Treatment of male Asian corn borer with sublethal doses of malathion also affected physiological responses. EAG responses of malathion-treated male moths to several ratios of pheromone blends (*E*12-14:OAc/*Z*12-14:OAc) were lower than those of the control insects (Figure 2). The average EAG value of malathion-treated males was 0.40 mV, compared to control males with 0.53 mV. The EAG responses of malathion-treated males at all pheromone dosages tested (ranging from 0.1 to 100,000 ng) were lower than those of acetone-treated controls (Figure 3). The saturation dose of perception for males in both the treated and control groups was 10,000 ng.

In wind tunnel tests, control males treated with acetone only showed typical behavioral responses to different pheromone blend ratios (Klun et al., 1980; Cheng et al., 1981; Huang et al., 1998). The ratio of *E*12-14:OAc and *Z*12-14:OAc from the Asian corn borer of Chinese population was about 5:5 (Yang and Du, 2003). Control males showed highest SC percentages at ratios of 4:6, 5:5, and 6:4. At the other ratios, the SC percentages were significantly lower (Figure 4). However, males treated with malathion showed different behavioral response patterns. At most ratios, the SC percentages were not different except at the ratio of 9:1, and SC percentages were low throughout (Figure 4). Furthermore, the dose response of acetone-treated control males peaked at the 10^2 and 10^3 ng levels, and further increment of the dosage caused lower response percentages. In contrast, the dose responses of malathion-treated

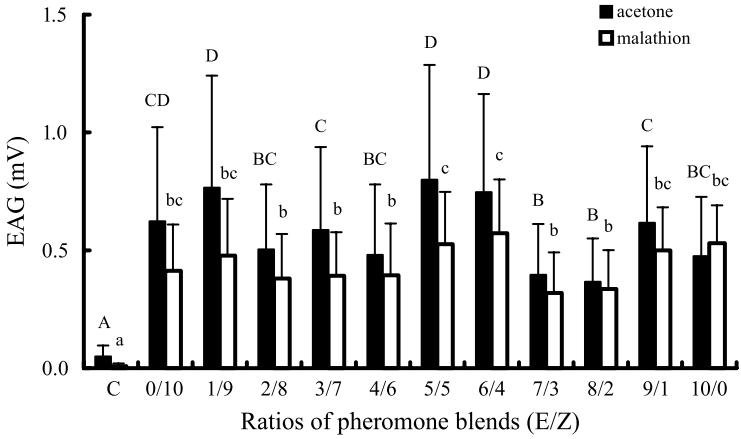

FIG. 2. Electroantennogram responses of male Asian corn borers to binary blends of *E*12-14:OAc and *Z*12-14:OAc (1 μg) after treatment with acetone or malathion (treated with 1 μl of malathion solution at the concentration of 90 ng/μl for each moth). Bars labeled by different letters differ significantly (Duncan's multiple range test, $P < 0.05$). Error bars represent 95% confidence intervals.

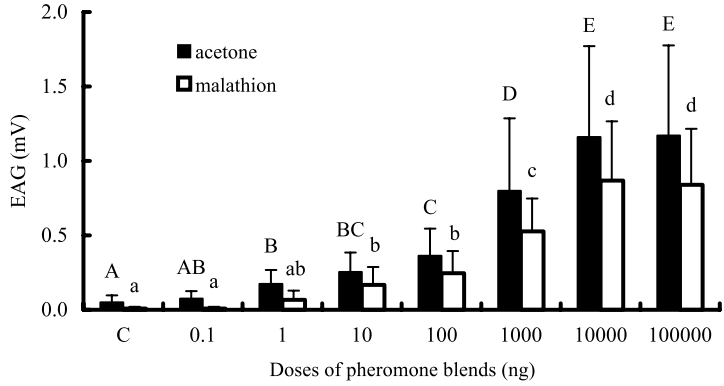

FIG. 3. Electroantennogram responses of male Asian corn borers after treatment with acetone or malathion (treated with 1 μl of malathion solution at the concentration of 90 ng/μl for each moth) to dosages of 1:1 blends of *E*12-14:OAc and *Z*12-14:OAc. Bars labeled by different letters differ significantly (Duncan's multiple range test, $P < 0.05$). Error bars represent 95% confidence intervals.

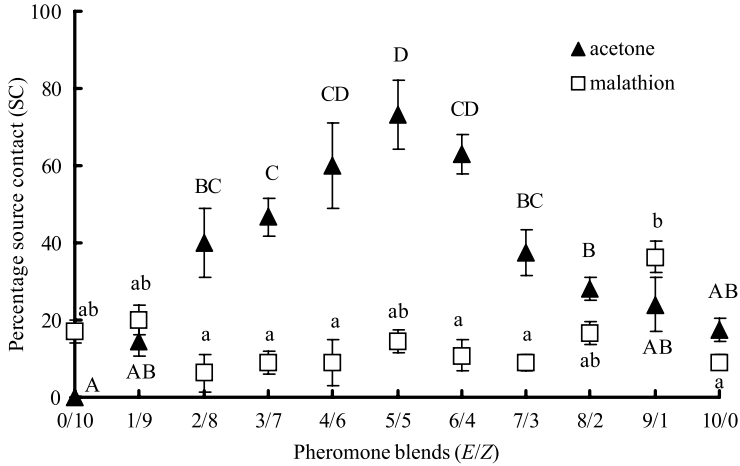

FIG. 4. Source contacts of male Asian corn borers responding to binary blends of pheromone after treatment with acetone or malathion (treated with 1 μl of malathion solution at the concentration of 90 ng/μl for each moth). $N = 60$ moths per experiment. The data series of the same pheromone ratio with the same letter are not significantly different at $P < 0.05$ (*t*-test). Error bars represent 95% confidence intervals.

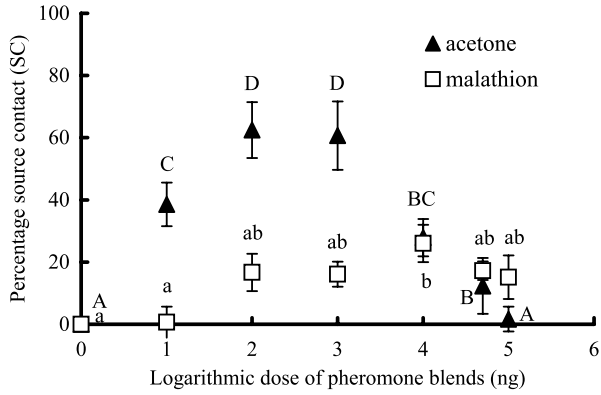

FIG. 5. Source contacts by male Asian corn borers responding to dosages of pheromone (*E*/*Z* = 1:1) after treatment with malathion (treated with 1 μl of malathion solution at the concentration of 90 ng/μl for each moth). The number of insects treated in each experiment was 60. The data series of the same logarithmic dose with the same letter are not significantly different at the level of 5% (*t*-test). Error bars represent 95% confidence intervals.

males were lower than those of acetone-treated males to 10^1, 10^2, and 10^3 ng doses, but not to 10^4 and above (Figure 5). These data suggested that malathion strongly affected behavioral responses of males to normal and abnormal pheromone blends and doses.

DISCUSSION

The present study revealed numerous sublethal effects of malathion treatment on the behavioral responses of male Asian corn borers, *O. furnacalis* (Guenée), to their sex pheromones. Sublethal treatment with malathion not only made males less likely to take flight, but also reduced the number contacting the pheromone source. In addition, the ratios of pheromone components that elicited the largest responses shifted from approximately 5:5 to 1:9 (*E*/*Z*) and 9:1. We conclude that treatment with sublethal doses of malathion significantly affected the reproductive behaviors of male Asian corn borers.

Sublethal effects of insecticides include both behavioral and physiological responses. Sublethal effects may influence the function of sense organs and thus alter pest behaviors by reducing or changing sensory information reaching the brain. For instance, sublethal insecticide treatment significantly affected sex pheromone communication in the parasitoid, *Trichogramma brassicae* (deltamethrin and chlorpyrifos, Delpuech et al., 1999, 2001), cabbage looper

(*Trichoplusia ni,* cypermethrin, Clark and Haynes, 1992), and diamondback moth (*Plutella xylostella,* fenvalerate, Tabashnik and Rethwisch, 1992).

Malathion is one of the organophosphate (OP) insecticides. OPs work by inhibiting enzymes in the nervous system, specifically acetylcholinesterases (AChE). The enzyme is phosphorylated when it becomes attached to the phosphorous moiety of the insecticide, a binding that is irreversible. AChE is involved with the transmission of nerve impulses. When this enzyme is inhibited, the transmission system "jams," resulting in restlessness, hyperexcitability, convulsions, paralysis, and death (Ware, 2000). The reduction of physiological and behavioral responses of the Asian corn borer males treated with sublethal doses of malathion may be connected with disruption of normal nerve cell transmission. As indicated by Haynes (1988), adult behavior is the final outcome of a sequence of neurophysiological events involving sensory neurons, interneurons, motor neurons, and finally muscular contractions. Disruption of any or all of these events will result in incorrect or inappropriate behavior. Because the sensitivity of male moths responding to given doses of pheromone blends and the preference for particular ratios of pheromone components are controlled by the central nervous system (CNS) (Linn and Roelofs, 1986), malathion may reduce neurophysiological responses by acting on the CNS at particular synapses between neurons (Zhang, 1987). The blocking or disruption of neural signals by insecticides will thus affect courtship behavior.

Haynes and Baker (1985) demonstrated that sublethal doses of permethrin effectively blocked key stages in the behavioral responses of pink bollworm male moths, but these effects disappeared 4 d after treatment. In our study, we did not find such a recovery after 5 d (Table 2). Pyrethroid insecticides like permethrin rapidly knock down the insect at sublethal doses, but treated insects may recover from the effects after a certain period. The difference between our data and other studies may be due to the different chemicals and/or insect species used in the experiments.

Efficient mate location in sexually reproducing organisms requires a signaling system in which both signal sender and receiver are tuned to the same signal. Female moths typically release a specific blend of sex pheromone components in a ratio to which the male's receptors are tuned. Our results show that Asian corn borer male moths treated with malathion responded optimally to unnatural ratios of pheromone blends, and that they showed a reduction in sensitivity to normal sex pheromones. Asian corn borer female moths also release a significantly lower amount of sex pheromone when treated with sublethal doses of malathion (unpublished data). These sublethal effects of insecticides may result in a lower percentage of males successfully locating females, and lower reproductive success. A better understanding of the interaction between behavioral responses to sex pheromones and sublethal

exposure to insecticides may help us to understand whether physiological and behavioral changes caused by exposure to sublethal doses of insecticides may contribute to the overall effectiveness of insecticides.

(Received February 12, 2003; revised February 16, 2005; accepted February 25, 2005)

Abstract—Phytotoxicity-directed extraction and fractionation of the aerial parts of *Mikania micrantha* H.B.K. led to the isolation and identification of three sesquiterpenoids: dihydromikanolide, deoxymikanolide, and 2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide. These sesquiterpenoids inhibited both germination and seedling growth of tested species with deoxymikanolide possessing the strongest phytotoxicity. In a bioassay against lettuce (*Lectuca sativa* L.), deoxymikanolide reduced radicle elongation at low concentration (IC_{50} = 47 μg/ml); dihydromikanolide showed a weaker effect (IC_{50} = 96 μg/ml), and 2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide exhibited the least effect (IC_{50} = 242 μg/ml). Deoxymikanolide caused yellowish lesions at the root tips of lettuce at a concentration of 50 μg/ml, and a 250 μg/ml solution killed lettuce seedlings. A bioassay against the monocot ryegrass (*Lolium multiforum*) revealed similar results on radicle elongation, which implied that the growth inhibition by these compounds was not selective. To evaluate their phytotoxicity to plants in natural habitats, three common companion tree species in south China, *Acacia mangium*, *Eucalyptus robusta*, and *Pinus massoniana*, were also tested and similar results were obtained. This is the first report on the isolation of 2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide as a naturally occurring product.

Key Words—Phytotoxicity, allelochemical, *Mikania micrantha*, exotic species, dihydromikanolide, deoxymikanolide, 2,3-epoxy-1-hydroxy-4, 9-germacradiene-12,8: 15,6-diolide.

INTRODUCTION

Mikania micrantha H.B.K. is a herbaceous vine that propagates by means of wind-dispersed achenes and stem fragments that root easily at the nodes. It grows and spreads so quickly that it is also called "mile-a-minute weed." This weed smothers trees and crops, suppressing the vigor and eventually killing the affected plants. Although native to tropical South and Central America, *M. micrantha* has become a serious problem in southeast Asia and the Pacific region, particularly in disturbed forests and plantation crops such as tea, teak, rubber, and oil palm. The weed changes the pattern of growth of affected plants, and it has been listed as one of the world's worst weeds (Parker, 1972; Holm et al., 1977). Records show that *M. micrantha* first invaded Hong Kong as an exotic species in 1919 (Kong et al., 2000), and specimens kept at the Herbarium of the South China Institute of Botany indicated that *M. micrantha* was transferred to China no later than 1984. In the past few years, *M. micrantha* has expanded widely in South China. On Neilingding Island, a natural reserve area, *M. micrantha* covers 40–60% of the surface of the island and nearly 33% of the native trees have been seriously affected. Furthermore, the weed creeps up banana trees on the island, thereby destroying a food source of native monkeys (He et al., 2000; Kong et al., 2000; Lan and Wang, 2001).

M. micrantha not only perturbs the growth and development of trees, crops, and ornamental plantings but also reduces the density of wild herbaceous species. Besides competition for nutrients with other plants, *M. micrantha* is believed to have allelopathic effects on neighboring plants (Ismail and Mah, 1993; Cock et al., 2000). Our field surveys suggested that phytotoxins might contribute to the growth suppression of plants in its vicinity. Previous studies demonstrated that leachate and aqueous extracts of *M. micrantha* inhibited germination and growth of some plants, and its debris, either incorporated or remaining on the surface of the soil, also inhibited the growth and germination of neighboring plants (Ismail and Chong, 2002). Ismail and Mah (1993) and Ismail and Chong (2002) identified four phenolic acids from leaf extracts of this weed, but no allelopathic sesquiterpenoids have been reported. In this study, we isolated and characterized three potential allelopathic sesquiterpenoids from *M. micrantha* extracts by activity-directed extraction and fractionation procedures.

METHODS AND MATERIALS

Instrumentation. IR spectra were measured on a Perkin-Elmer 783 spectrometer with KBr disks. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker

DRX-400 instrument with TMS as an internal standard and DMSO-d_6 as solvent. UV spectra were taken on a Perkin Elmer Lambda 25 UV/VIS spectrometer. EIMS were measured on a Micromass Platform EI-200 GC/MS instrument at 70 eV by direct insertion probe.

Preparation of Aqueous Extracts. Aerial parts of *M. micrantha* H.B.K. were collected from the Fairy Lake Botanical Garden of Shenzhen, China in December, 2000. Plant tissues were air dried at room temperature and ground into powder. Five g of the aerial parts were blended in 100 ml distilled water for 24 hr at room temperature, and aqueous extracts (0.05 g/ml) were obtained. pH values of the extracts and the solvent for control (distilled water) were adjusted to 6.0 with 2 M NaOH and HNO_3 (Quayyum et al., 1999).

Preparation of Organic Extracts. Five g of dried aerial parts of the plant were extracted three times with petroleum ether, ethyl acetate, and ethanol sequentially at intervals of 24 hr. Extracts were concentrated under reduced pressure and diluted to 0.05 g/ml.

Phytotoxicity Assays of Extracts. Growth inhibitory effects of the aqueous and organic extracts from the branches and leaves were evaluated through bioassays against three plants: radish (*Raphanus sativus*), ryegrass (*Lolium multiforum*), and white clover (*Trifolium repens* L.). Experimental seeds were surface sterilized with 0.5% $HgCl_2$ and 10 seeds were placed in each sterile Petri dish (9 cm diam) lined with Whatman No. 3 filter paper. Five ml of test extract were added to each Petri dish. For assays of the organic extracts, the method described by Anaya et al. (1999) was used with minor changes. Five ml of distilled water were added after the solvent had completely evaporated, and 5 ml of distilled water (pH 6.5) were added to each control Petri dish. Petri dishes were sealed with parafilm to prevent water loss and stored in the dark at 22 ± 2°. Treatments were allotted in a complete randomized design with three replicates for each treatment. After 5 d of incubation, length of radicles (primary roots) and plumules (primary shoots) were measured as described by Anaya et al. (1999) and Quayyum et al. (1999).

Phytotoxicity Assays of Purified Compounds. Bioassays against lettuce (*Lactuca sativa* L.), a commonly used species for phytotoxicity bioassays, and a monocotyledonous species, ryegrass, were conducted as previously described by Viles and Reese (1995). In these assays, five concentrations of sesquiterpenoids (25, 50, 100, 250, and 500 μg/ml) were used. Because deoxymikanolide showed the strongest inhibitory activity, bioassays against a monocotyledonous (radish) and a dicotyledonous plant (chives) were also performed. In order to confirm the effects, three ecologically relevant tree species, *Acacia mangium*, *Eucalyptus robusta*, and *Pinus massoniana,* which tend to be affected in actual habitats, were included in the assays (Romeo, 2000), and Harness (common name: Acetochlor, Monsanto Co., St. Louis, MO, USA), a commonly used herbicide, was used as a positive control in these assays.

Isolation of Phytotoxins. Dried and ground branches and leaves of *M. micrantha* (4.0 kg) were exhaustively extracted with 95% ethanol at room temperature. After filtration, the filtrate was concentrated under reduced pressure to yield a dark brown residue (300 g, 7.5% yield). The residue was suspended in water, and the suspension was sequentially extracted with petroleum ether, ethyl acetate, and *n*-butanol to yield petroleum ether extract (30 g, 0.75% yield), ethyl acetate extract (4.5 g, 0.11% yield), and *n*-butanol extract (10 g, 0.25% yield), respectively. Results from the bioassay with lettuce indicated that the ethyl acetate extract exhibited the strongest inhibitory effect. Thus 4.5 g of the ethyl acetate extract were fractionated on silica gel eluted with a step gradient elution ($CHCl_3$, $CHCl_3$–MeOH at 98:2, 96:4, 9:1, 8:2, 7:3, 6:4, 1:1, MeOH). Sixteen major fractions (M_1–M_{16}) were collected based on TLC profiles. Fraction M_8, which exhibited the most potent inhibitory effect, was further purified on silica gel eluted with benzene–$CHCl_3$ (1:1, 1:2, 1:3) to afford compounds A (35 mg, 0.00087% yield), B (41 mg, 0.001% yield), and C (22 mg, 0.00055% yield).

Scanning Electron Microscopy (SEM) Study of Root Morphology and Anatomy of Lettuce Seedlings. Specimens were prepared following the procedure outlined by Hedge and Miller (1992), and viewed with a JEOL JSM-T300 scanning electron microscope (data not shown).

Statistical Analyses. The significance of effects of aqueous and organic extracts from *M. micrantha* on seedling growth of tested species was first examined by ANOVA ($P < 0.05$) and then analyzed using Fisher's LSD test at $P < 0.05$ level. For the effects of the sesquiterpenoids on tested species, paired *t* tests at $P < 0.01$ level were conducted to determine the significant differences between treatments and controls.

RESULTS

Phytotoxicity Assays of Aqueous and Organic Extracts. Table 1 shows the effects of the aqueous and organic extracts on the growth of the tested plants. The aqueous extract of the aerial parts of *M. micrantha* showed a significant effect, inhibiting total seedling growth (radicle plus shoot growth) of radish, ryegrass, and white clover by 52%, 70%, and 72%, respectively. The petroleum ether and ethanol extracts caused no significant inhibition of tested plants. The ethyl acetate extract had the most significant effect, inhibiting more than 90% of seedling growth of all tested species. Therefore, the ethyl acetate extract was selected for further investigation.

Identification of Phytotoxins. Compounds A and B: Two compounds from the exotic extract were identified as dihydromikanolide (compound A) and

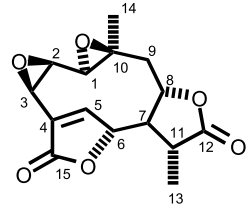
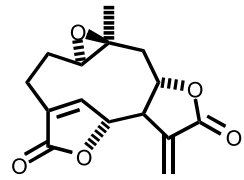
deoxymikanolide (compound B) by comparison of their spectral data with the values reported by Herz et al. (1970) and Cuenca et al. (1988).

Compound C: Colorless prisms, mp 281–282° (acetone); $[\alpha]_D^{24}$ + 59.1° (ca. 0.132, acetone); UV (MeOH) λ_{max} nm (log ε): 215 (3.59); EIMS *m/z* (%): 293 $[M + H]^+$ (1), 275 (0.5), 263 (5), 95 (100). Its IR and ^1H NMR data were in agreement with those previously reported by Herz et al. (1970) and indicated that compound C was 2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide. The previously unreported ^{13}C NMR data are presented as follows: δ 68.3 (d, C-1), 60.5 (d, C-2), 52.1 (d, C-3), 129.1 (s, C-4), 144.9 (d, C-5), 78.6 (d, C-6), 48.7 (d, C-7), 74.6 (d, C-8), 120.6 (d, C-9), 142.1 (s, C-10), 37.4 (d, C-11), 176.7 (s, C-12), 12.1 (q, C-13), 17.8 (q, C-14), 170.7 (s, C-15) ppm. This compound, previously obtained by Herz et al. (1970) from the acid-catalyzed rearrangement of dihydromikanolide, was isolated as a naturally occurring compound in the present study.

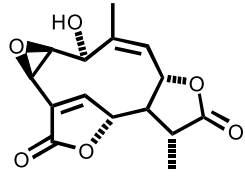
Bioassay of Purified Phytotoxins. The sesquiterpenoids isolated from the ethyl acetate extract (Figure 1) were tested for their growth inhibitory effects, and all of them exhibited biological activity. Their phytotoxicity varied with concentration as well as individual structures of the compounds. Figure 2 shows their inhibitory effects on seed germination of lettuce. Germination rates of all tested species were inversely proportional to concentration. Within the concentration range of 10–200 μg/ml, seeds germinated



A) Dihydromikanolide



B) Deoxymikanolide



C) 2,3-Epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide

FIG. 1. Chemical structures of dihydromikanolide, deoxymikanolide, and 2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide isolated from *Mikania micrantha*.

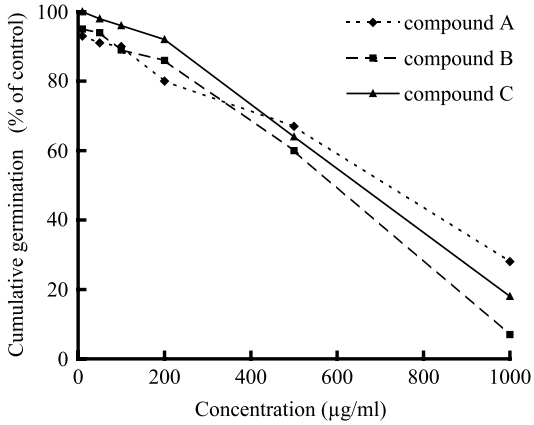


FIG. 2. Impact of three sesquiterpenoids on seed germination of lettuce. A = Dihydromikanolide, B = Deoxymikanolide, C = 2,3-Epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide.

normally. However, all sesquiterpenoids induced a significant inhibition of germination at a concentration of 500 μg/ml. At 1000 μg/ml, seed germination rates were 28% (dihydromikanolide), 7% (deoxymikanolide), and 18% (2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide) of those of controls.

A seed germination test with ryegrass also revealed that all sesquiterpenoids started to show significant inhibitory effects at 500 μg/ml. The 1000 μg/ml solution resulted in germination rates of 10% (dihydromikanolide), 4% (deoxymikanolide), and 29% (2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide), compared to controls.

Figure 3 shows the effects of six different concentrations of the sesquiterpenoids on radicle elongation of lettuce seedlings. Deoxymikanolide had the strongest effect, and linear regression analysis indicated an IC_{50} value of 47 μg/ml. It reduced radicle elongation to 8% of the control at a concentration of 500 μg/ml. At the 50 μg/ml concentration, deoxymikanolide started to cause yellowish lesions at the root tip. A 250 μg/ml solution caused the formation of brown lesions throughout the entire radicle surface and deformation of both hypocotyls and radicles. At a concentration of 500 μg/ml, radicles turned brown, resulting in gradual dehydration and arrested growth of the roots. To exclude any possible effects caused by low pH values of the culture solutions, pH values were measured but no significant differences were detected between treatments and controls. Dihydromikanolide had less effect on radicles (IC_{50} = 96 μg/ml), and 2,3-epoxy-1-hydroxy-4, 9-germacradiene-12,8:15,6-

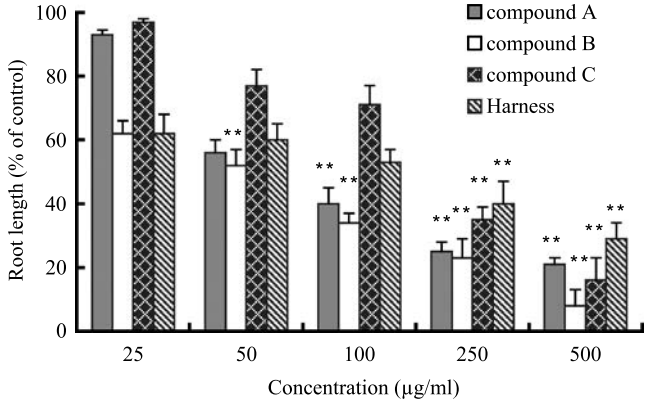

FIG. 3. Impact of three sesquiterpenoids on radicle growth of lettuce. **Significant difference between treatment and control as determined by the paired t test at $P < 0.01$ level. Compounds A, B, C as in Figure 2. D = Harness (commercial herbicide).

diolide showed the least effect (IC_{50} = 242 μg/ml). All sesquiterpenoids caused yellowish to brown lesions on radicles at high concentrations of 500 μg/ml.

Figure 4 shows the shoot lengths of lettuce seedlings treated with the three sesquiterpenoids. All three compounds had less effect on shoot growth compared to that on radicle growth.

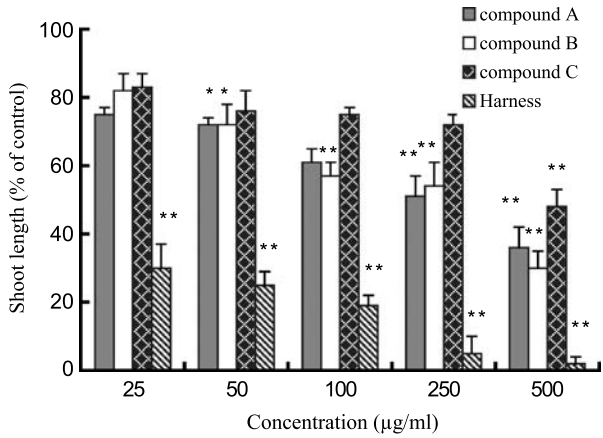

FIG. 4. Impact of three sesquiterpenoids on shoot growth of lettuce. **Significant difference between treatment and control as determined by the paired t test at $P < 0.01$ level. Compounds A, B, C as in Figure 2.

Bioassay against ryegrass showed similar results. For root growth, IC_{50} values for treatments were 230 μg/ml (dihydromikanolide), 67 μg/ml (deoxymikanolide), and 290 μg/ml (2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide). Compounds did not significantly reduce the shoot length of ryegrass until the concentration increased to as high as 500 μg/ml.

Because deoxymikanolide had the strongest inhibitory activity, it was selected for further investigations. Bioassays against radish, a dicotyledonous plant, and chives, a monocot, showed similar results to those of lettuce and ryegrass (figures not shown), further confirming the inhibitory activity. The IC_{50} values on root length were 74 μg/ml for radish and 88 μg/ml for chives.

These sesquiterpenoids were also toxic to three selected ecologically relevant tree species. Figure 5 shows the effects of these compounds on the root growth of *Acacia mangium*. They also affected the seedling growth of *Eucalyptus robusta* and *Pinus massoniana* (data not shown). The IC_{50} values on root length of *Acacia mangium* were 159 μg/ml (dihydromikanolide), 95 μg/ml (deoxymikanolide), and 201 μg/ml (2,3-epoxy-1-hydroxy-4, 9-germacradiene-12,8:15,6-diolide). For *Eucalyptus robusta*, the IC_{50} values were 149, 59, and 155 μg/ml, whereas for *Pinus massoniana*, the values were 120, 66, and 128 μg/ml.

Results of Scanning Electron Microscopy. Scanning electron microscopy (SEM) studies were conducted in plants treated with deoxymikanolide, the most toxic of the three compounds. Pregerminated lettuce seeds were treated with 50 and 100 μg/ml of deoxymikanolide solutions at 25°C for 26 hr. A 50 μg/ml deoxymikanolide solution reduced root hair length and density of lettuce seed-

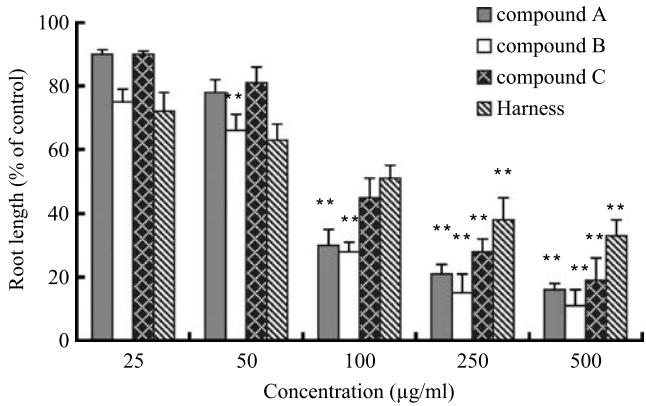

FIG. 5. Impact of three sesquiterpenoids on radicle growth of *Acacia mangium*. **Significant difference between treatment and control as determined by the paired *t* test at $P < 0.01$ level. Compounds A, B, C as in Figure 2.

lings significantly. There was no visible root hair development on radicles of seedlings treated with 100 μg/ml deoxymikanolide solution. After 5 d of continuous incubation, however, several root hairs with abnormalities developed. The root tip swelled into a small ball-like structure, which indicated its physiological response to the effects of the compound. SEM of the internal root anatomy was also characterized, but no significant difference was revealed (data not shown).

DISCUSSION

The widespread distribution of *M. micrantha* has received much attention worldwide. Despite its fast-growing characteristics, the growth of *M. micrantha* in its native habitat is restrained, probably due to control by its natural enemies, such as phytophagous insects and fungi. In a new ecosystem with a lack of natural enemies, this weed can spread quickly (Cock, 1982; Barreto and Evans, 1995). It has been speculated that allelopathy plays an important role on *M. micrantha*'s dominance beyond its competition for light and nutrition (Ismail and Mah, 1993; Cock et al., 2000). Several different sesquiterpenoids have been reported as allelochemicals (Macias et al., 1996, 2000; Bagchi et al., 1997), but the phytotoxic effects of these three sesquiterpenoids from *M. micrantha* are reported here for the first time.

Herz et al. (1970) noticed that extracts of many members of the large genus *Mikania* were used as folk medicine and suspected the presence of sesquiterpene lactones on phylogenetic grounds. They isolated and identified six new sesquiterpene dilactones from *Mikania scandens* (L.) Willd including compound A (dihydromikanolide) and compound B (deoxymikanolide). They also obtained compound C (2,3-epoxy-1-hydroxy-4,9-germacradiene-12,8:15,6-diolide) from the acid-catalyzed rearrangement of dihydromikanolide. Cuenca et al. (1988) identified dihydromikanolide and deoxymikanolide from *M. micrantha* during a study of Argentine Compositae. Although all three sesquiterpenoids were phytotoxic, the potency varied with structures. For example, the double bond between C-11 and C-13 may be important for potency, whereas the 2,3-epoxy group possibly decreases its activity.

Our bioassays demonstrated that these compounds are a group of important phytotoxins in this plant and may play a role in allelopathy. These sesquiterpenoids may be leached down to the soil by rainfall or gradually released with the decomposition of leaf litter, affecting the growth of the surrounding plants, and assisting *M. micrantha* to become a dominant species in new ecosystems. However, to demonstrate the possible allelopathic role of these compounds, it is necessary to verify that these sesquiterpinoids can accumulate in the soil in

concentrations sufficient to affect neighboring plants. (Kamo et al., 2003; Inderjit and Weston, 2000).

Abstract—Previous work has shown that hyperaccumulator levels of some metals can defend plants against herbivores, but the possibility of defense by metal concentrations at accumulator or normal levels is unexplored. This study tested the hypothesis that metals can defend plants at low concentrations. We determined the relative toxicities of eight metals commonly acquired by plants: Cd, Co, Cr, Cu, Mn, Ni, Pb, and Zn. Larvae of the diamondback moth (*Plutella xylostella*), a representative crucifer specialist, were fed with artificial diet amended with concentrations of metal varying from 2 to 3,000 μg/g. Different concentration ranges were used for each of the eight metals, and larval survival at 10–14 days was calculated for each concentration. All metals were toxic to diamondback moth larvae at hyperaccumulator levels. All metals, however, were also toxic to larvae at accumulator concentrations, far below those found in hyperaccumulating plants. Five metals (Cd, Mn, Ni, Pb, and Zn) were toxic below accumulator levels, Cd and Pb were toxic near the concentration ranges of normal plants, and Zn was toxic at a concentration within the normal range. Our results indicate that uptake of certain metals may provide a defensive benefit for plants, and that elemental defenses may be effective at concentrations far lower than previously hypothesized. This study implies that elemental defenses are more widespread in plants than previously believed, and that the ecological consequences of even low levels of metal accumulation need to be explored.

Key Words—Accumulator, diamondback moth, elemental defense, hyperaccumulator, metal, metal toxicity, *Plutella xylostella.*

INTRODUCTION

The concentrations of metals in the aboveground tissues of plants can be used to divide them into three somewhat arbitrary categories: normal plants, accumulators, and hyperaccumulators. These categories are defined in a relative fashion for each metal (Reeves and Baker, 2000), with normal plants having relatively low metal concentrations and accumulator and hyperaccumulator plants having increasingly extreme metal concentrations. According to Reeves and Baker (2000), normal plants typically contain low concentrations (generally <5 μg/g on a dry mass basis in aboveground parts) of several metals, including Cd (0.1–3 μg/g), Co (0.03–2 μg/g), Cr (0.2–5 μg/g), and Pb (0.1–5 μg/g). Normal concentrations of Ni and Cu can be somewhat greater: 5–25 μg Cu/g and 1–10 μg Ni/g. Still greater concentrations of Mn or Zn are typical, with normal concentrations of both metals ranging from 20 to 400 μg/g. Accumulator plants typically grow on mineralized soils and contain greater concentrations of metals (Baker, 1981; Macnair, 2003). Minimum accumulator concentrations, signifying unusually elevated metal concentrations, are 20 μg/g for Cd and Co, 50 μg for Cr/g, 100 μg/g for Ni, Cu, or Pb, and 2000 μg/g for Mn and Zn (Reeves and Baker, 2000).

Hyperaccumulators have exceptionally high concentrations of metals in their tissues (Brooks et al., 1977). These plants are almost exclusively found on mineralized or ultramafic soils (Brooks, 1987, 1998; Reeves and Baker, 2000; Boyd et al., 2004) that, in part because of their high metal concentrations, are unfavorable environments for most plants (Sieghardt, 1990; Reeves and Baker, 2000; Prasad and Strzalka, 2002). However, a number of species (about 400) actively take up and concentrate (hyperaccumulate) one or more of these metals (Baker et al., 2000; Reeves and Baker, 2000). Minimum tissue concentrations used to define hyperaccumulators of the above metals are as follows: 100 μg/g for Cd; 1000 μg/g for Co, Cu, Cr, Ni, and Pb; and 10,000 μg/g for Mn and Zn (Brooks, 1987; Pollard and Baker, 1997).

We know of no comprehensive study that has compiled the numbers of species in hyperaccumulator and accumulator categories for each metal. Pollard et al. (2002) showed that Ni levels among *Alyssum* species form a bimodal distribution with relatively few accumulator species, but noted also that the data were incomplete. Most surveys of plant metal concentrations are designed to discover hyperaccumulator species and, therefore, target taxa and geographic areas likely to yield them (e.g., Reeves et al., 1999). Researchers also may not proceed with detailed analyses of species that do not seem promising as hyperaccumulator candidates in initial sample screenings (e.g., Reeves et al., 1999). Thus, it seems likely that the number of accumulator species in the literature is underreported. For example, a recent survey of Cuban ultramafic species by Reeves et al. (1999) examined specimens from 277 species and documented 50 taxa of Ni hyperaccumulators and 25 of Ni accumulators.

The toxicity of hyperaccumulators to herbivores has been addressed by an increasing (but still relatively small) number of experiments. Much of this research has focused on determining the advantages a plant may receive from hyperaccumulation of an element (Boyd, 2004). Martens and Boyd (1994) suggested that hyperaccumulation may serve as an "elemental defense" against herbivory. Experiments with Ni (Boyd and Martens, 1994; Martens and Boyd, 1994; Boyd and Moar, 1999; Davis and Boyd, 2000; Boyd et al., 2002), Se (Hanson et al., 2003, 2004), Cu (Ernst, 1987), and, in some cases, Zn (Pollard and Baker, 1997; Jhee et al., 1999; Behmer et al., 2005) have supported this defense hypothesis. Other experiments have shown that not all herbivores are negatively affected by hyperaccumulator metal concentrations (e.g., Boyd and Martens, 1999), especially for Zn (Huitson and Macnair, 2003; Noret et al., 2005).

The above experiments deal with only a few of the elements hyperaccumulated by plants, targeting Ni, Zn, Cu, or Se hyperaccumulators. While Reeves and Baker (2000) reported that Ni is the most commonly hyperaccumulated metal, with 318 taxa (78% of known hyperaccumulators), a number of plants hyperaccumulate other metals: to date, there are 26 Co hyperaccumulators, 35 Cu hyperaccumulators, 14 Pb hyperaccumulators, and 16 Zn hyperaccumulators (Brooks et al., 1998; Reeves and Baker, 2000). There are also at least 11 species of Mn hyperaccumulators and at least one Cd hyperaccumulator (Brooks et al., 1998; Reeves and Baker, 2000). The protective function of these elements in plants has yet to be explored.

Although herbivore feeding experiments can demonstrate the toxicity of metals at hyperaccumulator concentrations, they do not show the minimum plant tissue metal concentration that can produce a negative or toxic effect (Boyd and Martens, 1998). Our experiment was, therefore, designed to investigate the toxic thresholds of Ni and Zn, as well as six other hyperaccumulated metals (Cd, Co, Cr, Cu, Mn, and Pb). Our goals were twofold: (1) to determine whether these metals are toxic to herbivores at hyperaccumulator levels, thus extending the defense hypothesis to other hyperaccumulated metals; and (2) to determine whether any of these metals could serve as elemental defenses at concentrations within the ranges of accumulator or normal plants, thus extending the defense hypothesis to new categories of plant species.

METHODS AND MATERIALS

Experiment Rationale. Our experiment used a representative herbivore raised on artificial diet amended with a range of metal concentrations. We used larvae of the diamondback moth (DBM), *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), a folivore that attacks plants of the Brassicaceae (Talekar and Shelton, 1993), a family that contains about 25% of all hyperaccumulator taxa

(Reeves and Baker, 2000). Lepidopteran larvae have been shown to be important herbivores of wild-growing species of *Streptanthus* (Brassicaceae) plants and can easily be responsible for the death of a plant. For example, Shapiro (1981a) reported that *Pieris sisymbrii* (Lepidoptera: Pieridae) is a specialist herbivore of several *Streptanthus* species, including *S. glandulosus* and *S. breweri*, both of which are found on ultramafic soils in California. He also noted that some populations of *S. polygaloides* may be attacked by *P. sisymbrii* (Shapiro, 1981b), and that a single *P. sisymbrii* oviposition on a plant of *S. tortuosus* could be effectively lethal if the resulting larva destroys the plant's leaves and fruits (Shapiro, 1981c).

Advantages of using DBM also include its short generation time, small size, ease of culture on artificial diet, and the commercial availability of a standardized artificial diet. Its short generation time (about 25 d from egg to adult for our colony) allowed us to rapidly assess survival at the completion of the larval stage (about 11–12 d). Use of artificial diet provided us with direct control over the concentrations of metal that the insects consumed. Experiments that have varied soil metal concentrations to obtain different plant metal concentrations have reported difficulties obtaining consistency within a treatment (Boyd and Moar, 1999), have had problems generating subhyperaccumulator concentrations of a metal within a plant species (Boyd and Moar, 1999), or have found it difficult to use a single plant species to accumulate the range of metals that we desired to study (e.g., Boyd and Davis, 2001).

Experimental Colony. The DBM colony used was established using eggs obtained from a colony at Cornell University (Harvey, 2002). Founder moths from the Cornell colony were collected from a field in Geneva, NY, USA. After the colony was established in Auburn, it was supplemented with wild individuals collected from Auburn, AL, USA. Artificial diet for the colony was obtained from Bio-Serv® (Frenchtown, NJ, USA). The diet's exact ingredients are proprietary information, but wheat germ and cabbage leaf powder are two of the main ingredients (Carpenter and Bloem, 2002). The diet was used to maintain the colony following a procedure similar to that of Shelton and Collins (2000).

Our colony maintenance protocol was as follows. Sheets of DBM eggs obtained from the established colony were sterilized in 10% bleach solution for 20 sec, rinsed in water for 1 min, and allowed to dry. Dried egg sheets were cut into strips, containing about 300–400 eggs per strip, and each strip was placed in a 250-ml paperboard cup with about 1 cm of congealed artificial diet covering its bottom. The cups were placed in an incubator (37°C, ~30–50% relative humidity) until they hatched and the first instar larvae began to feed (~60 hr). Empty egg sheets were then removed, and larvae were allowed to feed until pupation (~11–12 d after hatching). Pupae were then placed in screen cages where adults could emerge to mate and lay eggs (~4 d from pupation to

emergence). Eggs were collected on scored aluminum foil sheets that had been dipped in sterilized collard juice (an oviposition stimulant) (Shelton and Collins, 2000). Peak oviposition occurred between 2 and 6 d after adult emergence. Eggs collected from this time period had the greatest vitality; eggs collected after this time period produced larvae with 25–50% lower survival (from egg to adult) than average for the colony. Consistent with the Cornell colony, mean survival of larvae from egg to pupa was at least 50% (Shelton and Collins, 2000).

Artificial Diets Containing Metal. Artificial diet was amended with varying concentrations of the eight metals studied by using stock solutions of metal chloride salts (obtained from Sigma-Aldrich, St. Louis, MO, USA). These amended diets were used to determine metal toxicity by feeding different sets of DBM larvae different concentrations of a given metal. Experimental concentrations selected were based on preliminary results, and we attempted to include at least one nontoxic dose of each metal chloride salt. Five to seven concentrations were tested for each of the eight metals. For each concentration, 100 ml of diet were made to produce the concentrations listed in Table 1. Diet was distributed into 30-ml plastic cups to give 14 replicates of each

[a] mM data, as millimoles of metal chloride per liter, calculated from dilutions of stock solutions; μg/g data from elemental analysis of diet samples. Fourteen replicates were used for each concentration of each metal.

[b] Amounts of these elements were present in the original diet mix (Mn, Zn, Cu, and Ca) or result from contamination during sample preparation for ICAP analysis (Pb).

concentration, with each cup receiving about 2–3 ml. A 30-ml diet sample of each metal concentration was reserved for elemental analysis.

Use of chloride salts introduced the potential for chloride toxicity to affect the results. Thus, we created an experiment using diet amended with $CaCl_2$ to serve as a partial control. For this test, a range of $CaCl_2$ concentrations was used that included the highest molar concentration of chloride from all metals tested (Table 1). If the $CaCl_2$ amended diet did not cause significant larval mortality, whereas diets amended with other metals did, then we could conclude that chloride toxicity did not significantly influence our results.

Elemental Analysis. Elemental analysis of dried diet samples was used to determine metal concentrations expressed as parts per million (μg/g) of metal in each batch of diet. Diet was analyzed using inductively coupled argon plasma spectroscopy (ICAP) (Jarrell-Ash ICAP 9000: Genesis Laboratory Systems, Grand Junction, CO, USA) for Cd, Co, Cr, Cu, Mn, and Pb and atomic absorption spectroscopy (AA) (Instrumental Laboratory, IL 215) for Ni and Zn. For both processes, the 30-ml preserved sample of diet were dried at ~60°C for 5 d and ground to a fine powder. The AA samples were wet-ashed with nitric and perchloric acids, dissolved in HCl, diluted with deionized water, and analyzed. The ICAP samples were dry-ashed in a muffle furnace, oxidized with boiling nitric acid, dissolved in HCl, diluted with deionized water, and analyzed.

Metal Toxicity Tests. Each set of concentrations for a given metal was tested for toxicity to DBM larvae using eggs collected from a single cage containing adults that were 2–4 d posteclosion. Eggs were collected at the completion of a 24-hr period and sterilized as described above. After egg sheets dried, they were cut into strips that were divided among the 70–100 cups (of five to seven metal concentrations) that composed a single metal toxicity test. Between 60 and 100 eggs were placed in each cup of diet, yielding 30–50 first instars per cup.

Cups were placed into an incubator with the same temperature and humidity conditions used for the colony. Egg sheets were removed from cups after larvae hatched and had begun to feed (60–72 hr after the initial egg sheet was collected and sterilized). When egg sheets were removed, an initial count was made of first instars present in each cup. The number of larvae alive was then counted at 2- or 3-d intervals. When larvae began to pupate (generally 10–12 d after eggs were collected), the number of pupae plus larvae alive at that time was used to represent survival in each cup, and survival was expressed as the percentage of initial first instar larvae. Counting for all cups within a metal set was terminated when adults started to emerge in the control cups, usually 14–17 d after the eggs were collected.

Statistical Analysis. Survival data for each metal were analyzed to determine each metal's minimum toxic concentration. Survival values were arcsine square root transformed to satisfy the normality assumption (Zar, 1996) underlying one-way analysis of variance (ANOVA), and ANOVA (StatView:

Abacus Concepts, 1998) was used to determine if metal concentration significantly affected survival at $\alpha \leq 0.05$. For each metal, Fisher's protected least significant difference (PLSD) test was used to determine which concentrations significantly decreased survival relative to the control treatment at $\alpha \leq 0.05$ (Abacus Concepts, 1998).

RESULTS

Toxic effects of metal treatments on DBM larvae were due to metals and not to chloride toxicity. The test for chloride toxicity showed that concentrations of

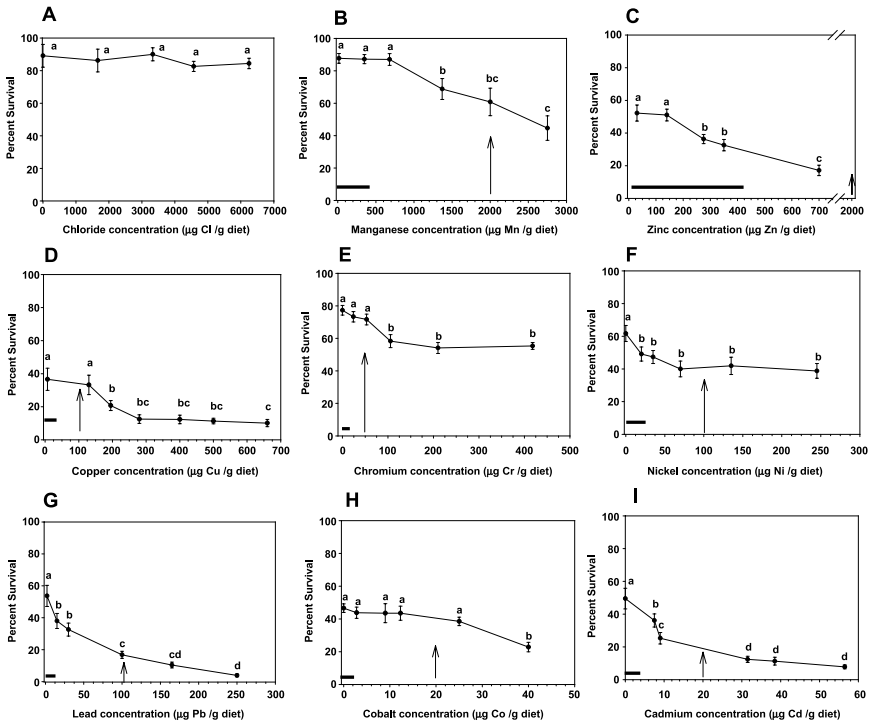

FIG. 1. Mean survival of DBM on $CaCl_2$ (A), $MnCl_2$ (B), $ZnCl_2$ (C), $CuCl_2$ (D), $CrCl_2$ (E), $NiCl_2$ (F), $PbCl_2$ (G), $CoCl_2$ (H), and $CdCl_2$ (I) amended diets. Bars represent the standard error of each mean. Means with the same letter are not significantly different (Fisher's PLSD test at $\alpha \leq 0.05$). A horizontal line denotes the normal concentration range for each metal in plant tissues (dry mass basis), and a vertical arrow shows the minimum concentration for accumulator plant status (Reeves and Baker, 2000).

TABLE 2. ANOVA RESULTS OF LARVAL MORTALITY DATA FROM THE EXPERIMENT FOR EACH METAL

Metal	*F*	*df*	*P* value
Cd	21	5, 78	<0.001
Co	5	6, 90	<0.001
Cr	10	5, 78	<0.001
Cu	7.7	6, 75	<0.001
Mn	4.7	5, 84	<0.001
Ni	3.4	5, 71	0.008
Pb	27	5, 70	<0.001
Zn	14	4, 76	<0.001

$CaCl_2$, which at their greatest exceeded the highest concentration of chloride of any other metal used (Mn: Table 1), produced no significant toxic effects (ANOVA: $F_{8,102} = 0.794$, $P = 0.609$) (Figure 1a). The mean survival for all experimental controls (no metal added to diet) was about 60%, a value above the minimum average survival of insects within the colony. These two control systems (chloride test and no-metal diet) showed that the main variable affecting larval survival was the addition of metals.

All metals affected larval survival at some concentration (Table 2). A concentration of 1,370 μg Mn/g produced the first significant decrease in survival for that metal (Figure 1b). For Zn, survival decreased at 275 μg Zn/g (Figure 1c). The lowest dose of Cu that produced significant toxicity was 195 μg Cu/g (Figure 1d), with that for Cr at 106 μg Cr/g (Figure 1e).

TABLE 3. NORMAL RANGE, MINIMUM ACCUMULATOR LEVEL, MINIMUM HYPERACCUMULATOR LEVEL, AND LEVEL TOXIC TO DBM LARVAE FOR THE METALS USED IN THIS EXPERIMENT[a]

Metal	Normal range	Minimum accumulator level	Minimum hyperaccumulator level	Minimum toxic level to DBM
Cd	0.1–3	20	100	7.5 (0.018 mM)
Co	0.03–2	20	1,000	40 (0.264 mM)
Cr	0.2–5	50	1,000	106 (0.88 mM)
Cu	5–25	100	1,000	195 (1.3 mM)
Mn	20–400	2,000	10,000	1,370 (17.6 mM)
Ni	1–10	100	1,000	20 (0.22 mM)
Pb	0.1–5	100	1,000	15 (0.044 mM)
Zn	20–400	2,000	10,000	275 (0.44 mM)

[a] Normal range, minimum accumulator level, and minimum hyperaccumulator level refer to tissue concentrations in field-collected plants and follow Reeves and Baker (2000). All values are expressed in μg/g (dry mass basis) with toxic levels also expressed parenthetically in mM wet diet so that metal toxicities can be compared.

We did not determine the toxic thresholds for Ni and Pb, as the lowest dose tested for each, 20 μg Ni/g and 15 μg Pb/g, showed significantly toxic effects (Figure 1f and g). For Co, 40 μg/g significantly decreased DBM survival (Figure 1h). The lowest dose of Cd tested, 7.5 μg/g, significantly decreased DBM survival (Figure 1i). Minimum toxic doses for each metal are summarized in Table 3, along with the normal range, minimum accumulator threshold, and minimum hyperaccumulator threshold for these metals.

DISCUSSION

Minimum toxic concentrations (in wet diet) of metals to DBM larvae varied greatly. Most toxic were Cd and Pb (<0.05 mM; Table 3) followed by Ni and Co at <0.3 mM. Zinc and Cr were toxic at <1 mM, with Cu toxic at 1.3 mM and Mn as least toxic at 17.6 mM (Table 3). The ranking of these metals in terms of their toxicity to DBM was not surprising, as essential metals such as Mn and Cu are generally less toxic than nonessential metals such as Cd and Pb (Yasutake and Hirayama, 2002). We note that we did not differentiate between toxic (where metal in diet caused a toxic effect on larvae) and antifeedant (where metal in diet caused larvae to stop feeding and starve) effects of dietary treatments and, thus, cannot address the mechanisms whereby these metals affected DBM larvae. Studies that address these questions (e.g., Behmer et al., 2005) are valuable extensions of the work reported here. However, regardless of the mechanism(s) involved, our experiments still allow us to make conclusions about the effectiveness of these metals as elemental defenses.

We conclude that hyperaccumulator concentrations of all metals tested are toxic to DBM. Table 3 shows that toxic levels were far below hyperaccumulator thresholds, in every case <20% of the minimum value used to define hyperaccumulation. Thus, for the representative crucifer herbivore used in our study (DBM), hyperaccumulation of any of the metals we examined would cause plant tissues to be toxic. Because these results show that metal hyperaccumulation could protect plants via toxic effects on a folivore, they support the defense hypothesis of metal hyperaccumulation. These results also support other studies that have shown toxic effects of hyperaccumulator species of Ni (e.g., Boyd and Martens, 1994; Martens and Boyd, 1994; Boyd and Moar, 1999; Boyd et al., 2002) and Zn (Pollard and Baker, 1997; Jhee et al., 1999; Behmer et al., 2005) to most folivores tested. Furthermore, our results extend the defense hypothesis to hyperaccumulated metals that have not yet been experimentally tested *in planta* (Cd, Co, Cr, Cu, Mn, and Pb) and suggest that, at least for DBM, metal hyperaccumulation would be a potent plant chemical defense. We should note that metal toxicity may depend on other constituents of

the diet, and further experimentation *in planta* is needed to confirm our results. In regard to this, recent research on the defensive effects of Zn hyperaccumulation (Behmer et al., 2005), using both Zn-amended artificial diet and plants containing varying levels of Zn, has shown that defensive effects occurred at similar Zn concentrations in both experimental situations.

All of the metals we studied were also toxic to DBM at concentrations in the accumulator range. Toxic levels extended into the accumulator range for Co, Cr, and Cu and below that range for Cd, Mn, Ni, Pb, and Zn (Table 3). Thus, for these metals, accumulator concentrations in plant tissues could also constitute elemental defenses. Five metals (Cd, Mn, Ni, Pb, and Zn) could have defensive effects at concentrations below accumulator levels. One of these metals (Zn) was toxic at a concentration within the normal range of plant tissues (Table 3). The other four were toxic at concentrations between the upper limit of the normal range and the start of accumulator levels. We, therefore, conclude that, in the case of Cd, Zn, Ni, and Pb, concentrations below the accumulator level may be toxic to some folivores and act as elemental defenses.

While the matrix within which a herbivore ingests a metal may serve to decrease that metal's toxicity, the reverse is also possible. Metals in plants may act in combination with other defense compounds in ways that may contribute to their effectiveness at low concentrations. This would result in the possibility that even lower concentrations of metals than shown by our study may contribute to plant defense. Our experiments determined the toxicity of single metals added to artificial diet. Under natural conditions, a single metal is only one chemical component of a particular plant's tissues. Some plants hyperaccumulate or accumulate more than one metal (Reeves and Baker, 2000). Furthermore, plants usually contain one or more of a wide variety of organic (or secondary) chemicals that also may be toxic to some herbivores. For example, members of the Brassicaceae, a family which contains many Ni hyperaccumulator species (Reeves and Baker, 2000), commonly produce glucosinolates that have defensive effects against some herbivores (Bodnaryk, 1992). Combinations of chemicals may act together, either additively or synergistically (Dyer et al., 2003), to be more toxic to a herbivore than each is alone. If this is the case with elemental defenses, as suggested by Boyd (2004), then concentrations less than those used in our single-metal studies could contribute to defensive effects against herbivores when combined with other plant chemicals. By this reasoning, the minimum toxic concentrations we detected may not be the least quantity of each metal that can have defensive value to a plant. Combination effects may decrease the effective defensive threshold of metals to levels even less than those shown in our study. A recent study by Jhee (2004) has shown just such combination effects for Zn paired with Cd, Ni, and Pb, and for Ni paired with some organic defense chemicals (tannic acid and

alkaloids). These considerations imply that elemental defenses are more important than heretofore recognized.

A defensive effect of metals at levels below hyperaccumulator concentrations is also notable because it suggests a mechanism whereby hyperaccumulation may have evolved. Boyd (2004) proposed that natural selection, driven by a defensive effect of metals against herbivores and/or pathogens, could have caused a stepwise magnification of metal levels in plants culminating in hyperaccumulation. Our study supports this hypothesis by showing that accumulation can itself have selective value against herbivory, leading to the survival of more toxic variants. Recent genetic studies of hyperaccumulation, summarized by Pollard et al. (2002), have demonstrated the existence of quantitative genetic variation in hyperaccumulation ability. Action of natural selection on similar variation in levels of accumulation could have resulted in the evolution of hyperaccumulation.

In summary, we suggest that elemental defenses may be more widespread among plants than previously suspected and may be more ecologically important than previously thought (Boyd, 2004). Our results show that plant species that accumulate or hyperaccumulate the metals that we studied will be toxic to DBM. These results also suggest that elemental defenses may be more widespread geographically than previously supposed. Most hyperaccumulator and many accumulator plant species are found on mineralized soils (Reeves and Baker, 2000), but the low concentration at which some metals (e.g., Zn; Figure 1c and Table 3) can be an effective defense suggests that some species growing on less mineralized soils may also be defended by metals. Our study extends the elemental defense hypothesis to plants other than hyperaccumulators, and suggests that hundreds or even thousands of additional plant species may be protected by elemental defenses.

Acknowledgments—The authors thank the Undergraduate Research Fellowship Program of the College of Sciences and Mathematics, the Fund for Excellence Program of the Department of Biological Sciences, and a Research Experience for Undergraduates (REU) supplement to National Science Foundation grant DEB-0074556 to M.D.E. for financially supporting this research. We also thank C. Harvey for colony establishment and maintenance advice. The first author also thanks B. Wells, M. Buckman, and Z. Delamar for advice and assistance with these experiments as well as family members for their support during the course of these investigations.

(Received December 14, 2004; accepted March 17, 2005)

Abstract—Leaves are an important dietary source of carbohydrates and protein, and an especially rich source of calcium for bats. Most studies of leaf eating by fruit bats have suggested that only male bats feed on leaves. In this study, 23 wild-caught Tongan fruit bats (*Pteropus tonganus*) were used in feeding trials conducted in an outdoor enclosure. The number of leaves and percentage of each leaf eaten were recorded for each bat on a daily basis, and these data were then multiplied by a calcium constant that was derived from a chemical analysis of leaves from *Callophylum neo-ebudicum*. Leaves of *C. neo-ebudicum* that were available in the enclosure were consumed by 82.7% of the bats. Overall, males consumed leaves in greater quantities and with higher frequency than females. Bats that consumed leaves on a regular basis consumed up to 46% more calcium to their diet compared with bats that did not regularly consume leaves. Leaves may represent a readily available, widely used, concentrated source of minerals for foraging bats, and have the potential to contribute significantly to the total amount of ingested calcium.

Key Words—*Pteropus tonganus*, *Callophylum neo-ebudicum*, calcium, folivory.

INTRODUCTION

Folivory, or leaf eating by bats, is a well-documented phenomenon (Marshall, 1985; Lowry, 1989; Funakoshi et al., 1993; Kunz and Ingalls, 1994; Kunz and Diaz, 1995; Banack, 1996; Tan et al., 1998; Ruby et al., 2000). Leaves are an important dietary source of minerals, carbohydrates, and protein for bats, and they are especially rich in calcium (Tan et al., 1998; Nelson et al., 2000; Ruby et al., 2000). Leaves also provide a consistent food source for fruit bats as they are available year-round and are predictable in time and space (Kunz and Ingalls, 1994; Rajan et al., 1999). Thus, leaves may provide a greater net return per foraging bout than ingestion of large amounts of more widely dispersed and low-protein fruit or the active pursuit of insects (Kunz and Ingalls, 1994; Tan et al., 1998). In addition, steroid hormones found in leaves of some species may have an influence on the timing of bat reproduction (Wickler and Seibt, 1964; Kunz and Diaz, 1995).

Bats consume leaves by leaf fractionation. This process includes masticating the leaves into a bolus, swallowing the liquid portion, and ejecting the flattened fibrous pellet (Lowry, 1989; Kunz and Ingalls, 1994; Kunz and Diaz, 1995). By rejecting the fibrous portion, bats are able to consume leaf nutrients without altering their digestive tract or increasing wing loading (Kunz and Ingalls, 1994). Frugivorous bats appear to be preadapted for folivory by leaf fractionation; their dentition and gut morphology are specialized for extracting and digesting a largely liquid diet (Tedman and Hall, 1985; Kunz and Ingalls, 1994). To shift their diet alternately between one of fruits to leaves would involve little or no change in function of the gut or dentition (Kunz and Diaz, 1995).

Folivory was once thought to be rare among fruit bats, with leaves taken only when other food sources were scarce (Marshall, 1985; Funakoshi et al., 1993; Pierson et al., 1996). However, recent studies have shown that leaf eating is both common and widespread among Old World flying foxes (Banack, 1996; Tan et al., 1998; Ruby et al., 2000). Folivory has been reported for at least 17 species of Old World Megachiroptera, and leaves eaten by bats include 44 species of plants (Kunz and Diaz, 1995). For example, *Cynopterus brachyotis* fed regularly on the leaves of 14 plant species (Tan et al., 1998), and *Pteropus dasymallus* on nine species (Funakoshi et al., 1993). The incidence of leaf pellets under feeding roosts was 37–50% and occurred almost throughout the year (Funakoshi et al., 1993). However, this estimate may be low because leaf pellets produced by foliage roosting bats often go unnoticed because the pellets are inconspicuous among other plant material on the forest floor (Kunz and Ingalls, 1994).

Calcium is of particular interest in bat biology (Barclay, 1994, 1995; Kunz et al., 1995; Bernard and Davison, 1996). It has been postulated that females

may be stressed for calcium because of the mineral demands of both pregnancy and lactation (Barclay, 1994, 1995). To compensate for the relatively large size of their offspring, bats donate their own skeletal calcium to build the bones of their young (Barclay, 1995). Calcium concentrations are often much higher in leaves than in fruit (Nelson et al., 2000; Ruby et al., 2000). While some fruits may be high in calcium, the calcium is not readily available if the Ca/P ratio is less than the optimum ratio of 2 to 1 (McDowell, 1992; Robbins, 1993). The Ca/P ratio is three times higher in leaves than in fruits, which suggests that leaves may be sought by bats for their high calcium content (Kunz and Diaz, 1995; Ruby et al., 2000).

This study examined folivory among captive, wild-caught Tongan fruit bats (*Pteropus tonganus*). It is the first study to examine the amount of leaves that are consumed by individual fruit bats in a single night and to estimate how much calcium that folivory contributes to total daily calcium intake. We also describe sex and age differences in leaf consumption and suggest why this pattern may exist.

METHODS AND MATERIALS

Research was conducted from December 2000 to August 2001 on the island of Tutuila, American Samoa (14°S, 170°W) in the South Pacific Ocean. All 23 (13 males, 10 females) Tongan fruit bats (*P. tonganus*) were captured using large mist nets and transported to the "bat house." Upon being removed from nets, bats were placed into cloth holding bags and transported to a field laboratory or "bat house." Four adult males, 9 juvenile males, 4 adult females (of which two were lactating), and 6 juvenile females were used for experimentation. The bat house consisted of a 4 × 3 m outdoor wooden structure with an adjoining 4 × 3 m screened outdoor pen constructed specifically to house bats. The outdoor pen was built around a single *Callophylum neo-ebudicum* (Clusiaceae) tree for roosting and was the only source of leaves in the present study (Trail, 1994; Whistler, 1994). Bats were able to fly and move easily within the outdoor enclosure. Each night, bats were offered twice their body mass in bat foods known from the island (Banack, 1996). Fruits were suspended individually from the ceiling of the pen on a dowel rod, and fruit remains were analyzed separately (see Nelson, 2003). Fruit types supplied to the bats varied each day depending on their availability on the island. Salt rings composed of salt (96–99%) and mineral oil (Pet Products, Inc., Hauppauge, NY, USA) as well as collected rainwater were available to the bats *ad libitum*. Feeding trials were conducted on individual bats and lasted 3–5 d preceded by a 2 d acclimation period, for a total of 7 d in captivity. Bats were tested one at a time in the outdoor enclosure. Raised screen platforms were placed on the floor of the

enclosure to catch food and leaves dropped by the bats while they were feeding. We assumed that the amount of time that bats spent in captivity neither altered nor adversely affected their mineral status. If this assumption is correct, any possible deficiencies or excesses from their native diet should not influence their consumption patterns while in captivity.

The number of leaves and percentage of a leaf eaten were recorded for each bat on a daily basis. Samples of *C. neo-ebudicum* leaves were collected and dried at 105°C for 24 hr. Leaf samples included both whole leaves and leaves partially eaten by the bats. To assess the calcium content of leaf tissue actually consumed by bats, we only analyzed the portion of leaves that did not contain the midrib. These samples were then compared with whole leaves that contained the midrib. Leaf samples were dried to a constant mass and digested according to Miles et al. (2001). Calcium concentrations (ppm) were assessed by atomic absorption spectrophotometry (Perkin-Elmer AAS 5000, Norwalk, CT, USA) in the Nutrition Laboratory at the University of Florida and were calculated on a dry matter basis.

Males and females, juveniles, and adults were compared to identify possible differences in leaf-eating behavior observed during the experiments. Bats that consumed leaves more than 50% of the days during the 5 d experimental period were classified as habitual leaf eaters. Bats that only occasionally consumed leaves for fewer than half of the days they were housed for the experiments were classified as occasional leaf eaters. Some bats never consumed leaves and were classified as nonleaf eaters. These three groups were compared for total calcium consumption.

Values of supplementary calcium were calculated for each group as the total amount of leaf matter eaten by a bat multiplied by the calcium (Ca) concentration of the leaves (8,861.47 mg/g Ca). To estimate how much calcium that folivory contributed to total daily calcium intake, we calculated the average amount of supplemental calcium consumed for each of the three groups and compared this value to the average total calcium ingested by that group (Nelson, 2003). Differences in consumption of leaves between sex and age were compared using two-tailed *t*-tests. The Kolmogorov–Smirnov test was used to evaluate assumptions of normality for each variable, and Levene's test was used to evaluate the assumption of normality between groups (Sokal and Rohlf, 1995). Total calcium consumption for the three leaf-consumption groups was compared using a one-way ANOVA.

RESULTS

Ninety-four feeding trials were performed on 23 Tongan fruit bats. Leaves were consumed by 82.7% of the bats in this study. More males (92%) consumed

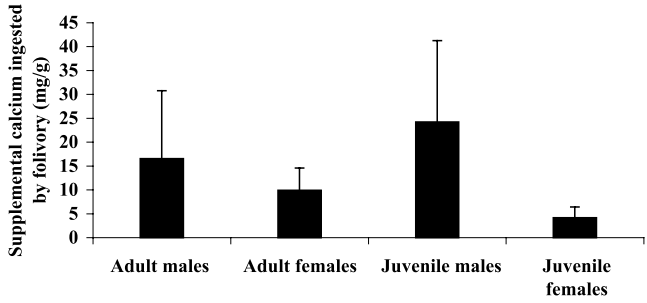

FIG. 1. Supplemental calcium ingested (mg/g) by folivory for adult males, juvenile males, adult females, and juvenile females.

leaves than females (70%). The total leaf mass eaten (g) differed ($P = 0.02$) between the sexes; males consumed an average of 9.55 ± 6.99 SD g, and females consumed an average of 2.97 ± 2.04 g over the period of the feeding trial. This resulted in 22.14 ± 16.00 mg/g of additional calcium for males and 7.06 ± 4.56 mg/g for females (Figure 1). The amount of additional ingested calcium was different ($P = 0.02$) between males and females. Juvenile male and juvenile female bats differed ($P = 0.04$) in their consumption of leaves (24.22 ± 17.03 and 4.19 ± 2.24 g, respectively), but adult male and female bats did not ($P = 0.40$). Twice as many juvenile males ate leaves than juvenile females

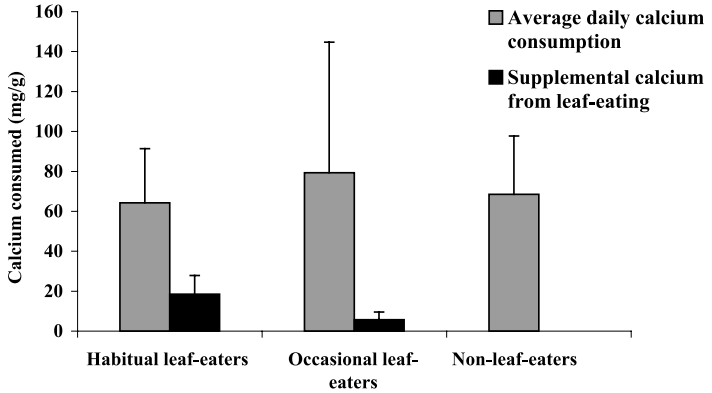

FIG. 2. A comparison of total calcium ingested among habitual, occasional, and nonleaf eaters. Total calcium is average daily calcium and supplemental calcium from leaf eating combined. Total average daily calcium values for each group are calculated from values found in Nelson, 2003.

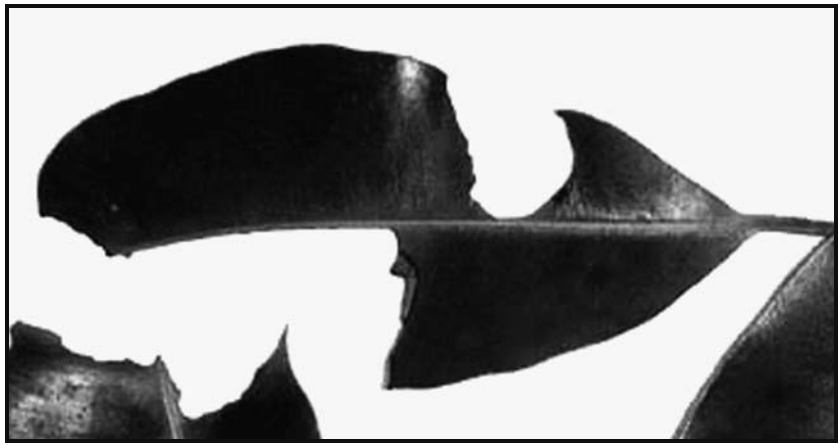

FIG. 3. Typical pattern of leaf consumption by *Pteropus tonganus* in American Samoa.

(eight males/four females). The number of leaves eaten by individuals over the 5 d experimental period ranged from 0.75 to 26 leaves. One young male ate 26 leaves in a single night.

Overall, folivory provided 2.3–32.26 mg/g of additional calcium to the diet of individual fruit bats. The numbers of habitual and occasional leaf eaters were similar (11 and eight, respectively); however, habitual leaf eaters consumed significantly more calcium than occasional leaf eaters ($P = 0.04$). Habitual leaf eaters consumed an average of 10 ± 6.56 leaves, which contributed an additional 23.89 ± 15.05 mg/g of dietary calcium (Figure 2). This represented an average dietary increase in calcium of 11–46% when compared to the daily calcium consumption for each bat in that group. Occasional leaf eaters consumed an average of 2.34 ± 1.54 leaves, which added an additional 5.75 ± 3.82 mg/g of calcium to their diet. Occasional leaf eating represented an average dietary increase in calcium of 3–22% when compared to the daily calcium consumption for each bat. Nonleaf eaters ($N = 4$) added no additional calcium to their diet.

When eating leaves, *P. tonganus* often avoided the fibrous midrib and instead ate around it (Figure 3). The portions of leaves with the midrib contained 15.08 mg/g of calcium, whereas leaves without midribs contained 8.86 mg/g of calcium. The manner in which Tongan fruit bats consumed leaves suggests that they are actively avoiding the fibrous midrib, possibly because of high levels of tannins or other secondary compounds. Unfortunately, this analysis was largely exploratory, and several leaves resulted in only one analyzed sample leaves containing the midrib and those without. Thus, a statistical analysis of these samples was not possible.

DISCUSSION

Previous studies reporting evidence of folivory (Marshall, 1985; Lowry, 1989; Funakoshi et al., 1993; Kunz and Ingalls, 1994; Kunz and Diaz, 1995; Banack, 1996; Tan et al., 1998; Ruby et al., 2000) were based on indirect and anecdotal means of quantifying leaf eating by bats. Thus, they were unable to determine either the amount of leaves eaten per bat or the sex and age of the consumer. The present study quantified both the number and quantity of leaves consumed by individual bats and how much this contributed to total dietary calcium intake. The majority (83%) of wild-caught Tongan fruit bats engaged in leaf eating during a 5-d experimental period. Both sexes consumed leaves, but male bats consumed more leaves than females, and juvenile males consumed both the greatest number and quantity of leaves for all groups. Habitual leaf-eating bats increased their dietary calcium consumption by 46%. Our results indicate that folivory is both commonly and frequently practiced by *P. tonganus* and thus has the potential to contribute significantly to the total amount of ingested calcium. In the present study, leaf consumption by the Tongan fruit bat involved only one plant species (*C. neo-ebudicum*) known from American Samoa, but levels of folivory could be even higher if leaves of other species had been available.

Kunz and Diaz (1995) observed only mature males carrying leaves, and they hypothesized that folivory may be limited to adult male bats. Leaf eating was practiced by both adult males and females in the present study, but it was observed most often in juvenile males. Other research has suggested that compounds extracted from leaves by fruit bats may influence their reproductive activity (Kunz and Ingalls, 1994; Kunz and Diaz, 1995). Leaves of *Erythrina*, consumed by *P. tonganus* on the island of Tonga (Harris and Baker, 1959), may contain one or more metabolites (alkaloids) important for reproduction. In addition to being a rich calcium source that supports rapid growth, leaves may also influence reproductive activity in young male bats. It is currently unknown if leaf consumption by female *P. tonganus* is influenced by hormonal compounds present in leaves.

Female bats may consume leaves to gain access to nutrients (e.g., protein) and minerals not available in some fruits (Kunz and Diaz, 1995). In general, leaves tend to have higher levels of calcium, sodium, manganese, and magnesium than ripe native or agricultural fruits (Nelson et al., 2000). Leaves are also widely available in both the wet and dry season (Whistler, 1994). Leaves analyzed from American Samoa provide rich sources of calcium and other macrominerals, and they may be particularly important for reproduction among Tongan fruit bats living there. Banack (1996) found that female Tongan fruit bats in American Samoa gave birth year-round, and young were observed on mothers during all months of the year. She also observed copulations with

pregnant females, suggesting that the female was nursing while allocating her own calcium for the skeletal formation of a new offspring (Barclay, 1995; Banack, 1996). Both gestation and lactation are nutritionally demanding, and their combined effect may promote leaf eating in females as a way to obtain additional minerals. Feeding trials on *P. tonganus* in American Samoa demonstrate high levels of calcium retention that suggest calcium stress (Bronner, 2003; Nelson, 2003). Together, the cumulative demands of gestation and lactation, with overlapping generations, and a diet low in calcium, may promote leaf eating by female bats in an attempt to gain supplemental calcium and other minerals.

Leaves also are widely available in both the wet and dry season (Whistler, 1994) in American Samoa, and leaf consumption is possible for *P. tonganus* throughout the year. Reports of year-around leaf consumption in other species are based on either analysis of fecal remains, leaf parts discarded beneath roosts (Lowry, 1989; Parry-Jones and Augee, 1991), or direct observation (Zortea and Mendes, 1993). Banack (1996) described year-round leaf consumption by both *Pteropus samoensis* and *P. tonganus* in American Samoa. Although folivory can contribute significantly to the total dietary calcium of leaf-eating bats, the motivation for folivory still cannot be attributed to a single factor. Our research has demonstrated that leaf eating is common among the Tongan fruit bat, and the leaves of *C. neo-ebudicum* provide a rich and concentrated calcium supplement to the potentially calcium-poor diet of this plant-visiting species in American Samoa.

(Received December 31, 2004; accepted April 7, 2005)

Abstract—*Conium maculatum*, a Eurasian weed naturalized in North America, contains high concentrations of piperidine alkaloids that act as chemical defenses against herbivores. *C. maculatum* was largely free from herbivory in the United States, until approximately 30 yr ago, when it was reassociated via accidental introduction with a monophagous European herbivore, the oecophorid caterpillar *Agonopterix alstroemeriana*. At present, *A. alstroemeriana* is found in a continuum of reassociation time and intensities with *C. maculatum* across the continent; in the Pacific Northwest, *A. alstroemeriana* can cause severe damage, resulting in some cases in complete defoliation. Studies in biological control and invasion biology have yet to determine whether plants reassociated with a significant herbivore from the area of indigeneity increase their chemical defense investment in areas of introduction. In this study, we compared three locations in the United States (New York, Washington, and Illinois) where *C. maculatum* experiences different levels of herbivory by *A. alstroemeriana* to determine the association between the intensity of the interaction, as measured by damage, and chemical defense production. Total alkaloid production in *C. maculatum* was positively correlated with *A. alstroemeriana* herbivory levels: plants from New York and Washington, with higher herbivory levels, invested two and four times more N to alkaloid synthesis than did plants from Illinois. Individual plants with lower concentrations of alkaloids from a single location in Illinois

* To whom correspondence should be addressed. E-mail: castells@life.uiuc.edu

experienced more damage by *A. alstroemeriana*, indicative of a preference on the part of the insect for plants with less chemical defense. These results suggest that *A. alstroemeriana* may act either as a selective agent or inducing agent for *C. maculatum* and increase its toxicity in its introduced range.

Key Words—Insect–plant interactions, *Conium maculatum*, *Agonopterix alstroemeriana*, chemical defenses, alkaloids, γ-coniceine, coniine, conhydrinone, evolution, herbivory.

INTRODUCTION

Flowering plants and the insects that eat them collectively constitute almost half of all terrestrial species (Berenbaum, 1995). Interactions between plants and herbivorous insects are of central importance in determining community structure in a wide range of terrestrial systems. Thus, perturbations that affect interactions can have profound impacts within terrestrial systems. Among the global perturbations of increasing concern is the introduction and incorporation of nonnative species into communities within which they have not evolved. Once established, invasive plants can cause direct economic damage by reducing crop yields and livestock growth, and indirect damage by altering community composition via displacement of native species (Vitousek et al., 1996; Pimentel et al., 2000). Invasive species can influence the evolution of native species via niche displacement, competitive exclusion, introgression, hybridization, and even extinction (Mooney and Cleland, 2001).

Because the rate at which invasive species enter and become established in the United States has been increasing (Mooney and Cleland, 2001), there is considerable interest within the scientific community in understanding the dynamics of invasion. Characterizing "invasibility," however, has proven difficult (Crawley, 1987; Rejmanek and Richardson, 1996; Reichard and Hamilton, 1997). Transport of a species out of its native habitat generally results in a reduction in herbivory by coevolved specialist insects. Indeed, the idea that plant populations in areas of indigeneity are regulated by herbivores underlies the practice of classical biological control of weeds (Huffaker, 1959; Willis et al., 2000). The fact that plants tend to grow taller and produce more seeds in areas of introduction than in areas of indigeneity has been attributed in part to release from herbivorous natural enemies (Crawley, 1987). Blossey and Nötzold (1995), in proposing what they call the evolution of increased competitive ability (EICA) hypothesis based on optimal defense theory (Zangerl and Bazzaz, 1992), argue that invasiveness results from changes in biomass allocation patterns; in areas of introduction, where herbivores are absent, genotypes with reduced resource allocation to herbivore defense and increased resource allocation to competitive abilities are favored. Although

preliminary tests of this hypothesis with purple loosestrife (*Lythrum salicaria*) were suggestive (Blossey and Nötzold, 1995) and have been confirmed in other systems (Siemann and Rogers, 2001; Blair and Wolfe, 2004), additional tests failed to document intraspecific variation in herbivore resistance according to plant origin (Willis et al., 1999; Stastny et al., 2005), and a broader survey suggests that differences in sizes of plants in indigenous vs. nonindigenous habitats may represent plastic phenotypic variation rather than evolutionary change (Willis et al., 2000). More recently, a comprehensive comparison of size, fecundity, and leaf areas of nonindigenous and indigenous populations of *Hypericum perforatum* provided compelling evidence of the capacity for rapid contemporary evolution of these traits in invasive species (Maron et al., 2004a).

In general, little quantitative and ecologically relevant information is available on phytochemical changes in plants that occur after introduction into a nonindigenous area and release from interactions with longtime insect associates (Daehler and Strong, 1997; Willis et al., 1999; Siemann and Rogers, 2003; Maron et al., 2004b). Perhaps equally important, little information is available on phytochemical changes that ensue when coevolved herbivore associates resume interacting with a host plant in a nonindigenous area. This scenario is of no small consequence in that classical biological control involves reconstructing such plant–herbivore associations in the area of introduction. The possibility exists that, in the area of introduction, a newly resumed interaction will differ dramatically in its dynamics from such interactions in the area of indigeneity, given the differences in the structure of the surrounding community. Understanding the selective impact of reassociated herbivores on the chemistry of their host plants in areas of introduction is of interest not only in the context of understanding the basic dynamics of plant–insect interactions, but also in predicting potential trajectories of classical weed biological control programs.

A system in which the chemical consequences of reassociation with a coevolved herbivore may be thoroughly examined involves the interaction between *Conium maculatum* (L.) (Apiaceae) (poison hemlock), a Eurasian weed, and its monophagous associate *Agonopterix alstroemeriana* (Clerck) (Lepidoptera: Oecophoridae), a leaf-rolling European caterpillar known only to feed on *C. maculatum*. *C. maculatum* is an herbaceous Eurasian biennial that is extensively naturalized in temperate North America, as well as in other parts of the world, including Australia, New Zealand, and South America (Parsons, 1976; Holm et al., 1979). The weed is generally regarded as noxious; all aerial parts are poisonous to livestock and to humans (Sperry et al., 1964; Widner, 1984; Markham, 1985; Hannam, 1985; Jessup et al., 1986; Panter et al., 1988; Panter and Keeler, 1989). The toxicity of *C. maculatum* to vertebrates is attributable primarily to its production of relatively high concentrations of coniine

and related piperidine alkaloids, including methylconiine, coniceine, and conhydrine (Fairbairn, 1971). Its tendency to invade fields of alfalfa and other forage crops has led to livestock death through contamination of green-chopped hay (Kubik et al., 1980; Panter et al., 1988). *C. maculatum* is frequently a target of eradication programs in populated areas because of its toxicity, as well as to its rank odor and profuse growth.

Relative to other introduced weed species, *C. maculatum* is attacked by few insect herbivores. In an extensive survey of poison hemlock in southern California, Goeden and Ricker (1982) reported "amazingly few insect species or individuals thereof. A clear majority, 16 (70%) of the 20 [*sic*] phytophagous insect species found on this weed were rare and were only encountered as a few individuals at one or two sites." Of the relatively few native insect species that have colonized the plant extensively throughout its range, the majority are species that feed generally on native and introduced plants in the Apiaceae; these species include *Papilio zelicaon* Lucas (Goeden and Ricker, 1982), *P. polyxenes asterius* Stoll (Feeny et al., 1985; personal observations) (Lepidoptera: Papilionidae), and *Euleia fratria* (Loew) (Diptera: Tephritidae) (Berenbaum, 1981; personal observations). The most abundant insect associate of the plant in California until recently has been an aphid, *Hyadaphis foeniculi* (Passerini), accidentally introduced from Europe, where it also feeds on poison hemlock (Goeden and Ricker, 1982).

A. alstroemeriana, a leaf-rolling oecophorid caterpillar monophagous on *C. maculatum* throughout its native range in Europe, was first reported on *C. maculatum* populations in the United States in Tompkins County, NY, in 1973 (Berenbaum and Passoa, 1983). *A. alstroemeriana* was subsequently reported in 1983 in northern California, Oregon, and Utah and by 1987 was established in mesic areas of Washington, Idaho, and Colorado (Powell and Passoa, 1991), where it remains reliably "collectible in large numbers" (Anonymous, 1995). An adult *A. alstroemeriana* collected in 1990 near Columbus, OH, marked the first appearance of this species in the Midwest (Powell and Passoa, 1991). In 1993, the existence of established populations of *A. alstroemeriana* in central Illinois was confirmed (Berenbaum and Harrison, 1994); McKenna et al. (2001) reported substantial populations of this insect at several sites throughout Champaign County, IL.

Thus, throughout its range in North America, populations of *C. maculatum* exist with varying histories of reassociation with a specialist herbivore from its area of indigeneity. This continuum of association allows us to test whether a specialist insect (and potential biological control agent) may act as a selective agent on the defense chemistry of its host plant. In this study, we set out to determine whether chemical defense production by *C. maculatum* changes in response to reassociation with a principal herbivore from its area of indigeneity.

METHODS AND MATERIALS

Sampling. Study sites were located in Champaign County, IL, USA (40.109°N, 88.203°W), Tompkins County, NY, USA (42.443°N, 76.503°W), and Whitman County, WA, USA (46.733°N, 117.161°W). These locations were selected because they represent a continuum in time of association with and intensity of herbivory by *A. alstroemeriana* on *C. maculatum*, with longer association and higher levels of herbivory in Washington and New York and shorter association and lower levels of herbivory in Illinois. In June 2003, we selected four sites located more than 2 km apart within each region. *A. alstroemeriana* larvae can be found on *C. maculatum* for a short period of time, between 30 and 45 days, with some differences in life cycle timing among the regions studied. Thus, *A. alstroemeriana* larvae can be found from late April to early June in Illinois (Berenbaum and Harrison, 1994), from early May to mid-June in New York (Berenbaum and Passoa, 1983), and from early June to mid-July in Washington (Piper, personal observation). *C. maculatum* sampling was conducted in early June in Illinois and New York and in late June in Washington to coincide with the presence of *A. alstroemeriana* larvae. Plants are in approximately the same developmental stage across regions when *A. alstroemeriana* is abundant (early to mid-flowering). At each site within a region, we estimated *A. alstroemeriana* damage levels. Five levels of intensity were identified: level 0, *A. alstroemeriana* leaf rolls absent; level 1, leaf rolls present, but no visible leaf damage; level 2, minor defoliation, with up to one quarter of leaf area damaged (as estimated by eye); level 3, mild defoliation, between one quarter and one half of leaf area damaged; level 4, major defoliation, with more than one half of leaf area damaged; and level 5, complete defoliation, with most of leaf area damaged.

In each region, we randomly sampled between 12 and 20 *C. maculatum* plants per site. Two subsamples of green foliage per plant, one for alkaloid analysis and one for nitrogen and leaf water content analysis, were placed separately into Eppendorf tubes and frozen *in situ* on dry ice. Samples were shipped on dry ice to our UIUC laboratory and stored at −80°C until analyzed.

Plant Extraction and Chemical Analyses. Leaf material (ca. 200 mg FW) was ground using a ball mill and extracted on a shaker for 1 hr with 1.5 ml of acidified methanol (70% MeOH, 30% 0.1 N HCl). After centrifuging, 1 ml of the resulting extract was concentrated to approximately 0.2 ml on a centrifugal evaporator (Jouan RC 10.10), extracted with hexane to remove nonpolar compounds, and placed back into the centrifugal evaporator to remove the residual hexane. The remaining solution was then basified with 10 M NaOH; these were extracted in 200 μl hexane with 0.01% hexadecane. Alkaloids were analyzed by flame ionization detection on a gas chromatograph equipped with capillary column (Alltech EC-1, 30 m, 0.23 mm) coupled with an autosampler

(HP 5890). Hexadecane was used as internal standard. The samples were run with the following temperature program: initial temperature 50°C, ramp 5°C min^{-1} up to 105°C, ramp 35°C min^{-1} up to 290°C, 5 min at 290°C. (±)-Coniine (Sigma) was used as a standard. Alkaloid concentrations were expressed as coniine equivalents on a dry weight basis and per milligram of nitrogen. Total alkaloid concentrations were calculated by adding the concentrations of each individual alkaloid.

Total nitrogen was measured to estimate the relative resource investment in defense compounds among the three regions studied. A subsample of fresh leaf material was weighed, oven-dried at 60°C overnight, and weighed again to obtain the FW/DW ratio. Samples (10 plants per site) were then ground and analyzed for total nitrogen in an elemental combustion analyzer (Costech Instruments ECS 4010).

Isolation and Identification of Alkaloids. Leaves of *C. maculatum* were collected during March 2004 at Phillips Tract Experimental Station located at 5 km of Urbana, IL, USA. Fresh leaves (200 g FW) were extracted in a blender with 70% methanol, 30% 0.1 N HCl and filtered through Whatman 1 filter paper. The residue was re-extracted two more times; fractions were bulked together (1 l in total) and filtered through reversed-phase C18 (Baker; 40 μm) previously rinsed with methanol to remove nonpolar compounds. The eluate containing the alkaloids was concentrated by rotary evaporator at low temperature (max 45°C) until the volume was reduced by half; the eluate was then partitioned with chloroform (3×'s) to further remove nonpolar compounds. In a separation funnel, the extract was basified with 10 M NaOH and liquid–liquid partitioning was conducted with chloroform (5×'s) to extract the alkaloids. The chloroform fractions were combined, mixed with 20% HCl in MeOH, and evaporated to obtain a mixture of alkaloids in hydrochloride form. Bulk alkaloids were resuspended in ethanol/0.1 N HCl (1:1), basified with 10 M NaOH, and extracted (3×'s) with a small volume of chloroform. Individual alkaloids were isolated using a 25 × 2.5 cm silica gel (Merck; 32–63 μm) gravity column eluted with 150 ml of chloroform/ethanol/NH_3OH (70:30:1) (Leete and Olson, 1972) at ca. 1 ml min^{-1}. Fractions (2 ml each) were monitored by spotting 5 μl on a TLC silica gel plate (Baker; 250 μm) and sprayed with Dragendorff (Jungreis, 1985) or 0.2% ninhydrin reagents (Sigma). Although individual alkaloids did not completely separate, we could obtain fractions with more than 95% purity for the two major alkaloids to be identified by nuclear magnetic resonance (NMR) (RT 6.5 and RT 10) as explained below. The low concentration of alkaloid RT 12.0 did not allow us to obtain enough pure material for structure elucidation. Coniine identity (RT 5.6) (Figure 1) was established by comparison with authentic material (Sigma).

Liquid Chromatography-ElectroSpray Ionization-Mass Spectrometry (LC-ESI-MS) Analysis for Hemlock Alkaloids. Samples were run on a Finnigan-

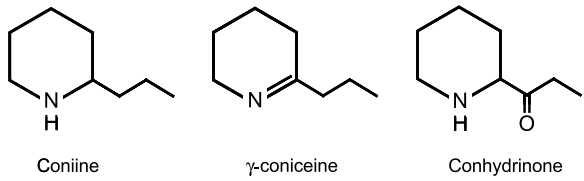

FIG. 1. Major piperidine alkaloids of *Conium maculatum* from Illinois, New York, and Washington.

Thermoquest LCQ LC-MS system (AS3000 autoinjector, P4000 HPLC pump, UV6000 PDA detector, LCQ mass spectrometer) (San Jose, CA) all running under the Xcaliber 1.2 software system. The MS was run with the ESI probe in the positive mode. The column was a 3 × 150 mm Inertsil reverse-phase C-18, ODS 3, 3-μm column (Metachem, Torrance, CA) with a Metaguard guard column. The source inlet temperature was set at 220°C, and the sheath gas rate was set at 90 arbitrary units. The MS was optimized for detection of hemlock alkaloids by using the autotune feature of the software while infusing a solution of coniine with the column effluent and tuning on an atomic mass unit of 128 $[M+H]^+$. The solvent systems were as follows: (A) water with 0.1 M ammonium acetate and 0.25% acetic acid; and (B) methanol with 0.1 M ammonium acetate and 0.25% acetic acid. The column was equilibrated with 2% B at a flow rate of 0.3 ml min^{-1}. After injection, the column was held at the initial conditions for 2 min, then developed with a linear gradient to 40% B over 23 min and then to 50% B over the next 10 min. The column effluent was monitored at 210 nm in the PDA detector. Mass data between 150 and 1000 AMUs was collected. Generally, the most significant sample ion generated under these conditions was $[M+1]^+$.

Gas Chromatography–Mass Spectrometry Analysis for Hemlock Alkaloids. Gas chromatography–mass spectrometry (GC-MS) was performed using a Hewlett-Packard (HP) 6890 GC system attached to an HP 5972A Mass Selective Detector. The column was a fused silica HP-5MS capillary (0.25-μm film thickness, 30 m × 0.25 mm ID). The GC operating parameters were as follows: splitless injection mode; temperature programmed from 50 to 315°C at 5°C min^{-1} with a 10-min initial temperature hold; He carrier gas flow rate at 1.1 ml min^{-1}, with the injector temperature set at 250°C. Spectra were compared to known standards or by computer with the Wiley/NBS Mass Spectral Registry (McLafferty and Stauffer, 1989).

Nuclear Magnetic Resonance Analysis of Hemlock Alkaloids. ^1H, Correlation Spectroscopy (COSY), Distortion less Enhancement by Polarization Transfer (DEPT), Heteronuclear Single Quantum Coherence (HSQC),

and ^{13}C-NMR spectra were obtained with a Bruker (Billerica, MA, USA) Avance 500 spectrometer equipped with a 5-mm inverse broadband Z-gradient probe (^{13}C NMR, 125 MHz; ^{1}H, 500 MHz). Nuclear magnetic resonance spectra were recorded in methanol-d4, which served as the internal reference (^{13}C, 49.0 ppm; ^{1}H, 3.30 ppm). The data were analyzed using the Advanced Chemistry Development, Inc., SpecManager 1D Processor and the HNMR and CNMR Predictor software suite (Toronto, ON).

Structure Confirmation of γ-Coniceine (RT 6.5). Positive ion LC-ESI-MS showed the presence of one major compound with a large mass ion $[M+H]^+$ of *m*/*z* 126. Prominent diagnostic GC-mass spectral ions and their relative intensities are as follows: EI-MS [*m*/*z* (%)]: 125 (M^+, 13), 124 (10), 110 (32), 97 (100), 96 (43), 82 (10), 70 (19), 55 (10), 54 (10); ^{1}H-NMR δ (CD_3OD): 3.65 (2H, bs), 2.82 (2H, m), 2.62 (2H, m), 1.90 (2H, m), 1.86 (2H, m), 1.71 (2H, m), 1.02 (3H, t, J = 7.4 Hz); ^{13}C-NMR δ (CD_3OD): 45.9, 41.0, 30.6, 20.3, 20.3, 17.9, 7.4. The ^{1}H-NMR and ^{13}C-NMR spectra identify a compound with a composition of $C_8H_{15}N$ consistent with the structure of γ-coniceine (Asensio et al., 1993; Fukuda et al., 1991) (Figure 1).

Structure Confirmation of Conhydrinone (RT 10). Positive ion LC-ESI-MS showed the presence of one major peak with a large mass ion $[M+H]^+$ of *m*/*z* 142. Prominent diagnostic GC-mass spectral ions and their relative intensities are as follows: EI-MS [*m*/*z* (%)]: 141 (M^+, 2), 98 (100), 84 (4), 70 (8), 55 (65); ^{1}H-NMR δ (CD_3OD): 4.04 (1H, dd, J = 12.3 Hz, J = 3.3 Hz), 3.39 (1H, m), 2.99 (1H, m), 2.63 (1H, m), 2.38 (1H, m), 1.91 (2H, m), 1.67 (2H, m), 1.54 (1H, m), 1.09 (3H, t, J = 7.2 Hz); ^{13}C-NMR δ (CD_3OD): 207.4, 64.4, 44.9, 32.6, 27.1, 23.2, 23.0, 7.4. The ^{1}H-NMR showed signals for an isolated ethyl group adjacent to a carbonyl carbon. The downfield proton is consistent with a proton attached to the carbon in the ring that is both adjacent to the nitrogen and attached to the side chain bearing the ketone. All assignments for conhydrinone could be obtained from the COSY spectrum. The ^{13}C-NMR revealed the presence of a keto carbonyl at 207.4 ppm. All the assignments were obtained from DEPT and HSQC experiments. The spectra match that of a compound with a composition of $C_8H_{15}NO$ corresponding to conhydrinone (Leete and Olson, 1972) (Figure 1).

Information on an Unknown Alkaloid (RT 12). Positive ion LC-ESI-MS showed the presence of one major compound with a large mass ion $[M+H]^+$ of *m*/*z* 126 and several minor contaminating TIC peaks. The retention time of this compound in the GC is significantly longer than of γ-coniceine; on this basis, we conclude that the compound has a different chemical structure. Prominent diagnostic GC-mass spectral ions and their relative intensities are as follows: EI-MS [*m*/*z* (%)]: 125 (M^+, 1), 124 (6), 110 (18), 97 (100), 96 (31), 82 (9), 69 (7), 55 (15). Examination of purified fractions containing this peak by NMR and IR yielded conflicting data as to the exact chemical structure of this compound.

At this time, we can say it appears to be a coniceine isomer with the exact location of the double bond undetermined.

Herbivory and Alkaloids. To determine whether *C. maculatum* chemistry is associated with differences in *A. alstroemeriana* abundance, we randomly selected 29 plants from one site in Champaign County, IL ("Yard waste site") in June 2003. For each plant, we counted the number of leaf rolls; two leaf samples per plant were then taken and alkaloids were analyzed as described. The number of leaf rolls was used as an estimate of herbivory intensity assuming a proportional relationship between the number of larvae and the number of leaf rolls made during larval development.

Statistical Analyses. All statistical analyses were performed using Statistica 6.0 (Statsoft, Tulsa, OK, USA). A one-way analysis of variance with "site" nested in "region" (Illinois, New York, and Washington) was performed to examine differences among populations in total alkaloid content, individual alkaloid content, and nitrogen content. A *t*-test was conducted to analyze the relationship between herbivory level and total alkaloid and N concentrations. *Post hoc* comparisons for "region" or "herbivory level" were conducted using Tukey's HSD test. The association between alkaloids and intensity of *A. alstroemeriana* herbivory was tested by conducting a simple regression analysis between total alkaloid concentrations and number of leaf rolls and a multiple regression analysis with coniine, γ-coniceine, conhydrinone, and RT 12 as independent variables and leaf roll number as the dependent variable. Data were log transformed to fit normality when necessary.

RESULTS

Herbivory. A. alstroemeriana herbivory levels on *C. maculatum* were lower in Illinois compared with New York and Washington, ranging from absence of leaf rolls (level 0) to minor defoliation (level 2) (Figure 2). In New York, herbivory damage ranged from minor defoliation (level 2) to total defoliation (level 5). However, in New York, especially at the Etna site (ET), the sampling was conducted earlier in the season compared with the other regions, as shown by the number of early instars found, and thus the actual damage to plants may be higher over the course of the season than that estimated here. In Washington, the damage inflicted by herbivores was severe, ranging from major (level 4) to complete defoliation (level 5) (Figure 2), and plants in many stands were found to be totally desiccated as a result of the damage by *A. alstroemeriana*.

Plant Chemistry. We found a total of four alkaloids in *C. maculatum* foliage: coniine, γ-coniceine, conhydrinone, and an unknown alkaloid (RT 12) (Table 1). Not all compounds were present in every plant, and when present,

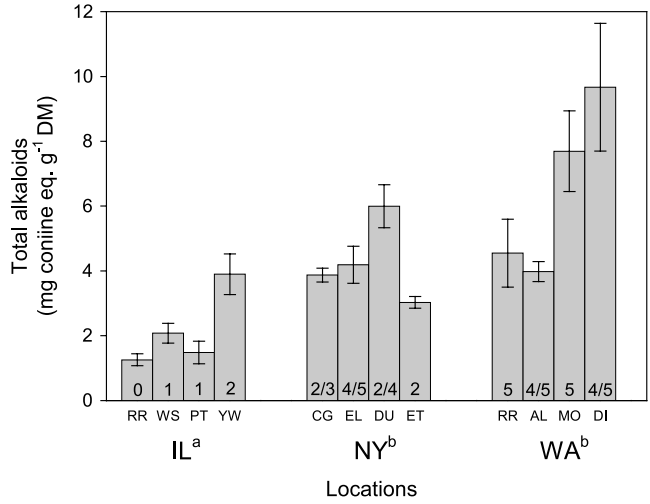

FIG. 2. Total alkaloid concentrations (mean ± SE) of *C. maculatum* plants by site in each region. In Illinois (IL): Railroad (RR), Windsor Rd (WS), Phillips Tract (PT), and Yard Waste (YW). In New York (NY): Coy Glenn (CG), Elm St (EL), Dump (DU), and Etna (ET). In Washington (WA): Railroad (RR), Albion (AL), Moscow (MO), and Ditch (DI). Averaged *Agonopterix alstroemeriana* herbivory levels for each site are indicated inside the graph bars (see a description of each level in Methods and Materials). Different letters indicate significant differences among regions at $P < 0.05$ by Tukey's *post hoc* comparisons test.

their concentrations were highly variable among individuals. Total alkaloid concentrations in plants expressed on a dry weight basis varied among the three regions (ANOVA, $P < 0.05$) and were lower in Illinois than in New York and Washington (Figure 2, Table 1). These lower levels reflected primarily lower concentrations of γ-coniceine, the major alkaloid in all three regions, constituting 80, 91, and 89% of the total alkaloids in Illinois, New York, and Washington, respectively. Plants in New York and Washington, although not different in total alkaloid content, differed in the concentrations of conhydrinone and RT 12, with lower values of both compounds in New York (Table 1). Coniine was present in about 16% of the plants growing in Illinois; however, in these plants, coniine reached such high concentrations that it constituted the second most abundant alkaloid after γ-coniceine. Coniine was not present either in New York or Washington (Table 1). Alkaloid concentrations expressed by unit N were significantly lower in Illinois and higher in Washington, partially because of differences in leaf N concentrations among regions (Figure 3). Total alkaloid concentrations were significantly higher in plants under increasing

TABLE 1. TOTAL ALKALOID CONCENTRATIONS (mg g^{-1} DM), INDIVIDUAL ALKALOID CONCENTRATIONS (mg g^{-1} DM), AND ALKALOID RELATIVE ABUNDANCE (%) IN *Conium maculatum* FROM ILLINOIS (IL), NEW YORK (NY), AND WASHINGTON (WA)

	Retention time (min)	IL	NY	WA
Total alkaloids		2.49[a]*	4.07[b]	6.48[b]
Coniine	5.7	[1.1][a] [(50.9%)]	0[b]	0[b]
γ-Coniceine	6.5	2.0[a] (80.8%)	3.96[b] (97.3%)	5.94[b] (91.7%)
Conhydrinone	10.0	0.22[a] (9.02%)	0.08[a] (1.96%)	0.37[b] (5.72%)
RT 12	11.9	0.07[a] (2.73%)	0.03[b] (0.68%)	0.16[c] (2.51%)

*Different letters indicate significant differences among regions at $P < 0.05$ by Tukey's *post hoc* comparisons test. Values of coniine shown in brackets indicate the average concentrations for the 16% of plants from the Illinois population that contain those alkaloids.

levels of *A. alstroemeriana* herbivory (Figure 4). No significant trends were found for herbivory levels relative to N concentrations (Figure 4).

Herbivory and Alkaloids. The number of leaf rolls in plants from Illinois, used as an estimate of *A. alstroemeriana* herbivory, was marginally negatively

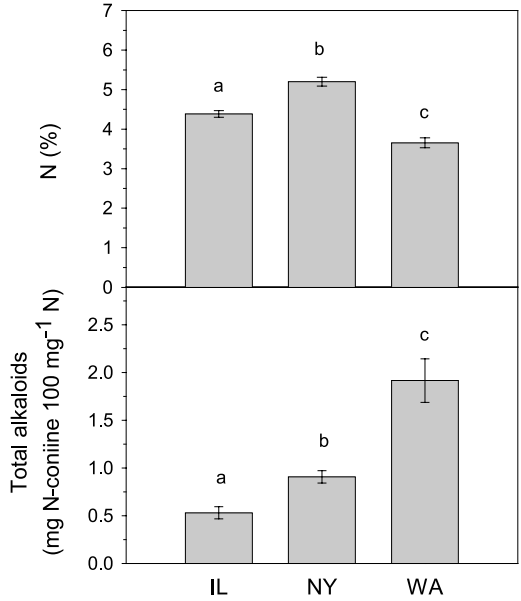

FIG. 3. Total N and total alkaloid concentrations (mean ± SE) expressed on N basis of *C. maculatum* growing in Illinois (IL), New York (NY), and Washington (WA). Different letters indicate significant differences at $P < 0.05$ by Tukey's *post hoc* comparisons.

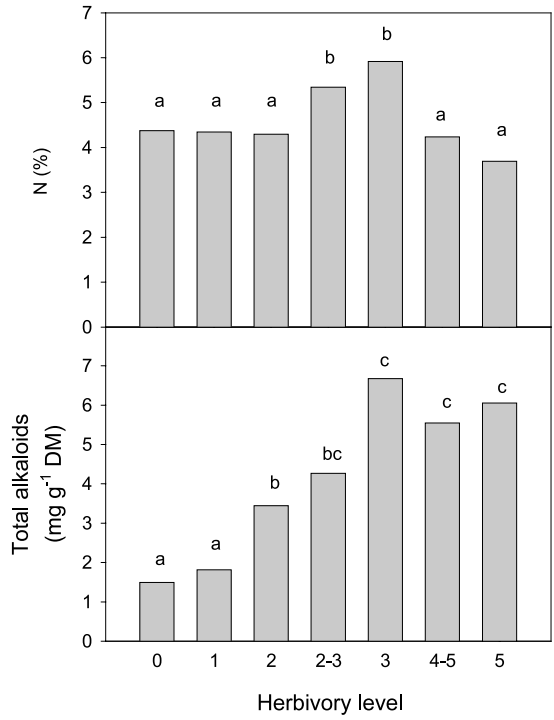

FIG. 4. Mean of N and total alkaloid concentrations at different *A. alstroemeriana* herbivory levels, from 0 to 5 with increasing levels of herbivory, as described in Methods and Materials. For total alkaloids, the back-transformed mean is shown. Different letters indicate significant differences at $P < 0.05$ by Tukey's *post hoc* comparisons.

correlated with total alkaloids (Figure 5a). In a multiple regression analysis, the number of leaf rolls was significantly correlated with γ-coniceine (Figure 5b), but no significant relationships were found for coniine, conhydrinone, or RT 12 (data not shown).

DISCUSSION

Poison hemlock has been established in Illinois for over 100 yr (Vasey, 1861; Patterson, 1876; Jones and Fuller, 1955). Despite the fact that the plant is extremely abundant locally, intermittent inspection over the last decade has consistently revealed few insect associates and little leaf damage by herbivores (personal observation). This same pattern has been documented in other parts

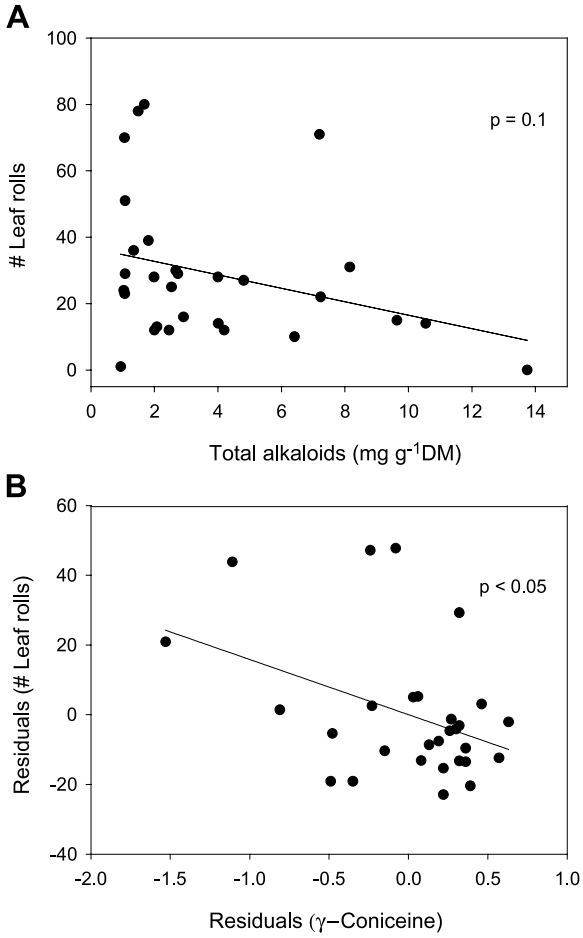

FIG. 5. (A) Simple regression between total alkaloid concentration and number of leaf rolls of 29 *C. maculatum* plants from Illinois. (B) Correlation between the residuals of γ-coniceine and the residuals of leaf roll number after performing multiple regression analyses with the independent variables coniine, γ-coniceine, conhydrinone, and RT 12.

of the United States—by Berenbaum (1981) in central New York and by Goeden and Ricker (1982) in southern California. Failure of insects to colonize this plant in large numbers over historical time may be attributable to its formidable array of chemical defenses. However, populations of poison hemlock in several localities in the United States are now experiencing unprecedented levels of herbivory because of colonization by and population

growth of *A. alstroemeriana*. It is of ecological and evolutionary interest to monitor changes in plant secondary compounds that may accompany this colonization. In this study, the chemistry of poison hemlock populations largely free from *A. alstroemeriana* (Illinois populations) was compared to populations in which *A. alstroemeriana* has become successfully established (New York and Washington populations) to determine under field conditions whether these herbivores, touted as potential biocontrol agents (http://www.bio-control.com, http://www.integratedweedcontrol.com), could reduce plant fitness and at the same time select for chemically based resistance factors (Berenbaum et al., 1986).

Changes in plant resource allocation between growth and chemical defenses driven by herbivore selective pressures have been discussed by the "optimal defense" hypothesis (Zangerl and Bazzaz, 1992) and the derivative "evolution of increased competitive ability" hypothesis, formulated in the context of invasion biology (Blossey and Nörtzold, 1995). According to these theoretical frameworks, when a plant species invades a new habitat where its native herbivores are absent, those genotypes with higher investments in growth and/or reproduction and reduced investments in defense are expected to have higher fitness and to increase their frequencies in the population. A logical corollary to this hypothesis is that defense investments should increase in the area of introduction commensurate with increases in herbivory, either by newly colonizing native species or by reassociation with introduced enemies from the area of indigeneity (as in the case of biological control). With the reassociation between the plant and the herbivore, such is the case of *C. maculatum* and *A. alstroemeriana*, the genotypes with increased levels of chemical defense should be favored by selection, particularly if, as is suggested in our study, high levels of alkaloid defense are deterrent to *A. alstroemeriana*. We found that C. maculatum plants from populations experiencing high levels of *A. alstroemeriana* herbivory (New York and Washington) had higher alkaloid concentrations in foliage than plants under lower levels of herbivory (Illinois). Because alkaloid concentrations in other species tend to increase with higher plant N availability (Gershenzon, 1984), concentrations in *C. maculatum* foliage were also analyzed to determine whether variation in the geographic pattern in *C. maculatum* alkaloid production could be related to differences in soils among regions. Nitrogen concentrations in the three populations varied significantly, with higher concentrations in New York and lower concentrations in Washington, but these differences were not consistent with the observed differences in alkaloid concentrations. Plants from New York and Washington invested two and four times more N to alkaloid synthesis, respectively, compared with plants from Illinois. In Washington populations, higher allocation of N to alkaloids was accompanied by lower total N concentration in foliage, which is suggestive of selection for higher constitutive or inducible alkaloid levels under more intense herbivory. Mechanistically, this pattern may

result from greater mortality on or avoidance of high levels of alkaloids by *A. alstroemeriana*; the negative relationship between the number of leaf rolls, and thus herbivory intensity, and the total alkaloid concentrations or γ-coniceine concentrations in Illinois plants is consistent with an increase in larval mortality with higher alkaloid concentrations.

Other environmental factors, such as water availability, could contribute to variation in the concentrations of alkaloids in *C. maculatum* across the United States. The different levels of alkaloid concentrations observed may reflect differential induced responses to herbivory (Castells et al., unpublished). Future studies, including a common garden experiment, will be necessary to determine definitively whether the geographic differences in alkaloids are genetically based and the result of a selection response to herbivory.

Although it was not deliberately introduced into the United States for biological control, *A. alstroemeriana* has demonstrated potential for systematic use as a biocontrol agent for poison hemlock. In the western United States, this insect has quickly become established naturally in infested locations and has established itself when it has been intentionally released (Piper, personal communication). Where it is established, it causes severe injury, including complete defoliation and destruction of inflorescences (Anonymous, 1995). However, the value of a biological control agent must be assessed not only by its ecological effect on population sizes, but also by its evolutionary impact on its target host plants. This study suggests that successful biological control agents may have the potential to alter the chemistry of their host plant, leading to increased allelochemical content, and potentially greater toxicity to livestock and humans who mistakenly ingest it.

Acknowledgments—We thank Dr. Paul Feeny and Dr. Gary Piper for their help in locating and sampling *C. maculatum* in Washington and New York, respectively. We also thank Lauren Jakubowski for field assistance. E.C. has a Fulbright-MECD (Spain) fellowship.

WITHIN-PLANT VARIATION IN GLUCOSINOLATE CONCENTRATIONS OF *Raphanus sativus* ACROSS MULTIPLE SCALES

ANGELA L. SHELTON*

(Received March 19, 2004; revised March 28, 2005; accepted April 6, 2005)

Abstract—Variation in chemical defenses remains underexplored. In particular, little is known about patterns of variation at small scales within leaves and spatial variation of induction. I examined variation in glucosinolate concentrations in the leaves of *Raphanus sativus* at several different spatial scales in two related experiments. I used samples equivalent in area to the amount an intermediate-sized caterpillar might eat in 1 d, a smaller scale than used in most previous studies. I examined variation due to induction and leaf age and small-scale spatial variation within leaves. The mean and variance of glucosinolate concentrations were higher in induced plants, young leaves, and the proximal half of leaves. Higher glucosinolate concentrations in the proximal half of leaves are previously unreported. Small-scale variation was extreme, accounting for 57% of the total random variation, and spatially random. There was no spatial autocorrelation found at scales as small as 1–2 cm. The high degree of small-scale, spatially random variation in glucosinolate concentrations in leaves is previously unreported. This small-scale variation and the variation caused by induction may have significant effects on herbivores and could be an important component of plant defense.

Key Words—Chemical defenses, induction, spatial patterns, small-scale variation, *Raphanus sativus*, glucosinolates.

INTRODUCTION

Many plants have high degrees of variation in chemical defenses, and numerous authors have proposed hypotheses about why this variation has been maintained and how it might improve the effectiveness of a plant's defense (e.g., Denno and McClure, 1983; Berenbaum, 1995; Hartmann, 1996). Spatial variation in defenses within or among individuals could slow the evolution of resistance by herbivores by creating uneven selective pressure on herbivores (Dolinger et al., 1973; Whitham, 1981, 1983; Schultz, 1983b). Chemical variation might also improve the effectiveness of a defense in ecological time. A plant that can change its defensive phenotype in response to damage may become a "moving target" for herbivores (Adler and Karban, 1994). If defenses have nonlinear effects on herbivores, such that high doses have much stronger effects than low or moderate doses, a plant may have a stronger defense if it distributes its defenses unevenly (Karban et al., 1997; Shelton, 2000).

Induction of defenses is currently the most thoroughly examined source of variation in chemical defenses. When a plant systemically increases its levels of defense in response to herbivores, this increases the spatial variation within a population of plants and increases temporal variation within a plant. Only a few studies, however, have examined how induction affects spatial variation within an individual. Orians et al. (2000) examined the induction of proteinase inhibitors (PIs) in tomato plants in each leaf in response to mechanical damage of the second leaf. They found that vascular connections among leaves had strong effects on induction: some leaves had large increases in PIs in response to the damage, others had slight increases, and still others had no increase at all, depending on the strength of vascular connections to the damaged leaf.

There also has been little effort to document patterns of chemical variation within leaves at the small scales relevant to herbivorous insects. Individual leaves or leaflets are usually the smallest scale examined. For many small herbivores, however, smaller scales may have important effects. Only a handful of studies have looked at chemical variation within individual leaves (Whitham, 1983; Niemalä et al., 1984; Stout et al., 1996; Orians, 2002), and these have shown variation within leaves. For many small herbivores with limited mobility, small-scale variation may be important (Shelton, 2004), and patterns at larger scales may not accurately represent the variation that exists at smaller scales.

Another aspect of chemical variation that has not been sufficiently examined is variation that cannot be explained by predictable patterns. Most studies have examined chemical variation due to environmental variation caused by light, moisture, or nutrient levels (e.g., Louda and Rodman, 1983a; Mattson and Haack, 1987) or in reference to optimal defense theory (McKey, 1974; Rhoades and Cates, 1976), which states that valuable or threatened parts of

plants should be protected more than other parts. Even after predictable patterns are accounted for, a great deal of variation remains unexplained (see Denno and McClure, 1983), and the potential consequences of this unpredictable variation on herbivore behavior and fitness have not been explored.

In this paper, I examine chemical variation at multiple spatial scales within *Raphanus sativus* plants, including small-scale variation within individual leaves, and at three different levels of damage. I used leaf samples of a size equivalent to that eaten by an intermediate-sized caterpillar in one feeding bout (Shelton, data not shown), so the smallest scale of variation corresponds to a biologically relevant size for these herbivores. *Raphanus* is an excellent study system for the study of chemical variation because its chemistry, particularly of predictable patterns of variation of glucosinolates, is well documented (e.g., Larsen, 1981; Feeny and Rosenberry, 1982; Louda and Rodman, 1983b; Chew, 1988; Rosa and Rodrigues, 1998) as is its induced response to damage by herbivores (e.g., Bodnaryk, 1992; Agrawal et al., 1999).

Here, I present the results of two observational experiments that build on the known patterns of glucosinolate distribution. I examined two levels of damage, two leaf ages, and four regions of individual leaves, subsequently three levels of damage, and focused on the spatial arrangement of small-scale variation of glucosinolates within leaves. These experiments reveal new information about the effect of induction on variation of glucosinolates, the magnitude of variation at different scales, and the patterns and variation in glucosinolates at small scales within individual leaves.

METHODS AND MATERIALS

Study System. R. sativus (Brassicaceae) is a cosmopolitan, herbaceous annual plant. It is common in disturbed areas, roadsides, and agricultural fields in northern California. Like all members of the Brassicaceae family, its dominant defenses are glucosinolates, which are effective against an array of pathogens and nonspecialized herbivores (Ettlinger and Kjaer, 1968; Chew, 1988). Glucosinolates are attractants for a number of specialist herbivores (e.g., Chew, 1975; Siemens and Mitchell-Olds, 1996) but may be deleterious even to some of these specialists at high doses (Agrawal and Kurashige, 2003). At least 15 different glucosinolates have been isolated from *R. sativus* (Fahey et al., 2001), many of which, primarily indole glucosinolates, are inducible, increasing in response to damage by herbivores (Koritsas et al., 1991; Bodnaryk, 1992; Doughty et al., 1995; Agrawal et al., 1999). These compounds differ in their inducibility (Fahey et al., 2001) and effects on herbivores (Louda and Mole, 1991; Renwick, 1996; Lambrix et al., 2001). I measured only total glucosinolate

concentration. Total glucosinolate concentration is a conservative measure of chemical variation because analysis of specific glucosinolates would magnify variation.

I collected *R. sativus* seeds from wild populations growing in Santa Cruz, CA, USA, planted seeds from the current year in 15.25-cm pots with ProMix HP soil mix topped with 1 cm of vermiculite, and weeded the pots to a single seedling after germination. Plants were kept in the Thimann Greenhouse at UC Santa Cruz at ambient light and temperature. All plants were pest-free throughout the experiment (with the exception of the herbivores used to impose the damage treatments). Plants were kept far enough apart to prevent any shading, and because all experiments were completed while plants were still rosettes, there was no self-shading. The plants were watered as needed, with plain water during the first 2 wk, and with 100-ppm solution of Peter's 20:20:20 N/P/K fertilizer thereafter.

Plants for Exp. A were grown from August to September of 1999. Plants for Exp. B were grown from May to August 2001. Because of logistical constraints, each of the three damage treatments in Exp. B was applied to a separate group of plants grown at different times in summer 2001. This confounds the treatment effect with any potential time effect, although such effects are likely to be minimal because of the controlled conditions in the greenhouse. In addition, I found similar effects of damage in Exp. A, in which all plants were grown at the same time, and in other experiments (Shelton, 2002, and unpublished data).

Experimental Design. I used one level of damage in Exp. A, one leaf eaten by caterpillars (low damage), and compared it with undamaged controls. In Exp. B, I added an additional damage level of two leaves eaten by caterpillars (high damage; Table 1). Damage treatments and sampling were performed according to the developmental age of the plant. One week after the seeds germinated,

TABLE 1. SUMMARY OF THE LEVELS OF EACH TREATMENT USED IN EACH EXPERIMENT

	Experiment A	Experiment B
Damage levels (no. of leaves eaten)	No damage (0) Low damage (1)	No damage (0) Low damage (1) High damage (2)
No. of plants/treatment	10 (no damage) 10 (low damage)	6 (no damage) 5 (low damage) 4 (high damage)
Leaf ages	1 young 1 old	1 young
Leaf parts (replicates per part)	Main leaflet (12), Proxima leaflets (4)	Main leaflet (7–25), Proxima leaflets (0–25)

I placed a *Pieris rapae* (Lepidoptera: Pieridae) caterpillar on each leaf to be damaged. At this time, most plants had two true leaves (range two to four leaves). For the low damage treatment, I placed a caterpillar on the first true leaf, and for the high damage treatment, I placed caterpillars on both the first and second true leaves. I restricted caterpillars to a single leaf with clip cages (constructed from 4-cm plastic petri dishes with the edges padded to protect the leaf, drilled with ventilation holes, and attached to an aluminum hair clip). At the time of the damage, leaves were small enough to fit entirely within the cages, so there was minimal damage from the cage. I removed the cages and caterpillars once they had entirely consumed the leaf (2–3 d).

I sampled plants in the undamaged and low damage treatments 2 wk after germination, when plants had produced four to six leaves (counting the consumed leaves). Because essentially all the true leaves were consumed in the high damage treatment, there were no leaves to sample at the 2 wk point. Therefore, I sampled the high damage plants 3 wk after germination, when they had regrown one to two leaves that were at the same developmental stage as the leaves sampled in the other treatments.

Developmental age of leaves has strong effects on glucosinolate concentrations, particularly the degree of leaf expansion (Porter et al., 1991; Fahey et al., 2001), so I sampled leaves at the same developmental stage, rather than the same absolute age or leaf number. In Exp. A, I sampled one young leaf, and one mature leaf, which I defined as the youngest fully expanded leaf, from each of 10 plants. Young leaves varied in leaf number (first true leaf = 1) from 3 to 5, and old leaves were leaves 1–3. In Exp. B, I sampled one young leaf only from

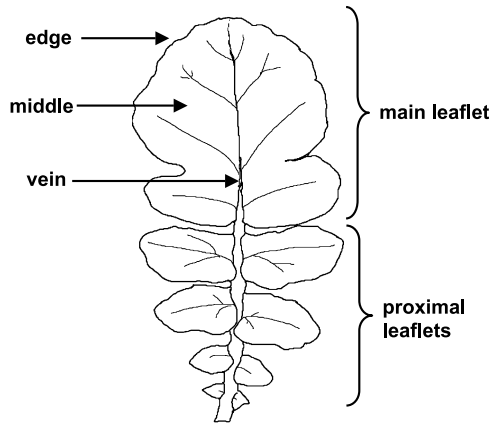

FIG. 1. Diagram of a typical leaf of *Raphanus sativus* indicating the regions of the leaf defined in Exp. A.

four to six plants in each treatment. I defined young leaves as the leaf closest to 50% of full expansion.

In Exp. A, I defined four regions of each leaf (Figure 1): three parts of the main terminal leaflet—the area including and within 1 cm of the midvein (vein), the area within 1 cm of the edge of the leaf (edge), and the rest of the main leaflet (middle)—and the proximal leaflets (leaflets). I cut four samples from each of the four leaf regions (for a total of 16 samples per leaf). The precise location within a defined region of the leaf varied among leaves.

In Exp. B, I sampled the entire leaf by dividing it into a grid of samples. I cut each leaf from the plant and scanned the leaves to a digital image. I then cut each leaf into separate samples with a razor blade and marked the spatial arrangement of the samples on the digital image. The area of samples was chosen to correspond to the amount eaten in 1 d by a third to fourth instar *Trichoplusia ni* caterpillar (Shelton, unpublished data). Glucosinolates tend to be present at high concentrations in young leaves and decrease as the leaf expands (Porter et al., 1991). As a result, leaf area may not be an ideal measure for glucosinolate concentration in rapidly expanding leaves. Therefore, I divided leaves according to the size and shape of the leaf rather than strictly controlling for area. The area of samples varied among the damage treatments (mean area = 2.7 cm^2 in no damage, 3.4 cm^2 in low damage, and 1.3 cm^2 in high damage). Smaller area of samples could overestimate variation within a leaf. To test whether this influenced the results, I summed the glucosinolate concentration of adjacent pairs of samples in the high damage treatment and statistically analyzed the data with these pairs treated as a single unit to increase the area of each sample. This had no qualitative difference on any of the results.

Chemical Analyses. Glucosinolates are stable and inactive in their intact form, but when cells are damaged, glucosinolates are exposed to thioglucosidase enzymes that break them into glucose and their composite mustard oils. I avoided degradation of glucosinolates by cutting samples from the leaves with a razor blade to minimize cell damage and the release of the enzymes. Within 15 min of removal from the plant, I cooked the samples in a microwave oven at full power for 2 min to denature the enzymes (Chew, personal communication). This method of heating has been shown to result in almost no residual myrosinase activity (Verkerk and Dekker, 2004). There was no detectable change in glucosinolate concentration between removal from the plant and completion of cooking of all samples (Shelton, unpublished data). I dried the samples in a 40°C oven overnight and stored them until analysis. Immediately before chemical analysis, each dried sample was weighed to the nearest 0.1 mg to standardize the chemical results to glucosinolate concentration per gram of dry leaf.

I quantified total glucosinolate concentrations following the protocol originally developed by Heaney and Fenwick (1981), modified by Siemens

and Mitchell-Olds (1996), and further modified by Stowe (personal communication). This method uses ion-exchange columns to isolate the glucosinolates, and then thioglucosidase enzyme is added to split off the glucose. Each molecule of glucosinolate releases one molecule of glucose, so glucose concentration is a direct proxy for the glucosinolate concentration. I ran two replicates for each sample with a glucose-reacting color reagent and measured the absorbance of the samples on a Labsystems Multiskan MCC/340 plate-reading spectrophotometer at 492 nm. I used DeltaSoft 3 spectrophotometer software (version 2.243 for the Macintosh, BioMetallics, Inc., 1999) to calculate the glucosinolate concentrations from glucose standards on each plate and divided these results by the sample weight to obtain glucosinolate concentration in μmol glucose/g dry leaf.

Spatial Analyses. I plotted the results of Exp. B using ArcView GIS software (v. 3.1) to visualize spatial patterns and to measure the distance between pairs of samples. I tested for spatial autocorrelation by calculating a variogram (Cressie, 1991) for each leaf with 1-cm increments. I determined confidence intervals for each variogram with randomization tests (Crowley, 1992; Hilborn and Mangel, 1997). To do this, I shuffled the measured glucosinolate concentrations within each leaf while retaining the spatial arrangement of samples, and then calculated a variogram for the randomized data. I used 10,000 randomizations per leaf and computed the 95% confidence intervals from the frequency distribution of the randomizations.

Statistical Analyses. I compared the differences in mean glucosinolate concentrations among treatments, leaves, and leaf regions with an ANOVA for each experiment. Even after $\log_{10}$ transformation, some heteroscedasticity remained, but because sample sizes are large, the data are reasonably balanced, and there was not a single group with particularly high variance, it should not significantly affect the results of the ANOVA (Underwood, 1997). The nested design of these experiments combined with the fixed effects of damage, leaf age, and leaf region includes both fixed and random effects.

The model for Exp. A includes the leaf and leaf region terms twice, once as a fixed effect and again as a nested random effect. This was necessary to separate the fixed effect of leaf age and leaf region across leaves, as well as to account for the random variation due to the specific leaf analyzed and the specific parts of the leaf that were sampled from a specified leaf region. The model for Exp. A was $G_{ijklmn} = \mu + T_i + A_k + B_l + P_{j(i)} + L_{k(ij)} + R_{l(ijk)} + S_{m(ijkl)} + \varepsilon_{n(ijklm)}$, where G is the log-transformed glucosinolate concentration of chemical replicate n of leaf sample m from region l on a leaf of age k on plant j with treatment i. T_i is the fixed effect of damage treatment, A_k is the fixed effect of leaf age, and B_l is the fixed effect of leaf region. The random effect of individual plant j in treatment i is represented by $P_{j(i)}$, $L_{k(ij)}$ is the random effect of a leaf, $R_{l(ijk)}$ is the random effect of the specific samples within a leaf region, and

TABLE 2. TOTAL GLUCOSINOLATE CONCENTRATIONS[a] FOR EACH LEVEL OF DAMAGE

	Treatment		
	No damage	Low damage	High damage
Exp. A			
Young leaves			
Main leaflet	7.27 ± 4.22 (116)	9.94 ± 6.16 (114)	
Edge	7.02 ± 4.50 (39)	9.82 ± 6.51 (40)	
Vein	7.14 ± 4.12 (38)	9.42 ± 6.28 (36)	
Middle	7.66 ± 4.11 (39)	10.55 ± 5.76 (38)	
Proximal leaflets	9.00 ± 5.85 (38)	13.82 ± 9.37 (39)	
Old Leaves			
Main leaflet	4.04 ± 2.88 (120)	7.11 ± 4.33 (124)	
Edge	4.35 ± 3.97 (40)	6.20 ± 3.70 (42)	
Vein	4.06 ± 2.05 (40)	7.23 ± 3.87 (40)	
Middle	3.74 ± 2.26 (40)	7.93 ± 5.12 (42)	
Proximal leaflets	5.47 ± 3.54 (36)	12.76 ± 10.47 (32)	
Exp. B			
Young leaves			
Main leaflet	3.46 ± 1.61 (64)	5.23 ± 2.66 (55)	9.85 ± 8.34 (90)
Proximal leaflets	3.40 ± 2.20 (37)	5.36 ± 3.52 (30)	10.51 ± 10.30 (60)

[a] Glucosinolate concentrations are means ± standard deviation in μmol glucosinolate/g dry leaf weight. Sample sizes are in parentheses.

$S_{m(ijkl)}$ is the random effect of individual leaf samples within a specific leaf region.

Exp. B did not include a fixed effect for leaf age because only young leaves were examined, and because the entire leaf was sampled, there is no random effect of samples within a leaf region. Thus, the statistical model was $G_{ijklm} = \mu + T_i + P_{j(i)} + B_k + S_{l(ijk)} + \varepsilon_{m(ijkl)}$ where G is the log-transformed glucosinolate concentration of chemical replicate m of plant sample l within region k of plant j in treatment i. T_i is the fixed effect of damage treatment, $P_{j(i)}$ is the random effect of plants, B_k is the fixed effect of leaf regions, $S_{l(ijk)}$ is the random effect of samples within a leaf region, and $\varepsilon_{m(ijkl)}$ is the experimental error. I determined the appropriate tests for each factor from the expected mean squares (Tables 2 and 3).

Because I was also interested in differences in variation in addition to mean differences, I used Levene's test for homogeneity of variances (Snedecor and Cochran, 1989) to test for differences in variation among damage treatments and among leaves within damage treatments. I performed these tests on the untransformed data because it better represents the variation experienced by caterpillars. I did all of the statistical analyses in PROC GLM of SAS version 6.12 for the Macintosh.

RESULTS

Differences Among Damage Treatments. Damage by herbivores increased both the mean and variation of glucosinolate concentrations in both experiments (Table 2). Consumption of one leaf increased glucosinolate concentrations approximately 1.5 times compared to the undamaged treatment in both experiments, and consumption of two leaves increased concentrations by 2.9 times. The increase in glucosinolates due to damage treatments was statistically significant in Exp. A (Table 3) but not in Exp. B (Table 4). This may be due to reduced power in Exp. B because fewer plants were examined. Variation of glucosinolates was significantly higher in the damaged treatments for both experiments (Levene's test: Exp. A, $F = 7.95$, $P = 0.011$; Exp. B, $F = 32.95$, $P < 0.001$). Among the three damage treatments in Exp. B, the high damage treatment had significantly higher variation than the undamaged treatment (Tukey's test, $P < 0.05$).

Differences Among Leaves. Young leaves had significantly higher glucosinolate concentrations than old leaves (Table 3). According to Levene's test, young leaves were also more variable than older leaves ($F = 15.15$, $P < 0.001$). There were differences among leaves within a damage treatment (random effects) in both Exps. A and B. Exp. A includes separate effects for plants and

[b] Variance components were calculated only for random effects.

leaves because both old and young leaves were sampled from each plant. The leaf effect was significant, but the plant effect was not (Table 3). Only one leaf per plant was sampled in Exp. B, so differences among leaves and plants are confounded. This plant/leaf effect was significant and contributed about 34.5% of the random variation in the data (Table 4). This is comparable to the sum of the random variation explained by the separate plant and leaf effects in Exp. A (38.5%).

Glucosinolate concentrations in Exp. B, which included only young leaves, were lower than concentrations for young leaves in Exp. A (Table 2). The reasons for this are unclear because the plants were of the same age, and the leaves were of the same relative age. It may be a result of differences in seeds or greenhouse conditions between years. The range of glucosinolate concentrations varies widely in other studies because of environmental or genetic effects. The values in both experiments of this study correspond to values found for similar species in other studies (Fahey et al., 2001; Agrawal and Kurashige, 2003; Brown et al., 2003).

Within-Leaf Spatial Patterns. Among the four leaf regions examined in Exp. A, the proximal leaflets had significantly more glucosinolates than all three regions of the main leaflet (Table 3). The three regions of the main leaflet (edges, veins, and middle) were not statistically different from each other. Proximal leaflets did not differ from the main leaflet in Exp. B (Table 4). However, there was a tendency for the proximal half of a leaf to have higher glucosinolate concentrations than the distal half. Of the highest 10% of observed glucosinolate concentrations in Exp. B, 82% (28 of 34) were in the proximal half of leaves ($X^2 = 11.155$, $P < 0.001$). The random variation among samples within a single leaf region was highly significant and accounted for approximately 57% of the total random variation in both experiments (Tables 3 and 4). This means that the

differences in glucosinolate concentrations among the replicate samples from a single leaf region (e.g., proximal leaflets) of one leaf were extremely variable.

This variation can be visualized in Figure 2, which shows the glucosinolate concentration for each section of the leaves in Exp. B. The glucosinolate

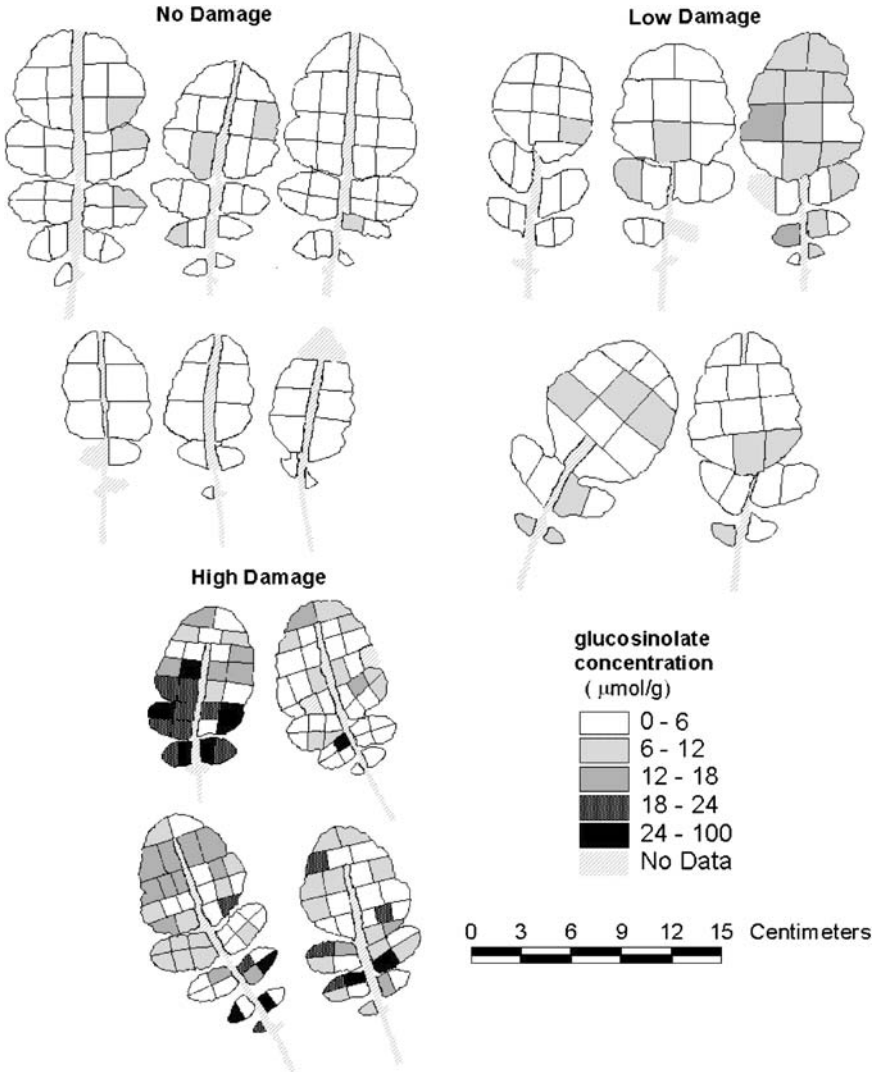

FIG. 2. Spatial distribution and glucosinolate concentrations of samples in Exp. B. Glucosinolate concentrations are measured as μmol/g dry leaf.

concentrations are patchily distributed within leaves, particularly in the high damage treatment. Leaves in the undamaged treatment had little variation among samples in a leaf, and leaves in the high damage treatment had a great deal of variation within a leaf. In addition, the frequency of high glucosinolate concentrations increased with the amount of damage.

Variograms for each leaf in Exp. B confirm the patchy distribution of glucosinolates. A variogram that increases with distance indicates spatial auto-

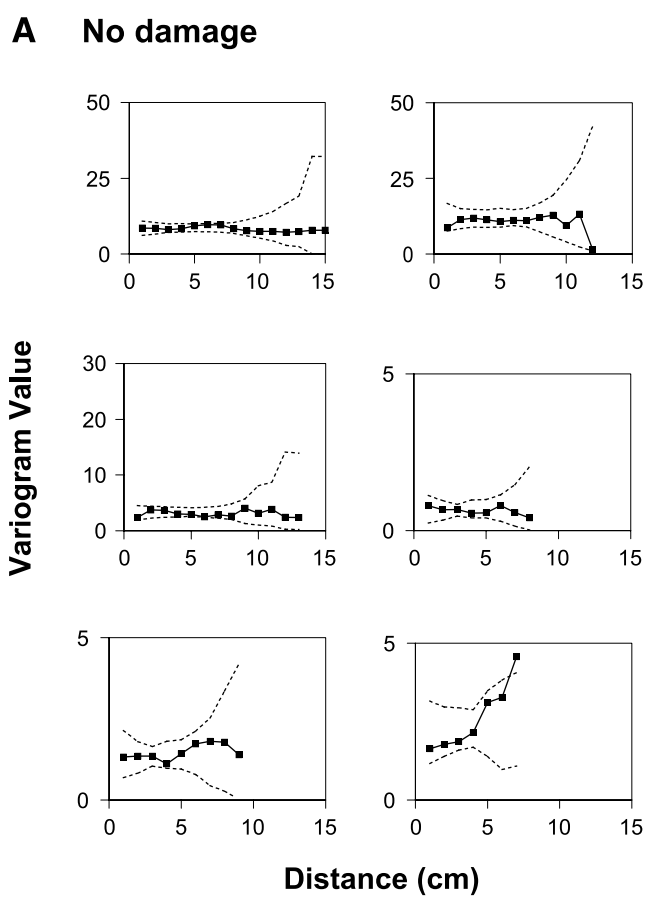

FIG. 3. Variograms for leaves from the no damage (A), low damage (B), and high damage (C) treatments in Exp. B. Solid lines are the variograms. Dotted lines are the 95% confidence intervals as determined by randomization tests. The differences in scales for the variograms are due to differences in the relative magnitude of variation within leaves.

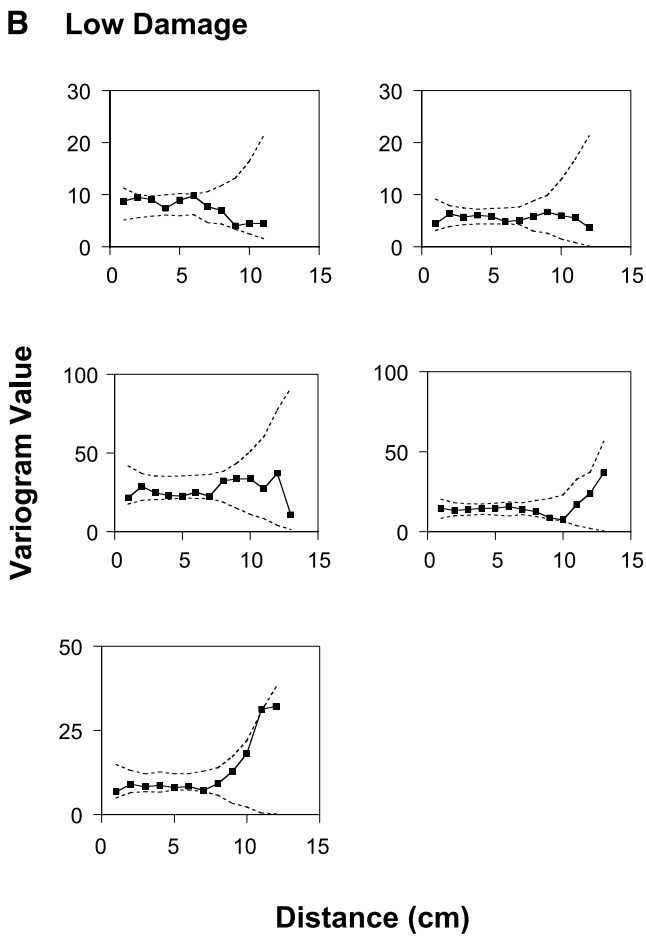

FIG. 3. Continued.

correlation, i.e., the closer the two samples are on the leaf, the more similar they are. A variogram that is level with respect to distance indicates that sample values are randomly distributed with respect to their distance from one another. The glucosinolates appear to be spatially random, indicated by the flat relationship of the variograms to distance (Figure 3). In the variograms for each leaf, only 7 of the 157 total points (15 leaves × 8–15 distances/leaf) fell outside the confidence intervals, matching the expected number according to a binomial probability at the 5% level (binomial mean, $N \times P = 157 \times 0.05 = 7.85$). This indicates that there is no spatial autocorrelation in the data at this scale. The

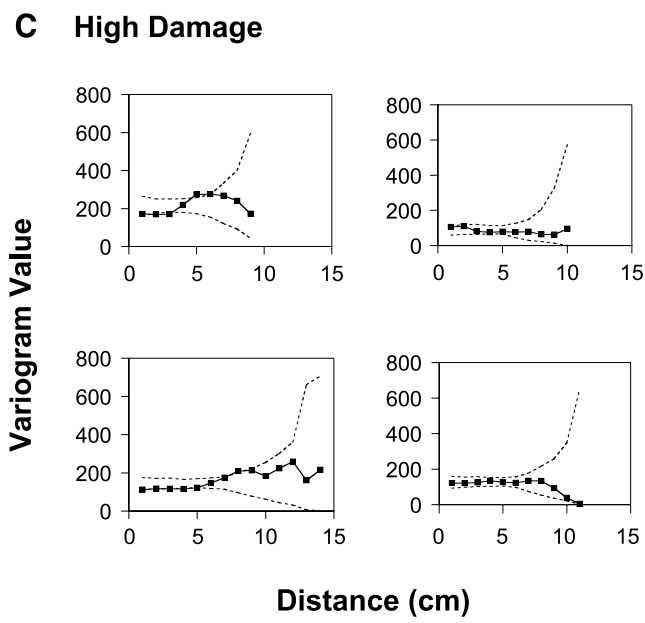

FIG. 3. Continued.

lack of spatial autocorrelation in these data may seem to contradict the differences in the frequency of high glucosinolate concentrations between the proximal and distal halves of leaves. However, because variograms examine samples in all directions from a focal point, they are not likely to detect a difference along a single gradient. The differences in the scales of the variograms among the three damage treatments are a result of the differences in variation among these treatments, but some of the increased variation in the high damage treatment is a statistical artifact due to the smaller size of samples.

The different factors that resulted in higher glucosinolate concentrations—herbivore damage, young leaf age, and proximal part of the leaf—all contributed to increased variation within leaves and to an increased frequency of high glucosinolate concentrations. Few samples from the least defended leaf type (undamaged, old leaves, main leaflets) had glucosinolate concentrations greater than 10 μmol/g, but over half the samples from the most defended leaf type (damaged plant, young leaf, leaflet) had concentrations this great (Figure 4). However, in leaf types with intermediate mean concentrations, the majority of samples had relatively low concentrations. Even in the most defended leaf types, low concentrations of glucosinolates are common (Figure 4).

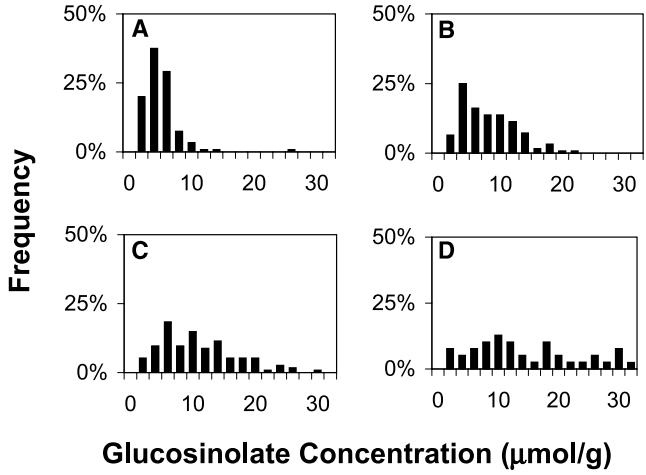

FIG. 4. Frequency of samples in Exp. A with different glucosinolate concentrations for four representative leaf types. Both the mean and variance of glucosinolates increased with the inclusion of each factor that led to higher defenses (damaged plant, young leaf, and proximal leaflets). The individual leaf types differed significantly in variation (Levene's test, $F = 8.71$, $P < 0.001$). Leaf type with the lowest mean and variation of glucosinolates: main leaflets of old leaves on undamaged plants (A). Intermediate glucosinolates: main leaflets of old leaves on damaged plants (B). Intermediate glucosinolates: main leaflets of young leaves on damaged plants (C). Leaf type with the highest mean and variation of glucosinolates: proximal leaflets of young leaves on damaged plants (D). Glucosinolates are μmol/g dry leaf weight.

DISCUSSION

There are three key results from this study. First, damage by herbivores not only increased mean concentrations of glucosinolates but also significantly increased the variation of glucosinolates. Second, the smallest scale examined—variation among samples within a specific region of a leaf—had the greatest variation of any of the scales examined, and this variation was spatially random within a leaf. Third, the proximal half of leaves had higher mean and variation of glucosinolates than the distal half of leaves.

Damage by herbivores increased the degree of small-scale stochastic variation. Damage and other factors, such as young leaf age or the proximal part of a leaf, that caused an increase in the mean concentration of glucosinolates did not cause higher glucosinolate concentrations throughout the leaf, but rather caused an increase in the frequency of high glucosinolate concentrations. Low concentrations were still common even in the leaves with the highest mean

concentrations (Figure 4). These results indicate that induction did not uniformly increase glucosinolate concentrations in a leaf. Concentrations increased dramatically in a few small patches of the leaf, and other parts were relatively unchanged.

Variation among samples within a leaf part accounted for 57% of the random variation in both experiments. Variation among leaves and plants explained only 34–38% of the random variation. Such high variation at a small scale is unusual and indicates that a great deal, perhaps the majority, of the variation in glucosinolate concentrations occurred at this small scale. The spatial results from Exp. B indicated that glucosinolate concentrations in adjacent samples were uncorrelated. This small-scale variation was the result of extreme patchiness of glucosinolates within leaves, which was spatially random.

The proximal part of leaves, defined as the distinct proximal leaflets in Exp. A and as the proximal half of the leaf in Exp. B, had higher means and variances than the distal part of leaves. To my knowledge, differences in glucosinolate concentration among different parts of leaves have not been previously reported in the Brassicaceae.

The differences due to damage and leaf age followed the predictions of optimal defense theory: previous damage presumably indicates an increased risk of future damage, and young leaves are more valuable because they have a higher future photosynthetic potential (Harper, 1989). Glucosinolate concentrations have also been shown to be higher in young leaves due to dilution of the chemicals through leaf expansion (Porter et al., 1991; Brown et al., 2003). It is less clear why the proximal part of leaves had higher levels of glucosinolates than the distal part. This pattern may be adaptive if herbivores often crawl onto a leaf from the base of the petiole and use the quality of the proximal part of the leaf as an indication of the quality of the leaf as a whole. In this case, plants may gain protection for the whole leaf by allocating more defenses to the proximal part of the leaf, causing it to act as a barricade for the rest of the leaf. This pattern might also be nonadaptive and purely physiological, resulting from vascular architecture, differences in cell size, or other factors. Behavioral experiments with herbivores are necessary to determine whether there is an adaptive purpose for higher glucosinolates in the proximal half of leaves.

Only a handful of other studies have directly examined patterns of chemical variation within plants. Suomela and Ayres (1994) and Suomela et al. (1995) compared several different traits, including concentrations of phenols, carbohydrates, and nitrogen across multiple different scales in the leaves of mountain birch. For most of these traits, the majority of variation was explained by the highest level differences among trees. This is the reverse of the pattern seen in glucosinolate concentrations in *R. sativus*. A gradient of defensive chemicals along the length of leaves has previously been reported for *Populus*

angustifolia, but the pattern is the opposite of that found in *R. sativus* leaves. Phenolics are higher at the tips of *P. angustifolia* leaves than at the base, and this difference causes aphids to preferentially place galls at the base of leaves (Whitham, 1981; Zucker, 1982).

Stout et al. (1996) examined within-plant spatial variation in induction by comparing the levels of several chemical defenses at different leaf and leaflet positions in relation to the site of the experimental damage. They found that damaged plants were more variable than undamaged plants: they found different patterns of induction at different leaf positions for each of the chemicals examined. In addition, the standard error of chemical concentrations was higher in damaged plants compared with undamaged plants. Vascular connections can explain some of the variation in induction. Orians et al. (2000) showed that in tomato plants, the near side of leaves adjacent and orthostichous to a damaged leaf had high levels of induction of proteinase inhibitors. The far side of these leaves and both sides of leaves on the opposite side of the plant showed little induction. The leaflets that had strong induction had direct vascular connections to the damaged leaves. Leaves with weaker vascular connection showed weaker induction, and leaves with no direct connections showed no detectable increase in proteinase inhibitors in response to the damage imposed.

Recent work has revealed that there are special glucosinolate-rich cells, dubbed "S-cells" for their high sulfur content (Koroleva et al., 2000), located adjacent to myrosinase-rich cells (Husebye et al., 2002). Both types of cells are adjacent to the phloem, and glucosinolates have been shown in other studies to be transported through the phloem and have higher concentrations in the veins of leaves (Mikkelsen et al., 2000; Reintanz et al., 2001). My research did not detect a difference in the veins of leaves compared to other parts, but this may be because my samples were too large to detect localization specifically in the veins.

Several recent papers have used genetic techniques of binding reporter genes to promoter sequences involved in the biosynthesis of glucosinolates and myrosinases in *Arabidopsis thaliana* to visualize where genes are active within plants. These studies have shown that, in addition to the cells adjacent to the phloem, myrosinases are active in the guard cells. The pictures of the leaves shown in these studies (Husebye et al., 2002; Thangstad et al., 2004) show spatial patchiness with pinpoints of high glucosinolate/myrosinase activity throughout the leaves and high concentrations in the veins. Some of the leaves shown in Thangstad et al. (2004) show a tendency for higher activity in the lower half of the leaf, but this is not discussed by the authors and may be only an artifact. The result of this localization of glucosinolates and myrosinases in the phloem and guard cells is a scattered accumulation of glucosinolates throughout leaves. This suggests a plausible physiological explanation for the patterns of glucosinolate distribution observed in this experiment.

Over half of the random variation in the data occurred at a small scale, and this variation was spatially random. This variation may have important effects on herbivore behavior and fitness because small herbivores are likely to experience frequent, unpredictable changes in glucosinolate concentrations. Small-scale stochastic variation in defenses may be adaptive in at least four ways. First, a random distribution of defenses provides the least information possible to herbivores about the location of low and high doses of defenses within a plant. A herbivore cannot discern anything about the quality of a leaf or a plant from feeding on one part of it; a high-quality bite is as likely to be followed by a low-quality bite as a high-quality one. Second, many herbivores have inducible detoxification systems to deal with plant toxins (Snyder et al., 1993; Glendinning and Slansky, 1995; Feyereisen, 1999); the rate of production of detoxification enzymes is determined by the amount of toxins consumed. If toxin levels continually change, and if there is any time lag in production of gut enzymes, herbivore detoxification systems are likely to be frequently out of phase with their food. Third, if the effects of toxins on herbivores increase nonlinearly such that high doses have much stronger effects as predicted by the "nonlinear averaging" theory (Karban et al., 1997; Shelton, 2000), then increasing the proportion of high toxin patches that a herbivore encounters should negatively affect the herbivore. Finally, herbivores exposed to varying levels of defense will experience reduced selection for resistance to the defenses. Thus, variation may enable plants to evolutionarily compete with the short generations and high recombination potential of insect herbivores (Dolinger et al., 1973; Whitham, 1981; Schultz, 1983a; Gardner et al., 1999).

Plants exhibited both predictable and unpredictable variations in glucosinolates at different scales. Herbivores experience both types of variation simultaneously. Plants appeared to distribute glucosinolates according to optimal defense theory at larger scales, but may use stochastic, spatial variation at smaller scales to increase uncertainty to herbivores. Predictable variation should optimize the distribution of a plant's defense, but herbivores can evolve strategies to avoid predictably highly defended plant parts. In contrast, it should be more difficult to evolve strategies to efficiently cope with stochastic variation. In addition, stochastic variation may mask the predictable patterns, slowing the herbivores' ability to evolve responses to them. The defensive strategy of *R. sativus* may be like a minefield. Most of a leaf has relatively low levels of defense, but small, randomly located patches have high doses of glucosinolates, and herbivores never know when they will encounter these toxic patches. When a plant increases its defenses, it increases the number of these high-dose patches in more valuable or more threatened parts, effectively putting more mines into the minefield.

This is one of the few studies to examine the patterns and magnitude of chemical variation at a scale important to herbivorous insects. Most previous

studies have looked at larger scales, such as among leaves or organs, or among plants. Sampling at larger scales will reduce the measured variation by averaging the variation at smaller scales, which would result in a systematic underestimation of the variation experienced by small herbivores. If variation affects herbivore fitness or behavior in any of the ways suggested above, simply examining the mean level of defense in a plant will not accurately represent the effect of the defenses on actual herbivores. To understand how variation affects herbivores, it is essential to examine variation at the scale at which herbivores experience it.

A model (Shelton, 2004) based on the results of this study suggests that larger-scaled predictable patterns of variation affect herbivore behavior and small-scale stochastic variation that may be deleterious to small, low-mobility herbivores such as caterpillars. The high degree of stochastic small-scale variation found in this study complicates the experimental approaches to this question because it suggests that it may not be possible to know precisely what concentrations of chemicals a herbivore consumes when it feeds on a plant. We need cleverly designed experiments with herbivores to determine if chemical variation is an important aspect of plant defense. If it is, studies that examine only mean levels of defenses and average over large areas of a plant may be missing information needed to understand the ecological interactions between herbivores and plant defenses.

Acknowledgments—This manuscript was greatly improved by comments from Anurag Agrawal, Suzanne Alonzo, Carol Boggs, Laurel Fox, Tom Miller, Paul Richards, Nick Wolf, and two anonymous reviewers. I thank Greg Gilbert, Jim Velzy, Linda Locatelli, Feinming Chen, Brian Fulfrost, and the UCSC GIS laboratory for resources and technical help. (Received September 21, 2004; revised March 14, 2005; accepted April 18, 2005)

Abstract—Induced volatiles provide a signal to foraging predatory insects about the location of their prey. In Iowa, early in the growing season of soybean, *Glycine max*, many predacious seven-spotted lady beetles, *Coccinella septempunctata*, were observed on plants with heavy infestations of soybean aphid, *Aphis glycines*. We studied whether the attraction of this beetle is caused by the release of specific volatile compounds of soybean plants infested by aphids. Volatile compounds emitted by soybean plants infested by aphids were compared with those of undamaged, uninfested, and artificially damaged plants. Gas chromatography–mass spectrometry analyses revealed consistent differences in the profiles of volatile compounds between aphid-infested soybean plants and undamaged ones. Significantly more methyl salicylate was released from infested plants at both the V1 and V2 plant growth stages. However, release patterns of two other induced plant volatiles, (D)-limonene and (*E*,*E*)-α-farnesene, differed between the two plant growth stages. Gas chromatographic–electroantennographic detection of volatile extracts from infested soybean plants showed that methyl salicylate elicited significant electrophysiological responses in *C. septempunctata*. In field tests, traps baited with methyl salicylate were highly attractive to adult *C. septempunctata*, whereas 2-phenylethanol was most attractive to the lacewing *Chrysoperla carnea* and syrphid flies. Another common lady beetle, the multicolored Asian lady beetle, *Harmonia axyridis*, showed no preference for the compounds. These results indicate that *C. septempunctata* may use

[3] Current address: Department of Entomology, Pennsylvania State University, University Park, PA 16802, USA.

methyl salicylate as the olfactory cue for prey location. We also tested the attractiveness of some selected soybean volatiles to alate soybean aphids in the field, and results showed that traps baited with benzaldehyde caught significantly higher numbers of aphids.

Key Words—*Glycine max*, soybean volatile, induced plant volatile, methyl salicylate, attraction, enhanced biological control, seven-spotted lady beetle, *Aphis glycines.*

INTRODUCTION

The soybean aphid, *Aphis glycines*, is a new, invasive insect species that threatens U.S. soybean, *Glycine max*, production. It is the only aphid species to develop large colonies on soybean in North America. Infestation stunts the plants so that fewer pods and seeds are developed, thereby lowering yield. Soybean aphids also transmit several plant viruses, including alfalfa mosaic, soybean mosaic, soybean dwarf, soybean stunt, and bean yellow mosaic, that distort soybean's growth and further reduce yield.

In soybean fields, soybean aphids are attacked by several predatory insects, including lady beetles (*Harmonia axyridis* and *Coccinella septempunctata*), lacewings (*Chrysoperla carnea*), true bugs (*Orius insidiosus*), and syrphid flies (Zhu, unpublished data). The complex of these natural enemies seems to play a key role in regulating aphid populations (Han, 1997; Fox et al., 2004). Among these predatory insects, *C. septempunctata* dominates early in the growing season, with an increasing abundance of *C. carnea* and *H. axyridis* as the season progresses.

Studies have shown that predators, parasitoids, and predatory mites locate their hosts by using volatile semiochemicals emitted from their hosts or from food plants infested by their hosts (Noldus, 1989; Vet and Dicke, 1992; Bernasconi et al., 1998; Dicke et al., 1998; De Moraes et al., 1998; Du et al., 1998; Ninkovic et al., 2001; Van den Boom et al., 2004; De Boer and Dicke, 2004). During our soybean aphid field experiments, we observed increased abundance of *C. septempunctata* in soybean fields where higher soybean aphid infestation occurred during the early growing season, compared with fields with lower soybean aphid infestation. We report here the identification of volatile compounds released from soybean plants at vegetative growth stages 1 and 2 (V1 and V2, defined when leaflets on the first through the third node leaf are unrolled). A soybean aphid-induced volatile compound that is attractive to *C. septempunctata* is discussed. We also report a volatile compound emitted from the undamaged soybean plant that is attractive to alate soybean aphids.

METHODS AND MATERIALS

Plants and Insects. V1- and V2-stage soybean plants (Garst Roundup Ready variety [80411203] grown in a greenhouse in small pots were used for infestation and entrainment. These two stages of plants were reported to be colonized by winged aphids emigrating from their overwintering host plant, buckthorn, *Rhamnus cathartica*, into soybean. Soybean aphids were collected from soybean fields at the University Farms in Ames, IA. They were maintained in a cabinet kept at 25 ± 2°C, with photoperiod of 14:10 (L:D) hr as a stock colony with only parthenogenetically produced females. Adults of *C. septempunctata* were collected from soybean fields during early summer and maintained under the same conditions as the soybean aphid colony, with 5% sugar water provided.

Volatile Collection. The collection apparatus for volatile compound collection consisted of two glass cells (9.5 cm ID × 12 cm in depth and 10 cm ID × 15 cm in depth), which when put together formed a chamber around the plant with the stem passing through a small slit. The remaining space around the slit was packed with glass wool held in place with Teflon tape. Moisturized and charcoal-filtered air was pumped into the chamber through the inlet, and the outlet of the chamber was connected with a prebaked (200°C overnight) glass tube (5 cm × 0.3 cm ID) containing 100 mg of Super Q (80/100 mesh, Alltech Associate, Deerfield, IL, USA) sandwiched with glass wool plugs. Airflow rates were measured at 2 l/min from the filtered house air pumped into the entrainment chamber (regulated by a flow meter, Barnant Company/Gilmont Instrument, Barrington, IL, USA) and 400 ml/min from the Super Q collector by using a digital flow meter (Hewlett Packard, Palo Alto, CA, USA). The entrainment was carried under the same condition as described for soybean growth.

Volatile entrainment was conducted from V1- and V2-stage soybean plants. Thirty second instars of soybean aphid were transferred onto leaves of one soybean plant, and collection was started 6 hr later. A control plant of the same stage was set up identically but without aphids (uninfested, undamaged). We also collected volatile emissions from a soybean plant of the respective stage by artificially damaging it with thin tungsten wires (5 μm ID). Leaves were punctured with 30 tiny holes. Volatiles were collected from d 1 to d 12, and the collection was extracted every other day. Volatile collection (24 hr) from only soybean aphids also was conducted in a 355-ml wide-mouth glass bottle with ~200 soybean aphids (second and third instars) under the same conditions described above but without soybean leaves. The trapped volatiles were eluted with 2 ml of HPLC-grade hexane (Burdick & Jackson Brand, High Purity, Des Plaines, IL, USA) containing 250 ng of pentadecane as an internal standard and then concentrated to 200 μl under a gentle nitrogen stream. Two microliters of extract were injected into either combined gas chromatography

and electroantennographic detection (GC-EAD) or gas chromatography–mass spectrometry (GC-MS) for quantitative and qualitative analyses.

Chemical Analyses. For GC-EAD analysis, a Hewlett Packard 5890 Series II gas chromatography equipped with a DB-wax column (30 m × 0.25 mm i.d., J & W Scientific, Folsom, CA, USA) and a 50:50 effluent split allowed simultaneous flame ionization detection (FID) and EAD of the collected volatiles. Helium was used as the carrier gas with a flow rate of approximately 30 ml/min for both FID and EAD. Extracts were injected in splitless mode. The injector temperature was 250°C, and the split valve was opened 1 min after injection. The oven initial temperature was set at 50°C for 3 min and then increased to 250°C at a programmed rate of 15°C/min. The outlet for the EAD was continuously supplied with a purified, moisturized airstream flowing over the antennal preparation at 0.5 l/min. An adult of *C. septempunctata* was restrained on a block of dental wax with thin copper wires for the EAD recording. A glass capillary recording Ag–AgCl electrode filled with 0.5 M KCl solution was brought into contact with the distal segment of the antenna. A ground electrode, filled with the same saline solution, was introduced into the intersegmental membrane of the beetle body. A high-input impedance EAG amplifier (Syntech, Hilversum, the Netherlands) with automatic baseline drift compensation was used for the GC-EAD analysis. GC-EAD software (version 2.3, Syntech) was used to process, record, and analyze the EAD and FID signals on a PC (Micron Inc., Minneapolis, MN, USA).

GC-MS analyses of volatiles collected from soybean plants were performed with a Hewlett Packard 5890 Series II gas chromatography interfaced to a Hewlett Packard 5972 mass selective detector (MSD). The GC-MS was equipped with the same columns as those used in the GC-EAD system described above. The temperature program was the same as that described for the GC-EAD analyses. Mass spectra were recorded from 30 to 550 amu with electronic impact ionization at 70 eV. The assignments of chemical identities to the soybean volatile compounds were confirmed by comparison of the retention indices and mass spectra with those of authentic chemical standards and reference spectra in a mass spectral library (Wiley 138K, John Wiley & Sons, Inc., New York, NY, USA).

Chemicals. All synthetic standards of soybean volatile compounds were purchased from Sigma-Aldrich (St. Louis, MO, USA), and the purity of each compound was examined by GC-MS, ranging from 98 to 99.5% (from solutions containing 200 ng of each standard compound in 2 μl of hexane).

Field Tests. Field trapping tests were conducted in a 10,000-m^2 soybean field in 2003 in Ames, IA, USA. The first test was designed to test the attractivity of selected volatile compounds emitted from undamaged soybean plants to alate soybean aphids. Synthetic compounds at a dose of 100 mg were prepared in either hexane or methylene chloride. A second test examined the

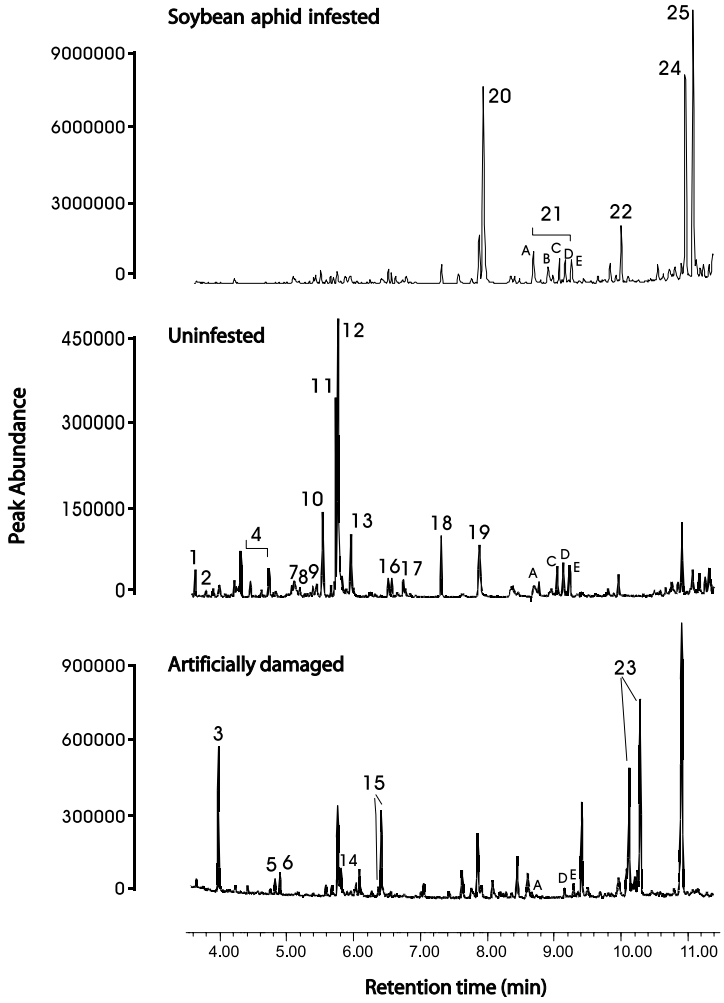

FIG. 1. Typical gas chromatograms (on a DB-5 column) of volatile compounds emitted from soybean aphid-infested, artificially damaged, and undamaged plants of *G. max* (V2 stage). Represented are (*E*)-2-hexenal (1), (*E*)-2-hexenol (2), unknowns (3 and 4), ethyl benzene (5), 1,3-dimethyl benzene (6), benzaldehyde (7), 6-methyl-5 heptanone (8), (*Z*)-3-hexenyl acetate (9), decane (10), 1,2,3-trimethyl benzene (11), dichlorobenzene (12), D-limonene (13), β-ocimene (14), unknown (15), linalool (16), 2-phenylethanol (17), unknown (18), naphthalene (19), methyl salicylate (20), unknown (21), tetradecane (22), unknown (23), α-humulene (24), and (*E*,*E*)-α-farnesene (25) (the labeled numbers on each peaks do not refer to those compounds that are only detected uniquely in each treatment, and the internal standard, *n*-pentadecane, is not shown due to its elution time is after 11.00 min).

trapping efficacy of the induced methyl salicylate and a previously identified lady beetle and lacewing attractant compound, 2-phenylethanol (also at 100-mg dose). In a third dose–response test, serial dilutions of synthetic methyl salicylate were made at doses ranging from 10 to 1000 mg. Medical peerless cotton wicks (5 cm in length, 100% cotton) were used as dispensers, and the trap used was constructed by stapling four yellow sticky traps together, which is similar to the Rebell trap described by Zhu et al. (1999), where the attractant lure was suspended in the center of this trap. The trap was hung from bamboo stakes, 1.2 m above the ground. Within a replicate (N = 10), the distance between traps was 15 m. The traps were checked daily and captured ladybugs were removed from sticky traps after checking. Trap position within a series

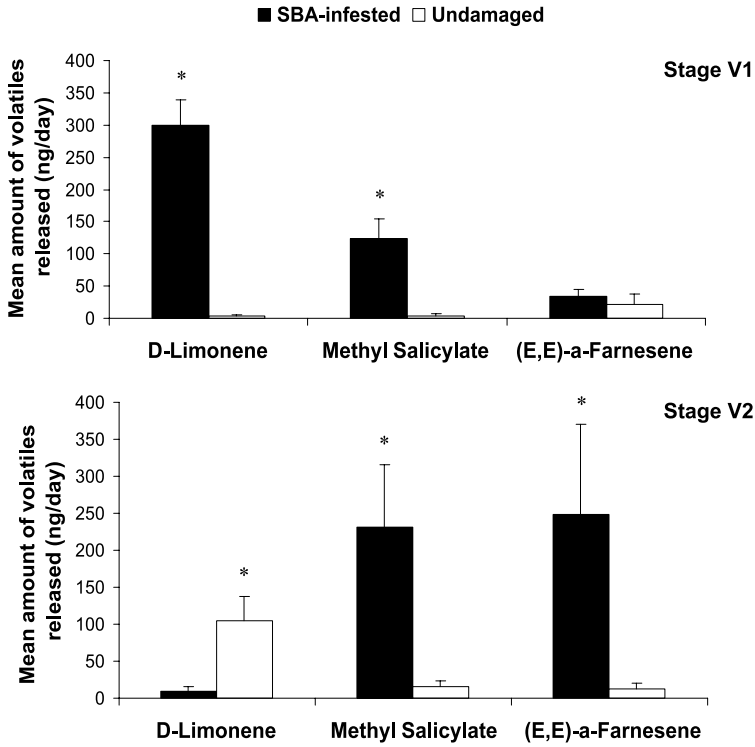

FIG. 2. Mean emission rates of three volatile compounds from plants at V1 (top) and V2 (bottom) stages of *G. max*. Asterisks indicate statistically significant differences in volatile release rates between soybean aphid-infested and undamaged plants (Student's *t*-test, $N = 6$, $P < 0.05$).

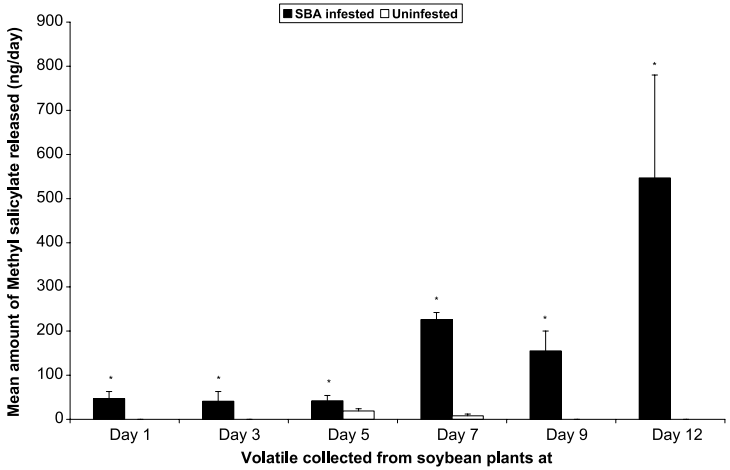

FIG. 3. Average released amounts of methyl salicylate at every other day from soybean aphid-infested and undamaged *G. max* plants during a 12-d collecting period. Asterisks indicate statistically significant differences in amounts of methyl salicylate released between soybean aphid-infested and undamaged *G. max* plants (Student's *t*-test, $N = 6$, $P < 0.05$).

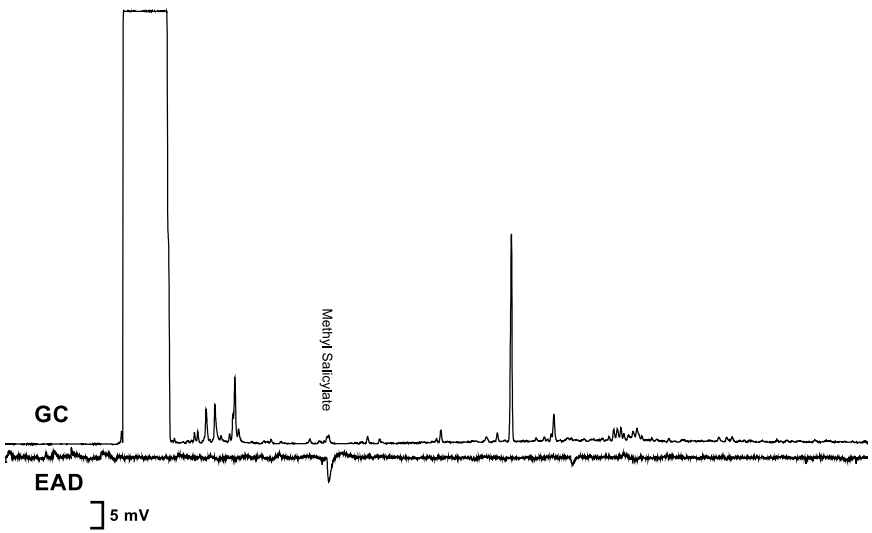

FIG. 4. Simultaneously recorded FID and EAD responses of antennae of a female adult *C. septempunctata* to extracts of soybean aphid-infested *G. max* (analyzed on a DB-Wax column).

was randomized after checking to minimize the effects of habitat heterogeneity. The trapping test lasted for 2 wk.

Statistical Analyses. Differences in volatile emission among treatments in the volatile collection experiments and field trap catches (means of trapped beneficial insects) were compared by either Student's *t*-test or analyses of variance (ANOVA) followed by Fisher's protected least significant difference test (FPLSD).

RESULTS

Volatiles from Soybean Aphid-Infested Soybean Leaves. In total, 19 volatile compounds were tentatively identified from emissions of both infested, uninfested and artificially damage soybean leaves by comparing their retention indices and mass spectra with those of synthetic standards (Figure 1). Most volatiles released from the soybean plants were common plant volatiles. Further quantitative GC and GC-MS analyses revealed consistent differences in emissions of D-limonene, methyl salicylate, and (*E*,*E*)-α-farnesene between the

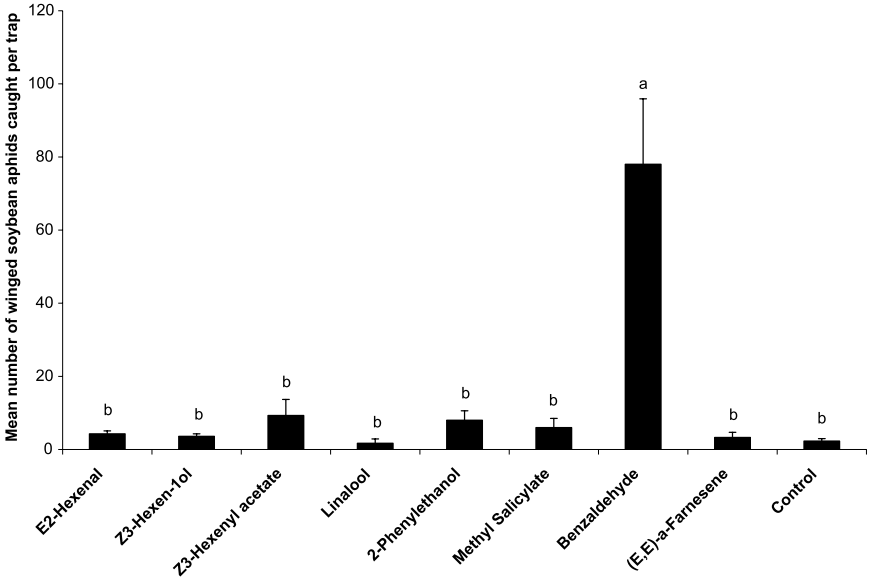

FIG. 5. Mean number of alate viviparous soybean aphids caught in traps baited with selected soybean associated volatile compounds (100 mg) in the soybean field (line indicates standard error). Columns with no letters in common are significantly different ($N = 10$, ANOVA followed by FPLSD test, $P < 0.05$).

aphid-infested and the undamaged, uninfested plants at the two growth stages (Figure 2). Among these three compounds, methyl salicylate was the only compound emitted in significantly higher quantities from aphid-infested plants at both V1 and V2 stages, relative to the undamaged, uninfested control. Significantly more D-limonene was released from the aphid-infested plants at the V1 stage, whereas more (*E*,*E*)-α-farnesene was produced by V2-stage plants. The amounts of methyl salicylate released from aphid-infested plants were significantly higher than those emitted from undamaged, uninfested plants, and amounts increased to maximum levels on d 12 of the collection period (Figure 3). No volatile compounds were found from extracts of soybean aphids only, except a trace of (*E*)-β-farnesene was identified.

Antennal Responses of Seven-Spotted Lady Beetles to Volatiles from Aphid-Infested Soybean Plants. Only one compound of the headspace of aphid-infested plants elicited a significant EAD response in *C. septempunctata.* The

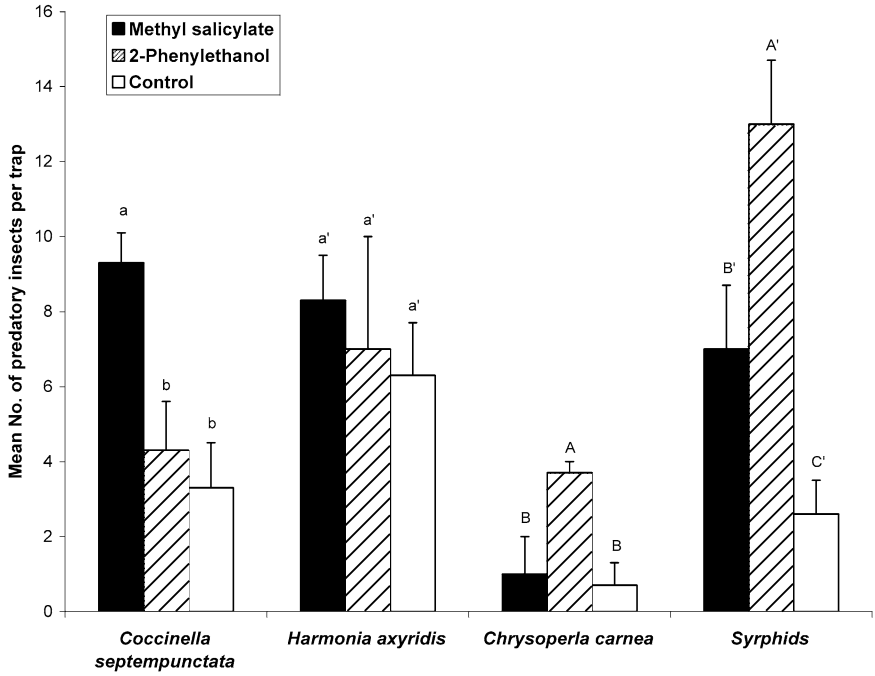

FIG. 6. Mean number of predatory insects (both sexes) caught in traps baited with 100 mg of methyl salicylate and 2-phenylethanol, and the control from an Iowa soybean field in 2003. Columns with no letters in common in four different categories are significantly different ($N = 10$, ANOVA followed by FPLSD test, $P < 0.05$).

retention time of this compound matched that of synthetic methyl salicylate (Figure 4). Further GC-MS analyses of the same extract confirmed its chemical identity as methyl salicylate.

Attraction of Aphids and Their Predators to Soybean Leaf Volatiles. Results from field-trapping tests using Rebell-type yellow sticky traps baited with either soybean leaf volatiles identified from this study or with previously reported leaf volatiles (Liu et al., 1989) showed that among eight common soybean plant-associated volatiles tested, benzaldehyde was the only compound attractive to alate soybean aphids (Figure 5). Relatively high numbers of four predatory insect species were captured in traps baited with 100 mg of methyl salicylate and 2-phenylethanol (Figure 6). Adults of *C. septempunctata* were significantly attracted only to methyl salicylate, whereas both adults of *C. carnea* and syrphid flies were attracted to 2-phenylethanol. However, there were no differences in catches of *H. axyridis* among traps baited with either of the two tested attractant compounds, compared with the control. A subsequent dose–response test with the synthetic methyl salicylate demonstrated that the highest attraction to adult *C. septempunctata* was at doses from 100 to 300 mg (Figure 7). A significant reduction in trap catch was observed at the highest tested dose of this compound.

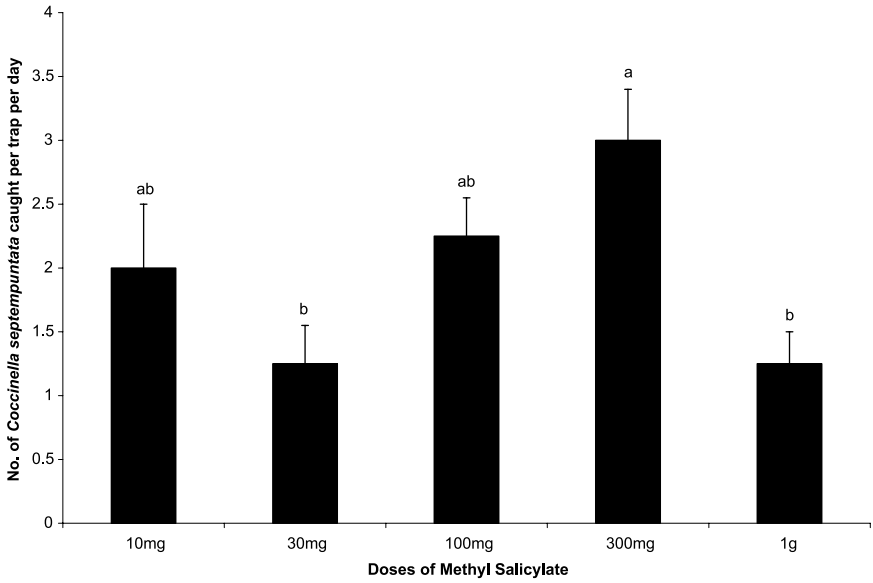

FIG. 7. Mean catches ±SE of *C. septempunctata* adults in traps baited with different doses of the synthetic methyl salicylate. Different letters on top of columns indicate significant differences ($N = 10$, ANOVA followed by Fisher FPLSD test, $P < 0.05$).

DISCUSSION

The analyses show that volatiles collected from soybean plants in their early growth stages (V1–V2) consist of aliphatic esters, aldehydes, alcohols, and ketones as well as some halogenated hydrocarbons and terpenoids. Some of these volatiles are similar to those that have been reported from a previous study (Liu et al., 1989), even though different cultivars of soybean were selected and different growth stages of plants were tested. Du et al. (1994) reported that alate viviparous soybean aphids are attracted or arrested by volatiles from soybean plants, and electroantennographic tests (EAG) have shown that these aphids show significant antennal responses to some volatiles from young leaves. Our field trapping experiments using the most common soybean volatile compounds also showed that alate viviparous soybean aphids are highly attracted to benzaldehyde, a component present in the headspace of soybean, and that this compound elicits significant EAG responses (Du et al., 1995; Zhu, unpublished data).

Despite large variation in the amounts of volatiles released from the plants we tested, methyl salicylate was consistently released at a significantly higher rate from aphid-infested plants compared with undamaged V1- and V2-stage plants or from artificially damaged leaves. This finding demonstrates that the infestation of aphids induces the emission of methyl salicylate, which is a volatile derivative of the plant hormone salicylic acid (Shulaev et al., 1997; Ozawa et al., 2000). Methyl salicylate has been identified in herbivore-induced plant volatile blends from at least 10 plant species infested with mites, aphids, beetles, and caterpillars (Walling, 2000; James, 2003; De Boer and Dicke, 2004; Van den Boom et al., 2004). This volatile plays an important role in the activation of plant defense responses (Yang et al., 1997), which also has been reported from tobacco plants inoculated with tobacco virus (Shulaev et al., 1997). The temporal emission patterns of two other volatile compounds, D-limonene and (*E*,*E*)-α-farnesene, differ between infested and undamaged plants at the two growth stages. Even though these two terpenes have been reported as herbivore-induced volatiles from several plant species (Paré and Tumlinson, 1999), it remains to be tested whether their emissions are triggered by soybean aphid infestation, or differ with plant growth stage.

Previous studies have shown that several parasitoids and predatory mites locate their hosts by using volatile semiochemicals emitted from their hosts and from the plants infested by their hosts (Vet and Dicke, 1992; Dicke and Vet, 1999). Recently, De Boer and Dicke (2004) and Van den Boom et al. (2004) showed that one of the major soybean volatiles induced by the herbivorous mite *Tetranychus urticae* is methyl salicylate, and that this compound is also attractive to its predatory mite *Phytoseiulus persimilis*. During the Iowa soybean growing season, we observed that a variety of insect predators attack soybean aphids. The complex of these natural enemies seems to play a key role in

regulating aphid populations. *C. septempunctata* dominates early in the growing season, when heavy aphid infestation is first observed in the field. Both larva and adults of this beetle can consume up to 90 aphids per day (Han, 1997). Our GC-EAD analyses showed that antennae of this lady beetle species exclusively responded to methyl salicylate, which may be induced by the infestation of soybean plants with aphids. Field trapping tests conducted in soybean fields further confirmed that synthetic methyl salicylate-baited traps are highly attractive to *C. septempunctata*. Methyl salicylate also has been demonstrated to be attractive to predatory mites *P. persimilis* and predatory bugs *Anthocoris nemoralis* as well as minute pirate bugs, *Orius tristicolor*; bigeyed bugs, *Geocoris pallens*, and lady beetle *Stethorus punctum* (Dicke and Sabelis, 1988; Drukker et al., 2000; James, 2003). In addition, several studies have shown that methyl salicylate can act as a repellent to several aphid species when they leave their overwintering places to colonize host plants in spring (Lösel et al., 1996; Ninkovic et al., 2003).

Relatively higher numbers of syrphid flies are attracted to traps baited with methyl salicylate compared with non-methyl salicylate-baited traps, which coincides with a previous report (James, 2003). However, James (2003) has reported that the catches of coccinellids in traps baited with methyl salicylate are not significantly different from those of control traps. The discrepancy in trap catches of coccinellids with methyl salicylate between the current study and that of James' field experiment could be attributed to geographical variation in populations of these coccinellids, different trap designs, and different doses of methyl salicylate. In the field experiment, James (2003) used ~1 g methyl salicylate (~1 ml), a dose that has been shown in our field trapping experiment to reduce attraction of *C. septempunctata.* Similar examples have been documented for several parasitic wasp species that are attracted to low doses of green leaf volatiles but are repelled by high doses (Whitman and Eller, 1992). One of the most abundant lady beetle species, *H. axyridis*, which accounts for most of the soybean aphid feeding during the late growing season in Iowa, was not attracted to methyl salicylate. The number of *H. axyridis* caught in traps baited with methyl salicylate was not statistically different from that in the control traps. A minor soybean volatile, 2-phenylethanol, identified from both aphid-infested and undamaged soybean plants is highly attractive to adults of *C. carnea,* which is similar to findings of Zhu et al. (1999).

The use of natural enemies as biological control agents for soybean aphids has great potential to suppress aphid populations. However, the biggest concern for the success of biological control is how to recruit predaceous insects into natural or damaged soybean fields and synchronize their presence with the targeted aphid pest, thereby increasing their predatory efficacy. The present study provides a base to help further development of enhanced biological control strategies via applications of attractants of predatory insects that attack aphids

early in the growing season, which is considered as an alternative to suppress their populations below the economic threshold level. The identification of methyl salicylate as a soybean aphid-induced plant volatile and the demonstration of its attractiveness to one of the most abundant lady beetle species (and to syrphid flies that also attack soybean aphids) may provide a tool to enhance the biological control of these aphids. This compound also has been reported to attract some *Orius* species, of which *O. insidiosus* has been considered as another key predator for soybean aphid biological control in the Midwest. The application of beneficial insect attractants such as methyl salicylate and 2-phenylethanol has been tested in soybean fields to enhance biological control of aphids. Although our preliminary results have shown positive impact on increasing predatory insect presence and on suppressing soybean aphid populations (Zhu et al., unpublished data), detailed further studies are necessary to implement such strategies. Negative effects caused by factors such as excessively high concentrations of attractants could repel predatory insects, and host deficiency might result in reduction of predation or parasitism due to relatively low-density prey in the natural habitat (Dicke et al., 1990).

Abstract—The parasitic mite *Varroa destructor* Anderson & Trueman reproduces on the immature stage of the honeybee, *Apis mellifera* L. Mites are found more often on drone brood than worker brood and only infrequently on queen brood. We investigated the chemical basis for the low incidence of mites on queen brood. *V. destructor* mites were deterred by a crude extract of royal jelly, a glandular secretion produced by nurse bees and fed to queen larvae. Bioassay-driven fractionation of the crude extract via column chromatography resulted in one active fraction that was as active as the crude extract. Compounds in the active fraction were identified using gas chromatography (GC) and coupled gas chromatography/mass spectrometry (GC-MS). Before injection, compounds were esterified with MeOH/sulfuric acid, followed by silylation of any hydroxyl groups present. The active fraction contained at least 22 compounds, all fatty acids, several of which contained an additional hydroxyl group on the alkyl chain. Synthesis of some of these compounds that are not commercially available is described. A synthetic mixture containing most of the compounds in the active fraction was as active as the active fraction in the bioassay.

Key Words—Honey bee, host location, royal jelly, parasitic mite, deterrent, *Apis mellifera*, *Varroa destructor*.

INTRODUCTION

Varroa destructor Anderson & Trueman is a parasitic mite of the honeybee *A. mellifera* L. and the greatest threat to beekeeping worldwide. Mites require the immature stage of their host for reproduction (reviewed in De Jong et al., 1982; De Jong, 1990). Those reproducing on drone brood (males) average 2.2–2.6 female offspring per host, whereas those reproducing on worker brood (females) average 1.3–1.4 female offspring per host (Schulz, 1984; Fuchs and Langenbach, 1989). Mites do not reproduce on queen brood (also females) (Romaniuk et al., 1988; Rehm and Ritter, 1989; Harizanis, 1991; Santillan-Galicia et al., 2002). The rate of infection of immature honeybees varies with their sex and caste, reflecting the opportunity each type of host affords the mite for reproduction. Mites are found more often on drone brood than worker brood, with average differences ranging between 5- and 12-fold (Grobov, 1977; Sulimanovic et al., 1982; Schulz, 1984; Issa and Goncalves, 1984; Fuchs, 1990, 1992; Boot et al., 1991; Calderone and Kuenen, 2001). Mites are found infrequently on queen brood (Harizanis, 1991; Calderone et al., 2002; Santillan-Galicia et al., 2002).

Numerous studies have sought to identify the mechanisms responsible for the different rates at which worker and drone brood are parasitized. Both chemical and physical factors appear to be involved (De Jong and Morse, 1988; Le Conte et al., 1989; Rickli et al., 1992, 1994; Goetz and Koeniger, 1993; Donzé et al., 1998; Kuenen and Calderone, 1998, 2000; Beetsma et al., 1999; Calderone and Kuenen, 2003; Calderone and Lin, 2001; Nazzi et al., 2001). However, the exact role of host kairomones and/or allomones has not been clearly established (Calderone and Lin, 2001).

The low incidence of mites on queen brood has received less attention. Calderone et al. (2002) found that the rate at which queen brood was infected was independent of the rate of infection of worker brood in the same colony. In addition, eliminating potential worker hosts from the nest had no effect on the incidence of mites in queen cells. However, Santillan-Galicia et al. (2002) and Harizanis (1991) reported that the absence of alternate hosts slightly increased the incidence of infection of queen brood. Trouiller et al. (1994) reported that queen larvae produce about half as much of three putative attractants as worker larvae. They proposed that these differences might account for the low frequency of *V. destructor* on queen brood. Supporting that hypothesis, Calderone et al. (2002) reported that mites in a bioassay were arrested at higher rates by crude extracts of worker larvae than by crude extracts of queen larvae. However, crude extracts of royal jelly (glandular secretions from adult worker bees fed to queen larvae) deterred mites (Calderone et al., 2002), and the larval extracts of the queen larvae may have been contaminated with small quantities of royal jelly, thereby reducing their attractiveness relative to extracts

from worker larvae. This possibility arises from the fact that queen larvae, unlike worker larvae, develop in a pool of royal jelly provided by worker bees in large amounts. In this study, we continue to explore the deterrent activity of royal jelly. We use a bioassay-driven fractionation of a crude extract of royal jelly to identify active fractions and their constituent compounds with deterrent activity.

METHODS AND MATERIALS

Royal Jelly Fractions. Royal jelly was collected from queen cells with larvae between 0 and 12 hr before cell capping. A crude extract of the royal jelly was obtained by extracting it with dichloromethane (four times with 2 ml per gram royal jelly) and then with dichloromethane:MeOH (five times with 1 ml per gram royal jelly) as previously described (Calderone et al., 2002). Bioassay-driven fractionation was performed as outlined in Figure 1.

Step 1: Crude extract equivalent to four gram of fresh royal jelly (4 g RJeq) was applied to a 10.5 × 300 mm open column of 10 g silica gel 60 (70–230 mesh, E. Merck). In the initial fractionation, hexane:ethyl ether at ratios of 2:1 and 1:1 yielded fractions F1 and F2, and ethyl ether and ethyl ether:MeOH (1:1) were used to elute fractions F3 and F4, respectively. Each fraction was ca. 50 ml.

