Abstract—Several *Streptomyces* species are known to produce metabolites that inhibit plant pathogens. One such compound is geldanamycin (GA), a benzoquinone ansamycin originally isolated from *Streptomyces hygroscopicus*. We examined the effect of geldanamycin on egg hatch and juvenile motility in *Caenorhabditis elegans* and in two populations of the plant-parasitic nematode *Heterodera glycines*. When *C. elegans* eggs were exposed to geldanamycin, both hatch and motility were reduced by GA doses between 2 and 50 μg/ml. The *H. glycines* inbred populations TN17 and TN18 exhibited low dose stimulation of hatch and motility, whereas levels occurring at higher GA doses were at or below control levels. These experiments represent the first demonstration of geldanamycin effects in *C. elegans* and *H. glycines* and suggest that the heat shock chaperone Hsp90, the known molecular target of geldanamycin, may be involved in nematode egg hatch and motility. This study also indicates that geldanamycin-producing strains of *Streptomyces* may be useful as biocontrol agents for nematodes.

Key Words—Soybean cyst nematode, *Heterodera glycines*, *Caenorhabditis elegans*, hatching, motility, behavior, eggs, geldanamycin, *Streptomyces*, Hsp90, biocontrol.

INTRODUCTION

Several species of *Streptomyces* have proven effective at reducing plant-parasitic nematode damage (reviewed in Siddiqui and Mahmood, 1999). In addition, metabolites produced by *Streptomyces* spp. were demonstrated to be nematicidal (Nair et al., 1995) or to inhibit nematode hatching (Lee et al., 1996) or motility (Mura et al., 1999). The ability to control bacterial or fungal plant pathogens has been demonstrated for the strains *Streptomyces violaceusniger* YCED-9 (Trejo-Estrada et al., 1998a,b) and *Streptomyces hygroscopicus* spp. *geldanus* EF-76 (Beauséjour et al., 2003), but neither has been tested on nematodes. Both of these strains produce the antibiotic geldanamycin (GA), a specific inhibitor of the heat shock protein chaperone Hsp90 (Whitesell et al., 1994). The impact of pure GA on nematodes was explored in a recent report by David et al. (2003). In that study, plate-grown *Caenorhabditis elegans* were exposed to a single, very high dose of GA, but no discernable effects on the nematodes were detected. We theorized that absorption or ingestion of GA by nematodes might be higher in a liquid culture system than on agar plates, and that the response to GA in plant-parasitic nematodes might differ from *C. elegans*. Thus, the objective of the current work was to determine the effect of GA exposure on *C. elegans* and the soybean cyst nematode *Heterodera glycines* in liquid culture bioassays.

METHODS AND MATERIALS

Test Organisms. *C. elegans* wild-type strain (var. Bristol-N2) and *Escherichia coli* strain OP50 were obtained from the *Caenorhabditis* Genetics Center (St. Paul, MN, USA). *H. glycines* strains TN17 and TN18 are inbred lines that were selected on the basis of relative hatching phenotypes. TN17 was selected for "fast hatching" and TN18 for "slow hatching" as defined by the relative number of eggs hatching early and late during a 2-wk period (Terry Niblack, personal communication). Despite nomenclature preferences that differ in the nematology subdisciplines, for simplicity we refer to immature forms of both *C. elegans* and *H. glycines* as "juveniles" (J2).

Nematode Culturing. *C. elegans* was routinely plate-propagated as previously described (Lewis and Fleming, 1995). *H. glycines* strains TN17 and TN18 were maintained on soybean (*Glycine max* (L.) Merr. cv. Essex) as previously described (Nitao et al., 1999).

Nematode Bioassays. Microwell assay procedures were similar to those described previously (Nitao et al., 1999). Assays were conducted in sterile 96-well tissue culture plates (polystyrene, flat bottom wells; Corning, New York, NY, USA). Each trial consisted of 10 replicate wells per treatment, with ~100

eggs/well (exact counts of eggs/well were determined), and the experiment was repeated for each treatment. Geldanamycin (Sigma-Aldrich, St. Louis, MO, USA) was prepared in dimethyl sulfoxide (DMSO) at 18 mM and subsequently diluted in deionized water as required. Controls and all treatments contained a final concentration of no more than 0.1% DMSO.

Caenorhabditis elegans. N2 embryos were harvested from gravid adults as described (Lewis and Fleming, 1995) and resuspended in M9 buffer. Aliquots (50 µl) of egg suspension were placed in each well of 96-well microtiter dishes, and the exact number of eggs per well was determined. GA dissolved in DMSO, or DMSO alone as control, was added to all eggs, and the plates were incubated in the dark at 20°C. GA concentrations tested were 0, 1, 2, 5, 10, 25, 50, and 100 µg/ml. Because GA is known to be light-sensitive (Queitsch et al., 2002) and unstable in aqueous solution (Wiesgigl and Clos, 2001), the compound was handled with care to minimize the possibility of degradation. Numbers of hatched eggs and of motile, hatched juveniles were counted after 21 hr. Motility of hatched juveniles was defined as any unprovoked movement within a 5-sec interval during which nematodes were observed under an inverted microscope.

Heterodera glycines. Eggs were collected from greenhouse-grown soybean [*Glycine max* (L.) Merr. cv. Essex] and surface-disinfested with 0.5% sodium hypochlorite (Nitao et al., 1999). Eggs were placed in 96-well microtiter plates as described above, treated with GA and/or DMSO, and incubated in the dark at 30°C, a temperature within the optimum growth range for *H. glycines* (Alston and Schmitt, 1988). Egg hatch and motility of second-stage juveniles were counted after incubation for 4 d.

Statistical Analysis. Data were analyzed using SAS® v9.1.3 for Windows (SAS Institute Inc., Cary, NC, UAS). Estimates of the percent hatched and percent motile for each nematode type at each concentration were obtained for each of two trials by summing recorded counts over the 10 wells observed per trial: % Hatched Eggs = 100% (# active + # inactive − # larvae)/# eggs; % Motile J2 = 100% (# active)/(# active + # inactive). For each of the three nematode populations, observed counts associated with each duplicate trial at each of the seven observed concentrations (i.e., $N = 14$ data points) were used to conduct all statistical analyses. For each nematode population, a nonlinear dose-response regression was fit to percent hatched and percent motile vs. GA concentration. A log-normal equation was fitted to the *H. glycines* TN17 and TN18 data, whereas a more general exponential equation was fitted to *C. elegans* data (Ratkowsky, 1990). R^2 is the ratio of the regression sum of squares to the total sum of squares (RegSS/TotSS), which reflects the proportion of the total data variability the regression equation has explained. Significant differences in hatching and motility observed at various GA concentrations vs. no GA were determined by conducting pairwise comparisons within an ANOVA

framework; specifically, a logistic regression using SAS® v9.1.3 Proc GLIMMIX with a logit link function and a binomial distribution were used to model percent hatched eggs and percent motile J2 for each nematode population. All statistical comparisons were conducted at the 95% level of significance.

RESULTS

To establish whether GA would interfere with nematode hatching or motility, we exposed *C. elegans* eggs to GA over a 100-fold range of concentrations, including 1, 2, 5, 10, 25, 50, and 100 μg/ml. Pairwise comparisons of percent hatched eggs or percent motile J2 among GA doses and the control are shown in Table 1. The relationships between percent egg hatch and percent juvenile motility vs. GA concentration were plotted (Figure 1). Statistical tests for linearity of the data failed; subsequently, nonlinear equations of exponential form exhibited the best fit to the data among all possibilities examined.

$$\%\,\text{Hatched Eggs} = 100\%[0.77 - 0.038 \cdot \%C_{GA} \cdot \exp(-0.038 \cdot \%C_{GA})]\; r^2 = 32.1\%$$

$$\%\,\text{Motile J2} = 100\%[0.498 - 0.038 \cdot \%C_{GA} \cdot \exp(-0.038 \cdot \%C_{GA})]\; r^2 = 37.5\%$$

Eggs that were exposed to GA concentrations of between 2 and 100 μg/ml exhibited hatch rates that were significantly lower than the control, but each was

Means followed by different letters are different ($\alpha = 0.05$) by pairwise comparisons conducted on logit-transformed binomial response data in a logistic regression ($N = 14$; duplicate trials at each concentration).
Reported means ± standard errors were back-transformed to percentages from logit-scale estimates.

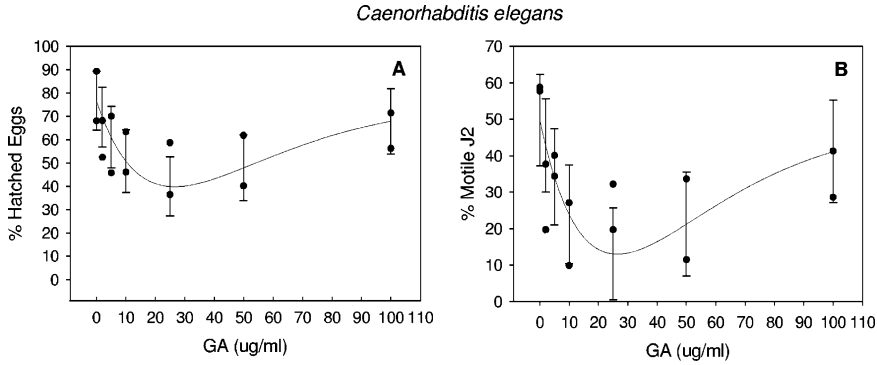

FIG. 1. Effect of geldanamycin (GA) on hatching and motility in *Caenorhabditis elegans*. Duplicate trials were used to fit a nonlinear dose-response regression to % hatched eggs and % motile juvenile values vs. GA concentration. Closed circles at each dose represent data means for the separate trials. Error bars were based upon the variation between duplicate trials pooled across the observed GA concentrations ($N = 14$) and indicate 95% confidence intervals for individual estimates of % hatched or % motile. (A) Percentage of *C. elegans* eggs that hatched after incubation for 20 hr in various concentrations of GA or DMSO control. (B) Percentage of *C. elegans* hatched juveniles that were motile after 20 hr incubation with GA or DMSO control.

similar to the hatch rate of at least one other GA concentration (Table 1). The dose showing the greatest decrease in egg hatch (47.6%) compared to control (79.6%) was 25 μg/ml GA. However, the suppressive effect on hatch rate reversed between 25 and 100 μg/ml GA, with the highest concentration (63.9% hatch) showing a similar effect to 2 μg/ml (60.9%) (Figure 1A). Geldanamycin also reduced the motility of *C. elegans* juveniles that hatched from treated eggs (Table 1, Figure 1B). Motility responses paralleled the hatch responses, with all GA levels showing significantly lower motility than the controls (Table 1). The greatest reductions in motile J2 were observed at 10 and 50 μg/ml GA (17.1% and 19.3% vs. 59.5% control). According to the nonlinear regression model, 25 μg/ml GA were shown to cause the greatest reduction in J2 motility. Curves constructed with nonlinear regression equations were U-shaped for both hatching and motility.

We also measured the effect of GA on egg hatch and juvenile motility in TN17 and TN18, two inbred populations of *H. glycines*. These strains were chosen on the basis of their selected hatching phenotypes (TN17, fast hatching; TN18, slow hatching), to determine whether they would respond differently to GA exposure. The hatch rate for each population was determined after 4 d of incubation in various GA doses suspended in DMSO or in the control treatment of DMSO alone. The dose–response relationships for TN17 and TN18 were

nonlinear. Log-normal equations were fit to the data to generate the curves shown in Figure 2.

TN17

$$\%\text{Hatched} = 100\% \cdot \left[0.098 + 0.086 \cdot \exp\left(-0.5 \cdot \left\{\log_e\left[(\%C_{GA} + 1)/5.3\right]/1.1\right\}^2\right)\right]$$

$$r^2 = 55.5\%$$

$$\%\text{Motile} = 100\% \cdot \left[0.20 + 0.38 \cdot \exp\left(-0.5 \cdot \left\{\log_e\left[\%C_{GA} + 1)/4.5\right]/1.7\right\}^2\right)\right]$$

$$r^2 = 65.5\%$$

TN18

$$\%\text{Hatched} = 100\% \cdot \left[-0.15 + 0.32 \cdot \exp\left(-0.5 \cdot \left\{\log_e\left[(\%C_{GA} + 1)/7.7\right]/3.7\right\}^2\right)\right]$$

$$r^2 = 31.7\%$$

$$\%\text{Motile} = 100\% \cdot \left[-0.05 + 0.36 \cdot \exp\left(-0.5 \cdot \left\{\log_e\left[\%C_{GA} + 1)/3.1\right]/2.2\right\}^2\right)\right]$$

$$r^2 = 89.8\%$$

Pairwise comparisons of percent hatched *H. glycines* eggs or percent motile J2 at each GA dose compared to control are shown in Table 2. For TN17, GA stimulated egg hatch between 2 and 25 μg/ml, but at 50 and 100 μg/ml, the percent egg hatch was similar to the control (Figure 2A). For TN18, a similar stimulation of egg hatch was observed, with both curves exhibiting an asymmetric inverse U shape (Figure 2C). None of the GA doses tested reduced the hatch rate to levels lower than the controls.

For TN17, percent motile J2 was higher than control at 2 and 5 μg/ml and declined to near control levels at 10–50 μg/ml GA (Figure 2B). At 100 μg/ml, the percent motile J2 was significantly lower (27.6%) than control (43.1%). For TN18, GA doses of 25 μg/ml and higher significantly reduced the motility of juveniles (Figure 2D).

DISCUSSION

Our experiments demonstrating the sensitivity of *C. elegans* to GA initially appear to contradict recent *in vitro* and *in vivo* evidence for GA resistance of *C. elegans* Hsp90 (David et al., 2003). In that study, nematodes were contin-

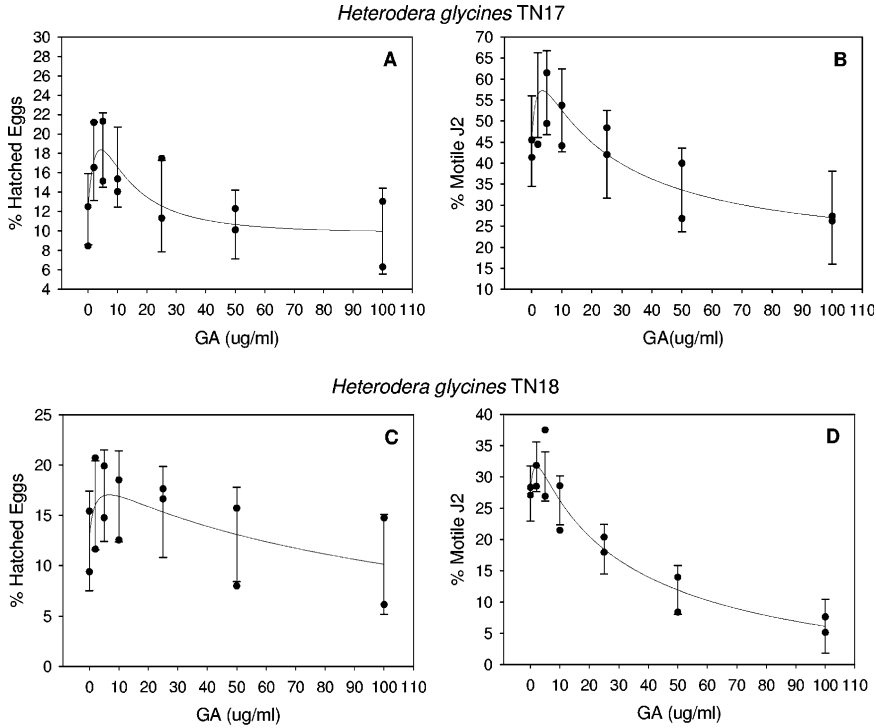

FIG. 2. Effect of geldanamycin (GA) on hatching and motility in *Heterodera glycines* inbred lines. Duplicate trials were used to fit a nonlinear dose-response regression to % hatched eggs and % motile juvenile values vs. GA concentration. Closed circles at each dose represent data means for the separate trials. Error bars were based upon the variation between duplicate trials pooled across the observed GA concentrations ($N = 14$) and indicate 95% confidence intervals for individual estimates of % hatched or % motile. (A) Percentage of *H. glycines* TN17 eggs that hatched after incubation for 4 d in various concentrations of GA or DMSO control. uously exposed to a single dose of GA, equivalent to our highest level (178 μM = 100 μg/ml GA), but no defects in viability, dauer formation, fertility, or life span were detected over several generations. This study followed the common procedure for testing compounds on nematodes, in which a high concentration is initially used to overcome the relative impermeability of the *C. elegans* cuticle (Rand and Johnson, 1995). In contrast, our multiple dose bioassays allowed us to uncover a complex response pattern that was not detectable with a single GA dose. The reversals of hatch and motility that we observed in *C. elegans* exposed

to high GA concentrations are, therefore, congruent with the prior study's inability to detect a phenotype at 100 μg/ml GA. Also, because the prior study administered GA to the surface of agar plates, it is not possible to discern whether uptake of GA by the nematodes was comparable in both studies. Comparison of low dose effects in both plate and liquid assay systems would be necessary to answer this question. These issues underscore the sensitivity of *C. elegans* to experimental conditions when testing responses to pharmacologic agents, and stress the importance of testing a range of doses and assay systems.

It is well established that Hsp90 is the definitive molecular target of geldanamycin binding (Prodromou et al., 1997; Stebbins et al., 1997). This fact, combined with information about the role of Hsp90 (*daf-21*) in *C. elegans*, provides clues about the possible pathways affected by geldanamycin. The different hatch responses to GA that we observed in *C. elegans* and *H. glycines* reflect differences in the way eggs hatch in each species. In *C. elegans,* all eggs are equally competent to hatch without any external stimulation (Albert and Riddle, 1988). The sensitivity of *C. elegans* egg hatch to GA exposure suggests the involvement of Hsp90 in this process, which is consistent with evidence for the presence of Hsp90/DAF-21 within the germline (Inoue et al., 2003). In contrast to *C. elegans*, the hatching process in cyst nematodes is complex, asynchronous, and influenced by environmental and host-derived factors (reviewed in Perry, 1997). The *H. glycines* TN17 and TN18 hatch responses to GA were similar to each other but very different from *C. elegans*. Because the hatching phenotypes of these inbred lines are temporal, exposure of eggs to one GA dose over time might reveal differences between these strains.

With respect to motility, in *C. elegans* the Hsp90 mutation *daf-21(p673)* is known to cause lethargy and defective chemotaxis to volatile odorants (Vowels and Thomas, 1994; Birnby et al., 2000). Also, the *C. elegans* protein UNC-45 functions as a cochaperone with Hsp90 for the folding and assembly of myosin, an integral component of muscle (Barral et al., 2002). Together, these associations predict a possible role for Hsp90 in movement or muscle development pathways in *C. elegans*, and GA inhibition of *C. elegans* juvenile motility is consistent with this interpretation. Overall, the differences in GA responses observed in *C. elegans* and *H. glycines* reflect the likely influence of genetic background upon the Hsp90-dependent pathways underlying hatching and motility. Because the gene for Hsp90 from *H. glycines* has recently been described (Skantar and Carta, 2004), further details of the Hsp90–GA interaction may be elucidated.

The complex nonlinear hatch and motility profiles in both nematode species display characteristics of hormesis, a model that describes the nonlinear responses of an organism to a wide range of compounds, including peptides, metals, and toxins (Stebbing, 2000; Calabrese and Baldwin, 2003). Whereas the external agent and the measured biological endpoint may vary, hormesis is commonly characterized by U- or inverse U-shaped dose–response curves. Prior studies pointed to the existence of hormetic effects in *C. elegans*. It has been established that different concentrations of pharmacological agents can cause contradictory effects in nematodes, and may indicate that the compound acts upon multiple targets (Rand and Johnson, 1995). Also, a hormetic link between thermotolerance and longevity has been described in *C. elegans* (Butov et al., 2001; Cypser and Johnson, 2002). The fact that *C. elegans daf-21*/Hsp90 is known to be involved in thermotolerance and upregulated by DAF-16 (McElwee et al., 2003) further supports involvement of Hsp90 in a hormetic biological switch involved in stress responses. Hsp90 could provide rheostatic control of client protein activities (e.g., protein kinases or hormone receptors), in response to cellular indicators of nutrient, thermal, or oxidative stress (Morano and Thiele, 1999; Knowlton and Sun, 2001). The reversal of egg hatching and J2 motility effects observed at GA doses may be such a manifestation of Hsp90-mediated hormesis. By profiling the GA doses that show observable effects, these studies should open the door to further investigations of Hsp90 and hormesis in nematodes.

Recent studies have shown that GA-producing strains of *Streptomyces* are effective against a variety of plant pathogens. The GA-producing strain *S. violaceusniger* YCED-9 was shown to antagonize the growth of seven fungal pathogens of turfgrass *in vitro* (Trejo-Estrada et al., 1998b). In greenhouse studies, this strain partially controlled grass seedling disease caused by *Rhizoctonia solani* and crown-foliar disease caused by *Sclerotinia homeocarpa* (Trejo-Estrada et al., 1998a). *S. hygroscopicus* spp. *geldanus* strain EF-76, was

shown to inhibit the causal agent of potato common scab, *Streptomyces scabies*, under field conditions, but did not affect potato yield (Beauséjour et al., 2003). In light of our GA results, these strains may have promise as biocontrol agents for nematodes as well.

RAPID COMMUNICATION

SELECTIVE AND pH-DEPENDENT BINDING OF A MOTH PHEROMONE TO A PHEROMONE-BINDING PROTEIN

WALTER S. LEAL,* ANGELA M. CHEN, and MELISSA L. ERICKSON

Maeda-Duffey Laboratory, Department of Entomology, University of California, Davis, CA 95616, USA

(Received June 4, 2005; revised July 14, 2005; accepted July 18, 2005)

Published Online July 28, 2005

Abstract—Fluorescence and circular dichroism (CD) data suggest that the major pheromone-binding protein (PBP) from the wild silkmoth, *Antheraea polyphemus*, ApolPBP1, undergoes a pH-dependent conformational change similar to that previously observed for the PBP from the silkworm moth, *Bombyx mori*, BmorPBP. All three constituents of the sex pheromone, E6,Z11-16Ac, E6,Z11-16Ald, and E4,Z9-14Ac, bound to ApolPBP1 with apparent high affinity at high pH, but reduced binding at low pH when tested individually in a "cold binding assay." In competitive assays, however, ApolPBP1 showed considerable preference for the major constituent of the sex pheromone, E6,Z11-16Ac. These data suggest that specificity of PBPs contributes at least in part to the remarkable selectivity of moth's olfactory system.

Key Words—pheromone-binding protein, *Antheraea polyphemus*, conformational change, circular dichroism, fluorescence, binding assay

INTRODUCTION

Pheromone-binding proteins (PBPs) assist in the transport of volatile, hydrophobic pheromones through the aqueous milieu separating the external environment from the odorant receptors in insect antennae (reviewed in Leal, 2005). Recent experimental evidence supports the hypothesis that PBPs are essential for the rapid uptake of pheromones from the external environment and

* To whom correspondence should be addressed. E-mail: wsleal@ucdavis.edu

delivery to the odorant receptors (Leal et al., 2005), but the literature regarding their role in pheromone discrimination is dichotomous (Wojtasek and Leal, 1999; Maida et al., 2000, 2003; Campanacci et al., 2001). For example, it has been found by fluorescence assays (Campanacci et al., 2001) that the three components of *A. polyphemus* sex pheromone, E6,Z11-16Ac, E6,Z11-16Ald, and E4,Z9-14Ac (Kochansky et al., 1975; Meng et al., 1989), were bound by the moth's major PBP, ApolPBP1 (Maida et al., 2000), with similar affinity (Campanacci et al., 2001). On the other hand, ApolPBP1 showed preferential binding to E6,Z11-16Ac over the other constituents of the sex pheromone in two different assays with radiolabeled pheromones (Maida et al., 2003). Ligand binding activity by *Bombyx mori* PBP, BmorPBP, was reduced at low pH because of a pH-dependent conformational change (Wojtasek and Leal, 1999), which is postulated to release the pheromone to the odorant receptor (Leal, 2005). By contrast, no pH influence was found for E6,Z11-16Ac binding to another PBP from the wild silkmoth, ApolPBP3 (Maida et al., 2003). These inconsistencies could be derived in part from different binding assays and recombinant proteins, and/or the unavailability of radiolabeled pheromones, which prevents employing the same standards by different laboratories. The present study was designed to address this controversy by using a recently developed "cold binding assay," which is based on the separation of bound and free ligands by a centrifugal device and does not require radiolabeled compounds (Leal et al., 2005). Here, we report that ApolPBP1 selectively binds the major pheromone constituent in competitive assays and undergoes a pH-dependent conformational change associated with a reduction of ligand binding at low pH.

METHODS AND MATERIALS

Protein Preparation. Recombinant ApolPBP1 was expressed in periplasmic space in *Escherichia coli* using a previously described pET-22b(+) expression system (EMD Biosciences; Wojtasek and Leal, 1999). The protein was extracted from the harvested cells with Tris–HCl 10 mM, pH 8, after three cycles of freeze (liquid nitrogen, 3 min) and thaw (room temperature), centrifuged at 16,000 $\times$ *g* to remove debris, and purified by multiple steps of ion exchange and gel filtration chromatography. Highly purified fractions [>99% monitored by liquid chromatography–electrospray ionization–mass spectrometry (LC-ESI/MS)] were lyophilized and stored at -80°C until use. LC-ESI/MS was performed with a LCMS-2010 (Shimadzu) upgraded with a stainless-steel capillary probe. Chromatographic separations were done on a ZorbaxCB C8 column (150 $\times$ 2.1 mm; 5 μm; Agilent Technologies) with a gradient of water and acetonitrile containing a modifier (2% acetic acid).

Fluorescence and CD Spectroscopy. Fluorescence spectra were recorded on a Shimadzu RF-5301 PC spectrofluorometer with 20 μg/ml of ApolPBP1 in 20 mM of one of the following buffers: NaOAc, pH 4–5; NH_4OAc, pH 5.5–7; Tris–HCl, pH 8. The protein solution was excited at 280 nm, and the emission spectra were recorded between 285 and 420 nm. Emission and excitation slit widths were set at 3 nm. Circular dichroism (CD) spectra were recorded by using a J-810 spectropolarimeter (Jasco) with 1 mg/ml or 0.3 mg/l of protein in 20 mM NH_4OAc buffer for near- and far-UV CD, respectively.

Cold Binding Assay. Binding tests were performed by the previously described "cold binding assay" (Leal et al., 2005). E6,Z11-16Ac, E6,Z11-16Ald, and E4,Z9-14Ac were purchased from Plant Research International (The Netherlands) and stocked at −80°C until use. Ethanol solutions (3.2 mM) were prepared after purity was confirmed by GC and GC-MS to be >98% for the acetates and >95% for the aldehyde. For competitive assays, we prepared one ethanol sample with 3.2 mM of each E6,Z11-16Ac, E6,Z11-16Ac, and E4,Z9-14 (Kochansky et al., 1975; Meng et al., 1989). One microliter of the test ligand was added to 50 μl of ApolPBP1 solution (6.2 μM) to make a final ligand-to-protein molar ratio of 10. GC and GC-MS analyses were performed on a 6890 Series GC system and a 5973 Network Mass Selective Detector, respectively. Both instruments were equipped with the same type of capillary column (HP-5MS, 25 m × 0.25 mm; 0.25 μm), which was operated at 100°C for 1 min, increased to 250°C at a rate of 10°C/min, and held at the final temperature for 10 min.

RESULTS AND DISCUSSION

We prepared a sample of recombinant ApolPBP1 by periplasmic expression, an expression system known to generate properly folded, functional PBPs (Wojtasek and Leal, 1999). Purity of rApolPBP1 was higher than 99%, as demonstrated not only by single bands in gel electrophoresis analysis (10 and 15% native PAGE; 15% SDS-PAGE) but also by LC-ESI/MS (Figure 1A). Both high-performance liquid chromatography trace and MS profile indicated a single protein peak with a molecular weight of 15,775 Da. This is in agreement

FIG. 1. (A) Mass spectral data for purified recombinant ApolPBP1. HPLC separation, mass spectrum of the major LC peak, and its deconvolution data (molecular mass of 15,775 Da). (B) Intrinsic fluorescence data indicating a great conformational transition between pH 6.5 and 5.5. (C) Far-UV CD and (D) near-UV CD spectra at pH 6.5 and 5.5 indicating minimal difference in helical content and a major change in the 3D conformation of the protein, respectively.

with the calculated molecular mass of ApolPBP1 (15,776 Da), considering the formation of three disulfide bridges.

Change in intrinsic fluorescence suggests a conformational transition between pH 6.5 and 5.5, with pronounced decrease of fluorescence signal between pH 6 and 5.5 (Figure 1B). Clearly, the large transition takes place above the p*I* (calcd., 4.74), whereas no significant change was observed when the pH was decreased below the p*I* (Figure 1B). Next, we obtained the far- and near-UV circular dichroism (CD) spectra of ApolPBP1. The far-UV CD spectrum at pH 6.5 (Figure 1C) indicated that ApolPBP1 is a helix-rich protein, in agreement with the reported NMR structure (Mohanty et al., 2004). Similarly to what has been found in BmorPBP (Wojtasek and Leal, 1999), the far-UV CD spectrum at low pH differed from the spectrum at high pH only in the minimal at ca. 228 nm (Figure 1C). Change in near-UV CD spectra at pH 6.5 and 5.5 (Figure 1D) is also strikingly similar to what has been observed in BmorPBP (Wojtasek and Leal, 1999). These findings are not consistent with the hypothesis that ApolPBP1 undergoes an overall conformational change involving most residues (Mohanty et al., 2004). The helical contents, nearly unchanged at low and high pH (Figure 1C), suggest that ApolPBP1 undergoes a pH-mediated helix formation compensated by some unwinding such as the formation of a C-terminus α-helix and unwinding of the N-terminus helix, as it has been documented for BmorPBP (Horst et al., 2001).

The pH-dependent conformational change in ApolPBP1 is reflected in binding affinity. ApolPBP1 binds E6,Z11-16Ac with apparent higher affinity at high pH and lower affinity at low pH (Figure 2A), as opposed to what has been observed for the association of the same ligand with ApolPBP3 (Maida et al., 2003). Next, we tested the specificity of this protein toward the three components of the sex pheromone system. When one ligand was tested at a time, ApolPBP1 bound to E6,Z11-16Ac, E6,Z11-16Ald, and E4,Z9-14Ac with the same apparent affinity (Figure 2B), but reduced binding at low pH (data not shown). However, in competitive assays in which the protein was incubated with equal amounts of the three compounds, ApolPBP1 selectively bound the major pheromone component, showed lower affinity for the shorter acetate, and had almost no affinity for the aldehyde (Figure 2C).

In summary, ApolPBP1 undergoes a pH-mediated conformational change, probably structurally related to what has been unveiled in BmorPBP. Whereas the basic form of ApolPBP1 bound the major pheromone constituent at the

FIG. 2. (A) Binding of ApolPBP1 at pH 7 and reduced binding at low pH. (B) When tested individually, ApolPBP1 bound all three constituents of the sex pheromone. (C) When subjected to an equal mixture of all three ligands at the same time in competitive assays, ApolPBP1 showed preferential binding to the major constituent of the sex pheromone, E6,Z11-16Ac.

sensillar lymph pH, binding is prevented or reduced in the acidic form. Assay methods testing one protein and one ligand at a time may conceal binding specificity. Under physiological conditions, PBPs encounter complex mixtures of compounds bombarding the sensilla. If they filter out some of these potential ligands, as the competitive assay suggests, the remarkable selectivity of the insect olfactory system does not have to rely entirely on the odorant receptors.

(Received December 17, 2004; revised June 20, 2005; accepted July 21, 2005)

Abstract—Previous studies have shown that some mammals are able to neutralize venom from snake predators. California ground squirrels (*Spermophilus beecheyi*) show variation among populations in their ability to bind venom and minimize damage from northern Pacific rattlesnakes (*Crotalus oreganus*), but the venom toxins targeted by resistance have not been investigated. Four California ground squirrel populations, selected for differences in local density or type of rattlesnake predators, were assayed for their ability to neutralize digestive and hemostatic effects of venom from three rattlesnake species. In Douglas ground squirrels (*S. b. douglasii*), we found that animals from a location where snakes are common showed greater inhibition of venom metalloprotease and hemolytic activity than animals from a location where snakes are rare. Effects on general proteolysis were not different. Douglas ground squirrels also reduced the metalloprotease activity of venom from sympatric northern Pacific rattlesnakes (*Crotalus oreganus oreganus*) more than the activity of venom from allopatric western diamondback rattlesnakes (*C. atrox*), but enhanced fibrinolysis of sympatric venom almost 1.8 times above baseline levels. Two Beechey ground squirrel (*S. b. beecheyi*) populations had similar inhibition of venoms from northern and southern Pacific rattlesnakes (*C. o. helleri*), despite differences between the populations in the locally prevalent predator. However, the venom toxins inhibited by Beechey squirrels did vary among venom from Pacific rattlesnake subspecies, and between these venoms and venom from allopatric western diamondback rattlesnakes. Blood plasma from Beechey squirrels showed highest inhibition of metalloprotease activity of northern Pacific rattlesnake venom, general proteolytic activity and hemolysis of southern Pacific

INTRODUCTION

Some species of mammals are known to be resistant to the venom of the viperid snakes that hunt them (Thwin and Gopalakrishnakone, 1998; Pérez and Sánchez, 1999). Viper venoms contain toxins with a variety of effects, including metalloproteases that break down the lining of blood vessels and extracellular matrix (Gutiérrez and Rucavado, 2000). Other venom components disrupt the normal processes of coagulation and induce hemolysis (Markland, 1998; Braud et al., 2000). In susceptible prey (and humans), venoms can lead to extensive hemorrhage, edema, tissue necrosis, and death (Russel, 1980; Ownby, 1982). Even if prey successfully evade ingestion by a viperid predator, venom-induced shock and the digestive effects of toxins pose a serious threat. To maintain the ability to survive and reproduce in an environment that holds challenges from predators, competitors, and conspecifics, mammals must minimize hemorrhage, tissue destruction, and disruptions to hemostasis that follow envenomation.

The interactions of California ground squirrels (*Spermophilus beecheyi*) and northern Pacific rattlesnakes (*Crotalus oreganus oreganus*) may be the most intensively studied example of the relationship between rattlesnakes and preferred prey. Ground squirrels are an important food resource for rattlesnakes throughout California (Linsdale, 1946; Fitch, 1948). Fitch (1949) estimated that *S. beecheyi* make up to 69% (by weight) of the diet for adult northern Pacific rattlesnakes (*C. o. oreganus*) at one site in the foothills of the Sierra Nevada. Field observations reveal that northern Pacific rattlesnakes are common near burrow systems during the reproductive season and periods of pup emergence, and are responsible for approximately 40% of pup and juvenile mortality in ground squirrel colonies (Linsdale, 1946; Fitch, 1948; personal observation). Sympatry between California ground squirrels and Pacific rattlesnakes is indicated in late Pleistocene fossil assemblages (Miller, 1912; Stock, 1918; Brattstrom, 1953). Elsewhere in the United States, middle Miocene fossil deposits indicate longer sympatry between rattlesnakes and the *Otospermophilus* ancestor of modern sciurids (Black, 1963; Holman, 1979). Therefore, the intensity of this predator–prey relationship is probably not a recent phenomenon, and represents an important biotic interaction for both ground squirrels and rattlesnakes.

It is not surprising, therefore, that *S. beecheyi* exhibit a variety of strategies to deter rattlesnake predation. Beyond a primary defense of vigilance, these squirrels will aggressively confront snake predators detected near their burrows. Prolonged staring, conspicuous tail flagging, substrate throwing, and biting are used to discourage hunting snakes, and provoke defensive displays such as hissing or rattling that aid in assessment of the danger posed by snake predators (Owings and Coss, 1977; Coss and Owings, 1989; Rowe and Owings, 1990, 1996; Swaisgood et al., 1999). However, active harassment requiring close approach to rattlesnakes exposes squirrels to the risk of envenomation. To protect against this risk, California ground squirrels possess innate blood plasma factors that allow them to survive envenomation by northern Pacific rattlesnakes (Poran et al., 1987; Poran and Coss, 1990). Serum–venom binding in radioimmunoassay (RIA) has been used extensively to characterize variation in resistance among *S. beecheyi* populations (Poran et al., 1987; Coss et al., 1993). Unfortunately, RIA binding levels provide only indirect information about functional differences in venom neutralization among *S. beecheyi* populations. Although the RIA binding of pooled sera from squirrel populations correlates highly with the same sera used to protect envenomated mice in approximate LD_{50} tests (Poran et al., 1987), this method does not reveal the underlying biochemical dynamics of toxicity and resistance. Enzyme–inhibitor binding, such as that described for the resistance of opossum to rattlesnake venom (Catanese and Kress, 1993), is indistinguishable from a variety of other protein–protein interactions resulting in high binding levels (Mishell and Shiigi, 1980).

Experimental Questions. Adult northern Pacific rattlesnakes (*C. o. oreganus*) possess venoms with multiple proteolytic and hemolytic venom toxins that ground squirrel prey must defend against (Mackessy, 1988, 1993, 1996). Biardi et al. (2000) showed that plasma from California ground squirrels can reduce the activity of venom proteases on hide powder azure and gelatin. However, this study did not specifically measure the activity of venom metalloproteases or toxins affecting clotting and hemolysis. A more detailed understanding of the biochemical basis of resistance is essential when attempting to clarify the relationship between RIA binding levels and functional resistance to venom. For example, previous research has revealed conflicting evidence about resistance in two populations of Douglas ground squirrels (*S. b. douglasii*) that vary in local rattlesnake density. One location (Winters, Yolo County, CA) is in oak woodland habitat in the foothills on the west side of the Sacramento Valley where rattlesnakes are common; this site also holds a winter hibernacula for rattlesnakes (W. Hamilton, personal communication). As expected, squirrels from this location show high RIA binding levels (Coss et al., 1993). A nearby site (Davis, Solano Co.) is on the floor of the valley less than 20 km to the east where rattlesnakes are extremely rare (Poran et al., 1987). RIA binding levels in

Davis squirrels are 59% lower, which Coss et al. (1993) interpreted as a decline in resistance correlated with colonization of this rattlesnake-rare habitat when the populations diverged about 8.6 ± 5.9 kyr. However, Biardi et al. (2000) showed that plasma from these two populations are indistinguishable in their capacity to inhibit proteolytic activity of northern Pacific rattlesnake venom. One interpretation of this discrepancy is that the correlation between RIA and approximate LD_{50} dose, determined using squirrels from sites where snakes are common (Poran et al., 1987), may not be an informative measure of resistance in squirrel populations where encounters with rattlesnakes are rare. An alternative interpretation is that reduced inhibition of other venom toxins is responsible for lower binding in the Davis population. One goal of this study is to use three additional measures of venom activity (metalloprotease activity, fibrinolysis, and hemolysis) in order to determine whether decreased RIA binding reflects venom resistance or nonfunctional binding interactions.

Additional measures of venom biochemical activity can also provide more detailed information on how ground squirrel plasma defenses deal with venoms from different rattlesnake lineages. Other mammal species seem to be broadly resistant to toxins from a variety of venom. For example, Soto et al. (1988) showed that sera from opossum (*Didelphis virginiana*) and woodrats (*Neotoma micropus*) were effective at preventing hemorrhage by all 47 species of snakes they examined; Huang and Pérez (1980) measured resistance in cotton rats (*Sigmodon hispidus*) to nine viperid venoms; and Tomihara et al. (1990) showed that mongoose (*Herpestes edwardsii*) are resistant to hemorrhagic effects of 28 snake venoms. However, northern Pacific rattlesnakes (*C. o. oreganus*) are the only pit vipers sympatric with ground squirrels in northern and central California (Klauber, 1972). Folsom Lake in the foothills of the Sierra Nevada east of Sacramento lies within the core of this range, and has a high density of northern Pacific rattlesnakes (Poran et al., 1987). Ground squirrels (*S. b. beecheyi*) from this site show high resistance when measured by experimental envenomation, *in vivo* protection of venom-challenged mice (Poran et al., 1987), and RIA binding levels (Poran and Coss, 1990). Squirrels from the Santa Ynez Valley inhabit snake-rich location southwest of the Central Valley within the zone of intergradation between northern (*C. o. oreganus*) and southern Pacific (*C. o. helleri*) rattlesnakes (Klauber, 1972). Squirrels from these two regions show differences in allozyme frequencies (Goldthwaite, 1989), reflecting divergence during the late Pleistocene (Coss and Goldthwaite, 1995; Coss, 1999). They have also been subject to predation from simultaneously diverging lineages of Pacific rattlesnake predators (Pook et al., 2000; Ashton and de Queiroz, 2001).

Mackessy (1988) found no significant differences between venoms from northern and southern Pacific rattlesnake venoms collected from Santa Barbara, San Luis Obisbo, and Ventura Counties across several assays of enzymatic

activity and toxicity (to lizards). Similarly, Bee et al. (2001) detected only minor differences in metalloprotease activity between these two venoms. However, genetic divergence and geographic separation in squirrel populations suggests the opportunity for coevolutionary change (Thompson, 1994, 1997; Nuismer et al., 1999; Gomulkiewicz et al., 2000) that may affect the ability of plasma defenses to deal with venom from these two subspecies. In other words, we expect plasma defenses in squirrels from Folsom Lake to be more effective against northern Pacific rattlesnake venom. Conversely, plasma defenses in squirrels from the Santa Ynez valley should be more effective against southern Pacific rattlesnake venom. Finally, venom from western diamondback rattlesnakes (*C. atrox*) constitutes a novel challenge to plasma defenses of squirrels in both of these locations. This venom also shows proteolytic, hemorrhagic, and hemolytic activity (Soto et al., 1988), but western diamondback rattlesnakes are a lower Sonoran species restricted to the deserts of the southeastern part of California (Klauber, 1972). We know that California ground squirrel plasma inhibits *C. o. oreganus* proteolytic activity more than *C. atrox* activity (Biardi et al., 2000), and we expect a similar result when measuring effects on other venom toxins. Therefore, a second goal of this study was to assess the specificity of plasma defenses by challenging them with venom from sympatric and allopatric predators.

METHODS AND MATERIALS

Blood Collection and Storage. We collected blood samples from ground squirrels in four locations that varied in the density or identity of rattlesnake predators. The method of determining local snake density (~predation intensity) is described by Poran et al. (1987), supplemented by information on rattlesnake distributions prior to extensive human disturbance of the Central Valley (Grinnell and Camp, 1917; Nussbaum et al., 1983).

Two populations of Douglas squirrels (*S. b. douglasii*) were sampled: Winters (Yolo Co.) is in the Coast Range foothills and has a high density of northern Pacific rattlesnake predators (*C. o. oreganus*); the Davis site (Yolo Co.) is on the floor of the Sacramento valley where rattlesnakes are extremely rare (only two *C. o. oreganus* reported during the last 25 years). Two populations of Beechey squirrels (*S. b. beecheyi*) were sampled: Folsom Lake State Recreation Area (El Dorado Co.) has a high density of northern Pacific rattlesnakes (*C. o. oreganus*); Sedgwick Natural History Reserve (Santa Barbara Co.) in the Santa Ynez valley also has a high density of rattlesnakes, and lies within the range of southern Pacific rattlesnakes (*C. o. helleri*). The number of individuals collected at each location were as follows: Davis = 11; Winters = 16; Folsom Lake = 10; Sedgwick Reserve = 9.

Squirrels were live-trapped and anesthetized with ketamine–HCl (50 mg/kg, i.m.). Approximately 3 ml of whole blood were collected from individual adults via cardiac puncture and stored in additive-free Vacutainer blood collection vials (Becton Dickinson, Irvine, CA, USA). Samples were maintained at 4°C overnight, then clots were removed and discarded. The supernatant was centrifuged at 3000 *g* for 10 min at 4°C to separate out any remaining erythrocytes, then stored at −70°C until used.

Venom Source and Preparation. Lyophilized venoms were purchased from Sigma (St. Louis, MO, USA). Although venoms were not collected from the same sites as squirrel plasma samples, venoms from Pacific rattlesnakes were obtained from regions within the geographic range of California ground squirrels (Hall, 1981). According to the supplier, northern Pacific rattlesnake (*C. o. oreganus*), venom was obtained from multiple snakes originating in northern California and Oregon. Venom from southern Pacific rattlesnakes (*C. o. helleri*) was obtained from snakes originating in southern California. Information on the site(s) of origin for western diamondback (*C. atrox*) venom was unavailable.

Venoms were reconstituted at a concentration of 10 mg/ml in a buffer containing 20 mM Tris–HCl + 1 mM $CaCl_2$, pH 8.0, and stored at −20°C until use.

Assays of Venom Toxicity. Four assays examined the effects of ground squirrel plasma in inhibiting the proteolytic, collagen hydrolysis, hemolytic, and fibrinolytic activity of rattlesnake venom. Agarose–gelatin plates were prepared according to the method of Palmer (1993) and used as a measure of total venom proteolytic activity. A template was used to punch equally spaced 3-mm-diam wells in the surface of the gel, and wells were loaded with 20 μl of sample. The gel was then incubated at 37°C for 24 hr in a humidified chamber. Following incubation, unhydrolyzed gelatin was precipitated in a saturated ammonium sulfate solution at 70°C for 10 min, and the area of hydrolysis was calculated from the product of two perpendicular diameters across the clear lysis zone.

Snake venom metalloprotease activity was quantified using Azocoll (Sigma) as a collagen substrate to model the effects on mammalian connective tissue and extracellular matrix. Aliquots (1 ml) of 1% Azocoll (w/v) solution in 20 mM Tris–HCl, pH 8.0 were prepared in a microcentrifuge tube. Sample (20 μl) was added, and the reaction mix was incubated at 37°C for 2 hr with occasional agitation. Following incubation, the tubes were centrifuged for 2 min at 16,000 *g* to pellet unreacted substrate. The absorbance of the supernatant was determined at 520 nm using a Shimadzu UV160 spectrophotometer.

BBL Stacker plates (Carolina Biological Supply) containing 5% defibrinated sheep's blood in Columbia agar were used to assay for hemolytic activity. Wells (3 mm diam) were punched in the substrate in a grid pattern. Samples (20 μl) were loaded into each well, then the plate was sealed with parafilm and incubated at 37°C for 24 hr. The area of hemolysis, defined as the transparent

zone around the well cleared of red blood cells, was calculated from two perpendicular measurements of well diameter.

Fibrin–agarose plates prepared by a modification of the method of Astrup and Müllertz (1952) were used to measure venom fibrinolytic activity. Bovine fibrinogen was dissolved in Tris–HCl, pH 8.0, to a concentration of 1 mg/ml using a sonicator bath. Ten milliliters of fibrinogen solution was placed in a 100 × 15 ml Petri dish and clotted by the addition of 100 μl of thrombin (100 units/ml). Clot formation was completed within 30 min, as determined by the opacity of the fibrinogen solution. Sample treatments (20 μl) were applied to the surface of the clot, and the plate was incubated at 37°C for 24 hr in a humidified chamber. Following incubation, the area of hydrolysis was calculated from the product of two perpendicular diameters across the liquefied lysis zone.

Relative Activity Scores and Statistical Analyses. Plasma samples from individual squirrels were screened against relevant venoms, and individual scores were recorded for each of the four assays as the mean of at least three replicates. Samples for each assay consisted of a venom-only treatment (10 μl venom + 10 μl buffer) and a venom + plasma treatment (10 μl venom + 5 μl plasma + 5 μl buffer), as well as negative controls (buffer only and plasma only). The difference in activity between venom-only and venom + plasma treatments was expressed as a ratio:

$$\text{Relative activity} = \frac{\text{activity of [venom + plasma]}}{\text{activity of [venom only]}}$$

This allows for testing qualitative differences in the outcome of interactions between venom toxins and plasma defensive factors across the four assays. It simultaneously adjusts for differences in scaling due to differences among venoms in baseline activity on these assays (Soto et al., 1988).

Because relative activity scores are proportions, they were subject to arcsine transformation prior to statistical analysis to yield measures that followed an approximately normal distribution (Zar, 1984). Data were analyzed using a one-factor between-subjects (populations) and two-factor within-subjects (assay type, venom type) repeated measures ANOVA. Specific comparisons of population and venom effects were tested with planned contrasts of the relevant group means.

RESULTS

Plasma Defenses in Douglas Ground Squirrels (S. b. douglasii). Effects of Douglas ground squirrel plasma on venom activity are shown in Figure 1. The

two populations differed significantly in their ability to inhibit venom from the northern Pacific rattlesnake ($F_{3,18} = 18.96$, $P < 0.0001$). This was primarily due to significantly higher inhibition by animals from Winters (where snakes are common) in the collagenase assay ($F_{1,20} = 56.97$, $P < 0.001$). Winters animals were also slightly more effective at reducing venom hemolytic activity ($F_{1,20} = 7.25$, $P = 0.014$), although the mean difference was small—a change in relative activity of only 2.4% of baseline venom activity. There were no significant

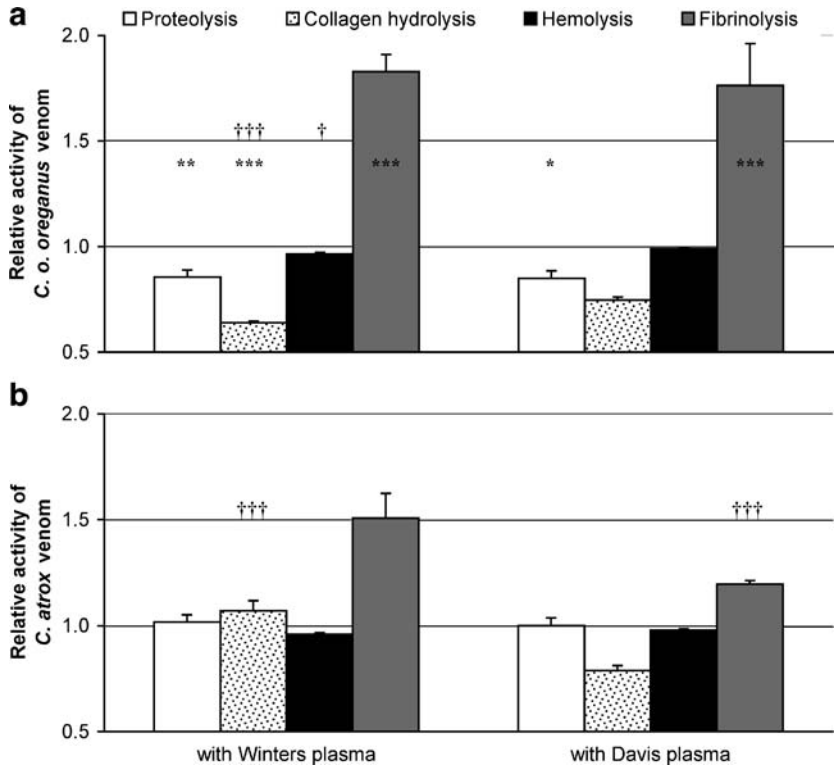

FIG 1. Activity (mean ± SE) of rattlesnake venoms incubated with plasma samples from two populations of Douglas ground squirrels (*S. b. douglasii*) that vary in local density of northern Pacific rattlesnakes (*C. o. oreganus*). Winters is a location where rattlesnakes are common, whereas Davis is a site where snakes are extremely rare. Western diamondback rattlesnakes (*C. atrox*) are allopatric with both populations of squirrels. Activity is expressed relative to venom-only controls as described in Methods and materials. Daggers indicate significant differences between the two squirrel populations (†$P < 0.05$; †††$P < 0.001$). Asterisks indicate significant differences between the two venoms (*$P < 0.05$; **$P < 0.01$; ***$P < 0.001$).

differences between plasma samples from Davis and Winters squirrels in their effects on general proteolytic activity of northern Pacific rattlesnake venom. The two populations also did not differ in their effect on fibrinolysis; in this case, relative activity increased to almost 1.8 times that of venom-only treatments (Figure 1a, b).

There were also significant differences in the effects of plasma samples on sympatric and allopatric venoms. Winters animals reduced proteolysis ($F_{1,25}$ = 17.21, P = 0.003) and collagen hydrolysis ($F_{1,20}$ = 115.45, $P < 0.001$) of northern Pacific rattlesnake venom more than western diamondback venom. Plasma samples from Davis animals were also more effective at reducing proteolytic activity of *C. o. oreganus* venom ($F_{1,25}$ = 6.44, P = 0.018), but showed no difference in their effect on collagen hydrolysis by the two venoms ($F_{1,26}$ = 0.67, $P > 0.05$). Plasma was less effective against *C. o. oreganus* venom than against *C. atrox* venom in the fibrinolytic assay ($F_{1,20}$ = 16.12, $P < 0.001$). There was no significant difference between venoms in the hemolytic assay ($F_{1,25}$ = 1.24, $P > 0.05$).

Plasma Defenses in Beechey Ground Squirrels (S. b. beecheyi). There were no differences between plasma from Folsom Lake and Sedgwick in their effects on venom proteolysis, collagen hydrolysis, or hemolysis (all tests: $P >$ 0.05) (Figure 2). Although plasma from Sedgwick squirrels generally induced higher relative activity in the fibrinolysis assays than Folsom plasma samples, this difference also was not statistically significant ($F_{1,10}$ = 1.43, $P > 0.05$). Consequently, data from the two Beechey populations were combined for analysis of the effects of plasma defenses across different venoms.

Beechey squirrel plasma varied in effectiveness against general proteolytic activity of the three venoms ($F_{2,32}$ = 19.8, $P < 0.001$)—Southern Pacific rattlesnake (*C. o. helleri*) venom was inhibited more than northern Pacific rattlesnake venom ($F_{1,16}$ = 11.09, P = 0.004), which in turn was inhibited more than western diamondback venom ($F_{1,16}$ = 18.24, $P < 0.001$). In contrast, Beechey plasma samples reduced northern Pacific rattlesnake metalloprotease activity more than southern Pacific ($F_{1,17}$ = 5.843, P = 0.032) or western diamondback ($F_{1,17}$ = 5.536, P = 0.031) venom. Hemolytic activity of western diamondback venom was reduced more than that of the two Pacific rattlesnake venoms ($F_{2,10}$ = 8.03, P = 0.008). There were no significant differences in the way Beechey plasma samples affected fibrinolysis by the three venoms.

DISCUSSION

Although California ground squirrel sera-to-venom binding level in RIAs correlates highly with approximate LD_{50} in mice, this method does not directly

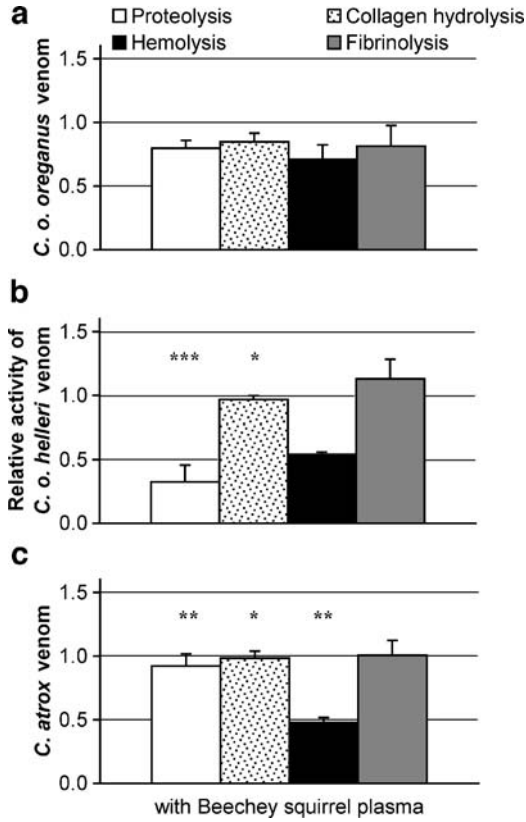

FIG 2. Activity (mean ± SE) of rattlesnake venoms incubated with plasma samples from two populations of Beechey ground squirrels (*S. b. beecheyi*) that are subject to predation by Pacific rattlesnakes. Folsom Lake is a site where northern Pacific rattlesnakes (*C. o. oreganus*) are common, whereas the Sedgwick Reserve is a site within the zone of intergradation between northern and southern Pacific (*C. o. helleri*) rattlesnakes. Western diamondback rattlesnakes (*C. atrox*) are allopatric with both populations of squirrels. Activity is expressed relative to venom-only controls as described in Methods and materials. Asterisks indicate significant differences from the effect on *C. o. oreganus* venom (*$P < 0.05$; **$P < 0.01$; ***$P < 0.001$).

measure the ability of prey sera to inhibit specific venom toxins. We observed distinct differences in the capacity of plasma proteins from California ground squirrels to affect the proteolytic and hemolytic activities of rattlesnake venoms. The protease, metalloprotease, and hemolytic activity of all three venoms were reduced in the presence of prey plasma from one or more ground squirrel

populations. However, Douglas squirrels are unable to decrease venom fibrinolysis. In fact, fibrinolytic activity of northern Pacific rattlesnake venom is almost twice as great when incubated with plasma from Douglas squirrels (Figure 1a) than when assayed alone (relative activity = 1.0) or against Beechey squirrel plasma (Figure 2a). Fibrinolysis may result from plasmin-like activity of venom toxins or from activation of endogenous serum components (Hofmann and Bon, 1987; Braud et al., 2000). Increased activity of venom when incubated with serum suggests that venom not only maintains effectiveness in the face of prey defenses, but can also capitalize on the biochemical properties of prey tissues. RIA binding levels, therefore, may represent a multitude of interactions between venom and prey tissues that simultaneously reduce and enhance the toxic activities of venom. Radioimmunoassays have been valuable in screening for population differences in venom resistance in California ground squirrels (Poran et al., 1987; Poran and Coss, 1990; Coss et al., 1993). However, assays of venom + plasma interactions clarify the functional basis of differences in binding levels, and will be more valuable in understanding the consequences of variation in prey defenses.

In contrast to enhanced fibrinolytic activity in the presence of Douglas blood plasma, samples from all four populations significantly reduced the metalloprotease activity of northern Pacific rattlesnake (*C. o. oreganus*) venom (Figures 1a and 2a). This is consistent with our understanding of antihemorrhagic factors identified in other mammalian prey of viperid snakes, which have been identified as snake venom metalloprotease inhibitors (SVMPI) (Pérez and Sánchez, 1999). The ability to inhibit hemorrhagic toxins appears to be a convergent response to envenomation, perhaps because the major threat of viper venoms, hemorrhage *in rhexis*, is thought to result from hydrolysis of collagen-rich connective tissue lining the capillary endothelium (Baramova et al., 1989; Tu, 1991). Minimizing the ability of venom toxins to rupture blood vessels can have a cascade of multiple subsequent protective benefits—including reduced access of other venom toxins to target tissues, reduced edema, and continued circulation of blood to regions near the bite—thereby enhancing tissue repair and minimizing necrosis (Gutiérrez and Rucavado, 2000; Anai et al., 2002). However, it is surprising that the metalloprotease activity of southern Pacific and western diamondback venoms was relatively unaffected, because defenses specialized to one or a few venoms seems to be rare. For example, Soto et al. (1988) showed that sera from opossum (*D. virginiana*) and woodrats (*N. micropus*) was effective at preventing hemorrhage by all 47 species of snakes they examined. California ground squirrels encounter only a single rattlesnake species (*C. o. oreganus*) from central California northward to British Columbia; we suspect that coevolution may have favored plasma defenses in populations from the Central Valley that are especially effective against venom from this species.

Generalized resistance to venom metalloproteases is similar to the pattern observed in animals from the Davis site, where rattlesnakes are extremely rare (cf. Figure 1a, b). Compared to the nearby Winters population, plasma factors were not as effective against the local rattlesnake predator (*C. o. oreganus*), but maintained some effectiveness against western diamondback (*C. atrox*) venom. Antihemorrhagic proteins isolated from other mammals show homology to proteins in the immunoglobin supergene family (Perales and Domont, 2002), which includes plasma serpins and other protease and metalloprotease inhibitors. Catanese and Kress (1993) identified differences in the amino acid sequence of oprin (the antihemorrhagic factor from *D. virginiana*) that distinguish it from other mammalian α_1-proteinase inhibitors. Presumably because of these differences, oprin can bind and inhibit venom metalloproteases while these toxins rapidly hydrolyze human α_1 proteinase. We suspect that consistent selection from northern Pacific rattlesnake toxins in the Winters, Folsom Lake, and Sedgwick Reserve animals has favored sequence changes in ground squirrel SVMPI that maximize effectiveness against this venom. As venom metalloproteases are also subject to selection favoring escape from inhibition by prey defenses, reciprocal changes may have led to SVMP and SVMPI variants unique to these species. Reactive center sequences in plasma serpins are hypervariable and affect protease recognition and inhibition effectiveness (Hill and Hastie, 1987; Goodwin et al., 1996). It will be interesting to see whether Davis dwellers, and squirrels from other sites where snakes are rare or absent, possess plasma factors with a reactive site sequence similar to the precursor of SVMPIs in this species. Such sequences may confer some level of protection against xenologous metalloproteases, including those from a variety of snake venoms, but may not represent a form optimized to inhibit SVMP from the lone sympatric species, northern Pacific rattlesnakes.

The contrast between squirrel blood plasma effects on metalloprotease and fibrinolytic activity may reflect alternative solutions to venom toxicity by rattlesnakes and ground squirrels. Although ground squirrel plasma factors can reduce the activity of venom metalloproteases, rattlesnakes may still benefit by immobilizing prey as they disrupt hemostasis. Elevated fibrinolytic activity of *C. o. oreganus* venom may aid snakes in subduing prey by the induction of hypotensive shock if internal bleeding after envenomation is prolonged (Mackessy, 1993; Mackessy et al., 2003). This would increase the likelihood of obtaining a valuable meal, as long as sufficient SVMP activity is maintained to facilitate the rupture of prey viscera after ingestion (Thomas and Pough, 1979). From the squirrel's perspective, avoidance of tissue damage from digestive venom toxins may be the crucial task of plasma defenses because behavioral defenses may buffer against the risk posed by venom-induced shock. Recruitment of other colony members to mob rattlesnakes (Owings and Coss, 1977; Hersek and Owings, 1993) may minimize the opportunity for snakes to

ingest envenomated squirrels, even if they are temporarily immobilized. In this case, the digestive effects of metalloproteases may pose a greater threat to fitness because of the potential for lasting damage to tissues. Studies of inhibition by plasma from rock squirrels, a closely related species that also shows aggressive confrontation of rattlesnake predators (Owings et al., 2001), likewise indicates that metalloprotease inhibition is of primary importance (Biardi, 2000).

Our four measures of venom activity also revealed significant differences between Pacific rattlesnake venoms when preying on the Beechey subspecies of California ground squirrels (*S. b. beecheyi*). We expected to find differences between squirrels from the Folsom and Sedgwick sites, but were unable to distinguish between them using any of the four assays of resistance. Instead, we observed striking differences between venoms. Northern Pacific rattlesnake venom maintained greater activity in the general proteolytic and hemolytic assays, whereas southern Pacific rattlesnake venom maintained greater effectiveness in the metalloprotease and fibrinolysis assays (cf. Figure 2a, b). This was surprising because previous studies have not identified clear differences in activity between these venoms (Mackessy, 1988; Bee et al., 2001). However, our results show that these venoms pose distinctly different threats to ground squirrels inhabiting a site (such as the Sedgwick Reserve) where they are likely to encounter both snake species.

The role of Douglas squirrel plasma in enhancing fibrinolytic activity, inhibition of venom metalloproteases by ground squirrel SVMPI, and the detection of differences in northern and southern Pacific rattlesnake venoms in the presence of Beechey squirrel plasma all highlight the adaptive context of venoms and resistance. Our assays of venom activity in the presence of resistance factors revealed variation that is not detected in assays of venoms alone, and reinforce the idea that the outcome of envenomation will depend on both predator and prey, and in turn will affect the evolution of both venom toxicity and resistance. Detection of previously cryptic differences between *C. o. oreganus* and *C. o. helleri* venoms may reflect an arms race that has generated variation within and between predators and prey. Relationships among species over evolutionary time can foster reciprocal adaptation of traits crucial to their interaction (Futuyma and Slatkin, 1983). Because populations of California ground squirrels vary in their ability to neutralize venom toxins (Biardi, 2000; Biardi et al., 2000; this study), and because this variation has important implications for the fitness of both predators and prey, both theoretical (e.g., Thompson, 1994, 1997) and modeling (e.g., Gomulkiewicz et al., 2000) approaches to coevolution predict corresponding local variation in venom from northern Pacific rattlesnakes. There are no published studies describing population differences in venom for this species; unfortunately, our use of pooled venoms also does not allow us to detect differences among

rattlesnakes at the population level. However, population variation in venoms related to diet is not unknown. For example, Daltry et al. (1996a,b) demonstrated that population variation in venom composition of the Malayan pit viper (*Calloselasma rhodostoma*) is strongly influenced by diet. However, this study related variation to the relative representation of different prey categories (amphibians, reptiles, and "endotherms") in the diet, making it unclear whether the effect is attributable to basic structural and physiological differences among prey categories, or more specific defenses to venoms such as we observe in ground squirrels. The subsequent debate between Sasa (1999a,b) and Wüster et al. (1999) centering on neutral vs. adaptive explanations for variability in snake venoms highlighted the importance of studying venoms in their natural context. To date, however, studies designed to test the coevolution of venomous snakes and their prey remain rare (e.g., Heatwole and Powell, 1998; Jorge da Silva and Aird, 2001).

Research on snake venom chemistry has an extensive history, driven primarily by interest in the clinical treatment of snakebite and the characterization of toxins in a therapeutic and research context. However, approaches to understanding venoms in a natural context (Mackessy, 1988; Daltry et al., 1996a,b; Kordis and Gubensik, 2000; Creer et al., 2003; Mackessy et al., 2003), especially considering venom resistance (Poran et al., 1987; Poran and Coss, 1990; Coss et al., 1993; Heatwole and Poran, 1995; Chiszar et al., 1999; Biardi et al., 2000; Heatwole et al., 1999), are becoming increasingly common. Future studies that simultaneously evaluate local populations of snakes and prey are likely to provide additional surprising insights into toxicity and resistance arising from the coevolutionary arms race at the molecular level.

(Received February 4, 2005; revised July 14, 2005; accepted July 16, 2005)

Abstract—Two alkylated 1,4-benzoquinones were identified from the defensive secretion produced by the neotropical harvestman *Goniosoma longipes* (Gonyleptidae). They were characterized as 2,3-dimethyl-1,4-benzoquinone and 2-ethyl-3-methyl-1,4-benzoquinone. We tested the effectiveness of these benzoquinone secretions against several predator types, including invertebrates and vertebrates. Different predators were exposed to the harvestmen's gland secretion or to distilled water in laboratory bioassays. Our results indicate that secretions containing the 1,4-benzoquinones released by *G. longipes* can be an effective defense against predation, and that the effectiveness of the secretion is dependent on the predator type. The scent gland secretion repelled seven ant species, two species of large wandering spiders, and one frog species, but was not an effective defense against an opossum. Our study also demonstrates that the scent gland secretion of *G. longipes* can work as a chemical shield preventing the approach of three large predatory ants for at least 10 min. The chemical shield may protect the harvestman against successive attacks of the same ant worker and also allow the harvestman to flee before massive ant recruitment. Our data support the suggestion that chemical defenses may increase survival with some but not all potential predators. This variation in defense effectiveness may result from many interacting factors, including the attack strategy, size, learning ability, and physiology of the predators, as well as the chemical nature of the defensive compounds, type of emission, and amount of effluent released by the prey.

INTRODUCTION

The species of the order Opiliones are characterized by the presence of a pair of exocrine glands located at the anterior margins of the cephalothorax near the base of the second pair of legs (Shultz, 1990). These glands produce a variety of volatile secretions that are released under the threat of predation (Eisner et al., 1978). To date, nearly 30 species have had their secretions chemically characterized, and a phylogenetic pattern may be observed. Species belonging to the suborder Eupnoi produce a variety of acyclic compounds, such as short-chain ketones and alcohols among the sclerosomatids and naphthoquinones among the phalangiids (references in Roach et al., 1980). In the suborder Laniatores, species of the superfamily Travunioidea produce mainly terpenoids, whereas among the Gonyleptoidea, the secretion is composed of phenols and alkylated 1,4-benzoquinones (references in Eisner et al., 1978; Acosta et al., 1993; Gnaspini and Cavalheiro, 1998). Quinones are widely distributed in the scent gland secretions of arthropods such as insects and millipedes (Blum, 1981), but the particular alkylated quinones produced by harvestmen seem to be of more restricted occurrence (Eisner et al., 1978).

Although much is known about the chemical nature of the compounds produced by harvestmen, knowledge about their biological role is still scarce. Several authors suggest that the scent gland secretions in harvestmen could be used for intraspecific communication, including trail marking, sexual recognition, mutual attraction, and alarm (see Holmberg, 1986; Machado et al., 2002). However, the main function attributed to the scent secretion is defense against predators (review in Holmberg, 1986). Laboratory observations have shown that ants are repelled by the secretion released by the cosmetid *Vonones sayi* (Eisner et al., 1971), the leiobunine *Leiobunum formosum* (Blum and Edgar, 1981), and the gonyleptid *Acanthopachylus aculeatus* (Eisner et al., 2004). Anecdotal observations indicate that some spiders may be also deterred by harvestman secretions (e.g., Cloudsley-Thompson, 1958; Juberthie, 1976), but others are not (e.g., Bristowe, 1949; Immel, 1954). Recently, Eisner et al. (2004) demonstrated that the scent gland secretion of the harvestman *A. aculeatus* was unable to deter the attack of a lycosid spider. The effectiveness of the scent gland secretion against vertebrates is also controversial because some species of frog seem to present a strong aversive response (e.g., Edgar, 1971), whereas some mammals feast on harvestmen (e.g., Pelegatti-Franco and Gnaspini, 1996). Despite these

field and laboratory observations, the defensive role of the secretion against invertebrate and especially vertebrate predators remains to be experimentally tested through a rigorous protocol.

In this study, we chemically characterized the scent secretion of *Goniosoma longipes* (Roewer, 1913; Gonyleptidae) and conducted a series of bioassays to test the effectiveness of the 1,4-benzoquinone secretions produced by this neotropical harvestman against several predator types. This is a comprehensive study on the defensive role of the fluids released by harvestmen and the first to assess experimentally that the specific alkylated benzoquinone secretions released by harvestmen can deter vertebrates. Because after releasing the odoriferous secretion, residual effluents remain on the harvestmen's body (Eisner et al., 1971), we also tested if the secretion can also work as a "chemical shield".

METHODS AND MATERIALS

Studied Species. The harvestman *G. longipes* is conspicuous (Figure 1A, B) and widespread in forested areas of southeastern Brazil. This species was chosen as the source of secretion because it is abundant in our study site and because individuals produce a great amount of secretion when disturbed (see Machado et al., 2000). Moreover, the ecology and behavior of the species were previously studied (see Machado and Oliveira, 1998; Machado et al., 2000), aiding the selection of more realistic potential predators. The external morphology of the ozopore of *G. longipes* has been described (see Figures 19 and 20 in Hara and Gnaspini, 2003), and the mode of emission occurs as follows: (a) first, a large transparent droplet of enteric fluid composed exclusively of water is regurgitated, slips along the lateral area of the dorsal scute, runs by capillarity in tegumentary grooves, and accumulates in the posterior portion of the body (Figure 1A); (B) if the harvestman is persistently disturbed, a second fluid may be secreted by the odoriferous glands, adding to the previously colorless fluid a yellowish coloration and a characteristic sour smell (Figure 1B). Sometimes, the secretion may also be sprayed as a jet directly toward the aggressor without mixing with enteric fluid (Machado et al., 2000; Hara and Gnaspini, 2003).

All individuals of *G. longipes* used in this study were collected inside caves at the Parque Florestal do Itapetinga (23°15′S, 46°45′W, 900- to 1300-m altitude, 1600 mm rain/year), Atibaia, São Paulo state, southeastern Brazil (for details on the study site, see Machado and Oliveira, 1998 and Machado et al., 2000). In the laboratory, adult *G. longipes* were maintained in a communal terrarium (60 × 40 cm base, 35 cm high) containing cotton wetted with water to maintain the humidity and fed with dead insects twice a week.

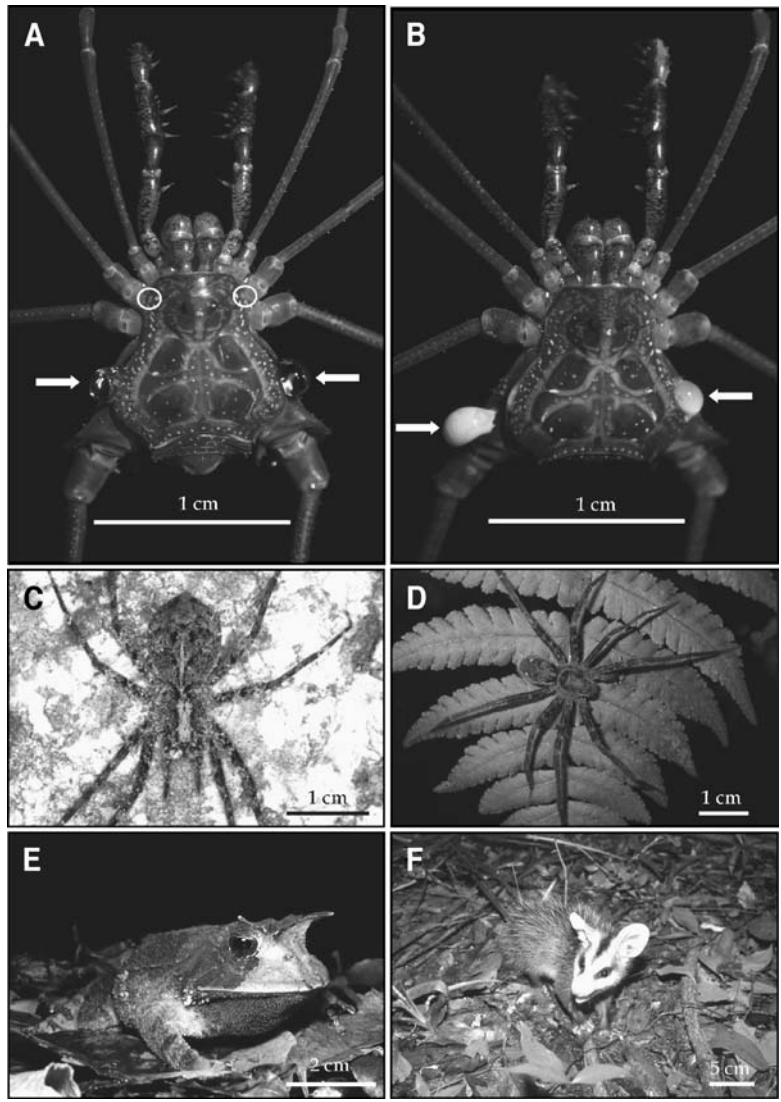

FIG. 1. Adult male of the harvestman *G. longipes* (A) with two droplets (arrows) of aqueous enteric fluid and (B) with a droplet of secretion (arrows) formed by the mixture of enteric fluid and defensive secretion (photos: B.A. Buzatto). The circles indicate the external opening of the scent gland. (C–F) Model predators used in the bioassays: (C) the hunting spiders *E. cyclothorax* (photo: R.J. Sawaya) and (D) *T. biocellata* (photo: G. Machado); (E) the small horned frog *Pr. boiei* (photo: I. Sazima) and (F) the white-eared opossum *D. albiventris* (photo: E.G. Martins).

Analyses of Defensive Secretions. Chemical secretions from *G. longipes* (about 8 mg/individual) were collected by pressing cotton wools (50–70 mg) onto the gland openings. The exudates were then either extracted with ethyl acetate (about 5 ml) and analyzed by gas chromatography–mass spectrometry (GC-MS) or with $CDCl_3$/tetramethylsilane (TMS) (600 μl) for the NMR experiments. GC-MS analyses were carried out using an HP 6890/5973 system equipped with an HP5 fused silica capillary column (30 m × 0.25 mm × 0.25 μm). Oven temperatures were programmed from 50 to 200°C at 10°C min^{-1}, and subsequently from 200 to 290°C at 16°C min^{-1}. The injector temperature was 250°C. Helium was used as carrier gas at a flow rate of 1 ml min^{-1}. The electron impact mass spectrum (EIMS) were taken at 70 eV. Scanning speed was 3.54 scans s^{-1} from *m/z* 40 to 450. High-resolution mass spectrum was obtained from VG AutoSpec EI (70 eV) equipment. Nuclear magnetic resonance (NMR) spectral data were acquired from Varian Inova spectrometer, operating at 499.88 MHz for ^{1}H-NMR and 125.71 MHz for ^{13}C-NMR. $CDCl_3$ was used as solvent and TMS as an internal reference (δ = 0.0 ppm). Chemical shifts δ were recorded in ppm and coupling constants *J* in Hz. Thin-layer chromatography analyses were performed on Merck F_{254} Aluminum Sheets, and the spots were visualized by UV light (254 nm). All solvents were of high analytical grade, bidistilled before using. Cotton wools were successively extracted with ethyl acetate, and the solvent was evaporated under vacuum.

Bioassays. The experiments were conducted from October 2002 to May 2003 and were performed between 19:00 and 23:00 hr under dim light conditions. Immediately before each trial, an adult individual of *G. longipes* was milked of secretion by seizing it by hand. Males and nonovigerous females were milked because the total amount of secretion released by them is not different (8.3 ± 4.4 mg). The exudate was collected with capillary tubes and diluted into a syringe with 100 μl of distilled water. The secretion was mixed with water because many harvestman species, including *G. longipes*, dilute their own gland secretion in aqueous enteric fluid (Eisner et al., 1971, 1978; Acosta et al., 1993; Gnaspini and Cavalheiro, 1998; Hara and Gnaspini, 2003; see also Figure 1A). Different syringes were used for each experimental group. A different unmilked individual was used in each trial because repeated milking of the same individual could reduce the concentration and quantities of the secretion (Eisner et al., 1971). Different model predators were exposed to the harvestmen's gland secretion (treatment) or to distilled water (control).

Most laniatorean harvestmen, including *G. longipes*, have spines covering the body and legs and present a variety of defensive behaviors that may be divided in evasive responses (fleeing and dropping from the substrate) and aggressive responses (Machado, 2002). The latter includes several mechanisms that threaten, harm, or deter aggressors, such as attacking with the

pedipalps, biting with the chelicerae, pinching with the sharp projections of the femora and coxae IV, and releasing scent gland secretions (Machado, 2002; Hara and Gnaspini, 2003). To test the potential defensive role of the glandular secretion only, and prevent other possible defensive mechanisms, individuals of *G. longipes* were not offered to the predators. Rather, the common cricket *Gryllus gryllus* (nearly 1 cm of body length) was used as model of prey in the experiments with spiders, frogs, and marsupials (see details below).

Tests with Ants. Two bioassays were conducted with ants: one in the field to test the potential of the scent gland secretion as a repellent and another in the laboratory to test the effectiveness as a "chemical shield". The field experiment consisted of the presentation of filter paper baits imbibed with honey solution, placed on plastic dishes (5-cm diam). These baits were randomly distributed on the forest floor 5 m from each other. In the treatment group, when ants had come to feed at the margin of the bait, the glandular secretion of one individual of *G. longipes* diluted in 100 μl of water was discharged in the center of the filter paper with a syringe. A similar procedure was used in the control group, but only 100 μl of water were discharged in the bait. In both experimental groups, the number of ants in contact with the bait was counted before and 5 sec after presentation of either secretion or water. Five ant species attended the baits in the field and were used in this experiment: (1) Formicinae—*Camponotus lespesi* (four baits; two controls and two treatments); (2) Myrmicinae—*Pheidole* sp. (eight baits; four controls and four treatments); (3) Ponerinae—*Gnamptogenys* sp. (eight baits; four controls and four treatments), *Odontomachus chelifer* (six baits; three controls and three treatments), and *Pachycondyla striata* (six baits; three controls and three treatments). After square-root transformations of the data, a repeated-measures ANOVA was performed on the number of workers of the five ant species in contact with the baits before and after the treatment in both experimental groups (Pagano, 1994).

Three ant species were used in the laboratory experiments: *Pachycondyla villosa* (one colony), *Odontomachus hastatus*, and *Camponotus crassus* (three colonies each). Inside the tray of each colony, we presented a glass coverslip (1 × 5 cm) divided in two sides randomly designated by the flip of a coin as treatment or control. The treatment consisted of a filter paper (1 cm^2) wetted with 200 μl of a saturated sugar solution mixed with the glandular secretion of one individual of *G. longipes*. The control side contained only a filter paper (1 cm^2) wetted with 200 μl of a saturated sugar solution. The ant's response was evaluated by counting the total number of workers feeding at the baits at 1-min intervals during 10 min after the first contact.

Tests with Spiders. Enoploctenus cyclothorax (Ctenidae) is a large (3- to 5-cm body length) wandering spider that is commonly found near cave

entrances (Figure 1C) and occasionally preys on adult *G. longipes* (Machado et al., 2000; Machado, personal observations), as well as other gonyleptid harvestmen (Willemart and Kaneto, 2004). *Trechalea biocellata* (Trechaleidae) is also a large (2- to 3-cm body length) wandering spider, abundant in the study site (Figure 1D), which is generally found near river margins or in other moist habitats, such as caves. An adult male of this spider was once observed preying on a harvestman, probably a *Discocyrtus* (Gonyleptidae), at night (Machado, personal observations). Individuals of both spiders were collected at the Parque Florestal do Itapetinga, from October 2002 to May 2003. They were maintained in individual cages (20 × 10 cm base, 15 cm high) containing cotton wetted with water to maintain the humidity and starved for 5–6 d before the experiments. Only subadults and adults of both sexes of *T. biocellata* (N = 40) and *E. cyclothorax* (N = 20) were used in the experiments. Individuals were offered a cricket, which they promptly took as prey. To ensure that the crickets were unable to promote injuries on the spiders, their hind legs (armed with several spines) were removed just before the experiment. After the spiders had started feeding, each individual was stimulated with either secretion of one harvestman diluted in 100 μl of water (treatment) or the same volume of distilled water (control), applied with a syringe directly to the base of the chelicerae. Individuals that extricated the chelicerae and abandoned the prey within 5 min were scored as respondents (cf. Eisner et al., 1997). The number of spiders that released the prey was compared between the two experimental groups using a Fisher exact test (Pagano, 1994). The time between the presentation of secretion and the response of the spiders was compared between species using a Mann–Whitney *U*-test.

Tests with Frogs. The effectiveness of the scent secretion against frogs was tested using adults (16 males and 4 females) of the small horned frog, *Proceratophrys boiei* (Leptodactylidae). The species is a leaf-litter dweller whose adults may reach 5–7.5 cm of body length (Figure 1E). Because of its large mouth, the diet of this species includes large ground arthropods, such as spiders, cockroaches, beetles, and crickets (Giaretta et al., 1998; Teixeira and Coutinho, 2002). Although there is no record of harvestmen among the food items of *Pr. boiei*, other species of the genus, such as *Pr. apendiculata*, include harvestmen in their diet (Machado, personal observations). Small horned frogs (N = 20) were collected at the Parque Florestal do Itapetinga during the breeding season from November 2002 to January 2003. They were maintained in a communal terrarium (60 × 40 cm base, 35 cm high) and starved 3 d before the experiments. They were offered a cricket, which they promptly took as prey. As soon as a frog swallowed the cricket, we caught it by hand, forced its mouth open, and used a syringe to inject either secretion of one harvestman diluted in 100 μl of water (treatment) or the same volume of distilled water (control). Anurans generally catch their prey by a quick flip of

their sticky tongue and may swallow chemically protected arthropods, such as millipedes or beetles, before the secretion of the prey is discharged (Eisner and Meinwald, 1966). Hence, the secretion might be released outside the mouth, inside the mouth, or even inside the stomach. Our experimental protocol simulated the mouth scenario. Individuals that regurgitated the prey within 5 min were scored as respondents. The number of frogs that regurgitated the prey was compared between the two experimental groups using a Fisher exact test (Pagano, 1994).

Tests with Opossums. The white-eared opossum *Didelphis albiventris* (Didelphidae) is a medium-sized mammal (0.5–2.0 kg; Figure 1F), whose omnivorous diet includes harvestmen (Cáceres and Monteiro-Filho, 2001; Cáceres, 2002). Although *D. albiventris* occurs at the Parque Florestal do Itapetinga, experimental individuals were collected at the Clube Náutico Araraquara (21°43′S, 48°01′W, 653-m altitude, 1300 mm rain/year), a forested area near Américo Brasiliense, São Paulo state. In this locality, the species is abundant, and juvenile individuals (150–450 g) can be trapped using Sherman live traps. The opossums ($N = 8$) were maintained in individual cages for 12 hr after collection, and 30 min before the experiment, they were transferred to a dark closed box (60 × 40 cm base, 35 cm high) and fed with a piece of banana to bring all of them to a similar hunger level.

The presentation of the prey was made by using a tube inserted in the box's wall that placed the cricket in the center of the cage. The first cricket introduced in the cage had a 4 × 8 mm piece of filter paper carefully placed under its wings (no glue was used), wetted with the glandular secretion of one individual of *G. longipes* diluted in 100 μl of water (treatment). Two minutes after the introduction of the first cricket, a second cricket with a piece of filter paper wetted with 100 μl of distilled water (control) under its wings was placed in the cage. Prey were offered in this sequence because if the first cricket was rejected and not the second, it would be possible to identify a rejection response. This second cricket was also a control of the hunger level of the opossums. We recorded the time elapsed between the presentation of the crickets and the attack of the opossums, as well as the behavioral response of the animals to each type of prey. Because species of the genus *Goniosoma* are capable of ejecting their secretion forcibly as a spray (Machado, 2002; Hara and Gnaspini, 2003), one adult individual of *G. longipes* was also introduced in each cage after the presentation of the crickets to investigate the response of the opossums to this special type of emission.

Vouchers. One of the trials with frogs and all trials with the marsupials were video recorded, digitalized, and are available from the authors upon request. Voucher specimens of all studied species (except *D. albiventris*) were deposited at the Museu de História Natural da Universidade Estadual de Campinas and Museu de Zoologia da Universidade de São Paulo, Brazil.

RESULTS

Chemistry. Two alkylated 1,4-benzoquinones were identified from the defensive secretion of the harvestman *G. longipes* (Figures 2 and 3):

2,3-Dimethyl-1,4-benzoquinone (compound 1). GC-MS *m*/*z* 136 (100), 108 (57), 107 (56), 82 (44), 79 (52), 65 (5), 54 (50); HRMS (EI, 70 eV): M^+ 136.05392 ($C_8H_8O_2$; calc. 136.05244); ^{1}H-NMR ($CDCl_3$, TMS, 499.88 MHz) δ (ppm) = 2.04 (s, H-7 and H-8, 6H), 6.72 (s, H-5 and H-6, 2H); ^{13}C-NMR δ (ppm) = 187.39 (C-1, C-4), 140.99 (C-2, C-3), 136.24 (C-5, C-6), 12.18 (C-7, C-8). Other spectroscopic methods as ^{13}C-NMR DEPT-135 and DEPT-90, ^{1}H–^{1}H gCOSY, ^{1}H–^{13}C ^1J HSQC, and ^{1}H–^{13}C ^nJ gHMBC were also employed (data not shown).

2-Ethyl-3-methyl-1,4-benzoquinone (compound 2). GC-MS *m*/*z* 150 (100), 135 (10), 122 (37), 121 (18), 107 (79), 82 (21), 79 (38), 67 (12), 54 (22); HRMS: 150.06824 ($C_9H_{10}O_2$; calc. 150.06810). For further spectroscopic data as ^{1}H-NMR ($CDCl_3$, TMS, 499.88 MHz), ^{13}C-NMR, DEPT-135 and DEPT-90, ^{1}H–^{1}H gCOSY, ^{1}H–^{13}C ^1J HSQC, and ^{1}H–^{13}C ^1J gHMBC, see Table 1.

The fragmentation pattern of compound 1 under EIMS was compared with literature (Budzikiewicz et al., 1967), and it was identical to the spectrum reported for 2,3-dimethyl-1,4-benzoquinone. Because of molecular symmetry, compound 1 displayed two singlets in ^{1}H-NMR spectrum: at δ = 2.04 ppm for six methyl protons and at δ = 6.72 ppm for the other two aromatic protons. This spectral simplicity allowed the structural identification of the other component in the mixture.

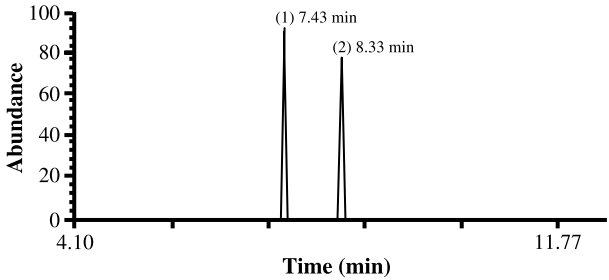

FIG. 2. GC-MS analysis of male *G. longipes* defensive secretion. Peaks corresponding to compounds 2,3-dimethyl-1,4-benzoquinone and 2-ethyl-3-methyl-1,4-benzoquinone are indicated as (1) and (2), respectively.

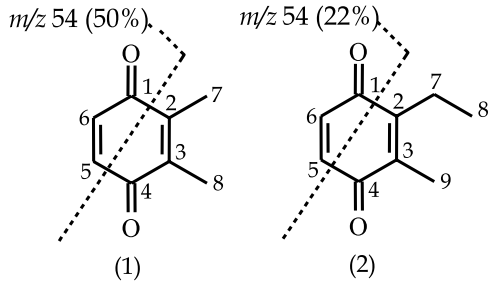

FIG. 3. Chemical defense compounds identified from the scent secretion of the harvestman *G. longipes*. The origin of the fragment *m/z* 54 in the EIMS spectra is also shown.

Compound 2 fragmentation pattern under EIMS did not match any mass spectral data available for other 1,4-benzoquinones derivatives identified in arthropods. The use of one and bidimensional NMR techniques allowed almost complete chemical shift assignments for this compound, which was identified as 2-ethyl-3-methyl-1,4-benzoquinone. The molecular formula $C_9H_{10}O_2$ was confirmed by high-resolution mass spectrometry (M^+ at *m/z* 150.06824; calc.

3	–	–	140.37	–	–	–
4	–	–	187.90	–	–	–
5	6.71(broad s, 1H)	–	136.19[a]	136.19 (C-5)[b]	187.90 (C-4)	CH
6	6.71(broad s, 1H)	–	136.37[a]	136.37 (C-6)[b]	187.10 (C-1)	CH
7	2.51 (q, *J* 7.6 Hz, 2H)	1.06	19.73	19.73 (C-7)	12.84 (C-8); 140.37 (C-3); 146.15 (C-2); 187.10 (C-1)	CH_2
8	1.06 (t, *J* 7.6 Hz, 3H)	2.51	12.84	12.84 (C-8)	19.73 (C-7); 146.15 (C-2)	CH_3
9	2.05 (s, 3H)	–	11.63	11.63 (C-9)	140.37 (C-3); 146.15 (C-2); 187.90 (C-4)	CH_3

The letters *a* and *b* indicate interchangeable assignments, and *c* indicates results from DEPT-90 and DEPT-135 experiments. Splitting pattern are as follows: s = singlet; t = triplet; q = quartet.

150.06810). A CH_2CH_3 substituent was easily characterized by the A_3X_2 spin system (δ = 2.51 ppm for 2H and δ = 1.06 ppm for 3H) in the ^{1}H-NMR spectrum, which was further confirmed by ^{1}H, ^{1}H homonuclear correlations spectrum (gCOSY). The substitution pattern of compound 2 was first suggested by the presence of the intense fragment at *m*/*z* 54 in the low-resolution mass spectrum, confirmed by HRMS (observed *m*/*z* 54.01036; calc. for C_3H_2O *m*/*z* 54.01056; Figure 3). This was corroborated by the H-7/C-3, H-7/C-1, H9/C-2, and H-9/C-4 ^3J correlations observed by ^{1}H, ^{13}C heteronuclear long-range correlations spectrum (gHMBC). Further spectroscopic methods as gHSQC (^{1}H,^{13}C ^1J), DEPT-135, and DEPT-90 were also employed in chemical shift assignments for compound 2 (Table 1).

The chemical composition of defensive secretions from male and female individuals was the same in *G. longipes*, but the proportion of the two components is slightly different. Compound 2 always displayed smaller relative abundance in GC-MS analyses. This feature was also explored in the interpretation of the NMR experiments, in which compound 2 signals were always less intense than those from compound 1.

Tests with Ants. The presentation of scent gland secretion in the treatment group induced a marked reduction in the number of ants tending the sugar baits in the field (Figure 4). This reduction was not observed in the control baits (Figure 4). The repellent effect was observed for recruiting species such as

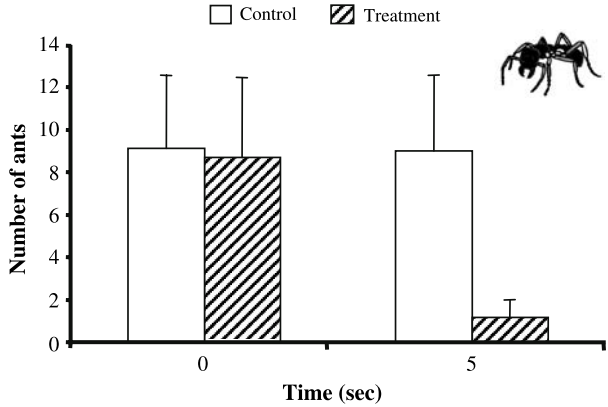

FIG. 4. Number of ants in the field tending sugar baits before (time = 0 sec) and after (time = 5 sec) stimulation with harvestman secretion (treatment) or distilled water (control). Data combined from 32 trials (16 controls and 16 treatments) on five species of ants. There was a significant effect of time (repeated-measures ANOVA, $F = 13.77$, $P < 0.001$) and experimental group (repeated-measures ANOVA, $F = 39.61$, $P < 0.001$).

Pheidole sp., *C. lespesi*, and *Gnamptogenys* sp. and also for solitary hunters such as *O. chelifer* and *P. villosa*. After leaving the treatment baits (but not the control baits), workers of all tested species typically cleaned their antennae and front legs.

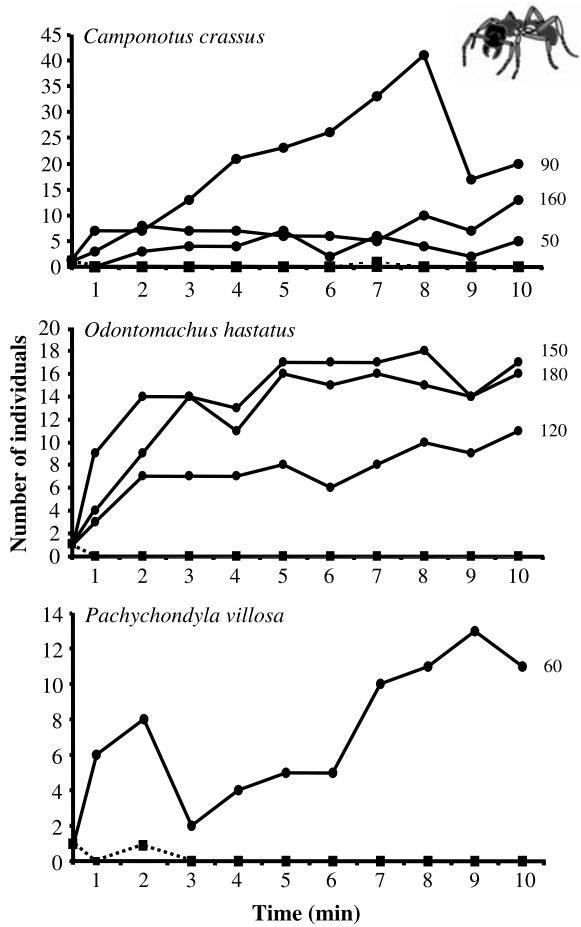

FIG. 5. Number of visits over time of three ant species tending control baits of sugar solution (circular dots, full line) and treatment baits of sugar solution mixed with harvestman secretion (square dots, dotted line) in the laboratory. The numbers at the right lateral of the graphics indicate the size of the ant colonies (for *C. crassus* and *Odontomachus*, three colonies each, and for *P. villosa*, one colony). Because the number of ants in contact with treatment baits was generally zero, it is not possible to distinguish the three dotted lines.

In the laboratory, the number of ants tending control baits generally increased during the 10-min period, whereas few or no ant contacted treatment baits (Figure 5). The workers that touched the filter papers of the treatment baits presented a behavioral response similar to that observed in the field experiment,

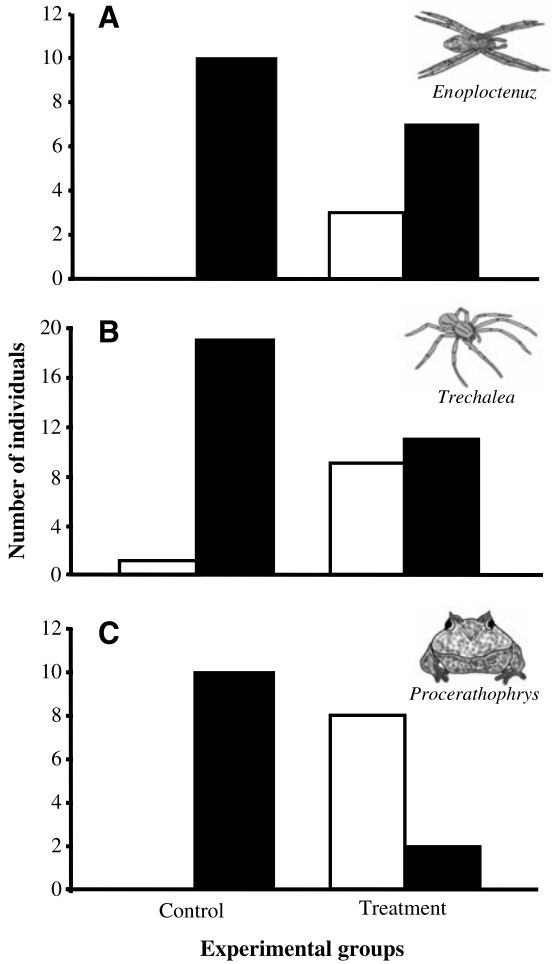

FIG. 6. Number of individuals of the spiders (A) *E. cyclothorax* and (B) *T. biocellata* that released (white bars) or not (black bars) the prey after stimulation with harvestman secretion (treatment) or distilled water (control). (C) Number of individuals of the small horned frog *Pr. boiei* that regurgitated (white bars) or not (black bars) the prey after stimulation with harvestman secretion (treatment) or distilled water (control).

i.e., they immediately cleaned their antennae and front legs and did not return to the bait.

Tests with Spiders. The frequency of individuals of *E. cyclothorax* (Fisher exact test, $P = 0.003$) and *T. biocellata* (Fisher exact test, $P = 0.008$) that released the prey in the treatment group was significantly higher than in the control group (Figure 6A, B). There was no difference between species in the frequency of individuals that released the prey in the treatment group (Fisher exact test, $P = 0.43$). Respondent individuals of both species extricated their fangs, dropped the prey, and rubbed their mouthparts against the substrate. The time elapsed between the presentation of the secretion and the release of the prey also did not differ between species ($U = 23.0$; $P = 0.37$) and ranged from 1 to 30 sec in *E. cyclothorax* and from 1 to 50 sec in *T. biocellata*.

Tests with Frogs. The frequency of individuals of *Pr. boiei* that regurgitated the prey in the treatment group was significantly higher than of those in the control group (Fisher exact test, $P = 0.004$; Figure 6C). Frogs in the treat-

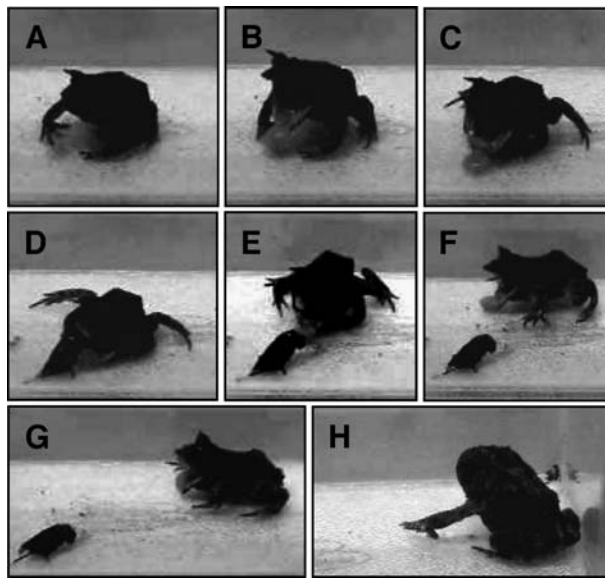

FIG. 7. (A–H) Sequence extracted from videotape showing the reaction of a small horned frog, *Pr. boiei*, to the scent gland secretion of the harvestman *G. longipes*. (A) The individual immediately before the test. (B) After the harvestman secretion was presented inside its mouth, the individual had abdominal contractions, and (C–E) regurgitated the cricket. (F–G) The frog scratched the mouth on the substrate and moved backward. (H) Nearly 30 sec after regurgitation, the individual still showed clear signs of aversion, maintaining the eyes shut and presenting strong abdominal contractions.

ment group presented clear aversion reactions such as scratching the tongue on the substrate, shutting the eyes, and strong abdominal contractions (Figure 7). These behavioral reactions occurred both before and after prey regurgitation. Interestingly, for all respondent individuals, the prey was regurgitated alive.

Tests with Opossums. All individuals of *D. albiventris* consumed the crickets of both experimental groups. There was no clear sign of aversion when the opossums ingested the crickets wetted with secretion. All opossums also ingested adults of the harvestman *G. longipes*. Four of five subadult individuals subdued the harvestmen using the front legs to step on it, which probably promoted the releasing of secretion. After that, the harvestmen were grasped with the front legs and consumed. One subadult and three juveniles subdued the harvestmen using the snout to bite the prey. The biting elicited the release of a jet of secretion that probably reached the nose and the eyes of the opossums. In these cases, the opossums responded to the discharge by releasing the prey and wiping their eyes and snout with their front legs for nearly 2 min. After this period, the opossums approached the dead body of the prey and ate it. In all cases, only the body of the harvestmen was consumed and the legs were discarded. During actual consumption, the opossum showed no clear signs of aversion, such as those presented by the small horned frogs.

DISCUSSION

Like most representatives of the superfamily Gonyleptoidea, the defensive secretion of the harvestman *G. longipes* is a mixture of compounds. The occurrence of alkylated 1,4-benzoquinones in *G. longipes* is chemotaxonomically in agreement with the constitution of the defensive secretions previously reported for other Gonyleptidae (Estable et al., 1955; Fieser and Ardao, 1956; Roach et al., 1980; Acosta et al., 1993; Eisner et al., 2004), including congeneric species, such as *Goniosoma spelaeum* (Gnaspini and Cavalheiro, 1998). The derivative 2,3-dimethyl-1,4-benzoquinone has been already identified in other harvestman species belonging to the families Cosmetidae, Gonyleptidae, and Manaosbiidae (Estable et al., 1955; Fieser and Ardao, 1956; Eisner et al., 1977, 2004; Roach et al., 1980; Acosta et al., 1993), but this is the first report of 2-ethyl-3-methyl-1,4-benzoquinone as a natural product. Moreover, the use of bidimensional nuclear magnetic resonance spectroscopy and high-resolution mass spectrometry is reported for the first time for chemical characterization of substances from harvestmen, providing additional protocols for studies of scent secretions in the group.

Alkylated benzoquinones are produced by harvestmen of the suborder Laniatores, millipedes of the orders Spirobolida, Spirostreptida, and Julida, and

insects of the orders Coleoptera, Dermaptera, Blattodea, Isoptera, Orthoptera, and Hemiptera (Eisner and Meinwald, 1966; Blum, 1981). The caustic, irritating, and odoriferous properties of these substances may cause invertebrate predators to desist from the attack and to perform vigorous cleaning activities (Eisner and Meinwald, 1966). Recently, Eisner et al. (2004) showed that the secretion of the gonyleptid harvestman *A. aculeatus* (Pachylinae) was an effective deterrent against the ant *Formica exsectoides*. Using a different protocol, we here demonstrate that secretions containing the 1,4-benzoquinones produced by the gonyleptid *G. longipes* (Goniosomatinae) effectively repel five species of ants belonging to three subfamilies. This result is expected because 1,4-benzoquinones from the secretion of several arthropods, including cockroaches, carabid, and tenebrionid beetles, have been shown to be highly repellent to ants (Eisner, 1958a,b; Peschke and Eisner, 1987).

As long as their defensive stores last, chemically defended arthropods can repel potential predators, but when exudates are depleted, they may quickly fall prey (Whitman et al., 1994). Many harvestmen, including representatives of the families Biantidae, Cosmetidae, Gonyleptidae, Manaosbiidae, Phalangodidae, and Sclerosomatidae, have mechanisms of emission that increase the evaporating surface of the defensive secretion (reviewed in Acosta et al., 1993; Hara and Gnaspini, 2003). These mechanisms are divided in two main types: (1) emission of secretion as fine spray that moistens the dorsum of the harvestman and (2) displacement of the secretion along the lateral area of the dorsal scutum. Both types of emission are supposed to create a "chemical shield" around the body of the harvestman protecting the animal after the emission of secretion (Acosta et al., 1993; Hara and Gnaspini, 2003). Our study demonstrates that secretions containing the 1,4-benzoquinones released by *G. longipes* in fact work as a "chemical shield" preventing the approach of three large predatory ants for at least 10 min. The "chemical shield" may protect the harvestman against the successive attacks of the same ant worker and also allow it to flee before massive ant recruitment. Because the families that have mechanisms to increase the evaporating surface of the defensive secretion are not closely related, it is possible that the "chemical shields" have evolved independently many times in the order Opiliones, and it may be related to the constant exposure to swarming insects, mainly ants.

The efficiency of the defensive secretion of harvestmen seems to vary among different spider families and genera. The ctenid *Ctenus fasciatus* is an important predator of gonyleptids in the wild (Gnaspini, 1996; Machado et al., 2000), and, therefore, it seems that the 1,4-benzoquinone secretions released by their prey have no effect on this spider. In captivity, individuals of the wolf spider *Lycosa ceratiola* (Lycosidae) were minimally affected by the effluent of the harvestman *A. aculeatus*, showing little response when the effluent was applied to their mouthparts as they fed on mealworms (Eisner et al., 2004).

Using a similar protocol, we demonstrate here that secretions produced by *G. longipes*, whose composition is almost the same of *A. aculeatus*, are able to repel two large species of wandering spiders, *E. cyclothorax* (Ctenidae) and *T. biocellata* (Trechaleidae).

Contrary to what would be expected, Eisner et al. (2004) reported that live individuals of *A. aculeatus* were consistently rejected by spiders immediately after contact, before they were even prompted to release the defensive secretion. Three previous studies have reported that individuals of *E. cyclothorax* attack gonyleptid harvestmen but immediately retreat, avoiding biting the prey (Sabino and Gnaspini, 1999; Machado et al., 2000; Willemart and Kaneto, 2004). Eisner et al. (2004) discuss that *A. aculeatus* may contain additional chemical factors on the tegument that are repellent to spiders. It is also possible that such a repellent property derives from some residual action of the secretion, which may function as a "long persisting chemical shield", and/or that harvestmen actually release small amounts of secretion, not able to be detected visually. Experimental specimens that are seized or pressed normally produce excessive amounts of fluids because of a highly stressful situation, but minimal amounts of fluids may be secreted in "slightly unpleasant" situations before an extremely shocking situation appears (Whitman, personal communication).

As far as we know, our study is the first to evaluate the defensive role of 1,4-benzoquinone secretions produced by a harvestman species against vertebrate predators. Given that the great majority of the neotropical Laniatores are nocturnal (Machado, personal observations), we focused on two groups of vertebrates that are active at night: frogs and marsupials. Both vertebrate predators used here occur syntopically with *G. longipes* and may include harvestmen in their diets, thus being appropriate model organisms for the bioassays. The defensive effluent of *G. longipes* stimulated a strong aversive reaction on the frogs, causing them to regurgitate the prey, which left the frogs' stomach still alive. Similar results were previously obtained in experiments using millipedes and beetles that have quinone-producing glands (see Eisner and Meinwald, 1966). As occurs with spiders, the effectiveness of the harvestmen secretion in anurans may vary among different species or genera. Especially in the genera *Bufo* (Bufonidae) and *Rana* (Ranidae), which are mainly constituted by large-bodied species, there are many records of predation on harvestmen (Bristowe, 1949; Smith and Bragg, 1949; Jenssen and Klimstra, 1966; Berry, 1970; Clarke, 1974; Acosta et al., 1995). Therefore, it is possible that the size of the frog influences the resistance to the secretion, so that smaller species are more likely to be affected than the larger ones. However, this suggestion remains to be tested.

Marsupials seem to be highly resistant to the chemical defenses of arthropods (Eisner, 1965, but see Whitman et al., 1994). Moreover, field data on the diet of some Brazilian didelphids has revealed that gonyleptid harvestmen

are important food items for at least three species: *Philander opossum*, which enter caves to feed on resting individuals of *G. spelaeum* (Pelegatti-Franco and Gnaspini, 1996), *D. albiventris*, and *Didelphis aurita*, in which harvestmen are the most frequent prey (Cáceres and Monteiro-Filho, 2001; Cáceres, 2002). Indeed, the tested white eared-opossum *D. albiventris* consumed all crickets in both experimental groups, as well as the adult harvestmen offered in our experiment. However, individuals that bit the prey were clearly affected by the spray of secretion released by *G. longipes*. This spray reached the eyes and the snout of the opossums, making them immediately release the dead prey and spend nearly 2 min grooming their face. Similar results were obtained by Eisner (1965) who offered the walkingstick *Anisomorpha* (Phasmida) to the mouse opossum *Micoureus demearare*. Individuals of *Anisomorpha* also sprayed their defensive secretion on the face of the marsupial, and, despite the "obvious discomfort" caused, the opossum attacked and consumed all walkingsticks that were introduced into the cage.

Many gonyleptids show gregarious habits, and among the representatives of the subfamily Goniosomatinae, this behavior is especially common (Machado, 2002). Recently, it was demonstrated that the defensive secretion of *Goniosoma* aff. *proximum* elicits alarming behavior among aggregated individuals and that the reaction response to the signal is negatively correlated with the size of the group (Machado et al., 2002). The time elapsed between the presentation of the secretion and the dispersion of the individuals ranged from 2 to 52 sec. If after the first strike toward a harvestmen aggregation, a naive marsupial takes up to 120 sec to recover from the exposition to the secretion, there is enough time for all aggregated individuals to disperse. Because the aggregated individuals are not close relatives, there is no apparent advantage to the attacked harvestman, which dies after the first strike of the marsupial. However, the emission of defensive secretion by one individual may retard the attack of the marsupial and enhance the escape capability of conspecifics in an aggregation of harvestmen (see Discussion in Machado, 2002). Gregariousness, therefore, may be a defensive mechanism especially important against mammal predators because harvestman secretions seem not to be so effective.

The results of our study indicate that the 1,4-benzoquinones released by *G. longipes* are an effective defense against predation, and that the effectiveness of the secretion depends on the predator type. The emission of scent gland secretions repelled seven species of ants, two species of wandering spiders, and one species of frog, but it was not an effective defense against an opossum. Our data support the suggestion that chemical defenses may increase survival with some but not all potential predators (e.g., Krall et al., 1999; Staples et al., 2002; Eisner et al., 2004). This variation in defense effectiveness may result from many interacting factors, including on one hand the attack strategy, size, learning ability, and physiology of the predators and, on the other hand the

chemical nature of the defensive compounds, type of emission, and amount of effluent released by the prey (Whitman et al., 1994). In this way, harvestmen are good model organisms because they release a great variety of compounds and are attacked by numerous potential and a few actual predators.

(Received May 4, 2005; revised June 22, 2005; accepted July 9, 2005)

Abstract—*Papilio glaucus* caterpillars encounter a diverse array of sesquiterpene lactones, including parthenolide, in the leaves of host plants *Liriodendron tulipifera* and *Magnolia virginiana*. These compounds are toxic to unadapted herbivores, and the development of *P. glaucus* caterpillars likely depends on their ability to excrete or detoxify them efficiently. A new metabolite of parthenolide, 2-α-hydroxydihydroparthenolide, identified by crystal structure determination and nuclear magnetic resonance, was present in the waste of the caterpillars. The parent compound was modified by the reduction of an α-methylene group, rendering the compound less reactive, and the addition of a hydroxyl group, which increases the polarity and prepares it for the conjugation reactions of phase II metabolism. Unmetabolized parthenolide was also present in large amounts in waste. *P. glaucus* larvae are apparently capable of excreting intact sesquiterpene lactones and sesquiterpene lactone metabolites during consumption of foliage rich in these compounds.

Key Words—*Papilio glaucus*, sesquiterpene lactone, parthenolide, 2-α-hydroxydihydroparthenolide, detoxification, Magnoliaceae, reductase, cytochrome P-450.

INTRODUCTION

Tiger swallowtail butterfly caterpillars, *Papilio glaucus* L. (Lepidoptera, Papilionidae), are polyphagous and can utilize hosts from several families. Their preferred hosts include tulip tree (*Liriodendron tulipifera* L.) and sweet

* To whom correspondence should be addressed. E-mail: crfrankf@olemiss.edu

bay (*Magnolia virginiana* L.), both in the family Magnoliaceae (Scriber, 1986; Scriber et al., 1991). The leaves of these trees contain a variety of toxic constituents, including sesquiterpene lactones (Doskotch et al., 1975; Song et al., 1998).

Sesquiterpene lactones, feeding deterrents to both vertebrates (Peters and van Amerongen, 1998) and invertebrates (Doskotch et al., 1981; Passreiter and Isman, 1997), are also toxic to a wide variety of organisms due to a relatively nonspecific mechanism of action. The toxic activity is attributed to the presence of various electrophilic groups, such as the α-methylene-γ-lactone, that react with electron-rich atoms such as sulfur and oxygen in proteins and nucleic acids (see Figure 1). The presence of multiple alkylating sites enhances activity and

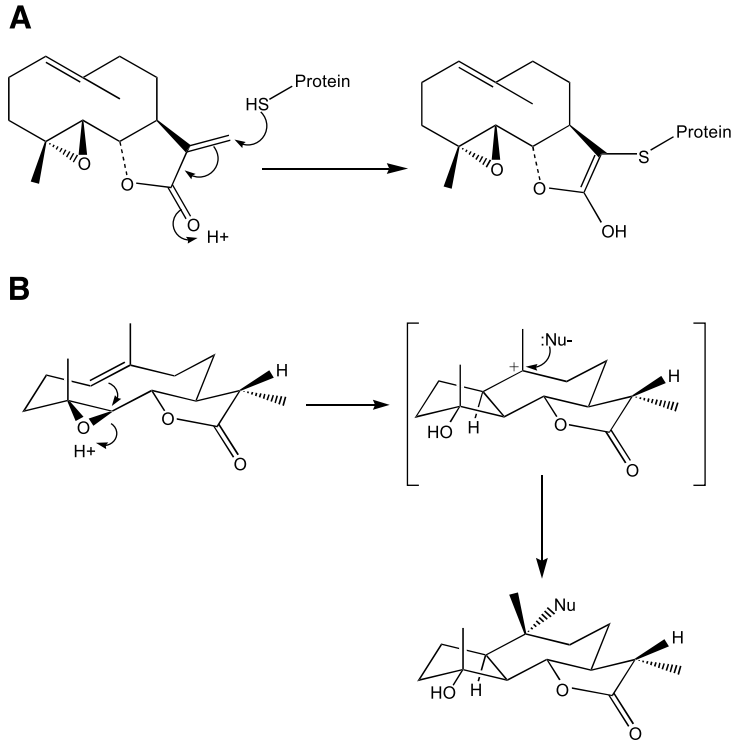

FIG. 1. Mechanisms of nucleophilic addition to parthenolide. (A) Michael addition of the sulfur group of a protein to the exocyclic α-methylene group of parthenolide. (B) Addition of a nucleophile (:Nu-) facilitated by transannular attraction of the double bond electrons for the electropositive carbon adjacent to the epoxide. (Adapted from Fischer et al., 1998). (Modified from Fischer et al. 1998 with permission from Elsevier).

may result in the cross-linking of DNA (Lee et al., 1971; Fischer et al., 1998; Schmidt, 1999a,b).

In addition to disrupting the function of critical macromolecules, parthenolide causes oxidative stress in cells, leading to apoptosis and the formation of gut lesions (Wen et al., 2002; Barbehenn, 2003). Parthenolide also causes the depletion of the tripeptide glutathione, an antioxidant found in all cells (Schmidt, 1999a), as well as the insect gut lumen (Barbehenn et al., 2001; Barbehenn, 2003). Glutathione scavenges free radicals, acts as cofactor for several antioxidant enzymes (Barbehenn, 2003), and forms conjugates with other electrophilic allelochemicals to facilitate their excretion. Therefore, its depletion may augment the phytochemically induced oxidative assault on insect cells.

Sesquiterpene lactones exert their cytotoxic effects at low concentrations, on the order of micrograms per milliliter (Lee et al., 1971; Wen et al., 2002). Fresh *M. virginiana* leaves can contain up to 0.5% parthenolide (W. Schühly, personal observation). Therefore, caterpillars feeding on sweet bay leaves may encounter substantial amounts, often consuming several milligrams per leaf. The successful utilization of parthenolide-containing plant tissues for growth and development demands the ability to tolerate large doses, expel it without absorption, or metabolize it to a less reactive and ultimately excretable form (Brattsten, 1986). In this paper, we analyzed the waste of *P. glaucus* caterpillars for parthenolide and its metabolites in order to examine the postingestion fate, which may suggest mechanisms responsible for the ability to use the toxic foliage as a food source.

