 68 (74), 67 (62), 61 (1) [$CH_3COOH_2^+$], 55 (39), 54 (57), 43 (100) [$O{=}CCH_3^+$]

[a] Temperature programs of GC column and determination of relative amounts of the gland components are described in "Methods and Materials."

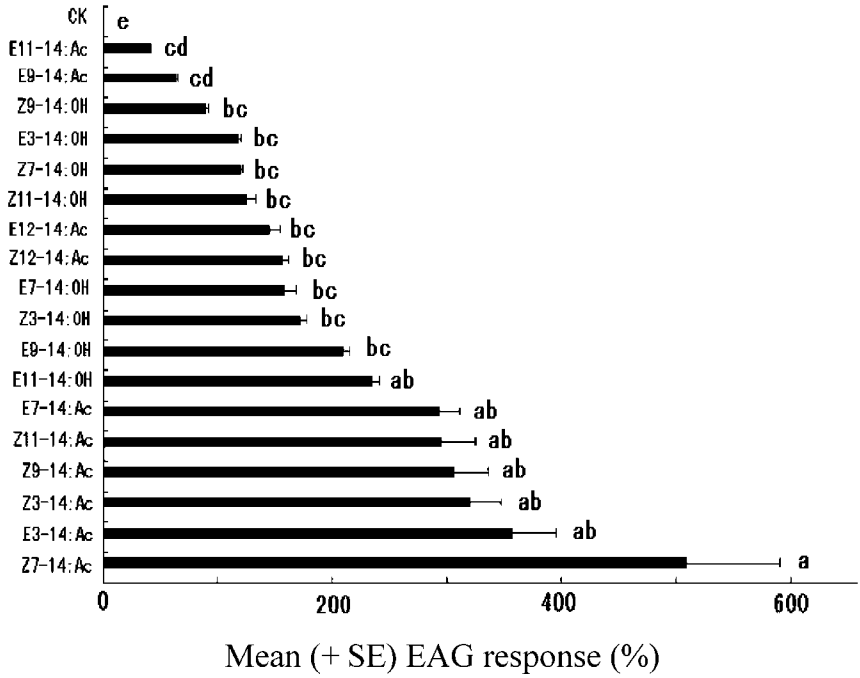

FIG. 2. EAG responses of male *H. hippophaecolus* (relative to responses to E5-14:OH) to a series of monounsaturated 14-carbon alcohols and acetates at doses of 10 μg ($N = 30$). Bars followed by different letters are significantly different at $P = 0.05$. Check control (ck). Response to standard application of 10 μg (*E*)-5-tetradecenol (E5-14:OH) was 4.56 $\pm$ 1.77 mV.

Electroantennographic Analyses. Male EAG responses to the gland components and their analogues varying in double bond positions and configurations are summarized in Figure 2. Results show that Z7-14:Ac elicited the strongest response (29.59 mV), followed by E3-14:Ac. Among tested compounds, the EAG response elicited from each acetate was higher than that from the corresponding alcohol, except for E11-14:Ac, which elicited a much lower EAG response than the corresponding alcohol, E11-14:OH.

Field Trapping. Traps baited with a single gland component, Z7-14:Ac or E3-14:Ac failed to attract male *H. hippophaecolus* males in the field. However, traps baited with the two gland components in a 1:1 ratio captured more males than control traps (Table 3). Catches were not affected by addition of Z7-14:OH and Z3-14:OH or the mixture of Z7-14:OH, Z3-14:OH, and E9-14:Ac.

TABLE 3. MEAN CATCHES OF MALE *H. hippophaecolus* IN TRAPS BAITED WITH VARIOUS SEX PHEROMONE GLAND CHEMICALS

	Composition of baits/μg[a]							
	Acetates					Alcohols		Mean ($\pm$ SE)

Notes. Mean difference: C–F = 1.7700, Sig.: C–F = 0.091; mean difference: C–G = 0.1500, Sig.: C–G = 1.000; mean difference: C–A, C–B, C–D, C–E, C–CK = 2.1429, Sig.: C–A, C–B, C–D, C–E, C–CK = 0.0000; mean difference: F–A, F–B, F–D, F–E, F–CK = 0.8714, Sig.: F–A, F–B, F–D, F–E, F–CK = 0.004; mean difference: G–A, G–B, G–D, G–E, G–CK = 2.4286, Sig.: G–A, G–B, G–D, G–E, G–CK = 0.0000.

[a] The ratios of the components in baits were similar to that found in the pheromone gland.

[b] The mean difference is significant at the $P = 0.05$ level.

DISCUSSION

We have demonstrated that E3-14:Ac and Z7-14:Ac are the major components of the sex pheromone of *H. hippophaecolus*. The two compounds are produced by adult females, and the antennae of male *H. hippophaecolus* were highly sensitive to both compounds. In field trials, traps baited with the two compounds in a 1:1 ratio were attractive to adult males (Table 3).

Both compounds were required for attraction to occur. Sex pheromones and attractants identified to date for carpenterworms have been mono- or di-unsaturated straight chain acetates, most being 14-carbon acetates. Although Z7-14:Ac has been reported as a pheromone component for species in many families of Lepidoptera, E3-14:Ac has been reported only in *Symmetrischema tangolias* (Gyen) (Gelechiidae) (Griepink et al., 1995).

During the course of our studies, we found that *H. hippophaecolus* lacks *instrumenta suctoria*. Adults are, therefore, unable to feed during their short lifespan. They mate and lay eggs within a short period of time, with female moths mating only once during their adult life (Tian and Tang, 1997). These facts suggest that it may be possible to control this important pest by mass trapping through focused trap efforts or by mating disruption. However, development of a mass trapping or mating-disruption system will require identification of the optimum pheromone dosage on lures and determination of any other potential synergists. Currently, a wing trap baited with the synthetic compounds Z7-14:Ac and E3-14:Ac in a 1:1 ratio at 500 μg dosage can be used to monitor population levels of *H. hippophaecolus* within plantations of sandthorn in China.

Acknowledgments—We greatly appreciate the through review and editing of the manuscript by Nancy Gillette and Dan Miller (USDA, Forest Service) and the helpful comments on the manuscript by M. Renou (INRA, Unite de Phytopharmacie et Mediateurs Chimiques, Versailles), Michael Smith (USDA, ARS) and Xun Liu (Institute of Zoology, Chinese Academy of Sciences). Thanks are also extended to Wu Jian, State Forestry Administration, and Zhang Liansheng, Jianping County Forest Pest Control Station, Liaoning Province for collecting insects used in the study and assistance in field trapping. This work was partially supported by the CAS Knowledge Innovation Program (KSCX1-SW-13).

(Received March 16, 2004; accepted September 22, 2004)

Abstract—Considering the vast Eurasian distribution of gypsy moth, *Lymantria dispar* (Lepidoptera: Lymantriidae), the many subspecies, and their presence in different lymantriid communities, we tested the hypothesis that *L. dispar* populations in eastern Asia employ one or more pheromone components in addition to the previously known single component pheromone (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [= (+)-disparlure]. Coupled gas chromatographic–electroantennographic detection (GC–EAD) analyses of pheromone gland extracts of female *L. dispar sensu lato* (including both AGM and NAGM) on four GC columns (DB-5, DB-23, DB-210, and SP-1000) revealed a new trace component that eluted just before (DB-5; DB-210) or after (DB-23, SP-1000) disparlure, and elicited strong antennal responses. Isolation of this compound by high-performance liquid chromatography and hydrogenation produced disparlure, suggesting that the new component had the molecular skeleton of disparlure, with one or more double bonds. Of all possible monounsaturated *cis*-7,8-epoxy-2-methyloctadecenes, only *cis*-7,8-epoxy-2-methyloctadec-17-ene co-chromatographed with the insect-produced compound on all GC columns and elicited comparable antennal responses. In field experiments in Honshu (Japan)

with enantioselectively synthesized compounds, (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene (7*R*8*S*-epo-2me-17-ene-18Hy) was weakly attractive to male *L. dispar*, but was less effective as a trap bait than (+)-disparlure, and failed to enhance attractiveness of (+)-disparlure when tested in blends. The antipode, (7*S*,8*R*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene, was not attractive, and when added to (+)-disparlure and/or 7*R*8*S*-epo-2me-17-ene-18Hy reduced attractiveness. Thus, the biological role of 7*R*8*S*-epo-2me-17-ene-18Hy remains unclear. It may enhance pheromone attractiveness or specificity in other *L. dispar* populations within their vast Eurasian distribution.

Key Words—Asian gypsy moth, North American gypsy moth, *Lymantria dispar*, nun moth, *Lymantria monacha*, (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene, (7*S*,8*R*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene, (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane, (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane, 2-methyl-(*Z*)-7-octadecene, (+)-disparlure, (+)-monachalure.

INTRODUCTION

Pioneering work by Bierl et al. (1970) identified *cis*-7,8-epoxy-2-methyloctadecane (= disparlure) as a sex pheromone component of the European gypsy moth (EGM), *Lymantria dispar* (Lepidoptera: Lymantriidae). Further studies (Klimetzek et al., 1976; Cardé et al., 1977; Miller et al., 1977; Plimmer et al., 1977) determined that only (+)-disparlure [(7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane] mediates attraction of male moths, whereas the presence of (–)-disparlure [(7*S*,8*R*)-*cis*-7,8-epoxy-2-methyloctadecane] reduced attractiveness of the lure. Pheromone reanalysis of European *L. dispar* revealed *cis*-7,8-epoxy-3-methylnonadecane (Gries et al., 1996), which enhances the specificity of the pheromone signal (Gries et al., unpublished).

The so-called "Asian gypsy moth" (AGM) in eastern Asia encompasses all those *L. dispar* forms with female moths capable of flight, unlike their North American gypsy moth (NAGM) and European gypsy moth (EGM) counterparts that cannot fly. The AGM populations have distinct morphological variations. In Japan alone, AGM populations have been divided into five subspecies, including *hokkaidoensis, japonica, obscura, tsushimensis*, and *postalba* (Inoue, 1957). Recent genetic analyses of these subspecies support the hypothesis that at least two of them are distinct and should be raised to species status (Bogdanowicz et al., 2000). Several species with wide distributions, such as *L. dispar,* have geographically specific pheromone blends. For example, populations of the congeneric nun moth, *Lymantria monacha,* in Bohemia (Europe) and Honshu (Japan) differ in both their pheromonal signal and diel periodicity of signaling (Gries et al., 2001). Conceivably, some *L. dispar* populations could utilize a pheromone signal in addition to, or other than, (+)-disparlure. Here, we report identification and field testing of (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene, a novel pheromone gland component from *L. dispar*.

METHODS AND MATERIALS

Experimental Insects

Female pupae of the NAGM were obtained from the laboratory colony maintained at USDA, Beneficial Insects Introduction Research Laboratory, Newark, DE. Additional NAGMs were field collected as late instar larvae at Welch Point, Elkton, Cecil Co., MD (N 39° 32′, W 75° 52′) and held in mesh cages in an outdoor insectary until eclosion of adult moths.

Egg masses of AGM were obtained from several locations in Asia, including Japan (Honshu, Okinawa), Korea (near Seoul and Cheju Island), and China (Hebei and Liaoning Provinces). The larvae were reared on standard gypsy moth diet (Bell et al., 1981) in the USDA Quarantine Facility, Newark, DE. Female pupae were held under a photoperiod of 14L:10D, 24–26°C, and 60–80% relative humidity, whereas male pupae were held at 15°C to retard development. Abdominal tips with pheromone glands of calling, 1- to 3-d-old virgin female moths were removed and extracted for 15–30 min in HPLC-grade hexane. Ampoules with the supernatant of pheromone extracts and male pupae were sent by courier to Simon Fraser University (SFU). Male pupae were held in SFU's Global Forest Quarantine Facility.

Analyses of Pheromone Extract

Aliquots of 1–3 female equivalents (FE) of combined pheromone gland extracts were analyzed by coupled gas chromatographic–electroantennographic detection (GC–EAD) (Arn et al., 1975) with procedures and equipment recently described in detail (Gries et al., 2002). Pheromone extract was fractionated by high-performance liquid chromatography (HPLC), employing a Waters LC 625 high-performance liquid chromatograph equipped with a Waters 486 variable wavelength UV–visible detector set at 210 nm , HP Chemstation software (Rev.A.07.01), and a reverse phase Nova Pak® C_{18} (3.9 mm × 300 mm) column (Waters) eluted with acetonitrile (1 ml/min). For HPLC fractionation, 200 FE of pheromone gland extracts were evaporated to dryness, 50 μl of acetonitrile were added, and the 50-μl extract was injected into the HPLC. Seventy-five 20-sec (200 μl) fractions of this pheromone extract (200 FE) were collected and analyzed individually without concentration by GC–EAD on a DB-5 column. Coupled GC–mass spectrometric (MS) analyses of pheromone extract and of synthetic standards employed a Varian Saturn 2000 ion trap GC–MS fitted with a DB-5 column (30 m × 0.25 mm ID; J&W Scientific, Folsom, CA).

General Methods and Instrumentation

Tetrahydrofuran (THF) and *N*-methylpyrrolidinone (NMP) were dried by standard methods. Oven-dried glassware was assembled hot under Ar flow, and

maintained under Ar; liquids were transferred by cannula under Ar pressure. Dry LiCl and $CuCl_2$ were weighed out in a dry box. Infrared spectra were recorded on Perkin-Elmer Paragon 1000 and 1600 FT–IR instruments. Optical rotations were measured on Jasco DIP-1000 and Perkin-Elmer 341 polarimeters. Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on Bruker 300 (at 300 MHz for ^{1}H and 75 MHz for ^{13}C) and Varian AS500 (at 499.77 MHz for ^{1}H and 125.68 MHz for ^{13}C) spectrometers, with chemical shifts reported in ppm relative to TMS (^{1}H, δ 0.00) and $CDCl_3$ (^{13}C, δ 77.00). Elemental analyses were performed using a Carlo-Erba model 1106 elemental analyzer.

Syntheses

(*2′S,3′R*)-*8′-Methyl-cis-2′, 3′-Epoxy-1-Nonyl (1S)-10-Camphorsulfonate* (**2**) (Figure 1). (2′*S*, 3′*S*)-4′-Bromo-*cis*-2′,3′-epoxy-1-butyl (1*S*)-10-camphorsulfonate (**1**, >99% ee; Aldrich) (11.0 g, 28.9 mmol) was melted *in vacuo*, and dissolved in THF (30 ml). The solution was cannulated into a 300-ml 3-neck flask fitted with a low-temperature thermometer, magnetic stir bar, and a pressure-equalizing 125-ml dropping funnel. A 0.1 M solution of Li_2CuCl_4 in THF (3 ml , 0.3 mmol) was cannulated in, followed by NMP (20 ml, 207 mmol). The red-orange solution was cooled to −30° (dry ice–acetone bath), and freshly prepared 4-methylpentylmagnesium chloride (large excess, 1.0 M in THF) was cannulated into the dropping funnel. Dropwise addition of this solution to the flask rapidly changed the color to colorless, then faint red-brown. Precipitate began to form after addition of 20 ml, and gummy solid stopped the stir bar soon after. Addition was continued (hand swirling, pot temp. −28° to −23°) until 38 ml (1.3 equiv.) of the Grignard reagent had been added. The NMR assay of an aliquot showed ∼90% consumption of **1**. After addition of more Grignard reagent (8 ml) at −23°, the mixture was allowed to stand from −23° to −20°, then poured into a mixture of Et_2O (100 ml) and 1 N aq. HCl (100 ml). The separated organic layer was washed with H_2O (5 × 100 ml) and brine (25 ml), dried over anhydrous Na_2SO_4–$MgSO_4$, filtered, and concentrated to a pale yellow oil. This was further stripped of volatiles (Kugelrohr oven, 75° @ <0.1 mm) to leave 10.21 g of impure **2** containing unreacted **1** and appreciable amounts of ring-opened alcohol (NMR assay). Column chromatography of this material (silica gel, elution with 5–10% Et_2O–hexanes) yielded 7.66 g of 90+% pure **2** still containing ring-opened alcohol, plus >700 mg of unreacted **1**. The 90+% pure **2** was dissolved in MeOH (80 ml) and stirred for 70 min at 23° with 440 mg of K_2CO_3. The mixture was partitioned between Et_2O and H_2O; standard workup afforded **2** containing terminal epoxide, and no detectable ring-opened alcohol (NMR assay). Column chromatography of this material as before gave 7.00 g of 99% pure **2** (67% yield, based on unrecovered **1**). Purified **2**: $[\alpha]_D^{26}$ +23.0° (*c* 3.50, $CHCl_3$); IR (film) 2954, 1748, 1365, 1171, 968 cm^{-1}; ^{1}H NMR δ 4.54–4.49 (dd, J = 11.4, 4.0 Hz, 1H), 4.30–4.24 (dd, J = 11.4, 7.2 Hz, 1H),

3.66 (d, J = 15.1 Hz, 1H), 3.26 (m, 1H), 3.06 (m, 1H), 3.06 (d, J = 15.1 Hz, 1H), 2.51–2.35 (m, 2H), 2.14 (t, J = 4.5 Hz, 1H), 1.96 (d, J = 18.5 Hz, 1H), 1.12 (s, 3H), 0.89 (s, 3H), 0.87 (d, J = 6.7 Hz, 6H); ^{13}C NMR δ 214.27, 68.60, 57.82, 56.68, 53.32, 48.00, 47.09, 42.64, 42.42, 38.70, 27.89, 27.78, 27.03, 26.79(2), 24.76, 22.52(2), 19.65, 19.58. HRMS (ESI) calcd for $C_{20}H_{34}O_5SNa$ (M^+ + Na) 409.2019, found 409.2004.

*(2R,3R)-1-Iodo-8-Methyl-cis-2,3-Epoxynonane (**3**).* To a solution of **2** (7.00 g, 18.1 mmol) in reagent grade acetone (50 ml) in an Ar-swept flask were added a few mg of $NaHCO_3$, and a solution of NaI (5.5 g, 37 mmol) in acetone (80 ml). Precipitation occurred almost at once. The magnetically stirred mixture was heated in a 45° bath (reflux condenser, positive Ar pressure) for 41 hr (no remaining **2** by NMR analysis). The solid was collected by suction filtration, and washed thoroughly with reagent acetone; the yellow filtrate was concentrated at 40°–45°, and taken up in H_2O (100 ml) and 10% Et_2O–hexanes (150 ml). The organic phase was washed with dilute Na_2SO_3 and water, dried (Na_2SO_4–$MgSO_4$), filtered through silica gel (5 g), stripped of solvent, and pumped under vacuum to leave 4.71 g (92%) of colorless oil: $[\alpha]_D^{26}$ +73.1° (*c* 4.85, $CHCl_3$); IR (film) 2952, 1466, 1166 cm^{-1}; ^{1}H NMR δ 3.36–3.27 (m, 2H, H-1 and H-2), 3.08–3.05 (m, 1H, H-3), 3.05–2.96 (m, 1H, H-1), 1.62–1.16 (3 m's, 9H), 0.88 (d, J = 6.6 Hz, 6H); ^{13}C NMR δ 59.91, 56.74, 38.74, 27.83, 27.21, 27.05, 26.77, 22.57(2), 1.33. HRMS (ESI) calcd for $C_{10}H_{19}IONa$ (M^+ + Na) 305.0373, found 305.0387.

*(7R,8S)-cis-7,8-Epoxy-2-Methyloctadec-17-ene (**4**).* A solution of 1-nonen-9-yl-magnesium bromide [freshly prepared from 2.70 g (13.20 mmol) of 9-bromo-1-nonene with 2 equiv. of magnesium turnings] in 50 ml of THF was added dropwise into a mixture of iodoepoxide **3** (1.24 g, 4.40 mmol), CuI (0.167 g, 0.88 mmol), distilled HMPA (4.60 ml, 26.40 mmol), and dry THF (2 ml) at −23°C. After stirring for 25 min, the reaction mixture was quenched with aq. NH_4Cl solution. The products were extracted with hexane–ether (1:1), the extracts were washed (water, saturated aq. $Na_2S_2O_3$, brine), and dried (anhyd. $MgSO_4$), and solvents and low-boiling byproducts were removed *in vacuo*. Flash chromatography (50 g SiO_2, 0–4% ether in hexane) yielded 0.813 g (2.90 mmol) of pure **4** (66%). $[\alpha]_D^{21}$ +2.3° (*c* 0.48, $CHCl_3$); IR (film) 2930, 2856, 1641, 1466, 1385, 1366, 992, 909 cm^{-1}; ^{1}H NMR δ 5.81 (m, 1H), 4.99 (dd, J =17.1, 2.1 Hz, 1H), 4.93 (d, J = 10.3 Hz, 1H), 2.90 (m, 2H), 2.04 (td, J = 7.6, 6.8 Hz, 2H), 1.15–1.57 (4 m's, 23 H), 0.87 (d, J = 6.6 Hz, 6H); ^{13}C NMR δ 139.18, 114.10, 57.24, 38.88, 33.78, 29.59, 29.49, 29.36, 29.08, 28.91, 28.90, 27.88, 27.85, 27.80, 27.32, 26.84, 26.58, 22.61, 22.60; Anal. calcd. for $C_{19}H_{36}O$ (%): C, 81.36; H, 12.94, found: C, 80.96, H, 12.91.

*(2′R,3′S)-8′-Methyl-cis-2′,3′-Epoxy-1-Nonyl (1S)-10-Camphorsulfonate (**2′**).* This epoxide was prepared from (2′*R*,3′*R*)-4′-bromo-*cis*-2′,3′-epoxy-1-butyl (1*S*)-10-camphorsulfonate (**1′**, >99% ee; Aldrich) (11.0 g, 28.9 mmol) essentially as described for synthesis of **2**, except that the amounts of Li_2CuCl_4 and NMP were

doubled, and sufficient 4-methylpentylmagnesium chloride was added to consume all of **1′**. No ring-opened alcohol was detected. A single column chromatography of the crude product (silica gel, elution as for **2**) gave 6.10 g of ∼98% pure **2′** (54%). Purified **2′**: $[\alpha]_D^{26}$ +40.6° (*c* 4.65, $CHCl_3$); IR (film) 2954, 1748, 1365, 1172, 969 cm^{-1}; ^1H NMR δ 4.50–4.44 (dd, $J = 11.4, 4.2$ Hz, 1H), 4.34–4.28 (dd, $J = 11.7$, 7.1 Hz, 1H), 3.66 (d, $J = 15.1$ Hz, 1H), 3.27 (m, 1H), 3.49–3.42 (m, 2H), 3.11 (d, $J = 15.1$ Hz, 1H), 3.08 (m, 1H), 2.50–2.35 (m, 2H), 2.14 (t, $J = 4.3$ Hz, 1H), 2.12–2.03 (m, 1H), 1.96 (d, $J = 18.5$ Hz, 1H), 1.12 (s, 3H), 0.89 (s, 3H), 0.87 (d, $J = 6.6$ Hz, 6H); ^{13}C NMR δ 214.21, 68.46, 57.86, 56.69, 53.34, 47.95, 47.18, 42.64, 42.41, 38.69, 27.86, 27.77, 27.02, 26.79(2), 24.85, 22.52(2), 19.66, 19.59. HRMS (ESI) calcd, for $C_{20}H_{34}O_5SNa$ (M^++ Na) 409.2019, found 409.1999.

*(2S,3S)-1-Iodo-8-Methyl-cis-2,3-Epoxynonane (**3′**).* This iodomethyl epoxide, prepared from **2′** in 93% yield as described for enantiomer **3**, was obtained as a colorless oil: $[\alpha]_D^{25}$ –73.4° (*c* 4.80, $CHCl_3$); all other physical data were identical to those recorded for **3**.

*(7S,8R)-cis-7,8-Epoxy-2-Methyloctadec-17-ene (**4′**).* Compound **4′** was prepared from iodoepoxide 3′ under the same conditions as described for **4** with 58% yield. $[\alpha]_D^{21}$ –2.1° (*c* 0.71, $CHCl_3$); all spectral data were identical to those recorded for **4**.

Field Experiments

All field experiments employed a complete randomized block design with 10 blocks (replicates) each, and were conducted in forests (N 39° 52′, E 141° 23′ and N 39° 53′, E 141° 18′) near (<35 km) the city of Morioka (Iwate Prefecture, Japan). *Lymantria dispar* experiments 1–4 were set up in forests with mixed oak, birch, and maple, and the *L. monacha* experiment (Exp. 5) in a forest with Japanese larch, *Larix leptolepsis*. Delta-like traps were made from 2-l milk cartons (Gray et al., 1984), coated with Tanglefoot (The Tanglefoot Company, Grand Rapids, Michigan, PA), and suspended from trees 1.5 m above ground at 15 to 20-m spacing. They were baited with a gray sleeve stopper (West Pharmaceutical Services, Lionville, PA) impregnated with candidate pheromone components in HPLC-grade hexane.

Experiment 1 tested 7*R*8*S*-epo-2me-17-ene-18Hy (50 μg) and 7*S*8*R*-epo-2me-17-ene-18Hy (50 μg) singly and in combination. Experiment 2 compared the relative attractiveness of 7*R*8*S*-epo-2me-17ene-18Hy (50 μg) with that of (+)-disparlure (50 μg). Experiment 3 tested whether attractiveness of (+)-disparlure could be enhanced by addition of 7*R*8*S*-epo-2me-17ene-18Hy (0.5, 5, or 50 μg). Experiment 4 explored whether attractiveness of (+)-disparlure was affected by addition of either 7*R*8*S*-epo-2me-17ene-18Hy (0.5 μg), 7*S*8*R*-epo-2me-17ene-18Hy (0.5 μg), or both (0.5 μg each). Final experiment 5 investigated whether 7*R*8*S*-epo-2me-17ene-18Hy enhanced species specificity of the *L. dispar* pheromone by testing the *L. monacha* pheromone blend

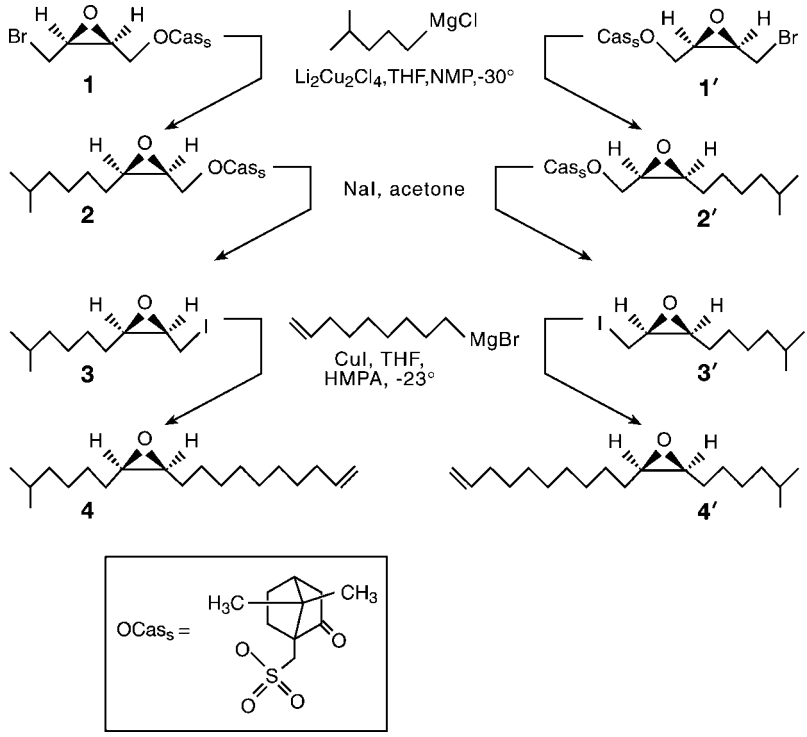

FIG. 1. Scheme for enantioselective syntheses of (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene (**4**), and (7*S*,8*R*)-*cis*-7,8-epoxy-octadec-17-ene (**4′**).

[(7*R*,8*S*)-*cis*-7,8-epoxy-octadecane = (+)-monachalure (50 μg); (+)-disparlure (50 μg); (*Z*)-2-methyl-7-octadecene (2me-*Z*7-18Hy) (5 μg)] vs. the *L. monacha* pheromone blend in combination with 7*R*8*S*-epo-2me-17-ene-18Hy.

Trap catch data were subjected to nonparametric analyses of variance (Friedman's test) followed by comparison of means by Scheffé test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS AND DISCUSSION

In GC–EAD analyses of pheromone gland extracts of female *L. dispar* from various geographic locations, a previously unknown component elicited strong antennal responses (Figure 2). Even in concentrated pheromone gland extracts [>300 FE], the unknown occurred below detection threshold of the GC–MS, and needed to be identified without spectroscopic data.

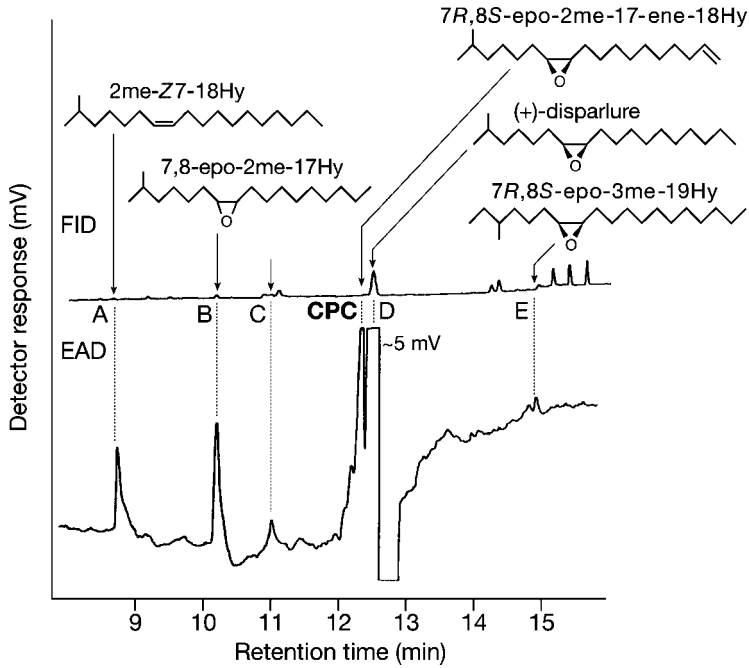

FIG. 2. Flame ionization detector (FID) and electroantennographic detector (EAD: male *L. dispar* antenna) responses to 1 FE of *L. dispar* pheromone gland extract. Chromatography: DB-5 column; 100°C (1 min), 20°C per min to 190°C (held for 8 min), then 25°C per min to 280°C. Except for (+)-disparlure, all components eliciting antennal responses occurred below detection threshold of the FID. Compound identities: **A** = (*Z*)-2-methyl-7-octadecene; **B** = *cis*-7,8-epoxy-2-methylheptadecane (absolute configuration not yet determined); **C** = unknown; **CPC** = candidate pheromone component = (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene; **D** = (+)-disparlure = (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane; **E** = (7*R*,8*S*)-*cis*-7,8-epoxy-3-methylnonadecane.

The GC–EAD analyses of pheromone gland extracts on four GC columns (DB-5, DB-23, DB-210, SP-1000) indicated that the unknown component had retention indices (RI) (Van den Dool and Kratz, 1963) of 2027 (DB-5), 2403 (DB-23), 2297 (DB-210), and 2304 (SP-1000) relative to straight-chain alkanes. Retention-indices assignments for the component on both DB-23 and SP-1000 columns remained tentative, because the compound eluted just after disparlure, and elicited only weak antennal responses, possibly due to an antennal refractory phase after a strong response to disparlure.

To confirm correct assignment of RIs for the compound on DB-23 and SP-1000 columns, seventy-five 20-sec (200 μl) HPLC fractions of pheromone extract (200 FE) were analyzed by GC–EAD on a DB-5 column. The fraction containing

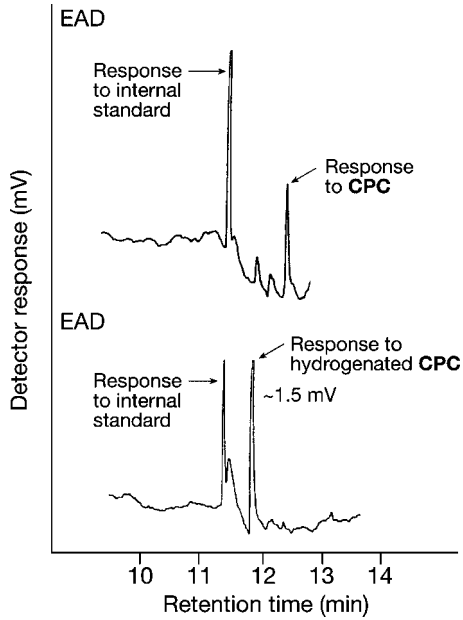

FIG. 3. Electroantennographic detector (EAD: male *Lymantia dispar* antenna) responses to the HPLC-isolated CPC before (top) and after (bottom) hydrogenation. Chromatography: DB-23 column; 100°C (1 min), 10°C per min to 200°C. Corresponding FID traces are omitted. Stronger response to hydrogenated CPC (bottom) may be explained by a more concentrated (×10) sample. (7*R*,8*S*)-*cis*-7,8-Epoxyoctadecane [(+)-monachalure (10 pg)] was used as an internal standard.

the unknown compound was further analyzed on all four columns, revealing antennal responses with the familiar RIs of 2027 (DB-5), 2403 (DB-23), 2297 (DB-210), and 2304 (SP-1000) (as mentioned earlier). Calculations of intercolumn RI differences (e.g., RI on DB-5 minus RI on DB-23; RI on SB-1000 minus RI on DB-23) suggested that the compound might be a monounsaturated epoxide. Hydrogenation and GC–EAD analyses of the fraction (Figure 3) exhibited a different antennal response with RIs on all columns consistent with those of disparlure. To confirm that the unknown compound had the molecular skeleton of disparlure, related 5,6-, 6,7-, 8,9-, and 9,10-epoxy-2-methyloctadecanes were synthesized (Table 1). Their GC characteristics were similar or identical to those of disparlure (Table 1), but their EAD activities were significantly lower.

To determine the double bond position in the unknown (= unsaturated disparlure), all possible *cis*-7,8-epoxy-2-methyloctadecenes were synthesized (Table 2). Of these, only *cis*-7,8-epoxy-2-methyloctadec-17-ene had GC- and EAD-characteristics entirely consistent with those of the novel compound.

"+" indicates strong EAD-activity.
"++" indicates very strong EAD-activity.

Enantiomers of *cis*-7,8-epoxy-2-methyloctadec-17-ene were synthesized according to the schemes in Figure 1. In the conversion of **1** to **2**, only 1 mol% of the copper complex catalyst and a minimal amount of NMP was used. Possibly as a consequence, the reaction could not be pushed to completion with excess Grignard reagent, which apparently reacted preferentially with already formed **2** to open the

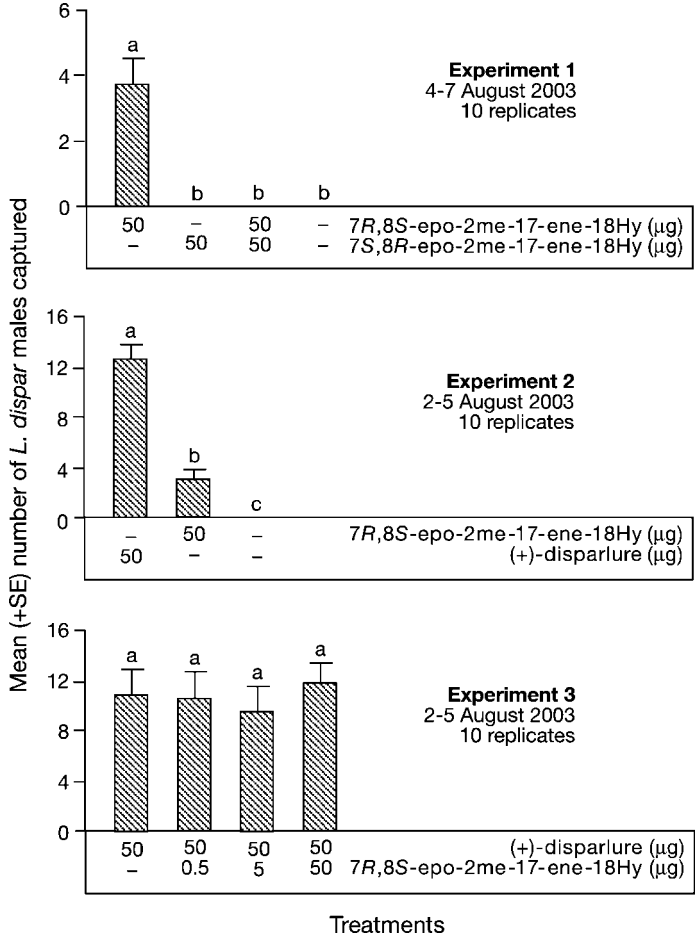

FIG. 4. Captures of male gypsy moths, *Lymantria dispar,* in experiments 1–3 in sticky traps baited with candidate pheromone components [(+)-disparlure = (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane; 7*R*8*S*-epo-2me-17-ene-18Hy = (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene; 7*S*,8*R*-epo-2me-17-ene-18Hy = (7*S*,8*R*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene]; mixed forests near Morioka (Honshu, Japan); in each experiment, bars with different letter superscripts are significantly different, $\alpha = 0.05$.

epoxide ring at the bond distal to the camphorsulfonate. The ring-opened alcohol thus formed could not be separated from **2** by chromatography. However, treatment of the mixture with K_2CO_3 in methanol rapidly and selectively converted the alcohol to the terminal epoxide, which then was easily separated by chromatography. In the conversion of **1**′ to **2**′, with the relative amounts of catalyst and NMP doubled, coupling went to completion, and no ring-opened alcohol was detected.

The biological role of (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene (7*R*8*S*-epo-2me-17-ene-18Hy) is not yet clear. It is present in pheromone glands (Figure 2), but it is not known whether it is released by calling females. By itself it attracted male moths (Figure 4; Exps. 1, 2). However, it neither enhanced attractiveness of (+)-disparlure (Figure 4, Exp. 3; Figure 5, Exp. 4) nor did it affect

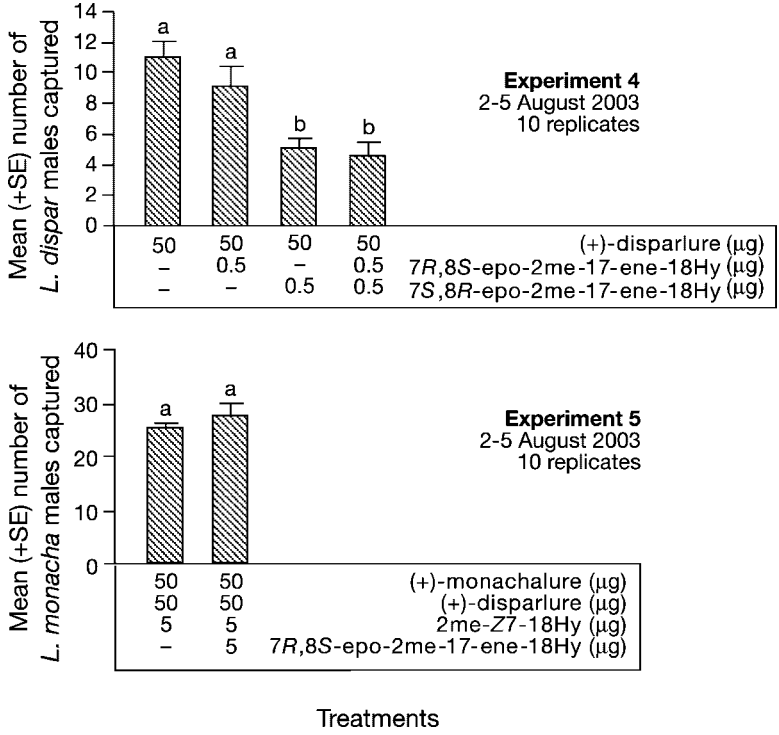

FIG. 5. Captures of male gypsy moths, *Lymantria dispar* (Exp. 4), and male nun moths, *Lymantria monacha* (Exp. 5), in sticky traps baited with candidate pheromonal and allomonal components [(+)-monachalure = (7*R*,8*S*)-*cis*-7,8-epoxy-octadecane; 2me-*Z*7-18Hy = (*Z*)-2-methyl-7-octadecene; other abbreviations as in caption of Figure 4]; Larch (*Larix* spp.) forest near Morioka (Honshu, Japan); in each experiment, bars with different letter superscripts are significantly different, $\alpha = 0.05$.

the specificity of the blend with regard to *L. monacha* (Figure 5; Exp. 5). A discernible effect of 7*R*8*S*-epo-2me-17-ene-18Hy may yet be discovered, if it were tested in a context other than long-range attraction of males (Cameron, 1981), or if it were dispensed from a more suitable release device. In field experiments with codling moths, *Cydia pomonella*, for example, secondary pheromone components failed to affect blend attractiveness when they were dispensed from rubber septa (El-Sayed et al., 1999a), but enhanced blend attractiveness when they were dispensed from a piezoelectric sprayer (El-Sayed et al., 1999b; El-Sayed and Trimble, 2002). It is also possible (although not likely) that the effects of 7*R*8*S*-epo-2me-17-ene-18Hy will only be manifested when this component is tested together with other components found in pheromone gland extracts, such as *cis*-7,8-epoxy-2-methylheptadecane or (7*R*,8*S*)-*cis*-7,8-epoxy-3-methylnonadecane (Figure 2; Gries et al., 1996; unpublished). Alternatively, 7*R*8*S*-epo-2me-17-ene-18Hy may be a trace component that provides insight into pheromone phylogeny, and may serve as a pheromone component or antagonist in *Lymantria* congeners.

Furthermore even though 7*R*8*S*-epo-2me-17-ene-18Hy had no detectable role in the *L. dispar* population of northern Honshu, it may be important in other *L. dispar* populations. In *L. monacha*, for example, (+) -disparlure is the most and least important pheromone component in populations in Bohemia (Europe) and Honshu (Japan), respectively (Gries et al., 2001). This contrasting role of (+)-disparlure may be attributed to reproductive character displacement caused by congeneric *L. fumida* on Honshu (Gries et al., 2001), which utilizes (+)-disparlure as its major pheromone component (Schaefer et al., 1999). Considering the wide distribution of *L. dispar*, and its presence in many different lymantriid communities, there may be some communities in which *L. dispar* maintains specificity of sexual communication by using 7*R*8*S*-epo-2me-17ene-18Hy in addition to, or as a substitute for, (+)-disparlure. Until such communities are found, synthetic (+)-disparlure as a single-component lure remains the best lure for detection of (Asian) *L. dispar.*

Acknowledgments—We thank C. M. Hadad (Ohio State University) for electrospray ionization mass spectra, Roger Fuester and Philip Taylor (USDA, Newark) for providing some female *L. dispar,* Susan Barth (USDA, Newark) for technical assistance, and Iwate University Personnel for permission to use their research forest near Morioka. The research was supported, in part, by a contract from the State of California, Department of Food and Agriculture (contract No. 98-0508), and by a grant from the Natural Sciences and Engineering Research Council of Canada to G. G. At SFU, experimental insects were maintained in the Global Forest Quarantine Facility, construction of which was completed through financial support from Global Forest (GF-18-2000-SFU-5).

(Received December 31, 2003; accepted August 17, 2004)

Abstract—Many mammals and birds roll on or rub themselves with millipedes that discharge benzoquinones. Chemicals transferred from millipedes onto the integument of anointing animals are thought to deter ectoparasites. We tested the lone star tick, *Amblyomma americanum* (L.), for responses to three widespread components of millipede defensive secretions, 1,4-benzoquinone; 2-methyl-1,4-benzoquinone (toluquinone); and 2-methoxy-3-methyl-1,4-benzoquinone (MMB). In toxicity tests, ticks were confined for 1 hr in filter-paper packets treated with serial dilutions of each of the benzoquinones or the commercial acaricide permethrin. Ticks were least affected by toluquinone, and most affected by permethrin. Of the benzoquinones, only MMB showed repellent activity. Behavioral assays were more sensitive than mortality for measuring the effects of the benzoquinones. Latencies for ticks to right themselves and to climb were greater with all compounds, even at the lowest concentrations, than with controls. Ticks exposed to low concentrations of benzoquinones appeared to recover over time, whereas those exposed to high concentrations exhibited behavioral abnormalities 1–3 mo later. Our results indicate that benzoquinones appropriated via anointing may reduce the tick loads of free-ranging animals,

although key questions remain on the amounts of these compounds available to and effectively appropriated by anointing animals.

Key Words—Benzoquinones, ectoparasites, ticks, anointing, repellent, toxicant.

INTRODUCTION

A number of vertebrates rub on, or roll in, selected plants, arthropods, and other scent-bearing materials. Chemicals topically appropriated by self-anointing are known or suspected to deter predators, ectoparasites, or microbial pathogens (summarized by Weldon, 2004). Millipedes are used for self-anointing by a variety of birds and mammals. Free-ranging birds in the New and Old Worlds have been observed rubbing these myriapods against their plumage (reviewed in Parkes et al., 2003). Among mammals known to self-anoint with millipedes are Malagasy lemurs (Overdorff, 1993; Birkinshaw, 1999) and Central and South American cebid monkeys (Baker, 1996; Valderrama et al., 2000; Zito et al., 2003). Most identified millipedes used in self-anointing belong to the orders Julida (Harper in Cramp, 1981; Harrup, 1992), Spirobolida (Clunie, 1976; Overdorff, 1993; Zito et al., 2003), or Spirostreptida (Overdorff, 1993; Birkinshaw, 1999; Valderrama et al., 2000). These taxa, which collectively occur throughout temperate and tropical regions worldwide, comprise the "quinone millipedes," so called because they characteristically secrete benzoquinones from their numerous paired segmental glands (Eisner et al., 1978).

Valderrama et al. (2000) reported that the spirostreptidan millipede *Orthoporus dorsovittatus* was used in self-anointing by free-ranging wedge-capped capuchin monkeys, *Cebus olivaceus*, in Venezuela. They hypothesized that mosquitoes are repelled by benzoquinones appropriated from this millipede. To evaluate this hypothesis, Weldon et al. (2003) presented female yellow fever mosquitoes, *Aedes aegypti*, with the two secretory compounds isolated from *O. dorsovittatus*, 2-methyl-1,4-benzoquinone (toluquinone) and 2-methoxy-3-methyl-1,4-benzoquinone (MMB), on nylon-reinforced silicone membranes placed over wells filled with human blood. Mosquitoes landed and fed less frequently, and flew more frequently (a possible indication of repellency), in the presence of membranes treated with benzoquinones than with controls.

Studies with a variety of other insects demonstrate that benzoquinones deter feeding (Loconti and Roth, 1953; Ogden, 1969; Mondal and Port, 1984), act as topical irritants (Ogden, 1969; Peschke and Eisner, 1987), or are toxic (Kanehisa, 1969). Some benzoquinones also have been shown to be noxious or toxic to vertebrates, and to inhibit microbial growth (De Rosa et al., 1994). However, apart from the recent findings with mosquitoes (Weldon et al., 2003), no studies have tested the effects of these compounds on the ectoparasites of tetrapods.

Ixodid (hard) ticks are important pests of a wide range of vertebrates, including mammals and birds (Sonenshine, 1993). Heavy infestations of these

ectoparasites can debilitate or kill even large mammals (Strickland et al., 1976), but tick-borne diseases caused by bacteria (e.g., rickettsiae, spirochetes), viruses, and protozoa may pose an even greater danger to wildlife (Strickland et al., 1976; Sonenshine, 1993). In the New World tropics and subtropics, wounds caused by tick bites can serve as entry sites for flesh-eating and potentially deadly screwworms, *Cochliomyia hominivorax* (Strickland et al., 1976). Ticks, therefore, exert significant selective pressure on host species.

We report here on the behavioral responses and morbidity of the lone star tick, *Amblyomma americanum* (L.), to three compounds that occur widely in the defensive secretions of millipedes, 1,4-benzoquinone; toluquinone; and MMB (Eisner et al., 1978) and, for comparative purposes, to permethrin, a commercially available synthetic pyrethroid used to repel and kill ticks (summarized by Sonenshine, 1993). *A. americanum* ranges from the south-central and southeastern United States northward along the Atlantic seaboard to New England (Keirans and Durden, 1998; Guglielmone et al., 2003). In order to complete its life cycle, *A. americanum* must find a host three times and remain attached for several days each time (Strickland et al., 1976). The genus *Amblyomma* is predominantly tropical and subtropical in distribution (Hoogstraal, 1973; Hoogstraal and Aeschlimann, 1982), and includes species known to parasitize the monkeys *C. capucinus* and *C. olivaceus* (Fairchild et al., 1966; Jones et al., 1972), which are known to self-anoint with benzoquinones. Various *Amblyomma* species feed on birds (Strickland et al., 1976).

METHODS AND MATERIALS

Subjects. Nymphs of *A. americanum* were obtained from a colony at the United States Department of Agriculture, Agricultural Research Service, Knipling-Bushland US Livestock Insects Laboratory, Kerrville, TX. They were maintained at 23–24°C, ≈99% RH, and on a photoperiod of 16:8 hr (L:D). At the time of testing, ticks had been in the nymphal stage 5–8 wk.

Chemicals. 1,4-Benzoquinone and toluquinone were obtained commercially (Sigma-Aldrich, St. Louis, MO). MMB was synthesized, as described by Weldon et al. (2003). Permethrin was obtained from FMC Corporation (Philadelphia, PA). Solutions of 7.8, 31.0, 125, and 500 mM in acetone were prepared for each compound; an additional solution of 1.9 mM was prepared for permethrin. This dilution series was chosen, on the basis of results from preliminary studies, to include threshold concentrations; the lower dilution of permethrin was included because this compound appeared to be more potent than the benzoquinones we used. Solutions were kept refrigerated (5°C) and removed only for bioassay.

Repellent Bioassay. Repellency tests were conducted on a plastic Petri dish (5.5 cm diam, 1.5 cm high) containing a flat layer of modeling clay 0.5 cm deep, and glued centrally within a larger (9 cm diam, 1.3 cm high) dish. Water (≈0.5 cm deep) was added to the space between the concentric walls of the two Petri dishes, creating a moat to contain ticks. A 2 ×10-cm rectangle was marked with a lead

pencil on a 3 × 11-cm rectangular piece of filter paper (Whatman No. 4), 1 cm from a long and short edge. The filter paper was placed into a glass Petri dish (15 cm diam, 2 cm high), and 165 μl of either solvent (acetone) or test solution were evenly applied by a pipettor to the 2 × 10-cm rectangular area. After drying for 10–15 min, the paper was rolled crosswise and taped together to form a short cylinder (≈3.2 cm diam, 3 cm high). The treated portion of the filter paper formed a continuous band around the inside surface of the cylinder. The untreated edge of the filter paper cylinder was pushed ≈3 mm into the central area of the modeling clay, allowing a ≈7 mm high band of untreated filter paper surmounted by the 2-cm high band of treated filter paper to project above the clay.

Three groups of 10 ticks were tested with acetone and a 500 mM solution of each compound. MMB also was tested as a 125 mM solution. A different filter paper cylinder was used for each group of ticks. Ten active and ostensibly healthy nymphs were placed into a Teflon-lined plastic test tube (9 cm deep). The ticks were dumped from the tube onto the clay in the center of the filter paper cylinder. The water moat confined ticks that climbed out of the filter paper cylinder. The locations of ticks were recorded at 15 min after they were released. Ticks on the clay or on the untreated lower portion of filter paper inside the cylinder were considered repelled.

Exposure Packets. The process by which ixodid ticks find attachment sites and begin to feed generally takes several hours. Thus, in the absence of strong repellency, ticks would have extended exposure to benzoquinones on pelage or plumage, which we attempted to simulate to evaluate its possible physiological consequences on ticks. A 5 × 6-cm rectangle of Whatman No. 4 filter paper was marked with a lead pencil with lines 0.5 cm from each side. The filter paper was placed into a glass Petri dish and 165 μl of solvent or one of the test solutions (7.8, 31.0, 125, and 500 mM, and for permethrin, 1.9 mM) were applied evenly with a pipettor to the 4 × 5-cm rectangle bordered by the pencil lines. After the filter paper had dried for 10–15 min, it was folded crosswise. A bulldog clip (5.3 cm wide) closed each of two margins of the folded filter paper. Ten active nymphs were placed into the cavity formed by the folded paper, and another bulldog clip was attached to the open end of the packet to enclose the ticks. The clips were affixed slightly more than 0.5 cm from the edges of the paper, so that the confined ticks could only contact the treated area of the filter paper. The packet holding the ticks was kept for 1 hr in a glass desiccator jar (≈2 l) containing water (below the shelf) to maintain high humidity (>95% RH). The jars were rinsed with water after each exposure. Five replicates of 10 ticks each were prepared for each concentration–compound combination.

Righting and Climbing Responses. The packet was removed from the desiccator, opened, and the 10 nymphs were removed singly with forceps. Each tick was placed on its dorsum on clay within an encircling cylinder of untreated filter paper similar to that used for the repellent test. As with the repellent test, the clay arena was situated in a moated Petri dish. To prevent ticks from using the forceps

as leverage to right themselves as they were released, they were grasped so that their legs did not contact the forceps. The number of ticks that were right-side-up, and the number of ticks that had climbed to the rim of the filter paper cylinder or beyond, were recorded at 0.5, 1, 5, 10, and 15 min after release. After 15 min, the ticks were placed into a plastic vial with holes in the cap and returned to a regime of 23–24°C, 99% RH and a photoperiod of 16:8 hr (L:D). We refer to these trials below as 0-hr trials because they immediately followed the 1-hr exposure to one of the solutions. To evaluate how long the exposure to the benzoquinones and permethrin affected the nymphs, the behavioral tests were repeated with the ticks that were used in the last three trials at 24 hr (referred to as 24-hr trials) and again 1–3 mo after exposure (1–3-mo trials). Only the ticks exposed to the acetone (control) and 125 mM solutions were used in the 1–3-mo trials.

Toxicity. At 24 hr after exposure in filter paper packets, the survivorship of ticks was determined by observing the ticks in a moated Petri dish. Ticks moving only in an uncoordinated manner and a distance of <5 mm were considered moribund. Ticks that failed to move after 5 min in the Petri dish, even when exhaled upon or prodded with forceps, were considered dead. The behavioral test was repeated 24 hr after exposure with ticks in the last three replicates. In the analysis, we combined dead and moribund ticks because ticks in neither category would pose a risk to hosts. Ticks that were alive 24 hr after exposure were again examined for toxic effects 1–3 mo later. The criteria for mortality used in the toxicity tests were applied to these ticks to determine whether they should be excluded from the trial.

Statistical Analysis. We used logistic regression (Proc Genmod in SAS, 1999) to analyze the repellency of the compounds at 500 mM at 15 min. Since MMB repelled all ticks, we subtracted 0.5 from one of the scores (changing 10/10 to 9.5/10) to obtain meaningful parameter estimates. We estimated four one-degree-of-freedom contrasts with the acetone control.

Data on the number of ticks that were dead or moribund (incapacitated) 24 hr following the 1-hr exposure were modeled as dose–response relationships by using the arcsine-transformed proportion of dead and moribund ticks as the dependent variable and the square root of concentration as the independent variable. The square-root transformation of concentration yielded a straight-line relationship for all compounds except permethrin. We modeled permethrin only at the lowest concentrations, and set the percent of incapacitated ticks to 100% for concentrations >7.8 mM. Since the bioactivity of the benzoquinone solutions appeared to deteriorate over time, and the first trial on each group of 10 ticks was conducted from 24 to 104 days after the solutions were prepared, we also included the age of solution in the model for incapacitated ticks and for the models of behavioral change (discussed subsequently). We used the log of age $-$ log (66) (66 days was the mean solution age) to reduce colinearity with the intercept term. We used the Proc Mixed routine in SAS (1999) for this analysis.

The behavioral data were not independent because each group of 10 ticks was observed five times within a concentration–compound combination on two different criteria and, for some groups, on three trials (0 hr, 24 hr, 1–3 mo following the initial 1-hr exposure). We found that the relationship between the arcsine-transformed proportion of ticks exhibiting the behavior (excluding incapacitated ticks) and the log of time was approximately linear. Therefore, for each of the six behavior-trial combinations (two behaviors, three trial times), we estimated a slope and an intercept (and their standard errors) for each concentration-compound combination. In effect, we modeled each group of 10 ticks with a straight line that relates the proportion (transformed scale) exhibiting the behavioral measure to observation time (transformed), yielding six lines (two behaviors, three trials) per group. For the righting behavior, we used all five observation time points to construct the lines, but for climbing behavior we used only the last four time points because the proportion for the first time point was zero for all groups.

We then created one degree-of-freedom contrasts (as t-values) between the control groups, which were modeled in the same way for each of the treatment groups. Each pair of contrasts compared the control intercept and control slope with the intercept and slope from one of the treatments. The magnitude and sign of the pair of contrasts indicate how the treatments differed from controls, with absolute values less than about two indicating no statistical difference. A positive value for an intercept contrast indicated that controls were more active at the earliest observation time. A positive value for a slope contrast indicated that, over the 15 min period, the proportion of ticks exhibiting the behavior in the treatment group increasingly lagged behind that of the control, i.e., differences between the treatment and control groups increased over time.

A multiple comparison adjustment was not required when comparing treatment effects within one of the three trials (0 hr, 24 hr, and 1–3 mo) and within one of the two behavioral measures. However, analyses of the two behaviors were correlated (ticks cannot climb if they have not first righted), as were analyses over the three trials (repeated measures of some ticks). Rather than present a recondite analysis with the data modeled jointly using a complicated covariance structure (to incorporate the time series structure and other potential dependencies), we present unadjusted t-values for the slopes and intercepts, which readers can interpret conservatively, and focus attention on their patterns.

Not all contrasts with controls could be made for two reasons. Because only live ticks were used to calculate these values for the 24-hr and 1–3-mo trials, there were some treatment combinations with no live ticks, and, thus, no possible estimate. In other cases, especially for higher concentrations, no living ticks exhibited the behavior for the entire 15 min observation period. In that case, a flat line of zero was estimated (with no variance), so a t-value based on a comparison with the control would be inappropriate. Model fitting was performed by using the R software (Ihaka and Gentleman, 1996), output was parsed, and t-values calculated using Perl programs. Other statistical comparisons were performed with standard t-tests.

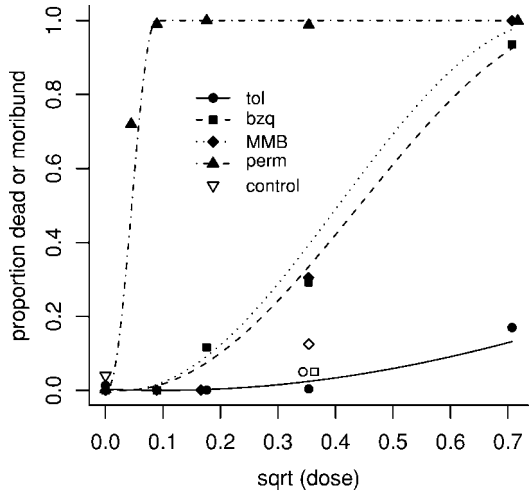

FIG. 1. Dose–response curves for incapacitation (morbidity and mortality) of *A. americanum* nymphs 24 hr after 1-hr exposure to benzoquinones or permethrin. The open symbols represent values for ticks tested 1–3 mo later. The compounds indicated are toluquinone (tol); 1,4-benzoquinone (bzq); 2-methoxy-3-methyl-1,4-benzoquinone (MMB); and permethrin (perm).

RESULTS

Repellency. Of the benzoquinones, only MMB repelled *A. americanum* nymphs ($\chi^2 = 17.56$, $P < 0.001$, 1 *df*). MMB repelled all nymphs at 500 mM (25.0 mM/cm^2), but none at the 125 mM (6.3 mM/cm^2) treatment. At 500 mM, permethrin repelled 63% of the nymphs, significantly more than the control ($\chi^2 = 14.94$, $P = 0.001$, 1 *df*).

Toxicity. Dose–response curves for incapacitation of *A. americanum* nymphs, adjusted to the mean solution age of 66 days and back-transformed to the original proportion scale, are shown (Figure 1). The model (on the transformed scale) is $t(p_i) = 0.982 + \beta_i \sqrt{\text{dose}} - 0.248 \log(d)$, where $t(p)$ gives the expected value of the arcsine-transformed proportion of incapacitated ticks, i indexes compounds, β_i estimates (standard errors) are 1.911 (0.189) for 1,4-benzoquinone, 2.084 (0.189) for MMB, 0.609 (0.189) for toluquinone, and 18.482 (1.482) for permethrin (only modeled for concentrations <7.8 mM), and d +66 is the number of days since the solution was prepared. The proportions of ticks incapacitated 1–3 mo after they were exposed to the 125 mM 1,4-benzoquinone treatment and acetone control also are depicted as open symbols in Figure 1.

Toluquinone was less toxic than either 1,4-benzoquinone or MMB ($P <$ 0.001, *t*-test, 84 *df*), with the latter two statistically indistinguishable ($P = 0.74$, *t*-test, 84 *df*). Only 2% of ticks exposed to 7.8 mM permethrin were alive and

active 24 hr after exposure. At this concentration, the other compounds had little or no effect. For 1,4-benzoquinone and MMB, the proportion of ticks incapacitated decreased 1–3 mo later, as some of the ticks moribund at 24 hr recovered. All ticks classified as moribund at 24 hr after exposure to permethrin died within 1–3 mo. The proportion incapacitated 1–3 mo later changed little for toluquinone.

Behavioral Responses—Righting. In general, slope differences between control and treatment groups were not as great as intercept differences (Figure 2). Thus, the proportion of ticks righting at the beginning of testing differed between the control and treatment groups, but righting rates following the initial observation were roughly the same for the remainder of the observations. In general, these contrasts mirrored the toxicity statistics, with larger t-values for higher doses within a compound and the smallest t-values for toluquinone, the least toxic compound. Many of the intercept t-values were quite large and all were >3 for the first trial (0 hr), even for toluquinone, indicating an effect of all compounds at all doses

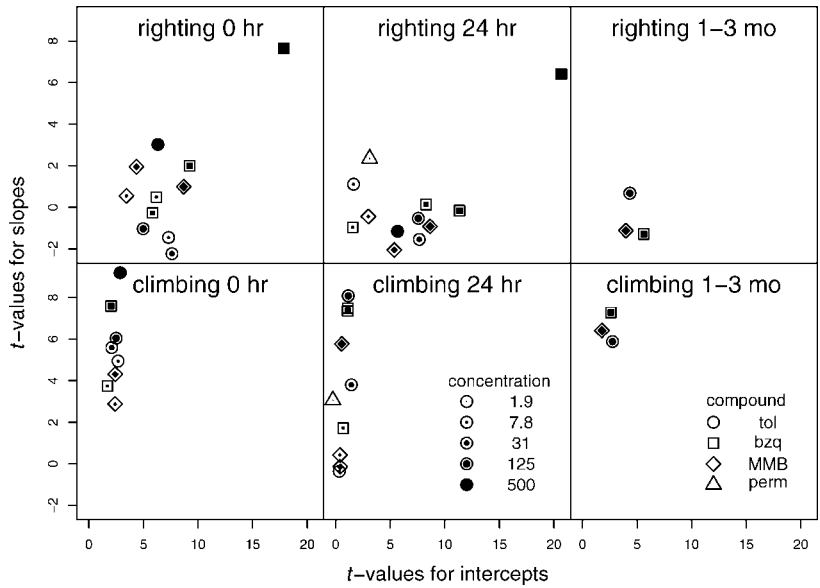

FIG. 2. Contrasts (as t-values) between treatment and control groups for the righting and climbing responses and for three trial times for the behavioral tests were calculated from regressing the arcsine-transformed proportion of ticks exhibiting the behavior on the log of time since the test started. Each point is associated with an intercept contrast (on abscissa) and slope contrast (ordinate). Increased filling of symbols indicates higher concentrations (mM). The greater the t-value differs from zero, the greater the behavioral difference between the treated and control group, with significant differences greater than about two. Not all treatment/dose combinations are given (see text).

on the righting behavior. One day later, some ticks appeared to have recovered at the lower concentrations, where the intercept *t*-values had moved toward 0 for all compounds, even permethrin. However, for higher concentrations, *t*-values for intercepts increased, indicating that the effect on ticks at these concentrations is more pronounced after 24 hr than immediately after exposure. There is evidence of continued recovery for the trials conducted 1–3 mo later: intercept *t*-values for compounds at these concentrations decreased relative to righting at 24 hr.

Behavioral Responses—Climbing. In contrast to righting, *t*-values were largest for slope contrasts (Figure 2). This is readily understood since intercepts, the estimates for 0 min, should be near 0 because all individuals, regardless of treatment, first had to right. However, intercept *t*-values did shrink from values close to 2.5 in the 0 hr trials to close to 0 in the 24-hr trials. Thus, earlier small, but consistent, differences in initial observations nearly disappeared 24 hr later.

In contrast to the intercept *t*-values, the slope *t*-values were large for almost all compounds at all concentrations. A clear concentration effect is evident, as the *t*-value order closely follows that of concentration. This indicates that the latency (or inability) to climb becomes more obvious over the 15-min observation period and depends on concentration. After 24 hr, there appears to be some return to control levels for low concentrations, as in the righting data. However, even after 1–3 mo, large lags in the climbing behavior of the ticks receiving the 125 mM concentration were evident. These individuals appeared to have suffered long-lasting effects from exposure to the compounds months earlier. With few exceptions, the differences between compounds were not as pronounced as differences between doses for both kinds of behavioral data. The highest concentrations generally are not depicted in Fig. 2 for either behavioral response because most ticks at these concentrations were incapacitated, and these contrasts could only be made for ticks that were not dead or moribund.

DISCUSSION

The phenomenon of anointing is unique among allelochemical interactions because organisms may respond in nature to chemicals from species with which they ordinarily do not interact (Weldon, 2004). Millipedes rarely and inconsequentially encounter tetrapod ectoparasites, but the responses of such ectoparasites to millipede chemicals may attain ecological relevance through the vehicle of avian and mammalian anointing. Our study is predicated on the assumption that ticks encounter benzoquinones deposited on the plumage or pelage of anointing animals.

The preprandial behaviors of ixodid ticks differ from those of mosquitoes and most other biting flies in ways that dispose ticks to receive greater exposure to anointing chemicals. Ixodids are highly selective in identifying feeding sites

(Waladde and Rice, 1982), wandering extensively on the skin before locating a suitable site of attachment (Kemp et al., 1982). Ticks crawling through the pelage or plumage of a host would be surrounded by anointed surfaces, encountering chemicals by contact or, in the case of volatiles, as fumigants. After penetration of their host's integument, many ticks secrete a hardened encasement around their feeding appendage, the hypostome, and proceed to engorge over a few days. Thus, the 1-hr confinement of ticks in treated filter paper packets during our bioassays was not excessively protracted in simulating chemical exposure to an anointed host.

A repellent, by definition, elicits movement away from a chemical source (Dethier et al., 1960). Our repellency bioassay allowed ticks to either crawl away from a treated area or fall off a vertical surface to avoid contact with repellent treatments. Only MMB at the highest dose we used (500 mM) prevented ticks from crawling across treated filter papers; the next lower dose (125 mM) of this compound had no detectable effect. These results are worth noting in light of numerous reports indicating that insects are irritated or repelled by benzoquinones (e.g., Ogden, 1969; Peschke and Eisner, 1987). Nonetheless, MMB was significantly more effective in preventing *A. americanum* from climbing out of treated filter paper cylinders than was permethrin, a synthetic pyrethroid marketed as a tick repellent and acaricide. Several ticks dropped from the permethrin-treated filter paper, whereas the ticks tended not to crawl on the MMB-treated filter paper. The repellency of permethrin may be due as much to its fast-acting toxicity requiring contact with treated surfaces as to actual avoidance (summarized in Sonenshine, 1993).

The morbidity/mortality of ticks in response to the compounds we used was greatest for permethrin, which was effective even at 1.9 mM. Morbidity/mortality in response to benzoquinones was manifest only at intermediate and high doses (125 and 500 mM), but ticks exposed even to the most dilute concentrations of these chemicals exhibited persistent impairments in righting and climbing abilities. The clearest behavioral difference in response to the three benzoquinones we tested, and among the doses of each, was manifest with respect to climbing. Climbing ability, an integral part of host acquisition by many ixodid ticks (Lees and Milne, 1951; Sonenshine, 1993), was found impaired upon retesting ticks more than 1 mo after exposure in our tests. Climbing inhibition would seriously impair a tick's ability to contact a suitable host, and may be a manifestation of a more basic behavioral or physiological impairment. The toxicities of toluquinone and other benzoquinones also have been demonstrated with insects (Kanehisa, 1969). Mosquitoes (*Ae. aegypti*) exposed to toluquinone and MMB on feeding membranes sometimes became immobilized and died, especially with MMB (Weldon et al., 2003).

The benzoquinones were not as toxic to ticks as permethrin. However, ticks exposed for 1 hr to benzoquinones even at low concentrations behaved abnormally, and intermediate concentrations clearly were toxic. Other than MMB, these

compounds do not seem to repel ticks, suggesting that, for protection against ticks, anointing animals must apply sufficient quantities of compound to disorient or physically disable potential tick parasites. Tests of climbing produced a clearer pattern than righting for detecting the behavioral effects of the compounds and their concentration effects. The climbing test also better showed concentrations at which effects were temporary and at which they were long-lasting. Both measures demonstrated that even low concentrations adversely affected these two behaviors important for successful host attachment.

The toxicities of benzoquinones demonstrated in our study of *A. americanum* indicate the potential for protection against ticks afforded by anointing with these compounds. Key questions remain, however, on the quantities of benzoquinones available to and effectively appropriated by free-ranging animals. Estimates of the quantities of benzoquinones produced by millipedes range up to 350 mg per individual for some tropical species (Fairhurst, 1993). These compounds may be appropriated from other sources, as well. Laughingthrushes (*Garrulax* spp.) from Fiume, Italy (currently Rijeka, Croatia), for example, are reported to anoint with tenebrionid beetles of the genus *Blaps* (Callegari, 1955), which may defensively discharge benzoquinones (Blum, 1981).

Because attachment and commencement of feeding in ixodid ticks takes hours and completion of feeding is a matter of several days, the exposure that ticks receive to chemicals applied to the integument of their hosts is protracted. Repeated anointment may be necessary to maintain the efficacy of topically applied compounds due to their volatility and/or degradation. We detected a reduced efficacy of the benzoquinones used in our tests over time, even though solutions were stored in cold, light-free conditions; this prompted us to include a time covariate for solution age when modeling the data. Quantitative studies of the transfer and retention of anointing chemicals, and of their efficacy in deterring ectoparasites on hosts, are needed.

Acknowledgments—We thank J. M. Pound and C. Santos, USDA, ARS Knipling-Bushland US Livestock Insects Research Laboratory, Kerrville, TX for supplying *A. americanum* nymphs, and J. E. Oliver and A. Weatherwax, USDA, ARS, Chemicals Affecting Insect Behavior Laboratory, Beltsville, MD for performing syntheses.

(Received February 9, 2004; accepted September 20, 2004)

Abstract—Grapevine moth *Lobesia botrana* is the economically most important insect of grapevine *Vitis vinifera* in Europe. Flower buds, flowers, and green berries of Chardonnay grapevine are known to attract *L. botrana* for oviposition. The volatile compounds collected from these phenological stages were studied by gas chromatography—mass spectrometry, and the antennal response of *L. botrana* females to these headspace collections was recorded by gas chromatography—electroantennography. The compounds found in all phenological stages, which consistently elicited a strong antennal response, were pentadecane, nonanal, and α-farnesene. In a wind tunnel, gravid *L. botrana* females flew upwind to green grapes, as well as to headspace collections from these berries released by a piezoelectric sprayer release device. However, no females landed at the source of headspace volatiles, possibly due to inappropriate concentrations or biased ratios of compounds in the headspace extracts.

Key Words—*Lobesia botrana*, host plant volatiles, kairomone, upwind attraction, wind tunnel, GC–EAD, electrophysiology, headspace collection, chemical analysis.

INTRODUCTION

Larvae of grapevine moth *Lobesia botrana* (Denis and Schiffermüller) (Lepidoptera, Tortricidae) feed on all developmental stages of grapevine *Vitis vinifera*, and occur in up to four generations throughout the growing season. Fungi, especially grey mold *Botrytis cinerea*, develop rapidly on the damaged grapes, causing entire clusters to rot. Grapevine moth is the most damaging insect throughout the European wine-growing area (4 million ha) as well as adjacent Mediterranean countries in North Africa and Asia Minor (Bovey, 1966; Fermaud and Le Menn, 1989; Gabel and Roehrich, 1995).

The female sex pheromone of *L. botrana* and male attraction to synthetic pheromone have been studied in detail since the seventies (Roelofs et al., 1973; Arn et al., 1988; El-Sayed et al., 1999). Today, pheromone-based disruption of mating is used on ca. 50,000 ha in Europe. However, the mating-disruption technique is not efficient at high population densities (Arn and Louis, 1996; Louis and Schirra, 2001; Varner et al., 2001). One important drawback is that only male behavior is affected, and not the behavior of gravid females. The efficacy of pheromonal methods may accordingly be enhanced by kairomonal chemicals affecting also female host-finding and egg-laying behavior, such as plant volatile compounds (Light et al., 2001; Bengtsson et al., 2001).

Volatiles from grape have been widely studied, especially with respect to aromas of flowers and ripe fruit (Schreier et al., 1976; Welch et al., 1982; Buchbauer et al., 1994, 1995; Rosillo et al., 1999; Darriet et al., 2002). Floral volatiles of cv. Müller-Thurgau have been shown to modify oviposition behavior in grapevine moth females (Thiéry and Gabel, 2000).

We demonstrate here that upwind flight attraction of female grapevine moth *L. botrana* is mediated by grape volatiles. As a first step towards the identification of host plant signals that mediate female reproductive behavior, we have used insect antennae to screen headspace collections from grape leaves, flower clusters, and berries for bioactive compounds.

METHODS AND MATERIALS

Headspace Collections. Headspace collections were made from branches with leaves (3–4 wk after bloom), flower clusters before bloom, clusters during early bloom (10–30% blossoms open), clusters at full bloom (100% blossoms open), and grape berries (3–4 wk after bloom) of the cv. Chardonnay. Five samples per phenological stage were analyzed by coupled gas chromatography and mass spectrometry (GC–MS), and six samples per developmental stage were analyzed by coupled GC and electroantennographic detection (GC–EAD).

Freshly cut branches or grape clusters (ca. 200 g) were placed in to a 2000-ml glass jar. The cut end of the clusters was in a 10-ml vial with water. Charcoal-filtered

air was pulled through the jar at 150 ml/min and over a Porapak Q cartridge containing 50 mg of adsorbent (Sigma-Aldrich). Collections were done for 22 hr in a climatic chamber at 25 ± 2°C and 30 lux. Volatiles were desorbed by eluting the cartridge with 500 μl hexane (redistilled; LabScan, Malmö, Sweden), and 500 ng heptyl acetate (99.8% chemical purity) were added as an internal standard. Sample volumes were reduced to 50 μl at room temperature in vials with an elongated tip (5 cm × 2 mm ID; Klimetzek et al., 1989). Samples were sealed in glass vials and stored at −18°C.

Solid Phase Microextraction. A manual solid phase microextraction (SPME) holder (Supelco, Bellefonte, PA) with a fiber coated with 100 μm of polydimethylsiloxane was used. The fiber was conditioned for 30 min in a GC injection port at 250°C. Meanwhile, flower clusters (early bloom) were placed in to a 2000-ml glass jar. Cluster stems were provided with water to maintain the physiological water content. The fiber was then placed into the jar above the plant material for 22 hr. After sampling, the fiber was immediately desorbed for two min in a GC injection port.

Gas Chromatography and Mass Spectrometry. Grape volatiles were identified with an Hewlett-Packard 5970B MS with electron impact ionization (70 eV), which was interfaced to an HP 5890 gas chromatograph, equipped with an HP-INNOWax column (30 m × 0.2 mm) with an oven temperature program of 5 min at 50°C, 10°C/min to 60°C, 1 min at 60°C, 2.5°C/min to 200°C, 30 min at 200°C.

Gas Chromatography and Electroantennographic Detection (GC-EAD). An HP 5890 GC, using both an HP-INNOWax (30 m × 0.2 mm) and a DB-Wax (30 m × 0.25 mm; J&W Scientific, Folsom, CA) capillary column, programmed from 60°C at 8°C/min to 220°C (10-min hold), was interfaced with an electroantennogram apparatus (Arn et al., 1975). The outlet of the GC column was split in a 1:1 ratio between the flame ionization detector (FID) and a cut antenna of a *L. botrana* female. The antenna was mounted in a holder, and the cut ends rested in two wells containing Beadle–Ephrussi Ringer solution. Compounds eluting from the capillary column were delivered to the antenna through a glass tube (12 cm × 8 mm) by a charcoal-filtered and humidified airstream. The antennal signal and the FID signal were amplified and recorded simultaneously using Syntech (Hilversum, The Netherlands) software.

Chemicals. The identity of most compounds in volatile collections was verified by comparison with purified, authentic plant compounds, and synthetic compounds. Compounds were purchased from Carlo Erba Reagenti (Milan, Italy), Sigma-Aldrich, Bedoukian Research (Danbury, CT), Firmenich (Geneva, Switzerland), Fluka, and Shin-Etsu Chemical Co. (Tokyo, Japan), or obtained as gifts from Hans Alborn (Gainesville, FL), Anna-Karin Borg-Karlson and Ilme Liblikas (Stockholm, Sweden), and Wittko Francke (Hamburg, Germany) (see Table 1). Compounds, which did not elicit antennal responses, and for which no standards were available, were tentatively identified using the Wiley mass spectral database.

Notes: Compounds in bold face type elicited responses from antennae of female grapevine moths in GC-EAD experiments (see Table 2). Identifications of asterisked compounds are tentative only.

[a] Amounts relative to (*E*,*E*)-α-farnesene. The average amount of (*E*,*E*)-α-farnesene collected from 200 g of clusters in full bloom and from 200 g of green berries was 0.25 ± 0.1 and 0.28 ± 0.15 μg/h, respectively ($N = 5$).

[b] Standards were obtained from Hans Alborn, Gainesville, FL (HA), Bedoukian Research Inc., Danbury, CT (B), Anna-Karin Borg-Karlson, Stockholm, Sweden (AB), Carlo Erba Reagenti, Milan, Italy (CE), Firmenich, Geneva, Switzerland (FI), Fluka (F), Wittko Francke, Hamburg, Germany (WF), Ilme Liblikas, Stockholm, Sweden (IL), and Sigma-Aldrich (SA). Compounds which were not available were tentatively identified according to the Wiley mass spectra library (W).

[c] Branches with leaves ($N = 5$).

[d] Clusters with flower buds ($N = 5$).

[e] Clusters with 10–30% flowers open ($N = 5$).

[f] Clusters with all flowers open ($N = 5$).

[g] Green berries, 5 wk after flowering, during the second generation of grapevine moth ($N = 5$).

[h] Porapak Q air filters.

[i] Solid phase microextraction, using clusters at early bloom.

Insects. A laboratory culture of grapevine moth was maintained on a semi-synthetic diet (Mani et al., 1978). Insects were collected in vineyards in Trento, Italy. Larvae and pupae were reared under a 16L:8D photoperiod and 22°C. Pupae were separated by sex and emerged were adults provided with sugar-water solution. Virgin females used for GC–EAD recordings were 2–3-days old.

Females used in wind tunnel bioassays were 2–4-days old. After eclosion, females were mated in 33 × 33 × 33-cm^3 Plexiglass cages. Their mating status was verified by placing them into glass tubes (12.5 cm × 2.5 cm^2); females laying eggs were used for wind tunnel experiments.

Wind Tunnel Bioassay. The Plexiglass wind tunnel had a flight section of 63 × 90 × 200 cm^3. Air was blown by a horizontal fan (Fischbach, Neunkirchen, Germany) at 30 cm/sec through activated charcoal filters (Camfil, Trosa, Sweden) into the tunnel (Arn et al., 1986). The flight section was lit diffusely from the side at 10 lux, and the room was kept at 23 ± 2°C and 40–60% RH.

Female moths were placed singly in to glass tubes (12.5 cm × 2.5 cm^2). The females were tested for 15 min, using batches of 10–16 females per test stimulus, during the first 2 hr of the scotophase. The glass tubes were positioned at the downwind end of the tunnel, 30 cm from the floor and ca. 180 cm from the source. The tubes were baked at 375°C for 8 hr before use.

Plant material and headspace collections were applied as odor sources, at the upwind end of the wind tunnel. Unripe grape clusters (ca. 150 g, berries 5–10-mm diam) or green branches (shoots with up to 10 green leaves) were kept in a 1-l Plexiglass cylinder covered with gauze. Thus, the plant material did not provide visual cues. Grapes were freshly picked and stored at 4°C and 100% RH for up to 2 days.

A headspace extract (see above) from green berries was reduced to ca. 50 μl and then diluted with ethanol (redistilled; LabScan, Malmö, Sweden) to contain the most abundant compound (*E*,*E*)-α-farnesene at 1 ng/μl. This extract was released from a sprayer, which allowed volatilization of all compounds at a known and constant rate, regardless of their vapor pressures (Gödde et al., 1999). The solution was fed into a glass capillary with an elongated tip, which was vibrated at ultrasonic frequency (ca. 100 kHz) by means of a piezo-ceramic disc. The solution volatilized within a few cm of the outlet of the capillary. A motor-driven syringe ensured a constant delivery of the solution at 10 μl/min, resulting in a release rate of 10 ng/min of (*E*,*E*)-α-farnesene. The sprayer was rinsed with 2 ml of redistilled ethanol before each treatment.

The numbers of females flying upwind over 150 cm and landing at the source was compared using Fisher's exact test ($P < 0.05$).

RESULTS AND DISCUSSION

Identification of Grapevine Volatiles. Compounds identified from different developmental stages of grapevine, from nonflowering buds to green berries, are

shown in Table 1. Compounds eliciting reproducible responses from antennae were identified according to their mass spectra and retention times, in comparison with synthetic or authentic standards. The most abundant compound in headspace collections from all phenological stages was (*E*,*E*)-α-farnesene. Comparison of volatiles recovered from clusters at early bloom by two sampling techniques, SPME and Porapak Q air filters, showed only quantitative differences (Table 1).

Grapevine Volatiles Eliciting an Antennal Response. The headspace collections used for identification of grape volatiles by GC–MS were also analyzed by GC–EAD. Antennae of grapevine moth females responded to 27 compounds (Table 1). These include the most abundant compounds, such as α-farnesene, (*E*)-β-farnesene, and (*Z*)-3-hexenyl acetate, but the antennae also responded to compounds that were present in much smaller amounts, for example β-caryophyllene, limonene, and heneicosane. Many alcohols, ketones, and hydrocarbons with straight carbon chains elicited antennal responses. In contrast, only a few cyclic compounds such as methyl salicylate, limonene, and caryophyllene elicited antennal responses (Table 2).

Further GC–EAD analysis, using synthetic or authentic compounds at a constant amount of 10 ng, was done to quantify the antennal responses. The most active compounds were 4,8-dimethyl-1,(*E*)3,7-nonatriene and α-farnesene (Table 2).

Changes in Headspace Composition During Phenological Development. Headspace collections from shoots with leaves included typical green odorants such as hexanoic acid, hexanal, (*E*)-2-hexenal, and (*Z*)-3-hexenal (Table 1; Hashizume and Samuta, 1997). Collections from flower buds contained only few volatiles. However, several of these elicited an antennal response, which is in agreement with a study by Gabel and Roehrich (1995), who reported that extracts of flower buds stimulated egg-laying in grapevine moth females. The seasonal flight period of grapevine moth starts before the onset of flowering and females oviposit on the flower buds.

Hydrocarbons were characteristic for partly flowering clusters, and many disappeared during full flowering. Flower clusters at full bloom contained, in comparison, a group of terpenoids (Table 1; Buchbauer et al., 1994, 1995). Green grapes contained fewer terpenoids, whereas several alcohols, aldehydes, esters, and aromatic compounds emerged. The relative abundance and the number of esters further increased in collections from mature grapes (data not shown). This increase in ester production associated with grape ripening is known (Hardy, 1970).

Wind Tunnel Bioassay. Mated *L. botrana* females flew upwind to clusters of green grapevine berries in the wind tunnel (Table 3). Female moths became activated and started to orient upwind between 2 and 11 min after they were exposed to grape odor. Twenty-five percent ($N = 140$) flew upwind over 150 cm, and 17.9% of the test females landed at the cage containing grape berries. The upwind flight pattern was similar to male flights towards female sex pheromone (El-Sayed et al., 1999). Fewer females landed at shoots without grapes, and females did not fly

upwind at all without a plant odor stimulus (Table 3). Attraction of females to grapes by flight, over a distance, demonstrates a role for plant volatile compounds in host-finding in *L. botrana*.

Volatiles from freshly picked grape berries eliciting upwind attraction were collected on Porapak Q, and the resulting extract was diluted to contain (*E*,*E*)-α-farnesene at 1 ng/μl and was then released from a sprayer at a rate of 10 μl/min into the wind tunnel. A significant number of grapevine moth females flew upwind towards this sprayed volatiles extract over at least 150 cm, but the females did not land at the source (Table 3).

The average amount of α-farnesene collected from 200 g of green berries was 0.28 ± 0.15 μg/hr (Table 1). In comparison, the release rate of the volatiles extract in the wind tunnel experiment was set to 10 ng/min or 0.6 μg/hr α-farnesene. Headspace collections on Porapak filters contain at least part of the odor cues responsible for female attraction to grape, as evidenced by the significant response to sprayed extracts (Table 3). However, both release rate and composition of the blend were probably suboptimal.

The composition of the bouquet emitted from plant material is likely to be different from the blend of compounds extracted from Porapak air filters. A distorted composition of this blend may be due to differences in the compounds' affinity to the glass jar holding the grapes, to filter material and solvent, as well as to their volatility, which affects the bleeding of compound through the air filter. No single volatile eliciting antennal activity (Table 2) is unique for grapevine; a blend of compounds is expected to mediate attraction of gravid *L. botrana* females to grapevine.

Future studies will include calibration of the headspace collection system for the compounds eliciting antennal responses (Table 2), in order to enable a reconstruction of the blend of compounds released from grapes. The focus of continued behavioral studies will be on compounds that were present throughout the season, in all phenological stages (Tables 1). First-generation females of *L. botrana* oviposit on flower buds and partly flowering clusters, whereas the second and third generation oviposits on berries (Bovey, 1966; Thiéry and Gabel, 2000). Availability of a laboratory bioassay (Table 3) will allow identification of the compounds eliciting attraction and egg-laying in gravid *L. botrana* females.

(Received March 9, 2004; accepted September 17, 2004)

Abstract—Two diterpenoid alcohols, *ent*-kauran-16α-ol (**1**) and *ent*-atisan-16α-ol (**2**), were isolated from pre bloom (R3-R4 stage) sunflower heads as oviposition stimulants for the banded sunflower moth, *Cochylis hospes*. Fractionation of a sunflower head extract, by normal-phase flash column chromatography, resulted in an early eluting fraction exhibiting significant activity in an egg-laying bioassay. Compounds **1** and **2**, along with *ent*-trachyloban-19-oic acid (**3**) and *ent*-kaur-16-en-19-oic acid (**4**), were isolated as the major components of this fraction and identified by their NMR and mass spectra. The purified compounds were individually tested for ovipositional activity in dose-response bioassays. In these bioassays, compounds **1** and **2** gave linear dose responses, with increasing numbers of eggs laid as the dosage of either increased. Compounds **3** and **4** failed to stimulate significant egg-laying at any of the dosages tested. A factorial design bioassay, using compounds **1** and **2**, showed that **1** was relatively more stimulatory than **2**, and that there was no synergistic effect on oviposition when the two compounds were combined.

Key Words—Diterpenoid, *ent*-kauran-16α-ol, *ent*-atisan-16α-ol, mass spectrum, HPLC, NMR, Lepidoptera, Cochylidae, *Helianthus annuus*, oviposition stimulant.

INTRODUCTION

The banded sunflower moth (BSFM), *Cochylis hospes* Walshingham (*Lepidoptera: Cochylidae*), is an important pest of cultivated sunflower (Charlet et al., 1997) in the northern Great Plains of North America. The larvae are restricted to feeding on sunflower (*Helianthus spp.*), and have been found on nine wild sunflower species, along with cultivated sunflower, *Helianthus annuus* (Charlet et al., 1997). BSFM females oviposit preferentially on pre bloom sunflower heads (R2-R4 stage), rather than early bud or post bloom (R5-R6) heads, with the majority of eggs being laid on the outer whorl of involucral bracts (Charlet et al., 1997). Experiments by Barker (1997) indicated that extracts of macerated sunflower bracts stimulated BSFM oviposition. Further experiments (Foster et al., 2003) showed that extracts made by dipping pre bloom heads (R3) in hexane, dichloromethane, or methanol, contained compounds that stimulated BSFM oviposition. Preliminary fractionations of hexane and dichloromethane extracts, using silica gel solid phase extraction tubes, resulted in the concentration of ovipositional activity in several fractions (Foster et al., 2003).

This paper describes the continuation of this work, with the isolation and identification of two diterpenoid alcohols, *ent*-kauran-16α-ol (**1**) and *ent*-atisan-16α-ol (**2**), that are oviposition stimulants for BSFM (Figure 1). Compounds **1**

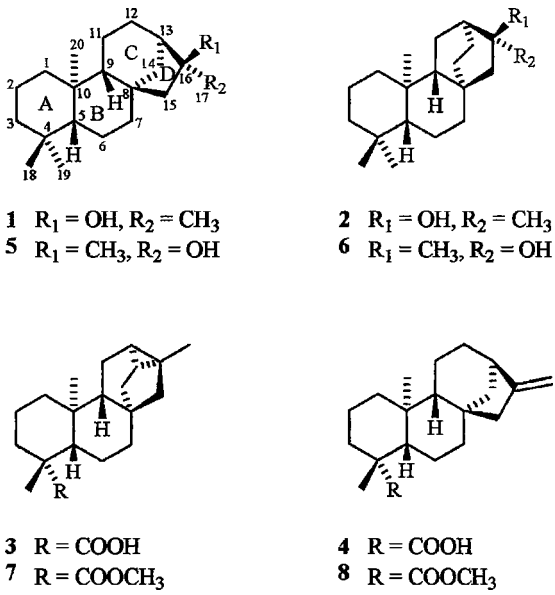

FIG. 1. Diterpenoid alcohols (1 and 2) and acids (3 and 4) isolated from sunflower heads, 16beta-epimers 5 and 6, and acid methyl esters 7 and 8.

and **2** were isolated by fractionation of dichloromethane extracts of sunflower heads. The diterpenoid acids *ent*-trachyloban-19-oic acid (**3**) and *ent*-kaur-16-en-19-oic acid (**4**) (Figure 1) were also isolated and found to be nonstimulatory at the concentrations tested.

METHODS AND MATERIALS

General Fractionation and Characterization Procedures. Flash column chromatography used either silica gel (60 Å, 130–270 mesh, Sigma-Aldrich, Milwaukee, WI) or, for argentation chromatography, silica gel impregnated with 10% $AgNO_3$ (200 mesh, Sigma-Aldrich). High performance liquid chromatography (HPLC) employed a Shimadzu LC-6A pump and SPD-10A UV detector, set to 220 nm, with a Luna column (5 μm normal-phase silica, 250 × 4.6 mm; Phenomonex, Torrance, CA). Solvents used were either Malinckdrodt nanograde (for column chromatography), Burdick and Jackson HPLC grade (for HPLC), or redistilled AR grade. Solvents were evaporated from fractions by rotary evaporator at 40°C for larger volumes, or by a gentle stream of nitrogen for smaller volumes. Diazomethane was prepared from *N*-methyl-*N*-nitro-*N*-nitroso-guanidine (Sigma-Aldrich) and 0.5 M $KOH_{(aq)}$ (Attygalle, 1998). Acetyl chloride was obtained from Sigma-Aldrich, and bis(trimethylsilyl)trifluoroacetamide (BSTFA) + 1% TMCS from Pierce (Rockford, IL). Coupled gas chromatography-mass spectrometry (GC–MS) was performed on an Hewlett-Packard 5890 Series II Plus gas chromatograph interfaced with an Hewlett-Packard 5972 quadrupole mass spectrometer operated at 70 eV ionizing energy. Zebron ZB-1 or ZB-5 capillary columns (25 m, 0.25 mm i.d., 0.25-μm-film thickness, Phenomonex) were used for analyses, with GC temperature programs of 80°C (1-min hold) to 290°C at 15°C/min, and 80°C (2 min hold) to 360°C at 15°C/min, respectively. The ZB-5 column was only used for analysis of BSTFA-derivatized samples. Splitless injection was used, helium being the carrier gas, at a linear velocity of 30 cm/sec. Mass spectra were compared with those in the Wiley Registry of Mass Spectral Data (7th Ed., John Wiley and Sons, NY). Nuclear magnetic resonance (NMR) spectra were obtained on Varian Inova instruments, either an 11.7 T spectrometer (499.67 MHz for ^{1}H and 125.65 MHz for ^{13}C) or a 9.4 T instrument (399.94 MHz for ^{1}H and 100.57 MHz for ^{13}C). All spectra were recorded in $CDCl_3$ (Sigma-Aldrich). ^{1}H chemical shifts were referenced to residual $CHCl_3$ at 7.26 ppm and ^{13}C shifts to the solvent signal at 77.0 ppm.

Extraction and Isolation. Sunflower plants (*H. annuus* cv. 'RHA 274') were grown in a greenhouse at 20–30°C between September 2002 and February 2003. Two extracts were prepared from pre bloom heads (R3-R4 stage); extract A, 42 heads (mean diam 2 cm) and extract B, 149 heads (mean diam 3.6 cm). Heads were dipped into dichloromethane for 60 sec, by holding the stalk and avoiding

extraction of the cut end, similar to the method for extracting the epicuticular waxes of wheat leaf, previously described (Morris et al., 2000). Celite (1 g for extract A, 6 g for extract B) was added to the crude extracts, to aid later transfer to the chromatography column, and the solvent removed by rotary evaporation. Rotary evaporation was stopped 5 min after apparent dryness.

Extract A (0.16-g-dry weight) was fractionated by normal-phase flash column chromatography on 50 g of silica gel. Fractionation used a stepped solvent gradient (pentane 200 ml, fraction 1; pentane/diethyl ether (9:1) 2 × 100 ml, fractions 2 and 3; pentane/diethyl ether (4:1) 2 × 100 ml, fractions 4 and 5; pentane/diethyl ether (1:1) 2 × 100 ml, fractions 6 and 7; diethyl ether 2 × 100 ml, fractions 8 and 9; ethanol 100 ml, fraction 10). All of these fractions were tested in the bioassay.

Fraction 5 (11.4 mg) was active in the bioassay. Preliminary GC–MS analysis showed it contained compounds **1**–**4** as the major components. These were isolated as follows, identified, and tested individually in the bioassay.

Compounds **1** and **2** were isolated from extract B (dry weight 1.1 g). This was fractionated on 50 g of normal-phase silica gel using a similar solvent gradient to that for extract A (above). Three fractions containing **1** and **2** were combined (dry weight 76 mg) and fractionated on 7 g of normal-phase silica gel using the following solvent steps: hexane 20 ml, fraction 1; hexane/diethyl ether (9:1) 20 ml, fraction 2; hexane/diethyl ether (4:1) 10 × 10 ml, fractions 3-12. Fraction 6 (4.6 mg) contained **1**, while fractions 7 and 8, both containing **2**, were combined (14 mg) and further fractionated on 5 g normal-phase silica gel, using the same solvent gradient, to improve separation of **2** from tailing C_{20} to C_{34} aliphatic alcohols. Compounds **1** and **2** were purified by HPLC using isocratic *i*-PrOH/hexane (2:98) at 1 ml/min. Compound **1** (1.1 mg) eluted at 6.3 min and **2** (1.4 mg) at 6.8 min under these conditions.

Compounds **3** and **4** were isolated from fractions 4 (12.3 mg) and 5 from the 50 g silica gel fractionation of extract A. Further fractionation of fraction 5 on silica gel separated acids **3** and **4** from alcohols **1** and **2**. Fraction 4 from the first column and fractions from the second column containing **3** and **4** were combined (14 mg) and fractionated by argentation chromatography on silica gel/10% $AgNO_3$ (50 g), using pentane/diethyl ether 9:1, 4:1, 7:3, and 1:1 solvent steps, with **3** (2.4 mg) and **4** (4.8 mg) eluting in the 4:1 and 1:1 fractions, respectively. Compounds **3** and **4** were further purified by normal-phase HPLC, using an isocratic mobile phase of *i*-PrOH/hexane (1:99) at 1 ml/min flow rate. Both **3** (1.9 mg) and **4** (2.7 mg) eluted at 6.2 min.

Insect Culture. BSFM were obtained from a laboratory colony established in 1988 and now maintained at the USDA-ARS Northern Crop Science Laboratory, Fargo, ND. The colony was established from the larvae collected in North Dakota and reared on a semi-synthetic diet (Barker, 1988). Annual addition of wild insects from North Dakota, use of R2 stage sunflower heads for oviposition in the rearing cycle, and regular tests for selectivity toward sunflower are carried out to ensure

that the colony does not lose specificity to the host plant (Barker, 1997). Adult BSFM were obtained <24 hr after emergence and kept as mixed groups (20–30 insects) in 28 ml clear plastic containers, with a moist cotton wick, for 24 or 48 hr to allow mating. Containers were placed in to a controlled temperature room (26 ± 1°C, 30% relative humidity, 16L: 8D photoperiod), that was also used for the bioassay.

Bioassay. The bioassay was a modification of what was carried out previously (Foster et al., 2003). Fractions, or purified compounds **1**–**4** (Figure 1), were applied as solutions, using a 500 μl syringe, to scored chromatography paper attached over the mouth of vials (45-mm height × 15-mm diam) with rubber bands. Parallel grooves were scored in the paper using a scalpel, approximately 1.5-mm apart and 2-mm deep, with 7 grooves per paper cap, similar to the method of Kanno and Harris (2000). Without scoring, very few eggs were laid on the treated caps, indicating the importance of physical stimulation for oviposition (also observed previously, Foster et al., 2003). Solutions were applied over approximately a 10 min period; each application was confined to the area of scored paper (approximately 1 cm^2) on the top surface of the cap.

From the first flash column fractionation of extract A, fractions 3–10 were taken to dryness (for weighing) and then redissolved in 1.5 ml of diethyl ether. Fractions 1 and 2 were reduced in volume to 1.5 ml, without being taken to dryness, to avoid loss of volatile monoterpenes, which were significant components of these fractions as indicated by GC–MS. A treatment was 80 μl [2.2 head equivalents (HE)] of a fraction applied to a paper cap, with 80 μl of diethyl ether for solvent controls. A HE was the mean weight of fraction per head. Vials were attached to the base of the bioassay container (17 cm diam × 14 cm high, Rubbermaid, Wooster, OH) with mounting putty (Manco Inc., Avon, OH), and evenly spaced around the perimeter, approximately 3 cm from the wall. A replicate consisted of one treatment of each fraction plus a control, placed in the same container. A 10-cm diam circle was removed from the lid of the arena and replaced with fine nylon mesh. The arena floor was covered with moist vermiculite.

For dose-response bioassays, compounds were each dissolved in hexane, and the appropriate amounts were applied to paper caps to give 50, 10, and 2 μg dosages; 100 μl (for testing **1** and **2**) and 50 μl (for **3** and **4**) of hexane were used for the solvent controls, volumes equal to the maximum amount of solution applied for each bioassay. Based on the weight of these compounds recovered after purification, 50 μg is approximately 7 HE for compound **1**, 5 HE for **2**, and 1 HE for **3** and **4**. Replicates consisted of one treatment of each dosage of a compound, plus a control placed in the same container. The factorial-design bioassay used 25 μg dosages of **1** or **2**, or 50 μg of a 1:1 mixture of **1** and **2**, each applied in 100 μl of hexane; 100 μl of hexane were used for the solvent control. For these experiments, the vials were placed, as mentioned above, in 14-cm diam × 11-cm high containers.

Insects were sexed and placed in the bioassay containers 2–3 hr before the start of scotophase. Between 25 and 35 females (approximately half 24–48-hr old and half 48–72-hr old), and 5–8 males were used for each replicate. After 4 nights, the number of eggs on the top surface of the paper caps was counted. Eggs laid around the rubber band holding the paper to the vial were excluded, even though the majority of the eggs were laid there, since the physical stimulation of the rubber band varied between treatments. Consequently, a relatively low number of eggs were counted per female moth.

Statistical Analysis. Data from the bioassay of fractions were not normally distributed (Shapiro–Wilk–Whitney test), even after log-transformation. Therefore these data were analyzed by the nonparametric Wilcoxon–Mann–Whitney test, using Statxact software (Cytel Corporation, version 5.0.3), comparing each treatment with the control. Data from the dose response bioassays were normal (Shapiro–Wilk–Whitney test), and were analyzed by Student's t-test or ANOVA, using JMPin software (SAS Institute, version 4.0.4). Results with a linear trend were analyzed by linear regression. Results of the factorial design bioassay were analyzed by JMPin, with the two compounds as the main effects.

RESULTS

Bioassay of Fractions from Sunflower Head Extract. Ten fractions, obtained from silica gel fractionation of extract A (42 sunflower heads), were tested in the egg-laying bioassay. Statistical analysis (Wilcoxon–Mann–Whitney test) showed that 4 fractions had a significantly ($P < 0.01$) greater number of eggs laid on them than the control (Figure 2). These were in two groups; fraction 5 eluting with pentane/diethyl ether (4:1), and polar fractions 8–10 (eluting with diethyl ether or ethanol).

Preliminary GC–MS analyses of fractions 1–6, showed that the major classes of compounds were monoterpenes (mostly α-pinene) and germecrenoid sesquiterpenes (in fractions 1 and 2), and even numbered C_{20} to C_{34} aliphatic aldehydes and alcohols (in fractions 3 and 6, respectively). Fraction 3 (53 mg) and fraction 6 (17 mg) made up 43% of the weight of the crude extract. The major components of fractions 4 and 5 were two diterpenoid acids, which reacted with ethereal diazomethane to give methyl esters (Attygalle, 1998). Fraction 5 also contained two diterpenoid alcohols, which reacted with acetyl chloride to give acetates along with dehydration products (St. Pyrek, 1984). Minor compounds in fraction 5 consisted of mono- and sesquiterpenoids, comprising <5% of the GC–MS total ion current. Further work described in this paper is restricted to the characterization of bioactive compounds from fraction 5. Since the alcohols differentiated active fraction 5 from inactive fraction 4, these were isolated and characterized first.

*Isolation and Identification of Compounds **1–4**.* Comparison of the mass spectra of the two alcohols with spectra in the Wiley library indicated that they

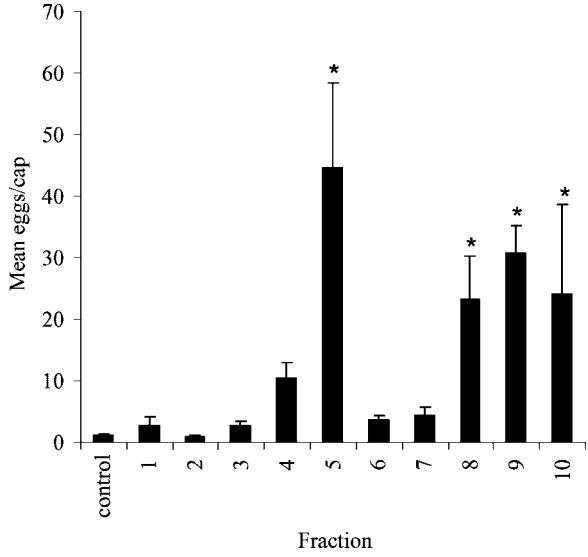

FIG. 2. Bioassay of fractions (2.2 HE/fraction) from a normal-phase flash column fractionation on silica gel, of extract A (42 sunflower heads). Mean number of eggs laid by *C. hospes* on paper caps, each treated with a fraction or solvent only as a control. Means were calculated from 5 replicates. Fractions with asterisks are significantly different from the control (Wilcoxon–Mann–Whitney test, $P < 0.01$). Bars are standard errors of means.

had kaurane and atisane skeletons. Their spectra were similar to literature data (Kalinovsky et al., 1970; St. Pyrek, 1984), for *ent*-kauran-16α-ol (**1**) or *ent*-kauran-16β-ol (**5**) (diagnostic ions at *m/z* (rel.int.): 290 (10) $[MH]^+$, 272 (100) $[M\text{-}H_2O]^+$, 257 (64) $[M\text{-}CH_3\text{-}H_2O]^+$, 232 (46), 217 (33), and *ent*-atisan-16α-ol (**2**) or *ent*-atisan-16β-ol (**6**) (ions at *m/z* (rel. int.) 290 (0.4), 272 (22), 257 (100), all previously isolated from sunflower heads (St. Pyrek, 1984). The two alcohols were isolated from extract B (149 heads), yielding 1.1 mg of **1** (or **5**) and 1.4 mg of **2** (or **6**) after normal-phase HPLC, which were pure (>99%) by GC–MS analysis of BSTFA-derivatized subsamples. The ^{1}H NMR spectra showed no contamination of **1** with **2** and vice versa, based on the methyl signals. These signals had shifts similar to the published values for **1** and **2** (St. Pyrek, 1984). Comparison of the ^{13}C NMR spectra of the alcohols with published data (Table 1) allowed their identification as the α-epimers, *ent*-kauran-16α-ol (**1**) and *ent*-atisan-16α-ol (**2**) (St. Pyrek, 1984). In particular, a signal at 32.37 ppm for **1** was similar to the literature value of 32.52 ppm for C-17 of *ent*-kauran-16α-ol (**1**), but differed from C-17 for *ent*-kauran-16β-ol (**5**) (24.52 ppm) (St. Pyrek, 1984). The signal for H-17 of isolated **1** (1.32 ppm) and was fount to be closer to the published for **1** (1.31 ppm) than **5** (1.36 ppm) (St. Pyrek, 1984). Similarly, the signals for C-17 and H-17 of

[d] Unresolved from baseline or solvent peak due to small sample size.

2 matched those for the α-epimer of *ent*-atisan-16-ol (Table 1) (St. Pyrek, 1984). The most obvious differences in the ^{13}C NMR spectrum of 2 compared with that of **1** was the large upfield shifts of signals assigned to carbons 8, 13, and 14 in **1**, as expected with the differences in structure of rings C and D. Compounds **1** and **2** were assumed to have the same *enantio* absolute configuration as the kauranols and atisanols previously isolated from *H. annuus* (St. Pyrek, 1984).

A subsample of fraction 4 from extract A (42 heads), containing the two diterpenoid acids also present in fraction 5, was methylated by treatment with ethereal diazomethane (Attygalle, 1998). The mass spectra of the resulting methyl esters were similar to those previously published for methyl-trachyloban-19-oate (**7**) and methyl-kaur-16-en-19-oate (**8**) (Figure 1) (St. Pyrek, 1970; Mitscher et al., 1983), indicating that the acids were probably *ent*-trachyloban-19-oic acid (**3**) and *ent*-kaur-16-en-19-oic acid (**4**). The acids from fractions 4 and 5 were separated by

flash column chromatography on silica gel/$AgNO_3$, then purified by normal-phase HPLC to give 1.9 mg of **3** and 2.7 mg of **4**. Both GC–MS and ^{1}H NMR indicated that each acid was clean and without cross contamination. The mass spectrum of **3** contained diagnostic ions at *m/z* (rel. int.): 302 (99) $[M]^+$, 287 (51) $[M\text{-}CH_3]^+$, 246 (100), 231 (55), with the *m/z* 246 ion (loss of 56 amu) indicating a trachylobane derivative (St. Pyrek, 1970). This was similar to data for *ent*-trachyloban-19-oic acid from Mitscher et al. (1983). The mass spectrum of **4** (ions at *m/z* (rel. int.): 302 (58) $[M]^+$, 287 (44) $[M\text{-}CH_3]^+$, 259 (51), 243 (43), 241 (43), 213 (31)) was similar to that for *ent*-kaur-16-en-19-oic acid in the Wiley library and in Mitscher et al. (1983). The ^{1}H NMR shifts for the methyl protons of **3** ($CDCl_3$ 100 MHz):δ 0.88, 1.13, 1.21) matched those of Beale et al. (1983), but were downfield by 0.7 ppm from values in Mitscher et al. (1983), while the methyl and H-17 shifts for **4** ($CDCl_3$ 100 MHz):δ 0.95, 1.24, 4.77 (d, $J = 23$ Hz) were identical to those of Mitscher et al. (1983). Comparison of the ^{13}C NMR spectra of **3**[3] and **4**[4] with published values (Ohno et al., 1979; Beale et al., 1983; Faulkner et al., 1985; Wu et al., 1996; Leong and Harrison, 1997), especially the shifts for rings C and D carbons, and the presence of signals for C-18 (equatorial), rather than C-19 (axial) methyl carbons, agreed with the assignment of **3** as *ent*-trachyloban-19-oic acid and **4** as *ent*-kaur-16-en-19-oic acid.

Bioassay of Compounds 1–4. The HPLC purified samples of compounds **1–4** were tested separately in dose response bioassays. Alcohols **1** and **2** had similar dose-response profiles (Figures 3 and 4). A linear regression of dose vs. number of eggs for **1** showed a linear fit ($F = 58.1$; $df = 1, 22$; $R^2 = 0.73$; $P < 0.001$) with a significant ($P < 0.001$) slope of 0.80 ± 0.10, indicating that there was an increase in the number of eggs laid with increasing dosage of **1**. For compound **2**, a linear regression of dose vs. number of eggs laid on treatments showed a linear fit ($F = 41.1$; $df = 1, 22$; $R^2 = 0.65$; $P < 0.001$), and a highly significant ($P < 0.001$) slope of 0.67 ± 0.10. For the dose-response bioassays of acids **3** and **4**, ANOVA showed no significant difference between the treatments (for **3** $F = 1.01$; $df = 3, 20$; $P = 0.41$, and for **4** $F = 0.80$; $df = 3, 20$; $P = 0.51$) (data not shown). In the factorial-design bioassay, testing both **1** and **2**, the main effect of **1** was significant ($F = 27.9$, $df = 1$, $P < 0.001$), but there was no significant effect for **2** ($F = 1.35$, $df = 1$, $P = 0.26$), or any significant interaction between the two compounds ($F = 0.26$, $df = 1$, $P = 0.62$) (Figure 5), indicating a lack of any synergistic effect of combining the two alcohols. This also showed that compound **1** was relatively more stimulatory to female BSFM than compound **2**.

[3] ^{13}C NMR spectrum measured for *ent*-trachyloban-19-oic acid (**3**)($CDCl_3$ 100 MHz): δ 12.47, 18.68, 19.70, 20.53, 21.73, 22.39, 24.25, 28.83, 33.11, 37.93, 38.87, 39.19, 39.42, 40.73, 43.55, 50.35, 52.74, 56.92, 182.41.

[4] ^{13}C NMR spectrum measured for*ent*-kaur-16-en-19-oic acid (**4**) ($CDCl_3$ 100 MHz): δ 15.60, 18.42, 19.08, 21.83, 28.94, 33.02, 37.87, 39.65, 39.69, 40.70, 41.27, 43.66, 43.85, 44.22, 48.96, 55.11, 57.02, 102.99, 155.91, 182.95.

Means were calculated from 6 replicates, bars are standard errors of means. Means with different letters were significantly different at $P < 0.05$ when compared by Student's *t*-test. A linear regression analysis of the data is described in the text.

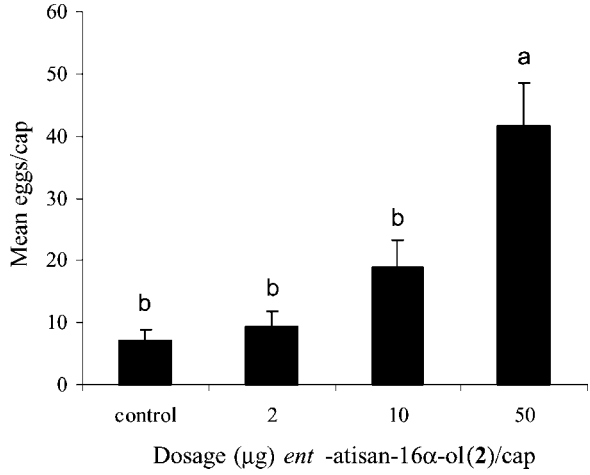

FIG. 4. Dose-response bioassay of *ent*-atisan-16α-ol (**2**). Mean number of eggs laid by *C. hospes* on paper caps treated with **2**, or solvent only for the control. Means were calculated from 6 replicates, bars are standard errors of means. Means with different letters were significantly different at $P < 0.05$ when compared by Student's *t*-test. A linear regression analysis of the data is described in the text.

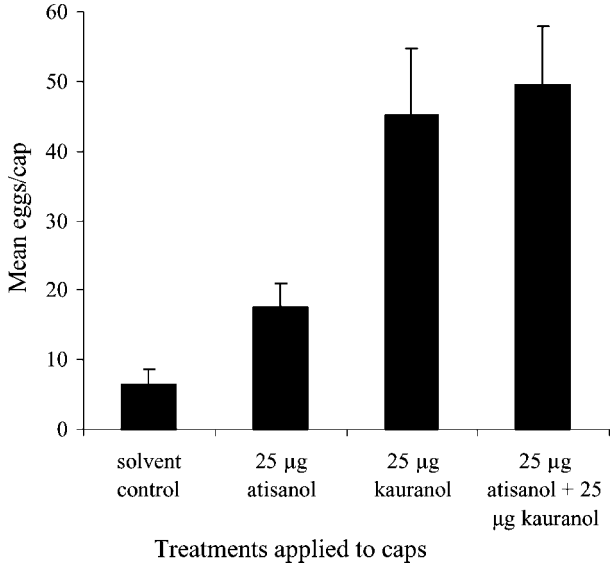

FIG. 5. Mean number of eggs laid by *C. hospes* in a factorial-design bioassay using paper caps treated with 25 μg or 0 μg of *ent*-kauran-16α-ol (**1**) and 25 μg or 0 μg of *ent*-atisan-16α-ol (**2**). Means were calculated from 8 replicates, bars are the standard errors of means.

DISCUSSION

In this study, we have isolated two diterpenoids from sunflower heads, *ent*-kauran-16α-ol (**1**) and *ent*-atisan-16α-ol (**2**), that stimulated oviposition by BSFM, when applied to an artificial substrate. Due to the unavailability of synthetic samples of these compounds, and the difficulty of total syntheses of atis-16-enes and kaur-16-enes (Toyota et al., 1998, 2000), samples for bioassay were obtained by fractionation of a sunflower head extract. The final HPLC separation yielded samples that were >99% pure by GC–MS analyses of their TMS ethers, and had no apparent signals for other compounds in their ^{1}H NMR spectra. This degree of purity reduces the likelihood that the ovipositional activity of the samples were due to unidentified minor components from the extract.

Although both *ent*-kauran-16α-ol (**1**) and *ent*-atisan-16α-ol (**2**) stimulated oviposition by BSFM when tested alone (Figures 3 and 4), only **1** was significantly active when these compounds were tested together (Figure 7). No synergistic effect of the addition of **2** to **1** was observed. *ent*-Trachyloban-19-oic (**3**) and *ent*-kaur-16-en-19-oic (**4**) acids were inactive at the concentrations tested. These results suggest a structure-activity relationship, with the alcohol group of **1** and **2**, absent

in **3** and **4**, being important for activity, along with the differences in the structures of rings C and D of **1** and **2** affecting activity.

Alcohols **1** and **2** have previously been isolated from macerated heads of *H. annuus* (St. Pyrek, 1984). Alcohol **1** has also been isolated from the leaves and stems of several other *Helianthus* spp. (Herz et al., 1982, 1983; Watanabe et al., 1982), and both **1** and **2** were found by GC–MS analysis to be widespread in the genus *Helianthus* (St. Pyrek, 1984). Therefore, it seems likely that these compounds are oviposition stimulants for BSFM on a number of *Helianthus* species in the host range of BSFM.

In preliminary experiments (Foster et al., 2003), extracts of both sunflower leaves and heads stimulated oviposition by BSFM, and it appeared that physical stimulation of the overlapping involucral bracts of heads resulted in eggs being laid on heads rather than leaves (Charlet et al., 1997). It is also possible that the concentrations of compounds **1** and **2** and/or other unidentified stimulatory compounds (in fractions 8–10, Figure 2) differ on leaves and heads, and could influence the preferential oviposition by BSFM on heads. While alcohols **1** and **2** are nonvolatile, and, therefore, require contact to stimulate oviposition, earlier work (Foster et al., 2003) showed that unidentified volatile compounds from sunflower head extracts were also behaviorally active for female BSFM and that these could act as attractants. Overall, it appears that BSFM use a combination of volatile, involatile chemical, and tactile stimuli in their oviposition behavior.

Several insects have been found to be stimulated by leaf waxes; cabbage leaf wax (inactive alone) had a synergistic effect on oviposition stimulation of the diamondback moth (*Plutella xylostella*), when combined with sinigrin (a glucosinolate) (Spencer, 1996), while Hessian flies were stimulated by C_{22} to C_{30} *n*-aldehydes from wheat leaf wax (Morris et al., 2000), and *H. zea* by long-chain alkanes from tomato (Breeden et al., 1996). Although our dichloromethane extract contained approximately 43% by weight leaf waxes, mainly C_{20} to C_{34} even-numbered *n*-aldehydes and lesser amounts of the corresponding alcohols, it appears that these do not stimulate oviposition by BSFM, since fractions 3 and 6 from the first silica gel fractionation, containing these compounds, were inactive in the egg-laying bioassay (Figure 2).

At present, further work is in progress to isolate and identify bioactive compounds in polar fractions (fractions 8–10 in Figure 2) from sunflower head extracts. Identification of these, along with compounds **1** and **2**, responsible for the chemical oviposition stimulation of BSFM on sunflowers, could be useful for studying differences in host preference between cultivars, and behavioral aspects of BSFM oviposition.

Acknowledgments—We thank Maboko Mphosi and Kirk Anderson for assistance in growing sunflowers. This work was partially supported by a grant from the National Sunflower Association and North Dakota SBARE.

(Received November 19, 2002; accepted August 27, 2004)

Abstract—Bioassay-directed fractionation of extracts of chrysanthemum leaves using a choice test permitted isolation of a fraction that exhibited repellent activity against the western flower thrips (WFT). Analysis of this fraction from cultivars exhibiting varying degrees of host-plant resistance to WFT by high performance liquid chromatography revealed a distinctive peak, the height of which correlated with the degree of resistance of those cultivars to WFT. The peak was attributed to a novel unsaturated isobutylamide, *N*-isobutyl-(*E*, *E*, *E*, *Z*)-2,4,10,12-tetradecatetraen-8-ynamide.

Key Words—Chrysanthemum, resistance, host-plant resistance, repellent, thrips, western flower thrips, *Frankliniella occidentalis*, isobutylamide.

INTRODUCTION

The western flower thrips (WFT), *Frankliniella occidentalis* (Pergande), has been the major insect pest of greenhouse floriculture in Canada since the late 1980s (Broadbent et al., 1987). In addition to feeding on leaves and flowers, thrips can vector diseases such as tomato spotted wilt virus, which affects a wide range of plants (Broadbent et al., 1990). Control of WFT has become difficult due to resistance to conventional insecticides (Immaraju et al., 1992; Broadbent and Pree, 1997).

Host-plant resistance to WFT, particularly in chrysanthemum, is recognized as having potential to reduce reliance on pesticides for control of this pest (Van Dijken, 1992; De Jager et al., 1993). A study of chrysanthemum cultivars revealed a wide variation in degree of host-plant resistance or susceptibility to WFT (Broadbent et al., 1990). Variation in pollen production (De Jager and Butôt, 1993), difference in color of blooms (Van Dijken et al., 1993), and leaf pubescence and toughness (De Jager et al., 1995a) were found to have little impact on this interaction. Secondary metabolites of chrysanthemum have been suggested to be the primary factor in host-plant resistance (De Jager et al., 1995b, 1996).

In this study, we used bioassay-directed fractionation of chrysanthemum leaf extracts to isolate a fraction which exhibited thrips-repellent activity. We analyzed this fraction from extracts of chrysanthemum cultivars exhibiting varying degrees of host-plant resistance against WFT to obtain their metabolite profiles by using high performance liquid chromatography (HPLC). A distinctive peak was identified whose concentration in chrysanthemum cultivars was correlated with the degree of resistance of those cultivars to WFT.

METHODS AND MATERIALS

Chrysanthemum Plants. Rooted cuttings were potted and grown in the greenhouse at the Southern Crop Protection and Food Research Centre in Vineland Station, Ontario. Cultivars used in the study included, in order of increasing host-plant resistance (Broadbent et al., 1990), Florida Marble, Amber, Bright Yellow May Shoesmith, Golden Polaris, Polaris, May Shoesmith, Super White, and Super Yellow, all supplied by Yoder Canada, Leamington, Ont.

Extraction and Analysis. The 7th fully expanded whole leaf from the top of a chrysanthemum plant (~40 days after transplanting) was extracted for 15 min with 10 ml solvent/g fresh leaf. Four solvents, hexane, dichloromethane, acetone, and water, were evaluated for repellency of extracts. Extracts were evaporated and redissolved in acetone before being applied to leaf disks for evaluation using the choice bioassay.

For HPLC analysis, a 0.5-ml aliquot of the extract was filtered (Acrodisk GHP, 0.45 μm, Gelman Sciences) and evaporated to dryness under a stream of nitrogen. This was re-dissolved in 0.5 ml of acetonitrile for analysis on a

Sphereclone ODS-2 column (15 cm × 4.6 mm, 5 μm, Phenomenex, Torrance, CA) using an acetonitrile/water gradient (10–25% acetonitrile over 37.5 min). The HPLC was an Agilent Technologies Model 1100 equipped with a diode array detector monitored at 254 nm. Three replicate samples of each cultivar were analyzed. The mean peak height of the identified compound was correlated with the resistance rank for each cultivar, the latter based on a visual rating of feeding damage by WFT (Broadbent et al., 1990).

To investigate the distribution of the identified compound within a plant, samples consisting of two adjacent leaves, beginning with the first fully expanded leaf at the top of the plant, were removed from plants of Florida Marble and Super Yellow and extracted and analyzed by HPLC. To investigate the influence of the age of the plant on the concentration of the identified compound, leaves from whole 20- and 42-day-old plants of Florida Marble and Super Yellow were removed, extracted, and analyzed by HPLC.

For TLC fractionation studies, fresh leaves of five chrysanthemum cultivars with varying degrees of resistance against thrips (Broadbent et al., 1990), Super White (resistant), Super Yellow (resistant), Polaris (intermediate), Florida Marble (susceptible), and Amber (susceptible), were collected, extracted, and partitioned as described in Tsao et al. (2003). The extract was then fractionated by TLC (2-mm layer, Silica gel GF, Analtech, Newark, DE) using hexane/ethyl acetate (1:1). The fraction of interest (Fraction 2) was collected and extracted with hexane–ethyl acetate (1:1). Fraction 2 of Super Yellow extract was further separated into 6 subfractions by TLC using hexane–ethyl acetate–dichloromethane (3:2:1).

Bioassays. To evaluate the repellent activity of extracts, or fractions of extracts, two leaf disks (1.5-cm diam.) of green pepper (California Wonder bell peppers, *Capsicum annuum*) were used, one treated with a solution containing the extract or fraction in acetone–water (1:1) at a rate of 0.3 mg extracted material/ml, the other with solvent only (control). The pair of disks was placed in a glass Petri dish (5-cm diam.). Ten adult female WFT were collected in a vial from flowering potted WFT-susceptible chrysanthemum plants grown in the greenhouse at Vineland Station and starved for 4 hr before being transferred to the Petri dish by hitting the bottom of the inverted open vial. The dish was then sealed with Dura Seal^{TM} film (Diversified Biotech, Boston, MA) and placed in a growth chamber (12:12 LD, 20°C). The number of thrips located on each leaf disk was recorded after 24 hr. Each experiment was replicated 10 times. A Student's t-test (two-sample assuming equal variances) was performed to determine if the means for the two disks were equal.

RESULTS AND DISCUSSION

Extraction Solvent Selection. Bioassay results showed that extracts obtained with solvents of high and intermediate polarity, i.e., water, acetone, and

dichloromethane, had significant repellent activity compared to the corresponding control. The mean number of thrips on the treated disk was significantly lower ($P < 0.05$) than the number on the control disk for all but the hexane extract. Acetone extracts exhibited the greatest degree of repellence; acetone was, therefore, chosen as the most appropriate solvent for extracting the active compounds.

Thin Layer Chromatography. The TLC profiles of susceptible, intermediate, and resistant cultivars exhibited similar pigment patterns at the top ($R_f > 0.65$), and bottom ($R_f < 0.3$) regions of the TLC, whereas differences were observed in the region $R_f = 0.3$–0.65 (Fraction 2), which became the focus of further characterization.

Median R_f values for the 6 TLC subfractions of Fraction 2 were 0.37, 0.44, 0.54, 0.60, 0.66, and 0.71. Leaf disks treated with the subfraction at $R_f = 0.44$ (subfraction 2-2) from Super Yellow extract were found to be those least preferred by the adult female WFT. This fraction was the focus of subsequent studies.

Chemical Profiling by HPLC. The TLC subfraction 2-2 exhibited a cluster of peaks at $R_t = 30$–35 min when analyzed by HPLC. Figure 1 illustrates chromatograms of Florida Marble, a WFT-susceptible cultivar, and Super Yellow, a WFT-resistant cultivar. The height of a peak at 31.7 min in chromatograms of leaf extracts of eight chrysanthemum cultivars showed a strong correlation ($r = -0.8286$, $P < 0.01$) with the mean cultivar rank reported by Broadbent

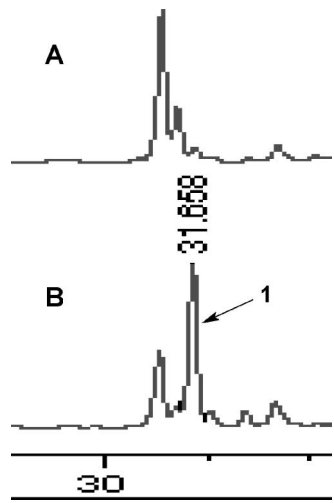

FIG. 1. HPLC chromatograms (monitored at 254 nm) of TLC subfraction 2-2 of leaf extracts from two chrysanthemum cultivars. A: Florida Marble (susceptible cultivar); B: Super Yellow (resistant cultivar).

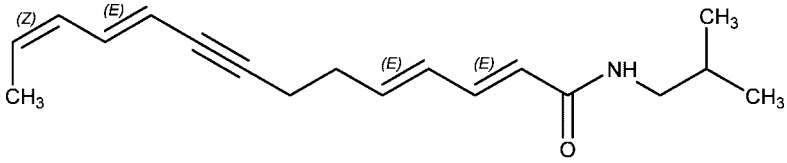

1

FIG. 2. Structure of *N*-isobutyl-(*E, E, E, Z*)- 2,4,10,12-tetradecatetraen-8-ynamide.

et al. (1990). Structure identification by spectroscopic methods (Tsao et al., 2003) attributed this peak to *N*-isobutyl-(*E*, *E*, *E*, *Z*)- 2,4,10,12-tetradecatetraen-8-ynamide (**1**, Figure 2), a novel compound. Figure 3 illustrates the relation between the peak height of **1** and mean cultivar rank using an exponential curve ($r^2 = 0.802$).

Distribution of **1** *in Plants*. The concentration of **1** in mature vegetative chrysanthemums was highest in the first pair of fully opened leaves, and decreased toward the bottom of the plants in both Super Yellow and Florida Marble (Figure 4). Figure 4 also illustrates that the difference in marker concentration within cultivars was significantly less than between susceptible and resistant cultivars. The highest concentration of **1** in Florida Marble was lower than the lowest concentration of **1** in Super Yellow. These observations, combined with greenhouse observations that more thrips damage is found on leaves positioned lower on the plants, provide additional support for the association of the concentration of **1** with host-plant resistance against thrips. Choice bioassay tests between leaf disks of upper (2nd)

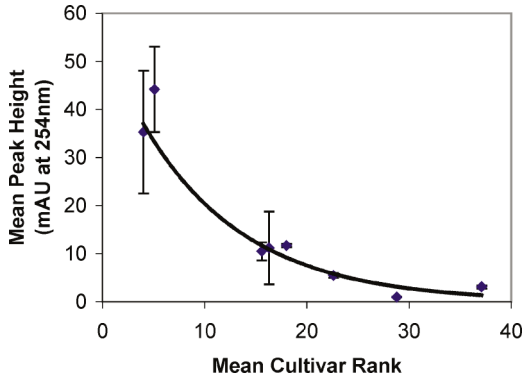

FIG. 3. Mean cultivar rank of eight chrysanthemum cultivars as determined by Broadbent et al. (1990) vs. mean peak height of compound **1** in each cultivar reported in milliabsorbance units (mAU) (mean of three replicates, error bars indicate standard deviation). The higher the cultivar rank, the more susceptible the cultivar is to damage by WFT.

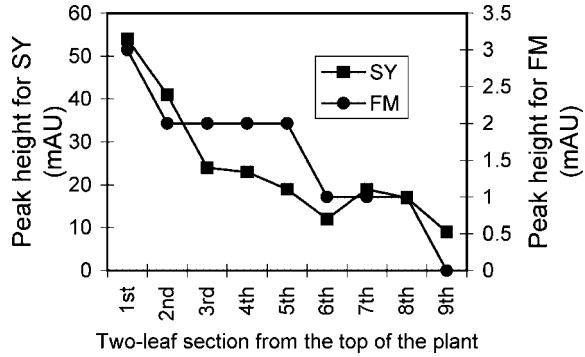

FIG. 4. Peak height of compound **1** in two-leaf sections from the top of Super Yellow (SY, left axis) and Florida Marble (FM, right axis) plants. mAU = milliabsorbance units

and lower (6th) leaves of the same plants of four cultivars confirmed that thrips preferred the lower leaves (Figure 5).

Concentration of **1** *in Chrysanthemums of Different Maturity.* The peak heights of **1** in leaf extracts of 20-day-old Super Yellow and Florida Marble plants (18.0 and 1.0 milliabsorbance units (mAU), respectively) were not appreciably different from those in leaf extracts of 42-day-old plants of the same cultivars (18.0 and 1.5 mAU, respectively). This suggests that the concentration of **1** may not be influenced by the age of the plant.

Other unsaturated isobutylamides have been shown to have insecticidal properties (Jacobson, 1971; Miyakado et al., 1989). The concentration of **1** in the leaves of chrysanthemum cultivars may be useful as a predictor of the degree of thrips-resistance exhibited by those cultivars. This information would be useful in breeding programs for identification of resistant parent and progeny lines.

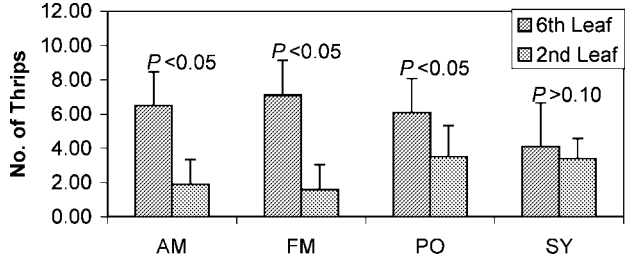

FIG. 5. Number of thrips (mean of 10 replicates) observed on leaf disks from lower (6th) and upper (2nd) leaves of Amber (AM), Florida Marble (FM), Polaris (PO) and Super Yellow (SY) plants.

Acknowledgments—The authors thank Flowers Canada (Ontario) Inc. for their financial contribution, and Yoder Canada (Leamington, Ontario) for providing chrysanthemum cuttings. We also thank Marta Hernandez, Delia Iezzi, Karen Wong, Edward Barszcz, Sean Haddock, Sandy McCutcheon, and Carla Carlson of the Southern Crop Protection and Food Research Centre, Vineland Station, for their technical assistance.

(Received February 16, 2004; accepted August 12, 2004)

Abstract—The essential oil and a number of extracts of *Rosmarinus officinalis* L. in solvents of increasing polarity were isolated, and their components identified and tested as pest control agents. Ethanol and acetone extracts attract grape berry moth *Lobesia botrana*. However, none of the extracts had a significant effect on western flower thrips *Frankliniella occidentalis*, which is attracted by 1,8-cineole, a major essential oil component.

Key Words—*Rosmarinus officinalis*, essential oil, *Lobesia botrana*, *Frankliniella occidentalis*, 1,8-cineole, insect attractants.

INTRODUCTION

Rosemary *(Rosmarinus officinalis* L.) is an evergreen shrub that grows in the Mediterranean region and is widely known for its culinary and folklore medicinal uses. The plant, belonging to Labiatae family, grows to a height up to 2 m, and has linear leathery leaves that are sharply pointed, deep green with revolute margins, and are whitish beneath. Its flowers are pale to mid-blue, 10–12 mm long, and borne in small lateral clusters (Blamey and Grey-Wilson, 1998).

The essential oil composition of rosemary has been investigated and reported in literature of several areas, mainly in the Mediterranean region. Studies in the Balkan and Northern Mediterranean regions include analyses of Greek, Yugoslavian, Bulgarian, Hungarian Portuguese, Spanish, French, and Italian oil.

* To whom correspondence should be addressed. E-mail: kater@chemistry.uoc.gr

Reports on South-Eastern Mediterranean regions include Egyptian, Tunisian, and Turkish oil, whereas studies from other areas include USA, Cuban, and Argentinean oil (Lawrence, 1979, 1989, 1993, 1995). The consistency of the oils varies depending of the origin of the sample; major oil components include 1,8-cineole (eucalyptol), α-pinene, camphor, borneol, myrcene, and *p*-cymene.

Plant volatiles play an essential role in communication between host plants and herbivorous insects, and affect their behavior by stimulating host orientation, landing, oviposition, feeding, sexual maturity, as well as by attracting parasitoids of pests searching for potential insect hosts (Finch, 1980; Ahmad, 1983; Harborne, 1987; Mitchell et al., 1990; Lewis et al., 1994). During the last 10 years, plant allelochemicals, especially volatile compounds, have received increasing attention as important adjuncts to sex-pheromone technology. Identification of plant odors that affect host locating, feeding, deterring, and reproductive behavior, could complement other control methods that aim at the control of the establishment, development, and dispersal of crop insect pests and their parasitoids (Visser, 1986; Mitchell and Tingle, 1996; Hanson and Christensen, 1999).

Plant produced semiochemicals provide a variety of opportunities to develop several alternative strategies, e.g., push-pull (Bennison et al., 2002), and to control crop pests. Plants that attract parasitoids can be located strategically in and around cultivated crops as an "incubating" pool to increase the population dynamic of biological agents. Khan et al. (1997) reported that the parasitization of *Chilo partellus* (Swinhoe) (Lepidoptera: Crambidae) and *Busseola fusca* Füller (Lepidoptera: Noctuidae) increased significantly in maize crops surrounded by Sudan grass as compared to the monoculture. The combination of trap and repellent plants has been also used successfully in a push–pull strategy. Several plants with such properties have been identified (Khan et al., 2001). Among them, Napier grass, *Pennisetum purpureum* Schumach, and Sudan grass, *Sorghum vulgare sudanense* Stapf, appeared to be most promising (Khan et al., 2001). Moreover, application of selected chemicals can mask pest attractants emitted by plants and confuse orientation to breeding areas (Thiéry and Visser, 1986).

The grape berry moth *Lobesia botrana* Den. and Schiff. (Lepidoptera: Tortricidae) is the most serious pest of grape berries causing heavy crop losses of up to 80% in Crete and Greece. It is a polyphagus insect that develops–two to four generations in vineyards per year, depending on the climate conditions. The 2nd and 3rd generations are destructive to grapes (Stellwaag, 1928; Bovey, 1966; Stoeva, 1982; Roditakis, 1987; Roditakis and Roditakis, 2003). Rosemary is a favorable autumn host of *L. botrana* in Greece, on which it develops a fourth generation (Roditakis, 1987; Roditakis and Roditakis, 2003). The role of volatiles emitted from this host plant in the orientation, host finding, egg laying, feeding, etc. of the insect is unknown. Gabel et al. (1992, 1994) reported that tansy flower extracts, a nonhost plant, and certain components of its extracts were attractive to *L. botrana*.

Western flower thrips *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae) is also one of the most serious pests of vegetables grown either in greenhouse or as outdoor crops in Crete (Roditakis, 1991; Roditakis et al., 2001). As *F. occidentalis* is resistant to most registered insecticides and a vector of tomato-spotted wilt virus, it can cause heavy crop losses in several vegetable fruits even in very low populations (Cho et al., 1989; Immaraju et al., 1992). Consequently, alternative control methods are needed.

Both insects have a wide range of host plants (Roditakis, 1987; Mantel and Van De Vrie, 1998; Roditakis and Roditakis, 2003). Studies on pest–host plant relations, based mainly on volatiles emitted from host plants (semiochemicals), can lead to new, effective, natural means of insect control. Pheromones have been used successfully for sex confusion control methods or to monitor the grape berry moth (Charmillot and Pasquier, 2000). Promising results have been obtained using neroly spec, the commercial essential oil, in mass trapping methods of *F. occidentalis* in greenhouse cucumber crops (Roditakis et al., 2002).

The aim of this study was to examine a pest control strategy using natural compounds from host plants of grape berry moth and western flower thrips. The essential oil and a number of increasingly polar extracts of *Rosmarinus officinalis* L. were isolated, and their components identified, and tested as biological agents in pest control.

METHODS AND MATERIALS

Chemical Analysis. The essential oil and extracts were analyzed by GC–MS on a Shimadzu GC-17 A gas chromatograph coupled with a Shimadzu GCMS-QP 5050 mass selective detector. A Supelco SBP-5 fused silica capillary column of a 30 m $\times$ 0.25 mm i.d. (0.25-μm film thickness) was used for the analysis. The carrier gas was helium (He) at flow rate of 0.9 ml/min, the injector temperature was 250°C, the detector temperature was 230°C, and the column was temperature programmed as follows: 50°C for 2 min, the temperature increased to 150°C at a rate of 10°C/min, increased to 290°C at a rate of 4°C/min, and then held constant at 290°C for 20 min. This oven program resulted in the best component resolution with a total analysis time of 67 min. The mass unit conditions were: ionization energy 70 eV, ion source 195°C, with 0.5 scans/sec from 35 to 450 m/z. Chromatographs and mass spectra were recorded using the CLASS 5000 program. Components were identified on the basis of their mass spectra using the NIST 64 and NIST 120 GC-MS libraries and the comparison of their retention times with those of reference compounds.

The essential oil from the leaves of the plant was received as follows: powdered leaves of *R. officinalis* (60 g, dw) were hydrodistilled to a total of 1.5 l of distillate (three fractions of 500 ml); 50 g NaCl were added to each fraction, which consequently was extracted four times with 40 ml of diethyl ether. The organic

phases were combined, dried over anhydrous magnesium sulfate, filtered, and the solvent was removed *in vacuo* to a volume of 1 ml. The remainder of the solvent was removed by a stream of nitrogen.

Leaves of *R. officinalis* were extracted as follows: powdered leaves (10 g) were extracted successively using a Soxhlet extractor, with hexane, dichloromethane, acetone, and ethanol. The extracts were filtered, the filtrate was evaporated to a volume of 1 ml, and the rest of the solvent was removed under a stream of nitrogen. Samples from the essential oil and the four extracts were diluted in methylene chloride to a concentration of 1 mg/ml and analyzed by GC-MS as described earlier.

Plants. Rosmarinus officinalis L. was collected from the island of Crete in Heraklion on September 1999 (coll. N. Roditakis). The plant was identified by Dr. Z. Kypriotakis, Technical University of Crete, and voucher specimens deposited at the Plant Protection Institute of National Agricultural Research Foundation (Heraklion Crete, Greece). Samples were dried in a dark, air conditioned room at $24 \pm 1^{\circ}$C. Although some volatiles might have been lost during the drying process, dry samples were used instead of fresh material for comparison with literature data.

Insects and Bioassays. Two types of olfactometers were used in the bioassays: (1) a modified "star" four arm Plexiglas olfactometer consisting of two plates ($105 \times 105 \times 6$ mm^3) with an air pump system directing a weak air stream from each of four arms towards the center, suitable for thrips olfactometer tests (Peterson, 1970; Pow et al., 1999), and (2) a Y-tube olfactometer designed for grape berry moth tests. The latter consisted of two cylindrical glasses (8 cm diam $\times$ 10 cm high) connected with a Y-tube (0.5 cm diam, 7 cm arm length). An electric pump was used to pump air from the Y-joint. The tested material was put onto cylindrical glasses. Air speed was regulated by a flow meter (GPE 314-271 UK) at 4.8 m/min. Laboratory tests on *L. botrana* were performed on the Y-tube olfactometer in a rearing conditioning room ($25 \pm 1^{\circ}$C, $50 \pm 5\%$ RH, and 3000 lux light intensity). Three quantities of neat extracts (20, 40, and 60 μl) were compared with the respective extraction solvent. Control experiments using air vs. air and solvent vs. solvent indicated that each arm of the Y-tube was equally visited.

Newly emerged virgin female adults of grape berry moth (3–4), from a laboratory colony grown on artificial media (Tzanakakis and Savopoulou, 1972) for 9 generations per year, were placed into the test tube, and their movement to the arms was recorded at 1, 2, and 24 hr at $25 \pm 1^{\circ}$C, $50 \pm 5\%$ RH, and 3000 lux. A total of 30–34 adults were tested per treatment.

Data Processing and Statistics. The choice test was statistically evaluated. Ten adults of western flower thrips were tested in each assay. Certain volatile compounds of plant extracts were also chosen for further tests on *L. botrana* and *F. occidentalis* under laboratory conditions ($25 \pm 1^{\circ}$C, $60 \pm 5\%$ RH). In the case of *L. botrana*, 1,8-cineole, camphor, and 1-borneol, major components of rosemary extracts, were tested. The attractiveness of linalool, and 1,8-cineole, components

of extracts of *R. officinallis,* were tested on *F. occidentalis*, and compared with *p*-anisaldehyde, a known component of floral scents attractive to *F. occidentalis* (Harborne, 1987; Teylon et al., 1993), and salicylaldehyde, previously tested at 1% concentration in paraffin oil under working greenhouse conditions by Roditakis and Lykouressis (1996).

RESULTS AND DISCUSSION

Results of the component analyses by GC–MS are listed in Table 1. The essential oil contains a group of major components, listed in decreasing abundance, and includes camphor, eucalyptol (1,8-cineole), and borneol, followed by α-terpineol, 4-terpineol, cuminal, cuminol, *trans*-carveol, and τ-cadinol. Major components in the essential oil appear also in most solvent extracts and in the same order of abundance. α-Pinene, mentioned as a major component in most literature reports, was not present in any of the analyzed samples, and β-pinene appeared as a trace component in the essential oil. α-Terpineol was identified as the major (5.67%) component in contrast to most literature reports. However, its presence in relatively large amounts (>5%) has been reported before (Boutekedjiret et al., 1999). Its large abundance combined with the absence of α-pinene could be used as a means of identification of the plants growing in the area.

L. botrana is attracted by certain extracts of tansy flowers *Tanacetun vulgare* L., even though it is not a host plant (Gabel et al., 1992, 1994). Analysis of extracts by GC–EAG methodology showed that a number of monoterpenes including *p*-cymene, *d*-limonene, α-thujene, α-thujone, a blend of β-thujone, and thujyl alcohol elicited responses in 70% of females (Gabel et al., 1992) Hurtrel and Thiéry (1999) reported that photoperiod, age, and mating plays a role on flight activity of grape berry moth. During a 24 hr ligh/dark period, its activity increased close to the end of the photophase. One-day old females did not fly as often as older ones, and mated females showed better response to plant odors from tansy flowers.

In our olfactometer tests, we used 1-day-old females for quick tests since they have to make a double choice (volatile vs. solvent), running (and not flying) a 2–3 cm glass tube up to the arena in 24 hr (8 hr:16 hr D:L).

Adults did not respond during the first 2 hr of their exposure to volatiles. However, there was a distinct response close to the end of the photophase. A small percentage (20–40%) of adults tested remained immobile in the test tube for unknown reasons during the whole experimental period, while the rest made a choice between solvent and extract (Figures 1 and 2).

Given that *R. officinalis* is a good autumn host plant (Roditakis, 1987; Roditakis and Roditakis, 2003) for *L. botrana*, its response to three different quantities (20, 40, and 60 μl) of plant extracts was tested. The response depended on the type of extract as well as its quantity (Figures 1 and 2). Increasing quantities of acetone extract from 20–60 μl caused a linear response, while the corresponding

ethanol extract quantities peaked at 40 μl. Insects were attracted by rosemary acetone extracts at 60 μl, as well as ethanol extracts at 40 μl quantities. It appeared that these quantities of extracts had the optimum concentration of active attractants. Chi square analysis on the number of one-day-old females of *L. botrana* attracted by different quantities of extracts vs. those attracted by the corresponding extraction solvent (Table 2) showed that 60 μl of acetone extract and 40 and 60 μl of ethanol extracts of *R. officinalis* exhibited significant attractiveness. The response of insects to hexane extracts was minimal; further experiments were not

performed due to the limited availability of sample. Traces of methylene chloride in the extracts were fatal to insects.

Among selected components, 20 μl samples of 1,8-cineole (1% in paraffin oil) showed distinct activity (Table 3), borneol was neutral, and camphor was repellent. All three of these are known components of flowers in many plants (Harborne, 1987). Single compounds are less attractive than complete blends. Gabel and Thiéry (1995) reported that odorant traps with a complete floral blend of tansy flowers, and two floral blends reduced to eight and six monoterpenes, respectively, attracted many more *L. botrana* females than a binary blend consisting of α- and β-thujone. Although camphor and borneol were not attractive, we believe that they should be studied further at several doses or in blends before proper conclusions can be drawn.

Camphor	59	36	61
Borneol	38	16	23

[a] 20 μl dose, 1% in paraffin oil.

Analysis of rosemary extracts (Table 1) showed that, with the exception of *p*-cymene and α-terpineol, other components were different than tansy flowers' (Gabel et al., 1992). The attractive blend of *L. botrana* used by Gabel et al. (1992) had only two components (*p*-cymene and α-terpineol), similar to those of rosemary extracts. Analysis of volatiles in grape leaves, grapes, and immature grapes (Schreier et al., 1976) indicated that only 1-octene-3-ol, α-terpineol, and (±)-linalool were similar to the components listed in Table 1. The only component present in the above-mentioned host and nonhost plants, which is listed in Table 1, is α-terpineol. Studies on antenal lobe neuronal responses of *L. botràna* to α-terpineol showed significant differences between male and female insects and between mated and unmated females. The number of responding neurons was higher in mated females (Masante-Roca et al., 2002). α-Terpineol could be a promising attractant, but has to be tested further.

β-Thujone and thujyl alcohol, the main components of a nonhost plant that elicited the most frequent responses to antenal lobe neurons of grape berry moth (Masante-Roca et al., 2002), and also the main components in an attractive blend used by Gabel et al. (1992), are not present in its hosts, vines, and rosemary. Several functional hypotheses could be considered to provide an interpretation for their absence. (a) *L. botrana* may search for a more or less accurate "chemical image" from host and nonhost plants, or (b) the female adapts its behavior to different chemical compositions.

Rosemary essential oil at 0.1% and 1% concentrations in paraffin oil decreased feeding damage of onion thrips *Thrips tabaci*, while 1,8-cineole reduced oviposition rate by 30% in these concentrations (Koshier and Sedy, 2002). The attractiveness of these odors varies with the thrips species. Anisaldehyde attracted *F. occidentalis* but not *T. tabaci*. Salicylaldehyde in certain concentrations acted as repellent to *F. occidentalis*, but highly attractive to *T. tabaci* (Kögel and Koshier, 2002).

On the basis of these data, we tested the response of *F. occidentalis* to *R. officinalis* extracts as well as to several other compounds of plant origin. None of the extracts caused a significant effect. Also, no responses were positively correlated with an increase in concentration of single compounds (Table 4). Linalool at 2.0%, anisaldehyde at 0.5%, salicylaldehyde at 0.5%, and 1,8-cineole at 1% induced a positive response in 70–80% of the adults tested.

Floral volatiles, e.g., *p*-anisaldehyde, benzaldehyde, and ethyl nicotinate, are very good attractants to western flower thrips and could be used for accurate monitoring (Teylon et al., 1993). Temperature and wind strength affect the response of insects to volatiles. Colored traps with volatile chemicals may be useful for control trapping in a protected environment such as a greenhouse. Roditakis et al. (2002) reported that the commercial essential oil, neroly spec, at 1% concentration in paraffin oil is promising for control of *F. occidentalis* in greenhouse cucumbers. Traps with volatiles may not kill so many thrips, but they could be used in combination with other methods as part of an integrated pest management program. The use of

[b] Not tested.

1,8-cineole, *p*-anisaldehyde, linalool, and salicylaldehyde in appropriate concentrations could be used either for monitoring purposes or for mass trapping of *F. occidentalis* on greenhouse crops as alternative means to chemical control of pests.

In conclusion, initial tests, employing extracts from *R. officinalis* as well as selected compounds, indicate the ability of these agents to attract insect pests. The effect of specific components from the acetone and ethanol extracts on *L. botrana* is currently under investigation.

FORAGING IN CHEMICALLY DIVERSE ENVIRONMENTS: ENERGY, PROTEIN, AND ALTERNATIVE FOODS INFLUENCE INGESTION OF PLANT SECONDARY METABOLITES BY LAMBS

JUAN J. VILLALBA* and FREDERICK D. PROVENZA

[1]*Department of Forest, Range and Wildlife Sciences*

(Received May 21, 2004; accepted August 30, 2004)

Abstract—Interactions among nutrients and plant secondary metabolites (PSM) may influence how herbivores mix their diets and use food resources. We determined intake of a food containing a mix of terpenoids identified in sagebrush (*Artemisia tridentata*) when present in isoenergetic diets of increasing concentrations of protein (6, 9, 15, or 21% CP) or in isonitrogenous diets of increasing concentrations of energy (2.17, 2.55, 3.30, or 3.53 Mcal/kg). Lambs were offered choices between those diets with or without terpenes or between diets with terpenes and alfalfa hay. Intake of the diets with terpenes was lowest with the lowest concentrations of protein (6%) and energy (2.17 Mcal/kg) in the diets, and highest with diets of 15% CP and 3.53 Mcal/kg. In contrast, when terpenes were absent from the diets, lambs consumed similar amounts of all four diets with different concentrations of protein, and more of the diets with intermediate amounts of energy. When given a choice between the diet with or without terpenes, lambs preferred the diet without terpenes. When lambs were offered choices between terpene-containing diets and alfalfa, energy and protein concentrations influenced the amount of terpenes animals ingested. Energy densities higher than alfalfa, and protein concentrations higher than 6%, increased intake of the terpene-containing diet. Thus, the nutritional environment interacted with terpenes to influence preference such that lambs offered diets of higher energy or protein concentration ate more terpenes when forced, but not when offered alternative food without terpenes. The nutrients supplied by a plant and its neighbors likely influence how much PSM an animal can ingest, which in turn may affect the dynamics of plant communities, and the distribution of herbivores in a landscape. We discuss implications

of these findings for traditional views of grazing refuges and varied diets in herbivores.

Key Words—Terpenes, refuges, nutrient–toxin interactions, choice, preference, foraging, energy, protein, sagebrush.

INTRODUCTION

Herbivores can change ecosystems by removing specific kinds and amounts of tissues from plants (Hobbs, 1996), but the mechanisms that explain "which" and "how much" tissues are eaten are not well understood. Plants produce diverse mixtures of biochemicals that provide herbivores with nutrients for survival and reproduction and secondary metabolites that can both cause toxicity and yield health benefits (Cheeke and Shull, 1985; Engel, 2002). Despite the diversity of chemicals ingested in a meal, with few exceptions our understanding of multiple interactions among nutrients and plant secondary metabolites (PSM) is rudimentary (Simpson and Raubenheimer, 2001; Villalba et al., 2002a). We have relied on univariate approaches to studying the isolated effects of PSMs or nutrients on food selection.

Plant secondary metabolites satiate herbivores (Garcia, 1989; Provenza, 1996), and the degree to which a PSM limits food intake is influenced by the kinds and amounts of nutrients herbivores ingest (Villalba et al., 2002a). Many PSM are lipophilic compounds that must be transformed into hydrophilic substances before excretion (Cheeke and Schull, 1985), and these processes deplete the body of amino acids and glucose (Illius and Jessop, 1995, 1996). Thus, ingesting appropriate amounts of nutrients should increase the threshold of PSM satiation and enable animals to ingest more of foods that contain PSM, although the willingness of herbivores to consume PSM as a function of the concentration of nutrients containing PSM is not known.

Outcomes of interactions among nutrients and PSM may help explain the dietary choices of herbivores. Browsing by black-tailed deer causes serious damage to young Douglas-fir trees, which contain an array of volatile terpenes that can inhibit rumen microbial fermentation (Connolly et al., 1980). Browsing begins shortly after bud burst (Crouch and Radwan, 1981), when concentrations of nitrogen and fermentability of the new growth is higher than in the old growth (Oh et al., 1970). Nitrogen fertilization increases protein content and fermentability of seedlings, which increases acceptability to deer (Oh et al., 1970; Crouch and Radwan, 1981). Thus, the amount of a chemically defended species an herbivore will eat is influenced by concentration of nutrients and PSMs, likely in relation to those in neighboring plants. Because concentrations of nutrients and toxins covary in the field, controlled experiments are needed to disentangle the influence of PSM and nutrients on foraging behavior.

We hypothesized intake and preference for PSMs are influenced by the nutritional context where herbivores experience PSM. We further hypothesized that the willingness of herbivores to ingest PSM is influenced by the nutritional composition of the food containing the PSM relative to the nutritional composition and availability of alternative foods. Based on these hypotheses, we predicted that intake of PSM would increase with an increase in the concentration of either energy or protein in the food, and that preference for PSM would increase with the increased capacity—due to energy and protein—to consume higher amounts of PSM, and/or with the decrease in nutritive value of alternative foods. To assess the effects of PSM on food intake and preference, we exposed lambs to isoenergetic foods with increasing concentrations of protein and to isonitrogenous foods with increasing concentrations of energy, with or without the addition of a mix of terpenoids in sagebrush (*Artemisia tridentata*). We then determined preference for terpene- and nonterpene containing foods.

METHODS AND MATERIALS

We determined intake and preference of lambs for terpenes in isoenergetic and isonitrogenous foods that differed across gradients of protein and energy, respectively. For each gradient, we used a different set of 32 lambs (commercial crossbreds, 4–5 mo age). Throughout each experiment, lambs were individually penned and had free access to mineral blocks and fresh water.

Ingestion of Terpenes across Gradients of Protein and Energy. Lambs were weighed and randomly assigned to four diets (8 lambs/diet) that differed in concentrations of energy or protein. Diets contained different proportions of the same ingredients (Table 1), ground to 1–5 mm particle size.

To modify the nutritional state of the animals and familiarize them with the food ingredients, for the first 10 d, Groups 1, 2, 3, and 4 were offered control diets 1, 2, 3, and 4, respectively, without the addition of terpenes from 0900 to 1300 hr. At 1300 hr, refusals were collected, intake was determined and no other food was offered until the next day.

For the next 10 d, we used the same procedures, but terpenes were added to each diet at the same relative concentrations found in *Artemisia tridentata* (Personius et al., 1987; Launchbaugh, unpublished results): 1.82% camphor, 1.1% 1,8-cineole, 0.12% methacrolein, 0.06% *p*-cymene, dissolved in vegetable oil and then mixed with the rest of the food ingredients on a daily basis (Table 1). These terpenes adversely influence intake and preference (Bray et al., 1991; Villalba et al., 2002a).

Preference Tests Immediately after Exposure. We then determined preference of lambs for food with or without terpenes, or for food with terpenes vs. alfalfa hay. From 0900 to 1300 hr the day after exposure to the terpene-containing diets,

[a] Calculated values of DE are based on values obtained from NRC (1985).
[b] Nitrogen was determined by Kjeldahl method (AOAC, 1975); CP calculated as $N \times 6.25$.

each group of lambs received simultaneously the two diets they received during exposure (control diet and diet with terpenes) for 2 d. Intake was determined and no other food was offered until the next day. For the next 2 d, preference tests were conducted as described earlier, but alfalfa hay (2.50 Mcal/kg; 16% CP) replaced the

control diet for each group of lambs. After preference tests, lambs were weighed, and daily weight gains (g/d) were estimated ([final BW–initial BW]/number of days elapsed between initial and final determination of BW).

Preference Tests 20 Days after Exposure. First, we put all lambs on a similar plane of nutrition after the initial preference tests by offering them *ad libitum* alfalfa pellets and 300 g of barley grain/lamb/day for 20 d. Then, we conducted preference tests as previously described.

Ingestion of Terpenes across a Gradient of Protein Concentrations. Lambs consumed terpenes in isoenergetic diets (2.55 Mcal/kg) with increasing concentrations of protein. Four groups of lambs were randomly assigned to four treatment diets, across a gradient of protein concentrations (Group 1 = 6%; Group 2 = 9%; Group 3 = 15%; Group 4 = 21% CP; Table 1).

Ingestion of Terpenes across a Gradient of Energy Concentrations. Lambs consumed terpenes in isonitrogenous (15% CP) diets with increasing concentrations of energy. Four groups of lambs were randomly assigned to four diets across a gradient of energy concentrations (Group 1 = 2.17; Group 2 = 2.55; Group 3 = 3.30; Group 4 = 3.53 Mcal/kg; Table 1). The concentration of protein was that where lambs had the highest intake of terpenes in the previous study.

Statistical Analyses. The statistical design for the ANOVA during exposure was a split-plot with lambs nested within Group (1–4) and day (1–10) as the repeated measure. Intakes were converted to g food ingested/kg metabolic body weight ($kg^{0.75}$). During preference tests, Group (1–4) was the between-animal factor, and lambs were nested within group. Diet (with terpenes, without terpenes, or alfalfa) was the within-animal factor in the analysis. Day (1–2) and period (immediately after exposure, 20-d after exposure) were repeated measures. When F values were significant ($P < 0.05$), means were compared using the LSD test. The ANOVA was performed using the MIXED procedure (Littell et al., 1996).

RESULTS

Ingestion of Terpenes across a Gradient of Protein Concentrations. Intake did not differ for diets with different concentrations of protein without terpenes (main effect; $P = 0.922$; group × day, $P = 0.731$; Figure 1). However, that pattern changed after the addition of terpenes to the diets (group × day, $P = 0.004$). Initially, terpenes caused a marked decline in intake of all diets, but intake then increased differently depending on the protein concentration in the diets (15% > 21% and 9% > 6% CP; Group effect, $P = 0.004$; Figure 1).

Ingestion of Terpenes across a Gradient of Energy Concentrations. When terpenes were absent from the diets (control diets), lambs in Groups 2 (2.55 Mcal/kg) and 3 (3.30 Mcal/kg) ate more food than lambs in Groups 1 (2.17 Mcal/kg) and 4 (3.53 Mcal/kg; Group effect; $P = 0.003$). As with protein, all groups decreased intake of the diets after the addition of terpenes, and intake diverged through time,

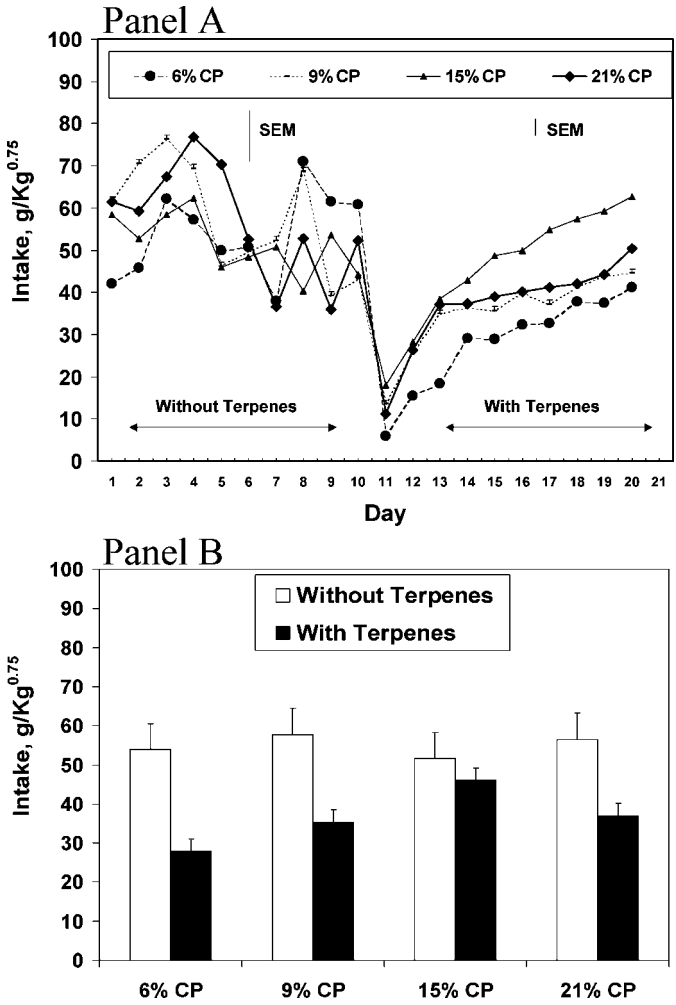

FIG. 1. Intake of diets with or without terpenes across a gradient of protein concentrations. Values are daily means recorded for 8 lambs/diet (Panel A), and averages with standard error bars for each 10-d period, when diets were fed without (without terpenes) or with (with terpenes) terpenes (Panel B).

particularly for lambs in Group 1 vs. Groups 2, 3, and 4 (group $\times$ day, $P < 0.001$; Figure 2); averaged across days, intake of food was Group 4 $>$ Group 3 $=$ Group 2 $>$ Group 1 ($P = 0.012$; Figure 2).

Preference Tests. Lambs avoided the terpene-containing diets, but the pattern of selection was influenced by the nutritional composition of the diets with terpenes

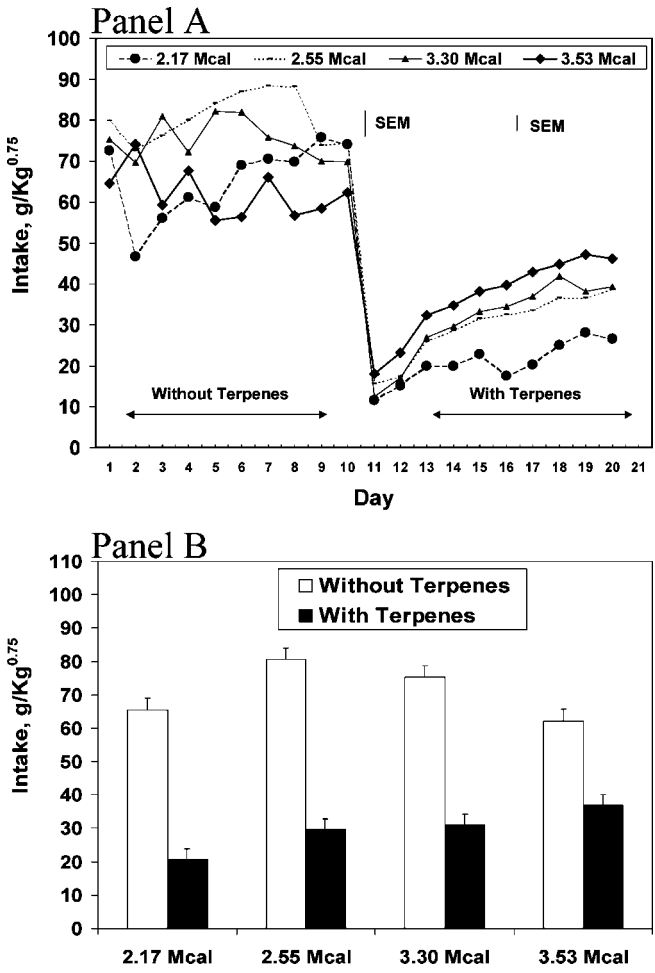

FIG. 2. Intake of diets with or without terpenes across a gradient of energy concentrations. Values are daily means recorded for 8 lambs/diet (Panel A), and averages with standard error bars for each 10-d period, when diets were fed without (without terpenes) or with (with terpenes) terpenes (Panel B).

as well as the nutritional quality of the alternatives (Diet effect; $P < 0.001$; Figure 3).

Preference Tests across a Gradient of Protein Concentrations. When lambs were offered a choice of their respective diets with or without terpenes immediately after exposure, they ate similar amounts of the diet with terpenes ($P > 0.05$). However, 20 d after exposure, only lambs fed the diet with 15% ate more of the

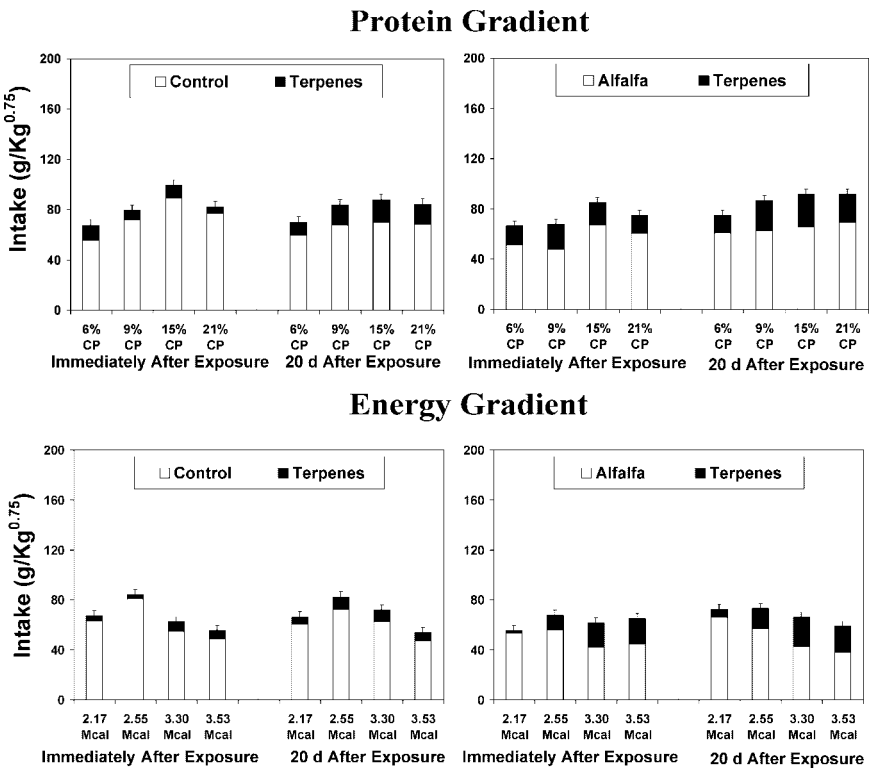

FIG. 3. Intake of diets with (terpenes) and without (control) terpenes, or with terpenes (terpenes) and alfalfa hay (alfalfa) by four groups of lambs during preference tests conducted immediately and 20-d after exposure to diets of different protein (protein gradient) and energy (energy gradient) concentrations. Values are means with standard error bars recorded for 8 lambs/group during 2 consecutive days.

diet with terpenes than lambs fed the diet with 6% CP ($P < 0.05$; Figure 3). Lambs fed 6% CP ate the least of the diet without terpenes in both periods ($P < 0.05$; Figure 3).

When lambs were offered choices between their respective diets with terpenes and alfalfa hay, lambs fed the diet with 9% CP (Group 2) tended to consume more diet with terpenes than lambs fed the diet with 6% CP (Group 1) immediately after exposure ($P = 0.10$). Lambs fed the 6% and 9% CP diets ate less alfalfa than lambs fed the 15% and 21% CP diets. After 20 d, lambs fed 6 % CP ate the least of the diet with terpenes ($P < 0.001$; Figure 3). All lambs ate the same amounts of alfalfa, except that lambs fed 21% CP ate more alfalfa than lambs fed 6% CP ($P < 0.05$; Figure 3).

Preference Tests across a Gradient of Energy Concentrations. When all groups were offered choices between their respective diet with or without terpenes, intake of the terpene diets did not differ among groups either when preference tests were conducted immediately or 20-d after exposure ($P > 0.05$; Figure 3). In both periods, lambs in Group 4 (3.53 Mcal/kg) ate the least amounts of diet without terpenes and lambs in Group 2 (2.55 Mcal/kg) ate the most of the diet without terpenes ($P < 0.05$).

When lambs were offered choices between diets with terpenes and alfalfa hay, lambs fed the diet with 3.53 (Group 4) and 3.30 Mcal/kg (Group 3) ate more diet with terpenes and less alfalfa than lambs fed the diet with 2.17 (Group 1) and 2.55 Mcal/kg (Group 2), both immediately and 20 d after exposure ($P < 0.05$; Figure 3). Lambs in Group 2 ate more terpenes than lambs in Group 1 ($P < 0.05$; Figure 3).

Body Weight Changes. With regard to diets differing in protein, groups did not differ in average daily weight gains ($P = 0.861$), but trends varied along a gradient. Lambs in Groups 1 (6% CP) and 2 (9% CP) lost weight (–22 and –13 g/d, respectively), lambs in Group 3 (15% CP) maintained weight, and lambs in Group 4 (21% CP) gained weight (6 g/d).

With regard to energy, daily weights changed along a gradient (Group effect; $P < 0.001$). Lambs in Group 1 (2.17 Mcal/kg) lost more weight than lambs in Group 2 (2.55 Mcal/kg) (–140 vs. –65 g/d), and lambs in Groups 3 (3.30 Mcal/kg) and 4 (3.53 Mcal/kg) gained weight (5 and 35 g/d).

DISCUSSION

Animals Forced to Consume PSM. We assessed the ability of lambs to consume terpenes across isoenergetic diets that varied in protein, and isonitrogenous diets that varied in energy. Protein and energy availability affected the amount of terpenes lambs ingested. Intakes of diets with terpenes were lowest with diets of 6% CP and 2.17 Mcal/kg, and highest with diets of 15% CP and 3.53 Mcal/kg (Figures 1 and 2). In contrast, when terpenes were absent from the diets, lambs ate similar amounts of diets with different concentrations of protein, and more of diets with intermediate energy (2.55 and 3.30 Mcal/kg) than of either low (2.17 Mcal/kg) or high (3.53 Mcal/kg) concentrations of energy.

Our results are consistent with modeling efforts that suggest the ability to ingest PSM depends on nutrient intake (Illius and Jessop, 1995, 1996). Detoxification processes deplete the body of protein and glucose, and, thus, adequate levels of nutrients are needed to tolerate ingesting PSM (Foley et al., 1995). Supplemental macronutrients increase intake of foods that contain toxins as diverse as lithium chloride (Wang and Provenza, 1996), terpenes (Banner et al., 2000; Villalba et al., 2002b), menthol (Illius and Jessop, 1996), and tannins (Villalba et al., 2002c).

Nonetheless, nutrient availability alone cannot increase tolerance for PSM, as nutritional imbalances can depress ingestion of PSM. Tannic acid affects *Locusta migratoria* performance only when the ratio of protein to carbohydrate in the diet is low (Simpson and Raubenheimer, 2001). Likewise, sheep and goats fed concentrates high in protein, or offered a choice between concentrates high in energy and high in protein, ingest more terpenes (Villalba et al., 2002b) and tannins (Villalba et al., 2002c) than when they receive only concentrates high in energy.

In our study, intake of the terpene-containing diets increased monotonically within the range of energy densities (2.17–3.53 Mcal/kg). In contrast, lambs fed a diet with 21% CP ate less terpene-containing food than lambs fed a diet with 15% CP (Figure 1), which indicates that intake of the terpene-containing diets did not increase monotonically with levels of protein, and that the protein–energy ratio was important. High protein concentrations may overload the animal's deaminating systems (Harper, 1974), and the addition of terpenes might have enhanced the negative effects of excess protein, promoting a decline in food intake relative to diets with lower nitrogen concentrations. Collectively, these results suggest a balanced ratio of protein–energy in the diet can be more important than the absolute concentration of a single nutrient.

Theorists usually regard PSM as fixed constraints on food intake (Belovsky and Schmitz, 1991), but our results argue against that contention (see also Simpson and Raubenheimer, 2001; Behmer et al., 2002). The effects of terpenes depended on the balance of energy and protein. Some also propose that animals cannot consume a food that exceeds a threshold ratio of PSM–nutrient unless they can dilute the ratio by adding other foods or nutrients (Illius and Jessop, 1996). However, by varying protein and energy concentrations we showed that diluting PSM with protein is different from diluting PSM with energy, and that ingesting terpenes as a function of energy and protein density is graded rather than an all-or-none response dependent on a threshold of nutrient supply.

Thus, we predict that when animals are forced to consume an abundant plant high in PSM, the amounts of biomass eaten will depend on the concentrations and balances of energy and protein supplied by the plant. The higher the concentration of nutrients in the plant, along with an adequate balance of protein–energy, the higher the potential amount of plant that can be ingested and the higher the likelihood to sustain maintenance and detoxification costs (Figure 4).

Plants lessen herbivory by reducing nutritive quality (Rhoades, 1979; Haukioja et al., 1991), provided animals are unable to compensate by increasing rates of consumption or time feeding (Augner, 1995). Intake also is restricted by PSM and their interactions with low or imbalanced amounts of nutrients (Figures 1 and 4). Compensatory feeding on a nutritionally imbalanced food, which is needed to satisfy requirements for a limiting nutrient, also can be restricted by PSM (Raubenheimer, 1992). Thus, when alternative plants are scarce, herbivory on abundant, defended plants may decline, even if concentrations of

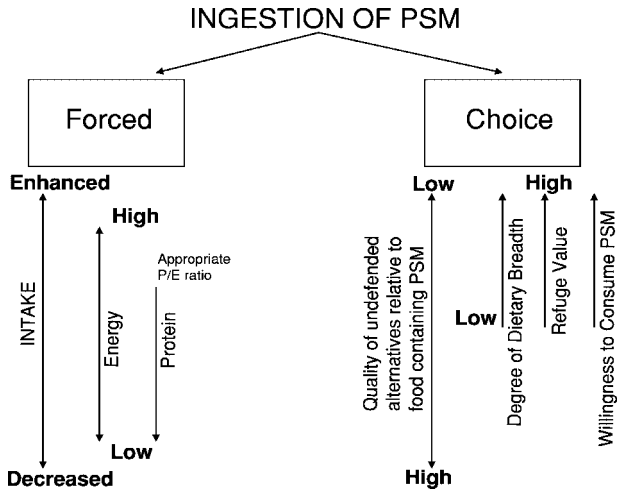

FIG. 4. Conceptual model of ingestion of PSM by herbivores based on results of this study. When animals are forced, due to lack of alternatives, higher concentrations of protein and energy lead to greater intake of PSM, but only when protein–energy ratios are appropriate (forced). When animals have choices of equally abundant defended and undefended plants, their willingness to consume PSM increases only when the quality of undefended alternatives declines relative to the quality of defended plants (choice). This increase in use of defended species increases the degree of dietary breadth due to more uniform use of all foods available, which increases the associational refuge value for undefended species.

PSM do not change, due to dilution or imbalance of nutrients in the plant.

Animals Offered Choices with Foods Containing PSM. All animals ate similar (low) amounts of the terpene-containing foods, regardless of energy or protein contents, when given a choice between diets with or without terpenes. Moreover, the physiological state of the animals—immediately after exposure vs. fed the alfalfa-based diet—did not influence choice, except lambs fed 6% protein ate less diet with terpenes than animals fed 15% protein 20 d after exposure (Figure 3). Thus, while lambs fed diets higher in energy or protein could eat more terpenes when forced (Figures 1 and 2), they did not do so when alternative foods of similar quality without terpenes were available. Thus, contrary to what some propose (Illius and Jessop, 1995, 1996), animals with higher nutrient intake may not always be more willing to eat PSM than animals with lower nutrient intake.

Experience and nutritional context both influence preference (Provenza et al., 2003). Experiences with combinations of PSM-containing foods that are complementary increase preferences for those foods, even when high-quality alternatives

are available *ad libitum* (Baraza et al., 2005; Villalba et al., 2004). Thus, "positive" experiences with PSM due to the presence of appropriate kinds and amounts of nutrients may lead to a higher preference for PSM than "aversive" experiences with PSM created by the absence of appropriate kinds and amounts of nutrients. In the current study, where only food with terpenes was available, lambs preferred less defended foods regardless of plane of nutrition (Figure 3).

Chemical defenses satiate detoxification capabilities of herbivores at critical thresholds of plant abundance. Below these thresholds, local extinction is more likely as species become less abundant because toxin satiation is not achieved and the relative removal of biomass of a species increases with its decline in abundance (Provenza et al., 2003). Results from our study suggest highly defended and rare plants with either high or low nutrient content may escape herbivory, provided that the quality of undefended neighbors is similar to the quality of the defended plant.

When lambs chose between the terpene-containing diets and alfalfa, the protein and energy concentrations of the former affected the amount of terpenes ingested (Figure 3). Energy densities higher than alfalfa, and protein concentrations higher than 6%, increased the likelihood of lambs ingesting the terpene-containing diet. This suggests the amount of defoliation a defended plant will sustain may be influenced by its nutritional quality relative to that of its neighbors. Lambs fed diets with more energy (3.30 and 3.53 Mcal/kg) ingested more terpene than animals fed diets with less energy (2.17 and 2.55 Mcal/kg), and lambs offered the diet with the least energy ingested the least terpenes. Lambs fed 6% CP ingested the least terpenes, but only during the second period of preference tests, after they received alfalfa pellets and barley for 20 d. The energy density of alfalfa was similar to the isoenergetic foods (2.50 Mcal/kg), and its protein concentration was similar to the isonitrogenous foods (16%). Thus, protein but not energy was different when alfalfa was tested against isoenergetic foods [alfalfa had more protein than foods offered to Groups 1 (6%) and 2 (9%), but less protein than the food offered to Group 4 (21%)], whereas energy but not protein was different when alfalfa was tested against isonitrogenous foods [alfalfa had more energy than the food offered to Group 1 (2.17 Mcal/kg), but less energy than foods offered to Groups 3 (3.30 Mcal/kg) and 4 (3.53 Mcal/kg)]. Higher energy densities increased intake of terpenes during the choice with alfalfa (Figure 3), but intake of terpenes did not increase along different protein concentrations tested against alfalfa. Intake of terpenes did not differ immediately after exposure, or among foods with 9%, 15%, or 21% CP, 20 d after exposure (Figure 3). Lambs typically show stronger preferences for energy than for protein (Villalba and Provenza, 1999), probably because ruminants require nearly five times more energy than protein on a daily basis (NRC, 1985), and because they are efficient at recycling nitrogen (Owens, 1988). Thus, lambs evidently did not need the protein provided by alfalfa when they were fed diets of 9% to 21% CP because they had enough protein to detoxify terpenes and

to complement the marginal levels of energy in the test diets (2.55 Mcal/kg) and alfalfa (2.50 Mcal/kg). Higher amounts of protein (21%) did not promote greater intake when animals were forced to eat just one food (Figure 1).

Accounts of partial preferences have received more attention (McNamara and Houston, 1987; Berec and Krivan, 2000) than explanations for their occurrence (but see Dearing et al., 2000 for a contrast between generalists and specialists). Dilution of PSM (Freeland and Janzen, 1974) and nutrient balancing (Westoby, 1978) are the main hypotheses for varied diets in herbivores, but these explanations are not mutually exclusive (Provenza, 1996; Behmer et al., 2002; Singer et al., 2002). The two mechanisms operate simultaneously, with the relative importance of each dictated by the kinds and amounts of PSM and nutrients. Based on our results, a uniform nutritional environment—choice between foods of similar quality with or without terpenes—narrows the diet constituents to the least defended species, regardless of food quality, whereas a diverse nutritional environment may broaden the diet if the quality of defended species is high relative to the quality of undefended species. If the concentration of nutrients in a plant is higher than the concentration of nutrients in an equally abundant and undefended neighbor, an herbivore may ingest higher amounts of the defended plant, and thus higher amounts of PSM. A diverse nutritional environment may also narrow the diet to the less defended plant species if the quality of the defended species is lower than the quality of the undefended neighbor (Figure 4).

Plant neighbors may be an important way plants cope with herbivores. The preference or avoidance of a plant species depends not only on factors internal to the plant, but also on the chemical and physical characteristics of neighbors (Atsatt and O'Dowd, 1976). While little attention has been given to these interactions (Milchunas and Noy-Meir, 2002; but see Hay, 1986; Pfister and Hay, 1988), the kinds and amounts of nutrients and toxins in a plant may influence how herbivores use their neighbors. Plant–plant–herbivore interactions may affect the probability of extinction of a plant chemotype within a plant community, and thus the diversity of plant species (Provenza et al., 2003). External factors for coping with herbivory include associational plant refuges (Atsatt and O'Dowd, 1976), which occur when "a plant that is susceptible to herbivory gains protection from herbivory when it is associated with another plant" (Pfister and Hay, 1988). Within a plant community, defoliation of an individual depends on the surrounding matrix of plant species (Milchunas and Noy-Meir, 2002). Thus, benefits and costs of a defense need to be weighed not only in terms of the individual, but also within the context of the association (Tuomi and Augner, 1993). Refuges may be essential for maintaining the diversity of plant communities and their resilience to changing grazing pressures (Milchunas and Noy-Meir, 2002). Factors that affect refuges include characteristics of the herbivore as well as the plant association. Palatable plants may gain associational protection from unpalatable plants when herbivores are selective between patches and unselective within a patch. On the other hand,

palatable plants are less likely to gain protection if herbivores are selective within a patch (Hjalten et al., 1993).

Nutrient–PSM interactions add another dimension to "palatability" and "unpalatability" within the context of associational plant refuges (Villalba et al., 2002a). Interactions among multiple nutrient and PSM dimensions may explain why certain plant–plant associations are of higher or lower preference to herbivores than predicted from the isolated effects of PSM repellency or plant palatability. Our results suggest undefended plants are more likely to gain protection, even if herbivores are selective within a patch, when the quality (energy density in our study) of the PSM-containing plant is higher than the quality of the undefended plant. In contrast, undefended plants are less protected from herbivory when the qualities of all plants, defended and undefended, in the patch are similar (Figure 4). Thus, the possible increase in herbivory of toxic plants promoted by their higher quality relative to their neighbors may enable palatable and less-competitive species to survive.

In summary, energy and nutrient concentrations influenced ingestion of terpenes in a graded fashion. The amounts of PSM that lambs ingested depended on the nutritional composition of the PSM-containing food relative to the nutritional composition of the alternatives (Figure 4). These interactions between PSM, nutrients, and neighbors can influence preference in ways that cannot be predicted solely by the isolated effects of nutrients or PSM. The effects of nutrients and PSM on herbivores can influence interactions and coexistence of plant species with different kinds and amounts of PSM, nutrients, and different competitive abilities. A formal integration of nutrient–PSM interactions into existing models of foraging behavior and plant community ecology will provide further insights into how protection or susceptibility function within plant communities to increase or decrease species richness.

Abstract—In this article, we analyzed the concentration of coumarins in leaves of female and hermaphrodite individuals of the gynodioecious shrub *Daphne laureola*, along an elevational gradient in southern Spain. Combining HPLC and NMR techniques, we identified three different glycosides of 7-methoxycoumarin in leaves of this species. Total coumarin concentration averaged between 60 and 120 mg/g dry weight for mature summer leaves of *D. laureola* growing at six different populations. As predicted by optimal theory, females tended to have a higher concentration of coumarins than hermaphrodites, thus upholding the idea that male reproductive function is costly for hermaphrodites. Furthermore, concentrations in females but not hermaphrodites were positively correlated with increasing population altitude, and the magnitude of gender divergence in coumarin concentration varied among populations, suggesting that the cost of the male function may be context dependent. To our knowledge, this is the first evidence of gender differences in chemical defenses of a gynodioecious species in the field.

Key Words—Coumarins, *Daphne laureola*, elevation, gynodioecy, plant–animal interactions, plant defense.

INTRODUCTION

In this study, we analyze the relationship between allocation to reproduction and chemical defenses, and its natural variation along an altitudinal gradient, in a long-lived perennial shrub. According to optimal theory, organisms allocate resources to survival, growth, and reproduction, such that their fitness will be maximized (Maynard-Smith, 1978). Plant defenses aim to decrease pathogen and herbivore attacks that may eventually reduce plant survival, growth, and reproduction and, thus, plant allocation to defenses can also be interpreted within optimal theory (Herms and Mattson, 1992). Within this framework, trade-offs (or opportunity costs) between growth, defense, and reproduction should exist whenever resources are limited. However, field measurements of trade-offs and other physiological costs in plant allocation to reproduction and defenses are not straightforward (see Obeso, 2002; Cipollini et al., 2003 for a review of each topic, respectively). Gender dimorphic species split the range of individual variance in reproductive allocation into categories, thus facilitating the assessment of consequences in terms of survival, growth, and defense of a higher reproductive allocation under natural conditions.

In dioecious species, allocation to reproduction in males is commonly higher than in females at flowering, though the opposite is true at fruiting time when the sink of resources to reproduction is maximum (Delph, 1990). Therefore, both the nature and magnitude of differences between genders in resource allocation may change with time (Ågren et al., 1999). Overall, herbivores usually distinguish and prefer males over females of dioecious plant species (Ågren et al., 1999, and references therein) suggesting that differences in reproductive allocation modify other plant features that in turn decrease quality of females as food for herbivores (e.g., Boecklen et al., 1990; Jing and Coley, 1990). Gynodioecy consists of populations having both hermaphrodite and female pollenless individuals. Thus, gender difference in allocation to reproduction is in principle lower and due to the male function only. The costs of male function are apparently more subtle, but still relevant (Eckhart and Seger, 1999), and there is also evidence for male-biased flower and seed predation favoring the maintenance of females in gynodioecious populations (Uno, 1982; Marshall and Ganders, 2001; Collin et al., 2002; reviewed in Ashman, 2002). To our knowledge there are no data available comparing physical or chemical defenses in gynodioecious species (but see Gouyon and Vernet, 1980) and, thus, whether gender differential consumption is mediated through distinct defenses or otherwise, for example through differential attractive properties, is unknown.

We explore the relationship between allocation to reproduction and defense in a gynodioecious species. Hermaphrodite and female *Daphne laureola* plants produce a similar number of flowers and fruits, and fruit size is also similar between genders (Alonso and Herrera, 2001). However, female flowers are smaller

and pollenless, thus leading to a lower allocation to reproduction of female individuals. In southern Spain, *D. laureola* is consumed by several species of Noctuid caterpillars. Defoliation has been related to plant architecture (Alonso and Herrera, 1996) and leaf nutrient composition (Alonso and Herrera, 2003), and caterpillars are able to distinguish among several plant structures (Alonso and Herrera, 2000). The role of allelochemicals in this plant-herbivore interaction remained unstudied. Coumarins are effective chemical defenses against herbivores in other plant species (Berenbaum, 2001 and references therein), and were known to exist in the *Daphne* genus (Hegnauer, 1973; Ulubelen et al., 1986; Zobel and Brown, 1988). Our expectation was that, if the increased reproductive allocation associated with the male function were costly, *D. laureola* females should have a higher concentration of coumarins than hermaphrodite conspecifics. Thus, we evaluated the concentration of the three most abundant coumarin glycosides found in leaves of female and hermaphrodite *D. laureola* individuals.

Furthermore, since the natural concentration of chemical defenses may vary geographically (Johnson and Scriber, 1994), the study was conducted in six different populations selected along an altitudinal gradient, that ranged from 950 to 1800 m asl. Increased exposure to UV radiation and low temperatures at higher altitudes may select for different chemical profiles in plants that in turn can affect herbivores (Johnson and Scriber, 1994; Stratmann, 2003). In particular, contents of UV-B absorbing compounds tend to increase at higher elevation sites in several plant species (Rozema et al., 1997). Coumarins are able to absorb UV radiation (Murray et al., 1982). Thus, we also expected an increase of coumarin concentrations in plants at higher elevation sites.

METHODS AND MATERIALS

Plant Species and Study Area. Daphne laureola L. (Thymelaeaceae) is a long-lived evergreen shrub distributed throughout the Palearctic region and generally found in the understory of coniferous and mixed montane forests in the Mediterranean area. In the Natural Park of Sierras de Cazorla, Segura y Las Villas (Jaén province, south-eastern Spain), where this study was conducted, the species is gynodioecious, and the proportion of female plants varies with site altitude (Alonso and Herrera, 2001).

In June 2002, we collected undamaged leaves from female and hermaphrodite individuals in six different populations comprising the entire altitudinal range of the species at our study area. Study locations were Coto del Valle (950 m elevation), Roblehondo (1235 m), Cañada del Espino (1575 m), Nava de las Correhuelas (1615 m), Cabeza del Tejo (1640 m), and Puerto Llano (1800 m), hereafter referred to as CV, RH, CÑE, NC, CT, and PLL, respectively. Aiming to have three replicates for each combination of gender per population, leaves of each individual ($N = 7$–20) were collected independently and later split into three different sets. Each

replicate had 8–17 g fresh mass. Leaves were collected when plants were bearing mature fruits and all plants were at the same phenological stage despite the fact that the different populations were collected on different dates due to altitudinal variation in plant phenology.

Chemical Analyses. Leaves were washed, dried with filter paper, and stored at −80°C prior to analysis. Frozen samples were weighed, deep-frozen with liquid nitrogen and ground in a coffee mill. As an internal control, 1.5 mg of esculetin (6,7 dihydroxy-coumarin, Aldrich) were added to each sample to evaluate potential process errors. Leaf powder was extracted 2 × 24 hr with methanol (80%), and the combined extract was filtered and concentrated to dryness under reduced pressure. The residue was dissolved in water and cleaned by sequential decantation with chloroform. Coumarins were detected as pale-blue spots on C_{18}-TLC (Alugram® RP-18W/UV_{254}) only in the aqueous phase, that was subsequently concentrated to dryness under reduced pressure to record the weight of the final residue. The residue was suspended in 15 mg of double-distilled water to obtain a 10% concentration of the internal control, esculetin. Three 750 μl aliquots were taken from this solution and centrifuged for 10 min at 12,000 rpm. The supernatant contained the target coumarins. For every aliquot, solid phase extraction was conducted on packed MFE C_{18} 3/500 columns (Análisis Vínicos S.L.) prior to HPLC analysis. On each occasion, a new packed column was gently washed with distilled water. The sample supernatant (250 μl) was loaded and elution started with 750 μl of methanol (85%) that was discarded. A mixture of methanol–water–glacial acetic acid (60:40:1, v/v; 1500 μl) was collected directly into an HPLC vial. Two injections of 10 μl from each vial were analyzed by HPLC, and the average peak area for each compound was used for further statistical analyses (see below).