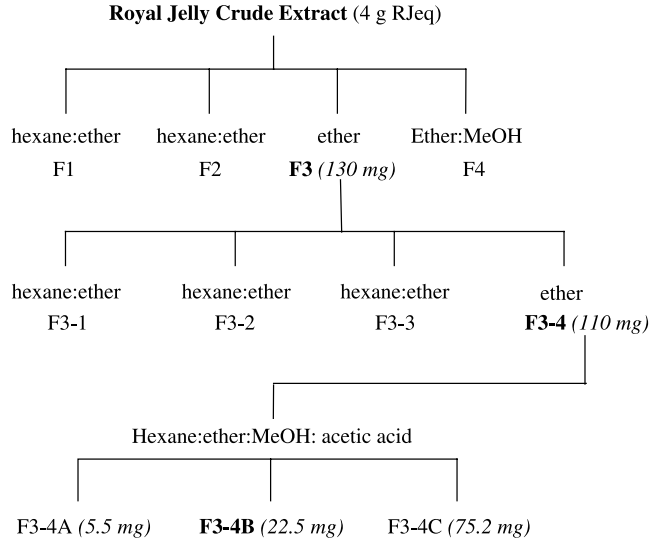

FIG. 1. Scheme for the bioassay-driven fractionation of royal jelly crude extract.

Step 2: Fraction F3, which retained nearly all of the deterrent activity (see below), was further fractionated on an open column of silica gel [10.5 × 300 mm, 10 g silica gel 60 (70–230 mesh, E. Merck)] with hexane:ethyl ether at ratios 2:1, 1:1, 1:2, and finally with 100% ethyl ether. Of the four resulting fractions (each 45 ml), fraction F3-4 eluted with ethyl ether retained deterrent activity (see below).

Step 3: Fraction F3-4 was further fractionated on an open silica gel column [10.5 × 300 mm, 10 g silica gel 60 (70–230 mesh, E. Merck)] with hexane:ether:MeOH (10:10:2) and 1% acetic acid as an eluent. Each 4–5 ml fraction was collected and analyzed with thin-layer chromatography (TLC) using the same eluent. Compounds were visualized using MeOH/sulfuric acid as a charring agent. Three groups of compounds were identified: F3-4A, F3-4B, and F3-4C.

In all steps of the fractionation process, each fraction was concentrated under N_2 to 1 g RJeq per ml CH_2Cl_2 for use in the deterrent contact bioassay. When acetic acid was used in the solvent system, recovered samples were dried under reduced pressure with added water and 2-propanol to remove acetic acid by azeotroping before use in the bioassay.

Chemical Analysis of the Royal Jelly Fractions. Fractions F3-4A, F3-4B, and F3-4C were analyzed by gas chromatography (GC) and gas chromatography/mass spectrometry (GC-MS) after methylation with methanol–sulfuric acid followed by silylation of the hydroxyl groups with bis(trimethylsilyl)trifluoroacetamide (BSTFA) (see below). The GC was an HP6890 (Agilent Technologies) with a flame ionization detector and an HP-5 column (30 m × 0.32 mm i.d., film thickness 0.25 μm). Injector and detector temperatures were 250°C. The oven was programmed at 40°C (2 min hold) then 4°C/min to 300°C.

GC/MS analysis was performed on an HP6890 GC interfaced to an HP6890 mass selective detector, equipped with an HP-1 column (30 m × 0.32 mm i.d., film thickness 0.25 μm). The oven was programmed at 70°C (2 min hold) then 4°C/min to 300°C (10 min hold). The mass spectrometer was operated at 70 eV, scanning from 40 to 500 amu at 1.5 scans/sec.

Fatty acids were identified as their methyl ester derivatives, and hydroxy fatty acids were identified as their methyl esters and trimethylsilyl (TMS) ethers. Identification of compounds in the extracts was carried out by GC/MS using retention times and mass spectra from reference compounds or with mass spectra from the NIST Mass Spectral Library.

Derivatizations. Methylation was carried out by evaporating all the solvent and then adding a solution of 2% sulfuric acid in MeOH (approx. 1 ml per 1 mg dried extract), and heating at 50°C for 2 hr. The reaction was quenched with deionized water and extracted three times with ether after which the combined organic layers were dried with anhydrous Na_2SO_4 and analyzed by GC and/or GC-MS. Where necessary, BSTFA was used as silylation reagent. Thus, the methyl ester extract was concentrated and BSTFA (100-fold excess) was added.

The reaction was carried out at 50°C for 30 min and directly analyzed with GC and GC-MS.

Chemicals. The following standards were purchased from Sigma-Aldrich Company (St. Louis, MO, USA): 3-hydroxyoctanoic acid, 8-hydroxyoctanoic acid, 3-hydroxydecanoic acid, sebacic acid, 10-hydroxydecanoic acid, 12-hydroxydodecanoic acid, 2-dodecenedioic acid, erucic acid [(*Z*)-13-docosenoic acid], oleic acid [(*Z*)-9-octadecenoic acid], nervonic acid [(*Z*)-15-tetracosenoic acid], (*Z*)-11-eicosenoic acid, (*Z*)-10-heptadecenoic acid, and (*E*)-12-octadecenoic acid.

The (ω-1)-hydroxy fatty acids (9-hydroxydecanoic acid, 11-hydroxydodecanoic acid, 13-hydroxytetradecanoic acid, 15-hydroxyhexadecanoic), the (ω-2)-hydroxy fatty acids (10-hydroxydodecanoic acid and 12-hydroxytetradecanoic acid), and (*E*)-2-decenedioic acid were synthesized as described below. 10-Hydroxy-(*E*)-2-decenoic acid was available in one of our laboratories (J. Kochansky). All solvents were distilled before use and all chemical reagents were of analytical reagent quality.

Syntheses. The (ω-1)- and (ω-2)-hydroxy fatty acids were synthesized in two steps. In the first step, an unsaturated fatty acid was ozonized and reduced, forming an oxo-fatty acid. The second step employed a Grignard reaction with an alkyl magnesium bromide.

General Method for the Ozonolysis. Approximately 100 mg of the unsaturated fatty acid [erucic acid, oleic acid, nervonic acid, (*Z*)-11-eicosenoic acid, (*Z*)-10-heptadecenoic acid, or (*E*)-12-octadecenoic acid] was dissolved in 8–10 ml dichloromethane. A small amount of 2-propanol was added to dissolve the longer fatty acids such as nervonic acid. The solution was stirred at −78°C while ozone was circulated through the reaction vessel until the solution turned blue. Excess ozone was then purged with nitrogen. The ozonide was reduced by adding 2 eq. dimethylsulfide and stirring for 8 hr at room temperature. Thereafter, the solution was concentrated on a rotary evaporator. The mixture was used directly in the Grignard reaction.

General Method for the Grignard Reaction. Ozonolysis products were dissolved in 10 ml dry ether per 100 mg starting material (from the unsaturated fatty acid). The solution was cooled to −30°C and 3–4 eq. of the Grignard reagent (ca. 0.5–0.6 ml of a 3 M solution) were slowly added [methyl magnesium bromide to get (ω-1)-hydroxy fatty acids and ethyl magnesium bromide to get (ω-2)-hydroxy fatty acids] and stirred for 1 hr. After removing the mixture from the dry ice/acetone bath, it was acidified with 1 N HCl to pH 3–4 and then extracted with ether and dried with anhydrous Na_2SO_4. Solvent was evaporated to yield an oily/solid substance, depending on the hydroxy fatty acid synthesized.

The (ω-1)-hydroxy fatty acids were purified with open column chromatography on silica gel [10.5 × 300 mm, 10 g silica gel 60 (70–230 mesh, E. Merck)] eluting with hexane:ethyl acetate (1:1) and 1% acetic acid. The (ω-2)-

hydroxy fatty acids were eluted with hexane:ether (1:1) and 1% acetic acid. Fractions of 4–5 ml were collected and visualized with TLC. Fractions containing the hydroxy acids were pooled and dried on a rotary evaporator. All hydroxy acids were obtained in >95% purity.

Synthesized compounds were identified by GC/MS and nuclear magnetic resonance (NMR). NMR spectra were recorded at 298 K with a Varian Unity+ (500 MHz proton; 126 MHz carbon) spectrometer. Chemical shifts are reported in parts per million (ppm) relative to the residual $CHCl_3$ peak in solvent $CDCl_3$ at 7.26 ppm unless noted otherwise.

9-Hydroxydecanoic acid: ^{1}H NMR ($CDCl_3$): δ 1.18 (d, 3H, J = 6.2 Hz), 1.25–1.5 (m, 10H), 1.62 (q, 2H, J = 7.3 Hz), 2.33 (t, 2H, J = 7.5 Hz), 3.8 (sextet, 1H, J = 6.1 Hz). ^{13}C NMR: δ 23.45, 24.84, 25.78, 29.12, 29.33, 29.53, 34.23, 39.27, 68.47, 179.55. MS (as TMS ether methyl ester): *m/z* (%) = 73 (51), 117 (100), 146 (8), 159 (11), 227 (13), 230 (13), 243 (2), 259 (7).

10-Hydroxydodecanoic acid: MS (as TMS ether methyl ester): 73 (65), 131 (100), 146 (6), 159 (11), 169 (14), 244 (11), 255 (14), 273 (46), 287 (2).

11-Hydroxydodecanoic acid: ^{1}H NMR ($CDCl_3$): δ 1.19 (d, 3H, J = 6.2 Hz), 1.23–1.5 (m, 14H), 1.62 (q, 2H, J = 7.4 Hz), 2.34 (t, 2H, J = 7.5Hz), 3.81 (sextet, 1H, J = 6.0 Hz). ^{13}C NMR: δ 23.49, 24.86, 25.88, 29.12, 29.36, 29.49, 29.65, 29.73, 34.25, 39.36, 68.51, 179.78. MS (as TMS ether methyl ester): 73 (40), 117 (100), 146 (6), 159 (16), 255 (19), 258 (17), 271 (4), 287 (8).

12-Hydroxytetradecanoic acid: ^{1}H NMR ($CDCl_3$): δ 0.94 (t, 3H, J = 7.5 Hz), 1.23–1.37 (m, 18H), 1.63 (q, 2H, J = 7.6 Hz), 2.34 (t, 2H, J = 7.5Hz), 3.54 (q, 1H, J = 4.7 Hz). ^{13}C NMR: δ 10.09, 24.57, 25.77, 29.17, 29.34, 29.50, 29.58, 29.69, 29.82, 30.23, 34.23, 37.00, 73.67, 179.64. MS (as TMS ether methyl ester): 73 (77), 131 (100), 146 (8), 159 (9), 272 (17), 283 (17), 301 (70).

13-Hydroxytetradecanoic acid: ^{1}H NMR ($CDCl_3$): δ 1.19 (d, 3H, J = 6.2 Hz), 1.22–1.5 (m, 18H), 1.63 (q, 2H, J = 7.4 Hz), 2.34 (t, 2H, J = 7.5Hz), 3.81 (sextet, 1H, J = 6.0 Hz). ^{13}C NMR: δ 23.56, 24.88, 25.91, 29.20, 29.37, 29.55, 29.66, 29.67, 29.74, 29.77, 34.23, 39.44, 68.53, 179.71. MS (as TMS ether methyl ester): 73 (34), 117 (100), 146 (6), 159 (12), 283 (12), 286 (10), 299 (2), 315 (2).

15-Hydroxyhexadecanoic acid: ^{1}H NMR ($CDCl_3$): δ 1.20 (d, 3H, J = 6.2 Hz), 1.24–1.35 (m, 22H), 1.64 (q, 2H, J = 7.4 Hz), 2.35 (t, 2H, J = 7.5Hz), 3.81 (sextet, 1H, J = 6.0 Hz). MS (as TMS ether methyl ester): 73 (24), 117 (100), 146 (8), 159 (11), 311 (13), 314 (9), 327 (2), 343 (4).

(E)-2-Decenedioic acid. The intermediate in the synthesis of (*E*)-2-decenedioic acid, 8-oxooctanoic acid, was synthesized from cyclooctene as described by Tolstikov et al. (1982). (*E*)-2-Decenedioic acid was then synthesized from 8-oxooctanoic acid based on a pathway described by Odinokov et al. (1983). A solution of 300 mg 8-oxooctanoic acid, 300 mg malonic acid, and 100 μl piperidine in 2 ml pyridine was kept at room temperature for 30 hr.

Thereafter, it was heated at 110–115°C for 2 hr, poured into a mixture of 3 ml concentrated HCl in 2.5 g of ice, and extracted three times with 3 ml ether per extraction. The ethereal extract was dried with anhydrous $MgSO_4$. After filtration, the ether was evaporated and a 10% solution of $NaHCO_3$ was added until a pH of 8–9 was reached. This solution was washed twice with 2 ml ether per wash. The aqueous layer was acidified with 10% HCl to pH 4, then extracted three times with 3 ml ether and dried with anhydrous Na_2SO_4, after which the solvent was evaporated. Purification of the dicarboxylic acid was carried out by recrystallization from hexane and ethyl acetate (1:1) at −20°C, and filtering at this temperature.

(*E*)-*2-Decenedioic acid:* ^{1}H NMR (acetone-d_6): δ 1.35–1.65 (m, 6H), 2.06 (quintet, 2H, J = 2.5 Hz), 2.24 (dq, 2H, J = 7.5, 1 Hz), 2.3 (t, 2H, J = 7.0 Hz), 5.83 (dt, 1H, J = 15.5, 1.7 Hz), 6.95 (dt, 1H, J =15.4, 6.9 Hz), 10.45 (s, 2H, –OH). MS (as dimethyl ester): 55 (83), 73 (46), 81 (77), 95 (73), 119 (54), 136 (100), 164 (66), 168 (57), 196 (22), 197 (20), 227 (1), 228 (0.1).

Deterrent Bioassay. Deterrent bioassays (Calderone et al., 2002) were conducted in a walk-in environmental chamber maintained at brood nest conditions (32–34°C and 50% RH). Extracts were presented on a 5.8 × 5.8 cm glass plate with one frosted surface. Glass plates were washed, heated to 175°C for 24 hr, soaked in acetone for at least 12 hr, and rinsed twice with CH_2Cl_2 before each test. A 5 × 5 cm pattern (Figure 2) was printed on paper and attached to the underside of the glass plate to serve as an area marker. An aliquot (2–10 µl) of extract was applied evenly to the frosted surface in each of the treatment lanes ("T" in Figure 2) and 10 µl dichloromethane (or ether, as required) were applied for control runs. After air-drying, the plate and pattern were placed on a moistened filter paper in a 9-cm Petri dish. Each bioassay

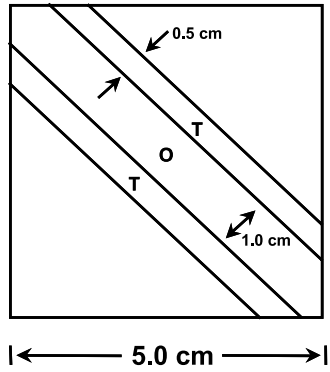

FIG. 2. Diagram of test pattern used to evaluate deterrent activity of extracts in the bioassay. See Methods and Materials section for details.

[a] Number corresponds with peak number in Figure 7.
[b] Auth: These compounds were identified by comparison of spectral and chromatographic data of authentic standards. Litt: These were identified according to spectral data from literature or comparing data from analogues (synthesized or commercially available).
[c] Compounds used in the synthetic mixture resembling the F3-4B fraction.

consisted of testing the response of 10–12 mites to a specific treatment, and each treatment was replicated 2–12 times, depending on the specific test.

Mites were obtained by using established methods (Kuenen and Calderone, 1997, 1998; Calderone and Lin, 2001). The bioassay was performed by first removing the Petri dish cover, introducing a single mite to the central lane at the point designated "O," and replacing the dish cover. Each test period lasted ≤3 min. A finding that a mite would not cross into or through either of the treatment lanes during the test period was used as evidence of a deterrent response. Therefore, a mite was scored as deterred if it moved off the plate while staying within the central lane or if it remained in the central lane for the entire 3-min period, moving and making returns when it contacted either of the treatment lanes. A mite was scored as not deterred if it failed to avoid either of the treatment lanes by moving into or through either of the treatment lanes during the 3-min observation period.

Fractions Evaluated. The royal jelly crude extract was evaluated at three doses (5, 10, and 20 mg RJeq). Fractions F1, F2, F3, and F4 and fractions F3-1, F3-2, F3-3, and F3-4 were each evaluated at 10 mg RJeq. These quantities are smaller than the 200–300 mg of royal jelly normally available to a queen larva in a queen cell (Schmidt and Buchmann, 1992).

Fractions F3-4A, F3-4B, and F3-4C were each evaluated at three doses: 5, 10, and 20 mg RJeq. The crude royal jelly extract in this test was evaluated at 10 mg RJeq because previous studies (Calderone et al., 2002) have found the response at this level to be equivalent to the response at both 5 and 20 mg RJeq.

A synthetic mixture resembling F3-4B (the most active fraction of the F3-4 fractions) was constituted by combining commercially available standards or synthesized versions of the 15 most prominent compounds identified in that fraction (Table 1). Ether was used as a solvent. Although 10-hydroxydodecanoic acid was synthesized and correctly identified by GC/MS, the yield was very low after purification due to unknown reasons. Therefore, this compound could not be included in the synthetic mixture, and no NMR data could be collected. GC analysis was used to ensure that the quantities and ratios of compounds in the synthetic blend were the same as the corresponding quantities and ratios in the original fraction. The activity of the synthetic mixture (Syn-F3-4B) was compared to that of the native fraction (F3-4B). The amount of the native active fraction (F3-4B) used was 10 mg RJeq. The equivalent dose of the synthetic mixture used was 52 μg/lane. Ether was used as a control.

Statistical Analysis. Arcsine square root transformed data were analyzed using PROC MIXED (SAS, 1996) with fraction modeled as a fixed effect and mite source and the interaction between fraction and mite source as random effects. The Tukey–Kramer (SAS, 1988) test was used to compare means.

RESULTS

Royal Jelly Fractions. Bioassay of the royal jelly crude extract at three concentrations (5, 10, and 20 mg RJeq) yielded the same results as previously described by Calderone et al. (2002) (data not shown). There were significant differences among the activities of the four fractions produced in Step 1 of the fractionation process (Figure 3; $F_{4,7} = 30.78$, $P < 0.001$). The deterrent activity of fraction F3 (yield of 130 mg from 4 g RJeq crude extract) was 96.15 ± 0.05%, which was greater than that of the control and the other three fractions (Figure 3; Tukey–Kramer, $P < 0.001$ for each significant comparison) and equivalent to the activity observed for the original crude extract (Calderone et al., 2002).

There were significant differences among the activities of the four fractions produced in Step 2 (Figure 4; $F_{4,10} = 15.33$, $P < 0.001$). The deterrent activity of fraction F3-4 (yield of 110 mg) was 89.40 ± 0.08%, which was greater than the activity of the control and the other three fractions (Figure 4; Tukey–Kramer, $P < 0.05$ for each significant comparison).

Fraction F3-4 was further fractionated into three fractions: F3-4A (yield of 5.5 mg), F3-4B (22.5 mg), and F3-4C (75.2 mg). Each fraction was evaluated at three doses (5, 10, and 20 mg RJeq). There were significant differences in deterrent activity among these fractions (Figure 5; $F_{10,67} = 18.73$, $P < 0.001$). The activity of each fraction at each dose was greater than the activity of the control (except F3-4A at 5 mg RJeq) (Figure 5; Tukey–Kramer, $P < 0.05$ for

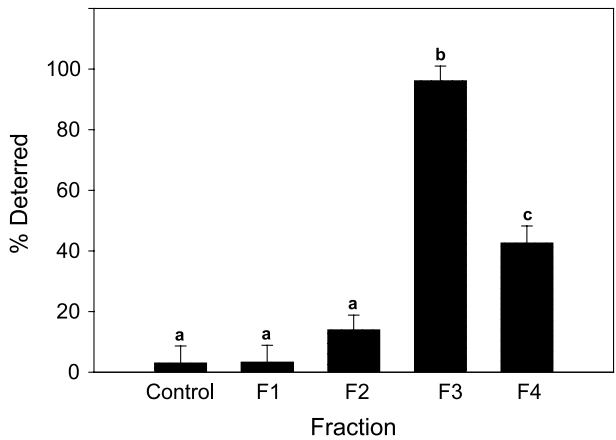

FIG. 3. Deterrent activity of the first four fractions of the royal jelly crude extract produced in Step 1 of the fractionation process. Each fraction was evaluated at 10 mg RJeq. Dichloromethane was used as a control. Bars with different letters are significantly different from each other (Tukey–Kramer, $P < 0.05$).

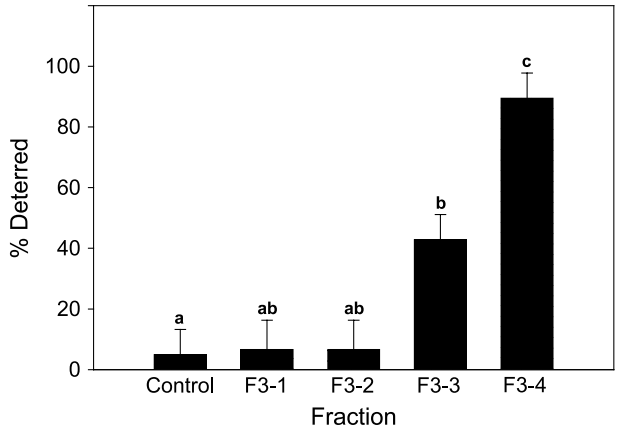

FIG. 4. Deterrent activity of the four fractions derived from fraction F3 in Step 2 of the fractionation process. Each fraction was evaluated at 10 mg RJeq. Dichloromethane was used as a control. Bars with different letters are significantly different from each other (Tukey–Kramer, $P < 0.05$).

each significant difference). The activities of fraction F3-4A and F3-4C at each dose were less than that of the crude royal jelly extract (RJ CE) (Figure 5; Tukey–Kramer, $P < 0.05$ for each comparison). The activity of F3-4B at each dose tested was equivalent to the activity of the original crude extract (RJ CE) (Figure 5; Tukey–Kramer, $P > 0.20$ for each comparison).

There were significant differences in the activities of the original F3-4B fraction, the synthetic F3-4B blend, and the control (Figure 6; $F_{2,40} = 171.19$, $P < 0.001$). The activity of the original F3-4B fraction and the synthetic F3-4B blend were both greater than that of the control (Tukey–Kramer, $P < 0.001$ each comparison) but not from each other (Tukey–Kramer, $P > 0.75$).

Chemical Analysis. Figure 7 shows the chromatogram of fraction F3-4B analyzed by gas chromatography after methylation and silylation. The compounds present are listed in Table 1. All the compounds identified were fatty acids; more specifically, the extract contained normal fatty acids, diacids, and β-, ω-, (ω-1)-, and (ω-2)-hydroxy fatty acids. Fraction F3-4A had a similar profile as F3-4B, except that the concentration of the compounds was much lower. The last fraction, F3-4C, was only analyzed on GC. It contained not only some of the compounds found in F3-4B, but also many larger molecules, according to their retention times.

The main reason for derivatization before injecting the samples in the GC was that previous experiments in our laboratory (data not published) as well as earlier studies (Brown et al., 1961; Lercker et al., 1981, and references therein;

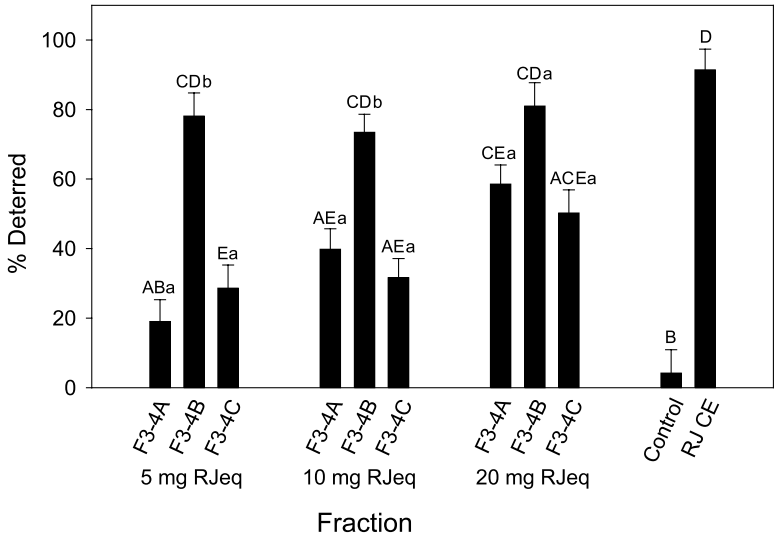

FIG. 5. Deterrent activity of the three fractions derived from fraction F3-4 in Step 3 of the fractionation process. Each fraction was evaluated at three doses: 5, 10, and 20 mg RJeq. Dichloromethane was used as a control and the response to crude extract of royal jelly (RJ) was included for comparison. Results of multiple comparison procedures are shown in lower and uppercase letters. Lowercase letters are valid for comparing responses to the three fractions within a single dose. Uppercase letters are valid for comparing the response of any fractions at one dose with the response to any fractions at the other two doses and to the control and crude extract. Bars with different letters are significantly different from each other (Tukey–Kramer, $P < 0.05$).

Lercker et al., 1982) showed that the fractions might contain hydroxy fatty acids. To confirm that these fatty acids were not present as their methyl esters in the original fraction, we carried out an experiment in which the active fraction was silylated with BSTFA without prior methylation. Analysis of this silylated extract revealed that only the TMS esters and TMS ethers of the acids were present; no methyl esters of the fatty acids were found.

The silylated β- and ω-hydroxy fatty acid methyl esters were identified by mass spectrometry according to an extensive study by Eglinton et al. (1968) and Capella and Zorzut (1968). The typical fragments of these fatty acids are given in Table 1. The ω-hydroxy esters all had characteristic peaks at M-15 and M-47 with a smaller peak at M-31. Other peaks present, such as $m/z = 73$ and 89, were all according to Eglinton et al. (1968). The β-hydroxy esters were identified with the same M-15, M-47, and M-31 peaks, but the relative intensities were different from the corresponding ions of the ω-hydroxy esters. Characteristic for

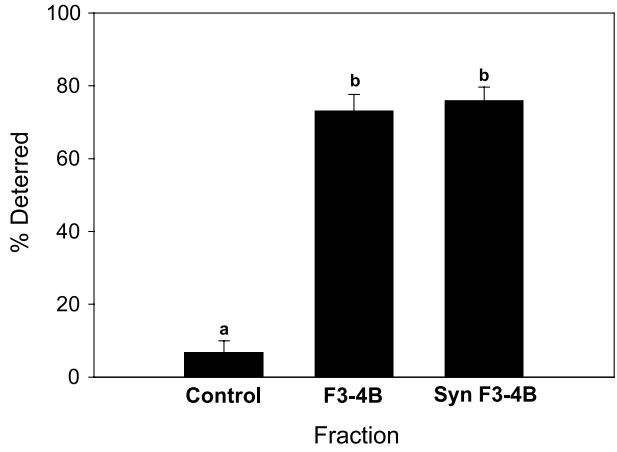

FIG. 6. Deterrent activity of the synthetic blend (Syn-F3-4B) and the original fraction (F3-4B). The amount of the original active fraction (F3-4B) used was 10 mg RJeq. The equivalent dose of the synthetic mixture used was 52 μg/lane. Ether was used as a control. Bars with different letters are significantly different from each other (Tukey–Kramer, $P < 0.05$).

these hydroxy esters was the loss of the alkyl chain adjacent to the hydroxy group, resulting in a loss of 56 amu (C_4H_8) for β-hydroxyoctanoic acid and a loss of 84 amu (C_6H_{12}) for β-hydroxydecanoic acid.

All the (ω-1)- and (ω-2)-hydroxy esters had the M-15, M-47, and M-31 peaks present. In addition to these peaks, an M-44 peak was present in the

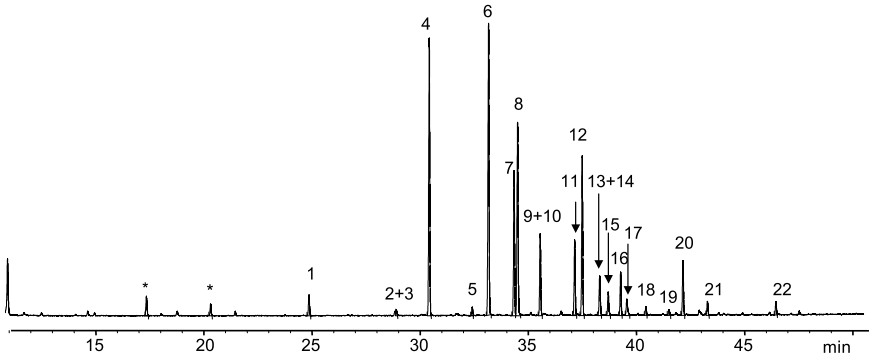

FIG. 7. Gas chromatogram of fraction F3-4B after methylation and silylation. For details on compounds, see Table 1. *Denotes compounds from the derivatization reaction.

(ω-1)-hydroxy esters and an M-58 peak was present in the (ω-2)-hydroxy esters. This M-44 (or M-58) peak corresponds to a shift of the TMS group from the hydroxy group to the carboxyl group followed by the elimination of $C_xH_{2x}O$. In the (ω-2)-hydroxy esters the M-31 peak was small and another peak, M-29 (loss of C_2H_5), was present in this type of ester.

Four unsaturated hydroxy fatty acids, that is, 10-hydroxydodecenoic acid, 11-hydroxydodecenoic acid, 12-hydroxydodecenoic acid, and 13-hydroxytetradecenoic acid, were not synthesized but were tentatively identified by comparison of their mass spectra with those of similar compounds (synthesized or commercially available). Each of these compounds had a similar fragmentation pattern to its analogue. Position and geometry of the double bond were not established in these compounds.

DISCUSSION

Varroa mites were deterred by crude extracts and fractions of crude extracts of royal jelly. Fraction F3-4B exhibited activity equivalent to that of the crude extract, and the activity of the synthetically reconstituted F3-4B fraction was equal to that of the native fraction. The tested amounts of crude extract, active fraction, or synthetically reconstituted fraction were all within the same range and thus comparable to each other. Compared to what a mite would encounter in a queen cell, the amounts used in the bioassay were ca. 10 times lower. However, the amounts per unit area were probably similar. Therefore, we think that the *in vivo* and *in vitro* responses would be similar. From studying the behavior of the mites in the bioassays, it appeared that the mites had to make contact with the extract before responding. However, whether contact is needed or whether being very close is sufficient to elicit a response still has to be investigated.

These results provide a possible mechanism to explain the low frequency of female *V. destructor* in capped queen cells. However, the difference in cell orientation between queen and worker/drone cells, as a possible contributing factor, has not been examined. In addition, our findings do not exclude a role for extractable compounds present on cuticles of worker and queen larvae (Trouiller et al., 1994; Calderone et al., 2002).

Most of the royal jelly compounds identified in this study have been reported previously (Brown et al., 1961; Lercker et al., 1981, and references therein; Lercker et al., 1982). Lercker et al. (1981) identified a large number of fatty acids and hydroxy fatty acids from royal jelly, and we have now identified several hydroxy esters listed as “unknown” by these authors. The composition of the active fraction F3-4B closely resembled that of the secretion of the mandibular glands of the workers (Simon et al., 2001). This is not surprising

because royal jelly is produced by the mandibular and hypopharyngeal glands of nurse bees. No 9-oxodecanoic acid (9-ODA, or queen substance) was found in the active fraction. Also, other components of the queen mandibular pheromone (QMP), such as the two enantiomers of (*E*)-9-hydroxy-2-decenoic acid, and 4-methyl-3-methoxyphenylethanol were not found. Only a small amount of methyl 4-hydroxybenzoate was found.

The next step in this research will be to determine the contribution of each of the 15 compounds in the synthetic blend to the deterrent activity exhibited by the native fraction. Field tests will be required to provide data on the possible application of these compounds for managing mite levels in honeybee colonies.

Acknowledgments—We thank Peter Borst and Liz Rowland for technical support. (Received December 6, 2004; revised February 23, 2005; accepted March 21, 2005)

Abstract—Male *Colletes cunicularius* bees pollinate the orchid, *Ophrys exaltata*, after being sexually deceived by the orchid's odor-mimicry of the female bee's sex pheromone. We detected biologically active volatiles of *C. cunicularius* by using gas chromatographic–electroantennographic detection (GC-EAD) with simultaneous flame ionization detection. After identification of the target compounds by coupled gas chromatography–mass spectrometry (GC-MS), we performed behavioral tests using synthetic blends of the active components. We detected 22 EAD active compounds in cuticular extracts of *C. cunicularius* females. Blends of straight chain, odd-numbered alkanes and (*Z*)-7-alkenes with 21–29 carbon atoms constituted the major biologically active compounds. Alkenes were the key compounds releasing mating behavior, especially those with (*Z*)-7 unsaturation. Comparison of patterns of bee volatiles with those of *O. exaltata* subsp. *archipelagi* revealed that all EAD-active compounds were also found in extracts of orchid labella. Previous studies of the mating behavior in *C. cunicularius* showed linalool to be an important attractant for patrolling males. We confirmed this with synthetic linalool but found that it rarely elicited copulatory behavior, in accordance with previous studies. A blend of active cuticular compounds with

* To whom correspondence should be addressed. E-mail: florian.schiestl@env.ethz.ch

linalool elicited both attraction and copulation behavior in patrolling males. Thus, linalool appears to function as a long-range attractant, whereas cuticular hydrocarbons are necessary for inducing short-range mating behavior.

Key Words — *Ophrys*, solitary bee, sex pheromone, pollination by sexual deception, alkane, alkene, floral mimicry.

INTRODUCTION

Colletes cunicularius (L.) (Hymenoptera: Colletidae) is a solitary oligolectic bee that nests in aggregations and mates soon after emergence. Males display a competitive mate-searching behavior based on olfactory cues. Females dig their nest cavities up to 1 m deep in sandy soil and line the brood cells with a secretion of the Dufour's gland (Cane, 1981). Males emerge first and patrol along the nest entrances in search of a mate. Using olfactory cues, males are able to accurately locate preemergent virgin females and distinguish them from mated females (Bergström and Tengö, 1978; Batra, 1980; Cane and Tengö, 1981). However, patrolling males are also attracted to preemergent males (Cane and Tengö, 1981). Females emerging from their nests stimulate scramble competition among large numbers of competing males (Müller, 1991). *C. cunicularius* is active in early spring from March to May when few bees or other insect species are in flight and at a time that restricts its primary pollen source to the early flowering *Salix* (Amiet et al., 1999). Males die during April/May, whereas females continue to provision nests until the end of May.

Previous studies on chemical communication in *C. cunicularius* concentrated on the effects of cephalic compounds, in particular linalool, because it is the major compound in the mandibular gland secretions of both sexes in all *Colletes* species examined (Bergström and Tengö, 1978; Hefetz et al., 1979; Cane and Tengö, 1981; Lindsley and Zavortink, 1997). In behavioral experiments, Cane and Tengö (1981) demonstrated that linalool acts as a pheromone that enhances attraction and directs local search behavior of patrolling males to emerging females. However, in these tests linalool rarely stimulated male excavating or pouncing (copulatory) behaviors. In contrast, head extracts of female *C. cunicularius* and even floral extracts of the orchid that mimics the female bees, *Ophrys arachnitiformis–sphegodes*, attracted more males, caused more local searching, and released more copulatory attempts than linalool alone (Cane and Tengö, 1981). The lack of full copulatory behavior and the occurrence of linalool in males as well as females led Cane and Tengö to suggest that the presence of linalool may function mainly as a long-range attractant or aggregation signal stimulating precopulatory behavior in males. They suggested that pouncing behavior and the ability of males to distinguish between virgin and mated females may involve other olfactory cues, such as

long-chain hydrocarbons that are present in *Colletes* and have subsequently been shown to be active in other bee genera such as *Lasioglossum* (Ayasse et al., 1999) and *Andrena* (Schiestl et al., 2000).

Recently, Borg-Karlson et al. (2003) showed enantiometrically pure (*S*)-(+)-linalool to be the main mandibular gland constituent of males and females of *C. cunicularius*, although both enantiomers induced electrophysiological responses from male antennae. Virgin females and males contain similar amounts of (*S*)-(+)-linalool (mean 71% of cephalic pentane extracts), whereas mated females had reduced amounts (mean 47%) (Borg-Karlson et al., 2003). Synthetic (*S*)-(+)-linalool attracted the highest number of male bees, followed by the racemate and (*R*)-(–)-linalool. Thus, (*S*)-(+)-linalool, present in *C. cunicularius*, was shown to be an important component of the mate attractant pheromone. The decrease in (*S*)-(+)-linalool in mated females was suggested to account for the loss of attractiveness of mated females to patrolling males. However, the role that other compounds might play in eliciting *C. cunicularius* mating behavior was not further discussed. The apparent simplicity in the chemical communication between sexes was posited to be a response to the low interspecific competition in chemical signals and to the harsh meteorological environment of the early European spring.

The mandibular glands of females are an important source of sex pheromones in eusocial stingless bees (Engels et al., 1990; Engels, 1993), bumble bees (van Honk et al., 1978), and carpenter bees (Gerling et al., 1989). However, recent studies indicate that male attractant pheromones can involve multiple compounds from cuticular as well as other glandular secretions (Ayasse et al., 2001). Studies on *Andrena* (Schiestl et al., 1999), *Lasioglossum* (Wcislo, 1987; Ayasse et al., 1999), *Osmia* (Ayasse and Dutzler, 1998), and *Nomia* species (Wcislo, 1992) have detected female sex pheromones consisting of compounds localized on the surface of the cuticle. In *Lasioglossum zephryum* (Halictidae), macrocyclic lactones produced by the Dufour's gland appear to function as a sex pheromone (Smith et al., 1985). However, behavioral tests using synthetic lactones did not elicit copulatory behavior. Examination of the related *L. malachurum* revealed that the Dufour's gland was not the sole source of sex pheromone activity (Ayasse et al., 1993). Rather, hydrocarbons, isopentenyl esters, and unsaturated macrocyclic lactones localized on the cuticle induced copulation attempts by males.

Cuticular hydrocarbons, although known to have a major function in desiccation resistance (Hadley, 1981), are also used as sex pheromones in many insect taxa, especially among Diptera (Howard, 1993; Singer, 1998). In *Andrena* bees (Andrenidae), species-specific blends of cuticular hydrocarbons function as sex pheromones attracting males (Schiestl et al., 2000; Schiestl and Ayasse, 2002). Chemical analysis of the floral odors of the orchid, *Ophrys sphegodes*, showed hydrocarbon patterns similar to those found in females of the pollinator

species, *Andrena nigroaenea* (Schiestl et al., 2000). Behavioral tests confirmed that *O. sphegodes* precisely mimics the female bee's olfactory cues and sexually deceives the pollinating *Andrena* males and thereby avoids the provision of floral rewards.

In this study, we reexamined the sex pheromone of *C. cunicularius*, the pollinator of *Ophrys exaltata* Tenore (*O. arachnitiformis* species group), a sexually deceptive orchid species from southern Italy (Paulus and Gack, 1990a,b; Delforge, 1994). Our objectives were to (1) identify all components of the female sex pheromone of *C. cunicularius*, (2) investigate differences in the patterns of volatiles between virgin and mated females, (3) examine the importance of different physiologically active compounds for male attraction, and (4) compare the pattern of physiologically active compounds in *C. cunicularius* with the volatiles of its orchid mimic, *O. exaltata*.

METHODS AND MATERIALS

Sample Collection. Virgin *C. cunicularius* females were collected during the early flight season in March at Neuhausen (Switzerland). Wherever a cluster of males with an attractive female in the center was detected, the female was separated from the males as fast as possible, placed in a Perspex vial, and kept in a chilled box. Mated females were collected after the disappearance of males in late April at Neuhausen. All sampled bees were freeze-killed on the day on which they were caught. A total of 56 virgin and 22 mated females as well as 10 males were collected. For cuticle extracts, the whole body was extracted in 400 μl hexane for 1 min., whereas for head extracts, the head was extracted in 150 μl hexane for 24 hr.

For the orchids, 69 samples of *O. exaltata* subsp. *archipelagi* Gölz and Reinhard, representing a subsample of those individuals sampled by Mant et al. (2005) were collected at two nearby populations in Monte Gargano (southeastern Italy). The labella were extracted in 200 μl hexane for 1 min. All samples were stored at −20°C.

Gas Chromatographic Analysis with Electroantennographic Detection (GC-EAD). Aliquots of 1 μl of the cuticle extracts of virgin females were injected splitless at 50°C (1 min) into an Agilent 6890 N gas chromatograph (Agilent Palo Alto, CA, USA) followed by programming to 300°C at 10°C min^{-1}. The gas chromatograph (GC) was equipped with an HP-5 column (30 m × 0.32 mm diam × 0.25 μm film thickness) and a flame ionization detector (FID). Helium was used as carrier gas. A GC effluent splitter (SGE International Pty Ltd, Sydney, Australia) was used, and a portion of the eluate was added to a purified and humidified air stream, directed over the excised antenna of a male

bee. The tip of the antenna was cut off, and the antenna was mounted between two electrodes using electrocardiograph gel. The electrode holding the base of the antenna was grounded. The distal end of the antenna was connected via an interface box (Syntech, Hilversum, the Netherlands) for signal transfer to a personal computer. EAD signals and FID responses were simultaneously recorded. Twelve GC-EAD runs were performed with antennae from six males to check the reproducibility of antennal responses.

Structure Elucidation. The structures of compounds that elicited GC-EAD responses were identified by coupled gas chromatographic–mass spectrometric (GC-MS) analysis and coinjection with authentic standards. Extracts were analyzed with an HP-5970 (Hewlett-Packard) gas chromatograph equipped with a DB-5 capillary column (30 m $\times$ 0.32 mm diam) operated at 120°C for 30 sec, then 4°C min^{-1} to 280°C. Structure elucidation of individual compounds was based on GC-MS analysis (VG70/250 SE instrument, Vacuum Generators, Manchester, England, UK, linked to an HP-5890 GC; conditions as mentioned above). Mass spectra (70 eV) were compared with those reported in the literature (McLafferty and Stauffer, 1989) and with those of authentic reference samples. Gas chromatographic retention times were checked by coinjection. Double bond positions in mono- and diunsaturated compounds were assigned according to Buser et al. (1983) and Dunkelblum et al. (1985). The stereochemistry of double bonds was determined by comparison of retention times using corresponding reference samples, including dimethyldisulfide (DMDS) derivatives, as the erythro- and threo-adducts could be separated by GC.

Synthetic Compounds. The following compounds were purchased from Aldrich: linalool, decanol, dodecanol, hexadecanol, eicosanol, tetradecanoic acid, hexadecanoic acid, oleic acid, linoleic acid, tetracosanoic acid, saturated hydrocarbons, (9*Z*)-tricosene, 1-alkynes. Aldehydes were prepared from commercially available alcohols by using Swern oxidation (Mancuso and Swern, 1981). Mass spectra of synthetic compounds matched the expected patterns (McLafferty and Stauffer, 1989) and GC retention times. Esters were prepared form the corresponding acid chlorides and the appropriate alcohols according to standard laboratory methods. Mass spectra of synthetic compounds matched the expected patterns (Francke et al., 2000) and GC retention times. Alkenes were prepared by Lindlar hydrogenation of the corresponding alkynes. In a typical synthesis, a 1-alkyne was coupled to a 1-iodoalkane according to Buck and Chong (2001). The crude product was purified by column chromatography (Merck silica 60, 120–400 mesh, hexane). Lindlar catalyst (440 mg) was added to a solution of 0.7 ml (5.8 mmol) freshly distilled quinoline in 10 ml hexane. After addition of 1.87 mmol of the alkyne in 5 ml hexane, hydrogenation was carried out for 4 hr at room temperature and atmospheric pressure. Subsequently, the catalyst was filtered off, and the solvent was removed *in vacuo*. Chromatography on silica provided the pure (*Z*)-alkene in over 95% yield and

99% chemical purity. Alkadienes were prepared from the corresponding alkadiynes by Lindlar hydrogenation. As an example, the synthesis of (8*Z*, 20*Z*)-nonacosadiene is described. The corresponding reaction scheme is shown in Figure 1.

2-(10′-Bromodecyloxy)-tetrahydropyrane ***1***

A solution of 1.47 ml (16.3 mmol) 2,3-dihydro-4*H*-pyrane in 10 ml dichloromethane was added to a solution of 2.5 ml (13.6 mmol) 10-bromodecan-1-ol **1** (Aldrich) and 51 mg (0.27 mmol) *p*-toluene-sulfonic acid hydrate in 100 ml dichloromethane, which was cooled to −15°C. The reaction mixture was stirred for 1 hr, and subsequently warmed to room temperature. After the addition of 75 ml hexane, 75 ml of a saturated aqueous sodium carbonate solution were added. After separation, the aqueous layer was extracted three times with 50 ml hexane. The combined organic layers were washed with brine, dried over magnesium sulfate, and concentrated *in vacuo*. The crude product was chromatographed on silica using hexane: ethyl acetate 15:1 (v:v). As a result, 3.25 g (10 mmol, 74%) of 2-(10′-bromodecylocy)-tetrahydropyrane were obtained.

MS (70 eV): *m/z* [%] = 368 (1.69, M^+), 183 (6), 102 (10), 101 (17), 97 (11), 87 (14), 86 (69), 85 (100), 84 (12), 83 (26), 71 (6), 69 (24), 68 (5), 67 (10), 58 (7), 57 (33), 56 (26), 55 (48), 43 (23), 42 (11), 41 (40).

Nonadec-11-yne-1-ol ***3***

A total of 6.7 ml (10.7 mmol) of a 1.6 M solution of *n*-butyl lithium in hexane were added dropwise to a solution of 1.94 ml (11.7 mmol) non-1-yne in 100 ml absolute THF, cooled to −78°C. The mixture was warmed to room temperature within 4 hr, and 3.59 g (9.74 mmol) of **2**, dissolved in 10 ml hexane, were added. The mixture was refluxed for 12 hr. After cooling, 100 ml of saturated aqueous ammonium chloride solution were added. After separation of the layers, the aqueous phase was extracted three times with 50 ml of diethyl

ether. The combined organic solutions were washed with brine, dried over magnesium sulfate, and concentrated *in vacuo*. The residue was dissolved in 50 ml absolute methanol, and 0.5 g *p*-toluene sulfonic acid hydrate were added. The mixture was stirred for 20 min at 50°C. After cooling to room temperature, the solvent was removed *in vacuo*, and the residue was partitioned between 100 ml diethyl ether and 100 ml water. Subsequently, the aqueous layer was extracted three times with 50 ml diethyl ether. The combined organic solutions were washed with brine and concentrated *in vacuo*. Purification was carried out by column chromatography using silica and hexane:ethyl acetate 10:1 (v:v). As a result, 2.06 g (7.35 mmol, 75%) of nonadec-11-yne-1-ol **3** were obtained.

^{1}H NMR (400 MHz, $CDCl_3$): δ [ppm] = 0.89 (t, 3H, *J* = 6.61 Hz, H-19), 1.28–59 (m, 26H, H-2-H-9/H-14-H-18), 2.13 (t, 4H, *J* = 6.86 Hz, H-10/H-13), 3.63 (t, 2H, *J* = 6.61 Hz, H-1).

^{13}C NMR (101 MHz, $CDCl_3$): δ [ppm] = 14.48 (q, C-19), 19.17/23.03/26.15/29.24/29.57/29.82/29.88/29.97/32.19/33.20 (t, C-2-C-10/C-13-C-18), 63.45 (t, C-1), 80.55/80.68 (s, C-11/C-12).

MS (70 eV): *m/z* [%] = 390 (1.28, M^+), 196 (6), 155 (9), 137 (6), 124 (5), 123 (19), 111 (5), 110 (11), 109 (29), 97 (12), 96 (16), 95 (54), 93 (12), 91 (11), 83 (21), 82 (23), 81 (83), 79 (37), 77 (15), 69 (42), 68 (20), 67 (100), 65 (12), 57 (13), 56 (11), 55 (66), 54 (23), 53 (16), 52 (7), 43 (65), 42 (14), 41 (96).

Nonacosa-8,20-diyne ***5***

A solution of 0.28 ml (1.54 mol) 1-decyne in 30 ml absolute THF was cooled to −78°C, and 0.8 ml (1.41 mmol) of a 1.6 M solution of *n*-butyl lithium in hexane was added. The stirred solution was warmed to room temperature within 3 hr. Subsequently, 0.5 g (1.28 mmol) nonadec-11-ynyliodide **4** was added, and the mixture was refluxed for 12 hr. After cooling to room temperature, 50 ml saturated aqueous ammonium chloride solution were added. After separation of the layers, the aqueous solution was extracted three times with 30 ml hexane. The combined organic layers were washed with brine, dried over magnesium sulfate, and concentrated *in vacuo*. Purification was carried out by column chromatography using silica and hexane. As a result, 312 mg (0.78 mmol, 61%) of nonacosadiyne **5** were obtained.

^{1}H NMR (400 MHz, $CDCl_3$): δ [ppm] = 0.88 (t, 6H, *J* = 6.86 Hz, H-1/H-29), 1.21–1.40 (m, 30H, H-2-H-5/H-12-H-16/H-24-H-28), 1.45–1.52 (m, 8H, H-6/H-11/H-18/H-23), 2.10–2.17 (m, 8H, H-7/H-10/H-19/H-22).

^{13}C NMR (101 MHz, $CDCl_3$): *δ* [ppm] = 14.32/14.48 (q, C-1/C-29), 19.24/23.10/23.18/29.01/29.21/29.26/29.32/29.71/29.98/30.02/30.05/32.18/32.25 (t, C-2-C-7, C-10-C-19/C-22-C-28), 80.42/80.72 (s, C-8/C-9/C-20/C-21).

MS (70 eV): *m/z* [%] = 400 (0.10, M^+), 301 (6), 287 (6), 203 (5), 189 (7), 175 (7), 161 (6), 149 (6), 147 (8), 135 (13), 133 (9), 123 (8), 122 (5), 121 (21), 119 (12), 110 (6), 109 (21), 108 (8), 107 (21), 106 (5), 105 (17), 97 (9), 96 (12), 95 (52), 94 (15), 93 (32), 92 (5), 91 (19), 83 (17), 82 (18), 81 (78), 80 (18), 79 (48), 77 (12), 71 (8), 70 (6), 69 (34), 68 (18), 67 (100), 66 (6), 65 (9), 57 (33), 56 (14), 55 (91), 54 (35), 53 (18), 52 (5), 43 (68), 42 (11), 41 (82).

(8Z,20Z)-Nonacosadiene ***6***

Sixty milligrams Lindlar catalyst (Lancaster) and 125 mg (0.31 mmol) nonacosa-8,20-diyne **5** were added to a solution of 0.09 ml (0.75 mmol) freshly distilled quinoline in 5 ml hexane. Hydrogenation was carried out at room temperature and atmospheric pressure. After filtration, the solvent was removed *in vacuo*. Purification was carried out by column chromatography using silica and hexane. As a result, 117 mg (0.29 mmol, 94%) (8*Z*,20*Z*)-nonacosadiene were obtained.

^{1}H NMR (400 MHz, $CDCl_3$): δ [ppm] = 0.88 (t, 6H, J = 7.12 Hz, H-1/H-29), 1.20–1.45 (m, 38H, H-2-H-6/H-11-H-18/H-23-H-28), 1.98–2.05 (m, 8H, H-7/H-10/H-19/H-22), 5.32–5.37 (m, 4H, H-8/H-9/H-20/H-21).

^{13}C NMR (101 MHz, $CDCl_3$): δ [ppm] = 14.50 (q, C-1/C-29), 23.08/25.74/27.62/29.63/29.68/29.73/29.97/30.19/32.29/32.32/32.88 (t, C-2-C-7, C-10-C-19/C-22-C-28), 130.25/130.32 (d, C-8/C-9/C-20/C-21).

MS (70 eV): *m*/*z* [%] = 404 (0.87, M^+), 152 (5), 138 (10), 137 (7), 125 (5), 124 (16), 123 (12), 111 (12), 110 (23), 109 (20), 97 (35), 96 (63), 95 (35), 84 (5), 83 (48), 82 (62), 81 (43), 80 (6), 79 (6), 71 (7), 70 (13), 69 (55), 68 (26), 67 (43), 57 (31), 56 (23), 55 (100), 54 (28), 53 (5), 43 (56), 42 (9), 41 (53).

Quantitative Analyses of GC Data. Gas chromatography was used for quantitative analysis of extracts of individual female bees and orchids, using the same parameters as for GC-EAD. For quantitative analysis, *n*-octadecane was added as an internal standard. Absolute amounts were calculated by dividing the peak area of each compound by the peak area of the internal standard and multiplied with the internal standard amount (head extracts 0.5 μg, cuticle extracts 1 μg). Means and standard deviations were calculated for all compounds within each group of samples (cuticle of virgin females, head of virgin females, cuticle of mated females, cuticle of males, labella of *O. exaltata*).

Behavioral Tests. Head extracts and cuticle extracts of ten bees were tested for their attractiveness during the 2003 season. All behavioral tests were performed at Neuhausen, Switzerland, except for tests with linalool, which were performed at a second *C. cunicularius* population site at Fussach, in western Austria. Dead male bees, made odorless by extraction with a mixture of hexane and dichloromethane for 24 hr, were used as dummies. For each 3-min test, 70 μl of the head extracts and 200 μl of the cuticle extracts were applied to a dummy. After the solvent had evaporated, the dummy was placed in a male patrolling area. Behavioral responses of *C. cunicularius* males were classified into two categories: (1) approach, a zig-zagging or undulating approach towards the scented source and (2) contact, either a short pouncing contact with the scented source or a longer contact involving copulatory behavior. To control for the effect of visual and tactile stimuli alone, odorless dummies were tested after every fifth test.

Bioassays with synthetic compounds were performed during the 2004 season using cylindrical, black plastic beads as dummies rather than dead, odorless males, but otherwise with unchanged conditions. A subtractive design was chosen to test the relative importance of various mixtures of active compounds. However, mixtures of only the 12 most abundant compounds were used because not all compounds were available as synthetic substances. The following mixtures were prepared and their attractiveness tested in comparison to controls: (1) 12 active compounds, (2) active alkenes, (3) active alkanes,

(4) active (*Z*)-7-alkenes. Synthetic blends were tested that matched the mean relative amounts of compounds found in virgin females at the Neuhausen *C. cunicularius* population. The absolute amount used corresponded to that found in one individual female bee. One hundred microliter solutions of each blend were applied to the dummies. In addition, to investigate the behavioral effects of linalool, the attractiveness of linalool alone was tested and in a mixture including all 12 active compounds, using synthetic racemic linalool (1 μg).

Statistical Analysis. To compare the relative amounts of odor compounds among groups Kruskal–Wallis tests were employed because variances were not homogeneous among groups. Mann–Whitney *U* tests were used for *a posteriori* multiple comparison with a Bonferroni correction and the level of significance set to $P = 0.05$ divided by the number of comparisons. To test for differences in male bee responses in the different behavioral experiments, either the *t*-test or Kruskal–Wallis test followed by Mann–Whitney *U* tests with a Bonferroni correction were used, as for the GC data. All calculations, tests, and graphics were performed with the statistical package SPSS 11 (Brosius, 2002).

RESULTS

Attractiveness of Virgin Female Extracts. Head extracts and cuticle extracts elicited similar numbers of approaches by male bees (Figure 2). However, cuticle extracts were more attractive than head extracts as they elicited significantly more "contacts" than head extracts.

Electrophysiology (GC-EAD). Because head extracts elicited few contacts in the behavioral tests, GC-EAD was performed only with cuticle extracts. Using GC-EAD, we detected 22 electrophysiologically active peaks representing 24 compounds in the cuticle extracts of virgin *C. cunicularius* females (Figure 3 and Table 1). Two GC peaks that elicited antennal responses consisted of more than one compound: hexadecanal and isopropyl tetradecanoate (peak 2), and dodecyl tetradecanoate and decyl hexadecanoate (peak 17). As a conservative approach, we treated both compounds found within each peak as active. The most abundant of the 22–24 electrophysiologically active compounds found in the cuticle were straight chain, odd-numbered alkanes and alkenes with 21 to 29 carbon atoms. Other compounds included two esters (compound numbers 2 and 17) three aldehydes (numbers 2, 5, and 13), and a terpene, linalool. The active compound A, which occurred in relatively small amounts, remained unidentified. The strongest reactions from male antennae were elicited by (*Z*)-9 and (*Z*)-7-alkenes and alkanes (Figure 3).

Differences in Volatiles among Female and Male C. cunicularius. Cuticle extracts of virgin and mated females differed with respect to the quantities of several bioactive compounds (Table 1, Figure 4). Virgin female cuticle extracts

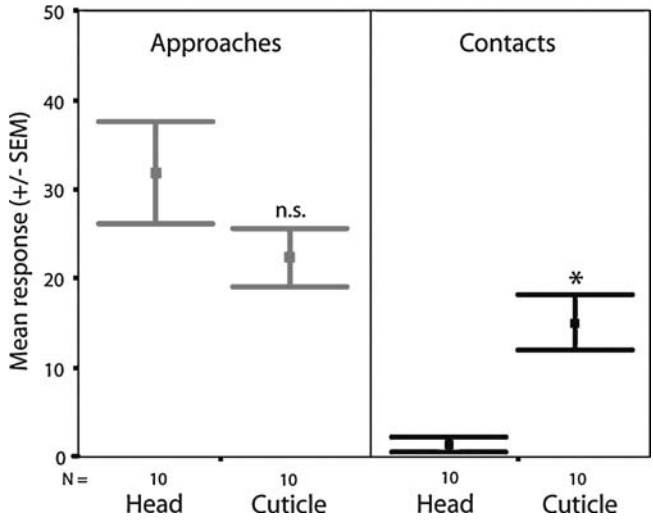

FIG. 2. Mean behavioral responses of *C. cunicularius* males exposed to head and cuticle extracts of virgin *C. cunicularius* females. Error bars are standard errors of means. Cuticle extracts elicited a similar number of approaches as head extracts ($t_{18} = 1.44$, $P = 0.17$), but cuticles elicited more contacts than head extracts ($t_{10,4} = -4.3$, $P < 0.01$).

had significantly more linalool, (*Z*)-7-heneicosene, heptacosane, hexadecanal, and eicosanal than mated female cuticles. Virgin females had less (*Z*)-9-heneicosene, dodecyl tetradecanoate, and decyl hexadecanoate.

Quantities of many compounds that did not elicit antennal responses also differed significantly between virgin and mated female cuticles. Three of these occurred in increased amounts in mated female cuticle extracts, namely, oleic acid (virgin cuticle 0.8% vs. mated female 27%), linoleic acid (0.6% vs. 8.6%), and the unidentified compound U3 (1.2% vs. 12%). These three compounds did not elicit EAD responses, but it should be noted that they were present only in small amounts in the virgin cuticle extracts used in the GC-EAD experiments. As for the cuticle extracts, head extracts of virgins contained significantly more linalool and (*Z*)-7-heneicosene than head extracts of mated females.

In male cuticles, the most abundant compounds were alkanes with 21 to 29 carbon atoms and (*Z*)-7-heneicosene. In particular, the EAD-active compounds heneicosane, tricosane, and (*Z*)-7-heneicosene occurred in relatively high amounts (Table 1, Figure 4). Other EAD-active compounds occurred in extracts from males in only minor amounts.

Differences in Odor between C. cunicularius and O. exaltata. All 22 compounds detected in cuticle extracts of *C. cunicularius* that elicited EAD

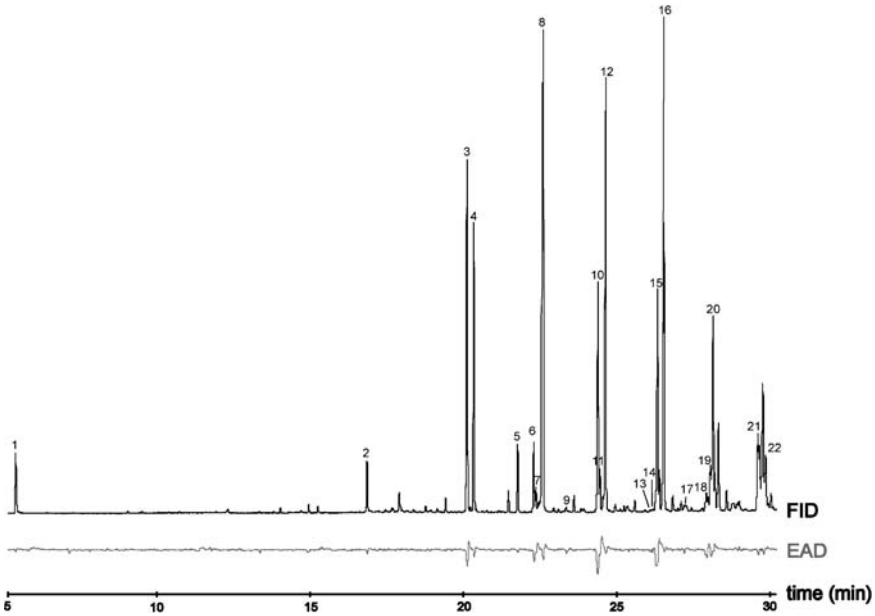

FIG. 3. Gas chromatographic analysis with electroantennographic detection (GC-EAD) of a cuticle extract of a virgin *C. cunicularius* female. Flame ionization detector and EAD responses were simultaneously recorded using an antenna of a *C. cunicularius* male. Numbered peaks correspond to compounds eliciting EAD responses. Compounds are listed in Table 1. Twelve GC-EAD runs were carried out with six males and the reproducibility of all responses at the same retention times was confirmed.

responses were found in the labellum extracts of *O. exaltata* subsp. *archipelagi* (Table 1, Figure 5). However, most of the compounds differed in their relative amounts between orchid and bee extracts (Figure 5). In particular, the (*Z*)-7-alkenes (C21, C23, C25) occurred in higher amounts in *O. exaltata* than in *C. cunicularius* females and, to a lesser extent, eicosanal and tetracosanal.

Behavioral Tests Using Synthetic Compounds. The first bioassay showed that linalool attracts patrolling males without eliciting corresponding contacts (pounces or attempted copulations) with the artificial odor source (Figure 6) (all tests using Mann–Whitney *U* test, with $P < 0.01$). The blend of 12 EAD-active odor compounds attracted a similar number of males to linalool alone, but elicited more contacts. When linalool was combined with the blend of active compounds, the number of males attracted was not different from the number attracted by linalool alone, but the number of contacts was higher than with the blend or linalool alone.

[1] Different letters indicate significant differences between groups as calculated by a Mann–Whitney *U* test, $P < 0.003$.
[2] Letters refer to the sources of reference compounds as described in Methods and Materials. Peak numbers 2 and 17 represent two compounds, with the second mentioned compound occurring in trace amounts.
[3] Compounds arranged according to retention time. *Indicates compounds used for bioassays.
[4] Corresponding peak in cuticle of virgin females is not tetracosanal.
[5] In postcopulatory females: hexadecyl decanoate (and decyl hexadecanoate).
[6] Identified in *Ophrys*, in mated females: mix of (7,15)-, (7,17)-, (7,20)-nonacosadienes (geometry of double bonds not determined).
[7] A selection of abundant nonactive compounds found in the extracts of *C. cunicularius*.

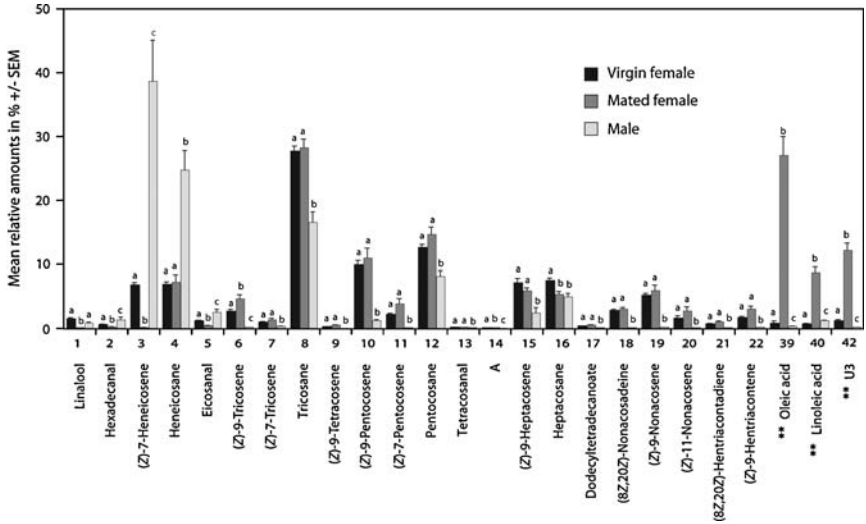

FIG. 4. Relative mean amounts of EAD-active compounds in cuticle extracts of males and virgin and mated females of *C. cunicularius*. Error bars are standard errors of means. Significant differences between groups for one compound are indicated by different letters according to Mann–Whitney *U* test. For compounds numbers 2 and 17 please compare Table 1 for details.

Bioassays using various synthetic blends (Table 2) showed that the mixture of all 12 EAD-active hydrocarbons and the (*Z*)-7-alkenes induced similar numbers of attractions and contacts (Mann–Whitney *U* test, with $P < 0.005$, Figure 7). Behavioral responses to the mixture containing only alkenes were not different from the responses shown to (*Z*)-7-alkenes, but elicited fewer attractions or contacts than the 12-compound blend. Responses to alkanes were equivalent to responses to controls.

DISCUSSION

This study has shown that sex pheromone components of *C. cunicularius* are associated with the cuticle of virgin females and are also present in head extracts. GC-EAD experiments demonstrated that electrophysiologically active compounds include linalool and straight-chain, odd-numbered alkenes and alkanes with 21 to 29 carbon atoms. The attraction of males to a subset of these compounds was demonstrated in tests using synthetic compounds, confirming their function as attractant pheromones.

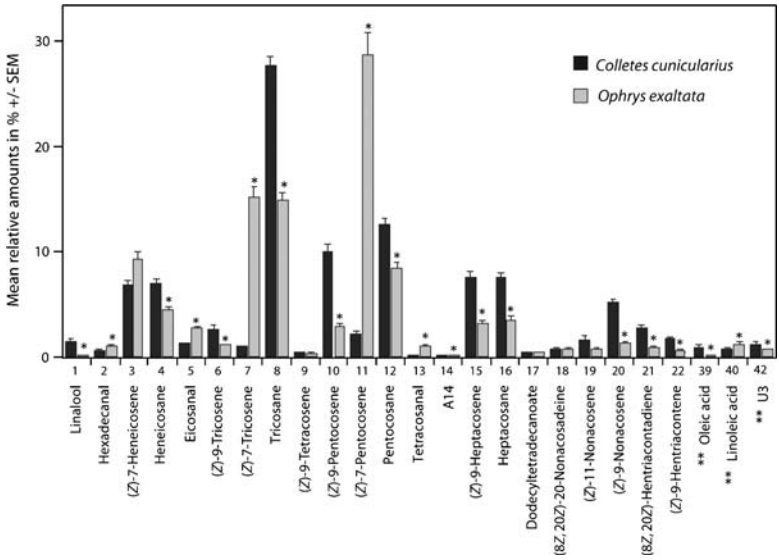

FIG. 5. Relative mean amounts of EAD-active compounds in cuticle extracts of virgin *C. cunicularius* females and labellum extracts of *O. exaltata*. Error bars are standard errors of means. Asterisk indicates significantly different relative amounts (see Table 1).

Linalool has previously been shown to have a sex pheromone function in *C. cunicularius* by its stimulation of an immediate increase in flight activity among patrolling males (Bergström and Tengö, 1978; Cane and Tengö, 1981; Borg-Karlson et al., 2003). Our study confirmed these earlier results by showing the attraction of patrolling males to synthetic linalool and to head extracts that contained high relative amounts of linalool. However, our behavioral tests also indicated that linalool alone rarely releases full mating behavior in males, consistent with previous findings (Cane and Tengö, 1981; Borg-Karlson et al., 2003). Head extracts containing high amounts of linalool elicited few contacts with the odor source, whereas this was frequently induced by cuticular extracts. Yet, more contacts were recorded with a mix of linalool and the blend of 12 active hydrocarbons than recorded with the blend of hydrocarbons or linalool alone. Presumably, the high amount of linalool in head extracts attracts patrolling males, whereas the relatively low amounts of other physiologically active compounds fail to trigger full mating behavior. These results lead us to support the contention of Cane and Tengö (1981) that linalool functions as a long-range sex attractant that enhances the onset of mating, whereas the presence of physiologically active cuticular hydrocarbons is necessary to induce copulatory behavior.

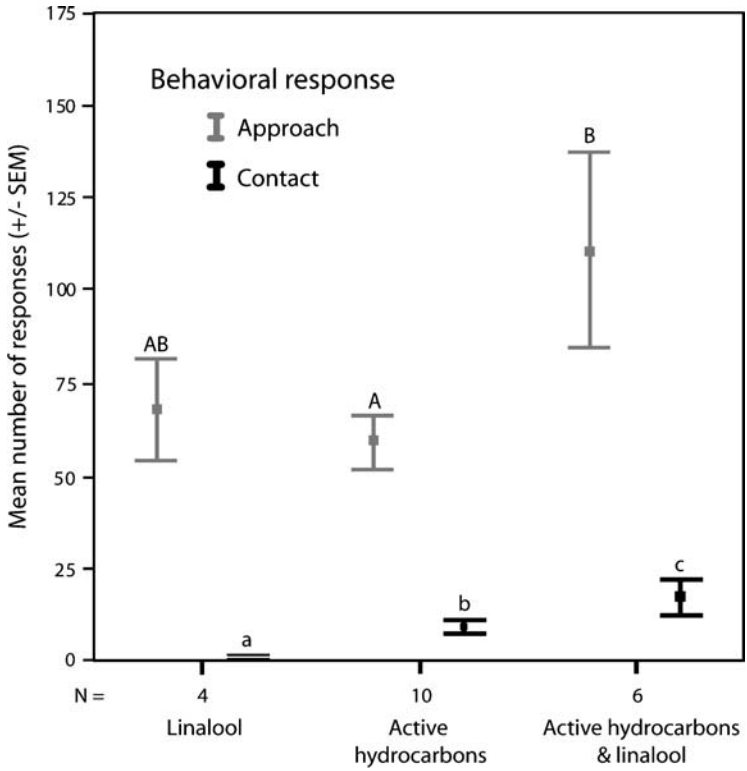

FIG. 6. Behavioral responses of *C. cunicularius* males to racemic linalool and a blend of EAD-active alkanes and alkenes (see Table 2 for blend composition). Different letters indicate significant differences among the test groups for "approaches" and "contacts" separately.

The behavioral tests with various subsets of the EAD-active compounds showed considerable differences in attractiveness to males. The most complete mixture of 12 compounds and the (*Z*)-7-alkenes were most attractive, followed by the blend of alkenes. The mixture of alkanes was not attractive (Figure 7). Interestingly, the mixture of 12 active compounds was more attractive than the full alkene blend, which suggests a synergistic effect among alkanes and alkenes, because the alkanes alone were not attractive. However, in our tests, there was a trend for the blend containing only (*Z*)-7-alkenes to be more attractive than the full alkene blend, suggesting that certain alkenes may inhibit the behavioral activity of the (*Z*)-7-alkenes. More behavioral tests are needed to confirm this. Generally, our results are similar to those from behavioral tests

TABLE 2. ABSOLUTE AMOUNTS (μg) OF SYNTHETIC COMPOUNDS USED FOR BIOASSAYS

[a] Virgin female

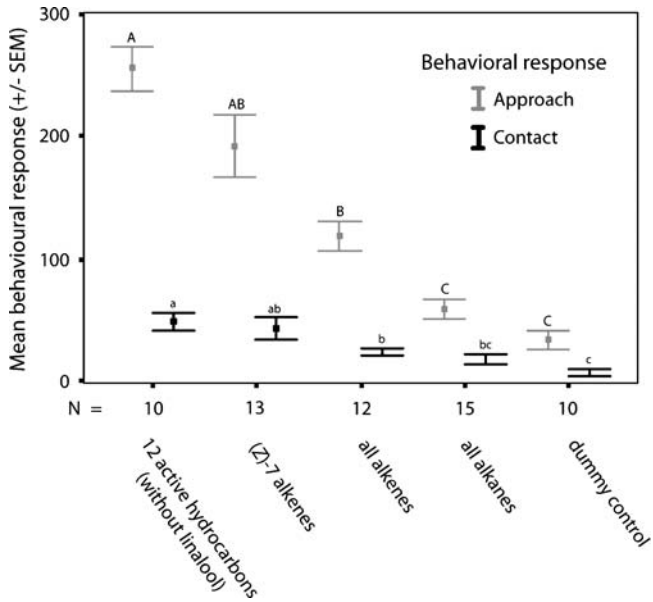

FIG. 7. Behavioral responses of *C. cunicularius* males to different blends of EAD-active compounds (see Table 2 for blend compositions). Different letters indicate significant differences among the synthetic mixtures for "approaches" and "contacts" separately.

with *A. nigroaenea* in which blends of alkenes triggered approaches and contacts, whereas blends of alkanes were unattractive (Schiestl et al., 2000).

Avoidance of mated females by males has been suggested to be mediated by olfactory cues (Cane and Tengö, 1981). In the solitary bee, *A. nigroaenea*, the avoidance of mated females by patrolling males is due to an increase in farnesyl hexanoate, an antiaphrodisiac compound released from the Dufour's gland of mated females (Schiestl and Ayasse, 2000). The repellent compounds are also produced in pollinated flowers of *O. sphegodes* and may function to guide pollinators to unpollinated flowers within an inflorescence, thus increasing the reproductive fitness of the plant (Schiestl et al., 1997; Schiestl and Ayasse, 2001). In *C. cunicularius*, three compounds that increased markedly in cuticle extracts of mated females may also function as repellent or deterrent compounds, namely, oleic acid, linoleic acid, and the unidentified U3 (Figure 4). However, behavioral tests with these compounds have yet to be performed, and we did not detect male antennal responses to them.

The drop in male response to mated females could also be due to a reduction in the compounds that comprise the sex pheromone. Of the physiologically active compounds in cuticle extracts, linalool, (*Z*)-7-heneicosene and eicosanal, and to a lesser extent, hexadecanal and isopropyl tetradecanoate, decreased in mated females. Of these compounds, only linalool and (*Z*)-7-heneicosene showed a strong decrease also in head extracts of mated females in comparison to virgin ones. Thus, our behavioral tests, by highlighting the relative importance of (*Z*)-7-alkenes and linalool (Figures 6 and 7), support the suggestion that a reduction in (*Z*)-7-heneicosene and linalool contributes to a reduction in responses of males to mated females. Of note is that these two compounds are also present among the volatiles of males, with linalool being the most abundant compound in head extracts of males (Borg-Karlson et al., 2003) and (*Z*)-7-heneicosene the most abundant compound in cuticle extracts of males (Table 1). The observation that patrolling males were attracted to preemergent males as well as to preemergent females (Cane and Tengö, 1981) may be due to the production of (*Z*)-7-heneicosene and linalool by males.

Behavioral observations have shown that the orchid *O. exaltata* mimics the sex pheromone of *C. cunicularius* in a sexual deceit that leads to effective pollination by male bees (Kullenberg, 1961; Paulus and Gack, 1990b; Mant et al., 2005). Patrolling males are attracted to and attempt copulation with hexane extracts of the orchid labellum on dummies (Cane and Tengö, 1981; Mant et al., 2005). Our comparison of the labellum extracts of *O. exaltata* subsp. *archipelagi* and the cuticle extracts of virgin female *C. cunicularius* revealed all physiologically active compounds to be present in both organisms. This result is in accord with those obtained with the sexually deceptive *O. sphegodes* and its pollinator, *A. nigroaenea* (Schiestl et al., 2000). Both systems are consistent with the expectation of chemical mimicry in *Ophrys* pollination.

However, the relative amounts of 19 of the 22 active compounds differed significantly between our *O. exaltata* and *C. cunicularius* extracts. In particular, *O. exaltata* showed higher relative amounts of (*Z*)-7-heneicosene, (*Z*)-7-tricosene, and (*Z*)-7-pentacosene, which we have shown to be key components of the sex pheromone of female *C. cunicularius* (Figure 5). The odor differences in the present study may be due to the geographic distance between the sampled populations of *Colletes* and *Ophrys*, the former from northern Switzerland, the latter from southern Italy (Mant et al., 2005). However, the pattern is also indicative of directional selection for higher production of key odor components, leading to a supernormal stimulus by the orchid, as suggested by Schiestl (2004) and Ayasse et al. (2003).

Acknowledgments—We thank Salvatore Cozzolino (University of Naples Federico II) for assistance, Andreas Müller (Zürich) for advice on local *C. cunicularius* populations, and the Museum of Natural History "Inatura," Dornbirn, for issuing collecting licenses. This study was funded by the Swiss National Fund Project 3100-068173, ETH-Zürich, and an Order of Leopold (ASBL), Belgium for N.J.V.

Abstract—Aggregation of *Rhynchophorus palmarum* weevils on host plants is mediated by a male pheromone (rhynchophorol: R) and host-plant volatiles (PVs) acting in synergy. Synthetic PV blends synergizing pheromone contain acetoin (A) and ethyl acetate (EtAc). R, A, and EtAc are detected by specialized olfactory receptor neurons (ORNs). In addition, particular types of ORNs are tuned to both A and R. To specify the role played by acetoin in pheromone perception, we recorded the responses of ORNs to 100 ng of A or R presented either separately or mixed. Behavioral responses to R, A, and EtAc were studied in a four-armed olfactometer and by field trapping. We screened 59 R-, A-, and AR-tuned ORNs by recording specific responses to odors presented either separately or mixed. Stimulations by blends elicited complex response profiles from the three ORN types: some gave synergistic responses, others were inhibited, and the remainder responded as though both odors were detected independently. Several gave either a weak or no response to a first stimulation by R, but responded clearly to a second stimulation after an intercalary stimulation by A. In the olfactometer, both sexes were more attracted to a blend of A + R (1 + 0.01 ng/sec) than to pure compounds, whereas EtAc did not enhance response to R. Pheromone-baited traps (1 mg/day) containing PV blends (650 mg/day) based on an ethanol/EtAc blend (1:1), plus either 5 or 10% A, or a more complex reference blend, or sugarcane (natural pheromone synergist), caught similar numbers of weevils and about twice as many insects as a control ethanol/EtAc blend. Traps with only pheromone caught about 10 times fewer insects. Behavioral results support the role of acetoin as a

* To whom correspondence should be addressed. E-mail: rochatd@versailles.inra.fr

pheromone synergist for *R. palmarum*, and electrophysiological data provide evidence of modulation of peripheral sensory responses to pheromone by acetoin. Sexual dimorphism was observed neither at the ORN nor at the behavioral levels.

Key Words—Coleoptera, *Rhynchophorus*, aggregation pheromone, acetoin, ethyl acetate, synergy, mixture effect, single sensillum recording, EAG, olfactometer, field trapping.

INTRODUCTION

Detection of pheromones and plant odors by insects is generally considered to operate through independent pathways in the olfactory system (Mustaparta, 1984; Hansson et al., 1989, 1999). However, the modulation of behavioral responses to pheromones by plant compounds has been reported in an increasing number of species (Landolt and Phillips, 1997). Thus, the distinction between processing signals from host plants and from conspecifics might be neither ecologically nor physiologically relevant.

Palm weevil, *Rhynchophorus palmarum*, males emit a volatile aggregation pheromone, rhynchophorol: (4*S*)-2-methyl-(5*E*)-hepten-4-ol (Rochat et al., 1991; Oehlschlager et al., 1993). However, in the field, attraction to traps baited with pure rhynchophorol is low, whereas the addition of plant material increases catches considerably (Oehlschlager et al., 1993). The identification of natural volatiles emitted by host plants has resulted in the development of multicomponent synthetic blends that also increase trap catches when mixed with rhynchophorol (e.g., blend G; Rochat et al., 2000) and may be used instead of plant material. Synergy between pheromone and plant volatiles (PVs) was confirmed by analyzing the locomotory responses of *R. palmarum* in a four-choice olfactometer (Saïd, 2003), and field trials identified the components in blend G that were necessary for the synergy with the pheromone (Morin and Ollivier, 2001).

To understand how these compounds were encoded by the olfactory system, the sensory structures in the antennae of *R. palmarum* were characterized morphologically by using scanning and transmission electron microscopy. In addition, the sensitivity and specificity of olfactory receptor neurons (ORNs) to rhynchophorol and related compounds, as well as to components of two PV reference blends, were determined (Saïd et al., 2003). The authors characterized 17 functional types of ORNs common to both sexes, according to their response spectra, and found certain ORNs with narrow tuning and high sensitivity to rhynchophorol. There were also ORNs with specific responses to certain components of PVs, particularly acetoin (3-hydroxy-2-butanone) and ethyl acetate that are released by fermenting sugarcane. Certain

sensilla simultaneously responded to PVs and rhynchophorol with different spike amplitudes, suggesting that they may cohouse ORNs tuned both to the pheromone and to PVs. Furthermore, 9% of the ORNs exhibited more complex responses, either coactivated by rhynchophorol and acetoin, or activated by rhynchophorol while inhibited by blend G, a mix of PVs.

In this study, we investigated the interaction between plant and insect volatiles using behavioral and neurophysiological approaches. We compared the responses of single ORNs to either rhynchophorol or acetoin as well as different blends of the two. In addition, we conducted assays to examine the responses of the insects to correlate the peripheral sensory coding of the signals with the synergistic effect on behavior. We focused on acetoin for two reasons: it was present in PV blends that synergized with the pheromone in field trials, and some of the ORNs that detected acetoin were also coreceptive to rhynchophorol.

METHODS AND MATERIALS

Insects. Adult *R. palmarum* were caught in French Guyana using traps baited with synthetic rhynchophorol and sugarcane. Males and females were separated and maintained, with a supply of sugarcane, at 23–28°C, RH 75–90%, 13:11-hr light–dark period. Unless otherwise stated, the number of males and females used in any given experiment was similar, as both sexes respond similarly to the aggregation pheromone and the PVs (Rochat et al., 1991, 2000; Saïd, 2003).

Chemicals. Chemicals used in the laboratory and field studies were purchased from the following sources: (1) a racemic blend (99% purity) of rhynchophorol (R) from EGNO-Chimie (Tancarville, France); (2) acetoin (A), a blend of enantiomers and *meso* form (97%) from Fluka (Switzerland); (3) ethyl acetate (EtAc) (99%) from Merck (Germany); and (4) 96° ethanol (99% purity) from Carlo Erba Reagenti (Italy). A PV blend (blend G) was prepared following the recipe of Rochat et al. (2000). All chemicals were stored below 8°C before use.

A and R were diluted in high-grade hexane. A + R blends (10, 25, 50, 75, and 90% R at a total concentration of 100 ng/μl) were prepared for single sensillum recordings. Decadic dilutions of a 50:50 A + R blend were prepared for electroantennography (EAG). Solutions were kept at −18°C between experiments.

Electroantennography. Excised antennae were fixed on a Plexiglas plate, and the EAGs were measured using glass microelectrodes filled with saline solution and connected to chloridized silver wires. The reference and recording electrodes were inserted into the scape and antennal club, respectively. Prior to stimulation, 1 μl of one stimulus was applied to a filter paper strip in a Pasteur

pipette. The pipette was connected to the airstream tube using an intermediary Teflon piece (6 cm long, one per pipette) to reduce contamination by odors. A new stimulus pipette was prepared before each experiment, and one with pure hexane was used as the control stimulus.

Antennae of six weevils were stimulated (0.5 sec; 20 ml/min) with pure air and solvent, A, R, and a 50:50 A + R blend, over a range of decadic doses from 1 pg to 1 μg. For a given dose, the compounds were delivered in a random order.

Data Analyses. For each antenna, amplitudes were normalized relative to the mean response in the series. Then, the mean relative responses to A + R were compared with that of pure R as well as to the arithmetic sum of the responses to half doses of A and R (interpolated from the experimental dose–response curves) using paired *t*-tests.

Single Cell Recordings. The activity of ORNs was recorded with tungsten microelectrodes electrically sharpened in a 10% KOH–$NaNO_2$ solution (Saïd et al., 2003). The indifferent electrode was inserted into the scape. The recording electrode was brought randomly into contact with the surface of the antenna club and gently pressed with a micromanipulator until action potentials were recorded. As in previous experiments, we used excised antennae rather than taking *in situ* recordings, as the movement of live insects impeded stable recordings of ORN activity. A flow of humidified, charcoal-filtered, air (40 ml/min) was directed constantly onto the antenna. When recording of firing activity was stable, the antenna was stimulated by puffing air (0.5 sec, 20 ml/min) into the permanent airflow through a Pasteur pipette loaded with the stimulus. There was >1 min between stimuli, during which a puff of fresh air was applied, so that neurons could return to basal activity. In some cases, when an unexpected response was recorded, stimulations were replicated to verify the repeatability or reversibility of the observed phenomena (see Results).

Signals were amplified (×1000), filtered (low pass 10 Hz; high pass 15 kHz) and digitized at 10 kHz, 12 bits. Acquisition, display, and analysis were performed with AWAVE, an application hosted by Microsoft Windows, and developed in visual C++ (Marion-Poll, 1995, 1996). Olfactory receptor neuron responses were expressed as numbers of action potentials, sorted according to shape and amplitude, emitted during 1 sec after the onset of the stimulation.

First Series. Olfactory receptor neurons were stimulated successively with 100 ng R (R_i: initial stimulation), 100 ng A, 100 ng A plus 100 ng R (obtained by applying 1 μl of 100-ng/μl solutions of each on the same filter paper), and finally, 100 ng R (R_f: final stimulation).

Second Series. Olfactory receptor neurons were stimulated successively with 10 ng R, 100 ng A, and then with 100 ng of 90:10, 75:25, 50:50, 25:75, and 10:90 A/R blends. Finally, the preparation was stimulated with a puff of 100 ng R. All preparations were stimulated in this same order. The sex ratio of this series was 2:1 male/female.

Data Analyses. The number of spikes fired during 1 sec before (r_0) and 1 sec after (r_{stim}) the onset of stimulation was measured, and the response of a cell was expressed as the difference: $r_{stim} - r_0$. Thus, there could be negative values. In both series of treatments, if a response to a blend differed by >20% from the maximum response observed with a single compound, then it was classed as a mixture interaction, whereas anything less was not. In addition, in the first series, a linear regression model: $rR_f = arR_i$, was used to evaluate the relationship of the initial (rR_i) and final (rR_f) responses to rhynchophorol, testing the hypothesis: $a > 1$, to validate that rR_f was greater than rR_i.

Behavioral Responses in Olfactometer. The responses of male and female *R. palmarum* were tested in a four-armed olfactometer (55 × 55 × 5.5 cm; Laucoin s.a., Thoiry, France), coupled to an olfactory stimulator delivering constant concentrations (R at 10 pg/sec; A and EtAc at 1 ng/sec) of each stimulus from diluted aqueous solutions (Bartelt and Zilkowski, 1998; Saïd, 2003). In the first assay ($N = 20$), the responses to A, R, A + R, or odorless air were compared, whereas in the second ($N = 18$), the stimuli were R, EtAc, EtAc + R, or odorless air. In the third ($N = 22$), the choices were A + R, EtAc + R, 0.5A + 0.5EtAc + R, or odorless air. The complete mixture was positioned between the simple odors in the olfactometer. A weevil was placed in the center of the olfactometer, and its locomotory behavior was monitored for 10 min to determine the first odor source chosen (first arm entered) and the time spent in each arm. All assays were run during the first to fourth hr of the scotophase.

Statistical Analyses. Binomial tests compared the numbers of first choices for each arm to random choice ($P = 0.25$). One-way ANOVAs (insects as blocks), followed by Newman–Keuls tests (multiple comparisons, $\alpha = 0.05$; Dagnelie, 1975), compared the mean time spent in each arm.

Field Trapping. These experiments were carried out on a coconut plantation in Municipio de Santo Amaro (Sergipe, Brazil) between October 24 and December 19, 2003. Trap (≈10 × 60 cm: diam × h) cylinders, with a 10 × 25 cm opening, were made of plastic soda bottles (PET trap: Ferreira et al., 2001). Traps were hung on trees or shrubs about 1 m above ground and 100 m apart. The assay was a complete block design with six treatments that all included rhynchophorol: (1) R alone; (2) R with MAJ [a blend of ethanol and EtAc (1:1 v/v) that served as a solvent to release minor components]; (3) R + A5, a blend of 5% (v/v) acetoin in MAJ; (4) R + A10, a blend of 10% acetoin in MAJ; (5) R + blend G, a mixture of 11% minor components among which acetoin represented 4.3% (Rochat et al., 2000) in MAJ; and (6) R plus six halved 10-cm-long sugarcane pieces. The synthetic PV blends were dispensed from modified 50-ml polyethylene Kartell vials (Italy) with a braided cotton wick, whereas polyethylene sealed sachets were used as pheromone dispensers (Rochat et al., 2000). Each week, the insects were removed and counted; the sugarcane was renewed and traps were rerandomized in the blocks. The experi-

ment was replicated eight times. The mean weekly catches were first analyzed using an ANOVA [GLM procedure on $\ln(x + 1)$ transformed data] and then by Tukey multiple comparison tests at 5% (Minitab, v.12.2).

RESULTS

Electroantennography. Electroantennography responses were greater to rhynchophorol than to acetoin ($t = 4.74$, $df = 42$, $P < 0.001$), whereas the acetoin–pheromone blend gave similar responses as rhynchophorol alone (Figure 1). The dose–response curve to the 1:1 A + R blend was significantly

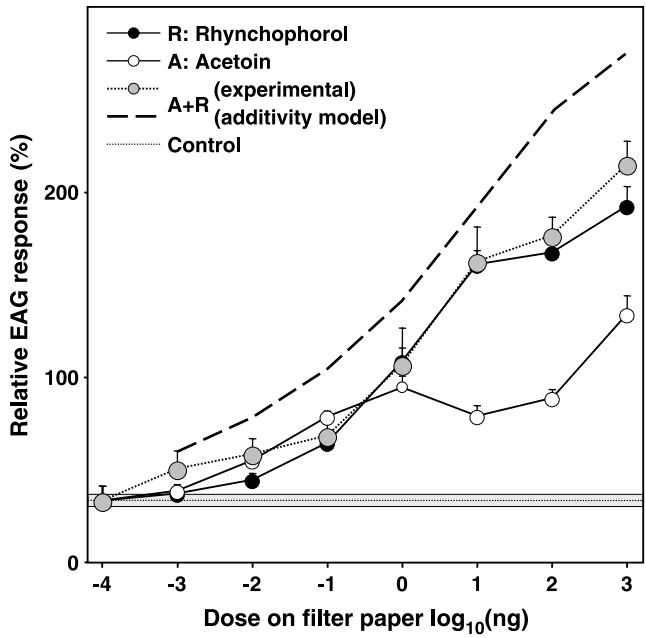

FIG. 1. Electroantennography (EAG) dose–response curves from eight *Rhynchophorus palmarum* antennae (six males + two females) to R (rhynchophorol: aggregation pheromone), A (acetoin: a host plant volatile), and A + R (a blend of both components), in relation to a pure air control and a theoretical response to A + R obtained under the hypothesis of simple additivity of EAG responses to R and to A. The EAG response (m + s.e.) is expressed as a relative EAG value, i.e., the percentage related to the mean response of the antenna to the series of stimulations.

lower than the theoretical curve calculated from the summed responses to the individual compounds (t = 6.79, df = 41, $P < 0.001$). This hypoadditivity suggests that rhynchophorol and acetoin are not detected independently but rather interact at the peripheral level.

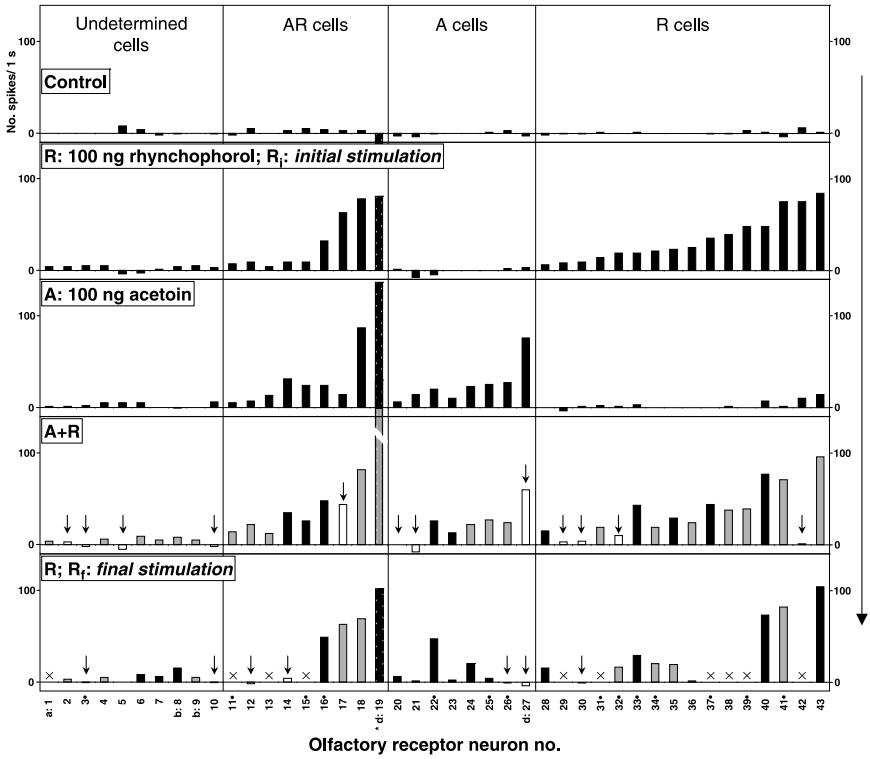

FIG. 2. Response profiles of *Rhynchophorus palmarum* olfactory neurons stimulated by 100 ng R (rhynchophorol: aggregation pheromone) at the beginning (R_i) and the end (R_f) of the series, 100 ng A (acetoin: plant volatile), and A + R (a blend of both components). *X*-axis: numbers of connected neurons. Dots: female antennae. The same letter associated with different neurons indicates firings obtained from the same recording and neurons probably housed in the same sensillum. Stimulations are given in chronological order from top to bottom (right arrow). The strong responses by neuron 19 (*) are shown at a three fourths scale. In the two lower profiles (A + R and R_f stimulations), black bars indicate greater (> 20%) and white bars plus arrow indicate lower (< 20%) neuron responses than the reference responses. Gray bars indicate responses within ±20% of the reference responses. *X* in the lowest profile: no recordings to R_f. The reference response to A + R was the maximum response to A and to R. The reference response to R_f was the response to R_i.

Single Cell Recordings. Of the 73 successful recordings, that showed the activity of one to three neurons, 75% were obtained from males. However, as we observed no sexual dimorphism in the entire set of responses in this or our previous work (Saïd et al., 2003), we present the data for both sexes combined.

Responses to acetoin and/or rhynchophorol were observed in 34 recordings (46%), and these were considered for further analysis (Figure 2). The spike amplitudes allowed us to recognized 43 different cells. The firing from the onset of stimulation ranged from −4 to 84 spikes. There was one exception, neuron 19, which exhibited a stronger activity, from −16 to 240 spikes. The most effective compound for each cell that fired >5 spikes upon stimulation was determined based on whether R or A induced the greatest response (r_{max}), when the relative difference between the responses to both molecules

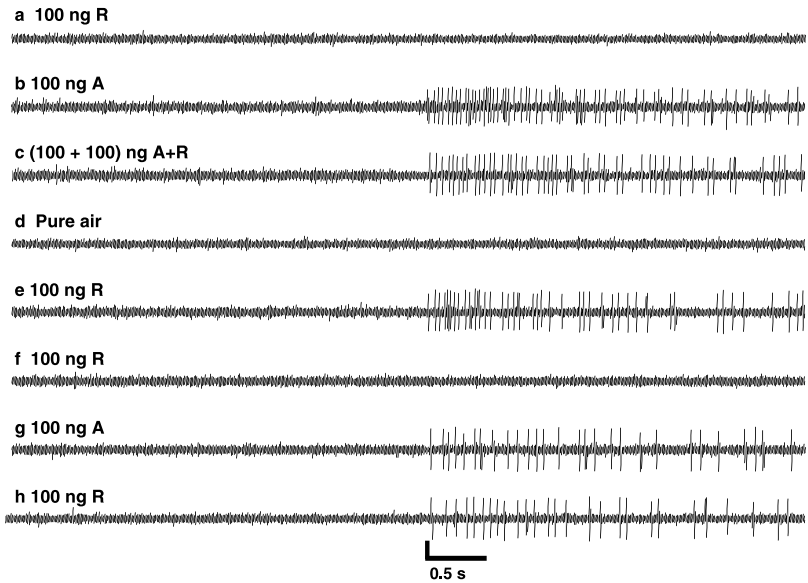

FIG. 3. Extracellular recordings of the activity of an olfactory receptor neuron of *Rhynchophorus palmarum* sensitized to pheromone stimulations (R) by acetoin (A: a plant volatile) in a reversible way. Successive stimulations by (a) R, (b) A, and (c) A + R elicited no response to R and a strong response to A and then to A + R. (d) The response to pure air (control) confirmed the absence of contamination of the preparation. (e) The second stimulation by R induced a response of the neuron similar to that induced by A. (f) The neuron did not respond to a third stimulation of 100 ng R, 3 min later. (g) Then it was resensitized by stimulation by A, and (h) it responded again to R. Scale: horizontal line, stimulation duration; vertical line, 1 mV.

was >25% ($r_{min} < 0.75r_{max}$). Using this criterion, we identified eight A cells and 16 R cells, whereas in nine others that responded to A and R, the relative differences were <25%. As neither the amplitude and shape of the action potentials nor the temporal pattern of firing allowed us to conclude that two different cells were present, we then checked their response to both stimuli using cross adaptation (Saïd et al., 2003). The results suggest that the same cells responded to both compounds and are referred to as AR cells. Neuron 19 was classified as an AR cell, although considering the level of response, two cells might have been involved (Figure 2). The remaining 10 cells were classified as "undetermined," as they fired ≤5 spikes following stimulation by either A or R.

In most recordings (30/34), cells responded to either A or R, indicating that acetoin and rhynchophorol are generally detected by receptor neurons housed in

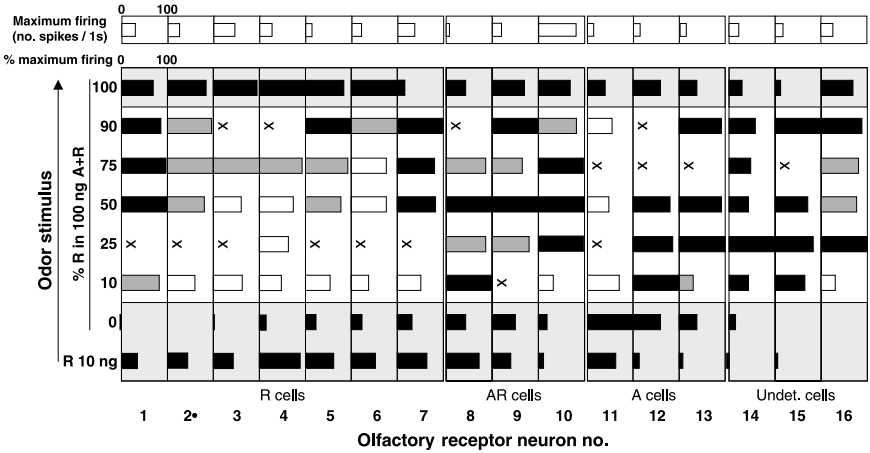

FIG. 4. Response profiles of *Rhynchophorus palmarum* olfactory neurons stimulated by 10 and 100 ng R, 100 ng A and 100 ng A + R, with relative proportions of the two compounds varying from 10 to 90%. The vertical arrow gives the chronology of stimulations. *X*-axis: numbers of connected neurons. Dot: female antenna. *X* in the central profiles: no recordings to the blend. Responses were quantified by the number of spikes emitted during 1 sec after the onset of the stimulation and are presented as the percentage of the highest neuron response (white bars in first row: number of spikes emitted during 1 sec). Central profiles (A + R stimulations): black bars indicate greater (>20%) and white bars plus arrow indicate lower (<20%) neuron responses than the reference responses. Gray bars indicate responses within ±20% of the reference responses. The reference response was the greatest response to 100 ng pure A, to 10 ng pure R, and to 100 ng pure R, shown with a gray background.

different sensilla. However, in four cases, A and R stimulated different cells, as attested by differences in spike amplitude or temporal pattern of firing, suggesting that some acetoin and rhynchophorol neurons may be colocalized in the same sensillum.

Responses to the A + R Blend (100 + 100 ng). Five R cells (nos. 28–43 in Figure 2) responded more to A + R than to rhynchophorol alone (rA + R > 1.2rR; black bars), whereas four responded less (rA + R < 0.8rR; white bars with arrow). The seven others gave similar responses to R and to A + R (0.8rR ≤ rA + R ≤ 1.2rR; gray bars).

Two of the eight A cells (20–27 in Figure 2) showed stronger responses to A + R than to acetoin (rA + R > 1.2rA), and three showed lower responses (rA + R < 0.8rA), whereas the remaining three responded equally to A + R and A (0.8rA ≤ rA + R ≤ 1.2rA). Three of the nine AR cells (11–19 in Figure 2) responded to A + R more than to acetoin or rhynchophorol alone [rA + R > 1.2max(rR, rA)], and one responded less [0.8max(rR, rA) < rA + R]. Responses to A + R by the remaining five cells to the blend were similar to that of the most active pure compound [0.8max(rR, rA) ≤ rA + R ≤ 1.2max(rR, rA)]. The 10 undetermined cells (1–10 in Figure 2) showed a similar ($N = 6$) or lower ($N = 3$) response to A + R than to either A or R alone.

Overall, the response to the second stimulation by rhynchophorol (R_f) after A + R ($N = 33$) was, on average, significantly greater than the first response (R_i) and is described by the following linear relationship: $rR_f = arR_i$ [$r^2 = 0.78$; $F(1, 31) = 198.6$, $P < 0.001$] with a significant slope of 1.091 ± 0.077 ($t = 15.25$,

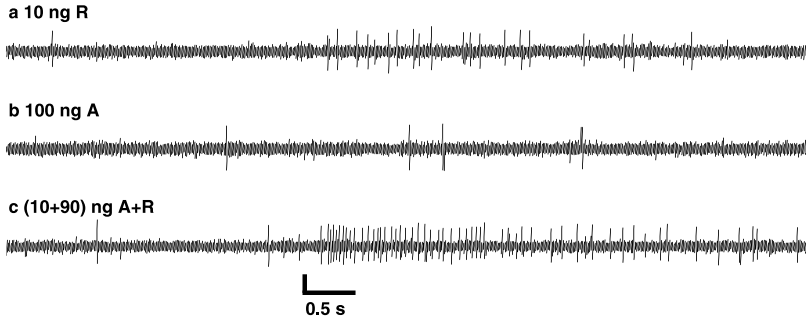

FIG. 5. Extracellular recordings of the synergistic response of *Rhynchophorus palmarum* olfactory receptor neurons to a blend of acetoin (A) and pheromone (R): (a) the high-spike-amplitude neuron responded feebly to 10 ng R and (b) did not respond to 100 ng A. (c) The blend of 10 ng R plus 90 ng A (A + R) induced a strong response of the high-spike-amplitude neuron. Scale: horizontal line, stimulation duration; vertical line, 1 mV. Responses are presented in chronological order.

df = 30, $P < 0.001$). This difference was seen in all cell types, and particularly the A cells (6/9). In 15 of the 33 cells, the second response was >20% higher than the first: $rR_f > 1.2rR_i$ (black bars, Figure 2). In two recordings, this effect was reversible, and the response to rhynchophorol returned to its initial value after a few minutes. However, after a second presentation of acetoin, response to rhynchophorol was restored (Figure 3).

Responses to Different A + R Blend Ratios. We were able to obtain an almost complete set of readings for the A + R blends from 16 neurons. The action potentials to the initial treatments with R (10 ng) and A (100 ng) alone ranged from −1 to 24, whereas the subsequent ones with the A + R blends were from −1 to 81. Using the same criteria mentioned above, we identified seven, three, three, and three R, A, AR, and undetermined type cells, respectively. Most responses to the blends showed mixture interaction (Figure 4). The

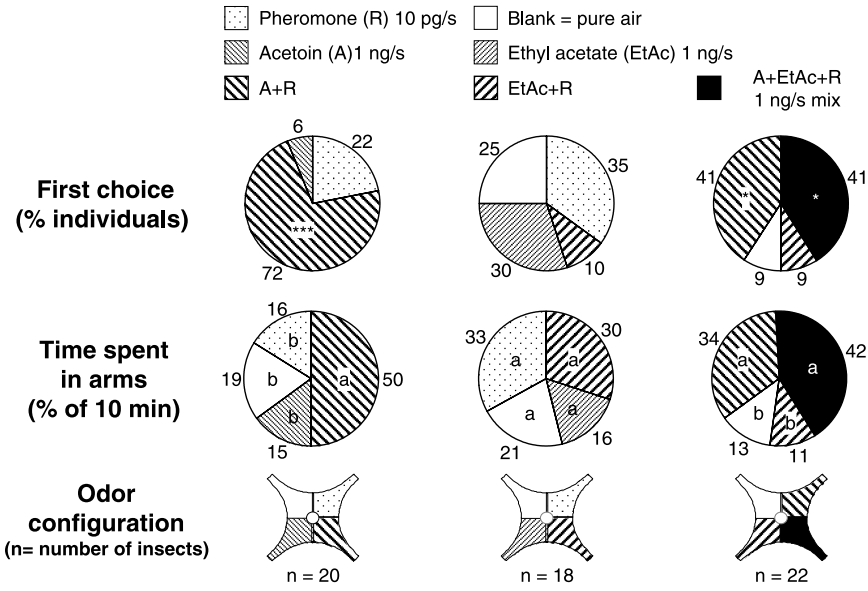

FIG. 6. Responses in a four-armed olfactometer of *Rhynchophorus palmarum* (ca. 1:1 sex ratio) stimulated simultaneously by the aggregation pheromone (R), a plant volatile: acetoin (A) or ethyl acetate (EtAc) and A + R, or by the three blends: A + R, EtAc + R, and A + EtAc + R. All tests included a blank arm. R and the plant compound(s) were delivered by an olfactory stimulator at 0.01 and 1 ng/sec, respectively. Two criteria were analyzed: (1) the arm chosen first [number of choices for a given arm was significant at $*P < 0.05$ or $***P < 0.001$ (binomial tests)] and (2) the time spent in each of the four arms (data with different letters differ statistically; Newman–Keuls tests, $P < 0.05$).

majority of R cells (1–7 in Figure 4) gave lower responses than expected with the blends, especially those containing ≤50% R. This suggests an inhibitory effect, as the response of four cells to the 90:10 A + R blend was lower than to 10 ng R alone, whereas the response to the 10:90 A + R blend was greater than to 100 ng pure R. All three AR cells (8–10 in Figure 4) gave maximum responses to the 50:50 A + R blend but not to pure A or R, whereas all the A and undetermined cells (11–13 and 14–16, respectively, in Figure 4) showed mixture interactions (Figure 4). All but one of these cells fired much more to the blends than A or R alone (Figure 5). A clear response to 100 ng R was also recorded from undetermined cell no. 16 that responded previously neither to 10 ng R nor to 100 ng A.

Behavioral Responses in Olfactometer. There was a significant preference, based both on first choice ($P < 0.001$; binomial tests) and time spent in a

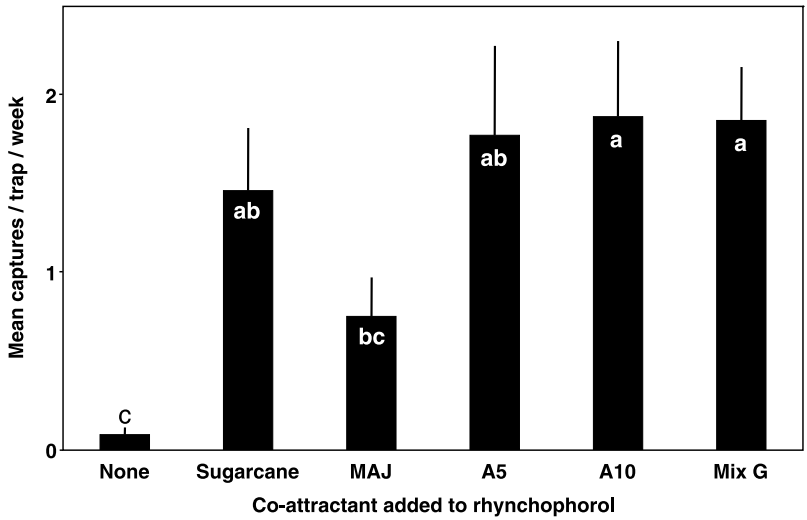

FIG. 7. Field catches of *Rhynchophorus palmarum* in traps baited with a dispenser of the aggregation pheromone, rhynchophorol (1 mg/day), and a co-attractant (either sugarcane or a synthetic blend emitted at 650 mg/day) (Municipio de Santa Amaro, SE, Brazil, October 20–December 15, 2003; $N = 6$ blocks). Four blends based on a 1:1 (v/v) blend of ethanol and ethyl acetate (EtAc) were evaluated: MAJ [pure ethanol/EtAc 1:1 (v/v) blend]; A5 (5% v/v acetoin in MAJ); A10 (10% v/v acetoin in MAJ), and blend (Mix) G (a mixture of 14 compounds representing 11% v/v minor fraction where acetoin accounts for 4.3% in MAJ, 89% v/v; Rochat et al., 2000). Catches associated with the same letter do not differ statistically [Tukey multiple comparison tests on $\ln(x + 1)$ transformed data].

given arm ($P < 0.05$, Newman–Keuls tests) for A + R than pure air, R, or A alone (Figure 6). In contrast, when offered a choice between EtAc, pure air, R, and a blend of EtAc + R, there were no significant preferences, either in first choice (binomial test: $P > 0.1$) or residence time [$F(3, 51) = 1.80$, $P > 0.15$]. In the assay where weevils had a choice between odorless air, A + R, EtAc + R, and A + EtAc + R, both indicators showed a significant but similar preference for A + R and A + EtAc + R over the other two air sources: EtAc + R and odorless (Figure 6; first choice: $P < 0.03$, binomial tests, and time spent in a given arm: $P < 0.05$, Newman–Keuls tests). Insects did not stay longer in the arm with A + EtAc + R (42% test duration) than with A + R (34% test duration).

Field Trapping. R with either A5, A10, or the complex pheromone synergist G made up in the same solvent (Rochat et al., 2000) performed equally well as R + sugarcane and captured significantly more than R alone (Figure 7, Tukey multiple comparison tests, $P < 0.05$). R + MAJ gave intermediate results and did not differ significantly from R alone or R with either sugarcane or A5 (Figure 7).

DISCUSSION

Acetoin, but not ethyl acetate, acted synergistically when mixed with the aggregation pheromone in the olfactometer at the dose used. Acetoin with ethyl acetate gave a somewhat higher response, and in the field, a mixture containing 5–10% acetoin in ethyl acetate was as effective a synergist with aggregation pheromone of *R. palmarum* as either a complex synthetic mixture or natural sugarcane odors. Thus, from a practical point of view, the simpler and cheaper synthetic pheromone synergist could be used instead of blend G for pest monitoring or control.

In the field, the synthetic plant odors included ethanol for homogeneity with past work and because of its solvent property for minor volatiles. In spite of its abundance in the synthetic blends or natural plant odors, the behavioral role of ethanol remains unclear in *R. palmarum*: only one specific ORN tuned to this compound was found in a study of 200 cells (Saïd et al., 2003), and its synergistic role with rhynchophorol appeared weak compared with ethyl acetate (Rochat et al., 2000).

Acetoin, a common volatile product of aerobic fermentation, is a pheromone compound of two scarab beetles: the dynast *Scapanes australis* (Rochat et al., 2002) and the chafer *Amphimallon solstitiale* (Tolasch et al., 2003). Numerous *R. palmarum* ORNs tuned to either acetoin or rhynchophorol have been found (Saïd et al., 2003), as one would expect in a system with independent pathways for pheromone and plant volatiles. In such a system, one would expect ORNs

with high specificity and sensitivity, as well as weak or no interactions between stimuli. However, while specificity and sensitivity of R and A cells have been confirmed, many recordings showed responses that did not agree with this model of specialist coding. First, some olfactory neurons responded at low doses (10 and 100 ng) to both chemicals that are neither structurally nor biologically related. Second, the level of responses to blends deviated from the level expected for independent detection of both compounds.

The pattern of ORN responses to blends of acetoin and rhynchophorol was complex, showing great variability in both the spontaneous activity of the receptor neurons and the responses to the odors. We cannot exclude that uncontrolled experimental factors have contributed to this variability. For example, stimulations were applied to the whole antenna so there may have been heterogeneity in the exposure of different sensilla to the odorized airflow. Some neurons may have been partly adapted (or sensitized) by preceding stimulations when we were recording from neighboring sensilla. However, given the correlations observed between types of responses to single compounds and to the blend (Figure 4), we believe this variability reflects intrinsic differences in sensitivity and specificity of neurons. Mixture suppression was observed mainly in neurons with high selectivity for acetoin and rhynchophorol, as well as in acetoin-tuned neurons. Generally, responses to A + R did not deviate from responses to R in neurons exhibiting high-level responses to rhynchophorol alone. Mixture enhancement was observed mainly in neurons responding to both A and R, as well as in neurons that only respond moderately to rhynchophorol. The latter result suggests a synergistic effect of acetoin on the concerned cells. The level of response to 100 ng was above the response thresholds of the R (0.01 ng) and A (1 ng) cells (Saïd et al., 2003), but the level of firing was not maximum. This situation, and the variability of the responses, made it difficult to establish the limit between additivity and synergy. To date, only one clear case of synergy between a pheromone component and a plant volatile has been reported. In *Helicoverpa zea*, stimulation with binary mixtures at a threshold dose of the pheromone component (*Z*)-11-hexadecenal and increasing doses of linalool or (*Z*)-3-hexenol increased the firing rate of pheromone-specific neurons compared to responses to the major component alone (Ochieng et al., 2002).

Considerable work has been devoted to understand and elucidate the mechanisms for encoding mixture quality by individual olfactory cells in lobsters, and different types of mixture interactions have been modeled (Ache et al., 1988; Derby et al., 1996; Cromarty and Derby, 1997, 1998). Such interactions were not expected to occur frequently in insects because of the narrow tuning of olfactory receptor neurons, especially those tuned to pheromone compounds. For instance, orientation to females by male *Agrotis segetum* moths results from the detection of a multicomponent blend, and responses of all types of the specific receptor neurons that are tuned to the individual sex pheromone

components are the same when stimulated with blends or specific excitatory compounds (Carlsson and Hansson, 2002). However, evidence of a contribution of mixture interactions at the receptor cell level to olfactory encoding in insects is now growing. Inhibition, or mixture suppression of receptor cells in response to blends compared to responses to pure odors, as reported in the American cockroach (Getz and Akers, 1997) and the Colorado potato beetle (De Jong and Visser, 1988), is the most commonly reported type of interaction. In *R. palmarum*, blends inhibited spontaneous firing (Saïd et al., 2003) or decreased responses (this study), mainly in A cells.

Sensitization by acetoin was repeatedly observed in R cells with low to moderate responses to rhynchophorol. Stimulation by acetoin, even a brief exposure (1 sec) to a nonsaturating dose, enhanced the sensitivity of certain of these neurons, resulting in increased firing when they received subsequent stimulations by rhynchophorol. This sensitization was reversible. Sensitization of pheromone responses by plant volatiles was also observed in two tortricid moths, *Argyrotaenia velutina* and *Choristoneura rosaceana*. The phenomenon was mediated by an increase of octopamine following the perception of plant odor (Stelinski et al., 2003). The behavior of *R. palmarum* following detection of acetoin and rhynchophorol relies on the interpretation of the entire sensory input provided by individual neurons. In spite of the variety of ORN responses, a global pattern of sensory input emerges. From a physiological perspective, the presence of acetoin increases sensitivity to rhynchophorol, whereas the detection of rhynchophorol decreases the level of detection of acetoin, both contributing to lower the global threshold of response when the two signals were presented simultaneously. From an ecological point of view, this modulation should improve detection of conspecifics in the presence of a plant signal. Conversely, the detection of pheromone should optimize the response to host plants odors (at least the acetoin), increasing the probability of *R. palmarum* localizing palm trees harboring conspecifics. Clearly, the synergistic response to the plant–pheromone message not only relies on the processing of sensory inputs in the insect brain, but also on interactions between the pheromone and a plant volatile at the receptor cell level. This property may reflect an adaptation of the olfactory system of insects exhibiting synergistic responses to "pheromone–kairomone" signals and should be searched in species from other families with similar chemical ecology, such as the Nitidulidae or Scolytidae.

In summary, our results about ORN outputs underline the absence of sexual dimorphism in the processing of host plant and pheromone cues by *R. palmarum*. This conclusion is supported by the behavioral responses reported previously (Rochat et al., 1991, 2000; Saïd, 2003). Contrary to other palm beetles, such as the dynasts *S. autralis* (Rochat et al., 2002) or *Oryctes elegans* (Rochat et al., 2004), *R. palmarum* aggregation pheromone appears to be more a male-produced signal for host-plant and trophic resources than a sexual signal.

Abstract—Coupled gas chromatographic–electroantennographic detection analyses of ovipositor extracts of calling *Contarinia nasturtii* females revealed two compounds that elicited responses from antennae of male midges. Using synthetic reference samples, these components were identified by gas chromatography–mass spectrometry and enantioselective GC as (2*S*,9*S*)-diacetoxyundecane and (2*S*,10*S*)-diacetoxyundecane. In addition, trace amounts of 2-acetoxyundecane were found in ovipositor extracts, and the (*S*)-enantiomer was synthesized. When tested in the wind tunnel, a blend of 5 ng (2*S*,9*S*)-diacetoxyundecane and 10 ng (2*S*,10*S*)-diacetoxyundecane (mimicking the ratio found in the extracts) did not attract any of the males tested, but when 0.1 ng (*S*)-2-acetoxyundecane was added to the blend, 86.8% of the males were attracted to the bait. Three-component blends with lower or higher relative concentrations than 1% of (*S*)-2-acetoxyundecane [relative to (2*S*,10*S*)-diacetoxyundecane] were less attractive. In a field trapping experiment with released laboratory-reared *C. nasturtii* adults, traps baited with 500:1000:10 ng of (2*S*,9*S*)-diacetoxyundecane/(2*S*,10*S*)-diacetoxyundecane/(*S*)-2-acetoxyundecane applied to rubber septa or dental cotton rolls

were tested. Traps without dispensers were used as controls. All three treatments were tested at 20 and 50 cm above ground. The estimated recapture rate was 30–50%, and 81.9% of the recaptured males were caught in traps positioned at 20 cm above ground, and 88.4% in traps with dental cotton rolls as dispensers.

Key Words—*Contarinia nasturtii*, swede midge, Cecidomyiidae, Diptera, sex pheromone, (2*S*,9*S*)-diacetoxyundecane, (2*S*,10*S*)-diacetoxyundecane, (*S*)-2-acetoxyundecane, GC-EAD, wind tunnel, field trapping.

INTRODUCTION

The swede midge, *Contarinia nasturtii* (Kieffer) (Diptera: Cecidomyiidae), occurs in many brassica-growing regions in Europe where it often causes serious yield losses, mainly in broccoli, cauliflower, and Brussels sprouts. Female midges oviposit in the shoots of host plants, where the larvae feed and develop. Feeding damage near the growing tips induces distortion and gall-like symptoms that prevent the plants from forming flower heads, or leave corky scars that render the heads unmarketable. Relatively recently, the occurrence of *C. nasturtii* was reported in Canada (Hallett and Heal, 2001), and it is now a quarantine pest in Canada (Canadian Food Inspection Agency, 2002).

One indirect reason for the high damage levels caused by *C. nasturtii* is the lack of a good monitoring method for determining the time of emergence of the adult midges, the life stage against which chemical control is most effective. Currently, the only available monitoring method is based on yellow pan traps filled with water and a detergent. These traps are not species specific, and the analysis of the trap contents is laborious and time-consuming. Furthermore, the trapping efficiency of yellow pan traps for *C. nasturtii* is low; the crop is frequently damaged by *C. nasturtii* even when no midges have been detected in traps. Temperature-based forecasting methods have been developed (Noll, 1959, 1961; Bouma, 1996) but have failed to give accurate field-specific prognosis. As long as monitoring or forecasting methods are not reliable, and damage thresholds are lacking, growers tend to rely on calendar-based insecticide sprays throughout the crop's growing period. As a consequence, supervised control (as opposed to scheduled spraying) against other important brassica pests, such as aphids and *Pieris* and *Mamestra* caterpillars, cannot be considered an option.

A successful pheromone-based monitoring system has been developed and commercialized for a closely related gall midge species, the pea midge, *Contarinia pisi* (Hillbur et al., 2000, 2001; Pillon and Hillbur, 2001; Biddle et al., 2002). Promising results with respect to pheromone-based monitoring have also been reported for two other cecidomyiids, the orange blossom wheat midge, *Sitodiplosis mosellana* (Gries et al., 2000), and the Douglas-fir cone gall

midge, *Contarinia oregonensis* (Gries et al., 2002; Morewood et al., 2002). Here, we report on the identification, synthesis, and testing of the sex pheromone of *C. nasturtii*.

METHODS AND MATERIALS

Insect Rearing. Larvae of *C. nasturtii* were collected in August 2000 from heavily attacked Brussels sprouts in a field near Kerzers, Canton Freiburg, Switzerland. Infested growing tips were placed on a peat–soil mixture in which larvae pupated when they had completed their development. Pots containing pupae were stored in cages, and from the emerging adults, a continuous laboratory culture was established. Similarly, larvae from a field near Ins, Canton Bern, Switzerland, were added to the culture in 2001.

Swede midge larvae were reared on cauliflower, *Brassica oleracea convar. botrytis*, cv. Candid Charm. Pairs of plants were grown in pots (Thermoform pots, 13-cm diam, 8-cm height, Desch Plantpak, The Netherlands) in a substrate consisting of 85% peat and clay (Floraton No. 5, Floragard, Oldenburg, Germany) in a greenhouse at 15–30°C with additional light supplied during winter. Plants were kept free from aphids and white flies by spraying, if necessary, once with pymetrozine (0.025% a.i.). Spraying was avoided during the last 3 wk before the plants were used for insect rearing. When plants had 8–10 true leaves and a tip diameter of 5–10 mm, they were placed in Perspex cages (50 × 50 × 50 cm) with two side walls consisting of fine-meshed screen. The cages contained 100–200 midges of both sexes and were transferred to environmental chambers with 16:8-hr light–dark period, 22°C, and RH 75%. The midges were allowed to mate and oviposit on the plants for 24 hr. The plants were then removed, replaced by the next batch, and incubated under the above-mentioned conditions. Every day, the tips of the plants, where larvae became visible 5–6 d after oviposition, were misted with tap water. Thirteen to fifteen d after oviposition, larvae left the plants and pupated in the peat substrate. Males emerged during the night, 18–20 d after oviposition. Females tended to emerge 1 d later, mostly during the night or the first hour of the photophase. In the cages, adult midges survived and oviposited for 3–5 d. Mating behavior was observed during the second to fourth hour of the photophase.

If larvae were used to supply the culture, aboveground plant parts were cut off on day 17 after oviposition. The pots with substrate containing the pupae were then placed in the oviposition cages where midges were allowed to emerge. If midges were to be used for electrophysiological experiments or for collection of pheromone gland extracts, aboveground plant parts were cut off on day 15 and the pots were sent by express mail from Wädenswil, Switzerland, to Alnarp, Sweden. Males for wind tunnel experiments were prevented from mating by

placing glass cylinders over pots. The morning after the night when the first midges had emerged, these cylinders, usually containing only males, were set aside before females started to emerge.

Extracts for Electrophysiological Analyses and Chemical Identification. Upon arrival in Alnarp, pots with soil containing *C. nasturtii* pupae were put in glass cages (28 × 28 × 33 cm) and kept at 18:6-hr light–dark period, 25°C, and RH 70% for the adults to emerge. After emergence, males and females were transferred to separate cages. Females were kept under the conditions mentioned, and males were kept at 18:6-hr light–dark period, 15°C, and RH 75%. Gland extracts were prepared by excising the ovipositors of females exhibiting calling behavior (extending their ovipositor; for a detailed description, see Harris and Foster, 1999). The ovipositors were collected in a vial kept in liquid nitrogen and then extracted for 1–2 min in redistilled hexane (LabScan). Extracts were kept in sealed glass capillaries at −18°C until use.

Extracts for Preliminary Wind Tunnel Assays. Calling females were collected from the laboratory culture and immersed in batches in hexane (p.a. grade, Fluka) for 15 min at room temperature. The supernatant was then decanted and concentrated by evaporating the hexane under N_2.

Electrophysiological Recordings. Antennal responses of males to ovipositor extracts were determined by gas chromatography with electroantennographic detection (GC-EAD; Arn et al., 1975), using a Hewlett-Packard 6890 GC (Palo Alto, CA, USA) with flame ionization detection and an Innowax column (30 m × 0.25 mm ID, H-P). The column was programmed from 80°C/2 min to 230°C at 10°C/min. Antennal recordings were made using a Plexiglas holder with two wells connected to an amplifier by gold wire electrodes (JoAC, Lund, Sweden; Zhang et al., 1997; Hillbur, 2001). Male insects were mounted in the holder as described by Hillbur et al. (2000). The antennal preparations were continuously exposed to a charcoal-filtered and humidified airstream (0.3 m/s) through a glass tube (8-mm diam.). Antennal signals were amplified (JoAC) before they were recorded and analyzed with ElectroAntennoGraphy software (Syntech, Hilversum, The Netherlands).

Chemical Analyses. Analyses were carried out by coupled gas chromatography–mass spectrometry (GC-MS). A Hewlett-Packard 5890 GC was linked to a VG 70/250 E double-focusing sector-field mass spectrometer (Vacuum Generators, Manchester, UK) operated at 70 eV. Alternatively, a quadrupole instrument (MD 800/GC 8060, Fisons, Ismaning, Germany) was employed. Using helium as carrier gas, separations were achieved with a 60 m × 0.25 mm ID, 0.25-μm film DB5-MS column (J & W Scientific, Folsom, CA, USA) under the following conditions: 50°C/2 min, then 5°C/min to 280°C. In addition, a 50 m × 0.25 μm ID, 0.27-μm film FFAP fused silica column (Macherey & Nagel, Düren, Germany) was used (50°C/3 min, then 3°C/min to 220°C). Separation of stereoisomers was carried out with a 25 m × 0.25 mm ID custom-

made fused silica column coated with a 1:1 mixture of heptakis-(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin and OV1701 (Hydrodex, Macherey & Nagel) using hydrogen as carrier gas and a temperature program of 80°C/3 min, then 3°C/min to 180°C.

Nuclear magnetic resonance (NMR) spectra of synthetic compounds were recorded with a Bruker AMX-400 instrument (Karlsruhe, Germany). Optical rotations were measured on a digital polarimeter at 589-nm (Jasco DIP-370, Tokyo, Japan).

Syntheses (see Figure 1). Chemicals and solvents were purchased from Aldrich or Merck and were of highest purity available. Purification of synthetic products was carried out by flash chromatography on silica gel (silica 32-63, 60 Å, ICN-Biomedicals, Eschwege, Germany) at 1.3 bar using mixtures of ethyl acetate and hexane. Tetrahydrofuran (THF) was dried before use. Extracts were dried over anhydrous $MgSO_4$ and concentrated under reduced pressure.

*(S)-9-Decene-2-ol **2**.* Under an argon atmosphere, a Grignard reagent was prepared from 10.0 g (56.6 mmol) of 7-bromo-1-heptene **1** (Aldrich) and 2.06 g (84.8 mmol) freshly ground magnesium turnings in 50 ml dry THF at 60°C. After cooling to room temperature, the solution was added dropwise to 3.3 g (4 ml, 56.7 mmol) (*S*)-methyloxirane (Aldrich) and 1.1 g (5.7 mmol) CuI in 40 ml THF at −78°C. The solution was warmed to room temperature and stirred for 1 hr. After addition of 300 ml saturated aqueous NH_4Cl, the mixture was extracted with 200 ml ethyl acetate. The aqueous layer was separated and extracted three times with 200 ml of a 1:1 mixture of ethyl acetate and hexane. The combined organic extracts were dried and concentrated. Purification by flash chromatography (10% ethyl acetate in hexane) furnished 6.2 g (39 mmol, 70%) of (*S*)-9-decene-2-ol **2**. Analytical data were in accord with those reported in the literature (Trollsås et al., 1996).

*(S)-2-Benzyloxydec-9-ene **3**.* To a suspension of 3.2 g (133 mmol) sodium hydride (freed from paraffin) in 105 ml, ice-cold dry THF was added 6.2 g (39.5 mmol) (*S*)-9-decene-2-ol **2** under argon. After stirring for 2 hr, 470 mg (1.3 mmol) *tetra-n*-butylammonium iodide were added, followed by dropwise addition of 13.5 g (9.4 ml, 78.9 mmol) benzyl bromide, and stirring was continued for 12 hr. Then, 50 ml saturated aqueous NH_4Cl were added at 0°C followed by 50 ml hexane. The aqueous layer was separated and extracted four times with 100 ml of a 1:4 mixture of ethyl acetate and hexane. The combined organic layers were dried and concentrated. Flash chromatography (5% ethyl acetate in hexane) furnished 9.7 g (39.4 mmol, 100%) (*S*)-2-benzyloxydec-9-ene **3**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ (ppm) 1.18 (d, 3H, J = 6.1 Hz, 1-H), 1.25–1.47 (m, 10H, 3-H to 7-H), 2.00–2.07 (m, 2H, 8-H), 3.49 (sext., 1H, J = 6.4 Hz, 2-H), 4.45 (d, 1H, J = 12 Hz, OC**H**$_a$-Ph), 4.56 (d, 1H, J = 12 Hz, OC**H**$_b$-Ph), 4.90–4.95 (m, 1H, 10-H$_b$), 4.95–5.02 (m, 1H, 10-H$_a$), 5.81 (ddt, 1H, $J_{10a,9}$ = 16.79 Hz, $J_{10b,9}$ = 10.17 Hz, $J_{9,8}$ = 6.61 Hz, 9-H), 7.23–7.34 (m, 5H, H$_{Ph}$); ^{13}C-

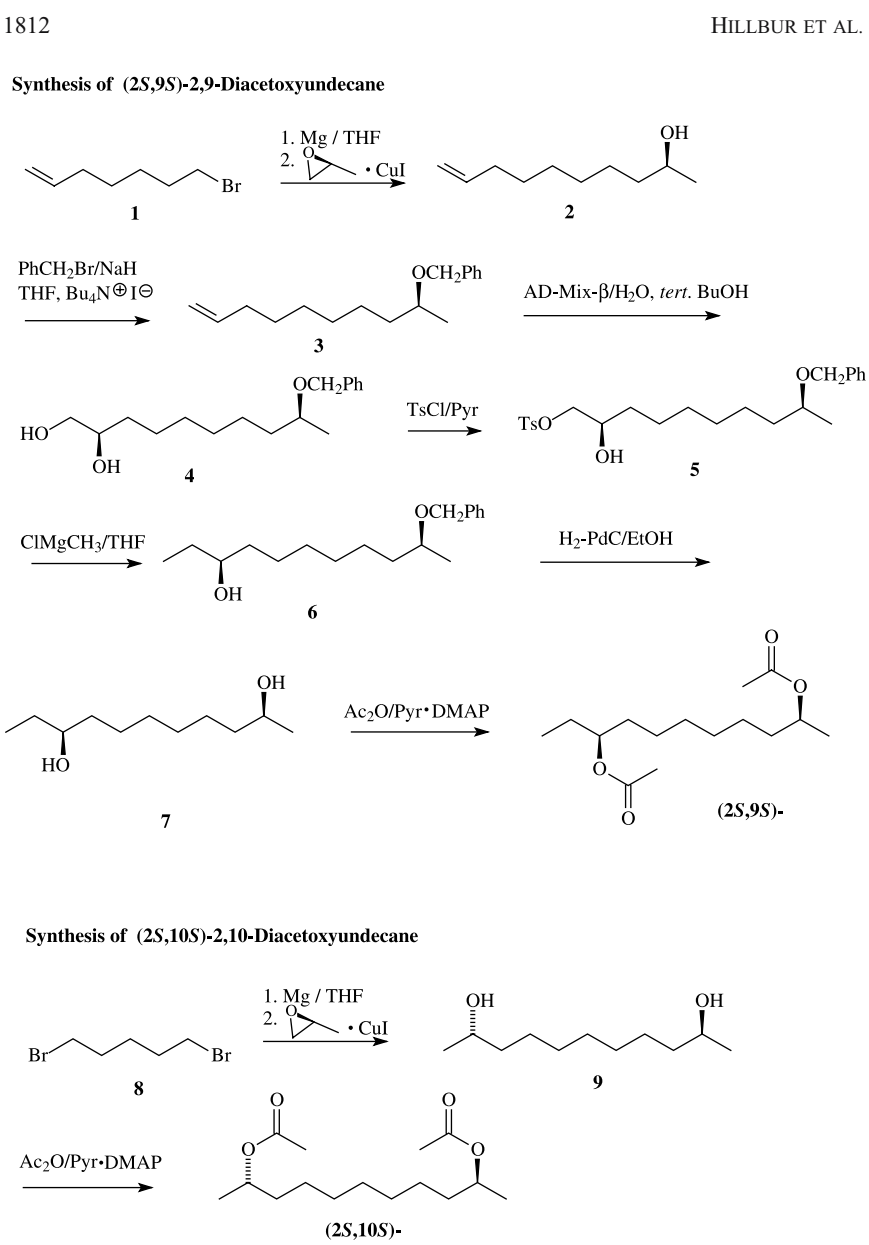

FIG. 1. Syntheses of (2*S*,9*S*)-2,9-diacetoxyundecane and (2*S*,10*S*)-2,10-diacetoxyundecane.

NMR (101 MHz, $CDCl_3$): δ (ppm) 19.63 (q, 1-C), 25.49/28.88/29.10/29.55/33.77 (t, 4-C to 8-C), 36.66 (t, 3-C), 70.28 (t, O**C**H_2-Ph), 74.90 (d, 2-C), 114.13 (t, 10-C), 127.32 (d)/127.60 (d, 2C)/128.73 (d, 2C)/139.18 (s) (C_{Ph}), 141.77 (d, C-9); MS (70 eV): *m*/*z* (%) 246 (0.2, M^+), 155 (0.5, $[M–Bn]^+$), 135 (12), 107 (18), 104 (6), 92 (16), 91 (100), 85 (7), 65 (7), 55 (10, $CH_2CHCH_2CH_2^+$), 43 (6), 41 (18), 39 (7).

(2R,9S)-9-Benzyloxydecane-1,2-diol ***4***. A vigorously stirred solution of 6.0 g (24.3 mmol) (*S*)-2-benzyloxydec-9-ene **3** in 300 ml of a 1:1 mixture of water and *tert*-butanol was cooled to −10°C. After addition of 29.2 g AD-Mix β (i.e., 1.2 g/mmol alkene), the mixture was stirred at 4°C for 40 hr. Sodium bisulfite (30.0 g, 158 mmol) was added, and the mixture was stirred at 20°C for another hour. The brownish suspension was extracted three times with 250 ml ethyl acetate. The organic layers were combined, dried, and concentrated. Flash chromatography (ethyl acetate and hexane 1:1) furnished 4.2 g (15 mmol, 62%) (2*R*,9*S*)-9-benzyloxydecane-1,2-diol **4** as a colorless oil. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 1.08 (d, 3H, J = 6.1 Hz, 10-H), 1.15–1.27 (m, 6H, 4-H to 6-H), 1.30–1.40 (m, 5H, 3-H, 7-H, and 8-H_a), 1.45–1.55 (m, 1H, 8-H_b), 1.76 (br.s, 2H, OH), 3.32 (dd, 1H, J = 11 Hz, 3.3 Hz, 1-H_a), 3.4 (sext., 1H, J = 6.4 Hz, 9-H), 3.54 (dd, 1H, J = 11 Hz, 3.0 Hz, 1-H_b), 3.57–3.64 (m, 1H, 2-H), 4.33 (d, 1H, J = 11.7 Hz, OC**H**$_a$-Ph), 4.46 (d, 1H, J = 11.7 Hz, OC**H**$_b$-Ph), 7.14–7.24 (m, 5-H, H_{Ph}); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 19.62 (q, 10-C), 25.43/25.46/29.57 (2C)/33.17/36.62 (t, 5-C to 7-C/4-C/8-C/3-C), 66.83 (t, 1-C), 70.28 (t, O**C**H_2-Ph), 72.26 (d, 2-C), 74.88 (d, 9-C), 127.35 (d)/127.61 (d, 2C)/128.29 (d, 2C)/139.14 (s) (C_{Ph}); MS (70 eV): *m*/*z* 280 (0.1, M^+), 135 (2), 131 (3), 108 (7), 107 (17), 92 (10), 91 (100), 55 (7), 43 (6), 41 (7).

(2R,9S)-9-Benzyloxy-1-(p-toluenesulfonyloxy)-decan-2-ol ***5***. A solution of 2.9 g (15 mmol) *p*-toluenesulfonyl chloride in 20 ml dry pyridine was added to an ice-cold solution of 4.6 g (16.4 mmol) (2*R*,9*S*)-9-benzyloxydecane-1,2-diol **4** in 50 ml dry pyridine. Stirring was continued for 5 hr at 0°C and 12 hr at 4°C. Then, 150 ml ice water (brought to pH 5 with 0.1% hydrochloric acid) and 60 ml diethyl ether were added. After separation of layers, the aqueous layer was extracted four more times with 120 ml diethyl ether. The combined organic layers were washed three times with 100 ml of saturated aqueous $CuSO_4$ and twice with 100 ml brine. The organic layer was dried and concentrated. Flash chromatography (10% ethyl acetate in hexane) furnished 4.6 g (10.5 mmol, 64%) (2*R*,9*S*)-9-benzyloxy-1-(*p*-toluenesulfonyloxy)decan-2-ol **5**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 1.08 (d, 3H, J = 6.1 Hz, 10-H), 1.15–1.35 (m, 11H, 3-H to 7-H and 8-H_a), 1.42–1.53 (m, 1H, 8-H_b), 1.77 (br.s, 1H, OH), 2.35 (s, 3H, CH_3-Tos), 3.39 (sext., 1H, J = 6.4 Hz, 9-H), 3.69–3.76 (m, 1H, 2-H), 3.78 (dd, 1H, J = 9.9, 2.5 Hz, 1-H_a), 3.93 (dd, 1H, J = 9.9, 2.8 Hz, 1-H_b), 4.34 (d, 1H, J = 11.7 Hz, OC**H**$_a$-Ph), 4.46 (d, 1H, J = 11.7 Hz, OC**H**$_b$-Ph), 7.15–7.28 (m, 7-H, H_{Ph}/Tol-H_b and Tol-$H_{b'}$), 7.70 (d, 2H, J = 8.4 Hz, Tol-H_a and Tol-

$H_{a'}$); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 19.62 (q, 10-C), 21.63 (q, 4-C_{Tol}-**C**H_3), 25.15/25.39/29.37/29.49/32.61/36.60 (t, 3-C to 8-C), 69.48 (d, 2-C), 70.27 (t, O**C**H_2-Ph), 73.96 (t, 1-C), 74.82 (d, 9-C), 127.33 (d, C_{Ph}), 127.60 (2C, d, 3-C_{Tol} and 3′-C_{Tol}), 127.94 (d, 2C, C_{Ph})/128.27 (2C, C_{Ph}), 129.93 (2C, 2-C_{Tol} and 2′-C_{Tol}), 132.73 (s, 4-**C**$_{Tol}$-CH_3), 139.13 (s, C_{Ph}), 145.02 (s, 1-**C**$_{Tol}$-SO_3-); MS (70 eV): *m*/*z* (%) 171 (0.1, Tol-SO_3^+), 135 (2, BnOCHCH_3^+), 107 (18), 92 (10), 91 (100), 65 (6), 55 (6), 43 (5), 41 (11), 39 (5).

(3S,10S)-10-Benzyloxyundecan-3-ol ***6***. Dry THF (20 ml) was added to 11.8 ml of 20% methyl magnesium chloride (31.4 mmol) in THF. The solution was cooled to −78°C, and 595 mg (3.14 mmol) CuI were added. After stirring for 15 min, a solution of 4.55 g (10.5 mmol) (2*R*,9*S*)-9-benzyloxy-1-(*p*-toluenesulfonyloxy)decane-2-ol **5** in 10 ml dry THF was added over 2 hr. The solution was warmed to −30°C and stirred 1 hr, then 150 ml saturated aqueous NH_4Cl and 50 ml diethyl ether were added at 0°C. The aqueous layer was extracted three times with 150 ml ethyl acetate. The combined organic layers were dried and concentrated. Flash chromatography (16% ethyl acetate in hexane) furnished 2.6 g (9.4 mmol, 90%) (3*S*,10*S*)-10-benzyloxyundecan-3-ol **6**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 0.93 (t, 3H, J = 7.3 Hz, 1-H), 1.18 (d, 3H, J = 6.1 Hz), 1.19–1.55 (m, 15H, 2-H/4-H to 9-H and OH), 3.45–3.54 (m, 2H, 3-H, and 10-H), 4.45 (d, 1H, J = 12 Hz, OC**H**$_a$-Ph), 4.56 (d, 1H, J = 12 Hz, OC**H**$_b$-Ph), 7.22–7.36 (m, 5-H, H_{Ph}); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 9.84 (q, 1-C), 19.91 (q, 11-C), 24.28/25.47/25.59/29.67/30.13/36.63/36.92 (t, 4-C to 9-C and 2-C), 70.25 (t, O**C**H_2-Ph), 73.28 (d, 3-C), 74.87 (d, 10-C), 127.31 (d)/127.59 (d, 2C)/128.26 (d, 2C)/139.14 (s) (C_{Ph}); MS (70 eV): *m*/*z* (%) 260 (0.8, M^+–H_2O), 108 (9), 107 (31), 104 (10), 92 (15), 91 (100), 69 (6), 65 (6), 59 (11), 57 (6), 55 (12), 43 (9), 41 (14).

(2S,9S)-Undecane-2,9-diol ***7***. Pd/C catalyst (20 mg) was added to a solution of 1.95 g (7 mmol) (3*S*,10*S*)-10-benzyloxyundecan-3-ol **6** in 30 ml ethanol, and the mixture was held under H_2 atmosphere for 12 hr at 40 atm. After completion of the reaction, the mixture was filtered through silica gel, and the solution was concentrated *in vacuo*. Flash chromatography (ethyl acetate/hexane, 1:1) yielded 1.2 g (6.4 mmol, 92%) (2*S*,9*S*)-undecane-2,9-diol **7**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 0.91 (t, 3H, J = 7.4 Hz, 11-H), 1.17 (d, 3H, J = 6.1 Hz, 1-H), 1.26–1.45 (m, 16H, 3-H to 8-H/10-H and OH), 3.45–3.52 (m, 1H, 9-H), 3.72–3.81 (m, 1H, 2-H); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 9.84 (q, 11-C), 23.48 (q, 1-C), 25.56/25.67/29.57/29.63/30.15/36.89/39.31 (t, 3-C to 8-C and 10-C), 68.13 (d, 2-C), 73.28 (d, 9-C); MS (70 eV): *m*/*z* (%) 171 (0.2, [M^+– H_2O]), 155 (0.86, [M^+–H_2O–CH_3]), 141 (11, [M^+–H_2O–CH_2CH_3]), 123 (43), 112 (8), 110 (5), 98 (6), 97 (17), 96 (10), 95 (21), 85 (12), 84 (23), 83 (37), 82 (23), 81 (100), 77 (14), 71 (15), 70 (28), 69 (42), 68 (16), 67 (49), 63 (10), 59 (83, $CH_3CH_2CHOH^+$), 57 (44), 56 (35), 55 (87), 53 (5), 45 (88) (CH_3CHOH^+), 43 (54), 42 (19), 41 (63), 39 (12).

(2S,9S)-Diacetoxyundecane. A solution of 1.40 g (7.4 mmol) (2*S*,9*S*)-undecane-2,9-diol **7** in 20 ml dry pyridine was cooled to 0°C. After addition of a small amount of 4-dimethylaminopyridine, 2.3 g (2.1 ml, 22.3 mmol) acetic anhydride were added dropwise, and the mixture was stirred for 2 hr at room temperature. Usual workup followed by flash chromatography (7% ethyl acetate in hexane) furnished 1.9 g (6.9 mmol, 93%) (2*S*,9*S*)-diacetoxyundecane. $[\alpha]^{20}_{D}$ −2.85 (*c* 1.06, $CHCl_3$). Enantioselective gas chromatography showed an enantiomeric excess of > 98 %. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 0.95 (t, 3H, *J* = 7.4 Hz, 11-H), 1.17 (d, 3H, *J* = 6.4 Hz, 1-H), 1.20–1.32 (m, 8H, 4-H to 7-H), 1.40–1.60 (m, 6H, 3-H/8-H, and 10-H), 1.99 (s, 3H, COC**H**$_3$), 2.76 (s, 3H, COC**H**$_3$), 4.77 (quin., 1H, *J* = 6.6 Hz, 9-H), 4.85 (sext., 1H, *J* = 6.4 Hz, 2-H); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 9.53 (q, 11-C), 19.92 (q, 1-C), 21.20 (q, CO**C**H$_3$), 21.34 (q, CO**C**H$_3$), 25.19/25.27/26.62/29.28/29.35/33.51/35.85 (t, 3-C to 8-C and 10-C), 70.95 (d, 2-C), 75.43 (d, 9-C), 170.73 (s, **C**O), 170.93 (s, **C**O); MS (70 eV): *m*/*z* (%) 209 (0.1, $[M–CH_3COOH]^+$), 148 (4, $[M–CH_3COOH–CH_3COOH_2]^+$), 141 (7), 123 (14), 110 (11), 103 (10), 97 (9), 96 (15), 95 (6), 83 (8), 82 (13), 81 (19), 69 (9), 68 (11), 67 (12), 57 (5), 55 (17), 43 (100, $COCH_3^+$), 41 (15).

For reference, a synthesis of the mixture of all four 2,9-diacetoxyundecanes was carried out. Racemic **3**, prepared from the bromide **1** and racemic methyloxirane, followed by protection of the hydroxyl group (see Figure 3), was oxidized with metachloroperbenzoic acid. The resulting epoxide was reacted with methylmagnesium bromide to yield 10-benzyloxyundecane-3-ol. After deprotection and acetylation, 2,9-diacetoxyundecane was obtained in good yield and high purity.

(2S,10S)-Undecane-2,10-diol ***9***. Under an argon atmosphere, a Grignard reagent was prepared from 2.5 g (10.9 mmol) 1,5-dibromopentane **8** (Aldrich), and 795 mg (32.6 mmol) freshly ground magnesium turnings in 25 ml dry THF at 60°C. After cooling to room temperature, the solution was added dropwise to 1.24 g (1.5 ml, 21.7 mmol) (*S*)-methyloxirane (Aldrich) and 420 mg (2.17 mmol) CuI, suspended in 10 ml dry THF at −78°C. Subsequently, the solution was warmed to room temperature and stirred for 1 hr. After addition of 250 ml of saturated aqueous NH_4Cl, the mixture was extracted with 100 ml ethyl acetate. The aqueous layer was separated and extracted three times with 150 ml of a 1:1 mixture of ethyl acetate and hexane. The combined organic extracts were dried and concentrated. Purification by flash chromatography (20% hexane in ethyl acetate) furnished 1.1 g (5.84 mmol, 54%) (2*S*,10*S*)-undecane-2,10-diol **9**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 1.15 (d, 6H, *J* = 6.1 Hz, 11-H and 1-H), 1.21–1.49 (m, 14H, 3-H to 9-H), 1.58 (s, 2H, OH), 3.70–3.80 (m, 2H, 2-H and 10-H); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 23.42 (q, 2C, 1-C, and 11-C), 25.68 (t, 2C)/29.51 (t, 3C)/39.28 (t, 2C), 68.06 (d, 2C, C-2, and C-10); MS (70 eV): *m*/*z* (%) 95 (6), 83 (6), 82 (6), 81 (8), 70 (8), 69 (12), 68 (6),

67 (8), 63 (7), 57 (9), 56 (12), 55 (18), 45 (100), 43 (24), 42 (6), 41 (21), 39 (7).

(2S,10S)-Diacetoxyundecane. A solution of 1.1 g (5.8 mmol) (2*S*,10*S*)-undecane-2,10-diol **9** in 15 ml dry pyridine was cooled to 0°C. After addition of a small amount of 4-dimethylaminopyridine, 1.79 g (1.66 ml, 17.5 mmol) acetic anhydride were added dropwise, and the mixture was stirred for another 2 hr at room temperature. Usual workup followed by flash chromatography (10% ethyl acetate in hexane) furnished 1.38 g (5.1 mmol, 87%) (2*S*,10*S*)-diacetoxyundecane. $[\alpha]^{20}_{D}$ −1.68 (*c* 1.07, $CHCl_3$). Enantioselective gas chromatography showed an enantiomeric excess of > 98%. ^{1}H-NMR (400 MHz, $CDCl_3$): δ 1.17 (d, 6H, J = 6.1 Hz, 1-H and 11-H), 1.20–1.57 (m, 14H, 3-H to 9-H), 1.90 (s, 6H, COC**H**$_3$), 4.85 (sext., 2H, J = 6.4 Hz, 2-H and 10-H); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 19.92 (q, 2C, 1-C, and 11-C), 21.34 (q, 2C, CO**C**H$_3$), 25.33 (t, 6-C), 29.35 (t, 4C, 4-C/5-C, and 7-C/8-C), 35.87 (t, 2C, 3-C, and 9-C), 70.99 (d, 2C, 2-C, and 10-C), 170.73 (s, **C**O); MS (70 eV): *m/z* (%) 87 (13), 61 (5), 55 (11), 43 (100), 41 (12), 39 (5).

For reference, the sequence described for the synthesis of (2*S*,10*S*)-diacetoxyundecane was also carried out using racemic methyloxirane.

(S)-Undecan-2-ol. A Grignard reagent was prepared from 2.8 g (14.7 mmol) 1-bromooctane (Aldrich) and 900 mg (37.0 mmol) freshly ground magnesium turnings and reacted with 853 mg (1.03 ml, 14.7 mmol) (*S*)-methyloxirane (Aldrich). The preparation procedure and workup followed the protocol as described for the synthesis of (*S*)-9-decene-2-ol. After flash chromatography of the crude product (20% ethyl acetate in hexane), 2.0 g (11.6 mmol, 79%) (*S*)-undecan-2-ol were obtained. The compound has been described earlier. Analytical data of our product matched those reported in the literature (Nakamura and Matsuda, 1998).

(S)-2-Acetoxyundecane. Acetylation of 2.0 g (11.6 mmol) (*S*)-undecan-2-ol followed the protocol as described above for the acetylation of the undecanediols. Workup followed by flash chromatography (5% ethyl acetate in hexane) furnished 2.3 g (10.7 mmol, 93%) (2*S*)-acetoxyundecane. $[\alpha]^{20}_{D}$ +2.29 (*c* 1.22, $CHCl_3$). ^{1}H-NMR (400 MHz, $CDCl_3$): δ 0.86 (t, 3H, J = 6.6 Hz, 11-H), 1.17 (d, 3H, J = 6.4 Hz, 1-H), 1.20–1.56 (m, 16H, 3-H to 10-H), 2.00 (s, 3H, COC**H**$_3$), 4.86 (sext., 1H, J = 6.1 Hz, 2-H); ^{13}C-NMR (101 MHz, $CDCl_3$): δ 14.07 (q, 1C, 11-C), 19.94 (q, 1C, 1-C), 21.36 (q, 1C, CO**C**H$_3$), 22.66/25.39/29.28/29.45/29.52 (2C)/31.87/35.93 (t, 3-C to 10-C), 71.07 (d, 1C, 2-C), 170.76 (s, **C**O); MS (70 eV): *m/z* (%) 87 (13), 70 (6), 69 (6), 61 (4), 57 (7), 56 (9), 55 (17), 43 (100), 41 (34), 39 (11).

Wind Tunnel. Wind tunnel experiments were performed in the second to fourth hour of the photophase at 22°C and RH 73% in a wind tunnel described in detail by Rauscher et al. (1984). Compounds were diluted in hexane (p.a. grade, Fluka). For the bioassays, 10 µl of the stimulus to be tested were applied

on a 1-cm^2 piece of filter paper (Chromatographiepapier "Schleicher & Schuell AG" Auer-Bittmann Soulié AG, Zürich, Switzerland, 69.2 g/m^2). The filter paper was placed in the wind tunnel 20 sec before the first male was tested. For each stimulus, a series of five males was tested individually, requiring a total of 5–10 min. For each series, a new piece of filter paper was loaded with stimulus.

Males were kept individually in glass tubes (10 cm, 15 mm ID) closed at one end with a screen (mesh size 1 × 1 mm) until tested. The tubes containing the males were transferred into the wind tunnel and placed horizontally 130 cm downwind from the odor source. The following behavioral steps were recorded: activation (expressed by wing fanning), takeoff, directed flight towards the odor source, flights closer than 30 cm from the source ("close in"), landing on the source, or landing elsewhere. The test was terminated when no activity or takeoff was registered for 2 min or when the insect landed elsewhere. When synthetic stimuli were tested, only the number of successful landings on the source was analyzed. Pairwise comparisons between different blends (for example, as shown in Figure 6) were based on Fisher's exact test, calculated with the software JMP 5.0.1 (SAS Institute Inc., Cary, NC, USA).

Field Assay. The blend with the highest attractiveness in the wind tunnel was tested in the field. Treatments tested were either dispensers consisting of red rubber septa (used as lids for serum bottles, VWR International, Sweden), dental cotton rolls (diam 14 mm, length 40 mm, IVF Hartmann AG, Neuhausen, Switzerland; Hillbur et al., 2000), or control traps without pheromone dispensers. Cotton rolls were cut in three, and one third was used per dispenser. Both dispenser types were loaded with a blend of 500 ng (2*S*,9*S*)-diacetoxyundecane, 1000 ng (2*S*,10*S*)-diacetoxyundecane, and 10 ng (*S*)-2-acetoxyundecane, diluted in 20 μl of hexane. Delta traps made of waxed cardboard were provided by PheroNet AB (Alnarp, Sweden). The traps had a height of 10 cm and were equipped with a 15.5 × 9 cm insert covered with a thin layer of Tangle Trap Insect Trap Coating (Tanglefoot, Grand Rapids, MI, USA). Dispensers were positioned 1–2 cm above the insert.

The field assay was performed in Wädenswil in a plot with broccoli (*B. oleracea convar. botrytis* var. *italica* cv. Fiesta) 2 wk before harvest. At this stage, plants were 50–70 cm high, the leaf canopy was closed, and many weeds were growing between the broccoli plants. On June 10, 2003, pots containing substrate with 150–250 pupae each of laboratory-reared midges were placed in the field. Two groups of five pots each were arranged in the center of the field, 8 m apart from each other. The pots were replaced by a new batch 7 d later. Groups of traps were placed at six locations between 3.5 and 5 m from the nearest release point. Each trap group consisted of two replicates of the three treatments, i.e., a total of six traps. Traps with the same treatment were attached to the same pole at 20 and 55 cm above ground. The distance between the poles

was 30–40 cm. The sticky inserts were replaced five times within the 10 d of the experimental period, and midges were counted using a binocular microscope.

RESULTS

Gas chromatographic–electroantennographic detection analysis of an ovipositor extract revealed two peaks that elicited a response from the male antenna (RT: 13.12 and 13.31 min) (Figure 2). The mass spectra of the antennal stimulatory peaks (Figure 3) were found to show similar fragmentation patterns to those of 2,11-diacetoxytridecane and 2,12-diacetoxytridecane (molecular masses 300), the major pheromone components of the pea midge, *C. pisi* (Hillbur et al., 1999). Signals in the higher mass region pointed to a molecular mass of 272 (detectable in the mass spectrum of one of the compounds that also showed *m*/*z* 243 = 272 − 29), strongly suggesting the target compounds to be the C11 analogs of the *C. pisi* diacetates: 2,9-diacetoxyundecane and 2,10-diacetoxyundecane. This was consistent with a diagnostic ion at *m*/*z* 152 representing an undecadiene fragment (loss of two molecules of acetic acid) and *m*/*z* 61 (CH_3COOH + H) as well as *m*/*z* 103 (for a diacetate). Key fragments at *m*/*z* 87 and *m*/*z* 101 revealed the positions of the acetoxy groups along the chain (see insert in Figure 3). Retention indices were found to be two carbon units lower than those of the *C. pisi* compounds.

The synthesis of an optically active stereoisomer of 2,10-diacetoxyundecane was straightforward (Figure 1). The *bis*-Grignard reagent of 1,5-dibromopentane was reacted with (2*S*)-2-methyloxirane to furnish (2*S*,10*S*)-undecane-2,10-diol.

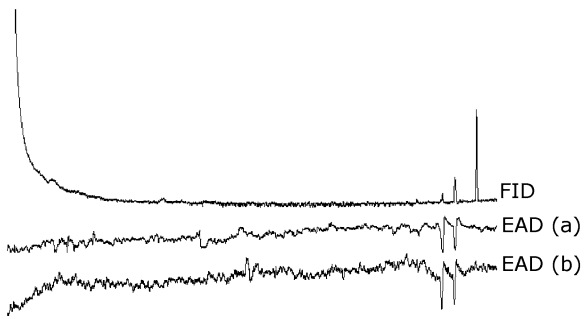

FIG. 2. Gas chromatogram with flame ionization detection (FID) and electroantennographic detector (EAD; a and b = separate male *Contarinia nasturtii* antennae) responses to a hexane extract of 30 *C. nasturtii* ovipositors (in both a and b). Repeatable antennal responses registered at 13.12 and 13.31 min.

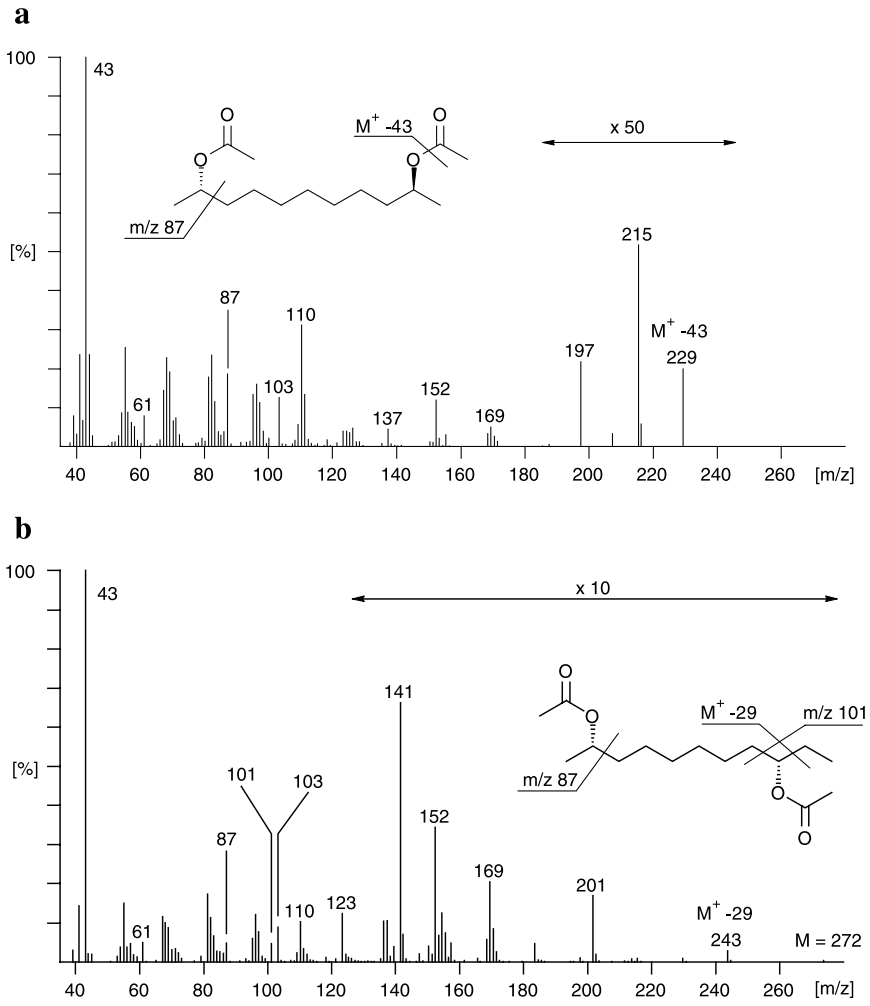

FIG. 3. Mass spectra (70 eV) and structures of (a) (2*S*,10*S*)-2,10-diacetoxyundecane and (b) (2*S*,9*S*)-2,9-diacetoxyundecane.

The corresponding diacetate was produced upon reaction with acetic anhydride. Following the same sequence but using racemic 2-methyloxirane furnished a mixture of the three stereoisomers in a ratio of 1:1:2. The two enantiomers of 2,10-diacetoxyundecane as well as the *meso*-form were well separated upon enantioselective gas chromatography. Hydrodex as a chiral stationary phase furnished an α value of tr(2*R*,10*R*)/tr(2*S*,10*S*) = 1.033 (36.36 min/35.21 min).

Structure assignment of stereoisomers was carried out by using (2*S*,10*S*)-2,10-diacetoxyundecane as a reference. Coinjection of the synthetic enantiomer and a *C. nasturtii* extract showed (2*S*,10*S*)-2,10-diacetoxyundecane to coelute with the natural product.

In analogy to the *C. pisi* pheromone, this result suggested the other EAD-active compound to be (2*S*,9*S*)-2,9-diacetoxyundecane. The synthesis of this target compound started from 7-bromo-1-heptene, which was chain elongated with (*S*)-methyloxirane via Grignard reaction (Figure 1). The resulting (*S*)-9-decen-2-ol was benzylated and reacted with AD-Mix-β to furnish (2*S*,9*S*)-9-benzyloxydecane-1,2-diol. After tosylation of the primary hydroxy group, chain elongation was carried out with methyl magnesium chloride in the presence of CuI. Debenzylation upon hydrogenation and acetylation completed the synthesis of (2*S*,9*S*)-2,9-diacetoxyundecane. Following a similar sequence but using racemic methyloxirane and nonstereoselective oxidation of a double bond furnished a mixture of the four stereoisomers, which were well separated upon enantioselective gas chromatography. Using Hydrodex as a stationary phase, the peak corresponding to (2*S*,9*S*)-2,9-diacetoxyundecane was assigned upon comparison of the retention time of the pure stereoisomer with those of the mixture

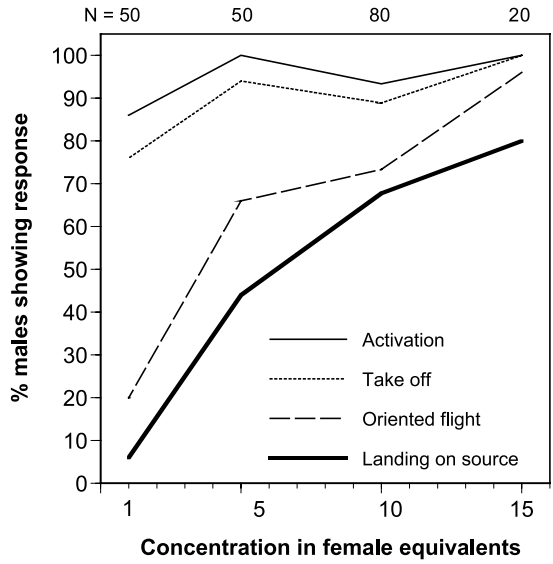

FIG. 4. Wind tunnel response of male *C. nasturtii* to extracts of calling females. The behaviors observed were activation (walking and wing fanning in glass tube), takeoff, oriented flight upwind towards the odor source, and landing on the odor source. *N* = number of males tested at each concentration.

of stereoisomers. On this column, synthetic (2*S*,9*S*)-2,9-diacetoxyundecane co-eluted with the natural product.

Because the structures of the two EAD-active compounds were closely related to the two main compounds of the pheromone system of *C. pisi*, we looked for the presence of another *C. pisi* analog, 2-acetoxyundecane. With a synthetic sample to check for retention times, and using single ion monitoring mass spectrometry (*m*/*z* 43, 87), we detected the target compound in the natural extract in extremely small amounts. Because of its low concentration, we were unable to determine the enantiomeric composition.

Wind Tunnel Assay. The number of males flying upwind and landing on the odor source increased with increasing doses of female extract on the filter paper (Figure 4). At the dose of 15 female equivalents, 92% of the males approached the odor source, and 80% landed on it. This result proved that the method was suitable for testing synthetic potential pheromone compounds.

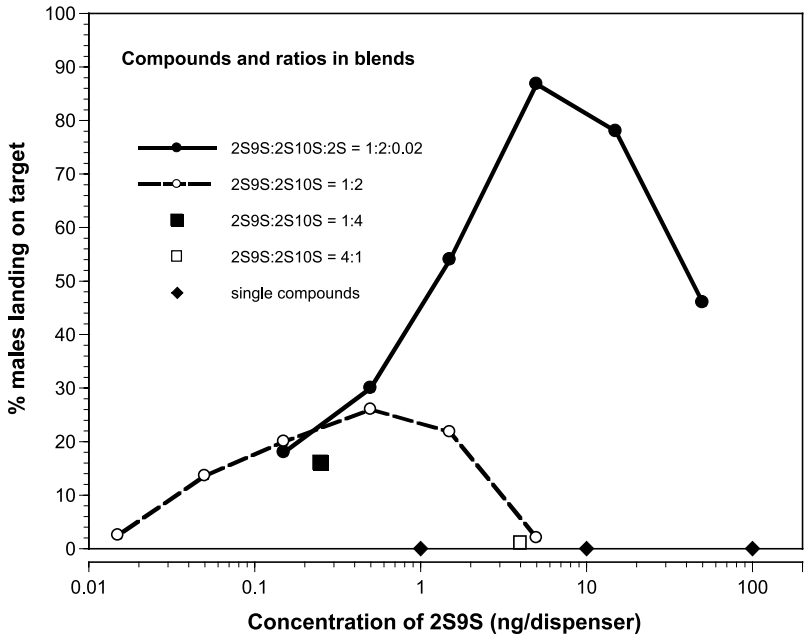

FIG. 5. *C. nasturtii* males (%) contacting the odor source in the wind tunnel when exposed to synthetic compounds. 2S9S = (2*S*,9*S*)-2,9-diacetoxyundecane, 2S10S = (2*S*,10*S*)-2,10-diacetoxyundecane, 2S = (*S*)-2-acetoxyundecane. Response to any one of the three single components at the doses indicated was always 0. $N \geq 50$ for all concentrations of blends tested; $N \geq 20$ for all concentrations of single components.

When tested singly, (2*S*,9*S*)-diacetoxyundecane and (2*S*,10*S*)-diacetoxyundecane did not elicit responses directed towards the odor source (Figure 5). Less than 15% of the tested males took off from the release point, and no males flew towards the odor source. A blend of the two components mixed in a ratio similar to that found in the pheromone gland extract at best stimulated 26% of the males to show the whole behavioral sequence from takeoff to landing on the odor source (Figure 5). Changing the ratio in the mixture more towards either (2*S*,9*S*)-diacetoxyundecane or (2*S*,10*S*)-diacetoxyundecane did not result in a higher proportion of males approaching the odor source (Figure 5). However, adding only 2% of (*S*)-2-acetoxyundecane to the blend gave a much more attractive blend with a landing rate of 87% for the most attractive dose, 5 ng (2*S*,9*S*)-diacetoxyundecane, 10 ng (2*S*,10*S*)-diacetoxyundecane, and 0.1 ng (*S*)-2-acetoxyundecane per dispenser (250 males tested, Figure 5). At this dose and ratio, the two-component blend made up of the two diacetates was unattractive to males, and the percentage landing did not differ significantly from 0 (Fisher's exact test; $P = 0.51$). The three-component blend was also significantly more attractive than the two-component blend at 1.5 ng/dispenser

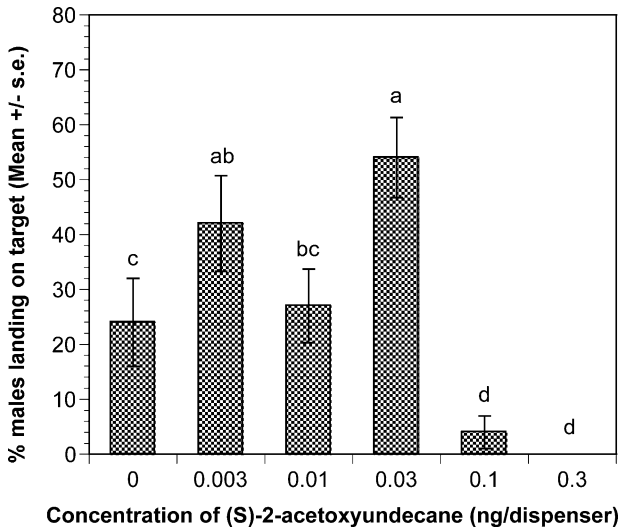

FIG. 6. *C. nasturtii* males (%) contacting the odor source in the wind tunnel in response to three-component blends with varying doses of (*S*)-2-acetoxyundecane. The dose of (2*S*,9*S*)-2,9-diacetoxyundecane and (2*S*,10*S*)-2,10-diacetoxyundecane was constant in all blends (1.5 and 3 ng/dispenser, respectively). Each dose of (*S*)-2-acetoxyundecane was tested with 45 (0.01 and 0.1 ng) or 50 (other doses) males. Different letters indicate values that are significantly different from each other in pairwise comparisons (Fisher's exact test; $P < 0.05$).

of (2*S*,9*S*)-diacetoxyundecane (Fisher's exact test; $P = 0.002$), whereas at the two lower doses tested, 0.15 and 0.5 ng/dispenser, there was no significant difference in attractiveness between the two- and the three-component blends (Fisher's exact test; $P > 0.05$).

To further investigate the influence of the relative ratio of (*S*)-2-acetoxyundecane, blends were tested with constant doses of (2*S*,9*S*)-diacetoxyundecane (1.5 ng/dispenser) and (2*S*,10*S*)-diacetoxyundecane (3.0 ng/dispenser) and varying doses of (*S*)-2-acetoxyundecane. Of the tested doses, 0.03 ng (*S*)-2-acetoxyundecane per dispenser was most attractive (Figure 6). At that dose and

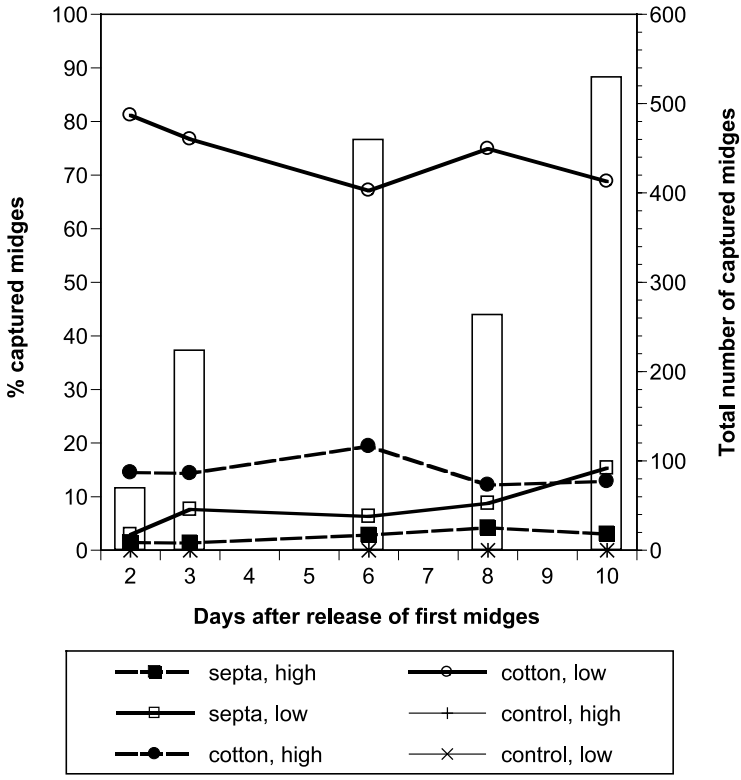

FIG. 7. Field assay with released midges and pheromone traps baited with a three-component pheromone blend [(2*S*,9*S*)-2,9-diacetoxyundecane/(2*S*,10*S*)-2,10-diacetoxyundecane/(*S*)-2-acetoxyundecane = 500:1000:10 ng] on either rubber septa or cotton rolls. Traps without dispensers were used as controls. For each treatment, traps were positioned at 20 cm (low) and 55 cm (high) above ground. Bars indicate the total number of midges in all traps on respective days. Lines indicate the distribution (%) of these midges among the treatments.

lower, at least as many males landed on the source as when exposed to the binary blend [Figure 6, dose (*S*)-2-acetoxyundecane = 0]. Higher relative ratios of (*S*)-2-acetoxyundecane significantly reduced the proportion of males landing (Figure 6). A ratio of components corresponding to the blend with 0.03 ng/dispenser in this experiment, i.e., (2*S*,9*S*)-diacetoxyundecane/(2*S*,10*S*)-diacetoxyundecane/(*S*)-2-acetoxyundecane = 1:2:0.02, was therefore used in the following field experiments.

Field Assay. An estimated total of 3000–5000 males were released in this experiment, and 1543 males were captured in the traps over 10 d. None of the control traps (without pheromone dispensers) ever caught a *C. nasturtii* male (Figure 7). During the whole assay, the traps in the lower position caught on average 81.9 ± 2.1% of the males (mean ± SE, $N = 5$ dates of counting midges). Traps with cotton roll dispensers caught 88.4 ± 2.4% of all midges captured (mean ± SE, $N = 5$ dates of counting midges), indicating that the pheromone blend released from the cotton rolls was more attractive than that released from the rubber septa.

DISCUSSION

Accumulating data on gall midge pheromones have revealed a high degree of conservatism with regard to molecular structure of pheromone components within the family Cecidomyiidae (identified compounds are listed in Choi et al., 2004). The behaviorally active three-component pheromone blend of *C. nasturtii* shows a striking similarity to that of *C. pisi*, consisting of (2*S*,11*S*)-diacetoxytridecane, (2*S*,10*S*)-diacetoxytridecane, and 2-acetoxytridecane (Hillbur et al., 1999). Except for the difference in chain length—11 carbons in *C. nasturtii* and 13 carbons in *C. pisi*—they seem identical, with regard to the number of compounds, their ratios in female gland extract, and the stereochemistry of the diacetates. In both species, however, the enantiomeric composition of the monoacetate is still unknown because the minute amount of the compounds present in gland extracts has prevented determination by GC-MS. Still, the clear behavioral activity of (*S*)-2-acetoxyundecane confirms that it is a pheromone component and that the (*S*)-enantiomer is likely to be identical with the female-produced compound. All presently identified pheromone components in gall midges are chiral compounds, and males have been shown to respond enantiospecifically, i.e., only to the female-produced stereoisomer (Harris and Foster, 1991; Gries et al., 2000, 2002; Hillbur et al., 2001; Choi et al., 2004).

At the optimal dose of the three-component blend that induces landing in almost 90% of the males, the two-component blend was unattractive. However, at low doses, the blends were equally attractive. This response pattern is partly inconsistent with the response specificity observed in several moth species using

multicomponent pheromone blends (reviewed by Linn and Roelofs, 1995). In these species, males need to perceive the natural blend of components to exhibit the complete behavioral response and will display their lowest response threshold to that blend (Linn and Roelofs, 1995). Further experiments will be needed to explain the observed behavior in *C. nasturtii*. The result of the GC-EAD analysis obtained with several pheromone gland extracts that showed no male antennal response at the retention time of (*S*)-2-acetoxyundecane suggests that the antennal sensitivity to this compound may be relatively low. To verify this, electroantennography (EAG) could be used to establish antennal dose response curves for all three pheromone components. The rather high release rate from filter paper, presumably higher for the monoacetate than for the diacetates, may distort the blend emitted. Thus, at low doses, the males may have been exposed to three-component blends with an amount of the monoacetate below the antennal detection threshold. Consequently, at the physiological level, the mixture of the two diacetates and the three-component blend may have seemed identical to the males.

In the experiment investigating the relative ratio of (*S*)-2-acetoxyundecane, 0.03 ng/dispenser [1% of the dose of (2*S*,10*S*)-diacetoxyundecane]—i.e., the same relative dose that was used in the preceding wind tunnel experiment (Figure 5)—elicited the highest behavioral response. Lower and higher relative ratios of (*S*)-2-acetoxyundecane were significantly less active (Figure 6), suggesting an optimal relative ratio of approximately 1%. An optimal relative ratio of the monoacetate was not conclusively demonstrated for *C. pisi* (Hillbur et al., 2000). In the wind tunnel, a blend with a relative proportion of 1% of the monoacetate was as attractive as pheromone gland extract of the same dose, but no other ratios were tested, and a three-component blend with a high ratio of the monoacetate (presumably 1:1:1) was not inhibitory in the field (Hillbur et al., 2000). With regard to the optimal relative ratio of (*S*)-2-acetoxyundecane in *C. nasturtii*, the inhibitory effect of higher ratios demonstrated in the wind tunnel ought to be considered if the pheromone is used for monitoring.

The field assay was conducted in a field that had had little *C. nasturtii* damage during recent years. Hence, the indigenous population was likely to have been low during the experiment. Therefore, a comparison between the estimated number of released midges and captured males indicates a high recapture rate of between 30 and 50%. This high recapture indicates that the trap is highly efficient within the tested range (3–5 m), despite the simultaneous presence of calling females. The majority of the males were caught down low in the crop (20 cm above ground), suggesting that *C. nasturtii* males, at least for short-range dispersal within the fields, fly close to the soil. The same behavior has been reported for *C. pisi* (Wall et al., 1991). Water traps at 0–30 cm above ground caught high numbers of *C. pisi* males during the morning hours, whereas traps positioned higher up caught almost exclusively females later in the day.

The result was explained by flight activity in the early morning being dominated by males in search of calling females, followed by flight of mated females to suitable oviposition sites during the afternoon (Wall et al., 1991). The *C. nasturtii* field bioassay also showed that dental cotton rolls were most effective as dispensers. Similar results were obtained previously in a field experiment with the *S. mosellana* pheromone (Celander and Hillbur, 2003) and in a release rate experiment in the laboratory with the *C. pisi* pheromone (Hillbur et al., 2000). Dental cotton rolls baited with small amounts of pheromone (1–100 μg) have also been found to stay attractive for several weeks in the field (Hillbur et al., 2001; Celander and Hillbur, 2003; Baur et al., unpublished). Cotton rolls may thus be a suitable and economic dispenser material for these types of pheromone compounds.

An important characteristic of pheromone-based monitoring systems is species specificity. To confirm the specificity of the *C. nasturtii* lure, a total of 100 male midges, retrieved from sticky papers of pheromone traps, were identified based on a molecular diagnosis method (Frey et al., unpublished). All analyzed specimens were *C. nasturtii*, confirming that attraction is species specific. To verify this finding, the pheromone blend will be tested throughout the world in regions with *C. nasturtii* populations, so that the species specificity of the catches can be assessed for the respective regions.

Acknowledgments—We thank Cristina Marazzi, Sandra Jakob, and Reinhard Eder for assistance in insect rearing, wind tunnel experiments, and fieldwork. (Received December 23, 2004; revised April 6, 2005; accepted April 9, 2005)

Abstract—Male-specific compounds, previously identified from *Phyllotreta cruciferae* and synthesized or isolated from natural sources, attracted both sexes of the beetle in field trials and therefore function as components of a male-produced aggregation pheromone. Six field experiments of 7 to 10 d duration each were conducted over 2 yr using modified boll weevil traps and two doses of pheromone. Treatments containing two doses of allyl isothiocyanate (AITC), a breakdown product of glucosinolates in *Brassica napus* L., a host plant of the beetles, were included in the study. A dose response was observed for both the pheromone components and AITC, and combinations of the pheromone and AITC generally attracted greater numbers of flea beetles than did either component itself. This increased attraction to a combination of beetle-produced compounds and host odors has not been previously demonstrated in halticine beetles and could help explain patterns of movement by *P. cruciferae* into field crops.

Key Words—*Phyllotreta cruciferae*, crucifer-feeding flea beetle, aggregation pheromone, Chrysomelidae: Alticinae, field trials, kairomone.

INTRODUCTION

The crucifer flea beetle *Phyllotreta cruciferae* (Goeze) (Coleoptera: Chrysomelidae) is a major pest of canola and crucifer crops in North America and is consistently found feeding in oilseed rape or canola fields (*Brassica rapa* L. or *B. napus* L.) on the Canadian prairies (Burgess, 1977; Lamb and Turnock, 1982; Lamb, 1989). Damage and control costs for this and a related species, *P. striolata* (F.), exceed $300 million annually (Knodel and Olson, 2002). Insecticides are the main means of control of flea beetles in canola crops, with more than 90% of the 5 million ha seeded to canola in North America treated with insecticides (Waite et al., 2001). Integrated methods of management of this chronic agricultural pest are urgently needed, including tools based on pheromones and host plant volatiles.

Males of *P. cruciferae* were previously reported to emit an aggregation pheromone that attracts both sexes based on field and laboratory experiments with live beetles (Peng and Weiss, 1992; Peng et al., 1999). Subsequently, the volatiles emitted by the beetles were analyzed, and six sesquiterpenes were identified (Figure 1). These were produced only by males, but at least one was readily sensed by the antennae of both sexes (Bartelt et al., 2001). Thus, these compounds or a subset of them was thought likely to constitute the pheromone. All six compounds are chiral, and only the enantiomers shown in Figure 1 are emitted by the beetles. Racemic forms (50:50 mixtures of the two enantiomers) of **1**, **3**, **5**, and **6** were synthesized (Bartelt et al., 2003). Subsequently, Muto et al. (2004) synthesized the individual enantiomers of compounds **1**, **3**, **5**, and **6**, using citronellal of known configuration as the chiral starting material. These studies confirmed the basic structures determined by Bartelt et al. (2001) and resolved uncertainty about the absolute configurations of these compounds.

The host range of *P. cruciferae* is confined to the order Capparales, principally to the family Brassicaceae (Feeny et al., 1970). All members of this family contain one or more anionic glucosinolate compounds. Glucosinolates and their metabolites are thought to act not only as deterrents for generalist insect feeders, but also as attractants and stimulants for specialist crucifer feeders such as crucifer-feeding flea beetles (*Phyllotreta* spp.) (Chew, 1988; Louda and Mole, 1991). The mustard oil allyl isothiocyanate (AITC), a glucosinolate breakdown product, is attractive to *P. cruciferae* in the field (Vincent and Stewart, 1984; Pivnick et al., 1992). Host plants also can affect the production of, and responses to, insect pheromones. In particular, male-produced pheromones of various bark beetles, weevils, nitidulid beetles, and other insects act synergistically with volatiles from the host plant (Landolt and Phillips, 1997). However, there is no specific information about such interactions in halticine flea beetles.

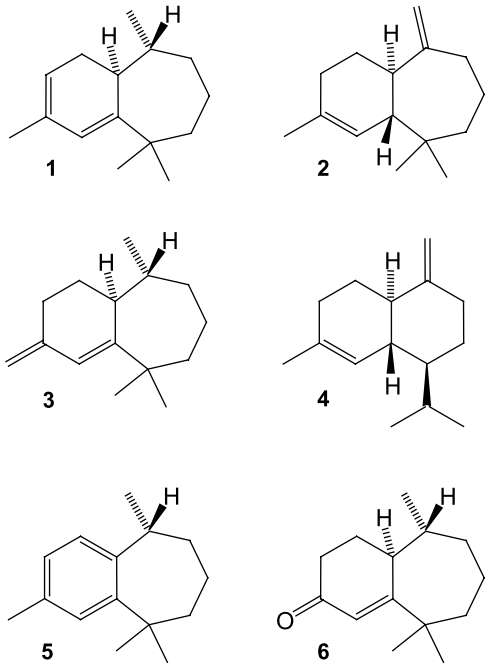

FIG. 1. Male-specific compounds previously identified from *P. cruciferae*. The compounds are numbered in the order of elution from a nonpolar GC column.

The primary objective of this research was to test whether the compounds identified from male *P. cruciferae* and subsequently synthesized were attractive to beetles in the field, relative to controls and to the host-derived attractant, AITC. A second objective was to explore beetle responses to the combination of male-specific compounds and the host plant volatile AITC.

METHODS AND MATERIALS

Male-Specific Compounds. Racemic compounds **1**, **3**, **5**, and **6** were synthesized as described previously (Bartelt et al., 2003). Compound **2** was not available for field tests. Compound **4**, γ-cadinene, was isolated from citronella essential oil (Vig et al., 1970) in a procedure described in the Appendix (available online at www.springerlink.com; search for DOI: 10.1007/s10886-005-5929-2; Electronic Supplementary Material can be found at the end of the article).

Pheromone Lures. Rubber septa (McDonough, 1991) were used as dispensers for the beetle-produced compounds in field experiments. Before loading the chemicals, all septa (20 × 11 mm diameter, Aldrich Chemical Co., Milwaukee, WI, USA) were cleaned by Soxhlet extraction for 8 hr with methylene chloride. Septa with the high dose were prepared such that the total weight of the natural enantiomers of **1**, **3**, **4**, **5**, and **6** was 500 μg and that the proportions of these enantiomers in the initial emissions from the septa were the same as the emissions from male *P. cruciferae* (Bartelt et al., 2001). The correct blend was found by an iterative approach because the proportions of the applied compounds differed from those emitted due to widely differing volatilities. Details are given in the Results section. Low-dose septa were prepared with 50 μg of the same blend used in the higher dose septa. After loading the chemicals, all septa were aired in a hood until the solvent had evaporated and then stored in tightly closed vials at −20°C until used for field tests.

The emissions from four high-dose septa were monitored in the laboratory for 2 wk to evaluate changes over time. Each septum was placed into a 50-ml flask through which air was passed at a rate of 100 ml/min. Volatile emissions were collected onto Super Q filters (Bartelt et al., 2001). The collection apparatus was kept in an incubator in the dark at 27°C. Volatiles were recovered every 1–3 d by rinsing the filters with hexane and quantified, relative to the internal standard nonadecane, by gas chromatography (GC) with a flame ionization detector. Emission per day was modeled for each component over time by linear regression.

Host Volatile Lures. Technical grade (95%) allyl isothiocyanate (AITC) (Sigma-Aldrich Chemicals, Oakville, ON, Canada) was placed in the traps in one of two configurations. In high-dose AITC lures, disposable glass culture vials (50 × 6 mm, 3.8 mm inside diameter, 1 ml capacity, Kimble Co., Nepean, ON, Canada) were filled with 0.2 ml AITC so that approximately 40 mm of the vial remained empty. At the end of the first trial, some of the vials contained one to several flea beetles in or near the surface of the AITC. Thus, in all subsequent trials the top of each vial was plugged with a small piece of foam rubber to prevent beetles from entering the vial. Evaporation rates of AITC were tested from capillary tubes with and without plugs by weighing before and after several days in the field. Plugs did not appear to hamper evaporation of the AITC.

For low-dose AITC lures, a 200-μl capillary tube (125 × 2.2 mm, 1.6 mm inside diameter, Goldseal Glassware, Becton Dickinson and Co, Parsippany, NJ, USA), was filled with approximately 10 μl AITC so that 70 mm of the inside length of the tube was not filled.

All vials and microcapillary tubes containing the AITC were weighed immediately before being placed in and after removal from the field traps to determine the average rate of AITC emission per day.

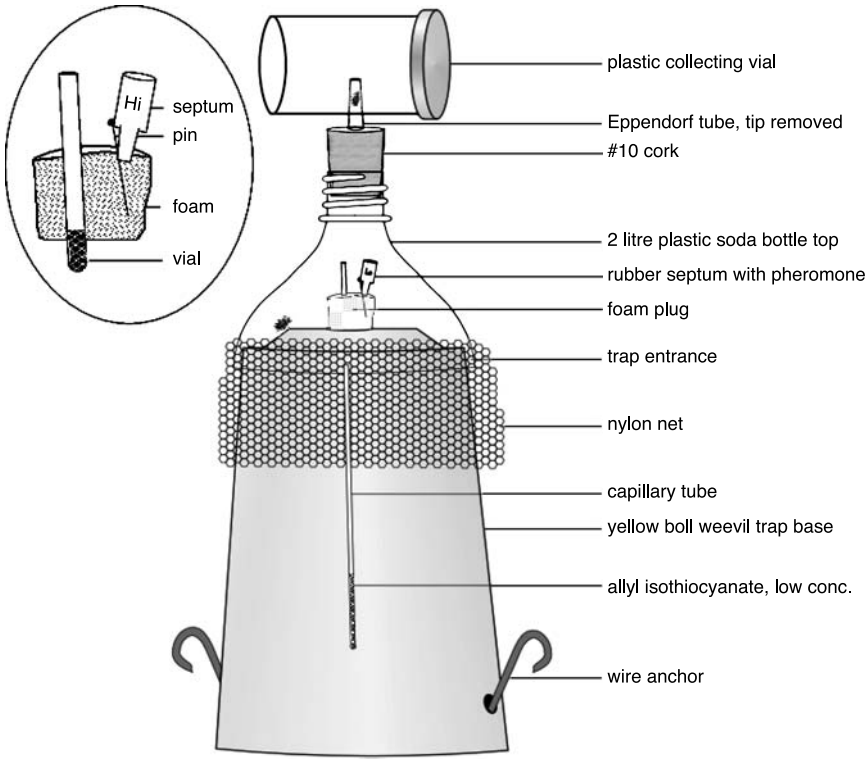

FIG. 2. Schematic diagram of trap used to test attractiveness of synthetic flea beetle compounds and/or AITC to crucifer-feeding flea beetles, *Phyllotreta* spp., in the field near Saskatoon, SK, 2001–2002. Trap shows Treatment 9, low concentration of AITC in a capillary tube, and low concentration of pheromone on a rubber septum. Enlargement shows Treatment 6, high concentrations of both allyl isothiocyanate and pheromone.

Traps. Yellow plastic boll weevil traps were used (Story Chemical Co., Starkville, MS, USA) modified as follows (Figure 2): the funnel-shaped plastic top of each trap was replaced by the upper third portion of a clear, 2-l plastic soft drink bottle and glued to the base of the trap. A No. 10 cork (30 × 20 mm diameter) was drilled with a No. 2 cork borer, and a Gilson Diamond D1000 plastic micropipette tip (Mandel Co., Guelph, ON, Canada) was placed through the cork with the tip up. Approximately 1 cm of the micropipette tip end was removed to form a hollow tube of the remainder, and the cork and modified pipette were inserted into the neck of the soft drink bottle. A #2 sized hole was bored into the side of a 100-ml plastic collecting vial, which was placed firmly on top of the pipette. A 30 × 20 mm diameter foam plug was placed in the hole

at the top of the yellow base through or onto which was inserted the appropriate treatment.

The three lure elements, that is, glass vials with AITC, capillary tubes with AITC, and rubber septa with beetle-produced compounds, were inserted onto the foam plug so that the top of each was at the same level above the top of the foam plug. In the first two trials, larger insects congested the traps. In Trials 3 to 6, a strip of nylon netting wide enough to hang one third of the way down the yellow base was taped to the soda bottle top to prevent access by large insects to the trap. Entry by flea beetles and other small insects into the traps was not impeded by the netting.

Field Sites and Experimental Design. Field trials were conducted at the Agriculture and Agri-Food Canada, Saskatoon Research Centre farm and at the Crop Development Centre of the University of Saskatchewan, near Saskatoon, SK, Canada, latitude 52°09′N, longitude 106°34′W, for 7 to 10 d duration on six occasions: early June, late June, and early September, 2001, and mid-June, late June–early July, and early September, 2002. The trials were set up in a randomized complete block design of six replicates and nine treatments per replicate, with randomization only at the beginning of each trial. For five of the trials, traps were set in a line along the edge of canola fields, with a minimum of 10 m between traps and with traps within 0.3 m of canola (*Brassica napus*) plants. In the trial conducted in September 2001, the traps were placed 5 m apart within replicates, with traps separated from canola by approximately 1.5 m. The first trials in both years were arranged in an east–west orientation, whereas all other trials were arranged in a north–south orientation. Prevailing winds in the area are from the northwest. The nine experimental treatments in each trial were the high and low pheromone doses; the high and low AITC doses, the four possible combinations of high and low doses of pheromone and AITC, and the control (foam plug alone).

The contents of the collecting vials were emptied daily (every second day in Trial 3) into plastic bags, returned to the laboratory, and the number of flea beetles counted. Flea beetles were identified to species level according to the characters described by Burgess (1977). In a subsample, the sex of 20 randomly selected flea beetles in each sample was determined by examining the ventral surface of the abdominal tip or by gently squashing it and examining the extruded genitalia. The tip of the male terminal abdominal segment is cup shaped; the male copulatory organ is a sclerotized, tobacco-colored, spoon-shaped aedeagus. Female abdomens are usually larger, with a smooth terminal abdominal segment and a clear spermatheca with a red line through the center, ending in cilia externally. The number of newly emerged or teneral adults from a 100-beetle subsample from each replicate on September 10, 2001, and from a 20-beetle subsample from each treatment and replicate of each day of Trial 6 in September 2002 also was determined. Teneral flea beetle adults, those that had emerged from

pupation less than 2 d from collection, had discernibly lighter elytra and other body parts than older flea beetles.

Statistical Analyses. For each of the six trials, the daily trap catches were summed over the days of the experiment for each of the 54 individual trap sites (9 treatments × 6 blocks). These sums were then transformed to $\log_{10}(x + 1)$ to stabilize variance, and analysis of variance was conducted using the mixed model procedure of SAS ("Proc Mixed") (SAS Institute, Inc., 2001) or Statistix software (Analytical Software, 2003). Treatments were considered as fixed effects and blocks were considered as random effects. If a significant F statistic resulted, comparisons of means were conducted. Initially, comparisons were made between the various treatments and the control using Dunnett's test (Steel and Torrie, 1980). Linear contrasts were then constructed, using means in the $\log_{10}(x + 1)$ scale, to compare the overall effects of pheromone or AITC at differing doses with the four pheromone/AITC interactions. For example, the contrast for effect of the high-pheromone dose was the mean over the three treatments that contained the high-pheromone dose (high pheromone, high pheromone plus high AITC, and high pheromone plus low AITC) minus the mean over three corresponding treatments that did not contain pheromone (control, high AITC, and low AITC). The other contrasts involved analogous sets of means. Probability values for the t statistics for these contrasts are presented with the results. The antilog of each contrast value represents the *factor* by which the subject effect increased the trap catch above the number found in the unbaited control. In analyses of beetle sex ratios, data were transformed by arcsine square root to stabilize variances. Analyses were conducted on data from individual trials, on data combined over June and September trials, and on data combined over all trials. When a significant F statistic resulted, Tukey's Studentized comparisons of means were determined.

RESULTS

Lure Emission Data. The preparation and emission properties for the high dose of male-specific compounds are summarized in Table 1. The proportions of emitted compounds differed slightly from those that were applied because of different volatilities. Compound **1** was the most volatile and became depleted most rapidly from the lures. However, the composition of the emitted blend was relatively stable over a 1-wk period.