METHODS AND MATERIALS

Isolation of Metabolite from Caterpillar Frass. Adult female *P. glaucus* butterflies were captured in Highlands and Levy counties in Florida. The adult females were set up for oviposition at the Archbold Biological Station in Lake Placid, FL, USA, in clear plastic containers with locally growing *M. virginiana* leaves (Scriber, 1993). Each day eggs were collected, and females were fed a 20% honey solution. Hatchling caterpillars were reared together in plastic containers on *M. virginiana* leaves. To retain leaf moisture, petioles of the leaves were placed in water-filled aquapiks. As the majority of the caterpillars reached the fifth instar, frass (waste) was collected in plastic Ziploc bags and stored in the freezer until it was transported on ice to the University of Mississippi. Frozen frass (325 g) was ground in a blender with 100% methanol and extracted exhaustively to yield 42 g of extract. Two 20 g aliquots of the crude extract were partitioned between chloroform and water (3×300 ml). The chloroform layer (31 g) was concentrated by vacuum, and aliquots were

subjected to vacuum liquid chromatography (VLC) (silica gel, 40–63 μm, EM Science, Gibbstown, NJ, USA; 100% hexane with increasing amounts of ethyl acetate, then increasing methanol). Thin-layer chromatography (TLC) and nuclear magnetic resonance (NMR) were used to compare fractions. Fractions containing a major compound by TLC (R_f = 0.28, 30:70 hexane/ethyl acetate, blue spot after spraying with vanillin/H_2SO_4 and heating) were combined (0.3 g) and rechromatographed by VLC (80:20 hexane/ethyl acetate, with increasing ethyl acetate and methanol). Compound-containing fractions were again pooled (0.16 g) and resubjected to VLC (60:40 hexane/ethyl acetate, 100% ethyl acetate, 100% methanol). One of these fractions yielded crystals suitable for analysis by X-ray crystallography [crystal data: $C_{15}H_{22}O_4$, orthorhombic space group $P2_12_12_1$, a = 7.6930(10), b = 11.446(2), c = 15.637(3) Å, V = 1,376.9(4) Å^3, Z = 4, T = 100 K, 18,811 data with MoKα radiation by Nonius Kappa CCD, R = 0.033 for 2,937 observed (of 3,101 unique) data having <33.7° and 181 refined parameters, Cambridge Database deposition number CCDC 266646]. Reverse-phase high-performance liquid chromatography (HPLC) was used to purify the compound from additional fractions with an isocratic 70% methanol solvent system (Phenomenex ultracarb 5 ODS 30 5 μ 250 × 10.00 mm, Torrance, CA, USA), and 1-D and 2-D NMR spectra were also used to elucidate the structure of the compound (Figures 2 and 3).

Isolation of Pure Parthenolide. *M. grandiflora* leaves were collected from the University of Mississippi campus, air-dried, ground (1,000 g), and extracted three times with hexane–ethyl acetate (1:1) to yield 65 g of crude extract. Ten grams of this extract were subjected to VLC (120 g Silica 60, 40–63 μm,

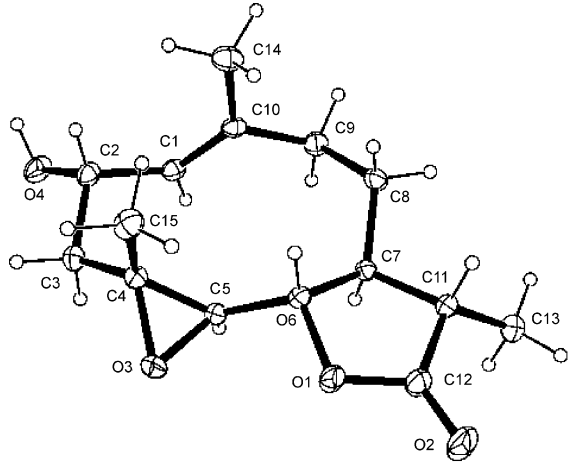

FIG. 2. Crystal structure of 2-α-hydroxydihydroparthenolide.

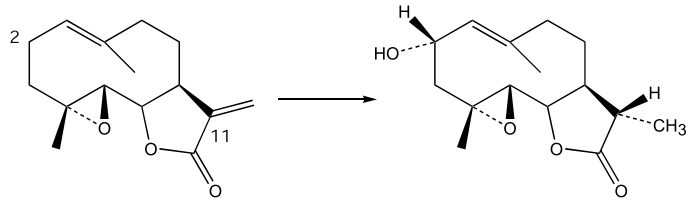

FIG. 3. Conversion of parthenolide to 2-α-hydroxydihydroparthenolide in the caterpillar gut. The hydroxylation at C2 and reduction at C11 are proposed to be catalyzed by a cytochrome P-450 monooxygenase and an NADPH reductase, respectively.

Sorbent Technologies, Atlanta, GA, USA) with hexane and increasing amounts of ethyl acetate. TLC revealed that the fraction eluting with approximately 7:3 hexane/ethyl acetate contained mainly parthenolide. The crude parthenolide (250 mg) was subjected to solid-phase extraction on an RP-18 SepPak cartridge (5,000 mg) using a gradient of water with increasing amounts of methanol to remove chlorophyll and other impurities. Parthenolide-containing fractions were combined, and parthenolide crystallized as clear prisms from the methanol/water. The ^{1}H and ^{13}C NMR spectra of the pure compound matched the values given in the literature (Fischer et al., 1992).

Parthenolide Feeding Study. *P. glaucus* females were collected in Oglethorpe County, GA, USA and sent to the University of Mississippi. Hatchling caterpillars from each mother were randomly assigned to either the parthenolide or control group, and were reared individually in 5.5-in.-diam plastic Petri dishes. For the first three instars, all caterpillars were reared on black cherry (*P. serotina*) leaves, which do not contain sesquiterpene lactones. The petioles of the leaves were inserted into water-filled floral piks to prevent desiccation. During the last two instars, the parthenolide group received black cherry leaves coated with parthenolide, in an amount equivalent to 0.2% of the weight of the cherry leaf. Parthenolide was dissolved in methanol to make a stock solution, and the correct volume was applied evenly to the top surface of each preweighed leaf by syringe. The control group received leaves treated similarly with methanol only. The solvent was allowed to evaporate before the leaves were offered to the caterpillars. Leaves were replaced as needed, which amounted to every other day for early fourth instars and every day for fifth instars. The leaves were made up the day that they were needed, and frass from each group was collected daily and stored at −20°C until its extraction. Once the caterpillars voided their guts and entered the prepupal state, they were removed from the experiment.

Extraction of Frass from Parthenolide Feeding Study. Frass from the parthenolide (106 g) and control (52.2 g) treatments was freeze-dried and

extracted sequentially with hexane, ethyl acetate, and methanol (3 × 700 ml each) and concentrated in vacuo. TLC revealed the presence of a spot in the methanol extract of the treated frass that was not present in the control frass, and this compound was chosen for purification. An aliquot (2.6 g out of 8.4 g total) of the methanol extract of the parthenolide treatment was dissolved in 100% deionized H_2O and filtered. The resulting filtrate was freeze-dried to yield 1.5 g, and 1 g of this was vacuum chromatographed (silica gel, 32–63 μm, Sorbent Technologies, GA, USA) with a gradient of chloroform and methanol (98:2 chloroform/methanol to 100% methanol). Fractions 20–21 were combined based on TLC and eluted through a SepPak with 60:40 hexane/2-propanol before normal-phase HPLC (Phenomenex Luna 10 μ silica 100 Å, 250 × 10 mm, gradient of 90:10 hexane/2-propanol to 70:30 in 35 min). Like fractions from multiple runs were combined and rechromatographed on the same column in isocratic 85:15 hexane/2-propanol. The pure compound was subjected to NMR, confirming its identity as the previously isolated metabolite.

RESULTS AND DISCUSSION

The compound isolated from the frass of *Magnolia*- and parthenolide-fed caterpillars was determined to be 2-α-hydroxydihydroparthenolide by X-ray crystallography as well as 1-D and 2-D NMR (Figures 2 and 3). ^{1}H NMR (MeOD) δ 5.29 (1H, d, J = 10.3 Hz, H-1), 4.63 (1H, ddd, J = 10.5, 10.4, 5.8 Hz, H-2), 3.99 (1H, dd, J = 9.1, 9.1 Hz, H-6), 2.91 (1H, d, J = 9.1 Hz, H-5), 2.45 (2H, m, H-3, H-11), 2.33 (1H, dd, J = 12.9, 6.4 Hz, H-9), 2.15 (1H, dd, J = 12.4, 12.4 Hz, H-9), 2.03 (1H, m, H-7), 1.96 (1H, dd, J = 15.1, 6.3, H-8), 1.80 (3H, s, H-14), 1.78 (1H, m, H-8), 1.31 (3H, s, H-15), 1.26 (3H, d, J = 7.0 Hz, H-13), 1.16 (1H, dd, J = 11.3, 11.3 Hz, H-3); ^{13}C NMR (MeOD) δ 179.2 (C-12), 136.1 (C-10), 129.1 (C-1), 82.5 (C-6), 66.8 (C-5), 66.0 (C-2), 61.2 (C-4), 51.8 (C-7), 45.6 (C-3), 42.4 (C-11), 41.2 (C-9), 29.2 (C-8), 17.6 (C-15), 16.7 (C-14), 12.3 (C-13).

Subsequent feeding experiments confirmed that the compound is a metabolite of parthenolide, which has been modified in the gut by the reduction of the exocyclic methylene group and the addition of a hydroxy group to the 2 position (Figure 3). These chemical modifications likely occur in two steps mediated by different enzymes. The addition of an oxygen atom to an allylic position is a typical cytochrome-P-450-catalyzed reaction (Wolf, 1982). The reduction of the double bond of sesquiterpene lactones is commonly seen in microbial systems (Clark and Hufford, 1979; Galal et al., 1999; Kumari et al., 2003), and is likely carried out by an nicotinamide adenine dinucleotide phosphate (NADPH)-dependent reductase, such as an α,β-ketoalkene double bond reductase (Takeda et al., 1997). The 2-α-hydroxydihydroparthenolide may be a

by-product of microbial metabolism or larval detoxification enzymes present in the midgut or Malpighian tubules. In the latter case, the hydroxy group increases the polarity of the compound and could promote subsequent conjugation to sugars or glutathione to facilitate efficient excretion or removal from tissues by ATP-dependent glutathione transport pumps (Ishikawa, 1992). The role of reductases in the detoxification of natural products may be common; the ketone group of the cardenolide uscharidin is metabolized to two isomeric alcohol products by homogenates of monarch caterpillar guts in an NADPH-dependent reaction. This reaction is unaffected by monooxygenase inhibitors but is blocked by boiling or the addition of denaturing solvents, suggesting an enzyme-mediated but cytochrome-P-450-independent event (Marty and Krieger, 1984).

Although not quantified, a substantial amount of unmetabolized partheno-lide was also present in the frass. The excretion of unaltered secondary metabolites has been reported for several moth and butterfly larvae of varying diet breadth (Bowers and Puttick, 1986; Boros et al., 1991; Fiedler et al., 1993), and may reflect incomplete digestion of plant material. However, specialized species with highly efficient and inducible enzyme systems tend to metabolize toxic compounds more efficiently than their unadapted counterparts (Cohen et al., 1992). For example, the black swallowtail butterfly, *P. polyxenes*, which feeds exclusively on furanocoumarin-containing host plants, metabolizes 73% of the xanthotoxin consumed to two major metabolites in 4 h compared to 9% metabolized by the fall armyworm, *Spodoptera frugiperda*, a species that does not normally encounter this compound. Consequently, the armyworms contained much higher levels of xanthotoxin in their body tissues than the black swallowtail caterpillars (Ivie et al., 1983). In contrast to the specialist *P. polyxenes*, the lycaenid butterfly larvae *Callophrys rubi* feed on plants from several unrelated angiosperm families including the alkaloid-containing flowers of *Lupinus polyphyllus* and *Genista tinctoria*, and the HPLC alkaloid profile of the waste mirrors that of the flowers (Fiedler et al., 1993).

The presence of unaltered diet-derived compounds in the waste of polyphagous species may either reflect barriers to the absorption of allelochem-icals through the gut or highly efficient absorption and excretion through the Malpighian tubules. Maddrell and Gardiner (1976) demonstrated that the Malpighian tubules dissected from *Manduca sexta*, *Pieris brassicae*, and *Rhodnius prolixus* all efficiently excreted nicotine from the fluid bathing them. However, mechanisms for the removal of this potentially charged and polar molecule may not extend to more lipophilic compounds. In addition, absorption, excretion, and even sequestration necessitate the buildup of higher levels of toxic allelochemicals in the hemolymph of the insect that may not be tolerated in the absence of efficient detoxification enzymes or target site insensitivity in the gut, body fat, or other tissues (Berenbaum, 1986). Whereas fifth instar *M. sexta*, a solanaceae specialist, survived injection with 500 μg of nicotine and

continued feeding, *P. brassicae* larvae were readily killed by devouring young cabbage leaves that had taken up nicotine through the roots, despite the high rate of nicotine excretion in the Malpighian tubules (Maddrell and Gardiner, 1976 and references therein). Similarly, Isman (1985) found that although *Melanoplus sanguinipes* tolerated sesquiterpene lactones such as parthenin when ingested or applied topically, they proved toxic when injected into the hemocoel of the grasshoppers, suggesting that the alimentary canal and integument provide effective barriers to sesquiterpene lactones. Although the exact mechanism is unknown, the larvae of the tortoise beetle, *Physonota arizonae* (Cassidinae) uses egestion to its advantage by covering itself with diet-derived, sesquiterpene lactone-rich fecal deposits as protection from predation (Aregullín and Rodríguez, 2003).

Cell-based assays with parthenolide and related compounds indicate that the cell membrane does not pose a barrier to their entry into the cell (Lee et al., 1971; Fischer et al., 1998; Schmidt, 1999b), so other barriers may prevent their penetration through the gut wall to the hemolymph. Insects have a peritrophic membrane, consisting of a mixture of proteins, glycoproteins, and proteoglycans attached to a chitin microfibrillar mesh that lines the gut and is shed periodically. Reactive sesquiterpene lactones may bind to the nucleophilic amino acid side-chain groups present in the peritrophic membrane (Barbehenn, 2001) preventing their absorption, or lipophilic aggregates of allelochemicals may be size excluded from absorption through the peritrophic membrane.

Many other species in the genus *Papilio* feed on plants in the Lauraceae, Rutaceae, and Apiaceae that produce either sesquiterpene lactones or furanocoumarins (also containing an α,β unsaturated lactone group), or both types of compounds (Scriber et al., 1991; Berenbaum, 1995). Therefore, the long, historic association of this genus with these reactive constituents may have led to the evolution of mechanisms to minimize their toxicity, either through highly efficient mechanisms of excretion, the deployment of detoxification enzymes, or barriers to their absorption through the gut.

Acknowledgments—The authors are grateful to Drs. Mark Scriber and James Maudsley for the collection of the female butterflies in June of 2001 and 2002. Dr. Nikolaus Fischer first observed the presence of sesquiterpene lactone peaks in the NMR spectra of the frass of the *Magnolia*-fed caterpillars and provided helpful advice and comments throughout the isolation.

(Received January 11, 2005; revised April 5, 2005; accepted June 30, 2005)

Abstract—Ithomiine butterflies (Nymphalidae) have long-lived, aposematic, chemically protected adults. However, little is known about the defense mechanisms in larvae and other juvenile stages. We showed that larvae *Mechanitis polymnia* are defended from ants by a chemical similarity between their cuticular lipids and those of the host plant, *Solanum tabacifolium* (Solanaceae). This is a novel defense mechanism in phytophagous insects. A field survey during one season showed that larval survivorship was up to 80%, which is high when compared with other juvenile stages. In a laboratory bioassay, live larvae on their host plant were not attacked by the predatory ant *Camponotus crassus* (Formicidae). Two experiments showed that the similarity between the cuticular lipids of *M. polymnia* and *S. tabacifolium* protected the larvae from *C. crassus:* (a) when the caterpillar was switched from a host plant to a non-host plant, the predation rate increased, and (b) when a palatable larva (*Spodoptera frugiperda*, Noctuidae) was coated with the cuticular lipids of *M. polymnia* and placed on *S. tabacifolium* leaves, it no longer experienced a high predation rate. This defensive mechanism can be defined as chemical camouflage, and may have a double adaptive advantage, namely, protection against predation and a reduction in the cost of sequestering toxic compounds from the host plant.

Key Words—*Camponotus crassus*, cuticular hydrocarbons, chemical camouflage, chemical defense, Formicidae, Ithomiinae, *Mechanitis polymnia*, chemical mimicry, Solanaceae, *Solanum tabacifolium*.

INTRODUCTION

Insects use chemicals to defend themselves in unique and varied ways (Evans and Schmidt, 1990, and references therein). Defense through chemical similarity *via* cuticular components has been suggested for insects and may involve crypsis or mimicry (e.g., Espelie et al., 1991; Buckner, 1993). Indeed, many inquilines of social insects are likely to use this mechanism (Howard, 1993; Lenoir et al., 2001; Howard and Blomquist, 2005, and references therein). However, phytophagous insects have not been shown to avoid predation by using cuticular chemical profiles similar to those of their host plant. In this paper, we provide evidence that this phenomenon occurs in the larvae of the ithomiine butterfly *Mechanitis polymnia*. Ithomiinae butterflies are long-lived, aposematic butterflies that are well-protected against predation through the sequestration of pyrrolizidine alkaloids from adult food sources, such as nectar and withered leaves of *Heliotropium* (Boraginaceae) and *Eupatorium* (Asteraceae) (Brown, 1984, 1985, 1987; Masters, 1990, 1992; Trigo et al., 1996). In more primitive genera (*Tellervo*, *Tithorea*, *Aeria*, and *Elzunia*), the larvae feed on Echitoideae vines (Apocynaceae) (Brown, 1985; Drummond and Brown, 1987; Brown and Freitas, 1994) from which they sequester pyrrolizidine alkaloids (Trigo and Brown, 1990; Orr et al., 1996; Trigo et al., 1996). The other ithomiine genera feed on Solanaceae, but the sequestration of chemical compounds from their host plants is poorly understood; *Placidula euryanasa* larvae sequester tropane alkaloids from their host plant *Brugmansia suaveolens* (Freitas et al., 1996), and calystegines found in adults of *M. polymnia* are probably sequestered from their host plants (Nash et al., 1993). There are no reports on the defensive mechanisms of larvae in this subfamily.

Mechanitis polymnia is a common butterfly in southeastern Brazil, and the adults are well protected against the orb weaving spider *Nephila clavipes* by pyrrolizidine alkaloids (Brown, 1984, 1985). Female *M. polymnia* lay their eggs on the upper surface of the leaves of several *Solanum* species, *Lycopersicum esculentum*, *Cyphomandra velutina*, and *Cyphomandra fragrans* (Brown, 1984; Drummond and Brown, 1987; Brown and Freitas, 1994). In a study of the natural history of immature *M. polymnia*, Portugal (2001) found that the rate of predation on larvae (about 20%) was lower than in the other stages. Only two species of unidentified Vespoideae, *Crematogaster* ants, and the reduviid *Montina confusa* were found to prey upon *M. polymnia* larvae (Trigo pers. obs.). Comparison of the high survivorship in all instars of *M. polymnia* (data from Portugal, 2001) with that of other insects suggested that a specific defensive mechanism was responsible for this difference, since a high survivorship is not usual in immature stages of insects but depends of the organism's life history (for a review, see Cornell and Hawkins, 1995). The ant *Camponotus crassus* patrols the host plants of *M. polymnia* and sometimes

attends homopterans, but never has been observed preying upon immature *Mechanitis*.

These observations led us to investigate whether cuticular chemistry was involved in the defense of the larva. We designed experiments to examine the hypothesis that the larvae were camouflaged by the similarity of their cuticular chemistry to that of their host plants and were, therefore, less likely to be preyed upon by chemically-oriented predators such as ants.

METHODS AND MATERIALS

Study Sites and Organisms. Eggs and larvae of *M. polymnia casabranca* Haensch on *S. tabacifolium* Dunnal were collected from Fazenda Santa Elisa, which belongs to the Instituto Agronômico de Campinas, Campinas (22°49′S, 47°17′W), and on the campus of the Universidade Estadual de Campinas (UNICAMP), Campinas (22°49′S, 47°05′W). Plant specimens were deposited in the herbarium of the Departamento de Botânica, Instituto de Biologia, UNICAMP (UEC). Larvae were reared on mature leaves collected daily from field individuals at UNICAMP and kept in plastic pots until they reached the 5th instar (at 25°C, 12 hr L/D cycle, uncontrolled relative humidity). The pots were cleaned, and leaves were change daily. In 5th instar, the larvae were killed by freezing and maintained at -15°C until the bioassays or chemical extraction.

Predation Bioassays. Since ants are important predators of immature butterflies (Smiley, 1985; Freitas and Oliveira, 1996), we used the neotropical ant *C. crassus* Mayr (Formicidae, Formicinae) as a generalist predator to test our hypothesis. This species nests in live trees and in dead and decaying logs (Kusnezov, 1951), and is frequently seen patrolling *M. polymnia* host plants and tending homopterans.

The colonies of *C. crassus* were collected from the Reserva Biológica e Estação Experimental de Mogi-Guaçu, Instituto de Botânica, Mogi-Guaçu (22°18′S, 47°10′W), and immediately transferred to test tubes (20 cm long, 2 cm diam) covered with red plastic film. The colonies were reproductive (immatures were also observed), and had a similar number of ants (about 50–70), as judged by visual inspection. Test tubes were placed in a plastic container (20 × 20 × 5 cm) the walls of which were coated with Fluon© to prevent the ants from escaping. This container was connected to a foraging arena (16 cm diam, 5 cm high) where the experiments were done. By doing the experiments in a foraging arena we avoided any defensive behavior by the ants that could result because of proximity to the nesting chambers. The colonies were kept at 25°C on a 12 hr L/D cycle and uncontrolled relative humidity, and were fed daily with a honey-water solution and weekly with 5–6th instar larvae of the palatable noctuid moth *Spodoptera frugiperda* L. The nests were fed 5–6th instar *S. frugiperda* larvae

48 hr before the bioassays. During the bioassays, five 5th instar *M. polymnia* larvae were offered on leaves of their respective host plant in order to simulate gregariousness. The mature leaves of host plant, collected immediately from field individuals at UNICAMP, were temporarily stored in a vial with water to prevent drying. Larval mortality was recorded after 24 hr.

Alteration of the Chemical Similarity by Changing the Host Plant. We predicted that the predation rate would be higher in the predation bioassay if we reduced the chemical similarity of *M. polymnia* larvae by changing their host plant. To simulate this scenario, we used freeze-dried 5th instar larvae of *M. polymnia* on mature leaves of their own host plant (*S. tabacifolium*) and on *Brugmansia suaveolens* mature leaves, a solanaceous plant not used by *M. polymnia* (Brown, 1987; Drummond and Brown, 1987), in a predation bioassay similar to the predation with live larvae. If, after 24 hr, the *M. polymnia* larva was undamaged by the ants, we offered a palatable freeze-dried 5th instar larva of *S. frugiperda*. We thus validated the bioassay if this second larva was damaged by the ants within 24 hr.

Alteration of the Chemical Similarity by Changing the Lipid Profile of the Larvae. We also predicted that the ants would not recognize larvae as prey that had the same lipid profile as the plant on which the larvae were offered. To test this we first ran preliminary bioassays using a cuticular lipid extract from *M. polymnia* larvae since the amount of extract was limited because of the low number of *M. polymnia* larvae captured in the field. Five 5th instars were dipped in 5 ml of hexane (SupraSolv, Merck, Germany) for 5 min (modified from Haverty et al., 1996, and Young and Schal, 1997) and then removed. The hexane was subsequently treated with anhydrous Na_2SO_4, filtered, and dried gently in a stream of N_2.

The bioassay was done using freeze-dried 2nd instars of *S. frugiperda* coated with the cuticular lipids of *M. polymnia* larvae. We removed the cuticular lipids from *S. frugiperda* by dipping the larvae in 5 ml of hexane for 10 min. Young and Schal (1997) demonstrated that this time is sufficient to extract all cuticular lipids from nymphs of *Blattella germanica* (Blattellidae). One *S. frugieperda* larva was treated with 50 μl of hexane extract from 10 equivalent larvae of *M. polymnia* (treated larvae, TC). The larval equivalent was calculated based on the ratio of the dry weight of *S. frugiperda* to the dry weight of *M. polymnia* larvae. We used ten times the equivalent to compensate for the loss of hexane extract since part of it could penetrate the body of the larvae instead of remaining on the external cuticle. The second larva was treated only with 50 μl of hexane (non-treated larvae, NTC). After the treatment the hexane was gently dried on a N_2 flux. Ten min after, both were placed on the upper surface of a leaf of *S. tabacifolium* and a recruitment index was calculated as the percentage of ants in contact with the first larva relative to the total number of ants recruited to both larvae during a 30 min period. After either larva was found for the first time by the ants, the number of ants in contact with each larva

was recorded at the end of each minute. At the end of the experiment, there were 30 records for each of the larvae. With the sum of the 30 records for each larva, the recruitment index (RI) was calculated as follows:

$$\mathrm{RI} = \left(\frac{\text{number of ants on TC}}{\text{number of ants on TC} + \text{number of ants on NTC}} \right) \times 100$$

A RI of 50 or close to it indicated no preference for the two larvae, whereas an index lower than 50 indicated a preference for the non-treated larva, and an index higher than 50 indicated a preference for the treated larva. Since the RI ($\bar{X} \pm$ SE) in preliminary bioassays was 2.66 ± 0.83 ($N = 5$), indicating that ants did not recruit to larvae treated with the hexane extract of *M. polymnia*, we ran double choice bioassays in a more elaborated design, using a hexane extract from *S. tabacifolium* leaves. We applied the chemicals to freeze-dried 5th instars of *S. frugiperda* treated as described above, with three experimental groups as follows:

1. High similarity condition: one larva was treated with 50 μl of hexane extract from *S. tabacifolium* (treated larvae, TC), using the same amount of hexane extract equivalent to ten 5th instar larvae of *M. polymnia*; a second larva was treated only with 50 μl of hexane (non-treated larvae, NTC). Both larvae were placed on the upper surface of a *S. tabacifolium* leaf. Recruitment index was subsequently calculated as described above.
2. Low similarity condition: one larva was treated with 50 μl of hexane extract from *S. tabacifolium* as above (TC) while a second larva was treated only with 50 μl of hexane (NTC). Both larvae were placed on the upper surface of a *B. suaveolens* leaf and the recruitment index was calculated as described above.
3. Control: one larva was treated with 50 μl of hexane (TC) while a second larva was not treated with hexane (NTC). Both larvae were placed on the upper surface of a *S. tabacifolium* leaf and the recruitment index was calculated as described above.

RESULTS

Of 125 individuals of *M. polymnia* bioassayed against ants in the laboratory (45 1st, 20 2nd, 20 3rd, 15 4th, and 25 5th instar), only five individuals of the 1st instar and four of the 2nd were attacked and killed, indicating a low predation rate (4%). *Camponotus* ants did not seem to recognize *Mechanitis* larvae as prey and walked over them without showing any aggressive behavior. This suggested that *M. polymnia* larvae had some kind of chemical protection in their cuticle that prevented them from being recognized as prey by *Camponotus* ants.

Freeze-dried 5th instar *M. polymnia* larvae placed on the non-host plant (*B. suaveolens*) were attacked significantly more (67%, $N = 15$) than those placed on the natural host plant (27%, $N = 15$) (binominal test for two proportions, $Z = 2.196$, $P = 0.028$).

The recruitment of ants, based on the RI, also varied with treatment. The RI was significantly lower than 50 for 2nd instar *S. frugiperda* larvae that had the chemical profile of *M. polymnia* and were placed on *S. tabacifolium* (RI = 2.66 ± 0.83, $t = 56.92$, $df = 4$, $P < 0.001$, $N = 5$). The same results were obtained when 5th instar *S. frugiperda* larvae were treated with the chemical profile of *S. tabacifolium* and then placed on *S. tabacifolium*. Larvae that had the chemical profile of *S. tabacifolium* and were placed on *B. suaveolens* and those treated only with hexane in the control experiment had a high RI (one way ANOVA followed by the Tukey multiple comparison test, $F_{2,27} = 24.02$, $P < 0.01$, Figure 1;

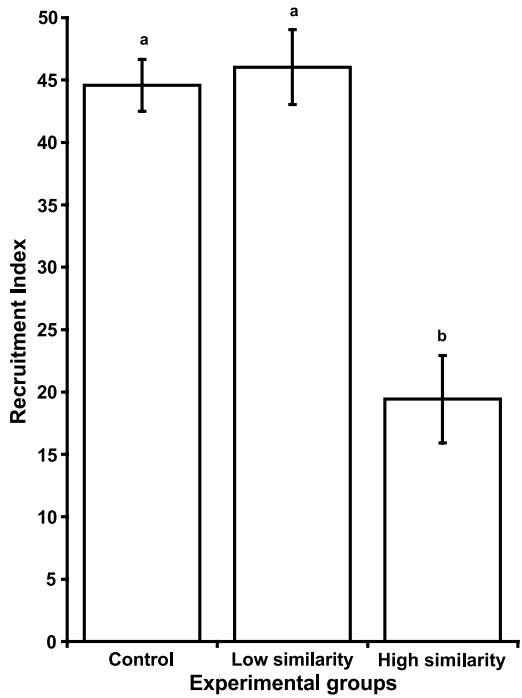

FIG. 1. Recruitment index ($\bar{X}$ ± SE) to *Solanum tabacifolium*-treated larvae of *Spodoptera frugiperda* placed on leaves of *Solanum tabacifolium* (high similarity) or *Brugmansia suaveolens* (low similarity) and to hexane-treated larvae (control). Ten replications were done for each experimental group. Different letters indicate a significant difference ($P < 0.05$).

FIG. 2. Bioassay with freeze-dried *Spodoptera frugiperda* larvae placed on a leaf of *Solanum tabacifolium* with ants (*Camponotus crassus*). The larva on the right was treated with the *Solanum tabacifolium* extract and the one on the left was treated with hexane only.

see also Figure 2 for a picture of the bioassay). We did not compare the RIs among the two bioassays since variations in larval size of *S. frugiperda* (2nd instar used for chemical profile of *M. polymnia* and 5th instar for chemical profile of *S. tabacifolium*) could have influenced the distribution of the chemicals applied to their cuticle and, consequently, ant recruitment.

DISCUSSION

The high similarity between the profile of cuticular lipids in insects and that of their biotic environment has been considered as a mechanism that enable insects, such as syrphid flies, eucharitid wasps, scarabeid and staphylinid beetles, and other ant species, to live with ants, by mimicking them. Generally, these interactions lead to parasitism and predation of the models by the mimic (see reviews in Dettner and Liepert, 1994; Stowe, 1988; Singer, 1998). Cuticular

lipids have also been shown to mediate other interactions among prey and predators. (Espelie et al., 1991) suggested a possible defense mechanism for phytophagous insects based on the similarity between their cuticular lipids and those of their host plants. Fishlyn and Phillips (1980), Hay et al., (1990), and Stachowicz and Hay (1999) described chemical defense mechanisms for marine herbivores based on chemical similarities between them and their host plants; the nature of these chemicals are unknown. However, as pointed out by Stachowicz and Hay (1999) there are few rigorous demonstrations of prey using such a mechanism to avoid predators. Our results in laboratory bioassays suggest that *M. polymnia* is not perceived by the predatory ant *C. crassus* due to the similarity of the cuticular lipids profile with its host plant *S. tabacifolium*. Although the lipids have not yet been chemically analyzed, the bioassays showed that *C. crassus* may perceive the contrast between larval lipids and plant lipids and recognize the larvae as prey. Among ants, the discrimination of nest mates and intruders is essentially based on the perception and similarity of cuticular substances (Hölldobler and Wilson, 1990; Vander Meer and Morel, 1998). In field and laboratory bioassays, predatory ants sometimes walk over larvae, which stay immobile; this thanatose-like behavior, together with a postulated chemical similarity may enhance the protection of *M. polymnia* larvae.

How similar the lipid profiles need to be to protect the larvae remains an open question. Besides chemical analyses, additional bioassays with different blends of lipids will be needed to verify if qualitative differences in the cuticular lipid profile between larvae and host plants are as important as quantitative ones for defense. Another question is the effectiveness of this defense mechanism against other chemically oriented predators (e.g., predatory ants, bugs). Whether larvae sequester lipids from plants or biosynthesize them *de novo* will be subject for future studies. Both mechanisms have been reported for insects. For example, a scarab beetle acquires cuticular hydrocarbons from its ant host (Vander Meer and Wojcik, 1982), and a staphylinid beetle biosynthesizes them, mimicrying their specific termite host (Howard et al., 1980). Feeding experiments with labeled lipid precursors (such as amino acids or acetate) could answer this question.

In respect to definition of this defense mechanism, the nomenclature distinguishing chemical mimicry from chemical camouflage is confusing (Dettner and Liepert, 1994). We adopt the definitions of Vane-Wright (1976), where mimicry involves an organism (the mimic) simulating the signal properties of a second living organism (the model), which are perceived as signals of interest by a third living organism (the operator) in such a way that the mimic enhances its fitness as a result of the operator identifying it as an example of the model. Camouflage or crypsis involves the simulation by organisms of background or uninteresting objects, or forms, i.e., the frame of reference in which

the operator searches for things of importance (but see Endler, 1981 for another definitions of mimicry and camouflage). *Mechanitis polymnia* has characteristics of a model (*S. tabacifolium* leaf chemistry) that is not of interest to the operator, *C. crassus*, thereby camouflaging itself against the ants.

Regardless of the open questions on the acquisition of cuticular lipids by larvae and the definitions used, to our knowledge, this report is the first to demonstrate that phytophagous insects can hide from predators by the similarity between their cuticular lipids and those of their host plants. Orivel and Dejean (2000) reported that the larvae of the hesperiid butterfly *Vettius tertianus* were not attacked by the ponerine ants *Pachycondyla goeldii*, although they do not display defensive devices. However, those authors did not find similarities when comparing the hesperid larval cuticular hydrocarbons with those of the host plant, *Aechmea mertensii*, or of the ants.

Chemical camouflage due to cuticular hydrocarbons may provide a double adaptive advantage to *M. polymnia* larvae. The first, and most obvious, is protection against predation, and the second is to free *M. polymnia* from the burden of using other defensive mechanisms against predation, such as restricted feeding periods or the sequestration of toxic compounds, which could involve an energetic cost (Bowers, 1993; Salazar and Whitman, 2001). Although this chemical hiding does not involve the modification of the foraging mode to avoid predators or the sequestration of toxic compounds, it implies the sequestration or biosynthesis of cuticular lipids by *Mechanitis*. The costs are not known yet.

DIVERGENCE IN STRUCTURE AND ACTIVITY OF PHENOLIC DEFENSES IN YOUNG LEAVES OF TWO CO-OCCURRING *Inga* SPECIES

(Received February 3, 2005; revised June 23, 2005; accepted July 9, 2005)

Abstract—The leaves of tropical forest trees are most likely to suffer herbivore damage during the period of expansion. Herbivore selection on young leaves has given rise to a variety of leaf developmental strategies and age-specific chemical defense modes. We are studying correlations between leaf developmental types and chemical defenses in the Neotropical genus *Inga*. We have characterized defense metabolites in *Inga goldmanii* and *Inga umbellifera*, two species that co-occur in the lowland moist forest of Panama. These congeners have markedly different young-leaf developmental phenotypes but suffer approximately equal rates of herbivory. Bioassays of whole and fractionated leaf extracts using larvae of *Heliothis virescens* show that *I. goldmanii* chemical defenses are nearly three times more inhibitory than those of *I. umbellifera*. In both species, most of the inhibitory activity resides in complex mixtures of monomeric and polymeric flavan-3-ols. This group comprises >30% of young leaf dry weight in both *I. goldmanii* and *I. umbellifera*. The species' phenolic chemistry differs markedly, however, both in the structure of the monomeric units and in the distribution of polymer sizes. The differences in chemical structure have pronounced effects on their bioactivities, with *I. goldmanii* flavans being twice as inhibitory to *H. virescens* larvae as *I. umbellifera* flavans, and more than three times more efficient at protein binding. Given the extraordinarily high polyphenol concentrations that are found in the young leaves of these species, protein precipitation could be an important mechanism of growth inhibition. Nevertheless, our data show that another mode of phenolic action, possibly oxidative stress, occurs simultaneously.

INTRODUCTION

Young leaves of tropical forest trees suffer far higher rates of herbivory than mature leaves of the same species. Surveys of leaf herbivory across a range of tree species in a moist forest in Panama show that nearly 70% of lifetime herbivore damage occurs during the days to weeks of leaf expansion (Coley and Aide, 1991; Coley and Barone, 1996). This is a remarkable finding in that the leaves of tropical moist-forest trees typically last several years. High herbivory pressure on young leaves has led to a variety of developmental and defense chemical phenotypes. We are investigating correlations between developmental pattern, chemical defense, and herbivory in young leaves of the Neotropical genus *Inga* (Fabaceae). As a starting point, we have identified two co-occurring *Inga* species that have markedly different young-leaf development. *Inga goldmanii* is a "normally greening'' species in which leaves flush singly, expand slowly, and are photosynthetic. In contrast, *Inga umbellifera* is a "delayed-greening'' species: Leaves are deployed in large flushes, expansion is rapid, and full chloroplast development occurs only after leaves have reached full size. Populations of these two species growing in lowland moist forest on Barro Colorado Island, Panama, suffer approximately equal rates of young-leaf herbivory, approximately 22% (Coley 2 et al., in press).We are characterizing the full range of defense metab-olites synthesized in these two species to determine: (1) the relative contributions of chemistry to overall herbivory-avoidance strategies, (2) the structure/activity relationships of defense metabolites, and (3) whether chemical defenses, like developmental strategies, have diverged in these congeners.

We have developed an insect growth assay using larvae of the noctuid lepidopteran *Heliothis virescens*. We used the assay to test whole young-leaf extracts and to guide chemical fractionation. We found pronounced differences between *I. goldmanii* and *I. umbellifera* in the bioactivities of whole young-leaf extracts. Through assays of individual chemical fractions, we showed that, in both species, complex mixtures of phenolic compounds are accumulated at high concentrations and account for the majority of insect growth inhibition. In this paper, we describe the phenolic chemistry in these two species and show that structural divergence within this class of compounds has led to marked differences in bioactivities.

METHODS AND MATERIALS

Collections of Plant Material. Collections from *I. goldmanii* and *I. umbellifera* were made at Barro Colorado Nature Monument (BCNM, 9°10'N, 79°50'W), Republic of Panama. Young leaves, 5–80% of full expansion, were collected from shaded, understory trees during periods of leaf flush between January 2001 and December 2002. Collections were made randomly from trees across BCNM. Leaves were pooled during a given harvesting period, typically 3–4 mo. Tissues were processed shortly after collection by maceration, first in a Waring blender and then a Polytron 3100 (Brinkmann Instruments, Westbury, NY, USA) in 95% EtOH. Suspensions (leaf solids + dissolved extractables) of each species were shipped to the University of Utah on dry ice and then stored at −80°C until processing.

Fractionation of Plant Material, Isolation of Phenolic Components, and Determination of Phenolic Mass. Two sets of extractions were made, one to prepare a whole-leaf extract for bioassay, and one to separate phenolics from leaf solids and all other leaf extractables. The whole-leaf extract contained all soluble metabolites. To prepare this, a portion of leaf material (usually 5–10 g fresh weight) was filtered and extracted repeatedly with 80% EtOH/water, 70% acetone/water, dichloromethane (DCM), and 25 and 70°C water. All solutions were combined and reduced under vacuum to a concentration of 10–20 mg/ml. (Low molecular weight terpenes are not present in the shade phenotypes of these species.) The exact concentration was determined gravimetrically by vacuum-drying 5-ml subsamples.

A second extraction was performed on the remainder of the sample to (1) isolate phenolic components into purified fractions and (2) determine the mass percentage of phenolics of the total extractable metabolites. Leaf samples were submitted to a partitioning process (details in Index), which resulted in five extract fractions plus the marc. Two of these were shown by subsequent high-performance liquid chromatography (HPLC) and mass/nuclear magnetic resonance (NMR) spectral analyses to be composed nearly entirely of phenolic components, and were designated phenolics I and II. Except where noted, these were combined into a single "phenolics" fraction. The remaining three fractions, "lipids", "proteins", and "aqueous", were vacuum-dried along with the marc. The weight of each fraction was recorded to determine total leaf dry weight (DW) and the mass percentage of phenolics. The crude and phenolic fractions were submitted to bioassay (details below). The marc was further processed (see the following section).

Butanol–HCl Digestion of Marc. Samples of *I. goldmanii* and *I. umbellifera* marc were acid digested following the method of Porter et al. (1986). After digestion, the marc was washed with water to remove the acid and then extracted with BuOH until most of the cyanidin had been removed. The marc

was dried, lyophilized, and its mass recorded. Portions of extracted and unextracted marc were subsequently submitted to bioassay (details below).

Chromatographic Separations of Phenolics. Characterization of the phenolic content of *I. goldmanii* and *I. umbellifera* began with the isolation of individual components. Low molecular weight compounds were separated from EtOAc extracts of the phenolics fraction of *I. goldmanii* by flash chromatography on silica gel using dichloromethane/MeOH, 92:8 → 80:20. A similar separation of low molecular weight compounds from *I. umbellifera* is described elsewhere (Lokvam et al., 2004).

A higher molecular weight phenolic compound, a procyanidin trimer (compound **1**, Figure 1a), was isolated from *I. goldmanii* by HPLC. The compound was separated on a 10 × 200 mm polyhydroxyethyl aspartamide (PHA) semipreparative column (5 μm, PolyLC Corp., Columbia, MD, USA) and then purified using a 10 × 250-mm Microsorb ODS semipreparative column (5 μm, Varian Analytical Instruments, Walnut Creek, CA, USA) with a guard column (ODS, 8 μm, Varian). Compound structural characterization was based on one- and two-dimensional NMR spectra (described below) and on the high-resolution matrix-assisted laser desorption initiation time-of-flight (HR-MALDI-TOF) mass spectrum, obtained using a Voyager DE-STR spectrometer (MDS Sciex, Concord, ON, CA) with the sample dissolved in MeOH/CHCA. The separation and characterization of individual procyanidins from *I. umbellifera* are described elsewhere (Lokvam et al., 2004).

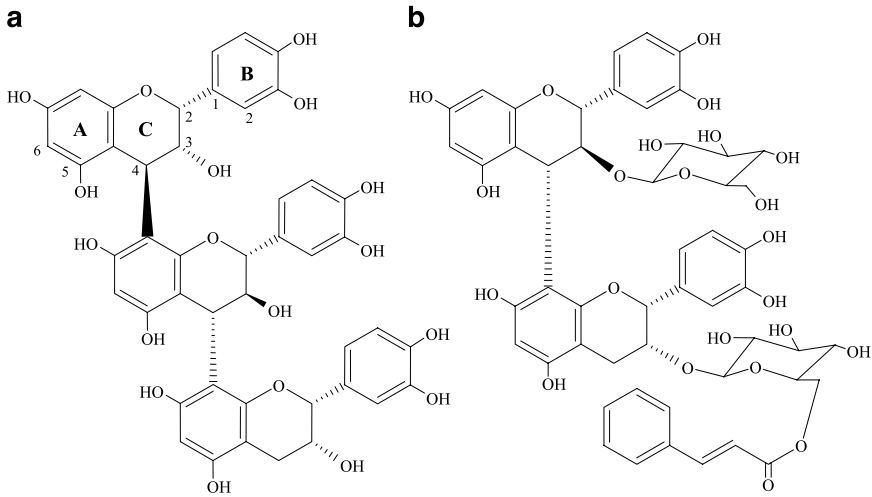

FIG. 1. (a) Trimeric procyanidin (compound **1**) from *I. goldmanii*. (b) Representative substituted procyanidin from *I. umbellifera*.

As a qualitative test of the purity of the phenolics extracts, phenolics from both *I. goldmanii* and *I. umbellifera* were analyzed by HPLC using a diode array detector (DAD) and an evaporative light-scattering detector (ELSD, SEDERE S.A., Alfortville, France). For both sample analyses, comparisons of the ELSD and DAD outputs were made to check for the presence of non-UV-absorbing compounds. *I. umbellifera* phenolics were further analyzed by liquid chromatography/electrospray ionization mass spectrometry (LC/ESI-MS; details below).

NMR. ^{1}H and ^{13}C NMR spectra were acquired on a Unity iNOVA 500-MHz spectrometer (Varian). The *I. goldmanii* trimer was dissolved in CD_3OD. ^{1}H and ^{13}C spectra were referenced to the centerline of the solvent multiplets, 3.31 and 49.15 ppm from trimethylsilyl, respectively. Acquisition temperatures were $-39°C$ (for trimer ^{13}C spectrum) and $-20°C$ (for trimer ^{1}H spectrum), respectively. ^{1}H–^{1}H connectivities as well as short- and long-range ^{1}H–^{13}C correlations were observed with gradient-selected DQCOSY, HSQC, and HMBC pulse sequences.

Electro-Spray Ionization Mass Spectrometry. I. goldmanii phenolics were analyzed with a Finnigan LCQ (Thermo-Finnigan, Bremen, Germany) operated in the negative ion ESI mode. *I. umbellifera* phenolics were analyzed with a MicroMass Quattro II mass spectrometer (Waters, Milford, MA, USA) operated in the positive ion ESI mode. For both analyses, phenolic solutions in MeOH at a concentration of approximately 0.1 μg/μl were introduced into the instrument by direct infusion at a rate of 5 μl/min. *I. umbellifera* phenolics were further analyzed by LC/MS using a Waters 2690 HPLC system with a Waters 2487 UV Detector (recording at 280 nm) configured in tandem with the MicroMass spectrometer described above.

Separation of I. goldmanii Phenolics into Size Classes. Samples of *I. goldmanii* phenolics I (0.75 g) and phenolics II (0.3 g) dissolved in 50% MeOH were each applied to a water-equilibrated LH-20 column and eluted with 50% MeOH and 70% acetone. Solvents were removed under reduced pressure, and all fractions were vacuum-dried. This gave four fractions, designated phenolics I–MeOH, phenolics I–acetone, phenolics II–MeOH, and phenolics II–acetone. (*I. umbellifera* phenolics cannot be separated on LH-20 under the protocol described here.)

Estimation of Degree of Polymerization. The mean degree of polymerization (mDP) and catechin/epicatechin ratios of each of the *I. goldmanii* LH-20 fractions were determined by thiolysis, acid-catalyzed degradation of polymers in the presence of benzylmercaptan (Thompson et al., 1972). This reaction releases lower units as free monomers and extender units as their respective thioethers. Product mass percentages were estimated by comparison of their peak areas (280 nm) to calibration curves made with catechin or epicatechin standards (Sigma, St. Louis, MO, USA) or the purified thioethers. Following

conversion to moles, the mDP was calculated by the formula: (catechin + epicatechin + thioethers) / (catechin + epicatechin). HPLC analyses of derivatized and underivatized phenolics yields the relative masses of catechin and epicatechin as free monomers and as lower or extender units.

The mDP and the monomer/dimer mass percentages of *I. umbellifera* phenolics were estimated using a combination of mass and evaporative light scattering detection following the HPLC separations outlined above. The molecular ion masses of the major ELSD-detected peaks were determined using LC/ESI-MS. From these data, the number of flavanol + pyranose + cinnamate units in each of the major peaks was deduced. The overall monomer/dimer mass percentages were determined by summing the appropriate peak area percentages. Upper and lower bounds for the mDP of *I. umbellifera* phenolics were estimated by mass correction of each major polymer peak, so that area percent value reflected flavan-monomer number. The mDP was calculated from the weighted area percentages of the major polymer peaks.

Procyanidin–Protein Binding. A bovine serum albumin (BSA) precipitation assay (Hagerman and Butler, 1978) was used to assess protein binding by *I. goldmanii* and *I. umbellifera* procyanidins. This method measures the quantity of procyanidin (as absorbance of iron-phenolate at 510 nm) that precipitates with protein from a standard BSA solution over a range of total phenolic concentrations (0.125–3.0 mg/ml). Binding curves are thus obtained. The slopes of the linear portions, reported as absorbance units per milligram total phenolics per milliliter, are used as a relative measure of procyanidin–protein binding capacity. In both cases, r^2 values were >0.99.

Insect Feeding Trials. The bioactivities of whole-leaf extracts, all phenolic fractions, and the pre- and post-butanol-extracted marcs from both species were tested in growth trials using larvae of *H. virescens* (Lepidoptera: Noctuidae). Larvae were fed an artificial diet amended with plant products, and their growth relative to controls was measured. The diet was modified from Chan et al. (1978). Whole-leaf extracts (as the solutions that were described above) and phenolics (as powders) were added at prescribed mass percentages of the total diet DW. For the marc assays, marc was ground to a fine powder using a Retsch MM 200 Mixer Mill (Retsch GmbH, Haan, Germany) and was substituted at the same mass percentage (35% total diet DW) for the cellulose in the diet. Once prepared, the diet was divided into individual portion cups, typically 16 per treatment level. Controls were prepared in the same manner as treatments but without the addition of plant products. (We have verified that following high vacuum-drying there are no effects from solvents used in the whole-leaf extracts, so solvent controls were omitted.) One freshly hatched, unfed *H. virescens* larva was sealed into each cup with a vented lid and kept in a 75% RH controlled growth chamber on a 12–12 h L/D schedule for 8 d. At the end of this period, treatments and controls were weighed. Treatment weights were divided

by the control weight (GRC = growth relative to control) and fitted to the following dose–response function using the NLIN procedure in SAS:

$$\mathrm{GRC} = \frac{a_0 - a_0}{1 - (\log\ C/b_2)^{b_1}}$$

where a_0 is the response at low concentration, C is the dose in percent, b_1 is the slope, and b_2 is the logarithm of the concentration that inhibits growth by 50%. The antilog of b_2, the GI_{50}, was used to compare the relative inhibitory capacities of given plant chemical classes (Streibig et al., 1993). This statistic is based on the combined results of several assays, such that it can be assigned a 95% confidence interval (CI). If, for a given *I. goldmanii*/*I. umbellifera* assay class (whole-leaf extract or phenolics), there was no overlap in 95% CIs, the GI_{50} values were considered statistically different.

RESULTS

I. goldmanii Phenolics. I. goldmanii phenolics are composed almost entirely of monomeric catechin and epicatechin or polymers of these subunits.

[a]All values relative to the center line of the solvent multiplet (3.31 ppm for ^{1}H, 49.15 ppm for ^{13}C).

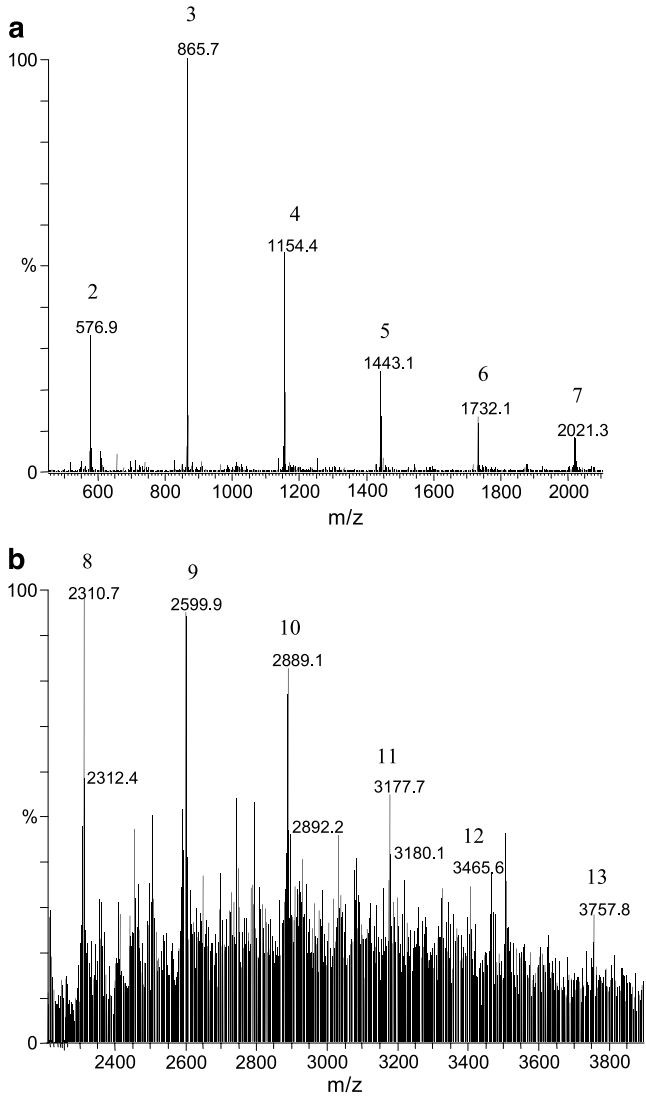

FIG. 2. ESI mass spectra of *I. goldmanii* phenolics. The low mass spectrum (a) shows masses from 500 to 2100 amu; the high mass spectrum (b) shows masses from 2200 to 3900 amu. Peaks are labeled by mass and polymer length.

This conclusion was based on NMR and mass spectral analyses and on thiolytic degradation followed by HPLC separation and diode array detection. Both catechin and epicatechin were isolated as monomers by flash chromatography on silica gel. They were identified by comparison of their ^{1}H NMR spectra to standards (Sigma). In addition, a procyanidin trimer, compound **1** (Figure 1a) was isolated by semipreparative HPLC. The structure of this compound, epicatechin-4β→8-catechin-4α→8-epicatechin, was deduced from 1D (Table 1) and 2D NMR spectra. HR-MALDI-TOF MS gave an $[M + Na]^+$ ion of *m/z* 889.1996, calculated for $C_{45}H_{38}O_{18}Na$ (5.1 ppm error) and consistent with a singly linked trimeric procyanidin. Compound **1** was first isolated but only minimally characterized by (Hsu et al., 1985).

The ESI mass spectrum of *I. goldmanii* phenolics showed only molecular masses consistent with monomeric catechin/epicatechin or singly linked polymers thereof (Figure 2). $[M - H]^-$ ions were observed ranging from 576.9 to 3757.8 amu, corresponding to degrees of polymerization 2 to 13. No evidence of multiply charged ions was detected. Thiolytic degradation of *I. goldmanii* phenolics followed by HPLC separation and diode array detection of the products indicated that the great majority of the product mass is catechin/epicatechin and their thioethers. This was corroborated using HPLC separation and detection by evaporative light scattering, a mass-sensitive technique, which showed no other major components.

TABLE 2. MASS PERCENTAGES, PHYSICAL PROPERTIES, AND BIOACTIVITIES OF SOME *I. goldmanii* AND *I. umbellifera* METABOLITE FRACTIONS

	% DW	mDP[a]	PP[b]	GI_{50}[c]	95% CI

[b] Procyanidin–protein binding capacity: slope of linear binding curve (absorbance per milligram phenolic per milliliter).
[c] Concentration (% DW) of extract in insect diet that is required to reduce growth by 50% relative to controls.
[d] Weight average, based on LH-20 fractions.
[e] Free monomer content removed.

I. goldmanii phenolics I and II fractions were analyzed for percent monomer composition and degree of polymerization after separation on LH-20 (96 and 94% recovery, respectively). Monomeric catechin and epicatechin in the *I. goldmanii* phenolics were approximately 15.0 and 0.8%, respectively, of the total phenolic mass as estimated by HPLC analysis of underivatized phenolics I–MeOH, the only fraction that contained detectable quantities of free monomer. The mDP of the *I. goldmanii* phenolics was determined by HPLC analysis following thiolysis of the interflavanyl linkage in the presence of toluene-α-thiol (Table 2). Phenolics I–MeOH contained monomeric catechin/epicatechin and low molecular weight procyanidin with an mDP estimated to be 2.0. Phenolics II–MeOH was not amenable to analysis by these methods and gave only low concentrations of the normal thiolysis products, i.e., free monomers and thioethers. Based on its weak protein-precipitation ability, it appears to contain procyanidin. We suspect that this fraction consists of low molecular weight procyanidin/carbohydrate complexes whose chemistry prevents acid hydrolysis under the conditions we used. Phenolics I– and II–acetone contained higher molecular weight procyanidins with mDPs estimated to be 6.1 and 15.3, respectively. Based on the weighted averages of the individual fractions, the mDP of the entire phenolic population was estimated to be 7.2. Catechin–epicatechin ratios of the free monomers and for each of the *I. goldmanii* LH-20 fractions are listed in Table 3. Catechin is the predominant monomeric form and the most common procyanidin initiator unit, particularly in the higher molecular weight polymers. In contrast, epicatechin comprises more than half of the extender units in all *I. goldmanii* fractions.

I. umbellifera Phenolics. I. umbellifera phenolics, like *I. goldmanii* phenolics, are composed entirely of compounds based on catechin and epicatechin. In contrast to *I. goldmanii*, however, *I. umbellifera* flavanols are each substituted at the C3 position with either a simple hexose or a hexose that is mono- or disubstituted with a cinnamoyl ester (see Figure 1b). These conclusions are based on several lines of evidence. Purification and rigorous structural characterization of several *I. umbellifera* flavans (Lokvam et al., 2004) yielded the building blocks of these compounds: catechin/epicatechin, hexose (glucose in each case that was explicitly determined), and cinnamate. ESI mass spectra showed that all observed molecular masses in *I. umbellifera*

2,536.1	5	5	2
2,693.1	6	5	1
2,856.1	6	6	1

phenolics can be accounted for by combinations of the known monomeric subunits (Figure 3, Table 4, and the following section). *I. umbellifera* flavanols, unlike mixtures of unsubstituted *I. goldmanii* procyanidins, separate cleanly by ODS HPLC. DAD chromatograms of *I. umbellifera* phenolics showed over 40 (mostly minor) peaks having UV absorbance spectra nearly identical to the purified monomeric and dimeric compounds already structurally characterized. In addition, evaporative light scattering detection showed only minor contributions to the phenolics fraction mass from non-UV-absorbing components.

The ESI mass spectrum of *I. umbellifera* phenolics (Figure 3, Table 4) was recorded between 200 and 4000 amu. It showed monomer molecular masses of 605.2 and 735.2, and polymer masses between 893.2 and 2856.1 amu. These latter correspond to polymer sizes ranging from dimer (monoglucosyl, monocinnamoyl) to hexamer (hexaglucosyl, monocinnamoyl). As with *I. goldmanii*, no evidence of multiple charging was observed. The monomer and dimer concentrations and mDP of *I. umbellifera* phenolics were estimated following separation by HPLC and detection by complementary modes, mass and evaporative light scattering (Figure 4). Monomeric forms comprise approximately 30% of the total phenolic mass, and dimeric forms an additional 37%. Following mass correction of each peak to molar flavanol equivalents, the mDP of the *I. umbellifera* polymer population was estimated to be between 2.2 and 3.4.

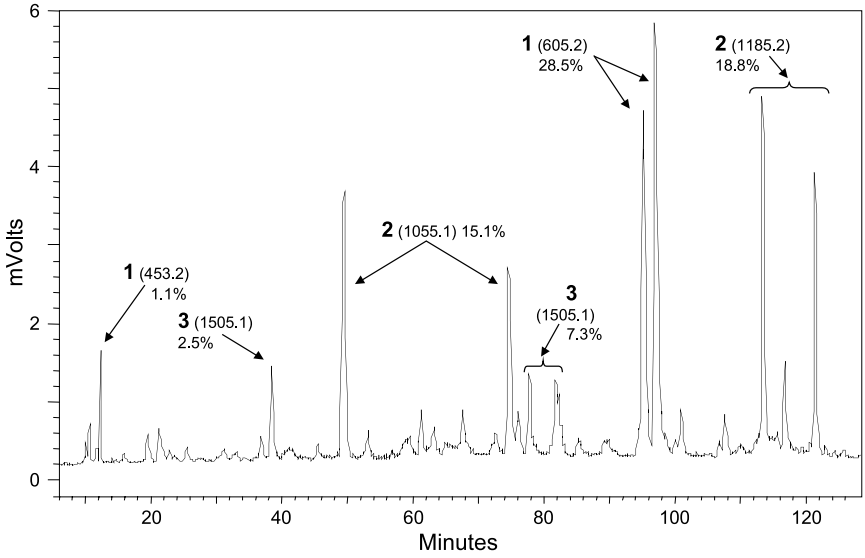

FIG. 4. HPLC chromatogram of *I. umbellifera* phenolics as detected by evaporative light scattering. Main peaks are labeled by flavanol number, mass (M + Na ions), and area percent of the full integrated chromatogram. For structural inferences, see Table 2.

Total Phenolics Mass. The extraction procedure used removed approximately 30% of young leaf DW as phenolics from both *I. goldmanii* and *I. umbellifera* (Table 2). In both species, approximately 70% of the extractable phenolics dissolved into aqueous EtOH. A further 30% of the extractable phenolics was removed using aqueous acetone. In addition to soluble leaf phenolics, butanol/HCl extraction of the marc produced a dense cyanidin solution, the result of acidolysis and oxidation of carbohydrate-bound procyanidins (Shen et al., 1986). The extraction removed approximately 32 and 52%, respectively, of the starting mass of the marcs of *I. goldmanii* and *I. umbellifera* (Table 5). The exact

TABLE 5. PRE- AND POST-ACID DIGESTED MASSES AND BIOACTIVITY OF *I. goldmanii* AND *I. umbellifera* MARC

	% Leaf DW	GRC[a]	*P*
I. goldmanii marc (+) phenolics	52	0.12	<0.05
I. goldmanii marc (−) phenolics	35	0.69	<0.01
I. umbellifera marc (+) phenolics	39	0.12	<0.05
I. umbellifera marc (−) phenolics	18	0.87	n.s.

[a] Growth relative to the control at a single concentration (35% of dry weight).

proportion of the extracted mass that was phenolic was not determined, but this proportion was likely considerable.

Procyanidin–Protein Binding. Procyanidin–protein binding curves were obtained for phenolics from both species. The linear portions were 0.125–1.0 mg phenolics/ml for *I. goldmanii*, and 0.125–2.5 mg phenolics /ml for *I. umbellifera*. In both cases, r^2 values were >0.99. The slopes of the linear portions of the binding curves were used to compare procyanidin–protein binding between the two species (Table 2). In comparison to *I. umbellifera* phenolics, approximately 3.5 times more *I. goldmanii* phenolics were involved in precipitating protein from a standard BSA solution. A similar analysis of *I. goldmanii* phenolics I–MeOH/acetone and phenolic II–acetone (Table 2) having mDPs of 2.0, 6.1, and 15.3, respectively, showed that protein-binding capacity increases sharply as a function of polymer length.

Bioactivities of I. goldmanii and I. umbellifera Young Leaf Metabolites. Whole-leaf extracts of the young leaves of *I. goldmanii* and *I. umbellifera* gave GI_{50} values (Table 2) of 1.1 and 2.8%, respectively, in the *H. virescens* larval growth assay. Assays of specific fractions (see "Methods and Materials'') showed that phenolics accounted for more than 50% of the growth-inhibiting activity observed in the whole-leaf extracts of each species. The *I. goldmanii* phenolics fraction, however, was more than twice as inhibitory as that from *I. umbellifera* (GI_{50} = 0.59 and 1.45%, respectively, 95% CIs nonoverlapping). The marcs from both species were assayed before and after digestion with BuOH/HCl to remove tissue-bound phenolics (Table 5). When substituted into the insect diet at the mass percentage of cellulose (35%), marc (+) phenolics reduced insect growth by more than 80% relative to controls in both species. In contrast, the growth reduction caused by marc (−) phenolics was not significant for *I. umbellifera* and was approximately 30% for *I. goldmanii*.

DISCUSSION

Feeding trials with larvae of the noctuid moth *H. virescens* show that whole-leaf extracts of young leaves from *I. goldmanii* and *I. umbellifera* have markedly different growth-inhibitory capacities. Overall, the suite of extractable metabolites synthesized by the normally greening species, *I. goldmanii*, is nearly three times more inhibitory than those synthesized by the delayed-greening species, *I. umbellifera*. Isolation and bioassay of the phenolic portion of the extractable metabolites shows that most of the observed activity is caused by metabolites in this fraction. Detailed chemical characterization indicates that, in both species, the phenolic fraction consists of a complex mixture of monomeric and polymeric flavan-3-ols.

In *I. goldmanii*, flavan-3-ols are synthesized as monomeric catechin/epicatechin and oligomeric to highly polymerized procyanidins. The polymeric forms have an average length of approximately 7.2. In *I. umbellifera*, like *I. goldmanii*, catechin and epicatechin are the only phenolics that were detected. In this species, they occur exclusively as their 3-*O*-glycosyl or 3-*O*-(cinnamoyl)-glycosyl derivatives. Moreover, in contrast to *I. goldmanii*, *I. umbellifera* flavan-3-ols are dominated by lower molecular weight monomeric and dimeric forms.

Flavan-3-ols are a primary line of chemical defense in *I. goldmanii* and *I. umbellifera*. This class of compounds is synthesized at extraordinarily high concentrations in the young leaves of these species. The phenolic extraction protocol used in this study was not exhaustive, yet approximately 30% of the dry weight of both species was recovered as soluble flavans. In addition, an acid–butanol digestion of the marc showed the presence of appreciable amounts of tissue-bound flavans such that flavanol content may approach 50% of the leaf dry weight. In the *H. virescens* assay, the GI_{50} values for the whole phenolics extracts were 0.6% for *I. goldmanii* and 1.3% for *I. umbellifera*, concentrations that are far below what *Inga* herbivores encounter in the wild. Assays of pre- and post-acid-digested marc indicate that tissue-bound phenolics also contribute substantially to the overall phenolic toxicity. Bioassays such as these, against a naive, generalist herbivore, demonstrate the potency.

Structural differences in the phenolic metabolites expressed by *I. goldmanii* and *I. umbellifera* produce differentiable effects on the growth of *H. virescens* larvae. *I. goldmanii* phenolics are composed of unsubstituted procyanidin polymers. On a mass basis, this set of compounds is more than twice as inhibitory as the substituted forms produced by *I. umbellifera*. Similar results were observed in bioassays conducted in Panama with *Phoebis philea*, a lepidopteran that specializes on mimosoid legume leaves (Lokvam and Kursar, unpublished data).

Phenolics are among the most widely distributed and abundant secondary metabolites in plants (Bate-Smith, 1962, 1968), but their mode of action and ecological function have proven difficult to define, particularly with respect to insects. Following Feeny's (1969) observation that polyphenols could interfere with herbivore digestion by precipitating enzymes and/or dietary proteins, considerable attention was focused on the defensive role of high molecular weight phenolics (Feeny, 1976; Rhoades and Cates, 1976; Swain, 1979; Zucker, 1983). Their mechanism of action, however, remains obscure. The "tannin–protein binding'' mode of action has been questioned since (1) the guts of many herbivorous lepidoptera, with their high pHs and detergent content, are well adapted to prevent formation of polyphenol/protein complexes (Martin and Martin, 1984; Blytt et al., 1988), and (2) this mechanism has never been demonstrated *in vivo*. Martin et al. (1987) showed that in *Manduca sexta* gut fluid hydrolyzable tannin–RUBISCO ratios must be at unity or greater for appreciable protein precipitation to occur. They suggest that such high

polyphenol/protein ratios would only rarely be encountered in nature, and that protein precipitation is, therefore, probably not an ecologically relevant process. The extraordinarily high procyanidin content that we observe in young *Inga* leaves, however, argues against this point. At concentrations of 25–30% leaf dry weight, procyanidins could inhibit digestion through protein binding.

Simple phenolics do not precipitate protein, yet have been shown to have strong negative effects on insect herbivores. For instance, functioning as pro-oxidants, the *o*-diphenols, caffeic and chlorogenic acid, were shown to alter gut chemistry in *Helicoverpa zea* (Summers and Felton, 1994), and are correlated with low larval growth rates in that species. These compounds function as toxins by degrading the gut epithelium. A distinction can be made then between the activity of *o*-diphenols (which include procyanidins) as outright toxins and high molecular weight phenolics as "digestibility reducers'' (Duffey and Stout, 1996). In a chemically complex group like the flavan-3-ols, the distinction must allow for considerable functional overlap (Butler et al., 1986; Blytt et al., 1988), but it is likely that there are multiple modes of activity that occur simultaneously.

Using LH-20, we separated *I. goldmanii* procyanidins into size classes having mean degrees of polymerization of 2.0, 6.1, and 15.3. The BSA precipitation assay showed that there is a strong positive correlation between protein-binding capacity and procyanidin molecular weight, a finding that is in agreement with earlier studies (Kumar and Horigome, 1986; Horigome et al., 1988). Bioassays showed, however, that both the low and high molecular weight fractions were equally inhibitory to *H. virescens* larvae. Similarly, comparisons of the BSA binding characteristics of *I. goldmanii* and *I. umbellifera* phenolics showed a pronounced difference in binding efficiency. The simple, unsubstituted *I. goldmanii* phenolics were approximately four times more efficient than the substituted forms from *I. umbellifera*. This is almost certainly due to the presence in *I. goldmanii* phenolics of high molecular weight procyanidins. Nevertheless, *I. umbellifera* phenolics are potent growth inhibitors for larvae of *H. virescens*. Assuming that *in vitro* BSA precipitation approximates the *in vivo* interaction between procyanidin and dietary protein, our data are consistent with a multiple-mode view of phenolic bioactivity in *Inga*: oxidative stress due to the presence of *o*-diphenols, for example, and protein precipitation due to high molecular weight procyanidins. *H. virescens* is not a suitable assay organism for testing the multiple-mode concept. A rigorous bioassay will require a specialist herbivore, one that can tolerate diets containing the high levels of phenolics found in *Inga* leaves.

Simple procyanidins are likely the primitive form in this class of compounds. It appears that a novel set of selection pressures has led to a derived form of phenolic metabolites in *I. umbellifera*. The evolution of the delayed-greening/rapid expansion phenotype in the young leaves of *I. umbellifera* has likely imposed physiological constraints on the production

and storage of phenolics at the high concentrations seen in these species. The derived phenolics in *I. umbellifera* may have diverged from the ancestral form in parallel with the divergence in developmental strategy (Kursar and Coley, 2003). A more thorough knowledge of the phenolic chemistry of other delayed-greening *Inga* species, as well as an understanding of the whole-genus phylogenetic relationships, will certainly shed some light on this question.

THE EFFECT OF POLLINATION ON FLORAL FRAGRANCE IN THISTLES

(Received January 21, 2005; revised May 25, 2005; accepted June 30, 2005)

Abstract—We investigated postpollination changes in fragrance composition and emission rates, as well as pollinator discrimination in hand-pollinated flower heads of two thistle species: Canada thistle (*Cirsium arvense*) and sandhill thistle (*C. repandum*). Following pollination, neither species emitted any novel compounds that could function as repellents. Scent emission rates declined in pollinated plants of both species by approximately 89% within 48 hr. This decline was evident in all 13 scent components of *C. arvense*. *Apis mellifera*, the dominant pollinator in the study population of *C. arvense*, was nearly three times more likely to visit an unpollinated rather than a pollinated flower head. A more complex pattern was observed for *C. repandum*, whose scent comprised 42 compounds. Quantities of aromatic and sesquiterpenoid volatiles declined after pollination, whereas two classes of scent compounds, fatty acid derivatives and monoterperpenoids, continued to be emitted. In *C. repandum*, discrimination against pollinated flower heads by *Papilio palamedes* (its primary pollinator) was not as marked. Unpollinated control plants of both species maintained moderate levels of scent production throughout this experiment, demonstrating that senescence and floral advertisement may be delayed until pollination has occurred. We expect postpollination changes in floral scent contribute to communication between plants with generalized pollinator spectra and their floral visitors. This study provides the first field study of such a phenomenon outside of orchids.

Key Words—Asteraceae, Canada thistle, *Cirsium arvense*, *Cirsium repandum*, dioecious, fragrance, herbivory, pollination, floral volatiles.

INTRODUCTION

Floral fragrances advertise the site of reproductive structures (and rewards), luring pollinators from great distances (Metcalf and Metcalf, 1992). This manipulation of pollinators is often reciprocally beneficial, as floral scent promotes pollinator fidelity and pollinator efficiency (Marden, 1984; Dornhaus and Chittka, 1999). However, herbivores also navigate within a landscape of floral fragrances; plants that increase their apparency through floral display may be attracting their own enemies (Galen and Butchart, 2003). Advertising with visual and olfactory displays is only necessary prior to successful pollination. Following pollination, it may be beneficial to reduce the apparency of a flower to avoid attracting unwanted visitors. Research on pollination-induced changes has centered on documenting changes to the visual rather than the olfactory display. Fragrance is a complex trait. Over 150 compounds can be contained within a floral scent blend. However, it is also a quantifiable trait, and even small changes can be measured (Tollsten, 1993). As yet, pollination-induced changes to the *full set of components* in the fragrance blend have not been quantified from flowers other than orchids.

Postpollination changes, which can include withering, closing, or abscission of petals, color change, positional adjustment (becoming inaccessible to pollinators), cessation of nectar production, and scent alteration, have not been extensively tested across the angiosperms. There has been a widespread expectation that flowers almost universally undergo postpollination changes (Wheiss, 1995; see van Doorn, 1997 for exceptions). However, few studies directly test for pollination-induced changes (Gori, 1983; Primack, 1985; van Doorn, 1997), and when tested directly, color changes in flowers, for example, have often been found to be a result of floral aging, rather than a consequence of pollination (Casper and LaPine, 1984; Delph and Lively, 1989). Most studies on pollination-induced changes have centered on orchids, whereas only half of the remaining angiosperm families with animal-pollinated species have been examined for this phenomenon (van Doorn, 1997).

Scent changes induced by pollination have the potential to function similarly to color change, the best studied of the pollination-induced changes (Wheiss, 1995). First reported in the literature in the 1700s (Wheiss, 1995), color change allows flowers to continue contributing to the floral display after they are pollinated, in some cases even increasing visitation to a plant (Gori, 1989; Niesenbaum et al., 1999). Pollinators are recruited from a distance by the colorful display, but experienced pollinators avoid older flowers at closer proximity. The response of pollinators and/or nectar thieves to floral color change involves learning and represents an informed "decision". This has been demonstrated for a number of species (Wheiss, 1997). Wheiss (2001) suggests that for some plants, color change may not be advantageous, for example, if their

pollinators are incapable of associative learning. Interestingly, flowers pollinated exclusively by beetles do not undergo postpollination color changes.

Similar to the learned behavior associated with color changes, postpollination changes in floral fragrance could inform an experienced pollinator of the age and/or reward status of a flower. However, such a phenomenon need not depend upon associative learning, as floral scent can specifically target a pollinator's preconditioned behavior. In that case, the pollinator does not need to be experienced or have the ability to learn, as scent changes could result in signals that are already informative. This is the case for the sexually deceptive orchid, *Ophrys sphegodes*, in which Schiestl and Ayasse (2001) documented an increase in specific components that appear to act as pollinator repellents, rather than a general cessation of odor. This orchid species is pollinated through pseudocopulation by males of the solitary bee *Andrena nigroaenea*. The postpollination floral repellent, farnesyl hexanoate, mimics a compound produced by female bees and used in brood cells to decrease mating attempts (Bergström and Tengo, 1974). In the orchids, postpollination changes have been attributed to energy conservation (Arditti, 1979). However, the promotion of effective pollen deposition (outcrossing) is clearly the best explanation for scent change in this case, where pollinators must be duped not once but twice, and visits are rare events (Borg-Karlson, 1990).

Rather than altering in composition, fragrance may simply decline once pollination has taken place as the flower senesces, thus reducing herbivore attraction, discouraging ineffective pollen deposition, and conserving metabolic energy (Dudareva and Pichersky, 2000). In the orchid *Platanthera bifolia*, Tollsten observed a decrease in scent production just 24 hr after pollination, with a continual decline 2 and 5 d after, whereas the visual display remained unchanged for up to 1 wk (Tollsten and Bergström, 1989; Tollsten, 1993). The maintenance of floral display in *P. bifolia* suggests that factors besides energy conservation or floral senescence may mediate pollination-induced floral change in this orchid.

We sought to determine how the fragrance composition and total scent emissions might change in plants with generalized pollination biology. In such a system, postpollination signals are likely to act broadly on insect visitors rather than elicit behaviors from one specific pollinator. We conducted our study on two species of thistle, *Cirsium* (Asteraceae), whose flower heads attract and are pollinated by several species of insects. Would these thistles act similarly in spite of their different growing conditions, pollinator spectra, and fragrance chemistry? We sought to answer the following questions: (1) Are there pollination-induced changes in the floral scent in *C. arvense* and *C. repandum*? If so, what are the time scales and nature of these changes, i.e., are new compounds emitted, or does scent simply decline? (2) Do pollinators respond to changes in scent by avoiding pollinated flower heads? (3) Finally, in the absence of pollination, is senescence delayed and/or is the emission of fragrance enhanced as the risk of not getting fertilized increases?

METHODS AND MATERIALS

Natural History of Species. Cirsium repandum Michaux, sandhill thistle (Asteraceae), is native to the coastal plain of SE North America. It is an erect biennial or perennial that grows to 0.5–0.8 m tall and is found in sandy habitats common to North Carolina and South Carolina (Radford et al., 1968). Its range also includes parts of southeastern Virginia to eastern Georgia, but it is rare in these regions. The flower heads are protandrous, dark pink, with 1–5 flower heads per plant; flowering extends from May through July. Pollinators include Lepidoptera and Hymenoptera to a lesser degree. *C. arvense* (L.), Canada thistle, is also referred to as creeping thistle because of the creeping root system that leads to dense clonal stands. It is an erect perennial 0.3–2 m in height. *C. arvense* is an aggressive invasive species native to Europe, Western Asia, and North Africa, and was probably introduced into Canada in the early 17th century (Peschken and Derby, 1992). The plants have few to many flower heads comprising pink-purple disk flowers, which bloom from July through September and are pollinated by many species of generalist flower visitors in the orders Diptera, Hymenoptera, and Lepidoptera (Proctor et al., 1996).

Study Sites. C. repandum was studied at the Belle W. Baruch Institute of Coastal Ecology and Forest Science at the Hobcaw Barony located in Georgetown, SC, USA (79°18′W, 33°35′N). The field site is located in the shaded understory of a mixed loblolly pine and oak forest. *C. arvense* was studied at the U.S. Fish and Wildlife Wallkill River National Wildlife Refuge (Sussex, NJ, USA; 74°54′W, 41°26′N) established in 1990. Part of this refuge is situated on an old soccer camp, where our field site was located. The site is an open meadow with populations of both native and exotic invasive plants.

Hand Pollinations of C. repandum and C. arvense. To determine if there are pollination-induced changes in floral scent, flower heads restricted from natural pollination were hand-pollinated or kept unpollinated. Forty flower heads from each species of thistle—*C. repandum* and *C. arvense* (pistillate plants only)—were bagged in pairs just before florets had begun to emerge. Bags were made from insect screening 192 mesh (International Greenhouse Company, Sidell, IL, USA), with a strip of Velcro sewn at the base. In *C. repandum*, bagging began on June 10 and June 14, 2002. In *C. arvense*, bagging began on July 21 and July 23, 2002. Bagging occurred over 2 d to stagger data collection. Each flower head in a pair was randomly assigned to a pollination treatment. Three times a day, florets were brushed with cut flower heads that were producing pollen, and pollen-covered pipe cleaners. Bags covering unpollinated flower heads were similarly opened and reclosed three times a day to simulate the pollination treatment. Pollination manipulation was initiated on the 1st d that florets emerged and continued until all florets had emerged. The

two treatments, pollinated and unpollinated, were tested for pollination-induced changes either through observing pollinator behavior or scent changes (see below); flower heads were then rebagged and left to mature. Three wk after the experiment, flower heads were dissected, and the success of the pollination manipulation was established. Although *C. repandum* was not emasculated, self-fertilization did not occur in the unpollinated treatment.

Pollinator Observations. Half of the bagged pairs of flower heads were observed for differences in pollinator visitation. Observations were made 1 d after pistillate florets had entirely emerged, usually 2 d after pollinations began. Twenty flower heads from each species were unbagged and observed for 30 min at midday. All visitors and their bout lengths were documented to determine the number of visits per flower head, and the bout length for the two treatments. When possible, the pollinated and unpollinated treatments were observed simultaneously, otherwise observations were consecutive.

Scent Collections. To track postpollination scent changes, fragrance was collected from flower heads beginning after the entire flower head had emerged and had putatively entered the pistillate phase. All pollinations began as soon as the first florets emerged. In pistillate *C. arvense*, scent was collected after 24 hr, 1 d after the initial pollination (1 DAIP) and continuing until 3 d later (3 DAIP). In *C. repandum*, scent was collected on 2 DAIP and on 3 DAIP. In *C. arvense*, with the same sample size as *C. repandum*, we collected scent for 3 d, but only from an individual flower head for 2 consecutive d. From half of the plants we collected scent on 1 DAIP and on 2 DAIP. From the other half, we collected scent on 2 DAIP and on 3 DAIP. In *C. arvense*, pistillate maturation takes approximately 1 or 2 d. Therefore, in *C. arvense*, not all florets were necessarily pollinated in the pollination treatment on the 1st d of scent collection. In hermaphroditic *C. repandum*, pistillate maturation typically takes at least 2 d. We collected scent from *C. repandum only* after full pistillate maturity, which usually took place 48 hr after the initial pollination; we defined this day as 2 DAIP. Scent was collected from each individual flower head for 2 consecutive d.

Volatiles were collected using dynamic headspace sampling in the field. Intact flower heads were enclosed within a nylon resin oven bag (Reynolds Consumer Products, Richmond, VA, USA; Raguso et al., 2003). A glass cartridge was packed with 100 mg of the adsorbent Porapak Q (80–100 mesh). Ambient air was then pulled through an open hole into the bag across the flower head, through the cartridge and the adsorbent material at a flow rate of ca. 250 ml min^{-1} using a vacuum manifold, Air Check 52 or Air Check 2000 (SKC Inc., Eighty Four, PA, USA). Collections of ambient and vegetative volatiles allowed for identification of the floral compounds. Scent collections continued from 11:00 until 15:00 hr. Three flower heads were chosen to match the range of variation for the mass of the experimental plants. These prototypes were cut and dried (60°C) to estimate the dry weights. After a scent collection, cartridges

were eluted with 3 ml of hexane, at which time an internal standard of 3 μl of 0.01% anisole was added. After concentrating the samples to 75 μl, a 1-μl aliquot of sample was injected splitless onto a polar column [diam: 0.25 mm, length: 30 m, film thickness: 0.25 μm (EC WAX); Alltech Associates, Inc. Deerfield, IL, USA] at 240°C into Shimadzu gas chromatograph GC-17A equipped with a Shimadzu QP5000 quadrupole electron impact mass spectrometer as a detector. The carrier gas, helium, had a 1 ml min^{-1} flow rate and a split ratio of 12:1. The temperature program for the column began at 60°C for 3 min and was then ramped 10°C per min up to 260°C where it was held for 7 min. The pressure program was set at 60.6 (kPa) and then increased with a pulse of 400 (kPa) for 48 sec before returning to 60.6 for 2 min. Pressure was then increased at 3.9 (kPa) per minute until it reached 132.9 (kPa), where it was held for 7 min.

Compounds were identified through a combination of retention time (from previously injected standards) and mass spectral libraries [Wiley 1995 and NIST 1998 libraries (with more than 120,000 mass spectra)]. Quantification was achieved by relating mass ions of each scent compound to the mass ions of the internal standard, using previously run serial dilutions (Theis, 2003).

Statistical Analysis. Data were analyzed using SYSTAT 10.0 (Systat Software Inc., Richmond, CA, USA). For all scent data, neither relative amounts nor flux rates adhere to assumptions of normality, nor do insect distributions. Many of the compounds in the blend are produced by the same biosynthetic pathway and are correlated. In the absence of behavioral assays with specific compounds and/or blends, we expressed scent data in both relative amounts as well as flux rate: ng (g dry floral tissue)$^{-1}$ hr^{-1}. All compounds or compound classes (in the case of *C. repandum*) were tested for significant differences using the Mann–Whitney *U* test for pairwise comparisons. All *post-hoc* comparisons of individual days were tested using Bonferroni adjusted *P*-values (Sokal and Rohlf, 1995). In *C. arvense*, this resulted in a total of three *post-hoc* tests $\alpha < 0.017$, and two *post-hoc* tests for *C. repandum* $\alpha < 0.025$. A decline in scent due to aging was tested in unpollinated plants over days using the Mann–Whitney *U* test for *C. repandum*, and Kruskal–Wallis test for *C. arvense*. Pollinator visitation was analyzed using Fisher's exact test to differentiate between pollinated and unpollinated flower heads (received a visit/never visited). The Mann–Whitney *U* test was used for analyzing the number of pollinator visits and the bout lengths at pollinated and unpollinated flower heads.

RESULTS

Scent Reduction in C. repandum. Pollination of *C. repandum* flower heads resulted in a decrease in total scent production (Mann–Whitney *U* test, $U = 1.0$,

$P < 0.001$) (Figure 1; Tables 1 and 2). This drop was significant for either the relative or the absolute abundance of all five classes of compounds on 2 DAIP (1 DAIP was not recorded for this plant) (Table 2). Comparison of median flux rates from pollinated vs. unpollinated flower heads of the same age shows that pollination reduced scent production by 89% on 2 DAIP and by 92% on 3 DAIP. Age alone reduced scent by 43% in unpollinated flower heads (2 DAIP vs. 3 DAIP); this decline was restricted to the aromatics (Mann–Whitney U test, $U = 81.0$, $P = 0.003$). In pollinated plants, the decrease in total scent was a result of a decrease in three classes of compounds: aromatics, sesquiterpenoids, and 6-methyl-5-hepten-2-one, an irregular terpene, with the sharpest decline in the aromatics. The three dominant aromatic compounds, phenylnitroethane, phenylacetonitrile, and 2-phenylethanol, all decreased in flux rate based on pollination treatment (Table 1). In contrast, fatty acid derivatives did not decline with treatment and only some monoterpenoids declined. As a result, monoterpenoids and fatty acid derived compounds increased in relative abundance in pollinated flower heads, whereas compounds that did decline in flux rate maintained their relative abundance (except for 6-methyl-5-hepten-2-one, which declined in relative abundance).

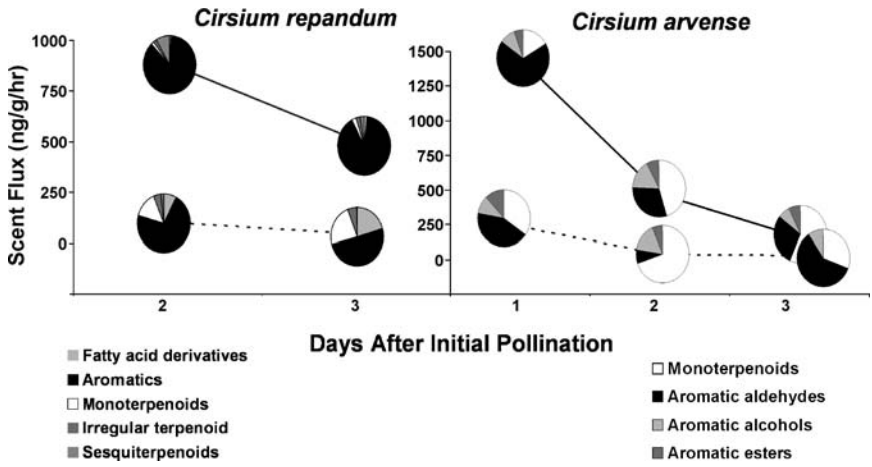

FIG. 1. Median postpollination scent changes in *Cirsium repandum* and pistillate *Cirsium arvense* beginning 1 d after the initial pollination. The solid line represents the total scent flux from unpollinated flower heads. The dashed line reflects scent flux from pollinated flower heads. Each pie graph depicts the relative contribution of the 13 compounds grouped into four classes for *C. arvense* and five classes for *C. repandum*. Sample sizes for *C. repandum*: pollinated 2 DAIP (9), 3 DAIP (9); unpollinated 2 DAIP (9), 3 DAIP (9). Sample sizes for *C. arvense*: pollinated 1 DAIP (5), 2 DAIP (10), 3 DAIP (5); unpollinated 1 DAIP (5), 2 DAIP (10), 3 DAIP (5).

C. arvense Scent Reduction. There was a reduction in total scent production in pistillate flower heads as a result of pollination (Mann–Whitney *U* test, $U = 54.0$, $P < 0.001$; Figure 1, Tables 3 and 4). One d after pollination (1 DAIP), scent from pollinated flower heads was 84% lower than scent from unpollinated flower heads. On 2 DAIP, scent from a pollinated flower head was 92% lower than from an unpollinated control, and 81% lower on 3 DAIP. These differences are attributable to the precipitous decline in scent produced by pollinated flower heads. Unpollinated flower heads also declined in scent production over time, although not as severely as pollinated ones; in fact, one anomalous unpollinated flower head increased in scent production from 2 DAIP to 3 DAIP. There was a decline of 89% in the median flux rate from an unpollinated flower head from 1 DAIP to 3 DAIP. This decline was significant only for phenylacetaldehyde (Kruskal–Wallis test, $df = 2$, $H = 6.21$, $P = 0.045$) and benzaldehyde ($H = 7.202$, $P = 0.027$, Table 4), aromatic compounds that dominate the floral scent blend in both pollinated and unpollinated *C. arvense* (Table 3). The greatest difference between the flux rates of pollinated and unpollinated flower heads occurred on 2 DAIP, when all 13 components of the scent blend were significantly lower in unpollinated flower heads (Table 4).

Pollinator Discrimination on C. repandum. Papilio palamedes accounted for 91% of all pollinator visits during the 30-min observation periods on pollinated and unpollinated flower heads of *C. repandum*. *P. palamedes* visited nine out of ten of the unpollinated flower heads and five out of nine of the hand-

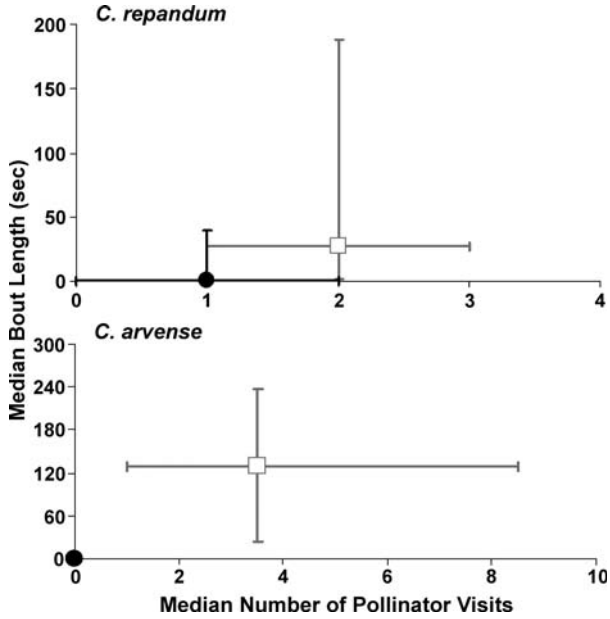

FIG. 2. Pollinator response to pollinated (●) and unpollinated (□) flower heads 2 d after initial pollination manipulation. The number of visits per flower head, per 30-min observation period, by the dominant pollinator (*P. palamedes* to *C. repandum*, *A. mellifera* to pistillate *C. arvense*) is shown (median, quartile). The bout length (sec), per 30-min observation period, by the dominant pollinator is also shown (median, quartile). In *C. repandum*, these response variables were not significant. In *C. arvense*, both bout length and the median number of pollinator visits were significant.

pollinated ones, but this difference was not significant ($P = 0.14$, two tailed Fisher's exact test). Other measures of pollinator preference, such as the number of pollinator visits and bout length, were not significantly greater at unpollinated flower heads (Mann–Whitney U test, pollinator visits: $U = 25.0$, $P = 0.095$, bout length: $U = 26.0$, $P = 0.11$; Figure 2).

Pollinator Discrimination on C. arvense. Pollinators discriminated between pollinated and unpollinated flower heads in *C. arvense*. The dominant visitor *Apis mellifera* made up 91% of all visits. *A. mellifera* visited 8 out of 10 of the unpollinated flower heads and only 2 out of 10 of the pollinated flower heads. This difference was significant ($P = 0.023$, two-tailed Fisher's exact test) as was the higher number of pollinator visits to unpollinated flower heads (Mann–Whitney U test, $U = 16.0$, $P = 0.007$), and longer bout length per visit (Mann–Whitney U test, $U = 15.5$, $P = 0.006$; Figure 2).

DISCUSSION

Fragrance emissions decreased in both *C. arvense* and *C. repandum* following pollination, whereas unpollinated plants maintained moderate levels of scent emissions. This decline is consistent with that demonstrated for the total scent blend in *Silene latifolia* (bladder campion) (Dötterl et al., 2005), the dominant component of *Nicotiana attenuata* (tobacco) (Euler and Baldwin, 1996), and both *Petunia hybrida* (petunia) and *Antirrhinum majus* (snapdragon), where pollen tubes reached the ovary at around 34 hr resulting in the decline of scent (Negre et al., 2003). In theory, scent compounds that are emitted at a higher flux rate following pollination could function as repellents (either to prevent additional pollinator visits or to deter predispersal seed predators). However, we did not detect any compounds emitted at significantly higher levels following pollination. In fact, in *C. arvense*, all components of the blend significantly declined following pollination. Interestingly, in *C. repandum*, the flux rate of the monoterpenoids and fatty acid derivatives did not decline as dramatically as in other classes, and the relative abundance of these classes increased. These compounds could potentially play a role in repellence of pollinators and herbivores. Given the chemical complexity of most floral scent blends, it cannot be assumed that all volatile components function solely as pollinator attractants (Raguso, 2003). Further tests of these compounds are necessary to determine if they have repellent qualities (e.g., Ômura et al., 2000). Perhaps it is not surprising that we did not detect novel repellent compounds following pollination in either thistle. Broadly repellent compounds are infrequently reported in the literature (Tollsten and Ovstedal, 1994), and, furthermore, compounds that have initially repellent properties can become attractive, as generalist insects show considerable plasticity, through learned behavior (Dobson, 1994). Repellent compounds emitted from pollinated plants, potentially informative to a variety of insects, could also inform herbivores of developing seeds.

Pollinators preferred to visit unpollinated flower heads. The most conservative estimate of pollinator behavior, whether or not a plant was visited at all, was consistent with other measures such as the "number of visitors", which may include pseudoreplication, and bout length, which is likely influenced by the amount of standing nectar. All three measures demonstrated a pollinator preference for unpollinated *C. arvense* plants. In *C. repandum*, there was more variation, and although there was a trend for pollinators to prefer unpollinated plants, these measures were not significant. A number of factors could account for the observed difference in pollinator discrimination between these two species of thistle. These thistle species have distinct pollinator guilds, different growing habits, and vastly different fragrance composition. *Post-hoc* explanations could be developed to explain the limited discrimination we observed on *C. repandum*, including the interplay between visual and olfactory floral cues

in swallowtail butterfly attraction (e.g., Wheiss, 1997). However, with a larger sample size, it is likely that we would be able to detect a significant preference for unpollinated flower heads of *C. repandum* by *P. palamedes*.

For the duration of this experiment, both species continued to produce scent from unpollinated flower heads, albeit at lower levels than unpollinated flower heads. Whereas scent in pollinated plants diminished almost entirely, scent from unpollinated plants declined but continued to be emitted; this decline was most apparent in the dominant aromatic compounds. Aging has a demonstrated degenerative effect on floral scent production (Tollsten, 1993; Pichersky et al., 1994; Dudareva et al., 1998). We speculated that scent might actually increase in unpollinated flower heads on the time scale of this experiment in order to solicit pollinators, but this was observed in just one flower head of *C. arvense*. In *C. repandum*, as unpollinated flower heads aged, there was a decrease in the relative abundance of the aromatics, including phenylacetaldehyde and phenylacetonitrile, compounds generally known to attract butterflies (Honda et al., 1998; Ômura et al., 1999; Andersson et al., 2002). We also observed a relative increase in the fatty acid derived compounds of the aging flower head, many of which are derived from the lipoxygenase pathway, and may convey a wound signal to insects (Hatanaka, 1993; Bate and Rothstein, 1998), including pollinators. Although we did not measure visitation to flower heads on the final day of the experiment, these changes are likely to have reduced discrimination between pollinated and unpollinated flower heads by *P. palamedes*. Our results suggest that there is a window of attraction for an aging flower head that has not yet been pollinated, albeit a brief one.

In both species of *Cirsium*, there appears to be a feedback mechanism for maintenance of the floral display based on pollination status. In dioecious *C. arvense*, this applies only to pistillate plants. In natural populations, staminate *C. arvense* flower heads do not demonstrate as dramatic a decline in scent production over time as pistillate flower heads do (Theis, 2003). In a prior study, we found that mature staminate flower heads, on average, emitted five times more scent per gram of dry tissue compared to pistillate flower heads. This difference increases dramatically to 9-fold in "past mature" flower heads (Theis, 2003). Feedback from pollination status (e.g., pollen tube growth or fertilization) in pistillate plants may be the mechanism behind the heightened disparity in scent production of older dioecious flower heads. Here, our results demonstrate that pollination can have direct impacts on floral longevity. In a literature survey, Primack (1985) found that for dioecious species there is more variation in floral longevity for pistillate than for staminate flower heads. Interestingly, two of the studies were performed in a greenhouse where zero variation is reported for pistillate flowers. Studies of floral longevity should take place under conditions matching those under which the plant is likely to have evolved, including pollinator assemblages (Ashman and Schoen, 1996). If pollination-induced

senescence is a factor for a given species, floral longevity will be directly related to pollination status. Results from our study demonstrate the importance of taking into account the effect of pollination in studies of floral longevity.

The proximate mechanism for a pollination-induced change has been identified as a coordinated genetic program involving ethylene, abscicic acid (ABA), and cytokinins (Van Staden et al., 1988; van Doorn, 1997; Chang et al., 2003); however, various explanations have been implicated to explain the ultimate mechanisms or the selection pressures that have led to these changes, including energy conservation and senescence physiology, herbivore avoidance, and pollinator signaling, or a combination of these factors (Gori, 1983). Of these, pollinator signaling for effective pollen transfer is the most common explanation. However, if pollinator efficiency were the driving force behind the cession of scent production in *C. arvense*, then like pistillate flower heads, staminate plants should also cease scent production after pollen has been removed. However, this is not the case. Older staminate flower heads lacking nectar or pollen continue to produce high levels of scent. In spite of this high emission rate, pollinators are not attracted to these flower heads either because of the altered ratios of the scent blend, or because of the visual changes that also occur (Theis, 2003). Perhaps the difference in scent production between staminate and pistillate flower heads could be better explained by energetics. Energy saving mechanisms may be more important in pistillate plants, as resources may be allocated away from scent production and toward seed production (Bierzychudek and Eckhart, 1988). However, the cost of the production of scent volatiles, which is measured in $\mu g\ d^{-1}$, is not very high and may not be as expensive to the plant as the potential ecological cost of attracting herbivores to developing seeds (Loughrin et al., 1992; Baldwin et al., 1997; Grison-Pige et al., 2001).

Floral herbivory, another explanation for pollinator induced scent changes, has largely been overlooked in understanding the evolution of floral display. In staminate *C. arvense*, the stage following pollen production is relatively impervious to harm, whereas after pollen has been deposited and fertilization has taken place, pistillate plants are vulnerable to herbivory. If pollinator visits are no longer required, scent emission is an unnecessary risk, and should be reduced. Therefore, decreased scent production following pollination in flowers would be crucial for pistillate plants, but not for staminate ones. Floral herbivores and their larvae can be very harmful by consuming or destroying floral tissue, pollen, and seeds (Augspurger, 1980; Louda and Potvin, 1995). Thus, although selection on floral display has typically been considered to be pollinator-mediated, floral herbivores may influence the evolution of floral traits directly, through tissue destruction, or indirectly, by deterring pollinators (Strauss, 1997; Krupnick et al., 1999).

In this work, we have presented the first nonorchid field experiment to quantitatively measure all of the components in the floral fragrance blend fol-

lowing pollination. We documented a clear pattern of decreased floral scent production following pollination. Flower heads that were not pollinated continued to produce moderate levels of scent. In *C. arvense*, the dominant pollinator *A. mellifera* preferentially visited those flower heads. In our analysis, we found no novel compounds emitted following pollination and no clear candidates for repellency. Scent production is just one component of the floral display, and both nectar reduction and color change also contribute to the apparency of the flower head. To measure the relative importance of olfactory display to reproductive fitness, we have undertaken field experiments with behavioral assays that manipulate scent quality while controlling for visual cues and nectar (Theis, 2003).

Abstract—The growth–differentiation balance hypothesis (GDBH) postulates that variation in resource availability can increase or decrease allocation to secondary metabolism, depending on how growth is affected relative to carbon assimilation. Growth and leaf area of black poplar (*Populus nigra*) increased substantially in response to increased nutrient availability, while net assimilation rate and photosynthesis were less strongly affected. In response, total phenolic glycoside concentrations declined, which is consistent with GDBH. Drought stress decreased net assimilation rate and photosynthesis as well as growth, while increasing total phenolic glycoside concentrations. This pattern does not follow GDBH, which predicts lower secondary metabolism when resource limitation decreases both growth and carbon assimilation. However, there was a strong negative correlation between growth and total phenolic glycoside concentration consistent with a trade-off between primary and secondary metabolism, a key premise of GDBH. Drought decreased the growth of gypsy moth (*Lymantria dispar*) larvae but had no effect on white-marked tussock moth (*Orgyia leucostigma*). Increased nutrient availability had a positive linear effect on growth of whitemarked tussock moth, but no effect on gypsy moth. Treatment effects on gypsy moth corresponded closely with effects on total phenolic glycosides, whereas effects on whitemarked

* To whom correspondence should be addressed. E-mail: bethanhale@yahoo.co.uk

tussock moth more closely tracked changes in nutritional quality. Localized gypsy moth herbivory elicited rapid induced resistance to gypsy moth, with the effect being independent of water and nutrient availability, but did not affect whitemarked tussock moth, indicating that the effects of biotic and abiotic stress on insect resistance of trees can be species-specific.

Key Words—Growth–differentiation balance hypothesis, resource availability, allocation, phenotypic plasticity, gypsy moth, whitemarked tussock moth.

INTRODUCTION

Some studies have shown drought stress to increase secondary metabolism and decrease host quality of trees for insect herbivores (Ross and Berisford, 1990; Craig et al., 1991; Mopper and Whitham, 1992), whereas others have found the opposite (Wagner, 1986; Cobb et al., 1997; Roth et al., 1997). Fertilisation also has been shown to have divergent effects on the secondary metabolites of woody plants (Kytö et al., 1996; Koricheva et al., 1998a; Herms, 2002). The growth–differentiation balance hypothesis (GDBH) (Loomis, 1932; Lorio, 1986; Herms and Mattson 1992) provides a potential explanation by predicting a quadratic response of constitutive secondary metabolism across a resource gradient. Thus, increased resource availability can either increase or decrease secondary metabolite concentrations, depending on the initial status of the plant (Herms and Mattson, 1992).

Rapidly growing plants are predicted by GDBH to have low secondary metabolite concentrations as a result of a resource-based trade-off between primary and secondary metabolic pathways. However, moderate water or nutrient limitation slows growth more than carbon assimilation (Bradford and Hsiao, 1982; Luxmoore, 1991), which can result in the accumulation of carbohydrates in source leaves (Wardlaw, 1990; Geiger et al., 1996). This may increase the substrate available for secondary metabolism (Waterman and Mole, 1989), resulting in a negative correlation between growth and secondary metabolites (Herms and Mattson, 1992). However, when resource limitation is severe enough to depress carbon assimilation, secondary metabolism is predicted to fall because of energy and substrate constraints on biosynthesis. In this case, increased resource availability is predicted to increase both growth and secondary metabolite concentrations, generating a positive correlation between them (Herms and Mattson, 1992). Few studies have simultaneously quantified carbon assimilation rate, growth, and secondary metabolism across a range of conditions, which is necessary to test predictions of GDBH (Stamp, 2003, 2004).

Differential effects of resource availability on constitutive and induced resistance could influence host quality for herbivores (Lewinsohn et al., 1993;

Lerdau et al., 1994; Lombardero et al., 2000; Glynn et al., 2003). Rapid induced resistance is a form of host resistance in response to herbivory that impinges on insect generation causing the damage (Haukioja, 1990). The few studies that have addressed the effects of nutrient availability on rapid induced resistance of woody plants show that results vary depending on plant (Hunter and Schultz, 1995; Mutikainen et al., 2000) and insect species (Glynn et al., 2003). To our knowledge, effects of drought on rapid induced resistance of woody plants to folivores have not been investigated.

The objectives of this study were to test predictions of GDBH by quantifying effects of water and nutrient availability on carbon assimilation, growth, and total foliar phenolic glycoside concentration of black poplar, *Populus nigra* (L.), and on constitutive and rapid induced resistance to gypsy moth, *Lymantria dispar* (L.), and whitemarked tussock moth, *Orgyia leucostigma* (Smith).

MATERIALS AND METHODS

On March 29, 2003, 250 cuttings of the black poplar clone NC5271 were taken from stock plants, wrapped in moist paper, and stored at 4°C. Relative to other poplar clones, NC5271 is one of the fastest growing (Robison and Raffa, 1994) and most inducible to various elicitors including gypsy moth feeding (Havill and Raffa, 1999). Ten d later, cuttings were removed from storage, dipped into Hormex Rooting Powder No. 3® (Brooker Chemical, Hollywood, CA, USA) (0.3% indole-3-butyric acid), planted in Premier ProMix BX® (Premier Horticulture Ltd., Dorval, Quebec, CA) and maintained in a greenhouse (25°C, 12:12 L/D cycle). On May 16, rooted cuttings were transplanted to 10 l plastic pots containing the same medium and transferred to an outdoor nursery under 50% shade cloth to acclimate.

On June 2 (d 1), 180 of the most uniform cuttings were sorted into five blocks of 36, with assignment based on height and number of apical shoots. To quantify initial biomass and total leaf area, six plants in each block were selected at random for immediate harvest. Stems and foliage were harvested by cutting plants at ground level, and roots were extracted from container media with minimal damage using a low-pressure, high-volume air stream (Air Spade®, Concept Engineering Group, Inc., Verona, PA, USA). Shoots, leaves, and roots were oven-dried at 60°C for 96 hr and weighed to the nearest milligram. The remaining 150 plants were transferred to an outdoor gravel bed in full sunlight, where the 30 plants in each block were subjected to one of three fertilisation levels.

Fertility treatments were initiated by means of a computer-controlled fertigation (irrigation and fertilisation) system (Hansen et al. 2000): 30, 75, and 150 ppm N, with $N/P_2O_5/K_2O$, supplied in a ratio of 3:1:2 from calcium nitrate,

monoammonium phosphate, and potassium nitrate. Each plant was irrigated with 0.5 l of nutrient solution whenever the potting medium moisture tension (PMMT) dried to −4 kPa, as recorded by computer-monitored tensiometers (15 cm Mini "LT" Remote Sensing Units (0–25 kPa); Irrometer Company, Inc., Riverside, CA, USA) installed in one pot per treatment in the block containing the largest plants, because they dried out the fastest. Tensiometers, which were positioned to a depth of 8 cm midway between the pot wall and the plant, were also installed in one pot per treatment in two additional randomly selected blocks. This resulted in one tensiometer per treatment combination in three of five blocks, which provided a continuously monitored, experiment-wide estimate of mean PMMT for each treatment. On July 22 (d 51), 10 plants from each fertility treatment were destructively harvested as described above, with two selected randomly from each block, leaving a total of 120 plants in the experiment.

On July 24 (d 53), a drought-stress treatment was applied to half of the remaining plants in each fertility treatment by withholding irrigation until PMMT reached −25 kPa, whereas the rest were irrigated as described above, resulting in two discrete treatments that were maintained over the next 75 d. The irrigation of drought-stressed plants was controlled using scheduled events ($\approx$200 ml pot^{-1} event^{-1}), with approximately four daily events required to maintain PMMT at the required levels. Well-watered plants continued to be irrigated according to PMMT as described above. Tensiometer readings showed that mean PMMT of well-watered and drought-stressed plants generally remained between −3 and −4 kPa and −10 and −25 kPa, respectively, with precipitation having little effect (Figure 1).

On September 10 (d 101), half the plants in each treatment combination were randomly assigned a short-term, localized herbivory treatment designed to elicit rapid induced resistance. Three fourth-instar gypsy moths were confined within mesh sleeves on leaves 4–7 on the terminal shoot, with leaf 1 designated as the youngest leaf longer than 2 cm. Larvae were allowed to feed until at least 80% of the enclosed leaves had been consumed on all plants, whereupon sleeves and insects were removed. To control for potential effects of the enclosures on induced responses, corresponding leaves on the remaining (constitutive) plants were also enclosed by sleeves containing no larvae.

All remaining plants were harvested on October 7 (d 128). Thus, the first 52 d of the experiment consisted of three fertility treatments, whereas the final 75 d consisted of a 3 × 2 × 2 complete factorial design, with three fertility, two irrigation, and two defoliation treatments, with each of 12 treatment combinations replicated 10 times within each of five blocks, for a total of 120 plants.

Plant Growth and Dry Matter Allocation. Growth analysis (Hunt, 1978; Lambers and Poorter, 1992) was used to document treatment effects on plant relative growth rate and dry matter allocation. Relative growth rate (mg g^{-1} d^{-1}) was calculated as [(ln(final total mass − *ln*(initial total mass)] / time], with

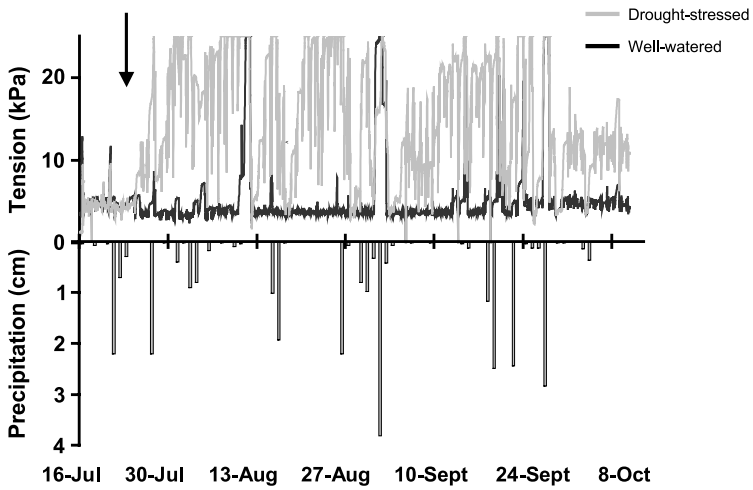

FIG. 1. Potting medium moisture tension (PMMT) for well-watered (dark line) and drought-stressed (gray line) plants over the course of the experiment (upper *y*-axis) and daily precipitation over the experimental period (lower *y*-axis). The arrow indicates date of initiation of the irrigation treatment.

initial and final mass determined from destructive harvests as described above. Specific leaf mass (g m^{-2}) was determined by measuring the area and dry weight of the leaves sampled for nitrogen analysis (described below). Leaf area was measured using a LI-3100 area meter (LI-COR, Inc., Lincoln, NE, USA). The dry weight of foliage sampled for foliar nitrogen and phenolic glycoside analyses (described below) was added to that subsequently obtained from the whole plant harvest. Total leaf area per plant (m^2) was estimated as total leaf biomass / specific leaf mass. Leaf area ratio (m^2 g^{-1}) was calculated as the quotient of total leaf area / total plant mass, and net assimilation rate (g m^{-2} d^{-1}) as relative growth / leaf area ratio. Percent root mass was calculated as (root mass / total plant mass) $\times$ 100. Initial mass for each plant (used to calculate relative growth rate and net assimilation rate) was estimated as the treatment mean for each block at the beginning experiment, as determined from destructive harvests before initiation of treatments.

Photosynthesis. Light-saturated net photosynthesis (μmol CO_2 m^{-2} sec^{-1}) was measured on d 23 and 48 (June 24 and July 19) prior to initiation of the drought-stress treatment on d 53, and on d 72 and 100 (August 12 and September 9) after initiation of the drought stress. Measurements were made using a portable photosynthesis system (LI-6200, LI-COR, Inc. Lincoln, NE, USA) on fully expanded, undamaged leaves from randomly selected plants, on cloud-free mornings between 08:30 and 11:30 EDT. Sample sizes were 10 for

each fertility treatment (two replicates from each block) on d 23 and 48 and five for each fertility–irrigation treatment combination (one replicate per block) on d 72 and 100.

Phytochemistry. To quantify the effects of nutrient and water availability on foliar nitrogen and phenolic glycoside concentrations, a subset of foliage was sampled just prior to whole-plant harvests on d 51 from all harvested trees and on d 128 from all trees not subjected to the defoliation treatment. For foliar nitrogen analysis, every fourth leaf was sampled from all branches on the tree. Leaves were dried at 60°C and then ground in a mill (Cyclotec EC 1093, Tecator AB, Hoganas, Sweden) to pass through a 0.4-mm mesh screen. Total foliar nitrogen content (mg g^{-1}) was determined using a Carbo Erba CNH analyser, Model NA 1500 (Daun and DeClerq, 1994). For foliar phenolic glycoside analysis, 12–15 fully expanded, undamaged leaves were sampled from between leaf positions 10–20 on random branches. Leaves were immediately frozen in liquid nitrogen and placed on ice before being transported to the laboratory where they were freeze-dried at −4°C within 1 hr of sampling. Dried leaves were subsequently ground to pass through a 0.4-mm mesh screen as described above.

Tremulacin and salicortin are dominant phenolic glycosides in *Populus* species (Lindroth et al., 1987; Clausen et al., 1989a,b; Lindroth and Hwang, 1996). We quantified their combined concentration using gas chromatography by first converting their cyclohexan-5-ene-2-one-1-ol carboxylate moiety to the volatile compound methyl 2-methoxybenzoate by extracting 1 g of each sample in 15 ml anhydrous methanol containing 2 mg of capric acid as an internal standard. Capric acid is converted to methyl decanoate under the reaction conditions, which has a similar retention time to that of methyl 2-methoxybenzoate. The solution was left to stand overnight, after which extracts were decanted and two drops (about 100 mg) of 98% sulfuric acid were added. After being left to stand for 12 d at room temperature, extracts were analysed using a Hewlett-Packard 6890 gas chromatograph equipped with a flame ionization detector and a 30 m × 0.25 mm bonded EC-1 column with a 0.25-μm film thickness (Alltech, Deerfield, IL, USA). The injector and detector temperatures were held at 275 and 300°C, respectively, the He flow rate was 2.5 ml min^{-1}, and the temperature program was set at 60°C for 3 min, 60–100°C at 7°C min^{-1}, 100–150°C at 5°C/min, and 150°C for 2 min. In all runs, 1.0 μl of sample was injected (splitless mode). Methyl 2-methoxybenzoate and methyl decanoate eluted at 12.62 and 12.47 min, respectively. Total phenolic glycoside concentration (mg g^{-1} dry weight) was calculated by summing the molar quantities of the two individual compounds (tremulacin plus salicortin) and expressing this as the percent mass of an equivalent molar amount of salicortin.

Insect Bioassays. Laboratory bioassays were conducted with first instar gypsy moth and whitemarked tussock moth to quantify treatment effects on

constitutive and induced resistance. Eggs of both species were obtained from the Canadian Forest Service, Insect Production Laboratory, Sault St. Marie, Ontario, CA. Three d after termination of the defoliation treatment, the two leaves immediately distal to those that had been confined in mesh sleeves were detached from plants and placed in separate Petri dishes (15 cm diam) with five neonate larvae of one of the two species. Larvae were reared in a growth chamber at 25°C with a 16:8 (L/D) photoperiod. To control for ontogenetic variation, half of the replicates for each insect species within a treatment combination received the oldest leaf (position 3), and the other half received the youngest (position 2). A plaster base in each dish saturated with distilled water throughout the bioassay maintained high humidity and leaf turgor. The five larvae in each Petri dish were weighed as a group at the start of the bioassay and again 72 hr later. Mean larval weight was calculated by dividing total weight by number of larvae. Larval growth (mg) was calculated as the difference between mean final and mean initial mass.

Data Analyses. Treatment effects on plant and insect variables were analysed using ANOVA (PROC GLM, Type III sums of squares; SAS Institute, Inc., 2000). All responses met assumptions of normality of residuals and homogeneity of variance. Data are reported as least square means ± 1 SE. Linear and quadratic contrasts were calculated to characterise significant effects of fertility level on treatment means (Chew, 1976; Mize and Schultz, 1985), with coefficients for the unequally spaced treatments calculated according to Robson (1959). Pearson correlation coefficients (PROC CORR; SAS Institute, Inc., 2000) were used to quantify relationships between dependent variables.

RESULTS

Plant Growth and Biomass Allocation. At the intermediate harvest on d 51, nutrient availability had significant linear and quadratic effects on plant growth and biomass allocation (Table 1). Total plant biomass, relative growth rate, and total leaf area increased by 50, 12, and 75%, and percent root mass and specific leaf mass decreased by 16 and 9%, respectively, as fertilisation rate increased from low to high (Table 2). Nutrient availability had no effect on net assimilation rate (Tables 1 and 2).

At the final harvest on d 128, nutrient availability continued to have significant linear effects on total leaf area and percent root mass. However, the effects of fertility on total plant biomass and relative growth rate varied within the two irrigation treatments (significant quadratic effect and fertility × irrigation interaction) (Table 3). The effect of nutrient availability of total plant mass was stronger in the drought stress than in the well-watered treatment,

TABLE 1. *F* VALUES FROM ANOVA FOR GROWTH AND DRY MATTER ALLOCATION OF POPLAR, *Populus nigra*, IN RESPONSE TO THREE FERTILITY LEVELS FOR 50 DAYS

Response variable	Fertility—main effect	Fertility—linear contrast	Fertility—quadratic contrast	Error *df*
Total biomass (g)	20.1***	35.9***	5.3*	22

increasing 95 and 42%, respectively, as fertility increased from low to high (Table 4). In the drought-stress treatment, relative growth rate increased 29% as fertility increased. However, in the well-watered treatment, relative growth rate was less than 9% higher in the intermediate than in both the high and low fertility treatments (Table 4). When averaged across the two irrigation treatments, total leaf area increased 28% and percent root mass decreased 12% as fertility level increased from low to high (data pooled from Table 4). The effects of fertility on net assimilation rate were also dependent on the irrigation treatment (significant fertility × irrigation interaction). Nutrient availability had no effect on the net assimilation rate of drought-stressed plants, but had a quadratic effect on the well-watered plants, it being 11 and 24% higher in the intermediate treatment than in the high and low fertility treatments, respectively. Nutrient availability had no effect on specific leaf mass on d 128 (Tables 3 and 4).