HPLC was conducted on a Waters 2690 separation module with a Waters 996 PDA detector (Waters Cromatografía S. A., Barcelona, Spain) that allowed coumarin identification by way of their characteristic UV spectrum with two maxima absorption lengths around 260 and 320 nm (Murray et al., 1982). A Waters ODS2-3 μm RP-HPLC column (4.6 mm i.d. × 15 cm length) was used for quantification. Analyses were conducted in isocratic mode at a flow-rate of 1 ml/min, using a mixture of water–methanol–glacial acetic acid (84.8:14.2:1, v/v) as mobile phase (modified from Thompson and Brown, 1984). Double distilled water and HPLC quality solvents were used for the analyses. A calibration regression line was obtained for esculetin by varying the volume injected of two different solutions w/w in methanol. Regression of peak area on amount of esculetin injected explained 99.8% of peak area variation. Analyses of esculetin recovery based on this calibration showed that on average 76% of the esculetin initially added to leaf samples was lost during sample processing. Thus, error for each individual sample was calculated as the ratio between the expected and observed area of esculetin peak.

Each coumarin was purified by liquid chromatography, and the ^{1}H and ^{13}C NMR (DMSO-d_6) obtained on a Bruker AVANCE 500 spectrometer were compared to literature data for molecule identification.

Data Analyses. Statistical analyses were performed using the SAS statistical package (SAS Institute, 1996). Peak areas were transformed into coumarin concentrations assuming that for each sample coumarin quantification had the same recovery error as that observed for esculetin, and using esculetin regression to transform peak areas into quantities. Results obtained for each aliquot were averaged by sample, and concentration was referred to total leaf dry weight of the sample. Differences between genders and populations on concentration of coumarins were analyzed by General Linear Models (Procedure GLM). Gender, population, and their interaction were treated as fixed effects.

RESULTS

The methanolic extract of *D. laureola* leaves contained three major components (Figure 1) that were identified as three different glycosides of 7-methoxycoumarin. The observed molecular structures based on ^{1}H and ^{13}C NMR, and the references where these compounds were previously reported (Konishi et al., 1993;

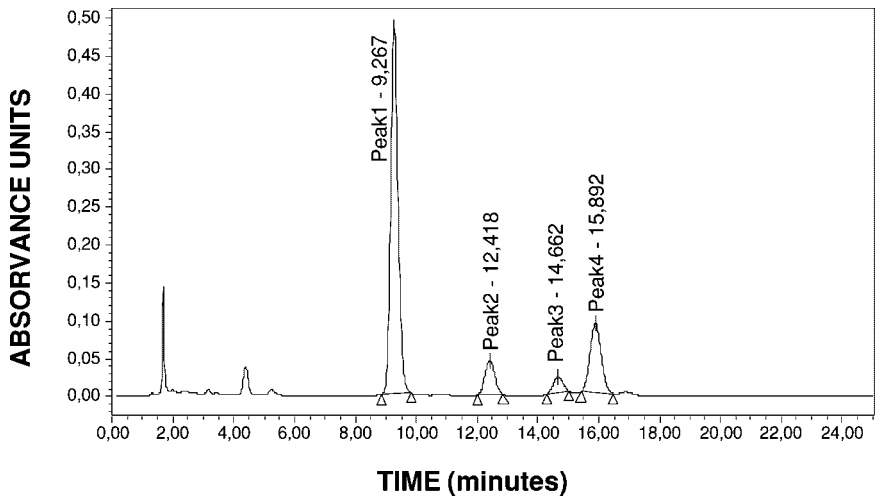

FIG. 1. HPLC chromatogram of the methanolic extract of *D. laureola* leaves with esculetin added, recorded at 320 nm wave length. Key to peak identity: Peak 1: 5-O-β−D-glucosyl-7-methoxy-8-hydroxy coumarin (**1**); Peak 2: 5-O-β−D-glucosyl-(6←1)-β-glucosyl)-7-methoxy-8-hydroxy coumarin (**2**); Peak 3: esculetin; Peak 4: 5-hydroxy-7-methoxy-8-O-β−D-glucosyl coumarin (**3**).

Jung et al., 1994) are shown in Table 1. The major component (**1**) averaged 54,938 (±17,646) ppm leaf dry weight, whereas average concentration of the other two compounds were 10,403 (±4182) ppm and 17,940 (±5787) ppm for (**2**) and (**3**), respectively. Concentrations of all three *D. laureola* coumarins into a sample were positively correlated ($N = 42$; $0.78 < r < 0.91$; $P < 0.001$ in all cases).

Populations differed in the concentration of the major coumarin glycoside (**1**) ($F_{5,30} = 4.56$, $P = 0.003$; Figure 2). Population × gender interaction was not statistically significant ($F_{5,30} = 1.09$, $P = 0.38$). Females tended to have greater concentrations of compound (**1**) than hermaphrodites, except in the CV population (Figure 2), when samples from this population were excluded from the analysis, differences between genders were statistically significant ($F_{1,24} = 5.76$, $P = 0.025$). Although the patterns were similar, gender differences were less apparent for concentrations of compounds (**2**) and (**3**) (analyses not shown). Populations also differed in the average concentration of compounds (**2**) and (**3**). Plants of the CT population had the highest concentration of both coumarin glycosides (14,471.0 ± 3986.0 ppm and 22,763.8 ± 7203.7 ppm for (**2**) and (**3**), respectively), whereas plants of the RH population showed the lowest concentrations of both (7614.9 ± 1818.4 ppm, and 14,903.7 ± 2355.6 ppm, respectively).

Since the concentration of the three coumarin glycosides was positively correlated, we calculated total concentration of coumarins in *D. laureola* leaves by adding them. The average concentration of total coumarins in female individuals of different populations was positively correlated to site altitude ($N = 6, r = 0.90$, $P = 0.01$; Figure 3). However, such a relationship was not found for hermaphrodite individuals ($N = 6, r = 0.27$, $P = 0.60$; Figure 3).

DISCUSSION

The three most abundant coumarin glycosides found in leaves of *D. laureola* were previously reported from other natural sources. Strangely, compounds (**1**) and (**2**) were isolated from mosses (Jung et al., 1994), compound (**1**) was found in *Polytricum formossum* and *Atrichum undulatum*, and compound (**2**) only in *P. formossum*. Compound (**3**) was previously isolated from leaves of the congeneric *Daphne pseudo-mezereum* (Konishi et al., 1993). No evidence for a similar coumarin daphnetin (7,8-dihydroxy coumarin) was detected in *D. laureola* leaves, despite a former report on its presence in the bark of this species (cf. Murray et al., 1982). This highlights that further analyses are needed to determine the identity and abundance of coumarins in other plant structures. The three compounds found in leaves are 5,7,8 trioxygenated coumarins. Apparently, all coumarins with an oxygen-containing substituent at the 7-position seem to be biosynthetically distinct from those that lack such a function, and derived from *p*-coumaric acid, an intermediate in lignin biosynthesis (Brown, 1970). It is also remarkable that all *D. laureola* coumarins share a 7-methoxy function, differing only in the nature and

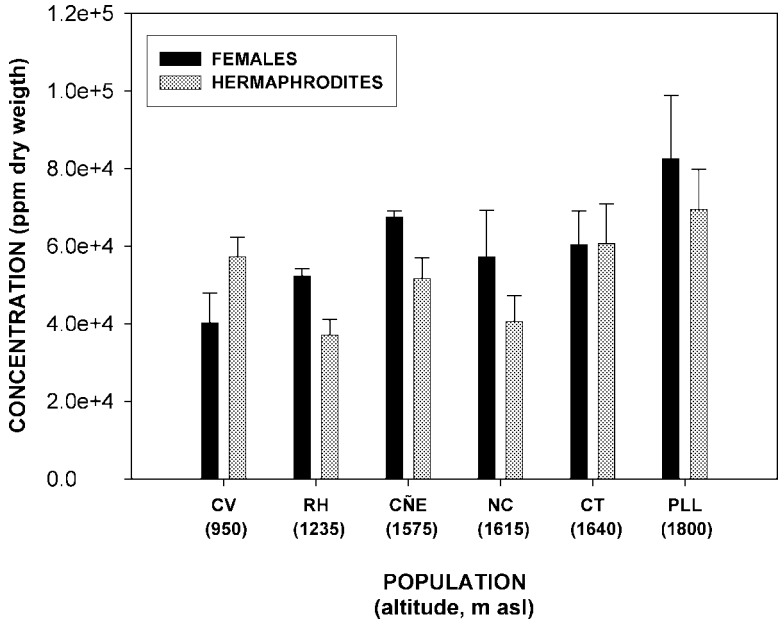

FIG. 2. Average concentration (+SE) of the most abundant coumarin, 5-O-β−D-glucosyl-7-methoxy-8-hydroxy coumarin, in leaves of female and hermaphrodite *D. laureola* individuals from six populations in southern Spain. Note that populations are ordered from lower to higher elevation.

position of the glycoside substituent, suggesting a common biosynthetical pathway. Further studies are needed to elucidate the metabolic relationships between these compounds and other plant physiological processes such as leaf maturation, since it is known that hydroxycoumarin content in *Daphne mezereum* from the Moscow region is maximal during leaf formation and at the end of the growth period (cf. Murray et al., 1982).

Our estimates of total coumarin concentration averaged between 60 and 120 mg/g dry weight for mature summer leaves of *D. laureola*. This figure is ca. 10 times higher than the concentration of dihydroxycoumarins reported for mature summer leaves of *Daphne mezereum* (Zobel and Brown, 1988), although the difference could partially reflect differences in the accuracy of the methods applied. The use of esculetin as internal standard in all samples allowed us to estimate the actual process errors and be confident of our estimates. Moreover, the low rates of standard recovery we observed revealed that further efforts to improve our methods would be important it to detect less abundant compounds.

Female and hermaphrodite individuals of *D. laureola* growing in the same population can have differential concentrations of secondary compounds. As

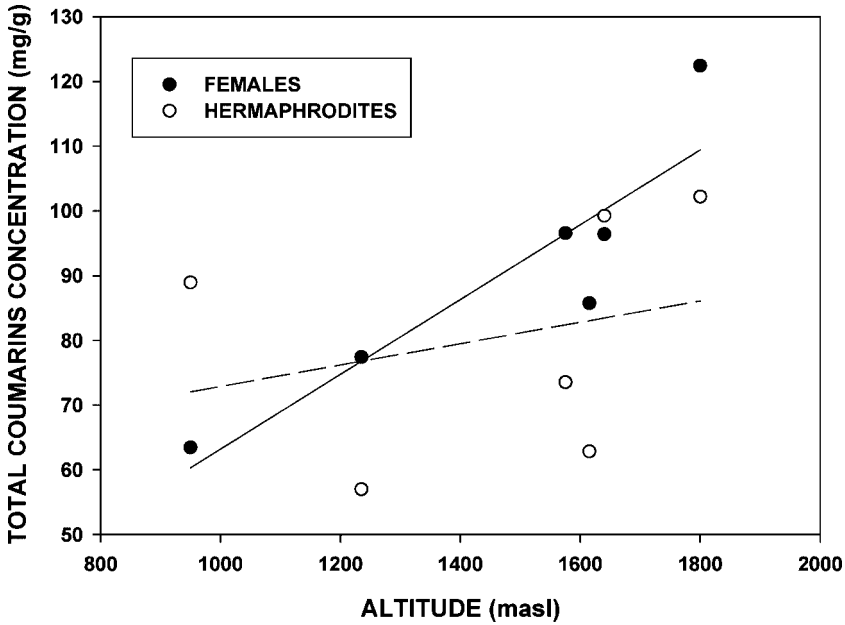

FIG. 3. Average concentration of the sum of all coumarins found in hermaphrodite and female *D. laureola* individuals at six different Spanish populations and the relationship with site altitude (solid line for females and dashed line for hermaphrodites).

expected from optimal theory, due to lower allocation to flowers, female leaves had on average higher concentrations of coumarins, upholding the idea that male function is costly for hermaphrodites (Eckhart and Seger, 1999). However, the magnitude of the difference was not constant, and even in the CV population, the one at the lowest altitude and with the highest proportion of females, the sign of the difference was reversed (Figure 2). Thus, costs of male (and likely also female) reproduction seem to be context dependent.

Finally, we found that average coumarin concentrations differed among *D. laureola* populations within a relatively small region. Heterogeneous spatial distribution of allelochemicals seems to be ubiquitous in both managed and natural systems (Hoy et al., 1998). Occurrence and concentration of plant allelochemicals may vary with latitude, elevation, sun exposure, and other environmental factors (Louda and Rodman, 1983; Dudt and Shure, 1994; Johnson and Scriber, 1994; Salmore and Hunter, 2001; Gómez et al., 2003). A negative relationship between elevation, occurrence, and concentration of some alkaloids (Salmore and Hunter, 2001) and glucosinolates (Louda and Rodman, 1983) has been found in some species, although unrelatedness and nonlinear relationships were found for

different alkaloids and glucosinolates in the same species. Also the content of UV-B absorbing compounds increases with site elevation in several plant species (Rozema et al., 1997). *D. laureola* showed a gender-specific response to site altitude since concentration of coumarins in leaves of female shrubs increased with population altitude, but hermaphrodites did not show a similar altitudinal pattern. On one hand, a higher concentration of coumarins could benefit plants by increasing the UV absorbance in higher elevation sites. Apparently, mostly females would be able to benefit from this advantage, once more supporting the existence of a cost of the male function in this species. Interestingly, some field experiments have shown that plants exposed to ambient solar UV-B radiation are more resistant to herbivorous insects than plants grown under filters that excluded the UV-B component of solar radiation (Stratmann, 2003). In addition to the flavonoids, isoflavonoids, and tannins quoted by Stratmann (2003), coumarins could be also associated with the observed overlapping between plant physiological responses to UV radiation and herbivory. Ongoing studies aimed at specifically evaluating the defensive role of *D. laureola* coumarins against insect defoliation will help to clarify the consequences of gender and altitudinal variation in coumarin concentrations in leaves herein reported.

Acknowledgments—We are particularly indebted to Carlos M. Herrera, Manuel M. Lomas, Jesús Méndez, and Adelina Vázquez for advice and support. Special thanks to Isabel M. García and Asunción Vargas, who assisted in the lab, and to Tenji Konishi for providing coumarins. We also thank Consejería de Medio Ambiente Junta de Andalucía for authorizing us to work in Cazorla; and the Estación Biológica de Doñana, the Consejería de Educación y Ciencia Junta de Andalucía, and the Spanish Ministerio de Ciencia y Tecnología (MCyT, BOS2003-02235) for funding the study. C.A. gratefully acknowledges a grant from the Ramón y Cajal Program from MCyT. The manuscript was improved thanks to comments of two anonymous referees and English revision by Pauline Agnew.

Abstract—We characterized the distribution of nutritional and defensive biochemical traits in galls elicited on chestnut oak (*Quercus prinus* L.) by the gall wasp *Andricus petiolicolus* Basse (Cynipidae) in comparison with gypsy moth-wounded and unwounded leaves. Gall cortex and epidermis exhibited elevated soluble peroxidase (POX) and soluble invertase activities, and greater condensed tannin concentrations than did nutritive tissues or leaves. Nutritive tissue, on which the insect feeds, contained few polyphenols, and lower POX and invertase activities compared with other gall tissues and leaves. Elevated total POX activity arose from a complex pattern of enhanced and suppressed isoform activities in galls. Invertase enzyme activity decreased in all tissues over the course of the 7-d study, although gypsy moth wounding suppressed this decline slightly in ungalled leaves. Our results indicate that the distribution of biochemical defenses in this typical cynipid gall differs significantly from the leaf tissue from which it is formed and support a role for invertases in establishing the gall as a sink. *A. petiolicolus* larvae do not induce, and may suppress, plant defense responses in nutritive tissue, while enzymatic activity and phenolic accumulation are enhanced in gall tissues surrounding feeding sites. These patterns suggest that the gall is manipulated by the insect to enhance its food and protective value.

Key Words—Plant–insect interactions, gall, oak, cynipid, peroxidase, invertase, tannins.

INTRODUCTION

Galls are specialized plant structures formed when a galling organism alters the development of normal plant tissue (Kinsey, 1920; Felt, 1940). Oak trees support a diverse assemblage of galling insects (Dreger-Jauffret and Shorthouse, 1992), the most prevalent of which are wasps of the family Cynipidae (Kinsey, 1920; Bronner, 1983). Cynipid galls consist of an outer layer of epidermal tissue, a cortex of schlerenchyma, and one or more nutritive tissue chambers that contain and nourish the larvae.

While galls may provide diverse benefits to the insects that elicit them (Price et al., 1987), considerable evidence supports the view that the gall provides a superior food source to the insect (the "Nutrition Hypothesis" [Price et al., 1987; Bronner, 1992]). For example, galling aphids elicit proliferation of phloem elements, on which they feed (Wool et al., 1999). The plant's nutritive value to insect and microbial gallers may be enhanced further *via* formation of strong metabolic sinks in the gall (Bronner, 1977, 1983; Larson and Whitham, 1997). All galls so far examined constitute enhanced sinks for photosynthate (Inbar et al., 1997, Larson and Whitham, 1997). Sink strength is functionally linked to invertase activity in normal plant tissues (Ricardo and Ap Rees, 1970; Leigh et al., 1979; Huber, 1989; Patrick, 1990; Yelle et al., 1991; Scholes et al., 1994; Zhang et al., 1996) and bacterial galls (Weil and Rausch, 1990).

Most galls contain specialized, distinctive "nutritive tissues" on which the insect feeds and which may contain elevated or altered nutrient concentrations (Paclt and Hässler, 1967; Bronner, 1977, 1992; Schonrogge et al., 2000). Putative antiherbivore defenses may be increased or decreased in gall tissues (Hartley, 1998; Nyman and Julkunen-Tiitto, 2000), but recent evidence from sawfly systems indicates that at least phenolic concentrations are reduced in nutritive tissues compared with the rest of the gall or other tissues (Nyman and Julkunen-Tiitto, 2000).

We studied the globular gall elicited on petioles and midribs of chestnut oak (*Quercus prinus* L.) leaves by the cynipid wasp *Andricus petiolicolus* Basse. Like other members of its genus, *A. petiolicolus* larvae chew and progressively destroy the nutritive tissue inside the gall as they develop (Kinsey, 1930; Bronner, 1983). Chewing by free-living insects induces defensive biochemical responses in many tree species (Karban and Baldwin, 1997), including chestnut oak, which responds to gypsy moth (*Lymantria dispar* L.) attack by increasing production of polyphenols in the leaves (Hunter and Schultz, 1995). Plant defense responses may also include increased activity of oxidative enzymes such as peroxidases (POXs) and polyphenol oxidase (PPO), which activate and polymerize polyphenols and are implicated in biochemical responses to insects and pathogens (Vaughn and Duke, 1984; Appel, 1993; Felton et al., 1994; Bi et al., 1997). The Nutrition Hypothesis predicts that such defensive responses should be suppressed in tissues consumed by galling insects.

We examined these aspects of the Nutrition Hypothesis by measuring the concentrations of protein, of putatively defensive phenolics, and activities of oxidative and sink-inducing enzymes in nutritive and non-nutritive tissues of *A. petiolicolus* galls as compared with galled and ungalled leaves, and with leaves wounded by a nongalling chewing insect, the gypsy moth (*Lymantria dispar* L.).

METHODS AND MATERIALS

Tissue Collection. Twenty-six *Q. prinus* L. saplings parasitized by *A. petiolicolus* were selected in late May, 1997 near State College, Centre County, PA, USA. Three to five ungalled and 3–5 galled leaves were collected from each tree on May 24 (Date 1) by plucking the leaf at the base of the petiole. Chilled galls were quickly dissected and separated into cortex, epidermis, and nutritive tissues. Ungalled leaves, galled leaf, and gall tissues were flash frozen in liquid N_2 and stored at -20°C. Nutritive tissue from several trees was pooled to provide enough sample for analysis. Epidermis was separated from cortex for colorimetric analyses of polyphenols. Because of assay sensitivity limitations and the small amounts of nutritive tissues, phenolic contents could not be quantified colorimetrically, so staining was used instead (below).

To assess the impact of wounding on leaf traits, on May 24 (Date 1) we confined 4–7 third-instar gypsy moth larvae within window-screen cages and allowed them to feed on the chestnut oak saplings for 7 d (until May 31, "Date 2"; see Rossiter et al., 1988). Each sapling received 5 cages, and each cage contained both galled and ungalled leaves, producing wounded and unwounded galled and ungalled leaves after 1 wk.

Enzyme and Protein Extraction. Frozen gall and leaf tissue was homogenized in an ice cold mortar and pestle with potassium succinate (KSuc) buffer, pH 5.5, containing 10% (v/v) glycerol and 10% (v/v) polyvinylpolypyrrolidone. Buffer was added to plant tissue at a ratio of 10:1 (v/w), and 10% (v/v) Triton X-100 was added at a rate of 0.8 μl/mg tissue. Nutritive tissue samples were diluted further to obtain enough extract for analysis. All extracts were sonicated for 15 min and centrifuged at 1100 $\times$ g for 15 min at 4°C. The supernatant was removed, stored at -20°C, and later used as the source of protein and enzyme activity. All chemicals were purchased from Sigma Chemical Company, St. Louis, MO, or Bio-Rad Laboratories, Hercules, CA.

Protein Assay. Total protein was measured in each sample extract using the Bradford reagent method (Bio-Rad, Inc.). Bovine serum albumin was used as a standard, and standard curves were prepared with the same concentration of Triton X-100 as in the samples to account for detergent effects on the assay.

Peroxidase: Total Soluble Activity. POX activity was assayed by using a modified version of Bi et al. (1997) spectrophotometric procedure. Twenty μl of extract were added to 980 μl of 88.2 mM H_2O_2 and 4.6 mM guaiacol in 0.1 M KSuc,

pH 5.5, and vortexed for 5 sec. The increase in absorbance due to the formation of tetraguaiacol was monitored for 60 sec at 470 nm.

Peroxidase: Nitrocellulose Blotting. To determine the location of POX in gall tissue layers, sectioned galls were pressed to wet nitrocellulose, and the blot was stained for POX activity according to Spruce et al. (1987). *A. petiolicolus* galls were sliced in half with a scalpel, and the cut face was pressed to the nitrocellulose for 60 sec. After 3–5 water rinses, the nitrocellulose was stained with 20 mM guaiacol, with or without 60 mM H_2O_2, in 0.1 M KSuc, pH 5.5, for 2–5 min. Orange staining indicated the location of POX activity.

Peroxidase: Tissue Staining. POX activity within the gall tissue was examined using diaminobenzidine (DAB) as a substrate (Harris et al., 1994). Galls were sectioned into 1 mm slices and rinsed with water to remove POX that smeared across tissue layers during cutting. Tissue slices were then exposed to the following substrates (in 0.05 M Tris–HCl, pH 7.6): no substrate, 2.3 mM DAB, 2.3 mM DAB + 5.9 mM H_2O_2, 2.3 mM DAB + *Aspergillus niger* catalase. Slices were immersed in the substrate or control solutions for 8 min, rinsed with water, and examined for POX activity indicated by orange–brown staining.

Peroxidase: Isoelectric Focusing. POX isozymes were separated using polyacrylamide gel electrophoresis/isoelectric focusing (IEF) with a Model 111 mini-IEF unit (Bio-Rad, Inc.). Gels were cast using 50 μl 3/10 ampholyte, 200 μl 8/10 ampholyte, and 700 μl 3/5 ampholyte, 5.05 ml H_2O, 2.0 ml 24.25% acrylamide with 0.75% bis-acrylamide, and 2.0 ml 25% glycerol (v/v). Fifty μl of 0.44 M ammonium persulfate (w/v) and 5 μl tetramethylethylenediamine were added to initiate gel polymerization.

One μl of crude extract was added to each well of a 10 well sample template and allowed to diffuse into the gel for 5 min. Isozymes were separated by stepwise increases in voltage of 100, 200, and 450 V for 15, 15, and 45 min, respectively. Following focusing, gels were soaked in 0.1 M KSuc, pH 5.5, for 10 min to equilibrate the pH throughout the gel. POX isozymes were visualized by immersing the gel in substrate solution for 30 min. The substrate solution was made by dissolving 8 mg/ml *o*-dianisidine in methanol, combining 2.5 ml of this solution with 97.5 ml 0.1 M KSuc buffer, pH 5.5, and adding 44.8 μl 30% H_2O_2. Gels were then rinsed 4–6 times in KSuc buffer. Relative isozyme activity was quantified by using a Shimadzu CS-9000U dual-wavelength scanning densitometer.

Polyphenol Oxidase: Total Soluble Activity. We used a spectrophotometric assay for PPO activity developed by Tono and Fujita (1995) that employs caffeic acid as substrate. Ten μl enzyme extract were added directly to a cuvette containing 490 μl of 0.06 mM caffeic acid in 0.1 M KSuc, pH 5.5, shaken 4 times, and the absorbance monitored at 310 nm for 30 sec.

Polyphenol Oxidase: Nitrocellulose Blotting. To determine the location of PPO activity in gall tissue, the same blotting procedure used for POX was repeated

with 14 mM L-DOPA in 0.1 M KSuc, pH 5.5, as a substrate. Orange staining indicated the location of PPO activity.

Polyphenol Oxidase: Tissue Staining. Galls were sectioned as in the POX procedure, and PPO activity was visualized in the gall by immersing tissue slices in 10 mM L-DOPA in 0.1 M KSuc (pH 5.5). Slices were immersed in the substrate solution or a control solution without L-DOPA for 45 min at room temperature.

Soluble Invertase Activity. Soluble invertase activity was determined by using the dinitrosalicylic acid (DNSA) method (Sumner, 1925; Arnold, 1965) with modifications by Miller (1959). Fifty μl of enzyme extract were added to 950 μl 0.1 M sucrose in 0.1 M KSuc, pH 5.5 (Tang et al., 1996), and incubated for 40 min at room temperature. One ml Sumner's reagent (44 mM 3,5-DNSA, 53 mM phenol, 0.25 M NaOH, 4 mM Na_2SO_3) was added to the reaction mixture, and the solution was boiled for 15 min. Before cooling, 330 μl of 1.42 M sodium potassium tartrate were added to the mixture. The absorbance was read at 560 nm on a spectrophotometer and converted to a reducing sugar concentration based on a glucose standard curve. The above procedure was repeated without the 40 min incubation in order to determine the concentration of reducing sugar already present in the enzyme extract; this amount was then subtracted from the final concentration before calculating the enzyme activity. Blanks contained all components except the enzyme extract, for which the sucrose/KSuc solution was substituted.

The results for all enzyme assays were expressed as activity per milligram total protein to reflect the amount of enzyme abundance or activity relative to other proteins, and as activity per gram fresh weight to assess the activity an herbivore or pathogen is likely to encounter in the hydrated plant tissue.

Phenolics: Tissue Concentrations. Leaf, gall cortex, and gall epidermis were assayed for (1) "Folin-reactive polyphenols" with the Folin-Denis assay (Appel et al., 2001), which measures the ability of extracts to reduce a mixture of phosphomolybdic and phosphotungstic acids, (2) *condensed tannins* using the Butanol-HCl assay (Appel et al., 2001), which quantifies hydrolyzed proanthocyanidin residues, and (3) *hydrolyzable tannins* with the potassium iodate method modified for quantitative use (Schultz and Baldwin, 1982), which quantifies galloyl esters. Purified chestnut oak tannins from the same trees were used as standards (Appel et al., 2001), and results are expressed as mg phenolics per mg tissue dry weight.

Phenolics: Tissue Staining. The location of polyphenols in gall tissue was determined by using the nitroso reaction according to Harris et al. (1994). Galls were sliced into 1 mm sections with a scalpel and immersed in equal volumes of 1.2 M $NaNO_3$, 3.3 M urea, and 1.7 M acetic acid for 5 min before adding 2 volumes of 2 M NaOH. Sections were rinsed in water and examined immediately under a Zeiss light microscope for red staining, indicating the presence of polyphenols.

Data Analysis. Chemical variation among chestnut oak tissues (2 gall tissues, ungalled, galled, and gypsy moth-wounded leaves) was subjected to analysis of variance (ANOVA) with the SAS MIXED procedure (SAS Institute, Inc.,

1999). We used an incomplete block design without replication with individual trees as blocks and tissue type, wounding, and date as fixed effects. Because they were pooled from several trees, nutritive tissues were assigned unique block numbers. Differences of adjusted least square means ($\alpha = 0.05$) were used to identify significant differences among the 4 tissue types and 2 dates. One-way ANOVA was used to determine significance of differences among tissues in polyphenol concentrations.

RESULTS

Protein Content. Protein concentrations declined with time in ungalled leaves, but overall variation with date was not statistically significant (Table 1, Figure 1A). Protein concentration in the gall cortex was 25–50% lower than in ungalled leaves; other differences among tissues were not statistically significant (Table 1, Figure 1A). Gypsy moth wounding had no effect on protein concentration of any tissue.

Peroxidase: Total Soluble Activity. Total soluble POX specific activity differed significantly among tissues, but not among dates (Table 1). POX activity in gall cortex + epidermis was double the activity in leaves (galled or ungalled) and 5 times the activity in the nutritive tissue (Figure 1B). POX activity was not altered when leaves were wounded by gypsy moth larvae (Table 1, Figure 1B).

TABLE 1. ANOVA RESULTS FOR CHEMICAL VARIABLES

Variable	Effect	*df* (num., den.)[a]	*F*-value	*P*-value

[a] Numerator and denominator degrees of freedom for the *F*-test.
[b] Wounding consisted of 1 wk of herbivory by caged gypsy moth larvae.
[c] Tissues were ungalled leaf, galled leaf, gall body, and nutritive tissue.
[d] Peroxidase.

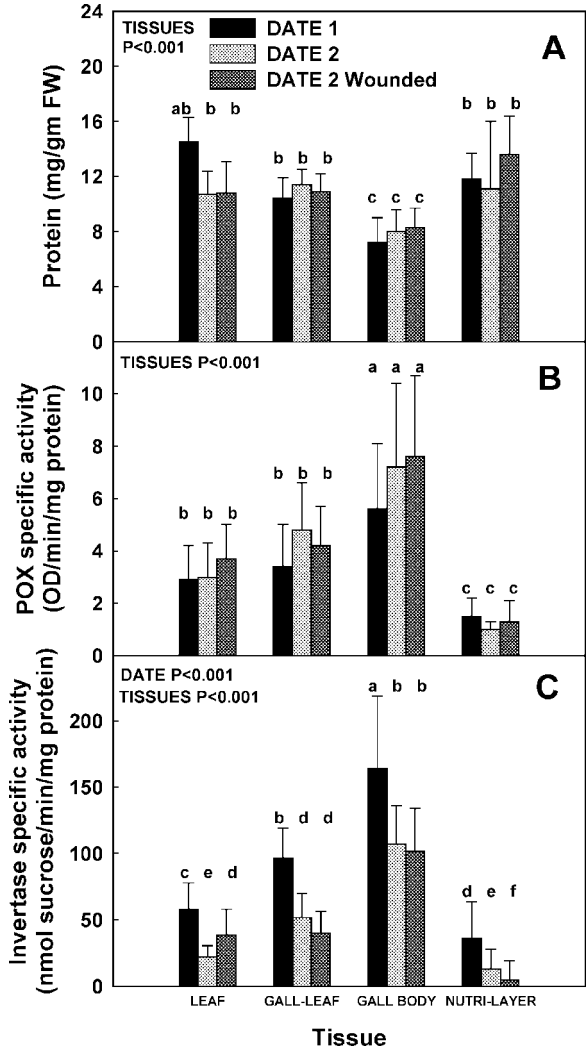

FIG. 1. Means (standard deviation) of total soluble protein concentration (A), peroxidase (POX) specific activity (B), and invertase specific activity (C), by tissue, date, and wounding treatment. Means with the same lowercase letters are not significantly different ($P > 0.05$). Leaf = ungalled leaves; gall-leaf = leaf on which there was one gall; gall body = gall cortex + epidermis; nutri-layer = dissected nutritive tissue from feeding chambers.

Patterns in POX activity and statistical significance were the same when activity was expressed per gram fresh tissue (data not shown).

Peroxidase: Nitrocellulose Blots and Tissue Staining. Nitrocellulose blots of *A. petiolicolus* galls revealed POX activity in the gall cortex immediately surrounding nutritive tissues, but little or none directly within the nutritive tissue (Figure 2A and B). Moderate staining occurred in the gall cortex and intensified in the epidermis of the gall structure. No POX staining was observed when H_2O_2 was excluded from the substrate solution as a control (not shown). Direct POX staining (Figure 2E) was generally consistent with the results of the nitrocellulose blotting. Staining within the nutritive tissue was weak (Figure 2E), while intense staining was observed around the gall epidermis (not shown) and in the cortex just outside the nutritive tissue.

Peroxidase Isozymes. Isozyme activities in leaves and gall cortex + epidermis were examined with IEF (Figure 2F). Activity of several isozymes appeared to be elevated in gall tissues and/or galled leaves compared to leaves on the same tree, while others were depressed. The gel resolution limited our ability to determine statistical significance of most of these differences. However, quantitative scanning densitometry indicated that gall cortex + epidermis contained significantly greater activity of one anionic and one cationic isozyme (Figure 2F, arrows) and lower activities of most other isozymes. This pattern was observed in all 3 sets of chestnut oak leaves and galls measured.

Polyphenol Oxidase: Total Soluble Activity, Nitrocellulose Blots, and Tissue Staining. Although our assays were able to detect PPO in extracts of other plant species under the same conditions (data not shown), our chestnut oak extract exhibited no PPO activity and actually inhibited auto-oxidation of the substrate. In contrast to the POX assay, no PPO staining of the nitrocellulose membrane was observed with L-DOPA as a substrate (not shown). No PPO staining was observed in any gall sections in the absence of H_2O_2 (not shown), indicating that this enzyme is either not present or not detectable by this method in *A. petiolicolus* gall tissue.

Soluble Invertase Activity. Specific activity of soluble invertase differed significantly among tissues and dates (Table 1), with similar patterns observed for invertase activity per unit fresh weight (data not shown). Activity was greatest in gall cortex + epidermis and lowest in nutritive tissue on the first date; galled and ungalled leaves had intermediate activities (Figure 1C). Invertase specific activity declined over the week in all tissues, but there was some indication that gypsy moth wounding may have limited this decline in ungalled leaves (Figure 1C). A *post-hoc* Tukey analysis of wound effects supported this observation (Figure 1C). However, wounding did not have a statistically significant effect on invertase activity across all tissues and dates.

Polyphenol Tissue Concentrations and Staining. Colorimetric assays indicated that gall epidermis had significantly elevated condensed tannin (ANOVA, $F_{2,41} = 20.8$, $P < 0.001$) and nearly-significant elevated Folin-reactive contents

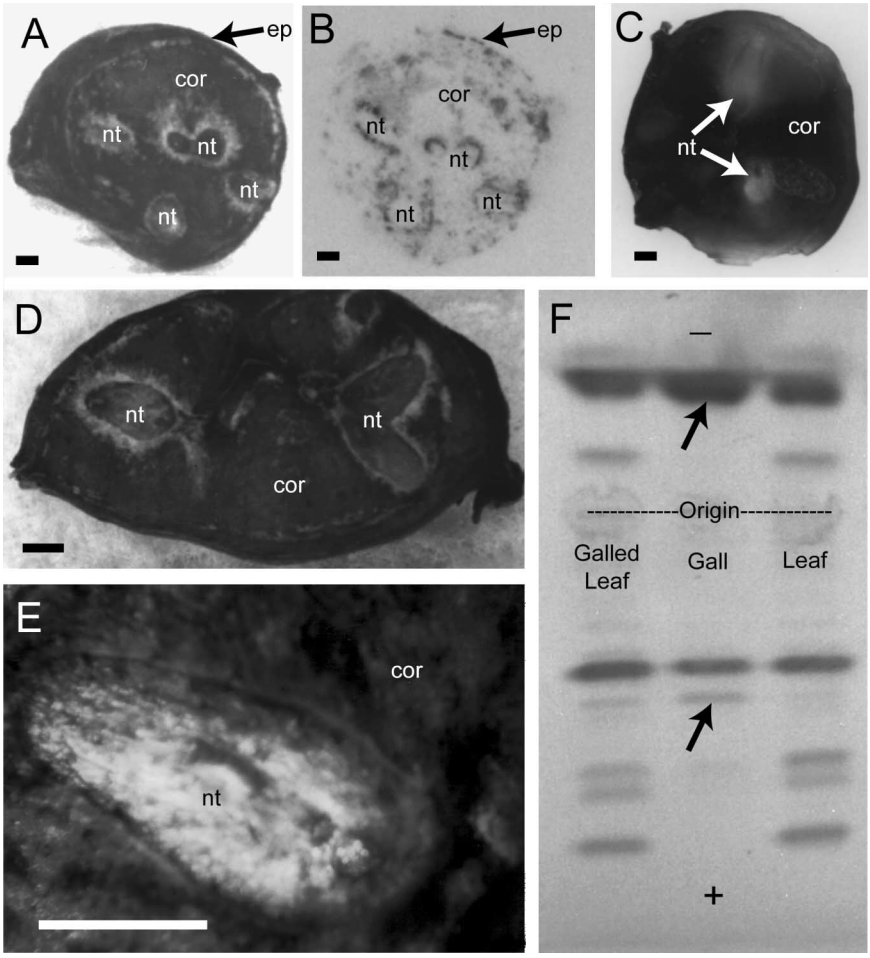

FIG. 2. Unstained *A. petiolicolus* gall section (A) with its nitrocellulose blot (B). In (B), note the absence of peroxidase (POX) staining within, and intense POX activity immediately outside of nutritive tissue (nt). ep = epidermis, cor = cortex. (C) *A. petiolicolus* gall stained for polyphenols. Staining is reduced or absent in the nutritive tissue (arrows). (D) A second unstained *A. petiolicolus* gall section with associated close-up (E) of nutritive tissue stained for POX with DAB. Note lighter color (less POX activity) in nutritive tissue compared to surrounding cortex. All scale bars = 1 mm. (F) IEF gel showing POX isozyme activities in *A. petiolicolus* galls from chestnut oak. "Galled leaf" indicates the leaf on which the gall formed, "gall" indicates gall cortex + epidermis, and "leaf" indicates a control leaf from the same tree with no galls. (–) = direction of migration for cationic POXs, (+) = direction of migration for anionic POXs relative to the origin. Arrows indicate isozymes that were significantly more active in gall tissue.

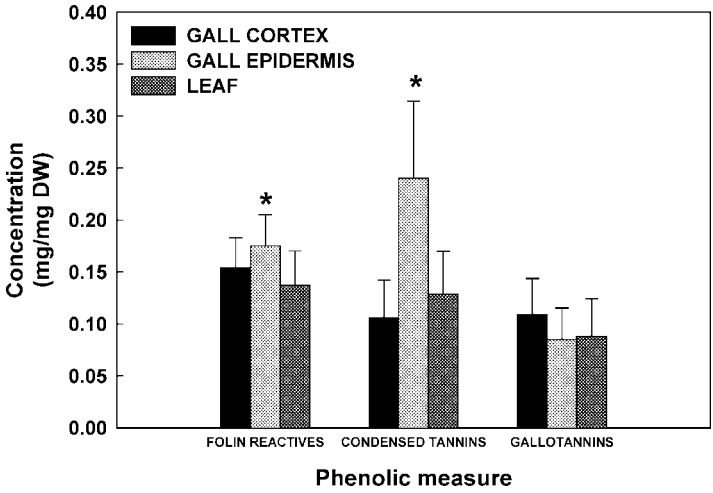

FIG. 3. Mean (standard deviation) polyphenol concentrations of gall tissues and ungalled leaf on last day of study. (*) indicates mean differs at $P = 0.08$ for Folin-reactives, and $P < 0.05$ for condensed tannins.

($F_{2,41} = 2.56,\ P = 0.08$), while cortex phenolic concentrations were indistinguishable from those of the adjacent leaf tissue (Figure 3). Dark red staining for polyphenols with the nitroso reaction revealed lower polyphenol concentrations in the nutritive tissue than in the gall cortex or epidermis (Figure 2C). Globules of polyphenols were present in some cortical cells.

DISCUSSION

Our biochemical characterization of *A. petiolicolus* galls provides support for the Nutrition Hypothesis and reveals a previously undescribed shift in POX isoforms within cynipid gall tissue. The pattern of POX isoform activity in gall cortex + epidermis differed from that of adjacent leaf tissue; some isoforms were more abundant or active in galls, while others were suppressed there. Enhanced activity of particular POX isoforms is frequently associated with responses to wounding, pathogen infection and other stresses (Mäder et al., 1980; Grisebach, 1981; Christensen et al., 1998; Hiraga et al., 2000a,b). Differential activation of various isoforms has been seen in response to pathogens (Lebeda et al., 2001), ethylene and abscisic acid (Kim et al., 2000), cytokinins (Limam et al., 1998), and aphid feeding (Chaman et al., 2001), and diverse stimuli elicit differential accumulation of mRNAs for a wide range of POXs in rice (Hiraga et al., 2000). It is important to note that differences in POX isozyme activity were not detectable in the present study by the spectrophotometric assays of total POX activity.

The distribution of POX in *A. petiolicolus* galls is likely to reduce the food quality of the outer part of the galls for many herbivores and pathogens, but should improve food quality in the tissues the cynipid larva actually eats. Total POX activity (per mg protein) was elevated above that of leaves in gall cortex + epidermis, a finding similar to that of Gopichandran et al. (1992) in thrips galls. In contrast, nutritive tissue had less total POX activity than did leaf and cortex. The results from our nitrocellulose blots (Figure 2B) and direct staining for POX (Figure 2E) confirm that most of the POX activity within galls is concentrated in the cortex and epidermis, rather than the nutritive tissue where it could adversely affect the developing larvae.

Elevated POX within the gall cortex and epidermis could benefit cynipid larvae by deterring other organisms from consuming or entering the gall. POX activity can produce reactive oxygen species (ROS) such as H_2O_2 and O^{2-} (Bolwell, 1996; Bi et al., 1997) and catalyzes the oxidation of *o*-dihydroxyphenolics to *o*-quinones in the presence of H_2O_2 (Kahn, 1985; Bi et al., 1997). Appropriate phenolic substrates for POX are known to be present in many oak galls, particularly those of cynipids (Figure 3; Nierenstein, 1930; Cornell, 1983; Hartley, 1998), and were present at high levels in non-nutritive tissues of *A. petiolicolus* galls (Figure 2C). In the gall cortex, POXs and oxidized phenolics may toughen cell walls through lignin production and cross-linking with cell wall proteins (Gaspar et al., 1982; MacAdam et al., 1992; Lamb and Dixon, 1997).

Because both phenolic compounds and POX activity were found to be localized away from the nutritive tissue, *A. petiolicolus* larvae are likely to consume few POX-associated ROS (Tenhaken et al., 1995; Doke et al., 1996; Lamb and Dixon, 1997; Wojtaszek, 1997) harmful to herbivores (Appel, 1993; Felton et al., 1994; Bi and Felton, 1995). These gross patterns are consistent with the view that gall chemistry may be influenced by the galling insect (Hartley, 1998) to provide protection from herbivores (Janzen, 1977; Schultz, 1992), fungal entomopathogens (Taper et al., 1986; Barrett et al., 1998), or fungal endophytes that can threaten galling insects (Carroll, 1988; Wilson, 1995), while preserving or enhancing the food quality of the nutritive tissues.

Schonrogge et al. (2000, and personal communication) have suggested that cynipid galls resemble plant seeds in tissue structure and/or physiology. Patterns in POX isoform activity (Gijzen et al., 1999) and invertase activity (Wobus and Weber, 1999) seen in developing seeds resemble those we found in galls and suggest that cynipid gall development might incorporate aspects of seed development.

As in crown galls formed by *Agrobacterium* (Weil and Rausch, 1990) and galls of the aphid *Hormaphis hamamelidis* (Rehill and Schultz, 2003), our results implicate elevated invertase activity as a means by which insect galls become sinks. Galls are known to act as sinks for plant assimilates (Bronner, 1977, 1983; Larson and Whitham, 1997), and high levels of soluble invertase are associated with the establishment of sink characteristics (Patrick, 1990; Sturm and Chrispeels, 1990;

Yelle et al., 1991). Within the gall tissue, vacuolar acid invertase may hydrolyze sucrose to provide the hexoses required for elevated metabolic activity (Billet et al., 1977; Zhang et al., 1996), and invertases in the nutritive tissue are known to hydrolyze sucrose to glucose and fructose (Bronner, 1977). While gypsy moth wounding may also elicit invertase activity (Arnold and Schultz, 2002), the increase brought about by gallers was much greater than that caused by 1 wk of gypsy moth feeding in this study.

Although gall formation is associated with significant biochemical changes, not all aspects of plant biochemistry necessarily differ in gall tissues. Previous studies have found increased nitrogen and protein content (Paclt and Hässler, 1967; Schonrogge et al., 2000), extensive protein synthesis (Rohfritsch and Arnold-Rinehart, 1991), and large amounts of soluble amino compounds, ribosomes, and mRNA in the nutritive tissue of other cynipid galls (Bronner, 1977, 1992). However, nutritive tissues of *A. petiolicolus* galls had protein levels similar to those of ungalled leaves, despite having lower protein levels in the cortex. We also found that neither galled nor control chestnut oak tissues contained PPO, although we have measured vigorous PPO activity in tissues from other plant species under the same analytical conditions. Although PPO is present in a number of plants (Richard-Forget and Gauillard, 1997; Shin et al., 1997; Halder et al., 1998) and could reinforce some anti-herbivore functions of POX (Felton et al., 1994; Haruta et al., 2001), it may be absent (Grisebach, 1981) or difficult to extract from some plant tissues (Hsu et al., 1988; Burton and Kirchmann, 1997). We have found previously that PPO activity is low or absent in the leaves of chestnut oak (H. M. Appel and J. C. Schultz, unpublished data), and conclude that this enzyme either is not present in chestnut oak tissue, is present in an inactive form, or is not detectable using the methods employed.

Our data show that *Andricus* galls are biochemically distinct from their host leaves. Altered and redistributed activity of various POX isoforms, concentration of polyphenols away from feeding sites, and the increase in invertase activities in *A. petiolicolus* gall tissue relative to leaves probably combine to improve plant quality for this galling insect. It is also clear that while some responses typically induced by chewing insects are active in *A. petiolicolus* gall cortex or epidermis, they are not induced or are suppressed in the insects' food tissue; this may represent manipulation of host plant quality by the insect (Hartley, 1998; Nyman and Julkunen-Tiitto, 2000).

Acknowledgments—Thanks to Sharie Ketcho and Brian Rehill for help in the lab and field as well as discussion, and Heidi Appel for comments on the manuscript. Two anonymous reviewers also provided helpful comments on the manuscript. This work was completed in partial fulfillment of the requirements for the Bachelor of Science Degree with Honors in the Schreyer Honors College, Pennsylvania State University, and was supported by NSF grants DEB-9974067 (JCS) and BIR-9413204 (JCS and E. J. Pell).

BIOFUMIGANT COMPOUNDS RELEASED BY FIELD PENNYCRESS (*Thlaspi arvense*) SEEDMEAL[1]

STEVEN F. VAUGHN,* TERRY A. ISBELL, DAVID WEISLEDER, and MARK A. BERHOW

New Crops and Processing Technology Research
USDA, ARS, National Center for Agricultural Utilization Research
1815 N. University St., Peoria, Illinois 61604, USA

(Received May 27, 2004; accepted September 16, 2004)

Abstract—Defatted field pennycress (*Thlaspi arvense* L.) seedmeal was found to completely inhibit seedling germination/emergence when added to a sandy loam soil containing wheat (*Triticum aestivum* L.) and arugula [*Eruca vesicaria* (L.) Cav. subsp. *sativa* (Mill.) Thell.] seeds at levels of 1.0% w/w or higher. Covering the pots with Petri dishes containing the soil-seedmeal mixture decreased germination of both species at the lowest application rate (0.5% w/w), suggesting that the some of the phytotoxins were volatile. CH_2Cl_2, MeOH, and water extracts of the wetted seedmeal were bioassayed against wheat and sicklepod (*Senna obtusifolia* (L.) H. S. Irwin & Barneby) radicle elongation. Only the CH_2Cl_2 extract was strongly inhibitory to both species. Fractionation of the CH_2Cl_2 extract yielded two major phytotoxins, identified by gas chromatography–mass spectrometry and NMR as 2-propen-1-yl (allyl) isothiocyanate (AITC) and allyl thiocyanate (ATC), which constituted 80.9 and 18.8%, respectively, of the active fraction. When seeds of wheat, arugula and sicklepod were exposed to volatilized AITC and ATC, germination of all three species was completely inhibited by both compounds at concentrations of 5 ppm or less. In field studies, where seedmeal was applied at 0.50, 1.25, and 2.50 kg/m^2 and tarped with black plastic mulch, all of the treatments significantly reduced dry weight of bioassay plants compared to the tarped control, with the highest seedmeal rate decreasing dry matter to less than 10% of the control 30 d after seedmeal application. Field pennycress seedmeal appears to offer excellent

potential as a biofumigant for high-value horticultural crops for both conventional and organic growers.

Key Words—Field pennycress, *Thlaspi arvense*, brassicaceae, seedmeal, glucosinolate, allyl isothiocyanate, allyl thiocyanate, phytotoxicity, soil amendment.

INTRODUCTION

Biofumigation is the exploitation of plant biochemicals with pesticidal properties that may serve as ecologically-friendly alternatives to chemical fumigants such as methyl bromide (Angus et al., 1995). Additionally, organic growers lack most of the soil fumigation/sterilant options available to conventional growers. Several plant families, especially the Brassicaceae or mustard family, have been extensively studied as green manure crops, as mustards have been shown to suppress weeds (Grossman, 1993; Boydston and Hang, 1995; Brown and Morra, 1995; Vaughn and Boydston, 1997; Al-Khatib et al., 1997; Boydston and Vaughn, 2002), soil pathogens (Papavizas, 1966; Lewis and Papavizas, 1971; Papavizas and Lewis, 1971; Ramirez-Villapudua and Munnecke, 1988; Muelchen et al., 1990; Vaughn et al., 1993; Mayton et al., 1996; Brown and Morra, 1997; Williams-Woodward et al., 1997; Olivier et al., 1998; Sarwar et al., 1998), nematodes (Mojtahedi et al., 1991, 1993; Donkin et al., 1995), and insects (Brown et al., 1991) when plant tissues were incorporated into the soil. Mustards are characterized by the presence of glucosinolates, a class of glucose and sulfur-containing organic anions (Figure 1), whose biologically-active degradation products are produced when plant vacuoles are ruptured and the glucosinolates present in vacuoles are hydrolyzed by the enzyme myrosinase (β-thioglucosidase glucohydrolase; EC 3.2.3.1) (VanEtten and Tookey, 1983). These products include substituted isothiocyanates, thiocyanates, nitriles, and oxazolidinethiones that vary depending on the side-chain substitution, pH, and iron concentration (Cole, 1976; Fenwick et al., 1983; Uda et al., 1986; Chew, 1988). Many of these hydrolysis products have pesticidal properties (Vaughn, 1999). Seedmeals from glucosinolate-containing plants have also been identified as potential soil amendments for weed and insect control (Brown and Morra, 1995; Vaughn et al., 1996; Walker, 1996; Elberson et al., 1997; Vaughn and Berhow, 1999). The wide range of glucosinolates found in the Brassicaceae provides the opportunity to select those species that have the highest biofumigation potential (Kirkegaard and Sarwar, 1999; Warton et al., 2001).

Field pennycress (*Thlaspi arvense* L.) is a weedy annual/winter annual species of the Brassicaceae that is a native of Europe but has a wide distribution throughout temperate North America (Rollins, 1993). Field pennycress is considered a major agricultural weed that competes with crops causing significant yield losses (Holm et al., 1997). The plant produces an unpleasant, garlic-like odor that has caused it to be widely known as stinkweed (Mitich, 1996). Each plant may produce

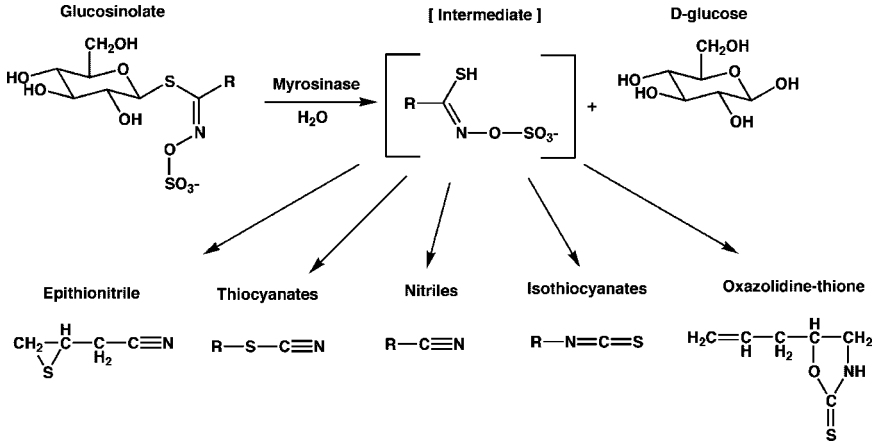

FIG. 1. The general structure of glucosinolates and their enzymatic degradation products. Adapted from Rask et al. (2000).

up to 15,000 seeds, and fields heavily infested with field pennycress yield up to 1345 kg seed/ha (Best and McIntyre, 1975). Field pennycress seed contains the glucosinolate sinigrin (Daxenbichler et al., 1991). Sinigrin can be hydrolyzed by endogenous myrosinase to form principally allyl isothiocyanate (AITC), a potent biocide that may be involved in allelopathy (Vaughn and Berhow, 1999), with allyl nitrile, allyl thiocyanate (ATC), and epithiopropylnitrile also being formed at other pH values or in the presence of reducing compounds (Cole, 1976; Springett and Adams, 1989). However, Lüthy, and Benn (1977) found that field pennycress seed flour extracts converted radiolabeled sinigrin into ATC without any AITC being formed. While AITC has been shown to be an effective biocide against a wide range of organisms, relatively little data have been published concerning the biocidal activity of ATC (Shofran et al., 1998; Tsao et al., 2002). Our interest in using glucosinolate-containing seedmeals as biofumigants prompted us to further investigate the use of field pennycress seedmeal as a soil amendment for weed suppression in high-value, low-acreage crops, and if active, to identify those compounds responsible for phytotoxicity.

METHODS AND MATERIALS

Seedmeal Bioassays. Field pennycress seeds were harvested on June 30, 2003 from a native population present in a limited-tillage soybean field near Hanna City, IL, USA Seeds were dried at room temperature for at least 30 d before use in bioassays. Seeds were ground in coffee grinder and defatted with hexane for 24 hr in a Soxhlet apparatus. The dry seedmeal was stable for an extended period

(>30 d at room temperature), but was used within 2 d of being defatted in all experiments. Seedmeal was thoroughly mixed with soil (Onarga sandy loam; Typic Argiudoll) at rates of 0.5, 1.0, and 5.0% (w/w). The seedmeal-soil mixture was added to 200-ml cups, and 10 seeds of wheat (*Triticum aestivum* L.) and arugula [*Eruca vesicaria* (L.) Cav. subsp. *sativa* (Mill.) Thell.] seeds (both of which exhibit nearly 100% germination) were added and covered with approximately 3 cm of the soil-seedmeal mixture. Nonamended soil was used as the control. Each cup received 10 ml of a solution containing 1g/l thiabendazole (excessive saprophytic fungal growth occurred at the higher seedmeal rates without this fungicide that we thought might influence the results), and then additional water was added to bring the soil to field capacity. Half of the treatments were covered with plastic Petri dishes for the initial 72 hr to prevent loss of potential volatile compounds, similar to what would be done with tarping in the field. All cups were placed in a growth chamber set at a 16 hr, 25°C d/8 hr, 20°C night regime. Emerged seedlings were counted after 14 d, and the above ground tissue of the emerged seedlings were counted. Each treatment was replicated five times in a completely randomized design, and the experiment was repeated. Data were subjected to analysis of variance (SAS, Cary, North Carolina).

Extract Preparation. One hundred grams of defatted seedmeal were wetted with 100 ml ddH_2O and allowed to sit in a beaker covered with aluminum foil for 4 hr. The wet seedmeal was extracted with three successive 250 ml aliquots of CH_2Cl_2. The CH_2Cl_2-extracted seedmeal was dried in a fume hood at room temperature to remove residual solvent, and then extracted $\times 3$ with 250 ml aliquots of MeOH. Extracts from both solvents were pooled and concentrated by rotoevaporation. A water extract was obtained by soaking the solvent-extracted seedmeal in 250 ml of distilled water overnight in a refrigerator at 2°C, after which the marc was washed with two additional 250 ml aliquots, and the extracts lyophilized. The crude CH_2Cl_2 extract subsequently found to be active in the bioassays was separated on a lipophilic Sephadex LH-20 (Supelco, Inc., Bellefonte, PA) column into three separate fractions using 100% $CHCl_3$; 50% $CHCl_3$/50% MeOH; and 100% MeOH as solvents.

Seedling Radicle Elongation Bioassay. Wheat and sicklepod (*Senna obtusifolia* (L.) H. S. Irwin & Barneby) seeds were surface sterilized with 0.5% commercial chlorine bleach for 15 min, after which they were rinsed with and then soaked in sterile distilled water for 2 hr. Seeds were wrapped in sterile paper towels saturated with water and incubated overnight in darkness at 25°C. All crude and column extracts were assayed by adding extracts to which solvents had been completely evaporated to autoclaved water agar (1.0% w/v containing 500 mg/l chloramphenicol) at the rate of 1 mg extract/ml agar (this concentration is generally effective at identifying active fractions), after the agar had cooled to ~40°C. Fifteen ml of the agar-extract mixtures were placed in 9.0-cm plastic Petri dishes, and five germinated seedlings were placed on the agar in the Petri dishes. The dishes

were incubated in darkness at 25°C on 45° slants for 24–48 hr, then evaluated for inhibition of radicle growth.

Chromatography and Spectroscopy. Gas chromatography–mass spectrometry (GC–MS) was performed using an Hewlett-Packard (HP) 6890 GC system attached to an HP 5972A Mass Selective Detector. Quantitation of compounds was performed on an HP 5890 gas chrmoatograph equipped with a flame ionization detector. Columns used in both systems were fused silica HP-5MS capillaries (0.25-μm-film thickness, 30 m $\times$ 0.25 mm ID). The GC operating parameters were as follows: splitless injection mode; temperature programmed from 40° to 315°C at 5°C/min with a 20-min initial temperature hold; He carrier gas flow rate at 1.1 ml/min, with the injector temperature set at 100°C, as ATC has been reported to decompose to AITC at higher injection temperatures (Lüthy and Benn, 1977). Spectra were compared with known standards or by computer with the Wiley/NBS Mass Spectral Registry (McLafferty and Stauffer, 1989). Proton and carbon-13 spectra were obtained on a Bruker Avance 500 spectrometer (Billerica, MA, USA) equipped with a 5-mm inverse broadband Z-gradient probe (^{1}H NMR, 500 MHz, ^{13}C, 125 MHz). The software used to obtain the NMR data was ICON 3.5. The solvent was deuterated chloroform.

Effect of Volatilized AITC and ATC on Seed Germination. AITC and ATC, the active compounds identified in the extract, were tested for inhibition of seed germination of wheat, annual ryegrass (*Lolium multiflorum* Lam.), sicklepod, arugula, and velvetleaf (*Abutilon theophrasti* Medicus). Due to the difficulties involved in isolating and purifying large amounts of the compounds from seedmeal extracts, synthetic AITC and ATC were used in these tests. ATC was synthesized according to the method of Slater (1992) while AITC was purchased from Sigma. Ten seeds of each species were placed into 9-cm Petri dishes on Whatman No. 1 filter paper disks saturated with sterile distilled water. The dishes were then placed into 2.4 l glass desiccators containing a filter paper disk onto which AITC or ATC were added (neat) on a volume compound-headspace volume basis at rates of 0.0, 0.1, 0.5, 1.0, 5.0, 10.0, and 20.0 ppm. Flasks were placed in darkness in a growth chamber at 25°C for 4 d, after which germination was scored. Each treatment consisted of three replicates per species and the experiment was repeated.

Isolation and Quantification of Glucosinolates from Seedmeal. For quantitation of seedmeal glucosinolates, a modification of a high-performance liquid chromatography (HPLC) method developed by Betz and Fox (1994) was used. Replicates of defatted seedmeal (5.0 g) were added to 200 ml boiling 70% (v/v) MeOH with stirring for 15 min, cooled, and then filtered through Whatman No. 2 filter paper. The marc was washed twice with 50 ml aliquots of 70% MeOH. The resulting extract was concentrated to 5–10 ml by rotoevaporation, and diluted to 25 ml to form a working solution. The extract was run on a Finnegan Thermoquest P4000 HPLC system (San Jose, CA) using a C_{18} column (250 $\times$ 4.6 mm^2;

RP-18, 5; Licrosorb, Alltech, Deerfield, IL). Peaks were detected with a Finnegan Thermoquest P6000 photodiode array detector set at 237 nm. The initial mobile phase conditions were 12% methanol/88% aqueous 0.005M THS at a flow rate of 1 ml/min. The binary gradient was developed to 70% methanol/30% aqueous 0.005 M THS for 20 min, and held at these conditions for an additional 15 min. Quantitation was determined from a standard curve prepared from pure sinigrin (Sigma, St. Louis, MO). Each treatment was run in triplicate and the experiment was repeated.

Field Studies. Seedmeal was tested for its ability to suppress plant germination and growth when applied to tarped field plots. Experiments were conducted in a randomized complete block design with four replications (each replicate measured 0.75 m by 1.5 m) on a field site soil which was an Orthents complex containing a silt loam surface of 30–40 cm underlaid with a silt clay loam. The site was conventionally tilled 1 wk prior to experiments. In addition to native weed seeds present in the soil, each plot was spiked prior to seedmeal incorporation with 75 g of a bioassay seed mixture containing 1:1:1 amounts of annual ryegrass, white mustard (*Sinapis alba* L.), and sicklepod seeds. Defatted seedmeal prepared as previously described was applied to test plots at rates of 0.5, 1.0, and 2.5 kg/m^2 by sprinkling the seedmeal evenly over the test plots and incorporating the seedmeal into the soil with pitchforks to a depth of approximately 10 cm. The plots were then watered (approximately 5 l per plot) thoroughly, and covered with polyethylene plastic sheets (0.1-mm thickness, 0.91 m by 2 m; Sunbelt Plastics, Minneapolis, MN) that were covered with soil at the edges to prevent loss of volatiles. Controls consisted of untarped plots and tarped plots without seedmeal. Tarps were removed after 7 d, and all plots were watered as needed. After 30 d, the plant biomass of the plots was determined by digging up and washing all of the plants after which they were placed in a 50°C drying oven for 48 hr before being weighed. Data were subjected to analysis of variance (SAS, Cary, NC). Dry weight mean separation was performed using the Student–Newman–Keuls multiple range test ($P < 0.1$).

RESULTS AND DISCUSSION

Bioassays. After 14 d, field pennycress seedmeal added to soil completely inhibited germination of wheat and arugula at rates of 1.0% or higher (Table 1). Covering the cups increased inhibition at the 0.5% rate over uncovered meal at the same rate, suggesting that some or all of the phytotoxins were volatile. Indeed, when the covers were removed after 72 hr, all of the cups possessed a distinctive garlic-like odor regardless of application rate, which could also be detected initially from the seedmeal after watering. At the 5% rate, this odor was still detectable after 3 d from uncovered cups as well as covered ones.

Identification of the Phytotoxins. The crude CH_2Cl_2 extract strongly inhibited sicklepod and wheat radicle elongation, while the MeOH and water extracts had no

effect. Fractionation of the crude CH_2Cl_2 extract on a Sephadex LH-20 column yielded one fraction (100% $CHCl_3$) that was inhibitory to radicle elongation in bioassays when tested at 1 mg extract/ml agar. This fraction contained two major peaks as determined by GC–FID. The compounds were identified by GC–MS spectra and by NMR analysis as AITC and ATC. Prominent diagnostic mass spectral ions and their relative intensities for ATC are as follows: EI–MS [*m/z* (%)]: 99 (M^+, 91), 86 (6), 84 (10), 72 (35), 58(12), 41 (100). Prominent diagnostic mass spectral ions and their relative intensities for AITC are as follows: EI–MS [*m/z* (%)]: 99 (M^+, 100), 98 (9), 72 (28), 71 (8), 41 (47). The AITC and ATC peaks accounted for 80.9 and 19.1%, respectively, of the active fraction as quantitated by GC–FID. ^{1}H NMR and ^{13}C spectra for ATC are as follows: ^{1}H NMR δ ($CDCl_3$): 5.86 (1H, m) CH=; 5.32 (1H, d, $J = 16.8$ Hz) CH =; 5.28 (1H, d, $J = 10$ Hz); 3.49 (2H, d, $J = 7.3$ Hz) CH_2. ^{13}C NMR δ ($CDCl_3$): 130.5 (C=); 121.4 (CH_2=); 111.7 (C); 36.7 (CH_2). ^{1}H NMR and ^{13}C spectra for AITC are as follows: ^{1}H NMR δ 5.78 (1H, m) CH=; 5.33 (1H, d, $J = 16.9$ Hz) CH =; 5.22 (1H, d, $J = 10.3$ Hz) CH =; 4.08 (2H, m) CH_2. ^{13}C NMR δ ($CDCl_3$): 132 (C); 130.3 (CH=); 117.7 (CH_2=); 47.1 (CH_2). In the proton NMR spectrum of ATC, the aliphatic methylene protons are observed at δ 3.49, in the AITC spectrum the methylene protons resonate at δ 4.08. Differences in the ^{13}C spectra for the two compounds are striking. The resonance for the nonprotonated carbon in ATC is observed at δ 111.7. In AITC, the nonprotonated carbon is observed as a small, broad signal at δ 132.0. The changes in aliphatic methylene resonances also demonstrate the difference between the two compounds.

Intact Glucosinolate Analysis. Analysis of intact glucosinolates from defatted seedmeal by HPLC found only one major glucosinolate peak, tentatively identified by retention time as sinigrin. LC–MS analysis of the peak confirmed the mass of the unknown to be 358, affirming that the compound was indeed sinigrin. Total amounts of sinigrin contained in the seedmeal were found to be 39.7 ± 3.8 mg sinigrin/g defatted seedmeal.

Inhibition of Seed Germination by AITC and ATC. Both AITC and ATC were inhibitory to seed germination, with 5 ppm levels of both compounds completely

TABLE 2. MINIMUM INHIBITORY CONCENTRATIONS OF AITC AND ATC

	Concentration (ppm)				
Volatile	Wheat	Ryegrass	Arugula	Sicklepod	Velvetleaf
AITC	1	0.5	5	5	1
ATC	1	1	5	1	0.5

inhibiting the germination of the five species tested (Table 2). The lowest level tested (0.1 ppm) did not inhibit the germination of any of the species, although annual ryegrass seed germination was completely inhibited by both compounds at 0.5 ppm levels. Interestingly, arugula, the only bioassay species to possess the glucosinolate-myrosinase system, was the most tolerant of the five species to both compounds. Although thiocyanates have been shown to have activity against plants, they are generally thought to be less active than their respective isothiocyanates (Vaughn, 1999). However, Shofren et al. (1998) found that ATC had similar inhibitory activity to AITC against several bacteria, while Tsao et al. (2002) found that the LC_{50} (concentration required to kill 50% of the population) values of ATC as a fumigant against house fly (*Musca domestica* L.) and lesser grain borer (*Rhyzopertha dominica* Fabricius) adults was lower than AITC.

Field Studies. At all three rates tested, field pennycress seedmeal reduced plant biomass as compared to both the tarped and untarped controls (Figure 2). At the highest rate of incorporated seedmeal, biomass was reduced to less than 9% of the tarped control and less than 8% of the untarped control. All of the treatments exhibited visual reductions in seed germination compared to controls, and in the two highest treatment levels the ground remained completely bare in the center of each plot at the time of harvest. This seems to indicate that volatile compounds were primarily responsible for the inhibition, as leakage of volatiles near the edges of the tarps would decrease their concentrations compared to the centers. At the 0.5 kg/m^2 rate, there was some fungal growth found upon tarp removal near the plot edges that was lacking at the higher rates, although visible evidence of this fungi dissapeared within several days after removal of the tarps. Tarping alone appeared to promote rapid seed germination, possibly due to increased soil temperatures under the tarps, but many of the seedlings that had germinated either died after tarp removal or took longer to recover.

Using glucosinolate-containing plant material and processed seedmeals offer excellent potential in controlling weeds and soilborne pests, whether for organic or conventional growers. Because the bioactive degradation products dissapate rapidly, they pose less environmental risk than compounds that persist for greater periods of time. Field pennycress seedmeal offers potential as a biofumigant if the

agronomic obstacles associated with growing the plant as a crop are solved. Additionally, unlike synthetic fumigants, field pennycress seedmeal also is an excellent organic fertilizer, containing approximately 4% nitrogen.

Acknowledgments—We wish to thank Mr. Ray Holloway and Ms. Christina Parrish for providing technical assistance.

Abstract—Published studies focused on characterizing the allelopathy-based weed suppression by rye cover crop mulch have provided varying and inconsistent estimates of weed suppression. Studies were initiated to examine several factors that could influence the weed suppressiveness of rye: kill date, cultivar, and soil fertility. Ten cultivars of rye were planted with four rates of nitrogen fertilization, and tissue from each of these treatment combinations was harvested three times during the growing season. Concentrations of a known rye allelochemical DIBOA (2,4-dihydroxy-1,4-(2H)benzoxazine-3-one) were quantified from the harvested rye tissue using high performance liquid chromatography (HPLC). Phytotoxicity observed from aqueous extracts of the harvested rye tissue correlated with the levels of DIBOA recovered in harvested tissue. The amount of DIBOA in rye tissue varied depending on harvest date and rye cultivar, but was generally lower with all cultivars when rye was harvested later in the season. However, the late maturing variety 'Wheeler' retained greater concentrations of DIBOA in comparison to other rye cultivars when harvested later in the season. The decline in DIBOA concentrations as rye matures, and the fact that many rye cultivars mature at different rates may help explain why estimates of weed suppression from allelopathic agents in rye have varied so widely in the literature.

Key Words—Allelopathy, cover crop, residue, redroot pigweed (*Amaranthus retroflexus* L.), goosegrass (*Eleusine indica* L. Gaertn.), 2,4-dihydroxy-1,4-(2H)benzoxazine-3-one, DIBOA, maturity, phenology, rye (*Secale cereale* L.).

INTRODUCTION

Rye cover crop residues have been well studied for their weed suppressive capabilities (Barnes and Putnam, 1983; Masiunas et al., 1995; Creamer et al., 1996; Nagabhushana et al., 2001). Reviews of this literature have noted that estimates of weed control attributable to rye mulch allelopathy have varied considerably between studies (Weston, 1996; Foley, 1999). Foley (1999) suggested that these differences could be due to the use of different cultivars of rye. Support for this theory was found in a recent study of an important allelochemical, DIBOA. Among eight cultivars of rye, there was over a 10-fold difference in the concentration of DIBOA (Burgos et al., 1999). While the relative contribution of DIBOA to rye allelopathy is still under debate (Blum, 1995), its high phytotoxicity to many weeds and relative abundance in the plant have often singled it out for study (Barnes et al., 1987; Niemeyer, 1988). The large differences among cultivars in the production of this compound may explain the discrepancies in weed suppression among studies that utilized different cultivars.

Another factor that may be causing discrepancies among studies is differences in the date at which the rye is killed. The typical date of kill varies considerably among regions depending on temperatures and soil moisture, and also which crop is being planted after the rye. As a result, the rye residues from various studies differ dramatically in the age of the tissue and the developmental stage at which it was killed. Age and developmental stage have proven important factors in greenhouse studies of DIBOA production in rye (Burgos et al., 1999). These factors may also interact with the cultivar effect to determine allelochemical concentrations. Some cultivars are slower to develop phenologically, with as much as a month's difference in flowering time having been observed in fall-sown rye (Reberg-Horton, 2002). The biggest difference in the development of cultivars is seen between winter and facultative types of rye. Winter types will only flower and complete their life cycle if sown in the fall. Facultative types can be planted in spring or fall and will develop normally. The facultative types also appear to develop more rapidly in the southern US (Reberg-Horton et al., 2003). The impact of differing developmental rates on allelochemical concentrations has not been explored.

Fertility is another factor that may be impacting allelochemical production. In the only study examining the effect of fertility on rye allelopathy, Mwaja et al. (1995) found that low to moderate rates of fertilization led to higher DIBOA production than higher rates. This effect was also evidenced in their bioassays of the rye tissues.

How to measure the impact of any of these factors on allelopathy has been much debated in the literature (Blum et al., 1999; Inderjit and Weston, 2000). Many studies have utilized weed seedling bioassays due to their simplicity and ability to screen for general phytotoxicity, without invoking a bias about which compounds are the most important. Critics, however, argue that most bioassays

do a poor job simulating natural systems and often overestimate the toxicity of plant extracts. Another approach is to quantify individual compounds that have proven to be phytotoxic. For this approach to be reliable, extensive prior research is required to identify the likely toxic compounds. Fortunately, rye allelopathy has been well researched with the identification of multiple allelopathic compounds including the extensively studied benzoxazinone, DIBOA (Shilling et al., 1986; Barnes et al., 1987). Not only is this allelochemical highly toxic to most weed seedlings (Barnes et al., 1987; Burgos and Talbert, 2000), it is also produced in abundance by rye (Burgos et al., 1999). By using DIBOA quantification in parallel with bioassays, this study was able to examine allelochemical production both at the specific compound and general toxicity level. Both methods were used to examine how date of kill, cultivar, and fertility affect rye allelopathy.

METHODS AND MATERIALS

The experimental design was a split plot with the main plots laid out in randomized complete blocks. The main plots were fertilized with four rates of nitrogen: 0, 22, 45, or 90 kg N ha^{-1} applied as ammonium nitrate (34-0-0). The nitrogen was spread with a Gandy drop spreader and incorporated prior to planting. Ten rye cultivars comprised the subplot factor: 'Aroostook,' 'Bates,' 'Elbon,' 'Maton,' 'WinterGrazer 70,' 'Wrens 96,' 'Wrens Abruzzi,' 'Wheeler,' 'Bonel,' and NC unnamed. NC unnamed is not an actual cultivar, but comes from a large seed distribution chain with the variety unstated.

Plots were located at the Center for Environmental Farming Systems in Goldsboro, North Carolina on a well-drained, Wickham loamy sand (fine-loamy, mixed, semiactive, thermic Typic Hapludult). The rye was planted on raised 1.2 m beds by using an Almaco grain drill with an 18 cm row spacing at 124.3 kg ha^{-1} with 6 rows fitting on each bed. They were seeded on November 16th, 2000 in plots that were 3 beds wide and 9.1 m long. Aboveground biomass was measured by clipping shoot tissue at ground level in 0.5 m^2 quadrants, placed in the center 4 rows of a bed. Samples were taken on March 1, April 5, and April 23, 2001. Tissue was placed in cotton bags and dried at 60°C for 2 d in a forced-air oven and weighed. A portion of this tissue was reserved for bioassays and quantifying DIBOA, making sure that whole plants were kept so that all shoot tissues were fairly represented. Tissue was ground using a Wiley mill with a 1 mm mesh size and stored at room temperature in the dark.

Bioassay Methods

Bioassays were conducted on all cultivar and sample date combinations and on 2 of the 4 nitrogen rates: the 22 and 90 kg N ha^{-1} treatments. To make the rye

extracts, 1 g of ground tissue was added to 40 ml de-ionized water, placed on a shaker for one hr, vacuum filtered through Whatman no. 1 filter paper, and kept for 12 hr at 4°C. Five ml aliquots of the extract were added to 90 mm diam by 15 mm high culture dishes containing three Whatman no. 1 filter papers. Ten seeds of redroot pigweed or 25 seeds of goosegrass were placed on the filter papers, and the dishes were sealed with parafilm and incubated in a germination chamber at 28°C with constant light. Root elongation of each seedling was measured to the nearest mm after 72 hr.

A 1:40 ratio (wt/v) for the extracts was chosen based on past research with the technique that showed optimal separation of the cultivars at this concentration (Reberg-Horton, unpublished). However, tissue from the March 1 sampling date was so inhibitory that many petri dishes had no seeds germinating. These samples were subsequently bioassayed at a dilution of 1:160 (wt/v).

Data were square root transformed before being analyzed over time using a Repeated Measures ANOVA model (SAS Institute, 2002). Preplanned orthogonal contrasts were used to test for difference among cultivars. Choices of comparisons to make were based on previous work with these cultivars (Reberg-Horton et al., 2001). The Wilk's Lamda statistic was used to test the effect of time and all interactions with time. Root measurements were converted to percentage of untreated plants after the statistical analysis.

Quantification of Diboa

The interactions of all combinations of cultivars, nitrogen rates, and time on DIBOA levels were not quantified. Three of the 4 nitrogen rates were used: 0, 45, and 90 kg N ha^{-1}. Four cultivars were chosen for DIBOA quantification based on the bioassay results and past research. Two of these cultivars, 'Wheeler' and NC unnamed, are winter types of rye, and the shoot tissue had demonstrated relatively high levels of allelochemical activity in preliminary work done the year prior. The other two cultivars, 'Bonel' and 'Wrens Abruzzi,' are facultative types of rye, meaning they can be planted in the fall or spring. 'Bonel' was chosen due to published reports of high DIBOA production (Burgos et al., 1999) and 'Wrens Abruzzi' due to its popularity in the South. The decision to choose 2 facultative and 2 winter types was based on observations of the growth and development of these different classes over time. Facultative types produce more biomass early in the season and flower earlier than winter types.

DIBOA content in the tissue was determined by using a protocol modified from previously published methods (Yenish et al., 1995; Melansom et al., 1997). Ground tissue (0.5 g, see above) was first extracted in water, and then incubated for 1 hr (to hydrolyze the DIBOA-glycoside into DIBOA). Methanol was then added (to 60%, v/v) and the mixture vigorously agitated. The extract was then filtered through 2 layers of Miracloth, and centrifuged at 20,000 $\times$ g for 20 min. The

supernatant was retained and extracted twice with a 2-fold (v/v) excess of ethyl-acetate, and the combined nonpolar phases were dried under vacuum (Speed-Vac). The dried sample was re-solubilized with 0.5 ml mobile phase (see below) and filtered through a 0.2 μ filter.

Chromatographic separation of the extracts was conducted by using an isocratic mobile phase consisting of 40% methanol and 60% water (0.02% phosphoric acid). The chromatography was facilitated by using a Waters system high performance liquid chromatography (HPLC), and a Beckman Ultrasphere ODS, 5 μ, C18 column (4.6 $\times$ 250 mm^2). The detector used was a Perkin Elmer variable wavelength, UV–Vis detector, monitored at 254 nm. DIBOA was identified and quantified utilizing a chemically synthesized analytical standard (provided by Dr. Scott Chilton, NCSU). BOA was identified and quantified using a standard purchased from Sigma Chem. Co.

The HPLC method was found to effectively resolve BOA, DIBOA, and the DIBOA-glycoside. DIBOA was the principal benzoxazinone found in the extracts, and only trace levels of DIBOA-glycoside and BOA were observed. The identity of the DIBOA glycoside was deduced by incubating subsamples of a rye extract in the presence of almond glucosidase (Sigma Chem. Co.) for different times. The successive decrease in the area of the peak eluting at 6 min, and the corresponding increase in the DIBOA peak at 8 min indicated that the 6 min peak was the DIBOA glycoside. (Subsequent, efforts with GC-MS have established that the 6 min peak is the DIBOA glycoside, details to be published).

The DIBOA content per gram of dry tissue derived from the HPLC analysis was multiplied by the biomass production for each plot to generate estimates of the rate of DIBOA being produced on a per unit area basis. This variable is likely a useful predictor of weed suppression in the field. DIBOA rates and concentrations were analyzed over time by using a Repeated Measures Analysis ANOVA (SAS, 2002). Preplanned orthogonal contrasts were used to compare winter and facultative types and within type differences. The Wilk's Lamda statistic was used to test the effect of time and all interactions with time.

Harvesting by Developmental Stage

A separate study was conducted simultaneously using the same 10 rye cultivars. The study was planted at the Cunningham Research and Extension Center in Kinston, North Carolina. A three replicate completely randomized design was utilized. The rye was planted on October 20, 2000 in single row plots 1.2-m long, spaced 0.3-m apart. Twenty-two kg N ha^{-1} was applied as a top dressing in early February 2002. A key difference between the two studies is when the tissue was harvested. In this study, tissue was not harvested at specific dates, but whenever each cultivar reached the early boot stage (Feeke's growth stage 9). Using this

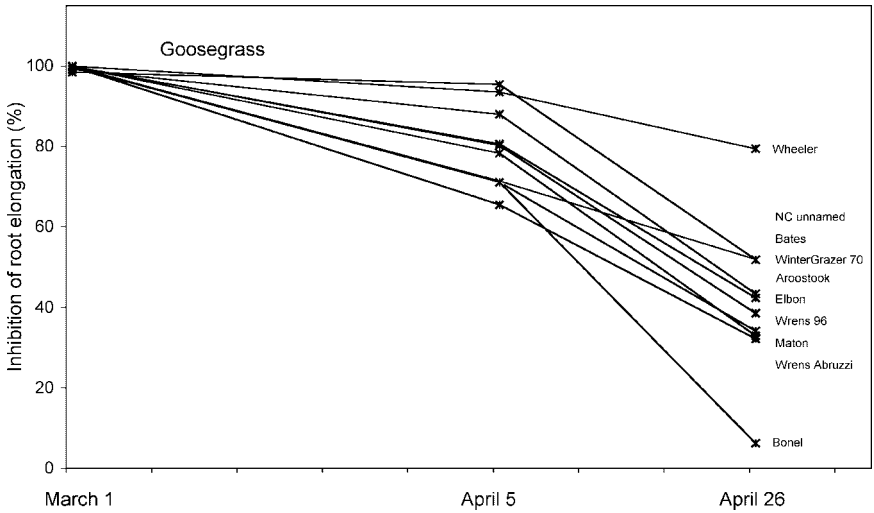

FIG. 1. Inhibition of goosegrass root elongation in shoot tissue extracts form different rye varieties.

criterion, the harvest date varied from March 12 for 'Wrens Abruzzi' to April 11 for 'Wheeler.'

RESULTS AND DISCUSSION

Bioassays

Root elongation of goosegrass (Figure 1) and pigweed (Figure 2) was inhibited by the aqueous extracts from all rye cultivars. Tissue extracts from all varieties on the March 1st harvest inhibited root elongation of both test species by greater than 95%. The relative phytotoxicity of extracts for all cultivars progressively decreased over time. This decrease was rapid and was significant at the 0.001 level for both weed species. By the April 5th harvest, inhibition of pigweed and goosegrass root elongation ranged between 60 and 95%. At the April 26th harvest, the relative phytotoxicity had decreased, with 20–60% inhibition for pigweed, and 5–75% for goosegrass. The rate of decreasing phytotoxicity was similar for extracts from all cultivars when pigweed was the indicator species (Figure 2). Goosegrass, however, revealed differences between the cultivars in the rate at which phytotoxicity decreased (Figure 1). 'Wheeler' had a slower rate of decrease in phytotoxicity in comparison to the other 9 cultivars when goosegrass was the indicator species ($P = 0.004$). The declining phytotoxicity of the extracts as the growing season progressed suggested that a time dependent factor at the time of kill,

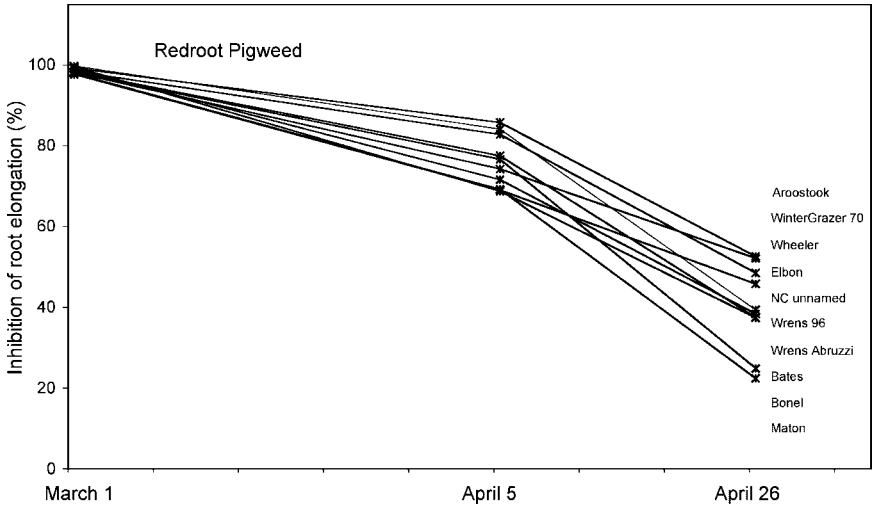

FIG. 2. Inhibition of pigweed root elongation in shoot tissue extracts form different rye varieties.

e.g., developmental stage of growth, is important in determining the allelopathic potential of rye tissue.

DIBOA

DIBOA concentrations likewise varied over time and among the cultivars (Figure 3). DIBOA concentrations in rye tissue decreased over time ($P < 0.001$) in a pattern similar to changes in the phytotoxicity of the extracts at different harvests (Figures 1 and 2). At the March 1st harvest, 'Bonel' contained the highest amount of DIBOA (1.8 mg g^{-1} dry wt), and 'Wrens Abruzzi' contained the least (1.0 mg g^{-1} dry wt). At the April 5th harvest, 'Wheeler' and NC Unspecified contained between 0.7 and 0.9 mg g^{-1} dry wt, and 'Wrens Abruzzi' and 'Bonel' contained 0.2–0.3 mg g^{-1} dry wt. By the April 26th harvest, all varieties contained less than 0.2 mg g^{-1} dry wt. Though the DIBOA concentrations in all varieties declined over time, the rate of decline varied with the cultivar. The changes in the winter types ('Wheeler' and NC Unspecified) were different from the facultative types over time ($P < 0.001$). The winter types declined more slowly between March 1 and April 5, but all cultivars had similar levels by April 26th.

Another factor that distinguishes the winter and facultative types of rye is evident in the graph reporting growth stage changes over time (Figure 4). 'Wheeler' and NC Unspecified are the slowest to develop phenologically. At each sampling date, these two winter types were at an earlier stage of development than the other

[b]Goosegrass bioassays found no significant differences.

cultivars. Because the allelochemical content in rye tissue was greater earlier in the season and decreased over time, the levels may be related to the developmental stage of growth. The winter types of rye had slower phenological development, and had higher levels of DIBOA later in the season when compared to the facultative types (Figure 3). This suggests that the relative rates of maturation of winter and facultative varieties play a role in the change of DIBOA content.

At the Kinston study site, cultivars were harvested at the same developmental stage (Feeke's Stage 9, or 'boot stage'), but on different harvest dates (Table 1). The results from this experiment further emphasized that the varieties had distinct developmental profiles over time because 'Wheeler' and NC Unspecified reached boot stage by April 11, nearly 1 mo later than 'Wrens Abruzzi,' which reached boot stage on March 12. The other varieties reached the boot stage during March.

When the varieties were harvested at the same growth stage, even though there was a 1-mo period between the harvest of the first and last varieties, reaching Feeke's 9, inhibition of goosegrass by extracts from the different varieties was not different (Table 2). However, there was variation in the inhibition of pigweed root elongation by extracts of the different varieties. If the pigweed inhibition data for each variety from Table 2 is graphed according to each harvest date, there is a negative correlation ($R^2 = 0.67$) between phytotoxicity and date of harvest, with the earlier harvests more toxic. If the developmental stage of growth were the only determining factor in allelochemical production, then harvesting at the

TABLE 2. ROOT GROWTH INHIBITION BIOASSAYS OF EXTRACTS (1:160, W/V DILUTION) FROM DIFFERENT RYE CULTIVARS HARVESTED MARCH 1

Cultivar	Inhibition of root elongation (%)	
	Pigweed	Goosegrass

same growth stage should have eliminated the differences between varieties, as observed with the goosegrass data. Remaining differences between varieties could be due to the environmental conditions previous to harvest. During the month over which varieties reached the boot stage, temperature, rainfall, and soil moisture were changing rapidly. The varieties may also differ due to genetic factors that are not related to developmental rate. The pigweed data suggest that developmental stage is not the only factor affecting a cultivars allelopathic potential.

While the general phytotoxicity of the rye tissue (as measured by the bioassay) and DIBOA content decreased over time, biomass increased (Table 3). The field rate (kg ha^{-1}) of allelochemical(s) that would be (potentially) available for weed suppression is a function of both biomass and allelochemical content of the tissue. The field rate of DIBOA increased between March 1 and April 5 for the winter types but decreased during the same time for facultative types ($P < 0.001$, Figure 5). After reaching a maximum level, the DIBOA rates in the winter types decreased. DIBOA rates for all cultivars were similar by the last sampling on April 23.

The rye extracts from the March 1 harvest were so toxic to the seedlings at 1:40 dilution, that all the varieties inhibited growth >95% (Figures 1 and 2). The same tissue was subsequently bioassayed at a dilution of 1:160 (Table 2). The more dilute extracts were still toxic, with inhibition of either goosegrass or redroot pigweed ranging from 9 to 35% for all the rye varieties. The more dilute bioassay from the March 1 harvest also allowed for treatment mean separation with goose

grass, but not pigweed. No clear division between winter and facultative types can be seen at this date. All cultivars were between Feeke's Stage 5 and 7. Given the high toxicity of the young tissue relative to that of the later harvests, using the early-harvest 1:160 data as a predictor of field performance of the different cultivars may be unreliable.

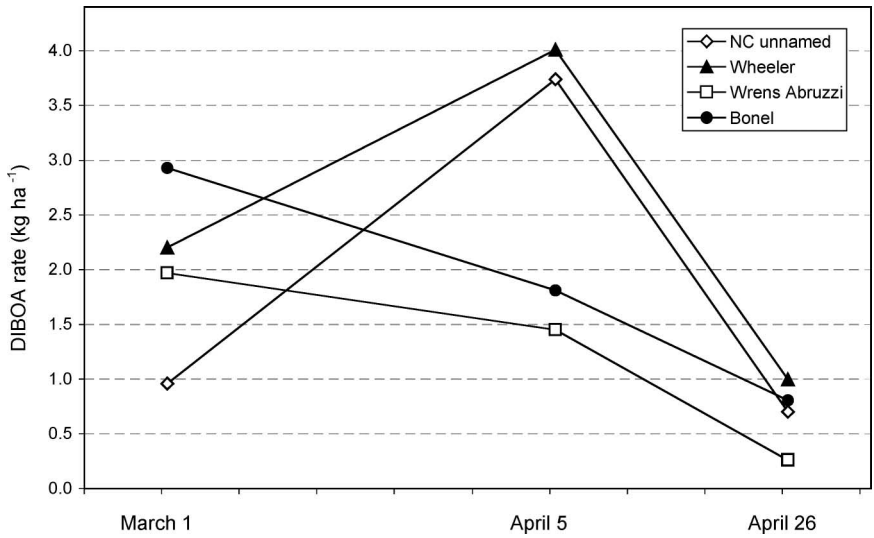

FIG. 5. DIBOA rate (concentration × biomass) for different rye varieties over time.

Fertility Effects

The rate of N fertilization had no effect on biomass accumulation for any of the varieties (data not shown). Soil N was tested on February 9, 2001, which demonstrated a high level of total soil N in the 0 N treatments (40–70 kg N ha^{-1} at 0–30 cm depth; and 65–75 kg N ha^{-1} at the 30–60 cm depth: see Reberg-Horton, 2002 for details). Others have reported fertility levels in greenhouse grown rye influenced allelochemical production (Mwaja et al., 1995). Given the high N levels and biomass production at the 0 N rate, we conclude that the residual N in the field was too high to either observe a growth response or induce low N stress. In addition, the bioassays failed to detect any N effects. However, a significant effect of N was observed in the DIBOA levels ($P = 0.008$), but only at one point in time. 'Wheeler' had higher DIBOA concentrations (LSD, $\alpha = 0.05$) in the 0 N rate at the March 1 sampling (data not shown). No differences in DIBOA levels due to N treatments were present at the other sample dates. Because neither an N growth response nor evidence of N stress was observed in this study, a fair test of N effects on allelopathy was not achieved. The observation that DIBOA levels were higher at the 0 N treatments was not expected, but the results parallel the observations of Mwaja et al. (1995). We can only speculate as to the mechanism for a greater DIBOA level at low N, but because no N stress was apparent, a stress-induced increase in DIBOA is an unlikely hypothesis.

Time and Cultivar Effects

These data demonstrated that the allelochemical content in field-grown rye changed over the growing season. For any given variety, comparing the kill dates selected, the younger tissue produced greater phytotoxic effects on selected bioassay species and contained a greater amount of DIBOA than older tissue. These results confirm other research that describe a temporal profile of benzoxazinones (BX) levels in rye and other species (Nakagawa et al., 1995; Collantes et al., 1998; Burgos et al., 1999; Copaja et al., 1999; Cambier et al., 2000; Gianoli et al., 2000). BX biosynthesis begins after germination, and the content (g g^{-1} dry wt) increases over time to some maximum level, and then decreases. In the greenhouse, Burgos et al. (1999) found the maximum to be about 60 d after germination. In corn, the maximum BX content occurs between 7 and 10 d. The date or growth stage at which the maximum DIBOA/allelochemical content in field grown rye occurs is not known. The factors that regulate the allelochemical content in cover crops needs to be defined to obtain optimum weed suppression from a cover crop mulch.

While date of kill was a critical factor, all cultivars were not affected equally. Winter types of rye, such as 'Wheeler,' had higher concentrations of allelochemicals later into the season. 'Wheeler's' ability to retain these high concentrations may be due to its later maturation, although more research is needed to accurately compare the differences between winter and facultative types of rye.

It is likely that the allelopathic components in the cover crop mulch that function in weed growth suppression represent a mixture, rather than a single chemical. Several potential allelochemical compounds have been identified in rye (Zuniga et al., 1983; Shilling et al., 1986; Barnes et al., 1987). Though information of the complex of allelochemical compounds is limited, there is a growing body of information about DIBOA and related chemicals (Friebe, 2001; Gierl and Frey, 2001; Sicker et. al., 2001). The temporal changes in the content of the individual allelochemicals in rye may be different, but our data demonstrate that the total phytotoxic potential of rye extracts declines over time, as does the DIBOA content. The observation that the DIBOA and general allelochemical content of rye decreased over the growing season was verified by additional studies the following year (data not shown). Given the phytotoxicity of DIBOA to multiple weed species (Barnes et al., 1987), the similarities between the quantity of DIBOA found in leaf tissue and the phytotoxicity demonstrated in the bioassay suggest an important role for DIBOA.

Allelochemical content is not the only factor in determining how much weed control will be provided by rye mulch. The quantity of mulch determines how much weed control will be obtained through physical suppression (Teasdale and Mohler, 2000). NC Unspecified is a low biomass producer (Table 3), and this may negate the impact of high DIBOA rates. However, 'Wheeler' maintained high DIBOA levels and produced high biomass, and, thus, may be a better choice for weed management. Crops that can be planted early to mid April will be able to capitalize on the high DIBOA rates provided by winter types of rye.

The weed suppression provided by cover crop mulch is most likely due to both the allelochemical content in the tissue and the total biomass present. Thus, the dramatic changes in the rate of DIBOA in the field (Figure 5) over time and among varieties suggests that the specific variety used, and time at which the cover crop is killed play a critical factor in weed suppression, and a knowledge of the tissue levels of allelochemicals is necessary for optimum weed management.

Further work is needed to elucidate factors that regulate allelochemical content in rye. Opportunities for delaying maturation of rye also need to be explored. Possibilities include later plantings, repeated mowing, plant growth regulators, and breeding for later maturation. The implications of these temporal changes in allelochemical content, and their interaction with different cultivars, have not been fully integrated into cover crop utilization.

Acknowledgments—The authors thank Ken Fager, Will Hall, Dana Ivey, Danielle Treadwell, and Matthew Finney for their careful technical assistance on this project. A special thanks to Dr. Bill Swallow for his statistical consultations. Abstract—Phlorotannins are ubiquitous secondary metabolites in brown algae that are phenotypically plastic and suggested to have multiple ecological roles. Traditionally, phlorotannins have been quantified as total soluble phlorotannins. Here, we modify a quantification procedure to measure, for the first time, the amount of cell-wall-bound phlorotannins. We also optimize the quantification of soluble phlorotannins. We use these methods to study the responses of soluble and cell-wall-bound phlorotannin to nutrient enrichment in growing and nongrowing parts of the brown alga *Fucus vesiculosus*. We also examine the effects of nutrient shortage and herbivory on the rate of phlorotannin exudation. Concentrations of cell-wall-bound phlorotannins were much lower than concentrations of soluble phlorotannins; we also found that nutrient treatment over a period of 41 days affected only soluble phlorotannins. Concentrations of each phlorotannin type correlated positively between growing and nongrowing parts of individual seaweeds. However, within nongrowing thalli, soluble and cell-wall-bound phlorotannins were negatively correlated, whereas within growing thalli there was no correlation. Phlorotannins were exuded from the thallus in all treatments. Herbivory increased exudation, while a lack of nutrients had no effect on exudation. Because the amount of cell-wall-bound phlorotannins is much smaller than the amount of soluble phlorotannins, the major function of phlorotannins appears to be a secondary one.

Key Words—Phenolics, phlorotannins, plant defense, *Fucus vesiculosus*, brown alga, cell-wall-bound, exudation.

INTRODUCTION

Tannins are a subgroup of phenolic compounds that are produced as secondary metabolites by a host of diverse plant species. These water-soluble compounds differ from other phenolics in their ability to bind proteins (Stern et al., 1996; Strack, 1997; Harborne et al., 1999). Tannins can be divided into soluble tannins, occurring in cytoplasm or within cell organelles, and insoluble tannins, bound to the cell wall (Strack et al., 1988; Peng et al., 1991). Phlorotannins, a subgroup of tannins, are produced entirely by polymerization of phloroglucinol (1,3,5-trihydroxybenzene) (Ragan and Glombitza, 1986; Waterman and Mole, 1994; Arnold and Targett, 1998), which is the product of the acetate–malonate pathway, also called the polyketide pathway (Waterman and Mole, 1994).

Phlorotannins are known only from brown algae (Phaeophyceae), where soluble phlorotannins can constitute up to 25% dry weight (e.g., Targett et al., 1992; Van Alstyne et al., 1999). They are suggested to have multiple ecological roles: some phlorotannins act as chemical defenses against herbivory (e.g., Steinberg, 1988; Targett and Arnold, 1998; Arnold and Targett, 2000; Pavia and Toth, 2000a) and as antifouling substances (Sieburth and Conover, 1965; Wikström and Pavia, 2004), although the evidence for this function is equivocal (Jennings and Steinberg, 1997). Concentrations of phlorotannins show phenotypic plasticity in response to environmental parameters, such as salinity, nutrient and light availability, ultraviolet irradiation, and intensity of herbivory (Yates and Peckol, 1993; Peckol et al., 1996; Pavia et al., 1997; Pavia and Toth, 2000b; Honkanen et al., 2002; Swanson and Druehl, 2002). This implies that the pools of soluble phlorotannins are not stable but rather in a state of flux, and their concentration may be determined by the balance between rates of synthesis and turnover (Arnold and Targett, 2000). Existing data on phlorotannins are based solely on soluble phlorotannins, which limits our knowledge of factors controlling their metabolism and degradation.

Soluble phlorotannins are stored in cell organelles, physodes, which are round to elliptical, highly mobile, vesicle-like, strongly refractive bodies observed in the cytoplasm of brown algae (Ragan and Glombitza, 1986; Schoenwaelder, 2002). Phlorotannins are suggested to transform into components of the cell walls of brown algae when physodes fuse with the cell membrane and the phlorotannins are secreted into the cell wall, complexing finally with alginic acid (Arnold and Targett, 2003). The cell walls of brown algae are mainly composed of polysaccharides: alginic acid, alginates (carboxylated polysaccharides, salts of alginic acid), and fucans (sulfated polysaccharides), which comprise up to 40% of the thallus dry weight (Mabeu and Kloareg, 1987; van den Hoeck et al., 1995). Schoenwalder and Clayton (1998) have suggested that phlorotannins are likely to be integral structural components of brown-algal cell walls. There are few quantitative data on cell-wall-bound phenolics or their functional roles (but see Strack et al., 1989; Peng et al., 1991; Viriot et al., 1993). One possible generalization is that phenolic compounds are bound into the cell wall during maturation (Peng et al., 1991).

Resource availability is expected to have an impact on algal growth and secondary metabolism. Resource-based hypotheses assume that under conditions of good nutrient availability, the allocation of carbon will shift from the production of secondary metabolites to growth (e.g., Bryant et al., 1983; Herms and Mattson, 1992). Often, negative correlations have been found between the contents of available nutrients and the production of soluble phenolic compounds, both in terrestrial plants (reviewed by Herms and Mattson, 1992) and brown algae, although much spatial and temporal variation in this relationship exists (e.g., Yates and Peckol, 1993; Steinberg, 1995; Peckol et al., 1996; Pavia and Toth, 2000b). Variation in the contents of soluble phlorotannins has also been found among different parts of algae. In actively growing meristems, soluble phlorotannins have often been found in lower concentrations than in older vegetative parts (Jennings and Steinberg, 1997; Van Alstyne et al., 1999).

In addition to soluble and cell-wall-bound phenolics, brown seaweeds release phlorotannins into the surrounding water directly via exudation (Carlson and Carlson, 1984; Ragan and Glombitza, 1986; Jennings and Steinberg, 1994; Toth and Pavia, 2000; Swanson and Druehl, 2002). Phlorotannins may also be released indirectly as a consequence of grazing or tissue erosion. The occurrence of phlorotannin excretion in healthy, relatively unstressed algal tissues *in situ* has been confirmed in several studies (Sieburth and Jensen, 1969; Ragan and Jensen, 1979; Swanson and Druehl, 2002). However, few data are available on quantities of exuded phlorotannins (but see Toth and Pavia, 2000) or on their ecological function.

In this study, we modified a quantification procedure for cell-wall-bound phlorotannins, optimized the quantification of soluble phlorotannins, and used these procedures to examine the contents of soluble, cell-wall-bound, and exuded phlorotannins in the brown alga *Fucus vesiculosus* (L.). In two manipulative experiments, we explored the environmental variation of these different types of phlorotannins. In the first, we compared the contents of phlorotannins between growing and nongrowing parts of the thallus in order to clarify the consequences of active growth for the dynamics of soluble vs. insoluble phlorotannins. We also tested the effect of nutrient enrichment. In the second experiment, we quantified the amount of exuded phlorotannins, and studied the effects of nutrient shortage and grazing action by the isopod *Idotea baltica* (Pallas) on the amount of exudation.

METHODS AND MATERIALS

Study Organisms

F. vesiculosus is a perennial, brown alga dominating the littoral rocky bottom of our study area in the Archipelago Sea, SW Finland. The thallus grows by dichotomous branching; it consists of both vegetative apices and, during the

reproductive period, generative apices. *F. vesiculosus* has an apical meristem, so growth occurs only at the blade tips. Individuals live for many years, so most of the thallus is nongrowing tissue. In our study area, the alga has only one important herbivore, the isopod *I. baltica*; this is a generalist feeder, but prefers *F. vesiculosus* over other potential host species (Jormalainen et al., 2001).

Experimental Growing Conditions of Algae

Effect of Ambient Nutrients on Soluble and Cell-Wall-Bound Phlorotannins in Growing and Nongrowing Thalli. We conducted the study at the Archipelago Research Institute of the University of Turku (60° 14′ N, 21° 40′ E). On June 10, 1999, we collected 20 *F. vesiculosus* individuals from one population in the Archipelago Sea of Finland and randomly assigned them to 10 microcosms of 60 l, two individuals in each. Microcosms were located outdoors, with natural light and diurnal rhythm, and were protected from rainfall by a thin plastic cover, permeable to UV light; they had continuous seawater through-flow of 200 l/d. Five microcosms were randomly assigned to a nutrient-enrichment treatment, while the others served as controls. The fertilizer [nutrient content of dry mass: N 20% ($NO_2 + NO_3$ 3.7%, NH_4 11.3%), P 2.0%, K 8.0%, Mg 1.0%, S 9.0%, B 0.03%, Fe 0.1% (Kemira, Agro OY)] was applied by automatic feeders, which added 0.03 g of the fertilizer into the pools three times a day. The mean ($\pm SE$, $N = 2$) content of total nitrogen, $NO_2 + NO_3$, NH_4, and PO_4 (μg/l) in the control microcosms was 255 ($\pm$120.1), 6 ($\pm$3.4), 1 ($\pm$2.6), 8 ($\pm$11.8), and mean ($\pm SE$, $N = 5$) in the fertilized ones were 420 ($\pm$90.6), 12 ($\pm$1.8), 7 ($\pm$1.7), 25 ($\pm$8.7), respectively. Samples of water for chemical analysis were collected immediately after collecting the algae for the chemical analyses. We did not conduct statistical contrasts on nutrient concentrations due to low replication of control-tank measurements and, consequently, low statistical power. However, the existence of the treatment effect was confirmed because the algae responded to our manipulation. At the end of the experiment (20 July), we took samples for analyses of soluble and cell-wall-bound phlorotannins from each individual (now numbering 17: 9 individuals from the nutrient-enrichment treatment and 8 from the control), from both the apical parts that had grown during the experiment, and the older parts (nongrowing) of the thallus. Samples were freeze-dried, homogenized, and stored at –20°C until analysis. Contents of soluble and cell-wall-bound phlorotannins were measured as described in subsequent paragraphs.

Effects of Nutrient Shortage and Herbivory on Exudation of Phlorotannins. For this experiment, we collected four *F. vesiculosus* individuals, split each individual into three equal-sized pieces (approximately 40 g fresh weight), and placed them individually into plastic, transparent, 2.5-l aquaria. The aquaria were aerated and placed under greenhouse light (400 W sodium vapor lamps, Sylvania, MA, USA). Pieces of algae were randomized among three different treatments in such

a way that one piece from each individual was assigned to each treatment. The first treatment was a control, to which nutrients were added every second day [$c(NH_3)$ = 120 μg/l, V(added) = 1.5 ml; $c(NO_3)$ = 40 μg/l, V(added) = 1.0 ml; $c(PO_4)$ = 30 μg/l, V(added) = 0.75 ml] to maintain availability of nutrients during the experiment. In the second treatment, no nutrients were added. Because algae in closed aquaria, when light is not limiting, quickly deplete the ambient nutrients, the algae in this treatment faced a nutrient shortage. In the third treatment, five *I. baltica* individuals were placed in each aquarium to graze. As in the control, nutrients were made available by nutrient additions. The experiment was maintained for 14 d, after which the water from each aquarium was filtered (pore 0.45 μm diam.) and stored in dark bottles at 4°C for a few days before a half-liter aliquot was taken from each sample, evaporated to an exact volume of 100 ml, and the amount of exuded phlorotannins measured as described subsequently.

Extraction and Quantification Methods

Optimizing Extraction Efficiency. Freeze dried and ground *F. vesiculosus* powder was extracted with eight different extractants (Figure 1) to examine extraction efficiency of soluble phlorotannins. Three replicates for each extractant were extracted ×4 described as follows. Freeze dried and ground algal aliquots (200 mg dry weight) were weighed and placed into screw-top test tubes (16 mm diam. and length 100 mm). Samples were treated with 10 ml of extractant for 1 hr with continuous shaking, after which they were centrifuged (10 min at 3200g). Supernatants were collected and a fresh extractant aliquot was added. After the fourth extraction, supernatants from each replicate for a specific extractant-type were collected into one container, thus producing only one independent assessment for each extractant type. However, the sample thus obtained was composed of three independently weighed and extracted subsamples prior to pooling of the samples. After volatile solvents were removed in the fume hood, both aqueous extracts and insoluble residues in the extraction tubes were freeze dried. Freeze-dried extracts were dissolved in a known amount of water, their phlorotannin content was analyzed, and the residuals were stored in a freezer; the insoluble residues were also weighed and stored in the freezer. In a separate test, we tested the efficiency of the extraction of phlorotannins by performing consecutive extractions with 70% aqueous acetone and analyzing each extract separately.

Soluble Phlorotannins. Dried and ground aliquots (200 mg dry weight) from the first experiment were extracted ×4 (1 hr) with 10 ml of 70% aqueous acetone. Samples were centrifuged (10 min at 3200g), and the supernatants were combined. Acetone was removed in open air, and the aqueous extracts and insoluble residues in the extraction tubes were freeze dried. Extracts of soluble phlorotannins were dissolved in water (2 × 2.5 ml) and stored in a freezer.

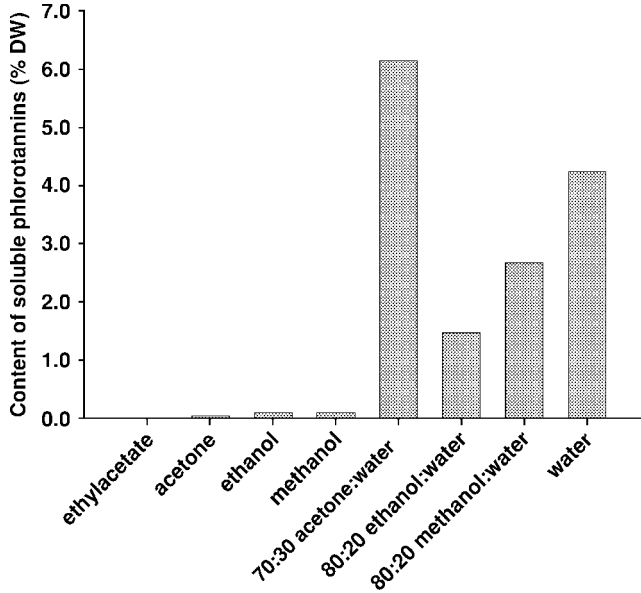

FIG. 1. Acquisition (*as a mean of three replicates*) of soluble phlorotannins with the different extractants. Extractants are ranked by increasing order of polarity according to Hildebrand solubility parameters (Barton, 1983): ethyl acetate (polarity δ (SI) 18.6 $MPa^{1/2}$), ethanol (26.0), methanol (29.6), acetone (20.2), 70% aqueous acetone (28.5), 80% aqueous ethanol (41.1), 80% aqueous methanol (42.4), water (47.9).

In order to remove the remaining soluble phlorotannins from the freeze-dried insoluble residues, they were treated (according to Strack, 1989) with the following solvents (10 ml) for 15 min with stirring followed by centrifugation (5 min at 2400*g*): (1) MeOH; (2–4) H_2O; (5–9) MeOH; (10,11) Me_2CO; (12, 13) Et_2O. After this washing, the remaining insoluble residues (cell-wall fraction) were oven dried at 60°C for 1 hr.

Insoluble Phlorotannins. Phenolic compounds bind with four major types of bonds—hydrophobic, hydrogen, ionic, and covalent—in order of increasing strength (Appel, 1993). Possible linkages between the cell wall (alginic acid) and phlorotannins are the ester bond and the hemiacetal bond, both of which are covalent, irreversible bonds, thus requiring strong conditions to degrade.

Cell-wall-bound phlorotannins were quantified with a modified alkaline-degradation method described by Strack et al. (1989), which was originally developed to degrade phenolics other than phlorotannins. In addition to alkaline degradation, an acidic-degradation method (Peng et al., 1991) was tested: samples were treated with methanol hydrochloric acid (9:1, v/v) at 120°C for 160 min. Preliminary tests showed alkaline degradation to be slightly more effective than

acidic degradation (data not shown); we, therefore, chose to continue with the alkaline-degradation method. To modify the method to suit our purposes, we tested the reaction time, the strength of the sodium hydroxide (NaOH) solution, the number of repeats, and the volume of acid addition.

The total insoluble residue of the alga remaining after the extraction and washing of soluble phlorotannins was suspended in 8 ml of 1 M aqueous NaOH solution (80°C) and stirred for 2.5 hr at room temperature. Samples were centrifuged (5 min at 2400*g*), and 1 ml aliquots were neutralized with 45 μl of H_3PO_4; the remaining NaOH was discarded. The alkaline treatment was repeated $\times 4$, with the aliquots of each treatment analyzed separately.

Spectrophotometric Determination of Phlorotannins. The contents of total phlorotannins in the extracts of soluble and cell-wall-bound phlorotannins were determined according to a modification of the Folin–Ciocalteu method (Waterman and Mole, 1994), using phloroglucinol (ICN Biomedicals Inc.) as a standard agent. Samples were diluted taking into account the measurable range of the spectrophotometer [e.g., a 0.05 ml aliquot of extract of soluble phenolics (samples from the first experiment) was mixed with 4.95 ml water]. A 1.0 ml aliquot of the diluted sample was mixed in a test tube with 1.0 ml of 1 N Folin-Ciocalteu reagent (Merck). The mixture was allowed to stand for 3 min, after which 2.0 ml 20% Na_2CO_3 were added. Samples were incubated in the dark at room temperature for 45 min and centrifuged for 8 min (1600*g*), after which the absorbance of the supernatant was measured at 730 nm on a Unicam Helios ε UV–VIS spectrometer. Total phenolic content is expressed as percent dry weight (soluble and cell-wall-bound phlorotannins) or as percent dry weight per day (exuded phlorotannins).

RESULTS

Method Development

Soluble Phlorotannins. The most efficient extractant was 70% aqueous acetone (Figure 1). Quantitatively, most of the soluble phlorotannins (78% of the total amount in 13 consecutive extracts) were acquired during the first extraction (Figure 2a). After the extraction tubes were allowed to stand in the refrigerator overnight, the amount of phlorotannins extracted (fifth and ninth repeat) was slightly higher than in the preceding extraction. On the basis of this result, we decided to use only four extractions, which could be completed in a single day. These four extractions yield 93.5–95% of the amount of soluble phlorotannins acquired with the 13 consecutive extracts. When analyzing soluble phlorotannins from ecological experiments, we used four extractions.

The amount of soluble phlorotannins from the first study (34 samples, pooled over all data) was 7.99% ($\pm$0.23). After extraction of soluble phlorotannins, before analyzing the insoluble ones, the residue was washed with several extractants in

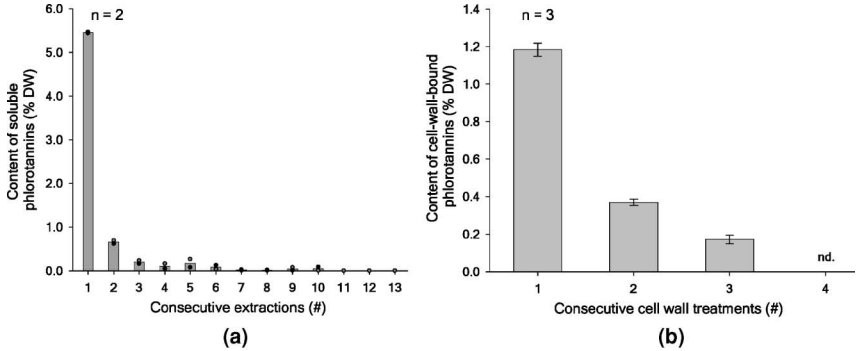

FIG. 2. Acquisition of soluble (values and their mean) (a) and cell-wall-bound (mean ± *SD*) (b) phlorotannins in consecutive extractions. nd. = not detectable.

order to remove all remaining soluble phlorotannins. Extractants were combined and the mean content (±*SE*) of remaining soluble phlorotannins (34 samples, pooled over all data) was 0.36% (±0.03) of dry weight.

Insoluble Phlorotannins. The alkaline degradation of cell-wall-bound phenolics originally included acid addition, i.e., the reduction of pH in the insoluble phenolics liquor aliquot from 13 to 2. The effect of pH on the amount of phlorotannins measured with the Folin–Ciocalteu method was tested with solutions rich in phlorotannins. The effect of this pH range on phlorotannin content is almost linear; the variation between the high and low ends of the range is about 2% in phloroglucinol units (Figure 3). Because soluble phlorotannin extracts were in

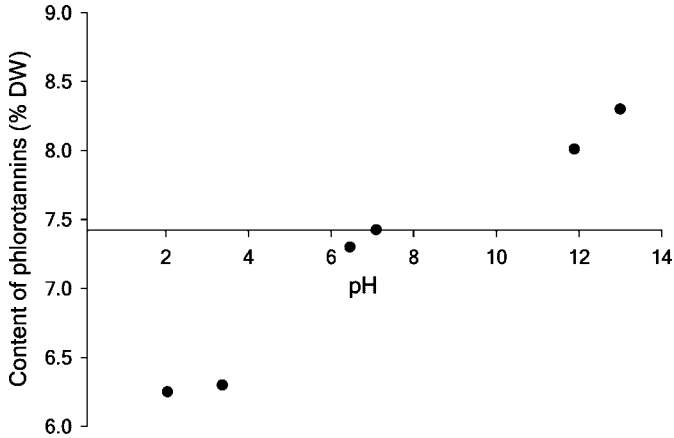

FIG. 3. Effect of pH in the crude extract on quantification of phlorotannins with Folin–Ciocalteu method.

distilled water, i.e., near neutral pH, we added acid to neutralize the solution of phlorotannins that were degraded from the cell wall in alkaline conditions. This allowed a comparison of the quantifications of these two phlorotannin fractions.

The final results were obtained by combining the results of the first three treatments, since in the fourth repeat, they were no longer at a detectable level. Similar to soluble phlorotannins, most of the cell-wall-bound phlorotannins (68%) were released by the first alkaline treatment (Figure 2b).

Experimental Growing Conditions of Algae

Effect of Ambient Nutrients on Soluble and Insoluble Phlorotannins in Growing and Nongrowing Thalli. The amount of phlorotannins in the cytoplasm was significantly higher than in the cell wall (Figure 4, Table 1). The average content of soluble phlorotannins was 8.0 ± 0.2% (mean ± *SE*), while that of insoluble

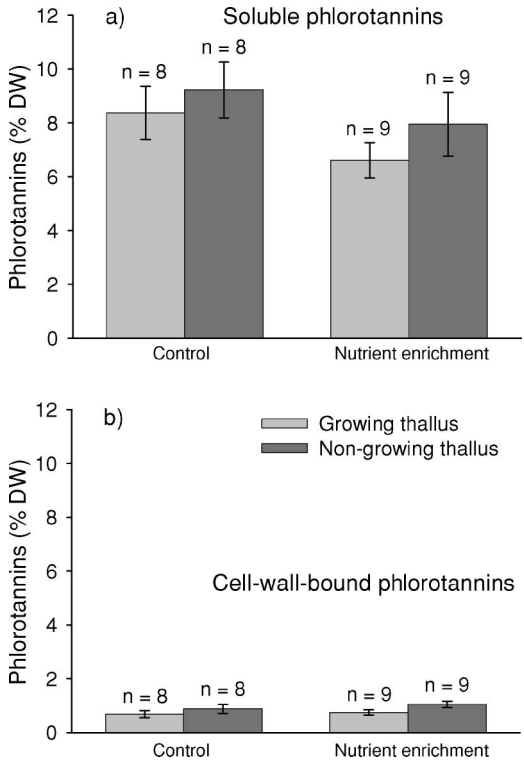

FIG. 4. Mean (±*SE*) content of soluble and cell-wall-bound phlorotannins from growing and nongrowing parts of algae grown in control or nutrient enrichment treatment.

[b] Thallus type × aquaria (nutrient enrichment) as an error term.

phlorotannins was only 0.84 ± 0.03%. The concentrations of both were lower in growing tissue than in nongrowing tissue (Figure 4, Table 1). Nutrient enrichment reduced the content of soluble phlorotannins in both growing and nongrowing thalli (Figure 4, Table 1). However, nutrient enrichment did not have a significant effect on the content of cell-wall-bound phlorotannins in either type of thallus (Figure 4, Table 1). Algal growth rates, measured in terms of numbers of vegetative apices, did not differ among treatments (final number of vegetative apices in control treatment: 212.0 ± 16.1, $N = 9$; in nutrient enhancement treatment: 200.5 ± 15.3, $N = 10$; ANCOVA, initial number of apices as a covariate, nutrient effect: $F_{1,9} = 0.07$, *ns*).

In nongrowing thalli, there was a negative correlation between soluble and cell-wall-bound phlorotannins (Figure 5a), whereas in growing thalli we found no such correlation (Figure 5b). There was a positive correlation between the contents of soluble and cell-wall-bound phlorotannins in both nongrowing and growing thallus (Figures 5c and d).

Effects of Nutrient Shortage and Herbivory on Exudation of Phlorotannins. Algae growing under control conditions with abundant nutrients exuded phlorotannins into seawater at a rate of 0.49×10^{-3} % dry weight × d^{-1}. The amount of exudation varied in three treatments (Figure 6; one-way ANOVA $F_{2,9} = 10.47$, $P < 0.01$). When algae were grazed by *Idotea*, the amount of exuded phlorotannins was over twice that of the other treatments (Tukey *a posteriori* comparisons with other groups; $P < 0.05$). Phlorotannin exudation was not affected by nutrient shortage (Tukey: NS). Soluble phlorotannins did not differ among the treatments in either growing or nongrowing thalli (mean ±*SE* in control, nutrient shortage

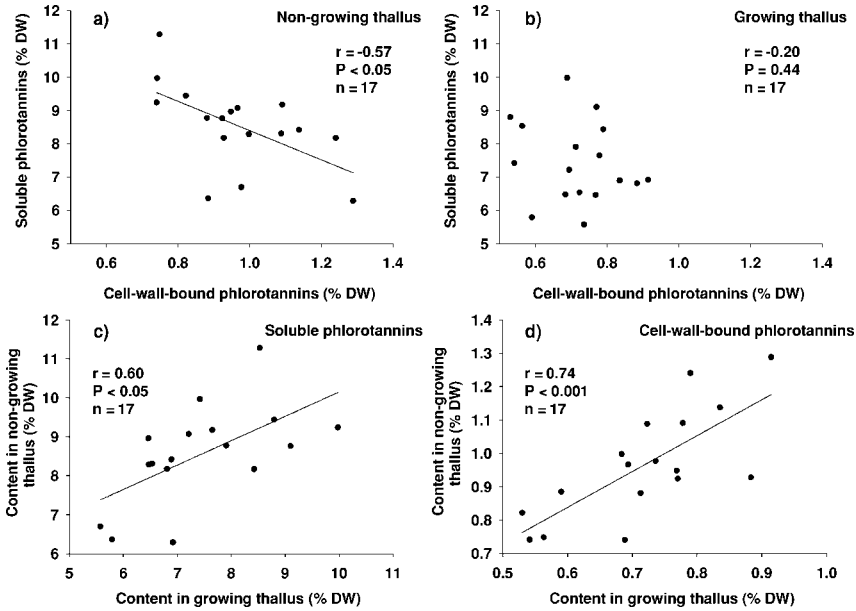

FIG. 5. Correlations between soluble and cell-wall-bound phlorotannins in (a) nongrowing and (b) growing parts of *F. vesiculosus*, and correlations of (c) soluble and (d) cell-wall-bound phlorotannins between nongrowing and growing parts of the thallus.

and grazing treatments, respectively: 8.0 ± 0.53, 7.8 ± 0.61, 7.9 ± 0.29, ANOVA: $F_{2,8} = 0.06$, $P = 0.94$). The difference between nongrowing and growing tissue, on the other hand, was significant (8.5 ± 0.34 and 7.3 ± 0.32, respectively; ANOVA: $F_{1,8} = 8.97$, $P < 0.05$).

DISCUSSION

Alkaline degradation was effective in releasing cell-wall-bound phlorotannins so that they could be quantified; after three consecutive treatments, all detectable phlorotannins were released. Alkaline degradation is also repeatable as judged by the small variance among the three replicates. We cannot, however, exclude the possibility that there may be compounds classifiable as phlorotannins still left in the cell wall due to tight bonding, which were not released by the method. The method used here, however, was more effective than the one of Peng et al. (1991), implying that it is capable of efficiently releasing cell-wall-bound phlorotannins. We also suggest that the washing treatments prior to alkaline degradation minimize the amount of soluble phlorotannins in the fraction of insoluble phlorotannins (see Salminen, 2003).

Both the polarity of the extractant and the solubility of the compounds of interest are crucial for the yield of polyphenols, and extraction of different phenolics from different plant material requires different polarities (Waterman and Mole, 1994; van Beek, 2002). Phenolic compounds are usually most soluble in extractants less polar than water. The general recommendation for extractant selection is a mixture of water and methanol, ethanol, or acetone (Waterman and Mole, 1994).

The extraction efficiency of a solvent generally increased with increasing polarity. An exception to this trend is 70% aqueous acetone—which was the most efficient extractant, better than expected on the basis of its polarity. It was followed in efficiency by water, the most polar extractant among those tested. It may be that acetone increases the total yield by inhibiting interactions between tannin and proteins during extraction (Hagerman, 1988) or even by breaking hydrogen bonds (Porter, 1989). In the analyses of proanthocyanidins, monomers and low-molecular weight compounds can be generally extracted with anhydrous organic solvents, while the addition of water to the extractant increases the solubility of higher molecular weight compounds (Rohr, 2002). We also found a marked difference between extractions with anhydrous organic solvents and solvents containing water. The solvents most commonly used to extract phlorotannins from *F. vesiculosus* have been aqueous mixtures of ethanol and acetone (e.g., Ragan and Glombitza, 1986), and in several studies the efficiencies of different solvents in extracting tannins have been similar to ours (Hagerman, 1988; Keinänen, 1993; Salminen, 2003). The solubility of most phenolic compounds in polar extractant enables for instance the use of LC-ESI-MS, which requires at least semipolar conditions, to analyze polyphenols (Wang and Cole, 1997).

Ecological experiments revealed that in both growing and nongrowing tissue of *F. vesiculosus*, the amount of phlorotannins in soluble form within the cells was greater by approximately an order-of-magnitude than those bound to the cell wall. This is because they are either bound only in very small amounts, or in the process of binding may have been transformed chemically into other compounds that cannot be quantified as phlorotannins. In addition, a part of the phlorotannins passes through the cell wall and is exuded. Although phlorotannins, like other tannins, are terminal products of their synthetic pathway, they can further degrade, for instance, via demethylation, hydration, or oxidation (Strack, 1997). They may bind temporarily to the cell wall, and then undergo turnover or degradation, e.g., into cell-wall building compounds, complexing with alginic acid. Based on the small amount of phlorotannins found in the cell wall, they seem to play a minor role in cell-wall construction as such; if, however, degradation regularly occurs in the cell wall, they may function as important transitional compounds in cell-wall construction, as suggested by Arnold and Targett (2003).

In higher plants, it is suggested that phenolic compounds are esterified or etherified into cell-wall components (Lozovaya et al., 1999), while phlorotannins, due to their structure, may become involved in the cell wall via esterification or a hemiacetal reaction. One suggested function may be in cell-wall hardening (Schoenwaelder and Wiencke, 2000). Thallus toughness may function as a defense against herbivory (reviewed in Lucas et al., 2000), but it may also be part of the necessary adaptation to life in the intertidal littoral zone, where on the one hand wave exposure, and on the other periodical desiccation set demands on the structural strength of the thallus.

The lack of correlation between soluble and cell-wall-bound phlorotannins in growing parts of algae may be an indication of active phlorotannin production. In growing parts, phlorotannins are produced intensely, probably in the cytoplasm or chloroplasts like other phenolic compounds, and subsequently stored in physodes (Schoenwalder, 2002). Although phlorotannins are both exuded and bound to the cell wall, the high rate of production may explain the excess of soluble phlorotannins.

We assume that phlorotannin production does not stop as the thallus gets older. Rather, production decreases because of the thickening of the thallus and the consequent decrease in photosynthesis. A trade-off develops when phlorotannins are bound to the cell wall and soluble phlorotannins are no longer effectively replenished by synthesis. However, it is worth noting that the levels of both soluble and cell-wall-bound phlorotannins remain higher than those in actively growing parts. On the other hand, phlorotannins can differ qualitatively at different stages of age: in young thallus, they may be rather short oligomeric forms. As the thallus ages, they may polymerize into longer and more complex forms, which may be more difficult to degrade or exude through the cell wall. Disappearance of soluble phlorotannins from cytoplasm happens rather fast, which is primarily explained

with excretion and incorporation into the cell wall (Arnold and Targett, 2000). Detailed information, however, awaits the development of a suitable chromatographic method for separating individual phlorotannin oligomers and polymers.

Nutrient enrichment had an effect only on soluble phlorotannins, indicating that phlorotannins bound to the cell wall may be relatively stable with respect to environmental variation. A constant and minor amount of phlorotannins appear to be bound to the cell wall, regardless of the amount produced, which varies with environmental conditions. Nutrient enrichment decreased the amount of soluble phlorotannins. While such a nutrient effect is often explained by an increase in growth at the expense of allocation to the production of soluble phlorotannins, this was not the case in our experiment, since growth rate was not affected. In through-flow mesocosms, nutrient enrichment commonly leads to increased growth of epibiota (Honkanen and Jormalainen, unpublished data; Jormalainen et al., 2003); this, in turn, causes shading and may thereby explain the decrease in phlorotannin production. As such, the dynamic behavior of soluble phlorotannins together with the relative stability of cell-wall-bound phlorotannins supports an approach that uses soluble phlorotannins as the basis for studying phlorotannin plasticity.

There was considerable variability among individuals in the contents of both soluble and cell-wall-bound phlorotannins; some individuals have a concentration only half that in others. Variation in the contents of soluble phlorotannins is to a large extent genetic (Jormalainen et al., 2003), but variation in cell-wall-bound phlorotannins has never been measured. Since soluble and cell-wall-bound phlorotannins were not positively correlated, higher production does not necessarily mean a thicker cell wall. The variation in the contents of cell-wall-bound phlorotannins seems to be due to different causes and it may be related to genetic or phenotypic variation in cell-wall characteristics. When there was a large amount of phlorotannins—soluble or cell-wall-bound—in growing parts, there was also a large amount in nongrowing parts.

In all of our treatments, we found exudation of phlorotannins into the water. The amount of exudation was not affected by nutrient shortage. Since a shortage of nutrients may slow the growth rate and increase the amount of secondary metabolites (Herms and Mattson, 1992) our result suggests that a diminished need of phlorotannins for cell-wall construction would not lead to an increase in their exudation. The amount of exudation may be relatively independent of the growth rate, for instance if exudation also takes place in the old, nongrowing thallus that comprises a major part of the algal biomass. However, exudation did increase compared to the other treatments when the alga was grazed by *Idotea*. There are two possible explanations for the increase. The feeding process may induce an indirect defense in algae, i.e., increased excretion of phlorotannins into the water. By indirect defenses, plants reduce losses to herbivory by facilitating the enemies of herbivores (Karban and Baldwin, 1997). There is evidence from terrestrial plant–herbivore systems for indirect defenses based on volatile plant metabolites

(reviewed in Sabelis et al., 1999; Dicke and van Loon, 2000; Dicke et al., 2003). Alternatively, phlorotannins end up in the water without any induction in the alga, as a consequence of the breaking of the surface, chewing action, or digestion of *Idotea*. In both cases, the consequence of herbivory is an increase in exudation, and it is possible that predators or other plants use exuded phlorotannins as a signal of the presence of herbivores. If the defense were induced, however, we would expect an increase in phlorotannin production, and also in the level of soluble phlorotannins found in the algae. The content of soluble phlorotannins found in both growing and nongrowing parts of the alga, however, showed no change, thus supporting the latter explanation.

In summary, the quantification of phlorotannins from *F. vesiculosus* revealed only a small amount bound to the cell wall, while the bulk was found in soluble form in the cytoplasm. This suggests that the chemical role of phlorotannins is mainly secondary; in other words, there is no evidence for a role as primary metabolites, but they may have adaptive functions in interactions with other organisms or the abiotic environment. Phlorotannins, after degradation, may become part of the cell wall, and thereby have a function as primary metabolites, but at least quantitatively this is minimal. If, however, degradation to other, nonphenolic compounds occurs commonly in binding to the cell wall, this conclusion needs reassessment. Clarification of the biosynthetic pathway of phlorotannins, the enzyme systems involved, and the turnover and degradation processes is needed before our understanding of the functional role of these compounds is complete.

Acknowledgments—We thank Anne Hemmi, Nina Heikkilä, Outi Vesakoski, and Johanna Oja for help in conducting the experiment on the effects of ambient nutrients, and the Archipelago Research Institute for providing facilities. Jenni Kunttu helped in performing the tests with different extractants. The study was financed by the Academy of Finland (Projects 44086 and 53832)

ROLE OF HOST PLANT VOLATILES IN MATE LOCATION FOR THREE SPECIES OF LONGHORNED BEETLES

MATTHEW D. GINZEL[1] and LAWRENCE M. HANKS*

Department of Entomology, University of Illinois at Urbana-Champaign, Urbana, IL 61801

(Received August 2, 2004; accepted August 31, 2004)

Abstract—Stressed woody plants represent an ephemeral and unpredictable resource for larvae of some species of longhorned beetles (Coleoptera: Cerambycidae) because prime subcortical tissues are rapidly degraded by a guild of xylophagous competitors. Selection favors efficient mechanisms of host and mate location to expedite colonization of hosts by larvae. Based on previous research, we hypothesize that mate location in some species of the subfamily Cerambycinae involves three sequential behavioral stages: (1) both sexes are attracted to larval hosts by plant volatiles; (2) males attract females over shorter distances with pheromones; and (3) males recognize females by contact pheromones in their epicuticular wax layer. We already have evidence of second-stage and third-stage behaviors in three species in this subfamily whose xylophagous larvae feed in hardwood trees: *Xylotrechus colonus*, *Megacyllene caryae*, and *Neoclytus mucronatus mucronatus*. In this report, we evaluate the first behavioral stage of mate location behavior (i.e., independent response of both sexes to host plant volatiles) for the same three species. Supporting our hypothesis, both males and females responded to volatiles emanating from hickory logs in Y-tube olfactometer bioassays.

Key Words—Host location, mating behavior, pheromone, Cerambycidae, *Xylotrechus, Megacyllene*, *Neoclytus*.

INTRODUCTION

A better understanding of host and mate location is critical for developing management strategies of longhorned beetles (Coleoptera: Cerambycidae), among the most important pests of woody plants in natural and managed systems world wide

*To whom correspondence should be addressed. E-mail: hanks@life.uiuc.edu
[1]Current address: Department of Biochemistry and Molecular Biology, University of Nevada, Reno, Nevada 89557, USA.

(Hanks, 1999). Disparate studies of many species in this family have suggested that the sexes are brought together by a mutual attraction to the larval host rather than by long-range pheromones (reviewed by Hanks, 1999). Recent research on several species in the subfamily Cerambycinae, however, has revealed that males produce pheromones that operate over short or moderate distances (reviewed by Lacey et al., 2004). The pheromones are comprised of single or multiple compounds based on a common structural motif: straight chains of six, eight, or ten carbons with hydroxyl or carbonyl groups at C_2 and C_3.

We have documented the first aggregation pheromone in a longhorned beetle, that of the cerambycine species *Neoclytus acuminatus acuminatus* (F.) (Lacey et al., 2004), and the structure of the single active component conforms to this structural motif. Nevertheless, both sexes of *N. a. acuminatus* also are attracted in the field by volatiles emanating from larval hosts, dying hardwoods (Lacey et al., 2004). Adults of other cerambycine species also respond to plant volatiles (e.g., Hanks et al., 1996; Fettköther et al., 2000), and males use their antennae to recognize females by contact chemoreception of cuticular hydrocarbons (Ginzel and Hanks, 2003; Ginzel et al., 2003). We, therefore, hypothesize that mate location and recognition in cerambycine species involves three sequential behavioral stages: (1) both sexes are independently attracted to larval hosts by plant volatiles; (2) males attract females over shorter distances with pheromones; and (3) males recognize females by contact pheromones.

In this paper, we evaluate the first stage of mate location in three species of cerambycines by testing the hypothesis that adult males and females are independently attracted to volatiles produced by larval hosts. We have evidence of second-stage behaviors in two species: male *Xylotrechus colonus* F. and *Megacyllene caryae* (Gahan) produce compounds consistent with the pheromone structural motif, and we are evaluating their activity (E. S. Lacey, J. G. Millar, L. M. Hanks, unpublished data). We predict that males of the third species, *Neoclytus mucronatus mucronatus* (F.), also produce pheromones because it is a congener of *N. a. acuminatus* and the males display a "perching" behavior that is associated with release of pheromones in that species (Lacey et al., 2004). We have documented the third-stage behaviors for all three species: males use their antennae to recognize females by contact chemoreception (Ginzel and Hanks, 2003; Ginzel et al., 2003).

All three study species are native to eastern North America and their larvae commonly feed in stressed or moribund hickories (Linsley, 1964). Both sexes of all three species congregate on freshly cut logs of hickory in the area of the study (Ginzel et al., 2003; unpub. data). This behavior could be cued by host plant volatiles or entirely by long-range pheromones. Larvae of *X. colonus* develop in many species of hardwoods, and the crepuscular adults are active from May to September (Linsley, 1964; Ginzel et al., 2003). Larval hosts of *M. caryae* include several species of hardwoods, but especially hickory, and adults are diurnal, aposematically-colored wasp mimics that are active from April to June

(Linsley, 1964). Larvae of *N. m. mucronatus* develop in hickories, and the adults are crepuscular and nocturnal and active in June and July (Linsley, 1964).

METHODS AND MATERIALS

We collected adult beetles of all three species from felled shagbark hickories, *Carya glabra* (Mill) Sweet, or reared them from the logs. Adult *X. colonus* were collected at dusk from trees felled in May and June 1998 at Allerton Park, Piatt County, IL. Adult *M. caryae* emerged in March–April 2001 from logs of a tree felled in Athens County, OH, in Spring 2000. Adult *N. m. mucronatus* emerged in May 2003 from logs of a tree felled at Allerton Park in June 2002.

We housed beetles individually in the laboratory in cylindrical cages of aluminum window screen (9 cm diam, 12 cm tall) with clean 9-cm glass Petri dishes at top and bottom. Every 2–3 days we provided fresh 10% sucrose solution in a glass vial into which was inserted a cotton dental roll (Patterson Dental, South Edina, MN). Reared beetles could have mated with a few individuals before they were caged, but the mating history of field-captured beetles was unknown. Beetles used in bioassays had been isolated in cages for at least 24 hr and were active.

We measured the response of walking adult beetles to volatiles from logs of shagbark hickory with a glass Y-tube olfactometer (6 cm diam, main tube 26 cm long, arm length 22 cm, angle between arms 70) positioned on a table with the arms directed toward north-facing windows. Bioassays were conducted under laboratory conditions and natural light during the normal activity periods of the species: late afternoon and evening (*X. colonus* and *N. mucronatus*) or morning (*M. caryae*). To bioassay *X. colonus*, we placed a freshly cut hickory log (~15 cm diam, 30 cm long) in a Plexiglas® box (30 × 30 × 120 cm tall) with the open bottom sealed by standing it in ~10 cm of water. Air entered the box through a hose connector at the top, and air was drawn from the box through another hose connector on the opposite side of the top that was connected with 1 cm i.d. Teflon® tubing to one arm of the Y-tube. An empty box of identical design was connected to the other arm of the Y-tube as a control. To bioassay *M. caryae* and *N. mucronatus*, we placed a hickory log (~8 cm diam, 15 cm long) in a plastic cylinder (10 cm diam, 20 cm long) sealed at one end with aluminum foil with a ~3 cm diam hole to allow air to enter and the other end connected with Teflon® tubing to one arm of the Y-tube. An identical cylinder containing moistened cotton dental rolls served as a control. Air was drawn through these systems (~1.7 l/min) with a 1 hp vacuum cleaner (Shop-vac®, Williamsport, PA) on a variable power supply, and entering air was purified with ~450 g of activated charcoal.

Odor sources were randomized between arms of the olfactometer for each bioassay to control for location effects, and the olfactometer was rinsed with acetone and air dried between trials. A beetle was released in the olfactometer at the downwind end of the main tube and responded by walking at least

TABLE 1. PERCENTAGES OF FEMALE AND MALE LONGHORN BEETLES OF THREE SPECIES THAT RESPONDED IN AN OLFACTOMETER TO VOLATILES EMANATING FROM HICKORY LOGS VERSUS A BLANK CONTROL

Species	Sex	N	# Responding	% Responding		χ^2statistic (P)
				Hickory	Control	
Xylotrechus colonus	Female	36	30	77	23	8.53 ($P < 0.01$)
	Male	34	30	80	20	10.8 ($P < 0.01$)
Megacyllene caryae	Female	36	30	80	20	10.8 ($P < 0.01$)
	Male	40	30	73	27	6.53 ($P < 0.01$)
Neoclytus m. mucronatus	Female	25	25	80	20	9.0 ($P < 0.01$)
	Male	30	30	83	27	13.3 ($P < 0.001$)

16 cm down one of the arms. Beetles that did not enter either arm of the olfactometer within 15 min were recorded as "no response." We tested 25–40 males and females of each species and compared percentages of beetles responding to hickory volatiles with percentages responding to the control with a χ^2 goodness-of-fit test.

RESULTS AND DISCUSSION

Adult beetles of all three species showed a significant response to plant volatiles, with an average of ~80% of each sex responding to volatiles produced by hickory logs (Table 1). These findings support the hypothesis that the sexes are brought together by a mutual attraction to volatiles of the larval host. These data also lend support to our proposed three-stage behavioral sequence of mate location.

Stressed and dying host trees become available to wood borers sporadically and unpredictably when they are damaged or weakened by such environmental factors as wind, lightning strike, fire, and water deficit (reviewed by Hanks, 1999). Their quality as hosts declines rapidly, however, as subcortical tissues are degraded by xylophagous competitors, including buprestid and scolytid beetles, as well as by other cerambycid species. Thus, the quality of larval nutrition depends on the timing of colonization by larvae, and selection favors behaviors in adults that expedite that process, including mutual attraction of males and females to the larval host, and brief copulation followed immediately by oviposition. Adults of other species of the Cerambycinae that require stressed hardwood hosts show similar reproductive behaviors, presumably due to convergent selective pressures (Hanks, 1999).

Acknowledgments—We thank the University of Illinois at Urbana-Champaign Committee on Natural Areas and David Bowman for permitting research at Allerton Park, Kelli Johnson and Emerson

Lacey for beetle specimens, and Ann Ray, Kamryn Rinkenberger, and Eric Jackson for help with bioassays and beetle colonies. This research was in partial fulfillment of a Ph.D. degree for MDG from the University of Illinois at Urbana-Champaign and was supported by grant AG-FS01JV11231300088 from the US Forest Service.

CALL FOR PAPERS

The Journal of Chemical Ecology will devote a special issue to Chemical Defense. The issue will contain invited reviews and contributed papers. Manuscripts should be submitted online by April 1, 2005 and identified as potential submissions for this special issue. The anticipated publication date is October, 2005. Please address all queries concerning this issue to the Editor-in-Chief at jce@chuma1.cas.usf.edu.

BIOMIMETIC MEASUREMENT OF ALLELOCHEMICAL DYNAMICS IN THE RHIZOSPHERE

JEFFREY D. WEIDENHAMER[1,*]

[1]*Department of Chemistry, Ashland University, Ashland, Ohio 44805, USA*

(Received July 20, 2004; accepted October 12, 2004)

Abstract—Polydimethylsiloxane (PDMS) materials were used to quantify levels of the photosynthesis inhibitor sorgoleone in the undisturbed rhizosphere of sorghum plants. The materials used included stir bars coated with PDMS (stir bar sorptive extraction), technical grade optical fiber coated with a thin film of PDMS (matrix-solid phase microextraction), and PDMS tubing. PDMS tubing retained the most sorgoleone. As analyzed by high performance liquid chromatography, amounts of sorgoleone retained on the PDMS materials increased with time. Other materials tested (polyurethane foam plugs, C18 and Tenax disks, and resin capsules) proved less suitable, as they were subject to sometimes extensive penetration by fine root hairs. These results demonstrate the potential for PDMS-based materials to monitor the release of allelochemicals in the undisturbed rhizosphere of allelopathic plants. Unlike extraction procedures that recover all available compounds present in the soil, PDMS functions in a manner more analogous to plant roots in sorbing compounds from soil solution or root exudates. Information on chemical dynamics in the rhizosphere is crucial for evaluating specific hypotheses of allelopathic effects, understanding allelopathic mechanisms, and assessing the importance of allelopathic processes in plant communities.

Key Words—Methods, *Sorghum bicolor x Sorghum sudanense*, sorgoleone, rhizosphere chemistry, polydimethylsiloxane, stir bar sorptive extraction, matrix-SPME, biomimetic extraction, allelopathy.

INTRODUCTION

The knowledge of the chemical basis of allelopathy has advanced greatly since Putnam and Tang's (1986) observation that "chemistry has been the Achilles' heel of allelopathy." Several allelochemicals with toxicity rivaling that of synthetic herbicides are known, including α-terthienyl (Campbell et al., 1982), artemisinin

* To whom correspondence should be addressed. E-mail: jweiden@ashland.edu

(Duke et al., 1987), and sorgoleone (Einhellig and Souza, 1992; Nimbal et al., 1996). α-Terthienyl has been found in the rhizosphere beneath the source plants (Campbell et al., 1982; Tang et al., 1987; Martin and Weidenhamer, 1995; Thijs, 1999), and sorgoleone exudation by sorghum roots has been the subject of numerous investigations (Einhellig and Souza, 1992; Czarnota et al., 2001, 2003).

Unfortunately, analysis of rhizosphere chemistry has lagged behind advances in natural product characterization. The general lack of understanding of the qualitative and quantitative dynamics of allelochemicals in the rhizosphere is perhaps the present Achilles' heel for research in this field (Weidenhamer, 1996). The need for such information has been emphasized repeatedly. Fuerst and Putnam (1983) considered knowledge of the amount of toxin released to the environment and taken up by the target plant crucial to proving a hypothesis of allelopathy. Radosevich and Holt (1984) concurred, arguing "research in this area must be designed specifically to prove that a toxic substance is produced and that it accumulates or persists long enough at concentrations in the environment sufficient to inhibit development of other plants." Williamson and Weidenhamer (1990) went a step further, arguing that knowledge of concentrations alone is not enough because soil concentrations reflect the current balance of input vs. output rates for a compound. Plant roots compete with both microorganisms and other processes to remove allelochemicals from soil solution, and the rate at which allelochemical concentrations are replenished will determine how much is available for plant uptake. Allelochemical flux rates are, thus, likely to be a key component of toxicity.

Blum et al. (1999) assert that the research focus in studies of allelopathy needs to shift to the soil, and "specifically the barrier of the rhizosphere through which allelochemicals must pass." In a recent review of rhizosphere chemistry, Bertin et al. (2003) note that root exudates vary greatly in both chemical composition and biological effects, and argue for the development of techniques that will deepen our understanding of the chemical and biological dynamics of the rhizosphere. The results of Tang et al. (1987) and Weidenhamer and Romeo (2004) underscore these points. Tang et al. (1987) found much higher concentrations of 5-(4-hydroxy-1-butynyl)-2,2-bithienyl (BBT-OH) relative to other thiophenes in the rhizosphere than in roots of *Tagetes patula*, and concluded that analysis of the rhizosphere was more important than analyses of plant tissues for studies of allelopathy. Weidenhamer and Romeo (2004) showed that soil microorganisms rapidly convert the hydroquinone glycoside arbutin to hydroquinone and then to benzoquinone. The latter two compounds are suspected to be the allelopathic agents of the Florida scrub perennial *Polygonella myriophylla*, but they do not occur in free form in the plant itself. The question, then, is what methods can be used to gain insight to the chemical dynamics of the rhizosphere.

Tang and Young (1982) developed a method to analyze compounds produced by plant root systems. Plants are grown in open-bottomed pots in sand, and water and/or nutrient solutions circulate through a trap containing XAD-4

resin. Hydrophobic compounds are eluted from the XAD-4 resin with methanol and identified by standard methods. Tang (1986) pointed out that with typical soil extractions, it is impossible to be certain that all fine roots have been removed from soil beneath potentially allelopathic plants prior to analyses, and, thus, one cannot be sure that the compounds extracted are actually from the soil rather than from root fragments. The Tang and Young method has the virtue of monitoring allelochemicals in root exudates, and has been successfully employed in the investigation of root exudates of several species (Brown et al., 1983; Stevens and Tang, 1986; Tang and Zhang, 1986). Müller et al. (1993) adapted the method to preparative-scale by using a 250 g bed of XAD-4 resin. However, for the quantitative measurement of allelochemical release rates over time, the Tang and Young technique has serious disadvantages. First, the ecological realism of the technique is limited by the requirement to use sand as the growing medium and the abnormally high flow of water through the root zone. Second, and perhaps more importantly, it is not applicable to field situations.

Environmental researchers have devised a number of approaches to attack a similar problem—the qualitative and quantitative measurement of bioavailable concentrations of hydrophobic organic pollutants in surface and ground water and sediment. Several of these methods offer two key advantages over the trapping technique of Tang and Young (1982): simplicity, and potential adaptability to field monitoring.

Materials used in the study of anthropogenic pollutants include adsorbents such as Tenax-TA (Yeom et al., 1996), octadecyl-modified (C18) silica disks (Verhaar et al., 1995; Tang et al., 1999; Krauss and Wilcke, 2001), polyurethane foam (PUF, Farag and El-Shahawi, 1991), and various encapsulated carbonaceous resins (Johns and Skogley, 1994; Morse et al., 2000). The polymer polydimethylsiloxane (PDMS) has also found many uses in environmental analysis. In contrast to *adsorptive* materials in which analytes adsorb to the surface, PDMS is classified as a *sorptive* material in which analytes actually dissolve into the PDMS phase (Baltussen et al., 2002). PDMS is used in a number of forms. In solid phase microextraction (SPME), a fiber coated with a sorptive or adsorptive phase, often PDMS, is used to extract volatile organics from water or headspace. These are then analyzed by gas chromatography (GC) after thermal desorption, or by high performance liquid chromatography (HPLC) after liquid desorption (Arthur and Pawliszyn, 1990). A wide variety of fiber coatings and applications have been developed (Pawliszyn, 1999). However, the fragility of the fiber limits its utility in soil analysis to the sampling of volatiles in pore spaces. A recently developed alternative to SPME with potential applications to rhizosphere analysis is matrix-SPME (Mayer et al., 2000). In this technique, a technical grade optical fiber coated with a thin film of PDMS was used to extract PCBs and other persistent and bioaccumulative pollutants from sediment. The low cost of optical fiber allows for disposable usage, which is not practical with regular SPME because of the

high cost of the individual fibers. Stir bar sorptive extraction (SBSE) is a recently developed method in which a stir bar is coated with a layer of PDMS (Baltussen et al., 1999). After concentration of the analytes on the stir bar, it is desorbed with solvent or thermally. The larger volume of the PDMS phase compared to SPME allows for higher recovery and as much as a 500-fold increase in sensitivity with SBSE (Baltussen et al., 1999). Reported applications include the extraction of water (Baltussen et al., 1999; Popp et al., 2003), direct analysis of fruit by insertion into strawberries (Kreck et al., 2001), and analysis of volatiles emitted by living plants (Vercammen et al., 2000).

The objective of this study was to evaluate the ability of several materials to analyze the undisturbed rhizosphere of living plants. The materials compared were: (a) SBSE (PDMS coated stir bar); (b) matrix-SPME using PDMS coated optical fibers; (c) PDMS tubing; (d) Tenax TA disks; (e) C18 disks; (f) PUF plugs; and (g) capsules containing XAD-7 or Ambersorb 563 resin. Sorghum was chosen as the plant species for this study. The highly phytotoxic sorgoleone is known to be the principal component of the root exudate. Varieties of sorghum that produce greater or lesser quantities of sorgoleone are known (Nimbal et al., 1996). Furthermore, root exudates can be readily analyzed for sorgoleone content by HPLC (Czarnota et al., 2003).

METHODS AND MATERIALS

Chemicals. All chemicals used were reagent grade. Chromatography solvents were HPLC grade.

Sorgoleone Isolation and Purification. The isolation and purification procedure followed that of Rimando et al. (1998). Seeds of *Sorghum bicolor* (L.) Moench cv. Bundle King, a hybrid forage sorghum (Browning Seed Co., Plainview, TX), were sown in a flat containing a sandy loam soil. Seeds were laid on a fiberglass screen and covered with approximately 1 cm soil. After 20 d, the roots beneath the fiberglass screen were cut, washed with water to remove adhering soil, and blotted dry. Roots were extracted twice by covering with methylene chloride (0.25% acetic acid, v/v) for 2 min. The resulting extract was dried with granular sodium sulfate, filtered, and concentrated by rotary evaporation. A crude extract of 41 mg was obtained from 103 g (fresh mass) roots. Sorgoleone was purified by preparative thin layer chromatography on silica gel using hexane/isopropanol (90:10) as the developing solvent. The UV spectrum, TLC, and HPLC profiles of the purified material matched those reported in the literature (Czarnota et al., 2003). This purification procedure does not eliminate several minor analogs of sorgoleone that have been reported (Kagan et al., 2003) but these have low concentrations. Sorghum root exudates contain 85–90% pure sorgoleone by weight (Nimbal et al., 1996).

Sorghum Growth Conditions. Approximately 20 seeds of *Sorghum bicolor x sudanense* cv. High Sugar, an experimental sorghum–sudangrass hybrid (Browning Seed Co., Plainview, TX), were planted in Spinks soil (a sandy, mixed mesic Lamellic Hapludalf) in 3.8 l polyethylene nursery pots. This variety was chosen on the basis of a preliminary screening study of sorghum and sorghum–sudangrass hybrid cultivars in which it produced the greatest quantities of sorgoleone. The pot bottom was covered with fiberglass screen and a 2.5-cm layer of gravel to hold in the soil.

Plants were grown in a greenhouse during January–April 2004. In general, daytime temperatures ranged from 21°C to 30°C and nighttime temperatures from 14°C to 18°C. Temperature extremes were 13°C and 43°C. Pots were laid out in three replicates in a randomized block design. Pots were thinned to a density of four seedlings 11 days after planting (DAP). Plants were watered as needed. Natural sunlight was supplemented by 3 hr of mixed metal halide and sodium vapor lighting beginning 28 DAP. Plants received 300 ml of a general purpose fertilizer solution (Expert gardener®all purpose plant food, 15-30-15 plus B, Cu, Fe, Mn, Mo, and Zn) at 25, 33, and 47 DAP to supplement soil nutrients. Plants were harvested and extractant materials removed and analyzed (see below) on 29, 55, and 88 DAP. Fresh shoot and root biomass of all pots were measured at harvest.

Rhizosphere Adsorbents and Sorbents. Suppliers, conditioning procedures, placement in soil, and extraction methods are summarized in Table 1. A different extractant was buried in each pot, and extractants were removed only at harvest. There were three replicates of each treatment per harvest, and extractants buried in unplanted pots served as background controls. Once prepared, all extracts were transferred to autosampler vials. For extracts of 350 μl volume or less, microvial inserts were used. All samples were analyzed in duplicate.

HPLC Analysis. HPLC procedures followed those of Czarnota et al. (2003). The HPLC system included a Spectra Physics Model 8800 ternary gradient pump, manual Rheodyne injection valve, Econosphere (Alltech Associates) octadecylsilyl (C18) column (250 $\times$ 4 mm^2, 5 μm particle size), and a Dionex variable wavelength detector set at 280 nm. A Varian 4270 integrator was used for peak integration and retention time measurements. Compounds were eluted at 1.75 ml/min with a gradient of (A) water containing 2.5% (v/v) acetic acid and (B) acetonitrile. Gradient conditions were: 0–15 min, 45% A/55% B isocratic; 15–22 min 55–100% B linear gradient, 22–25 min 100% B, 25–26 min 100–55% B, 26–30 min 45% A/55% B equilibration. The injection volume was 25 μl.

Samples from the final harvest were analyzed with the same column on an Agilent diode array HPLC that included a model 1050 quaternary pump, model 1050 autosampler, and model 1100 diode array detector. Samples were analyzed isocratically (45% A/55% B) at a flow rate of 1 ml/min. The monitoring wavelength was 280 nm and injection volume was 50 μl.

TABLE 1. SUMMARY OF CONDITIONING PROCEDURES, PLACEMENT IN SOIL AND EXTRACTION METHODS FOR ADSORBENT AND SORBENT MATERIALS SELECTED FOR THIS STUDY

Material	Supplier	Conditioning	Soil placement	Extraction
Tenax-TA membranes (47 mm)	Alltech associates (Deerfield, IL)	Soaked in excess methanol 5 min (4×), followed by water rinse (4×)	5 cm depth over fiberglass screen	Extracted in 5 ml acetonitrile overnight. Evaporated to dryness and taken up in 500 μl acetonitrile
Empore C18 disks (47 mm)	3 M filtration products (St. Paul, MN)	Rinsed with 2 × 10 ml methanol, 6 × 10 ml water	5 cm depth over fiberglass screen	Same as Tenax-TA
Polyurethane foam plugs, (4.5 cm hr × 3.5 cm d)	Fisher scientific (Fairlawn, NJ)	Successive 24 hr, Soxhlet extraction in acetone and methanol. Stored dry in sealed jar	Centered in pot at 5 cm depth	Same as Tenax-TA, but with 25 ml acetonitrile
Envi-2 capsules, 2 cm diam, containing Ambersorb 563 non-ionic carbonaceous resin, 1100 m^2 surface area	Unibest (Bozeman, MT)	Washed with shaking in methanol, acetonitrile, followed by five successive rinses with water	Centered in pot at 5 cm depth	Same as Tenax-TA, but with 7 ml acetonitrile
Envi-2 capsules, 2 cm diam, containing XAD-7 resin, approx. 1100 m^2 surface area	Unibest (Bozeman, MT)	Washed with shaking in methanol, acetonitrile, followed by five successive rinses with water	Centered in pot at 5 cm depth	Same as Tenax-TA, but with 7 ml acetonitrile
PDMS-coated stir bar (SBSE, Gerstel "Twister," 10 mm)	Gerstel, Inc. (Baltimore, MD)	None for first use	Placed at 5 cm depth over fiberglass screen with Teflon-coated magnetic stir bar	250 μl acetonitrile, 30 min
PDMS tubing (Silastic, 0.30 mm ID × 0.64 mm OD)	Dow corning, Inc. (Midland, MI)	Soaked in acetonitrile 30 min, washed with water	Four 10 cm strands placed at 5 cm depth over fiberglass screen	500 μl acetonitrile, 30 min
PDMS-coated optical fiber (Matrix-SPME, core diamter 200 μm, PDMS coating 15 μm)	Fiberguide industries (Stirling, NJ)	Nylon coating removed by dipping in hot (180°C) propylene glycol. Cut in 10 cm lengths and soaked in acetonitrile 30 min, washed with water	Four fibers inserted into center of pots to depth of 9 cm, leaving 1 cm exposed for later removal	350 μl acetonitrile, 30 min

HPLC-MS Analysis. To confirm the presence of sorgoleone in the rhizosphere extracts, one sample and standard were analyzed by HPLC-Mass Spectrometry (MS). Experiments were performed on a Micromass LC-TOF(tm) II (Micromass, Wythenshawe, UK) mass spectrometer equipped with an orthogonal electrospray source (Z-spray) operated in positive ion mode. Sodium iodide was used for mass calibration for a calibration range of m/z 100–2000. Optimal ESI conditions were: capillary voltage 3000 V, source temperature 110°C, and a cone voltage of 55 V. The ESI gas was nitrogen. All ions transmitted into the pusher region of the TOF analyzer were scanned over m/z (100–500) with a 1 sec integration time. Data were acquired in continuum mode during the LC run.

The HPLC system consisted of a Waters Alliance 2690 Separations Module (Waters, Milford, MA). A Supelco (St. Louis, MO) Discovery C18 HPLC Column ($250 \times 4.6\,\text{mm}^2$, 5 μm particle size) was used for the separation. A 100 ml injection was made of the samples. The mobile phase [45% water containing 2.5% (v/v) acetic acid and 55% acetonitrile] flow rate was maintained at 1 ml/min and was split postcolumn by using a microsplitter valve (Upchurch Scientific, Oak Harbor, WA) to ~20 μl/min for introduction to the ESI source.

RESULTS

Sorgoleone quantitation was linear (r^2 values 0.97–0.99) over a range of 0.1–50 mg/l^{-1} for both peak area vs. concentration and log area vs. log concentration. The approximate detection limit was 0.25 ng per injection (corresponding to a concentration of 0.01 mg/l^{-1} on the HPLC system used for the first two harvests). Chromatograms of both a standard and SBSE sample are presented in Figure 1.

The non-PDMS materials proved to be problematic to work with. The capsules, foam plugs, and disks were all penetrated by sorghum roots to greater or lesser extent. Analyses of these materials are, therefore, suspect, given that any sorgoleone recovered might be from root fragments that could not be removed rather than from sorgoleone adsorbed from the rhizosphere by these extractants. Also, several blanks showed contaminant peaks that overlapped sorgoleone. For these reasons, results for the analysis of the non-PDMS materials are not presented. However, PUF plugs as well as the C18 and Tenax disks all showed reddish-purple stains suggestive of sorgoleone.

All three PDMS-based materials trapped measurable amounts of sorgoleone that increased with time (Table 2, Figure 2). Sorgoleone in the samples was identified on the basis of its retention time compared to the known standard. Where UV spectra of peaks could be obtained (diode array HPLC, final harvest), these were consistent with sorgoleone. LC–MS analysis of a sorgoleone standard and one of the SBSE samples from the first harvest confirmed the presence of sorgoleone (m/z 359) in the rhizosphere extract. The PDMS tubing gave the highest recovery of the three PDMS materials used, and the amounts recovered

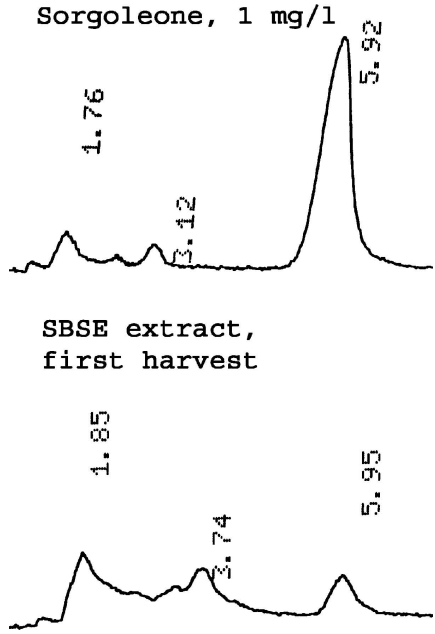

FIG. 1. HPLC chromatograms of sorgoleone standard (1 mg/l^{-1}, injection corresponds to 25 ng sorgoleone) and SBSE rhizosphere extract from the first harvest (determined to have concentration of 0.17 mg/l^{-1}). The peak in this sample was confirmed as sorgoleone by LC–MS.

correlate well with sorghum plant growth over the 88 days of the experiment (Figure 3).

DISCUSSION

These results demonstrate PDMS can be used to sorb and measure root-exuded allelochemicals in the undisturbed rhizosphere of living plants. While this experiment was conducted in pots, all of the PDMS materials used could readily be taken into the field. Both PDMS tubing and optical fiber are fairly inexpensive and, therefore, applicable to large-scale studies.

Of the three PDMS-based materials tested, PDMS tubing recovered higher amounts of sorgoleone and was also more consistent in recovering some sorgoleone in all samples (Table 2). However, because of the different placement of the optical fiber (vertically, rather than being buried) and the different volumes and surface areas of the PDMS materials used in this study, conclusions cannot be drawn about which material was most efficient in extracting sorgoleone. This

TABLE 2. RECOVERY OF SORGOLEONE (ng) from PDMS Materials for all Replicates

Harvest (DAP)	Replicates (ng sorgoleone)			Mean[a]
Optical fiber				
29	68.3	nd[b]	nd	22.7

[a] Means and standard errors were calculated using values of zero for samples below detection limits.
[b] nd = not detected.

experiment was not designed to compare extraction efficiencies of the different PDMS materials, but rather to demonstrate the feasibility of using PDMS to monitor allelochemical dynamics in the rhizosphere. PDMS tubing had both a larger PDMS phase volume and surface area than the optical fiber and PDMS-coated stir bars. The four 10 cm strands of tubing had a surface area of 812 mm^2, compared to 243 mm^2 for the optical fiber and 69 mm^2 for the stir bar. Approximate PDMS volumes were 241, 55, and 7 μl for the tubing, stir bar, and optical fiber, respectively.

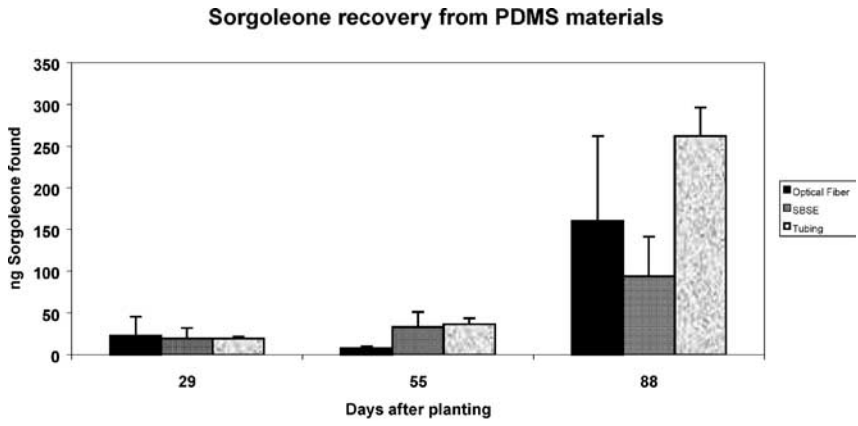

FIG. 2. Mean recovery of sorgoleone with PDMS materials. Bars indicate standard errors.

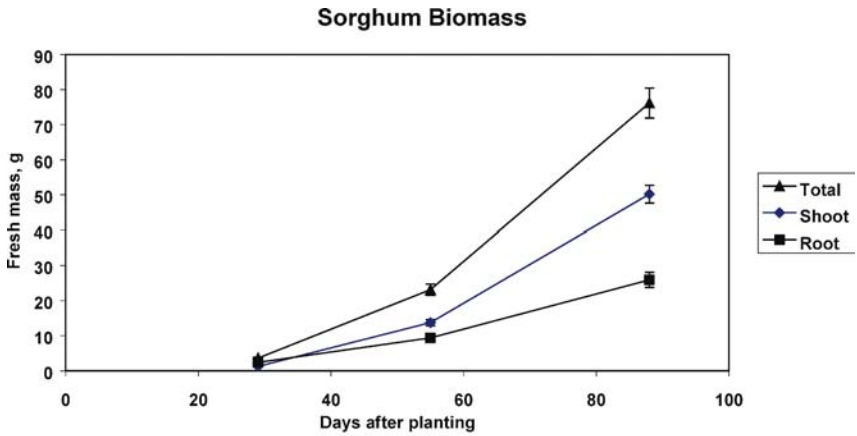

FIG. 3. Total, shoot and root fresh biomass of sorghum–sudangrass at each harvest. Bars indicate standard errors. If not shown, standard errors are too small to depict visually.

The volume estimates have been adjusted for the estimated 40% (v/v) of fumed silica found in PDMS tubing by Baltussen et al. (1999). The greater volume and surface area of the tubing may provide some integration of the presumably heterogeneous distribution of sorgoleone in the rhizosphere.

It is recognized that other forms of the non-PDMS materials—e.g., beads or resins mixed with soil and recovered by centrifugation (Thien and Myers, 1991; Lake et al., 1996; Yeom et al., 1996)—could provide usable results and avoid the problems with fine root penetration of capsules and disks. However, field placement in soil would be problematic, recovery would be destructive, and the extraction procedure would be much more difficult than the aqueous rinse followed by acetonitrile soak used for the PDMS materials. The importance of minimizing disturbance of roots is illustrated by the results of Paavolainen et al. (1998), who measured volatile organic compounds (VOCs) from soil in conifer forests by using microair passive diffusive samplers. These samplers use charcoal as an adsorbent for volatile compounds. The samplers were placed in 30 cm-deep holes (5 cm diam.) bored into the soil, and samplers were suspended within the borehole, which was capped. Significant quantities of monoterpene emissions were measured, but the authors noted that increased production of monoterpenes is a known result of root injury. Thus, there is no way of knowing whether the release rates measured by these researchers bear any relation to undisturbed forest.

Because PDMS rhizosphere sorbents do not extract a known volume of soil, the amounts of sorgoleone found cannot be directly translated into estimates of flux rates. The data provided by these sorbents estimate relative, rather than absolute, flux rates. However, even with this limitation, PDMS sorbents could

be useful in deepening our understanding of the qualitative and quantitative flux rates of allelochemicals in the rhizosphere. Ion-exchange resin capsules, used for the measurement of soil nutrients, have similar limitations and potential. Skogley (1992) buried ion exchange capsules in burned and unburned sites at three different locations. He found striking differences between burned and unburned sites in the amounts of nitrate, potassium, and sulfur recovered from capsules buried for 8–20 months. In addition to monitoring rhizosphere concentrations over time in response to external treatments or variables, PDMS materials could be used to map allelochemical distribution in the rhizosphere (Fan et al., 1992) or to follow microbial degradation of allelochemicals.

Existing methods for determination of allelochemical concentrations in soil have relied on aqueous or solvent extractions of the soil (e.g., Ponder and Tadros, 1985; Dalton et al., 1987) or direct analysis of soil solution (e.g., Gallet and Pellissier, 1997). The low concentrations of allelochemicals typically found in analyses of soils beneath allelopathic plants, and the often rapid degradation of allelochemicals by soil microorganisms, are commonly cited as evidence against these compounds playing a significant role in plant–plant interactions (Schmidt, 1988). However, static concentrations in the environment reflect the balance of input vs. output rates for a compound at a given point in time. As such, static concentrations do not provide information about these input and output rates any more than static concentrations of ammonium and nitrate in the soil indicate the magnitude of the processes of nitrogen mineralization, denitrification, and so on (Williamson and Weidenhamer, 1990). Seldom have attempts been made to quantify the input and output rates for suspected allelopathic compounds.

An additional problem with existing methodology is that bioassays of allelochemicals are normally conducted by one exposure of a test species to a known concentration of a compound, which then decreases in concentration over the length of the assay. This is a quite different situation than in nature, where small pulses of allelochemical inputs may disappear due to microbial degradation, plant uptake, and other processes, but be replenished by new inputs such as root exudation or leaching by precipitation throughfall. Chronic exposure to a low dose of allelochemical may inhibit plant growth significantly (Blum and Rebbeck, 1989), but this has seldom been examined. Weidenhamer et al. (1987) showed that in standard Petri dish germination assays using cucumber seeds and ferulic acid, the ferulic acid rapidly disappeared. When concentrations of ferulic acid were stabilized by either decreasing the number of cucumber seeds used per dish or by making a larger reservoir of ferulic acid available to the seeds, much greater inhibition of cucumber germination and growth resulted. If soil processes maintain the concentration of an allelochemical within a certain range, the potential toxicity of the compound will exceed that seen in bioassays where the concentrations available in soil are mimicked but decrease without replenishment over the course of the assay. Thus, data on the dynamic availability of

allelochemicals are essential to the serious evaluation of hypotheses of allelopathic activity.

The term "biomimetic" is proposed to describe the PDMS rhizosphere sorbents. Krauss and Wilcke (2001) used this term to describe the extraction of PAHs and PCBs from soil with C18 disks. Their intent was not to quantitatively extract all hydrophobic material from the sample, but an amount corresponding to what might be taken up by an organism. Allelochemical extraction procedures seek to recover all of a certain fraction of a compound present at a certain point in time (e.g., soil solution, reversibly/irreversibly adsorbed) (Blum et al., 1999). In contrast, the PDMS materials function in a manner more analogous to plant roots in sorbing compounds from soil solution or through direct contact with root exudates. In principle, allelochemicals sorbed by PDMS traps should be potentially available to roots of other plants. For this reason, the term "biomimetic extraction" is proposed to describe this technique.

Further research is needed to clarify the potential of biomimetic PDMS extractants for analysis of the rhizosphere. Questions that need to be addressed include: (a) How stable are adsorbed allelochemicals on PDMS over time? Do the amounts of sorgoleone found reflect the cumulative amount trapped by PDMS, or is some sorgoleone sorbed and subsequently desorbed over time? Should PDMS be found to desorb allelochemicals over time, such materials might also be used to provide controlled release of known doses of allelochemicals to measure their effects in the absence of the source plant. (b) How broad a range of allelochemicals can be effectively sorbed by PDMS? PDMS is a nonpolar material, and analyte recoveries have been correlated with $K_{o/w}$ (octanol–water partition coefficient) values. Higher recoveries are found for nonpolar compounds (Baltussen et al., 1999). However, SBSE has been used successfully to quantify the polar benzoic acid in beverages (Tredoux et al., 2000). Quantitation was linear for concentrations of 1–1000 ppm in both water and diluted soft drinks. Thus, PDMS would seem to have potential to measure both nonpolar and polar allelochemicals in the rhizosphere. (c) Do other forms of PDMS, e.g., membranes (Bruheim et al., 2003) or rods (Montero et al., 2004) have potential advantages for rhizosphere extraction? What proportion of PDMS volume to surface area is optimal? (d) Can relative flux rates of rhizosphere allelochemicals be correlated with the results of soil bioassays? Szmigielska et al. (1998) and Szmigielska and Schonenau (1999) applied such an approach to the analysis of herbicide residues. The utility of PDMS soil probes for the evaluation of hypotheses of allelopathic effects would be enhanced if the results obtained by soil analyses with the probes could be correlated to bioassays of soil activity, and (e) How effective is solvent extraction of PDMS materials compared to thermal desorption and analysis by GC? Solvent desorption is advantageous in that it does not require additional instrumentation beyond liquid or gas chromatographs that are available in many laboratories. However, in solvent desorption, only a portion of the desorbed sample is injected, so the

sensitivity is inherently less than thermal desorption, where the PDMS material is heated in a closed chamber and all of the volatized analytes transferred into the GC. Most applications of PDMS as a sorbent for anthropogenic pollutants use thermal desorption because of the greater sensitivity, although some compounds are unstable during the thermal desorption process or at high temperatures in the GC.

The demonstration that fluxes of allelochemicals can be measured in the rhizosphere will not prove that allelopathic interactions are occurring. Yet, it is also true that demonstration of allelopathic interactions without data on allelochemical dynamics in soil will remain problematic. PDMS-based materials provide a new tool for obtaining this information, and helping to assess the importance of allelopathic processes in plant communities. In principle, PDMS should also be an effective, low-cost sorbent for large-scale collections of rhizosphere exudates.

Acknowledgments—Sorghum and sorghum–sudangrass seeds were a gift of Browning Seed Co. (Plainview, TX). Gerstel, Inc. supported this research by waiving the license fee for its Twister technology. Acquisition of the Agilent HPLC was supported by the National Science Foundation, DUE-9952552. Jeanne Durkalski assisted with greenhouse operations. Warren A. Dick of the Ohio Agricultural Research and Development Center—Ohio State University provided greenhouse space. The HPLC–MS analyses were performed by K. Green-Church and the staff at the Ohio State MS and Proteomics Facility. The mass spectrometer was purchased by a grant from the Hayes Investment Fund of the Ohio Board of Regents. Udo Blum and an anonymous reviewer provided helpful comments on the manuscript.

INVOLVEMENT OF REACTIVE OXYGEN SPECIES GENERATED FROM MELANIN SYNTHESIS PATHWAY IN PHYTOTOXICTY OF L-DOPA

MAYUMI HACHINOHE[1] and HIROSHI MATSUMOTO[1,*]

[1]*Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan*

(Received June 9, 2004; accepted October 13, 2004)

Abstract—L-DOPA is an active allelochemical that inhibits plant growth. To determine whether the phytotoxicity is due to the reactive oxygen species generated during its oxidation to melanin, oxidative damage, melanin accumulation, and the effect of antioxidants on its phytotoxicity were examined in L-DOPA-tolerant (barnyard grass) and -susceptible (lettuce) plants, and in suspension-cultured carrot cells. L-DOPA suppressed root elongation in lettuce compared to barnyard grass. Levels of melanin and thiobarbituric acid reactive substances (TBARS) increased remarkably in L-DOPA-treated lettuce roots, but not in barnyard grass. L-DOPA also suppressed carrot cell growth to 60% of the control at 1 mM. Melanin content in 1 mM L-DOPA-treated carrot cells increased continuously; however, ascorbic acid and α-tocopherol suppressed accumulation. When melanin formation was inhibited by ascorbic acid and α-tocopherol, growth of L-DOPA-treated cells was restored. TBARS levels were higher in 1 mM L-DOPA-treated carrot cells than in untreated control cells 2 d after treatment, but not at 4 or 6 d. Ascorbic acid and α-tocopherol suppressed the production of lipid peroxide during the initial 2 d. These results suggest that the phytotoxicity of L-DOPA is due to oxidative stress caused by reactive oxygen species from the melanin synthesis pathway.

Key Words—L-DOPA, inhibition of root elongation, melanin synthesis pathway, lipid peroxidation, reactive oxygen species.

INTRODUCTION

L-DOPA (L-3, 4-dihydroxyphenylalanine), a precursor for alkaloids, phenylpropanoids, flavonoids, lignin, and melanin (Halbrock and Scheel, 1989) is an active allelochemical. Velvet bean (*Mucuna pruriens*), a leguminous species, exudes a

* To whom correspondence should be addressed. E-mail: hmatsu@biol.tsukuba.ac.jp

large amount of L-DOPA from its root and inhibits the growth of nearby species (Fujii et al., 1991). Previous studies have revealed that L-DOPA suppresses the growth of roots more significantly than shoots, and the inhibitory effect is selective among plant species (Fujii, 1994; Fujii et al., 1991; Nakajima et al., 1999; Hachinohe et al., 2004).

In the past few decades, natural toxins, including allelochemicals that suppress or eliminate competing plant species near the source plant, have received special attention due to their agricultural potential as herbicides (Dayan et al., 2000). Although hundreds of allelochemicals have been identified, the mode of action of many of these is not yet clear. This study focuses on the phytotoxic mechanism of L-DOPA, which is synthesized via oxidation of tyrosine in the presence of the copper-containing enzyme tyrosinase and molecular O_2. In plant cells, L-DOPA is metabolized to several chatecholamines, phenylpropanoids, and melanin (Pattison et al., 2002). Nakajima et al. (1999) reported that cucumber plants detoxify L-DOPA to nontoxic amino acids such as phenylalanine or tyrosine. We previously compared the metabolic activity of L-DOPA in barnyard grass (*Echinochloa crus-galli* L.: tolerant) and lettuce (*Lactuca sativa* L. cv. Great lakes 366: susceptible) (Hachinohe et al., 2004). There was no significant difference in the composition of metabolites between the species; however, L-DOPA accumulated solely in lettuce suggesting that it is an active principle of the phytotoxic action.

There are numerous studies on the effect of L-DOPA in animal cells. It is a potential therapeutic agent for Parkinson's disease; however, there is considerable concern about the long-term effects caused by L-DOPA-induced cell apotosis and cytotoxicity (Basma et al., 1995; Lai and Yu, 1997; Melamed et al., 1998; Haque et al., 2003). L-DOPA can be oxidized non-enzymatically to form melanin (Riley, 1997); a process that generates reactive oxygen species (Kruk et al., 1999). The cytotoxicity of L-DOPA in nerve cells is due to oxidative damage from reactive oxygen species and can be suppressed with antioxidative enzymes or antioxidants in many cases.

This study was conducted to determine whether the phytotoxicity of L-DOPA is due to reactive oxygen species formed during oxidation to melanin. Oxidative damage and the effect of antioxidants on phytotoxicity were examined in L-DOPA-tolerant (barnyard grass) and -susceptible (lettuce) plants, and in suspension-cultured carrot cells.

METHODS AND MATERIALS

Plant Materials. Seeds of barnyard grass and lettuce were sown on aluminum mesh trays covered with cheesecloth and set on plastic boxes ($310 \times 220 \times 5$ mm^3) containing distilled water. They were germinated in a growth chamber

under 25°C/20°C (day/night, 12 hr each, 80–100 μmol m^{-2} s^{-1}). The uniformly germinated seeds, 1-d-old lettuce and 4-d-old barnyard grass were used for the experiments.

Effect on Root Elongation. Ten germinated seeds of barnyardgrass and lettuce were placed in a plastic box (60 × 60 × 100 mm^3) containing 200 ml of a 0.5% agar culture medium (pH 6.0) with L-DOPA (0.1 mM). They were kept in the chamber, and their root lengths were measured at 1, 2, 3, and 5 d. Each experiment was conducted using five boxes, and the experiment was repeated three times.

Cell Culture and Effect on Plant Growth. Suspension cultures of carrot (*Daucus carota* L. cv. Harumakigosun) cells were grown in Murashige and Skoog medium (MS medium), pH 6.0, containing 30 g L^{-1} of sucrose and 2 mg L^{-1} of 2,4-dichlorophenoxyacetic acid (Matusmoto et al., 2002). Cultures were maintained on a gyratory shaker (NR-20; TATITEC Corporation, Saitama, Japan) agitated at 100 rpm under dim light at 25°C, and subcultured at 2-wk intervals by transferring 20 ml of cell culture into 100 ml of fresh medium. Cell cultures were grown with medium containing L-DOPA with/without ascorbic acid or α-tocopherol for 6 or 8 d. The effect on growth was determined by measuring packed cell volume (Warabi et al., 2001) at 2, 4, and 6 d after treatment.

Spectrophotometric Assay of Melanin. Total melanin was determined according to Wakamatsu and Ito (2002). Roots of lettuce and barnyard grass (30 mg FW) were homogenized in 3 ml of a 90% (v/v) Soluene-350 solution, and solubilized completely by incubation for 30 min at 100°C. After cooling, absorbance at 500 nm was determined by using synthetic melanin as a standard. In carrot cells, the yellow pigments were removed with methanol before the cells, 0.2 ml, were homogenated in 3 ml of Soluene-350.

Determination of Lipid Peroxidation. Lipid peroxidation was determined with the thiobarbituric acid (TBA) test (Velikova et al., 2000). Roots of lettuce and barnyard grass (500 mg) were homogenized in a 0.1% (w/v) TCA solution (5 ml). The homogenate was centrifuged at 10,000 *g* for 20 min, and 0.5 ml of the supernatant were added to 1 ml of 0.5% (w/v) TBA in a 20% TCA solution. The mixture was incubated for 30 min at 98°C, and the reaction was stopped by cooling in an ice bath. The samples were centrifuged at 10,000 *g* for 5 min, and the absorbance of supernatants was analyzed at 532 nm. The value for nonspecific absorbance at 600 nm was subtracted. The amount of thiobarbituric acid reactive substances (TBARS) was calculated with an extinction coefficient of 155 mM^{-1} cm^{-1}.

Statistical Analysis. Data were analyzed with Statcel (OMS, Saitama, Japan), and tested for normality and homogeneity of variances (F-test or Bartlett test) followed by ANOVA or simple linear regression analysis. Differences between treatments were determined by Fisher's PLSD test, Student's t-test, or Welch's t-test.

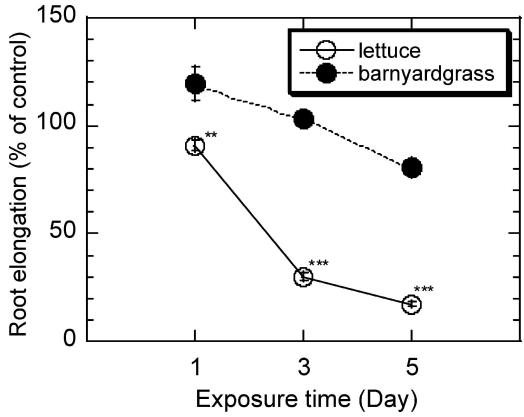

FIG. 1. Effect of 0.1 mM L-DOPA on growth of barnyard grass and lettuce roots. Bars indicate ±SE of the mean ($N = 5$). Asterisks indicate a significant preference between control and L-DOPA treatment ($^{**}P < 0.01$; $^{***}P < 0.001$).

RESULTS

L-DOPA caused selective suppression of root elongation in barnyardgrass and lettuce (Figure 1). The root lengths of both L-DOPA-treated species were approximately 80% and 20% of untreated control root lengths, respectively.

Although L-DOPA induced accumulation of melanin in the roots of both species, the increase was more remarkable in lettuce (Figure 2). Melanin content was positively correlated with growth inhibition of L-DOPA-treated roots

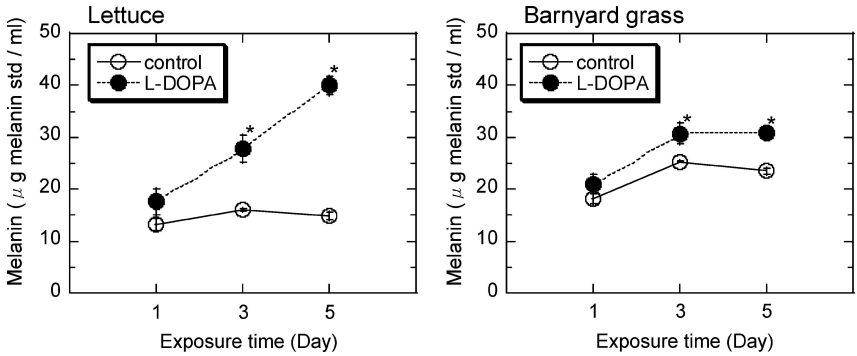

FIG. 2. Melanin levels in roots of barnyard grass and lettuce treated with L-DOPA. Bars indicate ±SE of the mean ($N = 3$). Asterisks indicate a significant preference between control and L-DOPA treatment ($^{*}P < 0.05$; $^{**}P < 0.01$).

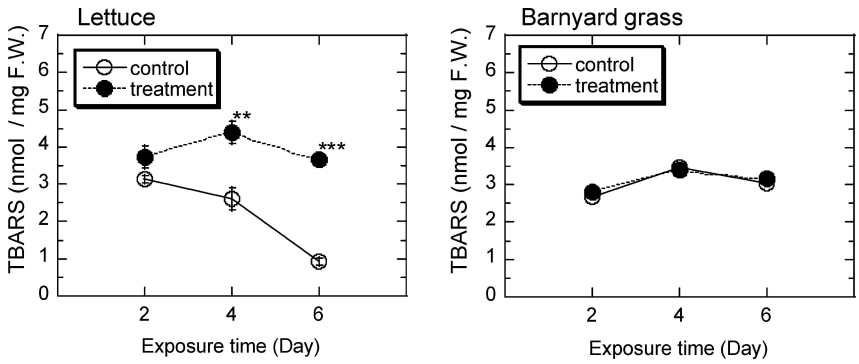

FIG. 3. Effects of L-DOPA on TBARS levels in roots of barnyard grass and lettuce. Bars indicate ±SE of the mean ($N = 3$). Asterisks indicate a significant preference between control and L-DOPA treatment (**$P < 0.01$; ***$P < 0.001$).

($r^2 = 0.85$, $F_{1,28} = 152.8$, $P < 0.001$). Levels of TBARS were higher in L-DOPA-treated lettuce roots, but not in barnyard grass (Figure 3). Lipid peroxidation also correlated with growth inhibition ($r^2 = 0.67$, $F_{1,10} = 20.4$, $P < 0.05$) in the regression analysis.

Toxicity of L-DOPA in nerve cells is caused by the reactive oxygen species, H_2O_2, $^1O_2$, O_2^-, and $OH^\bullet$, generated from its oxidative metabolism to melanin (Graham et al., 1978; Rosenberg, 1988; Kruk et al., 1999; Pattison et al., 2002). Cytotoxicity was restored with the addition of antioxidative enzymes or antioxidants (Parsons, 1985; Basma et al., 1995; Lai and Yu, 1997; Haque et al., 2003). To investigate the involvement of this oxidative process in L-DOPA's action, melanin content and TBARS content were determined in carrot cells cultured with MS medium. Suspension-cultured carrot cells were used for the experiments because it is easy to regulate concentrations of chemicals in the medium.

At 6 d after treatment, L-DOPA suppressed cell growth to 85% and 60% of the control level at 0.1 mM and 1 mM, respectively (Figure 4). The melanin content increased continuously in 1 mM L-DOPA-treated cells for 6 d (Figure 4). The amount of melanin accumulated in cells depended on the concentration of L-DOPA (data not shown). Ascorbic acid and α-tocopherol suppressed melanin formation in L-DOPA-treated carrot cells (Figure 5). When melanin production was inhibited by ascorbic acid and α-tocopherol, growth of L-DOPA-treated cells was restored (Figure 6). TBARS levels were higher in 1 mM L-DOPA-treated carrot cells than untreated control cells 2 d after treatment, but not at 4 and 6 d (Figure 7). Ascorbic acid and α-tocopherol suppressed this initial increase in the formation of the lipid peroxide.

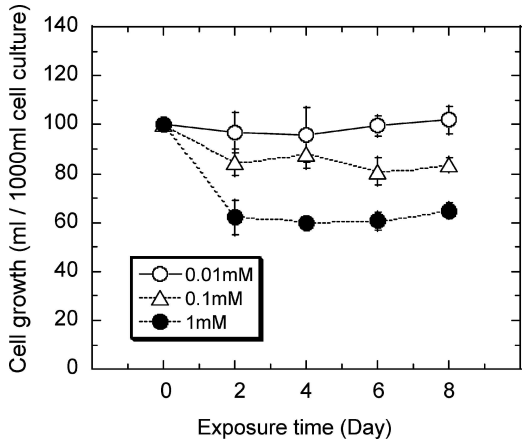

FIG. 4. Effect of L-DOPA on growth of carrot cells. Bars indicate ±SE of the mean ($N = 3$). A one-way ANOVA was performed ($F_{11,24} = 7.22$, $P < 0.001$).