The high-dose dispensers released 4300, 5500, 5200, 7200, 8200, and 4800 μg per day of AITC for Trials 1–6, respectively (means over 18 dispensers per experiment). The low-dose AITC dispensers had mean ($N = 18$) release rates of 620, 220, 340, 310, 590, and 280 μg per day for experiments

TABLE 1. EMISSION RATES OF SYNTHETIC *Phyllotreta cruciferae* PHEROMONE COMPONENTS FROM HIGH-DOSE RUBBER SEPTA

Compound	Weight of natural enantiomer per septum (μg)[a]	Relative amounts applied (**1** = 100)[b]	Natural relative emission rates (**1** = 100)[c]	Measured relative emission rates (**1** = 100; mean ± SE for others)[b]		Measured emission rates (μg/day) (mean ± SE)[a]	
				Initial	After 7 d	Initial	After 7 d
1	250	100	100	100	100	11.8 (±0.4)	8.2 (±0.3)
3	17	6.7	4.4	4.4 (±0.3)	5.4 (±0.2)	0.54 (±0.03)	0.41 (±0.02)

[a] Synthetic compounds **1**, **3**, **5**, and **6** were racemic, whereas compound **4** was the pure beetle-produced enantiomer. Thus, the actual gravimetric and achiral GC measurements for the amounts of **1**, **3**, **5**, and **6** were double the values shown. SE = standard error of fitted value from regression (see text).
[b] Ratios of compounds applied or measured are based on the amounts of natural enantiomers present. SE = standard error of fitted value from regression.
[c] Relative emission rates based on Bartelt et al. (2001).

1–6, respectively. Typical standard errors were in the range of 5–20% for both dosages. Release rates per day did not appear to vary appreciably over the short length of the experiments (7–10 d). For example, in the third trial, high-rate vials were removed after the second day and were found to have lost an average of 7700 μg AITC per trap per day, whereas over the entire 10 d of the test the average release rate was 5180 μg per trap per day. Flea beetle elytra were noted in some of the microcapillary tubes and may have contributed to the variability in the amount of AITC dispersed in this treatment by partially blocking air flow.

Field Experiments: General Observations. Large numbers of flea beetles were captured during the study, and over 99.5% of them were *P. cruciferae*. The totals for *P. cruciferae* captured in Trials 1 to 6, respectively, were 8,610; 10,151; 13,908; 12,940; 1,460; and 73,321. Other flea beetles captured included a total of 5 *P. striolata* and 94 *Psylliodes punctulata*, numbers too low to make inferences about treatment effects. Hymenoptera of various species also were captured in the experiments. Traps in Trials 1 and 2 frequently contained up to four *Banchus flavescens* Cresson, a large ichneumonid parasitoid of the bertha armyworm (*Mamestra configurata* Walker). Flea beetles may have been hindered in entering traps already containing *Banchus* because numbers of beetles tended to be lower in traps with the large parasitoids. After the netting was put on in Trials 3–6, larger insects were excluded from the traps. Of the micro-Hymenoptera collected, most were *Microctonus vittatus* L., a native parasitoid of *P. cruciferae*. Details of parasitoid responses to the various treatments will be the subject of a subsequent paper.

Weather conditions had a critical effect on the number of flea beetles captured, with highest numbers found after warm, sunny, and calm days, and low numbers found after cold, rainy, or windy days. Total numbers of flea beetles caught in the 54 traps in a 24-hr period varied from 1 flea beetle on June 6, 2001 (average daily temperature 12.9°C, 13 mm precipitation, north wind 10–20 kph), to 20,061 flea beetles on September 15, 2002 (average daily temperature 19.0°C, sunny, light winds). Flea beetles displayed little activity and were not attracted to any traps in very hot weather. For example, relatively few beetles were collected in Trial 5, during which maximum temperatures exceeded 35°C for several days.

Treatment Effects. Differences among treatment means were found in all six experiments (Table 2). The treatment containing high levels of both pheromone and AITC collected the greatest number of flea beetles, being more attractive than the control at $P \leq 0.001$ in all trials except the second one. All combined pheromone–AITC treatments had greater numbers of flea beetles than did the control. Furthermore, all later treatments with combinations of attractants had numerically greater numbers of flea beetles than single attractants (Table 2). In later trials, when modifications excluded large para-

sitoids from the traps and flea beetles from the AITC vials, the means for combination treatments frequently exceeded the sum of the means for the individual treatments, indicating a synergistic response.

An examination of single-lure treatments found that the pheromone-only treatments had greater numbers of flea beetles than did the controls for the high dose in Trials 3 and 4 according to Dunnett's test (Table 2). Similar trends were seen with the AITC-only treatments, wherein high-dose AITC had a significant effect in experiments 1, 3, and 4.

The significant treatment effects indicated by the F tests were further elucidated by linear contrasts (Table 3). Overall, the high dose pheromone treatment significantly increased trap catches in all trials, and low dose pheromone traps failed to do so only once, in Trial 2. Similarly, the high dose of AITC always increased flea beetle capture, and the effect of low dose of AITC was significant in all but Trials 1 and 2. For both types of lures, the effects of the

Contrasts were calculated in the $\log_{10}(x + 1)$ scale. The antilog of the calculated contrast shown here represents the effects of the treatments, expressed as *factor increases* in numerical trap catch when the treatments are present vs. when they are not. The null hypothesis for the *t*-tests was that the value of the contrast is equal to 0, which is equivalent to saying that the factor of increase is equal to 1.00. * $P = 0.05$, ** $P = 0.01$, *** $P = 0.001$.

high doses were numerically higher than those for the low doses, except for pheromone treatments in Trial 5 (Table 3). Comparable trends can be seen in the treatment means in Table 2. These results indicate positive dose–response relationships for both types of attractants.

Over the entire study, the three treatments that contained the high dose of pheromone had mean trap catches that were 1.5–6.5 times higher than the corresponding treatments without the pheromone. For the low dose of pheromone, the factors ranged from 1.2 to 4.8; the 1.2 value, from Trial 2, was not significantly different from 1.0. All of the values for high-dose effects of AITC (1.8 to 55), were significant, as were four of the six values for low-dose effects of AITC (1.9 to 24). Only two values for the low dose of AITC, those for Trials 1 and 2, were not significantly different from 1.0 at the $P = 0.05$ level (Table 3).

Generations, Sex Ratios, and Teneral Adults. Newly enclosed adults responded similarly to trap lures (Trials 3, 6 in Table 2) as did overwintered adults (Trials 1, 2, 4, 5 in Table 2). However, absolute numbers of beetles caught in September were considerably higher than those caught in June. The pattern of attraction to treatments was different between the sexes, with greater numbers of females collected in traps with high and low levels of AITC alone than in unbaited control traps or in traps baited with high levels of pheromone alone (Table 4).

The proportion of teneral adults measured from the September 10, 2001, subsamples was 15.2% of the flea beetles caught on that date. A slightly greater

proportion of teneral adults was noticed at the beginning of the trial. In contrast, in 2002 the number of teneral adults averaged 5.47% over the 7-d period ending September 18, with the greatest number of new adults collected on the last day of the trial. The proportion of teneral adults did not vary among trap treatments (data not presented).

DISCUSSION

The present results support the hypothesis that compounds **1**, **3**, **4**, **5**, and **6**, or a subset of these, function as a male-produced aggregation pheromone for *P. cruciferae*. Furthermore, the pheromone compounds act in conjunction with the host volatile AITC, in combination generally attracting greater numbers of beetles than each semiochemical source additively. In these ways, the chemical communication system in *P. cruciferae* is similar to those in various curculionid, scolytid, and nitidulid beetle species (Borden, 1985; Landolt and Phillips, 1997).

The dose responses of *P. cruciferae* to AITC alone were consistent with results reported earlier. Pivnick et al. (1992) found that in the field the lowest rate of AITC able to attract large numbers of flea beetles was 4000 μg/d, with minimum thresholds of about 400 μg/d, and with beetles responding to baits from less than 2 m away (Pivnick and Jarvis, 1991). It is likely that lower release rates would be attractive when insects are very close to the source or when flight occurs on calm days (Pivnick and Jarvis, 1991). Interestingly, the

responses to AITC and the male-specific compounds by themselves were generally similar in terms of trap catch, yet the emission rates for AITC were nearly 1000 times higher than for the male-specific compounds. The attraction of female *P. cruciferae* to AITC has been shown previously (Wylie, 1981; Vincent and Stewart, 1984). In our trial, one possible reason why female beetles appear to be less attracted to lures baited with pheromone may be the lack of AITC attractant in these treatments rather than the pheromone acting as a repellent. Curiously, the pheromone was still active in September, at a time of year when adults are preparing to enter overwintering diapause, rather than reproduce. This is undoubtedly a complex semiochemical system with as yet unknown biological and environmental factors affecting the way the attractants function and interact.

Several issues need to be resolved regarding the male-produced pheromone blend of *P. cruciferae*. First, it is unknown whether male-specific compound **2** elicits behavioral responses, either alone or as part of a blend. Compound **2** is a relatively minor constituent of the male-specific volatile emissions (7%) (Bartelt et al., 2001), but relative amount does not necessarily correlate with biological activity. Testing of compound **2** will be possible only when sufficient material becomes available through synthesis or isolation from a natural source. Second, racemic forms of **1**, **3**, **5**, and **6** were used in the present study, rather than the pure enantiomers that are emitted by the beetles. It is unknown whether the unnatural enantiomers in the racemic blends have any behavioral effect, either positive or negative (e.g., Mori, 1998). However, because beetles were attracted to the racemic compounds, the "unnatural" enantiomers cannot be strongly antagonistic. Third, it is unknown whether all of the compounds added to the rubber septa were in fact essential for attraction. There are examples known of male-specific compounds that are chemically related to the aggregation pheromones of nitidulid beetles, for example, that have no defined behavioral activity (Bartelt, 1999). Determining the minimum combination of chemicals required to attract flea beetles will be critically important for potential commercialization of the pheromone.

The pheromone system in *P. cruciferae* is one of only a few known examples of male-produced aggregation pheromones in leaf beetles of the Chrysomelidae, a large and important family whose pheromone biology and chemistry is poorly characterized. The first Chrysomelid pheromones to be characterized were from the *Diabrotica* spp. rootworm beetles. These are produced by females and attract only males (reviewed by Krysan et al., 1989). However, more recent identifications in other species have found male-produced pheromones that attract both sexes. These include the Colorado potato beetle (Dickens et al., 2002) and the cereal leaf beetle (Cossé et al., 2002; Rao et al., 2003). Crucifer-feeding flea beetles are an economically important insect group in the chrysomelid subfamily Alticinae. Continued exploration and elucidation of the pheromone systems of this beetle will aid in the understanding of

communications within the Alticinae and in the utilization of pheromones in practical insect management in canola.

Acknowledgments—We thank the Saskatchewan Association of Rehabilitation Centres SARCAN Recycling for donation of the trap tops and the University of Saskatchewan Crop Development Centre for use of test sites. The technical help of Larry Grenkow and Jennifer Holowachuk is greatly appreciated.

PRIMER AND SHORT-RANGE RELEASER PHEROMONE PROPERTIES OF PREMOLT FEMALE URINE FROM THE SHORE CRAB *Carcinus maenas*

MATTIAS EKERHOLM* and ERIC HALLBERG

Department of Cell and Organism Biology, Lund University, Zoology Building, Helgonavägen 3, S223 62 Lund, Sweden

(Received November 17, 2004; revised March 18, 2005; accepted April 3, 2004)

Abstract—The European shore crab *Carcinus maenas* is considered to rely on a female pheromone when mating. Evidence, however, is scarce on how the urine pheromone in itself affects males. We investigated male primer and releaser responses to female pheromones with methods that minimized effects from females, delivering female urine either as a pump-generated plume or deposited on a polyurethane sponge. We delivered the pheromone at different concentrations in far, near, and close/contact range to get a picture of how distance affects behavioral response. Our results show that substances in premolt female urine (PMU) function as primer and potent short-range releaser pheromones. Based on the olfactometer and sponge tests, we conclude that PMU stimulus in itself is sufficient to elicit increased search and mating-specific behaviors such as posing, posing search, cradle carrying, and stroking. Pheromone concentrations do not seem to be important for attenuating search and posing as long as the level is above a certain threshold concentration. Instead, pheromone levels seem to play a role in male acceptance of females, recruiting more males to respond, and generating better responses with increasing concentration.

Key Words—*Carcinus maenas*, Crustacea, shore crab, green crab, olfaction, chemical communication, sex, urine pheromone, primer, releaser, scaling, lek, hot spot.

INTRODUCTION

During reproduction, matched event timing between the sexes is essential for individual fitness. The need for synchronous reproductive readiness is especially evident for mating by decapods because they can mate only during a limited time after the female has molted. Different signals (chemical, visual, and tactile) may be used by crustaceans to guarantee that a male and a female are in contact during this period.

In decapod crustaceans, mating is highly dependent on chemical cues. The presence of female sexual pheromones has been indicated in lobsters (Atema and Engstrom, 1971), crayfish (Stebbing et al., 2003), crabs (Ryan, 1966; Eales, 1974; Gleeson, 1980; Asai et al., 2000; Kamio et al., 2000), hermit crabs (Hazlett, 1996), and shrimp (Kamiguchi, 1972; Diaz and Thiel, 2004). There are also indications that tactile, visual, and hydrodynamic stimuli affect sequences of mating behavior (Bamber and Naylor, 1997; Sneddon et al., 2003). Attraction of a partner may occur on the individual level, i.e., a solitary female or a male will attract members of the opposite sex. It can also take place in a social context where groups of animals attract individuals of both sexes over a long range. This behavior is referred to as lekking and has been described in a number of animal groups (Davies, 1991), from arctiid moths (Willis and Birch, 1982) to black grouse (Hovi et al.,1997) and harbor seals (Hayes et al., 2004). According to van der Meeren (1994), lekking behavior is present in *Carcinus maenas*, but the mechanism of this long-range attraction is unknown. At near range, male cancrid and portunid crabs are able to locate a female conspecific and guard her for a period before, during, and after the molt (Hartnoll, 1969). This behavior, males locating and guarding females, is considered to be controlled by female sexual pheromones (Gleeson et al., 1984; Bamber and Naylor, 1996a). In both the blue crab *Callinectes sapidus* and the shore crab *C. maenas*, the main pheromone source in the females is believed to be the urine, although additional sources or release sites may be present (Bamber and Naylor, 1997; Bushmann, 1999). Differences in female molt state generate variation in male pheromone response (Christofferson, 1978; Bamber and Naylor, 1996b) and courtship behavior (Jivoff and Hines, 1998), reflecting changes in pheromone content or composition.

Animals showing more or less complex social hierarchies are known to use primer pheromones for regulating social and sexual behaviors. Priming pheromones from mammals such as mouse, rat, and goat (Iwata et al., 2000; Moffatt, 2003) and insects such as fire ants (Fletcher and Blum, 1981) and honeybees (Le Conte et al., 2001; Grozinger et al., 2003) are described, but evidence for primer pheromones in crustaceans is lacking. Aggregative social and dominance behaviors seem to play a role in shore crab mating (van der Meeren, 1994; Sneddon et al., 2003). Further, earlier studies on releaser

pheromones in portunid crabs have revealed temporal variability (Gleeson, 1991) and increase in precopula male responsiveness (Bamber and Naylor, 1996a). These facts have led us to believe that primer pheromones may be used in shore crab chemical communication. In decapods, physiological modification of behaviors through neurohormonal action is a well-known phenomenon (Kravitz, 1988; Wood and Derby, 1995; Doernberg et al., 2001; Tierney and Mangiamele, 2001), which supports the notion of primer pheromones modifying mating behaviors.

Crab mating systems are a complex web of chemical communication, and only basic parts are presently understood. To better understand reproductive signaling, the role of each stimulus in eliciting a part of the behavioral sequence needs to be isolated, and the responses to specific signals studied without influence from the other cues. The aim of this study was to investigate which primer and releaser effects are induced in male *C. maenas* by controlled delivery of female premolt urine. We chose female premolt urine as the stimulus for the investigation because no additional sources have been identified. To ascertain that no other uncontrolled female-released stimuli were present, premolt urine was delivered artificially by using either a stimulus pump or a treated sponge. Urine pheromone-induced priming effects were investigated at close/contact range, whereas releaser behaviors were investigated in three different spatial contexts: far range, near range, and close/contact range.

METHODS AND MATERIALS

Animals. Shore crabs *C. maenas* (L.) in the releaser experiments were caught during mating season, between July and September, with funnel nets off the Swedish west coast. Animals were discarded if they lacked a cheliped or more than one pereopod on each side. Crabs showing external signs of sacculinid infestation were also removed. Water for the tanks was pumped from outside the Gullmar fjord from a depth of 5 m. During the experimental period, water temperature was 16–22°C and salinity 27–32 ppt. Animals in holding tanks were kept at ambient lighting regimes and fed *ad libitum* amounts of blue mussels or white fish daily, the surplus food being removed 4–5 hr later. In these experiments, only males with green to orange-yellow carapace were used. This was because of the notable differences in both behavior and physiology that occur between males of long (red carapace color) and short (green carapace color) intermolt duration in this species (Abello et al., 1994; Reid et al., 1994, 1997).

Urine Collection. Female shore crabs were kept at high density ($100/m^2$) in communal tanks ranging from $1 \times 1 \times 0.5$ to $2 \times 2 \times 0.7$ m. One male crab for every 10 females was added to the tank to find females of the appropriate molt status, indicated by male precopulatory cradle carrying. Twice daily, tanks were

searched for precopula pairs, which were removed from the communal tanks and separated. After separation, males were transferred back to the communal tanks, while females were transferred to screening aquaria, each containing three males. Females in renewed precopula after 2 hr were transferred to individual tanks for urine sampling. Urine was collected from the opening of the antennal opercula with a micropipette (Bamber and Naylor, 1997). Collection from each female was made at a daily basis until 7 d after molt. The urine from each individual female was transferred to a microcentrifuge tube and immediately frozen at −20°C. Time of urine sampling and molting were noted for future reference. Two weeks after molt, each female was dissected and checked for internal signs of sacculinid infestation. Urine samples from parasitized females were not used because this parasite has a profound effect on crab physiology that interferes with molting processes and reproductive behavior (Hoeg, 1995). For sponge and olfactometer tests, urine samples from females between 2 d and 12 hr before molt were used.

Stimulus Preparation. Urine from *C. maenas* females between 2 d and 12 hr pre-molt was diluted according to the following plan and used as a stimulus source for all the experiments.

The primer experiment used frozen urine from 15 females, pooled, and diluted to 1:10 in distilled water to make a 4-ml stock. Seventy aliquots of 55 μl from the stock and 70 aliquots of 55 μl of the distilled water were used to dilute the samples and frozen for use as stimulus [premolt female urine (PMU)] and controls, respectively. Aliquots were stored at −20°C until used.

For the far-range experiment, a total of 5-ml urine from 123 females was pooled and diluted 1:40 in 200-ml filtered seawater. Two hundred milliliters of filtered seawater taken at the same time served as control.

The near range experiment used frozen urine samples from 19 females, pooled and diluted to 1:10 in distilled water to make a stock of 7 ml. Dilutions were made by sequentially taking 700 μl from the prior, tenfold more concentrated stock and diluting it to 7 ml in distilled water. Forty aliquots of 150 μl were taken from each of the 1:10, 1:100, 1:1000, and $1:10^4$ dilution stocks. These and 40 150-μl aliquots of distilled water serving as controls were frozen in microcentrifuge tubes and stored at −20°C until used. Immediately before each stimulus presentation, the 150-μl aliquot was thawed and diluted to 150 ml in filtered seawater, making final dilutions of 10^4, 10^5, 10^6, and 10^7 times.

For the close/contact experiment, frozen urine from 68 females was pooled to make a stock of 3.5 ml. Dilute stocks were made by sequentially taking 350 μl from the prior, tenfold more concentrated stock and diluting it to 3.5 ml in distilled water. Fifty four aliquots of 55 μl were taken from the undiluted pooled urine (1:1) and each of the 1:10, 1:100, and $1:10^4$ dilutions and frozen in microcentrifuge tubes. Fifty four aliquots of 55 μl of the distilled water were

used to dilute the samples, frozen, and used for controls. Aliquots were stored at −20°C until used.

Sponge Preparation. Dummy females used in the primer and close/contact experiment were made from 35 × 20 × 10 mm polyurethane (PU) sponges, prepared the following way. All sponges were washed in water, 95% alcohol, and water again to remove residual chemicals from manufacturing (crabs may eat them otherwise; Ekerholm, personal observations). They were then weighted with two 37-mm galvanized nails and immersed in a petri dish with Artificial Sea Water (ASW) (Aqua-medic reef salt®). Sponges were compressed to remove air and allow full absorption of ASW. For the primer and close/contact experiment, the sponge was placed with the long side protruding a few millimeters above the water surface to allow 50 μl of the stimulus or control (above) to be pipetted onto the front end of the sponge, immediately before serving it to the male. Each sponge was only used once.

Polyurethane sponges used for the far-range experiment were 70 × 20 × 25 mm. Before use, they were washed as above and allowed to dry. Each sponge was then saturated with liquid by absorption of 10 ml of the test stimulus (control or PMU 1:40) in a plastic bag. Sponges in bags were stored at −20°C until used. All sponges in the far-range experiment were used frozen to prolong the substance release time.

Behavioral Criterion. The following behaviors shown by males when searching for or contacting females were used. These were chosen on the grounds that they represent true sexual behaviors and could not easily be confounded with eating or agonistic behaviors.

(1) Posing: Males exposed to females or their pheromones stand up high on pereopods 2, 3, and 4 with the propodus of the chelipeds pointing forward at an angle of 90° to the front of the carapace. Pereopods 5 are held almost horizontally at or above carapace level. Bamber and Naylor (1996b) described this as a reliable criterion for sexual arousal in *C. maenas*.
(2) Posing search: Males sufficiently stimulated start a slow high-stance walk using only pereopods 2, 3, and 4 for most of the time, while keeping chelipeds and pereopods 5 as in (1).
(3) Cradle carrying: Keeping a fairly upright stance, the male grabs and holds the female with pereopods 2 or 3, not using the chelipeds. In pre- and post-copulatory behavior, the female carapace faces the male sternum, while in-copula pairs have the sterna facing each other (Bamber and Naylor, 1996b).
(4) Stroking: While cradle carrying, the male uses the medial side of the propodus and dactylus of the chelipeds for stroking against the front of the female.
(5) Pleopod insertion: The male unfolds the abdomen and inserts his pleopods in the female vulvae.

In addition to the mating-specific behaviors, number of search bouts and time spent per search bout in response were recorded in the olfactometer to see if PMU altered these. A search bout was defined as an activity period mainly directed towards the stimulus source. A search bout ended when the crab entered the shelter zone (Figure 1) to stay there for more than 90 sec.

Dummy Female Assay. For the primer experiment, and close/contact experiment, we used a modified version of the dummy female assay (Kamio et al., 2000) to examine pheromone elicited sexual behavior of male crabs towards a pheromone-treated target sponge. Male crabs were exposed to stimulus- and control-treated sponges the following way. Each sponge was submersed in the test tank approximately 10 cm from the crab and slowly moved toward the male, making sure the sponge was below the upper carapace level of the test crab. At a distance of 1–5 mm from the antennular exopodites, the sponge was held still for 20 sec, waiting for the crab to respond. When the crab grabbed the sponge with claws or second pereopods, the sponge was released. If the crab did not grab the sponge after 20 sec, the sponge was released onto the bottom. Recording of the behavior began as soon as the sponge entered the water and

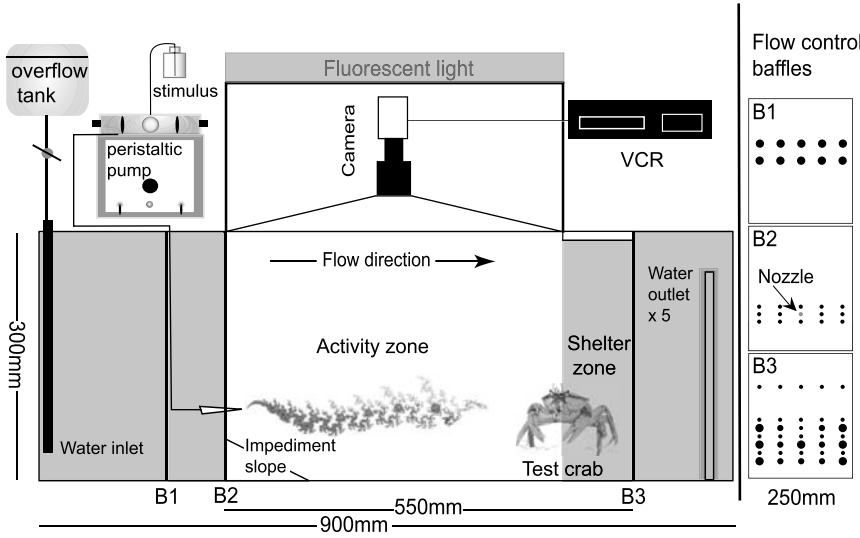

FIG. 1. Olfactometer setup for recording PMU-related activity changes in male shore crabs. The activity chamber consisted of a lighted activity zone and a dark shelter zone. PMU and control stimuli were delivered using a peristaltic pump. Activity patterns were recorded by an overhead video camera and were later analyzed manually. Baffles for controlling the stimulus flow through the activity chamber (B1, B2, and B3) are depicted to the right. Black circles represent holes mediating flow through the baffle.

continued until 90 sec had passed from the release of the sponge. Behaviors (1) and (3)–(5) (above) were registered directly into a score card, but were also videotaped for reference and later recording of cradle-carrying times. The small size of the test aquaria prevented us from reliably registering behavior (2).

Primer Experiments. To investigate if PMU has any priming effects on male behavioral response, 16 males caught off mating season (first week of April) were exposed to the following treatments. Three days before experimentation day, they were brought up to room temperature (18–21°C) and summer season lighting regimes (14:10 light/dark period) in individual 150 × 150 × 110 mm glass aquaria oxygenated by an airstone. The next day, animals were each fed with a shrimp. Water was changed daily during the whole experiment, on experimental days immediately before testing. After 4 d, the animals were considered fully acclimatized, and experimentation began. Before each test sponge, a control sponge was served to detect unselective sexual responses. None were detected in this experiment.

On the first treatment day, animals were divided into two groups (N = 8 each) and subjected to the dummy female assay (above) using either a PMU or a control sponge (above). After each test, sponges were squeezed with the forceps three times to release PMU or control water. The released substances served to prime the crabs, which were left in the treated water until the next day. By subjecting one group to control the first day, differences due to acclimatization time were controlled. On days 2, 3, and 4, both groups were tested with PMU sponges, and were left in PMU water until the next day. In this experiment, only cradle carrying and stroking behavior were analyzed. One crab in each group was excluded from the analysis because of internal sacculinid infestation or death.

Far-Range Releaser Experiments. Foldable square crab traps (700 × 500 × 250 mm) were baited with PMU-treated sponges in a setup using the pheromone as a cue for long-range search and capture. Each replicate con-

TABLE 1. RESULTING CATCHES OF SHORE CRABS *Carcinus maenas*, FROM FIELD-TRAPPING EXPERIMENTS, USING A PAIRED CONTROL-FEMALE PREMOLT URINE TREATMENT SETUP WITH 20 REPLICATES

	Statistics

Female catches	0.55 ± 0.21	0.85 ± 0.37	Wilcoxon Z = 0.45	ns

sisted of two crab traps baited with control and PMU sponges ("Stimulus Preparation," above), respectively. Pairs of traps were connected by a 6-m line. Each trap was weighted to minimize wave actions. From each trap, a rope led up to a surface marker.

Twenty pairs of traps were laid out between the 15th and 20th of August at between 1900 and 2000 hr and were taken up at between 0600 and 0700 hr the following morning. Traps were only laid out in areas where overnight food-baited trapping usually catches approximately 10 crabs. Care was taken to ensure matched environments (nearby rocks and vegetation, distance to shore and reefs) for both traps in a pair. Immediately after taking up the cages, a subset of the sponges (eight) was tested for residual pheromone activity using the dummy female assay (above). Cradle carrying was evoked in response to 63% of these, showing activity at the end of the experiment.

Near-Range Releaser Experiments. Males used for experiments were held in large communal tanks without females for between 1–2 wk at natural photoperiod. Three days before the experiment, males were put in small tanks together with two other males and an intermolt female. This equalized environments for the experimental males and avoided increased aggressiveness due to isolation effect. During these days, they were fed *ad libitum* amounts twice daily.

Search activity of 37 males was investigated with a controlled flow olfactometer. It consisted of a four-chambered flow-through tank (900 × 260 × 300 mm) with three baffles for guiding the flow (Figure 1). The activity chamber was located between baffles 2 and 3, which served to direct the stimulus flow. Inlet of ambient temperature seawater from the Gullmar fjord (see above) was regulated via a constant level overflow tank and a tap. Flow rates were 1 cm/sec, based on fluorescein dye visualization 10 cm above the activity chamber floor. Five standpipes provided controlled outlet. Stimuli were delivered through a micropipette tip in the center of baffle 2, 10 cm above the olfactometer floor. Ninety-second stimulus pulses, followed by pauses of the same duration, were generated by a Harvard apparatus 55-1762 peristaltic pump with Tygon® Pharmed® (3.2/6.4 mm inner/outer diam) tubing. Pulsed stimuli were used because continuous stimulus delivery resulted in decreasing male activity (Ekerholm, personal observation). Flow rates of the stimulus jet were adjusted to obtain a filamentous plume, shedding periodical vortices at 2- to 3-cm intervals. This corresponded to a flow rate of 150 μl/sec. An impediment slope prevented the crab from passively locating itself below the nozzle (Bamber and Naylor, 1996a).

Prior to an experiment, each crab was put into the activity chamber of the olfactometer and acclimatized for at least 4 hr without any chemical stimulus. The crab was then familiarized with the hydrodynamic stimulus from the pump by pumping filtered seawater through the experimental chamber for 30 min. During experimentation, crabs were exposed to odorants for 30 min in

order of successively higher PMU concentrations. Presentations of PMU were separated by a 15-min interval in which seawater was pumped through the experimental chamber. Seawater control and dilutions of $1{:}10^7$, $1{:}10^6$, $1{:}10^5$, and $1{:}10^4$ were used. The nonrandom approach was used to minimize effects of contamination and residual activity from previous treatments. Between trials, the tank was thoroughly washed, and the activity chamber coral gravel bedding was changed. Activities of the subject crabs were recorded using a Sony DCR-TRV730E digital-8 camera connected to a Panasonic S-VHS recorder. Number of search bouts, search time in the activity zone, and posing search were registered from video recordings. The tapes were analyzed in random order to minimize biasing.

Close/Contact-Range Releaser Experiments. Behavioral responses to PMU dilutions from $1{:}10^4$ to 1:1 were performed using the dummy female assay (above). Before testing, crabs were taken from communal holding tanks and allowed to acclimatize 2–4 hr in individual test aquaria (glass, 200 × 150 × 170 mm) with 28 ppt ASW. Temperatures were between 16 and 19°C. Fifty male crabs were subjected to a sequence of test sponges treated with increasing concentrations of PMU. Control and dilutions of $1{:}10^4$, 1:100, 1:10, and 1:1 (see "Stimulus Preparation" above) were used. After each treatment, the animal was moved to a new aquarium containing fresh ASW and given 20 min to acclimatize. Cardboard box covers minimized interference from the surroundings.

Statistics. Statistical analysis for all experiments was performed using SPSS 12.01 (SPSS Inc.) for Windows XP. For the primer experiment, presence or absence of cradle carrying and stroking was entered as dichotomous data for each exposure time and individual and analyzed using Cochran's *Q*-test for overall comparison between groups of different exposure time. Two McNemar tests were used for planned comparisons between groups of 0- and 1-d and of 1- and 2-d exposure time. Far-range trap catches were analyzed using Wilcoxon's signed ranks test. Results for each individual behavior in the near-range and close/contact-range experiments were analyzed with a global repeated measures test for all concentrations and controls followed by planned comparisons between control and individual dilutions and between pairs of sequential dilutions. Data on time per search bout (near-range experiment) was log-transformed to meet the assumptions of the following repeated-measures ANOVA. Planned comparisons used a LSD test. In the case where the transformed values (number of search bouts: near-range experiment; cradle-carrying time: close/contact range experiment) did not meet the ANOVA assumptions, Friedman's test was used together with multiple Wilcoxon's signed ranks tests. Presence/absence of posing, posing search, cradle carrying, and stroking were entered as dichotomous data and analyzed using Cochran's *Q*-test for overall comparison and multiple McNemar tests for the planned comparisons. Tests between individual treatments in the nonparametric analyses were corrected for repeated testing

using the sequential Bonferroni method (Holm, 1979) for a total experimentwise error rate of 0.05.

RESULTS

Primer Experiment. No unprimed or control primed animals responded to the PMU sponges, irrespective of groups. In both groups, three of seven animals cradle-carried the PMU sponges after 1 d of PMU exposure. After one additional day of PMU priming, six of seven animals responded to the PMU sponge by cradle carrying it. Control sponges did not yield cradle carrying or stroking responses. Because both groups showed equal trends irrespective of the 1-d adaptation length difference, statistical analysis was based on data pooled over pheromone exposure duration. Only the first three tests with PMU sponges (i.e., unprimed or control primed, 1-d pheromone priming and 2-d pheromone priming) were analyzed. The proportion of cradle-carrying and claw-stroking males differed between priming treatments (Cochran $Q_2 = 18.00$, $P < 0.001$ and Cochran $Q_2 = 13.00$, $P = 0.001$, respectively). The number of crabs showing cradle-carrying behavior differed between control and 1 d PMU-treated animals (McNemar, $P = 0.031$) and also between 1 d and 2 d PMU-treated animals (McNemar, $P = 0.031$) (Figure 2A). The number of crabs showing claw stroking differed between control and 1 d PMU-treated animals (Figure 2B) (McNemar, $P = 0.031$). No difference in claw stroking between 1 d and 2 d PMU-treated animals was found (McNemar, $P > 0.05$).

Far-Range Releaser Experiment. There were no significant differences in total, male or female trap catches (Table 1).

Near-Range Releaser Experiment. Male search activity increased in response to higher PMU concentrations in the olfactometer, indicated by a higher number of search bouts (Figure 3A) (Friedman $\chi^2_4 = 20.70$, $P < 0.001$) and longer search bouts (Figure 3B) (rmANOVA: $F_{4,144} = 8.47$, $P = 0.001$). More males responded with a posing search to higher PMU concentrations (Figure 3C) (Cochran $Q_4 = 19.82$, $P < 0.001$), verifying the sexual nature of the activity increase. Comparisons between controls and individual PMU treatments and between all pairs of sequential PMU concentrations revealed a similar pattern for the three parameters investigated. More and longer search bouts were evoked, and more males displayed a posing search at a threshold dilution of 10^6 (LSD test, $P < 0.05$; Wilcoxon, $P < 0.05$; McNemar, $P < 0.05$), but responses did not increase more with a further increase in concentration (LSD test, $P > 0.05$; Wilcoxon, $P > 0.05$; McNemar, $P > 0.05$).

Close/Contact-Range Releaser Experiment. The dummy female assay successfully elicited posing, cradle carrying, and, at higher concentrations,

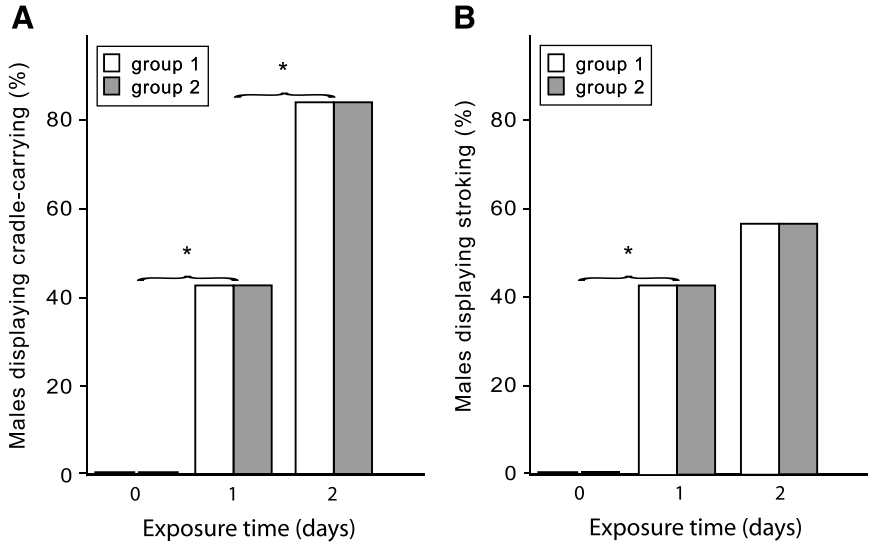

FIG. 2. Proportion of the off-mating season male *Carcinus maenas* responding to a sponge treated with 50 µl PMU diluted 1:10. (A) The percentage of males displaying cradle carrying at each exposure time. (B) The percentage of males displaying claw stroking at each exposure time. On the first experiment day, group 1 males (white bars) received a control sponge, whereas males in group 2 (gray bars) received a PMU-treated sponge serving to test and prime the animal. This generated a 1-d difference between groups in exposure time in relation to experiment days. On experiment d 2–4, both groups received PMU treatments. Crabs having no previous exposure of PMU did not cradle-carry or stroke the sponge irrespective of experiment day. After 1 d of PMU exposure, significantly more males displayed cradle carrying and stroking than in the control (both groups pooled). After 2 d of exposure, more males displayed cradle carrying than after 1 d, whereas no differences in displayed claw stroking were found. *indicates statistically significant ($P < 0.05$) differences between groups exposed to PMU for different durations.

stroking behaviors. No pleopod insertion response was observed in response to any of the dilutions. Males displaying posing differed between treatments (Cochran $Q_4 = 29.00$, $P < 0.001$). Male-characteristic pose response to PMU-treated sponges occurred at dilutions of 10^4, but significantly more poses than in the control only occurred with PMU dilutions 100 or 10 (McNemar, $P < 0.05$) but not 1 (McNemar, $P > 0.05$) (Figure 4). Male display of cradle carrying and stroking increased with concentration (Cochran $Q_4 = 91.33$ and 46.18, respectively, $P < 0.001$). Males showed cradle carrying when subjected to PMU diluted 100 times or less. The number of responding males increased with

(Friedman $\chi^2_4 = 67.52$, $P < 0.001$). Dilutions 100, 10, or 1 differed from the control. Longer cradle-carrying times were observed at the dilution 10 compared with 100 (Wilcoxon, $P < 0.05$). There were no differences between dilutions of 1 and 10 (Wilcoxon, $P > 0.05$) (Figure 5).

DISCUSSION

Our investigation shows that in *C. maenas*, female premolt urine has both primer and short-range releaser functions. The female PMU is sufficient to elicit a chain of precopulatory behaviors in male crabs. These behaviors are elicited according to a response hierarchy where lower concentrations ($1{:}10^6$ dilution) evoke increased search activity and posing search. Increasing PMU concentrations to a 1:100 dilution evokes cradle carrying, and finally a 1:10 dilution evokes cheliped stroking.

Novel Primer Pheromone Function. The priming function of PMU, inducing male cradle-carrying responsiveness to PMU, represents a previously unknown pheromone quality of the female premolt urine. Because a direct behavioral reaction to the PMU was not present on the first exposure, the effect

fits the description of a primer pheromone, functioning to induce or increase male receptivity to the component(s) in PMU responsible for generating cradle carrying. When using stroking behavior as a response quality indicator, it is notable that primed off-season males responded at least as well as males caught in mating season (Figures 2 and 4). It will be impossible to determine whether the priming effect is caused by the same chemical eliciting cradle carrying and stroking until the substance(s) have been identified.

Reproductive pheromones possessing both primer and releaser properties are known in other aquatic species, such as goldfish and salmonids (Vermeirssen et al., 1997; Sorensen et al., 1998; Yambe et al., 1999; Stacey, 2003). The best understood of these are preovulatory steroids and postovulatory prostaglandins in goldfish (Stacey, 2003). As in crabs, these pheromones are released in urine, but may also be released across the gills. Regardless, the PMU-pheromone synthesis is probably not dependent on gonad maturity in *C. maenas* because gonad maturation occurs at a considerable time after the molt (Hartnoll, 1969). A more probable candidate would be a secondary metabolite or hormone indicative of molt status and female sex. Bamber and Naylor (1997) speculated that the pheromone may be a low molecular weight substance, associated with early ovarian development, carried in the hemolymph. Hardege et al. (2002) have made further progress towards identifying the pheromone, a low molecular weight substance, less than 1 kDa in size.

Because little is known about the identity of the primer pheromone, and how it exerts its effects, one may only speculate about physiological actions. In the blue crab *C. sapidus*, neuromodulatory action working in courtship display has been described by Wood et al. (1995). They showed that the peptide proctolin and the amines dopamine and octopamine influence courtship display postures. Application of dopamine modulates proctolin-evoked courtship display by lowering response thresholds, whereas application of octopamine extinguishes the display (Wood, 1995). A possible role of the primer pheromone may be to regulate activities affected by neuromodulators, which is consistent with previous observations suggesting that at least some reproductive behaviors are under neuromodulatory control (Wood, 1995).

Our investigation shows that off-season males respond better to PMU-treated sponges when previously exposed to PMU. None of the male crabs caught off mating season responded to the PMU-treated sponges when previously unexposed to the PMU. This suggests a seasonal decrease in male receptivity to the pheromone, which can be reversed with PMU exposure.

Multiple Releaser Effects. In the long-distance attraction experiment, no differences in male, female, or total trap catches were detected between control and treatment sponges. The question is why these fairly high amounts of pheromones fail to attract and capture them. The traps were baited with a much higher concentration than required to elicit posing search (2.5×10^4 times), had

a much larger volume (500 times) than needed for eliciting cradle carrying, and were placed where food-baited traps earlier caught approximately 10 males each. We believe that males do not use these pheromones to locate females over longer distances. But, we do not know the properties of the flow environments for each cage, or how well the sponge system mimics the female urine release pattern, so it is possible that hydrodynamic factors account for the lack of male attraction and capture. However, long-distance attraction of males may not be necessary in shore crab mating because premolt females seek out hot spots where mates are readily available (van der Meeren, 1994).

Search responses and posing search behaviors were elicited to PMU diluted 10^6 times or lower in the olfactometer. Number of search bouts and time spent per search bout increased by three to six times compared to the controls. Males also started displaying posing search behavior at the same PMU dilution. Increased male activity in the presence of premolt females or female-treated water has been reported in several investigations (Seifert, 1982; Bamber and Naylor, 1996b; Hardege et al., 2002). Our results further show that there is a threshold stimulus concentration, where a shift to mating-related search occurs. Higher PMU concentrations did not increase search activity. Although not indicated here, this concentration information could be important for locating females.

Posing, cradle carrying, and stroking associated with mating were evoked in response to the dummy females. Posing was present in males exposed to female dummies at PMU diluted 10^2. Most poses were displayed in response to PMU 10^1, whereas undiluted PMU did not differ from control. Cradle carrying was evoked in a concentration-dependent manner. Some males displayed cradle carrying, starting at PMU diluted 1:100, and increasing proportions at 1:10 or 1:1. Cradle-carrying time varied in the same manner indicating that increases result from both a higher proportion of males responding and stronger responses from individual males. Stroking behavior is also indicative of response quality. This only differed from the control in 10^1 or 10^0 diluted PMU treatments. The PMU-evoked cradle carrying concurred with a previous study, where premolt female treated water caused a pairing stance similar to cradle carrying (Hardege et al., 2002). Also, the threshold level of PMU-evoked cradle carrying agrees well with data for postmolt urine in *Telmessus cheiragonus* (Kamio et al., 2000). Hence, no female input apart from urine odor (and a target) is required for establishing the first steps towards mating.

Roles for PMU in Chemical Communication During Mating. Male *C. maenas* congregate at hot spots weeks before mating season (van der Meeren, 1994). During mating season, premolt females enter the hot-spot area, where they are intercepted and cradle-carried by one or more males until molt. The flow environment of the shore crabs may limit the ability of males to locate individual females over long distances. Our results suggest that PMU functions

as a short-range, signal-stimulating increased local search activity by males, who initiate search and posing behavior upon perception of the pheromone(s) in female urine. This posing may serve as a visual cue for the female, signaling male readiness to mate. Females actively seek out males (Bamber and Naylor, 1997; Sneddon et al., 2003). When the male and female get closer to each other, the male perceives more concentrated female pheromones. At a certain distance, the optimum male response is to stop posing and to seize and cradle-carry the female. According to our experiments, this shift happens between dilutions of 1:10 and 1:1, corresponding to distances of a few centimeters. At contact distance, a higher pheromone concentration may instead indicate a female closer to molt, given that pheromone concentrations increase throughout the premolt period. From a male perspective, pheromone concentration would then be correlated to the time and, therefore, the cost involved in guarding the female until molt and mating. A cost-based male choice fits well with our results, which clearly show that a higher proportion of the males cradle-carry female dummies at higher PMU concentrations. In addition, increased stroking behavior and cradle-carrying times of the individual males verifies increased attractiveness to increased PMU concentrations, which further supports the notion of PMU concentration as a cost/benefit indicator for the male.

The priming quality of the female urine represents a possible way for the female to increase male receptivity and responsiveness at the mating site. The primer pheromone could also strengthen the bond to the male presently carrying her, thereby securing her mating and survival past molt.

In summary, our results show that substances in premolt female urine function as primer and potent short-range releaser pheromones. Based on the olfactometer and dummy female test, we conclude that PMU stimulus in itself is sufficient to elicit search behaviors and mating-specific behaviors such as posing, posing search, cradle carrying, and stroking. Search and posing are elicited at threshold concentrations but do not increase with greater concentrations. Cradle carrying and stroking behavior, however, increase in a dose-dependent manner. From this, we conclude that pheromone levels are not important for attenuating search and posing as long as the level is above a certain threshold. Pheromone levels seem to play a role in male acceptance of females, recruiting more males to respond, and generating better responses with increasing concentration. The chemical communication system in *C. maenas* reflects a higher degree of complexity than previously thought. Semiochemical dependency, stereotypical behavior, and lekking in this species offer possibilities for answering many ecological and physiological questions involved in marine chemical communication.

Acknowledgments—We thank Prof. Christer Brönmark, Dr. Almut Kelber, Dr. Jamie Theobald, and two anonymous reviewers for providing constructive criticism on the manuscript.

We thank the ever-helpful staff at Klubban Biological Station for providing animals and facilities. Grants from the Royal Physiographic Society in Lund and The Swedish Research Council for Environment, Agricultural Sciences, and Spatial Planning provided financial support.

(Received September 8, 2003; revised November 22, 2004; accepted April 3, 2005)

Abstract—*Neanthes acuminata* Ehlers (1868) is a monogamous coastal polychaete with male parental care and a high level of sexual selection. We measured the level of prezygotic isolation among allopatric populations of *N. acuminata*; from the East and West Coast of the USA, a population from Hawaii, and a laboratory culture originating from Los Angeles, CA. All populations were found to preferably mate with members of their own population. Individuals from populations from Atlantic vs. Pacific Ocean failed to pair and to mate, either during the 10 min or 48 hr experiments. Instead, individuals showed high levels of aggressive behavior. Experiments measuring the levels of interpopulation aggression, established that individuals can recognize and discriminate among different populations of *N. acuminata* on the basis of olfactory cues. Aggressive behavior was induced by exposure of animals to seawater "conditioned" by individuals from the other populations, thus demonstrating the role of olfaction in the detection of "home" populations. The aggressive display was stronger upon exposure to seawater conditioned with "unrelated" populations and especially between Pacific and Atlantic populations.

Key Words—*Neanthes acuminata*, premating isolation, sex pheromones, population variations in chemical cues.

INTRODUCTION

The reproductive behavior of nereidid polychaetes has been studied for many years, and most species are known to spawn as heteronereids following a metamorphosis into this sexually mature form. In the broadcast spawning species, reproduction takes place in the free seawater column when performing a typical swimming behavior, the "nuptial dance," which culminates in the release of gametes by the sexual partners (Hardege, 1999). The reproduction of an individual is timed via environmental triggers including temperature, day length, lunar cycle, and additional cues such as daytime and weather conditions (Hardege et al., 1990, 1994; Bentley and Pacey, 1992) to coincide with the majority of worms in the same population. For monotelic species that die after reproduction, such coordination is essential to ensure successful fertilization (Denny and Shibata, 1989). The spawning process itself is controlled by sex pheromones released from sexually mature individuals of the opposite sex (Boilly-Marer and Lassalle, 1980), a number of which have been identified (Zeeck et al., 1996, 1998; Hardege, 1999).

Nereis (*Neanthes*) *arenaceodentata* (Moore, 1903), also known under the synonyms *Nereis* (*Neanthes*) *caudata* (Delle Chiaje, 1841) and *Neanthes* (*Nereis*) *acuminata* (Ehlers, 1868), is widely distributed along coastlines of North America, Europe, Africa, and the Indo-West Pacific (Pettibone, 1963; Day, 1973). This population complex is characterized by numerous paragnaths on both rings and hooked falcigerous seta on the proboscis. The "original" species was described as *Neanthes caudata* from European waters. Pettibone (1963) corrected this and named it *Neanthes arenaceodentata* based on the material from New England. Day (1973) renamed a North Carolina population as *Neanthes acuminata*. Reish established a laboratory population in 1964 from six specimens collected at Los Angeles Harbor, and referred to it as *N. arenaceodentata*. Weinberg et al. (1990) studied the chromosome number of different populations in this species complex. *N. acuminata* from New England has $2N = 22$, *N. arenaceodentata* from Reish's laboratory culture has $2N = 18$; collections from the mouth of San Gabriel river and Newport Bay has $2N = 18$, but the centromere of one chromosome is in a different location, and a Hawaii population has $2N = 28$. We are using the name *N. acuminata* to designate the New England populations and use *N. arenaceodentata* for California populations with specific site designation.

For over 40 yr, the species has been used as a laboratory experimental animal for ecotoxicology studies because of the ease of culture and its well-studied reproductive behavior and early development (Reish and Stevens, 1969; Reish, 1985). Among the nereidids, it is an unusual species because of its premating pairing behavior, male parental care, and the direct development of the young (Reish, 1957; Reish and Alosi, 1968). Typical behavior in encounters

between individuals, especially between those of the same sex, often involves aggressive displays, and fights that can cause cannibalism and mortality (Starczak, 1984). In contrast, intersexual encounters of ripe individuals show little degree of aggression (Reish, 1957), with the partners passing each other, and secreting mucus to form a burrow/tube inside which they remain for 1–3 wk. During reproduction, the male will increase movement (rhythmically beating of tail) within the tube and release a small amount of a white, mucus-like cloud that resembles the gamete release behavior of broadcast spawning nereidids (Weinberg and Starczak, personal communication). This is followed by the release of eggs by the female that are fertilized by the male, releasing a whitish cloud of gametes. Once the female has laid her eggs into the mucus-lined tube, she dies outside of the tube within a few hours. The male then incubates the young; the exact nature of his care is unknown but it was observed that males rhythmically beat the length of the body while positioned in the mucus tube adjacent to the egg mass. The larvae leave the parental tube after a period of approximately 21–25 d (under laboratory conditions) and construct their own individual tubes. The adult male may then find a second mate and may continue to mate. In total, the life cycle takes approximately 12–16 wk to complete in the laboratory (Reish, 1985).

When attempting to pair individuals from populations of *Neanthes acuminata* collected from various sites off the Atlantic and the Pacific coast of the US, Weinberg et al. (1990) found a significant level of interpopulation aggression that in some cases prevented the worms from pairing. While two populations from the Los Angeles area (San Gabriel River and Newport Beach) showed little aggression toward each other, there was some initial aggression between two Atlantic coast populations (Falmouth, MA, and Stonybridge, CT), but eventually these animals did pair during an observational period of 36 hr. In contrast, all attempts to pair Atlantic populations with Pacific populations failed, and the worms showed high levels of aggression and a substantial number of casualties because of the intense fighting. Interestingly, Weinberg et al. (1992) found that both Pacific populations failed to pair and mate with individuals taken from the above-mentioned laboratory-cultured collected at Los Angeles Harbor by Reish in 1964. Although these three sampling sites are separated by less than 25 miles, no successful offspring could be reared, and aggression levels were high. These results suggested evidence for a rapid species isolation following a founder event (Weinberg et al., 1992), a theory that was since rejected by Rodriguez-Trelles et al. (1996). Based on allozyme electrophoretic studies, the authors found differences between these populations that were as large as those to the Atlantic populations, and concluded that at the time when the Los Angeles Harbor (laboratory culture) population was collected it was already genetically distinct from the San Gabriel and Newport populations.

None of these studies provided an explanation of the possible causes of interpopulation aggression that prevent mating and may function as mechanisms in reproductive isolation. Weinberg et al. (1990), discussing the interpopulation aggression, suggested that one of the mechanisms by which individuals may be able to recognize kin could be the use of population-dependent chemical signals, which he described as "differences in their sex pheromones." Sex pheromones have been described in a number of nereidid polychaetes (see Hardege, 1999 for review), but little is known about pheromone variability among populations in marine invertebrates. "Kin recognition" and "detection of self" via chemical signals has been described in a number of species (see Cardé, 1986 for review) including lizards (Cooper et al., 1999; Bull et al., 2000), bumblebees (Ayasse et al., 1999), and salamanders (Rollmann et al., 2000). In the aquatic environment, little is known about the chemistry involved, and few studies have addressed this topic. Stanhope et al. (1992) describes behavioral assay-based evidence for a habitat-modified, race-specific sex pheromone in amphipods (*Eogammarus confervicolus*) based on genetic differences in the algal diet of the gammarids. Here, we demonstrate that premating isolation in *N. acuminata* populations is based on chemical cues rather than visual or tactile ones. "Conditioned seawater" taken from the various populations induces "fighting behavior" indicating that the species is capable of chemically based kin (population) recognition.

METHODS AND MATERIALS

Experimental Animals. Experimental animals represent cultures originating from collections by Dr. J. Weinberg from the intertidal sands at the mouth of the San Gabriel River, Long Beach, CA, USA, from the upper bay at Newport Beach, CA, from Alwife Cove, New London, CT, USA, West Falmouth Harbor, MA, USA, Hawaii, and the laboratory culture of Dr. D. Reish. The latter culture ("Reish culture") was established in 1964 from six animals collected at Los Angeles Harbor, allowed to grow into a population of thousands of individuals, and is maintained until today at California State University, Long Beach. A subculture of the "Reish culture" was established at Woods Hole, MA, by Weinberg in 1986. Additional cultures were established by Weinberg from field collections at West Falmouth Harbor, MA, Hawaii, San Gabriel River, Long Beach, CA, from the upper bay at Newport Beach, CA, and from Alwife Cove, New London, CT in the early 1990s. For the present study, approximately 300 individuals per population were obtained from Weinberg and cultured in the laboratory starting in 1995. Collection of worms in the field was undertaken in June between 1997 and 2002 at West Falmouth Harbor, MA, and Alwife Cove (New London), CT.

Laboratory Animal Culture. Worms were kept in natural seawater at a salinity of 32‰ and a water temperature of 20°C. Seawater was changed on a weekly basis, and the temperature and salinity were checked twice a week. The nereids were initially fed four times a week with fish food flakes (Tetra Min™) as the primary source of food, and later with low protein rabbit food and freeze-dried or frozen algae (*Enteromorpha* ssp.). These were soaked in seawater before feeding. The small particles were pipetted and dispersed through the water. The term "sexually mature" is used as a loose definition to distinguish "adult" nereids from the immature individuals. It is not a direct indication of the specimen's level of sexual receptiveness, although this is intrinsically linked. Females were identified as being mature on the basis of visible presence of eggs in the coelom. Occasionally, males could be distinguished by the whitening of coelom, due to the presence of sperm. An increase in size from the juvenile stages was the most obvious indication of maturity. Behaviorally, the mature males were also easily recognized, as they would often attempt to pair and mate. Only those worms that had been previously paired with an individual from their own population were used in behavioral experiments. This procedure was chosen to guarantee that all worms were capable of pairing given contact with the "right" partner. "Conditioned seawater" samples were produced through incubating 100 ml sterile filtered seawater (0.2 μm) with five mature males for 24 hr.

Behavioral Assays. For prezygotic isolation experiments (intra- and interpopulation aggression), individuals were taken from culture and were defined as sexually mature on the basis of physical morphology as described above, and then isolated in small glass beakers (50 ml) for 24 hr. Two individuals (one of either sex) were placed in a Petri dish with seawater and left for a 10-min period to determine if they would pair. Pairing was defined as "both individuals laying alongside one another with no signs of aggression toward or movement away from the other individual" as stated by Weinberg et al. (1990). The pairing as defined above indicates a pair bond between two individuals, which would eventually lead to mating. All experiments were carried out over a 6-wk period to minimize any differences in aggression through seasonal effects, and all measurements were taken between 12:00 and 17:00 hr to reduce diurnal variations in aggression that may occur. A Petri dish (diam 6.6 cm) was filled three quarters with seawater, and two individuals were placed into the dish, one immediately after the other. Timing was initiated at the first point of contact (proximity of less than 0.5 cm, usually followed by behavioral change such as extending jaws within seconds, but not always followed by physical contact) between the two specimens. "Conditioned water" samples used to investigate whether the observed kin recognition behavior is based on chemical cues were obtained by placing 25 individuals of a given population in 50 ml sterile filtered (0.2 μm) seawater for 2 hr. Samples were

applied to individual worms with glass pipettes (0.1 ml) at 1 cm distance in front of the individuals, and this was defined as "contact" to "odor samples." "Point Sampling" (action at a particular point in time) was used at 30-sec intervals to compare the action of the nereids with the aggression score. Sampling continued for 10 min, and all scores were tallied. Scoring of aggression was modified slightly from Reish and Alosi (1968, modifications are shown in italics): Score 0—no aggressive behavior; Score 1—defensive or avoids contact with other specimen; palpi may be flared; *or aggressive displays may be shown while the two nereids are distanced within 1 cm from one another*; Score 2—fighting position assumed; palpi flared and jaws may be extended; Score 3—aggressive, with violent attacks upon other specimen; jaws extended and biting, *following a level 3 aggression further aggressive displays may be shown while the two nereids are distanced no more than 1 cm from one another and worms actively avoid close contact*.

Statistical analysis of variance within and differences among samples was undertaken using a median test and a Kruskal–Wallis test (ANOVA). A rigorous Wald–Walfowitz test (ANOVA) was used for testing significant differences between "exposure to conditioned seawater" and direct encounters.

RESULTS

Pairing of sexually mature individuals from the five populations show significant levels of premating aggression among all specimens, except when paired with individuals from their "own" population (Figure 1a, e.g., San Gabriel males vs. other populations: $\chi^2 = 24.996$, $FG = 4$, $P < 0.001$ median test, $P < 0.001$). Specimens used for the experiment were taken from tanks with populations kept in the laboratory for at least 3 mo and in some cases ("Reish culture") nearly 40 yr. Although San Gabriel River and Newport Beach populations are separated by less than 15 miles, significant levels of premating isolation ($\chi^2 = 15.7$, $P = 0.013$ median test, $P = 0.011$) were observed with aggressive encounters reaching behavioral score 3.

Exposure of mature specimens to seawater "conditioned" by individuals from other populations also induced a behavioral response in the worms, which in some cases resulted in attacks on the glass pipette used. Similarly to worm–worm encounters, aggression levels were higher between populations than within the populations (e.g., San Gabriel male conditioned seawater: $\chi^2 = 26.499$, $FG = 4$, $P < 0.001$, median test, $P < 0.001$; Figure 1b). The chemically induced (population odor) premating isolation levels were generally lower than during worm–worm direct contact encounters, but not often statistically significant. For example, in the San Gabriel worms "conditioned seawater" was only significantly less effective than direct contact using samples from the

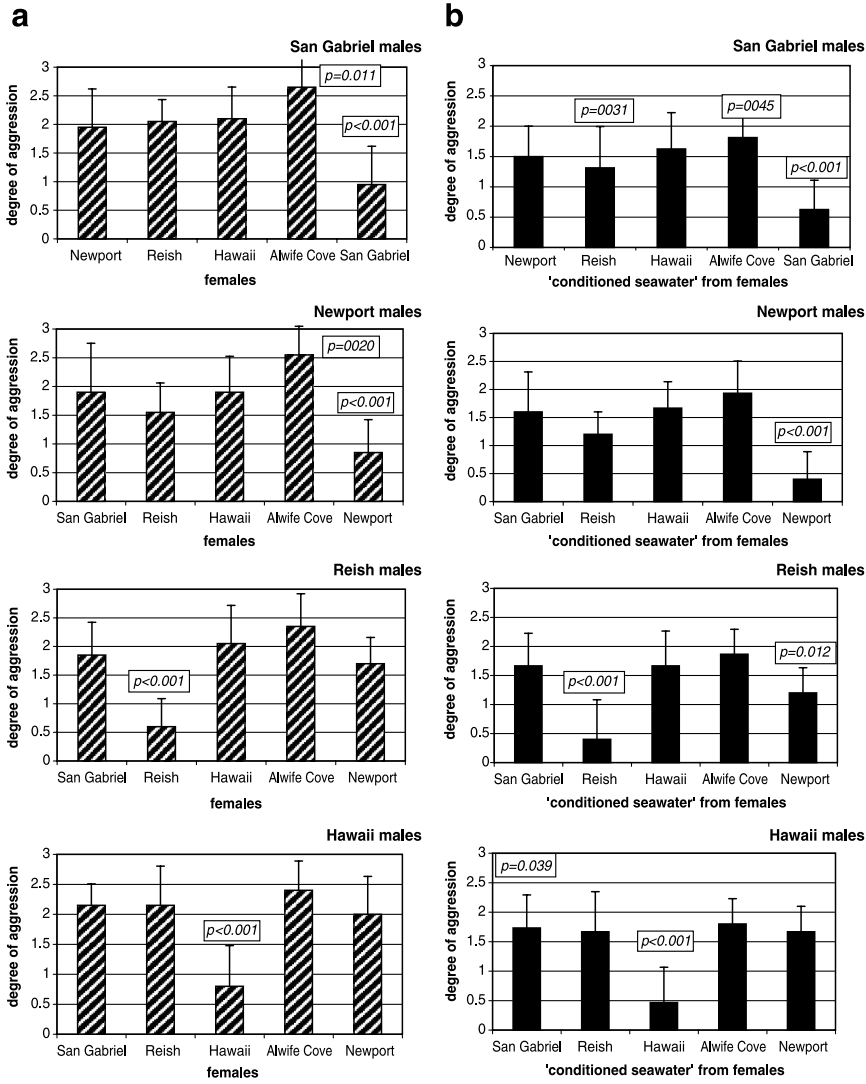

FIG. 1. Behavioral assay on pairing behavior towards various populations using: (a) exposure of individual mature males to females and (b) to "conditioned seawater" representing the (female) odor of the various populations. The *P* values, presented in boxed text, show significant differences using Wald–Walfowitz tests (ANOVA) for testing significant differences between "exposure to conditioned seawater" and direct encounters (b vs. a), and a Kruskal–Wallis test (ANOVA) to examine differences within an experiment. Number of pairing experiment repeats vary between different combinations ($N = 19-22$ repeats) due to availability of worms, error bars represent mean/SD.

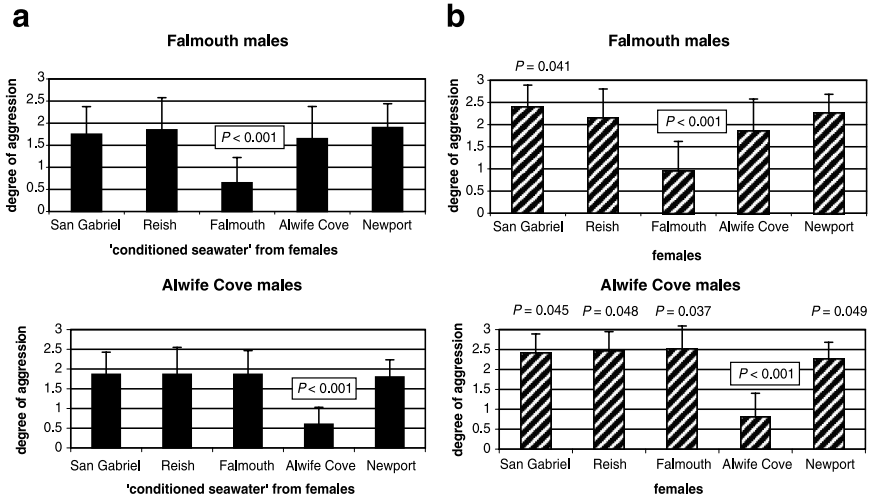

FIG. 2. Behavioral assay on pairing behavior of mature male individuals from Alwife Cove (Connecticut) and Falmouth harbor (Massachusetts) collected in the field 2 wk prior to the assays towards various populations using: (a) exposure to males, and (b) exposure to "conditioned seawater" representing the (male) odor of the various populations. The *P* values, presented in boxed text, show significant differences using Wald–Walfowitz tests (ANOVA) for testing significant differences between "exposure to conditioned seawater" and direct encounters, and a Kruskal–Wallis test (ANOVA) to examine differences within an experiment. Number of pairing experiments: $N = 21$ per data set, error bars represent mean/SD.

Alwife Cove and Reish culture samples (Reish vs. Reish H_2O: $P = 0.03$, Alwife Cove vs. Alwife Cove H_2O: $P = 0.045$; Figure 1b).

Figure 2 shows data obtained from specimens collected in the field (Falmouth, Alwife Cove) and assayed within less than 2 wk after sampling. As with all assays with culture-reared worms, the field collected population from Falmouth and from Alwife Cove showed aggressive displays toward all other populations expect to individuals of their own population ($\chi^2 = 22.467$, $FG = 4$, $P < 0.001$ median test, $P < 0.001$; Figure 2b), and the aggressive display was also inducible using "conditioned seawater" (Figure 2a).

DISCUSSION

Extreme levels of inbreeding are found in a number of species, particularly in species that are of "domestic use" and as such artificially selected and reared for consistency. In rodents, such inbreeding is thought to compromise an

individual's ability to discriminate among individuals (Nevison et al., 2000). Individual recognition and kinship play an important role in social organisms and influence competition and mate choice. In mice, as with the majority of animals, mate choice is influenced by chemical signals, pheromones. Hurst et al. (2001) demonstrated that wild house mice (*Mus domesticus*) use mouse urinary proteins (MUPs) that bind and release small volatile pheromones to mediate individual recognition. Wild mice show a large degree of diversity in the expression of MUPs that might be as great for the major histocompatibility complex (MHC) that has been suggested as the main source of the immense odor complexity in rodents, fish, and possibly in humans (Yamazaki et al., 1999). Consequently, "odor individuality" in mice and other organisms that use urine marking may be based on specific release rates of such volatile compounds rather than differences in MHC. Currently, we do not have a well-characterized aquatic invertebrate system to study this question, but the observed population differences in *Neanthes acuminata* may enable us to address this in the future. This will require studies of the chemistry involved as well as the biodiversity of MHC complexes.

The use of chemical signals in discrimination between self-produced, own population, and those produced by conspecifics has been studied in gregarious lizards, *Cordylus cordylus* (Cooper et al., 1999) and *Egerinia stockesii* (Bull et al., 2000), a number of insects (Gemeno et al., 2001; Evenden et al., 2002), and rodents (Hurst et al., 2001). In the aquatic environment, a number of studies have shown that closely related species can distinguish other species by the use of odor (e.g., stomatopods, *Gonodactylus zacae* and *G. bahiahondensis*; Caldwell, 1982), but little is known about the chemical basis of such phenomena. Kin recognition studies have focused on amphipods, *Eogammarus confevicolus*, where race-specific sex pheromones were postulated by Stanhope et al. (1992), and copepods, *Tigriopus californicus* (Palmer and Edmands, 2000).

Our experiments using *Neanthes acuminata* confirm that marine invertebrates can use odor for kin recognition. Aggression levels within a population were lower than between populations (Figure 1a), and the high degree of fighting behavior suggests that this could lead to premating reproductive isolation among the different populations. Exposure of male individuals to "conditioned seawater"—meaning incubation water in which females from various other populations were kept (see Methods and materials)—induces "aggressive display" demonstrating the importance of "chemical cues" in this behavior (Figure 1b). Odors induced aggression levels between worms from the East and West Coast of the USA are significant and confirm the allozyme electrophoretic studies by Rodriguez-Trelles et al. (1996), and the chromosome complements undertaken by Pesch et al. (1988), suggesting that it is unlikely that successful offspring can occur. Nevertheless, in all "conditioned seawater" experiments, the aggression levels are lower than in direct confrontation be-

tween worms. Although these differences are only in some cases statistically significant (see Figures 1b and 2), the ubiquitously lower level of chemical odor induced aggression (many P values between 0.06 and 0.14) indicates that the level of such interactions may not be solely chemical. Behavioral responses, such as avoidance, fleeing, and aggression display, cause additional stress, which increases the level of fights between "unfamiliar" individuals while exerting little to no effect upon "familiar, own population" pairs. This is known from crayfish (Breithaupt and Eger, 2002) and American lobster, *Homarus americanus* (Bushmann and Atema, 2000; Breithaupt and Atema, 2000), both of which use chemical signals for dominance fights to establish social hierarchies. Specimens collected in the field (Falmouth, Alwife Cove) and assayed within less than 3 wk after sampling (Figure 2b) showed aggression levels not significantly different from those obtained from the cultured worms (Figure 1a, b), indicating that culture in the laboratory did not influence the behavioral responses.

Aggression levels among individuals from the three Los Angeles area populations are significantly higher than within these populations, suggesting that all three southern Californian populations can discriminate each other, are independent, and have different odor profiles. Further genetic evidence is required to test whether these odor differences have led to the existence of at least three races within the L.A. area or even "represent a case for rapid speciation" in the laboratory, as hypothesized by Weinberg et al. (1992), but disputed by Rodriguez-Trelles et al. (1996). In addition to population genetics studies, future research will focus on high-performance liquid chromatography (HPLC) analysis of odor profiles from the various populations by using "conditioned seawater." Today, only a few examples exist where odor profiles of aquatic organisms have been studied. These includes lobster, where urine derived proteins may function in individual recognition (Karavanich and Atema, 1998; McLaughlin et al., 1999), and salmon, where odor profiles are implicated in "homing" (Solomon, 1973; Brannon and Quinn, 1990).

Acknowledgments—We thank Dr. Jim Weinberg for kindly providing us with the *Neanthes* cultures and fruitful discussions, Dr. T. Breithaupt for help on statistics, and J. Duck and V. Swetez for assistance with the culture of the worms. The authors gratefully acknowledge funding for this work by the Royal Society and by the Marine Biological Laboratory, Woods Hole, through a summer research fellowship to J.D.H.

(Received December 15, 2004; revised February 24, 2005; accepted March 12, 2005)

Abstract—Lettuce seeds (*Lactuca sativa* L.) and other crop species are often used in phytotoxic bioassays that are designed to detect allelochemicals. The seeds of these species are considered ideal because they are readily available, germinate rapidly and uniformly, and are routinely used in laboratories around the world. Despite their common use, however, the seeds of these species are often not as sensitive or responsive to some phytotoxic chemicals as are the seeds of other species. While searching for a more sensitive test species for phytotoxic bioassays, the Columbia ecotype of *Arabidopsis thaliana* exhibited greater sensitivity to seven potent allelochemicals than did lettuce seeds, which, in some cases, did not respond at all to those substances. Sensitivity satisfies one of the criteria for selecting a test species for bioassays. We now report on the results of our study and offer additional reasons for using *A. thaliana* seeds.

Key Words—Allelopathy, allelochemicals, phytotoxicity, phytotoxic bioassays, *Arabidopsis thaliana*, *Lactuca sativa*.

INTRODUCTION

Despite being first mentioned approximately 2000 years ago, allelopathy is a relatively new field of research (Rice, 1995) and refers to the interactions of secondary metabolites between neighboring plants as well as interactions between plants and other organisms such as bacteria, fungi, and algae (Rice, 1995). Secondary compounds, or allelochemicals, can induce both inhibitory

* To whom correspondence should be addressed. E-mail: mpennacchio@chicagobotanic.org

and stimulatory effects on organisms and may play roles in shaping plant and microbial communities.

In the past, plants and their seeds have served as useful test organisms for screening allelochemicals that may affect seed germination, root growth, shoot elongation, membrane function, and photosynthetic activity (Hoagland and Williams, 2004). Where phytotoxic bioassays that specifically focus on detecting allelochemicals are concerned, lettuce seeds (*Lactuca sativa* L.) and other crop species have routinely served as the test species of choice. There is concern that these species do not reflect what is actually occurring in natural ecosystems (Inderjit and Dakshini, 1999). Jefferson and Pennacchio (2002) recently reported that lettuce seeds alone would not have detected, for example, that extracts from Australian chenopod species promote germination and growth in some of their own species instead of inhibiting it. Despite such concerns, bioassays of this type offer researchers a starting point from which to learn more about phytotoxicity and allelochemicals. Before seeds are selected for use in phytotoxic bioassays, however, they must first satisfy a number of selection criteria: be readily available; be affordable; germinate quickly, completely, and uniformly; and produce repeatable and reliable results. They must also be sensitive enough to respond to a variety of chemicals with different biochemical effects. This is especially critical where crude extracts are concerned (Hoagland and Williams, 2004). Another consideration is that the test species need to offer researchers a means by which to help identify the mechanisms of action of active compounds.

We evaluated the potential use of *Arabidopsis thaliana* (L.) Heynh (Brassiaceae) seed for use as part of a set of standard target species (STS) in phytotoxic bioassays. In our study, we tested seven potent allelochemicals and compared their effects on the seeds of Columbia (Col-3) ecotype of *A. thaliana* with those of the more commonly used lettuce seeds.

METHODS AND MATERIALS

Phytotoxicity Study. Commercially available lettuce (*L. sativa*) seed were used in this study, along with the Col-3 ecotype of *A. thaliana* seeds. This ecotype was selected after a factorial study involving 20 commonly used ecotypes. Temperature and pH studies revealed that it germinated rapidly and at a variety of temperatures and pH ranges. Furthermore, it could be tested under the same laboratory conditions as lettuce seed, which were previously established by Macias et al. (2000).

A total of 25 lettuce seeds were evenly spaced onto sterile Petri dishes (90 mm diam) lined with Whatman filter paper No. 1. Since it is known that filter

paper may influence seed germination in *A. thaliana* seeds (Rehwaldt, 1968), paper from the same batches was used in each trial. In addition, because of their smaller size, 50 *A. thaliana* seeds were used in each replicate. There were four replicates for each control and treatment group. Each Petri dish received either 3 ml of distilled water (control) or one of three different concentrations of allelochemicals. All Petri dishes were sealed with parafilm (Pechiney Plastic Packaging, Neenah, WI, USA) and incubated at 25.0°C and at a pH of 6.0. Lettuce seeds were also tested at a pH of 6.0 and at a temperature of 25.0°C as recommended by Macias et al. (2000).

All seeds were monitored for germination for a period of 7 d. Only those seeds with an emerging root length of 1 mm or greater were considered germinated. Attempt was made to minimize contamination by fungi and bacteria, but no fungicides or other antimicrobial agents were used. The study was designed to evaluate specifically the effect of allelochemicals on seed germination, and no attempt was made to determine the effects on root and shoot length. However, measuring the lengths of the emerging roots and shoots is useful in phytotoxicity studies since both may be affected regardless of whether or not germination is affected.

Allelochemicals. Seven known and commercially available compounds were used as test solutions. The allelochemicals tested were tannic acid (Sigma Chemicals), juglone (5-hydroxy-1,4-naphthoquinone, $C_{10}H_6O_3$; Acros Organics), cinnamic acid (Acros Organics), caffeic acid (MP Biomedicals), coumarin (Acros Organics), salicyclic acid (Acros Organics) and 1,8-cineole (1,8-epoxy-*p*-menthane, 1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane, $C_{10}H_{18}O$; Aldrich Chemicals). These were tested at the following concentrations: control: distilled water; 1,8-cineole (0.65, 6.5, and 65 mM); coumarin (0.01, 0.10, and 1.00 μM); juglone (1, 10, and 100 μM); tannic acid (0.1, 1.0, and 10.0 mM); cinnamic acid (0.01, 0.1, and 1.0 mM); caffeic acid (0.001, 0.01, and 0.1 M; salicyclic acid (0.01, 0.1, and 1 mM).

Concentration ranges were selected based on the results of previous studies and reports, e.g., cineole concentrations for lettuce seed by Flematti et al. (2001) and coumarin concentrations by Vyvyan (2002). Those that were not reported in the literature were determined during a preliminary concentration–response study (data not shown). Because of their poor water solubility, coumarin and 1,8-cineole were initially dissolved in acetone (Sigma Chemicals), which was allowed to evaporate completely from the filter papers lining the Petri dishes. The volumes used for both acetone and water depended on the final concentration for each trial. Juglone and caffeic acid were gently heated in distilled water to dissolve these chemicals. Each of the compounds was distributed evenly across the filter paper.

Data Analysis. Germination counts were performed daily for a period of 7 d. Final germination percentage (FG%), rate of germination (RG), and mean

Different letters indicate significant differences between extract concentrations, using Tukey's compromise test. FG% = final germination percentage; RG = rate of germination (d); MPFG = mean period to final germination (d); At = *A. thaliana*; Ls = *L. sativa*. See Methods and materials for calculation of RG and MPFG.

period to final germination (MPFG) were calculated to determine the percentage of seed that had germinated at the conclusion of the study. They also revealed the rate at which germination had occurred. These three germination parameters, previously reported by Saxena et al. (1996), were calculated as follows: (1) FG%: This is the maximum average percentage of seeds that germinated during the experiment; (2) MPFG = $\sum N_i D_i$/FG; (3) RG = $\sum N_i / D_i$; where N is the daily increase in seedling number, D is the number of days from seed placement, and $\sum$ is the sum of the others.

Final germination percentages were arcsine transformed before statistical analyses according to Ott (1998). Both RG and MPFG data were $\log_{10}$ transformed. All data were analyzed by using the statistical package Systat (v. 10.2). A one-way analysis of variance (ANOVA) was performed on all transformed data to reveal differences in means. Probabilities of less than 0.05 were considered significant. Differences between means were determined by using Tukey's compromise test. Means ± SE are included in the results.

RESULTS

Sensitivity to Allelochemicals. The Col-3 ecotype of *A. thaliana* seeds was significantly more sensitive to all seven allelochemicals than were the lettuce seeds (Table 1). The FG%, RG, and MPFG were all affected in a concentration-dependent manner (Table 1). Lettuce germination was not inhibited by any concentration of tannic acid, juglone, or caffeic acid (Table 1). The RG and MPFG of lettuce were, however, affected by the highest concentration of juglone ($P < 0.001$ for both). In contrast, tannic acid inhibited *A. thaliana* FG% ($P < 0.001$) and RG ($P < 0.001$) at a concentration of 1.0 mM and prolonged MPFG at a concentration of 10.0 mM (Table 1). Juglone significantly inhibited *A. thaliana* seed germination (i.e., FG%, RG, and MPFG) at 100 μM, whereas a concentration of 0.01 M caffeic acid was sufficient to significantly affect all aspects of germination (Table 1).

Caffeic acid's chemical analog, cinnamic acid, significantly inhibited germination in both seed types (Table 1). The FG%, RG, and MPFG of both species were inhibited at a concentration of 0.01 mM ($P < 0.001$ for all). Coumarin, in contrast, produced mixed results. For example, the FG% of lettuce seed was inhibited, whereas MPFG was prolonged starting at a concentration of 0.01 μM (Table 1). The RG decreased initially at 0.01 μM (4.6 ± 1.0), but then increased at 0.1 (10.8 ± 2.1) and 1.0 μM (9.1 ± 1.8). The Col-3 ecotype was more consistent. It was inhibited ($P < 0.001$ for all three germination parameters) at a concentration of 0.01 μM (Table 1).

Finally, salicyclic acid inhibited the Col-3 ecotype at a concentration of 0.10 mM. *L. sativa* seed germination (all three measured parameters), in con-

trast, was inhibited at a higher concentration of 0.1 mM (Table 1). Eucalyptol (1,8-cineole) inhibited ($P < 0.001$) the Col-3 ecotype seed germination (i.e., FG%, RG, and MPFG) at the lowest concentration of 0.65 mM, whereas *L. sativa* seed germination was inhibited at a higher concentration of 6.5 mM (Table 1).

DISCUSSION

Other researchers, such as Leather and Einhellig (1986), Inderjit and Dakshini (1995), and Inderjit and Nilsen (2003), have discussed the shortcomings of using bioassays in laboratory-based phytotoxicity studies. However, despite some of the problems associated with them, they are useful because they focus on important aspects of allelopathy, e.g., detecting the presence of allelochemicals, mapping the fate of compounds in soil, and determining the effects on microbes in an ecosystem (Inderjit and Nilsen, 2003).

One test species, which is ideal for use as part of a set of STS in bioassays, is the cruciferous weed, *A. thaliana*. This species is sensitive to a variety of potent allelochemicals and satisfies all of the selection criteria for target species. In addition, it has been researched extensively in laboratories worldwide for a broad spectrum of molecular and other purposes. Many have already increased our understanding of plant growth and development, plant–pathogen interactions, plant pattern formation, plant physiology, and plant biochemistry (Bowman, 1994). Furthermore, the entire genome of this species has recently been mapped (The Arabidopsis Genome Initiative, 2000). As a result, there are approximately 10,000 references to this species alone in the literature and in various databases.

Also of significance are the more than 200 qualitative mutations that have been linked with the five chromosomes of *A. thaliana* (Griffing and Scholl, 1991). Some of the more interesting mutants include herbicide resistance, which may make it an attractive model for determining the mechanisms of resistance to toxic substances (Mitterbauer and Adam, 2002). This mutant and others could potentially help with identifying the mechanisms of action of certain allelochemicals.

In addition, proteomic studies will reveal the biochemical pathways affected by allelochemicals during seed germination and growth. Using a reverse proteomics approach, Gallardo et al. (2002) highlighted the importance of methionine biosynthesis in *Arabidopsis* seed germination. Tomita-Yokotani et al. (2003) reported that *A. thaliana* seed exudates promoted their own growth while inhibiting that of the fungus, *Neurospora crassa*.

With such an extensive resource available to researchers, along with the sensitivity to potent allelochemicals exhibited by the Col-3 ecotype of

A. thaliana seed and seedlings, we believe that it is should be included as part of a set of STS in allelopathy studies. A number of different ecotypes and mutants exist, many of which can be used in comparative studies, as well as for templates for the discovery of new phytotoxic substances.

Acknowledgments—Britt Forsberg is thanked for assisting us with the preparation of our seed germination studies. Associate Professor Emilio L. Ghisalberti is thanked for editorial and other advice.

Abstract—Rye (*Secale cereale* L.) is an important cover crop that provides many benefits to cropping systems including weed and pest suppression resulting from allelopathic substances. Hydroxamic acids have been identified as allelopathic compounds in rye. This research was conducted to improve the methodology for quantifying hydroxamic acids and to determine the relationship between hydroxamic acid content and phytotoxicity of extracts of rye root and shoot tissue harvested at selected growth stages. Detection limits for an LC/MS-MS method for analysis of hydroxamic acids from crude aqueous extracts were better than have been reported previously. (2*R*)-2-*β*-D-Glucopyranosyloxy-4-hydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA-G), 2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA), benzoxazolin-2(*3H*)-one (BOA), and the methoxy-substituted form of these compounds, (2*R*)-2-*β*-D-glucopyranosyloxy-4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIMBOA glucose), 2,4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIMBOA), and 6-methoxy-benzoxazolin-2(3*H*)-one (MBOA), were all detected in rye tissue. DIBOA and BOA were prevalent in shoot tissue, whereas the methoxy-substituted compounds, DIMBOA glucose and MBOA, were prevalent in root tissue. Total hydroxamic acid concentration in rye tissue generally declined with age. Aqueous crude extracts of rye shoot tissue were more toxic than extracts of root tissue to lettuce (*Lactuca sativa* L.) and tomato (*Lycopersicon esculentum* Mill.) root length. Extracts of rye seedlings (Feekes growth stage 2) were most phytotoxic, but there was no pattern to the phytotoxicity of extracts of rye sampled at growth stages 4 to 10.5.4, and no correlation of hydroxamic acid content and phytotoxicity (I_{50} values). Analysis of dose–response model slope coefficients indicated a lack

* To whom correspondence should be addressed. E-mail: ricec@ba.ars.usda.gov

of parallelism among models for rye extracts from different growth stages, suggesting that phytotoxicity may be attributed to compounds with different modes of action at different stages. Hydroxamic acids may account for the phytoxicity of extracts derived from rye at early growth stages, but other compounds are probably responsible in later growth stages.

Key Words—DIBOA glucose, (2*R*)-2-*β*-D-glucopyranosyloxy-4-hydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one, DIBOA, 2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one, BOA, benzoxazolin-2(*3H*)-one, DIMBOA glucose, (2*R*)-2-*β*-D-glucopyranosyloxy-4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one, DIMBOA, 2,4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one, MBOA, 6-methoxy-benzoxazolin-2(3*H*)-one.

INTRODUCTION

Rye (*Secale cereale* L.) is a popular winter annual cover crop in conventional and conservation tillage production systems of major vegetable and field crops including sweet corn (*Zea mays* L.) (Burgos and Talbert, 1994), soybean (*Glycine max* L.) (Liebel et al., 1992), and tomatoes (*Lycopersicon esculentum* Mill.) (Masiunas et al., 1995). Rye has many desirable attributes that make it a suitable winter cover crop for cool, northern climates: seeds germinate quickly, seedlings establish in cool weather, young plants produce deep roots that reduce soil erosion and recycle nutrients, and mature plants yield 7–8 t/ha of biomass that can enhance soil tilth. Rye residues exhibit numerous physical and chemical attributes that can influence subsequent crops and their environment. Physical attributes of rye on the surface of soils can affect the radiation, thermal, and hydrological environment that in turn can influence emerging crops, weeds, and pests (Teasdale and Mohler, 1993; Teasdale et al., 2004). Chemical release of toxins and production of phytotoxic microbial products from rye residues has been widely documented (Putnam, 1985; Niemeyer, 1988; Weston, 1996).

Allelopathy in rye is attributed to two major compounds: 2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA) and its breakdown product, benzoxazolin-2(*3H*)-one (BOA) (Barnes et al., 1987). Both DIBOA and BOA are abundant in rye. They arise sequentially as DIBOA glucose (DIBOA-G) is enzymatically degraded to DIBOA. BOA is formed by the natural breakdown of the DIBOA (Niemeyer, 1988). Additional allelopathic compounds have also been identified in rye (Shilling et al., 1986), but they are considered to have lower activity and are seldom considered when chemical-specific allelopathy studies on rye are carried out (Barnes et al., 1987; Niemeyer, 1988).

The concentrations of DIBOA and BOA in rye may be affected by many variables. Burgos et al. (1999) reported over a tenfold difference in the concentration of DIBOA among eight cultivars. Mwaja et al. (1995) showed that DIBOA and BOA concentrations and allelopathic activity varied with plant

fertility, being higher when rye was grown at low to moderate fertility than at high fertility. Reberg-Horton et al. (2005) found major concentration differences of DIBOA within several rye cultivars based on plant age and stage of development. Several studies have compared differences in phytotoxicity of rye root *versus* shoot tissue with conflicting results (Barnes and Putnam, 1986; Chase et al., 1991; Hoffman et al., 1996). Research is needed to determine changes in allelopathic compounds in rye tissue as a function of plant development.

When assessing the main allelopathic chemicals in rye, many researchers have attributed the major activity to DIBOA (Barnes et al., 1987; Burgos and Talbert, 2000). In the intact rye plant, the major form of DIBOA is the glycone form, DIBOA glucose (DIBOA-G), which rapidly loses the glucose moiety through enzymatic cleavage when the plant tissues are damaged (Hietala and Virtanen, 1960). Subsequent breakdown of DIBOA to BOA is enhanced through heating and mechanical action of the macerated plant extracts (Tang et al., 1975). These three DIBOA-related compounds make up the hydroxamic acid content in rye as described by Burgos et al. (1999). However, the methoxy-substituted family of hydroxamic acids has also been detected in rye, e.g., DIMBOA glucose, DIMBOA (Hofman and Hofmanová, 1969) and MBOA (Tang et al., 1975). Thus, to assess the total hydroxamic content of rye, one needs to measure both the DIBOA family, referred to here as the hydroxamic acid (HA) content, and the DIMBOA family, referred to as methoxy-substituted (MHA). Note that HA also has been classified as "BX" by Reberg-Horton et al. (2005) in reference to the fact that "B" and "X" are unique letters in the chemical name common to all of these compounds, "benzoxaz...one." Assessment of the total hydroxamic acid content of rye (HA + MHA) was a major goal of this study.

There are few analytical methods that have adequately accounted for all members of the hydroxamic acid (HA + MHA) family of compounds from rye. Early research focused on methods utilizing colorimetry and spectrophotometry by measuring the absorbance of a blue complex with $FeCl_3$ (Baker and Smith, 1977). This approach was laborious and limited by the fact that benzoxazolinones (BOA and MBOA) do not react with $FeCl_3$ (Lyons et al., 1988). At present, identification and quantification of HA and MHA are typically done by high performance liquid chromatography-ultraviolet (HPLC-UV) (Gutierrez et al., 1982; Lyons et al., 1988; Burgos et al., 1999) or gas chromatography (GC) (Tang et al., 1975; Woodward et al., 1979a,b). However, none of these methods is capable of detecting low (<1 μg/g dry wt) concentrations in rye. Gas chromatographic (GC) methods, both GC/flame ionization (FID) (Tang et al., 1975; Woodward et al., 1979a) and GC/mass spectrometry (MS) (Woodward et al., 1979b), provide sensitivities similar to HPLC-UV methods, and the MS method provides additional qualitative assurance of compound identity. However, current GC methods require lengthy derivatization steps that make the techniques

more complicated than LC. Only two studies report the presence of MHA components in rye, Hofman and Hofmanová (1969) and Tang et al. (1975). Most investigators do not look for the MHA compounds, even though Tang et al. (1975) reported fairly high levels in their study, i.e., 120 μg/g fresh wt. leaves of rye and 310 μg/g fresh wt. in rye roots using gas chromatographic methods. They reported 710 μg/g fresh wt. of BOA in these same extracts.

With the advent of liquid chromatography coupled to triple quadrupole mass spectrometry using electrospray ionization methods (LC/ESI/MS-MS), and the numerous improvements to simultaneous qualitative and quantitative characterization of liquid chromatographically separable materials that it offers, we decided to use these methods to develop a new analytical method for determining the analysis of benzoxazinone derivatives in rye extracts. Other investigators (Cambier et al., 2000; Bonnington et al., 2003a) explored variations of these methods for analysis of benzoxazinones in wheat and corn. The analytical goals were to develop an LC/ESI/MS-MS method that would work directly on crude aqueous extracts and one that would provide lower method detection limit values than currently available. Consequently, this study was undertaken to: (1) develop an LC/ESI/MS-MS method to work directly on crude aqueous extracts and lower detection limits; (2) evaluate phytotoxic activity in aerial and root tissues at various stages of plant growth from seedling to maturity; and (3) determine potential correlations between hydroxamic acid concentration and phytotoxicity at these different growth stages.

METHODS AND MATERIALS

Plant and Tissue Preparation. The experiments were conducted at the Beltsville Agricultural Research Center, Maryland, USA. Common "Abruzzi" rye was seeded in mid-September, 2002, using a no-tillage John Deere grain drill (Model No. 450, Westminster, MD, USA). Seeding rate was 90 kg/ha in rows 19 cm apart. No herbicide, fertilizer, or irrigation was applied until the last sample was taken on 17 June 2003. Rye aerial and root tissue was sampled at five dates from March through June of 2003, covering growth stages 4 to 10.5.4 on Feekes growth scale (Large, 1954), and again in November of 2002 corresponding with growth stage 2. Only aerial tissue was taken on the June sampling date due to the difficulty of recovering senescing root tissues.

Whole plants with intact roots were carefully dug, and the soil was washed gently from the roots. Weeds were separated and discarded. Aerial tissues were separated from roots, and the tissues were washed several times with distilled water and blotted on paper. They were then cut into 5-cm pieces, dried for 3 d in a forced-air oven at 65°C, ground in a Wiley mill (Model No. A75-A, Arthur Thomas Co., Philadelphia, PA, USA) to pass through a 40-mesh screen, and

stored in airtight bags at 4°C until use. Aqueous crude extracts from aerial and root ground tissues were prepared following established procedures (Barnes and Putnam, 1986; Burgos et al., 1999; Burgos and Talbert, 2000) with slight modification. Ground tissues (12 g) were incubated in 180 ml deionized water (1:15 w/v) in 500-ml Erlenmeyer flasks. The flasks were sealed with a parafilm layer, placed on a shaker (Gyrotory G-2; Edison, NJ, USA), and incubated for 24 hr in the dark at 4°C with constant shaking at 100 rpm. The slurry was filtered through six layers of cheesecloth and centrifuged for 10 min at 3,046 $\times$ *g* in a refrigerated centrifuge. The supernatant solution (134 $\pm$ 2 ml), which represented the crude aqueous extract, was held in ice until used in bioassays. Electrical conductivity of the crude extract was determined using a conductivity meter. Portions of the supernatant were filtered by using a 0.7-μm Whatman glass microfiber filter, and aqueous filtrate solutions were injected directly onto an LC column connected to the LC/ESI/MS-MS as will be described later.

Analytical Procedures. Chemicals used were derived from the following sources: benzoxazolin-2(3*H*)-one (BOA) (98%) and 6-methoxy-benzoxazolin-2(3*H*)-one (MBOA) (97%) were bought commercially from Sigma-Aldrich (St. Louis, MO, USA); 2,4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIMBOA) and (2*R*)-2-*β*-D-glucopyranosyloxy-4-hydroxy-7-methoxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIMBOA-G; estimated >90%) were isolated from corn according to the methods described by Klun et al. (1967); and 2,4-dihydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA) and (2*R*)-2-*β*-D-glucopyranosyloxy-4-hydroxy-(2*H*)-1,4-benzoxazin-3(4*H*)-one (DIBOA-G) were synthesized following the methods of Sicker et al. (1989) for DIBOA (estimated >95%) and Kluge et al. (1997) for DIBOA-G (estimated >95%).

Analytical method development was aimed at improving the detection limits for the hydroxamic acids expected to be present in the various extracts. Initial full-scan analyses were carried out to determine what types of hydroxamic acid-related compounds could be found. The initial data produced spectra that could potentially arise from the hydroxamic acid family of compounds. Therefore, standards were obtained or synthesized to quantify these compounds as well as β-hydroxybutyric acid and β-phenylacetic acid.

Spike recovery experiments were carried out on leaf extracts from rye sampled at Feekes stage 2. These extracts produced the greatest amount of co-extracted materials, i.e., pigments and suspended cell materials that tended to clog the 1-μm pore size syringe filters used to clarify extracts for LC injection. Because of this clogging, only about 1 ml of material could be obtained before clogging occurred.

Instrumentation. The LC instrument was a Waters 2690 XE Separation module (Waters Corp., Milford, MA, USA). The LC column was a Waters X-Terra MS C-18 column, (5 μm 2.1 $\times$ 150 mm). The separation method was

adapted from Lyons et al. (1988). These conditions were set using known standards of the analytes. The liquid chromatographic protocol involved an isocratic elution program after a 10-μl injection of the sample. The mobile phase consisted of 75% solvent A, 30:70 (v/v) mixture of methanol and 1% formic acid and 25% solvent B, distilled water. A flow rate of 0.3 ml/min was maintained while maintaining the column temperature at 45°C.

Electrospray ionization mass spectrometry (positive and negative ion; ES+/−, MS/MS) was performed on a Quattro LC benchtop triple quadrupole mass spectrometer (Micromass Ltd., Manchester, UK) and analyzed using the multiple reaction monitoring mode (MRM). Exact identification and quantitation was aided by the specificity of the MS that monitored characteristic daughter ions from parent masses of BOA, DIBOA, DIBOA-G, MBOA, DIMBOA, and DIMBOA-G, and the selectivity of the LC separation producing matching peaks at the predetermined retention times for the standards. Nonspecific mass spectrometer settings were set as follows: capillary voltage was set at 3.0 kV; source and desolvation temperatures were set at 140 and 400°C; liquid nitrogen was used to supply the nebulizer and desolvation gas (flow rates were approximately 70 and 600 l/h, respectively). Argon was used as collision-induced decomposition gas to fragment the parent ions, typical pressure 2.9×10^{-5} mbar. MRM was chosen because it allows high sensitivity and selectivity by setting both quadrupoles to transmit selected ions only; the goal of analysts is typically to set the first quadrupole to select the quasi-molecular ($[M\text{-}H]^+$ or $[M\text{-}H]^-$) molecular weight ions (the exceptions here were DIBOA and DIMBOA-G; Table 1) that are allowed to react in the collision cell, and the second quadrupole is set to transmit only specific daughter ions. The compound-specific settings for each parent and daughter ion used for compound identification and quantification are listed in Table 1, along with the optimized cone voltages and collision energies used. Resulting retention times for the specific column conditions are also shown.

TABLE 1. COMPOUND-SPECIFIC MASS SPECTROMETER SETTINGS AND LC RETENTION TIMES

Compound	Parent ion (m/z)	Daughter ion (m/z)	Ionization mode	Retention time (min)	Cone (V)	Collision (eV)	Molecular weight
DIMBOA-G	380	218	ES+	5.8	36	20	373
DIMBOA	212	166	ES+	7.7	12	9	211
MBOA	166	110	ES+	11.4	35	20	165
DIBOA-G	342	134	ES−	5.3	15	11	343
DIBOA	164	80	ES+	7.0	15	20	181
BOA	136	108	ES+	10.2	35	16	135

Quantification was carried out by external standard method using a 5-point standard curve that included 0 with standards ranging from 0.05 to 5 ppm. Peak integration and quantification were performed automatically using the MassLynx 4.0 software (Micromass Ltd.) Instrumental Limit of Detection (LOD) and Limit of Quantification (LOQ) were estimated in terms of the baseline noise. LOD values were calculated using the Eurochem guidelines, where the standard deviation of the lowest visible standards was multiplied by 3.3 to provide method detection limit values (Standards Council of Canada, 2003). Quantification limits were based on the lowest standard that produced a signal to noise ratio greater than 3:1 (Table 2).

Bioassay Methods. Crude aqueous extracts were prepared in proportions of 1.0, 0.5, 0.25, and 0.125 for use in Petri dish bioassays to determine the suppressive activity of rye aerial and root tissue on germination and growth of "Great Lakes" lettuce and "Rutgers" tomato seeds. Lettuce and tomato seeds (50 per dish) were germinated in 100 × 15 mm Petri dishes over a Whatman No. 1 filter paper using 2.5 ml of extract per dish. Dishes were sealed with parafilm, placed on trays, and held in the dark in a growth chamber at a constant 26°C. Trays were positioned at a 45° angle to encourage geotropic growth and facilitate hypocotyl and root measurements (Burgos and Talbert, 2000). Percent germination and hypocotyl and root lengths were measured after 3 d for lettuce and after 5 d for tomatoes. There were five replications for each sampling date, extract, and proportion, and all extractions were repeated once. Data were expressed as the ratio of the treatment value divided by the control in which seeds were germinated in deionized water.

At the May 27 sampling, rye plants reached a growth stage of 10.3 on the Feekes scale. By that time, flowering was complete and the uppermost leaves were still green, whereas the lower leaves were senesced. Plants were harvested, and the aerial tissues were separated into upper green leaves, lower senesced

TABLE 2. ANALYTICAL METHOD PERFORMANCE

Compound	Limits of quantification (μg/g dry wt.)	Limits of detection (μg/g dry wt.)	Spike recoveries (%)	Precision for spike tests [(RSD[a,b] (replicates)]
DIMBOA-G	0.75	0.4	60	0.18 (N = 6)
DIMBOA	0.84	0.1	104	0.12 (N = 9)
MBOA	0.36	0.7	102	0.07 (N = 9)
DIBOA-G	0.75	0.6	60	0.10 (N = 9)
DIBOA	0.84	0.3	125	0.04 (N = 9)
BOA	0.36	0.5	102	0.03 (N = 9)

[a] RSD = relative standard deviation of the means.
[b] Spike concentrations varied from an average of 39–120 μg/g dry wt.

leaves, and leafless stems. The tissues were dried and ground as described earlier. Crude extracts from these tissues were used in bioassays to determine suppressive activity.

Statistical Analysis. All analyses were conducted using SAS Version 8.2 (SAS Inc., Cary, NC). Analysis of variance and mean separations were conducted using PROC MIXED. The nonlinear dose–response function $Y = 100/(1 + (X/c)^{**}b)$, where Y is the assay species response, X is the extract proportion, and c and b are coefficients, was determined using PROC NLIN (Seefeldt et al., 1995). The I_{50} value was determined by the c coefficient. Correlations among hydroxamic acid concentrations and I_{50} values were determined using PROC CORR.

RESULTS AND DISCUSSION

Analytical Observations. DIBOA and BOA (HA group) were the major compounds measured in shoot extracts, whereas DIMBOA-G and MBOA (MHA group) were the dominant constituents of root extracts (Table 3). The relative proportions of BOA and DIBOA agree with data from rye reported by other investigators (Barnes et al., 1987; Mwaja et al., 1995; Burgos et al., 1999; Reberg-Horton et al., 2005). The proportions depend on how completely the enzyme has reacted to remove the glucose precursor, and this may vary depending on extract preparation methods. Furthermore, many researchers do not monitor all of the precursor species or the methoxy-substituted forms. Our rediscovery of MBOA in rye may have significance as an important chemical responsible for toxicity.

Precision checks during routine processing resulted in duplicate analyses, one leaf and one root sample both from rye sampled at Feekes stage 2. For DIBOA in leaves, the relative standard deviation (RSD) was 0.08 [relative percent difference (RPD) of 12%], for BOA in the leaves the RSD was 0.22 (RPD 30%), and for root it was 0.47 (RPD 67%), and for MBOA in the root sample the RSD value was 0.19 (RPD 27%). Based on these routine tests, the overall precision of the analyses during processing of the samples was considered acceptable, e.g., <0.25, except for BOA in roots, which may have been caused by the relatively low concentration of this compound in these samples. Precision of the general method was also tested by using spike recovery experiments, where triplicate sample sets were analyzed on high (average of 120× background), low (average of 40× background), and nonspiked materials (concentrations ranged from 0.8 to 500 μg/g dry wt). There did not appear to be any effect of concentration on the precision of these results, which allowed all replicates to be averaged. Thus, the respective

average RSD values for the analytes measured by this method were as follows: 0.18, 0.12, 0.07, 0.10, 0.04, and 0.03 for DIMBOA glucose, DIMBOA, MBOA, DIBOA glucose, DIBOA, and BOA, respectively (Table 2).

Spike recovery tests with Feekes stage 2 material revealed that all compounds were recovered at or greater than 60% (Table 2). The glucose-substituted forms of the hydroxamic acids were consistently low (60% ± 2.1 to 3.6% standard error, respectively, for DIBOA-G or DIMBOA-G compared to 102–125% for the other nonglucose-substituted compounds). Because of the low and consistent recovery of the two glucose-substituted forms, there could be a small amount of matrix suppression occurring here. This type of interaction is not uncommon when using the electrospray interface (Reemtsma, 2001). These matrix effects need to be assessed, especially when working with more contaminated extracts, such as were encountered in these analyses. Methods to correct for these effects include standard additions or passing the crude extracts through solid-phase cleanup cartridges, e.g., C-18 cartridges (Bonnington et al., 2003a; Schmitz-Afonso et al., 2003). The ideal method to compensate for possible matrix effects with these methods is to use isotope dilution methods utilizing labeled standards that behave exactly as the unlabeled materials. Even though they coelute with the natural material, each can be separately identified and distinguished because of unique molecular weights. Unfortunately, such isotopes are sparingly available and often require costly and time-consuming custom synthesis.

Whereas most current LC/UV methods require several steps to isolate the hydroxamic acid and related products, i.e., aqueous-phase extractions followed by organic solvent extractions of the aqueous phase and final solvent exchanges and filtration (Gutierrez et al., 1982; Lyons et al., 1988; Yenish et al., 1995; Melanson et al., 1997), our method requires a simple aqueous phase extraction, filtration, and analysis. Niemeyer et al. (1989) successfully employed a similar preparation procedure using LC/UV detection (263 nm) to analyze DIBOA and DIMBOA in wheat and rye tissues. Aside from some graphical data on spike performance, recoveries near 100%, and what appears to be low standard deviation of their replicated spikes, there was little additional detail on method performance. The authors made no mention of detecting any benxozalonones (BOA and MBOA) in their extracts.

Our studies had one drawback, namely, that crude extracts have limited shelf lives and must be analyzed within 1 d of preparation or the HA and MHA compounds appear to degrade. If longer holding times are necessary, then organic solvent extractions could be employed or additional studies might be needed. There appeared to be some minor matrix effects with the most contaminated extracts; however, cleanup of these extracts did not appear to be necessary because accurate quantitative and qualitative determinations were possible.

Detection limits were better than have been reported by others (Table 2), with the exception of the Bonnington et al. (2003a), who also employed LC/ESI/MS-MS methods. Their limit of detection values (μg/g dry wt) varied from 0.1 to 1.1, whereas our values ranged from 0.1 to 0.7 for the same analytes. Lyons et al. (1988) reported detection limits with their method, HPLC with UV detection (λ = 280 nm), in terms of lowest standard injected for DIMBOA-G and DIMBOA of 0.2 nmol (2.2 ppm DIMBOA and 3.8 ppm DIMBOA-G). Comparing this to our lowest standard of 0.056 ppm that was injected in 10 μl, our detection range was >39 times and >140 times lower for DIMBOA and DIMBOA-G, respectively. Using the LOD values in Table 2, our detection limits were >314 times lower than those of Lyons et al. (1988). Using their method for calculating limits of detection, our values computed to range from 0.7 to 2.8 pmol. Woodward et al. (1979a) used a GC/flame ionization detection (FID) method for DIMBOA and DIBOA and reported detection limits for 10 μl injections of 0.02 and 0.05 nmol for DIBOA and DIMBOA, respectively. Their analytical variation was expressed as a standard error of 2% of the mean, and their recoveries were 106% and 78% for DIMBOA-G and DIMBOA, respectively. Their standard error values for precision on five replicates were 434 ± 13 and 1,066 ± 19 for DIMBOA-G and DIMBOA, respectively, in corn that would correspond to RSD values of 0.067 and 0.040, respectively, for DIMBOA-G and DIMBOA. Gutierrez et al. (1982) also used HPLC-UV for quantification of DIMBOA and MBOA in corn extracts and reported recoveries of 104 ± 2% for DIMBOA and 106 ± 3% for MBOA. The variability values were not clearly defined and they did not provide detection limit data.

Qualitative identification of the different analytes is vastly improved using LC/MS methods *versus* non-MS methods discussed above, e.g., LC/UV and GC/FID. Cambier et al. (2000) utilized LC/MS for qualitative and semi-quantative analysis of the glucosylated forms of DIMBOA in corn tissues. They chose to use atmospheric pressure chemical ionization methods (APCI) rather than the electrospray ionization methods utilized here. Their investigation did demonstrate the utility of LC/MS for better characterizing the family of compounds comprising the benzoxazinone group. Bonnington et al. (2003a) conducted a more detailed study using LC/MS. Their LC/ESI/MS-MS methods differed from ours in that they conducted their acquisition in negative ionization mode *versus* the positive electrospray ionization method used here. Under negative ionization methods, the analytes produce different characteristic ions than in positive mode. For their method, more fragment ions were produced and quasi-molecular ions near the molecular weights were seldom detected. This apparently limited the choices of ion transition pairs that Bonnington et al. (2003a) selected for their quantitation parameters. Thus, they used identical daughter ions for three analyte pairs and, in two cases, the parent-to-daughter transition ion pairs were the same for two different compounds (DIMBOA and

MBOA). All of this limited the selectivity of their method, especially when compared to ours where none of the transition pairs were the same and in most cases (4 out of 6) the parent ion was the quasi-molecular $[M\text{-}H]^+$or $[M\text{-}H]^-$ form for the compound's molecular weight (Table 1). DIBOA was one of the compounds whose quasi-molecular parent ion was different, e.g., 18 mass units lower than its molecular weight; this suggests an initial loss of water from the molecule prior to formation of the MH^+ parent. The daughter mass for this pair was 80 *m*/*z*, which was also identified by Bonnington et al. (2003b). These authors also described many of the other transition ions observed here, excluding the glucosylated compounds. The DIMBOA glucose parent ion had a mass 7 units higher than its molecular weight. A possible explanation for this would be the formation of a sodium adduct of the glycosylated DIMBOA after loss of oxygen. While most sodium adduct molecules are stable to further breakdown, it has been observed that some sodium adducts of glucose-substituted molecules are susceptible to loss of the aglycones under collision induced fragmentation (Tolonen, 2003). Loss of the aglycone (162 *m*/*z*) seems the best explanation for the 282 *m*/*z* daughter fragment observed here, Table 1.

Two additional allelopathic compounds of lower activity, β-phenylactic acid and β-hydroxybutyric acid (Shilling et al., 1986), were also searched for in the rye extracts. However, consistent levels were not detected and the data are not presented. The absence of these compounds may have been caused by degradation during the 24-hr period of incubation of the crude extracts where myrosinase activity was allowed to proceed in order to convert the glucosides to their respective aglycones.

The levels of various hydroxamic acid (HA) and methoxy hydroxamic acid (MHA) compounds (Table 3) are similar to those reported by other researchers for rye. Niemeyer et al. (1989) reported fresh weight data that, if expressed on a dry weight basis, would have ranged from approximately 7,000 to 550 ppm. Several cultivars of rye were tested by Burgos et al. (1999) in which levels of BOA ranged from 18 to 229 μg/g dry wt and those of DIBOA ranged from 127 to 1,469 μg/g dry wt. The highest levels measured in our study were 287 μg/g DIBOA, 155 μg/g MBOA, and 114 μg/g BOA (Table 3). MBOA was highest in root tissues and DIBOA and BOA were higher in above ground tissues. Few researchers have reported concentrations for MBOA in rye. Hofman and Hofmanová (1969) were perhaps the first to mention that this methoxy-substituted form was present in rye. Their statement was that it was in "minute amounts." In our study, the nonglucose-substituted forms predominated when the tissues were younger, but by May, the glucose-substituted forms became more predominant, particularly in root tissue (Table 3). Appearance of these glucose-substituted forms could indicate that the enzymatic cleavage of the glucose moiety was not as efficient in these sample

preparations as it was in extracts of younger tissue. Paired comparisons of extraction results using our aqueous extraction methods *versus* use of organic solvents as has been utilized by other researchers (Lyons et al., 1988; Burgos et al., 1999) might have permitted more HA and MHA compounds to be recovered; however, measuring the levels in the aqueous extracts, as we have done here, was more relevant to the bioassay exposures that was the primary intent of the method.

Some of the important advantages in using our method include: the ease and speed at producing extracts for analysis, e.g., aqueous extraction, followed by filtration and the low detection limits possible, e.g., at least an order of magnitude lower than conventional detection methods, and the certainty of compound identification, since molecular mass identification is part of the detection method. While the detection levels are much lower than may be currently needed to associate concentration with allelopathic activities, following the fate of these compounds in the environment and in their biogenesis in plant tissues clearly becomes easier with these lower detection limits.

Bioassay Observations. Lettuce root growth was the most sensitive assay for phytotoxicity studies. Averaged over all factors, lettuce root length was inhibited by 49% by rye extracts, tomato root length was inhibited by 19%, and none of the other assays using hypocotyl length or germination showed inhibition greater than 10%. Averaged over all factors for both species, hypocotyl length was inhibited by 9%, and germination was the least sensitive assay of all, being inhibited by 4%. These results confirm previous results showing that lettuce root growth is a sensitive indicator of phytotoxic activity (Barnes and Putnam, 1986; Burgos and Talbert, 2000). Our results also confirm previous research showing that root growth is more sensitive than hypocotyl growth (Burgos and Talbert, 2000). Subsequent discussion of our results will focus on the lettuce and tomato root length assays. Similar results were obtained using other assays, but were less pronounced because of the relative insensitivity of these assays.

Across all proportions, extracts from rye shoot tissue were more phytotoxic than extracts from rye root tissue using either the lettuce or tomato root length assays (Figure 1). Barnes and Putnam (1986) also showed that rye shoots were more phytotoxic than rye roots. Lettuce was more sensitive than tomato to both rye shoot and root extracts. Tomato responses to extracts were insufficient to adequately fit the dose–response model and determine an I_{50} value; consequently, subsequent analyses of the influence of sampling date will be presented for the lettuce assay only.

Extracts of rye root and shoot tissue that were sampled at selected dates in the spring and fall differed in their phytotoxicity to lettuce root length (Figure 2). The dose–response model c parameter represents the proportion of

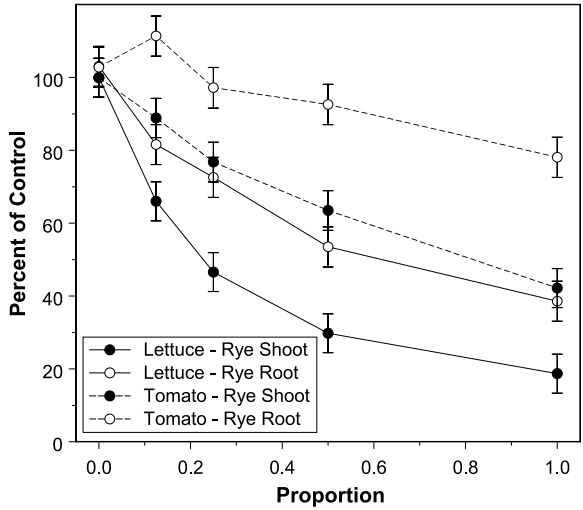

FIG. 1. Lettuce and tomato root length in response to proportions of full-strength extracts of rye shoot or root tissue averaged over spring sampling dates. Error bars represent the standard error (SE) of the mean.

full-strength extract required to inhibit lettuce root length by 50% (I_{50}). The I_{50} values were lowest (indicating the highest level of phytotoxicity) for both rye shoot and root tissue harvested in November, followed by that harvested in April (Table 4). There was not a clear decline in phytotoxicity with age of tissue

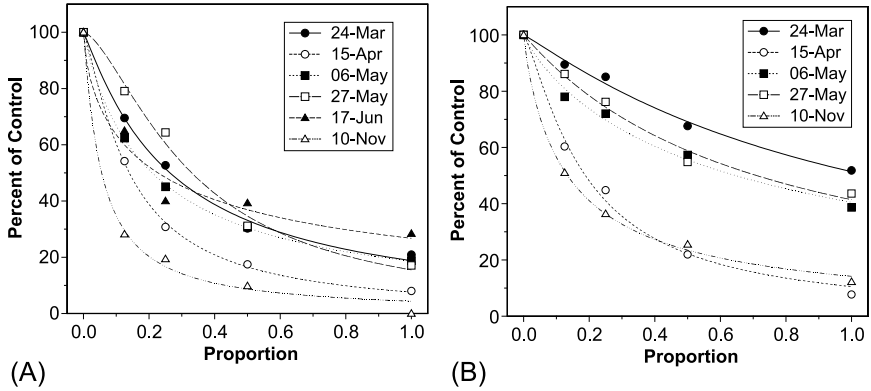

FIG. 2. Lettuce root length in response to proportions of full-strength extracts of rye shoot tissue (A) and rye root tissue (B) harvested at various sampling dates. Model parameters are presented in Table 2.

TABLE 4. DOSE–RESPONSE MODELS[a] OF LETTUCE ROOT LENGTH IN RESPONSE TO RYE SHOOT AND ROOT EXTRACTS

Rye tissue	Date	c (I_{50})	b	R^2
Shoot	10 Nov.	0.055 d	1.068 abc	0.78
	24 Mar.	0.264 b	1.100 b	0.82
	15 Apr.	0.140 c	1.267 ab	0.91
	6 May	0.210 b	0.944 bc	0.81
	27 May	0.330 a	1.531 a	0.90
	17 Jun.	0.227 b	0.679 c	0.58
Root	10 Nov.	0.134 d	0.895 b	0.88
	24 Mar.	1.053 a	1.084 ab	0.59
	15 Apr.	0.188 c	1.280 a	0.91
	6 May	0.645 b	0.880 b	0.82
	27 May	0.710 ab	1.017 ab	0.86
	17 Jun.	–	–	–

[a] Parameters c and b are from the model $Y = 100/(1 + (X/c)^b)$, where Y is percent of control and X is proportion of extract. Parameter c represents the proportion of the full-strength extract required to inhibit lettuce root length by 50 percent (I_{50}). All regression models were significant ($P < 0.0001$). Parameters within columns and rye tissue followed by the same letter were not significantly different according to 95% confidence limits.

during the spring months because shoot tissue sampled on March 24, May 6, and June 17 had similar I_{50} values, and root tissue sampled on May 27 had a similar I_{50} value to that sampled on March 24 and May 6.

The model b parameter defines the steepness of slope around the c parameter. A comparison was conducted between the model fitted with a common b parameter for all dates *versus* a model with separate b parameters for each date (Seefeldt et al., 1995). F values for these comparisons were significant for rye shoot extracts ($F = 8.31$, $P < 0.01$) and for rye root extracts ($F = 2.77$, $P < 0.05$), indicating that separate b parameters were required for each date. Comparison of 95% confidence intervals also indicated that b parameters differed between sampling dates (Table 2). The lack of equivalence among these steepness parameters indicates a lack of parallelism among models that suggests different modes of action may have occurred among extracts derived from different aged rye tissue (Streibig et al., 1993). The models also indicate that the b parameters did not follow any clear pattern relative to the age of tissue (Table 2). This result suggests that different compounds were probably responsible for the toxicity of extracts from different aged tissue.

Extracts of rye upper leaf tissue harvested on May 27 were more phytotoxic to lettuce and tomato root length than extracts of lower leaf or stem tissue at extract proportions of 0.5–1.0 (Figure 3). Extracts of lower leaf tissue, which was senescing at the time of harvest, varied in toxicity, exhibiting activity

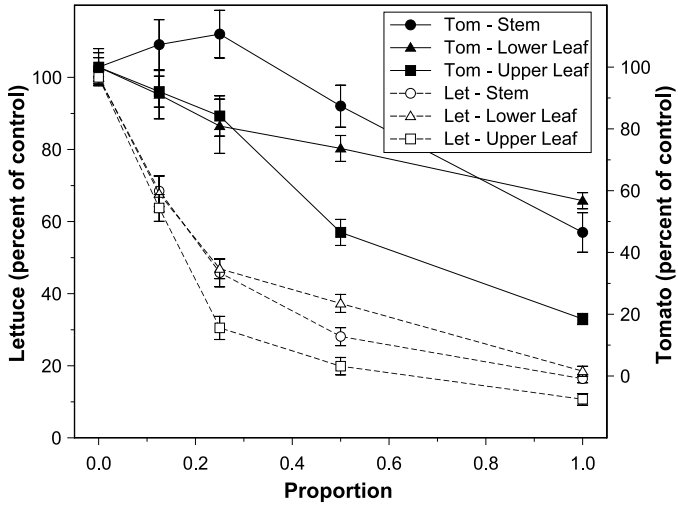

FIG. 3. Lettuce (Let) and tomato (Tom) root length response to extracts of stem, lower leaf, and upper leaf tissue of rye harvested on May 27, 2003. Error bars represent the standard error (SE) of the mean.

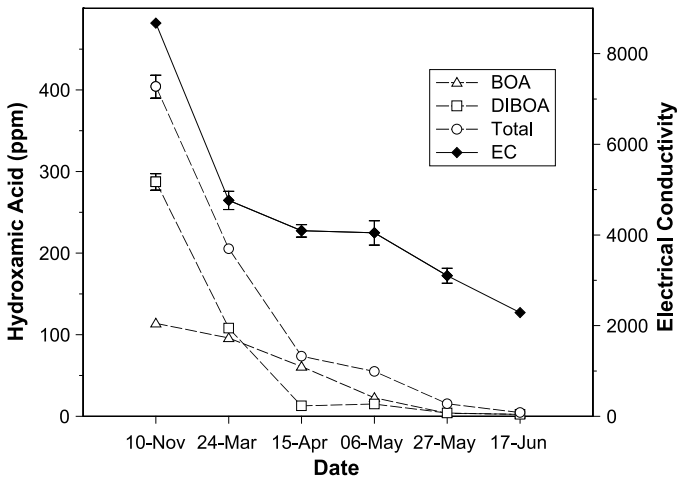

FIG. 4. Total hydroxamic acid, BOA, and DIBOA concentration and electrical conductivity (EC) of rye shoot tissue harvested at various dates. Error bars represent the standard deviation (SD).

greater than that of stem tissue in some cases, but not in others. These data suggest that more actively growing tissue tended to have the more phytotoxic extracts.

Total hydroxamic acid, DIBOA, and BOA as well as electrical conductivity were highest in rye shoot tissue at the earliest growth stage in November and declined as tissue aged through the spring (Figure 4). All of these measurements were highly correlated. Correlation coefficients between BOA and DIBOA were 0.84; between BOA and DIBOA with total hydroxamic acids they were 0.91 and 0.99, respectively; and between BOA, DIBOA, and total hydroxamic acids with electrical conductivity they were 0.86, 0.96, and 0.97, respectively. These high correlations suggest that it would be difficult to determine which hydroxamic acids may have contributed to the phytoxicity of these extracts, or whether other ionic compounds that contributed to electrical conductivity may also have been involved. The phytotoxicity of extracts did not follow a similar steady decline over time (Table 2) as that of the compounds in Figure 4. Correlations between phytoxicity as determined by I_{50} values and either the prominent hydroxamic acids, their totals, or electrical conductivity were not significant for rye shoot or root tissue. Burgos et al. (1999) also reported a low correlation between phytoxicity and HA content. These results suggest that compounds other than hydroxamic acids contributed to phytoxicity. DIBOA has been shown to be more phytotoxic than BOA (Barnes et al., 1987; Burgos and Talbert, 2000) and to be capable of inhibiting lettuce root growth at the concentrations observed in our November and March extracts (Burgos and Talbert, 2000). Thus, hydroxamic acids probably contributed to the phytoxicity of tissue sampled at early growth stages, but had minimal contribution at later harvest dates when tissue concentrations dropped to low levels.

Acknowledgments—Dr. Park's sabbatical at the USDA-ARS Sustainable Agricultural Systems Laboratory was supported by a grant from Cheju National University. We also acknowledge Jim Oliver, USDA-ARS – Chemicals Affecting Insect Behavior Lab (CAIBL), for his kind assistance to Frédérick Adam in synthesizing DIBOA and DIBOA-G; Jerry Klun, USDA-ARS-CAIBL, for providing DIMBOA-G and DIMBOA; and Peter Ewashkow for technical assistance conducting bioassays.

RELATIONSHIPS BETWEEN PHENOLIC ACID CONCENTRATIONS, TRANSPIRATION, WATER UTILIZATION, LEAF AREA EXPANSION, AND UPTAKE OF PHENOLIC ACIDS: NUTRIENT CULTURE STUDIES

UDO BLUM[1,*] and THOMAS M. GERIG[2]

[1]*Department of Botany, North Carolina State University, Raleigh, NC 27695, USA*
[2]*Department of Statistics, North Carolina State University, Raleigh, NC 27695, USA*

(Received June 7, 2004; revised January 28, 2005; accepted April 8, 2005)

Abstract—Phenolic acid treatments of cucumber seedlings (*Cucumis sativus* cv "Early Green Cluster") inhibited transpiration, water utilization, leaf area, and absolute and relative rates of leaf expansion. The cinnamic acids, ferulic and *p*-coumaric acids, were two to five times more inhibitory than the benzoic acids, *p*-hydroxybenzoic acid and vanillic acid. When phenolic acid concentrations were maintained at inhibitory concentrations through multiple successive treatments, percent inhibition of water utilization remained relatively constant for a given concentration and phenolic acid, percent inhibition of leaf area initially increased and then leveled off to a constant percent, and percent inhibition of transpiration and rates of leaf area expansion declined over time. Subsequently, *p*-coumaric acid was chosen as the model compound for further study. When *p*-coumaric acid was inhibitory, percent inhibition of transpiration, water utilization, and rates of leaf area expansion of actively growing leaves rapidly declined (i.e., was lost) as *p*-coumaric acid concentrations surrounding roots decreased. Absolute and relative rates of leaf expansion, for example, declined approximately 12 and 14%, respectively, for every 0.1 mM decline in *p*-coumaric acid concentration. Uptake of *p*-coumaric acid by cucumber seedling roots was continuous over the 24- or 36-hr periods monitored, but was not consistently related to the initial *p*-coumaric acid treatment concentrations. However, declining *p*-coumaric acid concentrations monitored at 6- or 12-hr intervals over the 24- or 36-hr periods continued to be highly correlated to the initial *p*-coumaric acid treatment concentrations. A 25% depletion by 13-d-old cucumber seedlings took 8.5, 12, 19.5, 25, and 29.5 hr for 0.125-, 0.25-, 0.5-, 0.75-,

* To whom correspondence should be addressed. E-mail: udo_blum@ncsu.edu

and 1-mM treatments, respectively. Uptake during periods when phenolic acid concentrations and root uptake (depletion from solution) were related appeared to represent periods dominated by apoplastic movement into the intercellular spaces of roots. Uptake during periods without this relationship likely represented periods dominated by symplastic movement. The ability of cucumber seedlings to modify active phenolic acid concentrations surrounding their roots suggests that cucumber seedling can directly influence the magnitude of primary and secondary effects of phenolic acids through feedback regulation.

Key Words—Absolute and relative rates of leaf expansion, feedback regulation, inhibition, phenolic acids, phenolic acid depletion and uptake, recovery, transpiration, water utilization.

INTRODUCTION

Root membranes are a primary site of action for phenolic acids. Contact of phenolic acids with root cell membrane leads to depolarization, an efflux of ions, and a reduction of hydraulic conductivity and net nutrient uptake (Glass, 1973, 1974; Einhellig, 1986, 1995; Lyu and Blum, 1990; Bergmark et al., 1992; Booker et al., 1992; Baziramakenga et al., 1995; Lehman and Blum, 1999). Subsequent resulting changes in plant water relations and mineral nutrition lead to a cascade of secondary, tertiary, etc. effects, frequently referred to as secondary effects. Included among these are reductions in photosynthesis (Einhellig et al., 1970; Patterson, 1981), carbon allocation to roots (Blum and Rebbeck, 1989), leaf expansion (Blum and Dalton, 1985), transpiration (Blum et al., 1985a), increases in abscisic acid (Hollapa and Blum, 1991), and closure of stomata (Einhellig and Kuan, 1971; Patterson, 1981). The intensity and duration of primary and secondary effects are dependent on species sensitivity and the continued presence of active phenolic acid concentrations surrounding roots (Einhellig and Kuan, 1971; Glass and Dunlop, 1974; Blum and Dalton, 1985; Blum et al., 1985a, b; Blum and Rebbeck, 1989; Lehman and Blum, 1999). Soil solution concentrations of active phenolic acids are a function of the inputs of phenolic acids (e.g., leaching of plant materials, microbial activity, root secretions and exudations, and root cell autolysis; see Rice, 1984), losses of phenolic acids (e.g., sorption by soil particles, microbial utilization, uptake by roots; see Siqueira et al., 1991; Blum et al., 1999a, b), state of protonation (see Blum et al., 1985b, 1999b), and soil water content. Because seedlings can regulate transpiration rates and thus soil moisture, take up and detoxify phenolic acids, regulate phenolic acid utilizing microbes in the rhizosphere, and increase or decrease protonation of phenolic acids (pK_a approximately 4.5) through adjustments of rhizopshere and solution pH (Shann and Blum, 1987a, b; Blum et al., 1985b, 1999b; Blum, 2004), seedlings should also have the capability to

self-regulate the degree of expression of both primary and secondary effects of phenolic acids. In summary, phenolic acids affect seedling processes of sensitive species. Affected and unaffected seedling processes in turn reduce the active concentrations of phenolic acids surrounding their roots, and the resulting changes in active concentrations of phenolic acids surrounding roots lead to feedback regulation of or a decline in the effects. Feedback regulation is defined as a response in which the product of one of the final steps in a chain of events affects one of the first steps in this chain; fluctuations in rate or concentration are minimized with negative feedback or amplified with positive feedback (Lambers et al., 1998).

To explore the relationships between phenolic acid concentrations surrounding roots and transpiration, water utilization, phenolic acid uptake, and leaf area expansion, and as a first step towards understanding the role of seedling-induced feedback regulation, we experimentally addressed the following questions by using a cucumber seedling–nutrient culture system:

- How do phenolic acids affect transpiration, water utilization, and leaf area expansion?
- How do phenolic acid concentrations influence phenolic acid depletion from solutions surrounding roots?
- How does depletion of phenolic acid from solution surrounding roots influence transpiration, water uptake, and leaf area expansion?

METHODS AND MATERIALS

Experimental Designs. Experiment 1: Four phenolic acids (ferulic, *p*-coumaric, *p*-hydroxybenzoic, and vanillic acids); five concentrations (0, 0.25, 0.5, 0.75, and 1 mM); 8 AM phenolic acid treatment on 3 d (d 6, 8, and 10); four replicates; data collection: 8 AM and/or 5 PM on d 8–12; and final harvest on d 12. Experiment 2a: 1 Phenolic acid (*p*-coumaric acid); five concentrations (0.125, 0.25, 0.5, 0.75, and 1 mM); 8 AM phenolic acid treatment on d 13; four replicates; data collection: 8 AM, 2 PM, 8 PM, and/or 8 AM; and final harvest on d 14. Experiment 2b: 1 Phenolic acid (*p*-coumaric acid); five concentrations (0.125, 0.25, 0.5, 0.75, and 1 mM); 8 PM Phenolic acid treatment on d 14; three replicates; data collection: 8 PM, 8 AM, 2 PM, and/or 8 PM; and final harvest on d 15. Experiment 3: 1 Phenolic acid (*p*-coumaric acid); four concentrations (0, 0.125, 0.25, and 0.5 mM); 8 AM phenolic acid treatment on d 12; two solution changes (no change or every 4 hr over 36 hr); four replicates; data collection: 8 AM, 8 PM, 8 AM, and/or 8 PM; and final harvest on d 13. Experiment 4: 1 Phenolic acid (*p*-coumaric acid); two concentrations (0 and 0.5 mM); 8 AM phenolic acid treatment on d 12; three nutrient strengths (0.5, 1,

and 1.5); two aeration (plus or minus); four replicates; data collection: 8 AM, 8 PM, 8 AM, and/or 8 PM; and final harvest on d 13.

Nutrient Culture System. Cucumber seeds (*Cucumis sativus* cv. "Early Green Clusters," Wyatt Quarles Seed Company, Raleigh, NC, USA) were germinated for 2 d in the dark at 30°C in glass trays containing moist vermiculite. The resulting exposed hypocotyls were placed under a fluorescent light bank [cool white, 12-hr photoperiod (8 AM to 8 PM), 140 $\mu E/m^2/sec$] for 2 d to allow for the development of autotrophic seedlings. Resulting seedlings were transplanted into glass jars containing 110 ml Hoagland's solution (Hoagland and Arnon, 1950). The pH of all solutions was adjusted to 5.0 with sodium hydroxide. Seedlings were suspended by foam collars inserted through holes in the lids of the jar. Jars were inserted through holes in a wooden panel located under a light bank to protect the solutions from light. With the exception of treatment periods for experiments 3 and 4, solutions were completely changed every other day. Distilled water was added to jars daily at 8 AM as needed to compensate for water utilization for experiment 1 and for pretreatment seedling development of all other experiments. Water was not added during the 24- or 36-hr treatment periods for experiments 2–4. Light banks were located on laboratory benches. For additional details, see Blum and Dalton (1985).

Dry Weight, Leaf Area, and Absolute and Relative Rates of Leaf Expansion. Dry weights of tops and roots were based on oven-dried samples (100°C). Leaf areas were determined from leaf length (L) and width (W) measurements and the following equation: leaf area in $cm^2 = -1.457 + 0.008 (L \times W)$, $P < 0.001$, $r^2 = 0.98$, where L and W are in mm (Blum and Dalton, 1985). Surface areas for cotyledons were determined by measuring cotyledon length (L) and width (W) and the following equation: area of cotyledon in $cm^2 = 1.293 + 0.006 (L \times W)$, $P < 0.001$, $r^2 = 0.76$, where L and W are in mm. The absolute rates of leaf expansion (cm^2/seedling/unit time) for the cotyledons and/or true leaves were determined as follows: leaf area at $time_{x+1}$ − leaf area at $time_x$. The relative rates of leaf expansion (cm^2/cm^2/unit time) were determined as follows: ln (leaf area at $time_{x+1}$) − ln (leaf area at $time_x$). For a discussion on calculating growth rates, see Radford (1967).

Transpiration and Water Utilization. Transpiration (ml/cm^2 leaf area/hr) and water utilization (ml/seedling/hr) were determined by solution depletion over various time intervals. Volumes of solution in the jars at a given time were determined by the following regression: ml in jar = −10.549 + (1.523 × solution level), $P < 0.001$, $r^2 = 0.99$, where solution level in jar is in mm.

Depletion of Phenolic Acid from Nutrient Culture. One-milliliter subsamples were taken at various times from the treatment jars; the subsamples were filter sterilized with 2-μm filters (Supor −200, Gelman Sciences, Ann Arbor, MI, USA) before being injected into a high-performance liquid chromatograph (HPLC) to determine the amounts of phenolic acid in the sub-

samples (Blum et al., 1994). Total phenolic acid in jars and depletion of phenolic acid over time from jars were based on the HPLC data and the solution levels in the jar. Depletion of phenolic acid from jars was assumed to represent total uptake of phenolic acid by the cucumber seedling roots. Depletion associated with microbial utilization was not determined; however, HPLC-detectable breakdown products of *p*-coumaric acid were determined for experiment 4. Individual breakdown products were not identified. Breakdown products were quantified as *p*-coumaric acid equivalence.

Data Analysis. The data were analyzed using SAS© system (SAS Institute Inc., 1999) primarily employing procedures SAS/GLM, SAS/MIXED, and SAS/NLIN procedures. For each data set, models were developed with the joint goals of providing a parsimonious explanation of the data while maintaining maximum predictive power. Initial model screening and the computation of the r^2 statistic were handled using procedure SAS/GLM. However, for many of the analyses, the data contained observations on the same unit measured repeatedly over time. This created a violation of the assumptions for standard analysis of variance and the need to use methodology for handling linear models with repeated measures. The tool used in this case was the SAS/MIXED procedure (Littell et al., 1996). In one set of analyses, the models employed used the concept of relative potency of a compound relative to a standard. In this case, the resulting models were nonlinear and required use of procedure SAS/NLIN.

RESULTS

How Do Multiple Treatments of Phenolic Acids Affect Transpiration, Water Utilization, and Leaf Area Expansion?

Effects of Phenolic Acids. Seedlings treated with the cinnamic acid derivatives, ferulic acid and *p*-coumaric acid, had lower overall mean transpiration rates, water utilization, leaf areas, absolute and relative rates of leaf expansion, and shoot and root dry weights than the seedlings treated with the benzoic acid derivatives, *p*-hydroxybenzoic acid and vanillic acid (Table 1). Relative potencies for the phenolic acids expressed in terms of ferulic acid (1.00) ranged from 0.76 to 1.00, 0.10 to 0.33, and 0.03 to 0.42 for *p*-coumaric acid, *p*-hydroxybenzoic acid, and vanillic acid, respectively (Table 1). As treatment phenolic acid concentrations were increased, overall mean transpiration rates, water utilization, leaf areas, absolute and relative rates of leaf expansion, and shoot and root dry weights declined in a quadratic (concave up) or linear manner (Table 1). For comparative purposes, utilizing the models of Table 1, 0.5 mM of the cinnamic acids (ferulic acid and *p*-coumaric acid) and the benzoic acids

[a] Where transpiration, water utilization, leaf area, absolute and relative rates of leaf expansion, and dry weights on a given day = Intercept for a given day + (linear coefficient for a given day × [concentration × relative potency of phenolic acid of interest]) + (quadratic coefficient for a given day × [concentration^2 × relative potency^2 of phenolic acid of interest]); transpiration and water utilization were based on water depletion during each 8 AM to 5 PM time period; leaf areas were determined at 8 AM on each day.

[b] Standard errors in parenthesis.

[c] Where FER = ferulic acid, PCO = *p*-coumaric acid, POH = *p*-hydroxybenzoic acid, and VAN = vanillic acid; concentrations ranged from 0 to 1 mM; phenolic acid treatments were given on d 6, 8, and 10.

(*p*-hydroxybenzoic acid and vanillic acid) inhibited transpiration by 36 and 15%, water utilization by 65 and 25%, leaf area by 42 and 16%, absolute rate of leaf expansion by 62 and 22%, and relative rate of leaf expansion by 32 and 8%, respectively. On d 12, shoot dry weight was inhibited by 46 and 20%, and root dry weight was inhibited by 27 and 5%, respectively.

Patterns of Percent Inhibition. With the exception of relative rates of leaf expansion, the relationships of the inhibitory effects for the four phenolic acids on transpiration, water utilization, leaf area, and absolute and relative rates of leaf expansion were fairly similar over concentration and time. The magnitude of inhibition, however, varied with phenolic acid, concentration, and time. The three-way interaction of phenolic acid × time × concentration was significant only for relative rates of leaf expansion. Because both cinnamic acid derivatives, ferulic acid and *p*-coumaric acid, reduced transpiration, water utilization, and leaf expansion of seedlings considerably more than the benzoic acid derivatives, *p*-hydroxybenzoic acid and vanillic acid, in nutrient culture (see relative potencies; Table 1) and *p*-coumaric acid was more inhibitory than ferulic acid in Cecil Ap horizon-soil culture (unpublished data) used in a subsequent study, we present only the patterns for *p*-coumaric acid (Figure 1). Percent inhibitions in Figure 1 were derived from the models of Table 1. For all but water utilization and leaf area, the levels of percent inhibition were greatest after the first *p*-coumaric acid treatment and then declined at various rates over time (Figure 1). Percent inhibition of water utilization was essentially constant over time. Percent inhibition of leaf area initially increased and then leveled off to a constant percent. A dramatic decline in percent inhibition occurred for relative rates of leaf expansion. In fact, relative rates of leaf expansion averaged over concentrations (0.25–1 mM) were significantly different from the control seedlings only for d 8 and 9, and d 9 and 10.

How Does a Single Treatment of p-Coumaric Acid Affect Transpiration, Water Utilization, and Leaf Area Expansion? How Do Concentrations of p-Coumaric Acid Influence p-Coumaric Acid Depletion from Solutions Surrounding Roots?

Experiment 2a (8 AM Treatment). As treatment concentrations of *p*-coumaric acid increased, transpiration and water utilization declined in a linear manner for morning, afternoon, day, night, and 24-hr period (Table 2). For comparative purposes utilizing the models of Table 2, 0.5 mM *p*-coumaric acid reductions ranged from 37 to 41% for transpiration and from 38 to 47% for water utilization. Average leaf area and absolute and relative rates of leaf expansion of 13-d-old cucumber seedlings declined in a linear and quadratic manner (concave up), respectively, as *p*-coumaric acid treatment concentrations were increased (Table 2). For comparative purposes utilizing the models of Table 2, 0.5 mM *p*-coumaric acid significantly reduced average leaf area and absolute and relative rates of leaf expansion of seedlings by 6, 71, and 69%, respectively.

Uptake of *p*-coumaric acid (mM/g root/hr) by seedlings was based on the depletion of *p*-coumaric acid from the nutrient solution and thus may include some microbial utilization of *p*-coumaric acid. The models relating to uptake

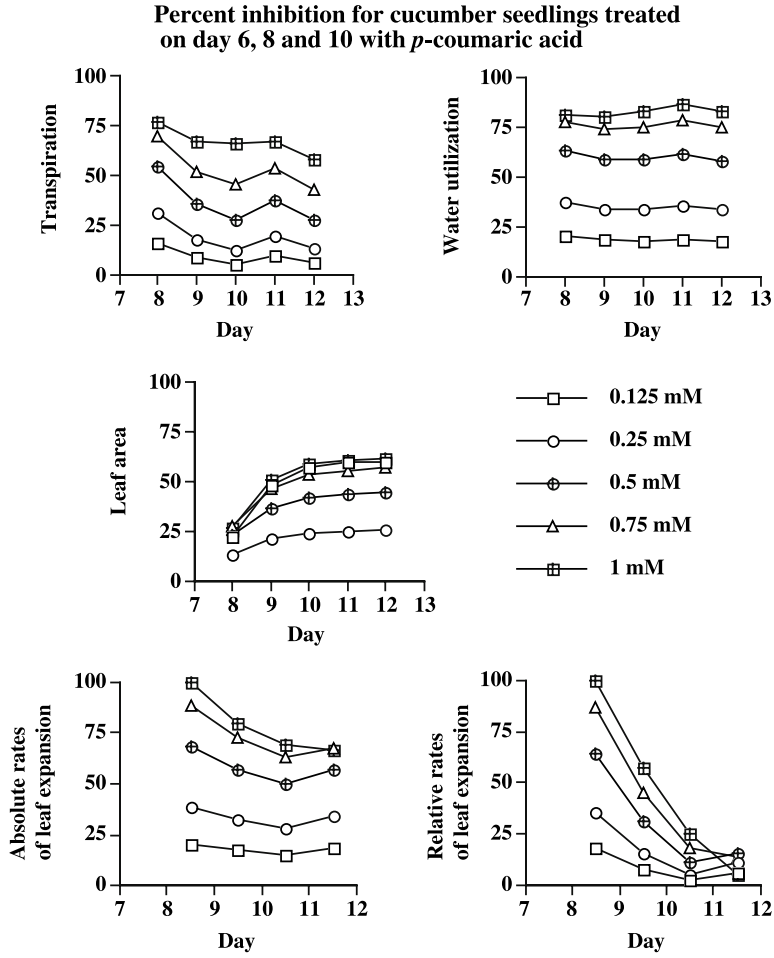

FIG. 1. Percent inhibition of 0.125 to 1 mM *p*-coumaric acid on cucumber seedling transpiration, water utilization, leaf area, absolute and relative rates of leaf expansion. Seedlings were treated to *p*-coumaric acid on d 6, 8, and 10. Nutrient solutions plus or minus *p*-coumaric acid were completely changed on alternate days starting with d 4.

had relatively low r^2 values indicating the existence of variability not explained by the models (Table 2). Uptake of *p*-coumaric acid increased linearly with increasing initial treatment concentrations of *p*-coumaric acid for the morning, and ranged from 0.013 mM/g root/hr for 0.125 mM to 0.035 mM/g root/hr for 1 mM. The increasing initial treatment concentrations of *p*-coumaric acid

[a] Where transpiration, water utilization, average leaf area, absolute and relative rates of leaf expansion, and *p*-coumaric acid uptake = Intercept + (linear coefficient × *p*-coumaric acid concentration) + (quadratic coefficient × [*p*-coumaric acid concentration]^2); seedlings were treated at 8 AM to concentrations ranging from 0.125 to 1 mM.

[b] Where the time interval for Morning = 8 AM to 2 PM, Afternoon = 2 PM to 8 PM, Day = 8 AM to 8 PM, Night = 8 PM to 8 AM, and 24-hr period = 8 AM to 8 AM.

[c] Standard errors in parenthesis.

were not significantly related to the uptake of *p*-coumaric acid for the afternoon, night, or the 24-hr period. Actual overall mean uptake rates for 0.5 mM *p*-coumaric acid ranged from 0.023 ± 0.002 mM/g root/hr (3.75 mg/g root/hr) for the morning to 0.034 ± 0.006 mM/g root/hr (5.64 mg/g root/hr) for the night. Mean shoot and root dry weight for the seedlings on d 13 were 0.127 ± 0.003 and 0.030 ± 0.0011 g, respectively.

To calculate the uptake rates of the previous section, the mM of *p*-coumaric acid left in the nutrient solution was determined at 0, 6, 12, and 24 hr after addition of *p*-coumaric acid. The mM of *p*-coumaric acid declined in a curvilinear (concave down) manner (Table 3). The intercepts were different, but the linear and quadratic terms were identical for all *p*-coumaric acid concentrations. Initial treatment concentrations of *p*-coumaric acid were highly correlated ($r = 0.98$) with the *p*-coumaric acid concentrations for all time periods monitored. Finally, based on the models of experiment 2a (Table 3), a 25% depletion of *p*-coumaric acid from the nutrient solution by 13-d-old seedling was estimated to take approximately 8.5 hr for the 0.125-mM, 12 hr for the 0.25-mM, 19.5 hr for 0.5-mM, 25 hr for 0.75-mM, and 29.5 hr for the 1-mM treatments. Because the *p*-coumaric acid treatment was terminated after 24 hr, depletion times longer than 24 hr are extrapolated.

Experiment 2b (8 PM Treatment). As treatment concentrations of *p*-coumaric acid increased, transpiration and water utilization declined in a linear manner for night, morning, afternoon, day, and 24-h period (Table 3). For comparative purposes utilizing the models of Table 3, 0.5 mM *p*-coumaric acid reductions ranged from 34 to 46% for transpiration and from 36 to 45% for water utilization. Absolute and relative rates of leaf expansion of cucumber seedlings for night, day, and 24-hr period also declined in a linear manner as

TABLE 3. PARSIMONIOUS MODELS FOR CHANGES IN *p*-COUMARIC ACID SOLUTION CONCENTRATIONS (mM) OVER TIME FOR CUCUMBER SEEDLINGS GROWING IN NUTRIENT CULTURE, EXPERIMENT 2A AND 2B[a]

[a] Where solution concentration = Intercept for a given concentration + (linear coefficient × time) + (quadratic coefficient × time^2), where time is in hours from treatment.
[b] Solution samples were taken a 0, 6, 12, and 24 hr from treatment; treatment was given at 8 AM.
[c] Standard errors in parenthesis.
[d] Solution samples were taken a 0, 12, 18, and 24 hr from treatment; treatment was given at 8 PM.

p-coumaric treatment concentrations were increased. Utilizing the models of Table 3, 0.5 mM *p*-coumaric acid reductions for rates of leaf expansion ranged from 39 to 43%. Average leaf areas of 14- to 15-d-old seedlings, however, were not significantly modified by the *p*-coumaric acid treatment.

As in the previous experiment (experiment 2a), the models relating to uptake had relatively low r^2 values indicating the existence of variability not explained by the models (Table 4). Uptake of *p*-coumaric acid increased linearly with increasing initial treatment concentrations of *p*-coumaric acid for the

[a] Where transpiration, water utilization, absolute and relative rates of leaf expansion, and *p*-coumaric acid uptake = Intercept + (linear coefficient × *p*-coumaric acid concentration); seedlings were treated at 8 PM to concentrations ranging from 0.125 to 1 mM.

[b] Where the time interval for Night = 8 PM to 8 AM, Day = 8 AM to 8 PM, Morning = 8 AM to 2 PM, Afternoon = 2 PM to 8 PM, and 24-hr period = 8 PM to 8 PM.

[c] Standard errors in parenthesis.

night and for the afternoon. Uptake rates during the night ranged from 0.013 mM/g root/hr for 0.125 mM to 0.023 mM/g root/hr for 1 mM, and for the afternoon from 0.019 mM/g root/hr for 0.125 mM to 0.046 mM/g root/hr for 1 mM. The increasing initial concentrations were not significantly related to the uptake of *p*-coumaric acid for the morning period. Actual overall mean uptake rates for 0.5 mM *p*-coumaric acid ranged from 0.022 ± 0.001 mM/g root/hr (3.66 mg/g root/hr) for the night to 0.037 ± 0.009 mM/g root/hr (6.05 mg/g root/hr) for the afternoon. Mean shoot and root dry weight for the seedlings on d 14 were 0.18 ± 0.008 and 0.037 ± 0.002 g, respectively.

To calculate the uptake rates of the previous section, the mM of *p*-coumaric acid left in the nutrient solution was determined at 0, 12, 18, and 24 hr after addition of *p*-coumaric acid. The mM of *p*-coumaric acid declined in a curvilinear (concave down) manner (Table 3). The intercepts were different, but the linear and quadratic terms were identical for all *p*-coumaric acid concentrations. Initial treatment concentrations of *p*-coumaric acid were highly correlated ($r = 0.98$) with the *p*-coumaric acid concentrations for all time periods monitored. Finally, based on the models of experiment 2b (Table 3), a 25% depletion of *p*-coumaric acid from the nutrient solution by 14-d-old seedling was estimated to take approximately 8 hr for the 0.125-mM, 11 hr for the 0.25-mM, 18 hr for 0.5-mM, 23.5 hr for 0.75-mM, and 28.5 hr for the 1-mM treatments. Because the *p*-coumaric acid treatment was terminated after 24 hr, depletion times longer than 24 hr are extrapolated.

How Does Depletion of p-Coumaric Acid from Solutions Surrounding Roots Influence Transpiration, Water Utilization, and Leaf Area Expansion?

Experiment 3. Subsamples taken to determine *p*-coumaric acid concentrations left in the nutrient solution and solution pH for the no-solution change treatment were combined by treatment concentration for each time period. The average *p*-coumaric acid concentrations and percent remaining, in parenthesis, for this treatment were 0.126 mM (100%), 0.254 mM (100%), and 0.492 mM (100%) at 0 hr, 0.059 mM (47%), 0.181 mM (71%), and 0.418 mM (85%) at 12 hr, 0 mM (0%), 0.012 mM (5%), and 0.149 mM (30%) at 24 hr, and 0 mM (0%) at 36 hr for 0.125, 0.25, and 0.5 mM, respectively. The solution pH increased by approximately 1 pH unit from pH 5.00 ± 0.02 at the start of the treatment period to 6.04 ± 0.03 at the end of the 36-hr treatment period (Figure 2).

Subsamples taken to determine *p*-coumaric acid concentrations left in the nutrient solution and solution pH after each 4-hr period were also combined by treatment concentration. The average mM at the end of the 4-hr periods were 0.095, 0.220, and 0.450 for the 0.125-, 0.25-, and 0.5-mM treatment solutions, respectively. The actual starting solution concentrations in this instance were 0.128, 0.256, and 0.497 mM. The mean reductions over the 4-hr periods were

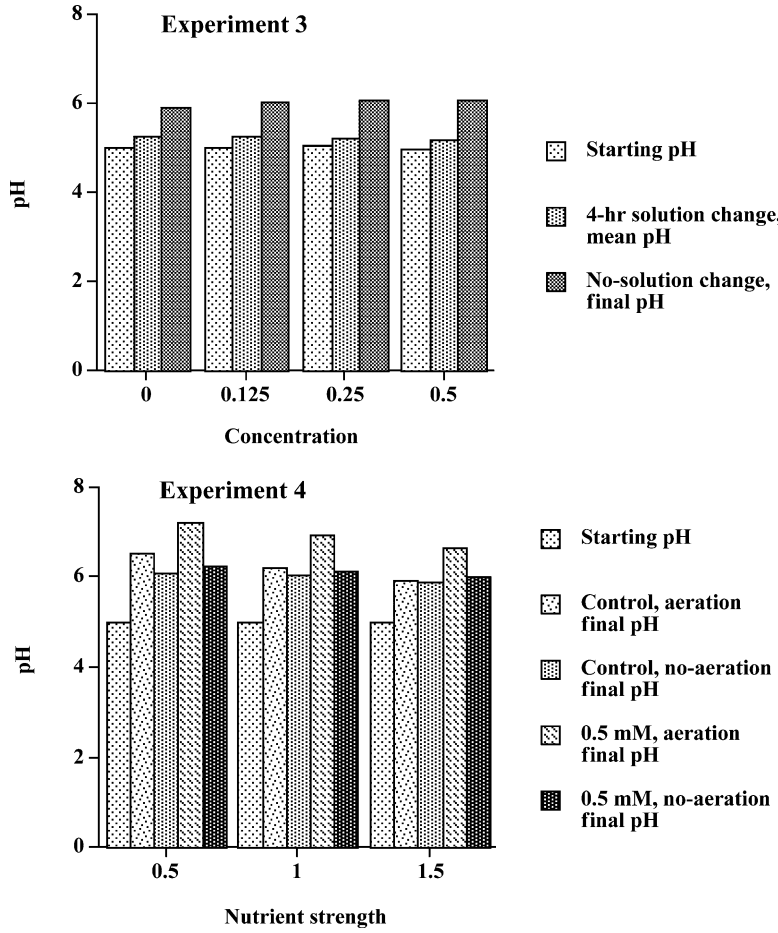

FIG. 2. Starting, mean, and final pH values for nutrient solutions of experiments 3 and 4.

thus 9, 14, and 5% for the 0.125-, 0.25-, and 0.5-mM treatments, respectively. The solution pH increased by approximately 0.25 pH unit from pH 5.00 ± 0.02 at the start of each 4-hr treatment period to 5.24 ± 0.02 at the end of each 4-hr treatment period (Figure 2).

The no-change solution treatment was used for all previous 24-hr treatment experiments. Thus, it was not surprising to find that over the first 24 hr, when effects were inhibitory, the inhibitory effects of 0.5 mM *p*-coumaric acid were consistent with previous experiments. The effects of *p*-coumaric acid on transpiration and water utilization, however, were inconsistently expressed over the

[a] Where transpiration, water utilization, mean leaf area, and absolute and relative rates of leaf expansion = Intercept + (linear coefficient × *p*-coumaric acid concentration) + (quadratic coefficient × [*p*-coumaric acid]^2); seedlings were treated at 8 AM to concentrations ranging from 0 to 0.5 mM.
[b] Solutions not changed (No) or solutions were changed every 4 hr (Yes).
[c] Where the time interval for Day 1 = 8 AM to 8 PM, Night = 8 PM to 8 AM, and Day 2 = 8 AM to 8 PM.
[d] Standard errors in parenthesis.

36-hr experimental periods and thus are not described further (see Table 5 for details). The most consistent effects of solution treatments occurred for absolute and relative rates of leaf expansion. For the no-solution change treatment and the 4-hr change solution treatment, 0.5 mM *p*-coumaric acid inhibited absolute rates of leaf expansion by 76 and 100% for d 1 (first 12 hr), 70 and 95% for night (second 12 hr), and 60 and 82% for d 2 (final 12 hr), respectively. The values for relative rates of leaf expansion were 73 and 100% for d 1, 68 and 88% for night, and 51 and 72% for d 2, respectively.

Shoot dry weight was reduced by *p*-coumaric acid treatment but not by the solution change treatment [shoot dry weight (g) = 0.152–0.632 × mM *p*-coumaric acid; $r^2 = 0.30$; $P = 0.001$]. Shoot dry weight was reduced by 40% by 0.5 mM *p*-coumaric acid. Root dry weight was not significantly modified over the 36-hr treatment period. Control values for shoot and root dry weights were 0.154 ± 0.008 and 0.026 ± 0.001 g, respectively.

Experiment 4. Changing nutrient strength did not significantly modify *p*-coumaric acid depletion from the nutrient solution. Aeration, however, increased the depletion of *p*-coumaric acid (Table 6; Figure 3). Based on the models of Table 6, a 25% reduction of *p*-coumaric acid took approximately 14.5 hr for the aerated treatment and 24 hr for the nonaerated treatment. A 50% reduction took 16.5 and 31 hr, respectively. At 36 hr, the end of the treatment period, the aerated treatment had <1% (0.002 mM) left in solution and the nonaerated treatment had 36% (0.18 mM) left in solution. The solution pH for the aerated and nonaerated treatments increased from pH 5.00 ± 0.02 at the start of the treatment period to 6.12 ± 0.10 for the controls and to 6.54 ± 0.20 for the 0.5 mM *p*-coumaric acid treatment at the end of the 36-hr treatment period (Figure 2). An additional difference between these two treatments was the accumulation of breakdown products of *p*-coumaric acid (Figure 3). The nonaerated treatment had an accumulation of breakdown products over time ending with 0.27 mM *p*-coumaric acid equivalence at 36 hr (Table 6; Figure 3). There was little accumulation of breakdown products in the aerated treatment. The maximum concentration for this treatment was 0.018 mM at 12 hr. At all other times monitored, no breakdown products were detected (Figure 3).

Nutrient strength had only a minor impact on the inhibition of *p*-coumaric acid for transpiration, water utilization, mean leaf area, and absolute and relative rates of leaf expansion. However, a decline in the inhibition of 0.5 mM

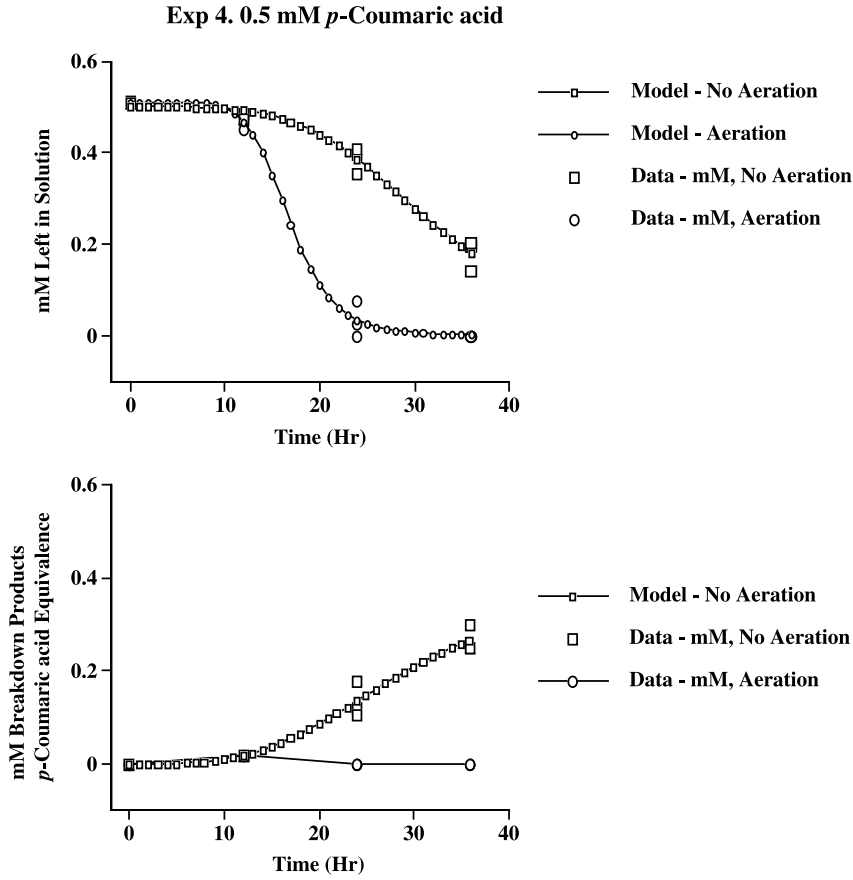

FIG. 3. Decline of 0.5 mM of *p*-coumaric acid and accumulation and/or decline of its breakdown products expresses as mM equivalents of *p*-coumaric acid in nutrient solutions surrounding roots of 12+ day-old cucumber seedlings. Nutrient solutions were aerated or not aerated. Experiment 4.

p-coumaric acid, because of the aeration of the nutrient solution, was evident after the first 12 hr of treatment. Utilizing the models of Table 7 and 8, 0.5 mM *p*-coumaric acid inhibited d 1 (first 12 hr) transpiration by 45 and 48%, water utilization by 48 and 51%, average leaf area by 5 and 4%, absolute rates of leaf expansion by 85 and 85%, and relative rates of leaf expansion by 84 and 85%, for aerated and nonaerated treatments, respectively. For night period (second 12 hr), the inhibitory effects for 0.5 mM *p*-coumaric acid were the following: transpiration by 9 and 13%, water utilization by 18 and 24%, average leaf area

[b] Standard errors in parenthesis.

by 12 and 11%, absolute rates of leaf expansion by 60 and 77%, and relative rates of leaf expansion by 54 and 75%, for aerated and nonaerated treatments, respectively. For d 2 (final 12 hr), the inhibitory effects for 0.5 mM *p*-coumaric acid were the following: transpiration by 8 and 33%, water utilization by 21 and 46%, average leaf area by 16 and 16%, absolute rates of leaf expansion by 14 and 62%, and relative rates of leaf expansion by 0 and 52%, for aerated and nonaerated treatments, respectively.

Final shoot and root dry weights were influenced by *p*-coumaric acid and aeration, respectively. The 0.5 mM *p*-coumaric acid treatment reduced shoot dry weight by 9% (shoot dry weight = 0.142–0.025 × *p*-coumaric acid concentration; $P < 0.001$, $r^2 = 0.49$). Aeration increased root dry weight by 23% [root dry weight = 0.024 + 0.006 × (1 for aeration and 0 for no aeration); $P < 0.001$, $r^2 = 0.23$].

DISCUSSION

Increasing concentrations of the cinnamic acids, ferulic acid, and *p*-coumaric acid, were approximately two to five times more inhibitory to cucumber seedlings transpiration, water utilization, leaf area, absolute and relative rates of leaf expansion, and shoot and root dry weights than the benzoic acids, *p*-hydroxybenzoic acid, and vanillic acid. Inhibitions ranged from 27 to 65% for the cinnamic acids and from 5 to 25% for the benzoic acids. These findings are consistent with previous studies utilizing cinnamic and benzoic acids and cucumber seedlings (Blum and Dalton, 1985; Blum et al., 1985a, b). As long as phenolic acid concentrations, for example, *p*-coumaric acid, were maintained at inhibitory concentrations (multiple treatments, experiment 1, Figure 1), the percent inhibition of water utilization remained relatively constant for a given concentration and phenolic acid, percent inhibition of leaf area increased and then leveled off to a constant percent, and percent inhibition of transpiration and absolute and relative rates of leaf expansion declined at various rates. Leaf area and leaf area expansion of these cucumber seedlings were primarily associated with the first true leaf, and thus as the leaf reached its maximum size, inhibition of leaf area leveled off and inhibition of leaf expansion declined. Final leaf area of individual leaves, however, was reduced permanently when inhibitory phenolic acid concentrations were maintained for a sufficient length of time during leaf development.

This is the first time that the relationships between treatment solution concentrations and uptake of phenolic acids by roots have been determined over an extended time period, i.e., 24 hr. Previous studies have determined uptake over a single time interval, e.g., mean uptake over 5 or 8 hr (Shann and Blum,

1987a; Lyu and Blum, 1990; Lehman and Blum, 1999). Uptake of *p*-coumaric acid from nutrient solutions by cucumber seedling roots occurred throughout the entire 24-hr periods monitored for experiments 2a and 2b. Relationships between initial treatment concentrations and uptake were, however, inconsistently expressed over 24 hr. For the 8 AM *p*-coumaric acid treatment (experiment 2a), the beginning of the photoperiod, significant positive relationships between uptake and initial *p*-coumaric acid concentration were only observed for the morning (8 AM to 2 PM), but not for the following afternoon (2 PM to 8 PM) and night (8 PM to 8 AM). For the 8 PM *p*-coumaric acid treatment (experiment 2b), the end of the photoperiod, significant positive relationships between uptake and initial *p*-coumaric acid concentrations were observed during the night, but not during the next morning. The relationship, however, reappeared in the afternoon. Periods without significant relationships between uptake and solution concentrations occurred, although initial concentrations of *p*-coumaric acid in both experiments were highly correlated (r = 0.98) with *p*-coumaric acid concentrations for all time periods monitored, including the end of the 24-hr treatment period. These findings suggested that periods with significant positive relationships between *p*-coumaric acid uptake and *p*-coumaric acid concentration may represent periods dominated by apoplastic movement of *p*-coumaric acid into the intercellular spaces of roots and the subsequent saturation of binding sites (e.g., covalent and noncovalent cross-links) on the cell walls in the apoplast (Fry, 1988), and that periods lacking significant relationships may represent periods dominated by symplastic movement (i.e., active transport across membranes and transfer by plasmodesmata from cell to cell). There is considerable evidence to suggest that absorption of secondary compounds, such as phenolic acid, by seedlings is an active process requiring energy and transporters (Martinoia et al., 2002; Taiz and Zeiger, 2002; Walker et al., 2003). Finally, the presence of periods without significant relationships between uptake and solution concentrations, although a broad range of solution concentrations was maintained over the 24-hr periods, suggested that even at 0.125 mM (lowest concentration used), the uptake sites on the root membranes of seedlings were saturated by *p*-coumaric acid.

We are not aware of any previous efforts to determine the influence of gradual phenolic acid depletion, i.e., declining concentrations, on the recovery of seedling processes, such as transpiration, water utilization, and leaf expansion. However, recovery after complete substitution of phenolic acid–nutrient solutions with just nutrient solutions has been determined (Blum and Dalton, 1985; Blum et al., 1985a, b; Blum and Rebbeck, 1989). In experiments 3 and 4, we attempted to manipulate *p*-coumaric acid concentrations over time by changing solutions at intervals to maintain roughly constant ranges of concentrations or increasing the rate of depletion by modifying nutrition and/or aeration. When *p*-coumaric acid was inhibitory, recovery (i.e., decline in inhibition) of

transpiration, water utilization, and rates of leaf expansion of actively growing leaves over a 36-hr period appeared to be related to the declining concentrations of *p*-coumaric acid.

To more fully characterize how cucumber seedlings responded to declining concentrations of *p*-coumaric acid, we chose to use the data for leaf area expansion, the most complete and consistent data set. To eliminate confounding due to the effects of treatment concentrations, only the data from the 0.5 mM *p*-coumaric acid treatments were used. Overall, there appeared to be a linear relationship between average mM *p*-coumaric acid at each interval [(mM at start + mM at end)/2] and percent inhibition of both absolute and relative rates of leaf expansion for 12+ d old seedlings (Figure 4). Based on the resulting regression, it would appear that for every decline in 0.1 mM, inhibition of absolute and relative rates of leaf expansion declined (i.e., recovered) by 12 and 14%, respectively.

One might, however, ask whether these differences in recovery were exclusively related to the physical decline of *p*-coumaric acid or whether other factors might also have been involved. For example, changes in solution pH could have been important in the observed differential rates of recovery

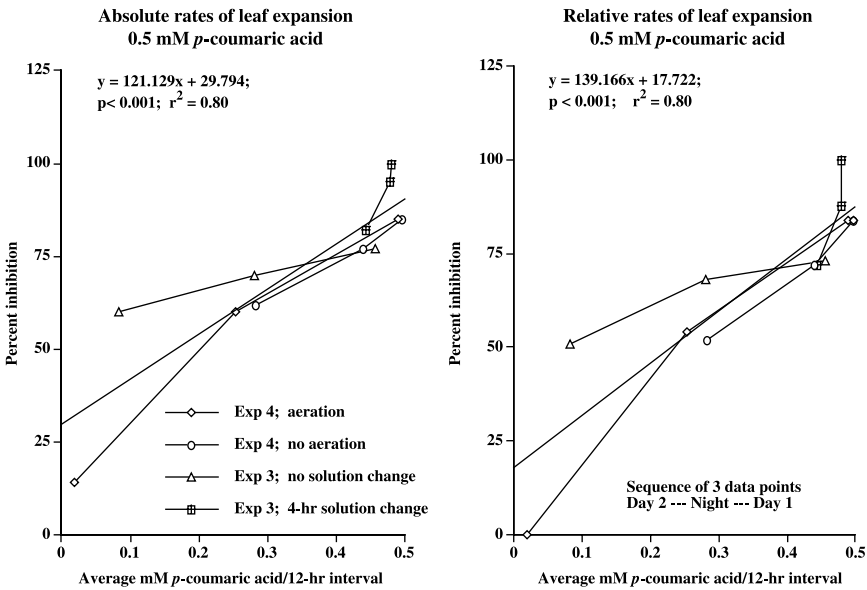

FIG. 4. Relationships between percent inhibition of absolute and relative rates of leaf expansion and the decline of 0.5 mM *p*-coumaric acid. Data derived from appropriate models in Tables 5–8. Each data point represents a 12-hr period, i.e., d 1, night, or d 2.

between the aerated and nonaerated treatments. It has been demonstrated that increasing solution pH will reduce the inhibitory activity of phenolic acids such as *p*-coumaric acid (Blum et al., 1985b); maximum inhibition and protonation occur under acidic conditions. *p*-Coumaric acid has a pK_a between 4.40 and 4.64 (Blum et al., 1999b). At the end of the 36-hr treatment period, the solution pH values for the aerated and nonaerated *p*-coumaric acid solutions were approximately 7 and 6, respectively. How important this may have been is not entirely clear; however, Blum et al. (1985b) observed that 0.5 mM *p*-coumaric acid had little inhibitory activity on cucumber seedlings above a pH of 6.25.

Finally, the range and magnitude of phenolic acid effects are determined by the sensitivity of seedling, seedling's ability to detoxify phenolic acids, the types and concentration of phenolic acids present, the rates of input and depletion of phenolic acids, and rhizosphere and rhizoplane pH (see Rice, 1984; Shann and Blum, 1987a, b; Blum et al., 1999b). Because cucumber seedling roots take up water and phenolic acids, detoxify phenolic acids, modify solution rhizosphere and rhizoplane pH, and regulate phenolic acid utilizing microbes within the rhizosphere, it would appear that cucumber seedlings themselves can readily change the active phenolic acid concentrations surrounding their roots and thus regulate the development, retention, and decline of both primary and secondary effects of phenolic acids through feedback regulation. This of course assumes that new input of phenolic acids does not replace or outpace losses. Feedback regulation is defined here as a response in which the product of one of the final steps in a chain of events affects one of the first steps in this chain; fluctuations in rate or concentration are minimized with negative feedback or amplified with positive feedback (Lambers et al., 1998). The findings here suggest that negative feedback regulation by seedling can be an important factor in determining the ultimate expression of inhibition by phenolic acid. It also would appear that unless care is taken in maintaining fairly constant phenolic acid concentrations and appropriate solution pH values surrounding roots over a given experimental period, the phytotoxicity of phenolic acids may be significantly over- or underestimated. Unfortunately, attempts to regulate solution pH values surrounding roots in nutrient culture by buffers for extended periods have met with little success (Blum et al., 1985a).

(Received June 3, 2004; revised February 11, 2005; accepted April 15, 2005)

Abstract—To investigate species-specific decomposition rates of litter from native (*Quercus faginea*) and introduced (*Eucalyptus globulus*) tree species in Portugal, we monitored changes in the phenolic signature of leaf litter during decomposition as mediated by an aquatic, *Proasellus coxalis* (Isopoda: Asellota), and two terrestrial, *Porcellio dispar* and *Eluma caelatum* (Isopoda: Oniscidea), detritivores. Although the litter of *Eucalyptus* and *Quercus* did not differ in overall protein precipitation capacity, we detected differences in terms of contents of particular phenolic compounds and phenol oxidation products. Accordingly, we observed food-specific consumption rates in *Proasellus*, but not in the terrestrial isopods. *Proasellus* digested *Eucalyptus* at significantly higher rates than *Quercus*, whereas the opposite was the case for *Eluma*, and *Porcellio* digested both litter types equally well. Despite slight differences in detail, effects of *Proasellus* on changes in the signature of litter phenolics were similar for both litter types, whereas terrestrial isopods—*Porcellio* and *Eluma*, although they differed from each other—digestively degraded phenolic compounds in *Eucalyptus* and *Quercus* litter, respectively, in different ways. Overall, however, degradation of litter phenolics was similarly effective on both litter types. From these data, we conclude that decomposition of *Eucalyptus* litter does not proceed more slowly than of litter from native Portuguese trees.

Key Words—Animal–microbe interactions, decomposition, *Eucalyptus*, Isopoda, neophytes, phenolics, *Quercus*, tannin degradation.

INTRODUCTION

Eucalyptus globulus Labill., native in Australia, has been planted during the last 170 yr in southern European countries, South America, and other parts of the world. In Portugal, *Eucalyptus* plantations nowadays occupy more than 20% of the forested area (Canhoto et al., 2002). Several studies demonstrated that *Eucalyptus* plantations affect invertebrate assemblages in soils (e.g., Pinto et al., 1997; Sousa et al., 1997) and freshwaters (e.g., Abelho and Graça, 1996; Graça et al., 2002). In freshwaters, invertebrate shredders may exert an important contribution to the decomposition of leaves entering streams (Graça, 2001); however, invertebrate shredders seem to have difficulties feeding on *E. globulus* leaves (Graça et al., 2002). In soil, terrestrial isopods apparently have the same difficulty using *E. globulus* litter (Sousa, personal communication). *Eucalyptus* litter is, therefore, considered a low-quality food for both freshwater (Mellilo et al., 1982; Campbell and Fuchshuber, 1995) and soil (Sousa, personal communication) detritivores. Such effects may be due to chemical and physical defense mechanisms in leaves. Canhoto and Graça (1999) showed that eucalyptus oils inhibit fungal growth and invertebrate feeding, and a thick cuticle retards microbial colonization of senescent leaves.

Another chemical defense of *E. globulus* leaves is polyphenolics. Canhoto and Graça (1996) observed a strong negative correlation between the phenol content of different native litter types and *Eucalyptus* litter and decomposition rates in a stream, whereas Canhoto and Graça (1999) showed that polyphenolics from eucalypt leaves decrease feeding by detritivores. Thus, effects of phenolics on detritivores may be one reason for the low decomposability of *Eucalyptus* litter. Overall, however, *Eucalyptus* litter decomposed at almost two times higher rates than the Portuguese oak, *Quercus faginea* Lam., the latter containing more than twice as much phenolics than the former but about the same amount of nitrogen (Canhoto et al., 2002). In the present study, we used leaf litter of the native Portuguese oak, *Q. faginea*, and the introduced *E. globulus* (both henceforth mentioned generically) to study in detail changes in the content of specific phenolic compounds during decomposition as mediated by aquatic and terrestrial detritivores.

Both terrestrial Oniscidea and freshwater Asellota had ancestors in the marine environment (that may have been closely related; Zimmer and Bartholmé, 2003). It has recently been discussed to what extent the ability to tolerate or even digest phenolic food compounds may have been important in the evolutionary step to utilizing terrestrial food sources (Zimmer et al., 2002a,b); despite their aquatic lifestyle, freshwater isopods mostly consume leaf litter of terrestrial origin (cf. Zimmer and Bartholmé, 2003) just like their terrestrial relatives do (cf. Zimmer, 2003). We were, thus, interested in whether representatives of different phylogenetic histories that are similar with respect to

available food sources are also similar in their digestive capabilities. Hence, we chose two terrestrial and one freshwater isopods as common Portuguese models for evolutionary ecological studies on digestive capabilities and detritivore–microbe interactions and their consequences for decomposition processes, in particular the degradation of phenolic leaf litter compounds.

METHODS AND MATERIALS

Leaf Litter and Detritivores. We collected leaf litter in spring 2002, when isopods were active in the field and started reproducing, in the Mata Nacional do Choupal, Coimbra (40°12′33″N, 8°90′27″W), Central Portugal. At this time of the year, with high feeding rates by isopods, *Quercus* litter had been lying on the ground for about 1–3 mo, whereas *Eucalyptus* litter was estimated to be up to 6 mo old. Thus, our choice of litter reflected the natural conditions detritivores face during their most active feeding period; many, but not all, species-specific compounds of the litter will have been leached at that stage. We selected leaves that did, upon visual inspection, not show heavy decomposition. In the laboratory, leaves were air-dried in the dark at room temperature and stored dry until needed to avoid further loss of phenolics through leaching or photoautoxidation. We did not test for differences in phenolic signatures of leaf litter before and after storage because we were interested in relative effects of detritivore activity on phenolic litter compounds during decomposition.

Terrestrial isopods, *Porcellio dispar* Verhoeff 1901 (Oniscidea: Porcellionidae) and *Eluma caelatum* [Miers 1877] (Oniscidea: Armadillidiidae), were collected in the Mata Nacional do Choupal by browsing through mixed leaf litter layers in spring 2002. In the laboratory, they were housed in plastic boxes with moist sand (16°C) feeding exclusively on *Quercus* or *Eucalyptus* for at least 5 d. *Proasellus coxalis* [Dollfus 1892] (Asellota: Asellidae) were collected in a small creek, Rio Pavia in Fail (40°36′17″N, 7°58′44″W), near Viseu, northeast of Coimbra, which belongs to the Mondego's drainage basin. In the laboratory, they were housed in plastic boxes with aerated water of the same origin (16°C) feeding exclusively on *Quercus* or *Eucalyptus* for at least 5 d.

Experimental Setup. During experiments ($N = 9$, each), groups of three (terrestrial) or five (aquatic) isopods were kept in small petri dishes, the lids of which were lined with moist filter paper to maintain high humidity or that were filled with filtered creek water, respectively. Feces were collected twice a day to minimize both coprophagy and postdigestive changes in phenolic compounds by picking up fecal pellets with forceps or by filtering the water from the petri dishes after removal of isopods and litter, respectively. Afterwards, isopods

were placed in fresh petri dishes with filter paper-lined lids or filtered creek water, respectively. Feces were immediately stored at −20°C until being used for HPLC analysis.

Single air-dried leaves, randomly chosen from the pool of hand-selected litter (see above), were cut in pieces, two of which were weighed and then placed in either isopod assays or isopod-free controls. Another piece of that same leaf was used to determine the initial phenolic signature of individual leaves as described below. An additional piece of each leaf was weighed, then oven-dried (60°C, 24 hr), and weighed again to obtain a factor to estimate the initial dry mass of litter (Zimmer and Huryn, in press). After the experiment, lasting for 5 d, litter remnants were weighed fresh to calculate mass loss. Litter obtained from parallel experiments that were not used for HPLC analysis was used to determine a factor for the estimation of final dry mass of litter (oven drying at 60°C for 24 hr) as described above.

Consumption rates [mg (mg d)$^{-1}$] were determined based on litter mass loss and mean isopod dry mass. Digestibility (%) was determined as percent of ingested litter that was not egested as feces (Zimmer and Huryn, in press). Direct effects of detritivores on litter chemistry through digestion were quantified by comparing the phenolic signature of litter prior to the experiment with that of isopod feces. Indirect effects of detritivores on litter chemistry (e.g., through mediating microbial decomposition; see Zimmer et al., 2002b, 2004) were estimated by comparing the phenolic signature of litter prior to the experiment with that of unconsumed litter remnants after the experiment. Such indirect effects could have occurred either through selective consumption of litter or through direct influences of detritivores (e.g., fecal amount and composition, mucus, urine, molt deposition, and so on) on type and abundance of microbiota (Zimmer et al., 2002b, 2004).

Leaf Litter Phenolics. For extraction of phenolics, 45–55 mg (dry mass) of leaf litter or 3–10 mg of feces were homogenized in 2 ml 50% aqueous methanol (cf. Van Alstyne, 1995) and shaken for 3 hr at 16°C. After centrifugation, the solvent was replaced by 2 ml 50% methanol, and samples were extracted overnight at 16°C. After centrifugation (10,000 × *g*, 10 min), supernatants were pooled and either used for the determination of protein precipitation capacity or for HPLC analysis after filtering (0.45 μm).

The capability of phenolics to precipitate proteins was measured using the radial diffusion assay (Hagerman, 1987). Portions of 9.5 ml of agarose (1%) containing 0.1% of bovine serum albumin (BSA) were dispensed in 8.5-cm diam petri dishes. Polyphenolics were extracted from 50 mg of leaf powder as described above. Aliquots of the supernatant (36 μl) were inoculated into 4-mm diam wells punched out from the agar plate. A protein precipitation ring was allowed to develop for 3 d at 16°C. The precipitation area was measured and compared to a standard curve using tannic acid (Merck; Ref.: 1.00773.0250;

Lot K18722673703), and the results were expressed in terms of "tannic acid equivalents." We are aware that different phenolic compounds will have different protein precipitation capacities, but because we could not determine most of the compounds, we refrained from using different standards.

For the detection of specific phenolic compounds in litter and feces extracts, we performed RP-HPLC using a Brownlee Column (Applied Biosystems) SPHERI-5 RP-18 (5 μm) 250 × 4.6 (OD-5A) with a NewGuard RP-18 (7 μm) 15 × 3.2 guard column. Peaks were detected at 280 nm. In preruns, no peaks were detected after 45 min; thus, we chose a run time of 45 min. According to previous studies (Scalbert et al., 1988; Streit and Fengel, 1994) and our own preexperiments, we chose a system of two eluants [A, 950:49:1, water/methanol/phosphoric acid (85%); B, 999:1, methanol/phosphoric acid (85%)] with a gradient of 0–5% B during the first 15 min and a subsequent gradient of 5–90% B during 15 min at a flow rate of 1 ml min^{-1} at 20°C.

Besides other phenolic compounds, tannic acid (mainly *penta*-galloylglucose), gallic acid, catechin, and gallocatechin have been isolated from *Quercus* leaves (e.g., Scalbert et al., 1988; Tanaka et al., 1995). We used these compounds (Sigma) as standards for HPLC in concentrations of 0.1, 0.5, and 1.0 mg ml^{-1}. Because tannic acid, rutin, quercetin, and catechol have, besides others, been determined in extracts of *Eucalyptus* leaves (e.g., Conde et al., 1997; Sasikumar et al., 2002), we used these compounds (Sigma) as standards in HPLC (0.1, 0.5, and 1.0 mg ml^{-1}). To detect oxidation products of these model phenolics in experimental extracts, we forced phenol oxidation in standards by both vigorously shaking these solutions for 60 min at RT and adding NaOH solution (32%, pH 12; 1 ml 100 ml^{-1}). After the generation of brown coloration, we determined the elution time of phenol-specific oxidation products by HPLC as described above.

Even with the slowly changing conditions during min 0–15 (see above), we could not unambiguously identify every single peak derived from a complex mixture of litter phenolics and their derivates (see Table 1). Difficulties in separating phenolic compounds by RP-HPLC with water–methanol gradients have previously been reported in flowers by Van de Casteele et al. (1983), in leaves by Koupai-Abyazani et al. (1992), and in wood by Streit and Fengel (1994). We, thus, refrain from assigning phenolic standards to particular HPLC peaks, but refer to phenolic compounds by the name of peaks in order of their elution.

From the areas (units ml^{-1}) of particular peaks as revealed by HPLC analysis of pre- and postexperimental litter and feces, we approximated changes in the content of particular phenolic compounds (%) in isopod-free controls, through isopod-mediated microbial activity, and through isopod feeding and digestion. Further, we estimated litter decomposition in terms of mass loss by calculating consumption rates of detritivores as described in Zimmer and Huryn

(in press). Because most of our data deviated from normal distribution, we chose median ± median absolute deviation for graphical presentation, and nonparametric tests were used for statistical analysis. Comparison of different treatments (leaf litter or detritivore species) was performed through Mann–Whitney *U*-tests. Differences between initial values and values after experimental treatment were tested with Wilcoxon sign tests.

RESULTS

General Patterns. Although *Quercus* and *Eucalyptus* litter did not differ from each other quantitatively in their initial protein precipitation capacity (radial diffusion assay: *Eucalyptus*, 24 ± 4 mg TA equivalents g^{-1}; *Quercus*, 18 ± 8 mg g^{-1}; $P > 0.7$), they differed qualitatively in terms of contents of different phenolic species and their oxidation products (Figure 1).

While microbial degradation (in animal-free assays) of *Quercus* leaves was not detectable in the terrestrial environment, litter lost 2 ± 1 μg $(mg\ d)^{-1}$ in the aquatic environment ($P < 0.05$), presumably because of microbial degradation and leaching. After correction of data for these control values, *Porcellio* [4 ± 2 μg $(mg\ d)^{-1}$], *Eluma* [7 ± 3 μg $(mg\ d)^{-1}$], and *Proasellus* [3 ± 2 μg $(mg\ d)^{-1}$] did not differ from each other with respect to consumption rates ($P > 0.3$). Digestibility of *Quercus* litter was similar in *Porcellio* (33 ± 17%) and *Proasellus* (31 ± 24%), but significantly higher ($P < 0.05$) in *Eluma* (62 ± 22%).

Microbial degradation and leaching (in animal-free assays) of *Eucalyptus* resulted in litter mass loss of 4 ± 1 μg $(mg\ d)^{-1}$ in the terrestrial environment and 11 ± 9 μg $(mg\ d)^{-1}$ in the aquatic environment ($P < 0.01$). After correction

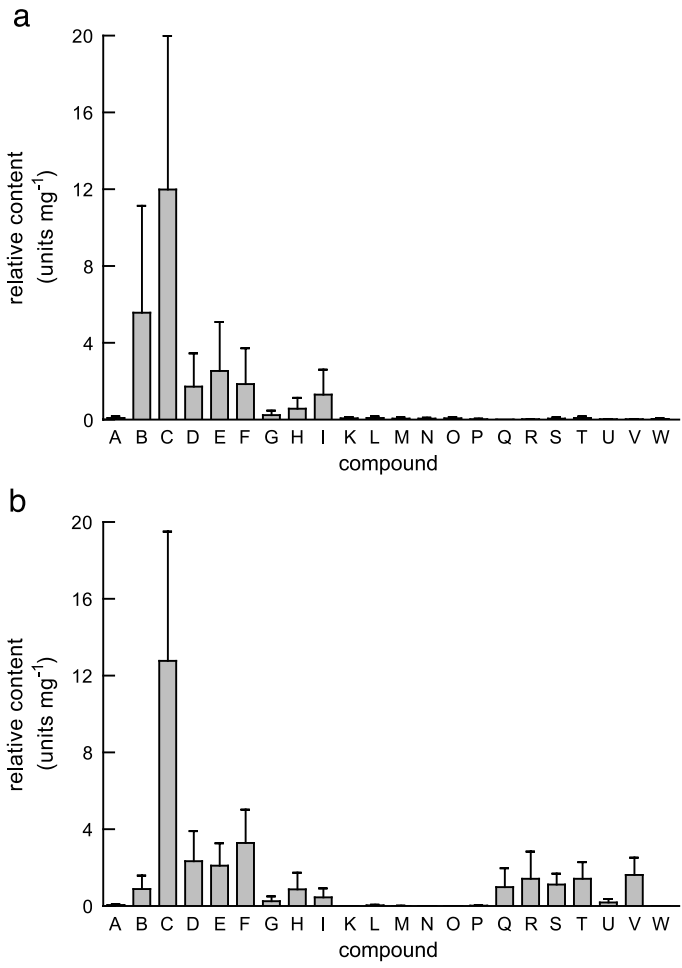

FIG. 1. Phenolic composition of leaf litter derived from *Quercus* (a) and *Eucalyptus* (b). Data are median ± median absolute deviation ($N = 9$).

of data for control values, *Porcellio* [5 ± 3 μg (mg d)$^{-1}$] and *Eluma* [3 ± 2 μg (mg d)$^{-1}$] did not differ from each other with respect to consumption rates ($P > 0.4$), whereas *Proasellus* [30 ± 20 μg (mg d)$^{-1}$] consumed about 10 times more than the terrestrial isopods. Thus, while the terrestrial isopods consumed about the same amounts of *Quercus* and *Eucalyptus*, *Proasellus* ingested significantly more *Eucalyptus* than *Quercus* ($P < 0.01$). Digestibility of *Eucalyptus* litter was similar in *Porcellio* (33 ± 13%) and *Eluma* (26 ± 20%), but significantly higher ($P < 0.05$) in *Proasellus* (71 ± 18%). Thus, *Porcellio* di-

gested both litter types equally well, whereas *Eluma* was significantly ($P < 0.01$) more efficient in digesting *Quercus*, and *Proasellus* digested *Eucalyptus* at significantly ($P < 0.01$) higher rates than *Quercus*.

According to these results, *Proasellus* ingested larger amounts of *Eucalyptus* than *Quercus*. Consumption of *Eucalyptus* differed between consumers, with *Proasellus* consuming the largest amounts, but *Quercus* was ingested in similar rates by all consumers. Accordingly, digestibility of *Eucalyptus* by *Proasellus* was higher than that of *Quercus*. By contrast, although *Eluma*, too, exhibited higher digestibility of *Eucalyptus* than *Porcellio*, the terrestrial species digested both litter types equally well.

General Changes in Phenolic Signatures

Quercus. In the aquatic environment, only compounds B, C, E, I, P, and W were not completely or at least mostly leached, degraded, or transformed in animal-free controls (Figure 2a); compounds E, P, and W were obtained in higher concentration after the experiment than before ($P < 0.05$). With isopods present, compounds C and I were microbially degraded or transformed in the leaf litter that was not consumed by isopods (Figure 3a); microbially processed litter was enriched in compounds N, P, U, and V ($P < 0.01$). On average, compounds B and I were digested completely by litter-feeding isopods (Figure 4a), whereas compounds E, F, H, M, P, T, and V were concentrated higher in feces than in the litter ($P < 0.01$).

In the terrestrial environment, only a few compounds were lost through leaching, degradation, or transformation in animal-free controls (Figure 5a); compounds D, P, and U were obtained in higher concentration after the experiment than before ($P < 0.001$). With *Porcellio* present, compounds I, V, and W were microbially degraded, and compounds E, M, and P became significantly reduced, probably through microbial activity, in the leaf litter that was not consumed by isopods (Figure 6a); microbially processed litter was enriched in compounds L and O ($P < 0.05$). With *Eluma* present, compounds D, E, F, O, and T were microbially degraded (Figure 7a), whereas compounds M, P, U, and V became enriched in the litter ($P < 0.001$). On average, compounds C, U, and V were digested completely in isopod guts, and about 90 and 50% of compounds E and I, respectively, was degraded digestively by *Porcellio* (Figure 8a), whereas compounds D, F, G, H, M, P, R, S, and T were concentrated higher in feces than in the litter ($P < 0.01$). *Eluma* digested all of the remaining compounds B, G, H, I, O, T, and V and reduced compound D by about 85% (Figure 9a), but led to a relative increase of compounds E, M, P, Q, R, U, and W ($P < 0.001$).

Eucalyptus. In the aquatic environment, only compounds B, C, E, H, P, U, and W were not completely or at least heavily leached or degraded in animal-free controls (Figure 2b); compounds H, P, and U were obtained in higher

DISCUSSION

Degradation of Particular Phenolic Compounds. Owing to the fact that we were unable to unambiguously assign different peaks of our HPLC analysis to distinct phenolic compounds (Table 1), we can only interpret our results based on rough interspecific differences between detritivores and tree species with respect to the reduction and/or increase in particular peaks. However, this information appears sufficient for a first ecosystemic approach to effects of interactions of different detritivores with different leaf litter types. Overall, however, interspecific differences deduced from our present results must be interpreted with caution because we do not know exactly whether the composition of single peaks we obtained by HPLC was the same in leaf litter from *Eucalyptus* and *Quercus*.

Ecosystemic Conclusions. The litter of *Eucalyptus* and *Quercus* we used in our study did not differ with respect to the overall content of phenolic compounds (protein-precipitating TA equivalents). The radial diffusion assay as used does not reveal phenol concentrations, but rather provides a measure of protein-binding capacity, and thus, one measure of potential biological activity of a mixture of phenolics that may or may not be correlated with phenol content. Further, tannic acid, which we used here, may not be an appropriate standard for protein precipitation by mixed phenolics because the species studied may differ in both amount and type of hydrolyzable tannins. Yet, comparison of data derived from this method still allows for an estimation of interspecific differences in phenol content or activity, and Domínguez (1994), using different methods, came to a similar conclusion of similar phenol concentrations in *Eucalyptus* and *Quercus*. Nevertheless, we found significant differences in consumption rates of these litter types by *Proasellus* but not in the terrestrial isopods. Thus, it is apparently not the total phenol content that determines detritivore consumption rates, but rather the phenolic signature.

In addition to phenolics (see Introduction), other compounds are considered responsible for mediating consumption and decay rates of plant tissue. While mainly phloroglucinol derivates, such as formylated phloroglucinol and acylphloroglucinol, are considered responsible for feeding deterrence towards mammals (e.g., Pass et al., 1998; Lawler et al., 1999; McLean et al., 2004), different essential oils of *Eucalyptus* spp. proved active against insect consumers (e.g., Lee et al., 2001; Wang et al., 2001). Whereas purely hydrocarbon components of essential oils (terpenes) are not water-soluble, and thus, will not be lost rapidly through leaching (and would have been present in the leaf litter we used in the present study if they had been so in freshly detached senescent leaves), their oxidized derivates may be leached at early decomposition stages. Thus, those essential oils that are common in *E. globulus* (e.g., 1,8-cineole and α-pinene; Li and Madden, 1995; Lee et al., 2001) are readily leached off litter (as can be deduced from, e.g., Krock et al., 2002; Rasmussen et al., 2003) and

probably were not present in our experimental litter. Those differences in consumption and digestibility of *Eucalyptus* and *Quercus* we observed herein were probably not due to essential oils. On the other hand, the lack of negative effects of *Eucalyptus* litter on decomposition through isopod feeding may be due to the lack of essential oils that had been lost from litter prior to collection.

According to our present results, phenolics in *Eucalyptus* appear to be less deterrent to the aquatic isopod, *P. coxalis*, than phenolics in *Quercus* (e.g., compounds B or I). In a previous study, *Eucalyptus* oils had stronger effects on aquatic fungal decomposers than phenolics (Canhoto et al., 2002). As expected, the loss of phenolics through leaching was almost complete and higher in the aquatic than in the terrestrial environment (but apparently had not been extensive under terrestrial conditions prior to litter collection). Thus, negative effects of *Eucalyptus* phenolics (if any exist) would be expected to be stronger for terrestrial detritivores than for aquatic, but we did not find any effect on consumption or digestibility by terrestrial isopods. From this, we conclude that decomposition of *Eucalyptus* litter does not proceed more slowly than that of litter from native Portuguese trees. In coincidence, Rezende et al. (2001) did not find significantly different decay rates of leaf litter derived from *Eucalyptus grandis*, introduced to Brazil, and *Dalbergia nigra*, a native Brazilian tree, after 1 yr.

As expected, we observed significant differences in phenol degradation, both between detritivores and between litter types. Digestive processes and effects on microbial activity obviously differ among detritivores, and both the identity of detritivores and the litter type affect phenol degradation (and probably also other decomposition processes) both directly and indirectly. Consequently, we cannot consider them functionally redundant, although they superficially belong to the same functional group (see Zimmer et al., 2002b, 2004; Chalcraft and Resetarits 2003a,b). Further, different litter types can obviously not substitute for each other in terms of their quality as food to detritivores (see Zimmer et al., 2004).

Overall, however, although the phenolic signature of *Eucalyptus* litter influences its degradation, we did not find consistent evidence for slowed-down decomposition processes of the litter of this introduced tree species that would have suggested impaired nutrient cycles. Thus, negative effects that *Eucalyptus* plantation may have on Portuguese forests and freshwater systems are not due to differences in tannins of *Eucalyptus* litter relative to common native trees.