Water availability had stronger effects on all measures of dry matter allocation compared to nutrient availability (Table 3). Relative to drought-stressed plants, the total biomass, relative growth rate, total leaf area, and net

assimilation rate of well-watered plants were 148, 78, 170, and 76% higher, respectively, when averaged across all three fertility levels (data pooled from Table 4). Percent root mass of drought-stressed plants was 9% higher than for well-watered plants (data pooled from Table 4). In the two lowest fertility levels (30 and 75 ppm N), specific leaf mass was 15 and 22% higher in the well-watered relative to drought-stressed plants, respectively, but was not affected by irrigation in the high fertility (150 ppm N) treatment (fertility × irrigation interaction) (Tables 3 and 4).

Photosynthesis. Nutrient availability had no effect on photosynthesis on d 23, but had a positive linear effect on d 48 (Table 5) when photosynthesis rate was 28% greater in the high relative to the low fertility treatment (Table 6). On d 72, 19 d after the initiation of drought stress, neither treatment had any significant effect on photosynthesis (Table 5). However, on d 100, drought stress significantly decreased photosynthesis rate by 51% relative to the well-watered plants, whereas nutrient availability had a significant positive linear effect on photosynthesis across both irrigation levels, being 55% greater in the high relative to the low fertility treatment (Table 5, data pooled from Table 6). There were no significant interacting effects of the irrigation and fertility treatments on photosynthesis, and no significant quadratic effects of fertility (Table 5).

Phytochemistry. Foliar nitrogen content significantly increased with nutrient availability on both harvest dates and was decreased by drought stress on the final harvest date (Table 7). On d 51, foliar nitrogen concentrations averaged 30 ± 1, 36 ± 1, and 39 ± 1 mg g^{-1} for the 30, 75, and 150 ppm N fertility treatments, respectively. On d 128, foliar nitrogen concentrations of well-watered plants averaged 33 ± 1, 38 ± 1, and 36 ± 0.1 mg g^{-1} for the 30, 75, and

150 ppm N fertility treatments, respectively. However, the foliar nitrogen concentrations for the drought-stressed plants averaged only 25 ± 1, 28 ± 1, and 31 ± 1 mg g^{-1}, respectively, as fertility increased.

On d 51, total phenolic glycoside concentrations were not affected by nutrient availability (Table 7). However, on d 128, fertility had a significant negative linear effect on total phenolic glycoside concentrations, with concentrations decreasing by 32%, averaged across both irrigation treatments, as fertilisation rate increased (data pooled from Figure 2). However, this effect was small compared to the larger effect of the irrigation treatment (Table 7), total phenolic glycoside concentrations being 89% higher in the drought-stressed relative to the well-watered plants (data pooled from Figure 2). There was no significant interaction between the drought stress and fertility treatments on total phenolic glycoside concentration (Table 7). Total phenolic glycoside concentrations were negatively correlated with total plant biomass (Figure 3).

TABLE 6. MEAN (±SE) NET PHOTOSYNTHETIC RATE (μ mol CO_2 m^{-2} sec^{-1}) OF POPLAR, *P. nigra*, IN RESPONSE TO THREE FERTILITY LEVELS ON DAYS 23 AND 48 AND THREE FERTILITY LEVELS CROSSED WITH TWO IRRIGATION LEVELS ON DAYS 72 AND 100

Insect Bioassays. Drought stress significantly reduced the growth of first instar gypsy moth ($F_{1,100} = 42.01$, $P < 0.001$), which was 36% higher on well-watered plants (data pooled from Figure 4a). Previous defoliation by fourth instar gypsy moth also decreased the growth of first instar gypsy moth ($F_{1,100} = 12.46$, $P < 0.001$), which was 27% higher on the nondefoliated than on the induced plants (data pooled from Figure 4a). Rapid induced resistance to gypsy moth was expressed in both well-watered and drought-stressed trees and across all levels of

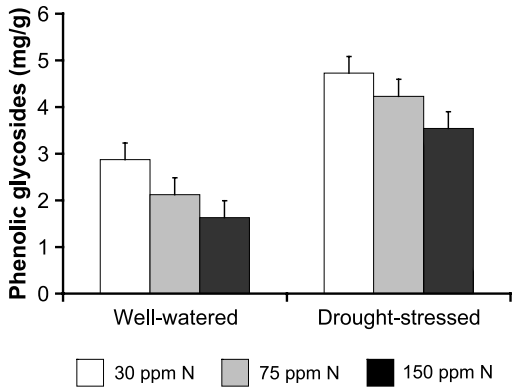

FIG. 2. Mean (±SE) total foliar phenolic glycoside concentration of poplar, *Populus nigra*, in response to three fertility levels for 52 d followed by three fertility levels crossed with two irrigation levels for 75 d. $P = 0.002$ for linear effect of fertility and $P < 0.001$ for main effect of irrigation; interaction, not significant.

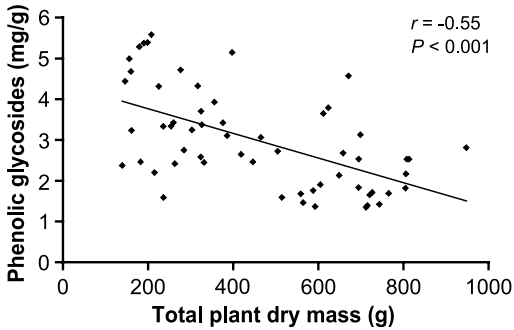

FIG. 3. Correlation between total biomass of poplar, *P. nigra*, and total foliar phenolic glycoside concentration in response to three fertility levels for 52 d followed by three fertility levels crossed with two irrigation levels for 75 d.

the fertility treatment (no significant interaction between defoliation and either the irrigation or fertility treatments). However, neither the irrigation nor the defoliation treatments had any effect on whitemarked tussock moth growth (Figure 4b). Fertility had no effect on gypsy moth growth, but growth of whitemarked tussock moth increased linearly as fertility increased ($F_{1,98}$ = 6.16, P = 0.015), being 18% greater in the high relative to the low fertility treatment (data pooled from Figure 5).

DISCUSSION

The patterns we observed conformed only in part with those predicted by GDBH (Herms and Mattson, 1992). Plant responses to nutrient availability were consistent, but effects of water availability diverged to some degree from responses predicted by GDBH. Consistent with GDBH, plant growth was more sensitive to nutrient availability than was carbon assimilation, as indicated by larger effects of the fertility treatment on plant biomass and leaf area than on net assimilation rate and photosynthesis. In response, total phenolic glycoside concentrations declined as nutrient availability increased. This observation is also consistent with previous studies on congeneric quaking aspen, *Populus tremuloides* (Michx.), in which phenolic glycoside concentrations also decreased as nutrient availability increased (Bryant et al., 1987; Hemming and Lindroth, 1999).

Plant responses to drought did not correspond as closely with the predictions of GDBH. Concentrations of total phenolic glycosides were low in the fast-growing, well-watered plants which is consistent with GDBH. However,

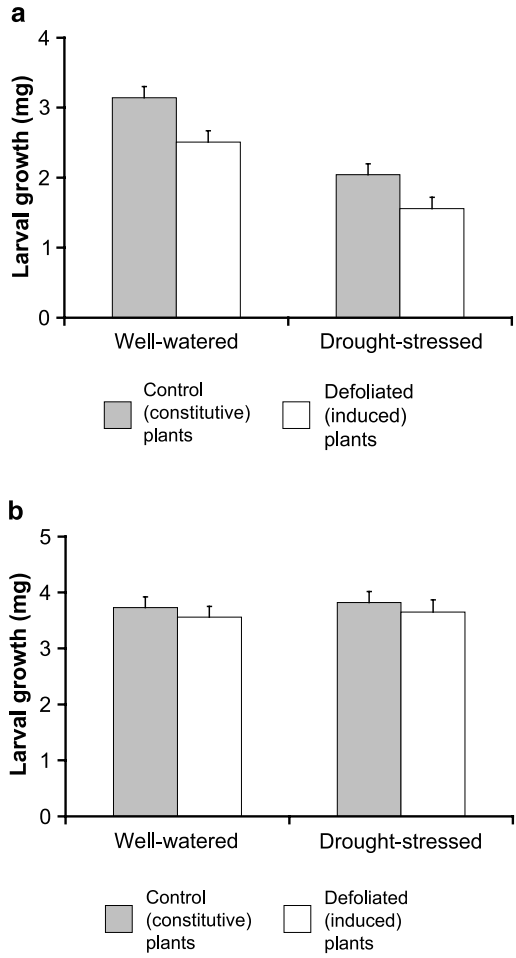

FIG. 4. Effects of short-term, localized gypsy moth herbivory and water availability on mean growth (±SE) of first instar (a) gypsy moth and (b) whitemarked tussock moth on poplar, *P. nigra*. For gypsy moth, $P < 0.001$ for main effect of irrigation and $P < 0.001$ for main effect of defoliation, interaction not significant; for whitemarked tussock moth, no effects significant. Data pooled across fertility treatments.

the high concentrations of total phenolic glycosides observed in response to drought stress were not consistent with GDBH, as both growth and carbon assimilation (as indicated by net assimilation rate and photosynthesis) were substantially reduced. In this contingency, GDBH predicts that foliar secondary metabolite concentrations should also decrease (Herms and Mattson, 1992). The

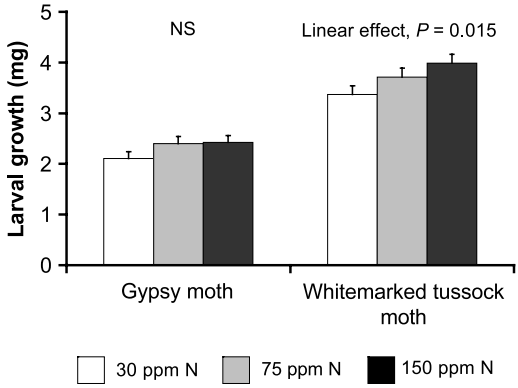

FIG. 5. Effects of fertility on mean growth (±SE) of first instar gypsy moth and whitemarked tussock moth on poplar, *P. nigra*. NS indicates effect is not significant. Data pooled across watering and defoliation treatments.

high total phenolic glycoside levels in drought-stressed plants contributed to a strong negative correlation with growth, which is consistent with the trade-off between primary and secondary metabolism predicted by GDBH (Herms and Mattson, 1992). Conclusions regarding effects on total phenolic glycoside concentration were not affected by expressing the data on a leaf area basis (mg cm^{-2}), as water and nutrient availability had smaller effects on specific leaf mass than on total phenolic glycoside content. Hence, treatment effects were attributable to changes in phenolic glycoside biosynthesis *per se*, rather than dilution or concentration effects resulting from variation in dry matter accumulation (Koricheva, 1999). Phenolic glycosides have been implicated as anti-Lepidoptera defences of *Populus* (Hemming and Lindroth, 1995, 2000; Hwang and Lindroth, 1997), and the adaptive advantage of high levels of defence was maintained even when drought-stressed plants were constrained by a smaller carbon budget, which would substantially increase the cost of producing and maintaining secondary metabolites. Contrary to our results, Roth et al. (1997) observed drought stress to decrease phenolic glycoside concentrations of quaking aspen.

Some studies have shown high fertility levels to amplify the negative effects of drought stress on plants (Walters and Reich, 1989; Miller and Timmer, 1994; Power et al., 1998) through such mechanisms as increased soil matric potential (Jacobs et al., 2004) or decreased root/shoot ratios (Linder and Rook, 1984; Linder et al., 1987), therefore, also potentially increasing the effects of drought stress on secondary metabolism and herbivore performance. However, we observed no evidence to support this hypothesis, even when plants were preconditioned to their respective nutrient treatment for 52 d prior

to exposure to drought stress. We did not observe a proportional reduction in growth of high fertility relative to low fertility plants when they were subjected to drought, nor were the nature of fertility × irrigation interactions on phytochemistry and insect performance consistent with enhanced effects of drought stress. Although percent root mass declined in response to increased nutrient availability, drought stress increased percent root mass, which may have had a counteracting effect. Both responses are consistent with theories of adaptive phenotypic plasticity (Bloom et al., 1985; Hirose, 1987; Ingestad and Ågren, 1991, 1992), which predict that plants will shift their allocation patterns in varying environments to increase acquisition of growth-limiting resources.

Outbreaks of phytophagous insects have been linked to droughts (Mattson and Haack 1987), although effects may be specific to particular feeding guilds (Larsson, 1989; Koricheva et al., 1998b; Huberty and Denno, 2004). This study did not provide any evidence to support the hypothesis that drought stress enhances folivore performance (White, 1984). In contrast, drought stress decreased the growth of gypsy moth, perhaps because drought also decreased foliar nitrogen and increased total phenolic glycoside concentrations, both of which are key determinants of gypsy moth performance on quaking aspen (Lindroth and Hemming, 1990; Hemming and Lindroth, 2000; Osier et al., 2000). Decreased foliar water content may also have contributed to lower insect performance (Scriber, 1977).

In contrast, drought stress had no effect on the growth of whitemarked tussock moth, perhaps because this species is less sensitive than gypsy moth to changes in phenolic glycosides, as whitemarked tussock moth has been shown to be relatively insensitive to other phenolic compounds (Karowe, 1989; Kopper et al., 2002). Environmental variation does not affect all secondary metabolites within a plant in the same way (Muzika, 1993; Reichardt et al., 1991; Kainulainen et al., 1996), which could also generate complex patterns of herbivore response. In two willow species, condensed tannin levels were decreased by mild drought, whereas simple phenolic compounds were not affected (Glynn et al., 2004). Additionally, positive effects of drought on nutritional quality, such as increases in free amino acids, soluble proteins, and soluble carbohydrates (Brodbeck and Strong, 1987; Mattson and Haack 1987), may counteract negative effects of increased secondary metabolite levels (Glynn et al., 2004). Nutrient availability had a positive linear effect on whitemarked tussock moth growth and foliar nitrogen, but had no effect on gypsy moth. This overall pattern of treatment effects on these two species is consistent with relatively high sensitivities of whitemarked tussock moth to nutritional quality and gypsy moth to phenolic glycosides.

Differential effects of resource availability on constitutive vs. induced resistance may be an important source of variation in herbivore performance (Lewinsohn et al. 1993; Lerdau et al. 1994; Lombardero et al., 2000). We are

not aware of other studies concerning effects of water availability on the expression of rapid induced resistance of woody plants to folivores, and are aware of only a few that have examined nutrient availability, all of which revealed some effect (Hunter and Schultz, 1995; Mutikainen et al., 2000; Glynn et al., 2003). In this study, however, rapid induced resistance to gypsy moth was not influenced by resource availability, it being expressed in all treatments. This study therefore emphasizes the difficulty in generalising about the effects of abiotic and biotic stress on host quality, even for insects within the same family.

Acknowledgments—We thank two anonymous reviewers for constructive comments that improved the article. Jeremy Christman and Adam Clark helped maintain the fertigation system. Bryant Chambers, Ann Hale, Richard Hale, Diane Hartzler, James Howell, Cathy Love, Cassie Mahl, Ben Marthey, Kyle Theibert, and John Watson aided with field and laboratory work. Bruce Birr (USDA Forest Service, Rhinelander, WI, USA) conducted the nitrogen analysis. Howard Lin contributed toward the technique used to analyse phenolic glycosides. Salaries and research support were provided by State and Federal funds appropriated to the Ohio Agricultural Research and Development Center, The Ohio State University.

PLANT SURFACE PROPERTIES IN CHEMICAL ECOLOGY

CAROLINE MÜLLER* and MARKUS RIEDERER

Julius-von-Sachs-Institut für Biowissenschaften, Universität Würzburg, Julius-von-Sachs-Platz 3, D-97082 Würzburg, Germany

(Received February 21, 2005; revised May 23, 2005; accepted June 29, 2005)

Abstract—The surface of the primary aerial parts of terrestrial plants is covered by a cuticle, which has crucial autecological functions, but also serves as an important interface in trophic interactions. The chemical and physical properties of this layer contribute to these functions. The cuticle is composed of the cuticular layer and the cuticle proper, which is covered by epicuticular waxes. Whereas the cutin fraction is a polyester-type biopolymer composed of hydroxyl and hydroxyepoxy fatty acids, the cuticular waxes are a complex mixture of long-chain aliphatic and cyclic compounds. These highly lipophilic compounds determine the hydrophobic quality of the plant surface and, together with the microstructure of the waxes, vary in a species-specific manner. The physicochemical characteristics contribute to certain optical features, limit transpiration, and influence adhesion of particles and organisms. In chemical ecology, where interactions between organisms and the underlying (allelo-) chemical principles are studied, it is important to determine what is present at this interface between the plant and the environment. Several useful equations can allow estimation of the dissolution of a given organic molecule in the cuticle and its transport properties. The implementation of these equations is exemplified by examining glucosinolates, which play an important role in interactions of plants with other organisms. An accurate characterization of physicochemical properties of the plant surface is needed to understand its ecological significance. Here, we summarize current knowledge about the physical and chemical properties of plant cuticles and their role in interactions with microorganisms, phytophagous insects, and their antagonists.

INTRODUCTION

The plant surface is bordered by a cuticle, which plays an important role in the physiology and autecology of the plant, but also serves as the first contact zone in interactions of plants with other organisms at all trophic levels. The cuticle covers all aerial parts of higher plants, i.e., stems, leaves, petals, and fruits, with the exception of stems that have undergone secondary growth. It is a continuous layer where the only gaps are the pores of the stomata. To understand the different ecological functions of the cuticle, it is important to understand its chemical and physical nature. Current knowledge of such properties enables us to evaluate cues on the outer surface that are used by microorganisms or insects. For example, early work by Bernays et al. (1976) showed already in the 1970s that locusts and grasshoppers can discriminate between susceptible and nonsusceptible plants simply by contact of their chemoreceptors with surface waxes.

The physical structure and chemical composition of the cuticle have been subjects of earlier reviews (e.g., Jeffree, 1996; Riederer and Markstädter, 1996; Barthlott et al., 1998). Also, various reviews have focused on individual aspects of surface characteristics, such as wetting ability (Holloway, 1969, 1970, 1971; Otten and Heminghaus, 2004 and others) or optical characteristics (Barnes and Cardoso-Vilhena, 1996). Functions of the cuticle have been reviewed by Jeffree (1986), Schönherr and Riederer (1989), Riederer (1995), Riederer and Schreiber (1995, 2001), Jenks and Ashworth (1999), and Bargel et al. (2004). The specific role of the cuticle in interactions with other organisms was summarized in earlier reviews with regard to microorganisms (e.g., Kolattukudy et al., 1995; Mendgen, 1996), herbivorous insects (Eigenbrode and Espelie, 1995; Eigenbrode, 1996), and effectiveness of predatory insects (Eigenbrode, 2004). This review aims to bring together present knowledge about the plant surface from the different fields of plant (eco)physiology, microbiology, entomology, and ecology in an integrative and comprehensive way. We feel that the complexity of the cuticle and its various functions have been underappreciated in previous ecological literature. The first part of this review will outline the basic cuticular chemistry and physics involved, whereas the second part will deal with the relevance of these properties in a chemical–ecological context. We provide the chemical ecologist with an overview of the most recent literature on these topics, with emphasis on established methodology, and new approaches. Because we do not attempt to cover all aspects in depth, we refer to major reviews on particular topics.

PHYSICOCHEMICAL PROPERTIES OF THE PLANT SURFACE

Chemical Composition of Cutin and Waxes. The functionally important lipophilic fraction of the cuticle consists of cutin and waxes. Cutin forms the matrix of the cuticle and is a polyester-type biopolymer. It is composed mainly of two families of hydroxy and hydroxyepoxy fatty acids derived from the most common cellular fatty acids, as well as from C_{16} saturated and C_{18} unsaturated fatty acids (Holloway, 1982a). The chief members are 16-hydroxy and dihydroxy hexadecanoic acids, the latter having one hydroxyl moiety at the terminal carbon and another in a mid-chain position. The C_{18} family is represented by unsubstituted and 18-hydroxy octadec-9-enoic acids, 18-hydroxy-9-epoxy, and 9,10,18-trihydroxy octadecanoic acids. The monomers are cross-linked by ester and, in some species, by nonester bonds, although the exact chemical nature of these has yet to be elucidated (Schmidt and Schönherr, 1982; Riederer and Schönherr, 1988). The cutin monomers cross-linked by ester bonds can be released for identification by treatment with bases or by esterases (cutinases). The composition and amount per unit area of cutin vary considerably among plant species and may differ relative to plant organs and ontogenetic states (Riederer and Schönherr, 1984, 1988). This variation makes species- and organ-specific recognition possible.

Cuticular waxes are present in the lipophilic fraction of the cuticle. Waxes in the chemical sense are esters of long-chain fatty acids with long-chain primary alcohols. Here, the term waxes is used in a broad sense to include cyclic compounds such as pentacyclic triterpenoids (Riederer and Markstädter, 1996). The aliphatic fraction of cuticular waxes consists of a complex mixture of compounds having a hydrocarbon backbone with 21 to >40 carbon atoms. Their biosynthesis depends on the action of elongases on moieties derived from fatty acid synthetase. Further reactions, predominantly the addition of oxygen-containing substituents and the removal of one carbon, lead to the aliphatic compound classes present in cuticular waxes (Kolattukudy, 1996).

The major compound classes of plant cuticular waxes are *n*-alkanes (chain-length C_{21}–C_{35}) and smaller proportions of iso and anteiso homologues, primary alcohols (C_{22}–C_{40}), fatty acids (C_{20}–C_{24}), aldehydes (C_{24}–C_{36}), secondary alcohols (C_{21}–C_{35}), with a tendency for mid-chain hydroxylation, ketones (C_{21}–C_{35}), β-diketones (C_{22}–C_{36}), and *n*-alkyl esters (C_{36}–C_{60}) resulting from the combination of long-chain primary alcohols and fatty acids (Baker, 1982; Walton, 1990). Each class consists of a homologous series of isomers. In many cases, one compound dominates the total composition of the cuticular wax. The particular pattern is highly characteristic for a given plant species, plant part, or developmental stage. In addition to the aliphatic portion of the wax, various amounts of cyclic compounds, such as pentacyclic triterpene acids, triterpene alcohols, triterpene ketones, and triterpene esters, as well as hydro-

xycinnamic acid derivatives, flavonoids, and their respective glycosides, may be present.

Fine Structure of the Cuticle and Cuticular Surfaces. The most common structural model of the matrix portion of the cuticle is that of a *bilayered* cuticular membrane (Figure 1), where the two layers are distinguished by their ontogeny, ultrastructure, and chemical composition. The outermost portion (called the cuticle proper) forms a continuous layer that is separated from the outer epidermal cell wall. It is synthesized first and is composed of cutin with ester and, in some species, nonester bonds. These nonester bonds make the cuticle proper fairly resistant against the effects of esterases produced by fungi. The inner layer, called the cuticular layer, arises from impregnation of the outer epidermal cell wall by cutin and thus contains substantial amounts of various embedded cell wall polysaccharides. For reviews of cuticular structure and ontogeny, see Holloway (1982b) and Jeffree (1996).

The outer portion of the cuticle is encrusted with waxes (intracuticular waxes), and a thin film of epicuticular waxes covers the outer surface. In certain species, a more or less dense cover of epicuticular crystals may occur (Figure 2), and this is responsible for the distinctive visual appearance (see below). The epicuticular crystals are composed primarily of the single predominant component of the wax, and show species-specific, substance-dependent habits (Jetter and Riederer, 1994, 1995). For a thorough synopsis of a structural nomenclature for epicuticular wax crystals, see the review by Barthlott et al. (1998). Methods for mechanically separating the epicuticular from the intracuticular waxes have become available (Ensikat et al., 2000; Jetter et al., 2000), and these provide evidence that the actual leaf surface, which is first contacted by insects and microorganisms, may differ drastically in chemical composition from the internal wax.

The quantitative coverage and qualitative composition of the total wax as well as those of the epicuticular layer may vary according to a number of

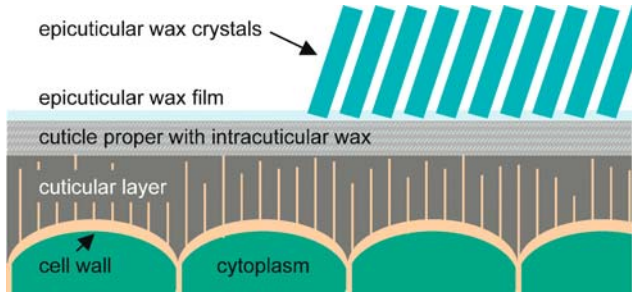

FIG. 1. Scheme showing the layering of the plant cuticle. The features displayed are not to scale. See text for further explanation.

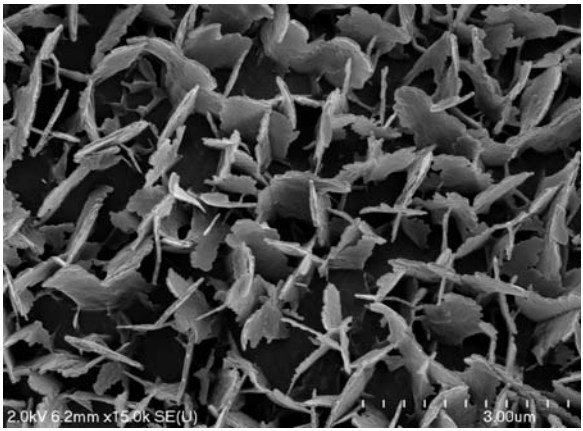

FIG. 2. Electron scanning micrograph of the upper leaf surface of pea (*Pisum sativum*). The upright crystals of cuticular wax consist mainly of 1-hexacosanol. This example is shown as representative for leaf surfaces where the very tips of epicuticular crystals represent the primary contact zone between an alighting organism and the leaf.

exogenous and endogenous factors. They may vary with season (Schütt and Schuck, 1973; Gülz et al., 1991; Gülz and Müller, 1992; Faini et al., 1999; Jenks et al., 2002), temperature (Reed and Tukey, 1982; Faini et al., 1999; Dodd and Afzal-Rafii, 2000; Dodd and Poveda, 2003), and light (Macey, 1974; Giese, 1975; Davis, 1978; von Wettstein-Knowles et al., 1980; Reed and Tukey, 1982; Steinmüller and Tevini, 1985; Upadhyaya and Furness, 1994; Shepherd et al., 1995). Erosion by wind and rain can also influence wax amounts and the density of cuticular wax blooms (Baker and Hunt, 1986; Hadley and Smith, 1989). Further exogenous factors of potential importance include carbon dioxide and ozone (Percy et al., 2002).

Endogenous factors influencing amount, composition, and distribution of the wax include ontogenetic states (Jetter and Schäffer, 2001; Ficke et al., 2004) and organ-specific regulation: differences in the cuticle exist between upper and lower leaf side (Premachandra et al., 1993; Kanno and Harris, 2000a,b; Müller and Hilker, 2001), and are especially pronounced in plants showing heteroblasty (Adati and Matsuda, 1993; Brennan et al., 2001; Steinbauer et al., 2004).

PHYSICAL PROPERTIES OF THE PLANT SURFACE

Hydrophobicity. The most important feature of primary plant surfaces is, because of their hydrophobicity, the repellence of water, aqueous solutions, polar mucilages, and small organisms with polar coatings. This feature is a

result of coverage by waxes that are essentially aliphatic and thus apolar. Therefore, wetting, i.e., the spreading of aqueous media on cuticular surfaces, is strongly impaired. The contact angle of pure water on such surfaces is approximately 112°.

Apolar surfaces become even more repellent when they are rough on a microscopic scale. This added repellency is due to epicuticular wax crystals and sometimes also by papillose epidermal surfaces or trichomes. Then, a sessile droplet of pure water may be completely round (contact angle about 180°), and the surfaces are beaded with water droplets that easily drip off (Barthlott and Neinhuis, 1997; Neinhuis and Barthlott, 1998). Higher wettability of the hydrophobic cuticular surface can be attained by apolar solvents or by aqueous solutions containing surface-active compounds such as synthetic or biological surfactants. Various aspects of leaf wettability have been the subject of reviews (Holloway, 1969, 1970, 1971; Hartley and Graham-Bryce, 1980; Watanabe and Yamaguchi, 1991a,b, 1992; Wagner et al., 2003; Otten and Herminghaus, 2004). Plant surfaces that are no longer pristine become increasingly wettable by aqueous solutions because of factors such as the deposition of salts (Klemm et al., 1987; Burkhardt et al., 2001) or the growth of microorganisms (Knoll and Schreiber, 1998). To assess the repellency of plant surfaces experimentally, various methods are available, the most prominent being contact-angle measurements (Pallas, 1997).

Mechanical adhesion of small particles, such as particulate matter from dry deposition, microorganisms, spores and conidia, as well as insect legs and eggs, may be impaired by the same factors that provide the surface with water-repellent properties (hydrophobic smooth and microrough surfaces). These biological consequences are discussed in a later section.

Optical Properties. Cuticular surface features also determine the optical properties of the primary parts of higher plants (Barnes and Cardoso-Vilhena, 1996) and can thereby influence their appearance for approaching insects (see below). On one hand, plant cuticles absorb ultraviolet radiation to varying degrees (Krauss et al., 1997), whereas they are translucent in the range of the photosynthetically active wavelengths of solar radiation. On the other hand, most radiation is reflected and scattered from cuticular surfaces. Leaf, fruit, and primary stem reflectance and scattering is partly due to roughness features on the surface with varying densities, dimensions, and refractivity and partly due to the cell walls of the underlying tissues (Slaton et al., 2001; Grant et al., 2003). Radiation emitted or reflected by plant surfaces may occur in the range from 280 nm to the infrared, including the wavelengths visible to the human eye and active in plant photosynthesis. In the visible range, reflection depends on the presence of epicuticular waxes and trichomes, which in extreme cases, may turn plant surfaces whitish as a result of broadband reflection in the visible part of the solar spectrum (Eller and Willi, 1977; Holmes and Keiller,

2002). In the ultraviolet range, radiation emission is influenced by the presence and dimensions (and thus scattering properties) of epicuticular wax crystals. When surface features have dimensions that approximate the wavelength of short-wave visible and UV radiation, these surfaces appear bluish and strongly emit in the ultraviolet (Clark and Lister, 1975; Riederer, 1989; Grant et al., 2003).

The radiation reflected from leaf surfaces has two principal components, i.e., diffuse and specular. The specular component is polarized to varying degrees, depending on microscopic leaf surface features (Grant et al., 1993; Brakke, 1994). Grant et al. (1993) have also shown that the polarized component may account for up to 90% of total reflection from adaxial leaf surfaces of some species. The visual system of some insects allows them to recognize and distinguish between various degrees of polarized light (see below).

Dissolution of Organic Molecules in the Cuticle. Plant surfaces not only have special physical properties that determine wetting and adhesion. They also interact with organic chemicals coming into contact with them either from the outside or from endogenous sources. These chemicals may be either in the gas or vapor phase or in solution. They may also be delivered to the plant surface by direct contact with a particle deposited there or with an organism alighting on the plant. Here, we deal with questions about types of chemicals that can move across the cuticle and factors that determine the sorption of extraneous material (e.g., pheromones) to the cuticle. Such movement will be discussed first from a physiological and physicochemical point of view to provide a basis for understanding their ecological implications.

The interaction of a molecule with the surface or the whole cuticle is referred to as sorption, which may involve adsorption and/or absorption (Schönherr and Riederer, 1989; Riederer, 1995). Sorption is a physicochemical phenomenon without involvement of any biological process. To understand sorption of organic compounds, we first have to consider their water solubility. The saturation concentration of a given compound in water ("aqueous solubility'') describes the interaction of a substance with an aqueous medium [e.g., a sessile droplet or water in the apoplast of the plant (Yalkowski and Banerjee, 1992)]. The tendency of a substance in an aqueous solution to move into and to accumulate in an adjacent organic phase such as the cuticle is expressed by the partition coefficient. This is a dimensionless property describing the degree of accumulation of a chemical in the organic phase relative to water. The most widely used measure for this accumulation tendency and, thus, the relative lipophilicity of a compound is the 1-octanol/water partition coefficient (K_{ow}) according to

$$K_{ow} = \frac{C_o}{C_w} \tag{1}$$

where C_o and C_w are the equilibrium concentrations of the substance in the 1-octanol and water phases, respectively (Hansch and Leo, 1979). When the organic phase is the cuticle, Equation 1 can be rewritten according to

$$K_{cw} = \frac{C_c}{C_w} \tag{2}$$

by substituting the equilibrium concentration in the cuticle (C_c) for the respective concentration in the 1-octanol phase.

Water solubilities and the 1-octanol/water partition coefficients are inversely related (Leo et al., 1971; Mackay et al., 1980; Yalkowski and Banerjee, 1992). With weak organic acids or bases, aqueous solubility and, thus, partition coefficients depend on the acidity constant pK_a and pH (Schwarzenbach et al., 1993). For volatile or semivolatile chemicals, the saturation vapor pressure (P_s in Pa) is an additional parameter determining the availability of a compound for absorption or adsorption to the surface of the cuticle. Values for water solubilities and octanol/water partition coefficients can be either obtained from the literature or estimated from fundamental properties of the compounds (Lyman et al., 1990).

Direct experimental measurement of the cuticle/water partition coefficient K_{cw} is feasible only for a small fraction of the large number of chemicals relevant in chemical ecology. Therefore, a quantitative property–property relationship (QPPR) was established between the cuticle/water partition coefficient and the 1-octanol/water partition coefficient (Schönherr and Riederer, 1989):

$$\log K_{cw} = 0.057 + 0.970 \log K_{ow} \quad (r = 0.987). \tag{3}$$

For illustrative purposes, Equation 3 can be used to estimate the cuticle/water partition coefficient of two glucosinolates, important contact allelochemicals in insect–plant interactions (see below). Brudenell et al. (1999) have measured log K_{ow} for 3-butenyl glucosinolate and allyl glucosinolate of -2.5 and -2.8, respectively. The values were independent of pH in the range from pH 7 to 4 because the pK_a of both compounds can be assumed to be much less than 0. The estimated log cuticle/water partition coefficients are -2.4 and -2.7, respectively. Thus, the equilibrium concentration of both glucosinolates in the cuticle will be 0.4 and 0.2% of that in the aqueous phase of the adjacent cell wall. As the corresponding wax/water partition coefficients are approximately one order of magnitude lower than K_{cw} (Burghardt et al., 1998), the equilibrium concentrations of glucosinolates in the outer wax layer will be negligible (0.02 and 0.04% for 3-butenyl glucosinolate and allyl glucosinolate, respectively). In addition, glucosinolates have only been localized in the phloem and in the

interior of cells (Chen and Andreasson, 2001; Chen et al., 2001), which suggests that the respective concentrations in the cell wall solution are extremely low or essentially zero.

These considerations demonstrate that only lipophilic uncharged organic chemicals can be sorbed onto plant surfaces. For volatiles, which are important in attraction or repellence of interacting organisms over a distance, lipophilicity and a low vapor pressure favor accumulation in the cuticle. The dissociated species of acids and bases and other polar organics such as carbohydrates or glucosylated substances as well as very small and volatile molecules in the vapor phase will not be absorbed or adsorbed to the cuticle, although transport across the cuticular pore is possible to some degree (see below). Also, such compounds might be removed easily from the plant surface. In contrast, the cuticle may act as a fixative for appropriate compounds enabling them to stay much longer on the surface and to exert their biological functions.

Transport. One of the main functions of the cuticle is to inhibit the loss and uptake of water and dissolved chemicals from and into the plant. Thus, it essentially controls the diffusive exchange between the plant and the surrounding environment (see below). From a physi(ologi)cal point of view, the cuticular pathway is the exclusive transport system for uptake into or release from the leaves and primary stems of compounds having specific characteristics. Liquids and relatively nonvolatile solutes contained either in the apoplast or in liquid or solid deposits as well as the unstirred air layer above the surface can use this pathway (Schönherr and Riederer, 1989; Riederer, 1995, 2004; Riederer and Schreiber, 1995). All apolar organics with low vapor pressures and sufficient lipid solubilities, including a wide variety of primary and secondary metabolites, belong to this class. Polar and charged compounds cannot partition into and diffuse across the lipid pathway of the cuticle. There is increasing evidence, however, that in some plant species, polar pathways exist that make possible the easy transport of small molecules (smaller than xylose with a molar volume ≤ 110 cm^3 mol^{-1} in *Hedera helix* leaf cuticles; Popp and Riederer, unpublished results) to the plant surface (Schönherr, 2002). In *H. helix* cuticles, transport of polar compounds above this size threshold was negligible.

Compounds with high volatility (e.g., gases, monoterpenes, glucosinolate-derived volatiles), in principle, can take two parallel paths between the interior and the outside as long as the stomata are open (Figure 3). The preferred pathway depends on the lipophilicity of the compound (i.e., its tendency to sorb in the cuticle) and on its saturation vapor pressure in the atmosphere above the cuticle (Riederer, 1990, 1995; Riederer et al., 2002). If stomata are closed or absent (in the case of some fruits), the diffusion of all volatiles and semivolatiles is restricted to the cuticular pathway.

Transport of material from the interior of a primary organ across the cuticle-covered plant/atmosphere interface or *vice versa* arises from a

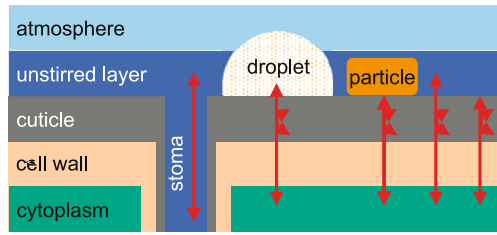

FIG. 3. Schematic representation of the compartments at the leaf/atmosphere interface and the pathways of diffusive transport connecting them. Compartments are not to scale, and only representative diffusion pathways are shown.

concentration gradient of solutes or vapors between the interior and the outside. However, from an ecological point of view, it is not important that a compound is transported at all, but how long it takes until biologically relevant doses are reached on the plant surface. From this, we can conclude that in an ecological context, the decisive function of the plant cuticle is not to act as an absolute barrier, but to exert kinetic control.

This overall process of transport across the cuticle can be visualized as the diffusion of a compound from a donor compartment (e.g., the solution in the apoplast or the vapor phase in the intercellular space) to a receiver compartment (e.g., the outer surface of the plant or the gaseous phase surrounding it). The compartments are separated by the cuticular transport barrier. Under steady-state conditions, the amount permeated linearly increases with time, and the flow N (mol a^{-1}) is given by

$$N = PA(C_d - C_r) \tag{4}$$

where C_d and C_r (mol m^{-3}) are the concentrations in the donor and receiver compartments, respectively, A (m^2) is the area of the cuticle exposed, and P (m sec^{-1}) is the permeance of the cuticle. At low concentrations and with nonelectrolytes, the gradient of chemical potential can be substituted by the difference of concentrations as driving force. In the steady state, when C_d = const. and $C_d >> C_r$, Equation 4 can be simplified to

$$N = PAC_d. \tag{5}$$

There is considerable variation among cuticular permeances determined for one chemical and the cuticles of a number of plant species. A study with 2,4-dichlorophenoxy acetic acid and the cuticles from 11 plant species showed that permeances may range over two orders of magnitude (Riederer and Schönherr, 1985).

The observation that cuticular permeances were correlated to partition coefficients, again, led to the attempt to establish quantitative relationships for predicting permeances of *Citrus aurantium* leaf cuticles (largest data set available) from more fundamental and easily accessible parameters. Such a correlation has been successfully established between the cuticular permeance and the 1-octanol/water partition coefficient (Schönherr and Riederer, 1989):

$$\log \mathrm{P} = 0.704 \log \mathrm{K}_{ow} - 11.2 \ (r = 0.91) \tag{6}$$

This equation can be used for estimating cuticular permeability for natural products not accessible to the direct experimental determination of permeances. Such calculations are useful to determine what an organism might find on a plant surface (see below). For instance, by using Equation 6, the cuticular permeances of 3-butenyl and allyl glucosinolate can be estimated from the experimentally determined log K_{ow} (Brudenell et al., 1999). The estimates for P are 9×10^{-14} and 5×10^{-14} m sec^{-1}, respectively. These values are much lower than any cuticular permeance measured so far. Given the very low or practically zero concentrations of glucosinolates in the cell wall solution, no glucosinolates will reach the cuticular surface via the cuticular pathway.

These predictions are supported by preliminary results from an experiment where a compartment containing a solution of 4-hydroxybenzyl glucosinolate was separated from a compartment with pure buffer by an isolated astomatous cuticle from *H. helix* leaves. Even after 14 d, no flux of the glucosinolate across the cuticle was observed (Popp and Müller, unpublished data). This demonstrates that glucosinolates are both too polar for the lipophilic pathway and too large for the polar pathway of *H. helix* cuticles. Future research will be needed to test whether this finding can be extended to the cuticles of other species.

FUNCTIONS OF PLANT SURFACES

Functions for Plants. The cuticle is the skin of plants and, as such, is both functionally and, in part, structurally analogous to the skin of vertebrates (Hadley, 1991). Cuticles are found with the oldest fossils of terrestrial plants (Edwards et al., 1996) indicating the reliance of plant life on this barrier to survive in the dry atmosphere. In this respect, the importance of the cuticular interface is equivalent to that of the arthropod cuticle (Hadley, 1989, 1991). Arthropods and higher plants share considerable similarities in the composition (waxes) and the function (low water permeabilities) of their respective cuticles (Hadley, 1981).

As a large driving force exists between the aqueous interior of a plant and its atmospheric surroundings, protection against uncontrolled water loss is the principal function of the cuticle. Plant cuticles are effective transpiration barriers reducing water loss to the same or even higher degree as would synthetic organic polymer sheets of comparable thickness (Riederer and Schreiber, 2001). This low (in many cases practically zero) water permeability allows plants to regulate the flow of water vapor almost exclusively by the stomatal pathway (Nobel, 1991).

Other common functions of skins and cuticles are retention of solutes in the body fluids, impeding the uptake of solutes and gases from the environment, protection against invasion by microorganisms, shielding of detrimental ultraviolet radiation, and, to a certain degree, mechanical defense (Figure 4).

To achieve these functions, the plant cuticle must have an array of suitable chemical and physical properties. The most important property is its hydrophobicity, which impedes the transport of water and the wetting of the outer surface (see above). Further hindrance of water loss is provided by the partial crystallinity of the cuticular waxes. The UV-shielding properties of plant surfaces result from phenolic compounds (flavonoids and hydroxycinnamic acid

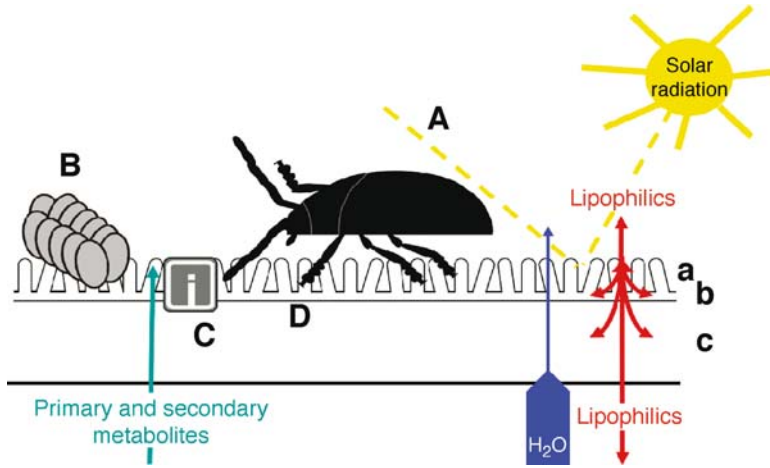

FIG. 4. Processes on the plant surface. (A) Reflectance, transmittance, and absorbance of solar radiation; (B) attachment of insect eggs (or spores of microorganisms, likewise); (C) physical and chemical cues used for host recognition by microorganisms and insects; (D) adhesion of insect legs and influences of surface characteristics on locomotion. Water and other metabolites diffuse in different degrees through the cuticular layer, formed by epicuticular wax crystals (a), the epicuticular wax film (b), and cutin and intracuticular waxes (c).

derivatives) associated with the cuticle or the outer epidermal cell wall (Krauss et al., 1997; Kolb et al., 2001, 2003). Many of these phenolics also have antimicrobial activity (Talley et al., 2002). A mechanical defense is provided by the relatively high tensile strength of the cuticle (Wiedemann and Neinhuis, 1998). The integrity of the cuticle may be compromised by microorganisms or insects making holes and by the mechanical action of wind (Hoad et al., 1992).

Interactions with Microorganisms. Under natural conditions, the cuticular surfaces in most cases are not as clean and pristine as usually shown by scanning electron micrographs. A variety of epiphyllic microorganisms such as filamentous fungi, yeasts, and bacteria colonize the leaf surface, forming a more or less dense biofilm. Under warm, humid conditions, the surface may also be covered with cyanobacteria and lichens (Blakeman, 1982; Andrews and Harris, 2000; Herrera-Campos et al., 2004).

The first requisite for microorganisms to become established on a plant is the ability to attach to the surface. To overcome the hydrophobic properties of the plant cuticle (see above), fungal spores and their hyphae excrete extracellular mucilage or release other liquids containing, for example, hydrophobic proteins that mediate an adhesive interaction with the leaf surface (Mendgen, 1996; Carver et al., 1999). Changes in wettability of leaf surfaces with age may be observed and are related to degradation of epicuticular wax crystals (Riederer, 1989) and to increasing coverage by epiphytic microorganisms (Knoll and Schreiber, 1998, 2000). Degradation of the waxes leads to higher leaf wettability, which offers, in general, a more suitable microhabitat for most phyllosphere organisms (Knoll and Schreiber, 1998), whereas surface wetness may hinder sporulation of others (Butler, 1996).

In addition to determining the wetting properties of the plant surface, cuticular waxes can serve as signals that induce spore germination (Kolattukudy et al., 1995) and can influence the growth pattern of the hyphae of biotrophic fungi (Mendgen, 1996; Mendgen et al., 1996). Specific long-chain alcohols and aldehydes are effective inducers (Ahmed et al., 2003; Dickman et al., 2003). These signals act as kairomones, allowing a pathogen to recognize its host plant. Also, cuticular waxes can relieve the self-inhibition of germination of conidia (Hegde and Kolattukudy, 1997). Cutin and long-chain fatty acids derived from the cuticular waxes may induce biochemical pathways that are required either for the pathogenicity of certain fungi (Ahmed et al., 2003; Dickman et al., 2003) or for the induction of plant defense reactions (Fauth et al., 1998). Thickness and three-dimensional structure of leaf wax crystalloids on leaves and fruits can contribute to resistance of plants against attack by fungal pathogens (Schwab et al., 1995; Ficke et al., 2004).

Colonization by epiphytic bacteria is, in part, limited by the availability of suitable carbon sources on the surface. These carbon sources are either carbohydrates or other small primary plant metabolites present at the surface

(Mercier and Lindow, 2000) or wax-derived hydrocarbons made available by biosurfactants (Georgiou et al., 1992). Several secondary metabolites present on the leaf surface exert antimicrobial properties and thus hinder colonization by microorganisms (Talley et al., 2002). Coumarins, flavonoids, monoterpenes, sesquiterpenes, and sesquiterpene lactones are primarily sequestered in glandular trichomes on the surface (Szafranek et al., 1998; Talley et al., 2002). These compounds are likely to be released onto the leaf surface as the cuticular sacs of the trichomes mature. In sagebrush populations, the quality and quantity of secondary metabolites on the leaf surface have been selected as a result of the abundance of fungi (Talley et al., 2002).

Mediation of Insect–Microorganism Interactions. The epicuticular waxes of leaves can affect germination of entomopathogenic fungi that infect herbivorous insects. Leaf surfaces of members of the Brassicaceae were shown to contain a mixture of stimulatory and inhibitory compounds to the entomopathogenic fungus *Metarhizium anisopliae*, influencing its virulence to the mustard beetle *Phaedon cochleariae* (F.). Surface leachates of nutrients increased the virulence (Inyang et al., 1999).

Spread of the fungal aphid pathogen *Pandora neoaphidis* was enhanced on pea plants with reduced compared to normal wax bloom. This effect was associated with better attachment of fungal conidia on the reduced wax surface (Duetting et al., 2003). Compounds produced from microorganisms such as yeast that accumulate on the leaf surface can have inhibitory effects on the oviposition by insects (Städler, 2002).

Interactions with Phytophagous Insects. After visual and/or chemical attraction to a host, all phytophagous insects will first come into contact with epicuticular wax layers when they land on aboveground primary parts of a higher plant. Here, they will encounter either a smooth waxy surface or epicuticular wax crystals. The chemical and physical properties of this contact interface differ drastically from those of the interior parts of the cuticle. Therefore, it is the outermost wax layer (except in the case of leaf surfaces having glandular trichomes) that harbors the physical and chemical cues involved in the primary step of the interaction between herbivores and the plant (Figure 4). These cues also can determine insect development and behavior. Such interactions mediated by surface properties have been studied mainly in crop plants such as cabbage, cereals, beans, and onion that are subject to infestation by several insect pests (Peter and Shanower, 2001). Only limited data are available on the role of the cuticle in nonfood plant–herbivore interactions (but see, for example, Edwards, 1982; Steinbauer et al., 2004).

Physical surface properties affecting plant–herbivore interactions include the microstructure of the epicuticular waxes. These wax properties determine optical characteristics by reflectance, transmission, or absorbance of specific wavelengths to varying degrees, as outlined above. The resulting visual

"Gestalt'' of a plant part offers an important cue in the host-finding process of insects, operating sequentially or simultaneously with chemical cues (Prokopy and Owens, 1983). For example, leaf color, determined by relative wavelength, significantly influences host preference of the potato leafhopper, *Empoasca fabae* (Harris) (Bullas-Appleton et al., 2004). As reflectance and scattering patterns change with senescence (Major et al., 1993), insects can use the optical information about age and, thus, the quality of their host. Insects with polarization-dependent color vision systems might be able to discriminate between shiny and matt surfaces (Hegedüs and Horváth, 2004). However, reflection polarization, as determined by the epicuticular wax structure, might also influence the color perception of insects visiting plants. Polarization of light can cause false perception of colors in *Papilio* butterflies, which have polarization-sensitive photoreceptors (Kelber et al., 2001).

Water droplets on the plant surface can be an important source of water for insects. They can also protect early instar larvae against desiccation or help them to stay on the plant (Raina, 1981). Contact with surface water offers a cue for termination of diapause in some species of Pyralidae (Lepidoptera) living in semiarid climates (Butler, 1996).

Primary metabolites, such as soluble carbohydrates, leak onto plant surfaces (see above) and can play a role as nutrients or stimulants for insects (Fiala et al., 1993; Derridj et al., 1996a,b). Sugar and sugar alcohols identified from apple fruit surfaces have been demonstrated to function as kairomones and evoke oviposition in female moths of *Cydia pomonella* L. (Lombarkia and Derridj, 2002). However, probably only relatively small- to medium-sized and uncharged organic molecules will leak to the outside (see above).

In interactions between phytophagous insects and plants, plant secondary metabolites provide major cues and understandably, therefore, have received the most attention as allelochemicals. A plethora of examples demonstrate how natural products act as feeding or oviposition stimulants, as deterrents, or in the case of volatiles, as attractants or repellents (Schoonhoven et al., 1998). Depending on their polarity and solubility (see above), secondary compounds can be released from plant tissues and accumulate either in the epicuticular waxes or in the cutin.

Volatiles may leave the inner leaf tissue either through the cuticle or the stomata. They may be absorbed by the cutin or adsorbed on the epicuticular wax layer. Such volatiles can attract or repel herbivores to or from a plant from a distance. For example, volatile isothiocyanates are attractive to specialist herbivores of Brassicaceae (Bartlet et al., 1997; Mewis et al., 2002), although their concentration in the headspace over undamaged leaves is extremely low (Tollsten and Bergström, 1988). However, volatiles also can be important in close-range orientation, acting synergistically with contact chemoreception cues (de Jong and Städler, 1999).

Nonvolatile secondary metabolites can be deposited on the plant surface *via* diffusion and associated with the waxes, or they can be stored in glandular trichomes (Bargel et al., 2004). The flavonol quercetin may be excreted from glandular trichomes on the leaf surface of tobacco, where it acts as a stimulant to the mirid *Tupiocoris notatus* (Distant; Roda et al., 2003). Many studies have addressed the presence of secondary metabolites on the plant surface of leaves, stems, or reproductive tissue (seeds and fruits) where they act as allomones or kairomones (Eigenbrode and Espelie, 1995; Brooks et al., 1996; Green et al., 2003). However, such compounds can also function as toxins for neonate larvae (Carter et al., 1989). Nonvolatile glucosinolates, the substrate from which isothiocyanates are formed, have been detected in surface extracts of Brassicaceae where they can stimulate feeding or oviposition (Städler, 1992; Hopkins et al., 1997; Griffiths et al., 2001; Marazzi et al., 2004). However, as pointed out above, the physicochemical properties of these polar compounds make it unlikely that they are present in the epicuticular layer itself. Several investigators have prepared "leaf surface extracts'' by dipping leaves in dichloromethane followed by methanol (e.g., Hopkins et al., 1997). However, this procedure may result in extraction of compounds from mesophyll or epidermal cells. Reifenrath et al. (2005) have recently suggested that glucosinolates are probably washed from the inner tissue when applying conventional extraction protocols, but that they are not naturally present on the leaf surface. When removing the epicuticular waxes mechanically from leaves of *Brassica napus* L. and *Nasturtium officinale* R. Br., they found no traces of these secondary compounds therein (Reifenrath et al., 2005).

To reexamine several of the examples described in the literature as well as for future studies, new techniques should be used that are available to probe the epicuticular layer selectively (Premachandra et al., 1993; Ensikat et al., 2000; Jetter et al., 2000). Stomatal aperture could be controlled by keeping plants shortly in darkness prior to extraction to avoid washing out of compounds Reifenrath et al. (2005). With these methods, the presence or absence of specific secondary compounds in the epicuticular layer might be unequivocally demonstrated.

If certain secondary compounds are virtually absent from waxes, insects might actually need to slightly damage the epicuticular layer by scratching it with their legs or ovipositor, thereby contacting compounds deeper in the cuticle or just beneath it (Städler, 2002). Indeed, an epicuticular layer with ubiquitously distributed aliphatic compounds could be adaptive for the plant, rendering it less detectable to specialists (Reifenrath et al., 2005).

Several insects use lipids of the wax layer, specifically various long-chain alkanes and alcohols, as cues in host plant selection (Adati and Matsuda, 1993; Lin et al., 1998; Powell et al., 1999; Morris et al., 2000; Coyle et al., 2003). For some insect species, lipids act only in synergy with secondary metabolites as

kairomones (Harris et al., 1987; Roessingh et al., 1992; Spencer, 1996; Spencer et al., 1999; Marazzi et al., 2004).

The quality and quantity of waxes can vary tremendously within a plant. Specialists can use these differences as information for orientation and for choosing a particular site for oviposition or feeding. This has been demonstrated, for example, in specialists on *Eucalyptus* spp. showing heteroblasty (Adati and Matsuda, 1993; Brennan et al., 2001; Steinbauer et al., 2004). Leaf-cutter bees make more cuttings on leaves of *Cercis canadensis* L. (Fabaceae) with crystalline adaxial surface wax than on glabrous leaves (Eigenbrode et al., 1999a). Also, differences between both leaf sides (abaxial or adaxial) in wax composition or structure can explain differences in attractiveness (Roessingh and Städler, 1990; Justus et al., 2000; Kanno and Harris, 2000a,b; Müller and Hilker, 2001). Hereby, recognition by the insect might be based on chemical and/or physical cues of the waxes. Coating with waxy substances can be a key cue in bioassays testing for stimulants, showing the importance of waxes as physical cues (Degen and Städler, 1997).

Conversely, substances contained in epicuticular waxes function as allomones, deterring oviposition, and feeding by herbivores (Juniper, 1995; Eigenbrode and Espelie, 1995; Eigenbrode, 1996), and leaf cutting by fungus-growing ants (Hubbell et al., 1984; Sugayama and Salatino, 1995; Salatino et al., 1998). In addition, they are potentially toxic to some insects (Espelie, 1996). It was found repeatedly that plant mutants or cultivars with an increased surface wax layer are more resistant to herbivores (Eigenbrode et al., 1996; Shepherd et al., 1999a). In other systems, the relative quantity of wax compounds could be correlated with plant resistance of different plant genotypes (Jones et al., 2002; Rapley et al., 2004). In the polyphagous grasshopper *Schistocerca americana* (Drury), rejection of unacceptable leaves was first dependent on biting the leaf, but subsequently occurred after palpation of the surface alone. Thus, leaf surface waxes can also be used as cues in associative learning (Woodhead and Chapman, 1986; Chapman and Sword, 1993).

Insect feeding can also induce wax production of the plant and change surface chemistry. *Beta vulgaris* leaves respond with increased wax development to the punctures of aphids (Bystrom et al., 1968). The amount of the triterpene squalene increases in apple leaves after infestation with leaf miners (Dutton et al., 2002).

Several insect species mark the spot of oviposition on a plant surface with an oviposition-deterring pheromone. Subsequent females arriving on the host will avoid oviposition at the same site, and thereby ensure that overcrowding on a limited resource does not occur. The persistence of these pheromones on the surface can vary from 1–2 hr up to 12 d (Anderson, 2002) and will depend on the saturation vapor pressure and the lipophilicity of the pheromone as well as the sorptive properties of the cuticular surface. Pheromones with low vapor

pressures and high lipophilicities will persist longer than those with high volatilities and a low tendency to accumulate in lipid phases (see above).

The surface chemistry of a herbivorous insect itself can vary drastically with different food sources. Larvae of *Manduca sexta* (L.) browsing on tobacco have high levels of duvatrienediols in their cuticular lipids. These compounds are probably transferred from the sticky globules of the host plant surface (Espelie and Bernays, 1989). Fatty alcohols with typical chain lengths of those on plant surfaces are present as white powder on some larvae of moths or sawfly species, suggesting that these waxes are of plant origin (Espelie and Bernays, 1989). The plant surface chemicals might be adopted (sequestered from the plant or synthesized *de novo*) by a herbivore, thus becoming chemically "camouflaged'' to predators, as a form of chemical mimicry (Espelie et al., 1991). In any case, such compounds could influence the behavior of foraging predators. It is even reported that the lipids of the seed and the fruit of apples (*Malus pumila* Mill.) are carried through to the lipids of the herbivore *Cydia pomonella* L. and further to its parasitoid *Ascogaster quadridentata* Wesmael (Espelie and Brown, 1990).

As mentioned above, the plant surface is capable of adsorbing and absorbing the vapors of organic compounds in the adjacent air layer. Sorption is enhanced by the unstirred air layers covering the plant surfaces. As a result, compounds of a herbivore that adsorb to or absorb in the plant surface can function as delayed signals for conspecifics. For example, the glandular defense secretion, (epi)chrysomelidial, of the mustard leaf beetle larvae of *Phaedon cochleariae* (F.) adheres to the leaf surface (Rostás and Hilker, 2002). Females of this species are deterred from feeding and oviposition by these secretions.

Epicuticular waxes also influence locomotion of herbivorous insects on a plant by determining the ability of tarsae to adhere to the surface (Woodhead and Chapman, 1986; Edwards and Wanjura, 1990; Eigenbrode, 1996). For example, epicuticular wax blooms can reduce the attachment forces of the mustard leaf beetle (Stork, 1980). Thus, glossy plants are often more heavily infested by herbivores than waxy ones, an important fact in choosing agricultural cultivars (Bodnaryk, 1992). The pedicles of flowers can be coated with "antirobbing'' devices, called the "greasy pole syndrome,'' thus preventing insects from reaching the reproductive tissue (Kerner, 1879; Juniper, 1995).

Interactions with Carnivorous Insects. Just as herbivores, which use visual cues that are characteristic of the plant surface, carnivorous insects also can respond to such cues for locating plants with potential prey. Recently, it was demonstrated that the parasitoid *Pimpla turionellae* (L.) can perceive changes in chromatic and achromatic plant surface characteristics evoked by infestation with endophytic hosts (Fischer et al., 2004).

Compounds from a herbivore that adsorb to the plant surface may also serve as host-finding kairomones for carnivorous arthropods. The sex phero-

mone of the moth *Mamestra brassicae* (L.) adsorbs on Brussel sprout leaves and increases the attractiveness for foraging females of *Trichogramma* egg parasitoids (Noldus et al., 1991). Small amounts of an unusual class of triacylglycerol were found on leaves visited by raspberry aphids. These compounds were derived from the aphid and probably arose from the presence of shed aphid skins on the leaf surface or by incorporation of cornicle secretions into the leaf wax (Shepherd et al., 1999a,b). Carnivores of aphids might use such cues for host exploitation.

Lipids of the plant bound to the herbivore (as explained above) might also be important in host finding for predators or parasitoids (Espelie and Bernays, 1989; Espelie and Brown, 1990; Espelie et al., 1991). Changes in surface chemistry induced by endophytic hosts such as leaf miners can help the parasitic wasp *Pholetesor bicolor* Ness (Hymenoptera: Braconidae) in host location (Dutton et al., 2002).

As for herbivorous insects, attachment of tarsae on plants is of primary importance for carnivorous insects. Adhesion of tarsae and thus predation efficiency is usually higher on plants with reduced amounts of epicuticular crystals, the same conditions that favor attachment of the prey (Eigenbrode, 1996; Eigenbrode and Kabalo, 1999; Eigenbrode and Jetter, 2002). This was demonstrated not only in the laboratory but also in field studies (Rutledge et al., 2003). Waxy blooms also influence parasitoids and can cause them to spend more time foraging on reduced epicuticular crystal cultivars (Chang et al., 2004). However, not all predators are impaired by epicuticular crystals (Eigenbrode et al., 2000). Different parasitoids of the same host insect are more or less sensitive to wax covers of the host plant (McAuslane et al., 2000). Therefore, the specific interactions of predators, parasitoids, and prey on crop plants need to be considered in planting strategies. Attachment of insects when they visit a plant has been elegantly quantified using centrifugal devices (Eigenbrode et al., 1999b; Federle et al., 2000; Eigenbrode and Jetter, 2002). For a review on the effects of epicuticular wax bloom on attachment and efficiency of predatory insects, we refer the reader to Eigenbrode (2004).

On *Macaranga* myrmecophytes, the epicuticular wax crystals allow only select symbiotic ants to walk on the stems. Thus, specialized ant species are protected mechanically against competitors that cannot climb the stems (Federle et al., 1997, 2000). The various physical properties of crystalline wax blooms of *Macaranga* species can be correlated to differences in chemical composition of the epicuticular triterpenoid blooms (Markstädter et al., 2000).

Cuticle Function in Carnivorous Plants. For pitcher plants that use insects as nitrogen and phosphorus sources, the structure of the epicuticular wax crystals within the trap plays an important role in preventing attachment of the

prey and thereby impairing escape from the trap (Knoll, 1914). Pitcher plants have a striking diversity of wax covers in the various zones of the pitcher. Peristomes of *Nepenthes* spp. traps are very slick for insects. Their slippery nature is due to water lubrication and anisotropic surface morphology. These physical properties lead to aquaplaning of a visiting insect, such as an ant (Bohn and Federle, 2004). The chemical composition of the surface of the peristomatal area is still not clear. In contrast, the chemical composition of the wax crystals in the zone below the peristome, the inner pitcher walls in the conductive zone, is mainly characterized by a polymer of C_{30} aldehydes. The exact mechanism by which this layer retains the insect prey within the pitcher has yet to be elucidated (Riedel et al., 2003). It has been conclusively shown that waxes do not play a role in the initial falling of the insect into the pitcher, but serve to retain caught insects within the trap (Gaume et al., 2002).

CONCLUSIONS

It is clear that the physicochemical and (eco)physiological characteristics of primary plant surfaces play a major role in chemical ecology. Our special reference to insect–plant relations allows us to reach general conclusions that are relevant to interactions of plants with a variety of organisms.

First, the physicochemical properties of the cuticle determine the wettability of a plant and its optical appearance. Furthermore, they influence the solubility as well as transport properties of molecules toward and away from the plant surface. These properties impact autecological features of the plant as well as interactions with other organisms (microbes, insects) that depend on first contact with the outermost surface.

Another important feature of the plant cuticle is the repellence of water, aqueous solutions, polar mucilages, and organisms with polar surfaces. The same physicochemical properties are involved in hindering attachment of microorganisms, herbivores, and carnivorous insects, as well as insect prey of carnivorous plants.

The presence or absence of chemicals in the epicuticular wax layer is determined primarily by their lipophilicity (1-octanol/water partition coefficient or aqueous solubility) and, in the case of volatiles, their saturation vapor pressure. Simple equations may be used to estimate the sorption in and diffusion of chemicals through the cuticle, and, thus, to assess the tendency of secondary metabolites to appear on plant surfaces. Polar and/or charged solutes that are readily soluble in water will not generally be found in or on the cuticle. Highly volatile, small substances will also not be present on primary plant surfaces for prolonged periods of time because they easily escape from the cuticle.

Microorganisms such as fungi may adopt hydrophobic qualities to enable them to attach to the surface. Furthermore, cuticular waxes can serve as signals in spore germination and growth of specific fungi, although secondary compounds on the surface may often have antimicrobial properties against an array of nonadapted organisms.

After approaching and landing on a plant, based on its optical characteristics and volatiles, an insect's behavior is influenced by water, primary and secondary compounds, and lipids present on the epicuticular waxes. However, only a limited range of compounds can be present at this outermost layer, and the waxes can even impair attachment as well as locomotion of insects to various degrees.

Methods are available for analyzing the composition of epicuticular separately from intracuticular waxes. These novel methods may now be used to clarify prior findings and to better understand the mechanisms whereby chemical surface cues may influence microorganism development or insect behavior.

The presence of chemical cues in or on the epicuticular layer does not only depend on the physical structure and chemical composition of the waxes *per se*. They may also result from transport of endogenous primary and secondary metabolites to the surface. In addition, exogenous volatiles or solutes adsorbed to the surface can serve as allelochemicals in the long and short range. The role of waxes as absorbents and release agents for biologically active material in chemical ecology has been underappreciated. Clearly, the interaction of epicuticular wax components with exogenous and endogenous substances makes the plant surface a chemical mosaic of signals that may evoke complex reactions in potential receivers such as insect herbivores, carnivores, or microorganisms.

The importance of plant surface properties as they relate to interactions with other organisms points to the need for future studies to focus on the role of the plant cuticle in chemical ecology. Present knowledge is based on the study mostly of crop plants and their pests. Such research should be expanded to include interactions of plants with their environments in natural ecosystems. In addition, the effects of changes in plant surface chemistry due to herbivore feeding or other stress factors may reveal additional information about the dynamics of surface chemistry in nature.

Acknowledgments—The authors receive financial support for their work from the Sonderforschungsbereich 554 "Evolution des Arthropodenverhaltens" of the Deutsche Forschungsgemeinschaft. They are also grateful to C. Hart, Syngenta Crop Protection, Jealott's Hill, UK, for providing Figure 2; to C. Popp for permission of showing some shared unpublished data; to E. Städler, M. Rostás, R. Reifenrath, and two anonymous referees for critically reading and commenting on an earlier version of this manuscript; and to A. Renwick for editing. We are indebted to M. Hilker for encouraging us to conceive and write this review.

(Received March 31, 2005; accepted July 16, 2005)

Abstract—We measured the concentrations of extractable bioactive compounds in heartwood of live yellow-cedar (*Chamaecyparis nootkatensis*) trees and five classes of standing snags (1–5, averaging 4, 14, 26, 51, and 81 years-since-death, respectively) to determine how the concentrations changed in the slowly deteriorating snags. Three individuals from each of these six condition classes were sampled at four sites spanning a 260-km distance across southeast Alaska, and the influence of geographic location on heartwood chemistry was evaluated. Cores of heartwood were collected at breast height and cut into consecutive 5-cm segments starting at the pith. Each segment was extracted with ethyl acetate and analyzed by gas chromatography. Concentrations of carvacrol, nootkatene, nootkatol, nootkatone, nootkatin, and total extractives (a sum of 16 compounds) for the inner (0–5 cm from pith), middle (5–10 cm from pith), and surface (outer 1.1–6.0 cm of heartwood) segments from each core were compared within each tree condition class and within segments across condition classes. Heartwood of class 1 and 2 snags had the same chemical composition as live trees. The first concentration changes begin to appear in class 3 snags, which coincides with greater heartwood exposure to the external environment as decaying sapwood sloughs away, after losing the protective outer bark. Within core segments, the concen-

trations of all compounds, except nootkatene, decrease between snag classes 2 and 5, resulting in the heartwood of class 5 snags having the lowest quantities of bioactive compounds, although not different from the amounts in class 4 snags. This decline in chemical defense is consistent with heartwood of class 5 snags being less decay-resistant than heartwood of live trees, as observed by others. The unique heartwood chemistry of yellow cedar and the slow way it is altered after death allow dead trees to remain standing for up to a century with a profound impact on the ecology of forests in southeast Alaska where these trees are in decline.

Key Words—*Chamaecyparis nootkatensis*, snags, decay resistance, chemical defense, carvacrol, nootkatin, antifungal compounds.

INTRODUCTION

Yellow cedar, *Chamaecyparis nootkatensis* (D. Don) Spach, is a socially, ecologically, and economically valuable tree in southeast Alaska. Its wood is highly desired in foreign markets, especially Japan. Around 1880, yellow cedar growing near open bogs, or on semibog sites with poor drainage, began to die, initiating a forest decline that continues to this day (Hennon et al., 1990a). Circumstantial evidence suggests that this decline was triggered by climatic warming (Hennon and Shaw, 1994), with minimal involvement of biotic agents (Hennon, 1990; Hennon et al., 1990b,c,d). Interactions of site characteristics with maritime-continental climate patterns are associated with tree mortality (Hennon and Shaw, 1997) that has left standing dead trees (snags) on more than 200,000 ha widely spread across the landscape. Yellow-cedar trees can remain standing for up to a century after their death because of the heartwood's natural durability and superior strength. As a consequence of this slow deterioration and the progressive nature of the decline, standing snags accumulate on affected sites and can average about 65% of the yellow-cedar basal area (Hennon et al., 1990c). Although live trees are commercially valuable, snags have been used primarily for firewood. With snags scattered over large distances and with limited road access, their commercial salvage is not economically justified unless their wood properties are comparable with those of live trees.

In an attempt to develop products with greater value, investigators compare the various heartwood characteristics of snags with those of live yellow-cedar trees. Snags can be visually sorted into six classes with increasing mean time-since-death of 4, 14, 26, 51, and 81 years, respectively (class 6 not dated; Hennon et al., 1990c) by evaluating their retention of foliage, twigs, and branches. By class 6, the heartwood is decaying and the bole is broken, often close to the ground. Mechanical properties of snag heartwood do not change much through class 5 (McDonald et al., 1997; Green et al., 2002), but there is a modest reduction in recoverable wood and grade from snags in classes 4 and 5,

compared with live trees and younger snags (Hennon et al., 2000). Decay resistance of heartwood from class 5 snags is adequate for products used above ground, but may be less durable than the heartwood from live trees and younger snags when in contact with soil (DeGroot et al., 2000).

Heartwood durability and decay resistance in yellow cedar have been attributed to the tropolone, nootkatin, that inhibits growth of various wood decay fungi (Rennerfelt and Nacht, 1955). Reducing its concentration in the heartwood decreases the wood's resistance to decay (Smith, 1970; Smith and Cserjesi, 1970). Carvacrol is another major component in yellow-cedar heartwood with antifungal properties (Voda et al., 2003). Because the heartwood of class 5 snags is less resistant to decay than heartwood from live trees and younger snags, it is likely to have lower concentrations of one or more of these bioactive compounds. The objective of this study was to measure the concentrations of carvacrol, nootkatin, and other extractable constituents in heartwood of live yellow-cedar trees and the five classes of snags to determine how they changed over the course of 80 years or more, in the slowly deteriorating, standing dead trees. Live trees and snags were sampled at each of four sites spanning a 260-km distance across southeast Alaska to evaluate whether geographic location had an influence on heartwood chemistry.

METHODS AND MATERIALS

Study Sites. Live and dead yellow-cedar trees were sampled at four locations in southeast Alaska (Figure 1): Goose Cove, Baranof Island (57°30′35N, 135°30′48W); Halibut Point near Sitka, Baranof Island (57°05′26N, 135°22′43W); Nemo Point, Wrangell Island (56°16′58N, 132°19′38W); and Sal Creek, Prince of Wales Island (55°48′41N, 132°32′13W). Each of these locations represents forests typical of yellow-cedar decline.

Tree and Snag Selection. Three dead trees from each of the five snag classes and three live trees were selected for sampling at each of the four study sites, yielding a total of 72. Snag classes were identified by their retention of dead foliage, twigs, and secondary or primary branches as described by Hennon et al. (1990c). Diameters of each bole were measured at breast height (dbh at 1.4 m) on the uphill side. All trees and snags sampled at a site were in close proximity to one another; most were separated by less than 100 m and none more than 200 m apart. They were sampled as encountered and discarded as unacceptable if decay prevented the removal of a continuous heartwood core to the pith.

Heartwood Samples. Two cores of heartwood extending to the center of the live tree or snag were removed with an increment borer (5.0 mm i.d.) on opposite sides of the bole at breast height. The boundary between sapwood and

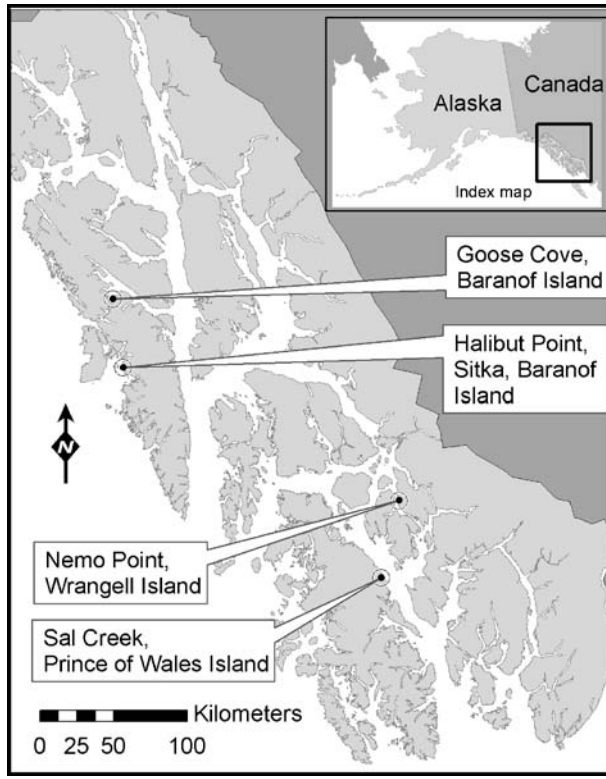

FIG. 1. A map showing the four sampling sites of yellow cedar in southeast Alaska.

heartwood was marked on cores from live trees and snags from classes 1 to 3 to assist the removal of sapwood in the laboratory. The pale yellow heartwood of yellow cedar is distinguishable from the white sapwood of live trees and black-stained or brown decayed sapwood of dead trees. Residual sapwood on class 4 snags was minimal (mean of 2–3 mm; Hennon et al., 2000) and readily detectable without marking. There was no sapwood remaining on class 5 snags. Each core was sealed in a plastic straw with tape (two straws for longer cores), placed inside a sealed plastic bag, and stored on ice in the field. Upon returning to the laboratory, cores were frozen at −36°C until analyzed.

Solvent Extraction. One increment core from each live tree or snag was removed from the freezer in random order and processed for extraction in a cold room at 7 ± 1°C. Cores were cut into consecutive 5.0-cm segments starting at the pith and progressing outward. The outermost heartwood segment was cut at the sapwood boundary (sapwood discarded) or terminated at the bole surface for

some class 4 and all class 5 snags. The two innermost segments from 0 to 5 and 5 to 10 cm from the pith are referred to as the inner and middle segments, respectively. The outermost or newest heartwood is referred to as the surface segment because it included the outer layer of heartwood left exposed after the sapwood had weathered away in class 4 and 5 snags. This surface segment varied in length. When greater than 1.0 cm, it was processed and extracted separately, but when 1.0 cm or less, it was combined with the previous segment yielding lengths ranging from just over 1.0 cm (11 surface segments between 1.0 and 1.9 cm) up to 6.0 cm. This resulted in seven small diameter individuals (one live tree, one class 1, two class 3, and three class 4 snags) having only two segments (inner and surface).

Each segment was sliced into disks 0.5–1.0 mm in thickness with a razor blade. The bulk of each sample was transferred to a preweighed vial (15-ml vol.) sealed with a Teflon®-lined screw cap for extraction. A small subsample was sealed in a preweighed 4-ml vial to measure the tissue water content. Both vials were adjusted to room temperature before recording tissue fresh weight. Four milliliters of ethyl acetate (Fisher Scientific, HPLC grade) were added to vials containing 3- to 6-cm length segments, whereas vials containing 2- to 3- or 1- to 2-cm segments were extracted with 2.0 and 1.0 ml of solvent, respectively. They were allowed to soak at room temperature (22 ± 1°C) for 7 d in the dark. Each extract was transferred by pipette into a 4-ml sealed vial containing anhydrous sodium sulfate (Mallinckrodt reagent grade, 0.68, 0.34, and 0.17 g/ 4-, 2-, and 1-ml solvent, respectively) to remove excess water. These were stored in a dark cold room until further processed for analysis. Just prior to analysis, 900 μl of room temperature extract were transferred into a 1.5-ml autosampler vial followed by 100 μl of ethyl acetate containing *R*-(+)-limonene (Aldrich, 99.7% purity) as the internal standard. Subsamples for water content measurements were dried at 102°C for 16 hr, then cooled to room temperature in a desiccator box before weighing.

Chromatography. Extracts were analyzed by gas chromatography using a Hewlett Packard 5890 Series II gas chromatograph (GC) equipped with a 6890 autosampler, flame ionization detector, and J&W Scientific DB-5 column (30 m × 0.25 mm, 0.25-μm film thickness). Helium was the carrier gas set at 1.0 ml/min flow through the column at the initial 100°C column temperature, with a split ratio of 1:10. The column oven was held for 1.0 min at 100°C, then increased to 150°C at 5°C/min, and then to 220°C at 3°C/min with no final temperature hold. Two microliters of extract were injected. Compound concentrations were calculated from a six-level standard curve of carvacrol (Sigma, 99%), with a limonene (Aldrich, 99.7%) internal standard at the same concentration as added to the extracts. All compound concentrations were calculated using the same response factor as carvacrol and normalized per gram dry weight using tissue water content measurements. Preliminary analysis indicated

that the response factors for carvacrol and nootkatin differed by less than 5%. Compounds were identified by GC–mass spectrometry using the same GC with an HP 5970 mass selective detector and a Phenomenex ZB-5 column (equivalent to the DB-5), with the oven conditions as above. Compounds were identified by comparison of their spectra with those in the spectral library or spectra obtained from authentic samples analyzed with this instrument.

Statistical Analyses. This sampling scheme is considered a balanced generalized randomized block because in all four blocks (sites), each of the six tree condition classes (live trees plus five snag classes) or treatments was independently received by three experimental units (trees or snags; Steele et al., 1997). This design allowed us to test whether any block (site) × tree condition class interactions were apparent. Each tree was repeatedly measured, once in each of the three heartwood core segments. Pearson's correlation coefficients among concentration estimates for the heartwood compounds provided information regarding the independence or correlation among these responses.

To assess whether there were systematic differences in dbh among snag age classes, the following one-way ANOVA model was fit to the data using SAS v8.2 PROC Mixed,

$$Y_{ijk} = m + \beta_i + a_j + \alpha_{ij} + \lambda_{ijk}$$

where Y_{ijk} is the dbh of the kth tree in the jth tree condition class in the ith block; m is the overall mean dbh for all trees; β_i is the random effect of block i ($i = 1, 2, \ldots, 4$); a_j is the effect of the jth tree condition class (j = live tree, snag class $1, \ldots, 5$); α_{ij} is the random error term that represents variability among sets of k trees ($k = 1, 2, 3$) from the same tree condition class among the blocks and is the error term used to test for condition class effect, $\alpha_{ij} \sim N(0, \sigma^2_\alpha)$; and λ_{ijk} is the random error term that represents variability among the k trees of the same tree condition class within the blocks, $\lambda_{ijk} \sim N(0, \sigma^2_\lambda)$, and is the error term used to test for site × tree condition class interaction.

The above model was expanded to model the concentration responses for the compounds described below using SAS v8.2 PROC Mixed (SAS Institute Inc., 1999),

$$Y_{ijkl} = m + \beta_i + a_j + \alpha_{ij} + \lambda_{ijk} + c_l + ac_{jl} + \varepsilon_{ijkl}$$

where Y_{ijkl} is the concentration of the compound of interest in the lth core segment of the kth tree in the jth tree condition class in the ith block; m, β_i, a_j, α_{ij}, and λ_{ijk} are defined as above; c_l is the effect of the lth core segment (l = inner, middle, surface); ac_{jl} is the interaction effect of the jth level of tree condition class and the lth core segment; and ε_{ijkl} is the random error term that

represents variability among core segments and is the error term used to test for effects of core segment and tree condition class by core segment interaction,

$$\varepsilon_{ijk} \sim \text{MVN}\left(\begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}\sigma_{11}^2 & \sigma_{12}\sigma_{13}\\ \sigma_{12}\sigma_{22}^2\sigma_{23}\\ \sigma_{13}\sigma_{23}\sigma_{33}^2\end{pmatrix}\right)$$

and represents the covariance among core segments within a tree.

A heterogeneous variance model was fit allowing different estimates of the values of this covariance matrix for each tree condition class. The appropriate within-tree covariance structure was selected using the minimum Akaike's information criterion (AIC). All individual compounds had a fully unstructured covariance [UN(3) model] with unequal variance among core segments and unequal covariances between segments. The total extractives had a much simpler within-tree covariance model [TOEP(1) model] with equal variance among core segments and covariance among segments estimated to be 0. Each compound response was also modeled with dbh as a covariate.

Scatter plots of the initial data for each compound revealed a few samples with excessively high values (5–10 times the mean) that were removed as outliers. Homogeneity of variances and normality were evaluated prior to analysis by examining plots of the residuals (observed vs. predicted) and normal probability plots. All five individual compounds (but not the total) required natural logarithm transformation to meet these assumptions. For carvacrol, nootkatene, and nootkatol (all with interactions between core segments and tree condition class), the differences among means (on the log scale) of core segments within tree condition classes, and differences among tree condition classes within segments, were determined with pairwise comparisons using Bonferroni adjusted confidence intervals (CIs). For nootkatone and nootkatin (on the log scale), and the total extractives (all without interactions between core segments and tree condition classes), the differences among means of the tree condition classes were determined by pairwise comparisons using Tukey 95% CIs. Transformed means and their 95% confidence limits were back-transformed to medians for presentation.

An F statistic, treating block as a fixed effect, was calculated to assess effectiveness of blocking and site-specific differences in average response for all response variables, including dbh.

RESULTS

Sixteen compounds were selected for quantitation in the ethyl acetate extracts of yellow-cedar heartwood. Based on the results from the GC-MS analysis, including spectral comparisons with some authentic samples recently

Tree condition class

isolated by Xioung (2000) or Khasawneh (2003), four compounds were identified as monoterpenes (3-carene, 4-terpineol, methyl carvacrol, and carvacrol), eight were sesquiterpenes (valencene, nootkatene, δ-cadinene, epi-nootkatol, nootkatol, valencene-13-ol, nootkatone, and valencene-11,12-diol), one was a tropolone (nootkatin), and three were unknown. Carvacrol, nootkatene, nootkatol, nootkatone, and nootkatin were selected for individual analysis (Figures 2 and 3) because of their biological activities, abundance, or chemical reactivity. A total extractives concentration using the combination of all 16 compounds was also analyzed (Figure 4). It is important to note that concentrations of the five individual compounds analyzed and the total extractives were related with one another as indicated by Pearson's correlation coefficients all greater than 0.62, except for nootkatene, whose coefficients with other compounds never exceeded 0.28. Differences in carvacrol, nootkatene, or nootkatol concentrations among core segments (Figure 2) were dependent on the tree condition class (significant interactions; Table 1), whereas concentrations of nootkatone and nootkatin (Figure 3) were dependent only on the tree condition class, with no differences among core segments within any of the condition classes (no interaction; Table 1).

Within live trees and class 1 snags, carvacrol concentrations in the inner core segments were significantly less than in the middle and surface segments (Figure 2A). This pattern began to reverse in class 2 snags resulting in surface core segments having lower concentrations than either the inner or middle segments, in all older snag classes. Within the surface core segments, carvacrol was significantly lower in class 5 snags than in live trees and all younger snags and significantly lower in class 4 than in live trees or class 1 and 2 snags. Concentrations of carvacrol within inner and middle core segments were significantly higher in class 2 snags than those in class 5.

Nootkatene concentrations within the middle and inner core segments were not different among any of the tree condition classes (Figure 2B). Quantities within the surface segments increased progressively starting in class 1, and by class 5, the concentrations were significantly higher than in live trees, with no other differences among classes. Within each tree condition class, the surface

FIG. 2. Median concentrations (±95% CIs) for the individual compounds carvacrol (A), nootkatene (B), and nootkatol (C) extracted with ethyl acetate from yellow-cedar heartwood of live trees and snags. Magnitudes of the CIs are indicative of the tree-to-tree variation about medians and are not accurate measures for identifying significant differences between medians. Within each tree condition class, the medians of core segments with similar letters above their symbols at the top of each graph are not significantly different. Within each core segment, the medians among tree condition classes with similar letters below their symbols at the bottom of each graph are not significantly different. In both instances, $\alpha = 0.05$.

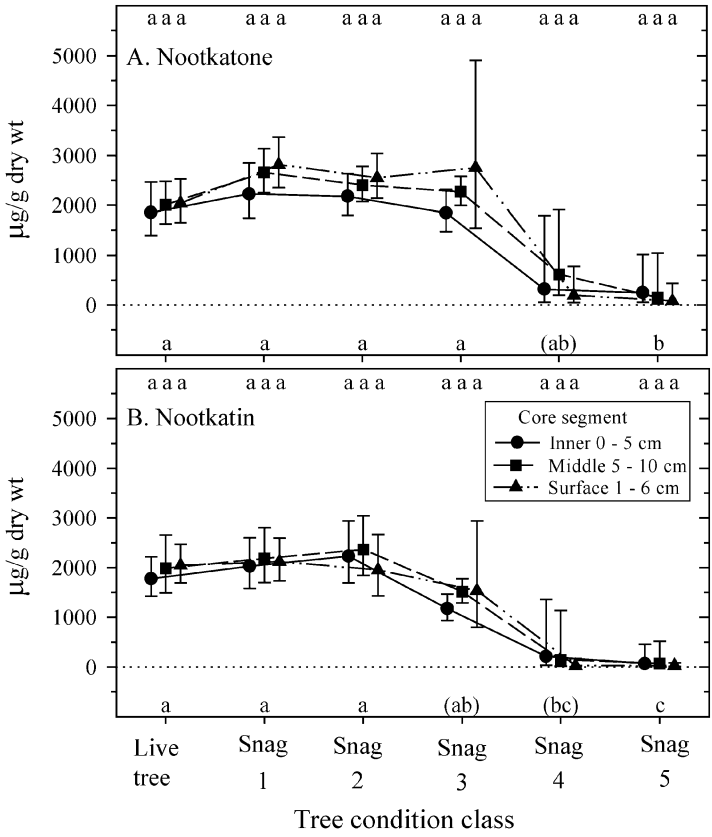

FIG. 3. Median concentrations (±95% CIs) for the individual compounds nootkatone (A) and nootkatin (B). The CIs and letters are the same as in Figure 2.

core segments contained significantly less nootkatene than the middle segments, and the inner segments in live trees and snags from classes 1 to 3. For live trees and class 1 or 2 snags, the inner core segments had significantly more nootkatene than the middle segments, with no differences between them in class 3–5 snags.

Nootkatol levels within live trees were highest in the surface core segments, followed by the middle and inner segments, with all differences being significant (Figure 2C). These relationships remained until class 3 when quantities generally declined, especially in the surface segments (but not significantly from levels in class 2). By class 4, nootkatol concentrations were the same in all core segments and significantly lower than in live trees and all previous snag classes. There were no differences in concentrations within segments or among segments for snags in classes 4 and 5.

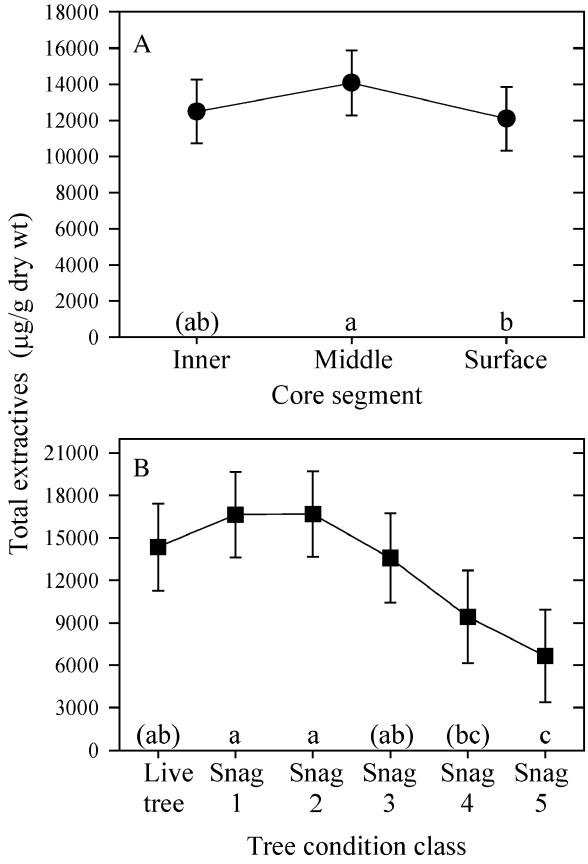

FIG. 4. Mean total extractives (±95% CIs) for 16 compounds removed with ethyl acetate from heartwood of live trees and snags of yellow cedar collected across southeast Alaska shown separately for core segments (A) and tree condition classes (B) because their interaction was not significant (Table 1). Means with the same letters at the bottom of the graph are not significantly different; $\alpha = 0.05$.

Nootkatone concentrations within all tree condition classes exhibited no significant differences among core segments (Figure 3A). Concentrations within segments remained unchanged from live trees to class 3 snags, followed by a nonsignificant decline in class 4. Class 5 snags had significantly less nootkatone than any of the more recent snags, except class 4.

Nootkatin exhibited a response similar to nootkatone, with no differences for core segments within any of the condition classes (Figure 3B). Within segments, the concentrations began to drop in class 3 rather than class 4.

TABLE 1. ANOVA RESULTS FOR EACH INDIVIDUAL COMPOUND AND THE TOTAL EXTRACTIVES FROM YELLOW-CEDAR HEARTWOOD

		Carvacrol		Nootkatene		Nootkatol		Nootkatone		Nootkatin		Total	
Factor in model	*df*[a]	*F*	*P*-value	*F*	*P*-value	*F*	*P*-value	*F*	*P*-value	*F*	*P*-value	*F*	*P*-value
Tree condition class (Tcc)	5, 15	6.51	0.002	2.30	0.097	22.58	<0.001	5.55	0.004	9.26	<0.001	8.75	<0.001
Core segment (Cs)	2, 173[b]	8.28	<0.001	103.64	<0.001	19.43	<0.001	1.41	0.246	2.87	0.059	4.68	0.011
Tcc × Cs	10, 173[b]	4.76	<0.001	4.32	<0.001	2.53	0.007	1.12	0.352	1.41	0.180	1.60	0.115

[a] Degrees of freedom for the numerator, denominator.
[b] Due to some missing values and removal of outliers, the denominator *df* is 172 for nootkatol, 171 for nootkatone and nootkatin, and 113 for the total extractives, which is much lower than for the individual compounds because of the different covariance structure used in the analysis.

Nootkatin concentrations in class 5 snags were significantly lower than all but class 4, and those in class 4 were lower than in live trees and class 1 or 2 snags.

Concentrations of the total extractives varied among core segments (Figure 4A), and among tree condition classes (Figure 4B), but without an interaction between them (Table 1). Middle core segments had significantly higher concentrations than the surface segments (Figure 4A). The class 4 snags had significantly lower amounts than class 1 and 2 snags, and the quantities in class 5 snags were lower than live trees, and all snag classes, except class 4 (Figure 4B).

The F statistic analysis showed that there were no differences among sites (all P values > 0.09) for the median concentrations of any compound or dbh. The analysis of variance (ANOVA) of compound concentrations with dbh as a covariate did not significantly reduce the variance, and the results were essentially unchanged from the ANOVA without dbh as a covariate. There was some evidence ($F_{5,15} = 2.57$, $P = 0.072$) that class 5 snags were smaller in diameter (averaging 25.6–33.2 cm dbh) than live trees or any of the other snag classes (averaging 31.2–41.3 cm dbh), with no differences among any of the latter.

DISCUSSION

Changes in compound concentrations in heartwood of yellow-cedar snags are associated with major physical changes of the boles as these standing dead trees deteriorate. Class 1 snags have intact outer bark and stained sapwood, whereas class 2 snags have sloughing bark and decaying sapwood. These changes, however, have minimal impact on heartwood chemistry, as the concentrations of most compounds in these snags remained the same as in live trees (Figures 2, 3, and 4B). By snag class 3, the outer bark is gone, the decaying sapwood is starting to slough away, and the heartwood surface begins to experience direct exposure to the external environment. This stage, some 25 years after tree death, marks the first substantial changes in heartwood chemistry. Because the outer heartwood is first exposed in class 3 snags, greater rates of chemical change might be expected to occur in the surface core segments compared with the middle and inner segments. This was observed, but only for nootkatol (Figure 2C). Tree to tree variation (as indicated by the larger confidence intervals) within the surface segments was greater in class 3 snags than in live trees or most younger snags for all individual compounds, except carvacrol. This probably reflects the variation in rates of sapwood decay and sloughing among class 3 snags, which results in different levels and durations of heartwood exposure to the environment. By snag class 4, all of the bark and most of the sapwood are gone from the bole, with checks or cracks penetrating about 3 cm deep into the heartwood (Hennon et al., 2002). Concentration changes that begin to appear in class 3 snags continue into class 4. Class 5 snags have no bark or sapwood

remaining and have deeper heartwood cracks (4 cm or greater) than in class 4. Heartwood of class 5 snags typically has lower concentrations of each compound (excluding nootkatene; Figure 2B) and total extractives than all younger snag classes, except class 4. Geographic location of the live trees and snags had minimal influence on their heartwood chemistry, probably because environmental parameters among the sites sampled in southeast Alaska were similar.

Potential mechanisms contributing to the concentration changes of heartwood components in aging yellow-cedar snags (Figures 2 Figures 3 Figures 4) are volatilization to the atmosphere, leaching, structural changes from reactions such as dehydration or oxidation, and possibly polymerization. As the heartwood surface becomes exposed to the elements, all of the compounds could be lost to some degree by volatilization, similar to the emissions of monoterpenes from the boles of lodgepole pine, *Pinus contorta murrayana* (Grev. and Balf.) Engelm. (Rhoades, 1990). Carvacrol is the most volatile of the individual compounds, and was likely impacted more by this mechanism than the other compounds, and partially responsible for the lower quantities measured in surface cores of class 4 and 5 snags with cracked and exposed heartwood. The forests of southeast Alaska are humid and wet (150- to 500-cm annual precipitation; Harris et al., 1974), so temperature and humidity both may function as the drivers of heartwood emissions to the atmosphere (Schade et al., 1999). Although these heartwood compounds all have limited water solubility, they could be gradually leached from the outermost layers of tissues exposed for many years to heavy rainfall.

Structural changes could be responsible for the decline of nootkatol, as a simple and facile dehydration reaction will yield nootkatene. Evidence supporting this rearrangement occurs in the heartwood of live trees, where the concentrations (transformed on the natural log scale) of these two compounds exhibit a nonlinear, inverse relationship (cubic polynomial; $R^2 = 0.567$). In addition, shifts in their relative concentrations appear to be associated with heartwood age. For example, surface core segments represent the youngest heartwood and contain 18.7 times more nootkatol than nootkatene (Figure 2B and C). In older, middle core heartwood, the concentrations of nootkatol are lower and the concentrations of nootkatene are higher than in surface core segments, resulting in nootkatol being only 2.5 times greater than nootkatene. The oldest heartwood from inner core segments of live trees contains the lowest nootkatol and highest nootkatene among the three segments, making the nootkatene 1.6 times more abundant than nootkatol. Loss of nootkatol from the surface cores is accelerated as the heartwood becomes more exposed between snag classes 2 and 4. Whereas nootkatene concentrations do increase in the surface core segments between these snag classes, the amount accumulated represents only a fraction of the nootkatol lost during the same period. Thus, nootkatol in exposed heartwood may be also changing to products other than

nootkatene (e.g., oxidation to nootkatone) or volatilizing to the atmosphere. Alternatively, nootkatene could be the initial rearrangement product of nootkatol, but is probably a transient intermediate because of the reactive conjugated double-bond system that is easily oxidized, thus minimizing the accumulation of nootkatene.

Longevity of yellow-cedar trees and the long persistence of standing snags in southeast Alaska are attributed to compounds in the heartwood functioning as a defense against disease and insects, with resistance to decay credited primarily to nootkatin, shown to have fungicidal activity at relatively low concentrations. This chemical defense also contributes to the durability of yellow-cedar wood used as lumber or other building materials (Rennerfelt and Nacht, 1955). Removal of nootkatin by the growth of a black-stain fungus, an organism that invades the wood of live trees and degrades this compound, dramatically decreased the resistance of the stained wood to decay fungi (Smith, 1970; Smith and Cserjesi, 1970). But other compounds also contribute to yellow-cedar durability. The antifungal properties of carvacrol were reported by Anderson in 1961 (cited in Barton, 1976), and it was one of the most active growth inhibitors of 22 compounds tested against the wood-decaying white rot, *Trametes versicolor*, and brown rot, *Coniophora puteana* (Voda et al., 2003). It also inhibits mycelial growth of various species of plant pathogens in the genus *Fusarium* (Thompson, 1996). Carvacrol is bactericidal toward a variety of human pathogens commonly found on meats, vegetables, rice, and dairy products (Ultee et al., 1999; Knowles and Roller, 2001; Friedman et al., 2002; Burt, 2004). Chamic acid and isochamic acid are two other monoterpenes that may contribute to decay resistance of yellow-cedar heartwood, but were not detected in our analysis because of their polarity. They have only 1/10th or less the activity of nootkatin (Rennerfelt and Nacht, 1955).

Extracts of yellow-cedar heartwood and some of the individual compounds are also biologically active toward a variety of invertebrates. Nootkatone repels and inhibits tunneling of Formosan termites, *Coptotermes formasanus* Shiraki (Maistrello et al., 2001; Zhu et al., 2001). Yellow-cedar fiber used in producing wall paneling was not eaten by eastern subterranean termites, *Reticulitermes flavipes* (Kollar), in free choice tests with five other panel wood products and pine sapwood as alternative choices (Kard and Mallette, 1997). However, in no-choice tests, the yellow-cedar fiber was severely damaged. Essential oil from yellow-cedar heartwood, nootkatone, carvacrol, valencene-13-ol, and nootkatol all have insecticidal and/or acaricidal activity toward various agricultural, stored products, or medicinal arthropod pests (Panella et al., 1997; Ahn et al., 1998; Khasawneh, 2003). Carvacrol also has nematicidal properties (Oka et al., 2000).

Loss of the antifungal compounds as dead trees deteriorate, as shown here, is most likely responsible for the reduced decay resistance of heartwood from class 5 yellow-cedar snags. In laboratory tests against the brown-rot fungus,

Gloeophyllum trabeum Pers. Ex. Fr., heartwood from class 5 snags lost significantly more weight (56.3%) from fungal decay than heartwood from live trees (21%) or class 3 snags (12%, not significantly different from live trees), when collected from individuals with a large diameter (425–535 mm or 17–21 in.) (DeGroot et al., 2000). A similar response was observed for smaller diameter snags (300–400 mm or 12–16 in.), but the average weight loss for class 5 heartwood (29.2%) was not significantly greater than heartwood from similarly sized live trees (15.9%). In a separate study of decay resistance, heartwood was placed in contact with soil for up to 4 years. As in the laboratory study described above, the wood from snag class 5 had significantly greater weight loss (i.e., decay) than wood from class 3 snags and live trees, which did not differ (Hennon, unpublished data). Furthermore, DeGroot et al. (2000) observed substantial tree-to-tree variation in decay resistance during laboratory bioassays, which probably results, in part, from the large tree-to-tree variation in concentrations of the antifungal compounds, as observed here. Because the composition and concentrations of chemicals in yellow-cedar heartwood protect it from fungal decay, it might be feasible to evaluate and rank the level of resistance for live trees or snags by quantifying the concentrations of nootkatin, carvacrol, and possibly other compounds. Development of an accurate predictive model for this purpose would require further testing of heartwood samples for decay resistance in conjunction with a quantification of their chemical constituents, as undertaken here.

Collectively, the studies of standing dead yellow-cedar trees suggest that changes in heartwood chemistry precede other major changes in wood properties. As demonstrated in this study, the heartwood constituents remain largely unchanged from live trees until snag class 3, about 25 years after tree death. Initiation of chemical changes corresponds with the class of snags experiencing increased heartwood exposure to external environmental parameters that can expedite these changes. Concentrations of most compounds, including those with antifungal activity, began to decline in class 3 snags. This gradual reduction in chemical defense continues as the snags age and subsequently leads to a decline in heartwood decay resistance. Whereas heartwood of class 5 snags is less decay-resistant than heartwood of live trees (DeGroot et al., 2000; Hennon, unpublished data), the strength properties of heartwood at the class 5 stage, some 80 years after death, remain unchanged from live trees (McDonald et al., 1997; Green et al., 2002). The unique heartwood chemistry and the slow way in which it is altered after tree death have profound ecological and economic implications. Dead yellow-cedar trees across southeast Alaska remain standing as snags for up to a century, and because the heartwood stays strong, hard, and undecayed, they probably offer little in the way of habitat for cavity-nesting animals. This limited deterioration and surprising persistence of wood properties also offer opportunities for recovering valuable wood products.

(Received March 14, 2005; revised June 21, 2005; accepted July 17, 2005)

Abstract—Contents of phenolic compounds and related enzymes before and after sorghum grain germination were compared between varieties either resistant or susceptible to biotic (sooty stripe, sorghum midge, leaf anthracnose, striga, and grain molds) and abiotic (lodging, drought resistance, and photoperiod sensitivity) stresses. Independent of grain germination, sorghum varieties resistant to biotic and abiotic stresses had on average higher contents of proanthocyanidins (PAs), 3-deoxyanthocyanidins (3-DAs), and flavan-4-ols than susceptible varieties. Results show that content of 3-DAs is a good marker for sorghum resistance to both biotic and abiotic stresses because it correlates with resistance to all stresses except for photoperiod sensitivity. The second good marker for stress resistance is content of PAs. Total phenolic compounds and the activities of related enzymes are not good markers for stress resistance in sorghum grains.

Key Words—Sorghum, proanthocyanidins, 3-deoxyanthocyanidins, phenylalanine ammonia lyase, peroxidase, polyphenol oxidase, stress, biotic, abiotic.

INTRODUCTION

Sorghum [*Sorghum bicolor* (L.)] Moench is a C4 plant grass of the hot, semiarid tropics and genetically diverse. On the basis of genetic diversity, some sorghum varieties are more resistant to stresses than others (Tao et al., 1993, 2003; Deu et al., 1994). The constraints of sorghum production are both biotic and abiotic stresses. Among biotic stresses, leaf anthracnose caused by the fungus *Colletotrichum graminicola*, sooty stripe incited by the fungus *Ramulispora sorghi*, and striga caused by the parasitic plant *Striga hermonthica* (Del.) Bent are the most damaging pests in West Africa in general, and particularly in Burkina Faso (Tenkouano, 1995; Neya and Le Normand, 1998; Trouche et al., 2001). In addition, sorghum midge caused by insects (*Contarinia sorghicola*, *Sitodiplosis moselana*, *Stenodiplosis sorghicola*, etc.) attack developing sorghum grains (Sharma and Hariprasad, 2002; Tao et al., 2003). Also, grain mold is a high constraint of sorghum production, and several molds are associated with sorghum caryopse damage (Melake-Berhan et al., 1996; Waniska et al., 2001). In Africa, the absence of grain mold resistance has been cited as a constraint to adoption of improved cultivars (Audilakshmi et al., 1999).

Important abiotic stresses limiting sorghum production in West Africa are drought, photoperiod sensitivity, and lodging (Tenkouano, 1995; Trouche et al., 2001). Lodging may be indirectly related to fungal infections, which weaken the plant (Waniska et al., 2001).

An increase in the activities of phenolic related enzymes and the accumulation of phenolic compounds have been correlated with resistance of cereals to biotic stresses (Mohammadi and Kazemi, 2002). Plant resistance to biotic and abiotic stresses is often regulated by the metabolism of phenolic compounds. Sorghum phenolic compounds, e.g., phytoalexins (3-deoxyanthocyanidins) or allelochemicals (*p*-hydroxybenzoates, *p*-coumarates, and flavanols), are involved in plant resistance to all kind of stresses (Lo et al., 1999; Weston et al., 1999, Weir et al., 2004).

Both biotic (fungi, insects, viruses, etc.) and abiotic (drought, temperature, photoperiod, nutrient deficiencies, etc.) stresses induce phenylalanine ammonia lyase (PAL; EC 4.3.1.5) synthesis (Chalker-Scott and Fuchigami, 1989; Tovar et al., 2002). PAL activity has been detected in the green shoots and leaves (Stafford, 1969; Mohan et al., 1988) of sorghum, and in sorghum, the infection of the plant with pathogens involves a rapid accumulation of PAL mRNA (Cui et al., 1996).

Also, peroxidases (POXs, EC 1.11.1.7; donor: H_2O_2 oxidoreductase) play an important role in stress-related resistance. One of the important physiological roles of POXs is the synthesis of cell-wall polymers (lignin and suberin), which constitute physical barriers for both biotic and abiotic stresses (Cosgrove, 1997).

In sorghum, POXs are involved in thermal tolerance (Choudhary et al., 1993) and resistance to fungal infection (Luthra et al., 1988).

Polyphenol oxidases (PPOs, EC1.14.18.1; monophenol, 3,4-*L*-dihydroxyphenylalanine: oxygen oxidoreductase) play an important role in plant defense via the oxidation of endogenous phenolic compounds into *o*-quinones, which are toxic to invading pathogens and pests (Mohammadi and Kazemi, 2002). PPO activity in plants increases under abiotic stress conditions (Mayer and Harel, 1991) and upon fungal infections (Luthra et al., 1988).

Several studies in other plant species have shown that the levels of phenolic compounds, and the activities of PAL, POX, and PPO are different between resistant plants and plants susceptible to stresses (Lo et al., 1999; Mohammadi and Kazemi, 2002). Comparing the effects of germination on the levels of phenolic compounds (Dicko et al., 2005a) and the activities of phenolic compounds related enzymes (Dicko et al., 2005b), the levels of these compounds were found to be highly variable in sorghum varieties. Whether the levels of phenolic compounds and related enzymes in sorghum grain could be linked to the grain or plant resistance or susceptibility to stress is unknown. The aim of the present study was to identify possible markers for the grain or plant resistance or susceptibility to these stresses. This was done by comparing the levels of endogenous phenolic compounds and related enzymes in ungerminated and germinated sorghum kernels of known grain or plant agronomic properties for resistance or susceptibility to biotic and abiotic stresses.

METHODS AND MATERIALS

Chemicals. 4-Hydroxyanisole (4-HA) and gallic acid (3,4,5-trihydroxybenzoic acid) were obtained from Aldrich (Steinheim, Germany). 3,4-Dihydroxyphenylpropionic acid (DHPPA) was from Acros Organics (Geel, Belgium). Folin-Ciocalteu's reagent, 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid (ABTS), insoluble polyvinylpyrrolidone (PVP), bovine serum albumin (BSA), and 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) were from Sigma Chemical Co. (St. Louis, MO, USA). Hydrogen peroxide was from Merck (Darmstadt, Germany). Sorghum apigeninidin, isolated and characterized by Kouda-Bonafos et al., (1996), was a gift of Dr. Eloi Palé from the Laboratory of Natural Substances, University of Ouagadougou, Burkina Faso. Cyanidin chloride was from Extrasynthèse (Lyon, France). Apple ciders procyanidin oligomers (average degree of polymerization = 7.4) were kindly provided by Dr. Stephanie Prigent (Wageningen University, Wageningen, The Netherlands) and Dr. Catherine M. G. C. Renard (INRA, Rennes, France). These procyanidins were purified by RP-HPLC and characterized by thiolysis-HPLC as described by Guyot et al. (2001). All other chemicals were of analytical grade.

Sorghum Grains. Fifty sorghum varieties were grown during the rainy season of 2002 at the experimental station of Saria, in Burkina Faso (West Africa). The environment was semiarid (temperature: 30–42°C; annual precipitation: 850 mm). Growth conditions have been described previously (Dicko et al., 2005a). For convenience, the sorghum varieties were classified in alphabetic order of their name followed by arabic numbers: V1 to V50 (Table 1). Mature grains (≥60 days after anthesis) were harvested, surface-sterilized, and germinated as described previously (Dicko et al., 2002, 2005a). Germinated and ungerminated sorghum grains were dried, ground, and stored (Dicko et al., 2005a). Flours of both germinated and ungerminated sorghum varieties were analyzed. The varieties were grouped according to their resistance or susceptibility to biotic stresses, e.g., sooty stripe, sorghum midge, leaf anthracnose, striga, and grain molds; and abiotic stresses, e.g., lodging, drought resistance, and photoperiod sensitivity (Table 2). Information on resistance and susceptibility to these specific stresses was obtained from sorghum breeders from the experimental station of Saria and Farakoba (Institut National pour l'Environnement et la Recherche Agronomique, Burkina Faso).

Extraction and Quantification of Phenolic Compounds. Sorghum phenolic compounds were extracted and quantified as previously described (Dicko et al., 2002, 2005a). Results were expressed as phenolic equivalent per gram of flour (w/w), on dry matter basis. Phenolic compounds were extracted from 50 mg of sorghum flour by continuous stirring with 1.5 ml of 1% (v/v) HCl in methanol at 25°C for 20 min, followed by centrifugation (5000 *g*, 10 min, 25°C), and supernatant collection. The residue was reextracted with 0.5 ml HCl/methanol as described above, the supernatants were pooled, and denoted total phenolic extract. The total phenolic extract was used directly for analysis or kept in the dark at −30°C. The same extract was used for quantification of total phenolics, proanthocyanidins (PAs), 3-deoxyanthocyanidins (3-DAs), and flavan-4-ols. The total phenol content was determined using the Folin-Ciocalteu's method adapted to a 96-well plate assay. To 10 µl of extract, 25 µl of Folin-Ciocalteu's reagent (50%, v/v) were added. After 5 min of incubation, 25 µl of 20% (w/v) sodium carbonate solution and 165 µl water were added. Blanks were prepared for each sorghum sample by replacing Folin-Ciocalteu's reagent with water. Gallic acid was used as a standard. The standard was always freshly prepared. The absorbances were measured after 30 min at 760 nm.

PAs and flavan-4-ols were assayed essentially as described by Melake-Berhan et al. (1996) with miniaturization to adapt the assay to a 96-well plate format as follows. To determine flavan-4-ols, 50 µl of the extract were added to 700 µl of reagent A (30%, v/v 12 M HCl in butan-1-ol) or to 700 µl of reagent B (15%, v/v 0.1 M acetic acid; 15%, v/v, methanol and 70%, v/v, butan-1-ol). The sample in reagent A was mixed by vortex and left at 25°C, for 1 hr, to allow formation of anthocyanidin pigments derived from flavan-4-ols (Melake-Berhan

TABLE 2. AGRONOMIC PROPERTIES OF SORGHUM VARIETIES

Type of stress	Plant/grain agronomic properties	Variety code
Biotic	Sooty stripe resistant ($N = 3$)	V23, V42, V45
	Sooty stripe susceptible ($N = 3$)	V3, V24, V28
	Anthracnose resistant ($N = 4$)	V11, V16, V22, V29
	Anthracnose susceptible ($N = 3$)	V7, V28, V42
	Sorghum midge resistant ($N = 4$)	V16, V24, V35, V44
	Sorghum midge susceptible ($N = 2$)	V12, V33
	Striga resistant ($N = 4$)	V18, V31, V42, V47
	Striga susceptible ($N = 3$)	V13, V15, V40
	Grain mold resistant ($N = 3$)	V19, V30, V44
	Grain mold susceptible ($N = 2$)	V3, V25
Abiotic	Lodging resistant ($N = 7$)	V3, V10, V16, V23, V25, V26, V44
	Lodging susceptible ($N = 2$)	V27, V28
	Preflowering drought resistant ($N = 3$)	V1, V27, V46
	Preflowering drought susceptible ($N = 1$)	V3
	Postflowering drought resistant ($N = 8$)	V3, V23, V32, V34, V41, V42, V43, V44
	Postflowering drought susceptible ($N = 4$)	V4, V11, V28, V49
	Photoperiod insensitive ($N = 14$)	V5, V7, V11, V23, V25, V27, V28, V29, V30, V32, V36, V41, V43, V44
	Photoperiod sensitive ($N = 7$)	V6, V18, V20, V21, V26, V42, V45

et al., 1996). Aliquots of the mixture (150 µl) were put in duplicate into a 96-multiwell plate, and the absorbance was read at 550 nm to quantify anthocyanidins formed from flavan-4-ols (Melake-Berhan et al., 1996). Cyanidin was used as standard to estimate the total amount of the anthocyanidins derived from flavan-4-ols. For quantification of PAs, the sample remaining in the tube with reagent A was further heated at 100°C, for 2 hr. Under these conditions, PAs are converted to anthocyanidins, and the unstable pigments formed from flavan-4-ols are destroyed. After cooling, 200 µl of the sample were put in duplicate in a 96 multiwell plate, and the absorbances of anthocyanidin compounds derived from PAs were read at 550 nm. Sample mixtures with reagent B, which were not heated, served as blanks for the quantification of both PAs and flavan-4-ols. Apple procyanidins with an average degree of polymerization of 7.4 and treated as indicated above were used as standards for sorghum PA quantification (Dicko et al., 2005a). For direct spectrophotometric quantification of 3-DAs, 50 µl of the total phenolic extract were mixed with 150 µl of methanol and the absorbances were read at 475 nm (Melake-Berhan et al., 1996). Sorghum apigeninidin was used as standard.

Enzyme Extraction and Determination of Protein Concentration. Enzyme extraction and total protein quantification were performed as described

previously (Dicko et al., 2002, 2005b). Enzyme extracts were prepared by mixing 250 mg of sorghum flour with 1.2 ml of 50 mM Tris–HCl buffer (pH 7.3) containing 0.5 M $CaCl_2$ and 2% (w/v) polyvinylpyrrolidone, at 4°C for 1 hr. The homogenate was centrifuged (14,000 *g*, 4°C, 45 min), and the resulting supernatant was denoted enzyme extract of PPO, POX, and PAL. Total protein was quantified by the linearized method of Bradford, using bovine serum albumin as standard.

Determination of Enzyme Activities. PAL activity was evaluated by measuring *trans*-cinnamic acid formation from L-phenylalanine as described previously (Tovar et al., 2002). Commercial sodium *trans*-cinnamate was used as standard. The spectrophotometric assay for PPO was performed as described previously (Dicko et al., 2002). 4-Hydroxyanisole (4-HA) and 3,4-dihydroxyphenylpropionic acid (DHPPA) were used as substrates to determine the monophenolase and *o*-diphenolase activities of PPO, respectively. The enzyme extract (10 μl) was incubated with 150 μl 50 mM sodium acetate, pH 5.5, 10 μl 40% (v/v) DMF and 10 μl 50 mM 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) at 25°C for 5 min. The reaction was started by addition of 20 μl 100 mM of the phenolic substrate (prepared in 0.15 mM phosphoric acid). The reaction was monitored at 500 nm. Blanks, in which the enzyme extracts or substrates were replaced by buffer, were performed. One unit of PPO activity (U) is defined as the amount of enzyme producing 1 μmol MBTH-*o*-quinone adducts/min resulting from the oxidation of 4-HA or DHPPA. Prior to determination of POX activity, extracts from ungerminated and germinated sorghums were diluted 400- and 1000-fold, respectively, in 50 mM Tris–HCl, pH 7.3, containing 0.5 M $CaCl_2$ and 1 mg/ml bovine serum albumin. POX activity was measured spectrophotometrically by monitoring the H_2O_2-dependent oxidation of ABTS, at 25°C (Dicko et al., 2002). The reaction mixture consisted of 10 μl of 200-fold diluted crude enzyme extract, 20 μl of 100 mM ABTS, 10 μl of 100 mM H_2O_2, and 160 μl of 50 mM sodium acetate, pH 4.0. Blanks, in which the enzyme extract or substrates were replaced by buffer, were performed. The reaction was monitored at 414 nm. One unit of POX activity (U) is defined as the amount of enzyme releasing 1 μmol ABTS radical/min under the assay conditions.

Statistical Analyses. Statistical analyses were carried out as previously described (Dicko et al., 2002, 2005a). All spectrophotometric assays were carried out in 96-well microtiter plates (Nunclon, Denmark) using a multiwell plate reader (μQuant Bio-Tek Instrument, Inc.) interfaced with a personal computer. Absorbances and slopes of absorbances per min (OD/min) were automatically recorded using KC junior software version 1.31.5 (Bio-Tek Instrument, Inc, USA). All assays were carried out at least in duplicate. Results were subjected to ANOVA performed with Statistica version 4.5 software for Windows. Significant differences in mean performance for each composition among sorghum varieties were determined by Student's *t*-test, where $P < 0.05$ implies significance.

RESULTS AND DISCUSSION

The contents of phenolic compounds and the activities of related enzymes in varieties grouped according to their agronomic properties are presented in Table 3. Difference in composition was determined using Student's *t*-test between varieties resistant and varieties susceptible to specific biotic or abiotic stresses (Table 4). Furthermore, the levels of significance were confirmed with ANOVA.

Correlations between Phenolic Compounds and Related Enzymes and Resistance or Susceptibility to Biotic Stress. In the present study, independent of grain germination, no significant difference in total phenolic compound content between sorghum varieties susceptible and those resistant to biotic stresses was found. However, leaves of sorghum resistant to fungi contained a higher content of total phenolics than leaves of susceptible ones upon pathogen challenge (Luthra et al., 1988). This suggests that total phenolic compounds content in sorghum grains, which are not challenged by pathogens, is not a good indicator for resistance to biotic stress.