DISCUSSION

L-DOPA is a strong neurotoxic agent owing to its ability to induce apotosis (Melamed et al., 1998; Haque et al., 2003) and adverse effects on neurological degenerative diseases in animals (Enochs et al., 1994; Bowling and Beal, 1995;

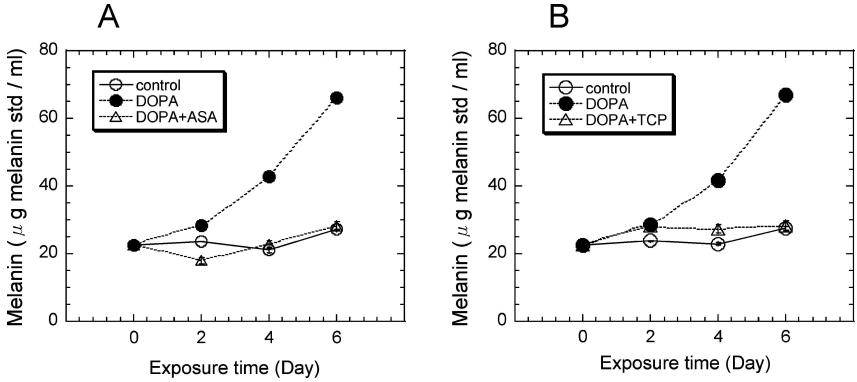

FIG. 5. Effect of ascorbic acid (A) and α-tocopherol (B) on melanin levels in carrot cells treated with L-DOPA. Concentrations of L-DOPA and antioxidants are 1 mM. Bars indicate ±SE of the mean ($N = 3$). A one-way ANOVA was performed: ascorbic acid at 4 d ($F_{2,6} = 2476.7$, $P < 0.001$); ascorbic acid at 6 d ($F_{2,6} = 980.2$, $P < 0.001$); α-tocopherol at 4 d ($F_{2,6} = 1221.2$, $P < 0.001$); α-tocopherol at 6 d ($F_{2,6} = 1223.3$, $P < 0.001$).

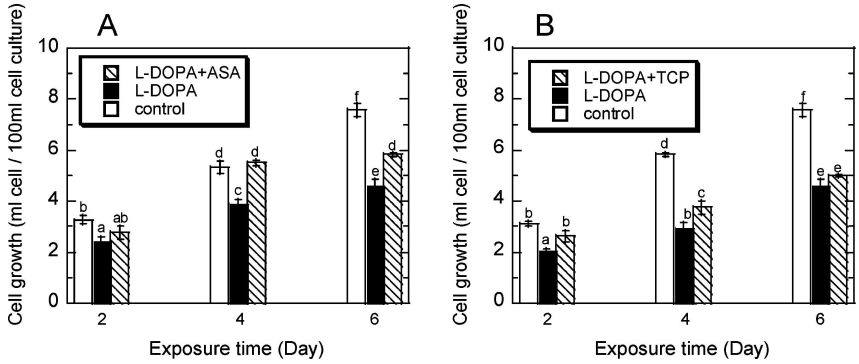

FIG. 6. Effect of ascorbic acid (A) and α-tocopherol (B) on growth of carrot cells treated with L-DOPA. Concentrations of L-DOPA and antioxidants are 1 mM. Bars indicate $\pm$SE of the mean ($N = 3$). A one-way ANOVA was performed: ascorbic acid ($F_{8,18} = 67.72$, $P < 0.001$); α-tocopherol ($F_{8,18} = 86.56$, $P < 0.001$). Bars labeled with same letters are not significantly different ($P = 0.05$).

Smythies, 1997). Several studies have proposed that the cytotoxicity is attributable to reactive oxygen species generated during its oxidation to melanin. The purpose of this study was to examine whether L-DOPA acts on plant cells as it does on animal cells.

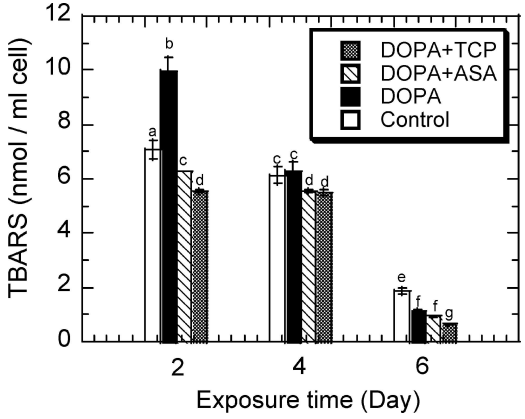

FIG. 7. Effect of antioxidants on TBARS levels in carrot cells treated with L-DOPA. Bars indicate $\pm$SE of the mean ($N = 3$). A one-way ANOVA was performed: ($F_{11,24} = 8376.87$, $P < 0.001$). Bars labeled with same letters are not significantly different ($P = 0.05$).

Based on our previous study, barnyard grass and lettuce were selected as L-DOPA-tolerant and -susceptible species, respectively (Hachinohe et al., 2004). First, we confirmed the difference in sensitivity between them (Figure 1). A greater melanin accumulation was observed in L-DOPA-treated lettuce (Figure 2). Our results indicate that the melanin synthesis pathway in plants metabolizes exogenously applied L-DOPA. From a regression analysis, the amount of accumulated melanin correlated with the growth inhibitory activity of L-DOPA. Therefore, the melanin synthesis pathway might be closely linked to the L-DOPA phytotoxic mechanism. We checked the effect of exogenously applied melanin on lettuce root. Elongation was not inhibited (92.9% of the untreated control) when plants were grown with 60 μg ml^{-1} melanin containing agar medium formed by polyphenol oxidase-catalyzed oxidation of medium containing 0.1 mM L-DOPA. Moreover, melanin itself has not been reported to be a cytotoxic substance, but is a free radical sink that protects cells from oxidative damage (Peters and Schraermeyer, 2001). Some intermediate(s) or by-product(s) of the melanin synthesis pathway may be involved in the phytotoxicity.

In neuroblastoma SH-SY5Y cells, Lai and Yu (1997) showed a correlation between L-DOPA cytotoxicity and formation of melanin. The cells suffered oxidative damage from reactive oxygen species that disrupted cell membrane integrity. This ultimately resulted in a reduction in growth or cell death. To estimate the oxidative damage due to L-DOPA in plants, amounts of lipid peroxides were determined. Lipid peroxides levels were much greater compared with the untreated lettuce control, but not in barnyard grass (Figure 3). This suggests the involvement of reactive oxygen species and a mechanism similar to cytotoxicity in animal cells.

Cytotoxic effects in animal cells can be completely prevented by antioxidants or antioxidative enzymes, particularly catalase, superoxide dismutase (SOD), ascorbic acid, and α-tocopherol (Parsons, 1985; Basma et al., 1995; Haque et al., 2003). We confirmed that the phytotoxicity of L-DOPA in carrot cells was stopped with ascorbic acid and α-tocopherol. However, the antioxidative enzymes catalase and SOD had less of a protective effect (data not shown). Macromolecules such as catalase and SOD may not easily penetrate cell membranes (Buckley et al., 1987; Beckman et al., 1988; Clement et al., 2002).

Growth of carrot cells was suppressed by L-DOPA in a concentration-dependent manner (Figure 4), although the cells were more tolerant than lettuce. A significant accumulation of melanin was observed in carrot cells (Figure 5), indicating that the melanin pathway functions in the metabolism of L-DOPA. Ascorbic acid and α-tocopherol suppressed the formation of melanin (Figure 5). Levels of TBARS in carrot cells decreased at 4 and 6 d in the untreated control (Figure 7). This is probably due to increased cell division in the new medium. In L-DOPA-treated cells, great peroxidation was observed at 2 d, but not at 4 or 6 d. When the synthesis of melanin was inhibited by the antioxidant chemicals, the levels of TBARS decreased at 2 d. These results suggest that the melanin

pathway is involved in oxidative damage, and that lipid peroxidation occurs in the early phase of the culture. Rapid recovery of carrot cells from lipid peroxidation might be due to greater levels of carotenoids, anitioxidants, and/or the rapid metabolism of L-DOPA to nontoxic metabolites other than melanin. Although melanin formation and lipid peroxidation were suppressed during the exposure period, the effect of α-tocopherol on cell growth was not remarkable compared to ascorbic acid. The reason for this difference is not clear, but, both antioxidants effectively reduced the phytotoxicity of L-DOPA in the early stages of exposure (Figure 6).

This study suggests that the phytotoxicity of L-DOPA is due to oxidative stress, and that reactive oxygen species generated by the synthesis of melanin are involved. This is the first report suggesting such involvement in the allelopathic activity of L-DOPA. Our future goals are to clarify the mechanisms behind the production of reactive oxygen species in the melanin synthesis pathway, and the selectivity difference between barnyard grass and lettuce.

(Received June 11, 2004; accepted October 14, 2004)

Abstract—Several volatile allelochemicals were identified and characterized from fresh leaf tissue of three distinct populations of the invasive perennial weed, mugwort (*Artemisia vulgaris*). A unique bioassay was used to demonstrate the release of volatile allelochemicals from leaf tissues. Leaf volatiles were trapped and analyzed via gas chromatography coupled with mass spectrometry. Some of the components identified were terpenes, including camphor, eucalyptol, α-pinene, and β-pinene. Those commercially available were tested individually to determine their phytotoxicity. Concentrations of detectable volatiles differed in both absolute and relative proportions among the mugwort populations. The three mugwort populations consisted of a taller, highly branched population (ITH-1); a shorter, lesser-branched population (ITH-2) (both grown from rhizome fragments from managed landscapes); and a population grown from seed with lobed leaves (VT). Considerable interspecific variation existed in leaf morphology and leaf surface chemistry. Bioassays revealed that none of the individual monoterpenes could account for the observed phytotoxicity imparted by total leaf volatiles, suggesting a synergistic effect or activity of a component not tested. Despite inability to detect a single dominant phytotoxic compound, decreases in total terpene concentration with increase in leaf age correlated with decreases in phytotoxicity. The presence of bioactive terpenoids in leaf surface chemistry of younger mugwort tissue suggests a potential role for terpenoids in mugwort establishment and proliferation in introduced habitats.

Key Words—*Artemisia vulgaris*, mugwort, allelopathy, monoterpenes, volatiles, invasive weed, volatile bioassay, glands.

INTRODUCTION

Mugwort (*Artemisia vulgaris* L.) is a rhizomatous perennial weed that commonly infests roadsides, waste areas, and landscapes. The US nursery industry considers

* To whom correspondence should be addressed. E-mail: jnb22@cornell.edu

mugwort as one of the ten worst weed problems impacting nursery production (Henderson and Weller, 1985; Holm et al., 1997). Mugwort is a Eurasian dicot that spreads quickly upon introduction via an extensive rhizome system, and is difficult, to control chemically or culturally (Bing, 1983; Henderson and Weller, 1985; Foy, 2001; Neal and Adkins, 2001; Barney and DiTommaso, 2003). With few effective control strategies, this aggressive weed has rapidly colonized new areas in the eastern United States. Mugwort is most troublesome, often forming dense monospecific stands, along roadsides, in turfgrass and rights-of-way, and is a lesser threat in agronomic settings (Barney and DiTommaso, 2003). Not surprisingly, diversity of native flora, namely early successional species, in these habitats has declined following mugwort colonization (Holm et al., 1997; Barney and DiTommaso, 2003). However, the exact mechanism(s) of interference (e.g., allelopathy and/or competition) is unknown.

Allelopathy has been reported in an increasing number of plant species in recent years, several of which are classified as invasive (Qasem and Foy, 2001; Bais et al., 2003; Hierro and Callaway, 2003). The invasive ability of certain vigorous and often nonnative plants was thought to be associated with greater competitive ability of the invasive species, or a release from natural enemies (Keene and Crawley, 2002; Mitchell and Power, 2003). Recently, allelopathic activity of invasive species also has been reported as a significant factor that negatively influences species biodiversity and ecosystem succession, while enhancing nonnative species establishment and proliferation (Ridenour and Callaway, 2001; Hierro and Callaway, 2003).

The presence of volatile allelochemicals in aromatic shrubs was first established in the early 1960s in the semiarid chaparral regions of California (Muller et al., 1964; Muller, 1965). Characteristic volatiles or essential oils of species in *Artemisia* and many other taxa have since been explored for their inhibitory effects on plant growth in both field and laboratory assays (Halligan, 1975; del Amo and Anaya, 1978; Kim and Kil, 1989; Abraham et al., 2000). Major inhibitory components of the California chaparral shrubs are terpenes. Several monoterpenes inhibit seedling root and shoot growth (Penuelas et al., 1996), with specific cytotoxic effects that include the reduction of intracellular mitochondrial and Golgi body populations, inhibition of respiration and photosynthesis, decreasing cell wall permeability, as well as accelerating the oxidative destruction of chloroplast pigments (Charlwood and Charlwood, 1991; Loreto et al., 1996; Abraham et al., 2000). The antimalarial drug artemisinin, a sesquiterpenoid from annual wormwood (*A. annua* L.), is inhibitory to several broadleaf weeds and crops, but its mode of action is unknown (Duke et al., 1987; Lydon et al., 1997). Other *Artemisia* species with terpenoid allelochemics include *A. absinthium* L. (Funke, 1943), *A. californica* Less. (Muller et al., 1964; Muller, 1966), *A. princeps* var. *orientalis* (Yun and Kil, 1992), and *A. tridentata* Nutt. ssp. *vaseyana* (McCahon et al., 1973; Weaver and Klarich, 1976; Weaver and Klarich, 1977). Most *Artemisia* species

produce predominately monoterpenes, which suggests that the mugwort might as well. Previous studies have suggested that mugwort has allelopathic potential, but the source of its inhibitory chemicals is largely unknown (Hale, 1982; Melkania et al., 1982; Inderjit and Foy, 1999). Inderjit and Foy (1999) suggested that decomposing mugwort foliage and rhizomes were highly suppressive to red clover (*Trifolium pratense* L.) seedling growth.

More than 80 compounds have been isolated from the foliage of mugwort populations around the world, many of these being terpenes (Misra and Singh, 1986; Banthorpe and Brown, 1989; Milhau et al., 1997; Pino et al., 1999). To date, none of these has been examined for suppressive potential. Therefore, the objectives of this research were to evaluate the allelopathic potential of several populations of mugwort, determine which terpenes are implicated in allelopathic activity, and establish the potential for soil activity of these volatiles.

METHODS AND MATERIALS

Plant Material. Two separate mugwort populations were collected from two geographically isolated areas in Ithaca, NY; specifically from a cemetery site (labeled ITH-1) and the Cornell Test Gardens (labeled ITH-2). Both populations were managed in a turfgrass setting that received regular mowing to a height of approximately 6 cm, and no additional irrigation or fertilization for at least 5 yr previous to this study. Plant material was collected in August of 2000, and subsequently maintained in a greenhouse at 30°C day/24°C night, under high-pressure sodium lighting (Sylvania LV 400/EC) with a 12/12 L/D photoperiod and an average of 300 μmol m^{-2} s^{-1} of overhead irradiance. Both biotypes were transplanted and potted in a Cornell 1:2:1 media mix (soil:peat:perlite) from 10 cm rhizome pieces and watered as needed with no fertilizer applied throughout the experiment. An additional biotype was obtained from seed, and is referred to as VT (Vermont, USA) for the location of the seed company from which it was purchased. On average, the ITH-1 population was taller (>1 m), exhibited densely pubescent stems and light green, and deeply dissected leaves; ITH-2 was shorter (0.75–1 m) with hairless stems and dark green, and deeply dissected leaves; and VT had a prostrate-like growth habit (>1 m in length) with moderate pubescent stems and light green-lobed leaves.

Species evaluated in the bioassays included curly cress (*Lepidium sativum* L.), foxtail millet (*Setaria italica* (L.) Beauv.), large crabgrass (*Digitaria sanguinalis* (L.) Scop.), white clover (*T. repens* L.), and mugwort (Le Jardin seed company, VT).

Chemical Standards. Terpenoids identified from mugwort foliage via gas chromatography coupled with mass spectrometry (GC-MS) that were commercially available were purchased from Sigma-Aldrich, including camphene,

camphor, eucalyptol, D-limonene, β-myrcene, α-pinene, and β-pinene. However, not all of the terpenes identified were available.

Allelopathic Potential of Mugwort Foliage: Volatile Bioassay. Freshly harvested leaves were evaluated for bioactive volatile activity in a manner that allowed only atmospheric contact between the test species and the mugwort foliage. Foliage was harvested from the three populations, ITH-1, ITH-2, and VT, at 60 days after planting (DAP). At harvest, stock plants were nearly 0.75 m tall, and were trimmed to the soil surface. All leaves were stripped from shoots, including small petioles. Sampled foliage was randomly mixed, to obtain leaves of various maturities. Foliage (2, 5, or 10 g f.w.) was placed into a single layer of Grade 50 cheese cloth. Ten seeds of the bioassay indicator species, curly cress, were placed onto a single layer of Whatman #1 filter paper moistened with 2.5 ml Milli-Q water in a 500 ml Erlenmeyer flask. To maximize volatile release, mugwort foliage was hand-crushed in cheese cloth before placement into the flask, which was immediately sealed with a rubber stopper. The negative control contained only cheese cloth and the receptor species with no mugwort foliage, while the positive control contained the receptor species plus 10 g tall fescue shoots (*Festuca arundinacea* Schreb.), in an effort to simulate other commonly released plant volatiles. Sealed flasks were incubated at 27°C for 72 hr in the dark, after which test species root and shoot lengths were recorded. All experiments contained three replicates and were arranged in a completely randomized design, repeated once in time. Data were pooled after homogeneity analysis, and analyzed using a two-sample t-test for comparison to the control.

To examine the effect of foliage age on phytotoxicity, the experiment was repeated with 60 and 120 DAP foliage collected from the VT population, as this mugwort population exhibited the greatest range in test species response in the previous experiment. Flasks were arranged in a completely randomized design, with three replicates of 60 and 120 DAP foliage using 2, 5, or 10 g fresh leaf biomass, in addition to a control (no mugwort biomass). Ten g of fresh mugwort foliage is the equivalent of approximately 15 mature leaves, which represents one plant, 0.3 m in height. Cress radicle elongation was recorded after 72 hr. The experiment was repeated once in time and data were analyzed as above.

Identification of Volatile Compounds. GC-MS was utilized to identify and quantify volatiles collected from the atmosphere surrounding mugwort foliage. One leaf from the top, middle, and bottom of the shoot of each population was selected at 60 and 120 DAP. After being crushed by hand to maximize the release of volatiles, three leaves from each plant were placed together in a 5 ml conical vial with a Teflon septum. The VT population was not available for examination at 60 DAP.

After 30 min of equilibration, a hypodermic needle was used to withdraw 10 μl of headspace from each vial, which were then injected into an Hewlett Packard 6890 GC equipped with a 30 m $\times$ 250 μm $\times$ 0.25 μm HP-5MS (5% phenyl

methyl siloxane) column and an Hewlett Packard 5973 Mass Selective Detector. The oven temperature gradient used was as follows: 35°C (1 min); 200°C at 15°C/min for 10 min; and 300°C at 40°C/min for 5 min. The quadrapole and source settings were 150°C and 230°C, respectively. Two replicates were analyzed for each sample, and peak values were averaged. Individual peaks were identified by comparison of their mass spectrum with published spectra, as well as by comparisons with both the retention times and mass spectra of authentic samples when available.

Response factors for the seven terpenes readily available as standards (camphene, camphor, eucalyptol, D-limonene, β-myrcene, α-pinene, and β-pinene) were determined using standard curves formulated with concentrations of 0.1, 1, 10, 100, and 1,000 mg/l in chloroform. Concentrations of Santolina triene, the only other identified compound in the headspace that was not available as a standard, were estimated using an average of the response factors of the other seven standards.

Phytotoxicity of Identified Terpene Components. Individual terpenes identified above, except Santolina triene, were tested for inhibitory potential, utilizing the volatile bioassay described above. Test tubes (13×100 mm^2) containing pure terpenes dissolved in methanol (30 μl aliquots) were placed inside closed 500 ml Erlenmeyer flasks, which contained the seeds of test species sown on moist filter paper. Activity of each terpene was examined at 0, 1, 10, 50, 100, 250, 500, and 1,000 mg/m^3, plus a methanol control, with a curly cress indicator. In addition, mugwort, white clover, large crabgrass, and foxtail millet indicators were examined at 1,600 mg/m^3 (chosen to exaggerate toxicity effects). Flasks were arranged as a completely randomized design with three replicates, and were incubated for 72 hr at 27°C in the dark, after which root and shoot lengths were recorded. Tests were conducted on multiple days, with two terpenes evaluated per analysis plus a water and methanol control. Control means were significantly different among days as shown by ANOVA analysis. Therefore, data was not pooled. Data for each day were analyzed using ANOVA and means were compared using Dunnetts tests for comparison to the methanol control (SAS ver. 8).

Test for Soil Activity. In order to determine if the mugwort volatiles could impart a residual effect in soils, an assay was developed to examine the germination and establishment of test species in soil that had previously been exposed to mugwort volatiles. ITH-1, ITH-2, and VT greenhouse grown plant material was harvested at 60 DAP, and the foliage was removed, including petioles. Harvested tissue within each population was mixed for uniformity, and 20 g of the foliage was used for each treatment, after hand-crushing. A fine sandy loam soil was dried for 96 hr at 90°C, and subsequently sifted through a 2-mm soil sieve. In a sealed 11.4-l plastic box, 75 g of the soil were placed into a separate 0.71-l plastic dish, adjacent to, but not touching 20 g of the hand-crushed mugwort foliage. An aquarium pump was included inside the box to aid in circulation of the volatiles. The chamber

equilibrated for 24 hr at room temperature before the soil was removed. The soil box was removed and subsequently wetted with 35 ml Milli-Q water, and sown with 25 curly cress seeds. The control consisted of the soil inside the sealed chamber in the absence of mugwort foliage. The soil box was then sealed and incubated for 72 hr at 27°C in the dark, after which time test species root and shoot lengths were recorded. Boxes were arranged in a completely randomized design with three replicates. The experiment was repeated once in time and data were pooled, with means analyzed using a two-sample t-test for comparison to the control.

RESULTS

Phytotoxicity of Mugwort Foliage via Volatile Bioassay. Curly cress radicle elongation is an excellent indicator of plant growth inhibition due to its uniformity of growth and overall sensitivity, and was used as the assay of choice for bioassay-directed identification of unknown volatiles. Of the three mugwort populations evaluated, ITH-1 and ITH-2 significantly inhibited cress radicle elongation at 2 g f.w. whereas the VT population showed minor cress stimulation (Figure 1). Inhibition ($P < 0.05$) of both curly cress root and shoot elongation was observed with 10 g fresh foliage of ITH-1, ITH-2, and VT populations. Only VT, the seed

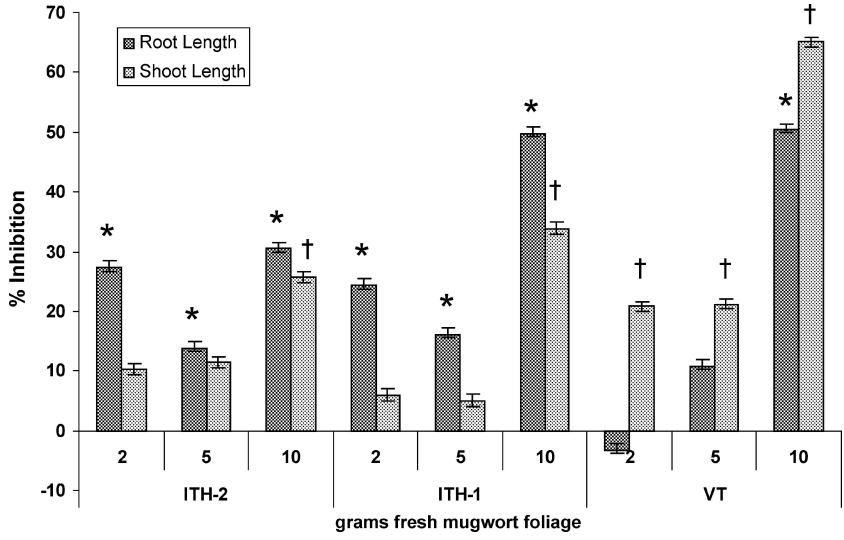

FIG. 1. Percent inhibition of root and shoot elongation of curly cress (*L. sativum*) compared with controls following 72-hr exposure to different amounts of fresh mugwort foliage. *Indicates significant radicle length inhibition ($P < 0.05$) and † indicates significant shoot inhibition compared to the control.

grown population, produced significant shoot growth inhibition of cress at 2, 5, and 10 g f.w. of foliage. Greater than 50% root growth inhibition and 65% shoot growth inhibition were observed with 10 g VT foliage, the most suppressive of all populations evaluated at this tissue concentration. Our findings show that population-level differences exist with respect to mugwort's potential phytotoxicity. Interestingly, percent inhibition of curly cress radicle elongation did not appear to follow a typical dose response relationship. Greatest tissue weight (10 g), however, did result in the greatest inhibition of both radicle and shoot length (Figure 1).

Harvest date, or plant age, also had an impact on phytotoxicity of foliar tissue (Figure 2). Foliar tissue (VT) was evaluated at 60 or 120 d after planting (DAP). The 60 DAP foliage significantly inhibited root elongation at 5 and 10 g, and shoot elongation at 2, 5, and 10 g. Conversely, the 120 DAP foliage significantly reduced cress shoot elongation at 10 g only, while cress radicle length was unaffected.

Test for Soil Activity. To determine if residual phytotoxicity was present in soils previously exposed to mugwort leaf volatiles, a soil bioassay was performed in an enclosed environment. Even after removal of the mugwort leaves, seeds that were germinated in soil that had 24 hr of prior exposure to leaf volatiles were inhibited with respect to root and shoot elongation (Figure 6). Root growth was inhibited up to 27%, whereas shoot growth was inhibited up to 50%. Differences

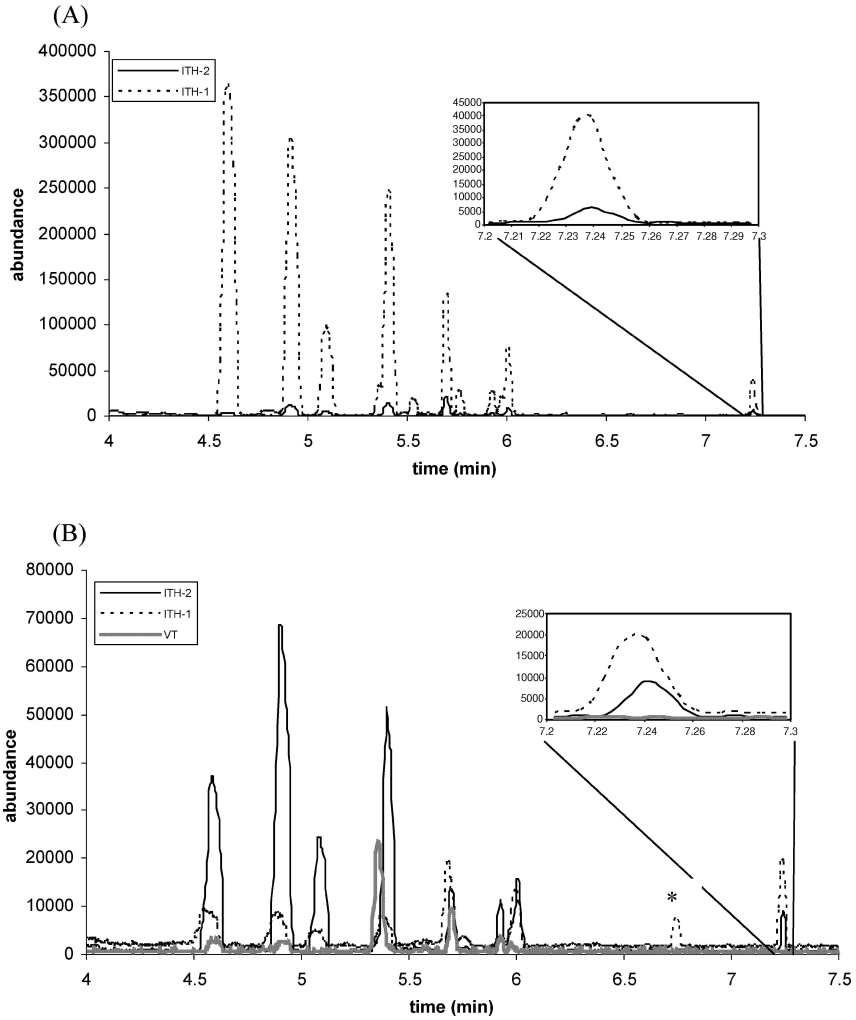

FIG. 3. GC-MS analysis of (A) 60-d-old and (B) 120-d-old plant material. Peaks labeled with "*" did not match any known compounds in the database.

among populations were observed with respect to shoot growth inhibition, with ITH-2 foliage causing greater phytotoxicity than ITH-1 and VT foliage.

Identification of Volatile Compounds. The components of the volatile atmosphere were collected and analyzed via GC-MS. Of the 10 identified peaks (Figure 3), 8 were monoterpenes, including Santolina triene, α-pinene, camphene, β-pinene, β-myrcene, limonene, eucalyptol (1,8-cineole), and camphor (Figure 4).

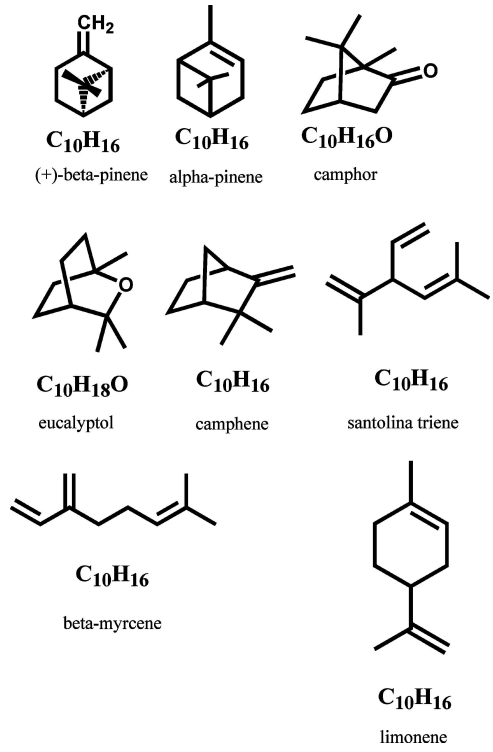

FIG. 4. Terpene structures identified in mugwort foliage.

The 60-d-old ITH-1 foliage contained between 1- and 28-fold higher concentrations of each of the compounds in the leaf headspace compared to older 120-d-old foliage (Table 1). ITH-2 60 DAP foliage contained between 1- and 12-fold greater concentrations of the identified compounds than did the 120 DAP foliage. The major component of ITH-1 foliage at 60 DAP was α-pinene (119.5 mg/m^3), with the second most abundant component being Santolina triene (86.9 mg/m^3). At 120 DAP, the most abundant volatiles were α-pinene and camphene (18.7 and 17.2 mg/m^3, respectively), followed by camphor (13.5 mg/m^3). Volatiles produced by the ITH-2 population included α-pinene (43.5 mg/m^3), followed by camphene (22.1 mg/m^3) at 60 DAP. At 120 DAP, the ITH-2 population contained α-pinene and camphene (19.8 and 17.0 mg/m^3, respectively) followed by camphor (12.0 mg/m^3). At 120 DAP, the VT foliage exhibited slightly different concentrations of volatiles than did ITH-1 and ITH-2 (Table 1). VT foliage at 120 DAP contained α-pinene (16.3 mg/m^3), followed by camphene (15.9 mg/m^3), while camphor and β-pinene were found at concentrations near 10 mg/m^3.

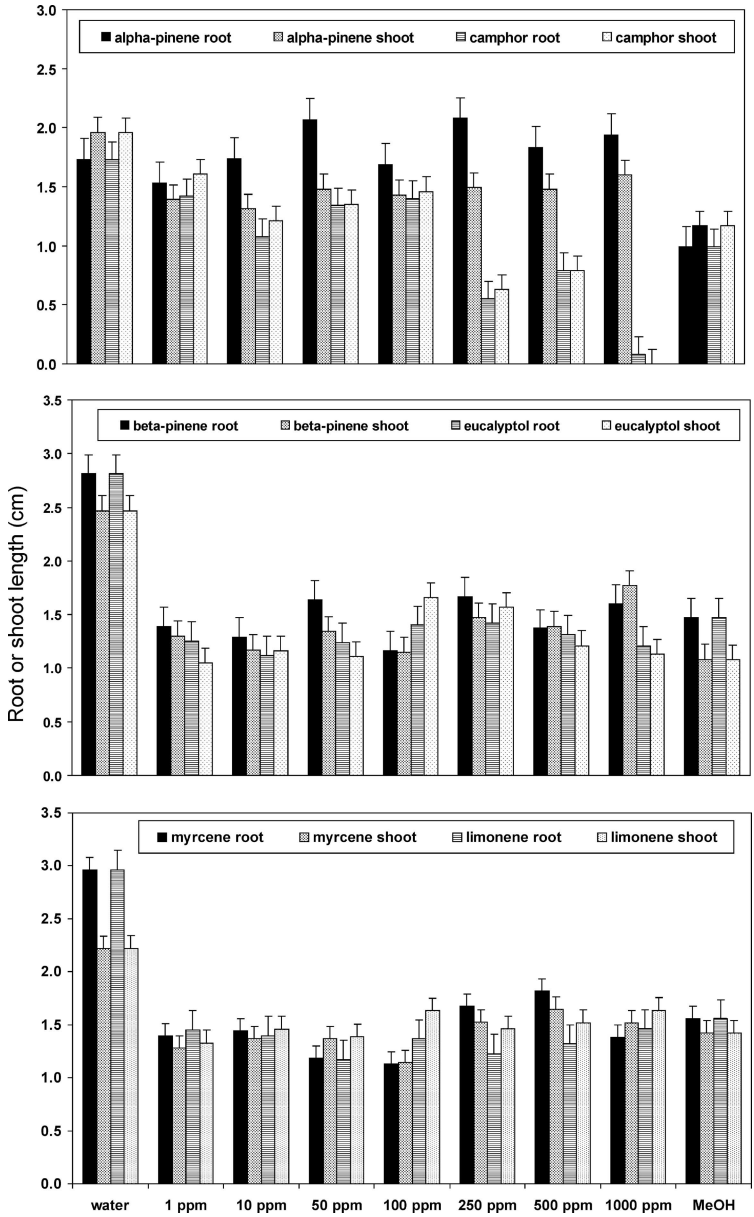

FIG. 5. Response of curly cress (*L. sativum*), to various terpenes identified from mugwort foliage as compared to a methanol and water control, as measured by radicle or shoot elongation. See Table 2 for significance values.

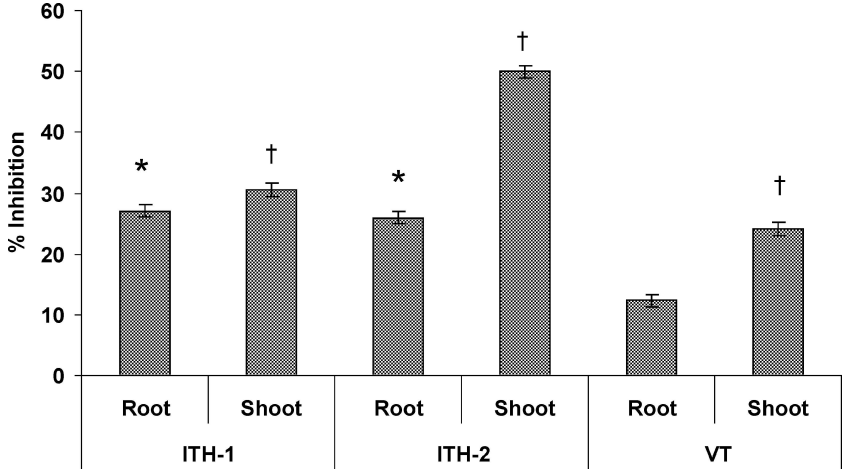

FIG. 6. Percent inhibition of curly cress (*L. sativum*) root and shoot elongation compared with controls after indirect exposure of soil to fresh mugwort foliage of different populations. *Indicates significant radicle length inhibition ($P < 0.05$) and † indicates significant shoot inhibition as compared to the control.

TABLE 1. INFLUENCE OF MUGWORT POPULATION AND TISSUE AGE, 60 AND 120 DAP, ON RELATIVE AMOUNTS OF TERPENES (MG/M^3) AS MEASURED BY GC/MS, AND ESTIMATED LOG Pk_{oc} AND WATER SOLUBILITIES OF COMPONENTS

TABLE 2. SIGNIFICANCE TABLE FOR INDIVIDUAL MONOTERPENES ASSESSED IN VOLATILE BIOASSAY

	Camphor		α-Pinene		β-Pinene	
[Terpene] (mg/m^3)	Root length	Shoot length	Root length	Shoot length	Root length	Shoot length
1	$*\uparrow$	$*\uparrow$	$*\uparrow$	ns	ns	ns
10	ns	ns	$*\uparrow$	ns	ns	ns
50	ns	ns	$*\uparrow$	ns	ns	ns
100	ns	ns	$*\uparrow$	ns	ns	ns
250	$*\downarrow$	$*\downarrow$	$*\uparrow$	ns	ns	ns
500	ns	$*\downarrow$	$*\uparrow$	ns	ns	ns
1,000	$*\downarrow$	$*\downarrow$	$*\uparrow$	$*\uparrow$	ns	$*\uparrow$

ns = Nonsignificant ($P > 0.05$), $\uparrow$= mean greater than MeOH control (i.e., stimulation), $\downarrow$= mean lower than MeOH control (i.e., inhibition). Terpenes not shown, myrcene and limonene, are all nonsignificant ($P > 0.05$).
$^*P < 0.05$.

Phytotoxicity of Terpene Components. Terpenes were tested at concentrations bracketing those calculated from the unknown injections (0–1,000 mg/m^3). Overall, myrcene, limonene, and β-pinene had no effect on the test species compared to the methanol control (Figure 5). Camphene had a pattern similar to both limonene and myrcene (data not shown). Eucalyptol had no phytotoxicity to radicle elongation, but did cause shoot length stimulation at 50 and 100 mg/m^3, while α-pinene stimulated cress radicle growth at all concentrations (Table 2). Only camphor suppressed radicle and shoot growth, showing a nonlinear trend (Figure 5 and Table 2). Methanol significantly reduced both radicle and shoot length compared to water ($P < 0.001$).

The terpenes were also evaluated on mugwort, crabgrass, and foxtail millet germination at 1,600 mg/m^3 to determine their phytotoxicity toward a variety of test species at high concentration (Table 3). Mugwort root and shoot inhibition was observed with all terpenes except camphene. Fewer inhibited monocotyledonous test species, suggest that broadleaf species may be more sensitive to the phytotoxic effects.

DISCUSSION

Plant species succession, whether in a natural or agroecosystem, is often disrupted by the introduction of a nonnative species that rapidly displaces native flora or interferes with crop production (Turner, 1988; Sax et al., 2002). Most often this phenomenon is attributed to the greater competitive ability of the introduced plant compared to the native flora or crops in a particular setting

TABLE 3. PERCENT GROWTH INHIBITION OF RADICLE ELONGATION BY MUGWORT TERPENES AT 1,600 MG/M^3

(Williamson, 1996; Williamson and Fitter, 1996; Lockwood et al., 2001). However, in the case of mugwort and about 80 other weedy species (Singh et al., 2001), habitat invasion and loss of biodiversity may be partially accomplished through the release of allelochemicals that can reduce seedling establishment and overall plant fitness (Ridenour and Callaway, 2001; Bais et al., 2003). A greater comprehension of the growth and ecology of nonnative species would assist in furthering our understanding of the mechanisms that contribute to invasiveness (Whittaker and Feeny, 1971; Wardle et al., 1998). A recent study by Callaway and Aschehoug (2000), suggested the importance of allelopathic interference in the ability of diffuse knapweed (*Centaurea diffusa* Lam.) to invade crop and rangelands across North America. The identified toxin in a related *Centaurea* species (*C. maculosa*), (–)-catechin, is believed to cause the formation of reactive oxygen species and lead to eventual root necrosis (Bais et al., 2003). This allelopathic response, deemed the "novel weapons hypothesis," states that nonnative species exude/emit compounds foreign to the native plant community, resulting in enhanced invasiveness (Bais et al., 2003). We attempted to test the "novel weapons hypothesis" in controlled laboratory studies using the invasive perennial weed mugwort, which belongs to a family known for their production of volatile aromatics.

We know that mugwort tends to establish in dense monospecific stands, gradually resulting in a decrease of plant biodiversity, while increasing its radius of expansion from the nucleus of introduction (Barney, 2003). Related *Artemisia* spp. are also reported to be invasive, and many are considered to be noxious weeds, and also known to contain volatile bioactive compounds, primarily terpenoids (Funke, 1943; Muller et al., 1964). Literature states that mugwort contains similar chemicals (LeFevre, 1964; Dung et al., 1992), although a thorough analysis of foliar chemistry has not been performed. Based on the hypothesis that many of the allelochemicals present in mugwort foliage would be volatile terpenoids, we developed a specific assay to assess this potential toxicity.

The assay allowed only indirect (atmospheric) contact between fresh mugwort leaves (donor) and the test species (receptor) in an enclosed environment. We observed significant inhibition of curly cress radicle elongation by volatiles released from as few as two mature mugwort leaves. Assays performed with leaves of various ages from identical mugwort populations demonstrated that the inhibitory potential of foliage, or quantity of volatiles produced, was leaf-age dependent. Similarly, monoterpene concentrations in peppermint (*Mentha* × *piperita* L.) leaves exhibited an exponential decrease with increase in leaf age (Rohloff, 1999; McConkey et al., 2000). This finding is consistent with the decrease of limonene concentrations in peppermint as the plant ages (Gershenzon et al., 2000), showing that terpene concentrations are not static throughout a plant's life cycle. GC–MS results obtained with the ITH-1 population indicate that younger foliar tissue contained up to 28-fold greater concentrations

of monoterpenes. This increase in total volatiles correlates with increased phytotoxicity, as younger tissue is significantly more inhibitory to seedling growth.

Volatile assays were conducted in enclosed receptacles using hand-crushed leaves, which may have resulted in greater volatile concentrations compared to actual field settings (Fehsenfeld et al., 1992). While this assay cannot mimic field conditions, our intention was to evaluate the potential impact of maximal terpene concentrations. If no phytotoxicity were observed with all possible monoterpenes (null hypothesis), one could assume that monoterpenes were not likely influencing the surrounding plant community structure.

Several studies have suggested the role of volatile compounds in suppression of neighboring vegetation. These include the chaparral species *Salvia* and *Eucalyptus*, and the rangeland weed *A. tridentata* (Muller, 1965; del Moral and Muller, 1970; Klarich and Weaver, 1973; Kohli and Singh, 1991), all of which create "monocultural islands" with no surrounding vegetation. These present studies suggest that foliar terpenes can influence the germinators of competing species. Interestingly, in field settings mugwort produces large quantities of foliage resulting in noticeable quantities of released aromatics (Barney, personal observation). Foliar tissues likely generate volatiles continuously over the course of the season, with environmental conditions influencing emission quantities and the association of potential allelochemicals with soil particulates, as observed in many forest and shrubby ecosystems (Lerdau et al., 1995; Guenther et al., 1996; Hayward et al., 2001). In addition, if terpene storage structures are ruptured, their contents are immediately released into atmosphere, with some terpenes likely partitioning into soil organic matter. Soils in a Sitka spruce forest (*Picea sitchensis* Bong.) re-emit monoterpenes accumulated throughout the growing season from the general emission of the spruce trees (Hayward et al., 2001).

Despite their volatility, these compounds have relatively high log pk_{oc} values, with lipophyllic monoterpenes having a 10-fold greater affinity for organic matter than the more polar terpenes. This suggests a potential for accumulation in soil organic matter over time. Association of phytotoxic terpenes with soil organic matter presents a possible mechanism for allelopathic interactions in natural settings. In addition, the solubility of terpenoids identified in mugwort foliage varies greatly (see Table 1), and toxicity is dependent upon concentration. Weidenhamer et al. (1993) showed that camphor in aqueous solution significantly inhibited germination of *Lactuca sativa* L. and *Rudbeckia hirta* L. with concentrations as low as 25 mg/l. Therefore, our results suggest that the affinity of various terpenoids for soil organic matter, coupled with their relatively high water solubility, may lead to accumulation in multiple environmental compartments.

It is possible that the terpenoids produced by mugwort foliage may be active in the environment. Mugwort tissue incorporation, or decomposition over time reduces neighboring species germination (Inderjit and Foy, 1999). The action

of rainfall or dew may also result in the transport of these compounds to the soil surface, resulting in reduced seed germination. Studies performed by Muller (1965) showed that *Salvia* spp. produced volatiles that bind to the soil surface underneath *Salvia* infestations, and subsequently reduce the growth of surrounding weedy species.

Our results indicate that volatile compounds are produced and released by the foliage of three separate mugwort populations. However, potential phytotoxicity varied with population. Numerous studies have shown similar variations in the production of allelochemicals with genotype and plant age (Weston et al., 1987; Fajer et al., 1992). In addition, Inderjit et al. (2001) found site variation, and likely concomitant mugwort population variation between sites, with respect to the effect of mugwort-infestation on soil characteristics. Population variation in phytotoxic chemicals likely explains some of the inconsistencies reported in field studies examining allelopathy (Muller, 1966; Fuerst and Putnam, 1983).

We attempted to identify the specific monoterpenes associated with the phytotoxicity observed in the presence of mugwort foliage, or soil associated volatiles. No one terpenoid could account for the phytotoxicity observed in foliar assays. Most of the monoterpenes produced no inhibition of either root or shoot growth, while some stimulated growth at low concentrations. Camphor treatments, however, did result in reductions to root and shoot growth of various indicator species. This finding is consistent with Abraham et al. (2000) who examined the effect of four monoterpenes on maize seed germination and found the following order of activity: camphor > eucalyptol > α-pinene > limonene.

It is possible that the toxicity observed in our initial experiments with mugwort foliage is due to synergistic combinations of phytotoxic terpenes. Due to the difficulty involved in accurately mimicking terpene mixtures in the lab, neither we nor any other researchers have examined terpene mixtures for allelopathic activity. Therefore, activity observed with mugwort foliage might include combinations of those tested in this study, as well as those untested, such as santolina triene, which occurs in substantial quantities in the foliage, but which was unavailable for evaluation. It is possible that Santolina triene, or unidentified components may influence the overall phytotoxic potential of mugwort volatiles emitted over time in an additive fashion.

Of the parameters assessed, shoot growth was generally slightly more sensitive than radicle elongation to the presence of mugwort volatiles. The quantity of the terpenes appears to be inversely proportional to plant tissue age, and is also population dependent. However none of the individual monoterpenes tested was highly suppressive. Further research on the production, release, and activity of volatiles produced by populations under field conditions are needed. In addition, the potential role of rhizome exudates should be

evaluated to elucidate the contribution of other allelochemicals involved in mugwort interference.

(Received August 19, 2004; accepted October 10, 2004)

Abstract—Atmospheric CO_2 concentrations have increased exponentially over the last century and continuing increases are expected to have significant effects on ecosystems. We investigated the interactions among atmospheric CO_2, foliar quality, and herbivory within a scrub oak community at the Kennedy Space Center, Florida. Sixteen plots of open-top chambers were followed; eight of which were exposed to ambient levels of CO_2 (350 ppm), and eight of which were exposed to elevated levels of CO_2 (700 ppm). We focused on three oak species, *Quercus geminata, Quercus myrtifolia, Quercus chapmanii*, and one nitrogen fixing legume, *Galactia elliottii*. There were declines in overall nitrogen and increases in C:N ratios under elevated CO_2. Total carbon, phenolics (condensed tannins, hydrolyzable tannins, total phenolics) and fiber (cellulose, hemicellulose, lignin) did not change under elevated CO_2 across plant species. Plant species differed in their relative foliar chemistries over time, however, the only consistent differences were higher nitrogen concentrations and lower C:N ratios in the nitrogen fixer when compared to the oak species. Under elevated CO_2, damage by herbivores decreased for four of the six insect groups investigated. The overall declines in both foliar quality and herbivory under elevated CO_2 treatments suggest that damage to plants may decline as atmospheric CO_2 levels continue to rise.

Key Words—Elevated CO_2, *Quercus myrtifolia*, *Quercus chapmanii*, *Quercus geminata*, *Galactia elliottii*, herbivory, nitrogen fixer, Kennedy Space Center.

INTRODUCTION

Atmospheric carbon dioxide (CO_2) concentrations began increasing with the advent of the industrial revolution and are continuing to increase at a rate of approximately 4 ppm annually. At the current rate of increase, CO_2 levels are expected to double by the end of this century to 750 ppm. The increase is expected to have significant effects on ecosystems, including short-term physiological changes in plants and long-term changes in ecosystem structure and function. Numerous studies have been conducted to determine the effects of elevated CO_2 on plants and their associated communities. Plant responses to elevated CO_2 concentrations are idiosyncratic within and among species (Williams et al., 1986; Lindroth et al., 1993; Curtis et al., 1996; Johnson et al., 1996; Mousseau et al., 1996; Cook et al., 1997; Van Gardingen et al., 1997; Woodward and Beerling, 1997). Some general trends, however, have emerged.

In the short term, elevated CO_2 increases photosynthesis across various ecosystems (Drake et al., 1997; Norby et al., 1999), including arctic tundra (Oberbauer et al., 1986; Tissue and Oechel, 1987), grasslands (Smith et al., 1987), and deciduous forests (Williams et al., 1986). After a period of time, some species adjust their photosynthetic rates whereas others show little or no adjustment (Williams et al., 1986; Smith et al., 1987; Tissue and Oechel 1987). Root to shoot ratio (Ceulemans and Mousseau 1994; Mousseau et al., 1996) and biomass tend to increase (Leadley et al., 1999; Owensby et al., 1999). Consistent plant chemical changes include increases in foliar C:N ratios and decreases in foliar nitrogen concentrations (Bezemer and Jones, 1998). According to some plant defense hypotheses, increases in carbon availability should result in increases in carbon based secondary metabolites (Bryant et al., 1983; Tuomi et al., 1984) though there have been no consistent affects of CO_2 on secondary metabolite concentrations (Bazzaz, 1990).

Resource availability appears to influence the degree to which plant species adjust to elevated CO_2 (Bazzaz, 1990; Lindroth et al., 1993). The effect of elevated CO_2 on plants is enhanced when other resources such as water, light, and nutrients are abundant (Bloom et al., 1985; Chapin et al., 1987), and the effects are mitigated when nitrogen or phosphorus is limiting (Zangerl and Bazzaz, 1984; Brown and Higginbotham, 1986). Plant responses appear to be linked to the ability of species to store carbohydrates by increasing the size and/or number of leaves, length of roots, and fine root turnover (Ceulemans and Mousseau, 1994; Johnson et al., 1996; Mousseau et al., 1996). Changes in the nutritional and defensive characteristics of host plants may result in behavioral and/or physiological changes in herbivores (Lindroth, 1996; Bezemer and Jones, 1998; Stiling et al., 1999). Lower levels of nitrogen and higher C:N ratios in plants under elevated CO_2 have generally been associated with compensatory feeding and subsequent increases in levels of damage or defoliation (Lincoln et al., 1984, 1993; Fajer et al., 1989; Lindroth

et al., 1993, 1995; Salt et al., 1995; Docherty et al., 1997; Kinney et al., 1997; Williams et al., 1997; but see Hamilton et al., 2004).

Leaf-chewing insects such as grasshoppers (Johnson and Lincoln, 1990) and lepidopteran larvae (Lindroth et al., 1993, 1995) generally consume more leaf area when fed plants that have been grown under elevated CO_2. Likewise, the area damaged by leaf-mining insects may also increase (Salt et al., 1995). Lepidopteran larvae exhibit increased mortality and slower growth rates when feeding on elevated CO_2 plants (Akey and Kimball, 1989; Fajer, 1989; Fajer et al., 1989, 1991). Consequently, herbivores may become more susceptible to pathogens, parasitoids, and predators (Price et al., 1980; Lindroth, 1996; Stiling et al., 1999). For example, increases in mortality of leaf miners feeding on elevated CO_2 plants has been linked to increases in parasitism (Stiling et al., 1999). In the longest field study to date, some insect herbivore populations have been shown to decline markedly under elevated CO_2 (Stiling et al., 1999, 2002, 2003).

Our study used open top chambers in a field-based experiment to examine the effects of elevated CO_2 on foliar chemistry and herbivore damage in a scrub oak community. We focused on four dominant plants species within the community; three oaks and a nitrogen-fixing legume, and hypothesized that the oak species would respond similarly with decreases in nitrogen and increases in C:N ratios and secondary metabolites under elevated CO_2. We further hypothesized that the nitrogen-fixing legume would exhibit little change in nitrogen concentrations since the ability to fix nitrogen may result in less nitrogen dilution. Additionally, we measured foliar damage by six different herbivore-feeding guilds on the four plant species. We hypothesized that herbivore damage would decline on the oaks under elevated CO_2 because we expected that herbivores would be unable to compensate for decreases in foliar nitrogen under the rigors of field conditions. We predicted that there would be little change in herbivore damage on the nitrogen-fixing legume.

METHODS AND MATERIALS

Study Site. Our study site lies within a 2-hectare native scrub-oak community located at Kennedy Space Center, Florida. This woody ecosystem is controlled by a natural fire return cycle of 8–12 yr and the mature canopy is 3–5 m high. The last burn cycle was in 1996 prior to site set up. Sixteen 3.6-m diam plots, each enclosed with a clear polyester film open-top chamber 3.4 m in height, were utilized to control CO_2 levels. Chambers were overlaid on an octagonal framework of PVC pipe with a removable access door and frustrum to reduce dilution of air within the chamber by outside wind. All re-growth was cut to ground level in May 1996 and, since that time, the vegetation in eight of the chambers has been exposed to almost twice ambient CO_2 (700 ppm), while the other eight have been

exposed to ambient levels (350 ppm). The CO_2 is supplied 24 hr a day. Monitoring and control of CO_2 injection into each chamber is done by infrared gas analyzer in conjunction with manually adjusted needle valves. In ambient CO_2 chambers, the airflow is identical to that of the elevated CO_2 chambers but is not supplemented with CO_2. Four species dominate this community and are present in every chamber: three oak species, *Quercus myrtifolia* Willd; *Q. chapmanii* Sargent; *Q. geminata* Small; and the nitrogen fixing legume, *Galactia elliottii* Nuthall. Chambers were originally established to investigate effects of elevated CO_2 on plant productivity and nutrient cycling. Studies of herbivores and leaf chemistry were a later addition to the project.

Foliar Chemistry. Samples of fresh leaves from each of the four study species were collected for chemical analysis. We haphazardly removed four undamaged leaves from each of three individuals per chamber from each of the three oak species every 3 mo (May 2001–May 2003). While in the field, a hole punch was used to remove two disks of leaf tissue from each leaf. One disk was used to obtain the dry weight of the disk, while the other was placed into 70/30 acetone/water with 1 mM ascorbic acid and used for subsequent phenolic analysis. The remaining portion of the leaf was returned to the lab on ice, dried, and used to measure C, N, and fiber (cellulose, hemicellulose, lignin). Because of its small leaf size, the collection method for *G. elliottii* differed slightly. Two opposite leaflets, each from three individuals were collected from each chamber. One leaflet was placed in acetone for phenolic analysis; the opposite leaflet in a bag and used to obtain leaf weights and, subsequently, C, N, and fiber content. Samples from different individual plants of a given species were pooled within chambers so that chambers (8 per treatment) acted as replicates. Dried leaves were ground to a fine powder and stored at -80°C prior to analysis.

Percent dry weight nitrogen and carbon were estimated from leaf powder on a Carlo-Erba NA1500 model C/N analyzer (Milan, Italy). These data also provided estimates of foliar C:N ratios. Subsamples of leaf powder (above) were also used to assess the effects of elevated CO_2 on foliar concentrations of cellulose, hemicellulose, and lignin by sequential neutral detergent/acid detergent digestion on an Ankom fiber analyzer (Abrahamson et al., 2003). Phenolic analysis was conducted using the leaf disks collected into 70% acetone in the field. Proanthocyanidins, an estimate of condensed tannin, were assayed by using N-butanol:HCL methods described in Rossiter et al. (1988). Total phenolics were estimated by using the Folin-Denis assay (Swain, 1979), and gallotannins (hydrolyzable tannins) were estimated with a potassium iodate technique developed by Bate-Smith (1977) and modified by Schultz and Baldwin (1982). Standards for tannin analysis were generated by multiple sequential washes of bulk samples (one for each species) by acetone extraction. All tannin assays produced colorimetric readings, in proportion to tannin concentration, which were quantified by using a BioRad microplate reader.

Damage Estimates on Green Leaves. We counted 200 randomly selected leaves from each of the species from each chamber every 3 mo starting in May 2001 and ending in May 2002. Each leaf was scored for the presence of six types of herbivore damage; leaf gall, eye spot gall, leaf tier, chewed leaf, mined leaf, and (*G. elliottii* only) leaf mite.

Statistical Analysis. All data met the assumptions of normality (Kolmogorov-Smirnov test, $\alpha = 0.05$) and were analyzed using parametric statistics. Foliar chemistry was analyzed over a 2-yr period (May 2001–May 2003). This represents 9 sampling dates for the oak species and 8 for *G. elliottii*, which was absent from all chambers during February 2003. Variation in foliar quality (carbon, nitrogen, fiber, and phenolics) under elevated and ambient CO_2 treatments across time was analyzed using repeated measures GLM with Tukey's HSD test for significant differences ($\alpha = 0.01$). Damage estimates were analyzed for a single year (May 2001–May 2002). Variation in herbivore damage under elevated and ambient CO_2 treatments across time was analyzed using repeated measures GLM with Tukey's HSD test for significant differences ($\alpha = 0.05$).

RESULTS

Foliar Chemistry. As predicted, foliar nitrogen concentrations declined and C:N ratios increased under elevated CO_2 treatments. The mean percent dry weight of nitrogen was 1.37 (SE $\pm$ 0.02) under ambient CO_2 conditions and 1.25 (SE $\pm$ 0.02) under elevated CO_2 conditions ($F_{1,38} = 9.20$, $P = 0.004$). The mean C:N ratio was 38.57 (SE = 0.56) in the ambient treatments and 41.74 (SE = 0.58) in the elevated treatments ($F_{1,38} = 13.39$, $P < 0.001$). Contrary to our predictions, foliar phenolics, total carbon, and fiber content were unaffected by elevated CO_2 (Table 1). There were no significant treatment (CO_2) by date or species interactions, suggesting that elevated CO_2 also caused reductions in foliar nitrogen of the nitrogen-fixer, *G. elliottii* comparable to those observed in the three oaks. Hydrolyzable tannin concentrations were greatest in *Q. chapmanii* and lowest in *Q. geminata*, while total phenolic concentrations were greatest in *G. elliottii* and lowest in *Q. geminata* (hydrolyzable tannins, $F_{3,33} = 4.94$, $P = 0.006$; total phenolics $F_{3,21} = 9.63$, $P < 0.001$). Nitrogen concentrations were highest and carbon and C:N ratios lowest for the nitrogen fixer *G. elliottii*, while *Q. myrtifolia* had the lowest levels of nitrogen and highest levels of carbon and C:N ratio (statistical values for species effects on nitrogen, carbon, and C:N ratio, respectively; $F_{3,38} = 9.74$, $P < 0.001$; $F_{3,38} = 7.09$, $P < 0.001$, $P < 0.001$, $F_{3,38} = 12.16$, $P < 0.001$. Q. geminata had the highest percentage of fiber (cellulose, hemicellulose). G. elliottii had the lowest levels of cellulose and hemicellulose (cellulose, $F_{3,37} = 9.18$, $P < 0.001$; hemicellulose, $F_{3,37} = 7.49$, $P < 0.001$). Species differed in their relative foliar chemistries over time (Figure 1). The only consistent

Note. Data represent % dry weights (except C:N ratio) and are the means of 72 samples except *G. elliottii* (64 samples). Standard errors are in parentheses. Significant teatment differences are in bold.

differences among species were higher nitrogen concentrations and lower C:N ratios in *G. elliottii* compared with the three oak species (Figure 1a and c).

Damage Estimates on Green Leaves. Herbivore damage by chewers, miners, eye spot galls, and leaf tiers declined under elevated CO_2 (chewed, $F_{1,52} = 29.01$, $P < 0.001$, mined $F_{1,52} = 17.06$, $P < 0.001$; eye spot galls, $F_{1,38} = 14.91$, $P < 0.001$, leaf tier $F_{1,38} = 6.92$, $P = 0.012$) (Figure 2). Additionally, there was a weak trend for leaf mite and leaf gall damage to decline under elevated CO_2 (Figure 2). Chewers and miners occurred on all species, while leaf galls, eye spot galls, and leaf tiers occurred exclusively on the *Quercus* species and leaf mites

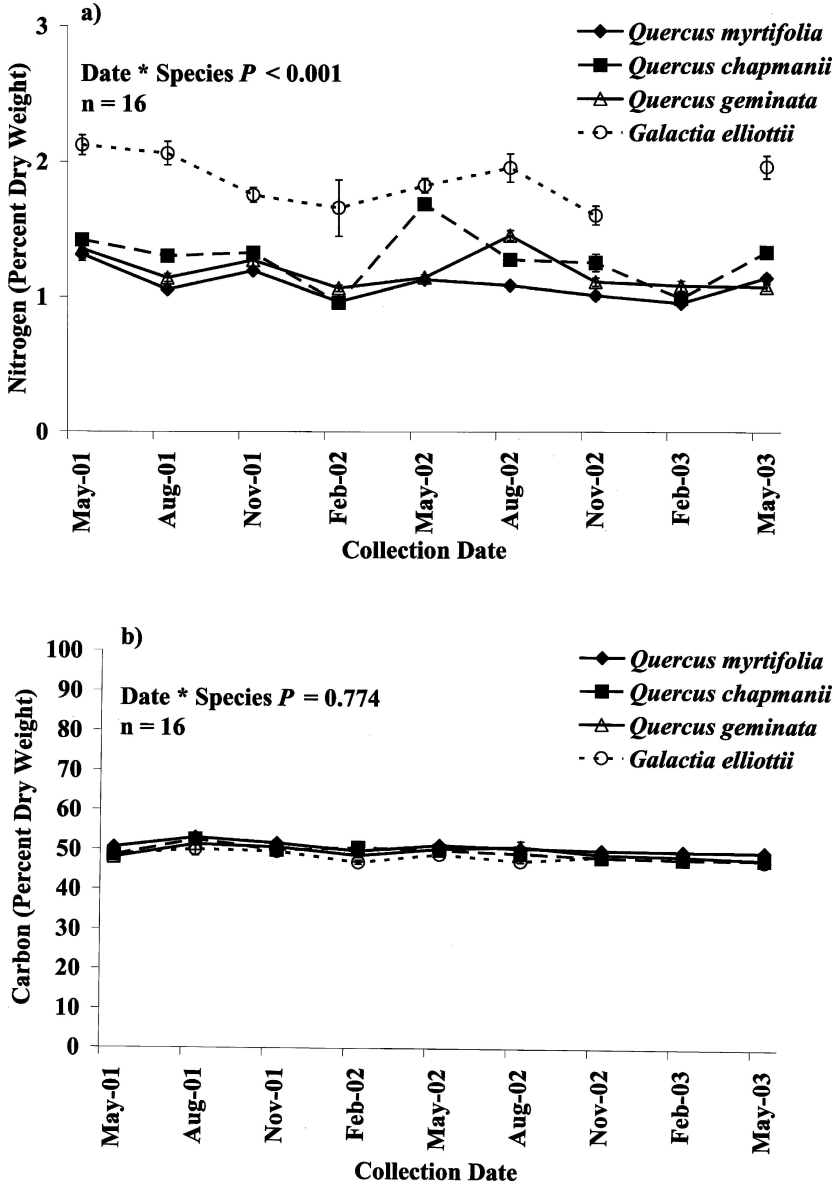

FIG. 1. Foliar chemistry of plant species over time. Nitrogen = a, carbon = b, C:N ratios = c, condensed tannins = d, hydrolyzable tannins = e, total phenolics = f, cellulose = g, hemicellulose = h, lignin = i. Data are the means of 16 samples (chambers). Bars represent standard errors. Note that G. elliottii was absent from all chambers in February 2003.

occurred exclusively on *G. elliottii* (Table 2). Chewing damage was higher under ambient than elevated CO_2 during all months except November (date* CO_2 interaction $F_{4,208} = 7.18$, $P < 0.001$, Figure 3a). Leaf tier damage was higher under ambient than elevated CO_2 during all months except May 2001 and February 2002 (Date* CO_2 interaction $F_{4,152} = 2.98$, $P = 0.021$ Figure 3b). Effects of elevated CO_2 on chewer damage were particularly pronounced on *Q. chapmanii* ($F_{3,52} = 4.30$; $P = 0.009$, Figure 4a), while CO_2 effects on eye spot galls were pronounced on *Q. myrtifolia* and *Q. geminata* ($F_{2,38} = 7.31$, $P = 0.002$, Figure 4b).

DISCUSSION

Though not all plants respond identically to increased concentrations of CO_2 (Bezemer and Jones, 1998; Hunter, 2001), all four of our study species responded in a similar fashion. While there were differences in overall chemical composition among the four species (Table 1), all exhibited declines in foliar nitrogen concentrations and increases in C:N ratios under elevated CO_2, while polyphenolics and fiber were unaffected. Changes in nitrogen levels and C:N ratios in the oak species are not surprising given the consistency with which this has been found in previous studies (Cipollini et al., 1993; Ceulemans and Mousseau, 1994; Luo et al., 1994; Curtis et al., 1996; Wilsey, 1996; Stiling et al., 1999; Reich et al., 2001).

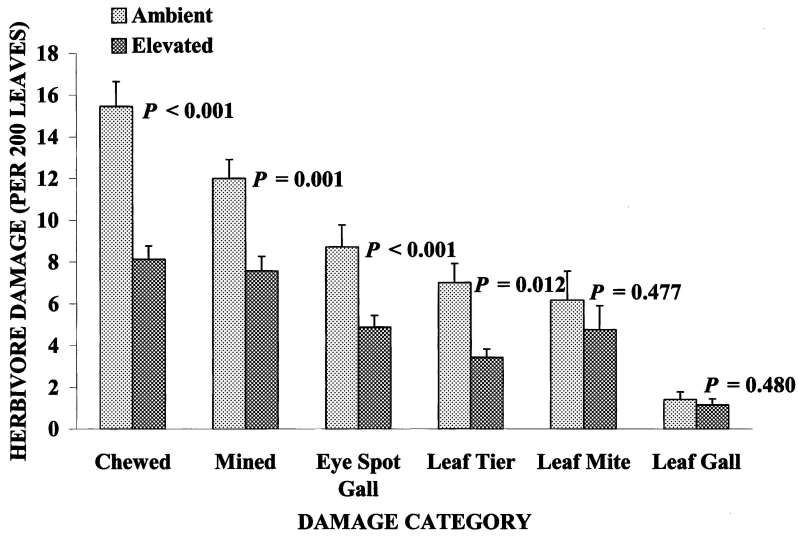

FIG. 2. Herbivore damage across all plant species. Data are the means of 160 samples for miner and chewer damage (occurred on all plant species), 120 samples for eye spot gall, leaf gall, and leaf tier damage (occurred only on oak species) and 40 samples for leaf mite damage (occurred only on the nitrogen fixer). Bars represent standard errors.

TABLE 2. HERBIVORE DAMAGE ON FOUR PLANT SPECIES AT THE KENNEDY SPACE CENTER, FLORIDA

Species	Chewing damage	Mined damage	Eye spot gall damage	Leaf tier damage	Leaf gall damage
Q. myrtifolia	11.61	13.35	12.56	5.56	2.17
	(1.07)	(1.01)	(1.40)	(0.76)	(0.55)
Q. chapmanii	18.75	12.49	0.43	5.60	0.33
	(2.14)	(1.34)	(0.15)	(1.13)	(0.13)
Q. geminata	9.84	7.60	7.12	4.59	1.27
	(0.96)	(0.88)	(0.70)	(0.73)	(0.37)
G. elliottii	7.45	5.89	—	—	—
	(0.86)	(1.00)	(·)	(·)	(·)
P value	$P < 0.001$	$P < 0.001$	$P < 0.001$	$P = 0.807$	$P = 0.018$

Note. Not all herbivore damage occurred on all plant species, therefore data are the means of 80 samples for chewers and miners and 60 samples for eye spot galls, leaf tiers, and leaf galls. Standard errors are in parentheses and *P* values represent the significance of species effects on herbivore damage.

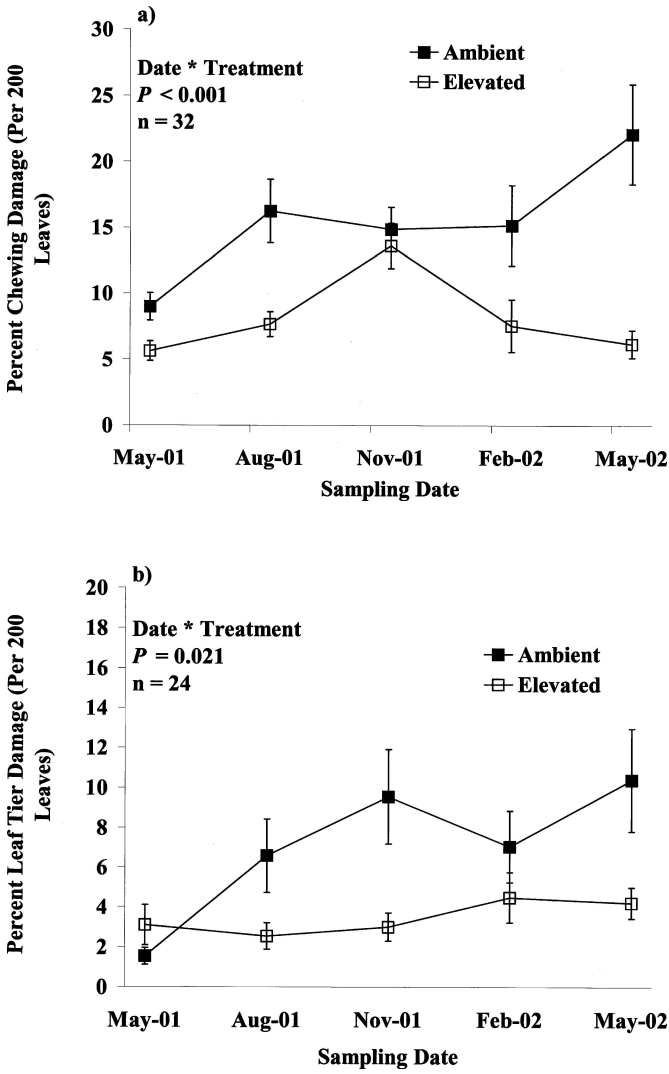

FIG. 3. Damage by chewing herbivores (a) and leaf tiers (b) under elevated CO_2. Data are the means of 32 samples for chewing herbivores and 24 samples for leaf tiers and bars represent standard errors.

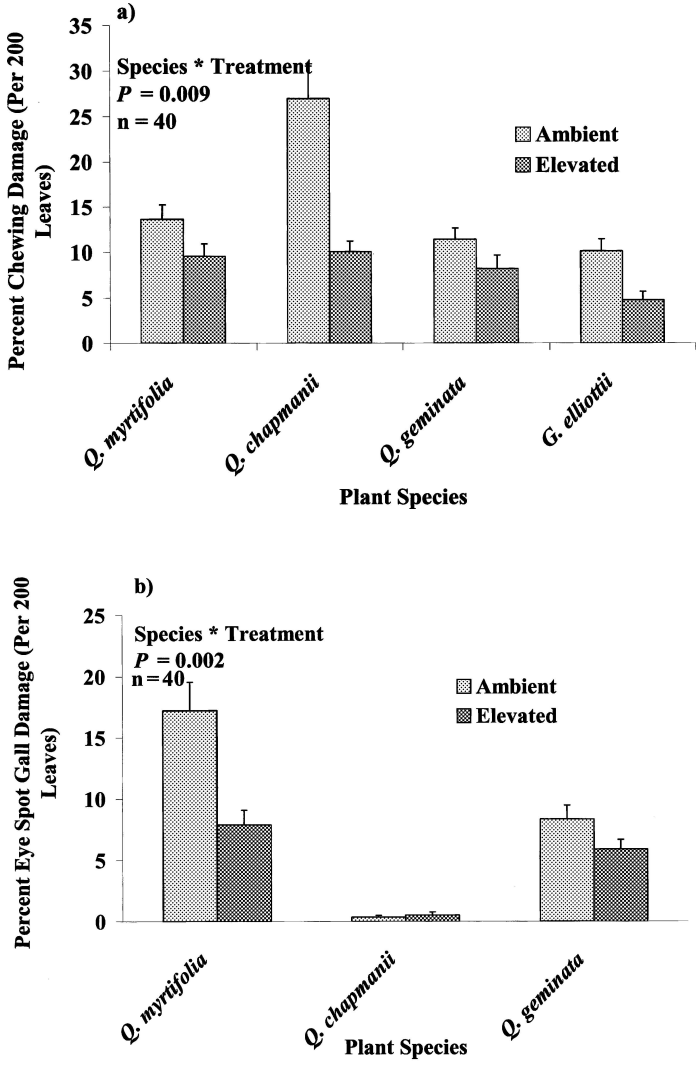

FIG. 4. Treatment effects by plant species for a) chewing damage and b) eye spot gall damage. Data are the means of 40 samples and bars represent standard errors.

Finding the same response in the nitrogen fixer, however, was not expected. Reich et al. (2001) did report that aboveground (foliar) nitrogen levels declined in four legumes (*Amorpha canescens, Lespedeza capitata, Lupinus perennis, Petalostemum villosuni*), while below ground (root) nitrogen levels remained unchanged

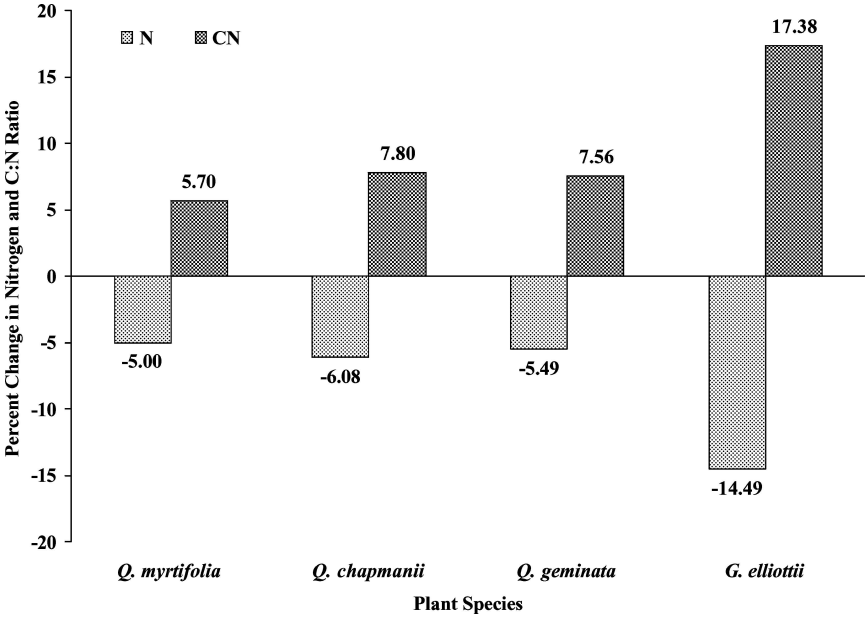

FIG. 5. The percent change in nitrogen and C:N ratio under elevated CO_2 treatments for *Q. myrtifolia*, *Q. chapmanii*, *Q. geminata*, and *G. elliottii*. Percent change values are shown.

under elevated CO_2. This indicates that even nitrogen fixers exhibit modified leaf nitrogen under elevated CO_2. More surprising, however, was the magnitude of change in nitrogen levels and C:N ratios of the nitrogen fixer when compared to the three oaks. The percent decrease in nitrogen and increase in C:N ratio of the nitrogen fixer under elevated CO_2 was more than twice the percent change seen in the three oak species (Figure 5). Given that lower nitrogen levels appear to be the primary driver affecting herbivores under elevated CO_2, the decrease in foliar nitrogen and increases in C:N ratios may be expected to have strong effects on herbivores that depend on nitrogen fixing plant species.

Though nitrogen levels were lower and C:N ratios higher under elevated CO_2 conditions, there were no treatment effects on the compounds measured (condensed tannins, hydrolyzable tannins, total phenolics, cellulose, hemicellulose, and lignin). It is expected that increased availability in carbon via increased levels of CO_2 would result in changes in carbon-based compounds in plants. However, studies thus far have been inconclusive. Some species increase in levels of phenolics, while others decrease or remain the same (Bezemer and Jones, 1998, Hamilton et al., 2004). Dury et al. (1998) found short term increases in phenolics in *Quercus robur*. Lindroth et al. (1993) examined seedlings of three

trees (*Populus tremuloides*, *Quercus rubra*, *Acer saccarum*) and found varying responses in phenolic concentrations with increases, decreases, and no changes being recorded. Phenolic concentrations also varied with leaf flush (i.e., time of CO_2 exposure). Williams et al. (1998) found that young leaves of *Quercus alba* had significantly lower leaf nitrogen content and significantly higher total nonstructural C:N ratio as plant CO_2 concentrations rose, while nonstructural carbohydrates and total carbon-based phenolics were unaffected. In some instances, total nonstructural carbohydrates (TNC), especially starch, show large increases in elevated CO_2 conditions (Saxe et al., 1998). Also, in woody species, available carbon might be allocated to woody tissue rather than foliar tissue. Therefore, it is possible that changes in carbon concentrations occurred in our species, but were not found because we did not measure TNC or woody tissue.

In our study, herbivore damage by a number of feeding guilds was lower under elevated CO_2. Additionally, there were no treatment by plant species interactions, indicating that the response to elevated CO_2 was the same across all species. The nutritional quality of plant foliage can have profound effects on herbivores (Feeny, 1968, 1992; Coley and Aide, 1991; Dury et al., 1998). Low nitrogen and high concentrations of polyphenolics and lignin indicate low nutritional quality. Nitrogen is often a limiting resource for herbivores, and limited nitrogen levels can lead to decreased growth rates, development, and fecundity (Scriber and Slansky, 1981; Schultz and Baldwin, 1982; White, 1984; Bazzaz, 1990). High concentrations of polyphenolics, such as tannins, may inhibit digestion. Increased fiber can lead to tougher and/or indigestible leaves (Feeny, 1968, 1992; Schultz and Baldwin, 1982; Schowalter et al., 1986; Coley and Aide, 1991; Dury et al., 1998; Williams et al., 1998).

Studies showing compensatory feeding by herbivores on high C:N foliage have occurred exclusively under laboratory conditions (Lincoln et al., 1986; Fajer, 1989; Johnson and Lincoln, 1990). Low nitrogen foliage may increase development time and under field conditions increase the risks posed to herbivores by natural enemies (Stiling et al., 1999, 2002, 2003) or abiotic factors.

The decline in foliar nitrogen concentrations and increase in C:N ratios in our study are the only indication of low foliar quality under elevated CO_2. Previous studies have shown that low quality foliage has negative impacts on leafmining insects (Stiling et al., 1999, 2002, 2003). These impacts appear to result from the combined effects of nutrient limitation and increases in parasitism and predation. Stiling et al. (1999) found that decreases in plant quality due to elevated CO_2 doubled leafminer mortality, while increases in parasitism due to elevated CO_2 quadrupled leafminer mortality. Insect herbivores often compensate for low foliar quality by increasing their food intake (Karban and Baldwin, 1997; Agrawal et al., 1999), yet such compensation did not act to increase the proportion of leaves damaged under elevated CO_2 in our study.

Herbivore damage can influence foliar and litter quality (Findlay et al., 1996; Agrawal et al., 1999) by a number of mechanisms including chemical induction and premature leaf abscission. These changes can affect vital ecosystem processes, such as decomposition and nutrient cycling. Therefore, elevated CO_2 can potentially influence these ecosystem processes via direct effects through changes in foliar quality and indirect effects through herbivores that change foliar and litter quality. Future research will investigate some of these ecosystem level effects.

Acknowledgments—This research was supported by the Office of Science (BER), U.S. Department of Energy, through the South East Regional Center of the National Institute for Global Environmental Change under Cooperative Agreement No. DE-FC03-90ER61010. We thank Chris Frost and Caralyn Zehnder for comments on a previous draft of this manuscript and Jane Rogers, Star Scott, and Oren Kleinberger for laboratory assistance. (Received January 6, 2004; accepted October 6, 2004)

Abstract—Studies in crop species show that the effect of plant allelochemicals is not necessarily restricted to herbivores, but can extend to (positive as well as negative) effects on performance at higher trophic levels, including the predators and parasitoids of herbivores. We examined how quantitative variation in allelochemicals (iridoid glycosides) in ribwort plantain, *Plantago lanceolata*, affects the development of a specialist and a generalist herbivore and their respective specialist and generalist endoparasitoids. Plants were grown from two selection lines that differed ca. 5-fold in the concentration of leaf iridoid glycosides. Development time of the specialist herbivore, *Melitaea cinxia*, and its solitary endoparasitoid, *Hyposoter horticola*, proceeded most rapidly when reared on the high iridoid line, whereas pupal mass in *M. cinxia* and adult mass in *H. horticola* were unaffected by plant line. *Cotesia melitaearum*, a gregarious endoparasitoid of *M. cinxia*, performed equally well on hosts feeding on the two lines of *P. lanceolata*. In contrast, the pupal mass of the generalist herbivore, *Spodoptera exigua*, and the emerging adult mass of its solitary endoparasitoid, *C. marginiventris*, were significantly lower when reared on the high line, whereas development time was unaffected. The results are discussed with regards to (1) differences between specialist and generalist herbivores and

* To whom correspondence should be addressed. E-mail: j.harvey@nioo.knaw.nl

their natural enemies to quantitative variation in plant secondary chemistry, and (2) potentially differing selection pressures on plant defense.

Key Words—Chemical defense, iridoid glycosides, *Melitaea cinxia*, multitrophic interactions, *Plantago lanceolata*, *Spodoptera exigua*.

INTRODUCTION

Many plants produce a range of toxic secondary compounds (allelochemicals) that are either constitutively expressed, or induced in response to herbivory (Karban and Baldwin, 1997). These chemicals may act as feeding deterrents or alter the physiology and development of herbivores, resulting in reduced rates of growth, smaller adult size, and increased mortality. However, plant allelochemicals not only affect the behavior and performance of herbivores feeding on the plant, but also the behavior and performance of organisms at higher trophic levels (Hare, 2002). Such effects have implications for the evolution of plant chemical defense. In some cases, higher-trophic level effects are beneficial for the plant and enhance the selective advantage of producing high levels of an allelochemical in the presence of parasitoids or predators of herbivores. For instance, allelochemicals that slow down the rate of herbivore development increase the exposure time or window of their vulnerability to parasitoids and predators (Turlings and Benrey, 1998). In other cases, these effects may be detrimental, especially if herbivores use plant allelochemicals for their own defense against parasitoids and predators (e.g., Campbell and Duffey, 1979). Many insect herbivores are specialized on plants producing particular groups of allelochemicals. For example, larvae of many species of checkerspot (fritillary) butterflies (Nymphalidae) are restricted to plants producing iridoid glycosides (Wahlberg, 2001). Specialized herbivores can often deal with high levels of specific phytotoxins in their diet (Nishida, 2002), even though their performance may be lower on plants containing high rather than low amounts of these phytotoxins (Adler et al., 1995). Although some herbivore species break down and excrete ingested allelochemicals during development, many others use them to their own advantage by sequestering them in hemolymph and other tissues, or concentrating them in the gut (Rimpler, 1991; Nishida, 2002).

A number of studies have reported that allelochemicals in herbivores reduce the performance of less well-adapted predators and parasitoids (e.g., Duffey et al., 1986; Gunasena et al., 1990; Barbosa et al., 1991). In contrast, in the handful of studies addressing the performance of specialized natural enemies, such as parasitoids that attack one or only a few related hosts in nature, development appears to be less affected by differences in allelochemicals (Barbosa et al., 1986; Sznajder and Harvey, 2003). The higher-tropic-level effects of allelochemicals are, thus, likely to depend on the level of specialization of the herbivores and parasitoids or predators involved.

We examined the developmental responses of a generalist and a specialist insect herbivore and their endoparasitoids to quantitative variation in iridoid glycosides (IGs) in ribwort plantain, *Plantago lanceolata* L. (Plantaginaceae), a perennial plant species with a worldwide distribution and a large ecological amplitude. IGs are a group of monoterpene-derived compounds that have been recorded in over 50 plant families (Jensen, 1991). The main IGs found in *P. lanceolata* are catalpol and its precursor aucubin (Bowers, 1991). Concentrations of IGs in natural populations of *P. lanceolata* range from undetectable to ca. 9% of plant dry weight, and vary both among populations and individuals within populations (Bowers, 1991; Nieminen et al., 2003). IG concentrations in *P. lanceolata* are partly under genetic control (Adler et al., 1995; Marak et al., 2000), but also vary in response to plant attributes such as leaf and plant age (Bowers and Stamp, 1993) and abiotic factors such as light and nutrient levels (Marak et al., 2003), and can be induced by both herbivores and pathogens (Darrow and Bowers, 1999; Marak et al., 2002a). In artificial diet studies, these compounds reduce the growth of generalist, but not specialist, insect herbivores (Bowers and Puttick, 1988; Puttick and Bowers, 1988). Specialist insects use these compounds as oviposition and feeding stimulants (Pereyra and Bowers, 1988; Nieminen et al., 2003) and sequester them for their own defense (Bowers and Collinge, 1992; Camara, 1997; Suomi et al., 2001).

The insect species used in this study were (i) the specialist herbivore, *Melitaea cinxia* L. (Lepidoptera: Nymphalidae) and its endoparasitoids, *Cotesia melitaearum* Wilkinson (Hymenoptera: Braconidae) and *Hyposoter horticola* Gravenhorst (Hymenoptera: Ichneumonidae) and (ii) the generalist herbivore, *Spodoptera exigua* Hubner (Lepidoptera: Noctuidae) and its endoparasitoid, *C. marginiventris* L. (Hymenoptera: Bracondiae).

M. cinxia, the Glanville fritillary, is a specialist feeder of plants containing iridoid glycosides. Larvae use IGs as feeding stimulants, whereas adults use them as oviposition cues (Nieminen et al., 2003; van Nouhuys and Kumar, unpublished data). The first five instars develop within a large silken web during the first year. The following spring, after diapause, larvae complete the final two instars. In Northern Europe, *M. cinxia* is univoltine. A detailed description of the life cycle is provided by Kuussaari et al. (2004). *C. melitaearum* is a specialist parasitoid of butterfly larvae in the genus *Melitaea* (van Nouhuys and Hanski, 2004). It attacks early and late instars of *M. cinxia*, ovipositing into the host hemocoel. Larvae feed primarily on host hemolymph and fat body. It may complete up to three generations in a single year. *H. horticola* is also a specialist parasitoid of *M. cinxia*. It produces only one generation per year and its development is closely synchronized with that of its host. It lays a single egg in first instar host larvae just before they hatch from the egg (van Nouhuys and Hanski, 2004; van Nouhuys and Ehrnsten, unpublished results). Although the eggs hatch within a few days, development is suspended as a first instar until the host has reached its fifth instar

and has broken diapause. Once the host has entered its final instar, the parasitoid larva starts attacking all tissues, ultimately consuming the entire host except for its cuticle.

S. exigua, the southern beet armyworm, is a highly polyphagous insect herbivore (Greenberg et al., 2001). It is endemic to South East Asia, but has been introduced over much of the world. Larvae complete five instars during development. In warm regions, it produces several generations per year. *C. marginiventris* parasitizes larvae of several species in the family Noctuidae. It parasitizes first to fourth instars of *S. exigua* and oviposits a single egg in the host hemocoel. Like the closely related species *C. melitaearum*, larvae of *C. marginiventris* feed primarily on host hemolymph and fat body.

In this study, we compare fitness correlates (development time and pupal or adult body mass) of the herbivores and their parasitoids reared on two lines of *P. lanceolata* containing different levels of iridoid glycosides. The results are discussed in terms of the role that generalist and specialist herbivores and their natural enemies play in selection for direct chemical defense.

METHODS AND MATERIALS

Plants. P. lanceolata used in this experiment was derived from an artificial selection experiment (for details see Marak et al., 2000), in which plants were selected on the basis of high and low concentrations of total leaf iridoid glycosides for four generations. Selection resulted in an average 3-fold difference in leaf iridoid glycoside concentration between upward and downward selected lines (Marak et al., 2000, 2003). Within each of these selection lines, iridoid glycoside concentrations vary considerably among maternal half-sib families, so that much larger, up to 20-fold, differences are present between extreme families from these selection lines. For the current experiment, seeds from the six most extreme female half-sib families from each selection line were used. Ten seeds from each family were germinated in a growth cabinet (14/10 hr and 25/15°C L/D), and transplanted individually into plastic 2.2 l pots with a mixture of potting soil and sand (4:1 v:v). Plants were grown in a greenhouse (16/8 hr and 22/18°C L/D) and regularly fertilized with half strength Hoagland's nutrient solution. Two extra plants per family were grown and harvested 5 wk after transplantation for chemical analysis. Of each plant, 50 mg from the freeze-dried and fine-ground leaf material were extracted overnight in 10 ml of 70% methanol for analysis of iridoid glycosides (aucubin and catalpol) using HPLC (methods in Marak et al., 2002b). Another 300 mg of each plant were used for analysis of total nitrogen and phosphorus using a Technicon Traacs 800 autoanalyzer (Technicon Instruments Corp., Tarrytown, NY) following methods described in Novozamsky et al. (1983).

Specialist Insects. Unless indicated otherwise, cultures of insect species were maintained in climate rooms under 16:8 hr L/D photoperiod under a constant temperature of 25 ± 0.5°C and 50 ± 2% RH. *M. cinxia* used in the experiments all originated from the Åland islands of SW Finland. Two different groups of *M. cinxia* larvae were used, one group (reared in 2000–2001) of which a subset was parasitized by *C. melitaearum* and another group (reared in 2001–2002) of which a subset was parasitized by *H. horticola*.

The first group of *M. cinxia* larvae consisted of approximately 200 offspring of field-caught butterflies that were reared at ambient temperatures in the laboratory from June to August 2000 (diapause as L5) on *P. lanceolata* plants that had been collected randomly from natural populations in the Åland islands. Larvae were maintained in diapause at 2°C under 6:16 hr L/D photoperiod until April 2001. At this time, diapause was broken by gently spraying water on the larvae. Upon resuming activity, larvae were randomly separated into two cohorts of approximately 100 individuals and placed into plastic boxes containing moistened paper towel and excised leaves of *P. lanceolata* containing either high or low levels of iridoid glycosides (see below for a quantitative measure). Leaves were selected from both plant lines, which were of approximately the same age and location on the plant, and were refreshed on a daily basis.

Approximately 100 cocoons of *C. melitaearum* were obtained from overwintering Åland laboratory populations in April 2001. Upon emergence, wasps were housed collectively in plastic Petri dishes (20 cm diam) at 10°C and were constantly supplied with honey and water. The remaining insects were reared according to standard protocol for cultures (top). Approximately half of the *M. cinxia* larvae reared on each line of *P. lanceolata* were randomly selected from culture as L6, and were presented individually to an adult female of *C. melitaearum* in small plastic vials. Oviposition was verified by a single insertion and removal of the ovipositor. Parasitized caterpillars were reared separately on leaves of *P. lanceolata* from either the high or low IG line, continuing the treatment prior to parasitism. Upon larval egression from the host, parasitoid brood sizes were determined, and following adult parasitoid emergence, wasps were killed by freezing. Egg-to-adult development time in days was determined, and adult (wet weight) body mass was measured using a Sartorius microbalance (accuracy 1 μg).

The second group of *M. cinxia* larvae was directly collected from the field. In contrast to *C. melitaearum*, experimental parasitation of *M. cinxia* by *H. horticola*, which parasitizes larvae before hatching, is extremely difficult. Therefore, eight larval groups of *M. cinxia* that had been observed being naturally parasitized by *H. horticola* (S. van Nouhuys, personal observation) were obtained from Åland populations in July 2001. *H. horticola* parasitizes 1/4 to 1/3 of the larvae in each larval group, so approximately 200 of the 800 larvae were parasitized. From L3, each larval group was split into two, and one half was reared (under standard rearing conditions, top) on intact plants from the high IG line and the other half on

plants from the low IG line. At the end of August, L5 larvae were removed from food-plants and maintained under diapause conditions at 2°C under 6:16 hr L/D photoperiod until April 2002. Thereafter, the experimental protocol was the same as for *C. melitaearum*.

The parasitized and the unparasitized larvae were reared together because they are indistinguishable from each other until just prior to pupation of the parasitoid. The development of healthy (unparasitized) larvae of *M. cinxia* reared on each line of *P. lanceolata* was monitored along with that of the parasitized larvae. At pupation, the development time (calculated in days from the breaking of disapause in L5 to adult butterfly emergence) and pupal wet weight (mg) of *M. cinxia* were measured from larvae reared on each line of *P. lanceolata*.

Generalist Insects. The host moth *S. exigua* was maintained on artificial diet as described by Vickerman and Trumble (1999). Moths were housed in 1 l plastic beakers containing a vermiculite base and were provided *ad libitum* with 20% sugar solution absorbed into cotton wool. Adult females oviposited onto filter paper placed inside the beaker. Newly hatched eggs were placed onto artificial diet. In rearing *C. marginiventris*, approximately 50 L1 larvae were placed into Petri dishes (20 cm diam) in which five mated female wasps were added. Wasps were allowed to parasitize hosts for several hours, after which they were returned to separate Petri dishes containing drops of honey and water. Cocoons of *C. marginiventris* were collected periodically, and wasps were allowed to emerge in Petri dishes (above).

For experiments, newly hatched larvae of *S. exigua* were reared on the two lines of *P. lanceolata* in April 2002. Newly molted L2 larvae of *S. exigua* were individually presented to female *C. marginiventris* in small plastic vials. Parasitism was verified by a single insertion and removal of the ovipositor. Parasitized larvae were reared using the same methods described for *M. cinxia*. At adult eclosion, wasps were killed by freezing, and wasps were weighed on a Sartorius microbalance. Egg-to-adult development time in days was also measured. The development of control (unparasitized) larvae was measured as for *M. cinxia*.

Statistical Analyses. Differences in weight and development time between hosts reared on high and low iridoid glycoside plants and between parasitoids developing on these two types of hosts were analyzed with independent t-tests if conditions for parametric analyses were met (Levene's test for homogeneity of variances and Kolmogorov–Smirnov's test for normality) or with Mann–Whitney U-tests otherwise. Differences in leaf concentrations of nitrogen, phosphorus, and the iridoid glycosides aucubin and catalpol between selection lines were analyzed with ANOVA. Line effects were tested over effects of maternal half-sib family within selection lines. Data for iridoid glycosides were square-root transformed prior to analysis to meet assumptions for parametric analysis. All analyses were performed using Statistica version 6.1 (StatSoft, Inc., Tulsa OK, USA).

RESULTS

Differences in Iridoid Glycosides, Nitrogen, and Phosphorus Among P. lanceolata Lines. Leaf iridoid glycoside levels differed 5-fold between plants from the low and from the high selection line (Table 1). The higher total iridoid glycoside level in the leaves was due to both higher levels of aucubin and of catalpol (Table 1). Nitrogen concentrations did not differ between selection lines (Table 1, $P = 0.10$). Phosphorus concentration varied among families within lines, but no consistent difference between selection lines was observed (Table 1, $P = 0.56$).

Development of Specialist Insects. Development time of *M. cinxia* postdiapause larvae until adult in 2001 was affected by plant line ($t_{17} = 2.49$, $P = 0.024$); butterflies developed more rapidly on plants containing high levels of iridoid glycosides (Figure 1a). However, host pupal weight was not affected by plant line ($t_{19} = 1.29$, $P = 0.21$), although there was a tendency for pupae to be slightly larger when reared on lines containing higher levels of iridoid glycosides (Figure 1b).

In line with 2001 results, development time in *M. cinxia* in 2002 was affected by plant line (Mann–Whitney U-test, $U_{30,24} = 502.5$, $P = 0.006$). Development proceeded more rapidly when larvae were reared on lines containing high levels of iridoid glycosides (Figure 1c). In both years, development was completed about 2 days earlier for cohorts reared on the line of *P. lanceolata* containing high levels of iridoid glycosides. As in 2001, the pupal weight of unparasitized individuals was not affected by plant line ($t_{68} = 0.70$, $P = 0.49$) although pupae tended to be somewhat larger than in the previous year (Figure 1d).

Development time ($t_{46} = 1.45$, $P = 0.15$) and adult body mass ($t_{46} = 0.97$, $P = 0.34$) of *C. melitaearum* were not affected by plant line on which their host had been reared (Figure 1e and f). Also, secondary clutch size of *C. melitaearum*

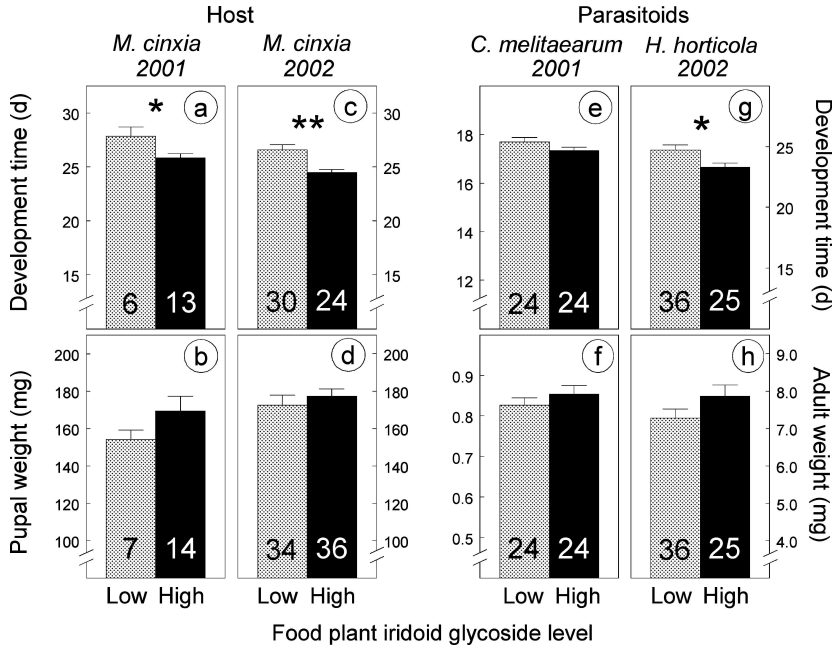

FIG. 1. Development of unparasitized caterpillars of the specialist herbivore *M. cinxia* feeding on *P. lanceolata* selected for low (gray bars) and high (black bars) levels of iridoid glycosides in 2001 (a and b) and 2002 (c and d) and development of its endoparasitoids *C. melitaearum* (e and f) and *H. horticola* (g and h) in parasitized caterpillars from the larval groups raised in 2001 and 2002, respectively. Numbers within bars represent sample sizes. Bars represent 1 SE of the mean. Asterisks indicate significant effects of plant selection line ($^{*}P < 0.05$; $^{**}P < 0.01$).

did not vary among wasps reared on *M. cinxia* that were fed *P. lanceolata* leaves containing high or low levels of iridoid glycosides ($t_{27} = 0.31$, $P = 0.76$). Brood sizes were on average only slightly higher for wasps reared from high (mean $\pm$ SE: 7.13 ± 0.69) than from low iridoid plants (6.71 ± 0.69).

As with the host *M. cinxia*, development time in *H. horticola* was significantly different when reared on hosts from the two lines of *P. lanceolata* ($t_{59} = 2.42$, $P = 0.019$). Parasitoids completed their development approximately 1–2 days earlier when originating from high iridoid lines (Figure 1g). However, plant line did not affect emerging adult parasitoid size ($t_{59} = 1.49$, $P = 0.14$) even though wasps tended be larger on high lines (Figure 1h).

Development of Generalist Insects. Egg-to-adult development time of *S. exigua* did not vary with the diet ($t_{19} = 0.78$, $P = 0.45$). Irrespective of iridoid glycoside content, larvae of *S. exigua* completed their development in

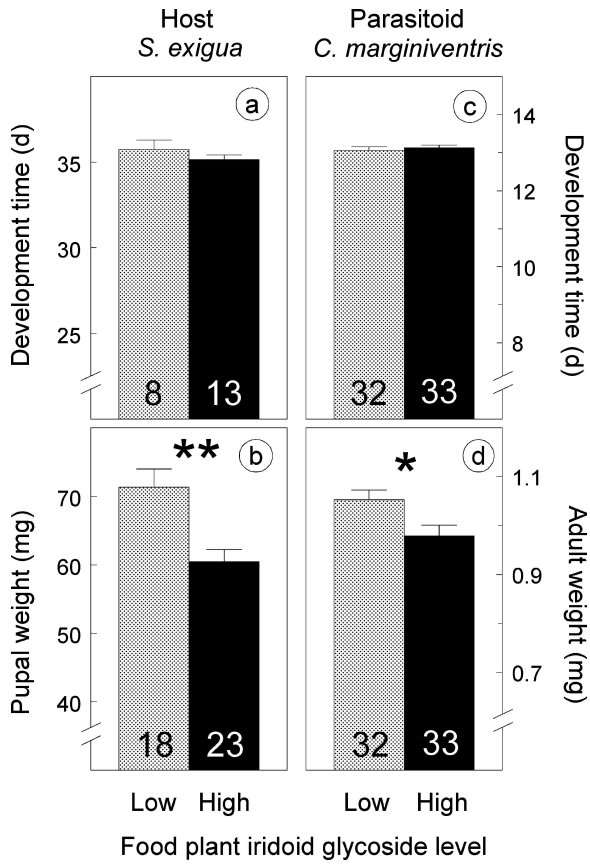

FIG. 2. Development of unparasitized caterpillars of the generalist herbivore *S. exigua* feeding on *P. lanceolata* selected for low (gray bars) and high (black bars) levels of iridoid glycosides (a and b), and development of its endoparasitoid *C. marginiventris* in parasitized caterpillars (c and d). Numbers within bars represent sample sizes. Bars represent 1 SE of the mean. Asterisks indicate significant effects of plant selection line ($^{*}P < 0.05$; $^{**}P < 0.01$).

approximately 35–36 days (Figure 2a). In contrast, pupal weight in *S. exigua* was strongly affected by the line of *P. lanceolata* upon which the larvae had developed ($t_{39} = 3.49$, $P < 0.001$). Pupae of *S. exigua* reared on the low iridoid line were some 15% larger than conspecifics reared on the high iridoid line (Figure 2b).

Similarly, development time in *C. marginiventris* was uniform when reared from *S. exigua* on both lines of *P. lanceolata* ($t_{63} = 0.51$, $P = 0.61$). Parasitoids typically took just over 13 days to complete their development in host caterpillars on the two iridoid lines (Figure 2c). However, like *S. exigua*, adult parasitoid size

differed with the plant line upon which their hosts had been reared ($t_{63} = 2.48$, $P = 0.016$). Wasps originating from the high iridoid line were 7% smaller than those originating from the low iridoid line (Figure 2d).

DISCUSSION

Our results show that the effect of genotypic variation in IG content in *P. lanceolata* on the development of herbivores differed between the generalist and specialist species used. High levels of IGs reduced the pupal weight of the generalist *S. exigua*. In contrast, IG levels did not affect the pupal weight of the specialist *M. cinxia*, and larvae of this specialist were able to complete their development more quickly on plants with higher levels of these allelochemicals. Levels of nitrogen and phosphorus did not consistently differ between the IG lines, suggesting that effects of allelochemical differences were not confounded by differences in primary metabolites. Our results are in agreement with previous studies on the effects of IGs from *P. lanceolata* on other generalist and specialist herbivores using artificial diet (Bowers and Puttick, 1988; Puttick and Bowers, 1988; Bowers, 1991); addition of aucubin and catalpol to artificial diet reduced larval growth rate of the generalists *Lymantria dispar* and *S. eridania*, but not of the specialist *Junonia coenia,* that developed more quickly on diets with higher amounts of IGs (but see Adler et al., 1995 for *in vivo* effects on *J. coenia*). This suggests that specialized mono- or oligophagous herbivores are better able to cope with plant allelochemicals than polyphagous herbivores. We note, however, that the generalist herbivore was derived from a lab-strain that did not necessarily have previous experience with *P. lanceolata*. As a consequence, it might have had limited opportunity to adapt to the chemistry of this host plant.

Recent studies provide insight into the effects of IGs on the performance of *S. exigua* and *M. cinxia*. Using the same selection lines, it was found (Biere et al., 2004) that the reduced growth of L4 *S. exigua* caterpillars on the high IG line was due to a reduced ingestion rate and not to a reduced digestibility or lower efficiency of conversion of ingested food. Thus, for the generalist, IGs act as feeding deterrents without additional post-ingestive effects, at least at this larval stage. In contrast, L4 caterpillars of *M. cinxia* had higher consumption rates on the high IG line (S. van Nouhuys and S. Kumar, unpublished results). Hence, for the specialist, IGs act as feeding stimulants. Moreover, L4 *M. cinxia* larvae ingested food from the high IG line more efficiently, and had a higher growth rate than caterpillars feeding on the low IG line. This contrasts with artificial diet studies of the specialist *J. coenia*, where lower efficiency of using high IG diets was observed due to reduced digestibility (Camara, 1997). As we did not observe a significantly higher pupal weight of *M. cinxia* reared on the high-IG plants in the present experiment, the higher growth rate of L4 *M. cinxia* may be instar-specific

or may not be sufficiently large to translate into a significant effect on weight at the pupal stage.

The development of endoparasitoids was also affected by the level of allelochemicals in the food plant of their herbivore hosts. For two of the parasitoids, developmental responses paralleled those of their hosts. High IG levels in host plants resulted in a more rapid development of both the specialist *M. cinxia* and its parasitoid *H. horticola* and in reduced weight in both the generalist herbivore *S. exigua* and its parasitoid *C. marginiventris*. In the only other study addressing effects of IGs on herbivore-parasitoid development (Mallampalli et al., 1996), a similar pattern, i.e., parallel responses of herbivore and parasitoid, was found. Early stages of the generalist herbivore *L. dispar* suffered reduced growth on diets with high levels of catalpol, but total larval development was not significantly affected, nor was that of the tachinid parasitoid *Compsilura concinnata* (Mallampalli et al., 1996). In the present experiment, only the parasitoid *C. melitaearum* was not affected by the IG level in the diet of its host, while its host showed a more rapid development.

A number of studies have reported detrimental effects of allelochemicals in the diet of host or prey on the growth and development of parasitoids and predators (Barbosa et al., 1986; Duffey et al., 1986; Gunasena et al., 1990; Havill and Raffa, 2000). In general, toxic phytochemicals in the plant tend to have more negative effects on the development of polyphagous herbivores and their natural enemies than on oligophages and their antagonists, presumably because the former are less-well adapted to cope with them (Gunasena et al., 1990; Barbosa et al., 1991; Sznajder and Harvey, 2003). Consequently, beneficial effects of the production of allelochemicals to the plant in terms of reduced plant damage by generalist herbivores may be partly mitigated by harmful effects of these allelochemicals on the natural enemies of the herbivore. On the other hand, slower development of generalist herbivores on more toxic host plants may increase their "window of vulnerability" to parasitoid or predator attack (the "slow-growth-high-mortality hypothesis," sensu Turlings and Benrey, 1998), enhancing the efficacy of natural enemies through higher parasitation rates, even if they have a slower development on these hosts. Since the development rate of neither *S. exigua* nor *C. marginiventris* was affected by IG level, such a mechanism does not seem to operate in the *P. lanceolata*—*S. exigua*—*C. marginiventris* system.

Positive responses (accelerated development while attaining similar size) to increased levels of IGs were observed for *M. cinxia* and the parasitoid *H. horticola*. This suggests adaptation of the parasitoid to the presence of IGs in its herbivorous host. Like other butterfly larvae that are restricted to feeding on IG producing host plants (Bowers and Collinge, 1992; Bowers, 2003), caterpillars of *M. cinxia* sequester IGs from their food plants (Suomi et al., 2001; Nieminen et al., 2003). Catalpol seems to be a more effective deterrent to predators than aucubin, and is also sequestered in higher proportions than aucubin in *J. coenia* (Bowers and

Collinge, 1992), *Ceratomia catalpae* (Bowers, 2003), and *M. cinxia* (Nieminen et al., 2003). Endoparasitoids must cope with sequestered or concentrated phytochemicals during their entire larval development because ingested allelochemicals cannot be excreted outside the host environment until after egression (Quicke, 1997). If we assume that *M. cinxia* caterpillars raised on food plants from the high-IG line sequester higher levels of IGs than caterpillars raised on the low line, then *H. horticola* does not appear to suffer from the higher levels of sequestered IGs in its host. On the contrary, like its host, *H. horticola* showed accelerated development while reaching similar weight, suggesting increased consumption or more efficient use of hemolymph, and later fat and other ingested tissues, from hosts raised on high-IG plants.

In contrast to *H. horticola*, the development of *C. melitaearum* was not affected by differences in IG levels in the diet of its host. In the field, parasitism of *M. cinxia* by *C. melitaearum* significantly decreased with increasing average level of catalpol in the *P. lanceolata* plant that larval groups of caterpillars had been feeding on (Nieminen et al., 2003). This trend could be the consequence of adult parasitoids avoiding oviposition into larvae that were feeding on plants with high levels of catalpol, or differential mortality of parasitoids developing in larvae feeding on high and low catalpol containing plants. Our results appear to support the first hypothesis.

The differential developmental responses of the two parasitoids may be due to the different host exploitation strategies they exhibit (Harvey and Strand, 2002). *C. melitaearum* is gregarious and passes through several generations during a single host generation. It completes development in a relatively short time, feeding primarily on host hemolymph until the last instar during which it feeds on a portion of the host fat body. In contrast, the development of *H. horticola* is more synchronized physiologically with that of the host. It inhabits hosts from early in the first host instar until just before the time that an unparasitized host would pupate. During most of this time, the parasitoid remains small and ingests little host hemolymph, but at the end of the final stage it consumes all host tissues except for the cuticle (E. Punju and S. van Nouhuys unpublished results; Lei et al., 1997). The positive effect of IGs on *H. horticola* development rate may be a direct response to an increase in host development rate mediated by allelochemicals ingested from its food plant.

Since the seminal paper by Price et al. (1980), many studies have assessed the effects of plant traits on the interaction between herbivores and their natural enemies (for reviews, see e.g., Bottrell et al., 1998; Turlings and Benrey, 1998; Cortesero et al., 2000), mostly by using agricultural, artificially assembled, biological control systems. Of great concern in classical biological control programs are cases where the combined effects of plant resistance and natural enemy impact on herbivores are less than the additive effect of each these components separately ("antagonistic" interactions sensu Hare, 2002). In

extreme cases, where natural enemies are more susceptible to plant resistance mechanisms than herbivores (e.g., Campbell and Duffey, 1979), chemical defense may prevent herbivore control by natural enemies ("disruptive interactions" sensu Hare, 2002). In agricultural systems, additive effects seem to predominate, and only few examples of disruptive interactions have been found (Hare, 2002).

In contrast to agricultural systems, knowledge of indirect effects of plant secondary metabolites on the natural enemies of herbivores in natural systems is scarce despite the fact that plant secondary chemistry has evolved under natural conditions. Non-additive effects might have a large impact on the evolution of levels of plant secondary metabolites ("direct defense") in natural populations. For instance, antagonistic effects may result in selection for lower levels of plant allelochemicals in the presence than in the absence of natural enemies, and we would not be able to understand patterns of selection in natural populations when studied in the traditional bitrophic plant-herbivore or plant-pathogen context (Hare, 1992, 2002).

Thus far, few studies have assessed the effects of quantitative allelochemical variation in non-agricultural plants on the development of higher trophic level organisms (e.g., Harvey et al., 2003; Sznajder and Harvey, 2003). As far as we know, our study is one of the first to document effects of genetic variation in secondary metabolites within a single natural plant species on the parasitoids of its herbivores. We suggest that there might be antagonistic effects of IGs on the generalist parasitoid of the generalist herbivore, but not on the specialist parasitoids of the specialist herbivore of *P. lanceolata*. Conclusive evidence for effects of natural enemies of herbivores on the evolution of concentrations of plant allelochemicals in natural populations still awaits studies that exploit natural study systems (i) in which there is evidence for top-down control of herbivores by parasitoids or predators, (ii) the pattern of selection on plant chemical defense differs in the presence and absence of natural enemies of the herbivores, and (iii) the evolutionary response to selection is investigated.

(Received March 17, 2004; accepted August 5, 2004)

Abstract—*Securidaca longepedunculata* Fers (Polygalaceae) is commonly used as a traditional medicine in many parts of Africa as well as against a number of invertebrate pests, including insects infesting stored grain. The present study showed that *S. longepedunculata* root powder, its methanol extract, and the main volatile component, methyl salicylate, exhibit repellent and toxic properties to *Sitophilus zeamais* adults. Adult *S. zeamais* that were given a choice between untreated maize and maize treated with root powder, extract, or synthetic methyl salicylate in a four-way choice olfactometer significantly preferred the control maize. Methyl salicylate vapor also had a dose-dependant fumigant effect against *S. zeamais*, *Rhyzopertha dominica,* and *Prostephanus truncates,* with a LD_{100} achieved with a 60 μl dose in a 1-l container against all three insect species after 24 hr of exposure. Probit analyses estimated LD_{50} values between 34 and 36 μl (95% CI) for all insect species. Furthermore, prolonged exposure for 6 days showed that lower amounts (30 μl) of methyl salicylate vapor were able to induce 100% adult mortality of the three insect species. The implications are discussed in the context of improving stored product pest control by small-scale subsistence farmers in Africa.

Key Words—*Securidaca longepedunculata*, Polygalaceae, methyl 2-hydroxybenzoate, methyl salicylate, olfactometer, fumigant toxicity, *Sitophilus zeamais*, *Rhyzopertha dominica*, *Prostephanus truncatus*.

INTRODUCTION

Interest in the discovery of new chemicals for the control of insect pests has continued to increase despite the commercial difficulties of bringing new products

* To whom correspondence should be addressed. E-mail: s.r.belmain@gre.ac.uk

to market (Isman, 1997). Although much of this work is agrochemically driven to find novel compounds and modes of action, other aspects of bioprospecting such as providing low-cost "natural" alternatives to synthetic pesticides, which are safer and less polluting, have also continued. Poor rural farmers in developing countries particularly have difficulty in accessing good quality and affordable synthetic pesticides that are suited to their needs (Belmain and Stevenson, 2001). These farmers, however, have access to local ethnobotanicals and indigenous knowledge systems that could help increase agricultural productivity with minimal human and environmental health hazards that are often experienced when synthetic pesticides are used inappropriately (Belmain, 2002).

Securidaca longepedunculata Fers (Polygalaceae) is commonly used as a medicine in many parts of Africa for the treatment of rheumatic conditions, fever, headache, and various other inflammatory conditions (Oliver-Bever, 1986; Assi and Guinko, 1991; Iwu, 1993). Powdered dried roots are also used as a pest control agent and have potential as a protectant against insect pests in stored grain (Belmain et al., 2001; Boeke et al., 2001). During research to investigate the active principles in *S. longepedunculata*, we analyzed the volatile fraction and found a single major component, methyl salicylate (methyl 2-hydroxybenzoate), accounting for over 90% of volatile material together with two related minor components (Jayasekara et al., 2002). In this report, we evaluate the deterrent and toxic effects of methyl salicylate, the crude root material of *S. longepedunculata,* and a methanol extract of the root material against three major stored product pests, *Rhyzopertha dominica*, *Sitophilus zeamais*, and *Prostephanus truncatus* to determine if methyl salicylate is responsible for use of the plant material as a pest control agent. The implications of these results in storage pest management are discussed.

METHODS AND MATERIALS

Insects and Test Materials. Strains of *Sitophilus zeamais* Motschulsky, *Rhyzopertha dominica* (Fabricius), and *Prostephanus truncatus* (Horn) originally collected in Ghana were reared in the laboratory on organic maize, wheat, and maize, respectively, at 27 ± 5°C, 60 ± 5% RH, and a 12L:12D photoperiod. Roots of *S. longepedunculata* were collected from northern Ghana where they were immediately shade-dried for a period of 2 wk before transport to the UK. The plant roots were ground to a fine powder and extracted in methanol according to the methods described by Jayasekara et al. (2002). Methyl salicylate (Aldrich, Gillingham, Dorset, UK; 98%) was used for all bioassays.

Four-Way Choice Olfactometer Bioassay. Maize grain was treated with *S. longepedunculata* root powder, its methanol extract, methyl salicylate, and methanol only (as the control). The dried methanol extract (0.3 g), prepared according to Jayasekara et al. (2002), was re-dissolved in methanol (5 ml) and

mixed with maize (25 g) in a 100 ml glass jar for 1 min. Treated maize was dried for 15 min under a fume hood at room temperature (18°C). Another two sets of maize (25 g each) were treated separately with methyl salicylate (1.4 mg in 5 ml methanol) and methanol only (5 ml) by following the same procedure described above. Three glass tubes (15 cm × 2 cm diam) were filled separately with the maize samples and connected with polythene tubes to three of the four outlets of a four-way choice olfactometer arena as illustrated by Bashir et al. (2001). The fourth outlet of the arena was connected to a tube containing maize (25 g) mixed with *S. longepedunculata* root powder (1.25 g). A continuous stream of air was passed through each treatment and into the arena by using a vacuum pump (DA7C, Charles Austin Ltd, UK). The airflow rate through each treatment into the arena was set at 150 ml/min by using flow meters (D1X640, Meterate GPE, UK). Unsexed *S. zeamais* adults (7–14-days old; 200) that had been deprived of food for 4 days were introduced into the center of the olfactometer arena. The location of each insect was recorded after 12 hr. The bioassay was carried out in a controlled temperature and humidity room (27 ± 5°C and 60 ± 5% RH). Each experiment was repeated ×12, rotating the tubes containing the different maize commodity clockwise to the adjacent delivery pipe between trials to correct for any potential photoresponse behavior. The mean numbers of live adults in each treatment were compared by ANOVA, and means were separated by the LSD test at the 95% confidence level.

Fumigant Potential of Methyl Salicylate. A piece of cotton wool (8 mm × 3.5 mm height) was fixed to the center on the interior surface of a plastic lid to serve as a vapor diffuser inside a glass jar (1 l). Methyl salicylate (10, 20, 30, 40, 50, 60, and 70 μl) was applied with a syringe to the diffusers with 10 replicates per concentration per insect species. Fifty unsexed *S. zeamais*, *R. dominica*, and *P. truncatus* adults (7–14-days old) were introduced separately into glass jars (1 l), and the jars were capped with the lids holding the diffusers. After 24 hr, the dead adults in each jar were removed to separate clean jars and kept for a further 24 hr to confirm whether they were dead or alive, at which time the numbers of dead adults were recorded. The numbers of dead adults were subjected to Probit analysis to estimate the LD_{50} values of methyl salicylate.

To evaluate the effect of prolonged exposure of adult insects to low concentrations of methyl salicylate, the above experiment was repeated using 10 and 30 μl methyl salicylate and an untreated control. Dead adults in each jar were removed at 2-day intervals up to 6 days and collected in separate clean jars. As previously described, the total number of dead adults in each clean jar was recorded after a further 24 hr. The mean numbers of dead adults in each treatment were analyzed by ANOVA with the significant differences between means compared by using the LSD test. All statistical analyses were carried out using the program SPSS v.10 (SPSS Inc., Chicago, IL 60606).

RESULTS

The data from the choice olfactometer bioassay showed that the number of live *S. zeamais* adults found in maize treated with the *S. longepedunculata* root powder, methanol extract of the roots, and methyl salicylate was significantly lower than the number of insects present in the control (methanol only) maize (LSD, $P < 0.05$, Figure 1). Approximately half of all "non-participating" insects remaining in the arena were recorded as dead at the end of the trial. Living insects in the arena that had not made a choice at the time of data collection had usually settled along the edges of the arena. There were no significant differences in the number of insects present among the three treatments, suggesting the repellent effects of the treatments were similar.

The fumigant effects of methyl salicylate were evident and showed that insect mortality increased with increasing concentration (Figure 2). Doses of methyl salicylate above 10 μl in the 1-l jar increased insect mortality in all three insect species when compared to the untreated controls (LSD, $P < 0.05$). The observed mortality rates were dose-dependent, and 100% mortality occurred at 24 hr when there was 60 μl of methyl salicylate in the jars. Linear and nonlinear regression analyses of the data showed cubic polynomial relationships for each insect species with R^2 values of 0.98, 0.97, and 0.97 for *S. zeamais*, *R. dominica*, and *P. truncatus*, respectively. The LD_{50} and LD_{90} values, estimated by Probit analysis, showed similar values for all three insect species (Table 1).

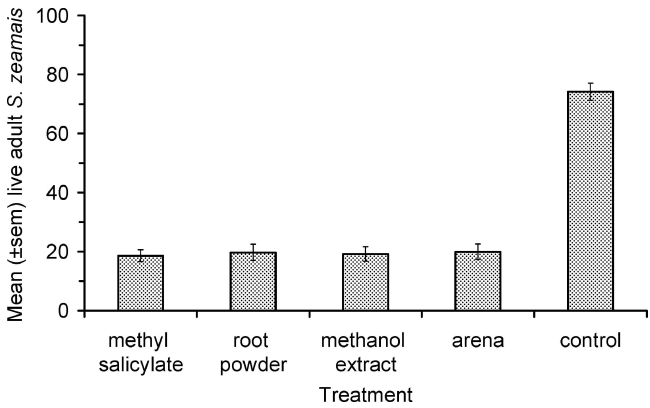

FIG. 1. Mean number of adult *S. zeamais* present in different treatments of maize grain after a period of 12 hr in a continuous airflow multiple choice olfactometer. Error bars represent the standard error of 12 means when 200 insects were initially introduced into the arena.

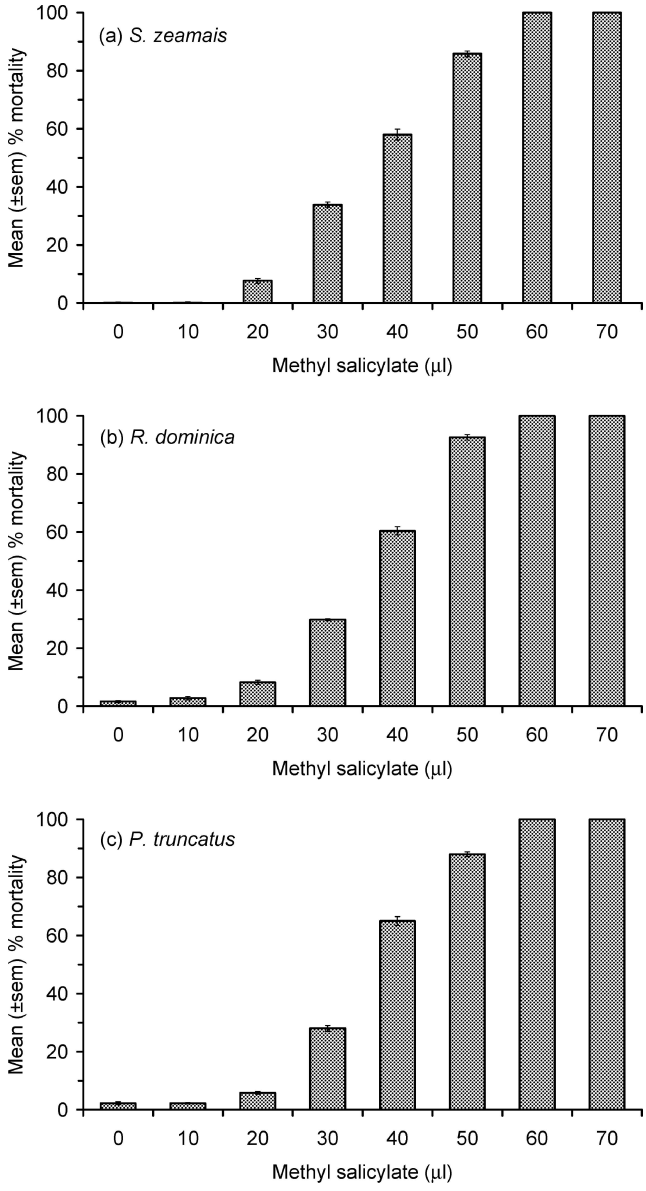

FIG. 2. The effect of dose (μl in 1-l jar) of methyl salicylate vapor on the adult mortality of (a) *S. zeamais*, (b) *R. dominica,* and (c) *P. truncatus* after a period of 24 hr. Error bars represent the standard error of 10 means when 50 insects were initially introduced into the fumigation chamber.

TABLE 1. PROBIT REGRESSION ANALYSIS ESTIMATES OF LETHAL DOSES OF METHYL SALICYLATE AGAINST *S. zeamais*, *R. dominica,* AND *P. truncatus*

Insect species	Probit Estimation	Dose (μl)		
		Lethal dose	Lower 95%	Upper 95%
S. zeamais	LD_{50}	36.17	35.46	36.88
	LD_{90}	51.27	50.23	52.41
R. dominica	LD_{50}	35.12	34.41	35.83
	LD_{90}	50.19	49.15	51.33
P. truncatus	LD_{50}	35.61	34.90	36.32
	LD_{90}	50.88	49.83	52.02

Amounts of methyl salicylate below the LD_{50} value resulted in high insect mortality with prolonged exposure times (Figure 3). After 2 days of exposure, 30 μl of methyl salicylate increased mortality compared to the control (LSD, $P < 0.05$), and 100% mortality was observed when insects were exposed to 30 μl of methyl salicylate vapor for 6 days. However, 10 μl of methyl salicylate did not show a strong effect on adult mortality even after 6 days of exposure.

DISCUSSION

Previous research has shown that methyl salicylate comprises more than 90% of the volatile components found in the roots of *S. longepedunculata* (Jayasekara et al., 2002). Methyl salicylate is a ubiquitous aromatic ester that is a well-known plant stress signal (Wees et al., 2000; Cardoza et al., 2002) acting as a semiochemical to recruit insect predators (Shimoda et al., 2002; James, 2003; De Boer and Dicke, 2004), is involved in host orientation and selection (Ninkovic et al., 2003), and has insect repellent properties (Hardie et al., 1994). Its antimicrobial and antifungal properties are well-established (Meiller et al., 2001; Papandreou et al., 2002), and these have been exploited in liniments, ointments, and toothpaste, and it has been widely exploited by the flavor and fragrance industry (Clark, 1999). The absorption of high concentrations of methyl salicylate in some traditional medicinal preparations can be fatal (Chan, 1996).

In this study, adult *S. zeamais* demonstrated clear orientation choices between the volatiles generated by untreated maize and maize that had been mixed with *S. longepedunculata* root powder, a methanol extract of the powder, or its main volatile component, methyl salicylate. This suggests that *S. zeamais* are able to detect methyl salicylate through olfaction and avoid it when given the choice. This could explain, at least in part, how the application of powdered roots of *S. longepedunculata* protects grain from insect infestation.

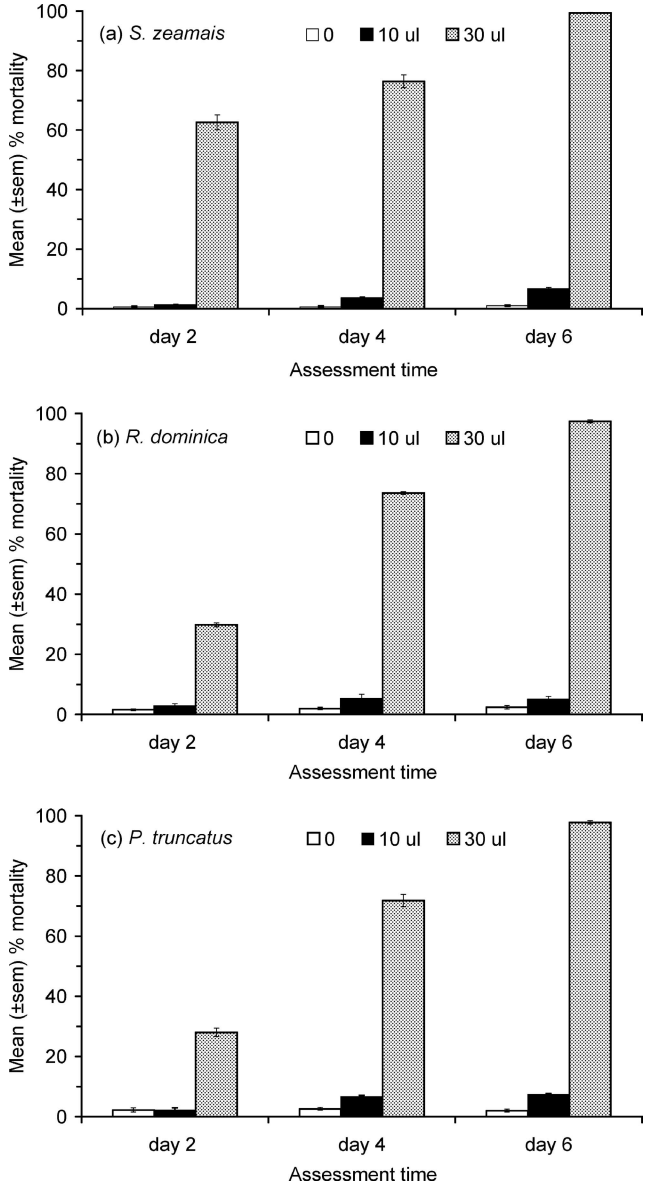

FIG. 3. The effect of prolonged exposure to methyl salicylate vapor on the adult mortality of (a) *S. zeamais*, (b) *R. dominica,* and (c) *P. truncatus* over a period of 6 days. Error bars represent the standard error of ten means when 50 insects were initially introduced into the fumigation chamber.

A number of stored product insects are attracted to host volatiles (Barrer, 1983; Phillips et al., 1993; Bashir et al., 2001). Pike et al. (1994) showed that *S. zeamais* is attracted to maize volatiles, and identified the main volatile components as hexanoic acid, nonanoic acid, nonanal, decanal, 2-phenylethanol, and vanillin. Methyl salicylate has not been previously reported to occur in the seeds of other grains or legumes, although it is emitted by damaged potato plants, and as a component of the blend attractive to the Colorado potato beetle, *Leptinotarsa decemlineata* (Coleoptera; Chrysomelidae) (Dickens, 2000). It would be interesting to test the effect of methyl salicylate on a species such as *P. truncatus* that does not orientate towards host volatiles and apparently relies on an aggregation pheromone (Hodges et al., 1998). However, the relative immobility of *R. dominica* and *P. truncatus* and their inability to walk through plastic tubing in comparison to *S. zeamais* prevented their inclusion in this experimental design. A different bioassay would be required to evaluate whether these species were similarly able to detect and avoid the volatile components of *S. longepedunculata* (Bashir et al., 2001). Methyl salicylate has been shown to induce plant defense responses (Ozawa et al., 2000; Wees et al., 2000), and it is possible that the avoidance of maize grains treated with methyl salicylate by *S. zeamais* is not due to the methyl salicylate itself but to other defense mechanisms induced by the methyl salicylate. This is considered to be unlikely due to the slow rate of metabolism of the grains, but the possibility cannot be excluded.

Avoidance of methyl salicylate vapors by *S. zeamais* was accompanied by a toxic effect on the insects. Dose- and time-dependant mortality effects were recorded when adult insects were in a sealed chamber containing the volatile compound. The low mortality recorded by 10 μl methyl salicylate in the 1-l container over 6 days may suggest that insects can tolerate low levels of methyl salicylate and potentially develop resistance to higher concentrations (Rajendran and Gunasekaran, 2002). However, this result may be an artifact of the experimental methodology because the fumigation chamber was opened every second day to remove dead insects, resulting in a partial loss of methyl salicylate from the chamber and diffuser.

Although there will be relatively minor volatile components present in the experimental treatments using the crude powder of *S. longepedunculata* roots and its methanol extract, our study suggests that it is the main volatile compound to which *S. zeamais* adults were responding. This is indicated by the similar numbers of insects found in the maize treated with the crude root powder containing approximately 4 mg of methyl salicylate in the experimental treatment (Jayasekara et al., 2002), the methanol extract of the root powder that also contained approximately 4 mg methyl salicylate, and the synthetic methyl salicylate at 1.4 mg per experimental treatment.

This research provides evidence that the indigenous strategy used by African farmers of mixing *S. longepedunculata* with their stored grain to protect it from

storage pests is valid. The study also helps elucidate the mode of action of the botanical through the effects of repelling and killing adult insects. For methyl salicylate to act as a true grain fumigant, the compound would have to possess sufficient grain penetrative properties to kill the insect developmental stages inside the grain (Shaaya et al., 1997; Lee et al., 2001). As with all fumigants, insect mortality will only be achieved if the material is applied within a sealed environment, ensuring the parameters of concentration and duration are sufficient to achieve 100% mortality (Rajendran, 2000; Reed and Pan, 2000). Using a volatile or essential oil compound to protect grain stocks may be more acceptable to some consumers than, for example, applying a dilute dust or powder that may result in higher residue levels (Shaaya et al., 1991; Isman, 2000). Nonvolatile, bioactive compounds present in *S. longepedunculata* have been recently characterized, and they also contribute to its observed efficacy in protecting stored grain (Jayasekara et al., 2003).

Evidence from other recent studies on *S. longepedunculata* indicates that there can be considerable variability in its bioactivity depending on the origin of the plant (Boeke et al., 2004). Therefore, potential phytochemical variability across African regions should be more adequately understood before the plant is promoted widely for pest control by small-scale African farmers. Although some preliminary evaluations of the potential vertebrate toxicity of *S. longepedunculata* have indicated that low concentrations of the material should be safe (Belmain et al., 2001), further investigations are essential to confirm the safety of mixing the botanical with stored grain.

(Received July 30, 2003; accepted October 20, 2004)

Abstract—The time-dependent natural release of hydrogen cyanide (HCN) was studied quantitatively using young croziers of the neotropical bracken fern *Pteridium arachnoideum*. HCN production was quantified in crushed tissue using a flow reactor at 30.0 ± 0.1°C. Released HCN was carried into appropriate traps with a moist air flow. Aliquots were drawn from the traps at fixed time intervals, and the HCN concentration was evaluated spectroscopically. All available prunasin (Pru), the only cyanogenic glycoside present, underwent decomposition into HCN in less than 1200 min. Fiddleheads ($N = 76$) contained 1.84–107.70 mg Pru g^{-1} dw in a continuous fashion suggesting genetic polymorphism. Acyanogenic morphs were rare (1/77). From the kinetics of the samples with Pru content near the median histographic distribution ($N = 46$), accumulated HCN formation as a function of time, initial velocities, average HCN production rate, and corresponding rate equations were obtained. Initial and average velocities correlated well with total Pru content. The yield of cyanide liberation varied widely between 0.51 and 47.86 μg HCN min^{-1} g^{-1} dw and was a linear function of $[Pru]_t$. However, the β-glucosidase enzyme involved in this reaction was not rate limiting and occurs in excess in the natural system. Enzyme activity was found to be independent of $[Pru]_t$. The contribution of HCN as an allomone-upon-request against herbivores was assessed quantitatively. Bracken fiddleheads produced a pulse of HCN soon after tissue injury that waned rapidly, leaving a large portion of intact prunasin to decompose more slowly in the herbivore's lumen. The balance between the external

* To whom correspondence should be addressed. E-mail: alonso@ula.ve

and internal courses was found to depend on the concentration of prunasin in the plant, the amount of crozier eaten, and the time used to consume it.

Key Words—Cyanogenesis, kinetics, defense, herbivory, *Pteridium arachnoideum*.

Abbreviations: $[Pru]_t$, Total prunasin contained in a given sample; v_A, Average velocity of HCN formation; v_R, Average velocity of HCN evolution relative to $[Pru]_t$ in the sample; v_i, Initial velocity of HCN formation during the first few minutes after tissue crushing; $\Re$, The time-dependent accumulated formation of HCN g^{-1} dw of crozier relative to $[Pru]_t$; $\Delta v_A/\Delta\tau$, Time-dependent variation in the velocity of HCN evolution.

INTRODUCTION

Cyanogenesis, or the emanation of hydrogen cyanide (HCN), has long been recognized as an effective means of deterring predation (Ellis et al., 1977; Conn, 1981; Nahrstedt, 1988; Schappert and Shore, 1999a; Magalhaes et al., 2000). Plants, in particular, are capable of yielding HCN (Jones, 1998; Vetter, 2000) when their tissues are crushed during maceration by chewing herbivores (Vetter, 2000). In some tropical environments where insect pressure is high, as many as 4% of woody plants are cyanogenic and concentrate HCN precursors in reproductive parts (Thomsen and Brimer, 1997).

Since HCN is not only toxic to many animals, but also deleterious to the producing organism, it is generally stored as a stable precursor or phytoanticipin, glycosylated α-cyanohydrins of which many are known. Under the operation of an appropriate β-glucosidase, the glycoside portion can be excised. The cyanohydrin, which may itself be implicated in xenobiosis (Magalhaes et al., 2000), either decomposes on standing by way of β-elimination or under the auspices of a second enzyme, a hydroxynitrile lyase. Both routes yield HCN and a carbonyl component, generally an aldehyde or ketone that may have deterrent functions of its own (Peterson et al., 1987).

Gaseous HCN so produced is likely to be involved in trophic interactions (Jones, 1973; Jones et al., 1978; Conn, 1979). Thus, during feeding, HCN escapes into the atmosphere immediately surrounding the producer. However, for HCN to be an effective deterrent, a sufficiently high concentration of the gas must be attained (Nahrstedt, 1985; Jones, 1998). To achieve this goal, and in attention to the natural diffusion of this gas in air and its dispersion by wind, two ingredients must participate from the producer standpoint: the amount of HCN precursors available and the rate at which the cyanogenic glycoside-enzyme system is capable of releasing HCN.

Much attention has been paid to the first of these factors (e.g., Conn, 1981; Seigler, 1998; Gleadow and Woodrow, 2002; Goodger et al., 2002), in terms of

frequency of cyanogenic genotypes, actual content of cyanogenic glycosides in tissues at risk, and impact on associated biota (Zagrobelny et al., 2004). A great deal of variability has been observed. For example, cyanogenic species such as *Trifolium repens* contain enough cyanogenic glycosides to give between 3.2 and 350 μg of HCN g^{-1} dw, while others like *Linum usitatisimum* and *Dimorphoteca ecklonis* are capable of yielding a total of 910 and 1580 μg of HCN, respectively (Butler, 1965). The seasonal variability in cyanogenic glycoside content has also been recognized (Cooper-Driver et al., 1977; Gleadow and Woodrow, 2000; Gebrehiwot and Beuselinck, 2001). However, the amount of cyanogenic glycosides alone and their static potential to yield HCN have not satisfied all questions open to cyanogenesis as an effective defense strategy (Hruska, 1988; Gleadow and Woodrow, 2002).

With regard to the second component, the kinetics of the natural HCN gas formation from crushed plant tissue has rarely been investigated in cyanogenic plants. One recent report (Goodger et al., 2002) records the initial velocity of HCN release from foliage of cyanogenic genotypes of *Eucalyptus polyanthemos* in Southern Australia between 0.02 and 0.14 μg g^{-1} dw hr^{-1}. This is the result of the rate of the combined reactions leading to the formation of HCN. In a first approximation, we had estimated the pseudo first-order rate of prunasin decomposition in *Pteridium aquilinum* (L.) Kuhn as $2.20 \pm 0.01 \times 10^{-4}$ sec^{-1} (Alonso-Amelot and Oliveros, 2000). Earlier, the kinetics of the enzymatic transformation of the mandelonitrile was examined *in vitro* using *Hevea brasiliensis* enzymes (Jorns, 1980; Bauer et al., 1999). Both reaction products, HCN and benzaldehyde, were found to act as substrate competitors against mandelonitrile to inhibit the enzyme, indicating a degree of product self-regulation. These advances provide thrust to develop kinetic data of natural cyanogenesis in plants that might help to understand the ecological significance of this defense line and the toxic potential to animals and humans.

One of the cyanogenic plants in which a clear selection against the cyanogenic genotypes by vertebrates has been recognized is *P. aquilinum* (Cooper-Driver et al., 1977; Hadfield and Dyer, 1986; Low and Thomson, 1990). Few insects use this abundant resource as feed (Lawton, 1976; Jones, 1983; Salinas and Ortega, 1990). Cyanogenesis stemming from its only precursor, prunasin (Kofod and Eyjolfsson, 1966; Berti and Bottari, 1968), among other lines of chemical defense (Alonso-Amelot, 2002), is thought to be in part responsible (Schreiner et al., 1984).

Therefore, bracken fern stood as well-suited for examining its cyanogenic potential in terms of the rate at which HCN is produced upon crushing, in light of the hypothesis regarding its ecological role. Among the *Pteridium* taxon, the species *P. arachnoideum* (Kaulf.) Maxon (Pteridophyta: Dennstaedtiaceae) was selected because of its abundance and success in mountainous regions of the neotropics (Ortega, 1990) where (year round) pressure by herbivory is high and there is a high frequency of cyanogenic morphs (99%, personal observation). Thus,

the time-dependent evolution of gaseous HCN from this plant, the initial velocity of its formation, its correlation with the amount of prunasin present, the variation of the reaction rate with time, and the rate dependence on total prunasin content were investigated in the young bracken crozier. No efforts to derive a molecular mechanistic elucidation were attempted, and the results are only interpreted within the ecological context.

METHODS AND MATERIALS

Warning. Solid picric acid and sodium picrate may explode spontaneously when stored for long periods. It is advisable to maintain this material always as a supersaturated water solution or suspension at temperatures not exceeding 20°C and avoid all contact with skin to prevent long-term toxic effects. Sodium cyanide is highly toxic and should never be handled as solid, in neutral or acidic solutions without proper protection or outside a fume hood.

Reagents and Apparatus. Sodium bicarbonate (J. T. Baker Chemical Co.) and picric acid (BDH Laboratory Reagents) were used without further purification. Sodium cyanide was purified by recrystallization from ethanol–dichloromethane solutions and dissolved in degassed water. Almond emulsin (Sigma-Aldrich, Milwaukee, Wisconsin) was used as source of β-glucosidase. Absorbances of sodium picrate–cyanide complex were determined at 515 nm using an Hewlett-Packard (Palo Alto, California) Vectra UV-Vis 8453 spectrophotometer controlled by a Vectra-Pentium I workstation. Field temperature measurements were determined from mid-April to mid-May of 1999 and 2002 at sites A and B with the aid of StowAway XTI field logs (Onset Computer Corp., Bourne, Massachussetts).

Plant Sampling. *P. arachoideum* grows in dense thickets in open areas affected by fire or cattle husbandry, and in natural grasslands in the Andes mountain range of western Venezuela. Plants can persist for many years without further human intervention (Alonso-Amelot and Rodulfo, 1996). Voucher specimens were collected and stored in the laboratory herbarium, and also sent to the New South Wales Botanical Gardens in Sydney, Australia (NSW 361276). Four sites for the survey of cyanogenic morphs were selected in the 1880–2100 m altitudinal range. All sites were located between 8°30′ to 8°42′N and 71°04′ and 71°19′W in the environs of the city of Mérida, Venezuela and surrounding mountains. Sampling was performed at the onset of the rainy season, between late March and May of 2003. At each site, 25–35 croziers of *P. arachnoideum* (30–40 cm long) were cut at ground level, stored in plastic clip bags, and brought to the laboratory within 2 hr. Ten of the collected croziers were analyzed for moisture content, and the remaining were used for chemical analysis. As it was determined that the crozier apex contained the greater amount of prunasin, only this part was used for the kinetic measurements.

Temperature Determination of Kinetics Runs. To emulate in the laboratory the thermal conditions where cyanogenesis of croziers takes place naturally in the field, it was necessary to determine the temperature at which bracken stands grow in our geographical area. An average temperature of 29.9°C during the hours of maximum insect activity (10 A.M.–5 P.M.) was recorded within the bracken canopy during the April–May period with the aid of field logs. Therefore, the kinetic runs were standardized at 30.0 ± 0.1°C.

HCN Analysis. The sodium picrate gas flow quantitation method of Alonso-Amelot and Oliveros (2000) was employed as it provided the selective detection of HCN through its picrate complex at $\lambda = 515$ nm without interference from other carbonyl volatiles possibly stemming from the plant sample. Indeed, an acyanogenic morph of bracken yielded no response in the picrate absorption spectrum between 480 and 700 nm, confirming the lack of interfering components not associated with the process of cyanogenesis. Benzaldehyde and other carbonyl compounds were trapped in the first dinitrophenyl hydrazine solution through which the gas flow was passed (see below). A known amount (0.6–1.2 g) of intact, fresh bracken crozier heads were crushed with mortar and pestle using acid-washed sand (3–5 g) as abrasive (−15°C for 3 min). The cold mass was rapidly placed into a 12 ml flow reactor constructed from a disposable plastic syringe. The syringe was inserted into the gas-flow system and immersed into a circulating water bath at 30 ± 0.1°C at time zero when the gas flow was started. The gas flow was conducted through a first trap of dinitrophenyl hydrazine in acidic water–ethanol solution as previously described, and then through a saturated alkaline picrate solution (10.0 ml) where all HCN was trapped. With the aid of a precision syringe, a 1.0 ml aliquot was drawn every 20 min for 180 min, and then every 60 min. One last measurement was performed after 1200 min (20 hr) when no additional HCN evolution occurred. Immediately after every aliquot was drawn, 1.0 ml of fresh picrate solution was added to the gas trap. Therefore, the corresponding dilution factor was applied to calculate the actual amount of HCN incorporated into the picrate solution in every time interval, using the following equation

$$[\mathrm{HCN}]_i = [\mathrm{HCN}]_{m(i)} - 0.81 \times [\mathrm{HCN}]_{(i-1)} \tag{1}$$

where

$[\mathrm{HCN}]_i$ = increment in HCN concentration during the ith time period
$[\mathrm{HCN}]_{(i-1)}$ = increment in HCN concentration during the previous time period
$[\mathrm{HCN}]_{m(i)}$ = spectrally measured HCN concentration in each aliquot corresponding to the ith time period

The dilution factor (0.81) was derived from the combination of the remaining HCN in the picrate when an aliquot (1.0 ml) was drawn and the 9 ml remaining

solution was brought back to 10.0 ml by the addition of fresh picrate (1.0 ml). $[HCN]_{m(i)}$ was determined by contrasting the spectral absorbance at 515 nm of the HCN–picrate complex against a calibration regression ($r^2 = 0.99$, $P < 10^{-4}$) of NaCN solutions in the standard basic picrate reagent (range: 2.0–200.0 μg HCN equivalents).

All samples were allowed to stand in the gas flow reactor for a total of 20 hr, to ensure that all the prunasin was decomposed into HCN. To confirm that the measured HCN represented the total content of prunasin, a phosphate buffered (pH = 6.8) β-glucosidase solution (0.2% w/v) was added to the moist sand-crushed crozier mass in the flow reactor after the end of the kinetics experiment. The passing gas was examined for the presence of HCN. No additional hydrocyanic acid could be detected. Therefore, Eq. (2) conveyed the total amount of prunasin present.

$$[HCN]_{(1200\ min)} \times \left[\frac{MW(p)}{MW(HCN)}\right] = [Prunasin]_t \qquad (2)$$

Here MW is the molecular weight of species. A total of 76 croziers were studied kinetically.

Isolation of Prunasin. Modification of the method suggested by Brinker and Seigler (1992) was used. Freshly collected crozier heads (314 g) were dried under high vacuum (72 hr) yielding 43.5 g of material that was blended to a fine powder. This material was extracted in boiling methanol–water 4:1 (800 ml × 2) to counteract possible enzymatic decomposition of the cyanogenic glucoside. Each batch was then placed into an ultrasound bath for 30 min at 35°C. A 5% solution of lead acetate was added to the filtrate at room temperature to precipitate tannin and pigments. After filtration and centrifugation of solids, methanol in the supernatant was removed by rotary evaporation below 35°C. The remaining aqueous solution was frozen and freeze dried to a light yellowish powder (4.6 g) This material was purified by flash column chromatography using TLC-grade silica gel. Fractionation was conveniently monitored by β-glucosidase treatment of each fraction (5 μl) after solvent exchange to water at pH = 5.5, Sep-Pack (Millipore) pre-purification and HPLC determination of the formation of benzaldehyde (reverse-phase C_{18}, 10 cm Radial Pack column, MeOH–H_2O 70:30, 1 ml min^{-1}, 6.06 min ret. time, λ_{max} = 210 and 245 nm). This method requires only very small amounts of β-glucosidase and is more specific than the sodium picrate paper-TLC sandwich procedure (Brimer et al., 1983). The fraction eluting with ethyl acetate–acetone–methanol–water 16:3:2:2 gave the only HCN-yielding component. This fraction was further purified by thick layer chromatography (same solvent mixture, 8:1:1:1, $R_f = 0.3$–0.45) and crystallization from methanol–dichloromethane–hexane mixtures (187 mg, mp = 146–148°C).

Comparison of Enzyme Activity. Twelve field collected samples from the same sites above, each consisting of seven bracken fiddleheads were vacuum-dried,

reduced to a fine powder, and stored at -15°C until use. Each sample was subdivided in two subsamples. The kinetics of natural decomposition of prunasin to HCN in the first subsample (0.400 g dw) was determined as above except that, at the time of cold sand maceration, the original water content was reconstituted (1.6 ml corresponding to 80% moisture content). After 1200 min, the total amount of HCN collected in the picrate trap gave the prunasin content of the sample. At the time of cold sand maceration, to each one of the second subset of samples was added enough purified prunasin [as a cold (2°C) water solution, 16–231 μl, plus enough distilled water to complete 1.6 ml) to give a final concentration of 12.0 mg g^{-1} dw of the cyanogenic glucoside. The kinetics was then determined as above. In both sets, the initial velocities were calculated from the first degree coefficient of the 2° polynome to which the plot of accumulated HCN g^{-1} dw vs. time, up to 180 min, was best adjusted ($r^2 > 0.997$).

In a second series of experiments, the exact weight ($\pm 10^{-4}$ g) of approx. 0.35 g of fresh crozier head was determined, and the remaining material was used to estimate its dry weight. The sample was crushed with 10 g of fine sand at -15°C for 1 min adding 500 μl of phosphate buffer pH 6.8. The mixture was quickly placed inside the flow reactor, warmed to $30.0 \pm 0.1^{\circ}$C and the kinetics of HCN evolution determined during the first 180 min as described. A second sample excised from the same bracken plant was processed similarly except that 500 μl of β-glucosidase solution in phosphate buffer pH 6.8 was added during maceration. The enzyme solution was prepared from 1.0 mg of commercial almond emulsin dissolved in 1.0 ml of phosphate buffer, from which 50 μl was drawn and dissolved in 450 μl of buffer. The kinetics of HCN evolution was determined as before.

Statistical Calculations. Data were analyzed with Kruskal-Wallis and ANOVA tests of comparison of the means were performed using Statistix V 7.0 package (Analytical Software, St. Paul, MN). Curve fitting, plotting, and accompanying statistics were accomplished with Origin Professional software package V 5.0 (Microcal Software, Northampton, MA).

RESULTS

P. arachnoideum *Cyanogenic Potential.* The crozier phenological stage of bracken was selected as the best sample, because it contained the largest concentration of prunasin (Lawton, 1976). It was also the more fragile phase, with softer tissues, only one irreplaceable meristem, and close to ground-bound plant predators.

Table 1 shows the results of a homogeneity test for prunasin content of the four field populations. There were no statistically significant differences between the means (ANOVA within differences: $F = 3.28$, $P = 0.037$). Prunasin content ranged from 1.84 to 107.70 mg Pru g^{-1} dw (mean $= 18.62 \pm 20.82$ mg Pru g^{-1} dw) in a continuous fashion (Figure 1A) with 70% of the samples containing between

TABLE 1. COMPARISON OF PRUNASIN CONTENT (μg g^{-1} dw) IN CROZIERS OF FOUR ALLOPATRIC POPULATIONS OF NEOTROPICAL *Pteridium arachnoideum* ($N = 46$)

Population	A	B	C	D
Mean	21,661	11,596	31,687	23,614
SE	3,200.1	1,524.5	8,859.8	64,221.8
Minimum	7,613.2	4,725.0	12,827.2	24,20.1
Maximum	33,948.8	15,886.1	64,239.3	64,133.1

2 and 39 mg Pru g^{-1} dw (Figure 1B). Of the 77 samples collected, only one was acyanogenic. Efforts to find other acyanogenic genets among *P. arachnoideum* in the typical bracken grounds in the fields near Mérida failed. Squeezing young crozier heads between the fingers released enough benzaldehyde—the co-product of prunasin decomposition—to be clearly noticeable by smell, a quality that allowed for the fast identification of strongly cyanogenic populations of bracken in the field.

Kinetics of Cyanogenesis. In the kinetic runs of crushed croziers, the average rate of HCN formation v_A(μg HCN min^{-1}) was calculated from the increments per 20-min period of the evolution of HCN during the first 180 min of incubation at 30.0 $\pm$ 0.1°C. v_A of each independent sample was a linear function of

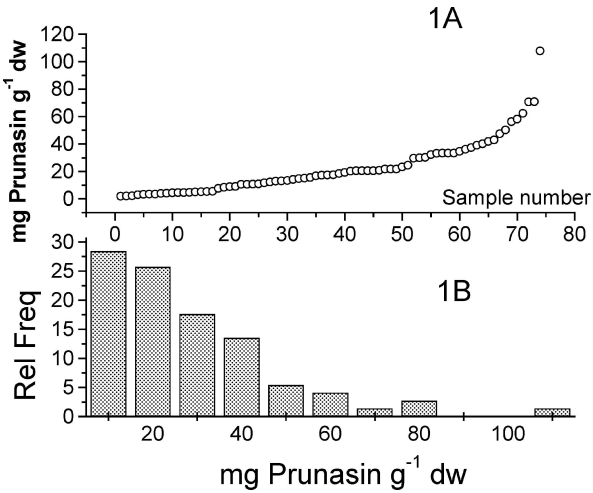

FIG. 1. Concentrations of prunasin in *P. arachnoideum* crozier head samples used in this study (A) ($N = 74$) and histogram of prunasin distribution in 10 mg g^{-1} dw intervals (B).

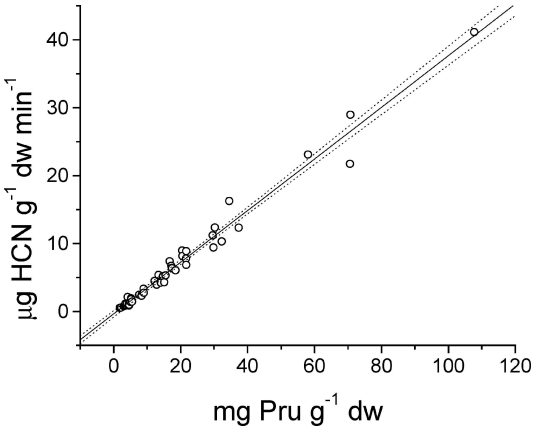

FIG. 2. Correlation between the increment of HCN production per unit time v_A (μg g^{-1} dw min^{-1}) and the total prunasin (Pru) (mg g^{-1} dw) contained in the crozier head. The linear regression followed the expression: HCN [μg g^{-1} dw min^{-1} $= -0.36$ ($\pm$0.23) + 0.38 ($\pm$0.008) $\times$ [Pru]$_t$. $N = 48$, $r = 0.989$, $SD = 1.180$, $P < 0.001$]. Dotted lines denote the 95% confidence limits of the regression.

the total prunasin [Pru]$_t$ available in the corresponding crozier (Figure 2). The slope of this equation gave v_R, which is v_A relative to [Pru]$_t$, 0.380 $\pm$ 0.008 μg HCN min^{-1} mg^{-1} [Pru]$_t$ during the first 180 min after tissue crushing. Based on this strong correlation, which suggests a first-order reaction on [Pru]$_t$, it was possible to examine collectively the whole set of kinetic experiments by normalizing all HCN g^{-1} dw of plant readings against [Pru]$_t$ in each individual crozier.

The time-dependent accumulated formation of HCN g^{-1} dw of crozier and relative to [Pru]$_t$ that emerged (Figure 3) followed a hyperbolic course whose mathematical expression [Eq. (3)] is the normalized rate equation of the HCN evolution in bracken croziers.

$$\Re(\mu\text{g HCN g}^{-1}\text{dw min}^{-1}) = \frac{P_1 t}{P_2 + t}[\text{Pru}]_t \tag{3}$$

where t = time (min)
$P_1 = 103.2 \pm 2.6$
$P_2 = 132.5 \pm 9.7$
$\chi^2 = 8.48$

In order to estimate the initial velocity v_i of the overall process, the accumulated formation of HCN (μg HCN g^{-1}dw) released during the first 180 min of individual bracken samples was adjusted mathematically to a 2° polynome. The

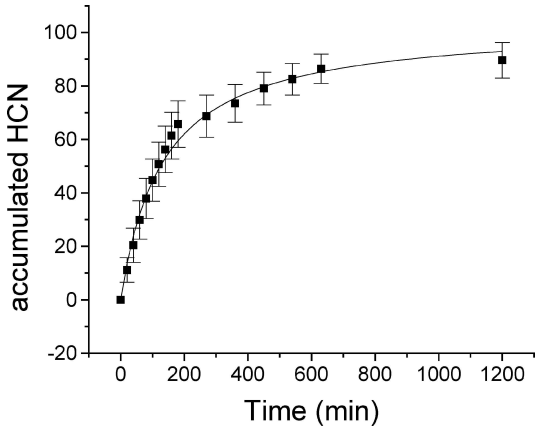

FIG. 3. $[Pru]_t$-standardized time-dependent accumulation of HCN [μg g^{-1} dw mg^{-1} $(Pru)_t$] produced by young croziers of *P. arachnoideum* until complete decomposition of the contained prunasin. Error bars are one standard deviation of the means ($N = 34$).

first degree coefficient, representing the slope at the onset of the data, gave v_i. It varied widely from 2.29 to 47.86 μg HCN g^{-1} dw min^{-1}, but it was also consistently positively associated with $[Pru]_t$ in each sample (data not shown) $v_i = 2.78\ (\pm 1.75) + 0.14\ (\pm 0.02) \times [Pru]_t$ g^{-1} dw; $r = 0.812$; SD $= 5.13$; $P < 0.001$).

Cyanide Evolution and Enzyme Activity. As the decomposition of prunasin not only depends on $[Pru]_t$ but also on β-glucosidase activity, there was the need to prove whether enzyme activity is tied to or is independent from $[Pru]_t$ in *P. arachnoideum*. To this end, the initial velocities of a set of 12 crozier samples were explored under two conditions: first, the kinetics of the accumulation of evolved HCN was monitored during the first 180 min, while $[Pru]_t$ was determined after 1200 min. To a second set of the same samples, enough purified prunasin was added to reach 12 mg g^{-1} dw and the kinetics was again determined. After 180 min, 57.24 $\pm$ 9.88% of $[Pru]_t$ had decomposed in the first set, whereas 49.86 $\pm$ 6.30% decomposed in the $[Pru]_t$ normalized group. Both figures were undifferentiated (ANOVA $F = 3.36$, $P = 0.062$), although the range of v_i was visibly narrowed by normalization of the prunasin content in the set of croziers studied (Figure 4).

In relation to the kinetics of prunasin decomposition in the presence of additional β-glucosidase, the initial velocities of HCN evolution with and without added enzyme were 45.36 $\pm$ 4.42 and 47.86 $\pm$ 3.52 μg HCN min^{-1} g^{-1}, respectively. After 100 min, the proportion of decomposed prunasin relative to $[Pru]_t$ was 0.242 and 0.250 with and without, added enzyme, respectively.

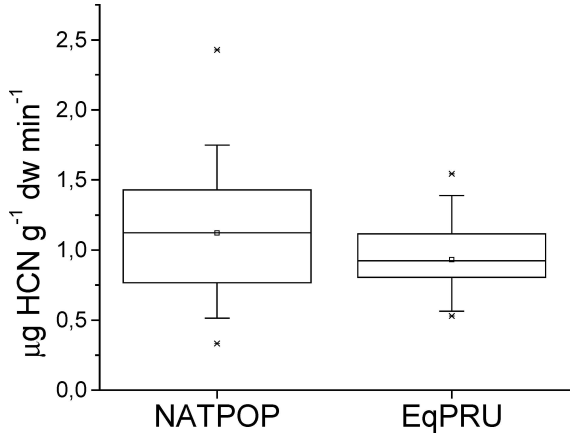

FIG. 4. Comparison of initial rates of HCN evolution (μg HCN g^{-1} dw min^{-1}) of a natural population (NATPOP) of *P. arachnoideum* croziers and the same samples whose prunasin content was corrected to 12.0 mg g^{-1} dw (EqPRU) by the addition of purified prunasin. The square symbol within the boxes denotes the means of the data, the horizontal lines in the box indicate the 25th, 50th, and 75th percentile values. Error bars denote 5th and 95th percentile values.

DISCUSSION

Tropical plants appear to be more stressed by invertebrate herbivory than those from temperate climates, due to greater insect species diversity and their year round presence. The ensuing pressure finds a response, for example, in the frequency of cyanogenesis (Thomsen and Brimer, 1997). Croziers of *P. arachnoideum* in the northern Andes appear to respond to this general pattern by their sole prunasin content, which collectively taken display a continuous trend (Figure 1A), and the elevated frequency of the cyanogenic genotype. Under the environmental constraints of these habitats, most of the population within the sampling universe of this study (>70%) synthesize and store 15–40 mg g^{-1} dw of prunasin, and some individual croziers contain in excess of 100 mg g^{-1} dw (Figure 1B). Upon complete conversion, this prunasin will turn into 1370–3660 μg HCN g^{-1} dw and occasionally up to 9150 μg g^{-1} dw. This quantity surpasses that found in some strongly cyanogenic strains of *Lotus corniculatus* such as the Aran variety from Ireland that can yield 2205 μg HCN g dm^{-1} and is selected against by voles (Viette et al., 2000). Within the sample range of $[Pru]_t$ found in *P. arachnoideum,* four populations (Table 1) that represented well the prunasin content of the majority of plants in the area were selected for the kinetic studies.

Prunasin content is insufficient to postulate a comprehensive cyanide-based defense in bracken. When the natural prunasin–HCN conversion rate is considered,

two defense strategies emerge. First, if the rate of conversion is sufficiently fast, the HCN evolved should have a deterrent effect on the plant predator as it feeds on its tissues and protection should take place in the brief feeding time span. As a result, damage to affected plant parts may be limited. Secondly, if the rate of HCN formation is much slower than the rate at which the plant tissue is devoured, little HCN will be available for immediate deterrence and a large proportion of prunasin will enter the gut of the predator and continue its decomposition in the digestive tract. Confined to the lumen, the HCN released would be bound to cause the greatest harm. This will depend on the size, eating strategy of the predator, amount of plant eaten, and the intervention of metabolic processes of detoxification such as the rhodanese sulfur transfer and the β-cyanoalanine pathway (Beesley et al., 1985). Inhibition of plant β-glucosidase activity by the herbivore mouth secretions is also conceivable. The frond itself would suffer the greatest damage, but the loss of fitness or even death of the predator—as it occurs in farm animals exposed to cyanogenic pastures—will eventually be to the advantage of the remaining plant fronds.

At the temperature profiles of the tropical mountains where bracken thrives, the conversion of prunasin into HCN in *P. arachnoideum* occurs relatively fast, as indicated by the average initial velocity of 0.418 ($\pm$0.014) μg HCN min^{-1} mg^{-1} [Pru]$_t$ which converts to a mean absolute velocity of 6.722 μg HCN min^{-1} g^{-1} dw of plant. When compared with the only available data (Goodger et al., 2002) for *E. polyanthemos* foliage for which the initial velocity was calculated as 0.02 to 0.14 μg HCN h^{-1} g^{-1}dw, meaning 0.33–2.3 $\times$ 10^{-3} μg HCN min^{-1} g^{-1} dw, it is apparent that *P. aquilinum* possesses a much more powerful cyanide response to the crushing of its fiddleheads. The standard plot in Figure 3 also gives an estimation of the variation of this velocity as time progresses that it was found to follow a rapidly decaying exponential function very closely represented by equation (4):

$$\frac{\Delta v_{\mathrm{A}}}{\Delta \tau} = \mathrm{A[Pru]}_t e^{-(t/b)} \tag{4}$$

where

$A = 0.703 \pm 0.024$
$b = 164.99 \pm 10.11$
$t =$ time (min)
$\chi^2 = 7.15 \times 10^{-4}$

The abrupt decay in the rate of HCN production indicates that in *P. arachnoideum* the overall decomposition of prunasin into HCN is modulated to yield a flash of defense material soon after injury of plant tissue. The initial rate v_i is a function of the activity of reaction components, prunasin, and lytic enzymes in bracken. The significant positive correlation illustrated in Figure 2 suggests

that the genes encoding for prunasin and β-glucosidase synthesis, though independent, may be activated in concert. Consistent with this is the conservative percentage of prunasin decomposed after 180 min that took place in croziers containing a natural quantity of prunasin ($57.24 \pm 9.88\%$) and the same croziers with added prunasin to yield the same amount of the cyanogenic glucoside ($49.86 \pm 6.30\%$). Namely, in both cases the same proportion of prunasin was broken down. This, in addition to the narrowing of the initial velocities (Figure 4) of the 12 samples used for this part of the study, is an indication that within this group of crosiers, β-glucosidase activity is not rate limiting and possibly exceeds the required activity for effective decomposition of the prunasin contained in these fiddleheads. A concurring result stems from the absence of statistical differentiation in the initial velocities of prunasin decomposition in croziers with and without added β-glucosidase (45.36 ± 4.42 and 47.86 ± 3.52 mg HCN min^{-1} g^{-1} dw). Hence, not only an excess of enzyme activity is contained in these crosiers, but also the activity of the enzyme is independent of $[\text{Pru}]_t$. A similar conclusion emerged from the work of Goodger et al. (2002) in *E. polyanthemos*, although other trees of this genus did not show such a correlation (Gleadow and Woodrow, 2000).

The application of Eq. (3) gives a more accurate estimate to these considerations. When the necessary variables are introduced [Eqs. (4) and (5)], it is possible to calculate the amount of HCN evolved into the atmosphere as a function of time and prunasin concentration while the predator feeds on the bracken fiddleheads, as well as the amount of prunasin that becomes part of its lumen.

$$\mu\text{g HCN evolved} = \left\{\frac{P_1 \times t}{P_2 + t}\right\} \times [\text{Pru}]_t \times \left\{\frac{27}{295}\right\} \times 10 \times W \tag{5}$$

and

$$\mu\text{g HCN (equiv) ingested} = [\text{Pru}]_t \times \left\{\frac{27}{295}\right\} \times 10 \times W \times \left\{100 - \frac{P_1 \times t}{P_2 + t}\right\} \tag{6}$$

where

$[\text{Pru}]_t$ = total prunasin content (mg g dm^{-1}) in the crozier
W = weight of the crozier as dry mass (g)

The 27/295 factor is the ratio of HCN–prunasin molecular weights, and "10" is the resulting conversion factor of mg [Pru] into μg HCN and the 100 to 1 scaling in the plot used (not shown).

Application of these expressions to a chewing insect that, for example, eats 100 mg of fresh crozier head containing 20 mg Pru and 88% moisture, in 10 min, results in 2.01 μg of HCN and by extension 7.89 μg of benzaldehyde being

released in and around the mouth parts of the predator in this time. In this model, we assume that the equimolar amount of benzaldehyde is produced at the same rate as HCN, since both are products of the same reaction. Although the LD_{50} of HCN has been determined for many animal species, it remains to be ascertained whether sufficient HCN diffuses into the air and is capable of affecting the feeding behavior of insect herbivores. Benzaldehyde is repellent against ants (*Myrmica americana*) ($ED_{50} = 375\ \mu g\ ml^{-1}$) in regurgitates of *Malacosoma americanum* larvae when the caterpillars were fed cyanogenic *Prunus* leaves (Peterson et al., 1987). If the fraction of this solution taken up by each individual ant is assumed to be 0.5 μl, ED_{50} would be 1.87 μg of benzaldehyde in Peterson's model. Obviously, this much benzaldehyde would not result from the decomposition of an equivalent amount of crozier tissue (about 0.5 mg) that an individual ant might conceivably nibble from the crozier. Hence, deterrence by the liberated allelochemicals during insects feeding time is likely to be insufficiently effective, at least against *M. americana* unless HCN and benzaldehyde act as synergists, as linamarin and histamine do in *Zygaena* butterflies (Muhtasib and Evans, 1987). No information exists on such synergy in prunasin–HCN–benzaldehyde at this time, nor quantitative data on the alteration of insects feeding behavior and toxicity by these materials acting together is available. Equations (4) and (5) also show that the larger the animal and, therefore, the greater the amount consumed together with feeding rate, the greater the amount of HCN (and benzaldehyde) released (Table 2), so a more effective feeding deterrence may result.

Equations (4) and (5) also reveal that after 10 min of feeding time in our model insect case, less than 10% of the total HCN potential will have been released. The remaining prunasin, which amounts to 91.7% of $[Pru]_t$ will be transferred into the gut, representing a toxic potential of 22.17 μg HCN if it all

TABLE 2. AMOUNTS OF HCN (μg) RELEASED TO THE AIR AND INSIDE THE HERBIVORE GUT AS A FUNCTION OF QUANTITY OF *P. arachnoideum* CROZIERS DEVOURED AND TIME USED IN FEEDING ON THESE

	Amount of crozier eaten (g)					
	0.1		5		100	
Time (min)	Evolved	Eaten	Evolved	Eaten	Evolved	Eaten
1	0.22	23.96	10.79	1,198.2	215.5	23,963.4
5	1.05	23.13	52.27	1,156.7	1,045.0	23,133.7
10	2.01	22.17	100.65	1,108.3	2,013.7	22,166.0
50	7.76	16.42	387.88	821.1	7,757.0	16,421.4
100	12.06	12.12	602.97	606.0	12,059.9	12,119.7

Note. An average content of 20 mg g^{-1}dw of prunasin was assumed. Calculations were performed using Eq. (4) and (5).

decomposes within the next few hours. This quantity, which amounts to 2217 ppm for a 1 g insect, and the accompanying 87.03 μg of benzaldehyde are bound to cause considerable damage unless the rate of rhodanese, β-cyanoalanine, or other enzyme based processing of HCN into innocuous material or the inhibition of prunasin decomposition into HCN is comparable or faster than the rate of prunasin–HCN conversion according to equation (3). At present, these combined digestive rates remain unknown.

Using a different animal model, sheep might be assumed to consume easily 50 g of fiddleheads mixed with pastures of the grassland in 5 min, hence evoking the evolution of 522 μg HCN in this time and ingesting enough prunasin to yield 11.6 mg of HCN in the gut, a potentially hazardous quantity. Adding the benzaldehyde co-product that is formed in an equimolar amount, 2.05 mg will be released into the sheep mouthparts possibly eliciting a sensory aversion reaction to the feed, while 45.5 mg of the aldehyde will be formed in the gut. The higher internal temperature of the herbivore would of course significantly enhance the rate of HCN–benzaldehyde production.

The model figures of Table 2 suggest that the emerging fronds of *P. arachnoideum* possess the potential capacity, in terms of $[\text{Pru}]_t$ and rate of HCN formation at temperatures commonly found in tropical bracken thickets, to embrace the two defense strategies postulated above, causing immediate feeding aversion in some herbivores, and preserving enough latent toxicity in its phytoanticipin form—prunasin—to cause damage inside the attacking organism. However, the balance of both defense routes in the overall HCN-based defense of bracken will depend strongly on the feeding rate, amount ingested by the specific herbivore, and its digestive detoxification reactions, thus opening opportunities to herbivore specialization.

Acknowledgments—The authors are grateful to Consejo de Investigaciones Científicas, Tecnológicas y Humanísticas of Universidad de Los Andes (CDCHT), and to the GQE-ADG Fund for providing financial support for this investigation. The taxonomic evaluation of Dr. John Thomson of the Sydney Botanical Gardens in Sydney, Australia is also gratefully acknowledged.

INFLUENCE OF DIET-RELATED CHEMICAL CUES FROM PREDATORS ON THE HATCHING OF EGG-CARRYING SPIDERS

DAIQIN LI[1,*] and ROBERT R. JACKSON[2]

(Received April 8, 2004; revised October 13, 2004; accepted October 16, 2004)

Abstract—Previous studies have shown that animals may make adaptive adjustments in response to chemical cues from predators, but hatching responses to diet-related chemical cues from predators have not been previously demonstrated. In the system studied here, the predator is an araneophagic jumping spider (Salticidae), *Portia labiata*, and the prey organism is a subsocial spitting spider, *Scytodes pallida* (Scytodidae). The spitting spider carries its eggs in its chelicerae, and carrying eggs is known to make it more vulnerable to predators. It is also known from an earlier study that the prior diet of the predator alters how dangerous the individual predator is to the spitting spider. In the experiments reported here, incubation time was shorter when volatile cues from the predator were present and longer in control tests when no chemical cues from the predator were present. The previous predator's diet also influenced incubation time: when in the presence of volatile cues from individuals of *P. labiata* that had previously fed on individuals of *S. pallida*, incubation time was shorter than when in the presence of volatile cues from individuals of *P. labiata* that had been feeding instead on house flies.

Key Words—Chemical cues, assessment, predation, anti-predator defence, hatching strategies, spiders, *Scytodes pallida*, *Portia labiata*.

INTRODUCTION

Animals can be envisaged as having ecological switch points at which they may exercise considerable adaptive plasticity. Evidence that chemical cues from predators influence switch-point decisions is now extensive, especially for aquatic species

* To whom correspondence should be addressed. E-mail: dbslidq@nus.edu.sg

(Peckarsky, 1996; Chivers and Smith, 1998; Kats and Dill, 1998; Tollrian and Harvell, 1999; Dicke and Grostal, 2001; Peckarsky et al., 2002). The effects of predator-derived chemical cues include, besides overt behavior such as fleeing from or attacking the predator, adjusting foraging behavior (Cowan and Peckarsky, 1994; Peckarsky and McIntosh, 1998; Abrams, 2000), changing level of general activity (Sih and Wooster, 1994; McIntosh et al., 2003), undertaking morphological transformations during development (Tollrian, 1995; Relyea and Werner, 1999; Peckarsky et al., 2001; Relyea, 2001), adjusting the timing of metamorphosis (Werner, 1986; Skelly and Werner, 1990; Rowe and Ludwig, 1991; Skelly, 1992; DeVito et al., 1998), and adjusting the timing of reproduction (Mangel and Clark, 1988; Crowl and Covich, 1990; Reznick, 1990; Ball and Baker, 1996).

Recent findings suggest that, for some animals, egg hatching is another important life history switch point and that individuals may base hatching on chemical cues from their predators (Sih and Moore, 1993; Moore et al., 1996; Blaustein, 1997; Chivers et al., 2001; Laurila et al., 2002). Embryos may sometimes have sensory and processing capacities more or less comparable to those of the animal after hatching, and embryos sometimes control the timing of their own hatching (Sih and Moore, 1993; Kats and Dill, 1998; Chivers et al., 2001). Alternatively, for species that attend their eggs, the parent may alter the timing of hatching (i.e., "incubation time") when chemical cues from predators are detected (Li, 2002).

Besides detecting cues that simply reveal the presence or absence of predators in the environment, animals may also discern the level of risk from the predator (Keefe, 1992), For example, they may discriminate between fresh and old volatile chemical cues (Venzon et al., 2002), with fresh cues representing greater risk because the probability of a predator still being present in the environment is normally higher when the cues are fresh. In some instances, the predator's sex and how dangerous it is as a predator may be related, and there are instances in which animals rely on chemical cues for discriminating the predator's sex (Lehmann et al., 2004).

Animals may also detect diet-related cues from predators, with especially strong responses being provoked when the predator has recently fed on other individuals of the responder's own species. Besides overt behavioral responses, animals may make life-history adjustments (Crowl and Covich, 1990; Lima and Dill, 1990; Chivers and Smith, 1998; Kats and Dill, 1998; Laurila et al., 1998; Chivers and Mirza, 2001; Venzon et al., 2002). Here, we use a spider predator–prey system to investigate a life-history adjustment that has not been investigated before. We consider whether risk-revealing diet-related cues from predators influence incubation time.

An earlier study suggested that a female of *Scytodes pallida* Doleschall, a subsocial spitting spider, exercises some control over when her eggs hatch. In particular, when egg-carrying females of this species detect chemical cues from *Portia labiata* (Thorell), a web-invading jumping spider that often preys on

S. pallida (Jackson et al., 1998), hatching is speeded up (Li, 2002), but these cues had no evident effect on hatching when eggs were unattended.

When carrying eggs in its chelicerae (Li et al., 1999; Whitfield, 1999), *S. pallida* is more vulnerable to predation by *P. labiata*, and this predator eats the eggs as well as the parent. By spitting, *S. pallida* can defend itself against *P. labiata*. However, before it can spit, it has to release the eggs, introducing a delay and giving *P. labiata* an advantage (Jackson et al., 2002). Compounding the problem, *P. labiata* is predisposed to choose egg-carrying rather than eggless individuals of *S. pallida* (Li and Jackson, 2003). By speeding up hatching, *S. pallida* can free its chelicerae, become ready to spit (Li, 2002), and remove itself from the predator's preferred prey category (Li and Jackson, 2003).

Here, we extend earlier work on spitting spiders by investigating a fine-grain adaptive adjustment in timing of egg hatching. In particular, we investigate, for the first time, whether the predator's recent feeding history influences incubation duration.

METHODS AND MATERIALS

All experiments and all rearing were carried out in a controlled-environment laboratory ($25 \pm 1^{\circ}$C; 60–80% RH; 12L:12D, with lights on at 08:00 hr) using procedures that numerous earlier studies have made standard (Jackson and Hallas, 1986; Li, 2002). Only critical details are provided here.

In each trial, there was a test spider (an egg-carrying adult female of *S. pallida*; body length ca 7 mm) and a source spider (an adult female of *P. labiata*; body length ca 10 mm). For details concerning how egg-carrying *S. pallida* were obtained, see Li (2002). Scytodid eggsacs are only sparsely wrapped in silk, and we could readily discern the status of the eggs through the silk. No individual was used more than once as a source spider or a test spider. In the experiment, the source spider provided a substrate (blotting paper) used as a source of potential chemical cues. For 2 wk before collecting the substrate, each individual of *P. labiata* was fed one prey item every second day (i.e., it fed on a total of 7 house flies or 7 scytodids). Source spiders were assigned at random to one of two groups. Individuals in one group were fed house flies (*Musca domestica* L.) (fly-fed group), and the individuals in the other group were fed eggless scytodid females (scytodid-fed group). The body length of each prey organism (house fly or scytodid) was about 7 mm.

The spiders we used originated from Labrador Park, Singapore. Individuals of *S. pallida* used as *P. labiata*'s prey were collected from the field as needed, but the individuals of *S. pallida* used as test spiders were from cultures (reared from eggs in the laboratory). We used a split sibship design for assigning individuals

from the culture to the experiment, where a "sibship" is defined as the progeny of a particular male and female parent. Eight sibships were used, with the number of test spiders from each sibship being about equal. The maintenance diet of *S. pallida* in the laboratory was a variety of insects. Before the experiment, none of the test spiders had been exposed to *P. labiata*, and none had been in the presence of potential cues from *P. labiata*.

All test spiders were in webs when testing began. This was achieved by placing the scytodid in a cage ($150 \times 100 \times 50$ mm^3) together with a leaf from a camwood tree (*Baphia nitida* Lodd). These waxy leaves have a slightly concave upper surface and are known to be optimal web sites for *S. pallida*.

Substrate was prepared by putting each source spider in a sterile Petri dish (diam 90 mm), with a circular piece of blotting paper covering the inside bottom surface of the dish. The source spider was left in the Petri dish for 24 hr, after which it was returned to its cage. The lid of the Petri dish was replaced with fine mesh (0.1 mm), and the blotting paper was left inside the dish. Testing began about 12 hr later. During testing, the mesh stayed in place, preventing the test spider from contacting the substrate.

One day after oviposition, test spiders were assigned at random to one of three treatment groups, defined by the substrate (20 test spiders in each group). For scytodids in the scytodid-fed group, the substrate was from an individual of *P. labiata* that had fed on scytodids. For scytodids in the fly-fed group, the substrate came from an individual of *P. labiata* that had been feeding on house flies. For scytodids in the control group, there was only clean blotting paper in the Petri dish.

Immediately before testing began (at about 09:00 hr), the test spider was transferred to the experimental cage ($200 \times 200 \times 200$ mm^3). The leaf, with the scytodid on board, was fastened with Blue Tack (Bostik, Australia) to one of the top corners of the cage. One test spider was present in a cage per trial, and two house flies were provided once a week during the trial.

A Petri dish containing the substrate was placed at the center of the inside bottom of the cage. For the duration of each trial, one Petri dish was present in the test spider's cage, but each day each dish was replaced daily with a new one containing freshly prepared substrate of the same type (or new blotting paper for the control). Cages were monitored daily until eggs had either hatched or died. For each test spider, we recorded incubation time, hatching success (the number of eggs that hatched divided by the total number of eggs oviposited), and hatchling size (body length of spiderlings when they hatched). These three variables are referred to collectively as "hatching traits."

Batch size (i.e., the total number of eggs oviposited per eggsac) was determined once all hatchlings had emerged from the eggsac or once 30 d had elapsed after oviposition. This was done by counting the hatchlings and by teasing away the silk and counting any unhatched eggs that were found. For each trial, we

determined hatchling size by calculating the mean body length of five hatchlings chosen at random.

All data met the assumptions for parametric statistics. After showing treatment effects using multivariate analysis of variance (MANOVA), we used univariate analysis of variance (ANOVA) for further analysis. The multivariate F-statistic (Wilks' λ) was used because it does not require compound symmetry. For *post-hoc* comparisons, Tukey honestly significant difference (HSD) tests were used to test for differences between treatment means (Zar, 1996). All statistical tests were run by using SPSS.

RESULTS

Batch size did not differ significantly among treatments (mean $\pm$ SE $=$ 20.8 ± 0.6, 22.5 ± 0.5, and 21.6 ± 0.5 for the control, fly-fed, and *Scytodes*-fed *Portia* treatments, respectively; ANOVA, $F_{2,57} = 2.332$, $P = 0.106$), but there were significant hatching-trait differences across treatments (Figure 1, Table 1). Regardless of diet, incubation time was shorter when substrate from the predator was present than when only clean blotting paper was present (Tukey HSD, fly-fed vs. control, $P < 0.01$; *Scytodes*-fed vs. control, $P < 0.001$). Moreover, when the substrate was from predators fed on scytodids, hatching time was shorter than when the substrate was from predators that had fed on house flies (Tukey HSD, Tukey HSD, $P = 0.034$).

For both diets, hatchling size was smaller in the presence of substrate from the predator than in the presence of clean blotting paper (Tukey HSD, fly-fed vs. control: $P < 0.001$; *Scytodes*-fed vs. control: $P < 0.001$). However, hatchling sizes when in the presence of cues from scytodid-fed and fly-fed predators were not significantly different (Tukey HSD, $P = 0.336$). Hatching success did not differ significantly among treatments (Table 1).

DISCUSSION

Egg-carrying females of *S. pallida* evidently detect and respond adaptively to diet-mediated cues from *P. labiata*, an araneophagic jumping spider and a natural predator. Although previous studies have shown the importance of predator risk on egg hatching traits in a wide range of animals (Sih and Moore, 1993; Moore et al., 1996; Warkentin, 2000; Chivers et al., 2001; Li, 2002), our findings are different because they show that the chemical signature of *P. labiata* is influenced by *P. labiata*'s diet, and that *S. pallida* responds to the *P. labiata*'s diet-derived signature by reducing incubation time. In particular, we showed that volatile chemical cues from individuals of *P. labiata* that had recently fed on *S. pallida* induced shorter incubation times than did volatile chemical cues from individuals

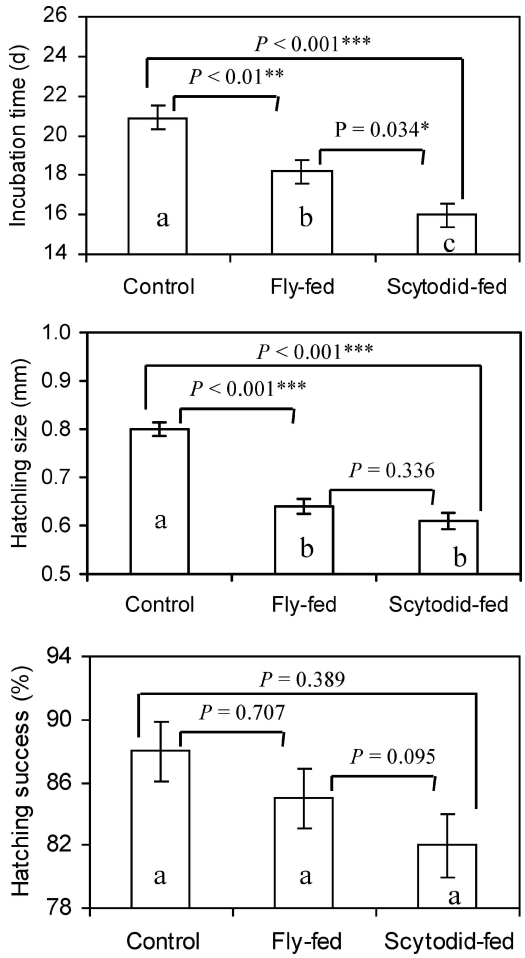

FIG. 1. Mean (±1 SE) incubation time, hatchling size, and hatching success of egg-carrying females of *Scytodes pallida* exposed to different potential volatile chemical cues. Cues from different substrates held in covered Petri dishes. Control: clean blotting paper. Fly-fed: blotting paper that had been in contact with a predator (*Portia labiata*) that had earlier been feeding on house flies. Scytodid-fed: blotting paper that had been in contact with a predator (*P. labiata*) that had earlier been feeding on *S. pallida*. Incubation time: interval between oviposition and hatching. Hatchling size: body length of spiderlings at hatching. Hatching success: number of eggs that hatched divided by total number of eggs oviposited. Different letters within bars indicate significant differences at $P < 0.05$, based on *post-hoc* Tukey's HSD tests.

TABLE 1. MANOVA SHOWING OVERALL EFFECTS ON *Scytodes pallida* OF TREATMENT (PREDATOR DIET) ON EGG HATCHING TRAITS (INCUBATION TIME, HATCHLING SIZE, AND HATCHING SUCCESS) AND ANOVA SHOWING EFFECTS OF EACH TRAIT

	Wilks' λ	*F*	*df*	*P*
MANOVA	0.264	17.379	6,110	<0.001
ANOVA				
Incubation time		15.633	2,57	<0.001
Hatchling size		52.748	2,57	<0.001
Hatching success		2.289	2,57	0.111

of *P. labiata* that had recently fed on house flies. When *S. pallida*'s eggs hatched sooner, they hatched at a smaller size (about 25% smaller) when in the presence of predator cues than in the controls. Additional research is needed for determining whether reduced size at hatching is in some way costly to the *S. pallida* female.

In a variety of animals (Chivers and Smith, 1998; Kats and Dill, 1998; Wisenden, 2000; Chivers and Mirza, 2001), including spiders (Persons et al., 2001), it is known that chemical cues from a predator that has been eating conspecifics elicit stronger anti-predator responses from the prey animals, and that chemical cues from predators that have been eating other types of prey elicit weaker responses. A reasonable interpretation of this literature might be that, after preying on a given species, various predators become more dangerous to other individuals of the prey species on which they just fed (see Persons et al., 2001), but this specific hypothesis is typically left implicit or else accepted as a foregone conclusion. However, this hypothesis was investigated explicitly in a recent study on *Scytodes–Portia* interactions (Jackson and Li, 2004). This study showed that *P. labiata*, after feeding on a single individual of *S. pallida*, forms search images for, and becomes more dangerous to, scytodids.

Scytodes pallida appears to be a prey species in which threat-sensitivity (Helfman, 1989; Bishop and Brown, 1992) is especially pronounced (i.e., it appears to be a species in which plastic response to different levels of threat from predators is pronounced). Evidently, the strength of *S. pallida*'s hatching response to *P. labiata* varies adaptively in relation to how dangerous the individual *P. labiata* becomes as a consequence of this individual's prior diet. This study provides the first experimental support for this conclusion.

There is a need for research designed to clarify the precise origin of, and to derive a biochemical characterization of, the volatile cues by which *P. labiata* influences the hatching of *S. pallida*. More is known about similar systems from aquatic animals (reviews: Chivers and Smith, 1998; Wisenden, 2000; Chivers and Mirza, 2001), and the extensive experimental work on aquatic systems will be a

useful starting point for future work on the chemical-mediation of *Scytodes–Portia* interactions.

Acknowledgments—Comments and suggestions from Naomi Diplock, Anssi Laurila, and Karen Warkentin greatly helped improve the manuscript. We are grateful to the assistance of Goh Poh Moi for rearing houseflies. This work was supported by grants (R-154-000-072-112 and R-154-000-188-112) to D. Li from the National University of Singapore Academic Research Fund.