EFFECTS OF JASMONATE-INDUCED DEFENSES ON ROOT-KNOT NEMATODE INFECTION OF RESISTANT AND SUSCEPTIBLE TOMATO CULTIVARS

W. R. COOPER,[1] L. JIA, and L. GOGGIN*

Department of Entomology, University of Arkansas, 320 Agriculture Building, Fayetteville, AR 72701, USA

(Received January 14, 2005; revised April 13, 2005; accepted May 1, 2005)

Abstract—Jasmonates, such as jasmonic acid (JA), are plant-signaling compounds that trigger induced resistance against certain pathogens and a broad range of arthropod herbivores. One goal of this study was to determine the effects of JA-dependent defenses in tomato on root-knot nematodes. Another was to determine if the artificial induction of these defenses could enhance nematode control on plants that carry *Mi-1.2*, a nematode resistance gene that is present in many tomato cultivars. At moderate soil temperatures, *Mi-1.2* can effectively suppress reproduction of most isolates of the common root-knot nematode species *Meloidogyne javanica*, *M. incognita*, and *M. arenaria*. *Mi*-mediated resistance has its limitations, however. *Mi-1.2* is reported to lose its effectiveness at soil temperatures above 28°C, and certain virulent nematode isolates can overcome resistance even at moderate soil temperatures. This study used a foliar application of JA to activate induced resistance in two near-isogenic lines of tomato (*Lycopersicon esculentum*) with and without *Mi-1.2*, and evaluated the effects of induced resistance at moderate soil temperatures on one avirulent nematode isolate (*M. javanica* isolate VW4) and two virulent isolates (*M. javanica* isolate VW5 and *M. incognita* isolate 557R). In addition, the effects of induced resistance on avirulent nematode performance were examined at a high temperature (32°C). The results indicate that JA application induces a systemic defense response that reduces avirulent nematode reproduction on susceptible tomato plants. Furthermore, JA-dependent defenses proved to be heat-stable, whereas the effects of *Mi*-mediated resistance were reduced but not eliminated at 32°C. JA

treatment enhanced *Mi*-mediated resistance at high temperature, but did not suppress either of the virulent nematode isolates tested.

Key Words—Induced resistance, octadecanoid pathway, jasmonic acid, *Mi*, temperature-sensitive resistance, nematode resistance, *Meloidogyne*, virulence, avirulence.

INTRODUCTION

Root-knot nematodes (*Meloidogyne* spp. Chitwood) are soil-borne roundworms that parasitize the root systems of a wide variety of crops, including cultivated tomato (*Lycopersicon esculentum* Mill). Symptoms include root galls, stunted growth, and increased susceptibility to drought stress and pathogen attack (Williamson, 1998). Heavy root-knot nematode infestations cause substantial yield reduction, making them among the most damaging agricultural pests worldwide (Williamson and Hussey, 1996). Furthermore, control of nematodes has become increasingly difficult due to the withdrawal of effective nematicides and soil fumigants such as methyl bromide from the market (Oka and Cohen, 2001). As a result, there is an increasing need for new nematode management techniques. Potentially, host plant defenses could be utilized to develop alternative control strategies for root-knot nematodes. The overall goal of this study was to determine the effects of two forms of host plant resistance, broad-spectrum induced resistance and highly specific heritable resistance, on root-knot nematode infection in tomato.

The term "induced resistance" (IR) is used to describe plant defenses that are induced by feeding damage, and that render plants less susceptible to subsequent attack by a broad range of herbivores (Karban and Baldwin, 1997). Activation of IR against caterpillars and other chewing insects is dependent on induction of oxylipins such as jasmonic acid and methyl jasmonate (Howe et al., 1996; McConn et al., 1997). These signaling compounds induce expression of plant defenses such as proteinase inhibitors and polyphenol oxidase, as well as volatile organic compounds that attract predators and parasitoids of herbivores (reviewed in Ryan, 2000; van Poecke and Dicke, 2004). We do not yet know the full range of pests against which jasmonate-dependent defenses are effective, and this remains an active area of research. A recent study demonstrated that jasmonates help suppress infestation by mites and thrips, which are classified as cell-content feeders (Li et al., 2002). Artificial induction of jasmonate-dependent defenses can also deter phloem-feeding insects such as aphids (Omer et al., 2001; Ellis et al., 2002; Bruce et al., 2003; Cooper et al., 2004; Cooper and Goggin, 2005). In addition to their role in arthropod resistance, jasmonates are also involved in plant defenses against certain pathogens, including several soil-borne fungi that invade root systems (Staswick et al., 1998; Vijayan et al.,

1998; Thaler et al., 2004). Furthermore, recent studies demonstrated that treating spinach and oats with methyl jasmonate reduced their susceptibility to plant-parasitic nematodes (Soriano et al., 2004a, b). The first objective of our study was to determine if induction of jasmonate-dependent defenses could reduce root-knot nematode infection on tomato. A second was to determine if these induced defenses could enhance nematode control on tomato cultivars that carry the nematode resistance gene *Mi-1.2*.

Mi-1.2 is a single dominant gene that confers resistance against three major species of root-knot nematodes (*M. incognita*, *M. javanica*, and *M. arenaria*), as well as the potato aphid (*Macrosiphum euphorbiae*) and the sweet potato whitefly (*Bemisia tabaci*) (Milligan et al., 1998; Rossi et al., 1998; Nombela et al., 2003). Based on its nucleotide sequence, *Mi-1.2* is categorized in a family of plant resistance genes (R-genes) characterized by leucine-rich repeats and nucleotide-binding sites (Milligan et al., 1998). R-gene-mediated resistance is thought to depend upon rapid, local defense responses triggered by direct or indirect interactions between the R-gene product and highly specific elicitors from the pest (Takken and Joosten, 2000). The signaling pathway(s) and proximal defenses responsible for *Mi*-mediated resistance have not yet been elucidated, but this form of resistance appears to require the plant signaling compound salicylic acid (Branch et al., 2004). Induction of *Mi*-mediated nematode resistance is correlated with increased activity of several enzymes implicated in defense, including phenylalanine ammonia-lyase, peroxidases, and polyphenol oxidase (Brueske, 1980; Bajaj et al., 1985; Zacheo et al., 1993). In addition, resistance is associated with rapid localized cell death around the invading nematode (Riggs and Winstead, 1959; Dropkin, 1969; Paulson and Webster, 1972).

Mi-1.2 is the only known source of heritable root-knot nematode resistance in cultivated tomato, and has been introduced through traditional breeding into many tomato cultivars used by commercial growers and home gardeners (Medina-Filho and Tanksley, 1983). Although it is widely used and is typically highly effective, *Mi*-mediated nematode resistance has several important limitations. Like many pathogen resistance genes, *Mi-1.2* is temperature-sensitive, and is reported to lose effectiveness at soil temperatures above 28°C (Holtzman, 1965; Dropkin, 1969). This could limit the use of resistant cultivars in warm growing regions such as Florida (Noling, 2002). It is also not effective against certain species of root-knot nematodes, such as *M. hapla*, a common species in temperate climates (Brown et al., 1997). Furthermore, virulent biotypes of *M. incognita*, *M. javanica*, and *M. arenaria* that can colonize resistant (*Mi*+) tomato cultivars have been identified in several tomato-growing regions around the world (Riggs and Winstead, 1959; Tzortzakakis and Gowen, 1996). These limitations suggest the need for supplemental control measures for root-knot nematodes. If jasmonate-dependent defenses in tomato were effective against root-knot nematodes, induction of these defenses could potentially

enhance nematode control on resistant cultivars. It is necessary, however, to determine if JA-dependent and *Mi*-dependent resistance are compatible. Signaling conflicts are known to exist between JA and salicylic acid, and induction of one signaling compound can, in some cases, inhibit induction of the other (Pena-Cortes et al., 1993; Doares et al., 1995; Thaler et al., 1999). Given that salicylic acid is involved in *Mi*-mediated resistance, prior induction of JA could have a negative impact on the function of *Mi-1.2*.

To investigate the effects of JA-induced defenses on root-knot nematodes, this study applied a foliar treatment of jasmonic acid to tomato cultivars with and without *Mi-1.2*, and assessed nematode reproduction on treated *versus* untreated plants. Treatment with exogenous jasmonates previously has been shown to trigger induced arthropod resistance in tomato, and to mimic herbivore induction of plant defenses such as proteinase inhibitors (Farmer et al., 1992; Thaler et al., 1996). To determine if JA-induced defenses could supplement *Mi*-mediated resistance, this study examined the effects of JA-induced defenses on nematode infection at high soil temperatures, and on two virulent nematode isolates that can overcome *Mi-1.2*.

METHODS AND MATERIALS

Plants Materials. Two near-isogenic cultivars of tomato, Moneymaker (*Mi*−), and Motelle (*Mi*+), were used for bioassays. All plants were grown in 0.95-l Styrofoam cups of autoclaved sand (Quikrete, Atlanta, GA, USA) under stable greenhouse conditions (~24–27°C; 16:8 L:D photoperiod). Plants were watered daily with a nutrient solution containing 1,000 mg/l $CaNO_3$ (Hydro Agri North America, Tampa, FL, USA) 500 mg/l $MgSO_4$ (Giles Chemical Corp., Waynesville, NC, USA), and 500 mg/l Hydroponic 4-18-38 Gromore fertilizer (Gromore, Gardena, CA, USA).

Nematode Cultures. Two closely related isolates of *M. javanica*, designated VW4 and VW5, and a *M. incognita* isolate (557R) were obtained from Dr. V. M. Williamson (University of California, Davis). Isolate VW4 is a clonal population that was established from a single female. At moderate soil temperatures (≤28°C), this isolate has extremely low survivorship on resistant (*Mi*+) tomato cultivars, and is, therefore, classified as avirulent (Milligan et al., 1998). VW5 is a virulent isolate that can establish large populations on resistant tomato, and that was derived from VW4 by artificial selection (Milligan et al., 1998). Both *M. javanica* isolates were maintained on tomato plants in hydroponic culture in aerated Miller's Supreme 16-4-16 fertilizer solution (Miller Chemical & Fertilizer Corporation, Hanover, PA, USA) (Lambert et al., 1992). Infective second-stage juveniles for use in bioassays were collected from these hydroponic cultures by vacuum filtration of the nutrient solution using

Nuclepore polycarbonate Track-Etch Membranes (Whatman International, Maidstone, England, UK). Nematodes were then resuspended in a small volume of distilled water and quantified by examining aliquots of the sample with a light microscope. To assay *M. incognita* isolate 557R, which can survive and reproduce on plants that carry *Mi-1.2* (Yaghoobi et al., 1995), we used eggs provided by the Williamson laboratory. The eggs were extracted from root systems using 10% sodium hypochlorite (Hussey and Barker, 1973).

Jasmonic Acid Application. Jasmonic acid (JA) (Sigma, St. Louis, MO, USA) was dissolved in acetone at a rate of 1 g/ml and dispersed in water to achieve a 1.5-mM JA solution (Thaler, 1999). Carrier solution, which consists of acetone dispersed in water (315 μl/l), was used as a control treatment. Tomato plants were treated at approximately 4 wk after planting, when the plants had four fully expanded true leaves. Plants were sprayed with JA solution or control solution applied at a rate of 1 ml per leaf using an atomizer (~4 ml/plant), while shielding the root systems from treatment.

Effects of JA Application on Nematode Performance. The systemic effects of JA application on *M. javanica* infection were measured on tomato cultivars, Moneymaker (*Mi*−) and Motelle (*Mi*+), sprayed with either JA or carrier solution (7 plants/treatment group). Forty-eight hr after chemical treatment, the sand surrounding the roots of each plant was injected with ~3,000 second-stage juvenile (J2) avirulent nematodes (*M. javanica* isolate VW4). Plants were maintained in a greenhouse (~24–27°C; 16:8 L:D photoperiod) long enough for the nematodes to complete their life cycle (6.5 wk), and nematode establishment and reproduction was compared by measuring the number of egg masses produced per plant. Root systems were washed of all sand and immersed for 10 min in erioglaucine solution (0.1 g/l) (Sigma) to stain the egg masses, and the total numbers of egg masses per plant were counted (Yaghoobi et al., 1995). Each root system was then dried at 45°C in an incubator, and the dry root weights were recorded.

The effects of JA application on *M. javanica* isolate VW5 (virulent) were evaluated by using the same experimental design described above (6–7 plants/treatment group). Preliminary experiments in which we inoculated plants with 3,000 VW5 juveniles indicated that this inoculum level generated more egg masses than could reasonably be counted. Therefore, for this experiment, plants were inoculated with ~1,500 J2 nematodes. To test *M. incognita* isolate 557R, we performed a similar assay using eggs rather than juveniles as our inoculum. To achieve infection levels comparable to those obtained with infective VW4 and VW5 juveniles, plants were inoculated with approximately 9,000 eggs to compensate for the lower viability of eggs compared with juveniles. Plants (5–6 plants/treatment group) were inoculated 48 hr after chemical treatment, and egg mass numbers were counted 6.5 wk after inoculation.

Effects of Temperature on JA-induced Resistance and Mi-mediated Resistance. The effects of JA treatment and *Mi-1.2* on the performance of

M. javanica isolate VW4 (avirulent) were compared at 25 and 32°C (8 replicate plants/treatment group). Twenty-four hr prior to the experiment, Moneymaker (*Mi*−) and Motelle (*Mi*+) plants were placed in two separate Conviron growth chambers (Controlled Environments, Inc., Winnipeg, Canada) to achieve the desired sand temperatures. All plants were then treated with a foliar application of JA or carrier solution and inoculated with VW4 infective juveniles as described above. Plants were watered by hand twice a day with nutrient solution acclimated to the temperature of each growth chamber. Plants were maintained in growth chambers for 7 d after nematode inoculation to allow sufficient time for nematode establishment, and were then moved to the greenhouse (24–27°C). The critical period during which temperature can influence the effectiveness of *Mi*-mediated resistance occurs within the first 2–3 d after inoculation (Dropkin, 1969). Egg mass production was measured 6.5 wk after inoculation as described above.

A second assay with a larger number of replicate plants (20 plants/treatment for Motelle; 10 plants/treatment for Moneymaker) was also performed to assess the effects of JA treatment and *Mi-1.2* on nematode performance at 32°C. Due to limited growth chamber space, plants were grown in 200-ml Styrofoam cups. When the plants had approximately four true leaves, plants were transferred to a growth chamber at 32°C and treated with JA or control solution as described above. All plants were inoculated with *M. javanica* isolate VW4 48 hr after treatment. Because of the small size of the plants and their root masses, a low inoculum level (~600 infective juveniles/plant) was used for this assay. Plants were incubated at 32°C for 7 d and then gently transplanted into 1-l cups and transferred to the greenhouse. Egg mass numbers per plant were evaluated 6.5 wk after inoculation.

Data Analysis. We evaluated nematode performance using the number of egg masses/dry root weight/plant, because temperature can influence the size of root masses (Haroon et al., 1993), which can in turn influence nematode reproduction on resistant cultivars (Melakeberhan, 1998). Unequal variances were stabilized by log transformation using the equation "log (Y + 1)," where Y is egg masses/dry root weight/plant (Gomez and Gomez, 1984). Statistical comparisons were performed using JMP version 5.01 (SAS, Cary, NC, USA). For each assay, foliar treatment and genotype were compared as independent fixed factors by full factorial two-way ANOVA. Comparisons between treatment combinations were analyzed by Student's t test.

RESULTS

Effects of JA on Avirulent Nematodes. Egg mass production by *M. javanica* isolate VW4 differed among treatment groups (F = 102.23; df = 3,24;

TABLE 1. EFFECTS OF JA-INDUCED DEFENSES ON AVIRULENT *M. javanica* ISOLATE VW4

Genotype	Treatment	Avg. root mass (g)	Avg. egg masses/gram root tissue
(*Mi*−)	Control	4.66 ± 1.25 a*	170.0 ± 114.5 a
	Jasmonic acid	5.79 ± 2.67 a	42.11 ± 30.78 b
(*Mi*+)	Control	5.71 ± 2.47 a	0.27 ± 0.39 c
	Jasmonic acid	5.88 ± 3.27 a	0 ± 0 c

* Within each column, values followed by different letters are significantly different at $\alpha = 0.05$. Statistics were performed on log-transformed data.

$P < 0.001$) (Table 1). There was a significant interaction between tomato cultivars and chemical treatment ($F = 7.07$; $df = 1,24$; $P = 0.014$). Nematode performance was dramatically reduced on the resistant cultivar Motelle (*Mi*+) compared to the susceptible cultivar Moneymaker (*Mi*−) ($t = -10.11$, $df = 24$, $P < 0.001$ for plants sprayed with control solution; $t = 13.87$, $df = 24$, $P < 0.001$ for plants treated with JA). This confirms previous findings that *Mi*-mediated resistance is effective against isolate VW4 (Milligan et al., 1998; Lambert et al., 1999). On the susceptible cultivar Moneymaker, egg mass production was lower on plants treated with JA than on plants sprayed with control solution ($t = 4.35$; $df = 24$; $P < 0.001$). Egg mass numbers were low on Motelle plants treated with control solution, and no egg masses were observed on Motelle plants treated with JA. There was no statistically significant difference between these two treatment groups ($t = 0.59$; $df = 24$; $P = 0.559$). Neither JA treatment ($F = 0.46$; $df = 1, 24$; $P = 0.503$) nor cultivar ($F = 0.35$; $df = 1, 24$; $P = 0.559$) influenced root weights in this assay (Table 1).

TABLE 2. EFFECTS OF TEMPERATURE ON JA-INDUCED DEFENSES AND *Mi*-MEDIATED RESISTANCE

Temperature (°C)	Genotype	Treatment	Avg. root mass (g)	Avg. egg masses/gram root tissue

TABLE 3. EFFECTS OF JA-INDUCED DEFENSES ON AVIRULENT NEMATODES AT 32°C

Genotype	Treatment	Avg. root mass (g)	Avg. egg masses/gram root tissue
(*Mi*−)	Control	8.16 ± 3.34 a*	17.98 ± 11.64 a
	Jasmonic acid	11.91 ± 5.48 a	9.80 ± 7.00 b
(*Mi*+)	Control	9.91 ± 3.94 a	0.88 ± 1.08 c
	Jasmonic acid	10.25 ± 3.83 a	0.24 ± 0.53 d

* Within each column, values followed by different letters are significantly different at $\alpha = 0.05$. Statistics were performed on log-transformed data.

Effects of Sand Temperature on JA-Induced Defenses and Mi-1.2. When the effects of JA treatment and *Mi-1.2* were compared at 25 vs. 32°C, egg mass production by *M. javanica* isolate VW4 differed significantly among treatment groups ($F = 70.58$; $df = 7,56$; $P < 0.001$). There was an interaction between temperature and plant genotype ($F = 107.62$; $df = 1, 56$; $P < 0.001$) but no interaction between genotype and chemical treatment ($F = 2.09$; $df = 1, 56$; $P = 0.154$), temperature and chemical treatment ($F = 0.23$; $df = 1, 56$; $P = 0.635$), or genotype, chemical treatment, and temperature ($F = 1.48$; $df = 1, 56$; $P = 0.229$) (Table 2). Nematode reproduction was lower on Motelle (*Mi*+) than on Moneymaker (*Mi*−) at both soil temperatures ($t = -14.57$, $df = 56$, $P < 0.001$ for plants at 25°C; $t = -2.97$, $df = 56$, $P = 0.004$ for plants at 32°C), although egg mass numbers on Motelle increased dramatically with temperature ($t = 11.34$; $df = 56$; $P < 0.001$). Trends in the data suggested that the impact of JA on resistant plants varies with temperature, and so Student's *t* tests were also used to compare the effects of chemical treatment on nematode reproduction. JA treatment reduced nematode performance on the susceptible cultivar Moneymaker at both soil temperatures ($t = -2.75$, $df = 56$, $P = 0.008$ for plants at 25°C; $t = 2.01$, $df = 56$, $P = 0.049$ for plants at 32°C). On the resistant cultivar Motelle, JA treatment had no effect at 25°C ($t = 0.09$; $df = 56$; $P = 0.933$). At 32°C, nematode performance was lower on Motelle plants treated with JA than on Motelle sprayed with control solution, but this difference was not significant at the $\alpha = 0.05$ confidence interval ($t = 1.78$; $df = 56$; $P = 0.081$).

TABLE 4. EFFECTS OF JA-INDUCED DEFENSES ON VIRULENT *M. javanica* ISOLATE VW5

Genotype	Treatment	Avg. root mass (g)	Avg. egg masses/gram root tissue
(*Mi*−)	Control	11.63 ± 1.75 a*	62.57 ± 3.26 a
	Jasmonic acid	17.34 ± 2.55 b	39.28 ± 9.85 a
(*Mi*+)	Control	10.07 ± 2.21 a	81.85 ± 26.52 a
	Jasmonic acid	11.66 ± 2.39 a	79.02 ± 42.39 a

* Within each column, values followed by different letters are significantly different at $\alpha = 0.05$. Statistics were performed on log-transformed data.

TABLE 5. EFFECTS OF JA-INDUCED DEFENSES ON VIRULENT *M. incognita* ISOLATE 557R

Genotype	Treatment	Avg. root mass (g)	Avg. egg mass/gram root tissue
(*Mi*−)	Control	7.38 ± 1.05 a*	193.81 ± 78.63 a
	Jasmonic acid	6.84 ± 1.57 a	213.73 ± 78.49 a
(*Mi*+)	Control	8.63 ± 2.23 a	171.80 ± 89.67 a
	Jasmonic acid	7.97 ± 1.25 a	143.20 ± 25.75 a

* Within each column, values followed by different letters are significantly different at $\alpha = 0.05$. Statistics were performed on log-transformed data.

In a second assay that tested the effects of JA and *Mi-1.2* at 32°C with a larger number of replicates, reproduction again differed significantly among treatments ($F = 92.84$; $df = 3,56$; $P < 0.001$), and there was no interaction between plant genotype and chemical treatment ($F = 0.85$; $df = 1,56$; $P = 0.362$) (Table 3). Egg mass numbers were lower on Motelle than on Moneymaker ($F = 266.74$; $df = 1,56$; $P < 0.001$), and JA treatment reduced nematode reproduction on both cultivars (for main effects of JA, $F = 11.72$; $df = 1, 56$; $P = 0.001$; for effects of JA on Moneymaker, $t = 2.66$; $df = 56$; $P = 0.010$; for effects of JA on Motelle, $t = 2.17$; $df = 56$; $P = 0.034$).

Effects of JA on Virulent Nematodes. Egg mass production by *M. javanica* isolate VW5 did not differ among treatment groups ($F = 1.03$; $df = 3,22$; $P = 0.399$) (Table 4), and there was no interaction between plant genotype and chemical treatment ($F = 5.13$; $df = 1,22$; $P = 0.481$). The overall effect of *Mi-1.2* was not statistically significant ($F = 1.95$; $df = 1, 22$; $P = 0.177$), which confirms previous findings that VW5 is virulent on resistant cultivars (Milligan et al., 1998; Lambert et al., 1999). The overall effect of JA treatment also was not significant ($F = 0.76$; $df = 1, 22$; $P = 0.393$), indicating that JA application is not effective against nematode isolate VW5.

Reproduction of *M. incognita* isolate 557R also did not differ among treatment groups ($F = 0.75$; $df = 3,18$; $P = 0.537$) (Table 5), and there was no interaction between plant genotype and chemical treatment ($F = 0.15$; $df = 1,18$; $P = 0.702$). This isolate established comparable numbers on resistant vs. susceptible plants ($F = 2.09$; $df = 1,18$; $P = 0.166$), confirming that it is indeed capable of overcoming *Mi*-mediated resistance (Yaghoobi et al., 1995). Reproduction of this isolate was also not deterred by JA treatment ($F = 0.05$; $df = 1,18$; $P = 0.825$).

DISCUSSION

This study demonstrates that application of synthetic JA to tomato foliage induces systemic effects that suppress root-knot nematode infestation. Relative-

ly few other studies have examined the effects of JA-induced defenses on belowground pests. Application of exogenous methyl jasmonate to roots is known to induce nematode resistance in spinach and oats (Soriano et al., 2004a, b), and treating the foliage of grapevines with jasmonic acid can reduce infestation by root-feeding phylloxera (Omer et al., 2000). Mutagenized *Arabidopsis* lines that are deficient in jasmonate signaling have increased susceptibility to the soil fungi *Pythium irregulare* and *P. mastophorum* (Staswick et al., 1998; Vijayan et al., 1998), and a tomato mutant that is deficient in JA synthesis is also highly susceptible to *Fusarium oxysporum* and *Verticillium dahliae* (Thaler et al., 2004). These studies indicate that jasmonates play a role in the protection of root tissues as well as in foliar defenses. The systemic nature of the induced response to foliar JA treatment in tomato and grape also supports the hypothesis that plant defenses can mediate indirect interactions between above- and belowground pests (van Dam et al., 2003).

As yet, we do not know the mechanism through which JA suppresses nematode infestation on tomato roots. JA is known to be transported from foliage to roots, where it can have a wide range of effects on development and metabolism (Baldwin et al., 1994; Zhang and Baldwin, 1997). Jasmonates influence root growth and nutrient partitioning (Tung et al., 1996; Staswick et al., 1998; Mader, 1999; Wang et al., 2002), which could potentially affect nematode parasitism. In this study, however, we did not observe a strong or consistent effect of JA treatment on the mass of our root systems (Tables 1–5). Jasmonates can also trigger synthesis of a wide range of secondary metabolites and defensive proteins in roots. For example, exogenous jasmonates stimulate production of 20-hydroxyecdysone in spinach (Soriano et al., 2004a), flavone-*C*-glycosides in oats (Soriano et al., 2004b), and nicotine in tobacco (Baldwin et al., 1994). All of these compounds are toxic to nematodes *in vitro*, and have been implicated in plant defenses against plant-parasitic nematodes (Davis and Rich, 1987; Soriano et al., 2004a, b). Exogenous jasmonates can also induce proteinase inhibitor (PI) expression in roots (Botella et al., 1996; Dammann et al., 1997; van Dam et al., 2001). When expressed at high constitutive levels in transgenic tomato, *Arabidopsis*, and rice, cysteine and serine PIs reduce the population growth of several species of plant-parasitic nematodes, including root-knot nematodes (Atkinson et al., 1996; Urwin et al., 1998; Atkinson et al., 2003). Furthermore, a transgene encoding a proteinase inhibitor from rice has successfully been pyramided with a source of partial nematode resistance in potato to achieve full resistance (Urwin et al., 2003). Potentially, PIs or other systemic defenses induced in tomato roots by JA treatment may be responsible for the partial resistance we have observed in treated plants.

This study also compared JA-induced resistance to *Mi*-mediated resistance, and examined the combined effects of these two plant defenses on nematodes. At a moderate temperature (25°C), *Mi-1.2* suppressed reproduction of avirulent

root-knot nematodes almost completely, whereas JA treatment imparted only partial resistance to a susceptible tomato cultivar (Tables 1 and 2). JA treatment did not inhibit *Mi*-mediated resistance, which suggests a lack of signaling conflicts between these two forms of defense (Tables 1–3). At a high temperature (32°C), *Mi-1.2* was significantly less effective than at 25°C, but nonetheless conferred partial nematode resistance (Tables 2 and 3). Despite many statements in the literature that *Mi-1.2* is inactive above 30°C, the majority of studies on the temperature sensitivity of *Mi-1.2* have compared nematode reproduction on resistant cultivars at different temperatures without making a statistical comparison between resistant and susceptible genotypes. Our results indicate that the effects of temperature on *Mi*-mediated resistance are quantitative rather than qualitative, and this finding is consistent with data presented by two other research groups (Araujo et al., 1982; Haroon et al., 1993). Unlike *Mi*-mediated resistance, JA-induced resistance was heat-stable (Table 2). Furthermore, at high temperature, JA treatment was capable of enhancing the control of avirulent nematodes on a resistant cultivar (Table 3). Thus, it appears that under certain conditions, *Mi*-mediated resistance and jasmonate-induced defenses can have an additive effect. JA treatment, however, was not able to suppress two nematode isolates that are virulent against *Mi-1.2* (Tables 4 and 5), including a virulent *M. javanica* isolate that is nearly isogenic to the avirulent isolate used in this study.

Further work is needed to understand the basis for virulence in resistance-breaking nematodes (Castagnone-Sereno, 2002; Williamson and Gleason, 2003). Because of its homology to many other plant genes that mediate gene-for-gene resistance against pathogens, it has been hypothesized that *Mi-1.2* may also act in a gene-for-gene manner (Milligan et al., 1998). In other words, *Mi*-mediated resistance may be due to a defense response that is triggered by the product of a single dominant avirulence (Avr) gene in the pest (Flor, 1955), and virulent nematodes may lack this elicitor. Alternatively, virulence in certain nematode isolates could be due to enhanced expression of pathogenicity factors, rather than to evasion of detection by the host plant. The enhanced pathogenicity hypothesis is consistent with the observation that nematodes can in some cases develop cross-resistance to more than one source of host-plant resistance. For example, some, but not all, root-knot nematode isolates that are virulent against *Mi-1.2* in tomato are also able to overcome the *Me3* resistance gene in pepper (Castagnone-Sereno et al., 2001). If virulence can be attributable to enhanced aggressiveness, this would more readily explain the ability of VW5 and 557R to overcome JA-induced defenses than the gene-for-gene hypothesis.

Our study demonstrates that artificial induction of JA-dependent defenses could play a role in the integrated management of root-knot nematodes on tomato. Furthermore, many other agricultural crops are heavily impacted by root-knot nematode infestations (Williamson and Hussey, 1996), and express

JA-dependent defenses (reviewed by Karban and Baldwin, 1997). Artificial induction of JA could potentially protect these crops from damage caused by nematodes, and be combined with sources of genetic resistance to reduce our current reliance on hazardous nematicides.

Acknowledgments—We are grateful to Dr. Valerie Williamson, Waclawa Pudlo, and Dr. Cynthia Gleason for providing nematode isolates for this project. We thank Fangyan Chen and John Geurber for their assistance with greenhouse maintenance, and Dr. Ron McNew and Dr. Andronikos Mauromoustakos for assistance with statistical analysis. We also appreciate the feedback of Dr. Robert Riggs and two anonymous reviewers on this manuscript. This research was funded by the Arkansas Agricultural Experiment Station and the California Tomato Commission, as well as by USDA Southern Agricultural Research and Education program (SARE) grant no. GS03-027.

(Received December 9, 2004; revised February 18, 2005; accepted May 11, 2005)

Abstract—The effects of limonene, a mixture of limonene + carvone (1:1, v/v), and methyl jasmonate (MeJA) on diamondback moth (DBM) (*Plutella xylostella* L.) oviposition, larval feeding, and the behavior of its larval parasitoid *Cotesia plutellae* (Kurdjumov) with cabbage (*Brassica oleracea* L. ssp. *capitata*, cvs. Rinda and Lennox) and broccoli (*B. oleracea* subsp. *Italica* cv Lucky) were tested. Limonene showed no deterrent effect on DBM when plants were sprayed with or exposed to limonene, although there was a cultivar difference. A mixture of limonene and carvone released from vermiculite showed a significant repellent effect, reducing the number of eggs laid on the cabbages. MeJA treatment reduced the relative growth rate (RGR) of larvae on cv Lennox leaves. In Y-tube olfactometer tests, *C. plutellae* preferred the odors of limonene and MeJA to filtered air. In cv Lennox, the parasitoid preferred DBM-damaged plants with limonene to such plants without limonene. *C. plutellae* females were repelled by the mixture of limonene + carvone. In both cultivars, exogenous MeJA induced the emission of the sesquiterpene (*E*,*E*)-α-farnesene, the homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and green leaf volatile (*Z*)-3-hexenyl acetate + octanal. The attractive effect of limonene and MeJA predicts that these two compounds can be used in sustainable plant protection strategies in organic farming.

Key Words—Limonene, methyl jasmonate, carvone, diamondback moth, *Cotesia plutellae*, cabbage, broccoli, vermiculite, olfactometer.

INTRODUCTION

The diamondback moth (DBM), *Plutella xylostella* (L.) (Lepidoptera: Yponometidae) is economically the most important pest of cruciferous crops throughout the world (Talekar and Shelton, 1993). DBM feeds on all cruciferous crop plants, cole crops, and several greenhouse plants (Reddy et al., 2004). In this context, one of the most important biological control agents for DBM is the braconid *Cotesia plutellae* (Kurdjumov) (Hymenoptera: Braconidae). *C. plutellae* is a potential larval parasitoid that can parasitize in the first three instars of DBM larvae (Reddy et al., 2002; Zu-hua et al., 2002).

Plants can defend themselves against herbivores by direct and indirect defense mechanisms. Direct defense affects the insect herbivore through toxic or antinutritional compounds or through repellents or deterrents (Karban and Baldwin, 1997). In indirect defense, after herbivore damage, plants produce volatiles that can attract predators or parasitoids, as has been shown in many plants (Dickens, 1999; Shiojiri et al., 2001; Dicke et al., 2003; Vuorinen et al., 2004a,b). These volatile compounds permit insect parasitoids and predators to discriminate between intact and damaged plants (Reddy and Guerrero, 2004; Vuorinen et al., 2004a). The parasitoid *C. plutellae* prefers the odor of damaged cabbage plants to that of intact cabbage in Y-tube olfactometer tests (Vuorinen et al., 2004a).

In previous studies, limonene alone or with other monoterpenes is deterrent (Ntiamoah et al., 1996; Ntiamoah and Borden, 1996) or repellent (Peterson et al., 1994; Nehlin et al., 1994; Ibrahim et al., 2001) toward insects. Chenier and Philogene (1989), for example, reported that monoterpenes, including limonene, attracted predators of conifer bark beetles. Carvone has been reported to inhibit the feeding of pales weevil (*Hylobius pales*) on *Pinus strobus* seedlings (Salom et al., 1996), of pine weevil (*Hylobius abietis*, Coleoptera: Curculionidae) on Scots pine (*Pinus sylvestris*) (Klepzig and Schlyter, 1999; Schlyter et al., 2004), and of the slug *Arion lusitanicus* on lettuce (Frank et al., 2002). Tripathi et al. (2003) reported feeding deterrence and contact and fumigant toxicity of carvone against stored product beetles, whereas Den Ouden et al. (1993) found a short-term oviposition repellence of carvone against cabbage root fly (*Delia radicum*).

Methyl jasmonate (MeJA) (a volatile derivative of jasmonic acid), which is involved in plant defense against herbivores, increases the activity of defense-related proteins (Thaler et al., 1996). MeJA was reported to protect genetically modified *Arabidopsis* plants (deficient in the jasmonate precursor linolenic acid) from attack by larvae of *Bradysia impatiens* (Diptera: Sciaridae) (McConn et al., 1997). The relative growth rate (RGR) of *Spodoptera exigua* larvae fed on MeJA-treated leaflets was found to be lower than that of those reared on control leaflets (Thaler et al., 1996). However, Oka et al. (1999) found that MeJA did

not show promising results as a nematocide to protect tomato from root-knot nematodes.

Natural compounds originating from plants might be potential alternative pesticide (Lee et al., 2001; Ibrahim et al., 2004) that are not persistent in the environment and are safe to natural enemies, nontarget organisms, and human beings for use in sustainable agriculture (Lacey and Shapiro-Ilan, 2003). Therefore, our aim was to investigate the role of limonene, a mixture of limonene + carvone, and MeJA in DBM control and the effects of these compounds on the parasitoid *C. plutellae*.

METHODS AND MATERIALS

Plant Material and Insects. Cabbage (*Brassica oleracea* L. ssp. *capitata*, cvs. Rinda and Lennox) and broccoli (*B. oleracea* subsp. *Italica* cv Lucky) seedlings, 4 to 5 wk-old, grown at 24/18°C (day/night) and relative humidity (RH) of 60% were used. Diamondback moth *P. xylostella* L. and the parasitoid *C. plutellae* (Kurdjumov) were from our own mass rearings (Vuorinen et al., 2004a). Second and third instars of *P. xylostella* feeding on broccoli plants were offered to *C. plutellae* females for egg laying. The emerged adults of *C. plutellae* were collected and released into a clean insect cage, and a honey–water solution (1:1) was provided for feeding. One- to three-d-old *C. plutellae* females were used in the behavioral assay.

Test Compounds. (*S*)-(+)-Carvone and (*R*)-(+)-limonene are the major compounds in the essential oil of caraway seeds (Bouwmeester et al., 1995, 1998; Hannukkala et al., 2002). Recently, there has been some interest in the use of caraway oil for plant protection purposes (Iacobellis et al., 2005). (*R*)-(+)-Limonene has been found to be more effective than (*S*)-(−)-limonene against the pine processionary caterpillar, *Thaumetopoea pityocampa* (Tiberi et al., 1999). (*R*)-(+)-Limonene (97% purity) and (*S*)-(+)-carvone (96%) obtained from Aldrich Chemical Co. Ltd. (Milwaukee, WI, USA), and methyl jasmonate (96%) provided by Bedoukian Research Inc. (Danbury, CT, USA) were used in this study.

DBM Egg-Laying Experiments. The following three experiments were conducted for the egg-laying study.

Experiment 1: Cabbage plants sprayed with 3% limonene solution in a 5% ethanol (99.5% purity) solution in water were offered to DBMs for egg laying in a two-choice test where the moths were allowed to choose between two treatments (control and treated) 24 hr after spraying in an acrylic polyester gauze cage (60 × 33 × 33 cm, external dimensions). Plants sprayed with 5% ethanol in 95 ml of water were used as controls. The amount of solution reaching the plant surface was estimated to be 3–4 ml. The test was replicated 15 times.

Experiment 2: Cabbage plants were exposed to limonene released from vermiculite (phyllosilicate mineral). Fifteen milliliters of limonene were mixed into 300 ml of vermiculite by vigorous stirring, and 25 ml of the mixture were placed at the base of each plant. For controls, 25 ml of vermiculite without limonene were placed at the base of the plants. Thereafter, the plants were introduced into the cages individually in a no-choice test where there was only one plant in a cage. The two tests were conducted simultaneously in two separate growth chambers, and each test was replicated ten times.

Experiment 3: As previously, 7.5 ml of limonene and 7.5 ml of carvone were mixed into 300 ml of vermiculite, and thereafter 25 ml of the mixture were placed at the base of each plant. For controls, 25 ml of vermiculite without test compounds were placed at the base of each cabbage and broccoli plant. Each test was replicated ten times.

Ten moths (1:1 sex ratio) were released into the cage and allowed to lay eggs for 48 hr for all three experiments. The moths were then removed from the cage and the eggs were counted.

Feeding Experiment. Cabbage (cv Lennox and Rinda) plants sprayed with 3% limonene (prepared as previously) or 4.5 mM MeJA in 5% ethanol (99.5% purity) in water were used. Plants sprayed with 5% ethanol in water served as controls. Twenty-four hr after spraying, the fully developed leaves of the sprayed plants were cut, and the petiole was inserted into a 1.5-ml Eppendorf tube filled with tap water. Thereafter, the leaf was placed into a plastic container (250 ml) with a lid. Late second or early third instars of DBM larvae were introduced onto the leaf and allowed to feed for 48 hr. The initial and final weights of larvae were measured to calculate the RGR, using the following formula: $\ln(W_f) - \ln(W_i)$, where W_f is the final weight and W_i the initial weight. The experiment was replicated 20 times for limonene and 15 times for MeJA treatments.

Olfactometer Experiments. Cabbage plants from the above-mentioned cultivars and broccoli were used. Ten microliters of limonene, 10 μl of MeJA, and 2 μl of a mixture of limonene + carvone (1:1 v/v) were applied by pipetting on Whatman filter paper (42.5 mm^2) and left in a fume hood for 10 min to evaporate. The filter paper with the elicitor was introduced into the glass container, as the odor source with a plant or without, depending on the test. The filter paper was placed on a piece of aluminum foil in the glass container. This experiment was conducted in a Y-tube olfactometer (main arm 10.5 cm, other arms 10 cm, inner diam 1.6 cm, angle between two arms ~90°). Plants were placed into 1-l glass containers closed with Teflon-sealed lids with two inlets. Pressurized air was filtered through activated-charcoal and passed through the glass container holding the plant with the odor source (with or without limonene, with or without limonene + carvone, and with or without MeJa), and then to one of the Y-tube arms. *C. plutellae* females were released individually into the opening of the main arm end of the Y tube and observed for 5 min or

until they made the final choice. This choice was recorded as the insect passed into the end of the Y-tube arm. The Y tube was rotated 180° after each test run. The source of the odor, the glass container, the Y-tube device, and the lids of the containers were replaced after testing eight *C. plutellae* females in the limonene and MeJA experiments. Ten females were used for each test in the limonene + carvone assays, the filter papers with the mixture, and the Y tube being replaced after testing five females.

Collection of Volatile Compounds. Volatiles emitted from the foliage of the two cultivars of cabbage plants were collected using the headspace collection technique and analyzed by gas chromatography–mass spectrometry (GC-MS) as described by Vuorinen et al. (2004a) 1 d after spraying with 3% limonene in 5% ethanol in water or 4.5 mM MeJA in 5% ethanol in water. Five and six (Lennox and Rinda, respectively) randomly selected seedlings per treatment were used for volatile collections. The roots of each sample plant were washed and pruned slightly before being inserted into a 15 ml vial filled with water. Thereafter, the whole plant was enclosed in a 1.5 l (Lennox) or 1-l (Rinda) glass vessel. The glass vessels had two inlets, one for purified air and one for sampling. Charcoal-filtered air was led through Teflon tubing at a flow rate of 200 ml min^{-1} to the Tenax TA adsorbent tubes (150 mg), where the volatiles were collected for 30 min per sample. Samples were analyzed by GC-MS (Hewlett Packard GC type 6890, MSD 5973). Compounds collected on the Tenax TA adsorbent tubes were released by thermodesorption at 250°C for 10 min. Compounds were cryofocused in a cold trap at −30°C and subsequently injected onto an HP-5 capillary column (50.0 m × 0.2 mm i.d. × 0.50 μm film thickness). The column temperature was first held at 40°C for 1 min. Thereafter, the temperature was programmed to increase from 40°C to 210°C at 5°C min^{-1} and finally to 250°C at 20°C min^{-1}. An interval of 30 to 300 *m*/*z* range was considered for the MS runs. Compounds were identified with different external standards, one for terpenoids and one for green leaf volatiles (GLVs), by comparing the mass spectra of a single compound with those of pure standards and those in the Wiley library. The amount of α-thujene, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and (*E*,*E*)-α-farnesene was calculated by assuming that the responses to them were the same as those to α-pinene, (*Z*)-ocimene, and (*E*)-β-farnesene, respectively. The shoot biomass of sample plants was determined to calculate the volatile emissions as nanograms per gram dry weight per hour (ng g DW^{-1} h^{-1}). Volatiles were collected at a room temperature of 22°C and light intensity of 250 μmol m^{-2} s^{-1}. Light intensity was measured with Quantum Sensor LI-185B (LI-COR, inc. Lincoln, NE, USA).

Statistics. Statistical analysis was performed using the SPSS 11.5 for Windows statistical package. One-way ANOVA and general linear models (GLM) procedures followed by Tukey's or Dunnett's T3 multiple comparison tests were used to determine the RGR of larvae and for normally distributed

volatile compounds. Other compounds that were not normally distributed were tested with the nonparametric Kruskal–Wallis test. The Mann–Whitney test with Bonferroni correction was used to analyze differences between treatments. Data from the DBM egg-laying tests were analyzed with the independent-samples *t* test. The response of *C. plutellae* was analyzed with the non-parametric binomial test.

RESULTS

Egg-Laying Experiments. DBM females laid marginally significantly more eggs on cabbage (cv. Rinda) plants sprayed with limonene (Figure 1A) in the two-choice tests and when limonene was released from vermiculite (Figure 1B) in the no-choice test than on control plants. The number of eggs laid by females on cabbage plants treated with limonene + carvone released from vermiculite was lower in both cultivars in the no-choice tests (Figure 1C). On broccoli plants, the difference was not significant.

Feeding Experiment. Limonene had no deterrent effect on DBM larvae when detached leaves from plants sprayed with this compound were offered to them. Larval weight was not influenced by limonene (Figure 2A), but was significantly lower in cv Lennox sprayed with MeJA (Figure 2B).

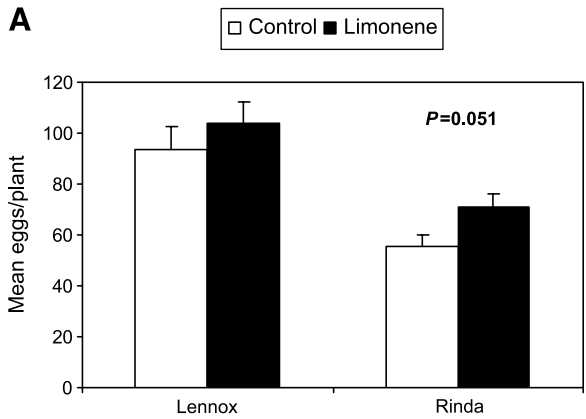

FIG. 1. *P. xylostella* ovipositioning results on (A) cabbage plants sprayed with 3% of limonene ($N = 15$) in 5% ethanol in water, (B) cabbage plants with limonene released from vermiculite ($N = 10$), and (C) cabbage (cv Lennox and Rinda) and broccoli plants exposed to the combination of limonene + carvone released from vermiculite ($N = 10$). The data were analyzed with independent samples *t* test, and error bars are from SE values. $^*P < 0.05$.

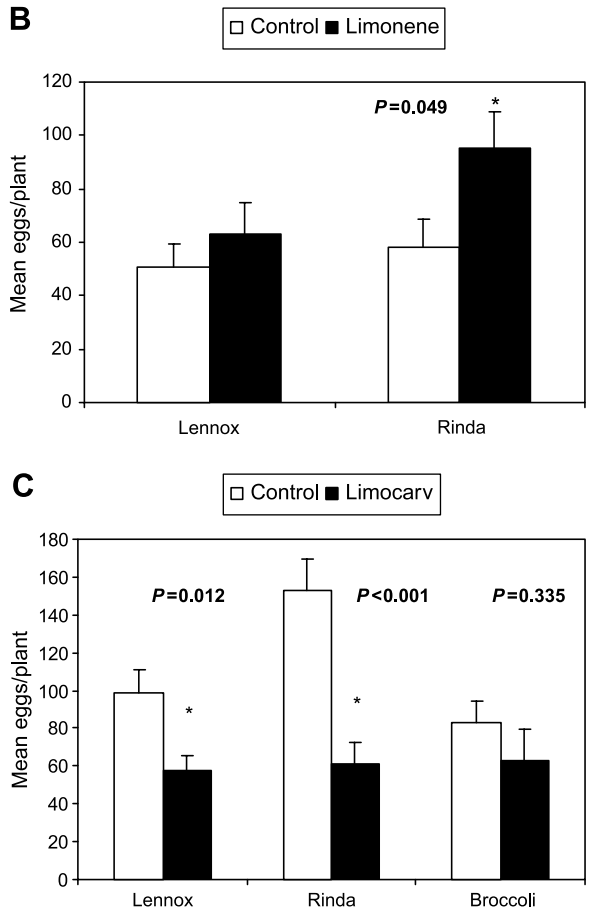

FIG. 1. CONTINUED.

Olfactometer Experiments. Females of *C. plutellae* preferred the odors of pure compounds (limonene and MeJA) to filtered air without plants in the Y-tube olfactometer tests (Figure 3A), but did not significantly discriminate between the limonene–carvone mixture and clean air. However, the number (N = 12) of *C. plutellae* females responding to any of the odor sources was lower ($P < 0.001$) than that of females (N = 38) that did not choose any of the odor source (Figure 3A). In another case, *C. plutellae* females showed a significant preference for the damaged plant with limonene over the damaged plant alone in cv Lennox (Figure 3B). In the tests with broccoli and with both cabbage cultivars, females preferred the damaged plant without limonene + carvone to

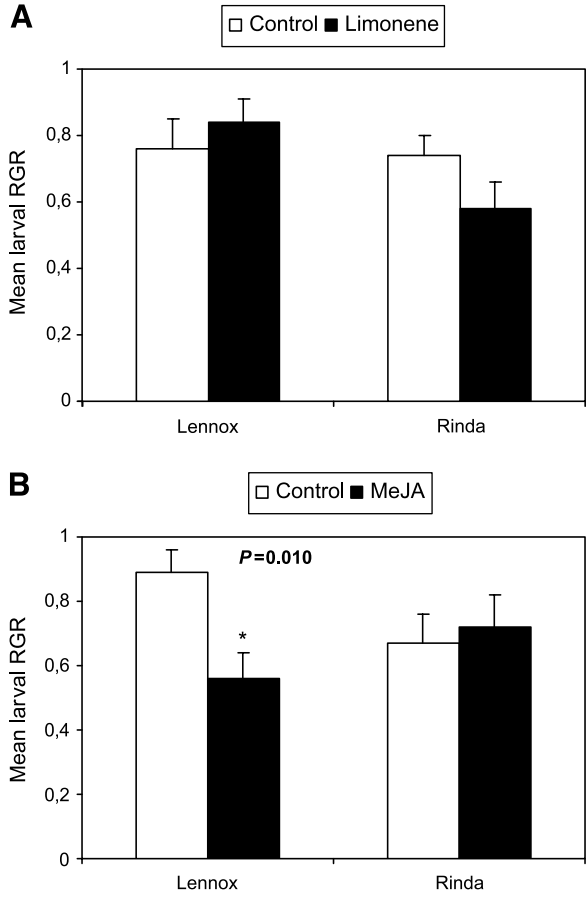

FIG. 2. Detached leaves from cabbage plants (cv Rinda and Lennox) sprayed with (A) 3% of limonene in 5% ethanol in water or (B) 4.5 mM of MeJA in 5% ethanol (99.5%) in water were fed to the DBM larvae for 48 hr and their RGR was calculated. Data were analyzed with one-way ANOVA and error bars are from SE values. $*P < 0.05$.

the damaged plant with the mixture of limonene + carvone (Figure 3C). Females were not able to differentiate between intact cabbage plants with limonene and those without it (Figure 3D). In the MeJA treatment, females did not show significant preference for any of the odor sources when tested with intact or damaged plants (data not shown).

Collection of Volatile Compounds. In both cultivars, emission of homoterpene DMNT and the sesquiterpene (*E*,*E*)-α-farnesene was induced in the

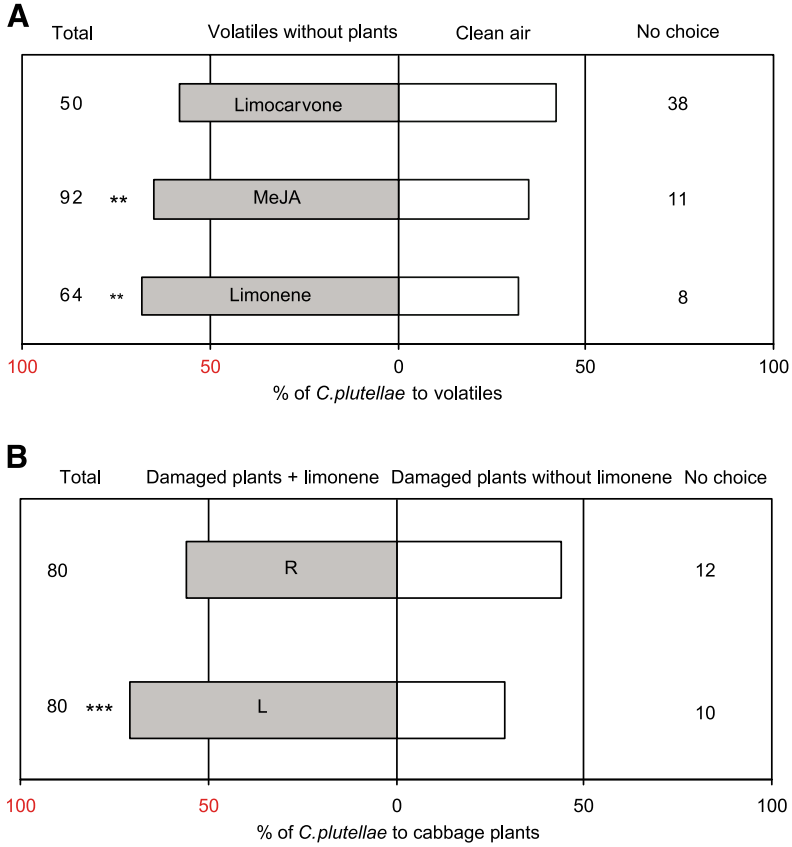

FIG. 3. *C. plutellae* responses in Y-tube olfactometer tests to (A) the odors of limonene, MeJA, and limonene + carvone without plants (treatment) and clean air; (B) damaged plants by DBM larvae + limonene (treatment) or damaged plants without limonene as control; (C) damaged plants with limonene + carvone as treatment or damaged plants without limonene + carvone serving as controls; and (D) intact plants + limonene (treatment) or without limonene as control. B = Broccoli, L = Lennox, R = Rinda. Total = the total number of females used in the experiment. No choice = the number of females that did not choose any of the odor sources. The data were analyzed using binomial tests: $*P < 0.05$, $**P < 0.01$, $***P < 0.001$.

MeJA treatment (Tables 1 and 2). In cv Rinda, the concentration of total monoterpenes was higher in the limonene treatment than in the other two treatments (Table 2). In cv Lennox, sabinene concentration was lower in the MeJA treatment. In both cultivars, the GLV (*Z*)-3-hexenyl acetate + octanal was higher in

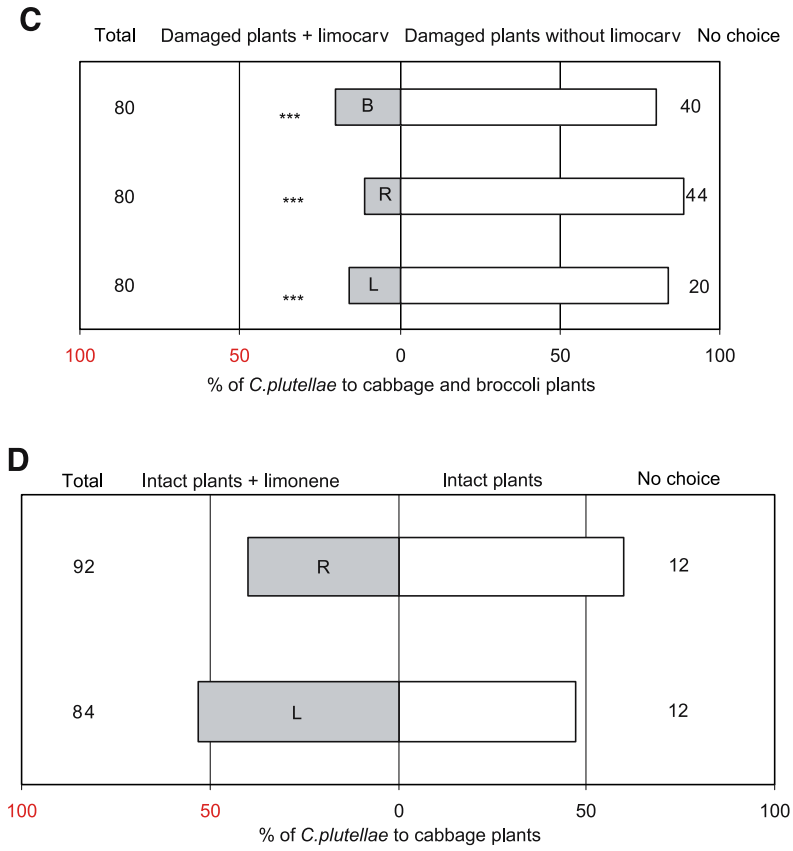

FIG. 3. CONTINUED.

the MeJA treatment than in the other two treatments. In cv Rinda, the total GLVs were higher in the MeJA treatment.

DISCUSSION

Limonene Attracts DBM and Its Parasitoid C. plutellae. We demonstrated for the first time that exogenous limonene alone attracts DBM females to cabbage cv Rinda for ovipositioning. Previously, Pivnick et al. (1994) showed that DBMs are highly sensitive to an uncharacterized combination of volatiles released by intact plants and probably dominated by terpenes. In this regard,

TABLE 1. CONCENTRATION (NG G DW^{-1} H^{-1}) OF MONO- AND SESQUITERPENES AND SOME GREEN LEAF VOLATILES IN THE HEADSPACE EMISSIONS OF CABBAGE CULTIVAR LENNOX 24 HR AFTER TREATMENT

Compounds	Control	Limonene	MeJA
Thujene	20.6 ± 1.7a	25.7 ± 4.6a	19.6 ± 5.5a
α-Pinene	11.6 ± 0.8a	14.5 ± 2.5a	8.5 ± 0.5a

γ-Terpinene	0.00 ± 0.00a	0.00 ± 0.00a	0.60 ± 0.60a
Total monoterpenes	370.89 ± 46.89a	809.422 ± 154.74b	348.55 ± 44.33a
DMNT [(*E*)-4,8-dimethyl-1,3,7-nonatriene]	0.00 ± 0.00a	6.46 ± 6.46ab	27.44 ± 3.86b
(*E*,*E*)-α-Farnesene	18.72 ± 15.17a	27.64 ± 21.03a	202.22 ± 38.74b
3-Hexen-1-ol	0.00 ± 0.00a	6.72 ± 4.35a	5.82 ± 2.47a
1-Hexanol	0.00 ± 0.00a	7.29 ± 3.00a	0.00 ± 0.00a
1-Octen-3-ol	0.00 ± 0.00a	17.09 ± 6.16a	0.00 ± 0.00a
(*Z*)-3-Hexenyl acetate + octanal	34.02 ± 15.38a	35.73 ± 9.81a	108.81 ± 20.57b
Nonanal	60.88 ± 3.90a	48.57 ± 12.75a	60.41 ± 3.22a
Total GLVs	94.91 ± 14.80a	115.42 ± 17.02ab	175.03 ± 24.06b

Control = 5% ethanol in water; limonene = 3% of limonene in 5% ethanol in water; MeJA = 4.5 mM of methyl jasmonate in 5% ethanol in water; GLV = green leaf volatile. ($N = 6$). Values are means ± SE. Means followed by different letters are significantly ($P < 0.05$) different.

limonene is one of the main volatile compounds in the headspace of intact cabbages (Shiojiri et al., 2001; Vuorinen et al., 2004b). However, DBM moths prefer the volatiles released from conspecific-damaged cabbage plants over undamaged plants (Shiojiri and Takabayashi, 2003). Vuorinen et al. (2004a) found that emission of total monoterpenes from cv Rinda was induced by the 48-hr feeding damage of DBM larvae. We found that the total monoterpene emission from limonene-treated cv Rinda was significantly higher than that in other treatments. This suggests that the volatile emission from exogenously limonene-treated cabbage cv Rinda resembles that of DBM-damaged cv Rinda.

Our results show that limonene has no deterrent effect on DBM larval feeding. This contrasts with the findings with other pest insects by Peterson et al. (1994), Nehlin et al. (1994), and Ntiamoah et al. (1996), who have shown that limonene deterred the oviposition of pickleworm moths (*Diaphania nitidalis*), carrot psyllids (*Trioza apicalis*), and onion maggots (*Delia antiqua* M.), respectively. In Y-tube olfactometer tests, *C. plutellae* females preferred infested plants with limonene to infested plants without limonene in cv Lennox. This observation agrees with our previous study, which indicated that limonene attracts the generalist predator *Podisus maculiventris* (Hemiptera: Pentatomidae) (Ibrahim and Holopainen, 2002).

Limonene + Carvone Improves the Repellent and Deterrent Effect. We found that a mixture of limonene and carvone reduces the number of eggs laid by DBMs on cabbage. These results are consistent with the findings of Ntiamoah et al. (1996) and those of Ntiamoah and Borden (1996), who have shown that a mixture of limonene, 3-carene, and *p*-cymene deters oviposition by the onion maggot (*D. antique* M.), and by the cabbage maggot (*D. radicum* L.), respectively. Similarly, limonene + carvone repels females of *C. plutellae* in Y-tube olfactometer tests. Although the use of this mixture in the Y-tube olfactometer has not been reported previously, our findings principally agree with those of Nehlin et al. (1994), Ntiamoah et al. (1996), and Ntiamoah and Borden (1996). This demonstrates that the deterrent effect of single monoterpene increases when it is combined with other terpenoids. In previous studies, Salom et al. (1996), Klepzig and Schlyter (1999), Frank et al. (2002), and Schlyter et al. (2004) reported a feeding deterrent effect of carvone on insects and slugs.

MeJA Induces the Emission of Volatiles. We found that MeJA treatment induces the emission of the sesquiterpene (*E*,*E*)-α-farnesene and the homoterpene DMNT, as previously reported by Rodriguez et al. (2001) for cotton plants treated with exogenous MeJA. Similarly, the exogenous application of MeJA on oilseed rape (*Brassica rapa* subsp. *oleifera*) increases the amount of these compounds (Loivamäki et al., 2004). In addition to constitutive monoterpenes (sabinene, limonene, β-pinene, myrcene, 1,8-cineole, α-thujene, and α-pinene), infested cabbage plants emit induced compounds such as DMNT, and (*E*,*E*)-α-farnesene, which are known to attract herbivores and their natural

enemies (Dicke et al., 1999; Rodriguez et al., 2001; Vuorinen et al., 2004a,b). Although the mechanism whereby MeJA induces DMNT and (*E*,*E*)-α-farnesene is not fully understood, Mandujano-Chavez et al. (2000) found that MeJA can induce the expression of sesquiterpene cyclase genes in tobacco cell cultures. However, MeJA has limited ability to induce later steps in the sesquiterpene pathway (Mandujano-Chavez et al., 2000). On the other hand, MeJA induces the expression of lipoxygenase in common bean (Porta et al., 1999) and in maize (Kim et al., 2003), which suggests that MeJA affects the emission of DMNT and (*E*,*E*)-α-farnesene via lipoxygenase pathway by inducing the accumulation of endogenous jasmonic acid.

As reported (Bogahawatte and van Emden, 1996; Potting et al., 1999; Vuorinen et al., 2004a), the volatile compounds emitted from plants damaged by DBM allow *C. plutellae* to discriminate between intact and damaged plants. In the present study, we demonstrated that the parasitoid *C. plutellae* is able to discriminate between limonene, MeJA, and clean air. The response of *C. plutellae* varies with the plant species and probably with the cultivar (Liu and Jiang, 2003), and the volatiles induced from infested plants seem to be important cues to *C. plutellae* (Shiojiri et al., 2001; Shiojiri and Takabayashi, 2003). Reddy et al. (2002) have also shown that DBM parasitoids, including *C. plutellae*, are attracted to a variety of chemical cues related to their host.

In summary, our results suggest that limonene and MeJA can be used as attractants for natural enemies of insect herbivores, particularly those of DBM, in organic agriculture. A mixture of limonene with carvone can act as a deterrent on crop plants, but deterrents have negative effects on natural enemies of DBM. Limonene can perhaps be used as an attractant of DMB on trap crop plants.

Abstract—Jasmonate signaling pathway plays an important role in induced plant defense against herbivores and pathogens, including the emission of volatiles that serve as attractants for natural enemies of herbivores. We studied the volatiles emitted from rice plants that were wounded and treated with jasmonic acid (JA) and their effects on the host-searching behavior of the rice brown planthopper, *Nilaparvata lugens* (Stål), and its mymarid egg parasitoid *Anagrus nilaparvatae* Pang et Wang. Female adults of *N. lugens* significantly preferred to settle on JA-treated rice plants immediately after release. The parasitoid *A. nilaparvatae* showed a similar preference and was more attracted to the volatiles emitted from JA-treated rice plants than to volatiles from control plants. This was also evident from greenhouse and field experiments in which parasitism of *N. lugens* eggs by *A. nilaparvatae* on plants that were surrounded by JA-treated plants was more than twofold higher than on control plants. Analyses of volatiles collected from rice plants showed that JA treatment dramatically increased the release of volatiles, which included aliphatic aldehydes and alcohols, monoterpenes, sesquiterpenes, methyl salicylate, *n*-heptadecane, and several as yet unidentified compounds. These results confirm an involvement of the JA pathway in induced defense in rice plants and demonstrate that the egg parasitoid *A. nilaparvatae* exploits plant-provided cues to locate hosts. We explain the use

of induced plant volatiles by the egg parasitoid by a reliable association between planthopper feeding damage and egg presence.

Key Words—Rice, jasmonic acid, *Nilaparvata lugens*, *Anagrus nilaparvatae*, plant volatiles, induced defense, host-searching behavior.

INTRODUCTION

It is widely accepted that plants respond to attack by specific herbivore species and tailor their induced direct and indirect defenses accordingly (Karban and Baldwin, 1997). Chemical defenses that target the herbivore directly result in herbivore death or retarded development (Barbosa et al., 1991; Karban and Baldwin, 1997; Agrawal, 1999; Lou and Baldwin, 2003; Sznajder and Harvey, 2003), whereas indirect defenses increase herbivore mortality through the recruitment of parasitoids and predators with volatile signals (Thaler, 1999; Kessler and Baldwin, 2001). Indirect plant defenses have been intensively studied since the late 1980s, and to date, this phenomenon has been reported in more than 23 plant species (see reviews in Vet and Dicke, 1992; Dicke, 1999; Sabelis et al., 1999; Turlings and Wäckers, 2004). Studies on the mechanisms leading to the production of herbivore-induced plant volatiles have revealed the role of herbivore-specific elicitors (Mattiacci et al., 1995; Alborn et al., 1997; Halitschke et al., 2001). These elicitors can activate various signaling pathways in the plant, causing an up-regulation of a large array of defense-related genes through cross-talk and resulting in accumulation or release of defense chemicals (Kessler and Baldwin, 2002).

Among these signaling pathways, the jasmonic acid (JA) pathway is the best studied and has been reported to play an important role in induced plant direct and indirect defenses (Hopke et al., 1994; Boland et al., 1995; Dicke et al., 1999; Schmelz et al., 2003). In the wild tobacco plant *Nicotiana attenuata*, for example, exogenous application of MeJA increases the release of volatile organic compounds (Halitschke et al., 2000), which enhances the mortality rates of the herbivores by attracting the natural enemies of herbivores (Kessler and Baldwin, 2001). Moreover, antisense suppression of a lipoxygenase gene LOX3, a specific wound- and herbivory-induced isoform involved in JA biosynthesis in *N. attenuata*, results in decreases in release of volatiles and nicotine and trypsin protease inhibitor levels (Halitschke and Baldwin, 2003). Exogenous application of JA to tobacco and tomato plants promotes parasitism and predation of the herbivores by natural enemies in nature (Thaler, 1999; Kessler and Baldwin, 2001). Chemical and behavioral analyses demonstrate that spider mite damage and JA treatment have similar, although not identical, effects on volatile induction in Lima bean plants (Dicke et al., 1999). In maize, caterpillar-induced volatile emissions are positively correlated with increased

JA levels (Schmelz et al., 2003). Ozawa et al. (2004) reported that maize plants treated with JA attract specialist parasitoids under laboratory conditions. In rice, the world's most important food crop, the role of JA signaling has been mainly studied for direct defenses. Exogenous application of JA on rice plants elicits the productions of proteinase inhibitors, phytoalexins, PRs, and salt-induced proteins (Tamogamia et al., 1997; Rakwal and Komatsu, 2000; Rakwal et al., 2001; Kim et al., 2003), and it may increase the emission of volatiles (Obara et al., 2002).

In this study, we investigated the effect of JA application to rice plants on the host-searching behavior of the rice brown planthopper *Nilaparvata lugens* and its mymarid egg parasitoid *Anagrus nilaparvatae*. *N. lugens* is one of the most important rice pests. It feeds on the plant's phloem and causes a decrease in leaf area, plant height, dry weight, leaf and stem nitrogen concentration, chlorophyll contents, and photosynthetic rate, but an increase in free amino acids, sucrose, and leaf iron content (Rubia-Sanchez et al., 1999; Watanabe and Kitagawa, 2000). The parasitoid *A. nilaparvatae* is a major natural enemy of the rice planthoppers. Previous studies have shown that rice volatiles play an important role in host plant location by *N. lugens* (Liu et al., 2002), and the volatiles emitted from rice plants in response to *N. lugens* attack attract the parasitoid (Lou and Cheng, 1996; Lou et al., 2002). However, little to nothing is known about the effect of JA application on rice volatiles and in turn on host-searching behavior of *N. lugens* and the parasitoid.

To determine if JA induces emission of volatiles that affect the host-searching behavior of the herbivore and the parasitoid, we first measured their responses to JA-treated plants and control plants in the laboratory. In additional greenhouse and field experiments, we then tested if JA treatment of rice plants enhanced the parasitism of *N. lugens* eggs by the parasitoid. Finally, we collected and identified volatiles that were released from JA-elicited and the control plants.

METHODS AND MATERIALS

Plant Growth. The rice variety used was TN1, which is susceptible to *N. lugens* (Lou and Cheng, 2003). Pregerminated seeds were sown in a greenhouse, and after 20–25 d, the seedlings were transplanted into small clay pots (8-cm diam × 10-cm height) each with one plant or big clay pots (16-cm diam × 10-cm height) each with three or six plants. For three plants per pot, they were arranged in an equilateral triangle 8 cm apart; for six plants per pot, they were arranged in two rows each with three plants and 8 cm between rows and 2 cm between plants. Plants were watered daily, and each pot was supplied

with 10 ml of nutrient solution [$Ca(NO_3)_2 \cdot 4H_2O$, 0.5g/l; $K(NO_3)_2 \cdot 4H_2O$, 0.125g/l; $MgSO_4 \cdot 7H_2O$, 0.125g/l; K_2HPO_4, 0.125g/l; $FeCl_2$, 0.005g/l] every 3 d. All plants were placed in a controlled climate room that was maintained at 23 ± 2°C, 70% r.h., and 18 hr photophase (25,000 lx). The plants were used for experiments 25–30 d after potting. Plantings were continued at regular intervals so that enough plants of suitable age were available for experiments.

Insects. The *N. lugens* culture was originally obtained from the China National Rice Research Institute (CNRRI), Fuyang, Zhejiang, and maintained on TN1 rice plants in a greenhouse. Late instar nymphs of *N. lugens* were captured from the greenhouse and reared on potted TN1 rice plants, which were confined in plastic cages (11-cm diam × 40 cm high). The caged rice plants were maintained in a controlled climate room at 28 ± 2°C, 12-hr photophase, and 70–80% r.h. Newly emerged adults of *N. lugens* were collected daily and fed on potted fresh TN1 rice plants. Using this procedure, *N. lugens* adults of uniform age were obtained.

A laboratory colony of the egg parasitoid *A. nilaparvatae* was started from individuals trapped in rice fields in Hangzhou using TN1 rice plants with *N. lugens* eggs as bait. The colony was propagated on *N. lugens* eggs in rice shoots enclosed in glass tubes (2.5-cm diam × 20-cm height), which were kept in a controlled climate room at 28 ± 2°C, 12-hr photophase, and 70–80% r.h. Each day, the newly emerged wasps were collected into clean glass tubes (2.5-cm diam × 20-cm height), with access to both water and honey solution, and held for at least 2 hr to ensure mating. From the second generation onwards, female parasitoids were used in experiments less than 24 hr after emergence.

Plant Treatment. The potted plants were washed with running water and trimmed to leave one, three, or six plants for each pot. Plants were individually damaged with a needle at the lower and upper position of rice stems each with 200 pricks, and then each damage site was treated by applying 20 μl of 10 or 1 mM jasmonic acid in 50 mM sodium phosphate buffer (titrated with 1 M citric acid until pH 8) (JA). Control plants (BUF) were wounded the same way and treated with 20 μl of the buffer on each of the two damaged sites. Plants were treated at 1700 hr, and then the plants were placed in the controlled climate room that was maintained at 28 ± 2°C, 12-hr photophase, and 80% r.h. Fifteen hours after treatment, i.e., at 0800 hr the next day, plants were used for experiments.

Effect of JA Elicitation on Host Plant Choice by N. lugens. Pots with six plants each were used for this experiment. Three plants in one row were wounded and treated with either 10 or 1 mM JA, and plants in the other row were wounded and treated with the buffer, thus obtaining two types of treatment pairs: 10 mM JA-treated plants vs. the buffer-treated plants or 1 mM JA-treated plants vs. the buffer plants. The potted plants were then individually placed into a sleeve cage (25 cm long, 25 cm wide, 50 cm high) that was maintained in a

controlled climate room at 28 ± 2°C, 12-hr photophase, 80% r.h. Fifteen hours after treatment, 30 macropterous *N. lugens* females (2 d old) were introduced into each cage. Subsequently, the number of *N. lugens* on JA-elicited and buffer-elicited plants were recorded 1, 2, 3, 4, 6, 12, 24, 36, 48, 60, and 72 hr after their release, respectively. Each of the two experiments was replicated five times.

Effect of JA Elicitation on Host-Searching Behavior of the Parasitoids

Olfactometer Test. Responses of *A. nilaparvatae* females to rice volatiles were measured in a Y-tube olfactometer. The olfactometer consisted of a Y-shaped glass tube of 1-cm diam. The base and the two arms of the Y tube were all 10 cm in length. Each arm was connected to an odor source container (a glass box, 10 × 10 × 30 cm). An air stream was generated and was divided in two, and each secondary air stream was led through a flowmeter, a tube with active charcoal, a humidifier bottle, and one of the odor containers. Subsequently, the two airstreams were led through the two arms of the Y-tube olfactometer at 150 ml/min. The Y-tube olfactometer was placed in a box painted white with an artificial light source consisting of a single 25-W lamp placed above the arms of the Y tube. All bioassays were conducted between 0900 and 1700 hr. During experiments, the temperature in the room was maintained at 25–28°C.

A. nilaparvatae females had the choice between odors from 1 mM JA-treated plants vs. the buffer-treated plants or 10 mM JA-treated plants vs. buffer-treated plants. To test for a possible effect of the treatment solutions *per se*, we added an experiment without plants, but with the solutions applied to filter paper (40 μl of 10 mM JA vs. 40 μl of the buffer). Fifteen hours after treatment, 10 plants that were individually planted in pots of each treatment were cut off at soil level, the cut stem was wrapped with wet cotton, and the entire plants were placed into one of the odor source containers. Mated female parasitoids were introduced individually into the base tube of the Y-shaped olfactometer and given 10 min to walk toward the end of one of the arms. Choice for an odor source was defined as a female crossing a line 7 cm after the division of the base tube and remaining there for at least 1 min. If a parasitoid did not make a choice within 10 min, this was recorded as no response. After testing two females, the olfactometer tube was washed with 98% alcohol and then was heated at 80°C for several minutes. To remove any asymmetrical bias, connections of the two arms of the olfactometer to the odor source containers were exchanged after testing two females, and the odor source containers were exchanged after testing eight females. The odor sources were replaced by a new set of 10 plants after testing 16 wasps, and for each odor source combination, at least 32 females were tested.

Greenhouse Experiment. Two plants, each with about 80–100 1-d-old *N. lugens* eggs, were transplanted into the center of a triangle of three plants that had been wounded 15 hr earlier and treated with either 10 mM JA, 1 mM JA, or with buffer. To obtain plants with *N. lugens* eggs, they were individually infested for 1 d with 10 gravid *N. lugens* females that were placed in two parafilm bags at the upper and lower position of the plant stems. After removal of the females, plants with 80–100 eggs were chosen. For each treatment, five pots were randomly placed into a cage (length 2.0 m, width 1.5 m, height 1.5 m) covered with nylon net into which 60 mated *A. nilaparvatae* females were introduced. The experiment was carried out in a greenhouse maintained at 24 ± 4°C. Two days later, the parasitoids were removed, and each pot was confined in a plastic cage (6.5 × 32 cm), all of which were placed into a controlled climate room at 28 ± 2°C, 12-hr photophase, and 80% r.h. Five days after placing them in the climate room, the plants were dissected, and the total of parasitized *N. lugens* eggs (the eggs become red) was recorded. The experiment was replicated five times.

Field Experiment. The treatments for plants were the same as the greenhouse experiment. Both JA (10 or 1 mM)-elicited plants and the buffer-elicited plants were placed at 10 locations in a rice field (20 × 30 m) in October 2000 (Figure 1). The field was surrounded by rice fields with plants in the "heading" stage. Each location included three pots of plants, each pot with one of the three treatments. The three-pot groups were arranged in two rows, each

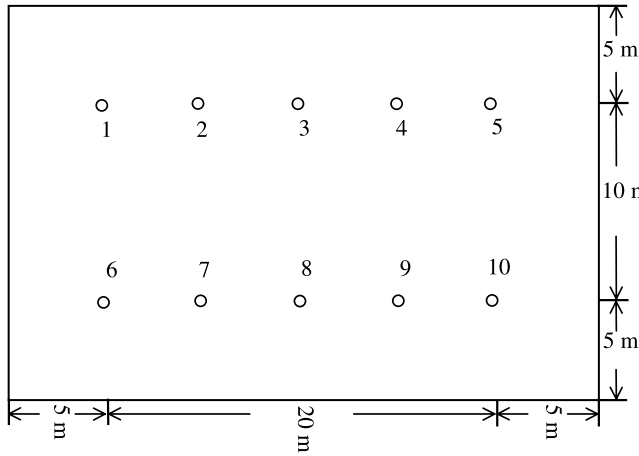

FIG. 1. Arrangement of the plants that were wounded and treated with 40 μl of either 10 mM JA in 50 mM sodium phosphate buffer (pH = 8), 1 mM JA in the buffer, or the buffer in a rice field. Numbers indicate locations, and each location includes three pots of plants, 10 mM JA-elicited plants, 1 mM JA-elicited plants, and the buffer-elicited plants.

included five groups placed 5 m apart. The distance between the two rows was 10 m (Figure 1). Two days after the plants were introduced into the rice field, the plants were transferred to the controlled climate room at 28 ± 2°C, 12-hr photophase, and 80% r.h., and each pot of plants was confined in an 11-cm diam × 40-cm-high plastic cage (herbivores, predators, and parasitoids on plants were all removed). Five days later, the plants were cut off at the soil level and dissected under a microscope to record the total, the parasitized, and the predated (sucked empty) *N. lugens* eggs. Parasitized eggs were carefully placed into petri dishes (6 cm in diam) that were lined with wet Whatman No. 1 filter paper. When the parasitoids were emerged, the species were identified.

Collection, Isolation, and Identification of the Volatile Compounds. The volatile collection system has been described in detail by Turlings et al. (1998). It consists of six vertically placed cylindrical glass tubes (9.5-cm i.d., 54 cm high). A split Teflon plate with a hole in the center at the base of a cylinder closed loosely around the stem of a plant, allowing the separation of the aerial part of a plant, in the cylinder, from the pot, which remained outside (Turlings et al., 1998). Purified and humidified air was pushed into each cylinder at a rate of 1 l/min and flowed over the plant. Around the base of each cylinder, just above the Teflon disk, eight openings served as ports that could hold the collection traps. Only one port was used during an experiment. For collections, air was pulled (0.8 l/min) through a Super-Q adsorbent trap (Heath and Manukian, 1994), whereas the rest of the air vented out through the hole in the bottom, thus preventing impure air from entering. The automated part of the collection system (Analytical Research System, Gainesville, FL, USA) controlled the flow through the trap. The climate chamber (CMP4030, CONVIRON, Winnipeg, Canada), in which the collection cylinders were housed, was kept at 17.5°C; because of the irradiation heat, the temperature inside the cylinders was 23 ± 3°C. During the light cycle, light intensity was about 20,000 lm/m^2.

Volatiles emitted from nonmanipulated plants and plants that were wounded and treated with either 10 mM JA or the buffer were collected. We also collected the volatiles from a blank, only a pot of soil without plants, to check if the system is clean. Collections started immediately after lights went on, 15 hr after treatment. Each collection lasted 4 hr. After each collection, traps were extracted with 150 μl methylene chloride (Lichrosolv., Merck, Whitehouse Station, NJ, USA), and 200 ng of *n*-octane and nonyl acetate (Sigma, Switzerland) in 10 μl of methylene chloride was added to the samples as internal standards. Each treatment was replicated six times.

Analyses were carried out with an HP 6890 series gas chromatograph equipped with an automated on-column injection system (HP G1513 A) and a flame ionization detector. Of each sample, a 3-μl aliquot was injected onto an apolar SE-30 capillary column (30 m, 0.25-mm i.d., 0.25-μm film thickness,

Alltech, Deerfield, IL, USA) preceded by a deactivated retention gap (5 m, 0.25-mm i.d.) and a deactivated precolumn (30 cm, 0.530 mm). Helium (24 cm/sec) was used as carrier gas. After injection, the column temperature was maintained at 40°C for 3 min, increased to 230°C at 8°C/min, and held at 230°C for 9.5 min. The detector signal was processed with HP GC Chemstation software.

To identify compounds, we collected volatiles emitted from 10 mM JA-elicited plants for 10 hr. A 3-µl aliquot from this sample was injected onto the same column and analyzed using the same temperature program. Volatiles were detected by a Hewlett-Packard 5973 mass selective detector (transfer line 230°C, source 230°C, quadrupole 150°C, ionization potential 70 eV, scan range 50–400 amu). Compounds were identified by comparison of GC retention times with those of authentic standards and by comparison of mass spectra with spectra of a NIST database.

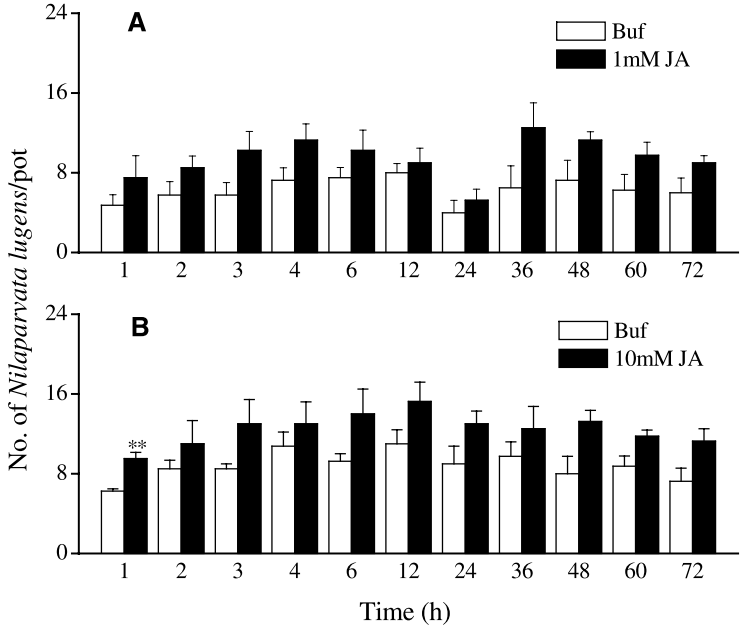

FIG. 2. Mean (±SE, $N = 5$) number of *Nilaparvata lugens* female adults on pairs of plants that were wounded and treated with 40 µl of 1 mM JA in 50 mM sodium phosphate buffer (pH = 8) (1 mM JA) vs. plants that were wounded and treated with 40 µl of buffer (Buf) (A), or that were wounded and treated with 40 µl of 10 mM JA in buffer (10 mM JA) vs. Buf (B), 1–72 hr after five replicated plant pairs were exposed to 30 insects. The exposure of the plants started 15 hr after the treatment. Asterisks indicate significant differences between members of a pair (JA vs. buffer, $P < 0.05$, *t*-test).

Data Analysis. Differences in behavioral responses of the parasitoid to JA-induced rice volatiles and the buffer-induced volatiles were determined by chi-square tests, whereas differences in behavioral responses of female *N. lugens* adults were determined by *t*-tests. To test for differences in parasitism among the treatments, we used the Fieldman rank sum test. Comparison of the data on plant volatiles was analyzed by MANOVA after the data were log transformed. If the MANOVA analysis was significant ($P < 0.05$), univariate ANOVAs for the individual effects and Fisher LSD *post hoc* tests to detect significant differences between groups were conducted. Data were analyzed with Statistica (Statistica, SAS Institute Inc., Cary, NC, USA).

RESULTS

Effect of JA-Elicited Plants on Host Preference of N. lugens. N. lugens female adults were recovered consistently more often from the JA-treated plants than from the buffer-treated plants, but this apparent preference was only

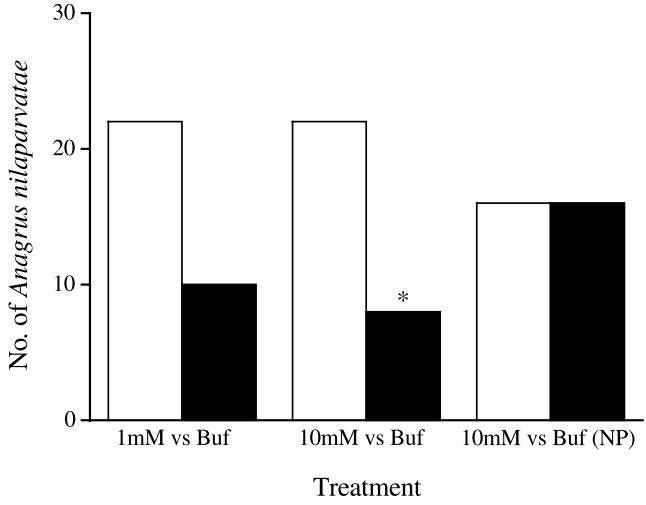

FIG. 3. Number of *Anagrus nilaparvatae* female adults attracted by volatiles released from either pairs of plants that were wounded and treated with 40 μl of 1 mM JA in 50 mM sodium phosphate buffer (pH = 8) (1 mM) vs. plants that were wounded and treated with 40 μl of the buffer (Buf), plants that were wounded and treated with 40 μl of 10 mM JA in the buffer vs. Buf, or a pair of chemicals, 40 μl of 10 mM JA vs. 40 μl of the buffer without plants [10 mM vs. Buf (NP)]. The plants were used 15 hr after the start of treatment. Asterisks indicate significant differences between members of a pair (JA vs. buffer, $P < 0.05$, chi-square test).

significant for the 10 mM JA dose at 1 hr after the start of the experiment (Figure 2). The data may not suffice to conclude that JA induction renders the plants attractive to *N. lugens* females, but it can be concluded that the induced volatiles are not repellent.

Effect of JA-Elicited Plants on Host-Searching Behaviors of the Parasitoids. In olfactometer tests, *A. nilaparvatae* preferred the volatiles emitted from JA-elicited plants to those emitted from the buffer-treated plants. JA itself did not attract the parasitoids (Figure 3).

In the greenhouse experiment, parasitism of *N. lugens* eggs by *A. nilaparvatae* on plants that were surrounded by JA-treated plants was higher than on the buffer-treated plants (Figure 4A, $Q = 8.40$, $P = 0.008$), especially for the 10 mM JA-treated plants on which the parasitism of *N. lugens* eggs by *A. nilaparvatae* was 2.35-fold higher than those on the control plants.

During the field experiment, only *A. nilaparvatae* wasp was observed parasitizing *N. lugens* eggs. As in the greenhouse experiment, JA treatments

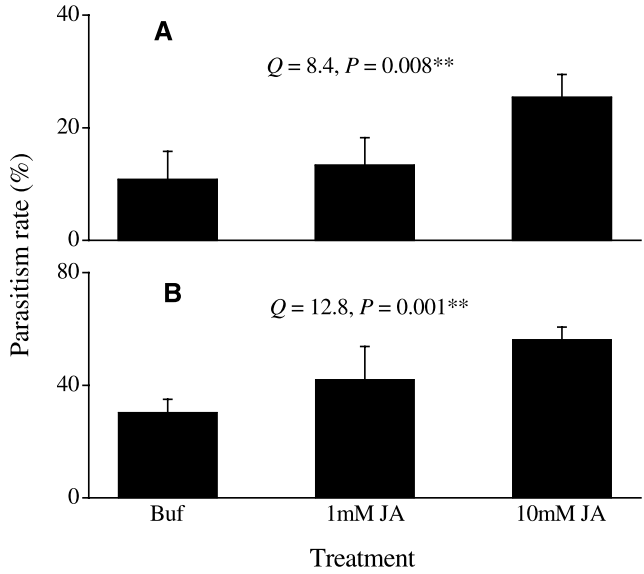

FIG. 4. Mean (±SE) parasitism rates (%) of *N. lugens* eggs by *A. nilaparvatae* in the greenhouse (A, $N = 5$) or field (B, $N = 10$) condition on rice plants surrounded by plants that were wounded and treated with either 40 μl of 1 mM JA in 50 mM sodium phosphate buffer (pH = 8) (1 mM), 40 μl of 10 mM JA in the buffer (10 mM), or 40 μl of the buffer (Buf). Fifteen hours after treatment, the plants were exposed to the parasitoid or the field for 2 d. The differences in parasitism among the treatments were determined by Fieldman rank sum test.

increased parasitism of *N. lugens* eggs by *A. nilaparvatae* (Figure 4B, Q = 12.80, P = 0.001). When 40 μl of 1 or 10 mM JA was applied to wounded plants, the parasitism of *N. lugens* eggs by *A. nilaparvatae* on plants that were surrounded by JA-treated plants were 1.39- and 1.85-fold higher than those on the control plants, respectively. *Cyrtorhinus lividipennis* Reuter (Hemiptera: Miridae) is the main predator of *N. lugens* eggs in the rice field. We found a tendency for predation rates of *N. lugens* eggs to be higher on JA-treated plants (1 mM JA 3.21 ± 1.00%; 10 mM JA 7.25 ± 5.07%; buffer 1.58 ± 0.66%), but the differences were not statistically significant (F = 0.944, df = 2,27, P = 0.402).

Analysis of Volatiles. Collection and analysis of the volatiles revealed that only small amounts were released by nonmanipulated rice plants, whereas the buffer- and JA-treated plants emitted 9.43 and 35.68 times larger amounts, respectively (Table 1; Figure 5). Most compounds were released in significantly larger amounts by JA-treated plants compared to buffer-treated plants: 2-heptanone, 2-heptanol, limonene, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene,

[c] (3*E*,7*E*)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene.

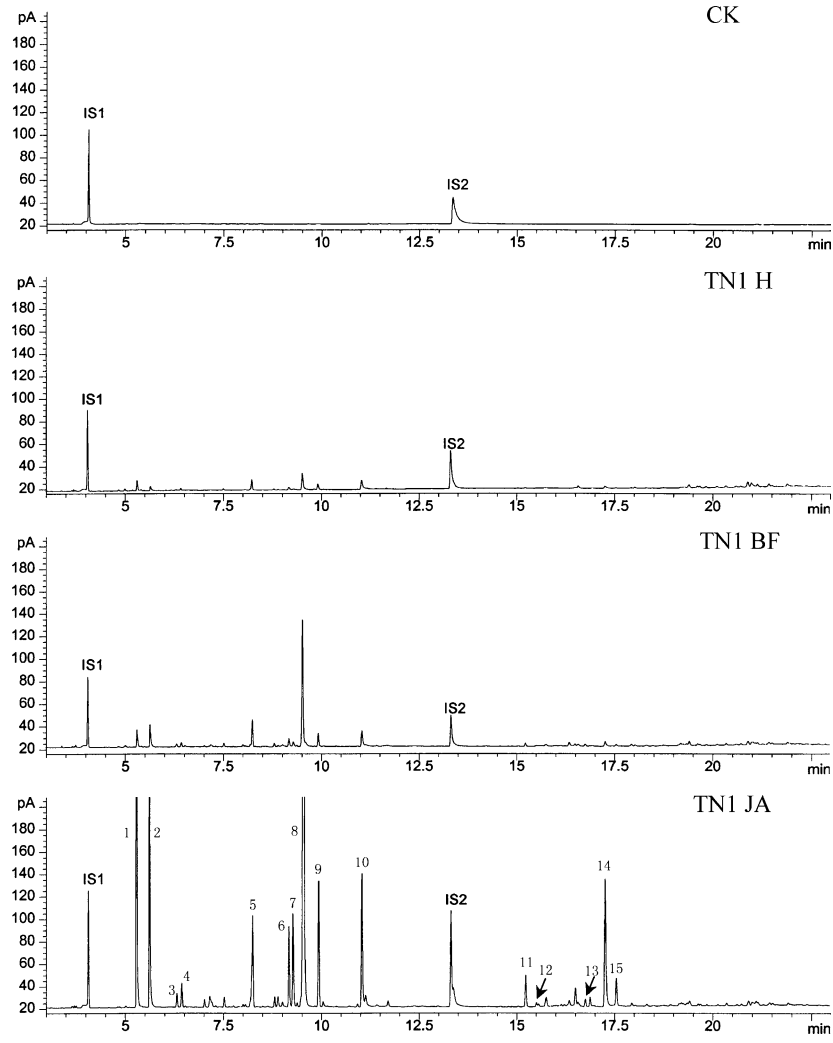

FIG. 5. Typical chromatograms obtained from headspace collections from an empty glass container (a pot of soil without plants) (CK), untreated rice plants (TN1 H), or rice plants 15 hr after they were wounded and treated with either 40 µl of 50 mM sodium phosphate buffer (pH = 8) (TN1 BF) or with 40 µl of 10 mM JA in the buffer (TN1 JA). (1) 2-Heptanone; (2) 2-heptanol; (3) unknown 1; (4) unknown 2; (5) limonene; (6) unknown 3; (7) unknown 4; (8) linalool; (9) (*E*)-4,8-dimethyl-1,3,7-nonatriene; (10) methyl salicylate; (11) beta-caryophyllene; (12) (*E*)-alpha-bergamotene; (13) *n*-heptadecane; (14) (*E*)-nerolidol; (15) (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

(3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, beta-caryophyllene, (*E*)-alpha-bergamotene, *n*-heptadecane, (*E*)-nerolidol, and two unknown chemicals (unknowns 1 and 2) (Table 1; Figure 5).

DISCUSSION

As reported for other plants, such as tobacco (Halitschke et al., 2000), maize (Schmelz et al., 2003), and lima bean (Dicke et al., 1999), wounding and application of JA to rice plants also resulted in an increase in volatiles emitted. The overall emission was almost fourfold higher than the emission of the buffer-treated plants. The increases involved aliphatic aldehydes and alcohols, monoterpenes, sesquiterpenes, methyl salicylate, *n*-heptadecane, and some unknown chemicals (Table 1; Figure 5). The composition of the odor blend was in part consistent with previous results reported for JA-treated rice plants (Obara et al., 2002). We too found a JA-mediated increase in the release of limonene, linalool, methyl salicylate, beta-caryophyllene, (*E*)-alpha-bergamotene, and several unknown chemicals. However, there are also some differences: the compounds 2-heptanone, 2-heptanol, *n*-heptadecane, (*E*)-4,8-dimethyl-1,3,7-nonatriene, (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, and (*E*)-nerolidol that we collected from the headspace of JA-treated plants were not reported by Obara et al. (2002). In turn, we did not detect the sesquiterpenes alpha-copaene, alpha-cadinene, alpha-humulene, and several others, which were identified by Obara et al. (2002). These differences may be due to treatment differences; they collected volatiles emitted from pieces of rice leaves (2.5 cm long) that were floating on a 0.5 mM JA solution for 7 or 48 hr. In maize, for example, it has been observed that excised leaves produced a 2.5- to 8.0-fold greater volatile in response to JA and the caterpillar produced elicitor volicitin than similarly treated intact plants (Schmelz et al., 2001). Herbivore- or elicitor-induced volatile releases also vary with time after treatment (Turlings et al., 1998), herbivore damage level (Gouinguene et al., 2003), and the applied elicitor amount (Halitschke et al., 2000). Compared to the nonmanipulated rice plants, wounding and application of the buffer also increased release of some volatiles (Figure 5), suggesting that wounding alone may be sufficient to induce a minor release of at least some of the compounds and that application of JA fortifies this effect.

The volatiles emitted from JA-treated rice plants were attractive to the parasitoid (Figure 2) and enhanced parasitism of *N. lugens* eggs in the greenhouse and field (Figures 3 and 4). This result is consistent with results reported from other plants (Thaler, 1999; Kessler and Baldwin, 2001). We have previously shown that linalool is attractive to *A. nilaparvatae* (Lou et al., 1999).

The higher linalool concentrations in the headspace of JA-induced plants compared to the buffer-induced plants might in part explain the difference in attractiveness. Which other compounds may be involved in the attraction remains to be elucidated.

We also studied the effect of treating rice plants with JA on the settling behavior of adult *N. lugens* females. A negative effect was expected, as JA is an important defense-related plant hormone. JA not only induces plants to release volatiles, but also elicits increases in many nonvolatile defense chemicals, such as phenolics, alkaloids, terpenoids, and proteinase inhibitors (Karban and Baldwin, 1997; Lou and Baldwin, 2003, 2004). These nonvolatile compounds are likely to affect the settling behavior of the planthoppers. Although numerous studies have shown that JA application results in reduced preference and performance of herbivores (Karban et al., 1997; Karban and Baldwin, 1997; Black et al., 2003), contrary effects have also been reported. For example, volatiles emitted by potato plants in responses to JA application enhanced the plant's attractiveness to female Colorado potato beetles (Landolt et al., 1999). In wild radish, responses induced by JA application increased feeding by some herbivores (Agrawal, 2000; Agrawal and Sherriffs, 2001). In addition, *N. lugens* female adults tended to prefer 10 mM JA-elicited plants to the buffer. The fact that this difference was only apparent 1 hr after release suggests that JA-induced rice volatiles were slightly attractive to female *N. lugens*, whereas JA-induced nonvolatile chemicals had no particular effect on host preference. The latter is somewhat surprising as JA elicitation increases the production of proteinase inhibitors, phytoalexins, and PRs in rice plants (Rakwal and Komatsu, 2000; Rakwal et al., 2001; Kim et al., 2003). *N. lugens* female adults are attracted to limonene (Lou et al., unpublished data). Hence, a slightly stronger attraction of JA-induced rice volatiles to *N. lugens* compared to the control can be related to higher levels of this and/or other compounds.

Thaler (1999) was the first to report that inducing plants with jasmonic acid increases parasitism of caterpillar pests in an agricultural field. Subsequent studies confirmed that JA treatment enhances the attractiveness of plants for parasitoids of lepidopteran larvae (Ozawa et al., 2004) and predatory mites that use induced plant volatiles to locate spider mite prey (Gols et al., 2003). These studies hold promise that field application of JA may enhance the efficacy of parasitoids and predators as biological control agents. Our results indicate that this may also be the case for egg parasitoids. The plants with *N. lugens* eggs that were used in our experiments were not elicited with JA; they were just placed near JA-treated plants. The supposed attraction of the wasps to the JA-treated plants did not prevent them from visiting neighboring plants, where they parasitized eggs. We have previously shown that the wasp does not discriminate between the volatiles emitted from *N. lugens*-infested plants and those from JA-induced plants (Wang et al., 2005). Therefore, it is likely that wasp uses only

few or a general blend of induced volatiles to locate plants that are potentially infested by its host, and that specific close-range attraction to the host is mediated by visual cues and/or kairomones released from *N. lugens*. Kairomones are attractive to the parasitoid at close range for all developmental stages of *N. lugens* (Lou and Cheng, 1994). A general attraction to induced plant volatiles is also evident from the fact that the volatile profiles from *N. lugens*-infested plants and JA-elicited plants are quite different, but both blends are attractive to wasps (Wang et al., 2005). In fact, the study by Wang et al. (2005) shows that *N. lugens* infestation does not trigger the JA pathway. However, some evidence is available showing the involvement of salicylic acid (SA) and ethylene in response to *N. lugens* feeding (Du et al., unpublished data). Hence, different defense pathways result in different volatile emissions, but all are attractive to wasps.

Egg parasitoids have been shown to respond to oviposition-induced plant volatiles in other studies, where herbivore feeding did not induce the volatiles attracting the egg parasitoids (Hilker et al., 2002; Hilker and Meiners, 2002; Meiners and Hilker, 2000). *A. nilaparvatae* females are equally attracted to volatiles emitted by rice plants infested by female *N. lugens* adults as to those from nymph-infested plants (Lou, unpublished data). Therefore, here we expect that the feeding damage is responsible for the induction. However, we do not rule out an effect of oviposition as well, especially because an ovicidal response of rice plants to oviposition by the rice white-backed planthopper *Sogatella furciferra* has been observed (Suzuki et al., 1996; Yamasaki et al., 2003). As the rice brown planthopper feeds and oviposits on the same plant (Cheng and He, 1996), the indirect association of feeding with egg presence is reliable and thus adaptive.

Acknowledgments—We thank Sandrine Gouinguené, Maria Elena Hoballah, Thomas Degen, Zhou Guoxin, and Wang Xia for their invaluable assistance with laboratory work and the Ministry of Science and Technology of China (973) (G2000016208) and the National Natural Science Foundation of China (30270233) for funding.

THE ROLE OF FRESH *VERSUS* OLD LEAF DAMAGE IN THE ATTRACTION OF PARASITIC WASPS TO HERBIVORE-INDUCED MAIZE VOLATILES

MARIA ELENA HOBALLAH[1] and TED C. J. TURLINGS*

Laboratory of Animal Ecology and Entomology, Institute of Zoology, University of Neuchâtel, Case postale 2, 2007 Neuchâtel, Switzerland

(Received January 10, 2005; revised April 8, 2005; accepted May 1, 2005)

Abstract—The odor produced by a plant under herbivore attack is often used by parasitic wasps to locate hosts. Any type of surface damage commonly causes plant leaves to release so-called green leaf volatiles, whereas blends of inducible compounds are more specific for herbivore attack and can vary considerably among plant genotypes. We compared the responses of naïve and experienced parasitoids of the species *Cotesia marginiventris* and *Microplitis rufiventris* to volatiles from maize leaves with fresh damage (mainly green leaf volatiles) *vs.* old damage (mainly terpenoids) in a six-arm olfactometer. These braconid wasps are both solitary endoparasitoids of lepidopteran larvae, but differ in geographical origin and host range. In choice experiments with odor blends from maize plants with fresh damage *vs.* blends from plants with old damage, inexperienced *C. marginiventris* showed a preference for the volatiles from freshly damaged leaves. No such preference was observed for inexperienced *M. rufiventris*. After an oviposition experience in hosts feeding on maize plants, *C. marginiventris* females were more attracted by a mixture of volatiles from fresh and old damage. Apparently, *C. marginiventris* has an innate preference for the odor of freshly damaged leaves, and this preference shifts in favor of a blend containing a mixture of green leaf volatiles plus terpenoids, after experiencing the latter blend in association with hosts. *M. rufiventris* responded poorly after experience and preferred fresh damage odors. Possibly, after associative learning, this species uses cues that are more directly related with the host presence, such as volatiles from host feces, which were not present in the odor sources offered in the olfactometer. The results demonstrate the complexity of the use of plant

volatiles by parasitoids and show that different parasitoid species have evolved different strategies to exploit these signals.

Key Words—*Cotesia marginiventris*, *Microplitis rufiventris*, *Spodoptera littoralis*, *Zea mays*, parasitoid, innate preference, associative learning, induced volatiles, green leaf volatiles, terpenoids, host location.

INTRODUCTION

Many parasitoid species make use of herbivore-induced volatiles to locate their herbivorous hosts. Various studies on host searching by parasitoids show that plant-provided cues are more important for the location of host habitats than odor cues from the host or host by-products (Turlings et al., 1990; Steinberg et al., 1993; McCall et al., 1993; Agelopoulos and Keller, 1994; Geervliet et al., 1994; Mattiacci et al., 1994; Takabayashi et al., 1995; Fukushima et al., 2002), but it remains largely unknown which compounds are the most crucial for the attraction.

That volatile blends can differ in their attractiveness is evident from various studies that show differential attraction mediated by odors of different plant species attacked by the same herbivore (Drost et al., 1988; McAuslane et al., 1991; Geervliet et al., 1996; De Moraes and Lewis, 1999). Also within one plant species, however, there can be considerable variation in attractiveness among genotypes. For instance, *Cotesia marginiventris*, a generalist parasitoid that attacks early instars of many Lepidoptera, prefers the caterpillar-induced odor of some specific maize varieties over others, and this preference is not simply a matter of differences in quantity of volatiles emitted (Hoballah Fritzsche et al., 2002). Moreover, several parasitoids show variable responses to odors emitted by the same plant species attacked by different herbivores, such as *Microplitis croceipes* (Zanen and Cardé, 1991), *Cotesia sesamiae* and *Cotesia flavipes*, (Ngi-Song et al., 1996), and *Cotesia glomerata* (Geervliet et al., 1997). Specialist parasitoids may use their ability to make such distinctions to focus only on plants that carry their specific hosts, as was found for *Aphidius ervi*, an aphid parasitoid with a limited host range (Du et al., 1998; Powell et al., 1998), and *Cardiochiles nigriceps*, which can only successfully develop in larvae of *Heliothis virescens* (De Moraes et al., 1998; De Moraes and Lewis, 1999). Equally intriguing is the observation that *Cotesia kariyai* can distinguish among odors produced by the same plant species fed upon by different larval stages of their respective host, *Pseudaletia separata* (Takabayashi et al., 1995). However, *Microplitis rufiventris*, which can also only develop in early instars of some Lepidoptera, does not show a preference for maize damaged by a particular larval stage of *Spodoptera littoralis* (Gouinguené and Turlings, 2003).

A review by Dicke (1999) shows that evidence for specificity in signals is highly variable, suggesting that different parasitoid species employ different strategies to exploit plant-provided signals to find hosts. As proposed by Vet and Dicke (1992), parasitoids use volatiles emitted by host-damaged plants rather than volatiles from the hosts themselves because plant volatiles are released in much larger quantities and are easier to detect. However, damaged plants are expected to provide limited information on the suitability as host of an herbivore that has been damaging it. This problem is partially solved by the ability of parasitoids to learn by association (Vet and Dicke, 1992). For various parasitoids, it has been shown that they learn to respond to a specific odor when they perceive it during contact with the host or host feces (Lewis and Tumlinson, 1988; Vet and Groenewold, 1990; Turlings et al., 1993; Vet et al., 1995). This ability may allow the wasps to learn subtle differences between odor blends and thus focus on odors that are more reliably associated with the presence of suitable hosts. *C. marginiventris*, for example, shifts its preference in favor of plant odors that it has experienced during an encounter with a host (Turlings et al., 1989, 1993). This wasp can even learn to distinguish between the odors released by maize plants fed on by two closely related *Spodoptera* species (Turlings et al., 1993).

What do generalist parasitoids such as *C. marginiventris* respond to before they have found their first host? One possibility is that they learn during emergence from the cocoon and initially focus on the same cues that guided their mother to hosts. Such early adult learning was found, for example, in *Microplitis demolitor* (Hérard et al., 1988), *Cotesia plutella* (Bogahawatte and Van Emden, 1996), and *Aphidius colemani* (Douloumpaka and Van Emden, 2003). A second possibility is that, as they emerge from the cocoon, the wasps will first cue on general plant odors, and that they will learn plant odors that are associated with the specific host only as soon as the first host is encountered and parasitized. Independent of plant genotype, the so-called green leafy volatiles (6-carbon aldehydes, alcohols, and acetates) are common and typically released from freshly damaged leaves, whereas herbivore-induced volatiles, such as blends of terpenoids, are more indicative of actual herbivore damage, and their composition varies among plant genotypes.

The aim of the current study was to test the hypothesis that inexperienced *C. marginiventris* females initially prefer blends with common fresh damage volatiles, and experienced females shift their preference toward a more specific blend. A second parasitoid, *Microplitis rufiventris* (Hymenoptera: Braconidae) with a more restricted host range, was included to determine a possible difference in exploitation of plant volatiles by generalists and specialists. These two parasitoids originate from different continents (near-arctic region and Northeast Africa, respectively). *C. marginiventris* parasitizes at least 25 Lepidoptera (including *Spodoptera* spp., *Helicoverpa* spp.) (Maes, 1989),

whereas *M. rufiventris* has been found only on *Spodoptera littoralis*, *Spodoptera exigua*, and *Heliothis armigera* (Hegazi and El-Minshawy, 1979). The hosts for both parasitoids can be found on many of the same crop plants (cotton, maize, cabbage, sweet potato, tomato, and other crops), implying that there is substantial overlap in potential plant cues that they can use.

Here, we used damaged maize plants as the odor sources. In all cases, plants were mechanically damaged and treated with caterpillar regurgitant. Such treatment results in the immediate release of several compounds, such as the green leafy volatiles, whereas the herbivore-inducible compounds, comprising mainly terpenoids and some aromatics, predominantly indole, appear at the earliest several hours after initial damage (Turlings et al., 1998). By offering the choice between odor of freshly damaged plants and the odor of plants with old damage to the wasps, the relative importance of the two volatile groups as attractants could be tested.

METHODS AND MATERIALS

Plants and Insects. Two-wk-old maize plants (var. Delprim) were used for all experiments. Two seeds per pot (200 ml, 6 cm high) were planted in commercial soil (COOP, Switzerland) and grown in a climate chamber (23°C, 60% r.h., 16D:8L, 50,000 lm m^{-2}). The day before an experiment was started, plants were transferred in glass pots that fit the olfactometer (250 ml, 4.5 cm diam, 11 cm high).

Spodoptera littoralis eggs were obtained from Syngenta (Stein, Switzerland). Rearing methods for hosts and parasitoids are described by Fritzsche Hoballah and Turlings (2001). Two parasitoids were used for the study, *C. marginiventris* and *M. rufiventris*. *C. marginiventris* was obtained from the USDA-ARS, Biological Control and Mass Rearing Research Unit (MS, USA), and *M. rufiventris* from the Faculty of Agriculture, Alexandria University (Egypt). Parasitized larvae and adult *C. marginiventris* were kept in an incubator (25°C and 16L:8D) until the day of the experiment, whereas parasitized larvae and adults of *M. rufiventris* were kept in the laboratory under ambient light and temperature conditions. Female parasitoids were used for the assays when they were 2–5 d old.

Six-arm Olfactometer Bioassay (Inexperienced Wasps). The six-arm olfactometer is described by Turlings et al. (2004). This system exposes wasps to six air streams entering a central choice chamber. Each stream, entering the chamber via a glass tube, can carry a different odor. In our bioassays, only three odor sources were offered to the parasitoids and each arm with odorous air stream was alternated with a neighboring arm carrying a stream of clean air. Charcoal filters purified and a bubbler humidified the air that was then pushed

into each odor source vessel at a rate of 1.2 l min^{-1}. During each bioassay, a portion of each odor was collected by pulling air from each vessel at a rate of 0.6 ml min^{-1} through Super-Q traps (see Heath and Manukian, 1992) that were attached to the vessels just above the treated pants (for details, see Turlings et al., 2004).

To induce volatile emissions in the plants that served as odor sources, we scratched the underside of two leaves over an area of 2–4 cm^2 on both sides of the central vein of the leaf with a razor blade, after which 10 μl of *S. littoralis* regurgitant were applied on each damaged site. The regurgitant had been collected from fourth and fifth instar *S. littoralis* caterpillars that had fed on maize leaves (var. Delprim) and had been stored at −70°C until just before use (for details, see Turlings et al., 1998). After treatment, the plants were placed under three fluorescent lamps (Sylvania standard F36W 133-T8 cool white, 5,000 lm m^{-2} at pot height) until used in bioassays.

Two combinations of three odor sources were offered as choice to inexperienced wasps. The combination of odors consisted of: (1) two maize plants treated 30 min before (fresh–fresh), two maize plants treated 6 hr before (old–old), and one plant treated 30 min before plus one 6 hr before (fresh–old) assaying; (2) two maize plants treated 30 min before (fresh–fresh), two maize plants treated 6 hr before (old–old), and two maize plants left unharmed, but treated with 20 μl of *S. littoralis* regurgitant on the leaf surface (spit) before assaying.

Wasps were released in groups of six into the choice chamber, and after 30 min, the wasps' choices for a particular arm were noted. Wasps that did not enter an arm after 30 min were considered a "no choice." For each replication day, the position of the odor sources was shifted. Between two and three replications per wasp species were carried out per day. On almost all replication days, both groups were tested using same odor sources (statistical tests confirmed that there was no influence of time of release even if some test days lasted 3 hr with three replications for each wasp species). After each experimental day, the olfactometer was washed with running tap water and soap, subsequently rinsed with acetone and pentane, and air-dried before being placed in the oven at 250°C for 3 hr. The Teflon tubes connecting the glass parts of the olfactometer were also rinsed with acetone and pentane.

A log-linear model fitted for the expected distribution of the wasps within the olfactometer (quasi-Poisson model) that do not conform to simple variance assumptions was used in statistical tests for odor preferences (Turlings et al., 2004). The numbers of wasps that chose one of the arms containing an odor source (three odor treatments plus three arms containing pure air as fourth treatment) for each released group (six wasps) were used as a replication. The numbers of replications for each test are given in the figure legends. We used the general linear model coefficients to determine preferences for one of the

treatments. *P* and *F* values are given only for the analysis of preference among the three odor cue treatments (not including the number of wasps that entered in the arm offering only clean air as odor cue). The software package R http://www.imsv.unibe.ch/cran) was used to test the model fitted by quasi-likelihood estimation, and its relative adequacy was assessed through likelihood ratio statistics and examination of residuals.

Six-arm Olfactometer Bioassay (Experienced Wasps). To provide them experience, the wasps were placed in a plastic box (9 cm top diam, 8.5 cm bottom diam, 3.5 cm high) containing maize leaves (var. Delprim) on which larvae of *S. littoralis* had been feeding for 24 hr. After females parasitized one or two larvae, they were considered experienced. This treatment is known to increase the responsiveness of parasitoids to the odors they perceive during the experience (Turlings et al., 1993). We gave only one oviposition experience to *M. rufiventris* to obtain approximately the same period of contact with the leaf–host complex for both parasitoid species, because *M. rufiventris* needs more time than *C. marginiventris* to parasitize the same number of hosts (Hoballah, personal observation).

Only one odor source combination was tested with experienced wasps: two maize plants treated 30 min before (fresh–fresh), two maize plants treated 6 hr before (old–old), and one plant treated 30 min before and one 6 hr before (fresh–old) assaying. Treatment of plants, odor collections, and statistical analyses were the same as for the bioassays with inexperienced wasps.

Volatile Collections and Analyses. Traps containing Super-Q (25 mg, 80/100 mesh; Alltech Associates, Inc., Deerfield State, USA) were used to collect odors from various treatments during the olfactometer experiments. Collections started 20 min before an olfactometer experiment and ended after a period of 3 hr had elapsed. After each collection, traps were rinsed with 150 μl methylene chloride. Two hundred ng of *n*-octane and nonyl acetate were added as internal standards. Three-μl aliquots of the samples were injected on column, with an automated injection system, into a Hewlett Packard model HP 6890 gas chromatograph equipped with a flame ionization detector. The HP-1 capillary column (30 m, 0.25 mm internal diam, 0.25 μm film thickness; Hewlett-Packard Company, USA) was kept at 50°C for 3 min and then programmed at 8°C min^{-1} to 230°C, where it was maintained for 9.5 min. The column was preceded by a deactivated retention gap (10 m, 0.25 mm internal diam; Alltech Associates) and a deactivated precolumn (30 cm, 0.53 mm internal diam; Alltech Associates). Helium (24 cm sec^{-1}) was used as carrier gas. HP GC Chemstation software was used to quantify all major components by comparison to the known quantity of internal standards. ANOVA and Student–Newman–Keuls *post-hoc* test were used to compare the quantities of collected volatiles (total of all compounds combined as well as of single compounds).

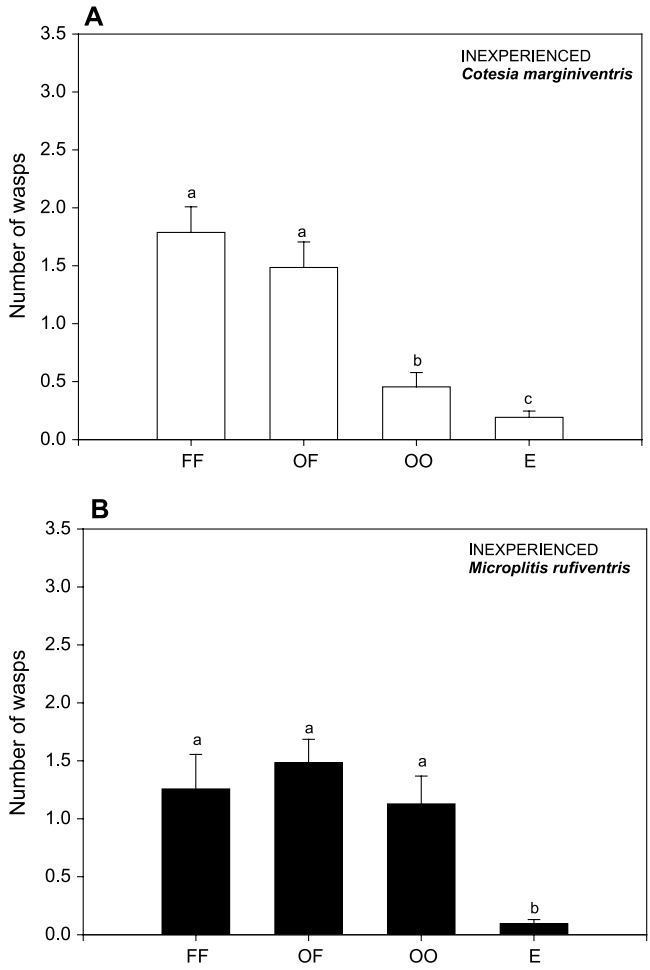

FIG. 1. Mean (±SE) of inexperienced *Cotesia marginiventris* (**A**, 33 replications, 26.8% "no choice") and *Microplitis rufiventris* (**B**, 31 replications, 30.1% "no choice") females that were attracted to a specific source in a six-arm olfactometer. FF: Two maize plants treated 30 min; OF: one plant treated 30 min and one plant treated 6 hr; OO: two plants treated 6 hr, respectively, before experiment started; E: clean air, mean (±SE) for the three empty olfactometer arms. Damage treatments consisted of scratching two leaves of a plant and adding *Spodoptera littoralis* regurgitant on the damaged sites. Different letters above bars indicate significant differences among total numbers of wasp that chose a particular odor source including clean air (preference for one of the three odor treatments: **A**, $P < 0.001$, $F = 15.87$, $df = 2$; **B**, $P = 0.608$, $F = 0.50$, $df = 2$).

RESULTS

Six-arm Olfactometer Bioassays (Inexperienced Wasps). C. marginiventris preferred the "fresh–fresh" and "fresh–old" odor to the odor of the "old–old" treatment, meaning that volatiles released after fresh damage are important for initial attraction (Figure 1A). Still, the "old–old" odor was more attractive than clean air (Figure 1A). In contrast, inexperienced *M. rufiventris* was equally attracted to all three treatments (Figure 1B). Both wasps rarely entered the three arms of the olfactometer carrying pure air, but almost one third of the wasps did not choose any arm (Figure 1).

The total amount of volatiles collected from the plants treated in different ways was not significantly different (mean ± SE for fresh–fresh: 613.6 ± 57 ng, fresh–old: 584.5 ± 72 ng, old–old: 610.6 ± 97 ng, ANOVA $P = 0.958$, $F = 0.043$). The odors collected during the olfactometer experiences show a

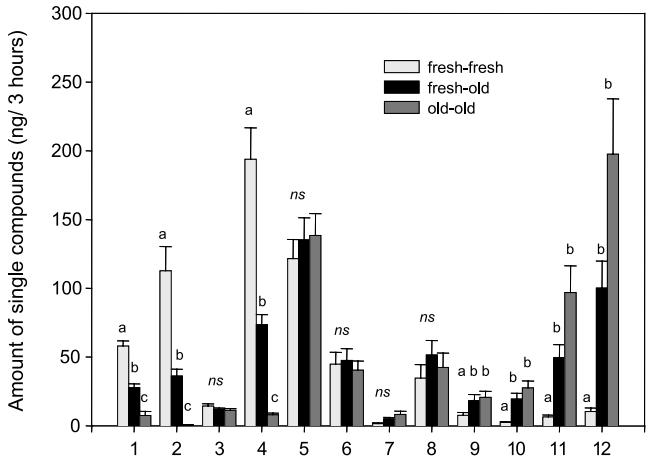

FIG. 2. Mean (±SE) amounts of major single volatile compounds of a blend collected for 3 hr from: two maize plants treated 30 min (fresh–fresh), one plant treated 30 min and one plant treated 6 hr (fresh–old), and two plants treated 6 hr (old–old) before experiments in a six-arm olfactometer started. Damage treatments consisted of scratching two leaves of a plant and adding *Spodoptera littoralis* regurgitant on the damaged sites. Different letters above bars indicate significant differences in amount of single compounds collected among treatments and *ns* indicate no significant difference among treatments. This graph includes the volatile collections of all experiments carried out with those treatments (experiments with inexperienced and experienced wasps, $N = 12$). **1**, (*E*)-2-Hexenal; **2**, (*Z*)-3-hexenol; **3**, β-myrcene; **4**, (*Z*)-3-hexenyl acetate; **5**, linalool; **6**, (*E*)-4,8-dimethyl-1,3,7-nonatriene; **7**, phenethyl acetate; **8**, 1-H-indole; **9**, geranyl acetate; **10**, (*E*)-β-caryophyllene; **11**, (*E*)-α-bergamotene; **12**, (*E*)-β-farnesene.

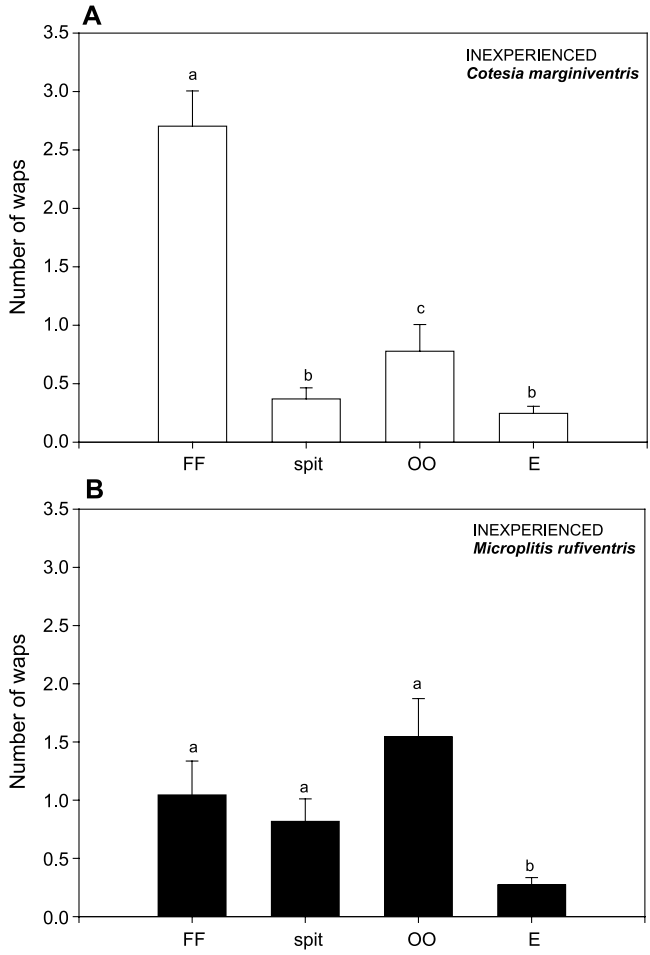

FIG. 3. Mean (±SE) of inexperienced *Cotesia marginiventris* (**A**, 27 replicates, 22.8% "no choice") and *Microplitis rufiventris* (**B**, 22 replicates, 27.3% "no choice") females that were attracted to a specific source in a six-arm olfactometer. FF: Two maize plants treated 30 min; spit: two undamaged plants on which *Spodoptera littoralis* regurgitant was smeared; OO: two plants treated 6 hr before experiment started; E: clean air, mean (±SE) for the three empty olfactometer arms. Damage treatments consisted of scratching two leaves of a plant and adding *Spodoptera littoralis* regurgitant on the damaged sites. Different letters above bars indicate significant differences among the numbers of wasp that chose a particular odor source including clean air (preference for one of the three odor treatments: **A**, $P < 0.001$, $F = 27.94$, $df = 2$; **B**, $P = 0.169$, $F = 1.83$, $df = 2$).

difference in the amounts of green leaf volatiles and terpenoids emitted by the treatments, with the "fresh–old" treatments showing intermediate release of both groups (Figure 2).

In the experiment where the wasps had a choice between (a) the odor of two freshly damaged plants, (b) the odor of two plants with 6-hr-old damage, and (c) the odor of two undamaged plants with regurgitant smeared on the leaves, *C. marginiventris* preferred the fresh damage (Figure 3A), whereas inexperienced *M. rufiventris* again showed no significant preference (Figure 3B). The relatively high number of *M. rufiventris* choosing the odor of undamaged plants treated with regurgitant was unexpected, because the amount of all major compounds released from this treatment was significantly lower than for the other two treatments (Figure 4).

Six-arm Olfactometer Bioassays (Experienced Wasps). When *C. marginiventris* wasps were given an oviposition experience on *S. littoralis* caterpillars feeding on maize (var. Delprim) leaves, their preference changed. Experienced

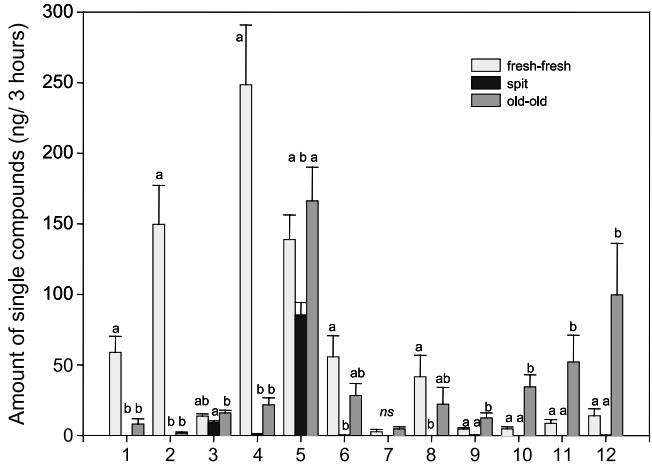

FIG. 4. Mean (±SE) amounts of major single volatile compounds of a blend collected for 3 hr from two maize plants treated 30 min (fresh–fresh), two plants smeared with *Spodoptera littoralis* regurgitant (spit), and two plants treated 6 hr (old–old), before experiments in a six-arm olfactometer started. Damage treatments consisted of scratching two leaves of a plant and adding *S. littoralis* regurgitant on the damaged sites. Different letters above bars indicate significant differences in amount of single compounds collected among treatments and *ns* indicate no significant difference among treatments. **1**, (*E*)-2-Hexenal; **2**, (*Z*)-3-hexenol; **3**, β-myrcene; **4**, (*Z*)-3-hexenyl acetate; **5**, linalool; **6**, (*E*)-4,8-dimethyl-1,3,7-nonatriene; **7**, phenethyl acetate; **8**, 1-H-indole; **9**, geranyl acetate; **10**, (*E*)-β-caryophyllene; **11**, (*E*)-α-bergamotene; **12**, (*E*)-β-farnesene.

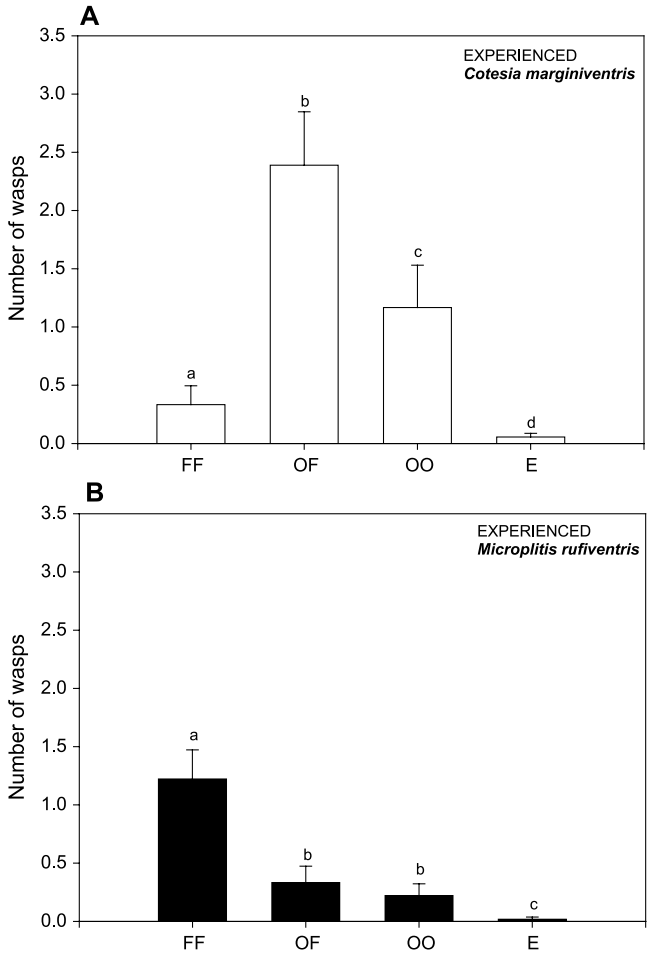

FIG. 5. Mean (±SE) of experienced *Cotesia marginiventris* (**A**, 18 replicates, 32.4 % "no choice") and *Microplitis rufiventris* females (**B**, 18 replicates, 69.4 % "no choice") that were attracted to a specific source in a six-arm olfactometer. Experience consisted of an oviposition in a host on maize leaves that had been damaged by hosts for 24 hr. FF: Two maize plants treated 30 min; OF: one plant treated 30 min and one plant treated 6 hr; OO: two plants treated 6 hr, respectively, before an experiment started; E: clean air, mean (±SE) for the three empty olfactometer arms. Damage treatment consisted of scratching two leaves of a plant and adding *Spodoptera littoralis* regurgitant on the damaged sites. Different letters above bars indicate significant differences among total numbers of wasp that chose a particular odor source including clean air (preference for one of the three odor treatments: **A**, $P < 0.001$, $F = 9.49$, $df = 2$; **B**, $P < 0.001$, $F = 9.16$, $df = 2$).

C. marginiventris females significantly preferred the complete blend (fresh–old) to blends containing larger amounts of green leaf volatiles (fresh–fresh), or terpenoids (old–old) (Figure 5A). Surprisingly, the majority of experienced *M. rufiventris* did not make any choice, and among those that did, the majority preferred the odor source containing more green leaf volatiles (Figure 5B). As was the case for inexperienced wasps, experienced wasps of both species rarely entered one of the three arms of the olfactometer that carried clean air (Figure 5).

DISCUSSION

Confirming our hypothesis, inexperienced *C. marginiventris* preferred blends containing a higher proportion of green leaf volatiles, indicating that, as expected, green leaf volatiles or compounds that are simultaneously released are important for initial attraction of inexperienced *C. marginiventris*. Odor released after recent damage is important also in attracting naïve *C. marginiventris* to cotton plants (Cortesero et al., 1997). Several parasitoids orient to individual green leaf volatile compounds in an olfactometer or flight tunnel tests (Whitman and Eller, 1990; Wickremasinghe and Van Emden, 1992; Reddy et al., 2002) or show strong electroantennogram responses to these compounds (Baehrecke et al., 1989; Li et al., 1992). However, there are exceptions. For instance, artificially damaged plants (an unspecific blend containing some green leaf volatiles) elicited little response in naïve *Cotesia kariyai* (Fukushima et al., 2002). The responses of *M. rufiventris* observed here show that for this species, green leaf volatiles are not crucial for initial attraction. In fact, inexperienced *M. rufiventris* responded well, but did not distinguish among the different odor blends offered. Surprisingly, even the undamaged plants that were treated with regurgitant were attractive to this wasp. It should be noted that several maize varieties, including Delprim, release some volatiles when they are not damaged (Turlings et al., 1998). It is possible that these compounds, which include linalool, are important for the attraction of *M. rufiventris*, and that some compounds in the other blends repel this wasp. A closely related species, *Microplitis croceipes*, is also equally attracted to the odors of artificially damaged plants and undamaged cotton plants (Röse et al., 1998). Apparently, these specialized wasps use cues other than the general volatiles emitted by the damaged plant, cues that are more specifically linked with their hosts. This also seems to be the case for the specialist *Cotesia rubecula*, which is more attracted by the odors of *Arabidopsis thaliana* damaged by its host (*Pieris rapae*) than by artificially damaged *A. thaliana* (van Poecke et al., 2001), and more by host-damaged plants compared to jasmonic acid treated plants (van Poecke and Dicke, 2002).

That inexperienced *C. marginiventris* and *M. rufiventris*, both solitary endoparasitic braconids, have different odor preferences may reflect differences in host location strategies between generalists and specialists. The generalist *C. marginiventris* oriented primarily toward odors released by freshly damaged plants, whereas the specialist *M. rufiventris* oriented to all treatment plants equally. A difference between the two species was also apparent after experience. *C. marginiventris* that experienced an oviposition on plants that had been damaged by host larvae overnight preferred the complete blend (fresh–old). Because the experience of oviposition was associated with the entire complex, host-damaged leaves, host larvae, and host by-products, it was to be expected that the wasps would be more attracted to the complete blend. Surprising was the preference of experienced *M. rufiventris* females for the blends containing a higher proportion of green leaf volatiles, as was the high proportion of experienced wasps that did not make a choice. It is possible that the experienced *M. rufiventris* searched for odors that are more specifically associated with the presence of hosts and that were not present among the cues offered.

It should be pointed out that we have emphasized green leaf volatiles and terpenoids as the groups of compounds associated with fresh and old damage; however, many other compounds are released in minor quantities, and these compounds may play a role in the attraction of the wasps as well. Electroantennogram studies have shown that some minor compounds elicit strong antennal responses in these parasitoids (Gouinguené et al., 2005), and current attempts to isolate and identify key attractants for *C. marginiventris* indicate an important role for minor compounds (M. D'Alessandro and T.C.J. Turlings, unpublished data). This does not invalidate the main conclusion from this study—that some generalist parasitoids use volatiles from fresh damage as general cues, and that truly herbivore-induced compounds, or other compounds directly associated with host presence, become more important after the wasps have experienced them while encountering hosts. Moreover, it can be concluded that parasitoids with comparable biologies, but different host ranges, employ different strategies in their use of plant-provided cues to locate hosts. Further insight into the host specificity and the circumstances under which wasps have to forage may provide explanations for these differences.

Acknowledgments—We thank Liselore Roelfstra and Yves Borcard for parasitoid rearing. Parasitoids with which we started our lab colonies were supplied by Donald Nordlund (*C. marginiventris*) and Esmat Hegazi (*M. rufiventris*). We also thank Syngenta (Stein, Switzerland) for the weekly shipment of *Spodoptera littoralis* eggs and caterpillars. Alex Aebi, Louis Felix Bersier, Marco D'Alessandro, Thomas Degen, Martine Rahier, and Cristina Tamò contributed with stimulating discussions and/or comments on the initial manuscript. We are grateful to Matthias Held, Ingrid Ricard, and Anthony Davison for the log-linear model construction and help with statistical analyses. This study was supported by grants from the Swiss Centre of International Agriculture (ZIL, ETH Zurich) and the Swiss National Science Foundation (grants 31-46237-95 and 31-44459-95).

Abstract—We investigated volatile infochemicals possibly involved in location of the generalist predatory mite *Neoseiulus californicus* to plants infested with spider mites in a Y-tube olfactometer. The predators significantly preferred volatiles from lima bean leaves infested with *Tetranychus urticae* to uninfested lima bean leaves. Likewise, they were attracted to volatiles from artificially damaged lima bean leaves and those from *T. urticae* plus their visible products. Significantly more predators chose infested lima bean leaves from which *T. urticae* plus their visible products had been removed than artificially damaged leaves, *T. urticae*, and their visible products. These results suggest that *N. californicus* is capable of exploiting a variety of volatile infochemicals originating from their prey, from the prey-foodplants themselves, and from the complex of the prey and the host plants (e.g., herbivore-induced volatiles). We also investigated predator response to some of the synthetic samples identified as volatile components emitted from *T. urticae*-infested lima bean leaves and/or artificially damaged lima bean leaves. The predators were attracted to each of the five synthetic volatile components: linalool, methyl salicylate, (*Z*)-3-hexen-1-ol, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate. The role of each volatile compound in prey-searching behavior is discussed.

Key Words—*Neoseiulus californicus*, *Tetranychus urticae*, lima bean, herbivore-induced volatiles, green leaf volatiles.

INTRODUCTION

Plant volatiles can be exploited by carnivorous natural enemies as cues for locating herbivorous victims (Lewis and Martin, 1990; Reddy et al., 2002). These infochemicals may originate from the food-plants of the herbivores, or from complexes of the herbivores and the food-plants (Steinberg et al., 1993). The importance of volatiles from the plant–herbivore complex (e.g., herbivore-induced volatiles) as foraging cues has been reported in many systems consisting of plants, herbivores, and carnivorous natural enemies (Takabayashi and Dicke, 1996; Dicke et al., 1998; Dicke, 1999a, b; Shiojiri et al., 2002). For example, laboratory studies have shown that volatiles from plants infested with spider mites are attractive to several species of insect predators and predatory mites, while those from spider mites, from uninfested plants, and from artificially damaged plants seldom or do not attract them (e.g., Sabelis et al., 1984; Maeda et al., 1999; Shimoda et al., 1997; Shimoda and Takabayashi, 2001).

There are relatively few studies that have identified predator attractants involved in volatile blends emitted from spider mite-infested plants despite the relevance of this topic from the ecological and biological control perspectives. Among the studies, for example, the predatory mites *Phytoseiulus persimilis* are attracted to volatiles from lima bean leaves infested with the two-spotted spider mite *Tetranychus urticae* (Sabelis and Van de Baan, 1983). In the volatile blend from *T. urticae*-infested lima bean leaves, each of the four herbivore-induced volatile compounds, linalool, methyl salicylate, (*E*)-β-ocimene, and (*E*)-4,8-dimethyl-1,3,7-nonatriene, is attractive to *P. persimilis*, whereas other volatile components in the blend, such as (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate, are not (Dicke et al., 1990). (*Z*)-3-Hexen-1-ol and (*Z*)-3-hexenyl acetate, called green leaf volatiles, are released by many plant species, including lima bean plants after physical damage as well as herbivory (Whitman and Eller, 1992; Reddy et al., 2002).

Neoseiulus (=*Amblyseius*) *californicus* is a predatory mite closely associated with spider mites, although it is regarded as a generalist predator that can exploit various foods such as pollen and small insects (Croft et al., 1998; Easterbrook et al., 2001). *N. californicus* is an effective biological control agent against *T. urticae* and other spider mite pests on agricultural crops (Garcia-Mari and Gonzalez-Zamora, 1999; Greco et al., 1999; Easterbrook et al., 2001). Although several studies have reported that *N. californicus* discriminates between plants infested with spider mites and uninfested plants (Janssen et al.,

1990; Llusia and Penuelas, 2001), the source of the predator attractants is still unclear. To clarify this point, we investigated possible volatile infochemicals involved in the location of *N. californicus* to spider mite-infested plants in a Y-tube olfactometer. We also focused on the predator response to single synthetic samples already identified as herbivore-induced volatiles in this tritrophic system (Dicke et al., 1990; Arimura et al., 2000), because no chemicals have been identified as attractants of *N. californicus*.

METHODS AND MATERIALS

Plants. Lima bean plants (*Phaseolus lunatus* cv. Sieva) were cultivated individually in plastic pots (9 cm diam, 7 cm depth) in a plant growth chamber (25 ± 1°C, 60 ± 10% r. h.). The fluorescent lights in the plant growth chamber (19,000 ± 3,000 lx) were switched on from 6:00 until 22:00 hours to maintain L16:D8 conditions. Young primary lima bean leaves of 14- to 16-d-old plants were used for rearing predators, bioassays, and headspace analysis. Kidney bean plants (*Phaseolus vulgaris* cv. Nagauzuramame) cultivated in a laboratory (20 ± 1°C, 60 ± 10% r. h.) were used for rearing the spider mites *T. urticae*.

Mites. N. californicus individuals were collected from Kudzu vine plants [*Pueraria lobata* (Wild.)] infested with *Tetranychus phaseolus* in a field at the National Agricultural Research Center in Ibaraki Prefecture, Japan, in 2001. The predatory mites were reared on lima bean leaf disks (8 cm diam) placed upside down on water-soaked cotton wool in plastic containers (14.5 × 19 cm, 5 cm in depth). To prepare *T. urticae*-infested lima bean leaves for rearing the predators, we first placed several kidney bean leaves infested with *T. urticae* on uninfested lima bean plants for several days in a climate-controlled room (25 ± 2°C, 60 ± 10% r. h. and 16L: 8D). Subsequently, a few lima bean leaves infested with *T. urticae* were offered to the predators in the lima bean leaf disks every 3 d. This predator culture had been maintained in the laboratory (23 ± 1°C, 60 ± 10% r. h., and L16:D8) for more than 1 yr. About 20 adult female predators after the final molting followed by mating were transferred from the leaf disk to a new one using a fine paintbrush. Fertilized adult female predators approx. 3–5 d after final molting were used for the experiments. To obtain starved predators for the bioassays, predators were individually placed in sealed plastic tubes (2 ml), which contained a small piece of moist filter paper, for 24 hr in the laboratory (25 ± 1°C and 16L: 8D).

Olfactometer Experiments. Each experiment was conducted in a Y-tube olfactometer with each arm connected to a glass container (1 l) containing an odor source. The airflow through each olfactometer arm (2.8 l/min) was checked with a flow meter. For details of the olfactometer set-up, see Takabayashi and Dicke

(1992). Predators were individually introduced at the start point on a steel wire that was positioned at the center of the glass tube, and observed until a predator reached the far end (finish line) of one of the arms. Predators that did not pass the finish line of either arm within 5 min (termed "no choice" subjects) were excluded from statistical analysis. We switched the arm containing the sample odor with that containing the control odor in the olfactometer every five bioassays. In every experiment, a total of 80 or more predators was tested over more than 4 d.

Experiment A: Origin of Volatiles that Attract Predators. To investigate possible volatile infochemicals involved in location of *N. californicus* to *T. urticae*-infested lima bean leaves, the following five experiments were conducted using six different types of odor sources: Experiment A1, uninfested leaves vs. clean air; Experiment A2, *T. urticae*-infested leaves vs. uninfested leaves; Experiment A3, artificially damaged leaves vs. clean air; Experiment A4, *T. urticae* plus visible products vs. clean air; Experiment A5: infested leaves without *T. urticae* vs. artificially damaged leaves, and *T. urticae* plus visible products.

(1) *T. urticae*-infested leaves. To prepare *T. urticae*-infested lima bean leaves, we placed several kidney bean leaves infested with *T. urticae* on primary leaves of uninfested lima bean plants; ca. 100 adult females together with larvae and nymphs were introduced to each leaf. The infested plants were incubated in a climate-controlled room (25 ± 1°C, 60 ± 10% r. h., and L16: D8) for 3 d. Just before the experiments, we cut five primary leaves infested with ca. 500 *T. urticae* individuals at all stages (approx. 100 of these were adult females) per leaf. The cut edge of the stem of each leaf was wrapped in a small piece of moist cotton wool and used as the odor source.

(2) Uninfested leaves. Several uninfested plants containing two primary leaves each were incubated in the climate-controlled room for 3 d. Five primary lima bean leaves were used as the odor source. Other conditions and procedures were the same as described above (1).

(3) *T. urticae* plus visible products. About 2,500 living spider mites at all stages (approx. 500 of these were adult females) and their visible products (feces, exuviae, eggs, egg shells, dead bodies, and silken webs) were carefully removed with a paintbrush from 5 infested leaves just before the experiments. The spider mites and their visible products were placed on moist cotton wool (10 × 10 cm) and used as an odor source. Other conditions and procedures were the same as described above (1).

(4) Infested leaves without *T. urticae*. All living spider mites and their visible products were removed from five lima bean leaves by washing. The water on each leaf was wiped with paper wipes (Kimwipe S-200), and then was used as an odor source. Other conditions and procedures were the same as described above (1).

(5) Artificially damaged leaves. Five lima bean leaves were damaged by rubbing with carborundum (Silicon carbide: 400) on a wet cotton wool pad.

After the treatment, the carborundum was removed by washing. Other conditions and procedures were the same as described above (1).

(6) Clean air. Five small pieces of moist cotton wool were used as the control odor source.

Experiment B. Predator-Response to Single Synthetic Samples. We investigated the olfactory responses of *N. californicus* to each of the five synthetic volatile components: linalool, methyl salicylate, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, and (*E*)-2-hexenal. The first two have been identified as minor components in a blend of herbivore-induced volatiles from *T. urticae*-infested lima bean plants (Dicke et al., 1990). The last three are also found in headspace samples of artificially damaged lima bean plants as well as in a blend of herbivore-induced volatiles from *T. urticae*-infested lima bean plants (Dicke et al., 1990; Arimura et al., 2000).

The synthetic samples were separately dissolved in hexane (10 μg, 100 μg, and 1 mg/10 μl hexane solutions). Ten μl of diluted chemicals were separately impregnated into a piece of cellulose sponge (2 × 2 × 0.5 cm). After evaporation of solvent for a few minutes, each sponge was doubly packed into two sealed polyethylene bags (Seinichi Unipack: 70 × 50 × 0.04 mm) and then used as a sample odor source. In the same way, a piece of cellulose sponge with pure solvent (10 μl of hexane) sealed in two polyethylene bags was prepared as a control odor source. The synthetic samples, of purity ranging from 96% to 98%, were obtained from Wako Pure Chemical Industries.

The following experiments were conducted: Experiment B1, linalool (10 μg); Experiment B2, linalool (1 mg); Experiment B3, methyl salicylate (10 μg); Experiment B4, methyl salicylate (1 mg); Experiment B5, (*Z*)-3-hexen-1-ol (10 μg); Experiment B6, (*Z*)-3-hexen-1-ol (100 μg); Experiment B7, (*Z*)-3-hexen-1-ol (1 mg); Experiment B8, (*E*)-2-hexenal (10 μg); Experiment B9, (*E*)-2-hexenal (100 μg); Experiment B10, (*E*)-2-hexenal (1 mg); Experiment B11, (*Z*)-3-hexenyl acetate (10 μg); Experiment B12: (*Z*)-3-hexenyl acetate (100 μg); and Experiment B13: (*Z*)-3-hexenyl acetate (1 mg). In each experiment, 10 μl of hexane were used as a control odor source.

Chemical Analysis of Volatiles. Headspace volatiles of each odor source used in Experiments A and B were collected by using a Tenax TA Thermal Desorption Tube (180 mg, 60/80 mesh; Gerstel) in a lidded glass bottle (2 l) for 30 min at a flow rate of 100 ml/min of clean air, purified by passing it through silica gel, molecular sieves, and activated charcoal (1 l each). Before collection of volatiles, a steady flow (200 ml/min) of purified air was circulated through the glass bottle containing each odor source for 10 min. Collected volatiles in each sample were analyzed with a GC-MS system [GC: Agilent Technologies 6890 with an HP-5MS capillary column (30 m long, 0.25 mm I.D., and 0.25 μm file thickness), injection temperature of 250°C; MS: Agilent Technologies 5973N mass selective detector, 70 eV] with Thermodesorption Autosampler

System and Cold Injection System (TDS A 2 and CIS 4: Gerstel). The oven temperature of the GC-MS was programmed to rise from 40°C (9 min hold) to 280°C at 10°C/min. The TDS A 2 and CIS 4 temperatures were programmed to rise from 20°C (1 min hold) to 280°C at 60°C/min and from −150°C (0.5 min hold) to 300°C at 12°C/min, respectively. The components were identified by comparing their spectra with mass spectra in the database (Wiley Library), along with our data regarding herbivore-induced volatiles from lima bean plants (Ozawa et al., 2000).

Statistics. The results from each bioassay experiment were subjected to a χ^2 test (Sokal and Rohlf, 1998). The null hypothesis was that predators exhibited a 50:50 distribution over the two odor sources. We applied the *t*-test or one-way analysis of variance (ANOVA) followed by Tukey–Kramer's test to the results of the chemical analysis. When necessary, data used in ANOVA were transformed using square root transformation of $\sqrt{(x + 0.5)}$ or logarithmic transformation of $\log_{10}(x + 1)$ to meet assumptions of normality.

RESULTS

Experiment A. When presented with a choice between uninfested leaves and clean air, predators did not discriminate (Exp. A1: $\chi^2 = 0.211$, $df = 1$, $P = 0.646$) (Figure 1). In contrast, the predators showed a strong preference for odors from *T. urticae*-infested leaves over uninfested leaves (Exp. A2: $\chi^2 = 23.027$, $df = 1$, $P < 0.001$). When artificially damaged leaves were offered vs. clean air, significantly more predators chose the former odor source (Exp. A3: $\chi^2 = 5.128$, $df = 1$, $P < 0.05$). The same tendency was observed when *T. urticae* plus visible products vs. clean air were compared (Exp. A4: $\chi^2 = 10.051$, $df = 1$, $P < 0.01$). Significantly more predators chose infested leaves without *T. urticae* than artificially damaged leaves, *T. urticae* plus visible products (Exp. A5: $\chi^2 = 20.513$, $df = 1$, $P < 0.001$).

Experiment B. When presented with a choice between linalool (10 μg) and hexane, predators did not discriminate (Exp. B1: $\chi^2 = 0.653$, $df = 1$, $P = 0.419$) (Figure 2). However, the predators showed a preference for linalool when offered at an amount of 1 mg (Exp. B2: $\chi^2 = 16$, $df = 1$, $P < 0.001$). They were also attracted to methyl salicylate when offered at an amount of 1 mg (Exp. B4: $\chi^2 = 16.327$, $df = 1$, $P < 0.001$). When the dose offered was only 10 μg, however, no positive response was observed (Exp. B3: $\chi^2 = 0.667$, $df = 1$, $P = 0.414$). This was also the case for (*Z*)-3-hexen-1-ol when offered at 10 μg (Exp. B5: $\chi^2 = 0.16$, $df = 1$, $P = 0.689$) (Figure 3). However, (*Z*)-3-hexen-1-ol attracted predators at 100 μg (Exp. B6: $\chi^2 = 7.364$, $df = 1$, $P < 0.01$) and 1 mg (Exp. B7: $\chi^2 = 5.343$, $df = 1$, $P < 0.05$). (*E*)-2-Hexenal was also attractive to predators at 1 mg (Exp. B10: $\chi^2 = 9.184$, $df = 1$, $P < 0.01$). However, no

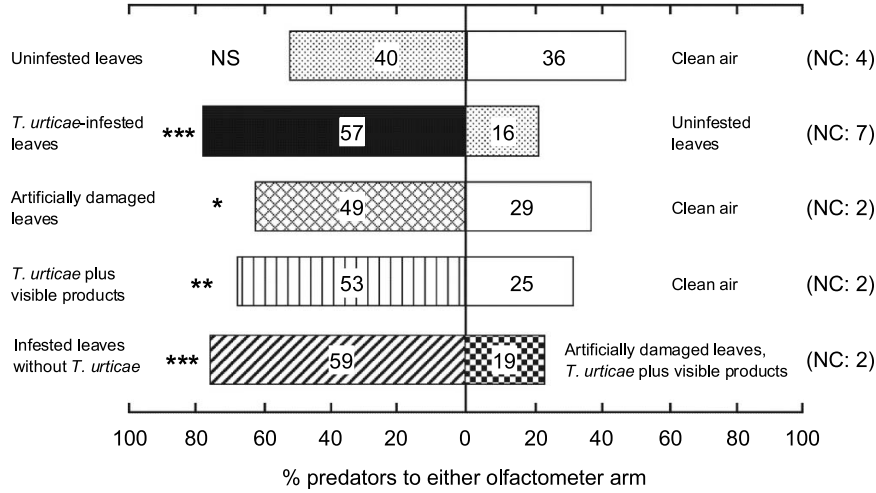

FIG. 1. Responses of adult females of *Neoseiulus californicus* in a Y-tube olfactometer when offered: Experiment A1, uninfested leaves vs. clean air; Experiment A2, *T. urticae*-infested leaves vs. uninfested leaves; Experiment A3, artificially damaged leaves vs. clean air; Experiment A4, *T. urticae* plus visible products vs. clean air; Experiment A5: infested leaves without *T. urticae* vs. artificially damaged leaves, *T. urticae* plus visible products. χ^2 test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (*$P < 0.05$, **$P < 0.01$, ***$P < 0.001$, NS: $P > 0.05$). Predators that did not reach the end of either olfactometer arm within 5 min [no choice (NC)] were excluded from the statistical analysis. For further explanation, see text.

positive response was observed when the dose offered was 10 μg (Exp. B8: $\chi^2 = 1.779$, $df = 1$, $P = 0.182$) and 100 μg (Exp. B9: $\chi^2 = 3.375$, $df = 1$, $P = 0.066$). Similar results were obtained with (*Z*)-3-hexenyl acetate at 100 μg (Exp. B12, $\chi^2 = 0.163$, $df = 1$, $P = 0.686$) and 1 mg (Exp. B13: $\chi^2 = 2.56$, $df = 1$, $P = 0.11$). However, (*Z*)-3-hexenyl acetate was attractive to predators at 10 μg (Exp. B11: $\chi^2 = 8$, $df = 1$, $P < 0.01$).

Chemical Analysis of Volatiles. Uninfested leaves emitted trace amounts of (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, and α-copaene (Table 1). Artificially damaged leaves emitted small amounts of (*Z*)-3-hexenyl acetate and (*E*)-β-ocimene in addition to these three components. *T. urticae*-infested leaves emitted (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, methyl salicylate, and eight terpenoids. Linalool, methyl salicylate, (*Z*)-β-ocimene, (*Z*)-4,8-dimethyl-1,3,7-nonatriene, (*E*)-4,8-dimethyl-1,3,7-nonatriene, β-caryophyllene, and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were found in the headspace of the *T. urticae*-infested leaves, but not found in that of the artificially damaged

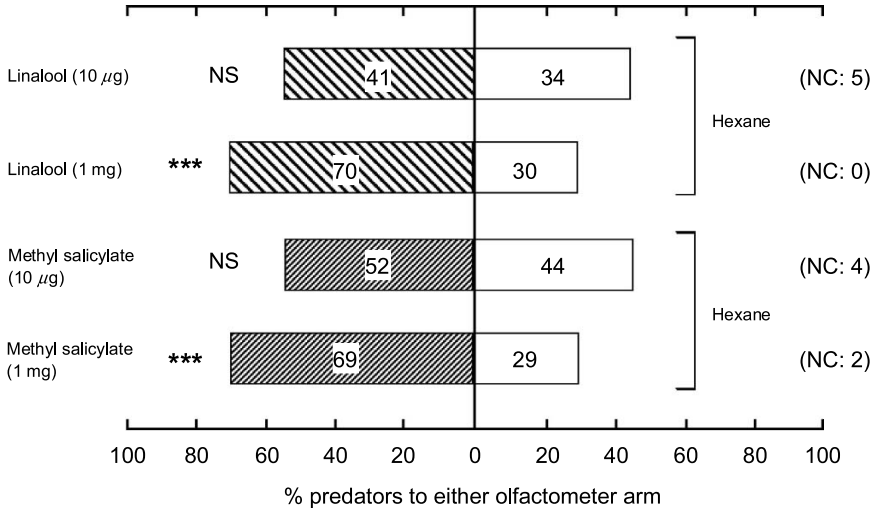

FIG. 2. Responses of adult females of *Neoseiulus californicus* in a Y-tube olfactometer when offered: Experiment B1, linalool (10 μg); Experiment B2, linalool (1 mg); Experiment B3, methyl salicylate (10 μg); Experiment B4, methyl salicylate (1 mg). The synthetic samples were separately dissolved in hexane to obtain different concentrations of each chemical (10 μg and 1 mg/10 μl hexane solutions). Aliquots (10 μl) of diluted chemicals were used as sample odor sources after evaporation of their solvent carriers. In each experiment, 10 μl of hexane were used as a control odor source. χ^2 test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (***$P < 0.001$, NS: $P > 0.05$). Predators that did not reach the end of either olfactometer arm within 5 min [no choice (NC)] were excluded from the statistical analysis. For further explanation, see text.

leaves. Furthermore, (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, and α-copaene were detected in significantly greater amounts within the former than within the latter odor source. Infested leaves without *T. urticae* emitted the same volatile components as detected in the headspace of *T. urticae*-infested leaves. There was no significant difference between these two odor sources as to the amount of each volatile component. No specific volatile components were found in the headspace of *T. urticae* plus visible products ($N = 3$), although this odor source was attractive to *N. californicus* in Experiment A.

A significantly greater amount of (*E*)-2-hexsenal was detected in the headspace of the glass bottle in which was placed either 10 μg, 100 μg, or 1 mg of the synthetic (*E*)-2-hexsenal in a cellulose sponge, double-packed in sealed polyethylene bags, than in the headspace of the glass bottle in which either artificially damaged leaves, *T. urticae*-infested leaves, or infested leaves without *T. urticae* were placed. We did not detect (*Z*)-3-hexen-1-ol when treated with

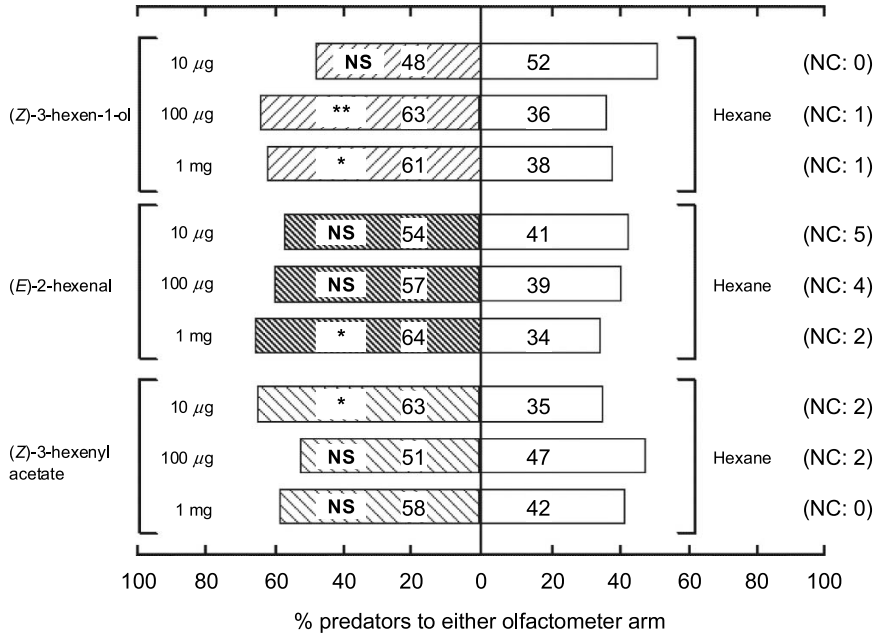

FIG. 3. Responses of adult females of *Neoseiulus californicus* in a Y-tube olfactometer when offered: Experiment B5, (*Z*)-3-hexen-1-ol (10 μg); Experiment B6, (*Z*)-3-hexen-1-ol (100 μg); Experiment B7, (*Z*)-3-hexen-1-ol (1 mg); Experiment B8, (*E*)-2-hexenal (10 μg); Experiment B9, (*E*)-2-hexenal (100 μg); Experiment B10, (*E*)-2-hexenal (1 mg); Experiment B11, (*Z*)-3-hexenyl acetate (10 μg); Experiment B12, (*Z*)-3-hexenyl acetate (100 μg); Experiment B13: (*Z*)-3-hexenyl acetate (1 mg). The synthetic samples were separately dissolved in hexane to obtain different concentrations of each chemical (10 μg, 100 μg, and 1 mg/10 μl hexane solutions). Aliquots (10 μl) of diluted chemicals were used as sample odor sources after evaporation of their solvent carriers. In each experiment, 10 μl of hexane were used as a control odor source. χ^2 test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (*$P < 0.05$, **$P < 0.01$, NS: $P > 0.05$). Predators that did not reach the end of either olfactometer arm within 5 min [no choice (NC)] were excluded from the statistical analysis. For further explanation, see text.

synthetic (*Z*)-3-hexen-1-ol (10 μg). When synthetic (*Z*)-3-hexen-1-ol (100 μg) was used as an odor source, a small amount of (*Z*)-3-hexen-1-ol was detected, which was at a similar emission level as that made by uninfested leaves, artificially damaged leaves, *T. urticae*-infested leaves, and infested leaves without *T. urticae*. A small amount of (*Z*)-3-hexenyl acetate was detected when treated with synthetic (*Z*)-3-hexenyl acetate (10 μg), which was an emission level similar to that made by artificially damaged leaves. When synthetic

Uninfested = uninfested leaves; Damaged = artificially damaged leaves; Infested 1 = *T. urticae*-infested leaves; Infested 2 = infested leaves without *T. urticae*; ND = not detected in the chemical analysis (excluded from statistical analysis); DMNT 1 = (*Z*)-4,8-dimethyl-1,3,7-nonatriene; DMNT 2 = (*E*)-4,8-dimethyl-1,3,7-nonatriene; TMTT = (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene.

Values with the same letter of the same compound are not significantly different (Tukey–Kramer's test or t test, $P > 0.05$).

linalool (1 mg) was used, a small amount of this component was detected, which was at an emission level similar to that made by *T. urticae*-infested leaves and infested leaves without *T. urticae*. This was also true for synthetic methyl salicylate (1 mg), *T. urticae*-infested leaves, and infested leaves without *T. urticae*, although a large amount of methyl salicylate was emitted from each odor source.

DISCUSSION

We showed that the volatiles from lima bean leaves infested with *T. urticae* were attractive to *N. californicus*, whereas those from uninfested lima bean leaves were not. This parallels other studies in which plants infested with spider mites elicit olfactory preference from their carnivorous natural enemies, such as predatory mites and predacious insects (e.g., Dicke, 1999a; Shiojiri et al., 2002). Volatiles from artificially damaged lima bean leaves and from *T. urticae* plus their by-products were also attractive to *N. californicus*, suggesting that this generalist predatory mite is capable of exploiting a variety of volatile infochemicals originating from its prey, from the host plants of the prey, and from the interaction between the prey and the host plants. Similar results were reported for the generalist predatory bug *Anthocoris nemorum*, which feeds on spider mites and other small insects (Dwumfour, 1992). On the other hand, several species of specialist predatory mites and insect predators appear to (almost) exclusively exploit volatile infochemicals originating from the prey-host plant complex, i.e., herbivore-induced volatiles, to locate spider mite-infested plants (Shimoda et al., 1997; Maeda et al., 1999; Shimoda and Takabayashi, 2001). There may be differences between specialist and generalist predatory mites in terms of the use of volatile infochemicals originating from prey, plants, and plant–prey complexes.

Artificially damaged leaves and uninfested leaves led to different olfactory responses of *N. californicus*, which were presumably attributable to the differences in their emissions of volatiles (Table 1). (*Z*)-3-Hexenyl acetate appears to play a partial role in the olfactory discrimination of these leaves, because *N. californicus* showed olfactory preferences for the synthetic chemical [(*Z*)-3-hexenyl acetate; 10 μg], detected only in the volatile blend of the artificially damaged leaves. Positive olfactory responses to synthetic (*Z*)-3-hexenyl acetate were reported in several species of parasitoid wasps, such as *Microplitis croceipes*, *Netelia heroica*, and *Cotesia plutellae* (Whitman and Eller, 1992; Reddy et al., 2002). Furthermore, (*E*)-β-ocimene may be involved in attracting *N. californicus* to artificially damaged leaves, because this volatile component was not found in the headspace of uninfested leaves. (*E*)-*β*-Ocimene is a key compound in the herbivore-induced volatile blend that plays a role in

attracting *P. persimilis* to *T. urticae*-infested lima bean leaves (Dicke et al., 1990).

(*Z*)-3-Hexen-1-ol might also have contributed to predator attraction to the artificially damaged leaves, the infested leaves without *T. urticae*, and the *T. urticae*-infested leaves (Figures 1, 3, Table 1). However, (*Z*)-3-hexen-1-ol is unlikely be involved in olfactory discrimination between the infested leaves without *T. urticae* and the artificially damaged leaves because no significant difference was obtained in emissions between the two odor sources. Infested leaves without *T. urticae* produced a greater variety of volatile components, including two herbivore-induced volatile components identified as linalool and methyl salicylate, than did artificially damaged leaves. No specific compound was detected from *T. urticae* plus their by-products in the chemical analysis. We showed that synthetic samples of linalool (1 mg) and methyl salicylate (1 mg) were attractive to *N. californicus*. Emission levels of linalool and methyl salicylate obtained by these chemical treatments (1 mg each) were similar to those made by the infested leaves without *T. urticae* (Table 1). These two herbivore-induced volatile components probably contributed to *N. californicus*' preference for the infested leaves without *T. urticae* over the artificially damaged leaves. This argument may also apply to the strong olfactory response of *N. californicus* evoked by *T. urticae*-infested leaves, because there was no significant difference in volatile emissions between *T. urticae*-infested leaves and infested leaves without *T. urticae*. Both methyl salicylate and linalool play roles in attracting *P. persimilis* to lima bean plants infested with *T. urticae* (Dicke et al., 1990). Methyl salicylate is also attractive to the predatory bug *Anthocoris numoralis*, which can partly account for the observed preference for volatiles from pear leaves infested with *Psylla pyricola* (Scutareanu et al., 1997; Drukker et al., 2000). It remains an open question as to whether or not other components [e.g., α-copaene, (*E*)-4,8-dimethyl-1,3,7-nonatriene, β-caryophyllene, and (*E*, *E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene] from infested leaves without *T. urticae* are also involved in attracting *N. californicus*.

We found that the five synthetic samples were all attractive to *N. californicus*. This finding prompts an interest in the potential of these synthetic samples for enhancement of their density and efficiency as biological control agents against *T. urticae* or other pest spider mites in agroecosystems. James (2003) reported the attraction of predaceous insects, such as *Orius tristicolor*, *Deraeocoris brevis*, and *Geocoris pallens*, to individual synthetic samples of (*Z*)-3-hexenyl acetate and methyl salicylate in a hop yard. Furthermore, James and Price (2004) recorded larger populations of natural enemies of spider mites, such as *Orius tristicolor* and *Stethorus punctum*, in a hop yard baited with methyl salicylate than those in an unbaited hop yard, which may account for a conspicuous reduction in the abundance of *T. urticae* in the baited yard. We are also interested in the use of synthetic predator attractants in, e.g., controlled

Japanese pear orchards in which *N. californicus* is an important natural enemy of *T. urticae*. To carry out field experiments of this type, it will be necessary to ascertain whether or not the five synthetic samples, individually or as synthetic blends, are equivalent to volatile blends from, e.g., *T. urticae*-infested lima bean leaves as predator attractants.

Acknowledgments—We thank Kimiko Kanbe and Yumiko Togashi for rearing the mites and plants. We also thank Dr. Yoshito Suzuki and Dr. Chie Goto for constructive comments during the study. This study was supported by the Bio-oriented Technology Research Advancement Institution.

Abstract—Herbivore feeding induces plants to emit volatiles that are detectable and reliable cues for foraging parasitoids, which allows them to perform oriented host searching. We investigated whether these plant volatiles play a role in avoiding parasitoid competition by discriminating parasitized from unparasitized hosts in flight. In a wind tunnel set-up, we used mechanically damaged plants treated with regurgitant containing elicitors to simulate and standardize herbivore feeding. The solitary parasitoid *Cotesia rubecula* discriminated among volatile blends from Brussels sprouts plants treated with regurgitant of unparasitized *Pieris rapae* or *P. brassicae* caterpillars over blends emitted by plants treated with regurgitant of parasitized caterpillars. The gregarious *Cotesia glomerata* discriminated between volatiles induced by regurgitant from parasitized and unparasitized caterpillars of its major host species, *P. brassicae*. Gas chromatography-mass spectrometry analysis of headspace odors revealed that cabbage plants treated with regurgitant of parasitized *P. brassicae* caterpillars emitted lower amounts of volatiles than plants treated with unparasitized caterpillars. We demonstrate (1) that parasitoids can detect, in flight, whether their hosts contain competitors, and (2) that plants reduce the production of specific herbivore-induced volatiles after a successful recruitment of their bodyguards. As the induced volatiles bear biosynthetic and ecological costs to plants, down-regulation of their production has adaptive value. These findings add a new level of intricacy to plant–parasitoid interactions.

Key Words—Induced plant defense, headspace analysis, tritrophic interactions, *Pieris*, *Cotesia*.

INTRODUCTION

Female parasitoids of herbivorous insects have to search for hosts to lay their eggs in or on them. Host searching is guided by volatile synomones that are mostly produced by the host plants after induction caused by herbivore feeding (Dicke, 1999; Shiojiri et al., 2001; Hilker and Meiners, 2002; Turlings et al., 2002; Steidle and van Loon, 2003). The ability to distinguish unparasitized from parasitized hosts and to reject the latter for oviposition (i.e., host discrimination) is widespread among hymenopteran parasitoids (van Lenteren, 1981; Vinson, 1985; van Alphen and Visser, 1990). The reproductive success of endoparasitoids is dependent on the quality and size of the hosts, because hosts provide a limited nutritional resource for their offspring (Godfray, 1994). Oviposition on or into already parasitized hosts by a conspecific parasitoid (i.e., superparasitism) can lead to competition with deleterious consequences such as mortality or reduced fitness. Therefore, avoiding superparasitism can have several advantages, including the optimization of foraging efficiency (van Lenteren, 1981; Godfray, 1994).

So far, host discrimination by parasitoids is known to be mediated by marking pheromones deposited by the ovipositing female either on or in the host, or within the explored patch. In addition, physiological changes in the host hemolymph induced by the parasitoid progeny (van Lenteren, 1981; Nufio and Papaj, 2001) or physical changes of the host surface acting as external markers (Takasu and Hirose, 1988) may provide cues for host discrimination. Marking pheromones are usually perceived through contact chemoreception (van Lenteren, 1981), although some examples of olfactory perception are known as well (Sheehan et al., 1993; van Giessen et al., 1993; van Baaren and Nenon, 1996).

Herbivore-induced volatiles are emitted in considerable quantities by plants, and the blend induced by herbivory differs in a qualitative and/or quantitative sense from the volatile blends of undamaged or mechanically damaged plants (Turlings et al., 1995; Dicke and Vet, 1999; Shiojiri et al., 2000). The emitted blend can be specific for the plant species, the herbivore species that damages the plant, and even for a specific stage of the herbivore (Turlings et al., 1995; Takabayashi and Dicke, 1996; Dicke and Vet, 1999). Based on the high detectability and reliability of herbivore-induced plant volatiles, parasitoids are able to use these cues to locate their hosts from a distance (Vet and Dicke, 1992). However, it is still unknown whether foraging females are able to distinguish unparasitized from parasitized hosts at a distance via olfactory cues produced by their host plant. Yet, this ability would save them foraging time and would reduce risks associated with host defense. We investigated this for a tritrophic system consisting of *Brassica* plants, *Pieris* caterpillars, and *Cotesia* parasitoids.

Brussels sprouts plants are known to emit a blend of volatiles when infested by *Pieris brassicae* L. (Lepidoptera: Pieridae) or *P. rapae* L. caterpillars. These induced volatiles attract *Cotesia rubecula* Marshall (Hymenoptera: Braconidae), a solitary endoparasitoid of the small cabbage white *P. rapae* and *Cotesia glomerata* L., a gregarious parasitoid of both *Pieris* species (Agelopoulos and Keller, 1994; Geervliet et al., 1994, 1998; Mattiacci et al., 1995, 2001). Differences between headspace volatiles collected from undamaged and *Pieris*-infested Brussels sprouts plants are extensively documented (Blaakmeer et al., 1994; Mattiacci et al., 1995, 2001; Smid et al., 2002). Coupled gas chromatography-electroantennography (GC-EAG) analysis has revealed that 20 of the headspace volatiles elicit a response in the antennae of *C. rubecula* and *C. glomerata* (Smid et al., 2002). The application of regurgitant of *P. brassicae* larvae or the enzyme β-glucosidase into a mechanical wound elicits induction of similar volatile blends in cabbage plants as in herbivory, showing that the plants recognize infestation through an elicitor in the oral secretion of *Pieris* caterpillars (Mattiacci et al., 1995).

In the present study, we investigate (1) whether females of the two *Cotesia* species prefer, in flight, induced odors emitted by plants fed upon by unparasitized caterpillars or treated with their regurgitant over odors emitted by plants fed upon by parasitized caterpillars or treated with their regurgitant, and (2) whether the induced plant odor blends differ, thereby providing a chemical basis for this discrimination behavior in the two wasp species.

METHODS AND MATERIALS

Plants and Insects. Brussels sprouts plants (*Brassica oleracea* var. *gemmifera* cv. *Cyrus*) were reared in a greenhouse (18 ± 2°C, 70% RH, 16L:8D). Plants (8 to 12 wk old) having ca. 14–16 leaves were used for the experiments.

P. rapae and *P. brassicae* were reared on Brussels sprouts plants in a climate room (21 ± 1°C, 50–70% RH, 16L:8D). The parasitoid wasps *C. rubecula* and *C. glomerata* were reared on *P. rapae* and *P. brassicae* larvae, respectively, feeding on Brussels sprouts plants under greenhouse conditions (see above).

For bioassay experiments, *C. rubecula* and *C. glomerata* pupae were collected and reared in gauze cages in a climate room (23 ± 1°C, 50–70% RH, 16L: 8D). Once eclosed, the wasps were provided with water and honey. They had no contact with plant material or caterpillars before the initiation of the bioassays. They are referred to as naive wasps.

Regurgitant Collection. Regurgitant was collected from unparasitized and parasitized fifth instar larvae of *P. brassicae*, and from unparasitized and

parasitized fourth instar *P. rapae* larvae 24 hr before the bioassay or headspace collection. Regurgitant droplets were collected with a 5-µl glass capillary tube after gently squeezing the caterpillars with forceps. About 5–10 caterpillars of each group (parasitized and unparasitized larvae) were used to collect 50 µl regurgitant, which was immediately put in separate vials on ice. Larvae that had been exposed to oviposition by female wasps were dissected before the regurgitant was pooled to ensure that they were indeed parasitized.

Plant Treatments. For the bioassay with *P. rapae* caterpillars, 30 first instars were offered to females of *C. rubecula*. Each caterpillar was observed to be stung by a wasp, and subsequently was reared on cabbage. Another 30 unparasitized L1 caterpillars were reared on cabbage under identical circumstances. After 4 d, 15 unparasitized larvae were placed on a Brussels sprouts plant. Another 15 larvae that were supposed to be parasitized were placed on a different plant. After 48 hr, the plants were used in the bioassay to investigate parasitoid odor preference. Parasitized caterpillars were reared until the last instar to examine whether they had indeed been parasitized and to assess the degree of parasitization.

In bioassays during which caterpillar regurgitant was used, each plant was damaged on the fifth fully expanded leaf, and for headspace collection on the fifth and sixth leaves from the top by using a pattern wheel. The wheel was rolled over the leaf surface on each side of the midrib, 10 lines in parallel, and 10 lines perpendicularly to the midrib creating a ca. 8 cm^2 field with punctures being distributed over about 1/3 of the leaf surface. Per artificially damaged leaf, 25 µl of regurgitant, freshly collected from either parasitized or unparasitized caterpillars, were applied with a micropipette and distributed with a brush. Afterwards, the plants were kept in a climate room (23 ± 1°C, 50–70% RH) for 18 to 24 hr until the bioassay or headspace analysis. After the induction period, only the treated leaves were used for both behavioral bioassays and headspace analysis.

Bioassays. Parasitoid odor preference experiments were conducted in a wind tunnel set-up (25 ± 5°C, 50–70% r.h., 0.7 klux) described by Geervliet et al. (1994), with a wind speed of 0.2 m/s. For the bioassays, only the treated leaves that were of the same physiological age and size were used and excised from the induced plants just prior to the experiment. In this way, a highly standardized set of odor sources was offered to the parasitoids in a choice situation (Mattiacci et al., 1994, 1995). The petioles were inserted in vials with water, and the two leaves acting as odor sources were placed at the upwind end of the wind tunnel, ca. 14 cm apart. Experiments were carried out on 9–12 d, spread out over 2–3 mo for each treatment. For each of these days, new plants and new wasps were used. Three different plant treatments were tested in a two-choice flight experiment in the wind tunnel: (1) cabbage leaves infested with either parasitized or unparasitized second instars of *P. rapae*, (2) artificially

damaged cabbage leaves treated with regurgitant collected from either unparasitized (UNPAR) or parasitized (PAR) *P. rapae*, and (3) artificially damaged cabbage leaves treated with regurgitant from either unparasitized or parasitized *P. brassicae* caterpillars. Two to 6-d-old, naive female wasps of each species were used. Each wasp was individually released on a microscope slide with a small part of a leaf from a caterpillar-damaged cabbage plant from which first instars had been removed just prior to the bioassay. For each *Cotesia* species, damage done by the *Pieris* species under test was used. This priming served to increase the responsiveness of the wasps during the bioassay. The microscope slide was placed in the middle of the release cylinder, which was 60 cm downwind from the odor sources.

After release, the behavior of the wasp was observed. Only flights that resulted in the first landing on one of the odor sources were recorded as response. All landings on other parts of the wind tunnel besides the release cylinder or odor source were recorded as no response. If the wasp remained longer than 10 min in or on the release cylinder, it was recorded as no response and discarded. During the bioassay, plant positions were changed from left to right and vice versa after every second wasp. Females of the two wasp species were alternately tested for every treatment with a maximum number of 15 females per species and day. The two species were tested on the same day to expose them to similar conditions. On each observation day, one leaf from one plant of each treatment was tested.

Collection of Headspace Volatiles. Headspace collection was performed at 23 ± 1°C, 50–70% r.h. and approximately 10 klux; nine replicate plants were used per treatment. Volatiles from the treatments to be compared were collected on the same day to minimize variation among plant and caterpillar batches as well as day-to-day variation. Four replicates were obtained from the same batch of 10- to 12-wk-old plants within 9 d in September 2002, and five replicates were obtained from the same batch of ca. 10- to 12-wk-old plants within 11 d in April 2003. First, incoming air was led through a 5-l glass jar for 1 hr, at a flow rate of 300 ml/min to clean the system. Then, two leaves of the same plant induced by regurgitant from unparasitized *P. brassicae* caterpillars, and two leaves from a different plant induced by regurgitant of parasitized caterpillars were excised and immediately placed into separate jars with their petioles in a vial with water. They were purged for a further 1 hr. During the third hour, the headspace was collected using traps (10 cm long), packed with 200 mg Tenax TA (Markes, Pontyclun, UK; 60–80 mesh) connected to the air outlet.

GC-MS Analysis of Headspace Samples. Volatiles were desorbed from the Tenax traps using an automated thermodesorption unit (model Unity, Markes) at 200°C for 10 min (He flow 30 ml/min) and focused in an electrically cooled (−10°C) sorbent trap to allow for narrow starting bands. Volatiles were injected into the GC in splitless mode by ballistic heating of the cold trap for 3 min to

270°C. After separation by capillary gas chromatography (column: 30 m × 0.32 mm ID RTX-5 Silms, film thickness 0.33 μm; temperature program: 40–95°C at 3°C/min, then to 165°C at 2°C/min, and finally to 250°C at 15°C/min), volatiles were introduced into a Finnigan quadrupole mass spectrometer (Model Trace) operating at 70 eV in EI ionization mode. Mass spectra were recorded with full scan mode (33–300 AMU, 3 scans/sec). Compounds were identified using deconvolution software (AMDIS) in combination with Nist 98 and Wiley 7th edition spectral libraries, and by comparing their linear retention indices with those of authentic references from our own library.

Other identifications were made by comparison of mass spectra and linear retention indices (Ruther, 2000; Adams, 2001), by interpolating homologous series, and/or by using reference substances. The identified peaks were integrated by Xcalibur software (Finnigan). To minimize any interference by coeluting compounds, specific ions were selected for each compound of interest. Generally, these ions were identical with the model ions indicated by AMDIS.

Statistical Analysis. The null hypothesis (H_0) was that there is no difference in the probability of wasps flying to the UNPAR treatment or PAR treatment. The alternative hypothesis (H_1) was that the wasps used herbivore-induced plant volatiles in host-discrimination, and thus, that they preferred volatiles from the UNPAR treatment over those from the PAR treatment. The choices of the wasps in the two-choice olfactometer conform to a binomial distribution. Therefore, choices of the wasps between two odor sources within a bioassay were analyzed by using a one-sided binomial test (Siegel, 1956). Responsiveness among the choice tests between the different treatments was analyzed with 2 × 2 contingency tables using chi-square statistics.

Amounts of volatiles trapped were analyzed on the basis of peak area, as determined in the GC-MS analysis. For the headspace analyses, samples of both treatments collected on the same day were analyzed as paired data. The Wilcoxon's matched-pair signed rank test was employed to test whether the peak area per compound differed between leaves treated with regurgitant collected from parasitized and unparasitized caterpillars. A sign test was used to determine whether the number of compounds that were emitted in larger amounts differed from a 50:50 distribution over the two treatments.

RESULTS

Parasitoid Behavior. Females of *C. rubecula* landed more often on leaves infested with unparasitized larvae of *P. rapae* than on leaves infested with parasitized caterpillars (Figure 1a; $P = 0.01$). Only those combinations of leaves were taken into account for which the parasitization rate after dissection was found to be minimally 50%.

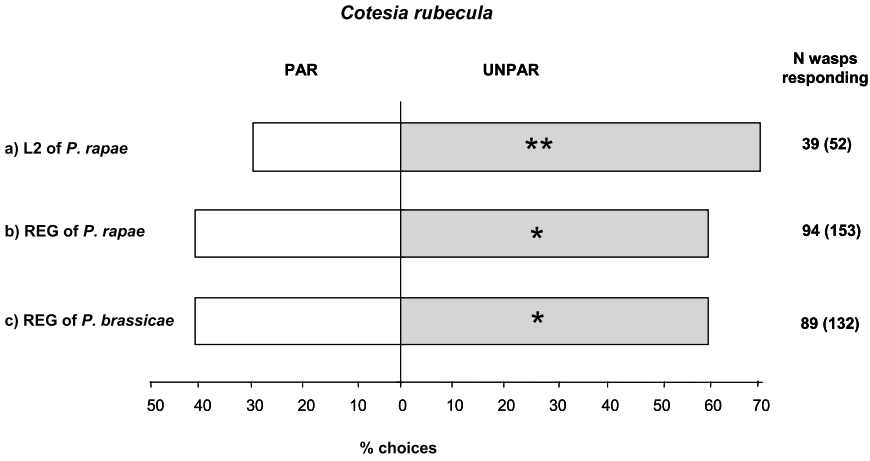

FIG. 1. Response of *C. rubecula* to cabbage leaves (a) exposed to parasitized (PAR) and unparasitized (UNPAR) second instar larvae of *P. rapae*, (b) artificially damaged and treated with regurgitant (REG) of PAR and UNPAR fourth instar *P. rapae* larvae, and (c) artificially damaged and treated with REG from PAR and UNPAR fifth instar *P. brassicae* larvae in a two-choice set-up. Asterisks indicate significant differences within a choice test: $*P < 0.05$, $**P < 0.01$ (binomial test). The bars show the percentages of wasps landing on either odor source. The numbers show the number of wasps responding; the numbers in brackets show the total number of wasps tested. All wasps were released on a leaf damaged by first instar larvae either of UNPAR *P. rapae* (a/b) or UNPAR *P. brassicae* (c).

Because the amount of leaf surface area removed from leaves fed upon by the unparasitized caterpillars was about 20% larger than from leaves fed upon by parasitized caterpillars, and the amount of *ad libitum* feeding could not be manipulated, we conducted subsequent bioassays with leaves to which a standardized amount of artificial damage and regurgitant were applied. In bioassays with regurgitant of *P. rapae* larvae, females of *C. rubecula* preferred to land on leaves treated with regurgitant of unparasitized caterpillars (Figure 1b; $P = 0.039$). Also, when leaves treated with regurgitant of *P. brassicae* were offered, *C. rubecula* females landed more often on the UNPAR treatment than on the PAR treatment (Figure 1c; $P = 0.045$).

C. glomerata wasps did not discriminate between artificially damaged cabbage leaves treated with regurgitant collected from either unparasitized or parasitized *P. rapae* larvae (Figure 2a). However, in tests using leaves treated with regurgitant of *P. brassicae* larvae, *C. glomerata* females showed a clear preference for landing on leaves treated with regurgitant of unparasitized larvae

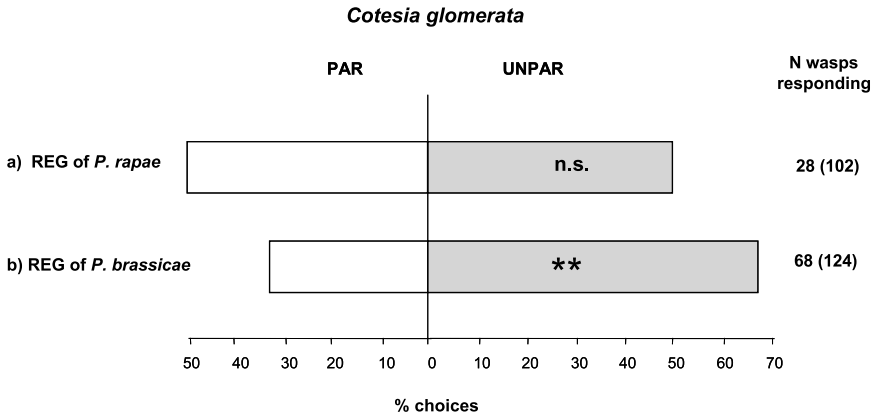

FIG. 2. Response of *C. glomerata* to artificially damaged cabbage leaves treated with regurgitant (REG) from parasitized (PAR) or unparasitized (UNPAR) *Pieris* spp. caterpillars of (a) 4th instar *P. rapae* larvae and (b) fifth instar *P. brassicae* larvae, and in a two-choice set-up. Asterisks indicate significant differences within a choice test: $^{**}P < 0.01$, n.s. not significant (binomial test). The numbers show the number of wasps responding; the numbers in brackets show the total number of wasps tested. All wasps were released on a leaf damaged by first instar larvae either of UNPAR (a) *P. brassicae* or (b) *P. rapae*.

(Figure 2b; $P = 0.002$). Additionally, the wasps' responsiveness was higher in the tests with leaves treated with *P. brassicae* regurgitant than in tests with regurgitant of *P. rapae* larvae ($P < 0.001$, $\chi^2 = 17.2$; $df = 1$).

Headspace Analysis. We focused our headspace analysis on those compounds that elicited electrophysiological responses from antennal olfactory receptors of the two *Cotesia* species (Smid et al., 2002). The plants treated with regurgitant of parasitized or unparasitized *P. brassicae* larvae emitted a volatile blend that consisted of green leaf volatiles, aldehydes, alcohols and esters, terpenes, and methyl salicylate. Averaged over nine replications, 19 out of the 22 compounds were emitted in larger amounts in the UNPAR treatment than in the PAR treatment ($P < 0.001$, sign test). In addition, higher amounts of the major terpenoids limonene ($P = 0.05$), α-thujene ($P = 0.04$), and 1,8-cineole ($P = 0.01$; two-sided Wilcoxon's matched pair signed rank test) were released in the UNPAR treatment (Figure 3). Thus, the quantitative profile of the emitted volatiles changes, and three volatiles are emitted in significantly lower amounts when cabbage plants are induced by regurgitant of parasitized *P. brassicae* compared to cabbage plants induced by regurgitant of unparasitized *P. brassicae*.

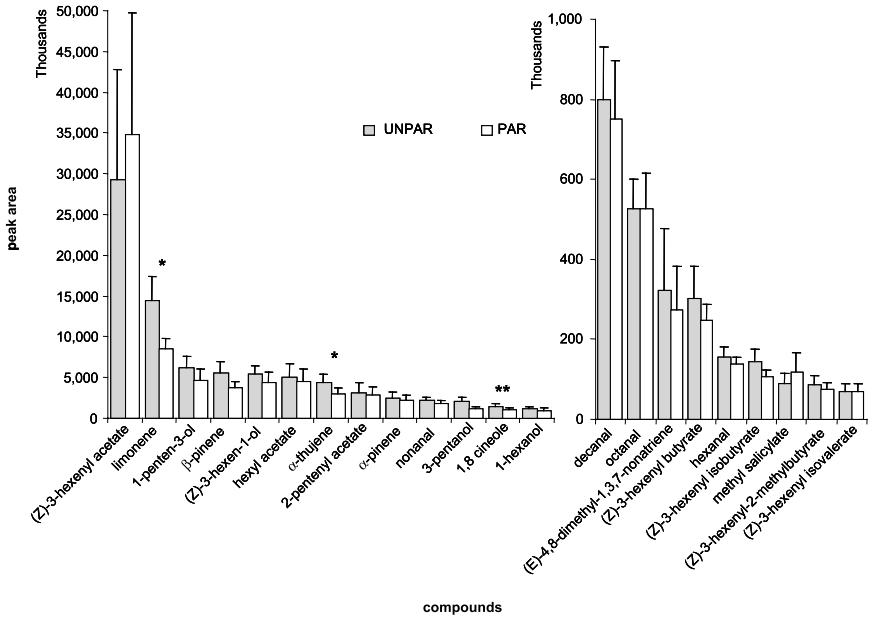

FIG. 3. Comparison of the volatile blends emitted by cabbage plants artificially damaged and treated with regurgitant of unparasitized (UNPAR) or parasitized (PAR) caterpillars of *P. brassicae* for 22 compounds expressed as mean peak area (in arbitrary units) and the standard error. For each compound, the mean of nine peak areas of the UNPAR treatments and nine peak areas of the PAR treatments are shown. Asterisks indicate significant differences: $*P < 0.05$, $**P < 0.01$ (Wilcoxon's matched pairs signed rank test).

DISCUSSION

The results show that *C. rubecula* females without oviposition experience discriminated suitable hosts, i.e., hosts that were not parasitized, from parasitized hosts in flight by using host-induced plant volatiles. Females of *C. glomerata* discriminated between host-induced plant volatiles induced by unparasitized and parasitized larvae in the case of their preferred host *P. brassicae*. As a result, the wasps save time compared to wasps that first have to land and explore a patch to detect nonvolatile marking substances left by previous parasitoid visitors. Additionally, *C. glomerata* females reduce the risk of being bitten or coming in contact with the regurgitant of *P. brassicae* caterpillars. *P. brassicae* caterpillars, unlike *P. rapae* caterpillars, vigilantly defend themselves and can seriously harm their parasitoids (Brodeur et al., 1996).

Especially for a solitary endoparasitoid such as *C. rubecula*, host discrimination is crucial because supernumerary larvae compete to the extent that only a single parasitoid can emerge (Salt, 1961). The older larva usually eliminates the younger. The extent of the disadvantage depends critically on the time that elapses between the two ovipositions. Thus, in cases with a limited number of hosts present, parasitoids should be more apt to attack recently parasitized hosts in which their larvae have a higher probability to survive. Internal markers released by the egg or physiological changes in the host caused by parasitism become more noticeable with time (van Lenteren, 1976; Godfray, 1994 and references therein).

In gregarious parasitoids such as *C. glomerata*, scramble competition may occur, i.e., no aggressive behavior toward other parasitoid larvae or physiological suppression occurs, and the parasitoids develop as long as food is available. Superparasitism can be an adaptive strategy under some conditions, such as when wasps are faced with a limited number of hosts for a longer period. However, an increase in clutch size is often associated with a decrease in size of surviving offspring and a reduced fitness of the emerging adults (e.g., Harvey et al., 1993; Potting et al., 1997).

Naive females of *C. glomerata* discriminate between parasitized and unparasitized hosts in close-range tests (Ikawa and Suzuki, 1982; Le Masurier, 1990). Experienced *C. glomerata* wasps regulate the number of eggs laid in response to the number of available suitable hosts (Ikawa and Suzuki, 1982). We used females experienced with a particular plant–host complex (as described before) to assess whether they discriminated in flight. Therefore, it remains unclear if the response was innate or triggered by the short odor experience just prior to the release in the wind tunnel. Other studies have shown that a single experience with a plant–host complex has no influence on the behavior of either *C. glomerata* or *C. rubecula* toward the offered plant–host complexes in the wind tunnel (Geervliet et al., 1998). However, in our case, the brief experience resulted in a higher response of *C. glomerata* that flew to one of the odor sources in tests with plants treated with regurgitant of *P. brassicae.*

When we offered leaves induced with regurgitant of *P. rapae*, a high proportion of females of our Dutch strain of *C. glomerata* were unresponsive, and those that did fly toward the plants did not discriminate. In the Netherlands, *C. glomerata* specializes on *P. brassicae*, which has been ascribed to the fact that *C. rubecula* outcompetes *C. glomerata* in *P. rapae* larvae (Geervliet et al., 2000). The solitary endoparasitoid *C. rubecula* always wins the competition for the same host against the gregarious *C. glomerata* (Laing and Corrigan, 1987). Our results suggest that the priming of *C. glomerata* wasps with leaf damage of first instar *P. rapae* caterpillars that we practiced just prior to the bioassay induced a low response and a failure to discriminate between plants treated with regurgitant of unparasitized or parasitized *P. rapae* larvae.

To the best of our knowledge, this is the first report in which elicitation of herbivore-induced plant volatile production, by controlling the amount of mechanical leaf damage combined with the application of regurgitant, has been shown to result in a reduced emission of specific plant volatiles when elicitors originate from parasitized caterpillars. Souissi et al. (1998) reported that unparasitized mealybug-infested plants or unparasitized mealybugs are more attractive to walking *Apoanagyrus lopezi* (Hymenoptera: Encyrtidae) endoparasitoids than plants infested with parasitized mealybugs or parasitized mealybugs alone. The amount of herbivore feeding was not controlled in their study, and it was not checked whether the plant was the source of the attractants. Sheehan et al. (1993) showed that females of *Microplitis croceipes* (Hymenoptera: Braconidae) were able to discriminate in flight between previously visited and unvisited sites in a plant patch, even in the absence of the host. In this case, herbivore-induced plant volatiles were not tested, and it was assumed that a chemical marking deposited on the substrate served as the cue for discrimination.

Presently, it is still unknown for any parasitoid species exactly which compounds are involved as synomones (Dicke and van Loon, 2000). Previous work on volatiles emitted by a different Brussels sprouts cultivar (Blaakmeer et al., 1994) showed differences between intact and caterpillar-damaged plants for hexyl acetate, (*Z*)-3-hexenyl acetate, sabinene, and 1,8-cineole. These compounds were also increased in the headspace of plants treated with regurgitant of unparasitized *P. brassicae* caterpillars compared to treatments with regurgitant of parasitized *P. brassicae* caterpillars. The headspace composition documented here also overlaps with that described by Smid et al. (2002), who studied yet another Brussels sprouts cultivar and used feeding first instar caterpillars during headspace collection. An obvious difference is that benzyl cyanide, a breakdown product of glucosinolates (the taxonomically characteristic secondary plant metabolites of Brassicaceous plants), is lacking in our samples. It was recently established (Wittstock et al., 2004) that this compound is released from the feces of *Pieris* caterpillars, which explains its absence from our samples. Limonene elicits an olfactory response in the antennae of both *Cotesia* species (Smid et al., 2002). The fact that the reduced emission of three volatiles correlated with discriminatory behavior that were shown to elicit electrophysiological activity suggests that the quantity of these compounds, possibly relative to those of other compounds, provides information to the parasitoids. We used leaves that were detached just prior to the experiments. For maize, it has been shown that excision of leaves may influence the emission rate of certain components in some treatments at some periods of the day, without affecting the overall effect of treatment (Schmelz et al., 2001). In our experiments, the treatments were maximally standardized with regard to leaf physiological age and size, and leaves from both treatments were excised to investigate locally emitted volatiles only.

Studies on the interrelationship of *Cotesia* larvae with their hosts show drastic effects of parasitism on the caterpillars' physiology such as changes in hemolymph protein titer and composition (reviewed by Beckage, 1993). Application of β-glucosidase, a component of *P. brassicae* regurgitant, to artificially damaged plants resulted in the release of a volatile blend similar to that of leaves treated with regurgitant (Mattiacci et al., 1995). Quantitative differences in headspace composition resulting from treating plants with regurgitant obtained from either parasitized or unparasitized caterpillars might be attributable to a reduced amount of β-glucosidase in regurgitant of parasitized *P. brassicae*.