When focusing on individual classes of phenolic compounds, it can be seen that PA levels were higher on average in varieties resistant to sooty stripe, sorghum midge, and grain mold than susceptible ones. In contrast, resistance to anthracnose and striga was not correlated with content of PAs. The high content of PAs in varieties resistant to mold is in agreement with previous observations showing that high PA containing sorghums are generally resistant to grain molding and weathering (Waniska et al., 2001). Sorghum midge resistance is also associated with PAs content in another study (Sharma and Hariprasad, 2002).

3-DA content is higher in all varieties resistant to the referred biotic stresses compared to that of susceptible ones. This indicates a function as phytoalexins (Weiergang et al., 1996; Lo et al., 1999). For example, the content of 3-DAs, notably apigeninidin, is an indicator of grain resistance to fungi such as *Colletrichum graminicola*, *Fusarium oxysporum*, *Gibberelle zeae*, and *Gliocladium roseum* (Schutt and Netzly, 1991) and of sorghum resistance to anthracnose (Lo et al., 1999). Colored phenolic compounds, probably 3-DAs, were suggested to be involved in sorghum resistance to striga (Arnaud et al., 1999). Recently, the importance of phenolic compounds as allelochemicals, involved in plant–parasite interactions, were indicated (Weir et al., 2004). Our results suggest that the content of 3-DAs in sorghum grain is not only an indicator of resistance to mold, but also to sooty stripe, anthracnose, sorghum midge, and striga.

The content of flavan-4-ols is on average higher in varieties resistant to mold than in susceptible ones. This agrees with previous findings showing that flavan-4-ol content is an indicator of grain resistance to molds (Schutt and Netzly, 1991; Melake-Berhan et al., 1996). Moreover, the results presented here show that

independent of germination, the flavan-4-ol content was on average higher in varieties resistant to sooty stripe, sorghum midge, leaf anthracnose, and striga than in susceptible ones. This suggests that the flavan-4-ol content in sorghum grain is a good indicator of plant resistance to sooty stripe, sorghum midge, and striga. For leaf anthracnose, no correlation could be found with the grain content of flavan-4-ols.

Before germination, PAL activity was higher in varieties resistant to sooty stripe and sorghum midge than in susceptible ones. However, after germination there was no difference. PAL activity in germinated varieties resistant to anthracnose was higher than in susceptible ones. This supports previous findings that high PAL activity in sorghum is associated with resistance to *Colletotrichum* species (Kamida et al., 2000).

POX and PPO activities before germination could not be linked to resistance or susceptibility to biotic stresses. Germination did not affect this trend for POX. After germination, the mono-PPO activity increased in the sooty stripe resistant varieties and decreased in anthracnose resistant varieties. These results are in agreement with findings that PPO may confer resistance to some fungal species such as *R. sorghicola* (sooty stripe agent) (Luthra et al., 1988).

Correlations between Levels of Phenolic Compounds and Related Enzymes, and Resistance Susceptibility to Abiotic Stress. Varieties resistant to lodging had significantly lower PAs than susceptible ones, both before and after germination. From these results, it may be inferred that the PA content of the grain is a marker for plant resistance to lodging. Independent of grain germination, varieties resistant to both preflowering and postflowering drought contained apparently more PAs, 3-DAs, and flavan-4-ols than susceptible ones. Results indicate the importance of polyphenols in drought resistance.

For other plants (*Mangifera indica*), the phenolic compound content is influenced by their response to light (Tovar et al., 2002). However, no significant difference in content of total phenolic compounds, PAs, 3-DA, or flavan-4-ols was found between the grain of sorghum varieties resistant or susceptible to photoperiod.

POX activity in ungerminated grains was not significantly different between varieties resistant or susceptible to abiotic stresses. After germination, POX activity appeared to be on average higher in varieties resistant to lodging than in susceptible ones. High activity of POX in varieties resistant to lodging could be related to the role of POX in the formation of physical polymeric barriers such as suberin and lignin (Cosgrove, 1997; Quiroga et al., 2000), which might confer the plant with high rigidity.

Specific POX isoenzymes in leaves, notably the cationic ones, are correlated with photoperiod sensitivity in sorghum, and play a role in plant adaptation (Pao and Morgan, 1988). However, in the present study POX activity of the grain could not be linked to the plant sensitivity to photoperiod.

TABLE 3. PHENOLIC COMPOUNDS AND PHENOLIC ENZYMES IN GROUPS OF SORGHUM VARIETIES RESISTANT AND SUSCEPTIBLE TO STRESSES

Type of stress		Total phenolics (%)[a]	PAs (%)	3-DAs (%)	Flavan-4-ols (%)	PAL (mU/mg)[b]	POX (U/mg)	Mono-PPO (mU/mg)	Dipheno-PPO (mU/mg)

	Photoperiod sensitive ($N = 7$)	NS	NS	NS	NS	NS	NS	NS	NS

PAs = proanthocyanidins; 3-DAs = 3-deoxyanthocyanidins; PAL = phenylalanine ammonia lyase; POX = peroxidase; mono-PPO = monophenolase activity of polyphenol oxidase (PPO); dipheno-PPO = *o*-diphenolase activity of PPO.
NS, not significant ($P > 0.05$); +, significantly high ($P < 0.05$); −, significantly low ($P < 0.05$).

Before grain germination, PPO activities could not be linked to abiotic stresses. After germination, both the monophenolase and *o*-diphenolase activities of PPO were higher in postflowering drought resistant varieties than in susceptible ones. This suggests a role of PPO in postflowering drought resistance, in agreement with earlier findings (Mayer and Harel, 1991). Independent of grain germination, PPO activities could not be related to resistance to lodging or photoperiod. PAL activity in the grain cannot be used as a marker for resistance to lodging, drought, and photoperiod variation as well.

Overall Impact of Phenolic Compounds and Related Enzymes in Stress Resistance. Results in Table 4 show that 3-DA content is a good marker for sorghum resistance to both biotic and abiotic stresses because 3-DAs are positively correlated with resistance to all stresses except for photoperiod sensitivity. The second marker for stress resistance is PA content. Total phenolic compounds and the activities of related enzymes are not good markers for stress resistance in sorghum grains. For photoperiod sensitivity, none of the screened biochemical compounds could be used as a marker of resistance in sorghum grain.

WHOLE PLANT RESPONSE OF LETTUCE AFTER ROOT EXPOSURE TO BOA (2(3*H*)-BENZOXAZOLINONE)

A. M. SÁNCHEZ-MOREIRAS[1,2] and M. J. REIGOSA[1,*]

Laboratory of Plant Ecophysiology, Faculty of Biology, University of Vigo, Campus Lagoas-Marcosende s/n, 36310 Vigo, Spain

(Received June 4, 2004; Revised March 22, 2005; accepted July 16, 2005)

Abstract—The goal of our work was to expand the knowledge about plant stress response to the allelochemical 2(3*H*)-benzoxazolinone (BOA). We focused on physiological processes that are affected by this secondary metabolite. Physiological and biochemical characteristics of plants exposed to BOA help us to better understand its mode of action and open the gate to the use of allelochemicals as "natural" herbicides. Measurements on photosynthesis, fluorescence, water relations, antioxidant enzymes (superoxide dismutase, peroxidase), ATPases, and lipid peroxidation indicated that a phytotoxic effect follows BOA exposition. This effect was intense enough to interfere with plant growth and development and to produce "induced senescence." Based on this, we propose a multifaceted mode of action for BOA with effects at different levels and in different parts of the plant.

Key Words—Allelopathy, plants, benzoxazolinone, mode of action, biopesticide, allelochemical, botanical compound, lettuce, *Lactuca sativa.*

INTRODUCTION

Plant compounds have been suggested as alternatives to conventional herbicides (Dayan et al., 1999). Understanding the mechanisms of whole plant-induced responses to allelopathic compounds will provide information about their application. 2(3*H*)-Benzoxazolinone (BOA) occurs naturally as an anti-*Fusarium* compound in rye seedlings (Virtanen et al., 1957), and is found in other grass species (Sánchez-Moreiras et al., 2004). BOA has been associated

[2] Current address: Max-Plank-Institut für Chemische Okologie, Beutenberg Campus, Hans-Knöll-Str. 8, 07745 Jena, Germany.

with dose-dependent germination inhibition and growth reductions (Chiapusio et al., 1997), and with effects on plant energy metabolism (Friebe et al., 1997). Phytotoxic effects of BOA have been found on root ultrastructure, where packed multiple columns of cells failed to lengthen at the root tip of cucumber plants (Burgos et al., 2004). Microarray technology has detected a range of defensive and detoxification processes when roots are exposed to BOA (Baerson et al., 2005).

The objective of this study was to analyze the biochemical and physiological mechanisms of BOA inhibition in a 15-d experiment to understand the relationships between molecular mode of action and physiological effects. Lettuce was used as an assay species, and several different metabolic and physiological processes were measured so that the complex stress response on whole-plant development after exposure to BOA could be better understood.

METHODS AND MATERIALS

Plant Material and Growth Conditions. Lettuce seeds (*Lactuca sativa* L. cv. Great Lakes, California) were germinated in plastic trays with 5 cm depth layer perlite, to which 500 ml 1:1 Hoagland's solution (Hoagland and Arnon, 1950) was added every other day. Seedlings were germinated in a darkened, temperature-controlled (20°C) chamber. For seedling growth, the environmental conditions were as follows: 12:12 (L:D) hr photoperiod, 18:8°C temperature, 60 ± 5% relative humidity, and 200 μmol m^{-2} sec^{-1} irradiance. One mo after germination (when plants had three fully expanded leaves), they were transferred to pots containing perlite (13 cm) to stimulate root system development, with the same mineral solution and growing conditions. One wk later, roots were exposed to 1:1 Hoagland's solution (control), and the same solution + 1 mM BOA (treatment) for 15 d.

In vivo Measurements. Photosynthesis was measured with an infrared gas analyzer LI-6400 (Li-Cor model 6400, Lincoln, NE, USA) in the first fully expanded leaf from six replicates per treatment after exposure. Photosynthesis values were recorded in leaves at 800 μmol m^{-2} s^{-1} quantum flux density (provided by 6400-02B led light source), 20°C leaf temperature, and 400 μmol s^{-1} CO_2 flow value. These parameters were fixed for all measurements. Values of transpiration (mol m^{-2} s^{-1}) were recorded. Any damaged plant was discarded.

Immediately after gas exchange measurements, the influence of BOA (1 mM) on the functional state of the photosynthetic apparatus was investigated by using different parameters of the *in vivo* chlorophyll fluorescence of whole plants. Pulse-modulated and continuous fluorescence were recorded for the same six replicates per treatment used for gas exchange measurements. Three values per plant were recorded for both fluorescence measurements. The pho-

tochemical yield of Photosystem II (PSII) was established by measuring two parameters (Genty et al., 1989), the first of which was the quantum efficiency of open Photosystem II centers (F_v/F_m ratio), recorded using a Plant Efficiency Analyzer from Hansatech Instruments Ltd. (Norfolk, UK). Lettuce leaf pieces were kept in darkness for 20 min and illuminated with a flash of saturating light. Parameters used were intensity of light (1800 μmol m^{-2} s^{-1}) and record length (3 sec). The other photochemical quenching parameter was the quantum yield of Photosystem II photochemistry (Φ_{PSII}), measured with a Fluorescence Monitoring System from Hansatech Instruments Ltd.

Plant Growth and Water Status. Information about plant growth was obtained by measuring plant height, root length, number of fresh and dry leaves, leaf and root biomass, fresh and dry weight, and specific leaf area. Following these measurements, leaf samples were ground and used for total C, N, and H content determination (w/w, dry basis %) with an elemental CHN analyzer (EA 1110 Automatic Elemental Analyzer; Fisons Instruments, Milan, Italy). Calculations were made to obtain the C/N ratio.

Plant water status of control and BOA-treated plants was evaluated by measuring the stomatal density (Meister and Bolhàr-Nordenkampf, 2001), relative water content (Reigosa and González, 2001), water potential (Ψ_w) with a pressure chamber technique (Scholander chamber, SoilMoisture Equipment, Santa Barbara, CA, USA; González, 2001), and leaf osmotic potential with a calibrated vapor pressure osmometer (Wescor 5500, Logan, UT, USA). Osmotic values were expressed in terms of osmolality (mmol kg^{-1}). All measurements were recorded for eight replicates per treatment. Leaves and roots from plants were harvested and separately stored at −80°C for later analyses.

Plant extracts were obtained for superoxide dismutase and peroxidase activities as two of the main components of the antioxidant defense system. Five replicates per treatment were used for leaf and root analyses. Superoxide dismutase activity was measured by the nitroblue tetrazolium reaction according to the method described by Beauchamp and Fridovich (1971). Superoxide dismutase leaf and root activities were measured in the sample at 560 nm with a WPA Spectrophotometer (Cambridge, UK). The enzyme unit was determined with the value of the nitroblue tetrazolium inhibition percentage. Superoxide dismutase activity was given in relation to the dry weight of the sample. Peroxidase activity was measured using 0.5% w/v guaiacol as hydrogen donor (Silva and Nogueira, 1984) in the presence of 0.1% v/v H_2O_2 at 25°C. To monitor the peroxidase reaction, measures were recorded for 7 min. The absorbance difference between final and initial reading was given per milligram of dry weight and per minute of measuring.

The level of lipid peroxidation was measured by the thiobarbituric acid reaction based on the method described by Dhindsa et al. (1981). With this method, we measured the quantity of malondialdehyde acid (MDA) present in

the sample, which is a product of lipid peroxidation and can be correlated with the lipid status of the sample. Lettuce leaves and roots from five replicates per treatment were employed. Malondialdehyde acid values were expressed in mmol/g DW using the extinction coefficient of 155 mM^{-1} cm^{-1} (Heath and Packer, 1968). Sulfhydryl groups were determined by Ellman's reactive, 5,5′-dithio-bis-2-nitrobenzoic acid (DTNB) in roots from five living plants per treatment. Color change was measured at 412 nm with a WPA Spectrophotometer (Prudencio-Ferreira and Areas, 1993). The extinction coefficient used for calculations was 13.6 mM^{-1} cm^{-1} (Peters et al., 1988).

ATPase activity was assayed according to the method described by Cruz-Ortega et al. (1990) in leaf and root microsomal fractions from five plants per treatment. Microsomal fractions were obtained according to the method of Friebe et al. (1997). Protein content of this fraction was assayed via the Bradford method (Bradford, 1976) with BSA as standard. Slight modifications to the Bradford method, suggested by Stoscheck (1990) to decrease variability in the chromogenic responses of different proteins, were used. Total, organular, plasma membrane, vacuolar, and mitochondrial ATPase activity were measured using the following inhibitors: Na_3VO_4 (plasma membrane ATPase inhibitor), NaN_3 (mitochondrial ATPase inhibitor), KNO_3 (tonoplast ATPase inhibitor), and Na_2MoO_4 (acid phosphatase inhibitor). ATP hydrolysis occurred at 30°C for 1 hr. Six repetitions were tested for each case. After hydrolysis, released inorganic phosphate was measured according to the method of Chifflet et al. (1988). Absorbance was read at 850 nm with a Spectronic® 20 Genesis™ Spectrophotometer (Spectronic Analytical Instruments, Leeds, UK). KH_2PO_4 was used as standard. Finally, nmol P_i mg^{-1} min^{-1} was calculated for each sample by considering the absorbance values, the quantity of protein, and the incubation time.

Total protein was quantified by using the spectrophotometric Bradford assay (Bradford, 1976) in lettuce leaves from five replicates per treatment. Commercial bovine seroalbumin (BSA) was used as standard. Values were expressed per gram of dry weight. In the same way, leaves from five replicates per treatment were used for free proline content determination according to the method described by Pedrol et al. (2000) and Ramos and Pedrol (2001). Commercial purified proline was used as standard. Values were expressed per gram dry weight. Free polyamines were determined by thin layer chromatography according to Pedrol and Tiburcio (2001). Commercial purified spermine, spermidine, and putrescine solutions were used as standards (Sigma). Separation of dansylamines was developed in a plate of silicagel 60 Å (Whatman LK6D) using 100 ml of 5:4 v/v cyclohexane/ethyl acetate solvent system. Thirty μl per extract were applied on the plate. Chromatography was allowed at 4°C for 40 min. Spermidine, spermine, and putrescine marked spots were excised and eluted in 2 ml ethyl acetate. Sample fluorescence was measured with a fluorescence spectrophotometer with excitation at 350 nm and emission at 495 nm. Spermine, spermidine, and putres-

cine contents were expressed as nmol g^{-1}. Polyamine contents were used for Pas/Das index (Spermine + Spermidine/ Putrescine) calculation.

Statistical Analyses. In all cases, there was a comparison between control and treatment using Student's *t*-tests.

RESULTS AND DISCUSSION

Data from 1 mM BOA-exposed plants were analyzed and compared to the control. Values and significance of differences between control and BOA-exposed plants for all variables are detailed in Table 1 (general measures) and Table 2 (stress metabolites and enzymatic activities).

BOA Effects on Plant Growth, Water Status, and Photosynthetic Efficiency. Plants growing in the presence of 1 mM BOA were smaller, with less fresh biomass and a significant increase in dry leaf biomass with respect to the control. Effects of BOA on plant appearance became obvious 3 d after application, and were evident after 1 wk of exposure (Figure 1). The previously detected effects of BOA on root growth (Chiapusio et al., 1997) were corroborated. As confirmed by statistical analysis in Table 1, lettuce plants had shorter and typically browning roots without hairs after 1 mM BOA treatment. However, BOA-exposed lettuce roots were also characteristically thicker, leading to a similar root biomass when compared to control. These results are consistent with those reported by Burgos et al. (2004), who found that increased width of cucumber cortical cells resulted in increased root diameter. When root/leaf ratio is analyzed, the results show a large increase in this ratio in BOA-exposed plants, reflecting the decrease in leaf biomass and the insignificant changes on root biomass.

This increase in the leaf/shoot ratio was positively correlated with an increased C/N ratio in the samples. In dry matter, the total C content analyzed was higher in BOA-treated plants compared to control after 15 d treatment, whereas total N was significantly lower. It is well known that plants with decreased growth from typical stresses (e.g., mild water or nutrient stress; Bradford and Hsiao, 1982) have reduced nitrogen concentrations and increased levels of immobile carbon-based secondary metabolites. This relative surplus of carbon results in increased lipid production and a thicker cuticle, whereas a diminution in nitrogen content can induce a decrease in amino acids, proteins, and chlorophyll present in plants (Chapin et al., 1986). Observed alterations could imply a higher rigidity of cell wall, thus preventing cell elongation and concomitant cell growth. These changes in dry matter, which also resulted in increased C/N ratios, may cause plants to have a higher production of fibers, lignins, and cell wall material (Larcher, 1980), and thus small leaves with lower leaf water content and more permeability.

As observed in Table 1 ("water relations"), a nearly 10% decrease in relative water content was correlated with a decline in leaf water potential (Ψ_w) from −1.8 in control to −3.23 MPa in BOA-exposed lettuce. It was directly correlated with a decrease in transpiration rate to one fourth in BOA-exposed plants when compared to respective controls. Osmotic potential (Ψ_s) in leaves of the treated plants remained unaltered, and proline was not affected (not showing osmoregulation). Short-term responses such as closing stomata or longer-term responses by reducing stomatal density (which decreased from 18.4 stomata per field in control to 15.8 in BOA-exposed plants) could be effective ways to reduce transpiration. Even so, Ψ_w in these plants was severely

decreased, revealing a strong loss of turgor in the plant cell, thereby limiting stomatal opening and growth expansion.

Net photosynthetic rate shows an almost twofold decrease in BOA-exposed plants. Decreased transpiration could be affecting P_n due to the limitation of CO_2 assimilation because of stomatal closure. *In vivo* chlorophyll fluorescence provided additional information: the photochemical yield of PSII (F_v/F_m ratio), typically affected by photoinhibition (Epron et al., 1992), was not affected by BOA; however, the quantum yield of electron flow through PSII *in vivo* (Φ_{PSII})

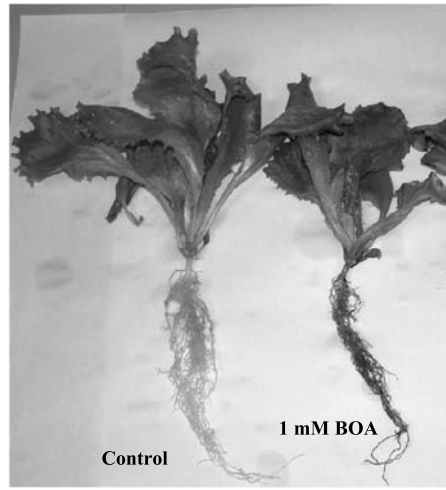

FIG. 1. Control and 1 mM BOA-exposed plants. Changes in leaf biomass and in root biomass were detected with highly significant differences after 15 d treatment.

was slightly affected. The unaltered F_v/F_m data suggest no changes on the intrinsic efficiency of PSII and, therefore, no direct damages on the PSII reaction centers. Nevertheless, the inhibition of Φ_{PSII} values could be a result of a weaker efficiency of PSII reaction centers, and it may indicate an alteration of the rate of linear electron transport (Nilsen and Orcutt, 1996), suggesting that the proportion of photons absorbed by PSII and used for photosynthesis was not the same as in control. This altered PSII efficiency, as well as the water unbalance observed on BOA-exposed plants, could be explained through an alteration on membrane properties.

Oxidative Damage after BOA Exposition. The antioxidant enzymes superoxide dismutase and guaiacol peroxidase were analyzed after 15 d BOA exposure in lettuce leaves and roots. Superoxide dismutase activity was severely inhibited in leaves and roots of the allelochemical-targeted plants with special relevance in roots, where the activity was reduced to 50%. Guaiacol peroxidase activity also suffered a strong decrease in lettuce leaves, although no effect was detected in roots (Table 2). The function of these two enzymes is essential for maintaining the equilibrium of free radicals, thus preventing oxidative damage (Zeng et al., 2001). This activity reduction can be produced by direct damage in the structure of enzymes, but it might also be due to a senescence process (Dhindsa et al., 1981). Decreased levels of both enzymes can imply increased levels of $O_2^{\cdot -}$, H_2O_2, and $OH^{\cdot}$ resulting in increased levels of lipid peroxidation and solute leakage (Dhindsa et al., 1981), which play a key role in the senescence process. $O_2^{\cdot -}$ that accumulated in the absence of superoxide dismutase

contributes to membrane damage, and it plays a key role in specific chains of signal transduction (Jabs et al., 1997). An excessive presence of H_2O_2 in the surroundings of the cell wall has been related to reduced plant cell expansion mediated by cell wall-associated peroxidases (Bacon, 1999). H_2O_2 diffusing into the continuous space of the cell wall is a limiting factor for its extensibility.

The low activities of superoxide dismutase and peroxidase, which suggest a negative effect of BOA on the protective ability of plant tissues against oxidative damage, can lead to an increased lipid peroxidation, which is highly significant for leaves as well as for roots in the BOA-targeted plants in the current experiment. The malondialdehyde acid (MDA) content of the samples treated with 1 mM BOA increased almost 100% in roots and 80% in lettuce leaves. Lipid composition of membranes is one of the main cellular targets susceptible to damage by free radicals (Davies, 1987). Lipid hydroperoxides, formed in the process of lipid peroxidation, have been found to alter membrane properties by increasing hydrophilicity of the internal side of the bilayer (Frenkel, 1991) with the consequent increase in membrane permeability and the alteration of nutrient balance. The structure of such important organelles as chloroplasts or mitochondria is also affected (Zeng et al., 2001). Lipid degradation products participate in the signal transduction cascade of the stress response (Blokhina et al., 2003). The reactive oxygen species (ROS) not only cause peroxidation of lipid membranes, but also "a depletion of reduced glutathione, oxidation of protein thiol groups and membrane depolarization" (Blokhina et al., 2003). The observed increase in soluble sulfhydryl groups due to BOA can be the result of ROS-induced damage on protein structure. Similar effects produced by other cyclic hydroxamic acids have been previously reported (Niemeyer et al., 1982; Friebe et al., 1997).

Total and plasma membrane ATPase activity are significantly reduced on lettuce roots exposed to BOA because of a decrease in plasma membrane ATPase activity. The inhibition of these primary pumps can disrupt the transport of ions, amino acids, sugars, and other molecules through plasma membranes. H^+-ATPase has been reported as an unlikely target site for nonspecifically interacting xenobiotics causing cytotoxicity by impairment of the plasma membrane (Palmgren, 1998). Inhibition of ATP synthesis in the presence of BOA via a direct action on the ATPase complex was first reported by Niemeyer et al. (1987). They attributed BOA's inhibitory effects to an impairment in the ATP synthesis as a result of BOA action on the mitochondrial electron transport and ATPase complex. An alteration of this enzymatic activity can result in an altered redox status by blocking proton pumping with a consequent decrease in the internal pH. This modification in the redox status can lead to the activation of the phenylpropanoid pathway and the subsequent lignification of the cell wall. Cell wall modifications are a common response of plants to environmental stress, limiting elongation and growth by altering the water balance. Alkalinization of apoplastic sap due to

reduced ATPase activities can be responsible for ABA-dependent restriction in leaf elongation rate (Bacon et al., 1998). In this sense, an increase in external pH due to alterations in the proton gradient will reduce cell wall expansins, whereas the cell wall-associated peroxidases will increase (Bacon, 1999).

Stress Markers. Reduction of total soluble leaf proteins in BOA-exposed plants could be the consequence of the increase in lipid peroxidation, which has been related with high levels of denatured proteins. Senescent plants have shown a diminution in their protein content by increasing proteolysis as well by reducing protein synthesis (Wen et al., 1996). This reduction of protein synthesis has been previously observed for BOA (Burgos et al., 2004) and other allelochemical compounds (Cameron and Julian, 1980).

Polyamines and diamines (Table 2) have been also largely implicated in free radical scavenging and plasma membrane stabilization, as well as in structural functions and protein and DNA synthesis (Schipper et al., 2000). Free spermine and spermidine have been reduced in BOA-exposed plants, whereas putrescinde content did not change significantly. Decrease in polyamines can lead to an alteration in the plasma membrane (Bors et al., 1989). Absence of free spermine and spermidine in the cell has been also reported as a common trait in apoptosis (Nitta et al., 2001), and can accelerate senescence (Borrell et al., 1997). The role of polyamines in the cell cycle control and cell membrane stabilization can lead to cell cycle arrest and direct or indirect apoptosis (Li et al., 1999), loss of cell integrity, and cell death (Schipper et al., 2000). Such alterations on free polyamine contents have been also found in the study of paraquat, a common herbicide known for its toxicity by way of oxidative damage (Kao, 1997). The protective effect observed here could be "specific to the pathway inducing apoptosis and may be mediated by activation of transcription of genes required for cell proliferation and survival" (Kilpeläinen, 2002).

Proposed Mode of Action. We attribute the results to the effect of BOA alone, although they could also be due to degradation products, both inside the plant and in the pots. We performed a parallel experiment to determine the fate of the allelochemical in solution (data not shown), and noted that it remained stable for 2 wk. Even so, some of the observed effects could still have been due to both BOA and degradation products.

BOA is acting at different physiological levels, and these effects are mutually correlated. BOA shows multiple modes of action where different altered metabolic processes must be considered in an interrelated manner. A scheme of the effects of BOA on lettuce metabolism is proposed (Figure 2). Besides particular metabolic effects, BOA exposure leads to a significant inhibition of plant growth and reduction in vigor.

As shown in Figure 2, BOA affects plant metabolism via oxidative damage. The data suggest that an alteration of cell redox status by acting on the oxygen protective cellular mechanisms (enzymatic system, polyamines, etc.) is

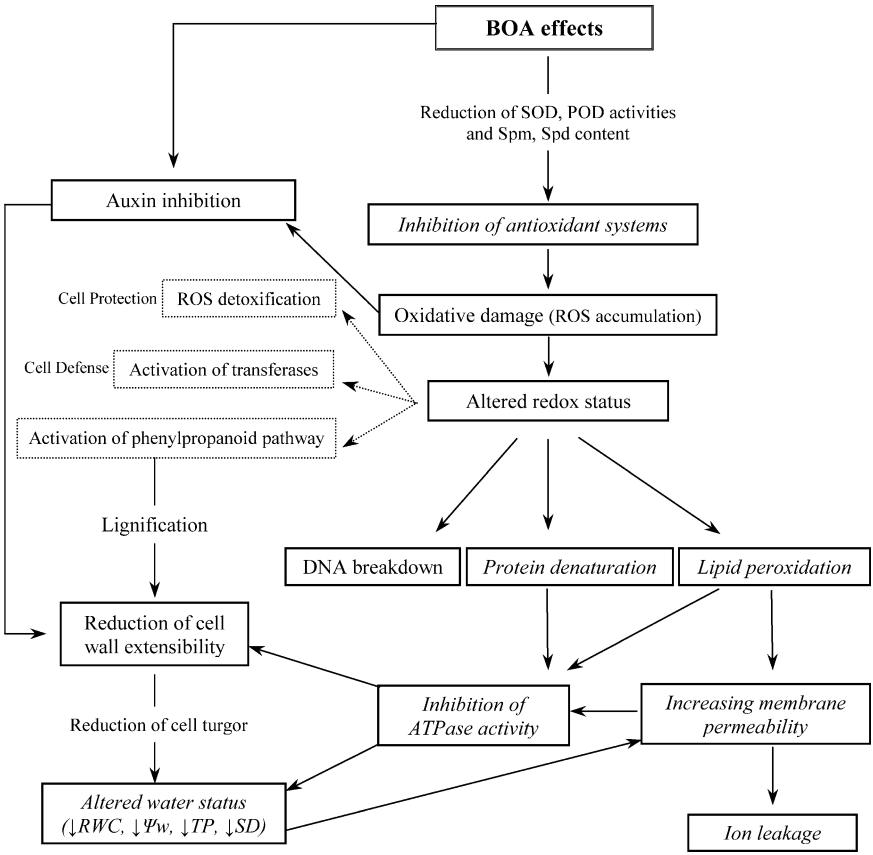

FIG. 2. Schematic representation of BOA toxicity via oxidative damage, auxin inhibition, or interference of both effects. Cell damage due to free radicals generated by BOA, and reductions in superoxide dismutase and peroxidase activities and spermine and spermidine contents lead to membrane alterations and water imbalance with drastic consequences for the cell. This proposed scheme is inspired by another theory proposed by Einhelig (1986) for the possible multiple mode of action of allelochemicals.

a direct metabolic consequence of BOA's presence. BOA could be interfering with key factors of the oxidative metabolism. Some effects on sulfhydryl groups of enzymes and on polyamine content should be considered important. The BOA redox cycle and its effects on antioxidant enzymes could generate the accumulation of free radicals that are toxic for the cell by direct action, increasing lipid peroxidation. In this sense, Burgos et al. (2004) found increased vacuolation and lipid content, concluding that BOA is reducing root growth by disrupting lipid metabolism and protein synthesis as part of its mode of action, protein

denaturation, chlorophyll bleaching, and DNA modifications. Indirect action is also considered to be important in BOA's mode of action: increasing membrane permeability, ion leakage, disrupting proton pump function, altering electron transport by modifications on chloroplast membrane. Simultaneously, ATPase activity is inhibited as a consequence of increased membrane permeability with the subsequent increase on ion leakage (reported in previous experiments; Reigosa et al., 2001) and modifications on membrane structure. A reduction in ATPase activity will increase pH level near the cell wall, and could cause a reduction of (indole-3-acetic acid) IAA-induced "acid growth." It could disturb the function of expansins causing a thicker cell wall. Decreases in cell wall extensibility will reduce turgor cell with the observed decreased Ψ_w and RWC. The strong reduction in transpiration and concomitantly in stomata density is a common mechanism of plants to avoid water stress due to this water imbalance. The decrease in transpiration and the previously detected effect on membrane integrity will be decisive factors in the severely reduced net photosynthetic rate, which will directly affect the C/N ratio and eventually plant growth and development.

Free radicals can act not only as toxic components on plant metabolism but also as signal factors. A plant mitogen-activated protein kinase (MAPK) pathway involved in mitotic regulation can be activated with an increased accumulation of free radicals such as H_2O_2 (reduction of guaiacol peroxidase activity) and $O_2\cdot^-$ (reduction of superoxide dismutase activity), resulting in the induction of stress-inducible genes and also in the inhibition of auxin-inducible genes (Hirt, 2000). The negative control on auxin genes would lead to decreased cell wall extensibility with reduction on cell turgor. It will lead to the previously discussed chain of effects: reduced transpiration, stomatal density, and net photosynthesis, but also diminished elongation, cell division, and lateral root growth. Reductions on lateral root growth and root length are similar to the effects in cucumber root tips following BOA exposure reported by Burgos et al. (2004), corroborating an important effect of this allelochemical on root ultrastructure. The consequences of these interactions will be reflected in decreased plant growth and development. In Perez (1990) hypothesized that hydroxamic acids could act as new auxin-inhibiting substances. We also report here that BOA could act at this level, probably by indirect action (oxidative damage).

In summary, we conclude that BOA affects the oxidative metabolism via multiple modes of action, and it likely interferes with auxin function by transcriptional regulation. It initiates a process of induced senescence with the consequent inhibition of plant growth and development in lettuce plants.

Acknowledgments—The authors are grateful to Drs. Luís González, Nuria Pedrol, and Pilar Ramos, as well as to Ángeles Domínguez, Rosa Bañuelos, Salvador Enguix, Carlos Bolaño, Ana Martínez, Xan X. Santos, and Eva Diéguez for laboratory and technical assistance. We thank also

Rocío Cruz Ortega from the Applied and Functional Ecology Department (Ecology Institute), Mexico, for her assistance in the ATPase measurements, and Oliver Weiss for his corrections to the manuscript. This research was supported by the Spanish Ministry of Science and Technology (DGICYT; BFI 2000-0987) and by the Galician Government (PGIDT00 PXI30114PR). Adela Sánchez was financially supported by the Spanish Ministry of Science with a research grant.

Abstract—Four himachalene sesquiterpenes and (+)-γ-cadinene, previously identified as possible pheromone components from males of a North American population of *Phyllotreta cruciferae* Goeze (Coleoptera, Chrysomelidae), were tested for attractiveness in field trapping experiments in Hungary. A mixture of the four synthetic racemic himachalene derivatives and (+)-γ-cadinene from a botanical source was slightly attractive to beetles, but much more attractive when blended with the known host-plant-derived attractant allyl isothiocyanate. This result was consistent with a previous study in North America. In tests with optically pure synthetic compounds, a blend of the same himachalene enantiomers found from male beetles was equivalent to the corresponding blend of racemic compounds, whereas a blend of the opposite enantiomers was not active. Through subtraction tests, it was found that the single compound, (6*R*,7*S*)-2,2,6,10-tetramethylbicyclo[5.4.0.]-undeca-9,11-diene [compound (+)-**A** in this study], was as active as the whole mixture, suggesting that this compound is the key pheromone component of the European population of *P. cruciferae*. During field trials, several

* To whom correspondence should be addressed. E-mail: h2371tot@ella.hu

congeneric species, including *P. vittula*, *P. nemorum*, *P. nodicornis*, and *P. ochripes*, also were caught, suggesting that the same compound(s) may be relatively widespread as pheromone components in this genus.

INTRODUCTION

Flea beetles of the genus *Phyllotreta* (Coleoptera, Chrysomelidae, Halticinae) are important pests of cruciferous crops such as cabbage, rapeseed, and radishes, both in Europe (Jourdheuil, 1966; Säringer, 1998) and in North America (Lamb, 1989). Their importance as pests is aggravated by the fact that several species are known to vector plant pathogens (Markham and Smith, 1949; Campbell and Colt, 1967; Ryden, 1989; Dillard et al., 1998; Glits, 2000).

Effective tools to detect and monitor flea beetles would be of great utility in their control. The secondary plant metabolite allyl isothiocyanate (allyl ITCN) has long been known as a feeding and oviposition stimulant and also as an attractant for *P. cruciferae* Goeze and other *Phyllotreta* spp. (Görnitz, 1956; Feeny et al., 1970; Hicks, 1974; Vincent and Stewart, 1984; Pivnick et al., 1992).

Male *P. cruciferae* produce an aggregation pheromone (Peng and Weiss, 1992; Peng et al., 1999). Analysis of volatiles emitted by males of a North American population of *P. cruciferae* identified six sesquiterpenes (Figure 1) as candidate pheromone components (Bartelt et al., 2001). These were produced only by males, although the major compound (**A**) was readily sensed by the antennae of both sexes (Bartelt et al., 2001). These compounds, or a subset of them, was thought likely to constitute the pheromone. All six compounds are chiral, and only the enantiomers shown in Figure 1 are emitted by the beetles. The beetle-derived enantiomers all have a positive optical rotation in hexane (Bartelt et al., 2001), and signs of rotation used below refer to dilute hexane solutions.

Assignment of the true stereochemistry for **A**, **C**, **E**, and **H** has been complicated. The configurations were initially determined by Bartelt et al. (2001): relative stereochemistry of the two stereogenic centers of **A**, **C**, and **H** was based on NMR and molecular modeling. Assignment of their absolute configurations was based on linking them to **E** through chemical conversions and comparison of the optical rotation of **E** to literature information. Pandy and Dev (1968) had reported an enantiomer of **E** from Himalayan cedar trees and established its absolute configuration as (*S*) by enantioselective synthesis. Beetle-derived **E** had a specific rotation that was of the same sign (+) as that

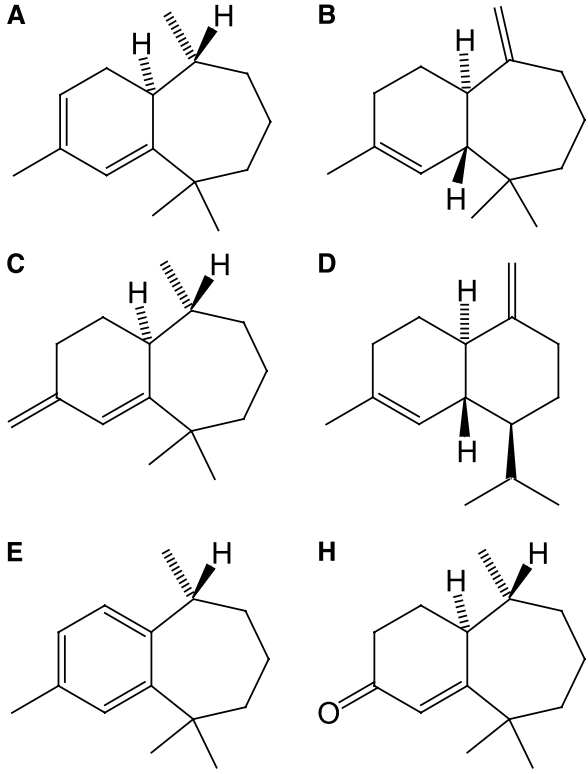

FIG. 1. Male-specific compounds emitted by *P. cruciferae*. Structure lettering corresponds to Bartelt et al. (2001); compounds **F** and **G** in that paper were found in *Aphthona* species but not in *P. cruciferae*. Absolute configurations shown for **A**, **C**, **E**, and **H** were established by chiral synthesis (Muto et al., 2004) and comparison to beetle-derived samples by chiral GC and polarimetry. (**A**) (+)-(6*R*, 7*S*)-2,2,6,10-Tetramethylbicyclo[5.4.0]-undeca-1(11),9-diene; (**B**) (+)-(1*R*,7*R*)-2,2,10-trimethyl-6-methylene-bicyclo[5.4.0]undec-10-ene; (**C**) (+)-(6*R*,7*S*)-2,2,6-trimethyl-10-methylene-bicyclo[5.4.0]-undec-1(11)-ene; (**D**) (+)-γ-cadinene; (**E**) (+)-(*R*)-*ar*-himachalene; (**H**) (+)-(1*S*, 2*R*)-2,6,6-trimethylbicyclo[5.4.0]undec-7-en-9-one.

reported by Pandy and Dev (1968) for the tree compound; thus, both were initially concluded to have the same configuration.

Bartelt et al. (2003) synthesized the racemic forms of the four compounds. Subsequently, Muto et al. (2004) synthesized the individual enantiomers of compounds **A**, **C**, **E**, and **H** using citronellal of known configuration as the chiral starting material. These synthetic studies supported the basic structures and relative stereochemistry reported by Bartelt et al. (2001), but disconcert-

ingly, the absolute configurations determined by Muto et al. (2004) were exactly the reverse of those proposed by Bartelt et al. (2001).

This contradiction was resolved by Mori (2005). The solvent used by Pandy and Dev (1968) to measure the optical rotation of **E** from cedar was chloroform, whereas that used by Bartelt et al. (2001) for beetle-derived **E** was hexane (because several of the beetle-derived compounds encountered in that study deteriorated in chloroform). Mori (2005) discovered, surprisingly, that the optical rotation of **E** in hexane is similar in magnitude—but opposite in sign—to that in chloroform, which explained the previous discrepancy in assigned configurations. Interestingly, compounds **A**, **C**, and **H** do not show a corresponding sign reversal with this solvent change (Bartelt, unpublished data). The structural assignments of Muto et al. (2004), shown in Figure 1, are considered definitive.

Field attractiveness of the sesquiterpenes was first tested by Soroka et al. (2005), using a blend of synthetic racemic **A**, **C**, **E**, and **H** (Bartelt et al., 2003), plus enantiomerically pure **D** (obtained from citronella oil; Soroka et al., 2005). The compounds were formulated on rubber septa so that the emitted ratios of beetle-related enantiomers would be the same as observed in volatile collections from the beetles (Bartelt et al., 2001). Compound **B** was not used in the study because no bulk source was found. Soroka et al. (2005) found that this blend by itself was modestly attractive at two doses, and that the pheromone effect was enhanced when allyl isothiocyanate (allyl ITCN) was present in the trap as well.

In the present paper, we report on the field activity of racemic and enantiomerically pure **A**, **C**, **D**, **E**, and **H** with a European population of *P. cruciferae*, in the presence or absence of allyl ITCN.

METHODS AND MATERIALS

The original objective of this research was to repeat the North American field tests (Soroka et al., 2005) on the European population of *P. cruciferae*. Subsequently, the pure synthetic enantiomers of **A**, **C**, **E**, and **H** became available (Muto et al., 2004), so that it was possible to compare these to the racemic materials. Because the initial field baits also contained **D**, an intermediate field experiment was run to measure its behavioral importance in the initial blend. Then the enantiomers of **A**, **C**, **E**, and **H** were compared directly, all as blends simulating beetle emissions, but lacking **D**. Finally, subtractive tests were conducted to determine whether the components present in minor amounts in the beetle emissions (**C**, **E**, and **H**) were important for attraction. All of the tests included treatments with allyl ITCN.

Electrophysiology. Additional data were acquired during 2003 to evaluate antennal responses of the North American strain of *P. cruciferae* to the six

male-specific compounds. Coupled gas chromatography–electroantennographic detection (GC-EAD) was done as described previously (Bartelt et al., 2001). A solution containing the beetle-derived enantiomers of **A**–**E** and **H** was prepared (ca. 10–20 ng/μl) and tested with antennae of female beetles (about 1 μl per injection, $N = 4$).

Field Sites. Tests in Hungary were conducted at Budakeszi, Pusztazámor (Pest county), and Nadap (Fejér county). Trapping tests were performed in rapeseed or white mustard fields. Traps were set at the soil level in the weedy edge of the fields. Traps were arranged as blocks so that each block contained one replicate of each treatment. Traps within blocks were separated by 8–10 m, and blocks were sited 15–20 m apart.

Capture data were transformed to $(x + 0.5)^{1/2}$ and were analyzed by ANOVA. Treatment means were separated by Games–Howell test or by Bonferroni–Dunn test, as appropriate (see also table and figure legends). All statistical procedures were conducted using the software packages StatView® v4.01 and SuperANOVA® v1.11 (Abacus Concepts, Inc., Berkeley, CA, USA).

Traps. CSALOMON® VARL+ funnel traps (Plant Prot. Inst., HAS, Budapest, Hungary) were used in the tests. These originally were developed for catching moths (Tóth et al., 2000; Subchev et al., 2004) but proved to be applicable also for capturing flea beetles (Tóth et al., 2004). The trap consisted of an opaque plastic funnel (top o.d.: 13 cm; funnel hole diam: 3 cm; height: 16 cm), covered with a 20 × 20 cm flat plastic roof, and connected below to a transparent plastic round catch container (about 1-l capacity; attached by a rubber band). The bait was suspended from the middle of the roof, and the bait dispenser was slightly above the level of the upper edge of the large funnel opening. A small piece (1 × 1 cm) of household pesticidal strip (Chemotox®, Sara Lee, Temana Intl. Ltd., Slough, UK; active ingredient 15% dichlorvos) was placed into the catch container as a killing agent for captured insects.

Chemicals. Racemic pheromone components **A**, **C**, **E**, and **H** were synthesized by described methods (Bartelt et al., 2003). The beetle-specific enantiomer of compound **D** was obtained from citronella oil (Soroka et al., 2005). The individual enantiomers (about 97% enantiomeric purity) of **A**, **C**, **E**, and **H** were available from Muto et al. (2004). Allyl isothiocyanate was purchased from Sigma-Aldrich Kft. (Budapest, Hungary) and was >95% pure as stated by the supplier.

Baits. The allyl ITCN baits for experiments 1 and 2 used 100-mg amounts administered onto a 1-cm piece of dental roll (Celluron®, Paul Hartmann Ag, Heidenheim, Germany), which was placed into a polyethylene bag (about 1.0 × 1.5 cm) made of 0.02-mm-thick polyethylene film. The dispensers were heat-sealed and were attached to 8 × 1 cm plastic handles for easy manipulation when assembling the traps. In later experiments, 2 mg of allyl ITCN was loaded into 0.7-ml polyethylene vials with lid (No. 730, Kartell Co., Italy). These vials

were used with lids closed (so that allyl ITCN penetrated through the walls) in the field tests. Baits were wrapped singly in pieces of aluminum foil and were stored at −65°C until use. In the field, old baits were replaced with new ones at 2- to 3-wk intervals.

Pheromone baits were prepared as described in detail by Soroka et al. (2005). When the standard dose of racemic **A**, **C**, **E**, and **H** was used, the load rates were 500, 34, 56, and 164 μg per septum, respectively. When pure enantiomers of **A**, **C**, **E**, and **H** were used, the weights of the compounds were one half of the racemic amounts (250, 17, 28, and 82 μg per septum, respectively), so that the amount of a given enantiomer was constant. Compound **D**, a single enantiomer, was used at 123 μg per septum. For subtractive blends, the amounts of the components that were included were as above. Low-dose septa were also prepared for experiments 1 and 2, and these had one tenth the amount of material in the standard dose.

Field Experiments. Experiment 1 and 2. These preliminary tests were aimed at studying the activity of the mixture of components **A**, **C**, **E**, and **H** (racemic) and (+)-**D** on its own and the influence of its addition to allyl ITCN. Treatments included traps with components **A**, **C**, **E**, and **H** (racemic) and (+)-**D** at two dose levels, allyl ITCN on its own, its combination with the beetle-related components, and unbaited traps. Polyethylene bag dispensers were used to dispense allyl ITCN. Experiment 1 was run at Nadap, April 1–18, 2003, with five replicate blocks, in the weedy edge of a field that had been planted in rapeseed in 2002. Traps were inspected twice weekly. Experiment 2 was conducted at Budakalász, March 27–May 1, 2003, with five replicate blocks, in the weedy edge of a 2002 white mustard field.

Experiment 3. This test was aimed at confirming results of the preliminary tests on the increase of catches when components **A**, **C**, **E**, **H** (racemic), and (+)-**D** and allyl ITCN were presented together in the same trap, but with a lower dose of allyl ITCN (polyethylene vials, see above). Treatments included traps with components **A**, **C**, **E**, **H** (racemic), and (+)-**D** on their own, their combination with allyl ITCN, allyl ITCN on its own, and unbaited controls. The experimental methods were similar to experiments 1 and 2. The site was Budakalász, August 19–27, 2003, with 10 replicate blocks in a white mustard field (after harvest). Traps were inspected every other day. Allyl ITCN dispensers were replaced with fresh ones on August 23.

Experiments 4 and 5. The objective was to measure the importance of (+)-**D** to the attractiveness of the mixture of beetle-related compounds. Treatments included traps with allyl ITCN on its own (polyethylene vial), its combination with component (+)-**D**, its combination with components **A**, **C**, **E**, and **H** (racemic), or its combination with all components **A**, **C**, **E**, and **H** (racemic) and (+)-**D** and unbaited control traps. These treatments were complemented with traps with a mixture of all components **A**, **C**, **E**, and **H** (racemic) and (+)-**D** on

its own in experiment 5. Two parallel tests were conducted: (1) at Budakalász, August 19–27, 2003, with 10 replicate blocks in a white mustard field (after harvest); allyl ITCN dispensers were replaced by fresh ones on August 23 (experiment 4); and (2) at Pusztazámor, September 10–19, 2003 (experiment 5), with six replicate blocks in the weedy edge of a harvested rapeseed field. Allyl ITCN dispensers were replaced by fresh ones on September 15.

Experiment 6. This test was aimed at studying the activity of pure enantiomers of components **A**, **C**, **E**, and **H**. Treatments included traps with allyl ITCN on its own (polyethylene vial), its combination with pure (+) or pure (−) enantiomers of **A**, **C**, **E**, and **H**, or with their racemic mixture, and unbaited control. The test was conducted at Budakalász, September 10–19, 2003, with 10 replicate blocks in a white mustard field (after harvest). Traps were inspected every other day. Allyl ITCN dispensers were replaced by fresh ones on September 15.

Experiment 7. This test measured whether components **C**, **E**, and **H** could be omitted from the test mixture without apparent loss of activity. A secondary objective was to confirm results in experiment 6 on the activity of pure enantiomers. Treatments included traps with allyl ITCN on its own (polyethylene vial) and traps with allyl ITCN in combination with pure (+), with pure (−), and with racemic **A**, **C**, **E**, and **H**, with only components **A** and **C** (racemic), and with only component **A** (racemic). Traps without bait were also set out as a control. The test was run at Pusztazámor, April 4–19, 2004, with five replicate blocks in the weedy edge of a white mustard field. Allyl ITCN dispensers were replaced by fresh ones on April 13.

RESULTS

Electrophysiology. In all of the GC-EAD analyses with *P. cruciferae* (example shown in Figure 2), compound **A** was the most strongly detected. Weaker responses were always elicited by **C** and **H** as well, but components **B**, **D**, and **E** elicited no antennal responses.

Field Experiments. Experiments 1, 2, and 3, activity of mixture of components **A**, **C**, **E**, and **H** (racemic) and (+)-**D** on its own, and the influence of its addition to allyl ITCN. In the test at Nadap (Figure 3A), few *P. cruciferae* were caught in traps containing only racemic **A**, **C**, **E**, and **H** and (+)-**D** (referred to below as **ACDEH**), although traps with the larger dose caught more beetles than unbaited traps. More beetles were found in traps with allyl ITCN than in unbaited traps. Catches increased further when dispensers with **ACDEH** were added to traps with allyl ITCN, the difference from addition of allyl ITCN being significant with the larger dose. Catches showed the same trend in the parallel

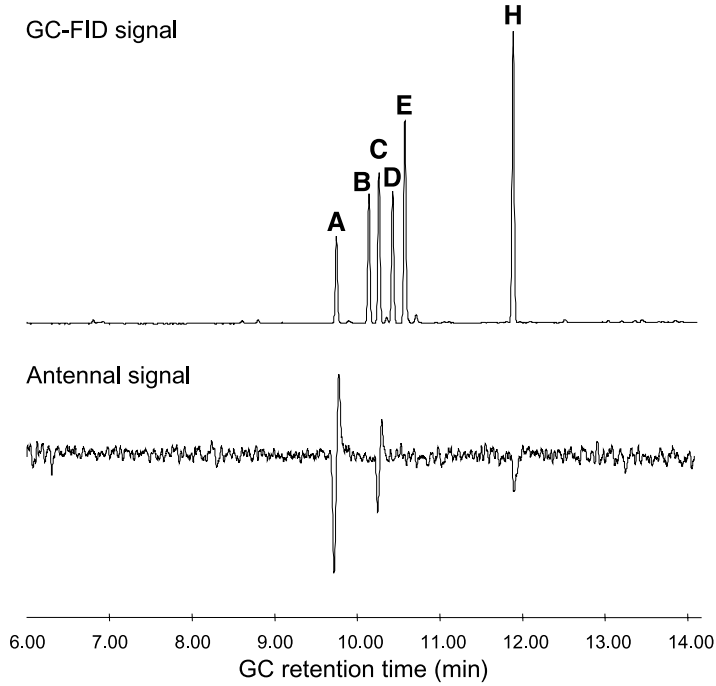

FIG. 2. Coupled GC-EAD response of an antenna from female *P. cruciferae* to a mixture of compounds **A**–**E** and **H**. Responses were noted to compounds **A**, **C**, and **H**.

test at Budakalász (Figure 3B), although there was no difference between traps with allyl ITCN on its own and those containing **ACDEH** + allyl ITCN.

Large numbers of the closely related *P. vittula* (Redtenbacher) were also caught. Traps with the combination of a high dose of allyl ITCN and **ACDEH** caught more than allyl ITCN alone in both tests (Figure 3A, B). Other treatments caught negligible numbers of beetles.

The catches of *P. nodicornis* (Marsham) and *P. ochripes* (Curtis) at Nadap (Figure 3A) and those of *P. nemorum* (Linnaeus) at Budakalász (Figure 3B) also showed similar trends.

In the ensuing tests (experiments 3–7), the dose of allyl ITCN was decreased in the hope that effects of the **ACDEH** mixture would be easier to detect. In experiment 3, traps with allyl ITCN plus **ACDEH** caught more *P. cruciferae* than allyl ITCN on its own (Figure 4). Both allyl ITCN and the **ACDEH** blend attracted more beetles than unbaited traps, and allyl ITCN on its own attracted more than the **ACDEH** blend. No other flea beetle species were caught in significant numbers in this test.

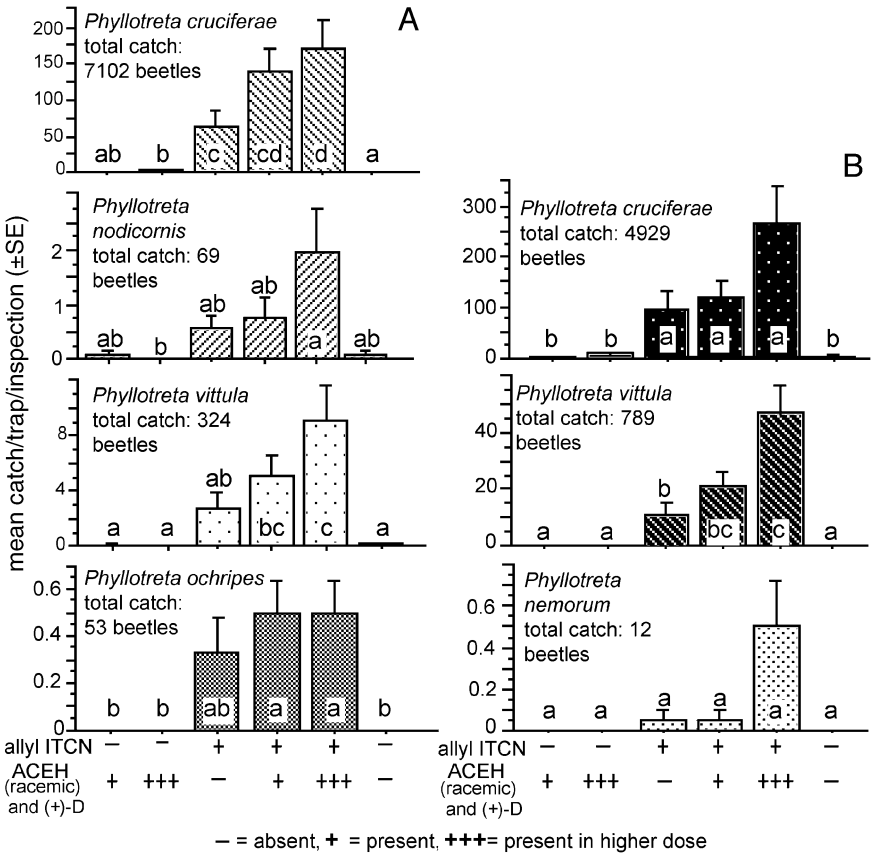

FIG. 3. Catches of flea beetles in traps baited with allyl ITCN, a mixture of racemic **ACEH** and (+)-**D** (at two doses), beetle compounds and allyl ITCN together, or controls. (A) Nadap, April 1–18, 2003 (experiment 1). (B) Budakalász, March 27–May 5, 2003 (experiment 2). Significance: within one diagram, bars with the same letters are not significantly different ($P > 0.05$, ANOVA then Games–Howell). In cases where one or more of the treatments caught no beetles, significant differences from zero catch were checked by Bonferroni–Dunn ($P > 0.05$).

Experiments 4 and 5, omission of component **D** from the mixture of **A**, **C**, **D**, **E**, and **H**. The largest catches of *P. cruciferae* were recorded in traps with allyl ITCN plus **ACDEH** or **ACEH** [component (+)-**D** subtracted from **ACDEH**], which differed significantly from catches of all other treatments (Figure 5A). Allyl ITCN attracted more beetles than unbaited traps, and allyl ITCN plus component (+)-**D** attracted more beetles than allyl ITCN alone,

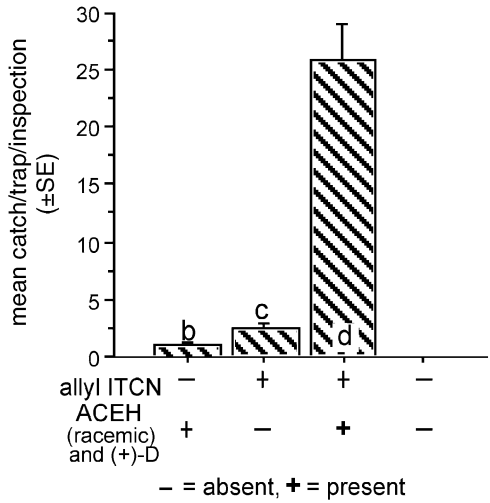

FIG. 4. Catches of *P. cruciferae* in traps baited with allyl ITCN as a single component, a mixture of racemic **ACEH** and (+)-**D**, both baits together, or controls (experiment 3). Budakalász, August 19–27, 2003. For significance levels, see Figure 3.

suggesting some activity for component (+)-**D**. In this test, *P. vittula* were caught in low numbers, the only treatment catching more beetles than unbaited controls being allyl ITCN plus **ACEH**.

In a supplementary test at Pusztazámor, *P. cruciferae* catches showed similar patterns (Figure 5B), with the exception that traps with the combination of allyl ITCN plus (+)-**D** were no better than allyl ITCN. The mixture of **ACDEH** without allyl ITCN (which was not tested in the previous test in Figure 5B) again showed minimal activity.

In this test, captures of *P. vittula* were best in traps with allyl ITCN plus **ACDEH** or **ACEH** (Figure 5B). Lower catches were observed in traps with allyl ITCN on its own. Unbaited traps or traps with **ACDEH** did not catch beetles.

Similar trends also were observed with *P. nigripes* (Fabricius) (Figure 5B), although no significant difference was found among traps containing allyl ITCN on its own or in combination with other components. Unbaited traps or traps with **ACDEH** alone caught fewer beetles than other treatments.

Experiment 6, activity of pure enantiomers of components **A**, **C**, **E**, and **H**. Blends of the pure enantiomers of **ACEH** with allyl ITCN and racemic **ACEH** with allyl ITCN were equally attractive to *P. cruciferae* (Figure 6). The blend of allyl ITCN with the (−) enantiomers of **ACEH** was no different than allyl ITCN alone.

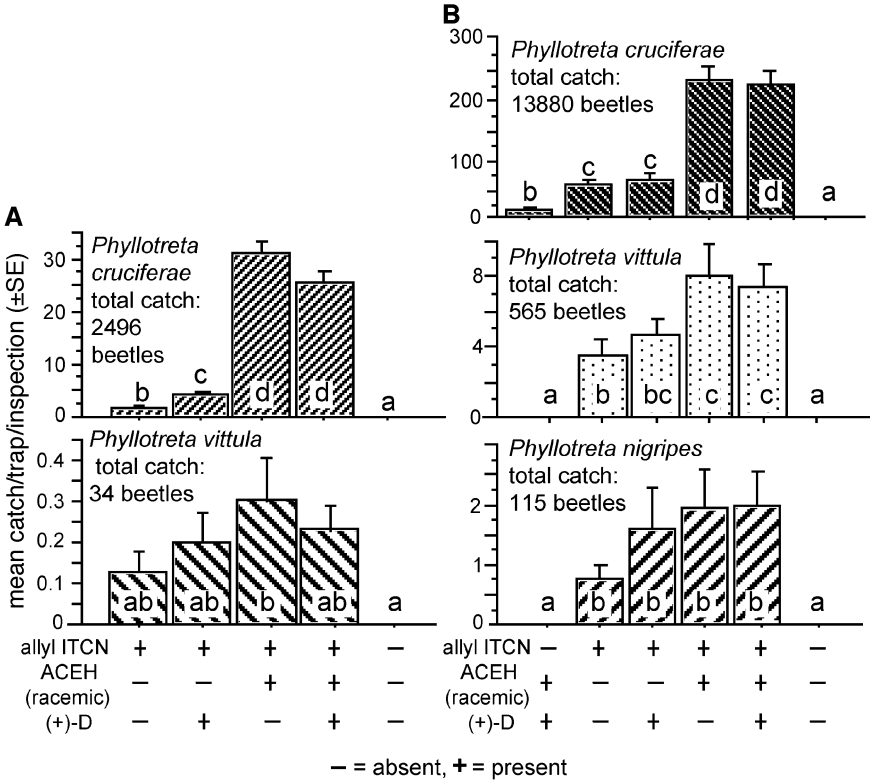

FIG. 5. Catches of *P. cruciferae* in traps baited with allyl ITCN as a single component, or in combination with component (+)-**D**, with racemic mixture **ACEH**, or with all five compounds. (A) Budakalász, August 19–27, 2003 (experiment 4); (B) Pusztazámor, September 10–19, 2003 (experiment 5). For significance levels, see Figure 3.

Several other species were caught [*P. vittula*, *P. procera* (Redtenbacher), *P. nigripes*, and *P. undulata* (Kutschera)] in low numbers, but, in general, no treatment was better than allyl ITCN (Figure 6).

Experiment 7, subtraction test of activity of pure enantiomers of components **A**, **C**, **E**, and **H**. More *P. cruciferae* were caught in traps baited with the (+) enantiomers or racemic **ACEH** plus allyl ITCN than in traps with the minus (−) enantiomers or with allyl ITCN on its own (Figure 7). Activity did not decrease when components **E**, **H**, and **C** were removed from the blends, indicating minimal or no role of **E**, **H**, or **C** as pheromone components.

Catches of *P. vittula* showed the same tendency, but the only treatment attracting more than allyl ITCN on its own was the racemic **ACEH** plus allyl ITCN combination (Figure 7).

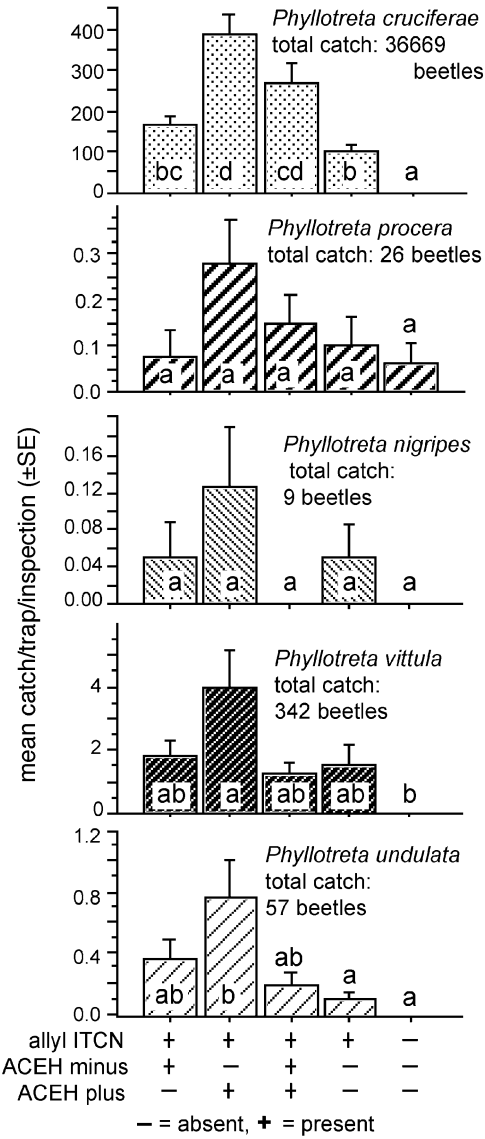

FIG. 6. Catches of *Phyllotreta* species in traps baited with allyl ITCN or its combination with (+) or (−) enantiomers of **ACEH**, or racemic **ACEH**. Budakalász, September 10–19, 2003 (experiment 6). For significance levels, see Figure 3.

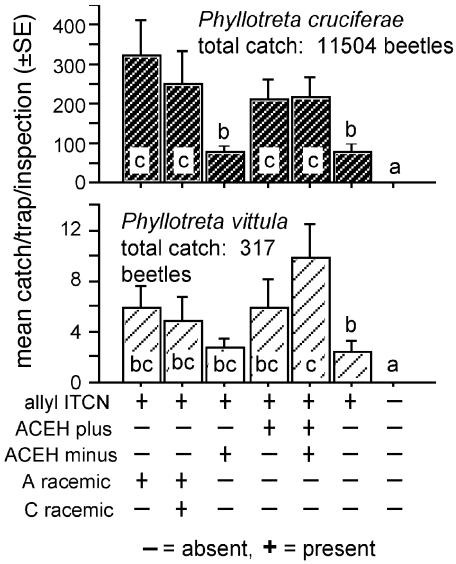

FIG. 7. Catches of *Phyllotreta* species in traps baited with allyl ITCN or its combination with (+) or (−) enantiomers of **ACEH** or with racemic **ACEH**, **AC**, or **A**. Pusztazámor, April 4–19, 2004 (experiment 7). For significance levels, see Figure 3.

DISCUSSION

In the present study, a mixture of components **A**, **C**, **D**, **E**, and **H**, although marginally attractive on its own, increased catches of *P. cruciferae* when presented together with the host-plant-derived attractant allyl ITCN. This is consistent with the results from North America (Soroka et al., 2005), suggesting that the pheromone compositions of the European and North American populations of *P. cruciferae* are similar.

There are a number of examples known of insect pheromones being synergized by host volatiles. In the well-documented case of *Melolontha* scarab beetles (Coleoptera, Scarabaeidae), males orient towards green leaf volatiles originating from damaged leaves from feeding female beetles (Ruther et al., 2000, 2002). Green leaf volatiles are somewhat attractive (Imrei and Tóth, 2002; Reinecke et al., 2002b), but many more beetles are attracted to blends of the green leaf volatiles with the pheromone components benzoquinone or toluquinone (Reinecke et al., 2002a; Ruther and Hilker, 2003). The quinones on their own show no activity. Similarly, with the scarab *Oryctes elegans* Prell. (Coleoptera, Scarabaeidae), the main aggregation pheromone component alone

was minimally attractive but, when presented together with host plant odor, it was clearly synergistic (Rochat et al., 2004).

Similar cases of strong synergism between pheromone components and host volatiles have been described for several species of *Rhynchophorus* weevils (Coleoptera, Curculionidae, Jaffé et al., 1993; Giblin-Davis et al., 1994; Oehlschlager et al., 1995; Rochat et al., 1995) and *Carpophilus* spp. sap beetles (Coleoptera, Nitidulidae; reviewed by Bartelt, 1999).

In the present study, beetles of both sexes were caught, but no special effort was made to study possible sex-specific differences in responses of *P. cruciferae*. In any case, effects would have been obscured by the activity of allyl ITCN, which attracts both sexes. It remains to be determined whether the communication strategy of *P. cruciferae* is sex-related, as in *Melolontha* scarabs, or is of the aggregation type as in the other examples above.

The biological activity of the insect-produced compounds was clearly connected with chirality. Because the (−) enantiomers were not inhibitory, racemic samples could be used as bait components in trapping studies. Furthermore, compounds **C**, **D**, **E**, and **H** had no obvious biological activity. Compound (+)-**A** [(6*R*,7*S*)-2,2,6,10-tetramethylbicyclo[5.4.0.]undeca-9,11-diene] was the only male-specific compound for which pheromonal activity could be clearly established for *P. cruciferae*. The closely related *P. vittula* responded in similar fashion to *P. cruciferae* with respect to the component mixtures and pure enantiomers tested. This suggests that compound **A** plays a role in pheromonal communication of this species as well. It remains to be seen whether *P. vittula* males produce this compound. *P. vittula* is among the economically most important pest flea beetles in Europe (Kaszab, 1962; Jourdheuil, 1966; Vig, 1996). Other *Phyllotreta* species were caught in low numbers, and the general trends resembled those seen with *P. cruciferae* and *P. vittula*. This suggests that the compounds tested may occur widely within the genus. Previously, compound **A** was found to be a common major component in the emissions collected from males of several North American flea beetle species (Bartelt et al., 2001) but at present, field activity data are available only for *P. cruciferae*.

Acknowledgements—The study was partially supported by grant OTKA T 043289 of the Hungarian Academy of Science. The authors are indebted to K. Vig for consultations in the species determination of captured specimens and to M. Szatmáry and B. Strasser from the Research Institute for Medical Plants (Budakalász, Hungary) for providing their experimental fields for some tests.

IDENTIFICATION OF A SEX PHEROMONE FROM MALE YELLOW MEALWORM BEETLES, *Tenebrio molitor*

GARETH P. BRYNING,* JOHN CHAMBERS, and MAUREEN E. WAKEFIELD

Central Science Laboratory, Sand Hutton, York, YO41 1LZ, UK

(Received March 15, 2005; accepted July 12, 2005)

Abstract—The sex pheromone released by the adult female *Tenebrio molitor*, 4-methyl-1-nonanol, is well known. In addition, there is evidence that adult males release a pheromone that attracts females. The purpose of the present study was to isolate and identify male-released pheromone(s). Emissions from virgin adult males and females were collected on filter paper and extracted with pentane. Extracts were analyzed by gas chromatography-mass spectrometry. One male-specific compound was detected and identified as (*Z*)-3-dodecenyl acetate (Z3-12:Ac). In arena bioassays, *E*3-12:Ac was attractive to females only, at 1 and 10 μg doses. E3-12:Ac was also attractive to females at a 10-μg dose. The presence of both male and female pheromones, each attracting the opposite sex, may contribute to maintaining a high-density population of both sexes.

Key Words—4-methyl-1-nonanol, bioassay, Coleoptera, (*E*)-3-dodecenyl acetate, electroantennography, male sex pheromone, *Tenebrio molitor*, (*Z*)-3-dodecenyl acetate.

INTRODUCTION

Tenebrio molitor L. (Coleoptera: Tenebrionidae) is a cosmopolitan secondary pest and scavenger of many stored cereal products. *T. molitor* are also found in chicken and other bird houses where feathers, food, and excrement are mixed (Cotton, 1956). The larvae of *T. molitor* are widely available as pet food for birds, fish, and reptiles (Rees, 2004).

Adult male and female mealworms both produce sex pheromone(s) that elicit responses from the opposite sex (Happ and Wheeler, 1969; Smart et al.,

* To whom correspondence should be addressed. E-mail: g.bryning@csl.gov.uk

1980). The sex pheromone released by the adult female, 4-methyl-1-nonanol, is well known (Tanaka et al., 1986).

Adult males release a pheromone that attracts females (Valentine, 1931; Tschinkel et al., 1967; Happ, 1969; August, 1971; Tanaka et al., 1986), and possibly also an antiaphrodisiac that inhibits the response of other males to the female scent (Happ, 1969). August (1971) reported that locomotion of females decreased in close proximity to males in response to a male-produced pheromone, resulting in females aggregating near live males. If the live male was moved to another chamber of the olfactometer, females reaggregated in this chamber within an hour. Live males or extracts thereof did not cause aggregation of males. The purpose of the present study was to identify the volatile pheromone(s) produced by male *T. molitor* that elicited this aggregation behavior.

METHODS AND MATERIALS

Insects. Tenebrio molitor, a laboratory strain kept in culture since 1958, was cultured on a 5:5:1 mixture by weight of wheatfeed, rolled oats, and yeast at 25°C, 70% RH, with a 16L:8D photoperiod. Insects were sexed at the pupal stage (Bhattacharya et al., 1970), kept separately, and tested as adults between 8 and 25 d after pupal eclosion.

Chemicals. 4-Methyl-1-nonanol was synthesized by $LiAlH_4$ reduction of 4-methylnonanoic acid (purity 99%; Aldrich Flavors and Fragrances, UK). (*Z*)-3-Dodecenyl acetate (Z3-12:Ac; isomeric purity 99%) and (*E*)-3-dodecenyl acetate (E3-12:Ac; isomeric purity 99%) were obtained from Pherobank, Research Institute for Plant Protection, The Netherlands. Pentane (glass distilled grade) was from Rathburns (UK). Cylclohexane (purity 99.99%) was from Aldrich (UK).

Preparation and Analysis of Extracts. Two sexed groups of five to six virgin male and female adults (8–25 d after pupal eclosion) were kept in glass jars (50 × 50 mm) for 24 hr at 20°C in a 16L:8D photoperiod with one 50-mm-diam disk of filter paper (Whatman qualitative No.1) placed in the lid of each jar. The filter papers were then placed into separate 5-ml Supelco glass microreaction vessels and extracted with 3 ml of pentane for 30 min, and the extracts concentrated to 50 μl by using a stream of nitrogen. A group of virgin males ($N = 11$) was also directly extracted with 5 ml of pentane for 1 hr and the extract was concentrated to 100 μl with a stream of nitrogen. This extract was used for ozonolysis of the male extract, and determination the stereochemistry of the male pheromone.

Extracts were analyzed on a Hewlett-Packard 5890 series II coupled to a VG Trio-1 mass spectrometer (MS). Aliquots of the extracts (3 μl) were injected in splitless mode (purge on after 1 min) at 250°C using helium as a carrier gas in

constant flow mode. A 50-m Chrompack CP-Sil 19CB column (0.25 mm i.d., film thickness 0.2 μm) was used except for the determination of the stereochemistry of the pheromone, where a CP-Wax 52CB column was used (0.25 mm i.d., film thickness 0.2 μm). The GC was programmed from 50°C 1 min to 270°C at 10°C/min, and maintained for 20 min. The MS was operated in electron impact ionization mode (EI, 70 eV) and scanned from 33 to 650 amu once every second. The MS and interface temperatures were 200 and 275°C, respectively.

Ozone was bubbled into a 5-ml glass microreaction vessel containing an extract of males in pentane for 1 min. An aliquot (3 μl) of the resulting extract was then analyzed by GC-MS on a CP-Sil 19CB column. The extract was repeatedly ozonolyzed until the male produced GC peak completely disappeared.

Authentic standards of Z3-12:Ac and E3-12:Ac were analyzed by GC-MS using the CP-Wax 52CB column. The oven was programmed from 50°C 1 min to 120°C at 8°C/min, hold for 27 min, then to 250°C at 10°C/min. An aliquot of an extract of males was analyzed under the same conditions.

Electroantennogram Studies. Prior to testing Z3-12:Ac in behavioral bioassays, the electroantennogram (EAG) response of both male and female *T. molitor* to Z3-12:Ac and E3-12:Ac was examined. Whole *T. molitor* proved difficult to restrain so head preparations were used, similar to EAG studies with other coleopteran species (e.g., Okada et al., 1992; Scholz et al., 1998).

Five male and five female adult *T. molitor* (less than 3 wk post-eclosion) were tested. Insects were removed from a culture approximately 1 hr prior to testing. The head was removed and secured using double-sided adhesive tape. The recording and indifferent electrodes were positioned in the terminal antennal segment and in the neck cavity, respectively. Electrodes were filled with saline (Roelofs, 1984) and connected, using chloridized silver wires, to a Grass P16 preamplifier and a chart recorder.

The odor delivery system was as described by White and Birch (1987). Z3-12:Ac and E3-12:Ac were presented at five doses ranging from 1 ng to 10 μg in 10 μl of cyclohexane. The test materials were presented at ca. 2-min intervals in ascending concentration and at each concentration the order of presentation was random. To account for variations due to fatigue, a standard of carob extract prepared from Porapak-Q collected volatiles from kibbled carob pods, was used (Wakefield et al., 2005). The standard was tested at the start and the end of each test and after presentation of each log dose of the two isomers. The absolute net EAG response to a test material or the standard was determined by first subtracting the mean response to a solvent control stimulation at the start and the end of each test from the response to the sample. Results were then expressed as a percentage of the response to the standard by:

$$\text{Relative net EAG}_x = \frac{2 \times \text{absolute net EAG}_x}{\text{absolute net standard}_x + \text{standard}_{x+1}} \times 100$$

Responses of males and females were compared using Student's *t* test. The perception threshold, defined as the lowest amount at which the absolute EAG response to the test stimulus was significantly greater than the mean of the control responses, was also determined.

Behavioral Bioassays. Pupae were removed from the culture and kept at 22°C and 16L:8D photoperiod, in individual glass tubes (75 × 25 mm) with a perforated plastic lid for ventilation and a folded filter paper as a crawling surface. The bioassay was adapted from the method described by Finnegan and Chambers (1993). Individual insects were placed in an arena comprised a 20-cm-diam metal ring on filter paper circles (27 cm diam, Whatman No. 1) and covered with a glass plate. The rings were 40 mm high and narrowed toward the top, making a considerable overhang for the insects to climb, thus preventing escape. Insects were allowed to settle for 30 min. One insect was introduced into the center of each arena. With the beetle at the perimeter of the arena, one 20-mm-diam filter paper disk (Whatman No.1) treated with test material in 10 μl of pentane and a control disk treated with 10 μl of pentane were placed 25 mm apart, equidistant from the center of the arena along a diameter perpendicular to the insect. The solvent was allowed to evaporate from the disks for 30 sec before they were placed in the arenas. The disk which was touched first was recorded (= a behavioral response). Bioassays were run for 10 min. Except where stated otherwise, each dose of each test material was tested against 40 adults of each sex.

Doses of 100 ng, 1 μg, or 10 μg of Z3-12:Ac in 10 μl of pentane were applied to test filter papers and tested against both males and females. E3-12:Ac was tested against females only at (10 μg), so that its biological activity could be compared with that of Z3:12:Ac, even though E3-12:Ac was not found in male extracts. The responses of males and females to each dose of Z3-12:Ac, and E3-12:Ac *versus* the controls were analyzed using χ^2 test with Yates' correction for 1 degree of freedom.

RESULTS

Identification of Material Produced by Males. The extract of filter papers exposed to females contained 4-methyl-1-nonanol, previously identified as a sex pheromone released by females (Tanaka et al., 1986). Its identity was confirmed by matching its mass spectrum and retention time on the CP-Sil 19CB column with those of an authentic standard.

Extracts of filter papers exposed to males (Figure 1C) contained a compound (peak 2) that was not detected in extracts of blank filter papers (Figure 1A), or filter papers exposed to females (Figure 1B). This compound gave a fragmentation pattern (Figure 2A) with ions at *m*/*z* 61, 96, 109, 124, 138,

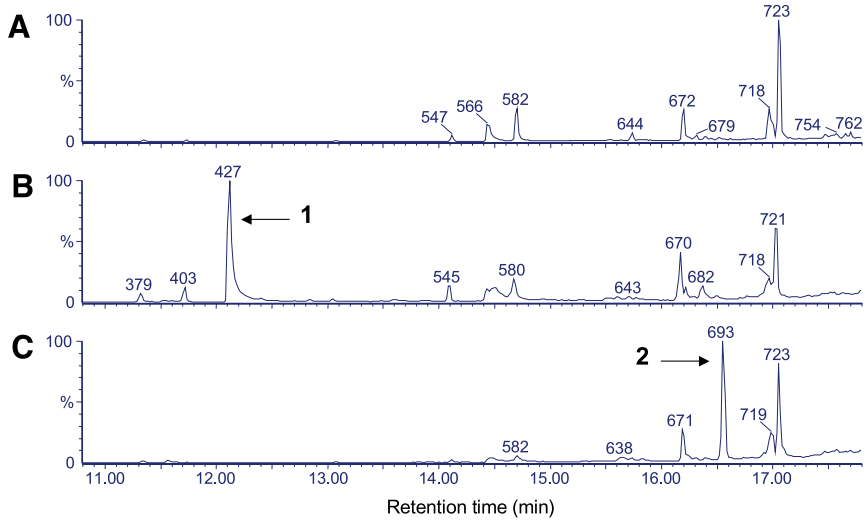

FIG. 1. Total ion chromatograms of extracts of filter papers which were (A) blank, (B) exposed to five females, and (C) exposed to five males. Identifications of peaks: (**1**) 4-methyl-1-nonanol, (**2**) Z3-12:Ac. CP-Sil 19CB column.

TABLE 1. MEAN EAG RESPONSES (± SE) IN MICROVOLTS TO Z3-12:AC AS A PERCENTAGE OF THE RESPONSE TO A CAROB EXTRACT STANDARD (N = 5)

Dose	Female	Male
1 ng	−4.5 ± 2.1	0.5 ± 3.7
10 ng	3.0 ± 3.4	0.8 ± 3.9
100 ng	23.6 ± 8.4	6.2 ± 6.0
1 μg	7.8 ± 8.7	35.4 ± 13.8
10 μg	40.5 ± 4.1*	21.9 ± 4.0*

*Significant difference (t = 3.28, df = 8, $P < 0.05$) between the means for males and females.

and 166, consistent with a dodecenyl acetate. The CI (isobutane) spectrum showed an ion at m/z 227 $(M + H)^+$, confirming the molecular weight as 226 (Figure 2B). After ozonolysis of the extract, peak 2 disappeared, confirming that the compound was unsaturated. A new peak appeared at scan 299 and was identified as nonanal from diagnostic fragment ions at m/z 142 (M +, 0.8), 124 (3), 114 (8), 98 (35), 82, (31), 70 (41), 57 (85), 55 (72), 43 (79), and 41 (100%). This indicated that the double bond was in the 3-position in the starting material. Authentic Z3-12:Ac and E3-12:Ac eluted at scans 2071 and 2056 respectively, on the CPWAX-52CB column. The compound of interest in the extract from males eluted at scan 2070, confirming the material as Z3-12:Ac. No E3-12:Ac was detected in the male extract.

Electroantennography. The mean responses to the carob standard based on the first presentation of the standard were 305 ± 45.5 and 183.5 ± 40.8 μV for females and males, respectively (N = 5). Based on the final presentation of the carob standard, the mean responses to the standard were 430 ± 79.6 and 257.5 ± 71.9 μV for females and males, respectively (N = 5). There was no significant difference (ANOVA, F = 2.81, $P > 0.05$, df = 19) between the first response and the final response to the carob standard or for the response by males and females at either point.

TABLE 2. MEAN EAG RESPONSES (± SE) IN MICROVOLTS TO E3-12:AC AS A PERCENTAGE OF THE RESPONSE TO A CAROB EXTRACT STANDARD (N = 5)

Dose	Female	Male
1 ng	−3.1 ± 2.5	0.1 ± 2.2
10 ng	2.1 ± 3.5	1.6 ± 4.3
100 ng	2.0 ± 5.8	32.3 ± 15.5
1 μg	12.8 ± 8.8	1.5 ± 4.3
10 μg	22.6 ± 8.0	39.2 ± 22.3

TABLE 3. TWO-CHOICE BIOASSAY RESPONSES OF MALE AND FEMALE *T. molitor* TO Z3-12:AC ($N = 40$)

Dose	Percent response[a]		
	Z3-12:Ac	Control	No response
Males			
100 ng	37.5	25	37.5
1 μg	55	40	5
10 μg	55	35	10
Females			
100 ng	50	35	15
1 μg	65*	20	15
10 μg	75**	20	5

[a] χ^2 test: $\chi^2 = 9.53$, $df = 1$, $P = 0.002$ (*); $\chi^2 = 12.74$, $df = 1$, $P < 0.001$ (**).

The mean EAG responses of female and male *T. molitor* to Z3-12:Ac and E3-12:Ac as a percentage of the response to the standard are shown in Tables 1 and 2, respectively. There was no difference in response by males and females except for 10 μg of Z3-12:Ac, where the response by females was greater than the response by males ($t = 3.28$, $P < 0.05$, $df = 8$). The perception threshold for both Z3-12:Ac and E3-12:Ac by females was 10 μg ($P < 0.05$, $df = 4$). In males, the response to Z3-12:Ac and E3-12:Ac did not differ significantly from the control response at the quantities tested ($P > 0.05$, $df = 4$).

Behavioral Bioassay Tests. Z3-12:Ac was not attractive to males at any dose tested (χ^2 test, $P > 0.05$) (Table 3). However, at 1 and 10 μg, Z3-12:Ac was attractive to females ($P = 0.002$ and $P < 0.001$, respectively) (Table 3). E3-12:Ac was also attractive to females at 10 μg (62.5% of females responded to E3-12:Ac and 22.5% to the control; $\chi^2 = 7.53$, $df = 1$, $P = 0.006$).

DISCUSSION

Males of many beetle species that infest stored products produce aggregation pheromones (Chambers, 1991). In contrast, Z3-12:Ac is a male-produced sex pheromone that elicits a response only from females. August (1971) tested live males and extracts of males over a range of doses in a choice test and found that one male equivalent of male extract caused attraction of females into a central chamber and the response was dose-dependent. In our study, in the highest dose of Z3-12:Ac tested (10 μg), approximately five male equivalents was highly attractive to females. August (1971) found that male extracts were not attractive to males. Similarly, we found that Z3-12:Ac was not attractive to males at any dose tested.

August (1971) also found that the response of females to live males (where the males were not visible to the females) was greater than to the optimally attractive dose of male extract (5 male equivalents). He suggested that this could be due to other semiochemicals present in the male extracts, which might be repellent to females at high concentrations. Happ and Wheeler (1969) found that males release an antiaphrodisiac after they are exposed to female scent, which reduces the attractancy of the female scent to subsequent males. When they tested a mixture of male and female scent against males, it was considerably much less attractive than the female scent alone. They also found that females often extruded their ovipositors on exposure to male sex attractant, and suggested that, together with the antiaphrodisiac component, males increase the probability that females will utilize their sperm before another male has a chance to mate. The male semiochemical(s) suggested by August (1971) and the antiaphrodisiac reported by Happ and Wheeler (1969) could be the same compound(s). Here, we found evidence for the production by males of 2,5-dimethylpyrazine, but the amounts were very small and we did not determine whether this compound has any biological activity in *T. molitor*.

E3-12:Ac (98%) and Z3-12:Ac (2%) are the two components of the sex pheromone of the potato tuber moth, *Scrobiphalpopsis solanivora* Povolny (Nesbitt et al., 1985). E3-12:Ac has also been identified as the sex pheromone of *Scrobipalpa ocellatella* Boyd (Renou et al., 1980). These are the only other species of insects reported to use E3-12:Ac or Z3-12:Ac as semiochemicals. Many species of moths are reported to use one or more isomers of dodecenyl acetate as components of their female sex pheromones, but to our knowledge, this is the first report of a dodecenyl acetate as a beetle pheromone.

It is unusual for both sexes of a species to release a pheromone that attracts the other sex. Both sexes of the Azuki bean weevil (*Callosobruchus chinensis* L.) release a nonvolatile, copulatory release pheromone, which affects only males and is distinct from the female-released sex pheromone (Tanaka et al., 1981). Male and female *Tribolium confusum* (the confused flour beetle) release three hydrocarbons which increase the frequency of copulation, but which affect only males (Keville and Kannowski, 1975). In contrast, the pheromone identified in our study acts as a sex attractant for females, as opposed to a contact copulatory release pheromone.

Studies of *T. molitor* mating behavior by Obata and Hidaka (1982) found a low rate of successful copulation due to relatively random mounting behavior by males, and suggested that a "critical" high-density population is needed to overcome this. A high-density "crowded state" was reported to accelerate oocyte development, pheromone emission, and mating success (Mordue, 1965; Happ and Wheeler, 1969; Gerber, 1973). As females do not respond to their own pheromone, a female pheromone would only lead to an increase in the density of males, and not of both sexes. The presence of both male and female

pheromones, each attracting the opposite sex may, therefore, contribute to maintaining a high-density population of both sexes.

Acknowledgments—We thank Dr. Larissa Collins and Mr. A. Prickett for statistical analysis of the behavioral bioassay results. This work was funded under the CSL Seedcorn budget by the UK Department for the Environment, Food, and Rural Affairs.

(Received December 22, 2004; revised July 12, 2005; accepted July 14, 2005)

Abstract—Recent studies have demonstrated a remarkable and unexpected complexity in social insect pheromone communication, particularly for honeybees (*Apis mellifera* L.). The intricate interactions characteristic of social insects demand a complex language, based on specialized chemical signals that provide a syntax that is deeper in complexity and richer in nuance than previously imagined. Here, we discuss this rapidly evolving field for honeybees, the only social insect for which any primer pheromones have been identified. Novel research has demonstrated the importance of complexity, synergy, context, and dose, mediated through spatial and temporal pheromone distribution, and has revealed an unprecedented wealth of identified semiochemicals and functions. These new results demand fresh terminology, and we propose adding "colony pheromone" and "passenger pheromone" to the current terms sociochemical, releaser, and primer pheromone to better encompass our growing understanding of chemical communication in social insects.

Key Words—*Apis mellifera*, honeybee, social insect, chemical communication, pheromone, chemoecology.

INTRODUCTION

In their preface to *Chemical Ecology of Insects* published in 1984, Bell and Cardé stated "Evolution of sociality seemed to spawn a chemical language that is equivalent to the visual and auditory repertoire of higher vertebrates." This is now revealed to be a prophetic insight (Bell and Cardé, 1984). At that time, the chemical communication systems utilized by social insects had been recognized

* To whom correspondence should be addressed. E-mail: leconte@avignon.inra.fr

as complex but seemed to conveniently compartmentalize into two pheromone categories, releaser or primer. A releaser pheromone initiates an immediate behavioral response upon reception, whereas a primer pheromone alters more long-term endocrine and reproductive systems in the recipient (Wilson and Bossert, 1963). Recent studies of honeybee pheromones suggest that chemical communication in social insects is deeper and richer than had been imagined by earlier generations of chemical ecologists. Pheromone signals in honeybees and likely other social insects are often enhanced by complexity, synergy, and the context in which they are deployed, mediated through both temporal and spatial distribution. Even our current limited view of social insect pheromones exceeds the boundaries of present terminology and requires a fresh appraisal. Our intention is not to review all the literature concerning honeybee pheromones as performed before (Free, 1987), but rather to suggest a new template with which to approach sociochemistry.

HONEYBEE SOCIOCHEMISTRY

Our understanding of the chemical language expressed by social insects is best provided through the pharmacopoeia of *Apis mellifera* L., the honeybee. The social organization of honeybee colonies is determined primarily by chemical signals that are actively produced and transmitted by the queen, the adult workers at various tasks and lifestages, and the brood. The honeybee dance language used to recruit foragers to food, water, and nest sites is better known (von Frisch, 1967), but constitutes only one fraction of the communication systems that operate in a functioning colony.

These chemical signals are made remarkably specific in function by temporal fluctuations timed to release specific behaviors or to prime key physiological characteristics of signal recipients, based on both context and synergistic interactions between components. Like a fire alarm, a constant chemical signal would be of no value; time and place are of the essence. The wealth of identified semiochemicals utilized by honeybees and their functions is unprecedented in the insect literature, possibly as a result of the extensive investigations that this agriculturally beneficial insect has stimulated, but also because of its inherent social complexity. Even a cursory review of the honeybee's chemical communication repertoire reveals a rich language.

DEFENSE: ALARM PHEROMONE

For the beekeeper, the banana smell of isopentyl acetate warns that the colony is aroused and that further stinging is imminent. A mixture of substances

is released from a honeybee worker sting gland in the act of stinging, thus recruiting other workers (Breed et al., 2004). Free (1987) lists isopentyl acetate and 24 other substances that are found in the sting gland and thought to be involved in the alarm reaction to colony attack. More recently, Hunt et al., (2003) discovered 3-methyl-2-buten-1-yl acetate as a new alarm component in the sting apparatus of Africanized honeybees. The necessity for chemical complexity of the alarm signal is not obvious. Some specific behavioral attributes have been ascribed to individual components, but no clear theme emerges (Winston, 1987). Many of the components are chemically quite distinct, constituting both aromatic and aliphatic molecules, ruling out complexity as a byproduct of closely related biosynthetic pathways.

ATTRACTION: NASANOV PHEROMONE

The incredible phenomenon of a cohesive honeybee swarm is partially mediated by a complex of the seven-component Nasanov pheromone (Pickett et al., 1980). The signal is released from the dorsal surface of the worker honeybee abdomen to attract her sister workers in a peaceful and organized manner during swarming or at colony entrances (Free, 1987; Winston, 1987). The lemon-grass fragrance we attribute to this bouquet is mostly because of our ready perception of three principal volatile components in this mixture: geraniol, geranial, and neral. The swarm cluster is initiated by alighting workers releasing Nasanov pheromone and then enhanced by the presence of the queen and her attractive signals (Avitabile et al., 1975). Many of the components of the Nasanov pheromone are biosynthetically related, so the complexity of this signal may be partially a function of their production.

ATTRACTION TO THE QUEEN: RETINUE PHEROMONE

A mated, laying queen is essential to the well being and proper functioning of the colony. She communicates her presence and manifests her influence by releasing a mixture of substances that is attractive to workers, enticing them to lick and antennate her to gather a small sample of her attractive blend. It is this retinue behavior of workers to the queen that was recognized by the earliest students of honeybee biology and distinguished her as "queen" of the colony. This "queen substance" was originally considered to be a single material, 9-oxo-(*E*)-2-decenoic acid (ODA) (Barbier and Lederer, 1960; Butler et al., 1961; Pain, 1961), and has been shown to be an essential component of the honeybee sex pheromone, attracting drones to the queen during her mating flight (Gary, 1962). However, queen-like amounts of ODA were neither

attractive to workers nor substituted for her in her absence. Even addition of the two enantiomers of ODA's biosynthetic precursor, (*R*)- and (*S*)-9-hydroxy-(*E*)-2-decenoic acid (HDA), failed to constitute an attractive blend for workers, although (*R*)-HDA is involved in the swarm-settling queen signal (Slessor et al., 1988). Two further components, methyl *p*-hydroxybenzoate (HOB) and 4-hydroxy-3-methyoxyphenylethanol (HVA), were finally recognized and formulated with the decenoic acids to provide a source as attractive as an equivalent extract from the mandibular glands in which the five compounds are produced (Slessor et al., 1988).

Individual components and even subsets of components are not attractive. Only when all five components of the queen mandibular pheromone (QMP) are combined does the blend elicit the full retinue response, a striking example of semiochemical synergy (Slessor et al., 1988). Another important aspect of QMP that distinguishes it from many insect pheromones is that the components are on the borderline of volatility, apparently requiring close proximity between the queen and the recipient worker.

Early in our studies of QMP, it became evident that some strains of honeybees did not find this blend at all attractive, yet they tended their queen and otherwise functioned normally in colonies, implying as yet unidentified, additional substances involved in the retinue response. After 15 years, four further synergistic substances were identified in this "simple" retinue response (Keeling et al., 2003). Disruptive selection for high and low QMP retinue responding workers using closed mating demonstrated this pheromone response to have a strong genetic component (Pankiw et al., 2000). Two-way selection of colony phenotypes for low QMP and high queen extract responders provided over 380,000 worker test subjects for bioassays and led to the elucidation of the nine-component retinue pheromone (QRP = QMP + methyl oleate, coniferyl alcohol, palmityl alcohol, and linolenic acid). The terminology shift to QRP was necessary because the three new fatty-acid-derived constituents are not of mandibular gland origin (Keeling et al., 2003). The complete identity of QRP is still not fully defined because a very small difference in response of specially bred workers to synthetic QRP and multiple queen extract is evident. To identify the material(s) responsible for this small difference would necessitate a new and more extensive bee breeding and chemical isolation program.

The queen signals her presence to the colony through the attractive 9+ component releaser pheromone QRP. Absence of the signal for a few hours results in the workers choosing a few freshly laid eggs to rear into new queens, and long-term absence results in some workers developing ovaries (de Groot and Voogd, 1954; Butler and Fairey, 1963). Thus, colony reproduction and worker physiology are partially under the control of QRP (Pankiw et al., 1998), making it a primer as well as a releaser pheromone. The retinue facilitates the

distribution of QMP that inhibits the development of worker ovaries (Hoover et al., 2003) and orients the comb building (Ledoux et al., 2001). It also facilitates distribution of a known primer component, ODA, that modulates the biosynthesis of juvenile hormone in recipient workers (Kaatz et al., 1992), regulating their age-related tasks (Robinson et al., 1989). Clearly, the synergistic releaser QRP embodies primer signals.

LARVAL SIGNALS: ESTER "BROOD PHEROMONE"

In the early 1990s, we identified a mixture of 10 ethyl and methyl esters of the common fatty acids palmitic, linoleic, linolenic, stearic, and oleic acids from larvae, and 4 of these methyl esters were originally considered to be a signal from larvae to adults to cap the brood cells prior to their pupation (Le Conte et al., 1990). The methyl esters of palmitic and oleic acid were most effective in recruiting workers to this role. In addition, differences in the proportions of esters provide a chemical signature of larval age (Le Conte et al., 1994, 1994/1995). Further studies demonstrated that individual esters and subsets of esters provide context-specific signals to bring about other behaviors. In the presence of a fully functioning queen, the workers will tear down any freshly constructed queen cells, but the presence of methyl oleate in or about these cells results in a greater acceptance of new queen cells by workers (Le Conte et al., 1994/1995). The action of methyl linolenate results in enhanced provisioning of these new queen cells with more royal jelly, facilitating the healthy development of new queen larvae (Le Conte et al., 1995). Each individual ester or ester subset provides a message to the worker recipient, indicating an action to be carried out.

In the 1990s, an even more important role for the esters began to emerge. Nurse honeybees feed larvae a mixture of nutrients that contains a proteinaceous gland exudate. When nurse bees are treated with a blend of methyl palmitate and ethyl oleate, protein levels in the gland are elevated, probably through stimulation of the gland's biosynthetic capacity (Mohammedi et al., 1996). This finding has recently been confirmed (Pankiw et al., 2004). In the prolonged absence of a queen and larvae, the ovaries of worker honeybees mature and in extreme cases become drone-laying workers (Winston, 1987). Two of the "brood" esters with demonstrated releaser effects, ethyl palmitate and methyl linolenate, partially inhibit the ovarian development of worker bees when they are isolated from a queen and brood (Arnold et al., 1994; Mohammedi et al., 1998). The inhibitory effects of these esters on the physiological development of the recipient workers' ovaries constitute a primer pheromone effect.

WORKER ESTERS

The tasks of adult worker honeybees change as they age, from in-colony duties, such as nursing larvae, to pollen and nectar processing, followed by outside responsibilities of guarding and foraging (Lindauer, 1953). Plasticity of ontogeny in behavioral development allows the colony to cope effectively with changing environments, including internal requirements such as the production of new workers, or external opportunities such as increased nectar flow. This organizational shift and its plasticity are well recognized, but its underlying control has been a mystery, likely involving hormonal and pheromonal components (Robinson, 1992). A major influence in a worker's developmental rate is provided by her older sister foragers whose presence slows the nurse's progression through the age-related tasks (Robinson, 1992; Huang and Robinson, 1996). Recently, the feeding of larval esters to experimental colonies has demonstrated inhibition in age to first foraging (Le Conte et al., 2001). Ethyl oleate is present at significantly higher levels in foragers than in nurses, and the presence of this ester accounts for the ontogenetic inhibition and task mediation in honeybee colonies (Leoncini, 2002; Leoncini et al., 2004).

QUEEN ESTERS

Chemical analysis of queens demonstrated the presence of seven esters including methyl oleate (Wossler and Crewe, 1999a), the palmitates, oleates, ethyl stearate, and two new esters, ethyl and methyl palmitoleate, with methyl oleate a synergistic component of queen retinue formation (Keeling, 2001). In the dispersal of QRP throughout the colony, queen esters are distributed as passive chemical passengers in the queen bouquet because they possess no attractive capability alone or in the QRP blend. For example, ethyl palmitate derived from the queen may well be the active agent in her ability to inhibit worker ovarian development as ethyl palmitate also was demonstrated to be produced by the larvae and to inhibit the ovary development of workers (Mohammedi et al., 1998). Thus, both the larvae and the queen manipulate the ovary development of workers to their advantage.

In addition, the major ester in the queen, ethyl oleate (Keeling, 2001), which is involved in regulating the ontogeny of the young workers who attend and feed the queen (Mohammedi et al., 1996), is a passive chemical passenger. Such a substance as ethyl oleate in the queen's effluvia, although not involved in the attraction process, but critically important in her pheromonal capabilities, can be regarded as a "passenger pheromone." Esters that play no role in the queen's releaser retinue response and yet are delivered as an integral part of that mixture are central to her impact on workers, functioning

as "primer pheromones." We propose that these be called "passenger pheromones" (Table 1).

COLONY ESTERS

Just as we had to revise the nomenclature of queen mandibular pheromone (QMP) to queen retinue pheromone (QRP) to properly reflect its multiglandular source, these fatty acid esters might now be properly viewed as "colony pheromones," defined as originating in multiple castes and developmental stages and having diverse releaser and primer roles. Palmitate and oleate ethyl are good examples of a colony pheromone (Table 1). Remarkably, the queen and larvae work in concert to inhibit the ovarian development of young adult worker bees (Jay, 1968, 1972; Free, 1987). Ethyl palmitate inhibits ovary development of workers (Mohammedi et al., 1998). The flux of ethyl palmitate from the two sources is unknown at present, although drone larvae ready for capping have ~90 ng (Le Conte et al., 1989), worker larvae somewhat less (Le Conte et al., 1990), and a mated laying queen contains ~300 ng (Keeling, 2001). Older foragers, the larvae, and the queen exhibit primer effects by influencing the developmental rate of their younger sisters and offspring through the release of ethyl oleate. Foragers contain roughly 45 ng, larvae 50 ng (Le Conte et al., 1989; Leoncini et al., 2004), and queens 6300 ng (Keeling, 2001) of ethyl oleate on average, although release rates remain unknown. Moreover, oleate and palmitate ethyl are known to be involved in larval recognition by workers (Le Conte et al., 1994). In addition to influencing the ontogeny of their sisters, the esters stimulate and release pollen foraging behavior and may prime bees for a particular foraging role at a young age (Pankiw and Page, 2001).

COMPLEXITY: WHY SO MANY?

The identified queen, worker, and brood substances essential for the functioning of this highly evolved social organism now number nearly 50 in all, and still are incompletely characterized. In human society, language with its vast oral and written vocabulary is the commerce of communication. In honeybee society, the vocabulary is an array of specific chemicals or blends of chemicals. A few of the substances now thought to be honeybee signal chemicals eventually may be recognized as inactive biosynthetic precursors and degradation products, the noise of this chemical language. However, even with the noise filtered out, honeybee language is undoubtedly more complicated than previously recognized (Slessor, 2003). The chemical complexity of the queen's tergal (Wossler and Crewe, 1999a,b), labial (Katzav-Gozansky et al., 2001a),

TABLE 1. MULTISOURCES AND TARGETS OF FATTY ACID ESTERS IN THE HONEY BEE

and Dufour's gland (Katzav-Gozansky et al., 1997, 2001b) implicates these and other worker, brood, and queen glands as informational sources. No components responsible for their effects, however, have yet been fully identified. Queen recognition, the ability of a colony to recognize its own queen (reviewed in Winston, 1987), worker policing of nonqueen laid eggs (Ratnieks and Visscher, 1989; Ratnieks, 1995), and colony/nestmate recognition (Breed et al., 1992, 1995) are examples of interactions that require further communication channels and suggest additional signal chemicals. Complex social interactions demand an intricate language. In the honeybee and likely in other social insects, the use of many highly specialized chemical signals provides that syntax.

CONTEXT, COMPLEXITY, AND SYNERGY

The majority of known insect pheromones are perceived as volatile materials diluted and carried by air currents, received, and processed through antennal reception. Honeybees utilize this dispersal mechanism for alarm and Nasanov pheromones, and, similarly, components of queen pheromone attract drones for mating and workers to swarm clusters (see Winston, 1987). However, a distinguishing feature of QRP and colony esters is that they are passed primarily by contact. Partially volatile components appear to be quickly absorbed into the wax matrix of the colony (Naumann et al., 1991), effectively removing them and ensuring their context dependence. Alternatively, the transmission of chemical components from wax can provide discrimination and nestmate recognition cues to naive individuals (Breed et al., 1995, 1998), underlining the integral role that wax plays. In the retinue, the young workers attend the queen, licking and antennating her, removing QRP from her body, and often obtaining sufficient QRP that they become attractive to other workers after they have left the queen (Seeley, 1979; Naumann et al., 1991). These messenger bees contribute to the dispersal of QRP, but when the QRP signal fails to be transmitted throughout the colony because of congestion and population growth (Naumann et al., 1993), workers consider themselves queenless and begin to build queen cells, the precursor to colony reproduction by swarming (Winston et al., 1991). If these signals were volatile and/or not removed by wax, they would be distributed virtually homogeneously throughout the colony by the continuous circulation of air maintained by the workers. The relative involatility of QRP and the absorptive nature of wax, thus, have important repercussions enabling synergy for multicomponent pheromones. Inactive on their own, QRP components are highly synergistic, the whole blend being required for a complete signal. Only if all components are perceived as a unit does the signal transmit the important message "the queen is here and functioning appropriately."

Synergy provides a further bonus for the organization because all chemical constituents need not be unique to the emitter. A single unique component is sufficient to render a distinctive identity and response when carried along with other ubiquitous and active ingredients. This phenomenon is particularly important where individuals are nearly all biosynthetically equivalent, as in a caste-based social organization (Plettner et al., 1996; Martin and Jones, 2004). In the honeybee colony, the queen must uniquely produce only HVA and coniferyl alcohol (and possibly HOB) to ensure that she transmits a blend with both releaser and multiprimer effects.

Context is less well documented and understood, but clearly plays an important role. Methyl oleate is perceived as a capping signal when emitted by larvae (Le Conte et al., 1990), but also is a synergistic component of QRP (Keeling et al., 2003; Table 1). Workers have reduced capacity to produce queen-like QRP components, and yet clearly respond to its primer effects. Young workers contain esters including ethyl oleate (Leoncini, 2002; Leoncini et al., 2004), which inhibits their ontogenetic development when received from the queen or their older sisters. Could it be that the receipt of primer pheromone through direct contact with antennae or other receptive sensory organs is the principal initiating mechanism, or is a threshold dosage the activating mechanism? At very dilute concentrations, QMP stimulates foragers to perceive a nectar source as a richer resource than the sugar concentration suggests (Higo et al., 1992). What underlying effects contribute to this contextual and dose misrepresentation of the queen signal?

Complexity of a signal is greatly facilitated by synergy, which, in turn, contributes to contextual uniqueness. These properties combined—complexity, synergy, context, and dose—appear to be hallmarks of social insect pheromones and distinguish them from the typical pheromones of nonsocial insects. Pankiw (2004) has recently described honeybee chemical communication as an emergent property of a complex system with dynamic properties requiring a complex systems approach for their analysis.

ISOLATION AND IDENTIFICATION: BIOASSAYS

Contextual dependence, synergy, and complexity make sociochemical identification extremely difficult. Chemical comparisons of interracial differences and similarities can provide clues to the involvement of specific substances of behavioral importance (Wossler and Crewe, 1999b; Brillet et al., 2002). However, no insect primer has yet been isolated and identified by bioassay. Substances have been designated with primer status only after their presence has been established through a releaser-based bioassay and then demonstrated in a primer bioassay. An effective bioassay must incorporate

transfer of the bioactive mixture in an appropriate manner and dose and be followed by some quantitative measure of the resulting effect. The process must be elegant and simple because it may have to be replicated many thousands of times, not only to show the involvement of an active ingredient but also to provide satisfactory proof that an inactive ingredient has no effect on the response being measured; a benign effect is considerably more difficult to demonstrate than a positive one. Dose dependency must be tested to ensure that the applied dose is biologically relevant, similar to that encountered by an individual in a normal situation. Highly replicated bioassays may require hundreds of thousands of animals at a specific point in their life or of a particular strain. Primer bioassays provide an even greater challenge, necessitating a time period for the physiological change to become apparent and the time and effort involved in measurement of the change, e.g., dissection and evaluation of ovarian development. Efficient primer isolation and identification requires new methodology, with molecular biology the most promising tool. Initiation of physiological changes may be monitored at the RNA or protein level rather than the behavioral or physiological level. Differential or microarray displays (Whitfield et al., 2002; Grozinger et al., 2003) offer tremendous advantages over multitudinous bioassays necessary for the isolation and identification of primer pheromones. Nevertheless, the primer bioassay remains essential to prove the function of the putative primer pheromone rather than directing its isolation.

SOCIOCHEMICALS: REFINING TERMS

The pheromone complexity of the honeybee suggests that the evolution of insect sociality created a large number of complex chemical languages. The term "sociochemical" refers to any chemical or defined mixture of chemicals that mediates social behavior (Bell and Cardé, 1984). Within this framework, honeybees utilize releasers, some apparently monofunctional, such as Nasanov pheromone, and others clearly multifunctional, such as "colony pheromone" (defined above as originating in multiple castes and developmental stages and having diverse releaser and primer roles, e.g., esters in honeybees). The latter, in addition to its releaser roles under appropriate context, functions in subsets as both stimulatory and inhibitory primers. Foragers modulate their sisters' physiological development with an inhibitory primer that may be transferred during nectar and pollen delivery.

The queen, by means of an attractive releaser (QRP), has at least one component (ODA) that mediates a worker's endocrine function. In addition, this attractive material carries with it several other passenger substances (ethyl oleate and palmitate) that are transferred passively during the retinue response. The ester blend released by larvae contains both context-dependent releasers

and primers with some apparently in passenger mode. This new concept of "passenger pheromones," substances that are transmitted in a pheromone complex, which are inactive in the transmission process, and yet which mediate some primer or releaser function upon reception, appears to be central to the functioning and understanding of the complex chemical language of social insects.

Extrapolation from the limited understanding of one species to the many social insect societies is fraught with uncertainty. What is clear after four decades of investigation is that Bell and Cardé (1984) were correct, and that chemical communication might equal or exceed the complexity of the better-known auditory and visual systems of vertebrates.

Acknowledgments—We appreciate the continued financial support of Natural Science and Engineering Research Council of Canada (K.S., M.W.) and of I.N.R.A., S.P.E. Department and Beekeeper associations in France (Y.L.C.). We acknowledge the hard work and insights of our students, employees, and colleagues in our pursuit to better understand these animals. We thank C. Brillet, H.A. Higo, C.I. Keeling, M. Ono, T. Pankiw, E. Plettner, and anonymous reviewers for their critical readings of this manuscript.

RAPID COMMUNICATION

SEXUAL ISOLATION AND CUTICULAR HYDROCARBON DIFFERENCES BETWEEN *Drosophila santomea* AND *Drosophila yakuba*

FLORE MAS and JEAN-MARC JALLON*

Laboratoire de Neurobiologie de l'Apprentissage, de la Mémoire et de la Communication, UMR-NRS 8620.Bat 446, Université Paris Sud XI, 91405 Orsay Cedex, France

(Received June 23, 2005; revised July 19, 2005; accepted July 20, 2005)

Published Online August 22, 2005

Abstract—*Drosophila santomea* and *Drosophila yakuba* are two sister species inhabiting Saõ Tomé island. Previous studies showed that both species display strong reproductive isolation, although they can produce a few viable hybrids. Our study tried to understand the mechanism of this ethological isolation between two allopatric strains. A strong sexual isolation was confirmed, with a marked asymmetry. Comparisons of latency times to either courtship or copulation suggest that males do not discriminate females, whereas *D. yakuba* females, but not *D. santomea* females, accept their homospecifics more quickly. Cuticular hydrocarbon compositions of both species and sexes were also established with gas chromatography (GC) and GC/mass spectrometry analysis. All have (*Z*)-7-tricosene as their major compound. There are several quantitative differences between species for few minor compounds. The largest difference concerns *n*-heneicosane, which is more abundant in *D. santomea* than in *D. yakuba* flies (up to seven times more between males). A similar quantitative difference was also found in a pair of sympatric strains. Furthermore, *D. yakuba* males artificially perfumed with *n*-heneicosane were discriminated negatively by *D. yakuba* females, suggesting a role for this compound in the sexual isolation between these two species.

Key Words—*Drosophila santomea*, *Drosophila yakuba*, reproductive isolation, courtship, hydrocarbon pheromone.

INTRODUCTION

Mate selection consists of both choosing a conspecific and identifying the opposite sex. For that purpose, the selection is made on the basis of courtship traits that are characteristic of each species. *Drosophila*'s courtship corresponds to a stereotypic sequence of behaviors involving visual, tactile, acoustic, and chemical stimuli (Ewing, 1983). Specifically, cuticular pheromones are involved in mate stimulation and discrimination (Jallon, 1984; Cobb and Jallon, 1990; Ferveur, 2005). These cuticular hydrocarbons (CHCs) are not very volatile compounds that are perceived only at short distances and may stimulate or inhibit potential partners. In the melanogaster subgroup, they may differ markedly between sexes as in *Drosophila melanogaster*, or be similar as in *Drosophila simulans* (Jallon, 1984; Jallon and David, 1987).

Drosophila santomea and *Drosophila yakuba* are two sister species living on the island of Saô Tomé (Lachaise et al., 2000). Coyne et al. (2002) showed a strong reproductive isolation between them, with similar amplitude for sympatric and allopatric strains. Nevertheless, both species can mate with each other, and hybrids are viable. It was concluded that the two species were recently isolated and that reproductive isolation resulted from a prezygotic barrier, possibly an ethological one (Llopart et al., 2002). *D. santomea* flies lack the abdominal dark pigmentation present in *D. yakuba* flies, but Llopart et al. (2002) showed that this visual cue is not important for interspecific mate discrimination.

In the present study, we first compared the possible behavioral temporal parameters in homospecific and heterospecific matings and then analyzed CHCs, which could be potentially involved in sexual selection between the two species.

METHODS AND MATERIALS

D. santomea flies originated from strain Car 1490-1, collected above the hybrid zone, at an altitude of 1,490 m on Saô Tomé. *D. yakuba* flies are issued from strain SJ 14, collected below the hybrid zone at low altitude. Two other strains collected in the hybrid zone were also used for chemical analysis: strain STO5 for *D. santomea* and SA1 for *D. yakuba*.

Both species were reared on the usual cornmeal–malt medium at 25°C under 12:12 light/dark conditions. All flies were sexed, isolated under carbon dioxide anesthesia within 12 hr after imaginal emergence, and maintained in glass vials (25 ml). Flies were 4-d-old when used for experiments. All tests were run in the morning, between 0900 and 1300 hours, under dim electric light in a temperature-controlled room.

Mating tests were set up in a chamber (2.15 cm diam × 4 mm height) with a glass roof, which could be divided into two parts by a removable separation; thus, each sex could be introduced on either side, and flies could habituate before removing the separation, at time 0. In each test, three females and three males were put together and observed during 45 min. In addition to the percentage of first copulations succeeding the first courtship (percentage of mating success), two temporal parameters were recorded: latency time to the first courtship for males that initiate courtship and latency time to the first copulation for females that accept or do not accept the males.

To analyze fly CHCs for each strain of each species and each sex, ten 4-d-old virgin flies were anesthetized, bathed individually in heptane, and their extracts analyzed in a PerkinElmer AutoSystem GC chromatograph or a Fisons MD800 (under electron impact at 70 eV) gas chromatography/mass spectrometry (GC/MS) apparatus, both equipped with a BP1 SGE capillary column (length 25 m, internal diam 0.22 mm, film thickness 0.1 μm) and at the same temperature program (180–270°C, 3°C/min) (Rouault et al., 2004). The relative proportions of the areas of the various peaks were calculated (in percent) and compared. An external standard, *n*-hexacosane, which is naturally absent in fly cuticle, was used in a given amount, and the area under each peak was compared to that of the standard to determine its absolute amount.

To perfume *D. yakuba* males or females, 3-d-old individuals were anesthetized under carbon dioxide and 0.2 μl of an acetonic solution containing 2 mg/ml *n*-heneicosane were applied topically on each fly, corresponding to more than twice the dose present on *D. santomea* flies. Perfumed flies stood 24 hr before experiments started. Control individuals received acetone alone, which evaporates quickly. Experiments with perfumed flies were done under the same conditions as previously described. Mating success was recorded over a 45-min period. After the experiment, all flies were chemically analyzed by GC.

For statistical comparisons, a Mann–Withney *U* test was applied to compare temporal parameters and a chi-square test for mating success.

RESULTS AND DISCUSSION

Table 1 presents the results of mating experiments within or between two strains of either species, *D. santomea* (Car 1490-1) and *D. yakuba* (SJ 14). They show that homospecific matings are preferred to heterospecific ones: 54% homospecific matings for *D. santomea* and 48% for *D. yakuba*. This confirms the existence of a behavioral reproductive barrier between the two sister species. Second, when comparing heterospecific matings, there is an asymmetrical preference for copulations of *D. yakuba* females with *D. santomea* males

TABLE 1. DIFFERENT PARAMETERS RECORDED DURING 45 MINUTES FOR INTRASPECIFIC AND INTERSPECIFIC MATING EXPERIMENTS

Crossing	Number of Tests	Mating success (%)	Time in minutes ± SD: Latency to first Courtship	Time in minutes ± SD: Latency to first Copulation

FM yak	105	48	1.2 ± 0.2	14.5 ± 1.8
Fsan-Myak	114	4	1.8 ± 0.6	9.7 ± 4.2
Fyak-Msan	99	11	2.2 ± 0.4	24.0 ± 3.3

F, Female; M, male; san, *D. santomea*; yak, *D. yakuba*.
Three males and three females are present in the mating chamber.

(Fyak–Msan, 11%) compared to 4% for *D. santomea* female–*D. yakuba* male pairs.

The courtship latency times of each type of male are not significantly different in the presence of either female, neither for *D. santomea* males ($P = 0.69$) nor for *D. yakuba* males ($P = 0.45$). This suggests that males are equally attracted by the two types of females and, therefore, do not discriminate between them.