PARALLEL ARMS RACES BETWEEN GARTER SNAKES AND NEWTS INVOLVING TETRODOTOXIN AS THE PHENOTYPIC INTERFACE OF COEVOLUTION

Abstract—Parallel "arms races" involving the same or similar phenotypic interfaces allow inference about selective forces driving coevolution, as well as the importance of phylogenetic and phenotypic constraints in coevolution. Here, we report the existence of apparent parallel arms races between species pairs of garter snakes and their toxic newt prey that indicate independent evolutionary origins of a key phenotype in the interface. In at least one area of sympatry, the aquatic garter snake, *Thamnophis couchii*, has evolved elevated resistance to the neurotoxin tetrodotoxin (TTX), present in the newt *Taricha torosa*. Previous studies have shown that a distantly related garter snake, *Thamnophis sirtalis*, has coevolved with another newt species that possesses TTX, *Taricha granulosa*. Patterns of within population variation and phenotypic tradeoffs between TTX resistance and sprint speed suggest that the mechanism of resistance is similar in both species of snake, yet phylogenetic evidence indicates the independent origins of elevated resistance to TTX.

Key Words—Coevolution, parallel evolution, resistance, *Taricha*, tetrodotoxin, TTX, *Thamnophis*, toxicity.

INTRODUCTION

Both the fitness consequences that drive an "arms race" and the traits that evolve as a result depend on the phenotypic interface of coevolution. In other words, the phenotypic traits that mediate the interaction between ecological partners serve as both agents and targets of selection (Brodie and Brodie, 1999b; Brodie and Ridenhour, 2003). In chemically mediated interactions, the phenotypic interface may revolve around a toxin. If the toxin is severe enough to drive an arms race between predator and prey, we would expect to see similar coevolutionary patterns in multiple predator–prey pairs wherein prey possesses this toxin. This scenario, of course, requires that the usual prerequisites for coevolution are met, including the genetic ability of each species to respond to reciprocal selection and the occurrence of ecological interactions that allow the traits to generate selection (Berenbaum and Zangerl, 1992). The existence of such "parallel arms races" would be evidence that the phenotypic interface in question is a driving force behind the patterns of trait covariation observed. Although parallel arms races might be observable as a single prey species with different successful predators in different parts of its range, the strongest case for the evolutionary significance of the phenotypic interface would be independent species pairs of coevolving predators and prey.

Parallel arms races might involve identical traits on both sides of the phenotypic interface or on only one. If two prey species share a common deadly toxin, their respective predators might have responded by evolving the same means of circumventing the toxin, or they might have evolved different mechanisms of exploitation. If both a chemical and mechanism of resistance to the chemical are similar in parallel arms races, this suggests that constraints of some type are involved in determining the evolutionary response to selection in the parallel systems. Some of the best examples of constrained parallel evolution come from the phylogenetically diverse but mechanistically similar adaptations of insects to insecticides (Mallet, 1989; McKenzie and Batterham, 1994). Conversely, other cases of insecticide resistance involve traits as varied as behavioral, enzymatic, and physiological defenses to the same classes of chemicals, indicating that evolutionary responses need not always play out in similar dimensions (Mallet, 1989; Denholm et al., 1999). Analogous possibilities exist for the other side of the interaction as well, such that different prey species might repeatedly evolve similar defenses with respect to a single predator, or evolve unique defenses with respect to a common exploitative trait of its predators. Characterization of the existence and nature of parallel arms races is a first step in understanding the generality of the ecological context related to any phenotypic interface of coevolution.

The phenotypic interface of the interaction between the garter snake *Thamnophis sirtalis* and the newt *Taricha granulosa* is the neurotoxin tetrodotoxin

(TTX). Tetrodotoxin binds to voltage-gated sodium channels in nerves and muscles, thereby blocking action potential propagation. Because TTX has high binding affinity for most sodium channel types in most species (Hille, 1992; Narahashi, 2001), it has broad and extreme toxicity. TTX is found in a wide variety of taxa (Miyazawa and Noguchi, 2001) including all species of newts in the genus *Taricha* (Brodie et al., 1974; Yotsu et al., 1990; Yotsu-Yamashita, 2001). Levels of TTX in *Taricha granulosa* can be extremely high, making the newts lethal prey to almost all potential predators (Brodie, 1968; Hanifin et al., 1999). The common garter snake, *Thamnophis sirtalis*, appears to have entered such an arms race. Some populations of *T. sirtalis* that are sympatric with toxic *T. granulosa* have evolved physiological resistance to TTX, and levels of resistance generally covary with toxicity of newts across a broad geographic range (Brodie et al., 2002). Phylogenetic comparisons suggest that the entire genus *Thamnophis* has slightly elevated resistance to TTX, predisposing this group to engagement at a phenotypic interface involving TTX (Motychak et al., 1999). Despite this predisposition to and apparent evolutionary lability of TTX resistance, *Thamnophis sirtalis* is the only species known to be apparently evolving with toxic newts. The apparent lack of parallel arms races involving TTX and resistant snake predators is paradoxical with predictions of the importance of dangerous prey to predator–prey coevolution (Brodie and Brodie, 1999b).

Following the observations of predation in the wild, we investigated TTX resistance and toxicity in sympatric populations of a second species pair of garter snakes (*T. couchii*) and newts (*T. torosa*) from California. Our results indicate that not only has this species of garter snake evolved elevated resistance to TTX present in local newts, but also that similar patterns of costs to TTX resistance exist, suggesting similar mechanisms of resistance. The phylogenetic relationships of *T. couchii* and *T. sirtalis* (de Queiroz et al., 2002) indicate independent origins of elevated TTX resistance in these two species. The similarity of both predator and prey sides of the phenotypic interface in these apparent parallel arms races indicates not only that TTX is a potent driving force behind coevolution in these taxa, but also that some form of evolutionary or physiological constraint has led to parallel phenotypic evolution in the predatory traits mediating this coevolution.

METHODS AND MATERIALS

Population Samples. Adult female garter snakes (*Thamnophis couchii*) and both juvenile and adult newts (*Taricha torosa*) were collected from Cold Springs Creek, nearby Tyler Creek, and small adjacent ponds, from the Greenhorn Mountains in the Sierra Nevada Range, Tulare County, CA, USA. Subjects were collected (18–20 May and 12–14 June 2001) and will be deposited at the California Academy of Sciences.

Snake Resistance. Tetrodotoxin resistance data were collected on 68 neonate snakes born in the laboratory to six wild-caught females 4 August-5 September, 2001. Females were housed individually in 10 gallon glass aquaria with a thermal gradient (24–30°C) and a 14:10 L:D photoperiod. Females had constant access to water and were fed farm-raised mollies (*Poecillia* sp.) weekly. After parturition, neonates were measured for mass, snout-vent length (SVL), and total length, housed individually in plastic tubs (15 cm diam by 10.5 cm tall), and watered once daily.

Resistance to TTX was scored by using a bioassay of whole organism performance (Brodie and Brodie, 1990; Brodie et al., 2002). At 3–5 d after birth, each individual was raced for 2 m on a 4-m by 0.1-m racetrack with a substrate of indoor/outdoor carpet and equipped with infrared sensors to electronically time sprint speed over 0.5-m intervals. Each neonate was tested twice on one day (3–4 hr apart) to determine "baseline speed." The maximum 0.5-m speed in each trial was taken as a measure of maximum sprint speed.

The following day (20–21 hr after the last speed trial) each neonate was given an intra-peritoneal injection of a known dose [see below) of TTX [crystalline $3\times$ in citric acid–sodium citrate buffer (Sigma) diluted in amphibian ringer solution]. Thirty min after injection snakes were tested on the racetrack to determine "postinjection speed." Forty-eight hr later, snakes were again tested, up to three times total per snake. Control injections of physiological saline have no effect on snake performance (Brodie and Brodie, 1990). "Resistance" was scored as the percentage of an individual's baseline speed crawled after injection (postinjection speed/baseline speed). Individuals that are greatly impaired by TTX crawl only a small proportion of their normal speed, while those unaffected by a dose of TTX crawl 100% of their baseline speed.

A population-level dose response curve was calculated from individual neonate responses to five levels of TTX injections (0.5, 1, 2, 5, and 10 μg) using the linear regression $y' = \alpha + \beta x'$, with the transforms $y' = \ln((1/y) - 1)$, where y is resistance as a percentage of baseline crawl speed, and $x' = \ln(x)$, where x is the dose of TTX in mass-adjusted mouse units ("MAMU") (for further details of analysis, see Ridenhour et al., 2004). From this regression model, we estimated the "50% dose," defined as the amount of TTX required to reduce the average snake to 50% of its baseline speed. Because TTX resistance is related to body size within and among some populations of *Thamnophis sirtalis* (Brodie and Brodie, 1990, 1999a; Ridenhour et al., 2004), and to compare levels of TTX resistance to populations of *Thamnophis sirtalis* (Brodie et al., 2002), we transformed doses using a population-level mass-adjusted measure. A dose in MAMUs was calculated by dividing a given dose of TTX by the mean neonate mass of the population (as measured after the final baseline speed trial), then dividing by the amount of TTX sufficient to kill 1 g of mouse in 10 min (Brown and Mosher, 1963); 1 "mouse unit" = 0.0143 μg of TTX. One MAMU is, therefore, one mouse

unit of TTX per gram of snake. Neonate garter snakes ($N = 56$) were tested at one common dose (0.005 mg TTX) to determine whether families differed with respect to average resistance at this dose; resistance scores were analyzed using a one-way ANOVA in JMP v 5.01 (JMP, 1989–2002).

Phenotypic tradeoffs between locomotor performance and TTX resistance have been detected in populations of *Thamnophis sirtalis* (Brodie and Brodie, 1999a). To investigate the presence of similar tradeoffs in *T. couchii*, we examined the slope of a regression of postinjection speed on baseline speed. If TTX affects all individuals equally, then the slope of the regression will be one, and the effect of TTX is purely additive and reflected in the intercept. If, however, the effect of TTX is related to the speed of an individual, then the slope should differ from one: a slope <1 indicates a tradeoff wherein the fastest individuals have low resistance, while a slope >1 indicates that faster individuals have greater resistance. Regression analyses were performed in JMP v 5.01 (JMP, 1989–2002). Because both variables are measured with error, reduced major axis (RMA) regression was also examined. Results of RMA converge quantitatively with Model I regression as the error ratio exceeds 2, and so only Model I results are reported.

Newt Toxicity. Newts were brought to the laboratory (Utah State University), weighed, SVL measured, and frozen at -80°C within 5 d of field collection. Individual tissue samples from each subject were taken from the dorsal surface between the pelvic and pectoral girdle. This region of skin has a uniform distribution of skin glands, and TTX levels from the dorsum show little within individual variation (Hanifin et al., 2004). We removed a small (5 mm diam) circle of skin with a human skin-biopsy punch (Acu-Punch^{TM}, Acuderm Inc.) for toxin analysis. Only skin and the thin layer of connective tissue between the skin and dorsal muscle was removed.

Toxin was extracted from each skin sample by grinding a single tissue plug (0.19 cm^2) with 800 μl extraction solution (0.1 M aqueous acetic acid). Samples were shaken, heated, and spun following procedures described previously (Hanifin et al., 1999, 2004). The levels of TTX were quantified by fluorometric HPLC following the protocol of (Yasumoto and Michishita, 1985; Hanifin et al., 1999). Data acquisition and chromatographic analysis were performed with System Gold software (version 8.1, Beckman Inc.). Peak area concentration curves were calculated with standards prepared from commercial TTX (Sigma).

We estimated whole newt toxicity by using the relationship of dorsal skin toxicity (from skin punches) to whole animal toxicity described by Hanifin et al. (2004). The relationships between TTX concentration and newt size SVL, and between whole newt toxicity and newt SVL were estimated with regression using JMP v5.01 (JMP, 1989–2002). Graphical comparisons of whole newt toxicity and snake resistance at the population-level were made using these whole newt toxicity measures and a projection of average snake resistance as a function of body size.

To determine how much toxin would reduce the performance of the average snake in a population by a given amount, we used the relationship of injected to oral doses of TTX (Williams et al., 2001) and interpolation of the population average MAMU dose from the population curve (described above or from Brodie et al., 2002 for Benton Co., OR *T. sirtalis*) yielding the equation: mg TTX = [(Mouse Unit × oral/injected dose) × snake mass] × resistance in MAMU. Curves were estimated for 15% (near immobility) and 50% baseline performance for the Cold Springs Creek population of *T. couchii* and sympatric *T. torosa*, and for the Benton Co., OR population of *T. sirtalis* and sympatric *T. granulose*. Data for *T. sirtalis* and *T. granulosa* were taken from Brodie et al. (2002) and Hanifin et al. (1999, 2002).

RESULTS

Snake Resistance. An adult *T. couchii* (50 g, 480 mm SVL-CAS 212868) was observed (J. V. Vindum and C. R. F., personal observation) swallowing a large juvenile *T. torosa* (1.85 g, 41 mm SVL-CAS 212869) in the wild at the Cold Springs Creek locality on 7 June, 2000. When discovered, the newt was visibly covered with secretion and was swallowed head first as far as its forelimbs. Upon collection, the snake disgorged the newt and both animals appeared unharmed for 3 d, after which they were preserved as voucher specimens.

At testing, the mean mass of neonate *Thamnophis couchii* ($N = 68$) was 3.7 ± 0.07 (SE) g, mean SVL was $195 + 1.3$ (SE) mm, and mean total length was 258 ± 1.7 (SE) mm. The average litter size was 11.2 and ranged from 7 to 15.

Neonate *Thamnophis couchii* from this population exhibit high levels of resistance to TTX. The population resistance curve was characterized by the regression: $y' = -6.91 + 1.55x'$. This relationship yielded an estimated 50% dose of 86.5 MAMU (95% CI 70.3–106.3 MAMU) for the population (Figure 1). Significant family level variation in resistance to 0.005 mg of TTX was detected (ANOVA: $F_{4,50} = 11.85$, $P < 0.001$).

Tradeoffs between resistance and locomotor performance were detected at the phenotypic level (Figure 2). The regression of postinjection speed on baseline speed was postinjection speed = 0.106 + 0.185 [baseline speed]. The slope of this regression was less than 1 ($t = -4.30$, df = 1, $P < 0.001$), indicating that slower snakes were relatively more resistant than faster snakes. An insufficient number of families prevented analysis of the genetic tradeoffs.

Newt Toxicity. Tetrodotoxin was detected in each of the newts collected from the Cold Springs Creek locality. Adult newts (>65 mm SVL; $N = 8$) had an average concentration of 0.065 mg TTX/cm^2 dorsal skin (range 0.028–0.133); juvenile newts (<50 mm SVL; $N = 11$) had an average concentration of 0.009 mg TTX/cm^2 dorsal skin (range 0.001–0.026). The concentration of

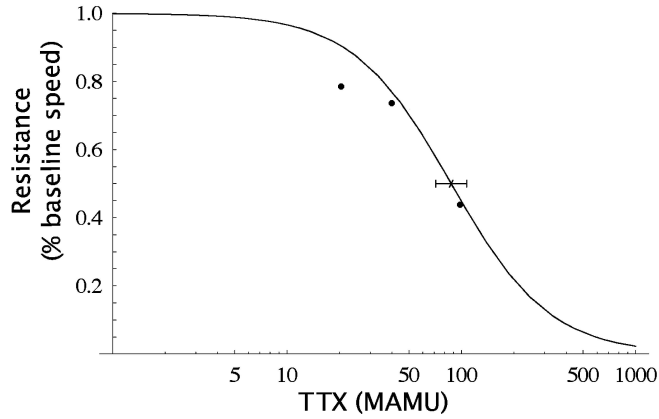

FIG. 1. Tetrodotoxin resistance in *Thamnophis couchii* from Cold Springs Creek, CA. The dose–response curve for neonate *T. couchii* was estimated over a range of TTX doses using curvilinear regression. The 50% dose (with 95% CI) is shown as a bar at 86.5 MAMU of TTX. Symbols indicate average response at each tested dose.

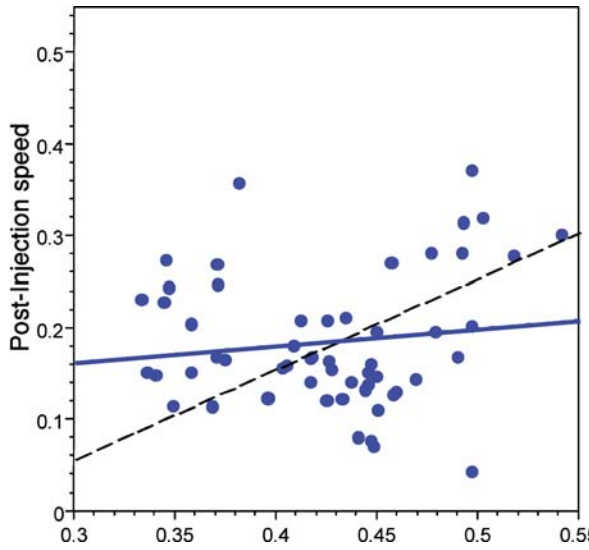

FIG. 2. Costs of tetrodotoxin resistance in *Thamnophis couchii*. Regression of postinjection speed on baseline speed (m/s) reveals a slope (solid line) significantly less than 1 (dashed line), indicating that slower snakes are relatively more resistant than faster snakes. Regression based on data from neonates snakes ($N = 56$) tested at 95.4 MAMU of TTX.

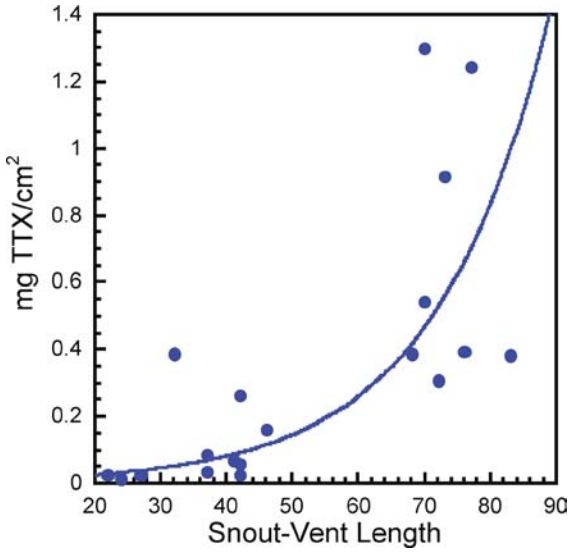

FIG. 3. Tetrodotoxin levels of *Taricha torosa* as a function of SVL (mm). The concentration (by area) of TTX in dorsal skin increases exponentially with SVL. This relationship appears to be driven primarily by differences between juvenile (<50 mm) and adult (>65 mm) newts.

TTX in dorsal skin increased with size of newt, but varied greatly among individuals [Figure 3; $\ln(\text{TTX/cm}^2)$ skin $= -7.596 + 0.642$ [SVL], $F_{1,17} = 54.34$, $P < 0.001$]. Whole animal estimates of TTX per individual indicated the average juvenile newt possessed 0.081 mg TTX in its skin, whereas the average adult newt possessed 2.41 mg of TTX. Whole animal TTX also increased with body size [TTX/individual $= -7.197 + 1.072$ [SVL]; $F_{1,17} = 145.77$, $P < 0.001$]. The effect of size on both skin concentration of TTX and total body TTX appeared to be primarily due to difference between newly metamorphosed and adult newts.

DISCUSSION

Thamnophis couchii from the Cold Springs Creek region of California have evolved high levels of resistance to tetrodotoxin (TTX). Previous studies of *T. couchii* and congeners from other parts of western North America have not detected TTX resistance in this group, even where these snakes are sympatric with newts of the genus *Taricha* (Motychak et al., 1999). As is the case for TTX resistance in another species of garter snake, *T. sirtalis*, among-family variation in level of resistance is apparent. Furthermore, tradeoffs between resistance and

locomotor performance similar to those detected in populations of *T. couchii* are observed in *T. sirtalis* (Brodie and Brodie, 1999a). The presence of such a cost suggests that similar physiological mechanisms might underlie TTX resistance in both species of snakes. Relatively high levels of TTX are present in sympatric *T. torosa*, though the quantity of the toxin varies among individuals and increases dramatically with size after metamorphosis (Figure 3). Field observations of an adult *T. couchii* eating a newt in the wild indicate at least some frequency of ecological interaction between these species.

Compared to known populations of *T. sirtalis*, the Cold Springs Creek population of *T. couchii* has relatively high resistance to TTX; this population would rank in the second highest category with only four populations of *T. sirtalis* exceeding its average 50% level resistance of 86.5 MAMU (Brodie et al., 2002). Interpopulational comparisons of snake resistance and newt toxicity in the *T. sirtalis* and *T. granulosa* interaction suggest fairly close phenotypic matching (Brodie et al., 2002). Projections of relative toxicity and resistance for a range of body sizes (Figure 4) suggest that adult *T. couchii* would be able to ingest most adult newts in the population without experiencing a complete loss of locomotor function. By contrast, adult *T. sirtalis* from the Benton County population in Oregon (one of the more resistant populations of snakes) are expected to frequently encounter newts toxic enough to fully immobilize them (Figure 4). Thus, the Cold Springs population of *T. couchii* appears to be more resistant relative to the toxicity of its sympatric prey than most studied populations of *T. sirtalis*.

Elevated resistance to TTX is a derived character state in the genus *Thamnophis* previously known only in *T. sirtalis*, despite investigations of other species of garter snakes that prey on amphibians and co-occur with *Taricha*. *Thamnophis sirtalis* and *T. couchii* are distantly related within the genus; *T. sirtalis* is a member of the sister group (with ribbon snakes) to all other garter snakes, whereas the aquatic garter snake species group that includes *T. couchii* is relatively derived (de Queiroz et al., 2002). The elevated resistance of Cold Springs Creek *T. couchii* likely represents an independent origin of TTX resistance within the genus, though other alternatives such as introgression of resistance alleles through hybridization currently cannot be ruled out. Species relationships among newts of the genus *Taricha* are less well known (Tan and Wake, 1995), but the presence of TTX in all three members of the genus, combined with the presence of TTX in *Notophthalmus* (the sister genus to *Taricha*) and other salamandrids (e.g., *Cynops* spp.) suggests that some level of TTX toxicity is ancestral in the group (Brodie et al., 1974; Yotsu et al., 1990; Yotsu-Yamashita, 2001). Previously examined populations of *T. torosa* from the Sierra Nevada of California possess TTX at levels well below those observed at the Cold Springs Creek locality (C. Hanifin, unpublished data). Although the source of TTX toxicity in newts is unclear, recent work (Hanifin et al., 2002; Shimizu, 2002; Cardall et al., 2004; Lehman et al., 2004) provides evidence that newts may be more active in the biosynthesis of their

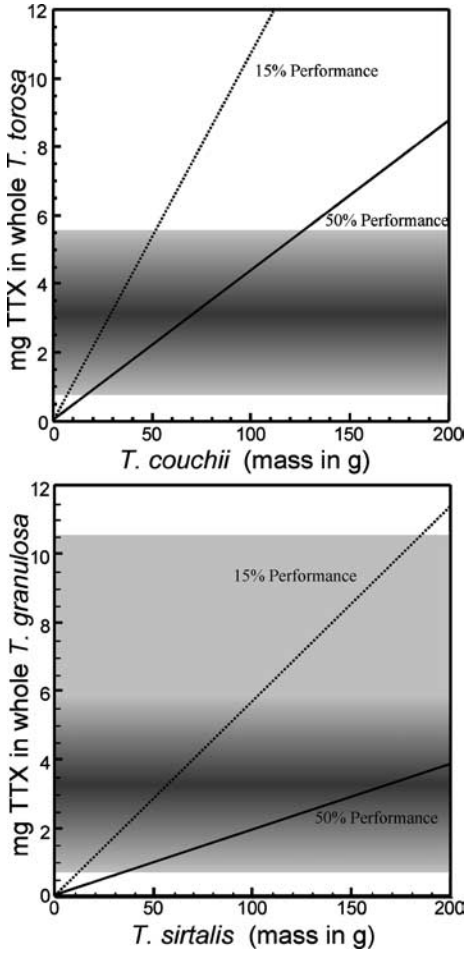

FIG. 4. Comparisons of prey toxicity and predator resistance from two localities. The average resistance for snakes as a function of body size is shown predicting the amount of ingested toxin that would reduce a snake to 15% (near immobility; dotted line) and 50% (solid line) baseline performance. On the vertical axis, the total skin toxicity of adult newts is shown, with the range of observed values shaded and the mean shown as a darker band. For a given size snake, the predicted effect of ingesting a newt of given toxicity can be estimated by finding the intersection of performance lines and newt toxicity. (A) Most adult *T. couchii* from the Cold Springs Creek, CA population (approximately 60–200 g) can ingest the average adult newt without suffering a performance reduction of 50%. (B) Few if any adult *T. sirtalis* (approximately 40–200 gm) from Benton Co., OR could ingest the average adult newt with less than a 50% reduction, and most would be expected to suffer much greater reductions of performance.

TTX than previously thought and that variation in newt toxicity within and among populations of newts may have a genetic basis. Taken together, these ecological and phylogenetic observations suggest that the predator–prey interaction between *T. couchii* and *T. torosa* in the southern Sierra Nevada of California has evolved in parallel to the interaction between *T. sirtalis* and *T. granulosa* in other parts of western North America.

Parallel "arms races" among distinct species pairs of TTX resistant garter snakes and toxic newts reveal both evolutionary lability and phylogenetic bias. The results presented herein show that resistance to TTX has evolved in at least two unrelated species groups in the genus *Thamnophis*, as well as at least twice within one species (*T. sirtalis*; Brodie et al., 2002; Geffeney et al., 2002). This pattern of diversity suggests considerable flexibility for a fundamental neurophysiological feature that is conserved across most vertebrates, the structure of voltage-gated sodium channels in skeletal muscle (Geffeney et al., 2002). Conversely, all known occurrences of elevated resistance to TTX by predators occur in just this single genus of snakes. Such restricted phylogenetic distribution of evolutionary response to dangerous prey is consistent with some form of historical bias, possibly related to the ancestral occurrence of low level resistance to TTX observed in the genus *Thamnophis* (Motychak et al., 1999). Similarly, TTX has been found throughout the genus *Taricha*, as well as in other salamandrids (Mosher et al., 1964; Brodie et al., 1974; Yasumoto et al., 1988), but not in other groups of urodeles. This restricted pattern of TTX distribution is difficult to interpret, however, because the mechanism of production of TTX in these species is still unclear.

The selective importance of deadly toxicity, and TTX in particular, as a feature driving predator–prey arms races is emphasized by the discovery of these parallel coevolutionary systems. The fact that independently derived predator lineages have evolved similar phenotypic responses to prey toxicity further suggests that there are phenotypic constraints to the array of evolutionary counteradaptations available to combat TTX toxicity. Lineage-specific constraints might also contribute to the phenotypic similarity in response, since the predator species in question belong to the same clade. Similar parallel evolution is known from other sorts of biological systems involving deadly toxins, most notably the evolution of insecticide resistance. Many phylogenetically diverse groups of insects have evolved resistance to human-introduced toxins through strikingly similar physiological and genetic mechanisms. In many cases, the parallelism of these adaptations can be attributed to the specific actions of insecticides designed to target fundamental metabolic or neurological pathways. Resistance to such toxins often is achieved by common changes to binding sites or enzymes targeted by the toxins (Mallet, 1989; McKenzie and Batterham, 1994; Ffrench-Constant et al., 2000). Parallelism in these cases is thought to result because there are limited ways to disable the toxins. A similar phenomenon might underlie the parallelism in predator resistance to TTX. Tetrodotoxin is known to bind to sodium

channels in nerves and muscles, thereby blocking action potentials. Resistance to TTX in one species of garter snake (*T. sirtalis*), as well as in other organisms that utilize TTX as a defense (pufferfish, newts), involves changes in the binding affinity of the sodium channel to TTX (Kao and Fuhrman, 1967; Kidokoro et al., 1974; Yotsu-Yamashita et al., 2000; Geffeney et al., 2002). If *T. couchii* shares a similar mechanism as suggested by the observed patterns of variation in and tradeoffs with resistance, then predator–prey arms races involving deadly prey may be under the same sort of metabolic control constraints as insect–insecticide systems.

Acknowledgments—We thank J. V. Vindum and M. S. Koo of the California Academy of Sciences for assistance in the field, M. Pfrender for comments on the paper, and B. Ridenhour for help with analysis and Figure 1. Specimens were collected with permission from the California Department of Fish and Game (scientific collecting permit 803045-04 to CRF). The use of vertebrate subjects was approved by the Utah State University IACUC (protocols 712, 693). Abstract—Hybridization in plants provides an opportunity to investigate the patterns of inheritance of hybrid resistance to herbivores, and of the plant mechanisms conferring this resistance such as plant secondary metabolites. We investigated how inter-race differences in resistance *of Eucalyptus globulus* to a generalist mammalian herbivore, *Trichosurus vulpecula*, are inherited in their F_1 hybrids. We assessed browsing damage of 3-year-old trees in a common environment field trial on four hybrid types of known progeny. The progeny were artificial intra-race crosses and reciprocal inter-race F_1 hybrids of two geographically distinct populations (races) of *E. globulus* north-eastern Tasmania and south-eastern Tasmania. Populations of trees from north-eastern Tasmania are relatively susceptible to browsing by *T. vulpecula*, while populations from south-eastern Tasmania are more resistant. We assessed the preferences of these trees in a series of paired feeding trials with captive animals to test the field trial results and also investigated the patterns of inheritance of plant secondary metabolites. Our results demonstrated that the phenotypic expression of resistance of the inter-race F_1 hybrids supported the additive pattern of inheritance, as these hybrids were intermediate in resistance compared to the pure parental hybrids. The expression of plant secondary metabolites in the F_1 hybrids varied among major groups of individual compounds. The most

common pattern supported was dominance towards one of the parental types. Together, condensed tannins and essential oils appeared to explain the observed patterns of resistance among the four hybrid types. While both chemical groups were inherited in a dominant manner in the inter-race F_1 hybrids, the direction of dominance was opposite. Their combined concentration, however, was inherited in an additive manner, consistent with the phenotypic differences in browsing.

Key Words—*Trichosurus vulpecula*, hybrid, plant secondary metabolites, generalist herbivore, additive inheritance, *Eucalyptus globulus*, hybridization.

INTRODUCTION

Understanding the genetic control of plant resistance to herbivores is crucial in understanding the evolutionary processes behind plant/herbivore interactions (Marquis, 1990; Mauricio and Rausher, 1997), and hybridization offers an ideal opportunity to investigate some of these processes (Bailey et al., 2004). The investigation of the differential resistance of hybrid plants to herbivores, compared to the pure parental plants, has provided insight into the mode of inheritance of resistance in plants. Studies have shown that responses of herbivores to hybrids can vary greatly among plant species and also among different herbivores within one plant species. Various patterns of hybrid resistance have been observed. Hybrid plants may be more susceptible to herbivores than the parental plants (hybrid susceptibility pattern; Floate et al., 1993; Fritz et al., 1998; Dungey and Potts, 2003), more resistant than the parental plant (hybrid resistance pattern; Boecklen and Spellenberg, 1990; Eisenbach, 1996), and exhibit resistance that is intermediate to the parental plants, which indicates additive inheritance of resistance (additive pattern: Aguilar and Boecklen, 1992; Fritz, 2001; Scott et al., 2002). In addition to these patterns, hybrids have also exhibited resistance similar to one of the parental plants (dominance pattern; Hjältén, 1997; Orians and Floyd, 1997; Fritz et al., 1998; Hjältén et al., 2000). If hybrids resemble the susceptible parent, then there is dominance for susceptibility, while if the hybrid resembles the resistant parent, there is dominance for resistance. Finally, hybrids can exhibit resistance that is no different to either of the parental plants (no difference pattern; Fritz et al., 1996, 1998; Orians and Floyd, 1997).

Research exploring the response of herbivores to hybrids has predominantly focused on invertebrates, and this has been highlighted in several reviews on the ecological and evolutionary processes of hybridization in plants (Strauss, 1994; Fritz, 1999; Fritz et al., 1999; Orians, 2000). In comparison, the susceptibility of hybrids to mammalian herbivores has received considerably less attention (but see Vila and D'Antonio, 1998; Dungey and Potts, 2002; Scott et al., 2002; Anderson and Paige, 2003). Additionally, while many studies have focused on the phenotypic patterns of resistance of hybrids to herbivores, relatively few have investigated the

inheritance patterns of the defensive plant characteristics conferring resistance, such as plant secondary metabolites (Orians, 2000 for review; Byrd et al., 1999; Orians et al., 2000; Fritz, 2001; Hallgren et al., 2003).

During the past two decades, aspects of the ecological interactions of *Eucalyptus* species and the mammalian herbivores that feed on them have been investigated (e.g., Landsberg, 1987; Hume and Esson, 1993; Lawler et al., 2000; Close et al., 2003). There is clear inter- and intraspecific variation in browsing damage to some eucalypt species by mammalian herbivores (Lawler and Foley, 1999; Lawler et al., 2000; O'Reilly-Wapstra et al., 2002; Scott et al., 2002; Close et al., 2003). Plant secondary metabolites play an important role as the mechanisms behind this variation in resistance (McArthur and Sanson, 1993; Lawler et al., 2000; Wallis et al., 2002; Marsh et al., 2003). Recently, the role of plant genotype in influencing the resistance of a eucalypt species, *Eucalyptus globulus*, to browsing by a generalist marsupial folivore, the common brushtail possum (*Trichosurus vulpecula* Kerr 1792), was documented (Dungey and Potts, 2002; O'Reilly-Wapstra et al., 2002), and inter-race differences accounted for the majority of the genetically based variation observed by O'Reilly-Wapstra et al. (2002). A group of plant secondary metabolites known as formylated phloroglucinol compounds (FPCs) (Eschler et al., 2000) were found to be the most significant defensive leaf trait conferring resistance in juvenile coppice foliage of *E. globulus* (O'Reilly-Wapstra et al., 2004). The mode of inheritance of plant resistance and plant defensive traits within this system and in other eucalypt/mammalian herbivore systems, however, remains unclear.

Hybrid resistance to herbivores is determined not only by the genetic background of the plant but is also influenced by variation in environmental factors (Fritz, 1999) such as access to nutrients (Orians and Floyd, 1997). To understand the consequences of herbivore feeding on hybrid plants, it is necessary to differentiate the genetic and environmental causes of the hybrid resistance. Many investigations have been conducted in natural plant systems and, in some cases, these studies have not controlled for environmental variation and often do not know the genetic status of the hybrid plants (Aguilar and Boecklen, 1992; Whitham et al., 1994; Gange, 1995). Managed plant systems that grow hybrids of known pedigree in common environment field trials are ideal for investigating the inheritance of resistance in hybrids, without confounding effects of environmental influences. In this study, we aimed to investigate the inheritance of resistance to browsing by *T. vulpecula* and the inheritance of the defensive plant compounds within *E. globulus*. We assessed the browsing damage by *T. vulpecula* on known F_1 progeny of two genetically differentiated geographical races of *E. globulus* from north-eastern Tasmania and south-eastern Tasmania (see Dutkowski and Potts, 1999 for race classifications of *E. globulus)*. The pedigreed progeny used in this present study were grown in a common environment field trial and, therefore, differences in susceptibility to browsing is most likely due to host genetics, not

environmental effects. The progeny were composed of artificial intra-race and reciprocal inter-race F_1 hybrids involving trees from north-eastern Tasmania and south-eastern Tasmania. Populations of trees from north-eastern Tasmania are relatively susceptible to browsing by *T. vulpecula* (O'Reilly-Wapstra et al., 2002) and contain lower concentrations of FPCs (O'Reilly-Wapstra et al., 2004). Conversely, populations from south-eastern Tasmania are relatively more resistant to browsing (O'Reilly-Wapstra et al., 2002) and have higher concentrations of FPCs (O'Reilly-Wapstra et al., in press). Therefore, this genetic material provided an ideal opportunity to investigate three main questions: 1. How are the racial differences in resistance of *E. globulus* to *T. vulpecula* inherited in their F_1 hybrids in a common environment field trial? 2. Is the variation in resistance in the field trial consistent with patterns of intake of *E. globulus* by captive animals? 3. Are there quantitative differences between the hybrids in leaf chemical characteristics, and does this reflect the observed pattern of resistance?

METHODS AND MATERIALS

Field Trial and Plant Material. Browsing *of Eucalyptus globulus* juvenile foliage on 3-year-old trees by *Trichosurus vulpecula* was assessed in a field trial located at Weilangta, in south-east Tasmania, Australia (42° 44′ S 147° 49′ W). The trial design is described in detail in Lopez et al. (2003). In brief, the trees planted in the field trial were progeny from an 8 × 8 diallel crossing (80% complete excluding selfs) design where all possible crosses among eight parents were carried out. The parents were random samples of trees in native strands of *E. globulus* from both north-eastern Tasmania (termed north) and south-eastern Tasmania (termed south) races (following Dutkowski and Potts, 1999). The parental trees were growing more than 10 km apart and were considered unrelated. Four parental trees were from the north and four were from the south. These crosses resulted in four hybrid types; intra-race crosses, north × north (NN) and south × south (SS) and two reciprocal inter-race F_1 hybrids, north × south (NS) and south × north (SN). The female parent is stated as the first letter in the cross, and the male parent is stated as the second letter in the cross. The field trial at Weilangta was planted in 1999, and a duplicate trial was planted at the same time at Geeveston, in south-east Tasmania, Australia (43° 09′ S 146° 51′ W). Trees were planted in a randomized block design with each hybrid represented as a single tree plot. There were 18 field replicates at Weilangta and 17 replicates at Geeveston. The Geeveston field trial was fenced to prevent mammal browsing, while the Weilangta field trial was not. In July (winter) 2002, all trees (648 in total) in the Weilangta field trial were assessed for browsing damage. Each tree was observed for damage by *T. vulpecula* and given a "browsing damage score," which was as follows: 0 = no damage; 1 = minor browsing damage evident in the crown; 2 = major structural branch damage

in the crown (due to *T. vulpecula*), with none to little browsing damage; 3 = major browsing damage in the crown; 4 = major structural branch damage and major browsing damage in the crown.

Feeding Trial. After assessing browsing damage in the Weilangta field trial, we tested the preferences of six captive *Trichosurus vulpecula* (three male and three female, 2.5–4.1 kg body mass) for juvenile foliage from the four hybrids (NN, NS, SN, SS) in a feeding trial. All animals were caught, housed, and maintained following McArthur et al. (2000). Foliage used in the feeding trial was selected from the Geeveston field trial, as it was un-browsed and hence avoided any possible effects of induced chemistry responses of the foliage. Juvenile foliage (cut branches) was selected from as many trees as possible from several replicates to ensure a full representation of each family in each hybrid sample. Cut branches from each hybrid type were combined to make up four bunches of foliage; NN, NS, SN, SS. The foliage for each trial was cut from the field at the beginning of each trial, and foliage was stored in a cool room (5°C) with cut stems in water. Animals were offered foliage as four, of the possible six, paired choice feeding trials, as the four pairs provided adequate comparisons to rank the relative preference of each hybrid type. The pairs were: Trial 1 = SN and SS; Trial 2 = NN and SS; Trial 3 = NS and SN; and Trial 4 = NN and NS. Each trial ran for 3 d and all 6 animals received the same foliage at the same time. For each trial, a random selection of cut stems were presented to each animal in its cage as two bunches (one bunch for each cross race type) in a container of water.

Sufficient foliage was presented to each animal to allow *ad libitum* feeding. On each day (at ~1500 hr) total fresh mass (g) of each bunch was measured before being placed in the container. The next morning (at ~0800 hr), the remains of each bunch were weighed (including any plant fragments found on the cage floor). Intake was estimated as the amount of foliage consumed (weight difference) from each bunch, and all intakes were expressed in terms of grams dry matter per kilogram of body mass of the consumer (gDM/kgBM), based on the fresh to dry weight ratios calculated from the control plants. During the feeding trial, animals were offered a basal diet (see McArthur et al., 2000) at the same time as the experimental foliage. The amount of basal diet offered was 75% of that required to maintain body mass. This ensured that animals would eat the test foliage by choice, not because they were hungry, and ensured that all animals maintained body mass throughout the trial. On each day of the trial, two bunches of each hybrid fed to animals were also prepared as controls. The mean overnight change in mass of the two controls was used to adjust for changes in mass of the experimental plants. On each morning of the trial, one bunch was stripped of the leaves, which were oven dried (35°C for 1 wk and 80°C overnight before weighing) to determine their absolute dry matter (DM). The second bunch was frozen for subsequent chemical analysis.

Chemical Analysis. For each hybrid type, the control plants from the feeding trials were combined, and foliage was randomly subsampled 4 times for each analysis for each variable. We assayed plants for nitrogen, plant cell wall components (neutral detergent fibre, acid detergent fibre, and lignin; $N = 3$ for these constituents), total essential oils and 1,8-cineole, total phenolics, condensed tannins, and six formylated phloroglucinol compounds (FPCs) (sideroxylonal A, sideroxylonal B, sideroxylonal C, macrocarpal A, macrocarpal B, and macrocarpal G; $N = 3$ for these constituents).

Primary Chemistry. Nitrogen was determined following the sulphuric acid and hydrogen peroxide method of Lowther (1980) using air-dried ground foliage, ground in a cyclone grinder through a 1-mm mesh sieve. Digested samples were colorimetrically analyzed for nitrogen (QuikChem method 10-107-06-2E, Lachat Instruments, Wisconsin, USA) on a continuous flow injection analyzer (QuikChem 800, Lachat Instruments). Standard samples of known nitrogen concentration and blank samples were included to validate the efficiency of digestion and elemental analysis. Nitrogen results are expressed as % DM.

Plant cell wall components were analyzed by sequentially fractioning dried ground foliage. Neutral detergent fiber (NDF), acid detergent fiber (ADF), and acid detergent lignin (lignin) were determined following the ANKOM Technology procedures (ANKOM $^{200/220}$Technology Operator's Manual, 1997). Results are expressed as % DM.

Secondary Chemistry. Essential oils (terpenes) were extracted using dichloromethane with heptadecane as an internal standard (100 mg of heptadecane was diluted in 1 l of dichloromethane) (O'Reilly-Wapstra et al., 2004). One g of thawed foliage, cut into 1-cm pieces was soaked in the dichloromethane solvent for 1 hr. Extracts were analyzed by combined gas chromatography-mass spectrometry (GC-MS) on a Varian 3800 Gas Chromatograph coupled to a Varian 1200 triple quadruple mass spectrometer, using a 30 m $\times$ 0.25 mm Varian "Factor Four" VF-5 ms column with a 0.25-micron film. One μl aliquots were injected into a Varian 1177 split/splitless injector at 200°C using a split ratio of 20:1, and a GC column temperature profile of 60–260°C at 12 degrees per min. The electron energy was 70 eV, and the range from m/z 35–350 was scanned on quadruple 1 three times per sec. Total ion currents (TIC) were determined separately for 1,8-cineole, the sum of all oil components (referred to as total oils), and for the heptadecane internal standard. Results for 1,8-cineole and total oils were standardized by dividing by the internal standard. A response factor for cineole relative to the heptadecane internal standard was determined from a pure standard, and the amount of 1,8-cineole was expressed as mg/g DM. The amount of total oils was expressed as equivalents of cineole (mg/g DM).

Total phenolics and condensed tannins were assayed using the modified Prussian blue assay for total phenolics (Graham, 1992) and the acid butanol assay for condensed tannins (Porter et al., 1986). Foliage for these assays was prepared

and extracted following the method outlined in Hagerman (1995). In brief, 0.6 g of air dried, ground leaf was weighed into glass tubes, and 5 ml of 70% acetone were added. Samples were sonicated at 4°C for 30 min and centrifuged for 10 min at 2800 g/min. The supernatant was poured off and saved at 4°C. This process was repeated $\times 3$ for each sample. The supernatants were combined for each sample. The concentration of the total phenolics (mg/g DM) was determined in relation to a gallic acid standard (SIGMA G-7384), and the concentration of condensed tannins (mg/g DM) was determined in relation to a purified sorghum tannin standard.

Formylated phloroglucinol compounds were extracted following the method outlined in Wallis et al. (2003). Specific representative FPCs were determined by HPLC using a Waters Alliance 2690 HPLC with a Waters 996 UV/Vis diode array detector. The chromatogram at 280 nm was generated for peak area measurements from diode array data acquired between 230 and 400 nm. The column was a 250 $\times$ 4.6 mm Wakosil C18RS 3micron (SGE), using a flow rate of 1 ml/min. A tertiary gradient system was used; solvent A was 0.1% trifluoroacetic acid in acetonitrile, solvent B was Milli-Q water, and solvent C was "hexanes" (85% *n*-hexane, Mallinckrodt). The initial mix was 93:7 A and B, then a linear gradient to 100% A between 13 and 15 min was used. At 20 min, the solvent mix was immediately changed to 95:5 A and C, and this was held until 27 min, when it was immediately changed to 90:10 A and C to help remove late eluting FPCs. At 38 min, it was ramped back to starting conditions through 100% A and equilibrated for 7 min before the next sample. Peaks were identified by retention times and UV spectra in comparison to authentic standards, and representative samples were also analyzed by combined negative ion electrospray HPLC-MS to confirm that the molecular weights and tandem MS data of the peaks selected from the UV trace were also consistent with the standards (Eyles et al., 2003). Under these conditions, retention times were: sideroxylonal A 10.53 min, sideroxylonal B 15.32 min, sideroxylonal C 11.11 min, macrocarpal A 8.26 min, macrocarpal B 9.86 min and macrocarpal G 25.00 min. Results are expressed as mg/g DM for sideroxylonal A and C and macrocarpal A and B. Results for sideroxylonal B are expressed as mg/g DM equivalents of sideroxylonal A and results for macrocarpal G are expressed as mg/g DM equivalents of macrocarpal A.

Statistical Analysis. Results from the field trial were analyzed by first fitting a mixed model to the individual tree browsing data to simply determine if there was any significant difference in browsing score across the four hybrids and to test for replicate effects in the field trial design. Residuals were checked for normality and homoscedasticity with the general linear model procedure (PROC GLM) in SAS (SAS Institute Inc., SAS version 8), and the data were log transformed. Log transformed browse score was the dependent variable and the fixed effect was the hybrid type. The random effects were replicate and replicate by hybrid type interaction. The model was fitted with a PROC MIXED procedure in SAS

(SAS Institute Inc., SAS version 8). *A posteriori* multiple pair-wise comparisons of significant effects (least squares means) were made using the Tukey-Kramer adjustment. We performed *a priori* contrasts (contrast statement, SAS Institute Inc., SAS version 8) to test among predicted patterns of browsing damage on the parental and F_1 hybrids (Fritz et al., 1996; Hjältén et al., 2000). Figure 1 illustrates the contrasts performed and the possible expected outcomes.

Results from the feeding trial were analyzed as four separate trials: Trial 1 = SN and SS; Trial 2 = NN and SS; Trial 3 = NS and SN; and Trial 4 = NN and NS. The PROC UNIVARIATE procedure in SAS was performed for each trial to determine if the difference in intake between the two pairs was significantly different from zero (SAS Institute Inc., SAS version 8).

Results for each chemical constituent were first analyzed by fitting a one factor general linear model (PROC GLM) for each chemical variable with hybrid type (SAS Institute Inc., SAS version 8). Residuals were checked for normality and

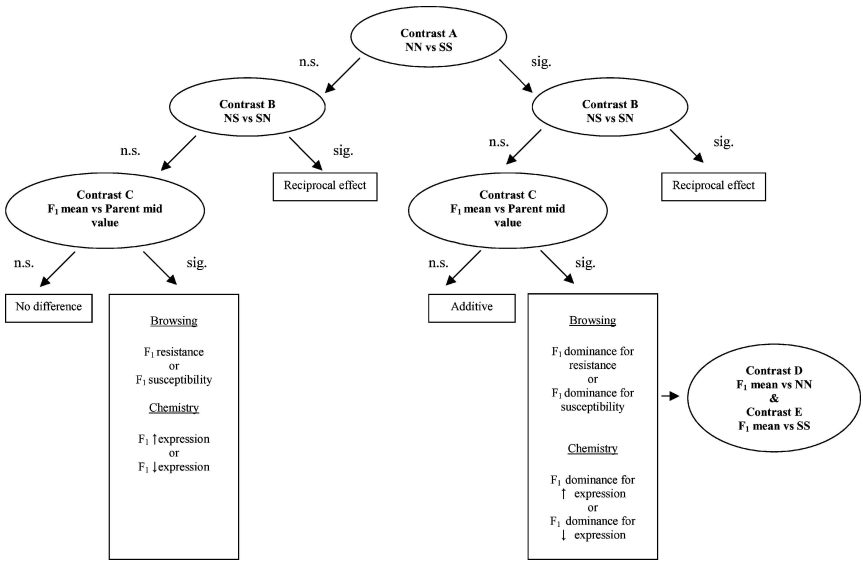

FIG. 1. Description of the contrast procedures and the potential outcomes of inheritance patterns of the browsing resistance to *T. vulpecula*, as assessed in the field trial, and of the concentration of chemical constituents of *E. globulus* foliage from the captive feeding trial. *NN* the hybrid from the northern Tasmania × northern Tasmania cross; *SS* the hybrid from the southern Tasmania × southern Tasmania cross; *NS* the hybrid from the northern Tasmania × southern Tasmania cross; *SN* the hybrid from the southern Tasmania × northern Tasmania cross. The first letter in the cross represents the maternal parent, *sig* a significant contrast; *ns* a non significant contrast.

homoscedasticity. Data for total oils and 1,8-cineole were log transformed, and data for macrocarpal A were inverse transformed (1/macrocarpal A). Following this, if there were significant effects, we performed *a priori* contrasts (PROC MIXED, SAS Institute Inc., 1990) to test among predicted patterns of concentration of chemical constituents on the parental and F_1 hybrids (Figure 1). If an effect was not significant following the general linear model analysis, no contrasts were performed.

RESULTS

Browsing damage by *T. vulpecula* on individual trees at the Weilangta field trial ranged in browsing damage score from 0 (no damage) to 4 (major structural branch damage and major browsing damage in the crown). There were no significant replicate or replicate * hybrid effects ($P > 0.05$). There was a highly significant difference in damage score among the four F_1 hybrid types ($F_{3,51} = 37.90$, $P < 0.001$, Figure 2). The intra-race NN cross was browsed more than the other three hybrid types, while the SS cross was browsed less than the other three hybrid types. There was no significant difference between the inter-race reciprocal F_1 hybrids (NS and SN), and these were intermediate in amount of browsing damage compared to the parental intra-race crosses, supporting the hypothesis of additive inheritance on the log transformed scale (Figure 2).

Table 1 illustrates foliage intake by *T. vulpecula* of each hybrid pair and results of the univariate statistical analysis for each feeding trial. In trial 1, there was no significant difference in intake between the two hybrids SS and SN. In trial 2, foliage from the NN cross was significantly more preferred by *T. vulpecula* than foliage from the SS cross. In trial 3, there was no significant difference in

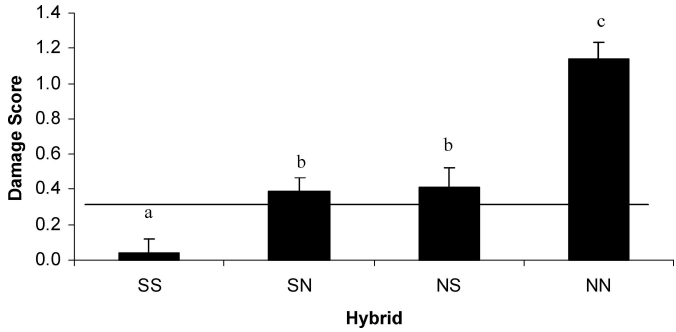

FIG. 2. Browsing damage by *T. vulpecula* for each hybrid type in the field trial. Values are least squares means with SE bars. Letters that differ indicate significant differences ($\alpha = 0.05$ after Tukey-Kramer adjustment for multiple comparisons). The line represents the back transformed mid parent value.

TABLE 1. MEAN INTAKE (GDM/KGBM) BY *T. Vulpecula* OF FOLIAGE FOR EACH HYBRID TYPE IN EACH CAPTIVE FEEDING TRIAL AND RESULTS FOR THE UNIVARIATE ANALYSIS OF EACH TRIAL

Trial	Hybrid pair	Intake (±SE)	*T*-value	*P*-value
1	SS	6.2 (0.59)	1.28	0.256
	SN	5.1 (1.20)		
2	NN	7.7 (1.51)	−3.81	0.012
	SS	4.6 (1.03)		
3	NS	7.7 (2.01)	−0.78	0.471
	SN	5.7 (1.36)		
4	NN	10.1 (1.66)	−2.27	0.073
	NS	6.7 (1.40)		

intake of foliage between the NS and the SN hybrids, while in trial 4 there was no significant difference in intake of the NN and NS hybrids, although the NN cross tended to be more preferred.

Several chemical constituents varied significantly ($P < 0.05$) among the four hybrid types (Tables 2 and 3). There was a significant difference in the nitrogen content between the four hybrid types. The NN hybrid cross had higher nitrogen content than the SS cross. A significant difference between the two F_1 hybrids indicates a reciprocal cross effect for nitrogen concentration (Table 3), with each F_1 hybrid tending to be closer to their maternal parent indicating a maternal reciprocal effect. However, the range in nitrogen concentration from 1.3 to 1.4%, may not be biologically significant. Results for acid detergent fiber show significantly higher acid detergent fiber content for the SS cross compared to the NN cross (Tables 2 and 3) and F_1 dominance for decreased expression (Table 3). There was significant variation in total oil and 1,8-cineole concentration among hybrid types (Table 3). Contrast A shows the two intra-race hybrid crosses differed in total oils and 1,8-cineole; SS had higher concentrations of oil than NN (Tables 2 and 3). There was no significant difference in concentration of total oils and 1,8-cineole between the two F_1 hybrids (contrast B), however, there was a difference between the mean F_1 hybrid concentration and the mid-parent value (contrast C). Significance at contrast D indicates F_1 dominance for increased expression of oil production. There was a significant difference in concentration of condensed tannins among the four hybrid types (Table 3). The SS intra-race cross had more condensed tannins than the NN cross (Tables 2 and 3) and there was F_1 dominance for reduced expression (Table 3). There was no significant difference between the four hybrid types in concentration of sideroxylonal A, however, there were differences in all other FPCs (Table 3) despite the concentrations of these compounds being low (Table 2). There was F_1 dominance for decreased expression of sideroxylonal B, and F_1 dominance for increased expression of sideroxylonal C, although these

patterns should be viewed with caution due to the low concentrations. A reciprocal effect was evident for all macrocarpal concentrations with the SN F_1 hybrid having higher concentrations of macrocarpals than all other hybrid types. There are no significant differences in concentration of total phenolics, neutral detergent fiber, and lignin among the four hybrid types (Table 3).

DISCUSSION

In this study, we had an *a priori* expectation that the two parental hybrids would exhibit differential susceptibility to browsing by *T. vulpecula* (O'Reilly-Wapstra et al., 2002). The patterns of browsing by *T. vulpecula* on *E. globulus*, in previous common environment field trials planted across different geographic areas of Tasmania, have consistently shown that populations of *E. globulus* from

Note. Contrast comparison A is between the two intra-race hybrid crosses (parental crosses), Comparison B between the two F_1 hybrids, comparison C between the mean of the F_1 hybrids and the mid-parent value, contrast D between the mean of the F_1 hybrids and NN (the susceptible parent), and contrast E between the mean of the F_1 hybrids and SS (the resistant parent). The final column refers to the hypothesis or inheritance pattern that is supported by the hybrid results. NDF, neutral detergent fiber, ADF, acid detergent fiber.

[a] Indicates mixed model analysis.

[b] Indicates log transformed data.

[c] Indicates either that no contrasts were performed as there were no significant differences between hybrids in the GLM analysis, or that further contrast analysis between hybrids was redundant.

[d] Indicates inverse transformed data.

north-eastern Tasmania are more susceptible than populations from south-east Tasmania (Volker and Orme, 1988; O'Reilly-Wapstra et al., 2002). This was supported in both the field trial and captive feeding trial results in this present study. The pure parental hybrid from the north-eastern Tasmania race (NN) was more susceptible to *T. vulpecula* than the parental hybrid from the south-eastern Tasmania race (SS). The pattern of hybrid resistance, however, was unknown. The phenotypic expression of resistance of the inter-race F_1 hybrids supports the additive pattern (Fritz, 1999) of hybrid resistance. On the log scale, the F_1 hybrid was intermediate in resistance, compared to the parental hybrids. This pattern of browsing was consistent over two separate years of field data (Potts, unpublished data). Numerous studies in plant hybrid/insect systems have demonstrated that the patterns of hybrid resistance are highly variable (e.g., Aguilar and Boecklen, 1992; Eisenbach, 1996; Hjältén, 1997; Fritz et al., 1998). In comparison, relatively few studies have examined the resistance of hybrids to mammalian herbivores (but see Vila and D'Antonio, 1998; Dungey and Potts, 2002; Scott et al., 2002; Anderson and Paige, 2003). However, the patterns of hybrid resistance to mammalian herbivores appear just as varied as those patterns expressed to insect herbivores. Increased hybrid resistance (Vila and D'Antonio, 1998), additive inheritance of resistance (Scott et al., 2002), dominance toward susceptibility (Dungey and Potts, 2002), and no difference in hybrid resistance compared to the parental plants (Anderson and Paige, 2003) have all been demonstrated.

Confirmation of the field trial results (the differential resistance of NN and SS) in the feeding trial indicate that the difference in resistance was most likely due to foliage characteristics, such as plant secondary metabolites, as opposed to other characteristics such as tree form. Based on our previous studies (O'Reilly-Wapstra et al., 2004) and research in similar systems (Lawler et al., 2000; Wallis et al., 2002), we expected the formylated phloroglucinol compounds (FPCs) to follow the pattern of hybrid resistance observed in this study and to provide the mechanism of resistance in these plants. On the contrary, there was no relationship between FPC concentration and relative resistance of the four hybrid types. The most likely reason for this is that, despite some significant differences in concentration of FPC compounds in these leaves, the actual concentrations were very low and, therefore, perhaps biologically ineffective in acting as deterrents to *T. vulpecula* in this particular foliage.

In comparison to the 3-year-old juvenile foliage used in this study, our previous and ongoing research with *E. globulus* and preferences by *T. vulpecula* has utilized foliage from coppice re-growth (O'Reilly-Wapstra et al., 2002; O'Reilly-Wapstra et al., 2004) and young seedlings (O'Reilly-Wapstra, unpublished data). Concentrations of FPCs in these two types of foliage was higher than that measured in the present study; sideroxylonal A concentration was 0.9–8.5 mg/g DM and 0.2–1.8 mg/g DM for coppice and seedling foliage, respectively. It is possible that the production of higher levels of FPCs in *E. globulus* coincides with the

period when the plant is most vulnerable to mammalian herbivores. *Eucalyptus* seedlings are particularly susceptible to browsing by mammals (Gilbert, 1961; Bulinski and McArthur, 1999). We suppose that coppice re-growth is also susceptible to mammal browsers, as has been demonstrated with insect herbivores feeding on *Eucalyptus* (Abbott et al., 1993; Steinbauer et al., 1998), and with *T. vulpecula* (O'Reilly-Wapstra et al., 2002). While the concentration of FPCs in the seedling foliage (O'Reilly-Wapstra, unpublished data) were still quite low, the differences in concentration among coppice, seedling, and 3-year-old juvenile foliage was consistent with this idea. Additionally, although *T. vulpecula* is an arboreal herbivore and is capable of consuming foliage at all successive *E. globulus* life stages, 3-year-old *E. globulus* trees (approximately 4 m in height) may be better capable of recovering from foliage loss. Consequently, defensive mechanisms to mammalian herbivory (FPC production) may not be necessary at this stage, and energy may be allocated to traits such as growth and reproduction. In this species, ontogenetic development of the tree results in heteroblastic leaf change from the seedling leaf phase to the juvenile phase at around 18 wk (James and Bell, 2001). Timing of juvenile to adult foliage phase change is variable (Jordan et al., 2000) but can occur at around 1.5–3 yr (James and Bell, 2001). Many studies have demonstrated developmental changes in leaf resistance to herbivores (e.g., Kearsley and Whitham, 1989; Fritz, 2001), including *E. globulus* resistance to insect herbivory (Steinbauer, 2002; Lawrence et al., 2003). Production of defensive chemistry to mammalian herbivory may, therefore, alter at these phase changes and become relatively unnecessary in older trees. However, further investigation of the chemical profile and timing of expression of plant secondary metabolites in *E. globulus* foliage at different life stages is necessary to elucidate this.

There were clear differences in resistance among the four hybrid types in this study, particularly among the two parental hybrids. We suggest that the combined effect of condensed tannin and essential oil concentrations conferred this difference. Condensed tannins and essential oils were significantly higher in the SS than the NN parent. These two groups of secondary metabolites decrease herbivory by mammalian herbivores in many systems (Harborne, 1991). Tannins decrease intake of *E. rossii* and *E. consideniana* foliage by *T. vulpecula* (Marsh et al., 2003). Tannins can decrease herbivory by mammals by binding with dietary proteins (Hagerman and Butler, 1991). The maximal flow rate of salivary proline-rich proteins (available to bind with dietary tannins) in *T. vulpecula* is relatively slow compared to other marsupial herbivores (McArthur et al., 1995). This may indicate a decreased ability to cope with ingested dietary tannins. The negative effects of increasing 1,8-cineole levels in artificial diets on intake by *T. vulpecula* has also been highlighted (Wiggins et al., 2003). While the levels of 1,8-cineole required to constrain intake in that study were much higher than in *E. globulus* in the present study, clear preferences at lower concentrations were still detected in the "choice" feeding trials in the latter study. We suggest, therefore, that

T. vulpecula respond to foliage chemical characteristics in choice feeding trials, even when levels do not physiologically constrain intake.

We also suggest that the combined effect of tannins and essential oils in *E. globulus* foliage explains the inheritance of resistance demonstrated in the inter-race F_1 hybrids. The SS parent had significantly higher levels of both compounds compared to the NN parent. While the F_1 hybrids deviate from the mid-parent value in each of these compounds, the direction of dominance was opposite. Condensed tannin levels in the hybrids showed dominance for decreased expression (similar to the NN parent), while essential oils showed dominance for increased expression (similar to the SS parent). Consequently, the combined effects of these two groups of compounds (condensed tannins + essential oil) show an additive pattern of expression: SS hybrid had the highest, NN hybrid had the lowest, and the two inter-race hybrids fell intermediate. This pattern is consistent with the observed patterns of additive inheritance of resistance.

In a review of the effects of hybridization on plant secondary chemistry, Orians (2000) found that hybrids typically express concentrations of compounds at intermediate levels (additive pattern) or at levels similar to one of the parents (dominance pattern). The majority of compounds in this study exhibited the dominance pattern of expression but, interestingly, the direction of dominance varied. As discussed above, the inter-race hybrids showed dominance for decreased expression of condensed tannins, while dominance for increased expression of essential oils was also evident. This could arise, for example, if a dominant gene(s) for the reduced expression of condensed tannins (from the susceptible NN parental hybrid) and a dominant gene(s) for the increased expression of essential oils (from the resistant SS parental hybrid) are expressed in these hybrids. Few studies have examined the pattern of inheritance of plant secondary metabolites in eucalypts, but two have reported that the inheritance pattern of essential oils in inter-specific hybrids varies. The additive pattern (Dungey et al., 2000; Farah et al., 2002) and the dominance and no difference pattern (Dungey et al., 2000) have all been demonstrated. The variable pattern of results from Dungey et al. (2000) indicates that different compounds, even from the same group (terpenes) can exhibit different inheritance patterns, as also demonstrated with the FPCs in this study.

In summary, we have demonstrated that the inter-race differences in the phenotypic expression of resistance to *T. vulpecula* in *E. globulus* are inherited in an additive manner. Variation in resistance of the foliage appeared to be due to the combined effects of condensed tannins and essential oils. These compounds were both in high concentrations in the SS cross and significantly lower in the NN cross. At present, there is no evidence to suggest that past or current densities of *T. vulpecula*, and consequently browsing pressures, differ between the north-east and south-east populations of *E. globulus*. Consequently, explanations as to why these populations differ in resistance and chemical profiles remain to be elucidated.

While oils and condensed tannins were inherited in a dominant manner in the inter-race F_1 hybrids, the direction of dominance was opposite, resulting in their combined concentration being inherited in an additive manner. This is consistent with the phenotypic differences in browsing. Five different patterns of hybrid inheritance of plant chemistry were demonstrated in this study. This highlights that patterns of inheritance of resistance and plant secondary metabolites vary not only among plant species, as demonstrated in numerous systems, but also vary considerably within a plant species and within closely related groups of plant compounds.

Acknowledgments—Animals were caught and maintained under the University of Tasmania Animal Ethics Committee, Project No. A6655; and Parks and Wildlife Service Permit No. FA03102. We thank Gunns Ltd and Forestry Tasmania for access to the field trials for assessment and foliage collection. We thank Hugh Fitzgerald for assistance with foliage collection and Ann Wilkinson for running the colorimetric analysis of the nitrogen digests. This project was funded by the University of Tasmania Postgraduate Scholarship and the CRC for Sustainable Production Forestry.

STIR BAR SORPTIVE EXTRACTION: A NEW QUANTITATIVE AND COMPREHENSIVE SAMPLING TECHNIQUE FOR DETERMINATION OF CHEMICAL SIGNAL PROFILES FROM BIOLOGICAL MEDIA

HELENA A. SOINI,[1] KEVIN E. BRUCE,[1] DONALD WIESLER,[1] FRANK DAVID,[2] PAT SANDRA,[2] and MILOS V. NOVOTNY[1,*]

[1]*Department of Chemistry, Institute for Pheromone Research Indiana University, Bloomington, Indiana 47405, USA*

[2]*Research Institute for Chromatography, Kennedypark 20, B-8500, Kortrijk, Belgium*

(Received July 27, 2004; accepted October 21, 2004)

Abstract—Various applications of a novel sampling procedure in chemical ecology are outlined. The stir bar extraction method features the analytical reproducibility needed in recording the analytical profiles of volatile and semivolatile components of biological mixtures. This methodology has been demonstrated here through the examples of small volume urine samples, glandular tissue volatiles, and the air blown through animal cages. Its analytical merits are compared with those of the previously established purge-and-trap (dynamic headspace) technique.

Key Words—Pheromones, chemical signals, hamster urine, methods, mouse urine, rat preputial gland, rat odor, volatiles, stir bar sorptive extraction, gas chromatography–mass spectrometry.

INTRODUCTION

Mammalian chemical communication is at least partially mediated by volatile and semivolatile compounds (mostly small, relatively hydrophobic molecules), which are often encountered in urine and glandular secretions (Novotny et al., 1990; Novotny, 2003). Some of these molecules process pheromonal activities, influencing both the social behavior and reproductive function in the recipient animals. At least some of these biological activities are presumably mediated through the vomeronasal organ, in which these molecules exhibit selective activities at their

* To whom correspondence should be addressed. E-mail: novotny@indiana.edu

target neurons (Moss et al., 1997; Leinders-Zufall et al., 2000; Boschat et al., 2002).

While searching for putative pheromones in biological materials, it is often advantageous to compare substance profiles under different genetic, endocrinological, or behavioral conditions. Such comparisons are now typically performed through the use of capillary gas chromatography–mass spectrometry (GC–MS), with a prior use of a sample extraction procedure. While capillary GC–MS has now been developed as a highly reproducible analytical tool, variations still exist in the sample preparation procedures. Quantitative analyses of the chemosignaling compounds in animal urine and other biological specimens are challenging due to a complexity of many biological matrices, frequently low concentrations of bioactive compounds, and a wide variation in their physical and chemical properties. Frequently, one sample isolation approach may be optimal for a class of compounds, but it may be discriminating toward other substance types. Typical approaches for isolating low-molecular weight compounds of a volatile and semivolatile nature in the analysis of aqueous biological samples are liquid–liquid extraction (Rasmussen et al., 1990; Burger et al., 1996), dynamic headspace extraction (purge-and-trap) (Novotny et al., 1974a,b; Schwende et al., 1984; Ma et al., 1999), and a solid-phase microextraction (SPME) using coated silica fibers (Zhang and Pawliszyn, 1993).

Solvent extraction is seemingly beneficial for extraction of moderately volatile compounds at relatively high concentrations. However, when solvent evaporation is needed for concentrating the analytes, loss of the more volatile compounds becomes unavoidable. Solventless trapping of volatiles on the surface of adsorption materials (e.g., porous polymers, such as Tenax GC—Novotny et al., 1974a,b) has long provided a means of effective preconcentration of urinary volatiles in pheromone studies in our laboratory (Novotny et al., 1980; Schwende et al., 1984; Ma et al., 1999). While this "purge-and-trap" (dynamic headspace) approach has been satisfactory in semiquantitative studies to observe large differences in pheromone excretion, it will be less satisfactory in the cases where subtle quantitative differences in profile constituents (Schwende et al., 1984, 1986) may account for recognition of a biological message. Typically, through this approach, multiple sampling is necessary to gain more reliability in quantification of volatiles in biological matrices (Jemiolo et al., 1994). Generally, adsorption-trapping procedures are beneficial in handling highly volatile, nonpolar compounds.

There are several disadvantages of the dynamic headspace, adsorption-based systems in a routine, quantitative profiling of biological samples. Even small variations in the preparation of trapping precolumns (amounts of the sorption material and its batch-to-batch variations) can lead to lower reproducibility. In addition, strong adsorption and nonquantitative desorption of certain solutes can hamper quantification, even when an appropriate internal standard is utilized to compensate for physical and chemical properties. A typical setup for the purge-and-trap

or the dynamic headspace system also requires specialized glassware and additional care to periodically clean the system's components with relatively large surface areas. Consequently, sample throughput using this methodology becomes a limiting step for the analysis of a large number of samples that are increasingly required in biological studies.

Current developments in analytical sampling seem to favor *absorption* rather than *adsorption* phenomena. Specifically, the organic polymers can be chemically attached to a mechanical device (a "sample holder") such as a silica fiber (Zhang and Pawliszyn, 1993), or a polymer-coated magnetic stir bar (Baltussen et al., 1999, 2002) to allow sample sorption and subsequent thermal desorption in a heated port of a gas chromatograph. Using SPME fibers, quantitative analyses have been documented for environmental pollutants and aroma components (Pawliszyn, 1997; Holt, 2001; Pino et al., 2002). Both aqueous (Luo et al., 1998) and headspace versions (Fustinoni et al., 1999; Dehnhard et al., 2001) of SPME have been utilized for recovering volatiles. However, the SPME fibers used typically in these extractions have relatively low extraction efficiency due to the low volume of a sorption polymer. This limits the use of such techniques in the applications targeting analytes at low concentrations. Further developmental steps to improve extraction efficiency of the SPME techniques have been to use larger surface to volume ratio of the extraction polymer. Recently, a thin-film microextraction approach was demonstrated as beneficial for the analysis of polyaromatic hydrocarbons (PAHs) in lake water (Bruheim et al., 2003).

The recently developed stir bar absorptive extraction techniques appear advantageous to deal with very dilute media and low-level samples. It has been demonstrated that a wide range of volatile and semivolatile substances (from both aqueous and gaseous media) can be retained on a polymer-coated magnetic bar (Twister^{TM}) (Baltussen et al., 1999, 2002; Tienpont et al., 2000). The volume of the polydimethylsiloxane (PDMS) coating on a stir bar can be precisely controlled, increasing the reliability of extraction. A typical polymer phase volume in the stir bar sorptive extraction (SBSE), which is 24–100 μl, well exceeds that used with the SPME technique (typically, 0.5 μl). Through the fast stirring action by a magnetic rod in the aqueous medium, the equilibrium state on the PDMS layer is ensured during the sorption, so that the analyte concentration stays constant and reproducible, leading to good analytical precision. A review dealing with the technical differences between the adsorptive and absorptive sampling has recently been published (Baltussen et al., 2002). The PDMS sorption-based analyses have been described in environmental studies (Baltussen et al., 1998; Peñalver et al., 2003), essential oils (Kreck et al., 2002), food flavor investigations (Tredoux et al., 2000; Bicchi et al., 2002), and analysis of volatile phenols in wines (Díez et al., 2004). Utilization of similar techniques for human biological samples has been reported for determination of polychlorinated biphenyls in human sperm (Benijts

et al., 2001) as well as terpenes, steroids, and drug residues in urine (Tienpont et al., 2002, 2003).

Following the success of SBSE sampling techniques in other areas, we wished to adapt this methodology to studies in chemical ecology. Specifically, we became interested in developing this methodology for routine and precise profiling analyses in mammalian communication projects. As an example of aqueous media, we demonstrate here a highly precise determination of urinary volatiles from hamsters (*Phodopus cambpelli*) and house mouse (*Mus domesticus*). The applicability of the SBSE technique was further tested with the rat preputial tissue and the air sample blown through the rat cages. Performance of the SBSE methodology was compared with that of a traditionally used dynamic headspace method. We further discuss its advantages in a parallel sample preparation and increased sample throughput.

EXPERIMENTAL

Sample Collection. Hamster urine originated from the colony of *Phodopus cambpelli* (Animal Physiology, Institute of Zoology, University of Tübingen, Germany) and mouse urine (Indiana University) samples were collected in metabolic cages and kept frozen at −20°C until analysis. Rat preputial glands originated from Long-Evans rats (Department of Psychology, Center of Alcohol Studies, Rutgers University, NJ) and were frozen at −20°C until analysis. Air quality in the rat cage was measured periodically according to the scheme shown in Figure 1 (Star Enterprises, Inc., Bloomington, IN, USA; a design for NASA-supported studies). In the case of air sampling, the analyses were performed immediately after sample collection. Unless otherwise stated in the text, each representative application was chosen through a single chromatographic profile to demonstrate different analytical assets of our procedure.

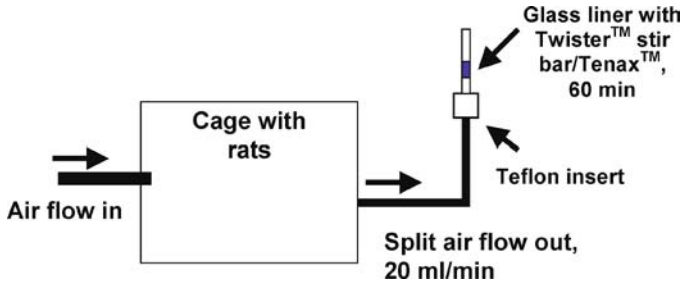

FIG. 1. Schematic of the air sampling system for a rat cage using Twister™ or Tenax™ for trapping volatiles.

Urine Sample Extraction by SBSE. All glassware used was washed with distilled water and acetone, and dried at 80°C. Volatile and semivolatile compounds were typically extracted from 1.0 ml of undiluted or water-diluted urine by sorptive extraction with a Twister™ PDMS polymer coated stir bar (10 mm × 0.5 mm film thickness, 24 μl PDMS volume, Gerstel GmbH, Mülheim an der Ruhr, Germany). A stir bar was placed in the 20 ml capped vial containing urine and stirred for 60 min. Stirring speed was 800 + rpm on the Variomag Multipoint HP 15 stirplate (H + P Labortechnic, Oberschleissheim, Germany). After extraction, stirbars were rinsed with a small volume of distilled water, dried gently on paper tissue, and placed in the glass injector liner for mass-spectrometric (MS) identification, or in the TDSA autosampler tube for the gas-chromatographic (GC) quantitative analysis. Standard compounds were obtained from Aldrich Chemical Company (Milwaukee, WI) or synthesized in our laboratory.

Urine Sample Extraction by Tenax™ Sorbent by Purge-and-Trap Analysis. Urine samples (1.0 ml) were placed in the glass vessel supplied with a helium flow (70 ml/min) purging the urine sample and collecting the sample headspace, as shown in Figure 2. The vessel was placed in the water bath at 40°C to improve transportation of volatiles. Helium flow carrying volatiles passed through an ice-water chilled section to minimize excess water before the volatiles were trapped on 8 mg of Tenax™ sorbent (TA, 35/65 mesh, Alltech, Deerfield, IL).

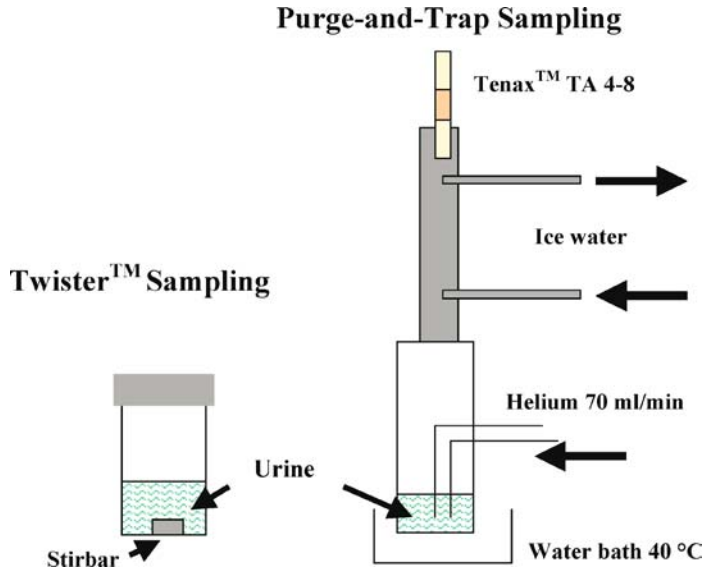

FIG. 2. Aqueous Twister™ and purge-and-trap Tenax™ sampling device for trapping volatiles from urine.

Rat Preputial Gland Extraction by SBSE. Whole gland was frozen with the aid of a small amount of liquid nitrogen and homogenized. About 500 mg of the homogenate were weighed into a 20-ml capped extraction vial. Stir bar extractions (Twister™) were performed with 20 ml of water or 5–10% (v/v) acetonitrile–water for 60 min.

Air Sampling. Rat cages were built as closed units with an air inlet and outlet. Air was pumped through the cage with a constant flow rate. Collection tubes were installed in the air outlet of the cage. Air samples were collected from the rat cages for 60 min with the air flow adjusted to 20 ml/min flowing through the collection tube equipped with Tenax™ or a Twister™ stir bar (as shown in Figure 1).

Gas Chromatography. GC equipment for the quantitative analysis consisted of an Agilent GC Model 6890 with an Atomic Emission Detector (AED) Model G2350A (Agilent Technologies, Inc., Wilmington, DE) and a Thermal Desorption Autosampler (TDSA, Gerstel GmbH, Mülheim an der Ruhr, Germany). The separation capillary was DB-5 (30 m $\times$ 0.25 mm, i.d., 0.25 μm film thickness, from J&W Scientific, Folsom, CA). Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection system CIS-4. TDSA operated in the splitless mode. Temperature program for desorption was 20°C (0.5 min), then 60°C/min to 280°C (10 min). Temperature of the transfer line was set at 280°C. CIS was cooled with liquid nitrogen to −60°C. After desorption and cryotrapping, CIS was heated at 12°C/sec to 280°C with the hold time of 10 min. Temperature program during the GC analysis was 40°C for 5 min, then increasing to 200°C at the rate of 2°C/min. The final temperature was held for 10 min. Carrier gas head pressure was 14 psi (flow rate, 1.2 ml/min). The GC unit was operated in the constant flow mode. The emission lines for carbon (193 nm), sulfur (181 nm), and nitrogen (174 nm) were monitored in the atomic plasma emission detection unit.

Capillary Gas Chromatography–Mass Spectrometry. Finnigan MAT Magnum ion trap GC-MS system was used for the compound identification (Finnigan MAT, San Jose, CA). The system was provided with a DB-5 capillary column (30 m $\times$ 0.25 mm, i.d., 0.25 μm film thickness, J&W Scientific, Folsom, CA). Helium carrier gas head pressure was 12 psi. At the beginning of the column, a loop of uncoated deactivated silica tubing (30 cm $\times$ 0.25 mm, i.d.) was attached using a universal Press-Tight Connector (Restek Corporation, Bellefonte, PA) as described earlier (Ma et al., 1999). The loop was cooled in liquid nitrogen, while the Twister™stirbar was held in the injector liner for 15 min at 250°C for the thermal desorption of the analytes. Subsequently, the desorbed compounds were cryotrapped into the liquid nitrogen cooled loop. After removing liquid nitrogen cooling, the GC temperature was held at 40°C for 5 min and increased to 200°C at the rate of 2°C/min. The final temperature was held for 10 min. The manifold and transfer line temperatures were 220°C and 300°C, respectively. The ion trap

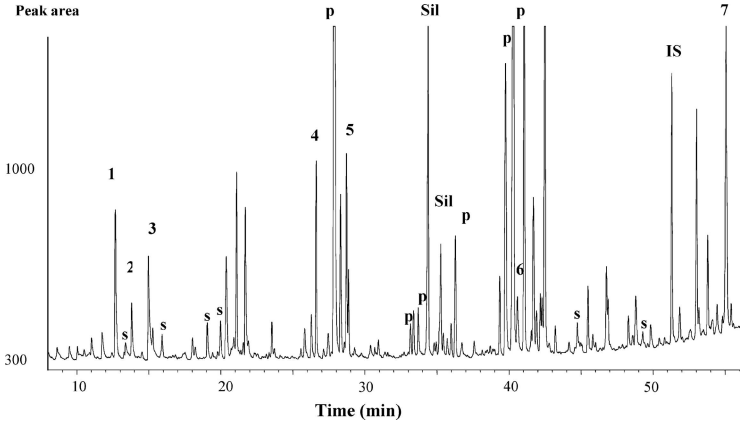

FIG. 3. Chromatogram of the SBSE-extracted and thermally desorbed compounds from male hamster urine (GC-AED, carbon emission, 193 nm). The numbers (1–7) indicate quantitatively measured compounds as seen in Table 1, "s" = sulfur compounds verified on sulfur emission (181 nm); "p" = partially identified pyrazines by GC-MS; Sil = siloxanes from a stir bar; IS = an internal standard, 7-tridecanone. Analytical conditions: as described in the text.

was operated in the positive ionization mode. Spectra were scanned from 40 to 350 amu (1 scan/sec).

RESULTS AND DISCUSSION

Urinary Profiles. GC profiles of the SBSE extracted compounds were compared using the GC-MS instrument, while the peak identities were established based on retention indices, mass spectra, and comparisons with known standard compounds. As an example, a urinary volatile compound GC profile from a pooled male *Phodopus campbelli* hamster urine sample is shown in Figure 3. The numbers indicate a selected compound identity (see Table 1). Male hamster urine characteristically contained a number of partially identified alkylated pyrazines, indicated as "p." Their strong endocrine dependency (data not shown) suggested that alkylated pyrazines are putative chemosignals for this hamster species (Soini et al., unpublished). Additional work is underway for a complete characterization of the individual pyrazine compounds. The peaks marked as "s" were verified as sulfur compounds using a GC-AED (data not shown). While accurately measurable, their levels were too low for unequivocal mass-spectral characterization.

Profiles of the pooled *Phodopus campbelli* hamster urine were compared between the SBSE method (Twister^{TM}) and the purge-and-trap method using

Tenax™ as an adsorbent. GC-MS profiles in Figure 4 show that SBSE method extraction efficiency was lower for the very volatile compounds (typically, 5–10%), but an increased extraction efficiency was observed for less volatile compounds like alkylated pyrazines (typically 50–100%). The ability to adsorb and desorb efficiently small nonpolar volatile compounds with Tenax-like adsorbents is based on a fast equilibrium following their adsorption on the surface through the weak van der Waals interactions. Subsequently, thermal desorption is efficient due to such weak interactions, which was shown with the slightly higher levels of the early eluting volatile compounds. Less volatile compounds (semivolatiles) generally reach the adsorption surface in lesser quantities and, furthermore, become difficult to remove thermally due to stronger adsorptive interactions on the surface (Baltussen et al., 2002). This is illustrated in Figure 4 as the almost nonexisting semivolatile compound region on the TIC of hamster urine after using purge-and-trap with Tenax™ sampling. On the other hand, Twister™ efficiently released semivolatile compounds during their thermal desorption. This feature adds substantial information on the previously unknown range of the putative chemical signaling compounds or the less volatile (semivolatile) compounds (later parts of a chromatogram).

Reproducibility and Quantitative Analysis. Partition into the PDMS phase can be estimated through water–octanol partition coefficients (EpiSuite™, 2000 U.S. Environmental Protection Agency). Using the phase ratios of 24 μl PDMS/10 ml water, the theoretical recoveries can subsequently be calculated. Relative standard deviations of the peak areas for seven compounds in male hamster urine ranged from 1 to 5% ($N = 4$), as shown in Table 1. This case is representative of the repeatability of other chromatographic profiles obtained from mammalian samples (Novotny et al., unpublished; Soini et al., unpublished). Theoretical solute

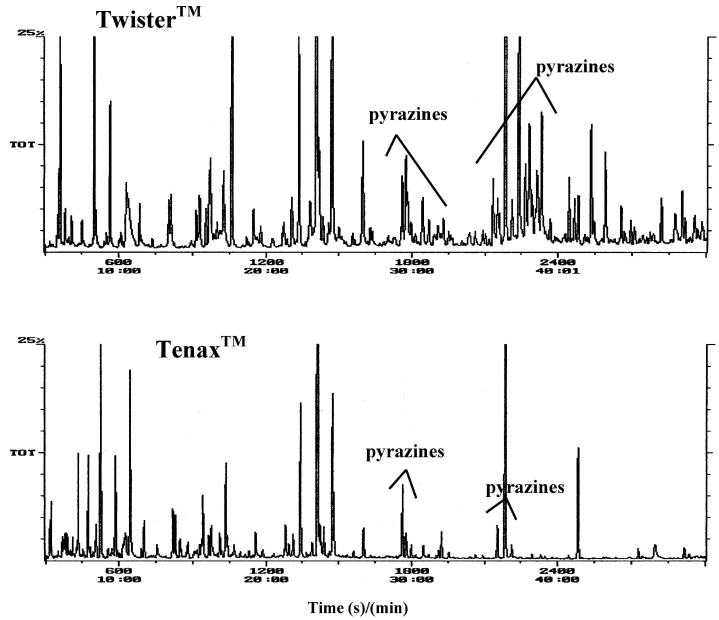

FIG. 4. Comparison of GC-MS total ion chromatogram (TIC) volatile profiles from hamster urine using Twister™ and Tenax™ methods. GC-MS conditions as described in the "Capillary Gas Chromatography-Mass Spectrometry" section.

extraction efficiencies into the PDMS phase varied between 3% and 88%. The more hydrophobic the compound, the higher is the extraction efficiency into the moderately hydrophobic PDMS polymer phase that can be expected. Hydrophobic compounds (e.g., geraniol) with high theoretical recoveries did not show improved extraction reproducibility compared with more hydrophilic compounds (e.g., 2,5-dimethylpyrazine). Overall, quantitative reproducibility of the SBSE extraction of volatiles from hamster urine was relatively constant over a respectable range of hydrophilic and hydrophobic compounds. The linearity of extraction was demonstrated by extracting benzaldehyde from aqueous solutions within the concentration range of 0.25 to 4.0 μg/ml for 60 min. The Coefficient of correlation (R^2, $N = 4$) was >0.99 over the measured range. Furthermore, stir bar extraction has proven to be well suited for the analysis of low levels of benzaldehyde found typically in biological samples. On the contrary, Tenax™ produces benzaldehyde as a degradation product from the polymer and thus would not be suitable for the low-level benzaldehyde analysis. There are often known and suspected artifacts of the interactions between solutes and the adsorbent, in addition to thermal degradation products of this polymer. The stir bar approach is relatively milder in this regard.

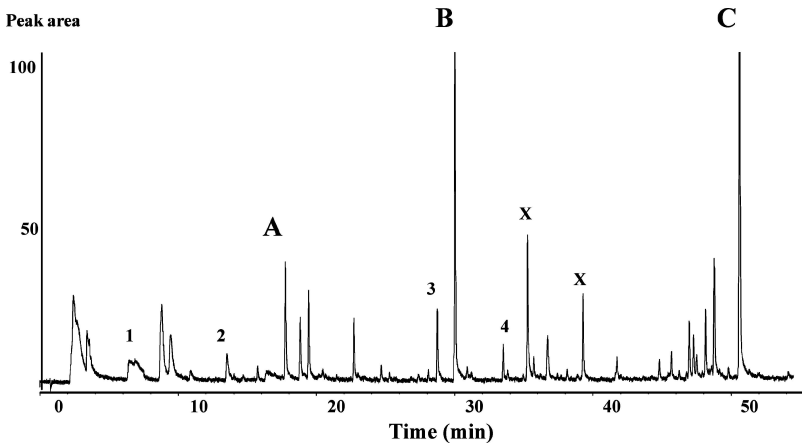

FIG. 5. Chromatogram of the SBSE-extracted and thermally desorbed compounds from male mouse urine (GC-AED, sulfur emission, 181 nm). 1 = dimethyldisulfide; 2 = bis(methylthio)methane; 3 = 2-sec-butyl-4,5-dihydrothiazole; 4 = benzothiazole; A, B, C unknown sulfur compounds; X = sulfur compounds from blank. Chromatographic separation conditions: as described in the text.

Effect of Dilution of Mouse Urine Matrix Proteins. Mouse urine contains relatively high concentrations (1–5 mg/ml) of major urinary proteins, MUPs (Finlayson et al., 1965). Several mouse pheromones are known to bind strongly inside the protein hydrophobic cavity (Zidek et al., 1999). We investigated whether a dilution of mouse urine and MUPs with water would change extractability of the mouse urinary constituents. A chromatogram of the extracted sulfur compounds from a pooled male mouse urine after 50:50 dilution with water is shown in Figure 5. Dilutions of 500 μl, 250 μl, and 100 μl of urine to 1 ml total volume with water decreased almost linearly the peak areas of selected sulfur compounds (Figure 6). Overall, the level of protein did not markedly affect extractability of mouse urine compounds. Detectability of about 0.2 ng of the sulfur urinary components, dimethyldisulfide and bis(methylthio)methane, was achieved with the SBSE method using 100 μl of mouse urine. Thus, the experiment, showed that relatively small biological sample volumes can be utilized reliably with the SBSE technique.

Suitability of SBSE for Tissue Samples. Tissue samples contain higher levels of hydrophobic matrix components, such as lipids and hydrophobic proteins, than urine. Hydrophobic matrix can compete in the sorption processes with the PDMS phase, lowering extraction efficiencies. In our processing of such samples, water proved to be an appropriate solvent for the extraction of volatiles from

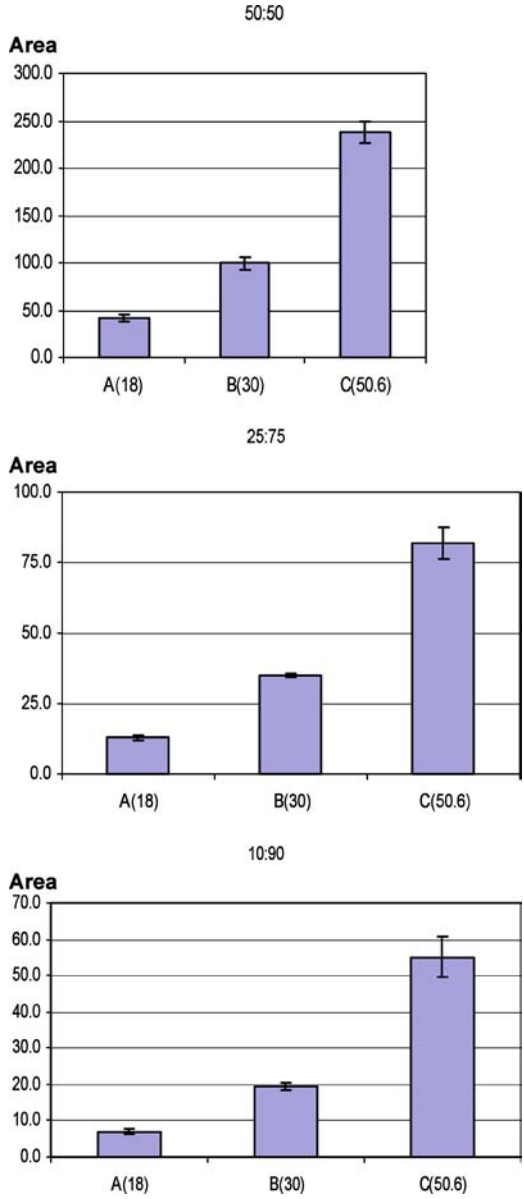

FIG. 6. Effect of dilution for stir bar extraction of selected sulfur compounds A, B, and C in mouse (*Mus domesticus*) urine. Standard deviation bars (SD, $N = 4$) indicate variation among repeated peak area measurements.

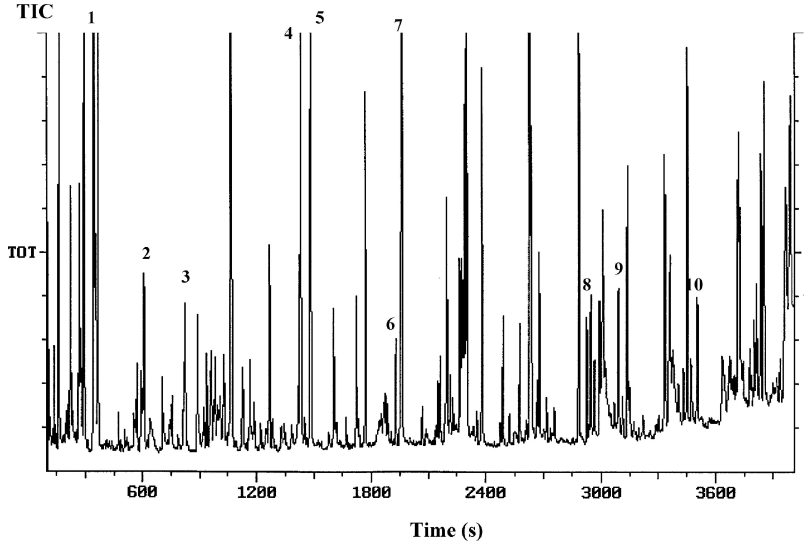

FIG. 7. A typical total ion chromatograph (TIC) obtained from the rat preputial gland by GC-MS after Twister™ extraction. Identified compounds: 1 = hexanal, 2 = heptanal, 3 = benzaldehyde, 4 = 2-nonanone, 5 = nonanal, 6 = decanal, 7 = benzothiazole, 8 = geranylacetone, 9 = α-farnesene, 10 = tetradecane. Analytical conditions: as described in the text.

rat preputial glands. A typical TIC (a total ion chromatogram) by GC-MS is shown in Figure 7. This extraction provided a wide range of tissue volatiles for quantification. We noticed that extraction efficiencies could be increased by using acetonitrile as an organic modifier in the extraction medium. However, acetonitrile (5–10%, v/v) increased also the levels of co-extracted matrix compounds, which were evidenced by the elevated baseline on a total ion chromatogram (data not shown). Work continues to optimize the extraction medium for the different tissue matrices.

SBSE in Sampling Volatiles from Air. Comparison of the extracted compound profiles by Twister™ SBSE and dynamic headspace with Tenax™ on rat odors is shown in Figure 8. During the dynamic headspace sampling of the relatively small air volume (1.2 l), stir bar extraction produced a wider range of compounds on thermal desorption than Tenax™. Difficulties in desorption of the higher molecular weight compounds on Tenax™ sampling were similar to those demonstrated with mouse urine. While no other porous polymers were investigated in this study, it is conceivable that specific methodologies may need to be developed for different applications in this area.

CONCLUSIONS

In summary, the novel sorptive extraction methodology with a PDMS coated stir bar proved to be highly reproducible and linear in aqueous sampling of volatiles and semivolatiles from mammalian urine and tissue samples. This technique allows the use of relatively small sample volumes (100 μl), as such samples could be diluted with water without significant component losses. In addition, the method was suitable for the extraction of small, organic, animal odor-related compounds in air samples in the dynamic sampling mode. Equilibrium properties of the PDMS material facilitated multiple sample extractions simultaneously and significantly

increased the analysis throughput. Efficient extraction and thermal desorption properties of the PDMS phase also produced previously unseen semivolatile compound patterns in the sample profiles, as demonstrated with the mouse and hamster urine samples. The matrix effects seen due to the urinary proteins (mouse urine) and tissue components (e.g., in glands) need more investigation to assess the quantitative attributes of the method in the presence of higher levels of lipids and macromolecular compounds.

Acknowledgments—We thank Dr. Ed Pfannkoch (Gerstel, Inc., Baltimore, MD) for helpful discussions concerning equipment and quantification, Mr. Rod Ginter and Dr. Jeff Alberts (Star Enterprises, Inc. Bloomington, IN) for providing rat odor samples, Dr. Larissa Pohorecky (Department of Psychology, Center of Alcohol Studies, Rutgers University, New Brunswick, NJ) for rat preputial glands, and Dr. Raimund Apfelbach (Animal Physiology, Institute of Zoology, University of Tübingen, Germany) for the specimens' of hamster urine. (Received April 28, 2004; accepted October 15, 2004)

Abstract—Currant clearwing *Synanthedon tipuliformis* (Sesiidae) has been a pioneering and successful target of mating disruption in New Zealand, with virtually universal black currant industry adoption since c. 1990. Recent unexplained control failures using mating disruption lead to questions about pheromone efficacy. In this study, we have investigated the possible reasons for reduced control from mating disruption, and report improvements in trap catch based on pheromone loading and trap color. No differences were found in electrophysiological responses to pheromone components from two New Zealand populations. Male moth catches in traps baited with synthetic lures were disrupted in the presence of mating disruption dispensers (>99.99%) indicating no apparent barrier to efficacy from the pheromone formulation. Field behavioral observations confirmed this result. Male attraction to yellow delta traps was equivalent to green delta traps, but was greater than to red, black, blue, or white traps. Solid yellow delta traps were more attractive than black traps with yellow stripes, the latter designed to mimic the color pattern of the insect. Solid yellow funnel traps were less attractive than a composite of green, yellow, and white funnel traps. Trap catch increased as a function of pheromone loading and trap color. In another experiment conducted in Tasmania, there was no difference in catch with single component [(*E*,*Z*)-2,13-octadecadienyl acetate] or two component lures [97% (*E*,*Z*)-2,13-octadecadienyl acetate:3% (*E*,*Z*)-3,13-octadecadienyl acetate], refuting the suggestion of a different pheromone strain there.

Key Words—Pheromone, mating disruption, currant clearwing, *Synanthedon tipuliformis*, delta trap, funnel trap, color, behavior.

INTRODUCTION

Currant clearwing *Synanthedon tipuliformis* (Clerck, 1759) (Sesiidae) is a worldwide pest of black currants (*Ribes nigrum*). It is difficult to control using insecticides because the cryptic larvae inhabit stems of black currants (Scott and Harrison, 1979), an important crop in New Zealand worth NZ$9m in 2002/03. The clearwing pest group includes congenerics with known pheromones, such as the apple clearwing *S. myopiformis* (Borkhausen), and peachtree borer *S. exitiosa* (Say) (Tumlinson et al., 1974; El-Sayed, 2004). The identification of the pheromone of *S. tipuliformis* (Priesner et al., 1986; Szöcs et al., 1990) led to the rapid development of mating disruption in New Zealand black currants (Thomas and Burnip, 1991), using polyethylene tubing dispensers.

The small size of the New Zealand industry, as well as the quick operational success of mating disruption across the entire industry, reduced interest in further research on the mechanisms and biology underlying disruption of this day-flying species. During the 1990s, growers progressively lowered application rates to as few as 200 dispensers/ha and appeared to maintain control, despite the original recommendations of 500 dispensers/ha (Thomas and Burnip, 1991). More recently, control failures have occurred in New Zealand, raising the question of whether the tactic was failing due to changes in the formulation, in grower practices (leading to a gradual build-up in the pest), or in the insect itself (e.g., through population adaptation). The mechanism of a possible change in the insect population was hypothesized to be sexual selection favoring individuals that were less affected by the synthetic blend, possibly through selection for additional components.

It was also suggested that Australian and New Zealand populations might be different (Szöcs et al., 1990), because there appeared to be differences between the optimal pheromone blends from New Zealand and Tasmanian trapping experiments, suggesting regional strains of currant clearwing, but the differences were never fully explored. The New Zealand insects responded best to 97% (*E*,*Z*)-2,13-octadecadienyl acetate [(*E*,*Z*)-2,13-18:Ac]:3% (*E*,*Z*)-3,13-octadecadienyl acetate [(*E*,*Z*)-3,13-18:Ac] compared to the Tasmanian population that responded optimally to 100% (*E*,*Z*)-2,13-18:Ac. However, the conclusion of a strain difference in Tasmania was taken from a single experiment with a 2-fold difference based on relatively low catches. Tests in Canada indicated a preference for the two component blend, similar to the European strain (Szöcs et al., 1998). Furthermore, catches in 11 countries across Europe showed little intraspecific variation, but catches in traps baited with (*E*,*Z*)-2,13-18:Ac alone were only 25% as high as catches in traps with the two component blend (Szöcs et al., 1991). James et al. (2001) also found the 97:3 ratio of the two component blend to be present from pheromone gland analyses of a Washington State, USA, population.

The goals of this study were to examine possible reasons for the change in efficacy of mating disruption, and to investigate whether trapping systems could

be improved to provide growers with better quality monitoring information. We first tested whether the ratio of the major and minor components of the black currant clearwing pheromone lures might influence male moth attraction in the presence of disruption (Minks and Cardé, 1988). Pheromone release rate is a key requirement for success of disruption (e.g., Suckling et al., 1999) and was also assessed. Both funnel traps and delta traps were used, depending on the aims of individual experiments.

A second series of experiments tested the effects of visual cues. Stüber and Dickler (1986) reported that male apple clearwing moths (*S. myopiformis*) exhibited upwind orientation to the characteristic red band on the female abdomen, highlighting the importance of visual stimuli in this species. Here, we investigated the color response of *S. tipuliformis* in greater detail with delta traps, because they are more readily manipulated, and available in more colors than funnel traps.

METHODS AND MATERIALS

Orientation Disruption (Experiment 1). This experiment compared catches in delta traps baited with a range of lures including caged virgin female moths, synthetic lures at doses of 0, 200 μg, 1, 3, and 10 mg [97% (*E*,*Z*)-2,13-18:Ac:3% (*E*,*Z*)-3,13-18:Ac (purity >95%)] in the presence or absence of mating disruption with 700 dispensers/ha (Shin Etsu Chemical Co., Tokyo, loaded with 97% (*E*,*Z*)-2,13-18:Ac:3% (*E*,*Z*)-3,13-18:Ac (purity >85%), placed in the field on November 11, 2002. Two separate properties in Canterbury, New Zealand were used for the experiment (Edenfield and Mullaghmore, 0.5 km apart), due to the need to separate blocks and avoid pheromone drift. Mullaghmore had consistently been treated with pheromone dispensers, whereas Edenfield had used mating disruption only intermittently (not in 2002/03 or 2003/04). The block used at Mullaghmore was planted in 1998 and was 0.75 ha in size. The Edenfield block was planted in 1994 and was 1 ha. The cultivar in both properties was cv. "Ben Rua." Six red delta traps (for each treatment above) were spaced within the crop at ≥20 m between traps, on metal poles at ca. 1 m height in the crop rows (total of 18 traps per property). Caged virgin female moths were of field origin as larvae and were 2-d old at the time of testing. A fine mist of water was applied to the inside of the cage enclosures each day between 08:00 and 09:00. Delta traps were operated from November 25 to December 12, 2002, randomly allocated to a position in the row and cycled to a new position daily at the time of insect counts. New sets of female clearwing moths were put out every 3–4 d.

Insect population levels in the treated and untreated blocks were assessed by analysis of canes on April 16, 2003. Destructive sampling of the ensuing larval population inside canes involved harvesting 60 shoots chosen at random (based on a pre-sample pilot study), measuring their length, and counting the number of larvae per shoot, to establish the number of larvae/m.

Orientation Disruption (Experiment 2). The same plots described above were maintained as treated or untreated for a second season. Three composite colored plastic funnel traps (green lid, yellow funnel, and white base) were operated in each block, with either the single component [(*E*,*Z*)-2,13-18:Ac)] or two component [97% (*E*,*Z*)-2,13-18:Ac:3% (*E*,*Z*)-3,13-18:Ac] lures (1 mg doses). Traps were maintained from November 10, 2003 to January 23, 2004, checked weekly, and the trap positions were rotated at each count.

Behavioral observations of male and female moths were made on three occasions in each treatment. One row was randomly selected in the treated and non-treated blocks and visual observations started between 13:00 and 14:00 and lasted for 20 min. Behavioral observations were made in consecutive time periods on warm (20–26°C) sunny days in each treatment (December 11, 12, and 15, 2003). Total incidence of male and female moths, flight activity of males, calling by females, and mating were recorded for each period. Wind speed and temperature were recorded at Lincoln University (5 km from sites).

Dispenser Release Rate (Experiment 3). Ten dispensers were put out in the field on November 11, 2002 at Edenfield, and measured weekly for pheromone content for 19 wk. Dispensers were shaken so that the fluid was at one end of the dispenser, and the rate of pheromone release from dispensers was estimated from the decrease of the length (mm) of the pheromone column inside the dispenser (Suckling and Shaw, 1992). A data logger (HortPlus temperature micrologger, Cambridge, NZ) recorded air temperatures hourly.

Electrophysiological Responses (Experiment 4). Coupled gas chromatography-electroantennogram recordings (GC-EADs) were made using excised male antennae from two New Zealand populations (Canterbury and Nelson) of currant clearwing. Responses of males to the mating disruption dispenser contents ($N = 5$ antennae), and to pheromone gland extracts of Canterbury ($N = 5$ antennae) and Nelson females ($N = 5$ antennae) were analyzed. An excised male moth antenna was positioned between two glass electrodes containing BE Ringer's solution with 10% polyvinylpyrrolidone (mol. wt. 360,000). Each glass electrode held a length of 1 mm silver wire that electrically connected the preparation to the recording unit preamplifier. The EAD exit port temperature was maintained at 200°C and the antennal preparation was placed in a filtered and humidified 400 ml/min airstream. Pheromone glands were excised from actively calling 1–2-d-old females held under ambient temperature and natural light in batches of five between 16:30 and 17:00 hr. All samples were analyzed using a Varian 3800 gas chromatograph (Varian, Walnut Creek, CA, USA), equipped with both HP-Wax and HP-5 capillary columns (Agilent, Palo Alto, CA, USA) of 30 m × 0.25 mm i.d. × 0.5 μm film thickness with a 1:1 split outlet, coupled to an INR-02 Recording Unit (Syntech Research and Equipment, Hilversum, The Netherlands). The retention times of the elicited antennal response peaks were compared with the retention times of standards (isomeric purity >98% (*E*,*Z*)-2,13-18:Ac and

(*E*,*Z*)-3,13-18:Ac; Pherobank, Wageningen, The Netherlands). Gas chromatographic conditions were as follows: splitless injections of either a 1 μl aliquot of a 0.1 mg/ml solution of disruption dispenser contents in hexane, or a 4 μl aliquot of gland extract, vented after 0.6 min to a 50:1 split and then to a 10:1 split after 1 min; injector 220°C; detector 300°C; nitrogen carrier gas at 1 ml/min, temperature program, 80°C for 1 min, 20°C/min to 240°C and held for 15 min. Chromatograms were converted to ASCII and averaged for presentation.

Trap Color Response (Experiment 5). This experiment at the untreated Edenfield site compared catches of males in delta traps of different colors, baited with 1 mg pheromone lures (ratio of 1,000:30 of the major and minor components). Traps were white, black, yellow (no lure), yellow, blue, green, and red [spectral reflectances are reported in Clare et al. (2000)], with three replicates of each deployed daily (and positions rotated) from December 19 to 24, 2002. Traps were placed at 20-m spacings, and the sticky inserts were changed after 25 moths were caught.

Influence of Yellow Banding on Catch (Experiment 6). The visual importance of the two color bands on the black body of the female moth to male behavior was tested at the untreated Edenfield site by comparing catches in delta traps of either solid yellow, white, and black colors, or black with 1–4 yellow stripes ($N = 3$ replicates, baited and operated from December 16 to 18, 2002 as in Experiment 5).

Effect of Color and Blend on Catch in Tasmania (Experiment 7). Delta traps ($N = 4$ replicates) were deployed in an untreated black currant block at a commercial planting near Hobart (Tasmania, Australia) with either the single component (100% (*E*,*Z*)-2,13-18:Ac) or the two component blend [97% (*E*,*Z*)-2,13-18:Ac:3% (*E*,*Z*)-3,13-18:Ac], using lures loaded with 100 or 1,000 μg, in both white or yellow delta traps at the lower dose, or yellow alone at the higher dose. Unbaited control traps of each color were also included. Traps were maintained from November 20, 2003 to January 16, 2004, and checked weekly.

Yellow and Green Funnel Traps (Experiment 8). This experiment compared green and yellow funnel traps [baited with synthetic pheromone (97:3) at 3 mg dose], after preliminary results in Experiment 1 indicated good attraction to this dose. Yellow funnel traps had a green lid, yellow top, and white base. Dichlorovos strips were used inside the funnel traps to kill the insects that were caught. Traps ($N = 9$ replicates) were placed at 20-m spacings in an untreated plot at the Edenfield site, and counts were made and traps rotated in position weekly from December 24, 2002 to January 22, 2003.

Effect of Color on Funnel Trap Catch (Experiment 9). Three different colors of funnel traps ($N = 3$ replicates) were deployed from December 1 to 16, 2003 in an untreated plot at the Edenfield site, using 1 mg lures (two component blend). Traps were checked weekly and re-positioned as above. Traps had three components with lid, funnel and base: (a) yellow, yellow, yellow, (b) green, yellow, green, or (c) green, yellow, white.

Statistical Analysis. In experiment 1, a two-way analysis of variance was conducted on log-transformed counts of trap catch (SAS Institute Inc., 1998), although untransformed means are presented for all experiments. Percentage disruption was calculated from the fraction of untransformed catch in treated over control plots. Except for experiment 8, significantly different treatment means were identified using Fisher's Protected Least Significant Difference Test (SAS Institute Inc., 1998) after analysis of variance on log-transformed counts, to stabilize the variance. In experiment 8, the significance of treatment effect was tested using an unpaired t test (SAS Institute Inc., 1998), after counts were found to be normally distributed ($P = 0.54$ and $P = 0.84$ for the two treatments). In the behavioral observation experiment, differences between treatments were identified using a χ^2 2×2 test of independence (SAS Institute Inc., 1998).

RESULTS

Orientation Disruption (Experiment 1). The orientation of male currant clearwing to traps baited with synthetic pheromone lures was successfully disrupted by dispensers releasing the same ratio of the two components (Figure 1), with over 1,623 moths caught in both treatments. The effects of pheromone treatment and lure loading were both significant, as was the interaction (two-way analysis of variance; treatment: $P < 0.001$, $F_{1,16} = 672$; lure: $P < 0.001$,

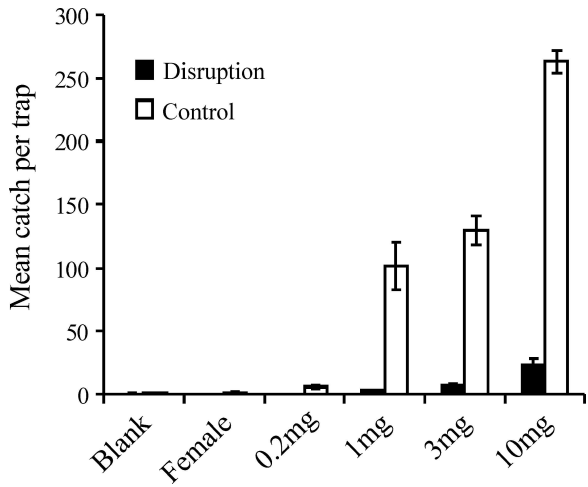

FIG. 1. Mean catch (SEM) of *S. tipuliformis* to synthetic pheromone lures at different doses deployed in delta traps placed in black currant blocks, with and without mating disruption.

$F_{3,16} = 215$; interaction: $P < 0.003$, $F_{3,16} = 6.99$). The significant interaction indicated that a reduction in percentage disruption occurred with increasing lure loading (100%, 97%, 94%, and 91% disruption with doses of 0.2, 1, 3, and 10 mg lures, respectively). There was no difference in catch in traps baited with caged virgin female moths and the unbaited traps, indicating that the female moths were unable to provide a measure of relative attraction of synthetic lures. The lack of attraction to virgin females may reflect insect handling or disruption of normal calling behavior in the cages. Male moths were periodically observed mating with female moths in the treated areas, indicating that mating was not completely prevented. Thomas and Burnip (1991) had reported low or no mating of sentinel females in treated plots, although 3–20% of captured feral females within the treatment were mated. A high population level was apparent in the present study, and cane analysis showed that differences in cane infestation were present between treatments at the end of the season [control: 1.16 ± 0.11 larvae/m of cane, treated: 0.70 ± 0.11 larvae/m of cane (mean $\pm$ SEM); $t = 2.21$, $P < 0.03$, df $= 98$). The lack of plot scale replication here prevents further interpretation of the impact of disruption on larval populations, although the starting population in the disrupted block for Experiment 2 would have been only 63% of the population in the untreated block in the second year.

The 200-μg lure was not effective in catching males compared to higher doses, and attracted no moths in the mating disruption plot. Thomas and Burnip (1991) reported complete trap shut-down of both 100 and 800 μg lures in several (but not all) trials. The experiments here extended this range to higher doses than similar tests with other species in this genus (e.g., Roccini et al., 2003).

Orientation Disruption (Experiment 2). In the second season, catches in the composite colored funnel traps in the untreated plot were high, but almost complete disruption of trap catches (>99%) was observed in the presence of mating disruption dispensers (Table 1), with a total of 2,929 moths caught in the trial. There was a significant effect of disruption ($F_{1,10} = 413.2$, $P < 0.001$), but no difference in trap catches in disrupted blocks with the addition of the second component in the 97:3 ratio. This result was unexpected because of the poor catches reported earlier from New Zealand to the single component (Szöcs et al.,

TABLE 1. CATCH (MEAN $\pm$ SE) OF *S. tipuliformis* IN COMPOSITE FUNNEL TRAPS TO SINGLE AND TWO COMPONENT LURES IN UNTREATED AND DISRUPTED BLACK CURRANT CROPS IN CANTERBURY, NEW ZEALAND

Disrupted	3.3 ± 1.5	2.3 ± 1.3
Control	481.0 ± 26.3	489.7 ± 50.9
% Disrupted	99.3%	99.5%

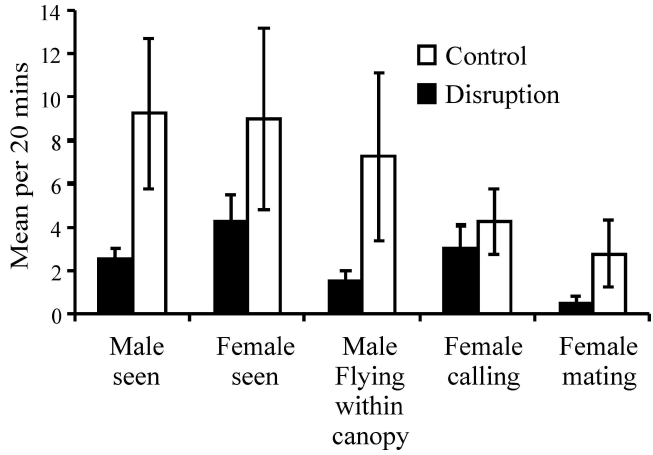

FIG. 2. Behavioral observations of male and female *S. tipuliformis* in black currant crops untreated or treated with mating disruption (same plots as for Table 1).

1990), although Szöcs et al. (1991) reported results close to this from one location in eastern Europe, of 11 locations trapped. Catches here were much larger than those reported from Europe.

Behavioral observations indicated (Figure 2) that male and female density may have been lower in the treated plots (27% and 47% of the control population of males and females, respectively). Although there was no significant difference between treatments, this trend is in the same direction as the estimate from cane sampling (the population in the treated area was 62% of the control population). Males were also observed flying less frequently in the treated crop ($P < 0.05$, $X^2 = 13.51$). In contrast, females were observed calling at relatively similar rates in both treatments (Figure 2), but mating occurred at lower rates in disrupted plots ($P < 0.05$, $X^2 = 11.88$).

Dispenser Release Rate (Experiment 3). The dispensers followed a zero order release, releasing a mean of 2.2% of the total amount of pheromone in the dispenser per week ($R^2 = 0.99$), at an average temperature over the period of ca. 14°C. The 50% life expectancy of the dispensers in the field was 110 d. One of the ten dispensers released pheromone at a rate of 6.3% of the total amount of pheromone per week, but it is unknown whether the sample accurately represents the proportion of malfunctioning dispensers. Dispenser content was confirmed by GC as 97% (*E*,*Z*)-2,13-18:Ac:3% (*E*,*Z*)-3,13-18:Ac (see Experiment 4).

Electrophysiological Responses (Experiment 4). Coupled GC-EAD analysis indicated antennal responses to both (*E*,*Z*)-2,13-18:Ac and (*E*,*Z*)-3,13-18:Ac in the commercial disruptant blend (Figure 3), and confirmed the presence of

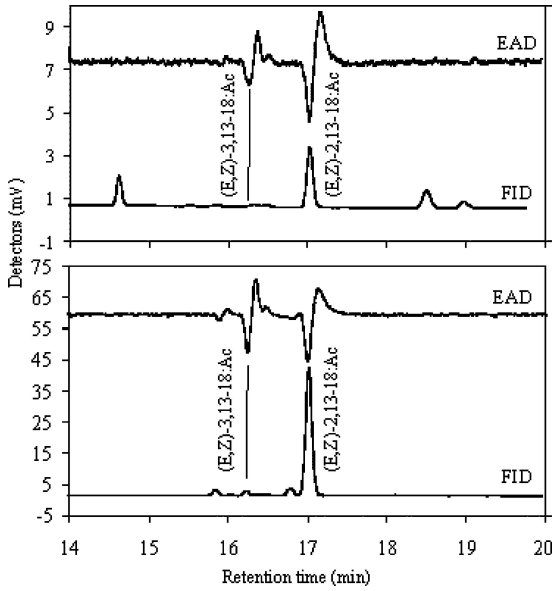

FIG. 3. Coupled gas chromatograph (bottom traces) and electroantennogram (top traces) analysis of the contents of (top) a polyethylene tubing dispenser (97:3 ratio, mean of 5 antennae), and (bottom) a pheromone gland extract (97:3 ratio, mean of 5 antennae).

these components in pheromone gland extracts (as reported by Szöcs et al., 1990; James et al., 2001) of females from Nelson (Figure 3) and Canterbury (not shown) populations of currant clearwing.

Trap Color Response (Experiment 5). Moth catch in delta traps was dependent on trap color ($F_{6,14} = 27.28$, $P < 0.001$). There was no difference between green and yellow delta traps, the two most preferred colors (Figure 4). These green and yellow traps have relatively similar spectral reflectances (Clare et al., 2000), which may account for the lack of difference in catches. Black and blue traps were ineffective, as were unbaited yellow traps. Red delta traps were also not very effective, but had been used earlier in Experiment 1. This suggests that even higher trap catches might have been obtained in mating disruption blocks if yellow traps with high pheromone doses had been used. A total of 473 insects were caught in the experiment.

Influence of Yellow Banding on Trap Catches (Experiment 6). Solid yellow was again favored over white (6-fold) or black traps (180-fold), including black traps with yellow bands designed to simulate the insect coloring ($F_{6,14} = 18.46$, $P < 0.001$) (Figure 5). There were no differences among catches in black traps with 1–4 yellow stripes. A total of 225 insects were caught in the experiment.

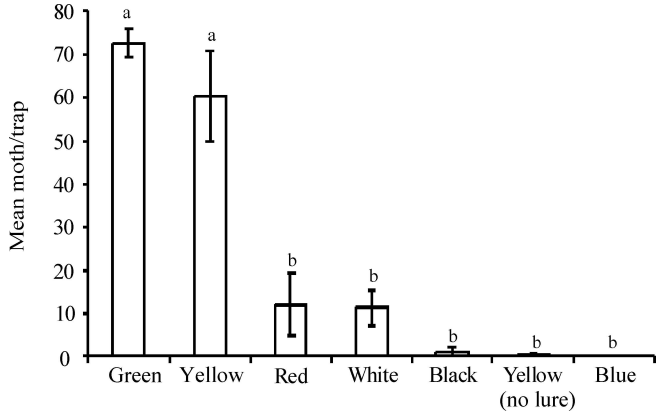

FIG. 4. Mean catches (SEM) of *S. tipuliformis* in a range of colored delta traps baited with pheromone or no lure. Different lower case letters indicate significant differences between treatments ($P < 0.05$).

Effect of Color and Blend on Catch in Tasmania (Experiment 7). A total of 3,016 moths were caught in commercial Tasmanian black currant plantings, with no catch in white or yellow blank traps (Figure 6). A one-way ANOVA on all treatments indicated a significant improvement of the combination of yellow traps

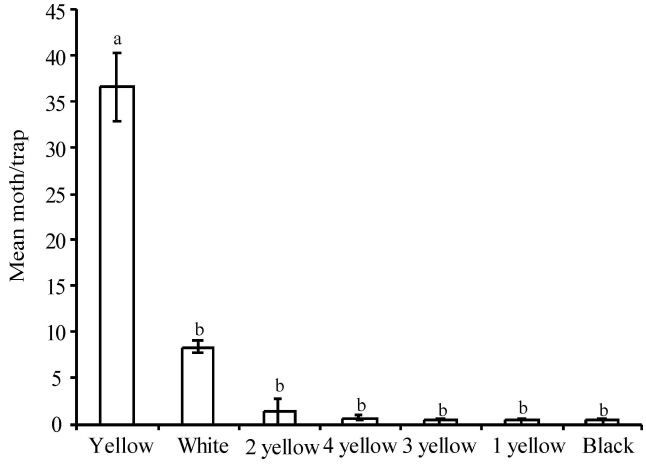

FIG. 5. Mean catches (SEM) of *S. tipuliformis* in pheromone-baited delta traps colored in solid colors, or in black with 1–4 yellow stripes. Different lower case letters indicate significant differences between treatments ($P < 0.05$).

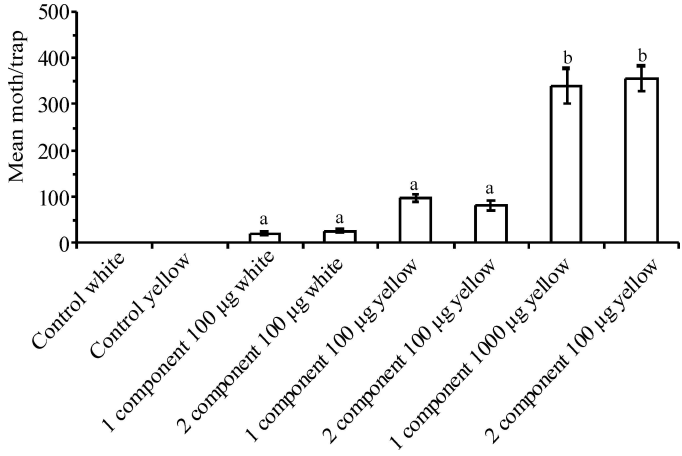

FIG. 6. Mean catches (SEM) of *S. tipuliformis* to pheromone-baited delta traps colored white or yellow, with single or two component blends at two doses. Different lower case letters indicate significant differences between treatments ($P < 0.05$).

baited with the high dose over the other treatments ($F_{7,24} = 19.58$, $P < 0.001$). There was no evidence of a blend effect, with single or two component lures, after one-way ANOVA of all baited treatments ($F_{1,22} = 0.05$, $P = 0.83$).

Yellow and Green Funnel Traps (Experiment 8). Composite yellow and white funnel traps caught more currant clearwing males (mean ± SEM: 238.9 ± 26.0) than green funnel traps (46.2 ± 9.2) ($t = 7.03$, $P < 0.001$, df = 9). This result suggests that larger catches could have been made in Experiments 5 and 6, if funnel traps had been used instead of delta traps.

Effect of Color on Funnel Trap Catch (Experiment 9). There were differences in catch between funnel traps of the three composite color patterns ($F_{2,6} = 18.34$, $P = 0.003$) (Figure 7), with the greatest catch in composite yellow and white funnel traps.

DISCUSSION

Disruption of male moth catches in pheromone-baited traps was successfully achieved in the block treated with polyethylene tubing pheromone dispensers, reducing the likelihood that large-scale changes in the response of the insect population to the pheromone had occurred. Such changes due to co-adaptation or "resistance" to the tactic of mating disruption have been hypothesized (Cardé and Minks, 1995), but there was no evidence for either in our study. At the start of this study, we hypothesized that resistance might be occurring due to selection for a

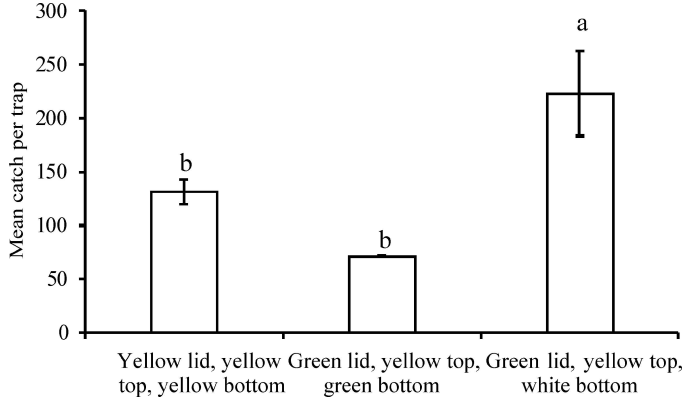

FIG. 7. Mean (±SEM) catches of *S. tipuliformis* in plastic funnel traps with different colored components.

shift in blend by calling females, possibly influenced by the presence of a mixture of the purported Tasmanian and New Zealand pheromone strains (Szöcs et al., 1990). Furthermore, the analysis of gland extracts found the presence of the two electrophysiologically active components, but did not find evidence of additional components that might provide the basis for mate location in the presence of two component mating disruption (as adopted across the majority of the habitat of this monophagous species since 1990).

There was no evidence of an intrinsic failure of mating disruption in controlling *S. tipuliformis* in black currant crops. It therefore seems more likely that the explanation for failure of mating disruption was the gradual increase in pest populations over time, possibly because of dispensers being deployed at densities below the threshold required for efficacy, and the industry shift away from any insecticides in the crop. A reduction in insecticide use after the introduction of mating disruption may have exacerbated pest populations during the 1990s. Because mating disruption works best at low population levels, it may be necessary to either return to higher dispenser rates or to use alternative tactics to regain control in areas with high pest populations.

Equivalent catches with the single component and two component lures in both New Zealand and Tasmanian populations (with data sets comprising high catches) challenge the earlier reports of the importance of the second component, even though this can be seen in the gland extract (Figure 3). The earlier reported preference in Tasmania for the single component over the two component blend (Szöcs et al., 1990) was not supported by the trapping in Tasmania reported here, and there was no evidence for differences between Australian and New Zealand populations in this regard.

Experiments with different trap colors and patterns showed that traps of solid yellow color were most attractive. This also highlights the importance of visual and olfactory cues in mate location in this day-flying species, although it is unclear why this species should be attracted to patches of yellow color. While there were hints of differences in catch with different multiples of yellow stripes, more work would be needed to provide a definitive understanding of the visual acuity of this insect. The combination of a high dose lure in combination with yellow traps improved catches, and this improvement suggests that the possibility of mass trapping of males may warrant examination for currant clearwing control. These results on visual cues also suggest that mating disruption using yellow dispensers could provide an improvement in control over clear dispensers, by combining false trail following to the odor plume with visual cues for mate location, and this approach may warrant further examination. Funnel traps were successful at catching large numbers of *S. tipuliformis*, and did not suffer from trap saturation under high pest densities (as noted for *S. myopifomis* by Voerman and van Deventer, 1984). Roccini et al. (2003) found no difference in catch of the Douglas fir pitch moth, *S. novaroensis* (Hy. Edwards) between sticky traps and funnel traps, but this may have been due to low catches in that study. The composite colored funnel traps with a yellow funnel were more effective than fully yellow traps, further suggesting a high degree of visual discrimination by this insect.

Acknowledgments—Black currants New Zealand Ltd. and AGMARDT funded this research, with a contribution from FRST programmes CO6X0212 and CO6X0301. We are grateful to the black currant growers for access to their properties for this project.

(Received August 23, 2004; accepted October 16, 2004)

Abstract—The defensive chemistry of two species of ants from Brunei in the genus *Crematogaster* (*Physocrema* group) has been investigated. Ants in this group release a white secretion from hypertrophied metapleural glands on their thorax when they are disturbed. Previously, one species in this group has been shown to produce alkylphenols and alkylresorcinols. In the present investigation, similar compounds along with salicylic acids and resorcylic acids that are anacardic acid and olivetolic acid homologs, respectively, are described from two species. The structures of these compounds were suggested by their spectroscopic data and confirmed by direct comparison with synthetic samples. Some of these compounds occur in lichens and have well documented physiological activities.

Key Words—*Crematogaster* spp., Hymenoptera, Formicidae, phenols, resorcinols, resorcylic acids, salicylic acids, chemotaxonomy, metaplural glands.

INTRODUCTION

The exocrine chemistry of ants in the genus *Crematogaster* has been investigated in many species. Typically, the alarm pheromones in these ants are volatile, acyclic alcohols and ketones produced in the mandibular glands (Crewe et al., 1969,

* To whom correspondence should be addressed. E-mail: jonesth@vmi.edu

1970; Schlunegger and Leuthold, 1972; Leuthold and Schlunegger, 1973; Brand and Pretorius, 1986; Scheffrahn and Rust, 1989). On the other hand, the Dufour's gland of this genus is the source of numerous long-chain, cross-conjugated dienone derivatives and furanocembrane diterpenes that function as defensive compounds (Daloze et al., 1987, 1998; Leclercq et al., 1997, 2000a,b; Pasteels et al., 1989) along with, in at least one case, some novel long chain trihydroxycyclohexanes (Laurent et al., 2003). Additionally, *Crematogaster difformis* (= "*deformis*") in the *Physocrema* group, collected at Gombak Valley Field Study Center of the University of Malaya, produces alkylphenols, alkylresorcinols, and mellien in the hypertrophied metapleural glands on its thorax (Attygalle et al., 1989).

In its more typical form, the metapleural gland occurs across major groups of ants, though it has been lost secondarily in some arboreal taxa and males of some species (Hölldobler and Wilson, 1990). Distinguishing the Formicidae from bees and wasps, which impregnate brood cells with antimicrobial compounds, this gland has likely played a key role in maintaining the cleanliness of the nest environment, enabling ants to colonize moist, microbe-ridden nest sites (Hölldobler and Wilson, 1990). Prior to studies of *C. difformis* products, secretions of this gland were known only for highly derived leafcutter ants (*Atta*), in which the gland produces antibiotic phenylacetic acid (Maschwitz et al., 1970). However, antifungal activity has been demonstrated for unidentified metaplural gland products of other ants (Beattie et al., 1986).

Here, we report a detailed analysis of the extracts of *C. difformis* F. Smith, *sensu lat*. and *C. inflata* F. Smith collected in Brunei Darussalam, showing that the major aromatic compounds present in these ants are salicylic acids and resorcylic acids, respectively, the apparent biological precursors of the alkylphenols and resorcinols. Analysis of the former species has revealed the presence of some of the previously reported phenols and isocoumarins along with larger quantities of 6-alkylsalicylic acids, while *C. inflata* contains 5-alkylresorcinols and larger quantities of the corresponding 6-alkylresorcylic acids.

METHODS AND MATERIALS

Field Studies. Collections of *C. difformis sensu lat*.(June 2002) and *C. inflata* (October 2003) in methanol were made at the Kuala Belalong Field Studies Center, run by the University of Brunei Darussalam, and located in the Batu Apoi Forest Reserve, Temburong District, Brunei Darussalam (4°32′N, 115°10′E). Specimens collected in ethanol from the same colonies were compared with type material, and vouchers have been deposited in the entomological collections of both the Brunei Museums and the Natural History Museum of Los Angeles County. *C. difformis sensu lat*. nested in the low arboreal zone and foraged arboreally, and *C. inflata* nested high in an isolated canopy tree and mass foraged in the leaf litter.

Chemical Analysis. Gas chromatography-mass spectrometry (GC-MS) was carried out in the EI mode using a Shimadzu QP-5000 GC-MS equipped with a RTX-5, 30 m × 0.25-mm i.d. column. The instrument was programmed from 60°C to 250°C at 10°/min. Vapor phase FT-IR spectra were obtained using an Hewlett-Packard model 5965B detector interfaced with an H-P 5890 gas chromatograph fitted with a 30 m × 0.25 mm RTX-5 Amine column. High-resolution mass spectrometry was performed on a JEOL SX102 instrument in the positive ion fast atom bombardment mode using a direct probe. Nuclear magnetic resonance (NMR) spectrometry was carried out in $CDCl_3$ solutions using a Varian Mercury 400 NMR spectrometer. The phenols and isocoumarins were suggested from their mass spectra (NIST/EPA/NIH, 1999) and retention times, and were confirmed by comparison with commercial or synthetic authentic samples.

Initial GC-MS analysis of the methanol extract of *C. difformis sensu lat.* revealed the presence of 3-*n*-propylphenol (**1a**), 3-*n*-pentylphenol (**1b**), and 3-*n*-heptylphenol (**1c**) in ca. a 1:1:1 ratio comprising ∼80% of the volatiles detected, along with small amounts of hydroxyisocoumarin (**2**) and mellein (**3**), 3% and 2%, respectively (Table 1). The mass spectra of the remaining poorly resolved components had a base peak at $m/z = 134$, suggesting that they might be methyl salicylates. The solvent was removed from a small amount of the extract *in vacuo*,

TABLE 1. AROMATIC COMPOUNDS DETECTED IN *Crematogaster* SPECIES

	% Composition	
	Before methylation	After methylation[a]
C. difformis sensu lat.		
3-*n*-Propylphenol (**1a**)	26.7	4.5
3-*n*-Pentylphenol (**1b**)	26.7	<1
3-*n*-Heptylphenol (**1c**)	26.7	<1
Hydroxyisocoumarin (**2**)	3	—
Mellein (**3**)	2	—
6-*n*-Propylsalicylic acid (**4a**)	—	41
6-*n*-Pentylsalicylic acid (**4b**)	—	34
6-*n*-Heptylsalicylic acid (**4c**)	—	19
C. inflata		
5-*n*-Pentylresorcinol (**5a**)	42.0	4.7
5-*n*-Heptylresorcinol (**5b**)	57.7	9.4
5-*n*-Nonylresorcinol (**5c**)	<1	<1
6-*n*-Pentylresorcylic acid (**6a**)	—	28.4
6-*n*-Heptylresorcylic acid (**6a**)	—	56

—Not detected.

[a]Samples were treated for 24 hr with excess CH_3I/K_2CO_3, and compounds were detected as their methyl esters and ethers. In this way, **4a–4c** were detected as **8a–8c**, and **6a–6c** were detected as **10a–10c**.

replaced with an equal volume of acetone, and treated with anhydrous K_2CO_3 and a few drops of CH_3I. After 24 hr, GC-MS analysis of the mixture showed the presence of equivalent amounts of three new homologous components, methyl 2-methoxy-6-propylbenzoate (**8a**), methyl 2-methoxy-6-pentylbenzoate (**8b**), and methyl 2-methoxy-6-heptylbenzoate (**8c**) (Table 1). The gas chromatographic retention times and mass spectra of **8a–8c** were identical to those of synthetic samples. The remaining volatile components were the three peaks whose mass spectra corresponded to the methyl ethers of the alkylphenols (**1a–1c**) MS *m/z* (rel.%) 121 (100).

The only aromatic compounds detected in the initial GC-MS analysis of the methanol extract of *C. inflata* were 5-*n*-pentylresorcinol (**5a**), and 5-*n*-heptylresorcinol (**5b**) (Attygalle et al., 1989; NIST/EPA/NIH, 1999), and a trace of 5-*n*-nonylresorcinol (**5c**) MS *m/z* (rel.%) 236 (M^+, 4), 138 (15), 137 (13), 136 (14), 124 (100), 123 (25), 107 (13), and 91 (17) (Table 1). The solvent was removed from a small amount of the extract *in vacuo*, replaced with an equal volume of acetone, and treated with anhydrous K_2CO_3 and a few drops of CH_3I. After 24 hr, GC-MS analysis of the mixture showed the presence of three new homologous components, methyl 2,4-dimethoxy-6-pentylbenzoate (**10a**), methyl 2,4-dimethoxy-6-heptylbenzoate (**10b**), and a very small amount of the two carbon homolog, methyl 2,4-dimethoxy-6-nonylbenzoate (**10c**) MS *m/z* (rel.%) 322 (M^+, 4), 291 (8), 223 (3), 210 (100), 191 (25), 179 (12), 152 (20), 151 (30), 135 (5), 121 (4), 109 (10), and 91 (7) (Table 1). The gas chromatographic retention times and mass spectra of **10a** and **10b** were identical to those of synthetic samples.

3-Heptylphenol (**1c**). A solution containing 0.49 g of 3-hydroxybenzaldehyde (4 mmol) in 5 ml of THF was added slowly to a THF solution of *n*-hexylmagnesium bromide made from 2.64 g (4 equiv.) of *n*-hexylbromide. The resulting mixture was heated to reflux for 1 hr, cooled, diluted with ether, and carefully acidified with 10% HCl. The layers were separated, and the aqueous layer was washed two times with 50 ml of ether. The combined ether layers were washed once with brine, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give 0.9 g of a waxy solid. This solid was taken up in 50 ml of ethanol and shaken under 3 atm. of hydrogen in the presence of 300 mg of 10% Pd/C until the uptake of hydrogen ceased. After filtration and removal of the solvent, kugelrohr distillation provided 0.8 g of **1c** that was >95% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.84 (t, $J = 7.6$ Hz, 3H), 1.24 (m, 8H), 1.53 (q, $J = 7.6$ Hz, 2H), 2.48 (t, $J = 7.6$ Hz, 2H), 5.9 (br s, 1H), 6.61 (d, $J = 7.6$ Hz, 1H), 6.63 (s, 1H), 6.70 (d, $J = 7.6$ Hz, 1H), 7.07 (t, $J = 7.6$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.39, 22.97, 29.48, 29.59, 31.61, 32.10, 36.12, 112.85, 115.68, 121.21, 129.65, 145.25, 155.62. MS *m/z* (rel.%) 192 (7, M^+), 149 (2), 121 (9), 108 (100), 107 (35), 77 (16), 43 (18), 41 (19). HRMS: Calculated for $C_{13}H_{20}O$ (M^+), 192.1514; observed 192.1506.

Methyl 2-Methoxy-6-Propylbenzoate (**8a**). A solution containing 0.47 ml of diisopropylamine in 7 ml of THF was cooled to −78°C and treated with 2.1 ml of 1.6 M *n*-butyllithium in hexanes. The mixture was warmed to 0°C for 15 min then cooled to −78°C, and a solution of 300 mg (1.3 mmol) of methyl 2-methoxy-6-methylbenzoate (**7**) in 2 ml of THF was added dropwise. After 10 min, a solution containing 0.2 ml of ethyl iodide and 0.5 ml of DMPU in 2 ml of THF was added, and the mixture was allowed to warm to room temperature. The mixture was poured into excess ether, extracted with 5% HCl, and water, dried over anhydrous $MgSO_4$, filtered, and concentrated *in vacuo* to give 0.4 g of **6a** that was >90% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.92 (t, $J = 7.6$ Hz, 3H), 1.60 (sextet, $J = 7.6$ Hz, 2H), 2.51 (t, $J = 7.6$ Hz, 2H), 3.81 (s, 3H), 3.909 (s, 3H), 6.76 (d, $J = 7.6$ Hz, 1H), 6.81 (s, 1H), 7.26 (t, $J = 7.6$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.25, 24.48, 35.72, 52.41, 56.08, 108.59, 121.75, 123.71, 130.45, 141.31, 156.42, 168.24. MS *m/z* (rel.%) 208 (23), 177 (37), 161 (100), 147 (31), 105 (20), 91 (33), 77 (28), 51 (25). HRMS: Calculated for $C_{12}H_{16}O_3$ (M^+), 208.1099; observed 208.1107.

Methyl 2-Methoxy-6-Pentylbenzoate (**8b**). The procedure described for **8a** with butyl iodide produced 0.3 g of **8b** that was >90% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.86 (t, $J = 7.6$ Hz, 3H), 1.30 (m, 4H), 1.57 (quintet, $J = 7.6$ Hz, 2H), 2.53 (t, $J = 7.6$ Hz, 2H), 3.79 (s, 3H), 3.89 (s, 3H), 6.74 (d, $J = 8$ Hz, 1H), 6.81 (d, $J = 8$ Hz, 1H), 7.25 (t, $J = 8$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.17, 22.64, 31.04, 31.87, 33.64, 52.30, 56.05, 108.85, 121.71, 123.71, 130.45, 141.57, 156.47, 169.15. MS *m/z* (rel.%) 236 (14), 205 (18), 179 (12), 161 (100), 148 (13), 121 (16), 105 (8), 91 (15), 77 (13), 65 (6), 41 (12). HRMS: Calculated for $C_{14}H_{20}O_3$(M^+), 236.1412; observed 236.1418.

Methyl 2-Methoxy-6-Heptylbenzoate (**8c**). The procedure described for **8a** with hexyl iodide produced 0.4 g of **8c** that was >90% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.87 (t, $J = 7.6$ Hz, 3H), 1.28 (m, 8H), 1.57 (br q, 2H), 2.53 (t, $J = 7.6$ Hz, 2H), 3.80 (s, 3H), 3.89 (s, 3H), 6.74 (*d*, $J =$ 8 Hz, 1H), 6.81 (d, $J = 8$ Hz, 1H), 7.25 (t, $J = 8$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.30, 22.86, 29.28, 29.67, 31.37, 31.97, 33.70, 52.30, 56.06, 108.57, 121.71, 123.70, 130.44, 141.59, 156.47, 169.16. HRMS: Calculated for $C_{16}H_{24}O_3$(M^+), 264.1725; observed 264.1725.

Methyl 2,4-Dimethoxy-6-Pentylbenzoate (**10a**). By using the procedure described for the preparation of **6a–6c**, 0.42 g of methyl 2,4-dimethoxy-6-methylbenzoate (**9**) was alkylated with butyl iodide. Radial chromatography of a sample gave 23 mg of **10a** that was >90% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.81 (t, $J = 6.8$ Hz, 3H), 1.2 (m, 4H), 1.5 (m, 2H), 2.47 (t, $J = 8$ Hz, 2H), 3.73 (s, 3H), 3.74 (s, 3H), 3.81 (s, 3H), 6.243 (d, $J = 2.4$ Hz, 1H), 6.252 (d, $J = 2.4$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.23, 22.68, 31.11, 31.91, 34.14, 52.31, 55.58, 56.09, 96.28, 105.96, 116.41, 143.32, 158.15, 161.57, 169.15. MS *m/z* (rel.%) 266 (21), 235 (30), 211 (10), 210

(100), 209 (18), 191 (37), 179 (12), 152 (10), 151 (45), 135 (11), 121 (7), 91 (17), 77 (22), and 41 (32).

Methyl 2,4-Dimethoxy-6-Heptylbenzoate (**10b**). By using the procedure described for the preparation of **8a**, 0.24 g of methyl 2,4-dimethoxy-6-methylbenzoate (**9**) was alkylated with hexyl iodide. Radial chromatography of a sample gave 86 mg of **10b** that was >90% pure by gas chromatographic analysis. ^{1}H NMR (400 MHZ, $CDCl_3$) δ: 0.80 (t, $J = 6.8$ Hz, 3H), 1.2 (m, 8H), 1.49 (m, 2H), 2.46 (t, $J =$ 8 Hz, 2H), 3.72 (s, 3H), 3.74 (s, 3H), 3.80 (s, 3H), 6.239 (d, $J = 2.4$ Hz, 1H), 6.258 (d, $J = 2.4$ Hz, 1H). ^{13}C NMR (100 MHZ, $CDCl_3$) δ: 14.34, 22.88, 29.32, 29.72, 31.45, 32.00, 34.19, 52.30, 55.57, 56.08, 96.28, 105.95, 116.40, 143.33, 158.16, 161.47, 169.16. MS *m/z* (rel.%) 294 (15), 263 (18), 223 (5), 211 (10), 210 (100), 209 (12), 191 (25), 179 (5), 152 (10), 151 (35), 135 (7), 91 (12), 77 (10), 55 (10), 43 (20), and 41 (30).

The ^{13}C NMR spectra, mass spectra and gas chromatographic retention times of **10a** and **10b** were identical to those of samples prepared by the exhaustive methylation of authentic samples of **6a** and **6b**, respectively.

RESULTS AND DISCUSSION

The initial analysis of the methanol extracts from *C. difformis sensu lat.* revealed that over 80% of the detectable volatiles were a 1:1:1 mixture of 3-propylphenol (**1a**), 3-pentylphenol (**1b**), and 3-heptylphenol (**1c**) accompanied by small amounts of 3,4-dihydro-8-hydroxyisocoumarin (**2**) and its 3-methyl homolog, mellien (**3**) (Figure 1). Except for **1c**, these compounds are well-known

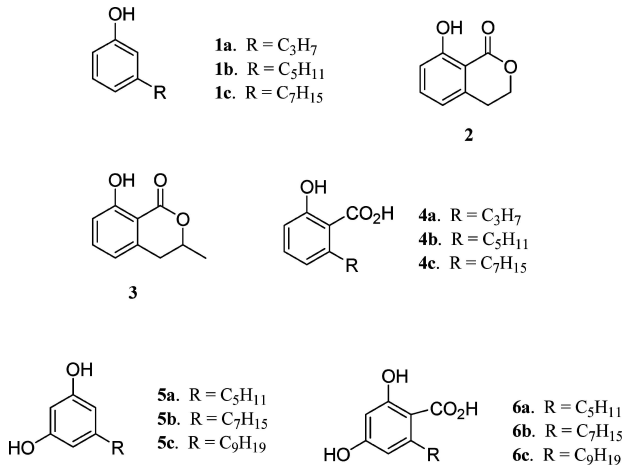

FIG. 1. Compounds found in *Crematogaster* cf. *difformis* and *C. inflata*.

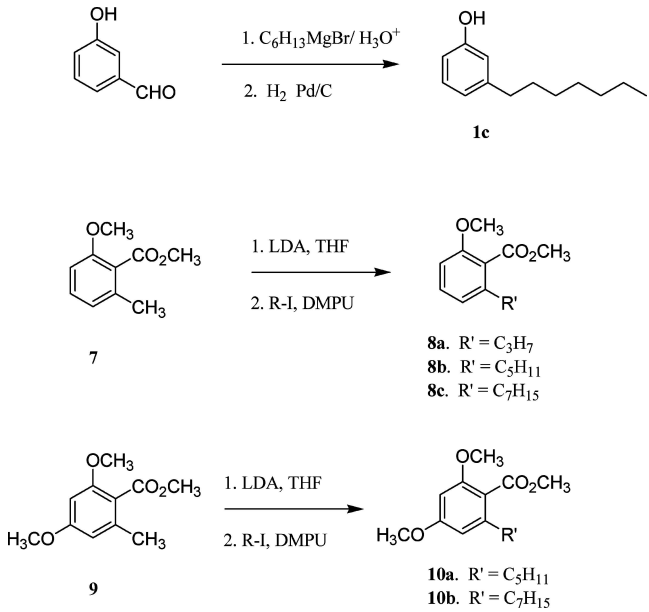
from insect sources and were identified from their published mass spectra (Lloyd et al., 1978; Attygalle et al., 1989). In the case of **1c**, identification was made by direct comparison with synthetic material.

In this analysis, some of the poorly resolved minor components had mass spectra with a base peak at $m/z = 134$ (100), suggesting the presence of hydroxybenzoic acids that had been esterified by the solvent. Exhaustive methylation with CH_3I/K_2CO_3 showed that the major components of the extract were the 6-alkylsalicylates **4a–4c**, which had been converted to the methyl 6-alkyl-2-methoxybenzoates **8a–8c** (Table 1). The structures of these esters were confirmed by direct comparison with synthetic compounds prepared by lateral lithiation and subsequent alkylation (Tyman and Visani, 1997) of methyl 6-methyl-2-methoxybenzoate (**7**) (Hauser and Pogany, 1980; Hauser and Ellenberger, 1987) with the appropriate alkyl iodide (Scheme 1). It was found that by using a solution of the alkyl iodide in THF containing an equal volume of DMPU instead of HMPA, this reaction provided a crude product that was nearly 90% pure.

Since the methoxyphenol derivatives of **1a–1c** were only a small percentage of the mixture after exhaustive methylation, and the dihydroisocoumarins **2** and **3** amount to only 1–2% of the aromatic volatiles present, these results indicate that



SCHEME 1. Syntheses of *m*-heptylphenol (**1c**), methyl 2-alkyl-6-methoxybenzoates (**6a–6c**), and methyl 2-alkyl-4,6-dimethoxybenzoates (**10a–10b**).

the major components of the extracts of *C. difformis sensu lat.* appear to be the 6-alkylsalicylic acids **4a–4c** (Table 1). Obviously, the underivatized 6-alkylsalicylic acids **4a–4c** are not amenable to gas chromatography under normal conditions.

In a similar manner, the initial analysis of the methanol extracts from *C. inflata* revealed only the presence of 5-alkylresorcinols **5a–5c**, along with the usual fatty acid methyl esters resulting from the methanol that the ants were collected in. Exhaustive methylation with CH_3I/K_2CO_3 showed that the apparent major components of the extract were the 2-alkyl-resorcylic acids **6a–6c**, which had been converted to the methyl 6-alkyl-2,4-dimethoxybenzoates **10a–10c** by this treatment (Table 1). The structures of esters **10a** and **10b** were confirmed by direct comparison with synthetic compounds prepared by lateral lithiation and subsequent alkylation (Tyman and Visani, 1997) of methyl 6-methyl-2,4-dimethoxybenzoate (**9**) (Wedekind and Fleischer, 1923; Gaucher and Shepherd, 1971) with the appropriate alkyl iodide (Scheme 1). The structure of the minor component **10c** was inferred from its mass spectrum. The relative amounts of the resorcinols (**5a–5c**) to the resorcylic acids (**6a–6c**) as their completely methylated derivatives are shown in Table 1.

The 6-alkylsalicylic acids **4a–4c** are lower homologs of the "anacardic" acids, extensively studied components of cashew nut oil (*Anacardium* spp.) and *Ginkgo biloba* (Tyman, 1979). These compounds and some of their analogs have antibacterial, antifungal, and antifeedant properties (Matsumoto and Sei, 1987; Muroi and Kubo, 1993; Kubo et al., 1993; Begum et al., 2002). Additionally, they are known to impart mite resistance to geraniums (Walters et al., 1988). It should be noted that the antibacterial activity of these compounds increases with increasing alkyl chain length (Muroi and Kubo, 1993). The antibiotic functions of these compounds are consistent with the current hypothesis for the functional significance of the metaplural gland (see "Introduction").

The resorcylic acids **6a** and **6b** are well known components of lichen depsides (Elix, 1974; Elix et al., 1994; Djura and Sargent, 1976). The repellency of the alkyl resorcinols such as **5a** has been described (Attygalle et al., 1989) so the resorcylic acids may only be present as their precursors, or they may also serve as antimicrobials (Fujikawa et al., 1953).

Although the ecology of *C. difformis sensu lat.* remains poorly studied, the species has been placed in the subgenus *Physocrema*, together with *C. inflata*, which also has hypertrophied metapleural glands [Forel, 1912, as *C.* (sic) *deformis*]. In the latter species, the propodeum, which contains the glands, is colored bright yellow and may function as aposematic coloration. Under attack by highly predacious weaver ants (*Oecophylla smaragdina*), *C. inflata* workers release a white secretion from their metapleural glands upon direct contact with the propodeum (Hölldobler and Wilson, 1990). It is likely that the metapleural glands of *C. difformis sensu lat.* function similarly. The integument of this ant is weak, and light pressure on the anterior thorax or head serves to evert the metapleural

glands, even in dead individuals. This, along with the observed behavior of the related *C. inflata*, and the noxious nature of the "anacardic" acids and alkyl phenols suggests a defensive role in interspecific combat with ants and other predators.

The chemistry before methylation of both *C. difformis sensu lat.* and *C. inflata* shows some similarity to that described for the Malaysian *Crematogaster* species (Attygalle et al., 1989), although no exhaustive methylation was carried out in that case. The phenols **1a–1b** and the isocoumarins **2** and **3** were detected in the Bruneian *C. difformis* and the Malayan species, while only the 5-pentylresorcinol **5a** is common to *C. inflata* and the Malayan species. On the other hand, no heptyl phenols or resorcinols were detected in the Malayan species. The specific name *C. difformis* has routinely been incorrectly rendered as "*C. deformis*" by various authors. It seems probable that our *C. difformis sensu lat.* from Brunei is a different species from the *"C. deformis"* from Malaya. In that case, a series of resorcinols, not observed in the Bruneian *C. difformis*, was detected along with alkylphenols, although neither 3-heptylphenol (**1c**) nor 6-alkylsalicylic acids were detected (Attgalle et al., 1989). Unfortunately, voucher specimens of the Malaysian samples were either never retained or were lost in subsequent years (U. Maschwitz, personal communication to RRS). There is thus no way to compare "*C. deformis*" with our *C. difformis*.

Crematogaster (*Physocrema*) is a well circumscribed assemblage within the genus, characterized by the hypertrophied metapleural glands, and limited to southeastern Asia. At present, there are nominally eight species plus an additional five infraspecific forms. These taxa are, on the whole, known with confidence only from original material; differentiation based solely on the available descriptions is nearly impossible. The present confusion reinforces the need for the deposition of voucher specimens in museum collections. Analyses of metapleural gland secretions may be useful in separating sibling species and investigating phylogenetic relationships among members of this group. However, they can only support the grouping of these taxa under *Physocrema* if similar compounds are determined to be unique to the group.

Acknowledgments—We thank officials of Universiti Brunei Darussalam and the Brunei Museums for granting or facilitating permissions to study and collect at Kuala Belalong. We also gratefully acknowledge the kind gifts of samples of **6a** by Professor T. M. Harris of Vanderbilt University and of **6a** and **6b** by Professor J. A. Elix of the Australian National University, Canberra. THJ and SRB gratefully acknowledge the support of the VMI Chemistry Department and the VMI Grants-in Aid of Research program. Funded by the U.S. National Science Foundation, IBN-9707932 (to DWD).

(Received May 28, 2004; accepted October 15, 2004)

Abstract—Gas chromatographic-mass spectrometric analysis of whole body extracts of *Platynothrus peltifer*, a desmonomatan oribatid mite that belongs to the family Camisiidae, exhibited a basic profile of seven compounds, comprising the monoterpenes neral, geranial, and nerylformate; the aromatics 3-hydroxybenzene-1,2-dicarbaldehyde (= γ-acaridial) and 2-formyl-3-hydroxybenzyl formate (= rhizoglyphinyl formate), and two unsaturated C_{17}-hydrocarbons, 6,9-heptadecadiene and 8-heptadecene. Neryl formate, γ-acaridial, and rhizoglyphinyl formate were the main components and amounted to 80% of the extracts. With the exception of γ-acaridial (relative abundance varied considerably among samples), this chemical profile was consistently present in extracts of *P. peltifer* from nine different localities in SE-Austria. In addition, two further components, 2,3-dihydroxy benzaldehyde and 7-hydroxyphthalide, both probably of non-oil gland origin, infrequently were detected in the extracts. The aromatic compound rhizoglyphinyl formate, also known from Astigmata, was found for the first time in extracts of Oribatida, whereas all other compounds have already been reported from other oribatid species. The hydrocarbons are generally considered to represent plesiomorphic characters of mite oil gland secretions, whereas the monoterpenes and γ-acaridial form a part of the so-called "astigmatid compounds" that are thought to be characteristic for middle-derivative Mixonomata and all more highly derived oribatid groups (including Astigmata).

Key Words—Astigmatid compounds, oil glands, opisthonotal glands, Oribatida, *Platynothrus*, rhizoglyphinyl formate.

INTRODUCTION

Oil glands (opisthonotal glands) represent the largest exocrine system in both oribatid and astigmatid mites, and constitute paired, large-reservoir glands that open to the notogastral surface via a single pore latero-dorsally on either side of the hysterosoma (Howard et al., 1988; Raspotnig et al., 2003). Apart from their biological significance as pheromonal, defensive, and protective organs (Kuwahara, 1991; Shimano et al., 2002; Raspotnig et al., 2003), these glands have proven useful as paradigms for oribatid and astigmatid phylogeny. With regard to current classification models, the presence of oil glands divides the Oribatida into basal nonglandulate groups (Palaeosomata and Enarthronota) and into the monophyletic group of glandulate oribatids, which includes the four more derived cohorts of Oribatida (Parhyposomata, Mixonomata, Desmonomata, and Brachypylida) and the Astigmata (Norton, 1998). Astigmatid mites, sharing the occurrence of oil glands with glandulate Oribatida, may have evolved from glandulate oribatid ancestors and thus in a strict sense may represent just a further oribatid group (Norton, 1998).

Beyond the phylogenetic implications of the occurrence or absence of oil glands, the study of the oil gland chemistry among glandulate groups has introduced a valuable and novel data set for further phylogenetic analyses. Chemical profiles of oil gland secretions have been shown to be species-specific (e.g., Sakata and Norton, 2003) and have been instrumental in the study of the evolutive origin of Astigmata, most probably from a mixonomatan-desomonatan lineage, confirming morphological evidence (Norton, 1998; Raspotnig et al., 2001; Sakata and Norton, 2001). From the multitude of components hitherto detected, Sakata and Norton (2001) have evaluated a characteristic set of five oil gland secretion components, so-called astigmatid compounds, which are widespread in Astigmata and also found in the middle-derivative oribatid species hitherto studied (Sakata et al., 1995, 2003; Raspotnig et al., 2001; Sakata and Norton, 2003). On the other hand, in early-derivative glandulate Oribatida such as Parhyposomata and basal Mixonomata, astigmatid compounds are conspicuously lacking. Thus, this set of compounds—including the monoterpenes neral, geranial, and neryl formate and the aromatics 2-hydroxy-6-methylbenzaldehyde (= 2,6-HMBD) and 3-hydroxybenzene-1,2-dicarbaldehyde (= γ-acaridial)—most likely has evolved first in middle-derivative Mixonomata, and would be expected to characterize the more derived part of Mixonomata and all groups above.

A prerequisite for such a hypothesis is a sufficient matrix of chemical data. However, the study of oribatid oil glands is fragmentary, not allowing generalizing statements on the chemistry of oribatid cohorts or even families. Whereas 67 substances from 52 species of Astigmata have been identified (Kuwahara, 1991; Sakata et al., 2003), chemical data are only available for two species of Parhyposomata, three species of Mixonomata (Raspotnig et al., 2001; Sakata and Norton,

2001), and five species of Desmonomata, four of them belonging to one family, the Trhypochthoniidae (Sakata et al., 1995, 2003; Shimano et al., 2002; Sakata and Norton, 2003).

As a first example of chemical characters from oil gland secretions of a further desmonomatan family, we have studied the oil gland chemistry of *Platynothrus peltifer*, a parthenogenetic and soil-dwelling representative of Camisiidae.

METHODS AND MATERIALS

Specimen Collection and Sample Preparation. Specimens of *P. peltifer* (C. L. Koch, 1839) (Oribatida: Camisiidae) were collected from the litter and fermentation layer of mixed forests, repeatedly from nine different localities in Austria (see Table 1). Altogether, 16 collections were carried out over a 2-yr period (from early spring 2002 to late autumn 2003), giving 33 different samples of adult *P. peltifer* (in all comprising 367 specimens) and 5 samples of juveniles (each sample containing a mixture of nymphal stages, i.e., proto-, deuto-, and tritonymphs, in all comprising 19 individuals). Oil gland secretions were extracted from whole mite bodies: due to the minute amounts of oil gland secretions and the small size of *P. peltifer*, pooled extracts were prepared by transferring a number of freshly collected specimens (usually 4–20) into solvent (100 μl hexane or ethyl acetate) and subsequent extraction for 30 min.

TABLE 1. SPECIMEN COLLECTION AND SAMPLE PREPARATION

Locality	Sample number (number of individuals)	Stage	Solvent
I. Ferlach, Osce (Carinthia)	1 (19), 2 (20)	Adults	Ethyl acetate
	3 (3), 4 (5), 5 (7), 6 (9)	Adults	Hexane
	7 (2)	Juveniles	Hexane
II. Ferlach, Moatsche (Carinthia)	8 (10), 9 (14)	Adults	Hexane
III. Ferlach, Rauth (Carinthia)	10 (7), 11 (5)	Adults	Hexane
IV. Deutschlandsberg (Styria)	12 (23), 13 (30)	Adults	Ethyl acetate
V. Heiligengeistklamm (Styria)	14 (18), 15 (15), 16 (11), 17 (7), 18 (10), 19 (10), 20 (10), 21 (11), 22 (11)	Adults	Hexane
	23 (6)	Juveniles	Hexane
VI. Tamischbachgraben (Styria)	24 (4)	Adults	Hexane
VII. Göltschach (Carinthia)	25 (4)	Adults	Hexane
VIII. Vasoldsberg (Styria)	26 (10), 27 (7), 28 (5), 29 (6), 30 (6), 31 (7), 32 (7), 33 (5), 34(44)	Adults	Hexane
	35 (6), 36 (2), 37 (3)	Juveniles	Hexane
IX. Graz, Plabutsch (Styria)	38 (7)	Adults	Hexane

Chemical Analysis. After extraction, the extracts were separated from mite bodies and stored at −20°C until analysis. Finally, an aliquot of crude mite extracts, in most cases between 1 and 3 μl, was analyzed by GC-MS, using a Fisons MD 800 GC-MS system (Thermo-Quest, Vienna, Austria). The GC column (ZB-5 30 m × 0.25 mm × 0.25 μm; Phenomenex via HPLC SERVICE, Vienna, Austria) was directly connected to the ion source of the MS. We kept the splitless Grob injector at 260°C and used helium as carrier gas at a constant flow rate (1.5 ml/min). The ion source (EI-source) was kept at 200°C, the transfer line at 310°C. We used the following temperature program: 50°C for 1 min, then 10°C/min to 200°C, then 15°C/min to 300°C and hold at 300°C for 5 min. DMDS (dimethyl disulfide) derivatives, to determine the positions of double bonds in unsaturated hydrocarbons, were prepared according to Vincenti et al. (1987).

Reference Compounds. Nerol, geraniol, and citral were purchased from Aldrich (Vienna, Austria). Isomerically pure neral and geranial were prepared by diluting the corresponding alcohols in acetone and stirring the solution with activated MnO_2 at room temperature and under nitrogen until the oxidation was complete. The reaction products were purified by silica gel chromatography using acetone: hexane (9:1) as eluent. Purity of compounds was checked by GC-MS (purity >99%). Neryl formate was prepared from nerol according to Kuwahara and Sakuma (1982). Rhizoglyphinyl formate (= 2-formyl-3-hydroxybenzyl formate) was synthesized according to Sato et al. (1993). As a reference for γ-acaridial (= 3-hydroxybenzene-1,2-dicarbaldehyde), we used a North American *Perlohmannia* species from West Virginia with γ-acaridial being an already characterized constituent of its oil gland secretion (Sakata and Norton, 2001).

Scanning Electron Microscopy. For scanning electron microscopy (SEM), specimens were fixed in glutaraldehyde, dehydrated, and mounted on small dishes prior to sputtering with gold. SEM was carried out on a Philips XL30 ESEM at the Institute of Plant Physiology, Karl-Franzens-University of Graz, Austria.

RESULTS

Oil Glands in P. peltifer. Oil glands in *P. peltifer* are well developed and open through one slit-like pore at either of the distal latero-dorsal margins of the notogaster (Figure 1). Oil glands turn brownish when specimens are stored in 70% alcohol or in Faure's liquid and then are visible through the cuticle.

Evaluation of Extract Profiles. From all 38 samples investigated, a total of nine different components could be separated by gas chromatography. Only seven of the detected components were present in all samples investigated, forming a characteristic and consistent basic extract profile (peaks A–G in Figure 2). Qualitatively, no differences between extracts of adults and juveniles (nymphs) were detected.

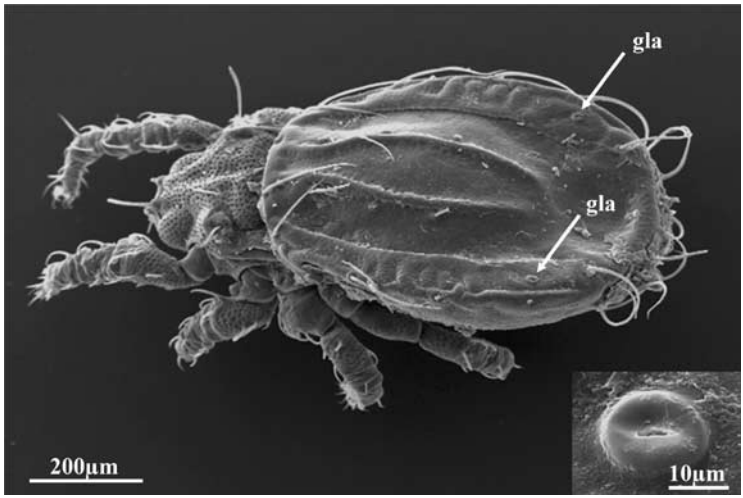

FIG. 1. Scanning electron micrograph of an adult individual of *Platynothrus peltifer*, dorsal view. White arrows point to oil gland openings (gla). Insert: Magnification of right oil gland pore.

Identification of Compounds. Gas chromatographic and mass spectral data of compounds A–G are summarized in Table 2. Peaks A and B exhibited a similar fragmentation pattern that only differed in the intensity of certain fragment ions. Both components appeared to be acyclic monoterpenes with their most prominent fragments at *m*/*z* 69 (from allylic cleavage) and *m*/*z* 41, and molecular ions of weak intensity at *m*/*z* 152. Peaks A and B were identified as neral and geranial, respectively, and their identities were confirmed by comparisons with authentic standards. Peak C also exhibited a monoterpenoid fragmentation pattern but did not show a molecular ion (ion of highest mass at *m*/*z* 136). The compound was identified as neryl formate by comparison with a standard. Peak D appeared to be an aromatic di-aldehyde, showing a prominent molecular ion at *m*/*z* 150 and repeated loss of CO and CHO, respectively, leading to the fragments at *m*/*z* 122 and *m*/*z* 121 (the base peak), and the fragments at *m*/*z* 93 and 92. The isotopic peak at *m*/*z* 151 had an intensity of 8.74% of the molecular ion, indicating the presence of eight carbon atoms, and supporting a molecular formula of $C_8H_6O_3$. The mass spectrum of the compound matched the spectrum of 3-hydroxybenzene-1,2-dicarbaldehyde (γ-acaridial) as recently reported (Sakata and Kuwahara, 2001), and a comparison of the retention time to authentic γ-acaridial from extracts of *Perlohmannia sp.* (Sakata and Norton, 2001) confirmed its identity. Peak E showed an aromatic fragmentation pattern with pronounced high and low aromatic series and the characteristic aromatic ion at *m*/*z* 77. The diagnostic fragments at *m*/*z* 151 and at *m*/*z* 134 (base peak) indicated the loss of an aldehyde group and the neutral loss of

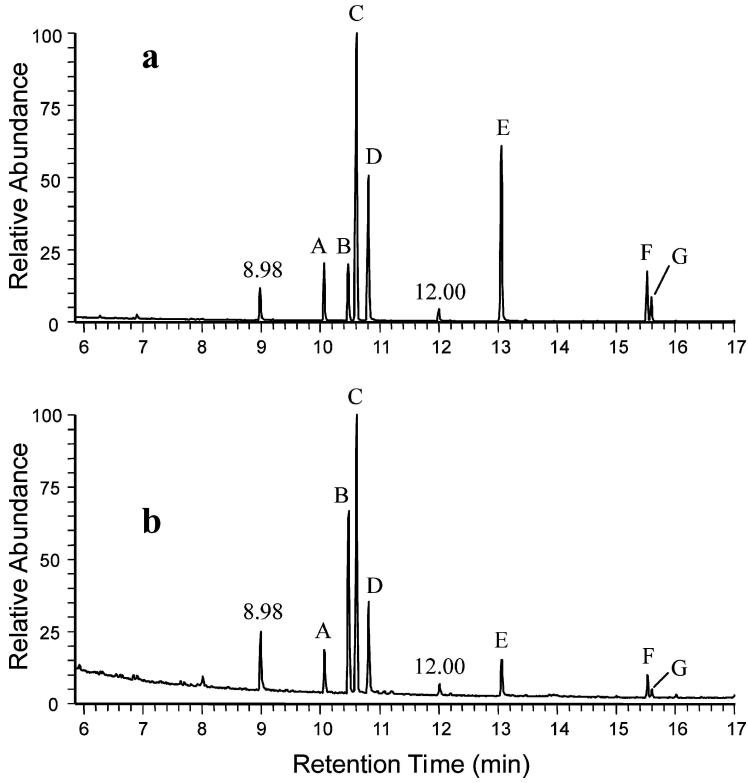

FIG. 2. Gas chromatogram of extract components in adults (a) and nymphs (b) of *Platynothrus peltifer*. Basic extract profile consists of compounds A–G: (A) neral; (B) geranial; (C) neryl formate; (D) γ-acaridial; (E) rhizoglyphinyl formate; (F) 6,9-heptadecadiene; and (G) 8-heptadecene. Infrequently occurring compounds are 2,3-dihydroxy-benzaldehyde at rt = 8.98 min and 7-hydroxyphthalide at rt = 12.00 min.

formic acid, respectively, from the molecular ion (at *m*/*z* 180). The isotopic peaks at *m*/*z* 181 ($M^+ + 1$ peak) and *m*/*z* 182 ($M^+ + 2$ peak) had relative intensities of 9.3% and 1.5% of the molecular ion, respectively, and suggested the presence of nine carbon and at least four oxygen atoms, and thus a molecular formula of $C_9H_8O_4$. The compound was finally identified as rhizoglyphinyl formate (= 2-formyl-3-hydroxybenzyl formate) by synthesis of an authentic standard. Peaks F and G had mass spectra typical of unsaturated hydrocarbons with molecular ions at *m*/*z* 238 and *m*/*z* 236, being consistent with a heptadecene and a heptadecadiene, respectively.

Determination of Double Bond Positions. The DMDS adduct of the heptadecadiene showed a molecular ion at *m*/*z* 362 (52% relative intensity), indicating

TABLE 2. GAS CHROMATOGRAPHIC AND MASS SPECTRAL DATA OF BASIC EXTRACT PATTERN

Peak No.	Retention time (min)	EI-fragmentation (relative intensity)	Identified as
A	10.06	152 (1), 137 (7), 134 (10), 123 (5), 119 (17), 109 (25), 95 (19), 94 (28), 84 (24), 81 (20), 69 (99), 67 (27), 59 (13), 57 (19), 55 (14), 53 (21), 41 (100)	Neral
B	10.47	152 (4), 137 (9), 134 (5), 123 (7), 119 (8), 109 (12), 94 (19), 91 (17), 84 (24), 81 (11), 69 (100), 67 (15), 57 (10), 55 (8), 53 (13), 43 (12), 41 (77)	Geranial
C	10.60	182 (M^+; trace), 137 (2.1), 136 (20), 121 (10), 107 (4), 80 (12), 79 (19), 77 (17), 69 (100), 53 (17), 41 (63)	Neryl formate
D	10.80	152 ($M^+ + 2$ peak; 0.69), 151 ($M^+ + 1$ peak; 4.2), 150 (M^+; 48), 122 (49), 121 (100), 93 (42), 65 (36), 63 (14), 57 (37), 43 (24), 41 (31)	γ-Acaridial
E	13.05	182 ($M^+ + 2$ peak; 0.3), 181 ($M^+ + 1$ peak; 1.86), 180 (M^+; 20), 151 (33), 135 (18), 134 (100), 106 (32), 105 (30), 79 (8), 78 (37), 77 (51), 65 (13), 63 (11), 51 (19)	Rhizoglyphinyl formate
F	15.51	236 (13), 152 (2), 138 (8), 124 (10), 110 (12), 109 (16), 96 (33), 95 (43), 82 (43), 81 (60), 79 (25), 77 (10), 69 (21), 68 (34), 67 (100), 57 (9), 55 (47), 43 (21), 41 (42)	Heptadecadiene
G	15.58	238 (8), 139 (3), 125 (15), 111 (36), 97 (72), 83 (83), 71 (35), 69 (100), 57 (80), 55 (91), 43 (77), 41 (81)	Heptadecene

the formation of a cyclic thioether with the loss of MeSMe (m/z 236 plus $2 \times m/z$ 94 minus m/z 62 = m/z 362). Diagnostic ions, originating from α-cleavage, comprised two acyclic fragments (formed by α-cleavage from the two MeS-bearing α-atoms, at m/z 131 [67%] and m/z 159 [68%]) and two ions containing the cyclic moiety (formed by α-cleavage at both sides of the cyclic thioether function at m/z 231 [41%] and m/z 203 [44%]). From ions containing the cyclic moiety, neutral loss of MeSH was observed (loss of 48 amu), leading to the most intense fragments in the spectrum at m/z 155 (base peak) and at m/z 183 (97%), respectively. These mass spectrometric data are consistent with a 6,9-heptadecadiene only. The DMDS adduct of the heptadecene

showed a molecular ion at *m*/*z* 332 (*m*/*z* 238 + *m*/*z* 94) and diagnostic ions from α-cleavage at *m*/*z* 159 and *m*/*z* 173, respectively, corresponding to 8-heptadecene.

Additional Components. In 21 (of the 38) samples, a minor component with short retention time (rt = 8.98 min) and the following mass spectrum could be detected: *m*/*z* 138 (M^+, 100), 137 (71), 120 (21), 109 (15), 92 (35), 81 (34), 79 (8), 64 (14), 63 (19), 55 (18), 53 (24), 52 (23), 51 (18). The stable and intense molecular ion along with hydride abstraction suggested the presence of an aromatic aldehyde. Diagnostic fragments showed the loss of water (*m*/*z* 120), loss of an aldehyde group (*m*/*z* 109), and loss of water and decarbonylation (*m*/*z* 92) from the molecular ion. The compound was tentatively identified as a dihydroxy-benzaldehyde, confirmed by comparison of retention time and mass spectral data with that of authentic 2,3-dihydroxybenzaldehyde.

A further component with a mass spectrum similar to γ-acaridial appeared in small amounts at rt = 12.00 min in 19 (of the 38) samples [*m*/*z* 150 (37), 149 (7), 122 (7), 121 (100), 93 (15), 65 (19), 63 (11), 51 (15)]. It mainly differed from the spectrum of γ-acaridial in the weak relative intensity of *m*/*z* 122 and was identified as 7-hydroxyphthalide by comparison of retention times with those of the authentic substance.

Quantitative Analysis. A quantitative analysis of the extracted compounds was done for 30 hexane extracts of adults (in all containing 275 individuals) and the 4 hexane extracts of nymphs (in all containing 17 individuals) by determining the abundances of single components in relation to the amount of the whole 7-compound profile (given in % peak area in the following). The basic pattern of the extracts occurred in constant proportions, irrespective of the locality of sampling or population. In all samples of adult *P. peltifer* investigated, neryl formate was the main component (36.3 $\pm$ 6.1%), followed by rhizoglyphinyl formate (25.2 $\pm$ 7.3%) and γ-acaridial (19.8 $\pm$ 8.9%), all three components together comprising more than 75% of the extracted material. Only the abundance of γ-acaridial showed high variations between samples, ranging from "not detected" (in one sample of locality VII: Göltschach) up to about 1/3 (36%) relative abundance in another sample. Usually, and independent of localities, it was the third-most abundant compound in the extracts. Mean values of the remaining compounds were as follows: neral 4.5 $\pm$ 2.2%, geranial 6.1 $\pm$ 3.0%, 6,9-heptadecadiene 5.2 $\pm$ 3.5%, and 8-heptadecene 3.0 $\pm$ 2.2%. In samples that had been collected in autumn 2003, the relative abundances of neral, geranial, and the hydrocarbons had decreased considerably and consistently were found to be below mean values.

In nymphal extracts, neryl formate (40.1 $\pm$ 3.7%), γ-acaridial (24.7 $\pm$ 10.5%) and geranial (22.2 $\pm$ 4.0%) were the main components. The mean relative abundances for the remaining components were neral 5.3 $\pm$ 2.7%, rhizoglyphinyl formate 5.4 $\pm$ 3.9%, 6,9-heptadecadiene 1.6 $\pm$ 1.2%, and 8-heptadecene 0.7 $\pm$ 0.5%.

DISCUSSION

Origin of Extract Components. All seven compounds that form the basic pattern of whole body extracts of *P. peltifer* most likely belong to the oil gland secretion of this species, because oil glands are the only exocrine glands in *P. peltifer* that are large enough to produce the detected amounts of secretion. Second, all seven components from extracts are already known from oil gland secretions of Astigmata (Kuwahara, 1991) and, with the exception of rhizoglyphinyl formate, also from other Oribatida (Sakata et al., 1995, 2003; Raspotnig et al., 2001; Sakata and Norton, 2001, 2003). Third, in whole body extracts of oribatid mites that do not possess oil glands—such as early-derivative species from Enarthronota—no sign of these components, which typically are found in oil gland-bearing groups, were detected (Sakata and Norton, 2001). Fourth, a definitive proof of the oil gland origin of some of these compounds has been carried out in the large mixonomatan *Collohmannia gigantea*. Whole-body extracts of individuals with different filling status of oil gland reservoirs were compared, resulting in a proportionate decline of oil gland compounds in the case of exhaustion of oil gland reservoirs (Raspotnig et al., 2001). Moreover, in *C. gigantea*, histochemical proofs have shown the presence of aldehydes (a predominant class of oil gland components) in oil gland reservoirs only, but not in other regions of the body. Comparably, a direct line of evidence for the oil gland origin of astigmatid compounds is provided by a recent study by Sakata and Norton (2003) who extracted the same set of components from whole mite bodies of *Archegozetes longisetosus* and from dissected glands of exuvial cuticles, respectively.

As in *C. gigantea*, oil glands of *P. peltifer* turn brownish or even black when specimens are stored in low-proof ethanol or Faure's liquid (Raspotnig et al., 2001). This phenomenon, also known from several Astigmata (Kuwahara, 1976), is reported to be due to the presence of certain monoterpenes (especially neryl formate) in oil gland reservoirs and may serve as a first (morphological) indicator for a monoterpene-rich oil gland secretion.

In contrast, the remaining two detected compounds (2,3-dihydroxybenzaldehyde and 7-hydroxyphthalide) may not be of oil gland origin. In our investigation, the amounts of these components varied considerably in repeated gas chromatographic analyses of the same sample, suggesting that the substances were artifacts formed in the course of analysis. However, 7-hydroxyphthalide has been described as a component of the oil gland secretion in the astigmatid mite *Oulenzia sp*. (Shimizu and Kuwahara, 2001). Also, an unidentified component with molecular weight 138—showing a corresponding mass spectrum to the 2,3-dihydroxybenzaldehyde found in our study—has been reported from whole body extracts of the astigmatid mite *Dermatophagoides pteronyssinus* and has been classed with its oil gland secretion (Kuwahara et al., 1990).

Characteristic Oil Gland Secretion Profile in P. peltifer. Apart from γ-acaridial, the secretion profile of *P. peltifer* appeared to be consistent, irrespective of the locality of sampling, and thus representing a species-specific pattern. Profiles of juveniles were qualitatively similar to those of adults but differed in the relative abundance of components, especially in the composition of citral, thus holding a "hybrid" position among oil gland secretions of Oribatida: while oil gland profiles of adults and juveniles are not distinguishable in mixonomatans such as *C. gigantea* (Raspotnig et al., 2001) and also in certain Desmonomata such as Trhypochthoniidae (e.g., Sakata and Norton, 2003), chemical profiles have been reported to change during the ontogenetic development in *Nothrus palustris* (Shimano et al., 2002) and possibly also in other Nothridae (Sakata et al., 2003). Also in higher Oribatida (Brachypylida), profiles of juveniles may differ considerably from adults (Norton, personal information). However, whether adult–juvenile polymorphism of oil gland secretions represents an evolutive trend cannot be decided with the current status of knowledge. In this respect, the composition of citral in the oil gland secretion of *P. peltifer*, changing from geranial-rich citral in juveniles to a more balanced neral–geranial ratio in adults, is of interest because citral is regarded to be a key component for phylogenetic analyses. Predominantly neral-rich citral is characteristic of oil glands of higher Astigmata, in contrast to the geranial-rich citral of basal Astigmata such as Histiostomatidae (Sato et al., 1993; Shimano et al., 2002), suggesting that astigmatid mites may have arisen from a geranial-rich citral-possessing oribatid ancestor (Shimano et al., 2002). However, in Oribatida and, as demonstrated in the present paper, even within stages of the same species, several types of citral may be present (see also Shimano et al., 2002; Sakata et al., 2003).

Phylogenetic Considerations. The oil gland secretion of *P. peltifer* contains the characteristic three chemical fractions (terpenes, aromatics, and hydrocarbons) that are well known from oil gland secretions of other Oribatida and from Astigmata. Among these fractions, four of the five so-called "astigmatid compounds" (sensu Sakata and Norton, 2001) are present; these components, as already mentioned, constitute an apomorphy of Oribatida (including Astigmata) higher than middle-derivative Mixonomata. By contrast, the C_{17}-hydrocarbons may be regarded as plesiomorphic characters of oil gland secretions. Short- and middle-chain hydrocarbons are widely distributed in oil glands of Astigmata and Oribatida, including the early-derivative groups such as Parhyposomata (Sakata and Norton, 2001). Even though the conformation of double bonds was not determined in our investigation, we might have been dealing with (*Z*)-8-heptadecene and (*Z*,*Z*)-6,9-heptadecadiene, both of which are found in other desmonomatan species (Sakata et al., 1995, 2003).

Apart from these common oil gland components, *P. peltifer* also contained an unexpected and novel component for oribatid oil glands: rhizoglyphinyl formate. This component seems to be rare among astigmatid mites as well, and

the only other natural sources hitherto known are the oil gland secretions of *D. pteronyssinus* (Sato et al., 1993) and *Rhizoglyphus sp.* (Tarui et al., 2002), respectively. Although, it is too early to evaluate the phylogenetic significance of rhizoglyphinyl formate, it may represent a highly derivative oil gland product of certain desmonomatan Oribatida, having arisen after the splitting-off of Mixonomata from the oribatid stem line.

Biological Role of Oil Gland Secretion. The biological role of the oil gland secretion of *P. peltifer* is still obscure. However, citral is known to possess antifungal properties (Cole et al., 1975), representing an important chemical protection if living in a humid, fungi-rich environment. In addition, in nymphs of *N. palustris*, geranial has been reported to function as an alarm pheromone (Shimano et al., 2002), and oil gland secretions of Astigmata are a source of diverse pheromones and protective agents (Kuwahara, 1991). Most recently, alarm pheromonal and defensive properties of oil gland-derived astigmatid compounds have been decribed for *C. gigantea* (Raspotnig et al., in press). Due to the characteristic construction of oribatid oil glands—large sac-like glands with a mechanism for the controlled emission of secretion—their most important biological roles may include defense and alarm pheromonal communication (Raspotnig et al., 2003).

QUANTIFICATION OF INVERTASE ACTIVITY IN ANTS UNDER FIELD CONDITIONS

MARTIN HEIL,[1,*] RITA BÜCHLER,[1] and WILHELM BOLAND[1]

(Received June 29, 2004; revised September 17, 2004; accepted September 18, 2004)

Abstract—Invertases (EC 3.2.1.26) are hydrolases that cleave sucrose into the monosacccharides, glucose, and fructose. They play a central role in carbohydrate metabolism of plants and animals. Methods presented so far to quantify invertase activity in ants or other animals have been hampered by the variability in both substrates and products of the enzymatic reaction in animals whose carbohydrate metabolism is highly active. Our method is based on a spectrophotometric quantification of the kinetics of glucose release. We first obtained an equilibrium state summarizing reactions of any carbohydrates and enzymes that are present in the extract. Sucrose was then added to quantify invertase activity as newly released glucose. Invertase activities differed significantly among species of ants. Variances were lowest among individuals from the same colony and highest among different species. When preparations were made from ants of the same species, invertase activity was linearly related to the number of ants used for extraction. Our method does not require ants to be kept on specific substrates prior to the experiment, or expensive or large equipment. It, thus, appears suitable for dealing with a broad range of physiological, ecological, and evolutionary questions.

Key Words—β-Fructosidase, carbohydrate metabolism, saccharase, sucrose, sugar.

INTRODUCTION

Invertases (β-fructofuranosidase, EC 3.2.1.26, also termed β-fructosidase, saccharase, or sucrase) are glycoside hydrolases (EC 3.2.1.-) that catalyze the cleavage of sucrose (α-D-Glucopyranosyl-β-D-fructofuranoside) into the two monosaccharides, glucose, and fructose (Henrissat and Bairoch, 1993; Sturm and Tang, 1999; Naumoff, 2001). Carbohydrates ingested by heterotrophic organisms undergo

* To whom correspondence should be addressed. E-mail: heil_martin@web.de

several metabolic steps, in the first of which polymeric carbohydrates are cleaved into their monomers, which then can pass through membranes. Invertase, thus, appears to be a particularly important enzyme for both plants and animals.

Feeding on animals as well as plant material, ants can metabolize many different food sources. Early investigations have indicated that differences among species in the activity of digestive enzymes may reflect the feeding habits of the ants (Ayre, 1967; Ricks and Vinson, 1972). Many ants feed on carbohydrate-rich liquid food sources, such as honeydew of homopterans, plant sap, and extrafloral nectar (i.e., nectar secreted on vegetative organs that is not functionally involved in pollination, see Heil and McKey, 2003). As sucrose is common in all these food sources, invertase activity is required to make use of such food sources.

Given this general importance, surprisingly few studies have tried to quantify invertase activity in ants (Ayre, 1967; Ricks and Vinson, 1972) or other animals (Martínez del Rio, 1990; Zhang et al., 1993). This might be due to the particular methodical problems arising from the quantification of invertase in animals whose carbohydrate metabolism is highly active. Invertase usually is quantified via the release of glucose from sucrose. Both substrate and product of the enzymatic reaction can be present at varying concentrations in the extract used to quantify enzyme activity. Earlier investigations (Ayre, 1963, 1967; Ricks and Vinson, 1972; Zhang et al., 1993) have been based on endpoint determinations of glucose after adding sucrose to extracts of insects (or parts of insects) and likely are hampered by the presence of glucose and/or sucrose in the reaction preparation prior to the enzymatic reaction. These problems might explain why even recent studies of digestive enzymes in ants have chosen indirect methods, such as feeding selected di- or oligosaccharides to living ants and quantifying monosaccharides as putative reaction products in the ants themselves (Boevé and Wäckers, 2003). The drawback of this method is that selected carbohydrates must be fed to cultivated ants, which have no access to other food sources. Otherwise, direct uptake of the monosaccharides, which are quantified as putative reaction products, would alter the outcome of the experiment. Moreover, carbohydrate metabolism does not stop at the level of monosaccharides, which are further metabolized in living organisms. Quantifying intermediate products can at best reveal semi-quantitative results concerning the velocity of the first step, since their quantities are dependent on both the reactions that lead to their production and by later reactions for which they serve as substrates.

To overcome these problems, we developed a method for quantifying invertase in extracts of ants, which is based on repeated and specific quantification of glucose by a spectrophotometrical method. This allows kinetics to be measured, instead of relying on an endpoint determination. Consequently, an equilibrium is obtained prior to the enzymatic reaction, which reflects reactions of any carbohydrates and enzymes that may be present in the extract. Sucrose is added after the

equilibrium has been reached to then quantify invertase activity as newly released glucose.

METHODS AND MATERIALS

Insects and Preparation. The experiment was carried out with ants freshly caught in their natural habitats in the vicinity of Puerto Escondido, Oaxaca, Mexico. Because these ants have different feedings strategies, they were likely to exhibit quantitative differences in invertase activity. Various glands that are located in the head or in the gaster may contribute differently to an ant's overall invertase activity (Ayre, 1967). Ants were, therefore, dissected in "Insect Ringer" solution (10.4 g NaCl, 0.32 g KCl, 0.48 g $CaCl_2$, and 0.32 g $NaHCO_3$ in 1 l water) in order to remove the largest parts of the content of head and gaster. Care was taken to include maxillary and postpharyngeal glands and the midgut, while poison glands and acid glands were discarded or, at least, emptied. Thoraxes and all chitin components were discarded. The parts putatively containing invertase were weighed and transferred to a 50 mm sodium phosphate buffer (pH 6.0). Preliminary experiments with different species of *Atta*, *Camponotus*, and *Crematogaster* revealed that this pH was close to the optimum for all ant species investigated. However, different pH conditions should be examined for other ant species in order to conduct the assays at an optimal pH. The contents of 1–10 individuals (equivalent to 8–28 mg fresh material) were combined and put into 300 μl buffer to which 50 μl solution of proteinase inhibitor (1 Complete Mini Tablet, Roche Diagnostics, Mannheim, Germany in 1.5 ml water) had been added. The material then was homogenized with sand and cleared by micromembrane filtration ("Rotilabo Spritzenfilter," 13 mm, 0.2 μm Nylon, Carl Roth, Karlsruhe, Germany). After clearing, the extracts were stored for ca. 1 hr at 4°C.

Quantification of Invertase. The quantification of enzyme activity is based on quantifying glucose released from sucrose with the Glucose (HK) Assay Kit (Sigma-Aldrich, Steinheim, Germany. The kit combines hexokinase and glucose-6-phosphate dehydrogenase). Ten microliters of extract and 100 μl HK reaction solution (prepared according to manufacturer's protocol) were introduced into cuvettes (70 μl micro disposable cuvettes, Plastibrand®, Brand, Wertheim, Germany) and placed immediately into a photometer (Genesys 20 Spectrophotometer, ThermoSpectronic, Cambridge, UK). A mixture of 10 μl buffer and 100 μl HK reaction solution served as a blank. Absorption was quantified at 340 nm every 5 min until a steady state was reached, usually by 30–45 min. In cases of very high initial absorptions (>0.3) and/or high increases in absorption, samples could be further diluted with HK reaction solution, since high initial values resulted from high amounts of glucose (absolute values) and/or sucrose and invertase (high increases) and, thus, were generally correlated with high invertase activities. After the steady state had

been reached, 20 μl sucrose solution (250 mg sucrose in 1 ml water) were added, and absorption was further quantified at regular intervals for 1.5–2 hr. Invertase activity was calculated from the slope of the linear increase in absorption after adding sucrose. For each ant species, 5–7 quantifications were conducted with different ants (usually representing different colonies). For each sample (i.e., ant colony), two extractions were conducted with different numbers of ants, and two replicates per extract were used for analysis; means were calculated from these four measurements.