Parasitization of *P. rapae* by *C. rubecula* has been shown to increase fitness of the brassicaceous plant *Arabidopsis thaliana* (van Loon et al., 2000). In the case of *C. glomerata*, which preferentially parasitizes the gregariously feeding *P. brassicae*, only a suppression of specific synomones, as documented here, would benefit the wasp, because for this parasitoid–host combination an overall reduction in the amount of volatiles released could signal a lower but still sufficient number of available unparasitized hosts rather than parasitized hosts. As we controlled the amount of mechanical damage and the volume of elicitor-containing regurgitant, we can exclude the involvement of other stress factors, such as viral, bacterial, or fungal pathogens, that might have interfered with the feeding performance of the caterpillars and consequently with induced synomone emission by the plants.

The induced volatiles bear biosynthetic and ecological costs (Dicke and Sabelis, 1989; Dicke and van Loon, 2000; Hoballah et al., 2004). Many of the compounds are produced through *de novo* biosynthesis (Paré and Tumlinson, 1997). Ecological costs in terms of attraction of herbivores can be much higher than the biosynthetic costs (Dicke and Vet, 1999). Thus, downregulation of induced volatile production is likely to be advantageous for plants.

In summary, we have shown that parasitoids can use herbivore-induced plant volatiles for host discrimination in flight, a crucial ability to enhance their reproductive success. Besides the fact that plant synomones are reliable and detectable indicators of the presence and identity of herbivores, we document that parasitoids can use them as a source of information on host suitability. Consequently, parasitoids can save energy and time in finding suitable hosts. From the plant's perspective, our study has uncovered an advantage through a reduced production of a subset of herbivore-induced volatiles, after having successfully recruited their bodyguards.

Acknowledgments—The authors thank Joachim Ruther, Joop van Lenteren, and Monika Hilker for advice and comments on an earlier version of this manuscript; Leo Koopman, Frans van Aggelen, and André Gidding for culturing the insects. Funding by the Bresillac Foundation is gratefully acknowledged. All experiments complied with the current laws of The Netherlands.

(Received September 28, 2004; revised April 26, 2005; accepted May 7, 2005)

Abstract—To identify simple screening tools for selecting condensed tannin (CT)-containing forages as candidate sources for further study, CT were isolated from nine legumes, and their molecular weights (MW), chromophore production, capacity to precipitate bovine serum albumin (BSA) and Fraction 1 protein (Rubisco) isolated from alfalfa, and inhibition of filter paper digestion were compared. Sources were as follows: leaves of sericea lespedeza (*Lespedeza cuneata* Dum.-Cours.), crown vetch (*Coronilla varia* L.), and sainfoin (*Onobrychis viciifolia* Scop.); stems of hedysarum (*Hedysarum alpinum* L.); seeds of alfalfa (*Medicago sativa* L.); and whole plants of birdsfoot trefoil (*Lotus corniculatus* var. *corniculatus* L.) and three varieties of big trefoil (*Lotus pedunculatus* Cav.), viz., *Lotus uliginosus* Schkuhr, *L. uliginosus* var. *glabriusculus*, and *L. uliginosus* var. *villosus*. Molecular weights and sizes (degrees of polymerization) of the CT varied considerably within and among plant species. Average MW ranged from 3036 Da (crown vetch) to 7143 Da (lespedeza). All CT exhibited greater capacity (w/w basis) to bind alfalfa Rubisco than BSA. Relative astringencies (μg CT required to precipitate 1 mg protein) against BSA ranged from 262.5 for CT from lespedeza to 435.5 for CT from *L. corniculatus*, and against Rubisco,

* To whom correspondence should be addressed. E-mail: mcallister@agr.gc.ca

from 49.6 (sainfoin) to 108.2 (alfalfa seed). Including CT at 300 μg/ml in cultures of *Fibrobacter succinogenes* reduced digestion of cellulose filter paper by 19.8% (sainfoin) to 92.4% (crown vetch) and increased the specific activity of cell-associated endoglucanase. There were no correlations between inhibitory effects of CT on filter paper digestion and (1) chromophore formation during CT assay by butanol–HCl, vanillin–HCl, or H_2SO_4; (2) precipitation of BSA or alfalfa Rubisco; and (3) MW of CT. The most inhibitory CT for cellulose digestion included those with broad and with narrow MW distributions. Sainfoin was the most desirable source of CT, as it had the highest capacity to bind alfalfa protein and was least inhibitory to cellulose digestion by *F. succinogenes*. This study suggests that these properties are not easily defined via chemical means, and that biological assays using rumen bacteria may help identify those CT with properties of nutritional interest.

Key Words—Condensed tannins, endoglucanase activity, cellulose digestion, legume, ruminant nutrition, *Fibrobacter succinogenes*, ribulose 1,5-bisphosphate carboxylase, Rubisco.

INTRODUCTION

Condensed tannins (CT) in forages are considered antinutritive factors for ruminants, owing to their capacity for binding to macromolecules such as fiber and proteins. At concentrations exceeding 6% of dietary dry matter (DM), CT depress feed intake, reduce the digestibilities of fiber and protein, and decrease the growth rate of ruminant livestock (Leinmuller et al., 1991). Although formation of CT–plant protein complexes occurs at CT concentrations <4% of dietary DM, feed intake is seldom affected (Barry et al., 1986). More recently, forages containing CT have been studied as potentially beneficial agents in ruminant nutrition (Waghorn, 1990; Butter et al., 1999). The reversible and pH-dependent nature of tannin–protein interactions (Perez-Maldonado et al., 1995) enhances the resistance of CT-bound protein to microbial degradation in the rumen, yet it enables dissociation of the complexes in the abomasum, thereby increasing the proportion of plant protein arriving at the small intestine (Barry and Manley, 1984; Mangan, 1988). Moreover, CT act in the rumen to prevent formation of the stable froth (Tanner et al., 1995) that is a prerequisite for development of pasture bloat. Bloat in cattle grazing alfalfa can be prevented by providing CT at 1.7% of dietary DM (Waghorn and Jones, 1989).

The effects of CT on nutrient utilization by ruminants are apparently dependent on the tannin type. For example, the growth rates of sheep fed with *Acacia cyanophylla* or *A. sieberiana* were less than half of those exhibited by sheep consuming *A. seyal*, although the CT concentrations were similar in all three forages (Reed and Soller, 1987). Presumably, these disparate effects arise from variations in the number of reactive phenolic groups present in CT and the

consequent variability in their capacity to bind carbohydrates and proteins (Asquith and Butler, 1986; Hagerman, 1992).

These observations of positive effects of CT on digestion in ruminants have led researchers to propose that pathways for their synthesis be genetically engineered into legume species prone to provoking bloat (Waghorn, 1990; Morris and Robbins, 1997). Before such projects are undertaken, however, it is imperative to identify the properties of CT responsible for these favorable changes in ruminal metabolism. The present study was conducted to isolate and analyze the CT from nine legumes with the objective of determining if correlations exist among their molecular weights, their capacities to precipitate protein, and their inhibitory effects on fiber digestion by the major cellulolytic ruminal bacterium, *Fibrobacter succinogenes*. It was hypothesized that fiber digestion by *F. succinogenes* may serve as a simple bioassay against which to assess the relative inhibitory effects of various sources of CT.

METHODS AND MATERIALS

Sources and Isolation of Condensed Tannins. Condensed tannins were isolated from whole plants of a high tannin cultivar of birdsfoot trefoil, *Lotus corniculatus*, and three varieties of big trefoil, *L. uliginosus*, *L. uliginosus* var. *glabriusculus*, and *L. uliginosus* var. *villosus*; from the leaves of high-tannin sericea lespedeza, *Lespedeza cuneata*, crown vetch, *Coronilla varia*, and sainfoin, *Onobrychis viciifolia*; from the stems of hedysarum, *Hedysarum alpinum*; and from the seeds of alfalfa, *Medicago sativa*. Vegetative plant material was harvested from experimental plots at the Agriculture and Agri-Food Canada Research Centre in Saskatoon, SK, Canada, and alfalfa seed was obtained from a commercial seed producer (Pickseed Canada Inc., Lindsay, ON, Canada).

Condensed tannins were extracted from plant material with aqueous acetone/petroleum ether/ethyl acetate as described by Bae et al. (1993b) and eluted from a 15 × 4 cm i.d. glass column packed with Sephadex LH-20 (Sigma Chemical Co., St. Louis, MO, USA), which excluded low-molecular-weight, non-CT polyphenols from the isolated material. The CT were eluted with 70% aqueous acetone, evaporated to the aqueous phase, lyophilized, and stored at 4°C in a dessicator held in the dark.

Determination of Molecular Weights of Condensed Tannins. Molecular weights of the extracted CT were determined by gel permeation chromatography (GPC) conducted on their peracetate derivatives. The peracetate derivatives were prepared by dissolving the CT in dry pyridine/acetic anhydride (1:1) and recovering the peracetates by filtration after dilution with water as described by Williams et al. (1983). An Ultrastyragel linear (7.8 × 300 mm) and a 10^3-Å

column (Waters, Milford, MA, USA) connected in series were used for GPC, with tetrahydrofuran at 1.1 ml/min (25°C) as the solvent. Relative molecular weights (M_r) were calculated after calibration with polystyrene M_r standards (M_r 687, 2000, 4136, 9000, and 32,660) and phloroglucinol (M_r = 252) and catechin peracetates (M_r = 500, 1000, and 1500 for the monomer, dimer, and trimer, respectively). The degrees of polymerization (DP) of the extracted CT were estimated on the basis of a constituent PA peracetate unit MW of approximately 500 (Williams et al., 1983).

Chromophore Production During Condensed Tannin Assays. The CT isolated from the nine plant sources were assayed in triplicate using four methods: butanol–HCl, vanillin–HCl, Prussian blue, and H_2SO_4 (Bae et al., 1993a). In each case, equal weights of CT were reacted, and results were expressed as a percentage of the value obtained for the sainfoin standard. Subsequently, the H_2SO_4 assay (Bae et al., 1993a) was used to generate calibration curves for each of the nine CT to enable comparison of chromophore production. Briefly, 2 ml of concentrated H_2SO_4 was added to triplicate 0.1-ml aliquots of aqueous stock solutions of each CT (containing 0–20 μg tannin), and absorbance at 580 nm was recorded after 1 hr of incubation at room temperature.

Isolation and Purification of Alfalfa Protein. Soluble forage protein was isolated and purified from leaves of alfalfa, *M. sativa*, by a method based on the procedure outlined by Jones and Mangan (1976). All steps of protein purification were carried out at 4°C to minimize proteolysis. The top 15 cm of herbage was cut from prebloom alfalfa in the afternoon, bagged, and allowed to wilt overnight (to improve protein yield; Mangan, personal communication). The next morning, leaves were stripped from the stems, and 100-g lots were each combined with 10 ml of extraction buffer prepared at 10-fold concentration (0.01 M sodium diethyldithiocarbamate, 0.01 M β-mercaptoethanol, and 10 g/l sodium ascorbate in 0.5 M phosphate buffer, pH 7.4), and the mixture was processed without heating using a commercial centrifugal juice extractor. The juice (plant extract) was combined with 300 ml of single strength extraction buffer (EB; 0.001 M sodium diethyldithiocarbamate, 0.001 M β-mercaptoethanol, and 1 g/l sodium ascorbate in 0.05 M phosphate buffer, pH 7.4). The residues were resuspended in 500 ml of EB, squeezed gently through two layers of Nitex HC3 cloth (53-μm pore size), and the expressed liquid was added to the plant extract.

Soluble protein in the extract was precipitated using 360 g/l $(NH_4)_2SO_4$ (pH 6.2) and collected by centrifugation (500 × *g*, 10 min, 5°C). Precipitated protein was redissolved in EB and purified by gel filtration on two columns of Sephadex G-75 (26 mm × 70 cm; 50 mm × 60 cm; GE Healthcare, formerly Amersham Biosciences, Baie d'Urfe, QC, Canada) and precipitated once again with $(NH_4)_2SO_4$ as described above. The centrifugal pellet was dissolved in EB

and dialyzed (12–14 kDa cutoff) three times in 40 hr against 0.1 g/l sodium azide in distilled water, then twice against distilled water for a further 7 hr to remove residual sodium azide. The tubes were frozen at −40°C, lyophilized, and dried protein was stored in a dessicator at 4°C.

Characterization of Purified Fraction 1 Protein. The UV absorbances of a microfiltered (0.2-μm cellulose acetate filter, Nalgene, Rochester, NY, USA) solution of 2 mg of lyophilized material in 5 ml of 0.05 M phosphate buffer (pH 7.4) were measured at 260 and 280 nm, and protein concentration (mg/ml) was calculated as $1.45A_{280} - 0.74A_{260}$ (Daniels et al., 1994). Soluble protein content of the Fraction 1 material was also determined by the Bradford (1976) microassay using BSA as the standard protein. Purified protein (in a 2-mg/ml solution) was further characterized by SDS-PAGE (Laemmli, 1970) conducted on a Mini-Protean II electrophoresis cell (BioRad Laboratories, Richmond, CA, USA) with 40 g/l acrylamide stacking gels and 120 g/l acrylamide separating gels. Molecular weight standards (10–100 kDa) and ribulose 1,5-bisphosphate carboxylase (Rubisco) EC 4.1.1.39 (Sigma Chemical Co.) were included in each gel.

Precipitation of Proteins by Condensed Tannins. The protein-precipitating capacities of CT from the nine forages were determined using a modification of the method of Martin and Martin (1982). Bovine serum albumin (BSA) and Rubisco from alfalfa were used as model proteins for determining the relative capacities of the extracted CT to bind protein. The BSA was dissolved (2 mg/ml) in 0.2 M acetate buffer (pH 5.0) containing 0.17 M NaCl, and the purified Rubisco was dissolved (2 mg/ml) in 0.1 M 2-[*N*-morpholino]-ethanesulfonic acid (pH 6.1) containing 0.17 M NaCl. One milliliter of either solution was combined with 0.5 ml of aqueous solutions containing 0, 100, 200, 300, 400, or 500 μg of CT from each source, for determinations with BSA, and 0, 20, 40, 60, 80, or 100 μg for determinations with alfalfa Rubisco. Each mixture was vortexed, allowed to stand at room temperature for 30 min, then centrifuged (15,600 × *g*, 5 min). The CT remaining in a 0.5-ml subsample of supernatant were removed by precipitation, accomplished by adding 0.5 ml of 10 mg/ml (aqueous) polyethylene glycol 6000 (Jones and Mangan, 1977). Protein remaining in solution was quantified colorimetrically using a commercial protein assay kit based on the Bradford (1976) assay (BioRad Laboratories, Mississauga, ON, Canada) against a freshly prepared solution of BSA or Fraction 1 protein as a standard. The assay was replicated six times for each dose of CT from each of the nine plant sources.

Effects of Condensed Tannins on Cellulose Digestion. The nine CT were each assessed for their effects on the cellulose-digesting activity of the ruminal bacterium, *F. succinogenes* subsp. *succinogenes* S85 (obtained from the Lethbridge Research Centre culture collection). The bacterium was grown in 10-ml volumes of the liquid medium of Scott and Dehority (1965), modified

by omitting the casein hydrolysate and soluble carbohydrates and adding autoclaved, clarified ruminal fluid (100 ml/l). A 1-cm^2 piece of Whatman No. 1 cellulose filter paper (8.8 ± 0.5 mg) was included in each tube as the sole source of carbohydrate during culture maintenance. Cultures were incubated at 39°C and transferred at 3-d intervals for 15 d prior to experimentation with CT. The anaerobic technique of Hungate (1950), as modified by Bryant and Burkey (1953), was used throughout the experiment.

For assay of the effects of the CT on the cellulose-digesting activity of *F. succinogenes*, each CT was dissolved in anaerobic salt solution (Bryant and Burkey, 1953) and filter sterilized, also under anaerobic conditions. Cells of *F. succinogenes* in 72-hr cultures were harvested by centrifugation (10,000 × *g*; 20 min; 4°C), and the pellets were resuspended in 1 ml of fresh medium. Triplicate tubes containing a preweighed piece of Whatman No. 1 filter paper (approximately 25 mg) in 4 ml of medium were inoculated with 0.1 ml of bacterial suspension and CT solution to yield 0 (control) or 300 μg tannin/ml and incubated at 39°C.

After 3 d of incubation, filter paper residues in the cultures were collected by vacuum filtration onto preweighed Whatman No. 54 filters. Culture filtrates were kept on ice, whereas residues were washed three times with 1 ml of 0.05 M sodium phosphate buffer (PB) at pH 6.5 and once with 1 ml of methanol (washings were discarded). Filter paper residues were dried at 80°C for 24 hr, and then weighed for estimation of extent of digestion (as mg digested/g incubated).

Collected filtrates (1 ml) were centrifuged (15,600 × *g*; 5 min; 4°C) to segregate cell-associated (pellet) and cell-free (supernatant) fractions. Supernatants were kept on ice. Pelleted cells were washed twice by resuspension in 1 ml of PB followed by centrifugation, then were suspended in PB at 4°C and disrupted by 30 sec of pulsed sonication with a Sonic 300 Dismembrator (Artek Systems Corporation, Farmingdale, NY, USA) set at 60% output. Crude cell extract was obtained by centrifuging the disrupted bacteria to remove cell debris.

Cellulase activity in the extracellular fluids and crude cell extracts was determined using the soluble chromogenic substrate ostazin brilliant red (OBR)–hydroxyethylcellulose (Biely et al., 1985) as described by McAllister et al. (1994). Endoglucanase activity was expressed against a commercial cellulase from *Penicillium funiculosum* (EC 3.2.1.4, Sigma Chemical Co.), with one unit of activity defined as the absorbance given by one unit of commercial cellulase per hour. Protein in a crude cell extract was also determined by the method of Bradford (1976) and used for calculation of specific activity of endoglucanase (cellulase).

Statistical Analyses. Data from the protein precipitation titration curves were analyzed using a nonlinear regression procedure (SAS, 1989). Specifically, the curves for each CT were fitted to the Weibull cumulative function for

sigmoid curves: $Y = \mathrm{P1} + \mathrm{P2}\left(1 - e^{-(X/\mathrm{P3})^{\mathrm{P4}}}\right)$ where Y = μg of protein (BSA or Fraction 1) precipitated, X = μg of extracted CT incubated, P1 = lower asymptote (set to 0), P2 = upper asymptote (μg of protein), P3 determines the range of values of X over which the sigmoid curve occurs (1/μg CT), and P4 is the distortion of the curve (Régnière and Beilhartz, 1987). The protein-precipitating capacity of each of the CT was expressed as the amount (μg) of the CT required to precipitate 1 mg of BSA or Fraction 1 protein. Least squares means of the capacities (N = 6) were compared using the PDIFF option of the GLM procedure of SAS (1989). Simple correlations among CT characteristics [mean MW, chromophore production, inhibition of cellulolytic activities (cell-associated and extracellular endoglucanase, and digestion of filter paper by *F. succinogenes*), and protein-precipitating capacities against BSA and Rubisco] were determined.

RESULTS AND DISCUSSION

Condensed Tannin Molecular Weights and Chromophore Production. Molecular weights and degrees of polymerization of the CT from nine sources varied considerably among and within the plants tested (Table 1). On average, CT from *C. varia* (crown vetch) were smallest (M_r = 3036), and those from *L. cuneata* (lespedeza) were largest (M_r = 7143). This inherent variability in CT even within an individual plant sample adds to the difficulty in attributing specific properties to a given polymer source. Other workers have reported MW of CT extracted from leaves (Foo et al., 1982, 1996; Koupai-Abyazani et al., 1993) or whole plants (Jones et al., 1976) from some of the legume species that were examined in leaves or whole plant extracts in the present study (Table 2). Our M_r values for *C. varia* were close to those previously reported, but our estimates of M_r for *Lotus* spp. and *O. viciifolia* were notably higher than those previously reported using GPC. Hedqvist et al. (2000) reported that there was substantial variation in the quantities of high molecular weight tannins in varieties of *L. corniculatus*, and it is possible that such variation in CT in other legume species may contribute to the higher values reported in our study. It is also possible that M_r varies with the portion of the plant from which the CT are isolated or the maturity of the plant at time of harvest.

Similar to MW determinations, variations in chromophore yield among the CT, as determined by butanol–HCl, vanillin–HCl, and H_2SO_4 methods, were also observed (Table 3). The colorimetric assays were each standardized against the production of chromophore by *O. viciifolia* CT. The consistency of ranking of chromophore yield of the sources of CT relative to *O. viciifolia* in the three assays was dependent on the source of CT. For example, *C. varia* exhibited the same rank regardless of the assay employed, whereas the

	Ultracentrifuge	Whole plant	17.0–28.1[b]	Jones et al. (1976)

[a] GPC: Gel permeation chromatography; NMR: nuclear magnetic resonance spectroscopy; HPLC: high-pressure liquid chromatography; Ultracentrifuge: ultracentrifugation technique.
[b] Analysis by ultracentrifugation yields measurement of M_z, which is proposed by Foo et al. (1982) to represent approximately three times M_n which is established by the other techniques, e.g., for *L. pedunculatus*, a MW of approximately 2.3 kDa is implied.

TABLE 3. CHROMOPHORE YIELD FROM ISOLATED CONDENSED TANNINS (CT) FROM THREE METHODS OF ANALYSIS

	Method of analysis					
	Butanol–HCl		Vanillin–HCl		H_2SO_4	
Condensed tannin source	Yield[a]	Rank	Yield	Rank	Yield	Rank
O. viciifolia	100	–	100	–	100	–
C. varia	99.1	2	103.9	2	137.5	2
H. alpinum	80.4	8	72.5	5	74.4	7
L. cuneata	101.1	1	77.4	3	84.4	6
L. corniculatus	81.0	6	69.5	7	85.3	5
L. uliginosus	93.2	3	71.7	6	126.5	3
L. uliginosus var. *glabriusculus*	90.6	4	64.3	8	89.0	4
L. uliginosus var. *villosus*	81.0	6	74.4	4	74.2	8
M. sativa	88.7	5	105.4	1	161.7	1

[a] Expressed as a percentage of the yield given by sainfoin, *O. viciifolia*. Equal weights of isolated polymer were reacted in each case. Mean values are presented ($N = 3$).

chromophore yield of *M. sativa* ranked first relative to *O. viciifolia* for the vanillin–HCl and H_2SO_4 assays but fifth in the butanol–HCl procedure. Differences in chromophore yield are a reflection of differences in CT structural properties and the specificity of the chemical reactions that result in the formation of the chromophore in each of the colorimetric procedures employed (Hagerman and Butler, 1989). None of the colorimetric procedures exhibited a strong correlation with the degree to which CT inhibited filter paper digestion by *F. succinogenes* (see below).

Characterization of Fraction 1 Protein (Rubisco). Yield of Fraction 1 protein from alfalfa was approximately 6.7 g/kg wilted weight of herbage. The protein content of a 0.4-mg/ml solution of purified Fraction 1 protein, as determined by UV absorption, ranged from 0.38 to 0.51 mg/ml (mean 0.44 mg/ml) for the five lots of purified Fraction 1 protein. The soluble protein content of the five lots ranged from 649 to 823 mg/g protein (mean 742 mg/g protein), as assayed by the Bradford (1976) method against a BSA standard. Characterization of the Fraction 1 protein by SDS-PAGE revealed two predominant bands, with MW of 55 and 16 kDa. These two bands match the subunits of ribulose-1,5-bisphosphate carboxylase (Rubisco; EC 4.1.1.39).

Whereas Rubisco is the most abundant protein in the world and constitutes the predominant protein in animal forage diets (Mangan, 1982), BSA is likely the most frequently used model protein in tannin–protein assays. Bovine serum albumin is a globular protein tightly cross-linked with disulfide bridges that confer a relatively higher resistance to proteolysis by ruminal microorganisms, compared to casein and Fraction 1 leaf protein (Nugent et al., 1983). In contrast,

Rubisco consists of 16 subunits of two sizes held together by hydrogen bonds, and the subunits possess linear structures lacking disulfide bridges. The isoelectric points of BSA and Rubisco from white clover are pH 4.9 and 5.5, respectively (Perez-Maldonado et al., 1995). Condensed tannins, in general, bind preferentially to hydrophobic and/or proline-rich regions of protein molecules (Hagerman and Butler, 1981) by noncovalent interactions, primarily hydrogen bonds and hydrophobic interactions. Thus, the primary and tertiary structures and isoelectric point will each affect a protein's solubility and tendency to bind with CT.

Precipitation of Proteins by Condensed Tannins. The CT studied in this experiment exhibited greater capacity to bind Rubisco than BSA, on a weight-to-weight basis (Table 4). This is consistent with a report by Martin and Martin (1983), in which tannic acid (a hydrolyzable tannin), quebracho tannin, and oak tannin all precipitated commercially prepared Rubisco to a greater extent than BSA. In that study, 203, 521, and 2801 mg of tannic acid, quebracho CT, and pin oak CT, respectively, were required to precipitate 1 g of BSA (at pH 4.1), compared with 48, 250, and 498 mg for Fraction 1 protein (at pH 6.1). Comparable values were recorded in the present experiment (Table 4) in which protein-precipitating capacities were assayed at pH of approximately 4.9 for BSA and pH 6.1 for Rubisco. In our study, relative protein-precipitating capacities (μg CT per mg protein) against BSA ranged from 262.5 for CT from lespedeza to 435.5 for CT from *L. corniculatus*, and against Rubisco from 49.6 (sainfoin) to 108.2 (alfalfa seed). Thus, both studies illustrate the variation in protein-precipitating capacities among tannins from different sources. The nine CT examined in the present study also differed in the ranking of their protein-precipitating capacities between the two model proteins, indicating that the propensity of a CT and a protein to bind depends on chemical and physical properties of both the target protein and the source of CT.

The number of potential hydrogen bonding sites on both the protein and the CT molecules will determine the extent of their capacity to bind one another. This is in turn influenced by the pH and presence of ions in the solvent in which they are suspended (Perez-Maldonado et al., 1995). The number of potential hydrogen bonding sites on a given molecule of CT is a function of the number and type of monomeric subunits (e.g., flavan-3-ols, flavan-4-ols, or flavan-3,4-diols), their stereochemistry, and the carbon–carbon linkages between them that create linear and/or branching polymers. For example, *L. corniculatus* CT consist of relatively homogeneous polymers of epicatechin-type procyanidin units, whereas *L. pedunculatus* CT contain a more heterogeneous mix of catechin and epicatechin-type prodelphinidin monomers (McNabb et al., 1998). This diversity in chemical structure of CT is a major factor in the differences in binding capacities and nutritional effects among CT from different plant sources.

TABLE 4. PROTEIN-PRECIPITATING CAPACITIES[a] AND WEIBULL CUMULATIVE FUNCTION PARAMETERS (P)[b] OF NINE CONDENSED TANNINS INCUBATED FOR 30 MIN WITH BOVINE SERUM ALBUMIN OR ALFALFA RUBISCO AS MODEL PROTEINS

	Bovine serum albumin						Rubisco

a–f: For each protein (BSA or Rubisco), mean PPC followed by different letters differ significantly ($P < 0.05$).

[a] Expressed as μg CT required to precipitate 1 mg of protein ($N = 6$). PPC: Protein-precipitating capacity.

[b] Data were fitted to the equation: $Y = \mathrm{P1} + \mathrm{P2}(1 - e^{-(X/\mathrm{P3})^{\mathrm{P4}}})$, where Y = μg of protein (BSA or Fraction 1) precipitated; X = μg CT; P1 = lower asymptote (P1 = 0); P2 = upper asymptote (μg of protein); P3 determines the range of values of X over which the sigmoid curve occurs (1/μg CT); and P4 is the distortion of the curve (from Régnierè and Beilhartz, 1987).

Aerts et al. (1999) found significant differences between CT from *L. corniculatus* and from *L. pedunculatus* in their prevention of ruminal hydrolysis of white clover leaf protein, although only minor differences existed in the molecular weights of the CT from the two plant species. However, Osborne and McNeill (2001) concluded that, in general, high MW CT from *Leucaena* spp. precipitate more protein than do the low MW CT. Previous and current observations illustrate clearly that the capacity of CT to bind proteins cannot be predicted solely on the basis of MW.

Bovine serum albumin has been widely used as model protein in tannin–protein precipitation assays. In the present study, however, CT from all nine sources precipitated more Rubisco than BSA (by a ratio of approximately 4.6:1, on average). This may be related to the formation of soluble tannin–BSA complexes (Martin and Martin, 1983; Hagerman, 1992; Haslam, 1998), which could potentially limit the efficacy of BSA precipitation as a model for estimating the propensity of a CT to bind protein. Rubisco is a more logical choice as a model protein, as it is the principal protein in fresh forage and will be a primary focus in the event that genes coding for CT are introduced into legumes as a means of increasing bypass protein and/or preventing pasture bloat (McMahon et al., 2000).

Effects of Condensed Tannins on Cellulose Digestion. Control cultures of *F. succinogenes* (i.e., those containing no CT) digested 514 mg/g of filter paper included as substrate during 3 d of incubation (Table 5). Inhibition of digestion by the nine CT extracts ranged from 19.8% by sainfoin CT (412 mg digested/g incubated) to 92.4% by crown vetch CT (39 mg digested/g incubated).

Including CT in cultures of *F. succinogenes* increased the specific activity of cell-associated endoglucanase, as compared with no CT (Table 5). Declines in the extent of filter paper digestion were strongly correlated ($R = 0.8501$ and 0.8027; Table 6) with the inhibition of endoglucanase activity, which is consistent with our previous study of *F. succinogenes* (Bae et al., 1993b). Variations in the extent of inhibition of cellulose digestion caused by the nine CT may have arisen from different concentrations of CT in the polymer preparations or differences in the number of reactive groups in the CT.

Grouping the GPC spectra of the CT by their relative inhibitory effects on endoglucanase activity (high, moderate, low) revealed by the data in Table 5 yielded no consistent patterns (Figure 1). To further examine possible factors involved in CT-mediated inhibition of cellulolysis, chromophore formation during the three colorimetric assays by each of the CT was plotted against inhibition of filter paper digestion (Figure 2), as was their capacity to precipitate BSA and Rubisco (Figure 3). There was no correlation between inhibitory effects on filter paper digestion and (1) chromophore formation in any of the colorimetric assays, (2) precipitation of BSA or Rubisco ($R^2 \leq 0.255$), or (3) MW (Table 6). Further, MW was not correlated with any of these characteristics

TABLE 5. EFFECT OF CONDENSED TANNINS (CT) ISOLATED FROM NINE FORAGE SOURCES ON DIGESTION OF WHATMAN NO. 1 FILTER PAPER BY *F. succinogenes* subsp. *succinogenes* S85 AND ON CELL-ASSOCIATED AND EXTRACELLULAR ENDOGLUCANASE ACTIVITIES IN 72-HR CULTURES

	Filter paper digested[a]	Inhibition of digestion (%)	Endoglucanase activity[b] (mU/ml)		Cell-associated protein (μg/ml)	Specific activity[c] (mU/mg protein)
			Cell-associated	Extracellular		
Control (no CT included)	514	0	17.5	292.3	35.7	488.7

[a] Butanol, vanillin, and H_2SO_4: chromophore production as measured by butanol–HCl, vanillin–HCl, and H_2SO_4 methods, respectively; *[i]*$CMCase_{CA}$ and *[i]*$CMCase_{EC}$: inhibition of endoglucanase (carboxymethylcellulase, CMCase) activities in cell-associated (CA) or extracellular (EC) fractions, respectively, of cultures of *F. succinogenes*; *[i]*FPD: inhibition of digestion of filter paper by *F. succinogenes*; PPC-BSA and PPC-Rubisco: protein-precipitating capacities against bovine serum albumin (BSA) and Fraction 1 protein (Rubisco), respectively.

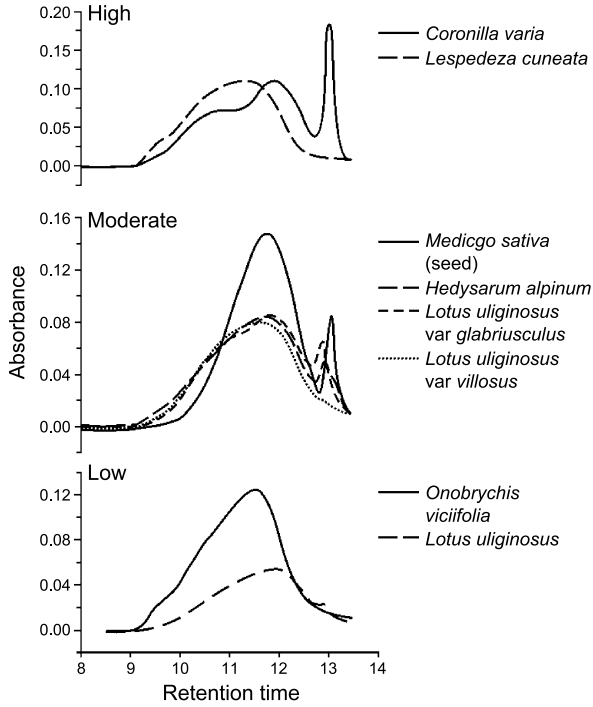

FIG. 1. Gel permeation chromatographic spectra of peracetate derivatives of the condensed tannins (CT) isolated from nine leguminous forage sources. The spectra are grouped to reflect the relative rankings of the effects of the nine CT preparations on cellulose-digesting activity of the ruminal bacterium *Fibrobacter succinogenes* (Table 5).

(Table 6). None of these parameters, therefore, was a reliable indicator for predicting the potential of a particular CT to inhibit cellulose digestion.

It has been suggested that the ability of CT to precipitate proteins is a suitable indicator of their relative astringency (Robbins et al., 1987; Hanley et al., 1992). However, correlation between the ability of the extracted CT to inhibit filter paper digestion and to precipitate BSA (R = 0.1744) or Rubisco (R = 0.5050) was very low (Table 6). Moreover, the most inhibitory CT for cellulose digestion included those with broad and with narrow MW distributions (Tables 1 and 5). In terms of ruminant nutrition, the CT from sainfoin, *O. viciifolia*, appeared to have the most potential of the nine examined, as it caused the least inhibition of cellulose digestion by *F. succinogenes* while exhibiting the greatest capacity to bind Rubisco from alfalfa. This response is consistent with our previous documentation of the bloat-prevention capacity

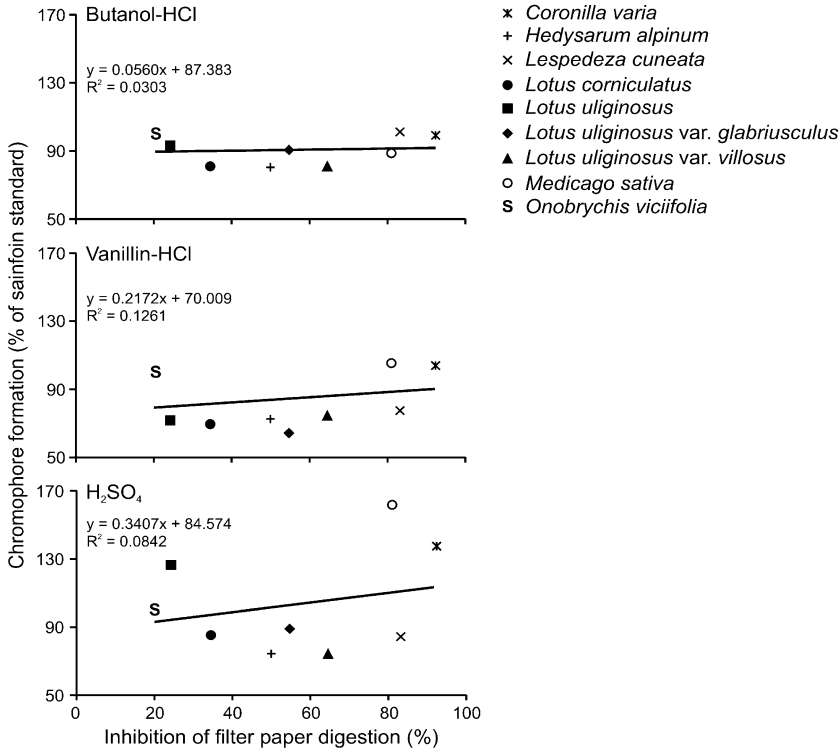

FIG. 2. Relationships between the inhibitory effects of condensed tannins (CT) from nine leguminous forage sources on filter paper digestion by *F. succinogenes* (as compared to digestion with no CT) and their production of chromophore (relative to sainfoin, S) during colorimetric assays (butanol–HCl, vanillin–HCl, or H_2SO_4).

of sainfoin when it is fed in combination with alfalfa to cattle (McMahon et al. 1999).

Characterization of the properties of CT that optimize ruminal escape protein and prevent pasture bloat, without impeding carbohydrate digestion, is pivotal to the success of strategies aiming to achieve these characteristics in alfalfa through the transgenic expression of CT. This study suggests that these properties are not easily defined via chemical means and that biological assays using rumen bacteria may help identify those CT with the most desirable properties. Identification of those CT that result in favorable alterations in protein metabolism without adversely affecting ruminal fiber digestion will be pivotal to the success of using these phenolic compounds to improve ruminant production. Development of similar assays using proteolytic ruminal bacteria could prove useful in achieving this goal.

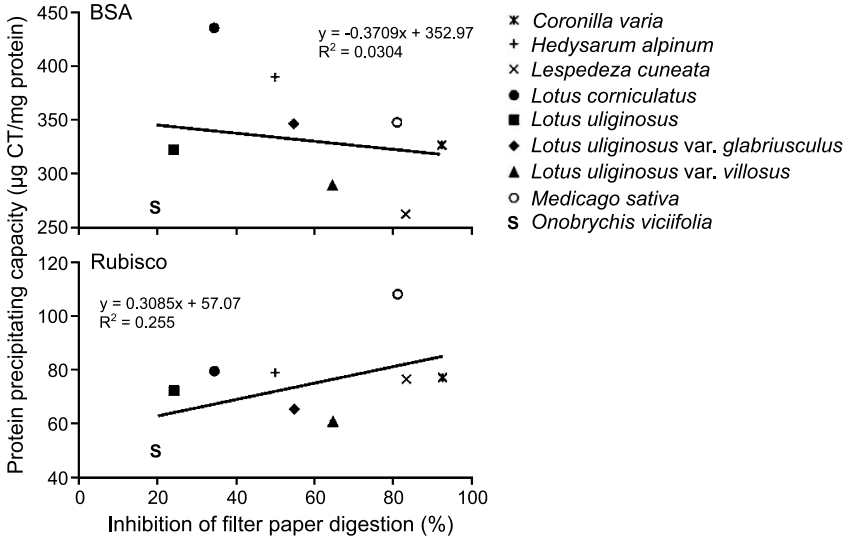

FIG. 3. Relationships between the inhibitory effects of condensed tannins (CT) from nine leguminous forage sources, including sainfoin (S), on filter paper digestion by *F. succinogenes* (as compared to digestion with no CT) and their capacity to precipitate bovine serum albumin (BSA) or Rubisco from alfalfa (µg CT required to precipitate 1 mg of the specified protein).

Acknowledgments—This study was conducted with partial funding from the Farming for the Future Program of the Alberta Agricultural Research Institute. The authors thank L. Ruth Barbieri, Katherine Jakober, and Zhong Xu for their contributions to this manuscript.

Abstract—Acting simultaneously or sequentially, plants encounter multiple stresses from combined abiotic and biotic factors that result in decreased growth and internal reallocation of resources. The plant stress hypothesis predicts that environmental stresses on plants decrease plant resistance to insect herbivory by altering biochemical source–sink relationships and foliar chemistry, leading to more palatable food. Such changes in the nutritional landscape for insects may facilitate insect population outbreaks during periods of moderate stress on host plants. We examined the plant stress hypothesis with field experiments in continental grassland (USA) using the C_4 grass *Bouteloua gracilis*. Water, nitrogen fertilizer, and herbivory from the grass-feeding grasshopper *Ageneotettix deorum* were manipulated. Combined stresses from water and mineral-N in the soil decreased plant growth and altered foliar percent total N (TN) and percent total nonstructural carbohydrate (TNC) concentrations in an additive fashion. Grasshopper herbivory affected final biomass only in dry years; plants compensated for tissue loss when rainfall was abundant. Foliar TN and TNC concentrations were dynamic with respect to variable climatic conditions and treatment combinations, showing significant interactions. Grasshopper herbivory had its greatest impact on TN or TNC in dry years, interacting with other forms of stress. Herbivory as a single factor had strong effects on TNC in years with normal precipitation, but not in a dry year. Performance (developmental rate and

survival) by the grasshoppers *Phoetaliotes nebrascensis* and *A. deorum* were not greatly affected by plant stress in a manner consistent with the plant stress hypothesis.

Key Words—Chewing insects, environmental stress hypothesis, functional-convergence-to-plant-stress hypothesis, grasshopper, insect herbivory, total foliar nitrogen, total nonstructural carbohydrates.

INTRODUCTION

Dynamic biochemical, physiological, and morphological responses by plants to environmental conditions are integrated at organ and whole-plant levels through a variety of source–sink relationships (Mooney and Chiariello, 1984; Bazzaz and Grace, 1997). The plant stress hypothesis states that environmental stresses on plants decrease plant resistance to insect herbivory by altering whole-plant source–sink resource allocation schedules and foliar chemistry, thus changing food palatability (Rhoades, 1983; Mattson and Haack, 1987; Louda and Collinge, 1992; White, 1993; Redak and Capinera, 1994; Koricheva et al., 1998; Huberty and Denno, 2004). Plant resource acquisition (light, water, carbon, elemental nutrients), internal resource allocation among tissues (source–sink relationships, translocation products), and partitioning of resources to different plant functions (growth, maintenance, reproduction, repair, defense, senescence) ultimately prescribe the nature and distribution of nutritional constituents within plants to herbivores (Mooney and Gilman, 1982; Bazzaz et al., 1987; Chapin et al., 1987; Mooney et al., 1991; Aerts and Chapin, 2000)—often considered growth optimization processes (Mooney and Winner, 1991). Variation in water and soil nutrient availability coupled to herbivory may cause unpredictable levels of stress that alters plant metabolism in response to the action of one or all factors with consequences for plant growth (Trlica and Cook, 1971; Bokhari, 1978; Mooney et al., 1991; Louda and Collinge, 1992).

The plant stress hypothesis was proposed as an environmentally determined explanation for outbreaks of insect herbivores operating through plant condition (Rhoades, 1983; Waring and Cobb, 1992; Watt, 1992; Koricheva et al., 1998), in which improved nutritional quality of host plants experiencing intermediate levels of stress resulted in increased demographic performance by herbivores. Rhoades (1983) extended the hypothesis to also include reduced production of chemical defenses under stress conditions in addition to elevated nutritional quality. Experimental tests of the plant stress hypothesis for forest insects provide little general support of the hypothesis (Rhoades, 1983; Waring and Cobb, 1992; Watt, 1992; Koricheva et al., 1998). Although some insect feeding guilds (e.g., boring and sucking feeders) responded as predicted in experimental tests in woody plants, other groups including chewing insects did

not generally respond to plant stress as predicted (Waring and Cobb, 1992; Watt, 1992; Koricheva et al., 1998; Huberty and Denno, 2004). However, about 67% of the examples are consistent with predictions (Waring and Cobb, 1992) in observational studies of trees along environmental stress gradients, although alternate explanations exist (Watt, 1992). Although this system may be prototypical for the action of the plant stress hypothesis, few tests with grasses exist (Waring and Cobb, 1992; Redak and Capinera, 1994).

We seek to clarify the nature of interactions among multiple stresses as they impact growth and variable leaf chemistry in blue grama grass, *Bouteloua gracilis* (H.B.K.) Lag. ex Griffiths, according to predictions of the plant stress hypothesis. *B. gracilis* is a dominant C_4 grass species in western North American (USA) grasslands. Two primary predictions of the plant stress hypothesis were examined in the short grass *B. gracilis* experiencing naturally occurring and variable abiotic conditions: (1) reduced water or soil nitrogen levels coupled to insect herbivory will negatively affect plant growth and increase the palatability of tissues to insect herbivores, (2) chewing insect herbivores will perform better on stressed host plants with higher concentrations of primary nutrients (protein and carbohydrate). In addition, we examined the relative contribution to responses of stresses when combined under field conditions. We examined direct effects and interactions among three common forms of stress to *B. gracilis*: water availability, plant nutrient availability, and grasshopper herbivory within natural levels in the field. Experiments repeated over 3 years included a wide range of weather conditions against which to gauge plant responses. We expected that the imposition of moderate water or nutrient stress should modify plant physiology in such a way that resistance to herbivores decreases, with a concomitant increase in availability of primary nutrients in leaves to herbivores. As food plant palatability increases following moderate stress to *B. gracilis*, performance by the grass-feeding grasshoppers *Ageneotettix deorum* (Scudder) and *Phoetaliotes nebrascensis* Thomas should be enhanced as levels of primary nutrients in leaf tissues, especially protein and carbohydrates, increase. *B. gracilis* does not produce allelochemicals that are expected to influence responses to primary nutrients by herbivores in this experiment (Mole and Joern, 1994), allowing us to restrict our attention to the nutritional component of the problem.

METHODS AND MATERIALS

Study System. We conducted field experiments at Arapaho Prairie (Arthur County, NE, USA), a protected research site in Nebraska sandhills grassland. The site is characterized by upland sandhills grassland composed of large stabilized sand dunes with steep upper ridges that gradually slope into broad flat

valleys. Most plants at Arapaho Prairie experience at least some water and nutrient stress in most years (Barnes, 1985; Mole et al., 1994).

Vegetation at Arapaho Prairie is an open-canopy mixed-prairie, modified by sandy substrate (Barnes, 1985). Grasses contribute 80% to total plant biomass, with long-term NAPP ranging between 75 and 250 g m^{-2} (unpublished data). C_3 and C_4 grass species typical of eastern tallgrass prairie and western shortgrass steppe grasslands intermingle at the site. Dominant plants in this sand dune landscape form loose but recognizable vegetation associations along the existing topographic gradient (Barnes, 1985). The grass canopy is intermingled with extensive bare ground, largely because of extensive disturbance from pocket gophers.

Long-term annual mean precipitation (1951–1980) recorded 15 km from Arapaho Prairie at Arthur County, NE, averaged 47.1 cm (SD = 8.98 cm) from

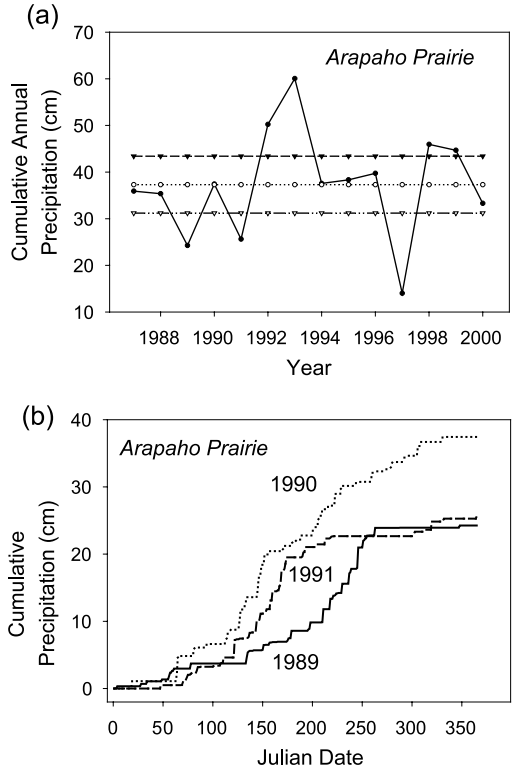

FIG. 1. Precipitation patterns at Arapaho Prairie. (a) Annual rainfall with mean and 95% confidence intervals, 1987–2000. (b) Seasonal pattern of precipitation illustrated by cumulative amount by date for the 3 years of the study.

US Weather Bureau records; the recent 14-year record from Arapaho Prairie (1987–2000) averaged 37.3 cm (SD = 11.4 cm). The amount and timing of precipitation at Arapaho Prairie varies greatly among years (Figure 1). Below-average precipitation was observed in two of the three years of this study (Figure 1a), with rainfall in 1990 equaling the average amount for the site. Perhaps more importantly, the seasonal timing of rainfall over the growing season differs in important ways among years (Figure 1b). Both 1989 and 1991 received approximately the same amount of precipitation, but rain fell early in the season in 1991 compared with late-season rainfall in 1989. In 1990, rainfall occurred throughout the growing season, compared with 1989 and 1991, each of which experienced large periods without significant amounts of rain.

Arapaho Prairie soils contain 80–85% sand with low nutrient concentrations (Barnes et al., 1984). Total nitrogen in soil in the top 10 cm ranges from 0.02 to 0.07% of total soil weight according to landscape position. Valleys exhibit the highest soil total N levels, but all landscape positions are generally low (Alward and Joern, 1993). Nitrate concentrations range from 0.04 to 15 ppm, and ammonium concentrations varied from 0.17 to 3.3 ppm. Light is seldom a major limitation to plant growth because of the open canopy and large proportion of sunny days at this site.

B. gracilis is an often dominant C_4 short-grass species throughout the shortgrass steppe of the Rocky Mountain foothills to the mixed-grass prairies of the central Great Plains of North America. In Nebraska sandhills grasslands, it is commonly found in fine-textured soils typical of dry valleys. At Arapaho Prairie, *B. gracilis* comprises up to 20–30% of the relative cover of valleys and midslope dunes but is nearly absent from dune ridges (Barnes et al., 1984). *B. gracilis* productivity is correlated with soil moisture, and biomass peaks in early August although yearly variability exists. *B. gracilis* is an important dietary component of graminivorous grasshopper species at this site, including *A. deorum* and *P. nebrascensis* (Joern, 1985).

Experimental Design and Statistical Analyses. Overall, two related experiments were run concurrently, one addressing effects of water, N fertilizer, and grasshopper herbivory on plant response, and the other investigating grasshopper performance in response to water and N-fertilizer treatments on plants. Rectangular cages (basal area 0.5 m^2, 80 cm high) were constructed of 0.64-cm mesh and buried 10 cm after severing possible root connections to neighboring ramets. Cages were placed over natural stands of *B. gracilis* "turf" in early June, corresponding to the initiation of growth. Cages housing treatment combinations of both experiments were intermingled randomly within each block, but experiments were analyzed separately.

Plant Responses. We manipulated levels of water, nitrogen fertilizer, and grasshopper herbivory within natural levels to understand variation in plant responses to stress. Biomass accumulation and foliar chemical responses (% total

nitrogen, TN; and % total nonstructural carbohydrates, TNC) by *B. gracilis* to multiple stresses was studied using a 3 × 2 × 2 full-factorial treatment combination (N fertilizer, water availability, and grasshopper herbivory, respectively) experiment in a randomized complete block design, nested within each of 3 years. Six sites (blocks) were arbitrarily selected in a range of natural habitats for *B. gracilis* along a gradient stretching from slope vegetation to valley vegetation. Sites were selected based on the criterion that a sufficient density of *B. gracilis* was available to set up a full set of treatment combinations. Treatment combinations were randomly assigned to predetermined patches of *B. gracilis* within each block.

Grasshopper Performance. Grasshopper performance was evaluated in a field experiment executed in parallel with the plant stress experiment by using a similar experimental design and identical water and mineral-N fertilizer additions using cages as described above. Cages were intermingled randomly with those of the plant stress experiment. The experimental design was a 3 × 2 full-factorial treatment combination experiment (N fertilizer and water availability, respectively) arrayed in a randomized complete block design, nested within each of 3 years. Six blocks were used. A repeated-measures analysis of variance (ANOVA) was used to examine grasshopper survival. Responses of two grasshopper species to plant stress were evaluated in different years (1989, *P. nebrascensis*; 1990, *A. deorum*), but specific responses between species cannot be compared directly because of overall differences in naturally occurring stress between years. Ten fourth instar nymphs were added to each cage in late June or early July to match natural phenological development of each species in the field. The number of survivors and the developmental stage of individuals were determined every 2–3 d from censuses of individuals remaining in each cage.

Statistical Analyses. Statistical analyses were performed using ANOVA, with treatments evaluated as fixed effects in the ANOVA. To normalize data, dependent variables expressed as percent of the total sample weight were transformed by applying arcsine(square root) to original data before statistical analyses. We present and discuss values in the nontransformed state. Treatment variables were treated categorically in analyses.

Manipulations of Plant Stress from Water, Mineral Nitrogen, and Grasshopper Herbivory

(1) *Water*. Two water levels were used: W+, in which water was added weekly for the 10-wk duration of the experiment, and W0, where no additional water beyond ambient rainfall was added. We considered W0 to be more stressful than W+ as water stress is common in grasses (Heinisch, 1981; Barnes, 1985).

In the first 2 wk of the experiment, all plots received water in addition to N fertilizer if scheduled for that cage. After this, W+ cages received 2 l m^{-2} wk^{-1} of supplemental water over the course of the experiment. No attempt was made to standardize the absolute level of plant water stress among years.

(2) *N-Fertilizer*. Soil-nitrogen levels were manipulated using ammonium nitrate (NH_4NO_3). Levels included 0, 3, and 6 g N m^{-2} of N fertilizer (N_0, N_3, and N_6 treatments, respectively). N fertilizer was applied in two half-strength additions over several days in early June in each year.

(3) *Grasshopper Herbivory*. Moderate densities of the *B. gracilis*-feeding grasshopper, *A. deorum*, were added to cages to assess foliar responses to insect herbivory. In the GH+ treatment, we added four adult grasshoppers to each cage in late June. This density corresponded to eight individuals per square meter, about double the long-term average of all grasshoppers at Arapaho Prairie (A. Joern, unpublished data), but about half the economic threshold. Moreover, the densities used in the experiments are routinely observed in some vegetation patches in most years. No grasshoppers were added to cages in the GH0 treatment. Initiation of the grasshopper treatment corresponded to the phenological presence of the adult *A. deorum* in the field. Grasshoppers were replaced weekly to maintain relatively constant levels of herbivory.

Final Biomass Estimates and Chemical Analyses of Leaf Material. Leaf samples of *B. gracilis* were collected at the end of the experiment (mid-August) and prepared for chemical analysis. Initially, a subsample of green leaf material [ca. 2–3 g dry weight (d.w.)] was collected, immediately flash-frozen in liquid nitrogen in the field, and then prepared for chemical analyses. Samples were lyophilized for 48 hr and stored under desiccant in a freezer. Dried leaf material was ground with a Wiley Mill (40-mesh sieve) before chemical analysis. After collecting leaf material for chemical analyses, remaining plant biomass in a cage was clipped, dried (80°C for 24 hr) and weighed.

Total Nitrogen. Total nitrogen was analyzed by using modified micro-Kjehldahl techniques (AOAC, 1984) with a standard digest on 100-mg samples of ground leaf material (2 ml H_2SO_4, a $CuSeO_4$ Kjeltab catalyst tablet). Total N was determined by measuring ammonia generated after adding 100 ml of 5 M NaOH to the digest using a selective ion electrode (Orion). The ammonium probe was calibrated daily with an ammonium sulfate standard.

Total Nonstructural Carbohydrates. Total nonstructural carbohydrates were extracted following the method of (Smith, 1981) except for the use of amylglucosidase (Sigma A-7255) as the enzyme preparation in the digest. These were analyzed by the titrimetric method of Smith (1981) with glucose as a standard without the hydrolysis of sucrose. Sucrose averaged about 0.4–0.5% d.w.

of plant material compared with 17–22% d.w. plant material for TNC as measured and did not vary with TNC concentration (S. Mole, unpublished data).

RESULTS

Total Plant Biomass. On average, total biomass in *B. gracilis* plots at the end of the season (Figure 2) was about 50–100% greater in an average rainfall

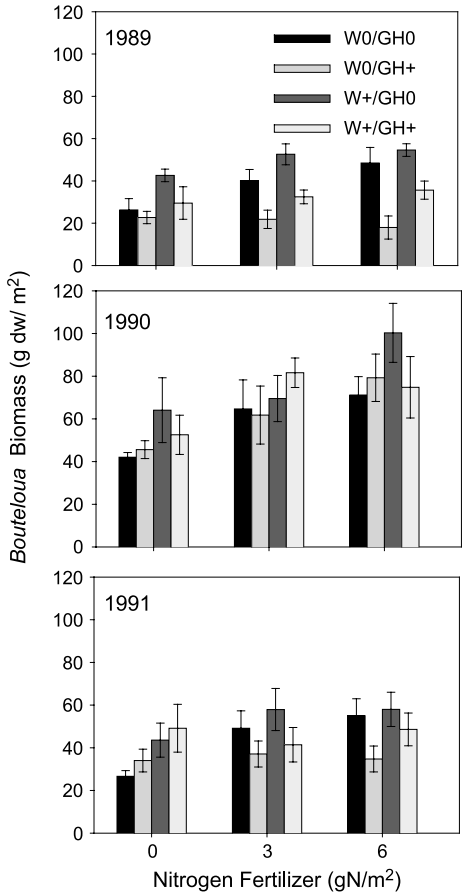

FIG. 2. End of season *B. gracilis* biomass (mean, SE) according to stress treatment conditions [water (W0, W+), N-fertilization (0, 3 and 6 g N m^{-2}), and grasshopper herbivory (GH0, GH+)] for each year of the study.

year (1990) as in dry years (1989, 1991), which were similar. *B. gracilis* biomass was significantly different among experimental treatments depending on the number of stresses applied, indicating that the plants in this study experienced varying degrees of overall stress. Both water (1989: $F_{1,56} = 17.4$, $P < 0.001$; 1990: $F_{1,56} = 6.6$, $P = 0.013$; 1991: $F_{1,56} = 11.3$, $P < 0.001$) and N fertilizer additions (1989: $F_{2,56} = 4.2$, $P < 0.021$; 1990: $F_{2,56} = 11.2$, $P < 0.001$; 1991: $F_{2,56} = 7.1$, $P < 0.001$) resulted in increased biomass in all years as additive, direct effects; no statistical interactions were detected for water and N fertilizer in any year (Figure 2).

Feeding by grasshoppers reduced the final *B. gracilis* biomass in the dry years of 1989 and 1991 (67% in 1989, $F_{1,56} = 34.8$, $P < 0.001$; 32% in 1991, $F_{1,56} = 6.5$, $P = 0.012$), but no effect from grasshopper feeding was detected in 1990, a year of normal rainfall. This indicates that complete compensation for foliage loss was observed in this year with normal rainfall. No statistical interactions among grasshopper herbivory, water availability, and N fertilizer treatments were observed in their combined effect on final *B. gracilis* biomass, but were additive instead. Although biomass estimates do not include the amounts consumed by grasshoppers, these should be similar between years as the grasshopper encounter rate was controlled.

Foliar Total Nitrogen. Foliar TN differed significantly among treatments, year, and block (Figures 3a and 4a, Table 1). TN concentrations were highest for all treatments in 1989, the driest year, a year with almost no precipitation occurring early in the growing period (Figure 1b). TN at the end of the experiments in August 1989 averaged 1.73% total dry weight in all treatment combinations compared with 1.01% (1990) and 1.14% (1991) TN in subsequent years, representing a notable decrease in 1990–1991 compared with 1989.

Foliar TN levels varied in response to both N fertilizer and water treatments in some fashion in all years (Figures 3a and 4a, Table 1), with water addition explaining the most variation in responses (Figure 5). Depending on the year, N fertilizer addition increased foliar TN levels from 5 to 21% dry mass compared with no fertilizer addition treatments. An average 13% increase in foliar TN over the 3-year period was observed. Differences in foliar TN between 3N vs 6N treatments were of smaller magnitude (3–10%), and only significantly different in 1991.

Although the main effects of treatments were pronounced in all cases (Figure 3), treatment interactions that were important and insightful to underlying processes were sometimes detected. W0 treatments resulted in a 10–20% higher level of total foliar-N compared with W+ treatments. The weakest response to water (9.5%) was observed in the driest year (1989), possibly because extreme drought stress in that year was not proportionally offset by the water addition treatment compared to other years. A significant N fertilizer by water interaction existed in 1989 and 1990 but with different

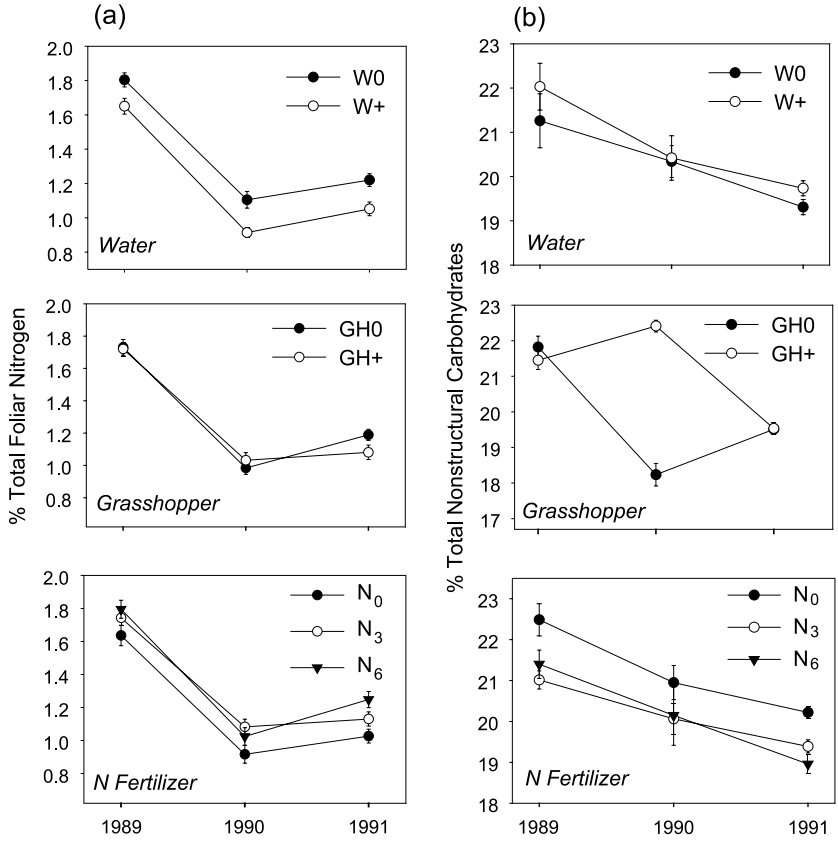

FIG. 3. Responses (mean, SE) in (a) % total N and (b) % TNC to main treatments (water addition, grasshopper herbivory, and N fertilizer) for each year.

responses between the 2 years (Figure 5). In very dry 1989, higher foliar TN levels were seen in W0 only for the N_0 treatment. No differences were seen between W0 and W+ for the N_3 and N_6 fertilization treatment levels. In a year of average rainfall (1990), there was no difference in foliar TN between water treatments at N_0, but significant and about equal increases in total N for N_3 and N_6 treatments in interaction with water availability.

Grasshopper herbivory affected foliar TN levels significantly as a main effect only in 1991. However, grasshopper feeding interacted with other treatments to influence total foliar TN in all years (Figures 4a and 5). In 1989, there was an increase in TN up to the maximum level observed at N_3, a TN level that was reached with N_6 with no grasshoppers. In 1990, grasshopper herbivory interacting with water availability led to higher TN level that was reached in the

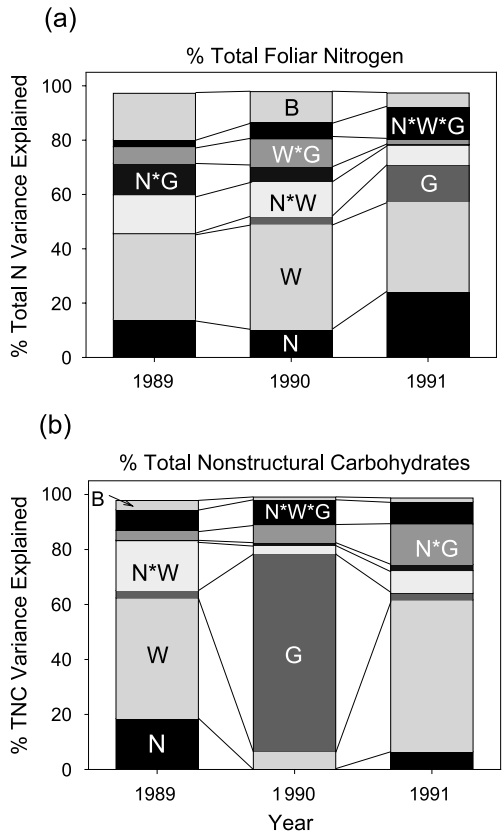

FIG. 4. Percentage of total variance in foliar nutrient responses explained by experimental treatments in each year of study. (a) % Total foliar nitrogen (TN) and (b) % total nonstructural carbohydrates (TNC). Letters refer to main effects (N, nitrogen fertilization; W, water; G, grasshopper herbivory) and statistical interactions (N*W, N*G, W*G) as indicated in the experimental design of Table 1. B is the block (site) effect. Percentage of total variance in response was calculated as the variance associated with the treatment combination compared with the total variance of the experiment.

W0 treatment compared with the W+ treatment for which there was no significant difference between grasshopper treatments.

Foliar Total Nonstructural Carbohydrates. Significant responses in foliar TNC concentrations were also observed (Table 1, Figures 3b, 5b, and 6) in response to combined stresses. Among-year differences averaged 5–10%, with 1989 exhibiting the highest foliar TNC levels. Differences in responses among all treatment combinations showed little variation in 1989 and 1991 compared

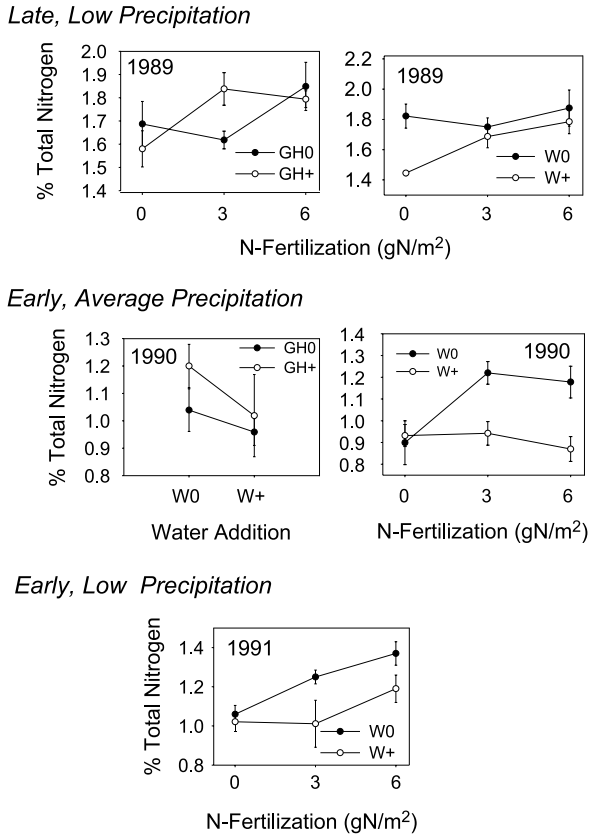

FIG. 5. Responses of significant interactions among treatments for % total foliar N (TN) for each year of study.

with 1990. Total variance in TNC levels among treatments was 1.5–5 times greater in the average rainfall year (1990) than in the other years. Over all 3 years, combined nitrogen fertilizer and grasshopper treatments for all levels were significant as main effects, with no significant statistical interactions. When compared against the N fertilizer treatments, W0/GH0 had the lowest TNC levels and W+/GH+ had the highest levels on average, with each decreasing along the N-fertilization axis. Levels of TN and TNC in leaves were uncorrelated in all years for all treatments combined (1989: $r^2 = 0.014$; 1990: $r^2 = 0.001$; 1991: $r^2 = 0.038$; $P > 0.05$ for all years). However, when years were analyzed separately, interesting differences were observed.

In general, TNC declined 4–6.5% with increased N fertilizer in all years, although no significant differences were observed between the 3 g and 6 g

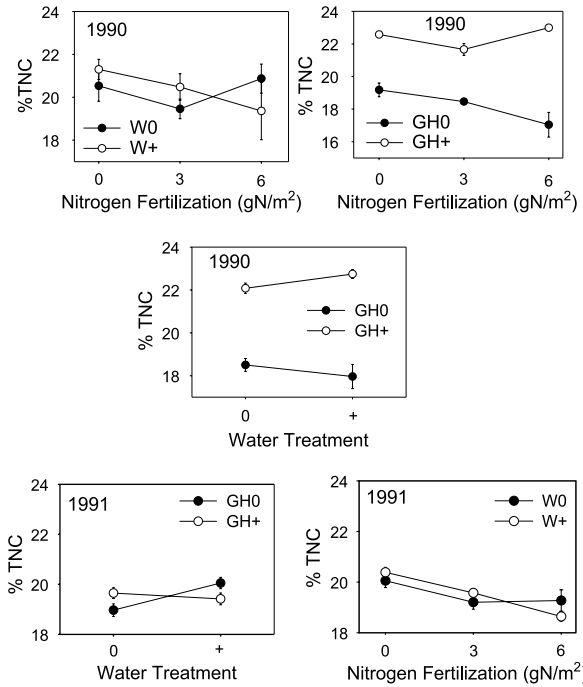

FIG. 6. Responses of significant interactions among treatments for % total nonstructural carbohydrate (TNC) for each year of study.

N fertilizer treatments. When water treatments were significant (1989 and 1991), TNC was greater in W+ compared with the W0 treatments, with differences on the order of about 3–4%. Generally, grasshopper herbivory was a factor when interacting with either N fertilizer or water treatments (Table 1). In 1990, GH+ resulted in a large 23% increase in % foliar TNC, and important interactions with N fertilizer and water were detected.

The nature of interactions among sources of plant stress differed among years. Numerous interactions were observed in both 1990 and 1991 (Figure 6), average and below average rainfall years, respectively. In 1990, all two-way interactions and a three-way interaction were significant. % TNC in the N_6 fertilizer treatment increased in the W0 treatment, but the trend otherwise was for TNC to drop with increased N fertilizer. Grasshopper treatments interacted with both N fertilizer and water in both 1990 and 1991, but the TNC responses were different. In the very dry 1989, no interactions were detected, and all contributions to the variance in TNC content were additive. Inclusion of grasshoppers resulted in increased TNC in high-resource environments (N or

water) compared with the GH0 treatments. In 1991, the opposite response was observed where TNC levels under high-resource conditions were lower if grasshoppers were present.

Grasshopper Performance. P. nebrascensis. This species was studied in a very dry year with late season rainfall. No significant effect of treatment combinations was observed for developmental rate although there is a suggestion that W0/6N develops faster. Repeated-measures ANOVA of the number of

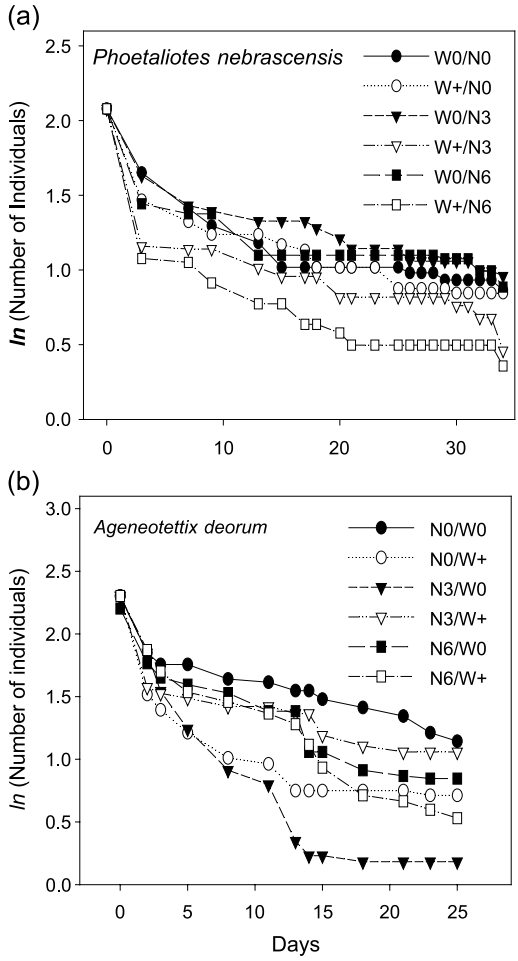

FIG. 7. Mean survival of two grasshoppers in response to plant stress treatments. Experiments were performed in different years as described in the text. Data are transformed as natural log of number alive at each census period.

individuals remaining in cages of *P. nebrascensis* (Figure 7a) was significant (Wilk's $\lambda = 0.10$, $P < 0.001$). However, although observed trends in survival may be suggestive, no significant effect of water and N fertilizer treatments were detected. The significant difference in the repeated-measures ANOVA reflected the decrease in the number of survivors over time, not treatments.

Ageneotettix deorum. This species was studied in a normal rainfall year. No significant effect of water and N fertilizer treatments on developmental rate was detected. *A. deorum* survival (Figure 7b) varied in response to experimental treatments (repeated-measures ANOVA, Wilk's $\lambda = 0.137$, $F_{6,21} = 22.06$, $P < 0.001$). A significant N Fertilizer × Water interaction was detected (repeated-measures ANOVA, $F_{2,6} = 6.3$, $P = 0.006$). In W0 treatments, survivorship was greatest in treatments with no N fertilizer and decreased when N was added. In W+ treatments, survival was highest on fertilized plots, at least for the first half of the trajectory when N0 and N6 N fertilizer treatments converged.

DISCUSSION

This study examines how multiple environmental stresses interact to affect growth and foliar chemistry in the grass *B. gracilis*, and whether plant responses to these stresses increase herbivore performance. Since White's (1993) formulations of the plant stress hypothesis, much effort has been directed at understanding its overall importance and generality to understanding insect herbivore population responses to plant stress (Waring and Cobb, 1992; Koricheva et al., 1998). Testing this hypothesis becomes a greater challenge when multiple stresses operate (Mooney et al., 1991). Soil nutrient stress varies according to substrate type and nutrient cycling characteristics of the site, and ecological processes that deplete nutrient availability such as uptake rates by plants or use by soil microbes (Aerts and Chapin, 2000). Water availability varies at multiple scales within and among years, where plants in natural environments are often water stressed, including *B. gracilis* studied here (Mole et al., 1994). For much vegetation, local light availability is influenced primarily by accumulated total biomass at the site, although intermittent cloud cover can be important. In this study, light was unlikely to limit photosynthesis because of the low stature of vegetation growing in an open habitat under conditions of sunny skies on most days. Tissue loss from herbivory further modifies physiological responses in plants and potentially interacts with other sources of stress in nonlinear ways (Mattson and Haack, 1987) and is the basis of Jones and Coleman's (1991) "phytocentric model" of plant–insect herbivore interactions.

In response to moderate stress to *B. gracilis*, plant growth decreased, concentrations of primary nutrients in leaf tissue increased, and the ability to compensate for tissue loss from herbivory was reduced. Here, foliar chemistry

in response to stress conditions is highly dynamic and effects of combined abiotic stresses are additive, but sometimes appear idiosyncratic when combined with herbivory from grasshoppers. Results observed for *B. gracilis* are consistent with those of other studies. Multiple environmental stresses to plants regularly reduce plant growth compared to the maximum performance possible (Mooney et al., 1991; Louda and Collinge, 1992), and nutrient and water stress or tissue loss often alter tissue palatability to herbivores (Mattson and Haack, 1987; Louda and Collinge, 1992; White, 1993; Redak and Capinera, 1994). Understanding the integrated responses by plants to combined stresses from abiotic conditions and herbivory is limited by our ability to incorporate the consequences of multiple stresses into a predictive framework (Jones and Coleman, 1991; Mooney et al., 1991; Bazzaz and Grace, 1997). Because plants function as integrated units, whole-plant growth responses reflect the underlying coordination and allocation among competing resource sinks (Mooney et al., 1991; Bazzaz and Grace, 1997).

Consequences of Environmental Stresses to B. gracilis. B. gracilis biomass varied significantly with manipulation of water availability, nitrogen fertilizer, and grasshopper herbivory treatments in the field, showing that these factors contribute importantly to plant stress. Responses differed among years as weather conditions varied (hot, dry vs normal precipitation), and both water and nitrogen fertilizer manipulations affected plant growth in each year in an additive fashion. Moreover, plant biomass decreased relative to controls in response to grasshopper herbivory in the driest years (1989, 1991), but herbivory did not affect final biomass accumulation in a year with normal rainfall (1990). These results indicate that *B. gracilis* compensates for tissue losses from herbivory when provided sufficient water and nutrients to support photosynthesis and growth.

Foliar chemistry of *B. gracilis* is highly variable among years; variability in foliar chemical concentrations should increase in response to stress according to variability in plant stress. This is to be expected, as critical soil nutrients, light, and water required for plant growth routinely shift in time and space (Bazzaz and Grace, 1997) under natural conditions. Water stress regularly resulted in increased concentrations of foliar TN in all years and was the most important stress to *B. gracilis*. However, N fertilizer, grasshopper, and year effects contributed greatly to the expression of TN, showing a variety of outcomes among years.

Insect herbivory should affect plants in a manner similar to other environmental stresses in that it alters the capacity for photosynthesis by removing leaf material and changes source–sink relationships to favor regrowth of leaves. Photosynthesis, growth, and foliar nutrients routinely vary in response to the timing and degree of herbivory (Redak and Capinera, 1994). Of greatest interest is the highly variable nature of responses of foliar

chemistry to grasshopper herbivory, especially among years and the large number of interactions that were observed between other plant stresses and grasshopper herbivory.

The Plant Stress Hypothesis. By influencing metabolic activity in general, environmental stresses often alter plant resistance to herbivory, especially because of changes in foliage quality to herbivores (Rhoades, 1983; Bazzaz et al., 1987; Mattson and Haack, 1987; Louda and Collinge, 1992). For example, reduced soil water availability often reduces resistance to herbivory because of increased nutrient concentrations in leaf tissue available to herbivores (McNeil and Southwood, 1978; White, 1993; Redak and Capinera, 1994), decreased or elevated concentrations of defensive compounds (Rhoades, 1983; Gershenzon, 1984; Redak and Capinera, 1994), or some trade-off between nutritional and defensive qualities in leaf tissues that make them more or less palatable to herbivores (Bazzaz et al., 1987). Consequently, increased nutritional quality combined with decreased defensive capability results in improved herbivore performance. Mature grasses contain few chemical defenses compared to other plant taxa (Mole and Joern, 1994), thus simplifying the problem. Primary nutrients are also typically found at much lower concentrations in grasses than are typically observed in forbs and wood plants, decreasing the plant's value as food to herbivores (Bernays and Barbehenn, 1987). Given the expected low concentrations of limiting nutrients relative to consumer needs, small shifts in their availability may provide large fitness consequences to individuals feeding on them (Joern and Behmer, 1997).

B. gracilis responded to multiple stresses more or less as expected, but grasshopper performance was not consistent with predictions of the plant stress hypothesis. No changes in developmental rate were observed in either species, and survival in *P. nebrascensis* showed no significant differences. Survival in *A. deorum* differed among stress treatments, but higher survival was observed in treatments with lower levels of foliar TN, contrary to survivorship patterns expected based on feeding studies with controlled diets (Joern and Behmer, 1997).

Reviews of the plant stress hypothesis on woody plants (Waring and Cobb, 1992; Koricheva et al., 1998; Huberty and Denno, 2004) indicate weak support for the notion at best. No significant concordance with expectations was observed in a meta-analysis of experimental studies (Koricheva et al., 1998; Huberty and Denno, 2004), although comparative studies in the field were reasonably consistent with expectations (Waring and Cobb, 1992; Watt, 1992). Fewer studies are available for nonwoody plants, especially for grasses, and results generally conflict with predictions of the plant stress hypothesis. Redak and Capinera (1994) showed that heavy defoliation of western wheat grass (*Pascopyrum smithii*) either by mechanical means in the laboratory or from herbivory by *P. nebrascensis* in the field altered foliar nutrients and palatability,

but in the opposite direction required for support. Similarly, polyphagous leaf miners on grasses respond positively as expected to foliar nutritional quality, but fertilizer stress has a negative impact on population responses (Scheirs and De Bruyn, 2004).

Without doubt, insect herbivores typically encounter heterogeneous nutritional landscapes while foraging, one largely resulting from the integrated responses of plants to variable environmental conditions (Jones and Coleman, 1991; Louda and Collinge, 1992). In turn, variable nutritional quality is expected to directly influence herbivore fitness and subsequent population fluctuations (Rhoades, 1983; Jones and Coleman, 1991; White, 1993). However, responses by chewing insect herbivores to plant quality are highly variable, with some species responding positively and others negatively or not at all to specific responses (Joern and Behmer, 1997; Fischer and Fielder, 2000). This is especially evident for understanding the dynamic changes in foliar TN and TNC in response to combined stress, which in turn affect subsequent levels of insect herbivory.

Results from our study with grasshoppers are consistent with others that examine free-living, chewing insects. Reviews of the plant stress hypothesis indicate that under continuous stress, most insect herbivore guilds either are negatively impacted or do not respond to plant stress (Watt, 1992; Koricheva et al., 1998). The best current model (Huberty and Denno, 2004) may be the "pulsed plant stress hypothesis" in which foliar nutrients accumulating from stress conditions only become available to herbivores, especially sap feeders, as plants recover from stress. Still, many other insect herbivore guilds are not explained.

Nutritional quality of host plants generally affects performance by grasshoppers, as documented by laboratory and field studies (Joern and Behmer, 1997; Simpson and Raubenheimer, 2001). Why does the plant-stress hypothesis not explain responses by free-living chewing insects, such as grasshoppers, despite the appealing logic inherent in the formulation of plant stress hypothesis? A combination of multiple factors might explain. It may not be possible to directly relate performance to stress treatments because of intervening pathways that interact in unknown ways. (1) Grasshoppers perform best on a diet that is balanced between protein and carbohydrates; as nutritional ratios deviate from the target, performance drops as well. Stressed plants may have elevated foliar protein that is not always in balance with carbohydrates. (2) Grasshoppers can compensate for poor-quality food by altering diets (Simpson and Abisgold, 1985) or by modifying retention time in the gut (Yang and Joern, 1994), a response that could affect nutrient acquisition and insect performance in a nonlinear fashion. Lack of response to stress may actually be "hidden" because of such physiological adjustments. (3) As observed in this study, chemical responses in *B. gracilis* leaves to stress treatment combinations are highly variable, making it particularly difficult to predict performance. Response by grasshoppers may best fit predictions of Price's (1991) "plant vigor hypothesis",

which argues for elevated insect herbivore performance on tissues in actively photosynthesizing tissue; this may allow for a wider range of combinations of protein and carbohydrate. It is noteworthy that TNC and TN concentrations among leaf samples were uncorrelated (unpublished data), making it particularly difficult for grasshoppers to use simple phagostimulatory cues to select balanced diets. (4) Effects of stresses themselves to plants are multifactorial (water, temperature, trampling, N addition, herbivory) such that the expected effects on grasshoppers are not predicted by simple plant stress models; Jones and Coleman (1991) provide a basis for a more comprehensive model. Ultimately, some combination of each of the above and other factors influencing foraging by free-living grasshoppers will determine the relative contribution of plant stress to performance in combination with other factors.

It is important to resolve the ability to relate insect herbivore response to plant stress. Historically, forecasts of insect pest outbreaks including grasshoppers often assume that insect populations do better under hot/dry weather conditions because of better food quality (Rhoades, 1983; Mattson and Haack, 1987). This weather-induced link between plant stress and insect performance is often circumstantial at best (Huberty and Denno, 2004) and remains to be vetted carefully before it is recognized as a key mechanism underlying insect outbreaks. However, it is also true that many experimental studies, including those with grasshoppers, implicate elevated host plant quality as an important determinant of insect performance and population responses in the field. Alternate explanations that include multiple factors (Belovsky and Joern, 1995) or incorporate more sophisticated views of nutritional contributions and environmental influences on observed population variability (Simpson and Raubenheimer, 2001) must be developed to fill the void left by the inability of the plant stress hypothesis to explain natural patterns.

Acknowledgments—Logistical support from Cedar Point Biological Station is gratefully acknowledged. M. Thomas, M. Zeisset, C. Holtmeier, S. Behmer, Y. Yang, and L. Kang provided help in the field. Y. Chen, T. Minnick, M. Thomas, L. Snyder, and M. Zeisset helped analyze plant samples. B. Danner and K. Stoner provided comments on the manuscript. Research was supported by USDA/NRI and the National Science Foundation.

Abstract—Butterfly caterpillars in the lycaenid subfamily Miletinae are predators of ant-tended Homoptera, yet they lack specialized secretory and call-production organs crucial to ant association in other lycaenids. Here, we address the question of how miletine caterpillars have invaded the ant–Homoptera symbiosis through a study of the only New World miletine, *Feniseca tarquinius*, a predator of the wooly aphid *Prociphilus tesselatus*. Previous interpretations have suggested that *F. tarquinius* and other miletine caterpillars avoid ant aggression by concealing themselves under silken webs. In contrast, our field data indicate that *F. tarquinius* caterpillars are less likely to be concealed in the presence of the ants *Camponotus pennsylvanicus* and *Formica obscuriventris* than in the absence of ants, although caterpillar and ant behaviors vary between years. Chemical analysis and behavioral assays suggest that chemical camouflage, not physical concealment, is responsible for the ants' failure to detect and remove *F. tarquinius* caterpillars from aphid colonies. Analyses by gas chromatography indicate that the cuticular lipid composition of caterpillars are similar to that of their aphid prey, although it varies with prey species. Behavioral assays confirm that solvent extracts of *F. tarquinius* caterpillars and *P. tesselatus* aphids evoke similar behavioral responses in *C. pennsylvanicus* ants. Chemical camouflage is well known in social parasites

of ants, but the present study represents one of a few documented cases where chemical deceit is important to interactions with ants outside the nest.

Key Words—Lycaenidae, Miletinae, *Feniseca tarquinius*, chemical camouflage, cuticular hydrocarbons, lycaenid–ant interactions, carnivorous caterpillars, *Camponotus pennsylvanicus*, Eriosomatidae, *Prociphilus tesselatus*.

INTRODUCTION

Caterpillars in the butterfly family Lycaenidae are unique in their propensity to form symbioses with ants. An estimated 6000 species of lycaenids account for nearly 50% of all butterflies, and about 75% of documented lycaenid caterpillars are associated with ants (DeVries, 2001; Pierce et al., 2002). Many lycaenid–ant associations are deemed mutualistic; here, ants protect caterpillars from predators and parasitoids in exchange for food secretions, and caterpillars mediate these symbioses through a suite of secretory and call production organs (Malicky, 1970; Atstatt, 1981; Cottrell, 1984; DeVries, 1988, 1990; Cushman et al., 1994; Pierce et al., 2002). Other lycaenid caterpillars are social parasites that infiltrate ant nests and consume ant brood or food regurgitations (Cottrell, 1984; Pierce, 1995). These caterpillars appear to employ one of two strategies. Some are recognized as intruders but are heavily armored to survive attack; others mimic the cuticular hydrocarbons by which ants recognize their brood and are accepted into the ant nest where they are tended and sometimes fed (Cottrell, 1984; Akino et al., 1999).

In marked contrast to other lycaenid groups, the predominantly Old World subfamily Miletinae has a unique relationship with Homoptera and ants. Miletine adults feed on the honeydew of homopterans, and the caterpillars are predators of the same homopterans, which are also tended by ants for their honeydew excretions (Clark, 1926; Cottrell, 1984). Thus, unlike other lycaenids, miletines compete with ants for homopteran resources (Cottrell, 1984; Maschwitz et al., 1988). All miletine caterpillars lack the secretory organs considered crucial to myrmecophily, and they are not exceptionally well armored (Cottrell, 1984). This raises the question of how miletines have invaded the ant–homopteran symbiosis, and how ants affect miletine fitness.

Our understanding of miletine–ant interactions is drawn from largely anecdotal evidence. Miletine caterpillars are often concealed under silken webs thought to protect them from aggressive ants (Edwards, 1886; Scudder, 1889; Atstatt, 1981; Cottrell, 1984). It appears that some miletine caterpillars are attractive or neutral to ants or are bitten only in moments of stress; others are known to survive within ant nests, perhaps as social parasites (Cottrell, 1984; Kitching, 1987; Maschwitz et al., 1988; Pierce, 1995). Further evidence is needed to clarify the nature of miletine–ant interactions. Here, we address the

behavioral and chemical ecology of the miletine caterpillar *Feniseca tarquinius* (Fabricius) and the ants that tend its aphid prey.

F. tarquinius is the only known miletine in the New World and is the sole representative of the genus. It is widespread in eastern North America and feeds predominantly on wooly alder aphids, *Prociphilus tesselatus* (Fitch), that are facultatively tended by various formicine, dolichoderine, and myrmicine ants (Scudder, 1889; Clark, 1926; Holldobler and Wilson, 1990; Youngsteadt, personal observations). Like other miletine caterpillars, *F. tarquinius* often conceals itself under a silken web covered with carcasses and "wool" of its aphid prey. A series of field and garden observations in the late 1800s gave rise to the prevailing hypothesis that physical concealment is crucial to survival of *F. tarquinius* caterpillars among ants (Edwards, 1886; Scudder, 1889).

Observations presented here suggest that physical concealment is not a defense against ants, but support the alternative hypothesis that *F. tarquinius* caterpillars are chemically concealed among their prey. Chemical mimicry and camouflage have been documented among taxonomically diverse nest parasites of social insects. Such parasites infiltrate their host's nestmate recognition system by bearing cuticular hydrocarbons similar to those of the host (reviewed in Holldobler and Wilson, 1990; see also Howard et al., 1990; Akino et al., 1996, 1999; Allan et al., 2002). Chemical similarity is deemed mimicry if a parasite synthesizes host-like hydrocarbons or camouflage if the parasite incorporates host-synthesized hydrocarbons into its own cuticle (Howard et al., 1990; but see alternative definitions in Dettner and Liepert, 1994). The mechanism by which camouflaged insects incorporate host hydrocarbons into their cuticles probably varies among species. One mechanism, implied or demonstrated in various insect–insect interactions, is passive transfer of hydrocarbons by physical contact (e.g., Vander Meer and Wojcik, 1982; Akino et al., 1996; Liang and Silverman, 2000).

Ants may also defend resources outside the nest, such as homopterans and extrafloral nectaries (Way, 1963; Holldobler and Wilson, 1990; Huxley and Cutler, 1991). Other insects invade these symbioses as competitors and circumvent ant defenses by various means (e.g., Eisner et al., 1978; DeVries and Baker, 1989; Liepert and Dettner, 1993, 1996). However, with the exception of one aphid parasitoid that evades ant aggression by chemical resemblance of its host aphids (Liepert and Dettner, 1993, 1996), the role of cuticular hydrocarbons in competitive interactions with ants outside the nest has received little attention. The present study of *Feniseca*–ant interactions offers further evidence for the role of chemical deceit in the exploitation of ant-tended resources outside the nest.

Here, we examine aspects of the *Feniseca*–ant interaction through field observations, chemical analyses, and behavioral assays that address two questions. First, is caterpillar physical concealment a defense against ants?

Second, is chemical camouflage responsible for the ants' apparent inability to perceive *Feniseca* caterpillars?

METHODS AND MATERIALS

Field Observations. To characterize the *Feniseca*–ant interaction, field observations were made on *F. tarquinius* caterpillars during August and September 2001, and July through September 2002, at two study areas in southeast Wisconsin (USA). At one site, the carpenter ant *Camponotus pennsylvanicus* (DeGeer) was the predominant species tending *P. tesselatus* aphids; at the other, *Formica montana* Emery and *F. obscuriventris* Mayr dominated. Ants were identified by using Creighton (1950), and voucher specimens are housed in Youngsteadt's collection.

In 2001, caterpillars were censused daily on all known aphid colonies and the following data were recorded: species and number of ants present on the host aphid colony, dimensions of the aphid colony, caterpillar instar, and presence or absence of a silken web over the caterpillar. Direct caterpillar–ant interactions and caterpillar disappearance were also recorded. Caterpillars develop over four instars, each 2–5 days in duration, before dropping from the aphid colony and wandering to a pupation site on other vegetation (Scudder, 1889; Youngsteadt, personal observations). Therefore, disappearance of a caterpillar prior to the second day of its fourth instar was attributed to death; later disappearance was attributed to pupation.

In 2002, censuses were conducted weekly, so fates of individual caterpillars were not followed; all other variables were recorded as in 2001. Survey intervals made it unlikely that an individual caterpillar was recorded repeatedly and certainly never more than once in a given instar.

Dependence of concealment behavior on presence and species of ants was evaluated by using a series of Fisher's exact tests (Sokal and Rohlf, 1981), in which, for each caterpillar instar, behavior in the presence of each ant species was compared with behavior in the absence of ants. Hence, up to three comparisons were performed per instar. Resultant P values were subjected to Bonferroni corrections to reflect family-wise type II error rates within each instar. Site effects were not considered in the analysis of concealment behavior because the entire study area was composed of similar habitat, caterpillar behavior varied between ant species within a site, and caterpillars at nontended colonies behaved the same way at both sites. Pupation rate was also tested for ant dependence with a Fisher's exact test (Sokal and Rohlf, 1981). A Mann–Whitney U-test compared ant density on aphid colonies between 2001 and 2002 (Sokal and Rohlf, 1981).

Chemical Analysis. Cuticular lipid composition of *F. tarquinius* caterpillars was compared to that of ants and aphids to evaluate whether chemical similarity to another species played a role in ants accepting caterpillars on aphid colonies. When results indicated that caterpillar surface lipid composition was similar to that of *P. tesselatus*, caterpillars were also reared on a novel aphid host to test whether caterpillars were true *P. tesselatus* mimics or whether they were camouflaged with surface lipids acquired from the host. Live specimens of *P. tesselatus*, *F. tarquinius*, *F. montana*, and *F. obscuriventris* were collected, frozen, and immediately stored at −80°C until analysis.

For the mimicry vs. camouflage experiment, five *F. tarquinius* caterpillars were reared from the second instar on an unidentified dogwood aphid species (Aphididae). Well into the fourth instar, caterpillars and their dogwood aphid hosts were killed and stored as above.

To extract cuticular lipids, insects (1 caterpillar, 5 ants, 7 *P. tesselatus*, or 60 dogwood aphids per extract) were placed in a 10 ml borosilicate conical bottomed screw-cap centrifuge tube and immersed in two sequential 3 ml hexane washes for 2.5 min each. The two washes were combined and spiked with 7.5 μg each of *n*-tricosane ($C_{23}H_{48}$) and *n*-dotriacontane ($C_{32}H_{66}$) as internal standards. The extract was concentrated to dryness under a gentle stream of N_2 and resuspended in 30 μl hexane. Periodically, a hexane blank including internal standards was prepared by the same method to confirm absence of contamination.

Extracts were analyzed by gas–liquid chromatography (GC). The gas chromatograph was a Hewlett-Packard 5890-II equipped with flame ionization detector and HP 3396-II integrator. Injection was split, with a split ratio of 129:1; injections were manual, 1.5 μl. The column was a fused silica capillary column (30 m × 0.32 mm) with a 1-μm DB-1 stationary phase. Helium was the carrier gas at a flow of 0.5 ml/min. Programmed conditions were as follows: injection port 280°C, FID 320°C, oven at 80°C 1 min, ramp at 10°C/min, 310°C for 30 min.

Components were distinguished by retention times. Bray–Curtis similarities, computed with fourth root transformed relative abundances of 42 components, were used to compare lipid profiles. The similarity matrix of pairwise comparisons among all samples was represented in a nonmetric multidimensional scaling ordination plot and analyzed in the statistical package Primer Version 5. Clarke (1993) and Elmes et al. (2002) discussed these methods. Included in the analysis were 5 extracts each of *P. tesselatus* and *F. tarquinius*, 3 extracts each of *F. montana*, dogwood aphids, and *F. tarquinius* reared on dogwood aphids, and 2 extracts of *F. obscuriventris*. Total cuticular lipids were considered, and these may include, in addition to hydrocarbons, other lipid classes not specifically implicated in ant recognition systems (Singer, 1998; Lahav et al., 1999).

To describe robust patterns of peak presence and absence underlying the mathematical similarities between caterpillars and aphids, we prepared a reduced dataset that included only those components that were present in all individuals of at least two species, or that were present in all individuals of at least one species but absent in all individuals of at least one other species. Excluded from this dataset were components that were variable in all species, present in one species but variable in all others, or absent in one or more species but variable in others. The remaining "indicator peaks" form the basis for descriptive statements about patterns of peak presence and absence.

Behavioral Assays. To test for behavioral relevance of the hexane extracts analyzed by GC, comparable extracts were offered to workers from three different *C. pennsylvanicus* colonies in the context of *P. tesselatus* colonies during September 2002. Extracts and blanks were prepared as described above, excluding the internal standards. Except for ants and aphids (as above), each extract was of a single insect. Solvent blanks ($N = 5$) and extracts of the following insects were offered: *Formica ulkei* Emery ($N = 7$ extracts); *P. tesselatus* ($N = 6$); adults of the aphid predator *Harmonia axyridis* (Pallas) (Coleoptera: Coccinelidae) ($N = 4$); and fourth instar *F. tarquinius* caterpillars ($N = 6$).

In the field, filter paper disks (5-mm diam) were treated with 30-μl insect extract (i.e., equivalent of 1 caterpillar, 1 beetle, 5 ants, or 7 aphids) or pure hexane, allowed to dry, then pinned onto the alder adjacent to the tended aphid colony. A single experimental set consisted of a blank and a series of the 4 extracts, or a subset thereof, in variable haphazard order. If conditions allowed for a second set to be presented immediately to the same ants, it was presented in reverse order to the previous series. Ant response to each extract was recorded for 20 min. Total number of ants present was recorded, along with the number of each of the following behaviors: lunge bite, bite, open-jawed lunge, open jawed inspection, closed-jawed inspection, ignore. Repeated instances of the same behavior were recorded when an ant discontinued, then reestablished physical contact with the disk. An encounter was scored as "ignore" if an ant made antennal contact with the disk in passing, but did not maintain contact or show observable change in behavior or orientation.

For analysis, behaviors were pooled as either aggressive or nonaggressive, and ant response to each extract or blank was quantified in two ways: proportion of aggressive acts out of total number of encounters and number of aggressive acts per ant per minute. Ant response to blanks and extracts was compared using two Kruskal–Wallis tests—one for proportional aggression and one for absolute aggression (Sokal and Rohlf, 1981). Transformation of proportion data was not necessary in this case (Zar, 1999). To test for qualitative differences in ant aggression toward different extracts and blanks, aggression was subdivided into its four component categories. Using a logistic regression model in the SAS

system proc genmod, extracts and blanks were tested for differences in the likelihood of eliciting each category of aggressive behavior.

Caterpillar Morphology. To determine whether the setae of *F. tarquinius* caterpillars are modified in such a way as to enhance collection or dissemination of semiochemicals, we preserved field-collected fourth instar *F. tarquinius* in 80% EtOH and examined them under a scanning electron microscope.

RESULTS

Field Observations. Table 1 presents frequencies of caterpillar concealment in 2001 and 2002. In 2001, behavior of second through fourth instar *F. tarquinius* caterpillars appeared to depend on the presence and species of ant: caterpillars were concealed less often in the presence of *C. pennsylvanicus* and *F. obscuriventris* than *F. montana* or no ants. First instar caterpillars showed a similar trend. In 2002, this effect was marginally significant only for third instars. Other caterpillars were predominantly concealed regardless of ants. However, density of attendant *C. pennsylvanicus* differed significantly among years (Figure 1). Ants tended *P. tesselatus* colonies at a consistently higher density in 2001, but this was lower and more sporadic in 2002.

Caterpillar survival data were available only for one site in 2001. Here, 54% of caterpillars on nontended aphid colonies disappeared prior to pupation, whereas only 35% of those on *C. pennsylvanicus*-tended colonies disappeared. Pupation among treatments did not differ significantly ($P = 0.472$, $N = 13$ for nontended colonies, 20 for tended colonies).

Few direct caterpillar–ant interactions were observed: ants generally ignored caterpillars or tapped them with their antennae before moving away. On one occasion, when a tended aphid colony was disrupted by the observer bumping a branch, a *C. pennsylvanicus* bit a third instar caterpillar and dropped it from the colony. However, the caterpillar remained suspended on a thread and returned to the colony unharmed and without further incident. Once a *C. pennsylvanicus* ant was observed to kill and consume a freshly pupated *F. tarquinius* that had anchored itself on a vine entwined with a tended aphid-infested alder.

Chemical Analysis. Representative chromatograms are shown in Figure 2. Mean Bray–Curtis pairwise similarities (Table 2) indicate that cuticular lipid similarity was higher within species (77–90%) than between any pair of species (41–76%). Of the between-species comparisons, two similarities were unusually large: that between *P. tesselatus* and "normal" *F. tarquinius* that had eaten *P. tesselatus* (76%) and that between "normal" *F. tarquinius* and *F. tarquinius* that ate dogwood aphids (71%). All other between-species comparisons,

TABLE 1. FREQUENCY OF CATERPILLAR CONCEALMENT ON APHID COLONIES IN THE ABSENCE OR PRESENCE OF EACH OF THREE ANT SPECIES

Ant species	*N*	Percentage of caterpillars concealed (%)	*P* (two-tailed)
Year: 2001 (caterpillars censused on 29 aphid colonies)			
Fourth instar			
C. pennsylvanicus	12	0	<0.001

Probabilities are shown for pairwise comparison of each ant species to "no ants" (Fisher's exact test with Bonferroni correction). No data are presented for *F. obscuriventris* in 2002 because no aphids established near the one known *F. obscuriventris* nest.
ns = Not significant.

including those between caterpillars and ants, yielded similarities ≤57%. The nonmetric MDS ordination plot (Figure 3) discriminates among species. Analysis of similarities (ANOSIM) is typically used to test for significance of MDS groupings (Clarke, 1993). The global ANOSIM test was significant for this

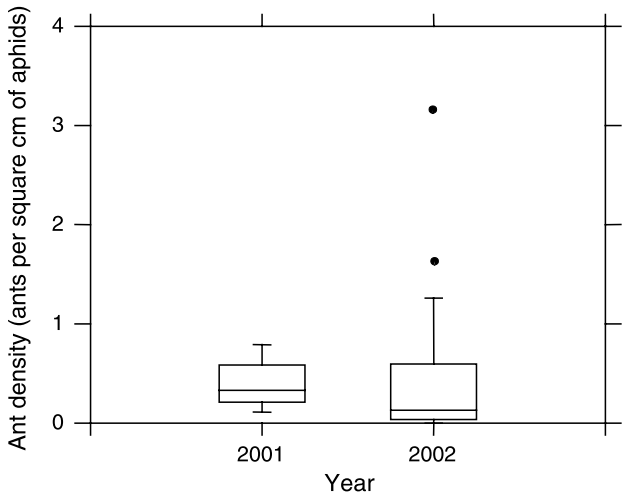

FIG. 1. Density of attendant *C. pennsylvanicus* ants on *P. tesselatus* aphid colonies in 2001 and 2002 based on 32 and 40 measurements, respectively. Mann–Whitney U = 859.0, P = 0.013. Each box encompasses the midrange; central horizontal line is the median; whiskers extend to furthest data points within 1.5 midranges of q1 and q3. Data points further dispersed are indicated by dots.

dataset (R = 0.97, P = 0.001), but sample sizes were too small for valid pairwise comparisons between species.

The "indicator peaks" found in *P. tesselatus*, "normal" *F. tarquinius*, dogwood aphids, and *F. tarquinius* that ate dogwood aphids are presented in Table 3. *P. tesselatus* and "normal" *F. tarquinius* have 15 indicator peaks in common, five of which are unique to this pair; they differ by only three. Of these three, two are present in *F. tarquinius* but not in *P. tesselatus*, whereas one is present in *P. tesselatus* but not in *F. tarquinius*.

All peaks present on *F. tarquinius* caterpillars that ate dogwood aphids were a subset of those found on "normal" *F. tarquinius*—including the two peaks absent in *P. tesselatus* aphids. On the other hand, "normal" *F. tarquinius* had five additional peaks not found in *F. tarquinius* that ate dogwood aphids, and all of these were shared with *P. tesselatus*. Peak 15 was notably more abundant in both caterpillar groups than in either aphid species.

Dogwood aphids had a simple lipid profile that included 10 indicator peaks. Two of these were absent from *F. tarquinius* that ate dogwood aphids. Six peaks were common to dogwood aphids and caterpillars that ate them, but were not unique to this pair, and three of these differed markedly and consistently in abundance. Finally, *Feniseca* that ate dogwood aphids had three

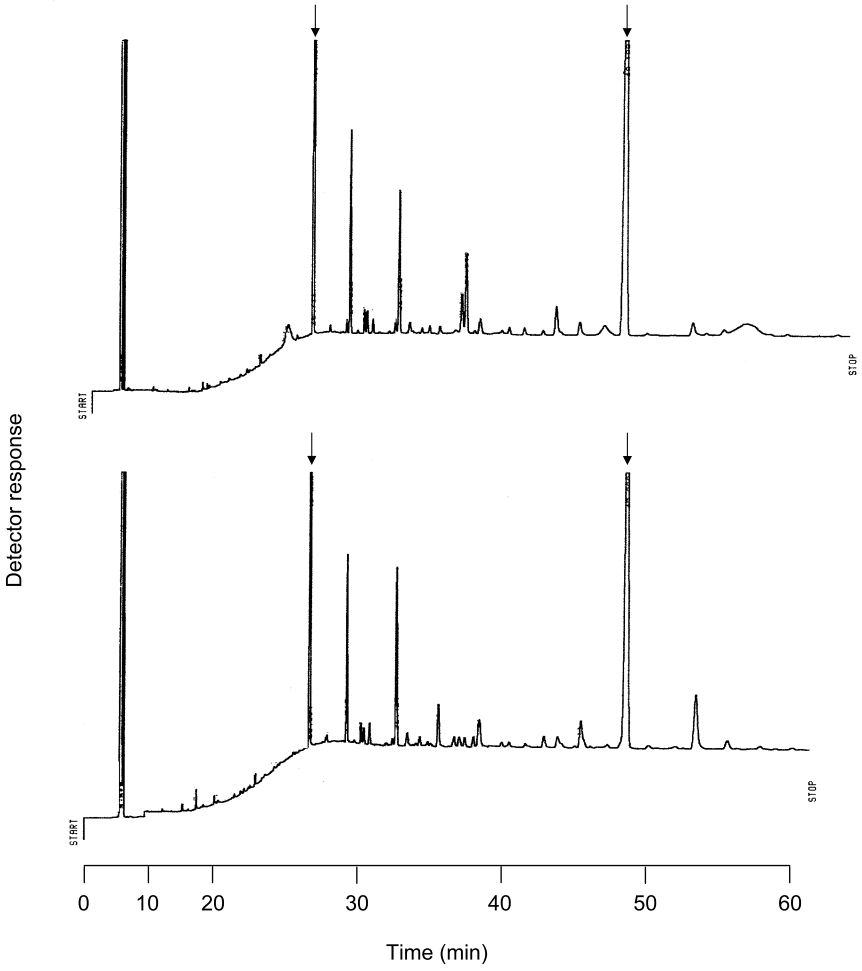

FIG. 2. Gas chromatograms of hexane extract of cuticles of fourth instar *F. tarquinius* caterpillar (top) and adult *P. tesselatus* aphids (bottom). Internal standards n-C_{23} and n-C_{32} are indicated by arrows.

peaks that were absent from those aphids, but which also occurred in normal *F. tarquinius*.

Although the *F. tarquinius* lipid profile varied with diet, the amount of lipids extracted did not differ between the two groups of caterpillars. Total cuticular lipids recovered per caterpillar were 4.73 ± 1.058 μg (mean ± SD) for normal caterpillars and 5.45 ± 0.433 μg for caterpillars reared on dogwood aphids (N = 8 and 5, respectively).

TABLE 2. MEAN BRAY–CURTIS PERCENT SIMILARITIES ± SDS WITHIN AND BETWEEN SPECIES IN THE *Feniseca* SYSTEM BASED ON 42 CUTICULAR LIPID COMPONENTS

	Pt	Ft	FD	DA	Fm	Fo
Pt	89.5 ± 4.9 (10)					
Ft	76.1 ± 4.3 (25)	86.9 ± 4.8 (10)				
FD	53.4 ± 4.3 (15)	70.5 ± 3.2 (15)	76.9 ± 9.5 (3)			
DA	52.8 ± 3.6 (15)	54.6 ± 6.9 (15)	57.2 ± 6.2 (9)	85.0 ± 2.5 (3)		
Fm	40.8 ± 3.0 (15)	53.3 ± 2.6 (15)	54.5 ± 4.4 (9)	43.1 ± 5.8 (9)	85.5 ± 4.8 (3)	
Fo	51.8 ± 3.0 (10)	51.8 ± 2.2 (10)	52.4 ± 3.1 (6)	49.3 ± 2.4 (6)	41.6 ± 5.5 (6)	77.8 (1)

Numbers of pairs are reported in parentheses.
Pt, *P. tesselatus* aphids; Ft, *F. tarquinius* caterpillars reared on *P. tesselatus*; FD, *F. tarquinius* reared on dogwood aphids; DA, dogwood aphids; Fm, *F. montana* ants; Fo, *F. obscuriventris* ants.

Behavioral Assays. Ant response to filter papers treated with solvent and insect extracts is shown in Figure 4, as proportion of aggressive acts. The absolute aggression measure yielded an identical pattern (Kruskal–Wallis test statistic = 18.89, $P < 0.001$; Bonferroni–Dunn *post hoc* test results were also exactly as described for relative aggression in Figure 4). *C. pennsylvanicus*

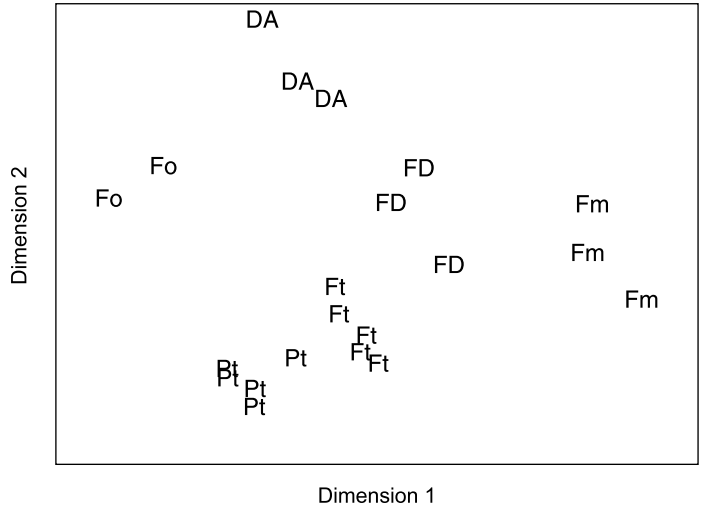

FIG. 3. Two-dimensional nonmetric multidimensional scaling ordination of 21 samples, derived from Bray–Curtis similarities between each pair of samples (stress = 0.13). Species are *P. tesselatus* aphids (Pt), *F. tarquinius* caterpillars reared on *P. tesselatus* (Ft), *F. tarquinius* reared on dogwood aphids (FD), dogwood aphids (DA), *F. montana* ants (Fm), and *F. obscuriventris* ants (Fo).

22	52.51	x	x	x	(v)
23	56.31	0	0	x	0

Pt, *P. tesselatus* aphids; Ft, *F. tarquinius* caterpillars reared on *P. tesselatus*; DA, dogwood aphids; FD, *F. tarquinius* reared on dogwood aphids. x indicates presence of a peak in all individuals of a "species", 0 indicates absence of a peak in all individuals of a species, and (v) indicates variability: the peak is present in some but not all individuals of the species.

workers were continuously hostile toward extracts of other ants and the aphid predator *H. axyridis*. Ants were initially aggressive toward caterpillar and aphid extracts and blanks—it was impossible to introduce samples onto aphid colonies without ants responding to the intrusion—but they quickly accepted the samples and did not display further aggression.

Ant response did not depend on the order in which extracts were offered. A Kruskal–Wallis test with position, rather than extract identity, as the grouping variable was not significant, and we observed that ant response to a given extract was consistent regardless of when it was presented relative to other extracts. Differences in aggression toward extracts and blanks were quantitative, not qualitative. Extracts and blanks did not differ in the likelihood of eliciting the four categories of aggressive behaviors (uncorrected P values ≥ 0.7 for all 10 comparisons between extracts and blanks).

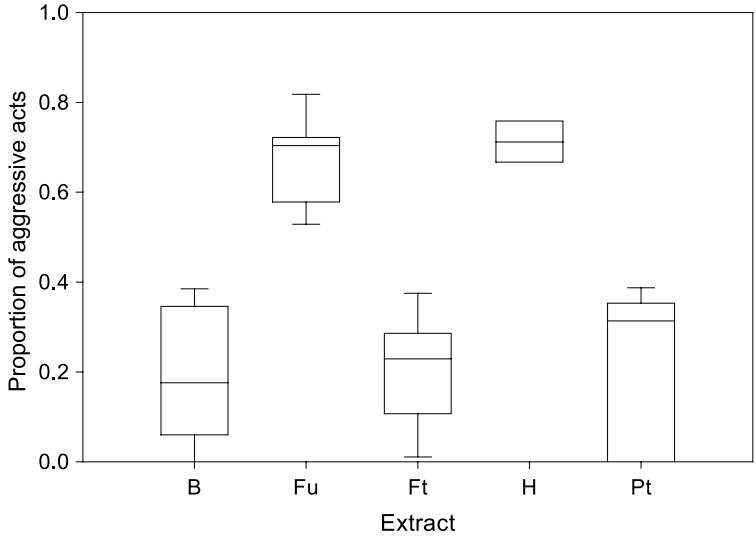

FIG. 4. *C. pennsylvanicus* response to filter paper dummies introduced to tended *P. tesselatus* aphid colonies. *Y*-axis indicates proportion of aggressive acts out of total number of encounters. Dummies were treated with solvent blank (B) or extract of one of the following insects: *F. ulkei* ants (Fu), *F. tarquinius* caterpillars reared on *P. tesselatus* aphids (Ft), *H. axyridis* beetles (H), or *P. tesselatus* (Pt). Median, box, and whiskers are as in Figure 1. Kruskal–Wallis test statistic = 19.623, $P < 0.001$. Bonferroni–Dunn *post hoc* comparisons confirmed that ant response to both *F. ulkei* and *H. axyridis* differed from response to each of the other three extracts ($P < 0.001$ for those six comparisons, ns for all others).

Caterpillar Morphology. Typical body setae of a fourth instar *F. tarquinius* caterpillar are shown in Figure 5. These setae are simple, resembling ordinary tactile and defensive body setae found in a wide range of nonmyrmecophilous lycaenid caterpillars (DeVries 1997, unpublished data).

DISCUSSION

Effects of Ants on Caterpillars. Given the prevailing notion that ants select for concealment behavior in *F. tarquinius* caterpillars (Edwards, 1886; Scudder, 1889; Atstatt, 1981; Cottrell, 1984), it was surprising to observe the reverse pattern in the field in 2001 (Table 1). It is tempting to speculate that concealment protects caterpillars from natural enemies, a function performed by ants when they are present. It is unclear why *F. montana* had no effect on

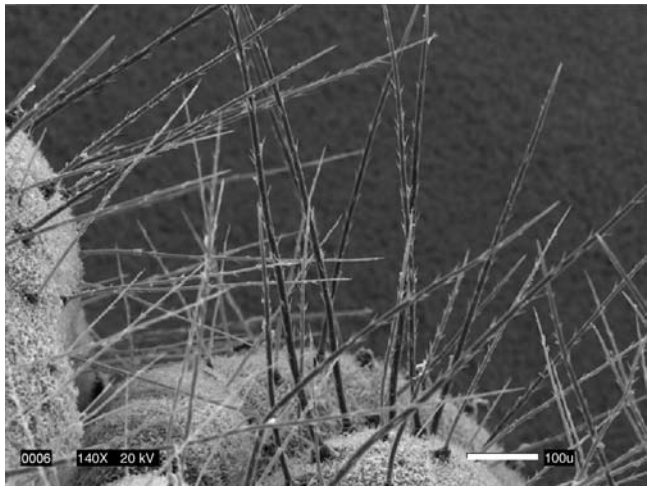

FIG. 5. Scanning electron micrograph of dorsolateral setae on the third thoracic (left) and first abdominal (right) segments of a fourth instar *F. tarquinius* caterpillar.

caterpillar concealment, but it may relate to interspecific differences in ant behavior. Although ant behavior was not quantified, it appeared that, relative to the other two species, *F. montana* had a higher rate of worker turnover on aphid colonies, was less likely to assume defensive posture, and more likely to move away or drop off the plant when disturbed. If these characteristics made *F. montana* less likely to deter intruders from aphid colonies, caterpillar behavior was consistent with the interpretation that caterpillars are concealed when not defended, albeit inadvertently, by ants. Similarly, low and sporadic density of *C. pennsylvanicus* in 2002 may have decreased its protective value and contributed to more universal caterpillar concealment that year.

In 2002, we reproduced the alder–wooly aphid system in a screened experimental garden. Alders were paired, and *C. pennsylvanicus* ants were allowed to tend aphids on one tree in each pair. Paired caterpillars were introduced to aphid colonies on paired trees. In this experiment, there was no effect of *C. pennsylvanicus* on *F. tarquinius* caterpillar growth rate, survival, or behavior. Thus, we found no evidence, in the field or garden, that ants were a threat to *F. tarquinius* caterpillars. Our suggestion that aggressive ants tending *P. tesselatus* colonies also defend resident caterpillars is speculative, but suggests testable hypotheses about interactions in the *Feniseca* system. Although the causes and cues for caterpillar concealment remain unknown, our observations indicate that ants are not aggressive toward *F. tarquinius* caterpillars and suggest that caterpillar concealment is not a defense against ants.

Chemical Resemblance Between Caterpillars and Aphids. Cuticular lipid analysis suggests a mechanism by which *F. tarquinius* invades the ant–aphid mutualism. The 76% similarity in lipid composition between *F. tarquinius* and *P. tesselatus* (Table 2) is comparable to the hydrocarbon similarity between another well-documented chemical mimicry pair. The cuticular hydrocarbon composition of the socially parasitic lycaenid caterpillar *Maculinea rebeli* is 72% similar to that of its host ant *Myrmica schencki* when similarity is calculated by the same methods used here; this level of similarity is adequate to maintain peaceful host–parasite relations within the host ant colony (Elmes et al., 2002). It seems plausible that *Feniseca–Prociphilus* similarity is also adequate to deceive ants. It is important to note that, although only hydrocarbons are specifically implicated in ant recognition systems (Singer, 1998; Lahav et al., 1999), and only hydrocarbons were considered in the case of *Maculinea*, the present study considers total cuticular lipids. Separation and identification of the hydrocarbon fraction from the total lipid extract remain for future studies of the *Feniseca* system.

Caterpillars could invade aphid resources by resembling ants, rather than aphids. However, our data do not support this scenario. Resemblance between *F. tarquinius* caterpillars and attendant ant species was ≤55%, compared to 76% similarity between caterpillars and *P. tesselatus*. Resemblance to a specific ant species would limit caterpillars to aphid colonies tended exclusively by that species. On the other hand, resemblance to the host aphids should allow caterpillars to feed on aphid colonies tended by any ant species. The latter ant–generalist strategy could explain why *F. tarquinius* coexists with many ant species across its geographic range and also with different ant species that tend the same aphid colonies at different times of day.

Behavioral assays confirmed that cuticular extracts contained behaviorally relevant information for *C. pennsylvanicus* tending *P. tesselatus* colonies. Ants responded to extracts of potential competitors for aphid resources, *F. ulkei* and *H. axyridis*, with high levels of both absolute and relative aggression (Figure 4). They responded to blanks and extracts of *P. tesselatus* with significantly lower levels of aggression. Notably, ants responded to *F. tarquinius* extract as they did to the chemically similar aphid extract, not as they did to the extracts of other competitors, suggesting that ants did not recognize *F. tarquinius* caterpillars as aphid predators. Although trace volatiles may have been present in cuticular extracts (as in Allan et al., 2002), our results support the idea that chemicals present on the caterpillar cuticle can account for low levels of ant aggression toward *F. tarquinius* compared to other insects that might "trespass" on an aphid colony.

Camouflage vs. Mimicry. Rearing experiments suggested that the *Feniseca–Prociphilus* resemblance was due to chemical camouflage, not mimicry. In this study, caterpillars reared on dogwood aphids lost their resemblance

to *Prociphilus*, a result consistent with camouflage. They did not, however, acquire a resemblance to dogwood aphids. Because caterpillars might acquire camouflage when aphid lipids rub off on them through physical contact, we suspect that this result was because of aphid size. Dogwood aphids are minute relative to *Prociphilus*, and feeding caterpillars had relatively little bodily contact with them, whereas caterpillars feeding on *Prociphilus* had constant and abundant bodily contact with their prey. Thus, dogwood aphid lipids would be unlikely to rub off on feeding caterpillars, which would, therefore, display only *Feniseca*'s native lipids. Caterpillars feeding on larger *Prociphilus* would still produce their native lipids, but additional lipids acquired from prey would alter the total lipid profile.

This interpretation is consistent with the pattern of similarities among caterpillars and aphids (Table 2 and Figure 3) where *Prociphilus*-reared caterpillars appeared intermediate between the lipid profile of their prey and that of putatively unaltered caterpillars (i.e., those reared on dogwood aphids). This pattern is also reflected in the presence and absence of "indicator peaks" (Table 3), which provide no evidence that *Feniseca* that fed on dogwood aphids (henceforth "dogwood *Feniseca*") acquired lipids from its prey. Dogwood aphids had few unique components that could serve as "labels" for tracing lipid transfer. However, the many disparities between the simple lipid profiles of dogwood aphids and dogwood *Feniseca* do not suggest hydrocarbon acquisition. The indicator peaks of normal *Feniseca* are the sum of those present on dogwood *Feniseca* and *Prociphilus*, also consistent with our suggestion that the lipid profile of normal *Feniseca* is the result of both biosynthesis and acquisition. However, to appreciate the significance of specific differences between species, chemical identifications are necessary. For instance, it is important to know whether the caterpillar-specific peaks (peaks 2 and 10, Table 3) were nonhydrocarbons or other chemicals unlikely to influence ant behavior.

Our results support the camouflage hypothesis and a hydrocarbon rub-off mechanism, but cannot exclude the possibility that observed differences in caterpillar lipid profiles were due to diet-induced shifts in biosynthesis. We can conceive of three approaches that might distinguish between these alternatives. *In vitro* hydrocarbon synthesis experiments could clarify which components are biosynthesized by caterpillars. Alternatively, aphids could be treated with a synthetic hydrocarbon normally absent from the system. If this hydrocarbon appeared unaltered on caterpillar cuticle, the rub-off mechanism would be implicated. Finally, caterpillar internal and external hydrocarbon composition could be compared. Insect cuticular and internal hydrocarbons are generally the same, so if caterpillars had cuticular hydrocarbons that were absent internally, such hydrocarbons were likely acquired by rub-off.

Some myrmecophilous butterfly caterpillars possess ant organs that appear to release semiochemicals that modify ant behavior (DeVries 1988, 1997;

Pierce et al., 2002), and when examined under high magnification, the setae associated with these organs may show flaps and convolutions that could act to disseminate volatile chemistry (DeVries 1997). Our data suggest that chemical camouflage is important to *F. tarquinius* caterpillars, but their setae showed no evidence of increased surface area or abrasive qualities that might aid in acquisition or dispersal of aphid chemistry (Figure 5). That *F. tarquinius* setae resemble the ordinary tactile and defensive body setae of nonmyrmecophilous lycaenid caterpillars is consistent with the mechanism of chemical camouflage by passive, nonspecialized lipid acquisition.

In summary, although the role of physical concealment in *F. tarquinius* caterpillars remains unclear, all evidence from this study points away from ant avoidance. Instead, acquisition of chemical resemblance to the aphid prey appears adequate to defuse ant aggression. Such a relationship admits the possibility that ants could indirectly benefit caterpillars, especially when ants are abundant, pugnacious, and effective at excluding caterpillar enemies from aphid colonies. This study points to the possibility that chemical camouflage occurs among Old World miletines and other aphid predators and may be as common among users of ant-tended resources as it is among social parasites of ant nests.

Acknowledgments—We thank Frank Laib for help with gas chromatography, Dave Kinnamon for access to his property, and Gretchen Meyer and the UWM Field Station for advice, support, and facilities. We acknowledge Samuel Scudder and Henry Edwards for reporting, a century ago, initial observations that inspired this work. (Received February 12, 2005; revised March 24, 2005; accepted April 20, 2005)

Abstract—Dichloromethane extracts of wolverine (*Gulo gulo*, Mustelinae, Mustelidae) anal gland secretion were examined by gas chromatography–mass spectrometry. The secretion composition was complex and variable for the six samples examined: 123 compounds were detected in total, with the number per animal ranging from 45 to 71 compounds. Only six compounds were common to all extracts: 3-methylbutanoic acid, 2-methylbutanoic acid, phenylacetic acid, α-tocopherol, cholesterol, and a compound tentatively identified as 2-methyldecanoic acid. The highly odoriferous thietanes and dithiolanes found in anal gland secretions of some members of the Mustelinae [ferrets, mink, stoats, and weasels (*Mustela* spp.) and zorillas (*Ictonyx* spp.)] were not observed. The composition of the wolverine's anal gland secretion is similar to that of two other members of the Mustelinae, the pine and beech marten (*Martes* spp.).

Key Words—Wolverine, *Gulo gulo*, Mustelinae, Mustelidae, scent marking, fear-defense mechanism, short-chain carboxylic acids.

INTRODUCTION

The wolverine (*Gulo gulo*) is the largest terrestrial member of the Mustelidae and is part of the subfamily, Mustelinae, which includes ferrets, fishers, martens, mink, stoats, weasels, and zorillas. Historically, two species of wolverine have been described, one from North America and the other from

* To whom correspondence should be addressed. E-mail: wfw2@humboldt.edu

Eurasia, but today only one species is recognized (Pasitschniak-Arts and Larivière, 1995). The wolverine, as with most mustelids, possesses paired glands that open on both sides of the anus, which produce a tannish-yellow, highly odoriferous secretion (Hash, 1987). Wolverine anal musking has been described by several authors (Haglund, 1966; Pulliainen and Ovaskainen, 1975; Koehler et al., 1980; Magoun, 1985) as a method of scent marking in addition to marking with feces or urine (Jackson, 1961). Others have suggested that anal gland secretions function primarily as a fear-defense mechanism (Krott, 1959; Ewer, 1973; Long, 1987).

The composition of the anal gland secretion from some members of the subfamily Mustelinae was described in a recent review (Burger, 2005). Odoriferous cyclic sulfides (thietanes and dithiolanes) and in some cases, sulfides, disulfides, and other organosulfur compounds, were found in the secretion from smaller members of this subfamily: American mink, *Mustela vison* (Brinck et al., 1978, 1983; Schildknecht et al., 1976, 1981); ferret, *Mustela putorius* (Crump, 1980b; Crump and Moors, 1985; Schildknecht et al., 1976; Schildknecht and Birkner, 1983); Siberian weasel, *Mustela sibirica* (Zhang et al., 2002, 2003); steppe polecat, *Mustela eversmanni* (Zhang et al., 2002, 2003); stoat, *Mustela erminea* (Brinck et al., 1983; Crump, 1978, 1980a; Crump and Moors, 1985; Schildknecht and Birkner, 1983); weasel, *Mustela nivalis* (Brinck et al., 1983; Buglass et al., 1991; Schildknecht and Birkner, 1983) and zorilla, *Ictonyx striatus* (Apps et al., 1988; Wheeler et al., 1997). These sulfur compounds are absent in anal gland secretion of the two other members of the Mustelinae that have been investigated, the pine marten (*Martes martes*) (Brinck et al., 1983; Schildknecht and Birkner, 1983) and the beech marten (*Martes foina*) (Schildknecht and Birkner, 1983). Schildknecht and Birkner (1983) reported short-chain carboxylic acids from these two species, whereas Brinck et al. (1983) identified benzaldehyde from the pine marten. We investigated the anal gland secretion of the wolverine and report the analysis of volatile components in the secretion.

METHODS AND MATERIALS

Anal glands from four individuals (sex not recorded) were obtained incidental to fur trapping during the winter of 2002–2003 from the Brooks Range in Alaska. These glands were excised from the trapped animals and immediately frozen at −20°C until they could be analyzed. Upon thawing, a 0.25-g sample of the secretion from both glands for each individual was pooled and extracted with 2 ml of CH_2Cl_2. Two additional pooled samples of anal gland secretion from a male and a female were obtained from Glacier National Park, Montana. These samples were kept at −20°C until they were extracted

with CH_2Cl_2 as had been done with the previous samples. Control samples of CH_2Cl_2 were analyzed to identify contaminants in the solvent.

Extracts were analyzed by gas chromatography–mass spectrometry (GC-MS) in splitless mode (0.5 min), using a Hewlett-Packard GCD Plus fitted with a 30 × 0.25-mm HP-5MS column. The GC was programmed from 40°C/4 min, then 30°C/min to 325°C/2 min. Mass spectral fragments below *m*/*z* 39 were not recorded. The relative amount of each component is reported as the percent of the total ion current (TIC). Minor components less than 0.1% of the TIC were not investigated and impurities found in the solvent were subtracted from the analyses.

Compounds were initially identified by comparison of mass spectra to those in the NIST 1998 mass spectral database. All compounds that did not match spectra in the NIST library were examined to see if they matched published spectra of thietanes, dithiolanes, and other organosulfur compounds reported from some members of the Mustelinae (Brinck et al., 1983; Crump, 1980a,b; Crump and Moors, 1985; Schildknecht et al., 1981; Schildknecht and Birkner, 1983; Zhang et al., 2002, 2003). Authentic samples were used to confirm identifications by comparisons of spectra and retention times, except for compounds that were not commercially available or were prepared synthetically (see Table 1). The chirality of compounds containing stereogenic centers was not determined. Reference samples were obtained from Aldrich Chemical Co. (Milwaukee, WI, USA) and Fisher Scientific (Acros, Pittsburgh, PA, USA), except the following, which were synthesized. Isoamyl laurate was prepared by acid-catalyzed reaction of the corresponding alcohol and carboxylic acid. 3-Methyl-dihydro-2(3*H*)furanone was prepared from 3-methyl-2(5*H*)furanone by catalytic hydrogenation with platinum oxide and H_2. 2-Methylpropanamide and 3-methylbutanamide were prepared from 2-methylpropanoic and 3-methylbutanoic acids by treatment with thionyl chloride to form the acid halides and subsequent reaction with ammonia.

RESULTS AND DISCUSSION

The CH_2Cl_2 extracts of the anal gland secretion from the six wolverines showed great variation between individuals. In all, 123 peaks were seen in the chromatograms, with the number per animal ranging from 45 to 71 (Table 1). We identified 49 of the 123 compounds in the extracts by comparison of their retention times and mass spectra with those of authentic samples. The tentative identification of ten additional compounds could not be confirmed because authentic standards were not available.

The secretions had few of these 59 compounds in common—26 of these compounds were observed in only one sample. Only six of the identified

compounds were common to all extracts: 3-methylbutanoic acid, 2-methylbutanoic acid, phenylacetic acid, 2-methyldecanoic acid (tentative identification only), α-tocopherol, and cholesterol. Hexadecanoic, linoleic, and stearic acids, and two tentatively identified compounds [5,6,7,7-tetrahydro-2(4*H*) benzofuran and 1,2-hexadecanediol] were common to five of the extracts. Only pentadecanoic and (*Z*)-9-hexadecenoic acids were common to four of the six samples.

The odoriferous thietanes or dithiolanes found in some other mustelines (*Mustela* spp.) were not observed in wolverine anal gland secretion. The fetid nature of the secretion is due in part to the short-chain carboxylic acids and phenylacetic acid found in all of the samples. Four of the samples contained

small amounts of dimethyl disulfide and/or dimethyl trisulfide, compounds that would also contribute to the odor, and one contained 8.0% of pungent 3-phenylpropanoic acid. All samples contained a large number of relatively nonvolatile components, including free fatty acids and cholesterol. Thus, the chemical composition of the wolverine's anal gland secretion is similar to that of the pine and beech marten (*Martes* spp.). The anal gland secretions from these species were reported to contain short-chain acids and benzaldehyde (Brinck et al., 1983; Schildknecht and Birkner, 1983), but not the cyclic sulfur compounds found in other members of the Mustelinae (ferrets, mink, stoats, weasels, and zorillas). These chemical differences are consistent with recent mitochondrial DNA (Dragoo and Honeycutt, 1997) and nuclear DNA studies (Koepfli and Wayne, 2003) that indicate the wolverine and martens are more closely related to each other than either is to mustelines of the genera *Mustela* or *Ictonyx*.

Mustelinae anal gland composition has been reported as variable, relating to differences in age, sex, and estrous condition (Crump, 1980a,b; Zhang et al., 2002, 2003), and also as relatively stable, not varying for individuals during the year, by sex, or during the reproductive period (Brinck et al., 1978). Similarities in chemical products within species have led to hypotheses regarding species and individual recognition, but the semiochemical function of anal sac secretions remains unclear (Albone, 1984). Future investigations would be benefited by an increased sample of anal gland material from wolverines of known sex, age, and season.

Acknowledgments—We thank Audrey Magoun, Allen Barrette of Fairbanks Fur Tannery, and Tom Seaton of the Alaska Department of Fish & Game for help in obtaining the samples.

(Received November 26, 2004; revised March 28, 2005; accepted May 1, 2005)

Abstract—Blends of abundant cuticular hydrocarbons are species-specific for termites (Isoptera) and can be used to identify a given taxon without the diagnostic castes, soldiers or adults. We demonstrate that hydrocarbon extracts of termite fecal pellets from damaged wood can also be characterized and used to identify termites responsible for damage, even though termites are no longer present or easily recovered. In structures infested by drywood termites, it is common to find fecal pellets, but difficult to extract termites from the finished wood in service. Nine species belonging to two families (Kalotermitidae and Termopsidae) were examined to compare the hydrocarbon composition of termites and their fecal pellets. Diversity was extensive: at least one half of the amount of the hydrocarbons from *Neotermes connexus*, *Incisitermes immigrans*, *Cryptotermes brevis*, *Cryptotermes cynocephalus*, *Procryptotermes corniceps*, and *Zootermopsis nevadensis nuttingi* was olefins. *Incisitermes minor* and *Pterotermes occidentis* incorporated only small amounts of olefins in cuticular hydrocarbons; *Marginitermes hubbardi* had no detectable olefins. Hydrocarbons extracted from fecal pellets were qualitatively and quantitatively similar to cuticular extracts and can be used to determine the termite species responsible without the termites present.

Key Words—Chemotaxonomy, cuticular hydrocarbons, dampwood termites, drywood termites, fecal pellets, frass, Kalotermitidae, Isoptera, species identification, Termopsidae.

INTRODUCTION

The cryptic nature of drywood and dampwood termites often precludes their collection for purposes of identification. Because they make their homes within wood, it is often not possible to collect them without destroying the wooden structure. A commonly utilized sign for determining the presence of wood-inhabiting termites is the associated occurrence of fecal pellets, which are ejected from the galleries inside the wood. These pellets are diagnostic for drywood and dampwood termites and can be used to distinguish their damage from other wood-destroying insects (Ebeling, 1975; Moore, 1992).

Drywood and dampwood termites excrete feces in the form of hard, evenly shaped fecal pellets. While collecting drywood termites in a survey of the termites of the Hawaiian Islands (Haverty et al., 2000; unpublished data), we gathered fecal pellets while removing termites from wood. Rather than simply signaling the general presence of termites, we wondered whether these pellets could be used for more precise diagnosis of the species of termite inhabiting the wood. We hypothesized that termite fecal pellets contain the same mixture of hydrocarbons as the insects that produced them, and because cuticular hydrocarbons are species-specific in termites (Page et al., 2002), we further hypothesized that the species can be identified by these chemicals in their feces.

The cuticle covering the outside surface of the termite also lines the inside of the rectum and likely also has a covering of wax composed mostly of hydrocarbons. Fecal pellets are formed in the elongate, bulbous rectum that is used for the temporary storage of undigested food particles (Child, 1934). Pellets are elongate and have six flattened sides that coincide with the rectal papillae. The six surfaces are a result of pressure applied by the six plates within the rectal epithelium. The hindgut is lined with chitinous intima that is continuous through the anus with the chitinous exoskeleton; the epithelial layer of the rectum is thickened and contains a heavily chitinous intima (Child, 1934).

Fecal pellets must be dehydrated before expulsion; resorption of water represents an essential ecological adaptation for xeric conditions (Noirot and Noirot-Timothée, 1969). The function of the rectum is to press out and conserve the water content of material that enters from the colon. Water is absorbed through the rectal wall. During compression for removal of water, it is likely that pellets acquire a hydrocarbon coating before extrusion. This may facilitate discharge of pellets.

Characterization of the cuticular hydrocarbons of termite species supports the concept of species specificity of hydrocarbon mixtures (Haverty et al., 1988, 1996a, 1997, 1999, 2000; Watson et al., 1989; Kaib et al., 1991; Brown et al.,

1994, 1996; Haverty and Nelson, 1997; Takematsu and Yamaoka, 1999; Clément et al., 2001; Nelson et al., 2001; Page et al., 2002). Owing to the ontogenic origin of the insect hindgut (Snodgrass, 1935; Romoser and Stoffolano, 1988), i.e., invaginated ectoderm, we hypothesized that external (cuticular) hydrocarbons are also present internally and are picked up by expelled fecal material.

METHODS AND MATERIALS

Collection of Termites. Termites were gathered from the British Virgin Islands (Haverty et al., 1997) and the Hawaiian Islands (Haverty et al., 2000). Collections of *Pterotermes occidentis* (Walker) and *Marginitermes hubbardi* (Banks) were made in the vicinity of Tucson, AZ, USA, and collections of *Zootermopsis nevadensis nuttingi* Haverty and Thorne were made near Mt. Shasta, CA, USA. In total, nine species belonging to two families were collected. Representatives of the Kalotermitidae included *Neotermes connexus* Snyder, *Incisitermes immigrans* Snyder, *Cryptotermes brevis* (Walker), *Cryptotermes cynocephalus* Light, *Incisitermes minor* (Hagen), *Procryptotermes corniceps* (Snyder), *P. occidentis*, and *M. hubbardi*; *Z. nevadensis nuttingi* was the sole representative of the Termopsidae.

Naturally infested wood samples were bagged and brought to the laboratory, where termites and fecal pellets were separated from wood and other debris. Samples of 15–20 pseudergates or nymphs were placed in separate vials, frozen, and dried (Haverty et al., 1997, 2000). As soon as the termites were completely dry, specimens were placed in vials that were tightly capped. Fecal pellets were separated from debris by sequentially sifting them through successively smaller sieves. Pellets were separated from fine debris by removing them with forceps or with an aspirator until 3–10 ml were obtained. Concurrently, fresh (i.e., not dried) termite voucher samples were preserved in 85% ethanol and deposited in the National Museum of Natural History, Smithsonian Institution, Washington, DC (Haverty et al., 1997) or in the University of Hawaii, Manoa Campus collection (Haverty et al., 2000).

Extraction Procedure and Characterization of Hydrocarbons. Hydrocarbons from the termites and fecal pellets were extracted, characterized, and quantified as reported in Haverty et al. (1997). Termites, as a group, or 3–10 ml of fecal pellets were extracted by immersion in 10 ml of *n*-hexane for 10 min. After extraction, hydrocarbons were separated from other compounds by pipetting the extract through 4 cm of activated Sigma silica gel (70–230 mesh) in Pasteur pipet minicolumns. An additional 5 ml of clean *n*-hexane were

dripped through the silica gel. The resulting extracts were evaporated to dryness under a stream of nitrogen and redissolved in 60 µl of *n*-hexane for gas chromatography-mass spectrometry (GC-MS) analyses. A 3-µl aliquot was injected into the GS-MS.

GC-MS analyses were performed on a Hewlett-Packard (HP) 5890 gas chromatograph equipped with an HP 5970B Mass Selective Detector interfaced with HP Chemstation data analysis software (HP59974J Rev. 3.1.2). The GC-MS was equipped with an HP-1 fused silica capillary column (25 m × 0.2 mm ID) and operated in split mode (with a split ratio of 8:1). Each mixture was analyzed by a temperature program ranging from 200 to 320°C at 3°C/min with a final hold of 11 or 16 min. Electron impact (EI) mass spectra were obtained at 70 eV.

n-Alkanes were identified by their mass spectra. Mass spectra of methyl-branched alkanes were interpreted as described by Blomquist et al. (1987) to identify methyl branch locations. Mass spectra of di- and trimethylalkanes were interpreted as described by Page et al. (1990a,b) and Pomonis et al. (1978). Alkenes were identified by their mass spectra, but double bond positions were not determined (see Haverty et al., 1997). Equivalent chain lengths (ECL) were calculated for some of the unsaturated compounds to distinguish the various isomers.

In the text and tables, we use shorthand nomenclature to identify individual hydrocarbons or mixtures of hydrocarbons. This shorthand uses a descriptor for the location of methyl groups (X-me), the total number of carbons (CXX) in the hydrocarbon component excluding the methyl branch(es), and the number of double bonds following a colon (CXX:Y). Thus, heptacosane becomes *n*-C27; 2-methylheptacosane becomes 2-meC27; 13,15-dimethylheptacosane becomes 13,15-dimeC27; and heptacosadiene becomes C27:2. Hydrocarbons are presented in the tables for each species and its feces in the order of elution on our GC/MS system.

Integration of the total ion chromatogram was performed using the HP Chemstation data analysis software. GC-MS peak areas were converted to percentages of the total hydrocarbon fraction. A summary of the relative amounts of each peak for termites and fecal pellets using a representative chromatogram of each species was prepared.

Cluster Analysis of Hydrocarbon Mixtures from Termites and Fecal Pellets. The percentage of each hydrocarbon was used as the response variable. The presence of coeluting compounds precluded exact quantification of many individual hydrocarbons; the quantity of each hydrocarbon in each such peak was equal to $1/n$ of the value for the peak, with n = the number of hydrocarbons in the peak. The Euclidean distance for all 18 combinations of termite species by insect or fecal pellets was calculated using all hydrocarbons (R Statistical Language, 2004).

RESULTS AND DISCUSSION

The cuticular hydrocarbons for five species [*N. connexus*, *C. brevis*, *C. cynocephalus*, *I. immigrans*, and *I. minor*] from Hawaii (Haverty et al., 2000), and one additional species [*P. corniceps*] from the British Virgin Islands (Haverty et al., 1997) were previously characterized. The composition of the hydrocarbon mixtures for these six species and the hydrocarbons from their fecal pellets are displayed in Figures 1–6 and summarized in Tables 1–6.

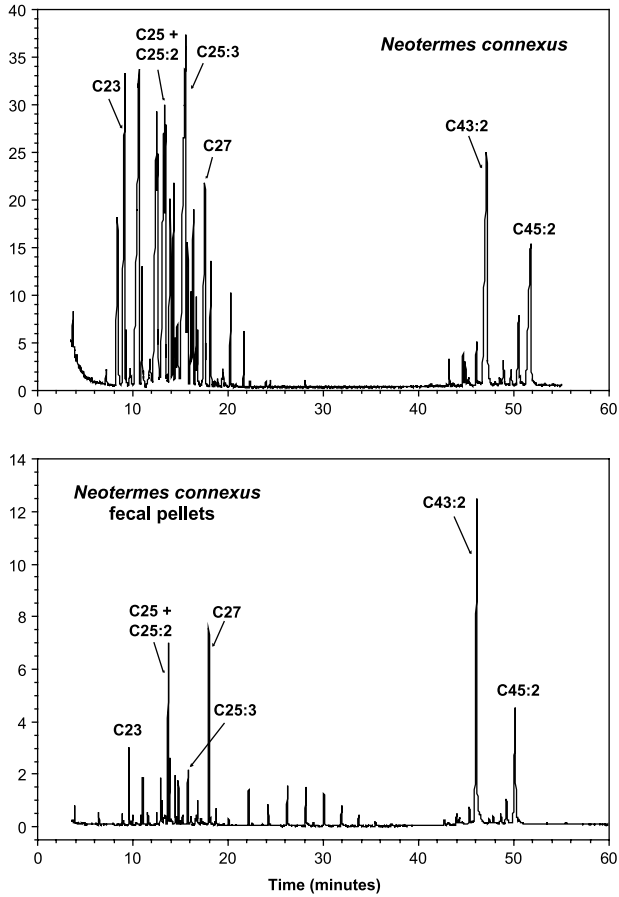

FIG. 1. Total ion chromatogram of the cuticular hydrocarbons from nymphs of *Neotermes connexus* Snyder from Iao Valley Lookout, Maui, HI, and from fecal pellets of *N. connexus* from junctions of Hwy 550 and 552, Kauai, HI.

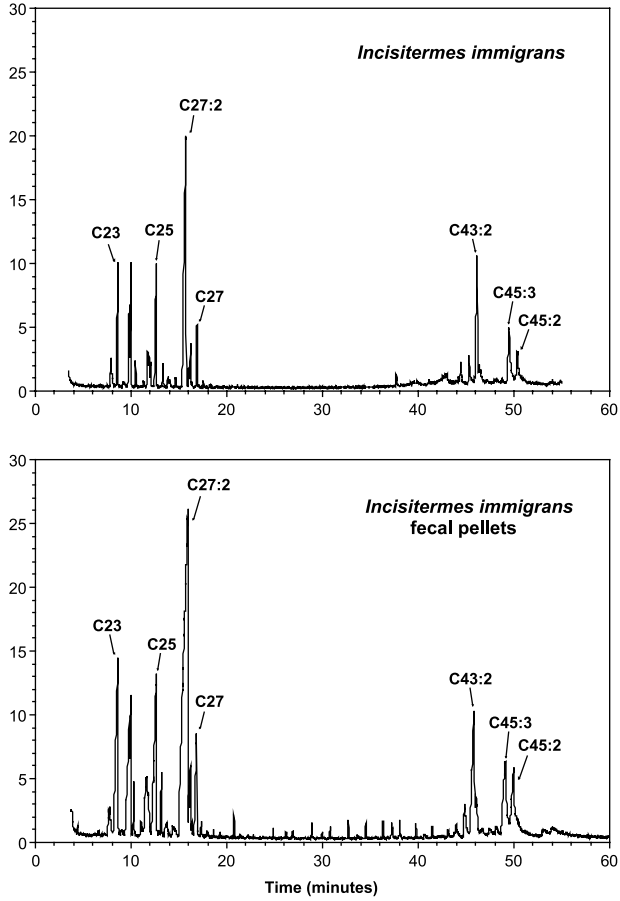

FIG. 2. Total ion chromatogram of cuticular hydrocarbons from pseudergates of *Incisitermes immigrans* Snyder from Poipu Beach, Kauai, HI, and from fecal pellets of *I. immigrans* from Kualoa Beach, Oahu, HI.

Detail for the cuticular hydrocarbon mixtures of two additional drywood termite species, *P. occidentis* and *M. hubbardi*, from Arizona, as well as the hydrocarbons from their fecal pellets, that have not been previously reported are shown (Figures 7 and 8, Tables 7 and 8). The composition of the cuticular hydrocarbons for frozen samples of *Z. nevadensis nuttingi* (*Zootermopsis* Phenoytpe III) has been described previously (Haverty et al., 1988). Here, we identify additional hydrocarbons not previously detected, as well as hydrocarbons from fecal pellets (Figure 9, Table 9). The results of the method used

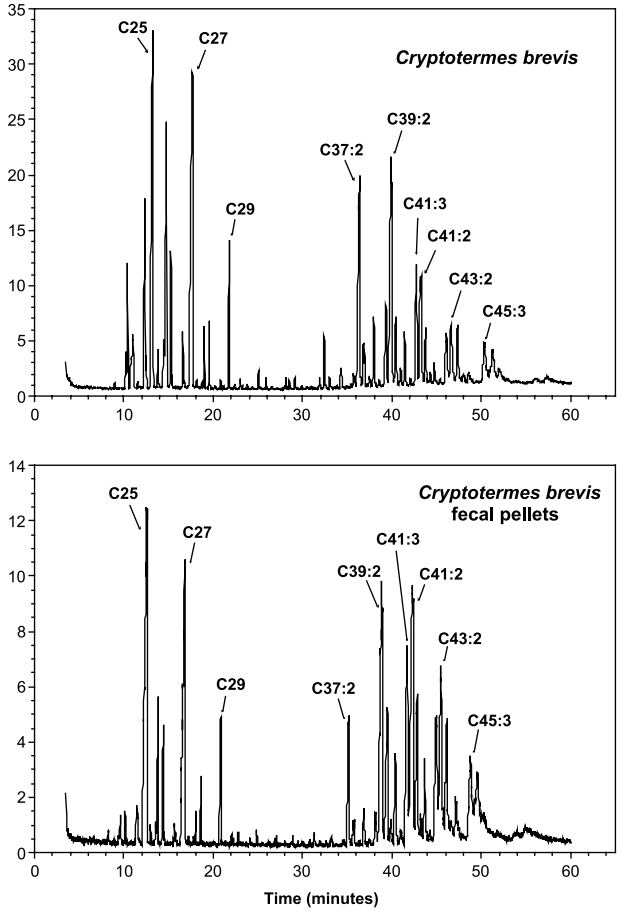

FIG. 3. Total ion chromatogram of the cuticular hydrocarbons from pseudergates of *Cryptotermes brevis* (Walker) from Honolulu, Oahu, HI, and from fecal pellets of *C. brevis* from NOAA laboratory, Kewalo Basin, Oahu, HI.

here are not equivalent to extracting live or freshly frozen termites, and demonstrate that there are quantitative differences in the composition of cuticular hydrocarbons extracted from dried specimens (Haverty et al., 1996b).

The cuticular hydrocarbon mixture of most drywood termite species examined thus far from the West Indies and Hawaii (Haverty et al., 1997, 2000) reflected a general pattern. Cuticular hydrocarbons occurred in two distinct groups: early eluting compounds (23 to 29 or 31 carbons in the parent chain) and late-eluting compounds (37 to 45 carbons in the parent chain). The mixtures

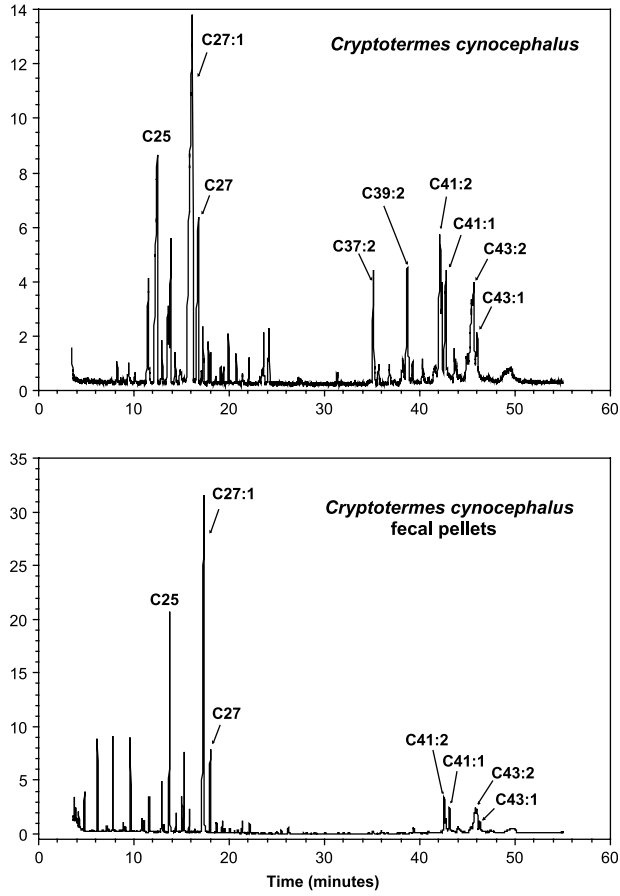

FIG. 4. Total ion chromatogram of the cuticular hydrocarbons from pseudergates of *Cryptotermes cynocephalus* Light from Waiahole Valley Road, Kamehameha Highway, Oahu, HI, and from fecal pellets from the same collection.

of *I. minor* and *M. hubbardi* were different in that hydrocarbons occurred continuously from the early eluting hydrocarbons with 23 carbons in the parent chain to the late eluting hydrocarbons with 43 carbons in the parent chain (Figures 5 and 8). *Z. nevadensis nuttingi* displayed a pattern similar to the general pattern for drywood termites with the addition of a few hydrocarbons with 31 carbons in the parent chain (Figure 9).

Hydrocarbons from Termites. N. connexus is generally found in rotting wood or living trees in moist, forested areas in Hawaii between 200 and 2000 m in elevation (Zimmerman, 1948). The chromatograms of cuticular hydrocarbons

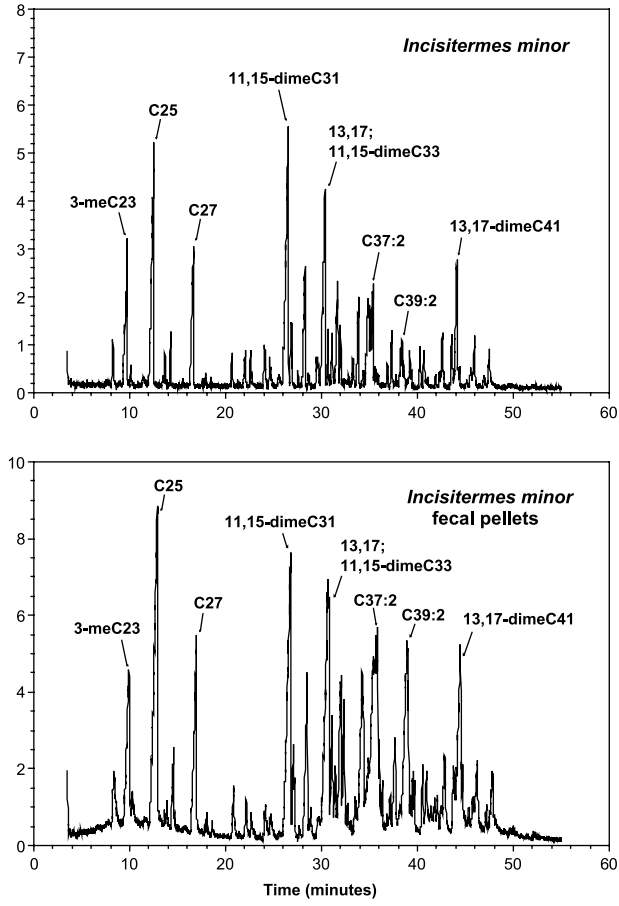

FIG. 5. Total ion chromatogram of cuticular hydrocarbons from pseudergates of *Incisitermes minor* (Hagen) from Fresno, CA, and from fecal pellets from the same collection.

reflected the general pattern of drywood termites (Figure 1, Table 1). *n*-Alkanes comprised 21.8% of the total hydrocarbon; *n*-C23, *n*-C25, and *n*-C27 were the most abundant. Olefins were, by far, the most predominant, representing over 52% of the total hydrocarbon; dienes and trienes were the most abundant olefins. Terminally branched monomethylalkanes, mainly 2-; 3-meC23; and 2-meC24, accounted for 23.6% of the total hydrocarbon. Internally branched monomethylalkanes were rare; neither dimethylalkanes nor trimethylalkanes were detected.

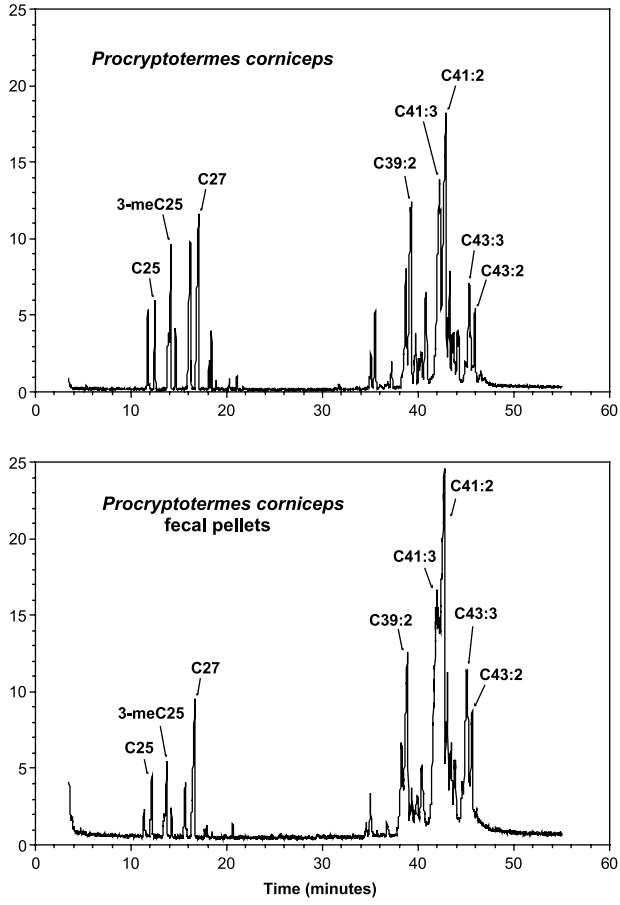

FIG. 6. Total ion chromatogram of the cuticular hydrocarbons from pseudergates of *Procryptotermes corniceps* (Snyder) from Guana Island, British Virgin Islands, and fecal pellets from the same collection.

I. immigrans is the predominant drywood termite in lowland xeric and coastal littoral forests, where it infests living and dead, standing trees, exclusive of man-made structures (Zimmerman, 1948). It is displaced by *N. connexus* at higher elevations, and the two species coexist at low elevations on mesic sites. The general appearance of the chromatograms of *I. immigrans* (Figure 2) was similar to those of *N. connexus* (Figure 1); over 75% of the hydrocarbons had 23 to 29 carbons (Table 2). *n*-Alkanes, primarily *n*-C25 and *n*-C27, comprised 24.8% of the total hydrocarbon. The unsaturated components constituted 59.4%

of the total hydrocarbon; olefins with 27 or 43 carbons predominate. The terminally branched monomethylalkanes comprised 14.4% of the total hydrocarbon. Small amounts of internally branched monomethylalkanes were detected; di- and trimethylalkanes were absent.

C. brevis is the common drywood termite found in structures in Hawaii; its distribution is pantropical. It is almost exclusively found in buildings and furnishings. The hydrocarbon mixture of *C. brevis* resembles the general pattern of drywood termites living in xeric, tropical habitats (Haverty et al., 1997). Hydrocarbons occurred in two groups: the early eluting compounds consisted almost exclusively of *n*-alkanes and terminally branched monomethyl alkanes, whereas late-eluting compounds were chiefly olefins (Figure 3, Table 3). *n*-Alkanes, primarily *n*-C25 and *n*-C27, comprised ca. 29.4% of the total hydrocarbon. Alkenes, alkadienes, and alkatrienes were the predominant class, representing over 50% of the total hydrocarbon. The terminally branched monomethylalkanes amounted to 16% of the total hydrocarbon. Internally branched monomethylalkanes and dimethylalkanes occurred in small quantities.

C. cynocephalus was recently discovered in native vegetation in Hawaii (Haverty et al., 2000; Scheffrahn et al., 2000; Grace et al., 2002), and is found in structures in the Philippine Islands (Scheffrahn et al., 2000). This species also reflects the general pattern of hydrocarbon mixtures of drywood termites living in xeric, tropical habitats (Haverty et al., 1997) and is similar to *C. brevis*.

[a] Percent of total hydrocarbon composition.
[b] An isomeric mixture or two or more compounds coelute in this peak.

Hydrocarbons occurred in two groups: the early eluting compounds were dominated by one olefin, C27:1; late-eluting compounds were predominantly olefins (Figure 4, Table 4). *n*-Alkanes comprised 16% of the total hydrocarbon. Alkenes, alkadienes, and alkatrienes were the predominant class of cuticular hydrocarbons, representing 70.3% of the total hydrocarbon; C27:1 accounts for 28% of the total hydrocarbon. Terminally branched monomethylalkanes amounted to 11.1% and internally branched monomethylalkanes 2.8% of the total hydrocarbon. No di- or trimethylalkanes were detected.

I. minor has an extensive geographical and ecological range. It is common in structures and in trees, especially at pruning scars, in the southwestern, coastal counties of California. Its distribution extends north to Mendocino County, south into Baja California and along the coast of western Mexico, and east into eastern Arizona and Utah (Weesner, 1970). *I. minor* has been introduced, and possibly established, in two separate locations on the island of Oahu (Grace et al., 2002). The general pattern of the chromatograms of *I. minor* (Figure 5) was more similar to that of *M. hubbardi* (see below) than that of *I. immigrans* (Figure 2), or other drywood termites from the tropics (Haverty et al., 1997, 2000). Hydrocarbons occurred in a continuous "series" from *n*-C23 to 13,17-dime C43 without the unoccupied region from C29 to C33 (Table 5). *n*-Alkanes comprised 17.7% of the total hydrocarbon. The unsaturated components constituted only 19.7% of the total hydrocarbon, a proportion much lower than that of tropical kalotermitids. Late-eluting olefins predominated in

[c] The exact methyl branch positions are uncertain.

this component. The terminally branched monomethylalkanes amounted to 6.7% of the total hydrocarbon, whereas internally branched monomethylalkanes totaled 6.9%. Dimethylalkanes were the predominant class of compounds, making up 42% of the total hydrocarbon. *I. minor* also made a homologous series of trimethylalkanes representing 7.0% of the total hydrocarbon.

P. corniceps is found throughout most of the islands of the West Indies (Scheffrahn et al., 1994; Haverty et al., 1997). It can be found in dead wood of native vegetation, including fence posts, but has not yet been recorded from structures (Collins et al., 1997). The cuticular hydrocarbon mixture of *P. corniceps* (Figure 6) was similar in gross comparison to that of *C. brevis* (Figure 3). The early eluting components were almost exclusively *n*-alkanes and terminally branched monomethylalkanes, and the late eluting compounds were primarily olefins (Table 6). *n*-Alkanes comprised 8.7% of the total hydrocarbon. As with *C. brevis*, the alkenes, alkadienes, and alkatrienes were the predominant class of cuticular hydrocarbons, totalling over 76% of the total hydrocarbon. The terminally branched monomethylalkanes made up 12.2% of the total hydrocarbon.

P. occidentis occurs primarily within the general limits of the Sonoran Desert in southern Arizona and Baja California. *P. occidentis* has been found in few tree species, most commonly in blue paloverde, *Parkinsonia florida* (Bentham ex A. Gray) S. Watson (Nutting, 1966). The cuticular hydrocarbon mixture of *P. occidentis* has never been published, therefore, we provide a detailed description here. Once again, cuticular hydrocarbons occurred in two distinct groups: early eluting (25 to 31 carbons in the parent chain) and late-eluting compounds (41 to 43 carbons in the parent chain). The early eluting

[c] This peak appears to be a mixture of unsaturated compounds, their exact identities are undetermined.

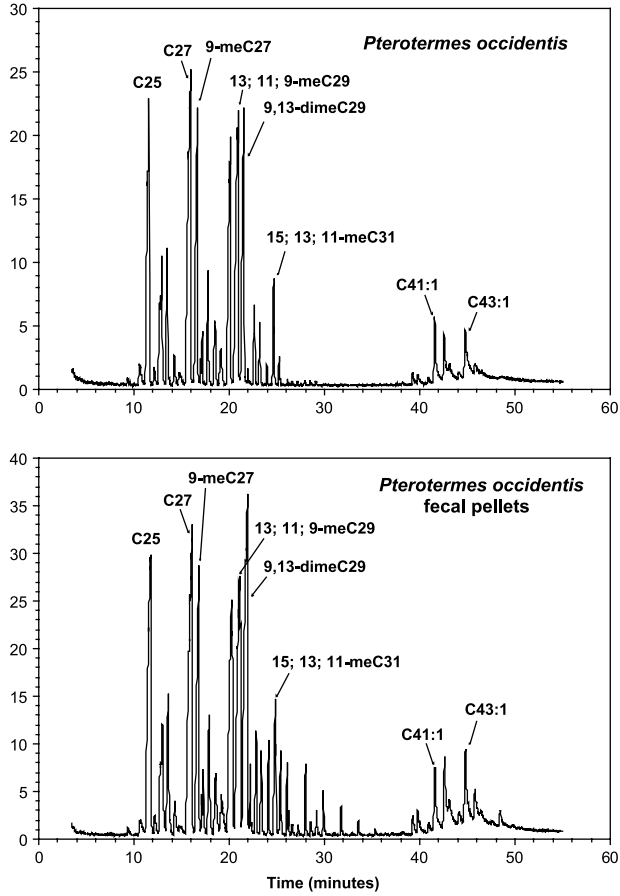

FIG. 7. Total ion chromatogram of the cuticular hydrocarbons from pseudergates of *Pterotermes occidentis* (Walker) from the Santa Rita Experimental Range near Tucson, AZ, and fecal pellets from the same collection.

compounds predominated, representing over 92 percent of the total hydrocarbon (Figure 7, Table 7).

n-Alkanes were, by far, the most abundant hydrocarbons representing over 40% of the total (Table 7). *n*-C25, *n*-C27, and *n*-C29 comprised ca. 10.5%, 14.7%, and 9.1% of the total hydrocarbon, respectively. The other *n*-alkanes accounted for 6.6% of the total (Table 7). In contrast to the tropical drywood termite species, olefins were not the predominant hydrocarbons, representing only 5.0% of the total (Table 7). Two monoenes, C41:1 and C43:1, made up the majority of these hydrocarbons.

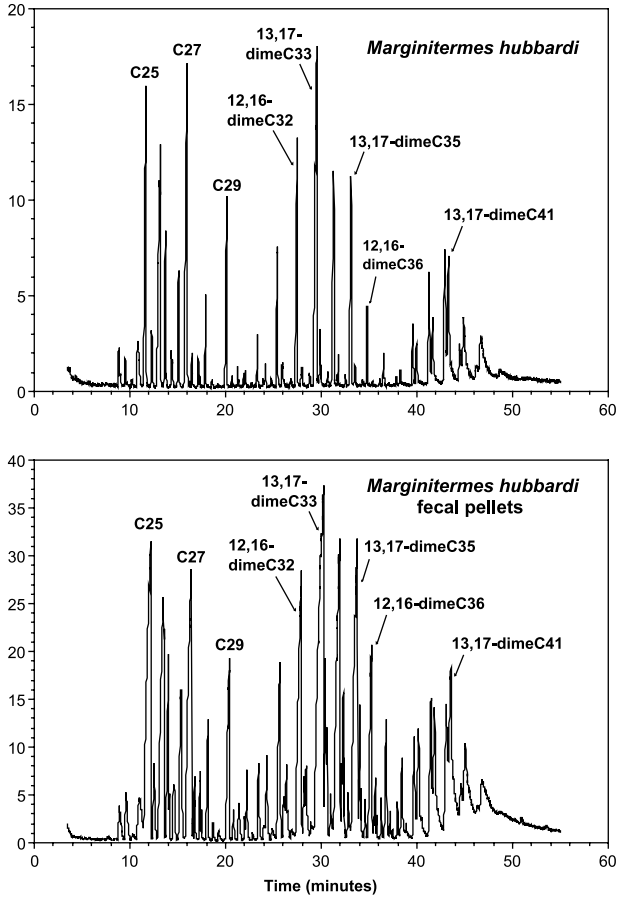

FIG. 8. Total ion chromatogram of cuticular hydrocarbons from pseudergates of *Marginitermes hubbardi* (Banks) from the Saguaro National Monument southeast of Tucson, AZ, and fecal pellets from the same collection.

Terminally branched monomethylalkanes were identified for C24 to C27 (Table 7). 2-MeC25 and 3-meC25 accounted for 2.8% and 2.6% of the total hydrocarbon, respectively. The remainder of these terminally branched monomethylalkanes comprised only 2.2% of the total. Internally branched monomethylalkanes comprised 33.0% of the total hydrocarbon (Table 7). The homologous series of internally branched monomethylalkanes, C27, C29, C31, and C41 constituted 26.9% of the total hydrocarbon; none of the other internally branched monomethylalkanes represented more than 0.85% of the total. Dimethylalkanes comprised 13.4% of the total hydrocarbon; 9,13-dimeC29

was the foremost member of this class with 9.6% of the total (Table 7). No trimethylalkanes were detected (Table 7).

M. hubbardi is one of the most common drywood termites in the Sonoran Desert. It is often found in the skeletal remains of the saguaro cactus, *Cereus giganteus* Englm., and is also commonly found in wood of structures. *M. hubbardi* replaces, or is more frequently encountered than, *I. minor* at lower elevations and drier regions of the Sonoran Desert (Weesner, 1970). As observed for *P. occidentis*, the cuticular hydrocarbon mixture of *M. hubbardi* has not been published, therefore, we provide a detailed description here.

[a] Percent of total hydrocarbon composition.
[b] Equivalent chain length.
[c] This peak appears to be a mixture of unsaturated compounds, their exact identities are undetermined.

The general pattern of the chromatograms of *M. hubbardi* (Figure 8) was more similar to that of *I. minor* (Figure 5) than that of other drywood termites from Hawaii or the dry tropics (Figures 1–4, 6). Hydrocarbons occurred continuously from *n*-C25 to dimeC43 without the unoccupied region from C29 to C33. *n*-Alkanes present were *n*-C24, *n*-C25, *n*-C26, *n*-C27, *n*-C28, *n*-C29 *n*-C30, and *n*-C31 (Table 8). *n*-C25 and *n*-C27 were the most abundant, comprising 7.8% and 9.7% of the total hydrocarbon, respectively (Figure 8). The remaining *n*-alkanes amounted to 8.1% of the total hydrocarbon. There were no unsaturated components detected.

Terminally branched monomethylalkanes were identified for C23 to C27; 3-meC25, representing 2.3% of the hydrocarbons, was the most abundant. Terminally branched monomethylalkanes constituted only 3.6% of the total hydrocarbon. Internally branched monomethylalkanes were the third most abundant class in *M. hubbardi*. Most were among the later-eluting compounds with carbon numbers in the parent chain ranging from 29 through 43 (Table 8). The isomeric mixture of 11-; 13-; 15-meC41 was the largest peak in this class accounting for 3.7% of the total (Figure 8).

In *M. hubbardi*, as in *I. minor*, dimethylalkanes were the predominant class of compounds, accounting for 53.9% of the hydrocarbon. The isomeric mixture of 11,15-; 13,17-dimeC33 was the most abundant peak accounting for 10.8% of the total hydrocarbon. *M. hubbardi* made a homologous series of internally branched dimethylalkanes (9,13-; 11,15-; 12,16-; 13,17-) from C24 to C43 (Figure 8; Table 8). *M. hubbardi* also made numerous trimethylalkanes with 25 to 39 carbons in the parent chain; these trimethylalkanes accounted for 3.9% of the total hydrocarbon (Table 8).

Z. nevadensis nuttingi is the common dampwood termite found in the coastal forests of California, Oregon, and Washington west of the Cascade Range (Thorne et al., 1993). *Zootermopsis* species infest standing dead trees, stumps, and logs in contact with the soil. Like drywood termites, *Zootermopsis* species produce pelletized feces that are stored in chambers within their workings. *Z. nevadensis nuttingi* was originally designated Phenotype III of the North American *Zootermopsis* (Haverty et al., 1988). It was later designated as a subspecies of *Z. nevadensis* on the basis of its cuticular hydrocarbon mixture and its ability to recognize the other phenotype or subspecies, *Z. nevadensis nevadensis*, and react aggressively toward it (Haverty and Thorne, 1989). Morphologically, *Z. n. nuttingi* remains indistinguishable from *Z. n. nevadensis* (Thorne and Haverty, 1989). Their distributions are, for the most part, allopatric or parapatric (Thorne et al., 1993; Haverty et al., unpublished data).

The hydrocarbon mixture of *Z. nevadensis nuttingi* has been published previously (Haverty et al., 1988). This subspecies has since been more thoroughly characterized, and several compounds have been identified that were not previously reported. In particular, numerous olefins were identified by their mass

spectra. These compounds can become unstable if not analyzed promptly after extraction, and this may account for their absence in the previous report (Haverty et al., 1988). Handling and extraction of specimens has been standardized to include drying of termites before extraction, thereby improving the recovery of hydrocarbons, especially olefins, from the cuticle (Haverty et al., 1996b).

The general pattern of the chromatograms of *Z. nevadensis nuttingi* (Figure 8) was similar to that of *N. connexus* (Figure 1), where the great majority of the hydrocarbons have 21 to 31 carbons in the parent chain. *n*-Alkanes present were *n*-C21, *n*-C22, *n*-C23, *n*-C24, and *n*-C25 (Table 9). *n*-C23 and *n*-C25 were the most abundant, comprising 15.3% and 9.1% of the total hydrocarbon, respectively (Figure 9). The remaining *n*-alkanes comprised 7.9% of the hydrocarbons.

The unsaturated components constituted 46.2% of the total hydrocarbon. Olefins with 23, 43, and 45 carbons predominated among the olefins. C23:2, C23:1, C43:3, and C45:3 accounted for 29.2%, 3.2%, 4.7%, and 3.0% of the total hydrocarbon, respectively (Figure 9; Table 9). The remaining unsaturated components amounted to only 6.1% of the total hydrocarbons.

2- and 3-Methylalkanes were identified for C21 to C25, with 3-meC23, representing 10.5% of the total hydrocarbon, being the most abundant (Table 9). These terminally branched monomethylalkanes represented 15.9% of the total hydrocarbon. A small amount of the internally branched 11-meC23 was seen. Dimethylalkanes were represented by a homologous series of 3,7-dimeCXX (Table 9).

Hydrocarbons from Termite Fecal Pellets. In general, the hydrocarbons from whole-body extracts of drywood termites were represented qualitatively and quantitatively in extracts of fecal pellets from the same species. Extracts of fecal pellets were more similar to those of their producers than they were to extracts of any other termite species or their fecal pellets. Cluster analysis with all hydrocarbons, using Euclidean distance, consistently paired the hydrocarbon mixture from fecal pellets with the hydrocarbon mixture from termites of the species that produced the pellets (Figure 10).

The hydrocarbon mixtures from whole-body extracts and that of fecal pellets were not identical; minor differences did occur and were likely the result of one or more factors. For example, some termite/pellet pairs were not from the same colony or location (*N. connexus*, *I. immigrans*, and *C. brevis*); thus, the minor qualitative and quantitative differences between termites and fecal pellets could reflect intraspecific variation. When certain hydrocarbons were found in the termites, but not in the fecal pellets, and *vice versa*, they often occurred in small quantities, usually less than 1.0% of the total hydrocarbon component (Tables 1–9). Therefore, the lack of certain hydrocarbons could also be a function of the concentration of the extracts.

Paraffins, a series of *n*-alkanes, were found in both termite and fecal pellet extracts, but long-chain *n*-alkanes were found only in extracts of termite fecal

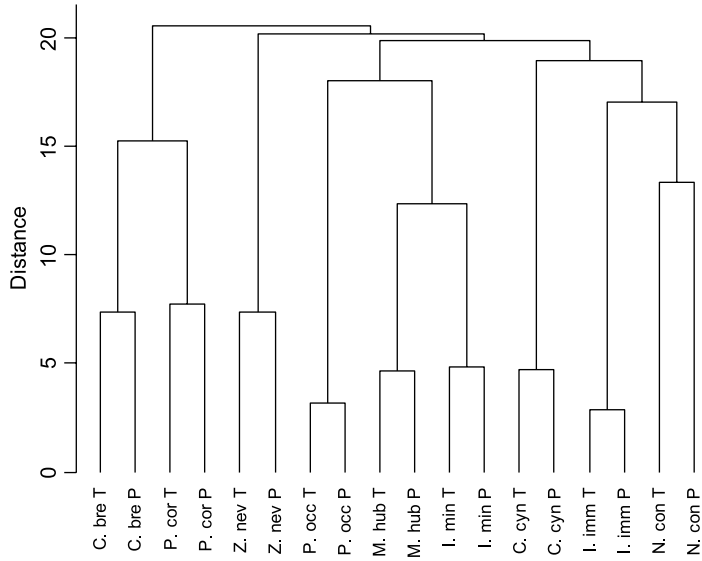

FIG. 10. Dendrogram from cluster analysis based on Euclidean distance of hydrocarbons extracted from eight species of drywood termites and one species of dampwood termite and their fecal pellets. N. con = *Neotermes connexus*, I. imm = *Incisitermes immigrans*, C. bre = *Cryptotermes brevis*, C. cyn = *Cryptotermes cynocephalus*, I. min = *Incisitermes minor*, P. cor = *Procryptotermes corniceps*, P. occ = *Pterotermes occidentis*, M. hub = *Marginitermes hubbardi*, and Z. nev = *Zootermopsis nevadensis nuttingi*.

pellets (Tables 1, 2, 7, 8; Figure 1). *n*-Alkanes with more than 31 carbon atoms are not usually seen in insects; insects apparently cannot synthesize *n*-alkanes containing more than 34 carbon atoms (Hadley, 1985). In plants, *n*-alkanes are the principal hydrocarbon fraction of the cuticlar lipids, ranging in length from 21 to 37 carbon atoms (Hadley, 1981). It is possible that the long-chain *n*-alkanes from drywood termite fecal pellets were a contaminant from plant origin, from the ubiquitous Parafilm® used in most laboratories, or even contamination from hand lotion. Such contamination complicated evaluation of chemotaxonomic characters of two species of Central American *Nasutitermes* (Howard et al., 1988).

Olefins comprised the majority of the hydrocarbon components in six of the nine termites discussed in this paper. Olefins are the least stable and most reactive of the cuticular hydrocarbons. However, for some reason, they remain stable in or on the cuticles of insects. For example, when hydrocarbons were extracted from 70-year-old museum specimens of scolytid cone beetles, *Conophthorus ponderosae* Hopkins, the mixtures were qualitatively identical to those collected and extracted by Page et al. (1990a). On the contrary, once

extracted, cuticular hydrocarbons of *Reticulitermes* spp. containing mono-, di- and trienes, lost much of the olefin component when dried and left in a vial for 24 hr, particularly the di- and trienes (Nelson and Haverty, unpublished observations). Thus, something prevents the oxidation of olefins while still in the cuticle. On or in fecal pellets, the olefins appeared to be as stable as they are within the cuticle of the termites.

The composition of the hydrocarbon mixture of insects is genetically controlled (Toolson and Kuper-Simbrón, 1989; Kaib et al., 1991; Page et al., 1991; Coyne et al., 1994). This composition can be slightly affected by diet and environmental conditions (Hadley, 1977; Espelie et al., 1994; Chapman et al., 1995; Howard, 1998; Woodrow et al., 2000). Because cuticular hydrocarbon mixtures are generally species-specific (see references in the Introduction), we did not expect to observe qualitative differences in cuticular hydrocarbon mixtures between recently collected *Z. nevadensis nuttingi* and those (Phenotype III) described by Haverty et al. (1988). Sevala et al. (2000) found similar qualitative differences between recently collected *Z. nevadensis nevadensis* and those (Phenotype I) reported by Haverty et al. (1988). In the present study, termites were extracted that had been dried, while Haverty et al. (1988) extracted freshly frozen (i.e., moist) termites. This could explain the difference, as drying termites first has been shown to enhance extraction of cuticular hydrocarbons, especially the late-eluting olefins (Haverty et al., 1996b). In addition, the olefin component of all four taxa reported by Haverty et al. (1988) was likely underreported, as samples were extracted, the extract dried under nitrogen, then sent to the University of Nevada for identification by GC-MS. Therefore, many (or all) of the olefins could have oxidized and no longer been present in the sample for identification. Furthermore, the equipment used by Haverty et al. (1988) (Finnigan 4023 mass spectrometer) was less sensitive than that used by Sevala et al. (2000) and in this study (HP5890 GC coupled with an HP5989 or 5970 MS, respectively). Thus, minor components and coeluting isomers could have been missed by Haverty et al. (1988).

From where do the hydrocarbons in drywood termite fecal pellets come? The answer to this question could be contamination from the cuticles of the termites moving within the gallery system strewn with fecal pellets. Three other scenarios are more likely, however. First, controlled cannibalism is a key to the nitrogen economy of a termite colony. Exuviae, injured or dead individuals, and excess members of any caste are commonly eaten (Moore, 1969). The hydrocarbons ingested could pass through the gut undigested, only to be compacted in the fecal pellets, although this has not yet been tested. Second, the termites moving and storing fecal pellets could secret a mixture of hydrocarbons from the various glands (labral, mandibular, labial, or salivary) associated with the mouthparts (Noirot, 1969). Third, and most likely, is that hydrocarbons are deposited onto the fecal pellets within the rectum during or after the fecal dehydration

process. Oenocytes transmit hydrocarbons within the hemolymph to their epicuticular destinations (Schal et al., 1998; Sevala et al., 2000). Because the rectum is lined with cuticle (Child, 1934), hydrocarbons are likely transferred to the epicuticular cells of the rectum and then transferred to the surface, or lining.

What is the significance of fecal hydrocarbons that are similar to those found in termite cuticles? With more sampling across additional taxa, diagnostic hydrocarbons could be identified (Haverty et al., 1997) and a key to species developed (Haverty et al., 2000) for either nondiagnostic castes, such as larvae, nymphs, and pseudergates or workers, or even fecal pellets alone. This knowledge could potentially have applications for quarantine operations to identify species or damage to wood products or solid wood packing material and contain the spread of invasive termite species. In addition, our findings open up the possibility of other chemicals, such as semiochemicals, being deposited on or within fecal pellets with the pellets functioning as a slow-release mechanism (Souto and Kitayama, 2000). The possibility also exists that other wood-destroying insects could also be identified to species according to the hydrocarbons in their feces.

Acknowledgments—The authors thank C.H.M. Tome, R.J. Oshiro, S.Y. Uchima, and T.K. Brown for technical assistance and J.A. Baldwin for assistance with the cluster analysis. We extend thanks to Dr. and Mrs. H. Jarecki, J. Lazell, and the staff of the Guana Island Club for support and hospitality during the portion of this project conducted in the British Virgin Islands. This research was made possible, in part, by a grant to MIH by the Conservation Agency (through grants from the Falconwood Foundation), by a cooperative agreement between the University of Hawaii and the Pacific Southwest Research Station, by McIntire-Stennis funds for forestry research (J.K.G.), and by USDA-ARS Specific Cooperative Agreement 58-6615-4-237.

CIRCADIAN RHYTHMS OF SEXUAL BEHAVIOR AND PHEROMONE TITERS OF TWO CLOSELY RELATED MOTH SPECIES *Autographa gamma* AND *Cornutiplusia circumflexa*[1]

MICHAL MAZOR* and EZRA DUNKELBLUM

Department of Entomology and Units of Chemistry and Nematology, Institute of Plant Protection, ARO, The Volcani Center, Bet Dagan 50250, Israel

(Received December 12, 2004; revised April 4, 2005; accepted April 14, 2005)

Abstract—Two closely related plusiinae moths, *Autographa gamma* Linnaeus and *Cornutiplusia circumflexa* Linnaeus, are sympatric in Israel. Both species use identical sex pheromone components but in different ratios, and do not attempt to mate with each other. In addition to the effective reproductive separation by their sex pheromones, the sexual behavior of both species was compared to determine whether the lack of selection pressure might create additional barriers to cross-attraction and cross-mating. We found the gamma moth to be sexually active almost equally throughout the scotophase, whereas the sexual activity of *C. circumflexa* was limited to a short period at the end of the scotophase when most of the gamma moths had already mated. Higher levels of calling were observed with older females. There was a close relationship between pheromone titer and calling activity in both species.

Key Words—*Autographa gamma*, gamma moth, *Cornutiplusia circumflexa*, Noctuidae, Plusiinae, calling behavior, male response, pheromone gland titer, circadian rhythm.

INTRODUCTION

The two closely related lepidopteran species, the gamma moth *Autographa gamma* Linnaeus and *Cornutiplusia circumflexa* Linnaeus (Noctuidae: Plusiinae) are sympatric in Israel. Both species are migratory, and adult migratory

* To whom correspondence should be addressed. E-mail: mmazor@Volcani.agri.gov.il
[1] Contribution from the Agricultural Research Organization (ARO), No. 51904.

flights are recorded in Israel in autumn and spring (Yathom and Rivnay, 1968; Kitching, 1987; Pedgley and Yathom, 1993). Overlapping populations of these moths have also been recorded in Egypt (Harakly, 1975; Etman, 1989) and Saudi Arabia (Wiltshire, 1990). The two species belong to the subtribe Plusiina of the tribe Plusiini (Kitching, 1987). The gamma moth is a palearctic species and is a serious polyphagous pest, particularly in the eastern part of Europe (Ghizdavu et al., 1979). In Israel, this moth damages potato and celery crops. *C. circumflexa* is a poorly studied paleotropical species, feeding mainly on Solanaceae, but it is of no economic importance.

The sex pheromones of both species contain (*Z*)-7-dodecenyl acetate (*Z*7-12:Ac) and (*Z*)-7-dodecenol (*Z*7-12:OH), with *Z*7-12:Ac being the major component of the *A. gamma* (Dunkelblum and Gothilf, 1983; Tóth et al., 1983), whereas *Z*7-12:OH is the major component of the *C. circumflexa* pheromone (Mazor et al., 1991). No cross-attraction was found between the two species in both wind tunnel and field test experiments (Mazor et al., 1991; Dunkelblum and Mazor, 1993).

This study was conducted to determine whether temporal factors may also contribute to reproductive isolation of these two species.

METHODS AND MATERIALS

Insect Rearing. Laboratory colonies of *A. gamma* and *C. circumflexa*, started in 1983, were maintained at 26 ± 2°C, 60 ± 5% relative humidity under a 14:10 light–dark (LD) photoperiod, and wild adults, captured by light trap, were introduced annually into the colony. Larvae were reared on a modified artificial diet for Noctuidae (Shorey and Hale, 1965). Pupae were segregated by sex and placed in 30 × 30 × 30 cm screen cages in different rooms under the same rearing conditions. One room was used for observations of calling and copulation behavior and the other for wind tunnel experiments. Both rooms were lit with two to three red incandescent light bulbs, with a light intensity of approximately 0.5 lx during the scotophase. The intensity of the light in the wind tunnel room was measured at several points on the outer surface of the transparent wind tunnel. Adults were provided with a 10% sucrose solution. Adults emerging between 0 and 24 hr were considered as 1-d-old.

Observations of Calling Behavior. Observations were conducted during the 10 hrs of the scotophase with two groups of 30 *A. gamma* females because mating appeared to occur throughout the scotophase. The first group was examined from the beginning of the scotophase for 5 hrs, and the second group was examined during the 5 hrs from the 6th hr of the scotophase to its end. Females, 0- to 24-hr-old, were placed individually in 500-ml glass jars containing a steel mesh support and a 10% sucrose solution. Observations were

made every 10 min during the 1st, 2nd, 3rd, 4th, 5th, 8th, and 10th nights. The mean value of the six recordings per hour was taken to calculate the proportion of calling females. Twenty *C. circumflexa* females were tested every 15 min during the 1st, 2nd, 4th, 5th, 7th, 9th, and 11th night during the last 4 hrs of the scotophase because preliminary observations indicated that sexual activity of this moth occurred at this time. The mean value of the four recordings per hr was used to calculate the proportion of calling females. Dead individuals were removed from the cages. The proportions of females calling in both species were calculated according to the number of surviving females.

Wind Tunnel Experiments. The response of males toward the appropriate synthetic sex pheromone was tested in a 195 × 60 × 60 cm wind tunnel with a wind speed of 0.5 m/sec (Snir et al., 1986). Rubber septa (Arthur Thomas Co., 5 × 9 mm) containing 10 μg *Z*7-12:Ac were used as lures for *A. gamma* males because no difference was found between males' responses to *Z*7-12:Ac alone or in combination with the minor component *Z*7-12:OH (Mazor and Dunkelblum, 1992). Septa containing a blend of 10 μg *Z*7-12:OH and 2 μg *Z*7-12:Ac were used as lures for *C. circumflexa* males. Males were tested individually, recording the following behavioral parameters: takeoff (within 1 min), directed flight, landing, and copulation attempts. The response of 30 *A. gamma* males was tested daily for moths aged 1- to 8-d- and 11-d-old, and the response of 20 *C. circumflexa* males was tested daily for 1- to 7-d- and 10-d-old moths. The responses of 45 *A. gamma* and 20 *C. circumflexa* males were tested at different hours of the scotophase at the age of maximal sexual activity (6-d-old for *A. gamma* and 7-d-old for *C. circumflexa*).

Copulation. Two groups of 75 *A. gamma* pairs were tested during each of the two halves of the scotophase on three different nights. Observations were conducted at 15-min intervals. Each group was divided to three subgroups of 25 pairs. Each subgroup was placed in a 30 × 30 × 30 cm screen cage and was supplied with 10% sucrose solution. Females were 4- to 6-d-old and males were 6- to 8-d-old, the appropriate age of maximal sexual activities. Mating pairs were gently transferred into a 5-cm diam petri dish for the measurement of copulation duration. This procedure did not disturb the mating pair or the remaining moths. The same procedure was conducted with *C. circumflexa*. Two groups of 10 6-d-old *C. circumflexa* pairs and 14 6- to 7-d-old pairs were placed in individual screen cages as described for *A. gamma*. Observations of 15-min intervals were conducted during the second half of the scotophase on two different nights. The percentages of pairs starting to copulate at different times of the scotophase were calculated for all the groups of each of the species, (75 pairs for *A. gamma* and 24 pairs for *C. circumflexa*).

Pheromone Titer Determination. Batches of 25 pheromone glands (considered as one replicate because of low amount of pheromone per gland) were excised and immersed for 15 min in approx. 150 μl hexane. The supernatant

solutions were transferred into small conical vials, sealed with a Teflon-lined screwcap. For quantification, 100 ng of 10-undecenyl acetate (10-11:Ac) and 100 ng of 10-undecenol (10-11:OH) were added as internal standards for *A. gamma* and *C. circumflexa*, respectively. Samples were concentrated to ~1 μl by passive evaporation in a fume hood before analysis. Quantitative analyses were conducted by capillary GC on a Carlo Erba 5300 instrument equipped with an FID detector and a splitless injector, using a 30 m × 0.25 mm DB-225 column (J&W Scientific, Folsom, CA) held at 60°C/2min, then programmed to 150°C at 10°C/min. After 21 min, the temperature was raised to 200°C at 10°C/min. The extracts were analyzed for *Z*7-12:Ac, *Z*7-12:OH, and the two internal standards. Changes in pheromone titer at different moth age were examined for *A. gamma* at the 7th hr of the scotophase and for *C. circumflexa* at the 9th hr of the scotophase. Changes in pheromone titer at different times of the scotophase were examined with glands of 4- to 5-d-old *A. gamma* females and with 5- to 6-d-old *C. circumflexa* females in 7 replicates for *A. gamma* and 4–14 replicates for *C. circumflexa*. The timing of the extractions was selected in accordance with the moths' maximal sexual behavior.

Statistical Analysis. Data for *A. gamma* calling behavior were analyzed using the GLM procedure available on SAS software. Repeated measures analysis of variance was conducted where repeated observations were conducted for each female at the various ages during each of the two halves of the scotophase. Multiple comparisons were conducted to determine differences between any pairs of ages at each of the two halves of the scotophase. The data for *C. circumflexa* calling behavior, which consisted of repeated measurements at various consecutive ages, were analyzed with a paired *t*-test to compare differences between means of all pairs of age levels. The Bonferroni procedure of multiple comparisons was used, and each *t*-test was declared significant at $P = 0.003$. Data from wind tunnel experiments were analyzed with Fisher's exact test. The percentages of the responding males for each parameter at k group (ages or different times during the scotophase) were compared at the $P = 0.05$ level of significance. If differences were significant, a closed testing procedure for multiple comparisons among l groups ($l < k$) was conducted (Marcus et al., 1976). Changes in pheromone titer were analyzed by ANOVA, and the means were separated by Student–Newman–Keuls multiple range test at $\alpha = 0.05$ level of significance.

RESULTS

Observations on Calling Behavior. Calling behavior was measured as the proportion of calling females and the duration of calling by each female during

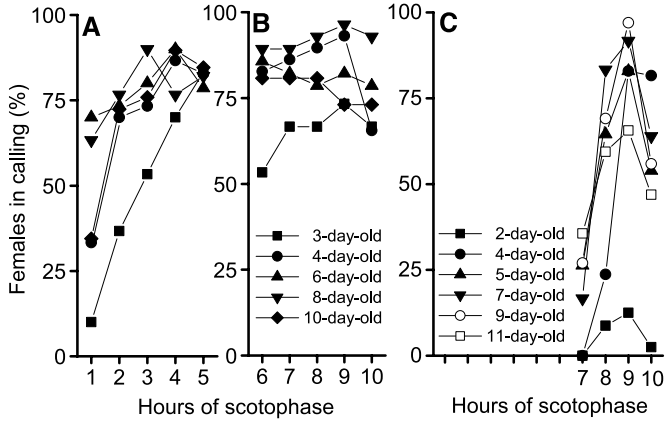

FIG. 1. The effect of age and time in scotophase on calling by *Autographa gamma* and *Cornutiplusia circumflexa* females. Observations on *A. gamma* were made on two groups (A and B) during the two halves of the scotophase at 10-min intervals ($N = 30$). Values represent the mean percentage of six recordings per hour. Observations on *C. circumflexa* were made during the last 4 hr of the scotophase (C) ($N = 20$). Values represent the mean percentage of four recordings per hour.

the scotophase. The pattern of *A. gamma* calling females at different ages during the two halves of the scotophase is shown in Figure 1A and B. The females called throughout the scotophase. However, there was marginally more calling due to more time spent in calling during the second half than during the first half

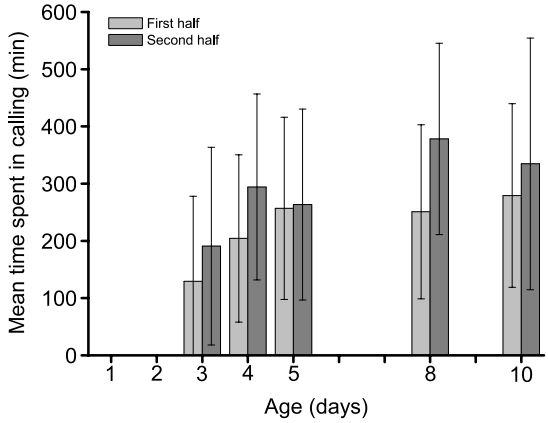

FIG. 2. The mean time (± SD) spent in calling by *A. gamma* females of different ages during the two halves of the scotophase ($N = 30$).

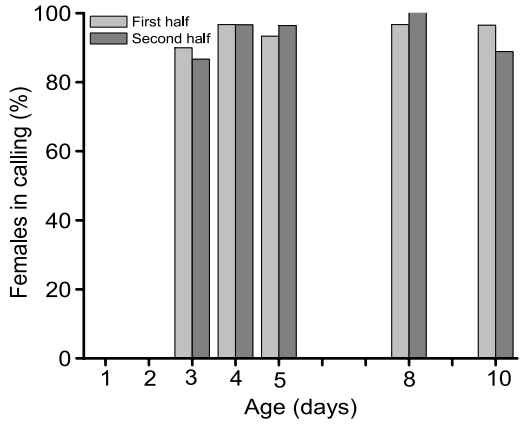

FIG. 3. The percentage of *A. gamma* calling females of different ages during the two halves of the scotophase ($N = 30$).

of the scotophase ($P = 0.053$) (Figure 2). Calling activity started on the 3rd night after emergence, and almost constant calling activity was observed thereafter (Figure 3). The effect of age on the time that was spent in calling was significant ($P < 0.001$) with more calling at advanced ages (Figure 4A).