When latency times to copulations are compared between females, there are differences. *D. yakuba* females accept homospecific males more quickly than *D. santomea* males ($P = 0.012$). The difference with *D. santomea* females is not significant, however, between the two types of males ($P = 0.49$). Thus, the temporal differences of male courtship and female acceptance suggest that females are the choosy sex and discriminate between the males.

Figure 1 presents the CHC composition of each sex within each species. We observed no qualitative differences between the two species; they all presented similar GC profiles, consisting of 15 peaks. GC/MS analysis led to the identification of long-chain hydrocarbons shown in Figure 1. Peaks 1, 2, 12, and 15 were reported neither in males nor females of the *D. yakuba* continental strain (from Cameroon) described by Jallon and David (1987). Their mass spectra show molecular peaks with *m*/*z* respective values of 296, 310, 380, and 408; moreover, compounds 7, 11, and 14 display mass spectra with M-43 peaks, which suggests a methyl branching on carbon 2. The repeated comigrations of tricosene peaks 3 and 4 and pentacosene peaks 8 and 9 with synthetic (*Z*)-9-tricosene, (*Z*)-7-tricosene, (*Z*)-9-pentacosene, and (*Z*)-7 pentacosene, respectively, suggest (*Z*)-9- and (*Z*)-7- for double bond positions A and B, respectively. Thus, (*Z*)-7-tricosene is the most abundant CHC, whichever sex and species, as in all "monomorphic" species of the melanogaster subgroup (Jallon and David, 1987). There is no significant difference in the absolute

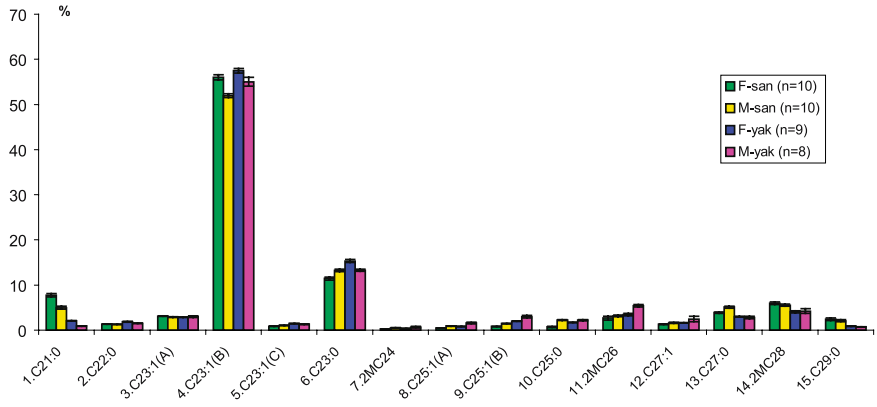

FIG. 1. Cuticular hydrocarbon profiles of 4-d-old virgin females and males of each species, *D. santomea* (strain Car 1490-1) and *D. yakuba* (strain SJ 14). Each peak has been associated with its area percentage over the sum of all CHC peak areas and is presented, with its GC/MS identification, in the order of increasing retention times.

amounts of this compound in the cuticle of either type of female (on average 1265 ± 68 ng per *D. santomea* female and 1281 ± 61 ng per *D. yakuba* female), and these females are not discriminated by either type of males. Thus, it is suggested that in *D. santomea*, (*Z*)-7-tricosene might also play an important role in female sex appeal (Cobb and Jallon, 1990).

There is also no significant difference in the total amounts of CHC in either type of female (2.2 μg/fly) but *D. santomea* males have more CHC (1.6 μg/fly) than *D. yakuba* ones (1.3 μg/fly). If one considers both sexes, there are significant quantitative differences between species for five compounds: *n*-heneicosane (peak 1), (*Z*)-9- and (*Z*)-7-pentacosene (peaks 8 and 9), *n*-heptacosane (peak 13), and *n*-nonacosane (peak 15). The largest difference, however, concerns *n*-heneicosane, which is more abundant in *D. santomea* flies, 3.9 times among females and 6.9 times among males. Analysis of the CHCs of the two other strains, *D. santomea* STO5 and *D. yakuba* SA1 collected in the sympatric zone, shows similar profiles. *n*-Heneicosane is also more abundant in both sexes of this second *D. santomea* strain, although the quantitative difference is not very different from that of the allopatric strains (4.7 times more for females, 5.7 for males).

This raises the possibility that this compound might be used to discriminate between heterospecific flies. To test this hypothesis, *D. yakuba* flies of both sexes were perfumed—or not—with a dose of *n*-heneicosane (400 ng) and presented to (nonperfumed) homospecific flies of the other sex. No significant differences

in mating success were observed between perfumed females and controls crossed with *D. yakuba* males (39 and 34%, respectively). On the other hand, whether perfumed or not, when *D. yakuba* males were crossed with *D. yakuba* females, fewer perfumed males mated with homospecific females: 30.0% compared to 55.5% with nonperfumed ($\chi^2 = 6.251$, $df = 1$, $P = 0.02$). This supports the hypothesis that *D. yakuba* females might discriminate negatively modified *D. yakuba* males that smell like *D. santomea* males.

In summary, our experiments support the classical role of females as the choosy sex in mate selection and suggest that this selection could result from a specific CHC. In *D. melanogaster*, Scott (1994) also showed an intraspecific female choice between males that bear in their cuticle more or less of the major CHC that has evolved among populations (Rouault et al., 2004). Here, females discriminate between heterospecific males using a less abundant compound.

Acknowledgments—We thank Dr Daniel Lachaise for providing all strains collected on Saõ Tomé island. Also, thanks to Helena Alvès for her technical help in CHC analyses and to Dr David Carlson for gifts of synthetic tricosenes and pentacosenes.

RAPID COMMUNICATION

JASMONATE IN LEPIDOPTERAN EGGS AND NEONATES

JOHN F. TOOKER* and CONSUELO M. DE MORAES

Department of Entomology, The Pennsylvania State University, University Park, PA 16802, USA

(Received August 4, 2005; Revised September 15, 2005; accepted September 16, 2005)

Published Online September 30, 2005

Abstract—Jasmonic acid (JA) is a key molecule initiating plant defensive responses to attack by pathogens and herbivores. This phytohormone is produced at sites of insect damage and is ingested by feeding insects, but its subsequent occurrence in insect tissues remains to be studied. We report the presence of JA in eggs and neonates of all nine lepidopteran species that we screened, representing four superfamilies and five families of Lepidoptera. Concentrations of JA in some lepidopteran species far exceeded those found in most plant species. Levels of JA varied significantly among species and between eggs and neonates of the same species. In some cases, eggs contained significantly more JA than neonates, but for at least one species (*Lymantria dispar*) neonates had more JA than their eggs despite lacking food upon emergence. The presence of JA in eggs and neonates across a wide taxonomic range may indicate that JA has an undescribed function in insects.

Key Words—Jasmonic acid, octodecanoid pathway, phytohormone.

INTRODUCTION

The phytohormone jasmonic acid (JA) is an important molecule in plants that has been implicated as a key signal initiating plant defensive responses to attack by herbivores and pathogens (Walling, 2000). Jasmonate is derived from linolenic acid via the octodecanoid pathway and activates defensive genes that initiate "induced systemic resistance'' against insect herbivores and the release of volatile compounds that attract natural enemies to herbivore-infested plants (Walling, 2000).

* To whom correspondence should be addressed. E-mail: tooker@psu.edu

While conducting another research project, we detected JA in eggs and neonates of the noctuid *Heliothis virescens* (Fabricius), prompting us to ask whether JA was present in eggs and neonates of other lepidopteran species. We are unaware of any previous studies that have examined levels of JA in insects; however, JA is produced by plants at sites of herbivory and is ingested by feeding lepidopterans (Walling, 2000; Li et al., 2002). In fact, JA activates detoxification genes in *Helicoverpa zea* (Boddie), apparently providing "early-warning'' signals that indicate imminent production by plants of toxic defensive compounds (Li et al., 2002). Here, we present evidence that this plant hormone is present in eggs and neonates of all lepidopteran species we screened, possibly indicating that JA plays an unknown functional role in insects.

METHODS AND MATERIALS

Insect Samples. We obtained eggs of nine moth species representing four superfamilies and five families of Lepidoptera (Table 1). Eight species were reared on artificial diets, and one was field-collected. After oviposition, we weighed eggs and either collected them into FastPrep® tubes (Qbiogene, Carlsbad, CA, USA) containing 1 g of Zirmil beads (1.1 mm; Saint-Gobain ZirPro, Mountainside, NJ, USA), freezing them at −80°C until processing (see below), or kept them in an incubator (25°C; 14:10 L/D; 60% RH) until hatching. Upon emergence, we collected neonates into FastPrep tubes with 1 g of Zirmil beads, weighing and freezing them at −80°C until processing. We observed no evidence of larval cannibalism. Because of the low mass of eggs and neonates (<0.1 mg), we combined multiple eggs or larvae into single samples (10–40 eggs per sample depending on mass; 5–10 neonates), processing five samples of both eggs and neonates for each lepidopteran species (total number of eggs analyzed per species: 50–200; total neonates per species: 25–50). We also collected 10 samples (~0.5 mg each) of the setae, which form the matrix of *Lymantria dispar* egg masses; these setae originate from the abdomen of the ovipositing mother. Finally, we obtained from the rearing facilities (Table 1) samples of the artificial diets used to rear these species, collecting and freezing five samples (~100 mg each) of each diet for processing.

Extraction and Quantification of JA and SA. To extract and detect JA, we modified a previously described protocol (Schmelz et al., 2003, 2004) that derivatized carboxylic acids to methyl esters, which were isolated by using vapor phase extraction and analyzed by gas chromatography-mass spectrometry (GC-MS) with isobutane chemical ionization with selected-ion monitoring. Our method deviated from that of the previous authors in that we quantified amounts of methyl jasmonate (meJA) by using standard curves made with the pure compound (Sigma-Aldrich, St. Louis, MO, USA), relying on internal standards

to confirm derivatization and recovery. We also processed samples without the derivatization agent to verify that the meJA we recovered was not itself present in eggs and neonates, but was derived from JA. To confirm the identity of meJA in our samples, we analyzed extracts by GC-MS with electron ionization, comparing retention times and spectra with that of the pure compound.

To normalize the data and stabilize variance, we square-root transformed our data and compared mean amounts of JA among samples by ANOVA

(Statistix, 2003), testing differences between eggs and neonates of each species as planned comparisons with the LSD means separation test (Sokal and Rohlf, 1995).

RESULTS AND DISCUSSION

We recovered JA from all the eggs, neonates, and diets we analyzed (Figure 1). Mass spectra of meJA recovered from lepidopterans and their diets were nearly identical to that of the pure standard, confirming the identity of JA in our samples (Figure 1A). Moreover, we did not recover meJA in absence of the derivatization agent, verifying that the meJA we measured was derivatized from JA and was not itself present in samples. Remarkably, concentrations of JA in eggs and neonates were in some cases hundreds of times greater than the concentrations in their diets (Table 1) and those typically found per gram of plant tissue (e.g., Schmelz et al., 2003). We suspect that the probable source of JA in eggs and neonates was the larval diet of ovipositing mothers and that the high concentrations resulted from bioaccumulation. If so, the presence of JA could conceivably be a nonadaptive by-product of larval feeding. Still, the presence of JA at such high concentrations in eggs and neonates raises the possibility that it may play some yet to be described functional role in these stages.

Amounts of JA in eggs and neonates varied within and among species (Figure 1B; ANOVA: $F_{18,97} = 26.2$, $P < 0.001$). Levels of JA were highest in eggs of the four noctuid species, and amounts of JA in eggs of these species were greater than amounts found in neonates (LSD, $P < 0.05$). Jasmonate levels in neonates were similar across noctuid species (LSD, $P > 0.05$), suggesting these species process JA similarly.

Ostrinia nubilalis, *D. saccharalis*, and *M. sexta* had low levels of JA that were similar in eggs and neonates (LSD, $P > 0.05$), but *L. dispar* neonates had greater amounts of JA than their eggs (LSD, $P < 0.05$). *Gnorimoschema gallaesolidaginis* neonates also had greater amounts of JA than their eggs, but only at the 0.1 significance level. Neonates did not have available food upon emergence, but consumed a small portion of their egg chorion in the course of emergence. Chorions appear to contain small amounts of JA (unpublished data),

FIG. 1. Jasmonic acid (JA) in lepidopteran species. (A) EI mass spectra of meJA: the pure standard (top); derivatized from JA and recovered from *Spodoptera frugiperda* eggs (bottom). (B) JA recovered from eggs and neonates of nine lepidopteran species. Data shown are untransformed. Species marked with asterisks had significant differences in JA concentrations between eggs and neonates (*$P < 0.1$; **$P < 0.05$; ***$P < 0.001$). See text for details on statistics.

but not enough to account for the elevated levels of JA in neonates of these two species. After emerging, *L. dispar* larvae may also have consumed some of the setae that form the matrix of their egg mass. Setae also contain JA (Figure 1B), and further research will be needed to determine if setae are a source of JA for neonates. If chorions and setae are not significant sources of additional JA in *L. dispar* and *G. gallaesolidaginis* neonates, the possibility remains that larvae of these species synthesize JA. Other insect species are suspected to produce phytohormones to manipulate their host plants (e.g., Mapes and Davies, 2001), and further research should explore this possibility.

All but one of the species we screened originated from laboratory colonies maintained on artificial diets containing JA (Table 1); therefore, the presence of JA in eggs and neonates, or its presence at the high concentrations we measured, could conceivably be artifacts of these man-made diets. The four species of noctuid exhibiting very high amounts of JA in their eggs were all reared on the same diet, which had relatively high concentrations of JA (Table 1). However, JA recovered from field-collected *G. gallaesolidaginis* indicates that artificial diets are not solely responsible for JA in eggs and neonates. Moreover, concentrations of JA in the artificial diets used (Table 1) appear to be comparable to those found in live plants and those used by other researchers (e.g., Li et al., 2002).

Oviposition by some insect species can elicit plant volatile responses that attract natural enemies (Meiners and Hilker, 2000). Similar volatile emissions can be induced by applying exogenous JA, suggesting that JA plays a role in the initiation of plant defensive responses (Meiners and Hilker, 2000). Despite the recent implication of a protein in oviduct secretions as an elicitor of volatiles in response to oviposition (Hilker et al., 2005), our discovery of JA in lepidopteran eggs provides a plausible mechanism that could contribute to volatile production following oviposition.

The consistent presence of JA in lepidopteran eggs and neonates raises the possibility that it may serve some adaptive function for the insects themselves. Significant similarities exist between hormone signals used in plant and animal systems (Schultz and Appel, 2004), so JA might have a signaling function in lepidopterans. Jasmonates convey messages between plants and insects, inducing detoxification genes in feeding caterpillars (Li et al., 2002). Moreover, JA has substantial structural similarities to eicosanoids, and to prostaglandins in particular, which serve a range of functions in invertebrates including mediating oviposition, salivary secretions, and immune responses (Stanley-Samuelson and Pedibhotla, 1996). Further research is underway to determine what role, if any, JA plays in lepidopteran eggs and neonates.

(Received May 25, 2005; revised August 11, 2005; accepted September 3, 2005)

Abstract—A radial diffusion assay was employed to quantify condensed tannins (CT) in feed and feces of mule deer (*Odocoileus hemionus*) and white-tailed deer (*O. virginianus*). This biological assay measures the precipitation of bovine serum albumin (BSA), with the area of the precipitation ring being proportional to the amount of extracted CT applied to the well. CT extracted from the bark of white spruce (*Picea glauca*) was used as the standard. CT were extracted with 70% (v/v) aqueous acetone and precipitated with 50% (v/v) aqueous methanol or 70% (v/v) aqueous acetone. Functional range of CT weights for suitable ring measurement was 0.5–4.0 mg, and equilibrium was achieved within an incubation period of 24 hr. Methanol (50%) was a more effective precipitation solvent than acetone (70%) having 13 ± 4% greater specific activity ($P < 0.05$) and superior capabilities for predicting CT content. Precipitation rings were evaluated on images magnified on a photocopier. Ring diameters measured on a 200% enlarged photocopy provided the most precise estimate of ring area ($R^2 = 0.98$). This convenient method reduced analysis times and enhanced accuracy and precision of tannin quantification. Analytical consequences and future research requirements are considered.

Key Words— Condensed tannins, radial diffusion assay, extraction, quantification, gel plate photocopy, Cervidae, mule deer, white-tailed deer, feed, feces.

INTRODUCTION

Tannins are polyphenolic compounds found in most plants and are generally thought to function as plant chemical defenses against pathogens and herbivory. Tannins are conventionally classified into two chemically distinct groups: hydrolyzable (gallotannins; HT), which occur mainly in fruit pods and plant galls; and condensed (proanthocyanidins; CT), which are the most common type found in forage legumes, trees, and shrubs (McLeod, 1974). CT can have a profound influence on herbivore nutrition, and hence, this paper will deal primarily with this type, as there is a limited presence of HT in natural feed in temperate regions (Martínez et al., 2004).

Mammal studies have shown that CT-containing forages can cause decreased digestibility and voluntary intake (Panda et al., 1983; Van Hoven, 1984), may reduce liveweight gain (Panda et al., 1983; Barry, 1985; Mehansho et al., 1987), wool growth (Barry, 1985), and mineral absorption (Disler et al., 1975; Roy and Mukherji, 1979), and can damage the intestine (Sandusky et al., 1977) or liver (Jones and Hunt, 1983). Therefore, it was thought that herbivores, particularly browsers, select forage to minimize CT intake (see Waterman and Mole, 1994).

However, recent evidence demonstrates the beneficial effects of CT when ingested in moderate amounts (<5% dry matter) (e.g., Verheyden-Tixier and Duncan, 2000; Min et al., 2003). For example, CT can act as natural detergents to reduce bloat (Waghorn and Jones, 1989; Tanner et al., 1995; Frutos et al., 2002) and decrease dependence on synthetic anthelminthic compounds for controlling internal parasites (Schrägle and Müller, 1990; Robertson et al., 1995; Niezen et al., 1995, 1998, 2002; Aerts et al., 1999; Hoskin et al., 2000; Molan et al., 2000; Kabasa et al., 2000). Furthermore, the biological value of forage may be enhanced with CT through reduced degradation of dietary protein to ammonia by rumen microbes, increasing protein outflow from the rumen, leading to increased absorption of amino acids from the small intestine (Waghorn et al., 1987). For example, improved production efficiency has been demonstrated with animals on diets having moderate concentrations of CT (2–4%), through increased wool growth, liveweight gain, milk yield, ovulation rate, and fecundity, while maintaining voluntary intake (Terrill et al., 1992; Wang et al., 1996a,b; Barry and McNabb, 1999; Min et al., 2003; Kabasa et al., 2004).

A lack of appropriate analytical techniques for extracting and quantifying CT has hindered investigations into tannin–protein associations in ruminants. Current methods, although precise, often involve elaborate sample preparation and tedious analytical procedures [e.g., thiolysis reversed-phase high performance liquid chromatography (HPLC; Guyot et al., 1998), spectrophotometric assay of dye-labeled protein (Asquith and Butler, 1985), precipitation of ribulose-1,5-bisphosphate carboxylase/oxygenase by tannic acid (Martin and

Martin, 1983), precipitation of iodine-125 labeled bovine serum albumin (BSA; Hagerman and Butler, 1980)]. These techniques were primarily used to measure CT in plant material and attempts to extract CT from feces have had little success. Our objective was to modify Hagerman's (1987) radial diffusion assay method for quantifying tannins in plant extracts, and to develop an improved protocol for extracting and quantifying CT in cervid feed and feces. This would facilitate a quick and easy analysis of large numbers of samples.

METHODS AND MATERIALS

Reagents. The assay gel contained BSA (fatty acid-free), agarose (Type I), 50 mM acetic acid, and 60 μM ascorbic acid (Sigma, St. Louis, MO, USA). Solvents used were 70% (v/v) aqueous acetone and 50% (v/v) aqueous methanol. All reagents were HPLC-grade.

Preparation of Standard. The assay was standardized with purified CT prepared from the ground bark of white spruce (*Picea glauca*) using an aqueous base extraction. The bark contained approximately 40% CT and the liquid extract was freeze-dried producing a black tannin powder. CT standards underwent nitrogen analysis (Leco FP-428 Nitrogen Determinator) to determine extent of protein contamination, which could interfere with the precipitation assay. Although not pure, impurities were removed and accounted for during the CT extraction procedure.

Feed and Study Animals. Feed used was standard deer ration (Cargill Nutrena Feeds, Camrose, AB, Canada) containing 31% barley, 25% alfalfa, 16% beet pulp, 14% wheat mince, 8.5% soy bean meal, 4% molasses, salt, and a vitamin/mineral mix. Bark CT extract was added to the ration to produce feeds containing 5% or 10% (w/w) tannin. Captive white-tailed deer (*Odocoileus virginianus*) and mule deer (*O. hemionus*) were divided into two groups: tannin and control. Following long-term maintenance on the standard deer ration, the tannin group was offered 5% CT feed for 5 wk, then 10% CT feed for a further 5 wk. The control group was maintained on CT-free ration prior to, and for the duration of the experiment. Fecal samples were collected from each group immediately before the introduction of the CT diet, at the end of 5 wk, and at the end of 10 wk.

CT Extraction. The same method was used for extracting CT from feed and feces, and preparing bark extract CT standard. Samples were freeze-dried for 48 hr at −60°C and ground through a 20-mesh screen in a Wiley mill. Ground samples (~500–600 mg feed/feces, ~200 mg CT standard) were dissolved in 5 ml extraction solvent (ES) (70% (v/v) acetone), vortexed several times over 20 min, centrifuged (5 min at 3000 rpm), and the supernatant was

transferred to a 15-ml plastic centrifuge tube. In total, three extractions were performed. The supernatant (~15 ml) was evaporated dry using a Multivap Nitrogen Evaporator (Organomation Associates Inc., Berlin, MA, USA). Pellets were resuspended in 3 ml precipitation solvent (PS) [i.e., either 70% (v/v) aqueous acetone or 50% (v/v) aqueous methanol], vortexed several times over 30 min, and centrifuged (5 min at 3000 rpm).

Following the third extraction, after removing the supernatant from the tube containing CT standard, the residue was air-dried and weighed. Also, following the addition of CT standard to gel plate wells, solution was centrifuged (5 min at 3000 rpm), the supernatant removed, and residue air-dried and weighed. Residue weights were cumulated and subtracted from CT standard weighed out to correct for impurities.

Gel Preparation. Gel plates were prepared according to Hagerman (1987). A solution of 50 mM acetic acid and 60 μM ascorbic acid was mixed, forming a solution of pH 2.8. This was adjusted to pH 5.0 by adding 0.1 M NaOH, as this has been reported as the optimum pH for maximum BSA precipitation (Hagerman and Klucher, 1986; López et al., 2004). The solution was heated to boiling while stirring, as 1% (w/v) agarose was added. The solution was cooled to 45°C and 0.1% (w/v) BSA added, while stirring. Aliquots of 9.5 ml were added to 8.5-cm-diam Petri dishes on a level surface (to obtain a gel of uniform thickness) and cooled. Gel plates were stored at 4°C to prevent bacterial growth.

Radial Diffusion Assay. Wells measuring 5.0 mm in diam were punched in the gel plates, spaced 1.5 cm apart. Using a micropipette, prepared solutions were added to wells (in duplicate) in 10-μl aliquots. As the solution was absorbed by the gel, several successive 10-μl aliquots were added, depending on the dilution of the solution. Wells were rinsed with successive 10-μl aliquots of PS [i.e., either 70% (v/v) aqueous acetone or 50% (v/v) aqueous methanol] to ensure all tannin was available to complex with BSA. Petri dishes were covered and sealed with Parafilm, and incubated at 30°C for 24–120 hr.

Ring Measurement. Following incubation, gel plates were photocopied at actual size, 200% enlargement, and 400% enlargement, and compared. Perpendicular ring diameters were measured to account for nonuniform ring development (rare) using microcalipers (actual size) and a standard mm ruler (enlargements). CT was quantified by squaring the mean of the perpendicular diameters (hereafter referred to as "area") and substituting this value into a calibration equation. This is the best-fit equation when ring area (mm^2) is regressed against known quantities of CT (mg) from feed and CT standard.

Calculations. All statistical analyses were performed using SPSS Base 12.0 (SPSS Inc., 2003). Simple linear regression was utilized to examine the predictive capabilities for quantifying CT and comparing ring measurement techniques. Student's paired *t*-test was used to compare ring areas when

determining specific activity of PS. Probabilities of $\alpha < 0.05$ were accepted as significant. Means are reported with standard errors.

RESULTS

The incubation period required for precipitation rings to achieve equilibrium (i.e., maximum size) was 24 hr for the range of CT weights used in this study. This time varies according to CT quantity, with longer incubation time required for higher CT concentration in wells.

Precipitation ring area (D^2, in mm^2) demonstrated a linear relationship with CT applied to wells (mg) (Figure 1). The calibration equations from experiments run separately were similar (Exp. 1: $y = 97.3 + 43.0x$, $R^2 = 0.98$, $P < 0.001$; Exp. 2: $y = 98.4 + 44.0x$, $R^2 = 0.88$, $P < 0.001$). All assays of extracts of feed not containing CT, fecal samples collected prior to experiment commencement, and fecal samples from deer in the control group, did not form precipitation rings (Table 1). Based on a presumed feed digestibility of approximately 70%, fecal CT concentrations from animals on CT diet were lower than expected (Table 1). The detection threshold for accurate measure-

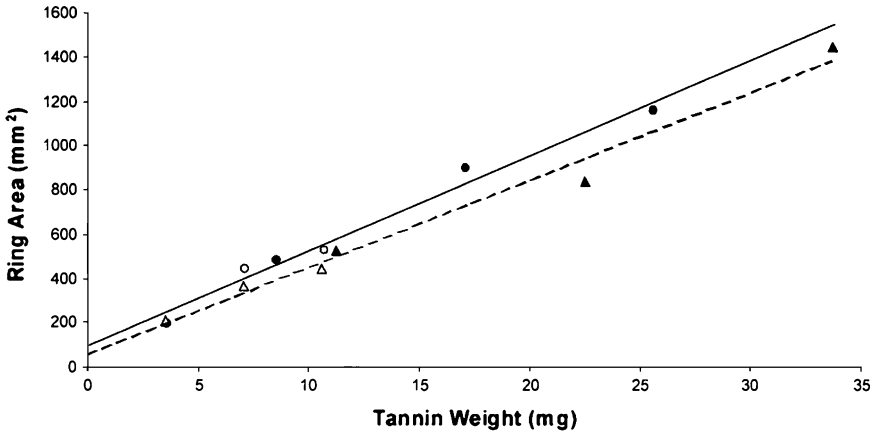

FIG. 1. Comparison of precipitation solvents for quantifying tannins. Ring area (mm^2) (measured from 200% enlargement) is regressed against known tannin weight (mg). Solid line represents 50% across aqueous methanol (●/○) ($y = 97.3 + 43.0x$, $R^2 = 0.98$, $P < 0.001$). Dashed line represents 70% acetone (▲/△) ($y = 56.0 + 39.4x$, $R^2 = 0.98$, $P < 0.001$). Closed symbols represent tannin standard bark extract from *Picea glauca*, whereas open symbols represent tannin extracted from cervid feed. Each point is the mean of duplicate ring areas.

TABLE 1. ESTIMATED TANNIN CONCENTRATIONS IN CERVID FECES

Cervid diet	N^a	Tannin concentration (%)[b]
0% Tannin	23	0.0 ± 0.0
5% Tannin	7	6.6 ± 2.5
10% Tannin	7	11.0 ± 1.6

[a] Indicates number of samples from which mean ± SE was calculated.
[b] The calibration equation area = 98.4 + 44.0 (CT weight) was used to estimate tannin weight. Tannin concentration is expressed as the percentage estimated tannin of tannin applied to well.

ment of precipitation rings is approximately 0.5 mg. It is recommended that CT applied to wells does not exceed 4.0 mg, as ring overlap precludes accurate measurement.

The Microanalytical Service Laboratory in the Department of Chemistry at the University of Alberta performed nitrogen analysis on the purified CT. Crude protein content (N × 6.25) was 1.3%, indicating negligible protein contamination. Removal of nontannin residue from bark extract after CT extraction revealed a purity of 75 ± 5%. This impurity was accounted for when determining standard calibration curves.

Greater specific activity was demonstrated with 50% aqueous methanol as a precipitation solvent (PS), than 70% aqueous acetone ($P < 0.05$), and hence, methanol was a more effective PS (Table 2). When equal quantities of CT were dispensed in wells, methanol formed rings with 13 ± 4% greater area than

acetone. Methanol also exhibited superior predictive capabilities to acetone for estimating CT concentration (Table 2). All ring area measurements included the area of the well. At 200% enlargement, the diameter of the well is 10 mm; therefore, the well area (D^2) is calculated as 100 mm^2. This suggests that the best-fit equation for perfect predictability when ring area (mm^2) is regressed against CT weight (mg), would have a y-intercept of 100. The best-fit regression equation, when 50% aqueous methanol was incorporated as the PS, had a y-intercept of 97.3 [area = 97.3 + 43.0(CT weight), $R^2 = 0.98$, $P < 0.001$] (Table 2), which is similar to that expected. Furthermore, precipitation rings with methanol PS had a distinct, clearly visible outer ring, facilitating easy, rapid measurement, whereas rings with acetone PS faded towards the outer edges.

Measuring ring diameter with a standard mm ruler on a photocopy enlarged 200% provided the most precise estimate of ring area ($R^2 = 0.98$) (Table 3). Accuracy of microcaliper measurements did not overcome the difficulty in visualizing the outer boundary of precipitation rings directly measured on the plate nor on an actual size photocopy ($R^2 = 0.89$). Rings on the photocopy enlarged 400% lacked the clarity necessary to accurately distinguish ring perimeter ($R^2 = 0.88$).

DISCUSSION

Radial diffusion assay reflects the ability of tannins to precipitate proteins. It is derived from the principle of radial immunodiffusion (e.g., Vaerman,

1981), in that tannin–protein interactions are similar to antigen–antibody reactions. For tannin quantification, more ecologically significant gel proteins could be substituted for BSA; however, Hagerman (1987) selected BSA for its homogeneity, solubility, and relatively low cost. The simplicity of the technique and the lack of complex reagents enhances reproducibility.

An advantage of the radial diffusion assay method is its specificity for tannins over other phenolic compounds. Other tannin quantification techniques depending on functional groups have been unreliable, as these functional groups are often not unique to tannins [e.g., Folin–Denis assay (Burns, 1963), Prussian blue (Price and Butler, 1977)]. Our samples that did not contain CT did not form precipitation rings. This suggests that the method is tannin-specific and experiences negligible interference from nontannin phenolics.

The 24-hr incubation period required for precipitation rings to reach equilibrium using this assay method is shorter than that recorded by Hagerman (1987) using a similar technique. Hagerman found that a 0.5-mg aliquot of tannic acid took 48 hr to reach equilibrium, whereas 1.0 mg required 96 hr. Within 24 hr, precipitation rings for the entire range of CT weights analyzed in this study (0.5–4.0 mg) achieved maximum diameter. This is convenient in that many analytical runs may be completed in a short time. The 70% aqueous acetone PS exhibited a faster diffusion rate through the BSA gel than 50% aqueous methanol; however, this is likely a result of the greater precipitation activity of methanol.

The tannin detection threshold of our technique (0.5 mg) was considerably higher than the 0.025 mg described by Hagerman (1987). This should not present a problem, as difficulties in measuring rings precipitated by a dilute sample can be obviated by dispensing more aliquots to the well until a suitable measurement may be obtained. Conversely, problems may also be encountered with solutions of high concentrations, as precipitation rings become so large that they interfere with the protein being precipitated from the adjacent well (ring overlap). This may be overcome by reducing the volume of solution dispensed in the well or increasing space between wells. Adjustments in volumes of solution dispensed in wells will provide optimal ring sizes for accurate measurement.

Acetone is considered to be one of the most efficient solvents for extracting tannins (Fletcher et al., 1977). For example, Yu and Dahlgren (2000) reported that 50% aqueous acetone extracted 20–59% more CT than 50% aqueous methanol. However, some precipitation techniques are highly sensitive to acetone interference (e.g., Hagerman and Butler, 1978; Asquith and Butler, 1985), and the presence of even small quantities of acetone may inhibit protein precipitation, requiring further procedures to remove the acetone (e.g., rotary evaporation). Hagerman (1987) reported that this radial diffusion assay method is unaffected by the presence of acetone. In our study, the combination of 70% aqueous acetone for extracting and 50% aqueous methanol for precipitating CT

provided maximum CT extraction and BSA precipitation. Furthermore, the clearly defined outer ring produced when precipitating CT using methanol (i.e., acetone-precipitated rings had faded outer edges) facilitates rapid, accurate measurement.

CT analysis is complicated by the complexity and variability of structures found with this group of compounds (Schofield et al., 2001). Structural variation among CT can introduce error when assays are used for quantification, and as such, selection of the standard is paramount to the success of tannin assays. Nelson et al. (1997) noted that errors can arise from an incorrect choice of external standard, particularly when it differs from the tannin being analyzed. In this study, we had the advantage of the CT standard and analyzed CT being the same, which likely contributed to the superior predictive capabilities demonstrated.

Although the bark extract employed as the standard in this study contained contaminants, removal of impurities during CT extraction was simple. In order to reliably predict CT quantities extracted from fecal samples, for every batch it is necessary to have duplicate standard reference wells on each plate, as well as producing precipitation rings from a suitably wide range of CT standard weights. From this, the simple regression calibration equation is developed by examining precipitation ring area (mm^2) in relation to known quantities of CT standard in each well. Several methods reviewed by Maxson and Rooney (1972) had significant variation in standard curves between days and/or laboratories. This highlights the importance of preparing individual standards for each analytical run. This ensures that samples and standards are prepared and run under identical conditions. Although variation in calibration curves among our batches was negligible, each batch should be restandardized with purified CT.

The unique, yet simple technique of ring measurement developed in this study provides an accurate and rapid method for determining ring area. Assay methods used in the past have depended on colorimetric measurement of absorbance using spectrophotometric laboratory equipment [e.g., dye-labeled protein assay (Asquith and Butler, 1985), vanillin-HCl assay (Price et al., 1978), Prussian blue (Price and Butler, 1977), butanol-HCl hydrolysis (Porter et al., 1986)]. This “gel plate photocopy” technique is convenient in that laboratory instruments are unnecessary. In fact, gel plates can be photocopied immediately after incubation and measurement carried out anywhere and at anytime thereafter. Also, photocopies can be reaccessed later, if further analysis is desired. Perhaps measurer bias may be reduced by scanning gel plates with a gel scanner or photocopies with a conventional image scanner, followed by computer analysis of the digitized images.

Fecal tannin concentrations reflected that of diet and perhaps could be used to monitor diets of wild deer using easily collected samples. However, lower than expected fecal CT concentrations suggest that differences in extraction

efficiency between feed and feces preclude its use as an internal marker for estimating feed digestibility. Feces may contain CT that has formed associations with proteins while passing through the gastrointestinal system. This radial diffusion assay technique does not have the ability to detect these bound tannins, as BSA cannot form associations with them to produce a precipitate. Therefore, further research into radial diffusion assays should attempt to account for the presence of bound tannins in feces. Phenol is a strong solvent that dissociates tannin–protein complexes (Hagerman and Butler, 1980). Perhaps simultaneous comparison of precipitation rings from CT solutions that have been exposed to phenol fractionation, to those that have not, will reveal ratios of bound to unbound proteins.

Effects of antioxidants on specific activity of protein precipitation should also be investigated further. Peng and Jay-Allemand (1991) found a 20% increase in protein precipitation when the antioxidant diethyldithiocarbamic acid was added to the agarose gel. They also demonstrated protein precipitation increases of 30% and 75% when the antioxidants ascorbic acid and sodium metabisulfite ($Na_2S_2O_5$), respectively, were added to the 50% aqueous methanol extraction solvent.

Hagerman (1987) found the radial diffusion assay method for quantifying tannins in plant extracts to be simple, sensitive, and specific, facilitating analysis of large numbers of samples. Complex reagents and elaborate instruments were not necessary and there was no apparent interference from nonphenolic compounds. Our experiments yielded comparable results, whereas modifications to the technique provided a more convenient method with augmented precipitation specific activity leading to shorter analysis times and enhanced accuracy and precision of CT quantification. Methods employed in this study had high reproducibility and exhibited excellent linear relationships between protein precipitation area and CT concentrations in wells. One must be aware of the limitations of this procedure for extracting and quantifying fecal tannins, because of its inability to reliably account for bound tannins. Modifications of this highly reliable technique will prove useful in future investigations into the tannin content of plants and nutritional effects on animals consuming these plants.

Acknowledgments—Financial support for this research was provided by Alberta Agriculture, Alberta White-tailed and Mule Deer Association, and Buchanan Enterprises Ltd. We greatly appreciate the efforts of Dr. Noble Donkor in producing the tannin standard powder from the liquid extract (a messy job!). We thank the students in the Food Chemistry Laboratory in the Department of Agriculture, Food, and Nutritional Science, for their useful and friendly advice, as well as kindly making available all necessary laboratory equipment and supplies. Use of the Multivap Nitrogen Evaporator was kindly provided by Dr. Douglas Korver. We are grateful to an anonymous reviewer who provided valuable comments on an earlier draft of this manuscript.

Abstract—The blood concentration of 1,8-cineole and its metabolites was measured in six male brushtail possums while they voluntarily fed on diets laced with varying concentrations of cineole for 3 d. On the third day, blood samples were collected during and after each bout of feeding for 3 hr. Blood cineole was measured by using headspace solid-phase microextraction (SPME), while cineole metabolites were measured by liquid–liquid extraction followed by gas chromatography-mass spectroscopy. Feeding patterns were measured by continual recording of residual food weight and time. Cineole absorption was rapid, resulting in a peak blood concentration at the end of each feeding bout. The blood concentration of cineole did not exceed a critical value (51.8 ± 14.1 μmol/l) regardless of the concentration in the diet. Food and, therefore, cineole intake was regulated. The amount of food ingested in the first feeding bout decreased from 236 ± 52 g on the control diet to 36 ± 20 g on the 4% cineole diet. The amount of cineole ingested in the first bout (1.18 ± 1.10 g) was the same regardless of the dietary concentration and was controlled by the size of the meal. Total food eaten during the 7-hr feeding session decreased by 64% from 368 ± 94 g (control diet) to 131 ± 52 g (4% diet). Total cineole intake increased from 2.47 ± 0.60 g (1% diet) to 5.05 ± 2.41 g (4% diet). Cineole metabolites accumulated throughout the sampling period and were generally still rising at the end of blood sampling period. Blood levels of metabolites were at least 10-fold higher than cineole levels.

* To whom correspondence should be addressed. E-mail: Rebecca.Boyle@utas.edu.au

The immediate control of feeding seems to be regulated by blood levels of cineole, whereas metabolites are likely to be more important in regulating the chronic ingestion of cineole.

Key Words—Absorption, antifeedant, blood concentrations, Brushtail possum, 1,8-cineole, cineole metabolites, plant secondary metabolites, terpenes.

INTRODUCTION

Diet selection is a complex process for herbivores that must strike a balance between meeting nutritional requirements and avoiding harm from plant defenses. Herbivores need to select a diet of foliage with sufficient nutritional content for optimal health and survival. Meanwhile, plants are armed with physical or chemical defense systems that deter browsing (Southwell, 1973; Cork, 1984; Raven et al., 1986; Palo and Robbins, 1991). Each herbivore has its own specific strategies for coping with plant defenses. Strategies are reflected and often identified as measurable alterations in feeding behaviors, particularly after the ingestion of toxic chemical plant defenses (Wiggins et al., 2003; Boyle and McLean, 2004; Villalba and Provenza, 2005).

In this study, we examined the voluntary ingestion of 1,8-cineole (1,3,3-trimethyl-2-oxabicyclo[2,2,2]octane), a monoterpene synthesized by many *Eucalyptus* species. 1,8-Cineole is a known antifeedant (Lawler et al., 1999; Boyle and McLean, 2004). We used the brushtail possum (*Trichosurus vulpecula*), a marsupial commonly found across the majority of vegetated Australia, as our model herbivore. The brushtail possum is considered a generalist herbivore and it includes *Eucalyptus* foliage in its diet.

There have been many studies observing and measuring changes in feeding behavior with the introduction, manipulation, or withdrawing of dietary toxins in herbivore diets (Guglielmo et al., 1996; Dearing and Cork, 1999; Dearing et al., 2000; Mangione et al., 2000; Atwood et al., 2001; Marsh et al., 2003; Wiggins et al., 2003; Boyle and McLean, 2004). Generally, the underlying physiological or toxicological mechanisms causing the change in feeding behavior have been speculative. Considering that cineole is a small lipophilic molecule and will readily cross the blood–brain barrier, it is likely to exert antifeedant effects as a consequence of low-grade toxicity associated with central nervous system (CNS) depression. We hypothesized that (1) the blood concentration of plant secondary metabolites (PSMs) is an important determinant of PSM ingestion, and (2) feeding behavior is modified as a result of critical concentrations of cineole and/or its metabolites. To address these hypotheses, we measured the concentrations of 1,8-cineole and its metabolites

in blood, as possums voluntarily consume a diet containing varying concentrations of 1,8-cineole.

METHODS AND MATERIALS

Animals. Six male brushtail possums (*T. vulpecula*) were trapped from bushland around the city of Hobart, Tasmania, Australia. Animals were housed in individual enclosed pens with wooden nest boxes (28 × 28 × 36 cm) attached to the walls. They were fed daily a freshly prepared maintenance diet of grated silverbeet (*Beta vulgaris*), carrot, apple, lucerne chaff, and sugar (McArthur et al., 2000). Cineole was added to this diet in appropriate amounts and mixed in well.

Prior surgical implantation of Vascular Access Ports (model TI200; titanium reservoir, reservoir volume 0.25 ml, silicone septum, preattached silicone catheter (5 Fr) cut to 15 cm; Access Technologies, Skokie, IL, USA) provided reliable long-term access to the jugular vein for blood sampling (Cleva et al., 1995). Animals were sedated with Zoletil (12 mg/kg, i.m.; Virbac Australia Pty Ltd, Peakhurst, NSW, AU) and anesthetized with isoflurane (Rhodia Australia Pty Ltd, Notting Hill, Victoria, AU). The surgical procedure was similar to that used in the koala (Cleva et al., 1995). Animals were allowed at least 1 wk to recover before experiments commenced. Ports were maintained by flushing them twice weekly with saline, and were kept filled with heparin saline (125 units/ml).

Experimental Design. Six possums were used in the experiments. There were five treatment periods of 3 d. Each started on the same day of the week for 5 consecutive wk. The first was for acclimation to the procedure, daytime feeding, and the feeding setup while receiving the 1% cineole diet (wet weight). The remaining four treatment diets were: (1) control diet (regular maintenance diet), (2) 1% cineole diet, (3) 2% cineole diet, and (4) 4% cineole diet. These were presented in a randomized crossover design.

Possums were fasted the night before the start of each treatment, and the treatment was presented each day for the next 3 d. Each morning possums were taken from their enclosures to the feeding apparatus in their usual nest boxes. They stayed in their nest boxes throughout the experiments. The treatment diet was presented for 7 hr. The length of the feeding session was arbitrarily chosen, balancing maximum exposure to food with convenience. The length of the session was appropriate, as it allowed time for possums to consume sufficient food, from multiple bouts if required, to maintain body weight. Possums were returned in their nest boxes to their usual pens each night. A single possum (BP8) became uncharacteristically active and agitated when offered the 4% cineole diet, and was withdrawn from this treatment.

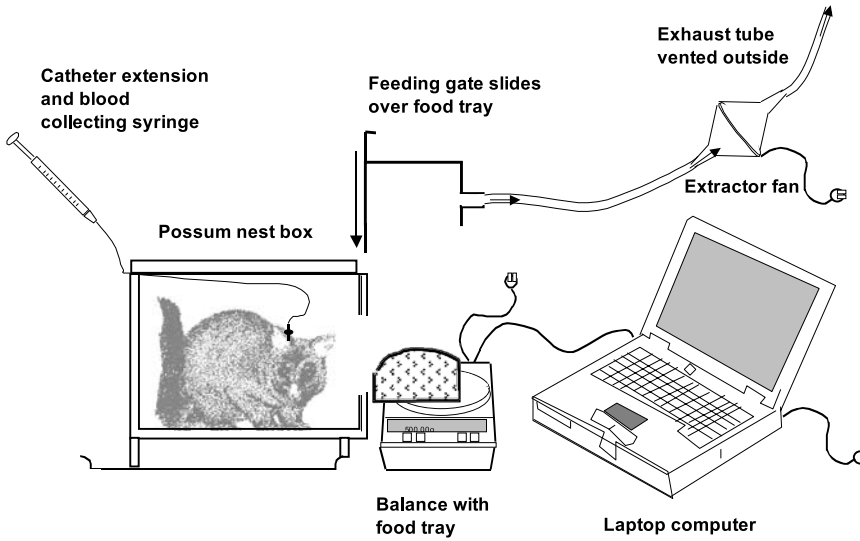

FIG. 1. Feeding and blood sampling apparatus. Possums remained in their own nest boxes. The port was accessed with a Huber needle and catheter that extended out of the box. The diet was weighed into a steel tray and secured onto the balance. The feeding gate slid over the entrance allowing possums *ad libitum* access to the diet. The tube at the rear of the feeding slide went to an extractor vented fan. The balance recorded time and weight into a laptop computer.

Feeding Setup. The feeding apparatus was designed so that detailed measurements of food intake in freely feeding possums could be taken throughout the day, while allowing regular blood samples to be collected at the same time. The setup, shown in Figure 1, was fitted to the nest box. Food was measured into a stainless steel dish that was placed on a balance positioned at the front of the nest box. The digital output from the balance was fed into a laptop computer, and a program (written in Qbasic) recorded the time and the weight of the food dish every 45 sec. A gate was slotted onto the front of the nest box and fitted snugly around the food tray. This ensured that the possum remained within the nest box while providing *ad libitum* access to food. Food intake was calculated from the weight of food lost from the feeding dish. From these data, the number, length, and size of feeding bouts were calculated.

A transparent top of the feeding gate was usually covered but, if necessary, allowed visual inspection of the possum as it fed. At the back of the feeding chamber, a vacuum hose (diam 32 mm) was attached to an extractor fan (flow rate ranged from 0.9 to 1.1 l/sec) and vented to a fume cupboard. This was necessary to prevent the accumulation of cineole vapor in the nest box and feeding area.

Blood Sampling. On the third day of each cineole treatment, blood was collected during the first 3 hr of feeding. The vascular access port was accessed and tested before the possum was allowed to start feeding. The port site was first cleaned with 70% sterile alcohol [Pharmacia (Perth) Pty Ltd., Bentley, Western Australia, AU], 0.05% chlorhexidine acetate, and 0.5% cetrimide aqueous antiseptic solution (Baxter Healthcare Pty. Ltd., Old Toongabbie, NSW, AU), and finally 10% povidone iodine (Betadine Antiseptic Solution, Faulding Pharmaceuticals, Salisbury, South Australia, AU). A saline-filled right angle noncoring Huber Infusion Set (22-ga., right angle, 1/2" tip-to-bend, 45 cm catheter tubing; Access Technologies, Skokie, IL, USA) was inserted into the port reservoir. The tail end of the catheter was capped and left outside the closed lid of the nest box, allowing blood to be collected as often as required without disturbing the possum. The dead volume of the port (0.5 ml) was withdrawn and discarded, a control blood sample (0.4 ml) was collected, and the port and catheter volume was refilled with heparinized saline [50 U/5 ml; Pharmacia and Upjohn (Perth) Pty. Ltd., Bentley, Western Australia, AU].

Blood samples were collected at the start of each feeding bout and then every 5 min until 10 min after the end of the bout. Samples were taken every 15–30 min thereafter, until the start of the next feeding bout or the end of the 3-hr collecting period. The volume of blood collected depended on the analyses to be performed. Blood cineole was measured in every sample collected, while metabolites were only measured in every other sample. Therefore, blood volumes collected alternated between 0.1 and 0.3 ml. The port and catheter were filled with heparinized saline between each blood sample to prevent blood clotting in the catheter.

Blood samples were transferred directly to a heparinized screw cap glass vial (2 ml volume). Vials were prepared by diluting heparin injection 25,000 U/5 ml [Pharmacia and Upjohn (Perth) Pty. Ltd.] to 25 ml and transferring 100 μl to each vial before drying in an oven at 60°C. After collection of blood, the vials were sealed with a PTFE/silicon septum (Bonnet Equipment Pty Ltd, Tarren Point, NSW, AU) and temporarily stored in an insulated box filled with salted ice. At the end of each experiment, all samples were frozen at −18°C until thawed for analysis.

Blood Analysis

Cineole. Blood cineole concentrations were measured by solid phase microextraction (SPME) using the method previously described by Boyle et al. (2002). Blood was thawed to room temperature, and 50 μl were measured into a 17 × 60 mm glass screw cap vial (Packard Bioscience, AU). The internal standard (250 ng linalool in 25 μl water) and 25 μl water were also added to the vial, which was capped using PTFE-lined silicon septa and then vortexed. The

fiber sheath was inserted through the septum, and the fiber was exposed to the headspace above the blood. The vial was heated at 35°C, and the fiber was exposed for 12 min. After absorption, the fiber unit was immediately transferred to the GC injector for desorption and GC analysis.

Cineole Metabolites. The method is based on our method used to analyze urinary metabolites of cineole (Boyle et al., 2000). Briefly, cineole metabolites, isolated from possum urine, were used as internal standards to prepare calibration curves for each metabolite. Metabolites were extracted from both unhydrolyzed and hydrolyzed blood samples by using liquid–liquid extraction and subsequently derivatized with *N*,*O*-bis(trimethyl)trifluoroacetamide (BSTFA; Alltech Associates, Deerfield, IL, USA) to form trimethylsilyl (TMS) derivatives. The derivatized extracts were analyzed by gas chromatography-mass spectroscopy (GC-MS), and the amount of metabolite was calculated by using prepared calibration curves for each metabolite.

Data Analysis. The balance output data were manipulated by subtracting each weight recording from the starting weight to give the cumulative amount of food eaten. Evaporation of water from the diet was measured during periods where the food was undisturbed for prolonged periods (>1 hr) on 20 occasions. The evaporation rate was 0.63 ± 0.25 g/hr. The amount of food presented to possums was 500 gm. Therefore, less than 1% of the starting weight of food was lost due to evaporation over the 7-hr feeding session. Evaporation of cineole from the wet bulky diet was also insignificant. The same diet, laced with 4% cineole, was analyzed by hexane extraction and GC for cineole concentration before and after it had been offered overnight to possums kept in metabolism cages. There was no significant difference in concentration between the fresh and the residual food (Boyle et al., unpublished data). Therefore, no correction for evaporation of water or cineole was needed. Each time reading was also converted to time from the start of the experiment.

We arbitrarily defined a feeding bout as an intake of more than 3 g, while rests of up to 2 min were accepted as part of the same feeding bout. From these data, we calculated the total food and cineole intake, the percentage of the food eaten in bouts, the size of the largest feeding bout, the total time spent eating, and the mean duration of feeding bouts. The rate of food and cineole consumption in each bout was also calculated by dividing the amount of food eaten by the time taken to eat it. We also determined the amount of food, and therefore cineole, consumed in the first feeding bout, the duration of the first

FIG. 2. Food consumption and blood concentrations of cineole and metabolites for each of the four dietary concentrations of cineole for a single possum (BP 11). Possums were offered the diet for 7 hr, and blood samples were collected during the first 3 hr of that period.

feeding bout, and the percentage of the daily food intake ingested in the first bout.

Although feeding data were recorded and calculated for each day of experiments, feeding behavior is reported only for the third day in order to compare directly to the measured blood levels.

Statistical comparisons used repeated-measures (RM) ANOVA, except where specifically stated otherwise. Separate RM ANOVA were performed for the following parameters: maximum cineole blood concentrations, amount of food ingested in the first bout, the amount of cineole ingested in the first bout, the time spent feeding on the first bout, the percentage of total food eaten in the first bout, the percent of total food eaten in bouts exceeding 3 gm, total food intake, total cineole intake, rate of food consumption, and rate of cineole consumption. The computer software program GraphPad Prism (version 4 for Windows, GraphPad Software, San Diego, CA, USA) was used for statistical analysis and graphing. Where data are summarized, values are expressed as mean ± SD.

RESULTS

Figure 2 overlays food ingested (and thus cineole ingestion) with both blood cineole and metabolite concentrations for each treatment for a single possum (BP 11). The control diet was eaten in 3 bouts, whereas with increasing cineole concentrations the feeding bouts became smaller and total food consumption progressively fell. Similar patterns were seen in all other possums.

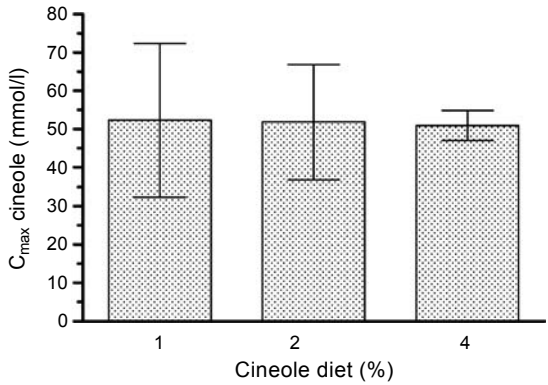

FIG. 3. The mean maximum blood cineole concentration after any feeding bout for each of the three dietary cineole concentrations. Data are shown as mean ± SD ($N = 6$, except for the 4% diet where $N = 5$).

For every feeding bout on a cineole diet, there was an associated rise in blood cineole levels. Cineole absorption was rapid with peak concentrations occurring before, or just at, the end of the feeding bout. Cineole blood levels then declined until the beginning of the next feeding bout.

The mean maximum cineole blood concentrations (C_{max}) for each cineole treatment were similar, regardless of the dietary concentration (51.8 ± 14.1 μmol/l, $N = 17$; repeated-measures ANOVA $F_{2,10} = 0.15$, $P = 0.87$; Figure 3). Variability in the mean C_{max} decreased with increasing percentage of cineole in the diet.

Each feeding parameter is summarized in Table 1 for all 3 d of data collection. Repeated-measures ANOVA for the 3 d was performed for each parameter, and significant results are indicated. The main differences across the 3 d was that food intake increased progressively on the cineole diets and the number of feeding bouts increased at the higher cineole concentrations.

TABLE 1. SUMMARY OF FEEDING PARAMETERS (MEAN ± SD) COLLECTED OVER THREE DAYS OF FEEDING

	Values recorded over three days (mean ± SD)

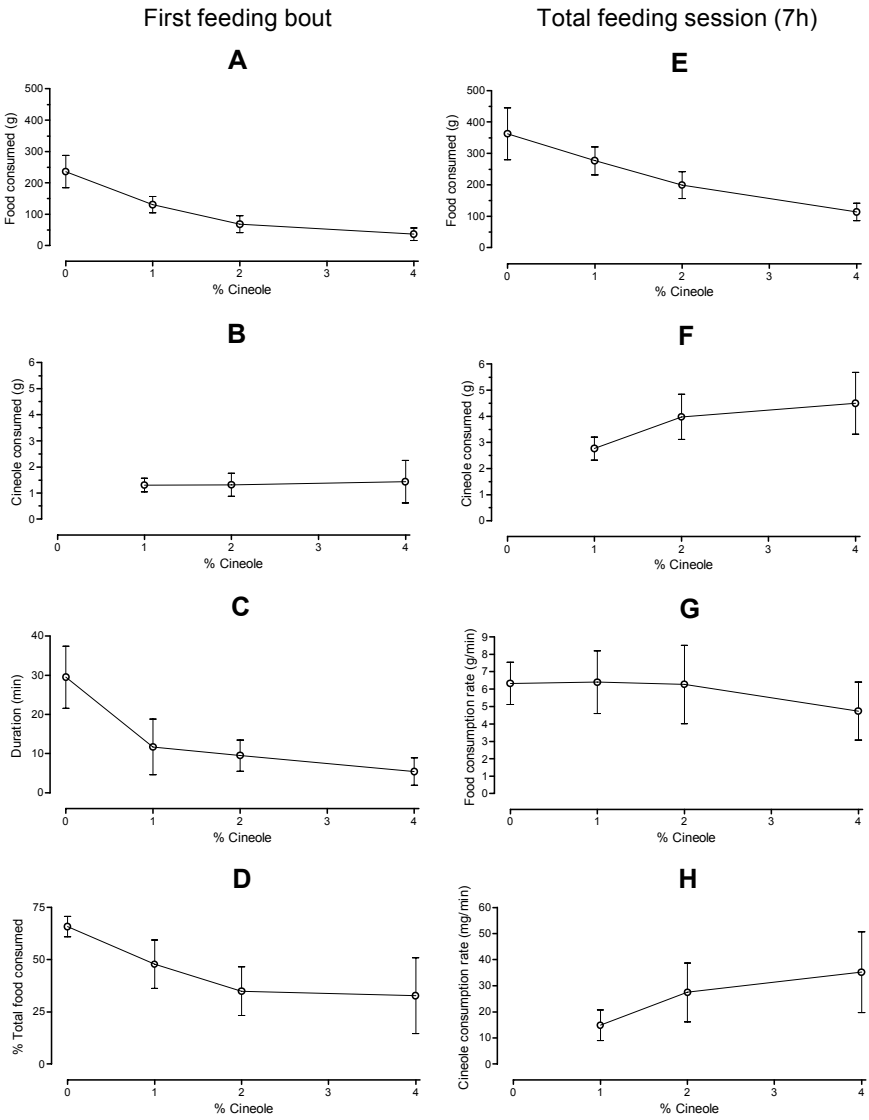
Repeated-measures ANOVA were performed on the means of each day for each parameter to identify significant changes in that parameter over the 3 d.

*Significantly different means.

**Linear trend in significantly different means over 3 d.

Feeding parameters recorded on the third day for each cineole concentration are the averages for all possums and are shown in Figure 4. This figure summarizes data for both the first bout and the total feeding session of 7 hr. The order of treatment was not associated with any trends in the amount of cineole consumed in the first bout.



In 18 of the 23 experiments, the first feeding bout was the largest meal of the day. The amount of food ingested in the first bout decreased from 236 ± 52 g (mean ± SD) on the control diet to 36 ± 20 g on the 4% diet (repeated-measures ANOVA $F_{3,15} = 40.7$, $P < 0.001$; Figure 4A). The amount of cineole ingested in the first bout was the same regardless of the dietary concentration (1.18 ± 1.10 g; repeated-measures ANOVA $F_{2,10} = 0.12$, $P = 0.89$; Figure 4B).

Time spent feeding on the first bout decreased with increasing cineole concentration (repeated-measures ANOVA $F_{3,15} = 0.94$, $P < 0.001$; Figure 4C). The percentage of total food eaten in the first bout also decreased progressively from 66% of the control diet to 33% of the 4% diet (repeated-measures ANOVA $F_{3,15} = 7.08$, $P = 0.004$; Figure 4D).

Most of the food consumed in the 7-hr session was accounted for in bouts of greater than 3 g, although the percentage decreased with increasing amounts of cineole (repeated-measures ANOVA $F_{3,15} = 0.87$, $P = 0.02$). While feeding on the control diet, 98% of the food loss throughout the feeding session was accounted for in feeding bouts (>3 g), whereas this value decreased to 88% on the 4% cineole diet. Total food intake decreased with increasing concentrations of cineole (repeated-measures ANOVA $F_{3,15} = 22.43$, $P < 0.001$; Figure 4E). Overall food intake on the 4% cineole diet (131 ± 52 g) was reduced by 64% compared to the control diet (368 ± 94 g). Cineole intake, however, increased with increasing concentrations of cineole in the diet (repeated-measures ANOVA $F_{2,10} = 7.27$, $P = 0.01$; Figure 4F). The amount of cineole eaten in the 1% diet (2.47 ± 0.60 g) was approximately half of that eaten in the 4% diet (5.05 ± 2.41 g). The rate of food consumption, measured during feeding bouts only, did not slow significantly with increasing cineole concentration (repeated-measures ANOVA $F_{3,15} = 1.71$, $P = 0.2$; Figure 4G), and this in turn resulted in an increasing rate of cineole intake (repeated-measures ANOVA $F_{3,15} = 17.61$,

FIG. 4. Summaries of feeding patterns on day 3 of each treatment. A, B, C, and D relate to the first feeding bout only, whereas E, F, G, and H relate to the total or overall feeding patterns. (A) The amount of food eaten in the first feeding bout of the day decreased as the percentage of cineole in the diet increased. (B) The amount of cineole ingested in the first bout was the same across all concentrations of dietary cineole. (C) The amount of time spent feeding during the first bout declined with increasing cineole. (D) The percentage of the total daily intake of food eaten in the first bout dropped with increasing cineole content. (E) The total amount of food eaten during the feeding session decreased with increasing cineole concentrations. (F) Total cineole intake increased with increasing cineole concentrations. (G) Possums ate the food at a similar average rate regardless of the concentration of cineole, although the rate was lower on the 4% diet. (H) Since the rate of food intake was consistent, the rate of cineole ingestion must increase with increasing concentration in the diet. Data are shown as mean ± SD ($N = 6$, except for the 4% diet where $N = 5$).

TABLE 2. CINEOLE METABOLITE CONCENTRATIONS (MEAN ± SD) MEASURED APPROXIMATELY 3 HOURS AFTER COMMENCING CINEOLE DIETS

Cineole diet (%)	Metabolite concentration (μmol/l)	Cumulative cineole dose (g)
1	570.8 ± 260.0	1.72 ± 0.71
2	968.3 ± 345.2	3.44 ± 1.47
4	980.5 ± 492.1	4.28 ± 1.78

$N = 4$.

$P < 0.001$; Figure 4H), although there were large fluctuations noted in the rate of cineole intake.

Eighteen oxidized metabolites of cineole have been found excreted in possum urine (Boyle et al., 2000). Thirteen of these were easily detected and quantified in the blood, and each was analyzed and quantified separately. The metabolites quantified were four hydroxycineoles (2-, 3-, 7-, and 9-hydroxycineole), two carboxycineoles (7- and 9-cineolic acid), and seven hydroxy carboxycineoles (positions of oxidations were not elucidated). The carboxycineole and hydroxy carboxycineole metabolites were generally measured at similar levels, and together they accounted for the majority of metabolites. The hydroxycineole metabolites accounted for only a small proportion of total metabolites in the blood. There was no marked change in the proportions of individual metabolites over the sampling periods, so the molar concentrations were summed to simplify interpretation of results. Cineole metabolites accumulated throughout the blood sampling period and were still rising after 3 hr (see Figure 2). The maximum concentrations of cineole metabolites are recorded in Table 2. These values were measured in the final blood sample (taken approximately 3 hr after the start of the experiment).

DISCUSSION

These are the first data on blood concentrations of an antifeedant and its metabolites during feeding, and are coupled with continuous food consumption data. Furthermore, we measured these parameters after manipulating the concentration of cineole in the diet, thereby changing feeding behavior. We are able to make some observations about the antifeedant mechanisms of terpenes such as 1,8-cineole in herbivores.

The example shown in Figure 2, the feeding pattern of one possum, overlaid with the respective blood cineole and metabolite concentrations, shows the association between eating and circulating blood levels of cineole and its metabolites. The conclusions and their implications on feeding are discussed below.

There were sharp peaks in blood cineole concentrations associated with every feeding bout. Cineole was found in the first blood sample collected after feeding commenced. Cineole concentration during each feeding bout peaked within a few minutes of the start of the bout and was associated with the time that the animal stopped feeding (Figure 2). From the possums' perspective, every time it eats a diet containing cineole it has to deal with a rapid surge of circulating blood cineole. Cineole is a small lipophilic molecule that readily crosses the blood–brain barrier, directly exerting its toxicity on brain function resulting in CNS depression (Patel and Wiggins, 1980; Webb and Pitt, 1993; Whitman and Ghazizadeh, 1993; Barnes, 1996). Surges in blood cineole are likely to rapidly transpose into adverse effects on the CNS that would not only compromise the functioning ability of the animals but also provide a rapid feedback mechanism to stop feeding on that diet.

The rapidity of cineole uptake was surprising, as the dose was dispersed in food. We had expected the food bolus to be retained in the stomach for digestion. It is possible that the immediate cineole peaks arise from absorption directly through the stomach. Rapid C_{max} have been seen after oral dosing of terpenes in other studies (Boyle et al., 2002; Sorensen and Dearing, 2003).

In Figure 3, we see that the maximum cineole concentration resulting from any feeding bout was the same regardless of the dietary concentration. In 11 of the 17 cineole diet experiments, C_{max} resulted from the first feeding bout of the day. The first day was when possums were at their hungriest, as they were starved the previous night. In these cases, subsequent feeding bouts resulted in substantially lower cineole blood levels associated with smaller feeding bouts and cineole intake.

Possums also adjusted their food intake in the first feeding bout such that the amount of cineole ingested was the same regardless of the dietary concentration (Figure 4B). Combined, these observations provide evidence that possums are able to titrate blood cineole concentrations, and that they stop cineole intake at a critical blood concentration (about 50 μmol/l).

The circulating blood cineole concentration dropped rapidly after feeding had stopped, yet feeding did not resume upon the levels returning to a low level. It is likely that cineole concentration in the brain lags behind circulating blood concentration, and it is the concentration in this organ that is important for resuming feeding. The degree of satiation after the initial feeding bout and the memory of the aversive experience may delay the possum from resuming feeding until driven by hunger.

It is interesting that there was less variability in C_{max} values measured on the 4% cineole diet compared to diets with a lower percentage of cineole. Several factors may account for this. First, the 1% diet consists of four times the bulk for the same cineole dose compared to the 4% diet. The food may act as a buffer and slow cineole absorption and delay the relay time between

food ingestion and peak blood concentrations leading to the higher blood concentrations. We attempted to reconcile the timing of C_{max} to the end of the respective feeding bout to show this effect, but we were unsuccessful, as individual possum feeding behavior was variable, making it difficult to identify patterns in such detail. Also, while feeding on diets with lower cineole concentrations, possums may have been satiated before the critical amount had been ingested, resulting in smaller blood cineole peaks. However, at 4%, possums are hungry and appear to eat as much cineole as they can tolerate before stopping. We suggest that the smaller bulk of food on 4% diets resulted in more controlled feedback of food intake. This was supported by food and cineole intake measured in the first feeding bout; food intake decreased with increasing cineole concentration, but the amount of cineole ingested remained constant.

A more general cause of variability in measuring the peak concentrations of cineole in the blood was the time interval between blood samples. The sample interval of 5 min was used as the minimum time interval we could reliably manage between samples. However, the true peak of C_{max} may not have been captured in each case, as the concentration rose and fell so rapidly.

In contrast to the reactivity in cineole blood levels during feeding, cineole metabolite levels rose steadily throughout the sampling period. Overall levels of metabolites increased with increasing dietary concentrations. The maximum metabolite concentrations measured in each experiment were at least 10-fold higher than cineole C_{max} values. Most cineole metabolites are acidic, and the accumulation and excretion of such large acid loads provides a significant challenge for the cineole-eating possum (Foley et al., 1995). We suggest that metabolite levels are also important in regulating cineole intake. Although blood cineole levels produce immediate feedback to the possum regulating feeding, metabolites levels are likely to control the total daily or chronic intake of cineole by limitations in excretion of the acid load.

Ideally, these experiments should be performed during the possums' active nighttime phase. However, possums are wild, agile animals with feisty characters. Although they are difficult to handle during their active phase, they are relatively compliant during the day, and for this reason the experiments were performed during the daytime. It might be expected that active possums stop feeding at a lower blood cineole titer, as the consequences of CNS depression in active and arboreal animals are more serious than in sleepy, nest-box-bound possums.

Acknowledgments—This research was supported by a grant from the Australian Research Council. The authors thank the staff at the Central Animal House, University of Tasmania for care and assistance with possum husbandry; particularly Barbara Arnst for preparing diet and care in the maintenance of vascular access ports. We are grateful for the surgical expertise and enthusiasm of Dr Eileen Wronski and Dr Rupert Woods, who were responsible for the implantation of vascular

access ports. We also acknowledge and thank Dr Noel Davies for GC-MS expertise, and Dr Omar Hassan who wrote the Qbasic program.

(Received March 28, 2005; Revised June 6, 2005; accepted August 1, 2005)

Abstract—The role of secondary compounds (SC) in deterring herbivores and pathogens from vegetative parts of plants is well established, whereas their role in plant reproductive organs such as floral nectar is unclear. The present study aimed to reveal the response of free-flying honeybees to naturally occurring concentrations of four SC in floral nectar. We selected nicotine, anabasine, caffeine, and amygdalin, all of which are found in nectar of various plants. In repeated paired-choice experiments, we offered 20% sucrose solution as control along with test solutions of 20% sucrose with various concentrations of the above SC. Except for anabasine, naturally occurring concentrations of SC did not have a deterring effect. Furthermore, low concentrations of nicotine and caffeine elicited a significant feeding preference. SC can, therefore, be regarded as postingestive stimulants to pollinators, indicating that the psychoactive alkaloids in nectar may be a part of their mutualistic reward. Further studies are needed to test our hypothesis that psychoactive alkaloids in nectar impose dependence or addiction effects on pollinators.

Key Words—Nectar, secondary compounds, naturally occurring concentrations, honeybees, attraction, deterrence.

INTRODUCTION

Many studies have focused on elucidating the role of secondary compounds (SC) in deterring herbivores and pathogens from plants (e.g., Rosenthal and Berenbaum, 1991). Others have determined the costs and benefits of producing

* To whom correspondence should be addressed. E-mail: sings@macam.acil

these compounds in the context of plant–herbivore interactions (Van Dam et al., 1996; Agrawal et al., 1999). The current concept is that the wide varieties of SC produced by higher plants play a multifunctional role in the complex biotic and abiotic interactions of plants (Izhaki, 2002; Harrison and Baldwin, 2004; Holopainen, 2004). The myriad challenges that plants face seem to promote natural selection for SC that possess multiple functions (Wink, 1999; Adler et al., 2001; Gronquist et al., 2001; Izhaki 2002). Although the role of SC in deterring herbivores and pathogens is well established (Karban and Baldwin, 1997), their role as mediators of plant–pollinator mutualistic relationships has been widely overlooked (Adler, 2000).

SC are not uncommon in floral nectar. Depending on the specific compound, SC have been found in 9–55% of surveyed species (Baker and Baker, 1975; Baker, 1977, 1978). The nectar of some plants may be deterrent or even toxic to floral visitors (Adler, 2000), and widespread "toxic nectar" is puzzling considering its attractive role in pollination (Faegri and van der Pijl, 1979). The deterrence and toxicity of SC in nectar may be activated through unpalatability or through an effect on the central nervous system of the flower visitors (Baker and Baker, 1975). Consequently, SC in nectar may mediate plant–pollinator interactions affecting the fitness of both plants and pollinators (Baker, 1977).

Several adaptive hypotheses have been proposed to explain the ecological and evolutionary roles of SC in nectar (Rhoades and Bergdahl, 1981; Adler, 2000). The most common claims that SC deter nectar robbers and generalists, or inefficient pollinators. Baker and Baker (1975) suggested that the level of tolerance to SC in nectar by pollinators is related to their efficiency in transferring conspecific pollen. This "pollinator fidelity" hypothesis holds that the nontolerant pollinators are also less efficient in transferring conspecific pollen in comparison to pollinators that are more tolerant to SC (Adler, 2000). However, toxic nectar may have no adaptive function but instead be a consequence of production and mobilization of SC in other plant tissues (Adler, 2000).

Most SC studied so far (e.g., alkaloids, glycosides, phenolic substances) actually deter bees (*Apis mellifera*) within a wide range of high concentrations (Detzel and Wink, 1993). The effects of SC on bees are dose- and season-dependent (e.g., Singaravelan et al., 2006). Low concentrations of phenolic substances such as caffeic and genistic acids elicited preference, whereas high concentrations deterred honeybees (Hagler and Buchmann, 1993). Likewise, bees preferred low concentrations of amygdalin during early summer but not later (London-Shafir et al., 2003). Some alkaloid-containing nectars attracted bees in the field even when alternative nectar sources were available (Ish-Am and Eisikowitch, 1998). This circumstantial evidence indicates that bees cope with naturally occurring concentrations of SC in nectar. Despite evolutionary and ecological implications, the interaction between bees and SC in nectar has not

been widely studied. Specifically, this study was designed to test the responses of honeybees to natural concentrations of SC in nectar, with *a priori* prediction that the latter will not impose strong deterrent effects.

In repeated paired-choice experiments with artificial nectar, we studied feeding preferences of free-flying honeybees (*A. mellifera*) under natural conditions. We offered the bees artificial nectar of 20% sucrose solution as a control, simultaneously with test solutions of 20% sucrose containing various concentrations of four SC. We tested nicotine and anabasine, naturally occurring in the nectar of *Nicotiana* spp. (Detzel and Wink, 1993; Tadmor-Melamed et al., 2004), caffeine that is most common in the nectar of *Citrus* spp. (Kretschmar and Baumann, 1999), and amygdalin that characterizes almond (*Amygdalus* sp.) nectar (London-Shafir et al., 2003). We examined the effects of naturally occurring concentrations of these SC on foraging behavior of honeybees.

METHODS AND MATERIALS

Experimental Arena and Training Procedures. We conducted the experiments on a flat rooftop of a building in the Oranim campus of University of Haifa, Israel, between January and April 2004. Hourly temperatures were recorded with a maximum–mininum thermometer. We conducted the experiments only when the ambient temperature was above 18°C. Honeybees were trained to feed on sucrose solutions (20% sucrose) from 250-ml translucent plastic beakers (6.5-cm diam). The mouth of the solution-filled beakers was covered with a Petri dish (8.6-cm diam and 1.3 cm deep) and turned upside down. The bees fed from the nectar trough formed around the beaker's mouth. Nectar spontaneously filled the trough whenever its level dropped below the mouth. This feeder allowed 70–80 bees to feed simultaneously. Each feeder was placed on a colored plastic plate (14-cm diam) that was placed on a white plastic tray (36 $\times$ 26 cm) on the floor. We started by training bees to feed from a 20% sucrose solution in one station. Then, we split them into five separate groups, each feeding from a feeder that was placed on different colored plate. Later, we gradually separated five feeders about 20 m apart. In a preliminary experiment, we marked 50 bees at each feeding station and monitored their visits for about a week to ensure that they established independent feeding groups. Indeed, about 85% of the bees fed only in the feeding station where they were marked, whereas only some (<15%) were observed also in another feeding station.

Secondary Compounds. We tested the bees' response to four SC: nicotine (Aldrich Ltd), anabasine, caffeine, and amygdalin (Sigma Ltd). We chose these SC because honeybees frequently visit flowers and feed on the nectar of *Nicotiana* spp., *Citrus* spp., and *Amygdalus* sp. that contain them, and their natural concentration in floral nectar is known (Table 1).

TABLE 1. NATURALLY OCCURRING CONCENTRATIONS OF SC AND THE CONCENTRATIONS TESTED IN EXPERIMENTS I AND II OF THE PRESENT STUDY

Secondary compounds	Plant species	Naturally occurring concentration in nectar (ppm)	References	Concentration tested in the present study (ppm)	
				Experiment I	Experiment II
Nicotine	*Nicotiana tabacum*	0.166[a]	Detzel and Wink (1993)	2.5, 5, 10, 20	0.5, 1, 2, 5
	Nicotiana glauca	0.56 ± 0.12 (0 to 2.5)	Tadmor-Melamed et al. (2004)		
Anabasine	*Nicotiana tabacum*	0.166[a]	Detzel and Wink (1993)	NT	2.5, 5, 10, 25
	Nicotiana glauca	5.4 ± 0.90 (0 to 50)	Tadmor-Melamed et al. (2004)		
Caffeine	*Citrus paradisi*	94.26 ± 2.90	Kretschmar and Baumann (1999)	50, 100, 150, 200	12.5, 25, 50, 100
	Citrus maxima	17.61 ± 0.97			
	Citrus limon	11.61 ± 0.39			
Amygdalin	*Amygdalus communis*	4 to 10	London-Shafir et al. (2003)	5, 10, 25, 50	2.5, 5, 7.5, 10

Natural concentration: mean ± SE; range, when available, is given in parentheses.
NT: not tested.
[a]Total alkaloid concentration.

Food Preference Trials. At each feeding station, we offered the bees simultaneously one feeder with a control solution (20% sucrose) and one feeder with a test solution (20% sucrose with a known concentration of one SC). In each experimental session, only one SC was tested, and in each experimental trial, the same concentration of the same SC was tested against the control in all five feeding stations. Thus, each test was replicated five times. We preferred the paired-choice design, as it is a compromise between multiple-choice tests, which simulate the natural situation but suffer from lack of independence among observations, and single-choice tests, which often underestimate preferences because of the lack of real choice (Manly, 1993). In the first experiment, we examined the response of bees to a wide range of concentrations (experiment I, Table 1) to obtain concentration–response information. This enabled us to determine the threshold minimal deterring concentration for each SC. In the second experiment, we repeated the same experimental design testing the range of naturally occurring concentrations of each SC (experiment II, Table 1).

To determine the consumption rate, we weighed (Precisa Instruments Ltd, Switzerland, electronic balances) each feeder before and after 1 hr of bee feeding. Simultaneously with the control solution, a particular concentration of SC test solution was offered in all stations simultaneously for 1 hr. The tested concentrations were changed after each hour. Whenever we changed the tested concentrations, we also changed the relative position of the control and test feeders randomly on the plastic tray to shun any possible association of any solution type with a certain position by bees. Each experimental session that tested a range of concentrations of a SC lasted 3–5 consecutive days. Between any two experimental sessions, we had an average time lag of 5 d, during which we offered only control solutions to the bees. On each experimental day, we tested all concentrations of a particular SC for its selected range. We changed the order of presentation of the various concentrations during each experimental day.

To detect correlations between number of bees and consumption rate of test solutions, we counted the number of bee visits in each station with a tally counter and stopwatch. Bees were counted for 1 min at the control feeder and 1 min at the tested solution feeder.

Data Analyses. We considered each experimental station as an independent replicate, as >85% of marked bees remained feeding only in one station. Thus, we obtained five replicates for each concentration of each SC. We calculated the percentage differences in food intake and in the number of bees per minute between control and experimental solutions for each preference trial and each station. We averaged the differences for the three experimental days. We analyzed these differences by two-tailed one-sample t test. One-way ANOVA was used to detect effects of SC concentrations on food consumption followed by Tukey's multiple comparison test ($P < 0.05$). We related the number of bees that visited the feeders and the consumption rate of test solutions with Pearson's

correlation. All proportions were arcsin-square-root-transformed prior to statistical analyses for normal distribution. Results are presented as mean ± SE.

RESULTS

Experiment I—Wide Range of Concentration Series. In this experimental series, the bees were not deterred from naturally occurring concentrations of nicotine, caffeine, and amygdalin (Figure 1). On the contrary, bees consumed these concentrations more than that of the control solutions. Bees were deterred by concentrations of nicotine and caffeine that were higher than natural concentrations in nectar (>2.5 and >100 ppm, respectively). The deterrence effect tended to increase with concentration by an order of magnitude. Notably, bees were not deterred by any of the tested amygdalin concentrations. The relative differences in consumption of treated solutions per hour from that of control varied significantly across concentrations for all SC except for amygdalin (Figure 1).

Experiment II—Natural Range of Concentration Series. Of the four SC tested within their natural range of concentration, bees significantly preferred the lower concentrations of nicotine and caffeine over the control. They were significantly deterred by three of four concentrations of anabasine. Although bees consumed more amygdalin at all tested concentrations than controls, the differences were not significant (Figure 1). This preferential intake of experimental solutions was significant for 0.5 and 1 ppm of nicotine and for 25 ppm of caffeine. Moreover, in this experiment, bees were not deterred by any of the tested concentrations of caffeine and amygdalin. The consumption of tested solutions relative to that of controls varied significantly across concentrations for all SC except amygdalin (Figure 1).

Consumption Rate vs. Number of Bees. We found a positive and significant correlation between number of bees feeding and consumption rate across concentrations and SC (nicotine: $R = 0.89$, $N = 40$, $P < 0.001$; caffeine: $R = 0.85$, $N = 40$, $P < 0.001$; amygdalin: $R = 0.40$, $N = 40$, $P < 0.01$; anabasine: $R = 0.82$, $N = 20$, $P < 0.001$). The number of bees feeding on the tested solutions relative to control solutions showed a similar pattern to that of the relative consumption of the solutions and is, therefore, not presented here.

DISCUSSION

Preference vs. Deterrence. Honeybees use multiple cues to identify food. They associate and/or memorize many chemical stimuli with sucrose to recognize or discriminate among differing mixtures of reward (Jakobsen et al.,

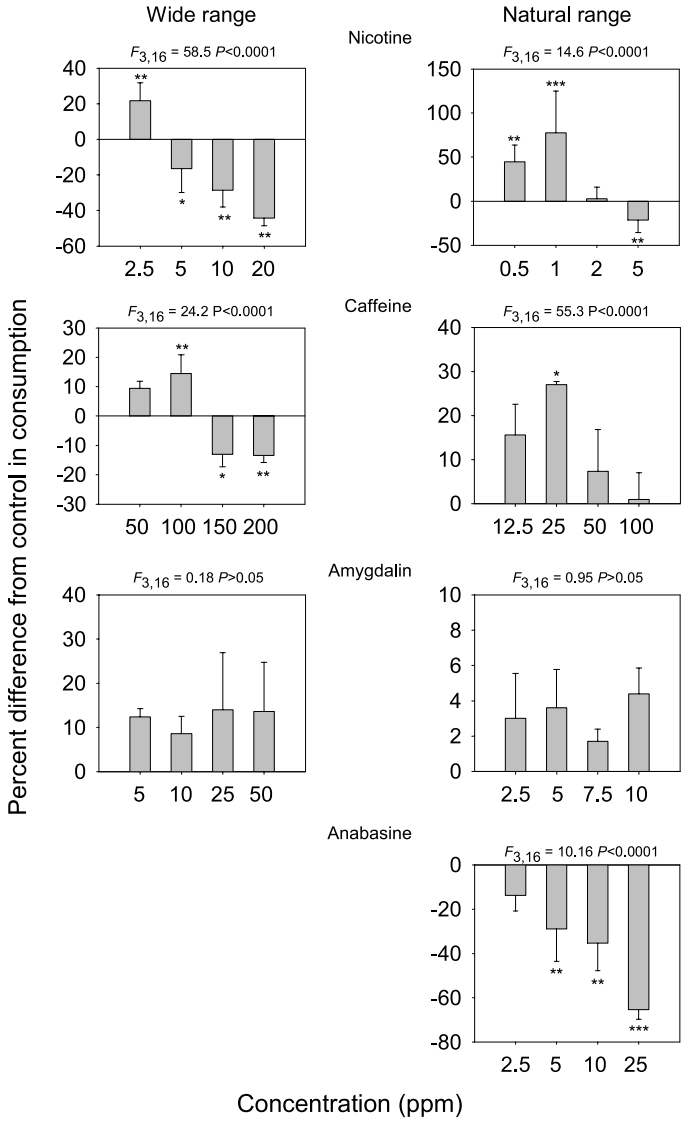

FIG. 1. Responses of *Apis mellifera* to various concentrations of four secondary compounds in artificial nectar of 20% sucrose. The relative differences (%) in nectar intake of the test solutions from controls were subjected to one sample, two-tailed t test, * = $P < 0.05$, ** = $P < 0.01$, *** = $P < 0.001$. Bars represent mean ± SE; positive bars indicate preference, and negative bars indicate deterrence. The effects of concentrations are presented as F and P values of one-way Anova.

1995; Laska et al., 1999; Paldi et al., 2003). For foraging bees, natural concentrations of SC are associated with artificial reward imitating natural floral nectar. Our results indicate that except for the strong deterrent effect of anabasine, which acts as a selective nicotinic acetylcholine receptor (nAChR) agonist for insects (Sultana et al., 2002), honeybees were not deterred by nicotine, caffeine, or amygdalin in their natural range of nectar concentrations. Furthermore, honeybees significantly preferred solutions with low concentrations of nicotine and caffeine over control (20% sucrose) solution. A similar but nonsignificant pattern was detected also for all concentrations of amygdalin (Figure 1). When offered a wide range of concentrations, bees consumed nicotine and caffeine solutions only within their natural concentration range and were deterred by higher concentrations. For amygdalin, bees were not deterred even by higher concentrations. It appears that some SC in nectar may furnish foraging cues to mutualistic pollinators as has been hypothesized for fruits and their frugivores (Cipollini and Levey, 1997).

Bees appeared to modulate their response to the differing concentration spectra of SC, as they chose the lower concentrations of nicotine and caffeine in both ranges. Such modulatory and/or differential responses across different concentration spectra are known for nectar compounds in general (Masson et al., 1993; Menzel, 1993) and SC in particular (London-Shafir et al., 2003). Nonetheless, the differential responses cannot be an outcome of choice behavior or side bias by bees to the feeders during choice experiments, as we noted a consistency in deterrence response to concentrations deviating from the natural range of nicotine and caffeine.

Response to Nicotine. The biphasic, dose-dependent response in nicotine intake might be the result of a dual motivational effect of nicotine (Laviolette and van der Kooy, 2004), rewarding (preference) at low concentrations on the one hand and aversive (deterrence) at higher concentrations on the other. Nicotine acts on endogenous nAChR prevalent in the central and peripheral nervous systems in almost all animal species (Laviolette and van der Kooy, 2004). The highly inducible nicotine, which acts as a feeding deterrent to herbivorous insects, can be found in vegetative plant parts in relatively high (300–5000 ppm) concentrations (Ohnmeiss and Baldwin, 2000). Our results demonstrated that honeybees were deterred even by much lower concentrations (≥5 ppm) of nicotine in sucrose solution.

Low concentrations of nicotine act as positive reinforcers both through intravenous and oral self-administration (Halladay et al., 1999; Laviolette and van der Kooy, 2004). Nicotine drinking has induced active nicotine preference in rats (Halladay et al., 1999). In insects, the actions are likely to be CNS-specific, where they appear to play a major excitatory role (Wolf and Heberlein, 2003). Repeated exposure to nicotine enforces subsequent neuronal changes in the mesolimbic dopamine system of the brain, which, in turn, evokes com-

pulsive nicotine-seeking behaviors in mammals (Laviolette and van der Kooy, 2004). Although the mechanism in insects has yet to be elucidated, there are some indications that invertebrates such as the nematode *Caenorhabditis elegans* (Schafer, 2004) and insects such as *Drosophila* (Bainton et al., 2000) adopt addictive behaviors when exposed to low concentrations. Given this, it is paramount to test rigorously whether nicotine in nectar imposes dependence or addiction effects on pollinators. The mammalian literature on addiction characterizes it as a progressive increase in preferential intake of psychoactive substances despite its toxic effects and/or even after deprivation of drugs over a stipulated period (Heyne and Wolffgramm, 1998). However, addiction (if any) to substances such as nicotine in nectar by pollinators needs to be studied in detail. It should be noted that natural concentrations of nicotine (Table 1) do not affect the fitness of caged honeybees (Singaravelan et al., 2006).

Response to Anabasine. The bees in our experiments were deterred even by naturally occurring concentrations of anabasine. Thus, we cannot rule out the possibility that certain SC at their natural concentrations deter honeybees. Indeed, anabasine is a selective nAChR agonist for insects with insecticidal activity at relatively high concentrations (Sultana et al., 2002) and an effective antifeedant (Gonzalez-Coloma et al., 2004). Nonetheless, anabasine and nicotine are both constituents of *Nicotiana* nectar; anabasine is the predominant compound in *N. glauca*, whereas nicotine is the major one in *N. tabacum* (Bush and Crowe, 1992). Notably, honeybees visit only the flowers of the latter. It would be of interest to study the response of bees to combinations of nicotine and anabasine simulating the natural situation.

Response to Caffeine. Caffeine acts as a mild reinforcer and psychostimulant to mammals such as rats (Vitiello and Woods, 1977). In contrast, it may function as an antifeedant to insects (Bernays et al., 2000), although it is not efficiently effective against insect pests of coffee (Guerreiro and Mazzafera, 2000). Caffeine in relatively high concentrations is deterrent (ED_{50} at 300 ppm) and even toxic to honeybees (LD_{50} at 2000 ppm; Detzel and Wink, 1993). In our study, bees preferred caffeinated 20% sucrose solutions, within its natural concentration range in nectar, over control 20% sucrose (Table 1). In natural situations, honeybees collect caffeine containing *Citrus* nectar (Ish-Am and Eisikowitch, 1998) and even prefer it to alternative nectar resources. Moreover, in Israel, during winter, when nectar resources are limited, honeybees often forage in trash bins on sweetened Coca-Cola (personal observations) that contains 103 ppm of caffeine (http://www.coca-cola.com; accessed 24 March 2005). These factors may help bees in dealing with caffeine in floral nectars.

Response to Amygdalin. Bees showed a nonsignificant higher intake of amygdalin-laced 20% sucrose solutions than 20% sucrose controls in both natural and wider concentration ranges. A previous study showed a variable seasonal response of honeybees to amygdalin. The intake of amygdalin-laced sucrose

varied with the availability of other seasonal nectar sources (London-Shafir et al., 2003). The cyanogenic glycoside amygdalin also did not have strong deterrent effect on folivorous orthopterans (Bernays, 1983), but reduced food intake in two noctuid caterpillars (Glendinning and Slansky, 1994). The preference and performance of a frugivorous cedar waxwing bird (*Bombycylla cedrorum*) were not affected by even high concentrations of amygdalin (Struempf et al., 1999).

SC in Nectar vs. Pollen. Detzel and Wink (1993) found that bees were deterred by many SC, but mostly at higher concentrations that we tested. Our concentration range was based on naturally occurring concentrations in floral nectar, whereas Detzel and Wink (1993) examined higher ones that occur mainly in pollen. However, foraging bees probably do not encounter in nectar high ED_{50} concentrations of SC (mentioned in their study). From an evolutionary perspective, to increase fitness, plants might have evolved higher concentrations of SC in pollen to deter pollen eaters and lower concentration in nectar to increase attractiveness to pollinators.

Possible Mechanisms. We found that honeybees can discriminate well among various concentrations of SC (Figure 1), as reported earlier (Hagler and Buchmann, 1993; London-Shafir et al., 2003). Such discrimination might be based on the universally bitter taste of alkaloids (Kingsbury, 1964). How do honeybees overcome this unpalatability? The presence of carbohydrates (sugars and sugar alcohols) can "mask" the unpleasant taste of some SC to herbivorous insects (Glendinning, 2000), as carbohydrates inhibit the response of deterrent taste cells (Shields and Mitchell, 1995). It appears that sucrose (20%) might have masked the unpalatable nature of low concentrations of nicotine and caffeine. Further studies should reveal the full spectrum of this tradeoff by evaluating the bee's responses to various concentrations of SC in various concentrations of sugar.

Ecological and Evolutionary Implications. As predicted, naturally occurring concentrations of nectar SC do not have a strong deterrent effect on bees (with the exception of anabasine); rather, some low concentrations of nicotine and caffeine even significantly stimulate them. Although honeybees are generalist pollinators, a few *Nicotiana* sp., *Citrus* spp., and *Amygdalus* spp. depend on bees for pollination (Detzel and Wink, 1993; Kretschmar and Baumann, 1999; London-Shafir et al., 2003). Thus, our results provide some support for the "pollinator fidelity" hypothesis, as honeybees are not deterred by SC and were even stimulated by the natural concentrations of nicotine and caffeine mimicking nectar. Notably, nicotine and caffeine are not restricted to nectars of *Nicotiana* spp. and *Citrus* spp. These alkaloids are distributed in nectars of other plant species (Naef et al., 2004). Thus, further studies should focus on the hypothesis that plants produce these compounds in nectar to "addict" faithful pollinators. Many insects are addicted to SC (Boppré, 1999; Renwick and

Lopez, 1999; Renwick, 2001), and plants may use SC to mediate various insect–plant relationships by a method of differential allocation of SC concentrations to different plant parts (Harborne, 1993; Boppré, 1999). Thus, SC in nectar may govern the selection of the best mutualistic partners. The prediction of a pollinator fidelity hypothesis remains to be studied.

In summary, pollinators are stimulated by a variety of constituents in nectar at substance-specific spectra of concentrations. They are stimulated mainly by substances such as sugars and amino acids to fulfill their energetic and nutritional demands (Baker and Baker, 1975) and are controlled by taste thresholds (Gardener and Gillman, 2002). They are also stimulated by essential oils (Detzel and Wink, 1993) and other volatiles/scents mediated by olfactory sense (Heinrich, 1979). These may be considered as "preingestive stimulants." In a similar manner, some SC, particularly the psychoactive alkaloids in nectar, may act as "postingestive stimulants" mediated possibly by their concentration-specific rewarding (pleasuring) effects on flower visitors. Conceivably, a considerable number of alkaloids in nectar (e.g., nicotine, caffeine, cannabinoids) have both addictive and aversive properties and have not yet been studied in an ecological context. It is a question of considerable interest whether preferential intake of low concentrations of nicotine and caffeine could impose dependence or addiction effects on bees.

(Received December 9, 2004; revised August 16, 2005; accepted September 2, 2005)

Abstract—A comparative chemical analysis of the larval nectar secretions and hemolymph from three unspecifically and facultatively ant-attended lycaenid species (*Polyommatus coridon*, *P. icarus*, and *Zizeeria knysna*) was performed by using high-performance liquid chromatography techniques. Sucrose was the main sugar component in all three species. In half of the samples of *P. coridon*, it was accompanied by glucose, whereas other sugars occurred only rarely. In *P. icarus* and *Z. knysna*, melezitose was the second-most important component, followed by fructose and glucose. Total sugar contents were 43.6 ± 14.8 g/l (mean ± SD) for *P. coridon*, 74.2 g/l for *P. icarus*, and 68.3 ± 22.6 g/l for *Z. knysna*. Up to 14 different identified amino acids were found in *P. coridon* nectar, with a total content of 9.7 ± 3.4 g/l. Leucine was always the major component (contributing 50% of overall amino acid content). Other important amino acids were tyrosine, proline, arginine, and phenylalanine. *P. icarus* nectar contained up to six amino acids with a total content of 1.2 g/l, dominated by tyrosine and phenylalanine. *Z. knysna* nectar contained alanine and proline, with only 0.3 ± 0.17 g/l total content. In the hemolymph of all species, up to 16 different amino acids occurred relatively regularly, with histidine dominating, followed by serine and proline. The amino acid pattern in hemolymph was considerably different from that of the nectar secretions. Larval diet weakly influenced *P. coridon* nectar sugars, and with a semisynthetic diet, a more homogeneous amino acid

* To whom correspondence should be addressed. E-mail: holger.daniels@vv.slu.se

pattern was detected. Comparison with reports from other lycaenid species shows that secretions rich in amino acids are related to intimate, often obligate ant associations, whereas facultative, unspecific myrmecophiles rely on carbohydrates.

Key Words—Lycaenidae, ants, myrmecophily, facultative mutualism, nectar secretion, sugars, amino acids.

INTRODUCTION

Lepidopteran caterpillars are slow-moving insects, with a soft body enclosed in a weakly sclerotized cuticle. Because they accumulate resources for the adult phase of life, they are full of nutrients and an attractive target for predators. Particularly, ants, as the leading terrestrial invertebrate predators, prey on caterpillars unless these are protected by mechanical (e.g., hairiness) or chemical (e.g., deterring or poisonous substances) means. Caterpillars in the butterfly family Lycaenidae provide a remarkable exception because they are either ignored or may even enter into stable associations with these aggressive social insects. More than half of the lycaenid species associate with ants during development (Fiedler, 1991; Pierce et al., 2002). The habit of lycaenid larvae (and many other arthropods) to associate with ants is termed myrmecophily. The intimacy of such associations is defined by the degree of dependence on the ant partner. Species that require specific ants for their survival, as protectors against enemies or as a food source, are obligate myrmecophiles. Species that can thrive with or without ants are facultatively myrmecophilous.

Caterpillar–ant interactions are mediated by several glandular organs (Malicky, 1969; Cottrell, 1984; Kitching and Luke, 1985). Most important for closely ant-associated, nonparasitic lycaenid caterpillars is the dorsal nectar organ (DNO, nomenclature after Cottrell, 1984), a gland situated on the seventh abdominal segment. Upon tactile stimulation of the surroundings of this gland by attendant ants (Malicky, 1969), larvae secrete droplets of an attractive clear fluid (herein called "nectar''). Nectar secretions are essential to induce food recruitment behavior in ants that have found a caterpillar (Fiedler and Maschwitz, 1989), and the importance of a DNO for maintaining stable ant associations is emphasized by comparative data (Kitching and Luke, 1985; Fiedler, 1991).

The delivery of nectar secretions is under the control of the caterpillar. Secretory behavior is finely tuned to the particular circumstances (Leimar and Axén, 1993), and only minute amounts are spent. This is different from ant associations of aphids and other Homoptera, to which Lycaenidae are often compared. Honeydew of aphids is a modified waste product that is excreted in

large amounts. It is easily available for chemical analysis, and its composition is well known for many homopteran species (e.g., Yao and Akimoto, 2002; Blüthgen et al., 2004; Woodring et al., 2004). In contrast, the collection of lycaenid larval nectar secretion is an arduous process (Daniels, 2004), and only a few species have been examined (Nomura et al., 1992; Cushman et al., 1994; Pierce and Nash, 1999). These studies are based on small sample sizes, and usually few quantitative data are reported. Furthermore, apart from two studies (Maschwitz et al., 1975; Wagner, 1994), all others deal with obligate myrmecophilous lycaenids. These larvae secrete comparatively large amounts of nectar, but represent the extreme end of a large range of different degrees of myrmecophily. Only 20% of all lycaenid species worldwide appear to be obligate myrmecophiles. In most geographical regions and phylogenetic lineages, facultative myrmecophiles are far more numerous (Fiedler, 1991, 1998; Pierce et al., 2002). For a better understanding of the evolutionary and functional ecology of butterfly–ant associations, precise data on the quality and quantity of nectar in facultative myrmecophiles are needed. This would also enable testing the hypothesis proposed by Pierce (1987) that more generalized myrmecophiles will secrete carbohydrates, whereas intimate and host-specific myrmecophiles will have a more nitrogen-biased nectar.

Here, the first comparative analysis of the secretions of three facultatively myrmecophilous lycaenid species was undertaken. As the major study organism, one of the most strongly ant-associated species in Europe, *Polyommatus coridon*, was chosen. It occurs in southern and central Europe, and larvae feed on *Hippocrepis* and *Coronilla* species (Fabaceae). A second species, *P. icarus*, has a less intimate ant association, a wider host plant range (various herbaceous Fabaceae), and is distributed throughout the Palearctic region. Finally, *Zizeeria knysna* from Africa and southern Europe was investigated. Its larvae are more polyphagous and have only occasionally been reported to be attended by ants (Fiedler, 1991). Within the subfamily Polyommatini, *P. coridon* and *P. icarus* are closely related representatives of the *Polyommatus* section, whereas *Z. knysna* is a more distant relative in the *Zizeeria* section (Wiemers, 2003). We aimed at answering the following questions:

- What are the nutrient contents of the nectar secretions, and how do these compare to other ant-visited nectar sources?
- To what extent is the nectar composition influenced by the diet that caterpillars consume during their development (cf. Burghardt and Fiedler, 1996)?
- Does the allocation of carbohydrates vs. amino acids differ among lycaenid species in relation to the intimacy of ant associations?
- Does nectar composition reflect phylogenetic relatedness, or ecological similarities, among species?

METHODS AND MATERIAL

Insect Rearing. Caterpillars for nectar samples were raised in captivity under standardized conditions from eggs laid by captive females or from individuals collected as second and third instars in the wild (*P. coridon*). *P. coridon* and *P. icarus* originated from northern Bavaria (vicinity of Bayreuth), and *Z. knysna* originated from Gran Canaria and Fuerteventura. Females were allowed to oviposit on host plants in cages lined with moist cellulose tissue (26:15°C, 75% r.h., 16-hr light/8-hr dark period). Butterfly cultures were maintained in climatic chambers over various generations.

Every 3 d, plant shoots with eggs were transferred to closed transparent plastic boxes (volume 250 or 1000 cm^3, dependent on group size) that were lined with moistened cellulose tissue for optimal humidity. In these boxes, caterpillars were raised at 25°C (16-hr light/8-hr dark) until pupation. *P. coridon* was reared on its two natural host plants [*Hippocrepis comosa*, *Securigera* (*Coronilla*) *varia*] and on a semisynthetic diet (Daniels, 2004; herein called "artificial food''). *P. icarus* and *Z. knysna* were reared on *Medicago sativa* and artificial food.

Sampling and Processing. Single caterpillars were associated in a certain time scheme together with laboratory-reared *Lasius flavus* ants (Daniels, 2004). Secreted droplets were collected with microcapillaries (0.5 µl, Hirschmann). The length of the fluid column obtained was immediately measured with a calibrated micrometer eyepiece (Wild M5A stereomicroscope, 25× magnification), allowing later calculation of the total secretion amount in the (convoluted) samples. Capillaries were immediately dispensed into 50 µl 70% ethanol–millipore–water and rinsed with 70% ethanol–millipore–water. Preliminary measurements showed that evaporation from the viscous fluid column started only after 1 min, so this did not constitute a problem. Although the association procedure allowed a comparatively efficient sampling, secretions were still dispensed only in minute amounts (Daniels, 2004). Thus, most samples had to be pooled from several individuals to achieve a volume amenable to reliable high-performance liquid chromatography (HPLC) analysis (*P. coridon* 4.2 ± 2.1, *P. icarus* 4–10, *Z. knysna* 22.2 ± 13.1 individuals, respectively). Only in *P. coridon* could four samples be obtained from single individual caterpillars. Individuals used to collect a cumulative nectar sample were always taken from the same food treatment. Late fourth instars and still moving prepupae were sampled, as these secrete more nectar than younger instars (Fiedler and Maschwitz, 1989; Burghardt and Fiedler, 1996). With the optimized harvesting method, one complete *P. coridon* sample (volume 0.4–2.0 µl, consisting of ca. 100–600 droplets) required repeated sampling over 1 wk (provided the appropriate instars were available). In *P. icarus* or *Z. knysna*, harvesting similar nectar volumes (0.4–1.3 µl, 300–1500 droplets) took up to 2 mo per sample.

Hemolymph was obtained by punctuating the dorsal vessels of late fourth instars with a sterile insect pin and subsequently collecting the fluids with microcapillaries. All samples were stored at −20°C until analysis.

Chemical Analysis. This was performed by using HPLC. Ethanolic samples were vacuum centrifuged, diluted in pure ion-free water, filtered (Spartan 3/20, 0.45-μm pores, Schleicher & Schuell), and split for separate sugar and amino acid analyses. For sugar investigation, Sentry Guard (3.9 × 150 mm), and Waters carbohydrate (4.6 × 250 mm) columns were used with isocratic 72% acetonitrile solvent at 35°C (Waters 510 pump, flow 1.4 ml min^{-1}). Sugar detection was performed with a refractive index detector (Waters 410).

Amino acid samples were derivatized with borate-buffered 6-amino-quinolyle-*N*-hydroxysuccinimidyle-carbamate. Sentry Guard (3.9 × 150 mm), and Waters AccQtag columns were used with a trinary solvent system (TEA/phosphate buffer with pH 5.5, acetonitrile, and water) at 37°C (Waters 600E pump, flow 1.0 ml min^{-1}). Amino acid detection was performed with a fluorescent detector (Waters 470). Nine carbohydrates (Fluka, Germany) and 17 amino acids (Waters) were used as standards. Tryptophan could not be identified by the derivatization method chosen. Fatty acids and proteins were not determined. Waters Millenium 3.0 software controlled the HPLC and created the respective chromatograms.

Statistical Analysis. Statistical analysis was performed in Statistica 6.0 and Primer v5 (Clarke and Warwick, 2001). If not mentioned otherwise, values are given as mean ± SD. Bonferroni correction, if required, follows Hochberg (1988) and is explicitly noted where applicable. Testing for differences in the coefficient of variation between groups was performed as described by Sokal and Braumann (1980). The principal component analysis (PCA) was calculated with the amino acid spectrum data as proportions of total amino acid content (100%). Two axes were extracted, and rotation procedure adopted was varimax standard. Various other versions of principal component analyses were performed with raw data, with subsamples and extracting more axes, delivering all the same general picture.

RESULTS

Sugar Composition and Concentration. Altogether, nine different sugars were identified in nectar secretions of the three study species (Table 1). Five additional peaks were detected but only one occurred more than twice (retention time 4.92 min, 11 times in 32 *P. coridon* samples).

The carbohydrate content of larval nectars of *P. coridon* caterpillars reared on natural food plants ($N = 23$) consisted mainly of sucrose. In less than half of the samples, sucrose was accompanied by glucose. Arabinose, fructose, maltose,

Symbols indicate sugar and amino concentration: ▼, <10%; ●, 10–50%; ■, >50% (mean percent of total weight of all identified sugars or amino acids, respectively). Open symbols (▽, ○, □) are given for substances that were not present in all samples of a source. Total concentrations as mean ± SD. *N* = number of samples.

trehalose, and lactose occurred rarely and in minor quantities (Table 1). Melezitose was not found in *P. coridon* nectar. Total sugar concentration was 43.55 ± 14.76 g/l. *P. coridon* nectar was neither clearly acidic nor alkaline. The pH value ranged from 5.0 to 8.0 (measurement with pH paper, pH 1–10, Merck).

The larval nectar secretions of *P. icarus* (N = 2, *M. sativa* fed) and *Z. knysna* (N = 8, 3 reared on *M. sativa*, 5 fed with artificial food) caterpillars were similar with regard to sugar content and composition. Main components were sucrose and melezitose, accompanied by fructose and glucose in successively lower concentrations. Additional uncommon sugars were melibiose (in one *P. icarus* sample) and probably erlose (in one *P. icarus* sample and one *Z. knysna* sample, not quantified). Total carbohydrate concentration was 74.2 g/l (median) for *P. icarus* and 68.3 ± 22.6 g/l for *Z. knysna*, respectively.

Trehalose was the dominant sugar in hemolymph, accompanied by a lower quantity of sucrose. Three other sugars were detected (glucose, fructose, and melibiose), each in only one hemolymph sample. Total sugar concentrations in hemolymph were 26.75 g/l (median, N = 3) for *P. coridon*, 33.92 g/l (N = 2) for *P. icarus*, and 13.18 g/l (N = 3) for *Z. knysna* hemolymph.

Amino Acid Composition and Concentration. Up to 14 different identified amino acids were found in the larval nectar secretions of *P. coridon*. Almost half of the overall content was contributed by a single amino acid, leucine (Figure 1). The next most important amino acids were tyrosine, proline, arginine, and phenylalanine. Histidine, methionine, alanine, threonine, isoleucine, and valine occurred in lower quantities, but still regularly (in >50% of all samples). Lysine, serine, and glycine were found occasionally; glutamate was rare and in highly variable quantities. The total amino acid content was 9.68 ± 3.39 g/l (N = 42, all food treatments combined).

Larval nectar of *P. icarus* contained much less amino acids. Tyrosine was the major compound, followed by phenylalanine, arginine, and, in minor quantities, proline, serine, and alanine (Table 1). Total amino acid content was only 1.2 g/l (median N = 2), i.e., roughly one tenth of the total amino acid content of *P. coridon* nectar. In *Z. knysna* nectar, alanine or proline either occurred alone or together, sometimes accompanied by threonine or arginine in low quantities (Table 1). The total amino acid content was lower (0.30 ± 0.17 g/l, N = 6), corresponding to 25% of *P. icarus* and 3% of *P. coridon* total amino acid content.

In hemolymph, up to 16 free amino acids were found, almost all of them regularly (in >75% of all samples). Only tyrosine, glutamate, and asparagine occurred irregularly (Figure 2). The dominant amino acid was histidine, followed by serine and proline. All other amino acids contributed less than 10%. Total amino acid content was high, with an average across all species and samples of 10.81 ± 7.92 g/l. Hemolymph composition was similar in the three

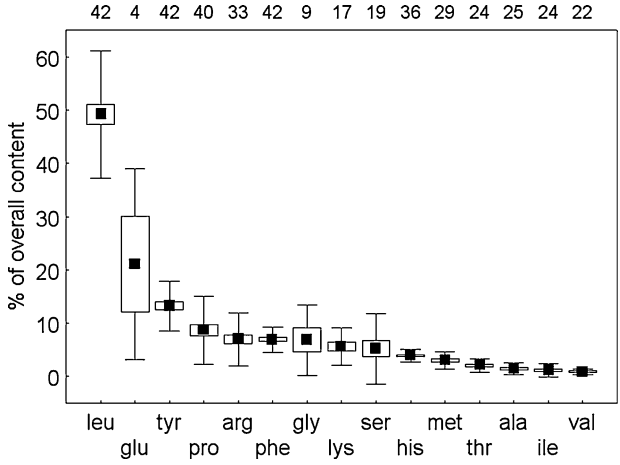

FIG. 1. Mean proportion of overall amino acid content (box: ±SE, whiskers: ±SD) contributed by different amino acids in *P. coridon* larval nectar secretions, ranked after their mean abundance. Figures above the graph denote the number of occurrences of each amino acid in the 42 secretion samples.

species. The pattern of amino acids in hemolymph differed considerably from the patterns found in the secretions. The mean content of the individual amino acids in nectar secretions and hemolymph correlated neither in *P. coridon* (Spearman $R_s = -0.06$, $P = 0.82$, $N = 16$) nor in *Z. knysna* ($R_s = 0.1$, $P = 0.73$, $N = 15$). The main components of hemolymph differed from the main components found in the secretions, as indicated by the arrows in Figure 2 (see also Figure 1 and Table 1).

Differences between Species. Nectar secretions of *Z. knysna* had a higher overall sugar content than *P. coridon* plant-fed caterpillars (Kruskal–Wallis ANOVA, $H_{2,33} = 9.17$, $P = 0.01$, *P. coridon* reared on plants vs. *P. icarus* vs. *Z. knysna*). Conversely, *P. coridon* nectar secretions had a higher content of amino acids ($H_{2,50} = 19.88$, $P < 0.001$), as well as a higher number of different amino acids ($H_{2,52} = 22.76$, $P < 0.001$). The sample size for *P. icarus* nectar secretions was too low to allow for meaningful statistical validation of results, but the pattern follows the same trend as *Z. knysna*.

Hemolymph of *Z. knysna* had a significantly lower overall sugar content than in *P. icarus* ($H_{2,8} = 6.25$, $P = 0.044$). There was neither a difference between the three species for total amino acid content ($H_{2,11} = 0.96$, $P = 0.62$) nor for the number of amino acids in hemolymph ($H_{2,11} = 2.09$, $P = 0.35$).

The Influence of Larval Food. Diet consumed by *P. coridon* caterpillars during their development had minor influence on sugar contents in the se-

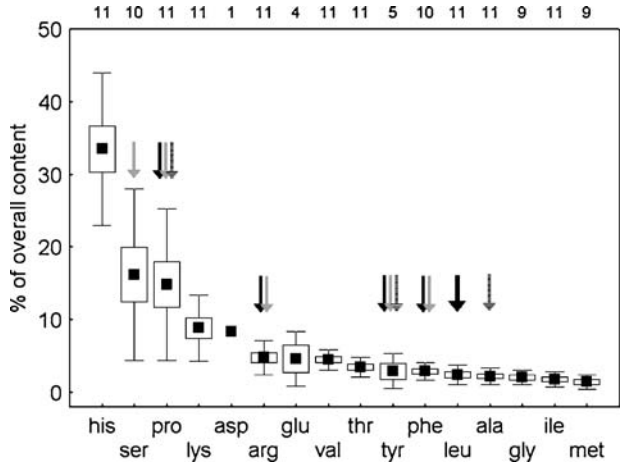

FIG. 2. Mean proportion of overall amino acid content (box: ±SE, whiskers: ±SD) contributed by different amino acids in hemolymph, ranked by their mean abundance. Black arrows indicate the main amino acids found in *P. coridon* nectar, gray arrows the main ones in *P. icarus*, and dashed arrows the main ones in *Z. knysna* nectar. Figures above the graph denote the number of occurrences of each amino acid in 11 hemolymph samples (*P. coridon*: 3 *H. comosa*-fed, 1 artificial food; *P. icarus*: 3 *M. sativa*-fed; *Z. knysna*: 3 *M. sativa*-fed, 1 artificial food).

cretions. Caterpillars fed with artificial diet secreted more sucrose than caterpillars fed with *H. comosa* (one-way ANOVA, $F_{2,29} = 17.78$, $P < 0.001$; Scheffé, $P < 0.001$) and those fed with *S. varia* (Scheffé, $P = 0.005$). The latter secreted as a trend slightly less than those fed with artificial diet (Scheffé, $P = 0.066$). However, concerning total sugar content, the pattern changed. Nectar from caterpillars reared with either *H. comosa* or artificial diet had higher total content than *S. varia* nectar, albeit nonsignificantly (one-way ANOVA, $F_{2,29} = 3.13$, $P = 0.058$). *H. comosa*-fed individuals secreted more often additional sugars (fructose, arabinose, maltose, trehalose; Table 1). For *Z. knysna*, no effects of the larval diet on the sugar contents of the nectar could be detected (Mann–Whitney *U* test, $U_{1,8} = 3$, $P = 0.18$), but because of the small sample size, the power of the test was low. Patterns of carbohydrate contents in *Z. knysna* nectar were similar irrespective of larval food (Table 1).

In *P. coridon*, larval food had no effect on total amino acid content (one-way ANOVA, $F_{2,39} = 1.65$, $P = 0.2$), but did on the number of amino acids in the nectar (one-way ANOVA, $F_{2,39} = 10.23$, $P < 0.001$). Caterpillars reared on *H. comosa* secreted more different amino acids than caterpillars reared on *S. varia* (Scheffé, $P < 0.001$; artificial diet vs. *S. varia*, $P = 0.055$). The amino

acid composition in secretions from *P. coridon* caterpillars fed with artificial diet was significantly more homogenous than in secretions from *H. comosa*-fed individuals (Figure 3; test for differences in the coefficient of variation in the PCA pattern—PC1: $t_{1,21} = 423.38$, $P < 0.001$; PC2: $t_{1,21} = 147.99$, $P < 0.01$). Feeding with *S. varia* caused higher variation in the amino acid profiles than feeding on artificial diet and *H. comosa* (*S. varia* vs. artificial diet—PC1: $t_{1,31} = 424.4$, $P < 0.002$; PC2: $t_{1,31} = 419.8$, $P < 0.002$; *S. varia* vs. *H. comosa*—PC1: $t_{1,32} = 597.65$, $P < 0.002$; PC2: $t_{1,32} = 400.65$, $P < 0.01$).

Comparison of the Amino Acid Profiles. Principal components analysis of the amino acid profiles of nectar and hemolymph revealed a clear pattern (Figure 3). The first two PCA dimensions explained 39.3% of the variance. These axes did not correlate with the acidic or alkaline character or the essentialness of the amino acids. Nectar samples harvested from *P. coridon* formed one large group with no segregation because of larval nutrition [one-way analysis of similarity (ANOSIM): $R_{\text{global}} = -0.012$, $P = 0.54$]. *P. icarus* secretions are relatively similar to those of *P. coridon*, whereas *Z. knysna* forms a separate group (Figure 3), with no further subdivision because of larval nu-

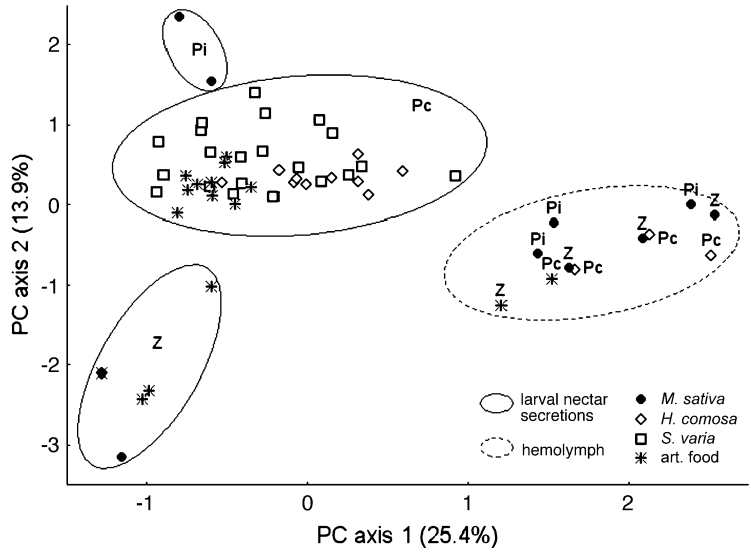

FIG. 3. Ordination of nectar and hemolymph samples from three facultatively myrmecophilous lycaenid species (Pc: *P. coridon*, Pi: *P. icarus*, Z: *Z. knysna*), based on a principle components analysis of amino acid proportions after varimax standard rotation. Caterpillars were reared on four different foods, as denoted in the legend. The contribution of the respective major axes to the explanation of observed variance is shown in parentheses.

trition (one-way ANOSIM: $R_{global} = -0.148$, $P = 0.70$). The secretion amino acid profiles of all species, however, are statistically different [two-way ANOSIM (food treatments nested in species): $R_{global} = 0.987$, $P < 0.001$].

Amino acid composition of hemolymph differs from nectar secretions (one-way ANOSIM: $R_{global} = 0.554$, $P < 0.001$) and is similar for all three species (one-way ANOSIM: $R_{global} = -0.173$, $P = 0.93$).

DISCUSSION

Myrmecophilous lycaenid butterfly larvae foster ant associations through nectar secretion. Here we report on how the precise composition may vary along with a number of factors, and how this correlates with the strength of myrmecophilous associations. Of main interest is the finding that nectar from one species, the strongly facultative myrmecophilous *P. coridon*, has highly elevated amino acid concentrations. As the closely related *P. icarus*, as well as *Z. knysna*, have low amino acid levels, this seems to point toward an overriding influence of the degree of myrmecophily on nectar composition. This is further corroborated by our finding that neither different diets nor hemolymph composition could explain the nectar composition, pointing toward a genetically determined function of the gland in composing nectar secretion. Phylogenetic relatedness seems to be less important than the degree of myrmecophily, as the differences in *P. coridon* and *P. icarus* nectar illustrate. The amino acid content of *P. coridon* secretion is greater than in almost any other alternative source, be it honeydew (Bernays and Klein, 2002; Yao and Akimoto, 2002; Woodring et al., 2004), floral or extrafloral nectars (e.g., Baker and Baker, 1986; Blüthgen et al., 2004), or other lycaenids (Table 2). This suggests an important role of amino acids in the formation of a strong association and supports Pierce's (1987) hypothesis and corroborates findings on other strongly myrmecophilous lycaenid species (DeVries and Baker, 1989; Nomura et al., 1992; Cushman et al., 1994; Table 2).