Standard Curves. Standardization was conducted by quantifying defined amounts of glucose (D-Glucose, Sigma-Aldrich; three replicates per glucose concentration) under the same experimental conditions, and by subjecting purified invertase to the same experimental procedure. Of a 0.01 units ml^{-1} solution of invertase in TRIS–HCl buffer, pH 4.5 (invertase from baker's yeast, ca. 300 units mg^{-1} solid, Sigma-Aldrich, pH according to supplier's suggestion), different volumes (0, 2.5, 5, 10, and 15 μl) were diluted with TRIS–HCl buffer to a volume of 20 μl and mixed with 200 μl HK reaction solution. Sucrose (20 μl of a 0.25 g ml^{-1} solution) was added after 15 min, and absorption was quantified every 10 min for at least the next 30 min (three replicates per concentration of invertase). Ant invertase activity, thus, can be expressed as ng glucose released per min and per mg ant fresh material, or as units (with purified invertase as standard).

RESULTS AND DISCUSSION

The use of purified invertase under the experimental conditions as described above resulted in a linear increase of absorption over time after addition of the enzyme's substrate, sucrose (Figure 1A). Increases in absorption were then linear for at least 1.5 hr (personal observations), and the slopes of these curves were highly correlated with invertase activity. The resulting calibration curve is linear from 0 to ca. 400 n units μl^{-1} and then tends to reach saturation (insert in Figure 1A).

Different ant species were used to quantify invertase activity in tissue of freshly caught animals. In contrast to the curves observed for purified invertase, ant extracts first showed an increase in absorption, which resulted from the presence of the substrate (sucrose) as well as the product (glucose) of the enzymatic reaction in the extract (Figure 1B). Depending on the species and the number of ants used, 15–45 min were required to reach the equilibrium, after which sucrose could be added. Addition of sucrose solution first resulted in a slightly reduced absorption due to dilution effects by the added volume of sucrose solution (Figure 1B). After 10–15 min, the resulting curves showed almost linear slopes, and invertase activity calculated from these slopes differed significantly among the species tested (Table 1). Variability among ant species was much higher than within a species, and

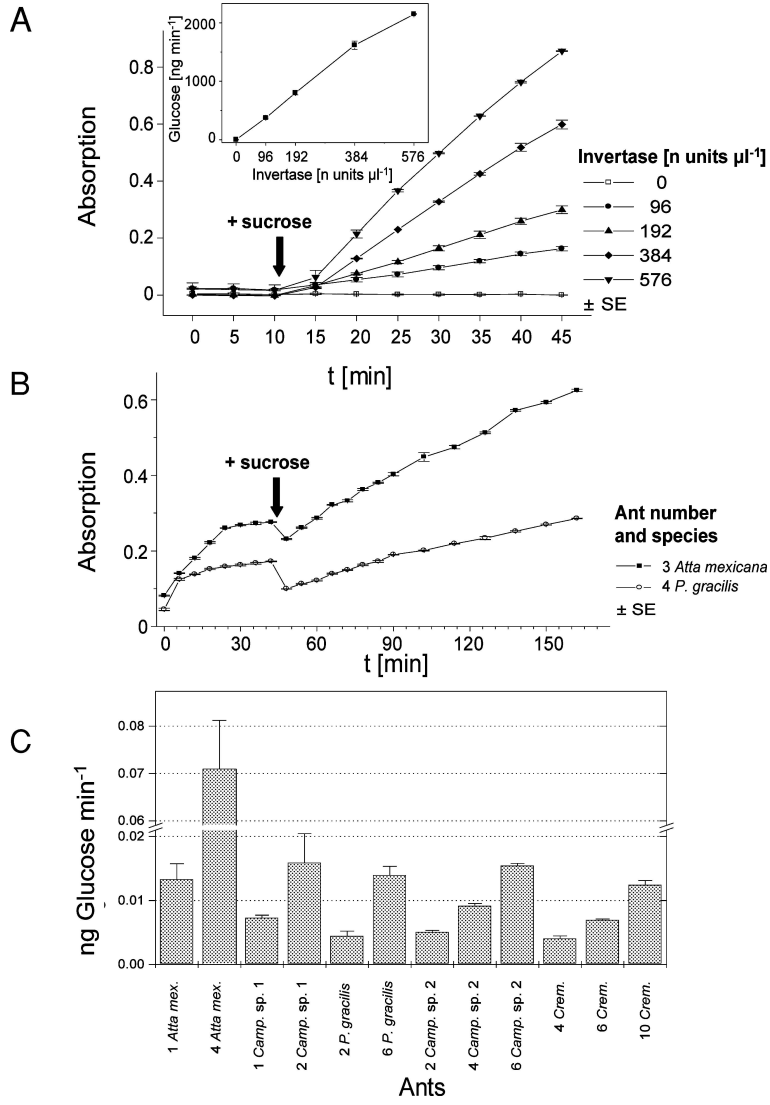

FIG. 1. Quantification of invertase and validation of the method. Time courses in absorption are given separately for purified invertase (A) and extractions of two ant species (B). Note the time at which sucrose was added. Use of the slopes of the curves representing different amounts of purified invertase for quantification of activity revealed an almost linear calibration curve (insert in panel A). Use of different numbers of ants (C) revealed linear dose–activity relations. *Atta mex.*, *Atta mexicana; Camp.*, *Camponotus; Crem., Crematogaster*; *P. gracilis*, *Pseudomyrmex gracilis*.

TABLE 1. MEAN INVERTASE ACTIVITIES IN DIFFERENT ANT SPECIES

	Atta mex.	*Camp.* 1	*P. gracilis*	*Camp. 2*	*Crem. spec.*
Activity (mean)	46.2	24.4	28.6	14.6	17.3
SE	5.4	3.9	6.3	0.9	2.3
N	6	4	5	6	5

Note. Invertase activity is given in ng glucose released per mg ant tissue per min; means marked with different letters are significantly different ($P < 0.05$ according to LSD *post hoc* analysis). *Atta mex*., *Atta mexicana; Camp*., *Camponotus; Crem., Crematogaster*; *P. gracilis*, *Pseudomyrmex gracilis*.

in general the values obtained from ants belonging to the same colony (genetically similar and usually having fed on the same food sources) were more similar than those obtained from ants from different colonies. When varying numbers of ants were extracted, an almost linear ant number—invertase activity relationship was found (Figure 1C).

The method described here allows the easy quantification of invertase activity in extracts of the digestive tracts of ants, and it should be applicable to other arthropods. The method is easy, does not require expensive or elaborate equipment, and can be applied under field conditions. Because the method measures enzyme activity, it is not suitable for identifying the presence of isoenzymes or for determining whether the enzyme is synthesized by the animal itself or, rather, is the product of endosymbiotic microorganisms. However, the method reliably measures the activity of a digestive enzyme and provides an analysis of the digestive capacity of the insect—or insect organ—used for extraction.

(Received July 6, 2004; accepted October 24, 2004)

Abstract—Interactions between the phytohormones ethylene, salicylic acid (SA), and jasmonic acid (JA) are thought to regulate the specificity of induced plant defenses against microbial pathogens and herbivores. However, the nature of these interactions leading to induced plant volatile emissions during pathogen infection is unclear. We previously demonstrated that a complex volatile blend including (*E*)-β-ocimene, methyl salicylate (MeSA), and numerous sesquiterpenes was released by tobacco plants, *Nicotiana tabacum* K326, infected with an avirulent/incompatible strain of *Pseudomonas syringae* pv. *tomato* (*Pst* DC3000). In contrast, a volatile blend, mainly consisting of MeSA and two unidentified sesquiterpenes, was released by plants infected with *P. syringae* pv. *tabaci* (*Pstb*) in a virulent/compatible interaction. In this study, we examined the interaction of multiple pathogen stresses, phytohormone signaling, and induced volatile emissions in tobacco. Combined pathogen infection involved the inoculation of one leaf with *Pst* DC 3000 and of a second leaf, from the same plant, with *Pstb*. Combined infection reduced emissions of ocimene and MeSA compared to plants infected with *Pst* DC 3000 alone, but with no significant changes in total sesquiterpene emissions. In the compatible

interaction, *Pstb* elicited a large ethylene burst with a peak emission occurring 3 days after inoculation. In contrast, the incompatible interaction involving *Pst* DC3000 displayed no such ethylene induction. *Pstb-induced* ethylene production was not significantly altered by *Pst* DC3000 in the combined infection. We postulated that *Pstb*-induced ethylene production may play a regulatory role in altering the typical volatile emission in tobacco in response to *Pst* DC3000 infection. To clarify the role of ethylene, we dynamically applied ethylene to the headspace of tobacco plants following infection with *Pst* DC3000. Consistent with *Pstb*-induced ethylene, exogenous ethylene reduced both ocimene and MeSA emissions, and selectively altered the ratios and amounts of induced sesquiterpene emissions. Our findings suggest that ethylene can regulate the magnitude and blend of induced volatile emissions during pathogen infection.

Key Words—Ethylene, jasmonic acid, *Nicotiana tabacum*, plant volatiles, *Pseudomonas syringae*, salicylic acid.

INTRODUCTION

The interactions between plants and microbial pathogens are specific, complex, and dynamic, often resulting in either disease (compatible interaction) or resistance (incompatible interaction). In an incompatible interaction, a plant mounts a rapid response to a virulent pathogen that leads to localized cell death at the site of infection; this in turn prevents further pathogen infection. Incompatible interactions are usually associated with a hypersensitive response (HR), which includes localized cell death and the appearance of necrotic flecks at the site of infection. In contrast, many compatible interactions result in slow, "normosensitive" (normal/expected sensitive response) cell death that spreads beyond the site of infection by a virulent pathogen. Because the complexity of plant responses, most studies on plant-pathogen interactions have focused on a single pathogen in a particular plant (Jeger and Spence, 2001). However, complexes of diseases commonly occur within a plant during its lifetime. In many cases, the induction of plant responses by one type of stress interferes with plant response against the other. These interactions should set the framework for future research in plant pathology in order to promote long-term plant health and crop sustainability (Jeger and Spence, 2001). So far, most studies on plants with multiple stresses have focused on the pre-inoculation of plants with one pathogen and the subsequent examination of plant responses to a secondary pathogen infection (Sticher et al., 1997; van Loon et al., 1998). In this study, we examine a different situation, namely the attack of multiple bacterial pathogens at the same time.

Despite the complexity of host responses to different pathogens, the interactions of three phytohormones ethylene, salicylic acid (SA), and jasmonic acid (JA) are believed to regulate the specificity of plant defense responses (Dong, 1998; Reymond and Farmer, 1998). Ethylene regulates a variety of growth and

developmental processes, but it also mediates responses to a range of biotic and abiotic stresses in higher plants (Bleecker and Kende, 2000; Ciardi and Klee, 2001). Increased ethylene production from infected plant tissue has been reported for numerous pathogens (Boiler, 1991), and the exogenous application of ethylene can induce the accumulation of defense-related enzymes (Ecker and Davis, 1987). Ethylene is an important signaling component in plant-pathogen interactions, but its role in pathogenesis and resistance is occasionally ambiguous (Knoester et al., 2001). Accumulating evidence demonstrates that ethylene signaling plays a significant role in resistance against some fungal, bacteria, and viral diseases. For example, tobacco expressing the dominant *Arabidopsis etrl-1* gene, a mutant allele that confers ethylene insensitivity to plants (Schaller and Bleecker, 1995), is susceptible to what is otherwise non-pathogenic soil fungi, the *Pythium* spp. (Knoester et al., 1998; Geraats et al., 2002). Ethylene also increases disease symptom development. For example, increased ethylene levels stimulate the expansion of lesions caused by tobacco mosaic virus (TMV) in tobacco (Knoester et al., 2001). In tomato, the ethylene-insensitive mutant *Never ripe* shows a significant reduction in disease symptoms compared to the wild type after inoculation with virulent strains *of Fusarium oxysporum*, *Pseudomonas syringae* pv. *tomato*, and *Xanthomonas campestris* pv. *vesicatoria* (Lund et al., 1998).

SA has been recognized as a central molecule in the signal transduction pathway leading to systemic acquired resistance (SAR) to pathogens (Sticher et al., 1997). It is well established that endogenous SA accumulates at the site of HR in tobacco after inoculation with TMV (Malamy et al., 1990). Additionally, exogenous SA induces the expression of pathogenesis-related (PR) genes and decreases disease symptoms both in tobacco and *Arabidopsis* (White, 1979; Uknes et al., 1992, 1993). JA, a ubiquitous wound signal known to activate various defenses against herbivores, is also involved in the activation of disease resistance and various defense-associated responses in plants (Pieterse et al., 1998; Kenton et al., 1999; van Wees et al., 2000). Cross-talk occurs among SA, JA, and ethylene-dependent signaling pathways in fine-tuning the defense reactions, but is complicated and poorly understood. There are examples indicating that SA, JA, and ethylene-dependent defense pathways can affect each other's signaling in positive or negative ways, with some interactions occurring at the level of phytohormone production (Lund et al., 1998; Reymond and Farmer, 1998; Pieterse and van Loon, 1999; van Wees et al., 2000; Pieterse et al., 2001; O'Donnell et al., 2003).

The complex array of chemical responses that plants display during pathogen attack includes the induced emissions of volatile organic compounds (Croft et al., 1993; Buonaurio and Servili, 1999; Cardoza et al., 2002; Huang et al., 2003). In plant-insect interactions, both JA and ethylene are involved in herbivore-induced plant volatile emissions (Schmelz et al., 2003a, b, c). Plant volatiles have

established roles in host recognition by many pest insects (Bernays and Chapman, 1994) as well as functioning as an indirect defense by attracting natural enemies of the insect herbivores (Turlings et al., 1990; De Moraes et al., 1998). Compared to insect-induced plant volatile emissions, the role of pathogen-induced volatile emissions is less clear. However, multiple studies have implicated that volatile emissions from pathogen-infected plants may be in part responsible for the early suppression of pathogen growth (Croft et al., 1993; Wright et al., 2000; Cardoza et al., 2002). Unlike insect-induced volatile emissions, the involvement of phytohormone signals in triggering pathogen-induced plant volatile emissions is largely unexplored.

We previously reported that a complex volatile blend including (*E*)-β-ocimene, linalool, methyl salicylate (MeSA), indole, caryophyllene, β-elemene, α-farnesene, and two unidentified sesquiterpenes are emitted by tobacco plants, *Nicotiana tabacum* K326, infected with the avirulent/incompatible strain of *Pseudomonas syringae* pv. *tomato* (*Pst* DC3000). In contrast, a volatile blend consisting primarily of MeSA and two unidentified sesquiterpenes was released by plants infected with *P. syringae* pv. *tabaci* (*Pstb*) in a virulent/compatible interaction (Huang et al., 2003). Here, we examine the interactions between compatible and incompatible *P. syringae* strains and their impact on the host plant simultaneously. Specifically, we compare differences in volatile emissions among plants infected with *both Pst* DC3000 and *Pstb*, but on different leaves, and plants infected with either of the two; we then measure endogenous SA and JA levels at different times after dual inoculation with these two strains. We further examine possible differences in ethylene production among plants infected with *Pst* DC3000, *Pstb*, or both of them but on different leaves. Based on results from these experiments, we postulated that *Pstb*-induced ethylene production may play an important regulatory role in altering the typical volatile emissions in response to *Pst* DC3000 infection. To clarify the role of ethylene, we dynamically applied ethylene to the headspace of tobacco plants inoculated with *Pst* DC3000 to study changes in volatile emissions by plants after the infections. Possible interactions among ethylene, SA, and JA were also studied by measuring endogenous SA and JA levels in the plants after ethylene application.

METHODS AND MATERIALS

Plant Material. Seeds of tobacco *(Nicotiana tabacum* strain K326) were sown in a commercial soil mix (MetroMix 300, Scotts-Sierra Horticultural Company, Marysville, OH, USA) and grown in an environmental chamber (E15, Control Environmental Limited, Manitoba, Canada) at 25°C, and a relative humidity of 60 to 70%. Illumination with 400W metal halide and high-pressure sodium lamps provided a photoperiod of 12:12 hr (L:D). After 16 days, the soil was gently

washed from the roots of seedlings with tap water, and each seedling was transferred to a 1.0 l plastic cup containing a nutrient solution described by Baldwin and Schmelz (1994) with modifications as follows (mM): KNO_3, 1; NH_4NO_3, 0.5; $Ca(NO_3)_2.4H_2O$, 0.5; $MgSO_4.7H_2O$, 0.75; KH_2PO_4, 0.5; NaCl, 0.25; K_2S0_4, 0.25; Fe-Na-EDTA, 0.06; H_3BO_3, 0.05; $MnCl_2.4H_2O$, 0.015; $ZnSO4.7H_2O$, 0.002; $CuSO_4.5H_2O$, 0.00025; $Na_2MoO_4.2H_2O$, 0.0002. The nutrient solution in each cup was replenished every 10 days. Plants were used for experiments about 30 days after seeds were planted and had 7 to 8 leaves including the newly emerged leaf.

Bacterial Cultures and Plant Inoculations. P. syringae pv. *tomato* DC3000 (*Pst*DC3000) (Whalen et al., 1991) was grown in King's medium B broth (King et al., 1954), supplemented with 50 μg/ml rifampicin for 18 hr at 28°C on a shaker at 200 rpm. *P. syringae* pv. *tabaci* (*Pstb*, Department of Plant Pathology, University of Florida, FL) was grown the same way, but with no rifampicin. Both *Pst* DC3000 and *Pstb* were stored in 15% glycerol at −70°C for later use.

One day prior to plant inoculations, the bacterial strains were cultured in King's medium B as described above. Bacterial cells were collected by centrifugation at 4000 g for 15 min and resuspended in 10 mM $MgCl_2$. The density of bacterial cell suspensions was determined as colony-forming units/ml (CFU/ml) at 600 nm with a Spectro 22 spectrophotomer (Labomed, Inc., Culver city, CA) (1 $OD_{600nm} = 10^9$ CFU/ml) and adjusted to 4×10^6 CFU/ml in 10 mM $MgCl_2$ for *Pst* DC3000 and 4×10^7 CFU/ml for *Pstb*. All bacterial suspensions were supplemented with 400 μl/l of Silwett L-77 (OSI Specialties, Inc., Friendly, WV) to help cells adhere to the leaf surface. Plants were inoculated by dipping the whole plants or selected leaves in a bacterial suspension for 20 sec.

Volatile Collection and Analysis from Plants Inoculated with Bacterial Pathogens. To study the effects of interaction between the avirulent strain *Pst* DC3000 and the virulent strain *Pstb* on volatile emissions of tobacco plants, the 4th leaf of a plant was dipped in *Pst* DC3000 suspension *(Pst* DC3000-C), while the 5th leaf on the same plant was dipped in *Pstb* suspension (*Pstb*-C, Figure 1). The 4th leaf from another plant dipped in *Pst* DC3000 suspension served as one control (*Pst* DC3000), and the 5th leaf from another plant dipped in *Pstb* suspension served as the other control (*Pstb*). Thus, in the combined infection, collected volatiles represent the combined emissions from *Pst* DC3000- and *Pstb*-infected leaves. This design was selected because no systemic induction of volatiles was detected from uninfected leaves on infected plants in a preliminary study. Within 1 hr after inoculation, treated plants were transferred from the original hydroponic cups to glass dishes (40 mm height × 80 mm diam.) containing 130 ml of hydroponic solution. Individual plants along with the dish were then placed inside a bell-shaped glass chamber (17.8 cm height × 16.5 cm diam. at base; Analytical Research Systems Inc., Micanopy, FL) (Figure 2). Air, purified by passage through a charcoal column, entered through a hole in the base of the collection chamber at approximately 2 l/min, passed over the plants, and volatiles

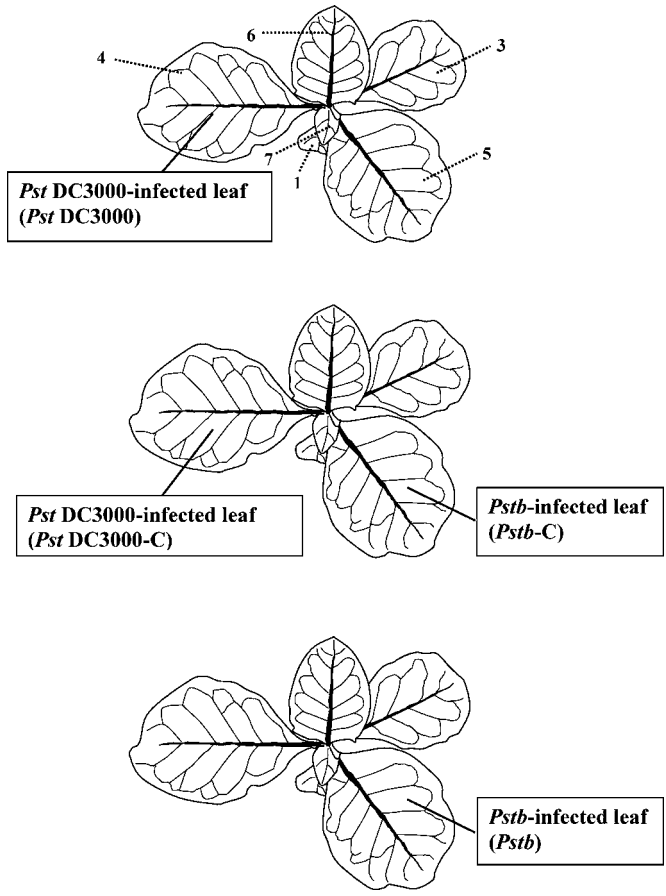

FIG. 1. Experimental design in the treatment of tobacco plants with avirulent *Pst* DC3000, virulent *Pstb*, and the combination of the two strains. Leaves are numbered from the bottom. The 2nd leaf is behind the 3rd and 6th leaves so it is not labeled. The 4th leaf of a plant was dipped in *Pst* DC3000 suspension (*Pst* DC3000-C), while the 5th leaf on the same plant was dipped in *Pstb* suspension (*Pstb*-C). The 4th leaf from another plant dipped in *Pst* DC3000 suspension served as one control (*Pst* DC3000) and the 5th leaf from another different plant dipped in *Pstb* suspension served as the other control (*Pstb*).

were sampled by pulling air from the top of the chamber at a rate of 500 ml/min through a trap containing 25 mg of Super Q adsorbent (Alltech Assoc., Deerfield, IL). The remainder of the air was vented out the bottom of the system. Thus, the quantity of volatiles analyzed represents 1/4 of the total plant volatile emissions. Volatiles were collected continuously in 24-hr periods for 3 days after inoculation.

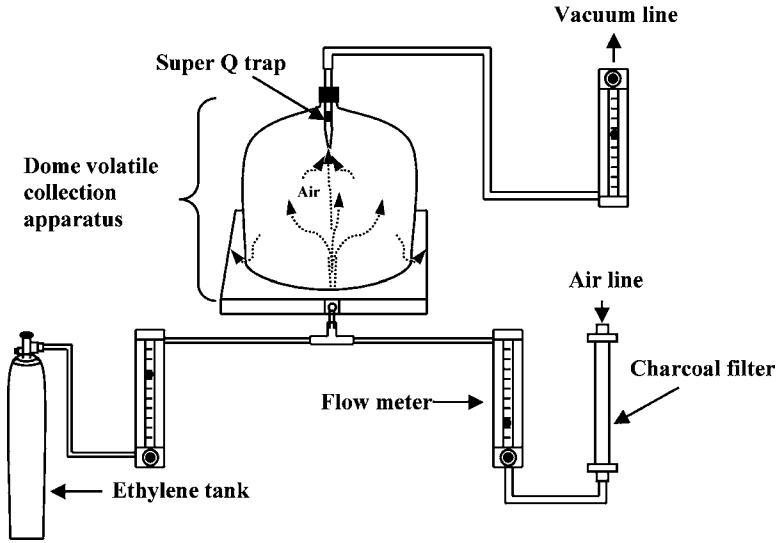

FIG. 2. Plant volatile collection and dynamic ethylene application system for analysis of plant response to bacterial infection. Clean air entered through a hole in the base of the collection chamber, passed over the plants, and volatiles were sampled by pulling air from the top of the chamber through a trap containing Super Q adsorbent. The remainder of the air was vented out the bottom of the system. In the experiment where ethylene was dynamically applied to the headspace of tobacco plants following infection with *Pst* DC3000, both clean air and air with ethylene from the tank were regulated to various flow rates to give final ethylene concentrations of 0, 10, 30, and 100 nl/1.

Compounds were eluted from the collection trap and analyzed as described by Huang et al. (2003). Each experiment was replicated 4 times.

Analysis of JA and SA. Plants were treated as described for the induction of volatiles (Figure 1). Healthy plants with one leaf dipped in 10 mM $MgCl_2$ were used as blank controls. Leaves exposed to each treatment were sampled at 0, 3, 6, 12, 24, and 48 hr post-inoculation, ground under liquid nitrogen, and stored at -70°C prior to hormone analysis. Five replicates for each time point were obtained for plants under the different inoculation treatments. The extraction and quantitative analysis of JA and SA followed the protocol of Engelberth et al. (2003).

Ethylene Analysis. To investigate whether plants produce ethylene in response to *Pst* DC3000 or *Pstb* infection, plants were inoculated by submerging their aerial portions either in a suspension of *Pst* DC3000 or *Pstb*. Control plants were mock-inoculated the same way but without bacteria cells. Treated leaves were detached from each plant at 0, 1, 2, 3, and 4 days post-inoculation of *Pst*

DC3000, while plants inoculated with *Pstb* were sampled at 0, 1, 2, 3, 4, 5, 6, and 7 days post-inoculation. Each detached leaf was placed into an 80-ml test tube sealed with a rubber septum. After 45 min, a 1-ml gas sample was withdrawn from the headspace with a syringe and analyzed by gas chromatography with an HP-5890 GC with injector, oven, and flame ionization detector temperatures of 150, 80, and 250°C, respectively, and an HayeSep Q column (80/100 mesh, 6 feet × 0.125 inches × 0.085 inches i.d., Alltech, Deerfield, IL) using nitrogen carrier gas flow rate of 100 ml/min. Quantification was based on an external standard curve constructed from 1-ml injections of known ethylene standards (Kao and Yang, 1983). Individual leaves were weighed, and ethylene production was calculated as nl g^{-1} hr^{-1}. Three replicates for each time point were obtained for plants under the different inoculation treatments. This experiment was repeated twice. Ethylene production was also measured in plants that were inoculated with avirulent and virulent strains simultaneously as described for the induction of volatiles (Figure 1).

Exogenous Application of Ethylene to Pst DC 3000-infected Plants. Based on *Pst* DC3000- and *Pstb*-induced ethylene emission patterns, we designed an experiment to assess the potential role of ethylene in regulating volatile emissions of plants in response to *Pst* DC3000 infection. In contrast to traditional application of ethylene that is added into a sealed container where a plant has no air exchange from outside, ethylene was dynamically applied to the headspace of tobacco plants following infection with *Pst* DC3000 by mixing air containing ethylene (1 μl/1; Boc Gases, Riverton, N.J.) with purified air. Both were regulated to give final ethylene concentrations of 0, 10, 30, and 100 nl/1 of air passed through a hole in the base of the collection chamber (Figure 2). The total air flow into each collection chamber was proximately 500 ml/min, 90% of which was sampled by pulling air through the filter trap. To study possible effects from ethylene alone, healthy plants were dynamically tested with ethylene at 100 nl/1. Collections and analyses of volatile organic compounds were performed as described above. To examine possible effects of ethylene on endogenous JA and SA levels in *Pst* DC3000 infected plants, plants were dipped in a) 10 mM $MgCl_2$ alone (control), or b) *Pst* DC3000 suspension alone (*Pst* DC3000), or c) *Pst* DC3000, then with 100 nl/1 ethylene to its headspace (*Pst* DC3000 + ethylene), or d) 10 mM $MgCl_2$ with 100 nl/1 ethylene applied in the headspace (ethylene). Different plants in each treatment were sampled at 0, 6, 12, 24 and 48 hr post-inoculation. Sample preparation and analysis for JA and SA were performed as described above. Five replicates for each time point were obtained for plants under the different inoculation treatments.

Statistical Analysis. All data were subjected to log (x + 1) transformations because the original data did not meet the assumptions of normality and homogeneity of variance required by ANOVA. Data generated from all the experiments were analyzed as a two way factorial design using Proc GLM except for the

experiment of ethylene measurement in the combined infection where randomized complete block design was used (SAS Institute, 1999). Significant ANOVAs were followed by Tukey's HSD test to separate means.

RESULTS

Interactions between Avirulent and Virulent Strains on Volatile Emissions. When one leaf of a plant was infected with *Pst* DC3000 and another leaf from the same plant with *Pstb*, the amount of (*E*)-β-ocimene emitted from plants with combined infection was significantly reduced ($P < 0.05$) and 30%, 31%, and 27% of that from plants with a single leaf infection (SLI) of *Pst* DC3000 on day 1, 2 and 3, respectively (Figure 3). Similarly, the combined infection produced only 27% and 18% of the MeSA found in the *Pst* DC3000 SLI on days 1 and 2, respectively (Figure 3A, B). In contrast, total sesquiterpene emission was not significantly altered by the combined infection except for SQ1 and 2 on day 2. Most of the sesquiterpenes in the combined infection were attributable to established patterns from the *Pst* DC 3000-infected leaves on day 1 and from the *Pstb*-infected leaves on day 3 (Figure 3C).

Interaction of Avirulent and Virulent Strains on Endogenous JA and SA. Leaves infected with *Pst* DC3000, both from plants with single leaf infection (SLI) and combined plant infection (CPI), produced both free and conjugated SA in significantly higher amounts than those infected with *Pstb* (whether from *Pstb* or *Pstb*-C plants) or controls (Figure 4A, B). Both free and conjugated SA levels increased rapidly and in similar amounts in the *Pst* DC3000-infected leaf from the CPI plant and the SLI plant infected with *Pst* DC3000 alone, except at 12 hr post-inoculation, when there was a statistically significant difference in the level of free SA ($P < 0.05$). The leaf infected with *Pst* DC3000 did not affect either free or conjugated SA levels in the other leaf infected with *Pstb* on the same plant compared to the leaf infected with *Pstb* on the SLI plant. Interestingly, JA was induced in higher amounts from leaves infected with *Pstb* alone ($P < 0.05$) when its free SA levels were low at 6 hr post-inoculation (Figure 4C). Likewise, Free SA levels in all *Pst* DC3000 infected leaves at this time point were high when JA levels were either lower than controls or not significantly different from controls.

Ethylene Production. Inoculation of tobacco plants with the virulent strain *Pstb* resulted in a large burst of ethylene emission compared to control plants treated with surfactant alone (Figure 5A). Ethylene was detected in higher amounts than controls at 2 days post-inoculation ($P < 0.03$). Substantial production occurred at 3 days post-inoculation; the average production rate was 252 nl g^{-1} hr^{-1}, almost 345-fold higher than control ($P < 0.001$). The *Pstb* induced ethylene burst declined but remained significantly elevated through day 6. Unlike *Pstb*, plants treated with *Pst* DC3000 did not release increased levels of ethylene (Figure 5B).

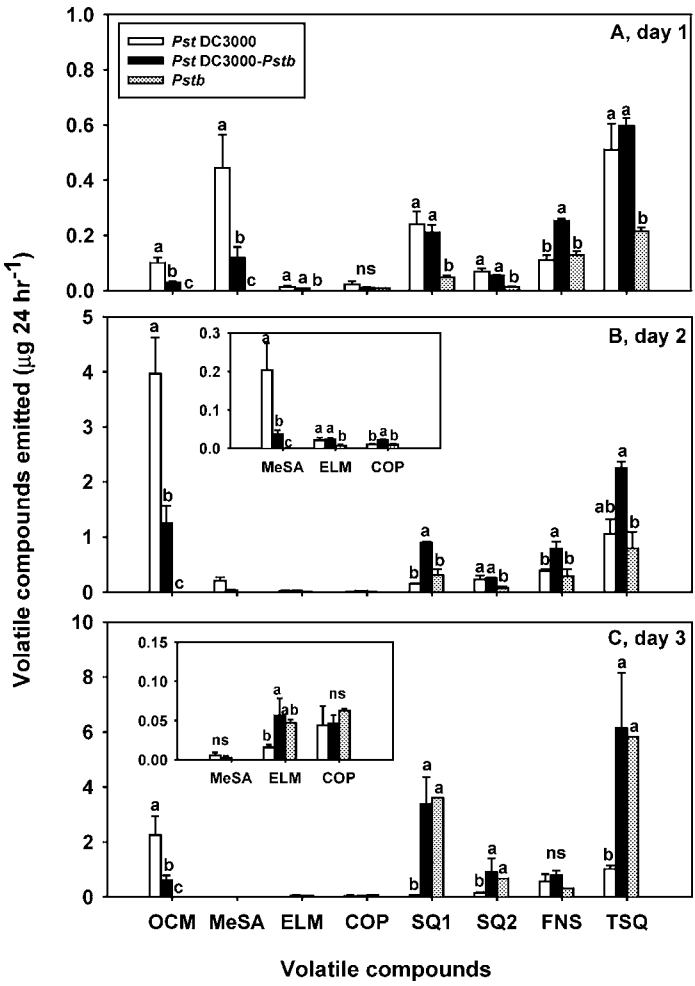

FIG. 3. Mean (+SE) volatile emissions (μg/24 hr^{-1}) from tobacco plants ($N = 4$) infected with both *Pst* DC-3000 at a titer of 4×10^6 CFU/ml and *Pstb* at a titer of 4×10^7 CFU/ml but on the different leaves (Figure 1) compared to control plants infected with either one of them alone. Volatiles shown were collected in 24-hr intervals, beginning immediately after inoculation and continuing for 3 days. Volatile compound abbreviation: OCM, (E)-β-ocimene; MeSA, methyl salicylate; ELM, β-elemene; COP, caryophyllene; SQ1, unknown sesquiterpene 1; SQ2, unknown sesquiterpene 2; FNS, (E)-α-farnesene; TSQ, total sesquiterpenes. Inserts shows an expanded view of amounts of MeSA, ELM, and COP emitted. Bars not sharing the same letters represent significant differences ($P < 0.05$, Tukey's HSD test).

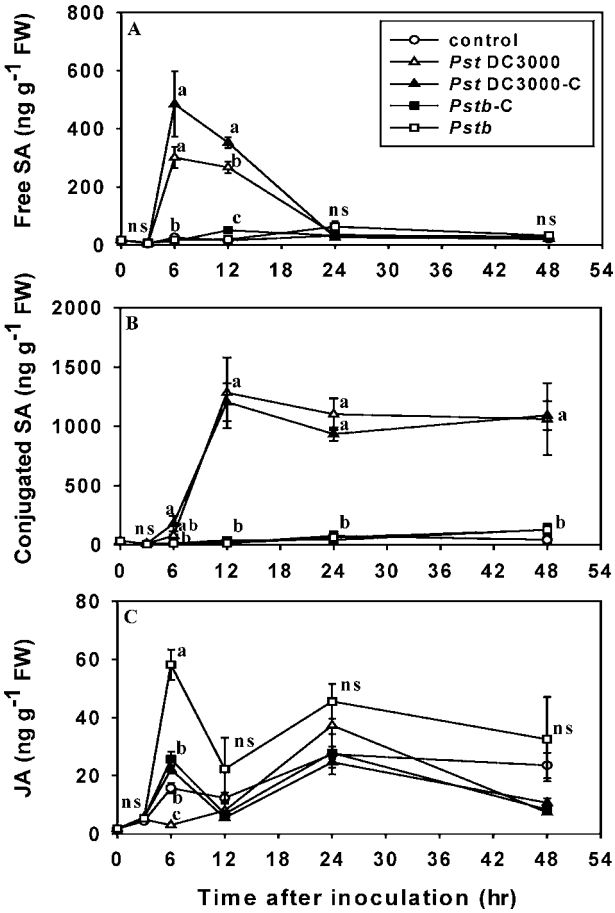

FIG. 4. Mean (±SE) A) free SA, B) conjugated SA, and C) JA levels (ng g^{-1} FW, $N = 5$) in individual tobacco leaves following inoculation of leaves with surfactant alone (control, ○), *Pst* DC3000 alone(△), *Pstb* alone (□), or plants with both *Pst* DC3000 (*Pst* DC3000-C, ▲) and *Pstb* (Pstb-C, ■) but on the different leaves (Figure 1). Hormonal analysis was performed only on the inoculated leaves. The titer of bacteria suspensions were 4×10^6 CFU/ml for *Pst* DC3000 and 4×10^7 CFU/ml for *Pstb*. Within each time point, symbols not sharing the same letters represent significant difference ($P < 0.05$, Tukey's HSD test).

Leaves infected with *Pst* DC3000 from combined plant infection (CPI) released very low levels of ethylene and were not significantly different from leaves infected with *Pst* DC3000 alone (Figure 5C). Likewise, leaves infected with *Pstb*, both from plants with single leaf infection (SLI) and CPI, produced similar but large amounts of ethylene.

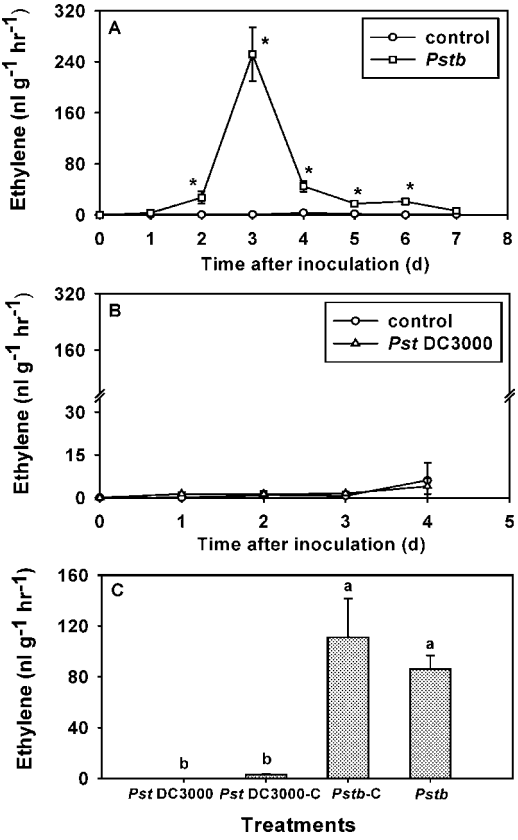

FIG. 5. Mean (±SE) ethylene emissions (nl g^{-1} hr^{-1}) from tobacco plants ($N = 3$) infected with either (A) *Pstb* (□) at a titer of 4×10^7 CFU/ml or (B) *Pst* DC-3000 (Δ) at a titer of 4×10^6 CFU/ml. (C) Mean (+SE) ethylene emission (nl g^{-1} hr^{-1}) from tobacco plants ($N = 5$) after 3 days of infection with both *Pst* DC-3000 and *Pstb* (using the inoculums above) but on the different leaves (Figure 1) compared to plants infected with either one of them alone. Control plants (O) (from A and B), were mock treated with the leaf surfactant Silwett L-77 alone. Asterisks denote significant increases in ethylene above control plants treated with the leaf surfactant alone ($P < 0.05$, Tukey's HSD test). Bars not sharing the same letters represent significant differences ($P < 0.05$, Tukey's HSD test). The experiment was repeated as least twice with similar results.

Interactions between Ethylene and Pst DC3000 on Volatile Emissions and Endogenous Hormones. Control plants with ethylene application emitted only trace amounts of sesquiterpenes and no ocimene or MeSA. Compared to plants infected with *Pst* DC3000 alone, ocimene emission was greatly inhibited in all

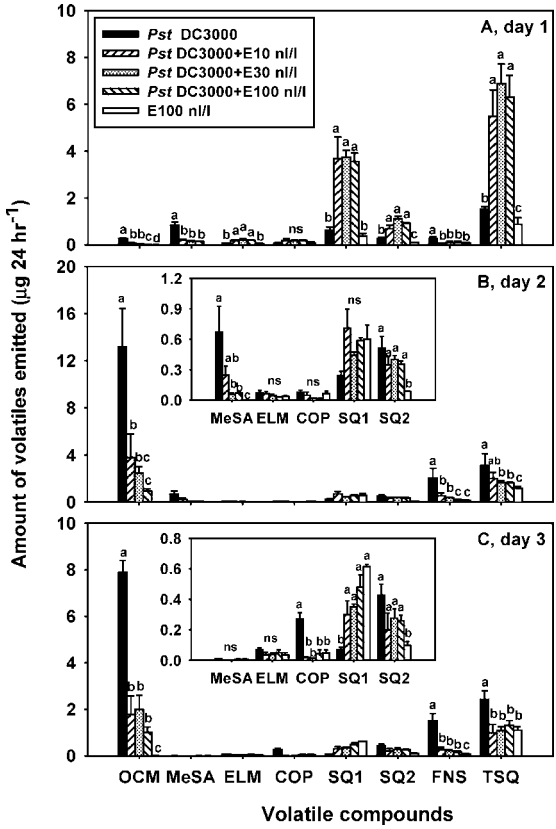

FIG. 6. Mean(+SE) volatile emissions from tobacco plants ($N = 4$) on A) day 1, B) day 2 and C) day 3 infected with *Pst* DC3000 at a titer of 4×10^6 CFU/ml and treated with ethylene at either 0, 10, 30, and 100 nl/1. A separate uninfected control for the highest ethylene treatment (100 nl/1) was also performed. Volatiles were collected in 24-hr intervals, beginning immediately after inoculation and continuing for 3 days. Volatile compound abbreviation: OCM, (*E*)-β-ocimene; MeSA, methyl salicylate; ELM, β-elemene; COP, caryophyllene; SQ1, unknown sesquiterpene 1; SQ2, unknown sesquiterpene 2; FNS, (*E*)-α-farnesene; TSQ, total sesquiterpenes. Inserts shows an expanded view of amounts of MeSA, ELM, COP, SQ1, and SQ2 emitted. Bars not sharing the same letters represent significant differences ($P < 0.05$, Tukey's HSD test).

ethylene treatments, even 10 nl/1 (Figure 6). Likewise, ethylene application significantly reduced MeSA emission from *Pst* DC3000 treated plants (Figure 6A, B). In contrast, the largest effect of ethylene on sesquiterpene emissions occurred on day 1 with a sharp increase in SQ1, SQ2 and elemene emissions, and a decrease in (*E*)-α-farnesene emission. Similar increases and decreases in the *Pst* DC3000-infected

plants treated with ethylene were also found on day 2, but with fewer changes and decreases in total sesquiterpene emissions compared to those treated with *Pst* DC3000 alone. With the exception of (*E*)-β-ocimene emission (Figure 6A, B), the different quantities of ethylene applied did not result in linear dose-dependent increases or decreases in volatile production, suggesting that the ethylene sensitivity threshold was below 10 nl/1. The combination of ethylene and infection resulted in a sustained decrease in free SA below that from plants infected with *Pst* DC3000 alone at 6 and 12 hr post-inoculation, yet there were no significant difference in conjugated SA levels throughout the whole experimental period (Figure 7A, B). Unlike SA, additions of ethylene during infection did not significantly increase the levels of JA. However, healthy plants, which were continuously exposed for 6 hr to ethylene, showed a small yet significant JA increase compared to the untreated control (Figure 7C).

DISCUSSION

Previously, we reported that tobacco plants release qualitatively and quantitatively greater amounts of volatiles in the incompatible interaction with *Pst* DC3000 compared to those in the compatible interaction with *Pstb* (Huang et al., 2003). Recognizing that both pathogen strains induce volatile emissions in tobacco, we were prompted to examine plant responses to multiple stresses initiated by both avirulent and virulent strains of *P. syringae*, which broadly represent two opposite, but common, outcomes of pathogen infection: disease and resistance. To investigate pathogen-pathogen interactions in the mediation of induced plant volatile emissions, we co-infected individual plants with one leaf inoculated with *Pst* DC3000 and the other with *Pstb*. Interestingly, the combined infection significantly reduced emissions of ocimene and MeSA compared to plants infected with *Pst* DC3000 alone, but sesquiterpene emissions were not dramatically affected except for SQ1 on day 2 (Figure 3). After examining free SA, conjugated SA, and JA, we found no convincing evidence that these changes were linked to alterations in the induced volatile emissions unique to the combined infection (Figure 3, 4).

The phytohormone ethylene is an important regulator of plant responses to pathogen infection (Bleecker and Kende, 2000; Ciardi and Klee, 2001). In the compatible interaction, *Pstb* triggered tobacco plants to produce an extremely large ethylene burst from 2 to 6 days after inoculation concomitant with the occurrence of disease symptoms; whereas the incompatible interaction involving *Pst* DC3000, which elicited strong HR, displayed no such ethylene induction. This outcome contrasts with the interactions of tobacco and tobacco mosaic virus (TMV), in which the increase in ethylene during an incompatible interaction is greater and more rapid than during a compatible interaction (De Laat and van Loon, 1982). However, there is also ample evidence for a positive correlation

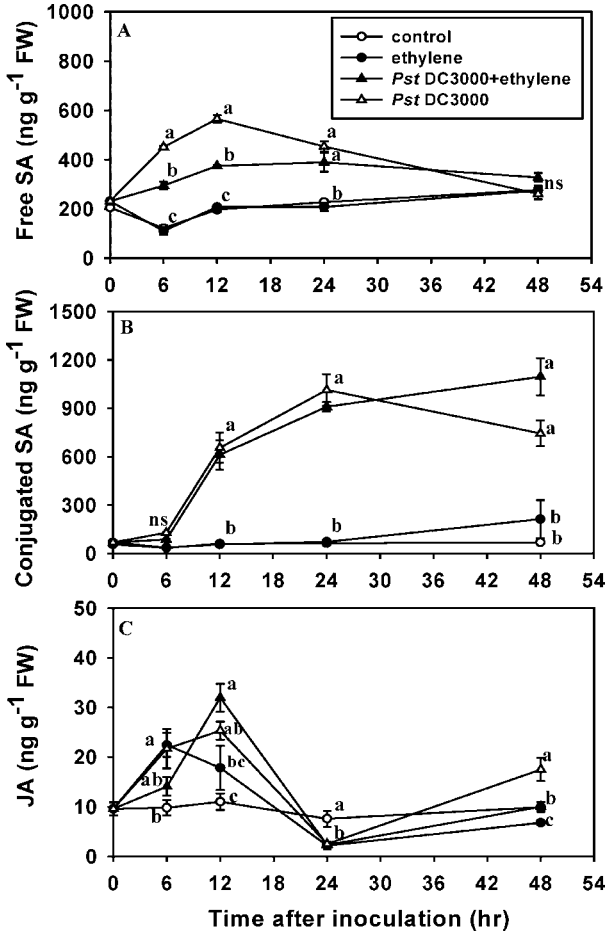

FIG. 7. Mean (±SE) A) free SA, B) conjugated SA, and C) JA levels (ng g^{-1} FW, $N = 5$) following inoculation of tobacco plants with the leaf surfactant alone (control, ○), 100 nl/l ethylene (●), *Pst* DC3000 + 100 nl/l ethylene (▲) or *Pst* DC3000 alone (Δ). Ethylene application was described in details in the Material and Method section. The titer of bacteria suspensions were 4×10^6 CFU/ml. Within each time point, symbols not sharing the same letters represent significant difference ($P < 0.05$, Tukey's HSD test).

of many plant diseases with ethylene production (Goto et al., 1980; Ben-David et al., 1986; Elad, 1990; Boller, 1991; Weingart and Völksch 1997). It is now becoming clear that ethylene plays an important role in the development of disease symptoms in response to certain pathogenic organisms (O'Donnell et al., 2001);

whereas ethylene does not appear to be essential for a resistance response in plants challenged with avirulent bacteria (Bent et al., 1992; Ciardi and Klee, 2001). Additionally, some fungi and bacteria can produce ethylene as a pathogenicity factor (Lund et al., 1998; Knoester et al., 2001). *Pstb* is believed to trigger ethylene production in plants, as this pathogen did not produce ethylene when isolated in culture (Weingart and Völksch, 1997). Importantly, ethylene induction by *Pstb* was not significantly altered in the combined infection (Figure 5C).

Therefore, we proposed that ethylene production induced by *Pstb* may play an important regulatory role in altering *Pst* DC3000-induced volatile emissions in tobacco. The role of ethylene was examined by continuous application to the headspace of *Pst* DC3000-infected plants. Consistent with *Pstb*-induced ethylene, application of ethylene resulted in sharp decreases in both ocimene and MeSA emissions, and also dramatically shifted the sesquiterpene profile. This supports the hypothesis that altered volatile profiles from the combined infection are due to the ethylene signaling pathway activated by *Pstb* from the same plants. The suppression of ocimene and MeSA emissions occurred as early as 1 day after inoculation, immediately prior to significant *Pstb* induced ethylene emission, suggesting that either only small amounts of ethylene emissions would be enough for this volatile inhibition, or some other factors in the ethylene signaling pathway were also involved, most likely ethylene perception (Hoffman et al., 1999; Ohme-Takagi et al., 2000). Ethylene effects on sesquiterpene emissions appear to be more closely linked to actual ethylene production, as they occur later.

SA, JA, and ethylene signaling pathways can be linked to each other in positive and negative ways (Dong, 1998; Reymond and Farmer, 1998; Díaz et al., 2002). We provide an additional example of possible antagonism between JA and SA by showing that *Pst* DC3000-infected leaves had very high free SA levels, but low JA levels not significantly higher than controls treated with leaf surfactant alone. In contrast, *Pstb*-infected leaves had elevated JA levels, but low control levels of SA at 6 hr post-inoculation (Figure 4). Moreover, ethylene alone did not affect SA levels in healthy plants, but it significantly inhibited *Pst* DCS3000-induced free SA levels. There is also evidence that ethylene can affect JA levels in healthy plants (Figure 7). However, we found little clear evidence for cross-talk among SA, JA, and ethylene pathways in the changes of pathogen-induced volatile emissions upon ethylene application or the combined infection in tobacco, except that there was a correlation of less SA with less MeSA emission in *Pst* DC3000-infected leaves after ethylene application, which was not observed in the experiment where plants were infected with both *Pst* DC3000 and *Pstb* simultaneously on different leaves. It is likely that factors in addition to ethylene are involved in alteration and regulation of pathogen-induced volatile emissions in the combination because the effect of interaction of avirulent and virulent pathogens on volatile emissions is more complicated than that from just application of ethylene alone.

Similar to pathogen infection, insect herbivory also stimulates ethylene and volatile emissions. While insect-induced plant volatiles have important roles in the attraction of natural enemies, less is known about the regulation of herbivore-induced volatile emissions. JA has been long considered as an endogenous regulator for insect-induced volatile emissions (Hopke et al., 1994, Schmelz et al., 2003a, b, c); however, a role for ethylene is just beginning to emerge. For example, exogenous applications of the ethylene precursor, 1-aminocyclopropane-l-carboxylic acid, in lima bean enhanced JA-induced emissions of ocimene and hexenyl acetate, but not the homoterpene (*E*)-4, 8-dimethyl-l,3,7-nonatriene (Horiuchi et al., 2001). The addition of ethylene to intact corn seedlings greatly promoted volatile emissions of caryophyllene, bergamontene, farnesene, and indole triggered by insect derived elicitors and JA application (Schmelz et al., 2003 a, b). However, ethylene burst in tobacco, *Nictotiana attenuata*, induced by *Manduca sexta* larvae or the application of its oral secretion suppresses JA-induced nicotine accumulation, yet does not alter the induced volatile emissions, namely the monoterpene linalool and the sesquiterpene bergamotene (Kahl et al., 2000). In the present study, ethylene regulates both the magnitude and blend of pathogen-induced volatile emissions during pathogen infection, probably through regulation of enzymes in volatile biosynthetic pathways. It has been reported that an ethylene responsive enhancer element was identified at the 1-kb upstream genomic region of a myrcene/ocimene synthase gene in *Arabidopsis*, which suggests that ethylene may regulate genes encoding terpene synthases at the transcriptional level in plants (Montgomery et al., 1993). Likewise, pollination-induced ethylene production in petunia (*Petunia hybridd*) flowers strongly down regulates the transcription of benzoic acid/salicylic acid carboxyl methyltransferases (BSMT), which convert the corresponding free acids into volatile methyl esters (Negre et al., 2003). It seems possible that similar ethylene mediated transcriptional regulation may also occur in leaf tissues.

Compared to the well-defined role for volatile emissions as indirect defenses in plant-herbivore interactions, little is known about their role in plant-pathogen interactions. Emission of volatiles from pathogen-infected plants may serve as a direct defense against pathogen infections. For example, lipid-derived volatiles, (*Z*)-3-hexenol and (*E*)-2-hexenal, emitted from *Phaseoltis vulgaris* (L.) leaves during HR response to *P. syringae* pv. *phaseolicola* are highly bactericidal (Croft et al., 1993). Corn-derived volatile compounds, hexenal and octanal, strongly inhibited radial growth of the fungus, *Aspergillus parasiticus* on solid culture media (Wright et al., 2000). MeSA has been shown to inhibit fungal growth *in vitro* (Cardoza et al., 2002), as well as to function as an airborne signal that can activate the expression of defense-related genes in tobacco (Shulaev et al., 1997). Similarly, herbivore-induced ocimene was found to function as an airborne signal in inducing transcript accumulation of an array of defense-related genes in lima bean leaves (Arimura et al., 2002). As a volatile, ethylene is a well-known inducer of necrosis, ripening, chlorosis, and senescence in plants. In the compatible interaction with

virulent *P. syringae*, there was no ocimene emission, much less MeSA at later time, but a dramatic ethylene burst throughout the disease symptom development in tobacco. In contrast, there were large ocimene and MeSA emissions, but no such ethylene induction in the incompatible interactions with avirulent *P. syringae*. Moreover, application of ethylene strongly inhibited ocimene and MeSA emissions, but selectively affected sesquiterpenes from tobacco plants infected with *Pst* DC3000. Possibly, *Pstb* uses ethylene emissions to inhibit other volatile emissions from plants that might compromise their growth in tobacco. This study provides new insights on pathogen-plant-pathogen interactions, especially from attacks by virulent and avirulent strains simultaneously, and provides evidence that ethylene plays an important role in mediating pathogen-induced volatile emissions.

Acknowledgments—We thank Julia Meredith, Peggy Brennan, Amy Howe, and Carolina Briceño (USDA-ARS/CMAVE, Gainesville, FL) for their technical support. We also thank Drs Jeffrey Jones (University of Florida, Department of Plant Pathology, Gainesville, FL) and Paul Paré (Texas Tech University, Department of Chemistry and Biochemistry, Lubbock, TX) for their critical and helpful reviews of the manuscript. This research was supported in part by a grant from Defense Advanced Research Projects Agency (DARPA).

Abstract—Differences in allelochemistry of plants may influence their ability to attract parasitoids. We studied responses of *Diadegma semiclausum* (Hellén), a parasitoid of the diamondback moth (*Plutella xylostella* L.), to inter- and intraspecific variation in odor blends of crucifers and a non-crucifer species. Uninfested Brussels sprout (*Brassica oleracea* L. gemmifera), white mustard (*Sinapis alba* L.), a feral *Brassica oleracea*, and malting barley (*Hordeum vulgare* L.) were compared for their attractivity to *D. semiclausum* in a Y-tube bioassay. Odors from all plants were more attractive to the parasitoid than clean air. However, tested against each other, parasitoids preferred the volatile blend from the three cruciferous species over that of malting barley. Wasps also discriminated between uninfested crucifers: mustard was as attractive as feral *B. oleracea*, and both were more attractive than Brussels sprout. Attractivity of uninfested plants was compared with that of plants infested by larvae of the host *P. xylostella*. Host-infested mustard and Brussels sprout were more attractive than uninfested conspecifics. Interestingly, the volatile blends of uninfested white mustard and infested Brussels sprout were equally attractive. We also compared the volatile composition of different plant sources by collecting headspace samples and analysing them with GC-MS. Similarities of volatile profiles were determined by hierarchic clustering and non-metric scaling based on the Horn-index. Due to the absence of several compounds in its blend, the volatile profile of barley showed dissimilarities from blends of crucifers. The odor profile of white mustard was distinctly different from the two Brassicaceae.

* To whom correspondence should be addressed. E-mail: tibor.bukovinszky@wur.nl

Feral *Brassica oleracea* odor profile was different from infested Brussels sprout, but showed overlap with uninfested Brussels sprout. Odor blends from infested and uninfested Brussels sprout were similar, and mainly quantitative differences were found. *D. semiclausum* appears to discriminate based on subtle differences in volatile composition of odor blends from infested and uninfested plants.

Key Words—*Diadegma semiclausum*, *Plutella xylostella*, *Hordeum vulgare*, *Sinapis alba*, *Brassica oleracea*, olfactometer, headspace volatiles, GC-MS.

INTRODUCTION

Plant-derived infochemicals are important for parasitoids of herbivores in the process of host location (Vinson, 1976; Vet and Dicke, 1992; Tumlinson et al., 1993; Völkl and Sullivan, 2000). The dietary breadth of both herbivores and their parasitoids may influence the degree to which plant odors are used in this process (Vet and Dicke, 1992). In general, odors from uninfested and mechanically damaged plants are easier to detect by a parasitoid than cues from the host, but they represent a weak predictor of host presence (Vet et al., 1991). On the other hand, information from the host itself (i.e., feces, frass, silk) is a more reliable indicator of a host, but is usually more difficult to detect than plant-derived volatiles. The solution to this reliability-detectability problem may rely on herbivore-induced volatiles. These are emitted upon damage by the host and are both reliable and detectable. In natural ecosystems, host-parasitoid interactions take place in habitats composed of several to many plant species, where both the expectancy of the host's presence and the specificity of volatile infochemicals may show great between- and within-plant variation (Takabayashi et al., 1994; De Moraes et al., 1998; Vet, 1999; Gouinguené, 2001). Variation in odors among plant species and cultivars can be greater than between damaged and undamaged conspecific plants (Geervliet et al., 1997), and such differences can be reflected in the attractance of parasitoids to plants (Elzen et al., 1983, 1986; Fox and Eisenbach, 1992; Geervliet et al., 1996). The differential ability of plants to attract natural enemies may even be responsible for further dietary specialization of herbivores exploiting specific plant taxa like the Cruciferae (Yano, 1994). For example, opposing choices at the plant-level could benefit the herbivore and lead to enemy-free space shaping host-parasitoid interactions (Fox and Morrow, 1981; Fox and Eisenbach, 1992; Bigger and Fox, 1997; Gratton and Welter, 1999; Oppenheim and Gould, 2002). If host-parasitoid interactions in ecosystems are to be understood, foraging behavior of parasitoids must be studied in relation to inter- and intraspecific variation in plant-derived infochemicals.

Crucifers are characterized by the presence of glucosinolates and their volatile by-products. These compounds play a role in the host searching behavior of parasitoid species that forage on hosts associated with plants of this family (Read et al., 1970, 1985; Shiojiri et al., 2001; Smid et al., 2002). Other studies show

effects of inter- and intraspecific variation in volatiles of cruciferous plants on their attractivity to parasitoids (Geervliet et al., 1996; Liu and Jiang, 2003; Kalule and Wright, 2004). Fox and Eisenbach (1992) found that *Diadegma insulare*, a parasitoid of larvae of *Plutella xylostella* L., preferred wild crucifers to collards. Higher levels of parasitism of *P. xylostella* by *Cotesia plutellae* were observed on common cabbage than on Chinese cabbage, which was attributed to differences in attractivity of plant odors for the parasitoid (Liu and Jiang, 2003).

Breeding programs involving glucosinolate chemistry largely focus on mammalian toxicity, and the demands of consumers in the utilization of plant organs (Mithen, 2001). Members of the Brassicaceae have undergone extensive breeding, resulting in huge variation in both the composition and the allocation of plant chemicals in different plant organs (Benrey et al., 1998; Mithen, 2001). Besides, the efforts to select for resistance in breeding programs mainly focused on direct defenses, ignoring effects on the third trophic level (Dicke, 1999; Bradburne and Mithen, 2000). It is possible that crucifer breeding programs have changed the apparency of plants not only for herbivores, but also for those parasitoids that use plant-derived infochemicals in habitat and host location. Therefore, domesticated plants might have an altered capacity to attract natural enemies, but experimental evidence is needed to test this assumption (Loughrin et al., 1995; Benrey et al., 1998; Cortesero et al., 2000).

We chose members of the family *Brassicaceae* to study how inter- and intraspecific variation in odor blends influence their ability to attract larval parasitoids. We examined the responses of *Diadegma semiclausum*, a specialist parasitoid of the diamondback moth (*Plutella xylostella*), in olfactometer bioassays. The uninfested plants compared were Brussels sprout, a naturalized population of previously cultivated *Brassica oleracea*, white mustard, and malting barley. The latter species was included in comparisons as a species not related to crucifers and a non-host for *P. xylostella*. Comparisons of host-infested and uninfested plants involved Brussels sprout and mustard.

METHODS AND MATERIALS

Plants. Plants used were malting barley (*Hordeum vulgare* L. cv Video) (Cyperales, Gramineae), white mustard (*Sinapis alba* L. cv Carnaval) (Capparales, Brassicaceae), Brussels sprout (*Brassica oleracea* L. gemmifera cv Cyrus) (Capparales, Brassicaceae), and a naturalized population of *Brassica oleracea* L. This feral population was found in a roadside hollow in 2001, it probably "escaped" from a local farm, and it is unknown how long it has been growing in the wild (Harvey et al., 2003). Plants were reared in a greenhouse compartment under a 16L; 8D photoperiod, 20–28°C, and 40–80% R.H. Plants were sown in ca. 1.2 l pots filled with standard compost (Lentse Potgrond®) with no extra fertilizer

added. To standardize the biomass of the plants to about 25 g, a different number of plants per pot were grown for each species; eighteen for barley (3–4 wk old), nine for mustard (3–4 wk old), and one for Brussels sprout (6–7 wk old) and the feral *B. oleracea* (6–7 wk old). White mustard was tested, when the first flower buds had started to develop. Before testing, each plant was removed from the pot and below-ground plant parts were wrapped in aluminium foil. The plant was then used for behavioral assays or headspace sample collection.

Insects. Diadegma semiclausum (Hellén) (Hymenoptera, Ichneumonidae) was collected from Brussels sprout fields in a woodland area in the vicinity of Wageningen (The Netherlands) and was maintained on *Plutella xylostella* L. (Lepidoptera, Plutellidae) reared on Brussels sprout (8D: 16L photoperiod, 20 ± 2°C and 70% R.H). In the rearing cages, parasitized host larvae were allowed to pupate on paper strips, then transferred into a plastic cage with neither host nor plant material present. Wasps emerging from cocoons were provided *ad libitum* with water and honey. Mated females of 5–10 days of age with no oviposition experience were used in olfactometer bioassays. To obtain infested plants (mustard or Brussels sprout), 20 second or early third instar *P. xylostella* larvae were evenly distributed over a test plant 14–16 hr before the experiment.

Olfactometer Bioassay. To test behavioral responses of individual *D. semiclausum* females to plant odors, a glass Y-tube olfactometer (diam. 3.5 cm, length of stem section 22 cm) was used (for details see Takabayashi and Dicke, 1992). The two arms of the Y-tube were connected to glass vessels containing the odor source. The volume of the containers was five-liter in all comparisons except those involving the feral *B. oleracea*. As this plant had long petioles, we used 30 l containers to accommodate the plants. When an odor source was compared with clean air, a piece of cotton-wool humidified with water was placed into the empty container. While the 5 l containers were directly attached to the olfactometer, the two 30-l containers were attached with a silicon hose. Air was filtered over charcoal and led into each container at 4 l/min. The air was extracted at the base of the olfactometer at 8 l/min. The olfactometer was illuminated from above with high frequency fluorescent lights at an intensity of 30–35 μmol photons/m^2/sec. Wasps were individually tested in the olfactometer, and each wasp was used only once. In order to increase their motivation to search for hosts (Potting et al., 1999), females were transferred from the cage into the Y-tube on a piece of Brussels sprout leaf, damaged by the host but not containing the host itself or its products. The observation started by releasing the wasp at the base of the Y-tube, at 4 cm distance from the opening. Wasps were either walking or flying towards the odor source. A finish line was drawn 1 cm from the sieve at the end of each arm. A choice occurred when a wasp crossed the finish line and did not return to the junction for at least 15 sec. Wasps that did not make a choice within 10 min after release and wasps that did not reach the junction of the olfactometer within 5 min were considered non-responding individuals. Odor sources were replaced after testing

5–7 females, and at least 8 sets of new plants were used for each comparison. To control for possible asymmetries in the set-up, the odor source was moved from one arm of the olfactometer to the other after testing 3–4 females.

The attractiveness of the odor blends from the following uninfested plants were tested against clean air and each other. Brussels sprout, feral *B. oleracea*, mustard, and barley. Odor blends of host-infested Brussels sprout and mustard were compared to uninfested conspecifics, and uninfested mustard was compared to host-infested Brussels sprout. The tests were carried out from March–September 2003.

Collection and Analysis of Headspace Volatiles. Headspace volatiles were collected from all plant sources tested in Y-tube bioassays (except for the *Plutella*-infested mustard), and were analyzed by GC-MS. Four to five samples of each were taken in the period of June-August 2003. Plants prepared for sampling as described in section "*Plants*" were transferred into 30 l collection flasks. Pressurized air was filtered through silica gel, molecular sieves 4A and 13X (Linde), and activated charcoal before entering the flask. The air inlet, air outlet, filters, and sampling jar were connected with 0.8 cm diam. teflon tubing. After the plant was placed into the collection flask, the system was purged for 1 hr at an airflow rate of 500 ml/min to remove volatile contaminants. Subsequently, volatiles were collected in a glass tube containing 90 mg Tenax-TA (20/35 mesh) for 4–5 hr at a flow rate of 150–250 ml/min. Blanks were taken in duplicate from empty collection containers. The collected volatiles were released from the Tenax by heating the trap in a Thermodesorption Cold Trap Unit (Chrompack) at 250°C for 10 min and flushing with helium flowing at 12 ml/min. The released compounds were cryo-focused in a coldtrap (0.52 mm ID deactivated fused silica) at a temperature of −85°C. By ballistic heating of the cold trap to 220°C, the volatiles were transferred onto the analytical column (DB5, 60 m × 0.25 mm ID, 0.25-μm film thickness), which was connected to a Finnigan MAT 95 mass spectrometer. The temperature of the column oven was programmed from 40°C (4 min hold) to 250°C (4 min hold) at a rate of 4°C/min, and the initial helium velocity was 25 cm/sec. The mass spectrometer was operated in the 70 eV EI ionization mode and was scanning from mass 24 to 300 at 0.7 sec/decade. Compounds were identified by comparison of the mass spectra with those in the Wiley 7th/NIST98 library and in the Wageningen Mass Spectral Database of Natural Products and by checking the retention index. Emission rates were measured by quantifying peak areas. Compounds are presented as peak area per liter of trapped air per gram above-ground fresh weight.

Statistical Analysis. A binomial test was used to determine whether preferences of parasitoids were significantly different from a non-preference situation ($p = q = 0.5$, two-tailed, $\alpha = 0.05$). Non-responding wasps were excluded from the analysis. To illustrate the dissimilarities between the odor blends of plants, classification (hierarchical clustering) and ordination (non-metric scaling)

methods were used. Those compounds not present in the blank and detected in at least two replicate samples were included in the analysis. The detected quantities of individual compounds within a sample were considered as variables, and dissimilarities among the 24 plant samples were calculated based on the Horn-index (average link method) (see Krebs, 1989, eqn. 1). We chose this index because the calculated similarities among the volatile blends are supposedly little affected by the number of compounds included in the analysis (Krebs, 1989).

$$R_0 = \frac{\sum[(x_{ij} + x_{ik})\log(x_{ij} + x_{ik})] - \sum(x_{ij}\log x_{ij}) - \sum(x_{ik}\log x_{ik})}{[(N_j + N_k)\log(N_j + N_k)] - (N_j \log N_j) - (N_k \log N_k)} \quad (1)$$

Where R_0 is the Horn's index of similarity for samples j and k, x_{ij}, and x_{ik} are the detected amounts of compound i in sample j and sample k, where N_j is Σx_{ij} the total amount of volatiles in sample j and N_k is Σx_{ik} the total number of compounds in sample k. Analysis was performed by the Syntax 5.1 program package (Podani, 1997).

RESULTS

Olfactometer Bioassay. When volatiles from different plants were tested against clean humidified air, 60% to 95% of wasps made a choice. Wasps preferred volatiles from all plant sources over clean air ($P < 0.01$) (Figure 1).

When offered a choice between blends of uninfested plants, 61% to 88% of the tested females made a choice (Figure 2). Parasitoids discriminated clearly among volatiles from different species of uninfested plants. All cruciferous plants were preferred over malting barley ($P < 0.001$), with wasps discriminating between

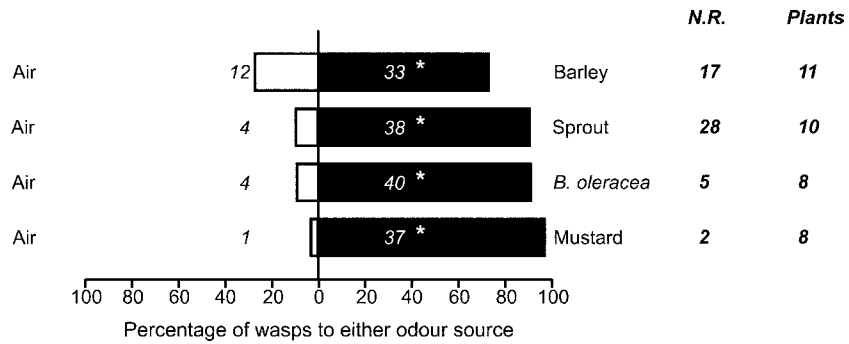

FIG. 1. Percentage of female *D. semiclausum* choosing either odor source when volatiles from uninfested plants are compared with clean air. Asterisks indicate significant preferences within tests (*$-P < 0.05$). Numbers next to graph are the number of non-responding (N.R.) individuals and the number of plants tested.

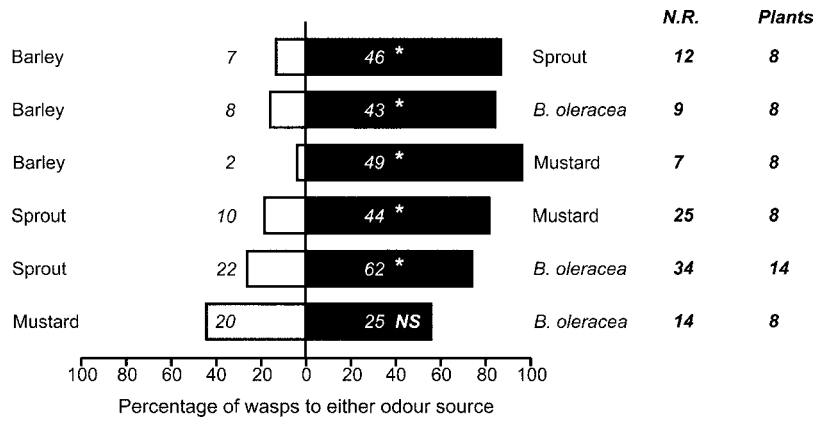

FIG. 2. Percentage of female *D. semiclausum* choosing either odor source from uninfested plants. Asterisks indicate significant preferences within tests ($^*-P < 0.05$). Numbers next to graph are the number of non-responding (N.R.) individuals and the number of plants tested.

the different cruciferous plants as well. Parasitoids preferred both mustard (82%) and the feral *B. oleracea* (74%) over Brussels sprout ($P < 0.001$) (Figure 2). The parasitoids were equally attracted to mustard and feral *B. oleracea*.

When parasitoids were exposed to volatiles from uninfested and host-infested cruciferous plants, 88% to 99% of individuals responded (Figure 3). Wasps discriminated between infested and uninfested conspecifics.

Parasitoids preferred both infested mustard (91%) and Brussels sprout (83%) to uninfested conspecifics. Interestingly, when females were offered a choice between host-infested Brussels sprout and uninfested mustard plants, no preference was observed.

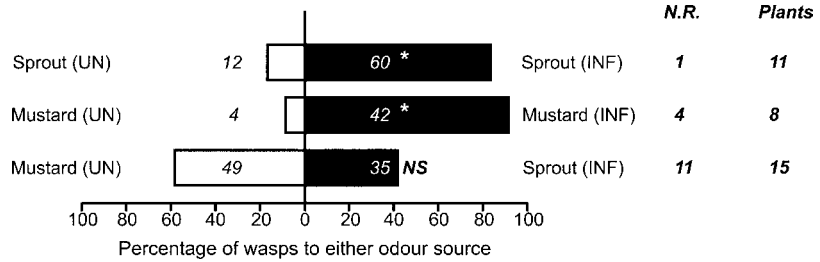

FIG. 3. Percentage of female *D. semiclausum* choosing either uninfested (UN) plants (Brussels sprout and mustard) or *P. xylostella*-infested plants (INF). Asterisks indicate significant preferences within tests ($^*-P < 0.05$). Numbers next to graph are the number of non-responding (N.R.) individuals and the number of plants tested.

Headspace Volatiles. In the 24 samples analyzed across treatments, 70 compounds were detected (Table 1). Compounds were identified as ketones, alcohols, aldehydes, esters, terpenoids, sulphides, nitrile, and others. In the headspace of barley, only 15 compounds were detected. Forty-six compounds were detected in the feral *B. oleracea* and in the mustard, 48 compounds were found in uninfested Brussels sprout and 59 in *Plutella*-infested Brussels sprout.

Characteristic GC traces of the plants tested are shown in Figure 4. Both quantitative and qualitative differences in headspace volatiles of tested plants were found. The smallest total amount of volatiles was emitted by barley, followed by mustard, feral *B. oleracea*, uninfested Brussels sprout, and host-infested Brussels sprout. Dissimilarities among the volatile profiles of different plants are presented in Figure 5. The volatile profile of barley showed the greatest dissimilarity among the treatments, with only 15 of the 70 compounds detected. Fourteen of these compounds were also present in the odor blend of at least one of the other plant sources. Compared to the crucifers, barley emitted few terpenoids. The dominant compounds produced by barley were the terpenoid linalool, which was also present in smaller amounts in the odor blend of infested Brussels sprout, 3-methyl-1-butanol, which was detected in smaller amounts both in the volatile blends of mustard and infested Brussels sprout, and the GLV (i.e., green leaf volatile) (*Z*)-3-hexen-1-ol, which was present in all samples.

The odor blend of the crucifers was dominated by the GLV (*Z*)-3-hexen-1-yl acetate, and the terpenoids sabinene, myrcene, limonene, and 1,8-cineole. The odor blend of mustard was more similar to the blends of the other crucifers than to that of barley, but it still grouped out from the blends of Brussels sprout and the feral *B. oleracea* (Figure 5). The 46 compounds detected in mustard greatly overlapped with those detected in the headspace of Brussels sprout and the feral *B. oleracea*. Four compounds, 2-methyl-1-butanol, 2-methyl-1-butyl acetate, 2-oxo-1,8-cineole, and germacrene D were detected in mustard alone. (*Z*)-3-hexen-1-yl 3-methylbutanoate and other compounds like 3-methyl-1-butanol, 3-methyl-1-butyl acetate, and indole were detected in mustard and infested Brussels sprout only. The compounds 3-methyl-1-butanol and 3-methyl-1-butyl acetate were also present in the odor blend of barley.

Infested Brussels sprout plants produced a similar odor blend to uninfested Brussels sprout and to a lesser extent to *B. oleracea*, but many of the compounds were emitted in considerably higher amounts by infested Brussels sprout. Four compounds, dehydroxylinalool oxide A, dehydroxylinalool oxide B, β-bisabolene, and cis-β-elemene were only present in the odor blend of feral *B. oleracea* (Table 1). (*E*,*E*)-α-Farnesene was found in high amounts in the feral *B. oleracea* and mustard only, whereas 3-methyl-2-pentanol was present in the volatile blend of the feral *B. oleracea* and that of infested Brussels sprout only.

The odor blends of infested and uninfested Brussels sprout plants showed the highest similarity. However, among the 59 compounds released by infested

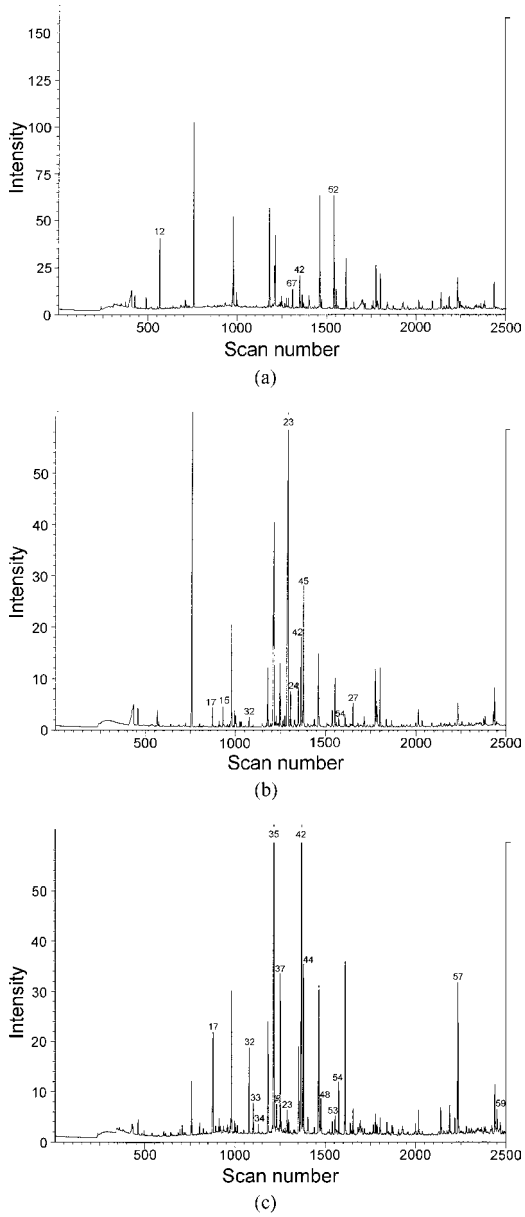

FIG. 4. Gas chromatograms of volatiles collected from (**a**) uninfested barley, (**b**) uninfested *S. alba*, (**c**) uninfested *B. oleracea*, (**d**) uninfested Brussels sprout, and (**e**) Brussels sprout infested by *P. xylostella*. Numbers next to peaks correspond to the compound numbers in Table 1.

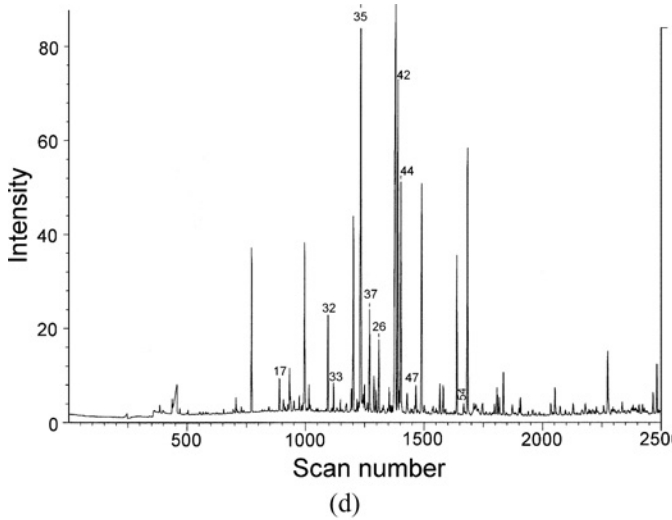

FIG. 4. Continued

Brussels sprout, 11 were not present in the odor blend of uninfested Brussels sprout (Table 1).

DISCUSSION

In this study, *D. semiclausum* preferred all plant species tested, including barley, over clean air. Yet, when uninfested plants of different species were tested

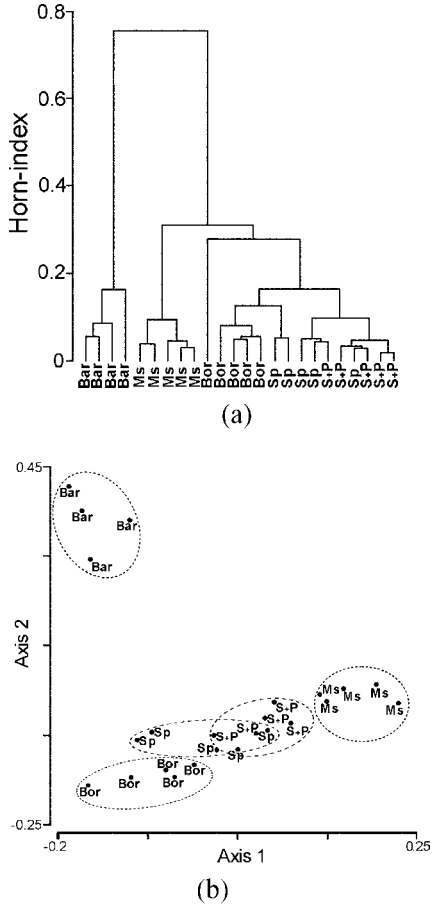

FIG. 5. Dissimilarities in volatile profiles of plants. (**a**) Hierarchic clustering and (**b**) non-metric scaling of dissimilarities in volatile profiles based on the Horn-index. "Bar"-barley, "Ms"-mustard, "Bor"-feral *B. oleracea*, "Sp"-uninfested Brussels sprout, "S+P"-Brussels sprout infested by *P. xylostella* larvae.

against each other, females preferred volatile blends of crucifers to barley. In a comparable study, *Cotesia kariyai* a parasitoid of the noctuid *Pseudaletia separata*, was attracted to several unrelated non-host food plants, which was explained by the presence of the same GLVs in the headspace of the different plant species (Takabayashi et al., 1991). Except for one compound, all the compounds produced by barley were also present in at least one of the crucifers. These included (*Z*)-3-hexen-1-ol, myrcene, and limonene. Linalool, the compound dominantly produced

by barley, was also detected in infested Brussels sprout. Therefore, the presence of those compounds in the odor blends of barley, which were present in the odor of crucifers, could explain the preference of wasps towards barley odors when compared with clean air.

Parasitoids also discriminated between odors of uninfested crucifers. Despite the lower amounts of total volatiles and the fewer compounds produced by both mustard and the feral *B. oleracea*, these plants were more attractive to *D. semiclausum* than Brussels sprout. Some alcohols and terpenoids emitted by mustard were present in this species only, and some alcohols, esters, and indole were detected both in mustard and infested Brussels sprout. The GLV (*Z*)-3-hexen-1-yl acetate is known to be produced by herbivore-infested Brussels sprout in greater quantities than by uninfested plants (Blaakmeer et al., 1994; Mattiacci et al., 1994; Geervliet et al., 1997). This was the dominant compound that mustard produced. However, this same compound was also the dominant compound in uninfested sprouts, and it was produced in larger quantities than in uninfested mustard. This finding indicates that (*Z*)-3-hexen-1-yl acetate alone was not responsible for the attraction of this parasitoid to mustard.

White mustard also contains specific aromatic hydroxy-benzyl and benzyl glucosinolates (McCloskey and Isman, 1993; Hopkins et al., 1998; Mewis et al., 2002). Aromatic derivatives of these glucosinolates were detected in the headspace of uninfested mustard (Tollsten and Bergström, 1988). We did not detect these derivatives in our samples, possibly due to differences in methodology for collecting and analyzing samples. Tollsten and Bergström (1988) used cut plants while we used potted plants.

Qualitative and quantitative differences in the odor blends of plants may enable natural enemies to discriminate between odor sources while searching for their prey or host (De Boer, 2004). *D. semiclausum* discriminated between odor blends of plants, and presence or absence of compounds in the blend combined with quantitative differences in blend composition could have played a role in this. While presence/absence of compounds in volatile blends could have been important for females to discriminate between odors of barley and crucifers, differences in quantity and ratios of compounds could be important in the discrimination between mustard, the feral *B. oleracea*, and Brussels sprout. This was suggested by the finding that the volatile profile of the feral *B. oleracea* was similar to that of uninfested Brussels sprout, with a few compounds detected exclusively in the feral *B. oleracea*. Yet, wasps were able to discriminate between these lines of *B. oleracea*. Furthermore, the greater amounts of plant volatiles produced by uninfested Brussels sprout compared to the feral *B. oleracea* combined with few qualitative differences, did not result in a stronger attraction of *D. semiclausum*. This indicates that subtle differences in volatile profiles of uninfested plants could be important in the attractivity of these plants for *D. semiclausum*.

Brussels sprout plants damaged by hosts are more attractive for the parasitoids *Cotesia glomerata*, *C. rubecula*, and *C. plutellae* than artificially damaged or intact Brussels sprout plants (Steinberg et al., 1992, 1993; Blaakmeer et al., 1994; Geervliet et al., 1996; Shiojiri et al., 2000). A recent study by Ohara et al. (2003) showed that *D. semiclausum* females were attracted by the odor blends of uninfested and infested cruciferous plants. The observed attraction was not due to the host or products directly associated with the host (i.e., feces, silk exuviae), but the damaged plant itself (Ohara et al., 2003). Our results also suggest that *D. semiclausum* assesses changes in volatile blends as a result of herbivore damage. The odor blend of infested Brussels sprout was similar to that of uninfested Brussles sprout, but many of the compounds were emitted in higher amounts by infested plants, which was in line with findings of other studies (Blaakmeer et al., 1994; Geervliet et al., 1997; Reddy and Guerrero, 2000; Smid et al., 2002). Compounds like (*Z*)-3-hexen-1-yl acetate, (*Z*)-3-hexen-1-ol, and limonene, which were also detected in our samples, could play a role in the attraction of the parasitoids *C. rubecula*, *C. glomerata*, and *C. plutellae*, and of the predatory lacewing *Chrysoperla carnea* (Geervliet et al., 1997; Reddy et al., 2002; Smid et al., 2002). The volatile profile of *Plutella*-infested Brussels sprout shares many similarities with the odor profiles from white cabbage and Brussels sprout infested by different *Pieris* spp. (Geervliet et al., 1997; Blaakmeer et al., 1994). Moreover, parasitoid species associated with *P. xylostella* and *Pieris spp.* differ in their ability to distinguish odor blends of plants that are infested by hosts or non-hosts (Shiojiri et al., 2001). It is not yet known what compounds may be involved in the ability of *D. semiclausum* to discriminate between blends of infested and uninfested Brussels sprout, or how the volatile composition of mustard is influenced by herbivore damage. These may be important factors to understand its searching behavior, and interactions with its host in the field. We currently study how inter- and intraspecific variation in plant volatiles influence the ability of this parasitoid to discriminate between plants infested by hosts and non-hosts.

Based on dissimilarities in the volatile profiles, wasps were able to discriminate between infested and uninfested Brussels sprout plants. Interestingly, such discrimination was not observed when infested Brussels sprout was compared with mustard, although the dissimilarity in odor blends compared to the dissimilarity of blends of infested versus uninfested Brussels sprout plants were greater. Hence, the lack of discrimination by *D. semiclausum* between infested Brussels sprout and mustard was not because of the great similarity of odor blends. Despite the considerable differences in blends, wasps did not discriminate, possibly because the "values" of information (i.e., expectancy of the host's presence) from the odors of infested Brussels sprout and mustard were similar. Based on studies of *Leptopilina heterotoma*, a parasitoid of *Drosophila* spp., Vet et al. (1998) hypothesized that parasitoids may actively not discriminate among subtle, quantitative

differences and rely on qualitative differences until they learn to discriminate via experiences. Data from a separate study suggest that such a mechanism may play a role in the searching behavior of *D. semiclausum* (Bukovinszky, 2004). While host location by inexperienced females on Brussels sprout is hindered by the greater preference of wasps to search on uninfested mustard, oviposition experience redirects odor preference in favor of host-infested Brussels sprout and enhances the efficiency of females to locate subsequent host-infested plants, irrespective of neighboring plant species (Bukovinszky, 2004).

Relative to other herbivores that are specialists on crucifers, *P. xylostella* has a broad host plant diet (Yano, 1994; Bigger and Fox, 1997). Mustard is a preferred food plant of *P. xylostella* and is used as a trap crop (Palaniswamy et al., 1986; Talekar and Shelton, 1993). *P. xylostella* develops faster and reaches greater body weight on white mustard than on Brussels sprout (R. Gols, unpublished data). Hence, if the occurence of *P. xylostella* on these plant species is different, it could be a viable strategy for *D. semiclausum* to have a preference towards volatile blends that reflects the food-plant preference of the host.

As plant breeding and biological control developed independently, we have limited information on what mechanisms are responsible for triggering different responses of parasitoids to different plant species and genotypes of the same plant species (van Lenteren et al., 1995; Bottrell et al., 1998; Cortesero et al., 2000). The finding that feral *B. oleracea* is more attractive than cultivated conspecifics might indicate that artificial selection in cultivated plants has altered their ability to attract natural enemies compared with their wild relatives. However, further studies are needed to explicitly test this hypothesis. Our results indicate that volatile traits responsible for the attraction of natural enemies to plants would be valuable to consider in breeding programs enhancing biological control. Although plant traits that increase attractivity for the parasitoid may also attract herbivores, such traits could still be valuable tools in developing pest-suppressive diversification strategies (i.e., companion planting, intercropping).

Acknowledgments—This study is part of the project "Enhanced biodiversity" funded by the section Earth and Life Sciences of the Dutch Scientific Organisation (NWO-ALW, project number: 014-22.031). We thank Wouter Tigges for rearing the parasitoids, Marcel Dicke, Jeffrey A. Harvey, and two anonymous reviewers for constructive comments on the manuscript. Suzanne E. Blatt helped correcting the English of the manuscript. J.A. Harvey provided the feral *B. oleracea* plants.

FURTHER FIELD EVALUATION OF SYNTHETIC HERBIVORE-INDUCED PLANT VOLATILES AS ATTRACTANTS FOR BENEFICIAL INSECTS

DAVID G. JAMES[1,*]

[1]*Department of Entomology, Washington State University*
Irrigated Agriculture Research and Extension Center
24105 North Bunn Road, Prosser, Washington 99350

(Received February 25, 2004; accepted October 24, 2004)

Abstract—Fifteen synthetic herbivore-induced plant volatiles (HIPVs) were field-tested for attractivity to beneficial insects in two experiments conducted in an open field and a hop yard in Washington State. Eleven insect species or families showed significant attraction to 13 HIPVs. The ladybeetle, *Stethorus punctum picipes*, was attracted to sticky traps baited with methyl salicylate (MeSA), *cis*-3-hexen-1-ol (He), and benzaldehyde (Be). The minute pirate bug, *Orius tristicolor*, was attracted to traps baited with MeSA, He, Be, and octyl aldehyde (Oa), and the bigeyed bug, *Geocoris pallens*, responded to MeSA, indole, and *trans*-2-hexen-1-al. The mymarid wasp, *Anagrus daanei*, was attracted to He, Oa, and farnesene. The chloropid fly, *Thaumatomyia glabra*, was highly attracted to methyl anthranilate. Insect families responding to HIPVs included Syrphidae (MeSA, He), Braconidae ((*Z*)-3-hexenyl acetate, He, *cis*-jasmone (J), methyl jasmonate (MeJA), methyl anthranilate (MeA)), Empididae (MeSA), Sarcophagidae (MeSA, Be, J, nonanal and geraniol), Tachinidae (Be), and Agromyzidae (MeSA). Micro-Hymenoptera (primarily parasitic wasp families) were attracted to MeSA, He, and indole. These results are discussed with respect to known properties and bioactivity of the tested HIPVs and to their potential as tools for recruiting natural enemies into agroecosystems.

Key Words—Herbivore-induced plant volatiles, attractants, natural enemies, conservation biological control.

INTRODUCTION

Plants respond to herbivore damage by producing volatiles that attract natural enemies of the herbivores responsible for the damage (Dicke et al., 1990a; Turlings

* To whom correspondence should be addressed. E-mail: david_james@wsu.edu

et al., 1990; Vet and Dicke, 1992; Stowe et al., 1995; Takabayashi and Dicke, 1996). Despite the accumulation of a substantial volume of literature on the biology and chemistry of herbivore-induced plant volatiles (HIPVs) during the past 10–15 years (e.g., Dicke et al., 1990b, 1998; Whitman and Nordlund, 1994; Pare et al., 1999; Sabelis et al., 1999; Thaler, 1999, Kessler and Baldwin, 2001; Scutareanu et al., 2003, Van Den Boom et al., 2004, Engelberth et al., 2004), field demonstration of the potential of synthetic HIPVs as beneficial insect attractants did not occur until recently (James, 2003a,b). These studies showed that sticky traps baited with synthetic versions of two HIPVs (methyl salicylate (MeSA), (*Z*)-3-hexenyl acetate) attracted significantly greater numbers of some predatory insect species in the families Chrysopidae, Miridae, Geocoridae, Anthocoridae, Syrphidae, and Coccinellidae. Subsequently, controlled-release dispensers of methyl salicylate were evaluated in hops and grapes in Washington and showed evidence of recruiting increased numbers of specific beneficial insects to treated sites (James and Price, 2004).

Methyl salicylate and (*Z*)-3-hexenyl acetate are only two of many HIPVs that have been identified to date (Whitman and Nordlund, 1994; Pare and Tumlinson, 1996; Dicke, 1999). Many HIPVs are available from commercial sources and suitable for field-testing as attractants for beneficial insects. Following the success in field-testing MeSA and (*Z*)-3-hexenyl acetate as attractants (James, 2003a,b) and subsequent demonstration of MeSA as a tool to recruit populations of beneficial insects to baited crops and perhaps improve biological control of pests (James and Price, 2004), thirteen additional synthetic HIPVs were field-tested in two experiments conducted in 2003.

METHODS AND MATERIALS

Two field experiments based on the protocols used in James (2003b) were conducted at Washington State University's, Irrigated Agriculture Research and Extension Center at Prosser in 2003.

Experiment 1. This was conducted in a 1 ha open field from 30 April-3 September 2003. Yellow sticky cards (23 × 18 cm, Trece Incorporated, Salinas, CA) were stapled to 25 × 25 cm wooden platforms attached by wire to wooden poles ~2 m above the ground. Cards were baited with 2 ml glass vials containing 1 ml of candidate HIPV solution or left unbaited (controls). Vials were loosely plugged with cotton wool and suspended by wire at a height of ~2 cm above the center of each card. Eleven HIPVs were tested (*cis*-3-hexen-1-ol (98%), *trans*-2-hexen-1-al (97%), linalool (97%), benzaldehyde (99.5%), indole (99%), methyl salicylate (98%), (*Z*)-3-hexenyl acetate (98%), geraniol (98%), methyl anthranilate (commercial formulation, Goose Chase™ 26.4%), *cis*-jasmone (90%), and methyl jasmonate (95%). All were obtained from Sigma-Aldrich, St Louis, MO, USA except methyl anthranilate, which was a gift from Leonard Askham, Bug

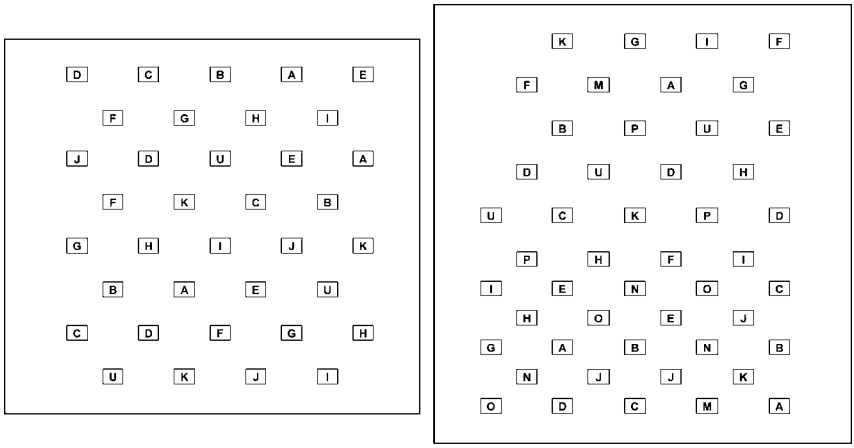

FIG. 1. Plot diagrams for Experiment 1 (A) and Experiment 2 (B) showing location details for traps and volatiles.). A – *cis*-3-hexen-1-ol, B – *trans*-2-hexen-1-al, C – linalool, D – benzaldehyde, E – indole, F- methyl salicylate, G – (*Z*)-3-hexenyl actetate, H – geraniol, I – methyl anthranilate, J – *cis*-jasmone, K – methyl jasmonate, M – nonanal, N – farnesene, O- - 3 – octanone, P – octyl aldehyde, U – unbaited.

Busters Ltd., Spokane, WA. All HIPVs were used undiluted (except indole, which was diluted 1:1 with hexenal) and solutions were replaced weekly. The cards were placed in a 6 × 6 grid with 15 m between the randomized treatments with three replicates of each treatment (see Figure 1 for details of trap/volatile locations). The field was cultivated and devoid of vegetation until June; thereafter it became weedy with Kochia (*Kochia scorparia* L) and Redroot pigweed (*Amaranthus retroflexus* L) dominating. Unsprayed vineyards bordered the field on two sides, alfalfa on one side and weedy waste ground on the other. Insects were abundant in these surrounding areas. Sticky cards were collected/replaced weekly and examined under a stereomicroscope. Trapped insects were identified (to species or family) and counted.

Experiment 2. This was conducted in a drip-irrigated, post-harvest hop yard at Washington State University-Prosser during 4 September-22 October 2003. The yard was bordered on three sides by weedy fields and on the fourth by a vineyard. Insects were abundant in the yard and the surrounding areas. Yellow sticky cards were tied vertically to wooden poles ∼2 m above the ground and baited with glass vials containing 1 ml of candidate HIPV solutions or left unbaited (controls). Fifteen HIPVs were tested; the eleven used in Experiment 1 plus nonanal (95%), farnesene (98%), 3-octanone (97%), and octyl aldehyde (99%). All were obtained from Sigma-Aldrich except methyl anthranilate (see Experiment 1). All HIPVs

were used undiluted (except indole which was diluted 1:1 with hexenal), and solutions were replaced weekly. Bait vials were taped vertically to the lower edge of the cards, which were placed in a 6 × 9 grid with at least 15 m between the randomized treatments (see Figure 1 for details of trap/volatile locations). All treatments were replicated three times. The hop yard was used for insecticide trials prior to the HIPV experiment, and large numbers of arthropod herbivores (primarily mites and aphids) were present in September. Weeds were also abundant in the yard. Sticky cards were collected/replaced weekly and examined under a stereomicroscope. Trapped insects were identified and counted.

Sixteen groups, families, or species of insects were sufficiently numerous to allow an assessment of attraction to HIPVs in one or both of the experiments. Abundance was judged by occurrence on unbaited sticky cards. Insects that were trapped regularly throughout the trapping period were recorded in this study. These were *Geocoris pallens* Stal. (Hemiptera: Geocoridae), *Orius tristicolor* (White) (Hemiptera: Anthocoridae), *Lygus hesperus* Knight (Hemiptera: Miridae), *Stethorus punctum picipes* (Casey) (Coleoptera: Coccinellidae), *Anagrus daanei* Triapitsyn (Hymenoptera: Mymaridae), *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae), *Thaumatomyia glabra* (Meigen) (Diptera: Chloropidae), Syrphidae, Braconidae, Empididae, Sarcophagidae, Tachinidae, Agromyzidae, Therevidae, Dolichopodidae, and micro-Hymenoptera [parasitic families including Scelionidae, Encyrtidae, and Mymaridae (excluding *Anagrus* spp.)]. *Lygus hesperus* and *F. occidentalis* can be pestiferous, but are also predatory on aphids and mites. Agromyzidae (leaf-mining flies) are pests of many vegetable and flower crops. Voucher specimens of the species mentioned in this work are held at Washington State University-Prosser. Trapping data were analyzed using either the Mann-Whitney Rank-Sum Test or the Kruskal-Wallis ANOVA on ranks.

RESULTS

Experiment 1. Three insect species, three insect families, and micro-Hymenoptera were attracted to some HIPVs (Figures 2–3). The minute pirate bug, *O. tristicolor* was attracted to traps baited with MeSA or *cis*-3-hexen-1-ol, while the bigeyed bug, *G. pallens* was attracted to MeSA, *trans*-2-hexen-1-al, and indole (Figure 2). The chloropid fly, *T. glabria*, was highly attracted to methyl anthranilate with a season mean (±SE) of 4450 ± 645/trap compared to 1.2 ± 0.2/trap on unbaited traps. No other HIPV trapped a season mean of more than 1.4 *T. glabra* per trap. Syrphidae (hover flies), Empididae (dance flies), and Agromyzidae (leaf-mining flies) were attracted to MeSA-baited traps, and syrphids also responded to *cis*-3-hexen-1-ol (Figures 2–3). Micro-Hymenoptera were attracted to MeSA, indole and *cis*-3-hexen-1-ol-baited traps (Figure 3).

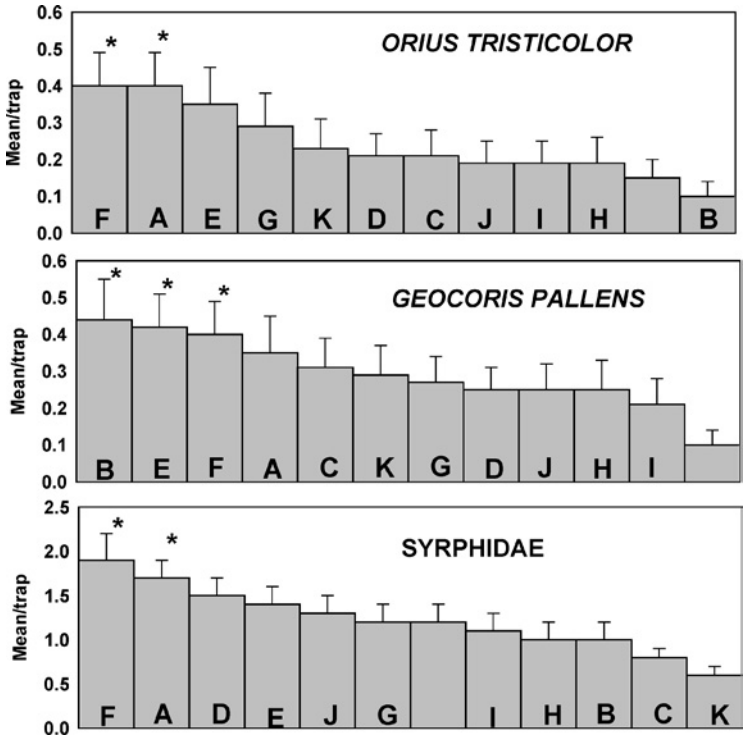

FIG. 2. Mean (±SE) captures of *O. tristicolor*, *G. pallens*, and Syrphidae in sticky traps baited with synthetic HIPVs during April-September 2003 (experiment 1). Unmarked columns represent unbaited (control) traps and asterisks indicate significant differences from unbaited traps ($P < 0.05$). See Figure 1 for HIPV identification.

Experiment 2. Three insect species and three insect families were attracted to some HIPVs in this experiment (Figures 4–5). The mymarid wasp, *A. daanei* was strongly attracted to traps baited with farnesene, octyl adehyde, and *cis*-3-hexen-1-ol (Figure 4). *Orius tristicolor* and *S. punctum picipes* were attracted to some HIPVs during the first 2–3 weeks of September (Figure 4), but not in late September and October. *Orius tristicolor* was attracted to traps baited with octyl aldehyde or benzaldehyde, while *S. punctum picipes* responded to traps baited with MeSA, *cis*-3-hexen-1-ol, or benzaldehyde (Figure 4). Wasps in the family Braconidae were attracted to traps baited with (*Z*)-3-hexenyl acetate, geraniol, methyl anthranilate, methyl jasmonate, *cis*-jasmone, and *cis*-3-hexen-1-ol (Figure 5). Flesh flies (Sarcophagidae) were attracted to benzaldehyde, nonanal, geraniol, and *cis*-jasmone baited traps, while tachinid flies were attracted to benzaldehyde (Figure 5).

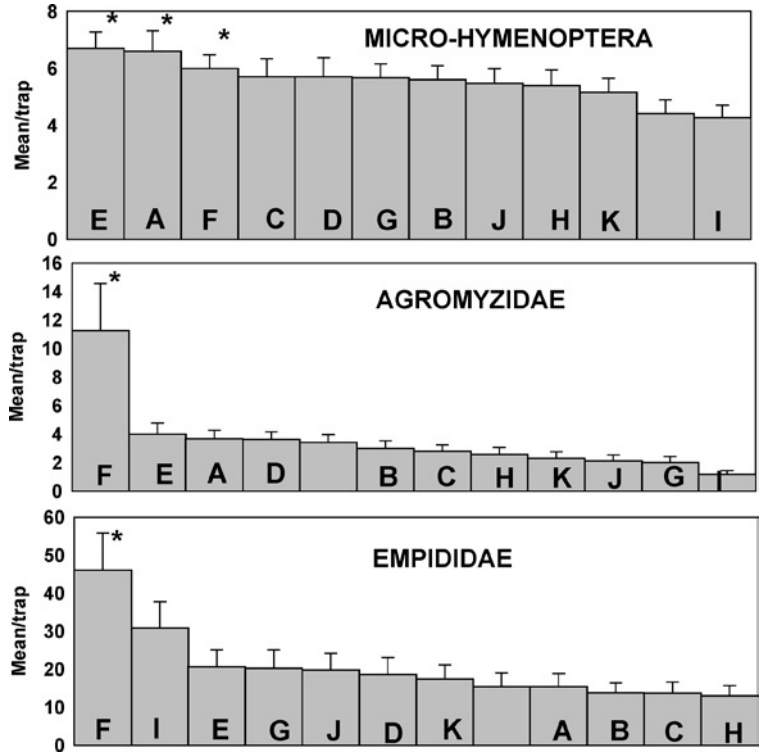

FIG. 3. Mean (±SE) captures of Empididae, Agromyzidae, and micro-Hymenoptera in sticky traps baited with synthetic HIPVs during April-September 2003 (experiment 1). Unmarked columns represent unbaited (control) traps and asterisks indicate significant differences from unbaited traps ($P < 0.05$). See Figure 1 for HIPV identification.

DISCUSSION

The data presented here together with results from previous studies (James, 2003a,b) indicate that synthetic HIPVs have potential as attractants for beneficial insects. Simple field attraction experiments formed the basis of these studies, and indicate that eleven HIPVs in addition to methyl salicylate and (*Z*)-3-hexenyl actetate are attractive to beneficial insects (James, 2003a,b). A summary of these compounds and the insects they attract in the field is presented in Table 1. Western flower thrips, *F. occidentalis*, Lygus bug, *L. hesperus*, long legged flies (Dolichopodidae), and stiletto flies (Therevidae), despite good abundance during both experiments, were not attracted to any HIPV (data not presented).

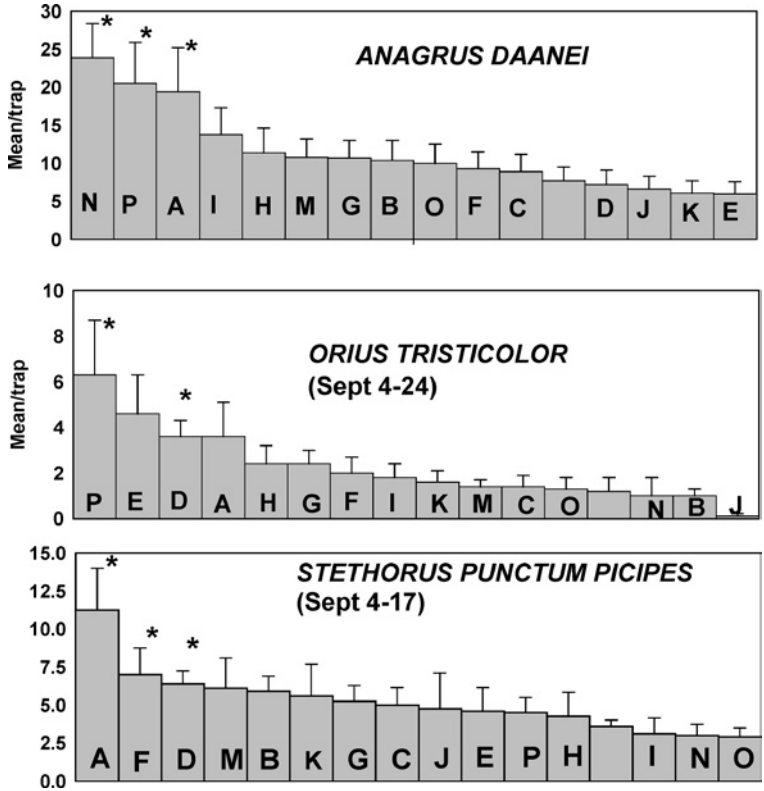

FIG. 4. Mean (±SE) captures of *A. daanei*, *O. tristicolor*, and *S. punctum picipes* in sticky traps baited with synthetic HIPVs during September-October 2003 (experiment 2). Unmarked columns represent unbaited (control) traps and asterisks indicate significant differences from unbaited traps ($P < 0.05$). See Figure 1 for HIPV identification identification.

Green leaf volatiles (GLVs) are typically released by plants immediately after wounding or herbivore attack and are ubiquitous in the environment. Nevertheless, they appear to serve as signals to some natural enemies including braconid and ichneumonid wasps (Whitman and Eller, 1990, 1992). In this study, the GLV, *cis*-3-hexen-1-ol was attractive to *O. tristicolor*, *S. punctum picipes*, *A. daanei*, braconid wasps, and micro-Hymenoptera, while *trans*-2-hexen-1-al was attractive to *G. pallens*. Another GLV, (*Z*)-3-hexenyl acetate, was shown earlier to be attractive to *O. tristicolor* and the predatory mirid, *Deraeocoris brevis* (James, 2003b). Recently, a priming role for GLVs was described in which chemical defense

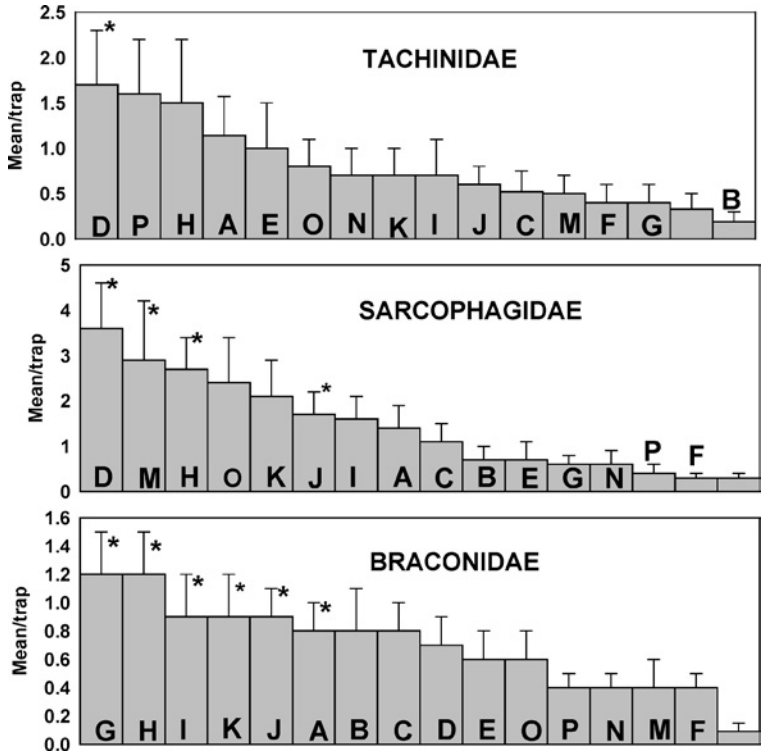

FIG. 5. Mean (±SE) captures of Tachinidae, Sarcophagidae, and Braconidae in sticky traps baited with synthetic HIPVs during September-October 2003 (experiment 2). Unmarked columns represent unbaited (control) traps and asterisks indicate significant differences from unbaited traps ($P < 0.05$). See Figure 1 for HIPV identification.

responses in plants near herbivore-damaged plants were enhanced by exposure to these volatiles (Engleberth et al., 2004).

Benzaldehyde is a common plant volatile associated with flowers and ripening fruit (Buchbauer et al., 1993; Leskey et al., 2001; Plepys et al., 2002). However, it is also an induced volatile in tea plants damaged by aphids (Han and Chen, 2002). Attractiveness of benzaldehyde to three natural enemy species (*Coccinella septempunctata* L. (Coleoptera: Coccinellidae), *Aphidius* sp. (Hymenoptera: Braconidae), and *Chrysopa sinica* Tjeder (Neuroptera: Chrysopidae) was demonstrated in electroantennogram and olfactometer tests (Han and Chen, 2002). In the current field study, benzaldehyde was attractive to *O. tristicolor*, *S. punctum picipes*, and flies in the families Tachinidae and Sarcophagidae. Han and Chen (2002) also showed geraniol and indole were HIPVs in aphid-damaged tea plants. Both compounds

TABLE 1. SUMMARY OF POSTIVE RESPONSES BY INSECTS TO SYNTHETIC HIPVS IN FIELD EXPERIMENTS CONDUCTED IN WASHINGTON STATE 2002–2003

Absence of positive data for an insect species or family does not necessarily mean no response. It may not have been present during one or more of the 4 studies.

also attracted beneficial insects in the current field study. Indole attracted micro-Hymenoptera and *G. pallens*, while geraniol attracted sarcophagid flies and braconid wasps. Indole is a component of the HIPV blend produced by caterpillar-damaged cotton and cabbage plants, utilized by hymenopteran parasitoids to locate their caterpillar hosts (Pare and Tumlinson, 1997; Dicke, 1999; Fukushima et al., 2002).

Farnesene is a common component of HIPV blends from a number of plants including cotton, corn, bean, pear, and apple (Du et al., 1988; Turlings et al., 1991; Boeve et al., 1996; Pare and Tumlinson, 1997; Scutareanu et al., 1997). It has also been shown in the laboratory to be attractive to parasitic wasps including *Aphidius ervi* (Haliday) (Hymenoptera: Aphididae) (Du et al., 1998), a ladybeetle, *Coleomegilla maculata* (Degeer) (Coleoptera: Coccinellidae) (Zhu et al., 1999), a lacewing, *Chrysoperla carnea* (Stephens) (Neuroptera: Chrysopidae) (Zhu et al., 1999), and a pirate bug, *Anthocoris nemoralis* (Fabricius) (Hemiptera: Anthocoridae) (Scutareanu et al., 1997). In the current field study, the parasitic mymarid wasp, *Anagrus daanei*, was the only insect attracted to farnesene. This wasp along with other *Anagrus* spp. is an important egg parasitoid of grape leafhoppers (*Erythroneura* spp.) in Washington State and California.

In a study by Birkett el al. (2003), 3-octanone and octanal (octyl aldehyde) were shown to be volatiles emitted by bean leaves. Substantially greater amounts of 3-octanone were emitted by whitefly-infested than by clean leaves, indicating that it is an HIPV. Octanal was also more common from whitefly-infested leaves but to a lesser extent. Octanal was reported as a minor component of the HIPV blend released by cabbage infested with caterpillars of pierid butterflies (Dicke, 1999). No response by insects to 3-octanone was detected in the field experiments, but two species, *A. daanei* and *O. tristicolor*, showed significant attraction to octanal. This is the first report of beneficial insects responding to this compound. Nonanal was also shown by Birkett et al. (2003) and Dicke (1999) to be an HIPV from whitefly-infested bean leaves and caterpillar-infested cabbages, respectively. In these field experiments, it attracted sarcophagid flies. De Greet and Poland (2003) showed nonanal was attractive to the herbivorous beetle, *Hylastes opacus* Erichson (Coleoptera: Scolytidae).

The two jasmonates, *cis*-jasmone and methyl jasmonate (MeJA), play a role in plant-plant communication. Methyl jasmonate is released by some herbivore-attacked plants and is a signal to neighboring plants that respond by producing predator-attracting volatiles (Bruin and Dicke, 2001). A direct role as attractants for predators and parasitoids of herbivores has not been well described for MeJA and *cis*-jasmone. Park et al. (2001) showed that the parasitic wasp, *Microplitis croceipes* (Cresson) (Hymenoptera: Braconidae) responded to MeJA in electroantennogram studies. Braconid wasps showed some attraction to *cis*-jasmone and MeJA-baited traps in this study, and sarcophagid flies responded to *cis*-jasmone.

Methyl anthranilate is a common secondary plant metabolite occurring in flowers (Knudsen et al., 1993) and in fruits of *Vitis labrusca* L. (Stern et al., 1967). It is currently marketed in the United States as a non-lethal bird repellent (Aronov and Clark, 1996). Kairomonal activity of methyl anthranilate was observed in the flowers of *Cimicifuga simplex* for butterflies (Pellmyr, 1986), and Murai et al. (2000) showed it is an attractant for two herbivorous thrips species and a thrips parasitoid, *Ceranisus menes* Walker (Hymenoptera: Eulophidae). Tscharntke et al. (2001) reported methyl anthranilate as a component of the HIPV blend produced by black alders attacked by psyllid insects, *Psylla alni* L. (Homoptera: Psyllidae). In the current field tests, methyl anthranilate was attractive to the predaceous frit fly, *T. glabra*, which was attracted by the hundreds, often within minutes of setting out the vial. A high degree of attraction of this species to methyl anthranilate was first reported by Landolt et al. (2000). *T. glabra* is widely distributed in western North America and considered beneficial because of its predation as larvae on root-feeding aphids (Summers and Newton, 1989). The only other insects to respond to methyl anthranilate were braconid wasps.

Attraction of *S. punctum picipes*, *G. pallens*, *O. tristicolor*, and syrphids to MeSA-baited traps was reported in earlier field-trapping studies (James, 2003b)

and also in a subsequent experiment evaluating controlled-release dispensers of MeSA for recruitment of predators to vineyard plots (James and Price, 2004). Attraction of these beneficial insects to MeSA here provides further evidence for the potency of this compound. More evidence for syrphid attraction to MeSA was also obtained in a short-term trapping experiment conducted in November 2003 in rose bushes with unusually high populations of flies present. Methyl salicylate-baited traps captured a mean of 43 $\pm$ 8 flies/trap/week compared to 5 $\pm$ 1 flies/trap/week on unbaited traps (James, unpubl data). James and Price (2004) also reported recruitment of micro-Hymenoptera ('parasitic wasps') and dance flies (Empididae) to MeSA-treated plots. Both of these groups were also attracted to MeSA in the current study. Additional evidence for MeSA-attraction of empidid flies was gained in the rose bush study: a mean of 122 $\pm$ 18 flies/trap/wk was captured on MeSA-baited traps compared to 30 $\pm$ 5 flies/trap/wk on unbaited traps. Herbivorous leaf-mining flies (Agromyzidae) were attracted to MeSA in the current study. This is the first (and so far, only) pestiferous insect group shown to be attracted to MeSA in our field experiments. Molleman et al. (1997) reported attraction of pestiferous Lepidoptera species to MeSA in pear orchards in The Netherlands.

The possibility that some insects may respond differently to HIPVs according to physiological condition, season, or other endogenous and/or exogenous factors, cannot be excluded. Some evidence for this possibility was obtained for *S. punctum picipes* and *O. tristicolor*. The responses shown by both species to some HIPVs in the first half of September, disappeared later in the month and in October (means for *S. punctum picipes* during September 17-October 22 were 1-3/trap/wk for all baited and unbaited traps and 0.5–2.0/trap/wk for *O. tristicolor*). Both species undergo adult hibernal reproductive dormancy in Washington State, and the behavioral/physiological switch to overwintering that occurs during autumn may alter responses to prey-finding stimuli like HIPVs. Interestingly, *O. tristicolor* failed to respond to MeSA during the autumn experiment, in contrast to the summer experiment and to earlier studies conducted during summer (James, 2003b; James and Price, 2004). Similarly, sarcophagid flies responded to MeSA in vineyard plots (James and Price, 2004) but did not respond to this HIPV during the autumn experiment.

Of the 15 HIPVs tested in the two field experiments, only two (linalool and 3-octanone) failed to attract any insect family or species. The simple sticky card/HIPV bait method used in this and earlier studies (James, 2003 a,b) appears to be sufficient to at least coarsely-screen synthetic HIPVs for attraction to beneficial insects. Presumably, if some attraction occurs, it is an indication of a degree of bioactivity that may be explored more rigorously with further experimentation. For example, demonstration of MeSA as an attractant for beneficial insects in sticky card studies (James, 2003 a,b) led to the use of this compound in controlled-release devices aimed at establishing the potential of enhancing recruitment and

retention of natural enemies in crop ecosystems (James and Price, 2004). The use of horizontally-oriented sticky cards in experiment 1 did not appear to improve trapping efficiency over the use of vertically-oriented cards, used in earlier work and in experiment 2. As in the earlier studies, no regard was given to volatilization rates of the HIPVs used, which in most cases were likely to be considerably above 'natural' levels. Thus, some HIPVs may have been repellent to some degree to some insects (see Whitman and Eller, 1992). Another factor that may have influenced insect attraction, was the presence of naturally-occurring HIPV's, particularly during the first month of experiment 2, when large populations of herbivores (mites and aphids) were present. Synergistic effects of naturally-occurring HIPVs on the attractivity of synthetic HIPV's during September, may have contributed to the greater responses by *S. punctum picipes* and *O. tristicolor* in this month. The possibility of positive or negative interactions between naturally-occurring and synthetic HIPV's adds another variable to field experiments, and this needs to be investigated further. Identification of a positive response by an insect to a synthetic HIPV in field screening tests should be viewed only as a first step towards detailed and controlled studies.

A number of other HIPVs that are commercially available remain to be field-tested, including other GLVs, ocimene, myrcene, pinene, limonene, nerolidol, etc. In addition, there are a number of HIPVs that are not available commercially (e.g., (*E*)-dimethyl-1,3,7-nonatriene), which should also be tested. The evidence for successful recruitment of beneficial insects in hops and grapes using controlled-release dispensers of MeSA presented by James and Price (2004), suggests that synthetic HIPVs may have potential in integrated pest management by increasing populations of predators and parasitoids. The HIPVs indicated in this study to be attractive to beneficial insects should be evaluated further for their potential as aids to crop pest management.

Acknowledgments—Tanya Price, Victor Reyna, Anna Brown, Pam Clark, Stacey Ballard, and Lawrence Wright are thanked for their help in examining sticky cards and identifying insects. This work was partly funded by the Washington Hop Commission and Hop Research Council.

SYNOMONE OR KAIROMONE? – *Bulbophyllum apertum* FLOWER RELEASES RASPBERRY KETONE TO ATTRACT *Bactrocera* FRUIT FLIES

TAN KENG-HONG[1,*] and RITSUO NISHIDA[2]

(Received May 23, 2004; accepted October 30, 2004)

Abstract—*Bulbophyllum apertum* flower (Orchidaceae) releases raspberry ketone (RK) in its fragrance, which attracts males of several fruit fly species belonging to the genus *Bactrocera*. Besides RK as a major component, the flower contains smaller amounts of 4-(4-hydroxylphenyl)-2-butanol, plus two minor volatile components, veratryl alcohol and vanillyl alcohol. Within the flower, the lip (labellum) had the highest concentration of RK with much smaller quantities present in petals; other flower parts had no detectable RK. Male fruit flies attracted to the flower belong to RK-sensitive species – such as *Bactrocera albistragata*, *B. caudatus*, *B. cucurbitae* (melon fly), and *B. tau*. Removal and attachment of the pollinarium to a fly's thoracic dorsum occurred when a male of *B. albistragata* was toppled into the floral column cavity, due to an imbalance caused by it shifting its body weight while feeding on the see-saw lip, and then freeing itself after being momentarily trapped between the lip and column. During this process, the stiff hamulus (the pollinia stalk protruding prominently towards the lip) acted as a crowbar when it was brushed downwards by the toppled fly and lifted the pollinia out of the anther. If the fly was big or long for the small triangular lip, it would not be toppled into the column cavity and would just walk across the column, during which time the pollinarium could be accidentally removed by the fly's leg, resulting in a failed transport of the pollinarium. This suggests an unstable situation, where the orchid relies only on a particular pollinator species in the complex ecosystem where many RK-sensitive species inhabit. Wild males of *B. caudatus* (most common visitors) captured on *Bulbophyllum apertum* flowers were found to sequester RK in their bodies as a potential pheromonal and allomonal ingredient. Thus, RK can act either as a floral synomone (pollinarium transported) or kairomone (accidental

* To whom correspondence should be addressed. E-mail: tan_kh@tm.net.my; khtan@thhonline.com.my

removal of pollinarium leading to total pollen wastage), depending on the body size of the male fruit flies visiting the flowers.

Key Words—*Bulbophyllum apertum* (synonym *Bu. ecornutum*), Orchidaceae, fruit flies, *Bactrocera* species, Tephritidae, floral fragrance, raspberry ketone, synomone, kairomone, pheromone, pollination, coevolution.

INTRODUCTION

Bulbophyllum (Orchidaceae) is probably the largest orchid genus, with over 1,000 species grouped under ca seventy sections, and has flowers that have a specialized hinged lip (labellum) mechanism that tips an attracted fly precisely against the column, thus facilitating and ensuring cross pollination. Most species of *Bulbophyllum* produce foul smelling and carrion-like scent to attract flies (Van der Pijl and Dodson, 1969; Dressler, 1981). Studies of some *Bulbophyllum* species have shown the flowers are pollinated by flies belonging to four dipteran families – Calliphoridae, Lonchaeidae, Milichiidae, as well as Tephritidae-without knowledge of the chemical component(s) responsible for fly attraction (Christensen, 1994). However, "a small and active fly" (probably a tephritid fruit fly) was reported to visit and 'fertilize' two species of *Bulbophyllum – Bu. macranthum* and *Bu. stritellum*, as well as *Dendrobium superbum* (synonym – *D. anosmum*) by Ridley in 1890. Fruit flies belonging to the genus *Strumeta* (currently *Bactrocera* Macquart [Diptera: Tephritidae]) appear to be the exclusive pollinators of *Bu. baileyi* F. Müel, the flowers of which release in the morning a fruity scent that is responsible for attracting flies (Symthe, 1969). A "pleasant odor" was also reported for flowers of *Bu. giellerupii* J. J. Smith and described as attractive to *Dacus* (currently *Bactrocera*) fruit flies for pollination (Howcroft, 1983). However, none of the chemical components of all *Bulbophyllum* floral fragrances were identified until the start of the millennium. Recently, the ginger orchid, *Bu. patens* King, was shown to release a ginger essence – zingerone, as a floral synomone that attracts several fruit fly species (Tan and Nishida, 2000); and the fruit fly orchid, *Bu. cheiri* Lindley, releases several phenylpropanoids, of which methyl eugenol is the major component, that attracts male flies of *Bactrocera papayae* Drew and Hancock (not a distinct species from *B. dorsalis*) that assist in pollination (Tan et al., 2002; Nishida et al., 2004).

Males of many *Bactrocera* species are attracted to either methyl eugenol (ME) or raspberry ketone (RK), both of which are plant attractants. The RK-sensitive species are also attracted to cue-lure - a synthetic analogue of RK that contains an acetyl group. However, zingerone is the only compound that attracts, though weakly, male flies of both ME- and RK-sensitive species (Tan and Nishida, 2000). Male flies of pest and non-pest species are important pollinators of *Bu. patens* and *Bu. cheiri*, which secrete specific floral fragrance containing zingerone and

ME, respectively. They are grouped under the section Sestochilus that has 60–70 species worldwide (Vermeulen, 1991). As the total number of RK-sensitive fruit fly species (>6) in Malaysia, is higher than that of the ME-sensitive species (3), it is important to search within the section Sestochilus for a *Bulbophyllum* species that secrete RK in order to further understand the coevolution between *Bulbophyllum* orchids and *Bactrocera* fruit flies.

Bulbophyllum apertum Schltr. (name published in 1906 before its currently used synonym *Bu. ecornutum* J. J. Sm. [J. J. Vermeulen, personal communication, 2003]) is an epiphyte with a widespread distribution in the tropics from Thailand to Moluccas, where it is found in podzolic forests and in shrubby forests on limestone hills at 400–1300m elevation. Its inflorescence is one-flowered with pale green, yellowish, or pale pink petals and sepals with or without purple markings; and has a bright orange hamulus – an appendage loosely attached to the pollinia (Vermeulen, 1991). The flower has 'no particular smell,' and the function of the hamulus is unknown (Ramussen, 1985). Nevertheless, the small and non-resupinate flower (Figure 1), with a floral fragrance resembling that of RK, is visited by male fruit flies belonging to several pest and non-pest species (Tan, 2000 a,b). The objectives of this paper are: a) to determine the species of attracted flies and to observe the behavior of fruit fly visitors; b) to observe the role of hamulus in pollinarium removal; c) to analyze the floral fragrance and confirm the presence of RK; and d) to determine the content of RK in various floral organs and fruit fly visitors.

METHODS AND MATERIALS

Plants and Flowers. Observations of the orchid flowers and plants were conducted in the Tenom Orchid Center (on the fringe of a tropical rainforest) Tenom, Sabah, East Malaysia. The *Bu. apertum* (subspecies verrucosum) plants were from the Nabawan population in Sabah. Flowers were individually collected, weighed, and immersed in ethanol (redistilled) for chemical analyses.

Observation of Fruit Flies Attracted to Bu. apertum *Flowers.* Fly attraction to the flowers was observed before and after they bloomed. Pollinarium removal by a fruit fly visitor was carefully observed with special attention paid to the role of the hamulus in this process. After observation, flies visiting the flower were collected in clear plastic bags whenever possible and identified to species.

Extraction of Floral Fragrance. Flowers of *Bu. apertum* were plucked in late morning on the day they bloomed (at 0600–0800 hr), as a day-old (1 d.o.), and on subsequent mornings as 2 and 3 d.o. under natural conditions, where fruit fly feeding could occur. Each flower was immersed in sufficient ethanol in a 5 ml glass vial and used for GC-quantifications. For individual floral organs (column, lip, petals, and lateral and medial sepals), each floral part was carefully removed from a freshly bloomed flower (within 3 hr after it bloomed and not

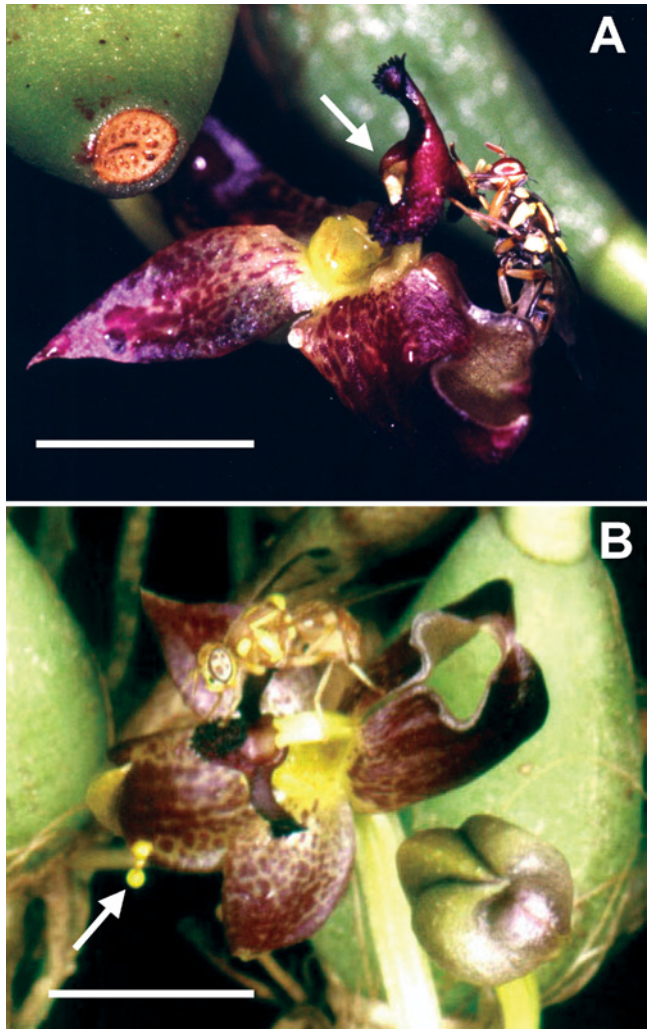

FIG. 1. (A) Flower of *Bulbophyllum apertum* with a male fruit fly of *Bactrocera caudatus* feeding on the triangular lip, which is in an open position and twisted by the fly [bar = 1 cm]. Note: a) Arrow points to hinge between the lip and column-foot, and b) the fruit fly is longer than the floral lip. (B) Flower of *Bulbophyllum apertum* with a misplaced pollinarium on the medial sepal, and a male melon fly (*Bactrocera cucurbitae*) feeding on the triangular purple lip, which is in a closed position, tilted towards the column [bar = 1 cm]. Note: a) arrow points to a pollinarium (pollinia + hamulus) freshly deposited after being removed accidentally by the fly's leg, b) the melon fly is longer than floral lip, and c) a floral bud at bottom right.

exposed to fruit flies), weighed and soaked in 0.5 ml ethanol in a 1 ml glass vial for quantification of RK. For GC-MS analysis, a combined extract of four flowers was concentrated under reduced pressure (ca. 20 mmHg, below 35°C) and partitioned between a mixture of hexane, benzene, and methyl acetate (1:1:2 v/v/v), and 1% sodium bicarbonate in water. The organic layer was washed with saturated sodium chloride in water and dried over anhydrous sodium sulfate and concentrated in partial vacuum, and a portion was used for GC-MS.

Extraction of Volatiles from Fruit Flies. Two *B. caudatus* male flies (main visitors) were captured after feeding for over 20 min on *Bu. apertum* flowers. The whole body was soaked in 0.5 ml ethanol in a 1 ml glass vial.

Chemical Analysis. GC-MS analyses were performed on an Hewlett Packard 5989B mass spectrometer coupled with an HP 5890 series II plus gas chromatograph, using an HP-5MS capillary column (30 m × 0.25 mm, 0.25 μm film thickness) and programmed from 60° (2 min holding) to 290°C at a rate of 10°C/min; the GC was equipped with a total ion monitor. GC-quantification of volatile chemicals was performed on an HP 4890A gas chromatograph using HP-1MS and HP-5MS capillary column (15 m × 0.25 mm, 0.25 μm film thickness) and programmed from 60° (1 min holding) to 280°C at a rate of 10°C/min; the GC was equipped with a total ion monitor and a flame ionization detection.

Quantification of Volatiles. 1) Flowers. Quantification of the volatile components in a whole flower and each floral organ was performed using GC under the conditions described above by comparing the FID-intensities with those of the standard samples.

2) Flies. Portions of the ethanol fly extract were subjected to GC-MS analysis and GC-quantification as described above for flowers.

3) Authentic Samples. Raspberry ketone (4-(4-hydroxyphenyl)-2-butanone) (**1**), vanillyl alcohol (**3**), and veratryl alcohol (**4**) were purchased from Tokyo Chemical Industries Co. Ltd. Rhododendrol (racemic, 4-(4-hydroxyphenyl)-2-butanol; synonymous with frambinol or betuligenol) (**2**) was synthesized by reduction of **1** using lithium aluminium hydride in ether.

RESULTS

Fruit Fly Species. Species of male fruit fly visitors to *Bu. apertum* flowers were identified as *B. albistragata* (de Meijere), *B. caudatus* (Fabricus), *B. cucurbitae* (Coquillett) (the melon fly), and *B. tau* (Walker), hereafter collectively referred to as RK-sensitive species. These fruit flies respond to cue-lure baited traps (Tan and Lee, 1982). Usually a fruit fly, rarely two, was seen on a flower at any one time under natural conditions. Except for *B. albistragata*, most male visitors appeared to be too big for the relatively small and moveable floral lip of the *Bu. apertum* flower (Figure 1A). Some of the larger flies were observed to feed on the lip until satiation while standing on a lateral sepal (Figure 1A). No other

insects were observed on the orchid flowers, with the exception of an occasional ant walking across a petal or sepal.

Pollinarium Removal and Pollination. In one instance, a male *B. albistragata* effectively removed a pollinarium. The fly first landed near a flower, climbed onto it, and then began to probe and lap with its proboscis the surface of a petal. It eventually climbed on top of the see-saw lip (normally on a higher plane than the column - a characteristic of a non-resupinate flower). The fly continued to feed and move slowly along the short lip, and suddenly, it was toppled into the column cavity by the lip due to an imbalance during shifting of the fly's weight from one side of the floral hinge to the other (facing the column). The fly became momentarily trapped between the closed lip and column. While the fly struggled to free itself from a tight situation, the pollinarium was dislodged. During this process, the viscidium (a sticky area at the base of the hamulus) was touched, and pushed downwards (during tilting of the fly), then upwards (as the fly moved backward to free itself), sticking to the fly's thoracic dorsum. The fly with the pollinarium stuck onto its thorax immediately took off. The stiff hamulus (the bulbous end that has a sticky viscidium protruded prominently in the direction of the floral lip from the anther) acted like a crowbar to lift the pollinia out of the anther. In several other cases, where the fly was too big for the lip mechanism to work effectively, the fly either just lapped on the lip surface while standing on one of the lateral sepals without alighting on the lip (Figure 1A), or if it did go onto the lip, it simply walked across the column during an imbalance. During these visits, mainly by *B. caudatus*, the pollinarium was either not removed or was accidentally removed. In the latter case, one of the fly's legs either trampled on or brushed downward onto the hamulus, thereby removing the pollinarium (four instances of eleven observed). Figure 1B shows a pollinarium freshly deposited on the medial sepal after being removed accidentally by a melon fly's leg.

One or two relatively large seedpods were observed in the study site on several occasions over a period of seven years among two clumps of *Bu. apertum* pseudobulbs on a tree trunk and side branches over 3 m above ground. The seedpods were positive evidence that successful pollination of flowers had occurred in the previous season.

Floral Components of Bu. apertum. Figure 2 shows the GC trace of an extract of the floral lip of *Bu. apertum* where the attractant chemicals were concentrated. The major volatile component **1** was identified as raspberry ketone (RK, 4-(4-hydroxyphenyl)-2-butanone). RK was accompanied by its corresponding alcohol - rhododendrol (**2**). Vanillyl alcohol (**3**) and veratryl alcohol (**4**) were also detected as minor constituents. The identification was done by comparing their mass spectra and GC-retention times (on HP-1 and HP-5) with those of the authentic samples:

Compound **1** (raspberry ketone). MS: *m/z*(%) 164(71, M^+), 149(9), 121(15), 107(100), 91(13), 77(14), 43(19). Compound **2** (rhododendrol). MS: *m/z*(%) 166(67, M^+), 148(36), 133(100), 121(7), 107(95), 94(7), 77(19), 45(12).

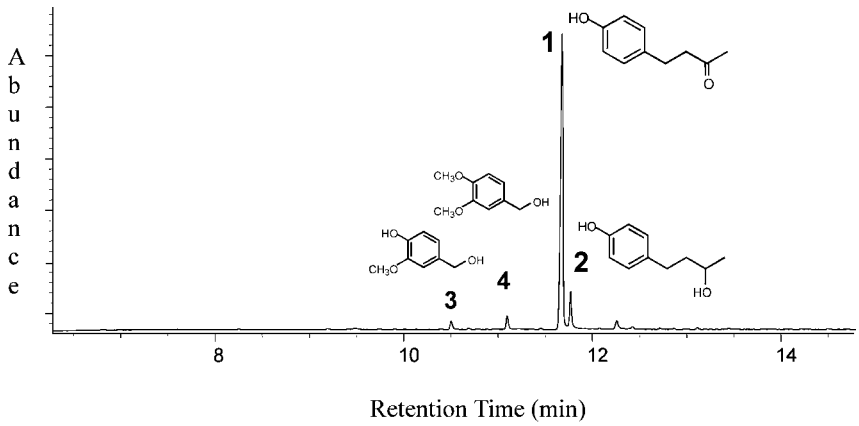

FIG. 2. Gas chromatogram of an extract from the lip of the *Bulbophyllum apertum* and structure of compounds. 1: Raspberry ketone, 2: Rhododendrol, 3: Vanillyl alcohol, 4: Veratryl alcohol.

Compound **3** (vanillyl alcohol). MS: *m/z*(%) 154(100, M^+), 137(38), 125(37), 122(26), 93(38), 65(33). Compound **4** (veratryl alcohol). MS: *m/z*(%) 168(100, M^+), 151(31), 139(45), 137(30), 109(20), 97(12), 93(13), 65(17).

Quantities of Raspberry Ketone in Floral Parts and Male Fruit Fly Bodies. Figure 3 shows the GC quantification and fresh weight of floral parts – column, lip, petals, and lateral and medial sepals. RK was almost exclusively in the lip, with small quantities (<0.5 μg) in the petals, and none or undetectable amounts in the other three floral parts. The quantity of rhododendrol in the lip was more or less proportional to that of RK (approx. 15% of **1**). Both vanillyl and veratryl alcohols were detected in low quantities (less than 1 μg/lip) in two of the ten lip specimens.

The mean ($\pm$SD) floral RK content for 1 d.o. was 7.8 $\pm$ 5.0 μg, 2 d.o. 9.2 $\pm$ 6.2 μg, and 3 d.o. 5.9 $\pm$ 3.8 μg. Although a slight decrease in RK was noted for the 3 d.o. flowers, there was no significant difference in RK content of the three different ages of flowers.

The total RK sequestered in the body tissue of *B. caudatus* after feeding on a *Bu. apertum* flower was 5.0 μg per fly.

DISCUSSION

Bu. apertum flowers show a large variation in their average RK content both within and among flower groups of different ages. Besides possible varietal differences, RK may be dependent on environmental factors such as temperature

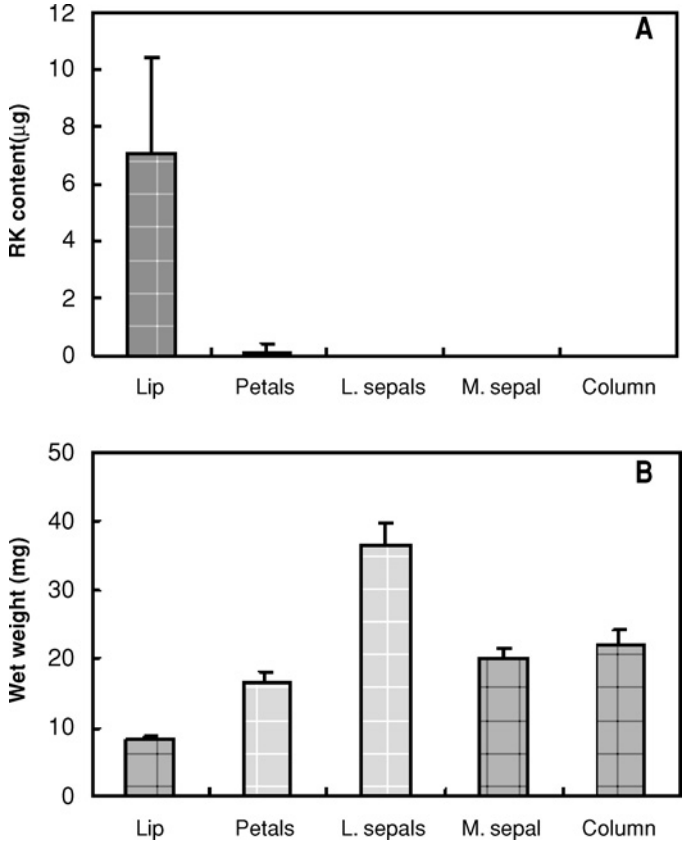

FIG. 3. Quantities of raspberry ketone in each floral organ (lip, lateral sepals, median sepal, petal, and column) ($N = 11$) (A), and fresh weight of floral organs ($N = 5$) (B) in each part of a *Bulbophyllum apertum* flower.

and light intensity that affect the synthesis/production of RK by individual flowers, as well as on the natural release rate by each flower and whether RK has been taken up by flies. These factors warrant further investigation.

The fact that RK is found almost exclusively in the lip of *Bu. apertum* explains why an attracted fly will eventually be led to feed on the lip surface. The see-saw lip seems designed to topple an attracted fly into the column cavity, and the precise removal of the pollinarium, which sticks onto the fly's thoracic dorsum, depends on the efficiency of this see-saw lip mechanism, and plays a vital role in pollination. However, this mechanism works only on flies with certain body sizes. If a fruit fly has a relatively large body, it can stand on one of the lateral

sepals and feed on the lip surface until satiation without climbing onto the lip, thus avoiding being toppled into the column cavity. Furthermore, if a large fly alights on the lip, it can just walk across the column during an imbalance of the see-saw lip; sometimes in this process it accidentally removes the pollinarium with its leg and deposits it on another part of the flower (Figure 1B). Although more cases of accidental removal of pollinarium were observed, leading to total pollen wastage, successful pollination must have also occurred as indicated by the presence of seedpods among some clusters of pseudobulbs.

The function of the hamulus as pollinia stalk is unclear (Rasmussen, 1985; J. J. Vermeulen, 2003, personal communication). The hamulus tends to break just below the bulbous swelling when touched after removal from the anther (Rasmussen, 1985). We propose that the hamulus, being stiff, acts like a crowbar that forces the pollinia out of the anther when the opposite end (bulbous swelling/viscidium) is pushed downwards by the toppled fly. When the pollinarium sticks to the dorsum of a fly, the pollinia on the hamulus protrude like small dumb-bells standing on one end. This is a different mechanism from *Bu. patens* and *Bu. cheiri*, where the pollinarium has no hamulus, but a flexible and soft pollinia stalk. When removed and transported during pollination, the pollinia become attached closely on the thoracic dorsum of a fruit fly (Tan and Nishida, 2000; Tan et al., 2002).

In two RK-sensitive species, *B. cucurbitae* and *B. tryoni* (Nishida et al., 1993; Tan and Nishida, 1995), RK is consumed and positively sequestered into the rectal (pheromonal) gland. We also found that it is sequestered into the body of wild *B. caudatus* after feeding on the *Bu. apertum* flower. The quantity of RK sequestered by the wild male (5.0 μg/male) was sufficient to provoke an aversive effect against a predatory Asian house gecko, *Hemidactylus frenatus*, when topically applied to houseflies (5.1 μg/fly) (Tan, 2000c). Thus, *Bu. apertum* seems to effectively endow a defensive benefit to its potential pollinator.

An attractant to monitor and control RK-sensitive fruit fly pest species has been developed commercially in the form of 'Cue lure' an analog of RK. This lure is not found in nature. It is spontaneously converted to RK in the presence of moisture (Metcalf, 1990). Males of the melon fly that were fed cue lure sequestered RK into the rectal glands (Nishida et al., 1990); wild male melon flies fed on cue lure mated more frequently than wild males not exposed to cue lure; and mass-reared flies that fed on cue lure were more successful in mating competition than control flies (Shelly and Villalobos, 1995). However, the advantage of feeding on cue lure is temporary - lasting less than three days (Shelly and Villalobos, 1995). Therefore, in order to maintain the sexual advantage, wild and polygamous flies may need to visit and feed on a natural RK source regularly. In the tropics, natural floral sources of RK have been previously detected in *Dendrobium superbum* flowers, which have fixed lips and where attracted *B. cucurbitae* male flies were observed to feed only on petals and sepals (i.e., there was no pollinarium removal and, thus, the flies played no role in pollination) (Nishida et al., 1993). Here,

we report the first case of a *Bulbophyllum* species emitting RK that potentially mediates a mutualistic association, in which the orchid flower gets its pollinarium transported during cross-pollination, and the fruit fly benefits by improving its reproductive performance as well as defense. Another species, *Bu. emiliorum*, also has a distinct scent of RK in the morning, to the human nose and its floral fragrance is currently under investigation.

There has been no information on the pollination of *Bu. apertum* by natural pollinators. Self-pollination of *Bu. apertum* has never been observed and appears unlikely (Ramussen, 1985). RK-sensitive fruit fly species seem to act as pollinators in the cross-pollination of the *Bu. apertum* flowers. However, flower visitation by species of male fruit flies whose bodies are apparently too long for effective pollinarium pickup may lead to wastage of pollinia via accidental removal, and the flower thereby loses all its pollen contained in the pollinia without gaining any ecological benefit. Only the smaller male fruit flies are effective pollinators for *Bu. apertum*. Consequently, the floral fragrance containing RK acts as a kairomone, which is a chemical signal where the perceiving organism, here the male fruit fly benefits, and the orchid emitter loses. This may create a situation that selects for *Bu. apertum* to evolve a more efficient lip mechanism -i.e., to produce larger flowers with longer lips to accommodate the long body length of other male fruit flies. Conversely, pollinarium removal by a male *B. albistragata* showed that the *Bu. apertum* flower is well adapted to attracting a relatively small-sized fruit fly that effectively pollinates the flowers, leading ultimately to the formation of seedpods. In this latter orchid-fruit fly association, both organisms benefit and the RK in the floral fragrance acts as a synomone.

From an overall behavioral and chemoecological viewpoint, RK in the floral fragrance of *Bu. apertum* can act as either a kairomone or synomone depending on the body size of the fruit fly visiting this orchid. In contrast, the floral fragrances of *Bu. patens* and *Bu. cheiri*, which contain zingerone and methyl eugenol, respectively, always act as synomones regardless of the fruit fly species attracted (Tan and Nishida, 2000; Tan et al., 2002). In the wild, the other three described species of tephritid fruit flies, *B. caudatus*, *B. cucurbitae*, and *B. tau* that have relatively longer body lengths than *B. albistragata* are more abundant. Therefore, it remains to be seen whether *Bu. apertum* will eventually adapt to the more abundant male fruit flies that have body lengths that are longer than the orchid's lip or maintain the *status quo* and remain dependant on the less abundant, smaller sized fruit flies such as *B. albistragata*, with consequently a lower chance of successful pollination in the tropical rain forest ecosystem.

Acknowledgments—We express our sincere appreciation to Herbert Lim and J. Linton and D. Gilong, of the Orchid Centre, Department of Agriculture, Tenom, Sabah, for the supply of orchid flowers and one of us (Tan) to conduct observations; and to J. J. Vermeulen for confirmation of the subspecies. This work was partly supported by the Grant-in-Aid for Scientific Research from JSPS (No. 15405022).

HYDROQUINONE IS NOT A PHAGOSTIMULANT FOR THE FORMOSAN SUBTERRANEAN TERMITE

ASHOK K. RAINA,[1,*] JOHN M. BLAND, and WESTE OSBRINK

(Received August 12, 2004; accepted November 5, 2004)

Abstract—It has been suggested that hydroquinone found in the labial glands of a number of termite species acts as a primary phagostimulating factor. We tested hydroquinone as a phagostimulant using workers from three colonies of the Formosan subterranean termite, *Coptotermes formosanus*, under both laboratory and field conditions. Hydroquinone at concentrations ranging from ca. 0.002–20.0 ng/cm^2 did not increase visitation by *C. formosanus* workers to treated over control filter papers, and was actually repellent at a 20 ng/cm^2 dose. No phagostimulant response to hydroquinone was observed in two colonies. In the third, there was a significant increase in feeding on filter paper treated with a 2 ng/cm^2 dose, but was significantly lower at a 20 ng/cm^2 dose. Furthermore, sand treated with a gradient of hydroquinone, did not evoke increased tunneling activity compared with controls. GC-MS analysis of *C. formosanus* workers indicated that hydroquinone was present at an average of 41 pg/worker. It was also determined that within one week about 11% hydroquinone in aqueous solution oxidized to 1,4-benzoquinone. Our findings indicate that hydroquinone alone does not act as a phagostimulant but instead may act as a repellent at higher concentrations. The attractant/arrestant of the Formosan termite may have multiple components of which hydroquinone, at low doses, could be one.

Key Words—Formosan subterranean termite, *Coptotermes formosanus*, hydroquinone, phagostimulant.

INTRODUCTION

Termite workers foraging for food use trail pheromones to guide other members of their caste to foraging sites (Pasteels and Bordereau, 1998). Once a suitable food source is located, the termites tend to stay and feed at that site.

* To whom correspondence should be addressed. E-mail: araina@srrc.ars.usda.gov

Reticulitermes santonensis and *Schedorhinotermes lamanianus*, have a highly polar, heat-resistant, and nonvolatile component of their labial glands, which when released onto food promoted aggregation and feeding, and was designated a phagostimulating pheromone (Kaib and Ziesmann, 1992; Reinhard and Kaib, 1995, 2001a,b; Reinhard et al., 1997). Using feeding bioassays conducted with *R. santonensis* and *S. lamanianus*, Reinhard and Kaib (2001b) reported feeding-stimulating activity in extracts of labial glands from 11 termite species from five families including one from the Formosan subterranean termite, *Coptotermes formosanus*. Based on these observations, they suggested that such a general feeding-stimulating signal might have evolved in many termite species. The feeding-stimulating component in the labial gland extract was subsequently identified as 1,4-dihydroxybenzene[2] or hydroquinone and varied in concentration from 0.02 ng in *Kalotermes flavicollis* to 10.0 ng in *Mastotermes darwiniensis*, with 0.03 ng in *C. formosanus* (Reinhard et al., 2002a). Doses of 5 and 10 ng hydroquinone applied to 2.5 cm^2 filter paper disks resulted in a phagostimulating effect in *M. darwiniensis*, as did a concentration of 100 ng/cm^2 in field tests carried out in Malaysia with *Coptotermes curvignathus* (Reinhard et al., 2002a).

The Formosan subterranean termite was introduced into the United States during the middle of the 20th century and has since become a serious pest of homes and living trees in several southern states. With increasing restrictions on the use of conventional insecticides, there is need to find environmentally safe technologies to manage this pest. Baiting was suggested a long time ago (Esenther and Beal, 1978) as a means of controlling infestations, and with the introduction of chitin synthesis inhibitors, it has become the treatment of choice (Su, 1994). However, a major constraint in the use of this technology is the failure of the baits to attract termites. Several additives have been used in bait matrices (primarily cellulose containing materials) to make these attractive (Chen and Henderson, 1996; Rojas and Morales-Ramos, 2001). Reinhard et al. (2002b) suggested the use of hydroquinone in bait systems for termite management as both laboratory and field tests, indicated increased feeding by *M. darwiniensis* and *C. acinaciformis* in response to the treatment. In addition, hydroquinone was also reported to act as an attractant over a short distance.

We have also observed that a substrate on which termites have been feeding for some time acts as an attractant/arrestant for conspecific individuals (unpublished information). Therefore, we undertook this study to evaluate hydroquinone as an attractant-arrestant phagostimulant for *C. formosanus* both under laboratory and field conditions.

METHODS AND MATERIALS

Insects. Three field colonies of *C. formosanus* from existing bucket traps were selected. Colonies S-67 and S-6B were from the grounds of Southern Regional Research Center and U-70 from the University of New Orleans (UNO), Lakefront campus, both in New Orleans, LA USA. After collection, the termites along with fresh spruce wood pieces were placed in plastic boxes and kept in an incubator maintained at 28 ± 1°C, 80 ± 5% RH and constant darkness.

Attraction/Phagostimulation Assay. A thin layer of sand (15 g) was poured into individual plastic Petri dishes (90 × 13 mm) and moistened with 2.5 ml distilled water. Two, 2.5 cm diam Whatman #1 filter papers were weighed and each lightly marked with a pencil either as T or C for treated or control, respectively. Hydroquinone (Aldrich, Milwaukee, WI) was dissolved in distilled water to obtain concentrations of 0.01, 0.1, 1.0, 10.0, and 100.0 ng/50 μl (hydroquinone was readily soluble at these concentrations). The filter paper disks were treated either with 10 μl of one of the hydroquinone solutions or water and placed at opposite ends of the Petri dish. Twenty workers were released into each dish, and the dishes were placed under a CCD camera (Emcal Scientific, Poway, CA) under low intensity red light. Distribution of the workers was recorded every 15 min for 3 hr, using a Panasonic AG-6740 time-lapse video recorder. After 3 hr, an additional 80 workers were released into each Petri dish (to obtain greater feeding) and placed in the incubator. After 24 hr, the filter papers were removed, washed, oven dried, and weighed. The assay was repeated six times for workers from each of the three colonies at all five concentrations of hydroquinone. Average consumption was determined for each treatment and each colony.

Tunneling Bioassay. A plastic container (75 × 75 × 30 mm) was connected to a glass T-tube via a piece of Tygon tubing inserted into a hole drilled into the side (Figure 1A). Each free end of the T-tube was connected with a Tygon connector to a 15 cm tube (plastic pipette, 5 mm ID) filled with fine sand. To one tube, a hydroquinone solution was added with a glass syringe through two small holes 5 cm apart (Figure 1B) at the proximal end to produce a gradient of 0.1 to 1.0 to 10.0 ng in 230 μl water, with the lowest concentration being closest to the T-tube. In the other, the sand was treated with distilled water and acted as control. Both tubes were covered with aluminum foil. Termite workers (100) were released into the square container, and tunneling activity through the sand in plastic tubes was monitored every 15 min for 2 hr and then every hour for the next 4 hr. The assay was repeated four times for each of the three colonies.

Field Test. In an initial test, paper towels treated with 125 ng/cm^2 hydroquinone, were strongly repellant, so in the actual field trials a weaker solution was used. In this test 20 × 20 cm paper towels (Bounty®, Procter and Gamble, Cincinnati, OH) were weighed and treated with either 800 ng hydroquinone (2 ng/cm^2) in 2.6 ml distilled water or just water. The towels were folded, enclosed

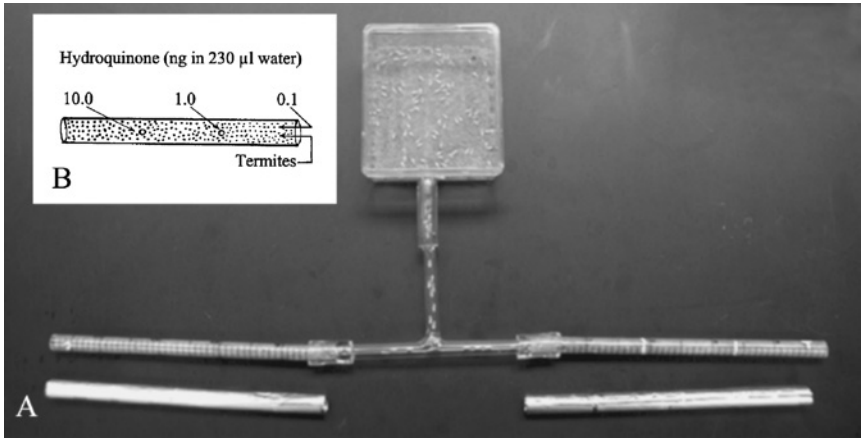

FIG. 1. Setup for tunneling assay. A. The square plastic container with the termites is connected to two tubes through a T-tube. Two aluminum foil covers were slipped over the tubes to exclude light. B. Each tube is filled with sand treated either with water or with hydroquinone in an increasing gradient.

in Tygon tubing (10 cm × 2.2 cm ID) and placed in three different bucket traps (three treated and three control tubes/trap) on the UNO campus after removing the wood. After 72 hr, the tubes and enclosed towels were removed. Each towel was carefully washed, oven dried, and weighed. Average consumption was calculated. The test was replicated four times for each of the three colonies.

Determination of Endogenous Hydroquinone. Freshly collected workers from the three test colonies were used for extraction of hydroquinone. Three samples of 300 workers from each of the three colonies were placed in 4 ml vials and frozen in liquid nitrogen. Water (2 ml) was added to each vial, and the tissue was sonicated (power level 9) with an ultrasonicator (Sonic Dismembrator 60, Fisher Scientific), three times each for 10 sec at 0°C. The aqueous samples were centrifuged for 30 min at 12,000 rpm (4°C), and the supernatant (minus the fat layer) filtered (0.45 μm Millex-GV), lyophilized, and then extracted three times with ether (3 ml) following the addition of $MgSO_4$. The ether was filtered, concentrated to dryness, and the oily residue was extracted with acetonitrile (3 × 100 μl). The acetonitrile solution was concentrated to dryness with nitrogen and dissolved in 45 μl ether. The samples were trimethylsilyl (TMS)-derivatized with N,O-bis-(trimethylsilyl)-acetamide (BSA) (5 μl) in a sonicating bath for 1 hr. A 2 μl aliquot of each sample was analyzed by GC-MS (6890 GC and 5973 MS, Agilent Technologies, Palo Alto, CA). Analysis conditions were: 70 eV EI source, HP-5MS capillary column (30 m × 0.25 mm, 0.25 μm *d*p), He carrier gas (1 ml/min), temperature programmed from 60°C with a 1 min hold to 110°C at 10°C/min

followed by a ramp to 160°C at 3°C/min. Quantitation was based on *m/z* 239 using a standard curve of TMS-derivatized hydroquinone.

Hydroquinone Oxidation Test. Hydroquinone (30 μg in 50 μl distilled water) was applied to 2.5 cm diam filter paper disks (Whatman #1) placed in three 100 × 15 mm plastic Petri dishes (5/dish) in addition to one dish containing water treated control paper disks, and stored at room temperature and in darkness. Five disks were removed after 0, 1, or 4 days and individually extracted with 3 × 100 μl ether. Extracts (1 μl) were tested by GC-MS as described above but with a temperature program from 30°C with a 1 min hold to 210°C at 10°C/min. Quantitation was done using single ion monitor (SIM) at *m/z* 110 and 108 for hydroquinone and benzoquinone, respectively.

Data Analysis. All the data were analyzed using an unpaired *t*-test, Graph Pad Prism version 4.0 (Graph Pad Software Inc. 2003, San Diego, CA).

RESULTS

In the choice test, the workers showed no significant preference for either treated or control disks at hydroquinone concentrations between 0.002 and 2.0 ng/cm^2, but in all three colonies a concentration of 20 ng/cm^2 had a significant repellant effect (Table 1). In two of the three colonies, there was no evidence that hydroquinone affected feeding behavior as the quantities of treated and control paper consumed did not differ significantly. In the third colony, there was evidence that hydroquinone acted as a phagostimulant at a concentration of 2.0 ng/cm^2 but was a feeding deterrent at 20 ng/cm^2 (Table 2).

In the tunneling assay, the distance tunneled in treated and control arms, as a function of time, did not differ significantly in any of the colonies tested (Table 3). For both control and treated tubes, the average distance tunneled in 6 hr was about

[a] Choice test with filter papers (2.5 cm diam) treated with hydroquinone (T) and water (C) presented to 100 workers over a period of 24 hr. Consumption is the average ±SE of 6 replicates for each colony. Means significantly different at $P < 0.05$(*).

79 mm. After 24 hr, workers of U-70 and S-6B had tunneled the entire length of the tube in all cases and come out at the open end (data not presented). Workers of colony S-67 had also tunneled through the tube but did not come out.

In the initial field test, hydroquinone at 125 ng/cm^2 of paper toweling strongly repelled the termites resulting in their abandoning the traps. In the subsequent test, there was no significant difference in consumption of the paper towels between the treated (2 ng/cm^2) and control groups for any of the three colonies tested (Table 4).

Hydroquinone was detected in the whole body extracts of all workers for the three test colonies (Figure 2). Levels ranged from 1–159 pg/worker across all samples with a colony average of 41 ± 37 pg/worker. Hydroquinone was fairly stable over the period used in the bioassays. After one day under conditions similar to assays with termites, recovery of hydroquinone was similar to 0 day, with no increase in the oxidation product (1,4-benzoquinone). Subsequently, the stability of hydroquinone was tested by observing the amount of 1,4-benzoquinone by GC-MS obtained from treated paper disks under conditions similar to the bioassay. The benzoquinone/hydroquinone ratio, after exposure to atmospheric conditions

U-101	1471.0 ± 376.6	1607.0 ± 279.7
Undesignated	1450.0 ± 156.9	1572.0 ± 382.9

Note. Consumption of hydroquinone treated (2 ng/cm^2) and control paper towels placed in traps for three days. Average mg ± SD, $N = 4$.

for up to 4 days, had not significantly changed (data not shown) although the total recovery had decreased.

DISCUSSION

Through a series of publications it was suggested that labial glands of a number of termite species contain a phagostimulating factor (Reinhard and Kaib, 1995; 2001a,b; Reinhard et al., 1997). The factor was subsequently identified as

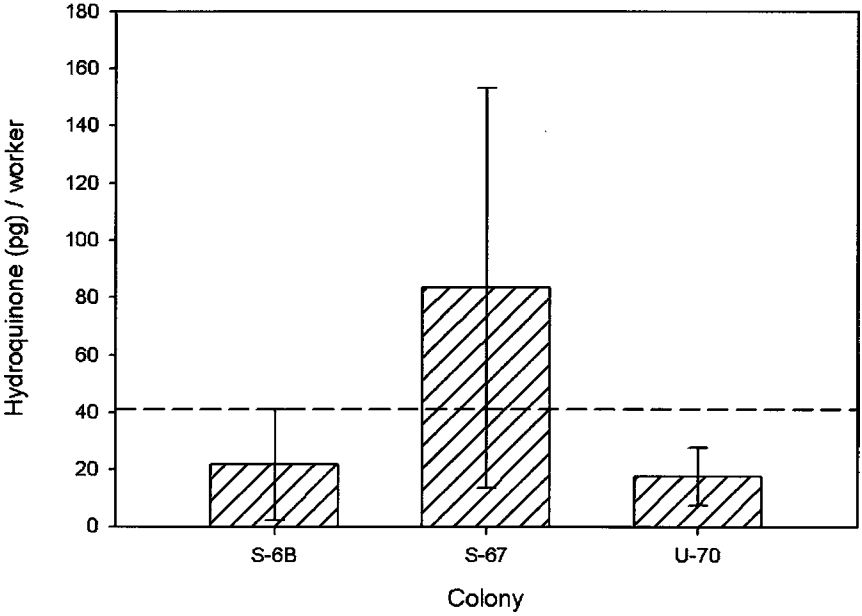

FIG. 2. Amounts of hydroquinone (mean ± SD, $N = 3$) from whole body extraction of three colonies of *C. formosanus* workers. Broken line indicates colony average.

hydroquinone (Reinhard et al., 2002a). It was also shown that hydroquinone was present in the labial gland extract from 15 termite species including *C. formosanus*. They further reported that the compound significantly stimulated feeding by *M. darwiniensis*, on filter papers treated at 2 and 4 ng/cm^2. Consequently, we tested hydroquinone as an attractant/phagostimulant for *C. formosanus*, in comparable tests carried out both in the laboratory and the field. Hydroquinone at concentrations ranging from 0.002–20 ng/cm^2 did not evoke preferred visitation by *C. formosanus* workers to treated filter paper over control paper. On the other hand, the compound was repellent at the 20 ng dose. In rare instances, we observed an initial attraction to hydroquinone treated filter papers with the workers quickly dispersing uniformly. Similarly, no significant phagostimulant response was observed except for workers from one of the test colonies and at only the 2.0 ng dose. However, what is puzzling is that in our experiments, hydroquinone acted as a strong repellent at higher concentrations. Recently, it was reported that in choice tests with *C. formosanus*, hydroquinone did not induce increased consumption at lower doses, whereas at higher doses (1 ng/mg filter paper) the compound acted as a feeding deterrent (Cornelius, 2003). Sand treated with a gradient of hydroquinone, did not evoke increased tunneling activity. In the field test, using a dose comparable to the one used by Reinhard et al. (2002a) for *C. curvignathus*, we found that the termites quickly abandoned the traps. When we used a concentration that had been shown effective for *M. darwiniensis* in the laboratory, there was no difference in feeding between control and treated paper towels.

Analysis of *C. formosanus* workers indicated that hydroquinone indeed was present at an average of 41 pg/worker (colony range: 20–80 pg). This is in conformity with the findings of Reinhard et al. (2002a). They reported an average of 30 pg hydroquinone per labial gland of *C. formosanus*. The stability of hydroquinone in aqueous solution was tested under conditions much more rigorous than the assay, and only a small increase in the amount of oxidation product (1,4-benzoquinone) was observed.

Our results indicate that response of termites to hydroquinone may be species or even colony specific. We have observed that extracts of substrate on which termites were allowed to feed for some time is active as an attractant/arrestant (Raina: unpublished results). The identification of active component(s) in the extract is in progress. It may well be multi-component, of which hydroquinone at very low concentrations could be one of the components. It is also possible that the active factor may be derived from the interaction of termite excretions, primarily from labial glands, on the cellulose-based substrate. Identification of such an attractant will be valuable for use in baits to increase their efficiency.

Abstract—Hybridization in plants provides an opportunity to investigate the patterns of inheritance of hybrid resistance to herbivores, and of the plant mechanisms conferring this resistance such as plant secondary metabolites. We investigated how inter-race differences in resistance of *Eucalyptus globulus* to a generalist mammalian herbivore, *Trichosurus vulpecula*, are inherited in their F_1 hybrids. We assessed browsing damage of three-year-old trees in a common environment field trial on four hybrid types of known progeny. The progency were artificial intra-race crosses and reciprocal inter-race F_1 hybrids of two geographically distinct populations (races) of *E. globulus*; north-eastern Tasmania and south-eastern Tasmania. Populations of trees from north-eastern Tasmania are relatively susceptible to browsing by *T. vulpecula*, while populations from south-eastern Tasmania are more resistant. We assessed the preferences of these trees in a series of paired feeding trials with captive animals to test the field trial results and also investigated the patterns of inheritance of plant secondary metabolites. Our results demonstrated that the phenotypic expression of resistance of the inter-race F_1 hybrids supported the additive pattern of inheritance, as these hybrids were intermediate in resistance compared to the pure parental

hybrids. The expression of plant secondary metabolites in the F_1 hybrids varied among groups of individual compounds. The most common pattern supported was dominance towards one of the parental types. Together, condensed tannins and essential oils appeared to explain the observed patterns of resistance among the four hybrid types. While both chemical groups were inherited in a dominant manner in the inter-race F_1 hybrids, the direction of dominance was opposite. Their combined concentration, however, was inherited in an additive manner, consistent with the phenotypic differences in browsing.

Key Words—*Trichosurus vulpecula*, hybrid, plant secondary metabolites, generalist herbivore, additive inheritance, *Eucalyptus globulus*, hybridization, Formylated phloroglucinol compounds, tannins, essential oils, 1,8-cineole.

INTRODUCTION

Understanding the genetic control of plant resistance to herbivores is crucial in understanding the evolutionary processes behind plant/herbivore interactions (Marquis, 1990; Mauricio and Rausher, 1997), and hybridization offers an ideal opportunity to investigate some of these processes (Bailey et al., 2004). The investigation of the differential resistance of hybrid plants to herbivores, compared to the pure parental plants, has provided insight into the mode of inheritance of resistance in plants. Studies have shown that responses of herbivores to hybrids can vary greatly among plant species and also among different herbivores within one plant species. Various patterns of hybrid resistance have been observed. Hybrid plants may be more susceptible to herbivores than the parental plants (hybrid susceptibility pattern; Floate et al., 1993; Fritz et al., 1998; Dungey and Potts, 2003), more resistant than the parental plant (hybrid resistance pattern; Boecklen and Spellenberg, 1990; Eisenbach, 1996), and exhibit resistance that is intermediate to the parental plants, which indicates additive inheritance of resistance (additive pattern: Aguilar and Boecklen, 1992; Fritz et al., 2001; Scott et al., 2002). In addition to these patterns, hybrids have also exhibited resistance similar to one of the parental plants (dominance pattern; Hjälten, 1997; Orians and Floyd, 1997; Fritz et al., 1998; Hjältén et al., 2000). If hybrids resemble the susceptible parent, then there is dominance for susceptibility, while if the hybrid resembles the resistant parent, there is dominance for resistance. Finally, hybrids can exhibit resistance that is not different from either of the parental plants (no difference pattern; Fritz et al., 1996, 1998; Orians and Floyd, 1997).

Research exploring the response of herbivores to hybrids has focused predominantly on invertebrates, and this has been highlighted in several reviews on the ecological and evolutionary processes of hybridization in plants (Strauss, 1994; Fritz, 1999; Fritz, et al., 1999; Orians, 2000). In comparison, the susceptibility of hybrids to mammalian herbivores has received considerably less attention (but see Vila and D'Antonio, 1998; Scott et al., 2002; Dungey and Potts, 2002; Anderson

and Paige, 2003). Additionally, while many studies have focused on the phenotypic patterns of resistance of hybrids to herbivores, relatively few have investigated the inheritance patterns of the defensive plant characteristics conferring resistance, such as plant secondary metabolites (Orians, 2000 for review; Byrd et al., 1999; Orians et al., 2000; Fritz et al., 2001; Hallgren et al., 2003).

During the past two decades, aspects of the ecological interactions of *Eucalyptus* species and the mammalian herbivores that feed on them have been investigated (e.g., Landsberg, 1987; Hume and Esson, 1993; Lawler et al., 2000; Close et al., 2003). There is clear inter - and intraspecific variation in browsing damage to some eucalypt species by mammalian herbivores (Lawler and Foley, 1999; Lawler et al., 2000; O'Reilly-Wapstra et al., 2002; Scott et al., 2002; Close et al., 2003). Plant secondary metabolites play an important role as the mechanisms behind this variation in resistance (McArthur and Sanson, 1993; Lawler et al., 2000; Wallis et al., 2002; Marsh et al., 2003). Recently, the role of plant genotype in influencing the resistance of a eucalypt species, *Eucalyptus globulus*, to browsing by a generalist marsupial folivore, the common brushtail possum (*Trichosurus vulpecula* Kerr 1792), was documented (O'Reilly-Wapstra et al., 2002; Dungey and Potts, 2002), and inter-race differences accounted for the majority of the genetic-based variation observed in O'Reilly-Wapstra et al. (2002). A group of metabolites known as formylated phloroglucinol compounds (FPCs) (Eschler et al., 2000) were found to be the most significant defensive leaf trait conferring resistance in juvenile coppice foliage of *E. globulus* (O'Reilly-Wapstra et al., 2004). The mode of inheritance of plant resistance and plant defensive traits within this system and in other eucalypt/mammalian herbivore systems, however, remains unclear.

Hybrid resistance to herbivores is determined not only by the genetic background of the plant but is also influenced by variation in environmental factors (Fritz, 1999), such as access to nutrients (Orians and Floyd, 1997). To understand the consequences of herbivore feeding on hybrid plants, it is necessary to differentiate the genetic and environmental causes of the hybrid resistance. Many investigations have been conducted in natural plant systems and, in some cases, these studies have not been controlled for environmental variation, and the genetic status of the hybrid plants was often unknown (Aguilar and Boecklen, 1992; Whitham et al., 1994; Gange, 1995). Managed plant systems growing hybrids of known pedigree in common environment field trials are ideal for investigating the inheritance of resistance in hybrids, without confounding effects of environmental influences.

In this study, we aimed to investigate the inheritance of resistance to browsing by *T. vulpecula* and the inheritance of the defensive plant compounds within *E. globulus*. We assessed the browsing damage by *T. vulpecula* on known F_1 progeny of two genetically differentiated geographical races of *E. globulus* from north-eastern Tasmania and south-eastern Tasmania (see Dutkowski and Potts,

1999 for race classifications of *E. globulus*). The pedigreed progeny used were grown in a common environment field trial and, therefore, differences in susceptibility to browsing is most likely due to host genetics, not environmental effects. The progeny were artificial intra-race and reciprocal inter-race F_1 hybrids involving trees from north-eastern Tasmania and south-eastern Tasmania. Populations of trees from north-eastern Tasmania are relatively susceptible to browsing by *T. vulpecula* (O'Reilly-Wapstra et al., 2002) and contain lower concentrations of FPCs (O'Reilly-Wapstra et al., 2004). Conversely, populations from south-eastern Tasmania are relatively more resistant to browsing (O'Reilly-Wapstra et al., 2002) and have higher concentrations of FPCs (O'Reilly-Wapstra et al., in press). Therefore, this genetic material provided an ideal opportunity to investigate three main questions:

1. How are the racial differences in resistance of *E. globulus* to *T. vulpecula* inherited in their F_1 hybrids in a common environment field trial?
2. Is the variation in resistance in the field trial consistent with patterns of intake of *E. globulus* by captive animals?
3. Are there quantitative differences between the hybrids in leaf chemical characteristics and does this reflect the observed patterns of resistance?

METHODS AND MATERIALS

Field Trial and Plant Material. Browsing of *Eucalyptus globulus* juvenile foliage on 3-yr-old trees by *Trichosurus vulpecula* was assessed in a field trial located at Weilangta, in south-east Tasmania, Australia (42° 44′ S 147° 49′ W). The trial design has been described in detail by Lopez et al. (2003). In brief, trees planted in the field trial were progeny from an 8×8 diallel crossing (80% complete excluding selfs) design where all possible crosses among eight parents were carried out. The parents were random samples of trees in native stands of *E. globulus* from both north-eastern Tasmania (termed north) and south-eastern Tasmania (termed south) races (following Dutkowski and Potts, 1999). The parental trees were growing more than 10 km apart and were considered unrelated. Four parental trees were from the north, and four were from the south. These crosses resulted in four hybrid types; intra-race crosses, north × north (NN) and south × south (SS), and two reciprocal inter-race F_1 hybrids, north × south (NS) and south × north (SN). The female parent is stated as the first letter in the cross, and the male parent is stated as the second letter in the cross. The field trial at Weilangta was planted in 1999, and a duplicate trial was planted at the same time at Geeveston, in south-east Tasmania, Australia (43° 09′ S 146° 51′ W). Trees were planted in a randomized block design with each hybrid represented as a single tree plot. There were 18 field replicates at Weilangta and 17 at Geeveston. The Geeveston field trial was fenced to prevent mammal browsing, while the Weilangta field trial was not. In

July (winter) 2002, all trees (648 in total) in the Weilangta trial were assessed for browsing damage. Each tree was observed for damage by *T. vulpecula* and given a 'browsing damage score,' which was as follows: 0 = no damage; 1 = minor browsing damage evident in the crown; 2 = major structural branch damage in the crown (due to *T. vulpecula*), with none to little browsing damage; 3 = major browsing damage in the crown; 4 = major structural branch damage and major browsing damage in the crown.

Feeding Trial. After assessing browsing damage in the Weilangta field trial, we tested the preferences of six captive *Trichosurus vulpecula* (three male and three female, 2.5–4.1 kg body mass) for juvenile foliage from the four hybrids (NN, NS, SN, SS) in a feeding trial. All animals were caught, housed, and maintained, following McArthur et al. (2000). Foliage used in the feeding trial was selected from the Geeveston field trial as it was un-browsed and hence avoided any possible effects of induced chemistry responses of the foliage. Juvenile foliage (cut branches) was selected from as many trees as possible from several replicates to ensure a full representation of each family in each hybrid sample. Cut branches from each hybrid type were combined to make up four bunches of foliage; NN, NS, SN, SS. The foliage for each trial was cut from the field at the beginning of each trial, and foliage was stored in a cool room (5°C) with cut stems in water. Animals were offered foliage as four, of the possible six, paired choice feeding trials, as the four pairs provided adequate comparisons to rank the relative preference of each hybrid type. The pairs were: Trial 1 = SN and SS; Trial 2 = NN and SS; Trial 3 = NS and SN; and Trial 4 = NN and NS. Each trial ran for 3 d and all 6 animals received the same foliage at the same time. For each trial, a random selection of cut stems were presented to each animal in their cage as two bunches (one bunch for each cross race type) in a container of water.

Sufficient foliage was presented to each animal to allow *ad libitum* feeding. On each day (at ~1500 hr), total fresh mass (g) of each bunch was measured before being placed in the container. The next morning (at ~0800 hr), the remains of each bunch were weighed (including any plant fragments found on the cage floor). Intake was estimated as the amount of foliage consumed (weight difference) from each bunch, and all intakes were expressed in terms of grams dry matter per kilogram of body mass of the consumer (g DM.kgBM^{-1}), based on the fresh to dry weight ratios calculated from the control plants. During the feeding trial, animals were offered a basal diet (see McArthur et al., 2000) at the same time as the experimental foliage. The amount of basal diet offered was 75% of that required to maintain body mass. This ensured that animals would eat the test foliage by choice, not because they were hungry, and ensured that all animals maintained body mass throughout the trial. On each day of the trial, two bunches of each hybrid fed to animals were also prepared as controls. The mean overnight change in mass of the two controls was used to adjust for changes in mass of the experimental plants. On each morning of the trial, one bunch was stripped

of the leaves, which were oven dried (35°C for 1 wk and 80°C overnight before weighing) to determine their absolute dry matter (DM). The second bunch was frozen for subsequent chemical analysis.

Chemical Analysis. For each hybrid type, the control plants from the feeding trials were combined and foliage was randomly sub-sampled 4 times for each analysis for each variable. We assayed plants for nitrogen, plant cell wall components (neutral detergent fiber, acid detergent fiber and lignin; $N = 3$ for these constituents), total essential oils and 1,8-cineole, total phenolics, condensed tannins, and six formylated phloroglucinol compounds (FPCs) (sideroxylonal A, sideroxylonal B, sideroxylonal C, macrocarpal A, macrocarpal B, and macrocarpal G; $N = 3$ for these constituents).

Primary Chemistry. Nitrogen was determined following the sulphuric acid and hydrogen peroxide method of Lowther (1980) using air-dried ground foliage, ground in a cyclone grinder through a 1-mm mesh sieve. Digested samples were colorimetrically analyzed for nitrogen (QuikChem method 10-107-06-2E, Lachat Instruments, WI, USA) on a continuous flow injection analyzer (QuikChem 800, Lachat Instruments). Standard samples of known nitrogen concentration and blank samples were included to validate the efficiency of digestion and elemental analysis. Nitrogen results are expressed as % DM.

Plant cell wall components were analyzed by sequentially fractioning dried ground foliage. Neutral detergent Fiber (NDF), acid detergent Fiber (ADF), and acid detergent lignin (lignin) were determined following the ANKOM Technology procedures (ANKOM $^{200/220}$Technology Operator's Manual, 1997). Results are expressed as % DM.

Secondary Chemistry. Essential oils (terpenes) were extracted using dichloromethane with heptadecane as an internal standard (100 mg of heptadecane was diluted in 1 l of dichloromethane) (O'Reilly-Wapstra et al., 2004). One gram of thawed foliage, cut into approximately one cm pieces, was soaked in the dichloromethane solvent for 1 hr. Extracts were analyzed by combined gas chromatography-mass spectrometry (GC-MS) on a Varian 3800 g chromatograph coupled to a Varian 1200 triple quadrupole mass spectrometer, using a 30 m × 0.25 mm Varian 'Factor Four' VF-5 ms column with a 0.25-micron film. One microliter aliquots were injected into a Varian 1177 split/splitless injector at 200°C using a split ratio of 20:1, and a GC column temperature profile of 60°C to 260°C at 12 degrees per minute. The electron energy was 70eV, and the range from m/z 35 to 350 was scanned on quadrupole 1 three times per sec. Total ion currents (TIC) were determined separately for 1,8-cineole, the sum of all oil components (referred to as total oils), and for the heptadecane internal standard. Results for 1,8-cineole and total oils were then standardized by dividing by the internal standard. A response factor for cineole relative to the heptadecane internal standard was determined from a pure standard, and the amount of 1,8-cineole was expressed as mg.g DM^{-1}. The amount of total oils was expressed as equivalents of cineole (mg.g DM^{-1}).

Total phenolics and condensed tannins were assayed using the modified prussian blue assay for total phenolics (Graham, 1992) and the acid butanol assay for condensed tannins (Porter et al., 1986). Foliage for these assays was prepared and extracted following the method outlined in Hagerman (1995). In brief, 0.6 g of air dried, ground leaf was weighed into glass tubes, and 5 ml of 70% acetone were added. Samples were sonicated at 4°C for 30 min and centrifuged for 10 min at 2800 g.min^{-1}. The supernatant was poured off and saved at 4°C. This process was repeated 3 more times for each sample. The supernatants were combined for each sample. The concentration of the total phenolics (mg.g DM^{-1}) was determined in relation to a gallic acid standard (SIGMA G-7384), and the concentration of condensed tannins (mg.g DM^{-1}) was determined in relation to a purified sorghum tannin standard.

Formylated phloroglucinol compounds were extracted following the method outlined in Wallis et al. (2003). Specific representative FPCs were determined by HPLC using a Waters Alliance 2690 HPLC with a Waters 996 UV/Vis diode array detector. The chromatogram at 280 nm was generated for peak area measurements from diode array data acquired between 230 nm and 400 nm. The column was a 250 mm × 4.6 mm Wakosil C18RS 3micron (SGE), using a flow rate of 1 ml/minute. A tertiary gradient system was used; solvent A was 0.1% trifluoroacetic acid in acetonitrile, solvent B was Milli-Q water, and solvent C was 'hexanes' (85% n-hexane, Mallinckrodt). The initial mix was 93:7 A and B, then a linear gradient to 100% A between 13 and 15 min was used. At 20 min, the solvent mix was immediately changed to 95:5 A and C, and this was held until 27 min when it was immediately changed to 90:10 A and C to help remove late eluting FPCs. At 38 min it was ramped back to starting conditions through 100% A and equilibrated for 7 min before the next sample. Peaks were identified by retention times and UV spectra in comparison to authentic standards, and representative samples were also analyzed by combined negative ion electrospray HPLC-MS to confirm that the molecular weights and tandem MS data of the peaks selected from the UV trace were also consistent with the standards (Eyles et al., 2003). Under these conditions, retention times were: sideroxylonal A 10.53 min, sideroxylonal B 15.32 min, sideroxylonal C 11.11 min, macrocarpal A 8.26 min, macrocarpal B 9.86 min, macrocarpal G 25.00 min. Results are expressed as mg.g DM^{-1} for sideroxylonal A and C and macrocarpal A and B. Results for sideroxylonal B are expressed as mg.g DM^{-1} equivalents of sideroxylonal A, and results for macrocarpal G are expressed as mg.g DM^{-1} equivalents of macrocarpal A.

Statistical Analysis. Results from the field trial were analyzed by first fitting a mixed model to the individual tree browsing data to determine if there was any significant difference in browsing score across the four hybrids and to test for replicate effects in the field trial design. Residuals were checked for normality and homoscedasticity with the general linear model procedure (PROC GLM) in SAS (SAS Institute Inc., SAS version 8), and the data were log transformed. Log transformed browse score was the dependent variable and the fixed effect

was the hybrid type. The random effects were replicate and replicate by hybrid type interaction. The model was fitted with a PROC MIXED procedure in SAS (SAS Institute Inc., SAS version 8). A *posteriori* multiple pair-wise comparisons of significant effects (least squares means) were made using the Tukey-Kramer adjustment. We performed *a priori* contrasts (contrast statement, SAS Institute Inc., SAS version 8) to test among predicted patterns of browsing damage on the parental and F_1 hybrids (Fritz et al., 1996; Hjältén et al., 2000). Figure 1 illustrates the contrasts performed and the possible expected outcomes.

Results from the feeding trial were analyzed as four separate trials: Trial 1 = SN and SS; Trial 2 = NN and SS; Trial 3 = NS and SN; and Trial 4 = NN and NS. The PROC UNIVARIATE procedure in SAS was performed for each trial to determine if the difference in intake between the two pairs was significantly different from zero (SAS Institute Inc., SAS version 8).

Results for each chemical constituent were first analyzed by fitting a one factor general linear model (PROC GLM) for each chemical variable with hybrid

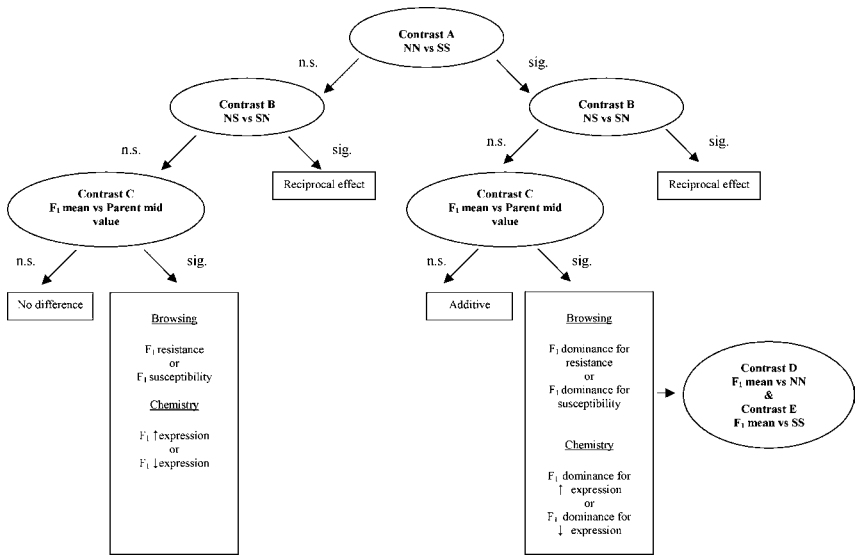

FIG. 1. Description of the contrast procedures and the potential outcomes of inheritance patterns of the browsing resistance to *T. vulpecula*, as assessed in the field trial, and of the concentration of chemical constituents of *E. globulus* foliage from the captive feeding trial. *NN* the hybrid from the northern Tasmania × northern Tasmania cross; *SS* the hybrid from the southern Tasmania × southern Tasmania cross; *NS* the hybrid from the northern Tasmania × southern Tasmania cross; *SN* the hybrid from the southern Tasmania × northern Tasmania cross. The first letter in the cross represents the maternal parent. *sig* a significant contrast; *n.s.* a non significant contrast.

type (SAS Institute Inc., SAS version 8). Residuals were checked for normality and homoscedasticity. Data for total oils and 1,8-cineole were log transformed, and data for macrocarpal A were inverse transformed (1/macrocarpal A). Following this, if there were significant effects, we performed *a priori* contrasts (PROC MIXED, SAS Institute Inc., 1990) to test among predicted patterns of concentration of chemical constituents on the parental and F_1 hybrids (Figure 1). If an effect was not significant following the general linear model analysis, no contrasts were performed.