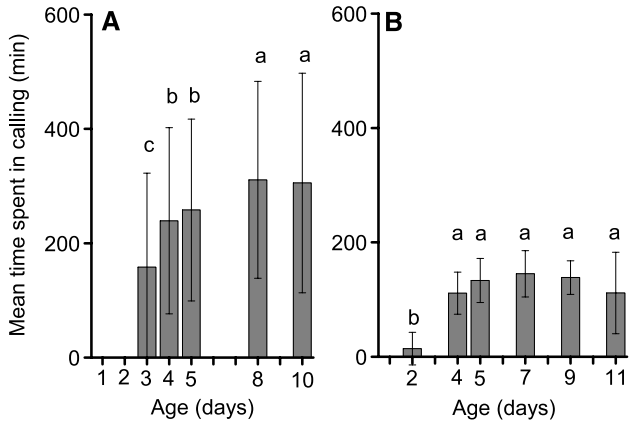

FIG. 4. The mean time spent in calling by (A) *A. gamma* ($N = 30$) and (B) *C. circumflexa* ($N = 20$) females of different ages. For *A. gamma*, GLM procedure followed by multiple comparisons were conducted. Columns with different letters are significantly different ($P < 0.001$). For *C. circumflexa*, a paired *t*-test followed by the Bonferroni procedure of multiple comparisons were conducted. Columns with different letters are significantly different at $\alpha = 0.05$.

[a] For *A. gamma*, tested males were 6-d-old ($N = 45$). For *C. circumflexa*, tested males were 7-d-old ($N = 20$). Percentages within columns followed by a different letter differ significantly at $P = 0.05$ according to Fisher's exact test followed by closed testing procedure for multiple comparisons.

Sexual activity of *C. circumflexa* occurred at the end of the scotophase, peaking during the 9th hr (Figure 1C). Only 25% of the females called on the 2nd night after emergence, whereas all females called on subsequent nights. A decrease in percent calling was observed on the 11th night after emergence when only 81% of females called. The total time spent in calling by females was low during the 2nd night (<20 min) and increased to >100 min for the rest of the period (4th night to the 11th night) (Figure 4B). There were no differences among the mean times spent in calling between the 4th night to the 11th night (Figure 4B).

Wind Tunnel Experiments. A. gamma males began to respond to their synthetic sex pheromone on the 3rd night after emergence and continued to respond well until the 11th and last night of the experiment (Table 1). The temporal pattern of response of *A. gamma* males during the scotophase paralleled the calling activity of the females with males responding to pheromone throughout the scotophase (Table 2). In contrast, the first weak response of *C. circumflexa* males was noticed during the 3rd night after emergence, with peak response not occurring until the 6th night (Table 1). Responses then remained unchanged until the end of the observations on the 10th night. *C. circumflexa* males responded strongly to their synthetic sex pheromone during the last 3 hrs of the scotophase (Table 2).

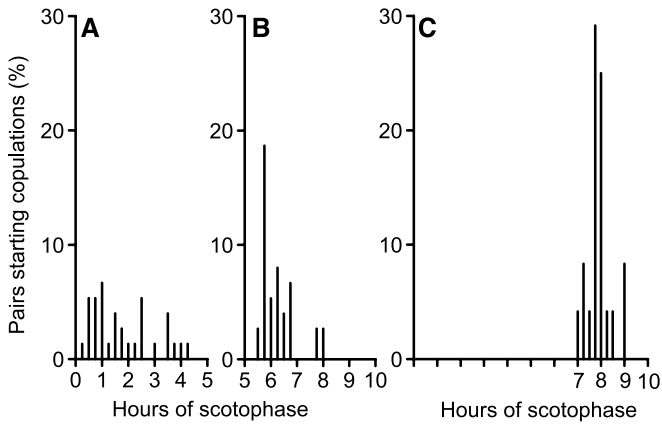

FIG. 5. The effect of time in scotophase on the percentage of *A. gamma* and *C. circumflexa* couples starting to mate. For *A. gamma*, observations were made at 15-min intervals during the two halves of the scotophase (A and B) on three groups of 25 couples each on three different nights. For *C. circumflexa*, observations were made at 15-min intervals during the last 4 hr of the scotophase (C) on two groups of 10 and 14 couples on two different nights.

[a] Twenty-five glands were considered as one replicate. For *A. gamma*, female glands were extracted during the second half of the scotophase. For *C. circumflexa*, female glands were extracted during the 9th hr of the scotophase. Means followed by different letters differ significantly at $P = 0.05$ (Student–Newman–Keuls test).

Copulation. Copulations of *A. gamma* started almost at the onset of the scotophase. A gradual increase, reflecting the calling activity of the females, was observed during the 1st hour of the scotophase (Figure 5A). The percentage of copulations initiated during the 1st hour of the second half of the scotophase was higher than that of the first half (Figure 5B) and is probably the result of more females ready to mate at the middle of the scotophase than at the beginning. Forty-four percent of the pairs initiated copulation during the first

TABLE 4. EFFECT OF TIME IN SCOTOPHASE ON PHEROMONE TITER IN PHEROMONE GLANDS OF *A. GAMMA* AND *C. CIRCUMFLEXA* FEMALES

Hour of scotophase	Pheromone titer, *A. gamma*[a] (ng/gland, mean ± SD)			Pheromone titer, *C. circumflexa*[a] (ng/gland, mean ± SD)			
	N	*Z*7-12:Ac	*Z*7-12OH	*N*	*Z*7-12:Ac	*N*	*Z*7-12OH
1	7	1.05 ± 0.12c	0.27 ± 0.09

[a] Twenty-five glands were considered as one replicate. For *A. gamma*, glands of 4- to 5-d-old females were extracted. For *C. circumflexa*, glands of 5- to 6-d-old females were extracted. Means followed by different letters differ significantly at $P = 0.05$ (Student–Newman–Keuls test).

half of the scotophase, and 49% copulated during the second half of the scotophase. The average duration of a copulation in the first half of the scotophase was 48.7 ± 9.9 min (mean ± SD; $N = 33$) and 42.6 ± 7.4 min in the second half of the scotophase ($N = 37$).

In *C. circumflexa*, copulation reflected the sexual activities of both sexes during the scotophase determined in our previous experiments (Figure 1C and Table 2). Copulations started at the beginning of the 8th hr, reached a peak about an hour later, and stopped an hour before light onset (Figure 5C). The average duration of copulation for *C. circumflexa* was 58.24 ± 12.12 min ($N = 18$).

Pheromone Titer Determination. The amount of *Z*7-12:Ac, the main pheromone component of *A. gamma*, reached a peak on the 5th night after emergence and remained unchanged until the 10th night. The amount of the minor component *Z*7-12:OH remained practically unchanged (Table 3). *Z*7-12:Ac titer peaked during the 7th hr of scotophase, whereas the minor component *Z*7-12:OH remained unchanged (Table 4).

The amount of the major pheromone component of *C. circumflexa*, *Z*7-12:OH, increased between the 4th and 6th night but otherwise remained unchanged (Table 3). Its titer was highest during the last 2 hr of the scotophase (Table 4). The amount of the minor component *Z*7-12:Ac remained constant for all tested ages (Table 3) and varied little throughout the calling period (Table 3).

DISCUSSION

The sexual behavior of *A. gamma* was studied in central Europe by Szöcs and Tóth (1979) and Tomescu et al. (1985), and in Great Britain by Hill and Gatehouse (1992). The origin of the moths examined, the environmental conditions during rearing and during the experiments, and the parameters studied differed from ours. Szöcs and Tóth (1979) and Tomescu et al. (1985) obtained similar results to ours concerning the sexual activity of the moths, which occurred throughout most of the scotophase. Discrepancy was observed between the above reports and ours as to the age at which sexual activity commenced. Szöcs and Tóth (1979) reported that sexual activity of the gamma moth began on the 1st night after emergence, whereas in our study, sexual activity started only on the 3rd night. Possible explanations for the discrepancy are the different strains used in the two studies, and the different photoperiods used in the two studies. The photoperiod used by Szöcs and Tóth (1979) was 18:6 LD, the typical photoperiod in central Europe during the summer when *A. gamma* populations are at their peak. In Israel, the moth is most common during spring and autumn; therefore, we used a photoperiod of 14:10 LD. Hill and Gatehouse (1992) examined two photoperiods, short (12:12 LD) and long (16:8

LD), and obtained significantly different mean precalling periods of 3.47 and 1.97 days, respectively. The fact that *A. gamma* is a migratory insect (Fisher, 1938; Yathom and Rivnay, 1968; Kitching, 1987; Pedgley and Yathom, 1993) may explain the impact of photoperiod on its sexual maturation. Migration usually takes place during the prereproductive period of adult life (Johnson, 1960; Dingle, 1972). Hill and Gatehouse (1992) confirmed that photoperiod has a significant effect on the prereproductive period of *A. gamma*, and that females have longer precalling periods under shorter day photoperiod. A similar photoperiodic effect on calling was reported by Delisle and McNeil (1986) for the true armyworm, *Pseudaletia unipuncta*, and by Del Socorro and Gregg (1997) for the Australian common armyworm, *Mythimna convecta*. Both are migratory species. McNeil (1986) suggested using the photoperiodic effect to identify migratory pest species.

The calling behavior of *A. gamma* and *C. circumflexa* females was age dependent. For both species, more calling was observed by older females, mainly due to advanced onset and longer periods of calling, because the percentage of calling females during the calling period was almost constant. An advanced onset of calling with age has been reported for several other moths (Swier et al., 1977; Webster and Cardé, 1982; Turgeon and McNeil, 1982; Howlader and Gerber, 1986; Schal and Cardé, 1986; Kou and Chow, 1987; Dunkelblum et al., 1987; Kamimura and Tatsuki, 1993; Delisle and Royer, 1994; Edmonds et al., 2000). It has been suggested that the advance in the onset of time of calling with age in lepidopteran species is an adaptation that permits older females to increase their chances of attracting mates before younger females start calling (Swier et al., 1977; Delisle, 1995). Delisle (1992) showed that the mean onset time of calling in *Choristoneura rosaceana* (Harris) advances with age, and that older females attract more males than younger ones, although less pheromone is produced by older females (Delisle and Royer, 1994). Older females would be at a disadvantage compared to younger ones if they did not expand their calling period.

The amount of pheromone and its composition in *A. gamma* and *C. circumflexa* were measured from extracts of excised glands at different ages and different times during the scotophase. The amount of pheromone in the gland may not be indicative as to the release rates (Shorey et al., 1968), but attempts to obtain more accurate information on the relationship between sexual behavior and pheromone release by collecting effluvia failed because of the low amounts of pheromone emitted by females of both species.

There was a synchronous relationship between the amount of pheromone in the glands and the calling activity at different ages for the two species. For *A. gamma*, calling started on the 3rd night, increased to the 5th night, and remained constant thereafter. The increase in pheromone titer paralleled the calling activity. For *C. circumflexa*, some calling was observed on the 2nd night from emergence, but a distinct increase in calling was seen only from the 4th night

onwards. The pheromone titer increased until the 5th night and remained almost constant thereafter.

The relationship between calling and pheromone titer during the scotophase also was almost synchronous in both species. The sexual activity of *A. gamma* was almost constant throughout the scotophase. However, there was more calling during the second half of the scotophase, accompanied by an increase in pheromone titer at the 7th hour of the scotophase. This might indicate intensified sexual activity during the second half of the scotophase. For *C. circumflexa*, calling and the pheromone titer were higher at the end of the scotophase, but calling declined during the last hour, whereas the amount of pheromone remained unchanged. Delisle and Royer (1994) summarized the literature available on the relationship between calling as a function of age and pheromone production, as well as between the diel pattern of calling and pheromone production in Lepidoptera. Some of the cases showed a synchronous relationship between calling and the amount of pheromone with age, as was found for *A. gamma* and *C. circumflexa*, whereas in others, such as the oblique-banded leafroller, *Ch. rosaceana*, the amount of pheromone decreased with age, although calling remained stable (Delisle and Royer, 1994). In the black cutworm, *Agrotis ipsilon* pheromone quantity coincided with calling, but unlike *A. gamma*, *C. circumflexa*, and *Ch. rosaceana*, the two parameters reached a peak for 2-d-old females during the scotophase and decreased progressively in older females (Gemeno and Haynes, 2000). Overall, 15 out of 25 spp. showed close synchrony of the two parameters. For the remaining 10 species, two different asynchronous patterns have been reported. In seven species, the peak of pheromone production occurred before the peak of calling, whereas in *P. unipuncta* (Delisle and McNeil, 1987) and the plusiinae species *Chrisodeixis chalcites* (Snir et al., 1986), the peak of pheromone production occurred after the peak of calling. In the last species, *Helicoverpa zea*, the relationship is not clear because of conflicting data (Raina et al., 1986, 1991).

Overlapping populations of *A. gamma* and *C. circumflexa* are frequently found in Israel during spring and autumn. The gamma moth is sexually active throughout the scotophase, whereas *C. circumflexa* is sexually active only during a short period at the end of the scotophase. There is no sharp temporal separation between the sexual activities of the two species, but most of the gamma moths have already been mated by the time *C. circumflexa* moths begin with their sexual behaviors. Furthermore, the inverse ratio between the two sex pheromone components, *Z*7-12:Ac and *Z*7-12:OH, seems to provide effective reproductive isolation (Mazor and Dunkelblum, 1992; Dunkelblum and Mazor, 1993). However, individual variations in the ratios of two components in both pheromone blends, combined with wider latitude of responsiveness of males as has been reported for other moth species (Ono and Orita, 1986; Löfstedt, 1990; Liu and Haynes, 1994; Löfstedt et al., 1994; Evenden et al., 2002), might limit

reproductive isolation based on different pheromone blend ratios between *A. gamma* and *C. circumflexa*. The temporal separation in sexual activity may provide an additional barrier in the reproductive isolation process between the two species. An analogous situation was reported for two plusiinae sibling species, *Diachrysia chrysitis* and *D. tutti* (Löfstedt et al., 1994). These two species are sympatric in large parts of their ranges and use sex pheromone blends in an almost opposite ratio, but despite the differences in blends, cross-attraction and potential hybridizations under natural conditions were confirmed.

Acknowledgements—We thank Prof. J. N. McNeil for his constructive comments which helped with the data analysis, and the late Prof. K. R. S. Ascher and Prof. R. Galun for useful comments on previous drafts of this manuscript. We also thank Dr. A. Genizi, Dr. R. Marcus, and Mrs. M. Zarchi for help with statistical analyses.

(Received September 23, 2004; revised March 31, 2005; accepted May 13, 2005)

Abstract—Three different types of traps were evaluated for a semiochemical-based trapping method for *Hylotrupes bajulus* (L.) (Cerambycidae). One, designated the ground trap, was the most efficient under both laboratory and natural conditions and had an active space of about 3.5 m. Significantly more beetles were captured in traps baited with a mixture of synthetic pheromones, (3*R*)-3-hydroxy-2-hexanone [(3*R*)-ketol] + 1-butanol, than in those with either single compound or with racemic mixtures. Furthermore, the synthetic lure captured more females than two virgin males in a laboratory bioassay. In addition, doubling the concentration of the synthetic pheromone significantly increased trap catches. The present findings have potential value of the management of this pest.

Key Words—*Hylotrupes bajulus*, Coleoptera, Cerambycidae, trap designs, effective distance, pheromone lure, pheromone mixture.

INTRODUCTION

Long-horned beetles have received attention in the recent past because of their pest potential (Hanks, 1999; Allison et al., 2004; Nerg et al., 2004, and references therein). The old-house borer, *Hylotrupes bajulus* (L.) (Coleoptera: Cerambycidae), is a cosmopolitan insect of high economic importance due to its

* To whom correspondence should be addressed. E-mail: reddy@guam.uog.edu

great potential to damage wood in houses. The beetle normally only feeds on sapwood, but in severe infestations may also attack the heartwood (White, 1954). Attacks often begin in the roof where larvae bore through rafters made of pine, spruce, and fir (Cannon and Robinson, 1982). Infestations spread when beetles fly from house to house in hot, sunny weather (Mares and Robinson, 1985), so an effective semiochemical-based trapping method would help to monitor and control *H. bajulus* populations.

Schröder et al., (1994) demonstrated that *H. bajulus* males produce a sex pheromone and identified (3*R*)-3-hydroxy-2-hexanone [(3*R*)-ketol] as a major component. Subsequently, chemical analysis of hexane extracts of dissected prothoracic glands, the source of the sex pheromone (Noldt et al., 1995), and headspace samples of both sexes revealed several male-specific compounds that were attractive to virgin females: (3*R*)-ketol, 2-hydroxy-3-hexanone, the diastereomeric alcohols [(2*R*, 3*R*)-2,3-hexanediol and (2*S*, 3*R*)-2,3-hexanediol, 2,3-hexanedione], and 1-butanol (Fettköther et al., 1995).

The objectives of this study were to determine the optimal pheromone dose, develop dispensers baited with pheromone mixtures, define the effective distance of the pheromone lure, and determine the efficiency of pheromone mixtures for use in trapping strategies.

METHODS AND MATERIALS

H. bajulus larvae are reared in darkness at 25°C and 75% RH at the Institute of Wood Biology and Wood Protection, Hamburg (Germany). The original culture was established in 1965, with adults collected at various roof sites in Schleswig-Holstein and Hamburg, and regularly restocked with specimens from other locations (Noldt et al., 1995). Newly emerged males and females were placed in individual Bellaplast boxes (Bellaplast AG, Altstätten, Switzerland) lined with moistened filter paper and then held in separate rooms at 20°C, 12 L:12 D photoperiod until needed. Food was not provided, since adult beetles do not feed under natural conditions (Becker, 1944). Beetles used in any given experiment were of the same age; however, age ranged from 5 to 15 days across all experiments.

Experiments were carried out in a greenhouse from April 15 to June 20, 1999, between 1200 and 1730 hours when insects are likely to be producing and responding to pheromones. Traps were evaluated in a gauze cage (450 cm long $\times$ 230 cm wide $\times$ 100 cm high) with six openings to insert or remove both traps and beetles. A ventilator was installed to facilitate a constant airflow of 2.5 m/sec and the contaminated air was removed during the experiment with an exhaust fan located on top of the cage.

Three trap types were evaluated, named ground, hanging, or wall traps, according to where they are placed. The ground trap (Figure 1A) measured 120 by 65 cm and had a slitted 50 by 8-cm baffle. The hanging trap (Figure 1B), suspended 75 cm from the floor, measured 50 by 12 cm and had a baffled slit on the upper surface. Wall traps (Figure 1C) were box shaped (40 cm high and 11 × 11 cm in cross section) with two 22-cm-long opening slits on the sides adjacent to the wall. All were constructed from 5-mm-thick brown cardboard, with a baffle near the openings to ensure that beetles caught did not escape.

Pheromone dispensers were made from 1-ml brown glass screw-top vials (N 8-1, Macherey-Nagel, Duren, Germany) capped with a 15 × 8-mm rubber septum (Thomas Scientific, Swedesboro, NJ, USA). Each vial was filled with 1,000 ml of pheromone mixture (purity ≥98.5%) obtained from the Department of Chemistry, Cornell University (USA) and the Institute of Organic Chemistry, University of Hamburg (Germany). Test chemicals were (3*R*)-ketol, 1-butanol (3 mg/vial/d), or racemic 3-ketol [(±)-3-ketol] (2.8 mg/vial/d), either alone at 1:100 or combined at 1:1:100 (by volume in hexane), respectively. Two

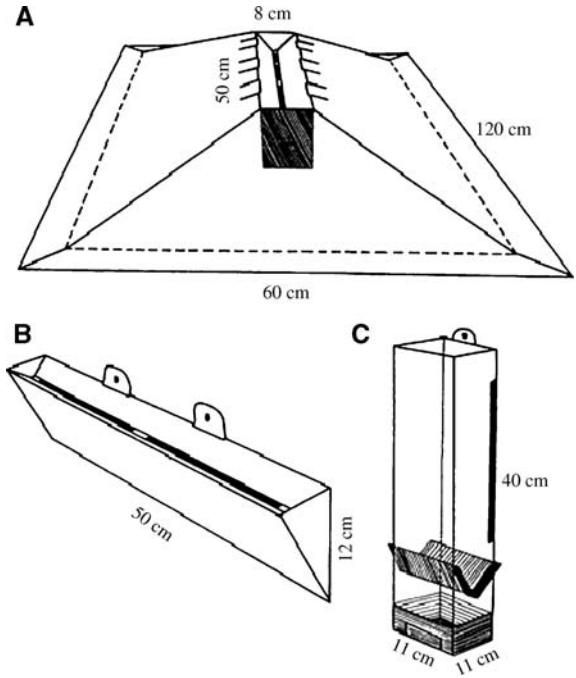

FIG. 1. Schematic diagram of three different pheromone traps tested for monitoring *H. bajulus*: (A) Ground trap, (B) hanging trap, and (C) wall trap.

dispenser vials were used per trap, unless otherwise stated. Dispensers were prepared the day before the experiment to allow volatile compounds to penetrate the rubber septa.

General Trapping Method. A trap baited with the test mixture was placed inside the greenhouse cage 2 hr before the release of the beetles so that pheromone could spread throughout the cage. Ten virgin female *H. bajulus* were released downwind of the trap at 1230 hr, and the number captured was counted after 3 hr. Temperature, relative humidity, and wind speed were measured with Meteo Digit III (Lambrecht, Klimatologische Messtechnik, Gottingen, Germany), whereas light intensity was recorded using a Lux-Meter (Testo GmbH & Co., Lenzkirch, Germany). All laboratory experiments were replicated eight times.

Radius of Maximum Attraction of Synthetic Pheromone Mixture. To determine the radius of maximum attraction of the synthetic pheromone, the ground trap was used, since it proved the most efficient in our previous experiment. Ten unmated females were released 1, 2, 3, 3.5, or 4 m downwind of a trap baited with (3*R*)-ketol + 1-butanol.

Effect of Pheromone Lure Composition on Capture of Unmated Females. Each trap was baited with (3*R*)-ketol (1.4 mg/vial/d), 1-butanol (1.6 mg/vial/d), (±)-3-ketol (1.2 mg/vial/d), or either two or four vials of (3*R*)-ketol + 1-butanol (standard; 3.0 mg/vial/d) or (±)-3-ketol + 1-butanol (2.6 mg/vial/d)). In each replicate, ten unmated females were released 3 m downwind of the trap.

Trapping Efficiency of Pheromone and Racemic Mixtures in the Presence of Males. Ten unmated females (5–15 d-old) were released 3 m downwind from two competing pheromone sources that were 50 cm apart. One was a ground trap baited the pheromone mixture (3*R*)-ketol + 1-butanol or (±)-3-ketol + 1-butanol and the other, two virgin males (5–15 d-old). The males, placed in a cavity within two pieces (13 × 13 × 13 cm) of pine wood held together with a rubber band were enclosed in a 30 × 20 × 20 cm nylon screen cage to prevent them from escaping. The beetles were replaced every 2 d. Data on the number of females approaching and entering the trap or coming into contact with the nylon cage containing the males were recorded. Females remaining on the nylon cage for 5 min were considered as trapped. Trapped beetles were removed from the experimental arena.

Efficiency of Traps under Natural Infested Conditions in the Field. The three trap designs were evaluated from July to October, 1999, in five naturally infested sites around the town of Bayreuth, Germany. Four ground, 30 wall, and 21 hanging traps were deployed in each of the five sites. The intertrap distance was 10 m, and their positions were re-randomized between replicates once every week. Traps were coated on the inner side with Hostaflon TF 5035 (polytetrafluoro ethylene) (Werk Gendorf, Burgkirchen, Germany) to prevent

trapped beetles from escaping. Four unbaited control traps of each type were used in the experiments. The number of beetles captured was recorded every morning.

Effect of Different Pheromone Blends in Recapturing H. bajulus in the Field. Ground traps baited with either the standard pheromone mixture (3*R*)-ketol + 1-butanol (3.0 mg/vial/d), an 86:14 blend of (3*R*)-ketol, and (3*S*)-ketol + 1-butanol (2.8 mg/vial/d), a 1:1 mixture of (±)-3-ketol + 1-butanol (2.6 mg/vial/d), as well as (3*R*)-ketol (1.4 mg/vial/d) or 1-butanol (1.6 mg/vial/d) as single components. Experiments were set up in barns at four different locations near Bayreuth, Germany, during July to October, 1999, with one trap in each location. The intertrap distance was 10 m in each location, whereas interlocation distance was approximately 2 km. Ten unmated females marked with color were released 2 m from the trap. Releases were made in the afternoon and the number of trapped beetles was recorded the following morning. The untrapped beetles were collected at the end of the experiment.

Statistical Analysis. Data were analyzed by Kruskal–Wallis nonparametric tests to compare the efficiency of traps, effective distance of pheromone mixture, or effect of pheromone compositions in recapturing *H. bajulus*. Mann–Whitney *U* tests (Sokal and Rohlf, 1995) were used to test for significant differences between the treatments.

RESULTS

Evaluation of Traps. In the greenhouse arena, the ground trap captured significantly more females than other traps baited with identical pheromone mixture ($P \leq 0.05$, Table 1). A similar trend was seen when tests were conducted in the infested roofs, trusses, and barns ($P = 0.001$, Table 1). Traps without pheromone mixtures, used as control, captured no beetles so they were not included in the analyses.

Radius of Maximum Attraction of Synthetic Pheromone Mixture. The baited ground trap was equally effective at distances up to 3.5 m, distances greater than previously reported for this species (Fettköther et al., 1995, 2000). However, there is a significant decline in captures when females are released 4m from the trap ($P \leq 0.05$; Table 2). The average temperature, relative humidity and light intensity prevailing during the study were 29.5°C, 30.5% and 1297.0 lx.

Effect of Different Pheromone Lures on Capture of Unmated Females. Ground traps baited with pheromone mixtures, except (±)-3-ketol + 1-butanol, were generally more attractive than those baited with any single compound ($P \leq 0.05$; Table 3). Increasing the dose increased trap catches with both blends,

TABLE 1. THE EFFICACY OF DIFFERENT TRAP DESIGNS, BAITED WITH (3*R*)-KETOL AND 1-BUTANOL, IN CAPTURING FEMALE *H. bajulus*

	Median captures of ten released females in a screen cage[a]	Capture of females in infested roof trusses and barns	
Trap design	Median ± MAD/trial (N = 8)	No. of traps used	Mean number of females caught ± SE
Ground trap	7.5 ± 0.5a	4	2.8 ± 0.2a
Wall trap	6.0 ± 0.5b	30	1.2 ± 1.0b
Hanging trap	3.5 ± 0.5c	21	0.1 ± 0.5c

[a] Captures in both greenhouse assays (Kruskal–Wallis ANOVA, P = 0.001) and naturally infested sites (Kruskal–Wallis ANOVA, P = 0.001) were significantly different. Median/Means followed by the same letter are not significantly different (Mann–Whitney U test, $P \leq 0.05$).
MAD = median absolute deviation.

but for any given concentration the (3*R*)-ketol + 1-butanol blend caught significantly more beetles than the corresponding racemic mixture (Table 3). The average temperature, relative humidity, and light intensity prevailing during this experimental period were 31°C, 25%, and 971 lx, respectively.

Trapping Efficiency of Two Pheromone Blends in the Presence of Males. Ground traps baited with the pheromone mixture captured significantly more females (median of six beetles captured) than two live males (median of four beetles captured) when tested concurrently in the greenhouse (F = 36.22, $P \leq$ 0.05; data not shown). In contrast, traps baited with (±)-3-ketol + 1-butanol captured significantly (F = 28.14, $P \leq 0.05$) fewer females than the males (medians of 3.0 and 5.0, respectively). The temperature, relative humidity, and

TABLE 2. EFFECT OF DISTANCE ON THE NUMBER OF *H. bajulus* FEMALES CAPTURED IN GROUND TRAPS BAITED WITH THE STANDARD PHEROMONE MIXTURE IN A GREENHOUSE TRIAL

	Median captures of ten released females in screen cage trial[a]
Distance (m)	Median ± MAD/trial (N = 8)
1	9.0 ± 0.5a
2	8.0 ± 1.0a
3	7.0 ± 1.0a
3.5	6.5 ± 1.5a
4	3.5 ± 0.5b

[a] Captures were significantly different (Kruskal–Wallis ANOVA; P = 0.011). Medians followed by the same letters are not significantly different (Mann–Whitney U test; $P \leq 0.05$).
MAD = median absolute deviation.

TABLE 3. EFFECT OF DIFFERENT PHEROMONE LURES ON THE CAPTURE OF UNMATED *H. bajulus* FEMALES IN GROUND TRAPS

Attractants	Quantity (no. of vials)	No. of females captured[a] Median ± MAD/trial
Single pheromone		
1-butanol	2	2.0 ± 1.5c
(3*R*)-ketol	2	2.0 ± 0.5c
(±)-3-ketol	2	1.0 ± 0.5d
Blend of pheromone		
(3*R*)-ketol + 1-butanol (standard)	2	6.0 ± 1.0b
(3*R*)-ketol + 1-butanol	4	8.0 ± 0.5a
(±)-3-ketol + 1-butanol	2	3.0 ± 0.5c
(±)-3-ketol + 1-butanol	4	5.0 ± 1.0b

[a] Captures were significantly different (Kruskal–Wallis ANOVA, $P = 0.012$). Medians followed by the same letters are not significantly different (Mann–Whitney U test; $P \leq 0.05$).
MAD = median absolute deviation.

light intensity prevailing during this experimental period were 31.5°C, 21.5%, and 983.0 lx, respectively.

Efficiency of Different Pheromone Mixtures in the Field. As with the greenhouse experiments, traps baited with pheromone mixtures were more efficient than those baited with either single pheromone component ($P \leq 0.05$; Table 4). Furthermore, the standard blend was more effective that any of the racemic mixtures (Table 4).

TABLE 4. PERCENTAGE OF FEMALE *H. bajulus*, RELEASED 2 M FROM GROUND TRAPS BAITED WITH DIFFERENT PHEROMONE MIXTURES, WHICH WERE RECAPTURED IN BARNS AT FOUR DIFFERENT LOCATIONS

DISCUSSION

The ground trap proved to be the most effective design tested partly because although females initially fly upwind in the pheromone plume they generally walk the final distance (about 50 cm) to the source, whereas the relative response of different beetles to racemic and pure pheromone blends varies with species (Iwabuchi et al., 1986; Hallett et al., 1995; Giblin-Davis et al., 1996; Miller et al., 1997). *H. bajulus* females are clearly less attracted to racemic blends. Furthermore, the racemic blend proved less effective than virgin males. Thus, we believe that ground traps baited with (3*R*)-ketol + 1-butanol offer a viable approach for the monitoring and control of *H. bajulus*.

However, additional work is required to further refine the system. For example, research examining the possible effects of physical characteristics such as color on the efficacy of the ground traps merits attention (Suckling et al., 2005). With respect to the lure, we saw an increase in trap catch when the concentration of the pheromone was doubled (Table 3). Thus, we need to determine if doses higher than those tested in this study increase the numbers of beetles caught. This merits attention because different dose-dependent responses were reported on other beetle species (Fadamiro, 1996; Fukaya and Honda, 1996). In addition, if trap catches do increase with increasing concentrations of pheromone, one needs to examine if this is related to having a larger active space. Furthermore, our previous studies (Fettköther et al., 2000) showed that the addition of α-pinene to the pheromone increased attraction and orientation of both sexes toward the source. Therefore, trials need to be carried out to determine how this and other compounds such as (−)-verbenone, *trans*-pinocarveol, and terpinen-4-ol (Fettköther et al., 2000) might be used with the pheromone to increase trap efficacy.

Acknowledgments—We thank Drs. Frank Schröder and Wittko Francke for providing the synthetic pheromone compound and Ms. Dorothea Martin Klöckner for technical assistance in rearing of beetles. We are grateful to the German Federal Foundation for the Environment (Deutsche Bundesstiftung Umwelt, Osnabrück) for financial support of the project. We thank Ms. Mary Finlay-Doney, University of Queensland (Australia), for helpful comments on earlier versions of the manuscript. Finally, we thank the Alexander von Humboldt Foundation, Bonn, for the Humboldt Research fellowship to the senior author. We also thank two anonymous reviewers and Dr. Jeremy N. McNeil for their valuable comments.

ALLELOPATHIC POTENTIAL OF *Robinia pseudo-acacia* L.

HABIB NASIR, ZAHIDA IQBAL, SYUNTARO HIRADATE, and YOSHIHARU FUJII*

Chemical Ecology Unit, National Institute for Agro-Environmental Sciences, 3-1-3 Kan-nondai, Tsukuba, Ibaraki 305-8604, Japan

(Received March 24, 2004; revised April 28, 2005; accepted May 8, 2005)

Abstract—*Robinia pseudo-acacia* L. (black locust) is a nonindigenous species currently invading the central part of Japanese grasslands. Several allelochemicals were identified and characterized from the leaf tissue. The growth of both radicle and hypocotyl in the tested species (barnyard grass, white clover, lettuce, and Chinese cabbage) was reduced when grown in soil mixed with the leaves of *R. pseudo-acacia* at various concentrations. Aqueous leaf extracts, when bioassayed, exhibited a significant suppression of radicle growth. Chromatographic separation of an ethanolic extract of *R. pseudo-acacia* leaves resulted in isolation of three compounds, identified as robinetin (**1**), myricetin (**2**), and quercetin (**3**) by nuclear magnetic resonance and mass spectroscopy. All inhibited root and shoot growth of lettuce. Robinetin, found in a large amount, caused 50% suppression of the root and shoot growth of lettuce at 100 ppm. The presence of these bioactive substances in leaf tissue suggests a potential role for flavonoids in *R. pseudo-acacia* invasion in introduced habitats.

Key Words—Allelopathy, allelochemicals, quercetin, robinetin, myricetin invader, *Robinia pseudo-acacia*, growth inhibitors, black locust.

INTRODUCTION

Plants produce a variety of secondary metabolites that are released into the soil, either as exudates from living plant tissues or by decomposition and leaching from plant residues (Rice, 1984; Putnam and Tang, 1986). Some may be associated with allelopathy and play a role in chemical interactions in natural communities (Einhellig, 1996; Seigler, 1996; Dayan et al., 2000). Various interactions among plant species are responsible for natural selection in plant

* To whom correspondence should be addressed. E-mail: yfujii@affrc.go.jp

communities. Some exotic invasive plants show competitive behavior that is different or not present in the natural community they invade. Allelopathy has been considered as a probable mechanism for the remarkable success of invader plants (Callaway and Aschehoug, 2000) because native species may be devoid of those chemicals produced by the invader plants. It is suspected that *Centaurea* species, one of the most destructive exotic invaders in North America, is using allelochemicals to displace native species (Goslee et al., 2001; Ridenour and Callaway, 2001; Bais et al., 2002).

Robinia pseudo-acacia L. belongs to the Fabaceae and is commonly known as black locust. It is widely distributed in temperate and subtemperate zones. It is a nitrogen fixer, has rapid juvenile growth (Hanover et al., 1992; Moon et al., 2001), and can propagate by seeds or sprouts. It is widely planted as an ornamental for shelterbelts and for land reclamation. This early successional plant spreads rapidly, creates dense stands that shade, and outcompete the nearby vegetation. It has interesting biological properties and medicinal activities (Fielder, 1975; Foster and Duke, 1990). It was brought to Japan about 100 years ago as an ornamental tree. It has been observed that in places where these trees dominate, other plants are lacking, and the vegetation beneath the tree is poor. It is known that 500 trees in one hectare will suppress the growth of other plants. In the central part of Japan, *R. pseudo-acacia* is reported to establish itself in monocultures on the river side and it cause damage to the apple trees that are the main fruit trees in this area (Maekawa and Nakagoshi, 1997; Maekawa, 1998). Based on this field observation and a previous bioassay study of fallen leaves of this plant by sandwich methods and of root exudates by plant box methods (Uraguchi et al., 2003), it was suggested that *R. pseudo-acacia* releases allelopathic compounds that inhibit the growth of other plants.

METHODS AND MATERIALS

Plant Material. R. pseudo-acacia is grown in the National Institute for Agro-Environmental Sciences, Tsukuba, Japan. Fresh and fallen leaves (1.5 kg) were collected from two sites in early autumn. The soil type was andosol, analyzed as 70% sand, 6% silt, 24% clay (pH 4.6), and 0.58% organic matter. The seeds of alfalfa (*Medicago sativa* L.), Italian rye grass (*Lolium multiflorum* Lam), barnyard grass (*Echinochloa crus-galli* P. Beauv. var. *crus-galli*), timothy (*Phleum pretense* L.), lettuce (*Lactuca sativa* L.), Chinese cabbage (*Brassica campestris* L.), and white clover (*Trifolium repens* L.) were used as bioassay species. All seeds were purchased from Takii Seed Co. Ltd., Kyoto, Japan.

Concentration-Dependent Phytotoxic Effects. Studies were conducted to determine the effect of leaf debris on the growth of test plants under fieldlike

conditions. Andosol soil (30 g each) was mixed with 0.17, 0.34, and 0.68 g of *R. pseudo-acacia* dried leaves. The soil was placed in black vinyl pots (7.5 cm diameter and 6.5 cm deep) (TO-R2, Kuromaru Nippori, Mitsubishi Chem. Co. Ltd., Japan). Four plant species, including two edible crop species (lettuce and Chinese cabbage) and two weed species (barnyard grass and white clover) were selected for the concentration-dependent pot experiments. The treatment is expressed as 0, 0.6, 1.14, and 2.3% (w/w) based on soil dry weight. These are consistent with those used for phytotoxic studies of other species (Bhowmik and Doll, 1982; Touchette et al., 1988; White et al., 1989). There were five replications of each concentration for each bioassay species. Pots placed in a greenhouse were watered daily. Temperature was maintained at 26°C day and 18°C night. Emergence was recorded after 4 d of planting, and after 7 d, each pot was thinned to the five healthiest plants. Plants were harvested after 3 wk, and the soil was carefully washed from the roots. Root/shoot length, and fresh/dry weight of roots were measured.

Phytotoxic Effects of Aqueous Extracts of Leaves. Aqueous extracts of leaves were tested for allelopathic potential on lettuce and other weed species. Ten grams of oven-dried leaves were soaked in 100 ml water in a flask and agitated for 24 hr on an orbital shaker (150 rpm) at room temperature (25 ± 3°C). The extract was strained through two layers of cheesecloth and then two layers of Whatman No. 2 filter paper. In an 8.5 × 8.5 × 1.5-cm culture dish lined with Whatman No.1 filter paper, ten seeds each of barnyard grass, white clover, Chinese cabbage, lettuce, timothy, and alfalfa were placed separately. Treatments were applied in 2.5 ml volumes per dish, and distilled water was used as control. Petri dishes were sealed with parafilm (Parafilm "M" laboratory film, American National Can) and incubated in the dark in the growth chamber for 72 hr at 25°C. Treatments were replicated three times. Root and shoot lengths were recorded after 72 hr.

Extraction and Isolation of Compounds. Fresh leaves (1.5 kg) were soaked in 80% aqueous ethanol (5 l) for 7 d. The ethanolic extract was concentrated to a crude, dark brown gum (100 g). The crude extract was partitioned against hexane and water. The original crude, aqueous, and hexane extracts were bioassayed using lettuce as a test plant. Comparison of bioassay results revealed that the major activity of the crude extract was in the aqueous extract. Bioassay directed silica gel (Wakogel C-200, 74–149 μm, Wako Pure Chemical Industries, Osaka, Japan) column chromatographic resolution of a portion of the aqueous fraction gave 12 main fractions (Figure 1). Each of these was bioassayed with lettuce, and among these Fr-1-6, Fr-1-9, and Fr-1-10 were active. A portion of fraction Fr-1-9 (500 mg) was therefore subjected to Sephadex gel LH-20 using $MeOH/H_2O$ (9:1) followed by reverse-phase chromatography on YMC gel (ODS-AQ 120-S50) and eluting with 90% aqueous methanol. Four main fractions were obtained, which were bioassayed,

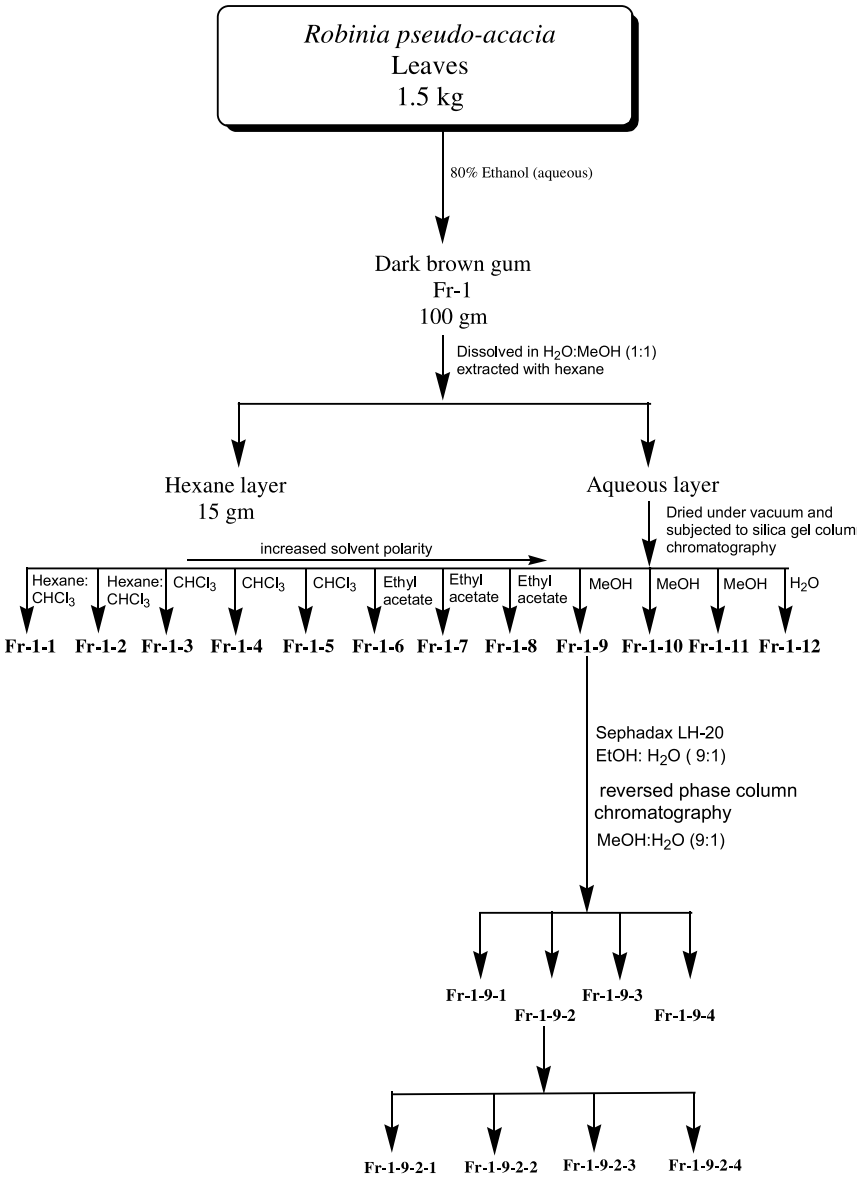

FIG. 1. Isolation scheme of active constituents of *R. pseudo-acacia* from the crude ethanolic extract of leaves.

and the most active one, Fr-1-9-2, upon further purification yielded compounds **1**, **2**, and **3** (Figure 2).

Identification. Structures of compounds **1**–**3** were determined by nuclear magnetic resonance (NMR) and mass spectroscopic techniques. NMR spectra were recorded using a JEOL JNMα-600 spectrometer operating at 600 MHz for ^{1}H and 150 MHz for ^{13}C using standard JEOL software (Alpha Data System). Spectra were recorded using acetone-d_6 as a solvent and tetramethyl silane (TMS) as internal reference. FAB-MS spectra were recorded on a JEOL

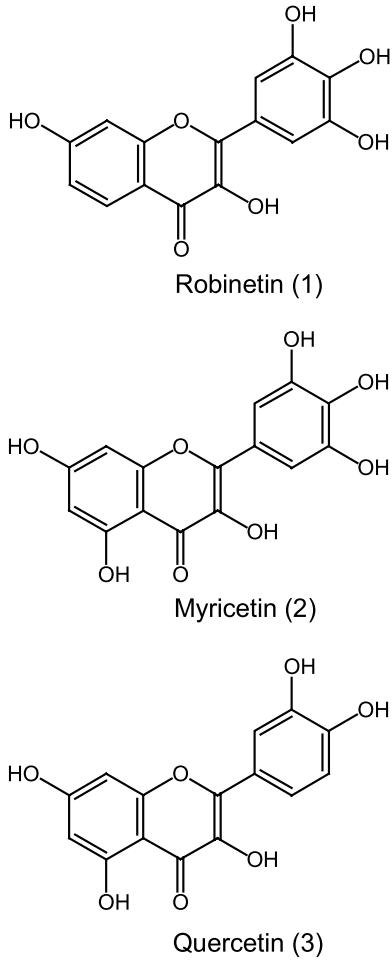

FIG. 2. Structures of robinetin (**1**), myricetin (**2**) and quercetin (**3**).

SX102A spectrometer. Samples were mixed with glycerol as a matrix and analyzed using a direct inlet system.

Bioassay. The crude ethanolic extract and its subfractions obtained after chromatographic resolution were subjected to bioassay with lettuce as the test species. Seeds were germinated on wet filter paper (No. 1, Toyo Ltd., Tokyo, Japan) for 18 hr at 25°C in the dark. The resulting five germinated seeds (2 mm radicle length) were placed on filter paper (4 cm diameter, No. 1, Toyo Ltd.) containing appropriate concentrations of test solution in a Petri dish (4 cm ID). The seedlings were grown at 25°C in the dark for another 2 days, followed by root and shoot length measurement. Elongation ratio was calculated by using the formula $(A/B) \times 100$, where A is the mean elongation of the hypocotyls or radicles in the presence of test compound, and B is the mean elongation length of the hypocotyls or radicles of control. Each treatment was replicated three times ($N = 15$).

Purified compounds **1**, **2**, and **3** were also tested for growth inhibitory activity at 100, 50, and 10 ppm, respectively, against lettuce. Experiment design and incubation conditions were the same as described above in the bioassay of crude extracts.

Statistics. The analysis of variance for all data was measured using the general linear model procedure by SAS/STAT (1990). Effective concentration required for 50% inhibition (EC_{50}) of test species was calculated based on fitted regression equations.

RESULTS

Concentration-Dependent Phytotoxicity. Radicle and hypocotyl growth of all tested weeds (barnyard grass and white clover) and edible crops (lettuce and Chinese cabbage) species was strongly inhibited when grown in soil mixed with *R. pseudo-acacia* leaves at three different concentrations. Seedling growth decreased as the concentrations of leaves increased in soil, and the highest inhibition was observed at 2.3% (w/w). The inhibitory effect was greatest on weed species, particularly on barnyard grass (Figure 3a). Incorporated leaves at a concentration of 0.17 g/30 g soil inhibited the root and shoot length of barnyard grass by 87 and 71% of control, respectively. Root and shoot growth of Chinese cabbage, however, was less sensitive at this concentration.

Fresh and dry weights of radicles in all tested plants significantly decreased when grown in soil mixed with *R. pseudo-acacia* leaves. Weed species, especially barnyard grass, experienced the highest weight decrease (Figure 4b). Total dry weight per plant was reduced to 86 and 78% for barnyard grass and white clover among weeds, and 79 and 75% for lettuce and Chinese cabbage

Extract (mg g^{-1} fw)	Alfalfa	Chinese cabbage	Barnyard grass	Lettuce	White clover	Timothy
0 (Control)	100 ± 4.3	100 ± 8	100 ± 6	100 ± 8	100 ± 8	100 ± 6
17	0	0	0	0	0	0
8.5	0	0	0	0	0	0
1.7	22 ± 5	23 ± 4	16 ± 5	23 ± 5	24 ± 5	15 ± 8
0.8	28 ± 6	29 ± 8	18 ± 7	34 ± 9	32 ± 6	20 ± 8
0.17	35 ± 8	40 ± 8	21 ± 8	46 ± 10	50 ± 8	31 ± 8

among the edible crops, respectively. The estimated leaf concentration required for a 50% reduction in root dry weight was less than 0.17 g/30 g of soil.

Phytotoxicity of Aqueous Extracts. Aqueous extracts of *R. pseudo-acacia* leaves [17, 8.5, 1.7, 0.8, 0.17 mg g^{-1} fresh weight (fw)] were applied in Petri dishes to six plant species. Growth of all test plants was completely inhibited at the two highest applied concentrations. However, at the other three concentrations, selective inhibitory effects on both hypocotyls and radicles were observed (Tables 1 and 2). In comparison, the inhibition of seedling growth was stronger in weeds than in the edible crop species and ranged between 65–79% and 40–63% in radicles and hypocotyls, respectively.

Isolation of Allelochemicals. The crude aqueous ethanolic extract inhibited the radicle elongation of lettuce seedlings more than 70% relative to the control (Figure 5A). After chromatographic resolution, inhibitory activity was found mostly in the methanol-eluted fraction Fr-1-9 (Figure 5B), which caused significant inhibition of radicle length in lettuce seedlings after 72 hr. Successive bioassay-directed chromatography of Fr-1-9 on Sephadex LH-20 and reverse-phase silica gel columns gave four main fractions. Among these, Fr-1-9-2 was the most active (Figure 5C). The fraction Fr-1-9-2 was therefore subjected to reverse phase column chromatography using MeOH–H_2O (9:1) as

the eluting solvent to obtain four fractions, which were bioassayed, and the most active fraction, Fr-1-9-2-1, was further purified on a lobar column using methanol/water (9:1) to obtain the flavonoid **1**. The second most active fraction, Fr-1-9-2-2, yielded two pure compounds, **2** and **3**. These were identified as robinetin, myricetin, and quercetin (Figure 2). The spectroscopic data of **1** were in accordance with those reported in the literature (Mabry et al., 1970; Coetzee et al., 1995). The ^{1}H and ^{13}C NMR data of **2** and **3** were identical to those of authentic samples.

Compounds identified from *R. pseudo-acacia* exhibited inhibitory effects on radicle and hypocotyl growth of lettuce seedlings (Figure 6). The order of potency of growth inhibition was robinetin, myricetin, and quercetin with EC_{50} values of 100, 108, and 110 ppm, respectively.

DISCUSSION

A number of plants have inhibitory effects on the growth of neighboring or successional plants by releasing phytotoxic chemicals into the soil, either as exudates from living tissues or by decomposition of plant residues (Putnam and Tang, 1986; Chou and Leu, 1992; Chou et al., 1998; Chaves et al., 2001). The presence of phytotoxins in leaves of *R. pseudo-acacia* was confirmed by four plant species grown in soil mixed with leaves of this plant at three different concentrations (0.17, 0.34, and 0.68 w/w). In all tested species, growth of both radicles and hypocotyls was inhibited. The magnitude of inhibition increased with an increase in concentration (w/w) of *R. pseudo-acacia* leaf debris (Figure 3a). Weed species, particularly barnyard grass, was the most sensitive to allelochemicals released from the decomposing leaves. Furthermore, a gradual decrease in fresh and dry weight was observed in all tested species. The reduction in fresh and dry weight ranged from 35–76% and 40–65% in roots and shoots, respectively. In these pot experiments, leaves of the tested plants changed to a yellowish-green color. This phenomenon is speculated as being due to a decline in total chlorophyll contents. *R. pseudo-acacia* leaf aqueous extract showed strong phytotoxicity in terms of radicle and hypocotyl growth inhibition when the aqueous extract was applied in five different concentrations (w/w) (Tables 1 and 2). In all bioassay species, both radicle and hypocotyl growth decreased proportionally with increasing concentration of leaf water-soluble extract. Compounds identified from *R. pseudo-acacia*, robinetin (**1**, 0.990 μmol g^{-1} fw), myricetin (**2**, 0.062 μmol g^{-1} fw), and quercetin (**3**, 0.099 μmol g^{-1} fw) exhibited inhibitory effects on radicle growth of lettuce. Robinetin was isolated in larger amounts and was identified as one of the major inhibitors in the leaves. Therefore, the major portions of the crude extract's inhibitory activity may

partially be attributed to robinetin and partially to other compounds. The EC_{50} of robinetin was 100 ppm, which is not especially low. However, the purified compound with its low specific inhibitory activity may play a greater role in the expressed inhibitory potential than those of high specific inhibitory activity by virtue of its being present in larger quantity (Lehle and Putnam, 1983). The other compounds also inhibited the root and shoot elongation of lettuce seedlings. Allelochemicals are present in all parts of plants including leaves, stems, and roots, and under appropriate conditions these are released into the environment and likely act additively or synergistically to affect the growth of neighboring plants (Weston and Duke, 2003).

In summary, this study demonstrates that allelochemicals released into the environment through accumulated fallen leaves inhibit the growth of various weeds and crop species. A species-selective inhibitory effect was observed. Allelopathy may play a role in the successful invasion of *R. pseudo-acacia*, but field trials are required to examine the significance of the allelochemicals on target species that co-occur with *R. pseudo-acacia* in nature.

Abstract—*Ageratum conyzoides* L. weed often invades cultivated fields and reduces crop productivity in Southeast Asia and South China. However, intercropping this weed in citrus orchards may increase the population of predatory mite *Amblyseius newsami*, an effective natural enemy of citrus red mite *Panonychus citri*, and keep the population of *P. citri* at low and non-injurious levels. This study showed that *A. conyzoides* produced and released volatile allelochemicals into the air in the intercropped citrus orchard, and these volatiles influenced the olfactory responses of *A. newsami* and *P. citri*. At test temperature (25°C), *A. conyzoides* fresh leaves, its essential oil, and major constituents, demethoxy-ageratochromene, β-caryophyllene, α-bisabolene, and E-β-farnesene, attracted *A. newsami* and slightly repelled *P. citri*. Field experiments demonstrated that spraying *A. conyzoides* essential oil emulsion in an *A. conyzoides* nonintercropped citrus orchard increased the population density of *A. newsami* from below 0.1 to over 0.3 individuals per leaf, reaching the same level as in an *A. conyzoides* intercropped citrus orchard. However, this effect could not be maintained beyond 48 hr because of the volatility of the essential oil. In contrast, in the *A. conyzoides* intercropped citrus orchard, *A. conyzoides* plants continuously produced and released volatile allelochemicals and maintained the *A. newsami* population for a long time. The results suggest that intercropping of *A. conyzoides* not only made the citrus orchard ecosystem more favorable for the predatory mite

A. newsami, but also that the volatile allelochemicals released from *A. conyzoides* regulated the population of *A. newsami* and *P. citri*.

Key Words—*Ageratum conyzoides* L., volatile allelochemical, citrus orchard, intercropping, predatory mite *Amblyseius newsami*, citrus red mite, olfactory response.

INTRODUCTION

The Compositae weed *Ageratum conyzoides* L. originated from Central America and is now widely spread in Southeast Asia and South China. It invades cultivated fields and reduces crop productivity in tropical and subtropical agroecosystems (Roder et al., 1997; Singh et al., 2003). However, when grown in citrus orchards, it effectively suppresses the growth of other weeds and spore germination of several fungal pathogens through release of allelochemicals into the soil (Kong et al., 2004c). Additionally, intercropping *A. conyzoides* with citrus makes the orchards more favorable for predatory mites (*Amblyseius* spp.), which effectively control the major arthropod pest citrus red mite (*Panonychus citri* McG) in citrus orchards in South China (Tao and Luo, 1992). Therefore, *A. conyzoides* has been advocated for intercropping in citrus orchards and is utilized on more than 150,000 ha of citrus orchards in South China (Liang and Huang, 1994). The natural biochemical interactions between *A. conyzoides* and other organisms in the intercropped citrus orchard remain obscure.

A. conyzoides produces and releases volatile allelochemicals into the environment at various growth stages (Kong et al., 1999, 2002, 2004a,b). The concentration of volatiles in *A. conyzoides* intercropped citrus orchards is so high that an unpleasant odor can be detected. Studies have shown that volatile allelochemicals released by many plant species play an important role in tritrophic systems that include the host plant, herbivore, and parasitoid or predator (Dicke et al., 1990; Bruin et al., 1992; Dicke, 1999; Sabelis et al., 1999; Agrawal, 2000; Bruin and Sabelis, 2001; Kessler and Baldwin, 2001). It is possible that volatiles released by *A. conyzoides* may affect the behavior and population of mites in intercropped citrus orchards. Accordingly, our objectives in this study were to determine and identify the volatile allelochemicals in the *A. conyzoides* intercropped citrus orchard and to evaluate their effects on the predatory mite (*Amblyseius newsami* Evans) and the citrus red mite (*P. citri*).

METHODS AND MATERIALS

Sampling Citrus Orchards. Two orchards planted with *Citrus sinensis* (L.) Osb. (plants, 2.5 × 4 m) in Guangzhou Suburb, China (23°06′N, 113°18′E),

were selected. One orchard had been intercropped with *A. conyzoides* since 2001. The *A. conyzoides* plants grew luxuriantly and covered the orchard floor that was free from other weeds. Another citrus orchard without *A. conyzoides* served as the control. The major weeds in this orchard were *Bidens pilosa*, *Digitaria sanguinalis*, and *Cyperus difformis*. If any *A. conyzoides* appeared in the control site, they were hand-weeded since October 2002. The experimental orchards were in a subtropical climate zone, with a mean annual temperature of 21.8°C and a mean annual rainfall of 1682 mm. There were no significant differences in pH, organic matter content, and fertility status between the intercropped and control site soils (pH 5.6; organic matter 19.7 g kg^{-1}; total N 0.97 g kg^{-1}; available N 40.8 mg kg^{-1}; total P 0.48 g kg^{-1}; available P 13.8 mg kg^{-1}; total K 102.9 g kg^{-1}; available K 98.7 mg kg^{-1}).

Population Densities of Mites. A. newsami and *P. citri* were used because *A. newsami* is the most common *Amblyseius* spp. predatory mite and *P. citri* is a major citrus arthropod pest in citrus orchards in South China. Fifteen citrus plants, whose canopies did not touch each other, were randomly selected from two orchards, respectively. For the population census, 50 representative spatial leaves of each citrus plant were selected, and adult mites were counted twice a day (10: 00 a.m. and 4:00 p.m.) for three consecutive days (Tao and Luo, 1992). Data were subjected to ANOVA with Duncan's multiple range test. The mean number of individual mites (*A. newsami* or *P. citri*) per leaf indicated their population densities in the orchards.

Effect of the essential oil on the mites was studied in a nonintercropped citrus orchard (i.e., control without *A. conyzoides*). Twenty-seven citrus plants (3 × 9), whose tree canopies were separated from one another by at least 15 m, were randomly selected. Then, a 5% essential oil emulsion (10 kg) of *A. conyzoides* was sprayed on 18 citrus plants (2 × 9). Ten kg water served as a control (1 × 9 citrus plants). After 24 and 48 hr, the population densities (mean individuals per leaf) of adult mite *A. newsami* and *P. citri* on each of 50 representative spatial leaves of each plant were counted as described above.

Experiments were carried out in June 2003, when *A. conyzoides* was at its peak flowering stage, and mites *A. newsami* and *P. citri* were active and abundant. Sampling dates were cloudy with a 27 ± 5°C air temperature and 70 ± 10% relative humidity. Pesticides have never been applied in either citrus orchard since October 2002.

Collection and Analysis of Volatiles. Collection and analysis of volatiles in the orchards was as follows (Kong et al., 2004a). Nine sampling locations were randomly selected from both citrus orchards. Air samples 1 m above the ground at 2 × 9 locations each were collected by Timing Minipump air samplers with a flow meter TMP-1500 (China Electrical Instruments Co.) and pumped through the sampling tubes (Tekmar Co., USA) packed with Tenax and Carbonsieve at a flow rate of 0.5 l/min for 30 min. The volatile chemicals in air samplers were

adsorbed onto the solid adsorbents, and sampling tubes were installed into a Tekmar 6032 Aero-trap Autosampler for thermal desorbing. The tubes were rapidly heated to 225°C, and their volatiles were desorbed and carried by helium to a Tekmar 3000 Purge & Trap Concentrator where they were trapped again. The concentrator was heated at a rate of more than 400°C/min, and the trapped volatiles were transported to a Hewlett-Packard P 5972 GC/MSD with an HP-5 bonded stage fused-silica capillary column (30 m × 2.5 mm) for analysis. The initial oven temperature (70°C) was maintained for 2 min and then increased to 180°C at a rate of 10°C/min. The column was maintained at 180°C for 5 min, and then the oven temperature was raised to 250°C at 15°C/min. Mass spectra were repetitively scanned from 35 to 450 amu every 2 sec. Ionization was selected in the electron impact mode (EI) at 70 eV. The chemical constituents were identified by peak matching against standards in the NIST 95 Computer Library or by spectral similarity to an authentic reference compound (Aldrich Chemical Co.). The relative amounts of the chemical constituents were calculated by integrating all peaks with an area greater than 0.1%.

Collection and analysis of volatiles from fresh leaves and the essential oil of *A. conyzoides* were performed using the technique of multiple headspace solid-phase microextraction (Augusto et al., 2003; Ezquerro et al., 2003). GC/MSD and manipulation was the same as described above.

The essential oil was obtained by placing fresh leaves of *A. conyzoides* into a desiccator with a liquid nitrogen cold trap and pumped into a vacuum (Kong et al., 2002). It was then subjected to silica gel column chromatography with *n*-hexane/ether (9:1 and then 4:6; v/v) mixture. It produced five major components, ageratochromene, demethoxy-ageratochromene, β-caryophyllene, E-β-farnesene, and α-bisabolene.

Olfactory Responses of Mites to Volatiles. Adult mites of both *A. newsami* and *P. citri* were collected from citrus orchards and reared in a petri dish (9-cm diam.; 1.8-cm depth) at 25°C and 50% relative humidity. The dish was placed in a transparent container over a pad of black colored velvet and a sponge (8-cm diam.; 1 cm thick). Because the mites are translucent, the black background enhanced visual detection. The sponge was allowed to imbibe and maintain water by partially adding water daily.

The olfactory response of the mites to volatiles was studied with a slightly altered airflow four-armed olfactometer designed by Pettersson (1970). The size of the exposure chamber was halved (ray of crescents: 67.5 mm, inner height: 5 mm, inner diameter of stainless tubes: 3 mm). A flow rate of 300 ml/min through each arm was maintained to create odor fields with sharp boundaries. The exposure chamber and TV monitor screen (21″) were interfaced with a multifunctional MC-1 camera (China Optical Co.) with the following features: sensitive element, 1/3″, 500(H) × 582(V) lines; resolution, 420 lines; optical attachment, eyepiece adapter (39-mm diam for stereomicroscope and 23.3-mm

diam for the biological microscope); minimum illumination, 3 lx; shutter, 1/50–1/1000 sec autocontrol; objective, $F = 8$ mm, focus from 10 mm to infinity. A vacuum pump/compressor was connected to a hole in the center of the floor of the exposure chamber by silicone rubber tubing and was used to suck air through the arms of the device into the exposure chamber. Test mites were introduced into the exposure chamber through this hole with the extractor tube removed. Activated charcoal enclosed in dry cotton wool at each flow meter purified incoming air.

Trials were conducted in accordance with the protocols suggested by Vet et al. (1983). Each arm of the exposure chamber was connected to a set of three 50-ml glass vials. The vial closest to the chamber served as the trap to catch mites, the second one provided an odor source, and the outside vial contained distilled water over which the incoming air was passed to create uniform humidity. The odor source, *A. conyzoides* fresh leaves (500 mg), the essential oil (100 mg), or five components (100 mg) were each placed in the odor vial. An olfactometer with a single arm of humidified air served as control. With proper air pressure, four air streams of 300 ml/min were introduced into the central region through the flow meters into each of the different arms of the olfactometer. Fifty adult mites were individually introduced into the chamber, and they could make two choices. The first choice was made when a mite reached the arbitrary transverse diagonal of one of the odor compartments. Before the first choice was made, each mite was given 2 min in the exposure chamber, at the end of which it was regarded as unmotivated and not recorded. The remaining 8 min was allocated for the second choice that was recorded as the mite stayed in any of the odor compartments beyond the first choice line. Thus, a mite could express both choices or the first choice only. The total number of mites that expressed the first choice or both choices was recorded. To neutralize any asymmetry in the experimental setup, vials containing odor sources were reordered after testing 10–15 mites, followed by a thorough cleaning of the chamber with absolute alcohol and allowing the solvent to dry for 10–15 min. The experimental environment was at 25°C and 60–70% relative humidity.

Olfactory responses were analyzed using ANOVA with Duncan's multiple range test. The impacted degree (ID) was calculated based on the following formula (Mumcuoglu et al., 1996): degree of attraction = $[1 - (C/T)] \times 100\%$ and degree of repellency = $[1 - (T/C)] \times 100\%$, where T is number of mites in the treatment and C is number of mites in the control.

RESULTS

Population of Mites in the Citrus Orchards. Figure 1 shows that *A. newsami* and *P. citri* occurred in both the *A. conyzoides* intercropped and

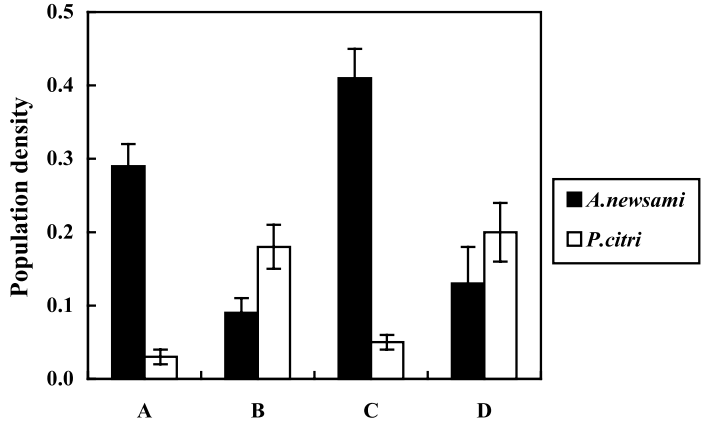

FIG. 1. Population density (mean individuals per leaf) of mites on citrus trees (**A**, in the *A. conyzoides* intercropped citrus orchard; **B**, in the *A. conyzoides* nonintercropped citrus orchard; **C**, in the *A. conyzoides* nonintercropped citrus orchard, after 24 hr of spraying 5% *A. conyzoides* essential oil emulsion; **D**, in the *A. conyzoides* nonintercropped citrus orchard, after 48 hr of spraying 5% *A. conyzoides* essential oil emulsion).

nonintercropped citrus orchards, but that their population densities had obvious differences. In the *A. conyzoides* intercropped orchard, the population density of *A. newsami* reached 0.3 individual per leaf, and the *P. citri* population was markedly decreased. In the *A. conyzoides* nonintercropped orchard, the *A. newsami* population was below 0.1 individual per leaf, and the *P. citri* population was increased over 0.2 individual per leaf. This indicated that intercropping with *A. conyzoides* in citrus orchards increased the *A. newsami* population and reduced the population density of citrus red mite to low and noninjurious levels. This was possibly correlated with volatiles in the air.

Volatile Allelochemicals and Their Effects on Mites. Several terpenes, such as carene, cubebene, copaene, limonene, myrcene, and pinene, were detected in the air in both the *A. conyzoides* intercropped and nonintercropped orchards. Abundant ageratochromene, demethoxy-ageratochromene, α-bisabolene, β-caryophyllene, and E-β-farnesene were found in samples from the *A. conyzoides* intercropped orchard, fresh leaves, and the essential oil of *A. conyzoides*, but these were not detected in the air samples above the *A. conyzoides* nonintercropped orchard (Table 1). These volatile components in the orchards might come from understory plants, soil, or other organisms, but ageratochromene, demethoxy-ageratochromene, β-caryophyllene, α-bisabolene, and E-β-farnesene were all major components of *A. conyzoides* fresh leaves and essential oil. Particularly, ageratochromene and demethoxy-ageratochromene are specific in the *Ageratum* genus (Kong et al., 2002, 2004a; Okunade, 2002). These

TABLE 1. CHEMICAL CONSTITUENT OF VOLATILES IN AIR SAMPLES COLLECTED FROM DIFFERENT SOURCES

Chemical constituent	Nonintercropped citrus orchard*	Intercropped citrus orchard*	Fresh leaf of *A. conyzoides* (headspace)	Essential oil of *A. conyzoides* (headspace)
Ageratochromene	0a	6.6 ± 1.3b	10.3 ± 1.0c	31.2 ± 5.1d
Demethoxy-ageratochromene	0a	8.9 ± 1.7b	9.8 ± 1.1b	21.5 ± 4.4c
β-Caryophyllene	0a	19.6 ± 4.5b	28.1 ± 2.4c	16.9 ± 3.3b
α-Bisabolene	0a	9.8 ± 1.9b	12.5 ± 2.9a	10.1 ± 1.7b
E-β-Farnesene	0a	10.2 ± 2.1b	13.4 ± 2.3c	9.3 ± 1.1b
Carene	6.7 ± 0.9a	2.2 ± 0.9b	0c	0c
Cubebene	8.6 ± 1.1a	7.8 ± 1.7a	9.3 ± 1.5b	3.9 ± 0.3c
Copaene	9.7 ± 2.3a	11.1 ± 2.6a	5.4 ± 1.7b	1.5 ± 0.7c

Limonene	33.2 ± 6.8a	5.5 ± 1.2b	0c	0c
Other unknown components	15.6 ± 3.8a	12.9 ± 2.1b	8.9 ± 2.2c	4.7 ± 1.9d

Data were the relative amounts (%) of constituents from each sample.

* Means ± SE from three independent experiments with nine sampling locations in the *A. conyzoides* intercropped or nonintercropped citrus orchards for each determination are shown. Data not followed by the same letter in a line are significantly different at $P < 0.05$, with Duncan's multiple range test.

chemicals did not occur in the air samples of the citrus orchard without *A. conyzoides*, indicating that they were primarily released from *A. conyzoides*. The presence of these volatile allelochemicals thus may make a contribution toward regulating the population of the mites in the *A. conyzoides* intercropped orchard.

Olfactometer trials showed that *A. conyzoides* fresh leaves, the essential oil, and its four components had different effects on the olfactory responses of *A. newsami* and *P. citri* (Table 2). The fresh leaves and essential oil as well as demethoxy-ageratochromene, β-caryophyllene, α-bisabolene, and E-β-farnesene strongly attracted *A. newsami* and slightly repelled *P. citri* at the test temperature (25°C). It is noted that an olfactory response of mites to ageratochromene was not achieved because ageratochromene is a crystal (mp 46–47°C) and difficult to volatilize at this test temperature. The olfactory response of *A. newsami* to each individual component was clearly lower than to those of *A. conyzoides* fresh leaves and the essential oil (Table 2), suggesting that this effect could be intensified with the combinations of several components from *A. conyzoides*.

Field experiments (Figure 1) showed that spraying the essential oil of *A. conyzoides* on the citrus trees in the *A. conyzoides* nonintercropped citrus

TABLE 2. OLFACTORY RESPONSE OF MITES ON VOLATILES AND ITS MAJOR CONSTITUENTS FROM *A. conyzoides*

Volatiles	Degree of attraction or repellency (%)	
	A. newsami	*P. citri*
Fresh leaf	61.11A (attraction)	7.69A (repellency)
Essential oil	95.45B (attraction)	14.81B (repellency)
β-Caryophyllene	59.09C (attraction)	7.69A (repellency)
α-Bisabolene	40.91D (attraction)	7.69A (repellency)
E-β-Farnesene	38.89D (attraction)	7.69A (repellency)
Demethoxy-ageratochromene	22.22E (attraction)	0.00C (repellency)

Data were mean value of three independent experiments with 50 mites for each determination and not followed by the same letter in a column are significantly different at $P < 0.05$, with Duncan's multiple range test.

orchard increased the *A. newsami* population greatly. It increased from below 0.1 to over 0.3 individual per leaf at 24 hr after the essential oil emulsion spray, which reached the same level as in the *A. conyzoides* intercropped citrus orchard. It then decreased to 0.13 individuals per leaf after 48 hr. The results indicate that the volatiles from *A. conyzoides* attract the predatory mite *A. newsami* and increase its population on citrus tree leaves in the field. This attraction was time-dependent, however, and could only be maintained for 48 hr because of the oil's volatility. The results suggest that the stable population density of *A. newsami* in an *A. conyzoides* intercropped citrus orchard is correlated with the continued release of volatiles from understory *A. conyzoides* plants. Thus, intercropping *A. conyzoides* may increase the predatory mite *A. newsami* population in citrus orchards.

DISCUSSION

The role of orchard ground cover plants in improving habitat and enriching natural enemies of pests has been known for a long time (Bugg et al., 1990; Fye, 1983; House and Alzugaray, 1989; Lawton, 1982). It is necessary to select beneficial plant species and pay attention to their chemical interactions with understory plants and other organisms in the orchards. A citrus orchard is a relative stable and complicated ecosystem. The population dynamics of mites in citrus orchards often depends on the associated organisms, atmospheric temperature, precipitation, and other factors (Liang and Huang, 1994). In this study, *A. conyzoides* produced and released volatile allelochemicals into the air. These were at least, in part, responsible for the population variations of mites,

particularly the predatory mite *A. newsami*. However, it remains obscure why and how *A. conyzoides* manipulates the relationship between predatory mite and citrus red mite through releasing volatiles.

Many plants defend themselves from herbivores by releasing volatiles that manipulate the relationships among plants, herbivores, and their natural enemies as soon as the plants are under attack (Dicke et al., 1990; Bruin et al., 1992; Dicke, 1999; Sabelis et al., 1999; Agrawal, 2000; Bruin and Sabelis, 2001; Kessler and Baldwin, 2001; Rausher, 2001). Many predatory mites are known to respond to odors released by plants (Janssen, 1999; Shimoda and Dicke, 1999; Maeda et al., 2001). However, most studies on the attraction of natural enemies have been carried out with host plants infested with herbivores. Our research suggests that the chemical interactions among predator, pest, and citrus can also be achieved through intercropping.

It is noted that allelopathic inhibition was not apparent in the intercropped citrus orchard. Generally, allelopathy occurs at the time of seed germination and in early growth stages of plant species. Perennially adult citrus trees may resist the allelochemicals released from understory *A. conyzoides* plants, or bulk rhizosphere and soil microflora of the citrus may be able to rapidly biodegrade any allelochemicals released into the soil from *A. conyzoides* (Liang and Huang, 1994; Kong et al., 2004c).

A. conyzoides has been a historical folk medicine in China and in several countries of the world. It contains a wide range of secondary metabolites including flavonoids, chromenes, benzofurans, and terpenoids that serve as antimicrobial, insecticidal, and nematocidal agents (Ming, 1999; Okunade, 2002). This species also appears to be a valuable agricultural resource. Its intercropping in citrus orchards has become popular in South China, and substantial ecological and economic benefits have been achieved. Our results suggest that there are natural chemical interactions among the organisms in *A. conyzoides* intercropped citrus orchards, and that further clarification and utilization of these interactions should be beneficial to integrated pest management in citrus orchards.

RAPID COMMUNICATION

BIOLOGICALLY RELEVANT CONCENTRATIONS OF PETROMYZONOL SULFATE, A COMPONENT OF THE SEA LAMPREY MIGRATORY PHEROMONE, MEASURED IN STREAM WATER

JARED M. FINE and PETER W. SORENSEN*

Department of Fisheries, Wildlife, and Conservation Biology, University of Minnesota, St. Paul, MN 55108, USA

(Received May 3, 2005; revised June 11, 2005)

Published Online July 2, 2005

Abstract—Adult sea lampreys locate spawning streams in the Great Lakes by using a migratory pheromone that is released by stream-resident larval conspecifics. Behavioral, electrophysiological, and biochemical analyses of larval release water have suggested that this pheromone is composed of several components, one of which is petromyzonol sulfate (PS), a known lamprey-specific bile acid. Its precursor, allocholic acid (ACA), has also been implicated. In this study, we employed high-performance liquid chromatography and mass spectrometry to look for both bile acids in various stream waters, thereby testing whether they might have a role in natural pheromone function. Although PS was measured at picomolar concentrations in streams known to contain larval lampreys and attract migratory adults, ACA was not. Neither compound was measured in streams lacking larvae. This finding indicates that PS is a component of the natural pheromone, and it suggests that ACA has little relevance.

Key Words—*Petromyzon marinus*, pheromone, petromyzonol sulfate, allocholic acid, migration, bile acid, sea lamprey.

INTRODUCTION

The sea lamprey (*Petromyzon marinus*) is an ancient fish whose larvae live in freshwater streams but, following a metamorphosis, spends 1–2 years in oceans or large lakes parasitizing other fish before eventually entering streams as

* To whom correspondence should be addressed. E-mail: psorensen@umn.edu

mature adults to spawn. Field and laboratory tests have provided evidence that migrating adult lampreys locate spawning streams by using a migratory pheromone released by stream-resident larval lampreys (Sorensen and Vrieze, 2003). Coordinated biochemical, physiological, and behavioral studies have demonstrated that adult lampreys detect and respond to a mixture of compounds released by larvae including the lamprey-specific bile acid, petromyzonol sulfate (PS) (Sorensen et al., 2003, unpublished results). The other components have not yet been identified, but two appear to be novel and more important than PS, whereas a potential fourth, allocholic acid (ACA), has uncertain function. These olfactory cues seem to function as a synergistic mixture (Sorensen et al., 2003). Although laboratory estimates of larval bile acid release rate indicate that lamprey streams in the Great Lakes Basin likely contain PS at concentrations of about 10^{-12} M, and ACA at even lower concentrations (Polkinghorne et al., 2001), their presence in streams has yet to be confirmed. In this study, we developed a method that employed high-performance liquid chromatography (HPLC) in conjunction with mass spectrometry to identify and measure PS and ACA (the components for which we have synthesized standards) in streams containing populations of larvae.

METHODS AND MATERIALS

Sample Collection and Purification. We selected nine Great Lakes streams that are routinely censused by sea lamprey biologists (Table 1). One-liter water samples were collected in carboys containing preservative and extracted using reversed-phase C18 (RPC18) within 2 d following established protocols (Polkinghorne et al., 2001). Extracts were dried under nitrogen and stored at −20°C until analyzed. When possible, samples were collected in triplicate.

Identification and Quantification. Because direct analysis of bile acids using liquid chromatography–mass spectrometry was precluded by the buffering system needed to separate these compounds, we developed a two-step process that used HPLC fractionation followed by RPC18 to purify them so that they could be identified and quantified by mass spectrometry (MS). Briefly, dried stream water extracts were reconstituted in 110 μl of methanol/water (60:40), spiked with an internal standard [^{14}C-chenodeoxycholic acid (CDCA), New England Nuclear, Massachusetts, USA], and then injected onto an HPLC equipped with an inflow scintillation monitor, and fractionated by following established protocols (Fine et al., 2004). We collected three 5-min fractions centered on the retention times of PS, ACA, and CDCA as determined by previous experience (Polkinghorne et al., 2001) and pilot HPLC runs that used ^{14}C-CDCA alone. Fractions were extracted by using RPC18, dried under nitrogen, and reconstituted in 35 μl methanol. Extraction/recovery efficiencies

[a] Nagel and Lone Pine represent a single springtime estimate by Vrieze and Sorensen (2001). Valley Creek is base flow (Newman, Department of Fisheries, Wildlife and Conservation Biology, University of Minnesota, personal communication). Values for the other rivers are averages and do not reflect seasonal variation (Schleen and Klar, 2000, 2002).

[b] Estimates for Nagel, Lone Pine, Ocqueoc, and Cheboygan Rivers are based on surveys by the U.S. Fish and Wildlife Service which have been extrapolated using their "Empiric River Treatment Ranking System" (Slade, Ludington Biological Station, MI, personal communication). Estimates for other streams are based on historical survey records (Schleen and Klar, 2000, 2002).

[c] Native lampreys include either *Lethenteron appendix*, *Ichthyomyzon fossor*, or both.

were estimated to be 64 ± 11.3% (mean ± SD). Identification and quantification of PS and ACA in the appropriate fractions were accomplished with MS. Briefly, a 5-μl aliquot of each fraction was injected into an ion trap mass spectrometer (LCQ Classic, Thermo Electron Corporation, Waltham, MA, USA) equipped with an electrospray ionization source. Because the molecular ion of PS did not fragment into daughter ions that could be measured by our instrument, profiles of 10 *m*/*z* units centered on the molecular ion of PS at 473.4 *m*/*z* were examined before employing selected ion monitoring centered on the molecular ion (see Fine et al., 2004). Selective reaction monitoring was used on those fractions thought to contain ACA because its molecular ion (407.4 *m*/*z*) consistently fragments at a normalized collision energy of 30% to produce a quantifiable ion at 380.9 *m*/*z* that we could measure. Peak sizes were measured for quantification and values measured compared to a standard curve that was generated by adding known amounts of PS and ACA (Toronto Research Chemicals, Canada) to 1-l water samples collected from a small inland stream (Valley Creek, Minnesota, USA) known to lack lampreys and to have a similar organic load. The 9-point standard curves we generated demonstrated a linear increase in peak size ($r^2 = 0.99$) between 250 and 6400 pg for each compound ($N = 4$). The detection limit of our assay was slightly less than 10^{-12} M for PS and ACA.

RESULTS AND DISCUSSION

Although a compound with an *m*/*z* ratio of 473.4, the same as PS, was discernable in six of the seven lamprey rivers, there was no indication of ACA in any sample. In those samples with good signal-to-noise ratios (about half), the isotopic ratio associated with the peak at 473.4 *m*/*z* matched that of authentic PS (Figure 1a), seemingly confirming its identity. Concentrations of PS in lamprey streams ranged from about 10^{-12} to 5×10^{-12} M (Figure 1b). These values are in close agreement with those estimated to be present by Polkinghorne et al. (2001) and above the estimated detection limit of the sea lamprey olfactory system which is approximately 10^{-12} M (Li et al., 1995). Experiments also find PS to have behavioral activity at these concentrations (Bjerselius et al., 2000; Vrieze and Sorensen, 2001; Fine and Sorensen, unpublished results). However, PS's activity is not strong. Its function may be to synergize that of other components as is sometimes seen with insect pheromones (Sorensen et al., 2003). Alternatively/additionally, this cue's function may be associated with short-range orientation within streams (i.e., at "higher" concentrations) vs. searching for cues from lakes/oceans. Finally, although our estimates did not show a clear correlation between larval density and PS concentration, this may be a consequence of the native lamprey species (which

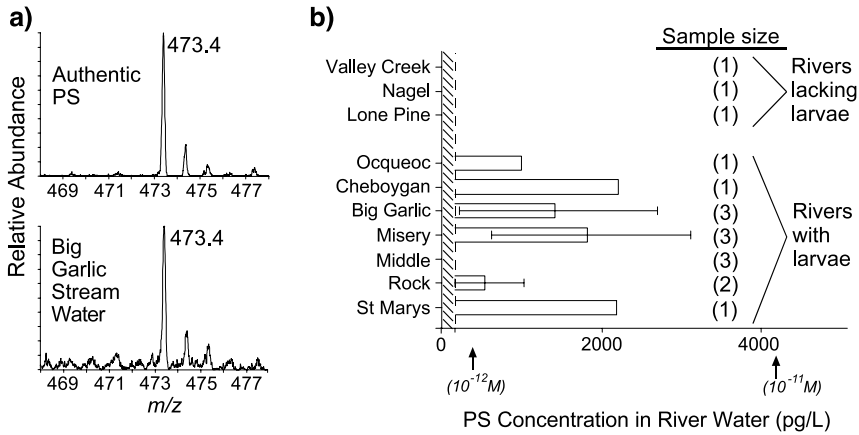

FIG. 1. (a) Electrospray ionization–mass spectrometry (ESI-MS) of 1 ng authentic petromyzonol sulfate (PS) added to methanol and an extract isolated from Big Garlic stream water. (b) Mean concentrations of PS (± standard deviation) measured in lamprey and nonlamprey streams as measured by ESI-MS. Concentrations are also noted as their log molar equivalents in parentheses. The putative detection limit of PS by our assay is represented by the dashed vertical line.

also release PS) also found in these rivers (Table 1; Fine et al., 2004), possible seasonal variation in larval metabolism (Polkinghorne et al., 2001), and/or degradation/binding of PS to organics in stream waters. We are presently attempting to adopt other more sensitive forms of MS so that we can evaluate how environmental variables influence natural concentrations of PS with greater precision and ease.

In summary, this study has demonstrated that PS is present in streams inhabited by larval sea lamprey at biologically relevant concentrations, thereby providing evidence that PS functions as a component of the natural pheromone. This appears to be the first time a fish pheromone, or component thereof, has been measured *in situ*. The lack of measurable ACA suggests that it is not a component of the cue. Recent pilot studies have added larval extracts containing $\sim 10^{-12}$ M PS and the other (unidentified) components to natural streams and have proven attractive to migratory adults (Jones, Michigan State University, personal communication). This work may provide guidance to fishery biologists attempting to employ extracts of the entire larval pheromone as an attractant to develop a means to remove sea lamprey from the Great Lakes where it is invasive (Twohey et al., 2003). Future studies will seek to identify and measure all components so they too might be employed in a pheromone-based sea lamprey control program.

Acknowledgments—Lance Vrieze (University of Minnesota), Roger Bergstedt and Jeff Locke (United States Geological Survey), and Doug Cuddy (Fisheries and Oceans Canada) collected river waters. Jeff Slade (United States Fish and Wildlife Service) provided estimates of larval abundance for some of the rivers. Thanks also to Thomas Krick and Leeann Higgins of the Mass Spectrometry Consortium for the Life Sciences at the University of Minnesota. Funding was provided by the Great Lakes Fishery Commission.

RAPID COMMUNICATION

METHYL JASMONATE APPLICATION INDUCES INCREASED DENSITIES OF GLANDULAR TRICHOMES ON TOMATO, *Lycopersicon esculentum*

ANTHONY J. BOUGHTON,* KELLI HOOVER, and GARY W. FELTON

Department of Entomology, Pennsylvania State University, University Park, PA 16802, USA

(Received March 21, 2005; revised May 31, 2005; accepted June 2, 2005)

Published Online July 5, 2005

Abstract—This study was designed to address whether applications of methyl jasmonate (MJ) or Benzothiadiazole (BTH) to cultivated tomato, *Lycopersicon esculentum*, induced elevated densities of defense-related glandular trichomes on new leaves. Four-leaf tomato plants were sprayed with MJ, BTH, or control solutions, and the density of type VI glandular trichomes on new leaves was subsequently determined at 3, 7, 14, 21, and 28 d. At 7, 14, and 21 d, the density of type VI glandular trichomes on new leaves was significantly higher on MJ-treated plants than on BTH- or control-treated plants. At 7 and 14 d after treatment, the mean density of glandular trichomes on new leaves of MJ-treated plants was ninefold higher than on leaves of control-treated plants. We observed entrapment of immature western flower thrips in trichomes on MJ-treated plants at higher rates than on BTH or control plants. Studies to evaluate potential trade-offs between reductions in pest populations by increased trichome density and possible negative impacts of trichome induction on biological control agents are needed.

Key Words—*Lycopersicon esculentum*, tomato, methyl jasmonate, induced resistance, glandular trichomes.

INTRODUCTION

Plants have evolved numerous defensive strategies to reduce herbivory or its effects on plant fitness (Karban and Baldwin, 1997). These defenses may be constitutively expressed or may be induced following attack by herbivorous arthropods. Induced responses to herbivory have been widely documented and may involve changes in plant secondary chemistry, reductions in plant nutritional quality, emission of volatiles that attract predators and parasitoids of herbivores (Kessler and Baldwin, 2002), or increases in trichome density (Traw and Dawson, 2002). Responses to herbivores may be mediated by the jasmonic acid (JA) or salicylic acid (SA) signaling pathways (Kessler and Baldwin, 2002).

Trichomes occur on the surfaces of many plants and can make a contribution to plant resistance against herbivores (Simmons and Gurr, 2004). Trichomes play important roles in arthropod resistance within the plant family Solanaceae and particularly within the genus *Lycopersicon* (Kennedy, 2003). Seven types of trichomes occur on *Lycopersicon* spp., including glandular trichomes (types I, IV, VI, and VII) and nonglandular trichomes (types II, III, and V) (Luckwill, 1943). Glandular trichomes have heads containing various sticky and/or toxic exudates that may be secreted onto the plant surface or may rupture on contact with herbivores, causing irritation, entrapment, or death (Simmons and Gurr, 2004). Nonglandular trichomes do not have heads and affect herbivores by mechanically obstructing their movement across the plant surface (Simmons and Gurr, 2004). Four-lobed type VI glandular trichomes are associated with high levels of arthropod resistance in *L. esculentum* (Kennedy, 2003).

Recent studies of the tomato mutant *jasmonic acid insensitive* 1 [*jai*1], which is defective in JA-based signaling, revealed several defense-related phenotypes, including abnormal glandular trichome production, suggesting a role for JA in glandular trichome-based defenses (Li et al., 2004). JA was recently shown to induce trichomes in Arabidopsis (Traw and Bergelson, 2003).

To our knowledge, jasmonates have not previously been demonstrated to induce elevated trichome densities in tomato. In preliminary studies, we found applications of methyl jasmonate (MJ) and BTH (Actigard™) to tomato reduced populations of *Myzus persicae* (Sulzer) (Homoptera: Aphididae) in the greenhouse (Boughton et al., unpublished data). Here, we present evidence showing that exogenous application of methyl jasmonate, but not BTH, induced dramatic increases in densities of type VI glandular trichomes on new leaves of *L. esculentum*. We suggest that resistance to herbivores induced by these elicitors probably operate by different mechanisms.

METHODS AND MATERIALS

Plants. Tomato plants (*L. esculentum* c.v. Trust) (DeRuiter Seeds) were grown in 4-in. plastic pots in sterile soil mix (peat–perlite–vermiculite, 55–20–25; Penn State Seed, Dallas, PA, USA). Plants were grown in the greenhouse under natural lighting with day and night temperatures varying between 21 and 33°C. Plants were irrigated daily with fertilizer solution (N–P–K, 4–18–38, Chem-Gro Tomato Formula; Hydro-Gardens Inc., Colorado Springs, CO, USA) containing supplemental magnesium sulphate and calcium nitrate.

Effect of Elicitors on Induction of Glandular Trichomes. Fourth-leaf tomato plants (45 per treatment) selected at random were treated with (1) 7.5 mM MJ (Bedoukian Research, Danbury, CT, USA), or (2) 0.1 mM BTH (Actigard®-Syngenta, Greensboro, NC, USA) (both in 0.8% ethanol and water), or (3) control solution (0.8% ethanol and water). Elicitor concentrations were within the range used in other studies and were selected in dose response trials as the lowest concentrations that induced resistance. Plants receiving different treatments were moved to opposite sides of the greenhouse and sprayed until leaves were saturated. After 24 hr, plants were arranged on three benches according to a randomized block design. At 3, 7, 14, 21, and 28 days post-treatment (DPT), three plants from each treatment were selected at random on each of the three benches, and the youngest terminal leaflet at least 5 cm in length on each plant was removed for sampling. This leaf selection process yielded terminal leaflets of similar sizes, which ranged from 5.8 to 8.0 cm in length, and 11.7 to 21.8 cm^2 in area. Two leaf disks (0.6 cm diam.) were punched midway between the leaf tip and leaf base, one on either side of the midrib, taking care to preserve trichomes on the upper leaf surface. Numbers of

type VI trichomes were determined by using a dissecting scope. Preliminary observations had suggested MJ treatments increase type VI trichome density. Other trichome types were not examined in this study. Plants were sampled only once. Trichome density data were evaluated with one-way ANOVA.

RESULTS

Results showed that application of MJ to tomato plants induced increased densities of type VI glandular trichomes on new leaves expanding after treatment (Figure 1). BTH treatment had no effect on trichome densities (Table 1). Highest densities of trichomes were present on leaves produced 14 d after MJ treatment. At 7 and 14 DPT, trichome densities were ninefold higher on MJ- than control-treated plants. Trichome densities were significantly higher (Tukey's test, $P < 0.05$) on MJ plants than on BTH or control plants at 7, 14 and 21 DPT. MJ-treated plants were observed to entrap higher numbers of immature western flower thrips than BTH- or control-treated plants (Boughton et al., unpublished data).

DISCUSSION

Increasing interest has focused on the use of elicitors of natural plant defensive responses, such as JA and MJ, to induce resistance to herbivores and

plant pathogens (Thaler, 1999). In tomato, jasmonate-induced resistance to herbivores has been documented in several field studies and has frequently been attributed to the action of defensive proteins such as polyphenol oxidase and proteinase inhibitors (Thaler, 1999). These proteins are induced within 24 hr of elicitor treatment, before any changes in type VI trichome density are detectable. However, over subsequent weeks it seems likely that a component of jasmonate-induced resistance may be a result of increased densities of type VI glandular trichomes, contributing to elevated polyphenol oxidase levels and increased repellency, entrapment, or mortality of arthropod herbivores. We suggest that elevated trichome densities were likely responsible for increased thrips entrapment observed in our studies.

Although it is likely that jasmonate-induced resistance in crop plants will have direct negative impacts on arthropod pests, which may be beneficial from a pest management perspective, it is also possible that induced plant defenses may have indirect effects on natural enemies, such as insect parasitoids and predators, which contribute to the regulation of pest populations (Thaler, 1999; Simmons and Gurr, 2004). Trichomes, for example, may have differing impacts on natural enemies ranging from positive effects, such as increased searching efficiency, to negative effects, such as hindered movement, irritation by trichome exudates, and entrapment (Obrycki, 1986).

The use of jasmonates to induce plant resistance to arthropod pests as a management tactic will require careful evaluation to ensure that benefits arising from negative impacts on pest fitness are not outweighed by adverse effects that might reduce the efficacy of biological control.

Acknowledgments—This research was funded by Pennsylvania Department of Agriculture (Contract ME 442289).

PLANT–PLANT SIGNALING: ETHYLENE SYNERGIZES VOLATILE EMISSION IN *Zea mays* INDUCED BY EXPOSURE TO (*Z*)-3-HEXEN-1-OL

JOACHIM RUTHER* and SVEN KLEIER

Abstract—Leaf alcohol (*Z*)-3-hexen-1-ol (Z-3-ol) is emitted by green plants upon mechanical damage. Exposure of intact maize plants to Z-3-ol induces the emission of a volatile blend that is typically released after caterpillar feeding and attracts natural enemies of the herbivores [herbivore-induced volatile organic compounds (HI-VOC)]. Thus, it has been suggested that Z-3-ol might have a function in indirect plant defense mediating plant–plant signaling and intraplant information transfer. Here, we demonstrate that HI-VOC induction by Z-3-ol is synergized by the phytohormone ethylene. Exposure to Z-3-ol at doses of 100 and 250 nmol induced HI-VOC emission in intact maize plants. HI-VOC emissions increased by 2.5-fold when ethylene was added. The effect of ethylene was more pronounced (5.1- to 6.6-fold) when only total sesquiterpene release was considered. In contrast, ethylene alone had no inductive effect but rather decreased the emission of the constitutive maize volatile linalool. We suggest that ethylene plays a synergistic role in plant–plant signaling mediated by green leaf volatiles.

Key Words—Plant–plant signaling, ethylene, (*Z*)-3-hexen-1-ol, herbivore-induced volatile organic compounds, sesquiterpenes, *Zea mays*.

INTRODUCTION

Evidence is increasing that volatiles emitted from damaged plants can induce defense responses in intact neighbor plants. This phenomenon has been interpreted as a prophylactic reaction toward impending herbivore attack (Dicke and Bruin, 2001). Among the compounds discussed as mediators for this information transfer are volatile phytohormones such as methyl jasmonate, methyl salicylate, and ethylene (Farmer, 2001) and also green leaf volatiles (GLV)

* To whom correspondence should be addressed. E-mail: ruther@zedat.fu-berlin.de

(Arimura et al., 2001), a series of six-carbon aldehydes, alcohols, and esters that are released from green plants after mechanical damage. (*Z*)-3-Hexen-1-ol (Z-3-ol), a major component of the GLV bouquet, is derived from linolenic acid by enzymatic degradation during the octadecanoid pathway (Hatanaka et al., 1995). Exposure of maize plants (*Zea mays* L.) to several different GLV [among them (*Z*)-3- and (*E*)-2-configured as well as saturated derivatives] induces the emission of a volatile blend consisting mainly of terpenoids, which is typically associated with caterpillar feeding [herbivore-induced volatile organic compounds (HI-VOC); Engelberth et al., 2004; Ruther and Fürstenau, unpublished data]. HI-VOC attract natural enemies of the caterpillars and have been shown to decrease oviposition rates of insect herbivores, thus representing both an indirect and a direct defense mechanism (Engelberth et al., 2004). Volicitin, *N*-(17-hydroxylinolenoyl)-L-glutamine, occurring in the caterpillars' oral secretion, and the phytohormone jasmonic acid (JA) are potent elicitors of HI-VOC when applied to artificially damaged maize leaves. Both HI-VOC induction by volicitin and JA can be synergized by ethylene (Schmelz et al., 2003). The present study demonstrates that ethylene also synergizes HI-VOC emission in maize plants exposed to Z-3-ol but has no volatile inducing effect on its own.

METHODS AND MATERIALS

Plant Material. Maize seeds (cv. Delprim) were planted individually in plastic pots (650 ml, 9 × 9 × 8 cm) filled with potting soil. Plants were grown in a green house at 20–25°C and 60% relative humidity. Supplemental artificial lighting was provided between 6 and 22 hr by SON-T Agro 400 high-pressure sodium vapor lamps (Royal-Phillips Electronics, Holland). After 3–4 wk, plants used in the experiments were approximately 40 cm high and had five to six fully developed leaves. The aboveground biomass of the tested plants was 14.4 ± 0.3 g (mean ± 1SE).

Plant Treatment and Volatile Collection. Plant treatment and volatile collection was performed in a glass cylinder (volume 8.8 l, 15-cm diam, 50 cm high) that was closed at the top and the bottom by Teflon plates (20-cm diam, 10 mm thick). The lower Teflon plate had a hole in the center (8-mm diam) and was split into two parts. By closing the two parts loosely around the stem of the maize plant, the intact aboveground part was placed into the glass cylinder whereas the pot was kept outside. For volatile collection, charcoal-purified air (1.2 l hr^{-1}) was pumped into the container via Teflon tube. The volatile-laden headspace was sucked at a flow rate of 1 l hr^{-1} through an adsorption tube (charcoal filter 5 mg, Gränicher and Quartero, Daumazan, France) connected to a mini vacuum pump (Neolab, Heidelberg, Germany) by another Teflon tube. Four identical cylinders were used simultaneously.

Plants were introduced into the container and exposed to the different chemicals: (1) 10 μl dichloromethane (solvent control), (2) 100 or 250 nmol of Z-3-ol dissolved in 10 μl dichloromethane, (3) 200 μl ethylene, (4) 100 or 250 nmol of Z-3-ol plus 200 μl ethylene. Solutions were applied onto the inner surface of the glass cylinder, and direct contact with the plants was avoided. GLV doses were in the range as released from maize seedlings after artificial or herbivore damage (Engelberth et al., 2004). Experiments were started between 2 and 3 P.M.; volatiles were collected for 8 hr after an incubation time of 14 hr. Trapped compounds were eluted from the filter with 20 μl of dichloromethane containing 50 ng μl^{-1} methyl nonanoate as an internal standard.

Chemical Analysis. Extracts (1 μl) were analyzed by GC-MS. Analyses were performed on a Fisons 8060 GC, and mass spectra were obtained on a Fisons MD800 quadrupole MS (EI mode at 70 eV). Volatiles were separated on a 30 m × 0.32 mm i.d. DB-5ms column, film thickness 0.25 μm (J&W Scientific, Folsom, CA, USA) with helium as carrier gas (2 ml/min). The temperature program was 40°C for 4 min, followed by a rate of 3°C min^{-1} to 280°C. Identification was performed by comparison of MS and retention data with authentic reference compounds or with those compiled in the essential oil library of Massfinder 3.12 scientific software (Detlef Hochmuth Consulting, Hamburg, Germany). Quantification (ng per g fresh weight) was performed by relating peak areas of individual compounds to the internal standard (50 ng μl^{-1}).

Statistical Analysis. Individual amounts, total sesquiterpenes, and total volatile amounts were analyzed by a nonparametric Kruskal–Wallis *H*-test followed by Mann–Whitney *U*-test for individual comparisons using Statistica 5.5 scientific software (StatSoft Inc., Tulsa, OK, USA). (*Z*)-3-Hexenyl acetate was not considered for estimation of total amounts because maize plants are able to transform externally applied Z-3-ol to (*Z*)-3-hexenyl acetate (Farag et al., 2005), and thus, transformed and induced amounts were not distinguishable.

RESULTS AND DISCUSSION

Intact control plants released only small amounts of volatiles (Figure 1; Table 1). Exposure to Z-3-ol at doses of 100 and 250 nmol resulted in a significant increase of HI-VOC emission. By exposure to combinations of Z-3-ol and ethylene, total HI-VOC emissions were increased by 2.5-fold when compared to Z-3-ol only. The effect of ethylene was more pronounced (5.1- to 6.6-fold) when only the total sesquiterpene release was considered. Exposure to ethylene alone did not induce any HI-VOC emission. Interestingly, the amounts of constitutively released volatiles (mainly linalool) dropped after just ethylene exposure.

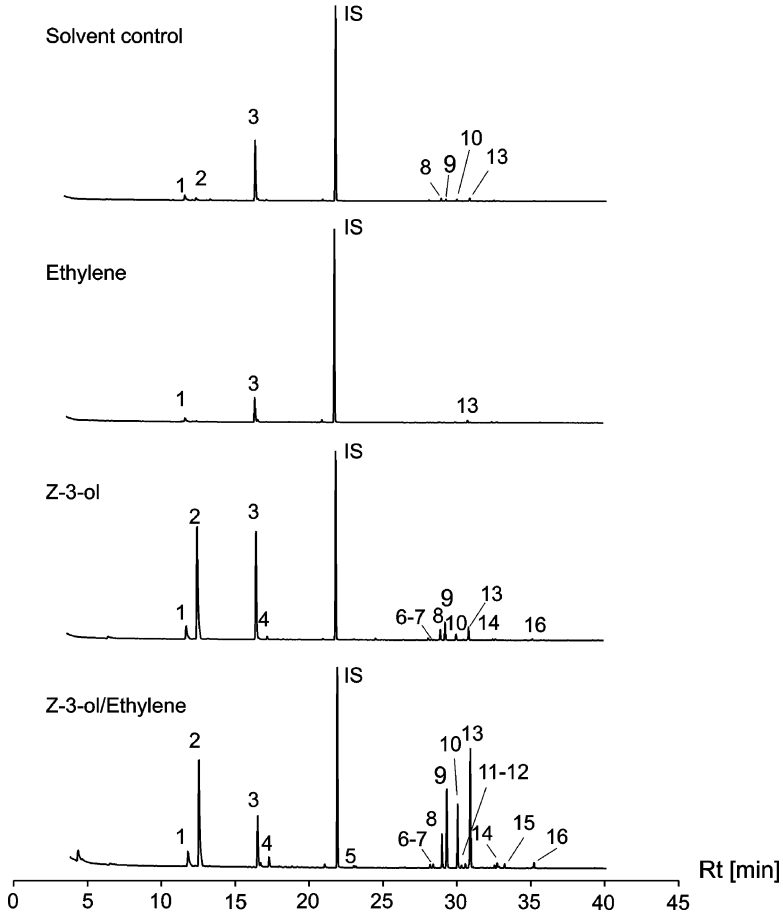

FIG. 1. Total ion current chromatograms of volatile extracts from maize plants (var. Delprim) exposed to 10 µl dichloromethane, 200 µl ethylene, 250 nmol Z-3-ol, and to 200 µl ethylene + 250 nmol Z-3-ol. Peak numbers correspond to Table 1; IS = internal standard.

Ethylene is a multifunctional signal molecule in plants also involved in various plant defense responses (Bleecker and Kende, 2000). Like Z-3-ol, it is released by plants upon mechanical damage (Tscharntke et al., 2001; Arimura et al., 2002). It has been suggested as mediator of plant–plant signaling because exposure of intact elder leaves to ethylene induced an increase of direct defense molecules such as phenols and proteinase inhibitors (Tscharntke et al., 2001). In maize, ethylene is selectively emitted upon insect feeding rather than from

artificial damage, and it has been shown to be involved together with volicitin and jasmonic acid in HI-VOC emission (Schmelz et al., 2003). The present study demonstrates that ethylene synergistically increases the responsiveness of maize to Z-3-ol. We suggest that ethylene plays an important role in plant–plant signaling mediated by GLV by synergizing HI-VOC emission in neighboring plants. The active ethylene might also be produced by the receiver plant itself because exposure to GLV and other HI-VOC has been shown to induce genes related to ethylene biosynthesis in intact lima bean plants (Arimura et al., 2002). However, GLV and ethylene might not only mediate plant–plant signaling but also be involved in the information transfer between damaged and intact parts of the same plant, thus enabling a fast systemic defense response.

Abstract—The clover root weevil, *Sitona lepidus*, frequently feeds on N_2 fixing rhizobial root nodules of white clover (*Trifolium repens*), which may contain isoflavonoids with defensive and plant regulatory properties. This study investigated the isoflavonoids present in N_2 fixing (active) root nodules, root nodules that were not fixing N_2 (inactive), and roots without nodules, and tested the behavioral responses of neonatal *S. lepidus* larvae to aglycones of the identified compounds. Formononetin concentrations were higher in the active nodules compared with inactive nodules and roots alone. Moreover, there was a statistically significant attraction to formononetin by *S. lepidus* in arena experiments, whereas the other isoflavonoids were unattractive. It is suggested that *S. lepidus* may have become tolerant to the toxic effects of formononetin with repeated exposure, and that it may play a role in root nodule location. Such coevolutionary relationships are widely reported for aboveground insects and plants, but the present study suggests they may also occur belowground.

INTRODUCTION

The clover root weevil *Sitona lepidus* Gyllenhal (Coleoptera: Curculionidae) is a destructive pest of white clover (*Trifolium repens* L.), attacking the plant aboveground as adults and belowground as soil-dwelling larvae. The adults lay eggs aboveground that ultimately fall to the soil surface, giving rise to soil-dwelling larvae that attack root nodules as neonates, before feeding on progressively larger roots. We recently reported that the neonatal larvae could distinguish white clover roots from nonhost plant roots in the soil from up to 6 cm (Johnson et al., 2004). Hackell and Gerard (2004) demonstrated that neonatal larvae showed a strong preference for root nodules that were fixing N_2, compared with those that were not, suggesting that compounds associated with N_2 fixation may be phagostimulatory or even enable larvae to locate nodules. While not obligate feeders on such root nodules, survival and development is drastically reduced when neonatal *S. lepidus* larvae do not feed on root nodules (Gerard, 2001). The larvae possibly benefit from the high concentrations of amino acids in root nodules.

Isoflavonoids are a particularly important group of chemicals in white clover, underpinning many microbial symbiotic relationships. Several play important roles during root nodule organogenesis and subsequent N_2 fixation. For instance, 7,4′-dihydroxflavone (DHF) accumulates in nodule progenitor cells where it inhibits auxin breakdown during cell division. After several rounds of cell division, DHF levels decrease as formononetin levels increase (Mathesius, 2001). This switch is associated with auxin breakdown, caused by the stimulation of auxin catabolites [e.g., indole-acetic acid (IAA) oxidase/peroxidase] by formononetin (Mathesius, 2001). Formononetin levels are, therefore, likely to accumulate in nodules that are fixing N_2 because these nodules are not actively undergoing cell division.

It has been suggested that formononetin also has a defensive role in roots (e.g., Cook et al., 1995), so it is perhaps paradoxical that *S. lepidus* larvae should target active root nodules of white clover, because these are likely to have high levels of formononetin. The effects of isoflavonoids can be variable, however, depending on the species of plant and insect, with some insects becoming tolerant or even capable of sequestering isoflavonoids with repeated exposure (Simmonds, 2003). The efficacy of formononetin as a defensive compound against root-feeding insects, in particular, is equivocal because neither the grass grub (*Costelytra zealandica* White) nor the African black beetle (*Heteronychus arator* F.) was negatively affected by formononetin (Sutherland et al., 1980). *Heteronychus arator* was highly susceptible to the other isoflavonoids tested, so formononetin may be relatively benign (Sutherland et al., 1980).

The objectives of this study were to identify and quantify the isoflavonoids present in white clover roots and root nodules and to test the behavioral responses of neonatal *S. lepidus* larvae to them.

METHODS AND MATERIALS

Plant Growth, Inoculation, and Chemical Analysis. Ten white clover plants (cv. Gwenda) were grown from seed in acid washed sand and supplied with 25 ml of Arnon's nutrient solution per day (see Johnson et al., 2004), modified to encourage nodulation. The plants were grown at 16L:8D at 15°C, and each treated with 2.5 ml of *Rhizobium* inoculate (ca. 0.1 ml of *Rhizobium* culture) on d 14. To make the inoculate, *Rhizobium* bacteria were isolated from nodules taken from field grown *T. repens*. Nodules were surface sterilized and crushed in a Petri dish under aseptic conditions, streaked onto manitol yeast extract agar plates, and incubated at 26°C for 2 d. Purity of cultures was verified by Gram strain and restreaking. After 36 d, two plants were randomly selected and sacrificed to verify infection and N_2 fixation by examining nodules for pink coloration. The remaining plants were harvested after 42 d. The roots were cleaned of sand and all root nodules removed and characterized as active (N_2 fixing) or inactive (not fixing N_2). Inactive nodules had either not yet started to fix N_2, or had become dormant. Roots and root nodules were weighed and immediately frozen (−18°C) pending chemical analysis.

Defrosted material (ca. 100 mg) was extracted with hot methanol (MeOH) (HPLC grade) at 20°C for 24 hr. Plant material was washed with MeOH and extracts concentrated to dryness by rotary evaporation at 40°C after being centrifuged at 13,000 rpm for 3 min. The residue was dissolved in 0.5 ml 100% HPLC MeOH and diluted as necessary for HPLC analysis by linear gradient elution on a Bondapak phenyl C_{18} column (4 × 30 mm; packing particle size, 5 μm) fitted with a Hichrom Hypersil phenyl guard cartridge. Elution was with a 65:35 mixture of 2% aqueous acetic acid (HOAc) and MeOH/HOAc/distilled H_2O (18:1:1) changing to 100% of the second solvent at 20 min. The flow rate was 1 ml min^{-1}, temperature 25°C, and UV detection at λ 270 nm for formononetin and λ 331 nm for DHF and the respective glycosides. Quantification was done by peak height against the following concentrations of authentic markers: DHF, 0.0153 mg ml^{-1}; formononetin, 0.0175 mg ml^{-1}; and formononetin 7-glucoside, 0.039 mg ml^{-1}. The DHF marker was used for the quantification of the respective glycoside, as this was deemed adequate for comparative purposes.

Bioassays. A captive population of adult *S. lepidus* was maintained at 20°C, 85% humidity and 16L:8D. Eggs were collected, placed on dampened filter paper inside sealed Petri dishes, and incubated at 25°C until larvae emerged for bioassays.

DHF, formononetin and genistein (supplied by PlantechUK, Reading, UK) were tested to determine whether they elicited a behavioral response from neonatal *S. lepidus* larvae at 0.1 and 0.01 M. The aglycones of the isoflavonoids were tested as the conjugates identified in the chemical analysis were found in

much lower concentrations. While not detected in the Gwenda cultivar, genistein is among the more common isoflavonoids found in white clover, and it has been suggested that it has functional similarities with formononetin in terms of auxin breakdown (Mathesius, 2001). Bioassays were conducted in circular arenas (90 mm diam) lined with moistened (1.5 ml distilled H_2O) filter papers inside a darkened chamber (20°C ± 1°C). Stock solutions of isoflavonoids were made by dissolving in 1 ml ethanol and diluting with 9 ml of distilled H_2O. For each bioassay, 250 μl of the compound were injected onto the filter paper at one side of the arena and a single neonatal larva was placed in the center. The control consisted of 250 μl of a solution of ethanol and distilled H_2O in a 10:90 ratio, respectively. Larvae were tracked using a specialized digital camera (Pro-150ES, Pixera Corp., Los Gatos, CA, USA) above the arena that relayed images at 10-sec intervals for 15 min to an image analysis unit incorporating a tracking algorithm (Image-Pro Plus™, Media Cybernetics Inc., Silver Spring, MD, USA.). Thirty replicates were conducted for each treatment using fresh filter paper, larvae, and test compounds (and control) on each occasion.

RESULTS AND DISCUSSION

Four isoflavonoids were detected in significant quantities in the roots and root nodules of white clover; DHF, DHF glycoside, formononetin, and formononetin 7-glucoside (Table 1). DHF and DHF glycoside concentrations were higher in the roots than the root nodules, whereas formononetin concentrations were higher in active nodules than the roots alone and inactive nodules. Formononetin 7-glucoside was not detected in active nodules and occurred in lower concentrations in the inactive nodules compared with the roots alone (Table 1).

When the test areas in the arenas included 0.1 and 0.01 M formononetin, there was a significant preference by *S. lepidus* larvae for this region. Larval attraction did not differ significantly from the control when the test area included DHF and genistein (Figure 1). These findings differ from studies that have correlated higher formononetin levels in white clover roots with reduced susceptibility to pests (e.g., Cook et al., 1995). Indeed, when *S. lepidus* larvae fed on red clover roots containing formononetin, they gained less weight than those reared on a cultivar of white clover roots containing negligible levels of formononetin. There was, however, no difference in the amount of root tissue consumed for larvae reared on the two types of plant, and there was also no relationship between larval weights and the levels of formononetin in red clover (Gerard, personal communication). It is conceivable that with repeated exposure

Larval response compared to control using Fisher's exact *P* test: *formononetin* 0.1 M $P < 0.01$, 0.01 M $P = 0.04$; *genistein* 0.1 M $P = 0.08$, 0.01 M $P = 0.15$; *DHF* 0.1 M $P = 0.99$, 0.01 M $P = 0.99$. Statistical significance: $^{**}P < 0.01$, $^{*}P < 0.05$. Line indicates larvae moving to test area by chance alone (control).

to formononetin in N_2-fixing root nodules, neonatal *S. lepidus* larvae have become tolerant of its effects, as has been reported for other insects feeding on legume roots (Sutherland et al., 1980). Such a coevolutionary relationship between root defensive compounds and root-feeding insects has been reported elsewhere. For example, carrot root fly larvae (*Psila rosae* F.) use a neurotoxin (falcarindiol) exuded by the roots as a host plant location cue (Maki et al., 1989).

While not statistically significant, it is interesting that a number of larvae were attracted to 0.1 M genistein ($P = 0.08$), which has a similar chemical structure to formononetin (Figure 1). Chemical analogs frequently elicit similar behavioral responses in insect–plant interactions because of the compatibility of molecular binding sites on the insect's sensory organs. Whether formononetin acts as a distinct location cue for neonatal *S. lepidus* remains unclear, but its attractive properties suggest that it may play a role in nodule location when larvae are in close proximity to roots because formononetin is exuded into the immediate rhizosphere (e.g., Mathesius, 2001).

HERBIVORES, VASCULAR PATHWAYS, AND SYSTEMIC INDUCTION: FACTS AND ARTIFACTS

COLIN ORIANS*

Department of Biology, Tufts University, Medford, MA 02155, USA

(Received March 22, 2004; revised December 1, 2004; accepted May 18, 2005)

Abstract—Over the past 10 years there has been tremendous growth in our understanding of molecular, chemical, and morphological induction of traits involved in the resistance of plants to herbivores. Although it is well established that the patterns of induction can be constrained by a plant's vascular architecture, studies often fail to account for these constraints. Failure to do so has the potential to severely underestimate both the patterns and extent of induction. Here I review (1) the evidence for vascular control of induced responses, (2) how interspecific variation in phyllotaxy influences spatial patterning of induction, (3) the factors, phloem transport and volatile production, that may break down vascular constraints and lead to more widespread induction, and (4) the experimental approaches that could be compromised when vascular architecture is not considered. I show that vascular constraints in systemic induction are commonplace, but vary among species. I suggest that when induction is more widespread than expected from patterns of phyllotaxy, differences in vascular connectivity and volatile production may be responsible. I argue that advances in the mechanisms of systemic induction, cross-talk between different signal transduction pathways, specificity of induction, costs and benefits of systemic induction, and the effects of induced changes on herbivores and their natural enemies require that experiments be designed to examine and/or control for vascular constraints in systemic induction.

Key Words—Systemic induction, vascular architecture, sectoriality, long-distance transport, source–sink dynamics, volatiles, experimental design.

INTRODUCTION

It is widely recognized that constitutive defenses limit the scale of the initial herbivore attack, whereas induced defenses determine patterns of subsequent

attack (Karban and Myers, 1989; Haukioja, 1990; Jones et al., 1993; Karban and Baldwin, 1997). Induction has been documented in over 100 species of plants (Agrawal and Karban, 1999) and can be morphological, chemical, local, systemic, and highly specific (see Karban and Baldwin, 1997). For the purposes of this review, I define systemic induction as molecular, chemical, or morphological changes that occur in distant undamaged leaves. Recent advances have improved our understanding of plant responses to attack and the effects of these responses to herbivores. We now know that (1) damage results in long-distance transport of signal molecules that elicit changes in distant leaves (Zhang and Baldwin, 1997; Stratmann, 2003); (2) mechanical damage and damage by specific herbivores (and pathogens) generally elicit unique molecular, biochemical, and morphological responses (e.g., Baldwin, 1988; Thomma et al., 1998; Agrawal, 2000; Schittko et al., 2000; Walling, 2000; Voelckel and Baldwin, 2004); (3) induced responses can selectively affect the performance of herbivores and the behavior of natural enemies (Thaler, 1999a,b; Thaler et al., 1999, 2002; Agrawal, 2000; De Moraes et al., 2001; van Poecke et al., 2001); (4) there can be reproductive costs of induction (Baldwin et al., 1990, 1998; Agrawal and Karban, 1999; Heil and Baldwin, 2002; Zavala and Baldwin, 2004; Zavala et al., 2004); and (5) ontogeny sink and strength modify both the strength and pattern of induction (e.g., van Dam et al., 2001; Arnold and Schultz, 2002; Arnold et al., 2004).

We have made excellent progress in our understanding of the mechanisms, costs, and consequences of local and systemic induction. Unfortunately, the importance of spatial variation in systemic induction is often ignored but is critical to future progress. In this review, I focus on herbivore-induced induction within plants and argue that (1) vascular architecture, the pathway of signal movement to and away from the damaged leaf, is a key controller of systemic induction patterns; (2) when induction in some species is more widespread than expected, differences in phloem transport, release, and retrieval along the phloem pathway, and volatile production may allow for greater integration of the induced response; and (3) experimental designs that fail to account for spatial variation in induction are likely to underestimate or even fail to detect systemic induction. The points made apply to signal transduction following pathogen attack provided that the pathogen does not move systemically itself.

VASCULAR ARCHITECTURE

In this section, I first describe how vascular architecture determines patterns of systemic induction and then review inter- and intraspecific factors that control patterns of vascular architecture.

Vascular Architecture and Long-Distance Transport. Botanists have known for years that the transport of photosynthate, signal molecules, and hormones among leaves is controlled by vascular architecture (reviewed by Murray et al., 1982; Watson and Casper, 1984; Watson, 1986; Dickson and Isebrands, 1991; Sachs et al., 1993; Marshall, 1996). There is evidence for both phloem and xylem transport of signal molecules associated with chemical induction (Malone and Alarcon, 1995; Stratmann, 2003).

From a phloem perspective, the anatomy of sieve cells has evolved so that the path of least resistance is longitudinal, through the sieve plates (van Bel et al., 2002), and there is little symplastic transport between mature cells, and this limits movement among sieve cells (reviewed by Thorpe et al., 2005). The bulk of carbohydrate and signal transport is both longitudinal and toward sink leaves, but modified by vascular connectivity (Watson and Casper, 1984; Dickson and Isebrands, 1991; Preston, 1998; Arnold and Schultz, 2002). Connectivity is based on orthostichy—the phyllotactic arrangement of leaves that describes the distribution of vascular traces. Export from one leaf is greatest to orthostichous leaves because these leaves share primary vascular traces. Export to leaves in adjacent orthostichies is intermediate because these leaves have partial connectivity, and export is absent to leaves in opposite orthostichies because they lack vascular connectivity (Murray et al., 1982; Watson and Casper, 1984). There may be xylem transport of signal molecules as well (Malone and Alarcon, 1995). These authors suggest that upon leaf tissue damage, signal molecules can be drawn into the xylem and transported systemically. Since leaf-to-leaf connectivity is similar for xylem and phloem (see Orians et al., 2000; Zwieniecki et al., 2003; and reviewed by Orians et al., 2005), vascular constraints on signal transport are expected by either mechanism.

Whichever pathway of transport, xylem or phloem, within-plant variation in systemic induction is commonplace (Davis et al., 1991; Shulaev et al., 1995; Rhodes et al., 1999; Orians et al., 2000; Schittko and Baldwin, 2003). In cottonwood (*Populus trichocarpa* × *Populus deltoides*, Davis et al., 1991), tobacco (*Nicotiana* sp., Shulaev et al., 1995; Schittko and Baldwin, 2003), and tomato (*Lycopersicon esculentum*, Rhodes et al., 1999), leaves with direct vascular connections to the damaged leaf show greater defensive chemical induction than leaves without vascular connections. Systemic induction in tomato not only exhibits leaf-to-leaf variation, but within-leaf variation as well (Orians et al., 2000). Orians et al. (2000) found that proteinase inhibitor induction in tomato was greatest in leaflets that have direct vascular connections and lower in leaflets without direct connections. That tomato leaflets without direct connections exhibited induction suggest that signal transduction is not completely isolated to specific sectors (see Beyond Vascular Architecture for discussion of possible mechanisms).

Such chemical changes are ecologically relevant. Jones et al. (1993) demonstrated that differential induction alters leaf beetle performance on cottonwood (*Populus deltoides*). More recently, Viswanathan and Thaler (2004) found induced resistance in orthostichous leaves, but induced susceptibility in non-orthostichous leaves of *Solanum dulcamara* when damage was intense. This suggests that induction changes source–sink relationships (*sensu* Arnold and Schultz, 2002) and may result in greater allocation of resources toward resistance traits in the damaged sector and lowered allocation of resources toward resistance traits in other sectors.

Inter- and Intraspecific Variation in Phyllotaxy. Differences in vascular architecture among plants can alter patterns of systemic induction. Most angiosperms have a 2/5 phyllotaxy (Moore et al., 1998). A 2/5 phyllotaxy reflects the fact that every fifth leaf is vertically aligned after two spirals around the plant. In this arrangement, carbon exported from leaf 1 accumulates most in leaves 4 and 6, to a lesser extent in leaf 3, and minimally in leaves 2 and 5 (Dickson, 1991). However, some species have a 1/2 or 3/8 phyllotaxy (Moore et al., 1998). Moreover, since phyllotaxy may change through development—the phyllotactic arrangement of leaves in *Populus* changes from 2/5 to 3/8 to 5/13 with plant development (Larson, 1977)—it is essential to map the phyllotaxy with dyes (Orians et al., 2000) or isotopes (Larson, 1977) to determine the operative vascular connectivity.

BEYOND VASCULAR ARCHITECTURE

Vascular constraints on systemic induction are common; however, there is increasing evidence that induction in some species is less constrained (i.e., more integrated) (Shea and Watson, 1989; Mutikainen et al., 1996). Shea and Watson (1989) found that localized damage to fireweed, *Chamaenerion angustifolium*, despite having a 3/8 phyllotaxy, had little effect on fruit production within that orthostichy. They also report that ^{14}C flow was less restricted. More recently, Orians et al. (2000) and Kiefer and Slusarenko (2003) showed that leaf tissues lacking direct vascular connections are induced in tomato and *Arabidopsis*, respectively. What might lead to induction in other sectors? I suggest that two factors may facilitate greater integration: (1) symplastic and apoplastic pathways in long-distance phloem transport and (2) volatile release at the site of damage and subsequent induction within distant plant tissues.

Throughout development, there is extensive apoplastic exchange—release and retrieval—of phloem constituents along the phloem pathway (Minchin and Thorpe, 1984,1987; van Bel et al., 2002; van Bel, 2003; Thorpe et al., 2005). Such release and retrieval requires an extensive array of specialized transfer

cells and membrane-bound transporters (Pate and Dieter Jeschke, 1995; Fisher, 2000). Most importantly, from the perspective of integration, species differ both in type and in density of transporters (van Bel, 2003). Clearly, transport of damage-induced signal molecules could lead to more widespread induction. Further work is necessary to examine how interspecific variation in apoplastic exchange alters the degree of symplastic isolation and subsequent spatial patterning of systemic induction.

It appears that signals are most likely to reach young developing tissues in other sectors. There is little symplastic exchange among mature sieve elements, but early in tissue development there can be extensive symplastic transport due to high sieve element and plasmodesmal density (van Bel, 2003; Thorpe et al., 2005). This allows for greater movement between adjacent sieve elements in young developing tissues, and modification of microchannel size of the plasmodesmata can facilitate even greater exchange of carbohydrates, viruses, and perhaps signal molecules (Lucas, 1997; Ishiwatari et al., 1998; Ruiz-Medrano et al., 1999). Although many details remain unresolved, recent evidence suggests that modification of microchannel size is a highly regulated and active process (Ruiz-Medrano et al., 2004). Thus, symplastic transport, especially in combination with apoplastic exchange, could result in widespread induction in young developing tissues. Whether plants have evolved mechanisms to facilitate movement of signal molecules from one sector to another requires further study.

I suggest that volatile release from damaged tissues may also result in more widespread induction. In fact, volatiles may be the only mechanism to induce leaves on distant branches where vascular connections are lacking. It is well known that volatiles released from damaged tissues and can cause molecular and chemical changes in adjacent plants, and alter subsequent resistance (Farmer, 2001; Kessler and Baldwin, 2001). The implications of this work are great because they suggest that plants may eavesdrop on their neighbors and adjust their allocation to defenses accordingly. However, it appears that eavesdropping requires that plants be in close proximity (within 15 cm) (Karban et al., 1997). Air turbulence and movement serves to dramatically reduce the concentration of volatiles arriving at distant plants, and as a consequence, there is considerable debate concerning the importance of interplant communication under field conditions (Lerdau, 2002; Dicke et al., 2003). Given that volatile signals become increasingly dilute with distance, volatiles may be more important for intraplant communication. Such tissues are in close proximity and likely to have the appropriate receptors to respond but may be on different branches with no vascular connections (Watson, 1986). Although intraplant volatile communication has been hypothesized to occur (Farmer, 2001), no studies have examined the importance of intraplant volatile communication as a mechanism to bypass vascular constraints in systemic induction.

EXPERIMENTAL APPROACHES

Despite the potential for more widespread induction than would be predicted by vascular architecture alone, the presence of vascular constraints is common. Therefore, failure to account for vascular constraints in systemic induction can: (1) underestimate the strength of induction; (2) lead to erroneous conclusions about specificity of induction; and (3) hide important within-plant heterogeneity in leaf quality. In this section, I review the approaches researchers have taken in their experiments and highlight which of the approaches are likely to underestimate the strength of induction and lead to inappropriate conclusions. It is not my goal to provide an exhaustive literature review, but to use a few case studies to highlight how knowledge of vascular architecture might improve our understanding of systemic induction and ultimately lead to more carefully designed experiments.

To date there have been three approaches to studying induction and each differs in the importance of vascular architecture to the results (Table 1). (1) Some studies have released herbivores on young plants and then, later in development, measured induction of specific traits or induced resistance (hereafter termed "immunization"; Karban, 1986; Agrawal et al., 1999). (2) Other studies have isolated herbivores on specific leaves (or manually damaged the leaf) and then measured induction in undamaged leaves shortly thereafter (hereafter termed "localized damage"; Davis et al., 1991; Jones et al., 1993; Stout et al., 1996a,b). (3) More recently, researchers have sprayed plants with powerful elicitors such as jasmonic acid and salicylic acid (Cipollini and Redman, 1999; Thaler, 1999a,b; Thaler et al., 1999; Moran and Thompson, 2001; Redman et al., 2001; Cipollini, 2002). Most of the elicitor studies applied inducing agents to the entire plant and then measured whole-plant induction (or if applied to a specific leaf, induction was only measured in that same leaf; Cipollini and Redman, 1999). Because most experiments involving elicitors have effectively measured local induction, vascular architecture should have no effect on the outcome of experiments and will not be discussed further.

Immunization studies that give herbivores free access to plants early in development and then measure systemic induction later in development appear robust. For example, Karban (1986, 1987) showed that when young cotton, *Gossypium hirsutum*, seedlings are attacked by mites, the plants often show increased resistance to subsequent mite attack. Agrawal et al. (1999) obtained similar results with cucumber, *Cucumus sativus*. In these studies, cotyledons/leaves were damaged and the whole plant was assayed for subsequent resistance. Since the initial damage was systemic, we would not expect induction to vary among leaves (Table 1).

Problems may arise when initial damaged is localized to specific leaves and induced responses are measured in other parts of the plant. Induction could

TABLE 1. TYPICAL TREATMENTS IMPOSED IN INDUCTION STUDIES, THE TYPES OF RESPONSES MEASURED, AND THE IMPORTANCE OF VASCULAR ARCHITECTURE TO PATTERNS OF SYSTEMIC INDUCTION

Treatment	Response	Importance of vascular architecture	Possible consequences[a]
(1) Immunization e.g., cotyledon inoculation followed by removal of damaging agent	Subsequent leaves, e.g., first true leaves	Minimal	None (if initial damage is dispersed)
(2) Localized damage to specific leaf or leaves	Whole plant	→ Very	Underestimate
	Specific tissue	→ Very	Underestimate or failure to detect
(3) Application of chemical elicitors to whole plant	Whole plant	Not	None
	Specific tissue		(functionally equivalent to localized induction)

[a] Consequences of failure to control for vascular architecture range from none, to underestimation, to failure to detect induction.

be underestimated if damage is concentrated on specific leaves, but induced responses are examined at the whole-plant level or might be severely underestimated in studies that only assay specific leaves for induced responses when the previous damage was concentrated on other leaves (Table 1). As illustration, Agrawal (2000) placed a caterpillar of one of four herbivore species (*Plutella xylostella*, *Spodoptera exigua*, *Pieris rapae*, or *Trichoplusia ni*) on one leaf and then measured how these herbivores performed on the remainder of the damaged plant. He found that previous damage by *Plutella* (a specialist) and *Spodoptera* (a generalist) resulted in increased resistance to all species. In contrast, previous damage by *Pieris* only induced resistance to *Spodoptera* and *Pieris*, and damage by *Trichoplusia* (a generalist) failed to induce resistance to the other herbivores. Although these results clearly indicated specificity of induction, some of the differences in herbivore responses may reflect differences in feeding behavior. Perhaps, *Plutella*—the species that appeared to be least affected by previous feeding—tended to avoid feeding on leaves with direct vascular connections to the damaged leaf and, thus, avoided the most heavily induced leaves. The later explanation is intriguing and deserves further examination.

More recently, Traw and Dawson (2002) released herbivores on four-leafed *Brassica nigra* and then quantified differences in foliar trichome density and sinigrin concentration on specific leaves between damaged and undamaged plants. They found evidence for trichome induction, but the effect was often insignificant and varied among plants. Perhaps differences in initial damage,

which they report, but did not control for in their analysis, limited their ability to detect differences. Because they did not quantify the pattern of initial damage, they could have detected (1) no induction—if damaged was concentrated on a single leaf that did not have direct connections to the sampled leaf; (2) moderate induction—if damage was dispersed; or (3) high induction—if damage was concentrated on the leaf with direct vascular connections to the sampled leaf.

An extreme example of uneven damage exists in studies in which damage is applied to one leaf and induction is measured in other leaves. Since some leaves lack direct vascular connections and others have only partial connections, induction might be underestimated. For example, Stout et al. (1996a) used different leaflets from a leaf adjacent to the damaged leaf to examine how different enzymes are induced following damage. Since some of the leaflets had direct connections whereas others did not, it is possible that differences in induction reflect the experimental design, and not differences in the enzymes. If true, failure to detect induction could be an artifact of the experimental design. It would be better to measure induction in leaflets or leaves known to share direct vascular connections. Alternatively, researchers could distribute damage across several consecutive leaves to make sure all sectors were damaged (as done by Constabel et al., 2000).

CONCLUSION

Whether studying molecular mechanisms of systemic induction, cross-talk between different signal transduction pathways, specificity of induction, costs and benefits of systemic induction, or the effects of induced changes on herbivores and their natural enemies, *a priori* knowledge of vascular constraints on systemic induction will help researchers make robust conclusions. Care should be taken to control for (or to examine) the effects of vascular architecture on induction. Controlling for vascular architecture necessitates that initial damage is dispersed across all sectors of the plant. Examining its effects requires mapping the vascular connections and quantifying the amount of damage to specific leaves. Since within-plant heterogeneity in leaf quality may affect herbivore behavior or performance (Denno and McClure, 1983) and may even influence foraging patterns of natural enemies, we can even use vascular architecture to create and study the effects of heterogeneity on herbivores (reviewed by Orians and Jones, 2001). As we learn more about the mechanisms of within-plant communication, both by long-distance signal transport of dissolved substances within the vascular system and by volatiles, we will gain an even greater understanding of the importance of vascular architecture in systemic induction across species.

Acknowledgments—I thank Danush Viswanathan, Anurag Agrawal, Michael Thorpe, and two anonymous reviewers for comments on an early version of this manuscript and the National Science Foundation (DEB 9981568) and the Andrew Mellon Foundation for financial support.

(Received November 12, 2004; revised June 9, 2005; accepted June 15, 2005)

Abstract—This study investigates variation in the secondary chemistry of the bark of three closely related, winter-dormant species of white birch (*Betula resinifera*, *B. pendula*, and *B. platyphylla*) at different ontogenetic stages by using different plant parts (top and base). The experimental birches were grown for 4 years in two growing conditions (pot and field) at different nutrient levels. There was considerable species-specific quantitative and qualitative variation in the secondary chemicals in bark, but this was also affected by fertilization and the age of the plant. In general, there was greater chemical diversity in saplings than in seedlings. The study revealed three new components, secoisolariciresinol 9-*O*-β-glucopyranoside and two of its derivatives, that have not been reported previously for the bark of white birches. Principal component analysis showed that the species studied had a similar chemical composition at the juvenile stage, but as the plants grew, they became more clearly differentiated, which indicates that the species of older plants can be identified by chemotaxonomy. Evidently, the secondary chemistry of birches is under genetic control, but it is affected by properties of growing conditions and ontogeny.

Key Words—*Betula pendula*, *B. resinifera*, *B. platyphylla*, birch, ontogeny, fertilization, phenolic compounds, terpenoids, mountain hare, field vole.

INTRODUCTION

The concentrations of secondary chemicals in the bark of forest trees are genetically controlled (Rousi et al., 1989, 1993, 1996, 1997; Berenbaum and Zangerl, 1992; Laitinen et al., 2002b, 2004c, 2005), but there are indications that carbon-based secondary chemistry is also modified by environmental variation (Bryant et al., 1983; Waterman and Mole, 1989; Herms and Mattson, 1992; Rousi et al., 1996; Jones and Hartley, 1999; Herms 2002; Laitinen et al., 2002a, 2004c, 2005). Studies have revealed highly variable chemical responses to different growing conditions (e.g., Bryant et al., 1987; Muzika, 1993; Rousi et al., 1996; Haukioja et al., 1998; Mutikainen et al., 2000; Laitinen et al., 2002a). For example, levels of individual phenolics increase after fertilization (e.g., Muzika, 1993), although the total amounts of phenolics decrease (Bryant, 1987; Price et al., 1989; Muzika and Pregitzer, 1992; Muzika, 1993). Concentrations of terpenoids also respond variably to fertilization. Bryant et al. (1987) found reduced terpenoid production in fertilized plants, but Laitinen et al. (2005) found that different birch terpenoids showed different reactions to differences in site fertility. Concentrations of secondary metabolites may also depend on plant part (Palo et al., 1985; Tahvanainen et al., 1991) and ontogeny (e.g., Reichardt et al., 1984; Bryant and Julkunen-Tiitto, 1995; Julkunen-Tiitto et al., 1996; Hartley and Jones, 1997).

Previous studies of secondary chemistry variation in birch bark have generally used plants of the same age grown in the same environment (e.g., Tahvanainen et al., 1991; Vainiotalo et al., 1991), plants of the same age given different treatments (Lavola and Julkunen-Tiitto, 1994; Lavola et al., 1994), or plants of different ages grown under the same conditions (e.g., Julkunen-Tiitto et al., 1996). Our aim was to gain a more comprehensive understanding of the effect of environmental heterogeneity and ontogenetic changes on secondary chemistry of birch, by studying the chemical profiles of 1-, 3-, and 4-yr-old seedlings and saplings of three closely related species of white birch (*Betula resinifera*, *B. pendula*, and *B. platyphylla*) (de Jong, 1993) grown in different environments and given different fertilization treatments.

METHODS AND MATERIALS

Plant Material. We used exotic *B. resinifera* (North American origin), *B. platyphylla* (Japanese origin), and native *B. pendula* species grown at Punkaharju Forest Research Station (61°48′N, 29°20′E), Finland, for four growing seasons. After 1 year of growth in a greenhouse, seedlings were transferred to two outdoor growing sites: some were planted in 3 l pots (pot experiment), and the others were planted in a field (field experiment). Four

fertilization treatments were applied annually on each site for 4 yr. Pot seedlings were fertilized with liquid fertilizer (Superex, Kekkilä Yhtiöt, Eurajoki, Finland) for the first 3 yr, but in the fourth year, granular fertilizer was used, as in the field experiment (Kemira Y1) (Table 1). Pot seedlings were watered when necessary; field seedlings were not. A more detailed growth protocol is presented in Laitinen et al. (2004a).

Pot seedlings were divided into three replicate blocks, each containing 12 plots with 60 seedlings each (species × fertilization treatment). Field seedlings were in three replicate blocks, each divided into 11 plots, because one treatment (highest fertilization) was not available for *B. platyphylla* due to a lack of seedlings. Only healthy seedlings were transplanted to the field, so the number of seedlings/plot varied: most replicate plots contained 30–60 plants, but one replicate plot contained only 13 seedlings (replicate 3 for *B. pendula*, highest fertilization).

After the first and third years, three plants from each treatment (species/fertilization combination) in blocks 1 and 2 of the pot experiment and two plants from each treatment in block 3 were collected for measurement and chemical analysis. In the fourth year, eight saplings were taken randomly from each treatment in the pots and the field. Growth of the 1-yr-old seedlings and 3-yr-old saplings was measured. For the 4-yr-old saplings, previously published growth data were used (Laitinen et al., 2004a). Samples for chemical analyses were taken from the top of the plant (1st, 3rd, and 4th years), 1 cm below the terminal bud, and from the base (1st and 3rd years). The length of the top samples varied in different years. In the first year, it was only 10 cm because the total length of the seedlings was small. In the third year, samples were 15 cm long because there was sufficient material for longer samples. In the fourth year, the diameter of the saplings varied greatly, and to obtain samples with approximately the same biomass, the length of the samples had to vary between 5 and 10 cm. Base samples were 10 cm long. Resin droplets were classified visually into four categories: 0 = no resin droplets, 1 = some resin droplets, 2 = moderate number of resin droplets, and 3 = large number of resin droplets. Samples were stored in plastic bags at −20°C.

Extraction of Phenolics and Triterpenoids. Bark was separated from wood, and buds were removed. Each bark sample was cut into small pieces and methanol was added. The sample was left to stand on ice for 20 min and then homogenized in an Ultra-Turrax homogenizer for 3 min and filtered. The residue was extracted with methanol ×2 for pot samples and once for field samples. The sample was left on ice for 10 min the first time and 5 min the second time. Finally, to ensure extraction of triterpenoids, the residue was extracted once with diethyl ether, allowed to stand for 5 min on ice, and then homogenized for 3 min.

The residue in each of the extractions was washed with methanol. All extracts were filtered and combined, and the methanol and diethyl ether were

4	40	320	384

(1 = the lowest, 4 = the highest). N g/seedling (a) and N kg/ha (b) are also shown. Superex9 contained 19.4% N (7.2% NO_3–N), 5.3% P, 20.0% K, and 0.20% Mg; Superex5 contained 10.9% N (9.1% NO_3–N), 4.0% P, 25.3% K, and 1.5% Mg; Superex7 contained 0% N, 6.9% P, 31.9% K, and 1.0% Mg. Micronutrients (Fe, Mn, B, Zn, Cu, Mo, and Co) were included in all Superex fertilizers. Kemira Y1 contained 10.0% N (3.0% NO_3–N), 7.0% P, 14.0% K, and 2.0% Mg. In addition, Kemira Y1 included S, B, Cu, Fe, Mn, Mo, Zn, and Se. For more details, see Laitinen et al. (2004a).

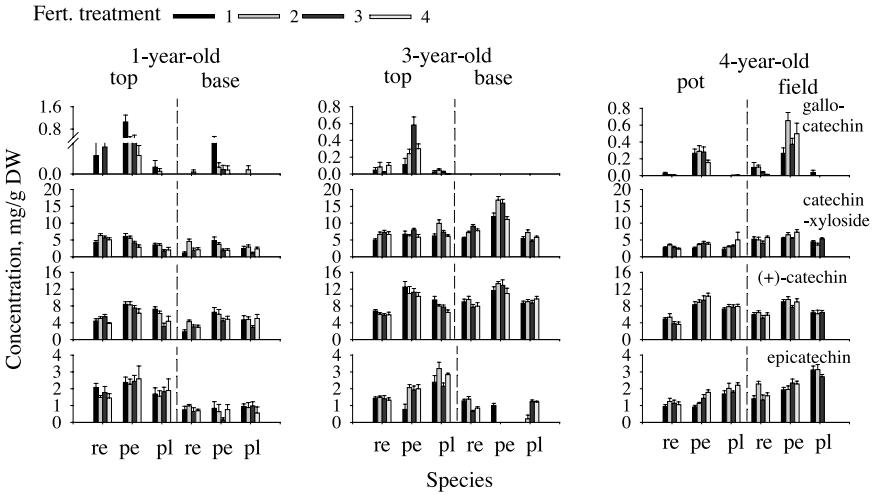

FIG. 1. Concentrations of catechin derivatives (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*Betula resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha in each year, see Table 1.

vacuum-evaporated. Samples were redissolved in 10 ml of methanol, and aliquots of 2 × 1 and 1 × 2 ml were evaporated to dryness under nitrogen and stored at −20°C.

HPLC-DAD and HPLC-MS Analysis. Phenolics in the bark were analyzed by high-performance liquid chromatography diode array detection (HPLC-DAD) by using 1-ml samples dissolved in water–methanol (1:1). HPLC conditions were as described in Julkunen-Tiitto et al. (1996), except that the injection volume was 15 μl. Identification of compounds was based on their retention times and UV spectra monitored at 220 and 320 nm. The concentrations of individual compounds were calculated using reference factors of the following commercial standards: picein (Extrasynthese, Geney, France) for 3,4′-dihydroxypropiophenone-3-glucoside (DHPPG); acacetin (Roth, Karlsruhe, Germany) for acacetin derivatives; apigenin-7-glucoside (Roth) for apigenin derivatives; (+)-catechin (Aldrich, Steinheim, Germany) for catechin derivatives; chrysoeriol (Roth) for chrysoeriol; chlorogenic acid (caffeoylquinic acid) (Aldrich) for neochlorogenic acid, chlorogenic acid derivatives, and cinnamic acid derivatives; gallic acid (Aldrich) for ellagic acid derivative; quercetin-3-galactoside (Roth) for quercetin derivatives; kaempferol-3-*O*-glucoside (Extrasynthese) for kaempferol-3-glucose; luteolin (Roth) for luteolin

derivatives; myricetin-3-rhamnoside (Roth) for myricetin derivative; naringenin for naringenin; pentagalloylglucose (provided by Prof. Ann Hagerman, Miami University, Miami, OH, USA) for pentagalloylglucose; platyphylloside (provided by Dr. Kerstin Sunnerheim-Sjöberg, Uppsala) for platyphylloside; protocatechuic acid for protocatechuic acid derivatives; salidroside (provided by Prof. H. Thieme, Berlin) for salidroside, lignan 1 (secoisolariciresinol 9-*O*-β-glucopyranoside), lignan 2 (lignan derivative 2), lignan 3 (lignan derivative 3) (Strack et al., 1989), and rhododendrin derivatives; and triandrin (Prof. H. Thieve, Berlin) for triandrin. In a few samples, some compounds were detected in only small amounts, so (+)-catechin is the sum of (+)-catechin and B3 (tentatively) (Figure 1); the quercetin derivative 1 is the sum of five different quercetin derivatives (Figure 2); the compound group of cinnamic acid

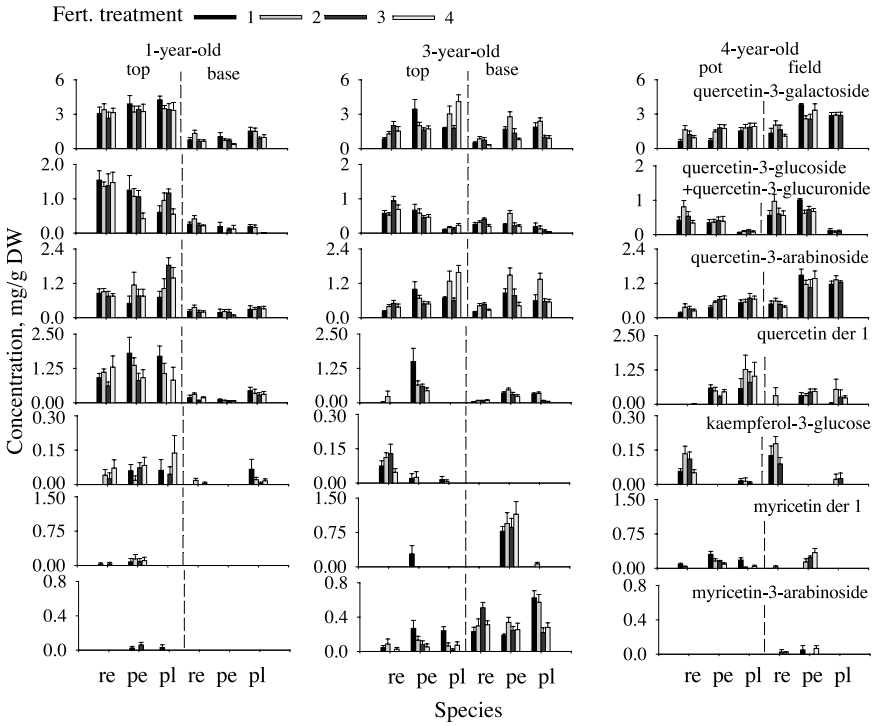

FIG. 2. Concentrations of flavonol glycosides (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha in each year, see Table 1.

derivatives is the sum of six cinnamic acid derivatives (Figure 7); and the chlorogenic acid derivative 1 is the sum of six different chlorogenic acid derivatives (Figure 3). Small concentrations of myricetin-3-galactoside, three myricetin derivatives, two apigenin derivatives, two luteolin derivatives, and two acacetin derivatives were also found in a few samples. These compounds are included in the sums of the respective compound groups.

The HPLC-DAD data for phenolics were verified by using HPLC/atmospheric pressure electrospray ionization (HPLC/API-ES), which produced the following molecular weights: chlorogenic acid 355 (M + 1) and 377 (M + 23); myricetin 3-galactoside 481 (M + 1) and 503 (M + 23); myricetin 3-arabinoside 451 (M + 1) and 473 (M + 23); quercetin 3-galactoside 465 (M + 1) and 487 (M + 23); quercetin 3-glucoside 465 (M + 1) and 487 (M + 23); quercetin 3-glucuronide 479 (M + 1) and 501 (M + 23); kaempferol 3-glucoside 449 (M + 1) and 471 (M + 23); salidroside 323 (M + 23); rhododendrin 351 (M + 23); platyphylloside 499 (M + 23), and 315 (M + 1); (+)-catechin 291 (M + 1); catechin xyloside 423 (M + 1); lignan 1 709 (M + 23).

Triterpenoids were analyzed quantitatively by HPLC–mass spectrometry (MS) by using 1-ml terpenoid samples dissolved in 8 ml 94% ethanol. The HPLC/API-ES conditions were as follows: the column was a Hypersil RP C-18, 2.1 mm ID × 10 cm; the ES fragmentor voltage was 100 V, and the flow rate

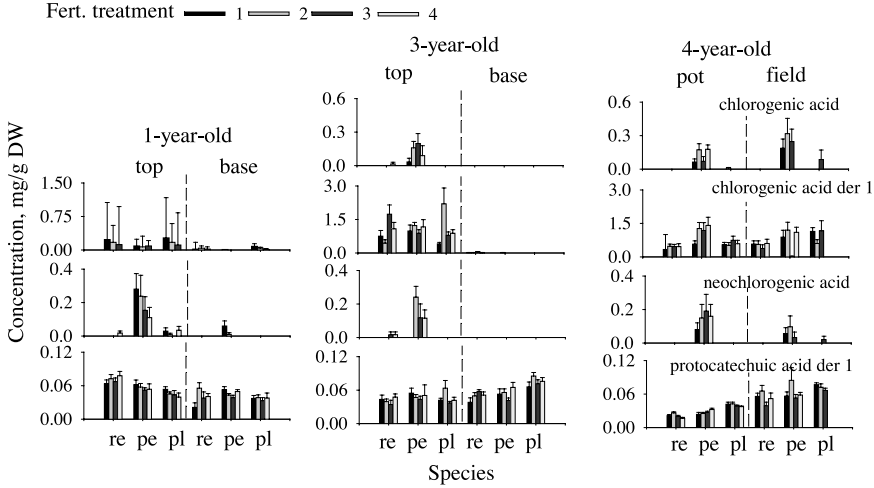

FIG. 3. Concentrations of caffeoylquinic and other acids (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha in each year, see Table 1.

was 0.2 ml/min. Isogratic elution was used with EtOH (94%): aqueous 1.5% tetrahydrofuran + 0.25% acetic acid (75:25, pH 5.4). The MS-SIM analyses were based on the following ions: papyriferic acid 627 (M + 23), 643 (M + 39), 423 (M + H-59-143); pendulic acid 611 (M + 23), 627 (M + 39), 511, 407; and deacetylpapyriferic acid 585 (M + 23), 601 (M + 39). Triterpenoid components were quantified by using purified papyriferic acid (provided by Prof. Paul Reichard, University of Alaska, USA). The concentrations of pendulic acid and deacetylpapyriferic acid are considered to be relative.

Concentrations of condensed tannins were determined from the dissolved methanol (1st, 3rd, and 4th years) and the extraction residue (4th year), using the butanol–HCl test according to Hagerman (1995). Quantification was based on purified tannin equivalents from *Betula nana* leaves.

Dry Weight and Nitrogen Analysis. To determine the amounts of phenolics and terpenoids, 5-cm samples were taken from just below (top samples) or above (base samples) those taken for chemical analyses. They were left to dry at room temperature for 2 d or dried at 105°C for 24 hr, after which their dry weight was determined. The amounts of nitrogen in the 3rd year bottom samples and 4th year top samples were measured with a nitrogen analyzer (Leco FP-528, Leco, St. Joseph, MI, USA).

Statistics. Effects of species, plant part, age, fertilization, and growing site on chemistry were analyzed using ANOVA. The model for individual compounds in 1- and 3-yr-old saplings and within the plant (top, base) was a full factorial model of fixed effect: species, fertilization, plant part, and age. For the age effect, the design was a split-plot design in which whole plot treatments were defined by species and fertilization, whole plots were defined by block, species, and fertilization, and split-plots were defined by block, species, fertilization, and age. The design for the plant part effect was also a split-plot design, in which split-plots were defined by block, species, fertilization, and plant part. The random effects of the ANOVA model were, therefore, block*species*fertilization, block*species*fertilization*age, block*species*fertilization*age*plant, and block*species*fertilization*age *plant. The analyses were performed by using the SPSS GLM procedure, which computes the degrees of freedom of the error terms by Satterthwaite's method (SPSS 11.0 for Windows 2001). The interpretation of high-order interactions is somewhat problematic, and to save space, only interactions up to the third degree are presented in the ANOVA tables in Appendices 1–3 (available online at http://www.springerlink.com; search for DOI: 10.1007/s10886-005-7100-5; Electronic Supplementary Material can be found at the end of the article). Concentrations of analyzed compounds were transformed with square root or natural logarithm transformations [$\ln(x + 1)$, $\ln(x + 0.5)$, or $\ln(x + 0.1)$]. The normality of the residuals was checked with probability plots, and the homogeneity of variances was checked by plotting residuals against fitted values. To evaluate the impact of species,

growing habitat, and age, the data for the compound groups were also analyzed by using principal component analyses (PCA). Correlations between different parameters were determined with Pearson's correlation or Spearman's nonparametric correlation test.

RESULTS

The concentrations of different secondary chemicals under different fertilization treatments within species, different species, and sites, and different plant parts and different years varied greatly and in many cases significantly (Appendices, Figures 1–9). Fifty-eight compounds were identified as phenolics and terpenoids. *B. pendula* contained all 58, *B. resinifera* 51, and *B. platyphylla* 52. Some compounds were present in both plant parts of the three species in all treatments. They included catechin-xyloside and (+)-catechin (Figure 1), quercetin-3-galactoside and quercetin-3-arabinoside (Figure 2), protocatechuic

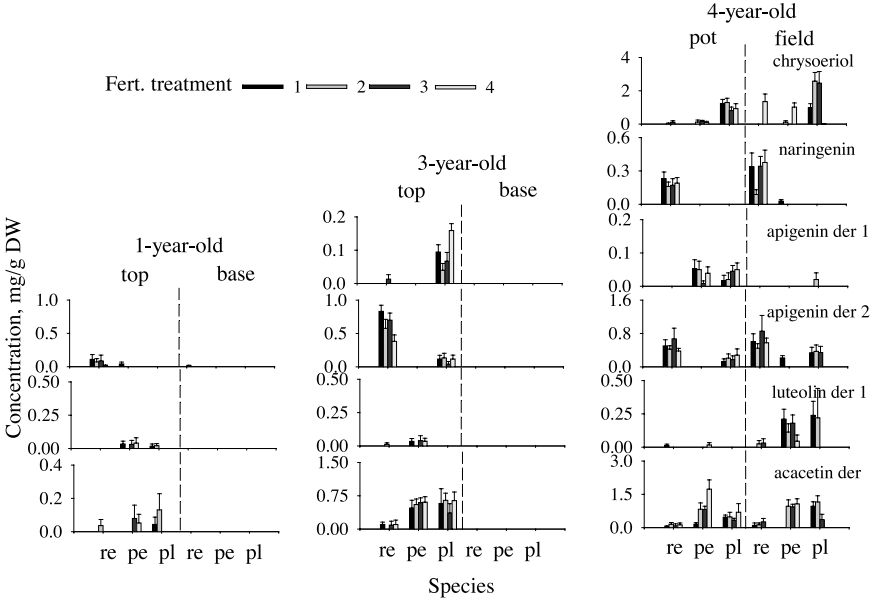

FIG. 4. Concentrations of flavonoid aglycones (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha in each year, see Table 1.

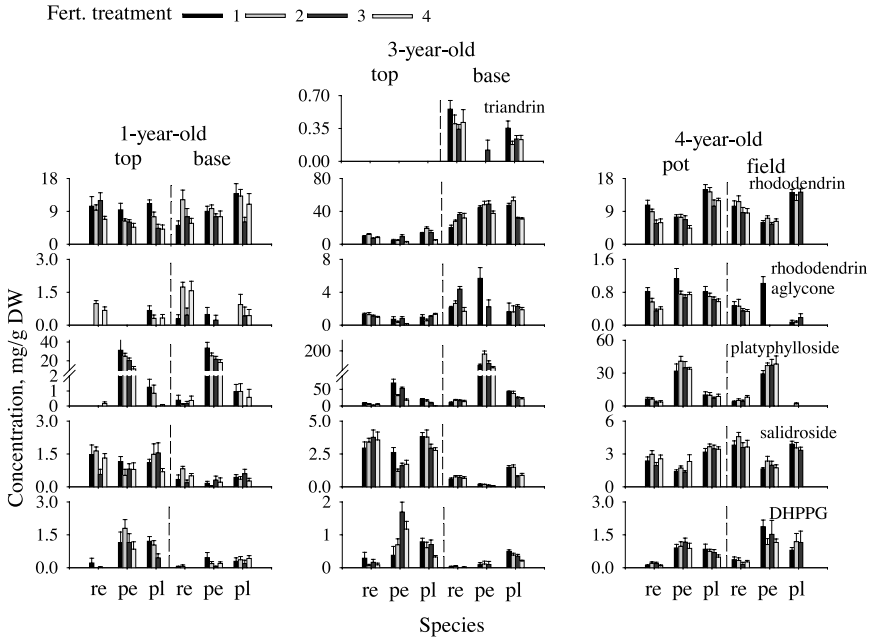

FIG. 5. Concentrations of other phenolic glycosides and small molecular weight derivatives (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1.

acid derivative 1 (Figure 3), rhododendrin and salidroside (Figure 5), and pendulic acid (Figure 8). There was also secoisolariciresinol 9-*O*-β-glucopyranoside and two of its derivatives, lignans 2 and 3, which have not previously been identified in birch bark (Figure 6).

Total concentrations of HPLC-phenolics in seedling base samples were much higher than those of total terpenoids (Figures 7 and 9). Particularly large concentrations of platyphylloside, a phenolic glycoside, were found in base samples from 3-yr-old saplings of *B. pendula* (Figure 5), and there were much higher concentrations of soluble condensed tannins in base samples from 3-yr-old saplings than in top samples (Figure 6). Concentrations of soluble tannins in 4-yr-old saplings were smaller than those of insoluble condensed tannins (Figure 6). Triandrin (Figure 5) and lignans 2 and 3 (Figure 6) were found only in base samples from seedlings and 3-yr-old saplings of *B. resinifera* and *B. platyphylla*. Flavonoid aglycones (Figure 4) and pentagalloylglucose (Figure 6) were found mostly in the top parts of the plants.

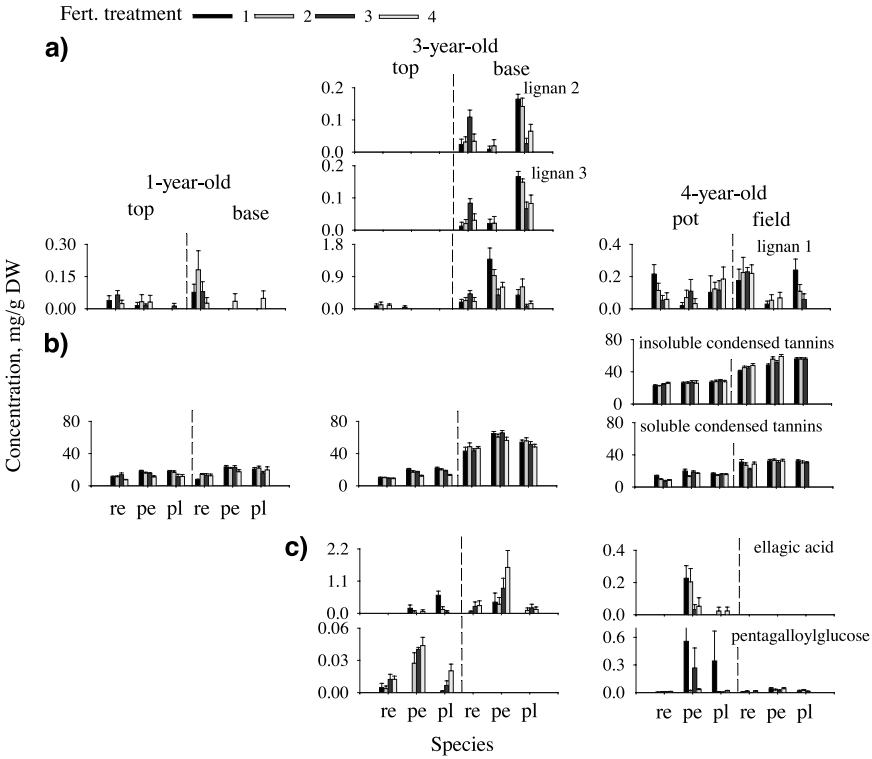

FIG. 6. Concentrations of (a) lignans, (b) condensed tannins, and (c) hydrolyzable tannins and their precursors (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1. Note the differences in scale on the vertical axes. Note also that insoluble tannins were determined only at the age of 4 yr.

Although the birches tested have fairly similar chemical profiles, the three species were clearly distinguished by PCA (Figure 10). Separation is greatest in fourth year field samples and hardly exists in seedlings (Figures 3–7).

The effect of fertilization on chemical profiles was dependent on age and species of plants (Appendices, Figures 1–9). Although there was considerable variation in responses to fertilization, the amounts of phenolics in 1-yr-old and 3-yr-old plants often fell with increasing fertilization (Figures 1–3 and 5–7). The effect of fertilization on terpenoids in 4-yr-old plants was variable (Figures 8 and 9).

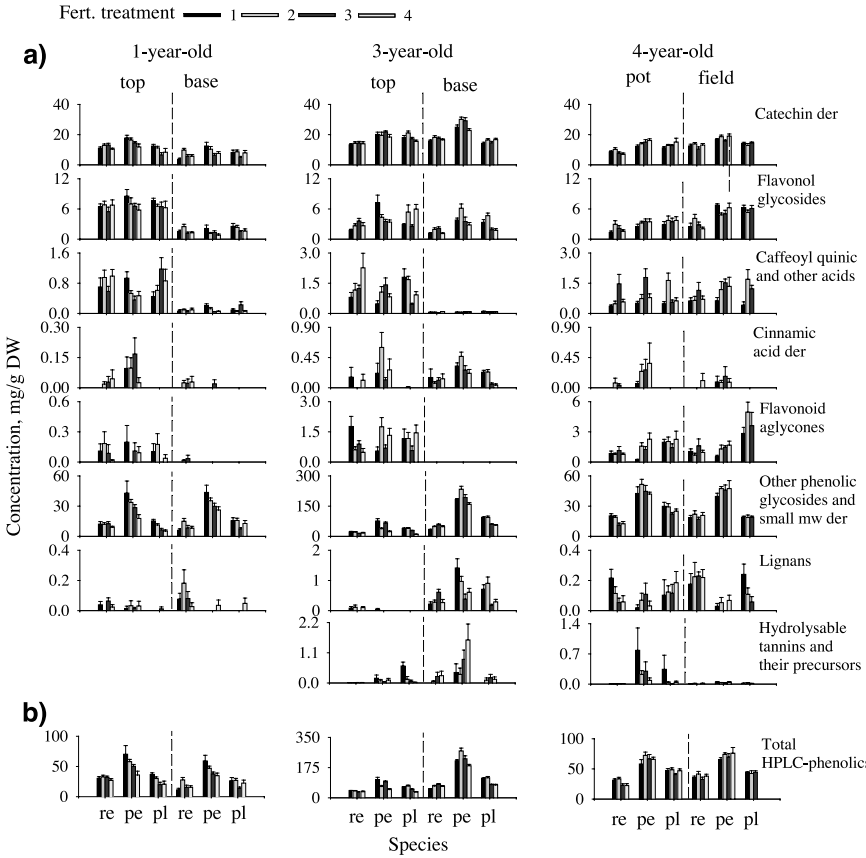

FIG. 7. Concentrations of (a) phenolic compound groups (mean ± SE, mg/g of DW = dry weight) and (b) total phenolics in seedlings and saplings of (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1. Note the differences in scale on the vertical axes. der = Derivative.

The effect of the growing site was dependent on species and compound (Appendices, Figures 1–9). When 4-yr-old saplings grown in pots were compared with those grown in the field, noticeably higher concentrations of condensed tannins were found in the latter (Figure 6). PCA also shows that, with regard to chemical profiles, 4-yr-old plants are differentiated by growing condition (Figure 10, Table 2).

Concentrations of some phenolic groups (catechin derivative, flavonoid aglycones, other phenolic glycosides, and small molecular weight phenolics;

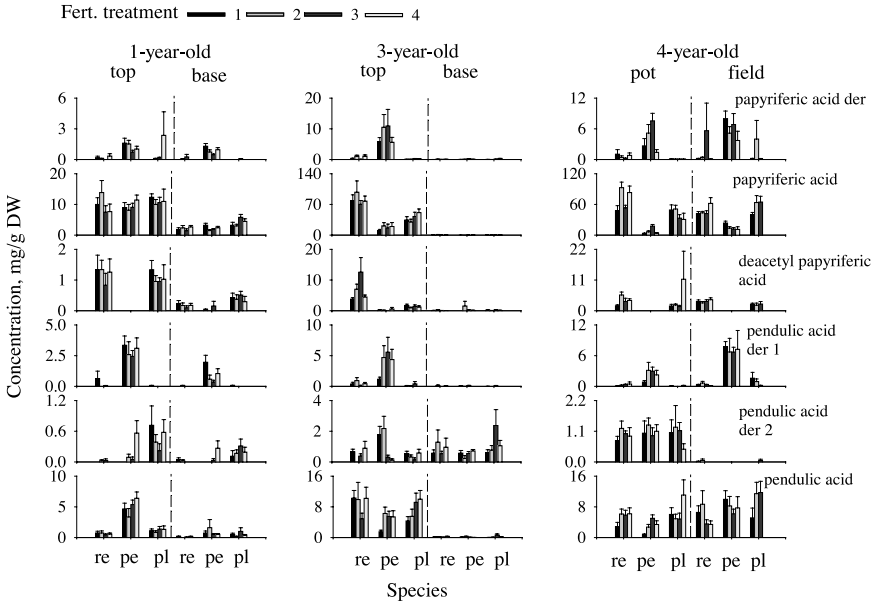

FIG. 8. Concentrations of terpenoids (mean ± SE, mg/g of DW = dry weight) in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1. Note also the differences in scale on the vertical axes. der = Derivative.

Figure 7) were higher in 3-yr-old plants than in 1- and 4-yr-old ones. This was particularly the case in base samples from 3-yr-old saplings (Figures 1, 3, 5, and 6).

The highest concentrations of terpenoids were found in top samples from older saplings. However, except for pendulic acid derivative 2 (Figure 8), the concentrations of terpenoids in the base parts of plants declined with age (Figures 8 and 9). Correlations between resin droplets and individual terpenoid compounds or compound groups were positive but not statistically significant (Spearman rank correlation $P > 0.05$).

DISCUSSION

Species-specific quantitative and qualitative variation in secondary chemicals was considerably higher than that caused by site (pot vs. field), fertilization treatment, or ontogeny (Appendices, Figure 10). These genetic differences

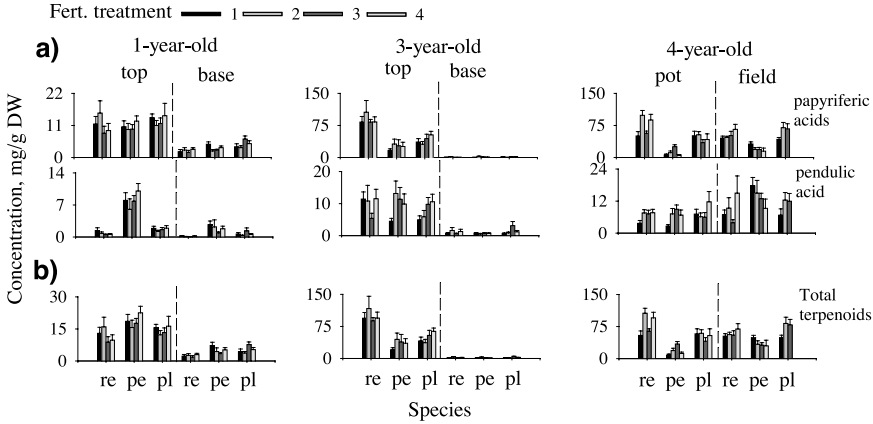

FIG. 9. Concentrations of (a) terpenoid compound groups (mean ± SE, mg/g of DW = dry weight) and (b) total terpenoids in seedlings and saplings (*B. resinifera* = re, *B. pendula* = pe, and *B. platyphylla* = pl) in top samples (at 1-, 3-, and 4-yr-old) and base samples (ages 1 and 3) in pot and field experiments with different fertilization treatments. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1.

among different species are manifested in variations in survival, growth (Figure 11), and morphology found in research station experiments (Laitinen et al., 2004a). *B. pendula* particularly contained high concentrations (up to 20% dry weight) of platyphylloside, which is the most abundant individual compound in the bark of European white birch (Julkunen-Tiitto et al., 1996).

Many of the compounds analyzed [catechin-xyloside, (+)-catechin, quercetin-3-galactoside, quercetin-3-arabinoside, protocatechuic acid derivative 1, rhododendrin, salidroside, and pendulic acid] appeared in both seedlings and saplings. Others were found mainly in a specific species or at a particular developmental stage (e.g., chlorogenic acid, myricetin 3-arabinoside, neochlorogenic acid). We also detected three new components, secoisolariciresinol 9-*O*-β-glucopyranoside and two of its derivatives, which have not previously been reported for white birches. Two of these (lignans 2 and 3) appeared only in base samples from 3-yr-old saplings.

In our study, quantitative variation in secondary chemistry among age classes was specific to species (Appendices, Figures 1–10) and plant part. Quantitative variation in secondary metabolism is generally a reflection of site differences or seasonal and year-to-year variation in weather (Laitinen et al., 2000), whereas qualitative variation seems to be more affected by ontogeny. The considerable impact of growth conditions can be seen, for example, in the amounts of condensed tannins, which were higher in plants grown in the field

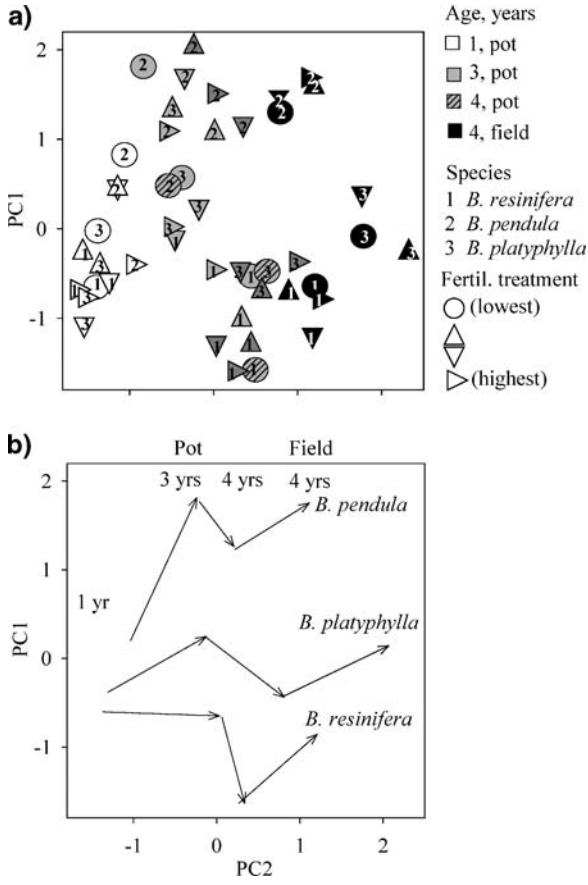

FIG. 10. Principal components analysis (PCA) on secondary compound groups of different species (*B. resinifera*, *B. pendula*, and *B. platyphylla*) in different fertilization treatments and years (a). (b) Simplified diagram of PCA.

than in those grown in pots (Figure 6). The poor growth (Figure 11) and survival rate of plants grown in the field indicate that the growth conditions there were not as favorable as those in the pots (Laitinen et al., 2004a). Poor growth may have led to an excess of carbon for the synthesis of condensed tannins, which are the end products of the phenolic biosynthetic pathway. On the other hand, in the pot experiment, both plant growth and the allocation of carbon to secondary chemicals may have been affected by increased root binding over 4 yr. Consequently, no general conclusions can be drawn from the pot experiment with respect to ontogenetic changes in the secondary chemistry.

TABLE 2. PRINCIPAL COMPONENT MATRIX OBTAINED BY PCA OF CHEMICAL COMPOUND GROUPS FOUND IN *B. resinifera*, *B. pendula*, AND *B. platyphylla*

	Component	
	1	2
Catechin der	0.872	
Other phenolic glycosides and small mw der	0.825	
Caffeoylquinic acids	0.712	
Cinnamic acid der	0.615	
Total pendulic acid	0.598	0.498
Soluble condensed tannins	0.563	0.302
Hydrolyzable tannins and their precursors	0.257	
Total papyriferic acids	−0.267	0.786
Lignans	−0.255	0.715
Flavonoid aglycones	0.346	0.696
Flavonol glycosides		−0.623

Insoluble condensed tannins are not included.
mw = molecular weight, der = derivative.

Although in a few cases fertilization reduced the total levels of phenolics, which accords with many earlier studies (e.g., Bryant, 1987; Price et al., 1989; Muzika and Pregitzer, 1992), individual compounds or compound groups reacted in a highly variable manner, and they were also affected by ontogeny. In general, with increasing fertilization, the amounts of phenolics seemed to decrease, especially in 1- and 3-yr-old birches. The concentrations of terpenoids were also affected by fertilization, but not as predictably as the concentrations of phenolics. Although it has been argued that terpenoids arising from the mevalonic acid pathway (Torssell, 1983; Seigler, 1998) do not directly compete with protein synthesis and should not be affected by changes in nutrient

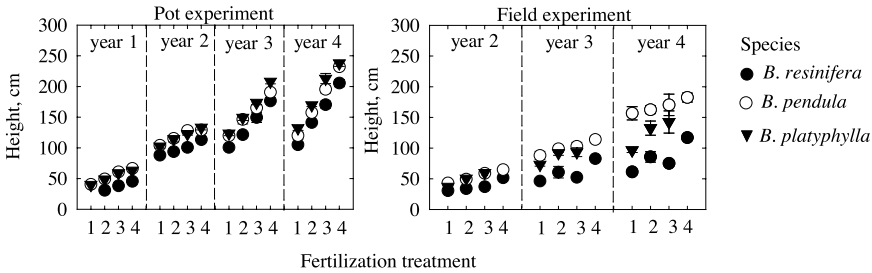

FIG. 11. Height of *B. resinifera*, *B. pendula*, and *B. platyphylla* seedlings and saplings grown in pots and in the field. The fertilization treatments are: 1 = lowest, 4 = highest. For N g/seedling and N kg/ha each year, see Table 1 (modified from Laitinen et al., 2004a).

availability (Muzika, 1993; Haukioja et al., 1998), earlier studies have also shown them to be affected by environment, in some cases even more so than phenolics (Laitinen et al., 2004c). It has been suggested that variation in the concentrations of individual phenolics in relation to the availability of nutrients is caused by a trade-off of substrates between different branches of the biosynthetic pathway of phenolic compounds (Haukioja et al., 1998), i.e., the concentration of one compound may increase at the expense of another (Keinänen et al., 1999; Koricheva et al., 1999).

The concentrations of terpenoids were markedly higher in base samples from 1-yr-old seedlings than from 3-yr-old saplings. Resin droplets, which contain terpenoids, are formed in current year shoots (Lapinjoki et al., 1991); as the plant ages, the bark gets thicker and the resin droplets tend to fall off, resulting in a decrease in the amount. Consequently, strong species × plant part interactions in secondary chemistry may be an indication of the varied abiotic and biotic pressures that the species have encountered in their original growing sites (Close and McArthur, 2002).

One-year-old seedlings of all these white birches are chemically similar, but at the sapling stage, the species are clearly differentiated (Figure 10). Alaskan *B. resinifera* and Japanese *B. platyphylla* seem to be similar chemically, whereas European *B. pendula* appears to be more distinct (Figure 10). Our results, thus, indicate (Figure 10) that secondary chemicals can be used for chemotaxonomic identification of older birches (see also Julkunen-Tiitto et al., 1996), as long as they are growing on sites to which they have adapted.

Secondary compounds in the bark of birches affect depredation by field voles (*Microtus agrestis*; e.g., Harju and Tahvanainen, 1991) and mountain hares (*Lepus timidus*; e.g., Reichardt et al., 1984; Laitinen et al., 2004b). When we compared the secondary chemistry of *B. resinifera*, *B. pendula*, and *B. platyphylla* with the feeding preference of field voles and mountain hares (Laitinen et al., 2004b) for the same experimental plants, we did not find any clear correlations. The effects of bark secondary compounds on vole feeding, in particular, varied and were dependent on the species and age of the plants.

The results of this study indicate that white birch species are differentiated by their secondary chemistry. They also show that secondary metabolism is considerably affected by ontogeny and environment, and that these effects are variable, depending on the properties of the growing sites and possibly also on seasonal and year-to-year variation in weather conditions.

Acknowledgments—We are grateful to the staff of Punkaharju Forest Research Station for help in growing and measuring the plant material. We thank Anneli Kurkkio, Irma Lantto, Outi Nousiainen, and Sinikka Sorsa for help with the laboratory work. Sincere thanks are due to Joann von Weissenberg and Kenneth Meaney for grammar revisions. This study was supported by the Graduate School of Forest Sciences, which is funded by the Finnish Ministry of Education and by

the Finnish Centre of Excellence Program 2000–2005, Centre for Excellence for Forest Ecology and Management, project no. 64308.

Abstract—We examined the relationship between internal resources (root reserves), external resources (soil fertility), and allocation to defense vs. growth in the clonal, perennial herb *Solanum carolinense*. In a short-term (9 d) greenhouse experiment, plants were treated once with jasmonic acid (JA) to determine if polyphenols and glycoalkaloids were inducible by simulated herbivory. In a longer-term (4 wk) greenhouse experiment, we measured the cost, in terms of growth, of treatment with JA every 3 d, to determine if the induced response was due more to carbon limitation or nitrogen limitation. We manipulated the resources available to the plants by varying soil fertility and the size of root cuttings from which plants were grown, and assessed how different resource levels affected the growth and production of polyphenols and alkaloids under JA treatment or control conditions. In the short term, JA increased the concentration of polyphenols in both above- and belowground plant parts, as well as alkaloid concentrations in the roots. In the long term, the only significant secondary chemistry response to JA was an increased polyphenol concentration in above ground tissues. The total amount of polyphenols produced was the same for JA and control plants, indicating that the higher concentration was a result of the lower biomass of treated plants. In contrast, alkaloid concentrations in plants treated with JA for 4 wk did not differ from controls, but JA-treated plants contained lower total amounts of alkaloids in above ground tissues, as a result of decreased growth. Fertilizer level and root cutting size had effects on growth and the production of secondary compounds and influenced the cost of induction. Plants grown under high

[3] Current address: Department of Ecology and Evolution, Stony Brook University, 650 Life Sciences Building, Stony Brook, NY 11794-5245, USA.

fertility had a greater reduction in growth in response to JA than plants grown under low fertility, indicating a greater trade-off between growth and defense for high fertility plants. Plants from larger root cuttings grew bigger without any reduction in the concentration of polyphenols and alkaloids. We demonstrated that the phenotype of *S. carolinense* was plastic in response to simulated herbivory, fertility level, and root cutting size, and that there was a significant growth cost to induction that varied with the environment and appears to be due in large part to the allocation of limited carbon reserves.

Key Words—*Solanum carolinense*, horsenettle, inducible defenses, herbivory, nitrogen, carbon, nutrients, root reserves, polyphenols, alkaloids.

INTRODUCTION

Herbivore attack is nearly universal for plants; as a result, all plants possess some form of defense against herbivory (Strong et al., 1984). Despite the clear benefits of defenses against herbivores, natural selection does not always maintain constitutively high levels of defensive traits (Karban and Baldwin, 1997). If constitutive defense traits have costs that outweigh their benefits in some environments, contrasting selection pressures in different environments can promote selection for plasticity in responses to herbivores (Sultan, 1987; Via et al., 1995; De Witt et al., 1998; Kliebenstein et al., 2002). In theory, there should be selection for inducible defense traits when herbivore pressure is variable and when defense traits have a high cost in the absence of herbivores (Givnish, 1986; Karban and Baldwin, 1997). The ultimate measure of the cost of any trait is an associated reduction in fitness. For plants, the accumulation of biomass during growth is often correlated with survival and reproduction and can be used as a surrogate for fitness. Costs of constitutive or inducible defense production may arise by many mechanisms, including allocation trade-offs, ecological interactions, and genetic effects such as pleiotropy (Heil and Balwin, 2002). There may also be a cost of plasticity *per se* (De Witt et al., 1998; Agrawal et al., 2002; Relyea, 2002).

Many studies have quantified the cost of resistance manifested as a reduction in growth or reproduction (see reviews in Bergelson and Purrington, 1996 and Strauss et al., 2002), but the results are equivocal. In the survey by Bergelson and Purrington (1996), a cost was detected in only 29% of the cases. Some studies have demonstrated a cost (e.g., Baldwin, 1998; Redman et al., 2001), while others have not (e.g., Gianoli and Niemeyer, 1997), and still others found a cost in some situations but not in others (Agrawal, 1999; Siemens et al., 2002). It is becoming clear that the costs of a particular defensive phenotype are dependent upon the environment in which they are measured, including the resources available to the plant and the ecological interactions of the community

(Heil, 2002; Koricheva, 2002; Strauss et al., 2002). Inclusion of ecological costs and consideration of the conditions under which they are measured has improved the ability to identify them (Koricheva, 2002; Strauss et al., 2002), yet some theoretical predictions of when costs should be present lack strong empirical support. For example, Bergelson and Purrington (1996) suggested that costs of defense should increase in stressful environments because of resource limitation. This prediction is supported by some studies (Bergelson, 1994; Cipollini and Bergelson, 2001), but not by others (Karban, 1993; Siemens et al., 2002).

Allocation models, in which plants divide limited resources among growth, reproduction, and defense, are one of the more widely used theoretical approaches to studying phenotypic costs (reviewed in Stamp, 2003). How much a plant allocates to a particular function is assumed to depend on how much of the resource is available (Bryant et al., 1983; Maschinski and Whitham, 1989; Herms and Mattson, 1992; Hunter and Schultz, 1995), which in turn depends on the external environment (e.g., edaphic conditions or light levels) and on the internal environment (e.g., maternal effects or stored reserves). Correlated effects can complicate the measurement of allocation to inducible defensive traits; for example, plant hormones involved in responses to herbivory, such as jasmonic acid (JA) and abscisic acid, may also have effects on plant growth (Sembdner and Parthier, 1993; León et al., 2001; Heil and Balwin, 2002). Although there are models to explain the evolution of inducible defense responses that do not depend directly on an analysis of costs and benefits (e.g., Adler and Karban 1994; Karban et al., 1997; Jokela et al., 2000), we use the cost/benefit model here because it remains central to the study of inducible responses to herbivory.

The majority of studies that measure costs of inducible defenses use annual herbs because of the obvious advantage of being able to more accurately assess lifetime fitness; however, this has also limited the generality of the results. In this study, we used the clonal herb *Solanum carolinense* L. (Solanaceae) to look for a trade-off between the production of inducible secondary compounds and growth, and to gain an understanding of how root reserves and soil fertility influence that trade-off. *S. carolinense* is a long-lived perennial plant native to eastern North America, common in old fields and as an agricultural weed.

Our first objective was to determine if the levels of two classes of putative resistance compounds, polyphenols and alkaloids, were plastic in response to simulated herbivory in *S. carolinense*. Polyphenols can be directly toxic, or can reduce the digestibility of plant tissue, slowing the growth of herbivores and reducing feeding damage (Herms and Mattson, 1992; Appel, 1993; Karban and Baldwin, 1997). Polyphenol content in plants is a plastic trait that can increase with actual or simulated herbivory (Baldwin, 1998; Tscharntke et al., 2001; Francheschi et al., 2002; Rudell et al., 2002). Alkaloids contribute to plant resistance through toxicity. Work in species closely related to *S. carolinense* has

demonstrated that alkaloid levels can increase under actual and simulated herbivory, and that this can increase a plant's resistance (Baldwin et al., 1990; Baldwin, 1998; Baldwin and Hamilton, 2000). However, increased alkaloid content may not increase resistance to all herbivores, because many insects are specialists that can tolerate high levels of toxic compounds or use them for their own defense (Mullin et al., 1997; Bolser and Hay, 1998; Cipollini et al., 2002; Marcel et al., 2002; Siemens et al., 2002). The evolution of an increased production of alkaloids as a plastic response to herbivory will depend on the ratio of the levels of damage by specialist vs. generalist herbivores.

Our second objective was to determine if induction has a fitness cost in the absence of herbivores. JA is an endogenous plant-signaling molecule, which increases in plants under herbivore attack. When applied externally, it can stimulate plant defenses in the absence of herbivores (Zhang and Baldwin, 1997), allowing defense costs to be measured without the confounding affects of tissue loss. JA has been used successfully to induce defense responses in other members of the Solanaceae (Thaler et al., 1996; Baldwin, 1998; Cipollini and Redman, 1999; Baldwin and Hamilton, 2000; Redman et al., 2001). We used growth as the sole measure of fitness, because lack of pollinators in the greenhouse prevented seed production. We believe growth accurately represents fitness in *S. carolinense*, because its indeterminate growth form leads to a strong correlation between growth and flower and fruit production (Cipollini et al., 2002; Cipollini et al., 2004). Furthermore, vegetative reproduction is often the most important means of population growth and maintenance for clonal plants, while establishment by seed is used primarily for dealing with severe disturbance or for long distance dispersal (Cook, 1985; Erickson, 1993; Bazzaz, 1996; Pan and Price, 2002). Allocation to root growth in particular is an important component of fitness in clonal plants (Wijesinghe and Whigham, 1997), especially in weeds such as *S. carolinense* that survive tillage by sprouting new plants from severed root pieces (Tisdell, 1961; Rhode Island Agriculture Experimental Station, 1962).

Finally, we sought to understand how external and internal resource supply influenced the potential cost of exhibiting the induced phenotype in the absence of herbivores. We examined the influence of root reserves and soil fertility on patterns of allocation to growth and to the putative defense compounds polyphenols and glycoalkaloids. We expected soil fertility to influence allocation to growth vs. defense because of its influence on the C:N ratio (Bryant et al., 1983). Likewise, root reserves could influence allocation to growth vs. defense if root reserves are a significant source of C or N. We determined whether C and/or N limitation was responsible for the cost of producing inducible defenses in *S. carolinense*, that is, if there is a resource-based trade-off. If it is limited by N, then supplying excess N should reduce or eliminate the trade-off between growth and defense. If the production of an inducible defense is limited by C, then there should be less of a trade-off between growth and defense when C is abundant relative to N, such as under low fertility.

METHODS AND MATERIALS

Plant Material. In May 2001, fleshy roots of *S. carolinense* were excavated from an old field in Julian, PA, USA. Roots were collected from 24 locations, with each at least 2 m apart. Although *S. carolinense* has been known to produce lateral roots up to 15 m long (Rhode Island Agriculture Experimental Station, 1962), excavation at the field site did not reveal any longer than 1.5 m (R. Walls, personal observation), so the 24 plants used should represent a mix of genotypes.

Roots were rinsed with tap water and cut into small, medium, or large segments. Small root cuttings had a fresh mass of 0.400–0.500 g, medium cuttings had a mass of 1.0–1.199 g, and large root cuttings had a mass of 2.0–2.199 g. A mixture of small, medium, and large cuttings was taken from each genotype. To insure viability, all cuttings were sown in flats in Metro-Mix 250 (Scott's Corporation, Marysville, IN, USA). Two wk after sowing, all cuttings had sprouted shoots, except approximately 5% of the small cuttings. Root cuttings with sprouts were transferred into individual pots, 18 cm diam and 25 cm tall. The growth medium was Pro-Mix BX (Premier Horticulture Inc., Red Hill, PA, USA), a peat-based medium with no added nutrients. The pots were placed on a bench in a greenhouse, supplied with supplemental lighting from 8:00 A.M. to 8:00 P.M. daily, and watered as necessary with tap water. The placement of pots on the benches was randomized every 3 d to reduce microclimatic variation.

Experiment 1: Short-term Induction Experiment. A short-term experiment was conducted to determine if exogenous application of JA would increase the concentrations of glycoalkaloids (GA) and polyphenolics (PP) in *S. carolinense*. Twenty-four plants grown from medium and large root cuttings, as described above, were raised in the greenhouse for 2 wk after sprouting. They were fertilized weekly with approximately 1 l 18-18-21 Miracle-Gro for Tomatoes (Stern's Miracle-Gro, Port Washington, NY, USA), diluted to approximately 300 ppm N. Plants were treated on July 2, 2001 (day 0). One half were sprayed until saturation with 1 mM JA (JA treatment), and the other half with a solution of 0.8% ethanol in distilled water (control treatment). JA solution was made by dissolving 250 mg JA (Sigma, St. Louis, MO, USA) in 10 ml ethanol, then dissolving the JA/ethanol solution in 1.189 l water. To prevent contamination of control plants, JA-treated plants were sprayed in the hallway of the greenhouse, downwind of the airflow through the bays, and allowed to dry before being returned to the bench.

Three, 6, and 9 d after treatment, four plants from each treatment were harvested. Each had a main shoot and one to three side shoots. Young leaves were harvested by cutting the distal portion of each stem containing the terminal bud and two semiexpanded leaves. Old leaves were harvested by cutting all fully expanded leaves (except those touching the soil surface) at the petiole. After leaves were harvested, the stem was clipped at soil level, and the roots were rinsed

with tap water to remove growth medium. All tissues were placed in envelopes immediately after harvest, flash-frozen in liquid nitrogen, and maintained at −20°C until being freeze-dried. After freeze-drying, all tissues were ground in a UDY Cyclone Mill to prevent heating. The lyophilized powder was stored in sealed plastic vials at −20°C. Subsamples of young leaf tissue, old leaf tissue, and root tissue from each plant were analyzed for PP concentration (see below). Because there was insufficient young leaf tissue, GA concentration was analyzed in old leaves and roots only (see below). The data were analyzed using the MANOVA option of general linear model (GLM) in SAS 6.12 (SAS Institute, Cary, NC, USA), with JA treatment as the independent variable and PP and GA concentration in the leaves and roots as response variables. *Post hoc* contrasts were conducted for the response variables that showed a significant effect due to JA, with α adjusted by stepwise Bonferroni correction (Rice, 1989).

Experiment 2: Factorial Long-term Induction Experiment. One hundred and twenty plants were assigned to 12 different treatments. Treatments were full-factorial combinations of three cutting sizes (small, medium, and large), two fertility levels (low and high), and two hormone levels (1 mM JA and control). Different genotypes were assigned randomly to each treatment. High fertility treatments were watered every 3 d with approximately 1 L 18-18-21 Miracle-Gro for Tomatoes (Stern's Miracle-Gro, NY USA), diluted to approximately 300 ppm N. Low fertility plants were watered every 6 d with approximately 1 l 18-18-21 Miracle-Gro for Tomatoes, diluted to approximately 100 ppm N. Additional tap water was supplied as needed. JA and ethanol solutions for the hormone treatments were the same as those described for the short-term induction experiment. Plants were sprayed until saturation with JA or ethanol solution every 3 d for approximately 4 wk.

After 4 wk, plants were harvested for analysis. Each was cut at soil level and all aboveground tissues, including stems, leaves, and flowers, were placed into an envelope, flash-frozen in liquid nitrogen, and maintained at −20°C until freeze-drying. Roots were rinsed with tap water and handled as aboveground plant parts. Because the growth medium was peat-based, there was some contamination of the roots, but the same person rinsed all roots, so the level of contamination (approximately 2–4% peat fibers) was consistent for all plants (R. Walls, personal observation). Plant tissues were freeze-dried, ground and stored as described above, and weighed to the nearest 0.1 g.

Data were collected on growth parameters and levels of secondary compounds. Growth was measured as shoot mass, root mass, total plant mass (all dry masses), and relative growth. Relative growth was calculated as whole plant mass divided by the cutting size (0.45, 1.1, or 2.1 g). The concentrations of PP and GA in both roots and aboveground tissues were determined as described below. Total amount of PP and GA in roots and aboveground tissues was calculated as the product of concentration × dry mass. Data were analyzed

with the MANOVA option of the GLM in SAS 6.12, using all of the above response variables, with cutting size, fertility, and JA, plus first-order interactions, as effects. To control for possible correlations between the concentration of secondary compounds and plant mass, we conducted an analysis of covariance in the GLM using PP and GA concentrations as response variables, cutting size, fertility, and spray treatments, plus interactions, as effects, and total plant mass as a covariate. As no significant effect of total plant mass was found for any of the variables, PP and GA concentrations were included in the main MANOVA. *Post hoc* contrasts were conducted for all response variables that showed a significant effect as a result of any of the treatments, with α adjusted by stepwise Bonferroni correction (Rice, 1989).

Polyphenol Analysis. We used purified PP from the plant tissues collected from each experiment as standards. The use of self standards takes into consideration the variability in PP composition that occurs with different treatments and harvest dates, and provides a more accurate measurement of PP concentration than the use of commercial standards (Appel et al., 2001). Bulk samples were prepared for use as a standard by mixing together approximately 0.2 g of lyophilized tissue from each plant. Separate standards were prepared for each tissue type (roots, young leaves, and old leaves for experiment 1, and roots and aboveground tissues for experiment 2). For experiment 1, separate standards were prepared for each harvest date. Purified PP for standards was extracted using the method of Hagerman and Klucher (1986). Five g of tissue were washed with 75 ml ether $\times$ 3 to remove pigments and waxes, then extracted under sonication once with 50 ml 70% acetone and $\times$ 3 with 25 ml 75% acetone. Acetone was removed by evaporation under reduced pressure. Nonphenolics were removed by thoroughly mixing the extract solution with a slurry of 50 g Sephadex (Pharmacia, Piscataway, NJ, USA) in 1 l of 95% ethanol then centrifuging. This process was repeated until the eluant tested negative for the presence of PP (Appel et al., 2001). PPs were removed from the Sephadex by mixing with 150 ml of 70% acetone and shaking for 5 min. The acetone rinse was repeated until the eluant tested negative for the presence of PP with Prussian blue. Acetone was removed by evaporation under reduced pressure, and the resulting solution was freeze-dried to yield dried, powdered tannins for use as standards.

PP concentration of plant tissues was analyzed using the Folin Denis assay (Swain and Hillis, 1959; Swain and Goldstein, 1964; Appel et al., 2001). PPs were extracted from 0.01 g freeze-dried tissue with 2 ml of 50% methanol then rinsed with 2 ml hexane. The concentration of PP in each extraction was calculated by measuring absorbance at 725 nm after reaction with Folin Denis reagent and converting absorbance to g total polyphenols/g dry tissue.

Glycoalkaloid Analysis. GA concentration in tissue samples was analyzed with the method of Birner (1969). In this technique, GAs of *S. carolinense*

(primarily solasonine and solamargine) are simultaneously extracted and hydrolyzed to their steroidal base solasodine. An advantage of this technique is that it uses fairly large quantities of tissue and is sensitive in the analysis of plant tissues with low alkaloid concentrations. Because GAs in *S. carolinense* hydrolyze to the single compound, solasodine, this technique is adequate to estimate allocation to glycoalkaloids as a group. Freeze-dried tissue (0.2 g) was first dissolved in 5 ml 1 N HCl, hydrolyzed for 2 hr at 100°C under reflux conditions, then neutralized with 5 ml 1 N NaOH. Five ml glacial acetic acid were added, and the hydrolyzed extract was filtered and diluted to 25 ml with ddH2O. Commercial solasodine (Sigma, MO, USA) was used as a standard. Duplicate 5-ml aliquots of samples and standards were added to reaction tubes followed by 5 ml acetate buffer (pH 4.7), 1 ml 5% methyl orange solution, and 5 ml methylene dichloride. The tubes were vortexed, contents allowed to separate, and the methylene dichloride layer was removed to a spec tube. Absorbance was read at 420 nm and converted to mg solasodine/g dry tissue.