Nectar of the weaker myrmecophilous *P. icarus* and *Z. knysna* nectar may contain slightly more sugar than *P. coridon* nectar, yet these are still depauperate compared with aphid honeydew (Woodring et al., 2004) and plant nectar (e.g., Baker and Baker, 1986; Blüthgen et al., 2004). *P. icarus* nectar was at least similar to these sources in amino acid content, though. Both *P. icarus* and *Z. knysna* nectars also contained the sugar melezitose. This trisaccharide is commonly found in aphid honeydew (e.g., Hendrix et al., 1992; Blüthgen et al., 2004), probably serving osmoregulatory functions in the gut (Wilkinson et al., 1997). These are presumably not required in the lycaenid nectar gland with its own chitinized reservoir (Malicky, 1969). Melezitose is preferred by a number

of ant species (Völkl et al., 1999; Tinti and Nofre, 2001), although not universally (Cornelius et al., 1996; Blüthgen and Fiedler, 2004; Daniels, 2004). The presence of melezitose uniquely in these two weaker myrmecophilous lycaenids may function to advertise a resource, which is valuable for ants in the normal trophobiotic context. This would circumvent predation and would assure more ant attendance for these lycaenids. In contrast, the more costly amino acids in *P. coridon* nectar secure a unique niche among nectar producers and afford a stronger ant association.

Although the data do support Pierce's (1987) hypothesis, variations and exceptions exist. Total amino acid content in the nectar of the strongly, but facultatively myrmecophilous *P. coridon* is the highest value reported so far for lycaenid species, only surpassed by the riodinid *Thisbe irenea* (DeVries and Baker, 1989; Table 2). Sugar content in the *P. coridon* nectar is comparable with the values reported for the ant-parasitic *Niphanda fusca* (Nomura et al., 1992; but see Chogyoji in Wada et al., 2001). The sugar content in the nectar of the two facultatives *P. icarus* and *Z. knysna* is similar to the nectar of the obligate *Jalmenus evagoras* (Pierce, 1983; Pierce and Nash, 1999; Table 2). Nevertheless, from our analyses and the few values reported in the literature, a pattern emerges. Nectar of myrmecophilous lycaenid species contains about 5–10% sugar, with the possible exception of the Australian obligate ant-mutualist *Paralucia aurifera* (Cushman et al., 1994; Table 2). In all lycaenid and riodinid species analyzed thus far, the main sugar components are uniformly either sucrose or glucose (Table 2). The amino acid content of nectar, in contrast, seems to be determined by the intimacy of associations with attendant ants, more strongly myrmecophilous species providing a richer and more diverse mixture. There are differences among the species with regard to the main nectar amino acids: serine in *J. evagoras*, glycine in *N. fusca*, glycine, glutamine in the riodinid *T. irenea*, and leucine in *P. coridon*. In all facultative myrmecophiles considered here, serine and glycine were not significant, in contradiction to the notion of Yao and Akimoto (2002) who proposed a universally important role for these two amino acids in myrmecophilous insect–ant interactions. One potential explanation for the differences between lycaenid species regarding identity of the leading amino acid as well as contents could be that nectars are specifically tuned to match the gustatory preferences of the major ant visitors. However, only *J. evagoras* (with a few *Iridomyrmex* species) and *N. fusca* (with *Camponotus japonicus*) are host-specific myrmecophiles. In contrast, ant visitors of the numerous facultatively myrmecophilous species are unpredictable. Preferences for amino acids vary tremendously across ant species (Lanza and Krauss, 1984; Kay, 2002) and also have a conditional component (Blüthgen and Fiedler, 2004). Ultimately, preferences of particular ant species for nectar secretions, and, thus, the success of lycaenid larvae in initiating a lasting association, have to be tested experimentally for each combination of

partner species. For facultatively myrmecophilous lycaenid species with their unpredictable ant associates, it is impossible to present an ideal secretion equally attractive to all possible visiting ant species. In general, more strongly associated species can nevertheless use (rich) mixtures of amino acids as currency in the interaction, whereas the weaker associated species cash in on sugar. Further nectar analyses over the whole range of lycaenid myrmecophily would certainly be desirable to corroborate or challenge this pattern.

In addition, further study is required on how diet influences nectar secretion. We could find only minor effects in our study. Several other plant diets tested for *P. icarus* and *Z. knysna* did not yield sufficient nectar for analysis. Whether this was an artifact in our experiments or was caused by suboptimal growth or an inherent property of certain host plants remains to be tested, but would certainly be a significant factor in ant association (compare Burghardt and Fiedler, 1996).

Acknowledgments—We are grateful to Hans Malchus for technical assistance with the HPLC. The district government of Oberfranken kindly issued permits to collect individuals in the field for starting of laboratory populations. Dr. Klaus G. Schurian provided *Z. knysna* larvae from the Canary Islands, and Annick Servant contributed to rearing of *P. icarus* and *Z. knysna* caterpillars. Teun Dekker, Stefan Dötterl, Robert Wiedemann, and Wiltrud Daniels provided helpful comments on the manuscript. This study was conducted at the University of Bayreuth, supported by a scholarship within the Graduate College 678 of the Deutsche Forschungsgemeinschaft.

(Received February 23, 2005; revised July 22, 2005; accepted August 7, 2005)

Abstract—The polyphenol contents and compositions in desiccated leaves of *Myrothamnus flabellifolius* plants collected in various locations in Namibia and South Africa were analyzed using UV spectroscopy and high-performance liquid chromatography–mass spectrometry. A study of the genetic relatedness of these populations was also performed by determination of the DNA sequence of the intergenic spacer region between the *psbA* and the *trnH* genes in the chloroplast genome. Namibian *M. flabellifolius* plants contained significantly more polyphenols than South African plants. Namibian plants essentially contained a single polyphenol, 3,4,5-tri-*O*-galloylquinic acid, whereas South African plants contained a variety of galloylquinic acids including 3,4,5-tri-*O*-galloylquinic acid together with higher molecular weight galloylquinic acids. Sequence analysis revealed a 1.4% divergence between Namibian and South African plants corresponding to the separation of these populations of approximately 4×10^6 years. The significance of the polyphenol content and composition to the desiccation tolerance of the two populations is discussed.

Key Words—Polyphenol, mass spectrometry, Myrothamnaceae.

INTRODUCTION

Resurrection plants are a unique group of plants, the majority of which occur in southern Africa, capable of surviving dehydration to an air-dried state (Gaff, 1971, 1977). The resurrection plant, *Myrothamnus flabellifolius*, is a woody shrub with a widespread distribution throughout southern Africa (Kruger, 1998), where it grows in shallow, well-drained crevices in sandstone and in granite outcrops (Child, 1960; Mauve, 1966). Populations of *M. flabellifolius* occur along the west coast of Namibia, in central southern Zimbabwe, and in north-eastern South Africa (see Glen et al., 1999 for a general distribution map). This region experiences high summer temperatures and irradiance, with extremes of water availability (Mauve, 1966). Growing conditions on the rocky outcrops are such that the plants must sometimes survive for a year or more in a dry quiescent state, rehydrating only after summer rainfall (Farrant and Kruger, 2001). In attempting to elucidate the "resurrection" mechanism, we recently noted an extremely high polyphenol content in the leaves of this plant, with the main polyphenol present in plants collected in Namibia determined to be 3,4,5-tri-*O*-galloylquinic acid. In addition, we demonstrated that 3,4,5-tri-*O*-galloylquinic acid was able to protect membranes against desiccation and oxidation damage (Moore et al., 2005). The Namibian and the Zimbabwean/South African populations of *M. flabellifolius* are not only separated by the Kalahari Desert (Puff, 1978; Glen et al., 1999), but these two populations also occur in different biomes, with the Namibian population occurring in a dry Karoo biome and the Zimbabwean/South African population occurring in a moist savannah biome (Sinclair et al., 2002). In this report, we have investigated whether the Zimbabwean/South African population of *M. flabellifolius* also has high concentrations of 3,4,5-tri-*O*-galloylquinic acid present in the leaves. Because this population was found to have a different polyphenolic profile from plants collected in Namibia, we also investigated the genetic variation between the two populations based on nucleotide sequence comparisons of regions of the chloroplast genome.

METHODS AND MATERIALS

Plant Material. Desiccated plant material was obtained from populations in Namibia (N1–N5), namely, the Komas Hochland, near the Cunene River, and around Outjo, as well as from populations in South Africa (S1–S4), namely, Vaalwater in the Limpopo Province, near Lydenberg, and the Blouberg Mountains, Mpumalanga Province (see Figure 1 for a map of the region). The dry leaf material was stored at 20°C in the laboratory until use.

Polyphenol Extraction, HPLC Analysis, and Mass Spectrometry. Phenolic extraction was performed by homogenizing leaf material for 5 min in MeOH/

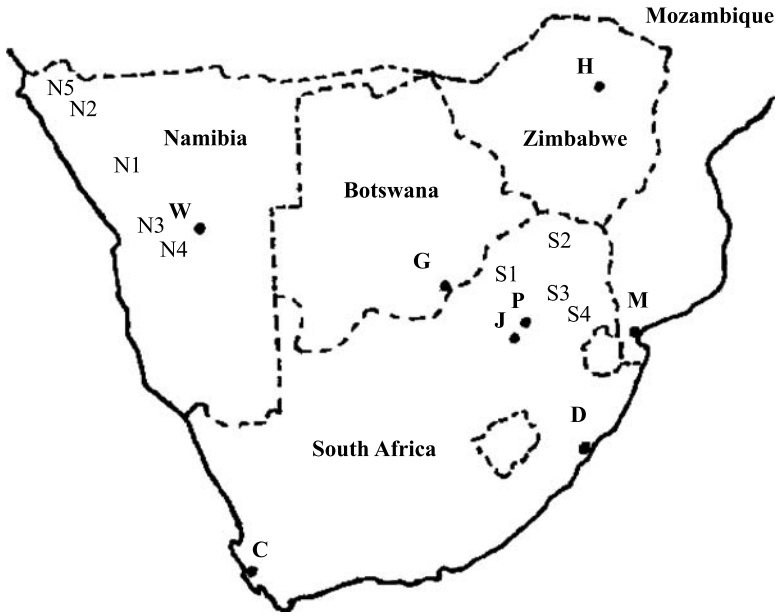

FIG. 1. Map of Southern Africa showing international borders. Major towns are shown as single letters—C: Cape Town; D: Durban; G: Gaberone; H: Harare; J: Johannesburg; M: Maputo; P: Pretoria; W: Windhoek. Collection sites in Namibia (N1–N5) were Outjo (N1), the Komas Hochland (N3 and N4), and near the Cunene River (N2 and N5). Collection sites in South Africa (S1–S4) were Vaalwater (S1), the Blouberg Mountains (S2), and near Lydenberg (S3 and S4).

H_2O (7:3, v/v) using a Polytron Homogenizer (Kinematica PT 2000). The homogenate was then subjected to sonication (Bandelin Sonorex bath sonicator) for 5 min, after which it was centrifuged (6000 × *g* for 5 min). The pellet was twice re-extracted using 3 volumes solvent per mass of sample. The supernatants were pooled, and the spectrum between 200 and 400 nm was determined. The polyphenol content was determined from the UV absorption at 280 nm using the previously measured molar extinction coefficient of 3,4,5-tri-*O*-galloylquinic acid of 21,000 (Altmann and Falk, 1995). Data reported are the mean ± standard deviation of three plants from each population analyzed in duplicate. Means were compared using a Student's *t* test with the level of significance set at $\alpha = 0.05$ (Microsoft Excel).

A 20-µl aliquot of the supernatant was subjected to analytical high-performance liquid chromatography (HPLC), performed on a Shimadzu LC-10A binary gradient system equipped with Photo-Diode Array detection (Shimadzu, Kyoto, Japan; Moore et al., 2005). Fractions were eluted from a

Jones chromatography RP-C18 (250 × 4 mm) column using a linear gradient between TFA/H_2O (1:1000, v/v) and TFA/acetonitrile (1:1000, v/v) over 40 min at a flow rate of 0.7 ml/min. MALDI-TOF mass spectra were obtained on a Perseptive Biosystems DE-PRO MALDI mass spectrometer equipped with a TOF analyzer (Perseptive Biosystems, Framingham, MA, USA). A 1-μl sample aliquot was dissolved in acetonitrile : water (1:1), mixed with 1 μl 2,5-dihydroxybenzoic acid matrix, and applied to a gold sample plate. The mixture was air-dried prior to use. The spectrometer was operated in positive and negative ion mode.

DNA Extraction, PCR Amplification, Purification, and Sequencing. Leaf material was frozen, lyophilized, and ground in a mortar using liquid nitrogen prior to DNA extraction. Total DNA was extracted using a modified CTAB DNA extraction protocol (Gawel and Jarret, 1991). The standard CTAB buffer was supplemented with 20 mg poly-(1-vinyl-pyrrolidine-2) (PVP; Merck, Darmstadt, Germany) and 1 ml of 2-mercaptoethanol : H_2O (1:1000, vol : vol; Gawel and Jarret, 1991). DNA purity was assessed using the A_{260}/A_{280} ratio and by agarose gel electrophoresis. The polymerase chain reaction (PCR) reaction mixture consisted of SuperTherm buffer, 0.025 U SuperTherm *Taq* polymerase, 5 mM $MgCl_2$, 0.1 mM dNTP, 0.33 μM each of the forward and reverse primers, and 3 μl template DNA in a total volume of 30 μl. The amplification program consisted of 95°C for 2 min, 30 cycles of 95°C for 1 min, 52°C for 1 min, and 72°C for 2 min with a final extension of 72°C for 7 min. The forward and reverse primers were 5′GTTATGCATGAACGTAATGCTC3′ and 5′CGCGCATGGTGGATTCACAAATC3′, respectively. PCR reactions were supplemented with various amounts of soluble PVP (Merck) to reverse polyphenol inhibition (Koonjul et al., 1999). Amplified products were purified using a QIAquick PCR purification kit (Qiagen, Hilden, Germany). Product quantity and purity were estimated using agarose gel electrophoresis. Purified products were sequenced on a MegaBACE 1030 sequencer (Amersham BioSciences, Amersham, UK). DNA sequences were edited using Chromas 2.01 software (Technelysium PtyLtd., Helensvale, Queensland, AU). Alignment of sequences was performed using DNAMAN (Lynnon Corporation, Vaudreuil-Dorion, Quebec, CA) and MegAlign 3.08 software (DNASTAR, Madison, WI, USA).

RESULTS

We initially quantified the total leaf polyphenol content from plants collected in Namibia and in South Africa. Leaf material from each population was exhaustively extracted in MeOH/H_2O (7:3, vol : vol), and the polyphenol content was determined from the UV absorption at 280 nm. A significant difference in the total mean polyphenol content was observed between plants

TABLE 1. PERCENTAGE POLYPHENOL CONTENT IN DESICCATED LEAVES OF PLANTS COLLECTED FROM VARIOUS LOCATIONS IN NAMIBIA (N1–N5) AND SOUTH AFRICA (S1–S4)

Namibian locations	% Polyphenol content[a]	South African locations	% Polyphenol content
N1 Outjo	41.7 ± 6.7	S1 Limpopo	26.7 ± 0.7
N2 Cunene	30.1 ± 5.2	S2 Blouberg	21.7 ± 5.3
N3 Komas Hochland	28.3 ± 1.3	S3 Lydenberg	25.3 ± 4.6
N4 Komas Hochland	32.7 ± 6.7	S4 Lydenberg	22.9 ± 1.0
N5 Cunene	30.9 ± 0.1		
Average	32.7 ± 5.2	Average	24.4 ± 2.2

[a]Polyphenol content is expressed in 3,4,5-tri-*O*-galloylquinic acid equivalents in % g polyphenol per g dry weight. A minimum of three plants from each population was analyzed in duplicate. The data are expressed as the mean ± standard deviation; $P < 0.05$.

from Namibia and from South Africa. Plants collected in Namibia contained 32.7 ± 5.2% in contrast to plants collected in South Africa, which contained 24.4 ± 2.2% (Table 1, $P < 0.05$).

HPLC analysis of the extracted polyphenols was performed to determine whether South African *M. flabellifolius* plants contained the same polyphenol species as Namibian plants. The chromatograms obtained (Figure 2) revealed distinct compositional differences, the major difference being an abundance of a single polyphenol in Namibian plants (Moore et al., 2005). In contrast, South African plants contained a wide variety of different polyphenols. The main polyphenol present in leaves of Namibian plants (peak 1, Figure 2A) was ascribed to 3,4,5-tri-*O*-galloylquinic acid (Moore et al., 2005) and confirmed by mass spectrometry of the extract; this yielded a mass of 647 Da. The remaining phenolic peaks (peaks 2 and 3) in the chromatogram represented gallic and ellagic acid esters of 3,4,5-tri-*O*-galloylquinic acid. These assignments were made after mass spectrometry of the material eluting in these peaks yielded masses that varied from one another by an integral mass of either 152 Da, the mass addition of one extra galloyl group to the core molecule, or 298 Da, the mass addition of one extra ellagic acid moiety to the parent structure. A mass of 799 Da was found for the material eluting in peak 2 and a range of masses, namely, 799, 936, 953, 1570, and 1722 Da for that in peak 3. These latter masses were assigned to represent tetra-, penta-, nona-, and decagalloylquinate esters (Moore et al., 2005). In contrast, HPLC analysis of polyphenols extracted from leaves of South African *M. flabellifolius* showed that no single polyphenol was present in abundance. Instead, a variety of polyphenols were present, some of which were identical to those present in Namibian plants, but the majority of which eluted with longer retention times (Figure 2B). In general, there was a relationship between the molecular weight of the polyphenol and the HPLC retention time (Table 2). Fractions 1, 2, and 3 from South African plants had

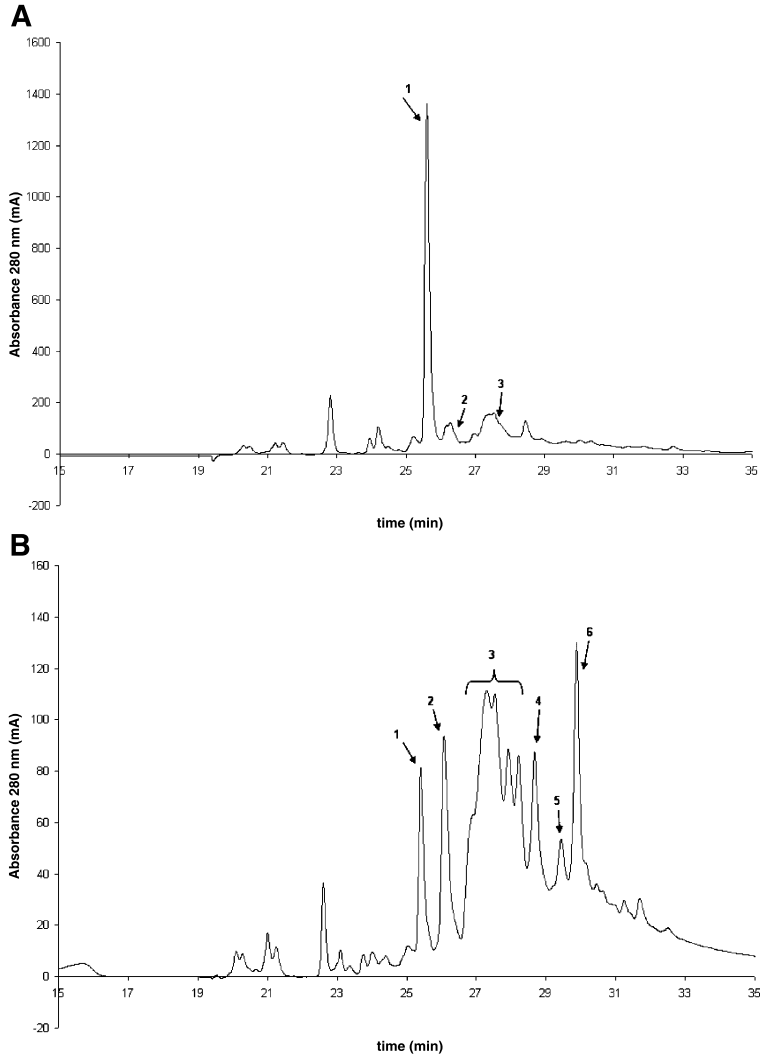

FIG. 2. High-performance liquid chromatography (HPLC) chromatograms of polyphenols extracted from leaves of *M. flabellifolius* collected in (A) Namibia and (B) South Africa and separated on a C_{18} column using a linear gradient between TFA/H_2O and TFA/acetonitrile as described in text. Fractions were pooled and lyophilized prior to analysis. The absorbance is shown in milliabsorbance units (mA). Note that the ordinate scale for (B) is 10^{-1} times of that shown in (A).

similar polyphenols as the same fractions from Namibian plants. Polyphenols that eluted in fractions 4–6 were unique to South African plants (Figure 3). As expected, the polyphenols in the later eluting fractions had higher masses, brought about by the addition of either gallic acid or ellagic acid moieties to the core molecule, 3,4,5-tri-*O*-galloylquinic acid (Table 2). A range of masses between *m*/*z* 636 and 2203 was evident; other masses present, e.g., 1322 Da, could be ascribed to the fragmentation of one of these parent molecules. Peaks displaying masses of 1874, 2054, and 2203 Da represent novel octa-, nona-, and decagalloylquinate ester molecules (assuming 3,4,5-tri-*O*-galloylquinic acid as the core molecule), respectively, each with the addition of a single ellagic acid moiety. These species were only found to be present in South African plants (Figure 2; Table 2). The final major peak eluting after approximately 30 min displayed masses of 882, 939, 1088, and 1322 Da. The mass of 1088 Da represents a hexagalloylquinic acid that was not found in plants collected in Namibia. We observed no change in galloylquinate ester composition between desiccated and hydrated plants (data not shown).

Because the two *M. flabellifolius* populations have distinct differences in their polyphenol content and composition, we investigated their genetic relatedness. The intergenic spacer region between *psbA* (photosynthetic subunit A)

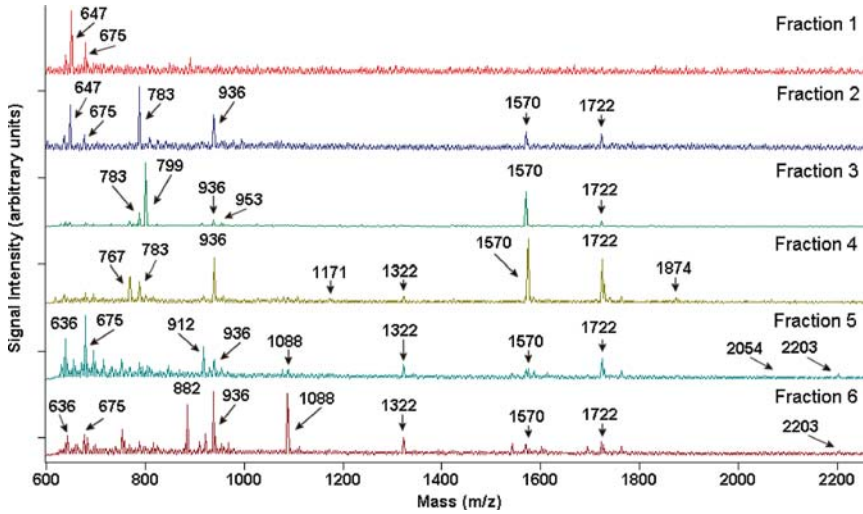

FIG. 3. Mass spectral analysis of HPLC fractions containing polyphenols extracted from leaves of *M. flabellifolius* collected in South Africa. Note that the ordinate scale is in arbitrary units and varies from fraction to fraction depending on the amount of material present.

and *trnH* (histidine amino acid biosynthesis) on the chloroplast genome was chosen. This region has been shown to evolve at a rate suitable for assaying population level differences (Aldrich et al., 1988; Sang et al., 1997). An approximately 400-bp fragment was consistently amplified from DNA extracts of both populations. Sequence analysis revealed that this fragment represented 288 bp of the intergenic spacer region with the remaining sequence derived from the 3′ and 5′ ends of *psbA* and *trnH*, respectively (Figure 4). The DNA

FIG. 4. Chloroplast DNA sequence from leaves of *M. flabellifolius* representing the 3′ end of *psbA*, the intergenic spacer, and the 5′ end of *trnH* from plants collected in South Africa (S) and Namibia (N). Arrows denote the 3′ end of *psbA* and the 5′ end of *trnH*, respectively.

sequence of this region was identical for all plants collected from South Africa, but distinct from plants collected from Namibia, all of which displayed an identical sequence. Alignment of the 288-bp intergenic sequences obtained from all samples revealed four consistent differences between plants from South Africa and from Namibia. These differences occurred at positions 88, 154, 176, and 221 in the intergenic spacer, and represented a sequence divergence of 1.4% between the two populations. We also observed an insertion of 12 bp in *psbA* from all plants collected in Namibia (Figure 4).

The genus *Myrothamnus* is distantly related to the genus *Melianthus*, which has been proposed to have diverged from its sister group *Greyia* at a mutation rate of 0.0035 substitution per site per 10^6 years (Henning, 2003). Assuming an equal mutation rate, a divergence rate of 0.014 substitution per site yields a time of divergence for the Namibian and South African *M. flabellifolius* populations of approximately 4×10^6 years.

DISCUSSION

This work reports that the Namibian and South African populations of *M. flabellifolius* have distinct differences in their polyphenol content and composition. Whereas plants collected in Namibia essentially contained a single polyphenol, 3,4,5-tri-*O*-galloylquinic acid, South African plants contained a mixture of polyphenols that were derivatives of this molecule. Although both the Namibian and South African populations occur in similar geological environments, the rainfall patterns of the regions in which these populations occur are very different. South African plants grow in a region that experiences dry winters and regular annual summer rainfall. In contrast, Namibian plants grow in a more arid region of dry winters and irregular summer rainfall patterns. Farrant and Kruger (2001) reported that South African *M. flabellifolius* plants are only capable of surviving 9 months in a desiccated state. Whereas South African plants must only survive the dry winter months, Namibian plants must be capable of surviving not only a dry winter but also the ensuing dry summer and the following dry winter. In this instance, "dry" means that no rainfall whatsoever is experienced. Anecdotal evidence suggests that Namibian *M. flabellifolius* plants are capable of surviving for extended periods (3 or more years) in a quiescent state. We propose that the presence of the single polyphenol 3,4,5-tri-*O*-galloylquinic acid contributes toward this degree of desiccation tolerance. In support of this hypothesis, Moore et al. (2005) demonstrated that 3,4,5-tri-*O*-galloylquinic acid protects membranes against desiccation-induced damage as well as against free radical-induced oxidation.

M. flabellifolius in Africa south of the Sahara was originally divided on morphological grounds into three subspecies, namely, *M. flabellifolius sensu*

stricto, *elongata*, and *robusta*, the latter only occurring north of the Zambesi River in Zambia and Mozambique (Weimarck, 1936). A later revision resulted in the abandonment of *M. flabellifolius elongata* as a subspecies because of it being indistinguishable from *M. flabellifolius sensu stricto* (Puff, 1978). Because polyphenols do not display rapid turnover during plant growth and metabolism (Boudet et al., 1985; Haslam and Lilley, 1985), these molecules serve as useful chemotaxonomic markers for studies of plant systematics and evolution. Our data, therefore, suggest a new division of *M. flabellifolius* based on the phenolic compounds. This division would correlate with the biogeography of the species. We propose that there are two distinct populations on either side of the Kalahari Desert, respectively. This hypothesis is supported by the genetic data presented here that show that plants collected in Namibia were genetically identical and distinct from plants collected in South Africa, which were also genetically identical. The 1.4% genetic variation within the *psbA*/*trnH* intergenic region corresponds to a time of divergence of approximately 4 million years. This figure correlates with the climate change that occurred approximately 5 million years ago when the Karoo region along the western part of southern Africa changed from a wet to an arid region (Klak et al., 2004). Our hypothesis is that this climate change resulted in a requirement for Namibian population of *M. flabellifolius* to remain in a quiescent state for extended periods. The separation of the two populations by over 1000 km of desert presumably prevented cross-pollination and wind dispersal of the seeds (Child, 1960), resulting in two separate populations. Current research is focused on the relationship between the polyphenol content and the ability of Namibian plants to survive in a quiescent state.

(Received March 11, 2005; revised August 12, 2005; accepted September 2, 2005)

Abstract—Larvae of the pipevine swallowtail, *Battus philenor*, feed on plants in the genus *Aristolochia*, which contains aristolochic acids, toxic alkaloids unique to the Aristolochiaceae. Pipevine swallowtails sequester these compounds and, as a consequence, are chemically defended against many natural enemies. In California, the primary aristolochic acid present in the butterfly is aristolochic acid I. Newly eclosed adult females possess greater amounts of these sequestered toxins compared to males. However, over the course of the flight season, the aristolochic acid content of females in the population declines, whereas male aristolochic acid content remains relatively constant. Transference of sequestered aristolochic acids to eggs by females might explain the decline of these sequestered chemical defenses observed over time. We found no evidence that males transfer aristolochic acids to females via the spermatophore. The possibility that females at the end of the flight season may be automimics of males is discussed. Temporal variation in the aristolochic acid defenses exhibited by this pipevine swallowtail population is both age- and sex-dependent.

Key Words—Aristolochic acid, chemical defense, sequestration, phenological variation, pipevine swallowtail, *Battus philenor*, automimicry.

INTRODUCTION

Many phytophagous insects, such as some Lepidoptera, sequester plant toxins that they use for their own chemical defense (Nishida, 2002). Plant-derived chemical defenses of insects are known to vary geographically and temporally. Geographic and temporal variation in sequestered chemical defense can reflect intra- and interspecific variability in the amount and types of toxins provided by host plants (Nelson et al., 1981; Urzua and Priestap, 1985; Ritland, 1994), phenological shifts in host use patterns (Malcolm and Brower, 1989; Malcolm et al., 1989; Moranz and Brower, 1998), or changes in plant toxicity over time (Nelson et al., 1981; Fordyce, 2000). Additionally, the quantity and quality of sequestered chemical defenses can vary over the life span of an individual. For example, (Alonso-Mejía and Brower 1994) showed that the concentration of cardiac glycosides in the monarch butterfly, *Danaus plexippus*, decreases as the animal ages. Variation in chemical defense may affect the defensive efficacy of sequestered plant compounds and can potentially affect inter- and intraspecific mimicry relationships (Malcolm and Brower, 1989; Alonso-Mejía and Brower, 1994; Ritland, 1994; Moranz and Brower, 1998; Fordyce, 2001).

Variation in toxicity might also reflect differences in sequestration ability between the sexes; adult female butterflies often contain higher concentrations of sequestered toxins (Dixon et al., 1978; Rothschild et al., 1979; Alonso-Mejía and Brower, 1994; Sime et al., 2000). Transference of specific sequestered compounds to mates, such as pyrrolizidine alkaloids found in the spermatophore of some arctiids (Gonzalez et al., 1999) and danaids (Dussourd et al., 1989), might also result in the sex-specific decline of sequestered compounds following successive matings. Similarly, female transmission of sequestrates to eggs (Nishida and Fukami, 1989; Sime et al., 2000) may result in a substantial loss of these compounds following multiple oviposition events. Here, we examine this possibility by assessing sex-dependent loss of sequestered toxins over time in the spring brood of the pipevine swallowtail, *Battus philenor* L. (Papilionidae, Troidini), in California.

Like all members of its genus, *B. philenor* is a specialist on plants in the genus *Aristolochia* (Aristolochiaceae) (Racheli and Pariset, 1992), commonly called pipevines. The *Aristolochia* contain nitrophenanthrene carboxylic acids called aristolochic acids, which are unique to the Aristolochiaceae (Chen and Zhu, 1987). *B. philenor* sequester these toxins as larvae; adults have no means of obtaining these compounds. The presence of aristolochic acids render larvae and adults unpalatable to many invertebrate and vertebrate predators (Brower, 1958; Codella and Lederhouse, 1989; Uesugi, 1996; Fordyce, 2001). As a consequence, *B. philenor* is an effective model for many mimetic butterfly species, including *Papilio troilus*, *P. polyxenes*, *P. glaucus* (Papilionidae), *Limenitis astyanax*, and *Speyeria diana* (Nymphalidae) (Brower, 1958; Brower and

Brower, 1962; Platt et al., 1971; Jeffords et al., 1979; Codella and Lederhouse, 1989). Aristolochic acids are present on the eggs of *B. philenor* (Sime et al., 2000), presumably conferring some defensive benefit to their clutch (Brower, 1984). In California, there is only one naturally occurring host plant available for *B. philenor*, *Aristolochia californica*, an endemic liana characteristic of riparian habitats in the northern Central Valley and surrounding foothills of the Coast Range and Sierra Nevada mountains. There are at least two broods of *B. philenor* in California. The largest brood occurs in the spring following pupal diapause, with maximum densities of adult butterflies and larvae occurring between late March and early May. Later broods occur at much lower densities and larvae are rarely observed after May.

This study focused on the large, spring brood of *B. philenor*. We examined whether aristolochic acids present in the butterflies change over time as the butterflies age, mate, and lay eggs. We predicted that changes in male and female aristolochic acids over time should differ as a result of parental investment of sequestrates. However, we did not have an *a priori* expectation as to what sex might show a decline in aristolochic acids, because the origin of these toxins coating the eggs, whether donated in the spermatophore or directly from the female, was heretofore unknown. Additionally, we examined differences in aristolochic acids in newly eclosed males and females to assess sex-related differences in the amount of these sequestered compounds.

METHODS AND MATERIALS

Butterfly Samples. Captive reared butterflies were used to assess differences in aristolochic acid sequestration between the sexes. In the spring of 2002, eggs were collected in the field from naturally laid clutches. One egg from each of 67 naturally laid clutches was placed in a common cage and fed fresh, field-collected *A. californica* as needed. Field-collected plants were provided to larvae within 24 hr of collection, and replaced with fresh material within 72 hr. During the third instar, larvae were haphazardly dispersed among separate containers consisting of groups of 5–7 individuals and were continually fed fresh *A. californica* until pupation. Larvae and pupae were maintained under ambient photoperiod between 21 and 27°C. Emergence following diapause occurred between March and June of 2003. Butterflies were collected within 24 hr after eclosion, after they had expelled meconium and their wings had hardened. Butterflies were stored in glassine envelopes at −20°C until chemical extraction and analysis. Differences between males and females in total aristolochic acid content and concentration were determined using a *t*-test.

To examine phenological changes in aristolochic acid content, wild adult *B. philenor* were collected in March through May, 2000–2003 ($N = 76$). This period corresponds to the first brood following winter pupal diapause. To ensure that collection was restricted to the first brood, two independent lines of evidence were used to estimate *B. philenor* phenology. First, naturally laid clutches were monitored in the field to assess the development of larvae. Second, captive larvae, reared from eggs collected in the beginning of the flight season, were monitored in the laboratory until pupation. All butterflies included in this study were collected before ultimate instars in the field were observed pupating, and before the laboratory-reared caterpillars pupated.

Butterflies were stored in glassine envelopes at −20°C until chemical extraction and analysis. All were collected adjacent to, or at Stebbins Cold Canyon Ecological Reserve (Solano Co.), part of the University of California Natural Reserve System. Phenological changes in aristolochic acid content were determined using an ANCOVA, with day of capture, sex, year, and all interactions included in the model. To account for among-year variation in emergence date, which can be influenced by climatic variation, we used a phenological date based on the first day *B. philenor* was observed in the field. All aristolochic acid data were log-transformed prior to statistical analysis to meet the assumption of normality.

Additionally, we explored the possibility that variation in adult aristolochic acid content might be a consequence of reproductive life history, specifically female transference of aristolochic acid to the eggs and male transference of aristolochic acid via the spermatophore. We obtained seven recently mated female *B. philenor* from a population in Knox County, TN, USA; including one captive reared female that was mated in captivity. The exact time since mating of the wild-caught females was unknown; however, based on physical condition, they appeared to be newly eclosed, and their corpus bursa was swollen with a spermatophore. Older females and unmated females have a conspicuously smaller corpus bursa. The corpus bursa, each containing a spermatophore, and all ova were removed from each female by dissection. Aristolochic acids were extracted from each corpus bursa ($N = 7$), unfertilized ova ($N = 45$), and laid eggs ($N = 18$) as described above.

Extraction Procedure. Butterflies were dried under reduced pressure prior to extraction, and weighed to the nearest milligram. Each entire butterfly was placed in a 15-ml centrifuge tube, homogenized in 5 ml of hexane, and sonicated for 20 min at 50°C to remove fat. Samples were centrifuged, and the fat-containing hexane was removed. This procedure was repeated once to ensure fat removal from each sample. Analysis of a subset of the hexane extracts indicated that no aristolochic acids were present. Defatted butterfly tissue was extracted two times with 5 ml of 100% ethanol and sonicated for 30 min at 50°C. The ethanol extract was dried under reduced pressure in a test tube

leaving a yellow residue. The residue from entire butterfly samples was resuspended in 0.5 ml of 100% methanol and passed through a 0.45-μm filter into an autosampler vial for high-performance liquid chromatography (HPLC) analysis. The residue from the corpus bursa, ova, and laid eggs was resuspended in 0.03 ml of 100% methanol.

HPLC Procedure. Sample analyses were performed using a Waters Alliance HPLC system with a 2996 diode array detector and Empower Pro Software. Each injection was 10 μl eluted isocratically with a mixture of methanol, water, and 1% acetic acid (52:47:1) at a rate of 1 ml/min on a Symmetry® C-18 reverse phase column (3.5 μm, 4.6 × 75 mm) (Waters Corp.). Aristolochic acid content was determined using retention time and absorption spectra compared to known standards.

A mixture of aristolochic acid (AA)-I and AA-II was obtained from Sigma Chemical. These are the primary aristolochic acid constituents of California *B. philenor* and *A. californica* (Fordyce, 2000). The aristolochic acids provided in this mixture were separated and isolated through successive HPLC runs using a sample fractioner. These fractions were dried and weighed (in μg) and separate standard curves based on a dilution series were generated for AA-I and AA-II. Aristolochic acids were quantified by absorbance at two separate wavelengths, 320 nm for AA-I and 248 nm for AA-II.

RESULTS

The aristolochic acid content of newly eclosed, captive-reared butterflies differed between the sexes. Females ($N = 32$) sequestered more aristolochic acids than males ($N = 26$), measured both as concentration ($t = 5.130$, $df = 56$, $P < 0.001$, Figure 1a) and total aristolochic acids ($t = 3.736$, $df = 56$, $P < 0.001$, Figure 1b). All captive reared butterflies emerged between March 21 and May 23 (except one female that emerged on September 25). We explored the possibility that time of emergence might explain variation in aristolochic acid content by using an ANCOVA that included emergence date, sex, and the interaction in the model. We found no effect of date of emergence ($F_{1,53} = 0.046$, $P = 0.832$), or its interaction with sex ($F_{1,53} = 0.771$, $P = 0.384$), on total aristolochic acid content. Excluding the single late emerging female from the analysis did not alter the conclusion. Analysis of aristolochic acid concentration gave the same qualitative results (not shown).

The dominant aristolochic acid found in our samples was AA-I, consistent with previous examinations of *B. philenor* aristolochic acid chemistry (Fordyce, 2000; Sime et al., 2000). AA-1 constituted over 90% of the total aristolochic acids present. On average, field-collected individuals had 22.01 ± 3.13 μg

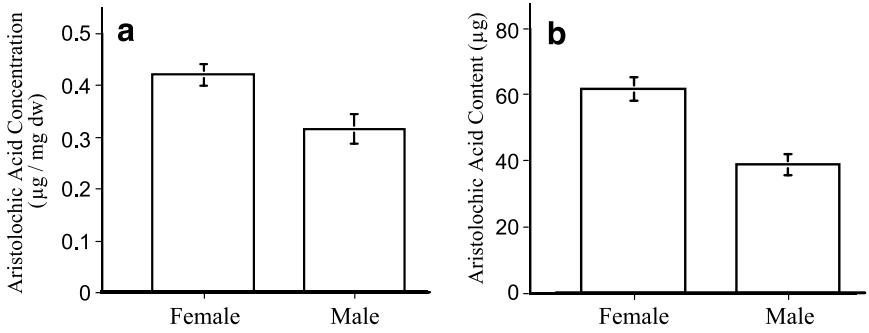

FIG. 1. The difference between male and female *B. philenor* aristolochic acid concentration (a) and total aristolochic acid content (b). Sexes are significantly different at $\alpha < 0.05$ for both measures of aristolochic acid content. Error bars are ±1 SE.

(mean ± SE) of AA-I, and only 1.55 ± 0.24 μg (mean ± SE) of AA-II. Based upon the absorbance spectra of another peak, AA-Ia might also be present in some of the butterflies.

Aristolochic acid content of *B. philenor* declined in population over the course of the flight season. This decline was evident when measured as total amount (Table 1) and amount per mg dry weight (Table 2). Both of these analyses showed that loss of aristolochic acids over time differed between sexes, indicated by the significant interaction term. Subsequent regressions for each sex indicated that females showed a greater decline over time compared to males. Only butterflies captured in 2001 and 2002 could be included in the full ANCOVA model because low numbers of females captured in 2000 and 2003 resulted in insufficient degrees of freedom. Phenological date was used to adjust for among-year variation in emergence date, although using Julian date gives the same qualitative answer based on these analyses. Figure 2 shows the change

in total aristolochic acids over time for each sex and includes all individuals collected for this study, including the years excluded from the ANCOVA model.

The results of ANCOVA on total aristolochic acids are more straightforward in interpretation than the analysis on aristolochic acid concentration, which has multiple significant interaction terms. This is likely a consequence of

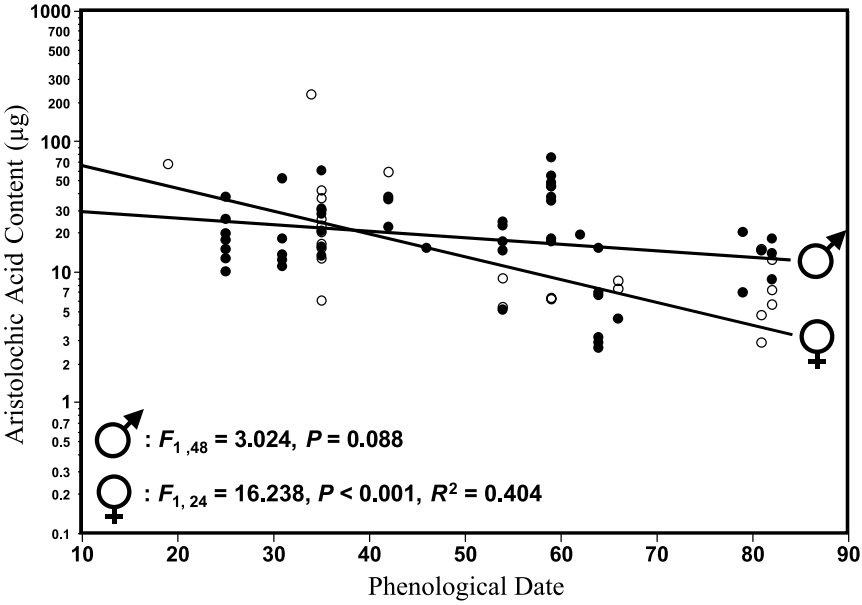

FIG. 2. Change in total aristolochic acid content observed in *B. philenor* sexes over phenological time. Open circles indicate females and solid circles indicate males. Log scale for aristolochic acid content.

the nature of concentrations, which can be affected by changes in the numerator (total amount of aristolochic acids) or the denominator (dry weight) for each individual. A model including dry weight as the response variable indicated that females lose significantly more weight (dry weight) over the course of the flight season compared to males (phenological date × sex: $F_{1,55} = 6.085$, $P = 0.017$).

We found no evidence that males transfer a substantial amount of aristolochic acids to females during mating. The average amount of aristolochic acids found in the corpus bursa, which contained a spermatophore, was 0.300 μg (range: 0.082–0.727 μg). The average aristolochic content of laid eggs was 0.452 μg (range: 0.002–0.951 μg) and unfertilized ova dissected from females was 0.224 μg (range: 0.008–0.415 μg). Thus, the total amount of aristolochic acids associated with the spermatophore was comparable to that found in a single egg.

DISCUSSION

The greater amounts of sequestered aristolochic acids detected in females compared to males at eclosion is consistent with previous analyses of *B. philenor* from other populations (Sime et al., 2000) and other butterfly species sequestering toxic plant chemicals (Dixon et al., 1978; Rothschild et al., 1979; Alonso-Mejía and Brower, 1994). There are two, not necessarily mutually exclusive, explanations for this phenomenon. First, female *B. philenor* adults and pupae weigh more than males (Fordyce, unpublished data), presumably because of their required reproductive investment in egg production. Females might accumulate greater amounts of aristolochic acids if prolonged larval feeding is required to obtain greater mass. Alternatively, females may possess a greater ability for sequestering aristolochic acids.

Females transfer aristolochic acids to their eggs. We found no evidence that males donate a substantial quantity of aristolochic acids to females via the spermatophore. In fact, our analyses indicate that the total amount of aristolochic acids associated with the spermatophore is comparable to that of a single egg. The greater quantities found in newly eclosed females may be a consequence of selection favoring efficient sequestration of these compounds by the female, thus providing her eggs with adequate chemical defenses. Females exhibited a significant decline in aristolochic acids over the course of the flight season, further supporting the hypothesis that the source of egg aristolochic acids is the female. If males were donating significant amounts of these compounds, we would expect them to show a similar decline in aristolochic acids over time. The general effectiveness of egg aristolochic acids as defenses against natural enemies is not known, however, and ants have been frequently observed as predators on *B. philenor* eggs in California (Fordyce, personal

observations). The eggs of *B. philenor* are orange, generally regarded as aposematic, and in California are laid in clusters (Fordyce, 2003). The effectiveness of egg chemical defenses might be enhanced when eggs are laid in clusters; egg clustering is frequently observed in species with toxic, warningly colored eggs (Stamp, 1980; Brower, 1984).

It is important to consider that the phenological change in aristolochic acid content indicated here was observed at the population level. Although *B. philenor* larvae were monitored in the laboratory and in the field until pupation as a means to avoid collecting wild adults from a second brood, the exact age of field-collected butterflies was unknown. It is likely that none of the females collected in May had emerged in early March. We have no estimates for adult longevity in the field, although captive individuals can survive up to 4 wk. However, it is likely that individuals collected late in the flight season are, overall, older than individuals collected early in the season. The time, specifically the order, of eclosion in captive reared butterflies did not explain the variation in aristolochic acid content, nor did it explain the phenological changes in toxicity observed between males and females. Further investigation is required to determine if the observed decline in female toxicity is unequivocally due solely to egg transference, or if female metabolism might also be involved. In general, however, females emerge with higher levels of aristolochic acids than males, but by the end of the flight season males are the more toxic sex observed in the population.

Although *B. philenor* is generally regarded as unpalatable to predators (Brower, 1958), there exists variation among individuals and populations in their acceptability and toxicity to predators (Codella and Lederhouse, 1989). Variation in butterfly toxicity likely reflects variation in aristolochic acid content of host plants, which can vary substantially within and among individual plants and, thus, directly affect butterfly chemical defense (Fordyce, 2001), in addition to the age-associated decline in toxicity observed in this study. Throughout most of its range, *B. philenor* is an effective model in Batesian mimicry complexes (Platt et al., 1971; Jeffords et al., 1979). However, there are no mimics in California. The absence more likely reflects the recent arrival of *B. philenor* to California (Fordyce and Nice, 2003), rather than its palatability (Codella and Lederhouse, 1989; Fordyce, 2000). The substantial decline in female toxicity over time might have important implications in regard to intersexual mimetic relationships, where females possibly become automimics. The development of automimicry as adults lose sequestered defenses over time, or as a consequence of phenological host shifts, has been suggested for *Danaus gilippus* (Ritland, 1994; Moranz and Brower, 1998) and *D. plexippus* (Alonso-Mejía and Brower, 1994). Unlike the examples in the danaines, where both sexes lose chemical defenses as they age (Alonso-Mejía and Brower, 1994), only female *B. philenor* show a decline in chemical defense over time. For

California *B. philenor*, males might function as the effective, honest signal for deterring predators as the females become less toxic over the course of the flight season.

Females showed a decline in toxicity measured as both total amount of aristolochic acids present, and as a measure of concentration. The relative importance of each of these measures as it relates to chemical defense will undoubtedly depend on how a predator samples the butterflies. Beak marks on the wings of butterflies are traditionally construed as evidence of bird rejection following tasting the presence of noxious compounds in the wings (Brower, 1984; but see Kassarov, 1999). Regardless of whether beak marks are a consequence of rejection or escape, if such a small volume of butterfly tissue is to be an effective signal to predators, the concentration of chemical defenses will be important. If, however, predators consume the entire butterfly, the total amount of chemical defenses may be more relevant than the concentration alone, unless there is a dilution effect associated with the biomass of the prey. Regardless of which measure of the amount of chemical defenses is most biologically relevant, both measures of aristolochic acid chemistry declined over time in female *B. philenor* included in this study.

The phenological variation observed for *B. philenor* in California indicates that determining the average amount of sequestered toxins present in the population is sensitive to the time at which individuals are collected. Similarly, determining the difference in aristolochic acid content between males and females is sensitive to the age at which individuals are examined. Female *B. philenor* begin the flight season containing more aristolochic acids. However, by the end of the season, they contain substantially less of these plant derived toxins and, thus, may be less chemically defended against natural enemies compared to males.

(Received May 4, 2005; revised August 26, 2005; accepted September 1, 2005)

Abstract—Calcium tartrate crystals were observed in the midgut of grape leafhoppers. This unique compound was found for the first time in insects. The size of the crystals varied strongly between and within individuals with a mean length of 153 ± 87 μm and a mean width of 71 ± 46 μm. In addition, the number of crystals per individual showed a broad variation and ranged from 1 to 150 crystals/individual. The occurrence of calcium tartrate crystals as well as the number of crystals per individual followed the same seasonal pattern as seasonal vine leaf concentrations of tartaric acid found in a previous study, indicating that calcium tartrate is formed to neutralize the tartaric acid in the gut system. It further implies that the grape leafhopper, rather than being a pure phloem sucker, employs a mixed feeding strategy to satisfy its demands for calcium uptake.

Key Words—Calcium tartrate crystals, midgut, grape leafhopper, *Empoasca vitis*.

INTRODUCTION

Various insects contain crystalline structures such as calcium oxalate or calcium urate that are predominantly found in the Malpighian tubules (Clark, 1958; Teigler et al., 1972; Wigglesworth, 1965). In particular, the urine of plant-feeding caterpillars is loaded with granules and crystals of calcium carbonate and calcium oxalate (Wigglesworth, 1965) that are derived from the diet (Takahashi et al., 1969; Teigler et al., 1972) and are thought to either bind and eliminate excess calcium (Clark, 1958; Teigler et al., 1972) or, in the case of calcium oxalate, to neutralize and eliminate the oxalic acid (Wigglesworth, 1965). However, some caterpillars, e.g., the sphinx moth *Pergesa elpenor*, feed exclusively on plants containing calcium oxalate raphides that are passed unchanged through the digestive tract (Clark, 1958).

Storage of calcium oxalate has been found in the fat body of *Phytomyza* sp. and *Bombyx mori* (Clark, 1958) and calcium urate in specialized urate cells in the fat body of hymenopteran larvae and cockroaches (Dettner and Peters, 1999). Calcium salts have also been reported in the eggs of various insects adding to the rigidity of the shell. Ito (1924) reported calcium oxalate crystals embedded in the eggshell of the cockroach that were produced in the left accessory gland of the females. Calcium citrate crystals that derive from the ventral body wall gland were found adhering to the ootheca of the praying mantis (Parker and Rudall, 1955).

A different type of crystalline structures called brochosomes has been reported in the Malpighian tubules of some leafhoppers consisting mainly of protein and lipids (Rakitov, 2002). The minute dodecahedral crystals are secreted and spread over the body with the hind legs, thus serving as a water repellent (Vidano and Arzone, 1984; Rakitov, 2002).

The grape leafhopper *Empoasca vitis* is an ubiquitous polyphagous phloem sucker (Vidano, 1963, 1967) that reproduces on vine. It overwinters as an adult on evergreens such as yew and spruce (Cerutti et al., 1991, personal observation). In early spring, the grape leafhopper feeds on a variety of host plants (Cerutti et al., 1991). Shortly after bud burst of the vines, it invades the vineyards and deposits its eggs in the veins of the vine leaves (Böll and Herrmann, 2004a). At the beginning of flowering, the first leafhopper larvae emerge, passing through five instar stages before they turn into adults. In contrast to most other German wine regions, in Franconia, only one generation of grape leafhoppers is produced each year (Böll and Herrmann, 2004b). The majority of the leafhoppers of the new generation leave the vineyards to feed on a broad variety of woody host plants before they retreat to overwintering sites in autumn (Cerutti et al., 1991).

In this paper, we report that grape leafhoppers (*E. vitis*) were found to carry translucent crystals in the midgut (Figure 1).

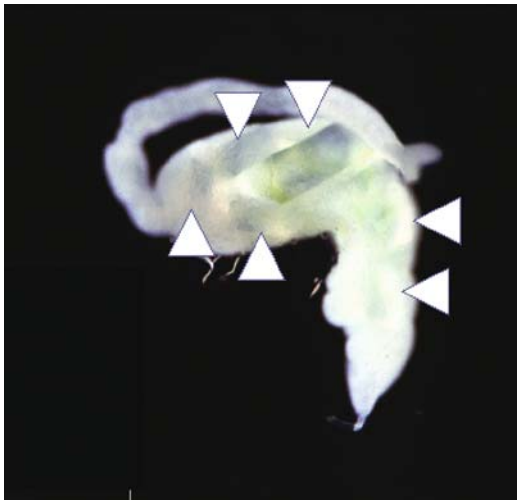

FIG. 1. Isolated midgut of a grape leafhopper packed with calcium tartrate crystals (see arrows).

METHODS AND MATERIALS

Sampling. In 2002 and 2003, grape leafhoppers were collected at least once per month, except for April and May 2002, when no collections were made. From July to October 2002 and May to December 2003, collections were taken on a weekly basis. For this purpose, overwintering sites as yew and spruce (during winter), various shrub and deciduous plant species (during spring and autumn), and vines (during the vegetation period) were beaten, and their specimens were caught in a funnel-shaped scooping net. All sampled specimens were killed either with CO_2 and dissected immediately thereafter or by deep-freezing, in which case dissections took place one to several days later. Abdominal preparations were carried out in 70% alcohol under a stereomicroscope (Leica M420) at a magnification rate of 60×. The sex of each specimen was determined by genital preparations. If present, crystals were extracted from the midgut, counted, and subsequently stored in 70% alcohol. Altogether, in 2002, 981 and in 2003, 756 specimens, respectively, were dissected. Captures with less than five specimens of either sex or developmental stage were not included in the analysis.

The length and width of 100 crystals from six grape leafhoppers were measured under a stereomicroscope (Leica M420) at a magnification rate of 60× to the nearest micrometer.

Crystal Structure Analysis by HPLC-MS. Analyses were performed on a triple-stage quadrupole TSQ 7000 liquid chromatography–tandem mass spectrometry (MS/MS) system (Finnigan MAT, Bremen, Germany). Data acquisition and data evaluation were carried out on a Personal DEC station 5000/33 (Digital Equipment, Unterföhring) and ICIS 8.1 software (Finnigan MAT). The data of the product ion spectra were collected within a mass range between 20 and 180 units. For high-performance liquid chromatography (HPLC), an Applied Biosystems dual syringe pump model 140B (BAI, Bensheim) was used. Crystals from dissected specimens and from purchased (+)-calcium L-tartrate dihydrate (Sigma, Taufkirchen) were dissolved in water, and 10 µl were directly injected [loop–electrospray ionization (ESI)–MS/MS] using 50% 5 mM NH_4Ac in H_2O (LiCrosolv, Merck, Darmstadt, Germany) and 50% MeCN (LiCrosolv, Merck) as mobile phase. ESI in negative mode was used. The temperature of the heated capillary was set to 230°C, and the capillary voltage was set to 3.4 kV. Nitrogen served both as sheath (60 psi) and auxiliary gas (10 l/min).

Crystal Structure Analysis by X-Ray Diffraction. Several crystals isolated from grape leafhoppers were investigated by X-ray diffraction. Each crystal was mounted in inert oil (perfluoroalkylether, ABCR) on a glass fiber and transferred to the cold nitrogen stream of the diffractometer (Stoe-IPDS, graphite-monochromated MoKα-radiation, λ = 0.71073 Å, T = 243 K). The structure was solved (program SHELXS; Sheldrick, 1990) and refined (program SHELXL97; Sheldrick, 1990, 1997) except for the position of hydrogen atoms.

RESULTS

Crystal Structure Analysis by HPLC-MS. The HPLC-MS data of diluted crystals from the leafhoppers were compared with the data from purchased Ca-tartrate. The product ion mass spectra in negative ion mode showed identical fragments for both m/z 149 $[M]^-$; m/z 105 $[M - CO_2]^-$, 87 $[M - CO_2–H_2O]^-$, 73, 59, 43. The anion was identified as tartrate.

Crystal Structure Analysis by X-Ray Diffraction. $C_4H_4O_6Ca{\cdot}4H_2O$, colorless translucent block, size 0.05 × 0.05 × 0.07 mm, orthorhombic, space group $P2_12_12_1$ (no. 19), a = 9.2141(18), b = 9.6434(19), c = 10.589(2) Å, V = 940.9(3) $Å^3$, Z = 4, $F_{(000)}$ = 528, μ = 0.708, $\rho_{(calc)}$ = 1.808 g/cm^3, 9846 refls. (R_{int} = 0.16), $-12 < h < 11$, $-13 < k < 13$, $-14 < l < 14$, completeness: 98.5%, 2509 independent refln, $1834 > 2\sigma_{(I)}$, 145 params., 3 restraints, GooF 0.958, Flack param. 0.12(8), largest difference peak and hole: 0.59/−0.75 e/$Å^3$, $R_{1(obs)}$ = 0.0627, $R_{1(all)}$ = 0.088.

The crystals were identified as Ca-tartrate $C_4H_4O_6Ca{\cdot}4H_2O$ (Figure 2), the structure of which is already known (Boese and Heinemann, 1993). The Flack parameter 0.12(8) obtained in the refinement of the model indicates that the

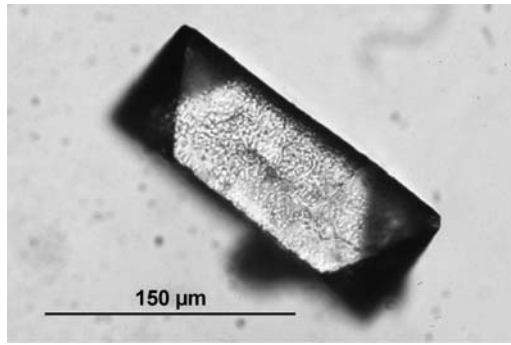

FIG. 2. Calcium tartrate crystal isolated from the midgut of a grape leafhopper.

tartrate crystal investigated is of the normal configuration (2R,3R), provided it is an enantiomerically pure crystal (Flack and Bernadinelli, 2000).

Seasonal Occurrence of Calcium Tartrate Crystals in Grape Leafhoppers. In 2002, calcium tartrate crystals were found in the midgut of grape leafhoppers from July through October, whereas in 2003, crystals already appeared in May, but ceased abruptly in September (Figure 3). In this exceptionally hot and dry

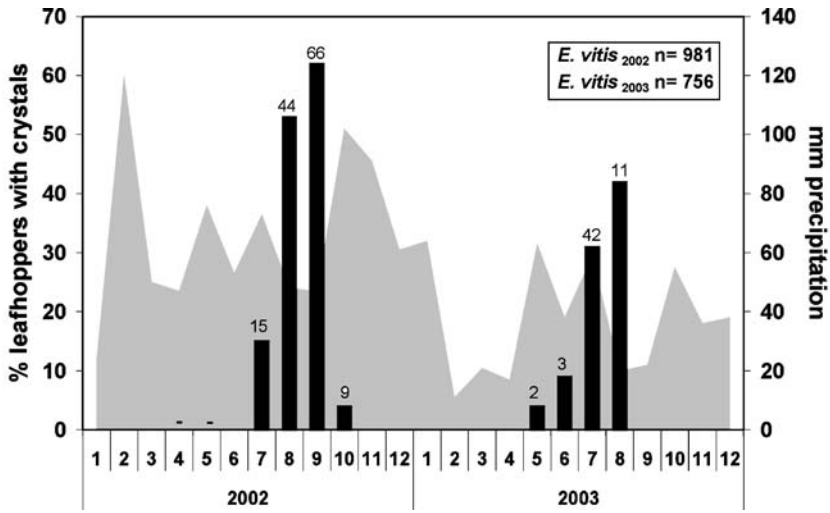

FIG. 3. Percentage of adult grape leafhoppers with calcium tartrate crystals during the seasons 2002 and 2003. The shaded area shows the rainfall pattern over the two seasons. –: No collections were carried out.

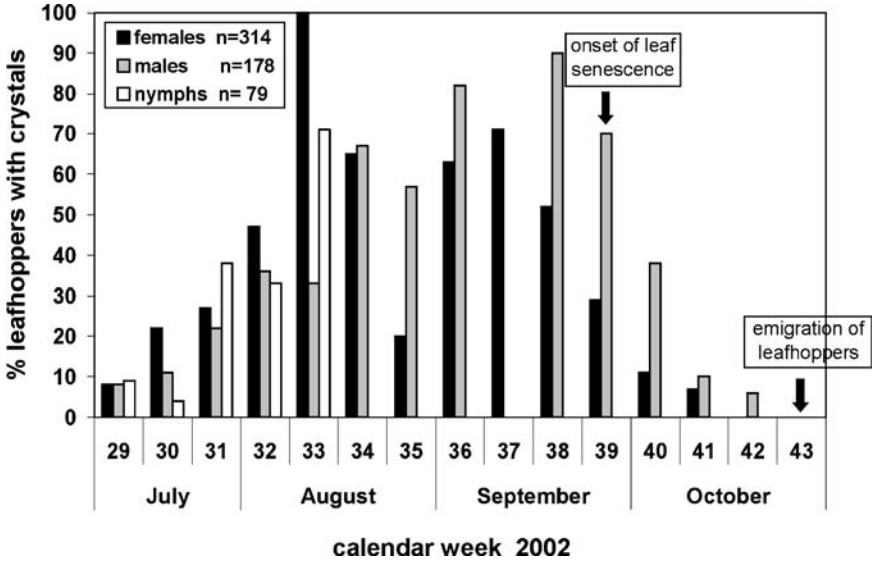

FIG. 4. Percentage of grape leafhoppers with calcium tartrate crystals during July–October 2002.

summer, the grape leafhopper left the vineyard earlier than usual at the end of August. Crystals were found in males as well as in females and nymphs (Figure 4). The percentage of leafhoppers showing crystals rose steadily during both vegetation periods, but dropped with the beginning senescence of vine leaves, and went to zero after the emigration of the leafhoppers (Figures 3 and 4). Following the same pattern, the number of crystals found in the gut per individual varied over the season and ranged from 1 to 150 crystals/individual. The size of the crystals varied greatly between and within grape leafhoppers (Table 1), with a total mean length of 153 ± SD = 87 μm and a mean width of 71 ± SD = 46 μm (range:

TABLE 1. CRYSTAL SIZE RANGE

Analyzed no. of crystals/ total no. of crystals/ individual	Length of crystal (μm), mean ± SD	Width of crystal (μm), mean ± SD
8/9	186 ± 144	72 ± 34
14/31	163 ± 40	83 ± 24
11/20	155 ± 69	71 ± 24
12/16	188 ± 81	74 ± 27
18/38	185 ± 100	68 ± 45
37/48	114 ± 74	56 ± 33

length 50–563 μm, width 25–225 μm, $N = 100$). In comparison, the abdomen of the grape leafhopper had a mean length of 1168 ± SD = 158 μm and a mean width of 568 ± SD = 62 μm ($N = 10$).

DISCUSSION

Translucent crystals occurring in the midgut of grape leafhoppers were identified as L-(+)-calcium tartrate. This is the first report of this compound in insects. Whereas other calcium salts such as calcium carbonate, calcium urate, or calcium oxalate that have been observed in a variety of insects usually occur in the Malpighian tubules, the calcium tartrate crystals were found in the midgut of the grape leafhopper. Only in rare cases, e.g., in *B. mori* (Waku and Sumimoto, 1971) and the fulgorid *Pyrops candelaria* (Ammar, 1985), has an accumulation of calcium salts been observed in the midgut of insects.

The functional significance of the temporary accumulation of large amounts of calcium tartrate crystals in the grape leafhopper has yet to be determined. As this species overwinters as an adult on evergreens exposed to harsh temperatures, calcium tartrate could serve as an antifreezing agent. However, this is unlikely as alcohols, such as glycerol, sorbitol, or trehalose, usually serve this purpose in insects (Dettner and Peters, 1999). In addition, no calcium tartrate was found in grape leafhoppers once they had left the vineyards to retreat to overwintering sites. Another possible function of the sequestration of calcium tartrate might be chemical defense. However, calcium tartrate is neither a particular toxic substance nor does it belong to the predominant compound groups that play a role in chemical defense in insects, such as terpenes, fatty acid derivates, aromatic compounds, or alkaloids (Dettner and Peters, 1999).

Alternatively, the observed calcium tartrate crystals in the grape leafhopper might simply result from passive accumulation of this compound, as it seems to follow the seasonal pattern of tartaric acid concentrations in the vine leaves. Calcium tartrate crystals were not observed in the midgut of grape leafhoppers until several weeks after migration to the vineyard, when tartrate concentrations in the vine leaves start to increase (Kliewer, 1966). With further increase of tartrate concentrations in the leaves during continued vegetation growth and ripening of the vine (Kliewer, 1966), the percentage of leafhoppers carrying crystals increased as well. This was accompanied by a continuous calcium tartrate accumulation in the midgut of the leafhoppers that can be densely packed with up to 150 crystals per leafhopper. The crystals, varying greatly in size even within individuals, can reach huge dimensions attaining lengths that are equivalent to the width of the abdomen of the leafhopper. At the onset of the senescence of the vine leaves, when tartrate concentrations in the leaves drop (Kliewer, 1966), the presence of crystals as well as the number of crystals per

leafhopper declined accordingly. During overwintering and spring migration, no crystals were found in the midgut of grape leafhoppers.

Occurrence of tartaric acid in higher plants is relatively rare; nevertheless, in the vine, this substance usually represents quantitatively the most important component within the acid pool of leaves and berries (Kliewer, 1966; Ruffner, 1982). The physiological function of the tartaric acid is not completely understood, although, at least in part, it serves as a calcium-binding agent. The vine has a high uptake of calcium that accumulates in the leaves during the vegetation period, particularly in the tips. Calcium tartrate is stored in crystalline form in specialized large cells, known as idioblasts, that are located in intercostal sections of the leaves with the highest density in the serrated tips (Ruffner, 1982).

In the grape leafhopper, the situation is rather the reverse. Generally considered as a pure phloem sucker as described by Vidano (1963, 1967), it has to cope with increasing tartrate concentrations in the leaves until the senescence of the leaves sets in. Calcium uptake poses a problem. As calcium is transported in the xylem, phloem-feeding hemiptera are usually in short supply of calcium (Raven, 1983). Thus, the grape leafhopper might not produce calcium tartrate crystals to bind an excess of calcium, as is the case with the vine, but rather to neutralize the relatively strong tartaric acid in the gut system. The stabilization of the pH in the midgut might be a prerequisite particularly for the nymphs of *E. vitis* to be able to feed exclusively on vine as a host plant.

The question then remains how *E. vitis* accomplishes a sufficient intake of calcium. Mixed feeding of closely related leafhopper species is known. Hunter and Backus (1989) have shown that the closely related sister species *Empoasca fabae*, which was also thought to be a pure phloem sucker, feeds as well on the mesophyll. Furthermore, mixed phloem and mesophyll feeding has been found in *Empoasca decipiens* (Günthardt and Wanner, 1981). All *Empoasca* species so far studied that cause hopperburn on the host plant employ the same feeding behavior of multiple cell laceration, which leads to a mixed diet (Backus et al., 2005). Likewise, *E. vitis*, a typical hopperburn species, might not be a pure phloem sucker as hitherto thought. On the contrary, the presence of calcium tartrate crystals in the midgut during the summer as well as the observed greenish color of the midgut (Figure 1) suggests strongly that the grape leafhopper employs a mixed feeding strategy that enables it to satisfy its calcium demands for neutralizing tartaric acid accumulations in the gut system. However, to determine the exact nature of the feeding behavior of *E. vitis*, electronic penetration graph monitoring should be employed (Backus et al., 2005).

Acknowledgments—We thank Michael Kraus for evaluating the HPLC-MS data and Mareike Niethammer for measuring the size of the crystals. We also thank two anonymous referees for constructive comments on the manuscript. This work was in part supported by the Bavarian Ministry for Agriculture and Forestry (grant A/02/08).

(Received May 17, 2005; revised June 30, 2005; accepted July 26, 2005)

Abstract—The milfoil weevil *Euhrychiopsis lecontei* is a specialist aquatic herbivore that feeds, oviposits, and mates on the invasive freshwater macrophyte *Myriophyllum spicatum*. We characterized the weevil's preference for *M. spicatum*, and through bioassay-driven fractionation, isolated and identified two chemicals released by *M. spicatum* that attract *E. lecontei*. Mass spectrometry and nuclear magnetic resonance spectroscopy were used to identify the attractive compounds as glycerol and uracil. Dose-response curves for glycerol and uracil indicated that weevil preference increased as sample concentration increased. Weevils were attracted to a crude sample of *M. spicatum*-released chemicals from 0.17 to 17 mg/l, to glycerol from 18 to 1800 μM (0.0017–0.17 mg/l), and to uracil from 0.015 to 15 μM (0.00014–1.4 mg/l). Although glycerol and uracil are ubiquitous, weevils are likely responding to high concentrations that are released as a result of the rapid growth of *M. spicatum*. Uracil concentration was greater in the exudates of *M. spicatum* than other *Myriophyllum* spp. *E. lecontei* was attracted to glycerol at a concentration similar to that at which terrestrial insects are attracted to sugar alcohols. This is the first example of a freshwater specialist insect being attracted to chemicals released by its host plant. Analysis of the water milfoil–weevil interaction provides further understanding as to how insects locate their host plants in aquatic systems.

Key Words—Freshwater macrophyte, host location, *Myriophyllum spicatum*, *Euhrychiopsis lecontei*, specialist herbivore, chemical attractant, aquatic plant–herbivore interactions.

INTRODUCTION

Plants produce and release chemicals that can be used by herbivores to locate mates, food sources, and oviposition sites. There is a great variety of compounds that attract terrestrial insects, including ubiquitous chemicals such as ethanol, hexanal, and sugars, as well as species-specific chemicals, such as polyphenols and isothiocyanates (Metcalf and Metcalf, 1992; Bernays and Chapman, 1994). Some ubiquitous chemicals, such as sugars, are nutrients that act as phagostimulants (Chapman, 2003). Common volatiles, such as ethanol and six-carbon alcohols, can be used as long-range attractants (Bruce et al., 2005). However, in aquatic systems, natural products are transported through water rather than air. Therefore, their mobility and persistence in the environment can be different. Simple sugars and amino acids can be rapidly degraded by microorganisms. Nonvolatile chemicals located on leaf surfaces, which typically have low mobility in the air, may become mobile in water. The dynamics of plant–insect interactions will undoubtedly be similar in both aquatic and terrestrial systems, but the mechanism of the interactions and the chemicals involved in those interactions may be different (for a review, see Hay and Steinberg, 1992).

In aquatic systems, studies of animal response to chemical stimuli have focused primarily on fish and noninsect invertebrates. Feeding stimulants are often common metabolites of low-molecular weight. For example, amino acids, such as glycine, attract lobster, shrimp, and several species of fish (Carr, 1988). Amino acids, nucleotides, simple sugars, and organic acids have been used to assess the attraction of marine invertebrates (primarily crustaceans) to their prey (see review by Weissburg et al., 2002).

Recent studies on the functional ecology of natural products in freshwater macrophytes have demonstrated the role they play in defense against generalist herbivores (Kubanek et al., 2001; Choi et al., 2002; Cronin et al., 2002; Walenciak et al., 2002). Furthermore, several weevil species have a specialist or close association with freshwater macrophytes (Buckingham and Bennett, 1995; Cronin et al., 1998; Solarz and Newman, 2001; Center et al., 2002). However, the role of chemistry in these specialist–macrophyte interactions is unknown.

The sole example of a specialist insect being attracted to a submersed freshwater macrophyte is the *Myriophyllum spicatum* L. (Haloragaceae)–*Euhrychiopsis lecontei* Dietz (Coleoptera: Curculionidae) system (Solarz and Newman, 1996, 2001). Eurasian water milfoil *M. spicatum* is an aquatic macrophyte exotic to North America that is typically abundant in the littoral zone of mesotrophic to moderately eutrophic lakes (Smith and Barko, 1990). It may remain unnoticed for years, then suddenly grow, forming a dense canopy that shades out other plants, impedes navigation, and adversely affects recreational activities (Smith and Barko, 1990; Boylen et al., 1999). Reductions

in *M. spicatum* populations have occurred in lakes where *E. lecontei* was present and in controlled experiments with *E. lecontei* (Creed and Sheldon, 1995; Sheldon and Creed, 1995; Newman, 2004).

Water milfoils native to North America, such as the northern milfoil *Myriophyllum sibiricum* Komarov, are the presumed original hosts of *E. lecontei*, which has expanded its host range to include *M. spicatum* (Creed and Sheldon, 1994; Solarz and Newman, 1996). *E. lecontei* has shorter development times, greater mass, and higher survival on the invasive Eurasian water milfoil than on its native host plants (Newman et al., 1997; Solarz and Newman, 2001). Based on field observations, oviposition studies, and behavioral bioassays, Solarz and Newman (1996) hypothesized that there may be chemical cues that attract weevils to *M. spicatum*. In this study, we tested their hypothesis that the weevils are attracted to *M. spicatum*, and we isolated two chemicals involved in that interaction.

METHODS AND MATERIALS

Plant and Insect Material. Plants were obtained from various lakes in Minnesota, USA. *M. spicatum* was collected from Lake Auburn (Carver County), Cedar Lake, Lake of the Isles, and Smith's Bay in Lake Minnetonka (all in Hennepin County), *M. sibiricum* from Christmas Lake (Hennepin County) and Smith's Bay, *M. spicatum* × *M. sibiricum* hybrid from Otter Lake (Anoka County) and White Bear Lake (Washington County), *Myriophyllum alterniflorum* DC from Lake Sissabagamah (Aitkin County), *Myriophyllum tenellum* Bigel from Graham Lake (Carlton County) and West Twin Lake (St. Louis County), and *Ceratophyllum demersum* L. (Ceratophyllaceae) from Lake Auburn. The identities of *M. spicatum* × *M. sibiricum* hybrid, *M. alterniflorum*, and *M. tenellum* were confirmed by sequence comparison of nuclear and chloroplast markers (analysis performed by M. Moody, University of Connecticut; see Moody and Les, 2002 for methodology).

Preparation of Exudates. All plants were collected from stands with no apparent damage from the aquatic weevil *E. lecontei*. Stems were held in lake water until laboratory processing, which occurred within 24 hr of collection. The top 20 cm of the plants was inspected for herbivore damage and cleaned of algae and detritus. Plants were then placed in well water (characterized by Oseid and Smith, 1974) to avoid contamination with chlorine and other additives in tap water. Plants were incubated for 2–4 d in direct sunlight or under constant illumination in a laboratory light bank that delivered 1065 μmol m^{-2} sec^{-1} photosynthetically active radiation. Temperature was at or below 30°C. After incubation, plants were removed and spun in a salad spinner for 15 sec to remove excess water. Plant material was weighed and frozen for future

use. The water containing the milfoil exudates was filtered through cheesecloth, stored in plastic bags (Ziploc™), and frozen at −20°C until processing. Adult *E. lecontei* were collected biweekly from several of the same area lakes and held in a 0.545-m^3 stock tanks (61 × 183 × 76 cm) located in an outdoor setting or in 76-l aquaria on fresh *M. spicatum*.

Chemicals and Other Materials. Ultrafiltration membranes used to concentrate extracts were obtained from Millipore, Bedford, MA, USA, and the ultrafiltration cell was obtained from Diaflo Amicon, W. R. Grace & Co., Beverly, MA, USA. Diethylaminoethyl (DEAE) ion exchange and Sephadex G-10 resins and the Superdex Peptide HR10/30 column used in the isolation of attractants were purchased from Amersham Biosciences, Piscataway, NJ, USA. Several additional high-performance liquid chromatography (HPLC) columns, C18, C8, and Source columns were obtained from the same manufacturer. The Magic C-18 column for liquid chromatography–mass spectrometry was from Michrom BioResources, Auburn, CA, USA. Uracil, used as a standard, was from Aldrich Chemical Company, Milwaukee, WI, USA. Glycerol was purchased from Spectrum Chemical Manufacturer, Gardena, CA, USA. The milfoil polyphenol, tellimagrandin II [β-1,2,3-tri-*O*-galloyl-4,6-(*S*)-hexahydroxydiphenoyl-D-glucose], was a gift from E. Gross, Limnological Institute, University of Konstanz, Germany.

Behavioral Bioassays. Adult *E. lecontei* preferences were determined using a two-way choice test performed in Y-tubes according to published procedures described in Solarz and Newman (1996, 2001). Assays were designed to maximize the behavioral analysis with small amounts of material. The experimental apparatus consisted of a glass Y-tube, 1.2-cm diam with 14-cm-long arms and stem. Each end of the tube was sealed with a cork, and the Y-tube was filled with well water. The control material was randomly placed into one arm of the Y-tube. Control material was either a plastic plant or a blank tube when fresh milfoil was used or a 6-mm diam filter paper saturated with well water or solvent for the chemical choice tests. Sample material, similarly prepared, was introduced into the second arm, and a weevil into the stem of the Y-tube. The Y-tube stem was covered with an opaque cloth and placed at a 10° incline (Solarz and Newman, 1996). A choice was indicated by the weevil swimming to or within 1 cm of either the control or sample material within a 10-min period. Choice and the time required to make that choice were recorded. No choice weevils were excluded from analyses. Weevils usually made a choice within 5 min. There was no difference in weevil choice between a plastic plant and a blank tube ($N = 20$, $P = 0.37$); therefore, either one was used as a control. As an alternative to the plastic plant or blank tube, exudates from a common co-occurring aquatic plant, *C. demersum*, were prepared as above and also tested against *M. spicatum* exudates and isolated fractions. Y-tubes were rinsed with 95% ethanol, then rinsed three times with well water after every three to six

trials to ensure that previous test weevils did not affect the behavior of subsequent ones, and that chemicals did not diffuse into both arms of the Y-tube (Solarz and Newman, 2001). Throughout the isolation, Y-tube choice tests were used to determine whether weevils were attracted to the fractions.

For Y-tube bioassays, an aliquot from a known concentration of sample was infiltrated into filter paper disks, then used in the choice test. For dose–response curves, a range of concentrations of *M. spicatum* exudates and each isolated chemical was infiltrated. An estimate of the dose perceived by the weevils is the applied amount (in mg or mol) divided by the volume of one arm of the Y-tube (12 ml). This value in mg/l or molar amounts is indicated in the appropriate figure captions, and can be considered an average concentration that the weevils perceived during a trial. Likely, weevils were able to detect lower concentrations as the material dispersed throughout the Y-tube. Approximately 50 (range 20–127) randomly selected weevils were tested at each concentration level.

Chemical Isolation and Identification. Plant exudates and partially purified fractions were kept frozen at −20°C. Exudates were thawed, filtered through Whatman No. 1 cellulose filter paper, and lyophilized. The powder was resuspended in Milli-Q water and used in the Y-tube bioassay to confirm attraction. The resuspended exudate was fractionated into large and small molecules by using ultrafiltration. Ultrafiltration was performed with a 76-mm YM1 membrane (MWCO 1000) in a model 8400 Diaflo Amicon ultrafiltration cell under a 70-psi N_2 atmosphere. Both the retentate (mw > 1000) and the filtrate (mw < 1000) were tested vs. water in the Y-tube bioassay.

Active filtrate was loaded onto a DEAE-anion exchange column (3.5 × 10 cm column) that had been previously equilibrated with Milli-Q water. The column was eluted with Milli-Q water at a flow rate of at 1.7 ml/min. The effluent was monitored at 254 nm, and fractions were collected. A single UV-absorbing peak was observed. Fractions from this peak were pooled, concentrated by lyophilization, and tested in the Y-tube bioassay. Material that was eluted with 0.5 M NaCl was also collected, but showed no activity in the bioassay.

The DEAE pool was further purified by size exclusion chromatography on a G-10 Sephadex column (30 × 2.5 cm) that had been previously equilibrated with Milli-Q water. The column was eluted with water at a flow rate of 0.3 ml/hr, the effluent monitored at 254 nm, and fractions collected. Four peaks were eluted, and fractions from each were pooled separately, concentrated by lyophilization, and tested in Y-tube bioassays.

The active peak, with an absorbance maximum at 259 nm, was analyzed by atmospheric pressure chemical ionization–mass spectrometry (APCI-MS) to assess its purity and obtain information about the components. The active pooled fraction from the G-10 column was loaded onto a Superdex Peptide HR

10/30 size-fractionating column (30 × 1 cm) that had been equilibrated with Milli-Q water. The column was eluted with water at a flow rate of 0.3 ml/min. One major peak with an absorbance maximum at 259 nm showed a very broad shoulder. The active pooled fraction was concentrated by lyophilization, and the components were identified by a combination of positive ion APCI and electron impact mass spectrometry and NMR spectroscopy. The purification procedure is summarized in Table 1.

APCI analyses were performed on a ThermoElectron LCQ Classic Ion Trap mass spectrometer (Waltham, MA, USA) fitted with an APCI ionization source. The APCI heated capillary temperature was set at 450°C and controlled at 10 μA. Xcaliber™ (ThermoFinnigan Corp.) was used to acquire the data. Several LC-MS runs with C18, C8, and Source columns correlated the absorption spectrum to the molecular weight, but did not further separate components of the active fraction.

Samples for NMR spectroscopy were dissolved in D_2O. NMR spectra were performed on Varian Inova 500, 600, and 800 spectrometers (University of Minnesota) using standard pulse sequences and water suppression. Identity of the active compounds was confirmed by comparison to standards using ^{1}H, ^{13}C, ^{1}H–^{1}H correlated spectroscopy (COSY), ^{1}H–^{13}C COSY, MQ COSY, heteronuclear multiple quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC) NMR spectra.

Uracil content of partially purified plant exudates (DEAE pool) was measured with a QTrap LC/MS/MS hybrid triple quadrupole/linear ion trap mass spectrometer (Applied Biosystems, Inc., ABI, Foster City, CA, USA). A 5-μl sample was withdrawn with a Agilent 1100 Micro Autosampler and transferred by an Agilent 1100 Capillary Pump to a Magic C18 column (150 × 0.2 mm) with 5-μm, 200-Å pore size particles. Components were sequentially eluted with a gradient. Solvent A was 98:2 water/acetonitrile containing 0.1% formic acid. Solvent B was 5:95 water/acetonitrile containing 0.1% formic acid. Using a flow rate of 5 μl/min, the gradient went from 100% A to 75% A in 4 min, was held for 3 min at 75% A, then ramped over 3 min to 25% A. The LC system was in line with the QTrap equipped with a TurboIonSpray ion source. The electrospray voltage was set at 5500 V. Samples were analyzed using a multiple reaction monitoring scan mode. Ions with a m/z of 113.10 in positive polarity were detected in quadrupole 1, autofragmented in quadrupole 2, and a m/z of 69.90 (a fragment of uracil) was monitored in quadrupole 3. Analyzst 1.3.1 (ABI) was used to acquire and analyze the data. A standard solution of 1.0 mg/ml of material that eluted from the DEAE column was spiked with uracil to a final concentration ranging from 0.09 to 900 μM to generate a standard curve. These samples were used to estimate the concentration of uracil present in DEAE pool samples from *M. spicatum*, *M. sibiricum*, *M. spicatum* × *M. sibiricum* hybrid,

M. alterniflorum, *M. tenellum*, and *C. demersum*. Peak areas from standards were used to determine uracil concentrations.

Statistical Analyses. Y-tube data were tested with a χ^2 analysis. Dose–response curves for exudates and each isolated attractant were developed using logistic regression based on the amount of sample infiltrated into filter disks used in Y-tube bioassays. Comparisons among models were made using χ^2 analyses of model deviances. Weevil preference was determined in the Y-tube bioassay. Glycerol and uracil were combined in Y-tube bioassays to test for possible synergistic effects. Differences in uracil content between *M. spicatum*, *M. sibiricum*, and *M. spicatum* × *M. sibiricum* hybrid were determined with an analysis of variance.

RESULTS

Behavioral Bioassay. E. lecontei adults were attracted to *M. spicatum* in preference to control ($P < 0.001$), *M. sibiricum* ($P < 0.001$), and *C. demersum* ($P = 0.003$; Table 1A). Weevils did not show this level of preference for their native host plant *M. sibiricum*; they chose a control nearly as often as they selected *M. sibiricum* ($P = 0.131$). The *M. spicatum* × *M. sibiricum* hybrid attracted weevils, but different hybrid populations elicited different reactions. Weevils were attracted to hybrid milfoil from White Bear Lake ($P < 0.001$) and only moderately to hybrid milfoil from Otter Lake ($N = 179$, $P = 0.059$). Neither of the other milfoil species, *M. alterniflorum* nor *M. tenellum*, nor the non-milfoil plant *C. demersum* were attractive ($P = 0.78$, $P = 0.13$, and $P = 0.45$, respectively).

To determine the chemical identity of the weevil attractant(s), exudates of *M. spicatum* were tested for weevil preference, lyophilized, and retested for weevil preference (Table 1B). Weevils were attracted to certain *M. spicatum* exudates ($P < 0.001$) but not to *M. sibiricum* exudates ($P = 0.62$) or *C. demersum* exudates ($P = 0.41$). The *M. spicatum* exudates were separated into low-molecular weight (<1000 amu) and high-molecular weight (>1000 amu) compounds. Weevils were attracted to the low-molecular weight fraction ($P < 0.001$) and preferred it to *C. demersum* exudates ($P = 0.017$; Table 1C). The low-molecular weight fraction was purified using an anion exchange column, and weevils were attracted to the one major peak that passed through this column ($P < 0.001$) and preferred that peak to *M. sibiricum* exudates ($P = 0.028$; Table 1D). The anion exchange column pool was purified by size exclusion chromatography, and weevils were attracted to the third ($P = 0.001$) of the four peaks that eluted from the column (Table 1E). The active G-10 pool contained several components as determined by MS, and was further purified by

[a]The two choices are listed as A vs. B in the treatment column. Number of Y-tube trials is indicated in the column '*N*.' '% *A*' is the percent of weevils that selected choice A.
[b]Glycerol at 22 or 220 μmol, combined results, amount applied to filter disk.
[c]Uracil at 18 or 180 nmol, combined results, amount applied to filter disk.
[d]Glycerol 220 μmol + uracil 180 nmol and glycerol 22 μmol + uracil 18 nmol, combined results, amount applied to filter disk.
[e]Tellimagrandin II at 2.1 or 21 nmol, combined results, amount applied to filter disk.

HPLC. Mass spectral analysis indicated that the attractant consisted of two major components.

Chemical Isolation and Identification. Uracil and glycerol were identified as active components of the *M. spicatum*. Monitoring of column effluents by UV absorption led to the isolation of uracil, which has an UV absorption maximum at 259 nm. Glycerol does not absorb in the ultraviolet spectrum; however, its presence in the attractive fraction of the *M. spicatum* exudates was apparent in NMR spectra of the final fraction. Uracil was identified by low-resolution positive ion APCI and by high-resolution chemical ionization mass spectral analysis. Direct infusion APCI of the isolated fraction showed a base peak of *m*/*z* 113.1 $[M + H]^+$, which, upon fragmentation, yielded peaks at 95.9 and 69.9 *m*/*z*. Under high-resolution CI, the molecular ion of 113.0346 $[M + H]^+$ was observed consistent with a molecular formula of $C_4H_4N_2O_2$. Electron ionization MS also showed the fragmentation pattern characteristic of glycerol (61.0, 43.0, and 31.0 *m*/*z* values).

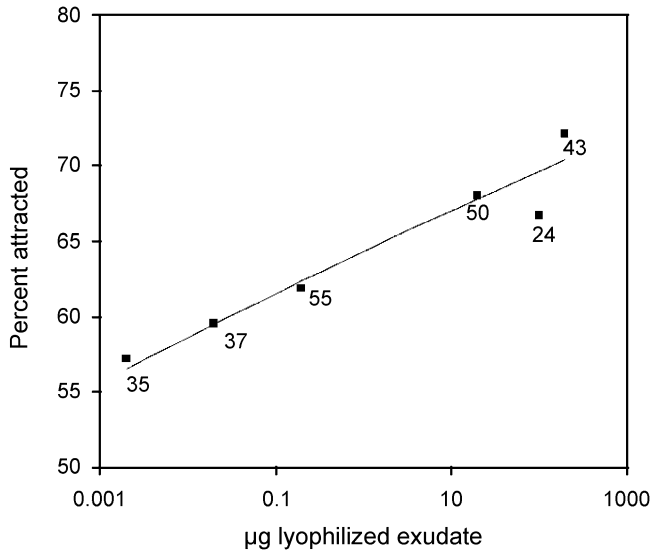

FIG. 2. Weevil response to increasing amounts of *M. spicatum* exudates. Exudates from *M. spicatum* were lyophilized, weighed, and resuspended in water. An exudate amount (amt) of 0.002–200 µg was infiltrated into filter paper discs. The estimated concentrations of exudates in one arm of the Y-tube ranged from 0.00017 to 17 mg/l. The Y-tube bioassays were performed as described in Methods and Materials. The number of weevils used in each sample is indicated next to each point. The logistic regression line is defined as percent attracted $= 1/\left(1 + e^{-(0.5890 + 0.1207 \times \log_{10}(\text{amt}))}\right)$ and is significant as a first-order curve ($P = 0.10$).

The presence of uracil and glycerol was confirmed by NMR spectroscopy. ^{1}H-NMR spectra showed an aromatic region with peaks at 5.4 and 7.4 ppm corresponding to uracil and a multiplet at 3.6 ppm and two doublet of doublets at 3.4 and 3.5 ppm corresponding to glycerol. The ^{13}C-NMR spectra revealed peaks at 165.5, 153.4, 143.7, and 101.2 ppm corresponding to uracil and 72.2 and 62.6 ppm corresponding to glycerol. The COSY ^{1}H-NMR spectra showed that the aromatic protons coupled at 5.6 and 7.4 ppm were consistent with the spectral properties of uracil. The MQ COSY spectra confirmed the coupling of the 3.4- and the 3.5-ppm doublet of doublets with each other and the multiplet consistent with the spectrum of glycerol. HMQC and HMBC spectra permitted the correlation of protons and carbons. The identities of uracil and glycerol were confirmed by comparisons to standards. A third compound was also present in some samples, but could not be separated from other components or identified.

The presence of uracil in the exudates of *M. spicatum*, *M. sibiricum*, *M. alterniflorum*, *M. tenellum*, and *C. demersum* was determined using a Qtrap LC-MS. Uracil was present in the exudates of all of the aquatic plants tested (Figure 1).

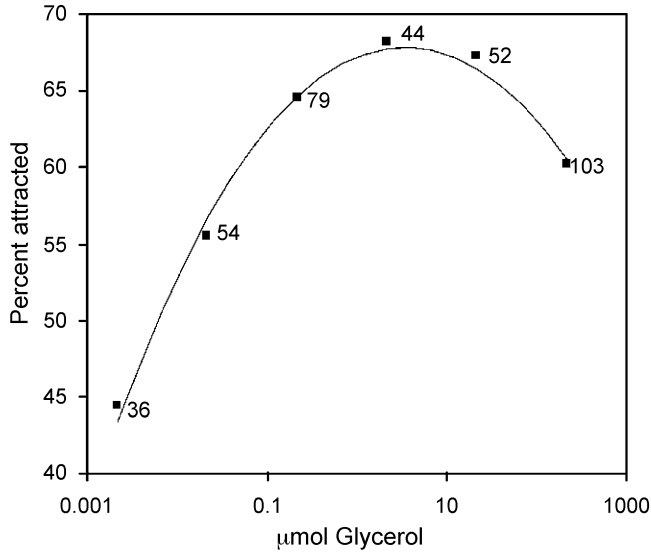

FIG. 3. Weevil response to an increasing amount of glycerol. An aliquot of glycerol was infiltrated into filter paper discs for a final amount (amt) of 0.00217–217 μmol glycerol. The estimated concentration in one arm of the Y-tube is 0.00018–18 mM glycerol. The Y-tube bioassays were performed as described in Methods and Materials. The number of weevils used in each sample is indicated next to each point. The logistic regression line is defined as percent attracted $= 1/(1 + e^{-(0.7180 + 0.1061 \times \log_{10}(\text{amt}) - 0.988 \times \log_{10}(\text{amt}) \times \log_{10}(\text{amt}))})$ and is significant as a second-order curve ($P = 0.026$).

Concentration of uracil was higher in *M. spicatum* than in *M. sibiricum* or the *M. spicatum* × *M. sibiricum* hybrid (ANOVA, $F_{2,10} = 11.63$, $P = 0.004$).

Weevils were attracted to standards of glycerol ($P < 0.001$), uracil ($P < 0.001$), and the combination of glycerol + uracil ($P < 0.001$; Table 2). Glycerol was preferred to *C. demersum* exudates ($P = 0.005$). Weevils were attracted to glycerol + uracil (70%) at a percentage intermediate to the levels of attraction to uracil or glycerol. They were not attracted to a characteristic milfoil polyphenol, tellimagrandin II (55%, $P = 0.32$; Table 2; Gross et al., 1996).

A dose response curve was determined for exudates, glycerol, and uracil. Weevil preference for exudates increased as the amount of exudates used in each test increased (Figure 2); a similar response was seen for glycerol (Figure 3) and uracil (Figure 4). A minimum amount of 20 μg significantly attracted *E. lecontei* to exudates vs. a control; 68% of weevils selected the exudates (Figure 2). Based on extrapolation of the regression curve, the minimum threshold that attracts weevils is probably closer to 2 μg (0.17 mg/l), which would attract 65% of the weevils. The minimum dose of 0.217 μmol (0.018 mM) significantly attracted *E. lecontei* to glycerol vs. a control; 64% of the weevils were attracted

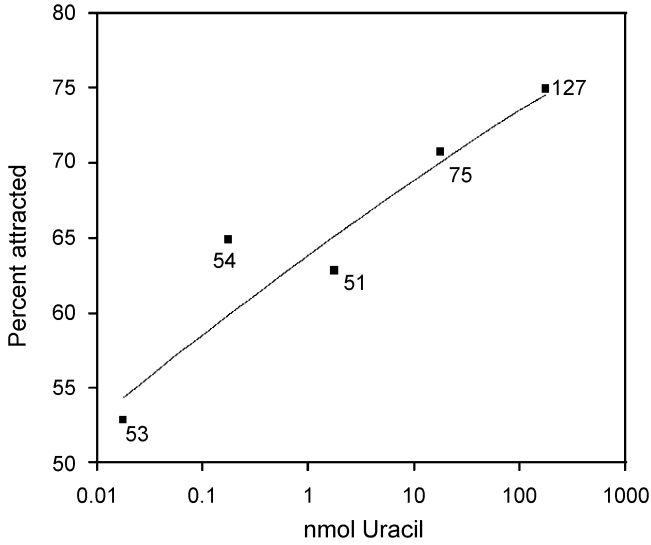

FIG. 4. Weevil response to increasing amount of uracil. An aliquot of uracil was infiltrated into filter paper discs for a final amount (amt) of 0.0178–178 nmol. The estimated concentration in one arm of the Y-tube is 0.0015–15 μM. The Y-tube bioassays were performed as described in Methods and Materials. The number of weevils tested in each sample is indicated next to each point. The logistic regression line is defined as percent attracted $= 1/\left(1 + e^{-(0.5675 + 0.2254 \times \log_{10}(\text{amt}))}\right)$ and is significant as a first-order curve ($P = 0.003$).

(Figure 3). At 217 μmol glycerol (18 mM), the highest amount of glycerol tested, there was a decrease in weevil preference. Sixty-five percent of *E. lecontei* were attracted to uracil at a minimum amount of 0.178 nmol uracil (0.015 μM; Figure 4).

The slopes of the curves in Figures 2–4 can be used to indicate whether the weevil is responding differently to increasing doses of the different chemicals. Glycerol and uracil curves are significantly different (χ^2 goodness of fit test, $\chi^2 = 12.1$, $df = 2$, $P = 0.002$), but the curve of the exudates is not significantly different from that of either uracil or glycerol. This suggests that the exudates attract the weevil at a level between that of glycerol and uracil.

DISCUSSION

This study together with the previous work by Solarz and Newman (1996) provides evidence that a fully aquatic specialist insect is attracted to plant-released chemicals. Solarz and Newman (1996) demonstrated that *E. lecontei* was attracted to *M. spicatum* in the dark as well as in the light. Using bioassay-driven fractionation, we identified uracil and glycerol as two compounds released from *M. spicatum* that attract *E. lecontei*. Although herbivore attraction to plant-released chemicals is a well-known phenomenon in terrestrial systems, this interaction has not previously been shown for a submersed freshwater plant and insect herbivore.

In two-way choice tests, *E. lecontei* preferred *M. spicatum* to a plastic plant (control), its native host *M. sibiricum*, and the co-occurring unrelated macrophyte *C. demersum*. Although historically associated with *M. sibiricum* (Creed and Sheldon, 1994), the weevils used in this experiment did not prefer *M. sibiricum* or its exudates to either a control or to *C. demersum*. This lack of preference for *M. sibiricum* may be a response to the host plant on which weevils developed (collected from *M. spicatum* at Lake Auburn). Solarz and Newman (2001) found that larvae reared on or adults exposed to *M. spicatum* preferred *M. spicatum*, but larvae reared on *M. sibiricum* had no preference. Alternatively, *M. sibiricum* and *E. lecontei* are presumed to have coevolved, and, therefore, *M. sibiricum* may exude deterrents or lack a specific attractant. The weevil's response to one co-occurring species, *C. demersum*, and three additional milfoils, the *M. spicatum* × *M. sibiricum* hybrid, the morphologically similar *M. alterniflorum*, and the morphologically dissimilar *M. tenellum*, all of which have some uracil in their exudates, was variable. Only the *M. spicatum* × *M. sibiricum* hybrid attracted weevils.

Attraction of *E. lecontei* adults to *M. spicatum* is a result of chemical compounds in exudates that were released by *M. spicatum* (Table 1B). *Myriophyllum* spp. release chemicals, including sugars, proteins, cyanogens, tannic substances,

and polyphenols, into the water (Lyr and Streitberg, 1955; Godmaire and Nalewajko, 1990; Nakai et al., 2000; Gross, 2003). By testing *M. spicatum* exudates, we avoided weevil exposure to chemicals that may be present in the plant tissue, but are not released into the water (Hay et al., 1998).

Like terrestrial plants that release volatiles as a result of the oxidative degradation of leaf lipids (Bernays and Chapman, 1994; Paré and Tumlinson, 1999), aquatic plants release hydrophilic metabolites as a by-product of rapid growth (Nalewajko and Godmaire, 1996). Peptides with water-soluble groups were suggested by Decho et al. (1998) to be good attractants in aquatic systems. Glycerol and uracil are two ubiquitous, low-molecular weight compounds that fit this profile.

Glycerol is a common metabolite and can also protect against abiotic stresses. The identification of glycerol-specific transporters in cell membranes of *Arabidopsis thaliana* indicates that it plays a role as a general osmolyte (Weig and Jakob, 2000; Eastmond, 2004). Glycerol content in the leaves of several agriculturally important plants such as maize and alfalfa typically ranges from roughly 0.1–0.4 mM (10–39 μg/g wet weight) to as high as 6 mM (554 μg/g wet weight) in *Zea mays* after a rain event, which may increase the demand for intracellular osmolytes (Gerber et al., 1988). Carbohydrates are also found on leaf surfaces of terrestrial plants at concentrations up to 0.01 mM at which point they act as feeding stimulants for insects (Bernays and Chapman, 1994). Carbohydrates located on leaf surfaces of aquatic plants will dissolve in water and may then function as foraging kairomones that attract herbivores (Ruther et al., 2002). Glycerol produced by *M. spicatum* attracts *E. lecontei* at 0.018- to 1.8-mM range, which is similar to the range that attracts insects to similar compounds in terrestrial systems (Bernays and Chapman, 1994).

Uracil is effective at a much lower concentration. Weevils were significantly attracted to uracil at 0.015–15 μM. At these concentrations, *E. lecontei* adults are responding at a concentration more indicative of a plant-specific attractant than a nutrient. For example, the terrestrial weevil *Ceutorhynchus assimilis* adults were attracted to a 120 μM phenylacetonitrile, a metabolite common in their host plant *Brassica napus* (Bartlet et al., 1997). In marine systems, shrimp *Palaemonetes pugio* were attracted to amino acids and nucleotides at a concentration of 0.1–1000 μM, a range that Carr (1988) suggests is intermediate between background noise and the concentration in prey tissue. Although it is not a species-specific attractant, the presence of uracil in the water may indicate either a damaged plant or an actively growing one suitable to *E. lecontei* for feeding and oviposition.

Like glycerol, uracil is also ubiquitous in plants. We found it in exudates of all plants tested, including all *Myriophyllum* spp. and *C. demersum*. However, its presence in exudates raises the question as to why a plant would release an expensive metabolite. In plants, uridine nucleosides and nucleotides are the second most common in cells after adenosine. In *Arabidopsis*, ureide permease transporters have been identified as the main transporters of uracil in phloem

(Schmidt et al., 2004). Uracil in exudates may be a function of its abundance and ubiquity in rapidly growing cells, such as the apical meristems, where pyrimidine salvage is needed to support the high demand for nucleotides. Of the pyrimidines, plants can only salvage uracil (Wagner and Backer, 1992).

An alternative use for uracil in plants is the production of alkaloids and pseudoalkaloids (*sensu* Waterman, 1998). Plants that use uracil in this capacity have pools of the pyrimidine for rapid synthesis (Brown and Turan, 1995). Ostrofsky and Zettler (1986) reported that alkaloids were present in *M. spicatum*. However, no alkaloids or pseudoalkaloids were detected in our collections (Stermitz, Colorado State University, unpublished data, see Marko and Stermitz, 1997 for methods), suggesting that uracil-based natural products are not produced in these aquatic plants, or that they are found in low concentrations.

The concentration of uracil was highest in *M. spicatum* exudates, intermediate in *M. spicatum* × *M. sibiricum* hybrid, and lowest in *M. sibiricum*. *M. spicatum* grows faster than *M. sibiricum* and starts growing earlier in the season (Madsen et al., 1991). Therefore, it would produce and release glycerol and uracil sooner than other co-occurring plants.

The presence of uracil in aquatic plant exudates may also be a result of damage because of abiotic stressors such as UV radiation that can damage nucleic acids. The sun-exposed meristem tips of *M. spicatum* form dense mats at the water surface. This greater surface exposure may lead to more UV stress than that experienced by other milfoils located below the surface, potentially resulting in the loss of cell contents, including uracil. Ultraviolet radiation can also induce the production of polyphenols in aquatic plants (Meijkamp et al., 1999; Rozema et al., 1999). The higher concentration of polyphenols found in *M. spicatum* compared to *M. sibiricum* (Spencer and Ksander, 1999; Marko et al., unpublished results) suggests that it is under greater UV stress.

Polyphenols in *M. spicatum* deter feeding by herbivores (Leu et al., 2002; Li et al., 2004). Li et al. (2004) found that *M. spicatum* had higher phenolic content than co-occurring aquatic plants, and that in two-way choice tests, the snail *Radix swinhoei* ate less *M. spicatum* than five of the seven tested plants. One polyphenol in *M. spicatum*, tellimagrandin II, is known to inhibit the growth of periphyton and deter the growth of the lepidopteran herbivore *Acentria ephemerella* (Gross et al., 1996; Choi et al., 2002). However, tellimagrandin II was neither attractive nor deterrent to *E. lecontei* at the concentrations tested. This suggests that the weevil does not respond to all *M. spicatum*-released chemicals, but rather that it is specifically attracted to glycerol and uracil.

Host plant attraction often involves a mixture of chemicals, and the effective concentration of one attractant can be modified by a specific mixture (Roseland et al., 1992; Bartlet et al., 1997). For example, *C. assimilis* adults were more attracted to phenylacetonitrile plus a mixture of isothiocyanates than to phenylacetonitrile alone (Bartlet et al., 1997). Synergism between glycerol

and uracil was not detected in the *M. spicatum–E. lecontei* system. Similar percentages of *E. lecontei* adults were attracted to *M. spicatum* exudates, uracil, and a combined fraction of uracil + glycerol.

In both aquatic and terrestrial systems, there is considerable variation in herbivore response to chemical attractants, and sometimes, it is the presence of a trace chemical that drives the plant–insect interaction. For example, in terrestrial systems, *Hylobius pales* (Curculionidae) adults show a dose-dependent response to some chemicals, but not others (Salom et al., 1994). Furthermore, weevil response can depend on whether the study is conducted in the field or in the lab. In field studies, *C. assimilis* exhibited a dose response to known attractants (Smart et al., 1997), but not under laboratory conditions (Bartlet et al., 1997). Bartlet et al. (1997) suggest that the ratio of chemicals and the presence of trace compounds may ultimately affect behavior in the field. Variation in *E. lecontei* behavior to *M. spicatum* populations was observed throughout these experiments. Certain populations of *M. spicatum* did not attract the weevils, and environmental variables such as weather also affected weevil response. Because *M. spicatum* is a nonindigenous plant, it may release chemicals that attract *E. lecontei*, whereas native milfoils may have been selected to release fewer attractant chemicals. Undoubtedly, the attraction of *E. lecontei* to *M. spicatum* is a complex process that involves a variety of factors.

In terrestrial systems, ubiquitous plant volatiles, such as phenylpropanoids, fatty acid derivatives, and isoprenoids, are involved in the attraction and deterrence of insects to their host plants (Bruce et al., 2005). In aquatic systems, common low-molecular weight compounds, such as amino acids, sugars, and nucleotides, perform the same function (Weissburg et al., 2002). These water-soluble compounds may be reversibly bound to leaf surfaces or released from trichomes. Aquatic herbivores probably rely on taste receptors rather than odor for host location (Spänhoff et al., 2005). Additionally, because many of these chemicals are readily taken up by bacteria, they may act as short-term signals. Alternatively, compounds released by plants may be degraded by epiphytes, and the degradation products may serve as semiochemicals. Comparisons of chemical mobility and persistence in different environments will provide an understanding of the ecological and evolutionary relationships among aquatic insects and their host plants.

Acknowledgments—We thank Elisabeth M. Gross for the gift of tellimagrandin II and Frank R. Stermitz for analysis of alkaloid content. We are grateful to Tom Krick, Letitia Yao, Beverly Ostrowski, and LeeAnn Higgins for assistance and advice with the mass spectral and NMR analyses. We thank M. Moody for molecular identification of *Myriophyllum* spp. Assistance with specimen collection and analyses were provided by D. Ward, C. Lemmon, S. Daugherty, S. Coloso, J. Dehn, K. Eichstaedt, C. McCollum, and K. Mann. We thank LeeAnn Higgins and two anonymous reviewers for their comments on the manuscript. (Received November 17, 2004; revised July 22, 2005; accepted July 23, 2005)

Abstract—Individual recognition is a key element in the social life of many invertebrates. However, most studies conducted so far document that several species are capable of a "binary" discrimination among conspecifics, but not of a "true individual recognition." Our objective was to learn more about the mechanisms that underlie individual recognition by odor in hermit crabs by individuating some of its properties. Using *Pagurus longicarpus* Say 1817 as a model species, we conducted four series of experiments in which the response of every test crab (the "receiver") to the different odor treatments (emitted by a "sender") was evaluated from its investigative behavior toward an empty, high-quality shell. After having excluded the possibility that crabs chemically recognize familiar/unfamiliar shells and/or shells of high/low quality, we explored whether the receivers discriminate odors from two familiar senders and whether this discrimination also occurs with unfamiliar crabs. We also asked whether crabs form an association between the odor of a familiar sender and some of its relevant attributes, i.e., rank, size, and shell quality. Finally, the shells inhabited by familiar individuals were manipulated to modify the association between odor and shell quality. Results showed that: (1) there is no odor specific of a rank; (2) individual crabs discriminate their own odor from the odor of other individuals; (3) they can chemically discriminate between larger crabs inhabiting higher-quality shells and smaller crabs inhabiting lower-quality shells, provided that these crabs are familiar to them; (4) they associate the odor of an individual crab with the quality of the shell it inhabits; and (5) this association quickly changes when social partners switch to shells of different quality. These results indicate that the nature of chemical recognition in *P. longicarpus* is more refined than a simple binary

system. The receiver appears able to associate a type of information from the sender with memories of past experiences, therefore suggesting the hermit crab's potential for relatively high-order knowledge about conspecifics.

Key Words—Individual recognition, odors, dominance hierarchies, hermit crabs, *Pagurus longicarpus*.

INTRODUCTION

Individual recognition is a key element in the social life of many organisms, where it can play an essential role in the structure and stability of a number of behavioral networks, such as dominance hierarchies, territorial defense, competitive aggression, pair bonds, mate selection, and kin favoritism (reviewed in Zayan, 1994). The most detailed information available in the literature concerns the recognition of vocal signals by birds (e.g., Falls, 1982). Many studies have demonstrated the ability of nonhuman mammals to discriminate individuals by the use of chemicals (e.g., Halpin, 1980, 1986; Brown et al., 1990; Hurst et al., 2001). Particularly in the last few years, considerable effort has been directed at defining in vertebrates the processes of identification and recognition (Beecher, 1989): at the cognitive analysis level, questions have been addressed on the nature of individual representation exhibited by a handful of vertebrate taxa and on the evolutionary pathways leading to high-order knowledge about individuals (e.g., Johnston and Bullock, 2001).

To date, a relatively small body of literature exists that analyzes these issues in invertebrates (see, e.g., Leonard et al., 1974 in *Drosophila* spp.; Barrows et al., 1975 in halictid sweat bees *Lasioglossum zephyrum*; Liechti and Bell, 1975 in the cockroach *Byrsotria fumigata*; Linsenmair and Linsenmair, 1971 in the desert wood louse *Hemilepistus reaumuri*). Even fewer studies exist that have advocated pheromones as the basis of individual recognition in aquatic invertebrate species (Wickler and Seibt, 1970 in the clown shrimp *Hymenocera picta*; Johnson, 1977 in the banded shrimp *Stenopus hispidus*; Caldwell, 1985 in the mantis shrimp *Gonodactylus festae*; Karavanich and Atema, 1998 in the American lobster *Homarus americanus*).

Among other aquatic invertebrates, hermit crabs are optimal model organisms to investigate the mechanisms of chemically mediated individual recognition. The ability to recognize individuals in *Pagurus bernhardus* (Hazlett, 1969) or to discriminate familiar from unfamiliar conspecifics in *P. longicarpus* (Gherardi and Tiedemann, 2004a) was assumed to be a means to maintain stable hierarchical relationships. In fact, dominance hierarchies (Allee and Douglis, 1945; Winston and Jacobson, 1978) seem not to be laboratory artifacts, but they may develop in the small temporary aggregations of hermit

crabs that often form in tide pools (Scully, 1978), mostly around gastropod predation sites (Rittschof, 1980a).

A number of behavioral studies have shown that olfaction in hermit crabs can mediate a form of chemical recognition. Several species display adaptive behaviors when exposed to odors that signal shell availability (e.g., Rittschof, 1980a; Rittschof et al., 1992; Rittschof and Hazlett, 1997; Gherardi and Atema, 2005a), and chemical cues in the medium affect investigatory responses toward shells occupied by conspecifics (Hazlett, 1996a,b; Rittschof and Hazlett, 1997; Hazlett, 2000). Recently, Gherardi and Tiedemann (2004b) showed that *P. longicarpus* spends more time investigating an empty shell in the presence of odors released by unfamiliar, rather than familiar, conspecifics.

Based on these premises, our objective here was to learn more about the mechanisms that underlie chemical individual recognition in hermit crabs by using *P. longicarpus* as a study species. After having excluded the ability of crabs to recognize shells by odor, we explored whether they discriminate between two familiar individuals of different rank, size, and shell quality and whether this ability is expressed also toward unfamiliar crabs. Experiments have documented a binary discrimination between familiar and unfamiliar individuals, but have failed in demonstrating a recognition of one out of many, known individuals (Gherardi and Tiedemann, 2004a), even if provided suggestions of its potential (Gherardi and Atema, 2005b). Our experimental design here showed that the number of the individuals *P. longicarpus* can recognize is wider than previously thought. Then, two general questions were raised. The first was whether hermit crabs form an association between the odor of a familiar conspecific and one of its relevant attributes (rank, size, or shell quality). In other words, what does the odor of a crab mean to another individual? Finally, because the odor appeared to be associated with the high/low quality of the shell occupied by the "sender" crab (here defined as the crab releasing the odor, without any implication of signal selection for communication), we investigated the plasticity of this association by experimentally altering shell quality.

METHODS AND MATERIALS

Subjects, Collection, and Housing Conditions. The long-clawed hermit crab, *P. longicarpus* Say 1817, is common in shallow waters along the western Atlantic coasts of North America, from Nova Scotia south to eastern Florida, and in the northern Gulf of Mexico from the west coast of Florida to Texas (Williams, 1984).

Between July and August 2003, we hand-collected around 400 hermit crabs with the major chela width (CW) of 0.1–0.4 mm (corresponding to individuals

with shield length of about 4–6 mm) from Little Sippewissett salt marsh (Massachusetts, USA) during diurnal low tides. Immediately after capture, crabs were separated into small groups and transferred to the Marine Biological Laboratory in Woods Hole, where they were maintained in groups of up to 25 individuals in a temperature-controlled room (22°C) and under a natural 14-h light–10-h dark cycle. They were kept in separate 20-l holding aquaria containing constantly aerated seawater and fed with a diet of commercial shrimp pellets every third day. Water was changed weekly. After being used in experiments, crabs were released at the collection site.

Experimental Design. We conducted four series (A–D) of one to three related experiments (conditions). Each condition consisted of a 24-hr familiarization phase immediately followed by a test phase in which every test crab (the "receiver") was subjected to two to three different odor treatments in a random sequence. A preliminary experiment (experiment A) aimed at exploring whether hermit crabs chemically recognize familiar/unfamiliar shells (condition A1) and/or shells of high/low quality (condition A2). Then, we aimed at understanding in Experiment B whether crabs discriminate between two familiar conspecifics of different rank, size, and shell quality (condition B1) and whether this discrimination occurs also toward unfamiliar conspecifics with similar attributes (condition B2). In experiment C (with conditions C1, C2, and C3), we asked whether receiver crabs form an association between this odor and relevant attributes of the sender, i.e., its rank, size, and shell quality. Finally, experiment D was a continuation of C3, in which the shell inhabited by the sender was manipulated to modify the association between odor and shell quality. The logic behind our study is shown in the flowchart of Figure 1, and details of each experiment are given in Table 1.

Experimental Methods. All experiments and conditions were staged in opaque plastic bowls (10-cm diam), containing 160-ml unfiltered seawater at 22°C, illuminated during observations by a 75-W incandescent light, 50 cm above the water level. Observations were always conducted between 0900 and 1600 hr.

At least 10 d from the collection and 2 d before the beginning of experiments A–C, each crab was randomly assigned to one of the two or three conditions. We always used intact individuals (no missing limbs), and, for experiments B and C, we formed groups composed of three crabs ("trios"), using animals taken from separate holding aquaria to ensure that they had no memory of one another (in fact, crabs forget a familiar conspecific after 5 d of separation; Gherardi and Atema, 2005b). According to the major chela width, crab size was categorized as large, L (CW > 0.33 mm), medium, M (CW 0.23–0.33 mm), or small, S (CW < 0.23 mm). Sex was not noted because sex has been shown to exert no effect on agonistic interactions in this and other hermit crab species (Hazlett, 1966; Winston and Jacobson, 1978), at least during the

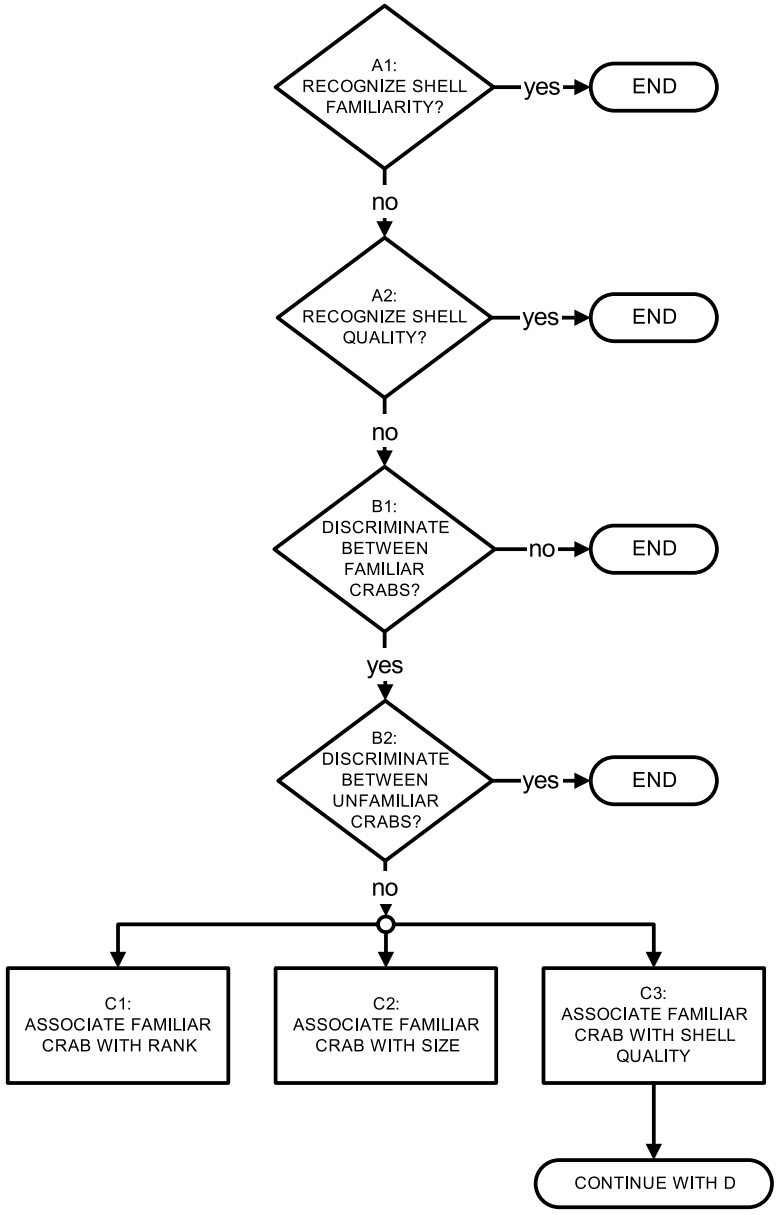

FIG. 1. A flowchart showing the sequence of questions addressed in this study. A1, A2, etc. denote experiments/conditions. Experiment D consisted of altering the association between familiar crab and shell quality.