RESULTS

Browsing damage by *T. vulpecula* on individual trees at the Weilangta field trial ranged in browsing damage score from 0 (no damage) to 4 (major structural branch damage and major browsing damage in the crown). There were no replicate or replicate hybrid effects ($P > 0.05$). There was a highly significant difference in damage score among the four F_1 hybrid types ($F_{3,51} = 37.90$, $P < 0.001$, Figure 2). The intra-race NN cross was browsed more than the other three hybrid types, while the SS cross was browsed less than the other three hybrid types. There was no significant difference between the inter-race reciprocal F_1 hybrids (NS and SN), and these were intermediate in amount of browsing damage compared to the parental intra-race crosses, supporting the hypothesis of additive inheritance on the log transformed scale (Figure 2).

Table 1 illustrates foliage intake by *T. vulpecula* of each hybrid pair and results of the univariate statistical analysis for each feeding trial. In trial 1, there was no significant difference in intake between the two hybrids SS and SN. In trial 2, foliage from the NN cross was more preferred by *T. vulpecula* than foliage from the SS cross. In trial 3, there was no difference in intake of foliage between the NS and the SN hybrids, while in trial 4 there was no difference in intake of the NN and NS hybrids, although the NN cross tended to be more preferred.

Several chemical constituents varied significantly ($P < 0.05$) among the four hybrid types (Table 2 and 3). There was a difference in the nitrogen content among the four types. The NN hybrid cross had higher nitrogen content than the SS cross. A difference between the two F_1 hybrids indicates a reciprocal cross effect for nitrogen concentration (Table 3), with each F_1 hybrid tending to be closer to its maternal parent indicating a maternal reciprocal effect. However, the range in nitrogen concentration from 1.3% to 1.4% may not be biologically significant. Results for acid detergent Fiber show significantly higher acid detergent Fiber content for the SS cross compared to the NN cross (Table 2 and 3) and F_1 dominance for decreased expression (Table 3). There was variation in total oil and 1,8-cineole concentration among hybrid types (Table 3). Contrast A shows the two intra-race hybrid crosses differed significantly in total oils and 1,8-cineole;

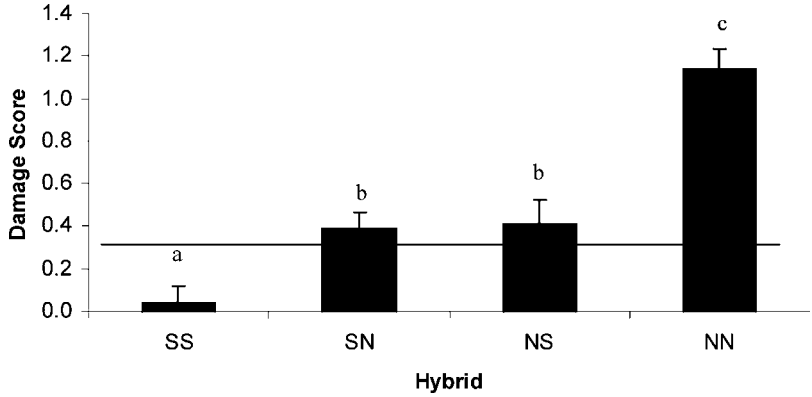

FIG. 2. Browsing damage by *T. vulpecula* for each hybrid type in the field trial. Values are least squares means with SE bars. Letters that differ indicate significant differences ($\alpha = 0.05$ after Tukey-Kramer adjustment for multiple comparisons). The line represents the back transformed mid parent value.

SS had higher concentrations of oil than NN (Table 2 and 3). There was no difference in concentration of total oils and 1,8-cineole between the two F_1 hybrids (contrast B), however, there was a significant difference between the mean F_1 hybrid concentration and the midparent value (contrast C). Significance at contrast D indicates F_1 dominance for increased expression of oil production. There was a significant difference in concentration of condensed tannins among the four hybrid types (Table 3). The SS intra-race cross had more condensed tannins than the NN cross (Table 2 and 3), and there was F_1 dominance for reduced expression (Table 3). There was no difference among the four hybrid types in concentration of sideroxylonal A, however, there were significant differences in all other FPCs (Table 3) despite the concentrations of these compounds being low (Table 2). There was F_1 dominance for decreased expression of sideroxylonal B, and F_1 dominance for increased expression of sideroxylonal C, although these patterns should be viewed with caution due to the low concentrations. A reciprocal effect was evident for all macrocarpal concentrations with the SN F_1 hybrid having higher concentrations of macrocarpals than all other hybrid types. There are no significant differences in concentration of total phenolics, neutral detergent fiber and lignin among the four hybrid types (Table 3).

DISCUSSION

In this study, we had an *a priori* expectation that the two parental hybrids would exhibit differential susceptibility to browsing by *T. vulpecula* (O'Reilly-Wapstra et al., 2002). The patterns of browsing by *T. vulpecula* on *E. globulus*,

	NS	6.7 (1.40)		

in previous common environment field trials planted across different geographic areas of Tasmania, have consistently shown that populations of *E. globulus* from north-eastern Tasmania are more susceptible than populations from south-east Tasmania (Volker and Orme, 1988; O'Reilly-Wapstra et al., 2002). This was supported in both the field trial and captive feeding trial results in this present study. The pure parental hybrid from the north-eastern Tasmania race (NN) was more susceptible to *T. vulpecula* than the parental hybrid from the south-eastern Tasmania race (SS). The pattern of hybrid resistance, however, was unknown. The phenotypic expression of resistance of the inter-race F_1 hybrids supports the additive pattern (Fritz, 1999) of hybrid resistance. On the log scale, the F_1 hybrid was intermediate in resistance, compared to the parental hybrids, and this pattern of browsing is consistent over two separate years of field data (Potts, unpublished data). Numerous studies in plant hybrid/insect systems have demonstrated that the patterns of hybrid resistance are highly variable (e.g., Aguilar and Boecklen, 1992; Eisenbach, 1996; Hjältén, 1997; Fritz et al., 1998). In comparison, relatively few studies have examined the resistance of hybrids to mammalian herbivores (but see Vila and D'Antonio, 1998; Dungey and Potts, 2002; Scott et al., 2002; Anderson and Paige, 2003). However, the patterns of hybrid resistance to mammalian herbivores appear just as varied as those patterns expressed to insect herbivores. Increased hybrid resistance (Vila and D'Antonio, 1998), additive inheritance of resistance (Scott et al., 2002), dominance towards susceptibility (Dungey and Potts, 2002), and no difference in hybrid resistance compared to the parental plants (Anderson and Paige, 2003) have all been demonstrated.

Confirmation of the field trial results (the differential resistance of NN and SS) in the feeding trial indicates that the difference in resistance is most likely due to foliage characteristics, such as plant secondary metabolites, as opposed to other characteristics such as tree form. Based on our previous studies (O'Reilly-Wapstra et al., 2004) and research in similar systems (Lawler et al., 2000; Wallis

TABLE 2. CONCENTRATION (LEAST SQUARES MEANS (±SE)) OF PRIMARY AND SECONDARY CHEMICAL CONSTITUENTS OF FOLIAGE OF THE FOUR HYBRID TYPES OFFERED TO *T. VULPECULA* IN THE CAPTIVE FEEDING TRIALS[a]

Constituent	Units	Hybrid			
		SS	SN	NS	NN

[a] Contrast Comparison a is Between the Two Intra-Race Hybrid Crosses (Parental Crosses), Comparison B Between the Two F_1 Hybrids, Comparison C Between the Mean of the F_1 Hybrids and the Mid-Parent Value, Contrast D Between the Mean of the F_1 Hybrids and NN (the Susceptible Parent), and Contrast E Between the Mean of the F_1 Hybrids and SS (the Resistant Parent). the Final Column Refers to the Hypothesis or Inheritance Pattern that is Supported by the Hybrid Results. *NDF*, Neutral Detergent Fibre, *ADF*, Acid Detergent Fiber

[b] indicates mixed model analysis.

[c] indicates either that no contrasts were performed as there were no significant differences between hybrids in the GLM analysis, or that further contrast analysis between hybrids was redundant.

[d] indicates log transformed data.

[e] indicates inverse transformed data.

et al., 2002), we expected the formylated phloroglucinol compounds (FPCs) to follow the pattern of hybrid resistance observed in this study and to provide the mechanism of resistance in these plants. On the contrary, there was no relationship between FPC concentration and relative resistance of the four hybrid types. The most likely reason for this is that, despite some differences in concentration of FPC compounds in these leaves, the actual concentrations were very low and, therefore, perhaps biologically ineffective in acting as deterrents to *T. vulpecula* in this particular foliage. This point requires further discussion.

In comparison to the three-year-old juvenile foliage used in this study, our previous and ongoing research with *E. globulus* and preferences by *T. vulpecula* has utilized foliage from coppice re-growth (O'Reilly-Wapstra et al., 2002; O'Reilly-Wapstra et al., 2004) and young seedlings (O'Reilly-Wapstra, unpublished data). Concentrations of FPCs in these two types of foliage are higher than those measured in the present study; sideroxylonal A concentration was 0.9–8.5 mg.g DM^{-1} and 0.2–1.8 mg.g DM^{-1} for coppice and seedling foliage, respectively. It is possible that the production of higher levels of FPCs in *E. globulus* coincides with the period when the plant is most vulnerable to mammalian herbivores. *Eucalyptus* seedlings are particularly susceptible to browsing by mammals (Gilbert, 1961; Bulinski and McArthur, 1999), and we speculate that coppice re-growth is also susceptible to mammal browsers, as has been demonstrated with insect herbivores feeding on *Eucalyptus* (Abbott et al., 1993; Steinbauer et al., 1998) and with *T. vulpecula* (O'Reilly-Wapstra et al., 2002). While the concentration of FPCs in the seedling foliage (O'Reilly-Wapstra, unpublished data) are still quite low, the differences in concentration between coppice, seedling and three-year-old juvenile foliage is consistent with this idea. Additionally, although *T. vulpecula* is an arboreal herbivore and is capable of consuming foliage at all successive *E. globulus* life stages, three year old *E. globulus* trees (approximately 4 m in height) may be better capable of recovering from foliage loss. Consequently, defensive mechanisms to mammalian herbivory (FPC production) may not be necessary at this stage, and energy may be allocated to traits such as growth and reproduction. In this species, ontogenetic development of the tree results in heteroblastic leaf change from the seedling leaf phase to the juvenile phase at around 18 wks (James and Bell, 2001). Timing of juvenile to adult foliage phase change is variable (Jordan et al., 2000) but can occur at around 1.5–3 yr (James and Bell, 2001). Many studies have demonstrated developmental changes in leaf resistance to herbivores (e.g., Kearsley and Whitham, 1989; Fritz et al., 2001), including *E. globulus* resistance to insect herbivory (Steinbauer, 2002; Lawrence et al., 2003). Production of defensive chemistry to mammalian herbivory may, therefore, alter at these phase changes and become relatively unnecessary in older trees. However, further investigation of the chemical profile and timing of expression of plant secondary metabolites in *E. globulus* foliage at different life stages is necessary to elucidate this.

There were clear differences in resistance among the four hybrid types, particularly between the two parental hybrids. We suggest that the combined effect of condensed tannin and essential oil concentrations conferred this difference. Condensed tannins and essential oils were significantly higher in the SS than the NN parent. These two groups of plant secondary metabolites have been demonstrated to decrease herbivory by mammalian herbivores in many systems (Harborne, 1991). Tannins have been shown to decrease intake of *Eucalyptus rossii* and *E. consideniana* foliage by *T. vulpecula* (Marsh et al., 2003). Tannins can decrease herbivory by mammals by binding with dietary proteins (Hagerman and Butler, 1991). The maximal flow rate of salivary proline-rich proteins (available to bind with dietary tannins) in *T. vulpecula* is relatively slow compared to other marsupial herbivores (McArthur et al., 1995). This may indicate a decreased ability to cope with ingested dietary tannins. The negative effect of increasing 1,8-cineole levels in artificial diets on intake by *T. vulpecula* has also been highlighted (Wiggins et al., 2003). While the levels of 1,8-cineole required to constrain intake in that study were much higher than in *E. globulus* in the present study, clear preferences at lower concentrations were still detected in the "choice" feeding trials in the latter study. We suggest, therefore, that *T. vulpecula* still responds to foliage chemical characteristics in choice feeding trials, even when levels do not physiologically constrain intake.

We also suggest that the combined effect of tannins and essential oils in this *E. globulus* foliage explains the inheritance of resistance demonstrated in the inter-race F_1 hybrids. The SS parent had significantly higher levels of both compounds compared to the NN parent. While the F_1 hybrids deviate from the mid-parent value in each of these compounds, the direction of dominance was opposite. Condensed tannin levels in the hybrids showed dominance for decreased expression (similar to the NN parent), while essential oils showed dominance for increased expression (similar to SS parent). Consequently, the combined effects of these two groups of compounds (condensed tannin + essential oil) shows an additive pattern of expression: SS hybrid had the highest, NN hybrid had the lowest, and the two inter-race hybrids fell intermediate. This pattern is consistent with the observed patterns of additive inheritance of resistance.

In a review of the effects of hybridization on plant secondary chemistry, Orians (2000) found that hybrids typically express concentrations of compounds at intermediate levels (additive pattern) or at levels similar to one of the parents (dominance pattern). The majority of compounds in this study exhibited the dominance pattern but, interestingly, the direction of dominance varied. As discussed above, the inter-race hybrids showed dominance for decreased expression of condensed tannins, while dominance for increased expression of essential oils was also evident. This could arise, for example, if a dominant gene(s) for the reduced expression of condensed tannins (from the susceptible NN parental hybrid) and a dominant gene(s) for the increased expression of essential oils

(from the resistant SS parental hybrid) are expressed in these hybrids. Few studies have examined the pattern of inheritance of plant secondary metabolites in eucalypts, but two have reported that the inheritance patterns of essential oils in inter-specific hybrids varies. The additive pattern (Dungey et al., 2000; Farah et al., 2002) and the dominance and no difference pattern (Dungey et al., 2000) have all been demonstrated. The variable pattern of results from Dungey et al. (2000) indicate that different compounds, even from the same group (terpenes) can exhibit different inheritance patterns, as also demonstrated with the FPCs in this study.

In summary, we demonstrated that the inter-race differences in the phenotypic expression of resistance to *T. vulpecula* in *E. globulus* are inherited in an additive manner. Variation in resistance of the foliage appeared to be due to the combined effects of condensed tannins and essential oils. These compounds were both in high concentrations in the SS cross and significantly lower in the NN cross. At present, there is no evidence to suggest that past or current densities of *T. vulpecula*, and consequently browsing pressures, differ between the north-east and south-east populations of *E. globulus*. Consequently, explanations as to why these populations differ in resistance and chemical profiles remain to be elucidated. While oils and condensed tannins were inherited in a dominant manner in the inter-race F_1 hybrids, the direction of dominance was opposite, resulting in their combined concentration being inherited in an additive manner. This is consistent with the phenotypic differences in browsing. Five different patterns of hybrid inheritance of plant chemistry were demonstrated. This highlights that patterns of inheritance of resistance and plant secondary metabolites vary not only among plant species, as demonstrated in numerous systems, but also considerably within a plant species and within closely related groups of plant compounds.

Acknowledgments—Animals were caught and maintained under the University of Tasmania Animal Ethics Committee, Project No. A6655; and Parks and Wildlife Service Permit No. FA03102. We would like to thank Gunns Ltd and Forestry Tasmania for access to the field trials for assessment and foliage collection. We thank Hugh Fitzgerald for assistance with foliage collection and Ann Wilkinson for running the analysis of the nitrogen digests. This project was funded by the University of Tasmania Postgraduate Scholarship and the CRC for Sustainable Production Forestry.

(Received July 8, 2004; accepted November 8, 2004)

Abstract—We examined the interaction between host trees and fungi associated with a tree-killing bark beetle, *Dendroctonus frontalis*. We evaluated (1) the response of four *Pinus* species to fungal invasion and (2) the effects of plant secondary metabolites on primary growth of and secondary colonization of three consistent fungal associates. Two of these fungi, *Entomocorticium* sp. *A* and *Ophiostoma ranaculosum*, are obligate mutualists with *D. frontalis*, and the third associate is a blue-staining fungus, *O. minus*, that is commonly introduced by beetles and phoretic mites. *O. minus* negatively affects beetle larvae and in high abundance can impact *D. frontalis* population dynamics. Size of lesions formed and quantity of secondary metabolites produced in response to fungal inoculations varied significantly among *Pinus* species. However, monoterpene composition within infected tissue did not significantly vary across treatments. While all eight tested metabolites negatively affected the growth rate of *O. minus*, only 4-allylanisole, *p*-cymene, and terpinene reduced the growth of the mycangial fungi. Surprisingly, growth rates of mycangial fungi increased in the presence of several secondary metabolite volatiles. *O. minus* out-competed both mycangial fungi, but the presence of secondary metabolites altered the outcome slightly. *O. ranaculosum* out-performed *E.* sp. *A* in the presence of dominant conifer monoterpenes, such as α- and β-pinene. Volatiles from the mycangial fungi, particularly *E.* sp. *A*, had a negative effect on *O. minus* growth. In general, phloem phytochemistry of particular *Pinus* species appeared to alter the relative growth and competitiveness of mutualistic and non-mutualistic fungi associated with *D. frontalis*. The outcome of interactions

* To whom correspondence should be addressed. E-mail: rwh@Dartmouth.edu

among these fungi likely has important consequences for the population dynamics of *D. frontalis*.

Key Words—*Dendroctonus*, *Ophiostoma*, *Entomocorticium*, monoterpenes, plant defenses, competition, mycelial interactions, antagonism, symbiosis, resin.

INTRODUCTION

The oleoresin system of pines is a primary mechanism of tree resistance against subcortical invasion by insects and pathogens (Paine et al., 1997; Trapp and Croteau, 2001). The physical properties of resin, particularly the quantity of resin flow, are important in deterring and excluding attacking insects such as tree-killing bark beetles (Smith, 1966; Raffa and Berryman, 1982; Christiansen and Horntvedt, 1983; Paine and Stephen, 1987; Franceschi et al., 2000). Alternatively, chemical properties of oleoresin are likely more important in disrupting the activity of insects within trees by altering the nutritional quality of subcortical tissues (Smith, 1963; Coyne and Lott, 1976; Hodges et al., 1985). Differences in the chemical composition and physical properties of oleoresin among pine species are thought to be related to differences in resistance to insects and pathogens (Hodges et al., 1979; Tisdale et al., 2003).

More specifically, differences in the oleoresin chemistry among tree species may indirectly affect tree-killing bark beetles by altering the colonization success (Christiansen, 1985; Raffa and Smalley, 1988), growth rate (Bridges, 1987; Ross et al., 1992), and competitiveness of fungi associated with beetles (Raffa, 2001). Mutualistic fungi are thought to enhance the access of beetles to phloem tissues either by helping kill the tree (pathogenic; Solheim, 1992; Paine et al., 1997), neutralizing secondary metabolites within phloem (Paine, 1984), or providing phloem nutrients directly or indirectly to progeny (Barras, 1973; Beaver, 1989). Additionally, mutualistic fungi that are antagonistic to, or resist displacement by, non-mutualistic fungi could contribute to the successful development of beetle larvae (Goldhammer et al., 1990; Klepzig and Wilkens, 1997).

Variation in primary phytochemistry (e.g., N, P, carbohydrates) and secondary phytochemistry (e.g., terpenes, phenolics) likely leads to differences in the relative success and abundance of mutualistic and non-mutualistic fungi (Raffa, 2001), which would influence beetle fitness and subsequently the initiation and speed of beetle population growth (Showalter and Filip, 1993; Trapp and Croteau, 2001). The growth of and interactions between beetle-fungal associates on substrates varying in primary and secondary phytochemistry, however, have not been thoroughly studied.

Here, we focus on three questions dealing with the effects of tree metabolites on the growth and competitiveness of fungi associated with bark beetles: 1. Do trees vary in their response to various fungi associated with bark beetles? 2. Are

growth rates of the various fungal species differentially affected by plant secondary compounds within plant tissues? 3. Are intraguild interactions among fungi influenced by tree-secondary metabolites and beetle by-products? We selected the fungal community associated with the southern pine beetles, *Dendroctonus frontalis* Zimmerman (Coleoptera: Scolytidae), as a study system because (1) *D. frontalis* colonize a broad range of *Pinus* hosts, but have differential reproductive success across pine species and sites (Hodges et al., 1979; Veysey et al., 2003), (2) the reproductive success of *D. frontalis* depends on the presence of mutualistic fungi living in phloem (i.e., endophloedic) (Barras, 1973; Goldhammer et al., 1990), and (3) the presence of non-mutualistic fungi appears to affect larval development and influence broad patterns in *D. frontalis* population dynamics (Lombardero et al., 2003; Hofstetter et al., unpublished data).

We addressed the first question by quantifying the response of four *Pinus* species to artificial inoculations of three prominent fungal associates of *D. frontalis*. We hypothesized that localized tree response (lesion size and chemical composition) to fungal infection is influenced by (1) environmental conditions and (2) tree species. To address whether the response by *Pinus* to fungal infection is an effective defensive mechanism against both fungal invasion and beetle colonization, we quantified the effects of secondary metabolites of *Pinus* on fungal colonization and growth. We used a paired-confrontation assay to determine whether secondary metabolites alter the ability of fungi to resist or suppress invasion, or colonize substrate currently occupied by another fungus. We hypothesize that the presence of particular secondary metabolites alters the competitive interaction between fungi associated with *D. frontalis*.

METHODS AND MATERIALS

Study System. *Dendroctonus frontalis* is a destructive forest pest in the southeastern United States (Price and Doggett, 1978; Coulson and Witter, 1984). This beetle is efficient at finding and exploiting potential hosts (Payne et al., 1978; Nebeker et al., 1993) and can kill large numbers of otherwise healthy, vigorous pine species (Schowalter and Filip, 1993). Successful host colonization and subsequent reproduction of *D. frontalis* depend on the presence of mutualistic fungi, *Entomocorticium* sp. A. and/or *Ophiostoma ranaculosum* (formerly *Ceratocystiopsis ranaculosus*; Jacobs and Kirisits, 2003), that are carried from tree to tree in specialized glandular structures (mycangia) within the prothorax of female beetles (Francke-Grosmann, 1967; Barras and Perry, 1972). The two mycangial fungi are only found in the presence of *D. frontalis*, and the symbiosis is apparently a product of coevolution (Harrington, 1993). In the presence of mycangial fungi, adult beetles lay more eggs, which produce larvae that grow faster, survive better, and produce larger adults (Barras, 1973; Bridges, 1983; Bridges and Perry, 1985;

Goldhammer et al., 1990). However, the two species of mycangial fungi are not equivalent; larvae that feed on *E*. sp. A grow faster and become larger than those feeding on *O*. *ranaculosum* (Goldhammer et al., 1990).

A blue staining fungus, *Ophiostoma minus*, is commonly associated with *D*. *frontalis* (Barras, 1970; Bridges et al., 1985). In southern pine forests, *O*. *minus* is primarily an ectosymbiont of *D*. *frontalis* (Nelson et al., 1934), but it may also be carried by other insects associated with *D*. *frontalis* (Hofstetter, 2004). *O*. *minus* is detrimental to developing beetle larvae (Barras, 1970; Goldhammer et al., 1990; Lombardero et al., 2003), apparently because it displaces the mycangial fungi or disrupts the interactions between larvae and mycangial fungi within phloem tissue (Ross et al., 1992; Klepzig and Wilkens, 1997). In the presence of blue-stain, adults burrow away, while larvae produce atypical, winding galleries and usually die (Barras, 1970; Lombardero et al., 2003). This is unlike beetle species that carry other species of blue staining fungi within their mycangium, in an apparent mutualism (Paine and Hanlon, 1994; Six and Paine, 1998). High levels of *O*. *minus* can contribute to the decline of local beetle populations and the collapse of regional epidemics (Hofstetter, 2004).

Fungal Cultures. We isolated mycangial fungi (*E*. sp. A, *O*. *ranaculosum*) directly from the mycangia of female *D*. *frontals* (methods similar to Barras and Perry, 1972) collected from beetle infestations in the Homochitto National Forest, Mississippi, in June 1998. We isolated *O*. *minus* from the surface of *D*. *frontalis* beetles collected from *D*. *frontalis*-infested bark, also collected in Mississippi, June 1998. We cultured five strains of each fungus on malt extract (2%) agar (MEA) and incubated them at 25°C in darkness.

1. *Do Trees Vary in Their Response to Different Fungi Associated with D*. *frontalis?* We conducted two experiments to assess the response of healthy trees to fungal inoculations. In the first, we tested the hypothesis (1a) that the localized tree response (lesion size and chemical composition) to fungal infection is influenced by soil nutrient availability. In 1993, 45 loblolly pines, 25 years of age, located within an even-aged, thinned loblolly pine plantation in Camp Beauregard near Pineville, LA (31°22′ N, 92°22′ W), were selected for fertilization treatments. Half of the trees (randomly chosen) were fertilized with di-ammonium phosphate (150 kg/ha of phosphorus and 134 kg/ha of nitrogen) during each winter from 1993 to 1998. In August 1998, we inoculated 15 fertilized and 15 unfertilized *Pinus taeda* with the three fungal species. Points of inoculation were 1 m above the ground and separated horizontally around the tree by more than 10 cm. We removed 3 phloem and bark disks (1.22 cm diam) from each tree using a sterile cork borer, inoculated the tree with one of the three fungi, and replaced and sealed the outer bark with duct tape. We randomly selected one of the five strains of each fungus for each inoculation. The inoculums consisted of a 5 mm diam agar plug of culture. After 14 d, we removed the outer bark from the inoculation site, and measured the phloem lesion area (length, width, and total area). We evaluated

fungal growth rate using an ANOVA model (JMP 3.2.1, SAS Institute Inc. 1997) that included the parameters fertilization treatment, fungal species, fertilization-fungus interaction, and tree (nested within fertilization). The parameter fungus strain (within fungal species) was not included in the model because no appreciable difference was observed in fungal growth rate among fungal strains. To correct for heteroscedasticity, we log-transformed lesion size.

In the second experiment, we tested the hypothesis (1b) that localized tree response (lesion size and chemical composition) to fungal infection is influenced by tree species, fungal species, and wounding treatments. We tested four *Pinus* species commonly attacked by *D. frontalis*. In May 1999, we inoculated (as above) 15 trees of *P. echinata* (shortleaf), *P. palustris* (longleaf), and *P. taeda* (loblolly) within one mixed-species stand in the Oakmulgee Ranger District of the Talladega National Forest, Alabama, and 15 trees of *P. virginiana* in the Bankhead National Forest, Alabama. Each tree was inoculated at separate points with each of the three fungal species and chitosan (product of fungal/beetle cell wall; methods of Klepzig and Walkinshaw, 2003) and 2% MEA control. All trees were 30–40 yr of age and 20–30 cm diam trunk (d.b.h.). We also measured phloem thickness and resin flow (methods of Lombardero et al., 2000) just before the inoculations. After 21 d, we removed the outer bark and measured the lesion area. After measurement, we removed one half of each lesion for phytochemical analysis (stored at -80°C) and the other half (stored at -5°C) for fungal isolations. We analyzed total N and C using a Carlo-Erba C:N Analyzer. We analyzed monoterpene content by placing phloem samples (1.00 g) from each lesion into HPLC grade pentane with a *p*-cymene internal standard for 24 hr then analyzed the pentane samples using a 6890 GC equipped with a 5973 MS (Hewlett-Packard Corp., Palo Alto, CA) with an HP-5MS 30 m length $\times$ 250 um ID $\times$ 0.25 um thickness column. The temperature program was 60°C for 1 min- 6°C/min to 200°C, then 15°C/min- to 250°C. Flow rate was 0.9 ml/min, and the injector temperature was 200°C. We identified compounds by their mass spectra and matched the retention time with known standards.

We evaluated lesion size (total area) and lesion phytochemistry using an ANOVA model (JMP 3.2.1) that included *Pinus* spp, fungal spp, *Pinus*-fungus interaction, and tree (nested within *Pinus*). No appreciable difference in lesion size was observed within fungal strains and, thus, was not included in the model. To correct for heteroscedasticity, we log-transformed lesion areas and square root-transformed secondary metabolite concentrations. We computed Pearson product-moment correlations among lesion size, total secondary metabolites, and tree traits with a Bonferroni correction. Individual compounds were analyzed with a MANOVA (same model as previous ANOVA, but with each individual terpene as a dependent variable). Wilk's lambda and Roy's Maximum Root statistic were used to quantify main effects for tree species, inoculation treatment and their interaction.

2. Are Growth Rates of Fungi Differentially Affected by Primary and Secondary Metabolites Within Phloem? We conducted three experiments to assess the effects of volatiles from tree secondary metabolites and fungal metabolites on fungal growth. First, we determined whether growth among fungi varies in the absence of secondary metabolites. Second, we determined whether fungal growth rates change in the presence of particular tree-secondary metabolites. Third, we determined whether volatile byproducts from neighboring fungi influenced fungal growth.

We hypothesized (2a) that differences in primary phytochemistry of trees influences the growth rate of each fungal species. We assessed the growth rates of fungi on intact phloem tissue from which volatile secondary metabolites had been removed. In August 1998, we removed a phloem disk (10 cm diam) from each of 15 fertilized and 15 unfertilized *Pinus taeda* at the Camp Beauregard site. We discarded the outer bark and autoclaved the intact phloem for 20 min at 121°C to volatilize secondary metabolites and sterilize. We divided each phloem disk into thirds and placed them on a thin layer of water agar within a Y-shaped Petri dish (Fisher Scientific Inc.). We then placed on each section a disk of MEA (5 mm diam) that had been previously colonized by *O. minus*, *O. ranaculosum*, or *E.* sp. *A*. The sealed dishes were then incubated at 20°C in the dark. Beginning three d after the inoculation, and every two d thereafter, we traced the area of phloem occupied by hyphae on the lid of the dish. Once the phloem disk was completely colonized by fungi, we removed the lids and analyzed growth (both area captured and linear growth/day) with a planimeter. Prior to inoculation, we analyzed total nitrogen and carbon of each phloem sample using a Carlo-Erba C:N analyzer. We recorded annual tree growth using dendrometer bands affixed at 2 m above ground, and measured tree height growth with a hypsometer. Lombardero et al. (2000) previously reported effects of crown size, fertilization, and drought conditions on tree growth and resin production at this site. Linear growth and area captured by fungi on phloem disks were quantitatively similar within each fungal species. For simplicity and consistency with other experiments, we used linear growth in our statistical tests. We evaluated fungal growth rate using an ANOVA model (JMP 3.2.1, SAS Institute Inc., 1997) that included fertilization treatment, fungal species, fertilization-fungi interaction, and tree (nested within fertilization). To correct for heteroscedasticity, we log-transformed fungal growth rate. We evaluated correlations among fungal growth rates and tree traits (yearly growth, height, resin flow, phytochemistry).

In the second experiment, we tested the hypothesis (2b) that particular compounds commonly found within lesion tissue reduce the growth of each fungal species. To determine the effects of individual compounds on the growth of each fungus, we placed a 0.5 cm disk of MEA colonized with actively growing hyphae of one of the three species (*O. minus*, *O. ranaculosum*, or *E.* sp. A) onto the center of a 100 × 20 mm Petri dish of 2% MEA. We tested seven volatile compounds

commonly found in oleoresin of yellow pines (Pearl, 1975; Hodges et al., 1979): α-pinene, (S,−)β-pinene, (R,+)limonene, γ-terpinene, *p*-cymene, 4-allylanisole (estragole), and myrcene (Sigma-Aldrich, Inc.). Each compound (1.0 ml) was absorbed on a sterile filter paper (55 mm diam) and placed inside the Petri dish and sealed with parafilm; this created an atmosphere that was approximately saturated with the compound. We incubated each plate upside down at 25°C in darkness. Each treatment and a control (filter paper alone) were replicated 10 times for each fungus. We traced the outer edge of fungal growth on the outside of the dish every 2 d using a map tracer. We measured growth in four directions (0°, 90°, 180°, 270°) and averaged them to give a value for each time period. We ended the assay when the fungus reached the end of the Petri dish.

In the third experiment, we tested the hypothesis (2c) that volatile compounds released by neighboring fungi negatively affect fungal growth. We measured the growth rate of *O. minus* in the vicinity of one of four fungi associated with *D. frontalis*. We placed newly inoculated malt-agar plates of *O. minus* (face down) 1 cm above a 20-d old plate of actively growing *O. ranaculosum*, *E.* sp. A, *O. minus*, *Leptographium terebrantis*, or blank malt-extract agar control. We measured the growth of the inverted *O. minus* culture every two d until the plate was completely colonized (∼10 d). We replicated each fungal combination 25 times within separate 60 cm^2 plastic Petri dishes. We analyzed the effects of volatile compounds released from fungi on growth of *O. minus* at 6 d using ANOVA (following square root transformation) followed by Tukey-Kramer HSD.

3. Are Intraguild Interactions Mediated by Secondary Metabolites? We conducted an experiment to assess the effects of secondary metabolites on interactions between fungi. We hypothesized that the presence of tree secondary metabolites alters the ability of each fungal species to resist and suppress invasion or capture territories occupied by another fungus. We quantified area of resources captured by each fungi and observed the interaction between paired fungi using a paired confrontation assay (*O. minus vs. O. ranaculosum*; *O. minus vs. E.* sp. *A*; *O. ranaculosum vs. E.* sp. *A*) on 2% MEA media in the presence of a secondary metabolite. We added an eighth treatment, uric acid, which is a large component of beetle frass and common in larval chambers. We replicated each combination and media treatment 10 times. We aseptically removed disks (5 mm diam) of colonized malt extract agar from actively growing colonies of each of two fungal species and placed the inoculum onto opposite sides of the Petri plate (100 × 20 mm). We placed the fungal disks upside down within 2 cm from the edge of the plate. We placed a filter paper (55 mm diam), saturated with a compound (1.0 ml), inside the Petri dish, or added uric acid (concentrations of 1% or 0.5% by volume) directly to media prior to poring agar into plates. We incubated the plates upside down at 25°C in darkness. We traced the outer edge of fungal growth on the outside of the dish every 2 d. At the termination of the experiment, we measured the area occupied (cm^2/2 d) and the linear growth of each fungus using a digital planimeter

for each time increment. We compared the qualitative interactions between fungi following a key by Porter (1924).

RESULTS

1. Do Trees Vary in Their Response to Different Fungi Associated with D. frontalis? Hypothesis 1a: Localized response (lesion size and chemical composition) to fungal infection is influenced by environmental conditions.-Fertilization of *P. taeda* had no effect on lesion size among fungal species ($F_{2,43} = 0.89$, $P = 0.41$). However, *O. minus* consistently produced larger lesions (mean $\pm$ std: 94.9 ± 57.9 cm^2) than both *E.* sp. *A* (2.4 ± 2.6 cm^2) and *O. ranaculosum* (5.4 ± 4.9 cm^2). Lesion sizes from *O. minus*-inoculations were positively correlated with percent nitrogen in uncolonized phloem ($r = 0.70$), lesion sizes from *O. ranaculosum* were negatively correlated with percent carbon in phloem ($r = -0.63$), and lesion sizes from *E.* sp. *A* were positively correlated with tree growth rate (change in trunk circumference) ($r = 0.55$). All other tree measurements were not correlated with lesion size ($P > 0.05$). Only *O. minus* was successfully isolated (i.e., producing a living culture) from lesion tissues. No fungi were isolated from phloem beyond the lesion area.

Hypothesis 1b: Localized response (lesion size and chemical composition) to fungal infection is influenced by tree species, fungal species, and wounding treatments.–Lesion size in response to fungal inoculations varied little among tree species (Table 1), although *O. minus* produced somewhat larger lesions in *P. taeda* and *P. virginiana* than *P. echinata* and *P. palustris* (Figure 1). The interaction between inoculation treatment and *Pinus* species had no effect on lesion size (Table 1). The only significant correlations (across trees within species) between lesion size and % nitrogen, % carbon, resin flow, or tree diameter (Table 2) was a negative relation between % C in *P. virginiana* and the lesion size from *O. minus* ($r = -0.74$).

The total amount of secondary metabolites within lesions varied among pine species and depended upon the fungal species that was inoculated (Figure 1B, Table 1). In general, *P. echinata* had higher volumes of secondary metabolites per gram of phloem, and *P. palustris* had lower volume of metabolites than the other two tree species. Inoculations of *O. minus* did not result in significant increases in total metabolites in any of the tree species relative to the other inoculation treatments (*O. minus* vs. mean of other treatments; $P > 0.05$). Six compounds were detected in moderate amounts: (in general order of most to least abundant) α-pinene, β-pinene, 4-allylanisole, myrcene, limonene, and camphene. Ratios of the compounds varied significantly among tree species (Table 1, Figure 2). For instance, *P. echinata* and *P. virginiana* had significantly lower concentrations of β-pinene and 4-allylanisole than *P. taeda* and *P. palustris* across all inoculation treatments ($P < 0.05$). Also, limonene concentration in *P. virginiana* was high

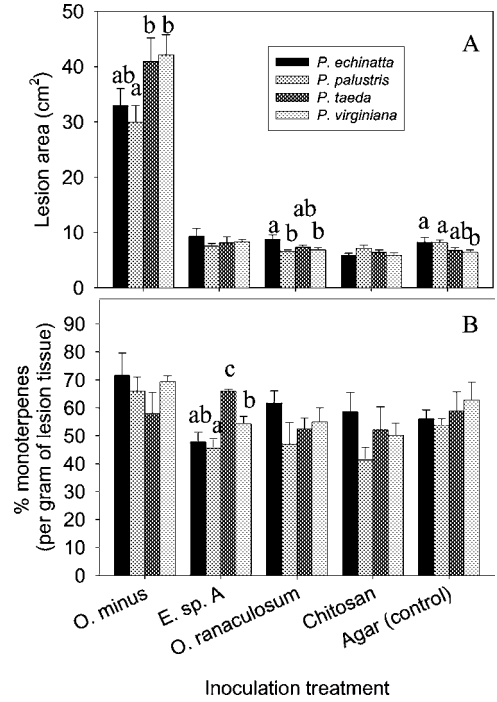

FIG. 1. (A) Lesion size (cm^2) and (B) monoterpene levels (including 4-allylanisole) in 4 *Pinus* species after 14 days in response to inoculation of *Ophiostoma minus*, *Entomocorticium* sp. *A*, *O. ranaculosus*, chitosan, and agar control.

relative to the other three *Pinus* species. Monoterpenes of low concentration (i.e., myrcene, limonene, and camphene) were not detected in some of the inoculation treatments within *Pinus* species (particularly inoculations other than *O. minus* in *P. echinata* and *P. palustris*).

2. Are Growth Rates of Fungi Differentially Affected by Plant Phytochemistry? Hypothesis 2a: Primary phytochemistry influences the growth rate of each fungus. Mean fungal growth on isolated phloem tissue varied across fungal species ($F_{2,43} = 291.1$, $P < 0.001$) with *O. minus* growing about twice as fast as *E.* sp. *A* or *O. ranaculosum* (mean $\pm$ SE $= 2.24 \pm 0.08$, 1.12 ± 0.03, and 0.97 ± 0.03 mm/d, respectively). Fertilization of *P. taeda* had no effect on fungal growth rates (for each fungus: $F_{1,14} < 3.1$, $P > 0.11$), nor did it interact with fungal species ($F = 0.52$, $P = 0.60$). Nitrogen content of phloem was similar between fertilized and unfertilized trees ($0.46 + 0.08$ vs. $0.43 + 0.08$; $F_{1,13} = 0.68$, $P = 0.42$). The growth of *O. minus* was negatively correlated with percent nitrogen in phloem and positively correlated with tree radial growth rate, but growth

rates of mycangial fungi were not correlated with any measured traits of trees (Table 2). Average fungal growth rates on intact phloem were 17, 24, and 50% less than on 2% malt-extract agar (*O. ranaculosum*, *O. minus*, and *E.* sp A, respectively; $P < 0.01$ for all).

Hypothesis 2b: Volatile compounds commonly found within lesion tissue reduce the growth of fungal species. Fungal growth rates on malt-extract agar were highly sensitive to volatiles of tree-secondary metabolites (Figure 3). Growth of *O. minus* was significantly reduced in the presence of all compounds tested. *Entomocorticium* sp. *A* grew faster in the presence of myrcene, but grew slower in the presence of all other compounds compared to 2% malt agar alone. *Ophiostoma ranaculosum* grew faster in the presence of limonene, myrcene, and α- and β-pinene than on malt agar alone. All fungi grew slowest in the presence of volatiles from 4-allylanisole followed by *p*-cymene.

Hypothesis 2c: Volatile compounds produced by neighboring fungi reduce fungal growth. Growth rate of *O. minus* was generally reduced by the volatiles of other actively growing fungi (Figure 4). Aerial contact with actively growing cultures of *O. minus*, *E.* sp. *A*, and *O. ranaculosum* all reduced the growth of *O. minus* relative to the control; in the middle of the trial, when growth rates were most rapid, these effects were all significant ($P < 0.05$). Mycangial fungi (particularly *E.* sp. *A*) had the greatest negative affect on *O. minus* growth. Only *L. terebrantis* did not reduce *O. minus* growth rate relative to the blank control.

3. Are Intraguild Interactions Mediated by Secondary Metabolites? Hypothesis 3: The presence of tree secondary metabolites alters the ability of each fungal species to resist and suppress invasion or capture territories occupied by another fungus. The ability of fungi to resist or suppress growth by neighboring fungi was altered by the presence of particular secondary metabolites (Table 3). For instance, interactions between *O. minus* and *O. ranaculosum* were altered in the presence of limonene and high uric acid concentrations. All volatiles except *p*-cymene and α-pinene altered the interaction between *O. minus* and *E.* sp. *A* relative to

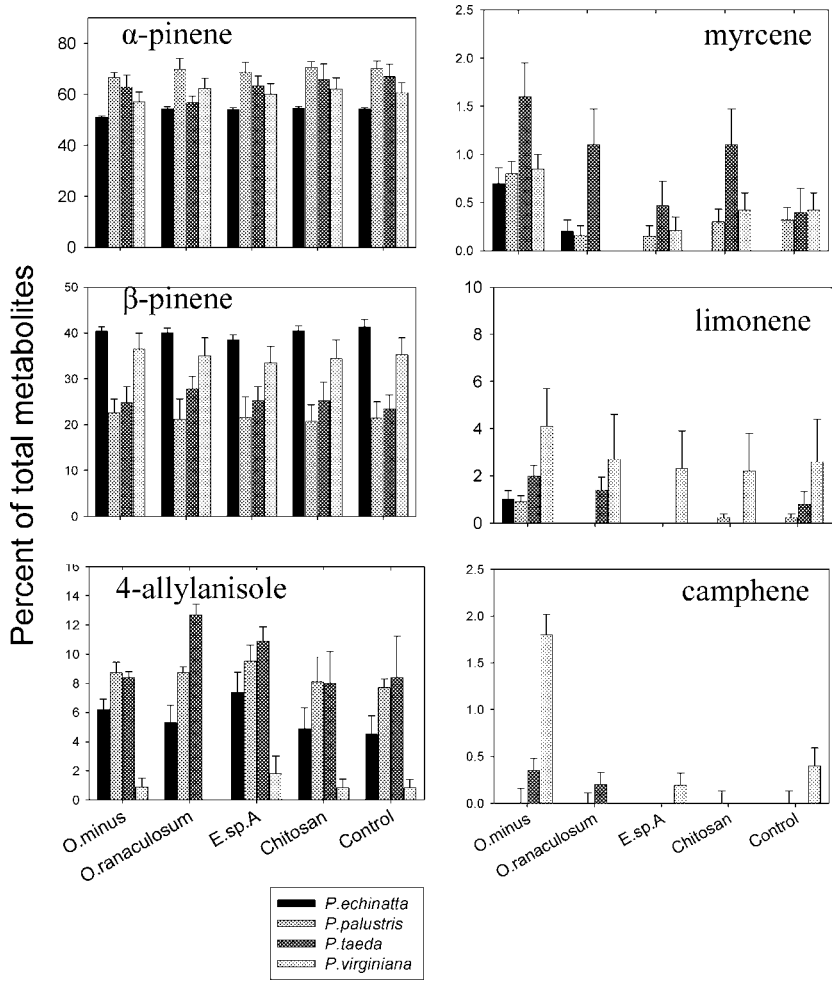

FIG. 2. Secondary metabolite concentrations in lesion tissues within *P. taeda*, *P. echinata*, *P. palustris*, and *P. virginiana* in response to an agar control, chitosan, *Entomocorticium* sp. *A*, *O. ranaculosum*, or *O. minus*.

the interaction observed between the two fungi on malt-extract agar alone. *Entomocorticium* sp. *A* and *O. minus* showed no signs of competitive interactions (no altered or slowed growth) in the presence of β-pinene. In the absence of secondary metabolites, *O. ranaculosum* captured about 46% of the area in competition with *E.* sp. *A* (control in Figure 5). However, *O. ranaculosum* captured significantly more resources in the presence of α-pinene, β-pinene, and 4-allylanisole, and

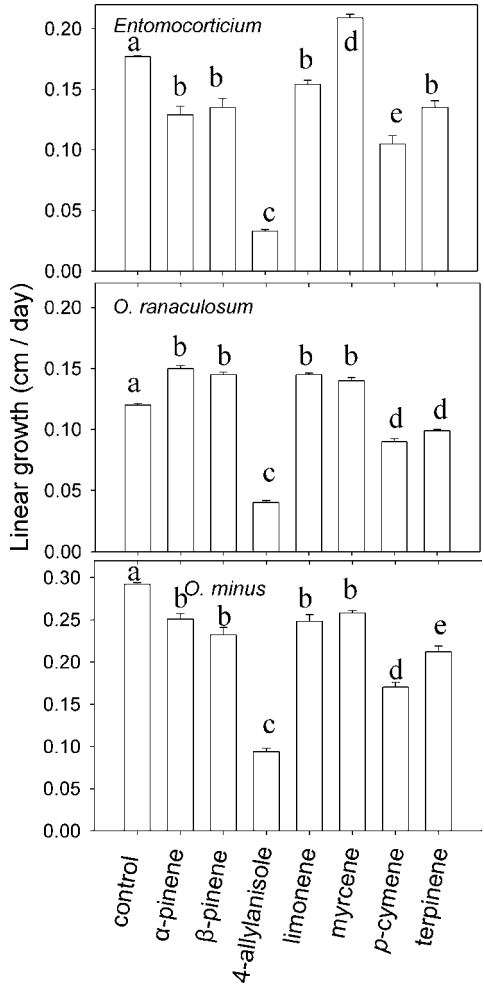

FIG. 3. Mean linear growth rate (cm/day) of each fungus on 2% malt-extract agar in the absence (control) or presence of volatiles from a particular monoterpene. Error bars indicate standard deviation and letters indicate significant differences across treatments ($P < 0.05$).

significantly less in the presence of myrcene, *p*-cymene and terpinene (Figure 5). *O. minus* always captured more area than either mycangial fungi (60–85% of the area; Figure 6). The amount of area captured by *O. minus* vs. mycangial fungi was highest in the presence of 4-allylanisole and similar in the other treatments. In the absence of secondary metabolites, but in the presence of *O. minus*, *E.* sp. *A* colonized more phloem area than *O. ranaculosum* (control in Figure 6).

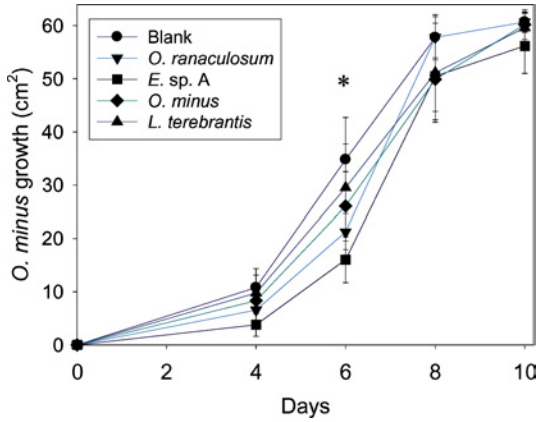

FIG. 4. Area growth (cm^2) of *O. minus* per day in presence of volatiles from other fungi associated with *D. frontalis*-infested trees, including other strains of *O. minus*. *Leptographium terebrantis* is usually found in the roots and does not usually colonize tissues inhabited by *O. minus*.

However, the relative performance of the two mycangial fungi (while in competition with *O. minus*) was altered by secondary metabolites; e.g., *O. ranaculosum* outperformed *E.* sp. *A* in assays with *O. minus* in the presence of α- or β-pinene volatiles (Figure 6).

DISCUSSION

1. Do Trees Vary in Their Response to Different Fungi Associated with D. frontalis? Secondary metabolites within lesion tissue vary depending on the infecting agent and pine species (Figure 2, Table 1). However, no clear pattern between chemical content and lesion size in phloem could be detected (Figure 1). Tree growth rate, d.b.h., % nitrogen or carbohydrates, and resin flow were correlated with lesion size in several tree species but there was no consistent pattern across all tree species. However, given that lesion size was not correlated with fungal growth rate on removed intact phloem from the same *P. taeda*, secondary metabolites (removed from intact phloem by autoclave) likely affect fungal growth ($\approx$lesion size) within trees. Greater induced response to *O. minus* relative to the other mycangial fungi *indicates* that (1) these tree species are highly sensitive (production of an elicitor within the tree; Delorme and Lieutier, 1990) to *O. minus* infection, (2) *O. minus* is pathogenic and thus triggers a greater response compared to that of the mycangial fungi, or (3) *O. minus* is capable of growing faster within resinous lesion tissues than the mycangial fungi. Particular secondary metabolites

TABLE 3. QUALITATIVE RESULTS FROM COMPETITION WITHIN PAIRED COMBINATIONS OF *E*. sp. A, *O. ranaculosum*, AND *O. minus* IN THE PRESENCE OF A MONOTERPENE VOLATILE OR URIC ACID ADDED TO GROWTH SUBSTRATE

Treatment	Pair combination		
	Entomocorticium vs. O. ranaculosum	*O. minus vs. O. ranaculosum*	*O. minus vs. Entomocorticium*
Control	1	2	3
p-Cymene	1	2	3
4-allylanisole	1	2	2,3
Myrcene	1,2[b]	2	2,3
Limonene	1[c]	1,2	2,3
α-Pinene	1,2[a]	2	3
β-Pinene	1	2	1,2
Terpinene	2[b]	2	2,3
0.5% Uric acid	1	2	2,3
1% Uric acid	1	2,3	2,3

Note. Following Porter (1924): "1" designates mutually intermingling growth; "2"-one fungus dominates, the other fungus shows little growth into other fungus; "3"-mutual slight inhibition (slowed growth) of both fungi than overgrowth by one of the fungi. Unless stated otherwise, *O. minus* dominated (grew over) the other fungus while the other fungus stopped growing. No two fungi where mutually inhibited at a distance greater than 2 mm. Two numbers per cell (e.g., 2, 3) indicate that replicates varied within the treatment.

[a] *O. ranaculosum* grew into area previously captured by *E*. sp. A.

[b] *E*. sp. *A* grew into area previously captured by *O. ranaculosum*.

[c] When fungi interacted, *E*. sp. *A* grew under *O. ranaculosum* (which grew only on the surface).

within induced resins may inhibit or slow growth of beetle-mutualistic fungi, or a reduction in available nutrients within lesion tissues might have a greater negative impact on beetle-mutualistic fungi than *O. minus*.

2. Are Growth Rates of Fungi Differentially Affected by Secondary Metabolites? Volatiles of secondary metabolites differentially affected the growth of fungus cultures (Figure 3). In the case of *O. minus*, all secondary metabolites reduced growth. Even with reduced growth rates, *O. minus* still grew faster than the mycangial fungi. Surprisingly, several secondary metabolites increased growth rates of the mycangial fungi relative to the growth rates in the absence of metabolites. Enhanced growth in the presence of a secondary metabolite might result from stimulated (increased) directional growth toward or away from the compound source (Rice, 1970), oxygenation of the compound (Knobloch et al., 1989), a specific response of the fungus to the optical rotation (chirality), number of double bonds (Cobb et al., 1968), or use as a carbon source (Paine and Hanlon, 1994). The two mycangial fungi responded differently to each compound, suggesting that each mycangial fungi might perform differently within different host trees. The major volatile constituents of induced phloem (and oleoresin) might not always enhance

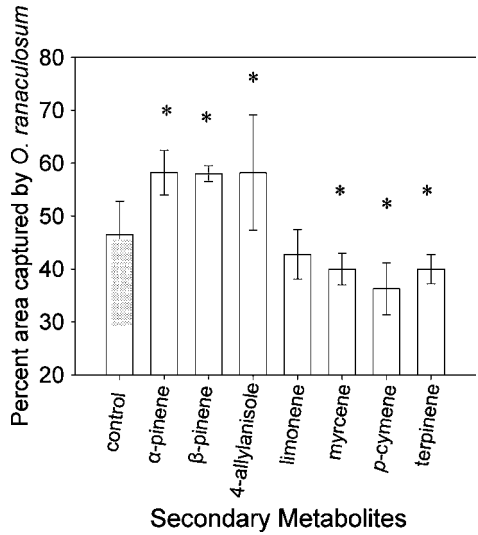

FIG. 5. Percent area captured after 30 days by *O. ranaculosum* compared to *E.* sp. *A* in the absence (control) or presence of a monoterpene (volatiles) in a paired-confrontation assay. Error bars indicate standard deviations and asterisks represent significant difference from control ($^{*}P < 0.05$, $^{**}P < 0.01$).

the resistance of trees to beetle invasion. Each fungus may also respond differently to various concentrations of each metabolite (Paine and Hanlon, 1994). However, small concentrations of secondary metabolites, like 4-allylanisole and terpinene can have strong negative effects on the mycangial fungi (Figure 3) and reduce the attraction of *D. frontalis* to host trees (Strom et al., 1994).

3. Are Intraguild Interactions Mediated by Secondary Metabolites? The relative growth and ability of the mycangial fungi *O. ranaculosum* and *E.* sp *A* to capture resources in the presence of *O. minus* was altered by secondary metabolites (Figure 6, Table 2). Thus, differences in compound concentrations or lack of particular compounds (e.g., no 4-allylanisole observed in *P. virginiana*) and the abundance of *O. minus* within trees may influence the relative frequencies of mycangial fungi within beetle infestations. In our competition studies, *E.* sp. *A* was more effective at reducing *O. minus* growth into colonized areas on artificial media than *O. ranaculosum* (Figure 6; Klepzig and Wilkens, 1997). However, secondary metabolites altered the relative ability of each mycangial fungus to compete with *O. minus*. For instance, *O. ranaculosum* was a relatively better competitor with *O. minus* than *E.* sp. *A* in the presence of α- or β-pinene. Goldhammer et al. (1989) found that high levels of uric acid in growth media reduced *O. ranaculosum* and *O. minus* growth, but increased the growth rate of *E.* sp. *A*. Uric acid

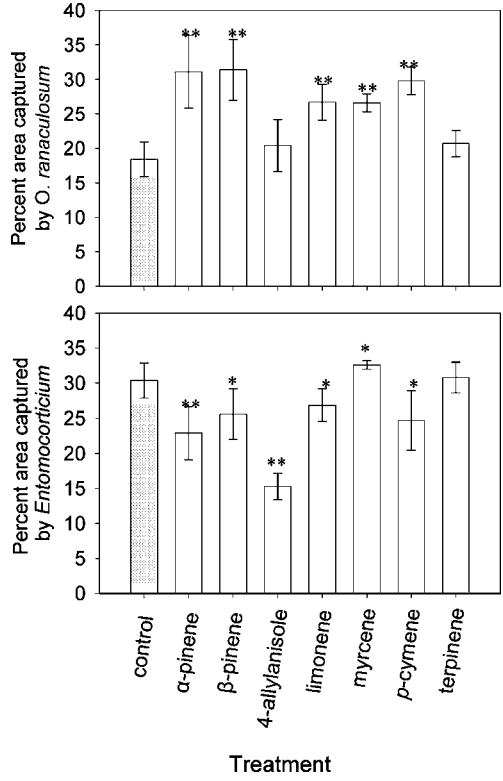

FIG. 6. Percent area captured after 30 days by *O. ranaculosum* or *E.* sp. *A* in paired assay with *O. minus* in the absence (control) or presence of a secondary metabolite (volatile). Error bars indicate standard deviations. Asterisks indicate significant difference from control ($^{*}P < 0.05$; $^{**}P < 0.01$).

also reduced *O. minus*' ability to capture resources previously captured by *E.* sp *A*. Uric acid levels likely increase in larval chambers as beetles develop, and, thus, become more important for competing fungi during the late larval or pupal stage. Phloem chemistry could affect the nature of interactions between fungi by altering the production, diffusion, or volatilization of fungal-produced compounds (Boddy, 2000).

Tree chemistry and interactions among fungi may select for the presence of multiple mutualistic fungi in beetle species that associate with mycangial fungi. Sampling of *D. frontalis* populations, ranging from one colonized tree to greater than 100 trees, have revealed the continual presence of both mycangial fungus (Bridges, 1983; Coppedge et al., 1995; Hofstetter, 2004). In fact, most bark beetle

species that have mycangial fungi appear to have two co-existing species of fungal mutualists (Six, 2002). Alternatively, the presence of mites (e.g., *Tarsonemus* guild) may promote the presence of a second mycangial fungus (e.g., "exploiter" species, Stanton, 2003) (Hofstetter et al., unpublished data).

Effect of Tree-Fungal Interactions on Beetle Populations

Differences in tolerance (represented by growth rate or competition) of the fungi to various compounds have ecological and economic significance. *O. minus* reduces survival of *D. frontalis* larvae (Lombardero et al., 2003) and reduces the growth rate and longevity of *D. frontalis* infestations (Hofstetter et al. unpublished data). Increased levels of *O. minus* within trees also reduce the economic value of wood as a result of blue staining in the xylem (Kreber and Byrne, 1994). All monoterpenes reduced the growth of *O. minus* and, thus, provide some defense against *O. minus* infection. High production of 4-allylanisole or terpinene, in particular, may reduce the relative abundance of blue-stain coverage within trees. Interestingly, increased growth and competitiveness of *O. minus* may minimize the destructive impacts of *D. frontalis* in pine plantations and forests by reducing beetle abundance (Lombardero et al., 2003; Hofstetter, 2004).

Differences in the frequencies of the two-mycangial fungi may affect beetle size, development rate, and reproduction within beetle populations (Goldhammer et al., 1990; Coppedge et al., 1995) and likely influences beetle population growth rate (Bridges, 1983; Ayres et al., 2000). Our results suggest that pine species composition within forests could affect the frequencies of each fungus within an infestation. For example, high levels of particular secondary metabolites within a stand of pines (e.g., shortleaf vs. longleaf) may favor the growth of *O. ranaculosum* relative to *E.* sp. *A*. Seasonal variation in secondary metabolites could generate seasonal variation in the relative abundance of mycangial fungi.

The frequency of each mycangial fungus within local beetle populations may change as beetle populations transition from low to outbreak densities. In endemic (low density) populations, *D. frontalis* usually colonizes trees that already have reduced defenses (e.g., lightning struck tree) that may favor the growth of *O. minus* and *E.* sp *A* relative to *O. ranaculosum* (Figures 3–5). Surveys of endemic populations (between September–December) by Bridges (1983) revealed that *E.* sp. *A* was more abundant than *O. ranaculosum* in 7 out of 8 *D. frontalis* populations. Alternatively, *O. ranaculosum* may become more prevalent in epidemic populations as a result of increased colonization of healthy (resinous) trees. Increased attack rates on trees may also favor *O. minus* growth (relative to mycangial fungi) if high attack rates result in lower secondary metabolites within host trees. Surveys of ten infestations during an epidemic in Alabama revealed that the relative proportions of *E.* sp. *A* and *O. ranaculosum* cycle throughout the year. Temporal variation in mycangial fungi may result from seasonal changes in beetle

attack rate, fungal growth rate, or interspecific interactions (Hofstetter, 2004). In any case, the relative frequency of each fungus in combination with the tree-host selection behavior of *D. frontalis* likely influences local population dynamics of *D. frontalis*.

Acknowledgments—We thank Erich Vallery, Matt Ungerer, and Fina Lombardero for assistance in inoculating and measuring trees; Mike Elliot-Smith for phloem analyzes; and Alexis McGuinness for hours of tracing fungal growth on the surface of Petri dishes. Transportation, equipment, and location of trees would not have been possible without the help of the USDA Forest Service in Pineville LA, and Talladega Ranger Districts, AL. The manuscript benefited from comments by Bill Mattson, Mark McPeek, and David Peart. This research was supported by U.S.D.A., NRI CGPs #9835302, #2001-35302-09921, and Dartmouth College.

Abstract—Addition of nitrogen (N) to the field layer of boreal forests has been shown to increase the occurrence of the parasitic fungus *Valdensia heterodoxa* on *Vaccinium myrtillus* plants. We investigated whether N addition to soil alters the levels of polyamines in *V. myrtillus* shoots, and discuss here whether such changes could promote the spread of the parasitic fungus on *V. myrtillus*. Using HPLC, we analyzed the concentrations of free and conjugated polyamines in healthy and naturally *V. heterodoxa*-infected *V. myrtillus* plants, which had received a moderate or high dose of N fertilizer, or no additional N. Fertilization with N increased the concentrations of free diamines (putrescine and diaminopropane), but had no significant effect on conjugated amines. Thus, N-induced changes in the constitutive levels of soluble conjugated amines do not seem to explain the increased parasite susceptibility of *V. myrtillus* under N enrichment. Generally, the concentrations of free diamines and insoluble conjugated putrescine were higher in diseased than in healthy shoots, suggesting parasite-induced accumulation of diamines. Free spermine seemed to accumulate in unfertilized, diseased plants, but in fertilized plants this induction was dampened, suggesting that N-induced alterations in spermine metabolism may promote the spread of parasites on *V. myrtillus* under N-enrichment.

Key Words—diaminopropane, putrescine, spermidine, spermine, nitrogen fertilization, boreal forest, plant-pathogen interactions.

INTRODUCTION

Increased rates of nitrogen (N) deposition, originating from heavy traffic, intensive agriculture, and industry, have been implicated as major anthropogenic factors affecting the structure and functioning of diverse ecosystems (Vitousek et al., 1997; Bobbink et al., 1998; Lee, 1998). N amendment may lead to increased N uptake by plants (Tomassen et al., 2003), for which N is an essential macronutrient and often available in growth-limiting amounts (Näsholm et al., 1998; Turkington et al., 1998), and to increased cellular content of N (Minocha et al., 2000 and references therein). Increased levels of N in plant tissues may change their chemical composition, and thus affect the nutritive value of the plants for consumers, i.e., microbes and herbivores. Hence, N amendment may have profound ecological consequences at different trophic levels of an ecosystem (Vitousek et al., 1997; Bobbink et al., 1998; Lee, 1998). The ecological effects of increasing N deposition may be especially pronounced in areas where background levels are historically low and the plants have physiologically adapted to the low availability of soil N (Bobbink et al., 1998). Such areas include boreal forest ecosystems.

Characteristic species in the field-layer of N-poor boreal forests are ericaceous dwarf shrubs, e.g., *Calluna* and *Vaccinium* species. Recent research indicates that N fertilization of the field layer in boreal forests leads to a transition from *Vaccinium myrtillus* L.- dominated to grass- (especially *Deschampsia flexuosa* (L.) Trin.) dominated vegetation (Nordin et al., 1998; Strengbom et al., 2002, 2003). In parallel, the incidence of a parasitic fungus, *Valdensia heterodoxa* Peyronel (Ascomycota, Sclerotiniaceae; Vogelgsang and Shamoun, 2002) on *V. myrtillus* leaves increases, leading to severe necrosis and premature shedding of *V. myrtillus* leaves (Strengbom, 2002; Strengbom et al., 2002, 2003). Thus, N amendment seems to predispose *V. myrtillus* to parasite infection. Earlier studies elucidated changes that occur in secondary phenolic metabolism (Witzell and Shevtsova, 2004) and in the primary N metabolism (amino acids) of N-fertilized *V. myrtillus* plants (Nordin et al., 1998; Strengbom, 2002). Nevertheless, the metabolic basis of the N-induced susceptibility of *V. myrtillus* to *V. heterodoxa* is still not completely understood.

Nitrogen amendment is likely to influence the activity of several metabolic pathways in plants, leading to altered rates of production and accumulation of several plant chemicals that may be important in plant-parasite interactions. For instance, the levels of small aliphatic amines, polyamines, often increase in plants as a consequence of N application (Taulavuori et al., 1999; Minocha et al., 2000). This may result from N-induced increases in concentrations of the precursor amino acids (Weidner et al., 1996; Tomassen et al., 2003), such as ornithine and N-rich arginine, which can be decarboxylated to the diamine putrescine (PUT). Transfer of aminopropyl groups from decarboxylated S-adenosyl methionine (SAM) to PUT yields the triamine spermidine (SPD) and the tetramine spermine (SPM).

In addition to these ubiquitous polyamines, some plants also contain several less common amines, such as diaminopropane (DAP), which is formed by polyamine oxidation via the activity of polyamine oxidase (PAO) (Bouchereau et al., 1999; Bagni and Tassoni, 2001). Polyamines are involved in a myriad of physiological and developmental processes (e.g., cell proliferation and differentiation, flowering, and senescence) and are necessary for normal growth of plants (Bouchereau et al., 1999; Igarashi and Kashiwagi, 2000). The metabolism of polyamines is highly responsive to external stimuli, apparently reflecting their importance in the regulation of plant metabolism under environmental challenges (Bouchereau et al., 1999).

Plant polyamines occur as free bases, but since they are positively charged, they can readily bind to negatively charged molecules, such as proteins (forming insoluble conjugates; ISC). The insoluble fraction also includes di- or trisubstituted hydroxycinnamic acid conjugates, through which polyamines can link to cell wall polymers, such as hemicellulose and lignin (Bagni and Tassoni, 2001, and references therein; Walters et al., 2001). Polyamines can also conjugate with small molecules (forming soluble conjugates; SC), mainly phenolic acids, via amide bonds (Martin-Tanguy, 1997; Bouchereau et al., 1999; Walters, 2000). Changes in polyamine metabolism have been recorded in several plant-pathogen interactions (Walters, 2000). Much of the research on polyamines in plant-pathogen interactions has focused on SC forms (Walters, 2000, 2003a,b). Some of the phenolic conjugation partners of amines possess defensive or anti-microbial activity (Nicholson and Hammerschmidt, 1992; Bennett and Wallsgrove, 1994; Dixon and Paiva, 1995), and it has been proposed that conjugation with polyamines may reduce the toxicity of phenolics (Legaz et al., 1998; Bouchereau et al., 1999). On the other hand, increased concentrations of SC polyamines have been detected in some incompatible plant-pathogen interactions, and found to correlate positively with pathogen resistance (Walters, 2003a, and references therein). Recent studies have emphasized that in addition to conjugated polyamines, free polyamines also influence the outcome of some plant-pathogen interactions (Yamakawa et al., 1998; Walters, 2003a, and references therein).

The goals of our study were to investigate whether N fertilization changes the levels of free, SC, and ISC polyamines in boreal *V. myrtillus* plants, and to relate the data acquired to existing information (Strengbom, 2002; Strengbom et al., 2003, 2003) concerning N effects on the parasite resistance of *V. myrtillus*. We analyzed the concentrations of free, SC, and ISC PUT, SPD, and SPM in healthy and *V. heterodoxa*-infected annual shoots of *V. myrtillus* plants, grown in the herbaceous layer of a Norway spruce dominated boreal forest. The plants received no additional N (unfertilized control), a moderate, or a high dose of N fertilizer. We also compared the levels of some phenolic acids that were analyzed after hydrolysis of the polyamine extracts. We were especially interested in finding out whether putative N-induced changes in the pool of SC polyamines could be

linked to the increased susceptibility of *V. myrtillus* to parasite infection under N-enrichment.

METHODS AND MATERIALS

Study Site and Sample Collection. The plant material was collected from an experimental forest at the Svartberget research station, located in northern Sweden, 60 km NW of Umeå (64°14′N, 19°46′E). Norway spruce (*Picea abies* (L.) H. Karst) dominates the tree layer of the forest, and characteristic plant species of the field layer are *V. myrtillus*, *V. vitis-idaea* L., *Linnaea borealis* L., and *D. flexuosa*. In the study area, the background level of N deposition is about 3.5 kg N ha^{-1} y^{-1} (see Strengbom, 2002). The experiment was set up in 1996 as a randomized complete block design. Within each of five blocks (150 × 150 m), three 31.6 × 31.6 m plots were randomly assigned to N fertilization treatments, of 0 (unfertilized control), 12.5 (moderate N level), and 50 (high N level) kg ha^{-1} y^{-1}. The N doses used were ecologically realistic for northern and central European conditions (cf. Dise et al., 1998; Tietema et al., 1998). The incidence of *V. heterodoxa* leaf spot disease on the experimental plots was monitored during 1996–2000, and the data show that the disease is more prevalent on fertilized than on unfertilized plots (Strengbom, 2002; Strengbom et al., 2002).

In the beginning of June 2001, current annual shoots bearing symptoms of *V. heterodoxa* infection, i.e., brownish, necrotic spots (diseased shoots) and visibly healthy shoots (healthy shoots) were collected from unfertilized and fertilized plots (six replicate shoots per permutation, where the pooled material of three shoots made up one replicate). In order to control the physiological age of the shoots, only shoots without any senescence symptoms were collected. Moreover, all shoots were approximately the same size. We standardized the minimum distance between pairs of healthy and diseased shoot to approximately 2 m, to avoid large variations due to possible microclimatic differences within the plots. Since the structure and size of *V. myrtillus* clones in this area are not known, some healthy and diseased shoots may have originated from the same ramet. However, we considered the possible systemic inductions in polyamines as random variation, which could not be controlled. The plant material was transported from the forest on dry ice and stored at −20°C until analyzed.

Analysis of Polyamines and Phenolic Acids. About 0.2 g of frozen plant material was ground in liquid N, extracted in 5% $HClO_4$, and centrifuged at 37 000 g. The pellet was resuspended in the original volume of $HClO_4$. This suspension and the supernatant were hydrolyzed overnight at 110°C in 6N HCl in order to release polyamines from their conjugated forms. Polyamines in the crude and hydrolyzed supernatant (for free and SC polyamines, respectively) and the hydrolyzed pellet (ISC polyamines) were analyzed as dansylchloride derivatives as described earlier (Sarjala and Kaunisto, 1993).

Phenolic acids were released from crude $HClO_4$ extracts by hydrolysis as described by de Armas et al. (1999). The phenolic fractions from crude extracts before and after hydrolysis were analyzed using a Hitachi LaChrom HPLC system equipped with a PDA-detector. The compounds were separated on a Chromolith^{TM} RP-18e (Merck KGaA, Darmstadt, Germany) column (100 × 4.6 mm i.d.). The mobile phase consisted of methanol (B) and H_2O (pH adjusted to 3 with H_3O_4P; A). Elution gradient was: 12–13% B (0–2 min), 13–23% B (2–8 min); 23–35% B (8–12 min); 35–70% B (12–24 min). The flow rate was 2 ml/min and the column temperature 30°C. On the basis of their UV-spectra (200–400 nm), three of the most abundant peaks in the HPLC-chromatogram of the hydrolyzed samples were tentatively identified as *p*-hydroxybenzoic acid (λ_{max}224.7), protocatechuic acid (λ_{max}208.9, 256.7, 291.0), and a benzoic acid derivative (λ_{max}227.5). Peak areas (measured at 270 nm) per unit sample mass before and after hydrolysis were calculated, and the results are expressed as percentages of the respective compounds released by hydrolysis.

Statistics. The effects of fertilization, disease, and their interaction on the levels of polyamines were tested with 2-way ANOVA. Data were log (x + 1) or arcsin transformed prior to analysis when necessary. Student's *t*-tests were used to test the differences between means of healthy and diseased shoots within a single N fertilization level. Data related to phenolic compounds were analyzed using a Kruskall-Wallis test. All statistical tests were carried out using SPSS version 12.0.1 for Windows (SPSS Inc., Chicago, Illinois, USA).

RESULTS

Effects of N on Polyamines. PUT, DAP, SPD, and SPM were the major polyamines detected in *V. myrtillus*, SPD being the most abundant in unfertilized, healthy shoots. N addition resulted in elevated concentrations of free PUT ($F_{2,30} = 361.32$, $P = 0.003$; Figure 1). In addition, DAP levels tended to be higher in the shoots of fertilized plants, especially in diseased shoots (Figure 1). However, we did not find statistically significant N effects on DAP, free SPD, or free SPM. Addition of N did not significantly affect the levels of conjugated (SC or ISC) polyamines. Neither SC nor ISC forms of DAP were detected in *V. myrtillus* shoots.

Infection-associated Changes in Polyamines. The diseased *V. myrtillus* shoots had higher concentrations of free PUT ($F_{1,30} = 1930.80$, $P = 0.001$) and DAP ($F_{1,30} = 29.51$, $P = 0.032$; Figure 1) than healthy shoots. In most cases, the levels of free SPD and SPM also tended to be elevated in the infected shoots, but these differences were not significant. In unfertilized plants, however, the level of free SPM was higher in diseased plants (*t*-test for equality of means, $t = 2.45$, $d.f. = 5$, $P = 0.028$; Figure 1). This difference was reduced by N addition (Figure 1).

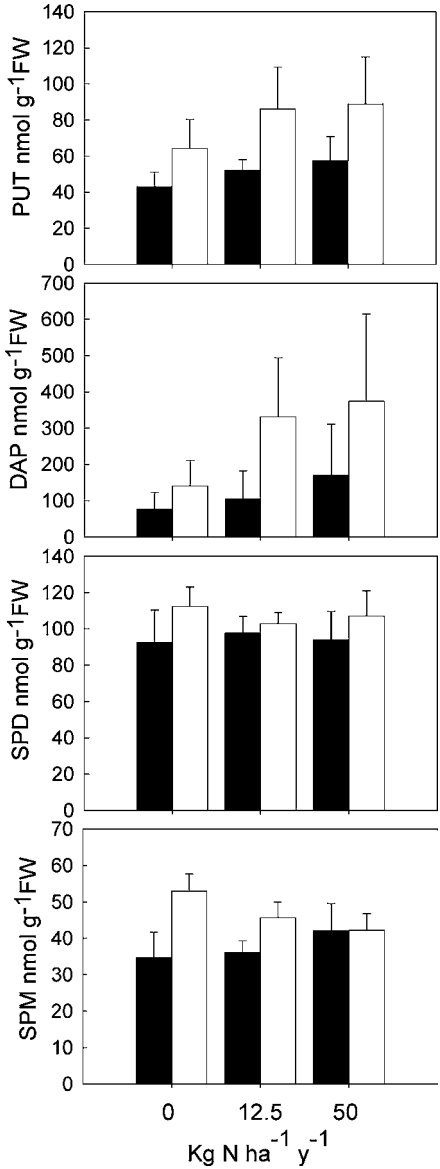

FIG. 1. Concentrations of free putrescine (PUT), diaminopropane (DAP), spermidine (SPD), and spermine (SPM) in healthy (closed bars) and diseased (*V. heterodoxa*-infected; open bars) shoots of *V. myrtillus* plants grown under three nitrogen treatments (0, 12.5 and 50 kg N ha^{-1} y^{-1}). (Vertical bars represent S.E.).

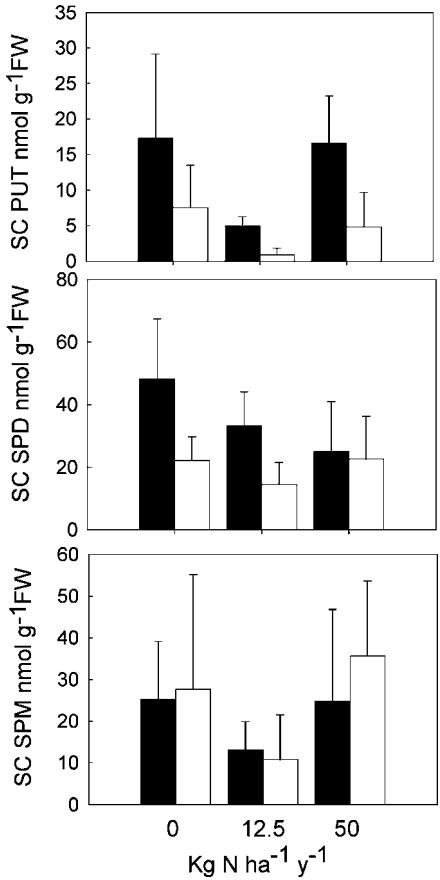

FIG. 2. Concentrations of soluble conjugated (SC) putrescine (PUT), spermidine (SPD), and spermine (SPM) in healthy (closed bars) and diseased (*V. heterodoxa*-infected; open bars) shoots of *V. myrtillus* plants grown under three nitrogen treatments (0, 12.5 and 50 kg N ha^{-1} y^{-1}). (Vertical bars represent S.E.).

The diseased shoots tended to contain less SC PUT, and in both the control and moderate N-treatments also less SC SPD in their leaves (Figure 2). However, we found no significant differences in levels of SC polyamines between healthy and diseased shoots.

The ISC PUT concentration was higher in diseased shoots than in healthy shoots ($F_{1,30} = 72.65$, $P = 0.013$; Figure 2). In unfertilized plants, the concentration of ISC SPM was higher in diseased plants than in healthy plants (t-test for equality of means, $t = 7.50$, $d.f. = 5$, $P < 0.001$; Figure 3).

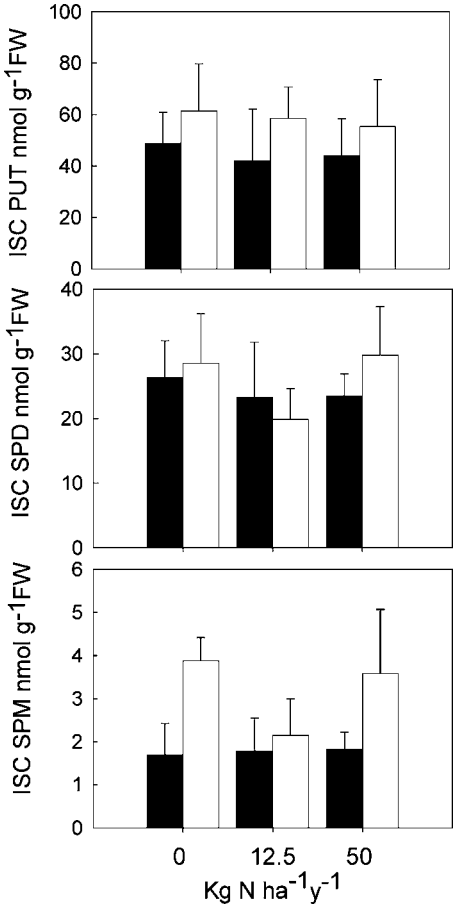

FIG. 3. Concentrations of insoluble conjugated (ISC) putrescine (PUT), spermidine (SPD) and spermine (SPM) in healthy (closed bars) and diseased (*V. heterodoxa*-infected; open bars) shoots of *V. myrtillus* plants grown under three nitrogen treatments (0, 12.5 and 50 kg N ha^{-1} y^{-1}). (Vertical bars represent S.E.).

Effects of N on the Relative Proportions of Free and Conjugated Polyamines in Healthy and Diseased Shoots. To display visually the effects of N fertilization on the relative proportions of specific polyamines within the free and conjugated pools in healthy and diseased shoots, results for PUT, SPD, and SPM are presented as percentages of their total sums (Figure 4). The total pool of PUT was dominated by the free and ISC forms, whereas SPD and SPM more frequently occurred as SCs. In healthy plants, less than 5% of the total SPM pool was present as the ISC form, whereas about 10% of the total SPD and about 40% of the total PUT pool

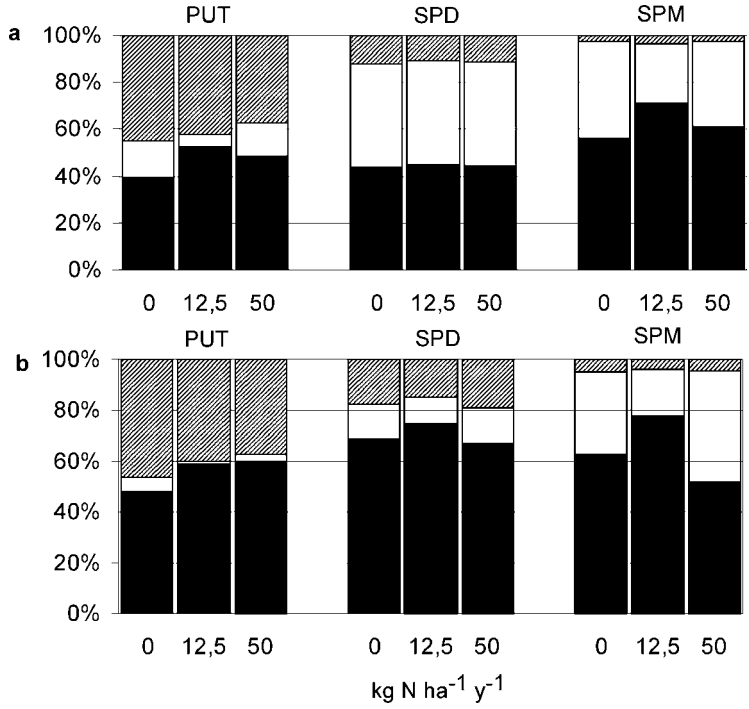

FIG. 4. Relative abundance of free (closed bars), soluble conjugated (open bars) and insoluble conjugated (hatched bars) forms of putrescine (PUT), spermidine (SPD), and spermine (SPM) in healthy (a) and diseased (*V. heterodoxa*-infected b) shoots of *V. myrtillus* plants grown under three nitrogen treatments (0, 12.5 and 50 kg N ha^{-1} y^{-1}).

was found as IS conjugates (Figure 4a). Nitrogen addition had no significant effect on the relative abundance of the different polyamine forms. Infection reduced the relative abundance of SC PUT at all N levels ($F_{1,30} = 4.409$, $P = 0.044$), but did not significantly change the relative abundance of different forms of other polyamines (Figure 4).

Hydrolyzable Phenolics in PCA-extracts. A significantly smaller proportion of p-hydroxybenzoic acid was released by hydrolysis from the extracts of fertilized plants than from unfertilized plants (N effect: $\chi^2 = 6.27$, $P = 0.043$), suggesting that relatively little conjugation of this compound with polyamines occurs under N-amendment. For the protocatechuic acid, a similar trend ($\chi^2 = 5.81$, $P = 0.055$) was observed, which seemed to be due to decreased conjugation in the moderate N-treatment (Figure 5). Parasite infection had no significant effect on the abundance of any of the analyzed hydrolyzable phenolic acids in PCA-extracts.

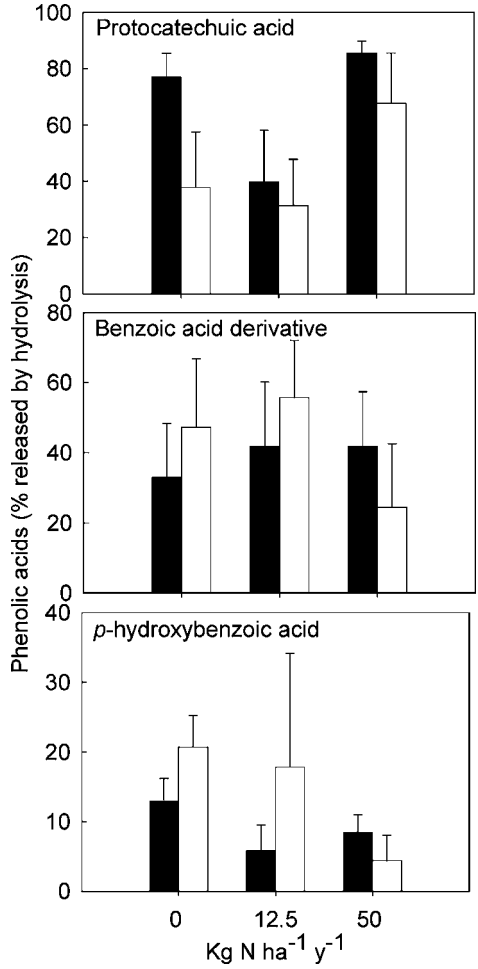

FIG. 5. Percentage of three phenolic acids released by hydrolysis from crude $HClO_4$ extracts of healthy (closed bars) and diseased (*V. heterodoxa*-infected; open bars) shoots of *V. myrtillus* plants grown under three nitrogen treatments (0, 12.5, and 50 kg N ha^{-1} y^{-1}). (Vertical bars represent S.E.).

DISCUSSION

The N-induced elevation we found in the concentration of free PUT is consistent with earlier reports concerning N effects on polyamines (Altman and Levin, 1993; Minocha et al., 2000). Accumulation of free PUT in fertilized plants may be due, at least in part, to stimulated biosynthesis, which could be fueled by

N-induced increases in the availability of amino acid precursors, particularly arginine (cf. Tomassen et al., 2003). Arginine dominates the amino acid profiles of *V. myrtillus* leaves during the late growth season, and its concentration increases in response to N additions (Ohlsson et al., 1995).

SC polyamines have frequently been associated with the expression of plant resistance to pathogen attacks (Legaz et al., 1998; Walters, 2000, 2003a). Therefore, we hypothesized that changes may occur in the constitutive levels of SC polyamines in N-fertilized *V. myrtillus* plants, and that these changes could be causally linked to the plants' increased susceptibility to parasitic fungi. We anticipated that N amendment could either increase or decrease the concentrations of SC polyamines. For instance, if N amendment increases the synthesis of polyamines, then higher proportions might be converted to conjugates as storage forms (Altman and Levin, 1993; Martin-Tanguy, 1997). If conjugation inhibits the antimicrobial actions of phenolics (Legaz et al., 1998), or those of the free polyamines (cf. Walters et al., 2001), increased conjugation could weaken the resistance of *V. myrtillus* to parasitic fungi.

On the other hand, the results from earlier studies indicate that N amendment may reduce the synthesis or accumulation of some phenolic acids in *V. myrtillus* leaves (Witzell and Shevtsova, 2004; for N-effect on phenolics, see also Haukioja et al., 1998). This, we postulated, could reduce the availability of phenolic conjugation partners for polyamines and, thus, SC levels. If SC polyamines have defensive activity in the studied plant-parasite association, N-induced reductions in phenolic acid-polyamine conjugates might explain the observed increase in susceptibility to pathogens. Indeed, the results from the phenolic analysis imply that N-amendment, at least at a moderate level, reduces the conjugation of some phenolics with polyamines in *V. myrtillus* shoots. Nevertheless, the results of the polyamine analyses show that although there was an apparent trend towards lower SC polyamine levels in plants that received a moderate N dose, neither the absolute concentrations of SC (or ISC) polyamines, nor their relative proportions, were significantly influenced by N amendment. Thus, our results suggest that N-induced effects on SC polyamines do not explain the increased susceptibility of *V. myrtillus* to parasites under N enrichment reported by Strengbom (2002) and Strengbom et al. (2002).

The increase in the absolute concentration of free diamines (PUT, DAP) in *V. myrtillus* shoots was associated with infection by *V. heterodoxa*. Since our results show that the increase of PUT in *V. myrtillus* shoots was not dependent on the N treatment, it appears to have been a general stress response to infection. Parasite-induced elevation of free DAP may be due to stimulated oxidation of SPM and SPD in diseased shoots (cf. Drolet et al., 1986; Bors et al., 1989; Bouchereau et al., 1999; Bagni and Tassoni, 2001; Walters, 2003b). The fact that free DAP increases in diseased *V. myrtillus* plants seemed to be strengthened by N-addition could be due to enhanced synthesis or activity of PAO under N enrichment. Elevated levels

of ISC PUT and SPM in infected plants could be linked to increased synthesis and accumulation of stress or defense-related proteins (cf. Terras et al., 1995; Yamakawa et al., 1998).

A significant increase in free SPM was associated with *V. heterodoxa* infection in unfertilized *V. myrtillus* plants, and a weaker increase in N-fertilized plants. In addition to its involvement in the induction of pathogenesis-related (PR) proteins (Yamakawa et al., 1998; Hiraga et al., 2000), spermine metabolism in diseased plants has been associated with enhanced oxidative metabolism, activation of cysteine proteases with aspartate specificity (caspases) that are active in the induction of programmed cell death, maintenance of membrane integrity, and retardation of senescence (Bouchereau et al., 1999; Walters, 2003b and references therein). Such activities of SPM could be important in interactions between plants and parasites such as *V. heterodoxa* that cause extensive necrosis and premature senescence of leaves. Given the increased susceptibility of *V. myrtillus* to *V. heterodoxa* in N-fertilized plants (Strengbom, 2002; Strengbom et al., 2002), the mitigating effect of N on the infection-associated accumulation of free SPM could be one of a number of metabolic changes promoting the spread of parasite infection under N-enrichment. However, an intriguing finding is that the level of macromolecule-bound (ISC) SPM was elevated by infection not only in unfertilized plants, but also in plants receiving the high N dose.

Throughout the studied range of N-regimes, the relative abundance of SC PUT was reduced in *V. myrtillus* shoots that were infected by *V. heterodoxa*, whereas the abundance of free PUT tended to increase in these (diseased) shoots. A similar trend was observed for SPD. This suggests that some of the SC polyamines may have been metabolized to yield free polyamines in infected *V. myrtillus* plants (cf. Cochlan and Walters, 1990). Thus, the free polyamines or their phenolic conjugation partners may be more active separately than as conjugates in this particular plant-pathogen association. The results from the phenolic analysis, which suggested that infection had no significant effect on the association of certain phenolic acids with polyamines, further support the view that SC polyamines do not play a central role in the resistance of *V. myrtillus* against *V. heterodoxa*.

In summary, we found that significant alterations in the absolute concentrations of polyamines in *V. myrtillus* leaves, as well as in the relative abundance of free and conjugated forms of individual polyamines, were associated with parasite infection. However, the *V. myrtillus* plants maintained stable levels of polyamines within the studied range of N-regimes, and we found no evidence suggesting that N-induced changes in SC polyamines could explain the earlier reports of increased susceptibility of *V. myrtillus* to *V. heterodoxa* under N-enrichment (Strengbom, 2002; Strengbom et al., 2002, 2003). Nevertheless, our results imply that infection-associated accumulation of free SPM could be involved in restricting the spread of this fungus on *V. myrtillus* plants in their natural, N-poor habitats. Therefore, SPM metabolism seems to be worthy of more detailed investigations

in future studies concerning N-induced effects on the pathogen resistance of *V. myrtillus* (cf. Walters, 2003a,b).

Abstract—The reversal of humic matter-induced inhibition of callus growth and metabolism by 2,4-dichlorophenoxyacetic acid (2,4-D) was studied in *Pinus laricio*. Two forest humic fractions (relative molecular mass (M_r) > 3500), derived from soil under *Fagus sylvatica* (Fs) and *Abies alba* (Aa) plantation, were used. *Pinus laricio* callus was grown for a subculture period (4 weeks) on Basal Murashige and Skoog (MS) medium plus forest humic matters (Fs or Aa), at a concentration of 1 mg C/l, and then was transferred, for an additional four weeks, to a MS medium culture without humic matter, but with different hormones: indole-3-acetic acid (IAA, 2 mg/1) or 2,4-dichlorophenoxyacetic acid (2,4-D, 0.5 mg/1) and/or 6-benzylaminopurine (BAP, 0.25 mg/1). Growth of calluse, glucose, fructose, and sucrose contents, and activities of soluble and bound invertases, glucokinase, phosphoglucose isomerase, aldolase, and pyruvate kinase were monitored. The results show a negative effect of humic fractions on callus growth, due to decreased utilization of glucose and fructose, and decreased activities of glycolytic enzymes. The effects are reversible. Substitution of humic fractions with 2,4-D+BAP or 2,4-D is followed by an increase of glycolytic enzyme activities and, consequently, by the utilization of glucose and fructose that induces a restart of growth. In contrast, the inhibitory effects of humic fractions persist when they are substituted with BAP alone, indicating that only the auxin 2,4-D is capable of reversing the negative effects. A possible competitive action on the auxin-binding site between 2,4-D and the chemical structures in the forest humic fractions is suggested.

Key Words—Humic substances, invertase, glucokinase, phosphoglucose isomerase, aldolase, pyruvate kinase, *Pinus laricio* callus, 2,4-dichlorophenoxyacetic acid.

INTRODUCTION

Soil organic matter is one of the most useful indicators of soil fertility. A considerable part of organic soil compounds is represented by humic substances. These molecules are characterized by large differences in molecular size, solubility, and chemical composition that are related to changes in climate, vegetation, parent material, and to numerous complex biological, chemical, and physical soil processes. There is much evidence to suggest that humic substances can exert beneficial effects on soil structure, increasing soil aggregation (Soane, 1990), water-holding capacity (De Jong et al., 1983), and cation-exchange capacity (Stevenson, 1994). Moreover, they can influence plant metabolism in regulating plant biochemical and physiological processes (Vaughan and Malcolm, 1985), irrespective of their stimulatory or inhibitory roles (Nardi et al., 1999). Numerous studies have investigated the biological activities of forest humic matter, indicating that vegetation cover is related to their biological activity (Pizzeghello et al., 2001), and also that forest species are affected in different ways by their humic substances (Nardi et al., 2000). In order to consider the biological activity of humic matter with respect to vegetation, our previous studies (Muscolo et al., 1999a, 2001a, 2002) were carried out by testing two forest humic substances derived from soil under *Fagus sylvatica*, L. (Fs) and *Abies alba*, Miller (Aa) plantation on *Pinus laricio* callus and *Pinus laricio* seeds. The results showed that both the humic substances utilized inhibited *Pinus laricio* seed germination, thus affecting the ascorbate system, the amylase activity, and the amino acid metabolism; these observations could explain the difficulty of the natural regeneration of *Pinus laricio* seeds in forest soils. The growth of *Pinus laricio* callus was inhibited by both humic fractions that blocked the utilization of hexoses, the only source of carbon skeleton for callus in culture (Muscolo et al., 1999b, 2001b).

This knowledge on the mechanism of the action of humic substances may be important in understanding the role of humus in the forest ecosystem, where the presence of a lot of active substances (i.e., organic acids, hormones) could interfere with its biological activity.

In the light of this, using an *in vitro* approach to avoid environmental interferences, we wanted to verify if the inhibitory effect induced by humic substances could be reversed by hormones. Thus, *Pinus laricio* callus was grown on Murashige and Skoog (MS) Basal medium supplemented with humic matter (Fs or Aa) and then was transferred into a culture without a humic fraction but with different hormones (IAA or 2,4-D and /or BAP).

Sucrose, fructose, and glucose, and the main enzymes involved in carbohydrate metabolism, were monitored.

METHODS AND MATERIALS

Humus Extraction. Humic matter was extracted from two experimental sites located in the North-East of Italy near the town of Cortina d'Ampezzo (latitude 46° 30′ 29″ N, longitude 12° 08′ 43″ E), each representative of one principal type of vegetation, which have been designated as "Aa" (*Abies alba*, Miller) and "Fs" (*Fagus sylvatica*, L.). The soils were classified as Calcic Luvisols (LVkm) and Humic Cambisols (CMu), according to the FAO-UNESCO system criteria (FAO-UNESCO, 1990). Humic substances were extracted by using 0.1 N KOH in a soil: solution ratio of 1:10 (w/v) at 50°C for 16 hr under a N_2 atmosphere. The extract was desalted by dialysis and ion (H^+) exchange chromatography on Amberlite IR-120 H^+ resin (Stevenson, 1994), then acidified to pH 2.1 with glacial acetic acid. After dialysis against distilled water in Spectrapore 3 tubings (3500 mol. wt cut-off), the retained high relative molecular mass and dialysed low relative molecular mass fractions were further purified by vacuum distillation and ion exchange chromatography (Nardi et al., 1991). In this study, only humic fractions of $M_r > 3500$ were used. Both humic fractions were adjusted to pH 6.0 and used at a final concentration of 1 mg C/l, according to the previous tests showing that in the range of 0.1–5.0 mg C/l, the concentration of humic matter that most interfered with *Pinus laricio* callus was 1 mg C/l. In addition, 1 mg C/l is the concentration of humic substances commonly present in forest soils (Cheng et al., 1996).

Chemical Characterization and Isotopic Determination. Quantitative ^{13}C-NMR spectra were obtained by suspending ca. 300 mg of humic extract in 0.5 ml of 2 M NaOH + 1.5 ml D_2O (Deuterium oxide) for one day at room temperature under N_2. The suspension was filtered through acid-washed glass wool, which was washed with 1 ml of D_2O, and the filtrates were combined. ^{13}C-NMR spectra were recorded at 125.7 MHz on a Bruker AMX-500 spectrometer, using inverse gated decoupling (IGD) experiments for quantitative intensity distribution. Peak areas were obtained by integration. The chemical shift was expressed in ppm on a scale relative to external 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid, sodium salt, at 0 ppm (Piccolo and Conte, 1998). The NMR spectra were divided in five regions: 0–48 ppm (Aliphatic C), 48–105 ppm (Peptidic and Carbohydratic C), 105–145 ppm (Aromatic C), 145–165 ppm (Phenolic C), and 165–190 ppm (Carboxylic C). These assignments were based, in part, on values given in Candler et al. (1997).

Callus Growth. Callus induction was attempted, *in vitro*, from needles of *Pinus laricio*. The initiation medium was composed of MS (Murashige and Skoog, 1962) Basal medium supplemented with Bacto agar (0.8% w/v), sucrose (3% w/v), and growth regulators (2,4-D 0.5 mg/1 and BAP 0.25 mg/1) adjusted to pH 5.7. Callus (1.0 g) was subcultured for 4 wk on MS Basal medium with Fs or Aa humic

fractions (filtered sterilized) but without 2,4-D or BAP (subculture period I). After this period, the callus was transferred to a MS Basal medium culture without humic matter but with BAP (0.25 mg/1) or 2,4-D (0.5 mg/1) or 2,4-D+BAP (0.5 + 0.25 mg/1) or IAA (2mg/1), for a consecutive subculture period of 4 wk (subculture period II). Callus continuously grown on MS basal medium without hormones or humic fractions was used as control. All treatments were carried out at 25°C in the dark. At the end of the treatment, the calluses were weighed and used for enzymatic analysis and soluble sugars determination.

Soluble Sugars Determination. Calluses were extracted ×3 with boiling 80% ethanol (v/v). Homogenates were centrifuged at 12000 *g*, and the ethanolic extract was evaporated under vacuum (Rotavapor RE 111; Büchi, Switzerland), resolubilized in distilled water, and subjected to enzymatic assay. Glucose, fructose, and sucrose were determined by using respectively, hexokinase, glucose-6-phosphate dehydrogenase, and phosphoglucose isomerase, and after enzymatic inversion to D-glucose and D-fructose by the enzyme β-fructosidase (Boehring test combination 716 260) (Bergmeyer and Bernt, 1974). Absorbance was detected at 340 nm (UV-2100 spectrophotometer; Shimadzu, Japan).

Protein Content and Enzyme Activities. Crude homogenates were prepared by grinding the calluses in a prechilled mortar and pestle, with 0.1 M HEPES-NaOH buffer (pH 7.7), containing 10 mM $MgCl_2$, 0.4 mM Na-EDTA, 100 mM Na-ascorbate, 1% (w/v) polyvinylpyrrolidone (PVP), 1% (w/v) bovine serum albumin (BSA), and 5 mM glutathione reduced form (GSH). Extracts were centrifuged at 20000 *g* for 20 min at 4°C. Soluble proteins were quantified with the method of Bradford (1976), using bovine serum albumin as a standard.

The supernatant resulting from this extraction was designated the soluble acid invertase (SAI, EC 3.2.1.26) free fraction. The pellet was suspended in a homogenizing buffer containing 1 M NaCl and left 12 hr at 4°C. The supernatant from this extraction was referred to as bound acid invertase fraction (BAI, EC 3.2.1.26). Invertase activity was measured by using 1% sucrose as the substrate, and the assay was performed at 30 °C in an acetate buffer at pH 4.6 for 1 hr (Borkowska and Szczerba, 1991). The resulting reducing sugars were estimated colorimetrically at 560 nm, by arseno-molybdate method (Nelson, 1944).

Pyruvate kinase (PK, EC 2.7.1. 40): to 450 μl 0.1 M triethanolamine (TEA) adjusted with NaOH to pH 7.75 were added 50 μl 3 mM β-NADH-Na_2-salt in 0.1 M TEA pH 7.75, 50 μl 0.15 M $MgSO_4$-$6H_2O$ and 0.15 M KCl in 0.1 M TEA (pH 7.75), 50 μl L-lactic dehydrogenase diluted to 225 U ml^{-1} with TEA (pH 7.75), and 50 μl extract. The reaction was started after a lag time of 10 min at 30 °C by adding 50 μl 0.225 M 2-phosphoenolpyruvate-Na-H_2O in 0.1 M TEA (pH 7.75) (Nowotny et al., 1998).

Phosphoglucose isomerase (PGI, EC 5.3.1.9): to 530 μl 0.2 M Tris adjusted with 0.1M HCl to pH 9.0 were added 75 μl 20 mM β-NADH-Na_2-salt in distilled water, 75 μl 80 mM fructose-6-phosphate-Na_2 in 0.2 M Tris, pH 9.0, and 20 μl

glucose 6-phosphate dehydrogenase (from yeast) diluted to 30 U ml^{-1} with 0.2 M Tris, pH 9.0. The reaction was started by adding 50 μl extract after a lag time of 20 min at 30 °C (Nowotny et al., 1998).

Glucokinase (GK, EC 2.7.1. 11) activity was measured by coupling glucose phosphate production with NAD reduction by glucose-6-phosphate dehydrogenase and monitoring at A_{340}. The assay contained 50 mM Bicine-NaOH (pH 8.5), 5 mM $MgCl_2$, 1 mM ATP, 1 mM glucose, 1 mM NAD, 1 IU/ml glucose 6-phosphate dehydrogenase, and 50 μl extract. The assay was initiated with glucose (Doehlert et al., 1988).

Aldolase (ALD, EC 4.1.2.13) was assayed spectrophotometrically at A_{340}. The assay contained 50 mM HEPES-NaOH (pH 7.2), 5 mM $MgCl_2$, 1 mM fructose-1,6-bis phosphate, 0.2 mM NADH, 1 IU/ml glycerol-3-phosphodehydrogenase, 1 IU/ml triose phosphate isomerase, and 50 μl extract (Doehlert et al., 1988).

Statistical Analysis. The reported data represent mean values of five replicates. Comparisons between the means were made using the Student-Newman-Keuls test (Sokel and Rohlf, 1969).

RESULTS AND DISCUSSION

Currently, NMR spectroscopy is considered an essential tool in the analysis of humic matter; it is employed to obtain structural information of carbon nuclei in humic matter and on relative amounts of each carbon fraction (Wilson et al., 1987; Preston, 1996). Quantitative ^{13}C-NMR spectra show different features between the two humic substances analyzed (Table 1). Fs humic fraction, derived from soil under *Fagus sylvatica* plantation, contained a greater amount of phenolic and carboxylic C groups than Aa humic fraction, suggesting a possible enrichment of lignin aromatic structures in Fs. In contrast, Aa humic fraction, derived from soil under *Abies alba*, had a higher content of aliphatic, peptidic, and carbohydratic C-groups obtained from polysaccharide and lipid decomposition (Table 1).

TABLE 1. DISTRIBUTION OF C INTENSITY IN DIFFERENT REGIONS (PPM) OF ^{13}C-NMR SPECTRA OF FOREST (FS AND AA) HUMIC FRACTIONS

	Relative intensity (total area %)[a]				
Humic fraction	0–48 aliphatic C	48–105 peptidic and carbohydratic C	105–145 aromatic C	145–165 phenolic C	165–190 carboxylic C
Aa	17.3 ± 0.3	39.8 ± 0.4	21.9 ± 03	9.3 ± 0.2	11.7 ± 0.2
Fs	16.0 ± 0.2	33.9 ± 0.2	21.9 ± 0.4	10.5 ± 0.2	17.7 ± 0.3

[a] Values are mean ± SE ($N = 5$).

Note. Subculture I and subculture II represent two consecutive culture treatments of 4 wk duration each of the same callus.
Control = callus on MS medium; 2,4-D = 2,4-dichlorophenoxyacetic acid; BAP = 6 benzylaminopurine; IAA = indole-3-acetic acid; Fs = humic fraction from *Fagus sylvatica* plantation; Aa = humic fraction from *Abies alba* plantation.
[a] Values are mean ± SE ($N = 5$). Mean ± SE in the same column, followed by the same letter are not statistically different at $P = 0.05$.

These findings provide evidence that the composition of humic substances may depend on origin and type of organic matter as previously reported by Tan (1998).

Callus incubated on basal medium without growth regulators or humic fractions had a slow growth during subculture periods I and II. A similar behavior was observed when IAA or BAP supplements alone were used. The treatment 2,4-D+BAP produced the largest mean callus weight. Aa or Fs humic fractions significantly decreased callus growth causing, at the end of subculture period II, the callus death (Table 2). Callus grown for four wk with Fs and then transferred, for a consecutive subculture period, to a basal MS medium with 2,4-D+BAP or 2,4-D alone, restarted growth. A significant restart of growth was also observed in callus treated initially with Aa and then with 2,4-D+BAP or 2,4-D alone. A slight restart was noticed when the calluses were cultured initially with Fs or Aa and then subcultered with IAA present (Table 2). Callus incubated initially on MS medium with Fs or Aa humic fractions and then transferred, for a subsequent four wk, to

a medium with BAP only, did not restart growth, showing values similar to those observed in callus grown continuously in the presence of humic fractions.

These results were confirmed by visible changes in the calluses; callus grown for the whole period with only humic fractions was brown, while that grown for 4 wk in the presence of humic fractions and for an additional 4 wk with 2,4-D+BAP or 2,4-D had a few small green areas on it, confirming the restored callus growth. In contrast, callus grown for 4 wk with humic fractions (Aa or Fs) and then for 4 weeks with BAP or IAA, appeared similar to that grown with humic fractions alone.

Heterotrophic cell cultures are dependent on an exogenous carbon source for metabolism, and, generally, this carbon source is the growth-limiting factor. A wide variety of carbon sources (sucrose, glucose, fructose) are used to support the growth of cell culture (Botha and O'Kennedy, 1998). In most cases, plant cell cultures are grown in a medium containing sucrose as the only carbohydrate source. Sucrose catabolism is necessary to provide carbon for respiration process; in most investigated species, it is rapidly hydrolyzed to glucose and fructose before use (Hawker, 1985). Sucrose may be metabolized either by sucrose synthase or invertase, although the contribution of each enzyme can vary with respect to tissue type, function, and age (Sung et al., 1989). Sucrose synthase is crucial to sucrose utilization in fruit development (Wang et al., 1993), and invertase is particularly active in growing tissue (Borkowska and Szczerba, 1991). In callus treated for the entire period (subculture period I and II) with Fs or Aa humic fractions, glucose and fructose levels, produced from sucrose, were higher compared to those detected in control and in callus treated with hormones.

In callus cultured for four wk on medium culture with Fs or Aa and then transferred to a culture medium with 2,4-D+BAP or 2,4-D alone, glucose and fructose values were lower compared to those observed in callus treated with humic fractions alone (Table 3). In contrast, in callus grown in presence of humic fractions for four wk and then with BAP or IAA, glucose and fructose values were similar to those in callus treated for the whole period with humic fractions Aa or Fs alone (Table 3). Moreover, as shown in Table 3, the decrease of sucrose content in callus tissue cultured with different treatments confirmed the cleavage of sucrose into two hexoses.

These data are supported by values of soluble and bound invertase activities. The results reported in Table 4 show that (during subculture period I) both humic fractions, and in particular the Fs, have increased activities in comparison to control and hormone treatments. At the end of subculture period II, humic substances caused callus death, so it was impossible to detect the enzymatic activities. In callus treated for four wk with Fs or Aa and then transferred to a Basal MS medium with 2,4-D+BAP or 2,4-D alone, it was possible to observe a decrease in levels of both invertases. These data indicate that the Fs or Aa humic fractions that inhibited growth and caused an accumulation of hexoses, resulted from an apparent increase of invertase activities.

Glucokinase, the enzyme that converted the products of sucrose cleavage to hexoses phosphates, was inhibited by humic fractions compared to the control and other treatments; this activity showed, at the end of the subculture period I, values of about 0.60 nmoles NADPH mg FW^{-1} min^{-1} (Table 5). The enzyme most affected by both humic fractions was PGI, which converts glucose-6-phosphate to fructose-6-phosphate (Appeldoorn et al., 1997). Callus grown with Fs or Aa showed a decrease in PGI activity compared to levels in the control treatment. In callus treated for four wk with Fs or Aa humic fractions and then with 2,4-D+BAP or 2,4-D alone, the levels of PGI activity increased remarkably, reaching values of about 35 nmoles NADPH mg FW^{-1} min^{-1}. In callus grown first with humic fractions and then with BAP or IAA, PGI activity was low (about 4.00 nmoles NADPH mg FW^{-1} min^{-1}) (Table 5).

In the presence of humic fractions, the values for the activity of aldolase, the enzyme that converts hexoses phosphates to triose phosphates (Ashihara et al., 1988), were lower than control and hormone treatments. In callus grown with humic fractions for four wk, and then transferred for an additional four wk to a

MS medium with BAP or IAA, a slight increase of ALD activity was observed (about 3.4 nmoles NADPH mg FW^{-1} min^{-1}); the highest levels of ALD activity were reached when the callus was transferred from humic fractions to 2,4-D+BAP or 2,4-D medium.

The same behavior was observed for PK activity, an important regulatory enzyme of the glycolytic pathway that catalyzes the conversion of phosphoenolpyruvate to pyruvate (Ambashi and Kayastha, 2002). Callus treated for the whole culture period with humic fractions and that grown first with humic fractions and after with BAP or IAA, both had a lower PK activity compared to other treatments (Table 6).

The results show that the callus fractions that utilized Fs or Aa were negatively affected; and the callus growth inhibition was due to the inhibition of glycolytic enzymes involved in carbohydrate catabolism. The block of the glycolytic pathway may induce an inadequate invertase activity response, suggesting that not only the levels of glucose and fructose, but also the amount of the end products of glycolysis

may stimulate or inhibit this enzyme. Moreover, these data show that the effect caused by these substances is reversible. After four wk, the substitution of humic fractions with 2,4-D+BAP or 2,4-D was followed by an increase of glycolytic enzyme activities and consequently by the increased utilization of glucose and fructose, that induced a restart of growth. The inhibitory effects on callus growth and metabolism were slightly reversed when these substances were substituted with IAA, but it persisted when these substances were substituted with BAP, suggesting that only the auxin 2,4-D is able to reverse these negative effects significantly.

This may be explained by the fact that 2,4-D and IAA have different roles on callus induction in various species (Tao et al., 2002); we have found that, in *Pinus laricio*, 2,4-D is better than IAA in inducing regenerative callus. As reported by Shafer et al. (1985), for carrot culture, auxin IAA does not induce regenerative callus, probably because it is partially degraded within the cells so that it is more difficult to reach the concentration necessary to induce callogenesis. This may

be true also for *Pinus laricio* and explain why IAA, possessing less callogenic activity, is not able to reverse the inhibitory effects of humic matter.

These results indicate competition between the humic fractions Fs and Aa and auxin 2,4-D, suggesting that this effect is due to interference with functional groups, in particular the carboxylic group, that, as suggested by Rubery (1981), is needed for auxin-binding receptors.

The data also show a different inhibitory effect of the two humic fractions. The Fs fraction mostly affects PGI activity, utilization of glucose and fructose, and, consequently, callus growth. The Fs humic fraction has a greater amont of phenolic and carboxylic-C groups that, as suggested by Mato et al. (1972) and Pflug and Ziechman (1981), could also play a role in determining humic substances activity.

Humic matter, thus, shows a complex biological activity depending on its origin and concentration, and, consequently, it can affect plant metabolic parameters in different ways.

Abstract—*Spiraea thunbergii* Sieb. contains 1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (CG) and 6-*O*-(4′-hydroxy-2′-methylene-butyroyl)-1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (BCG) as major plant growth inhibiting constituents. In the present study, we determined the inhibitory activity of CG and BCG on root elongation of germinated seedlings of lettuce (*Lactuca sativa*), pigweed (*Amaranthus retroflexus*), red clover (*Trifolium pratense*), timothy (*Phleum pratense*), and bok choy (*Brassica rapa* var *chinensis*) in comparison with that of two well-known growth inhibitors, 2,4-dichlorophenoxyacetic acid (2,4-D) and (+)-2-*cis*-4-*trans*-abscisic acid (*cis*-ABA), as well as two related chemicals of CG and BCG, *cis*-cinnamic acid (*cis*-CA) and *trans*-cinnamic acid (*trans*-CA). The EC_{50} values for CG and BCG on lettuce were roughly one-half to one-quarter of the value for *cis*-ABA. *cis*-Cinnamic acid, which is a component of CG and BCG, possessed almost the same inhibitory activity of CG and BCG, suggesting that the essential chemical structure responsible for the inhibitory activity of CG and BCG is *cis*-CA. The *cis*-stereochemistry of the methylene moiety is apparently needed for high inhibitory activity, as *trans*-CA had an EC_{50} value roughly 100 times that of CG, BCG, and *cis*-CA. Growth inhibition by CG, BCG, and *cis*-CA was influenced by the nature of the soil in the growing medium: alluvial soil preserved the bioactivity, whereas volcanic ash and calcareous soils inhibited bioactivity. These findings indicate a potential role of *cis*-CA and its glucosides as allelochemicals for use as plant growth regulators in agricultural fields.

Key Words—*Spiraea thunbergii* Sieb, Rosaceae, Thunberg Spirea, allelopathy, plant growth inhibitors, *cis*-cinnamic acid, *cis*-cinnamoyl glucosides.

INTRODUCTION

Environmental safety is a major concern in many countries. The use of natural products would be a helpful way to reduce the risk from synthetic agrochemicals because, in general, the ecosystem can decompose and recycle natural products. Compounds that regulate plant growth have been sought in plants and microorganisms, and plants contain growth-regulating compounds that control their own growth (phytohormones) or that of other plants (allelochemicals).

In recent decades, research aimed at identifying natural chemicals that might serve as commercial herbicides or as prototypes for the development of synthetic analogs has intensified. The most widely used herbicide in the world, 2,4-dichlorophenoxyacetic acid (2,4-D; Figure 1), is an auxin analog. Some

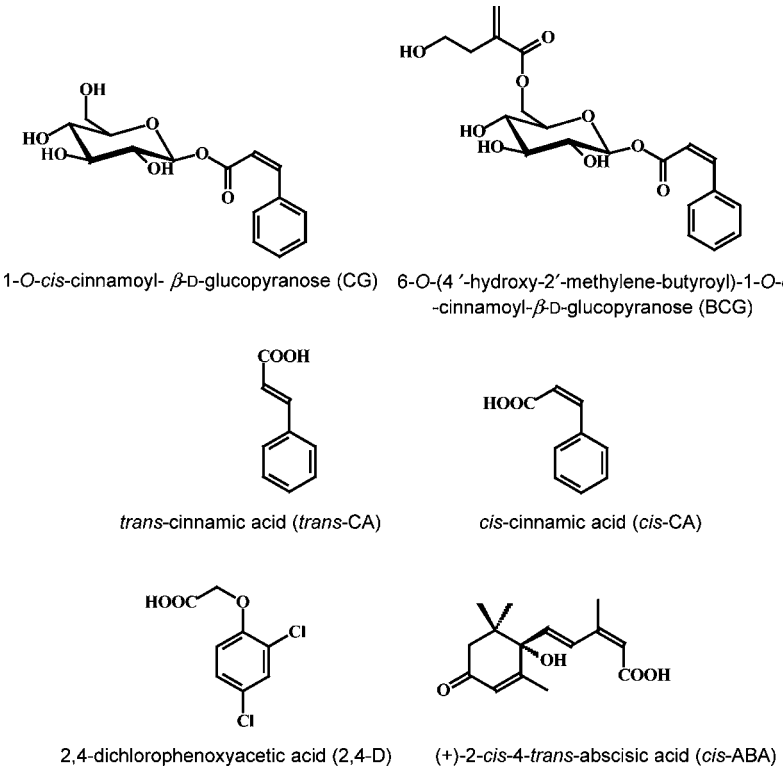

FIG. 1. Chemical structures of 1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (CG), 6-*O*-(4′-hydroxy-2′-methylene-butyroyl)-1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (BCG), *trans*-cinnamic acid (*trans*-CA), *cis*-cannamic acid (*cis*-CA), 2,4-dichlorophenoxyacetic acid (2,4-D), and (+)-2-*cis*-4-*trans*-abscisic acid (*cis*-ABA).

phytohormones, such as (+)-2-*cis*-4-*trans*-abscisic acid (*cis*-ABA; Figure 1), gibberellins, and brassinosteroids, are used as commercial plant growth regulators. The commercial herbicide phosphino-thricylalanylalanin (bialaphos) has also been found among the fermentation products of *Streptomyces hygroscopicus*.

Morita et al. (2001) clarified the growth-inhibition activity of leachates from the leaves of 56 species of woody plants grown in Japan, and found that three Rosaceae plants (*Spiraea thunbergii* Sieb., *S. cantoniensis*, and *S. pruniflora*) had the highest inhibitory activity when assessed with lettuce roots. Hiradate et al. (2004) isolated the inhibitory compounds from *S. thunbergii* using the concept of "*total activity*," which means biological activity per unit weight of the organism containing the bioactive compound, and elucidated the chemical structures from spectroscopic evidence. The compounds were novel *cis*-cinnamoyl glucosides: 1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (CG; Figure 1) and 6-*O*-(4′-hydroxy-2′-methylene-butyroyl)-1-*O*-*cis*-cinnamoyl-β-D-glucopyranose (BCG; Figure 1).

In the present study, we clarified the inhibitory activity (*specific activity*, biological activity per unit weight of the compound) of CG and BCG on the root elongation of five plant species by comparing the two compounds with two well-known plant growth inhibitors (2,4-D and *cis*-ABA). The inhibitory activity of CG and BCG was also compared with that of *cis*-cinnamic acid (*cis*-CA; Figure 1) and *trans*-cinnamic acid (*trans*-CA; Figure 1) to reveal the portion of the chemical structure that is essential for the inhibitory activity of CG and BCG. The activities of CG, BCG, *cis*-CA, and *trans*-CA were also tested in various soil types (alluvial soil, volcanic ash soil, and calcareous soil) to assess the effects of soils on the inhibitory activities.

METHODS AND MATERIALS

Chemicals. 2,4-D (Wako Pure Chemical Industries, Ltd., Osaka, Japan) and *cis*-ABA (Toray Industries, Inc., Tokyo, Japan) were used as reference compounds for the bioassay. Two natural plant growth inhibitors, CG and BCG, were isolated and purified from the leaves of *S. thunbergii* according to the method described by Hiradate et al. (2004). To prepare *cis*-CA, we transformed *trans*-CA (Wako Pure Chemical Industries, Ltd.) into an isomeric mixture of *cis*- and *trans*-CA by irradiating it with an ultraviolet lamp (254 nm) overnight. Pure *cis*-CA was isolated by separating the isomeric mixture using preparative HPLC as described by Sun et al. (2002). To determine the concentrations of CG, BCG, and *cis*-CA, we dissolved 60 μg of *trans*-CA in 0.60 ml of CD_3OD-d_4 in an NMR tube (5-mm i.d.). A solution of each of the purified compounds (hydrated) was also prepared by dissolving an unweighed quantity of the compounds in 0.60 ml of CD_3OD-d_4 in the NMR tube (concentration unknown). Hydrogen-1 (^1H) NMR signals of these samples were recorded quantitatively (acquisition time: 5.46 sec) using an NMR spectrometer (^1H: 600 MHz, JNM α-600, JEOL, Tokyo). We compared the

integrated peak area of the methylene ^{1}H of *trans*-CA with that of the methylene ^{1}H of the cinnamic acid moiety of each compound, and the concentration of each compound was calculated thereby.

Phytotoxic Activities in the Absence of Soil. A filter paper (27 mm diam, Type 1, Toyo Roshi Kaisha, Ltd., Tokyo) was placed in a glass petri dish (27 mm diam). Test compounds were dissolved in water at various concentrations and a 0.7-ml portion of each test solution was added to the filter paper in the petri dishes of each treatment. Five to six pre-germinated (20°C in the dark) seedlings of lettuce (*Lactuca sativa* cv. Great Lakes 366), pigweed (*Amaranthus retroflexus*), red clover (*Trifolium pratense*), timothy (*Phleum pratense*), and bok choy (*Brassica rapa* var. *chinensis*) were used as a single replicate for each treatment, with different species placed on different filter papers to avoid any potential allelopathic effects. Seedlings were incubated for 48 hr at 20°C in the dark, and the inhibitory activity of each test solution on root elongation was detected by measuring the length of each root and comparing it with that of the untreated control (with only distilled water provided). The effective concentration required to induce half of the maximum inhibition (EC_{50}) and its 95% confidence interval were calculated by using the probit method from SPSS for Windows ver. 11.0.1J statistical software (SPSS Japan Inc., Tokyo).

Phytotoxic Activities in the Presence of Soil. An Alluvial soil (Aquept, Soil Survey Stuff, 1999; Anthrosol, FAO, 1998) and a volcanic ash soil (Melanudand, Soil Survey Stuff, 1999; Silandic Andosol, FAO, 1998) were collected from the A_p horizons of paddy and upland agricultural fields in Tsukuba, Japan. A calcareous soil (Hapludalf, Soil Survey Stuff, 1999; Chromic Luvisol, FAO, 1998) was collected from the A_p horizon of an upland agricultural field in Yomitan, Okinawa, Japan. The soils were air-dried and finely sieved (<0.5 mm), and a 500-mg portion (oven-dry basis) of each soil was placed in each well (15.6-mm diam, 17-mm height, 1.9-cm^2 growing area) of a 24-well plate (Nunclon, NalgeNunc, Denmark). We then added 1 ml of a solution containing 10^{-8} to 10^{-2} M of plant growth inhibitor and 0.75% of agar (gelling temperature, 30 to 31°C; Nakalai Tesque, Inc., Kyoto, Japan) at 40°C to each soil-containing well and mixed the components. After incubating the mixture at 30°C for 24 hr in the dark, we placed four lettuce seeds on the gelled agar-soil mixture in the well. The lettuce seeds were grown for 72 hr at 20°C in the dark, and the inhibitory activity was detected by measuring root elongation and comparing it with that of the control (with no plant growth inhibitor, but in the presence of the corresponding soil). This experiment was replicated three times.

RESULTS AND DISCUSSION

Figure 2 shows the inhibitory activities of CG, BCG, 2,4-D, *cis*-ABA, *cis*-CA, and *trans*-CA on the root growth of lettuce seedlings in the absence of soil. In this

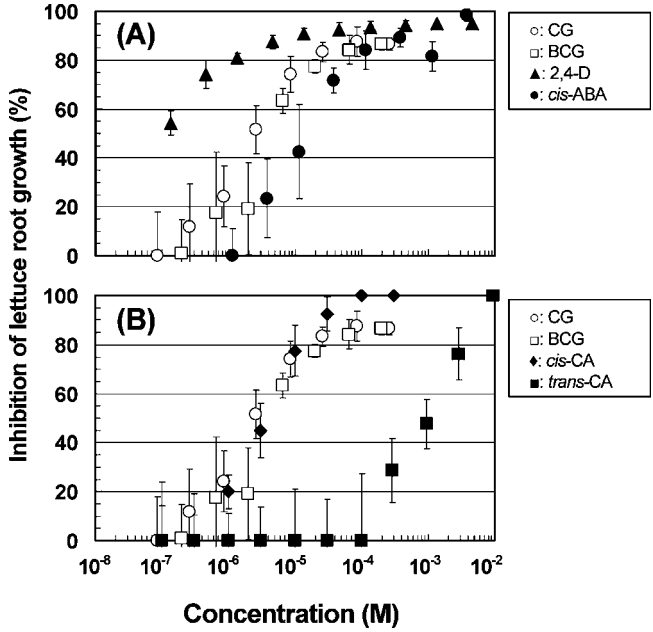

FIG. 2. Inhibitory activities of *cis*-cinnamoyl glucosides (○; CG, □; BCG) in comparison with those of the reference compounds (A: ▲; 2,4-D, ●; *cis*-ABA) and cinnamic acids (B: ♦; *cis*-CA, ■; *trans*-CA) in the absence of soil. Inhibition of root elongation was detected by comparing the root lengths with those of untreated controls after incubation for 48 hr at 20°C in the dark. Bars indicate standard deviations ($N = 5$–6).

experiment, the growth inhibition in the presence of CG, BCG, 2,4-D, *cis*-ABA, and *cis*-CA was attributable to the effects of the compounds themselves, and not to effects of pH or salts, because single treatment with 3×10^{-4} M HCl or 10^{-4} M $CaCl_2$ alone did not affect the growth of lettuce roots (data not shown). As shown in Figure 2, CG, BCG, 2,4-D, *cis*-ABA, and *cis*-CA inhibited the root growth of lettuce seedlings at concentrations below 10^{-4} M.

cis-ABA is one of the most active natural growth inhibitors. Koshimizu et al. (1966) reported that the effective concentration of *cis*-ABA required to induce half the maximum inhibitory action (EC_{50}) on the leaf sheath of rice seedlings was around the 10^{-6} M level. Structural modification of this compound has been attempted to strengthen its specific activity and to make it resistant against biodegradation into inactive forms (Nakano et al., 1995; Todoroki et al., 1997; Arai et al., 1999). In this study, the EC_{50} of *cis*-ABA for root elongation of lettuce seedlings was observed at the 10^{-5} M level (14.9 μM, Table 1).

TABLE 1. INHIBITORY ACTIVITIES OF REFERENCE COMPOUNDS (2,4-D AND *cis*-ABA), CINNAMOYL GLUOSIDES (CG AND BCG), AND CINNAMIC ACIDS (*cis*-CA AND *trans*-CA) ON ROOT GROWTH OF LETTUCE (*Lactuca sativa* CV. GREAT LAKES 366) SEEDLINGS IN FILTER PAPER AND AGAR BIOASSAY SYSTEMS IN THE ABSENCE OF SOIL, AS INDICATED BY THE EFFECTIVE CONCENTRATION AT 50% INHIBITION (EC_{50}) AND 95% CONFIDENCE INTERVAL VALUES (μM) DETERMINED BY PROBIT ANALYSIS

	On filter paper	On agar
2,4-D	0.34 (0.07–1.21)[a]	0.24 (0.19–0.30)
cis-ABA	14.94 (6.39–32.81)	—[b]
CG	3.98 (1.66–9.05)	2.61 (1.12–6.02)
BCG	6.88 (3.39–14.21)	8.68 (2.97–22.76)
cis-CA	3.67 (3.07–4.38)	1.62 (0.17–4.39)
trans-CA	770.92 (549.47–1120.47)	883.40 (379.72–2252.94)

[a] Data in parentheses indicate the 95% confidence interval.
[b] No data available.

The inhibitory activities of CG and BCG on root elongation of lettuce seedlings both occurred at the 10^{-6} M level (Figure 2, Table 1). The EC_{50} values for CG and BCG on lettuce were roughly one-half to one-quarter of the value for *cis*-ABA, meaning that CG and BCG had considerably stronger inhibitory activity than *cis*-ABA. Although the inhibitory activities of CG and BCG were almost one tenth that of 2,4-D, a synthetic commercial herbicide (Figure 2A, Table 1), their inhibitory potential is still among the highest yet reported for natural products.

To establish the portion of the chemical structure that is essential for the high inhibitory activity of CG and BCG, we compared their inhibitory activity with that of *cis*- and *trans*-CA. CG, BCG, and *cis*-CA had comparable levels of inhibitory activity (Figure 2B, Table 1). This suggests that *cis*-CA represents the chemical moiety that is essential for the high inhibitory activity of CG and BCG. We obtained additional confirmation that the stereochemistry of the methylene moiety of CA should be *cis* to provide high inhibitory activity by observing that the *trans*-isomer (*trans*-CA) showed an activity that was two orders of magnitude weaker than that of CG, BCG, and *cis*-CA (Figure 2B, Table 1).

Inhibitory activities of 2,4-D, *cis*-ABA, CG, BCG, *cis*-CA, and *trans*-CA on root elongation of pigweed, red clover, timothy, and bok choy were also established (Figure 3). In all plant species that we tested, the inhibitory activities of CG, BCG, and *cis*-CA were equally high, whereas that of *trans*-CA was significantly weaker. This result supports the suggestion that the portion of the chemical structure that is essential for high inhibitory activity is *cis*-CA and that the stereochemistry of the methylene moiety of CA needs to be *cis* to provide high inhibitory activity. This result is consistent with the observation that the *trans*-isomers of CG and BCG

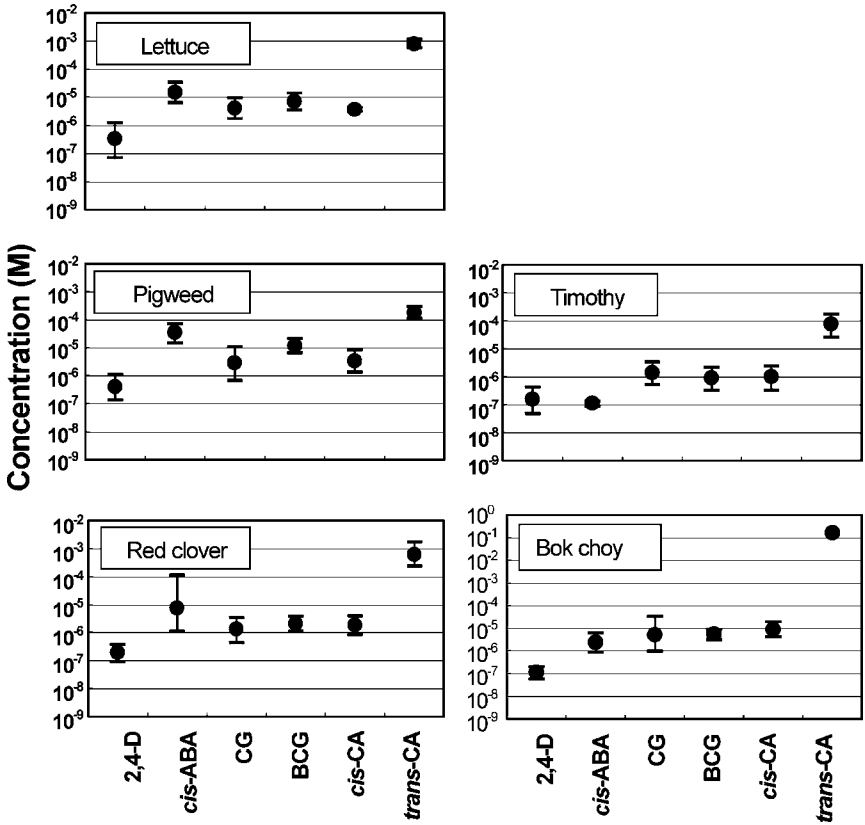

FIG. 3. Inhibitory activities of reference compounds (2,4-D and *cis*-ABA), *cis*-cinnamoyl glucosides (CG and BCG), and cinnamic acids (*cis*-CA and *trans*-CA) on root elongation of germinated seedlings of lettuce (*Lactuca sativa* cv. Great Lakes 366), pigweed (*Amaranthus retroflexus*), red clover (*Trifolium pratense*), timothy (*Phleum pratense*), and bok choy (*Brassica rapa* var. *chinensis*). Inhibition of root growth was detected by comparing root lengths with those of untreated control seedlings after incubation for 48 hr at 20°C in the dark. Data were subjected to probit analyses, and estimated EC_{50} values (•) and 95% confidence intervals (bars) are shown.

produce almost no inhibition of root elongation in lettuce seedlings (Hiradate et al., 2004).

trans-Cinnamic acid is a common phenylpropanoid synthesized from phenylalanine by L-phenylalanine ammonia-lyase (PAL). Bonner and Galston (1944) showed that *trans*-CA is secreted from the roots of guayule (*Parthenium argentatum*). Since then, the allelopathic potential of *trans*-CA has been frequently

reported (e.g., Baziramakenga et al., 1994; Chon et al., 2003). Since *trans*-CA can be converted into *cis*-CA by sunlight and by the presence of an electron-transfer facilitator, it is possible that the conversion of *trans*-CA into *cis*-CA is involved in the allelopathic phenomenon. This transformation might explain the reported synergism between *trans*-CA and polygodial (Fujita and Kubo, 2003) and ABA (Li et al., 1993).

The presence of natural *cis*-CA in plants has recently been reported in *Brassica parachinensis* (Yin et al., 2003). Its biosynthesis, however, is not well understood, but possible pathways have been proposed: (1) sunlight-mediated conversion from *trans*-CA, (2) spontaneous conversion from *trans*-CA in the presence of an electron-transfer facilitator, (3) isomerase-mediated conversion from *trans*-CA, and (4) direct enzymatic biosynthesis from L-phenylalanine (Yin et al., 2003). Further study is necessary.

The inhibitory activity of CG, BCG, and *cis*-CA was higher than that of *cis*-ABA for lettuce, pigweed, and red clover, but the reverse was observed for timothy and bok choy (Figure 3). This suggests that the mechanisms of growth inhibition might differ between *cis*-ABA and *cis*-CA derivatives. In any case, the inhibitory activity of CG, BCG, and *cis*-CA was generally comparable with that of *cis*-ABA.

The effects of soil on the inhibitory activities of these compounds is shown in Figure 4. In this bioassay system, we added agar to the soils to permit stable growth of the lettuce. This step was necessary because the addition of agar had been shown to decrease the coefficient of variation (CV) for the root growth of lettuce in our preliminary research (data not shown). The inhibitory activities of all compounds in the absence of soil (Figure 4, •) were almost identical to those in the filter paper bioassay system (Table 1, Figure 2), indicating that the adsorption of these compounds on the agar was negligible.

The inhibitory activity of CG, BCG, and *cis*-CA decreased in the presence of volcanic ash and calcareous soils (Figure 4). This was clear in comparisons made at 10^{-5} and at 3×10^{-5} M for each treatment. The alluvial soil had minimal effects on growth inhibition. In volcanic ash and calcareous soils, the amount of active surface hydroxyls, which adsorb and inactivate carboxylic acids by ligand exchange reactions, is larger than in alluvial soil (Hiradate and Uchida, 2004). Therefore, an alluvial soil would be more advantageous for the bioactivity of CG, BCG, and *cis*-CA than would volcanic ash or calcareous soils. It is possible that CG and BCG released from *S. thunbergii* work as effective allelochemicals in soil environments.

The inhibitory activity of CG, BCG, and *cis*-CA was lower than that of the synthetic commercial herbicide 2,4-D. The latter has been listed as a possible endocrine disrupter, along with its possible metabolite 2,4-dichlorophenol (Crosby, 1998). Both are frequently found in soils and in ground water (Hall et al., 1993;

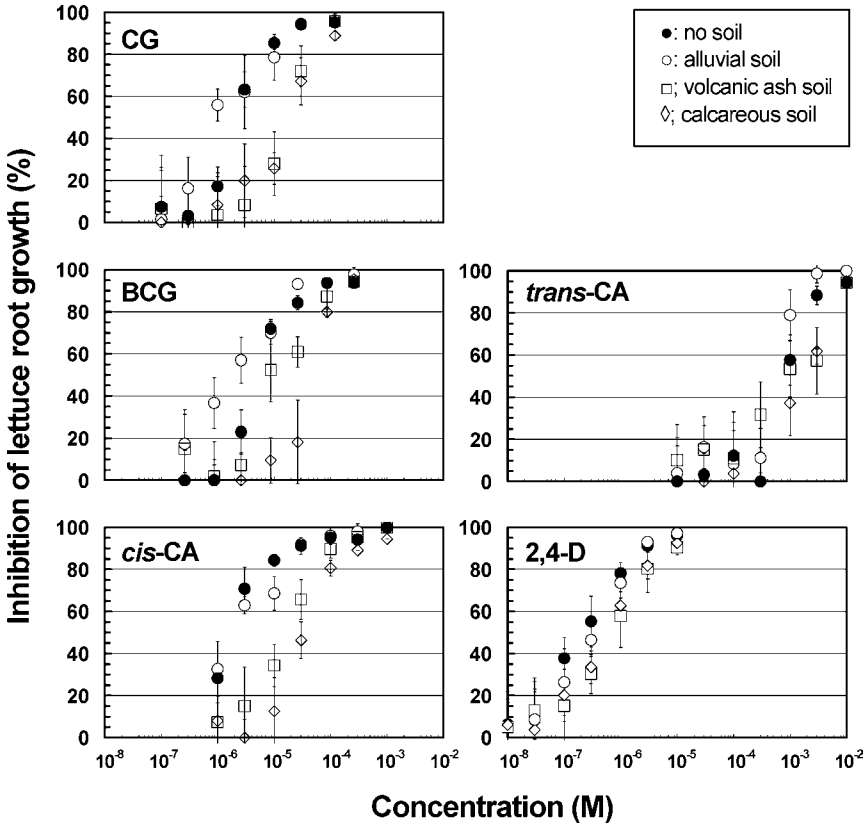

FIG. 4. Inhibitory activities of *cis*-cinnamoyl glucosides (CG and BCG), cinnamic acids (*cis*-CA and *trans*-CA), and the reference compound (2,4-D) on root elongation of lettuce (*Lactuca sativa* cv. Great Lakes 366) in agar media in the absence (●) or presence of soil (○; alluvial soil, □; volcanic ash soil, ◇; calcareous soil). Inhibition of root growth was detected by comparing the root lengths with those of untreated controls for each soil after incubating for 72 hr at 20°C in the dark. Bars indicate standard deviation ($N = 12$).

Wood and Anthony, 1997; Balinova and Mondesky, 1999; Pierzynski et al., 2000). Synthetic products such as 2,4-D often undergo little decomposition in soil environments because the enzymatic and other systems required to degrade them may not be present in nature. In contrast, both *cis*-CA and its glucosides are natural products that could be utilized by various indigenous soil organisms, because cinnamic acid is a common secondary metabolite in most organisms. It is, thus, likely that *cis*-CA and its glycosides are worth considering as plant growth regulators,

as they are inexpensive to synthesize and possess a low risk of environmental toxicity.

(Received April 14, 2004; accepted November 15, 2004)

Abstract—(*Z,Z*)-6,9-Heneicosadien-11-one (*Z6Z9*-11-one-21Hy) was identified as the major sex pheromone component of the painted apple moth (PAM), *Teia anartoides* (Lepidoptera: Lymantriidae), on the basis of (1) comparative gas chromatographic-electroantennographic detection (GC-EAD) analyses, GC-mass spectrometry (MS), high-performance liquid chromatography (HPLC)-MS, and HPLC-UV/visible spectroscopy of pheromone gland extracts and authentic standards; (2) GC-EAD analyses of effluvia of calling females; and (3) wind tunnel and field trapping experiments with a synthetic standard. In field experiments in Australia, synthetic *Z6Z9*-11-one-21Hy as a single component attracted male moths. Wind tunnel experiments suggested that a 4-component blend consisting of *Z6Z9*-11-one-21Hy, (6*Z*,9*R*,10*S*)-*cis*-9,10-epoxy-heneicosene (*Z*6-9*R*10*S*-epo-21Hy), (*E,E*)-7,9-heneicosadien-6,11-dione (*E7E9*-6,11-dione-21Hy), and 6-hydroxy-(*E,E*)-7,9-heneicosadien-11-one (*E7E9*-6-ol-11-one-21Hy) (all present in pheromone gland extracts) might induce more males to orient toward, approach, and contact the source than did

* To whom correspondence should be addressed. E-mail: gries@sfu.ca

Z6Z9-11-one-21Hy as a single component. Additional experiments are needed to determine conclusively whether or not Z6-9*R10S*-epo-21Hy, *E7E9*-6,11-dione-21Hy, and *E7E9*-6-ol-11-one-21Hy might be minor sex pheromone components of PAM. Moreover, attractiveness of synthetic pheromone and virgin PAM females needs to be compared to determine whether synthetic pheromone could replace PAM females as trap baits in the program to monitor eradication of exotic PAM in New Zealand.

Key Words—Lymantriidae, *Teia anartoides*, painted apple moth, sex pheromone, (*Z,Z*)-6,9-heneicosadien-11-one, (*Z,E*)-6,8-heneicosadien-11-one, (6*Z*,9*R*,10*S*)-*cis*-9,10-epoxy-heneicosene, (*E,E*)-7,9-heneicosadien-6,11-dione; 6-hydroxy-(*E,E*)-7,9-heneicosadiene-11-one.

INTRODUCTION

The painted apple moth (PAM), *Teia anartoides* Walker (Lepidoptera: Lymantriidae), is endemic to southeastern Australia (Common, 1990; Edwards, 1996). Caterpillars cause minor damage to a wide range of trees and shrubs (Edwards, 1996), especially Acacias (*Acacia* spp.), and many other native and introduced plants, including cultivated crops and forest trees such as *Pinus radiata* (Pinaceae) (Common, 1990).

In 1999, PAM caterpillars were discovered in Auckland, New Zealand (Ridley, 1999). Realizing the threat of this exotic moth to New Zealand's native plants, agricultural, horticultural, and silvicultural industries as well as international trade, New Zealand's government initiated a program to eradicate PAM. Progress in this ongoing program is monitored by traps baited with laboratory-reared virgin PAM females. Continuous trap captures of PAM males indicate the persistence of residual PAM populations. Synthetic female pheromone for use as trap bait would facilitate monitoring of the eradication program, and prompted attempts to identify the PAM pheromone.

A number of compounds have been reported as possible sex pheromone components of PAM, including (*Z*)-6-heneicosen-11-one (Suckling et al., 2002; Muto and Mori, 2003), (*Z,E*)-6,8-heneicosadien-11-one (Jury et al., 2003; Muto and Mori, 2003), (6*Z*,9*R*,10*S*)- and (6*Z*,9*S*,10*R*)-*cis*-9,10-epoxy-heneicosene, as well as (6*Z*,9*R*,10*S*)- and (6*Z*,9*S*,10*R*)-*cis*-9,10-epoxy-eicosene (Muto and Mori, 2003). None of these studies report bioassay data that demonstrate attraction of PAM males to either one or all of these components. Here, we report chemical analyses, and wind tunnel and field experiments, demonstrating that (*Z,Z*)-6,9-heneicosadien-11-one (*Z6Z*9-11-one-21Hy) is the major sex pheromone component of female PAM.

METHODS AND MATERIALS

Experimental Insects. PAM caterpillars were reared on gypsy moth diet (Bell et al., 1981) (photoperiod: 14L:10D; temperature: 24°C; relative humidity:

55–60%) at the USDA Quarantine Facility in Newark, DE, USA, and at Forestry Research, Rotorua, New Zealand. Male and female pupae were sent by courier to Simon Fraser University (SFU), and were kept in SFU's Global Forest Quarantine Facility.

Collection of Pheromones. Abdominal tips with pheromone glands of calling, 2- to 3-d-old females were removed and extracted in HPLC-grade hexane. To obtain effluvia of calling females, 30 females were placed in a Pyrex glass chamber maintained at a photoperiod of 14L:10D and a temperature of 25°C. A water aspirator was used to draw humidified, charcoal-filtered air at 80 ml/min through the chamber and through a glass column (6 × 30 mm) filled with Porapak Q (50–80 mesh, Waters Associated Inc. Milford, MA, USA). To minimize isomerization of volatiles, the Porapak Q trap was kept at 5°C. After 48 hr, absorbed volatiles were desorbed with 2 ml of redistilled pentane.

Analyses of Pheromone and General Instrumentation. Aliquots of 0.1 female equivalent (FE) of pheromone gland extract, or 30 female-hour equivalents (FHE = all volatiles released by 30 PAM females during 1 hr of aeration) of Porapak Q extracts were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD) (Arn et al., 1975) with a Hewlett-Packard (HP) 5890A gas chromatograph (GC) equipped with a column (30 m × 0.25 or 0.32 mm ID) coated with either DB-5, DB-210, or DB-23 (J&W Scientific, Folsom, CA, USA; further details in Gries et al., 2002). High-performance liquid chromatography (HPLC) of pheromone gland extract (100–200 FE) employed a Waters LC 626 chromatograph equipped with a Waters 486 variable wavelength UV/visible detector set to 210 nm, HP Chemstation software (Rev.A.07.01), and a reverse phase Nova-Pak C18 column (60Å, 4 μm; 3.9 × 300 mm) eluted with acetonitrile (1 ml/min).

HPLC fractions of pheromone gland extract containing the candidate chiral pheromone components *cis*-9,10-epoxy-heneicosene and (*Z,Z*)-6,9-heneicosadien-11-ol (as determined by GC-mass spectrometry) were extracted with pentane, concentrated to 2 μl, and analyzed by gas chromatography on a custom-made chiral stationary phase column [1:1 mixture of hepakis-(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin and OV-1701 (König et al., 1992; Pietruszka et al., 1992); splitless injection; temperature of injection port and FID: 240°C; temperature program: 120°C (0 min), then 5°C per min to 160°C]. *cis*-9,10-Epoxy-(*Z*)-6-eicosene, and 6-hydroxy-(*E,E*)-7,9-heneicosadien-11-one (*E7E9*-6-ol-11-one-21Hy) occurred at low quantities in pheromone gland extracts, and no attempts were made to determine their absolute configuration.

GC-MS analyses of pheromone extracts and of synthetic standards employed a Varian Saturn 2000 Ion Trap fitted with the above-referenced DB-5 column.

HPLC-MS analyses were carried out with an Agilent 1100 LC/MSD (G1946D) equipped with a binary pump, autosampler, thermostatted column compartment (set at 10°C), diode array detector (acquiring UV/Visible spectra from

190–600 nm), and an Agilent SB-C18 column (2.1 × 75.0 mm with 3.5 μm packing) fitted with a guard column (2.1 × 12 mm) consisting of XDB-C8 (5 μm particle size). The injection volume was 0.1 μl for both synthetic standards and pheromone extract. The mobile phase consisted of an isocratic solvent system, with 10% of solvent A [H_2O (95%): MeOH (5%)] and 90% of solvent B [MeOH (100%)] at a flow rate of 0.25 ml/min. MSD scan range and time, respectively, were 100–400 amu and 2.82 sec, with the fragmentator at 200 volts. The N_2 nebulizer pressure was 20 psi, and the flow rate of the drying gas 10 l/min at a temperature of 350°C. The capillary voltage was set at 3.5 kV. Samples were processed by atmospheric pressure electrospray (APES), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photo ionization (APPI).

Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on a Varian AS500 spectrometer at 499.77 MHz for ^{1}H NMR and 125.68 MHz for ^{13}C spectra. ^{1}H chemical shifts are reported as parts per million [ppm, relative to TMS (0.00 ppm)]. Infrared (IR) spectroscopy of synthetic compounds was conducted on a Bomem MB Series FTIR spectrometer. Elemental analyses of synthetic chemicals were performed with a Carlo Erba Model 1106 elemental analyzer.

Source of Synthetic Standards. (*Z,Z*)-6,9-Heneicosadiene (*Z6Z9*-21Hy), (9*R*, 10*S*)-*cis*-9,10-epoxy-(*Z*)-6-eicosene (*Z*6-9*R*10*S*-epo-20Hy), (9*S*,10*R*)-*cis*-9,10-epoxy-(*Z*)-6-eicosene (*Z*6-9*S*10*R*-epo-20Hy), (9*R*,10*S*)-*cis*-9,10-epoxy-(*Z*)-6-heneicosene (*Z*6-9*R*10*S*-epo-21Hy), and (9*S*,10*R*)-*cis*-9,10-epoxy-(*Z*)-6-heneicosene (*Z*6-9*S*10*R*-epo-21Hy) were donations from Edward W. Underhill (National Research Council of Canada, Plant Biotechnology Institute, Saskatoon, Sask. Canada). (*Z*)-6-Heneicosen-11-one (*Z*6-11-one-21Hy) was purchased (Bedoukian, Danbury, CT, USA). (*Z,E*)-6,8-Heneicosadien-11-one (*Z6E*8-11-one-21Hy) and (*Z,E*)-6,9-heneicosadien-11-one (*Z6E*9-11-one-21Hy) were available from previous work (Gries et al., 1997). (*Z,Z*)-6,9-Eicosadien-11-one (*Z6Z*9-11-one-20Hy) and (*Z,Z*)-6,9-heneicosadien-11-one (*Z6Z9*-11-one-21Hy) were produced by oxidation of corresponding alcohols available in our laboratory (Gries et al., 2003). Racemic (*Z,Z*)-6,9-heneicosadien-11-ol (*Z6Z*9-11-ol-21Hy), and enantiomers thereof, were available from previous work (Gries et al., 2003).

Syntheses. We describe syntheses and report spectroscopic data for (*E,E*)-7,9-heneicosadien-6,11-dione (*E7E9*-6,11-dione-21Hy) and 6-hydroxy-(*E,E*)-7,9-heneicosadien-11-one (*E7E9*-6-ol-11-one-21Hy), two previously unknown components in pheromone gland extracts of insects. Chemicals obtained from commercial sources were used without further purification unless otherwise indicated. All moisture- and air-sensitive reactions were conducted under argon. Column chromatography refers to flash chromatography using silica gel 60 (230–400 mesh, E. Merck, Darmstadt, Germany) (Still et al., 1978).

*6-Hydroxy-(*E,E*)-7,9-heneicosadien-11-one (7) and (*E,E*)-7,9-Heneicosadien-6,11-dione (8) (Figure 1)*. Silylation of 1-octyne-3-ol (**1**) (Aldrich Chem.

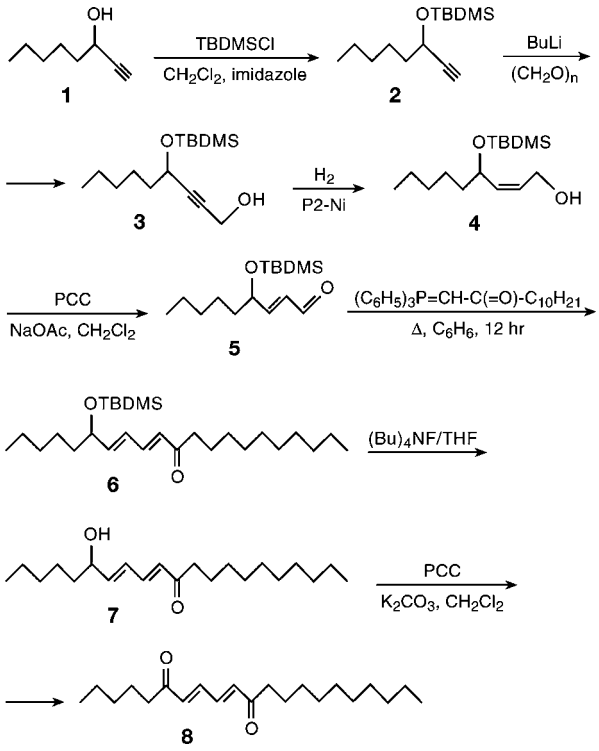

FIG. 1. Scheme for the syntheses of (*E*,*E*)-7,9-heneicosadien-6,11-dione and 6-hydroxy-(*E*,*E*)-7,9-heneicosadien-11-one.

Co) and subsequent formylation of silyl ether **2** (99% yield) gave alcohol **3** (94% yield) (Marshall and Zou, 2000). Hydrogenation of **3** (2.75 g, 0.01 mol) with P2-Nickel catalyst (Brown and Ahuja, 1973) afforded alcohol **4** (2.6 g, 96% yield) of which 50% (1.3 g, 4.7 mmol) was oxidized by pyridinium chlorochromate (PCC) (1.60 g) in dichloromethane in the presence of sodium acetate (0.60 g, 7.3 mmol). The reaction mixture was filtered through silica (15 g) with hexane-ether (19:1) as eluent, and solvents were removed *in vacuo*. Without further purification, crude aldehyde **5** (Hayashi, 1990) was refluxed 12 hr in benzene with the stabilized ylid 1-triphenylphosphoranylidene-2-dodecanone. This ylid was obtained (90% yield) by deprotonation (butyllithium) and alkylation (*n*-nonyl iodide) of 1-triphenylphosphoranylidene-2-propanone (Avocado Research Chem. Ltd., Lancashire, UK) (Taylor and Wolf, 1972; Black et al., 1996). Following reflux, benzene was removed *in vacuo*, and unreacted ylid and triphenylphosphine oxide were removed by filtering the resulting mixture through silica (15 g) with hexane-ether (9:1) as eluent. Without further separation, filtrates containing

silylated keto-alcohol **6** were concentrated and treated with a THF solution of Bu_4NF for 2 hr. The reaction mixture containing the desired keto-alcohol **7** (formation of only one geometric isomer observed) was diluted with water and extracted with ether, the ether layer was washed with water and brine, then dried ($MgSO_4$), concentrated, and purified by flash chromatography (50 g silica) with hexane/ether (3:1) and (1:1) as consecutive eluents. Yield of pure keto-alcohol **7** was 0.30 g (20% based on alcohol **4**, overall yield 17%). M.p. 43°C. Anal. calcd. for $C_{21}H_{38}O_2$ (%): C, 78.28; H, 11.88, found: C, 78.26, H, 12.20. IR (KBr): 3650, 3630, 2955, 2918, 2850, 1686, 1605, 1088, 996 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 0.90–0.98 (m, 6H), 1.21–1.35 (m, 20H), 1.54–1.64 (m, 4H), 2.55 (t, 2H, $J = 7.6$ Hz), 4.25 (1H, m), 6.13-6.23 (m, 2H), 6.37 (dd, 1H, $J = 15.0$, 11.0 Hz), 7.15 (dd, 1H, $J = 15.5$, 11.0 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.01, 14.11, 22.56, 22.67, 24.35, 24.94, 29.31 (2), 29.43, 29.48, 29.56, 31.68, 31.88, 37.05, 40.74, 72.09, 127.89, 129.81, 141.49, 145.62, 200.95.

Oxidation of **7** (0.15 g, 0.47 mmol) with PCC (0.15 g, 0.70 mmol) in the presence of potassium carbonate (0.050 g, 0.036 mmol) for 2 hr in dry CH_2Cl_2 afforded diketone **8** (0.14 g, 93% yield based on keto-alcohol **7**). M.p. 76°C. Anal. calcd. for $C_{21}H_{36}O_2$ (%): C, 78.70; H, 11.32, found: C, 79.08, H, 11.12. IR (KBr): 3650, 2955, 2916, 2850, 1678, 1587, 1407, 1216, 1096, 1010 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 0.86-0.92 (m, 6H), 1.28–1.36 (m, 18H), 1.59–1.67 (m, 4H), 2.60 (t, 4H, $J = 7.5$ Hz), 6.49 (dd, 2H, $J = 11.5$, 2.8 Hz), 7.18 (dd, 2H, $J = 11.7$, 2.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 13.91, 14.11, 22.45, 22.67, 23.72, 24.04, 29.22, 29.30, 29.40, 29.46, 29.55, 31.38, 31.88, 41.31, 41.35, 135.96, 135.97, 138.79, 138.80, 200.10, 200.11.

Wind Tunnel and Field Experiments. Wind tunnel experiments employed a wind tunnel (160 cm long, 68 cm wide, 70 cm tall) and protocol as developed by Miller and Roelofs (1978). The air speed was 30 cm/sec, and the temperature was 22°C (±2°C). Experiments bioassayed the responses of individually tested 1- to 3-d-old males to filter paper (Whatman International Ltd., Maidstone, England) impregnated with test chemicals in HPLC-grade hexane or acetonitrile. All test chemicals were >95% chemically pure. Six criteria (Table 1) were used to assess the attractiveness of lures. Experiment 1 tested *Z*6*Z*9-11-one-21Hy singly and in combination with either *Z*6-9*R*10*S*-epo-21Hy (a), *E*7*E*9-6,11-dione-21Hy plus *E*7*E*9-6-ol-11-one-21Hy (b), or (a) plus (b). Experiment 2 tested *Z*6*Z*9-11-one-21Hy singly and in binary, ternary, and quaternary combinations with *Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy (Table 1).

Field experiments were conducted in Campbelltown, N.S.W., Australia, in the residential area of Wedderburn (S 34 deg. 09 min., E 150 deg. 49 min) generally in forest types classified as "dry schlerophyll" (Sydney, Hawkesbury sandstone). The area was dominated by trees of *Eucalyptus* spp. with some *Acacia* spp., and stocked with numerous shrubs in formerly disturbed or open field habitats. Delta-type traps made from 2-l milk cartons (Gray et al., 1984) were coated with

[a]Compound abbreviations as follows: *Z*6*Z*9-11-one = (*Z*,*Z*)-6,9-heneicosadien-11-one (57 ng = 1 female equivalent of pheromone gland extract); *Z*6-9*R*10*S*-epo = (*Z*6,9*R*,10*S*)-*cis*-9,10-epoxy-heneicosene (7 ng); *E*7*E*9-6,11-dione = (*E*,*E*)-7,9-heneicosadien-6,11-dione (3.5 ng); *E*7*E*9-6-ol-11-one = 6-hydroxy-(*E*,*E*)-7,9-heneicosadien-11-one.

[b]A = Activation; F = flight; O = 4 orientation towards pheromone lure; H = halfway flight toward lure; Ap = approaching lure; L = landing on lure.

Tanglefoot (The Tanglefoot Company, Grand Rapids, MI, USA) and suspended from trees at a height of 2 m and spacings of 20–25 m in complete randomized blocks, which were separated by 0.1 to 3 km. Traps were baited with a piece of dental cotton roll (10 × 15 mm) (Richmond Dental, Charlotte, NC, USA), which was impregnated with test chemicals just prior (0–2 hr) to the onset (~10:00 am) of experiments. To prevent rearrangement of (labile) test chemicals during storage, they were placed in vials, diluted in solvent (hexane, pentane/ether, or acetonitrile), kept on dry ice, and allowed to warm up to ambient temperature only during the 15–30-min preparation of test lures.

Field experiment 1 tested the major candidate pheromone component *Z*6*Z*9-11-one-21Hy (5 μg) singly and in quaternary combination with secondary candidate pheromone components *Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy at ratios of 5:5:5:5 or 5:0.5:0.5:0.5. Taking into account that the 4-component blend (5: 0.5: 0.5: 0.5) appeared most attractive, experiment 2 tested *Z*6*Z*9-11-one-21Hy (5 μg) singly and in combination with either one or all three of *Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy at 10:1 ratios. Considering that *Z*6-9*R*10*S*-epo-21Hy appeared to enhance attractiveness of *Z*6*Z*9-11-one-21Hy in experiment 2, experiments 3 and 4 explored whether attractiveness of this 2-component blend could be enhanced by additional components. Experiment 3 tested *Z*6*Z*9-11-one-21Hy (5 μg) plus *Z*6-9*R*10*S*-epo-21Hy (0.5 μg) in combination with either *E*7*E*9-6,11-dione-21Hy (0.5 μg), *E*7*E*9-6-ol-11-one-21Hy (0.5 μg), or both, whereas experiment 4 tested *Z*6*Z*9-11-one-21Hy (5 μg) plus *Z*6-9*R*10*S*-epo-21Hy (0.5 μg) in combination with either *Z*6*Z*9-11-one-20Hy (0.5 μg), *Z*6-11-one-21Hy (0.5 μg), *Z*6*E*8-11-one-21Hy (0.5 μg), *Z*6*E*9-11-one-21Hy (0.5 μg), *Z*6*Z*9-11-ol-21Hy (0.5 μg) or *Z*6-9*R*10*S*-epo-20Hy (0.5 μg). Experiment 5 tested 3 components singly: *Z*6*Z*9-11-one (5 or 0.5 μg), the corresponding rearrangement product *Z*6*E*8-11-one-21Hy (5 μg), and *Z*6-9*R*10*S*-epo-21Hy (5 μg). In all experiments, lures were replaced after two days without re-randomizing treatment positions.

Trap catch data were analyzed by nonparametric analysis of variance (Friedman's test) followed by comparison of means by Scheffé test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS

Chemical Analyses. GC-EAD analyses of PAM pheromone gland extract revealed many components that consistently elicited antennal responses from male PAM antennae (Figure 2). By comparing mass spectra and retention indices (Van den Dool and Kratz, 1963) of PAM-produced compounds with those of our reference library of moth pheromones (RG & GG, unpublished), and by comparative GC, GC-MS, and GC-EAD analyses of PAM-produced components and authentic standards on three GC columns (DB-5, DB-23, DB-210), we determined

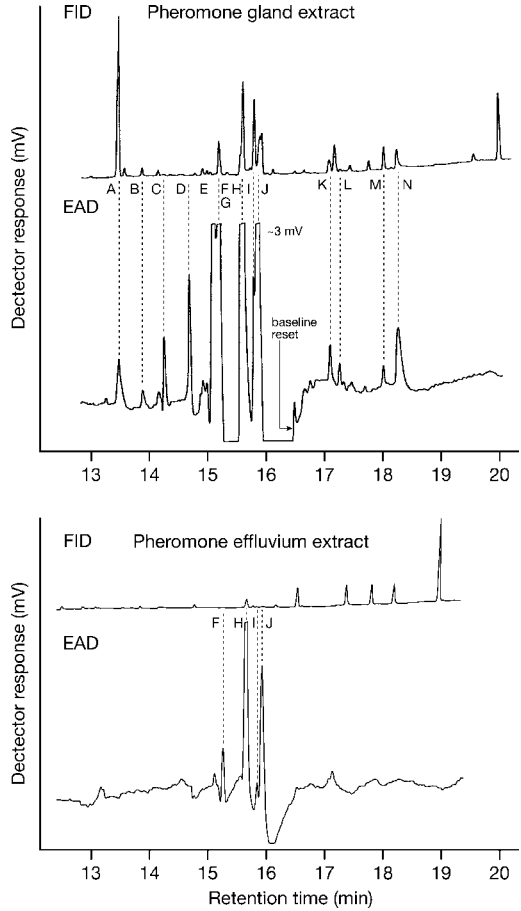

FIG. 2. Flame ionization detector (FID) and electroantennographic detector (EAD: male *Teia anartoides* antenna) responses to 0.1 female equivalent (FE) of pheromone gland extract of female *T. anartoides* (*top*), or to 30 female-hour equivalents (FHE = all volatiles released by 30 females during 1 hr of aeration) of Porapak Q extract (*bottom*). Chromatography: DB-5 column; splitless injection; temperature program: 100°C/1 min, 10°C per min to 280°C. **A** = (*Z*,*Z*)-6,9-heneicosadiene (Z6Z9-21Hy); **B** = heneicosatriene (with unknown double bond positions); **C** = (Z6)-*cis*-9,10-epoxy-eicosene (Z6-9,10-epo-20Hy); **D** = (*Z*,*Z*)-6,9-eicosadiene-11-one (Z6Z9-11-one-20Hy); **E** = (*Z*,*Z*)-6,9-heneicosadien-11-ol (Z6Z9-11-ol-21Hy); **F** = (Z6)-*cis*-9,10-epoxy-heneicosene (Z6-9,10-epo-21Hy); **G** = (*Z*)-6-heneicosen-11-one (*Z*6-11-one-21Hy); **H** = (*Z*,*E*)-6,8-heneicosadien-11-one (Z6E8-11-one-21Hy); **I** = (*Z*,*E*)-6,9-heneicosadien-11-one (*Z*6*E*9-11-one-21Hy); **J** = (*Z*,*Z*)-6,9-heneicosadien-11-one (*Z*6*Z*6-11-one-21Hy); **K** and **L** = unknown rearrangement products of *Z*6*Z*9-11-one-21Hy; **M** = (*E*,*E*)-7,9-heneicosadien-6,11-dione (*E*7*E*9-6,11-dione-21Hy); **N** = 6-hydroxy-(*E*,*E*)-7,9-heneicosadien-11-one (*E*7*E*9-6-ol-11-one-21Hy).

that components **A-J** were Z6Z9-21Hy (**A**), a heneicosatriene with undetermined double bonds (**B**), *Z*6-9,10-epo-20Hy (**C**), *Z6Z*9-11-one-20Hy (**D**), *Z6Z*9-11-ol-21Hy (**E**), *Z*6-9,10-epo-21Hy (**F**), *Z*6-11-one-21Hy (**G**), *Z6E*8-11-one-21Hy (**H**), *Z6E*9-11-one-21Hy (**I**), and *Z6Z*9-11-one-21Hy (**J**). Although labile *Z6Z*9-11-one-21Hy rearranges to *Z6E*8-11-one-21Hy during GC analyses (Gries et al., 1997; Wimalaratne, 1998), trace amounts of *Z6Z*9-11-one-21Hy remained detectable by PAM antennae (Figure 2), suggesting that pheromone extracts may contain larger quantities of this labile ketodiene than are evident from Figure 2.

To determine unequivocally the presence and ratio of the three ketodienes (*Z6Z*9-11-one-21Hy, *Z6E*8-11-one-21Hy, *Z6E*9-11-one-21Hy) in pheromone gland extracts, extracts were analyzed by HPLC-MS, a procedure that minimized isomerization of labile ketodienes. Comparative HPLC-MS analyses of synthetic *Z6Z*9-11-one-21Hy and of PAM pheromone extract revealed that the most abundant (~57 ng per FE) candidate pheromone component in PAM pheromone extracts eluted at the same time as synthetic *Z6Z*9-11-one-21Hy (Figure 3). Identical HPLC retention times (Figure 3), mass spectra (Figure 3), and UV spectra (Figure 4) of this component and of synthetic *Z6Z*9-11-one-21Hy confirmed that *Z6Z*9-11-one-21Hy was present in relatively large quantities in PAM pheromone extracts. *Z6E*8-11-one-21Hy and *Z6E*9-11-one-21Hy were also present but at lower quantities (Figure 3).

The absolute configurations of candidate pheromone components *Z6Z*9-11-ol-21Hy (**E** in Figure 2) and *Z*6-9,10-epo-21Hy (**F** in Figure 2) were determined by HPLC fractionation of PAM extract (20 FE), followed by GC analyses of concentrated (2 μl) HPLC fractions and authentic standards on a chiral stationary phase GC column. These analyses revealed that PAM females produce both enantiomers (1:1) of *Z6Z*9-11-ol-21Hy (data not shown), and the (9*R*,10*S*)-enantiomer of *Z*6-9,10-epo-21Hy (Figure 5).

Mass spectra and molecular weights of late-eluting components **M** and **N** (Figure 6) suggested that they were heneicosadienes with two oxygens. Considering that PAM females produce epoxides and ketones (Figure 2), we hypothesized that compound **M** (MW = 320) was an epoxy-ketone or diketone, and compound **N** (MW = 322) an epoxy- or keto-alcohol. Chromatographic "tailing" of **N** (Figure 2) suggested the presence of a hydroxy-group in **N**. Hydrogenation of the **M**- and **N**-containing HPLC fraction, and GC-MS analyses of the hydrogenation products, produced a new mass spectrum with fragmentation ion *m/z* 169 indicative of a carbonyl group on C11. To test the hypothesis that **M** and **N** were biosynthetically related to *Z6Z*9-11-one-21Hy or *Z6E*8-11-one-21Hy, and to confirm the presence of a second oxygen in **M** and **N**, we epoxidized and hydrogenated synthetic *Z6E*8-11-one-21Hy. One of the resulting compounds had the same retention time and mass spectral characteristics as the **M** hydrogenation product. Bearing in mind that epoxidation and hydrogenation of *Z6E*8-11-one-21Hy could afford both epoxy-ketones and diketone by-products (Malinovskii, 1965), we further hypothesized

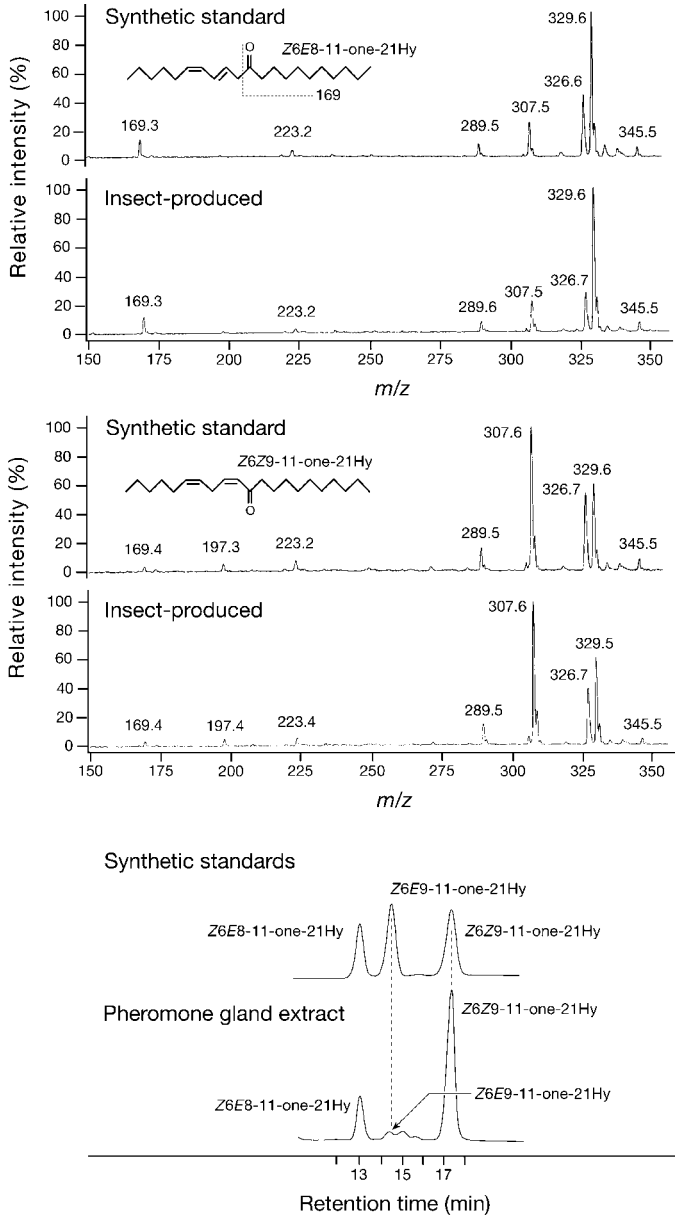

FIG. 3. (*Top*). High-performance liquid chromatography atmospheric pressure electrospray (APES) mass spectra (200 volts) of synthetic and insect-produced (*Z*,*E*)-6,8-heneicosadien-11-one (*Z*6*E*8-11-one-21Hy; ~10 ng/μl), and of (*Z*,*Z*)-6,9-heneicosadien-11-one (*Z*6*Z*9-11-one-21Hy; ~10 ng/μl); (*Bottom*) HPLC chromatograms of synthetic standards and pheromone gland extract of female *T. anartoides*.

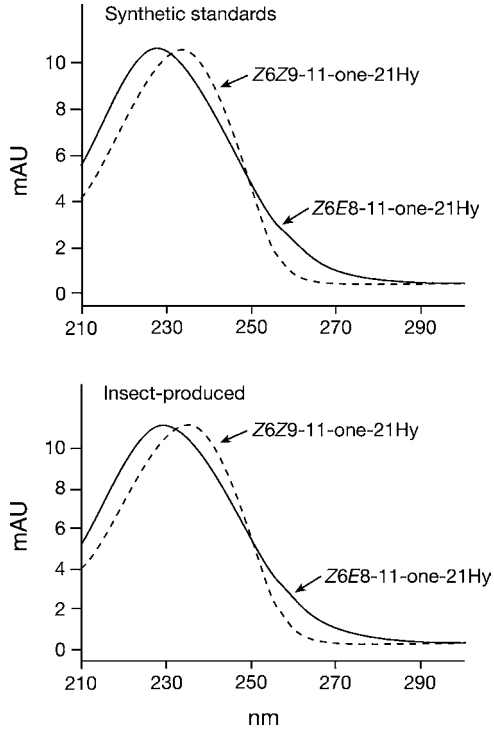

FIG. 4. UV/Visible spectra of synthetic and insect-produced (*Z*,*E*)-6,8-heneicosadien-11-one (*Z*6*E*8-11-one-21Hy) and (*Z*,*Z*)-6,9-heneicosadien-11-one (*Z*6*Z*9-11-one-21Hy). Injection volume on HPLC: 0.5 μl with ~5 ng per compound on column. Note contrasting absorption characteristics and peak maxima (234 nm and 228 nm) for *Z*6*E*8-11-one-21Hy and Z6Z9-11-one-21Hy.

that the second oxygenated group in **M** was either a *cis*-6,7- or *trans*-8,9-epoxide, or, a ketone at C6, C7, C8, or C9. Heneicosan-6,11-dione as our first synthetic candidate had the same mass spectrum and retention times on three columns as the **M** hydrogenation product. In assigning the double bond positions to the target heneicosadien-6,11-dione (**M** in Figure 2), we considered (a) known double bond positions (*Z*6, *E*8, *Z*9, *E*9) in ketodienes from *Orgyia* spp. (Gries et al., 1997; Lui, 1999; Grant et al., 2003), and (b) the large retention indices of **M** (DB-5: 2586, DB-210: 3275) that were indicative of extensive conjugation. (*E*,*E*)-7,9-Heneicosadien-6,11-dione was synthesized as the thermodynamically most stable target and was shown to have the same mass spectral (Figure 6) and retention characteristics as **M** in Figure 2. Moreover, the corresponding 6-hydroxy-(*E*,*E*)-7,9-heneicosadien-11-one met all identification criteria of component **N** in Figure 2.

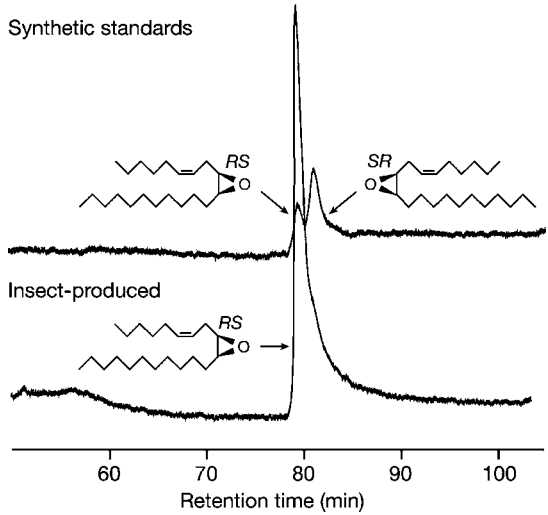

FIG. 5. Chromatogram of a mixture of synthetic enantiomers of (*Z*)-6-*cis*-9,10-epoxy-heneicosene (*top*) and of insect-produced (*Z*6,9*R*,10*S*)-*cis*-9,10-epoxy-heneicosene (50 female equivalents) (*bottom*) on a chiral stationary phase GC column.

Its mass spectrum is shown in Figure 6. Identifications of **K** and **L** were not attempted because both compounds were rearrangement products of *Z*6*Z*9-11-one-21Hy, suggesting that they are not likely part of the PAM pheromone.

GC-EAD analyses of effluvia of calling PAM females (Figure 2) revealed significant antennal responses to *Z*6-9,10-epo-21Hy, *Z*6*Z*9-11-one-21Hy, and *Z*6*E*8-11-one-21Hy (which forms from *Z*6*Z*9-11-one-21Hy during GC analyses), suggesting that the actual pheromone blend might be much simpler than suggested by the pheromone gland extracts.

Behavioral Bioassays. In preliminary wind tunnel bioassay experiments, attraction of male moths to *Z*6*Z*9-11-one-21Hy (the major candidate pheromone component) appeared enhanced by specific HPLC fractions of pheromone gland extracts, or corresponding synthetic candidate pheromone components. Besides *Z*6*Z*9-11-one-21Hy, three components (*Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy) seemed to affect the males' responses and were bioassayed as blends in experiments 1 and 2 (Table 1). When all three of these components were added to *Z*6*Z*9-11-one-21Hy, more PAM males appeared to orient towards the lure, flew midway through the wind tunnel, approached, and contacted the lure (Table 1).

In field trapping experiment 1 in Australia, *Z*6*Z*9-11-one-21Hy as a single component attracted PAM males. Moreover, experiment 1 suggested that the

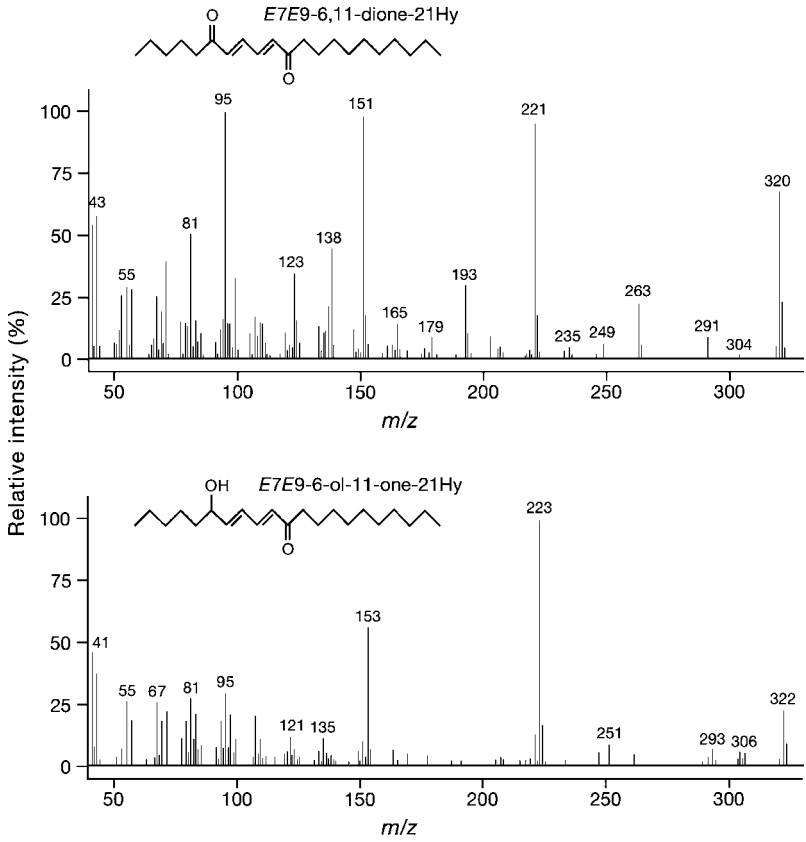

FIG. 6. Ion trap mass spectra of (*E*,*E*)-7,9-heneicadien-6,11-dione (*E*7*E*9-6,11-dione-21Hy) and 6-hydroxy-(*E*,*E*)-7,9-heneicosen-11-one (*E*7*E*9-6-ol-11-one-21Hy) identified in pheromone gland extracts of female *Teia anartoides*. Synthetic standards gave the same spectra.

4-component blend of *Z*6*Z*9-11-one-21Hy, *Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy at a 5:0.5:0.5:0.5 ratio might attract more PAM males than *Z*6*Z*9-11-one-21Hy alone. The 4-component blend at a 5:5:5:5 ratio was not attractive (Figure 7). However, experiments 2–4 failed to demonstrate conclusively whether any of the minor components, singly or in combinations, increased the attractiveness of blends relative to *Z*6,*Z*9-11-one-21Hy alone (Figures 7 and 8). In experiment 5, traps baited with *Z*6*Z*9-11-one-21Hy at 5 μg were more attractive than unbaited control traps, whereas *Z*6 *E*8-11-one-21Hy and *Z*6-9*R*10*S*-epo-21Hy (5 μg each) were not different from controls (data not shown).

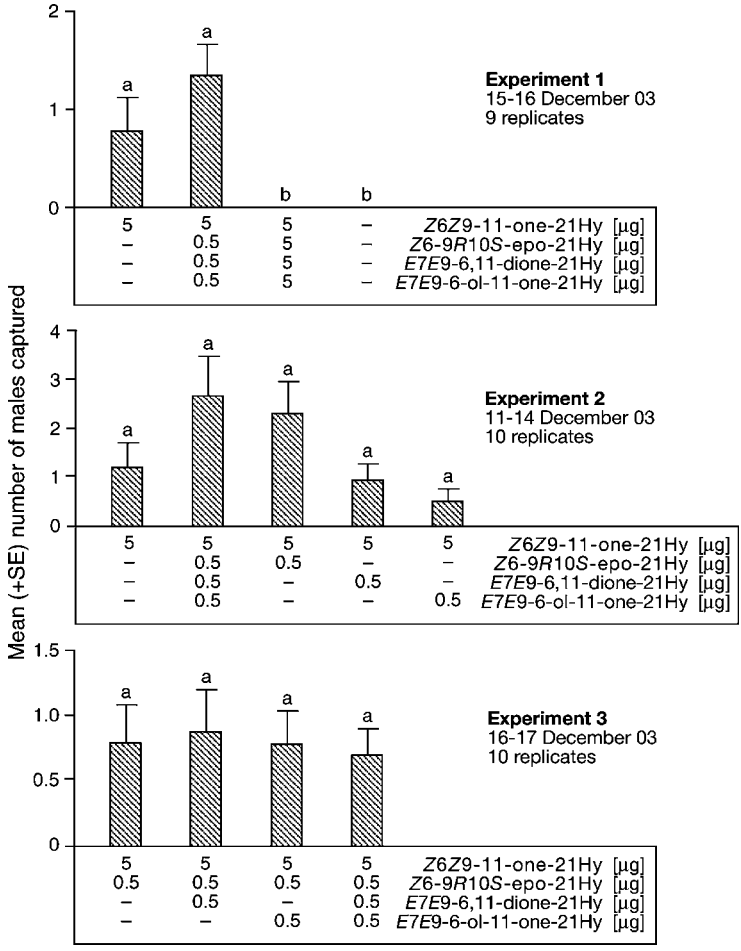

FIG. 7. Captures of male *Teia anartoides* in field experiments 1–3 in sticky traps baited with candidate pheromone components singly and in combinations; all experiments near Campbelltown, N.S.W., Australia. In each experiment, bars with the same letter superscript are not significantly different; $\alpha = 0.05$. Compound abbreviations as in Figure 2.

DISCUSSION

*Z*6*Z*9-11-one-21Hy appears to be the major sex pheromone component of PAM, on the basis of (1) analyses of pheromone gland extracts of PAM females by GC-EAD, GC-MS, HPLC-MS, and HPLC-UV/Visible spectroscopy; (2) GC-EAD analyses of effluvia of PAM females; and (3) wind tunnel and field experiments

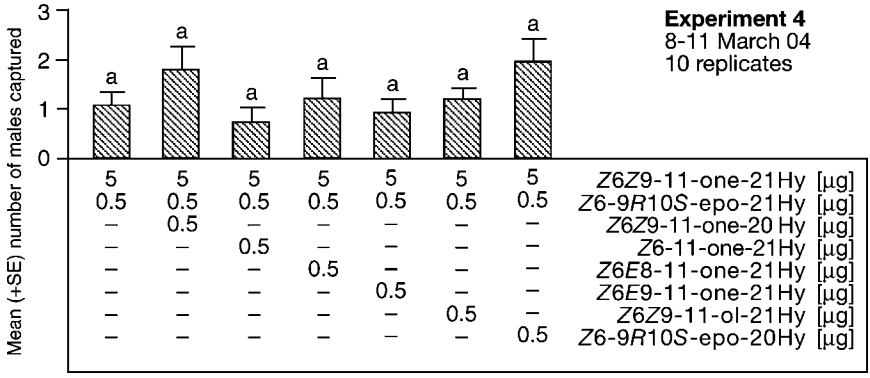

FIG. 8. Captures of male *Teia anartoides* in field experiments 4 in sticky traps baited with candidate pheromone components in various combinations; all experiments near Campbelltown, N.S.W., Australia. Bars with the same letter superscript are significantly different; $\alpha = 0.05$. Compound abbreviations as in Figure 2.

with a synthetic standard. The same compound has been reported as the major sex pheromone component of whitemarked tussock moth, *Orgyia leucostigma* (Liu, 1999; Grant et al., 2003). Whether *Z6E*8-11-one-21Hy is a (secondary) pheromone component of PAM females (Jury et al., 2003) is not easily determined because lures loaded with *Z6Z*9-11-one-21Hy as a single component will, almost immediately, also release the rearrangement product *Z6E*8-11-one-21Hy, thus complicating comparison of such lures with those baited from the beginning with both *Z6Z*9-11-one-21Hy and *Z6E*8-11-one-21Hy.

HPLC-MS was crucial in confirming the presence and ratio of Z6Z9-11-one-21Hy, *Z6E*8-11-one-21Hy, and *Z6E*9-11-one-21Hy in pheromone gland extracts. Aqueous methanol (90% MeOH) provided optimal reverse phase chromatographic separation between *Z6E*8-11-one-21Hy and *Z6Z*9-11-one-21Hy, with retention times reproducible within 0.1 min between runs. Among atmospheric pressure electrospray (APES), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photo ionization (APPI), APES provided the greatest sensitivity and most readily interpretable mass spectra. No APES mass spectra were obtained with acetonitrile as the solvent system. Changes in nebulizer gas temperature from 200°C to 350°C reduced sensitivity but did not result in changes to the mass spectra. A 150-volt fragmentation voltage revealed the major ions 307.5 amu $(MH)^+$ and 329.5 amu $(MNa)^+$ for both compounds, but at 200 volts (Figure 3) the fragmentation ion 169.3 amu and adduct ion 326.5 amu were particularly visible. The fragment ion m/z 169.3 is also observed in corresponding GC-MS analyses (data not shown).

In wind tunnel experiments (Table 1), the 4-component blend of Z6Z9-11-one-21Hy, *Z*6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy appeared more attractive to males than Z6Z9-11-one-21Hy as a single component. However, the biological activity of the former three components was not confirmed in field experiments, possibly as a result of inappropriate blend ratios, release rates, or trap designs. It remains to be determined whether or not Z6-9*R*10*S*-epo-21Hy, *E*7*E*9-6,11-dione-21Hy, and *E*7*E*9-6-ol-11-one-21Hy are indeed PAM sex pheromone components. The epoxide *Z*6-9*R*10*S*-epo-21Hy is the most likely candidate for a secondary pheromone component because it was present in the effluvia of calling females (Figure 2), and appeared to enhance attractiveness of *Z*6*Z*9-11-one-21Hy in field experiment 2 (Figure 7).

Attractiveness of synthetic pheromone lures and of virgin PAM females also will have to be compared in field trials to determine whether synthetic lures could replace PAM females as a trap bait in the program to monitor eradication of PAM in New Zealand.

Acknowledgments—We thank Dave Britton for arrangements and logistics that facilitated field trapping experiments; Dave and Letitia Silberbauer and Penny Truscott for generously hosting JC and PWS in their home and for allowing moth trapping on their property; Susan Barth and Bill Faulds for preparing insect diet and rearing of experimental insects; Nod Kay and John Bain for provision of quarantine space for wind tunnel assembly; Alan and Marcy Tracey for assistance in NMR analysis and interpretation; Wittko Francke for lending a custom-made chiral column; E. W. Underhill for donations of test chemicals; Elizabeth Carefoot and Robert Birtch for graphical illustrations; and Derek Vance Steel for word processing. The research was supported, in part, by grants from Global Forest (GF-18-2000-95 and GF-18-2000-96), and the Natural Sciences and Engineering Research Council of Canada to GG. At SFU, experimental insects were maintained in the Global Forest Quarantine Facility construction of which was completed through financial support from Global Forest (GF-18-2000-SFU-4).

Abstract—The sex pheromone of the painted apple moth, *Teia anartoides* (Lymantriidae) was investigated using GC-EAD and GC-MS analysis, derivatization, TLC analysis, and field cage and field trapping bioassays. The major sex pheromone components were identified as (6*Z*,9*Z*)-henicosa-6,9-dien-11-one and (6*Z*,9*Z*)-henicosa-6,9-diene. Other minor components of pheromone gland extracts included (6*Z*)-9*R*,10*S*-epoxyeicos-6-ene, (6*Z*)-9*R*,10*S*-epoxyhenicos-6-ene, (6*Z*,9*Z*)-henicosa-6,9-dien-11-ol, (6*Z*)-henicos-6-en-11-one, and (6*Z*,8*E*)-henicosa-6,8-dien-11-one, but the roles of these minor components remain equivocal. In field cage and field experiments, a blend of all seven identified components [(6*Z*,9*Z*)-henicosa-6,9-dien-11-one (relative amount 100), (6*Z*,9*Z*)-henicosa-6,9-diene (100), (6*Z*)-9*R*,10*S*-epoxyeicos-6-ene (5), (6*Z*)-9*R*,10*S*-epoxyhenicos-6-ene (10), (6*Z*,9*Z*)-henicosa-6,9-dien-11-ol (5), (6*Z*)-henicos-6-en-11-one (1), and (6*Z*,8*E*)-henicosa-6,8-dien-11-one (25)] was as attractive to males as calling females, but tests with blends of the major component(s) with subsets of the minor components did not produce consistent results that unequivocally showed the various minor components to be critical

components of the active blend. (6*Z*,9*Z*)-henicosa-6,9-dien-11-one is thermally labile and rearranges to (6*Z*,8*E*)-henicosa-6,8-dien-11-one and other products at ambient temperature, rendering the synthetic pheromone lure inactive after two days of field exposure.

Key Words—Pheromone, tussock moth, Lymantriidae, *Teia anartoides*, (6*Z*, 9*Z*)-henicosa-6,9-dien-11-one, (6*Z*,8*E*)-henicosa-6,8-dien-11-one, (6*Z*)-9*R*, 10*S*-epoxyhenicos-6-ene, (6*Z*)-9*R*,10*S*-epoxyeicos-6-ene, (6*Z*,9*Z*)-henicosa-6,9-diene, (6*Z*)-henicos-6-en-11-one, painted apple moth.

INTRODUCTION

The painted apple moth, *Teia anartoides* (Walker) is a native Australian moth that was accidentally introduced into New Zealand in 1999. It was first discovered in Glendene, west Auckland, and then spread to neighboring suburbs. This insect is a minor pest in Australia but has potential for significant economic and ecological damage to New Zealand horticulture and forestry because of its wide host range. Female painted apple moths are wingless, and the ballooning larvae are the main mechanism of dispersal in this species. On discovery of this pest, the New Zealand Ministry of Agriculture and Forestry initiated an eradication program using live female moths to monitor the distribution and dispersal of the moth.