RESULTS

Experiment 1: Short-term Induction Experiment. The MANOVA showed a multivariate effect for JA and date of harvest on PP concentration and GA concentration (JA: $F = 10.458$, $P < 0.001$; date: $F = 4.676$, $P < 0.001$). Application of JA resulted in a significant increase in PP concentration in young leaves, old leaves, and roots (Tables 1 and 2, Figure 1A). Date of harvest did not affect PP concentration in leaf tissue, but there was a rapid and significant decline in PP level in the roots of both JA and control plants over 9 d, independent of the effect of JA. GA concentration in roots, but not old leaves, was significantly higher in JA-treated plants than controls during the short-term

PP = polyphenols, GA = glycoalkaloids.

experiment (Tables 1 and 2; Figure 1B). There was no effect of date on GA concentration. Both PP and GA were 1 order of magnitude lower in leaves than in roots.

Experiment 2: Factorial Long-term Induction Experiment. There was a multivariate effect for JA, cutting size, and fertilizer on growth and secondary chemistry response variables (MANOVA results for JA: $F = 3.251$, $P < 0.001$; cutting size: $F = 25.923$, $P < 0.001$; fertilizer: $F = 27.939$, $P < 0.001$).

Experiment 2: JA Effects. Unlike experiment 1, treatment with JA led to significantly increased PP concentration in aboveground tissues but not in roots (Tables 3 and 4; Figure 2). Concentration of PP in aboveground tissues after 4 wk was 1 order of magnitude higher than that in young and old leaves in experiment 1 after 9 d, while the concentration of PP in root tissue after 4 wk was similar to that in roots after 9 d (Figures 1A and 2B). In contrast to concentration, JA had no significant effect on the total amount of PP in either the roots or the aboveground tissues (Table 3, Figure 2). Application of JA had no significant effect on GA concentration in either the aboveground tissues or the roots of plants in experiment 2 (Table 3, Figure 3). However, treatment with JA significantly lowered the total amount of GA in aboveground tissues (Tables 3 and 4, Figure 3C). JA treatment also had an effect on growth of *S. carolinense*. Plants treated with JA had lower relative growth, aboveground mass, root mass, and total plant mass (Tables 3 and 4, Figure 4).

Experiment 2: Fertilizer Effects. The application of fertilizer significantly increased plant growth (Table 3 and Figure 4). Although belowground mass was not influenced by fertility level, aboveground mass, total plant mass, and relative growth all increased under high fertility (Table 4). There was a significant JA $\times$ fertilizer interaction for total mass and relative growth, indicating that fertilized plants had a growth response to JA treatment and unfertilized plants did not (Figure 4). Fertilized plants had lower PP concentrations in both aboveground tissues and the roots, while the amount of PP in the roots was lower for fertilized plants, but the same in aboveground tissues (Tables 3 and 4, Figure 2). There were no interactions between fertilizer and cutting size or JA for PP

concentration or amount (Table 3). Fertilizer influenced GA concentration in the roots, but not in aboveground tissues, with fertilized plants having significantly lower GA concentrations in the roots (Tables 3 and 4, Figure 3B). Fertilizer affected the total amount of GA in both the roots and the shoots, with fertilized plants having higher amounts of GA in aboveground tissues, but lower amounts of GA in the roots (Tables 3 and 4, Figure 3C and D). There were no interactions between fertilizer and cutting size or JA for GA concentration, but there was a significant JA × fertilizer interaction for the amount of GA in aboveground tissues, with high fertility plants responding to JA while low fertility plants did not (Table 3, Figure 3C).

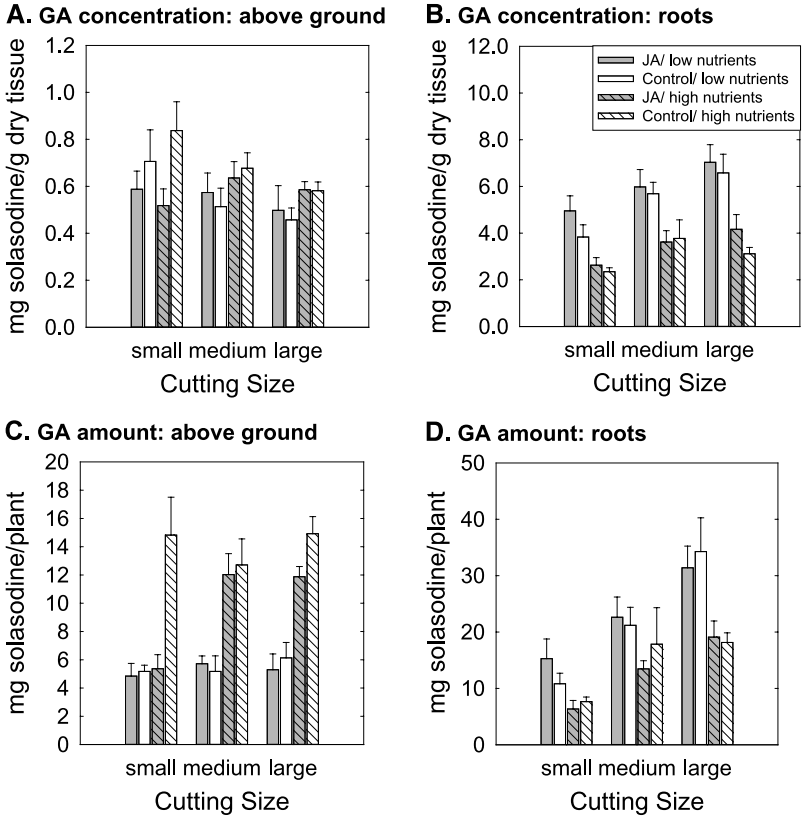

FIG. 3. Mean levels of total glycoalkaloids (GA) ± standard error in above- and belowground plant tissues of *S. carolinense*, measured as the steroidal base solasodine.

Experiment 2: Root Reserve Effects. Cutting size had a significant effect on the growth of *S. carolinense* in experiment 2 (Table 3, Figure 4). Plants from larger cuttings had greater root and aboveground mass, whereas plants from smaller cuttings had higher relative growth (Table 4). There was no significant JA × cutting size interaction for plant mass, but there was an interaction between JA and cutting size for relative growth. Plants from small and large cuttings had more of a reduction in relative growth when sprayed with JA than did plants from medium cuttings, a response due primarily to low fertility plants (Figure 4). Plants from larger cuttings had higher concentrations of PP in the roots but not in aboveground tissues, while the amount of PP in plants from larger cuttings was higher in both the roots and aboveground tissues (Tables 3 and 4, Figure 2). There were no interactions between cutting size and JA or

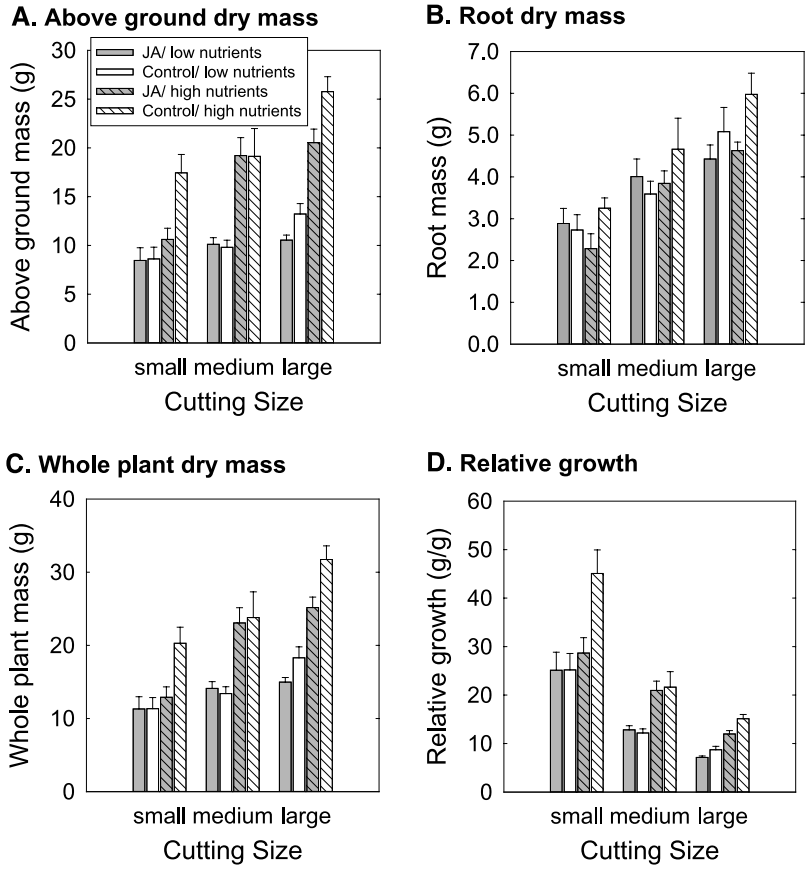

FIG. 4. Mean growth responses of *S. carolinense* ± standard error.

fertilizer for PP concentration or PP amount. Cutting size had a significant effect on GA concentration and amount (Table 3). GA concentration in the roots increased with cutting size. Although the ANOVA indicated an effect of cutting size on GA concentration in aboveground tissues ($P = 0.044$), the decrease in GA concentration in aboveground tissues between plants from small vs. large cuttings was only marginally significant (Table 4). GA amount increased with cutting size in the roots but not the aboveground tissues (Table 4). There was a significant interaction between JA and cutting size for both the concentration and amount of GA in the shoots (Table 3), showing that plants from smaller cuttings responded more to JA than plants from medium and large cuttings. This response was a decrease in GA concentration and amount under JA treatment for small plants (Figure 3).

DISCUSSION

Induction of Secondary Compounds. The first goal of this study was to determine if the levels of PP and GA would increase in response to the application of JA. We found a clear pattern of induction for PP concentration in the above ground tissues of *S. carolinense*, in both experiments 1 and 2 (dark vs. light stippled or solid bars in Figures 1A and 2A). PP concentration in above ground tissues after 4 wk in experiment 2 was approximately 5 times higher than PP concentration in leaves after 9 d in experiment 1. This difference in PP concentration between experiments may be attributable to the use of different tissues: leaves in experiment 1 vs. all aboveground tissue in experiment 2. However, it is unlikely that stems would have a much higher PP concentration than leaves. Alternatively, the increase may have resulted from an accumulation of PP in *S. carolinense* during the growing season that was not detectable during the 9-d time course of experiment 1. It could also be the result of the JA doses applied in each experiment. Plants in experiment 1 received only one JA application, whereas those in experiment 2 were sprayed every 3 d for 4 wk. Similar increases in the level of response variables with increasing jasmonate application have been shown in other studies (Thaler et al., 1996; Redman et al., 2001).

Unlike in shoots, application of JA increased PP concentration in roots only during the short-term experiment. At the end experiment 2, there was no significant difference in PP levels in the roots between JA and control plants, measured as either concentration or amount. However, PP levels in roots did change over the course of the growing season, independent of JA treatment. PP levels in roots declined during the 9 d of experiment 1 (Figure 1A), and the levels after 4 wk were similarly low in experiment 2 (Figure 2B). During experiment 1, PP concentrations in roots were almost 10 times higher than in leaves (~10–25% in roots vs. ~2.9–4.5% in shoots), whereas in experiment 2, the concentrations were similar in roots and aboveground tissues (~10–25%). The differences may relate to the functional role of PP in different tissues at different times, as well as how and when PPs are manufactured and stored by the plant. During the growing season, PPs are manufactured in the leaves, where they contribute to herbivore resistance. In the earliest part of the growing season, much of the carbon acquired by plants is shunted into growth. Later, as growth slows down, more carbon becomes available for secondary compounds, so levels of PP can be expected to increase. If the roots act as overwinter storage organs for PP, then levels in roots should be high early in the season (i.e., at day 3 in experiment 1) and decline as reserves are transferred to growing shoots (i.e., at day 9 in experiment 1 or at the end of experiment 2). High PP levels in the roots over winter and in the spring, and the plastic levels of PP in roots in the earliest part of the growing season may serve to protect roots at a time when there is little photosynthetic activity to replace lost root tissue, and

when belowground herbivores and pathogens may be more active because of higher soil moisture.

Induction of GA in response to JA was less consistent than induction of PP. The only significant effect of JA on GA concentration was in the roots of plants during the short-term experiment. Although average GA concentrations were roughly the same in experiments 1 and 2, there was more variability in experiment 2 (~3–5.5 mg/g in experiment 1 vs. ~2.5–7 mg/g in 2). The greater environmental variability of the factorial experiment may have masked the effects of JA that were detectable in the less complex short-term experiment. The lack of induction in experiment 2 may also have been a result of pot-bound plants. Baldwin (1988) demonstrated that pot-bound tobacco plants were not inducible for alkaloid production. Alternatively, like PP levels, GA levels in roots may respond to JA only early in the growing season. This temporal change in inducibility could arise if belowground herbivore pressure is more variable in the spring than summer, or if the production of GA and PP is more costly in the spring than summer (because, for example, plants need resources for rapid growth during the spring).

GA concentrations in aboveground tissues were low and did not respond significantly to JA treatment in either experiment. Although previous studies in the Solanaceae have demonstrated induction of alkaloids, most have concerned plants such as *Nicotiana* that produce tropane alkaloids (e.g., Baldwin 1988), which differ from the steroidal glycoalkaloids produced by *Solanum* in structure, activity, and the sites of biosynthesis. Furthermore, Cipollini et al. (2001) have shown that *S. carolinense* has relatively low levels of GA compared to congeners. Increasing concentration of GA in response to herbivory may be of little value against the primarily specialist herbivores of *S. carolinense* (Solomon, 1983; Wise and Sacchi, 1996), because studies have shown that specialists are unlikely to be negatively affected by increased alkaloids levels (Mullin et al., 1997; Bolser and Hay, 1998; Marcel et al., 2002). In experiment 2, the total amount of GA in the aboveground tissues of JA-treated plants was lower, especially for the smallest plants. (Table 4, dark vs. light bars in Figure 3C), but this was primarily due to the greatly reduced growth of high fertility plants in to response JA, especially for plants from small root cuttings (Figure 4).

The Cost of Induction. The second goal was to determine if there was a cost of possessing the putatively defensive phenotype (with higher JA levels) in the absence of herbivores. The factorial greenhouse experiment demonstrated a growth cost. Plants treated with JA had lower relative growth, lower root mass, and lower aboveground mass than controls. Stimulation of inducible defenses by JA can lead to reduced growth either through a direct trade-off of the resources allocated to defense or through inhibition of growth, irrespective of the allocated resources (Sembdner and Parthier, 1993; León et al., 2001). In a study of plant growth in response to JA and herbivory, Moore et al. (2003a,b)

found that both treatments caused similar decreases in expansion rates of subsequent leaves, suggesting that growth reduction is a feature characteristic of plant response to herbivory and not simply an artifact of JA. Although JA treatment increased the concentration of PP in aboveground tissues, it had no effect on the total amount of PP per plant (dark bars are higher than light bars in Figure 2A but not different in Figure 2C, Table 3). PP concentration did not covary with mass, but since concentrations are a function of the amount of chemical produced and plant biomass, changes in concentrations may be a result of either changes in production of the secondary compound or changes in biomass (Koricheva, 1999). Because we found an increased concentration of PP under JA treatment, a decrease in the aboveground mass, and no difference in the total amount of PP produced by JA-treated plants, it appears that *S. carolinense* did not necessarily allocate more resources to defense *per plant*, but instead allocated fewer resources to growth and more resources to defense *per gram of plant*. This allocation pattern does not conclusively distinguish between direct inhibition of growth and a trade-off between growth and defense, but much of the cost of induction appears to be associated with a trade-off in the allocation of limited carbon at the whole plant level (see below). Regardless of the mechanisms by which JA treatment reduced growth, turning on the defense response in *S. carolinense* in the absence of herbivores had an associated cost. This is consistent with the theory of the evolution of inducible defenses, and with theories of the evolution of plastic traits in general (Karban and Baldwin, 1997; De Witt et al., 1998).

The Trade-off Between Growth and Secondary Compounds. We found a clear pattern of reduced growth for plants treated with JA, which we interpret as a cost of induction. However, the cost was not independent of the environment. By examining how resource levels influenced the relative allocation to growth or defense, we were able to address our third goal of determining whether or not this cost was associated with carbon or nitrogen limitation. We hypothesized that if nitrogen limitation were largely responsible for the cost of induction, then under low nitrogen conditions there should be a trade-off between growth and defense, while under high nitrogen conditions there should be no (or less of a) trade-off. If carbon limitation were largely responsible, then under low carbon conditions (high fertility) there should be a trade-off between growth and defense, whereas under high carbon conditions (low fertility) there should be less of a trade-off or no trade-off. For this analysis, we focus on PP concentration as our measure of defense response, because PP concentration responded more consistently to JA than did GA concentration.

The pattern we found was consistent with carbon limitation and inconsistent with nitrogen limitation. Induction occurred in both low- and high nutrient environments, as is clearly seen by separately comparing the PP concentration in either roots or aboveground tissues for JA vs. control plants under

high and low fertility (compare dark vs. light solid bars or dark vs. light stippled bars in Figure 2A and B). This is supported by the lack of a significant JA × fertilizer interaction for PP concentration ($P = 0.76$ for aboveground tissues, $P = 0.99$ for roots). When comparing plants treated with JA to controls, high fertility (putatively high N and low C) plants had increased PP concentration but decreased growth (compare dark vs. light stippled bars in Figures 2A and 4D). Low fertility plants (putatively low N and high C) had increased PP concentration and the same growth when treated with JA or control solution (compare dark vs. light solid bars in Figures 2A and 4D). While JA treatment led to a strong reduction in growth for plants in the high nutrient environment, it did not affect growth in the low nutrient environment (Figure 4D). This result is supported by a significant JA × fertilizer interaction for relative growth ($P = 0.02$) and a marginally significant JA × fertilizer interaction for total plant mass ($P = 0.07$), and suggests that there was a trade-off between growth and defense under low C/N conditions and no trade-off under high C/N conditions.

The Effects of Fertilizer on Growth and Secondary Compounds. Independent of induction or cutting size, fertilizer had significant effects on growth and the production of secondary compounds. Fertilized plants were larger aboveground and had higher relative growth, as well as lower PP concentrations in both the roots and the aboveground tissue. Increased growth is a typical and expected reaction to fertilizer application. Lower PP concentration under high fertility is consistent with a number of plant defense models (e.g., Grime, 1979; Bryant et al., 1983; Coley et al., 1985; Herms and Mattson, 1992) proposing that when plants have access to unlimited nutrients, they are able to grow quickly and need not be so well defended against herbivores. Our results appear to contradict a recent study by Cipollini et al. (2002, 2004), who found an increase in PP concentration under high fertility for *S. carolinense*. Cipollini et al. (2002, 2004) analyzed PP concentration in leaf tissue only, whereas we analyzed it in the entire aboveground biomass. If fertilization changes the ratio of support tissue to leaf tissue, and if support tissue has substantially lower levels of extractable PP than leaf tissue, then increasing the proportion of support tissue under high fertility could lower the whole plant concentration of PP while maintaining high levels of PP in the leaves. This allocation pattern could help to offset a C-based trade-off between growth and defense under high N.

In experiment 2, high and low fertility plants had the same concentrations of GA in their aboveground tissues, consistent with the results of Cipollini et al. (2002). High fertility plants had higher total amounts of GA in their aboveground tissues, but this was due to the higher mass of fertilized plants. Similar to PP, fertilization led to *lower* concentrations of GA in the roots. Although other studies with plants in the Solanaceae have demonstrated an increase in alkaloid concentration under high fertility (e.g., Al-Humaid, 2003;

Armer et al., 2004), or an increased trade-off between reproduction and alkaloid production under low fertility (Baldwin et al., 1998), this study indicates that the production of GA in *S. carolinense* is limited more by C than by N. GAs are large molecules compared to most alkaloids, with a high C/N ratio, increasing the likelihood that C availability would limit their production. The much higher concentration of GA in the roots than in the aboveground tissues, and its plasticity in roots early in the short-term experiment (Figures 1 and 3) suggest that GAs play a more important role in defense belowground than in aboveground vegetative tissues. We were not able to measure GA levels or induction in fruits, but GAs are known to protect the fruits of *S. carolinense* from frugivores and fungal pathogens (Cipollini and Levey, 1997), and *S. carolinense* seems to maintain fairly constant GA concentration in its fruits (Cipollini et al., 2004).

The Effects of Root Cutting Size on Growth and Secondary Compounds. Like fertility, the size of the root cutting from which plants were grown had effects on growth and the production of secondary compounds. Although plants grown from smaller cuttings had higher (but more variable) relative growth (Figure 4D), plants from larger cuttings were larger after 4 wk (Figure 4C). In contrast to the fertility treatment, where larger plants had a decrease in the concentration of defense chemicals, plants from larger cuttings had higher concentrations of PP and GA in their roots and the same PP concentrations in the aboveground tissues (Table 4). Because of their larger size, plants from larger cuttings also had higher total amounts of PP in both their roots and their shoots and GA in their roots (Figures 3C–D and 4C–D). The contrasts between the effects of fertilizer and cutting size probably arise from their different effects on growth: high fertility leads to larger plants with higher relative growth, whereas larger cutting size leads to larger plants with lower relative growth. Lower relative growth appears to allow plants to accumulate higher concentrations of secondary compounds. This pattern was less clear for alkaloids in the aboveground tissues. Plants from larger cuttings had lower concentrations of GA in their aboveground tissues than plants from smaller cuttings, but the significance was marginal. Plants from larger cuttings still had greater total amounts of GA because of their greater shoot mass (Table 4).

Based on these results, larger roots in the beginning of the growing season could provide protection from herbivores in two ways: plants from larger cuttings have greater vegetative growth and have higher or equal production of putative defense chemicals. If the effects we observed in the greenhouse hold true for in the field, this advantage will be passed on and possibly magnified in the following season, as plants that started from larger roots one year will begin the following year with even larger roots. This prediction is based on the assumption that root mass in the middle of the growing season, which we measured, is directly related to the mass of the roots that survive the winter.

We analyzed our data to determine if larger root cuttings offset the trade-off between growth and secondary compound production in *S. carolinense*. The only significant interactions between JA and cutting size were for alkaloid concentration in the shoots and relative growth (Table 3). The JA × cutting size interaction for relative growth was uninformative. The interaction showed that plants from small and large cuttings had more of a reduction in growth when sprayed with JA than plants from medium cuttings, which does not lead to any conclusions regarding any allocation trade-off. Plants from smaller cuttings responded more to JA than plants from larger cuttings in aboveground GA concentration. However, as the overall results suggest that shoot alkaloid concentration does not respond to JA treatment, this result has little meaning. Overall, cutting size did not have an affect on the response to JA, so that plants from different size cuttings had the same proportional reduction in growth and the same proportional increase in PP level when treated with JA. Nonetheless, our data support the hypothesis that cutting size will affect the trade-off between growth and defense because of the positive effects of cutting size on both plant mass and levels of secondary compounds (Figures 2 and 4). Although the response was not qualitatively different than that of plants from small cuttings, plants from larger cuttings were better equipped to deal with herbivory, because they were bigger, had higher levels of PP, and had no reduction in GA levels.

Conclusions. In summary, the concentration of PP is an inducible trait in *S. carolinense* that responds not only to simulated herbivory, but also to exogenous and endogenous environmental conditions. However, the total amount of PP a plant produces is less variable. For example, plants have lower PP concentrations in aboveground tissues when fertilized and higher PP concentrations in aboveground tissues when treated with JA, but have the same total amount of PP under either treatment. Rather than change the total amount of resources allocated to PP production, *S. carolinense* plants appear to adjust allocation to growth in response to external environmental changes. This suggests a trade-off between PP production and growth in response to both JA and fertilizer. Larger root reserves, on the other hand, allowed plants to grow larger without reducing PP concentrations or amounts. Total GA production appears to be less plastic in response to JA, but does vary in response to resource supply (fertilizer and cutting size).

The application of JA resulted in reduced growth, demonstrating a cost of carrying the induced phenotype. This cost depended on the edaphic environment. In a low nutrient environment, there was no reduction in growth for treated plants, so induction with JA was not costly. In a high nutrient environment, induction carried a large cost in terms of growth. Based on this analysis, it appears that much of the cost was associated with PP production. However, other unmeasured defense responses, such as enzymes and trichomes, could also represent significant material investments for induced plants. Three

lines of evidence suggest that the cost of induction of a putatively defensive phenotype is due at least in part to carbon limitation and a resource trade-off. First, fertilized plants, which presumably had lower C/N ratios, had lower concentrations of PP and equal or lower concentrations of GA, suggesting that C was more limiting than N to PP and GA production. Second, there was a trade-off between induced defenses and growth, for which fertilizer (excess nitrogen) did not compensate. Although fertilized, induced plants were able to grow more than unfertilized, induced plants, they had lower concentrations of defense chemicals. Finally, large root reserves, which are likely a significant source of carbon, allowed plants to reduce the trade-off between growth and inducible defenses.

Acknowledgments—The authors are grateful to Toni Schaeffer for guidance in the greenhouse and in the lab, and to Eric Paulk for help with the GA analysis. Thanks are also due to Isabel Ashton, Adam Eher, and Elizabeth Leger for comments on an earlier draft of the manuscript. INFLUENCE OF SEASONAL NITROGEN NUTRITION FLUCTUATIONS IN ORANGE AND LEMON TREES ON POPULATION DYNAMICS OF THE GLASSY-WINGED SHARPSHOOTER (*Homalodisca coagulata*)

(Received January 27, 2005; accepted June 15, 2005)

Abstract—The glassy-winged sharpshooter (GWSS) is a xylem feeder that develops conspicuous, year-round populations in many citrus-producing regions of California. Field studies were conducted in a combined lemon and orange orchard to determine the influence of changing amino acid concentrations on relative densities of GWSS. Nineteen protein amino acids were detected in xylem fluid of both lemon and orange trees. Although annual profiles of total and essential amino acids were similar for each citrus species, mean concentrations were consistently higher in lemons than in oranges for most of the year, except for one critical period in late winter–early spring when concentrations were higher in oranges. Principal component analysis followed by factor analysis was performed individually on lemon and orange data sets to identify a reduced number of orthogonal factors composed of amino acids having similar seasonal profiles. Four factors were identified for each citrus species that accounted for 85% and 79% of the total variation in the orange and lemon analyses, respectively. These were then examined with respect to shifts in GWSS numbers that occurred asynchronously in lemons and oranges over the annual population cycle. Three distinctive number shifts were identified that included a peak in adult numbers in lemons during August 2001, significantly higher numbers in lemons relative to oranges during midwinter, and finally an increase in oranges of both adults and nymphs during spring 2002. Various groups of amino acids, i.e., factors, displayed peak annual or elevated levels during the intervals when shifts in GWSS numbers were occurring. Soluble protein levels in oranges and lemons did not correspond to shifting GWSS numbers as certain amino acids. However,

* To whom correspondence should be addressed. E-mail: jianbi@citrus.ucr.edu

soluble protein levels were higher in oranges during late winter/early spring when GWSS adults were sexually active. Potential roles of these amino acids and proteins in GWSS host selection are discussed.

Key Words—*Homalodisca coagulata*, GWSS numbers, *citrus*, free amino acids, soluble proteins, citrus–GWSS interactions.

INTRODUCTION

The glassy-winged sharpshooter (GWSS) *Homalodisca coagulata* (Say) is an exotic insect in California and important vector of *Xylella fastidiosa*, a xylem-limited, plant pathogenic bacterium that causes Pierce's disease (PD) in grapes (Purcell, 1981; Blua et al., 1999). Although it is unknown when and how GWSS first arrived in the state, the earliest recorded specimen was collected in 1989 near Irvine (Sorensen and Gill, 1996). During the 1990s, populations expanded throughout much of southern California and became conspicuous in citrus orchards and vineyards as well as in much of the urban landscape (Blua et al., 1999). In Temecula valley, a major wine grape production area in southern California, wineries have lost 20–30% of their vines to PD since 1997 (Hix, 2001). Although the disease has been in the state since the 1880s and outbreaks have occurred periodically over the last century, PD was apparently limited by the fact that native sharpshooters do not fly far from their preferred native habitats to develop large populations (Varela, 1996). With the introduction of the GWSS, which flies farther and feeds on a greater range of plants than California's native sharpshooters, PD problems in vineyards have been increasing dramatically (Blua et al., 1999). The threat from the GWSS is not limited to the grape industry. Since becoming established in California, the GWSS has also been responsible for vectoring oleander leaf scorch and almond leaf scorch diseases (Blua et al., 1999; Almeida and Purcell, 2003). In addition, citrus growers have been hampered by restrictions upon shipments of citrus fruits across county lines imposed by the State of California in an attempt to prevent spread of GWSS to new areas of the state. Less certain at this time is the potential impact on fruit quality and yield in some citrus orchards that have sustained heavy infestations of GWSS over the past decade.

GWSS is highly polyphagous and may feed on over 100 plant species (Turner and Pollard, 1959; Adlerz, 1980). One of the most important hosts in California is citrus and the proximity of citrus groves to vineyards has influenced the incidence and severity of PD in grapes (Perring et al., 2001). It is imperative that effective control strategies be implemented to curb the spread of the vector—vital to this effort would be establishing the host plant range of the GWSS and determining the physiological and biochemical mechanisms for host selection.

Dietary nitrogen is an important nutritional index impacting survival, growth, and reproduction of phytophagous insects (White, 1984; Bi et al., 1994, 1997, 2001, 2003; Simpson et al., 1995; Joern and Behmer, 1997; Blackmer and Byrne, 1999). Nitrogen nutrients are particularly limited for xylophagous insects, such as GWSS, because xylem fluid consists of over 95% water and is the most dilute food source for herbivores (Anderson et al., 1989, 1992). The primary nitrogen nutrients in xylem fluid are amino acids and soluble proteins (Anderson et al., 1989, 1992; Bi and Toscano, unpublished data). There are 19 amino acids detectable in the xylem fluid of most host plants, and amides (glutamine and asparagine) are predominant in most woody host plant species investigated (e.g., Anderson et al., 1989, 1992; Brodbeck et al., 1993, 1996, 1999). Adult GWSS prefers and performs best on host plants containing high contents of amides in the xylem fluid (Brodbeck et al., 1990; Anderson et al., 1992), whereas immatures require lower levels of amides and higher levels of many other amino acids (Brodbeck et al., 1996, 1999). Most of those results were derived from studies of GWSS interaction with grape, soybean, peach, or some wild host plant species (e.g., Anderson et al., 2003; Brodbeck et al., 2004).

GWSS host selection and utilization among citrus plant species and the related nutritional mechanisms have not been reported. As a year-round host in southern California, citrus plays a critical role in the feeding and reproductive ecology of GWSS. The present research was initiated to determine the influence of seasonal nitrogen nutrition fluctuations in xylem fluid on GWSS population dynamics on lemon and orange trees.

METHODS AND MATERIALS

Experimental Plots. A lemon and orange mix-planted orchard at the Agricultural Experimental Station, University of California, Riverside was used for the experiment. Three blocks of 30 orange (*Citrus orange* L. var. Frost Valencia grafted on Troyer Citrange) and 30 lemon (*C. lemon* L. var. Lupe grafted on Cook) trees adjacent to one another were used. Both orange and lemon trees were 30 yr old. Five trees of lemon or orange were randomly selected from each block to monitor the GWSS population dynamics and to extract xylem fluid.

Collection of Xylem Fluid. Xylem fluid was used for determination of nutritional quality because GWSS exclusively feeds on xylem fluid (Anderson et al., 1989). Collections of xylem fluid were done between 6:00 A.M. and 10:00 A.M. on biweekly sampling dates using a pressure bomb apparatus (Anderson et al., 1989, 1992). One to three terminal shoots from each tree were used for xylem fluid extraction because these shoots are the preferred feeding sites for GWSS on citrus plants (Mizell and French, 1987). Upon collection, the xylem fluid was immediately placed on dry ice before final storage in a −80°C freezer.

The samples were used for chemical analyses of free amino acids and soluble proteins. Sampling was initiated on June 8, 2001 and terminated on May 30, 2002.

Determination of Free Amino Acids and Soluble Proteins. Free amino acids were quantified with a Perkin Elmer Applied Biosystem Model 420A PTC derivatizer with an on-line Perkin Elmer Applied Biosystem Model 130A PTC Amino Acid Analyzer. After filtration with a 0.45-μm syringe filter, 20 μl of xylem fluid were reacted with phenylisothiocynate (PITC) to produce phenylthiocarbamyl amino acid derivatives. Following derivatization, a methanol solution containing the PTC amino acids was transferred to an HPLC system for separation. PTC amino acids were separated on a Spheri-5 PTC column (220 × 2.1 mm), and the PTC chromophore was detected at 263 nm. The buffer system used for separation was 50 mM sodium acetate pH 5.45 as buffer A and 70% acetonitrile/32 mM sodium phosphate pH 6.1 as buffer B. The program was run using a gradient of buffer A and buffer B with an initial 7% buffer B concentration and ending with a 60% buffer B concentration at the end of the gradient. A standard mixture of known quantities of individual amino acids (Sigma) was derivatized as described above and used for quantification and identification of individual amino acids.

Protein content was determined by the Bradford method (Bradford, 1976). Three 20-μl aliquots of each sample were mixed with 180 μl of Bio-Rad (Bio-Rad, Richmond, CA, USA) protein assay reagent. Absorbance of the reaction mixture was read at 595 nm with a spectrophotometer, and protein content was determined from a standard curve established using known quantities of bovine serum albumin (from Sigma) and the above reagent.

Sampling of GWSS. A bucket-sampling device (5-gal plastic bucket, with a funneling collector in the bottom, attached to an extendable pole), as described by Castle et al. (2005), was used to sample both immature and adult GWSS in orange and lemon trees. Seven beats were processed with the bucket in each of the five directions (360°/5) around the trees. Numbers of adults and nymphs in the collector from each tree were then counted. Population dynamics of both adult and immature GWSS were monitored on a weekly basis. The same 15 trees used for xylem fluid extraction from each citrus species were used for monitoring GWSS population dynamics.

Statistical Analyses. Multivariate statistical methods were used to identify groups of amino acids that exhibited similar dynamical behavior. Principal component analysis followed by factor analysis (SAS Institute Inc., 1989) was run separately for lemon and orange data sets. Outlier analysis using Mahalanobis distances was applied prior to factor analysis to eliminate outlying points from the analysis. Individual amino acids with loading values $> |0.6|$ within each factor were grouped and related to shifts in GWSS adult populations as characterized by increasing numbers in one citrus species while remaining static or decreasing in the other. Analysis of variance (ANOVA) and the least significant

difference (LSD) test in one-way randomized complete block general linear models (GLM) (SAS Institute Inc., 1989) were used to analyze the data and separate the means of protein data in each sampling date. A repeated-measures analysis of variance (SAS Institute Inc., 1989) was applied to time segments in which visible shifts in GWSS numbers were apparent by graphical analysis. Numbers of GWSS adults and nymphs from bucket-collected samples were $\log(y + 1)$-transformed before ANOVA to normalize the data (Little and Hill, 1978).

RESULTS

Free Amino Acids and Soluble Proteins. Annual amino acid profiles were similar for each citrus species, but levels were consistently higher in lemons than oranges for much of the year, save for one critical period in late winter–early spring when concentrations were higher in oranges (Figure 1). Levels of total amino acids fluctuated by >3-fold for lemons and >4-fold for

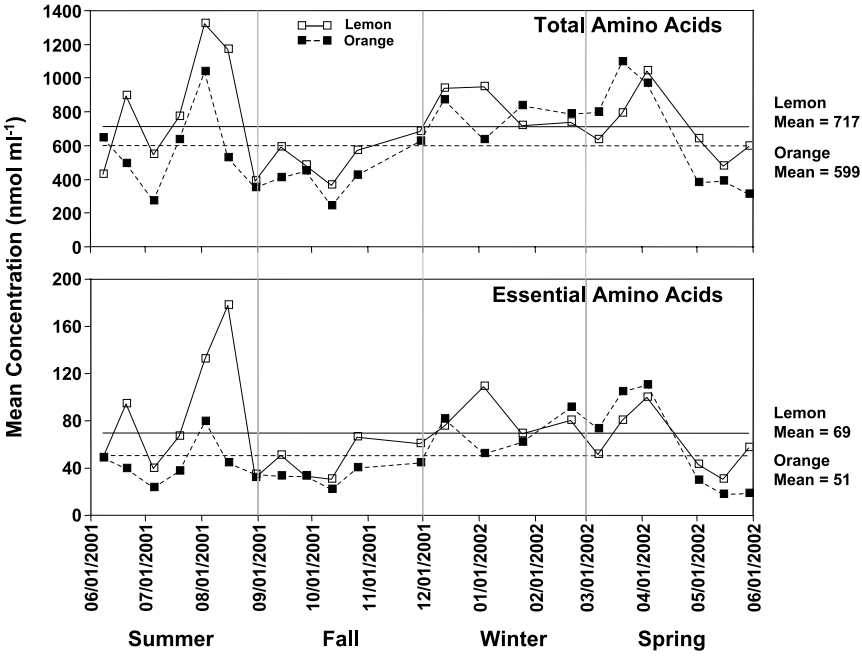

FIG. 1. Mean concentrations of total amino acids (top) and essential amino acids (bottom) from June 2001 through May 2002 in lemons and oranges. The solid horizontal line in each figure represents the annual mean for lemons, the dashed horizontal line is the annual mean for oranges.

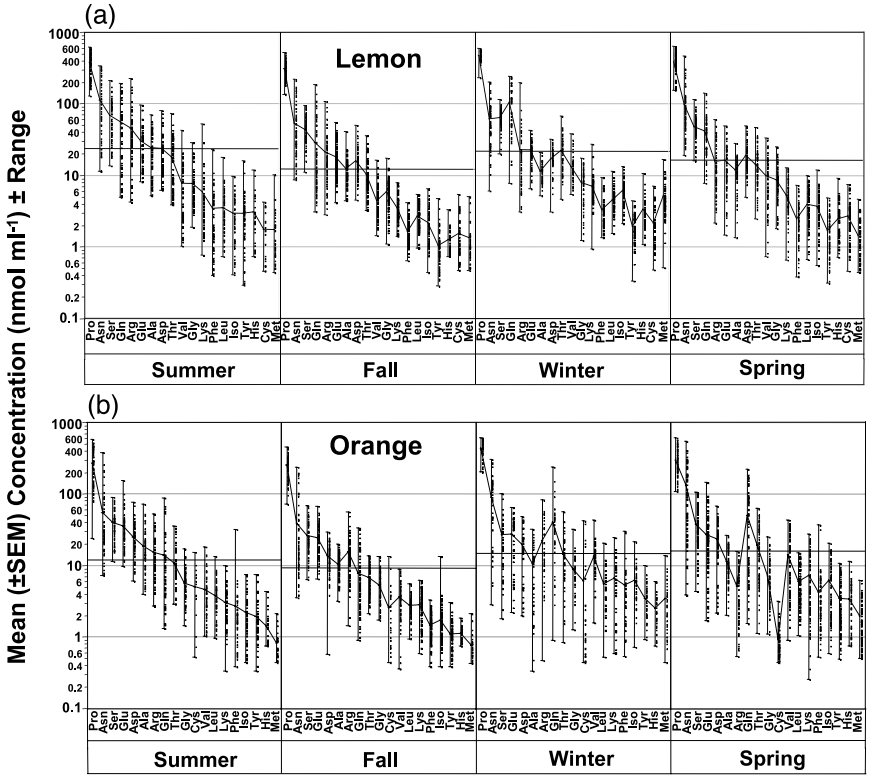

FIG. 2. Mean concentrations of 19 amino acids in xylem fluid of (a) lemons and (b) oranges collected over a 1-yr period and represented for each season. The amino acids for each citrus species were arranged in descending order for the June–August period and maintained in the same order for each subsequent season despite changes in rank. Each point represents the mean of all samples collected for a tree during the respective seasons. Vertical lines represent the range of mean concentrations for each amino acid, whereas the intersection with the traversing lines indicates the mean concentration. Seasonal means for 18 amino acids (excluding proline) are represented by the horizontal line in each panel.

oranges between the lowest and highest mean concentrations during the year-long evaluation with particularly large changes observed within summer and spring intervals. The annual mean levels of total amino acids in lemons and oranges were 717 and 599 nmol/ml, respectively (Figure 1). The subset of essential amino acids (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, valine, arginine, and histidine) for insect growth and development (Taylor and Medici, 1966; Brodbeck and Strong, 1987) showed a similar annual

profile for each species with higher levels in oranges occurring notably during the late winter–early spring period (Figure 1). Overall, however, the annual mean level of essential amino acids in lemons (69 nmol/ml) was higher than in oranges (51 nmol/ml).

Nineteen protein amino acids were detected in both lemon and orange xylem fluid samples. The proportion of total amino acids made up by individual amino acids varied more than 3 orders of magnitude in lemons and oranges. By far, the highest level of any amino acids was proline, varying between 52% and 62% of the total depending on species and time of year (Figure 2a, b). The mean level of asparagine was the next highest in both species during three out of four seasons, accounting for 7–17% of the total. Other amino acids in relative high levels were glutamine (1–12% of the total), serine (2–9%), and aspartate (1–6%). The rest of amino acids were less than 5% of the total. Mean levels for

individual amino acids ranged 10-fold or greater both within and among trees over each season (Figure 2a, b). Seasonal mean levels for all amino acids (exclusive of proline) varied by 1.8- and 2.2-fold for lemons and oranges, respectively, with fall representing the lowest mean concentrations for both species. Thus, less variation in mean levels of all amino acids was observed among seasons compared to the 3- to 4-fold shifts that occurred within particular seasons.

Distinctive groups of amino acids between lemons and oranges were apparent following factor analysis. Separate analysis on each species produced a rotated loading matrix that had four factors (eigenvalues >1) for lemons and three factors for oranges, but a fourth factor was subsequently included for orange based on an eigenvalue close to 1 (0.91) (Table 1). Over 63% of the variance in the solution for oranges was accounted for by factor 1 that contained 12 variables (asparagine, glutamine, glycine, histidine, threonine, tyrosine, valine, methionine, isoleucine, leucine, phenylalanine, and lysine) with loading values $>|0.6|$, but all the amino acids with the exception of glycine having values $>|0.8|$. Factor 2 accounted for 10.4% of the solution for orange and contained four variables (aspartic acid, glutamic acid, serine, and alanine) with loading values $>|0.6|$ (Table 1). A single variable (cysteine or arginine) was accounted for in factors 3 and 4 for oranges, bringing the total number of amino acids grouped by factor analysis to 18, the lone exception being proline. The cumulative variance explained by the solution for orange was 85.1% compared to 79% explained by the four factors in the lemon solution. Only seven amino acids (glutamine, histidine, threonine, proline, valine, methionine, and isoleucine) met the criterion for factor 1 in the lemon solution, but at a lower level of

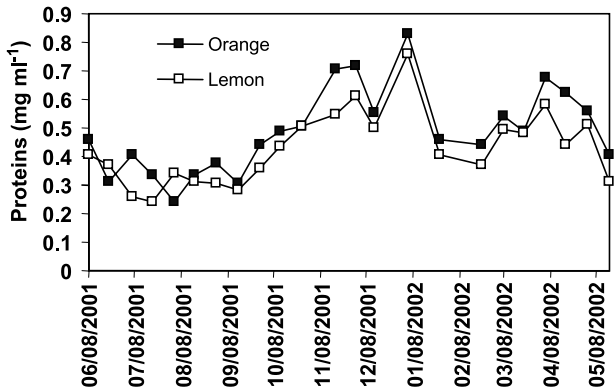

FIG. 3. Mean concentrations of soluble proteins from June 2001 through May 2002 in lemons and oranges.

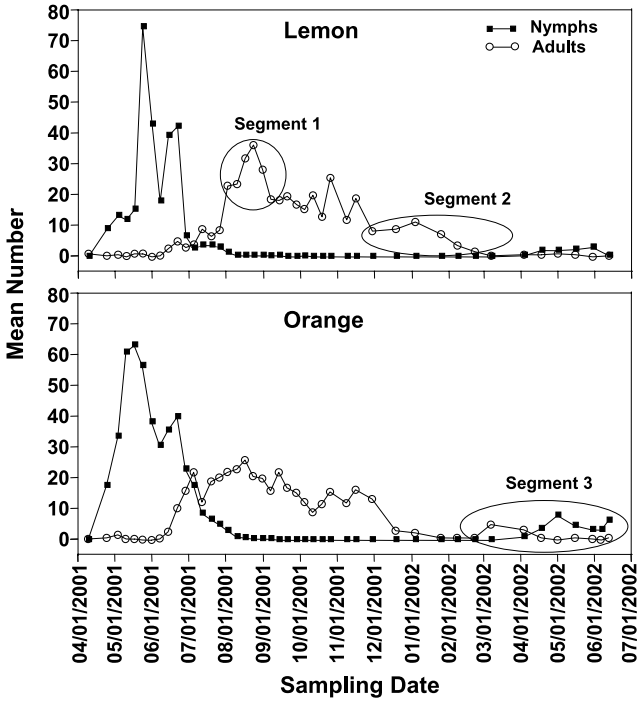

FIG. 4. Mean numbers of GWSS nymphs and adults in lemons (top) and oranges (bottom) between April 2001 and June 2002. Encircled areas in each chart are examined in greater detail in subsequent figures.

correlation than observed for factor 1 in the orange solution. Factor 2 for lemons contained all four amino acids that grouped in factor 2 for oranges, but also included alanine (Table 1). Factor 3 contained two amino acids (glycine and cysteine), but factor 4 for lemons contained six amino acids (asparagine, tyrosine, valine, leucine, phenylalanine, and lysine) compared to one for oranges. Only one amino acid (valine) in both analyses correlated with more than one factor (factors 1 and 4) in the lemon analysis.

Soluble protein contents in orange and lemon xylem fluid samples ($P > 0.05$) were similar throughout much of the experimental period with the exception of five sampling dates (September 28, 2001; November 17 and 30, 2001; April 18, 2002; and May 30, 2002, respectively) when the content was 18–40% higher ($P < 0.05$) in orange xylem fluid than in lemon xylem samples (Figure 3).

GWSS Numbers and Their Responses to the Nitrogen Nutrients. The annual profiles of GWSS nymphs and adults are quite similar for lemons and oranges

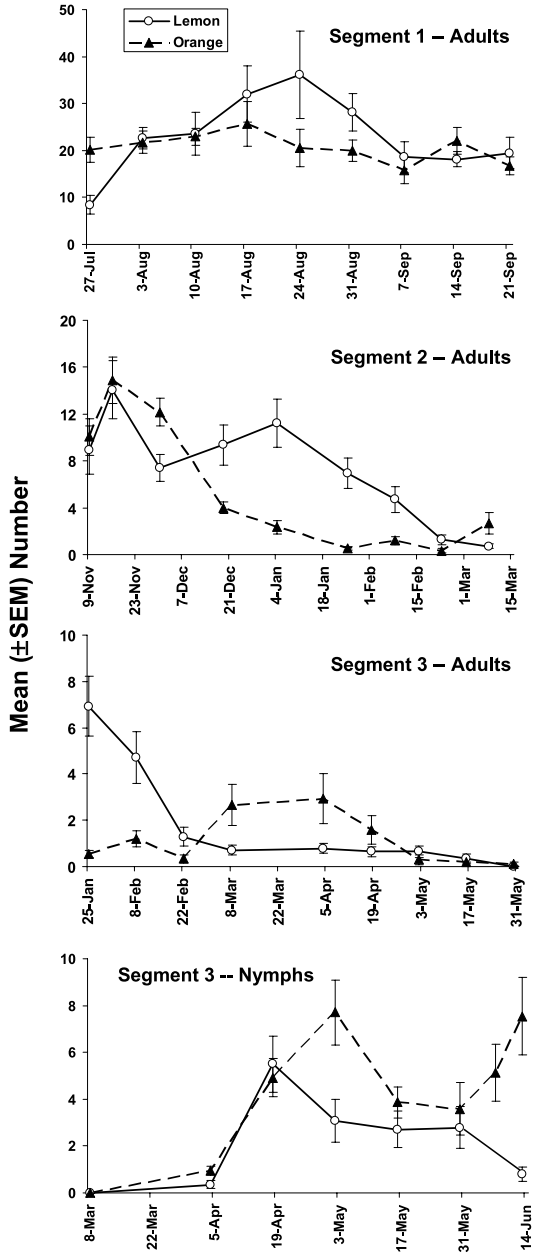

FIG. 5. Comparative numbers of GWSS adults and nymphs in lemons and oranges at three different periods during the annual cycle (see Fig. 4).

(Figure 4), but with notable fluctuations in GWSS numbers occurring at specific times on either lemons or oranges. We identified three intervals during the annual cycle that GWSS numbers increased on one species while remaining static or declining in the other. Two of these intervals occurred as increases in GWSS adults in lemons (Figure 4) while the third interval occurred with both adults and nymphs increasing in oranges (Figure 4).

To examine the changes in numbers on lemons or oranges more closely, the circled and numbered areas in Figure 4 were expanded to provide greater detail on GWSS numerical differences between lemons and oranges and to focus attention on near-synchronous changes that occurred in certain amino acids. The first departure of relative numbers of adult GWSS occurred on July 27–September 7, 2001 (Figure 5, Segment 1). Mean adult numbers on lemon trees had been depressed over three consecutive sampling dates from July 13 through July 27, but by August 3 had more than doubled to a level equivalent to the numbers on oranges (Figure 5, Segment 1). One wk later (August 10), adult numbers were again equal on lemons and oranges, but then increased over the next 2 wk on lemons while remaining fairly constant on oranges. After peaking on August 24, adult numbers on lemons and oranges declined over the next 2 wk with near parity between the two citrus species on September 7. A repeated-measures ANOVA conducted on the data from the seven sampling dates between July 27 and September 7 yielded a nearly significant result ($F_{6,12} = 2.86$, $P = 0.057$) of higher adult GWSS numbers in lemons than oranges. In the second example, adult numbers in lemons were significantly greater ($F_{5,13} = 6.03$, $P = 0.004$) than in oranges during the period November 30, 2001–February 22, 2002 (Figure 5, Segment 2). Adult numbers in oranges dropped quite drastically after November 30, 2001, while remaining stable in lemons and even gaining slightly (Figure 5, Segment 2). By early spring 2002, few GWSS adults were present on lemons or oranges, their numbers apparently having declined due to winter mortality. However, this is a critical time of the year as adults become sexually active and soon begin laying egg clutches that eventually emerge as adults beginning in June each year. A significant shift ($F_{4,33} = 3.03$, $P = 0.031$) in GWSS adult numbers to oranges from lemons occurred between February 22 and May 2, 2002 (Figure 5, Segment 3—Adults). Higher adult numbers in oranges during early spring translated into significantly higher nymphal numbers ($F_{4,33} = 2.98$, $P = 0.033$) in oranges between April 18 and June 13 (Figure 5, Segment 3—Nymphs).

The peak in GWSS adults reached on August 24 (Figure 5, Segment 1) corresponds closely to the rise and fall in levels of 10 amino acids that were grouped into two different factors in the lemon factor analysis (Table 1). The five amino acids that grouped into factor 2, including aspartic acid, glutamic acid, serine, alanine, and arginine (Figure 6a), had only one significant peak over the entire year that occurred in August. In contrast, the five amino acids grouped into factor 4, including tyrosine, lysine, asparagine, phenylalanine, and

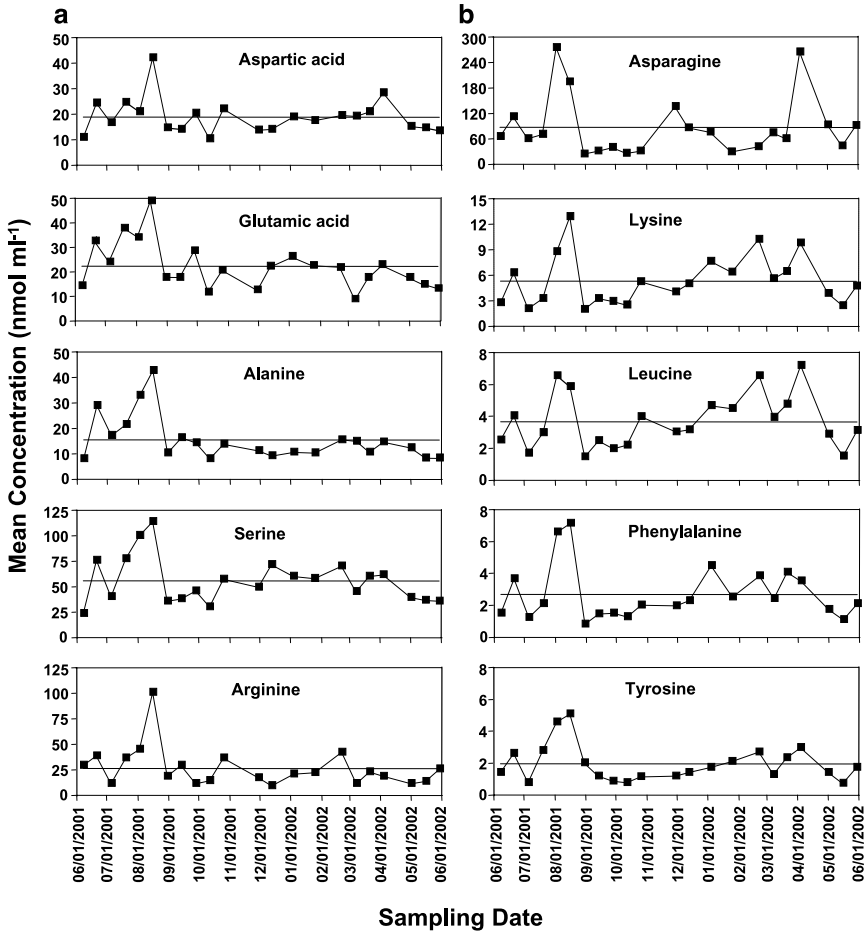

FIG. 6. Annual profiles of five amino acids that loaded onto (a) factor 2 in the lemon analysis, and another five amino acids that loaded onto (b) factor 4. The horizontal line in each chart is the annual mean concentration.

leucine (Figure 6b), had their highest peaks in August, but also showed secondary peaks in levels during the following spring. In addition to these 10 amino acids, six out of the seven amino acids that grouped into factor 1, including threonine, valine, isoleucine, glutamine, proline, and histidine (Figure 7), also displayed an early August peak in their levels that likely contributed to the increase in numbers of GWSS adults recorded on lemons relative to oranges.

A more critical role for the seven amino acids grouped in factor 1 of the lemon analysis (Figure 7) may have occurred in midwinter at a time that GWSS

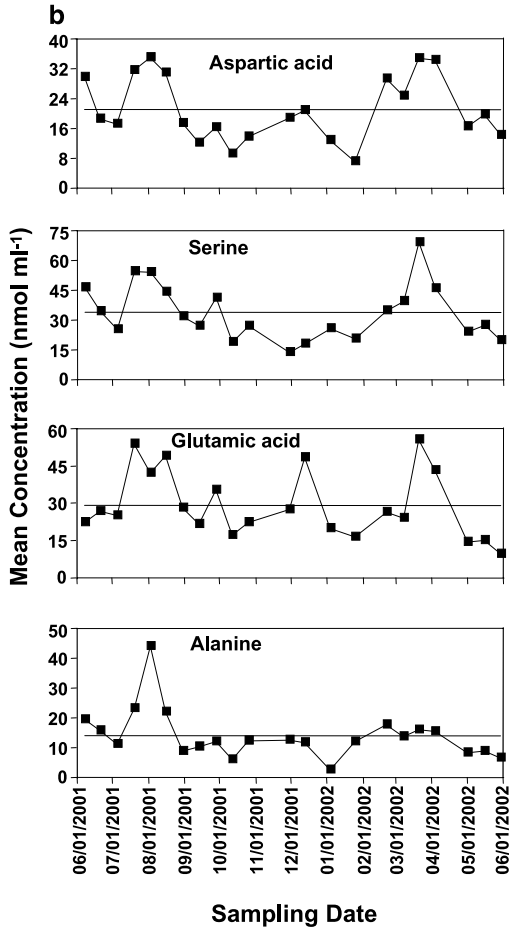

FIG. 8. Continued.

numbers in lemons consistently exceeded those in oranges (Figure 5, Segment 2). The levels of threonine, valine, histidine, and isoleucine all reached peaks on January 4, 2002 during this interval. Methionine and glutamine were also at near peak levels during this interval, reaching their peak levels one date earlier on December 19, 2001. In fact, annual peaks were attained for each of these amino acids with the exception of valine and threonine, whose concentrations during this period were just slightly below annual peak levels.

Amino acid concentrations in oranges also showed fluctuations from season to season, but on a different time frame than lemons. The most coherent group of amino acids in either the lemon or orange factor analyses occurred in

the orange analysis with 12 amino acids grouped into factor 1. These include valine, leucine, isoleucine, histidine, threonine, lysine, tyrosine, asparagine, glutamine, methionine, phenylalanine, and glycine (Figure 8a). Concurrent with the early spring peak in these 12 amino acids was a shift in GWSS adults (Figure 5, Segment 3—Adults) from lemons to oranges that subsequently resulted in a greater number of nymphs on orange (Figure 5, Segment 3—Nymphs). The levels of all 12 amino acids in factor 1 of the orange analysis had significantly increased by February 22, 2002, with most reaching their annual peak levels in late March or early April. This closely corresponds to the time in late winter and early spring when GWSS adults are reproductively active as evidenced by pairs in copula and the presence of brochosomes on adult females. In addition to the 12 amino acids in factor 1, three out of the four amino acids that grouped into factor 2 of the orange analysis also displayed peak levels during spring (Figure 8b). However, these three amino acids, aspartic acid, glutamic acid, and serine, also had other periods of peak levels during the year in contrast to the 12 amino acids in factor 1 that displayed a prolonged rise in levels peaking in early spring.

DISCUSSION

Throughout the experimental season, 19 protein amino acids were detected in both lemon and orange xylem fluid in this study. These results are consistent with previous reports on amino acids in xylem fluid of GWSS hosts such as *Baccharis halimifolia* (L.), *Lagerstroemia indica* (L.), *Prunus salicina* (Lindl.), *Prunus persica* (L.), *Pyrus communis* (L.), *Vitis hybrid*, *Catharanthus roseus* (L.), and *Glycine max* (L.) (Brodbeck et al., 1990, 1993, 1999, 2004; Anderson et al., 1992). The predominant amino acids detected in this study were proline and asparagine. Our results agree with a previous report in which proline was the most abundant amino acid in *C. sinensis* (L.) (Moreno and Garcia-Martinez, 1983). In contrast, asparagine and glutamine were predominant (over 50% of the total) in other GWSS hosts (Brodbeck et al., 1990, 1993, 1999, 2004; Anderson et al., 1992). Apparently, those differences may be due to the differences in host plant families and/or species.

Although GWSS is capable of feeding on over 100 plant species, well-defined host preferences vary seasonally and successful development often requires host switching (Mizell and French, 1987; Brodbeck et al., 1999; Redak et al., 2004). In many instances, host switching may represent multiway traffic as GWSS adults are highly mobile and often conspicuous in their movements to and from among various hosts. At times, however, population levels on particular host species are apparently higher over the others, presumably due to nutritional requirements being better satisfied by these host species. In the present study, only the two citrus species were available as hosts to the GWSS

population as the study area was centrally located within a 12-ha orchard split evenly between lemons and oranges. Despite the close relationship between lemon and orange and the apparent similarity in annual amino acid profiles (Figure 1), there were clear instances when the GWSS population was more concentrated in one species than the other (Figure 5). Factor analysis of each data set, lemon and orange, revealed different groups of amino acids that varied from one another in terms of their seasonal peak concentrations as well as the number of peaks they exhibited over the annual cycle. By aligning the three distinctive intervals of host switching by GWSS between lemons and oranges with amino acid groups from the lemon and orange factor analyses, it was possible to infer nutritional shifts that were occurring concomitantly to the GWSS population shifts.

This study revealed that adult GWSS numbers responded positively to higher levels of aspartic acid, glutamic acid, serine, alanine, aspargine, tyrosine, lysine, asparagine, phenylalanine, leucine, methionine, threonine, valine, histidine, isoleucine, glutamine, and proline in xylem fluid of lemons, and valine, isoleucine, threonine, tyrosine, glutamine, phenylalanine, leucine, histidine, lysine, asparagine, methionine, glycine, aspartic acid, glutamic acid, and serine in xylem fluid of oranges. These amino acids may serve as important nutrients to determine host preference for GWSS. Indeed, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, valine, arginine, and histidine are considered as essential amino acids for insect growth and development (Taylor and Medici, 1966; Brodbeck and Strong, 1987). In previous studies, the levels of asparagine and glutamine in xylem fluid of four host species (*L. indica*, *B. halimifolia*, *P. persica*, *and P. salinicia*) have been positively correlated with GWSS host selection (Brodbeck et al., 1990). The fact that glutamine and asparagine have high nitrogen/carbon ratios and account for high caloric value may make them an ideal host selection cue for generalist feeder GWSS (Brodbeck et al., 1990), especially adult GWSS in their sexually active status. Both of these amides are also considered phagostimulants for GWSS (Anderson et al., 1992). It is noted that adult GWSS females produce protein-containing brochosomes just prior to egg laying (Hix, 2001). Higher levels of these amino acids may be critical for the brochosome production.

Previous research indicated that adult GWSS prefers and performs best on host plants containing high contents of amides in the xylem fluid (Brodbeck et al., 1990; Anderson et al., 1992), while immatures require lower levels of amides and higher levels of many other amino acids, thus the more balanced amino acid profiles (Brodbeck et al., 1995, 1996, 1999). Our results showed that a majority of GWSS eggs are laid on oranges, and the immatures then grow and fully develop from April to July on oranges when amino acid (especially glutamine and asparagine, the second and third most predominant amino acids in the xylem fluid) fluctuations drop to minimal level to make the profiles more

balanced. During this period, levels of isoleucine, tyrosine, phenylalanine, and lysine are particularly higher in oranges than in lemons. It is known that tyrosine and phenylalanine are essential for insect cuticle formation (Bernays and Woodhead, 1984). Thus, immature GWSS may need higher levels of these two amino acids for their successful development of cuticle.

Increased protein quantity is frequently associated with enhanced insect survival, growth, and fecundity (McNeill and Southwood, 1978; Mattson, 1980; Ohgushi, 1992; Slansky, 1993). Protein quality also affects insect performance (Bi et al., 1994; Bi and Felton, 1995; Felton, 1996; Bi et al., 1997). Our results indicated that substantial amounts of soluble proteins exists in xylem fluid of GWSS host plants. Soluble protein levels in xylem fluid of oranges and lemons were similar except on a few of the sampling dates (e.g., mid-April) when levels were significantly higher in xylem fluid of oranges than in lemons. Although it is unknown how GWSS utilizes host proteins, soluble proteins may help GWSS female to produce brochosomes for the egg laying (Hix, 2001). Our results clearly indicated that the soluble protein levels in April and May were higher in oranges. The effect of protein quality in host xylem fluid on GWSS performance and host selection warrants further investigation.

(Received February 11, 2005; accepted June 15, 2005)

Abstract—An analytical method has been applied to determine volatile organic compounds in zucchini flowers. In a first step, the analytical method was applied to characterize the main scents emitted by whole male and female living flowers of three main commercial cultivars of zucchini (Tosca, Chapin, and Consul). In a second step, the compounds were quantified in different parts of the living flowers to identify the contribution of nectar, petals, anther, and stigma to the aroma profile of the flower. The analytical method is based on headspace solid-phase microextraction coupled on-line with GC and tandem MS detection (HS-SPME-GC-MS/MS). A reference compound is added to samples as part of the field quality control procedure to check for likely analyte losses or sample decomposition. The reference compound also acts as an internal standard for quantification purposes. Results have been statistically studied applying principal component analysis (PCA), which shows that three components explain more than 91% of the variance. PCA emphasizes the great importance of nectar as being the main source of 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene, which influence the aroma profile of flowers. The remaining components can be accounted for by emissions from petals and sexual organs (adroecium and gynoecium anthers or stigmas).

Key Words—zucchini, nectar, headspace solid-phase microextraction, tandem mass spectrometry, biogenic volatile organic compounds, flower aroma, PCA.

INTRODUCTION

Regulations and consumer attitudes lead agricultural practices toward an ever more environmentally friendly production with an optimization of agrochemical use. There is an increasing interest of growers in using beneficial insects in integrated crop management (ICM), with reduced chemical input, for example, the use of pollinators as an alternative to parthenocarpy in zucchini crops (Roldán Serrano et al., 2002; Roldán Serrano and Guerra Sanz, 2005), or the use of pheromones in traps, which act as attractants or repellents. From an ecological point of view, this requires a knowledge of the environment in which crops are grown and their interactions with the rest of the ecosystem. In this aspect, color and aromas play an essential role. For example, visual cues and floral scents are important in attracting pollinators; they can act over long distances as attraction cues and over short distances as orientation cues between different parts of the flower or between different flowers (Williams, 1983; Dobson et al., 1990). Scents are more complex, as floral fragrances vary widely among species in terms of the number, identity, and relative amounts of constituent volatile compounds. Insects are able to distinguish between complex floral scent mixtures and discriminate flower visits depending on floral scent content. In addition, different parts of the flower (e.g., pollen and petals) contribute to volatile production (Dobson, 1991; Flamini et al., 2002). The apparently ubiquitous occurrence of odor in pollen, its varying chemical composition, including insect repellents and antimicrobial compounds, suggests that pollen odor chemicals may have a range of purposes that include pollinator attraction, defense against destructive pollen-feeding animals and pathogens, as well as defense of the plant against competition from other species through the phenomenon of pollen allelopathy (Dobson, 1991; Dobson and Bergström, 2000; Stephen, 2000).

A knowledge of the composition and dynamic emission of aromas and, in general, of biogenic volatile organic compounds (BVOC) is fundamental because these play a role in processes of reproduction, defense, and communication between species (Ware and Compton, 1994; Dudareva and Pichersky, 2000; Augusto et al., 2003). Studies need to be based on data obtained using validated analytical methods, with special emphasis on sampling and identification steps (Egea et al., 2004), and on statistical interpretation of results (Martínez Vidal et al., 1998; Díaz-Maroto et al., 2002; Hernández Torres et al., 2002).

Choice of methods for sampling of volatile compounds depends partly on the availability of equipment, type of flower material (e.g., whole flowers vs. flower parts or pollen, laboratory vs. field plants), and the amount and general chemical composition of emitted volatiles. Methods involving separation steps to isolate volatile compounds for analysis run a greater risk of the loss of volatiles, and, although no method gives a complete picture of the actual

mixture emitted by a flower, headspace sorption appears to be an appropriate technique (Dobson, 1991).

Solid-phase microextraction (SPME) has demonstrated the utility of this technique for analysis of volatile compounds in several matrices, for example, environmental samples, food and beverages, etc. (Pawliszyn 1995, 1999; Stefen and Pawliszyn, 1996; Scheppers, 1999). For volatiles determination, the SPME fiber can be used as a passive sampler by exposing it to air containing compounds or to the headspace (HS) of vials containing the sample. SPME presents many advantages over other methods allowing sampling and preconcentration in a single step (Pawliszyn, 1997; Prosen and Zupancic-Kral, 1999; Sides et al., 2000; Kim and Lee, 2002; Augusto et al., 2003). Considering an optimum sampling time, compounds are concentrated in the fiber to amounts greater than detection limits; after that, the fiber is desorbed directly into the injection port of the GC, transferring all compounds to the column and detection system. The above steps can be performed with an automatic SPME injector, avoiding handling the sample, which is important to reduce analyte losses. In addition, this technique does not require the use of solvents, which minimizes coelution with volatile compounds of interest and has environmental and economic advantages. Finally, the use of MS/MS detection allows the mass spectral identification of compounds from two fragmentations, resulting in an analytical method with high selectivity and sensitivity.

In this work, we characterize the BVOC of three *Cucurbita* cultivars, with the aim of identifying differences in the volatile compounds emitted from the whole living male and female flowers and from different parts. The studies were conducted applying a previously validated analytical method (Mena et al., 2004). Initially, the fragrances emitted by whole living flowers were identified without disrupting the aroma profiles. Once the compounds had been identified, they were quantified in each of the individual parts of excised flowers. The objectives were to identify the likely influence of cultivar and flower gender on the aromas emitted by flowers, and, to identify the sources of each compound contributing to the whole aroma profile of flowers.

METHODS AND MATERIALS

Plant Material and Growing Conditions. Three cultivars of *Cucurbita pepo* (L.), Tosca (Clause Iberica, Vicar, Spain), Consul (Seminis Seeds, Aguadulce, Spain), and Chapin (Fitó, S.L., El Ejido, Spain) were cultured under plastic greenhouse conditions in the experimental station of CIFA La Mojonera (Almería, Spain). The crop was grown in Perlite sacks irrigated and nourished by drip irrigation. Sampling of nectar flowers was made in October 2003, when the blooming and crop were at their maximum level.

Flower Sampling. Ten whole living flower samples (five of each gender) of each cultivar were selected at random in the greenhouse and enclosed on the plant in a glass receptacle. The enclosed atmosphere was sampled with SPME fibers for 1 hr for qualitative analysis.

Target volatile compounds were identified and quantified in nectar, petals, anthers, and stigmas, which were sampled at the same time, from male and female flowers of each cultivar during flower anthesis hours (from 6:00 A.M. to noon time). Nectar samples consisted of 80 μl of nectar that were collected from nectaries using a micropipette. They were placed directly in 10-ml headspace (HS) vials, spiked with 5 μl of the internal standard (IS, *p*-xylene-d10) at 10-μg/ml concentration, and fitted with Teflon-lined septa.

Petal, stigma, and anther samples were taken in preweighed 10-ml HS vials and treated the same as nectar. Samples were transported to the laboratory within a period not greater than 2 hr in a portable refrigerator. Each vial was reweighed to determine the amount of floral tissue in each sample (results are referred to as amount of compound per gram of fresh mass of anthers, styles, and petals and per milliliter of nectar).

A field quality control was planned for ensuring that results were under statistical control. Three, 10-ml HS vials containing filter paper were spiked in the field with a standard mixture of all the target compounds, in the field and treated in the same way as flower samples. The control vials were transported, stored, and analyzed in the same batch as the rest of samples.

Aroma Analysis. Reference standards of volatiles known to be present in the flowers of cucurbits (Metcalf and Lampman, 1991; Metcalf et al., 1998), benzene, toluene, *o*-xylene, *m*-xylene, *p*-xylene, ethylbenzene, α-(+)-pinene, myrcene, (*R*)-(+)-limonene, eucalyptol, ocimene, linalool, 1,4-dimethoxybenzene, *p*-anisaldehyde, cinnamaldehyde, indole, cinnamyl alcohol, dibuthyl phthalate, eugenol, 1,2,4-trimethoxybenzene, and *p*-xylene-d10, were purchased from Sigma-Aldrich (St. Louis, MO, USA) or Tokyo Kasei (Nihonbashi, Tokyo, Japan). A reference standard solution was prepared for each compound using acetone as the solvent at 200-μg/ml concentration, and a multicompound working standard solution (2-μg/ml concentration) was prepared from the above by appropriate dilution with acetone and stored under refrigeration (4°C).

For SPME analysis, fibers of 65 μm polydimethylsiloxane–divinylbenzene (PDMS-DVB; Supelco, Bellefonte, PA, USA) were used to sample the headspace of nectar, petal, stigma, and anther samples. Samples were equilibrated in a thermostatic carrousel for 10 min at 60°C, known to be enough time to achieve transfer of the analytes to the fiber. After adsorption, the fiber was injected into the GC SPI/1079 split/splitless programmed-temperature injector operating at 250°C in splitless mode. The desorption time of analytes from the fiber was set at 9 min, which is enough to desorb and transfer the analytes to the analytical column (Mena et al., 2004). In fact, the desorption of

most analytes took place during the first minute, but a longer period avoided carryover between samples.

GC analysis was accomplished with a Varian 3800 gas chromatograph with electronic flow control (EFC) and fitted with a Saturn 2000 ion-trap mass spectrometer (Varian Instruments, Sunnyvale, CA, USA). High-speed analysis was carried out by connecting a fused silica untreated capillary column (2 m × 0.25 mm i.d. from Supelco) used as guard column, to a Rapid-MS (WCOT fused silica CP-Sil 8 CB low bleed of 10 m × 0.53 mm i.d. × 0.25 μm film thickness) analytical column, both obtained from Varian Instruments. The controlling computer system had an EI-MS/MS library that was specially created for the target analytes under our experimental conditions. Analytical conditions were as follows: oven temperature set to 35°C during injection, 9 min hold, increased at 1.5°C/min to 55°C, at 5°C/min to 65°C, and finally raised to 300°C at 100°C/min that was held for 5 min. Helium (99.999%) at a flow rate of 1 ml/min was used as carrier and collision gas.

The mass spectrometer was operated in the electron impact mode (EI) with electron energy of 70 eV. The transfer line, manifold, and trap temperatures were 280, 50, and 200°C, respectively.

Analyses were performed in MS/MS detection mode. The main parameters to be optimized were excitation storage level (González Rodríguez et al., 2002) and excitation amplitude (or resonance excitation voltage). To assure an appropriate definition of the chromatographic peaks, we selected two microscans, adjusting the m/z range to each compound (González Rodríguez et al., 2002).

Identification of the target compounds was based on the retention time windows (RTW) and on MS/MS spectra. Each MS/MS spectrum was compared with spectra stored in an in-house MS/MS spectral library prepared from standards under our working conditions. The results of the comparison (FIT parameter), obtained using the match algorithm of the Saturn software, are scaled, setting 1000 for the best match (identical spectra).

The procedure was validated (Mena et al., 2004), establishing the performance parameters that show the fitness for purpose of the method. For quantification, a reference compound (*p*-xylene-d10), acting as a surrogate analyte and also as internal standard, was included at the same concentration either in field samples, quality control samples, and calibration solutions. Such calibration is performed with each batch of samples, four standard solutions containing the target compounds at different concentration levels, and plotting the ratio analyte/internal standard vs. analyte concentration.

Data Analysis. Statgraphics 5.1 was used for data treatment. The statistic applied consisted of a multifactor analysis of variance and a principal component analysis. These studies allow classifying the samples, obtaining the influence of factors in the presence of a given compound, and to approach likely sources of aromas to the whole aroma profile of the flowers.

RESULTS AND DISCUSSION

The method allowed the quantification of volatile compounds in relation to the mass of sample analyzed. The field quality control carried out was satisfactory because the results are under statistical control. Most of the selected compounds were identified in living flower samples so they were targeted for quantification in each excised part.

The use of the reference compound *p*-xylene-d10 in this work had a double function. On one hand, it allowed monitoring of the volatilization of compounds and potential analyte losses during sample transport and analysis. The ratio analyte/reference peak area did not differ in field samples, spiked samples, and calibration curves. On the other hand, it acted as an internal standard for calibration purposes on the basis of signal ratio analyte/reference. The quality control performed showed that recovery rates of the field spiked samples ranged between 87 and 103%, calibration plots fit to straight lines with a relative standard deviation less than 12%, and a determination coefficient greater than 0.98.

Tables 1–3 show the concentrations of volatiles in petals, nectar, anthers, and stigmas of the three cultivars. The main compounds found in nectar were 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene, at concentrations around 60 mg/l in male flowers and 40 mg/l in female flowers. These compounds were almost exclusive to nectar, as they were found only at trace levels in anthers and stigmas and at the lowest concentration in petals (around 2 ppm). Terpenes were found in petals in a greater concentration than in nectar samples. In all cases, the dominant odor from zucchini petals was a blend of linalool, α-pinene, limonene, indole, and eucalyptol. The concentration of these compounds was between 3 and 25 mg/kg, with male flowers having a higher content of volatile compounds than female flowers. Indole was found exclusively in petal samples, at concentrations around 4 mg/kg. Linalool, eucalyptol, and ocimene were found in both anthers and stigmas, with linalool being the predominant compound encountered, at concentrations around 25 mg/kg in male samples and 5 mg/kg in female samples. Eugenol, myrcene, and 1,4-dimethoxybenzene were present at lower concentrations, but only in anther samples. Ocimene was the only compound found in greater concentrations in stigmas than in anthers.

Principal component analysis (PCA) was performed for compounds found in concentrations greater than 0.2 ppm. Three components explained 92% of the variance. The first component (PC1) explained the predominant odor of the whole flower, which was related to two different groups: the petals profile and the presence at high concentrations of two volatiles from nectar. Figure 1 shows that the factors with more weight in the negative axis of PC1 were compounds with a relative petals/nectar concentration of greater than 1, such as α-pinene, toluene, indole, limonene, linalool, eugenol, and *o*-xylene that are compounds principally found in flower petals. Less weight in PC1 was given to those

compounds with a petals/nectar ratio close to 1 (myrcene, ethylbenzene, *p*, *m*-xylene, and eucalyptol), and with more weight in the positive axis of PC1 were 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene, which had a petals/nectar ratio of concentrations less than 1. These findings concur with those of Dobson et al. (1990) with petals being the main source of the aroma profile of the whole flower. However, in zucchini, this is influenced by the high concentration of 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene in nectar. Such findings were also reported by Bergstrom et al. (1995) in *Ranunculus acris* and agree with qualitative data obtained in the analysis of the aromas from whole living flowers. Figure 2 shows that the main difference between genders is the higher proportion of 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene in the air surrounding female flowers. This is in agreement with the sexual dimorphism that is typical in monoecious flowers such as those belonging to the Cucurbitaceae. The headspace air concentration of compounds from whole living flowers is a consequence of the volatilization from the nectary. Less nectar volatilization is likely to occur in male flowers than in females because the nectary of the male flower is an enclosed receptacle, opened only by three opercula, whereas female flowers have an open receptacle.

The second principal component (PC2) was related to the nectar aromas profile, which showed that factors with most weight in PC2 were 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene having a petals/nectar ratio less than 1, and myrcene, ethylbenzene, *p*,*m*-xylene, and eucalyptol with a petals/nectar ratio close to 1. Finally, the compounds with most weight in the third component (Figure 3), were eucalyptol and linalool, which were present in anther samples, with a petals/anther ratio less than 1, which appeared to be related to the reported attraction effect of linalool on pollinator insects (Laloi et al., 1999; Henning et al., 1999).

The effect of the cultivar on the aroma profile was not shown in this analysis because this relationship was very low compared to the other variables analyzed, i.e., flower gender and flower parts. There were some differences in certain compound concentrations between cultivar Chapin and the other two cultivars (Tosca and Consul) that were grouped together (data not shown) in the PCA analysis. However, this difference was not significant. As a result, the effect of variety on aroma profiles was not proven in this experiment.

In summary, quantitative determinations of floral volatiles in *C. pepo* showed that the main sources are petals and nectaries, with a lesser contribution to the total flower scent by anthers and stigmas. PCA indicated that compounds found in petal samples had the greatest influence on the aroma profile of the flower, although some of the compounds found in nectar had a higher concentration than in petals and thus contributed to the aroma profile of the whole flower. Nectar scent is dominated by 1,4-dimethoxybenzene and 1,2,4-trimethoxybenzene, whereas petal odor mainly contained linalool, limonene,

and α-pinene. Indole was not present in nectar, but was in petals. Additionally, anther and stigmas had few compounds, with linalool and eucalyptol being the predominant compounds in these parts of the flower.

(Received April 9, 2005; revised May 23, 2005; accepted June 20, 2005)

Abstract—Primary plant surfaces, covered with cuticles consisting of cutin and waxes, are important substrates for interaction with insects. The composition of leaf surfaces of the myrmecophilic plant *Macaranga tanarius* was studied. The prenylated flavanone nymphaeol-C was identified in surface extracts and was localized exclusively in glandular trichomes on the abaxial leaf side. The epidermal pavement cells surrounding these trichomes were covered with a smooth film of epicuticular wax from which few small wax crystals protruded. The epicuticular wax amounted to approximately 8 μg cm^{-2}, corresponding to 85% of the wax load on the adaxial as well as the abaxial leaf sides. The epicuticular wax mixtures from both leaf surfaces contained more than 70% primary alcohols, 14% fatty acids, 2% aldehydes, and traces of alkyl acetates, with chain lengths ranging from C_{20} to C_{38}. In contrast, the intracuticular wax layer was largely dominated by triterpenoid alcohols α-amyrin, β-amyrin, and lupeol. Consequently, these characteristic compounds are not available for direct contact with insects on the plant surface.

Key Words—Epicuticular wax, leaf surface, plant insect interactions, glandular trichomes, isoprenoids, flavanones, nymphaeol-C, *Macaranga tanarius*.

INTRODUCTION

The surfaces of leaves, stems, flowers, and fruits are the stage for interactions between insects and their host plants. These aerial plant tissues, being in a primary state of development, are covered with a cuticle consisting of cutin and waxes (Walton, 1990). Within the latter, two layers of intracuticular and epicuticular waxes can be distinguished according to their location inside the cutin matrix and outside of it, respectively (Jeffree, 1986). The primary physiological function of the cuticle, to limit nonstomatal water loss, is likely associated with the intracuticular waxes (Baur, 1998), but the epicuticular waxes might also contribute to the transpiration barrier. Besides, the epicuticular waxes form the true surface of the plant organs and may serve important ecological functions in the interaction with insects and pathogens (Eigenbrode and Espelie, 1995).

The composition of plant cuticles has long been studied using superficial extraction of intact plant material with organic solvents (Walton, 1990). Solvent molecules enter rapidly into the deeper layers of the cuticle, thus releasing both epi- and intracuticular waxes (Jetter et al., 2000). Extracts reflect the total wax composition, averaging over the entire depth of the cuticular wax layers. The total wax mixtures of diverse plant species typically consist of homologous series of very long chain fatty acid derivatives, i.e., fatty acids, aldehydes, primary and secondary alcohols, ketones, and alkanes of chain lengths C_{20}–C_{36}, as well as alkyl esters with C_{38}–C_{70} (Tulloch, 1976). Besides, characteristic compounds such as triterpenoids and flavonoids can be present, in some species only in trace amounts and in others dominating the mixture (Wollenweber and Dietz, 1981; Baker, 1982).

In recent years, methods have been developed that allow independent and selective sampling from both the epi- and intracuticular waxes (Jetter et al., 2000; Jetter and Schäffer, 2001). Hence, it is now possible to describe the composition of plant surfaces more accurately. For example, it can be tested whether species-characteristic compounds are present at or near the plant surface and are hence available for direct contact with insects touching the plant cuticle. This is an important prerequisite for understanding the molecular mechanisms involved especially in early stages of interactions between insects and their host plants.

As one example of such an insect–plant interaction, the biology of ant–plant associations between the Asian pioneer tree genus *Macaranga* and its partner ants in the genera *Crematogaster* and *Camponotus* has been studied intensively (Fiala et al., 1994; Federle et al., 1997, 2000; Heil et al., 1998, 2001; Fiala et al., 1999). The partner ants nest inside the hollow shoots and feed predominantly on food bodies provided by the host plants. The ants actively search for and remove foreign objects touching the plant, thus providing indirect protection against epiphytes, herbivores, and pathogens. For various species of

the plant and ant genera involved, myrmecophilic or myrmecophytic associations are true mutualistic symbioses as they benefit both partners.

The stem waxes of various *Macaranga* species have been investigated, and in two instances their influence on the ant partners has been assessed. On one hand, host recognition by the colony-founding queen apparently involves surface cues of some *Macaranga* species (Inui et al., 2001). On the other hand, mechanical barriers located at the surface of various *Macaranga* species serve to protect partner ant species against generalist competitors (Federle et al., 1997). Thread-shaped epicuticular wax crystals that render the surfaces slippery for nonadapted ants generate these barriers. The surface crystals are formed by characteristic triterpenoids (Markstädter et al., 2000). In contrast, relatively little is currently known about the composition, properties, and functions of *Macaranga* leaf surfaces. Only in one species, *M. hypoleuca*, have adaxial and abaxial leaf waxes been studied in some detail (Markstädter et al., 2000). This investigation reports on the qualitative cuticular triterpenoids, aliphatic surface constituents, and large portions of the leaf waxes remain unidentified.

In the current study, we performed chemical analyses on *Macaranga tanarius* to address the questions (1) whether the cuticular waxes on adaxial and abaxial leaf surfaces differ, (2) whether gradients between the intra- and epicuticular wax layers on both sides of the leaves exist, (3) how much of the total cuticular wax is contributed by the intra- and epicuticular waxes, and (4) how the compositions of intra- and epicuticular wax layers on leaves differ from stems.

METHODS AND MATERIALS

Plant Material and Gland Preparation. Specimens of *M. tanarius* were taken from a continuous greenhouse culture in the Botanical Garden of the University of Würzburg, Germany. For the isolation of *M. tanarius* glandular trichomes, a protocol originally developed for preparing rose trichomes was adapted (Hashidoko and Urashima, 1995). Five mature leaves were harvested, cleaned carefully of food bodies using a paintbrush, and cut into pieces. Trichomes were sheared off the abaxial leaf surface by moving approximately 150 ml of glass beads with a diameter of 0.25–0.5 mm (Roth, Karlsruhe, Germany) in a highly viscous liquid, consisting of 650 ml of 0.4 M D-mannitol, 50 mM sodium L-(+)-ascorbate (both from Roth), and 5% glycerol (AppliChem, Darmstadt, Germany) at pH 6.8, in a 1-l round-bottom flask over the plant tissue. The flask was kept on a shaker for 90 min at 275 rpm. The resulting suspension was passed through a series of filtration steps by using nylon filters with different mesh sizes (125, 95, 74, 62, and 47 μm; Small Parts, Miami Lakes, FL, USA). Initially, big mesh sizes were employed to remove large fragments of leaflets and hair trichomes. At a mesh size of 62 μm, glandular

trichomes were collected nearly exclusively, whereas hair trichomes were only trapped on a mesh size of 47 μm. The filter residues were transferred into vials, and 3 ml of separation solution were added. The trichomes were ground into a paste, and 7 ml of chloroform and 10 μg of the internal standard of *n*-tetracosane were added. The mixture was vigorously agitated, and after phase separation the organic solution was removed, and the solvent was evaporated under a stream of N_2.

Sampling of Leaf Surface Compounds. Prior to use, gum arabic powder (Roth) was soxhlet-extracted in chloroform (Roth) for 3 hr. On freshly harvested leaves, several circles of 23 mm diam were marked with a felt pen, either on the adaxial or the abaxial side close to the center of the blade. The area inside the circles was cleaned carefully of food bodies with a dry paintbrush. Another paintbrush was used to apply an aqueous solution of gum arabic (ca. 0.8 mg ml^{-1}) onto the circular surface area. After 1 hr at 25°C, the hardened polymer film of gum arabic was lifted off the leaf together with adhering surface waxes. To separate wax constituents from gum arabic, the pieces of dry glue were transferred into vials containing a two-phase system of 7 ml each of chloroform and water. *n*-Tetracosane was added as internal standard, and the mixture was agitated vigorously. After phase separation, the organic phase was removed and concentrated under a gentle stream of N_2. The whole protocol could be repeated one more time on the adaxial side of the same leaf areas without damaging the cuticle or the underlying tissue, as was confirmed by scanning electron microscopy (SEM).

After the mechanical removal of epicuticular wax, the remaining cuticular wax was extracted with chloroform at room temperature. To this end, glass cylinders (13 mm diam) were gently pressed onto the leaf surface and filled twice with 1.5 ml of chloroform for 30 sec. Both chloroform solutions were combined, and *n*-tetracosane was added as internal standard. Alternatively, the total wax coverage was assessed by extraction of the cuticular wax from leaf surfaces without prior treatment with gum arabic.

Wax Analysis. Prior to GC analysis, chloroform was evaporated from all samples under a gentle stream of N_2 while heating the sample vials to 50°C. Next, all samples were treated with bis-*N*,*N*-(trimethylsilyl)trifluoroacetamide (BSTFA, Macherey-Nagel, Düren, Germany) in pyridine (30 min at 70°C) to transform all hydroxyl-containing compounds into the corresponding trimethylsilyl (TMSi) derivatives. The qualitative composition was studied with capillary GC (5890 II, Hewlett Packard, Avondale PA, USA; 30 m DB-1, 0.32 mm i.d., d_f = 1 μm; J & W Scientific, Folsom, CA, USA) with He carrier gas inlet pressure constant at 30 kPa and mass spectrometric detector (5971, Hewlett Packard). GC was performed with temperature-programmed injection at 50°C, oven 2 min at 50°C, raised by 40°C min^{-1} to 200°C, held for 2 min at 200°C, raised by 3°C min^{-1} to 320°C, held for 30 min at 320°C. The quantitative

composition of the mixtures was studied using capillary GC with flame ionization detection under the same gas chromatographic conditions described above, but H_2 carrier gas inlet pressure was programmed for 50 kPa at injection, held for 5 min, raised with 3 kPa min^{-1} to 150 kPa and held for 40 min at 150 kPa. Single compounds were quantified against the internal standard by manually integrating peak areas.

Identification of Nymphaeol-C. For identification of a novel surface component, intact leaves were extracted with chloroform. The resulting wax mixture was separated using thin layer chromatography (TLC) on silica gel with $CHCl_3$/EtOH (99:1) as mobile phase. Bands were stained with primuline, visualized under UV light, immediately removed from the plates, eluted with $CHCl_3$, and filtered. Finally, the solvent was removed in a stream of N_2, and samples were stored in the dark at 4°C. The target compound was detected in a fraction with R_f = 0.11. Hydroxyl groups were either transformed into TMSi ethers as described above, or acetylated by adding pyridine and Ac_2O to the dried fraction, heating the mixture to 70°C for 5 min, maintaining it at room temperature overnight, and then removing the solvent in a stream of N_2.

Circular dicroism (CD) spectra (25°C, MeOH, 0.02 cm cell) were recorded on a Jasco J-715 spectropolarimeter. ^{1}H NMR (400 and 600 MHz) and ^{13}C NMR (100 and 150 MHz) spectra were measured on Bruker Avance 400 and DMX 600 instruments, using $CDCl_3$ (δ 7.26 and 77.01) as a solvent and as the internal ^{1}H and ^{13}C standard. Proton-detected, heteronuclear correlations were measured using HMQC (optimized for $^1J_{HC}$ = 145 Hz) and HMBC (optimized for $^nJ_{HC}$ = 7 Hz) pulse sequences. EIMS of the underivatized compound was determined on a Fisons MD1000 instrument (70 eV) using the direct probe. Capillary GC analysis of the TMSi derivative was performed on a Hewlett-Packard 5890II gas chromatograph with FID and MS detection as described for wax analysis.

CD (CH_3OH) $\Delta\varepsilon_{207}$ −44.1, $\Delta\varepsilon_{222}$ +48.8, $\Delta\varepsilon_{293}$ −27.7, $\Delta\varepsilon_{333}$ +3.9; ^{1}H, ^{13}C NMR, and MS data were identical to those of the known (−)-nymphaeol-C isolated from *Hernandia nymphaefolia* (Yakushijin et al., 1980).

Scanning Electron Microscopy. Dried (overnight, 25°C) samples of untreated leaf disks and of leaf disks from the various treatments were mounted on aluminum holders, sputter coated with gold–palladium (Bal-Tec SCD005 Sputter Coater; 25 mA, 300 s; Balzers, Switzerland), and examined by SEM (Zeiss DSM 962, 15 kV; Zeiss, Oberkochen, Germany).

RESULTS AND DISCUSSION

Micromorphology of Leaf Surfaces. On *M. tanarius*, leaf hairs can be seen with the naked eye. Scanning electron microscopy revealed that hair trichomes

were unbranched and apparently unicellular, ranging from 10 to 15 μm in base diam and 100–150 μm in length, and ending in sharp points (Figure 1A). This type of trichomes was located mostly above vascular bundles on both sides of the leaf. A second type was restricted to the abaxial leaf surface, where they were located in shallow epidermal pits between principal veins (Figure 1A and B). These trichomes were characterized by segmental arrangement of eight cells in a circular head with a diameter of ca. 70 μm. Convex head segments were sharply delineated by sunken lines, likely above anticlinal cell walls.

Light microscopy showed that this cell shape and arrangement was present on fresh leaf material (data not shown) and could not be attributed to drying artifacts caused by sample preparation for SEM. This suggests that the trichome cells do not share a subcuticular cavity, as described for glandular trichomes on Lamiaceae leaves (Turner et al., 2000). Baker (1934) had reported similar trichomes for leaves of *Macaranga* species and called them bladder glands,

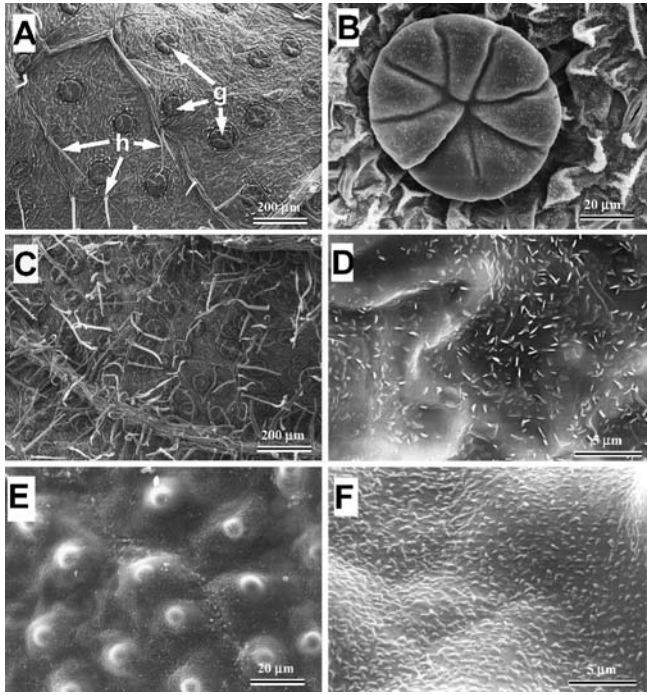

FIG. 1. Scanning electron micrographs of *M. tanarius* leaf surfaces. (A–B) Glandular trichomes (g) and hair trichomes (h) on the abaxial surface of mature leaves. (C) Abaxial surface of young leaf. (D) Detail of the wax structures on epidermal pavement cells of the mature abaxial surface. (E–F) Surface of pavement cells on the adaxial leaf.

whereas Elias (1983) designated comparable structures as scale-like nectaries. As neither the glandular character nor the nectary function has been verified for the structures on *M. tanarius* leaves, we will refer to them as scale trichomes.

On surfaces of young (<2 d) leaves of *M. tanarius*, both hair and scale trichomes were found in much higher density per surface area than on mature leaves (Figure 1C). In the course of leaf expansion, their numbers, sizes, and shapes stayed constant, whereas their densities gradually diminished. It can be concluded that both types of trichomes are formed early in leaf ontogenesis and reach maturity independently of epidermal pavement cells.

On epidermal pavement cells of both leaf sides, epicuticular wax structures were visible. The epicuticular waxes on the abaxial surface formed thin, upright platelets (length approximately 1 μm) with sharp edges (Figure 1D). In contrast, the adaxial surface was covered with a smooth wax film (Figure 1E), from which very small (approximately 500 nm), rounded granules protruded (Figure 1F). Compared to the surfaces of epidermal pavement cells, the scale trichomes were only sparsely covered with very small (approximately 500 nm) granules (Figure 1B), whereas the surface of the hair trichomes appeared smooth.

Identification of Nymphaeol-C. To prepare surface compounds for analysis, the adaxial and abaxial sides of intact *M. tanarius* leaves were first separately extracted with chloroform. While the two resulting solutions contained similar mixtures of typical cuticular wax constituents (see below), a single major compound was detected exclusively in the abaxial extract. As this compound had previously not been described in surface mixtures, its structure had to be assigned by a combination of spectroscopic techniques.

In a first experiment, the compound was purified from the crude surface extract by analytical TLC (R_f = 0.11 for chloroform/silica) and analyzed by GC-MS. The mass spectrum of the underivatized compound (Figure 2A) showed a prominent fragment *m*/*z* 69 that indicated the presence of one or more isoprenyl units. Other signals at *m*/*z* 368 ($[M-124]^+$), 221, 165, and 123 also matched with qualitative literature data for flavanones containing a dimethylallyl and a geranyl substituent (Yakushijin et al., 1980). In accordance with this tentative assignment, a molecular ion *m*/*z* 492 and a fragment *m*/*z* 477 $[M\text{-methyl}]^+$ were detected. The mass spectrum of the corresponding trimethylsilyl derivative (Figure 2B) further confirmed the prenylated flavanone structure by the presence of fragments *m*/*z* 73 and 147 (indicating multiple OTMSi groups), signals for *m*/*z* 780 $[M]^+$, 711 $[M\text{-dimethylallyl}]^+$, 643 $[M\text{-geranyl}]^+$, and for the corresponding daughter fragments *m*/*z* 765 $[M\text{-methyl}]^+$, 696 $[M\text{-dimethylallyl-methyl}]^+$, 628 $[M\text{-geranyl-methyl}]^+$.

Based on the spectral information given above, the novel surface component could be described as a prenylated flavanone with the overall formula $C_{30}H_{36}O_6$. Because reference data for possible isomeric representatives of this compound class had not been reported in the literature, the substitution pattern could not be

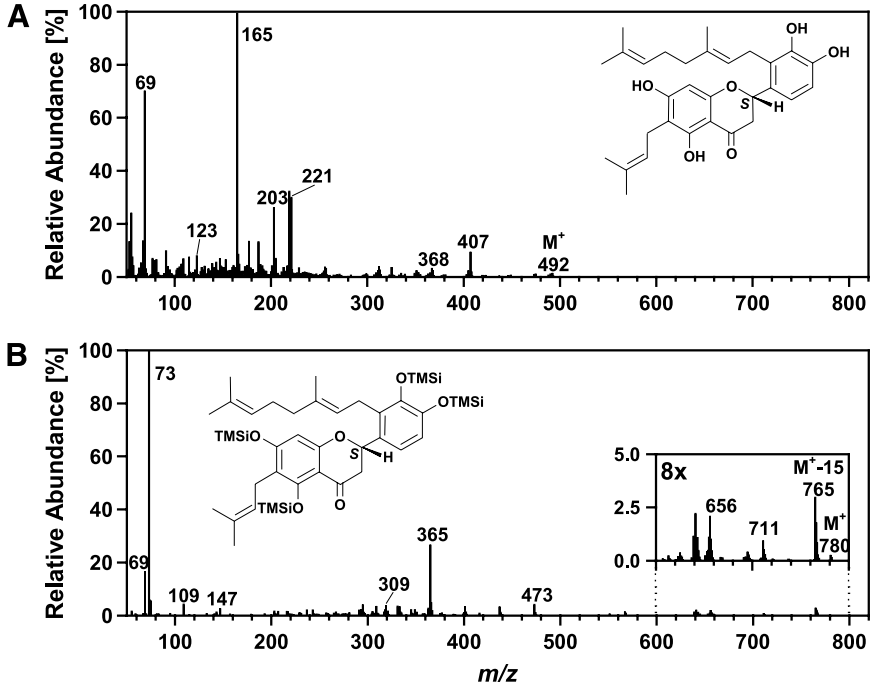

FIG. 2. Mass spectra of the prenylated flavanone nymphaeol-C. (A) Underivatized nymphaeol-C. (B) Trimethylsilyl derivate of nymphaeol-C.

assigned by using the fragmentation pattern alone. To allow the future identification of the compound employing GC-MS analysis, our mass spectral data had to be authenticated by other spectroscopic techniques. Therefore, in a second experiment, larger quantities of the compound were prepared by surface extraction of *M. tanarius* leaves, purified by TLC, and analyzed by NMR spectroscopy. The ^{1}H NMR spectrum showed the typical signals of a flavanone skeleton substituted with one geranyl, one γ,γ-dimethylallyl, and four hydroxyl groups. Both chemical shifts and coupling constants matched data previously reported for nymphaeol-C (Yakushijin et al., 1980). The constitution was corroborated by extended NOE, HMBC, HMQC, DEPT, and ^{13}C NMR measurements, proving that the novel surface constituent was indeed nymphaeol-C.

The absolute configuration at C-2 was confirmed to be *S* by comparison of the CD spectrum with that of (−)-nymphaeol-C (Yakushijin et al., 1980). Unfortunately, no CD data for the region <293 nm have as yet been published, apparently for instrumental reasons. Therefore, in this work we present these additional short wavelength CD data for the first time, thus making an unambiguous assignment of the compound easier in the future.

Localization of Nymphaeol-C in Scale Trichomes. The coincident occurrence of nymphaeol-C and scale trichomes, both restricted to the abaxial leaf surface of *M. tanarius*, suggested that the prenylated flavanone was produced and sequestered in these structures. This hypothesis was first tested by isolating the trichomes and subjecting them to chemical analyses. For this purpose, both types of trichomes were mechanically detached from the leaf surface and separated by differential filtration. As expected from the morphological data (see above), hair trichomes passed filter membranes with a mesh size of 62 µm, whereas scale trichomes were retained (Figures 3A and C). In the resulting scale fraction the amount of nymphaeol-C was 35 times higher than in the fraction of

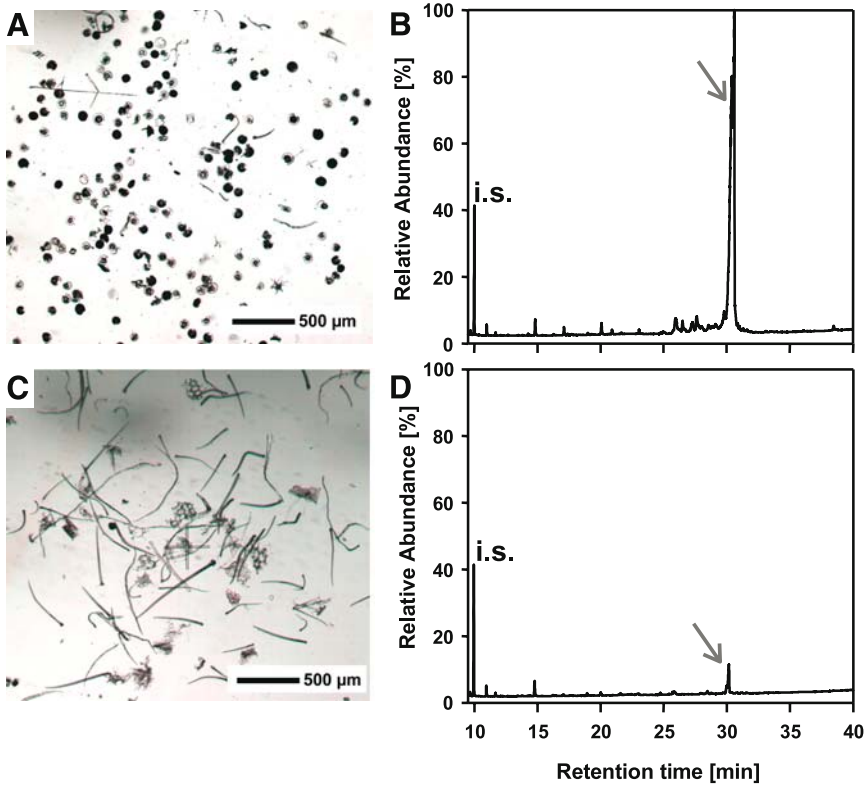

FIG. 3. Separation and extraction of scale and hair trichomes from *M. tanarius* leaves. (A) Light micrograph of the particle fraction from filtration through 62-µm mesh, containing mainly scale trichomes. (C) Light micrograph of the particle fraction from filtration through 47-µm mesh, containing mainly hair trichomes. (B and D) Normalized gas chromatograms showing quantities of nymphaeol-C (arrows) extracted from the fractions shown in (A) and (C), respectively (i.s.: internal standard *n*-tetracosane).

the hair trichomes (Figures 3B and D). Hence, the prenylflavanone is clearly associated with the scale trichomes, but not with the hair trichomes.

To further corroborate the localization of nymphaeol-C in these trichomes, we investigated the correlation between scale density and nymphaeol-C coverage per surface area. On individual leaves of various developmental stages, the amount of wax compounds per unit area was constant. In contrast, the amount of nymphaeol-C increased linearly with the number of scale trichomes ($r^2 = 0.93$ for linear regression, $P < 0.001$; Figure 4). It is, therefore, likely that this compound is accumulating exclusively in the scale trichomes, and not in the cuticular wax of the epidermal pavement cells. From the slope of the regression line, an average amount of 30 ng of nymphaeol-C per scale trichome can be inferred. Assuming a density of 1.4 g cm^{-3} for prenylated flavanones in a condensed phase (Kiehlmann et al., 1999), the neat compound should occupy 2.1×10^4 μm^{-3} per trichome, i.e., large portions of the head volume of approximately 3.5×10^4 μm^{-3} (calculated for 70 μm diam and 10 μm high). In accordance with this assessment, fluorescence microscopy of cross-sections through the scale trichomes showed green autofluorescence, similar to the appearance of flavonoid standards, throughout the volume of the head cells (data not shown). With all data

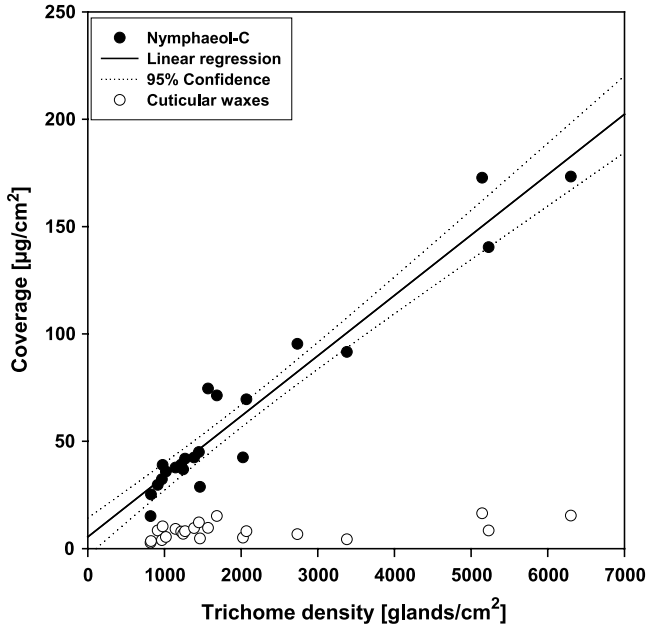

FIG. 4. Relationship between the coverage of nymphaeol-C or cuticular waxes and the trichome density.

taken together, the scale trichomes can be described as highly specialized glands, the head cells probably biosynthesizing and storing the prenylated flavanone.

Nymphaeol-C was first identified as a constituent of *Hernandia nymphaefolia* (Yakushijin et al., 1980). This compound had also been described as the major prenylated flavanone in fallen leaves of *M. tanarius* with a yield of 0.13 mg g^{-1} dry weight (Tseng et al., 2001). In the present study, an average of 60 μg cm^{-2} of nymphaeol-C was extracted from the abaxial leaf surface, corresponding to approximately 12 mg g^{-1} dry weight for mature leaves. As this value is more than 90 times higher than the result reported for fallen leaves, it is plausible that the entire amount of the prenylflavanone is located near the tissue surface. We conclude that nymphaeol-C is formed and stored exclusively in the glandular trichomes on the lower leaf surface of *M. tanarius*. Furthermore, the material is likely formed very early in leaf development and sequestered within the head cells without further turnover.

Although it has been reported that other prenylated flavonoids have cytotoxic properties inhibiting the growth of neighboring plants (Tseng et al., 2003), it is not clear whether this allelopathic effect represents the main ecological function of these constituents. The current results, localizing nymphaeol-C in scale trichomes restricted to the abaxial surface of *M. tanarius* leaves, show that this compound is exposed in high concentrations close to the plant surface. In analogy to the glandular trichomes of other plant families, the *Macaranga* scales might serve as defensive structures releasing allelochemicals upon mechanical damage (Werker, 1993). However, in sharp contrast to the essential oils produced by glandular trichomes of other plants, nymphaeol-C is not volatile and must exert its function(s) probably in direct physical contact between the plant surface and other organisms.

The present findings suggest a direct defensive function of nymphaeol-C against herbivores, in addition to the indirect defense exerted by partner ants on *M. tanarius*. This species is myrmecophilic, i.e., several relatively unspecific ant species can serve as partners that sometimes colonize the trees only late in development. This may leave *M. tanarius* plants without ant protection for long periods, additionally necessitating direct chemical defense mechanisms. This leads to the question whether other *Macaranga* species, either myrmecophytes (obligate ant–plants) or nonmyrmecophytes (including myrmecophilic species), have similar scale trichomes containing nymphaeol-C. Unfortunately, there are no published data that could be interpreted accordingly. In one report, only the total flavonoid amounts have been quantified for leaves of various *Macaranga* species including *M. tanarius* (Heil et al., 2002), but the flavonoid constituents and their localization have not been specified. In a preliminary survey, we found that scale trichomes, similar to those on *M. tanarius*, are present on the abaxial side of leaves of various *Macaranga* species. GC-MS analyses showed that in none of these cases—comprising the myrmecophytic

species *M. constricta*, *M. triloba*, and *M. winkleri*, the partially myrmecophytic species *M. hosei* and *M. pruinosa*, as well as the nonmyrmecophytic species *M. gigantea* and *M. heynei*—did the trichomes contain nymphaeol-C (data not shown).

Total Cuticular Wax Mixtures on M. tanarius *Leaves*. Cuticular waxes were extracted separately from the adaxial and the abaxial leaf surfaces, and analyzed using GC-FID and GC-MS. Preliminary tests had shown that this extraction was exhaustive for the soluble cuticular lipids, thus yielding total wax amounts. The adaxial leaf cuticle was found to contain 9.1 ± 2.5 μg cm^{-2} waxes, whereas the abaxial side (excluding the amount of nymphaeol-C) was covered with 10.9 ± 2.9 μg cm^{-2} of waxes (Figure 5).

On both leaf surfaces, characteristic patterns of diverse aliphatic compounds and small amounts of triterpenoids were detected, and overall 40 compounds were identified. In the total wax mixture on the adaxial leaf side, 13.6 ± 8.0% triterpenoid alcohols were found, mainly α-amyrin, β-amyrin, and lupeol, whereas 70.8 ± 7.0% were aliphatic compounds. The most abundant component class were the primary alcohols with 56.7 ± 11.5% (5.2 ± 1.8 μg cm^{-2}), followed by fatty acids with 11.0 ± 2.6% (1.0 ± 0.4 μg cm^{-2}) and aldehydes with 3.1 ± 2.2% (0.3 ± 0.2 μg cm^{-2}). Only 10.9 ± 5.2% of the adaxial wax mixture remained unidentified (Figure 6A). A similar pattern of compound classes was detected in total lipid extracts from lower leaf surfaces. In addition, the abaxial wax mixture contained small amounts of acetates with 3.5 ± 2.4% (0.4 ± 0.2 μg cm^{-2}) (Figure 6B).

The wax mixtures from both leaf sides contained homologous series of primary alcohols with chain lengths between C_{24} and C_{38} that had a strong predominance of even carbon numbers. The chain length distribution of

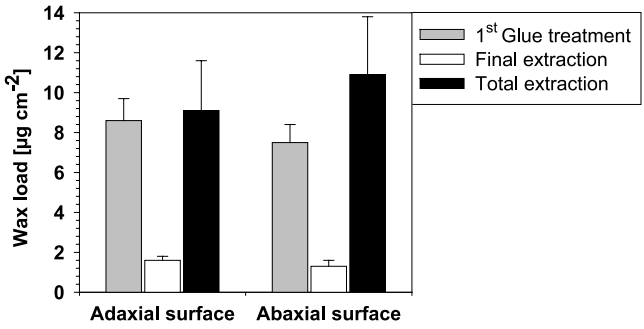

FIG. 5. Wax coverage on adaxial and abaxial leaf surfaces of *M. tanarius*. Yields from two independent experiments are given, one of them using selective mechanical removal with gum arabic and consecutive (final) extraction with chloroform, the other one using only extraction of bulk cuticular waxes (total extraction) with chloroform.

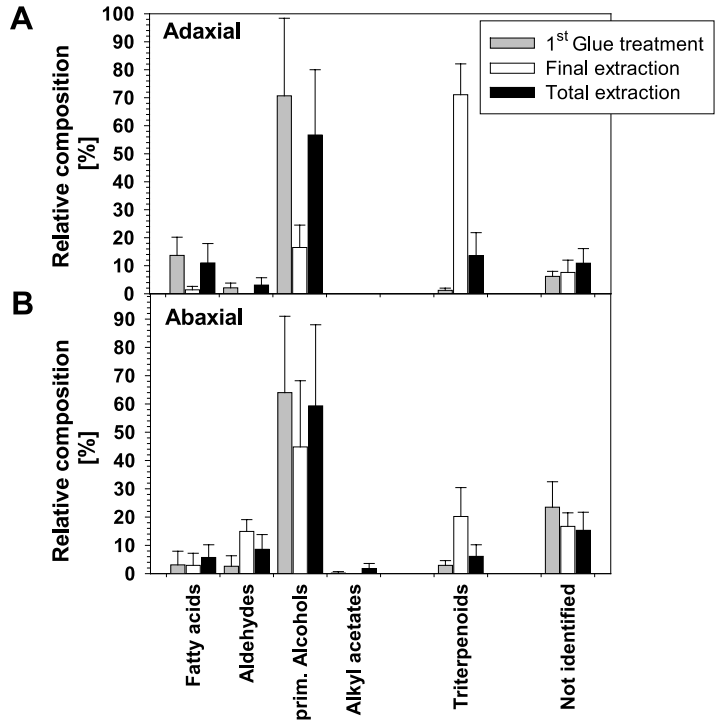

FIG. 6. Relative wax composition on leaf surfaces of *M. tanarius*. Amounts of the different component classes on (A) adaxial and (B) abaxial surfaces are given as percentages of respective wax mixtures.

alcohols from the upper leaf surface showed two maxima for C_{26} and C_{34}, whereas those from the lower leaf surface had only one maximum at C_{32}. The homologous series of fatty acids comprised chain lengths between C_{20} and C_{38}, while aldehydes with chain lengths between C_{26} and C_{34} were identified. Both compound classes were dominated by representatives with even carbon numbers and showed a maximum for C_{26} (Table 1).

Epi- and Intracuticular Wax Layers on M. tanarius *Leaves*. The contribution of epi- and intracuticular layers to the overall wax composition was assessed by successive mechanical and extractive probing. Hence, waxes were first removed from the surface using gum arabic as an adhesive. Two consecutive treatments of the adaxial surface yielded 8.6 ± 1.1 and 1.1 ± 1.0 μg cm^{-2} of waxes, respectively. A third gum arabic treatment caused the leaves to further dry and wilt, making a successive extraction for the investigation of intracuticular waxes impossible. Therefore, only a small number of samples were treated a third time

with glue, and found to yield no appreciable amounts of wax (data not shown). From this result, we conclude that the glue treatments had exhaustively removed a layer of waxes that was accessible to mechanical treatment. In contrast, a final extraction of the adaxial surface after two gum arabic treatments yielded 1.6 ± 0.2 μg cm^{-2} of waxes (Figure 5). This layer of wax must have been located inside a mechanical barrier that was likely imposed by the presence of the cutin

polymer matrix. Hence, in analogy to previous findings for other plant species (Jetter and Schäffer, 2001; Riedel et al., 2003; Vogg et al., 2004), the gum arabic samples can be interpreted as epicuticular waxes, while the final extraction yielded the remaining intracuticular waxes. This implies selective sampling of two distinct layers of waxes within the adaxial cuticle of *M. tanarius*, allowing a more accurate assessment of the wax composition at the surface of the leaf. In summary, on the adaxial leaf side 86% of the wax was located in the epicuticular layer.

For the abaxial side of the leaves, a first gum arabic treatment yielded 7.5 ± 0.9 μg cm^{-2} of waxes, while a consecutive extraction step released another 1.3 ± 0.3 μg cm^{-2} of wax (Figure 5). For this tissue, the mechanical treatment could not be repeated without disrupting the tissue. It can, therefore, not be directly assessed whether the mechanical treatment was exhaustive, and the selectivity of the sampling strategy cannot be evaluated. Nevertheless, the comparison of both experiments, i.e., the total wax extraction and the mechanical wax sampling, shows that the first gum arabic treatment likely released most of the epicuticular wax. The gum arabic samples give a fairly accurate representation of the abaxial surface composition. On the other hand, the samples from the successive extraction must largely reflect the intracuticular composition, even though they may have been contaminated with small amounts of epicuticular wax. The overall wax yields found in the second experiment for both adaxial and abaxial leaf surfaces were not significantly different from the corresponding results of the total wax extraction (Mann–Whitney *U*-test adaxial: $U = 4$, $P = 0.39$, abaxial $U = 7$, $P = 0.71$). Both experiments independently confirm each other.

The gum-arabic treated plant samples were inspected with SEM to visualize the mechanical removal of epicuticular waxes. After treatment with the glue, both adaxial and abaxial surfaces were smooth, whereas adjacent untreated areas showed the small crystal structures characteristic for native surfaces (see above). In transition regions between treated and untreated areas, a sharp edge could be seen (arrows in Figure 7A, B, and D). As a result of the gum arabic treatment, most of the gland heads were ripped off the abaxial leaf surface, exposing the end of short stalks that had apparently carried the gland scale. The stalks were located in shallow pits on the leaf surface, formed by the surrounding epidermal pavement cells (Figure 7C). The lower side of gum arabic represented a negative replica of the treated plant surface in which the outlines of pavement cells and stomata were clearly preserved. In addition, prominent structures with circular outlines comprising four or eight equal segments were visible. Both top and side views of these structures helped to identify them as glandular heads that had been broken off the abaxial leaf surface and were embedded in the gum arabic film (Figure 7E and F).

Especially on the adaxial leaf side, the chemical compositions of epi- and intracuticular waxes differed strikingly (Figure 6). The epicuticular layer

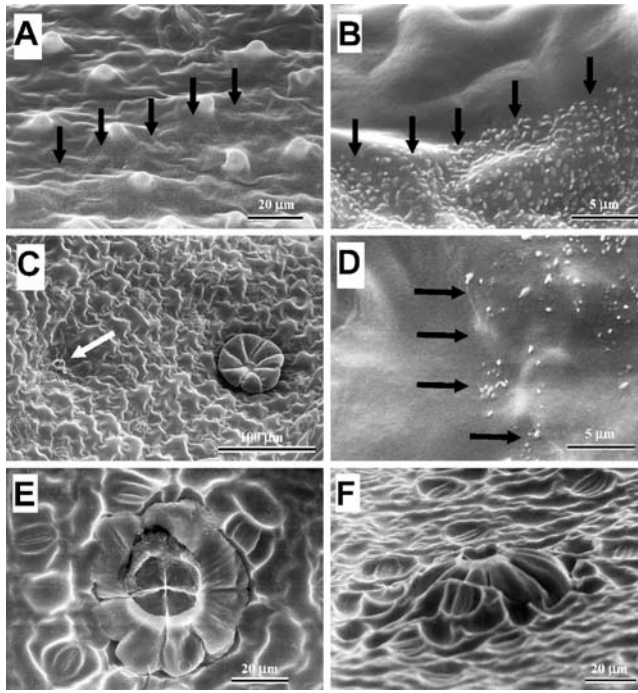

FIG. 7. Scanning electron micrographs documenting the treatment of *M. tanarius* leaf surfaces with gum arabic. (A–B) Adaxial leaf surface. (C–D) Abaxial leaf surface. (E–F) Lower surface of gum arabic films after treating the adaxial leaf surface.

contained large quantities of primary alcohols (70.1 ± 7.9%) and fatty acids (13.5 ± 4.4%), whereas only small amounts of triterpenoids were present (1.5 ± 0.9%). In contrast, the intracuticular wax was dominated by triterpenoids (71.1 ± 8.5%), whereas alcohols and fatty acids were found in relatively small percentages. Similar patterns could be observed for the epi- and intracuticular wax from the lower leaf surface, even though epi- and intracuticular waxes appeared to differ less than on the adaxial side (Figure 6). The relatively small differences between layers may have been in part due to contamination of final extraction products by epicuticular waxes remaining after the single gum arabic treatment (see above).

In summary, pronounced gradients existed between the epi- and intracuticular waxes on both sides of *M. tanarius* leaves. Both layers were not only mechanically, but also chemically distinct. On both sides of *M. tanarius* leaves, the cuticular triterpenoids were buried underneath a layer of aliphatic wax compounds, and are likely not available for direct contact with insects on the plant surface. This result leads us to question whether leaf cuticular triterpenoids serve

a direct function in moderating the behavior of insects living in contact with the plant surface, even though antifeeding properties have been reported for some triterpenoids (Schoonhoven et al., 1998).

The intracuticular localization of triterpenoids in *M. tanarius* leaf cuticles is of special importance for our understanding of the principles governing cuticle structure formation. On the one hand, it had previously been reported that other triterpenoids are also exclusively located in the intracuticular layer of *Prunus laurocerasus* leaves, which is a distantly related plant species (Jetter et al., 2000). This might reflect a general tendency of triterpenoids to accumulate in the intracuticular wax layer, possibly due to relatively high affinity to the cutin matrix. On the other hand, indirect evidence had shown that triterpenoids accumulate to high concentration in the epicuticular wax on stems of diverse *Macaranga* species (Markstädter et al., 2000). β-Amyrin is located at the surface of *M. tanarius* stems where it is involved in formation of epicuticular crystals that are important for the mechanical interaction with ants walking on the plant surface. Unfortunately, direct evidence is missing that would allow comparisons between the levels of triterpenoids in the intracuticular and epicuticular layers of the stems. It is consequently not clear whether gradients within the *Macaranga* stem wax exist, and currently it cannot be judged whether such triterpenoid gradients would be parallel or antiparallel to those described for *Prunus* and *Macaranga* leaves.

Acknowledgments—The authors thank Markus Riederer (University of Würzburg, Department of Botany II) and Walter Federle (University of Würzburg, Department of Zoology II) for fruitful discussions. Technical assistance by staff of the Botanical Garden of the University of Würzburg is gratefully acknowledged. Wilfried Schwab and Daniel Abanda (University of Würzburg, Department of Food Chemistry) provided advice with the gland isolation protocols. This work was supported by the SFB 567 "Mechanisms of interspecific interactions of organisms" and by a grant from the Fonds der Chemischen Industrie to G.B.

Abstract—Atmospheric CO_2 concentrations have increased dramatically over the last century and continuing increases are expected to have significant, though currently unpredictable, effects on ecosystems. One important process that may be affected by elevated CO_2 is leaf litter decomposition. We investigated the interactions among atmospheric CO_2, herbivory, and litter quality within a scrub oak community at the Kennedy Space Center, Florida. Leaf litter chemistry in 16 plots of open-top chambers was followed for 3 years; eight were exposed to ambient levels of CO_2, and eight were exposed to elevated levels of CO_2 (ambient + 350 ppmV). We focused on three dominant oak species, *Quercus geminata*, *Quercus myrtifolia*, and *Quercus chapmanii*. Condensed tannin concentrations in oak leaf litter were higher under elevated CO_2. Litter chemistry differed among all plant species except for condensed tannins. Phenolic concentrations were lower, whereas lignin concentrations and lignin/nitrogen ratios were higher in herbivore-damaged litter independent of CO_2 concentration. However, changes in litter chemistry from year to year were far larger than effects of CO_2 or insect damage, suggesting that these may have only minor effects on litter decomposition.

Key Words—Elevated CO_2, herbivory, litter quality, *Quercus myrtifolia*, *Quercus chapmanii*, *Quercus geminata*, Kennedy Space Center.

INTRODUCTION

Increasing atmospheric carbon dioxide (CO_2) is likely to alter ecosystem processes, yet most research to date has focused on the direct effects of CO_2 on plant physiological processes, with less attention to indirect effects on ecosystem processes, including those mediated by plant herbivores. Elevated CO_2 can alter foliar chemistry directly, for example by reducing nitrogen (N) concentrations in green leaves (Lincoln et al., 1993; Agrell et al., 2000; Hall et al., 2005). Elevated CO_2 could also alter leaf chemistry indirectly by affecting the feeding behavior of herbivores, in turn eliciting plant synthesis of chemical defenses. For example, elevated CO_2 can increase foliar concentrations of polyphenols, possibly a response to a CO_2-induced increase in herbivore feeding (Agrell et al., 2000). Changes in plant chemistry affect the quality of herbivore diets and may result in behavioral and physiological changes that influence subsequent herbivory (Lindroth, 1996; Stiling et al., 1999). Whether such changes in foliar chemistry persist in senesced leaves is not clear (Curtis et al., 1989; Coûteaux et al., 1991; Kemp et al., 1994; Finzi et al., 2001) but is important to determine given the importance of litter chemistry for decomposition and nutrient cycling.

The quality of leaf litter is an important determinant of decomposition rates and nutrient dynamics in many systems (Swift et al., 1979). Litter nitrogen, lignin concentrations, and C/N ratios are often good predictors of decay rates within and among species (Cotrufo et al., 1994). Carbon-based compounds such as polyphenols also decrease litter quality and may exert some control on litter decomposition (Hättenschwiler and Vitousek, 2000).

Elevated CO_2 may affect litter quality through several mechanisms including chemical changes in green leaf tissue that persist beyond leaf abscission or changes in patterns of herbivory that influence subsequent chemistry. The quality of green leaf tissue can change as a result of elevated concentrations of atmospheric CO_2 (Lindroth et al., 1995; Hall et al., 2005). Generally, nitrogen concentrations in green leaves decline and C/N ratios increase under elevated CO_2 (Lincoln et al., 1993; Hall et al., 2005). There may also be increases in polyphenolic concentrations in green leaves under elevated CO_2 (Agrell et al., 2000). It is unclear, however, if these changes persist in senesced leaves (Curtis et al., 1989; Coûteaux et al., 1991; Kemp et al., 1994; Finzi et al., 2001). Given the significance of litter chemistry to decomposition processes and nutrient dynamics (Heal et al., 1997), it is important to study the links among elevated CO_2, foliar chemistry, and litter chemistry.

In addition to possible direct effects of elevated CO_2 on litter quality, another potential route by which elevated CO_2 might influence litter quality is through its impact on herbivores. Changes in plant chemistry affect the quality of herbivore diets and may result in behavioral and/or physiological changes that influence subsequent herbivory (Lindroth, 1996; Stiling et al., 1999). For

example, to compensate for lower nitrogen concentrations in leaves under elevated CO_2, insect herbivores often increase their consumption rates by 20–80% (Lincoln et al., 1993). However, lepidopteran larvae can exhibit slower growth rates when feeding on elevated CO_2 plants (Fajer et al., 1991) and become more susceptible to pathogens, parasitoids, and predators (Lindroth, 1996; Stiling et al., 1999). At our field site, which hosts the longest continuous study of the effects of elevated CO_2 on insects, herbivore populations decline markedly under elevated CO_2 (Stiling et al., 1999, 2002, 2003; Hall et al., 2005).

Changes in the feeding behavior of herbivores alter ecosystem processes. Consumption of plant tissue by insect herbivores can have direct affects on ecosystem productivity. Herbivores can also influence ecosystem function by changing organic matter added to the soil (Chapman et al., 2003; Frost and Hunter, 2004). These changes may come from herbivore by-products (Stadler et al., 2001; Frost and Hunter, 2004), alteration of the plant community via selective herbivory (Ritchie et al., 1998; de Mazancourt and Loreau, 2000), or by altering the chemical properties of plant litter (Chapman et al., 2003).

Plant foliage responds to herbivore activity in multiple ways including changes in nitrogen concentrations and induction of secondary compounds (Schultz and Baldwin, 1982). If these changes carry over to litter, subsequent decomposition rates and related nutrient transformations may be altered (Melillo et al., 1982; Scott and Binkley, 1997). Chemical alteration of litter quality may also occur when herbivory instigates premature leaf abscission, which effectively limits nutrient resorption and results in litter with higher nutrient concentrations (Kahn and Cornell, 1983).

Given that herbivore damage can influence subsequent foliar and litter quality, declines in herbivore density under elevated CO_2 have the potential to influence decomposition and nutrient dynamics. Therefore, elevated CO_2 has the potential to cause changes in litter quality through direct effects on foliar chemistry and indirect effects mediated by herbivores. In this study, we explore the impacts of CO_2, herbivory and their interactions on scrub oak litter chemistry.

METHODS AND MATERIALS

Study Site. Our study site lies within a two-hectare native scrub oak community located at Kennedy Space Center, Florida. The scrub oak forest is xenomorphic, largely consisting of evergreen or semi-evergreen trees with a mature canopy height of 3 to 5 m. This plant community is fire controlled and was last burned January 1996. Prior to site burning, the plant composition consisted primarily of oak species (76% *Quercus myrtifolia*, 15% *Quercus geminata*, and 7% *Quercus chapmanii*). The remaining 2% of the community included *Serenoa repens* (palmetto), *Myrica serifera* (wax myrtle), *Lyonia*

ferruginea (rusty lyonia), *Ceratiola ericoides* (Florida rosemary), and *Galactia elliottii* (milk pea). Continuous ground cover and longleaf pine (*Pinus palustris*), wiregrass (*Aristida beyrichiana*), and turkey oak (*Quercus laevis*) are absent. Fire in scrub communities is a stand-replacing disturbance that typically removes all aboveground vegetation. Plant regrowth is rapid and there is little change in species composition. When fire is suppressed, the scrub community transitions into a pioneer xeric hammock, which is defined by the retention of some scrub species and the lack of traditional hammock species. The last burn cycle was in 1996 prior to site set up. Sixteen 3.6-m-diam plots, each enclosed with a clear polyester film open-top chamber 3.4 m in height, were utilized to control CO_2 levels. Chambers were overlaid on an octagonal framework of PVC pipe with a removable access door and frustum to reduce dilution of air within the chamber by outside wind. After burning, all regrowth was cut to ground level in May 1996, and, since that time, the vegetation in eight of the chambers was kept at ambient levels of CO_2 while the other eight chambers were exposed to elevated CO_2 (ambient + 350 ppmV). Carbon dioxide is constantly supplied to the elevated CO_2 chambers. In ambient CO_2 chambers, the airflow is identical to that of the elevated CO_2 chambers. (See Dijkstra et al. (2002) for a detailed description of the site setup.) Three oak species dominate this community and are present in every chamber: *Q. myrtifolia* Willd, *Q. chapmanii* Sargent, and *Q. geminata* Small.

Litter Chemistry. Leaf litter was collected quarterly for 3 yr (2000, 2001, 2002) from litter trays placed inside each chamber. Litter was sorted by species and by herbivore damage type (undamaged, chewed, mined). The oak species are evergreen and abscise leaves throughout the year; samples within a year were combined. This resulted in 144 samples (16 chambers $\times$ 3 plant species $\times$ 3 damage categories) per year. Chambers (8 per treatment) acted as replicates. Litter samples collected in 2000 were assayed prior to samples collected in 2001 and 2002, which were assayed concurrently. Otherwise, all samples were processed identically. The air-dried litter was ground to a fine powder and stored at -80°C prior to analysis.

Percent dry weight nitrogen and carbon were estimated from leaf powder on a Carlo-Erba NA1500 model C/N analyzer (Milan, Italy). These data also provided estimates of litter C/N ratios. Subsamples of leaf powder were used to assess the effects of elevated CO_2 on litter concentrations of cellulose, hemicellulose, and lignin by sequential neutral detergent/acid detergent digestion on an Ankom fiber analyzer (Abrahamson et al., 2003).

Proanthocyanidins, an estimate of condensed tannin concentration, were assayed using n-butanol/HCL methods described in Rossiter et al. (1988). Total phenolics were estimated with the Folin–Denis assay (Swain, 1980), and gallotannins (hydrolyzable tannins) were estimated with a potassium iodate technique developed by Bate-Smith (1977) and modified by Schultz and

Baldwin (1982). Standards for tannin analysis were generated by multiple sequential washes of a bulk sample by acetone extraction. The small amount of available litter material for some species resulted in a bulk sample that was a mix of all species of litter for each year. All tannin assays produced colorimetric reactions, in proportion to tannin concentration, which were quantified using a BioRad microplate reader.

Statistical Procedures. Data were initially analyzed with the GLM procedure of SAS 8.2. However, the residuals of the ANOVA models failed the test for normality (Kery and Hatfield, 2003). Data were transformed and reanalyzed and again failed the test of normality. Data were finally analyzed with the repeated-measures GENMOD procedure of SAS 8.2 (SAS Institute, 1999) and the log likelihood ratio was maximized. With the development of generalized estimating equations (GEE), GENMOD is a nonparametric alternative for repeated-measures data (Littell et al., 2002), although *post hoc* analyses are not performed. The GENMOD procedure allows the explanatory variables to be selected and changes in the goodness-of-fit statistics are used to evaluate the contribution of each variable to the model. Thus, the importance of each additional variable and interaction can be assessed, allowing a sequence of models to be tested while taking into account main effects as well as interactions. The data presented contain only those effects that made significant contributions to the model.

RESULTS

Except for condensed tannins, all measures of litter chemistry varied among the species of oak (Table 1). The only consistent effect of elevated CO_2 on litter chemistry was higher condensed tannin concentrations under elevated CO_2 ($\chi^2 = 19.34$, $P < 0.001$) (Figure 1). All other effects of elevated CO_2 on

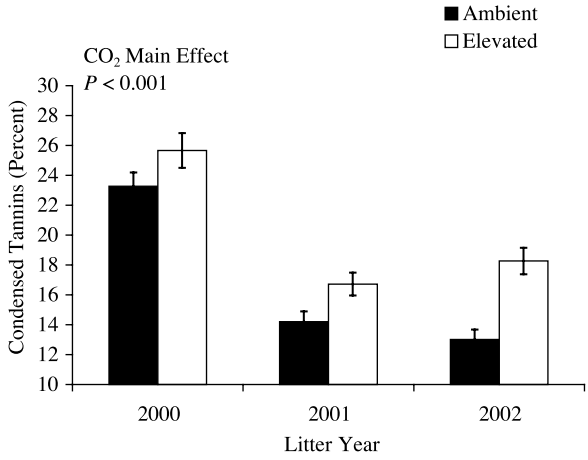

FIG. 1. Condensed tannin concentrations in litter across plant species. Data are the means of 72 samples and bars represent standard errors.

litter chemistry were either not significant (Table 2) or inconsistent among years (Figure 2a–c). The latter was one of our dominant findings—that interannual variation has a profound influence on the effects of elevated CO_2 on litter chemistry. A second result to emerge was that elevated CO_2 has no influence on litter nitrogen concentration or C/N ratio (Table 2). We have previously shown that in living green leaves of these oak species, nitrogen concentrations decrease whereas C/N ratios increase under elevated CO_2 (Hall et al., 2005). Apparently, these changes are lost by the time that leaves senesce.

Phenolic concentrations (condensed tannins, hydrolyzable tannins, total phenolics) were generally lower in chewed and mined litter than in undamaged

TABLE 2. RESULTS OF ANALYSES OF LITTER CHEMISTRY FOR CO_2 AND CO_2 × YEAR INTERACTIONS AT THE KENNEDY SPACE CENTER, FLORIDA

Litter chemistry	CO_2	CO_2 × year
Condensed tannins	$\chi^2 = 19.34$, $P < 0.001$	NS

litter (condensed tannins, $\chi^2 = 22.88$, $P < 0.001$; hydrolyzable tannins, $\chi^2 = 10.07$, $P = 0.006$; total phenolics, $\chi^2 = 15.55$, $P = 0.004$) (Figure 3a–c). However, mining only reduced hydrolyzable tannins and total phenolics in *Q. myrtifolia*

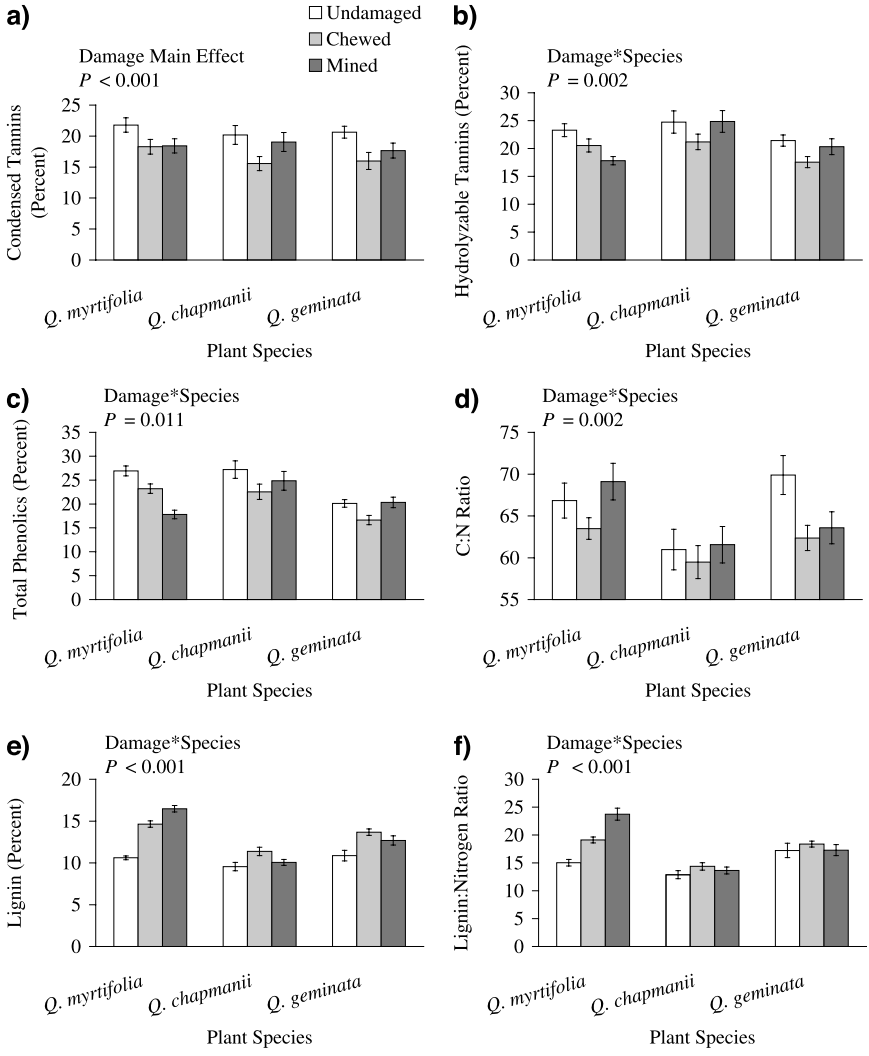

FIG. 3. Differences in litter chemistry among undamaged, chewed, and mined litter by plant species for (a) condensed tannins, (b) hydrolyzable tannins, (c) total phenolics, (d) C/N ratio, (e) lignin, (f) lignin/nitrogen ratio. Data are the means of 48 samples and bars represent standard errors.

(Figure 3b, c), and had no effect for the other species. Effects of damage on litter C/N ratios were inconsistent among the species ($\chi^2 = 20.73$, $P = 0.002$, Figure 3d) suggesting no dominant impact of damage on C/N ratios. Lignin concentrations and lignin/nitrogen ratios were higher in damaged litter from *Q. myrtifolia*, but

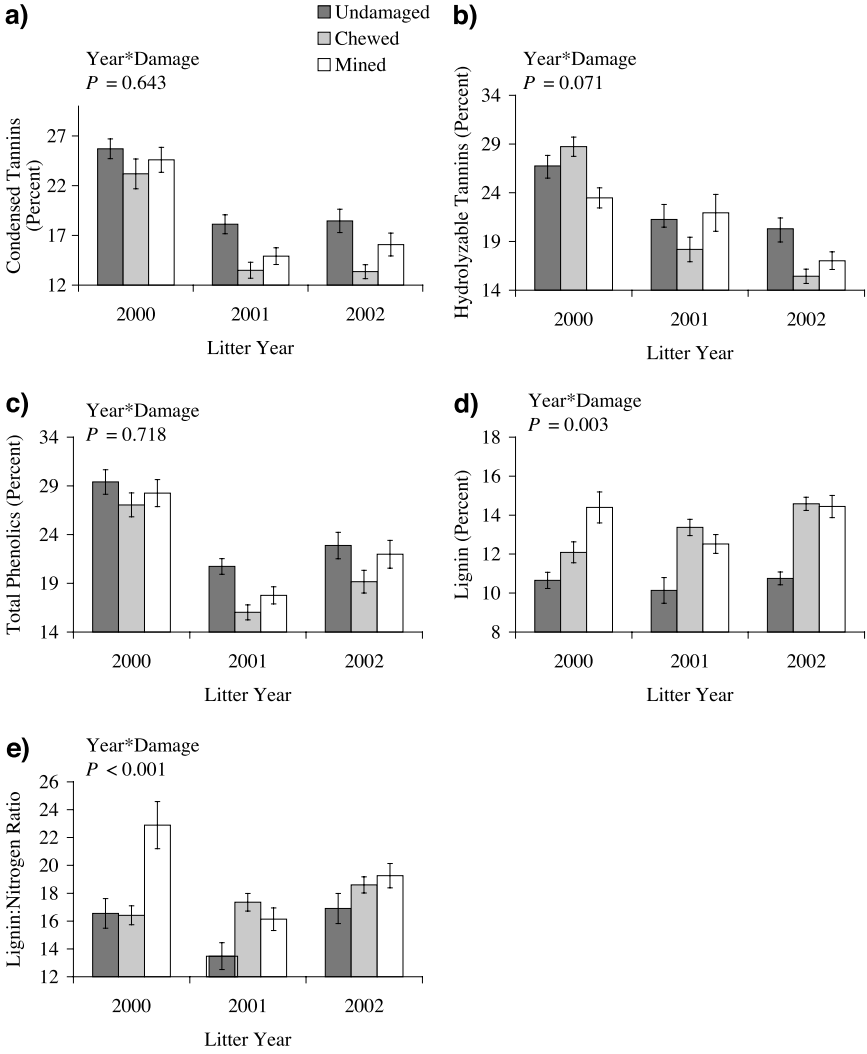

FIG. 4. Differences in litter chemistry of undamaged, chewed, and mined oak litter over time (a) condensed tannins, (b) hydrolyzable tannins, (c) total phenolics, (d) lignin, (e) lignin/nitrogen ratio. Data are the means of 48 samples and bars represent standard errors.

not from the other oak species (Damage × Species, $\chi^2 = 30.35$, $P < 0.001$, and $\chi^2 = 30.06$, $P < 0.001$ for lignin and lignin/nitrogen ratio, respectively, Figure 3e, f). As with the effects of CO_2, effects of damage on litter chemistry were relatively minor when compared to yearly variation from one growing season to the next (Figure 4a–e).

DISCUSSION

Climate and chemical composition of litter determine decomposition rates and nitrogen mineralization (Swift et al., 1979). Components influencing the quality of the litter include concentrations of nitrogen, lignin, and polyphenols. Typically, high concentrations of nitrogen are positively correlated with decomposition rates, whereas high lignin and polyphenolic concentrations are negatively correlated with decomposition rates (Swift et al., 1979). Low litter quality generally decreases decomposition, reducing nitrogen mineralization and soil nitrogen availability (Swift et al., 1979; Melillo et al., 1982). Previous studies of the effect of elevated CO_2 on litter quality have been equivocal. In some studies, increased levels of atmospheric CO_2 affected litter quality for several species (Coûteaux et al., 1991; Cotrufo et al., 1994; Parsons et al., 2004; Henry et al., 2005), whereas others have found no effect of elevated CO_2 on litter quality (Curtis et al., 1989; Finzi et al., 2001). Parsons et al. (2004) found that nitrogen concentrations declined and C/N ratios and condensed tannin concentrations increased under elevated CO_2 in paper birch (*Betula papyrifera*). Likewise, they found that mass loss was lower and decay rates were higher for birch litter from CO_2 environments compared to the control. Henry et al. (2005) found that lignin concentrations increased in grass and forb litter under elevated CO_2; however, they found no differences in total phenolic concentrations or percent nitrogen in the litter from elevated CO_2 environments. They found that the increase in lignin concentrations due to elevated CO_2 did not affect decomposition rates.

In our study, condensed tannin concentrations increased under elevated CO_2 regardless of species, herbivore damage, or growing season. Although the traditional measures of litter quality focus on lignin and nitrogen concentrations, there is growing consensus that polyphenols can have an effect on decomposition processes. Palm and Sanchez (1990) found that soluble polyphenolic concentrations were a better measure for predicting decomposition rates in leguminous litter in the tropics than were lignin or lignin/nitrogen ratios. Polyphenols may affect the rates of decomposition by influencing the composition and activity of the detritivore community (Hättenschwiler and Vitousek, 2000). In addition, polyphenols may alter the availability of nitrogen by binding with proteins and making the litter resistant to some detritivores, thus reducing the rates of nitrogen mineralization (Bernays et al., 1989). In our system, increased

condensed tannin concentrations under elevated CO_2 have the potential to affect ecosystem processes by slowing down litter decomposition and nutrient turnover. However, increases in condensed tannins were low (2–5%, Figure 1) and considerably smaller than interannual variation.

Prior work on green leaves in this system established that plant growth under elevated CO_2 reduced foliar nitrogen concentrations and increased C/N ratios by an average of 6 and 7%, respectively, across all three species (Hall et al., 2005). In contrast, secondary metabolites were unaffected in the green leaves (Hall et al., 2005). In this study of litter, however, there was no evidence of lower nitrogen concentrations or higher C/N ratios. Rather, the strongest CO_2 effects were seen in secondary metabolites, particularly condensed tannins (Figures 1 and 2a–c). Thus, differences in green leaf chemistry caused by growth under elevated CO_2 disappeared by the time leaves senesced. Few studies have directly compared foliar and litter chemistry under elevated CO_2. Curtis et al., (1989) found that nitrogen concentrations were lower and C/N ratios higher in green leaves of *Scripus olneyi* under elevated CO_2 but differences did not persist in senesced leaves. Finzi et al., (2001) found no effect of elevated CO_2 on total nonstructural carbohydrates or nitrogen in green leaves or in leaf litter of five tree species. Kemp et al., (1994), on the other hand, found significantly lower nitrogen concentrations in senesced foliage from *Poa pratensis* L. exposed to elevated levels of CO_2 compared to senesced foliage growing in ambient levels of CO_2. Similarly, Coûteaux et al., (1991) found that nitrogen concentrations were lower in leaf litter of chestnut trees grown in elevated CO_2 compared to ambient CO_2. The studies by Kemp et al., (1994) and Coûteaux et al., (1991) did not apply elevated CO_2 continuously to field plants, and this may account for the differences in their results from ours and other studies.

Phenolic concentrations were lower, whereas lignin concentrations and lignin/nitrogen ratios were higher, in litter following herbivore damage. Given that herbivores on oak generally induce increases in foliar phenolics (Schultz and Baldwin, 1982), it seems unlikely that the lower phenolic concentrations in damaged litter resulted directly from herbivore feeding. Rather, insect herbivores may be avoiding high phenolic leaves (Cooper-Driver et al., 1977; Bernays et al., 1989), leading to a preponderance of damage on low phenolic litter. This needs to be explored experimentally by manipulating herbivore abundance. Likewise, the apparent induction of lignification following damage (Figure 3e) requires experimental verification. Chapman et al., (2003) found that two insect herbivores from different feeding guilds (*Matsucoccus acalyptus* and *Dioryctria albovittella*) increased nitrogen concentrations and decreased C/N and lignin/nitrogen ratios in pinyon pine (*Pinus edulis*) litter. Moreover, these herbivore-induced changes resulted in increased litter decomposition rates. However, damaged litter in our study was lower in condensed tannins yet higher in

lignin and lignin/nitrogen ratios, changes that should have counteracting effects on decomposition rates. Herbivore-damaged litter may decompose more rapidly due to the decline in phenolic concentrations, particularly condensed tannins, compared to undamaged litter. Conversely, damaged litter may decompose more slowly due to higher concentrations of lignin and higher lignin/nitrogen ratios.

In our study, growing season had the dominant impact on litter chemistry so that yearly variation overwhelmed most effects of CO_2 or herbivore damage. Therefore, relative to the influence of seasonal variables, elevated CO_2 and herbivore activity may be less significant factors in leaf litter decomposition and ecosystem function. Although it is well known that climate and litter chemistry control the dynamics of decomposition (Swift et al., 1979), there has been little research on changes in litter quality based on yearly variation in climate. It is known, however, that the same plant species grown on different sites can vary in its litter chemistry (Vitousek et al., 1994; Scowcroft et al., 2000). Therefore, it is reasonable to expect within-site variation in litter chemistry from year to year due to climatic and other differences among the growing seasons. At our study site, climatic data available for precipitation and temperature did not offer insight to the yearly difference found in litter chemistry. Yearly precipitation, based on mean monthly data, varied only slightly with an average of 240 mm of precipitation recorded for 2000, 242 mm for 2001, and 263 mm for 2002. The average daytime temperature, based on mean monthly data, did not vary among years. The daytime mean temperature within CO_2 chambers was 27°C for all 3 years. The daytime mean temperature outside of chambers was 26°C for 2000 and 2002 and 25°C for 2001. Although precipitation and temperature did not vary among years, variation in monthly precipitation patterns based on timing of precipitation and litter fall may result in differential leaching of soluble compounds from year to year, thus leading to differences in litter chemistry. In addition to temperature and precipitation, differences in macro- and micronutrient supply as well as UV-B levels may affect litter quality (Heal et al., 1997; Horner et al., 1988). Given the magnitude of changes in litter chemistry from one growing season to the next, it is possible that decay rates and nitrogen mineralization will vary over time depending on the cohort of leaves that serve as substrate. Future work on the effects of climate change and herbivory on decomposition and nutrient cycling should occur over several years of study so that annual variation can be taken into account and key abiotic variables that drive variation in litter chemistry can be identified.

Acknowledgments—This research was supported by the Office of Science (BER), U.S. Department of Energy, through the South East Regional Center of the National Institute for Global Environmental Change under Cooperative Agreement DE-FC03-90ER61010. We thank Chris Frost and Caralyn Zehnder for comments on a previous draft of this manuscript and Jane Rogers, Star Scott, and Oren Kleinberger for laboratory assistance. We also thank two anonymous reviewers for comments on the manuscript.

ATTRACTION OF THE PARASITOID *Anagrus nilaparvatae* TO RICE VOLATILES INDUCED BY THE RICE BROWN PLANTHOPPER *Nilaparvata lugens*

YONG-GEN LOU,* BO MA, and JIA-AN CHENG

Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China

(Received January 30, 2005; revised May 3, 2005; accepted June 3, 2005)

Abstract—*Anagrus nilaparvatae*, an egg parasitoid of the rice brown planthopper *Nilaparvata lugens*, was attracted to volatiles released from *N. lugens*-infested plants, whereas there was no attraction to volatiles from undamaged plants, artificially damaged plants, or volatiles from *N. lugens* nymphs, female adults, eggs, honeydew, and exuvia. There was no difference in attractiveness between plants infested by *N. lugens* nymphs or those infested by gravid females. Attraction was correlated with time after infestation and host density; attraction was only evident between 6 and 24 hr after infestation by 10 adult females per plant, but not before or after. Similarly, after 24 hr of infestation, wasps were attracted to plants with 10 to 20 female planthoppers, but not to plants with lower or higher numbers of female planthoppers. The attractive time periods and densities may be correlated with the survival chances of the wasps' offspring, which do not survive if the plants die before the wasps emerge. Wasps were also attracted to undamaged mature leaves of a rice plant when one of the other mature leaves had been infested by 10 *N. lugens* for 1 d, implying that the volatile cues involved in host location by the parasitoid are systemically released. Collection and analyses of volatiles revealed that 1 d of *N. lugens* infestation did not result in the emission of new compounds or an increase in the total amount of volatiles, but rather the proportions among the compounds in the blend were altered. The total amounts and proportions of the chemicals were also affected by infestation duration. These changes in volatile profiles might provide the wasps with specific information on host habitat quality and thus could explain the observed behavioral responses of the parasitoid.

Key Words—Host location, induced plant volatiles, rice, *Anagrus nilaparvatae*, *Nilaparvata lugens*, tritrophic interactions.

INTRODUCTION

Herbivore-induced plant volatiles play a role in foraging behavior of predators and parasitoids of herbivores (Turlings et al., 1990; Takabayashi and Dicke, 1996; Sabelis et al., 1999; Dicke, 1999; Bertschy et al., 2001; Lou et al., 2002), and thus these volatiles are suggested to function as an indirect defense for plants (Vet and Dicke, 1992; Dicke, 1999; Sabelis et al., 1999; Turlings and Wäckers, 2004). So far, this phenomenon of indirect defense signaling has been reported in more than 23 plant species. It has been particularly well studied for corn, lima bean, cotton, and tobacco. In rice, a model monocot cereal species and one of the most important food crops in the world, however, few studies have examined the role of herbivore-induced volatiles in host or prey location by natural enemies of herbivores.

Nilaparvata lugens (Stål) is an important rice pest worldwide. It feeds on phloem sap, causing major physiological stress to the plant (Rubia-Sanchez et al., 1999; Watanabe and Kitagawa, 2000). Compared to chewing herbivores, sucking feeders that have been studied in the context of tritrophic interactions appear to cause only minor changes in volatile emissions, but these emissions are apparently used by natural enemies (Du et al., 1998; Turlings et al., 1998a; Birkett et al., 2003). Possible changes in volatiles profiles resulting from planthopper infestation have not yet been studied for any plant. In this study, we investigated the role of volatiles induced by the rice brown planthopper *N. lugens* in the host-searching behavior of *Anagrus nilaparvatae* Pang et Wang, an egg parasitoid of *N. lugens*. The parasitoid *A. nilaparvatae* is a major natural enemy of rice planthoppers, including *N. lugens* (Cheng and He, 1996). For host location, the wasp uses contact kairomones that are present in all developmental stages of the planthoppers as well as in their exuvia and honeydew (Lou and Cheng, 1994; Lou and Cheng, 2001), but volatiles released from hosts and by-products seem to have no attractiveness (Lou and Cheng, 1994). However, the volatiles emitted from planthopper-infested rice plants significantly attract the parasitoid (Lou and Cheng, 1996a). Nothing is known about the nature of these volatiles.

To elucidate the role of *N. lugens*-induced rice volatiles in the host-searching behavior of the parasitoid, we first measured the behavioral response of the parasitoid to the volatiles emitted from unmanipulated plants, artificially damaged plants, planthopper-infested plants, planthopper-damaged plants (planthoppers removed), as well as to volatiles from planthoppers alone or their by-products. Then, we checked the effect of infestation duration and planthopper density on attraction of the parasitoid. In an additional olfactometer experiment, it was shown that the volatiles are released systemically. Finally, we collected and identified the volatiles that were released from differently treated plants.

METHODS AND MATERIALS

Plants. The rice variety used was Zhe 852, which is susceptible to *N. lugens* (Lou and Cheng, 2003). Pregerminated seeds were sown in a greenhouse, and after 20 d, seedlings were transplanted into clay pots (16 cm diam × 10 cm height), each with 10 plants. Plants were watered daily, and each pot was supplied with 0.10 g of urea 10, 20, and 30 d after transplanting, respectively. All plants were placed in a controlled climate room that was maintained at 28 ± 2°C, 70–80% r.h., and 12 hr photophase. Thirty to 35 d after transplanting, plants were used for experiments. Plantings were continued at regular intervals so that enough plants of suitable age were available for experiments.

Insects. The *N. lugens* culture was originally obtained from the China National Rice Research Institute (CNRRI), Fuyang, Zhejiang, and maintained on Zhe 852 rice plants in a greenhouse. Late instar nymphs of *N. lugens* were captured from the greenhouse and reared on potted Zhe 852 rice plants, which were confined in plastic cages (11 cm diam × 40 cm high). Caged rice plants were maintained in a controlled climate room at 28 ± 2°C, 12 hr photophase, and 70–80% r.h. Newly emerged adults of *N. lugens* were collected daily and fed on potted fresh Zhe 852 rice plants. Using this procedure, we obtained *N. lugens* adults of uniform age.

A laboratory colony of the egg parasitoid *A. nilaparvatae* was started from individuals trapped in rice fields in Hangzhou, using Zhe 852 rice plants with *N. lugens* eggs as bait. The colony was propagated on *N. lugens* eggs in rice shoots enclosed in glass tubes (2.5 cm diam × 20 cm high), which were kept in a controlled climate room at 26 ± 2°C, 12 hr photophase, and 70–80% r.h. Each day the newly emerged wasps were collected into clean glass tubes with access to both water and honey solution and held for at least 2 hr to ensure mating. From the second generation onwards, female parasitoids were used in experiments less than 24 hr after emergence.

Bioassays. Responses of *A. nilaparvatae* females to rice volatiles were measured in a Y-tube olfactometer, which was described in detail by Lou et al. (2005). Briefly, the olfactometer consisted of a Y-shaped glass tube of 1 cm diam. The base and the two arms of the Y tube were all 10 cm in length. Each arm was connected to an odor source container (a glass box, 10 cm long, 10 cm wide, 30 cm high). An airstream was generated and divided in two, and each secondary airstream was led through a flowmeter, a tube with activated charcoal, a humidifier bottle, and one of the odor containers. Subsequently, the two airstreams were led through the two arms of the Y-tube olfactometer at 150 ml/min. The Y-tube olfactometer was placed in a box painted white with an artificial light source consisting of a single 25-W lamp placed above the arms of the Y tube. All bioassays were conducted between 0900 and 1700 hours, and the temperature in the room was maintained at 25–28°C.

Mated female parasitoids were introduced individually into the base tube of the olfactometer and given 10 min to walk toward the end of one of the arms. Choice for an odor source was defined as a female crossing a line 7 cm after the division of the base tube and remaining there for at least 1 min. If a parasitoid did not make a choice within 10 min, this was recorded as no response. For each odor source pair, at least 32 females were tested.

Response of A. nilaparvatae Toward Plant–N. lugens Complexes and Their Individual Components. In this experiment, the following odor sources were prepared:

1. Plant–*N. lugens* gravid female complex (PF). The potted plants were washed with running water and trimmed to leave 10 plants per pot. Plants were then individually infested with 10 gravid *N. lugens* females that were attached to the upper and lower position of the plant stems by using two parafilm bags, each with five females. One d later, the 10 plants (cut off at soil level and the cut end wrapped with a piece of moist cotton) with 100 females were used as an odor source for bioassays.
2. Plant–*N. lugens* nymph complex (PN). This treatment was nearly the same as in treatment (1). The only difference was that we used 4th–5th instar nymphs of *N. lugens* instead of gravid females.
3. *N. lugens* gravid female-damaged plants (FDP). This treatment was the same as in treatment (1), but 1 day after infestation, we removed the females and used the 10 plants, which now carried eggs, as an odor source for bioassays.
4. *N. lugens* nymph-damaged plants (NDP). The treatment was the same as in treatment (2), but 1 d after infestation, nymphs were removed and 10 plants were used as an odor source.
5. Mechanically damaged plants (MP). Ten plants were individually damaged with a needle at the lower and upper position of the stems by pricking each 150 times at the start of the experiment. Twenty-four hr later, the plants were damaged again using the same method and then were cut off at soil level and used as one odor source.
6. Unmanipulated plants (CP). Ten plants were cut off at soil level and served as one odor source.
7. *N. lugens* exuvia and honeydew. Exuvia and honeydew were collected from five glass tubes (2.5 cm diam $\times$ 20 cm) in which, for 24 hr, 20 4th–5th instar nymphs had been feeding on two rice plants that had been hung upside down, with their roots wrapped in wet cotton. Honeydew in the glass tubes was collected with a syringe, and the exuvia with forceps. Honeydew or exuvia was placed on a small piece of filter paper (3 $\times$ 3 cm) as an odor source.

8. *N. lugens* eggs. Ten plants were individually infested with 10 gravid N. lugens females. One day later, plants were cut at soil level and dissected under a microscope. All eggs were then carefully collected with a pin and placed on a small piece of filter paper (3 × 3 cm) as an odor source.
9. *N. lugens* nymphs and female adults. One hundred 4th–5th instar nymphs and female adults were individually collected and then used as odor sources.

The behavioral response of the parasitoid to the following pairs of odors were tested in the olfactometer: (1) blank control (BK) vs. CP, MP, PF, PN, NDP, or FDP, respectively; 2) PF vs. CP, MP, or PN, respectively; 3) PN vs. CP, or MP, respectively; and 4) BK vs. *N. lugens* exuvia, *N. lugens* eggs, *N. lugens* nymphs, *N. lugens* gravid females, or *N. lugens* honeydew, respectively.

Effect of Host Density and Infestation Duration on Attraction of A. nilaparvatae. In this experiment, we determined whether the duration of infestation or planthopper density had an effect on parasitoid attraction, using plant–female complexes infested with 1, 5, 10, 20, 40, or 80 gravid females per plant for 1 d. Plants without *N. lugens* served as controls. We used 10 plants per treatment.

To assess the effect of the duration of infestation, olfactometer tests were performed at 1, 2, 6, 12, 24, 48, and 72 hr after the plants had been infested by *N. lugens*. Each plant was infested with 10 gravid females and 10 plants were used per treatment. Plants without *N. lugens* served as controls.

Response of A. nilaparvatae to Undamaged Leaves of Infested Plants. In this experiment, we determined whether the *N. lugens*-induced rice volatiles were produced systemically and whether the infested leaf position had an effect on the attraction of the parasitoid to uninfested leaves. Plants with four fully expanded leaves, which were respectively assigned first, second, third, and fourth leaf position from the top to the base, were chosen. The uninfested leaves including leaf sheaths were individually collected and used for bioassay in a Y-tube olfactometer 24 hr after one of the fully expanded leaves (the first, second, third, or fourth leaf position) of plants was infested with 10 gravid *N. lugens* females who were fixed on the middle veins of the leaves by using two parafilm bags, each with five females. For example, if the first leaves of 10 plants had been infested by *N. lugens*, then we measured the response of the parasitoid to the volatiles released from either the second, third, or fourth leaves of the 10 plants, respectively. The corresponding leaves from uninfested plants (with two empty parafilm bags per plant at the same positions as the infested plants) served as controls.

Collection and Identification of Rice Volatiles. Rice volatiles were collected for 2 hr by using solid-phase microextraction (SPME, Supelco Co., Bellefonte, PA, USA) with a silica fiber coated with a 100-μm-thick film of

polydimethylsiloxane. For each treatment, 10 plants were used. The plant was cut off at soil level, and the cut part of the stem was wrapped in a piece of moist cotton to avoid desiccation. Ten plants were placed in a glass cylinder (5 cm diam × 30 cm), which was covered by a glass lid (5 cm diam) with a hole (1 mm diam) through which the SPME fiber was inserted for odor collection. The volatiles emitted from the following treatments were collected: plants that had been individually infested by 10 gravid *N. lugens* females for 1, 2, or 3 d, respectively; plants that had been individually infested by 10 *N. lugens* nymphs for 1 d; mechanically damaged plants (MP); and unmanipulated plants. We also collected volatiles from a control, (the glass cylinder without plants) to confirm that the system was clean. Each treatment was replicated three times. The experiment was conducted in a room at 26–28°C. After collecting each sample, the cylinder was rinsed with an acidic washing solution ($K_2Cr_2O_7$ 60 g/98% H_2SO_4 460 ml/H_2O 300 ml Caution! Highly corrosive!) followed by distilled water and then heated at 200°C for 1 hr. The SPME fiber was desorbed in a GC injector at 250°C for 15 min before use.

Analyses were done with a Hewlett-Packard (HP) 6890A gas chromatograph (GC) equipped with an HP-5 (30 m × 0.25 mm i.d., 0.25 μm film thickness) column. Volatile compounds collected on the SPME fiber were directly desorbed in the GC injector at 250°C for 1 min, in splitless mode. Following injection, the column was programmed from 40°C/2 min, 6°C/min to 250°C, hold for 2 min. Helium (1 ml/min) was used as the carrier gas. All compounds were analyzed by an HP 5970B mass spectrometer in the electron impact ionization mode. Compounds were identified by comparison of retention times and mass spectra with those of authentic standards. The authentic standard chemicals (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, limonene, cyclohexanol, linalool, β-cyclocitral, 1-undecene, *n*-tetradecane, *n*-hexadecane, dodecanal, *n*-heptadecane, *n*-octadecane, *n*-nonadecane, *n*-eicosane, and *n*-henicosane were purchased from Sigma Chemical (St. Louis, MO, USA); tetradecanal was purchased from ChemExper, Belgium. The relative proportions of the compounds in the blend were calculated according to their peak areas.

Statistical Analysis. Differences in behavioral responses of the parasitoid to pairs of odors were determined by χ^2 tests. Volatiles data were analyzed by ANOVA. If the ANOVA analysis was significant ($P < 0.05$), Fisher LSD *post hoc* tests to detect significant differences between groups were conducted. Data were analyzed with Statistica (SAS Institute Inc., Cary, NC, USA).

RESULTS

Response of A. nilaparvatae Toward Plant–N. lugens Complexes and Their Individual Components. Volatiles released from unmanipulated plants and

mechanically damaged plants were no more attractive to the parasitoid than blank controls, whereas the volatiles from plant–*N. lugens* complexes (PF, PN), and *N. lugens*-damaged plants (FDP, NDP) were attractive (Figure 1). The plant–*N. lugens* complexes were also more attractive than unmanipulated plants or mechanically damaged plants. No difference was observed in attraction of the parasitoid to volatiles emitted from plant–nymph complex and those from plant–gravid female complex (Figure 1).

The parasitoid was not attracted to the volatiles released from *N. lugens* materials, including *N. lugens* nymphs, female adults, eggs, honeydew, or exuvia (Figure 2).

Effect of Host Density and Infestation Duration on Attraction of A. nilaparvatae. N. lugens density had a significant effect on attraction of the parasitoid (Figure 3B). Plants that had been infested with 10 or 20 gravid females per plant for 1 d were more attractive than unmanipulated plants, whereas plants that were infested with 1, 5, 40, or 80 gravid females per plant were no different from uninfested plants (Figure 3B).

There was a similar effect of duration of infestation on the attraction of the parasitoid (Figure 3A). Plants that had been infested with 10 gravid *N. lugens* females for 6–24 hr were more attractive to the parasitoid than unmanipulated

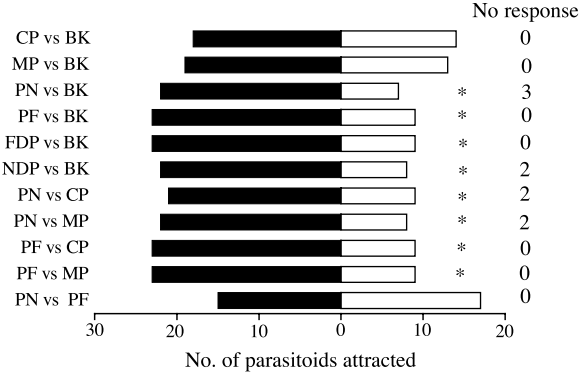

FIG. 1. Numbers of *A. nilaparvatae* adult females attracted by volatiles released from pairs of odors: Unmanipulated plants (CP) vs. blank control (BK); mechanically damaged plants (MP) vs. BK; *N. lugens* nymph–plant complex (PN) (infested for 1 d) vs. BK; *N. lugens* gravid female–plant complex (PF) (infested for 1 d) vs. BK; *N. lugens* gravid female-damaged plants (FDP) (females removed 1 d after infestation) vs. BK; *N. lugens* nymph-damaged plants (NDP) (nymphs removed 1 d after infestation) vs. BK; PN vs. CP; PN vs. MP; PF vs. CP; PF vs. MP; and PN vs. PF. For explanation of treatments and methodology see "Methods and Materials." Asterisks indicate significant differences between members of a pair ($P < 0.05$, χ^2 test).

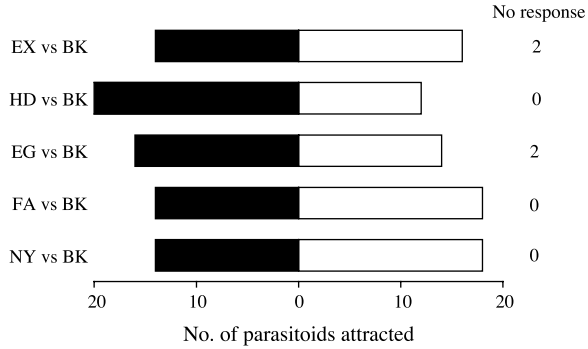

FIG. 2. Number of *A. nilaparvatae* adult females attracted by volatiles released from pairs of odors: *N. lugens* exuvia (EX) vs. blank control (BK); *N. lugens* honeydew (HD) vs. BK; *N. lugens* eggs (EG) vs. BK; *N. lugens* female adults (FA) vs. BK; and *N. lugens* nymphs (NY) vs. BK.

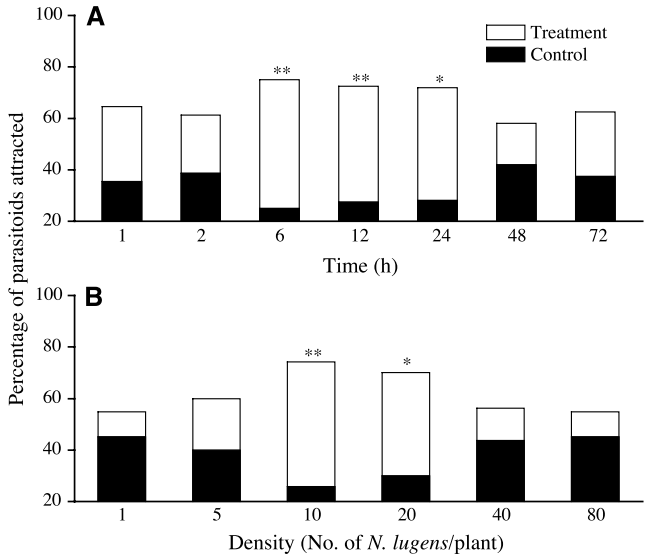

FIG. 3. Percentage of *A. nilaparvatae* adult females attracted by volatiles released from pairs of odors: unmanipulated plants (Control) vs. (A) plants that were individually infested by 10 *N. lugens* gravid females for 1, 2, 6, 12, 24, 48, or 78 hr (Treatment); (B) plants that were individually infested with 1, 5, 10, 20, 40, or 80 *N. lugens* gravid females for 1 d (Treatment). Asterisks indicate significant differences between members of a pair (*$P < 0.05$, **$P < 0.01$, χ^2 test).

plants, but plants that had been infested with 10 gravid *N. lugens* gravid females for a shorter (1–2 hr) or longer time (48–72 hr) were no different than uninfested plants (Figure 3A).

Response of A. nilaparvatae to Undamaged Leaves of Infested Plants. Infestation of one of the fully expanded leaves by *N. lugens* resulted in an increase in attractiveness of the other three undamaged leaves, and the leaf position that was infested by *N. lugens* had no effect on this attractiveness (Figure 4).

Volatiles Profile Comparisons. More than 20 compounds were collected from the headspace of rice plants by SPME, 16 of which were identified, including 8 aliphatic hydrocarbons, 3 aldehydes, 3 terpenoids, and 2 alcohols (Table 1). Of these compounds, aliphatic hydrocarbons, specifically 7 aliphatic hydrocarbons, dominated the blends, comprising more than 48% of the total peak areas of compounds emitted in every assay (Table 1). In addition, two green leafy volatiles, (*E*)-2-hexenal and (*E*)-2-hexen-1-ol, as well as tetradecanal and unknowns 1, 3, and 4 were also relatively abundant in the headspace of the rice plants (Table 1).

Compared to unmanipulated plants, *N. lugens* infestation did not induce rice plants to release new compounds, nor did the total amount of volatiles

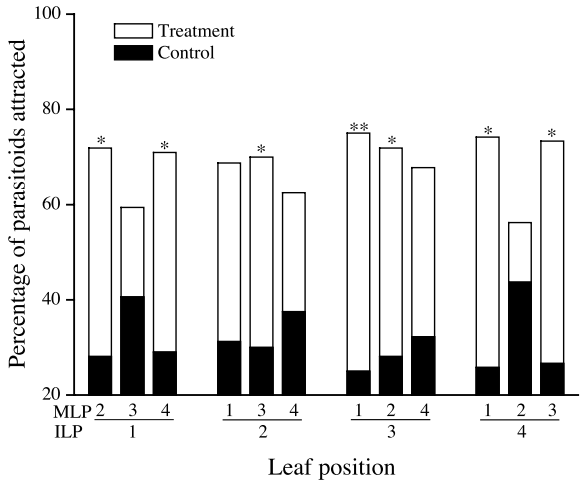

FIG. 4. Percentage of *A. nilaparvatae* female adults attracted by volatiles released from pairs of leaves: undamaged individual leaves, growing at positions 1–4, of 10 damaged plants on which a single leaf, at position 1–4, was infested with 10 *N. lugens* gravid females for 24 hr (Treatment) vs. the same leaves of unmanipulated plants (Control). MLP, measured leaf position; ILP, infested leaf positions. Asterisks indicate significant differences between members of a pair (*$P < 0.05$, **$P < 0.01$, χ^2 test).

change with duration of infestation (Table 1). However, *N. lugens* infestation altered the proportions of chemicals in the blend (Table 1). Compared to unmanipulated plants, *N. lugens*-infested plants (infested for 1 d) had a higher proportion of *n*-heptadecane and lower proportions of (*E*)-2-hexen-1-ol, cyclohexanol, *n*-octadecane, *n*-nonadecane, and *n*-eicosane. Moreover, 1 d of nymph infestation increased the proportions of (*E*)-2-hexenal and unknown 3 (Table 1). With duration of *N. lugens* infestation, the proportions of dodecanal, linalool, and unknown 4 increased, whereas the proportions of *n*-nonadecane, *n*-eicosane, and *n*-henicosane decreased (Table 1). Between the volatiles emitted from *N. lugens* nymph-infested plants and those from gravid female-infested plants, there was no significant difference except for the chemicals (*E*)-2-hexenal and unknown 3, both of which were released in higher proportions by nymph-infested plants (Table 1).

Mechanical damage resulted in no increase in the total volatiles compared to unmanipulated plants. However, the total volatiles released from mechanically damaged plants were higher than those from plants infested by *N. lugens* for 2–3 d (Table 1). The proportions of chemicals that decreased after *N. lugens* infestation did not decrease after artificial damage, except for the chemicals *n*-octadecane, *n*-nonadecane, *n*-eicosane, and *n*-henicosane (Table 1).

DISCUSSION

A. nilaparvatae was attracted to volatiles released from *N. lugens* plant complexes (damaged for 1 d), but not to those from unmanipulated plants or artificially damaged plants. Wasps also were not attracted to volatiles from *N. lugens* nymphs, female adults, eggs, honeydew, or exuvia. Moreover, no obvious difference was observed in attraction between *N. lugens* nymph–plant complex and gravid female–plant complex. These results were similar to those observed in a tritrophic system consisting of the phloem feeder *Phenacoccus herreni*, cassava, and an encyrtid parasitoid (Bertschy et al., 2001). This suggests that volatiles induced by *N. lugens* feeding on rice are used in host location by *A. nilaparvatae*, as has been reported for many parasitoids of insect larvae (Dicke and Vet, 1999; Turlings and Wäckers, 2004). *Nilaparvata lugens* is an insect pest with completely overlapping generations; all developmental stages can co-occur in the same plant and field. Therefore, the indirect association of *N. lugens* feeding with egg presence is reliable, suggesting that the response of the parasitoid to *N. lugens* feeding-induced volatiles is adaptive.

Anagrus nilaparvatae females were not attracted to volatiles from undamaged rice plants. It is commonly reported that healthy plants are unattractive to parasitoids (Turlings et al., 1990; Guerrieri et al., 1993; Potting

et al., 1995; Finidori-Logli et al., 1996; Du et al., 1996; Steidle and Schöller, 1997), which may be attributed to the minor amounts of volatiles released by healthy plants or the low reliability of such volatiles in informing the parasitoid of host presence (Vet et al., 1991; Vet and Dicke, 1992). Volatiles released by artificially damaged plants, such as green leaf volatiles, are often attractive to parasitoids (Turlings et al., 1990; Steinberg et al., 1993; Geervliet et al., 1994; Mattiacci et al., 1994; Potting et al., 1999; Hoballah and Turlings, 2005). Here, however, artificially damaged rice plants were not attractive to *A. nilaparvatae* females possibly because the limited amount of damage resulted in only minor changes to the green leafy volatiles (*E*)-2-hexen-1-ol and (*E*)-2-hexenal.

Nilaparvata lugens infestation for 1 d did not result in detectable production of new compounds, nor was there an increase in the total amount of volatiles compared to controls. However, infestation did alter the relative proportions among the volatiles compared to undamaged and artificially damaged plants. Thus, *N. lugens* infestation appears to alter the plant volatiles profile only slightly, which may be common for phloem feeders and is in contrast to the substantial induction caused by tissue feeders. For instance, Turlings et al. (1998a) found that the aphid *Rhopalosiphum maidis* induced no measurable emissions of volatiles in maize, even after heavy infestation, whereas feeding by caterpillars caused major increases in the volatile emissions. Similarly, infestation by the silverleaf whitefly *Bemisia tabaci* did not appear to induce volatiles emissions in cotton (Rodriguez-Saona et al., 2003). Phloem-sucking insects, such as rice planthoppers and aphids, inflict only minor physical damage to host plants, which is likely to reduce the chances of triggering a physiological reaction in the plant (Turlings et al., 1998a). Quantitative (amount) (e.g., apple fruit, Hern and Dorn, 2001) and/or qualitative changes (production of new compounds or changes in proportions) (e.g., maize, Turlings et al., 1990) in volatiles from plants in response to herbivory have been reported in many plant–herbivore systems, providing exploitable cues for parasitoids (Dicke, 1999; Gouinguené et al., 2001). The attraction of *A. nilaparvatae* females to *N. lugens*-infested plants is best explained by a change in the proportions among the volatiles, a qualitative change.

Systemic release of herbivore-induced volatiles in plants has been reported in many plant species (Turlings and Tumlinson, 1992; Dicke et al., 1993; Cortesero et al., 1997; Guerrieri et al., 1999; Halitschke et al., 2000; Neveu et al., 2002; Röse and Tumlinson, 2004). We too found an attraction of the parasitoid to the undamaged leaves of plants in which one of the mature leaves had been infested by *N. lugens* for 1 d. Wasps were similarly attracted to undamaged, mature leaves of plants that had been damaged by *N. lugens* on another leaf. Although the mature leaves of plants mainly export their photoassimilates to roots and younger leaves (sinks) via the phloem, a solute

exchange does occur between the phloem and the xylem (Fisher, 2000). Thus, the wound signal from infested mature rice leaves may reach other undamaged mature leaves via the xylem, eliciting the undamaged leaves to release volatiles.

We also studied the effect of host density and infestation duration on attraction of *A. nilaparvatae*, and both had a significant effect. The degree of attraction of the parasitoid and the *N. lugens* density or the infestation duration did not fit a dose related positive relationship as reported in other studies (Turlings et al., 1990; Gols et al., 2003), but rather reached a maximum at intermediate densities, with no attraction at low or very high infestations. A similar effect was found for the duration of infestation; wasps were not attracted early on, but attraction was strong after 6–24 hr of infestation, and then declined after 48 hr. The time lag for the induction of volatiles attractive to parasitoids has also been observed in other studies (Turlings et al., 1998b; Guerrieri et al., 1999), suggesting the involvement of active physiological and biochemical processes that result in changes in volatile profiles. A threshold for damage level has also been reported for the attraction of an aphid parasitoid to broad bean plants infested with varying aphid densities (Powell et al., 1998; Guerrieri et al., 1999), as well as for induced direct resistance in plants (Karban and Baldwin, 1997; Lou and Cheng, 1997). These results suggest that an adequately strong elicitation signal is needed for the induction of direct and indirect resistance.

The decline in attraction of the parasitoid to plants that had been infested by either 10 *N. lugens* females for 2–3 d or 30–40 females for 1 d may be related to the survival chances of the parasitoid offspring. *Nilaparvata lugens* feeds and oviposits on the same plant even if plants are heavily damaged. Heavy damage in the field by 50–90 female adults per hill (about 20 plants) causes susceptible plants to wilt and eventually die after ~10 d (Li et al., 1996). The parasitoid spends 9–10 d in the host egg before it emerges as an adult at appropriate temperatures of 25–28°C (Lou and Cheng, 1996b), and developing wasps may die due to desiccation if the plant dies before parasitoid emergence. This may explain the declining response with increasing levels of plant damage. Discrimination between heavily and lightly damaged plants may be possible due to the differences in volatile profiles. For example, volatiles released from plants that were infested by 10 females for 1 d showed lower proportions of unknown 4 and higher proportions of *n*-nonadecane, *n*-eicosane, and *n*-henicosane compared to plants that were infested by 10 females for 2–3 d. These differences could provide important cues on the profitability status of the plants for the parasitoid. To our knowledge, this is the first study to report a decrease in attractiveness in tritrophic interactions after heavy herbivore infestation. The possible adaptive value of the lack of response to heavily infested plants may warrant further investigation.

Acknowledgments—We thank Menghao Du, Guoxin Zhou, Xia Wang, and Bailu Liao for assistance with laboratory work and Ted Turlings for revising the manuscript. The study was sponsored by the Ministry of Science and Technology of China (973) (G2000016208) and the National Natural Science Foundation of China (30270233).

ROQUEFORTINE/OXALINE BIOSYNTHESIS PATHWAY METABOLITES IN *Penicillium* SER. *Corymbifera*: *IN PLANTA* PRODUCTION AND IMPLICATIONS FOR COMPETITIVE FITNESS

D. P. OVERY,* K. F. NIELSEN, and J. SMEDSGAARD

Center for Microbial Biotechnology, Technical University of Denmark, BioCentrum-DTU, Building 221, DK-2800 Kgs. Lyngby, Denmark

(Received March 5, 2005; accepted May 18, 2005)

Abstract—Three strains of each of the seven taxa comprising the *Penicillium* series *Corymbifera* were surveyed by direct injection mass spectrometry (MS) and liquid chromatography–MS for the production of terrestric acid and roquefortine/oxaline biosynthesis pathway metabolites when cultured upon macerated tissue agars prepared from *Allium cepa*, *Zingiber officinale*, and *Tulipa gesneriana*, and on the defined medium Czapek yeast autolysate agar (CYA). A novel solid-phase extraction methodology was applied for the rapid purification of roquefortine metabolites from a complex matrix. *Penicillium hordei* and *P. venetum* produced roquefortine D and C, whereas *P. hirsutum* produced roquefortine D and C and glandicolines A and B. *P. albocoremium*, *P. allii*, and *P. radicicola* carried the pathway through to meleagrin, producing roquefortine D and C, glandicolines A and B, and meleagrin. *P. tulipae* produced all previously mentioned metabolites yet carried the pathway through to an end product recognized as *epi*-neoxaline, prompting the proposal of a roquefortine/*epi*-neoxaline biogenesis pathway. Terrestric acid production was stimulated by all *Corymbifera* strains on plant-derived media compared to CYA controls. *In planta*, production of terrestric acid, roquefortine C, glandicolines A and B, meleagrin, *epi*-neoxaline, and several other species-related secondary metabolites were confirmed from *A. cepa* bulbs infected with *Corymbifera* strains. The deposition of roquefortine/oxaline pathway metabolites as an extracellular nitrogen reserve for uptake and metabolism into growing mycelia and the synergistic role of terrestric

acid and other *Corymbifera* secondary metabolites in enhancing the competitive fitness of *Corymbifera* species *in planta* are proposed.

Key Words—*Penicillium* ser. *Corymbifera*, roquefortine C, glandicoline A, glandicoline B, meleagrin, *epi*-neoxaline, terrestric acid, *Allium cepa.*

INTRODUCTION

Taxa of the *Penicillium* ser. *Corymbifera* are pathogenic agents causing blue mold storage rot upon a variety of flower and vegetable bulbs (Saaltink, 1971; Prince et al., 1988; Vincent and Pitt, 1989; Bertolini and Tian, 1996; Filtenborg et al., 1996), especially *Allium cepa* (onion) (Overy et al., 2005a). Seven species are recognized within the ser. *Corymbifera*: *P. albocoremium* (Frisvad) Frisvad, *P. allii* Vincent and Pitt, *P. hirsutum* Dierckx, *P. hordei* Stolk, *P. radicicola* Overy and Frisvad, *P. tulipae* Overy and Frisvad, and *P. venetum* (Frisvad) Frisvad. Extracellular enzyme profiling of the series demonstrated that all of the *Corymbifera* (with the exception of *P. hordei*) produce high levels of cellulase and hemicellulases compared to other *Penicillia*, but do not excrete extracellular proteases (Overy et al., 2005b). The *Corymbifera* extracellular enzymatic profile corresponds to the composition of *A. cepa* cells (high levels of cellulose, hemicellulose, and pectin with only a 1% protein content per cell dry weight; Mankarios et al., 1980; Séné et al., 1994), indicating that *A. cepa* bulbs are an ideal ecological niche for these specialized fungal invaders. An exception to this is *P. hordei*, which produces moderate levels of proteases (Overy et al., 2005b), reflecting this species' known association with cereal grains.

The *Corymbifera* species are reported to produce the alkaloids roquefortine C and sometimes meleagrin (Frisvad and Filtenborg, 1989; Overy and Frisvad, 2003); however, the extent to which each of the taxa produce intermediates of the roquefortine/oxaline (r/o) biosynthesis pathway (Figure 1) has not been evaluated for the series. Roquefortine C is a diketopiperazine, synthesized from tryptophan, histidine, and dimethylallyl pyrophosphate (Ohmomo et al., 1979). Both dehydrohistidyl–tryptophanyl–diketopiperazine and 3,12-dihydroroquefortine (roquefortine D) are known precursors to roquefortine C (Kozlovsky et al., 1996). C^{14} labeling experiments by Reshetilova et al. (1995) have demonstrated that roquefortine C is a precursor to glandicolines A and B (Kozlovsky et al., 1994), meleagrin (Kawai et al., 1984), and oxaline (Nagel et al., 1976), a series of biosynthetically related and structurally similar metabolites comprising the r/o biosynthesis pathway. A few reports of antibiotic activity (Kopp and Rehm, 1979) and neurotropic properties (Scott et al., 1976) of roquefortine C have prompted multiple studies into roquefortine production (Boichenko et al., 2002), uptake (Reshetilova et al., 1994; Kulakovskaya et al., 1997), and metabolism (Reshetilova and Kozlovsky, 1990).

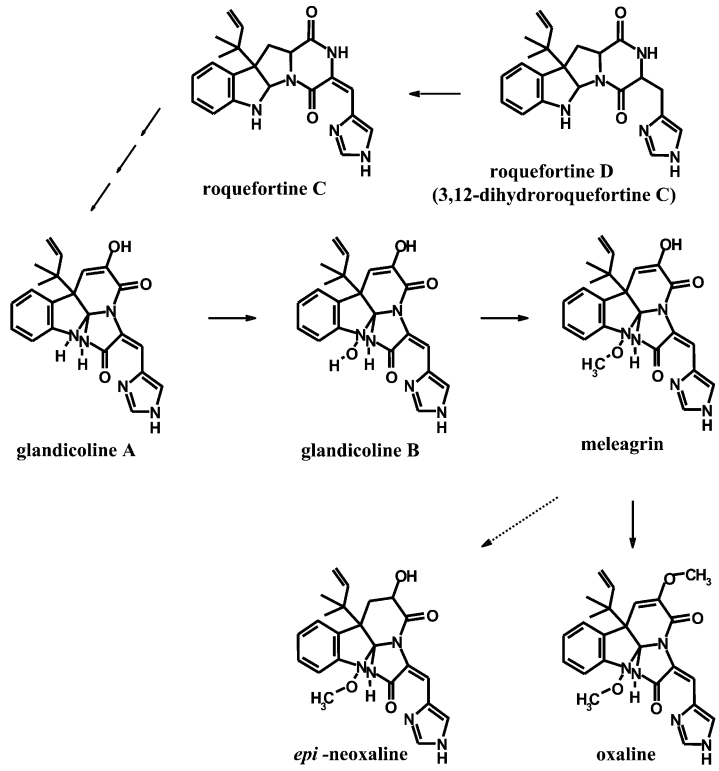

FIG. 1. Roquefortine/oxaline biosynthesis pathway as proposed by Reshetilova et al. (1995) and the proposed roquefortine/*epi*-neoxaline biogenesis pathway proposed for *Penicillium tulipae*.

The use of alkaloids as an exclusive, transportable nitrogen source has been previously proposed in plants (Wink, 2003), and we hypothesize that this strategy is also employed by fungi. Roquefortine C biosynthesis and excretion from fungal mycelia has been determined to be dependent upon the quantity of exogenous roquefortine C present in the surrounding media (Kulakovskaya et al., 1997). Additionally, ^{14}C-roquefortine C experiments demonstrated that roquefortine C was not only taken up by growing mycelia, but was also incorporated into protein and mycelial residues (Reshetilova et al., 1986, 1994; Reshetilova and Kozlovsky, 1990; Kulakovskaya et al., 1997). From *in vitro* experimentation on strains of *P. crustosum*, it was determined that transport of roquefortine C across the cellular membrane occurs via both energy-dependent and energy-independent processes (Reshetilova et al., 1994; Kulakovskaya

et al., 1997); thus, Kulakovskaya et al. (1997) proposed that roquefortine C may function as an extracellular nitrogen source for the producing organism.

Recent research efforts culturing ser. *Corymbifera* species upon host tissue-derived media have led to the stimulation and structure elucidation of a series of novel naphthalene lactones (Overy and Blunt, 2004). Preliminary investigation into the r/o biosynthesis pathway metabolites indicated that discrepancies in production might exist with the reported literature (Frisvad and Filtenborg, 1989). Media-dependent production of terrestric acid, a low molecular weight metabolite produced by five out of seven of the *Corymbifera* species, has also been observed (unpublished results). We conducted experiments testing the degree to which stimulation of the r/o biosynthesis pathway metabolites and terrestric acid occurs when *Corymbifera* strains are grown on plant-based media. To facilitate analysis of r/o metabolites from complex matrices, a preferential solid-phase extraction (SPE) methodology was applied. Subsequent *in planta* studies using the common host *A. cepa* (yellow onion) were carried out (1) to see if production of terrestric acid, the r/o pathway metabolites, and additional secondary metabolites, associated with the *Corymbifera* strains occurred, and (2) to suggest an ecological, synergistic function for these metabolites *in planta*.

METHODS AND MATERIALS

Fungal Isolates. The following isolates were revived from IBT culture collection (BioCentrum-DTU, Kgs. Lyngby, Denmark) and streak plated on Czapek yeast autolysate agar (CYA) to ensure purity: *P. albocoremium* (Frisvad) Frisvad (IBT 21502, IBT 22521, IBT 21071), *P. allii* Vincent and Pitt (IBT 3772, IBT 4112, IBT 21503), *P. hirsutum* Dierckx (IBT 12398, IBT 13033, 19340), *P. hordei* Stolk (IBT 4154, IBT 21532, IBT 23024), *P. radicicola* Overy and Frisvad (IBT 10693, IBT 10696, IBT 22526), *P. tulipae* Overy and Frisvad (IBT 3458, IBT 10676, IBT 10681), and *P. venetum* (Frisvad) Frisvad (IBT 22111, IBT 23039, IBT 23040). Spore suspensions of each isolate were then prepared by removing a loopful of conidia from axenic cultures into a semisolid medium (for media recipes, see Frisvad and Samson, 2004) and vortexed.

Preparation of Macerated Plant Tissue Agar. Plant tissue-based agars were prepared according to Overy and Blunt (2004). Bulbs of *A. cepa* (red and yellow onion) and *Tulipa gesneriana* (tulip) and tubers of *Zingiber officinale* (ginger) were inspected for symptoms of infection, and healthy tissue was selected and individually macerated in a blender. The macerate was transferred into weighed 2-l screw cap bottles, and deionized water was added to yield a

40% slurry (w/v) to which agar was added (2%; w/v). The mixture was autoclaved at 121°C for 20 min and then poured into 9-mm Petri dishes (15 ml/dish).

Strain Cultivation and Extraction. The selected ser. *Corymbifera* strains were three-point inoculated onto CYA and the various plant extract agar plates and incubated in darkness at 25°C for 14 d. Following this, colony extraction was divided into two parts. For metabolomic profiling by direct infusion electrospray mass spectrometry (Di-ESI-MS), three plugs were removed from each culture and individually extracted according to Smedsgaard (1997) [using a one-step extraction with ethyl acetate (EtOAc)]. For solid-phase extraction (SPE), an entire colony from one selected strain from each species (see Table 1) was removed in strips from the plate and inserted into 14-ml glass vials to which 8 ml of EtOAc were added. The vials were sonicated for 1 hr and the extraction solvent was subsequently decanted into clean 14-ml glass vials and evaporated *in vacuo* using a Christ rotational vacuum concentrator (RVC). The dry residues were dissolved in 2 ml of EtOAc, filtered through 0.45-μm PTFE filters to remove conidia and particulates, and evaporated to dryness under a stream of nitrogen in weighed glass vials. Selected extracts were subsequently dissolved in a volume of EtOAc to give the same concentration of raw extract, and a 1-ml subsample of the extract was dried down to be used for solid-phase extraction (equivalent to approx. 1 g of extract).

In Planta *Infection Trials.* Infection trials of *A. cepa* (yellow onion) bulbs and *Z. officinale* tubers were carried out using the selected ser. *Corymbifera* strains according to Overy et al. (2005a,b). Tubers and bulbs were purchased in

TABLE 1. SUMMARY OF SER. *corymbifera* SECONDARY METABOLITES PRODUCED *In Planta* IN INFECTED *A. cepa* BULBS[a]

Species	*In planta* secondary metabolite production
Penicillium albocoremium	Andrastin A, b. acid A, cyclopenin, gland A&B, meleagrin, roq C, viridicatin
Penicillium allii	Andrastin A, cyclopenin, fulvic acid, gland A&B, meleagrin, roq C, viridicatin
Penicillium hirsutum	Compactin, cyclopenin, gland A&B, roq C, terrestric acid, viridicatin
Penicillium hordei	Roq C (1/3), terrestric acid (1/3)
Penicillium radicicola	Andrastin A, cyclopenin, gland A&B, meleagrin, roq C, terrestric acid, viridicatin
Penicillium tulipae	Andrastin A, *epi*-neoxaline, gland A&B, meleagrin, roq C, terrestric acid
Penicillium venetum	Andrastin A, cyclopenin, roq C, terrestric acid, viridicatin

[a]Secondary metabolites were confirmed by LC-DAD-HR-MS analysis from EtOAc tissue extracts of three different species strains individually inoculated into separate *A. cepa* bulbs.

late spring and inspected for signs of damage or infection (bulbs had their outer skin removed). Tubers or bulbs exhibiting signs of damage or infection (this included physical damage, sunken lesions, brown spots, or visible rot) were discarded. Surface sterilization was done in three steps in a laminar flow bench: submerging in 96% ethanol for 1 min, then in a 3% hypochlorite solution for 1 min, and resubmerging in 96% ethanol for 1 min. Once dry, bulbs were inoculated with a spore suspension in the center of the basal root plate and tubers through the epidermis with a flame sterilized needle, and placed into perforated plastic bags, and incubated in the dark at 20°C. After 3 wk, explants approximately 2 cm^3, consisting of infected tissue displaying visible sporulation (including exposed conidiophores and hyphae), were removed to 14-ml screw cap vials to which 8 ml of EtOAc were added. Control samples were similarly prepared using visually uninfected tubers and bulbs. The vials were shaken on a rotary shaker for 2 hr, the extraction solvent subsequently decanted into clean 14-ml screw cap vials, and evaporated to dryness *in vacuo* prior to SPE.