TABLE 1. DETAILS OF THE EXPERIMENTS

Experiment/ condition	Test for	Receiver's attributes	Sender's attributes (A: shells; B–D: crabs)					
			Familiarity	Crab rank	Crab size	Shell size	Shell quality for the receiver	*n*
A1	Shell odor	Any crab	Yes/no				LTO, LTO	18
A2	Shell odor	Any crab	Yes				STO, LTO	17
B1	Familiarity	β (rank/size/shell quality)	Yes	α, γ	L, S	L, S	LTO, STO	26
B2	Familiarity	β (rank/size/shell quality)	No	α, γ	L, S	L, S	LTO, STO	21
C1	Rank	β (rank)	Yes	α, γ	M, M	M, M	OPT, OPT	15
C2	Size/rank	β (size/rank)	Yes	α, γ	L, S	M, M	OPT, OPT	13
C3	Shell quality/rank	β (shell quality/rank)	Yes	α, γ	M, M	L, S	LTO, STO	31
D	Plasticity	β (shell quality/rank)	Yes	α, γ*	M, M		STO, LTO	11

Experiment A evaluated the effect exerted on receiver crabs by the odor of shells with different familiarity and quality, and experiments B–D by the odor of crabs with different attributes (familiarity, dominance rank, size, and shell quality). The effect of the sender's odor was assessed from the investigatory behavior on a target shell performed by receiver crabs (any crab in experiment A and β crabs in experiments B–D). All the receivers were medium in their size and occupied medium-sized shells that were optimal for them. Asterisk denotes that individuals in D were the same individuals used in C3 but in shells of opposed quality, i.e., α and γ crabs of C3 occupying a STO and a LTO shell, respectively.
OPT: optimal shell size; STO: smaller-than-optimal shell size; LTO: larger-than-optimal shell size; L: large crab size and shell size; M: medium crab size and shell size; S: small crab size and shell size; α, β, and γ: dominance rank; *n*: sample size.

nonreproductive period (this species reproduces between October and May with a peak in autumn; Wilber, 1989). When crabs were tested in groups (experiments B, C, and D), the shells of every trio were marked by 0, 1, or 2 dots of permanent black ink to permit their identification. Individual hermit crabs were recognized by the length of their antennae and by slight differences in cheliped and pereopod color.

To make test animals as homogeneous as possible (for experiment A) and to obtain individuals that were similar (in C1 and C3) or different (in experiment B and in C2) for the quality of the occupied shell, crabs were extracted from their original shell by gently breaking it with a vise. Then, they were allowed to enter a new shell from a collection of five empty, undamaged, similarly sized shells that were prepared by collecting live periwinkle *Littorina littorea* (the dominant shell type used by the study population), boiling and removing the flesh, rinsing the shells several times in seawater, and air-drying them to remove odors of previous occupants (snail, epiphytes, etc.). Crabs were allowed 48-hr access to new shells, at which time they had ceased exploring and moving into new shells.

The size of the offered shells were changed in each experiment depending on the experimental protocol (see Table 1 and below). Shells were classified according to their length (measured from the base–apex axis in millimeters, SL) and to their adequacy for the body size of the inhabiting crabs. In fact, although hermit crabs can have preferences for various characteristics of shells, particularly in the case of the study species (Wilber, 1990), size is the most important determinant of shell selection.

Shells were categorized as L (SL > 18 mm), M (SL: 15–18 mm), and S (SL < 15 mm). The size of the optimal shell for a crab of a given size (OPT) was computed by regressing the equation $y = 37.9x + 7.3$, where y is SL and x is crab size (CW, in millimeters). This equation was obtained from a preliminary free-choice experiment in which every crab (of a total of 192) was allowed to choose among five empty shells of different size. Then, we defined as "larger-than-optimal" (LTO; and "smaller-than-optimal," STO) for a crab of a given size a shell whose size was about 10% longer (and shorter) than the size of the shell optimal for it.

Behavioral Assay: Crab Responses to a High-Quality Shell. The behavioral assay we used in the test phase was the investigative behavior shown by hermit crabs toward a novel shell that was about 10% longer than the optimal shell for the test crab's size (Gherardi and Tiedemann, 2004b). Notwithstanding its relatively large volume and heavy weight, this shell is highly attractive to *P. longicarpus*, as shown in a previous study (Gherardi, 2005). The cost of wearing a too large shell (e.g., the energetic costs of locomotion) seems to be overweighed in this species by a number of possible benefits. For instance, by accepting or even selecting an oversized shell, crabs may delay the need to find

larger shells to assure their growth and reproduction and gain some fighting advantages (Gherardi, 2005).

Tests were run in bowls containing 160-ml seawater that had been conditioned for an hour with the odor released by either shells (experiment A) or conspecifics (experiments B, C, and D). The experimental bowl was provided with an empty periwinkle shell placed with its apex upward, functioning as the target shell. This shell was prepared as described above for shell choice experiments; however, here, its aperture was blocked with a resin to avoid its occupation by the crab. Preliminary observations had shown that the resin and its odor had no effect on shell attractiveness.

Tests started by placing an individual (the receiver crab) into the bowl about 8 cm from the shell. Each receiver was subjected to two or three subsequent odor treatments, the sequence of which was varied systematically per crab. All hermit crabs of experiment A were used as receivers. In the other experiments in which we worked with trios, tests were conducted only on those crabs that had an intermediate score (hereafter defined β crabs) for dominance rank in experiments B and C1, for size (and rank, see below) in C2, and for shell quality (and rank, see below) in C3 and D.

For every odor treatment, the events occurring during 5-min observation and time were recorded on a voice tape and later analyzed to obtain: (1) latency in seconds (time until first shell investigation; when the test crab never investigated the shell, we arbitrarily assigned a time equal to 305 sec); (2) number of bouts of shell investigation; (3) total duration of shell investigation in seconds; and (4) total time spent in locomotion in seconds.

Experiment A: Recognizing the Odor of Empty Shells. Details for experiment A are given in Table 1. During shell choice, crabs were offered with shells optimal for their size. Then, they were kept isolated for 24 hr in bowls to become familiar with either one (LTO, A1) or two (one LTO and one STO, A2) empty, resin-blocked periwinkle shells. Treatments in the test phase were the odor from the familiar shell, as opposed to the odor from a novel shell (A1), and the odor from the LTO shell, as opposed to the odor from the STO shell (A2).

Experiment B: Discriminating the Odor between Familiar/Unfamiliar Conspecifics with Different Attributes. In this experiment, we investigated whether hermit crabs were able to discriminate by odor between two familiar (B1) or two unfamiliar (B2) conspecifics with different rank, size, and shell quality. Our purpose was to understand if crabs could chemically recognize more than one familiar individual while excluding the effects of rank odor. Trios were composed of α (large body size and large shells, OPT for the senders but LTO for the receivers), β (medium body size and medium shells, OPT for them), and γ (small body size and small shells, OPT for the senders but STO for the receivers) crabs. Other details are given in Table 1.

Familiarization started by placing three crabs in the experimental bowl and lasted 24 hr. The day after, we checked for shell switches that might have occurred overnight (none), and then we recorded the events taking place during 10-min observation; from these records, we evaluated the agonistic level of every trio from the number and the duration of fights. We defined as fights those interactions that started when one crab approached one or two rivals and ended when one or two opponents retreated to a distance greater than 3 cm and for at least 10 sec.

The dominance rank of an individual was defined from the relative number of wins. The winner was the opponent that did not retreat at the end of the interaction or that retreated after the other(s) withdrew into the shell. In the few instances in which the three crabs won the same number of interactions, we defined the ranks from the intensity of crab locomotion (i.e., the time spent exploring the experimental bowl). We never observed dominance reversal during any 10-min observation. Based on Winston and Jacobson's (1978) data, 24 hr were sufficient for the formation of a dominance hierarchy. In all groups analyzed, crabs that were classified as α, β, and γ for size and shell quality were also α, β, and γ, respectively, for rank. In the test phase, β crab behavior was analyzed in the presence of the odor released (1) by themselves (in both B1 and B2) or (2) by familiar (in B1) or unfamiliar (in B2) α and γ crabs.

Experiment C: Associating the Odor of Familiar Conspecifics with One Attribute. Because crabs seemed to discriminate between odors emitted by α and γ familiar conspecifics with different attributes, our aim was to investigate whether hermit crabs can associate the odor of the sender with one of its attributes. To this end, we analyzed crab behavior in the presence of odors from familiar conspecifics that differed for a single attribute (size in C2 and shell quality in C3), the other being equal. The results obtained from C2 and C3 were compared with C1, in which crabs differed for rank but had equal size and shell quality.

The familiarization phase was conducted as in experiment B. With only one exception in C3, crabs intermediate by size and by shell quality (i.e., β crabs in C2 and C3, respectively) were also β by rank. In the test phase, β crabs (the receivers) were presented with the odor of familiar α and γ crabs, which had the same size and shell quality as the receiver in C1, a different size (being either larger or smaller) but the same shell quality in C2, and the same size but either a LTO or a STO shell in C3 (see Table 1 for details).

Experiment D: Plasticity of the Association between Individual Odor and Shell Quality. We tested if crabs that had formed an association between the odor of a familiar conspecific and its shell quality would form a new association when the conspecific switched to a new shell of a different quality. In this experiment, we therefore investigated crab behavior when the familiar con-

specifics had been forced to occupy shells of poorer quality with respect to the shells they occupied previously.

We analyzed the results of 11 out of the 31 trios of C3, since five crabs died overnight and 15 shell switches occurred. Immediately after the test phase of C3, the shells occupied by α and γ crabs were gently broken with a vise, and crabs were forced to enter a novel shell that was STO for the former α crab and LTO for the former γ crab. After an hour of separation (not sufficient to forget former opponents; Gherardi and Atema, 2005b), we reconstituted the trios with the same individuals as in C3 but now with α in a low-quality shell and γ in a high-quality shell (see Table 1 for details). The new trios were then subjected to the familiarization phase and to the test phase as in experiment C.

Data Analyses. We applied nonparametric tests (Sokal and Rohlf, 1969; Siegel and Castellan, 1988) because the assumptions of normality of data and homogeneity of variance were not always met, and some measures taken represented ordinal data. We used Mann–Whitney *U* tests (statistics: *U* and *z* for samples >20) and Kruskal–Wallis one-way analyses of variance (statistic: *H*) to examine differences in the agonistic level reached by trios during the familiarization phase between/among the conditions of experiments B and C, respectively. We compared conditions for latency and for the other measures taken during the test phase using Wilcoxon matched-pairs signed-ranks tests (statistics: *T* and *z* for samples >25; experiments A, B, and D) and Friedman two-way analyses of variance (statistic: Fr; experiment C). When the null hypothesis was rejected after Friedman two-way analysis of variance, a multiple comparisons test (Siegel and Castellan, 1988) was used to determine which pairs of samples differed significantly. The test takes into account the correction of the α level for multiple comparisons (Siegel and Castellan, 1988). Text and figures provide medians and interquartile ranges (first–third quartiles). *P* values of less than 0.05 were considered statistically significant.

RESULTS

Experiment A: Recognizing the Odor of Empty Shells. Crab behavior in the test phase did not differ when water was conditioned with odor from either familiar or unfamiliar shells (A1) or from familiar shells of LTO/STO quality (A2; Table 2). Thus, crabs did not recognize familiar or high-quality shell attributes alone.

Experiment B: Discriminating Odor between Familiar/Unfamiliar Conspecifics with Different Attributes. In the familiarization phase, trios used for B1 and B2 displayed the same agonistic level (number of fights: $z = 0.86$, $P = 0.39$; duration of fights: $z = 1.44$, $P = 0.66$). This established that the results obtained

Sample size is shown in parentheses. The analyses were done by Wilcoxon matched-pairs signed-ranks tests (statistic: *T* and *z* for samples >25) except for B1 and B2, in which we used Friedman two-way analyses of variance (statistic: Fr). Significant differences in bold.

in test phases were not the effect of an inherent between-group difference in crab behavior.

In the test phase of experiment B1, β crabs investigated the target shell more often in the presence of odor from familiar conspecifics than with their own odor (Figure 2B, after multiple comparisons test: α crab odor = γ crab odor > self-odor). Shell investigation was also longer in the presence of α crab odor (Figure 2C, after multiple comparisons test: α odor > γ odor = self; Table 2). Different odors had no apparent effect on latency (Figure 2A) or on the duration of locomotion (Figure 2D). In experiment B2, β crabs discriminated between their own odor and the odor released by conspecifics, but they did not differentiate between unfamiliar α and γ crabs (Figure 2B, after multiple

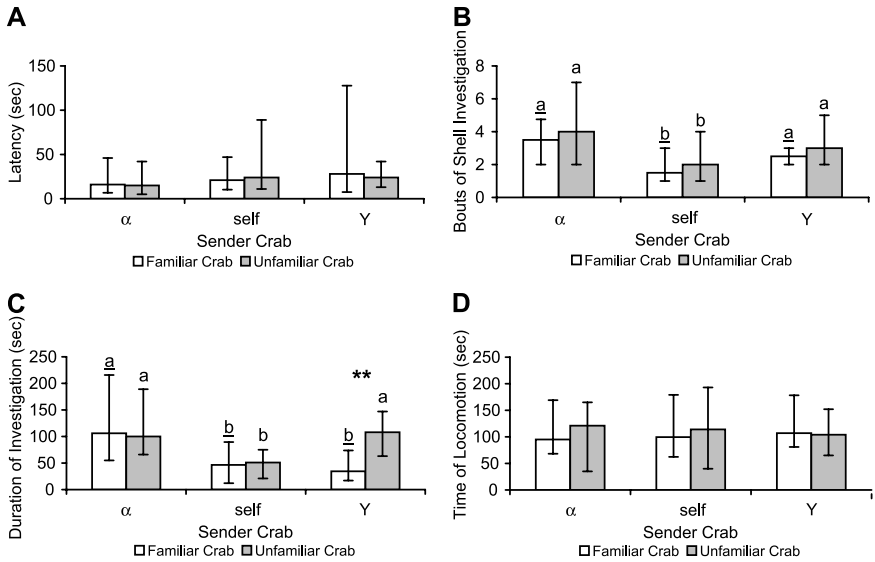

FIG. 2. Results from experiment B: discriminating odor between familiar/unfamiliar conspecifics with different attributes. Median values (and interquartile ranges) of latency (A), bouts of shell investigation (B), duration of shell investigation (C), and time of locomotion (D), compared between familiar (experiment B1) and unfamiliar (experiment B2) crabs, for three odor sources: α crabs, the test crabs (self, β crabs), and γ crabs. Alpha (and γ) crabs were the bigger (and smaller) crabs occupying a larger (and a smaller) shell compared to the β test crabs. See Table 2 for test statistics. Letters above bars (underlined for familiar crabs and not underlined for unfamiliar crabs) indicate differences among odor treatments (multiple comparisons test after Friedman two-way analysis of variance); ** denotes $P < 0.01$.

comparisons test: α odor = γ odor > self-odor; Figure 2C, after multiple comparisons test: α odor = γ odor > self-odor; Table 2).

Experiment C: Associating Odor of Familiar Conspecifics with One of Its Attributes. As in experiment B, trios used in C1, C2, and C3 showed the same agonistic level during the familiarization phase (number of fights: $H = 1.1614$, $df = 2$, $P > 0.05$; $H = 5.3524$, $df = 2$, $P > 0.05$; duration of fights: $H = 1.2573$, $df = 2$, $P > 0.05$; $H = 3.2290$, $df = 2$, $P > 0.05$), thus excluding inherent between-group differences in crab behavior.

In the test phase, crabs reacted in the same fashion to the target shell when the attributes of the senders differed for their rank only (experiment C1) or for their size (and rank) (experiment C2; Figure 3). However, in experiment C3, β

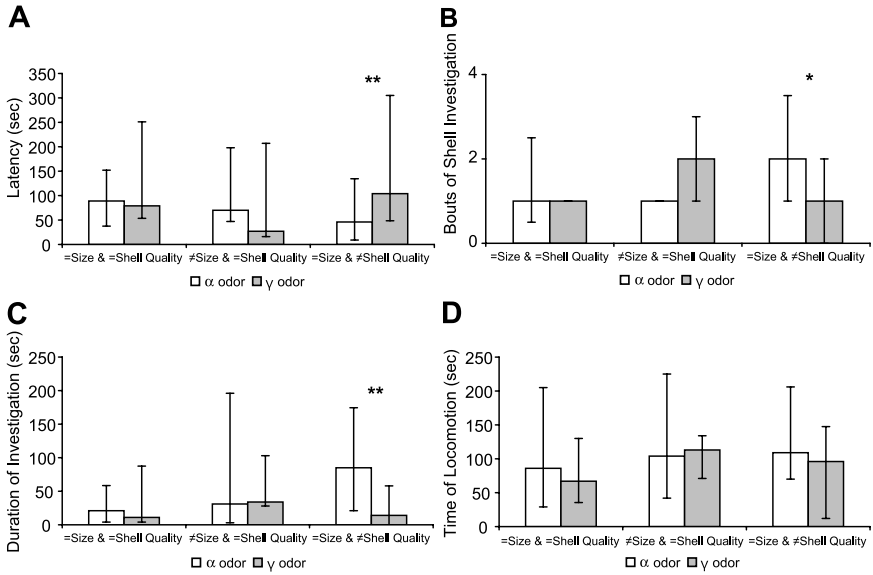

FIG. 3. Results from experiment C: associating odor of familiar conspecifics with one of its attributes. Median values (and interquartile ranges) of latency (A), bouts of shell investigation (B), duration of shell investigation (C), and time of locomotion (D), comparing treatments with odor from α and γ crabs in three conditions (same body size and same shell quality, C1, different body size and same shell quality, C2, and same body size and different shell quality, C3). Alpha (and γ) were the dominant (and subordinate) crabs in condition C1, the bigger (and the smaller) crabs in condition C2, and the crabs occupying a larger-than-optimal (and a smaller-than-optimal) shell in condition C3. See Table 2 for test statistics; * and ** denote $P < 0.05$ and $P < 0.01$, respectively.

crabs showed a quicker response to the target shell (Figure 3A), and they investigated it more often (Figure 3B) and for a longer time (Figure 3C) when the odor was emitted by crabs that occupied LTO (i.e., α crabs), rather than STO (i.e., γ crabs), shells (Table 2). No difference was found for the duration of locomotion (Figure 3D).

Experiment D: Plasticity of the Association Between Individual Odor and Shell Quality. Altering the quality of the shells occupied by α and γ crabs modified the behavior of β crabs. The quality of the shell, but not the identity of the sender crab inhabiting it, affected shell investigation by β crabs. Receivers (β crabs) reacted quicker (Figure 4A), with greater frequency (Figure 4B), and for a longer time (Figure 4C) in the presence of odor from senders in LTO shells regardless of their identity. The duration of locomotion (Figure 4D) did not differ significantly between experiments C3 and D (Table 2).

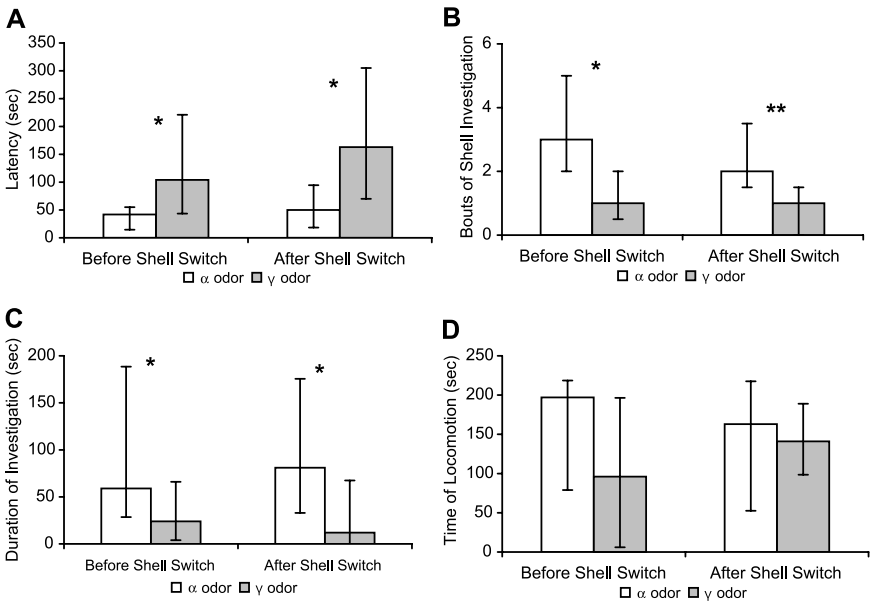

FIG. 4. Results from experiment D: plasticity of the association between individual odor and shell quality. Median values (and interquartile ranges) of latency (A), bouts of shell investigation (B), duration of shell investigation (C), and time of locomotion (D), comparing treatments with odor from α and γ crabs before (experiment C3) and after (experiment D) shell switch. Alpha (and γ) were the crabs occupying a larger-than-optimal (and a smaller-than-optimal) shell. Alpha (and γ) crabs in experiment D are the individuals that were ranked γ (and α) crabs in experiment C3. See Table 2 for test statistics; * and ** denote $P < 0.05$ and $P < 0.01$, respectively.

DISCUSSION

Our study revealed a number of properties that characterize the nature of individual recognition by odor in hermit crabs. First, it proved that *P. longicarpus* is unable to chemically recognize familiar and high-quality empty shells. Then, it showed that (1) there is no odor specific of a rank; (2) individual crabs discriminate their own odor from the odor of other individuals; (3) they can chemically discriminate between larger crabs inhabiting higher-quality shells and smaller crabs inhabiting lower-quality shells, provided that these crabs are familiar to them; (4) they associate the odor of an individual crab with the quality of the shell it inhabits; and (5) this association quickly changes when the social partners switch to shells of different qualities.

By excluding that individual recognition by hermit crabs could be simply a consequence of their ability to learn shell odors, this study confirms Gherardi and Tiedemann's (2004a) and Gherardi and Atema's (2005b) findings in the same species. To the contrary, Jackson and Elwood (1989) showed that *P. bernhardus* is able to discriminate, at least by sight, between familiar and novel empty shells, even if seemingly identical, by remembering certain subtle features of already investigated shells. Our results are also consistent in part with Gherardi and Tiedemann (2004b), who showed that *P. longicarpus* identifies its own odor from the odor of other individuals and is capable of chemically discriminating between familiar and unfamiliar conspecifics.

However, in Gherardi and Tiedemann's (2004b) study and in the majority of other studies on individual recognition in invertebrates (see Caldwell, 1985 for an exception), the tasks employed measured, at best, differences in responses to two "heterogeneous subgroups" of conspecifics (Barrows et al., 1975), i.e., familiar and unfamiliar subgroups. That is, results of such experiments simply arrived at documenting that the study animals were capable of a "binary" discrimination among opponents (Boal, 1996), but not of "true individual recognition" (i.e., the ability to discriminate one individual of a group from every other individual on the basis of "a unique set of cues defining that individual"; Beecher, 1989).

Our study has partly overcome this methodological limitation. By investigating graded animal responses to a target shell in the presence of odors of different provenience, we found that hermit crabs can chemically discriminate (1) between themselves and others and (2) between at least two familiar individuals with different attributes. As a consequence, *P. longicarpus* seems to rely on a form of recognition that is more complex than a simple binary system. Because crabs seemed not to discriminate among unfamiliar crabs with the same attribute differences as the familiar crabs, the ability to chemically recognize at least two different familiar individuals was not because of odors proper of a rank, of a size class, or of a shell type. To the contrary, our results

might be explained by hypothesizing that during the familiarization phase, the odor from a social partner is associated by the receiver with the rank, the size, or the shell quality of the sender (or with a combination of these three attributes).

Experiment C illustrated that *P. longicarpus* can associate odor from a conspecific with the quality of the shell it occupies and reacts accordingly in the presence of a target shell. It is likely that during the familiarization phase, individual odors became labels of shell quality; if these labels indicate a high shell quality, their detection evokes an intense shell investigation when the receivers are presented with a high-quality shell; otherwise, shell investigation would have been scarce or absent. This view was supported by experiment D that also showed the plasticity of individual odor–shell quality association. Once an individual crab had switched to a shell of a different quality, responses to the offered shell were consistent with the changed association. Shell investigation was strong in the presence of odor of former crab γ in a high-quality shell and weak in the presence of former crab α in a low-quality shell.

An explanation for these results might be provided by the model of classical conditioning. This has been advocated to describe the dynamics of odor learning involved in food location by honeybees (e.g., Menzel, 1999) and in host detection by parasitoid hymenopterans (e.g., Kaiser et al., 2003). In our case, hermit crabs may memorize a stimulus (conditioning stimulus, i.e., the odor of a social partner) when it is associated with an unconditioned stimulus (i.e., the high quality of the shell occupied by the sender). The conditioned stimulus then becomes predictive of the reward (i.e., the potential acquisition of a high-quality shell) and elicits a conditioned response identical to the response normally elicited by the unconditioned stimulus (unconditioned response, i.e., investigating the offered shell). However, a difficulty in applying this model to odor learning in hermit crabs arises when we examine the nature of the reward. Associative learning is usually highly sensitive to unrewarded presentations of the conditioned stimulus, and in our experiments, we tested only individuals that had not been successful in acquiring crab α shell. As a consequence, if associative learning is the mechanism underlying acquisition and retention of memory of individual odors in hermit crabs, the reward for these organisms should be regarded as neither immediate nor certain, but rather as prospective and likely.

The question remains why this hermit crab species relies on individual odors of conspecifics to identify the quality of a shell. The answer remains speculative and thus provisional without any systematic fieldwork. Previous studies (Rittschof, 1980a,b; Rittschof et al., 1992) have shown that *P. longicarpus*, and particularly individuals inhabiting badly fitting shells (e.g., Rittschof, 1980b; Gherardi and Atema, 2005b), are chemically attracted to gastropod predation sites by fluids from partly digested snail tissue. At these sites, the attracted crabs form temporary and relatively small aggregations (Scully, 1978),

in which they agonistically interact to establish dominance hierarchies (Winston and Jacobson, 1978). The dominant crab obtains the first opportunity to occupy the empty shell as it is released by the predator (McLean, 1975); afterwards, other individuals exchange shells down the hierarchy. As a consequence, these aggregations function as "shell markets" and benefit a large number of the predation site attendants (Rittschof et al., 1992). Having obtained a high-quality shell, a crab generally leaves the predation site (Rittschof, 1980a; Tricarico and Gherardi, unpublished data), thus subtracting the shell from the market. It would be advantageous for an individual to rapidly classify the quality of the shells inhabited by other attendants and to spend time combating or negotiating (Hazlett, 1978) for a "really good shell." Because of water turbidity typical of many salt marsh habitats, chemical cues signaling shell quality might provide more reliable information than visual stimuli emitted by the shell itself; on the other hand, the exclusive use of tactile information from the shell would require time and energy consumption in repeated investigatory acts. Previous studies have shown that *P. longicarpus* quickly learns the chemical identity of a social partner (Gherardi and Tiedemann, 2004b; Gherardi and Atema, 2005b), is inaccurate in discriminating shells by sight (Gherardi and Tiedemann, 2004a), and often switches shells without prior investigation (Scully, 1986). However, we cannot exclude that sight and touch might integrate olfaction and lead to the improved detectability and discriminability of signals (Gherardi and Tiedemann, 2004b).

In this scenario, the plastic nature of the association between the individual odor of a conspecific and the quality of its shell has a clear adaptive value. Obviously, any shell exchange breaks the link between a given hermit crab and a given shell. The aggregations of hermit crabs around gastropod predation sites are characterized by a cascade of shell switches as the effect of a vacancy chain process (Chase et al., 1988). Therefore, the plastic response to the cues associated with high-quality shells is a key factor to optimize shell acquisition and to reduce errors. Indeed, *P. longicarpus* learned the odor of a conspecific after less than 30-min exposure to a stimulus animal (Gherardi and Atema, 2005b).

A final intriguing result of our study is an outline of the kind of representation of social partners that hermit crabs may have. We found that the sender, labeled by its individual odor, was classified by the receiver in function of the quality of its shell; on the basis of this classification, the receiver seemed to modulate the intensity of its investigatory acts toward the offered shell. The mechanism needed for this kind of recognition is one that involves in the receiver the association of a type of information from the sender (e.g., chemical cues) with memories of past experiences with it (e.g., exploration of its shell; for a general discussion, see Johnston and Bullock, 2001). This representation could be thought of as hermit crabs having a "concept" of other individuals, and hints at potential for relatively high-order knowledge about conspecifics.

Acknowledgments—We thank three anonymous referees for constructive criticism to a previous version of the paper. The study was made possible by funds provided to F.G. by MBL Associates, Ann E. Kammer Memorial Fellowship Fund, H. Keffer Hartline Fellowship Fund, Frank R. Lillie Fund, and Plum Foundation.

PHEROMONE COMPONENTS FROM BODY SCALES OF FEMALE *Anarsia lineatella* INDUCE CONTACTS BY CONSPECIFIC MALES

(Received March 2, 2005; revised July 20, 2005; accepted August 19, 2005)

Abstract—Pheromonal communication of adult peach twig borers, *Anarsia lineatella* Zeller (Lepidoptera: Gelechiidae), was reinvestigated based on recent findings that virgin female-baited traps were more attractive to mate-seeking males than a two-component synthetic sex pheromone consisting of (*E*)-5-decen-1-yl acetate (1000 μg) and (*E*)-5-decen-1-ol (100 μg), suggesting that females use additional pheromone components. Hypothesizing that these additional components may be released from body parts other than abdominal sex pheromone glands, we extracted female body scales and analyzed aliquots by coupled gas chromatographic–electroantennographic detection (GC-EAD) and GC–mass spectrometry. Eight straight-chain and four methylated aliphatic hydrocarbons, as well as two acetates, all elicited responses from excised male antennae. In laboratory experiments with synthetic candidate pheromone components, a combination of octadecyl acetate, (*R*)-11-methyltricosane, and (*S*)-11-methyltricosane in the presence of gland-derived sex pheromone components were shown to elicit contact of female decoys by males. However, body pheromone components did not enhance attractiveness of sex pheromone components in field trapping experiments, suggesting that they are effective only at close range and that other stimuli are responsible for superior attractiveness of female-baited traps.

Key Words—*Anarsia lineatella*, peach twig borer, sex pheromone, body pheromone, scales, contact, close-range communication, enantiomer, octadecyl acetate, (*R*)-11-methyltricosane, (*S*)-11-methyltricosane.

INTRODUCTION

Roelofs et al. (1975) identified a two-component sex pheromone consisting of (*E*)-5-decen-1-yl acetate (*E*5-10:OAc; 87%) and (*E*)-5-decen-1-ol (*E*5-10:OH; 13%) in pheromone gland extracts of female *Anarsia lineatella* Zeller (Lepidoptera: Gelechiidae) that attracted conspecific males. Synthetic pheromones released from various dispensers and traps were tested as tools for monitoring populations of *A. lineatella* in commercial fruit orchards (Rice and Jones, 1975; Hathaway, 1981; Kehat et al., 1994). Deployment of synthetic pheromone for control of *A. lineatella* by pheromone-based mating disruption yielded unsatisfactory results (Rice, personal observation, cited in Millar and Rice, 1992). Re-analysis of the pheromone of *A. lineatella* led to the identification of several candidate pheromone components [decyl acetate, (*E*)- and (*Z*)-4-decenyl acetate, and (*E*,*E*)-3,5- and (*Z*,*E*)-3,5-decadienyl acetates; Millar and Rice, 1992], but none enhanced long-range attractiveness of the previously identified two-component blend (Roelofs et al., 1975). Traps baited with the two-component blend of *E*5-10:OAc (1000 μg) and *E*5-10:OH (100 μg) remained significantly less attractive than those baited with virgin female *A. lineatella* (Schlamp, 2005). These results suggested that if additional pheromonal communication signals existed, they probably were present in, or released from, body parts other than abdominal pheromone glands.

Contact- or copulation-inducing pheromones are typically present on the body surface of (signaling) insects. Although they appear effective only at short range, they often complement attractiveness of long-range sex or aggregation pheromones. Close-range pheromones have been noted and/or identified, in several orders of the Insecta, including Diptera (Stoffolano et al., 1997), Hymenoptera (Kimani and Overholt, 1995), Coleoptera (Ginzel et al., 2003), Isoptera (Clement, 1982), and Lepidoptera (Grant et al., 1987). Conceivably, similar pheromone components may exist in *A. lineatella* and play a role in short-range communication among males and females.

Our objective was to test the hypothesis that pheromone components derived from body scales of females are part of the sexual communication system in *A. lineatella*.

METHODS AND MATERIALS

Rearing of Insects. Insects were collected from peach orchards in Keremeos, British Columbia, and reared according to protocols developed and modified, respectively, by McElfresh and Millar (1993) and Sidney (2005).

Body Extraction of Moths. Separate groups of 10, 3- to 6-d-old males or females were submerged in pentane. After 5 min, the supernatant was withdrawn

and pipetted into a new vial. This procedure was repeated twice with the same group of moths, and extracts were then combined and concentrated such that 12.5 μl equaled one body-extract equivalent. All extracts were prepared during the photophase, well separated from the (pre)dawn calling period of females, thus minimizing potential extraction of sex pheromone components from abdominal pheromone glands.

Analyses of Extracts. Aliquots of body extracts were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD; Arn et al., 1975; Gries et al., 2002), employing a Hewlett-Packard 5890 gas chromatograph fitted with a GC column (30 m × 0.25 or 0.32 mm ID) coated with DB-5, DB-23, DB-210 (J&W Scientific, Folsom, CA, USA), or SP-1000 (Supelco, Bellefonte, PA, USA). For GC-EAD recordings, an antenna was gently pulled from an insect's head, the distal segment removed, and then suspended between glass capillary electrodes filled with Ringer's solution [NaCl (6.5 g/l), KCl (1.4 g/l), $CaCl_2$ (0.12 g/l), Na_2CO_3 (0.1 g/l), Na_2HPO_4 (0.01 g/l)] in distilled water. Coupled GC–mass spectrometric (MS) analyses of pheromone extract [300 female equivalents (FE)] and of synthetic standards employed a Varian Saturn 2000 Ion Trap GC-MS fitted with the above-referenced DB-5 column.

General Instrumentation and Syntheses. Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on a Varian AS500 (at 499.77 MHz for ^1H and 125.68 MHz for ^{13}C) spectrometer with chemical shifts reported in ppm relative to TMS (^1H, $\delta = 0.00$) and $CDCl_3$ (^{13}C, $\delta = 77.00$). Elemental analyses were performed using a Carlo-Erba model 1106 elemental analyzer. Optical rotations were measured with a Perkin-Elmer 341 polarimeter.

(*Z*)-11-Eicosenyl acetate (Sugawara et al., 1978) was obtained by reduction of (*Z*)-11-eicosanoic acid (Aldrich) with lithium aluminum hydride in tetrahydrofuran (THF) to (*Z*)-11-eicosen-1-ol and acetylation of this alcohol (Pederson et al., 2003) with acetic anhydride in the presence of pyridine.

Previously reported methylated hydrocarbons 11-methyltricosane (11me-23Hy), 2-methyltetracosane (2me-24Hy), 11-methylpentadecane (11me-25Hy), and 13-methylheptacosane (13me-27Hy) (Jackson, 1970; Tarvita and Jackson, 1970; Howard et al., 1978; Tsuda et al., 1981; Lange, 1993; Szafranek et al., 1994; Finidori-Logli et al., 1996; Wagner et al., 1998; Haverty et al., 2000) were synthesized from corresponding carbonyl precursors and ylids by Wittig reactions and by subsequent hydrogenation of the resulting olefins in the presence of platinum oxide.

*(S)-and (R)-11-Methyltricosanes (**8** and **12**, Figure 1). tert*-Butyldimethylsilylchloride (3.50 g; 1.1 equiv.) and 1.60 g (1.1 equiv.) of imidazole were added to 2.50 g of methyl (*R*)-3-hydroxy-2-methyl propanoate **1** (21.2 mmol; Aldrich) dissolved in 10 ml dimethylformamide. After stirring overnight at room temperature (RT), methyl (*R*)-3-*tert*-butyldimethylsilyloxy-2-methyl-

propanoate **2** was obtained in quantitative yield. Borane reduction of silyl ether **2** with 45 ml of a 1.0 M solution of BH_3 in a THF matrix under argon yielded known (*S*)-2-methyl-3-*tert*-butyldimethylsilyloxy-1-propanol (**3**) (King et al., 1995) after 48 hr. Ether **3** (quantitative yield) was isolated by quenching the reaction mixture with concentrated aq. $NaHCO_3$. The product was extracted with a 1:1 mixture of ether/hexane (3 × 50 ml), dried ($MgSO_4$), and the solvent was removed *in vacuo*.

All of monosilyl ether **3** (>99% pure, GC) was converted to (*R*)-mesylate **4** (King et al., 1995) at 0°C in dichloromethane with 1.1 equiv. of methanesulfonyl chloride and 1.5 equivalent of triethylamine. After 30 min of vigorous stirring at 0°C, the mixture was allowed to warm to RT and quenched with water. The organic layer was extracted with hexane, washed with 0.5 M HCl, concentrated aq. $NaHCO_3$ and brine, and dried ($MgSO_4$). After removal of excess solvents at 15 mm Hg, 10 ml of dry THF were added to the sulfonate. The mixture was transferred slowly via cannula under argon pressure to a stirred suspension of Grignard reagent [freshly prepared from 10.5 ml (55 mmol) of *n*-nonyl bromide and 2.7 g (111 mmol) of Mg] and CuI (0.84 g, 4.4 mmol) in 100 ml of THF at −23°C. After 1 hr, the reaction mixture was warmed to RT and quenched with a concentrated aq. NH_4Cl solution. The organic layer was extracted with hexane (2 × 75 ml), washed with water and brine, and dried (Na_2SO_4). The product was concentrated *in vacuo* and filtered through 10 g of silica to yield crude (*S*)-2-methyl-1-(*tert*-butyldimethylsilyloxy)-dodecane (**5**). Without any further purification, the silyl protective group was removed by stirring **5** with an excess of tetrabutylammonium fluoride in THF/H_2O

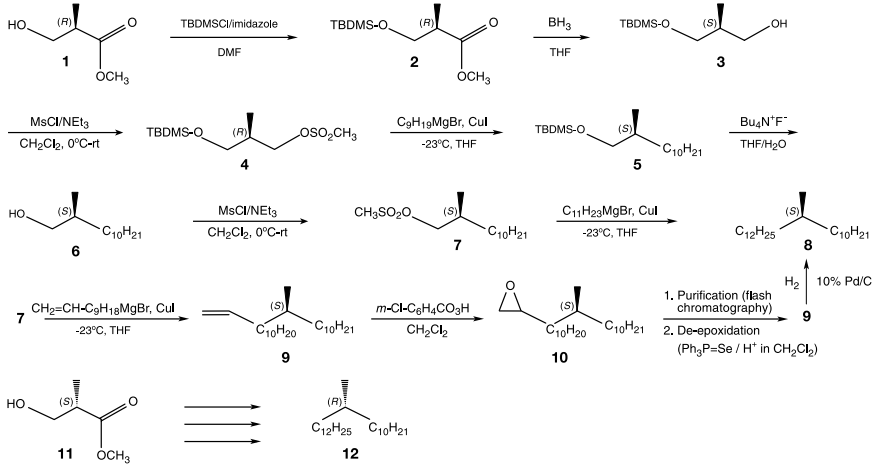

FIG. 1. Scheme for the syntheses of (*R*)- and (*S*)-11-methyltricosane.

overnight. Alcohol **6** was extracted from the reaction mixture with 100 ml of ether/hexane (1:1) and washed with water and brine. The organic layer was then dried ($MgSO_4$) and concentrated *in vacuo*. Flash column chromatography [50 g of silica, hexane/ether as eluent with gradual increase (5–15%) of the ether content] afforded 2.30 g (11.5 mmol, 54% yield based on propanoate **1**) of 96% pure (*S*)-2-methyl-1-dodecanol (**6**), $[\alpha]_D^{23} = -8.4°C$ (c 1.0; $CHCl_3$). Anal. calculated for $C_{13}H_{28}O$ (%): C 77.93, H 14.09; found: C 77.80, H 14.01. ^1H NMR ($CDCl_3$), δ (ppm): 0.87 (t, 3H, $J = 7.0$ Hz), 0.90 (d, 3H, $J = 6.7$ Hz), 1.22–1.40 (m, 17H), 1.59 (m, 2H), 3.39 (dd, 1H, $J = 6.2$, 10.5 Hz), 3.49 (dd, 1H, $J = 6.2$, 10.5 Hz). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.08, 16.54, 22.66, 26.96, 29.32, 29.62, 29.63, 29.65, 29.93, 31.90, 33.13, 35.73, 68.35.

Mesylation of alcohol **6** (2.00 g, 10.0 mmol; conditions, reagent ratio, and workup as described for conversion of alcohol **3** to mesylate **4**) and immediate Grignard coupling of methanesulfonate **7** with 10-undecen-1-ylmagnesium bromide in the presence of CuI [7.60 ml (35.0 mmol) of 11-bromo-undec-1-ene (Aldrich), 1.70 g (70 mmol) of Mg, and 0.57 g (3.0 mmol) of CuI; reaction conditions and workup as described for the synthesis of ether **5**] yielded (*S*)-13-methyl-1-tridecene **9** (28%) with the following impurities in the mixture: 1,9-undecadiene (7%), 1-undecene (52%), 10-undecen-1-ol (2%), 1,21-docosadiene (7%), alcohol **6** (2%), and mesylate **7** (1%). Polar impurities were removed by filtering the mixture through 10 g of silica with hexane. Filtrates containing hydrocarbons were concentrated *in vacuo* and added to a cold solution of 11.2 g (77% pure, 50 mmol) of *m*-chloroperbenzoic acid (Aldrich) in 20 ml of CH_2Cl_2. The mixture was stirred for 3 hr at 0°C, allowed to warm to RT, and then quenched with 100 ml of 1 N NaOH. The organic layer was extracted with ether (2×50 ml), washed twice with water and brine, dried ($MgSO_4$), and concentrated *in vacuo*, yielding a mixture of mono- and di-epoxides. Flash column purification (50 g of silica, 2% ether in hexane as eluent) of this mixture gave 3.10 g of epoxide **10** (61% pure by GC) with 1,2-epoxyundecane as the main impurity (30%). No di-epoxides were present as impurities. De-epoxidation of the mixture containing **10** was carried out with freshly prepared triphenylphosphonium selenide [obtained by stirring 8.26 g (31.5 mmol) of TPP and 2.49 g (31.5 mmol) of Se for 30 min] in 50 ml of CH_2Cl_2 with 1 ml of trifluoroacetic acid (Clive, 1978). After 1 hr of stirring at RT, solvents were removed *in vacuo*. The mixture was filtered through 20 g of silica with 150 ml of hexane. Olefin **9** (65% pure by GC) was then hydrogenated in hexane with 10% Pd/C (3 hr). The catalyst was eliminated by filtering through 5 g of silica, and the solvent was removed *in vacuo* at 15 mm Hg. Undecane and other low-boiling impurities were removed at 2–3 mm Hg (70°C, 2 hr), yielding >98% pure (*S*)-11-methyltricosane (**8**) (1.68 g, 4.96 mmol, 50% yield based on alcohol **6**, overall yield 26.5%). Anal. calculated for $C_{24}H_{50}$ (%): C 85.12, H 14.88; found: C 85.06, H 15.08. ^1H NMR (in $CDCl_3$), δ (ppm): 0.83 (d, 3H, $J = 6.6$

Hz), 0.88 (t, 6H, J = 6.9 Hz), 1.18–1.37 (m, 41 H); ^{13}C NMR (in $CDCl_3$), δ (ppm): 14.09, 19.70, 22.67, 27.06, 29.34, 29.63–29.68 (several unresolved peaks), 30.00, 31.90, 32.72, 37.07.

Coupling of the mesylate **7** with 1-undecylmagnesium bromide leads directly to hydrocarbon **8**, which was impossible to separate from by-product docosane. In the reaction mixture, **8** comprised 20%; after the removal of low-boiling and polar impurities, it was ~60% pure.

(*R*)-11-Methyltricosane (**12**) was synthesized through the same route, starting with methyl (*S*)-3-hydroxy-2-methylpropanoate (**11**; overall yield 20%). GC retention times and NMR data matched those of (*S*)-11-methyltricosane (**8**). Optical rotation for intermediate (*R*)-2-methyl-1-dodecanol: $[\alpha]^{23}_D$ = +6.1°C (c 7.7; $CHCl_3$).

Laboratory Experiments with Pheromone Components. Candidate body pheromone (BP) components were tested in laboratory bioassays, employing a mesh (200 μm) cage (90 × 90 × 100 cm; BioEquip Products, Inc., Rancho Dominguez, CA, USA), with one of the two test stimuli randomly assigned to opposite corners of the cage. A test stimulus consisted of a white Teflon® decoy (0.25 × 0.75 cm) pinned to the center of an inverted Petri dish (10 × 2 cm) and impregnated with gland pheromone (GP) components or GP plus synthetic candidate BP components at 10 FE. For each replicate, 10 3- to 6-d-old males were introduced into each cage and acclimatized for 12 hr to environmental conditions (23°C; >70% RH; 16-hr light–8-hr dark) prior to testing. Bioassays were initiated by introducing test stimuli, starting a custom-designed computer program (Raymond G. Holland, Electronic Supervisor, Science Technical Centre, SFU, unpublished data) that increased the intensity of the light source (60-W Phillips incandescent light bulb) from 0 to 600 lx within 15 min, and by manually turning on a desk swing fan (Windmere, Miramar, FL, USA) behind the bioassay cage, which delivered intermittent pulses of air (0.3 m/sec). For each bioassay, numbers of contacts with test stimuli were recorded for 15 min. Repeated contacts by the same male were recorded, if that male was more than one body length apart from the stimulus between consecutive contacts. Each of 15 replicates per experiment employed a new set of 10 males and test stimuli.

Ten instead of 1 FE of candidate BP components were bioassayed taking into account that body scales may be better pheromone dispensers than Teflon® decoys, or that live female *A. lineatella* may replenish their pheromone components over time, whereas we administered only a single application of test stimulus at the beginning of each 15-min bioassay. The experimental protocol did not allow more than three replicates per day, so group bioassays instead of single-insect bioassays were conducted. This ensured that some males responded to test stimuli in each bioassay despite the lack of sonic signals females emit in response to sonic signals from males (Hart et al., Gries laboratory, unpublished data).

Two synthetic GP components [*E*5-10:OAc (100 ng) and *E*5-10:OH (10 ng)] were tested alone or in combination with the following: (1) body extract of females at 10 FE (experiment 1); (2) a complete synthetic blend of candidate BP components, consisting of two acetates [octadecyl acetate (18:OAc), (*Z*)-11-eicosenyl acetate (*Z*11-20:OAc)], four methylated hydrocarbons [11-methyltricosane (11me-23Hy), 2-methyltetracosane (2me-24Hy), 11-methylpentadecane (11me-25Hy), 13-methylheptacosane (13me-27Hy)], and eight straight-chain hydrocarbons [docosane (22Hy), tricosane (23Hy), tetracosane (24Hy), pentacosane (25Hy), hexacosane (26Hy), octacosane (28Hy), nonacosane (29Hy), and tricontane (30Hy)] (experiment 2); (3–6) BP *minus* the two acetates 18:OAc and *Z*11-20:OAc (experiment 3), BP *minus* all hydrocarbons (experiment 4), BP *minus* methylated hydrocarbons (experiment 5), or BP *minus* straight-chain hydrocarbons (experiment 6).

BP blends lacking acetates (experiment 3) or methylated hydrocarbons (experiment 5) were not effective in increasing the number of body contacts, so follow-up experiments explored which acetate (experiments 7 and 8) or methylated hydrocarbon(s) (experiments 9–12) contributed to behavioral activity of the BP blend. 18:OAc appeared more effective than *Z*11-20:OAc (experiments 7 and 8), and 11me-23Hy was the single-most effective methylated hydrocarbon (experiment 11), so additional experiments were run to investigate which enantiomer of 11me-23Hy was behaviorally active by testing GP alone or in combination with 18:OAc plus (*S*)-11-methyltricosane [(*S*)-11me-23Hy] (experiment 13), (*R*)-11-methyltricosane [(*R*)-11me-23Hy] (experiment 14), or both (1:1; experiment 15). With the presence of both the *R*- and *S*-enantiomers of 11-methyltricosane needed for males to respond (experiment 15), experiment 16 tested GP plus female body extract vs. GP plus synthetic 18:OAc and (*R*)- and (*S*)-11me-23Hy at equivalent ratios and quantities. Paired mean contacts of paired stimuli by male moths were analyzed statistically using paired *t* tests (Zar, 1996). All statistical analyses were performed with JMP® Version 4 (SAS Institute, Cary, NC, USA).

RESULTS

Gas chromatographic–electroantennographic detection analyses of body extracts from female *A. lineatella* revealed small amounts (<0.2 ng) of the two sex pheromone components *E*5-10:OAc and *E*5-10:OH and numerous compounds that elicited responses from male antennae and several that did not (Figure 2). In GC-MS analyses, two of these EAD-active compounds with fragmentation ion *m*/*z* 61 (indicative of an acetate functionality) and with molecular ions *m*/*z* 312 and *m*/*z* 338 were identified as octadecyl acetate

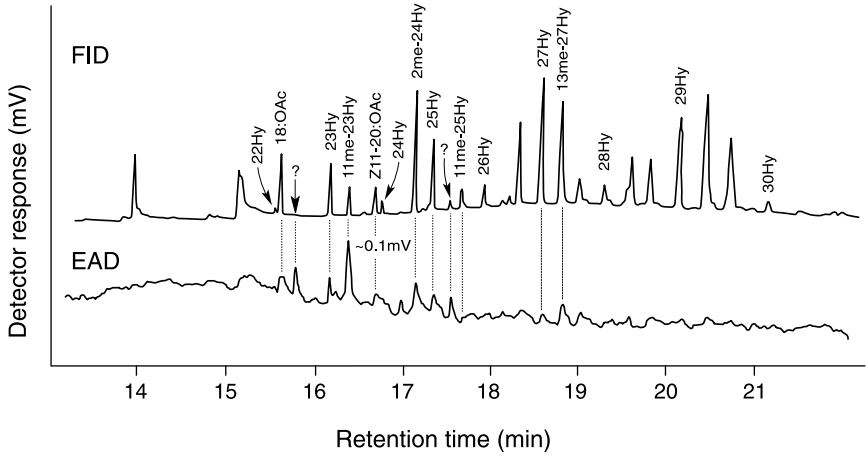

FIG. 2. Representative recording (N = 5) of flame ionization detector (FID) and electroantennographic detector (EAD: male *Anarsia lineatella* antenna) responses to 10 equivalents of body extract of female *A. lineatella*. Chromatography: splitless injection; injector and FID: 240°C, DB-5 column (30 m × 0.32 mm ID); temperature program: 50°C (2 min), then 15°C/min to 280°C (10 min). Compound abbreviation [with amounts per 1 female equivalent (FE) in parenthesis] as follows: 22Hy = docosane (7.4 ng); 18:OAc = octadecyl acetate (7.7 ng); 23Hy = tricosane (6.5 ng); 11me-23Hy = 11-methyltricosane (3.8 ng); *Z*11-20:OAc = (*Z*)-11-eicosenyl acetate (3.8 ng); 24Hy = tetracosane (1.8 ng); 2me-24Hy = 2-methyltetracosane (15.0 ng); 25Hy = pentacosane (9.1 ng); 11me-25Hy = 11-methylpentacosane (1.0 ng); 26Hy = hexacosane (3.1 ng); 27Hy = heptacosane (20 ng); 13me-27Hy = 13-methylheptacosane (19.0 ng); 28Hy = octacosane (3.6 ng); 29Hy = nonacosane (19.9 ng); 30Hy = triacontane (2.9 ng).

(18:OAc) and an eicosenyl acetate, respectively. Dimethyl disulfide treatment (Dunkelblum et al., 1985) of the latter without prior isolation yielded an adduct with GC-MS fragmentation ions *m*/*z* 173 and *m*/*z* 259, indicative of a double bond at C11. This compound was thus postulated and, through comparative GC-MS of an authentic standard, confirmed to be (*Z*)-11-eicosenyl acetate (*Z*11-20:OAc).

Mass spectra of other EAD-active compounds in female body extracts suggested that they were saturated hydrocarbons. Four of these had retention indices (Van den Dool and Kratz, 1963) indicative of methyl branches. Their mass spectra revealed fragmentation ions diagnostic of methyl branch positions (Pomonis et al., 1980; Francke et al., 1987, 1988; Gries et al., 1991, 1993, 1994) and suggested that they were 11me-23Hy, 2me-24Hy, 11me-25Hy, and 13me-27Hy, respectively. Comparative GC-MS of insect-produced and authentic standards confirmed the structural assignments.

Laboratory Experiments with Candidate Contact Pheromone Components. Teflon® decoys impregnated with body extracts from female *A. lineatella* at 10 FE plus GP components provoked more decoy contacts by male *A. lineatella* than GP components alone (Figure 3; experiment 1). These results could not be attributed to small (<0.2 ng) amounts of the sex pheromone components *E*5-10:OAc and *E*5-10:OH in body extracts of female moths because both treatment and control stimuli contained 100 and 10 ng, respectively, of synthetic *E*5-10:OAc and *E*5-10:OH.

A synthetic blend of all candidate BP components at ratios and concentrations equivalent to 10 FE plus GP provoked more contacts by males

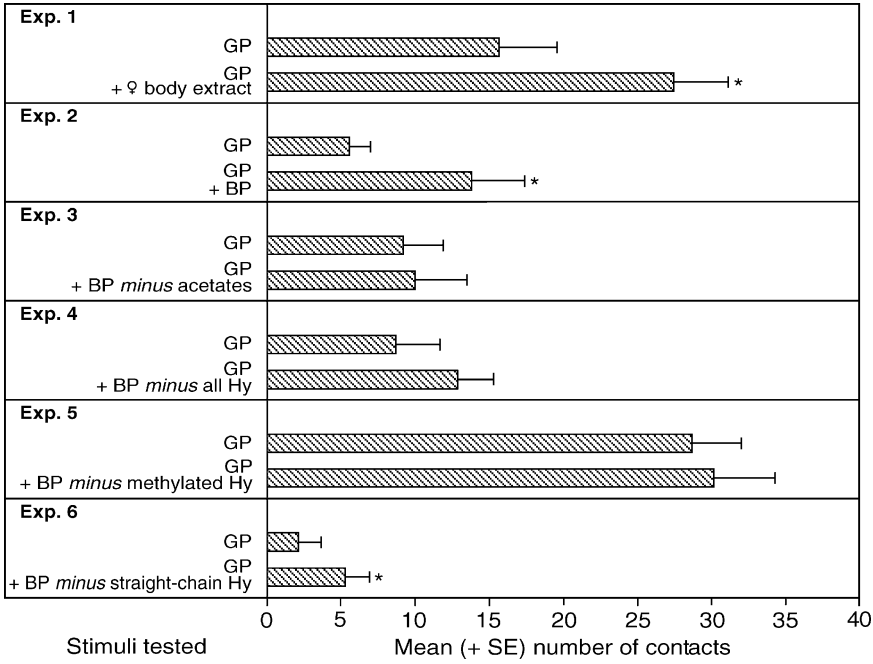

FIG. 3. Mean (+ SE) number of contacts made by male *Anarsia lineatella* in experiments 1–6 (15 replicates each) with a Teflon® decoy impregnated with various test stimuli. In each experiment, an asterisk (*) indicates a significant preference for a particular stimulus; paired *t* test, $P < 0.05$. Abbreviations as follows: GP = synthetic gland pheromone components [(*E*)-5-decen-1-yl acetate (100 ng) and (*E*)-5-decen-1-ol (10 ng)]; female body extract = body extract of female *A. lineatella* tested at 10 female equivalents; BP = synthetic body pheromone components consisting of two acetates [18:OAc, *Z*11-20:OAc], four methylated hydrocarbons (Hy) [11me-23Hy, 2me-24Hy, 11me-25Hy, 13me-27Hy], and eight straight-chain hydrocarbons [22Hy, 23Hy, 24Hy, 25Hy, 26Hy, 28Hy, 29Hy, 30Hy]. For full names of chemicals, see caption of Figure 2.

than GP alone (Figure 3; experiment 2). Synthetic BP blends lacking straight-chain hydrocarbons were still bioactive (Figure 3; experiment 6), but BP blends lacking acetates (Figure 3; experiment 3), all hydrocarbons (Figure 3; experiment 4), or all methylated hydrocarbons (Figure 3; experiment 5) were not. Neither *Z*11-20:OAc nor 18:OAc alone significantly enhanced the attractiveness of GP (Figure 4; experiments 7 and 8), but the opposite was true for 18:OAc combined with four methylated hydrocarbons (Figure 4; experiment 9).

Deleting a group of two or single methylated hydrocarbons from the BP blend determined that only 11me-23Hy, in addition to 18:OAc, is needed to retain the blend's behavioral activity (Figure 4; experiments 10–12).

The *R*- and *S*-enantiomers of 11me-23Hy in combination, but not singly, are BP pheromone components (Figure 5; experiment 15). A BP blend with the

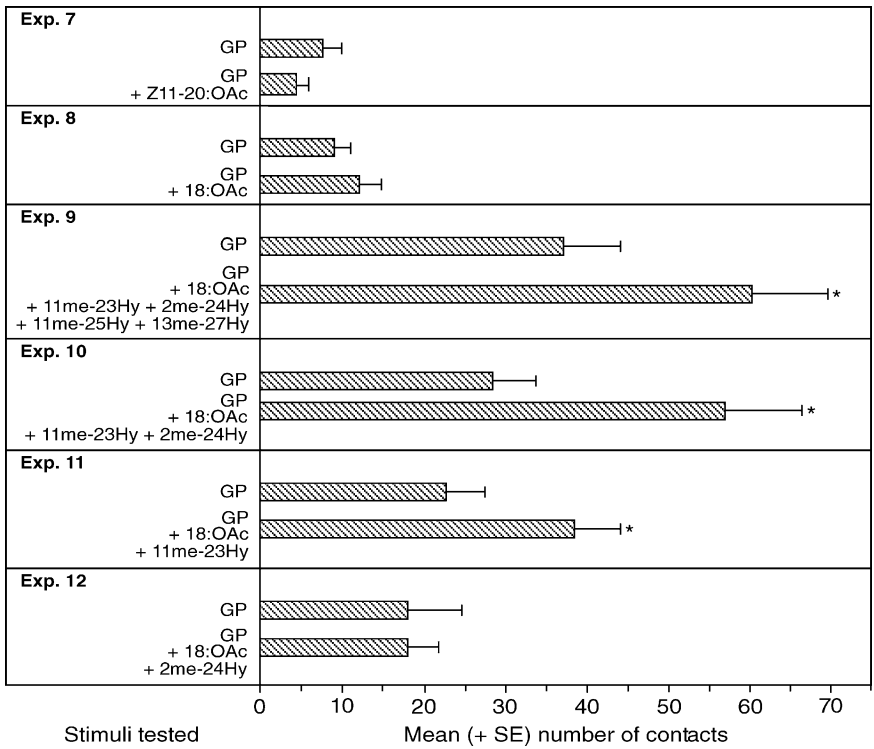

FIG. 4. Mean (+ SE) number of contacts made by male *Anarsia lineatella* in experiments (Exp.) 7–12 (15 replicates each) with a Teflon® decoy impregnated with various test stimuli. In each experiment, an asterisk (*) indicates a significant preference for a particular treatment; paired *t* test, $P < 0.05$. Abbreviations as in captions of Figures 2 and 3.

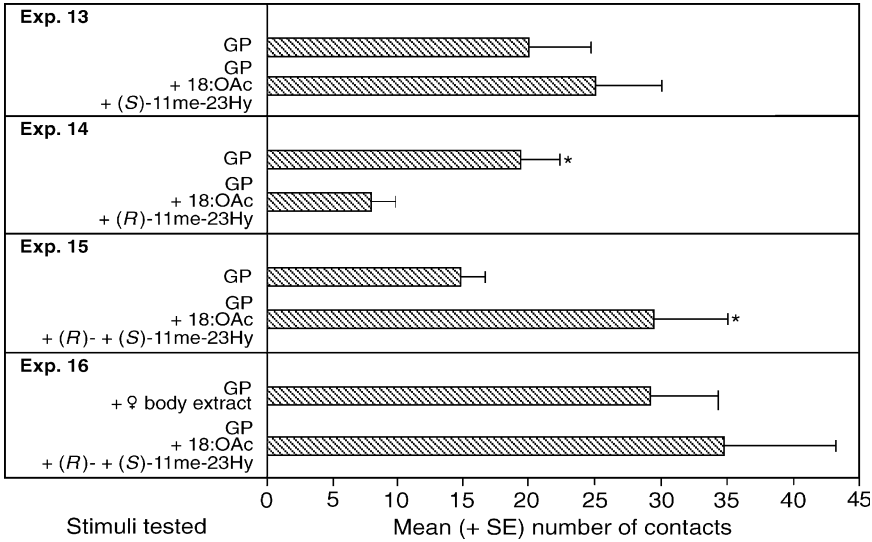

FIG. 5. Mean (+SE) number of contacts made by male *Anarsia lineatella* in experiments 13–16 (15 replicates each) with a Teflon® decoy impregnated with various test stimuli. In each experiment, an asterisk (*) indicates a significant preference for a particular treatment; paired *t* test, $P < 0.05$. (*R*)- and (*S*)-11me-23 = (*R*)- and (*S*)-11-methyltricosane, respectively. Other abbreviations as in captions of Figures 2 and 3.

S-enantiomer alone was benign (Figure 5; experiment 13) and was inhibitory with the *R*-enantiomer alone (Figure 5; experiment 14). The three-component BP blend consisting of 18:OAc, (*R*)-11me-23Hy, and (*S*)-11me-23Hy was as effective as a body extract in provoking contacts by male *A. lineatella* (Figure 5; experiment 16).

DISCUSSION

Significantly more captures of male *A. lineatella* in traps baited with conspecific virgin females than in those baited with a two-component synthetic sex pheromone (Schlamp, 2005) suggested that females use additional communication signals to attract mate-seeking males. Our data indicate that close-range communication signals include pheromone components from the females' body surface that may provoke contact by males.

Although numerous compounds were extractable from the females' body surface and elicited responses from male antennae (Figure 2), the body pheromone

(BP) seems to comprise only three components: 18:OAc, (*R*)-11me-23Hy, and (*S*)-11me-23Hy (Figures 4 and 5). Positive responses by males only to BP blends containing both the *R*- and *S*-enantiomers of 11me-23Hy (Figure 5; experiments 13–15), and even inhibition of response to blends containing only the *R*-enantiomer (Figure 5; experiment 14), indicate that (*R*)- and (*S*)-11me-23Hy are BP components of female *A. lineatella*.

Varying levels of responding insects to control stimuli from one experiment to another were likely because of the fact that we proceeded with experiments even at low atmospheric pressure, which is not conducive to high levels of response. Treatment stimuli also differed in their attractiveness, further modifying the overall level of response between experiments. However, with the same control stimulus retained in each experiment, we could assess the relative strength of a treatment stimulus within and between experiments.

Methyl (*R*)- and (*S*)-3-hydroxy-2-methylpropanoates (99% ee) were chosen as starting materials for the syntheses of the enantiomers of 11-methyltricosane by a route that did not affect the chiral center. When the Grignard coupling of mesylate **7** with *n*-undecylmagnesium bromide was performed, an inseparable mixture of desired hydrocarbon **8** and the Grignard reagent dimer by-product *n*-docosane formed. To obtain pure **8**, we coupled mesylate **7** with 10-undecen-1-ylmagnesium bromide. The unsaturated reaction products were converted into their respective epoxides, and mono-epoxide **10** was separated from the di-epoxide derived from the Grignard by-product. Regenerated (by de-epoxidation) olefin **9** was then hydrogenated to give the final compound **8**. Polarimetric studies of final products **8** and **12** did not yield measurable values of optical rotation.

Body pheromone components may serve as ultimate cues to confirm the proper species, and sex, of a prospective mate. The two acetates, 18:OAc and *Z*11-20:OAc, are indeed present only in body extracts of female but not male *A. lineatella* (data not shown), suggesting that they may help males recognize females. In contrast, 11me-23Hy is present in body extracts of both males and females (data not shown), suggesting that it is not suitable for mate recognition. However, considering that both enantiomers of 11me-23Hy were required to induce positive responses by males, the presence of only one (*R*) or both enantiomers may help reveal the signaler's sex. In field experiments (Schlamp, 2005), those contact pheromone components had no effect on long-range attraction of male *A. lineatella*, indicating that they play a role only at close range before or during courtship.

This type of close- and long-range communication system with components from sex pheromone glands and body scales has been reported in other species of moths. Live female gypsy moths *Lymantria dispar* or physical models of female *L. dispar* baited with sex pheromone and covered with female abdominal scales, elicited copulatory responses by males, whereas exposure of

males to sex pheromone alone did not (Charlton and Cardé, 1990). Similarly, males of the smaller tea tortrix moth *Adoxophyses orana* will attempt copulation only in the presence of female-produced sex pheromone and scales (Shimizu and Tamaki, 1980).

In summary, this study has revealed contact pheromone components derived from scales of female *A. lineatella*, which, together with gland-derived sex pheromone components, induce contacts by males. Contact pheromone components do not enhance the efficacy of sex pheromone in attracting males in the field (Schlamp, 2005). Thus, the superior attractiveness of virgin female *A. lineatella* as a trap bait compared with synthetic sex pheromone (Schlamp, 2005) must be due to other signals that need to be investigated.

Acknowledgments—We thank Kaaaly Levan and James Duperron for allowing us to conduct experiments in their orchards and Eberhard Kiehlmann for review of the manuscript. INTERSEXUAL DIFFERENCES IN CHEMICAL COMPOSITION OF PRECLOACAL GLAND SECRETIONS OF THE AMPHISBAENIAN *Blanus cinereus*

PILAR LÓPEZ* and JOSÉ MARTÍN

Departamento de Ecología Evolutiva, Museo Nacional de Ciencias Naturales, CSIC, José Gutiérrez Abascal 2, 28006 Madrid, Spain

(Received November 15, 2004; revised August 19, 2005; accepted August 28, 2005)

Abstract—Pheromonal communication seems to be especially important in amphisbaenians, a group of reptiles morphologically and functionally adapted to fossorial life. Both male and female amphisbaenians (*Blanus cinereus*) produce copious amounts of a secretion from the precloacal glands. Analysis by gas chromatography–mass spectrometry revealed that these secretions contain 29 major lipophilic compounds, including several steroids (mainly cholesterol and cholesteryl methyl ether), *n*-C_9 to *n*-C_{18} carboxylic acids (more diverse in males), and methyl and long-chain (waxy)-type esters of carboxylic acids, along with squalene (mainly in males) and tocopherol (only in females). There were clear intersexual differences in the presence/absence of some compounds, such as some fatty acids, steroids, and tocopherol, and in the relative proportions of some shared compounds, such as squalene. These differences may explain how the sexes of this amphisbaenian discriminate one another based on scent alone. The abundance of steroids and waxy esters in secretions of both male and female amphisbaenians may be useful to scent mark underground tunnels to facilitate orientation by these organisms.

Key Words—Amphisbaenians, *Blanus cinereus*, precloacal glands, fatty acids, steroids, mass spectrometry.

INTRODUCTION

Intraspecific communication by reptiles is often based on chemical cues (Halpern, 1992; Mason, 1992). Several studies have demonstrated the existence

* To whom correspondence should be addressed. E-mail: Pilar.Lopez@mncn.csic.es

of pheromones in different species of lizards, snakes, and amphisbaenians (e.g., Mason et al., 1989; Alberts, 1993; Cooper et al., 1994; Aragón et al., 2001a). Semiochemicals used for communication are frequently produced in precloacal or femoral holocrine glands (Mason, 1992; Alberts, 1993). In lizards, the secretory activity of these glands is greatest during the breeding season when males produce more secretions than females, and androgens can influence secretory development and maintenance of activity (Cole, 1966; Van Wyk, 1990; Alberts, 1993). The presence and relative concentration of pheromone components may convey information on the identity of an individual (Alberts, 1990, 1992, 1993) and serve a variety of functions, such as advertising residence in a home range to other males (Aragón et al., 2001b) or mate choice by females (Martín and López, 2000).

Amphisbaenians are a group of reptiles that are morphologically and functionally adapted to fossorial life (Gans, 1978). Morphological adaptations to burrowing include trunk elongation, head modification, reduced vision, and loss of limbs in most species (Gans, 1978). These adaptations constrain amphisbaenians to meet ecological demands with a suite of responses that differ from those of epigean reptiles (e.g., Martín et al., 1991; López et al., 1998). For a blind fossorial reptile, chemical discrimination may be the only means of detecting the presence of conspecifics and discriminating between sexes. Thus, previous experiments have shown that pheromonal communication seems to be especially important in amphisbaenians (Cooper et al., 1994; López et al., 1997).

Amphisbaenians have several precloacal pores connected to precloacal glands that produce copious holocrine secretions, especially during the breeding season. The structures of precloacal glands have been studied in some (Gabe and Saint-Girons, 1965; Whiting, 1967; Antoniazzi et al., 1993, 1994; Jared et al., 1999), suggesting that they might be similar to the precloacal or femoral glands of lizards (Gabe and Saint-Girons, 1965; Whiting, 1967, 1969). Morphological and microscopic examination of secretions suggested that as an amphisbaenian moves inside tunnels, the secretion plugs are abraded against the substrate, releasing a secretion trail (Jared et al., 1999). This trail may contain semiochemicals that might be important in intraspecific communication inside tunnels. In fact, behavioral studies have shown that males of the amphisbaenian, *Blanus cinereus*, are able to detect and discriminate between chemical cues of males and females (Cooper et al., 1994) and between their own scent and those of other males (López et al., 1997). The ability to discriminate sexes was greater from precloacal gland secretions than from skin chemicals (Cooper et al., 1994). Moreover, before starting to burrow in unfamiliar substrates, amphisbaenians emitted numerous tongue flicks and moved for significantly longer periods of time than when on familiar substrates, which suggest that they are able to recognize their own burrows by chemosensory cues (López et al., 2000).

In spite of the potential importance of chemical signals in intraspecific relationships of lizards and amphisbaenians, only a few studies have analyzed the chemicals found in the skin of lizards (Weldon and Bangall, 1987; Mason and Gutzke, 1990) or femoral or precloacal secretions of lizards (Chauhan, 1986; Alberts, 1990; Weldon et al., 1990; Alberts et al., 1992; Escobar et al., 2001, 2003). These studies have shown that gland secretions of lizards are composed of both lipids and proteins, with lipids being considered to be the main compounds involved in communication. In amphisbaenians, histochemical studies have detected the presence of mucopolysaccharides and protein, but not lipids, in the precloacal glands of *Amphisbaena alba* (Antoniazzi et al., 1993). However, because lipids are common in secretions of lizards and snakes (Mason, 1992), the potential presence of lipids in secretions of amphisbaenians bears further investigation.

B. cinereus is a fossorial amphisbaenian endemic to the Iberian Peninsula (Salvador, 1998). It is seldom seen above ground and is usually found under rocks located in areas with abundant leaf litter (Martín et al., 1991; López et al., 1998). Vision is reduced in amphisbaenians, but studies of tongue-flicking behavior showed that *B. cinereus* uses its vomeronasal system to detect and discriminate not only self and conspecific scents (Cooper et al., 1994; López et al., 1997) but also odors of prey (López and Salvador, 1992, 1994) and potential predators (López and Martín, 1994, 2001). To understand the role of semiochemicals produced by precloacal glands in intraspecific communication of *B. cinereus*, we report here a gas chromatography–mass spectrometry (GC-MS) analysis of the lipid fraction of precloacal secretions of males and females.

METHODS AND MATERIALS

Study Animals and Collection of Secretions. During May 2004, we captured 8 adult male and 12 adult female *B. cinereus* by lifting stones in various locations over a large area in Collado Mediano and Cercedilla (Madrid, Central Spain). This collection period coincided with the mating season of this species. Amphisbaenians were weighed [mass (mean ± SE) = 5.2 ± 0.6 g, range = 2.5–9.8 g], and their snout-vent length was measured (mean ± SE = 179 ± 5 mm, range = 148–203 mm). Amphisbaenians had a mean (±SE) number of precloacal pores of 3.1 ± 0.1 (range = 2–4). We extracted the secretion of the precloacal pores by gently pressing the area around pores with forceps and collected the secretion directly in glass vials with Teflon-lined stoppers. Vials were stored at −20°C until the analyses were performed. Amphisbaenians were released at the point of capture. To control for the introduction of contaminants from the handling procedure or from the environment where amphisbaenians were found, we also used the same procedure on each sampling occasion to

obtain blank control vials. These vials were treated in the same manner as those used to collect secretions, and the blank samples were also used to further examine the solvent for impurities in the laboratory.

Sample Analyses. Samples were analyzed using a Finnigan-ThermoQuest Trace 2000 gas chromatograph fitted with a poly (5% diphenyl/95%) dimethylsiloxane column (Supelco, Equity-5, 30-m length × 0.25 mm ID, 0.25-μm film thickness) and a Finnigan-ThermoQuest Trace mass spectrometer as a detector. The samples, 2 μl of each sample dissolved in 250 μl of *n*-hexane (Sigma, capillary GC grade), were injected in splitless mode with an inlet temperature of 250°C. The GC was programmed so that the oven temperature was kept at 50°C for 10 min, increased to a final temperature of 280°C at a rate of 5°C/min, and kept at this temperature for 30 min. The carrier gas was helium at 30 cm/sec. Ionization by electron impact (70 eV) was carried out at 280°C. Mass spectral fragments below $m/z = 39$ were not recorded. Impurities identified in the solvent and/or the control vial samples are not reported. Initial identification of secretion components was performed by comparison of sample mass spectra with those in the NIST/EPA/NIH 1998 computerized mass spectral library. When possible, identifications were confirmed by comparison of spectra and retention times with those of authentic standards. Authentic samples were purchased from Aldrich Chemical Co.

Statistical Analyses. Data in this paper are reported as mean ± standard error (SE). The relative amount of each component was determined as the percent of the total ion current. Major peaks present in all individuals and representing >1% relative peak area were selected, and together, these accounted for 96% of total area. The relative areas of the nine selected peaks were restandardized to 100% and transformed following Aitchison's (1986) formula: $Z_{ij} = \ln(Y_{ij}/g(Y_j))$, where Z_{ij} is the standardized peak area i for individual j, Y_{ij} is the peak area i for individual j, and $g(Y_j)$ is the geometric mean of all peaks for individual j. The homogeneity of variance of these variables was tested with Levene's test, and Bonferroni's correction was applied. The transformed areas were used as independent variables in a multivariate analysis of variance (MANOVA) to determine whether males and females differed in the abundances of shared compounds (Sokal and Rohlf, 1995). We used Statistica 6.0 software (StatSoft Inc., Tulsa, OK) for statistical analyses.

RESULTS AND DISCUSSION

Both male and female *B. cinereus* produced copious secretions from the precloacal pores during the mating season. The number of precloacal pores did

not differ between males (3.1 ± 0.1 pores/side) and females (3.1 ± 0.2; ANOVA, $F = 0.05$, $df = 1,18$, $P = 0.82$). In addition, the total amount of secretion, although not quantified, appeared similar in males and females.

Precloacal secretions of both male and female amphisbaenians have a great diversity of lipophilic compounds. A total of 29 major compounds were detected in these secretions (Table 1). Steroids (86.8%), squalene (4.6%, mainly in males), carboxylic acids, and one of their methyl esters (4.2%), and waxy esters (4.1%) were the main components, but tocopherol acetate (0.3%) was also uniquely present in females. There were clear intersexual differences in the presence/absence of some compounds (i.e., males had eight compounds that

70.3	Octadecyl hexadecenoate	0.17 ± 0.01	0.19 ± 0.14

[a]The relative amount of each component was determined as the percentage of the total ion current and reported as the mean ± SE.

were not found in females, and females had five compounds that were not found in males) and in the relative proportions of some shared compounds (Table 1). Thus, with respect to the 10 shared major compounds, males and females showed overall differences in relative proportions (MANOVA, Wilks' λ = 0.045, $F = 29.17$, $df = 8,11$, $P < 0.001$). Univariate tests showed that males had greater relative proportions of squalene (ANOVA, $F = 19.86$, $df = 1,18$, $P < 0.001$) and cholesteryl methyl ether ($F = 6.75$, $df = 1,18$, $P = 0.02$) and lower relative proportions of an unidentified steroid ($F = 24.45$, $df = 1,18$, $P = 0.001$; Table 1). There were no significant differences between sexes in proportions of the other six major shared compounds (i.e., dodecanoic acid, cholesta-5,7-dien-3-ol acetate, cholesterol, campesterol, octadecyl octadecenoate, and cholest-5-en-3-ol/tetradecanoate; $P > 0.15$ in all cases).

Lipids were not detected by histochemical methods in a previous morphological study of the amphisbaenian *A. alba* (Antoniazzi et al., 1993). This tropical species has a short mating season and shows reproductive characteristics only during the dry season (Colli and Zamboni, 1999). Thus, it is possible that amphisbaenians examined in that study, which had also been maintained in captivity, were not in a reproductive condition and did not produce precloacal secretions or produced secretions without lipids. We observed that precloacal secretions of *B. cinereus* were apparently absent outside of the mating season (unpublished data).

The presence of a similar quantity of precloacal secretion in male and female amphisbaenians is different from what has been observed in precloacal or femoral gland secretions of lizards (Mason, 1992). In lizard families, where these glands are present, both male and female lizards show femoral or precloacal pores. However, femoral or precloacal glands are larger in males, and significant secretory activity, which can be induced by androgenic hormones, is limited almost entirely to males (Cole, 1966; Mason, 1992). Nevertheless, secretions from the urodaeal gland of female broad-headed skinks *Eumeces laticeps* contain a biologically active lipid fraction, with cholesterol, cholesterol esters, and waxy esters, among other compounds (Cooper and Gratska, 1987), which seem to act as a sex pheromone in these skinks (Cooper et al., 1986). In addition, both male and female snakes have cloacal gland secretions (see references in Mason, 1992). Thus, precloacal glands of female amphisbaenians might have a similar function to urodaeal glands of female lizards or to the cloacal glands of snakes.

Cholesteryl methyl ether and cholesterol were the main lipids found in all secretions of male and female *B. cinereus*. Cholesteryl methyl ether was also found in the skin of a gecko (Mason and Gutzke, 1990), whereas cholesterol was also found in abundance in many lizards, both in the skin (Weldon and Bangall, 1987; Mason and Gutzke, 1990) and in femoral and precloacal secretions (Alberts et al., 1992; Escobar et al., 2001; López and Martín, 2005).

The abundance and ubiquity of cholesterol are thought to help to constitute an unreactive apolar matrix that delivers the compounds that are the true semiochemicals (Escobar et al., 2003). We also found other steroids in significant quantities. The abundance of steroids and waxy-type esters in secretions of both male and female amphisbaenians may be useful to scent mark underground tunnels and then to facilitate orientation of individuals or conspecifics within the tunnels (Jared et al., 1999; López et al., 2000). Interestingly, males and females differ in the presence of some steroids, which may contribute to sex identification (Cooper et al., 1994). Finally, it is interesting to find α-tocopherol, a form of vitamin E, only in females (Brigelius-Flohe and Traber, 1999). Tocopherol has not been reported from secretions of any lizard or snake, although it was found in secretions from the gular and paracloacal glands of the American alligator (Weldon et al., 1987, 1988).

One acyclic terpenoid, squalene, was found in secretions of *B. cinereus* and also in the femoral secretions of some lacertid lizards (López and Martín, 2005), skin of male and female leopard geckos (Mason and Gutzke, 1990), skin of male garter snakes (Mason et al., 1989), and paracloacal glands of crocodiles (García-Rubio et al., 2002), but not in femoral or precloacal gland secretions of iguanid lizards (Weldon et al., 1990; Escobar et al., 2001). Squalene was much more abundant in male than in female amphisbaenians, which is similar to the situation in the skin of garter snakes (Mason et al., 1989). Only male snakes present squalene, and courtship to females is partially inhibited if squalene is experimentally added to female skin (Mason et al., 1989). Thus, in amphisbaenians, squalene may be also part of the male sex recognition system.

Carboxylic acids found in precloacal secretions of *B. cinereus* ranged from *n*-C_9 to *n*-C_{18}, with dodecanoic and hexadecanoic acids being the most abundant in both males and females. Similar long-chain carboxylic acids have also been found in other lizards as common and major constituents of skin and femoral and precloacal glands (Mason and Gutzke, 1990; Weldon et al., 1990; Alberts et al., 1992; Escobar et al., 2001). Male amphisbaenians have a greater number of carboxylic acids than females, which, again, may explain how sex discrimination by tongue-flicking behavior is made in this amphisbaenian (Cooper et al., 1994). In addition, a greater diversity of carboxylic acids in males may be useful to produce scents with different individual signatures, which an individual can use to recognize his own scent from that of potential rivals, a capacity that has been shown in behavioral tests (López et al., 1997).

(Received February 14, 2005; revised July 11, 2005; accepted July 26, 2005)

Abstract—Analysis of extracts of sex pheromone glands of grapevine moth females *Lobesia botrana* showed three previously unidentified compounds, (*E*)-7-dodecenyl acetate and the (*E*,*E*)- and (*Z*,*E*)-isomers of 7,9,11-dodecatrienyl acetate. This is the first account of a triply unsaturated pheromone component in a tortricid moth. The monoenic acetate (*E*)-7-dodecenyl acetate and the trienic acetate (7*Z*,9*E*,11)-dodecatrienyl acetate significantly enhanced responses of males to the main pheromone compound, (7*E*,9*Z*)-7,9-dodecadienyl acetate, in the wind tunnel. The identification of sex pheromone synergists in *L. botrana* may be of practical importance for the development of integrated pest management systems.

Key Words—Grapevine moth, *Lobesia botrana*, Tortricidae, (*E*)-7-dodecenyl acetate, (7*E*,9*E*,11)-7,9,11-dodecatrienyl acetate, (7*Z*,9*E*,11)-7,9,11-dodecatrienyl acetate, sex pheromone, synergist

INTRODUCTION

The grapevine moth *Lobesia botrana* Denis and Schiffermüller (Lepidoptera, Tortricidae) is among the economically most important insects in Europe. It occurs throughout the wine-growing area of ca. 4 million hectares and completes two to four generations per year. The larvae feed on grapes, where *Botrytis cinerea* and other fungi rapidly develop, causing the entire grape cluster to rot (Fermaud and Giboulot, 1992). Pheromone-based control of *L. botrana* has been successfully adopted in wine-growing areas in Germany, Italy, and Switzerland. However, the cost effectiveness of the mating disruption technique needs to be improved (Arn and Louis, 1996).

The sex pheromone of *L. botrana*, which has been studied since the 1970s, consists of the main compound (7*E*,9*Z*)-7,9-dodecadienyl acetate (*E*7,*Z*9-12Ac) plus at least four other compounds: (7*E*,9*Z*)-7,9-dodecadien-1-ol (*E*7,*Z*9-12OH), (*Z*)-9-dodecenyl acetate (*Z*9-12Ac), (*E*)-9-dodecenyl acetate (*Z*9-12Ac), and 11-dodecenyl acetate (11-12Ac; Roelofs et al., 1973; Arn et al., 1988; El-Sayed et al., 1999). Here, we show that *L. botrana* pheromone glands contain further compounds, which are of potential interest for the development of integrated pest management systems.

METHODS AND MATERIALS

Insects. Insects were collected near Fribourg (Germany), San Michele (Italy), and La Rioja (Spain) and were reared in the laboratory on an artificial diet under a 16-hr light/8-hr dark photoperiod. Pupae were separated by sex, and adult moths were kept in 36-l Plexiglas cages.

Chemical Analysis. Excised glands of 2- to 3-d-old calling females were extracted for 1 min in 7 μl of redistilled hexane (Labscan, Malmö, Sweden). These extracts were analyzed on a Hewlett-Packard (HP) 5970B mass spectrometer (MS) with electron impact ionization, which was interfaced with a HP 5890 gas chromatograph (GC), using a polar DB-Wax column (30 m × 0.25 mm; J&W Scientific, Folsom, CA, USA). Gland extracts were further studied on an HP 6890 GC, using a DB-Wax column and a nonpolar SE-54 column (25 m × 0.32 mm; Kupper, Bonaduz, Switzerland). The oven temperature was programmed from 60°C/2 min, then at 10°C/min to 100°C, at 1.5°C/min to 150°C, and at 10°C/min to 230°C.

Gland extracts were also injected on an HP 6890 GC equipped with an HP-INNOWax capillary column (30 m × 0.25 mm), which was coupled to an electroantennographic detector (GC-EAD; Syntech, Hilversum, The Netherlands). The oven was programmed from 50°C (2 min hold) at 10°C/min to 230°C. The column outlet was split in a 1:1 ratio for simultaneous recordings by

EAD and the flame ionization detector of the GC. Excised antennae were mounted in a holder, which was 0.5 cm away from the GC outlet.

Synthesis. The syntheses of all compounds are described in detail in the online supplement (Appendix) (Electronic Supplementary Material is available for this article at http://dx.doi.org/10.1007/s10886-005-8404-1 and is accessible for authorized users). 3-Octyn-1-ol (Aldrich) was isomerized to 7-octyn-1-ol using the "acetylene zipper" protocol (Abrams and Shaw, 1988). The obtained octynol served as the starting material for the syntheses of (7*Z*,9*E*,11)-dodecatrienyl acetate (Scheme 1) as well as for the (7*E*,9*Z*,11) and the (7*E*,9*E*,11) isomers (Scheme 2). Preparation of the latter two acetates proceeded similarly to the synthesis of the corresponding 9,11,13-tetradecatrienyl acetates (Tellier, 1991; Tellier et al., 1991), whereas the approach to (7*Z*,9*E*,11)-dodecatrienyl acetate was essentially the same as the sequences described for (9*Z*,11*E*,13)-tetradecatrienal (Millar, 1990) and for (11*Z*,13*E*,15)-hexadecatrienyl acetate (Gries et al., 2004).

Hydrogenation of conjugated triple bonds with activated zinc in methanol produced (*Z*)-double bonds (Boland et al., 1987), whereas $LiAlH_4$ reduction yielded (*E*)-double bonds (Porter et al., 1985). All reactions were carried out under argon. Intermediates were purified by distillation *in vacuo* or by column chromatography on silica gel. In all three syntheses, the alcohols corresponding to the target acetates were carefully recrystallized from hexane/toluene at −25°C to furnish products with stereochemical purity >98%.

For the synthesis of (7*Z*,9*E*,11)-dodecatrienyl acetate, 7-octyn-1-ol was chain-elongated with (*E*)-1,2-dichloroethane (Sonogashira, 1991). The resulting ω-chloroalcohol was protected and, again, chain-elongated with vinyl magnesium bromide (Millar, 1990). The C_{14} chain obtained was easily transformed into the final product.

For the synthesis of the two (7*E*)-configured trienylacetates, 7-octyn-1-ol (**1**) was transformed in two steps into (*E*)-1-*t*-butoxy-8-iodo-7-octene (Alexakis et al., 1988; Alexakis and Duffault, 1988). Chain elongation of this key intermediate used Pd°-catalyzed alkynyl coupling (Sonogashira, 1991 and references cited therein). The syntheses of the target acetates were completed by conventional steps (Scheme 2).

Details of the syntheses are provided in the online supplement.

Wind Tunnel. The wind tunnel hardware and the test protocol have been described (Witzgall et al., 2001). The wind tunnel with a flight section of 63 × 90 × 200 cm was lit diffusely at 6.5 lx. Charcoal-filtered air was blown by a horizontal fan through the tunnel at 30 cm/sec, temperature was 23 ± 2°C, and relative humidity was 40–60%. The outcoming air was aspired by another fan and cleaned by two sets of charcoal filters.

Synthetic pheromone components in redistilled ethanol were released from a piezoelectric sprayer (El-Sayed et al., 1999; Gödde et al., 1999). The

solution was delivered at a rate of 10 µl/min through Teflon tubing to a 20-µl glass capillary tube with a drawn-out tip. The capillary was vibrated by a piezo-ceramic disk at ca. 100 kHz to produce an aerosol, which evaporated within a few centimeters from its tip. This "sprayer" allows application of pheromone chemicals at a constant rate and known chemical purity. Isomeric purity of the test compounds was ≥99%, except for 7*E*,9*E*,11-12Ac (98%) and 7*E*,9*Z*,11-12Ac (95%). Single females were held in glass tubes (2.5 × 5 cm) covered with gauze on both sides. Females were kept in the wind tunnel for at least 30 min before experiments until they showed the typical calling behavior.

Wind tunnel tests were carried out from 1 to 4 hr after onset of the scotophase. Four batches of 15 2- to 3-d-old males (N = 60) were tested per pheromone blend on four different days. Single males were placed in glass tubes (2.5 × 12.5 cm), which were stoppered with gauze on both sides ca. 15 min before testing. Males were tested individually and were given 2 min to respond. The number of males landing at the source, following upwind-oriented flight, in

each batch of 15 males was transformed to $\log(x + 1)$ and submitted to a one-way ANOVA followed by Duncan's multiple range test ($P < 0.05$).

RESULTS AND DISCUSSION

Chemical analysis of sex pheromone gland extracts of *L. botrana* females confirmed the presence of previously identified compounds. The main pheromone compound is *E*7,*Z*9-12Ac. The analogous *E*7,*Z*9-12OH and two saturated alcohols were present, in addition to several saturated, mono-, and diunsaturated acetates (Table 1; Arn et al., 1988; El-Sayed et al., 1999).

GC-EAD recordings (Figure 1) showed an additional, active compound eluting after *E*7,*Z*9-12OH. GC-MS studies indicated a conjugated trienylacetate because of characteristic fragments and its retention time. Co-occurrence of Δ7, Δ9-12Ac and 11-12Ac in *L. botrana* pheromone glands made Δ7, Δ9,11-12Ac a likely candidate. Synthesis of 7,9,11-12Ac isomers confirmed the presence of *E*7,*E*9,11-12Ac in glands of Italian females (Table 1). The *EZ* and *ZE* isomers were found in smaller amounts. These three trienyl acetates also were present in gland extracts of females from Germany and Spain (not shown in Table 1). This is the first report of a triply unsaturated compound in a tortricid moth (Arn et al., 2000). The extremely unstable (7*Z*,9*Z*,11)-dodecatrienyl acetate or corresponding products of its rearrangements (Näf et al., 1975; Rockach et al., 1980) was not detected. No attempts were made to synthesize this isomer.

Another compound that elicited antennal responses, which could not be associated with known *L. botrana* pheromone compounds, eluted shortly before *E*- and *Z*9-12Ac. This new compound was shown to be *E*7-12Ac. It was present in gland extracts of females from Italy (Table 1; Figure 1) and from Spain. However, *E*7-12Ac was not detected in insects from Germany (this study, data not shown), which corroborates analysis of insects from Switzerland (Arn et al., 1988). This suggests the occurrence of *L. botrana* pheromone dialects north and south of the Alps.

Wind tunnel tests were performed with the newly identified compounds, *E*7-12Ac, and the *EE*, *EZ*, and *ZE* isomers of 7,9,11-12Ac (Table 2). These compounds were tested in two-component blends with the main compound, using males of a lab population originating from northern Italy. A 10% addition of *Z*7,*E*9,11-12Ac significantly increased attraction followed by landing at the source from 24% of the test males with the main compound alone to 65% ($N = 60$; Table 2). The two other isomers, *E*7,*E*9,11-12Ac and *E*7,*Z*9,11-12Ac, were less active. A four-component blend of the main compound plus 10% of each of the three triene isomers attracted 61% of males to the source. The trienic *E*7,*Z*9,11-12Ac may mimic the main pheromone compound *E*7,*Z*9-12Ac because some males were attracted to this compound as a single component.

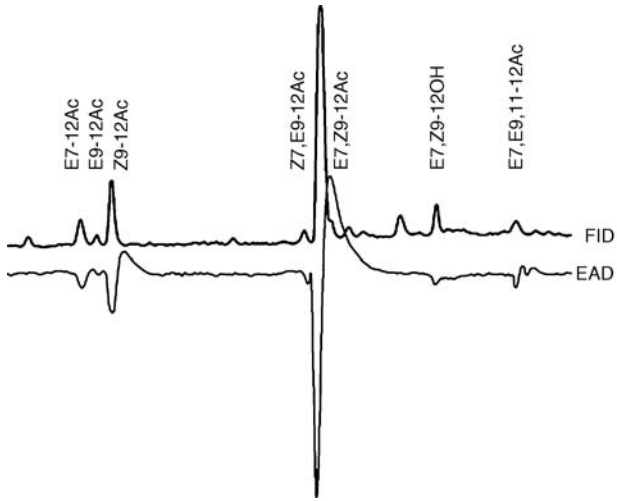

FIG. 1. Analysis of pheromone gland extracts of grapevine moth *L. botrana* females from Northern Italy ($N = 5$) by GC-EAD. FID: response of the flame ionization detector; EAD: response of a *L. botrana* male antenna.

*E*7-12Ac had a similar effect as *Z*7,*E*9,11-12Ac, with addition of 10% increasing landings to 67% ($N = 60$; Table 2). Male attraction to the best synthetic blends, at a release rate of 10 pg/min of the main compound, was not different from attraction to calling females. The female release rate is on the order of 10 pg/min (El-Sayed et al., 1999).

The monoene acetates *E*9-12Ac, *Z*9-12Ac, and 11-12Ac, and the alcohol corresponding to the main compound, *E*7,*Z*9-12OH, are known pheromone synergists of *L. botrana* (Arn et al., 1988; El-Sayed et al., 1999). Here, we show that *E*7-12Ac and *Z*7,*E*9,11-12Ac are additional, strong pheromone synergists. Partial blends are as attractive as calling females (Table 2; El-Sayed et al., 1999), and this may indicate redundancy in the pheromone signal of *L. botrana*, as described for the cabbage looper moth *Trichoplusia ni* (Linn et al., 1984).

Availability of new pheromone synergists is nonetheless of practical importance. Mating disruption of *L. botrana* by aerial dissemination of pheromone can be effective, but there are many reports of unexpected failures (Arn and Louis, 1996). For example, geographic pheromone races may contribute to inconsistent results. Studies of *L. botrana* sex pheromone have all relied on insects from Switzerland (Roelofs et al., 1973; Arn et al., 1988; El-Sayed et al., 1999), whereas pheromone-mediated mating disruption is used in vineyards both north and south of the Alps (Kast, 2001; Louis and Schirra, 2001; Varner

(Received April 23, 2005; revised July 26, 2005; accepted August 13, 2005)

Abstract—We identified, synthesized, and field-tested the sex pheromone of female red cedar cone midge *Mayetiola thujae* (Hedlin) (Diptera: Cecidomyiidae), a pest insect in red cedar *Thuja plicata* seed orchards. Coupled gas chromatographic (GC)–electroantennographic detection analyses of pheromone extract revealed three components (**A**, **B**, **C**) that elicited responses from antennae of males, all of which occurred below the detection threshold of the mass spectrometer and thus had to be identified without spectroscopic data. Taking into account (1) their retention indices (RI) on three GC columns (DB-5, DB-23, and DB-210), (2) intercolumn RI differentials, and (3) the molecular structures of known cecidomyiid pheromones, we synthesized seven candidate pheromone components: 2,10-, 2,11-, 2,12-, 2,13-, 2,14-, 2,15- and 2,16-diacetoxyheptadecanes. Of these, 2,12-, 2,13-, and 2,14-diacetoxyheptadecane had RIs on all columns consistent with those of **A**, **B**, and **C** and elicited strong antennal responses when tested at picogram levels. In field experiments with the twelve stereoselectively synthesized stereoisomers, only the *SS*-stereoisomers of 2,12-, 2,13-, and 2,14-diacetoxyheptadecane attracted male *M. thujae*. The three-component *SS*-stereoisomer blend was more attractive than the 12-component blend of all stereoisomers, suggesting that one or several nonnatural stereoisomers are inhibitory. One-, two-, and three-component lures of the *SS*-stereoisomers were equally effective in attracting male *M. thujae*, indicating redundancy in the phero-

mone. Identification of the *M. thujae* sex pheromone will allow development of pheromone-based monitoring, and possibly control, of *M. thujae* populations in *T. plicata* seed orchards.

Key Words—Red cedar cone gall midge, *Mayetiola thujae*, Cecidomyiidae, sex pheromone, stereoisomers, 2,12-diacetoxyheptadecane, 2,13-diacetoxyheptadecane, 2,14-diacetoxyheptadecane.

INTRODUCTION

Increasing interest in western red cedar *Thuja plicata* Donn *ex* D. Don reforestation in recent decades has led to the planting of *T. plicata* seed orchards in British Columbia and more recently in Washington and Oregon. Throughout the range of *T. plicata*, the western red cedar cone midge *Mayetiola thujae* (Hedlin) (Diptera: Cecidomyiidae) is a serious pest of *T. plicata* seed production (Hedlin et al., 1980). In the absence of control measures, 100% of *T. plicata* cones may be infested by immature stages of *M. thujae* (Hedlin, 1964).

Mayetiola thujae and its detailed life history have been described by Hedlin (1959, 1964). Most of the life cycle is spent within *T. plicata* cones. Adults emerge from overwintering puparia in previous-year cones in late winter/early spring during the *T. plicata* pollination period. Adults are short-lived. Emergence, mating, oviposition, and death occur in less than 1 wk. Larvae hatch shortly after oviposition and spend the spring and early summer feeding upon scale and seed tissues within developing cones. In late summer, larvae spin individual silk cocoons between cone scales. Pupation occurs during the winter, although some larvae enter a period of extended diapause and apparently pupate the next or subsequent winters.

During the annual *T. plicata* pollination period, the British Columbia Ministry of Forests determines population levels of *M. thujae* through a tedious process of sampling and dissecting cones and counting eggs. When population levels exceed a variable economic threshold, they may be reduced by killing larvae within cones with systemic insecticides. In Washington and Oregon, populations are controlled with sprays of contact insecticides made on a calendar basis, targeting adults during the pollination period. Identification and deployment of the *M. thujae* sex pheromone may help pinpoint the adult flight period, facilitate assessment of population levels, and offer alternative means of population control.

METHODS AND MATERIALS

Experimental Insects. In early February 2002 and 2003, *T. plicata* cones infested with *M. thujae* larvae were collected near the north shore of Elk Lake, Victoria, British Columbia (48°32′N/123°23′W), and shipped to Simon Fraser

University. Cones were kept in a mesh cage (30 × 30 × 45 cm high) at room temperature and with a photoperiod of 14-hr light/10-hr dark, inducing the emergence of *M. thujae* within 1–3 wk.

Preparation and Analysis of Pheromone Extracts. Insects were separated by sex, and ovipositors with pheromone glands of (calling) females were removed and extracted with hexane for 5–50 min. Aliquots of 5–10 female equivalents (FE) of abdominal tip extracts were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD; Arn et al., 1975), employing equipment and procedures previously described in detail (Gries et al., 2002). GC columns and temperature programs in this study were as follows—DB-5: 100°C (1 min), 15°C/min to 280°C; DB-23: 100°C (1 min), 10°C/min to 230°C; DB-210: 100°C (1 min), 20°C/min to 230°C. Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on a Varian AS500 spectrometer at 499.77 MHz for ^{1}H and 125.68 MHz for ^{13}C spectra, with chemical shifts reported in parts per million relative to TMS (^{1}H, δ = 0.00) and $CDCl_3$ (^{13}C, δ = 77.00). Elemental analyses were performed using a Carlo-Erba model 1106 elemental analyzer. Compounds were purified for elemental analyses with a Waters semipreparative high-performance liquid chromatograph (HPLC; Delta 600 Pump, 600 Controller, 2487 Dual λ Absorbance Detector) equipped with a Nova Pak® HR C18 preparative column (19 × 300 mm; 6 μm, 60 Å) eluted with 10 ml/min of acetonitrile. Melting points of chemicals are reported uncorrected.

Syntheses. Racemic 2,10-, 2,11-, 2,12-, 2,13-, 2,14-, 2,15-, and 2,16-diacetoxyheptadecane (2,10-17; 2,11-17; 2,12-17; 2,13-17; 2,14-17; 2,15-17; 2,16-17) were obtained by coupling freshly prepared α,ω-di-Grignard reagents with equivalent amounts of equimolar mixtures of two epoxides (e.g., two equivalents of propylene oxide for 2,16-17), hydrolysis, separation of the resulting diols by flash column chromatography, and acetylation of asymmetric diols (Figure 1). Diols were well separated by flash chromatography (Still et al., 1978; Choi et al., 2004) on 50–60 g of silica gel 60 (230–400 mesh, E. Merck, Darmstadt) inside a glass column (30 × 600 mm), using a gradual increase (20–90%) of ether in the eluent (ether/hexane) mixture. Diols were also separated by thin-layer chromatography [DC-Alufolien, Aluminiumoxid 60 F_{254} neutral (EM Science, PO Box 70, Gibbstown, NJ, USA); ether (2)/hexane (1)] with the following Rf values: 0.28 (**1a**), 0.09 (**2a**), 0.45 (**3a**); 0.23 (**1b**), 0.11 (**2b**), 0.40 (**3b**); 0.21 (**1c**), 0.13 (**2c**), 0.32 (**3c**). Enantioselective syntheses of 2,12-17, 2,13-17, and 2,14-17 are described below. Compounds were synthesized from optically active propylene oxides and 1,2-epoxyheptanes, 1,2-epoxyhexanes, or 1,2-epoxypentanes. Separation of diols (**1**, **2**, and **3** in Figure 1) and acetylation of asymmetric diols led to the 12 target chiral diacetates (**4**).

(*S*)- and (*R*)-Propylene oxides [>99% enantiomeric excess (ee)] were purchased (Avocado Research Chemicals Ltd., Heysham, Lancs, UK), whereas

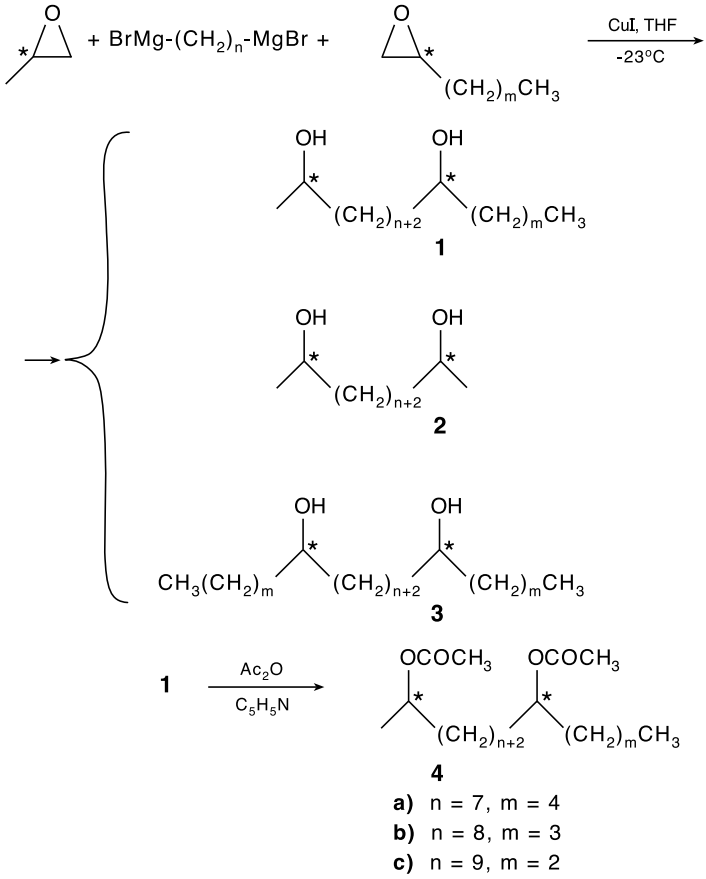

FIG. 1. Enantioselective syntheses of 2,12-, 2,13-, and 2,14-diacetoxyheptadecanes (**4a**, **4b**, and **4c**).

longer-chain (*S*)- and (*R*)-1,2-epoxides were synthesized according to methods previously reported (Tokunaga et al., 1997; Schaus et al., 1998). Enantiomeric excess of synthesized 1,2-epoxides (Table 1) was determined by ring opening with methylmagnesium chloride in the presence of CuI at −23°C, acetylation of the resulting alcohols with acetic anhydride in pyridine, and chromatography of resulting acetates on a custom-made chiral GC column coated with a 1:1 mixture of heptakis-(2,6-di-*O*-methyl-3-*O*-pentyl)-β-cyclodextrin and OV-1701 (König et al., 1992; Pietruszka et al., 1992); temperature program: 80°C (10 min), then 5°C/min to 120°C; split injection. (*R*,*R*)-, (*S*,*S*)-, (*S*,*R*)-, and (*R*,*S*)-2,12-, 2,13-, and 2,14-diacetoxyheptadecanes prepared from the epoxides were

assumed to have corresponding ee because chiral centers were not affected during the opening of epoxide rings and subsequent acetylation.

*(S,S)-2,12-Dihydroxyheptadecane (SS-**1a**, Figure 1).* At −23°C under argon and with vigorous stirring CuI (0.31 g, 1.63 mmol) was added to a freshly prepared solution of Grignard reagent [1,7-dibromoheptane (2.10 g, 8.14 mmol) and activated Mg (0.80 g, 32.9 mmol) were refluxed in tetrahydrofuran (THF; 50 ml) for 3 hr under argon excess of Mg was not removed]. After 5 min, a mixture of (*S*)-propylene oxide (0.63 ml, 8.95 mmol) and (*S*)-1,2-epoxyheptane (1.25 ml, 8.95 mmol, 98% by GC) in THF (5 ml) was added. The temperature was maintained at −23°C for 30 min. The reaction mixture was warmed to room temperature, quenched with saturated aqueous NH_4Cl, and extracted with ether (5 × 30 ml). Extracts were washed, dried, and concentrated. (*S*,*S*)-2,12-Heptadecanediol (*SS*-**1a**) was completely separated by silica (60 g) flash chromatography (35–45% ether in hexane as eluent) from the faster-eluting (*S*,*S*)-6,16-dihydroxyheneicosane (25% ether in hexane as eluent) and the slower-eluting (*S*,*S*)-2,12-dihydroxytridecane (50–80% ether in hexane as eluent). *SS*-**1a** was obtained in 72% yield (0.80 g, 2.94 mmol) as a white solid; m.p. 50–51°C; ^{1}H NMR: ($CDCl_3$): δ = 0.89 (t, 3H, J = 6.8 Hz), 1.18 (d, 3H, J = 6.4 Hz), 1.21–1.51 (m, 26H), 2.17 (s, 2H), 3.58 (m, 1H), 3.78 (m, 1H); ^{13}C NMR ($CDCl_3$): δ = 14.05, 23.49, 25.32, 25.63, 25.74, 29.49, 29.56, 29.57, 29.60, 29.63, 29.67, 30.93, 37.45, 37.46, 39.35, 68.19, 72.02. Anal. calcd. for

$C_{17}H_{36}O_2$ (%): C, 74.94; H, 13.32; found C, 75.30; H, 13.35. (*S*,*R*)-, (*R*,*S*)-, and (*R*,*R*)-2,12-Dihydroxyheptadecanes (*SR*-**1a**, *RS*-**1a**, and *RR*-**1a**, respectively) were obtained from 1,7-dibromoheptane, the corresponding (*R*)- and (*S*)-propylene oxides, and (*R*)- and (*S*)-1,2-epoxyheptanes (see above). Spectroscopic data for these alcohols matched those of *SS*-**1a**; m.p. of *SR*-**1a**, *RS*-**1a**, and *RR*-**1a** were 80–81, 80–81, and 50–51°C, respectively.

*(S,S)-2,13-Dihydroxyheptadecane (SS-**1b**).* This was obtained in 56% yield from 1,8-dibromooctane, (*S*)-propylene oxide, and (*S*)-1,2-epoxyhexane (see above). M.p. 56°C; ^{1}H NMR ($CDCl_3$): δ = 0.91 (t, 3H, J = 7.0 Hz), 1.18 (d, 3H, J = 6.4 Hz), 1.20–1.50 (m, 26H), 2.17 (s, 2H), 3.58 (m, 1H), 3.79 (m, 1H); ^{13}C NMR ($CDCl_3$): δ = 14.07, 22.76, 23.48, 25.63, 25.74, 27.83, 29.53, 29.57, 29.58, 29.60, 29.67, 30.93, 37.16, 37.46, 39.35, 68.20, 72.00. Anal. calcd. for $C_{17}H_{36}O_2$ (%): C, 74.94; H, 13.32; found C, 74.95; H, 13.10. (*S*,*R*)-, (*R*,*S*)-, and (*R*,*R*)-2,13-Dihydroxyheptadecanes (*SR*-**1b**, *RS*-**1b**, and *RR*-**1b**, respectively) were obtained from 1,8-dibromooctane, the corresponding (*R*)- and (*S*)-propylene oxides, and (*R*)- and (*S*)-1,2-epoxyhexanes. Spectroscopic data for these alcohols matched those of *SS*-**1b**; m.p. of *SR*-**1b**, *RS*-**1b**, and *RR*-**1b** were 80–81, 79, and 55–56°C, respectively.

*(S,S)-2,14-Dihydroxyheptadecane (SS-**1c**).* This was obtained in 40% yield from 1,9-dibromononane, (*S*)-propylene oxide, and (*S*)-1,2-epoxypentane (see above). M.p. 50°C; ^{1}H NMR ($CDCl_3$): δ = 0.92 (t, 3H, J = 6.8 Hz), 1.18 (d, 3H, J = 6.4 Hz), 1.24–1.51 (m, 26H), 2.17 (s, 2H), 3.60 (m, 1H), 3.80 (m, 1H); ^{13}C NMR ($CDCl_3$): δ = 14.11, 18.82, 23.47, 25.63, 25.75, 29.54, 29.55, 29.57, 29.59, 29.61, 29.64, 29.67, 37.48, 39.35, 39.65, 68.17, 71.72. Anal. calcd. for $C_{17}H_{36}O_2$ (%): C, 74.94; H, 13.32; found C, 75.25; H, 13.06. (*S*,*R*)-, (*R*,*S*)-, and (*R*,*R*)-2,14-Dihydroxyheptadecanes (*SR*-**1c**, *RS*-**1c**, and *RR*-**1c**, respectively) were obtained from 1,9-dibromononane, the corresponding (*R*)- and (*S*)-propylene oxides, and (*R*)- and (*S*)-1,2-epoxypentanes. Spectroscopic data of these alcohols matched those of *SS*-**1c**; m.p. of *SR*-**1c**, *RS*-**1c**, and *RR*-**1c** were 81, 79–80, and 50°C, respectively.

2,12-, 2,13-, and 2,14-Diacetoxyheptadecanes. The four stereoisomers each of 2,12-, 2,13-, and 2,14-diacetoxyheptadecane (**4a**–**c** in Figure 1) were obtained in 90–95% yields by stirring (12 hr) the corresponding diols **1a**–**c** (0.6–0.8 g) in pyridine (5 ml) and acetic anhydride (1.5 ml). Excess of the latter two reagents was eliminated *in vacuo*, and **4a**–**c** (all oils) were purified (94–98%) by flash chromatography [silica (15 g); 10% ether in hexane as eluent]. For NMR and elemental analyses, some material was further purified by HPLC.

Field Experiments. Field experiments were conducted in an abandoned *T. plicata* seed orchard immediately west of Blenkinsop Lake, Victoria, BC (48°29′N/123°23′W). Trees were 15–24 yr old and spaced 2.4 and 7.3 m within and between rows, respectively. At 10- to 15-m intervals, sticky 2-l milk carton traps (Gray et al., 1984) were suspended from trees 1.5 m above ground in complete randomized blocks. Traps were baited with a piece of dental cotton roll (10 × 15 mm; Richmond Dental, Charlotte, NC, USA) impregnated with candidate pheromone components in HPLC-grade hexane.

Experiment 1 was designed to determine which stereoisomers (*RR*, *RS*, *SR*, or *SS*) of 2,12-17, 2,13-17, and 2,14-17 are pheromone components of *M. thujae*. Four sets of three structural isomers, each with the same absolute configuration (*RR*, *RS*, *SR*, or *SS*), were tested singly and in quaternary combination. Taking into account that only the *SS*-stereoisomer blend attracted

male *M. thujae* in experiment 1, experiment 2 explored potential synergism between the three *SS*-stereoisomers by testing them singly and in ternary combination. Considering that the three *SS*-stereoisomer blends appeared more attractive than individual stereoisomers in experiment 2, experiment 3 tested the *SS*-stereoisomers in all possible binary and ternary combinations.

Trap catch data were analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Scheffé (Dunn) *t*-test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS AND DISCUSSION

Gas chromatographic–electroantennographic detection analyses of pheromone gland extracts of female *M. thujae* revealed three components (**A**, **B**, and **C** in Figure 2) that elicited responses from male antennae. All components occurred below detection threshold (~10 pg) of the flame ionization detector even in a concentrated (>100 FE) extract, requiring compound identifications without the benefit of mass spectrometric data.

Retention indices (RI; relative to alkane standards; Van Den Dool and Kratz, 1963) of the three components **A**, **B**, and **C** on each of the GC columns

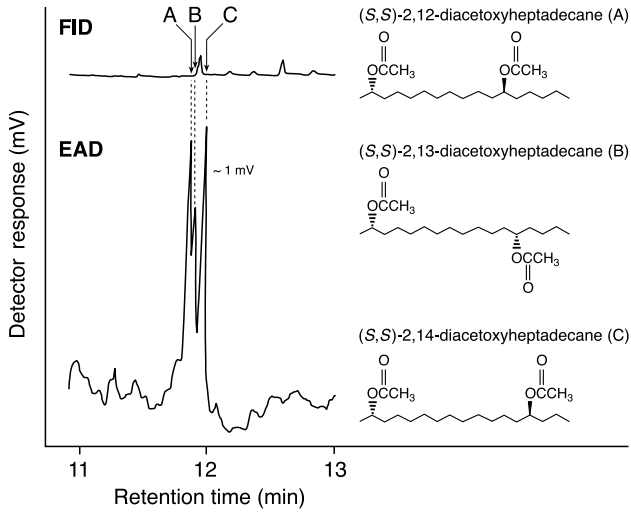

FIG. 2. Representative ($n = 7$) recording of flame ionization detector and electroantennographic detector (EAD = male *M. thujae* antenna) responses to one female equivalent of pheromone gland extract of female *M. thujae*. Splitless injection; injector and detector temperature: 240°C; DB-5 column, program 100°C (1 min), 15°C/min to 280°C.

(DB-5, DB-23, and DB-210) were similar (Table 2), suggesting that all three components had the same chemical functionality. Their RIs and antennal stimulatory activity remained unaltered in GC-EAD analyses of hydrogenated pheromone extract, indicating that all three components had no C–C multiple bonds. The RI intercolumn differentials of components **A**, **B**, and **C** were similar to those of 2,7-diacetoxytridecane (Table 2; Choi et al., 2004) and dissimilar to those of the acetoxy pheromone (2*S*,4*Z*,7*Z*)-2-acetoxy-4,7-tridecadiene (Table 2; Gries et al., 2002), suggesting that **A**, **B**, and **C** each had two acetate esters. The RIs of **A**, **B**, and **C** were 398–468 RI units higher than those of 2,7-diacetoxytridecane (Table 2), further suggesting that **A**, **B**, and **C** had four more carbons in the chain than 2,7-diacetoxytridecane. Taking into account (1) that most of the presently identified cecidomyiid pheromone components have an acetoxy group at C2 (Foster et al., 1991; Harris and Foster, 1991; Millar et al., 1991; Hillbur et al., 1999, 2000, 2001; Gries et al., 2002; Choi et al., 2004) and (2) that some cecidomyiid pheromone components have the second oxygenated group in ω-1 (2,12-diacetoxytridecane, Hillbur et al., 1999) or in ω-2 (2,11-diacetoxytridecane, Hillbur et al., 1999; 2,7-dibutyrox-

[d]Sex pheromone of *A. aphidimyza* (Choi et al., 2004).
[e]Sex pheromone of *C. oregonensis* (Gries et al., 2002).

ynonane, Gries et al., 2000), we synthesized 2,15- and 2,16-diacetoxyheptadecane. However, the RIs of these two compounds were too high on all columns (Table 2), suggesting that one of the acetate groups needed to be closer to the center of the molecule, thereby decreasing the RI of the molecule. We thus synthesized 2,10-, 2,11-, 2,12-, 2,13-, and 2,14-diacetoxyheptadecanes. The latter three (2,12-17, 2,13-17, and 2,14-17) had RIs on all columns (Table 2) consistent with those of antennal-stimulatory components **A**, **B**, and **C**, respectively, in pheromone gland extracts (Figure 2).