The tussock moths (family Lymantriidae) are represented in Australia by about 70 species in 16 genera and are mainly distributed in the north and east of the continent (Common, 1990). In the Lymantriidae, sex pheromones have been identified for nearly 20 species belonging to six genera (El-Sayed, 2004), representing less than 1% of the 2,500 species in this family. The identified sex pheromones are polyene-derived compounds, mostly epoxides, ketones, and diene or triene hydrocarbons, which are different from the alkenyl acetates, alcohols, and aldehydes found more commonly in other lepidopteran families (El-Sayed, 2004). No sex pheromones have been identified previously for any Australian lymantriids, despite the abundance of this group in the Australian fauna.

The objectives of the work described here were to identify and characterize the sex pheromone of the painted apple moth, *T. anartoides*, and to develop a synthetic pheromone blend to monitor its spread in New Zealand.

METHODS AND MATERIALS

Insects. A colony was established at Mt. Albert Research Center (Auckland) using insects collected from west Auckland. After pupation, the sexes were separated and maintained at 25°C under a 16:8 L:D photoperiod. Pupae required for the field cage experiments were transported to Lincoln Research Center in 9 × 2.5 cm Petri dishes and maintained in quarantine. Pupae and adults were held

under ambient temperature and natural light. All male pupae were sterilized by exposure to 100 Gy using 1.25 MeV gamma rays from a Cobalt^{60} source (Suckling et al., 2002). In the field trial conducted in Auckland, males were marked by allowing adults to emerge in Petri dishes containing fluorescent dyes (DayGlo Corp., Cleveland, OH, USA).

Pheromone Gland Extraction. The sex pheromone glands of 1–2-d-old calling females were removed between 9:00–15:00 hr (diurnal species) and extracted in ca. 10 μl of hexane for 5–10 min. For the preparation of gland extracts used in the field cage experiments, up to 100 sex pheromone glands were removed and extracted in ca. 300 μl of hexane for 10–20 min. Approximately 60 μl of this solution, equivalent to ca. 20 females, were dispensed on each substrate used in the test. Chemical analysis of gland extracts was performed using GC-EAD or GC-MS as described below.

Reduction of Female Extracts. Sex pheromone gland extracts were prepared from the glands of 100 females extracted for 10 min at ambient temperature. The hexane was decanted from the glands and concentrated under a stream of argon. The residue was redissolved in 500 μl of 96% ethanol, and $NaBH_4$ (4 mg, 0.10 mmol) was added. The reaction mixture was shaken for 5 min, and the solids were then removed by filtration through a glass wool plug. The reduced extracts were analyzed by GC-MS.

Chemicals. Chemicals used as authentic standards in chromatographic analyses or in the field experiments were either purchased, obtained as gifts, or synthesized locally. All compounds were >97% pure by GC and were stored at −80°C until used. (6*Z*)-henicos-6-en-11-one (*Z*6-11-one-21Hy) was purchased from Bedoukian Research, Inc. Danbury, CT USA. (6*Z*,9*Z*)-henicosa-6,9-diene (*Z*6,*Z*9-21Hy) was prepared according to Ando et al. (1995) and Jain et al. (1983). ^{1}H NMR ($CDCl_3$, 400 MHz) 5.36 (4H, m), 2.78 (2H, t, $J = 6.4$ Hz), 2.05 (4H,m), 1.4–1.2 (24H, br, m), 0.89 (3H, t, $J = 7.4$ Hz), 0.88 (3H, t, $J = 7.5$ Hz) ppm. ^{13}C NMR ($CDCl_3$, 100 MHz) 130.2, 127.9, 32.0, 31.5, 29.7, 29.7, 29.6, 29.4, 29.4, 29.4, 29.4, 29.3, 27.4, 27.3, 25.6, 22.7, 22.6, 14.2, 14.1 ppm.

Epoxides. (6*Z*)-9*R*,10*S*-epoxyeicos-6-ene (*Z*6-9*R*,10*S*-epo-20Hy), (6*Z*)-9*S*,10*R*-epoxyeicos-6-ene (*Z*6-9*S*,10*R*-epo-20Hy), (6*Z*)-9*R*,10*S*-epoxyhenicos-6-ene (*Z*6-9*R*,10*S*-epo-21Hy), and (6*Z*)-9*S*,10*R*-epoxyhenicos-6-ene (*Z*6-9*S*,10*R*-epo-21Hy) were synthesized according to the methods of Zhang et al. (1999) and Soulie and Lallemand (1995). A sample of *Z*6-9*R*,10*S*-epo-21Hy was provided as a gift from J. G. Millar (University of California, Riverside, CA, USA). *Z*6-9*R*,10*S*-epo-20Hy and *Z*6-9*S*,10*R*-epo-20Hy, ^{1}H NMR ($CDCl_3$, 400 MHz) 5.5–5.3 (2H, m), 2.9–2.8 (2H, m), 2.4–2.3 (1H, m), 2.3–2.2 (1H, m), 2.0–1.9 (2H, m), 1.5–1.3 (24H, br, m), 0.86 (3H, t, $J = 6.7$ Hz), 0.85 (3H, t, $J = 6.6$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 132.7, 123.8, 57.2, 56.5, 31.9, 31.5, 31.5, 31.5, 29.6, 29.3, 29.2, 27.8, 27.4, 26.6, 26.2, 22.7, 22.6, 22.5, 14.1, 14.0 ppm. *Z*6-9*R*,10*S*-epo-21Hy and *Z*6-9*S*,10*R*-epo-21Hy, ^{1}H NMR ($CDCl_3$, 400 MHz) 5.5–5.3

(2H, m), 2.9–2.8 (2H, m), 2.4–2.3 (1H, m), 2.2–2.1 (1H, m), 2.0–1.9 (2H, m), 1.4–1.1 (26H, m), 0.86 (3H, t, $J = 6.5$ Hz), 0.85 (3H, t, $J = 6.8$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 132.7, 123.8, 57.2, 56.6, 31.9, 31.5, 29.6, 29.6, 29.6, 29.6, 29.6, 29.3, 29.2, 27.8, 27.4, 26.6, 26.2, 22.7, 22.5, 14.1, 14.0 ppm. All epoxide enantiomers were estimated to be >93% enantiomerically pure (>86% e.e.)

Isomers of 6,8-Diene Ketones. All four isomers of 6,8-diene ketone, (6*Z*, 8*E*)-henicosa-6,8-dien-11-one (*Z*6,*E*8-11-one-21Hy), (6*E*,8*Z*)-henicosa-6,8-dien-11-one (*E*6,*Z*8-11-one-21Hy), (6*Z*,8*Z*)-henicosa-6,8-dien-11-one (*Z*6,*Z*8-11-one-21Hy), and (6*E*,8*E*)-henicosa-6,8-dien-11-one (*E*6,*E*8-11-one-21Hy)-were synthesized according to Comeskey et al. (2004), Muto and Mori (2003), and Jury et al. (2003). *Z*6,*E*8-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 6.38 (1H, ddq, $J = 15.2, 11.2, 1.2$ Hz), 5.98 (1H, dd, $J = 11.2, 11.2$ Hz), 5.73 (1H, dt, $J = 15.2, 7.4$ Hz), 5.40 (1H, dt, $J = 11.2, 7.7$ Hz), 3.20 (2H, d, $J = 7.4$ Hz), 2.43 (2H, t, $J = 7.5$ Hz), 2.18–2.12 (2H, m), 1.64–1.10 (22H, br, m,), 0.90–0.86 (6H, m, H1 and H21). ^{13}C NMR ($CDCl_3$) 209.2, 132.2, 129.4, 127.8, 125.0, 46.9, 42.4, 31.8, 31.4, 29.7, 29.5, 29.5, 29.4, 29.3, 29.3, 29.2, 23.7, 22.7, 22.5, 14.1, 14.0 ppm; MS: *m*/*z* (rel. int. %) 306 (M^+, 6), 221 (4), 170 (9), 169 (100), 109 (10), 95 (32), 85 (46), 81 (20), 71 (44), 67 (30), 57 (69), 43 (65). E6,*E*8-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 6.10-5.99 (2H, m), 5.74–5.59 (2H, m), 3.15 (2H, d, $J = 7.2$) 2.42 (2H, t, $J = 7.4$ Hz), 2.06 (2H, m), 1.70–1.60 (2H, m), 1.40–1.20 (20H, m), 0.89 (3H, t, $J = 6.6$ Hz), 0.88 (3H, t, $J = 6.7$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 209.3, 134.7, 134.2, 129.6, 122.8, 46.7, 42.3, 32.5, 31.9, 31.4, 29.5, 29.4, 29.4, 29.3, 29.2, 28.9, 23.7, 22.6, 22.5, 14.1, 14.0 ppm. E6,*Z*8-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 6.24–6.09 (2H, m), 5.78–5.71 (1H, m), 5.48–5.42 (1H, m), 3.26 (2H, dd, $J = 7.5, 1.2$ Hz), 2.43 (2H, t, $J = 7.3$ Hz), 2.11 (2H, m), 1.70-1.60 (2H, m), 1.50–1.30 (20H, m), 0.88 (3H, t, $J = 6.8$ Hz), 0.87 (3H, t, $J = 6.8$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 208.9, 137.1, 131.7, 124.8, 120.0, 42.3, 42.0, 32.0, 31.9, 31.4, 29.5, 29.4, 29.3, 29.2, 28.9, 23.8, 22.7, 22.5, 14.1, 14.0 ppm. *Z*6,*Z*8-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 6.44 (1H, m), 6.17 (1H, m), 5.61–5.54 (2H, m), 3.29 (2H, dd, $J = 7.5, 1.4$ Hz), 2.43 (2H, t, $J = 7.5$ Hz), 2.17 (2H, m), 1.60–1.40 (2H, m), 1.50–1.20 (20H, m), 0.88 (3H, t, $J = 6.8$ Hz), 0.88 (3H, t, $J = 6.2$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 208.8, 134.3, 126.5, 122.8, 122.1, 42.4, 41.7, 31.9, 31.4, 29.5, 29.4, 29.4, 29.3, 29.2, 29.2, 27.5, 23.8, 22.6, 22.5, 14.1, 14.0 ppm.

(6Z,8E)-henicosa-6,8-dien-11-ol. (6*Z*,8*E*)-henicosa-6,8-dien-11-ol (*Z*6, *E*8-11-ol-21Hy) has been prepared by Gries et al. (1997), however, this route yielded a mixture of isomeric polyenes requring extensive purification by silver nitrate mediated preparative chromatography. An alternative, more stereoselective route to *Z*6,*E*8-11-ol-21Hy described by Jury et al. (2003) was used to prepare this compound. ^{1}H NMR ($CDCl_3$, 400 MHz) 6.39 (1H, ddd, $J = 1.1, 11.0, 15.1$ Hz), 5.96 (1H, dd, $J = 11.0, 11.0$ Hz), 5.64 (1H, dt, $J = 7.5, 15.0$ Hz), 5.35 (1H, dt, $J = 7.6, 10.8$ Hz), 3.64–3.60 (1H,m), 2.35–2.29 (1H, m), 2.21–2.12 (3H, m),

1.73 (1H, br s), 1.46-1.25 (24H, m), 0.90–0.85 (6H, m) ppm. ^{13}C NMR ($CDCl_3$, 100 MHz) 131.4, 129.5, 129.0, 128.1, 71.1, 40.9, 27.7, 36.8, 31.9, 31.4, 29.6, 29.6, 29.3, 25.7, 22.7, 22.5, 22.5, 22.5, 22.5, 14.0, 14.1 ppm.

(6Z,9Z)-henicosa-6,9-dien-11-ol. (6*Z*,9*Z*)-henicosa-6,9-dien-11-ol (*Z*6, *Z*9-11-ol-21Hy) was prepared as described by Jury et al. (2003). ^{1}H NMR ($CDCl_3$, 400 MHz) 6.39 (1H, ddd, $J = 1.1$, 11.0, 15.1 Hz), 5.96 (1H, dd, $J = 11.0$, 11.0 Hz), 5.64 (1H, dt, $J = 7.5$, 15.0 Hz), 5.35 (1H, dt, $J = 7.6$, 10.8 Hz), 3.64–3.60 (1H, m), 2.35-2.29 (1H, m), 2.21–2.12 (3H, m), 1.73 (1H, br s), 1.46–1.25 (24H, m), 0.90–0.85 (6H, m). ^{13}C NMR ($CDCl_3$, 100 MHz) 131.4, 129.5, 129.0, 128.1, 71.1, 40.9, 27.7, 36.8, 31.9, 31.4, 29.6, 29.3, 25.7, 22.7, 22.5, 22.5, 22.5, 14.0, 14.1 ppm.

(7E,9Z)-henicosa-7,9-dien-11-one and (7E,9E)-henicosa-7,9-dien-11-one. (7*E*,9*Z*)-henicosa-7,9-dien-11-one (*E*7,*Z*9-11-one-21Hy) and (7*E*,9*E*)-henicosa-7,9-dien-11-one (*E*7,E9-11-one-21 Hy) were prepared according to Comeskey and Bunn (2004). *E*7,*Z*9-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 7.44–7.38 (1H, m), 6.37 (1H, m), 6.17–6.05 (1H, m), 5.92–5.90 (1H, m), 2.45 (2H, t, $J = 7.2$ Hz), 2.18 (2H, m), 1.30–1.10 (24H, m), 0.88 (3H, t, $J = 6.1$ Hz), 0.87 (3H, t, $J = 6.0$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 201.8, 147.2, 143.2, 127.6, 122.4, 44.3, 33.0, 31.9, 31.9, 31.6, 29.6, 29.5, 29.4, 29.3, 28.9, 28.8, 24.2, 22.7, 22.6, 14.1, 14.0 ppm. *E*7,E9-11-one-21Hy; ^{1}H NMR ($CDCl_3$, 400 MHz) 7.16–7.09 (1H, m), 6.17–6.15 (2H, m), 6.07 (1H, d, $J = 15.4$ Hz), 2.52 (2H, t, $J = 7.3$ Hz), 2.16 (2H, m), 1.50–1.30 (2H, m), 1.30–1.10 (22H, m), 0.87 (3H, t, $J = 6.7$ Hz), 0.86 (3H, t, $J = 7.0$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 201.2, 145.7, 142.9, 128.8, 127.9, 40.5, 33.1, 31.9, 31.6, 29.6, 29.5, 29.4, 29.3, 29.3, 28.8, 28.7, 24.5, 22.7, 22.5, 14.1, 14.0 ppm.

(6Z,9Z)-henicosa-6,9-dien-11-one (6*Z*,9*Z*)-henicosa-6,9-dien-11-one (*Z*6, *Z*9-11-one-21Hy) was prepared by adding Dess-Martin periodinane (40 mg, 0.094 mmol) to a solution of *Z*6,*Z*9-11-ol-21Hy (10 mg, 0.032 mmol) in dichloromethane (5 ml) at room temperature. The reaction was stirred for 1.5 hr at room temperature. Sodium bicarbonate (5 ml, sat. aq.) was added, and the organic phase was separated. The aqueous phase was extracted with dichloromethane (2×5 ml) and the combined extracts were dried over anhydrous $MgSO_4$. After filtration, the solvent was removed *in vacuo* and the residue was adsorbed onto silica gel. The crude product was purified by silica gel column chromatography (5% EtOAc in petroleum ether) giving pure *Z*6,*Z*9-11-one-21Hy as a pale yellow oil, (8 mg, 0.026 mmol, 81%). The product was immediately cooled and stored at -80°C prior to testing. ^{1}H NMR ($CDCl_3$, 400 MHz) 6.2–5.9 (2H, m), 5.5–5.3 (2H, m), 3.4–3.3 (2H, m), 2.5–2.4 (2H, m), 2.1–1.9 (2H, m), 1.7–1.5 (2H, m), 1.3–1.1 (20H, br, m), 0.87 (3H, t, $J = 6.5$ Hz), 0.84 (3H, t, $J = 6.5$ Hz). ^{13}C NMR ($CDCl_3$, 100 MHz) 201.9, 146.2, 132.0, 126.1, 126.0, 44.3, 31.9, 31.4, 29.5, 29.4, 29.4, 29.3, 29.2, 29.2, 27.8, 27.2, 23.9, 22.6, 22.5, 14.1, 14.0 ppm.

TLC Analysis of Extracts and Synthetic Chemicals. Freshly prepared gland extracts (50 FE/100 μl hexane), *Z*6,*E*8-11-one-21Hy (1 mg/ml in hexane), and *Z*6,*Z*9-11-one-21Hy (1 mg/ml in hexane) were analyzed using Merck Silica Gel 60 F_{254} TLC plates (10% EtOAc in petroleum ether). Visualization was by UV (254 nm) and by development with vanillin spray reagent (prepared from vanillin (3 g), ethanol (500 ml), and conc. H_2SO_4 (10 ml)) followed by heating with a heat gun. Samples of synthetics and female extract were co-spotted and eluted on the same plate for comparisons of Rf values.

TLC Study of Solutions of (6Z,9Z)-henicosa-6,9-dien-11-one under different light conditions. Freshly prepared *Z*6,*Z*9-11-one-21Hy (8 mg) was dissolved in hexane (2 ml), and this solution was divided into two 1 ml portions, each of which were stored in 1 ml volumetric flasks under argon. One of the samples was placed in bright sunshine on the windowsill, and the other was wrapped in aluminum foil and stored in a closed cupboard. Both samples were left overnight at room temperature, and each was analyzed by TLC as described above after 24 hr.

TLC Study of the Effect of BHT on Stability of (6Z,9Z)-henicosa-6,9-dien-11-one. Freshly prepared *Z*6,*Z*9-11-one-21Hy was dissolved in hexane (1 mg/ml). Solutions of BHT (2,6-di-*tert*-butyl-4-hydroxy toluene) were made at the following concentrations: 5% w/v, 1% w/v, 0.1% w/v, and 0.01% w/v in hexane. The TLC mixtures were made as follows: 200 μl of each of the BHT solutions were added to 200 μl of the ketone solution. The mixtures were then flushed with argon and stoppered. Each sample was analyzed by TLC as described above after 24 hr.

Determination of Absolute Configuration of (6Z)-9,10-epoxyhenicos-6-ene. A heptane extract of 90 painted apple moth pheromone glands was fractionated on 1 g of silica gel (Merck, Keiselgel 60) by column chromatography, using a step gradient from heptane to diethyl ether. The heptane/diethyl ether (9:1) fraction contained epoxide and ketone pheromone components by GC-MS. The chirality of (6*Z*)-9,10-epoxyhenicos-6-ene (*Z*6-9,10-epo-21Hy) was determined using a similar method to that applied by Qin et al. (1997) to (6*Z*,9*Z*)-3,4-epoxyoctadeca-6,9-diene. Thus, the fraction containing *Z*6-9,10-epo-21Hy was concentrated under a gentle stream of N_2, in a 6 × 50 mm culture tube. The residue was treated with 3 drops of 14% BF_3/MeOH (Sigma-Aldrich) for 4 hr, diluted with 100 μl heptane, and extracted with 100 μl water. The heptane layer contained 9-hydroxy-10-methoxy and 10-hydroxy-9-methoxy derivatives in a 2:1 ratio, respectively, by GC-MS. These were reacted with 1.2 μl (*S*)-2-acetoxypropionyl chloride (Sigma-Aldrich) in 20 μl pyridine for 16 hr, using a similar method to Slessor et al. (1985), to give two possible diastereoisomers for each alcohol. These were analyzed by GC and GC-MS (BPX-70 column, temperature program: 40°C (1 min hold) to 160°C at 10°C/min, followed by 160°C to 220°C at 4°C/min. Samples of *Z*6-9*S*,10*R*-epo-21Hy and *Z*6-9*R*,10*S*-epo-21Hy, purified by chiral HPLC

(Yamamoto et al., 1999), were derivatized under the same conditions, and the GC results were compared with those for the natural pheromone.

Gas Chromatography-Electroantennogram Detector Studies (GC-EAD). Coupled GC-EAD analysis of pheromone gland extracts and synthetic compounds was conducted on a Varian 3800 GC equipped with a flame ionization detector (FID) and a splitless injector. The column effluent was split 1:1 between the FID and EAD apparatus. Antennal depolarization was detected using a high-resistance EAD Probe, Signal Interface Box Type ID-02, and Intelligent Data Acquisition Controller Type IDAC-02 (Syntech, Hilversum, The Netherlands). Antennae from 2–3 d-old males were excised at the base and attached to the silver electrodes housed in a saline glass electrode using a micromanipulator. Up to 10 antennal preparations were used for GC-EAD analyses. A 30 m × 0.25 mm ID, BPX-70 capillary column (SGE, Ringwood, Victoria, Australia) (this column has higher polarity than a DB-Wax column and is comparable to DB-23) and a 30 m × 0.5 mm ID, DB-5 capillary column (J&W Scientific Folsom, CA, USA) and a Y splitter (Alltech, Deerfield, IL, USA) were used for the analyses. For the BPX-70 capillary column, the oven temperature was programmed from 80°C (held for 1 min) to 240°C at 10°C/min. For the DB-5 capillary column, the oven temperature was programmed from 100°C (held for 1 min) to 210°C at 10°C/min, held for 1 min, and then increased to 240°C at 1.5°C/min. Helium was used as the carrier gas.

Gas Chromatography (GC) Analysis. Gas chromatography of the gland extracts and synthetic standards was performed using three different 30 m × 0.25-mm i.d. capillary columns, DB-5, DB-Wax, and BPX-70. Helium was used as the carrier gas at a flow rate of 1 ml/min. Oven temperature was maintained at 80°C for 1 min, and raised to 240°C at a rate of 10°C/min and held for 30 min.

Gas Chromatography–Mass Spectrometry (GC-MS) Analysis. The gland extracts and synthetic chemicals were analyzed on two different GC-MS systems: a Saturn 2200 GC-MS (Varian Walnut Creek, CA, USA) using an ionization voltage of 70 eV and a mass range of 30 to 500, equipped with a 30 m × 0.25 mm i.d. × 0.5 μm film DB-5 MS capillary column (J&W Scientific) and splitless injection, and a Shimadzu QP5050A (Shimadzu, Kyoto, Japan) equipped with a 30 m × 0.25 mm i.d. × 0.25 um BPX-70 capillary column (SGE) also with splitless injection. In the former machine, the oven was programmed from 100°C (held for 1 min) to 210°C at 10°C/min, held for 1 min, and then increased to 240°C at 1.5°C/min and finally to 300°C at 15°C/min, while in the latter machine, the temperature was programmed from 80°C (held for 2 min) to 240°C at 10°C/min. Compounds were identified by comparing retention times and mass spectra with those of synthetic compounds.

Field Cage Experiments. In the first trapping experiment, we examined the efficacy of different substrates for releasing the unstable *Z*6,*Z*9-11-one-21Hy. Four substrates were used; cigarette filters (Moss Packaging Co. Ltd., Wellington,

New Zealand), 2 ml polyethylene vial closure containing a plug of bleached nonsurgical cotton batting (No. 60975d-3, Kimble Glass, Vineland, NJ, USA) (Grant et al., 2003), dental roll (Roeko, Langenau, Germany), and filter paper (Whatman International Ltd., Maidstone, England). Each substrate was loaded with 20 female equivalents (FE) of freshly prepared female gland extract dissolved in 60 μl hexane.

In the second experiment, different doses (50, 100, 200, and 400 μg) of synthetic *Z*6,*Z*9-11-one-21Hy were tested using the best two substrates in experiment 1 (i.e., cigarette filter and dental roll). In experiment 3, we tested the effect of adding other compounds to *Z*6,*Z*9-11-one-21Hy. The following treatments were compared: (*i*) 50 μg *Z*6,*Z*9-11-one-21Hy; (*ii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy; (*iii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy; (*iv*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy; (*v*) blank.

In experiment 4, the effects of omitting *Z*6,*Z*9-21Hy and the two ketones *Z*6,*E*8-11-one-21Hy and *Z*6-11-one-21Hy from the best blend (identified in experiment 3) were tested. The rationale for this experiment was a) if it was possible to omit the diene hydrocarbon without loss of activity, then this would significantly reduce the cost of production of a synthetic lure, and b) because synthetic *Z*6,*Z*9-11-one-21Hy rearranges to *Z*6,*E*8-11-one-21Hy and other ketones in the GC-MS system, the presence of these ketones in gland extracts may be due solely to the rearrangement of *Z*6,*Z*9-11-one-21Hy. To address these two issues, the following treatments were tested: (*i*) 50 μg *Z*6,*Z*9-11-one-21Hy; (*ii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy; (*iii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-o1-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy; (*iv*) 50 μg *Z*6,*Z*9-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy; 50 μg *Z*6,*Z*9-21Hy (*v*) blank.

In the fifth experiment, the two enantiomers of the two epoxides (6*Z*)-9,10-epoxyeicos-6-ene (*Z*6-9,10-epo-20Hy) and *Z*6-9,10-epo-21Hy were tested to determine the active enantiomers. The following treatments were tested: (*i*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy; (*ii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*S*,10*R*-epo-21Hy, 1.25 μg *Z*6-9*R*,10*S*-epo-20Hy, 1.25 μg *Z*6-9*S*,10*R*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy; (*iii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*S*,10*R*-epo-21Hy, 2.5 μg *Z*6-9*S*,10*R*-epo-20Hy, 50 μg

*Z*6,*Z*9-21Hy; (*iv*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 50 μg *Z*6,*Z*9-21Hy; (*v*) blank.

In the final field cage experiment, the attractiveness of virgin females and the best synthetic pheromone blend were compared. A 1–2 d old virgin female was placed in a 6 cm long × 4 cm diam plastic cage that was closed at each end with a metal screen (8 × 8 mm mesh), while the synthetic pheromone contained the following compounds: 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy. A blank trap was used as a control.

In all field experiments, the ratio of *Z*6,*Z*9-11-one-21Hy was arbitrarily set to 100%, while the relative ratio of *Z*6,*E*8-11-one-21Hy was based on the ratio of the *Z*6,*E*8-11-ol-21Hy to *Z*6,*Z*9-11-ol-21Hy in the reduced gland extract. The relative ratios of the other five compounds (*Z*6-11-one-21Hy, *Z*6,*Z*9-11-ol-21Hy, *Z*6-9*R*,10*S*-epo-20Hy, *Z*6-9*R*,10*S*-epo-21Hy, and *Z*6,*Z*9-21Hy) were based on their original amounts relative to the rearrangement products of *Z*6,*Z*9-11-one-21Hy in the non-reduced gland extracts. All field cage experiments were carried out in a field cage (8 m long × 8 m wide × 3 m high), covered with shade cloth (mesh size 3 × 3 mm). Compounds were applied to the substrates in 50–200 μl of analytical grade hexane in a fume hood. Immediately after preparation, lures were stored on dry ice and transported in an ice chest to the field cage for testing. White plastic delta traps (Suckling and Shaw, 1991) were placed approximately 2 m from the ground and 2 m apart from each other. Trap positions were rotated every day (four in total) of an experiment. Sterilized 1–2 d old painted apple moth males were placed in the field cage between 9.30 and 12.00 hr. A total of ca. 3,900 males were released in all of the field cage experiments. The significance of differences between treatments was identified using ANOVA. Significantly different treatment means were identified using Fisher's Protected Least Significant Difference Test (SAS Institute Inc., 1998).

Field Trapping Experiments. In experiments conducted in the field at Edenvale Park, Auckland from February 17–22, 2004, we tested the following synthetic blends in delta traps: (*i*) 50 μg *Z*6,*Z*9-11-one-21Hy; (*ii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy; (*iii*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy, 50 μg *Z*6,*Z*9-21Hy; (*iv*) 50 μg *Z*6,*Z*9-11-one-21Hy, 12.5 μg *Z*6,*E*8-11-one-21Hy, 0.5 μg *Z*6-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy; (*v*) 50 μg *Z*6,*Z*9-11-one-21Hy, 5 μg *Z*6-9*R*,10*S*-epo-21Hy, 2.5 μg *Z*6-9*R*,10*S*-epo-20Hy; (*vi*) 50 μg *Z*6,*Z*9-11-one-21Hy, 2.5 μg *Z*6,*Z*9-11-ol-21Hy; (*vii*) live female; (*viii*) blank. Five replicates of the eight treatments were placed in the area, with about 25 m

separation between replicates. During the experiment, approximately 6,000 sterile, dyed males were released near the trapping site as part of a Sterile Insect Technique (SIT) program to eradicate the painted apple moth (Suckling, 2003). The effect of treatment on the mean number of *T. anartoides* captured was tested using ANOVA (SAS Institute Inc., 1998) after variances were stabilized using the $\sqrt{x}$ transformation. Significantly different treatment means were identified using Fisher's Protected Least Significant Difference Test (SAS Institute Inc., 1998).

RESULTS

Identification of Pheromone Gland Components. Analysis of pheromone gland extracts by GC-EAD using polar (BPX-70), and non-polar capillary columns (DB-5) revealed that nine compounds consistently elicited antennal responses from male antennae (Figures 1 and 2). The mass spectrum of component 1 had the diagnostic ions *m/z* 292 $[M]^+$, 194 $[M\text{-}\ C_7H_{14}]^+$, 81 $[C_6H_9]^+$, and 67 $[C_5H_7]^+$ and was identical to the mass spectrum of the authentic standard *Z*6,*Z*9-21Hy. On GC analysis of the gland extracts on three different columns (BPX-70, DB-WAX, DB-5), component 1 and the authentic standard *Z*6,*Z*9-21Hy showed the same

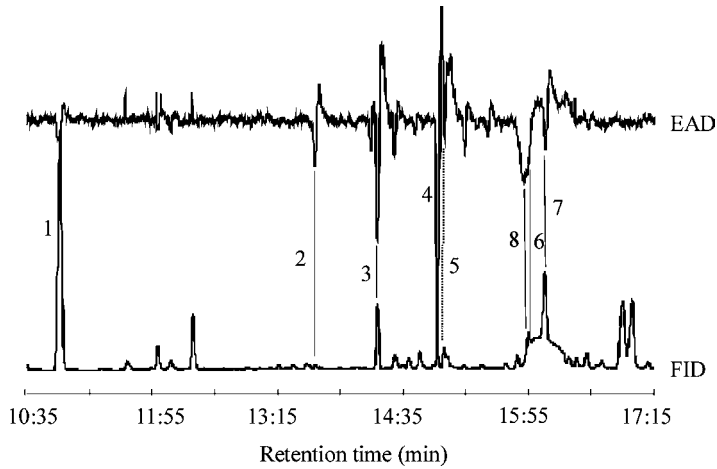

FIG. 1. Coupled GC-EAD responses of antenna of male painted apple moth, *T. anartoides*, to female gland extract. Peak identification: (6*Z*,9*Z*)-henicosa-6,9-diene (1), (6*Z*)-9*R*,10*S*-epoxyeicos-6-ene (2), (6*Z*)-9*R*,10*S*-epoxyhenicos-6-ene (3), (6*Z*)-henicos-6-en-11-one (4), (6*Z*,9*Z*)-henicosa-6,9-dien-11-ol (5), (6*E*,8*Z*)-henicosa-6,8-dien-11-one (6), (6*Z*,8*E*)-henicosa-6,8-dien-11-one (7), and (7*E*,9*Z*)-henicosa-7,9-dien-11-one (8). Chromatographic column and conditions: BPX-70, 30 m × 0.25 mm i.d.; program 80°C/1 min, 10°C/min to 240°C, 240°C/30 min.

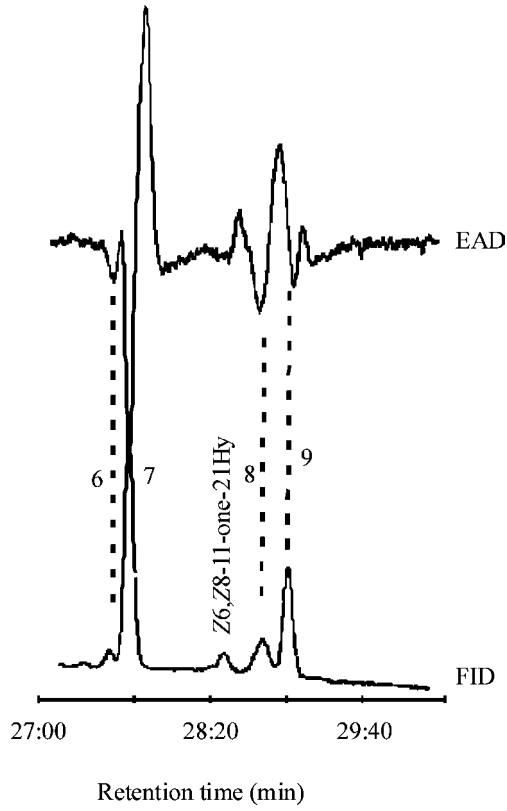

FIG. 2. Coupled GC-EAD responses of antenna of male painted apple moth, *T. anartoides* to female gland extract. Peak identification: (6*E*,8*Z*)-henicosa-6,8-dien-11-one (6), (6*Z*,8*E*)-henicosa-6,8-dien-11-one (7), (7*E*,9*Z*)-henicosa-7,9-dien-11-one (8), and (6*E*,8*E*)-henicosa-6,8-dien-11-one (9). Chromatographic column and conditions: DB-5, 30 m × 0.25 mm i.d.; program 100°C/1 min, 10°C/min to 210°C, isothermal for 1 min and 1.5°C/min to 240°C, then 15°C/min to 300°C, held for 30 min.

retention time. Mass spectra of components 2 and 3 were similar for most of the *m/z* values, such as 81 $[C_6H_9]^+$, 124 $[C_9H_{16}]^+$, and 153 $[C_{10}H_{17}O]^+$, except for their respective molecular ions at *m/z* 294 $[M]^+$ and 308 $[M]^+$, suggesting two mono-unsaturated epoxides with 20 and 21 carbon atoms, respectively. The mass spectra and GC retention times (three capillary columns) of components 2 and 3 were identical to those of the authentic standards *Z*6-9,10-epo-20Hy and *Z*6-9,10-epo-21Hy, respectively. On the DB-5 column, *Z*6-9,10-epo-21Hy (component 3) co-eluted with *Z*6-11-one-21Hy (component 4). The absolute configuration of

the *Z*6-9,10-epo-21Hy was determined to be 9*R*,10*S* by micro-derivatization (see below). Because of the small quantity present, derivatization was not possible for the *Z*6-9,10-epo-20Hy obtained from the gland extracts. However, field trapping experiments testing the two enantiomers (9*S*,10*R*; 9*R*,10*S*) confirmed that *Z*6-9*R*, 10*S*-epo-20Hy was indeed the active enantiomer (experiment 5).

The mass spectrum of component 4 had the diagnostic ions *m/z* 309 (M+ H^+), 291 [M+1-H_2O], 223 $[C_{15}H_{27}O]^+$, 169 $[C_{11}H_{21}O]^+$, and 167 $[C_{11}H_{19}O]^+$ suggesting a possible mono-unsaturated 21-carbon ketone. The spectrum of component 4 and its retention times on BPX-70 and DB-WAX were identical to those of the authentic standard *Z*6-11-one-21Hy. Component 5 showed diagnostic ions at *m/z* 308 $[M]^+$, 290 [M-H_2O]$^+$, 233 $[C_{17}H_{29}]^+$, 177 $[C_{13}H_{21}]^+$, 163 $[C_{12}H_{19}]^+$, 135 $[C_{10}H_{15}]$ suggestive of a di-unsaturated 21-carbon alcohol. The spectrum of component 5 and its retention times on three different columns were identical to those of authentic *Z*6,*Z*9-11-ol-21Hy. The mass spectra of components, 6, 7, and 9 were similar and had diagnostic ions at *m/z* 307 $[M+H]^+$ and 169 $[C_{11}H_{21}O]^+$ suggesting different stereoisomers of a di-unsaturated C21 ketone with a carbonyl group on C11. On a BPX-70 capillary column, the diene ketones were not fully separated (Figure 1) whereas in another GC-MS analysis aimed at improving the observed resolution and fully separating the diene ketones, a non-polar column (DB-5) and a slow temperature program were used, and the diene ketones were fully separated (Figure 2). GC and GC-MS analyses of gland extracts and the authentic standards *E*6,*Z*8-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, *Z*6,*Z*8-11-one-21Hy, and *E*6,*E*8-11-one-21Hy on the DB-5 capillary column confirmed that components 6, 7, and 9 were *E*6,*Z*8-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, and *E*6,*E*8-11-one-21Hy, respectively. The stereoisomer *Z*6,*Z*8-11-one-21Hy was also present in the gland extracts, although this compound did not elicit any antennal response (Figure 2). The mass spectrum of component 8 had diagnostic ions at *m/z* 307 $[M+H]^+$, 165 $[C_{11}H_{17}O]^+$, 169 $[C_{11}H_{21}O]^+$, and a base peak at 221 $[C_{15}H_{25}O]^+$ suggesting a different regioisomer of a C21 ketone. GC and GC-MS analysis of gland extracts, and the authentic compounds *E*7,*Z*9-11-one-21Hy and *E*7, *E*9-11-one-21Hy on BPX- 70 and DB-5 capillary columns confirmed that component 8 was *E*7,*Z*9-11-one-21Hy.

*Z*6,*E*8-11-one-21 Hy and *Z*6,*Z*9-21Hy were the major components present in the pheromone gland extracts. The relative amounts of the other seven components ranged from 0.5–100% of *Z*6,*E*8-11-one-21Hy (Table 1). *E*6,*Z*8-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, *E*7,*Z*9-11-one-21Hy, and *E*6,*E*8-11-one-21Hy elicited antennal responses, whereas *Z*6,*Z*8-11-one-21Hy did not (Figure 2). Of the nine compounds detected by GC-EAD, four diene ketones (*Z*6,*E*8-11-one-21Hy, *E*6,*Z*8-11-one-21Hy, *E*6,*E*8-11-one-21Hy, *E*7,*Z*9-11-one-21Hy), and a monoene ketone (*Z*6-11-one-21Hy) elicited the strongest antennal responses. The two epoxides, *Z*6-9*R*,10*S*-epo-20Hy and *Z*6-9*R*,10*S*-epo-21Hy, elicited medium responses, and the dienic hydrocarbon, *Z*6,*Z*9-21Hy and the

TABLE 1. COMPOUNDS IDENTIFIED BY GC-MS ANALYSIS[a] AND THEIR APPARENT RATIO IN THE SEX PHEROMONE GLAND EXTRACTS AND EFFLUVIA OF FEMALE PAINTED APPLE MOTH, *Teia anartoides*

Compound Name (abbreviation)	Chemical structure	Relative ratio
(6*Z*,9*Z*)-henicosa-6,9-diene (*Z*6,*Z*9-21Hy)		100
(6*Z*)-9*R*,10*S*-epoxyeicos-6-ene (*Z*6-9*R*,10*S*-epo-20Hy)		5
(6*Z*)-9*R*,10*S*-epoxyhenicos-6-ene (*Z*6-9*R*,10*S*-epo-21Hy)		11
(6*Z*)-henicos-6-en-11-one (*Z*6-11-one-21Hy)		0.5
(6*Z*,9*Z*)-henicosa-6,9-dien-11-ol (*Z*6,*Z*9-11-ol-21Hy)		5
(6*E*,8*Z*)-henicosa-6,8-dien-11-one (*E*6,*Z*8-11-one-21Hy)		3
(6*Z*,8*E*)-henicosa-6,8-dien-11-one (*Z*6,*E*8-11-one-21Hy)		100
(6*Z*,8*Z*)-henicosa-6,8-dien-11-one (*Z*6,*Z*8-11-one-21Hy)		4
(7*E*,9*Z*)-henicosa-7,9-dien-11-one (*E*7,*Z*9-11-one-21Hy)		5

[a]DB-5 capillary column, initial temperature 100°C for 1 min, raised to 210°C at 10°C/min, isothermal 1 min, raised to 240°C at 1.5°C/min and then to 300°C at 15°C/min, and then held for 30 min.

secondary alcohol, *Z*6,*Z*9-11-ol-21Hy elicited the lowest antennal responses (Figure 1).

Absolute Configuration of (Z6)-9,10-epoxyhenicos-6-ene. BF_3-catalyzed methanolysis of synthetic samples of *Z*6-9*S*,10*R*-epo-21Hy and *Z*6-9*R*,10*S*-epo-21Hy, followed by esterification with (*S*)-2-acetoxypropionyl chloride [(*S*)-AP Cl], resulted in three peaks when analyzed by GC and GC-MS. The peak with the lowest retention time corresponded to the (*S*)-AP ester of 6*Z*-(9*R*,10*R*)-9-hydroxy-10-methoxyhenicosene, whereas the peak with the longest retention time corresponded to the (*S*)-AP ester of 6*Z*-(9*S*,10*S*)-9-hydroxy-10-methoxyhenicosene (mass spectra with diagnostic ions *m*/*z* (rel. int.) 343 (10) [M-C_8H_{15}]$^+$, 322 (12) [M- (*S*)-AP acid]$^+$, 251 (12) [M- (*S*)-AP acid–C_5H_{11}]$^+$, 199

(31) $[C_{13}H_{27}O]^+$, 167 (100) [M- (*S*)-AP acid $-C_{11}H_{23}]^+$). The central peak was due to the (*S*)-AP esters of both 9*S*,10*S*- and 9*R*,10*R*-9-methoxy-10-hydroxy derivatives, which overlapped (mass spectra with diagnostic ions *m*/*z* (rel. int.) 343 (100), 322 (5), 155 (12) $[C_{10}H_{19}O]^+$. The (*S*)-AP esters derived from both *Z*6-9*S*,10*R*-epo-21Hy and *Z*6-9*R*,10*S*-epo-21Hy showed a small peak corresponding to the derivative from the epoxide of opposite configuration, even though they were purified by HPLC, indicating that approximately 10% racemization occurred during BF_3-catalyzed methanolysis, similar to the result of Qin et al. (1997). Comparison of the results from derivatization of the natural pheromone component, with those of the standards, indicated that the natural *Z*6-9,10-epo-21Hy had the 9*R*,10*S* configuration.

Identification of (6Z,9Z)-henicosa-6,9-dien-11-one. Initial wind tunnel bioassays in the laboratory and field trapping experiments with various blend combinations of the nine compounds that elicited antennal responses resulted in very few males responding to the synthetic blends, and then only in wind tunnel experiments. Therefore, we hypothesized that an essential compound (s) was/were missing, and that, based on the experience of Grant et al. (2003) with *Orgyia leucostigma* (J. E. Smith) (Lymantriidae), this/these compound (s) may be thermally labile, and rearrange to other compounds in the heated injection port of the GC-MS system. We therefore treated female gland extracts with $NaBH_4$ so that any ketones present in the extracts would be reduced to secondary alcohols, and analyzed the reduced extracts by GC and GC-MS. GC-MS analysis of a non-reduced extract suggested that *Z*6,*E*8-11-one-21Hy was the major dienic ketone in the gland extracts (Figure 3A). If this were true, then *Z*6,*E*8-11-ol-21Hy should be the major product in the reduced gland extract. However, *Z*6,*Z*9-11-ol-21Hy was found to be the major secondary alcohol in the reduced gland extracts (Figure 3B), with a lesser amount (>10% of *Z*6,*Z*9-11-ol-21Hy) of *Z*6,*E*8-11-ol-21Hy, demonstrating that *Z*6,*Z*9-11-one-21Hy was in fact the main dienic ketone in the gland extracts. The identity of *Z*6,*Z*9-11-ol-21Hy in the reduced gland extracts was confirmed based on the comparison of its retention time and mass spectral data with an authentic standard of *Z*6,*Z*9-11-ol-21Hy on two different capillary columns. Injection of synthetic *Z*6,*Z*9-11-one-21Hy in the GC-MS system confirmed the thermal rearrangement of this compound to the five diene ketones, *E*6,*Z*8-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, *Z*6,*Z*8-11-one-21Hy, *E*7,*Z*9-11-one-21Hy, and *E*6,*E*8-11-one-21Hy, with identical ratios and patterns as observed in the GC-MS analyses of the gland extracts (Figure 4). Upon TLC analysis of gland extracts and the two authentic standards, *Z*6,*Z*9-11-one-21Hy and *Z*6,*E*8-11-one-21Hy, *Z*6,*Z*9-11-one-21Hy was visible for the first time in the gland extract as compared to synthetic *Z*6,*Z*9-11-one-21Hy and *Z*6,*E*8-11-one-21Hy (Figure 5). A small amount of *Z*6,*E*8-11-one-21Hy was present in the gland extracts along with a larger amount of *Z*6,*Z*9-21Hy (Figure 5). All these results confirm that *Z*6,*Z*9-11-one-21Hy is present in

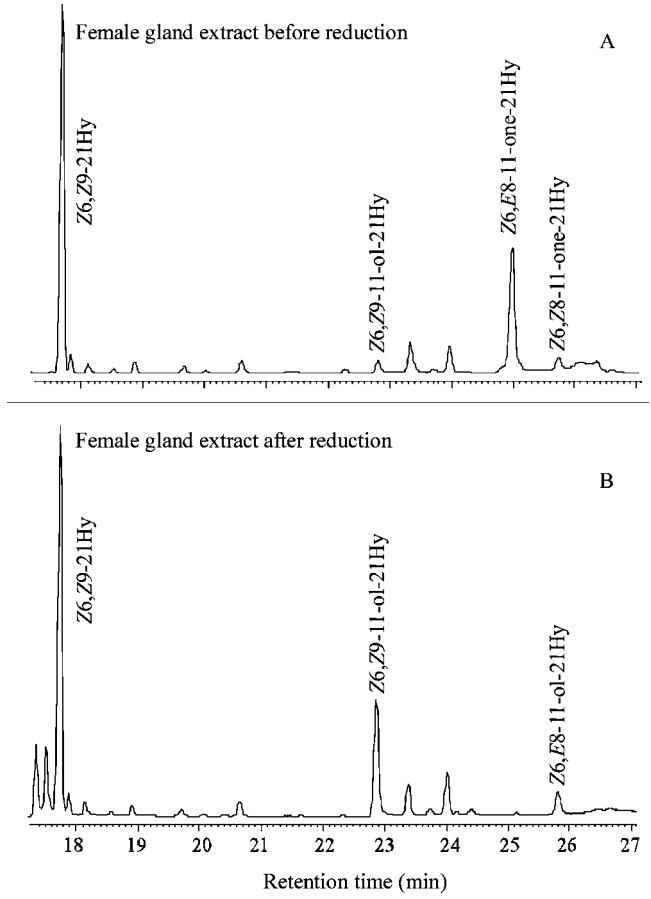

FIG. 3. Coupled GC-MS analysis of female painted apple moth pheromone gland extracts before (A) and after (B) reduction. Chromatographic column and conditions identical to Figure 2.

the gland extracts and rearranges to five diene ketones upon analysis by GC or GC-MS.

Field Cage Experiments. In the first trapping experiment, traps baited with 20 FE of the female gland extracts loaded on cigarette filters captured significantly more males than traps baited with 20 FE of the female gland extracts loaded on the three other substrates (i.e., dental rolls, polyethylene closures, and filter papers) (Figure 6). Among the four substrates tested, filter paper was the least effective substrate (Figure 6). Regardless of the type of substrate used, traps baited with the female gland extracts only caught moths on the first day of the trial.

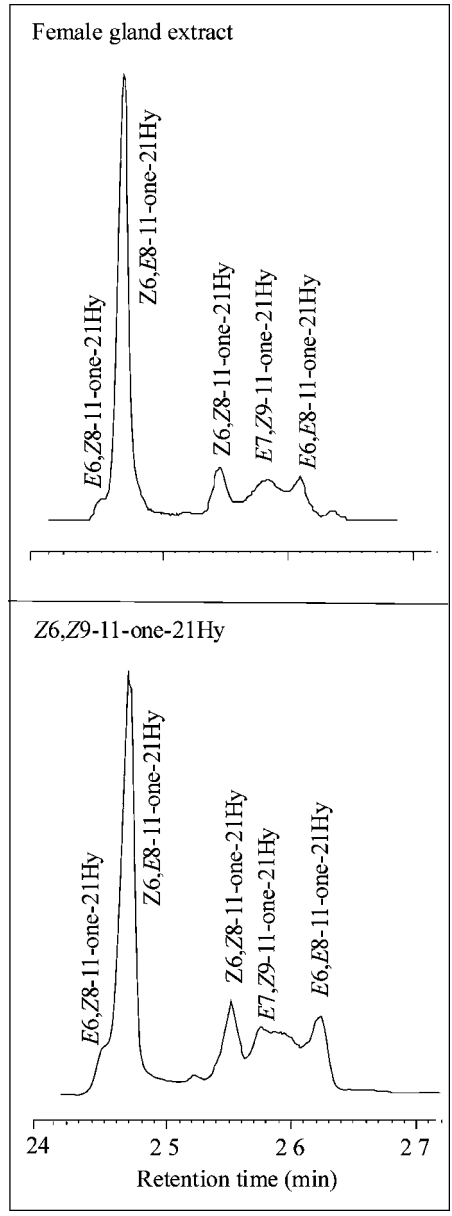

FIG. 4. Coupled GC-MS analysis of female painted apple moth pheromone gland extract and synthetic *Z*6,*Z*9-11-one-21Hy. Chromatographic column and conditions identical to Figure 2.

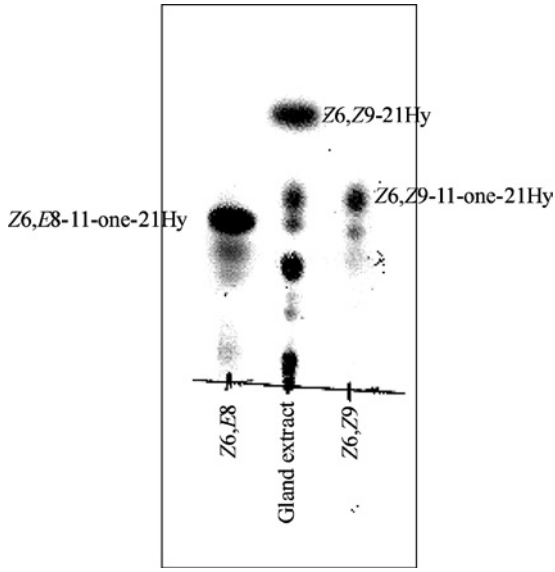

FIG. 5. TLC analysis on a Merck Silica Gel 60 F_{254} plate of female painted apple moth pheromone gland extract, synthetic *Z*6,*Z*9-11-one-21Hy, and *Z*6,*E*8-11-one-21Hy.

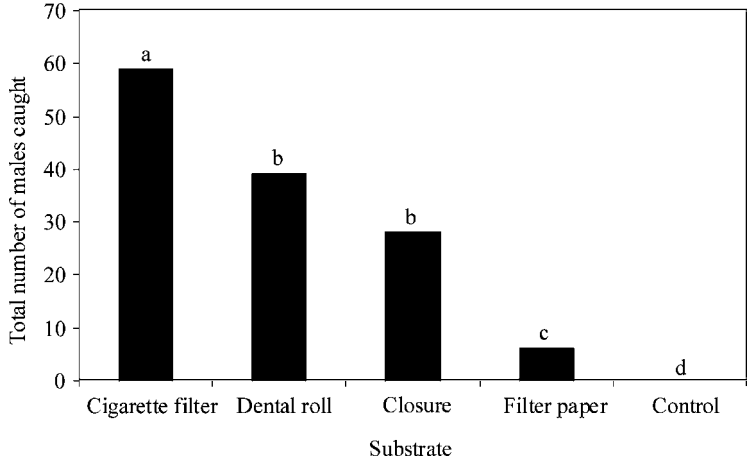

FIG. 6. Total number of *T. anartoides* males caught in traps baited with pheromone gland extract (20 FE) loaded on four different substrates in a field cage experiment. Treatments labeled with the same letters are not significantly different ($P > 0.05$).

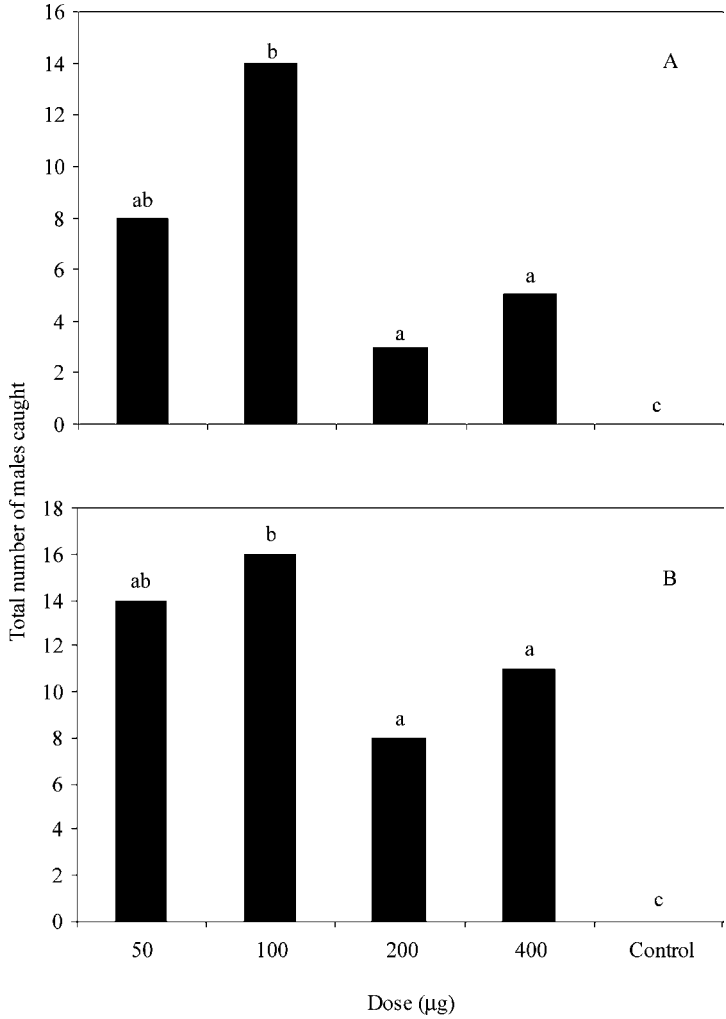

FIG. 7. Total number of *T. anartoides* males caught in traps baited with different doses of synthetic *Z*6,*Z*9-11-one-21Hy loaded on dental rolls (A) and cigarette filters (B) in a field cage experiment. Treatments labeled with the same letters are not significantly different ($P > 0.05$).

The second field cage trial, testing different doses of synthetic *Z*6,*Z*9-11-one-21Hy, showed that the 100 μg dose caught the greatest number of male moths regardless of whether the dental roll or the cigarette filter were used as releasing substrates (Figures 7A and 7B), although the numbers were not significantly

different from traps baited with 50 μg of this component. Increasing the dose to 200 or 400 μg resulted in a significant reduction in the number of males caught (Figures 7A and 7B). In the third field cage experiment, the addition of *Z*6,*E*8-11-one-21Hy or *Z*6,*E*8-11-one-21Hy and *Z*6-11-one-21Hy to 50 μg of *Z*6,*Z*9-11-one-21Hy did not enhance the attractiveness of lures compared to the major component alone. However, the blend containing the 7 compounds that elicited EAG responses gave the greatest catches of males ($P < 0.05$, Figure 8). In a further experiment, omission of *Z*6,*Z*9-21Hy or the two ketones *Z*6,*E*8-11-one-21Hy and *Z*6-11-one-21Hy caused a significant reduction in males caught ($P < 0.05$, Figure 9). These results suggest that these three compounds are part of the sex pheromone blend of the painted apple moth.

In the fifth field cage experiment, traps baited with the (9*R*,10*S*) enantiomer of *Z*6-9,10-epo-20Hy and *Z*6-9,10-epo-21Hy, respectively, captured more males than any treatment tested in this experiment (Figure 10). Traps baited with the racemic mixtures of the C20 and C21 epoxides captured significantly more males than traps baited with the (9*S*,10*R*) enantiomer of *Z*6-9,10-epo-20Hy and

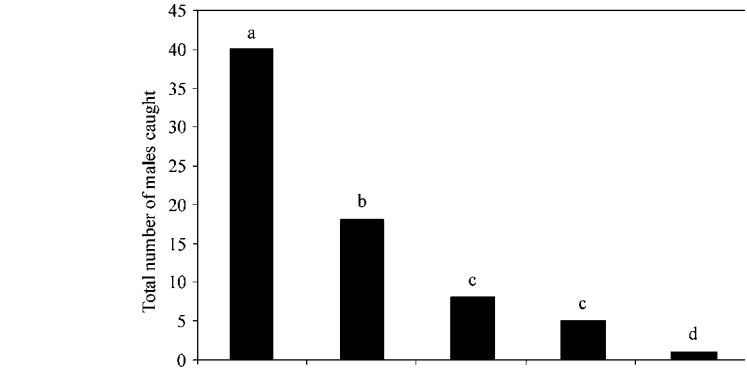
FIG. 9. Total number of *T. anartoides* males caught in traps baited with different blends of synthetic pheromone compounds loaded on cigarette filters in a field cage experiment. Treatments labeled with the same letters are not significantly different ($P > 0.05$).

*Z*6-9,10-epo-21Hy, the catches of which were equivalent to catches in traps without either of these epoxides (Figure 10). In the final field cage experiment, traps baited with the seven-component blend caught 9 males, whereas traps baited with one virgin female caught 6 males ($P > 0.05$). Trap catches in this experiment were low due to low ambient temperature (ca. 16°C).

Field Trapping Experiment. The full 7-component synthetic blend was the most effective synthetic blend, and caught more males than did traps baited with virgin females ($P < 0.05$, Figure 11). Traps baited with synthetic pheromones also caught moths for two consecutive days, with highest catch taking place in the first day.

Degradation Experiments. TLC analysis of synthetic *Z*6,*Z*9-11-one-21Hy over time showed that this compound disappeared after 24 hr when maintained in dilute solution at ambient temperature. In contrast, synthetic *Z*6,*E*8-11-one-21Hy was reasonably stable as compared to *Z*6,*Z*9-11-one-21Hy. Comparison of these TLC samples with other reference materials suggested that one of



*Z*6,*Z*9-21Hy	50	50	50	50	Control

the decomposition products was a related ketone, namely *Z*6,*E*8-11-one-21Hy, along with several other unidentified products. TLC analysis of the two *Z*6, *Z*9-11-one-21Hy solutions maintained under complete darkness or bright sunshine revealed that both samples had decomposed to an identical extent to a mixture of products, with only a trace of the original ketone present. This experiment, coupled with the fact that our synthetic pheromone lure was active for only two days suggested that thermal degradation rather than hydrolysis or photodegradation of this material was occurring. The addition of BHT has no effect on the stability of the ketone and the sample degraded to the same extent as a control sample without BHT.

DISCUSSION

We have identified seven possible components of the sex pheromone of *T. anartoides*, from extracts of the sex pheromone gland, including *Z*6,*Z*9-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, *Z*6-11-one-21Hy, *Z*6,*Z*9-11-ol-21Hy, *Z*6-9*R*,10*S*-epo-21Hy, *Z*6-9*R*,10*S*-epo-20Hy, and *Z*6,*Z*9-21Hy. The efficacy of the blend of

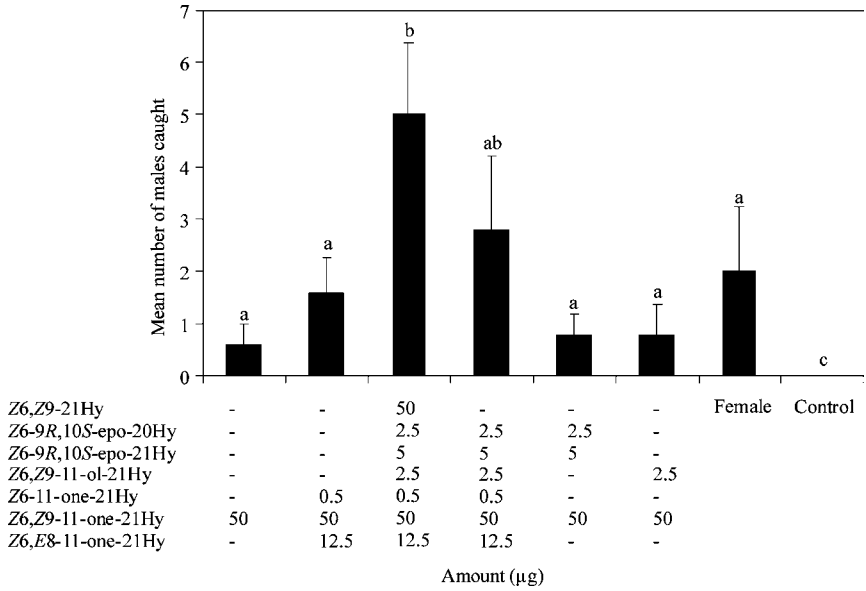

FIG. 11. Mean number of *T. anartoides* males caught in traps baited with different blends of synthetic pheromone compounds loaded on cigarette filters, or virgin females, in a field trapping experiment conducted in Auckland. Treatments labeled with the same letters are not significantly different ($P > 0.05$).

seven components was confirmed in a field trial in which traps baited with this blend caught significantly greater numbers of males than did traps baited with virgin females. Testing of the pheromone blend was complicated by the thermal lability of the major component, *Z*6,*Z*9-11-one-21Hy. In field trials, traps baited with the synthetic blends only caught males for one or two days. Grant et al. (2003) recently identified *Z*6,*Z*9-11-one-21Hy as the major sex pheromone compound of the whitemarked tussock moth, *O. leucostigma*, and also reported that the compound was extremely unstable, with a tentative half life of 12 hr at room temperature, due to the proximity of the carbonyl group to the homoconjugated diene system. To date, four dienone pheromones have been identified from lepidoptera, including (3*E*,6*Z*)-henicosa-3,6-dien-11-one in the douglas fir tussock moth, *Orgyia pseudotsugata* (McDunnough) (Lymantriidae) (Smith et al., 1978), (6*Z*, 9*Z*)-nonadeca-6,9-dien-3-one in the willow beauty, *Peribatodes rhomboidaria* (Schiffermüller) (Geometridae) (Buser et al., 1985), *Z*6,*E*8-11-one-21Hy in the douglas fir tussock moth, *O. pseudotsugata* (Gries et al., 1997), and *Z*6,*Z*9-11-one-21Hy in the whitemarked tussock moth, *O. leucostigma* (Grant et al., 2003).

A small amount of *Z*6,*E*8-11-ol-21Hy was present in the reduced female gland extracts, suggesting that the corresponding dienic ketone *Z*6,*E*8-11-one-21Hy might also be present. However, it was not clear whether *Z*6,*E*8-11-one-21Hy was produced by the female or was present only as a rearrangement product of *Z*6,*Z*9-11-one-21Hy. Furthermore, in two field cage experiments (Figures 8 and 9) and a field bioassay (Figure 11), addition of *Z*6,*E*8-11-one-21Hy and *Z*6-11-one-21Hy to *Z*6,*Z*9-11-one-21Hy did not increase trap catches significantly.

The di-unsaturated secondary alcohol, *Z*6,*Z*9-11-ol-21Hy, has been recently identified as a major sex pheromone compound in the tussock moth, *Orgyia detrita* (Guerin-Meneville) Lymantriidae (Gries et al., 2003). In the study reported here, this compound was identified as a minor component in the pheromone gland extract, but a blend of *Z*6,*Z*9-11-ol-21Hy with *Z*6,*Z*9-11-one-21Hy did not increase trap catches relative to *Z*6,*Z*9-11-one-21Hy as a single component (Figure 11).

Two monoepoxyalkenes, *Z*6-9*R*,10*S*-epo-20Hy and *Z*6-9*R*,10*S*-epo-21Hy, were also identified as minor components of female painted apple moth pheromone gland extracts, with both compounds eliciting strong antennal responses in coupled GC-EAD analyses. It is likely that both are important to the pheromone blend because dropping both compounds from the full seven-component mixture in a field cage test resulted in decreased trap captures. However, in a field trial, the three-component blend of the epoxides with *Z*6,*Z*9-11-one-21Hy was no more attractive than *Z*6,*Z*9-11-one-21Hy alone (Figure 11). Confirmation of the structure and absolute configuration of *Z*6-9*R*,10*S*-epo-21Hy was accomplished by derivatization and comparison with authentic samples, whereas *Z*6-9*R*,10*S*-epo-20Hy was present in quantities that were insufficient for the derivatization method. Unsaturated epoxides have been reported frequently as pheromone components of arctiid, lymantriid, geometrid, and some noctuid species (El-Sayed, 2004). Because these epoxides have two enantiomeric forms, each of which serves as a unique structure at the receptor level, male moths can be selective in their responses to the two enantiomers. For example, male mulberry looper, *Hemerophila atrilineata* (Butler) (Geometridae), respond mainly to (6*Z*)-9*S*,10*R*-epoxyoctadec-6-ene, whereas the other enantiomer of this compound is not attractive (Tan et al., 1996). Similarly, male crocus geometer, *Xanthotype sospeta* (Drury) (Geometridae), respond selectively to the (6*Z*)-9*S*,10*R*-epoxynonadec-6-ene and not the (9*R*,10*S*)-enantiomer (Millar et al., 1991). In our study, in one field cage trial (Figure 10), male painted apple moths appeared to respond selectively to *Z*6-9*R*,10*S*-epo-20Hy and *Z*6-9*R*,10*S*-epo-21Hy, whereas *Z*6-9*S*,10*R*-epo-20Hy and *Z*6-9*S*,10*R*-epo-21Hy elicited neither positive nor negative responses. Both of these epoxides have been previously reported as lepidopteran pheromone components. Racemic *Z*6-9,10-epo-20Hy has been reported as an attractant for *Hypenomorpha calamina* (Butler) (Ando et al., 1995). *Z*6-9,10-epo-21Hy of unknown absolute configuration was reported as a possible sex pheromone component of the ruby tiger moth,

Phragmatobia fuliginosa (Linnaeus) (Déscoins and Frérot, 1984), whereas the fruit-piercing moth, *Oraesia excavata* (Butler) uses *Z*6-9*S*,10*R*-epo-21Hy in its pheromone blend (Yamamoto et al., 1999).

We have fairly strong evidence that *Z*6,*Z*9-21Hy, identified in the sex pheromone gland of female painted apple moth, is indeed a pheromone component because omission of this component from the synthetic blend resulted in consistent decreases in trap catch in several trials. This compound has been previously identified in the sex pheromone glands of a number of geometrid, arctiid, and noctuid moths (Millar, 2000), and it has been implicated or proven to be a pheromone component in a number of these species (e.g., *Synegia esther* (Butler) (Ando et al., 1995)).

Overall, our data demonstrate that *Z*6,*Z*9-11-one-21Hy and *Z*6,*Z*9-21Hy appear to be critical components of the painted apple moth pheromone blend. However, the roles of the other components identified from pheromone gland extracts are not yet clear, because field cage bioassays and a field trial to test the effects of these components did not provide consistent and unequivocal results. Whereas the GC-EAD experiments show that the male moths detect these compounds, their possible roles as minor components of the pheromone blend remain to be elucidated.

Of the seven electrophysiologically active components observed, four chemical classes are represented: hydrocarbon *Z*6,*Z*9-21Hy, ketones *Z*6-11-one-21Hy, *Z*6,*E*8-11-one-21Hy, *Z*6,*Z*9-11-one-21Hy, epoxides *Z*6-9*R*,10*S*-epo-20Hy and *Z*6-9*R*,10*S*-epo-21Hy, and secondary alcohol *Z*6,*Z*9-11-ol-21Hy making the extracts of the sex pheromone gland of the painted apple moth a diverse chemical blend. All seven compounds appear to be derived from methylene-interrupted polyenes exhibiting, with the exception of *Z*6,*Z*9-21Hy and *Z*6,*Z*9-11-one-21Hy, a single oxidative modification/ rearrangement of one of the carbon-carbon double bonds.

In an attempt to evaluate the identified pheromone compounds for control of this pest, Suckling et al. (2002) investigated the potential use of the minor pheromone component *Z*6-11-one-21Hy alone for mating disruption. Only a moderate degree of mating disruption was achieved, suggesting that the major components or a more complete blend might be required in order to achieve an acceptable level of control. However, the instability of the major pheromone component may make it difficult to use sex pheromone based mating disruption against this pest. Currently, traps baited with live females are being used to monitor the distribution and dispersal of this insect in New Zealand. In this study, the synthetic blend was attractive for only two days, whereas live females remained attractive for up to seven days (Suckling et al., unpublished). Therefore, in the absence of a more stable formulation, live females should continue to be used for monitoring and detection of this pest in New Zealand. Work is underway to develop a more stable formulation of the synthetic pheromone.

Acknowledgments—We thank A. Barrington, (HortResearch, Mt. Albert) for rearing the insects, J. Daly and K. A. Moss (HortResearch, Lincoln), and J. Allan (HortResearch, Palmerston North) for technical assistance. We are grateful to G. Grant (Canadian Forestry Service, St. Sault Marie, Canada) for valuable discussion and for supplying a sample of *Z*6,*E*8-11-one-21Hy, and to J. Millar (University of California, Riverside, CA, USA) for supplying a sample of *Z*6-9*S*,10*R*-epo-20Hy. This work was supported by the New Zealand Ministry of Agriculture and Forestry (MAF) and underpinned by the Foundation for Research, Science and Technology (FRST). HortResearch staff are grateful for the Chairman's Award for Excellence for this work.

(Received April 12, 2004; accepted November 12, 2004)

Abstract—A single component in extracts of virgin female *Milionia basalis pryeri* moths elicited responses from male moth antennae. This compound (ca. 7 ng/female) was identified as (*Z*,*Z*)-(3*S*,4*R*)-3,4-epoxynonadeca-6,9-diene by GC-MS and NMR analyses, microchemical reactions, and comparative chiral HPLC. In a field test, synthetic (*Z*,*Z*)-(3*S*,4*R*)-3,4-epoxynonadeca-6,9-diene attracted male moths. The opposite enantiomer, the racemic mixture, and virgin female moths held in small cages attracted no more moths than the solvent controls.

Key Words—Sex pheromone, *Milionia basalis pryeri*, Geometridae, (*Z*,*Z*)-(3*S*,4*R*)-3,4-epoxynonadeca-6,9-diene.

INTRODUCTION

The geometrid moth *Milionia basalis pryeri* Druce (Lepidoptera: Geometridae) is found in Japan in southern Kyushu and the Amami and Ryukyu Islands (Okinawa),

* To whom correspondence should be addressed. E-mail: yasui@affrc.go.jp

and in Taiwan. This diurnal moth has a metallic blue body, blackish wings with an orange stripe on the forewings, and another orange stripe with black spots on the hindwings. The larvae of this species feed exclusively on the podocarp tree, *Podocarpus macrophyllus* (Podocarpaceae). *P. macrophyllus* is used as a building material, or as a street and garden tree in southern Japan. This tree contains substances toxic to some insect species (Ito and Kodama, 1976; Yasui, 2001), but *M. b. pryeri* has adapted to this plant and will occasionally cause significant damage to trees.

Control of this species is problematic. Large doses of synthetic insecticides are currently used (Gushiken et al., 1993). Biological control is likely to be ineffective because the larvae sequester toxic chemicals from the host plant (Yasui, 2001), and predation is rare. Therefore, we sought to identify the sex pheromone for potential use in control. In this paper, we report on the identification of the major sex pheromone component of *M. b. pryeri*, and the results of field trials with synthetic pheromone.

METHODS AND MATERIALS

Insects. M. b. pryeri larvae were collected from podocarp trees, *P. macrophyllus*, on Okinawa Is., Japan. The larvae were reared on podocarp leaves at 25°C and a 16L:8D photoperiod in the laboratory. Pupae were sexed and maintained in separate containers until emergence.

Extraction. Abdominal tips, including the pheromone gland, of 283 females at two or three days after emergence were excised with fine tweezers and soaked with hexane at ca. 10 tips/0.5 ml for 15 min. The extracts were filtered through a small wad of cotton, the residue was rinsed twice with the same volume of hexane, and the rinses were added to the extract. The extracts were accumulated and stored below −20°C until use.

Column Chromatography. Column chromatography was conducted on a silica gel column (particle size: 75–150 μm, Wako gel C-200, Wako Pure Chem. Ind., Ltd., Osaka, Japan). The crude extract from 270 female equivalents (FE) was concentrated to 150 μl and applied to 0.5 g of silica gel. Compounds were successively eluted with 2.5 ml of hexane, 2%, 5%, 15%, and 50% ether in hexane, and ether.

Gas Chromatography (GC) and Electroantennographic Detection (EAD). GC analyses were conducted on a Hewlett-Packard (HP) 5890 Series II (for GC-EAD) or HP 6890 (for quantitative analysis) gas chromatograph equipped with a flame ionization detector (FID). Injection was made with an on-column injector programmed at oven temperature plus 3°C. For GC-EAD, an HP-1 or HP-INNOWax fused silica column (15 m × 0.25 mm ID × 0.25 μm film thickness) was used with helium as the carrier gas at a column head pressure of 55 kPa

or 50 kPa, respectively. The GC oven temperature was held at 50°C for 1 min, increased from 50°C to 150°C at a rate of 20°C min^{-1}, raised to 270°C (HP-1) or 240°C (HP-INNOWax) at a rate of 5°C min^{-1} and then held at 270°C or 240°C for 5 min. The electroantennographic (EAG) response was obtained simultaneously with FID recording. The EAD was set up according to Struble and Arn (1984). For quantitative analysis, the HP-1 column was used with helium at an initial column head pressure of 67 kPa. The GC oven temperature was kept at 50°C for 1 min, increased from 50°C to 220°C at a rate of 25°C min^{-1}, and then held at 220°C for 2 min.

Coupled Gas Chromatography-Mass Spectrometry (GC-MS). GC-MS analyses were conducted with an HP 6890 gas chromatograph interfaced to a JEOL JMS SX-102A double focusing magnetic sector mass spectrometer (EI mode, 70 eV) and operated with an HP model 715/64 computer. The carrier gas was helium. The GC was operated under the same conditions and columns as GC-EAD, but in constant flow mode (1.6 ml/min). In some analyses, a mixture of normal alkanes with even numbers of carbon atoms from dodecane to octacosane was coinjected for calculation of retention indices.

High Performance Liquid Chromatography (HPLC). A) *Purification of the EAG-Active Component(s).* The EAG-active fraction (5% ether in hexane) of the female extract (220 FE) was further separated on an HP 1050 Series HPLC, equipped with a Chiralpak AD column (10 × 250 mm, Daicel Chemical Industry Co., Ltd., Tokyo, Japan), at room temperature. Peaks were monitored by UV-absorbance at 210 nm. The mobile phase was 0.1% 2-propanol in hexane, and the flow rate was 2.2 ml min^{-1}. Fractions were collected every 2 min from 2.0 min to 22.0 min. The fractions were analyzed with GC-MS. B) *Determination of the Stereochemistry of the EAG-Active Component.* The EAG-active fraction of the female extract (15 FE), synthetic (*Z*,*Z*)-(3*S*,4*R*)-3,4-epoxynonadeca-6,9-diene [(3*S*,4*R*)-isomer] (150 ng), and (*Z*,*Z*)-(3*R*,4*S*)-3,4-epoxynonadeca-6,9-diene [(3*R*,4*S*)-isomer] (150 ng) were analyzed on a Shimadzu 10ADVp system HPLC, equipped with a Chiralpak AD column (4.6 × 250 mm). Analysis was performed under the same conditions as above) but the flow rate was 0.45 ml min^{-1}. The absolute configurations of the first and second eluted compounds were assigned to be (3*S*,4*R*) and (3*R*,4*S*), respectively, by comparing the previously reported elution order using the same chiral HPLC column and conditions (Qin et al., 1997). The (3*S*,4*R*)- and (3*R*,4*S*)-isomers were eluted at 14.7 min and 15.4 min, respectively.

Nuclear Magnetic Resonance (NMR) Spectroscopy. NMR spectra were recorded at 303 K on a Bruker AVANCE800 spectrometer operating at 800.20 MHz (^1H) equipped with a 5 mm triple-resonance inverse probehead [$^1H/(^{13}C, ^{15}N)$]. ^1H-^1H-homodecoupling one-dimensional experiments were performed with presaturation technique. Spectra were measured in pyridine-d_5, using a 5-mm symmetrical

micro tube matched with methanol-d_4 (0.25 ml, Shigemi, Inc., Tokyo, Japan). The concentration of the sample was estimated to be ca. 1.5 μg/0.27 ml by comparison of the GC peak areas with docosane. The ^{1}H chemical shifts are given on the δ scale and referenced to the residual signal of partly un-deuterated solvent: δ (C_5HD_4N, H-2 and H-6) = 8.71 ppm.

Microchemical Reactions. A) *Diimide Reduction.* Polyenyl compounds were hydrogenated according to the method described by Yamaoka et al. (1976). A hexane solution containing the major EAG-active compound (ca. 20 FE), concentrated to about 5 μl in a 1-ml taper-bottomed vial, was combined with 10 μl each of hydrazine and hydrogen peroxide solution in ethanol (N_2H_4: 0.3 ml of hydrazine hydrate in 10 ml of ethanol, H_2O_2: 0.04 ml of 31% H_2O_2 in 10 ml of ethanol). The mixture was maintained at 55°C for 1 hr for complete hydrogenation. Then 2 μl of the reaction mixture was injected into the GC-MS. B) *Microozonolysis.* Microozonolysis was conducted according to Beroza and Bierl (1967). Ozone was bubbled into a ca. 10 μl hexane solution, containing the major EAG-active component (20 FE) cooled to −78°C, through a glass capillary tube for 1 min. Two μl of the reaction mixture was immediately injected into the GC-MS.

Chemicals. Racemic (*Z*,*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene was synthesized from linolenic acid, via epoxidation of (*Z*,*Z*,*Z*)-nonadeca-3,6,9-triene, (Ando et al., 1993). The (*Z*,*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene was separated from regioisomers with silica gel chromatography (Wako gel C-200, hexane, 0.5%, 0.7%, 1%, 1.5% ether in hexane, and the compound was eluted with 1% ether in hexane and later fractions).

Field Attraction. Field tests were conducted along podocarp hedges around a field of the Nago Branch of OPAES, in Nago, Okinawa, on 7 May, 2003. Tent-shaped sticky traps (white type, SE trap of Sankei Chem. Co., Kagoshima, 29 × 32 × 8 cm) with a 24 × 30-cm sticky bottom were used for field attraction.

Synthetic Chemicals. (*Z*,*Z*)-(3*R*,4*S*)-3,4-Epoxynonadeca-6,9-diene, its (3*S*,4*R*)-isomer, and the racemic mixture dissolved in hexane were dispensed onto one end, over a ca. 2 cm^2 area, of a 1 × 3-cm piece of filter paper (Toyo No. 2, Toyo Roshi Kaisya, Tokyo). A filter paper of the same size was treated with the same volume of hexane as an unbaited control. Immediately after the solvent evaporated, the treated papers were suspended about 2 cm above the sticky bottoms in traps at about 15:00 hr because the attraction of *M. b. pryeri* males occurred around 15:00–19:00 hr ($N = 5$). Virgin females in small mesh cages suspended in traps ($N = 3$) were used as positive controls. The traps were placed on stems of the podocarp trees, about 1 m above the ground, at 5-m intervals. Trap catches (X) were transformed to $(X + 0.5)^{1/2}$ and submitted to one-way analysis of variance. The means were ranked by Tukey's method.

RESULTS

GC and GC-EAD Analyses of the Female Gland Extract. The crude extract of 270 females was concentrated to ca. 150 μl, and ca. 0.5 μl of the extract (1 FE) was injected into the GC-EAD system. One distinct EAG-active component (peak A) was observed in conjunction with a number of FID peaks (Figure 1). The remaining crude extract was chromatographed on a silica gel column. The EAG-active component was eluted with 5% ether in hexane (the EAG-active fraction). In separate GC analyses, the amount of the component in the extracts was estimated to be 7 ng/female by comparison of FID peak areas, with 5 ng of docosane as an internal standard.

Identification of EAG-Active Component. The EAG-active fraction of the female extract (ca. 1 FE) was analyzed by GC-MS. The mass spectrum of the active compound showed a molecular ion at *m/z* 278 (relative intensity 7%, base peak: *m/z* 80), and diagnostic fragment ions at *m/z* 262 ($[M-16]^+$, 2%) and 260 ($[M-18]^+$, 8%), which suggested an unsaturated epoxide (Figure 2). Micro-scale reduction of ca. 100 ng of the component with diimide produced a single compound with a molecular ion at *m/z* 282 (M^+, 3%, base peak: *m/z* 83), 266 ($[M-16]^+$, 3%) and 253 ($[M-CH_3CH_2]^+$, 70%). The last ion indicated the position of an epoxy ring at C-3 and -4. The mass spectrum and retention values of the product were identical to those of authentic *cis*-3,4-epoxynonadecane. The ozonolysis of the EAG-active fraction containing ca. 100 ng of the EAG-active component and subsequent GC-MS analysis showed a mass spectrum typical of an aliphatic aldehyde, *m/z* 138 ($[M-18]^+$, 12%, base peak: *m/z* 57) and 128 ($[M-28]^+$, 14%), which was identical to that of decanal. Therefore, the position of one double bond was determined to be between C-9 and C-10.

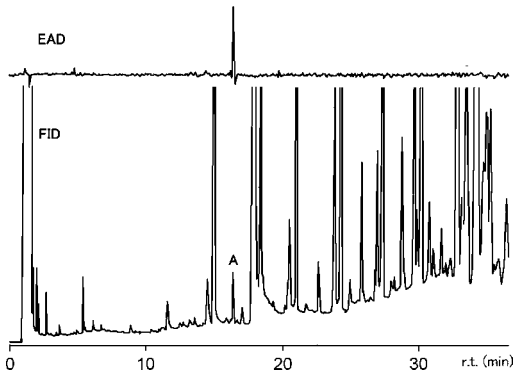

FIG. 1. GC-EAD chromatograms from analysis of hexane extract of abdominal tips of *M. b. pryeri* virgin females. A: FID peak corresponding to potent EAG response. HP-1 column, 15 m, FID:EAD = 1:1 split.

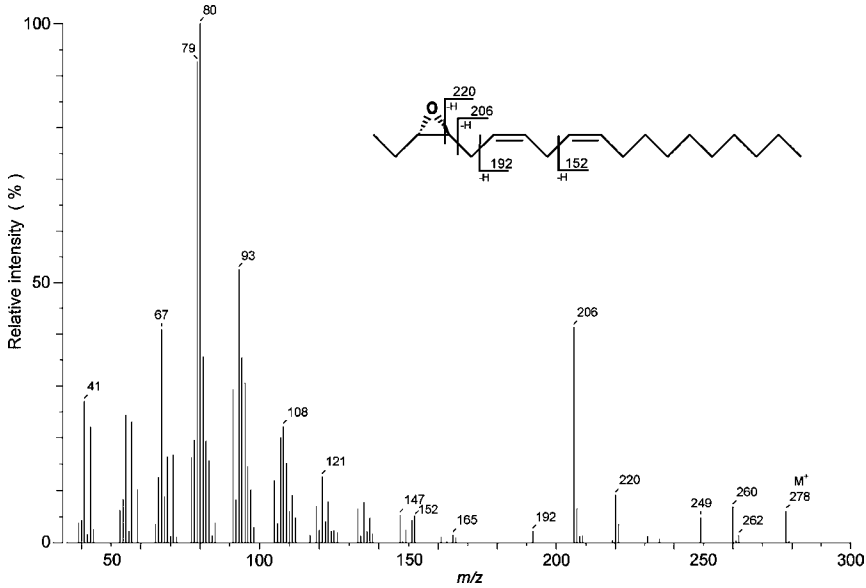

FIG. 2. EI mass spectrum and chemical structure of the major sex pheromone component in extracts of virgin *M. b. pryeri* females.

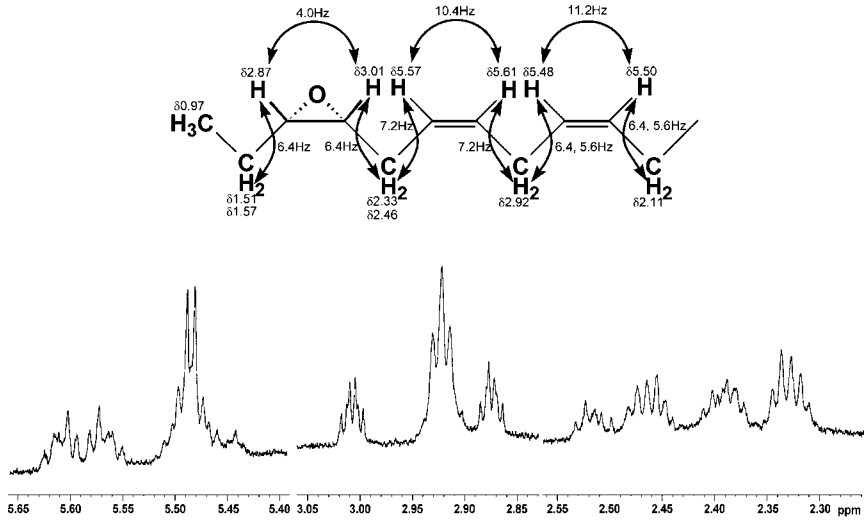

FIG. 3. ^{1}H NMR spectrum of the insect-produced pheromone component and the resulting partial structure. Signals at δ 2.39 and δ 2.52 are unrelated.

The ^{1}H NMR spectrum of the EAG-active component (220 FE, ca. 1.5 μg/pyridine-d_5 0.27 ml, Figure 3) indicated four olefinic protons (δ 5.45 − 5.65), in two pairs, with protons in each pair coupled to each other. The coupling constants between olefinic protons observed at δ 5.48 and δ 5.50, and δ 5.57 and δ 5.61, were determined to be 11.2 and 10.4 Hz, respectively, which indicated that the two double bonds had (*Z*)-configuration. The spectrum also showed the presence of two epoxide protons at δ 2.87 (1H, *dt*) and 3.01 (1H, *dt*), in which the coupling constant of 4.0 Hz confirmed a *cis*-epoxide structure (Silverstein et al., 1991). The decoupling experiments for all the olefinic protons, epoxide protons, and methylene protons next to double bonds or an epoxy ring revealed a partial structure with two double bonds and one epoxy ring (Figure 3). The correlation, starting from the epoxy ring, was as follows: a methylene group (δ 2.33 and δ 2.46) next to the epoxy ring (δ 2.87 and δ 3.01), then one double bond (δ 5.57 and δ 5.61) next to the methylene group (δ 2.33 and δ 2.46), another methylene group (δ 2.92, 2H) next to the double bond (δ 5.57 and δ 5.61), and then another double bond (δ 5.48 and δ 5.50) next to another methylene group (δ 2.92, 2H). The only possible structure of the active compound was, thus, (*Z*,*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene. The NMR and mass spectra of the natural epoxide were identical to those of the synthetic compound. The retention index values of the synthetic compound [KI = 2023 (HP-1), KI = 2386 (HP-INNOWax)] matched those of the natural component [KI = 2025 (HP-1), KI = 2386 (HP-INNOWax)].

Stereochemistry of Epoxydiene. (*Z*,*Z*)-*cis*-3,4-Epoxynonadeca-6,9-diene has two chiral centers, such that (3*S*,4*R*)- and (3*R*,4*S*)-enaitiomers are possible. Therefore, chiral HPLC analysis was performed to determine the stereochemistry of the natural component. The insect-produced epoxide eluted at 14.80 min, whereas the synthetic (3*S*,4*R*)- and (3*R*,4*S*)-enantiomers eluted at 14.75 and 15.25 min respectively. The retention times of the natural component and two synthetic enantiomers were replicated three times, confirming the natural component as the (3*S*,4*R*)-enantiomer.

Field Attraction of M. b. pryeri. Field tests were conducted with the synthetic (3*R*,4*S*)-enantiomer, (3*S*,4*R*)-enantiomer, the racemic mixture, virgin females, and a solvent control. The (3*S*,4*R*)-enantiomer attracted male moths, whereas all other treatments were no different from solvent controls (Figure 4). These results supported the identification of the (3*S*,4*R*)-enantiomer as the major sex pheromone component of *M. b. pryeri*. The male catch fluctuated greatly, for unknown reasons. The trap locations and/or conditions of females may have been factors.

DISCUSSION

Because *M. b. pryeri* is brightly colored and diurnal it was thought to use visual rather than olfactory cues in the mating system, as most butterflies

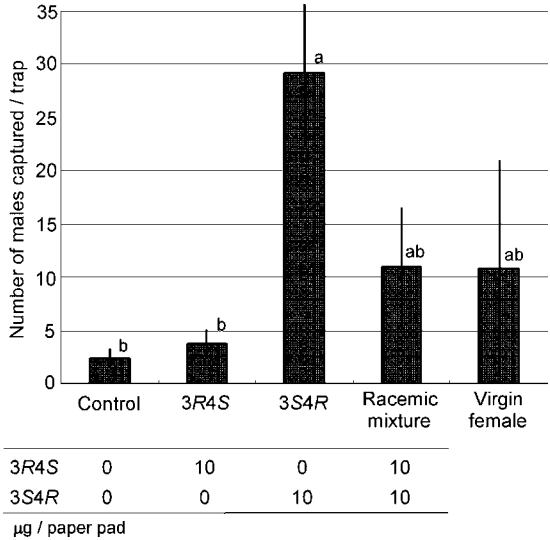

FIG. 4. Captures of male *M. b. pryeri* with synthetic (*Z*,*Z*)-(3*R*,4*S*)-3,4-epoxynonadeca-6,9-diene, (3*S*,4*R*)-enantiomer, the racemic mixture, and virgin females (in Okinawa, 2003). $N = 5$, virgin female: $N = 3$. Bar: S.E. Trap catches (X) were transformed to $(X + 0.5)^{1/2}$ and submitted to one-way ANOVA. The means capped with the same letters are not significantly different at the 5% level by Tukey's method.

do (Smith, 1989). In this study, however, we found that this species uses a sex pheromone analogous to other cryptically colored geometrid moths. (*Z*,*Z*)-(3*S*,4*R*)-3,4-Epoxynonadeca-6,9-diene appeared to be the only component in pheromone gland extracts that elicited EAG responses from antennae of males, and this compound attracted male moths. This compound is also a sex pheromone of other geometrid moths. For example, (*Z*,*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene has been reported as a major sex pheromone component of several species of geometrid moths (Becker et al., 1990; Millar et al., 1990; Cossé et al., 1992; Szöcs et al., 1993; Ando et al., 1997). The (3*S*,4*R*)-enantiomer has been identified as a sex pheromone component of *Agriopis aurantiaria* (Szöcs et al., 1993) and the giant looper, *Boarmia (Ascotis) selenaria* (Becker et al., 1990; Cossé et al., 1992). Those two species and *M. b. pryeri* use the same pheromone component, but have disjunct geographic distributions: *A. aurantiaria* is found in Central Europe (Szöcs et al., 1993), *B. selenaria* is found in Israel (Cossé et al., 1992), and *M. b. pryeri* is native to south Japan and Taiwan.

In contrast, with *A. aurantiaria*, the pure (3*S*,4*R*)-enantiomer attracted males, but a racemic mixture or the (3*R*,4*S*)-isomer attracted few males (Szöcs et al., 1993). In another example, male *Probole amicaria* moths were more attracted

when a second component was added to racemic (*Z*,*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene (Millar et al., 1990). The possible effect of minor components in pheromone gland extracts on mating behavior of *M. b. pryeri* is now under investigation.

Furthermore, the (3*R*,4*S*)-enantiomer is a sex pheromone component of the Japanese giant looper, *Ascotis selenaria cretacea* (Ando et al., 1997). Although *A. s. cretacea* females produce both the (3*S*,4*R*)- and (3*R*,4*S*)-enantiomers in a 53:47 ratio, only the (3R,4S)-enantiomer appears to act as a sex pheromone.

Acknowledgments—We thank the staff of the Nago Branch of OPAES for the use of their field for our experiments. We also thank Makoto Hattori of NIAS, Tadakazu Nakashima of the Forestry and Forest Products Research Institute, Minoru Narahara of the Oita Prefectural Citrus Experiment Station, Takeshi Fukuda of the Kagoshima Agricultural Experiment Station for graciously giving us podocarp leaves, and Ikuko Maeda of NFRI for measurement of the NMR spectra. Thanks are also due to Serge Glushkoff for editing the manuscript.

Abstract—The leaf beetle *Diorhabda elongata* Brullé (Coleoptera: Chrysomelidae) has been introduced as a biological control agent for saltcedars, *Tamarix* spp., an exotic, invasive weedy tree in the western United State. Gas chromatographic (GC) analysis of volatiles collected from feeding male or female beetles, or saltcedar foliage alone, showed two components produced almost exclusively by males. These compounds elicited responses from antennae of male and female beetles in GC-electroantennographic detection (EAD) analyses. The compounds were identified as (2*E*,4*Z*)-2,4-heptadienal (**1**) and (2*E*,4*Z*)-2,4-heptadien-1-ol (**2**) by GC-mass spectrometry (MS), and confirmed with authentic standards. The two compounds were also detected at trace levels from feeding females and foliage controls, but the amounts from feeding males were 8–40 times higher, typically 55–125 ng per day per male. The amounts of **1** and **2** in collections from females did not differ significantly from amounts collected from control foliage. In field trials, **2** as a single component was as attractive as a 1:1 blend of **1** and **2**. Compound **1** as a single component was more attractive than controls, but much less attractive than **2** or the blend. Males and females

were attracted in about equal numbers, indicating that this is an aggregation pheromone.

Key Words—*Diorhabda elongata*, Coleoptera, Chrysomelidae, aggregation pheromone, saltcedar, *Tamarix ramosissima*, (2*E*,4*Z*)-2,4-heptadienal, (2*E*,4*Z*)-2,4-heptadien-1-ol, biological control.

INTRODUCTION

Saltcedar (*Tamarix* spp.) is an exotic invasive weedy tree causing up to $285,000,000 of damage per year in water loss due to transpiration and flood damage due to stream channel alteration (Zavaleta, 2000). The invasion of *Tamarix* into riparian areas in the western United States has also caused ecosystem damage that is more difficult to quantify, such as decreased habitat quality for wildlife and native plant species, increased soil salinity, and increased fire risk (Deloach et al., 2000). Efforts to control saltcedar through conventional means such as herbicides or physical removal have been expensive and of limited success. For this reason, a multistate biological control program was initiated in the 1980's (Deloach, 1989). Currently, the only approved and released biological control agent is the leaf beetle *Diorhabda elongata* Brullé (Coleoptera: Chrysomelidae). A release made at Lovelock, Nevada, during 2001 has become particularly well established.

The beetles overwinter as adults in leaf litter and emerge in the spring (typically in May at Lovelock, NV) when saltcedar starts to produce new foliage. Eggs are laid on the foliage. The larvae feed on the leaves, and then pupate in the soil. There are two generations per year at Lovelock, with new adults emerging in July and again in August. Adults from the second generation enter overwintering diapause (DWB, unpublished; Deloach et al., 2004).

One important need in a biological control program is to be able to monitor the beetle populations accurately in the field, and a tool based on the pheromone of the beetles could serve this need. A pheromone-based monitoring system could be useful for studying population attributes such as dispersal rate and distance, local survival, abundance relative to habitat properties, and times of adult activity during the year. Such information can be difficult to obtain with standard sampling methods, especially when the population is sparse. Even in areas with high population density and heavy defoliation, pheromone-based monitoring in surrounding areas could yield information on the behavior of dispersing beetles.

Only a small number of chrysomelid beetle pheromones have been identified from the more than 1,400 chrysomelid species known from North America north of Mexico (Arnett, 1993), but both male- and female-produced long-range pheromones exist within the family. The pheromones are chemically diverse and can consist of either single compounds or blends. The first chrysomelid pheromone

to be chemically identified was that of the western corn rootworm, *Diabrotica virgifera virgifera* LeConte (Guss et al., 1982). This pheromone is emitted by female beetles and attracts only males. Chemically related, female-produced sex pheromones were subsequently defined for eight *Diabrotica* species and subspecies (summarized by Krysan et al., 1989). These pheromones all consist of methyl-branched esters or ketones.

In contrast, recent studies of chrysomelid chemical communication systems have found only male-produced aggregation pheromones. For example, six male-specific sesquiterpenes were identified from the flea beetle *Phyllotreta cruciferae* Goeze (Bartelt et al., 2001), and a blend of the synthetic compounds was shown to be attractive under field conditions both in Canada and Hungary (J. Soroka, M. Tóth, and R. Bartelt, unpublished). Male-produced aggregation pheromones have been subsequently reported from two other chrysomelid species, the cereal leaf beetle, *Oulema melanopus L.* (Cossé et al., 2002, Rao et al., 2003), and the Colorado potato beetle, *Leptinotarsa decemlineata* Say (Dickens et al., 2002). Chemically, the latter pheromones are unusual hydroxy ketones. In addition, male-produced sesquiterpenes that elicit antennal responses have been identified in three *Aphthona* species (Bartelt et al., 2001)

In the present study we report the identification of two male-produced components of the aggregation pheromone in *D. elongata*.

METHODS AND MATERIALS

Insects. D. elongata adults used in this study were obtained from a colony maintained at the USDA-ARS Exotic and Invasive Weed Research Unit, Albany, CA, USA. The beetles originated from sites near Fukang, in the Xinjiang province of northwestern China (DeLoach et al., 2003, Lewis et al., 2003). Upon arrival in Peoria, IL, adult beetles were kept at 25°C under a 17L:7D h photoperiod. *Tamarix ramosissima* Ledebour (Tamaricaceae) was grown year round in a greenhouse facility at NCAUR to provide food for the beetles.

Volatiles Collections. Initial volatiles collections were made to demonstrate and identify the pheromone, followed by additional collections to quantitate the pheromone emissions.

Beetles (7 to 10 d old) were sexed by inspection of the ventral side of the abdominal tip. A dark internal spot is visible through a sternite in females, and males have a v-shaped indentation at the apex of the last abdominal segment. Volatiles collections were made from individuals and groups of 10 male or female beetles feeding on saltcedar foliage, and from foliage alone. The beetles were placed into a horizontal glass tube (5 cm ID $\times$ 20 cm in length) containing a piece of saltcedar foliage (approx. 15 cm long) with the cut end in a small water vial. A Teflon seal in the cap of the vial kept the water from spilling. Collector equipment

and general volatiles collection procedures were reported earlier (Cossé et al., 2002).

Collections were made in an incubator (25°C, 17L:7D) and volatiles were collected on Super-Q traps (80–100 mesh, Alltech, Deerfield, IL) with an airflow-rate of 100 ml/min. Foliage was replaced daily, and any dead beetles in the collectors were replaced with fresh ones. Collected volatiles were eluted from the traps into vials using methylene chloride (300 μl) every 2–3 d. 1-Octanol (10 μl of a hexane solution containing 25 ng/μl) was added to each vial as a quantitative internal standard. Early in the project, trap breakthrough was evaluated by placing a second Super-Q trap in series with the first. Only compounds of six or fewer carbons were detected in the breakthrough trap.

Electrophysiology. Coupled gas chromatographic-electroantennographic (GC-EAD) analyses were made by methods and equipment generally described by Cossé and Bartelt (2000). GC-EAD connections were made by inserting a glass pipette silver-grounding electrode into the back of an excised beetle head. A second glass pipette silver-recording probe was placed in contact with the distal end of one antenna. Both pipettes were filled with Beadle-Ephrussi saline (Ephrussi and Beadle, 1936).

Instrumentation. Extracts were analyzed by GC with flame-ionization detection (GC-FID) and coupled GC-mass spectrometry (GC-MS). Samples were injected splitless using Hewlett Packard 6890 (Palo Alto, CA) instruments fitted with 30 meter DB-1 or DB-5 capillary columns (0.25 mm I.D., 0.25 μm or 1.0 μm film thickness, J&W Scientific, Folsom, CA). Temperature programs were from 50°C to 275°C at 10°C per min. Inlet temperatures were maintained at 250°C and GC-EAD effluent interface from the post-column splitter was kept at 275°C. Mass spectrometry was performed using an HP 5973 instrument (electron impact, 70 eV). The Wiley mass spectral library, with 275,821 spectra, was available on the MS data system (Wiley, 1995).

HPLC purification was carried out on synthetic heptadienals to separate geometrical isomers. A silica column (Econosphere Silica, 5-μm particle size, 4.6 × 250 mm, Alltech, Deerfield, IL), treated with silver nitrate (Heath and Sonnet, 1980), was used for this purpose. The solvent was benzene:hexane (1:1). The pump was a Waters 515 (Milford, MA) (flow-rate 1 ml/min), and the detector was a Waters R401 differential refractometer.

^{1}H-NMR spectra ($CDCl_3$) were obtained on a Bruker Avance 400 MHz instrument (Billerica, MA).

Analysis of Commercial Heptadienals. Initial GC-MS analysis suggested that one male-specific compound was identical to a minor (ca. 5%) constituent of commercial (2*E*,4*E*)-2,4-heptadienal. A sample of this minor compound was purified by HPLC (250 μg per injection, 10 injections) for identification by NMR. The target compound was recognized in HPLC fractions by GC retention. In preparation for NMR, the combined sample in benzene/hexane was applied to a

small open-column of silica gel (0.5 × 3 cm), which was then eluted with pure hexane to remove the benzene and finally with redistilled diethyl ether to recover the aldehyde. The ether solution was evaporated under a gentle stream of nitrogen and $CDCl_3$ was added.

Quantitation. The amounts of (2*E*,4*Z*)-2,4-heptadienal (**1**) and (2*E*,4*Z*)-2,4-heptadien-1-ol (**2**) in the volatiles collections were quantified by GC-MS in selected ion monitoring (SIM) mode. Two ions were monitored for both **1** and **2** (*m*/*z* 81 and 110 for **1**; *m*/*z* 83 and 112 for **2**). The selected ions for the internal standard, 1-octanol, were *m*/*z* 70 and 84. Quantitation was based on ions *m*/*z*, 110, 112, and 84, whereas ions at *m*/*z* 81, 83, and 70 served as qualifiers (proper ion ratios would support compound identity and purity in the GC peaks). Serially diluted solutions of synthetic **1**, **2**, and 1-octanol (0.01 ng/μl −30 ng/μl) were analyzed by GC-MS in SIM mode to obtain linear calibration curves (log dose vs. log abundance), which served as the basis of the quantitation. In SIM mode, **1** and **2** were still easily detectable at concentrations as low as 10 pg/μl.

Chemicals. Compounds **1** and **2** were synthesized according to Petroski (2003). The purities were checked by GC and found to be >95%; impurities were other geometrical isomers. Samples of (2*E*,4*E*)-2,4-heptadienal and (2*E*,4*E*)-2,4-heptadien-1-ol were obtained from Bedoukian (Danbury, CT).

Field Lures. The lures for 2003 consisted of a 1:1 mixture of **1** and **2** (500 μg of each component). These were prepared by adding solutions (50 μg/μl) of synthetic **1** and **2** in methylene chloride to mineral oil (250 μl) in 1.5-ml glass vials. Vials were sealed with Teflon disks, held in place by caps with central holes for use with septa (SRI, Eatontown, NJ). The vials were wrapped in aluminum foil to afford UV protection. A wire, wrapped around at the base of the cap, was used to secure the lure to a trap. Prior to field deployment, the Teflon disks were pierced with a single pinhole to allow compound release from the headspace. Vials were kept upright in the field. The lures for 2004 were prepared as above except that **1** and **2** were used at 2.5 mg each per vial, and additional lures had just **1** alone (2.5 mg) or **2** alone (2.5 mg).

The emission rate of **1** and **2** was measured from a freshly prepared lure (1:1 mixture of **1** and **2**, 500 μg of each component) in an incubator. The vial was placed in a volatiles collector at 25°C with an air flow-rate of 100 ml/min. Volatiles were collected daily for a period of 5 d and the release rates of **1** and **2** were measured by GC-FID using 1-octanol as the quantitative internal standard. Compounds were released in a ratio of nearly 1:1 and at a rate of about 7 μg/day for each compound. Emission was consistent over 5 d. Less than 1% degradation of the aldehyde to the more stable all-*E* isomer was found.

Field Study. The experiments were carried out in saltcedar stands along the Humboldt River (40°01′N, 118°31′W) 17 Km southwest of Lovelock, NV, where a population of *D. elongata* has been established (DeLoach et al., 2004). Two types of experiments were carried out.

The first set was a pair-wise comparison of a 1:1 mixture of **1** and **2**, using five lures of 500 μg of each component, and unbaited controls, on July 15 and August 10, 2003, when newly emerged beetles were present. The 2003 experiments were carried out in saltcedar stands with relatively little defoliation. This experiment was repeated, using single lures of the same total dosage, on May 4, 2004, when the overwintered beetles were becoming active. The 2004 site had experienced complete defoliation late in 2003, and little foliage was present on these weakened trees during the pheromone trial. The numbers of replications per treatment for the three experiments were 20, 15, and 22, respectively.

The second experiment measured the effects of the individual compounds and was set up on May 5, 2004. Treatments were a 1:1 mixture of **1** and **2**, **1** alone, **2** alone (all at 2.5 mg per component), and an unbaited control. A randomized complete block design was used (four traps per block), and there were 20 replicates of each treatment.

Traps were placed in trees that were about 10 m apart and similar in size, foliage density, and in accessibility to beetles flying from downwind (the prevailing wind at the site was from the west). There were always other saltcedar trees in the vicinity of the trap trees and usually between them as well. Yellow sticky traps (15.5 $\times$ 30.5 cm, AgriSense, Pontypridd, UK) were attached to branches (oriented vertically) in the upper half of the trees, typically at a height of 2–4 m, and every effort was made to place traps at nearly the same height. The higher locations were accessed by bending branches to within reach. Foliage or defoliated branches surrounding the traps were removed as needed so that there was a clear "flight path" to the trap. The protective paper was removed only from one side of the trap, so that the sticky side was oriented downwind. The choice of which trap would receive a particular treatment was made randomly by coin flip. The dispensers were activated when they were attached to the traps by making a pin hole in the Teflon seal.

Traps were set out in mid afternoon, when flight activity usually began to increase. They were then examined at intervals of about 2 h, and counts of beetles were recorded. The next morning, the traps were removed. Final counts were made and the beetles trapped on July 16 were saved for determination of sex.

Statistics. Amounts of compounds **1** and **2** collected from the beetles and foliage controls were submitted to analysis of variance (ANOVA) using Statistix for Windows software (Analytical Software, 1998). The amount data were transformed to a log scale to stabilize variance. The composition data (amount of **1** as a percentage of **1** + **2**) were submitted to ANOVA without transformation. For the field test, counts of *D. elongata* adults on traps were transformed using log (X + 1) to stabilize variance. The data from the pair-wise experiments were analyzed by paired *t*-tests, and data from the randomized complete block design were submitted to analysis of variance (ANOVA) and means were compared using the least significant difference (LSD) test.

RESULTS

Volatiles Collections. By GC comparison of volatiles extracts, males of *D. elongata* feeding on saltcedar emitted two compounds, **1** and **2**, that were not immediately obvious in volatiles extracts from females feeding on saltcedar or saltcedar foliage alone (Figure 1). The unlabeled peaks in Figure 1 were primarily saltcedar volatiles, based on GC-MS comparisons to uninfested plant materials.

Spectral Analysis and Identification. Mass spectra of the two male-emitted compounds indicated molecular weights of 110 for **1** and 112 for **2**. A search of the mass spectral library indicated close matches with (2*E*,4*E*)-2,4-heptadienal and (2*E*,4*E*)-2,4-heptadien-1-ol for **1** and **2**, respectively. Commercial samples of the aldehyde and alcohol closely matched the mass spectra of **1** and **2**, but their retention times were slightly later than the natural materials, indicating that **1** and **2** were probably geometrical isomers of the all-*E* standards. Fortuitously, the commercial sample of (2*E*,4*E*)-2,4-heptadienal contained an impurity (approx. 5%) whose mass spectrum, polarity (elution from open silica column with 10% ether in hexane) and retention time matched that of the natural aldehyde **1** exactly.

The impurity was isolated by HPLC ($AgNO_3$ on silica) and analyzed by ^{1}H-NMR. The configurations of the double bonds in the aldehyde impurity were determined based on vicinal coupling constants for the olefinic protons. The

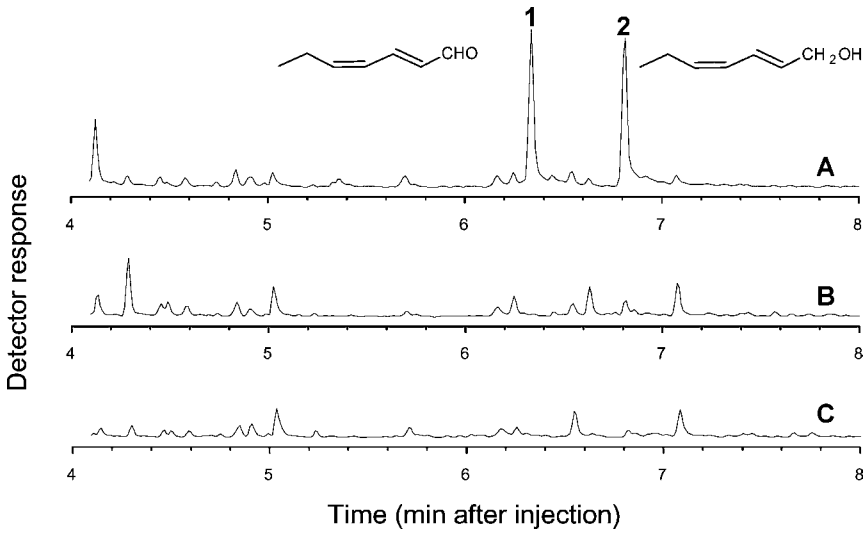

FIG. 1. Gas chromatographic profiles of volatiles collected from feeding *D. elongata*. A) males feeding on saltcedar foliage; B) females feeding on saltcedar foliage; C) saltcedar foliage control.

aldehydic proton (δ 9.61, 1H, d, $J_{1-2} = 8.0$, H-1) was coupled to one of these (δ 6.15, 1H, dd, $J_{1-2} = 8.0$, $J_{2-3} = 15.2$, H-2), and the magnitude of J_{2-3} established that the double bond in the 2 position had the *E* configuration (Williams and Fleming, 1980). The configuration of the second double bond was determined from the olefinic proton adjacent to the terminal ethyl group (δ 5.99, 1H, dt, $J_{4-5} = 10.7$, $J_{5-6} = 7.8$, H-5), and the magnitude of J_{4-5} indicated the *Z* configuration (Williams and Fleming, 1980). The other two olefinic protons (δ 7.44, 1H, dd, $J_{2-3} = 15.2$, $J_{3-4} = 11.5$, H-3; and δ 6.23, 1H, apparent br t, J_{3-4} and $J_{4-5} \cong 11$, H-4) were consistent with the above conclusions. The value of J_{3-4} also supported the conjugated diene system (Williams and Fleming, 1980). Thus, the configuration of the impurity and, therefore, of **1**, was 2*E*,4*Z*. Several of the olefinic proton signals were broadened by long-range allylic coupling. The ethyl group protons were observed (δ 2.39, 2H, apparent quin, J_{5-6} and $J_{6-7} \cong 7.5$, H-6; δ 1.11, 3H, t, $J_{6-7} = 7.5$, H-7).

The synthetic (2*E*,4*Z*)-2,4-heptadienal (**1**) was reduced with $LiAlH_4$ to give (2*E*,4*Z*)-2,4-heptadien-1-ol (**2**). The mass spectrum and retention time of this alcohol matched those of natural **2** exactly. Therefore, the two male-specific compounds were identified as (2*E*,4*Z*)-2,4-heptadienal (**1**) and (2*E*,4*Z*)-2,4-heptadien-1-ol (**2**) and subsequent synthesis of the two compounds further confirmed these identifications (Petroski, 2003).

A few of the extracts of male volatiles that showed relatively large amounts of **1** and **2** indicated the presence of at least two additional male-specific compounds (<1% of the total of **1** + **2**). These compounds eluted earlier from the GC columns than **1** and **2**, but they did not elicit antennal responses, and the small amounts available did not allow a more detailed examination.

Further examination of volatiles extracts from female beetles feeding on foliage and foliage controls by GC-MS did reveal trace amounts of **1** and **2**, based on both GC retention times (5.04 and 5.20 min, respectively) and mass spectra.

Electrophysiology. GC-EAD analysis of extracts of volatiles from male beetles feeding on saltcedar foliage showed that natural **1** and **2** were readily detected by the antennae of both sexes. Similar results were obtained for the synthetic materials (Figure 2). GC-EAD analysis supported the existence of **1** in volatiles from uninfested and female-infested saltcedar foliage. Antennal responses at the retention time for **1** (5.04 min) was observed in several cases in the initial analyses of female- and foliage-derived samples, and when such samples were combined and concentrated, antennal responses to **1** were observed more consistently. However, the presence of **2** (retention time, 5.20 min) in collections from foliage or feeding females was not verified by GC-EAD, presumably because the even lower amounts were below the antennal response threshold.

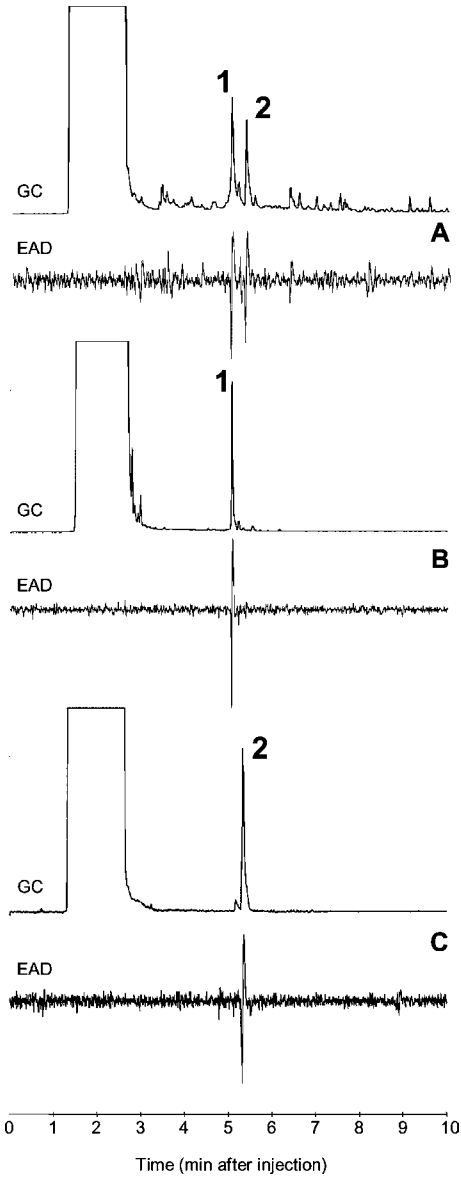

FIG. 2. Simultaneously recorded gas chromatogram (GC) and electroantennographic detection (EAD) of: A) female antenna responding to volatiles collected from male *D. elongata* feeding on saltcedar, including **1** and **2**; B) male antenna responding to synthetic **1**; C) male antenna responding to synthetic **2**.

Synthetic (2*E*,4*E*)-2,4-heptadienal and (2*E*,4*E*)-2,4-heptadien-1-ol were also detected by the antennae of both sexes (GC-EAD) when sufficient amounts of these isomers were injected (25 ng for each compound).

Emission Rates. Amounts of compounds **1** and **2** collected per day are shown in Table 1 for both sexes, and both densities (grouped and single) and for uninfested foliage. The amounts in the table are expressed both on a per-tube and a per-beetle basis, for comparison. Compounds **1** and **2** were obvious within days of placing new male beetles in the collection apparatus, and emission continued as long as the beetles lived (approx. 30 d) with fairly constant component ratios.

On a per-beetle basis, amounts of **1** and **2** from tubes with males were always significantly higher than from tubes with females (LSD, $P < 0.05$ level). Groups of males emitted significantly more of **1** and **2** compared to single males, but the trace amounts of **1** and **2** collected from tubes with grouped females did not differ significantly from those kept as individuals. The maximum amount of **1** and **2** collected from a single male was 1.57 μg/d.

Expressing amounts of **1** and **2** on a per-tube basis allowed the effect of foliage to be considered in comparisons, as well as beetles. The amounts of **1** and

TABLE 1. EMISSION OF (2*E*,4*Z*)-2,4-HEPTADIENAL (**1**) AND (2*E*,4*Z*)-2,4-HEPTADIEN-1-OL (**2**) BY SINGLE AND GROUPED (USUALLY 10) *D. elongata adults*

		Emission rate (ng/tube/day)			Emission rate (ng/beetle/day)

[2]Untranformed (log mean ± one standard deviation).

2 emitted by grouped males were dramatically higher than all other treatments, and the amounts from tubes with single males were higher than all treatments with females or foliage alone, except that the difference from grouped females was not significant. The amounts of **1** and **2** from tubes with females did not differ from those collected from the saltcedar foliage.

Considering composition, the percentage of **1** (relative to **1** plus **2**) was significantly lower in extracts from males than with the female or foliage-only extracts (Table 1). However, the percentage of **1** in extracts from females did not differ significantly from that found with uninfested foliage.

Field Study. Trapping experiments demonstrated the attractiveness of the two male-specific compounds to *D. elongata* in the field on four different dates with two different populations (Table 2). Significantly more adult *D. elongata* were trapped on traps baited with **1**, **2**, and a 1:1 mixture of **1** and **2** compared to the control traps.

However, compound **2** as a single component was as attractive as the 1:1 blend of the two components, whereas compound **1** as a single component was only weakly attractive (Table 2).

Male and female beetles were about equally attracted to the two component mixture. July 16, 2003 saw a total of 945 adults on the baited traps, with a male: female sex ratio of 1.1: 1; control traps caught a total of 351 beetles with a male: female sex ratio of 1.4: 1. Nearly all of the trapped beetles were caught between mid-afternoon and twilight, during the peak of flight activity. There was no evidence for beetles being caught between twilight and the final trap count the following morning.

DISCUSSION

Analysis of extracts of volatiles demonstrated that male *D. elongata* emitted two components, (2*E*,4*Z*)-2,4-heptadienal (**1**) and (2*E*,4*Z*)-2,4-heptadien-1-ol (**2**), which were sensed by antennae of both males and females.

However, in field trials, **2** was much more attractive than **1**, and **2** as a single component was as attractive as a 1:1 blend of **1** and **2**. Thus, the role of **1** as a component of the pheromone blend is not yet clear. Further trials with different blend ratios may reveal an additive or synergistic role for it in the blend. The synthetic pheromone attracted approximately equal numbers of males and females, indicating that it is an aggregation pheromone rather than a sex pheromone.

These compounds are quite different from previously described chrysomelid pheromones (see introduction), being smaller in size and simpler in structure (i.e., without branches or rings). Indeed, the compounds were overlooked in the early stages of this study because of their similarity to the well known, six-carbon "green leaf volatiles" (Visser and Avé, 1978).

An unusual result in this study is that compounds identical to the pheromone components could be found at trace levels in collections from feeding females and from the host plant. Of these two, the data suggest that the foliage is the actual source, rather than the females, because the collections from single, feeding females were essentially the same as collections from uninfested foliage. The collections from groups of females had significantly greater total amounts of the compounds than collections from single females, but on a per-beetle basis, the group collections did not differ significantly from the single beetles. A likely explanation is that the greater amount of feeding activity by groups of females led to a greater release of plant volatiles, including **1** and **2**. Further evidence for a foliar origin of the compounds in the collections from females is that a ratio of **1** and **2** was essentially the same as in the foliage, but was quite different from the collections from males.

It is not surprising that damaged foliage might emit aldehyde **1** because this compound is known to be an autoxidation product of the ubiquitous biochemical, linolenic acid (Frankel, 1998 and references therein). The more remarkable situation is that the amounts were so much higher when males were feeding on that foliage, and that the component ratios of **1** and **2** were so different from when males are absent, indicating that males exert a great deal of control over the emission of the compounds. Beyond the greater amounts and different ratios noted above, compound emission is closely linked to the physiology of the males and to their environment. For example, males induced to enter overwintering reproductive diapause by short daylength do not emit or induce the production of **1** and **2** (although they continue to feed), and a day/night emission rhythm has been observed in reproductive males. Furthermore, strains of beetles of various geographic origins also produce different, characteristic ratios of components **1**

and **2**. These (presently unpublished) examples of control over emission lead us to believe that males produce the pheromone within their bodies rather than inducing the host plant to emit them, despite the superficial similarity of the pheromone components to green leaf volatiles.

In the future, different doses and ratios of the two components should be tested in the field to determine whether alternative responses are possible. In addition, the blend/single component experiment should be repeated in areas with various degrees of defoliation, various population densities, and at various times of the year to further assess the effects of the single components and competition from natural sources of **1** and **2**. Also, volatiles collections in which components **1** and **2** were relatively abundant had additional, minor male-specific compounds, and the possible behavioral effects of these additional components remains to be evaluated. Finally, GC-EAD analysis indicated that some saltcedar derived compounds elicited antennal responses. Whether host odor is necessary for optimal field response will have to be studied, particularly as synergism between aggregation pheromones and host-related volatiles is known in the Chrysomelidae (Metcalf and Metcalf, 1992; Pivnick et al., 1992).

A pheromone-based monitoring system will be useful for studying several population attributes of *D. elongata*. The field results demonstrated the potential of using the synthetic pheromone for monitoring field populations of *D. elongata*, with the added benefit that both sexes can be monitored.

Acknowledgments—We thank David Weisleder for assistance in obtaining NMR spectra. We also thank David Laclergue, Tammy Wang, and Meghan Ware for assistance in the maintenance of *D. elongata* colonies and for help in monitoring traps in the field.

(Received April 8, 2004; revised September 18, 2004; accepted September 29, 2004)

Abstract—The big-handed brachyuran crab *Heterozius rotundifrons* extends the time spent in its anti-predator posture, limb extended posture, if exposed to chemical cues from crushed conspecifics. In this study, we tested whether crabs also respond to chemical cues from crushed heterospecific crabs, and if so, whether phylogenetic relations or ecological overlap is more important in influencing the duration of the anti-predator posture. Chemical cues from two other brachyuran crabs (*Cyclograpsus lavauxi* and *Hemigrapsus sexdentatus*), which do not overlap directly in ecological distribution with *H. rotundifrons*, elicited a duration of the anti-predator posture that was indistinguishable from that produced by conspecific chemical cues. In contrast, chemical cues from two anomuran crabs (*Petrolisthes elongatus* and *Pagurus novizealandiae*) that overlap in ecological distribution with *H. rotundifrons*, elicited durations of the antipredator posture that were significantly shorter than those of either conspecifics or more closely related crab species. Thus, phylogenetic relationship seems to be more important than ecological overlap in influencing anti-predator behavior in *H. rotundifrons*.

Key Words—*Heterozius rotundifrons*, alarm cues, heterospecific, ecological context, phylogenetic history, crabs

INTRODUCTION

Virtually all species of animals tested show an increase in anti-predator behaviors when chemical cues from an injured or crushed conspecific are detected (Smith,

* To whom correspondence should be addressed. E-mail: bhazlett@umich.edu

1992; Chivers and Smith, 1998; Wisenden, 2000). Because the execution of anti-predator behavior results in a decrease in successful predation (Mathis and Smith, 1993; Mirza and Chivers, 2001), it is not surprising that selection has favored lineages that respond to cues from damaged conspecific individuals. In some species, responses to cues from damaged heterospecific individuals also occur (Wisenden et al., 1999; Chivers, 2002; Mirza and Chivers, 2003). Given the generalized diet of many predators, it is reasonable to predict that prey would be selected to utilize any information that indicates elevated risk of predation.

While it is clear that some prey learn to recognize heterospecific cues (Brown and Chivers, In Press), the literature on the use of heterospecific cues is mixed as to whether phylogenetic relationship or ecological overlap is more important in determining what cues are utilized by prey. That is, do prey treat cues from more closely related animals as good indicators of predation risk or is the extent to which animal species overlap ecologically a stronger determinant of cue utilization? Learning cues would mandate experience, and, thus, ecological overlap, while related species might release similar cues to those released by damaged conspecifics, and be innately recognized.

Individuals of the Australian hermit crab *Clibanarius infraspinatus* responded to haemolymph from two congeners (*C. taeniatus* and *C. virescens*) just as strongly as to conspecific haemolymph but responded more weakly to haemolymph from the distantly related diogenid hermit crab *Diogenes avarus* (Hazlett, 1996) even though *D. avarus* overlaps in microdistribution with *C. infraspinatus* and *C. virescens* does not. Rittschof et al. (1992) reported individuals of the hermit crab *C. vittatus* did not respond at all to cues from *Pagurus* species (different families) even though they overlap in microdistribution. The *Pagurus* species each responded most strongly to fluids from conspecifics, less strongly to congeneric fluids and even less to fluids from *C. vittatus* (Rittschoff et al., 1992).

In contrast, Mirza and Chivers (2003) found that minnows respond to cues from injured damselfly larvae (obviously unrelated) but only when the minnows are small and in the same prey guild as damselfly larvae. In this case, ecological context appears more important than phylogenetic relatedness. Stenzler and Atema (1977) found that three species of the mud snail *Nassarius* responded to each others alarm substance, responded strongest to conspecific substance, but did not respond to cues from other gastropod genera. However, one species, *N. trivittatus*, responded to the sympatric, but taxonomically not closely related, *Urosalpinx cinerea* (Stenzler and Atema, 1977). Mirza and Chivers (2003) cite a number of cases in both aquatic and terrestrial systems where similarities in ecology appear to be more important than degree of relatedness.

Individuals of crayfish species in Australia (Gherardi et al., 2002), Italy (Hazlett et al., 2003) and North America (Hazlett, 2000), show distinct differences in whether or not they respond as strongly to heterospecific cues as to conspecific cues. However, the pattern of response does not seem to relate to phylogeny but

rather to whether species have evolved in specious regions and are successful invaders or being displaced. Those species that have recently successfully expanded their ranges respond more strongly to heterospecific danger signals, and this pattern of responses is not linked to how closely related the crayfish species are.

Heterozius rotundifrons is a New Zealand endemic crab that has an unusual anti-predator behavior. When stimulated by tactile input, crabs assume a limb-extended posture in which the cheilpeds are spread almost 180° apart (Field, 1990) and remain motionless in this posture for a number of minutes. This posture is an effective defense against fish predators (Hazlett and McClay, 2000), and the duration of the posture is extended upon introduction of fluids from crushed conspecifics (Hazlett and McClay, 2000).

The purpose of this study was to see if individuals of *H. rotundifrons* responsed to cues generated from crushed heterospecific crabs and, if so, which was more important in determining the strength of responses, phylogenetic relationship or ecological overlap.

METHODS AND MATERIALS

Heterozius rotundifrons A. Milne Edwards, 1867 used in this study were collected from the vicinity of the Edward Percival Field Station in Kaikoura, New Zealand and transported to the salt-water facility of the School of Biological Sciences, University of Canterbury, Christchurch, New Zealand. The experiments were conducted in May 2003 at the University of Canterbury. Individuals of *Heterozius rotundifrons* were tested with alarm cues prepared from one of five crustacean species, conspecific cues, and four other New Zealand species. We tested 20 different individuals of *H. rotundifrons* per species.

In all cases, the number of seconds spent in the limb-extended posture were recorded following induction of this defensive posture by grasping a crab, turning it upside-down and then placing it right-side up on the layer of gray sand in a plastic container with 750 ml of sea water and 25 ml of alarm cue. Field (1990) has shown that this method of tactile induction is the most reliable way to induce this behavior. The end of about of the limb-extended posture was recognized by the movement of any ambulatory leg or cheliped.

The five species used to prepare the alarm cues were *Heterozius rotundifrons*, *Cyclograpsus lavauxi*, *Hemigrapsus sexdentatus*, *Petrolisthes elongatus*, and *Pagurus novizealandiae*. *C. lavauxi* and *H. sexdentatus* are brachyurans, as is *H. rotundifrons*, but do not overlap directly in distribution in the intertidal, as these grapsids occur higher in the intertidal (McLay, 1988). In contrast, individuals of *P. elongatus* and *P. novizealandiae* overlap extensively in distribution with *H. rotundifrons*, but are anomurans (McLay, 1988). The number of individuals used to prepare the alarm cue varied but was equivalent in weight to two medium-size H. *rotundifrons*. For each preparation, the crustaceans used for making the

alarm cue solutions were thoroughly crushed and mixed in 200 ml of sea water and filtered with coarse filter paper. Twenty-five ml of the crushed crustacean solution were added to the plastic container in which the test individual of *H. rotundifrons* was placed.

A one-way ANOVA was used to compare the difference between number of seconds spent in the limb-extended posture by the 20 crabs placed in the different alarm cue preparations. The five test preparation values were compared with Tukey tests.

RESULTS

There was significant variation in the duration of the limb-extended posture among the five alarm cue preparations (ANOVA $F = 3.37$, $df = 4,95$, $P = 0.013$). As shown in Figure 1, the time spent in the posture was similar for the three brachyuran crab preparations (*H. rotundifrons*, *C. lavauxi*, and *H. sexdentatus*), and the Tukey test values comparing those three indicated no difference between them (*H. rotundifrons–C. lavauxi* $P = 0.809$, *H. rotundifrons–H. sexdentatus* $P = 0.962$). The number of seconds spent in the posture when the test crabs were placed in either of the anomuran crab preparations was significantly

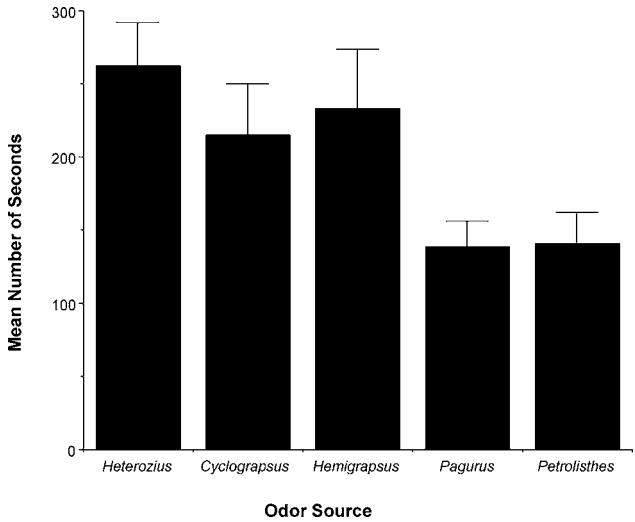

FIG. 1. Number of seconds (means + s.e.) spent in the limb-extended posture by individuals of *Heterozius rotundifrons* when placed in sea water containing chemical cues prepared with one of five crustacean species: *H. rotundifrons*, *Petrolisthes elongatus*, *Cyclograpsus lavauxi*, *Hemigrapsus sexdentatus*, and *Pagurus novizealandiae*.

lower (*H. rotundifrons–P. elongates* $P = 0.045$, *H. rotundifrons–P. novazealandiae* $P = 0.039$). These values were similar to the values reported in other studies when only tactile stimulation and no chemical cues were added (Hazlett and McLay, 2000, In Press).

DISCUSSION

Individuals of *H. rotundifrons* responded to the cues of crushed heterospecific crabs, but those in the same broad taxonomic group produced a significantly greater response. Their response to cues from species with whom they overlap extensively in ecological micro-distribution but that are more distantly related was significantly less than to related crabs. In previous investigations, the control group of physically stimulated crabs that received no chemical cues from damaged conspecifics showed durations of response similar to those seen here to the non-related crabs (Hazlett and McLay, 2000). This suggests that the shorter responses seen for the non-related crabs could, in fact, be no response to chemicals at all, just the response to being physically stimulated. *Heterozius* is a monotypic genus placed in the Family Bellidae, closely allied to the Family Xanthidae. Thus, while it is in the same order (Brachyura) as the two grapsid species used in this study, the three brachyruans are not closely related. The crabs in the Order Anomura are only distant phylogenetically. While tests with a range of concentrations would provide additional details and an assessment of the ecological reality of responding to these cues in the much lower concentrations that might be encountered in the field, the responses of *Heterozius* to approximately equal concentration of cue from two closely related vs. two distantly related crabs is consistent.

The results of this study suggest a priority of phylogeny over ecological overlap in determining the cues to which a potential prey species will respond. This finding is consistent with the majority, but not all, of similar studies using crabs. Of course individuals of a species could respond to chemical cues more or less strongly based upon both phylogeny and ecology (Stenzler and Atema, 1977). Certainly, ecological overlap sets the stage for learning to use heterospecific cues. However, individuals of *H. rotundifrons* responded less to cues from unrelated than to cues from related crabs, and given that previous studies with this species (Hazlett and McClay, 2000) show that tactile stimulation without any chemical alarm cues can cause anti-predator posture duration that is about equal to our treatments with unrelated crab cues, it is possible that there was no response to unrelated species. It is conceivable that *H. rotundifrons* does not share predators with the porcellanid, *P. elongatus*, or hermit, *P. novizelandaiae*, crabs. If that were the case there would be no advantage in utilizing cues resulting from the crushing/predation of individuals of those species. Indeed, Mirza and Chivers (2003) showed that the minnow, *Pimephales promelas*, responded to cues from

attacks on damselfly larvae, *Enallagma boreale* only when minnow size dictated the two species were in the same prey guild.

As has been pointed out elsewhere (Thacker, 1994), one might expect phylogenetic relationship to be important in determining cue use, because of the similarity of the chemicals released from the bodies of related species. Thus, individuals of *H. rotundifrons* could be responding to a cue that is common to all brachyurans but absent from anomurans. Unless a species evolved under predation pressure from a taxonomically very specialized predator, selection may favor use of a generalized cue.

Acknowledgments—Participation in this study by BAH was made possible by support from the Erskine Fund, University of Canterbury. We would like to thank Catherine Bach and Dan Rittschof for their comments on the manuscript.

LETTER FROM THE EDITOR-IN-CHIEF

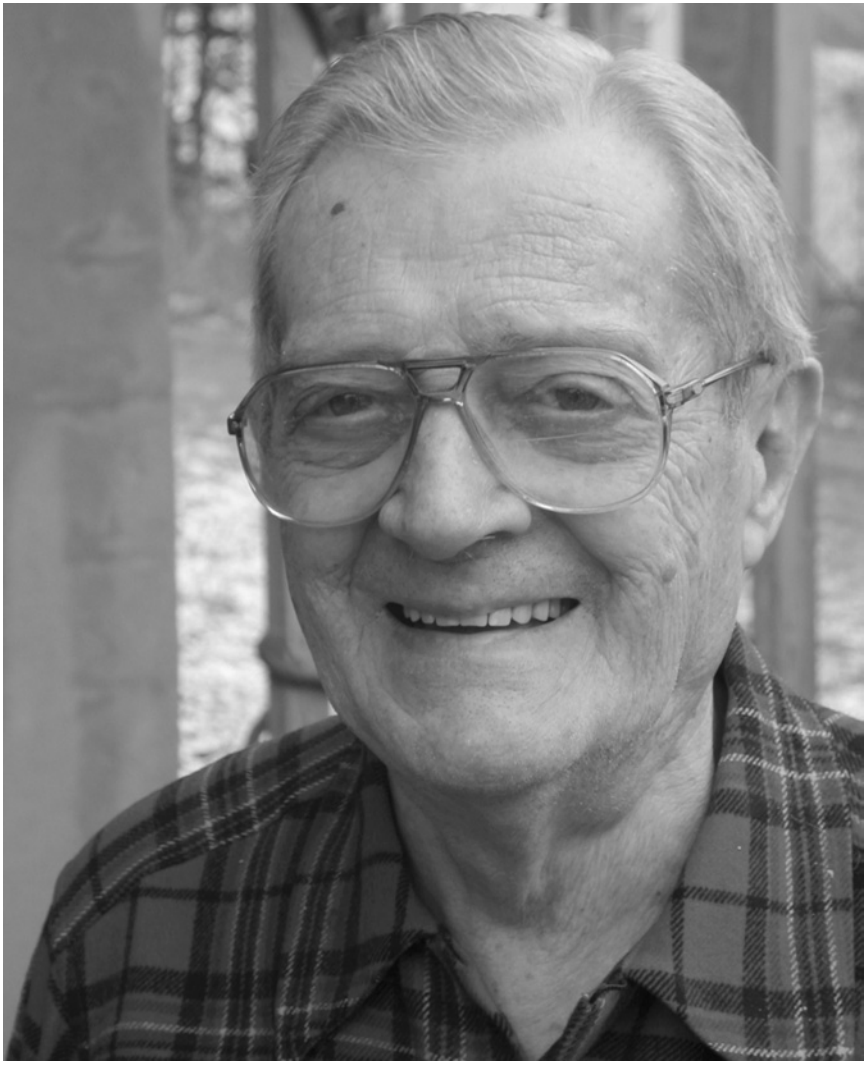
JOHN T. ROMEO (FOR THE ASSOCIATE EDITORS
AND EDITORIAL BOARD)

Everyone associated with the *Journal of Chemical Ecology* is saddened by the passing of John Simeone, one of the founding editors of the *Journal*. The *Journal* he envisioned with Robert Milton Silverstein was established in 1975, and the International Society of Chemical Ecology, which they also helped found, in 1983. John was a thinker ahead of his time; a tireless caretaker who devoted many years of his life to the *Journal*; and a warm human being who was the inspiration for countless "students" of our discipline.

The following tribute by Jim Nation, to whom John and Milt entrusted the *Journal* when the time came, reminds us of many of the important events in John's life, his gentleness and firmness, and his legacy. There will be appropriate forums in the future for those of you who wish to express your own feelings.

The Silverstein/Simeone award, which is awarded annually by the International Society of Chemical Ecology and funded by Springer Publishing, recognizes a scientist who is advancing the discipline of chemical ecology with innovative research.

We dedicate this issue of the *Journal* with respect and gratitude to John.



John B. Simeone 1919–2005

Journal of Chemical Ecology, Vol. 31, No. 3, March 2005 (© 2005)

JOHN B. SIMEONE 1919–2005

JAMES L. NATION (PROFESSOR EMERITUS)

Department of Entomology and Nematology, University of Florida
Gainesville, FL 32611-0620

All of us in chemical ecology and entomology were saddened to learn of the death of John B. Simeone. John passed away at home on January 10, 2005, after a short period of illness. John was born in Providence, Rhode Island, November 20, 1919. Etta, his wife of many years, two sisters, and nieces and nephews survive John. We will all miss him greatly. John was a friend, mentor, editor, and scientific colleague to many of us. Younger chemical ecologists and forest scientists who may not have gotten to know John truly missed one of the warmest personalities in our science. John did undergraduate work in biology at the University of Rhode Island, a master's degree in forestry at Yale School of Forestry, and a PhD from Cornell University. It was at Cornell in the fall of 1957 that I met John. We were assigned to be lab partners in the graduate course in insect physiology. I was a very green, first semester graduate student. John was about 38 years old then, and had served in World War II as a naval officer, participating in the landing at Normandy and other amphibious operations. He stayed in the naval reserves after the war, and eventually retired with the rank of commander. John always had a gentle, but commanding presence that was clearly evident to all who knew him. We often joked about which of us got the other through that graduate course; but when John said to get my portion of a lab report done, I did it. We both learned physiology from Professor Bob Patton, who taught the course, but I learned a lot from John and formed a life-long friendship that I have valued very highly. After John finished his PhD at Cornell, he returned to Syracuse University, where he had started his career in entomology in 1948 as a young entomologist in the Entomology Department. During a long career at Syracuse, he taught a wide variety of entomology and ecology courses, but his special interest was in the ecology and biology of wood destroying insects. In 1962, not long after returning with his PhD, John was asked to chair the Entomology Department. Some time about the middle of the 1960s, he teamed with Dr. Ernest Sondheimer to teach a seminar in chemical ecology at Syracuse. In 1970, Academic Press published these lectures in a book entitled *Chemical Ecology*, edited by John B. Simeone and Ernest Sondheimer.

In the meantime, Robert Milton Silverstein, an organic chemist and a specialist in instrumental methods of chemical identification, had moved from Stanford Research Institute to join the Chemistry Department at University of Syracuse. Milt not only had a premier reputation in organic chemistry, but he and David Wood at Berkeley had already initiated studies of the pheromone of the bark beetle *Ips confusus* (now *Ips paraconfusus*). They identified the pheromone as a three-component pheromone in 1966, which helped to dispel the early idea that each species might produce a single, but different pheromonal compound.

It is extraordinarily fortunate for the field of chemical ecology that Milt and John teamed with Plenum Publishing Corp. to publish the *Journal of Chemical Ecology*, the first journal devoted to chemical ecology. The first issue appeared in January 1975. They co-edited it for the next 20 years.

John continued as Chairman of Entomology until 1977, when he was asked to become Chairman of the newly formed Department of Environmental and Forest Biology at Syracuse. This was an amalgam of the departments of Botany/Plant Pathology, Zoology, and Entomology. John served as Chairman until 1983, when he retired. Well, not really; he continued to go to his office regularly, and helped in insect ID and biology of forest insects, interacted with colleagues and graduate students, and continued with Milt to edit the *Journal of Chemical Ecology* through 1994. Through the *Journal of Chemical Ecology*, John and Milt played a major role in defining, encouraging, and molding the field of chemical ecology. By the early 1980s scientists all over the world were devoting major efforts to understanding chemical ecology of insects, plants, vertebrates, terrestrial, fresh water and marine organisms and publishing their work in the *Journal of Chemical Ecology*. The time had come for a professional society, and John, Milt, Lincoln Brower, Jean Langenheim, Michael Martin, and Gerald Rosenthal founded the International Society of Chemical Ecology. The Society was incorporated in 1983, and its constitution approved in 1984 at the business meeting of the first annual meeting of ISCE at the University of Texas, Austin.

John taught, conducted research, chaired departments, and informally interacted with students and colleagues for more than 55 years at Syracuse. John and Etta established a Graduate Fellowship in Forest Entomology at Syracuse to support graduate students in entomology. John's many contributions to entomology were recognized in the awarding of the prestigious L.O. Howard Distinguished Achievement Award by the Entomological Society of America and by election as an Illustrious Emeritus Professor.

I am indebted to the obituary published in the *Post-Standard*, Syracuse, NY, to Etta Simeone, and to an article on John written by Cynthia King for information.

SEASONAL CHANGES IN FOLIAR TERPENES INDICATE SUITABILITY OF DOUGLAS-FIR BUDS FOR WESTERN SPRUCE BUDWORM

VINCENT G. NEALIS* and JASON R. NAULT

Natural Resources Canada–Canadian Forest Service, Pacific Forestry Centre, 506 W. Burnside Rd, Victoria, British Columbia V8Z 1M5 Canada

(Received July 30, 2004; accepted December 16, 2004)

Abstract—The terpene composition of current-year buds of Douglas-fir, *Pseudotsuga menziesii* (Mirb.) Franco, was analyzed from before budburst to after buds were fully flushed. Terpene composition was measured at weekly intervals for several seasons at eight different locations in the southern interior of British Columbia, Canada. Discriminant functions relating terpene composition to suitability of buds for newly emerged western spruce budworm, *Choristoneura occidentalis* Freeman, were developed based on terpene profiles of the buds and bioassays measuring the suitability to budworms of a sister group of buds. Changes in percent composition of bud terpenes before and during budburst were closely associated with changes in the suitability of the buds to utilization by budworms at both the tree and site by date levels. Use of a degree-day scale for bud suitability removed much of the year-to-year variation, but remaining differences among sites suggest additional sources of variation influencing the insect–host plant relationship. The success of correctly classifying bud suitability using terpene profiles demonstrates the value of foliar terpenes as indicators of seasonal changes in suitability of Douglas-fir foliage during the critical spring emergence period of western spruce budworm. This indicator could be used to screen individual trees susceptible to budworm damage and identify sites at high risk of damaging defoliation.

Key Words—Douglas-fir, *Pseudotsuga menziesii*, western spruce budworm, *Choristoneura occidentalis*, foliar terpenes, host suitability, phenology, seasonal development, chemical indicators.

INTRODUCTION

The western spruce budworm, *Choristoneura occidentalis* Freeman, is an important native defoliator of Douglas-fir, *Pseudotsuga menziesii* (Mirb.) Franco, in western North America. This insect–host plant association extends over highly varied climatic zones. Analysis of historical defoliation and impact records suggest that regional-scale outbreaks are associated with areas of optimal synchrony between bud development of the host tree and budworm-feeding activity (Thomson et al., 1984). Synchrony between budworm activity and foliage development also influences local patterns of defoliation. Differences in relative severity of defoliation of putatively "resistant" vs. "susceptible" Douglas-fir during outbreaks are the result of intertree differences in foliage phenology and relative synchrony with local, developing budworms (Chen et al., 2003). Thus, the relationship between phenology of budburst of Douglas-fir and of western spruce budworm development may provide insight into the host–plant relationship at several ecological scales.

Thomson and Moncrieff (1982) produced a robust, empirical method of predicting budburst in Douglas-fir, but their model was not referenced directly to insect performance. Shepherd (1983) used a system of photographs to classify seasonal development of Douglas-fir buds into nine stages ranging from fully closed winter buds to expanded summer shoots. He then identified the critical stages of bud development in terms of survival of western spruce budworm as: (1) the overwintering bud stage when budworms could not penetrate the hard bud; (2) the swollen, soft bud stage that could be penetrated by budworms; and (3) the stages following bud flush when budworms became exposed feeders (Shepherd, 1992). His analysis of budworm survival focused on stages following bud penetration by the budworm and during the period of exposed feeding. Similarly, investigations of the role of associated changes in foliage nutrients and terpene composition in budworm fitness have been restricted to the period of development following budworm penetration of the current-year buds (Wagner et al., 1989; Cates and Zou, 1990; Chen et al., 2002). Little information has been available on foliar chemistry or budworm survival early in the season as buds are just becoming available as a resource to foraging budworms (Clancy et al., 1993). Host–plant relationships at this early seasonal stage play an important role in the population ecology of conifer-feeding budworms (Campbell, 1993; Nealis, 2003).

Nault (2003) examined seasonal changes in terpene composition of Douglas-fir foliage over a 3-year period at several sites in British Columbia (BC), Canada. Measurements began in early spring before budburst and included the earliest phases of bud development identified by Shepherd (1983). The results revealed highly dynamic shifts in relative concentrations of different terpenes during the early spring period in contrast to their relative stability over

the remainder of the growing season (Nault, 2003). Seasonal changes in several terpenes characteristic of Douglas-fir buds resembled seasonal changes in the suitability of vegetative buds to spring-emerging larvae in other budworm systems (Nealis and Lomic, 1994). It seemed likely that these changes in terpenes could serve as indicators of bud suitability for western spruce budworm. Such an indicator would be less subjective than methods that rely on photographic interpretation (Shepherd, 1983) and would extend our understanding of the relationship between budworms and foliage chemistry to the critical period when budworms are foraging for feeding sites immediately following spring emergence.

This paper describes a set of discriminant functions based on terpene composition of current-year buds of Douglas-fir that accurately classify the suitability of those buds to exploitation by newly emerged western spruce budworm in early spring. The accuracy of predictions using terpenes as indicators of bud suitability is compared to predictions based on a degree-day model. Use of foliage chemistry results in models that are robust over a wide range of environmental conditions and allow rapid assessment of foliage suitability. This indicator can be used to quantify synchrony between local trees and budworms to interpret risk rating at the stand level as well as to identify relative susceptibility to defoliation of individual trees within a site.

METHODS AND MATERIALS

General. We used plant material collected directly from field sites. Eight sites were selected over a range of elevations where Douglas-fir dominates the forest community (Table 1). Sites 1 to 5 were in the Nicola Valley near Merritt, BC, and sites 6 to 8 were in the Okanagan Valley near Peachland, BC. All sites were in the Interior Douglas-fir (IDF) zone except site 5 which is an enclave of Douglas-fir within the Ponderosa Pine (PP) zone (Meidinger and Pojar, 1991). Temperature profiles for these sites for 1998 to 2003 were constructed from records obtained from the Meteorological Service of Canada for the two weather stations closest to the study sites: (1) Merritt STP (station #1125079, 50°7′N, −120°48′, 588 m); and (2) Peachland (station #1126070, 49°47′N, −119°43′, 345 m). Temperature regimes for each site were calculated using the program BioSIM (Régnière, 1996), which uses these nearest weather stations and adjusts for differences in location and elevation at the target sites based on estimated thermal gradients (Régnière and Logan, 2003). Daily degree-day accumulations above a temperature threshold of 4°C were calculated using daily maximum and minimum temperatures.

In seven sites, 10 codominant Douglas-fir trees were chosen at ~10- to 20-m intervals along a 200-m transect. Only five trees were similarly selected at

site 5 in 1998 and 1999, but this was increased to 10 trees after 1999. Samples were taken approximately weekly and consisted of a single 45-cm branch tip removed without regard to directional quadrant from the midcrown of each tree at each sample date using pole pruners equipped with a cutting head. Branches were bagged, labeled, and returned to the laboratory where they were stored at 2°C in the dark until buds could be excised, usually within 3 days. Defoliation estimates were made by applying the method of Fettes (1950) to branches sampled in August after feeding was complete. Defoliation estimates were expressed as percentage defoliation of current-year foliage for each tree in all years (V.G. Nealis, unpublished data).

Western spruce budworm used in bioassays were derived from wild populations collected as late-instar larvae or pupae in the previous season. These insects were reared to adult and allowed to mate in the laboratory. Female moths were provided cut host foliage on which to lay egg masses. Egg masses were placed into a Petri dish covered with parafilm to which a triple-layer patch of cheesecloth had been attached to the inside surface, facing the egg masses. The dish was placed into a paper envelope with a window cut to expose the cheesecloth patch and incubated at 20°C L:D 16:8 hr. As budworms hatched, they moved toward the light, became embedded in the cheesecloth, and spun hibernacula. After 2 wks at 20°C, hibernating larvae were stored at 2°C to satisfy their diapause requirements until needed the following spring. To activate the budworms, the cheesecloth patch with the budworms was saturated with water, placed into a dry glass tube, and incubated at 20°C.

Bioassays to Determine Bud Suitability. Current-year buds and 2-years' previous shoot growth were excised from each branch on each sample date to

determine their current suitability for western spruce budworm. The cut end of the shoot was inserted into a hole in a cork (3-cm diam). The cork served as a stand for the shoot. Freshly emerged western spruce budworms that were not fed yet were introduced to the base of the shoot at a ratio of one budworm per bud. Five buds per tree and five insects were used on samples from the earliest dates in the season. This was increased to 10 buds and 10 insects during the period of budburst and expansion. Thus, there were five or 10 buds tested for each of 10 trees on each sampling data at the site level.

A glass tube (3.5 cm in diam 15 cm long) was placed over the set-up to cage the budworms and the buds. These units were placed at 20°C, L:D 16:8 hr for 2 days to allow budworms to forage. After that time, the number of budworms that had successfully penetrated a bud was scored. This number was converted into a proportion of the cohort, ρ, that successfully established in buds and used as a measure of bud suitability for each tree on each sample date. An analogous measure for the site, P, was obtained by pooling across all trees within a site on each sample date.

Foliage Chemistry Assays. Detailed methods used to extract and analyze foliar terpenes are described by Nault (2003). Briefly, current-year vegetative buds were cut from the same branches as bioassay material and stored at −5°C until terpenes could be extracted (less than 1 mo). Sufficient buds from each branch sample were selected randomly to ensure a minimum total mass of ~0.3 g. To extract terpenes, tissues were homogenized in a solution of cold water, methanol, hexane, and an internal standard (methyl palmitate in iso-octane). The homogenized samples were centrifuged and the terpenes recovered in the hexane layer. Extracted terpenes in solution were analyzed on a gas chromatograph. Individual terpenes were identified by peak retention times. Identifications were confirmed by gas chromatography—mass spectrometry and gas chromatography—Fourier transform infrared spectroscopy. In all cases, blank samples without tissues were used to verify solvent purity. Individual terpenes were calculated as percent contribution to the total peak area recorded on the chromatogram and as milligrams per gram of green sample.

Analysis. Discriminant function analysis (STATISTICA, version 6.0; Stat-Soft Inc., Tulsa, OK) was used to develop classification algorithms distinguishing samples in which buds from individual trees were either unsuitable ($\rho < 0.5$) or suitable ($\rho \geq 0.5$) for budworms. The frequency of sampling and often rapid transition of buds from unsuitable to suitable (Figure 1A) precluded using more than two categories.

We explored several possible discriminant functions relating bud suitability to its terpene profile by dividing the available data into various, mutually exclusive training and test sets. To form a training set, the sample set was first divided into six, ordinal categories based on ρ values between 0 and 1. In order to avoid overrepresentation of extreme values ($\rho = 0.0$ or 1.0) and to ensure adequate

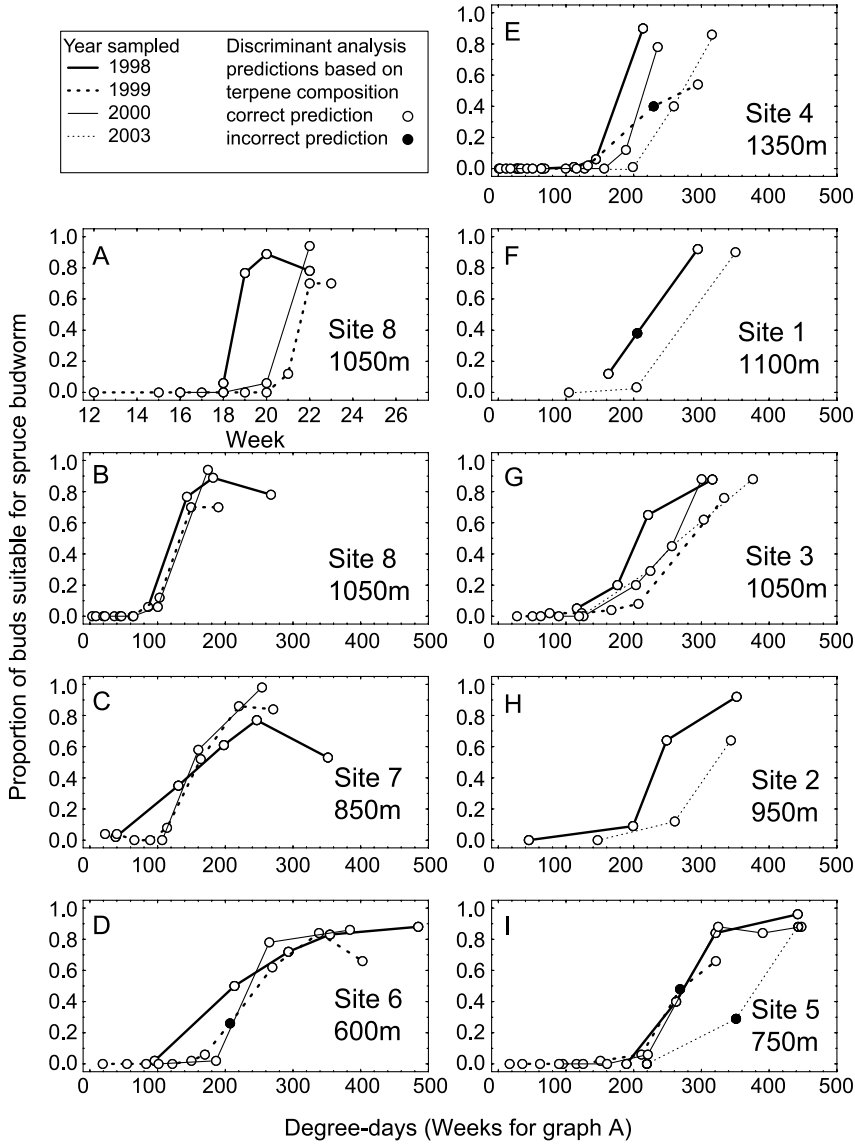

FIG. 1. Seasonal changes in bud suitability, *P*, for western spruce budworm **A** by week at site 8 and **B**–**I** by accumulated degree days above 4°C at all sites between 1998 and 2003. Open symbols indicate correct classifications and closed symbols indicate incorrect classifications using discriminant function B (Tables 2 and 3).

representation of observations throughout the range of ρ values, an equal number of samples was then randomly chosen from each of these six categories. Several discriminant functions were developed and tested as follows:

(1) Function A. Data were stratified by year(s) (1998–2000 vs. 2003) pooled over all sites (Table 2). The training set consisted of an equal number of samples from all sites from the 1998 to 2000 group selected as described above. The test set used all samples from all sites in 2003. The procedure was repeated using 2003 data to compile the training set and all 1998 to 2000 data as the test set. The discriminant functions distinguished suitable and unsuitable buds based upon percent composition of terpenes. Results are presented for each procedure as well as the sum of the two test sets combined. The identical procedures using actual terpene concentrations instead of percent composition of terpenes as the measure returned similar, but slightly less accurate, predictions and are not reported further.
(2) Function B. Data were stratified by sites pooled over all years (Table 2). The training set consisted of samples randomly chosen from four sites (two from each valley) in all years, and the test set was comprised of samples from the remaining four sites in all years. As in (1), the procedure

[b] Sample sizes given in parentheses. Bold figures represent mean for combined sets.

distinguished suitable and unsuitable buds based on percent composition of terpenes. Also, as in (1), the training and test sets were reversed and the procedure was repeated. Results are presented for each procedure as well as the sum of the two test sets combined.

(3) Function C. The same stratification and procedure were used as in Function A except degree-day data rather than terpene composition was used to develop the discriminant function.

(4) Function D. The same stratification and procedure were used as in Function B except degree-day data rather than terpene composition was used to develop the discriminant function.

To evaluate the performance of these discriminant functions at the site by date, rather than the tree level, an average bud suitability, P, and an average classification [unsuitable ($P < 0.5$) or suitable ($P \geq 0.5$)] for each site on each date was calculated from the test sets. These were compared to classifications at the site by date level just as was done for classifying suitability of trees (ρ).

To examine the possibility that fewer terpenes may provide equally good predictive value, training and test sets were developed using Function B, but selecting only the two best terpenes as determined by the stepwise procedure in STATISTICA for prediction.

RESULTS

Foliar Terpenes and Bud Suitability. Classifications using percent terpene composition predicted bud suitability for western spruce budworm correctly more than 80% of the time at the tree level and more than 90% of the time at the site by date level irrespective of whether data were stratified by year (Function A) or by site (Function B) (Table 2). Thus, terpene composition of buds provided highly accurate indicators of bud suitability for western spruce budworms over a wide range of site conditions with all of their attendant seasonal and annual variations in weather.

Analysis of misclassifications of individual samples ($N = 147$) revealed that misclassified samples were not necessarily statistical outliers (i.e., two or more standard deviations from the mean for a given site and date). Of more ecological interest, there was no difference in previous defoliation levels of misclassified and correctly classified samples [mean (SD) percent defoliation 30% (29%) vs. 31% (32%), respectively]. Thus, defoliation by the western spruce budworm does not seem to influence the reliability of terpenes as indicators of bud suitability. This confirms similar results of Chen et al. (2002) and further generalizes the utility of the indicator.

Each of the training sets in Table 2 provides a distinct set of coefficients to discriminate between unsuitable and suitable buds. The most accurate discrimination of bud suitability that we found was Function B using site = 2, 5, 6, 7 as the training set (Table 2). The coefficients for Function B using that training set along with the corresponding mean percent composition of the various terpenes are given in Table 3. To use for predictions, observed percent composition of each terpene is multiplied by its corresponding coefficients in Table 3, one for an unsuitable score and one for a suitable score. These products are summed to provide separate scores for unsuitable and suitable categories. The greater of the two scores is accepted as the prediction (suitable vs. unsuitable). Table 2 indicates the expected accuracy of such a prediction.

Comparison of percent terpene composition between suitable and unsuitable buds (Table 3) provides additional insight into the patterns of particular terpenes as buds change from unsuitable to suitable for western spruce budworm. The two dominant terpenes, α-pinene and β-pinene, reverse their relative positions with α-pinene more abundant in unsuitable buds and β-pinene more abundant in suitable buds. Some of the largest relative differences, however, are in the less dominant terpenes. For example, the percent composition of Δ-3-carene is, on average, almost twice as high in unsuitable than in suitable buds, while percent composition of camphene is almost twice as high in suitable than in unsuitable buds (Table 3).

TABLE 3. COEFFICIENTS FOR DISCRIMINANT FUNCTION B (TABLE 2, TRAINING SET IS SITE = 2, 5, 6, 7) AND MEAN (SD) PERCENT COMPOSITION OF TERPENES IN BUDS THAT WERE UNSUITABLE OR SUITABLE FOR WESTERN SPRUCE BUDWORM[a]

	Coefficients		Mean percent composition (SD)	
Terpene	Unsuitable	Suitable	Unsuitable	Suitable
Tricyclene	–	–	1.4 (0.8)	1.9 (0.9)
α-Pinene	0.902	0.755	35.3 (12.4)	24.3 (4.7)
Camphene	–	–	7.6 (5.5)	11.9 (5.9)
Sabinene	–	–	4.7 (4.2)	4.5 (5.3)
β-pinene	0.704	0.734	25.8 (10.9)	35.6 (9.5)
Myrcene	1.055	0.951	5.0 (3.0)	3.8 (1.8)
Δ-3-Carene	1.309	1.123	2.8 (3.5)	1.4 (1.6)
Limonene	1.123	0.985	10.9 (5.1)	9.7 (4.2)
β-Phellandrene	5.323	4.102	1.2 (0.6)	1.0 (0.2)
Terpinolene	–	–	2.7 (2.2)	1.8 (1.8)
Bornyl acetate	–	–	2.7 (1.9)	4.2 (2.7)
Constant	−39.425	−32.342		

[a] Blanks indicate cases where discriminant function did not utilize that particular terpene.

We found that good predictions could be obtained by using fewer terpenes. The best single terpene to use was α-pinene, a relatively dominant terpene that decreases rapidly in its contribution to total terpenes early in the season as budburst proceeds (Nault, 2003) and buds become suitable to budworms (Table 3, Figure 1). Using training and test sets described under Function B, predictions using α-pinene alone were 78.5% accurate at the tree level and 89.9% accurate at the site by year level compared to 87.6% accurate and 96.4% accurate, respectively, using as many as six terpenes (Tables 2, 3). Further increasing the accuracy of prediction using the single terpene by adding a second or third terpene was not straightforward because the second-best terpene added in stepwise development of the discriminant function varied with the selection of the training set. In other words, one would need to measure α-pinene plus several other candidate terpenes to obtain accuracies approaching those provided by all terpenes. More practically, there is no gain in either efficiency or cost by selecting a subset of terpenes to measure because the collecting, processing, and analytical procedures described above must be followed whether one is measuring one or many terpenes. Therefore, we consider the larger set of terpenes to be the preferred basis for prediction using the coefficients in Table 3.

Influence of Temperature. Classifications based upon accumulated degree days were not as accurate as classifications based on percent terpene composition whether stratified by year or site (Table 2: compare corresponding predictions from Functions A vs. C and B vs. D, respectively). Nonetheless, predictions based on degree days were also acceptably accurate as might be expected by the strong correlation between cumulative degree days and percent composition of individual terpenes (Nault, 2003). Analysis of cases of misclassification at the site by date level revealed that errors using terpenes tended to occur within a narrow range of bud suitability ($0.26 < P < 0.48$) whereas misclassifications using degree days covered almost the entire range ($0.0 < P < 0.94$).

The relative success of using terpene composition over degree days for classification suggests that terpenes are a more sensitive indicator of bud condition, probably because terpene levels are the result of biological integration of many more factors than air temperature alone. Degree days are useful, however, for scaling both changes in terpene composition (Nault, 2003) and bud suitability to budworms under different temperature regimes. For example, expressing changes in bud suitability on a degree-day scale removes much of the year-to-year variation at the site level (Figure 1A vs. B). Similarly, the degree-day scale reduces variation associated with elevation in any single year. However, interesting differences, remain at the site level. Note that within each region (Figure 1B–D and E–I, Okanagan and Nicola Valleys, respectively), there appears to be a negative correlation between degree days required for buds to become suitable and site elevation. In the Okanagan Valley, buds are mostly

unsuitable for budworms until accumulated degree days ≥ 200 in the low elevation site (Figure 1D), whereas almost all buds are suitable at the corresponding number of degree days at the higher elevation (Figure 1B). Similarly, in the Nicola Valley, buds do not become suitable for budworms until degree days ≥ 220 at 750 m (Figure 1I), but are ~50% suitable by that same thermal point at 1350 m (Figure 1E). There are other apparent site-related interactions that reduce the accuracy of using degree days to discriminate groups. Compare, for example, Figure 1B and G, both at 1050 m, but in different regions. Whereas expressing suitability in terms of degree days removes much of the year-to-year variation in site 8 (Figure 1B), there remains considerable year-to-year variation in site 3 (Figure 1G). Despite these complex site-related differences in the relationship between temperature and bud phenology, terpene composition predicted bud suitability to western spruce budworm very well in all sites (compare open vs. closed symbols in Figure 1). The fact that terpene composition tracks these site-to-site differences illustrates the value of this tool in detecting patterns that may be relevant in explaining spatial variation in defoliation caused by the western spruce budworm.

DISCUSSION

The suitability of current-year Douglas-fir buds to western spruce budworm following spring emergence depends upon the state of development of the buds (Shepherd, 1992). The phenology of this suitability varies by site and by date largely as a function of individual tree responses to ambient temperature. Discriminant functions based on percent terpene composition of buds can be used to indicate their biological suitability to budworm both at the tree and site levels. Using foliar chemistry as an indicator of bud suitability is an objective and repeatable method of describing plant phenology. We found that terpene profile was a consistent means of distinguishing buds that were suitable or unsuitable for penetration by the western spruce budworm in spite of considerable variation in site-specific and annual variation in ambient temperature and levels of previous defoliation. Thus, persistent differences in the response of particular trees or in specific site conditions and the effect of these differences on suitability to western spruce budworm can be investigated. Results can be used to provide real-time information to augment hazard-rating systems that are typically based on historical patterns as well as to identify individual trees with desirable phenological characteristics associated with reduced susceptibility to defoliation by the western spruce budworm.

Experimental studies exploring the possible role of terpenes as constitutive or induced plant defenses in the Douglas-fir/western spruce budworm system

have focused on the midseason phenological stages when shoots were elongating and budworms were feeding actively (e.g., Cates and Zou, 1990; Clancy et al., 1993). The results provided equivocal or little evidence of a role for terpenes as plant defenses (Clancy, 2002). The terpene profiles of Douglas-fir shoots during the later feeding stages of the western spruce budworm, however, are relatively stable compared to the dynamic shifts occurring in those profiles earlier in the season when buds are swelling and budworms are just attempting to establish feeding sites (Nault, 2003). Thus, although our results stress the use of terpenes as the indicators, not the causes, of foliage suitability, they may provide insight in the search for trees with lower susceptibility to western spruce budworm by revealing how variation in early-season rates of change in terpene chemistry are associated with host suitability.

Chen et al. (2003) showed the relative susceptibility of Douglas-fir to defoliation by the western spruce budworm was related to differences in the relative phenology of the tree's foliage and the budworm's development. Further, their experimental results indicate that relative susceptibility is determined by early-season phenology; once buds were penetrated by the insects, differences between susceptible and resistant trees was reduced or reversed. Our results show that these phenological differences among trees that determine host suitability for the western spruce budworm can be related directly to the terpene profile of individual trees early in the growing season. The relative phenology of bud development, and, therefore, susceptibility to western spruce budworm can be ascertained easily for individual trees, irrespective of their defoliation history—indeed, even in the absence of defoliation. This could provide an objective basis upon which to select desirable developmental characteristics of trees because both terpene characteristics and phenological development have a strong heritable component (von Rudloff and Rehfeldt, 1980; Chen et al., 2003).

The use of terpenes as indicators also has an application in population studies. Surveys of terpene profiles of trees within sites could identify the degree of homogeneity of particular phenological patterns in the host population. The degree of homogeneity in budburst phenology in combination with measures of population rates of change in budworms or severity of defoliation provides a direct link between weather, host–plant relationships, and outbreak dynamics. Similarly, known geographic differences in terpene profiles (von Rudloff and Rehfeldt, 1980) could help interpret large-scale patterns of outbreak behavior. We found systematic differences in the thermal requirements for buds to become suitable to budworm on trees at different elevations. If these differences reflect local adaptations by trees to ambient climate, then the relationship between insect outbreak behavior and weather may be mediated by the response of the host tree. The indicator provided by changes in the profile of terpenes makes this pathway tractable.

(Received March 9, 2004; accepted December 19, 2004)

Abstract—Plant secondary chemistry is determined by both genetic and environmental factors, and large intraspecific variation in secondary chemistry has frequently been reported. The heritability of specific tree secondary metabolites is, however, mostly unknown. We tested the effect of plant genotype, environment, and ontogeny on the variation in shoot secondary chemistry of juvenile and mature European white birches (*Betula pendula*). Phenolic compounds and triterpenoids were analyzed in 30 naturally regenerated 20-year-old parental trees and micropropagated plantlets that originated from 14 of those same parental trees, planted at four growing sites. Most of the variation for phenolic compounds was explained by differences between parental trees, whereas triterpenoids had a high variation both between parental trees and within the canopy of individual tree. The effect of ontogeny was strong for some individual compounds. In mature trees, the amount of triterpenoids was less than 1 mg/g (DW), whereas the concentration in juvenile plantlets was up to 64 mg/g (DW). Clonal plantlets and parental trees were generally quite similar in their phenolic contents, but there were significant differences for all analyzed compounds among clones. Environment had no significant effect on the accumulation of some compounds,

* To whom correspondence should be addressed. E-mail: marja-leena.laitinen@uku.fi

whereas for others, a significant environmental effect and/or significant genotype by environment interaction was found. These results suggest that birch shoot secondary chemistry is under strong genetic control and that the environmental effects depend on the studied chemical trait.

Key Words—Birch, clonal plantlets, clonal repeatability, condensed tannins, flavonoids, intraspecific variation, natural population, triterpenoids.

INTRODUCTION

Most plant secondary metabolites are thought to enhance the prospects for survival of the producer or its offspring through complex interactions with the environment (Waterman, 1992). The effect of environment on secondary chemistry has been considered to be of prime importance, as suggested by many ecological hypotheses such as the carbon nutrient balance hypothesis (see Bryant et al., 1983), the growth differentiation hypothesis (Herms and Mattson, 1992), and the protein competition model (Jones and Hartley, 1999). Although the role of environmental and genetic control of plant secondary chemistry is of major importance, few studies have concentrated on this question in forest trees. Hanover (1966) studied the heritability of five terpenes present in pine, and Orians et al. (1996) studied heritability of two phenolics in *Salix* (see also Hamilton et al., 2001). The reason for the paucity of studies on the heritability of tree secondary compounds might be the need for time-consuming field experiments and the complicated chemical analyses.

When birch species (*Betula* spp.), and even individuals within a species, have been compared, a high inter- and intraspecific variation in the types and concentrations of secondary compounds in leaves has been found (Keinänen et al., 1999 a,b; Laitinen et al., 2000, 2002; Salminen et al., 2002; Valkama et al., 2003). Similar results have also been reported in studies of bark chemistry, where different birch species have been compared (Taipale et al., 1994; Julkunen-Tiitto et al., 1996). Variations in the amounts of secondary compounds within birch species are known to be induced by both biotic and abiotic environmental factors such as defoliation, available nutrients, UV-light, temperature, etc. (Keinänen et al., 1999a; Tegelberg et al., 2001, 2002; Kuokkanen et al., 2001, 2003). However, in previous studies, the high phytochemical variation in naturally regenerated individual European white birch trees (Laitinen et al., 2000), and bark secondary chemistry among birch seedlings, were suggested to be mainly controlled by genotype (Tahvanainen et al., 1991). Accordingly, our previous study indicated large clonal differences among 1-yr-old greenhouse-grown plantlets, suggesting that intraspecific variation in bark phenolic chemistry could be explained, to a large extent, by genetic differences (Laitinen et al., 2004). However, the high variation in terpenoid

chemistry among clones and plantlets of the same clone suggests that for some genotypes, the environment might also modify the secondary chemistry and, thus, affect the resistance of birch against browsing of mammals (Laitinen et al., 2004).

During plant growth and ontogenetic development, secondary chemistry can change considerably. Generally, juvenile stages express stronger defenses than the mature stage (Bryant and Julkunen-Tiitto, 1995). At the birch population level, this would mean even more variation in secondary chemistry, which allows populations to adapt to different kinds of stresses. However, the causes of variation in chemistry within a natural population of *Betula pendula* are still scanty.

In the present study, we used samples from mature birch trees from our long-term study population (see Laitinen et al., 2000, 2002) and micropropagated clonal plantlets from the same trees. Clonal plantlets were grown in four experimental sites, to study the effect of genotype, environment, and ontogeny on the chemistry of *B. pendula*. The objectives were to: (1) examine variation in shoot secondary chemistry within a naturally regenerated population among individual trees and within a tree, (2) determine the degree to which genotype and environment affect birch shoot secondary chemistry, (3) estimate the heritability of secondary chemistry by studying clonal repeatability, (4) test how individual clones differ in their response to the environment, and (5) compare parental trees to clonal plantlets of the same trees in order to quantify the effect of ontogeny.

METHODS AND MATERIALS

Plant Material and Growing Conditions. A naturally regenerated birch (*B. pendula*) stand in Punkaharju (southeastern Finland; 61°48′N, 29°18′E) was selected for long-term studies on genetic variation within a natural population. From this stand, a random sample of 30 *B. pendula* trees were selected (for details, see Laitinen et al., 2000). The aim was to micropropagate 300 plantlets from each tree. In some cases, the micropropagation was not successful, which limited the number of clones in this study to 14. The identification numbers of the available trees and clones were 3, 4, 5, 6, 9, 15, 16, 17, 18, 19, 20, 24, 25, and 30. These are the same parent trees and clones that were also used in our previous studies (see Laitinen et al., 2000, 2002, 2004).

Parental trees were about 20-yr-old at the time of micropropagation. Small twigs were taken from the upper third of the trees, twice in June and once in August 1997, to get material for micropropagation. In the beginning of April 1998, micropropagated plantlets were transferred from laboratory cultures into 0.021 l plastic pots (EK 144) that contained perlite, unfertilized peat, and birch forest soil (2:2:1). Plantlets were grown in a greenhouse, where plantlets from

each clone were divided onto three tables in which the pots of all clones were placed randomly.

In May 1998, plantlets were transferred into 49 × 30 cm plastic containers (EK 28). Each container contained 28 pots of 0.28 l each, and each pot was filled with prefertilized commercial peat (VAPO, Finland). On the July 9, 1998, plantlets were transferred to an open-air exposure field in Punkaharju. Plantlets were watered as needed and fertilized once (April 22) with 0.1%, and six times (May 27, June 17 and 24, and July 1, 8, and 15) with 0.2% Kekkilä 9-Superex (N 19.4%, P 5.3%, K 20%) fertilizer. At the end of October 1998, winter-hardened plantlets were transferred to an unheated greenhouse where the roots were protected from freezing.

Plantlets for this study were planted in June 1999 into one of three growing sites in Punkaharju (Kuikanniitty 61°47′N, 29°21′E, 79 m above sea level, Putikko 61°43′N, 29°26′E 98 m above sea level, and Vaahersalo; 61°47′N, 29°17′E, 95 m above sea level) and one site in Parikkala (Parikkala 61°36′N, 29°36′E, 93 m above sea level), in southeastern Finland. The sites at Kuikanniitty and Vaahersalo were abandoned cultivated fields, whereas Parikkala and Putikko were *Myrtillus* forest-type areas. The soil type was defined as fine sandy till at all growing sites.

Plantations were established using a randomized complete block design. At each of the growing sites, there were six to nine blocks. In each block, four replicates (plantlets) of each clone were planted. A random selection of six blocks per site and one plantlet per clone per block (= six samples per clone per growing site) was made. A current year's growth from the first branch, from the top of clonal plantlets, and five branches of current year's growth from the upper third part of parental trees were collected on June 26, 2001. Branches were air-dried and stored at −20°C for chemical analysis.

Extraction of Compounds. Both phenolics and triterpenoids were analyzed from the same extract. For extraction, leaves were removed from study branches, and the current year's growth (≈ 10–15 cm) was cut into 2-mm pieces and weighed. Methanol (20 ml; 100%) was added, the sample was allowed to stand for 20 min on ice (≈ +4°C), and homogenized for 2 min using an Ultra-Turrax clipping homogenizer. The extraction was repeated ×2 with 15 ml of methanol and once more with 15 ml of diethyl ether for complete extraction of triterpenoids. The residue was washed with methanol. Extracts and washings were filtered and combined, and the solvents removed by vacuum evaporation. Each sample was redissolved in 10 ml of 100% methanol, and aliquots of 2 × 1, 1 × 2, and 1 × 3 ml were evaporated to dryness under nitrogen. Different aliquots were taken to ensure suitable concentrations for both HPLC-DAD and HPLC-MS runs. Dried samples were stored at −20°C for analysis by HPLC-DAD and HPLC-MS.

HPLC-DAD and HPLC-MS Analysis. Quantitative analysis of the low molecular weight phenolics (LMWP) in stem samples was done by HPLC using

gradient elution and diode array detection (DAD) as previously described by Laitinen et al. (2000). The wavelengths used for detection were 220, 270, 280, 320, and 360 nm. Identification of quercetin derivatives, 3,4′-dihydroxypropiophenone-3-β-D-glucopyranoside (DHPPG), caffeoyl quinic acids, cinnamic acid derivatives, and flavonoid aglycones, was based on comparison of HPLC retention times and spectral characteristics described in Keinänen and Julkunen-Tiitto (1998) and Julkunen-Tiitto et al. (1996). Secondary metabolites were quantified against commercial standards: salicin (Roth, Karlsruhe, Germany) for salidroside, DHPPG, rhododendrin, and platyphylloside; (+)-catechin hydrate (Aldrich Chemical Company, USA) for catechin derivatives; chlorogenic acid (Aldrich, Steinheim, Germany) for all phenolic acids, quercetin-3-*O*-glucoside (Extrasynthèse, Genay, France) for all quercetin derivatives; gallic acid (Aldrich) for gallotannins, and apigenin (Roth) for flavonoid aglycones. Before HPLC-DAD analysis, dried 1 ml phenolic samples were redissolved in 0.4 or 0.6 ml water/methanol (1:1), depending on sample concentration. Quantitative analysis of triterpenoid components was done by HPLC-MS. Isocratic elution was used with EtOH (94%): aqueous 1.5% tetrahydrofuran + 0.25% acetic acid (75:25, pH 5.4). HPLC/atmospheric pressure electrospray ionization (HPLC/API-ES) conditions were as follows: the column was a Hypersil RP C-18, 2-mm ID × 10 cm, the ES fragmentor voltage was 100 V, and the flow rate was 0.2 ml/min. Before HPLC-MS analysis, dried 1 ml terpenoid samples were redissolved in 5 ml clonal plantlets, and dried 3-ml samples were redissolved in 3 ml parental trees, 94% ethanol. Triterpenoid components were quantified by using purified papyriferic acid, which was kindly supplied by Prof. Paul Reichardt, University of Alaska, USA. The concentrations of pendulic acid were considered to be relative because papyriferic acid was used as a standard.

In our figures, phenolic acids are divided into two groups: neochlorogenic acid and chlorogenic acid, and six chlorogenic acid derivatives were grouped together as caffeoyl quinic acids, and three *p*-hydroxycinnamic acid-like compounds were grouped as total cinnamic acid derivatives. Catechin derivatives were combined as the total of four components [(+)-catechin and three catechin derivatives]. Total quercetin derivatives contained quercetin-3-galactoside, quercetin-3-glucuronide, quercetin-3-glucoside, quercetin-3-arabinoside, and four unknown quercetin derivatives. The flavonoid aglycone group contained several components, some of which could not be resolved in all samples by our method. Apigenin and one luteolin derivative were counted together, as was also done for chrysoeriol and one other luteolin derivative. In addition, a third luteolin derivative and two apigenin derivatives were included in the flavonoid aglycone group. Total low molecular weight phenolics (LMWP) include all of the analyzed phenolics, except condensed tannins. For triterpenoids, the papyriferic acid and four papyriferic acid derivatives were grouped as total papyriferic acid derivatives, and two pendulic acid derivatives were grouped to represent

the total of pendulic acid derivatives. Total triterpenoids include all analyzed triterpenoids.

Analysis of Condensed Tannins. Condensed tannins were analyzed from stem extract by an acid butanol assay as previously described in Porter et al. (1986). Quantification of tannins was based on purified *B. nana* leaf tannin.

Statistics. For evaluating chemical similarity in phenolic composition between parental trees within a population, a classification of parental trees to putative chemotypes was made by UPGMA clustering as previously described in Laitinen et al. (2000). Mean values of five samples per tree of all analyzed phenolic compounds were used for UPGMA-clustering analysis.

Due to nonnormality and heterogeneity of variances, the concentrations of the following compounds were transformed for statistical tests: a square-root ($x + 1$) transformation was used for parental tree concentrations of quercetin-3-glucuronide + quercetin-3-glucoside; a natural logarithm ($x + 1$) transformation of concentration was used for salidroside, chlorogenic acid, and quercetin-3-galactoside; a natural logarithm ($x + 0.5$) transformation of concentration was used for rhododendrin, quercetin-3-arabinoside, and quercetin derivative 3; and a natural logarithm ($x + 0.1$) transformation of concentration was used for platyphylloside, gallotannins, and all terpenoid compounds and compound groups. Data from micropropagated plantlets were treated by a square-root transformation for concentrations of quercetin-3-glucuronide + quercetin-3-glucoside. A natural logarithm of concentration + 1 transformation was used for papyriferic acid and total pendulic acids; a natural logarithm of concentration + 0.5 was used for DHPPG, catechin, chlorogenic acid, quercetin-3-galactoside, quercetin-3-arabinoside, and flavonoid aglycones, and a natural logarithm of concentration + 0.1 was used for gallotannins and platyphylloside.

Differences in the amount of chemical compounds or compound groups among parental trees, growing sites, and clones were tested by analysis of covariance (ANCOVA). For analysis of chemical data between clones and growing sites, the following model was used: site (S), clone (C), S × C, S × block (B), weight of the current year's growth was used as covariate. Growing site and clone were treated as fixed factors, and block was used as a random factor. Weight was used as a covariate to remove an additional factor that may give rise to variation, i.e., the wood-to-bark ratio, which varies with different sizes of branches. A sequential Bonferroni correction was used for evaluating the results of all ANCOVA tests for parental trees and for each growing site (Rice, 1989).

A variance component analysis was used to evaluate the effect of genotype on total chemical variation. For clonal plantlets, the observed phenotypic variance (V_P) can be partitioned into genotypic variance (V_G) and environmental variance (V_E), i.e., $V_P = V_G + V_E$. In the case of clonal material, plantlets within a clone have an equal genetic constitution, thus, the within clone, variance component is due to variation in the environment or an error in sampling and

measuring (Falconer, 1989). The between-clone component of variance is an estimate of V_G. The total genotypic variance component contains both the additive and nonadditive components, which cannot be separated by using clonal material. Thus, the extent to which individual phenotype is determined by genotype was expressed by the degree of genetic determination, i.e., heritability in a broad sense = V_G / V_P (Falconer, 1989). When studying clonal plantlets, there are environmental effects included in V_G, because some part of the environmental differences between parental plants may be transmitted to all of their clonal descendants. When the degree of genetic determination is estimated by using clones, the ratio V_G / V_P is an overestimate and, strictly speaking, it should be referred to as clonal repeatability as suggested by Falconer (1989, p. 128). Thus, the term clonal repeatability was also used in this study. The estimation of variance components was computed for all compounds and compound groups (varcomp procedure, REML), and the results are presented as variation between parental trees with 95% confidence limits (Searle, 1997) and as clonal repeatability ± SE (Falconer, 1989; Dickerson, 1969) for clonal plantlets. All figures are based on nontransformed data. All statistical analyses were made using SPSS 10.1.0, SPSS Inc., 1989–2000.

RESULTS

Chemical Variation among Parental Trees and within Individual Trees. There was significant variation among parental trees for all analyzed compounds and compound groups (univariate analysis of variance with sequential Bonferroni correction, $P < 0.001$) (Table 1 and Figures 1–5). The differences among parental trees accounted for most of the variation in chemical concentrations for phenolics, whereas for triterpenoid groups, pendulic acid derivatives, and total terpenoids, the variation within an individual parental tree was greater than that among parental trees (Table 1). For individual phenolic compounds, in many cases, the variation among trees was large. For example, in the case of (+)-catechin, the mean concentration of tree 25 was only 1.1 mg/g (DW), whereas several other trees contained more than 5 mg/g (DW) of (+)-catechin (Figure 3). With respect to chlorogenic acid, the differences among trees were more than 10-fold and nearly fivefold for salidroside (Figure 3).

Four distinct chemotypes were found among the 30 study trees by qualitative UPGMA clustering (Figure 1, groups 1–4). In the chemotype grouping (Figure 1), (+)-catechin and chlorogenic acid (compounds 7 and 8) were the main compounds in groups 1 and 2. One chlorogenic acid derivative (compound 6) was lacking from group 2; also, other chlorogenic acid derivatives (compounds 27 and 28) were lacking or only present in trace amounts. In group 3,

Notes: Sample weight was used as a covariate. Results of variance component analysis for variation between parental trees and between clones are presented as a proportion of total variation with 95% confidence limits for parental trees and as a clonal repeatability = V_G / V_P ± SE for clonal plantlets. Total variation (parental trees) = variation between trees + error (variation within a tree). Total variation (V_P) (clonal plantlets) = variation between clones (V_G) + variation due to clone × site and site × replicate interaction + error (variation within a clone).

[a] NS: Not significant.

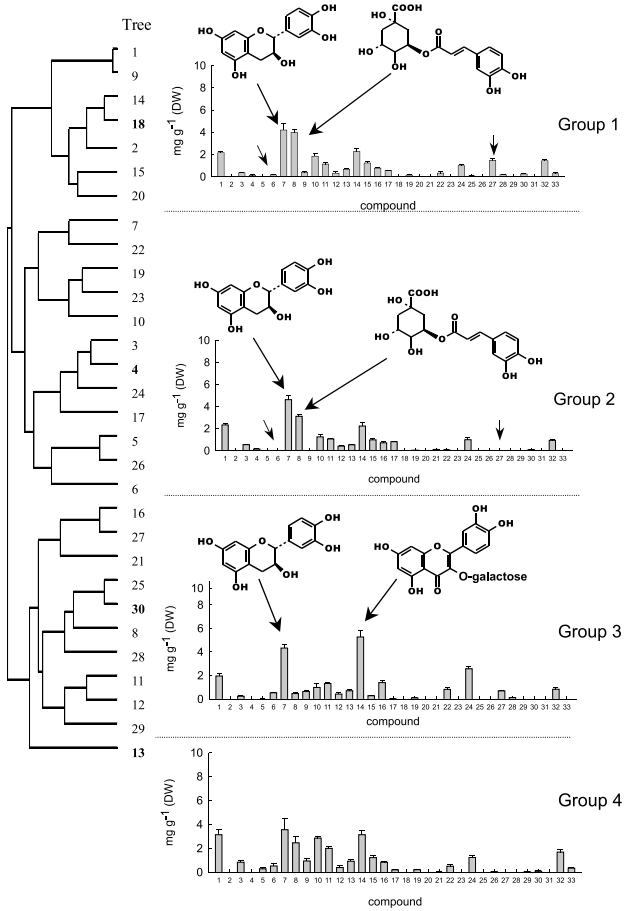

FIG. 1. UPGMA dendrogram for the chemical similarity in parental trees. Trees with an example chemical profile are marked with bold numbers. The chemical structures of main compounds used for defining different chemotypes are shown: for groups 1 and 2, (+)-catechin and chlorogenic acid; for group 3, (+)-catechin and quercetin-3-galactoside. Small arrows indicate the other compounds, which aided to define different chemotypes. Individual compounds are listed in order of retention times to illustrate the HPLC profile. Analyzed compounds that were used in UPGMA clustering are: 1 = salidroside; 2 = DHPPG; 3 = neochlorogenic acid; 4, 5, and 9 = *p*-OH-cinnamic acid derivatives; 6, 17, 21, 25, 27, and 28 = chlorogenic acid derivatives; 7 = (+)-catechin; 8 = chlorogenic acid; 10 = rhododendrin; 11, 12, and 13 = catechin derivatives; 14 = quercetin-3-galactoside; 15 = quercetin-3-glucoside + quercetin-3-glucuronide; 16 = quercetin-3-arabinoside; 18, 20, 23, and 24 = quercetin derivatives; 19 = pentagalloylglucose; 22 = platyphylloside; 26 and 29 = gallotannin derivatives; 30 = apigenin + luteolin derivative; 31 = chrysoeriol + luteolin derivative; 32 and 33 = apigenin derivatives.

the (+)-catechin and quercetin-3-galactoside were the main compounds. Tree 13 was separated from all other trees. It had no clear main compounds; that is, salidroside, (+)-catechin, chlorogenic acid, rhododendrin, catechin derivative 1, and quercetin-3-galactoside (compounds 1, 7, 8, 10, 11, and 14 in Figure 1) were all found in moderate concentrations. Minor compounds, such as p-OH-cinnamic acid derivatives, catechin derivatives, and platyphylloside, were present in all chemotype groups.

Clonal Variation in Chemistry: Effects of Genotype and Environment. There were significant differences among clones for all analyzed compounds and compound groups (Figures 2–5). For compound groups such as cinnamic acid derivatives, total quercetin derivatives, flavonoid aglycones, and gallotannins (Figure 2), and for individual compounds such as quercetin derivatives, DHPPG, and platyphylloside (Figures 3 and 4), there were significant differences only among clones; that is, there was no detected environmental effect in these cases. Especially high variation among clones for individual compounds was found for quercetin-3-glucoside + quercetin-3-glucuronide (these compounds could not be separated by our analytical method); the concentrations varied from 0.1 mg/g (DW) in clone 25 to 1.1 mg/g (DW) in clone 19. For DHPPG, the concentrations varied from 0 mg/g (DW) in clone 3 to 2.1 mg/g (DW) in clone 5 (Figures 3 and 4).

When the degree of genetic determination for the birch shoot secondary chemistry was calculated by the variance component analysis for compound groups, the highest values for clonal repeatability were found for caffeoyl quinic acids and cinnamic acid derivatives (Table 1). The genetic control of birch shoot secondary chemistry differed greatly among individual compounds or compound groups, as shown by high variation in repeatability values. For individual compounds, the clonal repeatability was highest (over 0.5) for chlorogenic acid, quercetin-3-glucoside, quercetin-3-glucoside + quercetin-3-glucuronide, and DHPPG (Table 1).