To confirm the identity of the fungal cultures excised and extracted for analysis, tissue explants were removed from the infected tissues where sporulation was visible and placed onto Petri dishes containing CYA media (+chloramphenicol, 100 ppm). Petri dishes were then incubated in the dark at 25°C and monitored for 3–7 d. Colonies emerging from the tissue explants were transferred to streak plates from which purified cultures were three-point inoculated onto CYA and incubated in the dark at 25°C for 7 d for identification based upon colony characteristics and micromorphology.

Solid-Phase Extraction. Solid-phase extraction columns were packed with approximately 300 mg of Silica 60 (0.015–0.040 mm, Merck, Darmstadt, Germany) pressed between two disks of 3-mm Vyon sheet (porous high-density polyethylene, FilterServe, West Midlands, UK) in 2-ml disposable syringes. The columns were placed onto a vacuum manifold, wetted with 2 ml of MeOH, and conditioned with 2 ml toluene/EtOAc/formic acid (TEF, 5:4:1, v/v/v). Sample extracts were redissolved in 200 µl TEF and loaded onto the column. The loaded column was then washed with 3.5 ml of TEF (fraction 1) and then with 1.5 ml EtOAc/MeOH (1:1, v/v; fraction 2). The fractions were dried *in vacuo* and resuspended in MeOH for liquid chromatography–ultraviolet–mass spectrometry (LC-UV-MS) evaluation.

Time Scale Study. P. tulipae IBT 3458 was three-point inoculated onto 18 CYA plates and incubated in the dark at 25°C. Three plates were grown to 5, 6, 7, 8, 9, and 10 d. One colony was removed from each dish with a scalpel, further cut into 2- to 3-mm rectangles, transferred to a 16-ml vial, and shaken twice with 10 ml EtOAc for 1 hr. The EtOAc phases from the double extraction were combined, evaporated *in vacuo*, and redissolved in 1000 µl MeOH for LC-UV-MS analysis. From the culture plates, ten plugs (6 mm ID) were taken from

the agar outside the colonies, transferred into a 4-ml vial, and shaken twice with 3 ml EtOAc for 1 hr. The combined EtOAc phases were evaporated *in vacuo* and redissolved in 500 μl MeOH for LC-UV-MS analysis.

LC-UV-MS Analysis. Extracts fractionated by solid-phase extraction were filtered through a 0.45-μm PFTE syringe filter and analyzed by reversed-phase chromatography combined with photodiode array detection (DAD) and high-resolution mass spectrometry on an Agilent 1100 HPLC system (Agilent Technologies, Waldbronn, Germany) coupled to a LCT (Waters-Micromass, Manchester, UK) orthogonal *Time of Flight* mass spectrometer operated in the positive electrospray ionization (ESI^+) mode as described in detail by Nielsen and Smedsgaard (2003). Samples were separated on a Phenomenex Luna C_{18} (II) column (2×50 mm, with 3-μm particles) using a flow of 0.3 ml/min. A linear acetonitrile–water (AcN:H_2O) gradient system (starting at 15% AcN and increasing to 100% AcN over 20 min and holding for 5 min) was used to elute compounds from the column. The water (MilliQ) contained 10 mM ammonium formate and 20 mM formic acid (both analytical grade) and AcN (gradient grade) containing 20 mM formic acid.

Peaks, from UV and/or ESI^+ MS, excluding those found in negative controls, were matched against the Mycology reference standard database (~550 compounds; Nielsen and Smedsgaard, 2003). Metabolites not available as reference standards were dereplicated (tentatively identified) by UV spectra combined with high-resolution ESI^+ spectra as illustrated in Nielsen and Smedsgaard (2003), and matched against literature data of *Corymbifera* species and other *Penicillia* as well as Antibase 2003 (ca. 30,000 microbial secondary metabolites, Wiley & Sons, Hoboken, NJ, USA). ESI^+ spectra confirmed by deconvolution, v.s., by plotting ion traces of ions found in the background subtracted spectra of the peak of interest. Target analyses of selected metabolites, andrastin A, barceloneic acid A, cyclopenin, compactin, *epi*-neoxaline, fulvic acid, glandicolines A and B, meleagrin, roquefortine C, terrestric acid, viridicatin, and viridicatol, were performed by plotting their $[M+H]^+$ ions ± 0.01 Da.

Di-ESI-MS Fingerprinting Analysis. Plug extracts developed from each of the three selected strains of the ser. *Corymbifera* species grown on the various experimental media were additionally fingerprinted by using direct infusion positive ES-MS on a QTOF (Waters-Micromass) orthogonal quadrupolequad-rupole *Time of Flight* mass spectrometer. A constant flow of 15 μl methanol/min was delivered from an Agilent 1100 (Agilent Technologies), and 1 μl of sample was injected into the carrier stream. Just prior to the source, 5 μl/min of water with 2% formic acid were added, giving a combined flow of 20 μl/min entering the ESI source. Spectra were collected from 100 to 1000 Da/e, at a rate of 1 spectrum/sec. The scans collected during the elution time (about 15 scans) were summarized into one scan for further processing. As roquefortine C is produced

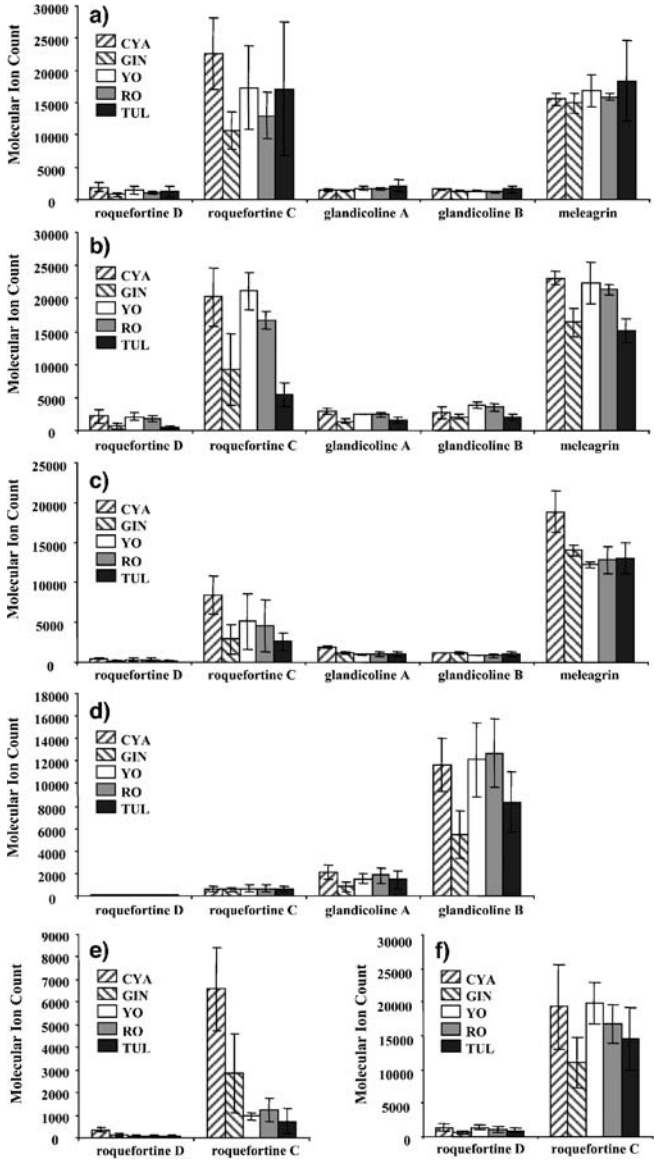

FIG. 2. Average molecular ion count calculated for roquefortine/oxaline biosynthesis pathway metabolites as produced by *Corymbifera* strains grown on Czapek yeast autolysate (CYA), ginger (GIN), yellow onion (YO), red onion (RO), and tulip (TUL) agars. (a) *Penicillium albocoremium*, (b) *Penicillium allii*, (c) *Penicillium radicicola*, (d) *Penicillium hirsutum*, (e) *Penicillium hordei*, (f) *Penicillium venetum*.

by all species and under all conditions, protonated roquefortine C (390.1930 Da/e) was used for internal mass calibration. In case of high roquefortine C intensity, the 13-C isotope was used instead. The ions from protonated terrestric acid and protonated metabolites from the roquefortine/oxaline biosynthesis pathway from each strain were averaged to give a representative species measure.

RESULTS

P. albocoremium, *P. allii*, and *P. radicicola* proceeded through the r/o pathway to meleagrin as an end product, producing roquefortine D and C, glandicolines A and B, and meleagrin. *P. hirsutum* produced roquefortine D and C and glandicolines A and B with glandicoline B accumulating as the end product. Both *P. hordei* and *P. venetum* produced roquefortine D and C, with roquefortine C accumulating as an end product. Although *P. tulipae* produced roquefortine D and C, glandicolines A and B, and meleagrin, it differed from other species in the production of *epi*-neoxaline. The time scale study of *P. tulipae* strain IBT 3485 (Figure 3b) showed that the internal mycelial concentration of meleagrin was stable after 7 d, whereas *epi*-neoxaline accumulation continued to increase gradually as colony diameter increased. Only *epi*-neoxaline could be detected as diffusing into the agar adjacent to the colonies after 8 d (3–4 ng/cm^2 detected), corresponding to approx. 20 times less than the internal mycelial concentration. Interestingly, meleagrin did not diffuse into the media.

Regardless of the media type applied for growth, r/o pathway metabolite expression for all of the *Corymbifera* species was carried through to the respective end product (Figures 2a–f, 3a). Some variation in the production of the various pathway metabolites was present between the three strains surveyed for each species as demonstrated by the error bar length for several of the media. It is important to note that the colony fitness of the species strains upon the various media were approximately equivalent as judged by the amount of sporulation as well as colony diameter (although colonies developing on TUL, YO, and RO agars did tend to produce more biomass). Colonies developing on ginger agar were an exception as they had a smaller diameter compared to the others, yet were otherwise phenotypically comparable to the CYA controls.

In general, when the margin of error was taken into consideration, the average r/o pathway metabolite expression observed for the *Corymbifera* strains grown on the various media remained relatively constant as compared to expression on CYA. For *P. albocoremium*, a decreased average production of the intermediate roquefortine C was observed on GIN and RO media; however, production of the remaining intermediates and the pathway end product meleagrin was comparable to production on CYA (Figure 2a). For *P. allii*, a

decreased production of all r/o pathway intermediates and the end product meleagrin was observed from GIN and TUL agar extracts compared to CYA, RO, and YO agars (Figure 2b). An average production of all r/o pathway metabolites was observed for *P. radicicola* strains grown on the various plant-derived media compared to production on CYA (Figure 2c). Of all the plant media used for *P. hirsutum* strains, GIN agar resulted in a decreased production of glandicoline B compared to CYA, RO, and YO agars (Figure 2d). Strains of *P. hordei* showed a definite decrease in roquefortine D, even more so in roquefortine C, on all of plant-based media (Figure 2e). However, *P. venetum* strains had relatively consistent production of these compounds on all plant-based media (although slightly lower on ginger agar; Figure 2f). For *P. tulipae* strains, an overall reduced average production of *epi*-neoxaline was observed when strains were cultured on GIN, RO, and YO media compared to CYA; in contrast, an increased expression of meleagrin production was observed for TUL compared to CYA, GIN, and YO media (Figure 3a).

Stimulation of terrestric acid production was evident when molecular ion counts were compared between culture extracts from plant-derived media and CYA (Figure 4). Terrestric acid stimulation was most pronounced for *P. venetum* grown on YO, RO, and TUL agars. For *P. hirsutum*, terrestric acid production was also stimulated on YO, RO, and TUL agars. In the case of *P. radicicola* and *P. tulipae* strains, terrestric acid stimulation was pronounced on TUL agar; however, stimulation did occur on YO and RO agars. Terrestric acid stimulation for *P. hordei* strains was noted from YO and RO agars. For all of the species, only minor terrestric acid stimulation occurred on GIN agar compared to the other plant-derived media. The greatest production stimulation occurred from *P. venetum* strains. Terrestric acid production for *P. albocoremium* and *P. allii* strains did not occur on CYA or the other plant extract agars.

With the exception of *P. hordei*, all of the ser. *Corymbifera* series species produced extensive rot (root disk covered in sporulating mycelium) in yellow onion bulbs after 3-wk incubation. Internal and external tissue necrosis was most extensive in *P. albocoremium*, *P. allii*, *P. hirsutum*, and *P. venetum* samples (with *P. hirsutum* and *P. venetum* being most extensive) and characterized by total necrosis of the root disk and meristematic region, tissue discoloration and rot of the outerleaf, first leaves, and leaf initials accompanied by pronounced sporulation of the bulb cavity (Figure 5a, d). Although the external symptoms of the *P. tulipae* and *P. radicicola* infection were similar in appearance, the internal decay caused by these strains was limited to necrosis and sporulation of the root disk, and meristematic tissue with the discoloration of first leaf and leaf initials (Figure 5b, e). For the *P. hordei* isolates, only minor sporulation was apparent, extending to cover one third of the root disk surface and internal discoloration limited to the root disk region (Figure 5c, f). In addition to the aforementioned compounds, the *Corymbifera* species we tested

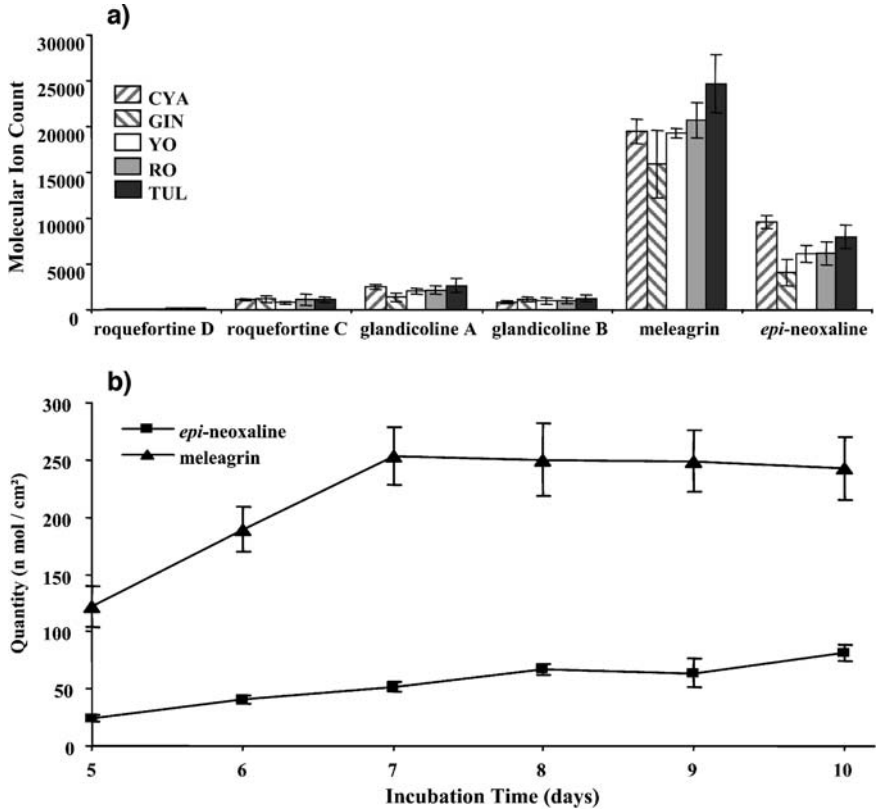

FIG. 3. Summary of roquefortine/*epi*-neoxaline biogenesis pathway metabolites produced by strains of *P. tulipae*. (a) Average molecular ion count calculated for *P. tulipae* strains grown on Czapek yeast autolysate (CYA), ginger (GIN), yellow onion (YO), red onion (RO), and tulip (TUL) agars. (b) Production of meleagrin and *epi*-neoxaline by *P. tulipae* strain IBT 3458 grown on CYA from days 5 to 10.

produced a variety of secondary metabolites (Table 1). None of the *Corymbifera* species we tested produced a rot on *Z. officinale* tubers.

DISCUSSION

Most fungi can absorb and utilize inorganic nitrogen (nitrates and ammonium) as well as organic nitrogen-containing compounds (proteins and amino acids) as a source of nitrogen. This is essential for the biosynthesis of complex molecules (i.e., amino acids, proteins, and nucleic acids); however, larger

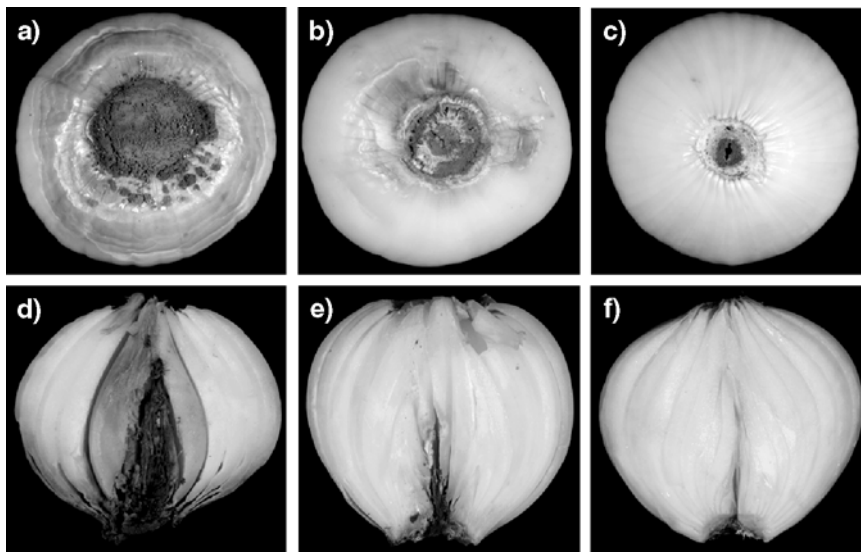

FIG. 5. Pathological symptoms displayed by *Allium cepa* bulbs infected with *Corymbifera* strains following 3-wk incubation in the dark at 20°C. (a–c) Root disk region of *A. cepa* bulbs inoculated with (a) *P. hirsutum*, (b) *P. radicicola*, and (c) *P. hordei*. (d–f) Bisection of *A. cepa* bulbs inoculated with (d) *P. hirsutum*, (e) *P. radicicola*, and (f) *P. hordei*.

extracellular polymers such as proteins must first be broken down by proteases into smaller units prior to transport. With the exception of *P. hordei*, all of the ser. *Corymbifera* species do not produce exogenous proteases and are, therefore, unable to breakdown extracellular proteins into transportable amino acids (Overy et al., 2005b). Perhaps in compensation, roquefortine C (and subsequent products of the r/o pathway) may serve as exogenous nitrogen sources. The fact that these compounds can enter and exit mycelia via both energy-independent and succinate energy-dependent mechanisms (Kulakovskaya et al., 1997) may make them particularly advantageous. In this case, nitrogen would not have to be actively pumped into mycelia. Following colonization and growth, r/o biosynthesis pathway intermediates and products accumulated in mycelia and bulb tissue infected by *P. albocoremium*, *P. allii*, *P. hirsutum*, *P. radicicola*, and *P. venetum* strains. Once accumulated in colonized tissue, these alkaloids could subsequently be taken up into growing hyphae and/or germinating conidia, metabolized into primary metabolites, and incorporated into proteins (Reshetilova et al., 1986; Reshetilova and Kozlovsky, 1990) to facilitate colonial expansion. Moreover, the antimicrobial properties reported for roquefortine C may help prevent the utilization of accumulated reserves of this amino acid resource by bacterial secondary infectors.

All of the ser. *Corymbifera* species produce and excrete organic acids: *P. hirsutum*, *P. hordei*, *P. radicicola*, *P. tulipae*, and *P. venetum* produce terrestric acid, whereas *P. albocoremium* produces barceloneic acids A and B, and *P. allii* produces fulvic acid (Overy and Frisvad, 2003, Frisvad and Samson, 2004); all of which are confirmed to be produced *in planta* in infected *A. cepa* bulbs. While r/o metabolites are deposited during colony development, accumulation of the *Corymbifera* organic acids *in planta* would lower the pH of the plant cellular environment. The pH optimum for roquefortine C excretion is 6–7 and uptake is 4.5 for *P. crustosum* strains (Kulakovskaya et al., 1997). Acidification of the infected region during colony development would therefore facilitate the uptake and subsequent metabolism of deposited r/o pathway alkaloids into germinating conidia and developing hyphae. Regional acidification would have an additional bactericidal effect, preventing the growth and competition of host-associated bacteria.

Several additional fungal secondary metabolites were produced *in planta* by *Corymbifera* strains. These compounds may act synergistically with terrestric acid and the r/o metabolites to improve the pathogenic ability and competitive fitness of the infecting strains. In addition to terrestric acid and roquefortine C, both cyclopenin and viridicatin have antibacterial properties (Bracken et al., 1954; Taniguchi and Satomura, 1970). Viridicatin also possesses phytotoxic properties, as is reported to inhibit root and shoot development in rice seedlings (Taniguchi and Satomura, 1970). Viridicatin may also act synergistically with the protein farnesyl transferase (PFTase)

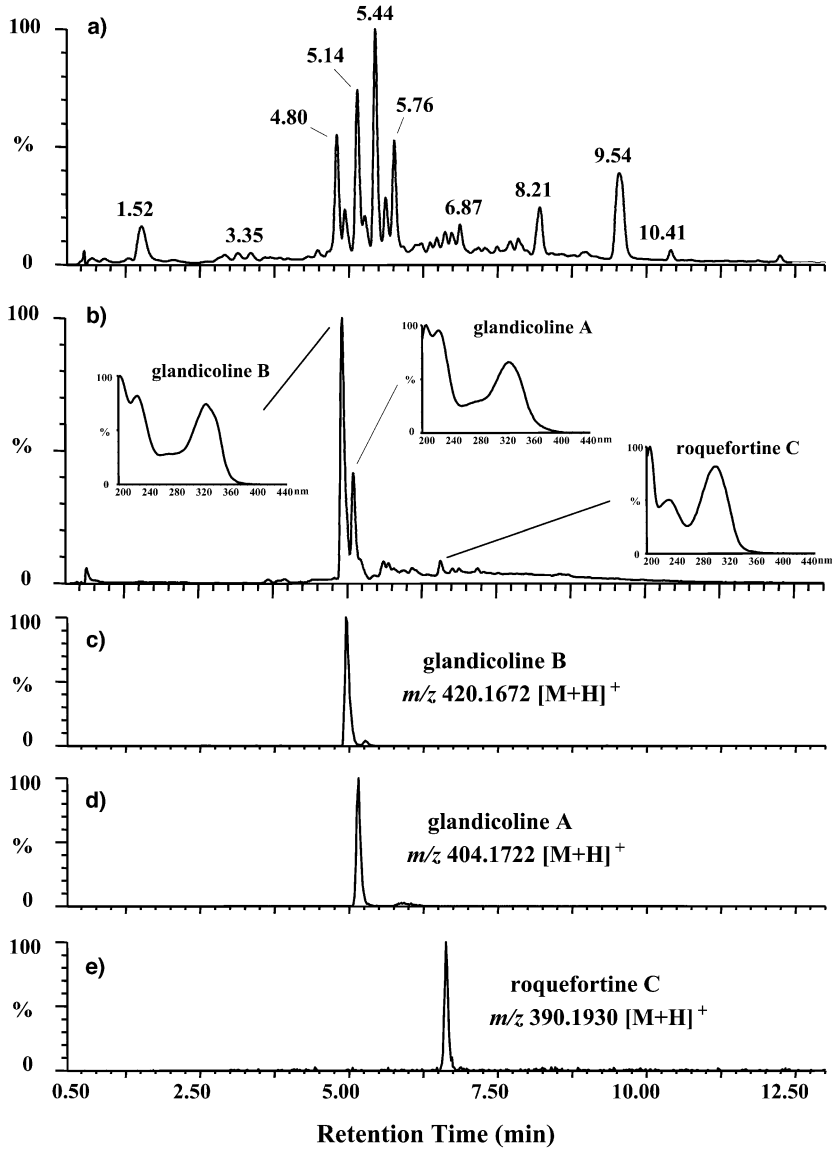

FIG. 6. LC-UV-MS traces demonstrating the preferential separation of r/o pathway metabolites from a *P. hirsutum*-infected *A. cepa* tissue extract: (a) crude extract, UV trace 300 nm (*y*-axis = relative absorbance); (b) following SPE, UV trace 300 nm (*y*-axis = relative absorbance); (c–e) accurate mass confirmation of $[M + H]^+$ ion using 100 ppm search window (*y*-axis = relative ion count).

inhibitors barceloneic acid A (Jayasuriya et al., 1995) and andrastin A (Omura et al., 1996) to weaken plant cell response to fungal infection (Overy et al., 2005c). PFTase inhibitors disrupt cellular signaling and division in developing plant cells (Morehead et al., 1995; Qian et al., 1996) resulting in decreased growth rates and stunted plants (Running et al., 2004). Compactin, produced *in planta* by *P. hirsutum* strains, is a well-known hydroxymethylglutaryl (HMG)–CoA reductase inhibitor, an enzyme responsible for the production of mevalonic acid, the biochemical building block involved in terpene biosynthesis. Although compactin has not been examined for phytotoxicity, lovastatin (a structurally similar compound) does inhibit cellular development in cultured carrot cells (Chen et al., 1987). Both compactin and lovastatin have reported antifungal properties (Brown et al., 1976; Huang et al., 1999), attributed to the inhibition of ergosterol biosynthesis in other fungi (Huang et al., 1999).

Terrestric acid production is stimulated by plant-based media. This compound is formed from the condensation of a C_4-TCA cycle intermediate with the methylene group of a fatty acid (Turner, 1971). Production of this fungal metabolite is, therefore, directly dependent upon the catabolism of glucose or other simple sugars to pyruvate during glycolysis. Ser. *Corymbifera* species produce an increased quantity of extracellular cellulases and hemicellulases as compared to other *Penicillia* (Overy et al., 2005b). This characteristic extracellular enzyme expression is ideal for the liberation and mycelial uptake of simple sugars through the enzymatic degradation of plant cell wall structural polymers (that are present in high concentrations in *A. cepa* cells; Mankarios et al., 1980). We conclude, therefore, that increased catabolic rates in the *Corymbifera* strains we tested were responsible for stimulating the production of TCA intermediates and subsequently terrestric acid production following an increased rate of respiration.

The SPE technique employed in this survey was successful in the preferential separation of the targeted r/o pathway metabolites from the various complex matrices (Figure 6), allowing the profiling of the r/o biosynthesis pathway in each of the ser. *Corymbifera* species. The r/o pathway profiles produced for five out of the seven species were in accordance with literature reports, with *P. hirsutum* and *P. tulipae* as exceptions (Frisvad and Filtenborg, 1989; Overy and Frisvad, 2003). *P. hirsutum* has been reported in the past to produce meleagrin based on TLC and HPLC-DAD analysis (Frisvad and Filtenborg, 1989); however, the results here based on preferential purification by SPE followed by LC-UV-MS analysis clearly demonstrates that glandicoline B is the r/o pathway end product for this species rather than meleagrin. Results from SPE profiling for *P. tulipae* allowed for the structural confirmation of *epi*-neoxaline (unpublished data), a metabolite previously reported as being similar to neoxaline and produced by *P. tulipae* (Overy and Frisvad, 2003). As *epi*-neoxaline rather than meleagrin was excreted by the *P. tulipae* strain IBT 3458 into the surrounding media, and because of the

progression of structural differences between glandicoline B, meleagrin, and *epi*-neoxaline, we propose that *epi*-neoxaline is the end product in the roquefortine/*epi*-neoxaline biogenesis pathway for *P. tulipae* (Figure 1).

In general, when cultured *in vitro*, terrestric acid production was stimulated, whereas the overall production of r/o metabolites was comparable to the CYA controls for most of the *Corymbifera* grown on most of the plant tissue agars. However, all of the ser. *Corymbifera* species demonstrated only minor stimulation of terrestric acid and a decreased overall production of r/o metabolites when cultivated on GIN media. Colony size on GIN media was reduced in comparison to CYA controls; however, sporulation and general colony morphology were comparable. None of these species have been reported to produce a rot on ginger and failed to grow when inoculated. An inability to grow on this substrate *in planta* may have resulted in decreased overall production of r/o metabolites when cultured *in vitro* on GIN media. This trend was also apparent for *P. hordei* when cultured *in vitro* and *in planta* on *A. cepa* (yellow onion), and for *P. allii* cultured on TUL agar. *P. hordei* did not cause rot in infected *A. cepa* bulbs, and *P. allii* is nonpathogenic on tulip bulbs (Overy et al., 2005a). With the exception of *P. hordei*, all of the ser. *Corymbifera* species are capable of producing rot on *A. cepa* (yellow onion), accompanied by the *in planta* production of terrestric acid and associated r/o pathway metabolites. The rot produced by *P. radicicola* and *P. tulipae* strains was less severe compared to the remainder of the infectious *Corymbifera*, which corresponds to a reduced production of r/o pathway end products when strains were cultured *in vitro* on YO agar. We propose that *in vitro* activities of fungi on plant-based media are predictive of *in planta* metabolite expression and pathogenic activity.

Abstract—Most snakes and lizards produce eggs with flexible shells that interact with the environment to maintain water balance. Geckos produce rigid eggshells that are independent of an external source of water and can be oviposited in more open, dryer locations. In this study, we analyzed and compared the amino acid composition of 24 lizard species, six snake species, and four outgroups (including avian and reptilian elastin and chicken eggshell). Rigid Gecko eggshells had significantly lower levels of seven of the 17 amino acids evaluated. Multivariate analysis showed that proline was the most important amino acid in distinguishing between these two groups of eggshells, occurring at significantly higher levels in flexible eggshells. High levels of proline have also been observed in the eggshells of other species. Proline and other amino acids are associated with the alleviation of water and salt stress in plants.

Key Words—Amino acid analysis, eggshells, squamate reptiles, proline, water relations, water–soil relations.

INTRODUCTION

Most species of squamate reptiles (lizards and snakes) are oviparous (Pianka and Vitt, 2003). Packard et al. (1982) have demonstrated that there are two types of squamate eggshells: flexible and rigid. Females of oviparous species with flexible eggshells deposit the eggs in nests in the soil or in organic debris, which serves as a source of the water necessary for successful development (Tracy, 1980; Packard et al., 1982). The passage of water from the surrounding medium through the eggshell and into the interior of the egg can be bidirectional, depending upon hydric dynamics (Sexton et al., 1979; Andrews and Sexton, 1981). In contrast, the eggs of those species with rigid eggshells are independent of an external source of water and can be oviposited in relatively open, dry locations (Sexton and Turner, 1970; Pianka and Vitt, 2003).

Krampitz et al. (1972) determined the amino acid composition of eggshells of some reptiles and birds and proposed that analyses of the amino acid composition of those eggshells represented "a basis for heterogeneously structured proteins which might be class-dependent if not even species-specific." Later, Kriesten (1975) determined that the flexible eggshells of the lizard *Iguana iguana* contained high levels of the amino acid proline. His finding was confirmed by Cox et al. (1982, 1984).

In this work, we will expand the scope of these earlier studies by surveying the relative abundance of the amino acids in the eggshells of a variety of oviparous squamate reptiles to determine what role they, and in particular proline, might play in the dynamics of water transfer between soil and egg from oviposition to hatching. We will demonstrate that there is a distinct difference between the amino acid composition of flexible vs. rigid eggshells. We will also briefly review the literature about the relationship between amino acid content and the hydric environment of other disparate taxa.

METHODS AND MATERIALS

Sample Collections. We examined the eggshells of 24 species of lizards of seven families and of six species of snakes in three families (Table 1). We obtained eggs collected in nature or from eggs oviposited by captive females. The geographic range of the species are: the United States of America, the Republic of Panama, Australia, northern Africa, southern Asia, Pacific atolls, the Galapagos Islands, and Caribbean Islands.

Procedure. Eggshell samples for amino acid samples were obtained by cutting 5-mm sections from each whole, air-dried shell. Samples were weighed, washed in distilled water, and hydrolyzed in constant boiling HCL at 105°C for 24 hr. We then dried the samples using a Speed Vac concentrator. We

determined the amino acid composition of each sample using a Beckman 119C analyzer with a program optimized for resolving elastin crosslinking amino acids (Mecham and Lange, 1982). We performed triplicate analyses on each sample. We selected the extracellular, fibrous proline-rich proteins, reptilian elastin and keratin (Sage and Gray, 1979), and avian elastin (Foster et al., 1975) as controls as well as chicken eggshell (Leach et al., 1981), because of the proteinacious, fibrous nature of reptile eggshells (Sexton et al., 1979; Cox et al., 1982; Packard et al., 1982; De–Salle et al., 1984; Heulin, 1990).

Statistical Analysis. We used Nei's index of genetic similarity (Nei, 1972) to compare pairs of samples. We employed *t*-tests to evaluate individual amino acids and multivariate tests to examine sets of amino acids. Discriminant function analysis was used to identify which set of amino acids best separated the various squamate taxa. Factor analysis was used to examine the relationships among amino acids to identify a smaller set of composite variables (factors), which were then used to examine differences among the squamate groups. In all cases, overall test alphas were maintained at $P = 0.05$; all tests were two-tailed. When several individual analyses (e.g., *t*-tests on each amino acid) were performed, the individual test alphas were divided by the number of comparisons (the Bonferroni adjustment) to conserve an overall alpha of 0.05. The statistical tests chosen assume that the character traits of taxa are independent. Because of phylogenetic relationships, this is likely not to be true, and so type 1 errors are likely to be inflated (Garland et al., 1993). The impact of phylogenetic relationship is addressed in the discussion.

RESULTS

Proline was the most abundant amino acid of the 17 amino acids examined for 29 of the 30 species of squamate eggshells although there was considerable variation among taxa (Table 1). Such variation could result from genetic or environmental factors. To determine if differences in eggshell composition have a genetic component, we compared the overall similarity of pairs of congeneric species with pairs of more distantly related species with the expectation that more closely related species would be more similar than more distantly related ones. In addition, if eggshell composition is largely genetically determined, then sets of species with similar diets should not be different from sets of comparisons of species with different diets. For this analysis, we used all species within the same family that differed at a relatively gross level of diet similarity, comparing within and between herbivorous and carnivorous species.

From the available data, there were five possible comparisons we could make between pairs of species within the same genus (three species of

Superscript categories A1 and A2 are lizard and snake species with flexible eggshells, respectively; B represents gecko species with rigid eggshells (shaded in gray). Within each family, species are ordered by declining levels of proline.

Anolis providing three comparisons, and two species each of *Eumeces* and *Cnemidophorus*, each providing a single paired comparison). We then randomly chose five pairwise comparisons of species from different genera within the same family. Pairs of congeneric species were significantly more similar to each other than were pairs of other confamilial species (Nei's $I = 0.995$ vs. 0.976; $t = 3.06$, $df = 8$, $P = 0.016$), providing evidence that variation in eggshell composition has a significant genetic component.

Within the iguanid lizards, three species, *I. iguana*, *Amblyrhynchus cristatus*, and *Conolophus pallidus*, are primarily vegetarian, providing three pairwise comparisons. The remaining six species of iguanids largely eat an animal diet. To maintain the same level of taxonomic relationship, we used only one species of *Anolis* (*A. stratulus*), which provided a total of four iguanid species for six pairwise comparisons. Vegetarian species had eggshell amino

Values in bold significantly differ between the two groups of lizards.

acid compositions more similar to each other than did carnivorous species. The nine paired comparisons of species with similar diets were not significantly different from the 12 paired comparisons of species with different diets (t = 0.835; df = 19; P = 0.41), suggesting that diet is not a significant determinant of differences in eggshell composition.

The key question is whether eggshell composition differs between squamates with flexible vs. hard-shelled eggs. Relative concentrations of seven of the 17 amino acids differed significantly between geckos and the other squamates when individually compared (Table 2). Factor analysis reduced the17 amino acids to five principal components (Factors), which accounted for 80.8% of the original variation. Both of the first two factors, which together accounted for 53.2% of the variation, differed significantly between geckos and the other lizard taxa (Table 2). Graphing Factor 1 against Factor 2 shows how each separates the two groups of lizards (Figure 1). Snakes are interspersed with the

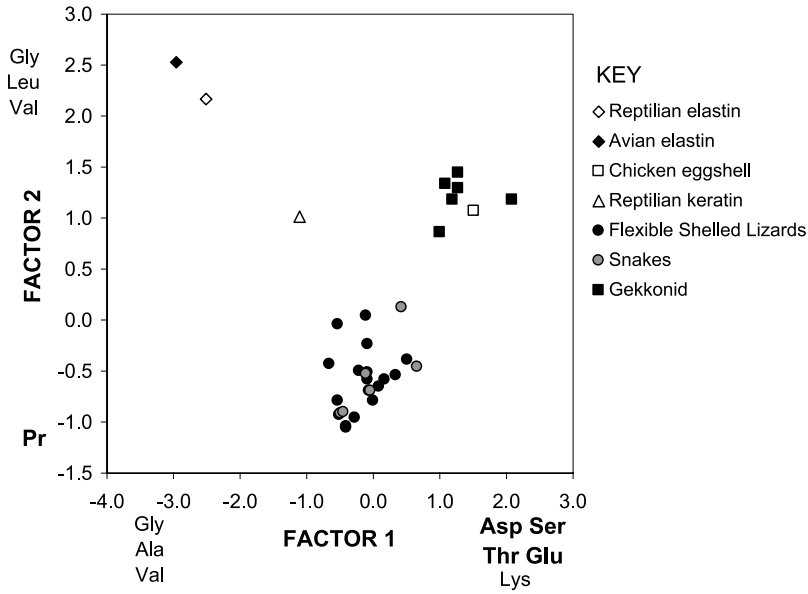

FIG. 1. Clustering of samples by factor analysis. The variables that load highest in Factor 1 are aspartic acid, serine, threonine, and glutamic acid, all of which are positively associated with Factor 1. The variable that loads highest in Factor 2 is proline and it is negatively associated with Factor 2. Variables that are more weakly correlated are included (but not in bold), and whether they are positively or negatively associated is indicated by their placement on the axis. Both factors clearly separate the flexible shelled lizards and snakes from the Geckos, although Factor 2 shows the better separation.

flexible-shelled lizards and, interestingly, the chicken eggshell nests with the hard-shelled geckos. The variables that load highest in Factor 1 are threonine, glutamic acid, aspartic acid, and serine (loading values: 0.85, 0.83, 0.81, and 0.78, respectively). Rigid eggshells are associated with high levels, flexible eggshells with lower values. The variable that loads highest in Factor 2 is proline (loading value, −0.91). High values of factor 2 are associated with flexible eggshells, lower values with rigid eggshells.

Stepwise discriminant function was used to determine which set of amino acids can best be used to separate the geckos from the flexible egg-shelled lizards. Proline, by itself, accounted for 90.8% of the differences between these two groups. Threonine, isoleucine, and phenylalanine significantly contributed to discrimination between the two groups, but together added less than 5% to the model. The best discriminant function (−4.193 + 0.028*Pro + 0.092*Ile − 0.098 Thr − 0.143*Phe) effectively separates members of these two groups. When the discriminant function is applied to the snakes, it places them all in the flexible-shelled lizards. When the equation is applied to the outgroups, it places the two elastin samples (reptile and avian) with the lizards and the chicken eggshell and reptilian keratin with the hard-shelled geckos.

DISCUSSION

We have clearly demonstrated that the amino acid composition of the eggshells of 24 species of flexible shelled squamate reptiles from nine different families differs from that of the six species of rigid-shelled geckos (Figure 1). Eggshell composition was shown to have a significant genetic composition, and, thus, it is possible that the differences observed are due to genetic relatedness and not to environmental adaptation. Recent phylogenetic analysis of the squamate reptiles places the Gekkoniidae and the Eublepharidae in a clade distinct from other squamates (Townsend et al., 2004). The eggshells of the two species of Eublepharidae in this study cluster with the other flexible shelled squamates and not with the more closely related Gekkoniidae. In addition, the clustering of the chicken eggshell with the rigid-shelled Geckos argues further that the differences observed in eggshell composition is an adaptation and not an artifact of common ancestry. The placement of snakes, all with flexible eggshells, within the flexible shelled lizards is consistent with both an adaptive explanation (all have flexible eggshells) and a phylogenetic one (see Townsend et al., 2004).

The eggs of some squamate species with flexible eggshells (e.g., *Sceloporus scalaris* and *S. virgatus*) can gain two to four times their mass through the influx of water from the surrounding medium (Andrews, 1997).

Proline, the predominant amino acid of pliable eggshells, is hydrophobic, and proline-rich sequences generally form extended structures and flexible regions that are hard to crystallize (Williams, 1994). During early external development of the egg, the inner surface of the eggshell first becomes covered by the yolk sac and later by the chorio-allantoic membrane (Andrews, 2004; Ackerman and Lott, 2004). Andrews (1997) has demonstrated that in *S. scalaris* and *S. virgatus* (members of the flexible eggshell group of squamates) much of the water influx during the incubation period occurs through the chorio-allantoic membrane. Hence, the eggshell serves as a porous, flexible barrier between the environment and the embryo with its associated embryonic membranes.

The presence of high levels of proline is not restricted to squamate eggshells. High levels have been reported from egg capsules of the skate, *Raja erinacea* (Cox et al., 1987), and from the eggshell of *Drosophila melanogaster* (Gigliotti et al., 1989; Waring et al., 1990). Proline also serves a conspicuous role in the alleviation of water and salt stress in plants (Larcher, 2003; di Toppi and Pawlik-Skowronska, 2003). Many species of plants, faced with drought or an excess of salt in the external environment, induce the synthesis of proline in the root system, and this serves as a protectant against negative hydric changes in the external environment (Kuznetsov and Shevyakova, 1999; de Ronde et al., 2000; Ramanjulu and Sudhakar, 2000).

Although the rigid eggshells of geckos contain lesser amounts of proline than flexible eggshells, they do contain higher levels of four other amino acids (Table 2). Of these four, aspartic acid/asparagine (ASX) and glutamic acid/glutamine (GLX) have been observed to accumulate in some plant species as nonspecific reactions to salt stress (Larcher, 2003). The high levels of these two amino acids in gecko eggshells may play an analogous role and may have indirectly played a role in accounting for the wide distribution of some species of geckos in the islands of the South Seas (Pianka and Vitt, 2003). The thesis is that gecko eggs, deposited on trees that were later blown into the sea, could have been transported by wind and wave to islands lacking that particular species, thus establishing a new colony.

These findings have further implications for: (1) the study of eggshell morphology of a variety of animals, (2) biochemical dynamics involved in hydric relationships between a wide variety of organisms and their environment, and (3) evolutionary relationships of various taxa.

Acknowledgments—This project was initiated under the auspices of a fellowship to OJS from the Dept. of Zoology, University of New England, Armidale, N.S.W., Australia, in the fall of 1984. Prof. Harold Heatwole and Audrey Heatwole provided basic support and guidance; Drs. Menna Jones and Jeff Miller aided the field work. The Smithsonian Tropical Research Institute in the Republic of Panama offered physical and intellectual support with special assistance provided by Dr. A. Stanley Rand. The Herpetarium of the St. Louis Zoo, St. Louis, MO, USA, provided eggshells of many species. Dr. Brian E. Viets provided us with eggshells of *Hemitheconyx* and

Dr. David Crews with *Cnemidophorus uniparens*. Many eggshells were obtained from the St. Louis area, particularly at the Washington University Tyson Research Center (Dr. Richard Coles, Director). Collecting in Missouri was carried out under a collecting permit from the Missouri Dept. of Conservation. Profs. Oscar Chilson, Daniel Kohl, and Robert Thach kindly reviewed early versions of this article, and two journal reviewers offered salient and helpful comments.

(Received January 3, 2005; revised April 18, 2005; accepted June 28, 2005)

Abstract—The strawberry poison frog *Dendrobates pumilio* (Anura: Dendrobatidae) and related poison frogs contain a variety of dendrobatid alkaloids that are considered to be sequestered through the consumption of alkaloid-containing arthropods microsympatrically distributed in the habitat. In addition to ants, beetles, and millipedes, we found that adults of two species of oribatid mites belonging to the cohort Brachypylina, trophically a lower level of animal than ants and beetles, contain dendrobatid alkaloids. Gas chromatography/mass spectrometry (GC/MS) of hexane extracts of adult *Scheloribates azumaensis* (Oribatida: Acari) revealed the presence of not only pumiliotoxin 251D (8-hydroxy-8-methyl-6-(2′-methylhexylidene)-1-azabicyclo[4.3.0]nonane), but also precoccinelline 193C and another coccinelline-type alkaloid. From the corresponding extracts of an unidentified *Scheloribates* sp., pumiliotoxin 237A (8-hydroxy-8-methyl-6-(2′-methylpentylidene)-1-azabicyclo[4.3.0]nonane) was detected as a minor component, and identified by synthesis. The presence of related alkaloids, namely deoxypumiliotoxin 193H, a 6,8-diethyl-5-propenylindolizidine, and tentatively, a 1-ethyl-4-pentenynylquinolizidine, were indicated by the GC/MS fragmentation patterns, along with at least another six unidentified alkaloid components. Thus, one possible origin of pumiliotoxins,

INTRODUCTION

The mystery as to why batracotoxin alkaloids are shared in poison dart frogs and toxic passerine birds was solved recently by the finding that melyrid beetles (genus *Choresine*) are a prey item common to both these species (Dumbacher et al., 2004). The origins of the other frog alkaloids—groups of pumiliotoxins, allopumiliotoxins, decahydroquinolines, indolizidines, quinolizidines, coccinellines, pyrrolizidine oximes, pyrrolidines, and piperidines that are found in three genera of dendrobatid frogs (*Dendrobates*, *Phyllobates*, and *Epipedobates*) and in at least three other genera of different anuran families (*Mantella*, *Pseudophryne*, and *Melanophryniscus*) (Daly et al., 1984, 1987, 1999, 2003; Vences et al., 1998; Mortari et al., 2004)—have not yet been fully identified. These alkaloids have been detected in skin extracts from dendrobatid and mantellid frogs in nature, but are not present in those of captive-raised frogs. Furthermore, the fact that alkaloids fed to frogs are readily accumulated in the skin and remain there for months suggests that their origins are dietary (Daly et al., 1994).

Pyrrolidines, piperidines, decahydroquinolines, indolizidines, and quinolizidines are known to exist in myrmicine ants, coccinellines in ladybirds, and pyrrolizidine oximes in millipedes (as summarized by Daly et al., 2000). Pumiliotoxins, suggested as being of arthropod origin (Daly et al., 2002), have been reported recently in formicine ants of the genera *Brachymyrmex* and *Paratrechina* (Saporito et al., 2004), and enzymatic oxidation of pumiliotoxins to more potent allopumiliotoxins has been reported in dendrobatid frogs (Daly et al., 2003). Ants are, therefore, one of the possible origins for the indicated groups of alkaloids. No evidence of biosynthesis, however, has been obtained among ants.

On the other hand, it is known in Dendrobatidae that toxicity is linked to aposematic coloration and to dietary specialization as microphagus foragers, which mainly dependent on ants and mites (Vences et al., 1998, 2003; Vences and Kniel, 1998; Summers and Clough, 2001; Santos et al., 2003; Summers, 2003). In the strawberry poison frog *Dendrobates pumilio*, regarded as an ant–mite specialist (Lieberman, 1986), Donnelly (1991) has reported that mites represent 49% of the prey items consumed by *D. pumilio* males, 38% by females, and 56% by juveniles. Certain species of ants are well-known predators of Oribatida (Masuko, 1994), and it is likely that alkaloids are accumulated via the food chain from soil mites. Therefore, other species of poison frogs may be ant–mite specialists, and

these frogs may similarly accumulate those groups of alkaloids from mites or mite-eating ants microsympatrically distributed in the habitat.

As preyed mite candidates in litter, there are three suborders of Acari: Mesostigmata, Astigmata, and Oribatida—and each suborder contains species emitting non-alkaloids compounds. Hydroxymethylnaphthoquinones are known to come from *Uroactinia hirschmanni* Hiramatsu (Mesostigmata, Uropodidae) (Sakata et al., 1997), but most species of Mesostigmata seem to be non-secreting. A total of 88 compounds have been isolated from 61 species of Astigmata belonging to 10 families as opisthonotal gland secretions with species-specific blends. Some of the compounds function either as alarm, aggregation, or sex pheromones, or as defense allomones (Kuwahara, 2004). These "Astigmata compounds" (Sakata and Norton, 2001) consist of 26 monoterpenes, two sesquiterpenes, eight aromatics, four aliphatic aldehydes, a ketone, two novel fatty acids, a novel alkyl formate, and 14 fatty acid esters together with 31 hydrocarbons (Kuwahara, 2004).

The same excretory gland is also distributed in the following four glandulate cohorts of Oribatida: Parhyposomata, Mixonomata, Desmonomata, and Brachypylina, but not in the non-glandulate cohort of Palaeosomata and Enarthronota (Sakata and Norton, 2001). At present, compounds from a total of 11 species of three cohorts have been studied: six species belonging to Desmonomata, *Trhypochthoniella crassus* (Sakata et al., 1995), *Nothrus palustris* (Shimano et al., 2002), *T. japonicus* (Sakata et al., 2003), *Trhypochthoniellus* sp. (Sakata et al., 2003), *Hermannia convexa* (Raspotnig et al., 2005a), and *Platynothrus peltifer* (Raspotnig et al., 2005b); three species of Mixonomata, *Collohmannia gigantea* (Raspotnig et al., 2001), *Nehypochthonius porosus* (Sakata and Norton, 2001); *Perlohmannia* sp. (Sakata and Norton, 2001), and two species of Parhyposomata (the most basal group with the gland), *Parhypochthonius aphidinus* and *Gehypochthonius urticinus* (Sakata and Norton, 2001). Major components are identified as "Astigmata compounds" together with aromatics not yet found in Astigmata, and no evidence of alkaloids has been reported.

In this study, we analyzed the secretion of two species (*Scheloribates azumaensis* and unidentified *Scheloribates* sp.) belonging to Brachypylina (one of the four glandulate cohorts of Oribatida) and demonstrated the presence of pumiliotoxins, coccinellid alkaloids, and other related alkaloids. We believe that oribatid mites belonging to Brachypylina are one important origin of pumiliotoxins and other alkaloids in poison frogs.

METHODS AND MATERIALS

Mites. Scheloribates azumaensis (Acari: Oribatida, belonging to the cohort Brachypylina), was isolated from a crop field in Fukushima, Japan, and main-

tained successively in a laboratory at the Upland Farming Division of the Tohoku National Agricultural Experimental Station, and raised in a culture dish (90 mm i.d. × 20 mm in height) with a wet floor made of calcium sulfate, and fed with dried chlorella (Nihon Chlorella Co. Ltd., Yokohama, Japan) at room temperature. The species (holotype, female, dark reddish brown) is 424 μm in body length and 288 μm in width (Enami et al., 1996), and its tritonymph (opaque or transparent in color) has an average body length of 436.8 μm. The other species, with a similar body size, is an unidentified *Scheloribates* sp. It was collected from organic soils around an athletic field at Kyoto University, and was raised on the same diet and under the same conditions. The rearing culture dish of each species was placed in a zip-lock plastic bag (240 × 170 mm, 0.04 mm in film thickness) to retain moisture, and maintained at room temperature.

GC/MS and GC/FT-IR Analyses. Gas chromatography/mass spectrometry (GC/MS) was carried out with a Hewlett Packard HP-5989B GC/MS operated at 70 eV in the split-less mode, using an HP-5 capillary column (0.25 mm i.d. × 30 m, 0.25 μm in film thickness, Hewlett Packard) with He as the carrier gas at a flow rate of 1.23 ml/min at a temperature programmed to change from 60°C (2 min) to 290°C at a rate of 10°C/min and then held for 5 min. A Bio-Rad FT-IRD instrument coupled with a GC system was used under the same conditions to obtain vapor phase IR spectra.

Preparation of Mite Hexane Extracts for GC/MS and GC/FT-IR Analyses. A group of mites (5–20) was transferred to a conical-bottomed glass tube (8 mm i.d. × 30 mm in height, handmade) with a needle, and soaked for three min in 3 μl of hexane with a microsyringe (10 μl, Hamilton Co.). The extract collected by the microsyringe was subjected to GC/MS and GC/FT-IR analyses without being concentrated.

Preparation of Authentic Pumiliotoxin 237A. Pumiliotoxin 237A (8-hydroxy-8-methyl-6-(2′-methylpentylidene)-1-azabicyclo[4.3.0]nonane) was prepared from 8-hydroxy-8-methyloctahydro-5-indolizidinone (Barrett and Damiani, 1999) as a key compound, by aldol condensation, dehydration, and reduction, following previously reported methods as summarized in Figure 1 (Fox et al., 1991; Santos and Pilli, 2001). GC t_R = 14.29 min, GC/MS *m*/*z* (%): 237(M^+, 16), 222(3), 194(26), 176(6), 166(71), 148(10), 123(16), 112(14), 95(7), 85(21), 70(100), 55(13) and 43(46).

RESULTS

The GC profile of *S. azumaensis* adults was composed of at least four major peaks (A, 1′, 2′, and 3′) [Figure 2(1)], among which the third (peak A,

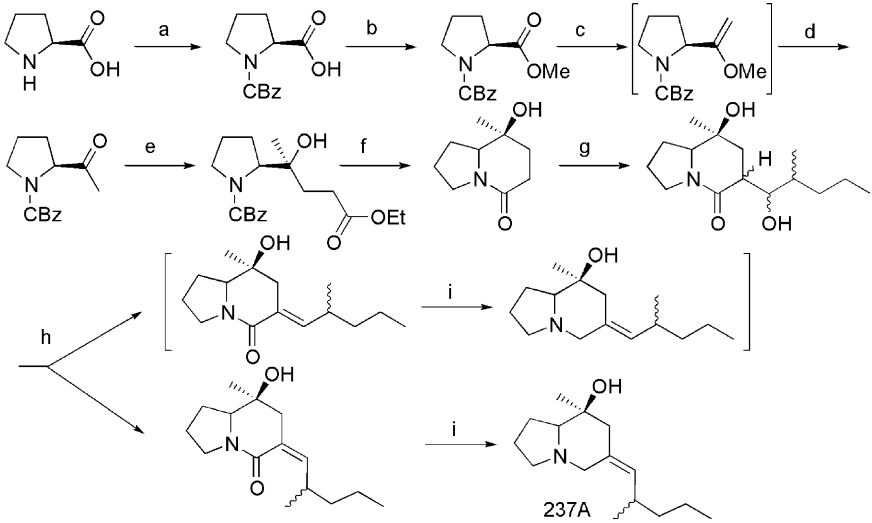

FIG. 1. Synthesis of pumiliotoxin 237A and its isomers, based on reported methods (Fox et al., 1991; Barrett and Damiani, 1999; Santos and Pilli, 2001). (a) $ClC(O)OCH_2Ph$, NaOH, THF; (b) H^+/MeOH; (c) Tebbe reagent, NaOH; (d) HCl/acetone, (e) ethyl ω-trichlorotitanylpropionate/CH_2Cl_2, (f) H_2, Pd/C, (g) LDA, THF, −78°C, 2-methylheptanal; (h) DCC, PhMe, CuICl, 110°C, or MsCl, pyridine, then KOH, or $(CF_3CO)_2O$, DBU, CH_2Cl_2, DMAP, −40°C; (i) $LiAlH_4/AlCl_3$ (3:1) in Et_2O, rt.

t_R = 15.72 min) gave an M^+ ion at *m/z* (%): 251(15) and base ion at *m/z* 166(100), together with characteristic fragment ions at *m/z* 236(3), 218(2), 208(15), 194(15), 176(7), 148(8), 137(9), 123(13), 112(12), 96(9), 84(17), 70(79), 55(7), and 43(19) (Figure 3). The mass spectrum was identical (quality index: 96) to that of pumiliotoxin 251D listed in the mass spectral libraries (Wiley Library, 6th edn., in HP Analytical CD-Rom MS ChemStation Libraries, version A.00.00) and to data previously reported (Daly et al., 1999). The IR spectrum (vapor phase, ν cm^{-1}) indicated the following absorption bands: 3543.1 (–OH, w), 2965.92 (s), 2936.14 (sh), 2884.92 (sh), 2797.13 (m), 2749.97 (sh), 1460.86 (w), 1382.48 (w), 1310.16 (w), 1140.23 (w), 1094.33 (w), and 962.62 (w). Although intensities and positions around the C–H stretching band region look a little different, appearances of all the other parts were identical to those of pumiliotoxin 251D (Daly et al., 1999). The compound was, therefore, concluded to be pumiliotoxin 251D.

The compound represented by peak 1′ [t_R = 7.00 min, Figure 2(1)] gave an M^+ ion at *m/z* (%): 150(39) and base ion at 121(100), together with ions at 135(53), 107(71), 93(27), 79(14), 67(16), 55(7), and 41(9). The mass spectrum indicates none of the alkaloid characteristics, and is similar to that for 2-(2-

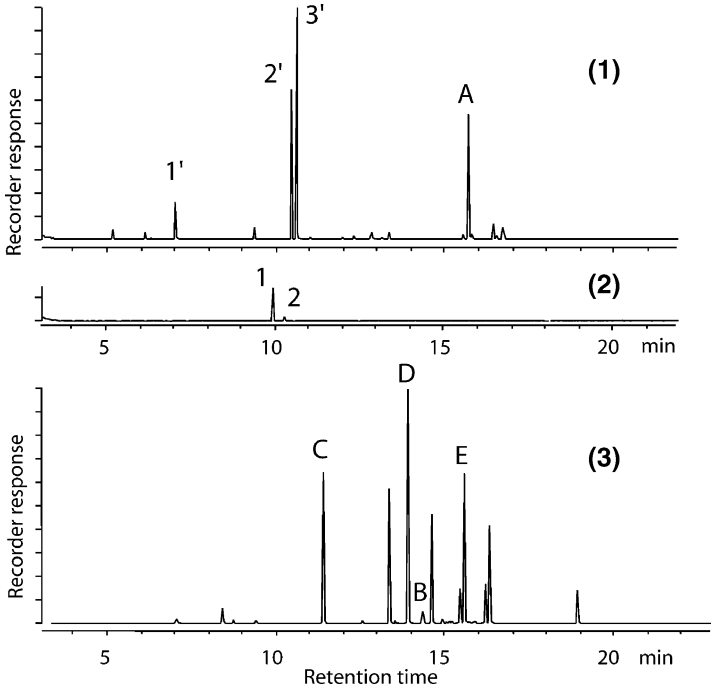

FIG. 2. Typical gas liquid chromatogram of *Scheloribates azumaensis* [(1) and (2)] and of *Scheloribates* sp. [(3)]: (1) 10 adults of *S. azumaensis*; (2) nymphal stages, 20 mites of *S. azumaensis*; (3) 5 adults of *Scheloribates* sp. Peak A: pumiliotoxin 251D. Peak B: pumiliotoxin 237A. Peak 1: geranial. Peak 2: 3-hydroxybenzene-1,2-dicarbaldehyde. Peak C: 8-deoxypumiliotoxin 193H. Peak D: a 6,8-diethyl-5-propenylindolizidine. Peak E: tentatively, a 1-ethyl-4-pentenynylquinolizidine. Peak 1′: 2-(2-pentenyl)-2-cyclopenten-1-one. Peak 2′: precoccinelline 193C. Peak 3′: a coccinelline-type alkaloid.

pentenyl)-2-cyclopenten-1-one in the mass spectral library. The compound represented by peak 2′ (t_R = 10.45 min) had an M^+ ion at *m*/*z* (%): 193(71) and base ion at 122(100), together with ions at 178(63), 164 (54), 150(99), 136(83), 108(28), 95(16), 82(30), 70(55), 55(21), and 41(22). The mass spectrum is very similar to that of the beetle alkaloid precoccinelline 193C (Daly et al., 1999). The compound represented by 3′ (t_R = 10.63 min) had an M^+ ion at *m*/*z* (%): 193(18) and base ion at 152(100), together with ions at 178(16), 164(12), 150(24), 136(25), 122(27), 110(11), 96(5), 82(6), 70(15), 55(6), and 41(6). The mass spectrum also suggests that it is another coccinelline-type alkaloid.

The hexane extracts from nymphs consisted of two components [Figure 2(2)]; one (peak 1) at t_R = 9.90 min with an M^+ ion at *m*/*z* (%): 152(8) and base

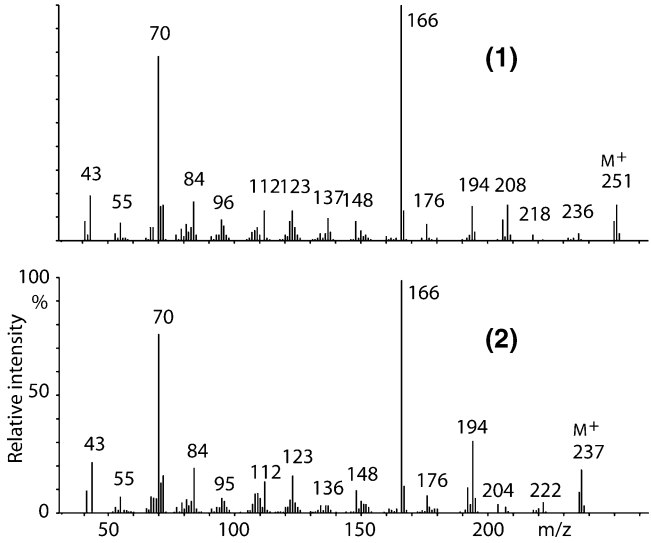

FIG. 3. Comparison of mass spectra between (1) compound A (pumiliotoxin 251D, t_R = 15.71 min) in *Scheloribates azumaensis* and (2) compound B (pumiliotoxin 237A, t_R = 14.31 min) in *Scheloribates* sp. Both compounds are homologs.

ion at 69(100), together with ions at 137(12), 123(9), 109(9), 94(23), 84(30) and 41(78), and the other (peak 2) at t_R = 10.21 min with an M^+ ion at *m*/*z* (%): 150(66) and base ion at 121(100), together with ions at 122(62), 93(43), and 65(33). From a comparison of GC t_Rs and mass spectra with authentic compounds, the compound at t_R = 9.90 min was identified as geranial [2(*E*)-3, 7-dimethyl-2,6-octadienal] (Kuwahara et al., 1980), and that at t_R = 10.21 min as 3-hydroxybenzene-1,2-dicarbaldehyde (Sakata and Kuwahara, 2001). Recorder responses of both peaks were also small and almost one-tenth of the intensity for peak A in adults.

GC/MS of the extract from *Scheloribates* sp. revealed that a minor component, peak B (t_R = 14.31 min) [Figure 2(3)], had a similar mass spectrum to pumiliotoxin 251D; an M^+ ion at *m*/*z* (%): 237(18) and base ion at *m*/*z* 166(100), together with the following diagnostic ions; 222(5), 194(31), 176(8), 148(10), 123(16), 112(14), 95(6), 84(19), 70(76), 55(7), and 43(22) (Figure 3). The compound was suggested as being pumiliotoxin 237A (Daly et al., 1999). The mass spectrum and GC retention time of the natural peak B were identical to those of synthetic pumiliotoxin 237A. Therefore, the chemical structure of peak B was identified as pumiliotoxin 237A (or its optical isomer). Based on the similarity in mass spectra between peak B of *Scheloribates* sp. and major peak

A (t_R = 15.71 min) of *S. azumaensis* (Figure 3), the structure of peak A was again confirmed to be pumiliotoxin 251D.

The extract from *Scheloribates* sp. comprised more than 10 peaks other than pumiliotoxin **237A**. Structures of three alkaloids were examined, based on GC/MS analyses (Figure 4) and fragmentation patterns as proposed (Jain et al., 1995; Daly et al., 1999) (Figure 5). Compound C (peak C, t_R = 11.41 min) had an M^+ ion at *m*/*z* (%): 193(6) and base ion at *m*/*z* 150(100) with a diagnostic ion at *m*/*z* 70(24). The structure of compound C was suggested to be 8-deoxypumiliotoxin 193H (6-(2′-methylpropylidene)-8-methyl-1-azabicyclo[4.3.0]-nonane), as reported (Jain et al., 1995; Daly et al., 1999). The mass spectrum of compound D (peak D, t_R = 13.97 min) showed an M^+ ion at *m*/*z* (%): 221(2) and base ion at *m*/*z* 180(100) with a diagnostic ion at *m*/*z* 124(15). The spectrum supported the structure of a 6,8-diethyl-5-propenylindolizidine (6,8-diethyl-5-propenyl-1-azabicyclo[4.3.0]nonane). The mass fragmentation is almost identical to that of indolizidine 223A (6,8-diethyl-5-propylindolizidine), reported by Garraffo et al. (1997) as an alkaloid often found in poison frogs. Toyooka et al.

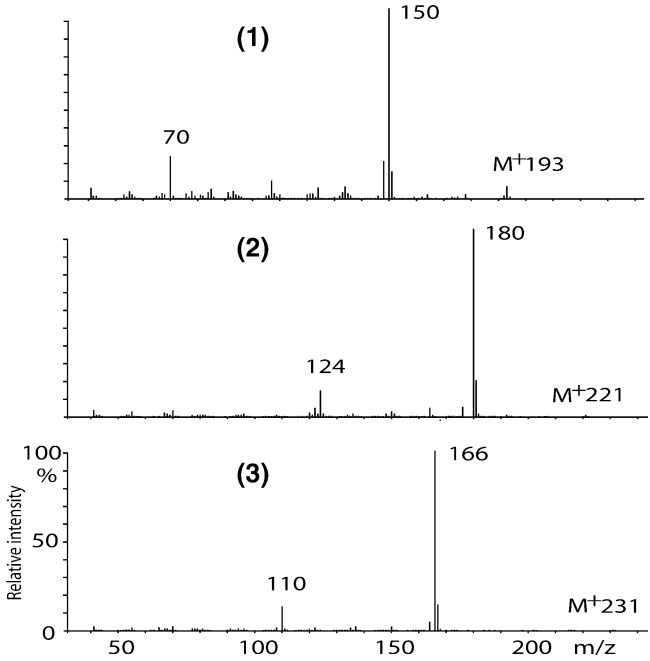

FIG. 4. Mass spectra of three components of *Scheloribates* sp. (1) Peak C (8-deoxypumiliotoxin 193H, t_R = 11.40 min). (2) Peak D (6,8-diethyl-5-propenylindolizidine, t_R = 13.95 min). (3) Peak E (1-ethyl-4-pentenynylquinolizidine, t_R = 15.58 min).

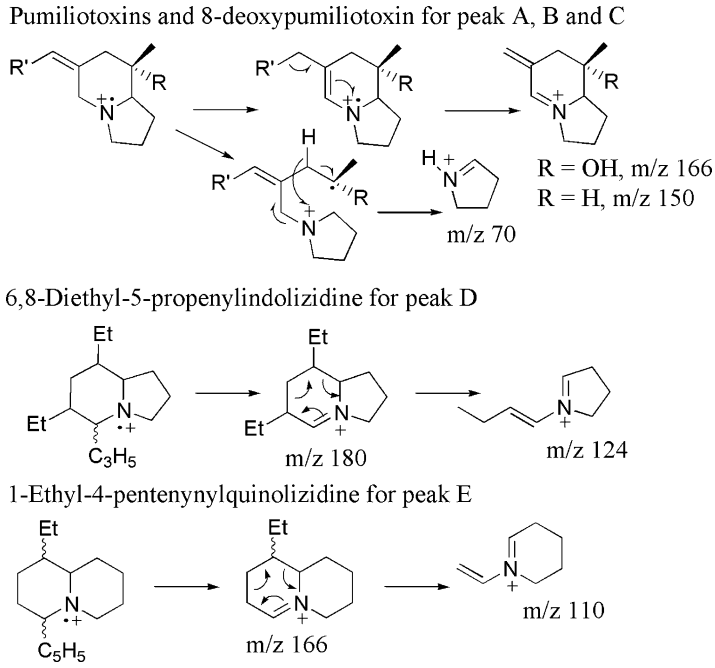

FIG. 5. Mass fragmentation pathways proposed for alkaloids from oribatid mites.

(2002) corrected the configuration at the C-6 of indolizidine 223A by synthesis. Compound E (peak E, t_R = 15.57 min) gave an M^+ ion at *m/z* (%): 231(1) and base ion at *m/z* 166(100) with a diagnostic ion at *m/z* 110(13). The structure was tentatively suggested to be a 1, 4-disubstituted quinolizidine 231A (1-ethyl-4-pentenynylquinolizidine), which was reported as a poison frog alkaloid (Jain et al., 1996; Daly et al., 1999). Structures other than the four compounds (peaks B, C, D, and E) in Figure 2(3) remain obscure, although they too are considered to be alkaloids, based on GC/MS analyses.

DISCUSSION

No alkaloids have been detected in species belonging to Mesostigmata (Sakata et al., 1997), Astigmata (Kuwahara, 2004), or in three cohorts of glandulate Oribatida (Sakata et al., 1995, 2003; Raspotnig et al., 2001, 2005a,b; Sakata and Norton, 2001; Shimano et al., 2002). Some compounds identified among Acari are known as alarm, sex, or aggregation pheromones, and most of them may function as defense allomones (Kuwahara, 2004).

In contrast, the hexane extracts from the present two oribatid mites (*S. azumaensis* and *Scheloribates* sp.) were composed mostly of alkaloids. Pumiliotoxin 237A was detected in the extract of *Scheloribates* sp., and the structure was identified by synthesis. The presence of pumiliotoxin 251D, detected in *S. azumaensis*, was concluded by an MS Library search, GC/FT-IR, and comparison of the GC/MS fragmentation patterns with those of pumiliotoxin 237A.

Three major components (peaks 1′, 2′, and 3′) other than peak A in the former species were suggested to be 2-(2-pentenyl)-2-cyclopenten-1-one, precoccinelline 193C, and a coccinelline-type alkaloid, respectively, based on GC/MS analysis. This is the first discovery of coccinellid alkaloids distributed in animals other than ladybird beetles and frogs. Likewise, structures of three peaks (peaks C, D, and E) in the latter species were elucidated as 8-deoxypumiliotoxin 193H, a 6,8-diethyl-5-propenylindolizidine, and a 1,4-disubstituted quinolizidine 231A (1-ethyl-4-pentenynylquinolizidine). Many compounds (more than seven peaks, not designated) in the latter were similarly suggested to be alkaloids via GC/MS, but their structures remain obscure. Although these compounds have yet to be identified by routine natural product chemistry, we can claim at the moment that pumiliotoxins 251D and 237A were present in *Scheloribates* mites, possibly functioning as defense allomones.

The presence of volatile alkaloids is also suggested in two other unidentified *Xylobates* species belonging to Xylobatidae, Oribatida (Sakata, personal communication). The stain made by crushing these mites on filter paper was turned orange by Dragendolff reagent, indicating the component(s) may be alkaloid(s). Thus, alkaloids might be widely distributed among *Scheloribates* species and/or species belonging to the same cohort. Although pumiliotoxin **251D** content was not determined in *S. azumaensis*, it may be more than 100 ng based on its recorder response.

Pumiliotoxins and other alkaloids are adult-specific components and are not detectable at the larval or nymphal stage, although all stages depend on the same diet. Secretions from nymphs and larvae consisted only of non-alkaloids, that is, "Astigmata compounds". This suggests that pumiliotoxins and other alkaloids are biosynthesized by adult oribatid mites. This immature/adult dichotomy in chemistry seems to be a general characteristic among the so-called "higher" oribatid mites Brachypylina (Raspotnig et al., 2005a).

Ants and mites are the two major prey items consumed by *D. pumilio* and related poison frogs (Lieberman 1986; Donnelly, 1991; Jones et al., 1999). It may be that many Brachypylina species are distributed upon the soil surface, and that several *Scheloribates* species (their body sizes vary from 330 to 980 μm; Hammer, 1958, 1967) are large enough to serve as prey items for frogs (body size 2–3 cm). The aposematic coloration and toxicity of poison frogs are linked with dietary specialization (Vences et al., 1998, 2003; Vences and Kniel,

1998; Summers and Clough, 2001; Santos et al., 2003; Summers, 2003). No aposematism has developed, however, in those alkaloid-containing Oribatida, possibly because their predators may be achromatopsic (defective in color vision). The present two *Scheloribates* are dark reddish brown and have a smooth body surface. Two other unidentified *Xylobates* species (as mentioned above) possess black bodies with bristles. There is no particular difference noticed from other oribatid species possessing "Astigmata compounds".

Alkaloids such as pyrrolidines, piperidines, decahydroquinolines, indolizidines, and quinolizidines are distributed in myrmicine ants (as summarized by Daly et al., 2000). More recently, Saporito et al. (2004) have identified pumiliotoxins 307A and 323A in formicine ants of the genera *Brachymyrmex* and *Paratrechina*. Certain species of ants are known as predators of Oribatida (Masuko, 1994). It is conceivable that ants may accumulate those dendrobatid alkaloids by consuming alkaloid-biosynthetic Oribatida. Currently, however, there is no evidence of sequestration by ants.

The genus *Scheloribates* is distributed worldwide, and is now perhaps the first of many alkaloid-containing genera of the Brachypylina cohort of the suborder Oribatida. If a food chain is established connecting such mites with frogs as predators, it will not be surprising to find that frogs are sequestering these mite alkaloids.

Acknowledgments—We are grateful to Dr. H. Katsumata (Yokohama Plant Protection Station, Ministry of Agriculture, Forestry and Fisheries, Yokohama, 231-0801 Japan) for measuring the body size of the *S. azumaensis* tritonymph. We also thank reviewers of this manuscript for their valuable comments. This study was partly supported by a Grant-in-Aid for Scientific Research (no.15580090) and the 21st century COE program for Innovative Food and Environmental Studies Pioneered by Entomomimetic Sciences, from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

(Received December 6, 2004; revised April 28, 2005; accepted June 6, 2005)

Abstract—Mycosporine-like amino acids (MAAs) have been reported as functional chemical sunscreens in a variety of marine organisms, but their role in development of marine embryos and larvae remains largely unexplored. In this study, we quantified MAAs from intertidal egg masses of 46 species of mollusks, two species of polychaetes, and one species of fish from southeastern Australia. We aimed to elucidate potential patterns of occurrence and variation based on egg mass maturity, adult diet, spawning habitat, phylogeny, and viability. Our analyses revealed that maturity and spawning habitat did not affect MAA composition within egg masses. In contrast, adult diet, phylogeny, and viability affected MAA composition. Herbivores had higher levels of certain MAAs than carnivores; similarly, viable egg masses had higher levels of some MAAs than inviable ones. MAA composition varied according to the taxonomic group, with nudibranchs and anaspids showing different MAA composition compared to that of neogastropods, sacoglossans, and polychaetes. Basommatophoran egg masses had more porphyra-334 than the other taxa, and anaspids had more mycosporine-2-glycine than the other groups. MAAs occurred in relatively high concentrations in intertidal molluskan egg masses when compared to adult mollusks and other common intertidal organisms. Despite the complexity of factors affecting MAA composition, the prevalence of MAAs in some species is consistent with protection afforded to offspring against negative effects of UV radiation.

Key Words— Gastropod, egg mass, larvae, marine invertebrate, chemical sunscreen, intertidal, mycosporine–glycine.

INTRODUCTION

Surface ultraviolet radiation (UVR) has been shown to deleteriously affect reproduction, development, growth, and behavior of many organisms including marine invertebrates (Haeder et al., 1998). Biologically significant UVR comprises UV-B (280–315 nm) and UV-A (315–400 nm) (Cockell and Knowland, 1999), with UV-B absorbed strongly by the ozone layer (Paul and Gwynn-Jones, 2003). Although UVR is attenuated in the water column, biologically significant levels of UV-B may still penetrate to 20 m or more (Booth and Morrow, 1997). Hence, organisms in shallow water or intertidal habitats are expected to be especially vulnerable. Recent research confirms that encapsulated larvae of intertidal mollusks are at high risk of UVR damage (Przeslawski et al., 2004).

Larvae and embryos may reduce or eliminate exposure to UVR in several ways. Offspring may simply avoid UVR as a result of adult spawning behavior. Many free-spawning invertebrates, for example, release gametes nocturnally so that fertilized eggs undergo early developmental stages in darkness (e.g., Pagano et al., 2004). Other organisms, particularly gastropods, enclose offspring within leathery capsules or gelatinous egg masses (see Przeslawski, 2004a). The embryos are essentially sessile for the duration of their encapsulation and reliant on adult spawning habitat for protection against UVR. Many gastropods only spawn under boulders or in other fully shaded microhabitats, but some species consistently deposit their egg masses in habitats exposed to sunlight (Benkendorff and Davis, 2004). The developing embryos within these egg masses are potentially exposed to high intensities of UVR with no visible protection. Nevertheless, gastropod embryos of species that consistently spawn in full sunlight are less vulnerable to the negative effects of UVR than embryos from species that only spawn in shaded habitats (Przeslawski et al., 2004).

Alternatively, some encapsulated embryos may be protected from UVR through chemical sunscreens, such as mycosporine-like amino acids (MAAs). MAAs are a suite of 19 compounds with absorption maxima at 310–360 nm. They are produced *de novo* via the shikimate pathway in algae, fungi, and bacteria (Bentley, 1990), and animals are assumed to acquire MAAs through diet or symbioses with these organisms (Shick and Dunlap, 2002). MAAs have been found in adults from a variety of organisms including algae, fish, cnidarians, mollusks, and echinoderms (reviewed by Shick and Dunlap, 2002). The concentration and composition of MAAs can vary in organisms according to latitude (Bosch et al., 1994), altitude (Tartarotti et al., 2001), depth (Gleason and Wellington, 1995), sex (Michalek-Wagner, 2001), and species (Xiong et al., 1999). MAAs have also been reported from the eggs and larvae of several invertebrates including urchins, corals, ascidians, and gastropods (reviewed by Karentz, 2001). Only two molluskan egg masses were covered in this review, so

Przeslawski (2004b) conducted a preliminary investigation on a further 46 gastropod egg masses. This revealed that the total MAA content varies significantly according to taxonomic group and adult diet, but it is still not clear how MAA composition varies with these and other factors. Larvae are generally considered the most vulnerable life stage, and so MAA composition in such species may be especially important to the overall success of a population.

In this study, we collected benthic egg masses from a range of intertidal invertebrates and quantified their MAA composition. We aimed to identify common MAAs in intertidal egg masses and to determine which factors account for variation in MAA composition and abundance. Here, we investigate the effects of egg mass maturity, adult diet, spawning habitat, taxonomic group (order), and embryo viability. We predicted that herbivores would have a richer complement of MAAs at higher concentrations in their spawn than carnivores, as they have a more direct link to *de novo* MAA sources. We also anticipated that egg masses of species that routinely spawn in habitats exposed to full sun would contain a larger number of MAAs at higher concentrations than those spawned in shaded habitats. In addition, we collected adults of several shelled species and predicted that adults would show fewer MAAs at lower concentrations than spawn due to the need for photoprotection of vulnerable developmental stages.

METHODS AND MATERIALS

We undertook a quantitative survey of MAA composition and concentration in egg masses from 49 intertidal organisms representing 46 gastropod species, two unidentified polychaete species, and one gobiesocid fish (Table 1). Most egg masses were collected from intertidal habitats along the Illawarra coast November 2001–February 2004. Some samples were collected from adults kept in laboratory aquaria, and egg capsules of *Nucella lapillus* were collected from Cornwall, England. Egg masses were identified to species level based on observations of laying adult or previous research where possible (Rose, 1985; Smith et al., 1989; Benkendorff, 1999). Potential spatial and temporal variation in MAA composition was examined on a subset of the egg masses. We restricted these analyses to species with three or more replicates. Spatial differences in MAA composition were analyzed for *Dolabrifera brazieri*, *Dicathais orbita*, *Placida* cf. *dendritica*, and *Siphonaria denticulata*. Temporal differences were examined in egg masses of *Agnewia tritoniformis*, *Conus papilliferus*, *Dendrodoris fumata*, *D. brazieri*, *P.* cf. *dendritica*, and *S. denticulata*. Nested analysis of similarities (ANOSIMs) revealed no significant spatial ($R = 0.049$, $P = 0.273$) or temporal ($R = 0.17$, $P = 0.114$) variations in MAA concentrations for any of the species examined. Therefore, egg mass data for all species collected from different sites and times were pooled in the remaining analyses.

Both capsular and gelatinous egg masses were collected. Egg masses from herbivores represented 16 species, and carnivores represented 30 species; the diet of three species was unknown (Table 1). We collected egg masses of six species from full sun habitats (exposed rock platforms), 13 species from partial sun (algae beds, sand, or vertical rock faces), and 30 species from shaded habitats (under boulders, overhangs, or caves) (Table 1). Egg masses were examined under a dissecting microscope (40× magnification) to determine development, and they were classed accordingly into one of four developmental stages: (1) undeveloped egg masses contained eggs that had not yet developed to the trochophore stage; (2) egg masses with intermediate development contained eggs with trochophores or early veligers; (3) mature egg masses had late stage veligers, crawling juveniles and/or showed signs of hatching; (4) inviable egg masses contained no viable eggs and often showed coloration changes associated with damage or stress (Pechenik, 1983; Przeslawski et al., 2004). After examination, egg masses were cleaned by agitation in filtered seawater for 30 sec, followed by gentle blotting to remove excess water. Egg masses were then lyophilized, and dry weight was recorded. Samples were stored at −80°C until extractions were performed. No degradation of MAAs was detected in an 18-mo storage period (data not presented), as also noted in previous studies (Dunlap and Chalker, 1986; Karsten et al., 1998).

Preliminary tests were performed to determine the ideal extraction conditions for these samples as recommended by Tartarotti and Saommaruga (2002). Samples were extracted using various temperatures (4, 20, and 40°C), sample weights (2, 10, 20, and 50 mg) and solvent concentrations (60% and 80% MeOH); and optimal extractions occurred at 20°C with a 20-mg sample in 80% methanol. Based on the preliminary extraction test, three serial extractions were performed on 20 mg dry weight of each egg mass in 0.5 ml 80% HPLC-grade MeOH for 1 hr at room temperature (≈20°C). Following extraction of each sample, the supernatant was pooled, and the absorption spectra from 250 to 450 nm of the extract was taken in a quartz cuvette by a scanning spectrophotometer (Shimadzu UV-1601). Extraction efficiency was tested on egg masses of *Bembicium nanum*, *Bursatella leachii*, and *S. denticulata*; and, we recovered over 95% of total MAAs after three of 6 extractions for each species.

MAAs were separated by reverse-phase high performance liquid chromatography (RP-HPLC) on a Phenosphere C8 column (5 μm, 4.6 internal diam × 250 mm) with guard (Phenomenex) at a flow rate of 0.8 ml/min. The aqueous mobile phase was 39.9:0.1:60 (water/acetic acid/methanol). Nine MAAs were identified and quantified using maximum wavelength absorption and cochromotography with prepared standards representing the most common MAAs (Karentz, 2001; Shick and Dunlap, 2002): standards for mycosporine–glycine and palythinol were prepared from *Palythoa tuberculosa*; mycosporine-2-glycine and mycosporine taurine from *Anthopleura elegantissima*; shinorine and

N = number of viable egg masses collected. Taxa refer to superfamily (SF), infraorder (IO), or order (O)

[a]Species used in analysis of maturity.

[b]Inviable egg masses of this species also collected.

[c]This species is either an omnivore or herbivore (Beesley et al., 1998). For statistical analyses, we have classified it as an herbivore since it likely ingests some algae.

[d]This species is tentatively identified based on crawling juveniles that emerged from capsules.

[e]Tentative identification based repeated sighting of adults on and near egg masses.

porphyra-334 from *Porphyra tenera*; palythine from *Mastocarpus stellatus*; and palythene and asterina-330 from the ocular lens of *Plecropomus leopardus*. Concentration was calculated based on standards and primary calibration of equipment at the Australian Institute of Marine Science and expressed in nmol/mg sample dry weight.

To provide a standardized comparison between egg masses and other organisms, we collected several intertidal organisms from full sun habitats ($N = 1$): *Actinia tenebrosa* (anemone), *Haliclona* sp. (sponge), *Hormosira banksii* (phaeophyte), and *Ulva lactuca* (chlorophyte). Adult gastropods from the following species were also collected ($N = 4$): *B. nanum*, *S. denticulata*, and *S. zelandica*. These specimens were removed from their shells and prepared and analyzed as described above with the exception that >20 mg dry weight of the whole adult (including gonads and *in vivo* eggs) were used in extractions.

Nonmetric multidimensional scaling (nMDS) plots of the data were used to clarify the distribution of MAAs in egg masses based on maturity, spawning habitat, adult diet, phylogeny (order), and viability. Nested ANOSIMs were conducted on data subsets encompassing all species, where $N \geq 3$ (Table 1). Samples without MAAs were given a nominal value of 0.0001 nmol/mg for mycosporine–glycine, to enable the calculation of Bray–Curtis similarity index for MDS plots and ANOSIMs. We used PRIMER v. 5 (Plymouth Routines in Multivariate Ecological Research) for all multivariate analyses. In addition,

two-way or nested ANOVAs were conducted on all species in JMP v. 4. These were performed separately for each MAA examined using egg mass maturity, adult diet, spawning habitat, order, and viability as factors in the analysis. Each species was considered independent and was appropriately nested or crossed with these factors (see Westoby et al., 1995a,b). Most data were skewed and/or had unequal variances, and data were log-transformed (Zar, 1998) to ensure that the assumptions of ANOVA were met. Tukey's HSD tests were used *post hoc* to reveal significant relationships. $\alpha = 0.05$ for all statistical analyses unless otherwise specified.

RESULTS

Spectrophotometry indicated the presence of UVR-absorbing compounds in many species as evidenced by maximal absorbance at UVR wavelengths (Figure 1). Of the 49 species tested, we detected and quantified MAAs in 43 viable egg masses (Table 2). We did not detect MAAs in the egg masses of the polychaetes or in egg masses from four species of mollusks (*Ranella australasia*, *Cominella eburnea*, *Mitra carbonaria*, and *Aplysiopsis formosa*) (Table 2). The mean total concentration of MAAs was over 20 nmol/mg in the egg masses

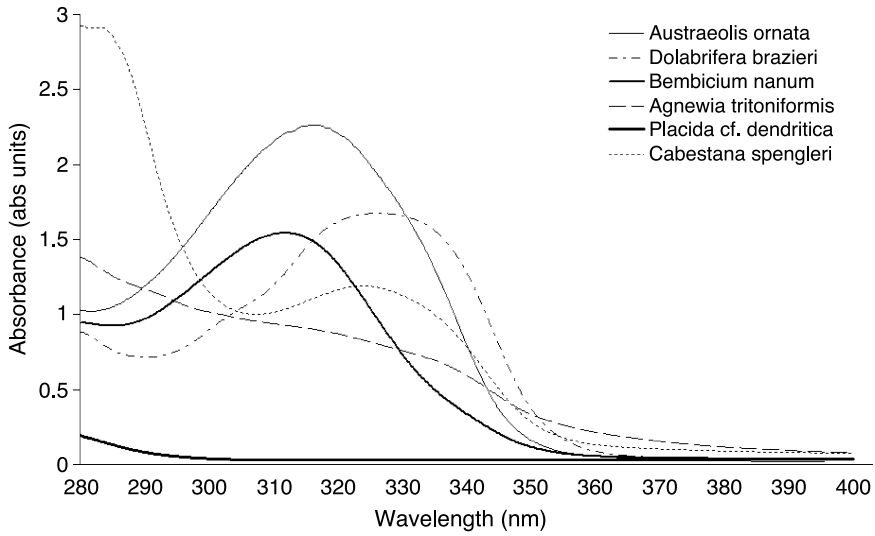

FIG. 1. UVR absorption of methanol extracts of egg masses from various species. All extracts are diluted 1:1 in 80% aqueous methanol except *Cabestana spengleri* and *Placida* cf. *dendritica*, which are undiluted.

[a]An unknown peak was detected in at least one egg mass from this species.

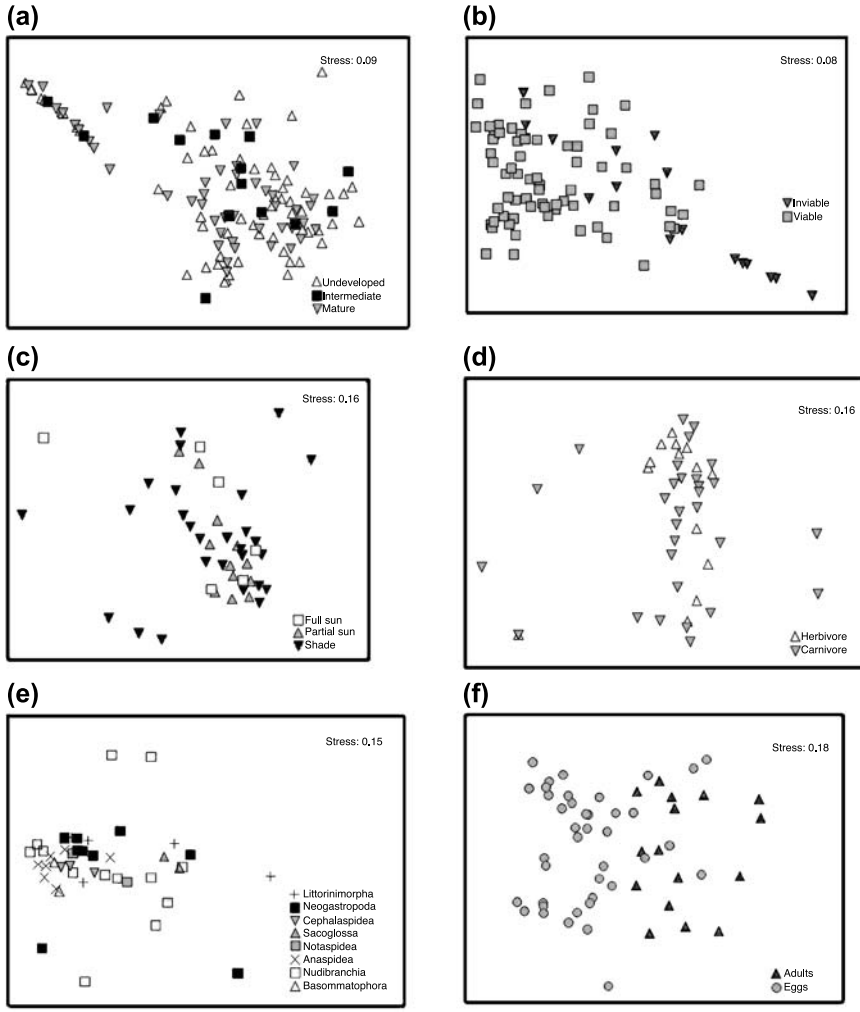

FIG. 2. Differences in the composition and relative abundance of MAAs in the egg masses of selected species as revealed by nMDS plots constrasting: (a) *Bembicium nanum*, *Siphonaria denticulata*, and *Siphonaria zelandica* adults and their egg masses; (b) effects of maturity on viable egg masses from 16 species; (c) effects of viability on egg masses from 10 species; (d) effects of spawning habitat on viable egg masses from 49 species (means shown); (e) effects adult diet on viable egg masses from 45 species with known diet (means shown); and (f) gastropod phylogeny on viable egg masses from 45 species (means shown).

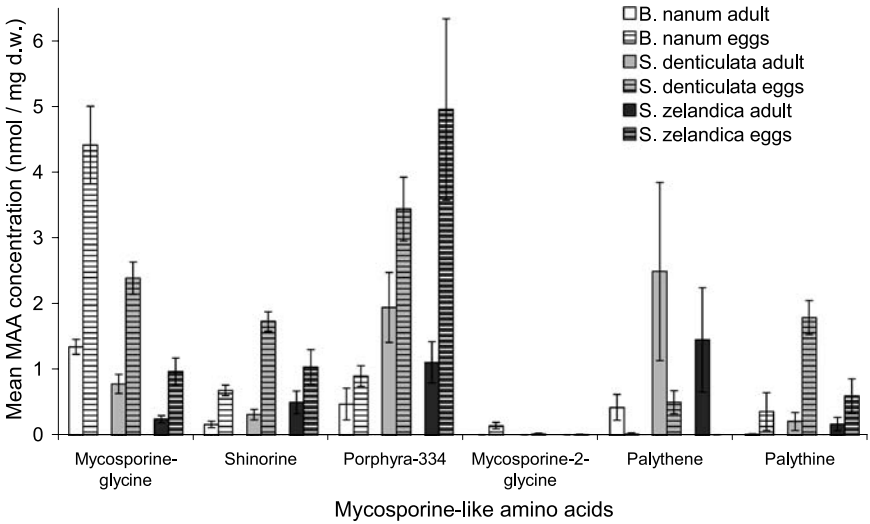

FIG. 3. MAA compositions of adults and egg masses of four species. Asterina-330 and palythinol are not included because only trace amounts were detected in these species (<0.05 nmol/mg), and no significant relationships were observed. Error bars are standard error of mean.

of *Austraeolis ornata* and was greater than 15 nmol/mg in the gelatinous masses from two other species of opisthobranch (*Stylocheilus striatus* and *Plocamopherus imperialis*). The other intertidal organisms examined showed a similar range in total MAA concentration to the mollusks, with the brown algae *Hormosira banksii* showing no detectable levels of MAAs, whereas low levels were found in the green algae *Ulva lactuca* (1.24 nmol/mg d.w.) and the sponge *Haliclona* sp. (2.18 nmol/mg d.w.). The anemone *Actinia tenebrosa* had moderately high levels of total MAAs (9.05 nmol/mg d.w.).

Eight of the nine MAAs analyzed in this study were detected in the egg masses examined. Overall, mycosporine glycine was the most common MAA, occurring in egg masses from 38 species (Table 2). Palythene was the least common, occurring in just eight species (Table 2). Palythine occurred at the highest concentration; one egg mass of the nudibranch *Austraeolis ornata* contained 16.833 nmol/mg palythine. Mycosporine–taurine was not found in any sample collected.

Unidentified HPLC peaks were detected in viable egg masses of the following species (approximate retention time in minutes, λ_{max}): *Agnewia tritoniformis*, *Lepsiella reticulata*, and *Dicathais orbita* (4.5, 307 nm); *Rostanga arbutus*, *Hoplodoris nodulosa*, and *Hypselodoris obscura* (6.3, 296 nm); *B.*

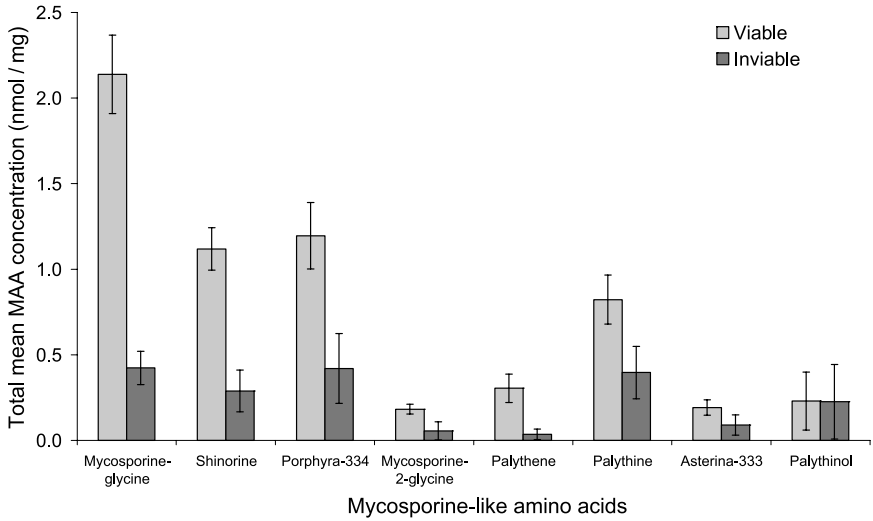

FIG. 4. MAA concentration in viable (N = 81) and inviable (N = 22) egg masses of *Bembicium nanum*, *Cabestana spengleri*, *Mayena australis*, *Cominella eburnea*, *Conus papiilliferus*, *Dicathais orbita*, *Lepsiella reticularis*, *Nucella lapillus*, *Aplysia juliana*, *Bursatella leachii*, *Dolabella auricularia*, and *Dolabrifera brazieri*. Error bars are standard error of mean.

leachii (12.2, 346 nm); *Siphonaria denticulata* (7.1, 334 nm), *Siphonaria zelandica* (2.9, 319 nm); and *A. costatus* (4.2, 325 nm). These peaks did not match with any of the MAA standards used and, therefore, could not be positively identified or quantified for analysis.

Comparison with Adults. An nMDS plot of viable egg masses and adults of species for which we had replicates revealed distinct clusters (Figure 2a), suggesting that MAA composition of egg masses was different from that of adults. ANOSIMs on each species confirmed differences between egg masses and adults of *B.nanum* (R = 0.556, P = 0.02), *S. denticulata* (R = 0.343, P = 0.016), and *S. zelandica* (R = 0.504, P = 0.019). The egg masses of these species contained higher concentrations of mycosporine–glycine (F = 23.5012, $P < 0.001$), shinorine (F = 21.214, P = 0.04), mycosporine-2-glycine (F = 11.6937, P = 0.001), and palythine (F = 8.385, P = 0.006) than the adults as revealed by a two-factor ANOVA (Figure 3). In contrast, adults had more palythene than egg masses (F = 40.873, P <0.001). An interaction between species and life stage was detected for palythinol concentrations (F = 51.336, $P < 0.001$), and Tukey's HSD tests revealed that *B. nanum* adults had more palythinol than the egg masses (Figure 3).

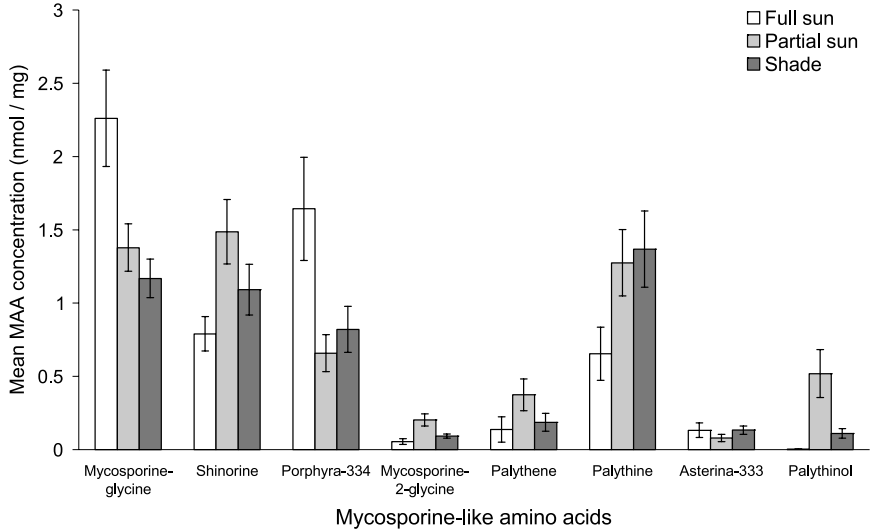

FIG. 5. Effects of spawning habitats on MAA concentration in all viable egg masses collected in this study. Habitats varied in spectral exposure and encompassed full sun (n = 54), partial sun (N = 76), and shade (N = 107). Error bars are standard error of mean.

Egg Mass Maturity and Viability. MAA composition did not vary as egg masses matured for all 16 species of mollusks tested. There was no apparent difference in MAA content between undeveloped, intermediate, and mature egg masses as revealed by an nMDS plot (Figure 2b) and a nested ANOSIM on data subsets including species where $N \geq 3$ (R = 0.079, P = 0.072) (refer to Table 1 for species tested). Thus, viable egg masses at all stages of development were pooled for each species in remaining analyses.

An nMDS ordination comparing MAA composition in viable and inviable egg masses of 10 species in which MAAs were present revealed minimal segregation of the samples (Figure 2c; see Table 1 for species tested). ANOSIMs were conducted separately on the five species where $N \geq 3$ for both viable and inviable egg masses, and these revealed species-specific effects. MAA concentration was significantly different between viable and inviable egg masses for two species: *B. nanum* (R = 0.927, P = 0.001) and *L. reticulata* (R = 0.274, P = 0.001). Similar trends were seen for *D. orbita* (R = 0.914, P = 0.06) and *D. brazieri* (R = 0.393, P = 0.054), although they were not significant at α = 0.05. No apparent differences were observed for *C. papilliferus* (R = 0.074, P = 0.274). Two-factor ANOVAs on the transformed data for these species revealed significant interactions between viability and species on concentrations of mycosporine–glycine (F = 10.03, $P < 0.001$), shinorine (F = 5.470, P = 0.001),

porphyra-334 ($F = 5$, $P < 0.001$), mycosporine-2-glycine ($F = 5.8418$, $P < 0.001$), and palythene ($F = 3.907$, $P = 0.007$). Tukey's HSD tests revealed that viable egg masses of *B. nanum* and *D. orbita* had significantly more mycosporine–glycine, shinorine, porphyra-334, and mycosporine-2-glycine than inviable egg masses; and viable *D. brazieri* egg masses had significantly more mycosporine-2-glycine and palythene than inviable egg masses (Figure 4).

Spawning Habitat and Adult Diet. An nMDS plot of MAA composition revealed no clear separation between egg masses deposited in full sun habitats compared to those deposited in shaded habitats (Figure 2d). Similarly, a nested ANOSIM failed to detect effects based on spawning habitat ($R = -0.048$, $P = 1$). Overall, the concentrations of mycosporine–glycine and porphyra-334 were highest in egg masses from species spawning in full sun, whereas palythine, palythinol, and shinorine concentrations were lowest in egg masses from these species (Figure 5). However, nested ANOVAs on the concentration of each MAA supported the multivariate results, showing no significant differences between spawning habitats.

A multivariate analysis of MAA composition in egg masses showed no overall effect of adult diet. The nMDS plot reveals no distinct separation of samples according to diet (Figure 2e), and a nested ANOSIM confirmed no significant differences between herbivores and carnivores ($R = -0.285$, $P = 1$). However, nested ANOVAs on individual MAAs did reveal some significant differences

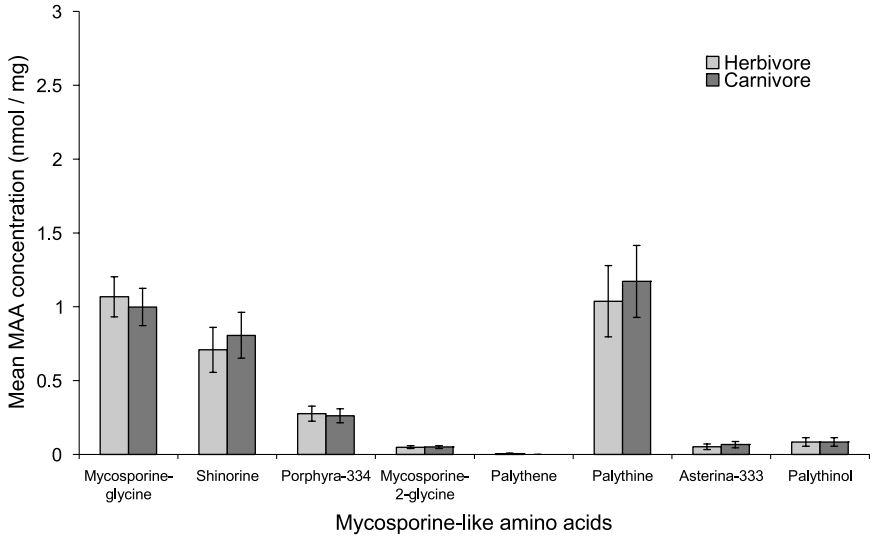

FIG. 6. Effects of adult diet on MAA concentration for all viable egg masses in which adult diet is known to be either herbivore ($N = 114$) or carnivore ($N = 112$) (refer to Table 1). Error bars are standard error of mean.

according to diet. Herbivores had significantly higher levels of porphyra-334 ($F = 5.24$, $P = 0.027$) and palythene ($F = 11.95$, $P = 0.001$), with no palythene recorded in any egg masses from carnivores (Figure 6). Although not statistically significant, similar trends were also detected for mycosporine–glycine ($F = 3.860$, $P = 0.056$) (Figure 6).

Gastropod Phylogeny. The taxonomic grouping (order) of gastropods correlated with MAA content in egg masses. An nMDS plot showed some taxonomic clusters, particularly within anaspids (Figure 2f). Considerable variation was observed within many orders (e.g., Nudibranchia and Neogastropoda), as evidenced by the large spread of points on the nMDS (Figure 2f) and relatively large error bars for individual MAA concentrations (Figure 7). A nested ANOSIM on all orders with two or more species indicated less variation within than between taxonomic groups in their MAA composition ($R = 0.082$, $P = 0.098$). Pairwise tests showed that the MAA content of anaspid egg masses was different from that of sacoglossans ($R = 0.818$, $P = 0.048$), and possibly neogastropods ($R = 0.248$, $P = 0.063$). The MAA composition of nudibranch egg masses appeared different from that of neogastropods ($R = 0.244$, $P = 0.057$) and sacoglossans ($R = 0.396$, $P = 0.056$). Although not significant

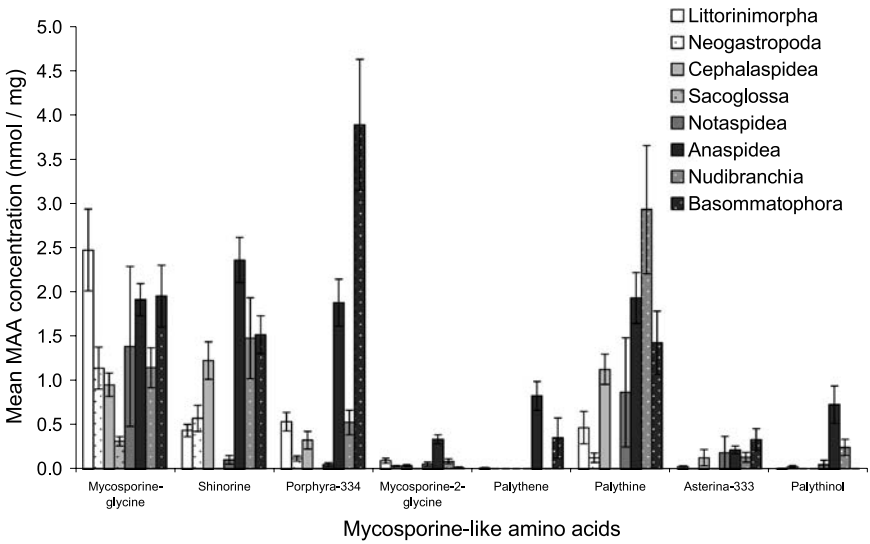

FIG. 7. Effects of gastropod order on MAA concentration in viable egg masses collected in this study: Littorinimorpha ($N = 4$), Neogastropoda ($N = 10$), Cephalaspidea ($N = 3$), Sacoglossa ($N = 3$), Notaspidea ($N = 3$), Anaspidea ($N = 7$), Nudibranchia ($N = 12$), and Basommatophora ($N = 2$), where n indicates number of species. Error bars are standard error of mean.

at $\alpha = 0.05$, nonsignificant results here should be interpreted cautiously because of the large intra- and interspecific variation in MAA complements (Figure 2f).

Nested ANOVAs of individual compounds confirmed significant phylogenetic differences in the quantity of shinorine ($F = 3.910$, $P < 0.001$), porphyra-334 ($F = 3.302$, $P < 0.001$), mycosporine-2-glycine ($F = 3.302$, $P < 0.001$), palythene ($F = 5.415$, $P < 0.001$), and palythine ($F = 2.956$, $P < 0.001$). Sacoglossans had significantly less shinorine than anaspids, cephalaspids, nudibranchs, and basommatophorans; and similarly, they had less palythine than anaspids (Figure 6). Anaspids had significantly more porphyra-334 and mycosporine-2-glycine than sacoglossans and neogastropods; and they had more palythene than all other orders except for the basommatophorans (Figure 7). Basommataphorans had significantly more porphyra-344 than sacoglossans (Figure 7).

DISCUSSION

This study is the first quantitative survey of mycosporine-like amino acid composition in eggs or extraembryonic structures. It confirms that MAAs are prevalent in the intertidal egg masses of many gastropods on temperate rocky shores. Unfortunately, it is difficult to directly compare MAA concentration of egg masses used here with organisms from other studies because of the persistent use of several different measures of concentration across the literature (Karentz, 2001). However, those studies that reported MAA concentration in the units used here (nmol/mg) show that nonsymbiotic animals have similar ranges of MAA concentrations to those exhibited in this study (McClintock and Karentz, 1997; Banaszak et al., 1998). For example, larvae of the urchin *Strongylocentrotus droebachiensis* contain 4–8 nmol/mg total MAAs (Adams and Shick, 2001), which represents the middle range of the concentrations we detected (Table 2). Indeed, direct comparisons with other intertidal organisms in the present study such as *Hormosira banksii*, *Ulva lactuca*, and *Haliclona* sp. confirm that MAA concentrations in egg masses of some species are relatively high.

Egg masses of *B. nanum*, *S. denticulata*, and *S. zelandica* are laid in habitats where they are directly exposed to UVR. They contained more MAAs than the whole adults examined (Figure 3), which is consistent with the suggestion that MAAs have a photoprotective role in these species. Other intertidal invertebrates have been found to sequester MAAs in spawn to minimize UV-induced damage to offspring in a potentially hostile environment. This trend has been recorded in the sea urchin *Strongylocentrotus droebachiensis* (Adams et al., 2001) and the sea hare *Aplysia dactylomela* (Carefoot et al., 1998; Carefoot et al., 2000). It remains unknown if species that spawn exclusively in shade sequester MAAs in eggs.

The relatively high concentrations of MAAs in some egg masses suggest that embryos of certain species are protected from the damaging effects of UVR. This is consistent with previous research in which embryos of species that consistently spawn in habitats exposed to full sun were more resistant to the damaging effects of UVR than embryos of species that only spawn in shaded habitats (Przeslawski et al., 2004). However, contrary to our prediction, we have found no clear pattern in MAA composition relating to spawning habitat (Figures 2d and 5). Furthermore, a direct comparison of total MAA concentration in egg masses of species used in both the present study and in a previous one by Przeslawski et al. (2004) revealed no significant correlation between MAA concentration and the difference in embryonic mortality between full spectrum and UV-blocked treatments ($R = 0.004$, $P = 0.795$). This suggests that MAAs are not the sole source of protection afforded to encapsulated intertidal embryos.

There are many other ways for marine organisms to mitigate the deleterious effects of UVR (Bandaranayake, 1998). Antioxidants may play an important role in minimizing UVR damage in marine organisms (reviewed by Dunlap et al., 1999). Indeed, the most common MAA observed in this study, mycosporine–glycine, is also a moderate antioxidant (Dunlap and Yamamoto, 1995). The potential importance of this compound is supported by comparisons with adults and inviable egg masses. Eggs had significantly higher concentrations of mycosporine–glycine than adults (Figure 3); and viable egg masses had higher concentrations than inviable egg masses (Figure 4). Furthermore, egg masses from species spawning in full sun contained the highest levels of mycosporine–glycine relative to species that spawned in partial or full shade (Figure 3). Mycosporine–glycine is the only MAA found in this study that absorbs maximally at 310 nm (Figure 1), the range of UVR (UVB) that is most biologically damaging (Paul and Gwynn-Jones, 2003). Thus, embryos encapsulated in environments exposed to UVR may use mycosporine–glycine in a dual protective role as a UV-B sunscreen and an antioxidant. Egg masses routinely deposited in habitats exposed to full sun may also possess other protection against damage caused by UVR. Other metabolites such as carotenoids may provide photoprotective antioxidant functions; such compounds have already been found in holothurian eggs (Bandaranayake, 1998) and warrant further investigation. In addition, high levels of the DNA repair enzyme photolyase have been found in several adult mollusks, including *B. leachii* (Carlini and Regan, 1995), a species used in this study. The capability of encapsulated intertidal embryos to repair UVR-induced DNA damage is currently unknown.

MAA composition in gastropod egg masses shows enormous phylogenetic variation (Figure 7), and phylogeny may well overwhelm the influence of all other factors examined in this study. Even unknown compounds detected in this study elicited phylogenetic patterns. For example, the same unknown peak was seen only in egg masses of three species of neogastropods; and a different

unknown peak, possibly deoxygadusol (see Shick and Dunlap, 2002), was found only in three species of nudibranchs. Previous research on sea anemones has similarly revealed that differences in MAA concentration primarily reflect phylogeny rather than environmental factors (Shick et al., 2002). Alternatively, phylogeny may be related to an ecological factor not considered in the present study; and indeed, variation based on phylogenetic and ecological factors is not often mutually exclusive (Westoby et al., 1995b).

Phylogeny and diet can often be confounded, but the effects of phylogeny are unlikely to be influenced by diet in the present survey. In general, egg masses from herbivores had higher levels of some MAAs than those from carnivores (Figure 6); but when analyzed according to order, egg masses of carnivorous nudibranchs had significantly more MAAs than egg masses from most herbivorous orders (Figure 7). Nevertheless, MAAs in eggs or larvae are likely dependent on adult diet, and studies on single species of mollusks and echinoderms reveal that eggs have higher MAA content if they are deposited by adults that consumed food rich in MAAs compared to adults that ate food containing few or no MAAs (Adams et al., 2001; Carefoot et al., 1998, 2000). The present study indicates that this diet dependence may extend to differences in MAAs between trophic levels (Figure 6).

Nevertheless, analysis of MAA composition based on adult diet was not as definitive as previous analyses of total MAA concentration in which herbivores unilaterally showed higher concentrations of MAAs than carnivores (Przeslawski, 2004b). In the present study, we found minimal differences in MAA composition between trophic levels (Figure 2e) and significant differences in only two of the eight MAAs detected (Figure 6). These results underscore the value of MAA composition analysis compared to the potentially overly simplistic interpretations arising from univariate analysis of total MAA concentration. For example, in the previous univariate analyses, it was suggested that herbivores have more direct links to sources of MAAs, and bioaccumulation does not occur in a broad range of species (Przeslawski, 2004b). However, the potential impact of MAA bioaccumulation cannot be ignored and has previously been recorded in a trophic chain including phytoplankton, herbivorous pteropods, and carnivorous pteropods (Whitehead et al., 2001). Indeed, the high concentrations of some MAAs in certain nudibranch egg masses are consistent with MAA bioaccumulation from their prey and associated zooxanthellae (Table 2). Furthermore, analyses of total MAA concentration cannot account for the different strategies employed by organisms based on MAA composition. Some species, such as *Siphonaria denticulata* used in this study, may incorporate several compounds at low or moderate concentrations (Table 2). Other species, such as *Bembicium nanum*, may use higher concentrations of a single MAA to confer protection (Table 2).

Viable egg masses had a richer complement of MAAs and had higher concentrations of individual compounds than inviable egg masses (Figure 4).

These results support previous univariate analysis of total MAA concentration in these egg masses (Przeslawski, 2004b). No previous study has investigated MAA composition in inviable eggs, and the mechanisms behind the relationship here are unclear. It is unknown if lower MAA concentration in these species resulted in the lack of viable embryos or if it was a consequence of inviability. The egg masses in this study were collected *in situ* after spawning so the history of the spawning adult and egg mass prior to collection was not known.

MAA concentration of egg masses varied tremendously within species (Table 2, Figure 1). Indeed, previous research has shown that unique MAA compositions can be used to identify clones within a species of coral (Diamond, 1986). The intraspecific variation in the present study may have limited the detection of significant differences according to habitat, diet, and taxonomic order. Notably, however, the present survey has generally incorporated more replicates than most other surveys of MAAs. Indeed, previous surveys have reported MAA concentration based on single samples for each organism (e.g., Karentz et al., 1991; McClintock and Karentz, 1997) or a low number of replicates (e.g., Bosch et al., 1994; Büdel et al., 1997; Teai et al., 1997; Xiong et al., 1999). This lack of replication may yield biased estimates of MAA concentrations; and results should be treated with caution, particularly in cases where MAA composition shows high intraspecific variation.

Although the magnitude of their effectiveness as sunscreens for organisms remains unclear, MAAs are likely important to developing encapsulated embryos. MAAs may play a role in osmotic regulation and developmental regulation (reviewed by Shick and Dunlap, 2002), and such functions would certainly be vital to encapsulated embryos developing in the intertidal. Unfortunately, there is a paucity of empirical research on alternate functions of MAAs to photoprotection in marine invertebrates. In contrast, there is a wealth of evidence that MAAs minimize UV-induced abnormality and mortality (reviewed by Karentz, 2001). Previous research shows MAA concentration is logarithmically correlated to developmental success in sea urchin embryos because of reduction in UVR exposure (Adams and Shick, 1996). No similar studies have been conducted on embryos of the species used in this study, but MAAs may indeed confer protection to embryos from species that consistently spawn in full sun habitats. However, MAA composition does not seem to be simply based on exposure to UVR, and instead likely represents complex and potentially confounding influences from both phylogenetic and ecological factors.

Acknowledgments—W. Dunlap at the Australian Institute of Marine Science generously provided guidance and facilities for MAA standard synthesis. S. Robinson assisted with HPLC analysis. Staff at the Australian Museum Fish Department helped identify the fish egg mass. This work was supported in part by a grant to R.P. from the Conchologists of America. This is contribution #257 from the Ecology and Genetics Group at the University of Wollongong.

(Received February 1, 2005; accepted May 16, 2005)

Abstract—A metal oxide sensor-based electronic nose was tested for its ability to discriminate among chrysanthemum cultivars with varying degrees of resistance to western flower thrips (WFT), based on volatile chemicals released from cut leaves. Cultivars that were susceptible, intermediate, or resistant to WFT [based on mean cultivar rank (MCR)] were used as standards, and were correctly classified (> 90%) by using discriminant function analysis. Several cultivars with unknown resistance were classified based on the standards, and were used as standards in a subsequent trial to classify other unknowns. The results of this study demonstrate some agreement between the WFT resistance categories as designated by the electronic nose and results of feeding bioassays (MCR), suggesting that this technique may serve as a useful screening tool for WFT resistance.

Key Words—Chrysanthemum, western flower thrips, electronic nose, resistance.

INTRODUCTION

Thrips are destructive to ornamental plants because of the physical damage caused by their feeding on tissues of developing and mature flowers and leaves. In addition, thrips can vector diseases such as tomato spotted wilt virus, which

* To whom correspondence should be addressed. E-mail: McKellarR@agr.gc.ca
† Contribution number S211 from the Food Research Program.

affects a wide range of plants (Broadbent et al., 1990). The western flower thrips (WFT), *Frankliniella occidentalis* (Pergande), has been the major insect pest of greenhouse floriculture in Canada since the late 1980s (Broadbent et al., 1987). Thrips adults and larvae are thigmotactic, preferring to hide in complex plant parts, flower buds, and other folded tissues, where they are difficult to detect and to reach with insecticides. Control of WFT has become even more difficult because of resistance to conventional insecticides (Broadbent and Pree, 1997; Immaraju et al., 1992). Alternate means of controlling thrips are clearly required.

Host-plant resistance to WFT, particularly in chrysanthemum, is recognized as having great potential to reduce reliance on pesticides for control of this pest (Van Dijken, 1992; De Jager et al., 1993). A study of chrysanthemum cultivars revealed wide variation in their degree of resistance or susceptibility to WFT (Broadbent et al., 1990). Variation in pollen production (De Jager and Butôt, 1993) and difference in color of blooms (Van Dijken et al., 1993) were found to have little impact on this interaction. Secondary metabolites of chrysanthemum have been suggested to be the primary factor in resistance (De Jager et al., 1995, 1996). Fung et al. (1999) also suggested a role for secondary metabolites in the chrysanthemum–thrips interaction. They concluded that primary metabolites such as amino acids did not contribute to the activity of chrysanthemum leaf sap against WFT.

The electronic nose (EN) is an analytical instrument designed to mimic the human nose (Gardner and Bartlett, 1994; Mielle, 1996; Bartlett et al., 1997; Dickinson et al., 1998). There are a number of different technologies available, but generally, an EN consists of a semiselective sensor array that reacts with volatile chemicals in the sample headspace. In our laboratory, we have used a commercial EN (Fox 3000, AlphaMOS, Toulouse, France), which consists of 12 metal oxide sensors, each of which has a particular specificity for a class of compounds, such as hydrocarbons, aldehydes, amines, or aromatics, depending on the type and amount of semiconducting film that has been applied (Table 1). As headspace gases from a sample are passed over the sensors, the reaction between oxygen, the film, and volatile molecules results in a change in conductivity of the sensor through oxidation (increases conductance) or reduction (decreases conductance) reactions to form a pattern (Mielle, 1996). The patterns are then processed and analyzed using advanced pattern recognition techniques such as principal component analysis (PCA) or discriminant function analysis (DFA). A database of known samples can then be created, and the EN can then be used to identify unknown samples by comparison with the database with a high degree of accuracy (AlphaMOS, 1997). We have used the Fox 3000 EN in a number of applications including the development of orange juice flavor (Farnworth et al., 2002), the detection of spoilage in packaged minimally processed lettuce (Odumeru et al., 2003), and the optimization of beer aging (McKellar et al., 2002).

TABLE 1. LIST OF SENSORS IN THE FOX 3000 ELECTRONIC NOSE

Sensors	Description	Specificity
SY/LG	Fluoride/chlorine	Fluoride/chlorine
SY/gCT	Nonpolar volatiles	Methane, propane
SY/Gh	Aromatic	Alcohol and aromatic
SY/G	Ammonia/sulfur	Amines/ammonia
SY/AA	Nonpolar volatiles	Hydrocarbon, methane, propane
P10/2	Nonpolar volatiles	
SY/gCTl	Organic solvents	Polar, ethanol, alcohol
P10/1	Nonpolar volatiles	
PA2	Organic solvents	
T30/1	Organic solvents	
P40/1	Fluoride/chlorine	
T70/2	Food aroma	Alcohol, volatiles

It is reasonable to hypothesize that thrips resistance might be related to volatile chemicals released by leaves. Thus, the purpose of the present study was to determine whether the EN could discriminate between resistance categories of chrysanthemums using samples of cut leaves.

METHODS AND MATERIALS

Chrysanthemum Plants. Rooted cuttings of all chrysanthemum cultivars were provided by Yoder Canada (Leamington, Ontario, Canada) and potted and grown in the greenhouse at the Southern Crop Protection and Food Research Centre of Agriculture and Agri-Food Canada (AAFC) in Vineland Station, Ontario. Mature (6 wk old) plants were shipped to the Food Research Program (Guelph, Ontario) and were watered and maintained in the lab while being analyzed by the electronic nose.

Two trials were conducted, with 11 cultivars tested in trial 1 and 13 in trial 2. In trial 1, five samples were taken from each of two replicate plants, whereas for trial 2, three samples were taken from each of three replicate plants. The exception was Icecap in trial 2, which was represented by two sets of three plants ($N = 18$ in total).

Operation of the Electronic Nose. The first pair of fully opened leaves from the top of each replicate plant was taken for sampling. Five leaf disks (#6 punch; 1-cm diam) were taken from the apex of each lobe of a leaf. If the leaf was too small to allow five samples, the other paired leaf was also used. The leaf disks were placed individually into 10-ml autosampler vials (Fisher Scientific) and capped with silicon/Teflon autosampler vial caps (London Scientific). Each vial was loaded into an autosampler (HS50, CTC Analytics, Switzerland) and heated

at 35°C for 5 min. Headspace (2500 µl) was removed from each vial by the autosampler and injected into the electronic nose with a 10-min delay between samples.

Data Analysis. Raw output from each of the 12 sensors was analyzed by DFA using UNISTAT® Version 5.5 (UNISTAT Limited, London, UK), a Microsoft® Excel add-in. DFA typically is used to determine which continuous variables (here the sensor outputs) discriminate between two or more naturally occurring groups. DFA provides orthogonal (independent) linear discriminant functions such that the first one provides the most overall discrimination among groups, the second provides the second most, and so on. In practice, two discriminant functions (here designated LD1 and LD2) are generally sufficient to describe most of the variation. The intention is to minimize the within-group differences and maximize the between-group differences. The common practice is to use discriminant functions to predict group membership of samples that were not used in the development of the original model. In the absence of such data, cross-validation can be performed. In this approach, each sample is removed sequentially from the model, and the model reformulated without that sample. The classification of the removed sample is then tested against the new model. Both unknown samples and cross-validations are presented in this study.

RESULTS

Preliminary results comparing different leaves on the same plant suggested that discrimination between susceptible, medium, and resistant cultivars was more effective using the first leaf, or pair of leaves, from the top of the plants (data not shown). This leaf was used in all further experiments.

The cultivars tested in trial 1 are listed in Table 2. Six (two each of susceptible, medium, and resistant) of the 11 cultivars were selected as standards, based on mean cultivar rank (MCR). The MCR is a ranking system used to compare thrips resistance based on the amount of feeding damage on leaves (Broadbent et al., 1990). A particular classification was deemed correct when the majority of the replicates were correctly classified. When the classification determined by one or more of the replicate plants differed from the results when the plant replicates were pooled, the pooled classification was taken as correct.

Overall, the six standards were correctly classified by cross-validation, with only a few incorrect classifications (Table 2). The percent correct for the individual plants and combined data were all > 90%; however, a lower percent correct was obtained when the data were pooled. Of the unknowns, Dark Bronze Charm was consistently classified as medium in resistance. Snowdon was deemed susceptible, although for plant A, more of the replicates were classified as either

TABLE 2. CLASSIFICATION OF CHRYSANTHEMUM CULTIVARS BY THRIPS RESISTANCE (TRIAL 1)

Cultivar		Combined	Plant A	Plant B
Percent correct		91.7	96.7	100.0
N	Initial assignment[a]	10	5	5
Amber	S	S[b]	S	S
Dark Bronze Charm	U	M (1S)	M (1S)	M (1S)
Florida Marble	S	S	S	S
Palisade	M	M (1R)	M	M
Polaris	M	M (3S)	M	M
Snowden	U	S (3R)	1S-2M-2R	S
Super White	R	R (1S)	R (1S)	R
Super Yellow	R	R	R	R
Vero	U	S (3R)	R (1S)	S (1R)
Yellow Favor	U	R (3M)	S (1R)	R (2M)
Yellow Vero	U	S (4R)	R (2S)	S (1R)

[a] Thrips resistance based on mean cultivar rank (Broadbent et al., 1990). S, susceptible; M, medium; R, resistant; U, unknown.
[b] First capital letter indicates the majority classification of the replicates. Numbers and classifications in parenthesis are those replicates that were misclassified by cross-validation.

medium or resistant. Of the other unknowns, Vero and Yellow Vero were susceptible, and Yellow Favor was resistant; however, this classification was reversed for plant A (Table 2).

Figure 1 shows the scatter diagram for the three resistance categories using pooled data from trial 1. Standards of known resistance from Table 2 were plotted as open symbols, with the closed symbols representing the unknowns (Figure 1a). The axes labels represent the first and second linear discriminant, with the percent variation explained in parentheses. Scatter diagrams are often difficult to interpret; thus, the centroid for each category was plotted with standard deviation bars in the *x*- and *y*-direction (Figure 1b). Unknown samples are adjacent to the standards of the same resistance category, with greater variation found with the unknowns as compared to the standards.

The ability of the electronic nose to distinguish among the individual chrysanthemum cultivars was assessed by initially assigning all replicate samples to the known cultivar and testing the prediction by cross-validation. When the data from all plants were pooled, > 80% of the samples were correctly classified into cultivar (Table 3). Higher correct classifications were found when individual plants were analyzed separately. Table 3 also shows that, for the pooled and plant B data, incorrectly classified samples were classified as another cultivar in the same resistance category in 76 and 62.5% of cases, respectively. This suggests

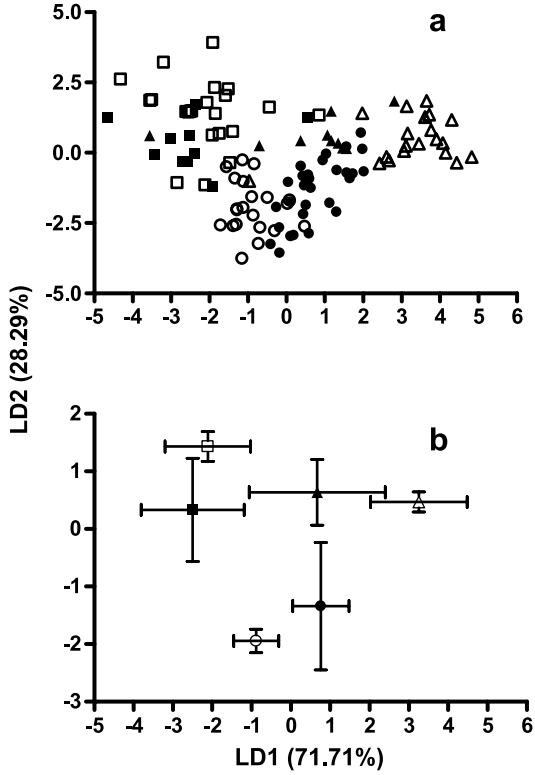

FIG. 1. Scatter diagram (a) and error (SD) bar plot (b) for western flower thrips resistance categories of chrysanthemums from trial 1 (pooled plants A and B). Standards of known resistance (open symbols) were used to classify unknowns (closed symbols) into susceptible (○), intermediate (□), or resistant (△). Values on axes are the percent variation explained by that linear discriminant.

that cultivar misclassification may be due, in part, to similarities between cultivars with respect to thrips resistance.

A second trial was performed in which 13 different cultivars were examined. One of these, Icecap, was represented by two sets of three plants, and the data for this cultivar were pooled. Susceptible standards were Snowdon and Vero, unknowns from trial 1. The medium standards (Polaris and Palisade) were the same as those from trial 1. The two resistant standards from trial 1 (Super White and Super Yellow) were also used as standards in this trial, as was the other resistant cultivar (Yellow Favor), unknown in trial 1.

Classification of the standards using the pooled data sets for the three plant replicates was >88% by cross-validation (Table 4). Up to 100% correct

TABLE 3. CLASSIFICATION OF CHRYSANTHEMUM CULTIVARS INTO VARIETIES (TRIAL 1)

	All plants	Plant A	Plant B
Number of replicates analyzed	110	55	55
% Correct	81.3	94.6	86.0
Number incorrect	21	3	8
% Incorrect	18.75	5.26	14.04
% Incorrect from same category	76.19	33.33	62.5

classification was obtained with plant replicates A and C. Classification of unknowns appeared to be less successful in this trial. Chardonnay was correctly classified as resistant; however, classification of the other unknowns was less clear. Fiery Barbara and May Shoesmith were designated resistant, although they were susceptible in two of the three plant replicates. Red Delano was designated susceptible, although it was resistant and medium in one each of the three plant replicates. Classification of Icecap was difficult; whereas it was susceptible in the combined data set, there was no clear classification in any of the plant replicates.

TABLE 4. CLASSIFICATION OF CHRYSANTHEMUM CULTIVARS BY THRIPS RESISTANCE (TRIAL 2)

Cultivar		Combined	Plant A	Plant B	Plant C

[a] Thrips resistance based on mean cultivar rank (Broadbent et al., 1990). S, susceptible; M, medium; R, resistant; U, unknown.

[b] First capital letter indicates the majority classification of the replicates. Numbers and classifications in parenthesis are those replicates that were misclassified by cross-validation.

[c] $N = 18$ for Icecap.

The difficulties experienced in classification of unknowns are reflected in the scatter diagrams for plant C, as an example (Figure 2). Whereas the standards showed little variation, large error bars were found with the unknowns.

Variation among cultivars appeared to be related to factors other than thrips resistance, as is indicated in Table 5. Classification into cultivars was poor for the combined trial 2 data set, with only 59% correct. Of the 55 incorrectly classified samples, only one third were from the same resistance category, no improvement over random assignment. Two of three misclassified plant A samples and one of two misclassified plant C samples were correctly placed in the same resistance category.

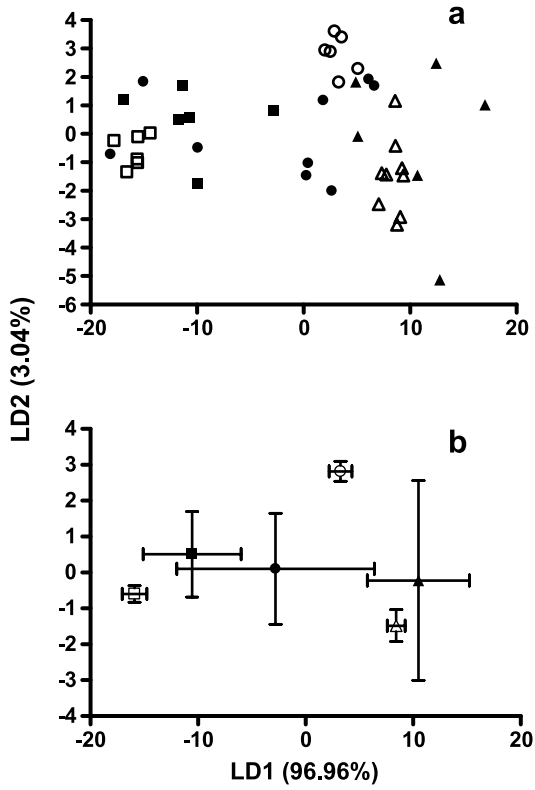

FIG. 2. Scatter diagram (a) and error (SD) bar plot (b) for western flower thrips resistance categories of chrysanthemums in trial 2 (plant C). Standards of known resistance (open symbols) were used to classify unknowns (closed symbols) into susceptible (○), intermediate (□), or resistant (△). Values on axes are the percent variation explained by that linear discriminant.

TABLE 5. CLASSIFICATION OF CHRYSANTHEMUM CULTIVARS INTO VARIETIES (TRIAL 2)

	All Plants	Plant A	Plant B	Plant C
Number of replicates analyzed	126	42	42	42
% Correct	58.7	98.3	100.0	95.2
Number incorrect	55	3	0	2
% Incorrect	43.65	7.14	0	4.76
% Incorrect from same category	34.55	66.67	0	50

Table 6 gives a summary of the results of the two trials, with the associated MCR values for cultivars for which they are available. Three of the cultivars in trial 2, which were treated as unknowns (Icecap, Chardonnay, and May Shoesmith), had been classified using the MCR system (Broadbent et al., 1990). Icecap was classified by the EN as susceptible, and the corresponding MCR was relatively high compared to the values for known medium resistant (Table 6). Chardonnay, designated resistant, had a MCR below 10, consistent with other resistant cultivars. In contrast, May Shoesmith had a MCR of 15.6, putting it in the medium region; however, the EN classified this cultivar as resistant.

TABLE 6. SUMMARY CLASSIFICATION OF CHRYSANTHEMUM CULTIVARS BY THRIPS RESISTANCE

[a] Mean cultivar rank (Broadbent et al., 1990).
[b] Used as standards in this trial: S, susceptible; M, medium; R, resistant.
[c] Classified by model in this trial.

A stepwise DFA was carried out to determine which of the 12 sensors were contributing the most to the classification into resistance categories. The SY/LG sensor, which detects fluorine/chlorine-containing compounds, was selected in all three of the analyses listed in Table 2. The other sensor most often selected (in two of the analyses) was SY/gCT, which detects nonpolar solvents such as methane and propane. For trial 2, the sensors most often selected were SY/gCTI (three of four analyses in Table 4), which detects organic solvents such as ethanol, and SY/G (two of four analyses in Table 4), which detects amines and ammonia.

DISCUSSION

This study has demonstrated that the EN has some capability to classify chrysanthemum cultivars into western flower thrips resistance categories using volatiles released from leaf disks. Standard cultivars that had been designated susceptible, medium, and resistant based on thrips feeding damage were well classified by cross-validation. Unknowns were less well classified, particularly in trial 2. When classification of plants into cultivars was attempted, misclassified cultivars were often assigned to the same resistance category, suggesting that cultivars in the same category are sufficiently similar to confound cultivar classification (at least in trial 1). Some difficulty was experienced in maintaining the quality of plants prior to sampling because of delays in delivery, which may have influenced the EN results. However, overall, there was fairly good agreement between unknowns in trial 2 and the MCR, suggesting that the EN can serve as an effective screening tool for thrips resistance.

The ability of the EN to discriminate among thrips-resistant cultivars suggests that volatile chemicals given off by the leaves are involved in resistance. Some evidence has been presented to implicate plant secondary metabolites in thrips resistance. De Jager et al. (1995) found that 76% of the variation in resistance of chrysanthemum cultivars was explained by the phytochemicals in leaf sap. This was later attributed to the synergistic effect of unidentified secondary metabolites fractionated from chrysanthemum leaves (De Jager et al., 1996). More recently, Tsao et al. (2003) extracted a new unsaturated fatty acid isobutylamide, *N*-isobutyl-(2*E*,4*E*,10*E*,12*Z*)-tetradecatetraen-8-ynamide, from chrysanthemum leaves, which correlated with thrips resistance (Tsao et al., 2005).

The EN is able to provide a "fingerprint'' of the volatiles released from cut chrysanthemum leaves, but is not able to identify the compounds involved in resistance. The relationship between volatiles detected by the EN and the putative resistance chemicals isolated from leaves is presently unknown. Recent findings (J.C. Young et al., unpublished results) suggest that thrips resistance in chrysanthemums is complex. Volatile chemicals given off by cut leaves were analysed

by solid-phase microextraction and GC/MS, and it was found that specific volatiles could be correlated with resistant and susceptible cultivars. Further studies to relate specific volatiles to the EN responses are warranted.

Acknowledgment—The authors thank Dr. J.C. Young (Food Research Program, Guelph, Ontario) for permission to discuss his unpublished results.

CUTICULAR HYDROCARBONS OF BUFFALO FLY, *Haematobia exigua*, AND CHEMOTAXONOMIC DIFFERENTIATION FROM HORN FLY, *H. irritans*

RUDOLF URECH,* GEOFFREY W. BROWN, CHRISTOPHER J. MOORE, and PETER E. GREEN

Department of Primary Industries and Fisheries (Queensland), Animal Research Institute, 665 Fairfield Rd, Yeerongpilly, Queensland 4105, Australia

(Received September 8, 2004; revised February 23, 2005; accepted June 11, 2005)

Abstract—We determined the quantity and chemical composition of cuticular hydrocarbons of different strains, sexes, and ages of buffalo flies, *Haematobia exigua*. The quantity of cuticular hydrocarbons increased from less than 1 μg/fly for newly emerged flies to over 11 μg/fly in 13-d-old flies. The hydrocarbon chain length varied from C_{21} to C_{29}, with unbranched alkanes and monounsaturated alkenes the major components. Newly emerged flies contained almost exclusively C_{27} hydrocarbons. Increasing age was accompanied by the appearance of hydrocarbons with shorter carbon chains and an increase in the proportion of alkenes. 11-Tricosene and 7-tricosene were the most abundant hydrocarbons in mature *H. exigua*. Cuticular hydrocarbons of *H. exigua* are distinctly different from those of horn flies, *Haematobia irritans*. The most noticeable differences were in the C_{23} alkenes, with the major isomers 11- and 7-tricosene in *H. exigua* and (*Z*)-9- and (*Z*)-5-tricosene in *H. irritans*, respectively. Cuticular hydrocarbon analysis provides a reliable method to differentiate the two species, which are morphologically difficult to separate. The differences in cuticular hydrocarbons also support their recognition as separate species, *H. exigua* and *H. irritans*, rather than as subspecies.

Key Words—Cuticular hydrocarbons, *Haematobia*, buffalo fly, horn fly, Diptera, chemotaxonomy, gas chromatography, mass spectrometry, alkenes.

INTRODUCTION

The buffalo fly, *Haematobia exigua* de Meijere (Diptera: Muscidae) abounds in the Oriental and Australian regions (Seddon, 1967; Williams et al., 1985). *H. exigua* is an obligate blood feeder spending most of its time on the host (MacQueen and Doube, 1988) and constitutes one of the major animal health problems to dairy and beef producers in northern Australia. The horn fly, *Haematobia irritans* (L.) a close relative of *H. exigua*, is found in the Americas, North Africa, and Europe, and is also considered a major arthropod pest of pastured cattle in the US and Canada (Drummond et al., 1986; Kunz, 1986).

Morphological differentiation of the adult fly species is difficult, and Pont (1973) indicated that the various larval stages were probably indistinguishable. While Zumpt (1973) recognized the two as subspecies of *H. irritans*, Skidmore (1985) subsequently recognized them as two separate species, *H. exigua* and *H. irritans*, although acknowledging their close relationship. Species and subspecies status are currently being applied to these flies by various authors. One approach to species identification that could clarify this situation is cuticular hydrocarbon profiling (Lockey, 1991), which has been successfully applied to a number of problem species (Carlson et al., 1993; Page et al., 1997; Brown et al., 1998; Broza et al., 2000; Howard et al., 2003). The cuticular hydrocarbons of *H. irritans* have been identified (Mackley et al., 1981), with the major components being odd-numbered, straight-chain C_{21}–C_{29} saturated hydrocarbons and monounsaturated C_{23}, C_{25}, and C_{27} alkenes. Double bond positions were established through oxidative cleavage followed by gas chromatography-mass spectrometry (GC-MS) of the resulting aldehydes.

In this study, we report the identification of *H. exigua* cuticular hydrocarbons and variations in their composition and quantity depending on the sex and age of the fly. We employ a more elegant and direct route to the determination of double bond positions through the formation and GC-MS analysis of dimethyl disulfide (DMDS) adducts (Scribe et al., 1988; Carlson et al., 1989). Considering the morphological and behavioral similarities between *H. irritans* and *H. exigua*, the resulting information is valuable and useful for taxonomic purposes.

METHODS AND MATERIALS

Flies. *H. exigua* were obtained from a colony of a field strain at the DPI Oonoonba Veterinary Laboratory, Townsville (DPI strain), and from the closed laboratory colony at CSIRO Entomology, Indooroopilly (CSIRO strain), Queensland, Australia. Both colonies were cultured on bovine hosts (Stegeman et al., 1996), and the CSIRO strain flies were collected from cattle kept in an

insectary. Pupae submitted from Townsville were kept in cardboard cylinders lined with filter paper at 27°C and 70–80% RH, and emerged flies were fed with bovine blood (Anderson, 1995). *H. irritans* were obtained from the colony of Prof. Butler at the University of Florida, Gainesville, FL, USA.

Hydrocarbon Extraction. One ml of hexane (UltimAR, Mallinckrodt) containing 5 μg *n*-tetracosane [internal standard (IS)] was added to 20 flies that had been immobilized (−20°C or carbon dioxide). After standing for 5 min, the hexane solution was passed through a silica gel plug (1 g) confined in a Pasteur pipette that was then washed with 5 × 1 ml hexane. The combined hexane solutions were dried with anhydrous sodium sulfate, filtered, evaporated to dryness, and reconstituted with 100 μl hexane. Single fly extractions were carried out analogously using 20-fold lower IS concentration and reconstituted with 5 μl hexane.

Chemicals. (*Z*)-9-Tricosene was obtained from ISP Fine Chemicals (Columbus, OH, USA).

Methylthiolation of Alkenes. DMDS adducts were prepared according the method of Carlson et al. (1989) with a reaction time of 16 hr at 40°C.

Analysis and Identification. Gas chromatography (GC) was carried out on an HP5890 gas chromatograph equipped with a capillary column (DB-5, J&W; 30 m × 0.25 mm, 0.25 μm film thickness) using nitrogen as the carrier gas (column pressure, 100 kPa) and with a flame ionization detector (FID). The oven temperature was increased (5°C/min) from 200 to 260°C (280°C for DMDS adducts) where it was maintained for 5 min. Data acquisition and processing were performed with an HP3392A integrator with peak area used for the quantitation of components (relative to tetracosane). Coupled GC-MS was performed on an HP5890 GC (same column as described above) with a VG Trio 2000 mass spectrometer. Ionization was by electron impact (EI), and the total ion current was accumulated from *m*/*z* 35 to 400 (500 for DMDS adducts) over 1 sec. Selected ion mass spectrometry of high-intensity mass fragments was used for the detection or confirmation of components at low abundance. The stereochemistry of (*Z*)-9-tricosene was confirmed by comparison of its GC retention time with the standard sample.

RESULTS

Cuticular hydrocarbon extracts from newly emerged, 2–3, and 13-d-old female *H. exigua* were analyzed by GC-FID (Figure 1). Relevant hydrocarbon peaks are designated with a reference number (for key, see Table 1). All alkanes were completely resolved from the alkenes. At least partial, but often complete, separation of homologous alkenes with double bonds at 5, 7,

and 9 positions was achieved, but the 9 and 11 alkenes coeluted. The hydrocarbon chain length varied from C_{21} to C_{29}, with a distinct shift in relative quantities to shorter hydrocarbons with increasing age of the flies (Figure 1, Table 1).

From newly emerged flies (DPI strain), only small quantities of hydrocarbons (<1 μg) were extracted, and these were mostly C_{27} alkenes and alkanes (Table 1). The flies, which were kept in cardboard cylinders and maintained on bovine blood, contained larger amounts of hydrocarbons at older ages, reaching over 11 μg per female fly at 13 d. With increasing age (13 d), the DPI strain had a higher proportion of shorter carbon chains (79% C_{23}) and a higher proportion of alkenes (60%). The CSIRO strain, which had been kept on cattle postemergence, contained at the age of 3 d a similar amount of cuticular hydrocarbons to the DPI strain of the same age, but its hydrocarbon pattern was more

similar to that of 13-d-old DPI flies. Eighty and twenty percent of the CSIRO (3 d) and DPI flies (13 d) were gravid, respectively.

Unbranched, odd-numbered C_{21} to C_{29} alkanes were recovered from most *H. exigua*. Heptacosane was the most abundant alkane in young flies, whereas tricosane was found in the highest quantities in mature flies. A series of methyl branched C_{27} alkanes was detected only in newly emerged flies.

The position of the double bond in C_{23} to C_{29} monounsaturated alkenes was established through derivatization with DMDS, GC-MS analysis of the adducts, and correlation of GC retention times of parent compounds and adducts. The presence of abundant fragments (often at or close to 100% abundance) corresponding to cleavage at the original site of unsaturation, now carrying thiomethyl groups at each end, defined the location of the double bond. For instance, four adducts of C_{23} alkenes showing intense ions at *m*/*z* 201/215, 173/243, 145/271, and 117/299 indicated the presence of 11-, 9-, 7-, and 5-tricosene, respectively. The most abundant hydrocarbon in mature (3 and 13 d old) female *H. exigua* was 11-tricosene, followed by 7-tricosene, which together constituted about 90% of all alkenes. 7-Tricosene was the most abundant hydrocarbon in mature (3 d old) male CSIRO flies. Other C_{23} alkenes included 5-tricosene and (*Z*)-9-tricosene, with the latter being detected only in the CSIRO strain in trace quantities. In the early stages of the DPI flies' development, C_{27} and C_{25} alkenes dominated the extract, with 7- and 9-heptacosene and 7-pentacosene as the major components.

The cuticular hydrocarbon content of individual *H. exigua* was consistent in quantity and composition within a sex/age group (Table 2). The standard errors of the means of the major components from replicated hydrocarbon extraction from individual flies were small (typically 5%). Furthermore, the mean values from single fly extractions closely match the normalized values from the batch extractions.

TABLE 2. QUANTITIES OF CUTICULAR HYDROCARBONS EXTRACTED FROM INDIVIDUAL FEMALE AND MALE *Haematobia exigua* [MEAN (SE)][a]

	Quantity (μg/fly)	
Cuticular hydrocarbon	Female	Male
11-C_{23}:1	2.3 (0.15)	0.82 (0.05)

C_{25}	0.13 (NA)	0.25 (0.03)
C_{27}	0.17 (0.01)	0.16 (0.01)

[a] CSIRO flies, 3 d old, $N = 5$, NA = not applicable.

Single fly extracts of female and male *H. irritans* yielded as major components (*Z*)-9-tricosene, 5-tricosene, 9-pentacosene, pentacosane, 9-heptacosene, and heptacosane (Table 1).

DISCUSSION

Analyses of *H. irritans* cuticular hydrocarbons were consistent with those published previously (Mackley et al., 1981; Milstrey, 1983), but were obtained in a more efficient fashion. This was a consequence of the superior resolving power of modern capillary GC columns compared with packed columns, avoiding the necessity for prior column-chromatographic separation of alkenes from alkanes. Structure elucidation of the hydrocarbons was achieved on the basis of GC retention times, methylthiolation, and mass spectrometry of the parent compounds and their adducts. Resolution of all unsaturated positional isomers was obtained with the exception of the 9 and 11 isomers, where the parent compounds as well as the DMDS adducts partially coeluted. However, these isomers could be distinguished by selected ion monitoring of the DMDS adducts, which showed clear differences in the major fragments obtained by EI ionization. The stereochemistry of the double bond could be assigned unambiguously only for (*Z*)-9-tricosene, the only unsaturated reference hydrocarbon that we were able to obtain. It is likely that all other alkenes share the *Z* configuration, based on their GC retention times and precedence from the structures of cuticular hydrocarbons from related flies (Mackley et al., 1981).

The cuticular hydrocarbon profile from newly emerged *H. exigua* was similar to the profile reported from a colony of newly emerged *H. irritans* (Milstrey, 1983). Normal C_{25} and C_{27} and methyl branched-C_{27} hydrocarbons provided the bulk of the alkanes, and 9-heptacosene and 9-pentacosene largely made up the alkenes. A few additional components not detected previously in *H. irritans* (Milstrey, 1983) were observed in *H. exigua*, including 9-nonacosene, 5- and 7-heptacosene, and 7-pentacosene; however, they were present only in small or trace quantities. Branched C_{27} alkanes were present in newly emerged *H. exigua* and *H. irritans*, but were not detected in any other age category in either species. The quantity of alkanes and alkenes extracted was lower in newly emerged *H. exigua* than in *H. irritans* (Milstrey, 1983). Similar to *H. irritans*, there was no marked difference in the composition of cuticular hydrocarbons between newly emerged female and male *H. exigua* (Table 1), although the quantity of the methyl branched C_{27} alkanes was lower in male flies.

Significant qualitative and quantitative changes in hydrocarbon composition were observed 2–3 d after the emergence of *H. exigua*. Shorter carbon chains were more prominent and alkenes constituted about 80% of the total hydrocarbons, compared to less than 35% in newly emerged flies (Table 1). Similar age-related

changes in hydrocarbon content have also been observed for *H. irritans* (Milstrey, 1983). However, qualitative differences between the composition of unsaturated hydrocarbons in *H. exigua* and *H. irritans* were obvious. Extraction of 2- to 3-d-old *H. exigua* kept in a cardboard cylinder since emerging (DPI strain, Table 1) yielded 5- and 7-tricosene, 7- and 9-pentacosene, 7- and 9-heptacosene (major component) and 9-nonacosene. *Haematobia irritans* (3–4 d old) yielded (*Z*)-5- and (*Z*)-9-tricosene (major components), (*Z*)-9-pentacosene and (*Z*)-9-heptacosene (Mackley et al., 1981; Milstrey, 1983), and 9-nonacosene (this study, see below). Thus, none of the (*Z*)-9-tricosene, which was the major alkene component in *H. irritans* (except newly emerged), was found in the DPI *H. exigua*. Conversely, 7-tricosene, 7-pentacosene, and 7-heptacosene were detected in *H. exigua* but not in *H. irritans*. The extraction of 13-d-old female DPI flies yielded a total of 11 μg cuticular hydrocarbons per fly, with the alkenes comprising 60% of these. Further evidence for the shift to shorter carbon chain length with age is provided by the detection of 11-tricosene and 11-pentacosene in the extracts of 13-d-old females. 11-Tricosene was the major component and, together with 7-tricosene and tricosane, contributed 79% to the total hydrocarbons. An inspection of a subsample of this population indicated that 20% of the female flies were gravid.

Extraction of CSIRO *H. exigua*, kept on cattle for 3 d postemergence, yielded a similar amount of hydrocarbons to the caged flies of the same age (Table 1). However, the resultant hydrocarbon profile was much more similar to that of 13-d-old DPI flies. All mature *H. exigua* had predominantly C_{23} alkenes, with 11- and 7-tricosene as the most abundant isomers. The 3-d-old female CSIRO flies were 80% gravid, and the close resemblance of their hydrocarbon profiles to those of the DPI flies (13 d old, 20% gravid) indicates that the observed change in the hydrocarbon profile is related to developments other than the attainment of sexual maturity. The CSIRO flies also showed quantitative differences between the sexes, with 11-tricosene and 7-tricosene as the major components in female and male *H. exigua*, respectively. However, results from this study may not fully reflect sexual dimorphism, as the flies were collected from mixed-sex populations, unlike the *H. irritans* study where pupae were individually contained (Milstrey, 1983). Transfer of cuticular hydrocarbons between female and male flies through mating has been documented (Scott et al., 1988). The CSIRO fly extracts also contained small amounts of (*Z*)-9-tricosene, the major alkene component of *H. irritans*. However, (*Z*)-9-tricosene was only detected in *H. exigua* with selected ion mass spectrometry, which provided higher sensitivity than total ion current or flame ionization detectors.

Variability in the quantity of major cuticular hydrocarbons extracted from individual *H. exigua* was low (Table 2). All major components were detected in all samples, and the standard errors of the means were all below

10% and typically around 5%. Thus, single fly extractions provide hydrocarbon profiles that are characteristic of the population with a reasonable degree of certainty.

To complete our study, we extracted one female and one male *H. irritans* and determined the structure of the unsaturated hydrocarbons by methylthiolation followed by GC-MS. We confirmed (except for the stereochemistry) the previous findings, obtained by ozonolysis of the parent components, that (*Z*)-9-tricosene, (*Z*)-5-tricosene, (*Z*)-9-pentacosene, pentacosane, (*Z*)-9-heptacosene, and heptacosane are the major cuticular hydrocarbons found in *H. irritans* (Mackley et al., 1981; Milstrey, 1983). Our *H. irritans* extracts also contained small quantities of 9-nonacosene, which was not previously reported, probably due to the lower sensitivity resulting from packed rather than capillary GC columns. Although the ages of the *H. irritans* samples were unknown, the resulting hydrocarbon profile indicated that they were at least a few days old.

Results presented in this study and comparison with previous reports (Mackley et al., 1981; Milstrey, 1983) demonstrate that cuticular hydrocarbon profiles of *H. exigua* and *H. irritans* are almost identical in newly emerged flies, but can readily be distinguished in flies older than 2 d (Table 3). This dissimilarity is independent of sex, feeding regimen (*in vivo* or *in vitro*), or sexual maturity. For chemotaxonomic differentiation, a simple analysis of C_{23} alkenes of flies aged 2 d or more provides an unambiguous identification, with each species possessing unique positional isomers (rows in bold italics in Table 3). The major alkenes were the 11- and 7-tricosene in *H. exigua* (both not detected

in *H. irritans*), and the (*Z*)-9- and (*Z*)-5-tricosene in *H. irritans*. Such a chemotaxonomic differentiation is more reliable and robust than the difficult differentiation based on morphological characters (Zumpt, 1973).

Cuticular hydrocarbons are utilized by insects as species recognition cues (Carlson et al., 1998; Howard et al., 2003). Clear differences in the cuticular hydrocarbon profiles of *H. exigua* and *H. irritans* thus provide support for their recognition as separate species. Additional cuticular hydrocarbon profiling and molecular, genetic, morphological, and cross-breeding studies of specimens of both species across their extensive distributions would be desirable to further explore species integrity.

In summary, we determined the qualitative and quantitative composition of cuticular hydrocarbons of different strains, sexes, and ages of *H. exigua*. We demonstrated that the hydrocarbon profile of mature *H. exigua* unambiguously differs from that of *H. irritans*, and that by determining the identity of a few key compounds in cuticular hydrocarbon extracts, fly species can be distinguished.

(Received March 9, 2005; accepted June 3, 2005)

Abstract—The sex pheromone of female dogwood borers (DWB) *Synanthedon scitula* (Harris) (Lepidoptera: Sesiidae) was determined to be an 88:6:6 ternary blend of (*Z,Z*)-3,13-octadecadienyl acetate (*Z,Z*-3,13-ODDA), (*E,Z*)-2,13-octadecadienyl acetate (*E,Z*-2,13-ODDA), and (*Z,E*)-3,13-octadecadienyl acetate (*Z,E*-3,13-ODDA) by gas chromatography–electroantennographic detection (GC–EAD) and gas chromatography–mass spectrometry (GC–MS). The major sex pheromone component, *Z,Z*-3,13-ODDA, was attractive as a single component. A blend of *Z,Z*-3,13-ODDA with 1–3% of *E,Z*-2,13-ODDA (binary blend) was more attractive than the single component. A third component, *Z,E*-3,13-ODDA, was sometimes observed in GC–EAD analyses, and enhanced attraction to the binary blend in some field bioassays. Lures containing 1 mg of binary and ternary blends attracted 18 and 28 times more male DWB moths, respectively, than caged virgin females in field trials. Attraction was strongly antagonized by addition of as little as 0.5% of *E,Z*-3,13-octadecadienyl acetate (*E,Z*-3,13-ODDA). In a period of 12 wk in 2004, more than 60,000 males were captured in sticky traps baited with synthetic pheromone blends in six apple orchards in Virginia, West Virginia, and North

Carolina. Lure longevity trials showed that ~76% of the pheromone remained in rubber septum lures after 12 wk in the field.

Key Words—Dogwood borer, *Synanthedon scitula*, sex pheromone, (*Z,Z*)-3,13-octadecadienyl acetate, (*E,Z*)-2,13-octadecadienyl acetate, (*Z,E*)-3,13-octadecadienyl acetate, (*E,Z*)-3,13-octadecadienyl acetate, pheromone antagonist.

INTRODUCTION

The dogwood borer (DWB), *Synanthedon scitula* (Harris) (Lepidoptera: Sesiidae), is an important pest of at least 19 species of fruit, nut, and ornamental trees in the eastern United States and Canada (Engelhardt, 1932; Eichlin and Duckworth, 1988; Bergh and Leskey, 2003). Since the 1980s, DWB has become an increasingly important economic pest of apple (Riedl et al., 1985; Warner and Hay, 1985; Kain and Straub, 2001) largely due to the increased use of clonal, size-controlling rootstocks in high-density orchards (Marshall and Andrews, 1994). Commercially available pheromone lures for DWB rely on generalized sex pheromone components identified from other sesiid species (Tumlinson et al., 1974; Nielsen et al., 1975, 1979). This has led to inconsistencies and variability in the results from published research on DWB conducted in apple orchards, native habitats, and managed urban landscapes (reviewed in Bergh and Leskey, 2003). Furthermore, different lures marketed for monitoring DWB vary considerably in their attractiveness to and selectivity for DWB (Bergh et al., 2004). A species-specific sex pheromone identified from DWB is needed for reliable, standardized detection and monitoring of this pest.

The objectives of this study were to determine the composition of the sex pheromone of DWB and to develop a species-specific and effective pheromone lure for monitoring. Species-specific sex pheromone baited traps would be useful for comparing the seasonal life history and relative abundance of DWB in its different habitats, and accurate information on population density would facilitate management decisions in apple orchards and ornamental nurseries. The failure of previous attempts to manage DWB using mating disruption (Pfeiffer and Killian, 1999) may have been due, in part, to an inadequate characterization of its sex pheromone. Mating disruption products for the congeneric peach tree borer, *Synanthedon exitiosa* (Say), and lesser peach tree borer, *S. pictipes* (Grote and Robinson), are effective (Gentry and Snow, 1984; Pfeiffer et al., 1991; Agnello and Kain, 2002) and commercially available, and identification of the DWB sex pheromone may enable development of this management approach for DWB as well. It will also enable the investigation of pheromone-based, premating reproductive isolation mechanisms among several sympatric sesiid congeners. This article describes the determination of the sex pheromone composition of the DWB, and field trapping studies that examined and compared the responses

of males to different geometric isomers, blend ratios, pheromone antagonists, and virgin females. The release rates and longevities of binary and ternary pheromone lures were quantified under field conditions.

METHODS AND MATERIALS

Insects. Larvae (~100) of DWB were excavated from burrknot tissue of apple trees (Jefferson and Berkeley Counties, WV, USA and Frederick County, VA, USA) with obvious signs of infestation, including frass and entry wounds, in October and November of 2002 and 2003. Larvae were brought to the laboratory and reared on general-purpose lepidopteran diet (Bioserv, Frenchtown, NJ, USA) in an incubator at 25°C (16L:8D) until pupation. Pupae were sexed according to the characteristics described by Leskey and Bergh (2003) and held individually in 1-oz clear plastic cups (Jet Plastica Industries, Hatfield, PA, USA) with a small piece of moistened cotton dental wick and topped with plastic caps. Pupae were sent to Beltsville, MD, USA in January 2002 and 2003. Upon arrival, the pupae were kept in an insectary at 25°C and 16L:8D photoperiod until adult emergence. Absorbent cotton moistened with 8% sugar water was provided as a food source for emerged moths. Female moths were transferred to an effluvial collection device for collection of volatiles.

Effluvial Collections. Volatiles were collected using six groups of 1- to 13-d-old virgin females (3–10 females per group) at room temperature and 16L:8D photoperiod. The moths were introduced separately into three 1-l, four-necked glass containers (Zhang et al., 1994). Air was drawn into the container through 6- to 14-mesh activated charcoal (Fisher Scientific, Pittsburgh, PA, USA) and out of the container through two traps (15 cm × 1.5-cm o.d.) containing Super Q (200 mg each; Alltech Associates, Inc., Deerfield, IL, USA) by vacuum (~1 l/min). Female moths were fed a 10% sugar solution on cotton balls and aerated continuously for 3–7 d at room temperature and 16L:8D photoperiod. The adsorbent traps were changed every 48 hr. Adsorbents were eluted with methylene chloride (4 × 0.5 ml, spectrometry grade, EMD Chemicals Inc., Gibbstown, NJ, USA) and the eluates (2 ml/sample) were concentrated to ~20 μl under a nitrogen stream and stored at −30°C until analysis.

Pheromone Gland Extractions. Pheromone gland extracts were obtained during photophase from the six groups of 2- to 13-d-old virgin females that had been used in aerations. A female abdomen was compressed gently until the ovipositor everted from the abdominal tip. The ovipositor was then excised with microscissors into a conical glass vial containing ~100 μl methylene chloride–methanol (3:1), and the glands were soaked for at least 2 hr at room temperature. The extracts were removed, and the glands were reextracted with 100 μl methylene chloride–methanol (Zhang and Polavarapu, 2004). The

combined solution was concentrated to ~20 μl under a nitrogen stream and stored at −30°C until analysis.

Electrophysiological Recordings and Mass Spectrometry. The coupled gas chromatography–electroantennographic detection (GC–EAD) system used was as previously described (Zhang et al., 1997; Zhang and Polavarapu, 2003). For GC–EAD analysis, an Hewlett-Packard (HP) 6890 gas chromatograph equipped with a 60 m × 0.25-mm i.d., 0.25-μm film-thickness DB-WAXETR capillary column (J&W Scientific Inc., Folsom, CA, USA; 120°C for 2 min, 10°C/min to 250°C, hold for 10 min) or a 60 m × 0.25-mm i.d., 0.25-μm film-thickness DB-5 capillary column (J&W Scientific Inc., 100°C for 2 min, 15°C/min to 250°C, hold for 10 min) in splitless mode with hydrogen carrier gas (1.4 ml/min) was used.

Gas chromatography–mass spectrometry (GC–MS) was conducted on an HP 6890 GC coupled to an HP 5973 mass-selective detector using an identical DB-WAXETR capillary column (120°C for 2 min, 15°C/min to 230°C, hold for 25 min), but with helium as carrier gas. A 70-eV electron beam was used for sample ionization.

Chemicals. (*Z,Z*)-3,13-Octadecadienyl acetate (~90% purity, Bedoukian Research, Danbury, CT, USA) was purified by flash chromatography using 15% $AgNO_3$ on silica gel 60 (230–400 mesh, EM Science, Gibbstown, NJ, USA), eluted with 2:10 CH_2Cl_2:hexane. The fractions with <0.3% of the impurity, *E, Z*-3,13-ODDA, were combined. All other pheromone standards were purchased from PheroBank (Wageningen, the Netherlands), and purities of chemicals were checked on a 60-m polar DB-WAXETR GC capillary column before preparing lures for field studies (>97% purity).

Field Trapping Tests. Red natural rubber septa (5 mm, Wheaton, Millville, NJ, USA) loaded with the desired rates of *Z,Z*-3,13-ODDA and the blends in ~20 μl of hexane solution were used for field trials with hexane controls. The same amount of solvent (hexane) was loaded on the septum for the blank control. After loading, the solvent was allowed to evaporate in a fume hood for 30 min. Lures were then wrapped in aluminum foil, stored in 20-ml plastic vials and shipped by express carrier on the same day. Upon arrival, the lures were kept in a freezer at −10°C until deployed.

All field tests were conducted in commercial apple orchards in West Virginia, Virginia, and North Carolina using Pherocon 1C (North Carolina and West Virginia) or Delta sticky traps (Virginia) (Trécé, Salinas, CA, USA). Traps were placed in trees at ~1.2 m above the ground (Riedl et al., 1985). At each location, experimental lures were randomized within each of three to five rows (depending on the number of replicates per test) that were separated by at least one buffer row, and traps were spaced at a minimum of ~20-m intervals within a row. Traps were rotated among positions within each row at weekly intervals for the duration of each test. The number of dogwood borer and other male sesiid moths captured were recorded weekly.

In the first comparison, the following lures were deployed: the single component (100% *Z,Z*-3,13-ODDA), the binary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA = 94:6), a second two-component blend (*Z,Z*-3,13-ODDA/*Z,E*-3,13-ODDA = 94:6), the ternary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA/*Z,E*-3,13-ODDA = 88:6:6), and the control. To evaluate the effect on trap catch of addition of a third component, 0.5, 1, 3, or 10% of *Z,E*-3,13-ODDA was added to the base binary blend. Similarly, 0.5, 1, 3, or 10% of *E,Z*-2,13-ODDA was added to a blend consisting of *Z,Z*-3,13-ODDA/*Z,E*-3,13-ODDA (94:6) to evaluate the addition of *E,Z*-2,13-ODDA on trap capture. In another comparison, 0.5, 1, 2, or 3% *E,Z*-3,13-ODDA was added to the ternary blend. Caged virgin females (2- to 4-d-old and one female per cage) were deployed in traps to provide a natural source of pheromone for comparison with traps baited with the binary and ternary blends over a 3-wk period.

Lure Analyses. The binary and ternary lures exposed in the field during 6, 8, and 12 wk were collected and placed individually into 20 ml hexane in a 25-ml vial and soaked for 48 hr. GC analyses of pheromone lures were conducted with an HP 6890 GC equipped with a DB-5 capillary column by injecting 1 μl of each extract. Pure *Z,Z*-3,13-ODDA was used as the standard, and remaining pheromone concentrations were obtained by comparison with this standard analyzed under the same conditions.

Statistics. Data from control traps were omitted from the statistical analyses because of zero trap catches. Unless otherwise specified, trap catch data from each test were log transformed (log $X + 1$) to normalize the variance before analysis. Means were compared by one-way analysis of variance (ANOVA) followed by Ryan–Einot–Gabriel–Welsch range test (SPSS 10.0 for Windows; George and Mallery, 2002) for significance at $\alpha = 0.05$.

RESULTS

Analysis of Sex Pheromone Components in Female Effluvial Collections and Gland Extracts. A typical coupled GC–EAD graph is shown in Figure 1, exhibiting two EAD responses in female gland extract (Figure 1A) and three EAD responses in effluvial extract (Figure 1B). The mass spectrum of the component in the gland extracts that elicited the largest EAD response (peak 1) exhibited the highest mass ion at *m*/*z* 308 (1) along with a comparatively strong mass fragment at *m*/*z* 248 (22) and other fragments: *m*/*z* 219 (6), 149 (14), 135 (27), 121 (24), 109 (37), 96 (66), 81 (85), 67 (80), and 55 (81). It closely matched the spectra of authentic 3,13-ODDA and 2,13-ODDA. Among the EAD responses, peaks 1 and 2 coincided with *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA, respectively, in GC retention times on both capillary columns (Table 1), suggesting that *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA were likely candidates for

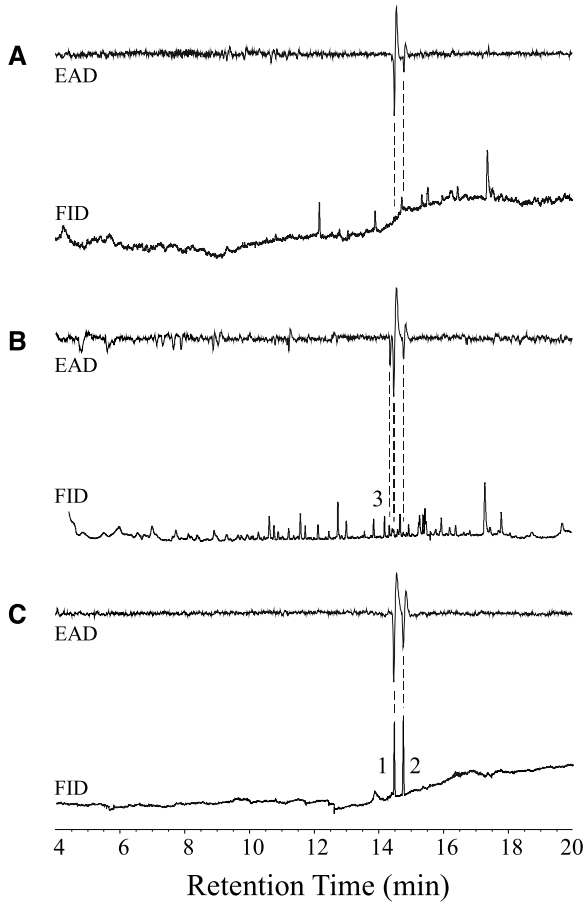

FIG. 1. Simultaneous EAD responses of an adult male dogwood borer (DWB) antenna and FID chromatograms of (A) a combined gland extract from two virgin female DWBs (3- and 5-d-old), (B) effluvia trapped for 48 hr from seven virgin female DWBs (3- to 13-d-old), and (C) synthetic *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA (1 ng each). Identification of peaks: 1, *Z,Z*-3,13-ODDA; 2, *E,Z*-2,13-ODDA; and 3, *Z,E*-3,13-ODDA.

the insect-produced compounds (peaks 1 and 2). The identity of the component corresponding to the greatest EAD response (peak 1) was confirmed by co-injection with a synthetic standard of *Z,Z*-3,13-ODDA. To confirm the identity of peak 2, identify the third GC–EAD active peak, and determine the ratio of the three components that elicited EAD responses, a combined extract of the glands of 20 females was analyzed by GC–MS. Even with selected ion monitoring of the *m*/*z* 248 (M − 60) ion, only two peaks were deleted, at the retention times of

TABLE 1. RETENTION TIMES OF EAD-ACTIVE COMPOUNDS OBTAINED FROM GLAND AND EFFLUVIAL EXTRACTS OF FEMALE DWB AND SYNTHETIC 3,13- AND 2,13-OCTADECADIENYL ACETATES

Compounds	Retention time (min)		EAD response to 10 ng dose (mV, mean ± SD)[a]
	DB-WAXETR	DB-5	
From females			
(*Z,Z*)-3,13-Octadecadienyl acetate	14.48	13.82	
(*E,Z*)-2,13-Octadecadienyl acetate	14.75	13.93	
Synthetic			
(*E,E*)-3,13-Octadecadienyl acetate	14.39	13.81	0.13 ± 0.03 ab
(*Z,E*)-3,13-Octadecadienyl acetate	14.42	13.80	0.24 ± 0.04 a
(*E,Z*)-3,13-Octadecadienyl acetate	14.44	13.83	0.30 ± 0.09 a
(*Z,Z*)-3,13-Octadecadienyl acetate	14.48	13.82	0.30 ± 0.10 a

(*E,Z*)-2,13-Octadecadienyl acetate	14.75	13.93	0.20 ± 0.13 ab

[a]Means followed by different letters are significantly different at $\alpha = 0.05$ ($N = 3$, $df = 7.16$, $F = 8.30$, $P < 0.001$).

Z,Z-3,13-ODDA and *E,Z*-2,13-ODDA, and with a ratio of 94:6. The identity of the second component eliciting an EAD response (peak 2) was confirmed by co-injection with a synthetic standard of *E,Z*-2,13-ODDA in GC–MS. Authentic standards of synthetic *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA also elicited strong antennal responses (Figure 1C). However, the third component of the effluvial extract that sometimes elicited EAD responses was not detected in gland extracts via selected ion monitoring. GC–EAD analyses of the four synthetic geometric isomers of 3,13-ODDA revealed that all elicited significant EAD responses (Table 1) and that the retention times of *Z,E*-3,13-ODDA were identical to those of peak 3 on both capillary columns. Therefore, the minor component in the effluvial extract (peak 3) that elicited antennal responses was tentatively determined to be *Z,E*-3,13-ODDA, and the ternary blend ratio was estimated to be 88:6:6 (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA/*Z,E*-3,13-ODDA).

Field Trapping Tests. The numbers of male moths caught in initial field studies by using traps baited with septa containing 1 mg of the single major component, two 2-component blends, and the ternary blend are summarized in Figure 2. Catches of male moths in orchards in three states all showed that the major sex pheromone component, *Z,Z*-3,13-ODDA, was attractive as a single component. The binary blend of *Z,Z*-3,13-ODDA with 6% *E,Z*-2,13-ODDA was more attractive than the single component. Addition of the second minor component, *Z,E*-3,13-ODDA, to create the ternary blend, further enhanced attraction (Figure 2).

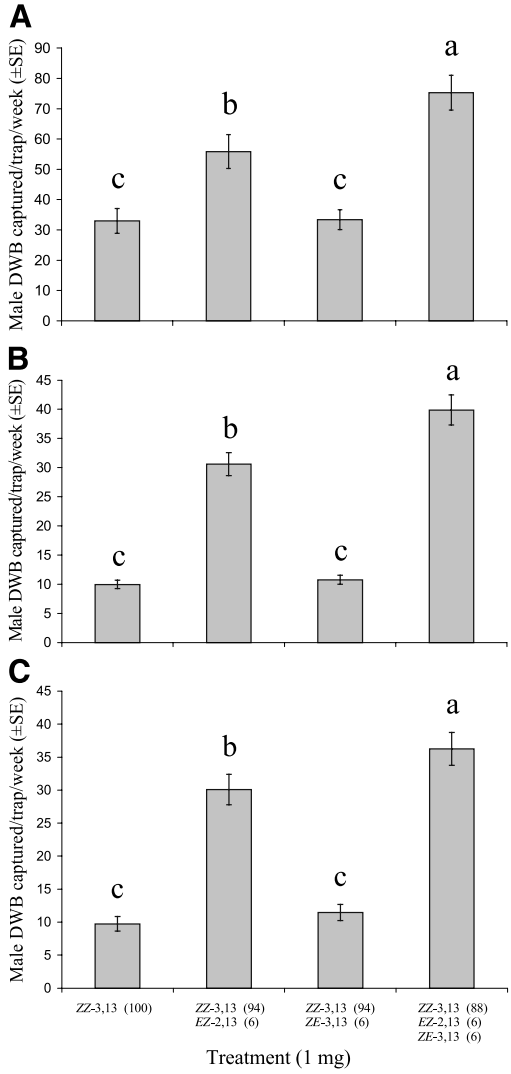

FIG. 2. Male DWB captured in traps with different DWB pheromone blends conducted (A) from May 18 to July 8, 2004, in North Carolina (total number of male DWBs trapped was 14,101, $N = 70$, $df = 3{,}276$, $F = 63.3$), (B) from June 2 to August 25, 2004, in Virginia (total number of male DWBs trapped was 11,917, $N = 130$, $df = 3{,}516$, $F = 112.1$), and (C) from June 1 to August 23, 2004, in West Virginia (total number of male DWBs trapped was 10,506, $N = 120$, $df = 3{,}476$, $F = 223.0$). Bars superscripted by different letters are different (arcsin $\sqrt{p}$ transformed, where p is the original proportion; $P < 0.05$).

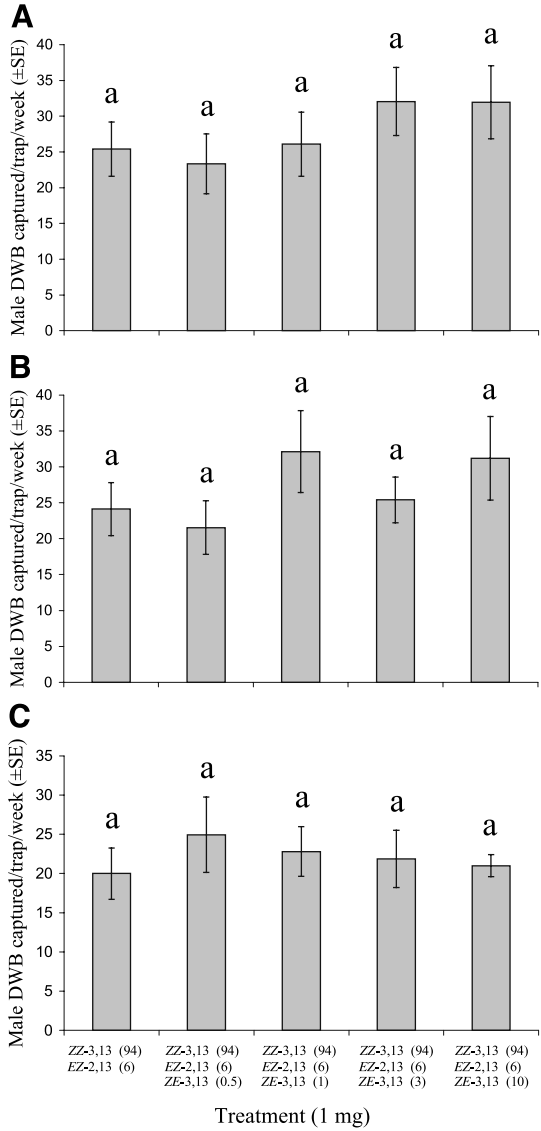

FIG. 3. Male DWB captured in traps baited with DWB pheromone ratio 1. Tests conducted (A) from July 13 to August 24, 2004, in North Carolina (total number of male DWBs trapped was 2,915, $N = 21$, $df = 4,100$, $F = 0.79$, $P = 0.53$), (B) from July 8 to August 5, 2004, in Virginia (total number of male DWBs trapped was 2,016, $N = 15$, $df = 4,70$, $F = 1.02$, $P = 0.41$), and (C) from June 21 to July 26, 2004, in West Virginia (total number of male DWBs trapped was 1,659, $N = 15$, $df = 4,70$, $F = 0.30$, $P = 0.88$).

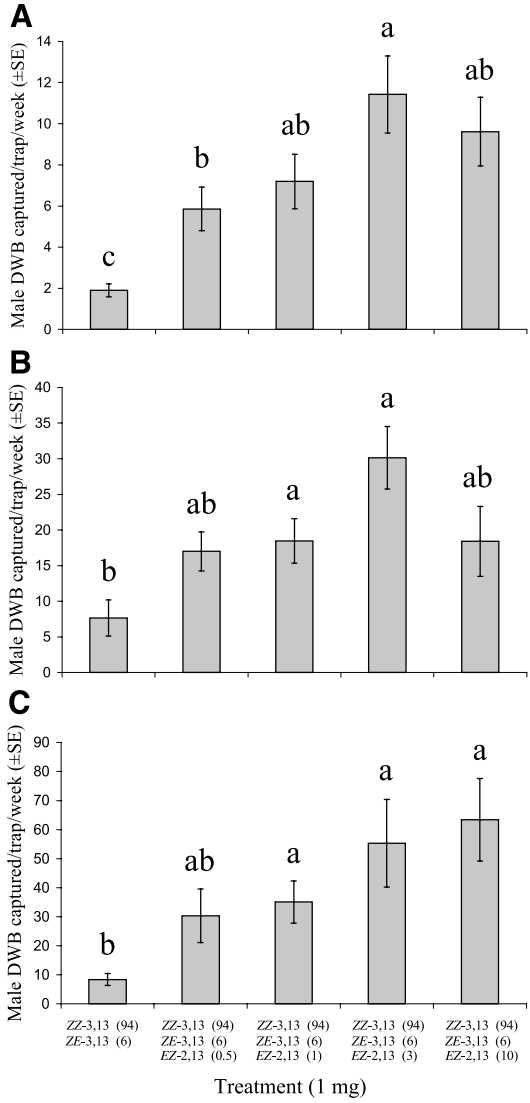

FIG. 4. Male DWB captured in traps baited with pheromone ratio 2. Tests conducted (A) from July 13 to August 24, 2004, in North Carolina (total number of male DWB trapped was 724, $N = 21$, $df = 4,100$, $F = 9.73$), (B) from July 7 to August 11, 2004, in Virginia (total number of male DWB trapped was 1,375, $N = 15$, $df = 4,70$, $F = 6.01$), and (C) from June 24 to July 23, 2004, in West Virginia (total number of male DWB trapped was 2,887, $N = 15$, $df = 4,70$, $F = 6.58$). Bars superscripted by different letters are different ($P < 0.05$).

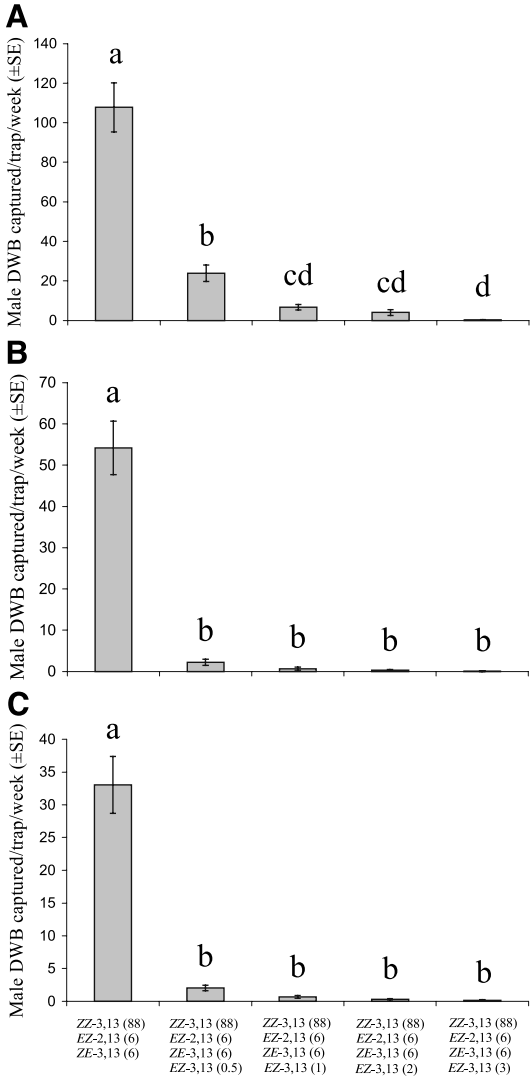

FIG. 5. Male DWB captured in trails of pheromone antagonists conducted (A) from July 14 to August 18, 2004, in North Carolina (total number of male DWB trapped was 2,568, $N = 18$, $df = 4,85$, $F = 83.85$), (B) from July 15 to August 12, 2004, in Virginia (total number of male DWB trapped was 861, $N = 15$, $df = 4,70$, $F = 156.7$), and (C) from June 24 to July 23, 2004, in West Virginia (total number of male DWB trapped was 1,086, $N = 30$, $df = 4,145$, $F = 181.4$). Bars superscripted by different letters are different ($P < 0.05$).

However, in a follow-up trial, addition of 0.5 to 10% of *Z,E*-3,13-ODDA to the binary blend of *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA (94:6) had no effect (Figure 3). In contrast, when 0.5 to 10% of *E,Z*-2,13-ODDA was added to a binary blend of *Z,Z*-3,13-ODDA and *Z,E*-3,13-ODDA (94:6), higher numbers of males were attracted to most of the ternary blends compared to the binary blend (Figure 4). In a subsequent test, the addition of as little as 0.5% of the geometric isomer, *E,Z*-3,13-ODDA, to the most attractive ternary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA/*Z,E*-3,13-ODDA = 88:6:6) strongly antagonized the attraction of male DWB to traps (Figure 5).

In the final field test, we compared the attractiveness of binary and ternary blends to virgin females. Rubber septa loaded with 1 mg doses of binary and ternary blends attracted more males than traps baited with one virgin female (Figure 6).

Our pheromone blends showed greatly improved species specificity in comparison to results reported from the use of commercially available lures (Rogers and Grant, 1990; Davidson et al., 1992; Braxton and Raupp, 1995; Pfeiffer and Killian, 1999; Bergh et al., 2004). In the most recent comparison of commercially available lures, the Scenturion dogwood borer lure was the most attractive and species specific, with the percentage of DWB captured ranging

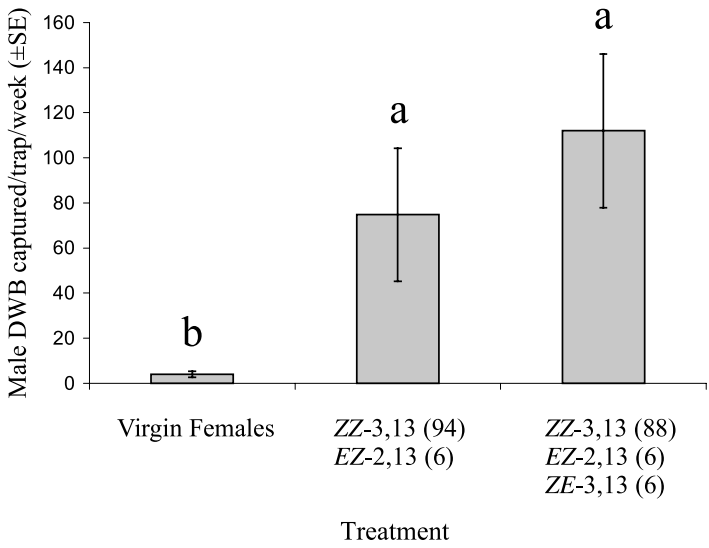

FIG. 6. Male DWB captured in traps baited with synthetic pheromone or virgin females from August 16 to September 13, 2004, in West Virginia (total number of male DWB trapped was 763, $N = 4$, $df = 2,9$, $F = 25.72$). Bars superscripted by different letters are different ($P < 0.05$).

TABLE 2. MEAN AMOUNT OF PHEROMONE COMPONENTS REMAINING IN LURES AFTER EXPOSURE UNDER FIELD CONDITIONS[a]

Orchard	Blend	Amount remaining (mg)/septum (mean ± SD in %)		
		6 wk[b]	8 wk[c]	12 wk[d]
1	Binary	0.87 ± 5.5		
2	Binary		0.79 ± 7.9	
1	Ternary	0.86 ± 9.4		
2	Ternary		0.84 ± 6.2	
3	Binary			0.72 ± 3.8
4	Binary			0.75 ± 1.7
3	Ternary			0.81 ± 2.6
4	Ternary			0.77 ± 5.1

[a] Original dose was 1.0 mg/septum. Values listed represent sum of remaining components.
[b] Exposed from May 18 to June 29, 2004, in North Carolina.
[c] Exposed from May 18 to July 9, 2004, in North Carolina.
[d] Exposed from June 2 to August 25, 2004, in Virginia.

from 33 to 86% of all Sesiidae captured (Bergh et al., 2004). In contrast, about 92% of all moths captured with our single-component or two-component blend (*Z,Z*-3,13-ODDA/*Z,E*-3,13-ODDA = 94:6) were DWB males. Even greater levels of specificity were observed with our binary (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA = 94:6) and ternary blends (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA/*Z,E*-3,13-ODDA = 88:6:6), with which over 97% of moths caught were DWB males (Leskey et al., 2005).

Lure longevity and release rate were evaluated using lures loaded with 1 mg of the binary and ternary blends and exposed in the field for 6, 8, and 12 wk. GC analyses indicated that 87% of the pheromone remained in the rubber septum lures exposed for 6 wk in the field (May 18 to June 29, 2004) in North Carolina, 82% of the pheromone remained in lures exposed for 8 wk (8 May to July 9, 2004) in Virginia, and 76% of the pheromone remained in lures exposed for 12 wk (June 2 to August 25, 2004) in Virginia (Table 2).

DISCUSSION

Following the discovery of *E,Z*- and *Z,Z*-3,13-ODDA as components of the sex pheromones of lesser peach tree borer and peach tree borer, respectively (Tumlinson et al., 1974), the geometrical isomers and corresponding alcohols of 3,13-ODDA have been reported as the main pheromone components of many sesiid species (Nielsen et al., 1979; Tumlinson, 1979; Snow et al., 1985). A positional isomer, *E,Z*-2,13-ODDA, was later identified as a component of the sex pheromone of other Sesiidae, including grape root borer, *Vitacea*

polistiformis (Harris), maple clearwing, *S. acerrubri* (Engelhardt), and squash vine borer, *Melittia satyriniformis* (Hübner) (Schwarz et al., 1983; Snow et al., 1987).

Z,Z-3,13-ODDA was reported as a sex attractant for DWB, based on a combination of electroantennogram tests and the results of field trapping tests in which many compounds were screened (Nielsen et al., 1975, 1979). However, specific identification of the DWB sex pheromone has not been reported previously. Based on GC–EAD analyses of effluvial collections, gland extracts, and synthetic isomers of 3,13- and 2,13-ODDA, and field trapping tests, we have confirmed that *Z,Z*-3,13-ODDA is the main pheromone component of DWB. As a single component, it attracts male DWB, in concurrence with the results of Nielsen et al. (1975). However, we also showed that two other components increased attraction of male DWB to Z,Z-3,13-ODDA. When *Z,Z*,-3,13-ODDA was combined with *E,Z*-2,13-ODDA in a 94:6 blend (the natural ratio), moth captures were greater than with *Z,Z*-3,13-ODDA alone or with the ternary blend of *Z,Z*-3,13-ODDA in combination with *Z,E*-3,13-ODDA (94:6). Our findings explain the results reported in previous studies, in which DWB moths were captured in traps used for evaluating seasonal flight activity of grape root borer, which contained lures with a blend of 99:1 (*E,Z*-2,13-ODDA/*Z,Z*-3,13-ODDA) (Alm et al., 1989; Snow et al., 1991). The ternary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA/*Z,E*-3,13-ODDA = 88:6:6) proved to be more attractive than any other treatment across all locations in one trial (Figure 2), but in other trials (Figures 3 and 6), it was no better than the 94:6 binary blend of *Z,Z*-3,13-ODDA:*E,Z*-2,13-ODDA.

Thus, two pheromone components, *Z,Z*-3,13-ODDA and *E,Z*-2,13-ODDA, appear to be essential for maximal attraction of male DWB. When as little as 1% *E,Z*-2,13-ODDA was added to a 94:6 (*Z,Z*-3,13-ODDA/*Z,E*-3,13-ODDA) blend, captures increased at all locations (Figure 4). However, we did not observe a similar response when *Z,E*-3,13-ODDA was added to a 94:6 (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA) blend (Figure 3). We believe that *Z,E*-3,13-ODDA may indeed synergize the response to the binary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA) based on the finding that in one set of trials, more male moths were caught at all locations with this ternary blend than with the binary blend (Figure 2). However, male DWB may not have been able to discriminate among treatments in our trial that evaluated the addition of 0.5–10% *Z,E*-3,13-ODDA to the binary blend (*Z,Z*-3,13-ODDA/*E,Z*-2,13-ODDA) (Figure 3), because the distances between stimuli were approximately 20 m, whereas in our other field trial that compared the binary and ternary blends with our other treatments, the distance between these two attractive stimuli was as much as 100 m.

E,Z-3,13-ODDA, the major component of lesser peach tree borer sex pheromone (Tumlinson et al., 1974), has been described as a potential antagonist to

the attraction of male DWB (Karandinos et al., 1977; Greenfield, 1978; Warner and Hay, 1985), whereas Snow et al. (1985) concluded that it had no effect on DWB response to *Z,Z*-3,13-ODDA. Here, we document the strongly antagonistic effect of *E,Z*-3,13-ODDA on the response of male DWB to its sex pheromone. In field trials, as little as 0.5% *E,Z*-3,13-ODDA added to our ternary blend strongly reduced trap captures at all locations (Figure 5). The importance of this particular compound in terms of niche separation is clear. In EAG studies, male DWB antennae responded as strongly to *E,Z*-3,13-ODDA as to *Z,Z*-3,13-ODDA (Nielsen et al., 1979). Interestingly, when *Z,Z*-3,13-ODDA, which is also a component of the peach tree borer sex pheromone, was added to *E,Z*-3,13-ODDA, the pheromone of lesser peach tree borer, addition of as little as 0.5% of *Z,Z*-3,13-ODDA completely antagonized the response of lesser peach tree borer males (Tumlinson et al., 1974; Karandinos et al., 1977; Mclaughlin et al., 1977). Understanding the role of attractants, antagonists, and synergists among isomers of 3,13-ODDA and 2,13-ODDA will aid in understanding mechanisms of reproductive isolation among sympatric, congeneric sesiid species.

Measurement of the amount of pheromone remaining in field-aged lures showed that the compounds that compose the DWB sex pheromone are released slowly from red rubber septa, with most of a 1-mg applied dose being recovered after 12 wk of field exposure (Table 2). The experiment was terminated only because of the seasonal decline in DWB populations, rather than due to a decline in the lure attractiveness, and we believe that lures formulated with 1 mg of pheromone or less (Leskey et al., 2005) will remain effective for the duration of the annual period of emergence and flight activity of DWB.

In summary, our synthetic lures were extremely attractive to male DWB. Traps baited with the ternary blend containing *Z,Z*-3,13-ODDA, *E,Z*-2,13-ODDA, and *Z,E*-3,13-ODDA (88:6:6) captured ~28 times more male DWB than traps baited with caged, virgin female DWB. The identification of the DWB pheromone represents a major advance in several respects. First, a reliable and standardized pheromone-based monitoring system can now be delivered to growers, providing them with the means to determine seasonal flight activity and infestation levels in orchards and nurseries, and enabling more informed management decisions. Second, the use of an improved, species-specific blend of compounds should advance our ability to investigate the effectiveness of mating disruption and attract-and-kill management tactics for this pest. Third, the behavioral antagonism shown by the addition of *E,Z*-3,13-ODDA to the ternary blend suggests strong reproductive isolation barriers between sympatric sesiid species. Characterization of the DWB sex pheromone will enable further investigation of premating mechanisms of reproductive isolation among DWB, peach tree borer, and lesser peach tree borer, based on their different behavioral responses to isomers of ODDA.

Acknowledgments—We thank Junying Nie of the USDA Chemicals Affecting Insect Behavior Laboratory (Beltsville, MD) for purifying synthetic pheromone components; Starker Wright and Torri Thomas of the USDA Appalachian Fruit Research Station (Kearneysville, WV), Jean Englemann of the Virginia Polytechnic Institute and State University (Winchester, VA), and Steve Schoof of North Carolina State University (Fletcher, NC), for technical assistance; and Dr. Tom Eichlin of the California Department of Food and Agriculture, Plant Pest Diagnostic Branch, California, for clearwing moth species confirmation and identification. We also thank West Virginia, Virginia, and North Carolina apple growers and horticultural societies. This work was supported in part by a grant from USDA-CSREES Southern Region IPM program.