In field experiment 1, traps baited with the *SS*-stereoisomer blend of 2,12-17, 2,13-17, and 2,14-17 captured significant numbers of male *M. thujae*, whereas the *RR*-, *RS*-, and *SR*-stereoisomer blends were not attractive (Figure 3A). Reduced attractiveness of the treatment containing the four stereoisomers of each of the three structural isomers (Figure 3A) suggested that one or more sets of stereoisomers (*RR*, *RS*, or *SR*) inhibited the males' response to the *SS*-stereoisomers. Considering that nonnatural stereoisomers in experiment 1, when tested at a 1:1:1 ratio with the attractive *SS*-stereoisomers, reduced but did not completely inhibit the responses of males, it is not likely that trace amounts of nonnatural stereoisomers (Table 1) in synthetic *SS*-pheromone components had significant behavior-modifying activity.

In experiment 2, the *SS*-stereoisomers of 2,12-17, 2,13-17, and 2,14-17, when tested individually or in a three-component blend, attracted similar numbers of *M. thujae* and significantly more males than unbaited control traps (Figure 3B) except for *S*,*S*-2,14-17, which was not different than either the 3-component blend or the unbaited control. In experiment 3, the *SS*-stereoisomers of 2,12-17, 2,13-17, and 2,14-17, when tested in all possible binary combinations and the ternary combination, were equally effective in attracting male *M. thujae*.

Our data suggest that *M. thujae* produces three pheromone components, each of which is equally active, with no apparent synergism between components, at least not at the 1:1:1 component ratio that was tested in experiments 2 and 3. Other blend ratios are not likely to reveal synergistic activity of components because there was no evidence that any one component was more important than the others. On the contrary, each component was attractive by itself (Figure 3), and each elicited comparable antennal responses in GC-EAD analyses, both of pheromone gland extract (Figure 2) and synthetic standards (10 pg each; data not shown).

The apparent redundancy of pheromone components in *M. thujae* contrasts with the strong synergistic activity of pheromone components in the pea midge *Contarinia pisi* (Hillbur et al., 2000, 2001). Significant attraction of male *C. pisi* requires the presence of each of the three pheromone components (*S*,*S*)-2,11-diacetoxytridecane, (*S*,*S*)-2,12-diacetoxytridecane, and (as yet not determined) (*S*)- or (*R*)-2-acetoxytridecane (Hillbur et al., 2000, 2001). With *M. thujae*, as with

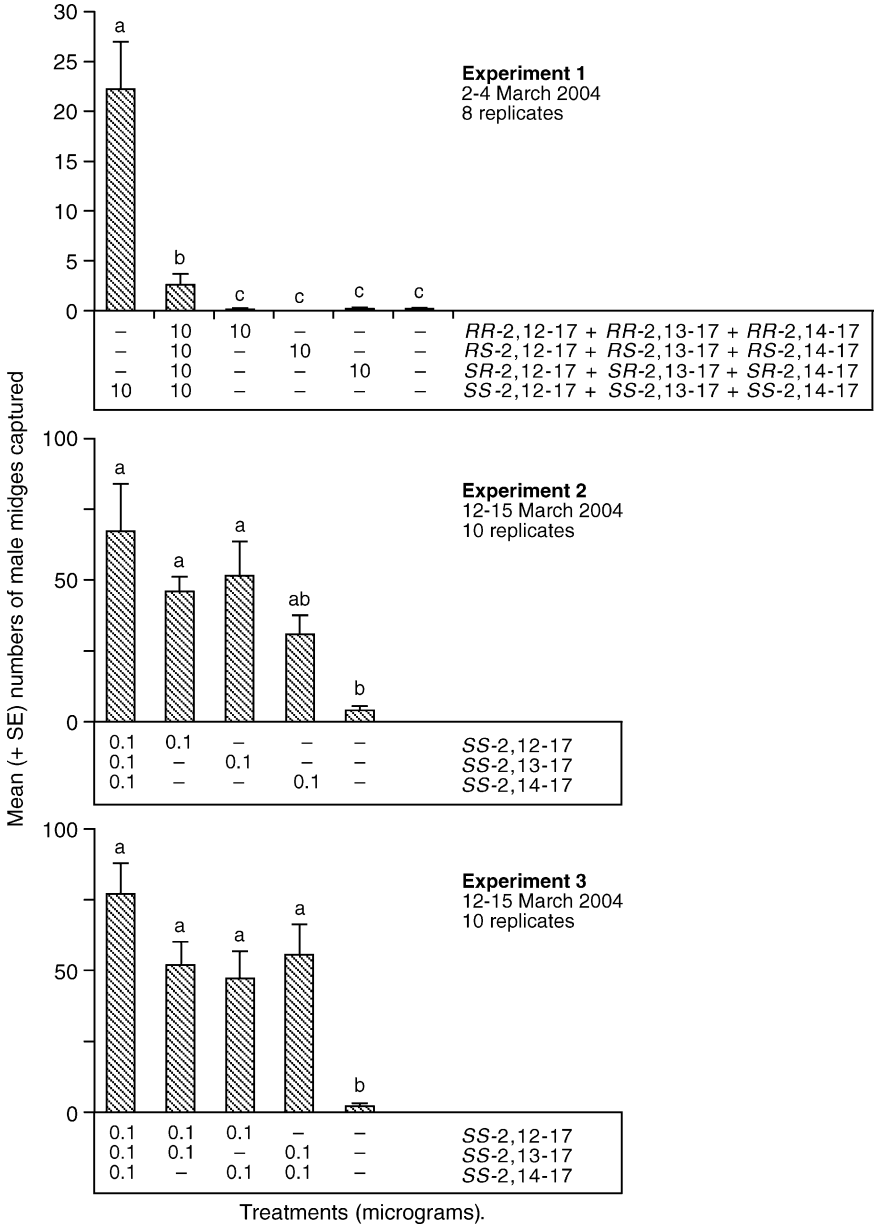

FIG. 3. Mean (+SE) number of male *M. thujae* captured in sticky traps baited with various blends of candidate pheromone components in microgram quantities. Red cedar, *T. plicata*, seed orchard immediately west of Blenkinsop Lake, Victoria, BC. Bars in each experiment with different letter superscripts are significantly different; nonparametric analyses of variance by ranks (Friedman's test) followed by comparison of means (Scheffé test), $P < 0.05$ (SAS/STAT, 1988).

C. pisi, only the *SS*-stereoisomers of the diacetoxy compounds are biologically active, whereas one or more of the other stereoisomers are inhibitory (Figure 3).

The pheromone components of *M. thujae* [(*S*,*S*)-2,12-diacetoxyheptadecane, (*S*,*S*)-2,13-diacetoxyheptadecane, and (*S*,*S*)-2,14-diacetoxyheptadecane] resemble those of other cecidomyiids[1] [(2*S*,10*E*)-2-acetoxy-10-tridecene: Hessian fly *Mayetiola destructor* (Foster et al., 1991; Millar et al., 1991); (*S*,*S*)-2,11-diacetoxytridecane, (*S*,*S*)-2,12-diacetoxytridecane, and 2-acetoxytridecane: *C. pisi* (Hillbur et al., 1999, 2000, 2001); (*S*,*S*)-2,7-dibutyroxynonane: orange wheat blossom midge *Sitodiplosis mosellana* (Gries et al., 2000); (2*S*,4*Z*,7*Z*)-2-acetoxy-4,7-tridecadiene: Douglas-fir cone gall midge *Contarinia oregonensis* (Gries et al., 2002); and (*R*,*S*)-2,7-diacetoxytridecane: *Aphidoletes aphidimyza* (Choi et al., 2004)] but have four more carbon atoms in the chain than most of the cecidomyiid pheromones. The saturated diacetoxy structure of the *M. thujae* pheromone components more closely resembles the pheromone components of the heterogeneric *C. pisi* and *A. aphidimyza* than the unsaturated acetoxy pheromone of the congeneric *M. destructor*. This suggests that one or more of the *M. thujae* pheromone components might be trace components of the sex pheromone blend of congeneric *M. destructor*. An alternative explanation is that *Mayetiola* is primarily a Palearctic genus, with most species being associated with grass host species. This suggests that the genus *Mayetiola* may need revision, with reclassification of *M. thujae* and some other Nearctic species (Gagné, 1989).

The identification of the *M. thujae* pheromone should lead to improved monitoring of *M. thujae* populations and better management decisions in seed orchards. For example, numbers of male *C. oregonensis* captured in pheromone-baited traps in seed orchards in Washington and Oregon were predictive of the level of seed damage at harvest (Morewood et al., 2002). Racemic *M. thujae* pheromone can be readily synthesized (Khaskin et al., unpublished data). If racemic pheromone is suitable for pheromone-based mating disruption of *M. thujae* populations (although the racemate is significantly less attractive than the *S*,*S* stereoisomers) it may be feasible to use the pheromone for control of *M. thujae* in seed orchards.

Acknowledgments—We thank Graeme Lee for access to the Blenkinsop Lake research site; Wittko Francke for lending a chiral GC column that separated enantiomers of synthetic intermediates; Bob Birtch for graphical art work; Derek Vance Steel and Sharon Oliver for word processing; Micky Young for help with elemental analyses; and Eberhard Kiehlmann for review of the manuscript. The research was supported, in part, by grants from the British Columbia Ministry of Forests Tree Improvement Branch and from the Natural Sciences and Engineering Research Council of Canada.

(Received November 15, 2004; revised August 11, 2005; accepted August 28, 2005)

Abstract—Volatiles from chocolate mediate upwind flight behavior in *Ephestia cautella* and *Plodia interpunctella*. We used gas chromatography with electroantennographic detection and found 12 active compounds derived from three different chocolate types, i.e., plain, nut-containing, and rum-flavored. Eight of the compounds were identified with mass spectrometry, and the activity of three compounds, ethyl vanillin, nonanal, and phenylacetaldehyde (PAA), was subsequently confirmed in both electrophysiological and behavioral assays. In the electroantennogram experiment, PAA and nonanal were consistently eliciting responses in both species and sexes. Ethyl vanillin was active in males of both species, and also in *P. interpunctella* females. *E. cautella* females showed no antennal activity in response to ethyl vanillin. All three volatiles were attractive to *E. cautella* males and *P. interpunctella* females in a flight tunnel. *E. cautella* females were significantly attracted only to ethyl vanillin. *P. interpunctella* males were attracted to PAA. Ethyl vanillin is a novel insect attractant, whereas both nonanal and phenylacetaldehyde mediate behavior in many insect species. A final experiment revealed that a blend of the three volatiles was required to induce landing in the flight tunnel bioassay, and that the landing rate was dependent on dose. The three-compo-

nent blend attracted both sexes of *P. interpunctella* and females of *E. cautella*, whereas *E. cautella* males were not attracted.

Key Words—Pyralidae, Lepidoptera, GC-EAD, GC-MS, EAG, flight tunnel, food volatiles, ethyl vanillin, phenylacetaldehyde, nonanal.

INTRODUCTION

Adult moths (Lepidoptera) of the Pyralidae family rarely feed, but volatiles from the larval host may still be used by females to locate oviposition sites and possibly by males to locate habitats with females (Ramachandran et al., 1990). A number of studies have identified chemicals mediating both oviposition and flight in pyralid females, e.g., both phenylacetaldehyde (PAA) and terpenes in *Ostrinia nubilalis* (Hübner) (Cantelo and Jacobson, 1979; Maini and Burgio, 1990; Binder et al., 1995; Binder and Robbins, 1997). Female *Amyelois transitella* (Walker) flew toward crude almond oil (Phelan and Baker, 1987), and the mediating chemicals were later identified as oleic acid and linoleic acid (Phelan et al., 1991).

Two pyralid moth species found in indoor habitats, e.g., pet food stores and chocolate factories, are the almond moth, *Ephestia cautella* (Walker), and the Indian meal moth, *Plodia interpunctella* (Hübner). A number of studies have shown that wheat odors induce flight and oviposition in gravid *E. cautella* females (Barrer, 1977; Barrer and Jay, 1980; Gothilf et al., 1993). Similarly, corn (Phillips and Strand, 1994), nuts and almonds (Hoppe, 1981), and walnut oil (Nansen and Phillips, 2003) induce upwind flight and/or oviposition of gravid females of *P. interpunctella*. A 1:1 mixture of acetic acid and isoamyl alcohol (3-methyl-1-butanol), initially developed from host plants of noctuid moths, has been used to trap female *P. interpunctella* in Hungary (Toth et al., 2002). Both males and gravid females of *E. cautella* and *P. interpunctella* fly toward a variety of chocolate products and extracts (Olsson et al., 2005).

Several studies have identified the volatile constituents of chocolate and hundreds of organic compounds were found (Ziegleder and Stojacic, 1988; Schnermann and Schieberle, 1997; Counet et al., 2002). However, their behavioral effect on insects has not been investigated. Our objectives were to identify electrophysiologically active volatiles in extracts of the chocolate varieties that eventually could be used in monitoring traps of the pyralid moths. We tested synthetic references of the identified substances with electroantennograms (EAG) and in a flight tunnel to observe their activity, both electrophysiologically and behaviorally. Finally, we tested a blend of the active volatiles to investigate if it was more behaviorally active than the individual volatiles when presented separately.

METHODS AND MATERIALS

Insects. Laboratory cultures of *E. cautella*, originating from a Swedish chocolate factory, and *P. interpunctella*, provided by the Danish Pest Infestation Laboratory at Lyngby, were used. Larvae were reared on (100 g) of a diet of a 10:2:1 mixture of wheat germ, Brewer's yeast, and glycerol. Insects were separated by sex at the pupal stage, and the adults were kept in separate climate chambers with L17:D7 photoperiod, at 24°C and 60% relative humidity. All insects used in the experiments were 2–5 d old.

Headspace Extracts. Volatiles from 15 g of either plain, nut-containing, or rum-flavored chocolate were collected on a charcoal filter at room temperature for 24 hr, using a closed loop stripping apparatus (Bestmann et al., 1988). The filter was extracted with 80 μl of dichloromethane, and the extract was diluted with 720 μl cyclohexane. The filter was cleaned with a 2:1 mixture of methanol and acetone between collections.

Steam Distillation Extracts. The steam distillation extraction technique was used to obtain more volatiles in higher concentrations from the chocolate samples. Water was boiled at elevated pressure, and the steam transferred to a vessel containing 200 g of chocolate maintained at 100°C. During 2 hr, the steam from the stirred water–chocolate mixture was collected and cooled to room temperature. The collected water layer was extracted three times with diethyl ether. The organic layer (300 ml), with a strong smell of chocolate, was dried with $MgSO_4$ and concentrated under reduced pressure to 2 ml.

Gas Chromatography with Electroantennographic Detection. A Hewlett Packard 5890 series II gas chromatograph with a nonpolar HP-1 column (30 m × 0.25 mm i.d.) was used. Samples were injected splitless, and the injector temperature was 225°C. The carrier gas was hydrogen. The column temperature was kept at 40°C for 2 min then increased by 10°C/min up to 230°C. The final temperature was kept at 230°C for 10 min. The injected sample was split between two outlets allowing simultaneous recording of response of the flame ionization detector (FID) and the electroantennographic detector (EAD). Nitrogen was used as a make-up gas for the split. The antenna was cut off at the first basal segment and at the tip segment, then placed between two glass capillaries filled with saline solution and containing a silver wire (Baker et al., 1991). The antenna was placed approximately 10 mm from the GC outlet tube. Recordings from antennae of virgin females and males were made to determine electrophysiologically active components in the chocolate extracts. Three antennae of each sex and species were tested for each of the extracts. All gas chromatography with electroantennographic detection (GC-EAD) recordings were analyzed with Autospike 32 software (Syntech, The Netherlands).

Gas Chromatography-Mass Spectrometry. Chocolate extracts were analyzed with a Hewlett Packard 5890 series II gas chromatograph equipped with an HP-1 nonpolar column. Helium was used as carrier gas. The initial temperature was maintained at 50°C for 2 min and then increased by 10°C/min to the final temperature 250°C. The effluent was analyzed with an HP5972 mass spectrometer in scan mode. Substances that repeatedly elicited antennal responses were identified by comparing retention times (maximum deviation ± 0.02 min) with synthetic references, and with mass spectra from MS libraries (NBS75k and Wiley275, match quality >90%) and synthetic references.

Chemicals. All synthetic references were >95% pure when checked by the gas chromatography-mass spectrometry (GC-MS) method described above. The chemicals were purchased from Sigma-Aldrich (cyclohexanone, ethyl vanillin, and vanillin), Acros Organics (nonanal), ICN Biochemicals (phenylacetaldehyde), and Fisher Scientific (two isomers of α-pinene and cyclohexanol).

Electroantennograms. Four doses, ranging from 10^{-2} to 10 μg, of the identified substances were tested for their electrophysiological activity. For α-pinene, both isomers were tested to determine which one was electrophysiologically most active. In the case of ethyl vanillin, 100 μg were also tested, to compensate for the lower vapor pressure of this chemical (vapor pressures: ethyl vanillin 8.84×10^{-4} Torr, nonanal 0.532 Torr, and PAA 0.368 Torr). The antenna was mounted and humidified as above. A 10-μl aliquot of a compound to be tested diluted in cyclohexane was applied on a 7 × 13 mm filter paper, which was inserted into a Pasteur pipette. The tip of the Pasteur pipette was inserted in a hole 200 mm from the opening of an 8-mm tube leading to the antenna, and air was puffed for 0.5 s at 5 ml/s flow rate with a stimulus controller (CS-02, Syntech). As positive standard, 5 ng of the four-component pheromone blend of *P. interpunctella* (Zhu et al., 1999) were used for males and 10 μl of headspace extract of rum-flavored chocolate, corresponding to 18 min collection in the closed loop apparatus, were used for females. Ten μl of cyclohexane were used as a negative control to distinguish olfactory from mechanical responses. The stimulation procedure was as follows: first the standard was used, followed by the negative control, and then the standard again. The antenna was then stimulated with the test substances with a standard stimulation every third time. This procedure was repeated for each dose, starting with the lowest to avoid adaptation of the receptors. At least 15-sec intervals were maintained between stimulations. The standardized EAG response of a substance was calculated by dividing the EAG response with the mean of the standard puffed after and before the substance (Hansson et al., 1991). Ten antennae from virgin moths were tested for each species and sex. The EAG recordings were analyzed with Autospike 32 software (Syntech, The Netherlands).

Flight Tunnel Experiments. A 0.7 × 0.7 × 2.0 m flight tunnel was used for all behavioral experiments (Zhu et al., 1999). Light intensity was 10 lx, temperature was maintained at 23 ± 2°C, and relative humidity at 30–60%. All flight tunnel experiments were conducted during the first 2 hr into the scotophase, and each moth was observed for 3 min. Mated females and unmated males were used for all experiments, as mating has a positive effect on female behavior and none on male behavior (Olsson et al., 2005). The chemicals were tested in the flight tunnel by using an ultrasonic sprayer (El-Sayed et al., 1999) at a frequency range of 290–320 kHz, to avoid the disturbing effects on moths hearing the ultrasound (Skals et al., 2003). The chemicals were released at 50 ng/min (10 ng/μl at 5 μl/min) rate after quantification (standard 10 ng decyl acetate) of the active components in the behaviorally active chocolate extracts (Olsson et al., 2005). The released dose was never more than 10 times greater than those found in the chocolate extracts, thereby minimizing the risk of arrestment behavior in response to too high concentrations. Cyclohexane was used as a negative control.

In a subsequent flight tunnel experiment, a blend of ethyl vanillin, nonanal, and phenylacetaldehyde was tested. Gas chromatography was used to analyze the three chocolate types extracted with the two different techniques and to determine the ratio between the volatiles in the blend used. Because nonanal was present in all extracts, it was set as a reference for the comparison, and given the value of 1 in the blend. A 2:1:2 blend of ethyl vanillin, nonanal, and phenylacetaldehyde was chosen as representative for authentic chocolate odors. The blend was released at three doses ranging from 2.5 (e.g., 0.5 ng/μl at 5 μl/min, in which 0.5 ng/μl equals 0.2 ng ethyl vanillin, 0.1 ng nonanal, and 0.2 ng PAA/μl) to 250 ng/min, and tested for both species and sexes. For all tests orientated upwind, flight at least halfway to the odor source and landing on the source were observed.

Statistics. EAG data were analyzed with ANOVA followed by Tukey's *post-hoc* test at $P < 0.05$ level in SPSS 10.0 for Macintosh. The flight tunnel data were analyzed at the $P < 0.05$ level with Ryan's multiple comparison test for proportions (Ryan, 1960).

RESULTS

Twelve electrophysiologically active compounds were found when analyzing the different chocolate types with GC-EAD (Figure 1). Some compounds were found in all samples, whereas others varied with both the type of chocolate and the extraction technique used (Table 1). Compounds 1, 3, 7, 8, and 10–12 were identified by comparing their mass spectra with synthetic samples. Compound 9 (Figure 1) was tentatively identified as 3-ethyl-2,5-

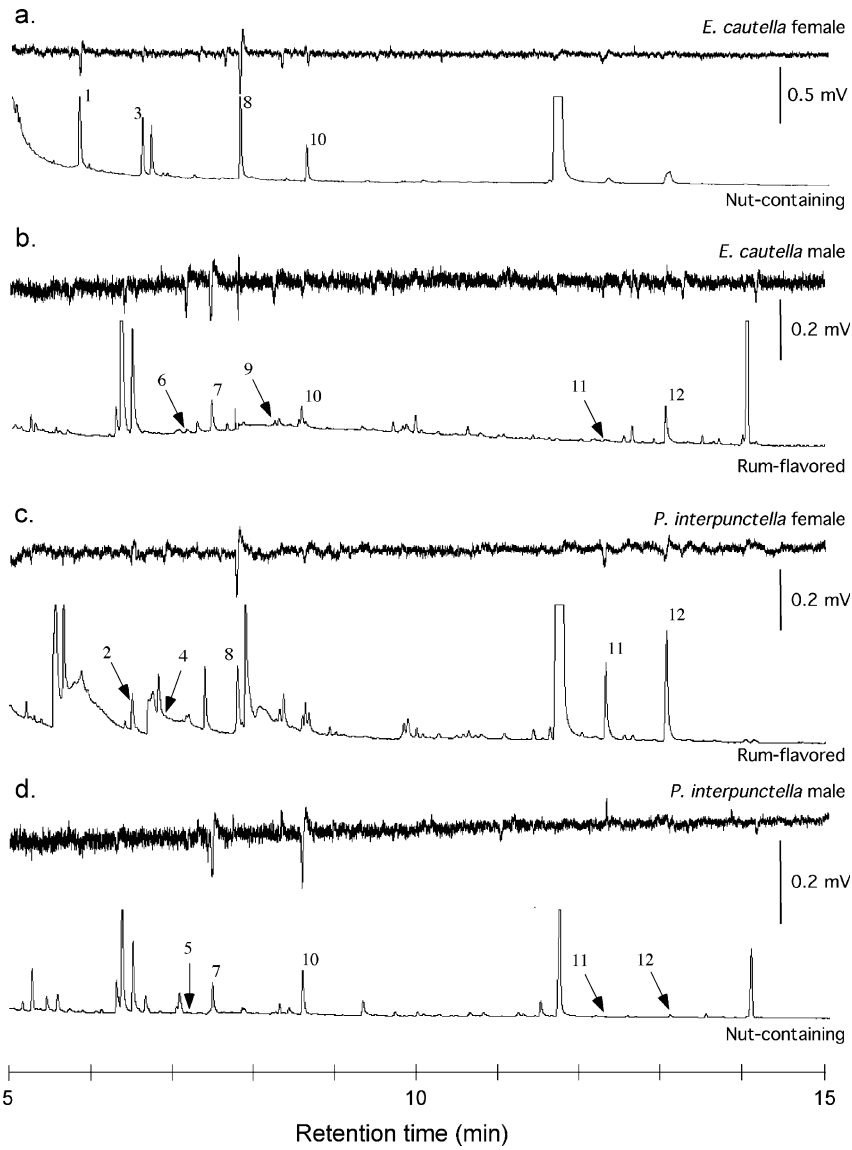

FIG. 1. Examples of GC-EAD runs showing (a) *E. cautella* female response to headspace extract of nut-containing chocolate, (b) *E. cautella* male response to steam distillation extract of rum-flavored chocolate, (c) *P. interpunctella* female response to headspace extract of rum-flavored chocolate, and (d) *P. interpunctella* male response to steam distillation extract of nut-containing chocolate. Chemical names corresponding to the peak numbers are found in Table 1.

dimethylpyrazine, by comparing its mass spectrum with a library mass spectrum. Remaining compounds (peaks 2 and 4–6 in Figure 1) were not identified. *E. cautella* females responded to 11 of the active substances and the males to 10 (Table 2). Both sexes of *P. interpunctella* responded to eight substances each, of which six were in common (Table 2).

In both sexes of both species, the two highest doses (1 and 10 μg) of phenylacetaldehyde and the highest dose (10 μg) of nonanal elicited EAG responses that were significantly different from the control (Figures 2 and 3). *E. cautella* males also responded to the second highest dose (1 μg) of nonanal (Figure 2b). All adults, except *E. cautella* females, responded to 100 μg of ethyl vanillin, and the males of both species also responded to 10 μg of ethyl vanillin (Figures 2 and 3). All other substances and doses were not electrophysiologically active when compared to the control. The difference in EAG response between active and nonactive substances was larger in males than in females for both species.

In the first flight tunnel experiment, males of *E. cautella* responded significantly to nonanal, PAA, and ethyl vanillin, whereas females only flew upwind to ethyl vanillin (Figure 4a). Males were generally more responsive than females, especially to nonanal and PAA where the intersexual differences were significant. In the case of *P. interpunctella*, females responded to nonanal, PAA, and ethyl vanillin, whereas males only responded significantly only to PAA

(Figure 4b). As with *E. cautella* males, *P. interpunctella* males were more responsive than females, with a significantly higher male response to PAA. However, when tested separately, PAA did not induce any significant landing on the source of either sex in either species.

In the second flight tunnel experiment, significantly more *E. cautella* females flew upwind to the intermediate dose (25 ng/min) of the three-component blend, and all doses induced significantly more landings at the source than in the control (Figure 5a). In contrast, *E. cautella* males were not attracted to the blend at any concentration tested. The frequency of upwind flight was positively correlated with the dose for *P. interpunctella* females, as the two highest doses (25 and 250 ng/min) were significantly different from the control (Figure 5b). Male upwind flight behavior was significantly higher at all doses compared with the control. The highest proportions of both *P. interpunctella* males and females landing on source were observed at the intermediate dose (25 ng/min), which was significantly different from the controls (Figure 5b).

DISCUSSION

The attraction of females to chocolate volatiles could be considered as adaptive, because they would guide females to suitable oviposition sites (Olsson

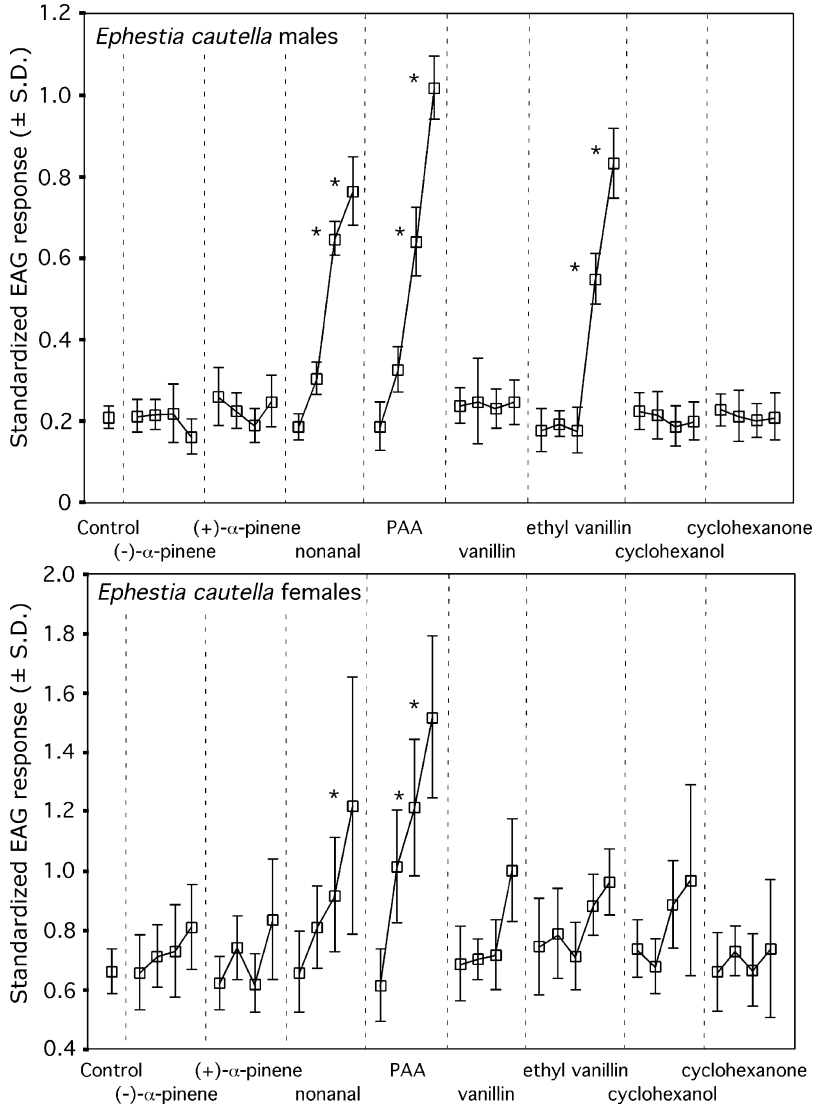

FIG. 2. EAG responses of *E. cautella* males and females to different doses (0.01–10 μg, except ethyl vanillin for which 100 μg were also tested) of chocolate-derived chemicals. *Data points are significantly different from control, when tested at the $P < 0.05$ level with Tukey's *post-hoc* test (ANOVA, males: $F = 73.40$, $df = 33$, $P < 0.001$; females: $F = 7.11$, $df = 33$, $P < 0.001$). Control was cyclohexane.

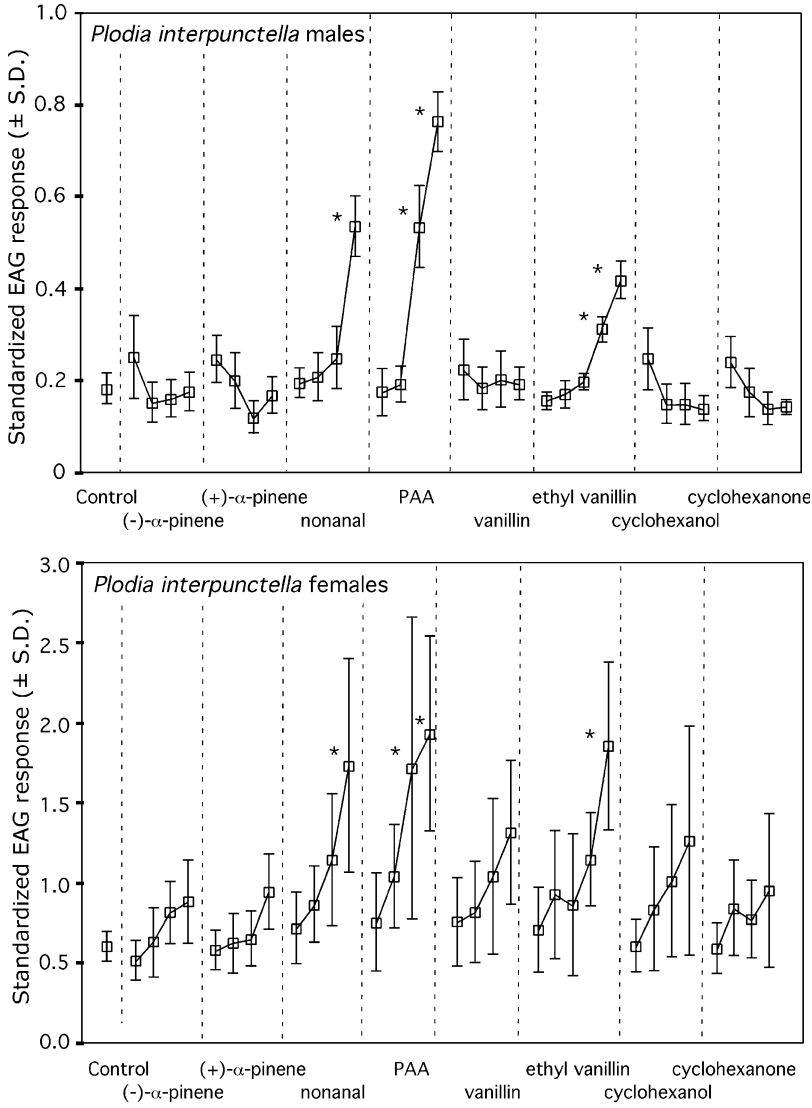

FIG. 3. EAG responses of *P. interpunctella* males and females to different doses (0.01–10 μg, except ethyl vanillin for which 100 μg was also tested) of chocolate-derived chemicals. *Data points are significantly different from the control, when tested at the $P < 0.05$ level with Tukey's *post-hoc* test (ANOVA, males: $F = 38.60$, $df = 33$, $P < 0.001$; females: $F = 4.70$, $df = 33$, $P < 0.001$). Control was cyclohexane.

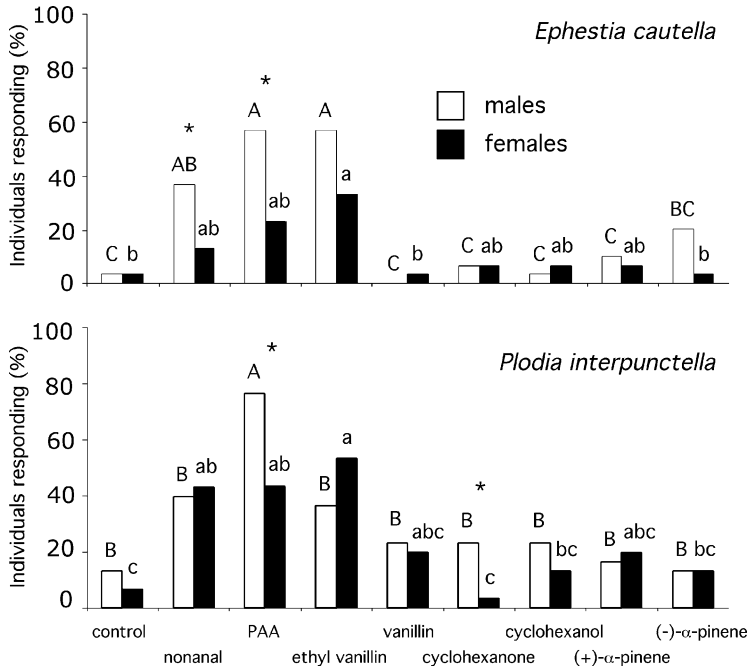

FIG. 4. Proportion of *E. cautella* and *P. interpunctella* males and females flying upwind in response to individual chemicals released at a rate of 50 ng/min. Bars with the same letters do not differ significantly at $P < 0.05$ level (Ryan's test). *Significant intersexual difference for that chemical. Control was cyclohexane.

et al., 2005). For males, a positive response could lead them to sites containing receptive females, and thus increase their reproductive fitness. The findings show that different chocolate products contain substances that elicit both electrophysiological and behavioral responses in both *E. cautella* and *P. interpunctella*. However, there are a number of interspecific and intersex differences in both the EAG and behavioral responses that are somewhat unexpected. A good example of differences between the EAG and behavioral responses is seen with *E. cautella* females and ethyl vanillin. While ethyl vanillin stimulation resulted in no significant EAG response, it did induce upwind flight, possibly due to the different techniques used to deliver the test material in the two experiments. Ethyl vanillin has a low volatility, so fewer molecules may be released in the EAG setup, resulting in low responses as fewer receptors are activated (Schiestl and Marion-Poll, 2002). In contrast, we used a sprayer in the wind tunnel so the volatility of ethyl vanillin would not influence release rates.

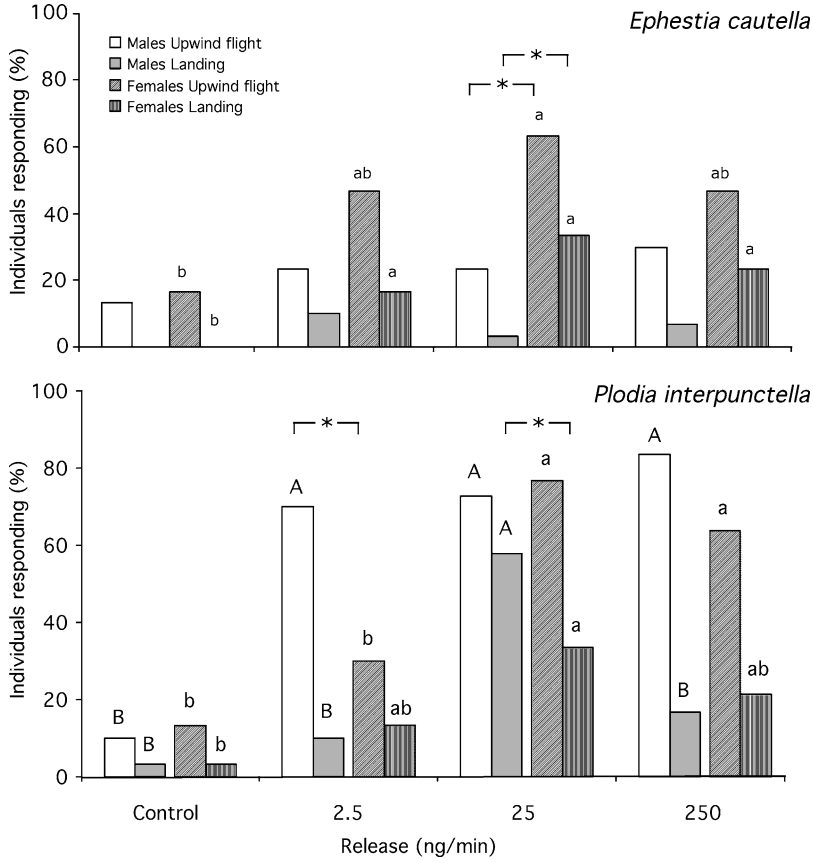

FIG. 5. Proportion of *E. cautella* and *P. interpunctella* males and females flying upwind and landing in response to a three-component blend of ethyl vanillin, nonanal, and phenylacetaldehyde, released at three different doses. Bars within the same category with the same letters do not differ significantly at $P < 0.05$ level (Ryan's test). *Significant intersexual difference within each behavioral step and dose. Control was cyclohexane.

Both sexes of *P. interpunctella* and *E. cautella* females exhibited better upwind flight to the blend than to individual components; *E. cautella* males responded to the individual components but not to the blend. Similarly, more males than females landed in response to the intermediate dose of the blend. This is surprising given that chocolate is more attractive to females than males (Olsson et al., 2005). Therefore, additional experiments will be required to elucidate the biological importance of these differences, including the possibility that there are still some unidentified compounds that elicit behavior.

Ethyl vanillin, identified from samples of milk chocolate, is a synthetic form of vanilla flavor not naturally occurring outside stored product environments (Hurst and Martin, 1982). The observed responses suggest that this is an adaptation to a man-made compound, which would allow moths to locate food sources suitable for larval development.

PAA is an attractant for several other lepidopteran species, e.g., the abovementioned *O. nubilalis*, for both sexes of *Trichoplusia ni* (Hübner) (Creighton et al., 1973), *Autographa californica* (Speyer) (Landolt et al., 2001), and *Pseudoplusia includens* (Walker) (Meagher, 2002). It was also used in the impressive multispecies survey of 72 different moths (Cantelo and Jacobson, 1979). Our results suggest that nonanal and PAA, both chocolate volatiles (Schnermann and Schieberle, 1997; Counet et al., 2002), might be useful in traps for monitoring females of the two indoor moth species and may work as a pheromone synergist enhancing male attraction to pheromone traps.

Acknowledgments—We thank Mats Ekeberg for providing chocolate products; Karin Johnson, Annika Söderman, and Martin Ohsé for assistance with the flight tunnel experiments; and two anonymous reviewers as well as members of the Pheromone Group for their comments on earlier versions of the manuscript. The study was a part of the research program "Pheromones and Kairomones for Control of Pest Insects" (Biosignal) sponsored by the Swedish Foundation for Strategic Environmental Research (MISTRA) and Cerealia R&D.

(Received February 2, 2005; revised August 2, 2005; accepted September 1, 2005)

Abstract—We examined the allelochemical effects of control soil, native soil (treated soil), and leaf extracts of *Phytolacca americana* (pokeweed) on the germination rate and seedling growth of *Cassia mimosoides* var. *nomame*. We also studied the resulting changes in root-tip ultrastructure and peroxidase isozyme biochemistry. *P. americana* leaf extract inhibited seed germination, seedling growth, and biomass when compared to control and treated soil. Root and shoot growth in treated soil was stimulated relative to control soil, but root growth was inhibited by 50% in the leaf extract treatment. Biomass of *C. mimosoides* seedlings grown on leaf extract was reduced sevenfold when compared to the control seedlings. The amounts of total phenolic compounds in the leaf extract, treated soil, and control soil were 0.77, 0.14, and 0.03 mg l^{-1}, respectively. The root tips of *C. mimsoides* treated with leaf extracts of *P. americana* showed amyloplasts and large central vacuoles with electron-dense deposits inside them when compared to control root tips. The activity of guaiacol peroxidase (GuPOX) in whole plant, roots, and shoots of *C. mimosoides* increased as leaf extract increased; maximum activity was observed in extract concentrations of 75% and higher. Root GuPOX activity was three times higher than in shoots. Therefore, we conclude that inhibition of *C. mimosoides* growth is related to the phenolic compounds in the *P. americana* leaf extract and the ultrastructure changes in root-tip cells and increased GuPOX activity is a response to these allelochemicals.

Key Words—Allelochemicals, enzyme activity, phenolic compounds, *Phytolacca americana*, seed germination, seedling growth.

INTRODUCTION

Allelopathy is an important phenomenon operating in natural and managed ecosystems. Many secondary metabolites, including phenolic, terpenoid, flavonoid, and alkaloid compounds, act as plant allelochemicals. Among these, phenolic compounds are the most abundant under field conditions (Rice, 1984; Williamson, 1990) and are known to affect seed germination, seedling growth, cell division, fungal activity, protein synthesis, and enzyme activity (Thijs et al., 1994; Inderjit, 1996; Seneviratne and Jayasinghearachchi, 2003). The phenolic compound, hydroxamic acid, affected membrane permeability resulting in reduced plant growth; and the interference of hydroxamic acid, 2-benzoxazolinone (BOA), and other hydroxamic acids with auxins inhibited the cell-cycle progression of *L. sativa* (Macias et al., 2003). Rye allelochemicals, BOA and 2,4-dihydroxy-1,4-benzoxazin-3-one (DIBOA), caused increased cytoplasmic vacuolation, reduced ribosome density and dictyosomes, reduced number of mitochondria, and reduced lipid catabolism (Burgos et al., 2004). Lovett (1982) found that root-tip cells affected by allelochemicals exhibited increased vacuolation, and the alkaloid of thornapple (*Datura stramonium*) caused an increase in amyloplasts as well as the size and number of microbodies in *Helianthus annuus* root tips (Lovett, 1982; Levitt et al., 1984).

The phytotoxic effects of water-soluble phenolic compounds in *Phytolacca americana* have not been studied in the context of morphological and physiological responses associated with seed germination and subsequent seedling growth. In 1979, *P. americana* was introduced into South Korea and became an important ecological problem in 1993 when it spread throughout the country, displacing many native species. It is a perennial weed that occurs worldwide and has been spreading especially in polluted areas of South Korea (Park, 1995). Under field conditions it interferes with the growth and establishment of competing plant species by releasing water-soluble compounds into the soil (Lee et al., 1997). Furthermore, at low concentrations, extracts of *P. americana* inhibited seed germination, seedling growth, and exhibited antimicrobial activity (Kim et al., 2000). Three *Phytolacca* species in South Korea exhibited allelochemical effects that were related to phenolic compounds (Kim et al., 2005).

Recently, the presence of soluble phenolic compounds was used to screen for disease-resistant cultivars of sugarcane and date palm (Daayf et al., 2003; Nutt et al., 2004). And although there is a great need to determine the effect of allelochemicals on enzyme activity, few studies have related physiological effects to peroxidase activity and gene expression in plant differentiation. Consequently, we studied isozymes in *P. americana*.

Impaired enzyme activity, identified by Rice (1984) as a primary target for phytotoxic activity, may explain the inability to metabolize starch. According to

Alscher and Hess (1995), plants produce enzymes such as peroxidase, catalase, and superoxide dismutase (SOD) for self-protection against external stress. In particular, peroxidase exists in the form of isotype enzymes, which have a different molecular structure while activating the same substrate. During organogenesis, the type of isoperoxidase is more important than the total amount of peroxidase (Scandalios, 1990), and is involved in plant growth as well as in many plant defense mechanisms (Lagimini, 1991). Phenolic compounds act as antioxidants by donating electrons to guaiacol peroxidase (GuPOX) for the detoxification of hydrogen peroxide (H_2O_2) produced under stress conditions (Asada, 1992; Sakihama and Yamasaki, 2002). Phenolic compounds also function cooperatively with ascorbate as antioxidants, particularly in vacuoles and apoplasts where they coaccumulate with GuPOX (Yamasaki et al., 1997; Ren et al., 1999; Xiujuan et al., 2002). Phenolic compounds inhibiting plant growth were reported to increase the activities of proteinase, peroxidase, and catalase (Loebenstein and Linsey, 1961; Gaspar et al., 1985), whereas caffeic acid and salicylic acid reduced phosphorylase and GuPOX activity, respectively (Rice, 1984; McCue et al., 2000).

The objectives of the present study were to: (1) determine the effect of *P. americana* leaf extracts, control soil, and soil from natural *P. americana* patches on seed germination and seedling biomass accretion; (2) examine subsequent growth and ultrastructure changes in *Cassia mimosoides* root tips treated with *P. americana* leaf extract; and (3) determine total peroxidase and GuPOX activity in organs of *C. mimosoides* after treatment with leaf extract from *P. americana*.

METHODS AND MATERIALS

Plant and Soil Collection. Seeds from *C. mimosoides* were collected from Chunan, Chungcheong Province, South Korea, and were used to study seed germination, seedling growth, root-tip ultrastructure changes, and guaiacol peroxidase (EC 1.11.1.7) activity. *C. mimosoides* seeds have a high germination rate, are widely distributed throughout South Korea, and are sensitive to water-soluble leaf extracts. These extracts were obtained from leaves of *P. americana* growing on Mt. Pardal located in downtown Suwon, Gyeonggi Province, South Korea. After removing the organic layer, the upper 5 cm of soil was collected under a patch of *P. americana* (treated soil). Control soil was obtained 2 m away in an area where *P. americana* was not present.

Leaf Extract Study. Two hundred g of fresh *P. americana* leaf were extracted with 1 l of distilled water at room temperature for 48 hr and then centrifuged at 15,000 rpm for 30 min (Centrikon T-1045, Kontron Co., Zurich, Switzerland). The supernatant was collected and stored at 4°C until used. The

leaf extract was filtered through Whatman No. 1 filter paper and used undiluted (100%), and diluted to 75%, 50%, 25%, and 10% concentrations, whereas the control consisted of water for bioassay and the GuPOX activity study. After being selected for uniform size, *C. mimosoides* seeds were sterilized for 3 min in a solution of 5% sodium hypochlorite and then rinsed three to five times with distilled water. Thirty seeds were sown in a Petri dish (90 mm diam.) and treated with a 25% leaf-extract solution. Seeds were incubated at 28°C under 400 μmol m^{-2} s^{-1} fluorescent lighting with 16/8 hr L/D periods for 6 d. Seed germination was assessed daily, while root tips were observed after 3 d. Seedling growth, biomass, and GuPOX activity were measured after 6 d. Enzyme samples were stored in the freezer (−50°C). The experiment was replicated three times. The bioassay method used was a modified version of the procedure described by Lodhi (1976).

Transmission Electron Microscopy of Root Tips. Root tips of *C. mimosoides* were cut to 0.1–0.2 mm in length and dehydrated in a Spurr mixed solution (Spurr, 1969) and stained (Reynolds, 1963). Samples were analyzed by transmission electron microscopy (TEM) at 80 kV.

Guaiacol Peroxidase Assay. The enzyme samples were extracted to measure GuPOX activity. One ml of extraction buffer containing 25 mM KPO_4, 1 mM ascorbate, and 1 mM EDTA was added to 0.3 g of liquid N-frozen root, shoot, and whole plant of *C. mimosoides*, and ground with a mortar and pestle. After being left to stand at 4°C for 20 min, the samples were centrifuged at 13,000 *g* for 20 min (Centrikon T-126, Kontron). The amount of soluble protein was measured with a protein assay kit (Bio-Rad, Hercules, CA, USA) using the method described by Bradford (1976). GuPOX activity was measured using the method described by Amako et al. (1994) and recalculated to units per microgram protein using enzyme kinetics software.

Statistical Analysis. Data were normally distributed, and significant differences between treatments and controls were calculated using one-way ANOVA and Duncan's mean separation test for the measured parameters. The data shown in figures are the mean ± SE.

RESULTS

Leaves of *P. americana* showed high concentrations of total phenolic compounds (0.77 mg l^{-1}), whereas the soil under the plants had concentrations about four times higher than the control soil (0.14 vs. 0.03 mg l^{-1}). Seed germination of *C. mimosoides* was significantly inhibited when treated with *P. americana* leaf extract and in the soil collected from under *P. americana* plants. The germination rate was reduced more in the leaf extracts than in the treated soil (Figure 1, $P < 0.001$). Germination was reduced by 40% in the leaf

extract when compared to the control (Figure 1A), whereas germination was reduced by only 10% in the treated soil (Figure 1B). In seedlings treated with leaf extract, shoot and root growth were significantly reduced compared to that of control (Figure 2, $P < 0.001$). Root growth was especially sensitive to the leaf extract, exhibiting more than a 50% growth reduction. Shoot growth was reduced

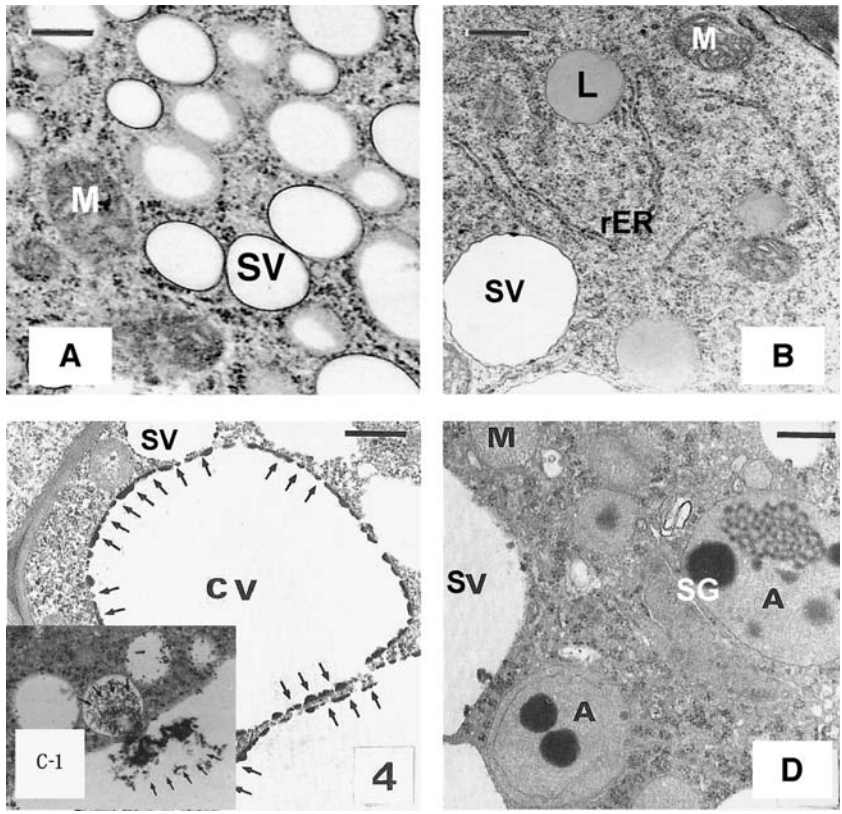

FIG. 4. TEM micrographs of *C. mimosoides* root tips: Control (A and B) and treated (C and D) with leaf extracts of *P. americana*. (A) A large number of small vacuoles and mitochondria are in the parenchyma cell. Bar = 2.4 μm. (B) Lipid bodies, mitochondria, small vacuoles and rER are in the cytoplasm. Bar = 2.4 μm. (C) Electron-dense deposits (arrows) are accumulated in the central vacuole (CV) along the tonoplast of a parenchyma cell. Bar = 1.5 μm, C-1: these arrows point to small vacuoles that are reduced in number, while this amorphous material was discharged into the central vacuole. Bar = 1.5 μm. (D) An amyloplast (A) near the central vacuole (SV) bounded by a double membrane containing two starch grains. Bar = 2.4 μm.

by about 33% in seeds treated with leaf extract (Figure 2). Biomass and seedling growth of *C. mimosoides* plants in treated soil was slightly higher than in the control soil, but the biomass differences were not significant (Figures 2 and 3).

The threshold leaf extract concentration was estimated to be 25% because the greatest changes in the bioassay were observed between 10% and 50% (data not shown). In the root tips from control plants, mitochondria and a large number of small vacuoles were observed in parenchyma cells (Figure 4A). Lipid bodies, mitochondria, and rough endoplasmic reticula (rER) were present in the cytoplasm (Figure 4B). In the root tips from seedlings treated with 25% leaf extract, the size of the central vacuole increased, and electron-dense deposits were observed to accumulate along the tonoplast in parenchyma cells of the stele (Figure 4C). Many small vacuoles joined the central vacuole, whereas amorphous materials were discharged from small vacuoles into the central vacuole (Figure 4C-1). Some cellular organelles were reduced in number, and amyloplasts, including starch grains, appeared in parenchyma cells (Figure 4D).

GuPOX activity dramatically increased in the shoots, roots, and the whole plant with increasing extract concentrations. Root GuPOX activity was three

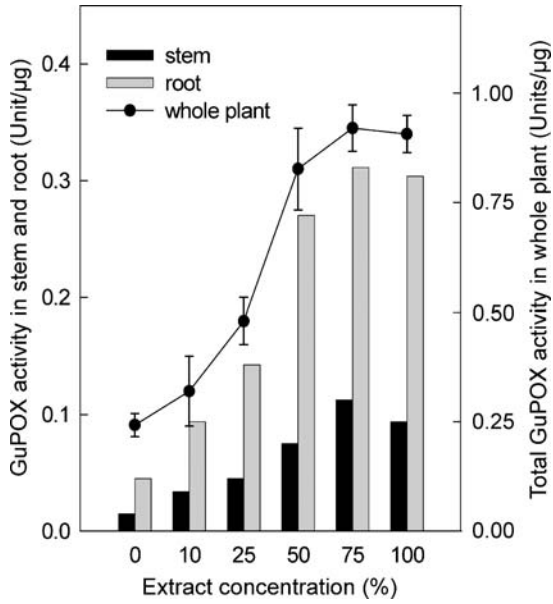

FIG. 5. Comparison of GuPOX activity in root, shoot, and whole plant of *C. mimosoides* treated with *P. americana* leaf extract. Bars represent SE of the mean. Organs treated with extract are indicated by symbols in the legend.

times higher than in the shoots. The highest GuPOX activity was observed in the sample treated with 75% leaf extract, whereas activity in the 100% extract sample was slightly lower. GuPOX activity in the roots exposed to 75% leaf extract increased more than sevenfold over the control (Figure 5).

DISCUSSION

Phenolic compounds found in leaf extracts and treated soil have been reported to reduce seed germination, seedling growth, and biomass (Williams and Hoagland, 1982; Rice, 1984; Einhellig, 1995; Inderjit, 1996) as observed in the present study (Figures 1, 2, and 3). Water-soluble compounds including phenolic compounds released by *Pluchea lanceolata* into the soil were found to significantly decrease seed germination and seedling growth of asparagus bean (*Vigna unguiculata*) (Inderjit and Dakshini, 1992). In the present study, seed germination in treated soil was inhibited (Figure 1B), whereas seedling growth and biomass were only slightly stimulated (Figures 2 and 3). Lodhi (1976) also found increased seedling growth in treated soil containing phenolic compounds. Under field conditions, Rice (1984) suggested that high concentrations of allelochemicals might not be maintained as a result of leaching and microbial degradation. In our study, the observed increase in seedling biomass in response to the presence of soil phenolic compounds has been reported previously (Lodhi, 1976; Rice, 1984). Concentrations of phenolics were found to be higher in leaf extracts (0.77 mg l^{-1}) than in treated soil (0.14 mg l^{-1}). Upon entry into the soil, chemical compounds may be degraded, transformed, and retained depending on the number and types of soil microbes present (Blum, 1995). Thus, bioassays using allelopathic compounds in treated soils may better reflect plant responses such as seedling growth and biomass accumulation, as observed in the present study.

TEM, combined with biochemical assays, suggested possible mechanisms of plant responses to phenolic compounds from *P. americana* leaf extract (Figure 4). In control root tips, a large number of small vacuoles, mitochodrias, rER, and lipid bodies were observed in parenchyma cells (Figure 4A and B). In root tips treated with leaf extract, the arrows point to small vacuoles that were reduced in number, whereas an amorphous material was discharged from the small vacuoles into the central vacuole (Figure 4C-1). It also showed the accumulation of electron-dense deposits along the inside of the tonoplast (Figure 4C). Elakovich and Wooten (1991) reported that plant cells were not affected by osmotic potential below 143 mOsm kg^{-1}. In this research, the osmotic potential of diluted extract 75%, 50%, 25%, and 10% is 72, 46, 18, and 8 mOsm kg^{-1}, respectively. We treated *C. mimosoides* with a 25% concen-

tration of *P. americana* leaf extract. Therefore, the result in Figure 4 suggested that the observed changes in the root tip ultrastructure was not a result of high osmotic potential as reported by Lee and Kim (2000), but may be attributable to phenolic compounds in the leaf extract of *P. americana* that caused the development of starch grains in amyloplasts and electron-dense deposits in the central vacuole. Lovett (1982) and Rizvi and Rizvi (1992) reported a similar response in vacuole size of root tips affected by allelochemicals. Kutchan et al. (1986) also suggested that vacuoles are important in segregating phytotoxic secondary metabolites and play a compartmentalizing role in detoxification (Lovett, 1982; Burgos et al., 2004). The accumulation of electron-dense deposits along the tonoplast has not been previously observed (Figure 4A and B), but is consistent with a detoxification role. The amyloplasts (Figure 4D) observed in the present study may function to accumulate toxic substances for self-protection against *P. americana* leaf extract. The amyloplasts were also found in sunflower (*H. annuus*) root-tip cells following treatment with alkaloids from thornapple (*D. stramonium*) (Levitt et al., 1984; Lovett et al., 1987).

Enzymes play a major role in protecting the plant from oxygen free radicals (Asada, 1992; Sakihama and Yamasaki, 2002; Xiujuan et al., 2002). The isoenzyme form of peroxidase was reported to be the most important one in the differentiation process of plants and many plant defense mechanisms (Scandalios, 1990). Enzyme activity associated with root differentiation was found to increase with stress from toxins, drought, and freezing damage (Alscher and Hess, 1995). Among peroxidase isozymes, GuPOX and AsPOX are representative enzymes that are induced in plants that are mechanically damaged, infected by pathogens, or externally stressed. Lee and Kim (2000) reported that AsPOX was not responsible for the increase in peroxidase activity on *C. mimosoides* treated with *P. americana* leaf extract. Therefore, we investigated GuPOX activity and isozyme forms of peroxidase to understand the physiological response to phenolic allelochemicals. GuPOX activity increased as *P. americana* leaf extract concentration increased. Root activity was three times higher than shoot activity in *C. mimosoides* treated with different concentrations of *P. americana* extract. In the present study, there was a positive relation between GuPOX activity and *P. americana* leaf extract concentration (Figure 5). In response to elevated GuPOX activity, root differentiation was inhibited (Figures 2 and 3). Yoo and Kim (1988) reported that root activity was highly sensitive to external factors. GuPOX activity is known to be sensitive to external stress and plays a major role in protection mechanisms (Gaspar et al., 1985; Ren et al., 1999; Xiujuan et al., 2002). As GuPOX activity increased, inhibition of root growth increased as well. *C. mimosoides* may have been protected by increased GuPOX activity in response to the stress of *P. americana* leaf extract. We suggest that up-regulation of GuPOX activity may be a protection mechanism.

Abstract—Lichens produce a great number of secondary metabolites that participate in ecological interactions and respond to environmental changes. We examined the influence of heavy metal accumulations on lichen secondary metabolism. Thalli of *Hypogymnia physodes* were transplanted for 6 months to the Cracow–Silesia industrial region. Based on heavy metal accumulations in lichen, two of the investigated sites were classified as highly polluted. The highest concentrations of Cd, Pb, and Zn were found in lichens transplanted in the vicinity of a Zn–Pb smelter. Significant accumulations of Cr and Ni were detected in *Hypogymnia* transplanted near a chemical industry. Physodic, physodalic, hydroxyphysodic acids, and atranorin were identified and analyzed in extracts obtained from specimen samples. The most detrimental changes were observed in lichen transplanted into the vicinity of a chemical industry producing chromium, phosphor, and sulfur compounds that contained 340-fold higher Cr levels than control thalli. Decreases in the levels of physodic acid, hydroxyphysodic acid, and atranorin were detected, and one additional polar compound (probably product of degradation of lichen acids) appeared in the extract. The content of physodalic acid increased in every thalli sample transplanted, suggesting a possible role of this compound in defense against stress caused by accumulated pollutants. The levels of physodic acid decreased in thalli from both of the most polluted sites compared to those of the controls—but were not changed in thalli transplanted to less polluted sites. Our results illustrate that lichen compounds are sensitive to heavy metal accumulation and could be used as biomarkers in environmental studies.

Key Words—Air pollution, heavy metals, sulfur, secondary metabolites, biomarkers.

INTRODUCTION

Lichens are the symbiotic association between a fungus and a photosynthetic partner such as an alga or cyanobacterium. They are perennial and maintain a uniform morphology over time. They grow slowly, have a large-scale dependence on the environment for nutrition, and do not shed parts during growth. The lack of epidermis, stomata, and cuticular waxes makes these organisms incapable of controlling gas exchange and allows absorption of different contaminants over the entire surface of the organism (Conti and Cecchetti, 2001). Thus, for over 40 years, lichens have been widely used in monitoring air pollution whether as bioindicators or bioaccumulators in environmental quality evaluation of industrial surroundings (Pilegaard, 1979; Bargagli et al., 1997; Loppi et al., 1997; Garty, 1988; Jezierski et al., 1999), urban areas (Nimis, 1986; Gonzales et al., 1998; Budka et al., 2002), protected areas (Glenn et al., 1995), and even on national scale (Puckett and Finegan, 1980; Herzig et al., 1989; Freitas et al., 1999). In areas that lack naturally grown lichens resulting from excessive air contamination, lichen transplantation is applied as a standard method to study airborne metal and sulfur pollutants (Conti and Cecchetti, 2001; Budka et al., 2002). This method was first introduced by Brodo (1961). The cosmopolitan epiphytic lichen *Hypogymnia physodes* (L.) Nyl. has been considered as a suitable lichen monitor of atmospheric pollution in view of its relative resistance both to heavy metals and sulfur contamination (Bennett, 2000; Jeran et al., 2002).

Lichens are well known for being rich in structurally unique phenolic derivatives with unclear biological roles (Caviglia et al., 2001; Stark and Hyvärinen, 2003). Only 50–60 of the 630 known lichen secondary metabolites have been found in other fungi or higher plants (Elix, 1996). These compounds represent usually 0.1–5% of dry weight; however, they can comprise up to 20% of thalli dry weight (Romagni and Dayan, 2002; Molina et al., 2003).

The significant investment in energy and carbon dedicated to the production of lichen secondary metabolites suggests their important physiological and ecological roles. Lichen phenolic substances probably regulate interactions between mycobionts and phytobionts in the thallus (Molina et al., 2003) and may increase the permeability of phytobiont cell walls (Huneck, 1999). Lichens are slow-growing organisms and need long-term defense against both lower and higher plants, microbes, and herbivores (Huneck and Yoshimura, 1996). Up to 50% of the lichen species studied synthesize substances with some degree of antimicrobial activity (Romagni and Dayan, 2002). Lichen substances can influence the growth and development of different fungal species, including wood-decaying, pathogenic, and parasitic species growing on the thallus (Lawrey, 1983; Goldner et al., 1986). Many of these are effective growth inhibitors of higher plants (Lawrey, 1983; Huneck, 1999) and

can act as antifeedants for insects and other animals (Clark et al., 1999; Huneck, 1999; Molina et al., 2003). Lichens typically grow under extreme conditions of temperature, humidity, intensity of light, or excessive exposure to heavy metals. The Acarosporetum was found to be the most metal-resistant lichen community (Beck, 1999). Some lichen metabolites are considered to be stress metabolites synthesized in response to biotic and abiotic stimuli. These substances may protect thalli from the dangerous toxic actions of free radicals produced by oxidative stress exposure (Huneck and Yoshimura, 1996; Caviglia et al., 2001).

Lichen secondary metabolites have been investigated mostly for chemotaxonomic purposes and in connection with their potential as phytomedicines and natural biopesticides (Huneck and Yoshimura, 1996; Peres and Nagem, 1997; Huneck, 1999; Dayan and Romagni, 2001; Manojlovic et al., 2002). Only a few studies have considered changes in lichen secondary metabolites caused by environmental stress (Calatayud et al., 2000; Caviglia et al., 2001; Conti and Cecchetti, 2001; MacGillivray and Helleur, 2001). Because these compounds may play a role in the adaptation of lichens to their environment, as well as in ecological interactions, they are suitable candidates for the detection of detrimental changes in ecosystems caused by contamination (Jezierski et al., 1999; Caviglia et al., 2001).

A given stressor might cause an increase in the production of a lichen acid, or the normal level of lichen acids might be reduced as they react or decompose in response to stress (MacGillivray and Helleur, 2001). Because the roles of lichen secondary metabolites have not been well established, lichen transplantation seems to be a relevant model system for such investigations. Moreover, lichen compounds in thalli transplanted to polluted areas have not been studied so far.

The goal of the present investigation was to establish the accumulation of metals and sulfur as well as a number of selected secondary metabolites profile in lichen *H. physodes* (L.) Nyl. transplanted to sites with different pollution exposure.

METHODS AND MATERIALS

Test Sites. The studies covered the Cracow–Silesia industrial region in southern Poland (Figure 1). This area has a population density of ca. 280 persons/km. It is one of the most polluted areas in Europe, and still has among the highest emissions of heavy metals in Poland. The investigated sites were located in the vicinity of major emission sources from industrial plants, all of which have been placed on the list of industries with the most harmful impact on the environment in Poland (Bereś et al., 2003). As a northwesterly wind predominates in this region of Poland, the locations of the test sites were selected

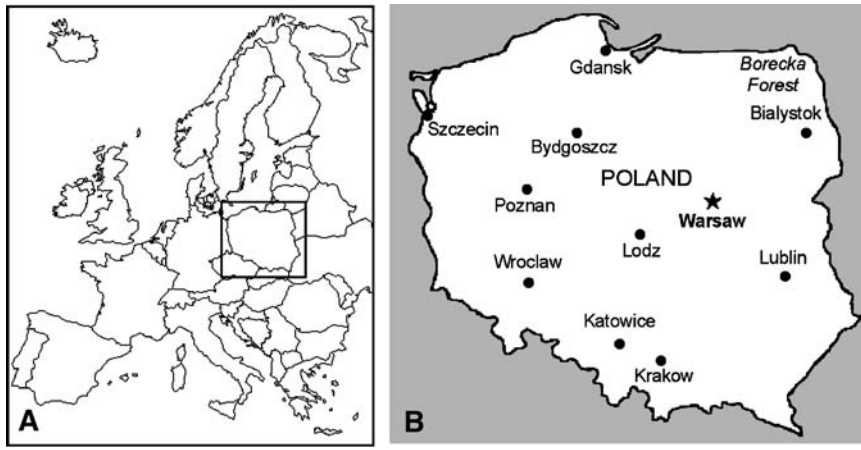

FIG. 1. A) The geographical location of Poland within Europe. B) Major cities in Poland, including the location of the unpolluted Borecka forest where the original lichen samples were collected (northeast of Poland), and the Cracow region where the tests were conducted.

southeast of the emission sources. The following sites of area 200 m^2 were chosen for the study:

1. Bukowno (Figure 2). This site is in the immediate vicinity of the "Bolesław" Zn–Pb smelter. This industry was founded in 1949 and mainly involves mining of zinc and lead, as well as production of their concentrates. In 1990, this industry emitted over 17, 7, and 0.3 tons of Zn, Pb, and Cd, respectively. Since then, successively lower emission levels have been observed. In 2000, emission of particulates reached 0.753, 0.0022, and 0.0002 tons of Zn, Pb, and Cd, respectively (data provided by the Zn–Pb smelter).
2. Młoszowa (Figure 2). The main pollution source in this site (the Trzebinia S.A. refinery) was established at the end of the 19th century. It produces fuels, asphalts, paraffin, and oils. The quality of the environment at this site may also be affected by emission from the "Siersza" S.A. power plant in Trzebinia. This study area is also relatively close to the A-4 Cracow–Katowice highway.
3. Jankowice (Figure 2). This site is affected by emission from the chemical industry "Dwory" S.A. in Oświęcim. This industry emitted 743,000 tons of gaseous pollutants (mainly PAHs, Cl, and S compounds) in 2000 (Bereś et al., 2003).
4. Alwernia (Figure 2). This site is located in the immediate vicinity of the "Alwernia" S.A chemical industry, which was established in 1924.

Currently, the industry produces chromium, phosphorus, and sulfur compounds. Emission of dusts from "Alwernia" in 2000 reached 78,000 tons, including 1.7 tons of Cr. In 2002, the industry emitted 1.3 tons of Cr and 263 tons of gaseous pollutants (data provided by "Alwernia" S.A.).

Lichen Transplantation. Control lichens for transplantation were collected in the Borecka Forest located in the northeastern part of Poland (Figure 1), far from large metropolitan areas or other pollution emission sources (Śnieżek, 1997). Samples of the epiphytic foliose lichen *H. physodes* (L.) Nyl., growing on branches of hazel tree (*Corylus avellana* L.), were collected and transplanted to the various study sites on April 15, 2002. Ten branches, ca. 30 cm long, containing about 10–15 g wet weight of the thalli in total, were brought to each site and hung on selected trees at a height of ca. 1.5 m (Figure 3). After 6 months, thalli were separated from the bark and analyzed. Untreated controls consisted of samples collected and transplanted within the Borecka Forest.

Elemental Analysis of Thalli Tissues. Thalli collected from the various test locations were oven-dried to constant weight at 60°C and ground in an electric mill. Samples weighing 0.3–0.5 g were digested in $HNO_3/HClO_4$ (4:1) on a water bath at 80°C for about 3 wk (until totally clear). Cd, Cr, Ni, and Pb levels

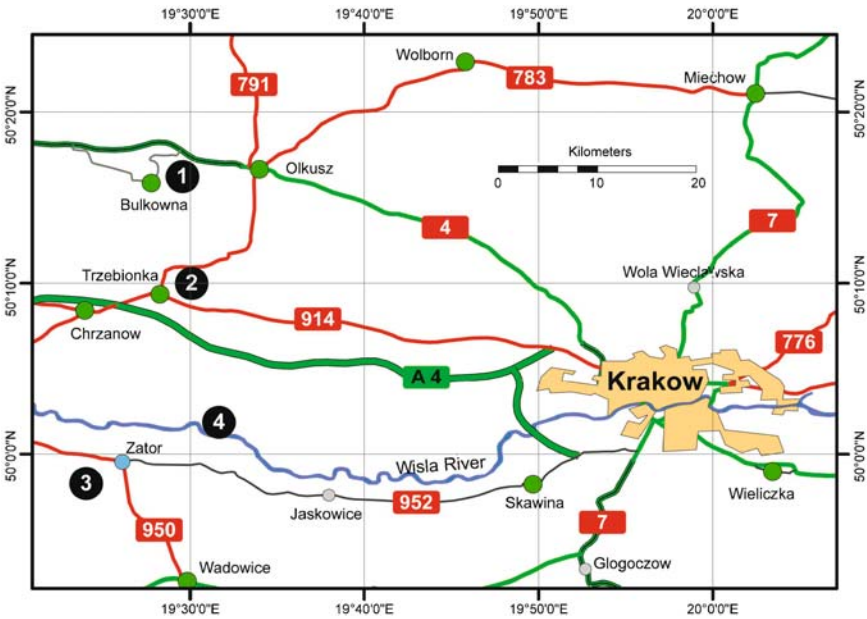

FIG. 2. The Cracow region showing the locations of the various test sites.

FIG. 3. Transplanted lichens hanging from a birch tree.

were determined by using an Aanalyst 800 Perkin-Elmer atomic absorption spectrophotometer with a graphite furnace. Cu, Fe, and Zn concentrations were determined with an IL 251 flame spectrophotometer. Results were expressed in $\mu g\ g^{-1}$ of dry weight. The accuracy of the analysis was checked against standard reference material, namely, Tomato Leaves SRM 1573a.

Total levels of sulfur in transplanted lichens were detected with the turbidimetric method by Butters-Chenry (Nowosielski, 1968). Homogenized thalli (0.2 g) were treated with 75% nitric acid and left for 24 hr at 18°C, evaporated, and treated with magnesium nitrate. This treatment was followed by oxidization at 450°C and treatment with 25% nitric acid, 50% acetic acid, 85% orthophosphoric acid, and 2% barium chloride. The resulting opaqueness was measured by colorimeter (Spectromom 204) at 290 nm. Concentrations of sulfur were calculated according to a $MgSO_4$ standard curve. Results were expressed in $\mu g\ g^{-1}$ of dry weight.

Analysis of Secondary Metabolites in Thalli. After transplantation, visually similar thalli (1.5–2 g of air-dried thalli) were extracted three times for 15 min with 100% ethanol (about 30 ml/g of lichen) with the use of a sonicator. Extracts were filtered and evaporated on a rotary evaporator. Crude extracts (2.5 mg) were diluted in 3 ml of methanol [high-performance liquid chromatography (HPLC) grade]. For separation and analysis of the secondary metabolites, 20 μl of samples were injected onto an analytical HPLC. The HPLC system consisted of a Waters 717 with autosampler, a Waters 600 controller, a Waters photodiode array detector, and 4.6 × 250 mm analytical column (Water Spherisorb 5 μm ODS).

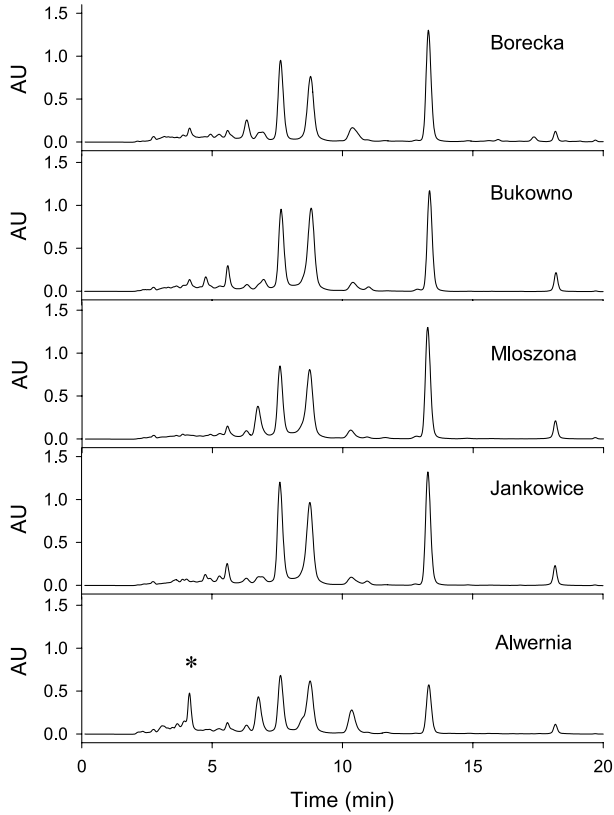

FIG. 4. Chromatograms of crude extracts from *H. physodes* samples from the various test locations. The retention time of hydroxyphysodic acid (7.7), physodalic acid (8.7), physodic acid (13.5), and atranorin (18.1) in the crude extracts matched those of the analytical standards at 7.6, 8.8, 13.3, and 18.2 min, respectively. The identities of the peaks were confirmed by comparing the UV spectra in the crude extract to that of the analytical standards. The polar peak in Alwernia chromatogram is denoted by an asterisk.

The best separation was obtained with 1% phosphoric acid in water (**A**) and methanol (**B**) (Feige et al., 1993, modified) using a gradient from 75 to 100% **B** over 15 min. The flow rate was 1 ml/min and pressure 1500–2000 mm Hg. Elution of the secondary metabolites was monitored at 254 nm. Concentrations of compounds were estimated and/or compared based on peak areas. Compounds were identified by comparison with standards (retention time and UV absorption). Except for the absolute amount, the percentage of total peak area in the whole extract was given. Crude extracts constituted 15–18% of the air-dried weight of thalli. Chromatographic separation revealed three major metabolites (Figure 4) identified as hydroxyphysodic acid (Rt = 7.6 min), physodalic acid (Rt = 8.8 min), and physodic acid (Rt = 13.3 min). Additionally, a smaller peak was recognized as atranorin (Rt = 18.2 min). The chemical structures of these compounds are given in Figure 5. Lichen standards were previously isolated from *H. physodes* at the Center for Research on Natural Products, University of Mississippi. The structures were identified by mass spectrometry and nuclear magnetic resonance. Standard deviations of the HPLC analysis reproducibility were lower than 2.5%.

Statistical Analysis. Means and standard deviations were calculated for elements and secondary compounds. Statistical differences in the concentrations of Cd, Fe, Ni, S, Zn, and lichen acids in thalli transplanted to different sites were established using ANOVA on logarithmic data, followed by Tukey honestly significant difference for equal sample sizes. For determination of statistical differences in Cu, Cr, and Pb concentrations, Kruskal–Wallis nonparametric tests were applied followed by paired comparisons of the mean ranks (Sachs, 1984).

RESULTS

Accumulation of Elements. Six months after transplantation of the lichens, the highest concentrations of Cd, Pb, and Zn were found in samples transplanted to the Bukowno location, in the vicinity of the Zn–Pb smelter, relative to both control thalli and thalli transplanted to the other sites (Table 1). Pb concentrations did not increase in the other locations, relative to the control thalli (about 10 $\mu g\ g^{-1}$). However, Pb reached 124 $\mu g\ g^{-1}$ in lichen transplanted to Bukowno (Table 1). Similarly, Zn accumulation was rather low in all of the studied sites, except for Bukowno where it increased from 55 $\mu g\ g^{-1}$ (control thalli) to 583 $\mu g\ g^{-1}$ (Table 1). Accumulations of Cd were found in all of the transplanted lichens. The level of this element in thalli from Bukowno was ca. 14-fold higher than control thalli. The level increased only 2–2.5-folds in thalli transplanted to the other sites studied (Table 1).

Significant accumulations of Cr and Ni were detected in *H. physodes* transplanted to the Alwernia location (Table 1). The level of Cr 6 months after transplantation to this site was as much as 343-fold higher than in control

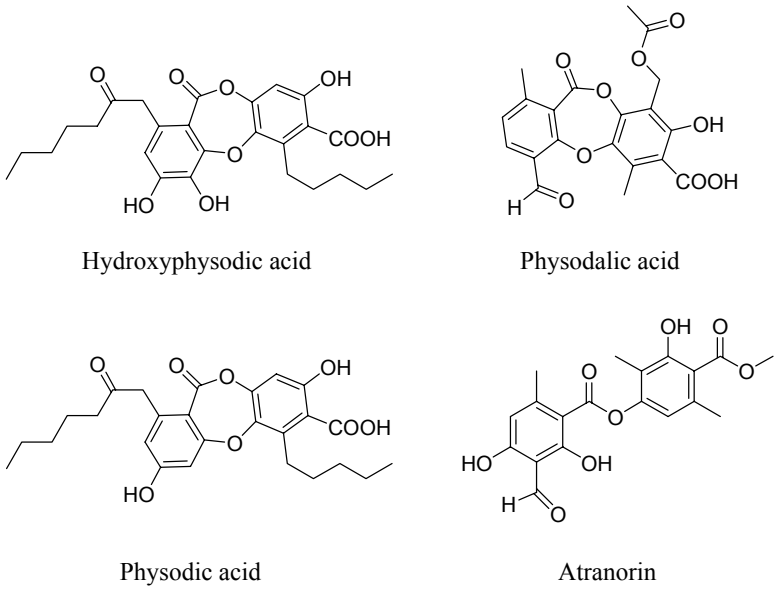

FIG. 5. Structures of the secondary metabolites detected in *H. physodes*.

lichens (Table 1). Ni increased to 9.18 μg g^{-1} compared to 1.08 μg g^{-1} in the control. Additionally, the concentration was slightly increased in thalli from the Bukowno location, but was not statistically different from the rest of the sites (Table 1).

Increases in Cu and Fe concentrations occurred in all thalli after transplantation, but the highest accumulations were noted in *Hypogymnia* samples from Bukowno and Alwernia (Table 1).

Finally, there were significant accumulations of sulfur in all transplanted lichens. Sulfur concentrations ranged from 1406 to 2188 μg g^{-1} in thalli transplanted to the polluted sites compared to 1237 μg g^{-1} in control thalli (Table 1).

Secondary Metabolites in Transplanted Thalli. Significant differences in the quantity of secondary metabolites were found between control thalli from Borecka Forest and thalli transplanted to the polluted areas, as well as among lichens transplanted to areas of different pollution levels.

The most significant decrease in physodic acid (−58% relative to control thalli) was detected in thalli transplanted to Alwernia. The level of physodic acid decreased also in transplanted lichens transplanted in Bukowno (−13% relative to the control thalli). The contents of this compound were not changed in *Hypogymnia* transplanted to Młoszowa or Jankowice (Figure 6A).

TABLE 1. CONCENTRATION OF ELEMENTS IN *Hypogymnia physodes* TRANSPLANTED TO THE CRACOW–SILESIA INDUSTRIAL REGION

Locations	Elements (μg g^{-1} dry weight)							
	Pb	Zn	Cd	Cr	Ni	Cu	Fe	S
Borecka	9.0 ± 0.4a	55 ± 7a	0.54 ± 0.02a	0.22 ± 0.04a	1.08 ± 0.19a	3.7 ± 0.4a	350 ± 47a	1237 ± 33a
Bukowno	123.7 ± 20.0b	583 ± 56c	7.70 ± 0.47d	0.79 ± 0.06b	1.91 ± 0.12b	10.8 ± 0.3d	1306 ± 164c	1842 ± 397b
Młoszowa	11.2 ± 1.5a	68 ± 6ab	1.37 ± 0.05c	0.48 ± 0.06b	1.36 ± 0.19ab	7.5 ± 0.4bc	720 ± 106b	1960 ± 109b
Jankowice	11.3 ± 1.2a	55 ± 4a	1.02 ± 0.12b	2.89 ± 0.54b	1.38 ± 0.06ab	5.9 ± 0.3b	597 ± 38b	1999 ± 242b
Alwernia	12.7 ± 3.1a	77 ± 5b	1.29 ± 0.10bc	75.85 ± 4.62c	9.18 ± 1.42c	9.9 ± 1.8cd	1202 ± 368c	1665 ± 109ab

Data represent mean ± SD. Means within a column with different letters are statistically different in the element levels between studied sites at $P < 0.05$ for $N = 5$.

The level of physodalic acid significantly increased in all transplanted lichens compared to control thalli from Borecka Forest (Figure 6B). The highest concentrations were in lichens transplanted to Bukowno and Alwernia (63 and 13% higher than in control samples, respectively; Figure 6B). Additionally, increases in the percentage contribution of physodalic acid in the crude extract were observed in samples from Borecka Forest (17.1% increase), in Bukowno (25.8% increase), and in Alwernia (20.6% increase) (Table 2).

Concentrations of atranorin increased in thalli transplanted to Jankowice (by 36%), Bukowno (by 30%), and Młoszowa (by 16%) (Figure 6C). A decrease in atranorin level was observed in lichen samples transplanted to

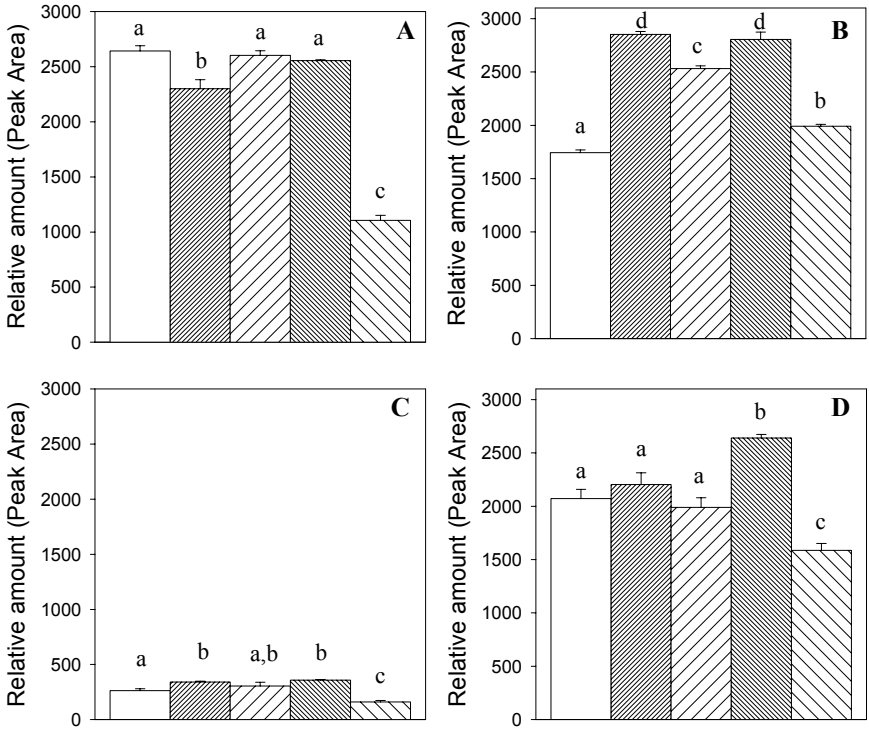

FIG. 6. Concentrations of (A) physodic acid, (B) physodalic acid, (C) atranorin, and (D) hydroxyphysodic acid in lichen *H. physodes* samples transplanted and acclimated to various levels of environmental pollution. = Borecka (control), = Bukowno, = Młoszowa, = Jankowice, and = Alwernia. Controls consisted of samples that had been collected and transplanted within the Borecka forest site. Data represent mean ± SD. Bars with the same letters are not statistically different based on ANOVA ($P < 0.05$), $N = 3$.

TABLE 2. RELATIVE AMOUNTS (%) OF THE SECONDARY METABOLITES IN THE EXTRACT ISOLATED FROM *H. physodes* FROM VARIOUS TEST LOCATIONS

Location	Unidentified (Rt = 4.4) (%)	Hydroxyphysodic acid (%)	Physodalic acid (%)	Physodic acid (%)	Atranorin (%)
Borecka	–	18.4	17.1	23.5	2.3
Bukowno	–	20.0	25.8	25.8	3.1
Młoszowa	–	18.7	23.7	24.4	2.9
Jankowice	–	21.7	24.4	22.2	3.1
Alwernia	12.1	16.5	20.6	11.5	1.7

Relative peak area was used.

Alwernia. Similar tendencies of this compound were noted on a percentage basis (Figure 6C, Table 2).

An increase in hydroxyphysodic acid concentration was observed in *H. physodes* transplanted to Jankowice forest (Figure 6D). However, the percentage in the crude extract was not changed (Table 2). In lichen transplanted to Alwernia, thalli contained lower levels of hydroxyphysodic acid than control thalli (Figure 6D).

Crude extracts obtained from lichens transplanted to Alwernia contained a lower percentage of physodic acid, hydroxyphysodic acid, and atranorin. Additionally, an unidentified peak (yellow oily compound) with a retention time (Rt) of 4.1 was observed in *H. physodes* samples from Alwernia and constituted 12% of the crude extract (Table 2).

DISCUSSION

Accumulation of elements in transplanted *H. physodes* revealed significant spatial diversification of air pollution in the investigated Cracow–Silesia industrial region. According to our results, sites were classified as either heavily polluted (Bukowno and Alwernia) or moderately polluted (Młoszowa and Jankowice), with less harmful impact of neighbor industries on the environment. Areas with high levels of air pollution are directly influenced by emissions from the Zn–Pb smelter (Bukowno) and from the chemical industry (Alwernia).

To assess whether our results were unusually high, the obtained concentrations of elements were checked against baseline values for chemical elements in *H. physodes*, the most studied lichen in the monitoring of air quality (compiled by Bennett, 2000; Table 3). We found the highest concentrations of Pb, Cd, and Zn in lichens transplanted near the Zn–Pb smelter, where values for these elements were either equal (Pb) or exceeded means for enriched areas

TABLE 3. STATISTICAL BASELINE VALUES FOR CHEMICAL ELEMENTS IN *H. physodes* (AFTER BENNETT, 2000)

	Elements ($\mu g\ g^{-1}$ dry weight)							
	Pb	Zn	Cd	Cr	Ni	Cu	Fe	S
Background average	19.5	73	0.56	2.11	1.72	6.0	621	738
Enriched average	126.9	427	2.56	43.50	12.28	28.6	3081	1695

"Background"—any site not in the city, nor near a point source, and not under any kind of local pollutant influence. "Enriched"—opposite to these criteria.

(Cd, Zn; Table 3). In the rest of the transplantation sites, concentrations of Zn and Pb were equal or lower than mean levels for background areas. Cd was lower than mean levels for enriched areas (Table 3). Baranowska-Bosiacka et al. (2001) found that Pb and Cd accumulated in *H. physodes* remained mainly on the surface of the thalli, whereas Zn and Cu penetrated into the protoplast. Microparticle-induced X-ray emission (PIXE) analysis of thalli transplanted to polluted sites revealed that Zn was concentrated in the algal layer and lower cortex, whereas Cu and Pb were detected only from analyses of smaller areas in individual layers of thalli (Budka et al., 2002). Although Cd was detected with AAS, it was not visible in PIXE studies that confirmed the surface deposition (Budka et al., 2004). We noted the highest levels of Cr and Ni in *Hypogymnia* transplanted near a chemical factory (Alwernia) producing chromium, phosphorus, and sulfur compounds. Cr values were twice the mean for enriched areas, whereas Ni was close to it. In the rest of our test sites, Cr and Ni levels were equal or lower than the mean for background areas (Table 3). Neither Cu nor Fe exceeded threshold levels, even in the most polluted sites (Table 3). PIXE analysis of transplanted *H. physodes* revealed the highest concentrations of Fe in the lower cortex, which suggests a transport mechanism within thalli or a nonatmospheric origin of this element. Additionally, low concentrations of Fe were found in the upper part of the lichen, which could be from dust distributed on the surface (Budka et al., 2004). Especially high values in relation to data given by Bennett (2000) were noted for S levels. Even control lichen from the Borecka forest had almost twice the S levels than the mean for background areas. These levels exceeded the threshold level in the rest of studied sites (Table 3) and reflect the widespread occurrence of air pollution containing sulfur compounds over Poland.

Before the symptoms of different kinds of stress, including pollution, can be visualized by morphological or ultrastructural changes, less obvious results occur on the molecular or chemical level. These less salient markers have become a subject of interest in recent years as they may be used as early indicators of environmental stress on a target organism before damage occurs.

The potential use of secondary metabolites as markers for environmental stress has been postulated for plants and lichens (Jones and Coleman, 1989; Zobel and Nighswander, 1990, 1991; Zobel, 1996; Rabotti and Ballarin-Denti, 1998; Loponen et al., 2001; Caviglia et al., 2001). Moreover, because secondary substances play a significant role in ecosystem interactions, and actions of different kinds of stressors cause modification in their quantity and composition, which, in turn, influences other ecosystem partners (Larcher, 1995). For this reason, secondary compounds can also be used as warning indicators for the surrounding ecosystem (MacGillivray and Helleur, 2001).

Extracts from *H. physodes* contained several biologically active compounds (Huneck and Yoshimura, 1996) and may influence the growth of other organisms in their surroundings. For example, physodic acid has anticancer, antimutagenic, antiviral, and allergenic activities and may inhibit cell division. Atranorin has anticancer, fungitoxic, and antimicrobial activities and may also influence growth of plants as well as growth and development of insects. Hydroxyphysodic acid has potent insecticidal activity (Huneck and Yoshimura, 1996; Hunek, 1999; Romagni and Dayan, 2002). Therefore, it is possible that changes in concentration may influence the fitness of lichens to their environment. Because all of the described metabolites may play a role in the interaction of a lichen with its biotic environment, any reduction in concentration may be reflective of the health of lichens and lower resistance to herbivore attack, diseases, as well as interactions with lower plants (e.g., algae and bryophytes; Huneck, 1999), and host trees. In another study, the metabolites from epiphytic lichen were found in the xylem of the host (Avalos et al., 1986).

The most detrimental changes were observed in secondary metabolites of lichens transplanted to Alwernia, which accumulated high levels of Cr. Significant decreases in hydroxyphysodic acid, physodic acid, and atranorin were observed in thalli collected 6 months after transplantation. Interestingly, crude extracts of lichens transplanted to Alwernia contained an additional unidentified polar peak in chromatograms (Rt = 4.1, denoted as an asterisk in Figure 4) that constituted as much as 12% of the crude extracts. This peak was not observed in lichen extracts from the other sites, including control thalli. After isolation, this polar fraction eluting as a single peak (Figure 4) was a dark yellowish, oily substance and most probably is the product of degradation of lichen acids caused by accumulated chromium ions. According to Jezierski et al. (1999), intensified free radical production in lichens exposed to air pollution is the result of degradation of lichen acids to β-diketones. The unidentified peak might also be a compound produced by lichens for the purpose of defense against stress associated with the accumulation of pollutants in thalli.

A decrease in physodic acid was observed in lichens transplanted to both of the most polluted sites—the forests in Alwernia and Bukowno. In Bukowno, significant accumulations of Pb, Cd, and Zn were noted in thalli collected after

the transplantation period. However, the decrease was more intense in thalli that accumulated Cr, suggesting the reductive power of this element on the degradation of physodic acid.

Thalli of lichens transplanted to all of the test sites in the Silesia–Cracow industrial region contained higher concentrations of physodalic acid than control thalli. Thus, biosynthesis of physodalic acid seems to be elicited in response to stress caused by exposure to heavy metals. Data found in the literature show physodalic acid as an antimutagenic compound (Romagni and Dayan, 2002). There has been no record of detoxifying activity for this substance. The slight increase in atranorin found in lichens transplanted to Bukowno, Młoszowa, and Jankowice suggests a possible role of this compound in detoxification, or it may be a precursor of other phenolic compounds.

In summary, significant, site-specific changes in chemistry of thalli were found in lichens transplanted to the polluted regions selected in this study. The most detrimental alterations were detected in thalli that accumulated high levels of Cr after transplantation near the chemical industry. Decreases in the levels of physodic acid, hydroxyphysodic acid, and atranorin were detected, and one additional peak appeared in the extract. A decrease in physodic acid concentration was also observed in lichens transplanted to the other most highly polluted site near the Zn–Pb smelter as the effect of accumulations of Cd, Pb, and Zn. An increase in the content of physodic acid in all transplanted lichens suggests a role of this compound in defense against stress caused by accumulated pollutants.

Acknowledgments—D. Białońska expresses her gratefulness to the Kosciuszko Foundation, New York, for financial support and to Professor Katarzyna Sawicka-Kapusta and Professor Alicja Zobel for supervision. We also thank Dr. Dhammika Nanayakkara, research chemist at the National Center for Natural Products Research at the University of Mississippi, for providing the lichen metabolite standards and Lance D. Published Online November 4, 2005

Abstract—Many bees are oligolectic and collect pollen for their larvae only from one particular plant family or genus. Here, we identified flower scent compounds of two *Salix* species important for the attraction of the oligolectic bee *Andrena vaga*, which collects pollen only from *Salix*. Flower scent was collected by using dynamic-headspace methods from *Salix caprea* and *S. atrocinerea*, and the samples were subsequently analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) to detect possible attractants of *A. vaga*. EAD active compounds were identified by gas chromatography coupled to mass spectrometry. Both *Salix* species had relatively similar scent profiles, and the antennae of male and female bees responded to at least 16 compounds, among them different benzenoids as well as oxygenated monoterpenoids and sesquiterpenoids. The strongest antennal responses were triggered by 1,4-dimethoxybenzene, and in field bioassays, this benzenoid attracted females of *A. vaga* at the beginning of its flight period, but not at the end.

Key Words—Floral scent, *Salix*, willows, GC-EAD, oligolectic bees, *Andrena*, GC-MS, flower visitor attraction.

INTRODUCTION

Bees are important pollinators of flowering plants. They visit flowers primarily to take nectar for their food and to collect nectar/oil and pollen for their larvae.

* To whom correspondence should be addressed. E-mail: stefan.doetterl@uni-bayreuth.de

Many of the about 30,000 bee species worldwide are oligolectic and collect pollen for the larvae only from a particular plant family or genus. So far, little is known about the cues used by the oligolectic bees to find host plants. However, it has been shown that naive bees of oligolectic *Chelostoma florisomne* (L.) rely on flower and especially pollen odors to recognize host plants (Dobson and Bergström, 2000), and floral scent compounds generally may be important for host plant finding by oligolectic bees.

Salix L. is a genus that hosts many different oligolectic bee species, probably because of its readily accessible pollen (Michener, 2000). *Salix* is a woody genus, distributed almost worldwide, but centered in the northern hemisphere (Newsholme, 1992). Plants are dioecious, and insects are important pollen vectors (e.g., Karrenberg et al., 2002). The often strongly scented flowers are borne in catkins. The scent is assumed to attract the pollinators (Tollsten and Knudsen, 1992). In Europe, several species of the genus *Andrena* are specialized on *Salix*, among them *Andrena vaga* Pz. (Westrich, 1989).

Here, we used coupled gas chromatography and electroantennography (GC-EAD) to elucidate the floral scent compounds of *Salix caprea* L. and *S. atrocinerea* Brot. that elicit signals in the antennae of female and male *A. vaga*. The compound that elicited the main signal in the antennae of bees was further tested for attraction in a field bioassay.

METHODS AND MATERIALS

Plant Material and Volatile Collection. Floral scent was collected from male plants of *S. caprea* and *S. atrocinerea* in the Ecological–Botanical Garden of the University of Bayreuth. For each sample, floral scent was collected from 30 to 40 catkins during daytime for 8 hr by using dynamic headspace methods. Flowering branches were cut in the field and placed in water in the laboratory for immediate scent collections (compare with Tollsten and Knudsen, 1992).

Flowering branches were enclosed in an oven bag (Nalophan), and the emitted volatiles were trapped in an adsorbent tube filled with 20 mg of a 1:1 mixture of Tenax-TA 60–80 and Carbotrap 20–40. The air was sucked from the bag over the adsorbent by a membrane pump (G12/01 EB, Rietschle Thomas, Puchheim, Germany). Volatiles were eluted with 80 μl of acetone (SupraSolv, Merck KgaA, Germany) to obtain odor samples for the chemical and electrophysiological analyses (see below).

Electrophysiology. Electrophysiological analyses of the floral scent extracts were performed with a GC-EAD system. Antennae from two females and two males of *A. vaga* were tested. The bees were caught on the 4th and the 21st of April at a nesting site in the Ecological–Botanical Garden. The GC-EAD system consisted of a gas chromatograph (Vega 6000 Series 2, Carlo Erba, Rodano, Italy) equipped with a flame ionization detector (FID) and an EAD

setup [heated transfer line, two-channel universal serial bus (USB) acquisition controller] provided by Syntech (Hilversum, Netherlands). One microliter of an odor sample was injected splitless at 60°C, followed by opening the split vent after 1 min and heating the oven at a rate of 10°C/min to 200°C. The end temperature was held for 5 min. A ZB-5 column was used for the analyses (length 30 m, inner diam 0.32 mm, film thickness 0.25 μm, Phenomenex). The column was split at the end by the four-arm flow splitter GRAPHPACK 3D/2 (Gerstel, Mülheim, Germany) into two pieces of deactivated capillary (length 50 cm, ID 0.32 mm) leading to the FID and to the EAD setup. Makeup gas (He, 16 ml/min) was introduced through the fourth arm of the splitter. For measurements, an excised antenna was mounted between glass micropipette electrodes filled with insect ringer (8.0 g/l NaCl, 0.4 g/l KCl, 0.4 g/l $CaCl_2$). The electrodes were connected to silver wires.

Chemical Analyses. To identify the EAD active compounds, 1 μl of the scent samples was analyzed on a Varian Saturn 2000 mass spectrometer and a Varian 3800 gas chromatograph fitted with a 1079 injector (Varian Inc., Palo Alto, CA, USA). Column and settings were as described in Dötterl et al. (2005). Component identification was carried out using the NIST 02 mass spectral database, or MassFinder 3, and was confirmed by comparison with retention times of authentic standards.

Behavioral Experiment. To test the attractiveness of 1,4-dimethoxybenzene, which elicited the main signal in the antennae of the bees, a two-choice bioassay was conducted in spring 2005 in the Ecological–Botanical Garden near the nesting site of *A. vaga*. One rubber GC septum impregnated with 10 μl of 1,4-dimethoxybenzene (99%, Aldrich) and one blank rubber GC septum were presented on a stand (distance of the septa, 1 m) around noon for 20 min, when activity of bees was high. The reaction of bees was classified as "zigzagging" when the bees flew upwind toward one of the septa up to within 10 cm and as "landing" when the bees had contact with a septum.

RESULTS AND DISCUSSION

Floral odors of *S. caprea* and *S. atrocinerea* elicited clear signals in the antennae of both sexes of *A. vaga* (Figure 1). At least 16 EAD active compounds were found, of which 11 were present in both *Salix* species. The antennae of the bees responded especially to different benzenoids and isoprenoids, and 1,4-dimethoxybenzene consistently elicited the main antennal response. Clear signals were also triggered by different monoterpene oxides, by the nitrogen-bearing compound indole, and by the sesquiterpene (*E*,*E*)-α-farnesene. The antennal responses of female and male bees were similar; however, female bees were more strongly tuned to oxygenated sesquiterpenes, such as (*E*)-nerolidol.

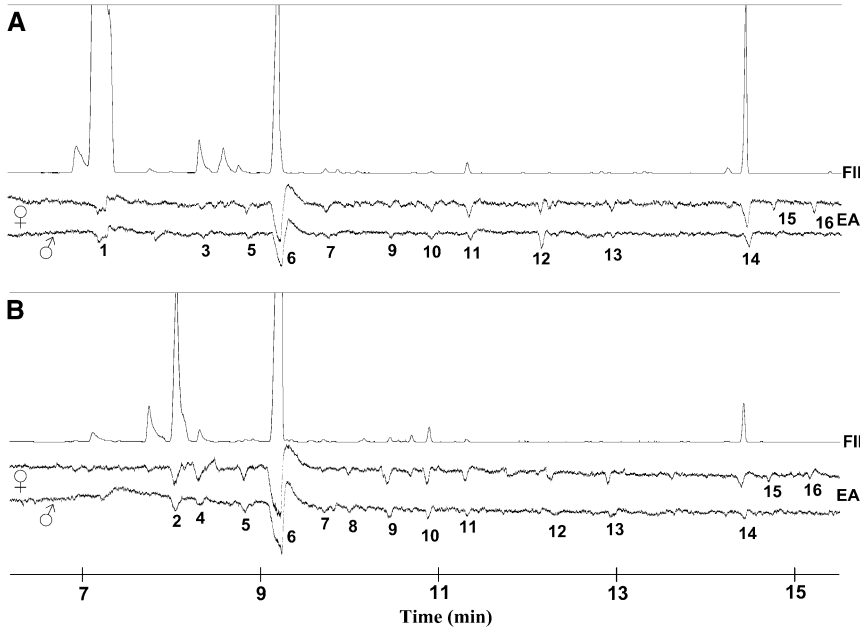

FIG. 1. Coupled gas chromatographic and electroantennographic detection (GC-EAD) of *Salix caprea* (A) and *S. atrocinerea* (B) flower scent samples using antennae of *Andrena vaga* males and females. **1**: (*E*)-β-ocimene; **2**: linalool; **3**: 4,8-dimethyl-1,3,7-nonatriene; **4**: 2-phenylethanol; **5**: 4-oxoisophorone/benzyl nitrile; **6**: 1,4-dimethoxybenzene; **7**: methyl salicylate; **8**: lilac alcohol isomer; **9**, **10**: monoterpene oxides; **11**: indole; **12**: eugenol; **13**: sesquiterpene; **14**: (*E*,*E*)-α-farnesene; **15**: sesquiterpene oxide; **16**: (*E*)-nerolidol.

TABLE 1. NUMBER OF FEMALES OF *Andrena vaga* ATTRACTED TO A SEPTUM IMPREGNATED WITH 1,4-DIMETHOXYBENZENE (DMB) AND TO A BLANK SEPTUM (CONTROL)

	"Zigzagging"		"Landing"	
Date	DMB	Control	DMB	Control
5 April	6	0	0	0
11 April	7	0	3	0
13 April	4	0	1	0
14 April	4	0	0	0
26 April	0	0	0	0
6 May	0	0	0	0

The bioassay proved that 1,4-dimethoxybenzene not only elicits antennal responses but also mediates behavioral responses (Table 1), at least in female bees. They flew upwind toward the septum impregnated with this benzenoid, and some landed on it for a short period of time. After landing, they did not show the nectar drinking or pollen-collecting behavior, which can be observed on *Salix* catkins.

However, in the first 2 weeks of April only, at the beginning of their flight season, females were consistently attracted to 1,4-dimethoxybenzene. End of April/beginning of May bees were not attracted at all. It seems that only freshly hatched, foraging-naive bees were attracted. This observation is consistent with the results of Dobson and Bergström (2000). They found that oligolectic *C. florisomne* relied on protoanemonin, the dominant pollen odor of its host plants (*Ranunculus*), only if the bees were foraging-naive, whereas foraging-experienced bees recognized their host plants on the complex volatile blend of a whole flower, which first has to be learned.

Not a single male of *A. vaga* was attracted by 1,4-dimethoxybenzene, although males also strongly responded to this substance in the GC-EAD study, and males were regularly observed on *Salix* species, probably drinking nectar. Because males of *A. vaga* hatch 2–3 weeks earlier than females (Westrich, 1989), we cannot rule out that they were already foraging-experienced when bioassays were conducted. Possibly, foraging-experienced bees have learned to recognize complex flower scents and do not rely on their innate preferences for single scent compounds (see also Dobson and Bergström, 2000).

1,4-Dimethoxybenzene is found in floral scents of all *Salix* species so far studied (this study and Tollsten and Knudsen, 1992). Furthermore, it is a common compound in orchids pollinated by perfume-collecting euglossine bees (Williams and Whitten, 1983; Gerlach and Schill, 1991), where it is suspected to be a good bee attractant (Williams and Whitten, 1983). 1,4-Dimethoxybenzene is also known to attract the chrysomelid beetle *Diabrotica speciosa* (Ger.) (Ventura et al., 2000).

To summarize, our results demonstrate that floral scent compounds of *Salix* can act as cues for the attraction of oligolectic bees, and that 1,4-dimethoxybenzene attracts female *A. vaga* bees. In oligolectic bees, males often search for females at the host plants; therefore, floral scent could be used by males in combination with female sex pheromones to find females. This is the first study analyzing antennal and behavioral responses of an oligolectic bee to the floral scent of its host plants.

Acknowledgments—Parts of the study were supported by the German Research Foundation (Research Training Group 678). The GC for the electrophysiological study was provided by Konrad Dettner, and Andrea Beran provided advice on this system. Friderike Beyer and Irmgard Schäffler helped with biotests. Taina Witt and two anonymous referees gave valuable comments on the manuscript.

(Received August 29, 2005; Revised October 31, 2005; accepted November 1, 2005)

Published Online November 11, 2005

Abstract—The sex pheromone of the obscure mealybug, *Pseudococcus viburni*, consists of (1*R**,2*R**,3*S**)-(2,3,4,4-tetramethylcyclopentyl)methyl acetate, the first example of a new monoterpenoid structural motif in which the two isoprene units forming the carbon skeleton are joined by 2′–2 and 3′–4 connections rather than the usual 1′–4, head-to-tail connections. This highly irregular terpenoid structure, and the irregular terpenoid structures of related mealybug species, suggest that these insects may have unique terpenoid biosynthetic pathways.

Key Words—Sex pheromone, nonhead-to-tail terpenoid, irregular terpenoid, (2,3,4,4-tetramethylcyclopentyl)methyl acetate, *Pseudococcus viburni*.

INTRODUCTION

The great majority of the more than 30,000 isoprenoid-derived compounds identified from natural sources are formed from 1′ to 4, head-to-tail connections between isopentenyl diphosphate and dimethylallyl diphosphate, the two

* To whom correspondence should be addressed. E-mail: millar@ucr.edu
† Deceased

5-carbon building blocks that are connected to form the carbon skeletons of all known terpenoids (Poulter, 1990; Rivera et al., 2001). Further cyclizations and rearrangements then produce the variety of known terpene skeletons. Irregular terpenoids in which the isoprene units are joined in nonhead-to-tail fashion are relatively rare, with most examples being found in members of the plant family Asteraceae (Poulter, 1990).

Its name notwithstanding, the obscure mealybug, *Pseudococcus viburni* (Signoret) (Homoptera: Coccidae), is a common and widely distributed insect that feeds on a variety of plants, including grapevines, glasshouse crops, and ornamental plants (Laflin et al., 2004). The relatively sessile adult females produce a powerful sex pheromone to attract the ephemeral, nonfeeding, winged adult males for reproduction. We report the discovery of a highly irregular, nonhead-to-tail monoterpenoid with a (2,3,4,4-tetramethylcyclopentyl)methanol carbon skeleton, as a female-produced sex pheromone component of the obscure mealybug. In contrast to the 1′–4 linkages of most terpenoids, the ring structure of this compound appears to be constructed from 2′–2 and 3′–4 connections of two isoprenoid units (Figure 1A), providing the first example of an entirely new class of monoterpenoid structures.[1]

METHODS AND MATERIALS

Mealybugs, originally collected from grapevines, were reared in cohorts by infesting butternut squash fruits (*Cucurbita moschata*) with newly hatched mealybug crawlers. After 1 wk, squash were sprayed with pyriproxyfen (10 ppm in 0.1% aqueous Triton-X) to eliminate males. Treated squash with mature virgin females were aerated in 5-l glass chambers, collecting headspace odors on 2.5 cm × 4 mm ID activated charcoal traps. Collectors were changed every 3–5 d, and eluted with pentane. Control collections were made with uninfested squash, squash with sexually immature females, and squash with mixed-sex cohorts.

An aliquot of extract was reduced with 5% Pd on carbon catalyst in a septum-capped vial with a balloon of H_2 attached. A second aliquot was concentrated just to dryness, then treated with 1 M NaOH in 95% EtOH.

The extracts from ~20 aerations were concentrated and fractionated by preparative GC (2 m × 2 mm ID glass column, 10% SP-1000 on 80/100 mesh Supelcoport, headpressure 240 kPa; program 50°C/1 min, 10°/min to 200°C, hold 20 min). Fractions were collected in glass capillaries chilled with dry ice.

[1] A recent report (Lavoine-Hannegalle and Casabianca, 2004) suggested that 1,1,2,3-tetramethyl-4-hydroxymethyl-2-cyclopentene might be present as a trace component of lavender oil. However, the identification was based solely on interpretation of a mass spectrum and must be regarded as tentative at best, pending isolation and unequivocal identification by other spectral methods.

FIG. 1. (A) Connections between the two isoprene units making up the skeleton of the pheromone; (B) EI mass spectrum of (1*R**,2*R**,3*S**)-(2,3,4,4-tetramethylcyclopentyl)-methyl acetate; (C) synthesis of (2,3,4,4-tetramethylcyclopentyl)methyl acetate as a mixture of diastereomers.

NMR spectra were taken on an INOVA-400 spectrometer in C_6D_6 or CD_2Cl_2. Mass spectra were recorded on an H-P 5973 mass spectrometer coupled to an H-P 6890 GC, with helium carrier gas, and an HP5-MS column (30 m × 0.25 mm ID).

A field trial was conducted in vineyards near San Luis Obispo, CA, USA, using sticky traps baited with 0.1-mg doses of pheromone in hexane loaded on gray rubber septa (six replicates).

RESULTS AND DISCUSSION

Comparisons of extracts from sexually immature and mature females, and from mature virgin females and mixed-sex colonies by gas chromatography revealed one major compound [Kovat's index (KI) 1308 on a DB-5 GC column] that was exclusively produced by sexually mature virgin females. The compound was unchanged after reduction with hydrogen and palladium-on-carbon catalyst, indicating that the structure contained no carbon–carbon multiple bonds. Hydrolysis with ethanolic NaOH produced an earlier eluting alcohol (KI 1175), indicating the presence of an ester function, with the 133-unit difference in KI values between the parent compound and the derivative suggesting an acetate ester. The KI values of both the alcohol and the parent ester were in the ranges typical of monoterpene alcohols and acetates (Adams, 1995).

The electron impact ionization (EI) mass spectrum of the parent compound (Figure 1B) supported these data. Specifically, a fragment of low intensity at *m*/*z* 138, derived from loss of acetic acid from the parent molecule of molecular weight 198 amu supported the presence of an acetate ester, whereas the tentative molecular formula of $C_{12}H_{22}O_2$, with no C–C double bonds present, suggested a single ring in the structure. Although the base peak at *m*/*z* 123 ($C_9H_{15}^+$) and the rest of the mass spectrum had similarities to database spectra of multiply substituted cyclohexylmethanols, no matches were found with any literature or database spectra. As expected, the mass spectrum of the alcohol derived from hydrolysis of the pheromone was similar to that of the parent compound, with a base peak at *m*/*z* 123.

Based on interpretation of the mass spectrum and considerations of known terpenoid biosynthetic pathways, several structures were postulated and synthesized, but none proved correct. Consequently, crude pheromone extracts collected from multiple cohorts of virgin females were combined to obtain sufficient material for NMR analysis. The pheromone was isolated from the combined extracts (>100,000 female days of collection) by preparative gas chromatography, yielding a few micrograms of purified material, sufficient for a proton NMR spectrum, and limited information from NOE and ^1H–^1H COSY spectra. Interpretation of the proton and partial NOE and COSY spectra

suggested structure **1** (Figure 1C), with the methyl groups on C_2 and C_3 tentatively assigned to the same side of the ring, and the relative stereochemistry at C_1 being impossible to determine from the small quantity available.

To verify the carbon skeleton, a nonselective synthesis was developed that produced all four of the possible diastereomers (Figure 1C). Thus, isobutyl methacrylate **2** was cyclized with polyphosphoric acid (Conia and Leriverend, 1970), yielding 2,4,4-trimethylcyclopent-2-en-1-one **3**. Methylation of enone **3** yielded a 1:4 mixture of *cis* and *trans* 2,3,4,4-tetramethylcyclopentanone diastereomers **4**. Reaction of ketones **4** with (methoxymethylene)triphenylphosphorane followed by hydrolysis of the resulting vinyl ethers **5** gave a mixture of aldehydes **6**, which were reduced with $NaBH_4$ in EtOH to give alcohol **7**. Acetylation produced a mixture of acetate diastereomers, one of which matched the insect-produced isomer. This isomer was isolated by preparative GC, and determined to be the (1*R**,2*R**,3*S**)-diastereomer **1** (Figure 1C) by nuclear Overhauser effect NMR analysis. Full ^{1}H and ^{13}C data NMR data are in the Online Supplement Table A1 (Electronic Supplementary Material is available for this article at http://dx.org/10.1007/s10886-005-9320-0 and is accessible for authorized users). To date, the absolute configuration of the insect-produced compound has not been determined. However, in preliminary field tests, the racemic compound was highly attractive to male mealybugs ($N = 6$; treatment, 211 ± 47 (mean ± SE) males caught; control 2.2 ± 1.6 males caught), indicating that the unnatural enantiomer is not inhibitory.

In addition to the relatively rare examples isolated from plants (Poulter, 1990), several examples of irregular monoterpenoid skeletons have been found in the Insecta. For example, cyclobutane structures with c1′-2′-3-2 connectivity have been isolated from several weevil species, such as the boll weevil *Anthonomis grandis* (Tumlinson et al., 1969). α- and β-necrodols, characterized by a 1,2,2,3,4-pentamethylcyclopentane nucleus with the ring formed from 2′–4 and 3′–2 connections, are produced as defensive compounds by the silphid beetle *Necrodes surinamensis* (Roach et al., 1990). However, mealybugs and the related armored scale insects (Dunkelblum, 1999) appear to be masters of irregular terpenoid biosynthesis. For the six mealybug species for which pheromones have now been identified (review, Millar et al., 2005), all of the pheromone components consist of irregular terpenoids, with all the components except that of the obscure mealybug having a 1′–2 linkage. Even within this unusual group, the obscure mealybug, with its unprecedented 2′–2 and 3′–4 linkages, stands out.

There are further implications. First, because each of these species produces only one or two of these irregular monoterpenoids, the biosynthesis of these compounds by the insects is clearly under tight control. Second, the fact that none of these terpenoid skeletons have been reported from any of the insects' typical host plants, which include well-studied crops such as citrus,

grapes, and tree fruits, suggests that these compounds may be synthesized *de novo*, rather than being derived from minor modifications of compounds sequestered from the host plants.

It is also noteworthy that all of the irregular terpenoid pheromones identified from mealybugs are unique structures. Unlike many other groups of closely related insect species, which create species-specific pheromone signals by using different ratios and subsets of compounds common to some or all members of the group, mealybugs appear to use species-specific chemicals to create unique communication channels, eliminating any possibility of interference in or competition for the pheromone channel. This lack of competition for the channel may explain why these insects are generally insensitive to stereoisomers or other analogs of their pheromones. This is in contrast to insects such as beetles and moths, which are frequently acutely sensitive to even traces of structural analogs of their pheromone components.

The evidence suggests that mealybugs have developed terpenoid biosynthetic pathways for production of their pheromones that are distinct from the typical terpenoid pathways found in other organisms. This ubiquitous insect family will likely prove to be an abundant source of irregular terpenoids, and the enzymes responsible for their synthesis.

Acknowledgments—This project was funded by the USDA Western Regional IPM Program, the Viticulture Consortium, the California Table Grape Commission, and the California Raisin Marketing Board. We thank Monica Cooper for carrying out the bioassay.