Significant environmental effects on some of the analyzed chemical groups were detected for the clonal plantlets, namely, for catechin derivatives, caffeoyl quinic acids, condensed tannins, and LMWP (Figure 2), and for total pendulic acid derivatives and total triterpenoids (Figure 5). For individual compounds, significant differences among growing sites were found for (+)-catechin, chlorogenic acid, rhododendrin, and salidroside (Figures 3 and 6a). For example, the mean concentration for (+)-catechin varied from 1.2 mg/g (DW) in Kuikanniitty to 2.7 mg/g (DW) in Vaahersalo (Figure 3). The minimum and maximum mean concentrations for chlorogenic acid were 0.83 mg/g (DW) in Kuikanniitty and 1.26 mg/g (DW) in Parikkala, respectively. Similar results were obtained for rhododendrin.

There was significant site × clone interaction for all individual terpenoid compounds and for total terpenoids (Figure 5), as well as for two of the phenolic

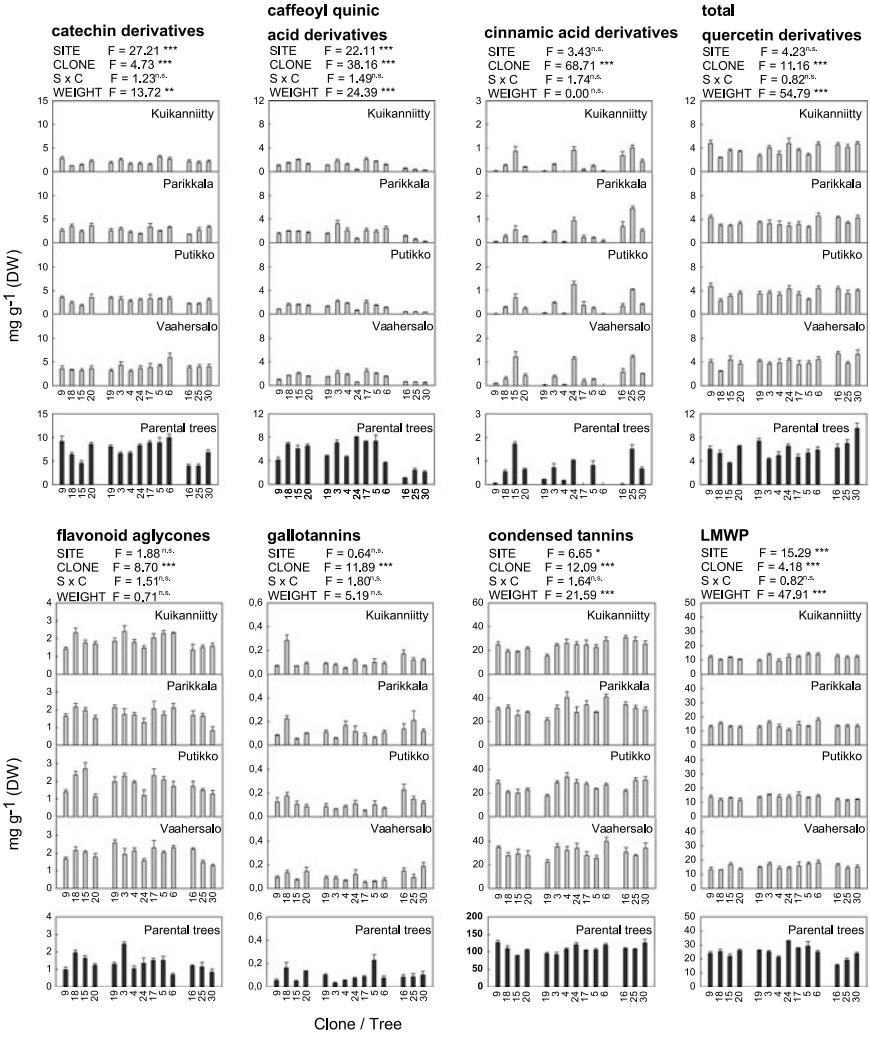

FIG. 2. Concentrations per parental tree or clone for analyzed compound groups. For parental trees, an average ± SE of five stem samples was used, and for individual clones, an average ± SE of six stem samples was counted for each growing site. Results are expressed as milligrams per gram of dry weight (DW) of plant material. Trees and clones are grouped by chemotype (see UPGMA clustering in Figure 1).

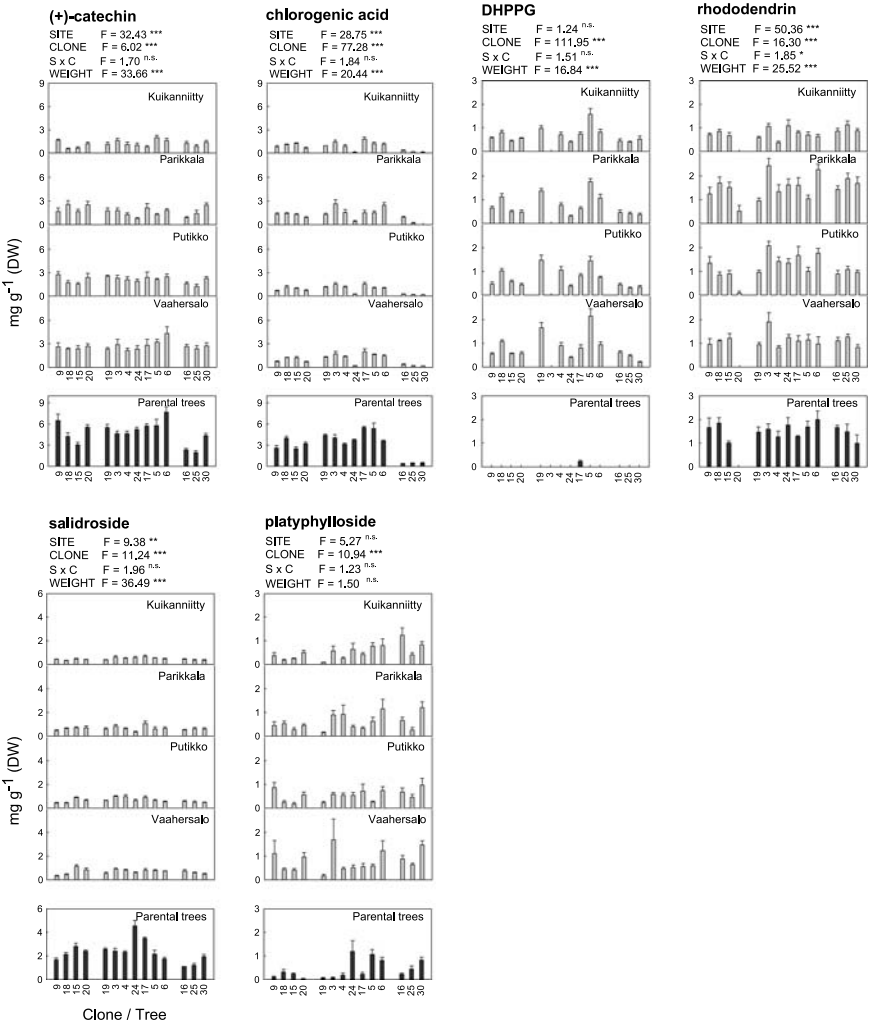

FIG. 3. Concentrations per parental tree or clone for main phenolic compounds: (+)-catechin, chlorogenic acid, DHPPG, rhododendrin, salidroside, and platyphylloside. For parental trees, an average ± SE of five stem samples was used, and for individual clones, an average ± SE of six stem samples was counted for each growing site. Results are expressed as millgrams per gram of dry weight (DW) of plant material. Trees and clones are grouped by chemotype (see UPGMA clustering in Figure 1).

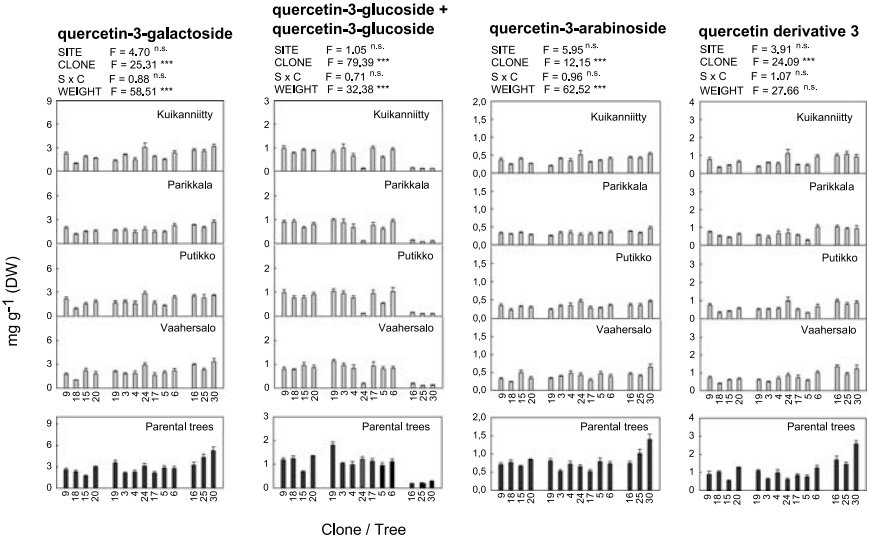

FIG. 4. Concentrations per parental tree or clone for main phenolic compounds: main quercetin derivatives. For parental trees, an average ± SE of five stem samples was used, and for individual clones, an average ± SE of six stem samples was counted for each growing site. Results are expressed as milligrams per gram of dry weight (DW) of plant material. Trees and clones are grouped by chemotype (see UPGMA clustering in Figure 1).

compounds, rhododendrin, and salidroside (Figure 3). This indicates that the response of individual clones to differences in growing environment differed among clones; that is, the environmental sensitivity was dependent on individual plant genotype (Figure 6b).

Comparison between Parental Trees and Clonal Plantlets. In both developmental stages of birches, the main phenolic compound group was condensed tannins (Figure 2). The greatest difference in chemical quality between parental trees and clonal plantlets was found in triterpenoids (Figure 5). The main phenolic compounds in the shoots of parental trees and in the shoots of young plantlets were salidroside, (+)-catechin chlorogenic acid, and quercetin-3-galactoside (Figures 1–4). For phenolics in general, the chemical profile was similar in parental trees and in their micropropagated plantlets. Two triterpenoid compounds, papyriferic acid, and one pendulic acid derivative were found in samples from parental trees (Figure 5), whereas in clonal plantlets, papyriferic acid and four papyriferic acid derivatives were found. In addition, two pendulic acid derivatives were found only in young shoots of micropropagated plantlets.

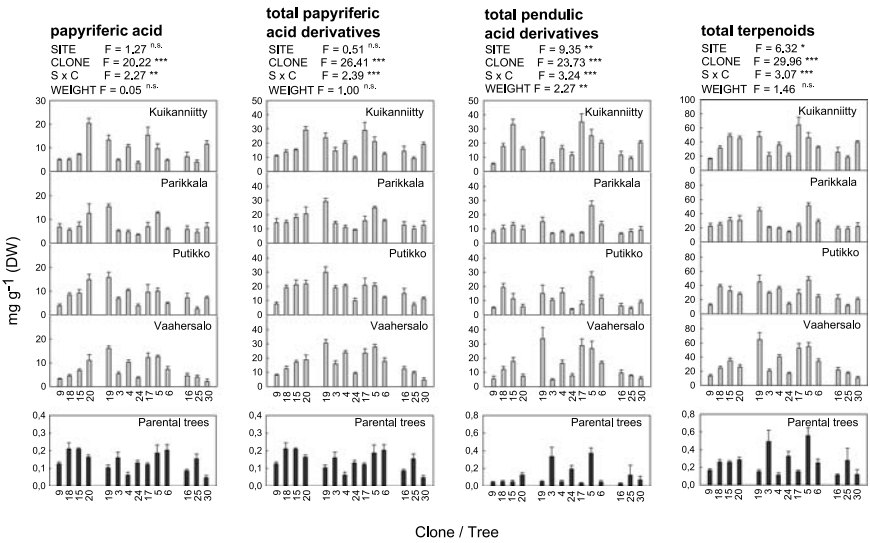

FIG. 5. Concentrations per parental tree or clone for papyriferic acid and triterpenoid groups. For parental trees, an average ± SE of five stem samples was used, and for individual clones, an average ± SE of six stem samples was counted for each growing site. Results are expressed as milligrams per gram of dry weight (DW) of plant material. Trees and clones are grouped by chemotype (see UPGMA clustering in Figure 1).

Quantitatively, there were great differences in secondary chemistry between parental trees and clonal plantlets. This difference can be seen when the results from phenolic compound groups are compared. The amount of condensed tannins in parental trees was twice the amount found in clonal plantlets (Figure 2). Also, the concentrations of catechin derivatives and caffeoyl quinic acid derivatives were clearly higher in parental trees. For

FIG. 6. Environmental sensitivities of individual clones. Environmental values are expressed as an average of all analyzed samples within a particular growing site, and genotypic values are expressed as an average of samples from one clone in a particular growing site. The value of each genotype is plotted against the environmental mean of all genotypes to determine differences in the environmental sensitivities of different genotypes. a Environmental values are 0.83 mg g^{-1} (DW) for Kuikanniitty (KU) and Putikko (PU), 1.02 mg g^{-1} (DW) for Vaahersalo (VA), and 1.26 mg g^{-1} (DW) for Parikkala (PA). b environmental values are 7.34 mg g^{-1} (DW) for PA, 7.44 mg g^{-1} (DW) for VA, 8.12 mg g^{-1} (DW) for PU, and 8.52 mg g^{-1} (DW) for KU. Linear regressions are presented as lines for all clones. The equation and R^2 values are presented for those clones differing mostly from each other.

triterpenoid concentrations, the difference between parents and clonal plantlets was even more pronounced (Figure 5). All parental trees had less than 1 mg/g (DW) of terpenoids in their current year growth. In clonal plantlets, the amounts of terpenoids varied from 10.2 mg/g (DW) (clone 30 in Vaahersalo) to 64.6 mg/g (DW) (clone 19 in Vaahersalo) (Figure 5).

When individual phenolic compounds such as (+)-catechin, chlorogenic acid, and salidroside were analyzed, the concentrations were clearly higher in samples from parental trees than in samples from clonal plantlets. On the contrary, DHPPG was only found in low concentration in samples from one of the parental trees (tree 17), whereas 0.2–2.1 mg/g (DW) was found in all clones except clone no. 3 (Figure 3).

DISCUSSION

Between parental trees, a high variation in birch shoot secondary chemistry was found. Variation within an individual tree and between branches at the same level of tree canopy was low for most of the studied compounds and compound groups (Table 1). This indicates a high population level variation in the secondary chemistry of the European white birch, a result that is in accordance with our previous results where leaf chemistry from these same parental trees was investigated (Laitinen et al., 2002). UPGMA clustering of shoot chemistry (Figure 1) gave different chemotype groups than grouping on the basis of leaf chemistry (see Laitinen et al., 2000). This is apparently due to qualitative differences between leaf and shoot chemistry's.

The main phenolic compounds were the same in both mature trees and young clonal plantlets of the same trees; that is, the chemical profiles were similar. This indicates genetic control of these secondary compounds in European white birch. Generally, the concentrations of defensive compounds in deciduous trees are thought to be higher during the juvenile stage (Bryant and Julkunen-Tiitto, 1995), which was also the case in our present study—especially for triterpenoids. The amounts of total terpenoids for some clones were almost 100 times greater in clonal plantlets than in parental trees (Figure 5). This is in accordance with a previous study on Alaska paper birch (*Betula resinifera*), where Reichardt et al. (1984) found 25 times greater amounts of papyriferic acid in juvenile stems than in mature twigs. Contrary to terpenoids, the concentrations of some phenolic compound groups and individual compounds, e.g., catechin derivatives, caffeoyl quinic acids, condensed tannins, (+)-catechin, and salidroside, were higher in parental trees (Figures 3 and 4). The reason for this difference may be related to the different roles for those compounds. Catechins play a role as important structural elements of condensed tannins (Strack, 1997; Seigler, 1998),

whereas triterpenoids are effective defenses against hares particularly in the juvenile developmental stages of white birches (e.g., Reichardt et al., 1984). Ontogenic differences make it difficult to predict the quantity of triterpenoids in clonal plantlets by only using results gained from parental trees, whereas a higher similarity between clonal plantlets and parental trees occurs for many studied phenolic compounds.

Previous studies have documented significant differences in the concentrations of foliar phenolic compounds, e.g., among clones of *Salix* sp. (Nichols-Orians et al., 1993; Hakulinen et al., 1995; Hakulinen, 1998) and *B. pendula* (Keinänen et al., 1999a). In this study, a statistically significant variation in shoot chemistry was also found among clones (Figures 2–5), which agrees with our previous study that used greenhouse-grown *B. pendula* clonal plantlets (Laitinen et al., 2004). Apparently, the higher environmental variation at the four growing sites in the present study increased the chemical variation within clones and may partly explain the slight differences in the pattern of chemical variation between these studies. Regardless of the differences, the results in these two studies are similar in cases where clonal repeatability (i.e., heritability in a broad sense) was found to be high. This indicates that genetic control of the accumulation of many birch shoot secondary compounds, such as chlorogenic acid, quercetin-3-glucoside + quercetin-3-glucuronide, and DHPPG, is strong (Table 1).

In clonal repeatability, the additive and nonadditive component of genetic variation cannot be separated (Falconer, 1989). However, it is used especially when the possible gain obtainable by vegetative production of trees is considered (van Buijtenen, 1992) and also because of the huge plant material needed for reliable estimates of narrow sense heritability (see King et al., 1997). Differences in heritability among different compounds may be due to both the origin and/or different bioactivities of the compounds (Orians et al., 1996). Intense selection for adaptive traits may lead to low heritability values. Thus, high heritabilities for compounds with high bioactivity may suggest a short period of selection time (Falconer, 1989; Orians et al., 1996).

The especially low heritability (i.e., clonal repeatability) in our study for (+)-catechin and catechin derivatives may be due to their role as important precursors for condensed tannin synthesis (e.g., Strack, 1997). Condensed tannins occur in ferns, gymnosperms, and angiospermous plants (e.g., Seigler, 1998), which indicates that they are of rather ancient origin. Some condensed tannins are also known to have a high degree of bioactivity (e.g., Waterman, 1988; Hagerman et al., 1998; Kraus et al., 2003); thus, they can be assumed to have been under selective pressures for a long time. Therefore, the low heritability found in this study for condensed tannins might be due to a strong, long-lasting selection that decreased heritability during generations of time. Some other phenolic compounds or compound groups had high heritabil-

ities that could indicate either low selection pressures or their more recent origin.

Many triterpenoids are characteristic especially for rapidly evolving (e.g., Dugle, 1966) birch species (e.g., Reichardt, 1981; Vainiotalo et al., 1991; Taipale et al., 1993; Julkunen-Tiitto et al., 1996). Triterpenoids are defensive compounds against mammalian herbivory (Reichardt et al., 1984; Risenhoover et al., 1985; Rousi et al., 1991; Laitinen et al., 2004). In spite of their ecological importance (i.e., high bioactivity), the heritabilities of triterpenoids were high. Therefore, we postulate that these compounds have a rather recent evolutionary origin. To further study the possibilities for the selection of genotypes, the additive genetic variation for these traits should be studied.

The profound effect of environment on plant secondary chemistry was seen in our study as statistically significant differences between growing sites for the accumulation of 45% of the studied phenolic compound groups and individual compounds, e.g., catechin derivatives, condensed tannins, (+)-catechin, chlorogenic acid, rhododendrin, and salidroside (Figures 2 and 3). The site with the highest or lowest concentrations differed, depending on the compound studied, indicating that the immediate environment affected different compounds or compound groups differently. For rhododendrin, salidroside, and terpenoids, both the effect of growing site and the genotype by growing site interaction were statistically significant (Figures 3 and 5), suggesting that different clones may respond differently to environmental variation; that is, genotypes are specialized (Via, 1984) in their production of such compounds in different environments (e.g., Figure 6b). These results agree with previous studies that have shown that in *B. pendula* leaves, there are significant genotype × environment (different fertilization, defoliation, and ozone treatments) interactions for some of the phenolic compounds (Keinänen et al., 1999a; Yamaji et al., 2003). Also, the secondary chemistry of some willow clones is more sensitive to environmental factors than other willow clones (Hakulinen et al., 1995; Veteli et al., 2002). It seems that there is a clear genetic component in the determination of secondary chemistry profiles in European white birches, and the sensitivity of chemical accumulation to environmental factors is highly dependent on the studied compound and tree genotype.

Acknowledgments—We thank Anna-Maija Niskanen for the micropropagation; Anneli Kurkkio for help with the laboratory work; Hanni Sikanen, Susanne Heiska, Päivi Immonen, Heikki Kinnunen, Kalevi Silvennoinen, Jussi Tiainen, Mari Tuominen, and Satu Turtola for their help with fieldwork and technical assistance; and Seppo Ruotsalainen, Markku Keinänen, and Sarita Keski-Saari for valuable comments on the manuscript. James Callaway and Ewen Macdonald kindly helped to revise the English text. This study was part of the Finnish Biodiversity Research Programme, was mainly funded by the Academy of Finland, and was partly funded by the Finnish Centre of Excellence Program 2000–2005, Centre for Excellence for Forest Ecology and management, project no. 64308.

(Received May 27, 2004; revised August 23, 2004; accepted December 3, 2004)

Abstract—Plant tissues may show chemical changes following damage. This possibility was analyzed for *Minthostachys mollis*, a Lamiaceae native to Central Argentina with medicinal and aromatic uses in the region. Effects of mechanical damage on its two dominant monoterpenes, pulegone and menthone, were analyzed by perforating *M. mollis* leaves and then assessing essential oil composition at 24, 48, and 120 hr; emission of volatiles was also measured 24 and 48 hr after wounding. Mechanical damage resulted in an increase of pulegone and menthone concentration in *M. mollis* essential oil during the first 24 hr. These changes did not occur in the adjacent undamaged leaves, suggesting a lack of systemic response. Postwounding changes in the volatiles released from *M. mollis* damaged leaves were also detected, most noticeably showing an increase in the emission of pulegone. Inducible chemical changes in aromatic plants might be common and widespread, affecting the specific compounds on which commercial exploitation is based.

Key Words—Phytochemical induction, aromatic plants, Lamiaceae, mechanical wounding, monoterpenes, pulegone, menthone, *Minthostachys mollis.*

INTRODUCTION

Plants respond to injuries or wounds from biotic or abiotic stresses by deploying various biochemical defense mechanisms (Karban and Baldwin, 1997). These

* To whom correspondence should be addressed. E-mail: banchioe@com.uncor.edu

defenses can be either direct, making the plant more resistant to further herbivory (e.g., toxic secondary metabolites, digestibility reducers) or indirect (e.g., volatiles released after attack). The latter facilitate "top-down" control of herbivore populations by allowing pathogens, predators, and parasitoids to distinguish between infested and noninfested plants, thus aiding them in host or prey location (Baldwin and Preston, 1999).

The distinction between both types of defenses is not clear-cut, since some direct defenses, particularly those that slow herbivore growth by reducing their digestive efficiency, may need the third trophic level to be effective (Jongsma and Bolter, 1997; De Leo et al., 1998). Hence, for some direct defenses, we should expect coordinated induction of both defense types (Baldwin and Preston, 1999).

Among the best studied examples of plant secondary metabolites with defensive functions, monoterpenes (the C10 members of the terpenoid family of natural products) occupy a prominent place. These colorless, lipophilic, volatile substances represent the major constituent in plant essential oils and have been implicated as defenses against a variety of insects and pathogens (Langenheim, 1994; Phillips et al., 1995; Isman, 2000; Ciccia et al., 2000; Bekele and Hassanali, 2001; Harrewijn et al., 2001).

Induced chemical changes could also be important from a different point of view, when aromatic or medicinal plants are considered. In this case, the change *per se* would matter, particularly if the specific compounds giving economic value to the plant, for fragrance, flavor, or pharmaceutical industries, are affected (Valladares et al., 2002).

In the present paper, we analyze changes, induced by mechanical damage, in the essential oil composition and emission of volatiles from *Minthostachys mollis* (Kunth.) Griseb., a Lamiaceae native to Central Argentina with medicinal and aromatic uses in the region. Damage-induced changes in essential oil composition and in the volatiles emitted have rarely been considered simultaneously (e.g., Zabaras and Wyllie, 2001).

We have dealt with monoterpenoids, since the most important compounds of *M. mollis* belong to this group (Valladares et al., 2002) and were given previous records of increased production of such compounds following herbivory in various plant species (Karban and Baldwin, 1997; Tumlinson et al., 1999; Valladares et al., 2002). Temporal and spatial (translocation) variations in the plant response have been included in the analyses.

METHODS AND MATERIALS

Plants. Healthy, pest-free, 6-month-old *M. mollis* plants, were grown in a glasshouse without supplementary lighting. In each plant, a 5-cm-diam hole was

punched in the middle of the lamina of five leaves (of approximately the same age and size, but from different nodes), thus removing 30–40% of the leaf area.

Damaged leaves were cut off after either 24, 48, or 120 hr. The undamaged leaves adjacent to wounded ones were collected at the same time and kept separately. Five leaves similar in size and age to the damaged ones from an undamaged plant were used as controls. All leaves were frozen until the chemical analysis was carried out. Ten different plants (replications) were used for each treatment.

Essential Oil Extraction. After weighing, the plant material was extracted by hydrodistillation in a micro-Clevenger-like apparatus for 40 min. The volatile fraction was collected in dichloromethane. Internal standard was added (12 μg of tymol in 2 μl dichloromethane). Essential oils of *M. mollis* contain 50 different compounds, with two monoterpenes accounting for about 80% of their volume: pulegone and menthone (Valladares et al., 2002). These two compounds were used for the present study. The monoterpenes were quantified with respect to thymol. The FID response factors for each compound generate an equivalent area with a negligible error (<5%).

Collection of Plant Volatiles. The volatile collection system consisted of a vacuum pump that created a constant air flow (300 ml/min) through a polyethylene terephthalate (PET) chamber (1500 ml in volume) containing a plant; the chamber was closed at one end with a cap predrilled to fit exactly the collection trap. At the other end, a cap, with a hole through which the plant stem passed, separated the bottom of the chamber from the plant pot ground. Air exited the chamber through a reusable glass collection trap packet with 30 mg Super Q absorbent (80–100 mesh)(Alltech), which was rinsed (5–10 ml dichloromethane) prior to each volatile collection to remove impurities. Volatiles were collected for 2 hr. Immediately after, the compounds were eluted from the absorbent traps with 200 μl dichloromethane and internal standard was added (12 μg of tymol in 2 μl dichloromethane). Collected volatiles were analyzed by gas chromatography (GC) as described below. Once the volatiles were collected, the plant was cut and weighed.

For each plant, volatiles were collected 24, 48, and 96 hr after damage. Volatiles were also collected from undamaged control plants. All plants were of the same age and size, and collections done taken under similar conditions of light, temperature (20–24°C), and relative humidity (~70%). Collections made without plants, from an empty chamber, established that the background of monoterpenes present was negligible. Each treatment was repeated at least five times.

Chemical Analyses. Analyses were accomplished by using a Perkin-Elmer Q-700 gas chromatograph equipped with a CBP-1 capillary column (30 m $\times$ 0.25 mm) and a mass-selective detector. Analytical conditions: injector and detector temperatures 250 and 270°C, respectively; oven temperature pro-

grammed from 60°C (3 min) to 240°C at 4°/min; carrier gas helium at a constant flow of 0.9 ml/min; and source 70 ev. Oil components were identified by a combination of mass spectral and retention time data, which were compared both with those of authentic compounds and with those published in Zygadlo et al. (1996). GC analyses were performed with a Shimadzu GC-RIA gas chromatograph, fitted with a 30 m × 0.25 mm fused silica capillary column coated with a Supelcowax 10. The GC operating conditions were: oven temperature programmed from 60°C (3 min) to 240°C at 4°/min; injector and detector temperatures 250°C; detector FID; carrier gas nitrogen at a constant flow of 0.9 ml/min.

Volatile Emission Rate. An estimation of the amount of monoterpenes emitted in relation to their content in the plant tissues was obtained by calculating, for each treatment, the quotient between the concentration values of menthone or pulegone in the headspace and their respective concentration in the essential oil (headspace/essential oil).

Statistical Analyses. Differences in menthone and pulegone content between treatments were tested for statistical significance using Mann–Whitney test, since data were not normally distributed.

RESULTS

Oil Concentration. Menthone and pulegone concentration in the essential oil of wounded leaves (Figure 1) increased six and four times, respectively, in comparison to control plants ($P < 0.05$, $U_{\text{menthone}} = 239.0$, $U_{\text{pulegone}} = 373.0$),

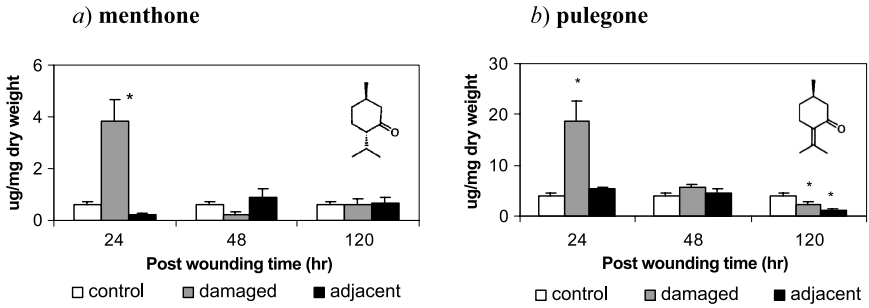

FIG. 1. Changes in oil concentration (means ± SE) of *a* menthone and *b* pulegone from *Minthostachys mollis* leaves as a result of mechanical damage. *Values significantly different from controls ($P < 0.05$, Mann–Whitney test).

TABLE 1. VARIATIONS IN THE MAIN VOLATILES RELEASED FROM *Minthostachys mollis* PLANTS AS A RESULT OF MECHANICAL DAMAGE

Compound	Control	24-hr Postwounding	48-hr Postwounding
Menthone	1.13 ± 0.14	0.85 ± 0.39	0.88 ± 0.37
Pulegone	0.21 ± 0.03	0.85 ± 0.27*	0.23 ± 0.07

Values are expressed in nanograms per milligram fresh weight (means ± SE).
*Values significantly different from controls ($P < 0.05$, Mann–Whitney test).

during the first 24 postwounding hours. After that time, concentration of both compounds returned to its prewounding level.

Undamaged leaves adjacent to wounded leaves did not differ significantly from controls regarding pulegone and menthone concentration after the first 24 hr ($P > 0.05$, $U_{\text{menthone}} = 48.0$, $U_{\text{pulegona}} = 241.5$), despite the dramatic increase observed in their opposite (damaged) leaves (Figure 1). However, and in coincidence with the damaged leaves, after 120 hr, their concentration of pulegone decreased below the level of control leaves ($P < 0.05$, $U = 56.0$).

Plant Volatiles. Headspace experiments showed a change in concentration of the compounds emitted by damaged plants compared with undamaged ones. Emission of menthone was similar in both damaged and undamaged plants ($P > 0.05$, $U_{24\ \text{hr}} = 46$, $U_{48\ \text{hr}} = 73.5$) and did not change over time (Table 1). Instead, emission of pulegone increased dramatically upon wounding ($P < 0.05$, $U_{24\ \text{hr}} = 105$) and then decreased back to prewounding levels ($P > 0.05$, $U_{48\ \text{hr}} = 73.5$) (Table 1).

Emission Rate of Volatiles. The emission rate of pulegone with regard to its concentration in the essential oil did not show important changes following

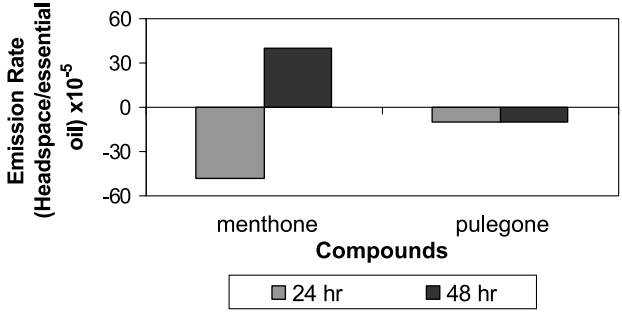

FIG. 2. Volatile emission rates of menthone and pulegone from *Minthostachys mollis* plants, 24 and 48 hr after being mechanically wounded, presented as differences from the corresponding rates in undamaged plants.

mechanical wounding, whereas the emission rate of menthone was noticeably lower at 24 hr and higher at 48 hr than that of control plants (Figure 2).

DISCUSSION

Oil Concentration. M. mollis plants responded to mechanical damage by dramatically increasing, after 24 hr, the concentration of the two most abundant monoterpenes (menthone and pulegone) in their essential oil. Zabaras and Wyllie (2001) found a comparable behavior in another aromatic plant, *Ocimum minimum*, whose main compound linalool increased 24 hr after suffering mechanical wounding.

In the present work, leaves adjacent to damaged ones remained unaltered in their chemical composition at least regarding menthone and pulegone concentration. In other systems, the defensive reaction has been recorded not only at or near the site of damage, but also throughout the plant, as a result of signaling molecules enabling communication among different plant tissues (Mc Auslane et al., 1997; Constabel and Ryan, 1998; Baldwin and Preston, 1999; Gatehouse, 2002). An elicitor may be required for a systemic response to be induced (Tumlinson et al., 1999).

In *M. mollis*, most of the essential oil transformations after injury occurred during the first 24 postwounding hours, after which the damaged leaves started to return to their prewounding metabolic state. From an ecological perspective, rapid chemical changes may be interpreted as an attempt to minimize subsequent predation (Clausen et al., 1991).

Monoterpenes are known to be induced by herbivore feeding in *M. mollis* (Valladares et al., 2002) and in other plant species (e.g., Mc Auslane et al., 1997; Paré and Tumlinson, 1999). Therefore, their role during the wounding response is likely to be involved in protecting damaged leaves from further attack. This function could be attributed mainly to pulegone, considering that its toxic (Fournet et al., 1996; Franzios et al., 1997; Ellis and Baxendale, 1997; Lamiri et al., 2001; Harrewijn et al., 2001), growth-inhibiting (Hummelbrunner and Isman, 2001), repellent, and oviposition-deterring (Harrewijn et al., 1994) properties have been demonstrated on various insect species. However, menthone has also showed insecticidal (Lee et al., 2001) and genotoxic activities (Franzios et al., 1997).

Plant Volatiles. In agreement with other studies (e.g., Turlings et al., 1990; Paré and Tumlinson, 1997), our results show that artificial damage can induce the release of volatile terpenoids. Although both major constituents of *M. mollis* essential oil increased after wounding, only the emission of pulegone changed. Zabaras et al. (2002) also found a dramatic increase of volatile emission in

Melaleuca alternifolia leaves after mechanical damage, but in that case, the compounds involved remained unchanged in the essential oil.

The increase in pulegone emission rate 24 hr after damage may be interpreted as an attempt to minimize subsequent predation (Harrewijn et al., 2001) or as a potential cue for natural enemies of herbivores (De Moraes et al., 1998).

Emission Rate of Volatiles. The amount of monoterpenes emitted as volatiles represented only a small fraction of the total monoterpenes present in the plant. Extrapolation over a typical 6-month growing plant suggests that <1% of total monoterpenes would be released to the atmosphere. A low rate of volatilization is consistent with observations in other Lamiaceae (e.g., Tyson et al., 1974; Gershenzon et al., 2000).

Even in undamaged plants, the relative concentration of various monoterpenes emitted from *M. mollis* was quite different from that found in the essential oil within the plant. Emitted monoterpenes contained higher proportions of menthone (60.2% in the headspace vs. 10% in the oil) and lower amounts of pulegone (11.1 vs. 85%). Studies on other plant species have also shown that the composition of emitted monoterpenes may differ from their presence in the plant oil (Werker, 1993; Guillet et al., 1998; Gershenzon et al., 2000). Membranes of storage compartments might be selectively more permeable to particular monoterpenes, or the emitted monoterpenes may be associated with entirely different secretory compartments than the stored compounds (Gershenzon et al., 2000).

It is likely that changes in both oil concentration and headspace serve important ecological roles during the leaf postwounding period. Moreover, from a commercial point of view, the effects of wounding on leaf oil composition could also have an important impact.

(Received September 15, 2004; accepted December 21, 2004)

Abstract—Browse species undergo seasonal changes in nutritional value and secondary plant compound concentrations. The capacity of herbivores to monitor such change through postingestive effects and to modify their food choice appropriately was investigated. Twenty-four goats were offered a different conifer species on four successive learning days per 7-d period for six periods. During conifer consumption on learning days, animals received either a positive or a negative digestive stimulus to simulate the nutritional rewards and toxic consequences of browse consumption. For each animal, a different postingestive stimulus treatment was associated with each conifer species. The treatments consisted of an increasing positive stimulus, a decreasing positive stimulus, an increasing negative stimulus, or a decreasing negative stimulus. The levels of the stimuli were adjusted in 20% increments in successive periods (from 0 to 100% for the increasing treatments and from 100 to 0% in the decreasing treatments) to simulate seasonal changes in browse characteristics. Diet preference was measured on d 5 of each period. Animals adjusted their diet choice in response to the changing intensity of the negative stimulus, but not the positive stimulus. Animals avoided foods associated with the negative stimulus to a greater extent when the stimulus was increasing each period compared to when it was decreasing. The results suggest that herbivores are adept at monitoring and responding to temporal change in secondary compound concentrations through assessing their changing postingestive effects and adjusting their food choice accordingly.

Key Words—Diet choice, mammalian herbivore, nutritional value, season, secondary plant compound.

INTRODUCTION

Browsing herbivores have a major influence on the composition of vegetation communities through their selective feeding behavior. They generally have access to a large range of plants and plant parts from which to construct a diet (Dejong et al., 1995; Ramirez et al., 1997), and an understanding of the mechanisms that underly their diet-choice decisions is important for better prediction of the impact of herbivores on vegetation composition. Factors that may influence whether or not a food item is consumed include the rate at which it can be harvested, the extent to which it contributes to gut fill, the rate at which it gives up its nutrients for absorption, and the likelihood that its ingestion will lead to toxic effects (Belovsky, 1981; Belovsky and Schmitz, 1994). The balance of these and other factors will determine optimal diet composition from a given array of food options.

However, the vegetation resource is not static: seasonal variation in food supply and quality is a feature of most ungulate foraging environments. The seasonal nature of plant growth and senescence leads to a continually changing food resource from which ungulate herbivores must construct their diet. The food resource for ungulate herbivores is inherently dynamic: nutrient yields from particular plant species may undergo systematic seasonal changes (Cederlund and Nystrom, 1981; Cooper et al., 1988; Owen-Smith, 1994). Similarly, secondary compound concentrations in plants and plant parts change with season and with the phenology of the plant (Jalal et al., 1982; Palo et al., 1985; Brooks et al., 1987). The optimum diet is not static in composition, but changes with the changing nature of the food resource, and this is reflected in major seasonal differences in the diet composition of ungulate herbivores (Cederlund and Nystrom, 1981; Watson and Owen-Smith, 2000).

Although a substantial component of this change is related to seasonal changes in food availability, adjustments of diet selection in response to the changing nutrient yield and toxic properties of particular food items are also likely to be important. One means by which such change in food quality might be detected is through changes in the postingestive consequences that follow consumption of particular food items. Recent research suggests that mammalian herbivores can monitor the positive and negative physiological consequences of consuming particular foods, associate such consequences with food flavors or other sensory characteristics, and adjust their diet preference accordingly (reviewed in Provenza et al., 2003). Changes in postingestive effects are not necessarily closely coupled to changing flavor or other preingestive cues; herbivores may learn to associate particular flavors with particular postingestive effects, but the flavors themselves may be unrelated to those effects (Lawler et al., 1999). There is some evidence for flexibility in the associations that herbivores make between food flavors and postingestive effects,

which would be necessary given the dynamic nature of natural browse diets (Launchbaugh et al., 1993). However, the extent to which ungulate herbivores monitor systematic changes in postingestive consequences and adjust their preference has not been studied.

In the work reported here, we set out to assess how effectively herbivores can monitor systematic changes in the positive and negative consequences of consuming particular food items and adjust their diet selection accordingly. We tested this by offering goats a series of conifer species, and by associating different postingestive stimuli with each. We made systematic changes in the strength of administered stimuli over time to simulate seasonal changes in nutritive value and toxicity, and monitored temporal change in diet choice.

METHODS AND MATERIALS

Experimental Design. Twenty-four male, juvenile Scottish Cashmere goats were used. The animals were 8 mo old at the start of the experiment and had not previously been exposed to conifer foliage. The experiment consisted of six periods lasting 7 d each; each period consisted of four consecutive learning days, followed by a preference test day, then by two rest days. On the four learning days, goats were offered a cut branch of a different conifer species each day. During learning days, goats were allowed to consume from their allotted conifer branch for 4 hr between 0900 and 1300 hr, and they were dosed at the end of each hour during conifer consumption with either an aversive stimulus or a nutrient stimulus according to their allotted treatments. In this way, a different postingestive consequence was associated with each of the four feed types. On d 5 of each period, all four conifer species were offered simultaneously without their associated postingestive stimuli to measure preference. Two rest days followed before the start of the next period. The conifer species used were *Picea sitchensis* (Sitka spruce), *Pseudotsuga menziesii* (Douglas fir), *Picea abies* (Norway spruce), and *Pinus sylvestris* (Scots pine).

Treatments and Their Allocation to Animals and Species. The strength of the imposed postingestive consequences of consuming conifer material was varied systematically over the six periods, according to treatment, to simulate seasonal changes in nutrient rewards or secondary compound concentrations. Four treatments were applied as follows: Inc_Pos, increasing dose rate of a positive stimulus; Dec_Pos, decreasing dose rate of a positive stimulus; Inc_Neg, increasing dose rate of a negative stimulus; and Dec_Neg, decreasing dose rate of a negative stimulus.

The positive stimulus, simulating nutrient release, was sodium propionate at a maximum dose rate of 90 mg/kg DM consumed. Sodium propionate is a short-chain fatty acid and one of the major end products of carbohydrate digestion in ruminants. Ruminants utilize short-chain fatty acids as a source of energy (McDonald et al., 2002). The negative stimulus was lithium chloride at a maximum dose rate of 20 mg/kg DM consumed. Lithium chloride stimulates the emetic system of vertebrates causing sensations of nausea without long-lasting toxic effects. Lithium chloride has been widely used as a model-aversive agent to simulate the aversive effects of plant secondary metabolites (Gustavson, 1977). The rates of administration of positive and negative stimuli used in this experiment have been shown to be effective in eliciting conditioned preferences and aversions in previous experiments (Du Toit et al., 1991; Villalba and Provenza, 1996; Duncan and Young, 2002).

Treatments were associated with conifer species and allocated to animals as illustrated in Table 1. A number of characteristics of the design contributed to its balance. Within each period, each animal received each conifer species and each treatment. Each order of treatment and each order of conifer species appeared exactly once in the design. Each combination of conifer species and treatment (e.g., Douglas fir, Inc_Neg) occurred exactly six times in the design. Each combination of species and treatment occurred exactly twice with each other possible combination (e.g., Douglas fir, Inc_Neg with Sitka Spruce, Dec_Pos). The design was such that once conifer species had been allocated to treatments and learning days for an animal, that animal would experience the same postingestive treatment on consumption of a particular conifer species for the same day each week throughout the experiment. Dose rates of stimuli were altered systematically with period and were either increased or decreased by 20% of the maximum dose rate in successive periods according to treatment as shown in Table 1. For example, goat 1 was offered Douglas fir on d 1 of each wk, and this was associated with the Inc_Neg treatment. This animal would, therefore, experience an increasingly aversive stimulus for Douglas fir as the experiment progressed.

Preference tests were used to assess the ability of each goat to monitor the changing postingestive effects of the different food sources. Preference tests consisted of 20-min tests during which each goat was offered all four conifer species simultaneously. Absolute intake of each conifer species during preference tests was measured by weighing material before and after offering it.

Feeding and Dosing Procedure. Cut branches of Sitka spruce, Douglas fir, Norway spruce, and Scots pine were offered to goats for 4 hr/learning day from 0900 to 1300 hr. At the start of each 4-hr feeding period and at the end of each hour within feeding period, branches were weighed with a spring balance accurately to within 5 g, and animals were dosed according to the consumption of foliage during the previous hour. LiCl pellets and sodium propionate pellets

Treatments imposed were Inc_pos, increasing dose rate of a positive stimulus; Dec_pos, decreasing dose rate of a positive stimulus; Inc_neg, increasing dose rate of a negative stimulus; and Dec_neg, decreasing dose rate of a negative stimulus. The positive stimulus, simulating nutrient release, was sodium propionate (VFA) at a maximum dose rate of 90 mg/kg DM consumed. The negative stimulus was lithium chloride (LiCl) at a maximum dose rate of 20 mg/kg DM consumed. Conifer species offered were Sitka spruce (*Picea sitchensis*), Douglas fir (*Pseudotsuga menziesii*), Norway spruce (*Picea abies*), and Scots pine (*Pinus sylvestris*) denoted Sitka, Fir, Norway, and Pine, respectively.

were prepared in advance, in a range of sizes, by using tissue paper and water-soluble glue to facilitate their rapid release in the rumen. A background diet of dried grass pellets (Vitagrass Farms, Grange-Over-Sands, UK; 18% CP) was fed daily to ensure that the animals were in a controlled nutritional state. All animals were fed-dried grass pellets at a level calculated to ensure that total food intake satisfied their energy requirements for maintenance (Agricultural Research Council, 1980). The background diet was fed at 1500 hr each day starting 14 d in advance of the conifer feeding phase, and continued throughout the experiment. Animals were weighed each week to verify that liveweights remained stable as confirmation that the nutritional state of the animals was constant throughout the experiment.

Conifer branches were cut in a commercial forestry plantation (Drumelzie Wood, Auchenblae, Kincardineshire, UK) each week. Monoterpene composition of conifers varies between species (Von Rudloff, 1975) and among individuals within species (Duncan et al., 1994). Because of the known influence of variation in terpene concentrations on food preference (Duncan et al., 1994), steps were taken to reduce variation in preference, which could have been caused by variation in terpene concentrations: within-day variation was minimized by using a single tree of each conifer species for each learning day. Systematic between-day variation was minimized by measuring foliar monoterpene concentrations of each tree in advance of the experiment and by distributing trees among periods and days on the basis of their terpene concentrations in order to avoid systematic temporal trends in background preferences. Samples of the conifer branches fed to goats were taken weekly during the experiment and were analyzed for monoterpenes by a modification of the method of Sjödin et al. (1996). Foliage was also analyzed for neutral detergent fiber (NDF) (Van Soest, 1963), acid detergent fiber (ADF), and acid-indigestible lignin (Van Soest and Wine, 1967). Crude protein concentrations were calculated as 6.25 $\times$ nitrogen concentrations determined by elemental analysis.

Statistical Analyses. Summaries of the proportions selected during preference tests were formed by calculating means of appropriate values to derive simple graphical presentations of the results that did not depend on the fitted model.

Formal analyses were performed on the relative amounts of the four species eaten by using log-ratio analysis (Aebischer, 1993) as in our previous work (Ginane et al., in press) to avoid the many difficulties otherwise associated with analysis of compositional data. For each preference test, we calculated the logarithms of the ratios of the amounts eaten of Douglas fir, Norway spruce, and Scots pine (the numerator species) to the amount eaten of Sitka spruce (the denominator species), although the results are not dependent on which species was used in the denominator (Aitchison, 1986). The calculated log ratios were analyzed by fitting linear mixed models using the method of residual maximum

likelihood (Patterson and Thompson, 1971) to handle the complex correlation structures in these data.

We selected the random effects in our analysis by taking a maximal fixed-effect model, then adding random terms and observing changes in the residual deviance. First, the three log ratios from each preference test were correlated because they are formed with respect to the same denominator: our analysis allowed for this by treating the three log ratios as coming from a multivariate normal distribution. Second, correlations exist in the data because of the repeated use of the same animals: we allowed for this in the analysis by introducing an additional error term for individual animal-based preferences. Thus, the structure of the analysis is described by the model: $y_{ijk} = \mu_{ijk} + e_{ik} + f_{ijk}$, where for animal i in period j, y_{ijk} is the observed log ratio for species k with respect to Sitka spruce, with corresponding mean, μ_{ijk}, and error terms, e_{ik} and f_{ijk}, at the animal and preference test levels, respectively. These error terms have a mean of zero and variances and correlations specified by the (estimated) covariance matrices $V = \text{cov}(e_{i1}, e_{i2}, e_{i3})'$ and $W = \text{cov}(f_{ij1}, f_{ij2}, f_{ij3})'$. Third, this error structure is itself augmented to allow for a lag-1 autoregressive correlation, c, in the trial-level error term.

We modeled the mean, μ_{ijk}, as being dependent on the interaction of species and period, together with additive effects of learning day, the applied treatments, and their interactions. Species, period, and learning day were always taken as categorical, whereas applied treatments were either treated as categorical or as linear contrasts. To respect the skew-symmetric nature of log ratios, namely, $\log(z_1/z_2) = -\log(z_2/z_1)$, contrasts were formed by treating positively the usual contrast value associated with the species in the numerator and treating negatively the corresponding value for Sitka spruce (which always formed the denominator). Categorical effects other than species were fitted by using dummy variables, formed in the same manner as for linear contrasts, with entries 1 for factor levels that were associated with the numerator species, -1 for the denominator species, or 0 for factor levels absent from the observations used to form a log ratio. Covariates for terpene concentrations on learning and preference test days were constructed in a similar manner as the difference between log-terpene concentrations on numerator species and the corresponding value for Sitka spruce.

The effects of principal interest were those due to treatment level, estimated in the animal by species stratum, and dosage within treatment, estimated in the animal by species by week stratum. As there were a large number of residual degrees of freedom in both strata, tests of the significance for treatment effects were estimated by referring Wald statistics to X^2 distributions with degrees of freedom determined by the treatment effects being tested. All models were fitted by using the REML directives of the statistical program Genstat for Windows release 6.1 (VSN International, Oxford). Where a species was not eaten during

the preference test, the observed zeros were replaced, in forming the log ratio, by one half of the smallest nonzero amount eaten in any of the trials used in the analysis.

Preliminary analysis suggested that a relatively simple fixed-effect model should be used for the presentation of results. This contained the interaction between species and period, the interaction between learning day and species, together with the interaction between treatments and dosage. The terpene covariate for preference tests was not required because it was absorbed within the interaction between species and period, while the terpene covariate for learning days was dropped because there was no evidence supporting its inclusion when fitted after tree species.

To demonstrate the effects of the Pos-treatments on preference, we fitted a model ignoring Neg-treatments, considering either the two Pos-series (Inc_pos and Dec_pos) as categorical or as summarized by two intercepts and two linear contrasts. Conversely, to demonstrate the effects of the Neg-treatments, we fitted a model ignoring Pos-treatments, considering either the two Neg-series (Inc_neg and Dec_neg) as categorical or as summarized by two intercepts and two linear contrasts.

RESULTS

General. Foliage consumption during preference tests in the early periods of the experiment was relatively low as animals gained familiarity with the novel browse species (Figure 1). Scots pine was initially favored by the goats,

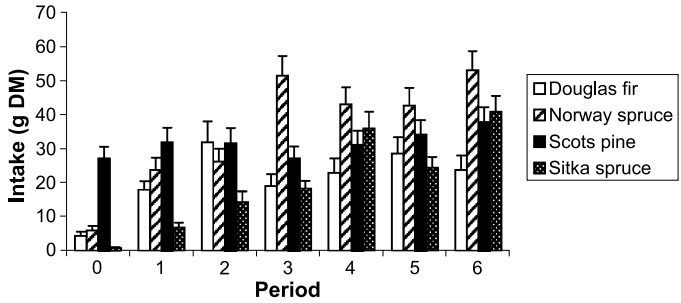

FIG. 1. Development of preference for conifer species over periods. Values represent mean proportions of total intake during preference tests. Error bars denote standard errors of means (N = 24). The conifer species used were *Picea sitchensis* (Sitka spruce), *Pseudotsuga menziesii* (Douglas fir), *Picea abies* (Norway spruce), and *Pinus sylvestris* (Scots pine).

TABLE 2. CHEMICAL COMPOSITION OF CONIFER FOLIAGE[a,b] OFFERED TO GOATS

	Douglas fir	Norway spruce	Scots pine	Sitka spruce
Nitrogen	1.25 (0.021)[c]	1.05 (0.028)	1.36 (0.034)	1.01 (0.048)
Lignin	21.9 (0.57)	19.2 (0.62)	16.8 (0.33)	22.2 (0.29)
Acid detergent fiber	37.9 (0.75)	41.3 (0.97)	42.0 (0.37)	43.4 (0.40)
Neutral detergent fiber	44.9 (0.57)	50.4 (0.95)	53.6 (0.45)	51.3 (0.52)
Total terpenes[d] (mg/kg DM)	10.80 (0.799)	0.30 (0.047)	5.52 (1.264)	0.48 (0.232)

[a] Values are averages of foliage samples pooled by period.

[d] For terpene data, values from samples collected on preference test days are presented.

and the amount of pine consumed during preference tests remained relatively stable over the course of the experiment. Norway spruce initially formed only a small component of the food consumed during preference tests, but by period 3, it was the most preferred species and remained so for the rest of the experiment. Intake of Douglas fir during preference tests followed a similar pattern to that observed for Scots pine, while consumption of Sitka spruce increased steadily throughout the experiment. The chemical composition of the conifer species were relatively similar (Table 2), and there was no evidence that nutrient composition varied systematically with time (data not shown). Results of fiber analyses need to be interpreted with some caution since studies have shown that in browse species, reported fiber fractions are contaminated with phenolic residues and are likely to be significant overestimates of the true fiber composition of the material analyzed (Makkar et al., 1995). Terpene concentrations varied markedly according to species. The balanced design employed in the current study, however, meant that between-species variation in nutritive value or terpene concentration was spread across treatments, and that the main effects of our applied treatments could be viewed in isolation from background, between-species differences in preference that could have arisen from variation in the chemical composition of the conifers. Many of the preference tests in period 1 included tree species that were uneaten by the goats. In view of the difficulty this causes the log-ratio analysis and the fact that the goats were evidently becoming accustomed to novel forages, we only analyzed data from periods 2 to 6 (which contained a total of 10 observed zero values). Live weights of animals remained stable throughout the experiment (period 1: mean 22.8 kg, SD 2.99; period 6: mean 22.3 kg, SD 3.07). Between-week coefficients of variation for individual goats were always less than 9%.

Treatment Effects. There was strong evidence to suggest that goats preferred species allocated Pos-treatments to those allocated Neg-treatments ($X_1^2 = 39.0$, $P < 0.001$) (Figure 2). Although there was also strong evidence of a

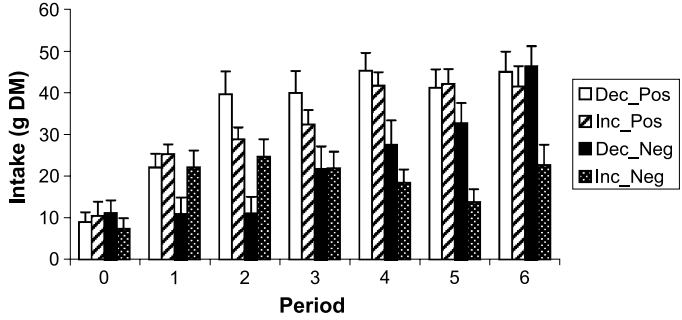

FIG. 2. Effect of associated postingestive consequences during learning on the relative preference for conifer species during preference tests. For treatment of Dec_Neg, a declining dose of lithium chloride was applied, while for Inc_Neg, an increasing dose of lithium chloride was applied. For Dec_Pos, a declining dose of sodium propionate was applied, while for Inc_Pos, an increasing dose of sodium propionate was applied. Values represent mean proportions of total intake. Error bars denote standard errors of means ($N = 24$).

difference in mean preference depending on whether Neg was increasing or decreasing ($X_1^2 = 15.2$, $P < 0.001$), the same was not true of the two Pos-treatments ($X_1^2 = 0.44$, $P = 0.51$). The linear contrast for dose level was highly significant for the Neg-treatments ($X_1^2 = 36.0$, $P < 0.001$) (Figure 3a), but did not appear to differ between the increasing series and the decreasing series ($X_1^2 = 1.15$, $P = 0.28$). The linear contrast for dose level was not significant for the Pos-treatments ($X_1^2 = 0.07$, $P = 0.8$) (Figure 3b).

The effects of the Neg-treatments relative to the average of the Pos-treatments and the Pos-treatments relative to the average of the Neg-treatments are shown in Figure 3. These reinforce the formal tests in showing for the Neg-treatments, linear regressions with mean levels, but not slopes, depending on whether dose rate was increasing or decreasing. Conversely, for the Pos-treatments, they show the absence of evidence for an effect of the dose rate.

Species Preferences. The overall effect of species on preference expressed as log ratios was highly significant ($P < 0.001$), indicating an underlying preference for Norway spruce over the course of the experiment (Figure 1). Mean log ratios for Norway spruce, Scots pine, and Douglas fir relative to Sitka spruce were 0.55, 0.13, and −0.18, respectively (SE 0.23). Species preferences changed with period ($P < 0.01$), indicating that these changed as the experiment progressed, although the balanced design allowed treatment effects to be assessed against this background of changing species preferences.

Effect of Learning Day. There was strong evidence that a goat's preference for a tree species was affected by the gap between the day of the preference test and the learning day on which that goat was given that tree species. The main

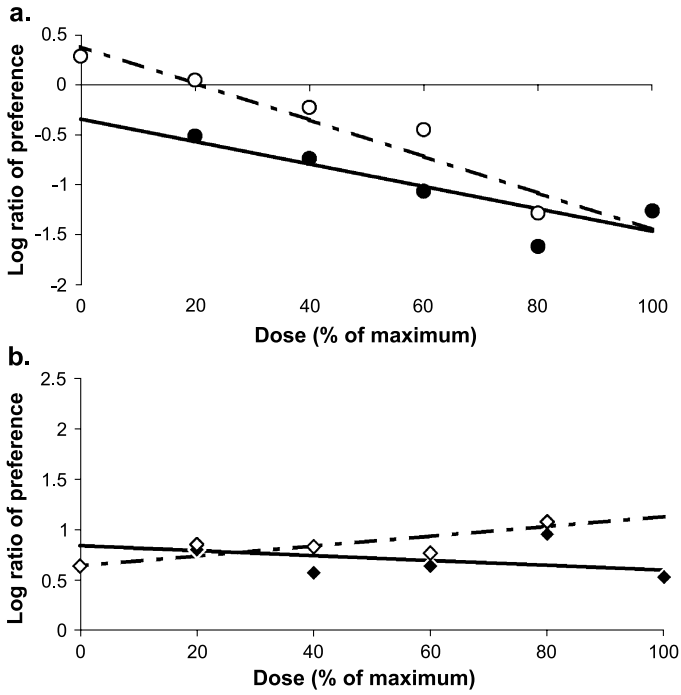

FIG. 3. Relationship between dose levels of a the negative stimulus and b the positive stimulus on parameter estimates for log ratio of preference. Data are expressed on the analysis (log-ratio) scale; log ratio of preference refers to the logarithm of the ratio of the amount of conifer eaten relative to the amount of Sitka spruce eaten during the same week. Points refer to categorical effects. Lines refer to linear contrasts. Separate points and lines are presented for the increasing (closed symbols, solid lines) and decreasing (open symbols, broken lines) series of each stimulus.

effect for day was highly significant ($P < 0.001$) with goats on preference test days tending to avoid the species given most recently although there was also evidence for an interaction with species ($P = 0.007$). Again, the balanced nature of the design meant that treatment effects could be assessed effectively despite the significant effect of learning day on preference.

DISCUSSION

The plant cues that herbivores use in coming to food selection decisions are not well understood. The animal may assess food quality by using general proximate cues such as color, taste, and texture (Bazely, 1990). However, these

cues are not necessarily a reliable indicator of nutritive value or toxicity. Recently, the role of postingestive cues as an alternative mechanism for learning, by herbivores, about the quality and toxicity of their food plants has gained credence (Provenza, 1995). The initial ideas arose from the psychological literature relating to conditioned learning mechanisms (Garcia et al., 1966). The idea that long-delay learning played a role in the development of food selection patterns among large herbivores soon appeared in the ecological literature (Zahorik and Houpt, 1977; Westoby, 1978). Many tests of the ability of large herbivores to associate postingestive effects with food flavors have since been reported, initially for the negative postingestive effects associated with toxicity (Provenza et al., 1990), but also, more recently, for the positive effects that follow nutrient ingestion (Villalba et al., 1999). The majority of these tests have relied on simple, two-way choice scenarios between flavored articificial foods, with animals given a series of learning opportunities over time. Some doubt remains as to the importance of learning, based on postingestive cues, to large herbivores foraging in botanically complex environments (Duncan and Young, 2002). This is because free-ranging herbivores encounter multiple food options simultaneously, making direct association of flavors and postingestive effects problematic. Furthermore, in natural situations, the consequences of ingesting particular plants changes with time since the nutritive value and secondary chemistry of plants change seasonally and with plant phenology (Jalal et al., 1982; Cooper et al., 1988). The current study was set up to explore the flexibility of the diet-learning mechanism when systematic simulated changes in nutrient rewards and toxic consequences were associated with a series of model browse foods. Natural browse species were used in preference to the flavored artificial foods used in many previous studies in order to more closely mimic the natural situation. Four different conifer species were used to allow each animal to associate each treatment with a particular species. The allocation of treatments to species was balanced across animals to allow the main effects of the postingestive treatments to be assessed using global means across species. The design of the experiment thus allowed the effects of the applied postingestive treatments to be assessed without the confounding effects of changing background preference for the different tree species.

The results of the experiment confirm the ability of goats to attribute different postingestive consequences to each of a series of foods and adjust their diet selection appropriately. Goats appeared more sensitive to negative than to positive postingestive effects. This may partly relate to the greater risks associated with making poor choices when toxic foods are involved than when nutrient-rich foods are offered. However, since the positive and negative stimuli had different currencies, we cannot draw firm conclusions about their relative effects in the current experiment. The success with which goats can associate positive postingestive effects with particular foods seems to decline as the

complexity of the diet increases. In our early work with three foods, one of which was associated with a fixed rate of sodium propionate administration, goats quickly learned which food was associated with positive postingestive effects (Duncan and Young, 2002). In later work (Ginane et al., in press) and in the current experiment with more complex learning scenarios, diet choice was not strongly influenced by association with the stimulus providing nutrient rewards, namely, sodium propionate. Similar conflicting results following use of sodium propionate as a positive conditioning stimulus have been found by others (Villalba and Provenza, 1996, 1997), and further work to investigate the preference response of ruminants to foods associated with sodium propionate and other short-chain fatty acids is required. By contrast, LiCl is a reliable negative conditioning stimulus, and this may explain its widespread use in conditioned aversion studies. Studies using natural negative stimuli found in plants have been reported (reviewed in Provenza, 1995) although welfare concerns have probably limited experimentation in this area. LiCl cannot be regarded as an adequately representative model of *all* plant secondary compounds in aversion studies, but given that it acts via the emetic system (responsible for sensations of nausea), it is likely to be a good model for plant secondary compounds that have some negative action at the level of the digestive tract.

The ability of animals to learn about temporally varying food resources through postingestive effects has been studied before. When lambs were offered flavored foods associated with a dose of LiCl that varied randomly on different days, the amount of food consumed was based on the maximum dose of toxin they had ingested, suggesting that animals were adopting a risk minimization strategy (Launchbaugh et al., 1993). In a further study, when the toxicity and energy rewards of test foods were changed unpredictably every 3 to 6 d, sheep quickly regulated their intake of the foods in line with expectations (Wang and Provenza, 1997). However, in this case, toxins and nutrients were incorporated directly into the feeds so changes in preference may not have been mediated only through associations with postingestive effects; animals may have adjusted preference based on the direct taste of the nutrients and toxins added to the test feeds.

In our own work, the learning scenario was more complex with four species being offered rather than two. Also, the changing quality and toxicity of food plants were simulated by oral administration of the postingestive stimuli thus removing the possible involvement of preingestive cues in mediating preference. Furthermore, systematic changes in quality and toxicity were used to simulate progressive seasonal changes. This allowed assessment of how the direction of change influenced the animals' ability to sense changes to their food plants and adjust their diet accordingly. In the case of negative postingestive effects, goats were able to adjust preference in line with changing toxicity, both when the strength of the toxic stimulus was increasing with time and when it

was decreasing. Animals appeared more sensitive to increasing toxicity than to decreasing toxicity; the relationship between the strength of the negative stimulus and preference differed, depending on whether toxicity was increasing or decreasing, although this was largely associated with a lower overall preference when toxicity was increasing (intercepts differed, but slopes did not). The greater caution that goats exhibited for foods whose toxicity was increasing with time may represent a strategy for minimizing risk: foods which are increasing in toxicity represent a greater risk than those whose toxicity is declining and hence require a more cautious approach.

We can say little about the relative sensitivity of goats to the direction of temporal change in nutritive value since no overall relationship between the positive postingestive stimulus we used and preference was evident in our data. The use of postingestive consequences by ruminant herbivores in assessing nutritive value may be less than for assessing toxicity since preingestive cues may be a more reliable indicator of nutritive value than of toxicity. Seasonal changes in digestibility, for example, might be relatively easily assessed by animals using characteristics such as texture and toughness so that postingestive mechanisms might be less important.

Seasonal changes in diet composition are often reported in the literature (Ramirez et al., 1997; Watson and Owen-Smith, 2000), but it is often difficult to disentangle the multiple influences which contribute to observed preference. For example, protein and condensed tannin concentrations in browse species on a South African savanna both vary seasonally, making it difficult to attribute changing foliage acceptability to any one factor (Cooper et al., 1988). In our study, we artificially restricted the change in simulated toxicity or quality to one characteristic per plant species offered, and we varied only the postingestive consequences of food consumption, keeping the sensory properties of the test foods constant. By using this approach, we have shown that goats can monitor changes in postingestive consequences simulating toxicity even when multiple food choices are available. Goats appeared less sensitive to simulated change in nutritive value, and this may be partly related to the complexity of the food-choice scenario.

In summary, our study has demonstrated the ability of ungulate herbivores consuming browse material to monitor systematic changes in the toxic consequences of consuming particular food plants and to adjust their food selection accordingly. Further work with a range of positive and negative postingestive stimuli is needed to assess the generality of this phenomenon.

Acknowledgments—The authors thank Dr. Glenn Iason and Dr. Graham Horgan for helpful comments on the draft manuscript. Roslyn Anderson lent expert technical assistance, and her contribution is gratefully acknowledged. The work was funded by the Scottish Executive Environment and Rural Affairs Department. The experiment reported was subject to local ethical review and was conducted under the ethical regulation of the UK Government Home Office.

(Received June 3, 2004; revised November 15, 2004; accepted December 14, 2004)

Abstract—Research on host selection by bark and wood boring insects has concentrated on flight orientation behavior. Less is known of the factors that govern the steps successive to host landing. Here, we discuss chemical factors involved in host acceptance by bark beetles and a new microassay. Adult males and females of *Ips typographus* were offered an artificial diet treated with various concentrations of different plant-derived compounds (host terpenes and nonhost compounds) in a no-choice mode. Beetles were tested individually in a glass tube for 4 hr, and the length of feeding was measured and compared to a control (diet with only solvent). The first effect was diet rejection, especially when nonhost compounds were tested at high concentrations. Most compounds reduced feeding, in proportion to concentration. Females fed more readily than males after addition of both host and nonhost compounds. Diet removal was significantly affected by all the tested factors (sex, compound, dose) as well as by their interactions. With increased concentrations, males were more responsive than females to antifeedants, as all compounds (except juglone) showed clear sex differences of diet consumption. 3-Octanol, 1-hexanol, and a Green Leaf Volatile (GLV)-blend (three C6 alcohols) showed the strongest antifeedant effects, which started at a low dose (0.1%) and had a low Effective Dose 50 (ED50, 0.3–1%). In contrast, host monoterpenes, limonene and α-pinene, inhibited feeding at high

doses (10–30%) only, with ED50 > 10%. The highest Antifeedant Indexes were shown by verbenone, carvone, and 1-hexanol (AFI = 0.90–1.00). Both host and nonhost compounds inhibited feeding at some concentration. No significant stimulation of feeding by any host compound at concentrations reported in the literature as optimal were found, with the possible exception of α-pinene at low concentrations in females.

Key Words—Host acceptance, host selection, tunneling, feeding, antifeedant, nonhost volatiles, NHV, monoterpene, assay, coleoptera, scolytidae, AFI, ED50, effective threshold.

INTRODUCTION

Host selection by bark beetles (Coleoptera: Scolytidae) is mainly individual and is governed by long-range attractive signals such as host volatiles (Wood, 1982; Schlyter and Birgersson, 1999). After a searching period, bark beetles land on a host tree and begin feeding activity (Paynter et al., 1990). If the chosen tree is found unsuitable, the flight is resumed and the process is repeated (Byers, 1995; Wallin and Raffa, 2002). For many xylophagous insects, avoidance of nonhost tree species is due either to lack of nutritional compounds or to the detection of potentially toxic secondary metabolites (Agelopoulos et al., 1999). Decisions regarding oviposition are often discerning and include both host species' recognition and the assessment of the host's defensive reactions (Safranyik et al., 1975). Thus, the chemical composition of the medium is the last threshold to be overcome before colonization.

During host selection, both attractive and repellent signals may be active. The former includes pheromones and kairomones, which act in a behavioral sequence (Wood, 1982; Raffa et al., 1993; Borden, 1997; Schlyter and Birgersson, 1999). The latter includes verbenone and angiosperm volatiles—such as nonhost volatiles (NHV)—which inhibit attraction to pheromones and kairomones in conifer-inhabiting Scolytidae (Borden, 1997; Zhang et al., 2000; Zhang and Schlyter, 2004). The use of NHV protects the potential host tree from being attacked, because the beetle does not recognize the substrate as suitable for reproduction.

The secondary plant metabolites important in insect host selection include mainly alkaloids, flavonoids, and terpenes (Frazier and Chyb, 1995), although quinones and phenols may also be important. Terpenes can either be repellent or attractive according to concentration or insect species. They can first increase then inhibit feeding activity once they have reached a toxic concentration (Reddemann and Schopf, 1996). Field bioassays indicate that different concentrations of bark monoterpenes (α-pinene and limonene) have different effects on the colonization rate of *Ips typographus* (L.) (Reddemann and Schopf, 1996).

Uninfested trees contained lower quantities of monoterpenes compared to colonized trees. Trunks colonized by *I. typographus* were characterized by a concentration of α-pinene ranging between 0.08 and 0.35 nmol mg^{-1} of fresh weight (Reddemann and Schopf, 1996). Similar results have also been obtained for American bark beetle species such as *I. grandicollis* (Eichhoff) for which α-pinene was not only attractive but also enhanced response to its pheromone (Erbilgin and Raffa, 2000). Consistent attraction to α-pinene is shown by the red turpentine beetle, *Dendroctonus valens* LeConte (Erbilgin and Raffa, 2000), although (−) α-pinene inhibits response to (+) α-pinene. Little is known about feeding deterrents in tree-inhabiting Coleoptera (Byers, 1995). Ascher et al. (1975) found that females of *Scolytus rugulosus* (Müller) [= *mediterraneus* (Eggers)] were deterred from feeding on peach twigs that had been dipped in hexa-methylditin. The number of *I. pini* (Say) entering a phloem-based medium decreases with increased concentrations of many monoterpenes (Wallin and Raffa, 2000). Evaluation of antifeedants (e.g., carvone) against the large pine weevil, *Hylobius abietis* L., has shown antifeedant effects of nonhost bark compounds in both sexes (Klepzig and Schlyter, 1999). A higher sensitivity to repellents, however, must be expected in the host-selecting sex. When responding to prelanding signals, males of *I. typographus* are more sensitive to verbenone (Schlyter et al., 1989) and NHV (Zhang and Schlyter, 2004), whereas females of *S. rugulosus* are more susceptible to hexa-methylditin than males (Ascher et al., 1975). In Europe, the spruce bark beetle *I. typographus* is a major mortality factor in mature spruce forests (*Picea abies* Karsten) (Christiansen and Bakke, 1988). Recent research on control strategies for the protection of conifers has focused on the use of antiattractive semiochemicals such as NHV from nonhost trees, mainly angiosperms (Zhang and Schlyter, 2004).

The aim of the present study was to develop a protocol for testing the feeding performances of bark beetles on an artificial diet, as well as the evaluation of antifeedant effectiveness of host and nonhost compounds on *I. typographus*.

METHODS AND MATERIALS

Insect Breeding and Handling. Adults of *I. typographus* were removed daily from breeding cages kept in climatic rooms (25±1°C, RH = 70%). Specimens having emerged from colonized spruce logs (10-cm diameter, 30 cm long) were sexed (Schlyter and Cederholm, 1981) and starved at room temperature for 24 hr before being tested.

Pilot Studies on Artificial Diet and Tunnels. Preliminary assays were performed to find the best experimental protocol. Tests were carried out using narrow strips of fresh bark, cut from spruce logs and inserted into artificial

tunnels consisting of transparent glass tubes (3-mm diameter, 30 mm long). Feeding activity could not be easily quantified, and bark characteristics (thickness, moistness, age, and amount of cork) were extremely variable. Later, an artificial agar-based diet modified from Šimsek and Führer (1993) (composed of 87.6% water, 2% cellulose, 2.6% glucose, 4.3% starch, and 3.5% agar) was tested. Cellulose was obtained from dry spruce sawdust, whereas starch was added as reground maize flour. After a few minutes heating, the diet was poured into Petri dishes to a thickness of 13 mm; the diet was allowed to cool down for few minutes and was transferred by pressing the previously employed glass tubes into the cold diet (Figure 1), where it was left to dry. A direct estimate of the extent of adult host acceptance and feeding could be deduced from the length of diet removed. Because tunneling and diet removal does not necessarily mean feeding, during preliminary analyses several adults were dissected in order to detect ingested diet. The gut of all these previously starved insects contained diet particles.

Feeding Tests. Compounds used were grouped into two sets: those from nonhost trees, such as juglone, 3-octanol, 1-hexanol, and a blend of GLV, and those host compounds normally present in low (verbenone and carvone) or high (limonene and α-pinene) quantities in healthy host tissues (*P. abies*), (Table 1). Different concentrations of each compound, diluted in ethyl acetate, were tested

TABLE 1. CHEMICAL AND COMMERCIAL PROPERTIES OF THE TESTED COMPOUNDS

Compound	Origin	Tested concentrations (% of applied solution)	Purity (% by GC)	Supplier
(±)-α-Pinene (low concentration)	Host	0.01–0.05–0.1–0.5	97.4	Acros, USA
(±)-α-Pinene (high concentration)	Host	1–5–10–30	97.4	Acros, USA
S-(−)-Verbenone	Host	0.1–1–3–5–10	75.2	Bedukian, USA
R-(+)-Limonene	Host	1–3–5–10	95.5	Aldrich, USA
R-(−)-Carvone	Host	1–3–5–10	99.7	Aldrich, USA
Juglone (5-Hydroxy-*p*-naphtoquinone)	Nonhost	0.1–1–3–5–10	ca 97	Aldrich, USA
(±)-3-Octanol	Nonhost	0.1–1–3–5–10	96.4	Acros, USA
1-Hexanol	Nonhost	0.1–1–3–5–10	96.4	Aldrich, USA
GLV-blend (1:1:1 of 1-hexanol, (*Z*)-3 Hexen-1-ol, and (*E*)-2-Hexen-1-ol)	Nonhost	0.1–1–3–5–10	86.8 (30:29:27)	Aldrich, USA

on adults of *I. typographus* (Table 1). Each concentration was tested individually on 20 adults (10 males and 10 females). A 10-µl solution of each compound (Table 1) or the solvent (blank) was added separately to the tube. The latter was kept open for 1 hr at 21°C for ventilation, thus allowing the solvent to completely evaporate (Figure 1). Subsequently, one beetle was inserted into each tube, closed with a plastic cap, and was allowed to feed on the diet for 4 hr under illumination. Previous tests have shown that 4 hr are sufficient for insects to tunnel through a diet. Each beetle was used only once. The amount of diet consumed was measured (mm) by using a graduated stereoscope. For each compound, 20 adults (10 males and 10 females) feeding in tubes containing only diet (solvent blank) were used as control.

Statistical Analysis. Data were analyzed by ANOVA to find differences between sexes, compounds, and their concentrations. Homogeneity of variance was tested using Cochran's test, and when necessary, data were log-transformed [$X' = \log(x + 1)$] or arcsin-transformed ($X' = \arcsin\sqrt{P_x}$) to obtain homogeneous variances. Wherever significant differences occurred, Tukey's honestly significant difference (HSD) multiple comparison test was applied for mean separation (Zar, 1984). Differences at $P \leq 0.05$ were considered significant for ANOVA and for the Effective Threshold (ET) concentration, at which the amount of eaten diet becomes statistically lower than the control. For each compound and concentration, an Antifeedant Index (AFI) varying between −1 (attraction) and 1 (repulsion) (Klepzig and Schlyter, 1999) was calculated as follows: $\text{AFI} = (C - T)/(C + T)$, where T = amount of diet consumed in the

tested treatment and C = amount of diet consumed in the control. In order to compare the effect of active compounds, Effective Dose 50 (ED50) was calculated. The ED50 concentration was obtained from the linear regression of AFI against the concentration.

RESULTS

Most tested chemicals decreased the feeding activity of adults of *I. typographus*, with an effect that was concentration-dependent. Sex was a factor both in diet acceptance and in feeding.

Diet Acceptance. Nonhost compounds had a strong effect on diet acceptance, showing a high level of rejection. At high concentrations, a variable percentage of specimens did not feed at all (Figure 2), whereas in the controls (solvent blanks), all insects feeding. Independently from compound and concentration, diet acceptance was always higher in females than in males (Figure 2). In several cases, males showed a concentration dependence trend similar to that of females, although male rejection started at lower concentrations compared to females. Host compounds, such as α-pinene and limonene, always showed a high feeding frequency (Figure 2), and reduction in feeding started only at very high doses (30% and 10%, respectively).

Diet Consumption. Diet removal was affected by all three of the considered factors: sex, dose, and compound (Table 2). Interactions among these factors were significant, indicating differences in concentration–response slopes due to both sex and compound.

Sex. Sex was the most important factor affecting consumption (Table 2). Males were more susceptible to antifeedants than females, and all compounds showed clear statistical differences between sexes, with the highest feeding responses found in females (Figure 3). Different compounds and doses had different effects on feeding responses of males and females (Table 2 and Figure 3). ED50 was always significantly higher in females, indicating that both host and nonhost compounds had a greater effect on male feeding (Table 3). Feeding performed on control (concentration = 0) showed no consistent difference between sexes (Figures 2 and 3).

FIG. 2. Diet acceptance frequency in the sexes, estimated as the proportion of insects showing >0 mm removal of diet (feeding) in glass tubes after 4 h. Binomial 95% Confidence Intervals. Females: —●— and males: - - -□- - -. Tree symbols, dark or pale, indicates compound origin from gymnosperm host or angiosperm non-hosts, respectively. Only *x*- axis values common to all tested compounds are plotted (i.e., values like 0.1% are not plotted).

TABLE 2. ANOVA OF FACTORS COMPOUND, DOSE, AND SEX AND THEIR INTERACTIONS IN THEIR EFFECT ON THE LENGTH OF DIET REMOVED IN TUNNEL FEEDING BY *Ips typographus*

Factor	*Df* effect	*Df* error	*F* value	*P* level[a]
Compound	7	732	136.06	*
Dose	4	732	286.82	*
Sex	1	732	685.63	*
Compound × dose	28	732	14.05	*
Compound × sex	7	732	8.69	*
Dose × sex	4	732	47.11	*
Compound × dose × sex	28	732	5.86	*

[a] The ANOVA was applied on $\log(x + 1)$ transformed data in order to approach normal distributions. The homogeneity of variances was tested using Cochran's test (Zar, 1984).
* $P < 0.001$.

Dose. Concentration was the second most important factor affecting diet removal (Table 2). In general, all compounds showed an antifeedant effect that increased with dose, although this was always stronger in males (Figure 3). In some cases [e.g., (−)-carvone, (−)-verbenone, and GLV-blend], differences between sexes disappeared at high concentrations, as the effects were strong enough to reduce even female feeding activity (Figures 2 and 3). Compounds and dose showed a significant interaction (Table 2), thus establishing that different compounds are active at different concentrations (Figure 3). Furthermore, *I. typographus* showed a variable sensitivity to compounds, which became effective (ET) at different concentrations (Table 3). For males, the ET was reached at the lowest dose (0.1%) of many compounds.

Compound. Host compounds always had higher ET and ED50 values than nonhost compounds, indicating lower antifeedant activity. Host monoterpenes, such as α-pinene and limonene, showed low activity as antifeedants; α-pinene at low doses (<1%) acted as a weak stimulus for females (Figure 3), whereas limonene affected diet consumption in females at the highest concentrations only. Oxygenated host monoterpenes (carvone and verbenone) showed similar trends (Figure 3), both having a strong antifeedant effect with a relatively high AFI (Table 3), which depended upon concentration (Figure 4). Nonhost compounds were the more active (Table 3 and Figure 2), with the strongest effect by 3-octanol, which showed both the lowest ED50 value (1.2%) and the highest mean AFI (0.6). Moreover, feeding inhibition caused by nonhost compounds increased rapidly and in a nonlinear way with increasing concentrations, especially for males (Figure 3).

Relative Feeding (AFI). In general, with the exception of α-pinene at low concentrations, mean AFI was always positive, indicating overall feeding

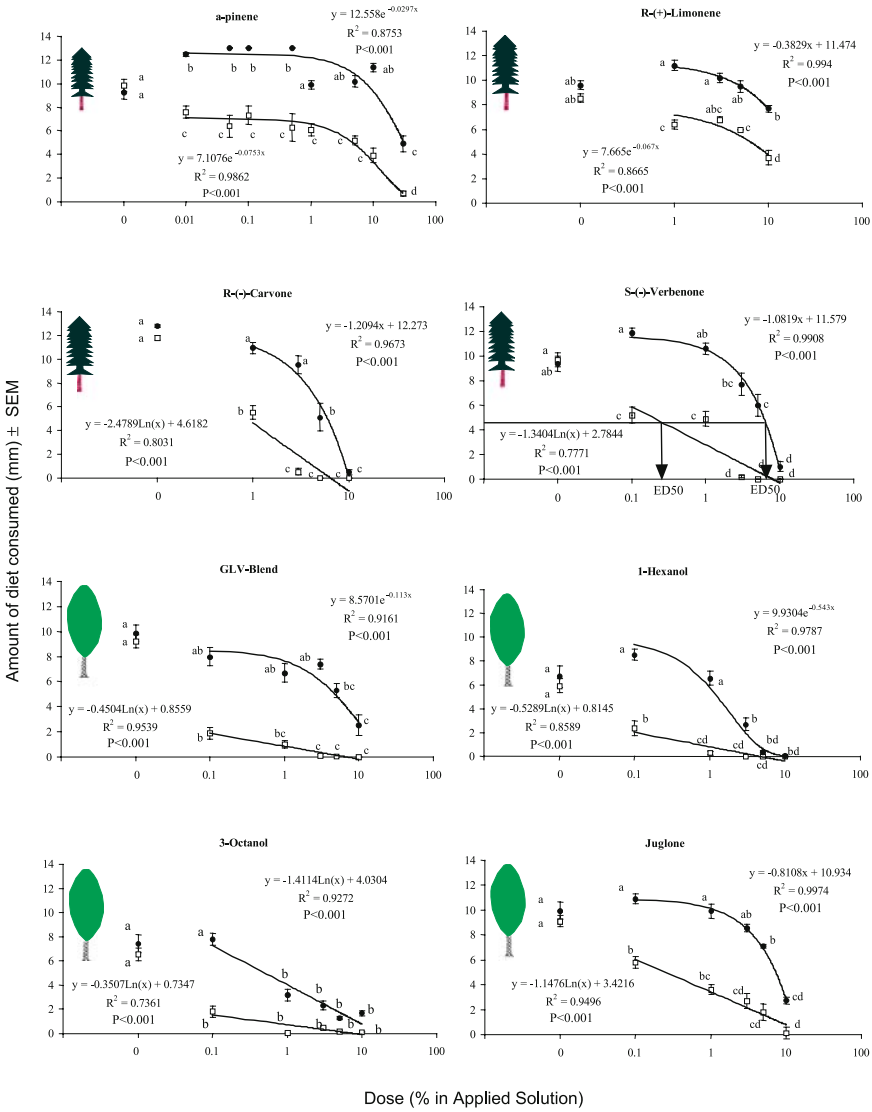

FIG. 3. Linear regressions of *Ips typographus* feeding activity for each tested compound. Females: ●, males: □. ED50: Effective Dose halving the feeding performances of the insects (indicated only for Verbenone as an example, see Table 3). For overall means per compound and sex, see Table 2. Data points with the same letter are not different by ANOVA on log(x + 1) followed by the Tukey's honestly significant difference post hoc test at α = 0.05.

TABLE 3. EFFECTIVE THRESHOLD (ET), EFFECTIVE DOSE 50 (ED50), AND ANTIFEEDANT INDEX (AFI) VALUES CALCULATED PER EACH TESTED COMPOUND

Compound	ET[a] males	ET females	ED50[b] males	ED50[b] females	AFI[c]
α-Pinene (low conc.)	–	–	–	–	−0.002
α-Pinene (high conc.)	1	30	6.4	34.7	0.21
S-(−)-Verbenone	0.1	10	0.2	6.4	0.39
R-(+)-Limonene	5	–	8.7	17.4	0.09
R-(−)-Carvone	1	5	0.6	4.8	0.56
Juglone	0.1	5	0.4	7.4	0.31
3-Octanol	0.1	1	0.001	1.2	0.61
1-Hexanol	0.1	3	0.02	2.2	0.59
GLV-blend	0.1	5	0.0002	4.9	0.50

[a] Effective Threshold: compound concentrations at which the feeding performances of *Ips typographus* become significantly lower than control ($P \leq 0.05$) by ANOVA test on $\log(x + 1)$ applied to diet removal.
[b] Effective Dose 50: compound concentrations (%) at which the feeding performances of *Ips typographus* become half than control (Figure 2).
[c] Mean of all concentrations of the Antifeedant Index calculated as $(T - C)/(T + C)$ (Klepzig and Schlyter, 1999).

inhibition (Table 3). AFI increased with compound concentration (Figure 4). High concentrations of carvone, verbenone, and 1-hexanol gave the highest AFI values (≈ 1), meaning total inhibition of feeding. In contrast, α-pinene and limonene showed low antifeedant indexes even at high concentrations. The moderately negative AFI values reported for α-pinene at several low concentrations (Figure 4) indicate a weak stimulating effect on feeding, especially females (Figure 3). At high concentrations (10% and 30%), most compounds showed strong antifeedant effects (AFI ≥ 0.5), whereas at low concentrations (1–3%), strong effects were obtained only for 1-hexanol, GLV-blend, and 3-octanol.

DISCUSSION

Several studies have demonstrated that conifer phloem contains extractable compounds that elicit feeding behavior in bark beetles. *Ips paraconfusus* Lanier recognizes susceptible ponderosa pines after having entered the phloem (Elkinton et al., 1981). Outer bark extracts of the host pine species stimulate feeding behavior in both the southern pine beetle, *Dendroctonus frontalis* Zimmermann (Thomas et al., 1981), and the mountain pine beetle, *D. ponderosa* Hopkins (Raffa and Berryman, 1982). Feeding stimulants have been identified also for bark beetles attacking angiosperms such as *Scolytus*

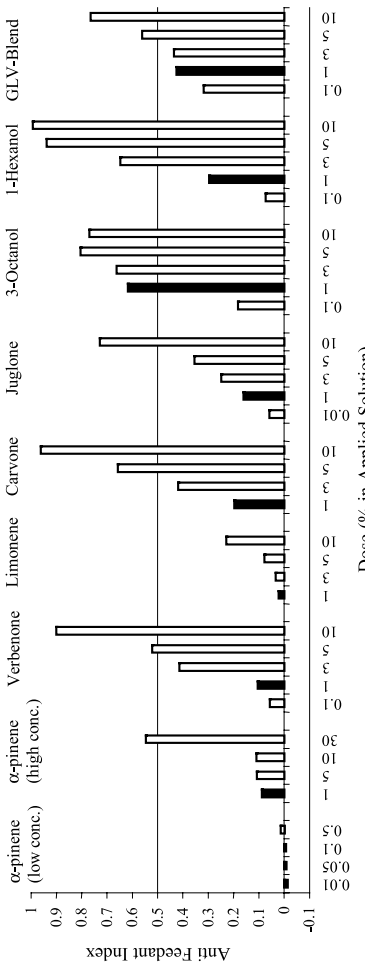

FIG. 4. Antifeedant Index calculated for each compound and concentration (black columns correspond to the 1% concentration), sexes joined.

multistriatus (Marsham) and *S. rugulosus* (Doskotch et al., 1970; Levy et al., 1974). Literature data suggest that phloem metabolites are mainly responsible for feeding stimulation (Bedard, 1966; Elkinton et al., 1981; Byers, 1995). McNee et al. (2003) reported that several chemicals extracted from ponderosa pine phloem, such as stilbenes, ferulic acid gluciside, and sugars, neither stimulated nor reduced male feeding activity in *I. paraconfusus*. Nevertheless, few studies have tested the possible antifeedant effect of host extracts on bark beetles. In the present study, an antifeedant effect, strongly dependent on sex, concentration, and origin (host or nonhost) of the compound, was established.

No significant differences between sexes in antennal responses to NHV have been recorded previously (Zhang and Schlyter, 2004), although a higher antennal sensitivity (lower response threshold) would be expected for the host-selecting sex (the males in the case of *I. typographus*). In this respect, Dickens (1981) reported that the male antennae of *I. typographus* were 10 times more sensitive to α-pinene than females. Rudinsky et al. (1971) reported that α-pinene and limonene attracted *I. typographus* adults in a ratio that favored males. High concentrations of verbenone and NHV skew the sex ratio of *I. typographus* trap samples towards females (Schlyter et al., 1989; Zhang and Schlyter, 2004), being more repellent to males. It was thought that the verbenone released by tunneling males could counteract the effect of the aggregation pheromone and shift the attack to uninfested neighboring trees (Schlyter et al., 1989). Comparing male and female feeding responses, controls did not generally show significant differences between sexes. However, when exposed to nonhost compounds, male feeding was inhibited at relatively low doses, ranging between 1 and 3%. Nevertheless, high doses of verbenone, carvone, and 1-hexanol decrease female feeding responses as well.

Terpenoids play a fundamental role in host acceptance by conifer-inhabiting bark beetles (Byers, 1995). Limonene, α-pinene, and β-pinene are involved in preexisting and induced defenses against bark beetles (Baier et al., 1999). Compared to many other insects, conifer bark beetles are relatively immune to toxic terpenes, although they can still be lethal at high doses (Everaerts et al., 1988). Some experiments suggest that some monoterpenes are still sufficiently toxic to bark beetles as to significantly influence their ecology. Studies by Sturgeon (1979) of the *P. ponderosa*/*D. brevicomis* LeConte association suggest that tree resistance is linked to higher limonene contents. In a study similar to ours, Wallin and Raffa (2000) found that the number of *I. pini* that entered a phloem-based medium decreased with increased concentrations of most monoterpenes. In particular, the total length of tunnels excavated in the medium decreased with increasing concentrations of α-pinene and limonene (Wallin and Raffa, 2002). Regarding host-tree status, high monoterpene concentrations correspond to trees that have begun to respond to an attack, whereas lower concentrations likely represent constitutive phloem

from unattacked trees (Erbilgin and Raffa, 2000). Long exposure to α-pinene- and limonene-saturated vapors can also be lethal for *I. typographus* adults (Everaerts et al., 1988). Smelyanets and Vasechko (1973), studying the chemotaxis of *I. typographus* to terpenoids, found α-pinene to be repellent at concentrations higher than 3%, whereas limonene was attractive only at concentrations of 0.2–0.6% and repellent above 3–4%. Verbenone, which in many bark beetle species is usually released by tunneling males as a repellent for colonizing adults, shows a concentration-dependent repellence pattern (Schlyter et al., 1989). No previous studies concerning the antifeedant characteristics of verbenone has been conducted. We observed a strong repellent effect at high concentrations, especially to males.

In general, compounds from nonhost trees have strong antifeedant effects. Green leaf volatiles (GLVs) are aliphatic 6-carbon primary alcohols, aldehydes, and acetates found in broad-leaved trees (Visser, 1986). In our experiment, the GLV-blend showed an effective threshold starting at low concentrations. Moreover, *I. typographus* antennae strongly respond to 1-hexanol (Zhang and Schlyter, 2004). Similar responses have also been found in *D. ponderosae*, *Tomicus piniperda* (L.), *T. minor* (Hartig), *I. duplicatus* (Sahlberg), and *I. sexdentatus* (Boerner) (Zhang and Schlyter, 2004). In our experiment, males of *I. typographus* were strongly affected by hexanol and GLV, indicating a possible sex-specific effect of one or more of these compounds. Among the tested nonhost chemicals, 3-octanol is an 8-carbon alcohol extracted from the bark of European birch species (*Betula pendula* and *B. pubescens*) and aspen (*Populus tremula*) (Zhang et al., 2000). This alcohol showed the strongest effect on the feeding responses of *I. typographus*, being active at low concentrations (0.1%). Finally, juglone is a quinone derivative (5-hydroxy-1,4-naphthoquinone) already known to inhibit the feeding activity of *Periplaneta americana* (L.) and *S. multistriatus* by reacting with aminoacids, especially cysteine (Ferkovich and Dale, 1971). In our study, however, juglone only showed a moderate antifeedant effect. Following starvation, the need for water induces beetles to ingest nonhost or neutral diet, thus masking low antifeedant properties of some compounds. As we found some antifeedant activity in all compounds, the optimal starvation period before test might be longer than that applied in our study. Raffa (1988) hypothesized that phloem colonization does not continue in the presence of repellents, but progresses in the absence of stimulants. This would indicate repellents as the key factor influencing tree colonization. Our results support that hypothesis.

Acknowledgments—We thank L. Ansebo, M. Tasin, F. Loreto, and S. Larsson for comments on earlier drafts, the Björnstorp Estate for provision of logs, and E. V. Jirle for cutting stems for beetle breeding. The authors are also grateful to the Chemical Ecology Section of the Department of Crop Sciences, SLU (Alnarp, Sweden) for providing facilities and laboratories.

DO NAÏVE RUMINANTS DEGRADE ALKALOIDS IN THE RUMEN?

RAMÓN AGUIAR and MICHAEL WINK*

Institut für Pharmazie und Molekulare Biotechnologie, Universität Heidelberg, Im Neuenheimer Feld 364, 69120 Heidelberg, Germany

(Received August 11, 2004; accepted December 22, 2004)

Abstract—Three different methods for the culture of rumen microorganisms (Hungate's technique, the Hohenheim *in vitro* gas production method, and the semicontinuous rumen simulation technique) were employed to study the influence of various alkaloids (sparteine, lupanine, cytisine, atropine, quinidine, lobeline, harmaline, arecoline, nicotine, caffeine, pilocarpine, gramine, senecionine, and monocrotaline) on rumen microorganisms. Rumen microorganisms from naïve ruminants (sheep, cattle) that had not been exposed to the alkaloids before were generally not able to degrade most of the alkaloids. Only the alkaloids pilocarpine, gramine, and monocrotaline appeared to be degradable. Rumen microorganisms from a sheep preconditioned to lupin alkaloids tolerated lupanine much better than nonadapted microorganisms, but no degradation occurred. The findings indicate that the main site of detoxification in naïve ruminants is not the rumen but more likely the liver and kidneys as in nonruminants.

Key Words—Rumen, ruminants, detoxification, alkaloids, alkaloid degradation, adaptation.

INTRODUCTION

Herbivores are often confronted with toxins in their diet and have evolved various mechanisms during evolution to overcome plant defenses (Harborne, 1993; Wink, 1993). Whereas some poisons are detoxified or degraded in the digestive tract, many others are metabolized by enzymes primarily after absorption. In vertebrates, the liver is the first postabsorptive organ and thus, responsible for the detoxification of xenobiotics. In most animals, the inducible

* To whom correspondence should be addressed. E-mail: wink@uni-hd.de

microsomal mixed function oxidase (MFO) system, including the cytochrome P-450, is the major metabolizing enzyme system (Freeland and Janzen, 1974; Smith, 1992). These enzymes are substrate nonspecific and are predominantly concentrated in the liver and kidney of vertebrates. Some mammalian herbivores avoid toxicity of plant secondary metabolites by inactivating them before they reach the digestive tract. Deer are known to produce a salivary protein that binds tannins, thus allowing the animals to feed on tannin-rich plants (Robbins et al., 1987). The digestive tract itself is another potential site of detoxification. Ruminants and other foregut fermenters, for example, have evolved complex stomachs with a fermentation chamber, e.g., the rumen, where food particles are degraded by a diverse bacterial and protozoal community. The main benefits of a foregut fermentation system are the microbial degradation of cellulose and the microbial *de novo* biosynthesis of proteins. Nevertheless, many authors suggest that microbial detoxification of xenobiotics has played an important role in the evolution of the foregut fermentation system (Freeland and Janzen, 1974; Van Soest, 1994).

Plants containing alkaloids are widespread in the plant kingdom, and due to their toxicity (review: Wink 1993, 2000), many of them represent an important farming problem and are responsible for extensive poisoning of both humans and livestock. In the western USA, severe livestock losses result from the poisoning by tansy ragwort, *Senecio jacobaea*, which contains pyrrolizidine alkaloids (Huxtable, 1979; Wachenheim et al., 1992a,b). Larkspur (*Delphinium* sp.) is responsible for more cattle death than any other poisonous plant in the USA (Cheeke, 1998), and the plants known as locoweed, *Astragalus* sp. and *Oxytropis* sp., which contain swainsonine and other indolizidine alkaloids, are responsible for the neurological syndrome known as "locoism" in mammals (Molyneux and James, 1982). The lupin alkaloids anagyrine and ammodendrine are present in numerous lupin species in the USA and are of particular importance because of their teratogenic effect in cattle, causing skeletal deformities referred to as "crooked calf disease" (Cheeke and Kelly, 1989). In Afghanistan, over 1600 people were poisoned in 1974 by consuming wheat contaminated with seeds of *Heliotropium*, which contain high amounts of pyrrolizidine alkaloids (Mohabbat et al., 1976). *Heliotropium europaeum* and *Echium plantagineum*, both containing pyrrolizidine alkaloids, are responsible for poisoning of poultry (Pass et al., 1979), cattle (Harper et al., 1985), sheep (Seaman, 1985), horses (Giesecke, 1986), and pigs (Jones et al., 1981) in Australia. Often ruminants are the target of poisoning. This is somewhat surprising since ruminants have several potential detoxification systems (rumen, liver). We were interested in studying the role and efficiency of the rumen in detoxifying dietary toxins, especially alkaloids.

According to the position of the enlarged chamber in the digestive tract, herbivores are divided into two groups. In hindgut fermenters, the microbial

action occurs after the stomach and the small intestine and takes place in the cecum or large intestine (e.g., rabbits and horses), which is anatomically similar to the organs of carnivores and omnivores but much enlarged. In foregut fermenters, the chamber precedes the stomach with its pepsin digestion and the small intestine and is either a separate organ, e.g., the crop in the hoatzin (*Opisthocomus hoazin*), the only avian with foregut digestion, or part of a complex stomach not found in carnivores or omnivores, e.g., the rumen in ruminants (Hungate, 1988; Van Soest, 1994). Other ruminant-like digestive systems without a rumen have been found in a wide variety of other herbivores: the hoatzin, *Colobus* and *Macaca* monkeys, and camelids, and many of them are regarded as "functional ruminants" (Van Soest, 1994).

Cellulose, hemicellulose, pectins, fructans, starches, and other polysaccharides are hydrolyzed by rumen microbes to monomeric and dimeric sugars, which are further fermented to acetic, butyric, and propionic acids, methane, and carbon dioxide (Bryant, 1977; Van Soest, 1994). The gases are released by the animal and are essentially waste products, but the acids are absorbed through the rumen wall into the bloodstream and finally converted into sugars and lipids required for energy and tissue building. Proteins are hydrolyzed to amino acids and peptides, which are then deaminated to ammonia and fatty acids. The latter are further metabolized, whereas most of the bulk of ammonia is absorbed through the rumen wall to be converted into urea (Stewart et al., 1997).

The rumen ecosystem is composed of a large number of different species of bacteria, protozoa, and fungi. Rumen bacteria are predominantly strict anaerobes, although a few facultative anaerobes exist (Van Soest, 1994). Strict anaerobic bacteria are present in the rumen in numbers of about 10^{10} ml^{-1} and, together with the rumen Archaea (methanogens), are considered as the true rumen bacteria (Stewart et al., 1997). Methanogens form methane from H_2, CO_2, or formate (Hungate et al., 1970). The bacteria account for about half of the total biomass in a normal rumen but are responsible for most of the metabolic work (Van Soest, 1994; Stewart et al., 1997). There is little information concerning geographical and interspecific differences in the composition of rumen bacterial communities. Most studies in wild ruminants have been limited to microscopic observations on morphology and the Gram stain. According to Yokohama and Johnson (1988), the major species of bacteria are ubiquitous in ruminants, and there is no evidence of host specificity. *Synergistes jonesii*, a bacterium capable of detoxifying the hydrolysis products of nonprotein amino acids, such as mimosine, 3-hydroxy-4(1*H*)-pyridone (3,4-DHP), and 2,3-dihydroxypyridine (2,3-DHP), is the only well documented case of geographical differences in rumen bacterial community composition (Jones and Megarrity, 1983, 1986; Allison et al., 1990; Hammond, 1995). *S. jonesii* was isolated from the rumen of Hawaiian goats and was absent in Australian ruminants.

Protozoa are the most conspicuous organisms in the rumen. Unlike bacteria, they are not essential for the survival of the host ruminant. The most obvious and most important protozoa in the rumen are the ciliates, of which two different groups are present, both in the subclass *Trichostomatia*, the holotrich protozoa that belong to the order *Vestibuliferida*, and the entodiniomorphs that belong to the order *Entodiniomorphida* (Williams and Coleman, 1992). The latter are well adapted to the rumen environment and utilize particulate rather than soluble food materials. In contrast, the holotrichs can use mostly soluble food materials and are more aerotolerant. Most protozoa, if not all, have bacteria in vesicles in their cytoplasm, and there is evidence that the species present reflect those in the surrounding medium and include methanogens (Finlay et al., 1994; Lloyd et al., 1994). Population densities of protozoa in the rumen under normal conditions are on the order of 10^4–10^6 ml^{-1} (Williams and Coleman, 1992) and form a large proportion of the rumen microbial biomass (20–40% of net microbial nitrogen); yet their output may be minimal because of high retention and slow turnovers (Williams and Coleman, 1992; Van Soest, 1994).

The presence of anaerobic fungi in the rumen has been known since the 1970s (Orpin and Joblin, 1997). Before that, swimming zoospores were mistaken for flagellated protozoan. The contribution of fungi to the microbial biomass may be small, and their major function in the rumen may be in causing or facilitating cell wall disappearance (Van Soest, 1994).

The benefits derived from symbiosis with rumen microbes have long been recognized and include predominantly the transformation of dietary constituents into nutrients needed for growth, milk production, and energy. Because of the observation that ruminants are often more resistant to plant toxins and other xenobiotics than nonruminants, several authors have proposed that the degradation of toxic compounds present in the diet of the ruminant is conducted by the rumen microorganisms (Carlson and Breeze, 1984; Dawson et al., 1997; Cheeke, 1998; Weimer, 1998). Similarly, other authors proposed that these detoxification activities might have been a driving force during the evolution of the foregut fermentation digestive system (Freeland and Janzen, 1974; Van Soest, 1994). Sometimes, degradation activities are related to adaptive changes in the rumen microorganism populations, which result in an acquired resistance to specific toxins (Duncan et al., 2000; Duncan and Milne, 1992; Blythe and Craig, 1994; Dawson et al., 1997; Newbold et al., 1997; Odenyo et al., 1997).

In this investigation, we examined the hypothesis that rumen microbes are involved in detoxification processes in ruminants (Freeland and Janzen, 1974; Van Soest, 1994). For this purpose, the degradation of a set of 14 alkaloids (sparteine, lupanine, cytisine, atropine, quinidine, lobeline, harmaline, arecoline, nicotine, caffeine, pilocarpine, gramine, senecionine, and monocrotaline), as one of the most prominent groups of toxins, by rumen microorganisms was analyzed *in vitro*. Three more widely used methods in the study of rumen processes were

employed: batch cultures using Hungate's technique, the Hohenheim *in vitro* gas production method (HFT, "Hohenheimer Futterwert Test"), and the semi-continuous rumen simulation technique (RUSITEC).

METHODS AND MATERIALS

Alkaloids. Except for lupanine and senecionine, all alkaloids were purchased from Sigma (Munich, Germany) or Roth (Karlsruhe, Germany). Senecionine was a gift from R. Molyneux (USDA). Lupanine was isolated and purified from seeds of bitter lupins (*Lupinus angustifolius*). Alkaloids were dissolved in PBS buffer. In order to improve the solubility of some alkaloids, the pH of the stock solution was acidified with HCl. The effect of the pH of the alkaloid solutions on the respective assays was tested using the same volume of test solution without alkaloid but at the same pH.

Isolation and Quantification of Alkaloids. Samples were dissolved in 20 ml, 0.5 M HCl and incubated overnight under agitation and in darkness. In order to detect the potential presence of N-oxides, 100 mg of zinc powder were added to the corresponding samples, and these were stirred for another 3 hr under continuous agitation. The solution was made alkaline with 6 M NaOH (pH 12). Samples were extracted using a solid–liquid phase system with Isolute (ICT) as solid and CH_2Cl_2 as liquid phase. The dichloromethane extracts were collected in round-bottom flasks and evaporated under vacuum (890 mbar) at 40°C. Alkaloids were recovered from the flask with 2–3 ml CH_2Cl_2 and transferred to a vial. The solvent was evaporated under N_2 flow or overnight in a hood and protected from light. Dried alkaloid samples were stored at −20°C until GLC analysis.

Two Carlo Erba gas chromatographs were used for the GLC analysis. The first gas chromatograph (series 5100) was equipped with a DB-1 capillary column (J&W, 15 m long and 0.25 mm inner diam) and the second GLC (series 6000) with an OV-1 column (Ohio Valley, 15 m long and 0.25 mm inner diam). Both GLCs were equipped with flame ionization detectors (FID). The split was 1:5 and 1:10, respectively. Helium was used as carrier gas. The temperature of the injector and the detector were 250 and 300°C, respectively. A 1-µl aliquot of each sample was injected into the gas chromatograph for analysis. The oven temperature program used for each alkaloid was 150°C for 3 min, 150–250°C at 15°C/min, and 250–300°C at 25°C/min for lupanine, sparteine, atropine, quinidine, harmaline, senecionine, monocrotaline, and pilocarpine, and 80°C for 2 min, 80–150°C at 10°C/min, and 150–300°C at 20°C/min for arecoline, caffeine, nicotine, gramine, and lobeline. Alkaloids were quantified by using external standards consisting of a solution in methanol.

Alkaloids were identified by GLC-MS using authentic alkaloids as reference. For GLC-MS, an OV-1 fused silica capillary column (30 m × 0.25 mm) was used coupled to a quadrupole Finnigan Mat 4515 mass spectrometer. EI-MS were recorded at 40 eV and evaluated with the INCOS data system. The conditions are as follows: carrier gas He; splitless injection; temperature 250°C; oven temperature program—initial temperature 120°C, 3 min isothermal, 120–300°C, 8°C/min.

Rumen Microbial Culture Techniques. Rumen microbes are sensitive to their environment, and successful cultures must satisfy both environmental and nutritional requirements. In *in vitro* cultures, all products accumulate in the system; thus, it is necessary that the maximum levels of acidic products remain below the limiting levels of osmotic pressure and buffer capacity, especially in closed systems. For this reason, *in vitro* cultures must be diluted by about an order of magnitude with respect to both feed and organisms to avoid hyperacidity and high osmotic pressures (Van Soest, 1994).

Diluting the substrate in the culture medium increases the susceptibility of fermentation to traces of oxygen. Therefore special precautions must be taken to protect dilute concentrations of rumen microorganisms from oxygen contamination. The methanogens and pure cultures are especially sensitive to traces of oxygen (Van Soest, 1994), but batch cultures in small volumes, such as the Hungate tubes and the syringes in the "Hohenheim *in vitro* gas production method" (HFT), also require an oxygen-free atmosphere (Hungate, 1969; Van Soest, 1994). Some anaerobes and the methanogens cannot initiate growth at redox potentials greater than -0.33 V, which corresponds to 10^{-75} of the concentration of oxygen in the atmosphere or 2.5×10^{-80} mmol O_2/l (Hungate, 1969). Normally, most of the oxygen is removed from the medium by boiling followed by gassing out with CO_2, and any residual oxygen is removed by adding cysteine. Commercial sources of CO_2 usually contain traces of oxygen and need to be purified by passing the gas through heated copper turnings (Hungate, 1969).

Hohenheim In Vitro Gas Production Method or HFT. The assay consisted of rumen batch cultures kept in glass syringes and incubated for up to 2 d in a water bath. The method was based on Menke et al. (1979). To determine the fate of lupanine and sparteine incubated *in vitro* with rumen liquor and their effect on fermentation parameters, 500-mg dry matter of hay has incubated in triplicate in 100-ml graduate glass syringes (Fortuna, Germany) containing 40 ml of the *in vitro* medium with bovine or ovine rumen liquor. Syringe pistons were lubricated with Vaseline to facilitate their movement allowing space for the increasing gas volume in the syringe. Two control sets were prepared: control 1 containing no hay and control 2 containing no rumen liquor. Alkaloids were added to the treatment and control syringes at a concentration of 1 mM. Three syringes were used as blank and were incubated without alkaloids. All

syringes were incubated under anaerobic conditions at 37°C for 36 hr and shaken manually every hour for the first 6 hr and every 3 hr for the rest of the incubation period in order to avoid the accumulation of hay on the superficies of the medium. Three syringes were collected every 6 hr for the treatment group and every 12 hr for each control group. Blank syringes were incubated for 36 hr. The content of each syringe was immediately acidified to pH 3 with 0.5 ml, 7 M HCl in order to stop any microbial reaction and then stored at −20°C for later analyses. These assays were performed at the Institute for Animal Production in the Tropics and Subtropics, University of Hohenheim.

Preparation of Culture Medium for HFT. Rumen inoculum was collected from a cow and two sheep fitted with permanent rumen fistulas, kept at the University of Hohenheim (Germany), and fed on a roughage-based diet. Rumen contents were obtained through the fistulas and immediately strained through sterile cheesecloth into insulated prewarmed thermoses, avoiding formation of air bubbles. Thermoses were transported to the lab within 15 min, where the experiments were started immediately.

Culture medium was prepared under anaerobic conditions. Constantly bubbling the medium with CO_2 (Messer Griesheim GmbH 4.5), previously passed through a column of heated cooper (350°C) in order to remove any oxygen traces (Hungate, 1969), provided acceptable anaerobic condition in the medium. Rumen liquor was added to the warm culture medium (37°C) under constant agitation and gas bubbling. The composition of the culture medium was as outlined by Menke et al. (1979).

Adaptation of Rumen Microorganisms to Alkaloids Present in the Diet. To investigate the possible induction of lupanine and sparteine degradation metabolism in rumen bacteria, two merino sheep were fed during 4 wk on a diet containing increasing amounts of seeds of alkaloid-rich *L. angustifolius* (lupanine was the major, 13-hydroxylupanine and angustifoline were additional alkaloids). During the first week, the sheep (40-kg weight) obtained 2.5 mg/kg alkaloids; the dose was increased via 5, 10, and 20 mg/kg during weeks 2, 3, and 4, respectively.

Rumen Batch Cultures using Hungate's Technique. Alkaloids were studied *in vitro* following the method described in Hungate (1969). Hungate tubes with butyl rubber stoppers (Bellco Glass) were filled with 5-ml culture medium 2 (Hobson, 1969), medium RA-1, or medium RA-2 under anaerobic conditions, and inoculated with 100-µl diluted fresh rumen liquor. An aliquot of concentrated alkaloid solution was injected into each tube in order to reach a final concentration of 1 and 10 mM. Rumen liquor was obtained as explained before and diluted 1:9 in medium 2. Controls without bacteria (blanks) or alkaloids were performed. All cultures were incubated at 37°C. Three tubes from each treatment and from the control group without rumen inoculum were collected after 0, 2, and 7 d in order to measure the alkaloid contents. An aliquot (100 µl)

of each 7 d-old culture was inoculated in fresh medium under the same conditions. The alkaloid content of the refreshed cultures was measured 0, 2, and 7 d later. An aliquot of 200 μl, 6 M HCl was added to each collected tube to stop any bacterial activity. Samples were then stored at −20°C.

Culture solution was boiled and bubbled with CO_2 (Messer Griesheim GmbH 4.5) under constant agitation with a magnet until the pink color of the resazurine disappeared (10–15 min). Resazurine is used to indicate oxidation–reduction potentials above −0.042 that are known to inhibit the growth of most ruminal strict anaerobic bacteria (Hungate, 1969). The culture medium was allowed to cool to about 60°C under CO_2 flow using a cold-water bath before cysteine was added as a reducing agent. Culture medium was distributed with a glass pipette into Hungate tubes, which were gassed for 30 sec with CO_2. Gassing was maintained for 30 additional sec after the medium was inoculated. The tubes were hermetically closed with the butyl rubber stoppers and autoclaved for 15 min at 121°C. Afterwards, culture tubes were stored at room temperature and darkness until used. Tubes in which the medium had turned to a reddish color were discarded. Purified rumen fluid was obtained by autoclaving (121°C, 15 min) and centrifuging rumen liquor at 4000 rpm for 30 min.

Rumen Simulation Technique. Since the rumen is a form of open and continuous culture, many researchers have attempted to establish *in vitro* continuous cultures of mixed rumen microorganisms with a volume of more or less whole rumen contents as the starting "inoculum." The most important of these methods is the RUSITEC (Czerkawski and Breckenridge, 1977, 1979a,b; Cheng and McAllister, 1997), allowing the culture of bacteria, protozoa, and fungi that inhabit the different physiological compartments of rumen for an almost indefinite period of time (Van Soest, 1994).

The RUSITEC technique is a semicontinuous rumen fermentation system consisting of four to six reaction vessels (fermenters). Fermentation patterns and processes observed in a RUSITEC closely resemble the fermentation patterns and processes observed in the rumen *in vivo*. The control fermenters of an already going 30-d-long assay were used in this study during the last 4 d. Fermenters were kept in a steady-state fermentation phase during at least 20 d before the assays. Control fermenters were then inoculated with alkaloids and treated as explained below. Values from the five previous days (before alkaloid addition) were used as control values.

A RUSITEC assay is started by placing in each fermenter 80 g of solid rumen digesta in one nylon bag (1-mm mesh), and the experimental diet (12-g dry matter of hay, and 3.4-g calf food concentrate pellets) in a second nylon bag. Both bags are inserted (the one with rumen content above) in a perforated cage and this cage into the reaction vessel with 500-ml fresh collected rumen liquor, 200-ml RUSITEC buffer (Czerkawski and Breckenridge, 1977), and

100-ml deionized water. The fermenters are placed in a water bath at 39°C, and the perforated cages are fixed to a motor that slides them with 6- to 7-cm amplitude at about 8–9 cycles/min. The fermenters are connected to a buffer reservoir allowing a buffer flow rate of 280–290 μl/min and then filled with CO_2 (Messer Griesheim GmbH 4.5). Buffer overflow is collected in a 2 l Erlenmeyer (filled with 40 ml, 7 M HCl), which is also connected to a collection gas bag (Linde, Art. No. 037660006).

After 24 hr incubation, the buffer flow is stopped, the gas bag changed, the overflow collected, and the solid inoculum bag removed and replaced with a new bag of experimental diet. The fermenter is filled again with CO_2 and connected again to a new Erlenmeyer and a new gas bag. The buffer flow is restarted. Subsequently, the older food bag is replaced with a new one each day, and the needed samples are collected to measure the fermentation parameters of interest. The content of the food bag is washed with RUSITEC buffer and pressed to squeeze out excess liquid, which is returned to the fermenter.

The fermentation parameters decrease during the first days but reach a steady state after 5–7 d, which can be maintained indefinitely with a balanced diet and correct handling of the fermenter. The steady state must be reached before an experiment can be started. Normally, two fermenters are used as control in an experiment, feeding them with the same diet and maintaining them in the steady state. In these experiments, the rumen liquor and the solid inoculum were collected from a fistulated cow 3 hr after the morning feeding.

Fate of Alkaloids in Rumen Simulation Technique. A concentrated alkaloid buffer solution was inoculated into each fermenter to a final alkaloid concentration of 2 mM during the daily change of the food bag. Alkaloid stock solutions were as concentrated as possible in order to use the smallest possible aliquot, but in such a way that every fermenter received the same volume of stock solution. Because the RUSITEC is a semiopen system, the alkaloid concentration in each fermenter constantly decreased even without alkaloids being degraded. The concentration decrease can be predicted with the equation $C_2 = (1-(\mathrm{fr}/\mathrm{Vt})^t)C_1$, where C_1 and C_2 are the initial and final concentrations, respectively, fr is the buffer flow rate, Vt is the total volume in the fermenter, and t is time. To measure the actual alkaloid concentration in each fermenter, 40 ml of fermenter content were taken at 0, 6, 12, 24, 48, and 72 hr. Every sample was divided into two 20-ml aliquots and stored at −20°C until they were processed for GLC analyses. Any microbial activity was stopped in each sample by adding 0.5 ml, 6 M HCl.

Determination of Fermentation Parameters

pH Determination. The pH value of a freshly taken aliquot (10 ml) of the fermenter content was measured using a calibrated pH meter (WTW, Type pH-91).

NH_3 Determination. The same aliquots, used for pH measurements, were immediately used to determine ammonia concentration. A calibrated ion-sensitive electrode (Orion 9515) and an ion analyzer (Orion 920-EA) were used. Samples were first treated with 100 µl, 2 M NaOH in order to change all ammonium ions in solution to free ammonia because the electrode can measure only the latter.

Volumetric Determination of Total Gas Production. The volume of gas produced during 24 hr in each fermenter and collected in hermetic gas bags (Linde, Art. No. 037660006) was determined by using the principle of water displacement. Three 1-l calibrated cylinders were filled with water and placed upside down in a bowl with water. The content of each gas bag was transferred with a plastic tube into the cylinders. The amount of water displaced corresponds to the amount of gas produced in the respective fermenter. During this procedure, a sample of gas was collected for the gas composition analysis.

Chromatographic Analysis of the Gas Composition. A sample was taken with a 1-ml syringe (Hamilton, TLL 1001) from the gas bag to determine the composition of the gas mixture. Each sample was collected immediately before GLC analysis. Samples (1 ml each) were injected manually into a gas chromatograph (Shimadzu, GC-8A). The impulses produced by the thermal conductivity detector (TCD) were processed on an integrator (Shimadzu, CR-3A). The GC was calibrated every day with a special gas mixture (Messer Griesheim). A correction factor for each gas was calculated by the integrator from the mean value of two consecutively injected calibration samples (1 ml each).

RESULTS AND DISCUSSION

Influence of Alkaloids on Gas Production in Bacterial Cultures from Rumen. The "Hohenheimer Futterwert Test" (HFT) and the Hungate anaerobic technique were used in a first approach to follow the fate of alkaloids in the rumen ecosystem that mainly targets the bacterial members. The total gas production in the rumen correlates linearly to the production of short-chain fatty acids (Van Soest, 1994; Blümmel et al., 1997b). Its reduction is indicative of a negative effect on ruminal fermentation processes. Since rumen microbes, especially bacteria, hydrolyze plant polysaccharides to monomeric or dimeric sugars, which are further fermented to acetic, propionic, and butyric acids, methane, and carbon dioxide, any effect on the total gas production in the rumen can be interpreted as an effect on the rumen microbial community.

The quinolizidine alkaloids lupanine and sparteine, which exhibit antimicrobial activities at higher concentrations (Wink, 1984), were selected for the first pilot experiments. At a physiological concentration of 1 mM, neither lupa-

nine nor sparteine had a significant effect on *in vitro* gas production (HFT) of microbial cultures derived from rumen liquor of cattle (Table 1, column c). Both alkaloids slightly decreased gas production when rumen liquor from a sheep fed on a roughage-based diet was used (Table 1, column a). The known antibacterial properties of lupin alkaloids (Wink, 1984) could be responsible for the negative effect of both alkaloids on the *in vitro* microbial fermentation of sheep.

Using rumen liquor from a sheep fed for 1 mo on a diet containing up to 3.2% of lupin seeds (containing lupanine as main alkaloid and no sparteine), we observed that lupanine increased *in vitro* gas production whereas sparteine had a negative effect (Table 1, column b). The effect of sparteine on *in vitro* gas production is four times stronger than the effect of lupanine. An even more pronounced adaptation of the bacterial community to lupanine was observed after feeding the sheep increasing amounts of lupin seeds (diet II) for 1 mo: Rumen bacteria from a sheep fed on a diet without alkaloids (diet I) were not able to grow at an alkaloid concentration of 10 mM in contrast to bacteria from a sheep fed on diet II, which showed an even better growth at 10 mM than at 1 mM (Table 2). After 7 d of incubation in media containing alkaloids as a sole carbon source (RA-1 and RA-2), only the microbes from diet II were able to grow after reinoculation in fresh medium. This finding suggests an acquired resistance to the added lupanine (Table 2).

Feeding a ruminant on a diet containing plant toxins can modify the microbial composition of its rumen, favoring those microorganisms that can tolerate or even metabolize such toxins (Duncan and Milne, 1992; Blythe and Craig, 1994; Newbold et al., 1997; Odenyo et al., 1997; Duncan et al., 2000). This could also be the case in our experiment, thus favoring the growth of those microbes able to tolerate the presence of lupanine in the rumen. If the favored microbes play an important role in the fermentation processes, this is observed as an enhancement of total gas production (Table 1). The higher negative effect

TABLE 1. EFFECT OF LUPANINE AND SPARTEINE ON THE TOTAL GAS PRODUCTION *In vitro* IN HFT

	Gas production (ml/200 mg hay)		
	a	b	c
Control	42.8 ± 0.28n	42.9 ± 0.99n	49.9 ± 1.04n
Lupanine 1 mM	41.6 ± 0.53m	44.5 ± 0.23m	47.9 ± 1.14n
Sparteine 1 mM	41.7 ± 1.45m	36.9 ± 0.14o	48.7 ± 0.92n

Rumen liquor was obtained from a sheep fed on a roughage-based diet (a) from a sheep fed on an adaptation diet, including increasing amounts of lupin seeds (b), or from a cow fed on a roughage-based diet (c).
Values are given in means and standard error. Assays were done in triplicate. Means with different letters in a column differ at $P < 0.05$ (ANOVA).

TABLE 2. GROWTH OF RUMINAL BACTERIA IN BATCH CULTURES WITH DIFFERENT CONCENTRATIONS OF ALKALOIDS

		Lupanine		Sparteine

of sparteine after the adaptation feeding trial can be interpreted as a differential activity of both alkaloids on the rumen microbial community. Although both lupanine and sparteine have a similar molecular structure (differing only by a ketone group in position 2 of lupanine), both have different biological activities. Sparteine is more active on Na^+ channels and muscarinic acetylcholine receptors than lupanine, whereas lupanine is more active on nicotinic acetylcholine receptors (Wink, 1993, 2000; Schmeller et al., 1994). Sparteine is also more toxic to mice but less toxic to insects (Wink, 1992).

Fate of Lupanine and Sparteine in HFT. Lupanine and sparteine were incubated *in vitro* in glass syringes. Incubations were conducted in triplicate and by using rumen fluid from only one animal in each assay. Both lupanine and sparteine were stable in control incubations for 36 hr. No degradation of alkaloids was found during an incubation period of up to 36 hr in the assays with rumen liquor, neither from a cow nor from a sheep fed on a roughage-based diet. In addition, in experiments with the Hungate technique, no degradation of either alkaloid could be detected.

The recovery data were about 94% in the assays using rumen liquor from a sheep preconditioned for 4 wk on a roughage-based diet with increasing amounts of lupin (*L. angustifolius*) seeds (Table 3). Although these values were lower than those of the corresponding experiments and could indicate some degradation, the differences from controls were not statistically significant.

Fate of Various Alkaloids in Anaerobic Batch Cultures using Hungate's Technique. Rumen inocula from a "naïve" cow that had not been exposed to alkaloids showed good growth in Hungate tubes together with alkaloids of different structures and biological activities (1 mM each; sparteine, lupanine, atropine, quinidine, harmaline, cytisine, and senecionine). GLC analyses showed no degradation of alkaloids after 7 d of incubation. All tested alkaloids were also

TABLE 3. FATE OF LUPANINE AND SPARTEINE IN HFT

	Recovery of alkaloids		
Alkaloid	a	b	c
Lupanine	108.3 ± 2.5	94.5 ± 3.75	124.5 ± 17.6
Sparteine	124.5 ± 17.6	93.8 ± 7.93	97.8 ± 2.49

Rumen liquor was obtained from a sheep fed on a roughage-based diet (a), from a sheep fed on an adaptation diet including increasing amounts of lupin seeds (b), or from a cow fed on a roughage-based diet (c).
Alkaloids were determined by GLC. Values are given in means and standard error of the percent of alkaloids recovered after 36-hr incubation. Assays were done in triplicate. No statistical differences were found at $P < 0.05$ (*t*-student), compared to the initial concentrations.

stable for 7 d in control incubations without active rumen inoculum (Figure 1). It is remarkable that the pyrrolizidine alkaloid (PA) senecionine is not degraded; several authors have reported that PAs can be degraded by rumen microorganisms. We suggest that they had used rumen microorganisms from preconditioned ruminants that had been exposed to PAs before (Swick et al., 1983; Craig et al., 1986, 1992; Cheeke, 1988, 1998; Wachenheim et al., 1992a,b).

Rumen Simulation Technique. It could be argued that the negative results from our HFT and Hungate experiments are due to the fact that rumen protozoa

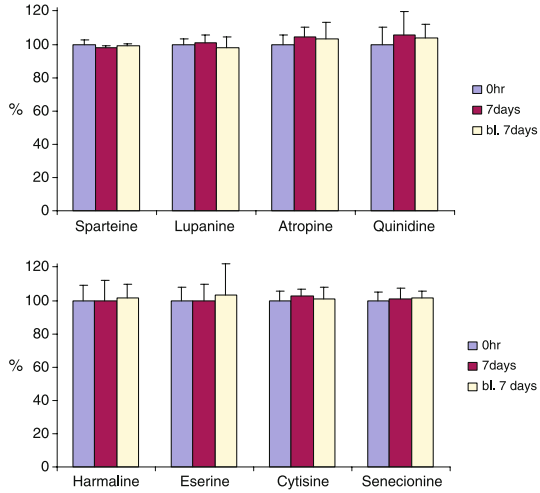

FIG. 1. Recovery of alkaloids after 7-d incubation in Hungate tubes inoculated with culture medium M2 and bovine rumen liquor. Values are given in mean and standard deviation. No significant differences were found between 0 hr and 7 d either for treatment or for blank (bl.) incubations at $P < 0.05$ (*t*-student).

and their associated bacterial consortia cannot be cultured by using Hungate's technique and that their culture in HFT is unstable. In addition, bacteria that live attached to food particles cannot be cultured using Hungate's technique or in HFT but in RUSITEC fermenters. In order to overcome the technical problems, we designed a second set of experiments with RUSITEC to study the fate of alkaloids in the rumen.

The following alkaloids of various structures and bioactivities (2 mM each of sparteine, lupanine, atropine, quinidine, lobeline, harmaline, arecoline, nicotine, caffeine, pilocarpine, gramine, and monocrotaline) were added on day 5 to the RUSITEC culture vessels. Several physiological parameters were determined during the run of the fermentation experiments, such as hydrogen ion and ammonia concentrations and gas and protein production.

Changes in hydrogen ion concentrations were analyzed continuously from the start of the cultures and 3 d after the alkaloids had been added to monitor any adverse effects. Hydrogen ion concentrations (pH values) varied between 6.56 and 6.99, being mostly between 6.7 and 6.9, both during the alkaloid-free control days (d 1–5) and the posttreatment days (d 6–8). These variations are within the normal pH variation found in previous RUSITEC experiments done in the Rumen Laboratory at the Veterinary School of Hannover (TiHo), indicating that alkaloids did not cause any drastic effect, thus confirming the findings from our Hungate experiments.

The concentration of ammonia in the fermenters showed a high variation already during the alkaloid-free days varying from 15 to 23 mmol/l but were within the range found in previous RUSITEC experiments. After addition of the alkaloids on d 5, a reduction of ammonia concentrations was observed in most fermenters (Figure 2). This effect was more pronounced for lobeline, harmaline, and atropine. Ammonia production in the rumen fluid is a consequence of amino acid and urea breakdown by both rumen bacteria and protozoa. Amino acids are deaminated to ammonia and fatty acids by most rumen protozoa (Allison, 1970) and a broad group of rumen bacteria, the latter being responsible for most of the ammonia production. Urea is broken down in the rumen only by bacteria (Sakurada et al., 1994). Considering this and the fact that weak antimicrobial activities seem to be exhibited by the applied alkaloids (Wink, 1993; Verpoorte, 1998), it is not surprising that the addition of alkaloids to the RUSITEC fermenters has a negative effect on fermentation parameters. The alkaloid concentration used was not high enough to have a more pronounced antimicrobial effect. The reduction of ammonia in the fermenters agrees with the results reported by Wiedmeier et al. (1987), who found that the ammonia concentration in cattle rumen decreased by 37% when the animals were fed on a diet containing the alkaloid pilocarpine at a dose of 4 mg/kg body weight.

Effect on Ruminal Gas Production. All fermenters showed a high variation in the daily total gas production. The amount of variation extends from 250 ml

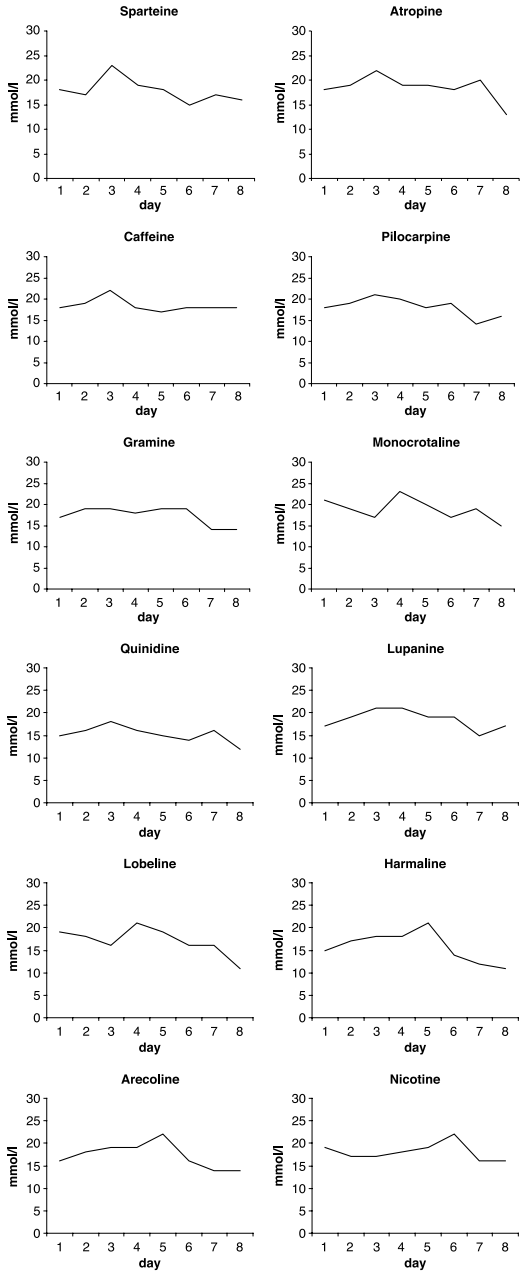

FIG. 2. Effect of alkaloids on ruminal NH_3 concentration measured in RUSITEC fermenters for 72 hr. Alkaloids were added on day 5 at a final concentration of 2 mM.

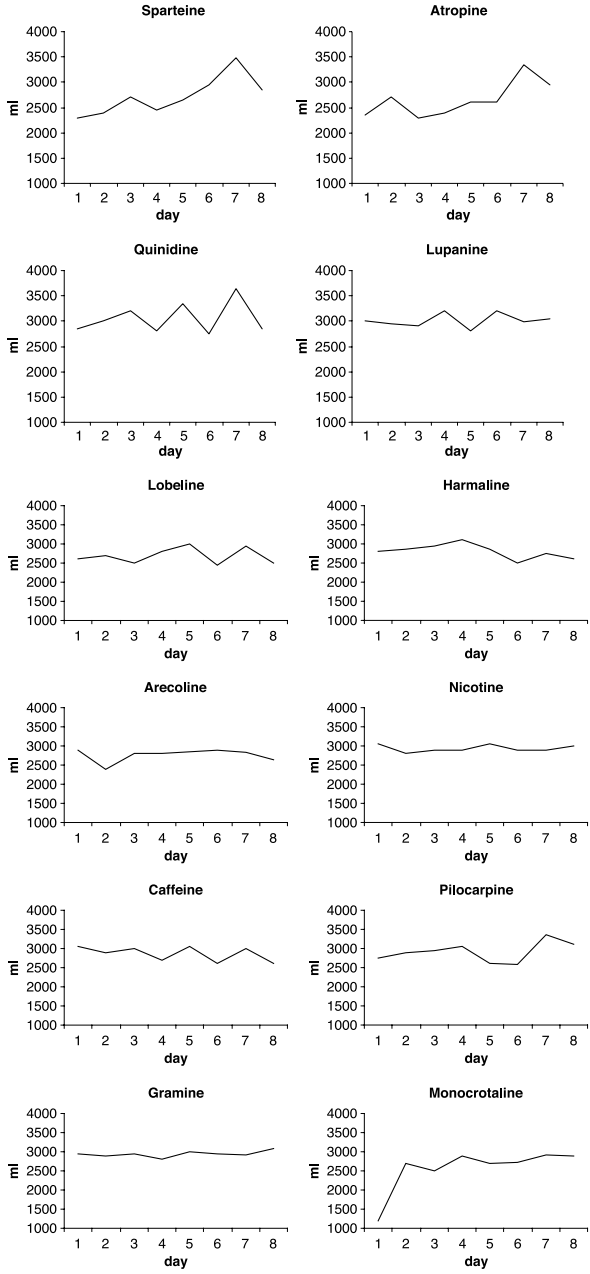

FIG. 3. Effect of alkaloids on ruminal total gas production measured in RUSITEC fermenters for 72 hr. Alkaloids were added on day 5 at a final concentration of 2 mM.

for arecoline and nicotine to 900 ml for quinidine (Figure 3). The extreme low value on the first day of the fermenter treated with monocrotaline is probably an artifact due to incorrect handling of the gas bag. However, a significant increase in total gas production is observed after the addition of sparteine, atropine, and pilocarpine (Figure 3). Harmaline, in contrast, has a negative effect on fermentation (it has pronounced antimicrobial properties; Wink, 2000), thus reducing total gas production.

A reduction of ammonia production in the fermenters was interpreted as a result of the antimicrobial activities of the employed alkaloids. This interpretation seems contradictory to the observation that some alkaloids also increased total gas production in the fermenters, which corresponds to an improvement of the microbial fermentation processes in the reaction vessels. Although total gas production correlates linearly to the production of short-chain fatty acids and consequently resembles the efficiency of the microbial fermentation, the latter is not only dependent on the microbial biomass, but also on the microbial fermentative capacities. It has been demonstrated that *in vitro* gas production can have an inverse relationship to microbial biomass production (Makkar et al., 1995a,b; Blümmel et al., 1997a,b). The addition of sparteine, atropine, and pilocarpine could favor those bacteria with the highest fermentative capacities. Similar results have been reported for caffeine (Campbell et al., 1976) and pilocarpine (Wiedmeier et al., 1987).

In contrast to total gas production, gas composition was almost constant for all fermenters during experiments (data not shown). Only in the fermenters treated with atropine, quinidine, and caffeine a slight increase in the proportion of CO_2 after addition of alkaloids was observed (data not shown), which suggests a slight improvement in the carbohydrate fermentation. In addition, quinidine appears to be the only tested alkaloid with a negative effect on the methanogen community with its concomitant reduction of methane production. Since total gas production was not affected by this alkaloid and since carbon dioxide, together with hydrogen, is the major precursor of methane in the rumen (Wolin et al., 1997), the observed increase of CO_2 can be interpreted as a direct effect of methane reduction.

Effect on Ruminal Protein Concentration. The addition of quinidine and caffeine (Figure 4) decreased the protein concentration in the fermenters by 43 and 47%, respectively. No significant effect was observed after addition of the other alkaloids. Since only bacterial protein was measured, a reduction of protein concentration resembles a decrease in the bacterial biomass and can correspond to antimicrobial activities of the alkaloids. Most alkaloids had a negative effect in at least one fermentation parameter, which can be interpreted as a result of antimicrobial activities (Verpoorte, 1998). Yet the bacterial biomass and most fermentation parameters were not disturbed; we can, therefore, assume that the microbes were alive and should have been able to degrade alkaloids.

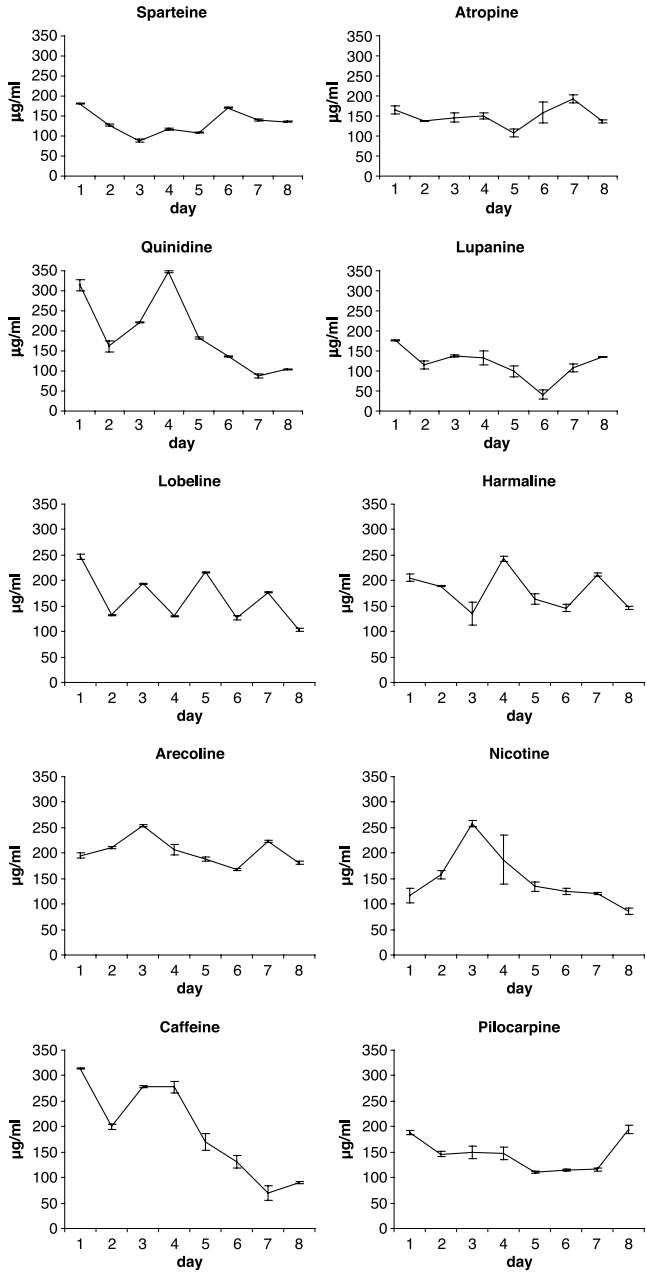

FIG. 4. Effect of alkaloids on ruminal protein concentration measured in RUSITEC fermenters for 72 hr. Alkaloids were added on day 5 at a final concentration of 2 mM.

Fate of Alkaloids in Rumen Simulation Technique Fermenter. All tested alkaloids were stable in control incubations that used sterilized rumen liquor to avoid possible degrading metabolism from rumen microorganisms. Most alkaloids were stable during the incubations and did not change (Figure 5). A decrease in the concentration was observed only for pilocarpine, monocrotaline, and gramine (Figures 6–8).

Pilocarpine showed the highest degradation rate being totally degraded after 12 hr incubation (Figure 6). The concentration of monocrotaline decreased to 38.9% within the first 12 hr and to 4.7% within the next 12 hr (Figure 7), which represents a degradation of 49.4 and 92.1%, respectively (in relation to the expected concentration). In Figure 7B, the gas chromatograms of the monocrotaline samples collected at time 0, 24, and 48 hr incubation are illustrated. It is possible that an ester hydrolysis of monocrotaline is involved in the degradation of this alkaloid by rumen microbes. Similar reaction mechanisms have been postulated for jacobine (Wachenheim et al., 1992a,b) and for the monoester heliotrine, along with modification of the necine base (Russell and Smith, 1968; Lanigan, 1971, 1976). Enzymatic hydrolysis of monocrotaline has been reported from hepatic microsomal incubation of guinea pigs, leading to the nontoxic necic acid and necine base (Dueker et al., 1992). There are substantial evidence and counterevidence for detoxification pathways in liver vs. rumen in the literature concerning pyrrolizidine alkaloids (Swick et al., 1983; Craig et al., 1986, 1992; Cheeke, 1988, 1998; Wachenheim et al., 1992a). Wachenheim et al. (1992b) found that pyrrolizidine alkaloids (PAs) were degraded more rapidly when incubated *in vitro* with ovine or caprine than

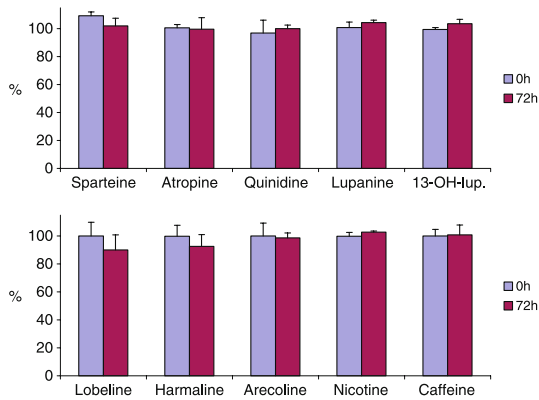

FIG. 5. Recovery of alkaloids after 72 hr incubation in RUSITEC fermenters. Values are given in mean and standard deviation. No significant differences were found between 0 and 72 hr at $P < 0.05$ (*t*-student).

with bovine rumen fluid, and by using the "most probable number procedure" for estimating PA-degrading bacteria in rumen, they demonstrated that cattle have these bacteria, but in much reduced numbers than sheep and goats. In contrast, Shull et al. (1976) and Swick et al. (1983) found that *S. jacobaea* is still toxic to rats after incubation with sheep rumen fluid. Nevertheless, the presence of alkaloid-degrading organisms in the rumen is far from ubiquitous in all ruminants. The apparently high frequency of reports on PA-degrading microbes found in the literature, compared with other toxins, seems to be rather a result of the intense investigation of this group of alkaloids and their economical importance in the range management (Swick et al., 1983; Craig et al., 1986, 1992; Cheeke, 1988, 1998; Wachenheim et al., 1992a).

Gramine suffered a lower degradation rate, 35.7 and 38.3%, respectively, of the expected concentration after 12 and 24 hr (Figure 8). The gas chromatograms of the gramine samples collected 0, 24, and 48 hr after incubation in RUSITEC are shown in Figure 8B. Since gramine occurs in young leaves of cereals and these plants are the main component of a roughage-based diet for

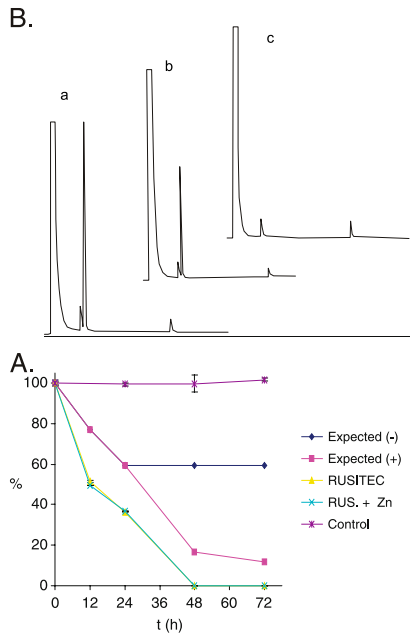

FIG. 8. Fate of gramine in RUSITEC fermenter. (A) Kinetics of gramine contents during fermentation; (B) GLC profiles of the cultures after 0 hr (a), 24 hr (b), and 48 hr (c); 1 = gramine.

ruminants, we would expect to find that rumen microbes from cattle kept in stables and fed on this kind of diet are able to metabolize this alkaloid.

We found no evidence for alkaloid N-oxide formation in any fermenter, which agrees with the hypothesis of Dawson et al. (1997) that oxidative reactions are not to be expected in the rumen because of the relatively low oxygen concentrations present.

In summary, our experiments using the Hungate and HFT approach provide no evidence for alkaloid degradation when rumen microorganisms from naive and unexposed sheep and cattle were assayed. Using the RUSITEC method, which takes a more complex rumen microbial community into account, most alkaloids appear to be stable and were not degraded. Evidence for degradation was obtained for gramine, pilocarpine, and monocrotaline, however, indicating a broader metabolic activity than would have been assumed from the bacterial cultures using Hungate and HFT alone.

Feeding sheep for a period of 4 wk on a diet containing increasing amounts of bitter lupin seeds was not sufficient to induce alkaloid-degrading metabolism in ovine rumen microbes. Nevertheless, rumen microbes could adapt to the presence of lupanine, and the fermentation processes, determined by total gas production, were, therefore, enhanced. Feeding ruminants a diet containing plant toxins can thus modify the composition of the microbial rumen community either by selecting those microorganisms able to tolerate higher concentration of the toxins consumed by the herbivore or by allowing the microorganisms to become adapted to the new conditions.

Most experiments are conducted *in vitro* using rumen fluid from animals (mainly cattle and sheep) kept in stables and fed on controlled grass-based diets. Many authors have reported that previous exposure to a diet containing the plant toxin is, in most cases, a requisite for the rumen microbes to be able to metabolize it or for the ruminant not to be affected by the toxin, suggesting an adaptation of the rumen microorganisms for metabolizing it (Smith, 1992). Allyl cyanide is degraded in the rumen of sheep fed on cabbage, but not in the rumen of grass-fed sheep (Duncan and Milne, 1992). Ethiopian sheep gradually adapted to a diet containing *Acacia angustissima* are protected from its toxins through rumen detoxification, whereas non-adapted animals die within a few days (Odenyo et al., 1997). The rumen flora of nonadapted deer is severely inhibited by the essential oils of Douglas fir needles, whereas no inhibition is found on rumen flora from deer previously adapted to a diet containing up to 50% Douglas fir needles (Oh et al., 1967). The antiprotozoal factor (saponins) of *Sesbania sesban*, an African leguminous tree, affects negatively the rumen protozoa of Scottish sheep but not of feral Ethiopian sheep, and *in vitro* experiments suggest that bacteria are adapted to detoxify this antiprotozoal agent (Newbold et al., 1997; Teferedegne et al., 1999). Culvenor et al. (1984) found that the *in vitro* degradation of *Echium* pyrrolizidine alkaloids incubated

with ovine rumen fluid can be improved up to 22 times when the donor sheep are previously fed with *Echium* for 12 wk. Sheep that have been reared on pyrrolizidine alkaloids can degrade them, but inexperienced sheep cannot. Similarly, the rumen flora of deer that have not previously been fed with Douglas fir needles are severely inhibited by it, but experienced deer can consume a diet of up to 50% needles without showing negative effects (Oh et al., 1967).

The results obtained in this study clearly emphasize that degradation of alkaloids does not occur to a substantial degree in the rumen of naïve ruminants, thus suggesting a prominent role of liver detoxification instead. More work is needed to understand the specific role of the rumen and the liver in the different susceptibility of ruminants to plant toxins and other xenobiotics. More attention should be paid to detoxification activity in hepatic tissues of ruminants and on their previous feeding conditions. In addition, the nature of the ruminant species should be taken into account when comparing interspecific differences. Grazing ruminants, e.g., cattle, have evolved on food plants (e.g., grasses) that are, in general, poorly chemically defended (Cheeke, 1998), depending more on growth habit and physical defenses. In contrast, browsers, e.g., sheep, goat, and deer, have evolved on food plants that are generally well equipped with chemical defenses. Thus, different detoxification mechanisms may have evolved in both groups, and their rumen floras have been subject to different evolutionary pressures.

Acknowledgments—We thank the Rumen Laboratory at the Veterinary University of Hannover (TiHo) and Institute for Animal Production in the Tropics and Subtropics (University of Hohenheim) especially Dr. H.P.S. Makkar and Prof. Dr. K. Becker for their support and the possibility to carry out some of the experiments in their laboratories. R.A. thanks DAAD for a doctoral fellowship.

(Received July 27, 2004; accepted December 9, 2004)

Abstract—The effect of heartwood extracts from *Acacia mangium* (heartrot-susceptible) and *A. auriculiformis* (heartrot-resistant) was examined on the growth of wood rotting fungi with *in vitro* assays. *A. auriculiformis* heartwood extracts had higher antifungal activity than *A. mangium*. The compounds 3,4′,7,8-tetrahydroxyflavanone and teracacidin (the most abundant flavonoids in both species) showed antifungal activity. *A. auriculiformis* contained higher levels of these flavonoids (3.5- and 43-fold higher, respectively) than *A. mangium*. This suggests that higher levels of these compounds may contribute to heartrot resistance. Furthermore, both flavonoids had strong 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity and laccase inhibition. This suggests that the antifungal mechanism of these compounds may involve inhibition of fungal growth by quenching of free radicals produced by the extracellular fungal enzyme laccase.

Key Words—*Acacia mangium*, *A. auriculiformis*, heartrot, heartwood extracts, flavanone, *Phellinus noxius*, *P. badius*, antifungal activity, antioxidant, laccase inhibition.

INTRODUCTION

Polyphenolic compounds are common in higher plants (Haslam, 1988) and have properties that afford plant tissues protection from the external environment including antimicrobial (Scalbert, 1991; Field and Lettinga, 1992; Mila et al., 1996), antifeedant (Butler, 1992), and antioxidant properties (Hagerman et al., 1998; Eyles et al., 2004). In woody tree species, polyphenolic compounds accumulate in bark, leaves, and heartwood, while lesser amounts are found in sapwood (Hillis, 1987). Extracts from bark and heartwood of many woody tree species have strong biological activities, such as enzyme inhibition (Mitsunaga et al., 1997; Shimizu et al., 1998; Juntheikki and Julkunen-Titto, 2000), antioxidant activity (Chang et al., 2001; Willför et al., 2003), and antifungal activity (Kishino et al., 1995). Durability of wood (resistance to fungal decay) is often attributed to extractive content (Hart and Hillis, 1974; Scalbert, 1992; Harju et al., 2002).

Acacia mangium is a fast-growing hardwood planted widely in many areas of Asia and is susceptible to heartrot (Lee et al., 1988; Mahmud et al., 1993; Ito and Nanis, 1994; Barry et al., 2004). Heartrot is caused by fungal infections of heartwood via dead or broken branches (Mahmud et al., 1993; Ito and Nanis, 1994). *A. auriculiformis*, a closely related species, and hybrids of *A. auriculiformis* × *A. mangium* are rarely affected by heartrot (Ito and Nanis, 1997). One explanation for the difference in susceptibility is an increased incidence of infections associated with the higher proportion of infection courts provided by large-diameter branches that occur more frequently in *A. mangium* than in *A. auriculiformis* (Ito and Nanis, 1997). Heartwood extractives may also influence susceptibility to fungal infection and require further investigation in these *Acacia* spp. (Barry et al., in press).

Extracts from *A. mangium* heartwood have been investigated (Tachi et al., 1989; Lange and Hashim, 2001; Barry et al., in press). 3,4′,7,8-Tetrahydroxyflavanone (**1**) (Figure 1) and 4′,7,8-trihydroxyfavanone (**2**) are the main flavonoid compounds in healthy *A. mangium* heartwood, but their levels are markedly reduced in decayed heartwood (Barry et al., in press). This decrease is

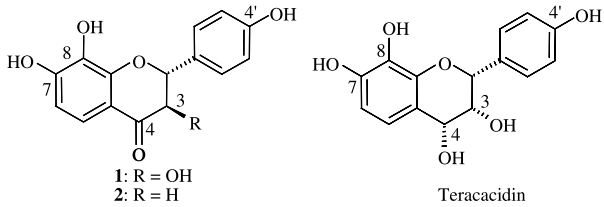

FIG. 1. Structures of compounds **1**, **2**, and teracacidin.

probably caused by enzymatic degradation of phenolic compounds associated with heartrot fungi (Barry et al., in press). While the identities of fungi causing *A. mangium* heartrot are not well known, *Phellinus noxius* has been isolated from early stages of decay in *A. mangium* (Lee and Zakaria, 1993; Lee and Yahya, 1999). *P. badius* has been isolated from the heartrot of *Acacia* spp. (Quraishi and Ahmad, 1973; Stalpers, 1978)

In this study, we compare the antifungal properties of heartwood extracts from *A. mangium* and *A. auriculiformis* against *P. noxius* and *P. badius* using *in vitro* bioassays. Possible antifungal mechanisms (extracts acting as antioxidants or laccase inhibitors) are investigated.

METHODS AND MATERIALS

Wood Materials. Six-year-old trees of *A. mangium* and *A. auriculiformis* were harvested from an experimental plantation in northern Queensland, Australia, in April 2003. Two trees from each species were analyzed. For bioassays, extracts from one tree of each species were used. Each tree was felled and then a billet was cut from a height of 3 m above ground level. The billets were dried at 40°C for 2 wk. The heartwood of each tree was separated from the bark and sapwood, and milled using a Wiley Mill (Thomas Wiley Mill Model 4; Arthur H. Thomas Company, USA). After drying at 40°C for 1 wk, the ground heartwood samples (600 g) were extracted (two times) for 2 d each with 5 l of methanol. Extracts were maintained in the dark at room temperature on a shaker. The methanolic extracts were filtered through Whatman No. 5 filter paper (UK). Solvents were evaporated to dryness on a rotary evaporator at 40°C. The total extracts of *A. mangium* and *A. auriculiformis* wood were abbreviated as M-T (yield = 2.9 and 4.0% based on air dried wood, w/w) and A-T (9.3 and 8.0%), respectively.

Successive Extraction. Extractions were carried out as previously reported (Barry et al., in press). Methanol extracts (13 g) of *A. mangium* and *A. auriculiformis* were dissolved in 10 ml of methanol and extracted with 1 l of diethyl ether, ethyl acetate, and *n*-butanol, successively. Each extraction was conducted at room temperature for 2 hr. Residues were collected by centrifugation (1400 × *g*, 10 min) and supernatants were evaporated at 40°C. Three fractions and the residue were obtained and coded as M-A (yield = 0.94% based on air dried wood, w/w), M-B (0.43%), M-C (0.37%), and M-D (0.35%) for *A. mangium*, and A-A (4.54%), A-B (1.04%), A-C (0.82%), and A-D (0.03%) for *A. auriculiformis*.

Isolation of Flavonoids. 3,4′,7,8-Tetrahydroxyflavanone (**1**), 4′,7,8-Trihydroxyflavanone (**2**), and teracacidin were isolated as previously described (Barry et al., in press). M-A (2 g) was dissolved in *n*-hexane/acetone (1:1, v/v),

applied to silica gel 60 for column chromatography (Merck, Australia), and eluted with *n*-hexane/acetone (7:3 then 1:1) and methanol. The *n*-hexane/acetone (1:1) fraction was further purified by preparative thin layer chromatography (TLC) to isolate compounds **1** and **2**. Preparative TLC was completed using silica gel 60 plates (Merck, Germany) with methanol/dichloromethane (8:92, v/v).

Teracacidin was isolated from the *A. auriculiformis* methanol extract because it occurred in much higher amounts than in *A. mangium*. Fraction A-A (3 g) was dissolved in 300 ml of ethyl acetate and extracted with water (3 × 200 ml) in a separatory funnel. The water-soluble fraction was purified by preparative HPLC using a reverse phase column (Develosil ODS-10, 20 mm i.d. × 250 mm; Nomura Chemical Co. Ltd., Japan) monitored at 280 nm. The solvent system used was as follows: a linear gradient elution for 40 min from 15% to 60% solvent B (methanol) in solvent A (0.01% TFA in H_2O) at a flow rate of 10 ml/min. The elution time of teracacidin was 18 min.

Antifungal Bioassays. The liquid medium bioassay was adapted from Hart and Hillis (1974). *P. noxius* (Melbourne C2558) and *P. badius* (Melbourne C3437) were subcultured on malt agar plates (1% malt, 1.5% agar) for 2 wk at 20°C and 36°C, respectively. A 2-ml aliquot of 13% aqueous ethanol solution containing a fixed amount of *A. mangium* and *A. auriculiformis* methanol extracts was added to 48 ml of 1% malt liquid media to obtain final concentrations of 0.1, 1.0, and 10.0 mg/ml extract. The malt liquid medium was inoculated with a 5-mm-diam plug of fungal culture and incubated at 20°C for 2 wk with shaking. After incubation, the cultures were filtered (Whatman filter paper No. 2, UK), the mycelia washed with methanol, dried at 50°C for 2 d, and the fungal weights measured. Three replicates were prepared for each treatment, and the results were averaged.

The agar dilution bioassay was adapted from Yoshimoto et al. (1984). A 1-ml aliquot of 20% aqueous ethanol solution containing a fixed amount of methanol extract and each fraction of *A. mangium* and *A. auriculiformis* was added to 9 ml of malt agar solution to obtain a final concentration of 0.1%, 0.3%, and 0.5% (w/v) extract. These malt agar solutions (2 ml) were transferred in sterile test tubes to make agar pieces 10 cm in length. The agar was inoculated by placing a 5-mm-diam plug of fungal culture on the edge of the agar (Figure 2) and incubated at 28°C. Mycelia growth was measured sequentially over a period of 30 d. Three replicates were undertaken for each treatment, and the results were averaged. The same method was used for bioassay of the pure compounds that were tested at a concentration of 8 and 15 mM.

Quantitative HPLC Analysis. Quantification of compounds **1**, **2**, and teracacidin was achieved by HPLC (CLASS M10A; Shimadzu Co. Ltd., Japan) analysis of methanol extracts of *A. mangium* and *A. auriculiformis* using a Develosil ODS HG-5 reversed phase column (4.6 mm i.d. × 250 mm; Nomura

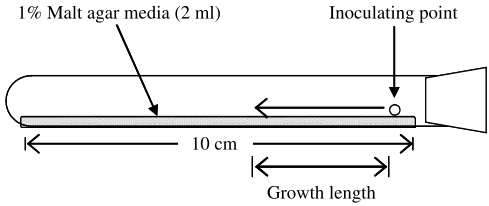

FIG. 2. Agar dilution bioassay method.

Chemical Co. Ltd., Japan) and monitoring at 280 nm. The solvent system used was as follows: a linear gradient for 45 min from 5% to 90% solvent B (methanol) in solvent A (0.01% TFA in H_2O) at a flow rate of 1 ml/min. The amount of each compound was calculated with a calibration curve of each pure compound based on the relationship of the HPLC chromatogram peak area and concentration of the compounds.

Evaluation of 1,1-Diphenyl-2-Picrylhydrazyl (DPPH) Radical Scavenging Activity. The DPPH radical scavenging activity was measured as previously reported (Mihara et al., 2004). A test sample (ethanol solution, 2 ml) was added to 0.5 mM DPPH in ethanol (1 ml) mixed with a 50 mM 2-monopholinoethanesulfonic acid buffer (pH 7.4, 2 ml), and the mixture was shaken vigorously. After 15 min incubation at 25°C, the relative decrease in absorbance of the test sample mixtures at 517 nm was measured on a Jasco V-520 UV/Vis spectrophotometer (JASCO Co. Ltd., Japan). The DPPH radical scavenging activity was expressed as the relative activity compared to the 0.5 mM butylhydroxytoluen (BHT). Quercetin and gallic acid were tested as positive controls of natural antioxidants (Amić et al., 2003; Eyles et al., 2004). The experiment was performed in duplicate, and the following formula was used to calculate results:

$$\text{DPPH radical scavenging activity}\,(\%) = \{(\text{ethanol alone}) - (\text{test sample})\}/\{(\text{ethanol alone}) - (\text{BHT})\} \times 100$$

Laccase Inhibitory Activity. This assay was conducted by using syringaldazine as a substrate (Leonowicz and Grzywnowicz, 1981). Laccase (EC 1.10.3.2) was purchased from Sigma-Aldrich Japan Co. Ltd. Each extract was dissolved in 10% aqueous dimethyl sulfoxide (DMSO) to give 0.3 mg/ml of sample solution. A 0.05-ml aliquot of sample solution was mixed with 0.9 ml of 0.1 M phosphate buffer (pH 6.5) and 0.067 ml of 0.5 mM syringaldazine ethanol solution. A 0.1-ml aliquot of laccase solution (288 U/ml) was added to the above mixture. After incubation at 30°C for 30 min, the absorbance at 525 nm was measured. For the control, 10% aqueous DMSO was used instead of the

sample solution. The experiment was performed in duplicate, and the following formula was used to calculate activity:

$$\text{Laccase inhibition (\%)} = \{(\text{control}) - (\text{test sample})\}/\text{control} \times 100$$

Enzymatic Reaction Kinetics. A 0.1-ml aliquot of syringaldazine ethanol solution (0.13–0.5 mM) was mixed with 0.74 ml of 0.1 M phosphate buffer (pH 6.5) and 0.06 ml of 0.1 mM teracacidin or 10% aqueous DMSO. A 0.1-ml aliquot of commercial laccase solution (288 U/ml) was added to the above mixture and incubated at 30°C. Absorbance at 525 nm was measured over 20 min. Reaction rates were calculated from the difference between absorbance at 15 and 20 min (absorbance increased linearly between 10 and 25 min).

Statistical Analysis. All statistical analyses were completed with SAS for Windows Version 8 (SAS Institute, 1999). For the liquid bioassay, a three-way ANOVA was conducted on log-transformed data with fixed factors of extract type (*A. mangium* or *A. auriculiformis*), extract concentration, and fungus type (*P. badius* or *P. noxius*). For the agar dilution bioassay testing different fractions, a two-way ANOVA was conducted on log-transformed data for fixed factors extract type and concentration. The ANOVA was conducted on the data from the final measurement at 30 d.

RESULTS

Comparison of Antifungal Activity. A. auriculiformis methanol extracts had strong antifungal effects on the growth of *P. noxius* and *P. badius*. *A. mangium* extracts showed no effect on *P. noxius* growth and little inhibition of *P. badius* compared to *A. auriculiformis* (Figure 3). ANOVA of the whole bioassay showed high significance ($P < 0.001$), and all main factors were significant, including fungal species and extract type ($P < 0.001$) and extract concentration ($P < 0.001$). Second-order interactions were significant between extract type × concentration ($P < 0.001$) and fungal species × extract concentration ($P = 0.039$).

The largest difference between the two *Acacia* spp. extracts was at the highest concentration (10 mg/ml) on the growth of *P. badius* (Figure 3). *A. auriculiformis* extract inhibited fungal growth, while *A. mangium* extract did not. The inhibitory effect of *A. auriculiformis* extracts on growth of both *P. noxius* and *P. badius* increased in a concentration-dependent manner.

An antifungal bioassay of fractions obtained by successive extraction was conducted with an agar dilution method using *P. badius* only because *P. noxius* growth appeared to be inhibited by ethanol (Figure 3). Fraction A-D was not tested due to low yield (56 mg). Only the results from the highest concentration

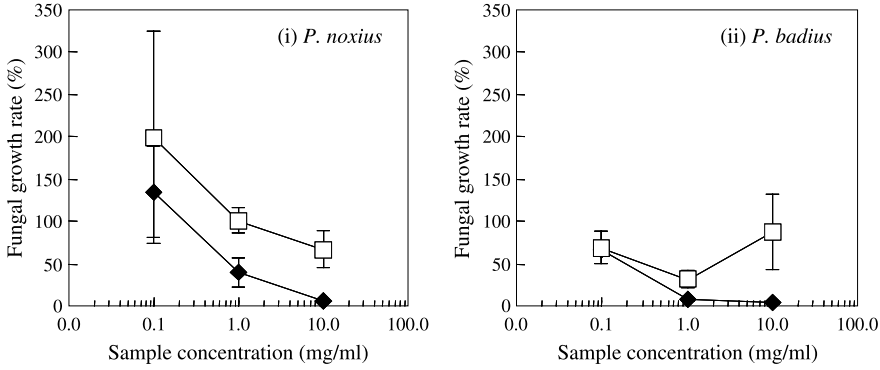

FIG. 3. Antifungal activities of methanol extracts from *A. auriculiformis* (filled diamond) and *A. mangium* (open square) heartwood against (i) *P. noxius* and (ii) *P. badius*. Error bars indicate ±SEM of three replicates. Fungal growth rates represented as percentage of fungal growth of water control. Fungal growth of ethanol control for *P. noxius* and *P. badius* was 59.3% (±9.5) and 94.7% (±18.8), respectively.

(0.5%) are presented (Figure 4). The test was statistically significant based on the two-factor fixed ANOVA ($P < 0.001$), and extract type ($P < 0.001$) contributed to this more than concentration ($P < 0.001$). However, the interaction between the factors was significant ($P = 0.007$). *A. auriculiformis* methanol extract (A-T) and fractions A-A, A-B inhibited growth of *P. badius*. Only the diethyl ether fraction of *A. mangium* (M-A) was inhibitory to *P. badius* (Figure 4). Other fractions of *A. mangium* and A-C accelerated fungal growth. HPLC analyses confirmed the presence of compounds **1**, **2**, and teracacidin in fractions A-A, A-B, and M-A, while A-C, M-B, M-C, and M-D showed amalgamation of broad peaks.

The same assay was conducted using compound **1** and teracacidin at two different concentrations. Compound **2** was not tested due to low yield. Both compound **1** and teracacidin were inhibitory against *P. badius* at a concentration of 15 mM, but not at 8 mM (Figure 5). Compound **1** showed slightly stronger activity than teracacidin at similar concentrations. *A. auriculiformis* heartwood contained 3.5-fold of compound **1**, 1.5-fold of compound **2**, and 43-fold of teracacidin per unit weight of dry wood compared to *A. mangium* (Table 1).

Antioxidant and Laccase Inhibitory Activity. The DPPH radical scavenging activities of *A. mangium* and *A. auriculiformis* extracts were determined (Table 2). DPPH radical scavenging activity was defined as the effective concentration of extract fraction needed to decrease the initial DPPH radical by 50% (EC_{50}). The EC_{50} value of A-T was ca. 3-fold higher than that of M-T. Fractions A-A, A-B, and M-A also had strong antioxidant activity. Furthermore,

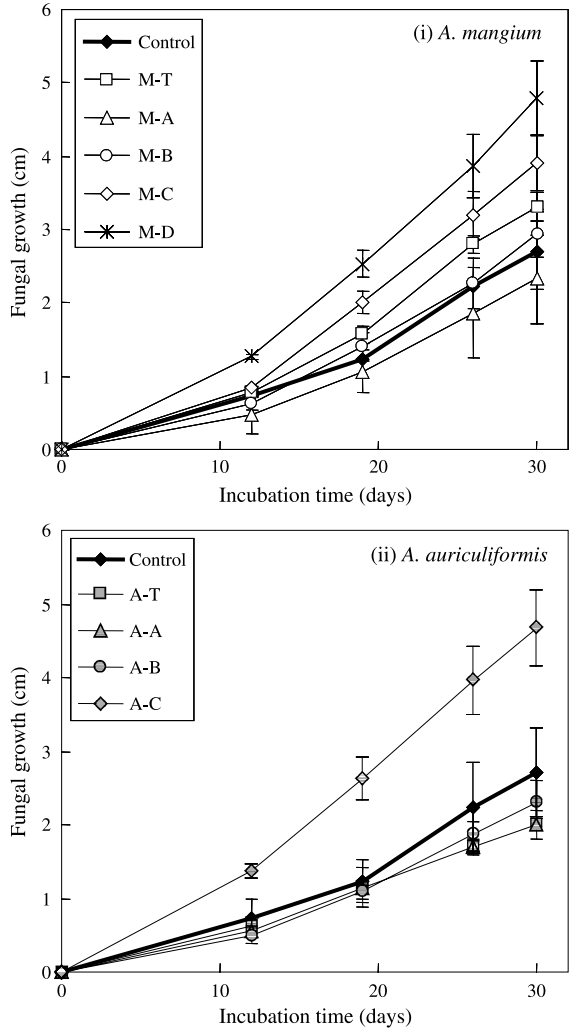

FIG. 4. Antifungal activities of successive extracts from (i) *A. mangium* and (ii) *A. auriculiformis* heartwood methanol extracts against *P. badius*. The concentration of extracts was 0.5% per agar medium. Error bars indicate ±SEM of three replicates. M-T and A-T correspond to methanol extracts of *A. mangium* and *A. auriculiformis* heartwood, respectively. M-A-C and A-A-C correspond to fractions obtained from *A. mangium* and *A. auriculiformis*, respectively, by successive extractions with diethyl ether, ethyl acetate, and *n*-butanol. M-D and A-D correspond to the extract residues.

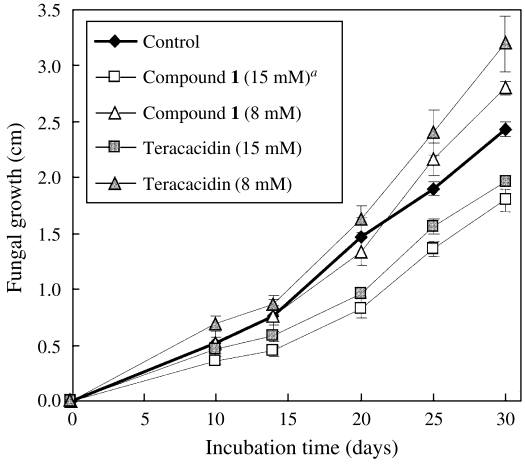

a. Final concentration of compounds in the agar medium.

FIG. 5. Antifungal activities of compound **1** and teracacidin against *P. badius*. Error bars indicate ±SEM of three replicates.

compounds **1**, **2**, and teracacidin (the main compounds of A-A) had strong antioxidant activity.

Compounds **1**, **2**, and teracacidin all had strongly inhibitory laccase activity (Table 2). The rank order of laccase inhibition by these compounds was the same as the DPPH radical scavenging activity (compound **2** > compound **1** > teracacidin). Fractions that were strongly antioxidant (M-A, M-B, A-T, A-A, and A-B) all inhibited laccase activity. Lineweaver–Burk plots of teracacidin activity toward syringaldazine as a substrate is shown in Figure 6. The results suggest that, for teracacidin, the type of laccase inhibition is uncompetitive.

Relationships between antifungal, antioxidant, and laccase inhibitory activity of each extract and fraction were explored using plots and calculating

FIG. 7. Relationship between (i) antifungal and antioxidant activities, (ii) antifungal activity and laccase inhibition, and (iii) laccase inhibition and antioxidant activity of *Acacia* spp. extracts.

correlation coefficients between each factor (Figure 7). Significant correlations (R^2 = 0.75–0.85) were obtained between all three factors.

DISCUSSION

A. auriculiformis heartwood extracts have stronger antifungal properties than *A. mangium* against *P. noxius* and *P. badius*. *A. mangium* heartwood extracts generally did not inhibit the mycelial growth of *P. noxius* and *P. badius* (Figure 3). Previous studies have shown that methanolic extracts of *A. mangium* contained ca. half the amount of total phenols compared to *A. auriculiformis* (Barry et al., in press). This may explain why *A. auriculiformis* extract (A-T) was inhibitory to fungal growth while *A. mangium* (M-T) was not, and also implies that the heartrot susceptibility of *A. mangium* may be related to lower quantities of active compounds in the extracts.

In the antifungal assays of each fraction obtained by successive extraction, the diethyl ether fractions (M-A and A-A) of both *Acacia* spp. showed antifungal activity (Figure 4). Compounds **1**, **2**, and teracacidin were present in highest concentrations in M-A and A-A. Compound **1** and teracacidin inhibited the growth of *P. badius* at 15 mM, but at 8 mM mycelial growth was accelerated compared to the controls (Figure 5). This indicates that a twofold increase in the concentration of these compounds can result in significant biological consequences for fungal growth. Quantitative analysis by HPLC revealed that *A. auriculiformis* contained 0.53% (w/w) of compound **1** and 7.3% of teracacidin in dry wood (Table 1). This is a substantially higher concentration compared to the *in vitro* biologically effective concentration of 15 mM (ca. 0.5% per agar medium, w/w). *A. mangium* contained only 0.15% (w/w) of compound **1** and 0.17% of teracacidin in dry wood (Table 1) and as the concentration of 8 mM (ca. 0.3% per agar medium, w/w) did not show *in vitro* antifungal effects, it can be postulated that *A. mangium* heartwood does not contain a sufficient concentration of antifungal compounds to inhibit *P. badius*. These results suggest that the higher amount of antifungal compounds in *A. auriculiformis* contribute to its heartrot resistance.

The *n*-butanol fractions (M-C and A-C) and M-D stimulated *P. badius* growth (Figure 4). The acid butanol reaction and high BSA adsorption ability of these fractions, as reported previously (Barry et al., in press), suggests that they consist of proanthocyanidins. In cultures containing proanthocyanidins, growth of several wood-rotting basidiomycete fungi also was accelerated (Mitsunaga et al., 1999). Therefore, the acceleration of *P. badius* growth could be induced by proanthocyanidins of *A. mangium*. Decolorization of samples was observed in agar medium containing M-D or A-C. It is possible that the proanthocyanidins in these fractions were decomposed by enzymes produced by *P. badius*

and then the products utilized as a nutrient source. Hashida et al. (2001) have shown that another white rot fungus, *Lentinus tigrinus*, decomposed proanthocyanidin from the bark of *A. mearnsii*. Our previous study reported that *A. mangium* had twofold higher proanthocyanidins per heartwood extracts compared to *A. auriculiformis* (Barry et al., in press). This may be another possible reason why heartwood extracts of *A. mangium* showed lower inhibitory effects against *Phellinus* spp. than that of *A. auriculiformis* (Figures 3 and 4).

The fractions (M-A, A-T, A-A, and A-B) that showed antifungal activity against *P. badius* also had strong antioxidant activity (Table 2). Because compounds **1**, **2**, and teracacidin showed high DPPH radical scavenging ability, it is suggested that the antioxidant properties of A-A and A-T can be attributed to these compounds. A-T contained 1.4-fold more of compound **1** and 17-fold more of teracacidin compared to M-T (Table 1).

The radical scavenging ability of several flavonoids could be due to the hydroxylation pattern of the B ring (Amić et al., 2003). The pyrogallol and catechol pattern of the B ring may impart radical scavenging activity. However, compounds **1**, **2**, and teracacidin have a hydroxyl group at the C-4′ position of the B ring (Figure 1). These compounds have a pyrogallolic hydroxylation pattern in the A ring that may be responsible for their antioxidant properties. Teracacidin showed lower antioxidant activity than compound **1** or **2**, which may be due to the absence of a 4-carbonyl group (Figure 1). This group could also play a role in the antioxidant behavior of flavonoids (Amić et al., 2003).

P. noxius and *P. badius* produce laccase (R. Mihara, unpublished data), which is typical of white rot fungi. Phenol oxidases such as laccase and polyphenol oxidase (PPO) oxidize phenolics by radical reactions (Guillén et al., 2000). The kinetics study of laccase with teracacidin as an inhibitor suggests that teracacidin might not act directly on the active site of laccase, but instead inhibit the radical reaction after laccase forms a complex with syringaldazine (Figure 6). Laccase activity is directly proportional to mycelial growth of a white rot fungus, *Agaricus bisporus* (Wood, 1979). Therefore, the antifungal fractions of *A. auriculiformis* and *A. mangium* may inhibit fungal growth as a result of quenching the radicals produced by the extracellular enzymes of *P. noxius* and *P. badius*. This hypothesis is further supported since the antifungal fractions that inhibited laccase activity also showed high DPPH radical scavenging activity (Table 2; Figure 7). The tannin fractions (M-C, A-C, and A-D) of *Acacia* spp., however, did not inhibit laccase activity. The structures of proanthocyanidins in these *Acacia* spp. extracts are unknown (Barry et al., in press) and further investigation is required.

While many previous studies have reported the antifungal and antimicrobial activities of polyphenols, the precise mechanisms involved with such activities are not clear. Enzyme inhibition by the astringent character of tannin and inhibition of the electron transport system on mitochondria have been

investigated (Scalbert, 1991). In this study, proanthocyanidin fractions (A-C, M-C, and M-D) did not show antifungal and laccase inhibitory activities. This suggests that the antifungal properties of *Acacia* spp. extracts were not due to the astringent character of proanthocyanidins (tannins). However, antifungal activity, DPPH radical scavenging activity, and laccase inhibition were all correlated with each other (Figure 7).

Mechanisms of wood degradation by wood-rotting fungi have been described. Backa et al. (1993) hypothesized that hydroxyl radicals were produced from the fungal degradation of wood. These hydroxyl radicals were produced by an extracellular, low molecular weight substance and as the rate of wood degradation increased so did the amounts of hydroxyl radicals (Tanaka et al., 1999). Therefore, the antifungal property of *A. auriculiformis* heartwood may be attributed to the scavenging of hydroxyl radicals as well as to laccase inhibition.

We focused attention on heartwood extracts of *A. mangium* and *A. auriculiformis* and found significant differences between the antifungal properties of both species that relates to the incidence of heartrot observed in these species during field studies. We tested extracts from two individual trees of both species; however, more trees should be sampled. It would be of interest to further investigate the antifungal property of hybrids of *A. mangium* and *A. auriculiformis*, of which some have been shown to be resistant to heartrot (Ito, 2002).

Acknowledgments—This research was partly funded by an ACIAR grant, project number FST/00/123. R. Mihara acknowledges the Japanese Academic Frontiers Student Exchange Promotion Program which funded a research visit to the University of Tasmania.

Abstract—The potential protection of *Picea glehnii* seedlings from damping-off by seed-epiphytic *Penicillium* species was investigated. We studied the chemical response of seed-epiphytic *Penicillium* species (*Pen. cyaneum*, *Pen. damascenum*, and *Pen. implicatum*) to *Pythium vexans*, a damping-off fungus, *in vitro*. *Penicillium* species were cultured singly or cocultured with *Pyt. vexans* for 14 or 18 d, and mycelial growth, pH of culture filtrate, antifungal activity of the culture filtrate against *Pyt. vexans*, and the amount of antifungal compound produced by each *Penicillium* species, were examined. The filtrate of both the single culture of *Penicillium* and the coculture of *Penicillium* and *Pyt. vexans* showed antifungal activity against *Pyt. vexans*. In a coculture with *Pyt. vexans*, *Pen. cyaneum* produced an antifungal compound (patulin) as in the single culture. *Pen. damascenum* cocultured with *Pyt. vexans* produced an antifungal compound (citrinin), as it did in the single culture and in larger amounts on day 10. *Pen. implicatum* produced two antifungal compounds, frequentin and palitantin, and the ratio of frequentin (with higher antifungal activity than palitantin) to palitantin was higher in the coculture with *Pyt. vexans* than in the single culture. Our results indicate that these *Penicillium* species have the ability to produce antifungal compounds and to keep antifungal activity under competitive condition with *Pyt. vexans*. The chemical

response of these *Penicillium* species to *Pyt. vexans* may contribute to protect *P. glehnii* seedlings from damage by *Pyt. vexans*.

Key Words—Seed-epiphytic fungi, *Penicillium damascenum*, *Penicillium implicatum*, *Penicillium cyaneum*, *Pythium vexans*, citrinin, frequentin, palitantin, patulin, *Picea glehnii*.

INTRODUCTION

Picea glehnii (Fr. Schm.) Masters is one of the dominant conifers in northern Japan (Hokkaido) (Tatewaki, 1958; Matsuda, 1989), where several pathogenic fungi can damage young seedlings in natural forest-regeneration areas (Takahashi, 1980; Endo et al., 1985). We have studied seed-epiphytic microorganisms that can protect *P. glehnii* seedlings from damping-off caused by *Pythium vexans*. We previously screened seed-epiphytic microorganisms that produce antifungal compounds against *Pyt. vexans*, and isolated three *Penicillium* species that produce particular antifungal compounds (Yamaji et al., 1999). *Pen. cyaneum* produces patulin, *Pen. damascenum* produces citrinin, and *Pen. implicatum* produces palitantin and frequentin. The damage to *P. glehnii* seedlings *in vitro* caused by *Pyt. vexans* is inhibited by coinoculation with seed-epiphytic *Pen. damascenum*. *Pen. damascenum* inhibits damping-off of the seedlings by (1) occupying the space around the seedling roots and (2) producing an antifungal compound citrinin (Yamaji et al., 2001). *Pen. cyaneum* and *Pen. implicatum* did not significantly protect seedlings from damage by *Pyt. vexans* because they did not grow vigorously in the coinoculation test (Yamaji et al., 2001).

How does *Penicillium* sp. interact with *Pyt. vexans* under competitive conditions when grown together? The antagonistic phenomena were classified into two categories: primary interaction, occurring mainly by direct contact between the two organisms, and secondary interaction, occurring mainly by changes in the environment between them (Dickinson and Lucas, 1982). In this study, we examined the chemical response of seed-epiphytic *Penicillium* species to *Pyt. vexans* under *in vitro* conditions competitive for their mycelial growth. We set up two culture conditions, the single culture of *Penicillium* species and the coculture (*Penicillium* species and *Pyt. vexans*). We examined (1) mycelial weight, (2) pH of culture filtrate, (3) antifungal activity of culture filtrate against *Pyt. vexans*, and (4) amount of antifungal compound produced by each *Penicillium* fungus.

METHODS AND MATERIALS

Fungi and Medium. P. glehnii seed-epiphytic *Pen. cyaneum* (Bainier et Sartory) Biourge (strain no. PGS-T5), *Pen. damascenum* Baghdadi (strain no.

PGS-O7), and *Pen. implicatum* Biourge (strain no. PGS-S16), which produced antifungal compounds against *Pyt. vexans* de Bary (Yamaji et al., 1999), and a damping-off fungus *Pyt. vexans*, which was isolated from the roots of *P. glehnii* seedlings in a nursery at Hokkaido University (Kasuya, 1995), were used. Potato dextrose (PD) broth (Wako, Tokyo, Japan) and potato-dextrose agar (PDA) containing 2% agar (Wako, w/v) were used for fungal cultivation.

Inoculation of Penicillium Fungus and Pyt. vexans. In the single culture of *Penicillium*, a spore suspension (10^5 spores/500 μl sterile water) was inoculated into a PD medium (30 ml) in an Erlenmeyer flask (50 ml). In the coculture, a mycelial disk (8 mm, i.d.) of *Pyt. vexans* grown on PDA for 2–3 d was inoculated into the medium simultaneously with a spore suspension of *Penicillium*. A single culture of *Pyt. vexans* was also prepared. The cultures were incubated in the dark at 25°C under stationary conditions for 2, 4, 6, 8, 10, 12, or 14 d for *Pen. cyaneum* and *Pen. damascenum*, and 2, 4, 6, 8, 10, 12, 14, 16, or 18 d for *Pen. implicatum.* Three replications were prepared for each incubation period and treatment.

Measurements

Mycelial Dry Weight. Fungal mycelia was recovered from broth culture by vacuum filtration on filter paper (Advantec, Tokyo, Japan) and was rinsed with deionized water three times. The culture filtrate was used to measure antifungal activity and to quantify the antifungal compounds. The filter paper with mycelia was dried in an oven at 110°C for 3 hr. Mycelial dry weight was calculated as the difference between the dry weights of filter paper with and without mycelia. In the coculture, it was impossible to separate the two fungi, therefore the total dry weight of the mycelia of the two fungi was measured. The values in the three cultures per incubation time were averaged.

pH. pH of three culture filtrates per incubation time was measured with an ISFET pH meter (Beckman Coulter, Inc., Fullerton, CA, USA), and the values were averaged.

Antifungal Activity. A mycelial disk (8 mm i.d.) of *Pyt. vexans* grown on PDA for 2–3 d was placed at the center of a PDA plate (90 mm i.d.). The culture filtrate (125 or 250 μl) was refiltered with a 0.22-μm syringe filter (Advantec), and aseptically dispensed into a sterile cylinder (6 mm i.d. × 10 mm, stainless steel) placed 1.5 cm from the margin of the *Pyt. vexans* disk. After a 36-hr incubation in the dark at 25°C, inhibitory zones (mm) were measured from the margin of the cylinder to the mycelia. Each test was conducted three times per culture filtrate, so the values of nine cylinders per incubation time were averaged.

Quantification of Compounds

Chromatographic Equipment. For analyses of patulin and citrinin, high-performance liquid chromatography (HPLC) equipped with a Hitachi L-6000 Intelligent pump (Hitachi, Tokyo, Japan) and a Hitachi L-4200 UV–VIS detector (Hitachi) set at 254 nm was used. For analyses of palitantin and frequentin, HPLC equipped with a Hitachi L-6320 Intelligent pump (Hitachi) and a Hitachi L-4250 UV–VIS detector (Hitachi) set at 254 nm was used.

Chemicals. All chemicals used as internal standards (3, 5-di-*tert*-buthylphenol, 4-*n*-butoxybenzoic acid, and orcinol) were of analytical grade (Kanto Co. Ltd., Tokyo, Japan). Chloroform, acetonitrile, and 2-propanol for elution were of HPLC grade (Wako). Patulin, citrinin, palitantin, and frequentin were isolated as previously reported (Yamaji et al., 1999, 2001) and used to make standard curves.

Chromatographic Conditions, Extraction, and Purification of Patulin. HPLC was performed using a LiChrosorb DIOL column (250 × 6 mm i.d.; Merck, Darmstadt, Germany), with chloroform as the eluent at a flow rate of 0.5 ml/min at ambient temperature. The culture filtrate was adjusted to pH 2 with 2 M HCl, then extracted with ethyl acetate (10 ml) three times. The combined organic layer was dried over Na_2SO_4, followed by vacuum concentration to dryness. The residue was then dissolved in 2 ml of chloroform and subjected to a Diol September-pak cartridge (Sep-pak Plus, short body type; Waters, Milford, MA, USA) preequilibrated with the same solvent. Patulin was eluted with 4 ml of chloroform, and the eluate was dried *in vacuo* and redissolved in 2 ml of chloroform including 3,5-di-*tert*-buthylphenol (1 mg/ml) as an internal standard. An aliquot (5 μl) of the solution thus prepared was analyzed. Each analysis was conducted per culture filtrate, and three values per incubation time were averaged. When concentrations of patulin were high, the sample solution was diluted before analysis.

Citrinin. HPLC was performed by using an Inertsil PREP-ODS column (250 × 5 mm i.d., G. L. Sciences Inc., Tokyo, Japan) with 0.25 M phosphoric acid–acetonitrile–2-propanol (55:35:10) as the eluent (Phillips et al., 1980) at a flow rate of 1.0 ml/min, at ambient temperature. The culture filtrate was extracted with ethyl acetate as described above. The residue was dissolved in 2 ml of water–acetonitrile–2-propanol (55:35:10) and subjected to a C18 September-pak cartridge (Sep-pak Plus, short body type; Waters) preequilibrated with the same solvent. Citrinin was eluted with 8 ml of water–acetonitrile–2-propanol (55:35:10), then the eluate was dried *in vacuo* and redissolved in 2 ml of acetonitrile including 4-*n*-butoxybenzoic acid (100 μg ml^{-1}) as an internal standard. An aliquot (5 μl) of the solution thus prepared was analyzed. Three replicates of every culture filtrate were analyzed and averaged. When the concentration of citrinin was high, the sample solution was diluted prior to analysis.

Palitantin and Frequentin. HPLC was performed by using a YMC-Pack Polymer C_{18} column (250 × 6.0 mm i.d., YMC, Tokyo, Japan) with Na_2HPO_4/NaOH (pH10)–CH_3CN (4:1) as the eluent at a flow rate of 1.0 ml/min at ambient temperature. Na_2HPO_4/NaOH (pH10) buffer was prepared according to Perrin and Dempsey (1974). The culture filtrate was extracted with ethyl acetate as described above. The residue was dissolved in 2 ml of acetonitrile–water (1:4) and applied to a C18 September-pak cartridge (Sep-pak plus, short body type; Waters) preequilibrated with the same solvent. The cartridge was rinsed with 3 ml of acetonitrile–water (1:4), and palitantin and frequentin were eluted with 8 ml of acetonitrile–water (1:1). The eluate was dried *in vacuo* and redissolved in 2 ml of acetonitrile, including orcinol (340 μg/ml) as an internal standard. An aliquot (5 μl) of the solution thus prepared was analyzed. Three replicates of each culture filtrate were analyzed and averaged. The solution of frequentin or palitantin was diluted as necessary before analysis.

Standard Curve. Patulin (31.3, 62.5, 125, 250, 500, and 1000 μg/ml acetone) or citrinin (125, 250, 500, 1000, and 2000 μg/ml acetone), or palitantin and frequentin (125 and 125, 250 and 250, 500 and 500, 1000 and 1000, 2000 and 2000 μg/ml acetone) was added to each PD medium (29 ml). Three replicate flasks were prepared for each concentration of compound. The medium was extracted with ethyl acetate, purified, and dissolved in the solvent including the standard compound by the methods described above. Analysis of three replicate samples was conducted and results were averaged. The standard curve was obtained via the internal standard method.

Statistical Analysis. Two-factor factorial ANOVA (Statview 5.1.0-Mac) with days and treatments as independent factors was used to examine differences in dry weight, pH, antifungal activity, and amount of antifungal compound between the single culture and the coculture. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Single Culture of Pen. cyaneum and Coculture with Pyt. vexans
